For the quenched sample, we have observed nonexponential behavior of T_1 below T_{tr} (257 K), which is unexplainable by a single relaxation process. We tentatively divided the observed inversion-recovery curve of the ^{1}H magnetization into two T_1 components because the presence of two different crystalline phases is expected from the DTA measurements. The intensity ratio of the short T_1 component to the long one was roughly estimated as $1/2 \sim 1/3$ in the whole temperature range below T_{tr} (257 K). As shown in Fig. 4, the T_1 values of the long component agree reasonably well with those for the annealed sample. The short T_1 values could not be determined accurately because this component gave a low intensity signal and it showed different T_1 values at each cooling run.

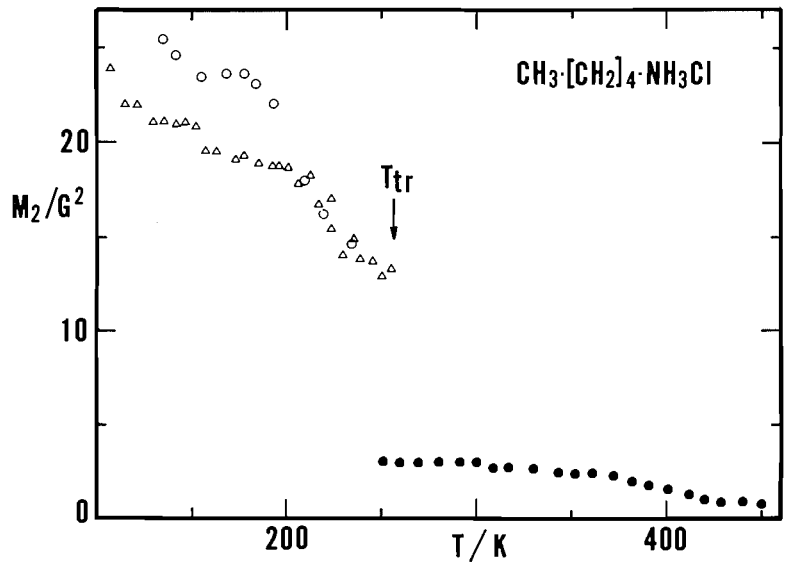

FIG. 3. Temperature dependences of ^{1}H nmr second moment (M_2) of pentylammonium chloride. Values in the room-temperature phase above the phase transition temperature (T_{tr}) are shown by ●. Those in the low-temperature phase below T_{tr} are given by △ and ○ for the quenched and annealed samples, respectively.

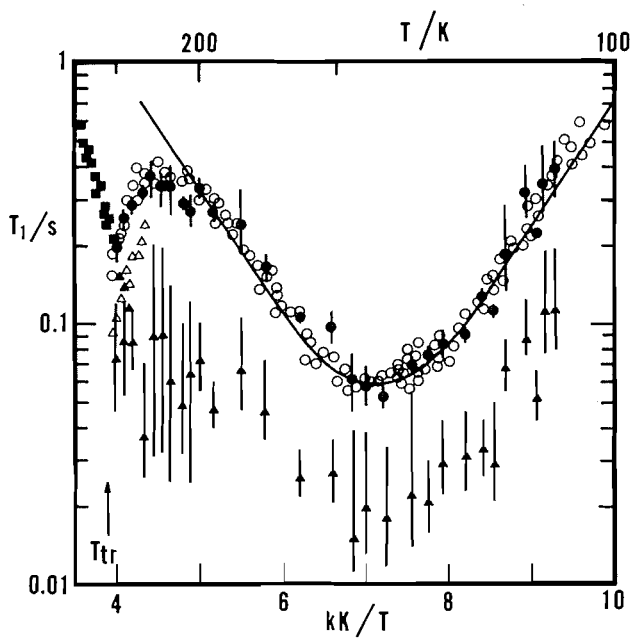

FIG. 4. Temperature dependences of ^{1}H nmr spin–lattice relaxation time T_1 in the room-temperature phase observed at 20 MHz (■), and the low-temperature phase for the annealed sample at 20 MHz (○) and 11.5 MHz (△). The quenched sample showed two T_1 values indicated by ● (long) and ▲ (short). The vertical line shows the extent of uncertainty for each T_1 value determined. The solid line is the best-fitted theoretical values.

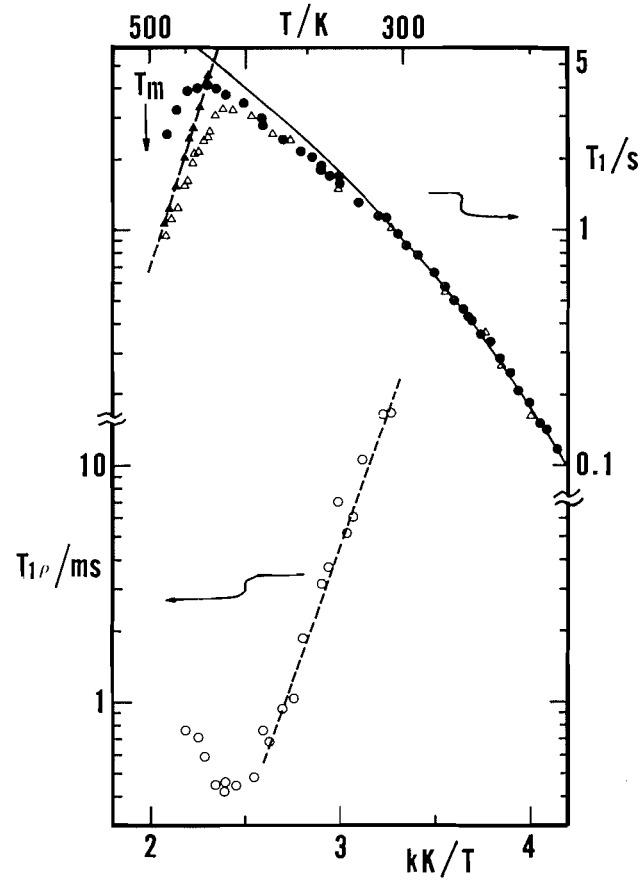

FIG. 5. ^{1}H nmr spin–lattice relaxation times in the laboratory frame T_1 and the rotating frame $T_{1\rho}$ for the room-temperature phase (rotator phase). T_1 values observed at 20 and 10.5 MHz are shown by ● and △, respectively, while $T_{1\rho}$ values at spin-locking field of 7.4 G are given by ○. T_1 observed at 10.5 MHz ($T_{1\,obs}$) was divided into two components $T_{1\,rot}$ (solid line) and $T_{1\,diff}$ (▲) which are expressed by $T_{1\,obs}^{-1} = T_{1\,rot}^{-1} + T_{1\,diff}^{-1}$. $T_{1\,diff}$ and $T_{1\rho}$ in the slow-motion limit were approximated by the dashed lines, whose slopes gave the activation energies of the cationic self-diffusion.

Figure 5 shows the temperature dependences of T_1 observed for RTP between T_{tr} (257 K) and its mp at the Larmor frequencies of 20 and 10.5 MHz, and $T_{1\rho}$ at an rf field of 7.4 G. In this phase, T_1 increased with increasing temperature and exhibited a maximum of 4.2 s around 440 K in the measurement at 20 MHz. Above this temperature, T_1 decreased rapidly up to mp. On the other hand, $T_{1\rho}$ yielded a minimum of 0.43 ms around 415 K.

The temperature dependence of electrical conductivity σ for RTP is shown in Fig. 6. The conductivity value of the order of

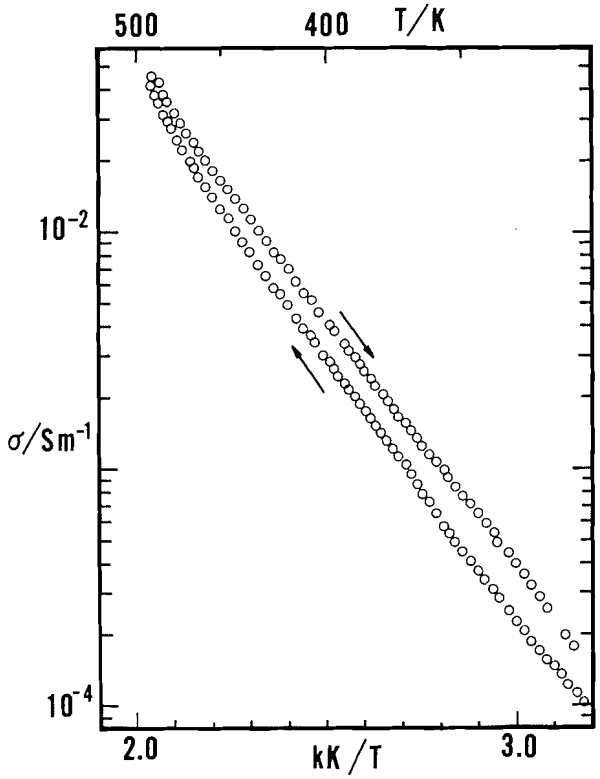

FIG. 6. The temperature dependence of electrical conductivities (σ) in the room-temperature phase (rotator phase) measured at 1 kHz. Arrows indicate the direction of the temperature change during the measurements.

10^{-5} S m^{-1} at room temperature, increased continuously with increasing temperature to that of the order of 10^{-2} S m^{-1} above 440 K. Near the mp σ increased more steeply with temperature than in the lower temperature range, and, on cooling from the neighborhood of the mp, it gave slightly higher values than those obtained for the heating runs. This thermal hysteresis seems to be due to the deformation of the sample by increasing the temperature, since the sample is fixed by the graphite electrodes. Such deformation is expected because slight plasticity of the crystals was observed even at room temperature when we tried to grind the crystal in a mortar. The plastic flow of the crystals could also be observed when a pellet was formed from the powder sample by applying pressure. A completely transparent pellet was prepared by a pressure of about 200 MPa at room temperature.

Discussion

Phase transitions

As shown in Fig. 2 and Table 1, a phase transition was always observed at 257 K in our DTA and DSC measurements performed at various scanning rates. This T_{tr} agrees well with that of 259 K reported by Tsau and Gilson (1), although it disagrees with either of two T_{tr}'s of 222 and 246.5 K observed in the heat capacity study (9). Since this transition at 257 K was observed for the annealed sample, it can be regarded as the transition between the low-temperature stable phase (abbreviated hereafter to LTSP) and RTP.

The experimental result that an exothermic DTA curve was recorded when the sample temperature was kept constant just after passing the exothermic peak starting at 238 K on the cooling runs indicates that the high temperature peak corresponds to the phase transition from RTP to a metastable phase, which transforms very slowly into LTSP. The exothermic anomaly superimposed on the low-temperature side of the peak starting at 238 K showed in Fig. 2*a* is attributable to this transition to LTSP partially occurring. Accordingly, the anomalies observed at 211 and 238 K on cooling and heating, respectively, are considered to be due to a transition between metastable phases, because these peaks disappeared in the measurements of the annealed sample. These results imply that unannealed samples consist of a mixture of LTSP and LTMP below T_{tr} (257 K).

With these interpretations of our DTA results, the two phase transitions reported by Southard *et al.* (9) at 222 and 246.5 K would correspond to those at 238 and 257 K on the heating runs in our measurements, respectively.

The fact that almost the same entropy change for the transition at 257 K was obtained for the samples cooled at the three different rates in our DSC measurement indicates that the entropy difference between LTSP and LTMP is not large and/or LTMP is contained only in a small amount in the quenched sample. It is noted that this transition entropy amounting to 33 J K^{-1} mol^{-1} is much larger than the melting entropy of 20 J K^{-1} mol^{-1}. The same reversed relationship of the transition entropies has been also found in *n*-butylammonium bromide (17) and iodide (18) for the transition from the low-temperature phase to the rotator one isomorphous with RTP of the present salt. This unusual relationship is well known in the plastic crystals, in which isotropic reorientations and translational self-diffusion of globular molecules are observed to take place quite frequently (7, 8). Accordingly, RTP can be expected to be in a highly dynamically-disordered state.

Second moments of ^1H nmr absorptions

Theoretical values of M_2 for (pna)Cl in five different motional states of the cations were calculated by use of Van Vleck's method (19). We employed the same bond angles and distances as those used in our M_2 calculation of *n*-butylammonium bromide (17) and iodide (18). *Trans* conformation of the alkyl chain was also assumed. Inter-ionic contributions to M_2 were roughly estimated using the lattice parameters in RTP reported by Southard *et al.* (9). The results of these M_2 calculations are summarized in Table 2, where the 180° chain flip means the reorientation of the cation by 180° about the chain axis, and the chain rotation is the reorientation jumps of cations among more than two orientations about the same axis.

The M_2 plateau of 23 G^2 exhibited by the annealed sample around 160 K agrees well with the calculated value for the model involving the reorienting CH_3 groups about their C_3 axes. On the other hand, the quenched sample yielded M_2 smaller than this plateau value by about 4 G^2 in the same temperature range. This implies that the quenched sample includes crystals in which the cations perform motions averaging magnetic dipolar interactions other than the CH_3 reorientation. Both annealed and quenched samples showed almost the same M_2 of 13 G^2 at the temperatures just below T_{tr} (257 K). This value is much smaller than the calculated M_2 for the cations with the CH_3 and NH_3^+ groups reorienting about their C_3 axes, but it is rather close to the theoretical value for the cations performing the 180° flip in addition to the above motions. This suggests that some kind of whole-cationic motions which inevitably result in disordered structures of the crystal take place even in the low temperature phases.

The small M_2 of 3 G^2 observed above T_{tr} (257 K) indicates the

onset of uniaxial rotation of cations about the long axis. According to Southard *et al.* (9), the tetragonal unit cell of RTP has the atomic arrangements as shown in Fig. 1. In this structure, the authors concluded that the cations, with respect to their orientation about their long axis pointing along the *c*-axis, are dynamically disordered in good agreement with the present M_2 analysis. The observed M_2 values in RTP, especially at high temperatures, however, are much smaller than the calculated value for the uniaxial rotation model. This result requires other kinds of dynamical positional disorders of the protons. As conceivable motions of the cations, we can envisage for example, partial conformational disorder of the alkyl chain, rotational and translational modes of lattice vibrations with large amplitudes, and self-diffusion of the cations, that is, cationic translational jumps to the vacant nearest neighbor lattice sites.

Spin–lattice relaxation times

Low-temperature stable phase (LTSP)

Since no detectable non-exponential T_1 behavior was seen for the annealed sample below T_{tr} (257 K), this sample can be regarded as almost pure LTSP including no significant amount of LTMP. The T_1 curve with a minimum observed for the annealed sample below about 200 K can be attributed to magnetic dipolar relaxation due to molecular motions, which is usually analyzed by the BPP theory (20). When T_1 is influenced by a single motional process, this theory predicts a T_1 curve expressed as

$$[1] \quad T_1^{-1} = C[\tau/(1 + \omega^2\tau^2) + 4\tau/(1 + 4\omega^2\tau^2)]$$

where C, τ, and ω denote the motional constant, the correlation time of the motion, and the angular Larmor frequency, respectively. We assume an Arrhenius type relationship between τ and the activation energy E_a of the motion written as

$$[2] \quad \tau = \tau_0 \exp(E_a/RT)$$

where τ_0 is the correlation time in the limit of infinite temperature. Equations [1] and [2] were fitted to the observed data by the least-squares method. The best-fitted calculated T_1 curve is shown in Fig. 4. The parameters, C, τ_0, and E_a determined are given in Table 3. The T_1 minimum can be attributed to the CH_3 reorientation about the C_3 axis by referring to the M_2 analysis in LTSP. In fact, the fitted motional constant C agrees well with the theoretical value of 1.67×10^9 s^{-2} for the CH_3 reorientation which was calculated using the equation given by (6)

$$[3] \quad C = \tfrac{3}{14}\tfrac{9}{20}\gamma^4\hbar^2 r^{-6}$$

where γ is the gyromagnetic ratio of the proton and the interprotonic distance r in a CH_3 group was evaluated by use of the geometry employed in the M_2 calculation. The fact that the observed T_1 curve could be explained well by a single BPP equation implies the following. The CH_3 groups are placed in such a homogeneous crystal field that no distribution of the correlation time (21) or non-exponential T_1 behavior can be observed. In the low-temperature phases of *n*-propyl- and *n*-butylammonium bromides (6, 17), corresponding to LTSP of the present salt, however, we have observed unusual T_1 curves explainable by considering distributions of τ. This suggests the presence of microscopic inhomogeneity for the atomic arrangements in these materials.

[b] τ_{0R} in text.
[c] Fitted value of T_0 (see text).
[d] The value in parentheses is the theoretical value.
[e] Assumed value.

The T_1 decrease observed above 200 K with increasing temperature is attributable to another molecular motion because a clear frequency dependence of T_1 was observed. The estimated activation energy for this motion from the slope of the log T_1 vs. T^{-1} plot is 28 ± 2 kJ mol^{-1}. The mode of this motion seems to be assigned to the NH_3^+ reorientation about the C—N bond because similar decreases of T_1 due to the NH_3^+ reorientation were observed in the same temperature range in *n*-butylammonium halides (17, 18).

Low-temperature metastable phase (LTMP)

The experimental result that T_1 for the long and major component in the two component values, separated from the observed free induction decay signals for the quenched sample, agrees well with that of LTSP indicates that the quenched sample consists mostly of LTSP. The short T_1 component regarded as a single component, can be assigned to LTMP. Since the T_1 values of the short component could not be determined accurately, it is difficult to discuss quantitatively its temperature dependence. The broad T_1 minimum of the short component appearing around 140 K seems to be partly contributed from the CH_3 reorientation. The T_1 values shorter than those in LTSP observed over the whole temperature range below T_{tr} (257 K) imply that other motional processes including such as those relating to the whole cationic motions also contribute to the relaxation, suggesting the presence of a more disordered atomic arrangement in LTMP than those in LTSP.

Room-temperature phase (RTP)

In this phase, T_1 increased with temperature and no frequency dependence of T_1 was observed up to ca. 400 K. It is noted that the gradient of the log T_1 vs. T^{-1} curve decreases with increasing

temperature. This is unexplainable in terms of the usual Arrhenius type excitation given by eq. [2]. Unusual T_1 curves similar to the above have been observed in the supercooled liquid state of glass-forming substances such as glycerol (22, 23), in which the correlation time τ_R of molecular reorientation can be given as

$$[4] \quad \tau_R = \tau_{R0} \exp [E_{aR}/R(T-T_0)]$$

where τ_{R0} and E_{aR} are defined for the molecular reorientation in a similar way as done for τ_0 and E_a in eq. [2], respectively. T_0 is a reference temperature supposed to exist near the glass transition temperature. In a previous study on (pra)Cl and (pra)Br (6), we have observed the T_1 behavior quite similar to that of the present salt in the room temperature phases having the crystalline unit cell with the same space group as that in RTP of the present salt. In these tetragonal phases containing cations with highly disordered orientations about their long axes, it is possible for the present salt to form an orientational glass at low temperatures. We performed a curve fitting calculation for the T_1 values observed in RTP up to 350 K using eqs. [1] and [4]. In this calculation, the motional constant C in eq. [1] was roughly evaluated using the equation given by (24)

$$[5] \quad C = \tfrac{2}{3}\gamma^2 \Delta M_2$$

where ΔM_2 is the M_2 reduction due to the onset of the cationic motion at room temperature. Since we have no information about the mode of this motion, we assumed ΔM_2 due to this motion to be equal to the difference between the calculated M_2 for the axial rotation of cations given in Table 2 and the observed M_2 just above T_{tr} (257 K), namely, $\Delta M_2 = (5.9 - 3.0)$ G^2. The best-fitted T_1 curve determined by inspection is shown in Fig. 5. The most probable values of the unknown parameters, E_{aR}, τ_{R0}, and T_0 are given in Table 3. The E_{aR} value of 6 kJ mol^{-1} obtained in the present calculation is very close to those of 6.4 and 4.8 kJ mol^{-1} experimentally obtained for the axial rotation of the cations in (pra)Cl and (pra)Br, respectively. The small activation energies indicate quite free whole-cationic rotation taking place already at room temperature.

With increasing temperature the T_1 decrease observed above about 400 K is attributable to the existence of a magnetic dipolar mechanism due to a new cationic motion because a frequency dependence of T_1 was observed. This new motion can be considered as the translational self-diffusion of the cation in the crystal by the reason given in the following section, although several other motions can be expected to occur. The T_1 data observed at 10.5 MHz above 400 K can be separated into two components given by

$$[6] \quad T_1^{-1} = T_{1\,\mathrm{diff}}^{-1} + T_{1\,\mathrm{rot}}^{-1}$$

where $T_{1\,\mathrm{diff}}$ and $T_{1\,\mathrm{rot}}$ are spin–lattice relaxation times due to the cationic self-diffusion and the whole-cationic uniaxial rotation, respectively. The whole-cationic uniaxial rotation is, as already described above, due to the relaxation mechanism involving the non-Arrhenius type correlation time. We estimated $T_{1\,\mathrm{rot}}$ by extrapolating the fitted non-Arrhenius T_1 curve to the higher temperature range. The $T_{1\,\mathrm{diff}}$ values determined by substituting $T_{1\,\mathrm{rot}}$ and T_1 observed at 10.5 MHz into eq. [6] are exhibited in Fig. 5.

Since RTP has the layer structure as shown in Fig. 1, it is highly probable that cationic self-diffusion within each layer occurs more frequently than that in the direction perpendicular to the layer. In such 2D diffusion, it has been reported (25, 26) that the relaxation times are expressed differently from the usual BPP equations (20). It can be shown, however, that the T_1 expression becomes almost the same as that for the BPP equation in the limit of slow motion, $\omega\tau_D \gg 1$ where τ_D is the correlation time of the self-diffusion of the cation (27, 28). Therefore, the activation energy for self-diffusion, evaluated from the slope of the log $T_{1\,\mathrm{diff}}$ vs. T^{-1} plot became 50 ± 4 kJ mol^{-1}.

The observed $T_{1\rho}$ minimum can also be assigned to cationic 2D self-diffusion by taking into account the general relationship between T_1 and $T_{1\rho}$ curves. We evaluated the activation energy as 44 ± 2 kJ mol^{-1} from the slope of the log $T_{1\rho}$ vs. T^{-1} plots observed for the low temperature side of the minimum in a similar manner to the analysis of T_1. This activation energy is close to that obtained from the T_1 data, supporting the suggestion that the same motional process contributes to both T_1 and $T_{1\rho}$. The activation energy for the cationic self-diffusion in (pra)Cl has been determined as about 40 kJ mol^{-1} (6) in a crystal with the layer structure isomorphous with RTP of the present salt. The fact that this value is a little smaller than that of the present salt is attributable to the differences in the size and mass of the two cations.

Electrical conductivity

The ionic conductivity in RTP having the layer structure is expected to be anisotropic. In other words, the conductivity within the layer and perpendicular to the cationic long axis ($\sigma_\perp$) is considered to be different from that in the direction parallel to this axis ($\sigma_\parallel$). For the powder sample, the observed conductivity can be expressed as

$$[7] \quad \sigma = (1/3)\sigma_\parallel + (2/3)\sigma_\perp$$

Here, we assume that the translational jumps of the ions within the layer take place much more frequently than those in the direction perpendicular to the layer, as already assumed in the analysis of the $T_{1\rho}$ data. Then we have

$$[8] \quad \sigma \simeq (2/3)\sigma_\perp$$

The self-diffusion constant $D_\perp$ in the direction perpendicular to the cationic long axis can be written, using the Nernst–Einstein equation as

$$[9] \quad D_\perp = \frac{3\sigma\lambda kT}{2(Ze)^2 N}$$

where λ, Ze, and N denote the spatial correlation factor, the electric charge of the diffusing ion and the number of the diffusing ions in a unit volume, respectively. For the monovacancy diffusion model within a 2D square lattice, λ has been calculated as 0.46694 (29). The temperature dependence of $D_\perp$, obtained by substituting the observed σ values into eq. [9], is shown in Fig. 7. Between room temperature and about 460 K, the plot of log $D_\perp$ vs. T^{-1} showed a linear relationship, indicating that a single Arrhenius-type activation process of diffusion accounts for most of the observed conductivity. From the slope of the log $D_\perp$ vs. T^{-1} plot, the activation energy was determined to be 46 ± 2 kJ mol^{-1}. This value agrees well with 44 and 50 kJ mol^{-1} obtained for cationic self-diffusion from the T_σ and T_1 data, respectively. Accordingly, it is concluded that the conductivity is determined by the cationic self-diffusion.

For 2D self-diffusion, the diffusion constant can be approximately related to the correlation time τ_D of the 2D self-diffusion by the equation (27, 30):

$$[10] \quad D_\perp = d^2/4\tau_D$$

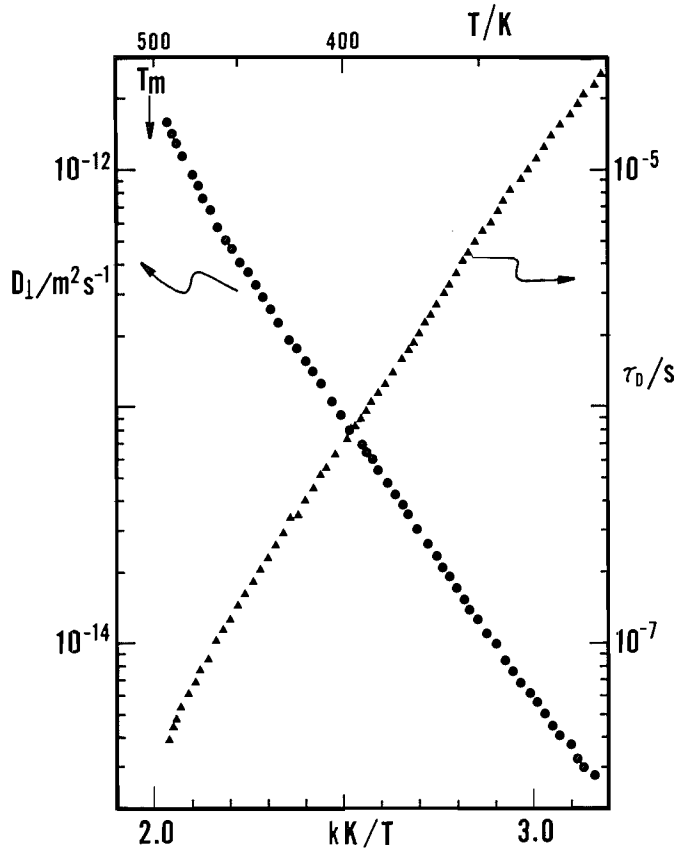

FIG. 7. The 2D diffusion constant $D_\perp$ and diffusion correlation time τ_D of pentylammonium cations in the room-temperature phase (rotator phase).

where d is the nearest jump distance. In the present monovacancy model, the cations can jump only to the nearest vacant lattice site of the cation. Then d can be taken as the length of the a axis in the tetragonal unit cell, reported as 5.01 Å at room temperature (2). The τ_D values evaluated by substituting $D_\perp$ into eq. [10] are shown in Fig. 7. Very short τ_D values of the order of 10^{-8} s were obtained above 460 K.

These short correlation times are of the same order of magnitude as those for the 3D self-diffusion observed in "ionic plastic crystals" such as the highest-temperature solid phases of methylammonium nitrate (16) and perchlorate (31). It has been reported also in the plastic phases of molecular crystals (7, 8) that diffusion correlation times are shortened to the order of 10^{-7} -10^{-8} s in the neighborhood of the respective melting temperatures. These results indicate that RTP of the present salt contains a high concentration of lattice defects at higher temperatures as is the case with the plastic crystals. In fact, marked plasticity of the crystals was definitely observed even at room temperature, as mentioned above. This free translational motion of cations can be considered as one of the origins of the large entropy change observed at the phase transition from LTSP to RTP. It should be noted, however, that this disorder with respect to the occupation of the lattice sites as well as the orientational disorder about the cationic long axis, observed in the present salt, takes place within layers. In each layer the rod-like cations, with partially deformed structures due to the conformational disorder, still do not gain the freedom of isotropic diffusion and isotropic reorientation that occur in the plastic crystals as well as in "the ionic plastic crystals."

Cationic motions in the rotator phases (α and α′)

It is interesting to compare the cationic motions found in RTP (α′-phase) of (pna)Cl and those in the room-temperature phase (α) and the high-temperature phase (α′) of (pra)Cl already reported (6). In (pra)Cl, the α′-phase can be obtained in a narrow temperature range of about 30 K just below its mp of 436 K, although it may be supercooled down to about 350 K. In (pna)Cl, on the other hand, the α′-phase is stable in a much wider temperature range, 257–503 K. Accordingly, we are interested in whether or not the high mobility of the cations in the α′-phase, which was observed only in the neighborhood of mp for (pra)Cl, exists in the isomorphous phase of (pna)Cl down to room temperature.

It is noted in the experimental results that surprisingly good agreement could be seen in the T_1 and M_2 values of these two salts observed in the temperature range (about 360–435 K) where both salts are in the α′-phase. This implies that the motional states of cations in these two salts are almost the same in the α′-phase. The fact that (pna)Cl in the α′-phase exhibited a constant M_2 of about 3 G^2 around room temperature shows a marked contrast to a large M_2 of 5.5 G^2 observed in the α-phase of (pra)Cl in the same temperature range. This indicates that the α′-phase has a much more disordered arrangement of cations than the α-phase even though comparison was made at the same temperatures.

An interesting result is that the non-Arrhenius type T_1 curve observed in the α-phase of (pra)Cl and (pra)Br (6) was also detected in (pna)Cl but in its α′-phase. At the present stage, we cannot explain definitely this unusual T_1 behavior, although it seems likely as described before that the orientational disorder of the cations about the long axis present in both phases is closely related to this phenomenon.

The electrical conductivity measurements can indicate another interesting difference between the cationic motions of the two salts. The conductivity in the α′-phase of (pra)Cl was just one order of magnitude higher than that in the same phase of (pna)Cl measured at the same temperatures. This result is attributable to the differences in the size and mass of the two cations, and hence supports our conclusion that the observed conductivity is due almost entirely to the cationic self-diffusion. On the other hand, the conductivity in the α-phase of (pra)Cl observed around room temperature was smaller by three orders of magnitude than that in the α′-phase of (pna)Cl measured at the same temperatures. We can conclude from these results that, in the α′-phase, not only the whole-cationic uniaxial reorientation, but also their translational self-diffusion takes place quite readily even at room temperature.

From the above discussion of the two kinds of rotator phases, α and α′, we can propose the possible cationic arrangements of these phases. In the α-phase, which can be found around room temperature in (pra)Cl and also in methylammonium bromide (32) and iodide (33) the only allowed whole-cationic motion is the uniaxial reorientation about the long axis. In other words, there is only a single kind of dynamical disorder involving the cations. This means that the cations, having an average structure like a rigid rod are packed regularly with their axes parallel to the crystallographic c axis between the layers made of the anions. On the other hand, the α′-phase formed by n-alkylammonium chlorides with alkyl chains longer than C_3 (2) is expected to contain a more disordered arrangement of cations around or above room temperature.

Of motions responsible for the above disorder, we have shown the presence of the rapid 2D translational jumps of the

cations. Other possible motions are partial conformational disorder of the alkyl chains, and large amplitude lattice vibrations such as precessional motions of cations with fixed polar ends. These motions strongly disturb the regular arrangement of the cationic axes parallel to each other. Accordingly, the long axes of the cations can be said to be directed along the *c* axis only when they are statistically averaged, although the cations are placed in a highly symmetrical crystal field made by the anions.

Applications of enzymes in the synthesis and hydrolytic study of 2-deoxy-α-D-glucopyranosyl phosphate

M. DAVID PERCIVAL AND STEPHEN G. WITHERS[1]

Department of Chemistry, University of British Columbia, Vancouver, B.C., Canada V6T 1Y6

Received January 28, 1988

This paper is dedicated to Professor Charles A. McDowell on the occasion of his 70th birthday.

M. DAVID PERCIVAL and STEPHEN G. WITHERS. Can. J. Chem. **66**, 1970 (1988).

The labile sugar phosphate 2-deoxy-α-D-glucopyranosyl phosphate has been synthesized enzymically in a two-step process from 2-deoxy-D-glucose-6-phosphate via an intermediate uridine 5′-diphospho-2-deoxy-D-glucose. Rate constants for acid-catalysed (1 M $HClO_4$) hydrolysis at several temperatures were determined by using an enzymic assay to measure remaining substrate. The values obtained were consistent with that anticipated on the basis of known hydrolysis rates for alkyl- and aryl-2-deoxy-D-glucopyranosides.

M. DAVID PERCIVAL et STEPHEN G. WITHERS. Can. J. Chem. **66**, 1970 (1988).

Utilisant le phosphate-6 du désoxy-2 α-D-glucose comme produit de départ et faisant appel à une méthode enzymatique impliquant deux étapes et le diphospho-5′ désoxy-2 D-glucose uridine comme intermédiaire, on a synthétisé le phosphate du désoxy-2 α-D-glucopyrannosyle, un phosphate labile de sucre. Utilisant une méthode enzymatique pour mesurer la quantité de substrat qui n'a pas réagi et opérant à diverses températures, on en a mesuré les constantes de vitesse d'hydrolyse catalysée par les acides (1 M de $HClO_4$). Les valeurs obtenues sont en accord avec celles que l'on peut attendre sur la base des vitesses connues d'hydrolyse des désoxy-2 D-glucopyrannosides d'alkyles et d'aryles.

[Traduit par la revue]

Introduction

Kinetic studies with deoxy- and deoxyfluoro-sugar substrates can provide useful insight (1, 2) into the mechanisms of both enzymic and nonenzymic reactions. The importance of charged intermediates in both enzymic and nonenzymic reactions can be probed as can also the importance of hydrogen bonding in the enzyme-catalyzed reaction. As part of our studies on the catalytic mechanism of the enzyme glycogen phosphorylase we have synthesized a series of deoxy and deoxyfluoro analogues of α-D-glucopyranosyl phosphate and determined rates of both their enzymic breakdown and acid-catalyzed hydrolysis. The synthesis of all the deoxyfluoro- and three of the deoxy-α-D-glucopyranosyl phosphates was relatively readily achieved via MacDonald (3) phosphorylation of the corresponding peracetylated sugars. However, despite claims (4) of a successful synthesis of 2-deoxy-α-D-glucopyranosyl phosphate by this procedure, we were unable to prepare this material at a satisfactory level of purity. These problems stem largely from its hydrolytic instability. We therefore elected to synthesize this compound by an alternate route, using a combination of three enzymes in a two-step synthesis. This paper describes the enzymic synthesis and purification of 2-deoxy-α-D-glucopyranosyl phosphate. It also describes a novel enzymic method for measurement of rates of acid-catalyzed hydrolysis of this extremely labile glycosyl ester.

Results and discussion

Synthesis of the title compound by direct MacDonald phosphorylation of 1,3,4,6-tetra-*O*-acetyl-2-deoxy-β-D-glucopyranose proved unsuccessful despite a number of attempts under varying conditions. Equally unsuccessful were attempts to add phosphoric acid across the double bond of 3,4,6-tri-*O*-acetyl-D-glucal. In each case the initial phosphorylation mix was saponified with 1 M LiOH to deprotect the sugar products as well as to remove excess phosphoric acid as its insoluble lithium salt, and reaction mixtures were assayed by ^{31}P nmr. A mixture of phosphate esters was detected in each case and all attempts to isolate the desired 2-deoxy-α-D-glucopyranosyl phosphate were unsuccessful.

A viable alternative approach to this synthesis, involving reactions performed under mild, neutral conditions, appeared to be an enzymic synthesis, based upon observations of others (5) of the ability of 2-deoxy-D-glucose to be converted into its uridine-diphospho derivative in partially purified tissue homogenates. The approach employed was necessarily a two-step synthesis since the direct conversion of 2-deoxy-D-glucose-6-phosphate to 2-deoxy-α-D-glucopyranosyl phosphate, achieved by phosphoglucomutase (6), is energetically unfavourable and would result in, at best, 5% yields of the desired compound and a very tricky separation.

In the first step (Scheme 1a), commercially available 2-deoxy-D-glucose-6-phosphate (Sigma Chemical Co.) was converted into uridine diphospho-2-deoxy-D-glucose by the combined actions of phosphoglucomutase and uridine diphosphoglucose pyrophosphorylase. This reaction was pulled to completion by inclusion of inorganic pyrophosphatase in the reaction mixture to remove product pyrophosphate. Progress of the reaction was monitored by the appearance of acid-labile phosphate, the product uridine diphospho-2-deoxy-D-glucose being readily distinguished by its pair of phosphate resonances ($\delta = 8.50$, $\delta = 10.53$). Since this crude mixture contained large quantities of phosphate, which would be difficult to separate from the desired product by anion exchange chromatography, it was treated with LiOH to pH 13 to precipitate the phosphate as its lithium salt, which was then removed by filtration. An additional advantage of this step is that it removes any uridine diphosphoglucose arising from the glucose 1,6-diphosphate added to activate phosphoglucomutase, or from contaminating glucose-6-phosphate, since at high pH values, uridine diphosphoglucose decomposes (7) via intramolecular attack of the sugar 2-hydroxyl on its phosphate moiety, producing uridine 5′-monophosphate and α-D-glucopyranosyl-1,2-cyclic phos-

phate. Such a decomposition is clearly impossible for the 2-deoxy derivative. After neutralization of the mixture it was purified by gradient elution from a DE52-cellulose anion exchange column. Product elution was monitored by ultraviolet spectroscopy and by the appearance of acid-labile phosphate.

Purified uridine diphospho-2-deoxy-D-glucose was then again treated with uridine diphosphoglucose pyrophosphorylase and a large excess of pyrophosphate to drive the reaction backwards towards optimal production of 2-deoxy-α-D-glucopyranosyl phosphate as shown in Scheme 1b. Reaction progress was monitored by ^{31}P nmr, and the product purified by gradient elution from a DE52 anion exchange column. Repeated freeze-drying of the product fractions gave the desired product, which was characterized by ^{31}P and ^{1}H nmr, but proved too unstable to provide a satisfactory microanalysis.

Acid-catalysed hydrolysis rate

On the basis of previously determined (8) relative rates of acid-catalyzed hydrolysis of phenyl β-D-glucopyranoside and its 2-deoxy analogue, the half-life of 2-deoxy-α-D-glucopyranosyl phosphate under the conditions used to study other hydrolyses of glycopyranosyl phosphates (1 M $HClO_4$, 25°C) was estimated to be approximately 5 s, i.e., too rapid for simple measurement. On that basis it was decided to measure rates of hydrolysis at lower temperatures (0–8°C) and to extrapolate to a value at 25°C. Reaction progress had previously (1) been monitored via appearance of phosphate. However, in this case, even the modified phosphate assay (9), which had previously proved suitable for analysis of phosphate levels in the presence of acid-labile phosphate esters, proved unsuitable, since there was very substantial hydrolysis of the 2-deoxy derivative during the 15-s exposure to acid prior to addition of the reducing agent.

A novel method for measuring the extent of hydrolysis as a function of time was therefore developed, based upon a sensitive enzymic method for estimating the concentration of remaining *substrate* under neutral conditions. This assay was performed by removing aliquots of the acidic reaction mixture and immediately quenching them in strongly buffered reaction mixtures containing excess phosphoglucomutase, glucose-6-phosphate dehydrogenase, nicotinamide adenine dinucleotide (NAD), and other necessary cofactors. Under these conditions, the aliquot was instantly neutralized, halting acid-catalyzed hydrolysis, and remaining substrate rapidly converted to 2-deoxy-D-glucose-6-phosphate, since phosphoglucomutase operates very efficiently on 2-deoxy derivatives (6).[2] This stable phosphate ester was then slowly converted, over 20–30 min, to 2-deoxy-D-gluconic acid-6-phosphate by glucose-6-phosphate dehydrogenase, with concomitant stoichiometric conversion of NAD to its reduced form, NADH. This process could be followed by uv/visible spectroscopy at 340 nm, the quantity of 2-deoxy-α-D-glucopyranosyl phosphate remaining in each aliquot being readily determined from the total change in absorbance at 340 nm. In this manner, the time course of acid-catalyzed (1 M $HClO_4$) hydrolysis was determined at temperatures of 0, 4, and 9°C and the kinetics of hydrolysis found to be accurately first order over two half-lives in each case. The rate constants measured are presented in Table 1, along with that value calculated by extrapolation of the data to 25°C using an Arrhenius plot. Comparison of the value obtained with that (1) for hydrolysis of α-D-glucopyranosyl phosphate under these conditions (4.1×10^{-5} s^{-1}) reveals that the 2-deoxy derivative is hydrolyzed some 2680 times more rapidly than the parent compound. This compares very favourably with the relative ratio of 2200:1 observed (8) for the acid-catalyzed

[2]Also, M. D. Percival and S. G. Withers. Unpublished results.

[b]Value obtained from extrapolation of previous data using an Arrhenius plot.

hydrolysis rates of phenyl 2-deoxy-β-D-glucopyranoside and phenyl β-D-glucopyranoside and with the relative ratios of 2090:1 calculated (11) for the corresponding methyl glycosides. It does not, however, agree with the relative hydrolysis rates of 9:1 claimed by other authors (12) for acid-catalyzed hydrolysis of the title compound and its parent sugar. However, it is also difficult to reconcile the rate constant claimed (12) for acid-catalyzed hydrolysis of α-D-glucopyranosyl phosphate in that publication with other published values (13–15).

The high rate of acid-catalysed hydrolysis for such 2-deoxy glucosides and glycosyl esters is consistent with the generally accepted mechanism (11) of this reaction, involving an oxocarbonium ion intermediate. The replacement of the hydroxyl at C-2 by more electronegative substituents such as fluorine or chlorine has been shown previously (1, 16) to result in decreased reaction rates due to inductive destabilization of the oxocarbonium-ionlike transition states. Conversely, replacement by the relatively less electronegative hydrogen is expected to result in higher reaction rates.

Experimental

All buffer chemicals, substrates, and enzymes were obtained from Sigma Chemical Company and were used as supplied. The nmr studies were performed on a Varian XL 300 nmr spectrometer. The ^{31}P nmr chemical shifts are referenced relative to orthophosphoric acid and ^{19}F nmr chemical shifts relative to $CFCl_3$.

Uridine-5′-diphospho-2-deoxy-α-D-glucopyranose (1)

To a solution of 100 mM Tris buffer (20 mL), pH 7.6, containing 30 mM magnesium chloride was added uridine-5′-triphosphate (0.168 g, 0.274 mmol), 2-deoxy-D-glucose-6-phosphate (0.070 g, 0.228 mmol), α-D-glucose-1,6-diphosphate (0.1 μmol), and bovine serum albumin (0.15 mg/mL). After readjustment of the pH to 7.6, phosphoglucomutase (100 units), uridine-5′-diphosphoglucose pyrophosphorylase (25 units), and inorganic pyrophosphatase (10 units) were added and the reaction incubated at 25°C. The course of the reaction was monitored by the appearance of inorganic phosphate using the Fiske–SubbaRow method. After 6 days the solution was diluted with water to 150 mL and the pH adjusted to 8.0. The mixture was chromatographed at 4°C on a DE52 cellulose column (1.8 × 30 cm) that had been previously equilibrated with 30 mM ammonium bicarbonate. After washing with 200 mL water, the product was eluted with a gradient of 0–0.2 M ammonium bicarbonate at a flow rate of 2 mL/min in a total volume of 2 L. The desired product was the first uv active peak, eluting at 60–70 mM salt, a concentration characteristic of dianions. After repeated freeze-drying to remove the volatile buffer, inorganic phosphate, which coeluted with the product, was precipitated by addition of 2 M lithium hydroxide to pH 13. The precipitated lithium phosphate was removed by filtration through Celite. The pH of the filtrate was readjusted to pH 7.6 by addition of Dowex 50 W-X8H^+ resin; ^{31}P nmr (121.4 MHz, D_2O) δ: 8.5 (d, $J_{P,P}$ 21Hz), 10.53 (d, $J_{P,P}$ 21 Hz).

2-Deoxy-α-D-glucopyranosyl [bis(ammonium)phosphate] (2)

The solution of **1** was added to 100 mM Tris (20 mL), pH 7.6, containing 30 mM magnesium chloride, sodium pyrophosphate (1.0 g, 225 mmol), and bovine serum albumin (0.15 mg/mL). Uridine-5′-diphosphoglucose pyrophosphorylase (25 units) was added and the solution incubated at 25°C. The course of the reaction was monitored by ^{31}P nmr. After 3 days the inorganic phosphate was removed as described above, the pH readjusted to 8.0, and the mixture chromatographed on a DE52 cellulose column (2.8 × 40 cm) exactly as described previously. The product was identified by the presence of phosphate according to the method of Bartlett (10), and the buffer removed by repeated freeze-drying to yield a white foam; ^{31}P nmr (121.4 MHz, D_2O) δ: 1.28 (dd, $J_{P,1}$ 6.8, $J_{P,2}$ 2.0 Hz); ^1H nmr (300 MHz, D_2O) δ: 5.55 (m, $J_{1,P}$ 7 Hz, 1H, H-1), 4.1–3.2 (m, 5H, H-3,4,5,6,6′), 2.15 (dd, $J_{2eq,2ax}$ 12, $J_{2eq,3}$ 5 Hz, 1H, H_{2eq}) 1.65 (m, $J_{2ax,2eq}$ 12, $J_{2ax,3}$ 12 Hz, 1H, H_{2ax}).

Phase transitions in adamantane derivatives: 2-chloroadamantane

RALPH M. PAROLI, NANCY T. KAWAI, IAN S. BUTLER,[1] AND DENIS F. R. GILSON[1]
Department of Chemistry, McGill University, 801 Sherbrooke St. West, Montreal (P.Q.), Canada H3A 2K6

Received November 27, 1987

This paper is dedicated to Professor Charles A. McDowell on the occasion of his seventieth birthday

RALPH M. PAROLI, NANCY T. KAWAI, IAN S. BUTLER, and DENIS F. R. GILSON. Can. J. Chem. **66**, 1973 (1988).

The phase transition behaviour of 2-chloroadamantane, 2-$C_{10}H_{15}Cl$, has been investigated by differential scanning calorimetry (DSC), and FT-IR and Raman spectroscopy. Two transitions were detected by both DSC and vibrational spectroscopy at 231 and 178 K, on cooling, and at 242 and 227 K, on heating. The measured enthalpies were 8.3 kJ mol^{-1} for the first transition (phase I → phase II), and 0.47 kJ mol^{-1} for the second (phase II → phase III). The entropies were 35 and 2.3 J K^{-1} mol^{-1}, respectively. These are similar to those observed for other 2-substituted adamantanes, but significantly different from those for 1-substituted derivatives. The large hystereses observed for the two transitions are independent of the DSC scanning rate and are characteristic of first-order phase transitions. The dramatic differences observed in the vibrational spectra of phases I and II provide clear evidence of an order–disorder transition at about 235 K.

RALPH M. PAROLI, NANCY T. KAWAI, IAN S. BUTLER, et DENIS F. R. GILSON. Can. J. Chem. **66**, 1973 (1988).

Utilisant la calorimétrie différentiel programmé (CDP) ainsi que la spectroscopie Raman et IR par TF, on a étudié le comportement du chloro-2 adamantane, 2-$C_{10}H_{15}Cl$, lors de sa transition de phase. Les trois méthodes ont permis de détecté deux transitions, soit à 231 et 178 K lors du refroidissement et 242 et 227 K lors du chauffage. On a évalué que l'enthalpie de la première transition (phase I → phase II) est de 8,3 kJ mol^{-1} et de 0,47 kJ mol^{-1} pour la deuxième (phase II → phase III). Les entropies sont respectivement de 35 et de 2,3 J K^{-1} mol^{-1}. Ces valeurs sont semblables à celles qui ont été observées pour d'autres adamantanes substitués en position 2; toutefois, elles diffèrent beaucoup des valeurs observées avec dérivés en position 1. Les hysterisis importantes que l'on observe pour chacune des deux transitions sont indépendantes du taux de balayage du CDP et sont caractéristiques de transitions de phase du premier ordre. Les différences dramatiques que l'on observe dans les spectres vibrationnels des phases I et II fournissent des preuves nonambigues que la transition à 235 K en est une d'ordre/désordre.
[Traduit par la revue]

Introduction

Molecular solids with high vapour pressures and melting points, and low entropies of fusion (<20 J K^{-1} mol^{-1}) are often referred to as "plastic crystals" (1–4). These materials are generally soft, colourless, transparent solids that are difficult to fracture or pulverize. Solid–solid phase transitions occur from an ordered to a disordered structure in which the molecules rotate about one or more of their axes in the crystal lattice. Furthermore, since the phase transitions are often strongly exothermic, these materials are currently receiving considerable attention as passive thermal storage systems (5–8).

The cage hydrocarbon, adamantane ($C_{10}H_{16}$), is one of the best known "plastic crystals" and its properties have been widely studied (9). The order–disorder transitions in 1-substituted adamantanes ($C_{10}H_{15}R$; R = 1-COOH (10), 1-$NH_3^+Cl^-$ (11), 1-CN (12), 1-Cl (16), 1-Br (16)) have been examined. Little work has been done on 2-substituted derivatives (13, 17, 18), and as part of a study of the phase-transition behaviour of adamantane derivatives, we report here the results of an investigation of the order–disorder transitions in 2-chloroadamantane, 2-$C_{10}H_{15}Cl$, by differential scanning calorimetry (DSC), and variable-temperature FT-IR and Raman spectroscopy.

Experimental

2-Chloroadamantane (Alfa Products) were purified immediately prior to use by slow vacuum sublimation (21°C, 10^{-3} Torr). Infrared spectra were recorded on an Analect AQS-18 FT-IR spectrometer equipped with a triglycine sulfate (TGS) detector. Raman spectra were obtained using an Instruments S.A. spectrometer with a Jobin-Yvon U-1000 1.0-m double monochromator that was interfaced to a Columbia Commandor microcomputer. The 514.532-nm line of a Spectra-Physics model 164, 5-W argon-ion laser was used to excite the Raman spectra; the laser power was 300 mW at the sample. The resolution for both the IR and Raman measurements was about 2 cm^{-1}. The Raman studies were done on samples sealed in glass capillary tubes which were mounted on to the cold finger of a cryostat using indium foil as the conducting junction. For the IR analysis, several sampling techniques were attempted: KBr pellets, diffuse reflectance, sublimation on to KBr windows, and pressing into a thin layer film. Since similar spectra were obtained in each case (including the large hystereses observed in phase transition temperatures), the KBr pellet technique was used as it proved to be the most convenient method. The effect of KBr pelleting on phase transitions has been studied previously and it was found that it only increases the degree of the hysteresis at a phase transition (14). Variable-temperature FT-IR and Raman spectra were recorded with the aid of a Cryodyne Cryocooler model 21 (Cryogenics Technology, Inc.) and a silicon-diode temperature sensor attached to a Cryophysics model 4025 controller (range 400–4 K). The sample temperatures remained essentially constant (±0.5 K).

Differential scanning calorimetric experiments were performed on a Perkin-Elmer DSC-7 calorimeter. The temperature and enthalpy calibrations were based on the phase and melting transitions of cyclohexane (Aldrich Chemical Co. "gold" grade). The sample weights were typically 5–10 mg, and the samples were hermetically sealed in aluminium pans. The phase transition temperatures and enthalpies did not show any dependence on scan rate (2.5 and 5 K min^{-1}).

Results and discussion

Two phase transitions (phase I → phase II → phase III) were detected by diffential scanning calorimetry. The transition temperatures were 231 and 178 K (on cooling) and 242 and 227 K (on heating) with enthalpies of 8.3 kJ mol^{-1} for the first transition and 0.47 kJ mol^{-1} for the second. Although large hystereses are observed (10 K for the first transition and 50 K for

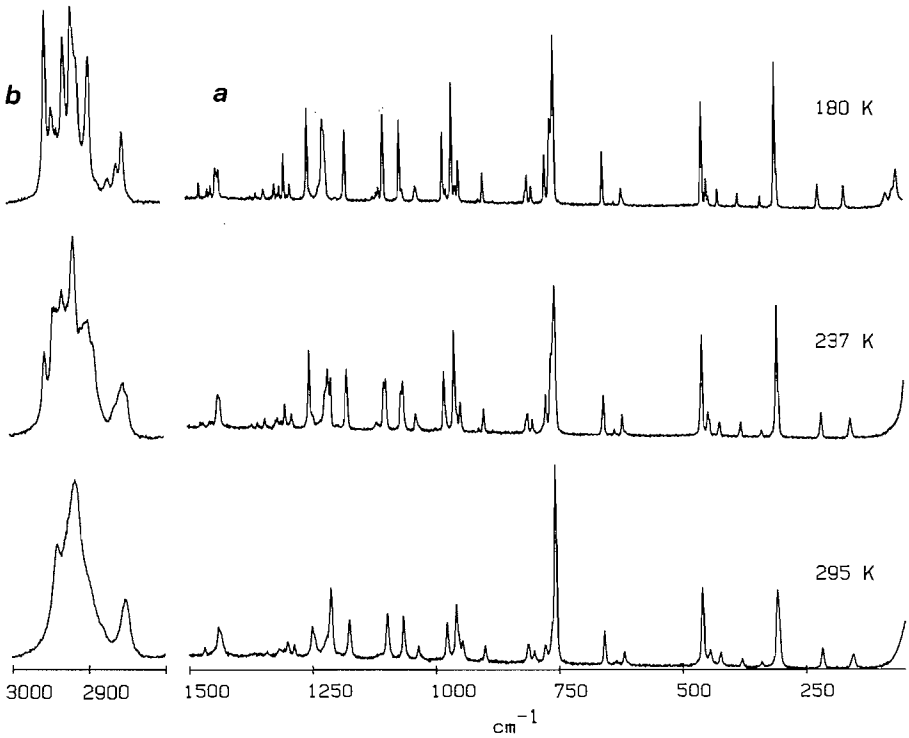

FIG. 1. Raman spectra on heating of phases I, II, and III of 2-$C_{10}H_{15}Cl$ in the (*b*) 3000–2800 and (*a*) 1500–50 cm^{-1} regions. Slits: 300 μm. Acquisition: 1 s pt^{-1}, 1 cm^{-1} step. Intensity: counts. Laser line: 514.532 nm, power 300 mW.

the second), 2-chloroadamantane did not exhibit any memory effects, i.e., the phase transition temperatures and enthalpies were not dependent on the previous thermal history of the sample. The hystereses are characteristic of first-order transitions. Rapid quenching, cycling at 20 K min^{-1}, did not reveal any exotherms on heating, hence no glassy state was formed. The entropies of transitions are 35 and 2.3 J K^{-1} mol^{-1} for the first and second phase transition, respectively. The entropy of the first phase transition is much larger than that of adamantane itself (15) and of various 1-substituted halo-derivatives which have entropies less than 25 J K^{-1} mol^{-1} (16), but is similar to the entropies of 2-bromoadamantane (17) and adamantanone (18) which are greater than 35 J K^{-1} mol^{-1}. Although the 2-derivatives (except 2-adamantanone) have lower symmetry (C_s), they still exhibit plastically crystalline behaviour (unpublished data).

The Guthrie and McCullough equation (19) for the interpretation of entropies of transition in plastic crystals is

$$[1] \quad \Delta S_{tr} = R \ln (N_1/N_2)$$

where N_1/N_2 is the ratio of the number of distinguishable positions on going from the ordered (N_2) to the disordered (N_1) phase. For the phase I → phase II transition the ratio is 70, while the second transition (phase II → phase III) only has a ratio of orientations slightly greater than one. This is an unreasonably large number of distinguishable orientations. Clark and coworkers (15, 16) have examined the entropies of transition for several cage hydrocarbons and proposed an empirical equation involving an excess entropy, which depends upon the temperature range of the disordered phase, eq. [2].

$$[2] \quad \Delta S_{tr} = R \ln(N_1/N_2) + 10.3 + 45 \exp \{- [0.0183(T_m - T_{tr})]\}$$

where $10.3 + 45 \exp \{- [0.0183(T_m - T_{tr})]\}$ is the excess entropy and $(T_m - T_{tr})$ is the temperature range of the plastically crystalline phase. There are two transitions in 2-chloroadamantane, and since phase II is probably partially disordered, the total entropy change between ordered and disordered structures is given by the sum of the two transition entropies, plus a small, negligible term for the heat capacity. Assuming that phase I is face-centered-cubic (fcc), which is typical for these materials, then there are 24 possible orientations for a molecule with C_s symmetry in the fcc lattice. Using eq. [2], with $T_m = 458$ K and $T_{tr} = 202.5$ K (the average of the heating and cooling transition temperatures), the calculated total entropy is 37.1 J K^{-1} mol^{-1}. This agrees very well with the experimental value of 37.3 J K^{-1} mol^{-1}. These results imply that there is a change in the unit cell dimensions that is accompanied by a decrease in volume only for the first phase transition.

Another method to probe phase transitions is by vibrational spectroscopy. The isolated 2-chloroadamantane molecule has C_s symmetry for which 72 normal modes of vibration are predicted (40A' and 32A''). Since the A' and A'' modes are both Raman and IR active, 72 peaks should be observed in both the Raman and the IR spectra.

The Raman and IR spectra of phases I–III are shown in Figs. 1*a*, *b* and 2*a*, *b*; the measured peak positions and the proposed vibrational assignments are given in Table 1. These assignments are based on literature values for various adamantane derivatives (20–22) and on Raman spectra of 2-$C_{10}H_{15}Cl$ in CCl_4 and CS_2 solution. Only 58 bands out of a possible 72 have been clearly identified, probably as a result of the overlapping of peaks. Even amongst those observed it is possible that some may be combinations and/or overtones.

Many interesting changes were observed in the Raman spectra as the sample was cooled and then heated between 298 and

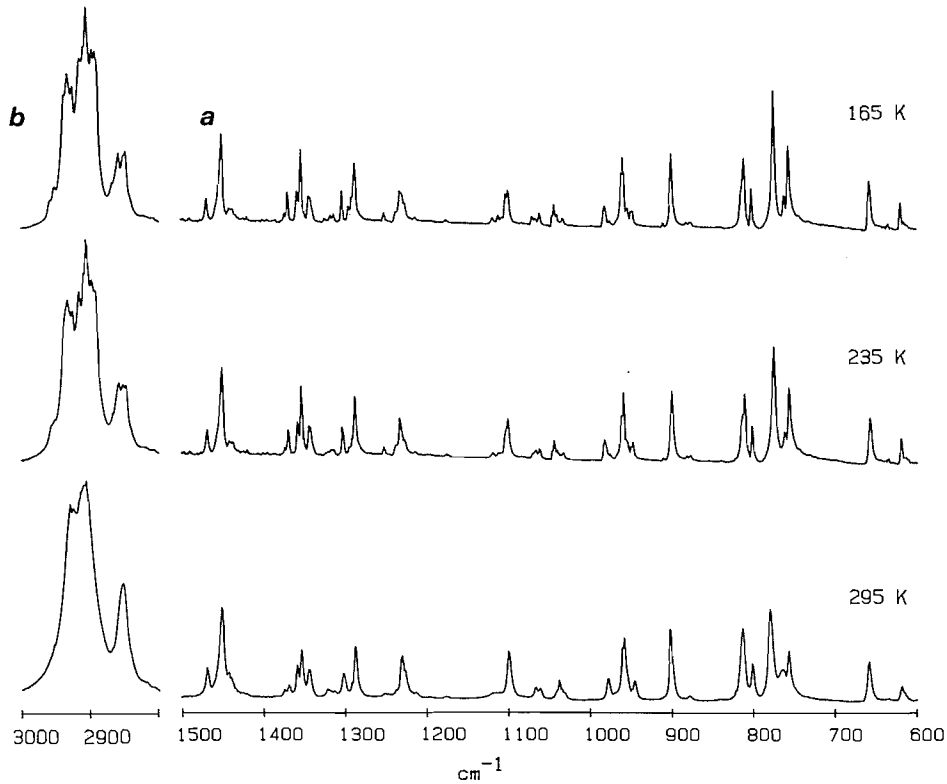

FIG. 2. IR spectra (in KBr) on heating of phases I, II, and III of 2-$C_{10}H_{15}Cl$ in the (*b*) 3000–2800 and (*a*) 1500–50 cm^{-1} regions. Intensity: absorbance units. Resolution: 2 cm^{-1}.

150 K. Consider the lattice region (100–20 cm^{-1}) shown in Fig. 3; the tail extending to 100 cm^{-1} in phase I is featureless. However, in phase II some weak features develop at ~60 and 80 cm^{-1}, and in phase III some very distinctive peaks appear. These results corroborate those of the DSC measurements, i.e., phase I is the completely disordered phase since it exhibits a total absence of lattice modes. The weak, broad peaks observed in this region for phase II indicate that it is orientationally disordered, while the sharp peaks in phase III show that it is a completely ordered phase.

In Fig. 3, the changes that occur in the Raman for the C—C—Cl bending mode are shown. In phase I, the peak appears at 156 cm^{-1}. As the sample is cooled down towards the first transition (phase I → phase II), the peak width narrows and the peak shifts to slightly higher wavenumber (159 cm^{-1}) once in phase II. However, on going from phase II to phase III, a new peak appears at 167 cm^{-1} and the 159 cm^{-1} peak decreases in intensity. The 167 cm^{-1} peak eventually shifts to 169 cm^{-1} and becomes a sharp singlet for phase III, while the peak at 159 cm^{-1} disappears completely.

The symmetric C—C stretching mode (Fig. 1*a*) also undergoes distinct changes as the sample proceeds from phase I to phase III. In the plastic phase, the peak occurs as a singlet at 760 cm^{-1} with a smaller peak at 780 cm^{-1}. In phase II, the 760 cm^{-1} peak is split into a doublet at 757 and 764 cm^{-1}. Moreover, the 780 cm^{-1} peak sharpens and increases in intensity moving finally to 775 cm^{-1}. Little change occurs as the sample progresses from phase II to phase III. Since this spectral region is solely due to C—C stretching, i.e., cage skeletal stretching, the observed changes must result from a change in crystal structure.

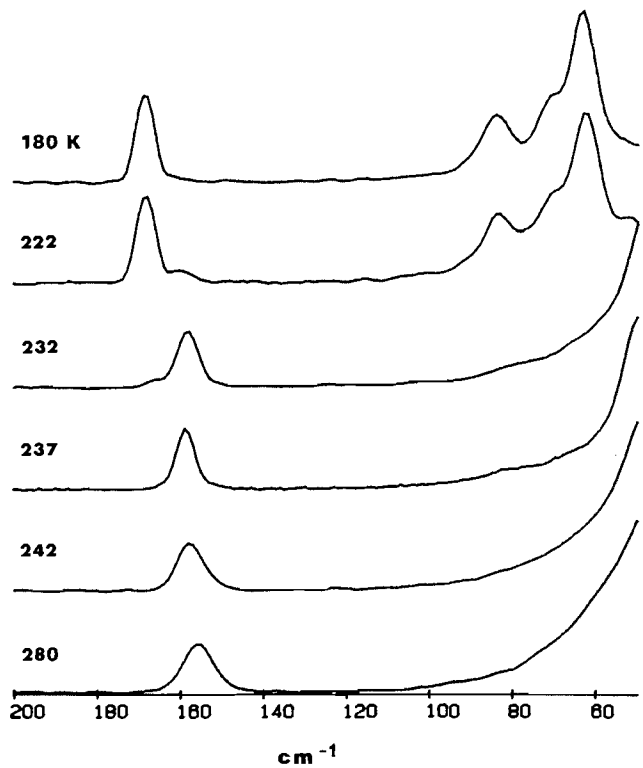

FIG. 3. Low frequency region of the Raman spectra of 2-$C_{10}H_{15}Cl$ on heating (180–280 K). Slits: 300 μm. Acquisition: 1 s pt^{-1}, 1 cm^{-1} step. Intensity: counts. Laser line: 514.532 nm, power 300 mW.

[a]In CCl_4 and CS_2 solutions

The C—C stretching and CH_2 twisting modes at 1067 cm^{-1} and the C—C—H deformation and CH_2 wag at 1100 cm^{-1} alternate between singlets and doublets as the sample goes from phase I to phase III. The doublets in phase I collapse to singlets in phase II which then split into doublets in phase III. Since the C—C and CH_2 modes contribute to the two bands, it is not surprising that the bands are sensitive to crystal structure (C—C) as well as to orientational (CH_2) changes. The same is true for the 3000–2800 cm^{-1} (symmetric and asymmetric CH stretching) region, which also undergoes dramatic changes as the sample transforms from phase I to phase III (Fig. 1*b*).

Figures 2*a* and *b* show variable temperature FT-IR spectra obtained for 2-chloroadamantane. As expected for a C_s symmetry molecule, all the changes parallel those observed in the Raman spectra. Again, phase III contains many sharp, well-resolved peaks indicating an ordered phase, whereas phase I has mostly broad, featureless bands implying a high degree of disorder. The 765 cm^{-1} peak is broad but well resolved in phase I. As the sample approaches phase II, the peak decreases in intensity until the transition to phase II in reached, at which point the peak becomes a shoulder. In phase III, the band reappears as a sharp, well-defined peak. The major differences between the IR and Raman data are that the effects observed in IR are gradual, as would be expected when using a KBr matrix (14), whereas in the Raman they are sudden. Moreover, some IR peaks are not observed in the Raman spectra, probably due to narrower peaks and better signal-to-noise ratio available for FT-IR.

Based on the vibrational splittings observed in phases II and III, the ordered phases have at least two molecules per unit cell.

Residence-time of muonium at micelles: Effect of added micelles on the reactivity of muonium towards ionic solutes in water

KRISHNAN VENKATESWARAN, MARY V. BARNABAS, BILL W. NG,[1] AND DAVID C. WALKER
Chemistry Department and TRIUMF, University of British Columbia, Vancouver, B.C., Canada V6T 1Y6

Received November 15, 1987

This paper is dedicated to Professor Charles A. McDowell on the occasion of his 70th birthday

KRISHNAN VENKATESWARAN, MARY V. BARNABAS, BILL W. NG, and DAVID C. WALKER. Can. J. Chem. **66**, 1979 (1988).

The effective rate constant for the reaction of muonium with NO_3^-, $S_2O_3^{2-}$, and Tl^+ ions in water is altered by the addition of micelles. There is a decrease when the charge on the micelle is the same as that of the solute and an increase when their charges are opposite. From the magnitude of the effect a mean residence-time for muonium of 2 ns has been deduced for dodecyl sulphate micelles. This suggests there is barely any preferred localization, because 2 ns is smaller, even, than the expected diffusion time if the micelle core is as viscous as reported. This use of muonium atoms to probe the dynamics of micelles seems to support the view that there are regions of low microviscosity and considerable water penetration within the micellar structure.

KRISHNAN VENKATESWARAN, MARY V. BARNABAS, BILL W. NG et DAVID C. WALKER. Can. J. Chem. **66**, 1979 (1988).

La constante de vitesse effective de la réaction du muonium avec les ions NO_3^-, $S_2O_3^{2-}$ et Tl^+ dans l'eau est modifiée par l'addition de micelles. Il se produit une diminution lorsque la charge de la micelle est la même que celle du soluté et une augmentation lorsque leurs charges sont opposées. En se basant sur l'amplitude de l'effet, on a pu déduire un temps moyen de résidence du muonium de 2 ns pour les micelles de sulfate de dodécyle. Ceci suggère que la localisation préférentielle existe à peine puisque 2 ns est un temps qui est plus court que le temps attendu de diffusion si le coeur de la micelle est aussi visqueux qu'on l'a rapporté. L'utilisation d'atomes de muonium pour étudier la dynamique des micelles semble apporter un support à l'hypothèse selencounters a micelle, then it will be isolated from the reactive species in ton laquelle il y a beaucoup de pénétration par l'eau et beaucoup de régions comportant de faibles microviscosités à l'intérieur de la structure des micelles.

Introduction

It was recently demonstrated that colossal enhancements can occur in the reactivity of muonium towards organic solutes when the solutes are incorporated in the lipid phase of dilute micelles in water (1). The simplest explanation for such enhancements lies with the possibility that muonium atoms *also* localize preferentially at the micellar phase because, if mutual confinement of both reactants occurred, there would be a "concentrating effect" that would naturally lead to an equivalent increase in the observed pseudo first-order rate constant. But muonium is a free thermalized neutral atom (2), and there are no obvious reasons why this light isotope of hydrogen (3, 4) should prefer the organic phase when initially formed in the bulk aqueous phase.

The experiments reported here were designed to look directly at the degree of localization of muonium at micelles, simply by observing the effect of added "empty" micelles on the rate of muonium reactions with ionic solutes taking place in water.

Experimental

Muonium atoms (μ^+e^-, chemical symbol Mu) form at the end of some muon tracks when energetic positive muons (from pion decays) are injected into water. They are observed in transverse magnetic fields by the muon spin rotation technique (μSR) (4, 5). Chemical reaction rate contants of Mu are then evaluated from the spin precession signals (as in Fig. 1) as the relaxation constant (λ) of the "triplet" muonium signal oscillating at the Larmor frequency of 1.39 MHz G^{-1}. A MINUIT χ^2-minimization fit of the muon lifetime histogram to eq. [1] gives λ as one of the fitted parameters. (In eq. [1], N_t is the number of counts in the histogram corresponding to time t; N_0 a normalization factor; τ the mean muon lifetime; A_M and A_D, λ_M and λ_D, and ϕ_M and ϕ_D are the asymmetries, frequencies, and initial phases of the "muonium atoms" and "diamagnetic muon components", respectively; and B is the time-independent background signal.) λ is related to a bimolecular chemical rate constant of Mu (k_M) through eq. [2], where λ is the observed value with solute present at concentration [S] and λ_O is the background value in the same medium, including micelle, but with [S] = 0. A narrow observational time-window of 0.3–4 μs is imposed by the μSR technique, because it is a nuclear physics technique based on the intrinsic decay of the muon (τ = 2.2 μs). Therefore, all solutions to be studied must have their muonium chemical lifetimes carefully selected so that λ falls in the limited range of $3 \times 10^6 - 2.5 \times 10^5$ s^{-1}. This precludes the possibility of studying broad concentration dependencies as one would normally like to undertake in a complete kinetic analysis. Furthermore, the micelle concentrations are restricted to $\leq 10^{-2}$ M because, with 50–80 surfactant molecules per micelle, the rate of reaction of muonium with surfactant, or its inseparable impurities, forces the "background" relaxation rate (λ_0) too close to λ for reasonable accuracy. In fact, hydrogen atoms cannot be studied at all under these conditions because of their much greater reactivity towards the surfactants (6).

$$[1]\quad N_t = N_0 \exp(-t/\tau)[1 + A_M \exp(-\lambda t)\cos(\omega_M t + \phi_M) + A_D \cos(\omega_D t + \phi_D)] + B$$

$$[2]\quad k_M = (\lambda - \lambda_0)/[S] = \Delta\lambda/[S]$$

The presence of added micelles creates a second phase, a microenvironment separated from the bulk aqueous phase (7, 8). If Mu preferentially localizes for its entire lifetime (~2 μs) as soon as it encounters a micelle, then it will be isolated from the reactive species in these systems (NO_3^-, $S_2O_3^{2-}$, and Tl^+ ions) because they are in the water. Under such conditions the "trapped" Mu would exhibit a decay constant characteristic of the micelle. To analyse for this the muonium fraction of eq. [1], the A_M term, was replaced by eq. [3] (9), with two independent exponentials for the two fractions of the Mu ensemble. A test target for this two-component modification of eq. [1] was constructed partly of aqueous NO_3^- solution (10^{-3} M where $\lambda = 1.8 \times 10^6$ s^{-1}) and partly of crystalline quartz ($\lambda \approx 0.3 \times 10^6$ s^{-1}) (10). A portion of the beam struck the quartz crystal and the muonium atoms formed therein were long-lived, being unable to react with the nitrate.

$$[3]\quad [A_{M_1}\exp(-\lambda_1 t) + A_{M_2}\exp(-\lambda_2 t)]\cos(\omega_M t + \phi_M)$$

[a] A is the aggregation number.
[b] R_C is the micelle's core radius and R_M the total radius (ref. 7).
[c] Taken as the micelle concentration when half the surfactant molecules are in micelles as calculated from $[mic] = ([surf] - CMC)/A$.

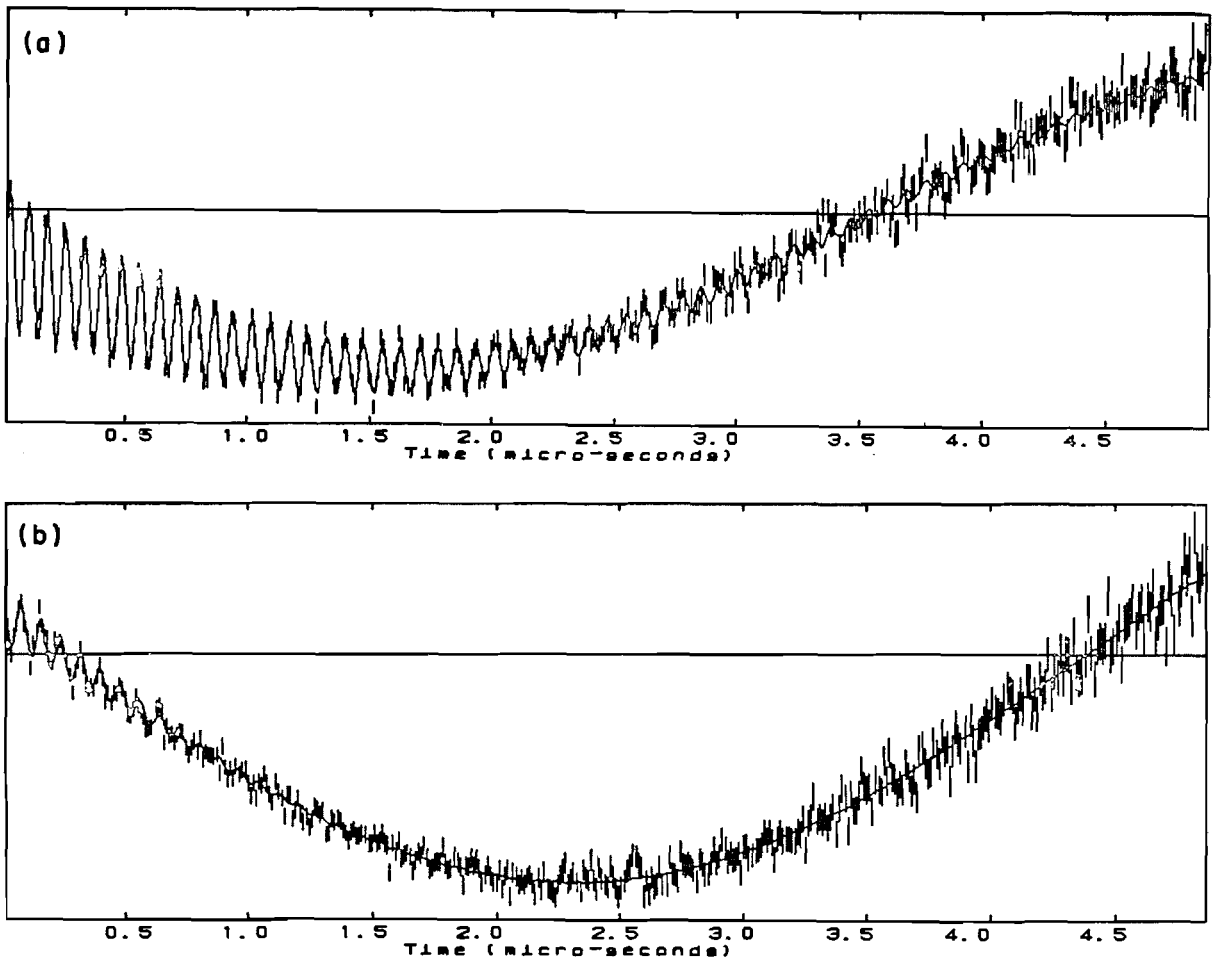

FIG. 1. (a) Asymmetry plot (A vs. t) for the quartz/NO_3^- solution artificial two-phase system. The solid line was obtained for the parameters in the text using the two-muonium function of eq. [3]. (b) Asymmetry plot for $[NO_3^-] = 0.7 \times 10^{-3}$ M and $[mic] = 10 \times 10^{-3}$ M. The line is the same as the usual one-component fit since $A_{M_2} = 0$.

Aqueous solutions were made from triply distilled water and reagent grade chemicals. They were thoroughly deoxygenated by bubbling with pure N_2. The μSR equipment on beamline M20 at the TRIUMF cyclotron was used. $NaNO_3$, $Na_2S_2O_3$, and $TlSO_4$ were used as reactive solutes for Mu, and the micelles were sodium dodecylsulphate (SDDS), dodecyltrimethylammonium bromide (DDTAB), and polyoxy(23)ethylenedodecanol (pEO). These ionic solutes were selected for their known values of k_M and matched appropriately with the charge on the micelle. Relevant k_M values and micelle properties are provided in Table 1. The concentration of the solute in water was always taken so that $\lambda \approx 1.5 \times 10^6$ s^{-1}, its most sensitive region. Micelles were added and the change in λ determined.

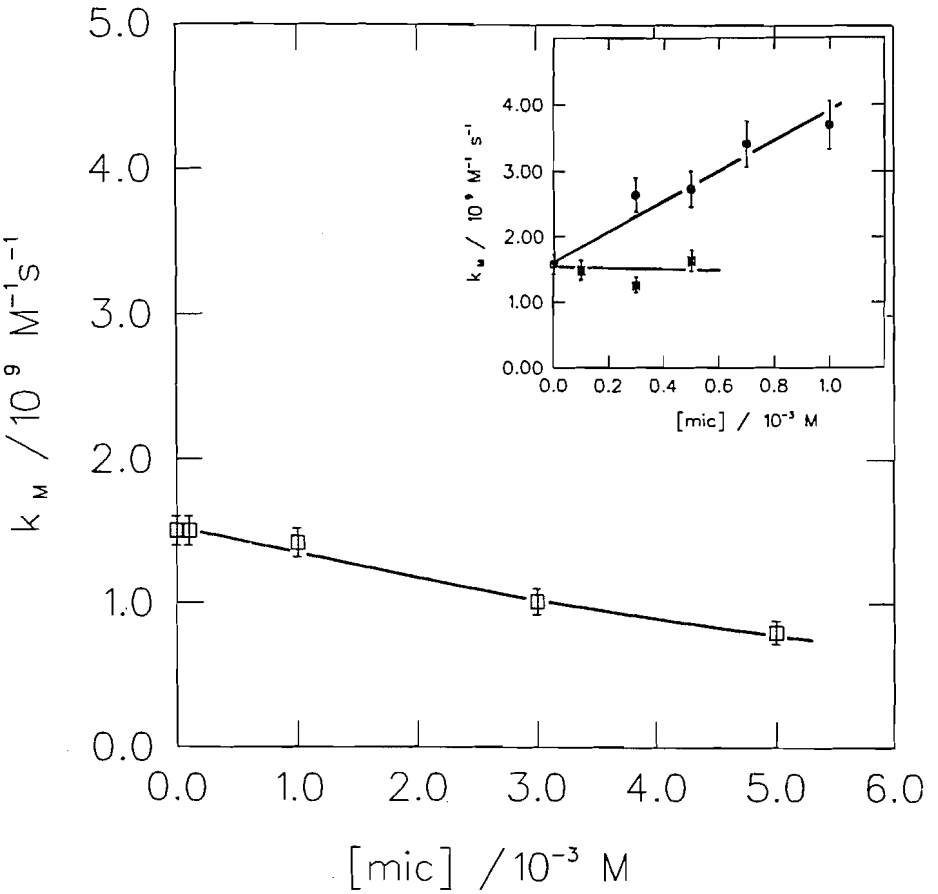

FIG. 2. Plot of k_M versus concentration of added micelles for NO_3^- solutions with [S] = 1×10^{-3} M (□) for SDDS, (●) for DDTAB, (⊠) for pEO micelles.

Results

The effect of adding micelles to 1.0×10^{-3} M NO_3^- solutions can be seen in Fig. 2. When the anionic micelle SDDS was added the observed muonium rate constant was reduced. With five times as many micelles as solutes the rate was essentially halved. On the other hand, a cationic micelle (DDTAB) increased the observed rate (doubling it approximately in a one-to-one mixture), while the neutral micelle (pEO) had no observable effect. These data are presented as k_M values determined from eq. [2]. Unfortunately pEO and DDTAB cannot be taken to higher concentrations because of their background corrections (λ_0). Similar effects, which depend primarily on the relative charge of solute and micelle, can be seen for other solutes. Table 2 shows data obtained for $S_2O_3^{2-}$ (which reacts with Mu at the diffusion-limited rate (10)) and for Tl^+ (which oxidizes Mu relatively inefficiently (10)).

The two-component overall muonium relaxation (eq. [3]) was found to apply well to the artificial two-phase system consisting of one-third quartz and two-thirds aqueous NO_3^- at 10^{-3} M. The asymmetry plot (after τ and B of eq. [1] were removed (4)) is shown in Fig. 1 (a). The best reduced χ^2 values are $A_{M_1} = 0.019$ with $\lambda_1 = 1.8 \times 10^6$ s^{-1} and $A_{M_2} = 0.033$ with $\lambda_2 = 3.5 \times 10^5$ s^{-1}. This is about what was expected since the muonium yield in quartz is 3.5 times larger than in water (10) but only one-third of the muon beam stopped in the quartz. These data verify that if the Mu ensemble is rapidly subdivided into two isolated fractions then the double-exponential fit of eq. [3] identifies it. However, for all the micelle solutions this two-component fit gives $A_{M_2} = 0$, regardless of how one tries to drive it with different limits on λ_1 and λ_2. An example is shown as Fig. 1 (b). It means that the regular fitting equation (eq. [1]) applies to micelle solutions, and, therefore, that *all* muonium atoms have access to the same decay channels.

We also report here that the data points of some of the occupied-micelle solutions studied previously (1) were subjected to eq. [3] incorporated in eq. [1]. In an aqueous solution containing styrene at 7.5×10^{-6} M and micelles at 1.5×10^{-5} M the best fit always gave $A_{M_2} = 0$. In this system the solute (styrene) was strongly localized in the micelle core without a significant chance of relocating during the 2-μs period corresponding to the muon lifetime. There are twice as many micelles as solutes in the solution, so about 61% of the micelles, based on Poisson distributions (11, 12), would be unoccupied, and about 8% would contain two styrene molecules. So, again, the failure of the analysis to see any fractionation of the Mu ensemble strongly implies that they localize at micelles for periods much shorter than their chemical lifetimes.

Discussion

These data show that muonium's effective rate of reaction towards a solute was decreased by adding a micelle of the same charge as the solute, increased by a micelle of the opposite charge, and barely affected when the micelle was neutral. Millimolar concentrations of micelles were needed to alter the chemical lifetime of muonium significantly.

In these experiments most muonium atoms were created

[a]Observed.
[b]Calculated from eq. [2] for each solution.

initially in the aqueous phase, because water was by far the major constituent, but on encountering a micelle during its random diffusion Mu could localize there. ("Localization" will be used here to mean that Mu spends a greater fraction of its time in the micelle than the volume fraction of that phase in the whole solution. It does not take account of the different diffusion coefficients in the two phases.) The distributions of the ionic solutes are also influenced by the micelles, being preferentially caught in the ion atmospheres when of opposite charge and specifically excluded when of the same charge. The enhanced rate when the solute is localized is consistent with Mu also being localized, especially if the "fjord-like" character of micelles is appropriate (7, 13, 14) where there is considerable water penetration. However, it is impossible to use these enhancement data quantitatively without knowing in detail about the mutual localization and local structure. Instead the discussion will focus on the decreased rates.

Four possibilities present themselves regarding the localization of Mu: (a) it may be confined exclusively to the aqueous phase, (b) treat micellar and aqueous phases alike (no localization), (c) localize "permanently" (a microsecond or so here) in the micelle phase, or (d) localize to a limited extent at the micelle. Possibility (a) can be discarded, because enhancements in Mu rates have been observed for many organic solutes (1) that are themselves fully localized in micelles. (b) can be ruled out, because there would have been almost no effect, and what little there was would have been in the opposite sense to that seen, because the solutes of opposite charge to the micelles would have been "bunched" around them, thereby reducing the effective concentration of solute as seen by a randomly diffusing Mu. (c) can also be discarded, because the rate did not drop to almost zero in the highest concentration NO_3^-/SDDS case, for instance, whereas Mu would have had the chance to react with NO_3^- only prior to its first localization with a micelle at 5×10^{-3} M. Furthermore, any such permanent disbursement of Mu into the micelle phase would have led to a two-component muonium fit, as with the quartz/NO_3^- experiment. This leaves possibility (d), a limited degree of localization.

In quantitative terms there are three approaches: (*i*) estimate the localization time from the failure to observe two separate Mu components, (*ii*) calculate the residence time from the extended lifetime of Mu divided by the total number of encounters it makes with micelles, and (*iii*) propose a kinetic model. Approach (*i*) can only give an upper limit and is not very useful because of the difficulty in actually evaluating the point at which separation would be evident. One can assert only that less than half the muonium atoms spent less than half their lifetimes localized. This puts an upper limit of ≈250 ns on the mean residence time (T_R). A lower limit of T_R can be deduced from the time Mu would take to traverse an equal volume of water using $T_R > \bar{d}^2/2D$, where D is its diffusion coefficient in water ($\approx 7 \times 10^{-5}$ cm^2 s^{-1} (15), taking it to be the same as H (10)) and $\sqrt{\bar{d}^2}$ is the mean diffusion distance (≈ micelle radius). For SDDS (r = 1.7 nm) this gives $T_R > 0.21$ ns, so we have $0.21 < T_R < 250$ ns.

The second approach (*ii*) is to calculate T_R from the changed Mu lifetime ($\Delta\lambda_{(mic)}^{-1} - \Delta\lambda_{(s)}^{-1}$) for a reaction of given efficiency ($k_M/k_{(diff)}$) due to the relative number of encounters with micelle and solute for solute-to-micelle ratios in concentration ([S]/[mic]) and radii ($r_{(s)}/r_{(mic)}$) according to eq. [4]. Based on the most sensitive NO_3^-/SDDS data (lines 1 and 2 of Table 2, extremes of Fig. 2) we have the Mu lifetime increasing from 670 to 1250 ns, with a concentration ratio of 1:5, for species whose radii ratio is ≈1:5, and for a reaction that occurs about once per 13 encounters ($k_M = 1.5 \times 10^9$ M^{-1} s^{-1} for NO_3^- whereas the diffusion controlled limit, $k_{(diff)}$, for Mu with ions in aqueous solution averages to 2×10^{10} M^{-1} s^{-1} (10)). These values yield $T_R = (1250 - 670)(1/13)(1/5)(1/5) = 1.8$ ns. Let us take T_R = 2 ± 1 ns in view of the uncertainty in the $r_{(s)}/r_{(mic)}$ factor (an effective encounter radius for NO_3^- of 0.3 nm has been assumed).

$$[4] \quad T_R = (\Delta\lambda_{(mic)}^{-1} - \Delta\lambda_{(s)}^{-1})(k_M/k_{diff})([S]/[mic])(r_{(s)}/r_{(mic)})$$

For approach (*iii*), the following mechanism is proposed:

$$Mu_{(aq)} + em \underset{k_e}{\overset{k_d}{\rightleftharpoons}} Mu_{(em)}$$

$$Mu_{(aq)} + S_{(aq)} \xrightarrow{k_M} P_1$$

$$Mu_{(aq)/(em)} \xrightarrow{\lambda_0} P_2$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 112.217.228.212 on 09/07/12
For personal use only.

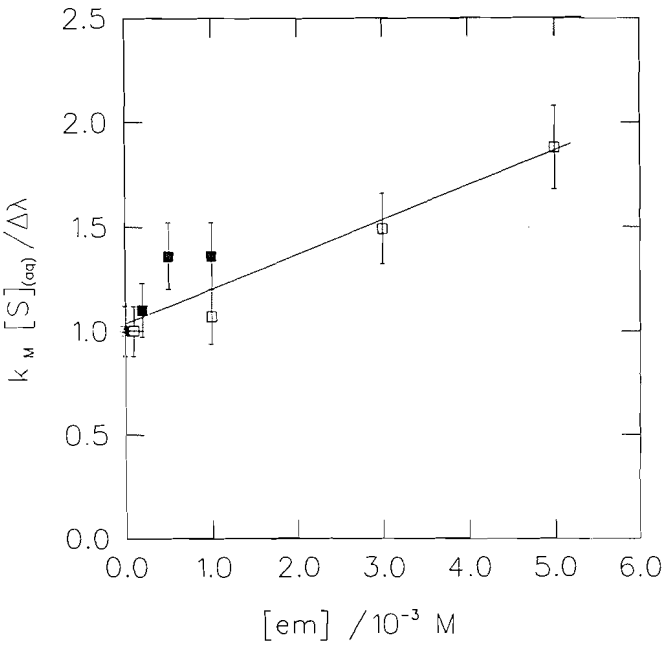

FIG. 3. $k_M[S]_{(aq)}/\Delta\lambda$ plotted against concentration of unoccupied SDDS micelles ([em]). (□) for NO_3^- as solute, (■) $S_2O_3^{2-}$ as solute.

where "em" represents an empty (unoccupied) micelle. In μSR experiments no distinction is possible between Mu in different phases, and because of (*i*) above, eq. [5] applies.

$$[5] \quad -d[Mu]/dt = \lambda([Mu_{(em)}] + [Mu_{(aq)}])$$

Since (*ii*) above has indicated that the Mu residence time (T_R) is very much shorter than the chemical lifetime (λ^{-1}), an analysis that leads to eq. [6], based on pre-equilibrium approximations, is appropriate. This can be rearranged to eq. [7], and the plot of the left-hand side against [em] is shown in Fig. 3 for the NO_3^-/SDDS data. A good straight line is obtained with slope equal to 175 ± 39 M^{-1}. The more limited $S_2O_3^{2-}$/SDDS data are also included, thereby giving an overall least-squares fit of 167 ± 37 M^{-1}. Since this equals k_d/k_e, an estimation of k_d must be made. Based on eq. [8], (since the micelle is much larger and more sluggish than Mu (10)), one gets $k_d = 8.8 \times 10^{10}$ M^{-1} s^{-1} using data already given. (This agrees well with the factor of ≈5 taken for radii ratios since $k_{(diff)}$ for small molecules is 2×10^{10} M^{-1} s^{-1}). Therefore, k_e is deduced to be 5.3×10^8 s^{-1} and T_R, its inverse, equals 1.9 ns. Everything points to a mean residence time for Mu at an empty SDDS micelle of 2 ns.

$$[6] \quad \Delta\lambda = k_M[S]_{(aq)}k_e/(k_d[em]_{(aq)} + k_e)$$

$$[7] \quad k_M[S]_{(aq)}/\Delta\lambda = 1 + k_d[em]/k_e$$

$$[8] \quad k_d = r_{(mic)}D_{(Mu)}(4\pi N_A 10^{-3})$$

This is much too short a localization time for "confined diffusion" to be responsible for the colossal enhancements that have been seen for some Mu reactions taking place inside micelles (1). The natural concentrating effect due to the water-to-micelle volume ratio evidently pertains only for 2 ns; therefore, the total number of encounters falls far short of that required to explain the 10^4-fold enhancements (1).

In fact, this 2 ns is probably no longer than the extended time scale caused by Mu having to traverse the more viscous phase of a micelle's interior. In this case localization has not occurred; the muonium atom has merely been slowed down by the changed microviscosity.

Pursuing this point further: if we assume Mu follows the Stokes–Einstein relationship inside micelles, as it does in water (10), then eq. [9] applies, where η is the local viscosity and $R_{(Mu)}$ is the effective radius of Mu. Even on taking the minimum value for the latter, namely the Bohr radius of 0.053 nm, one calculates T_R = 10 ns for η = 30 cP (which is reported to be the internal viscosity, from fluorescence studies based on the mobility of pyrene (16)). In other words, the expected diffusion time is at least fivefold larger than the observed residence time. Or, put the other way, using T_R = 2 ns in eq. [9], one gets an effective viscosity of only 6 cP. Since we know Mu penetrates the central core of micelles, because it reacts readily with organic solutes such as styrene localized there, our T_R value suggests that there is considerable water penetration into micelles and a large viscosity gradient across them. Coupled with this is the possibility that the hydrocarbon tails are more randomly oriented than hitherto supposed. The value of η = 6 cP presumably represents the mean microviscosity sensed by the track of a muonium atom; 6 cP lies squarely between that of pure water (0.30 cP) or dodecane (0.43 cP) on the one hand, and the viscous intertwining (30 cP) of surfactants in micelles as seen by a large organic molecule such as pyrene (16) on the other.

$$[9] \quad T_R = 3\pi d^2 R_{(Mu)}\eta / k_B T$$

Electron spin resonance and electron spin echo spectroscopic studies of Cu^{2+} sites in synthetic cancrinite zeolites

P. RAGHUNATHAN[1] AND L. KEVAN[2]

Department of Chemistry, University of Houston, Houston, TX 77004, U.S.A.

Received December 12, 1987

This paper is dedicated to Professor Charles A. McDowell on the occasion of his 70th birthday

P. RAGHUNATHAN and L. KEVAN. Can. J. Chem. **66**, 1984 (1988).

Electron spin resonance (ESR) and electron spin echo modulation (ESEM) studies of Cu^{2+} sites introduced by ion exchange are reported in two types of synthetic cancrinite zeolites, one of them a more hydrated sample, $Na_6Al_6Si_6O_{24}\cdot 8H_2O$ (denoted C1), and the other a less hydrated sample with entrained calcium carbonate, $Na_6Al_6Si_6O_{24}\cdot CaCO_3\cdot 8H_2O$ (denoted C2). ESR spectra reveal that C1 activated at 100°C contains Cu^{2+} sites of tetrahedral symmetry with $g_\parallel = 2.442$, $g_\perp = 2.068$, $A_\parallel = 83 \times 10^{-4}$ cm^{-1}, and $A_\perp = 18 \times 10^{-4}$ cm^{-1} while at a higher activation temperature of 400°C Cu^{2+} sites with a different symmetry are produced corresponding to $g_\parallel = 2.400$, $g_\perp = 2.081$, and $A_\parallel = 138 \times 10^{-4}$ cm^{-1}. C2 activated at 100°C contains almost exclusively Cu^{2+} sites of trigonal symmetry with $g_\parallel = 2.340$, $g_\perp = 2.040$, $A_\parallel = 147 \times 10^{-4}$ cm^{-1}, and $A_\perp = 35 \times 10^{-4}$ cm^{-1}. Two- and three-pulse ESEM experiments at 4 K give ^{2}D and ^{27}Al modulation patterns that corroborate these ESR assignments. Possible locations of the Cu^{2+} sites in the C1 and C2 structures are proposed.

P. RAGHUNATHAN et L. KEVAN. Can. J. Chem. **66**, 1984 (1988).

On a effectué des études par résonance paramagnétique électronique (rpe) et par modulation écho paramagnétique électronique (mepe) sur des sites Cu^{2+} introduits par échange d'ions dans deux types de zéolites cancrinite de synthèse; l'un est un échantillon plus hydraté, $Na_6Al_6Si_6O_{24}\cdot 8H_2O$ (dénommé C1) et l'autre est un échantillon moins hydraté contenant du carbonate de calcium entrainé, $Na_6Al_6Si_6O_{24}\cdot CaCO_3\cdot 8H_2O$ (dénommé C2). Les spectres rpe révèlent que l'échantillon C1, activé à 100°C, contient des sites Cu^{2+} de symétrie tétraédrique avec $g_\parallel = 2{,}442$, $g_\perp = 2{,}068$, $A_\parallel = 83 \times 10^{-4}$ cm^{-1} et $A_\perp = 18 \times 10^{-4}$ cm^{-1}; par ailleurs, lorsque cet échantillon est activé à une température plus élevée comme 400°C, il y a production de sites Cu^{2+} de symétrie différente correspondant à $g_\parallel = 2{,}400$, $g_\perp = 2{,}081$ et $A_\parallel = 138 \times 10^{-4}$ cm^{-1}. L'échantillon C2 activé à 100°C contient presqu'exclusivement des sites Cu^{2+} de symétrie trigonale avec $g_\parallel = 2{,}340$, $g_\perp = 2{,}040$, $A_\parallel = 147 \times 10^{-4}$ cm^{-1} et $A_\perp = 35 \times 10^{-4}$ cm^{-1}. Des expériences de mepe, effectuées à 4 K, produisent des patrons de modulation ^{2}D et ^{27}Al qui corroborent les attributions faites sur la base de la rpe. On propose des attributions de sites pour les Cu^{2+} dans les structures des échantillons C1 et C2.

[Traduit par la revue]

Introduction

Zeolite frameworks are important catalyst supports by virtue of their having structural reaction sites that provide the basis for shape-selective catalysis. A variety of Cu^{2+}-doped zeolites such as zeolite-X (1), zeolite-A (2), zeolite-Y (3), and zeolite H-rho (4) have been recently studied by electron spin resonance (ESR) and electron spin echo modulation (ESEM) spectroscopies (5). In the present work, we extend these investigations to Cu^{2+} exchanged into cancrinite, $Na_6[(AlO_2)_6\ (SiO_2)_6]$, a generic framework structure belonging to the felspathoid family of zeolites. Recent studies have shown that the cancrinite structure provides a very efficient matrix trap for a variety of interesting free radicals (6–8).

The unit cell of cancrinite is hexagonal, belonging to the space group $P6_3$ ($a = 12.5$–12.7 Å, $c = 5.1$–5.2 Å) (9, 10), and comprises an undecahedral building unit called the "cancrinite cage", which is made up of five 6-rings and six 4-rings. These cages are linked in columns parallel to the c-axis, six linked columns defining a 12-sided tubular channel along the c-axis. The resultant compact structure is of lower symmetry than the A- and X-zeolites, and the pore sizes are somewhat smaller. We consider two synthetic cancrinites, namely, the "free" cancrinite, $Na_6Al_6Si_6O_{24}\cdot 8H_2O$ (denoted C1), and the calcium carbonate-entrained cancrinite, $Na_6Al_6Si_6O_{24}\cdot CaCO_3\cdot 2H_2O$ (denoted C2).

Experimental

The two cancrinite specimens were prepared according to the well-established hydrothermal procedures of Barrer *et al.* (11–13). In a typical preparation of the carbonate-entrained cancrinite C2, 2 g of high-purity, iron-free kaolinite, $Al_2O_3\cdot SiO_2\cdot 2H_2O$ (E. Merck, Darmstadt) was reacted for 1 week at 80°C with 200 mL of 4 M NaOH containing an excess of dissolved Na_2CO_3 in a sealed Teflon container. For preparing the carbonate-free hydrate structure C1, $CaCO_3$ was left out of the above reaction mixture and a small amount of silica gel was added to the mixture being digested at 80°C, to prevent the formation of the sodalite hydrate structure (14). The crystal structures were identified by comparing the indexed X-ray powder diffraction patterns with the literature values (11, 15).

Variable amounts of Cu^{2+} were exchanged into the two cancrinite frameworks by the slow addition of 4, 6, or 8 mL of 10^{-3} M $Cu(NO_3)_2$ solution to a slurry of 1 g of the dried cancrinite in 100 mL of triple-distilled water. By this procedure, about 0.3–0.5 mol% of the Na^+ and Ca^{2+} ions in the original structure are replaced by Cu^{2+}.

Thermal activation of the cancrinite was made under two conditions, (*i*) a "mild" activation by evacuation at 100°C for ~6 h, and (*ii*) a "high-temperature" activation by evacuation at 400°C for 12 h, followed by exposure of the sample to flowing O_2 to reoxidize any zero- or monovalent copper formed and a He gas flush before sealing the sample.

D_2O exchange with the water molecules in the cancrinites was accomplished by repeated soaking of 0.25 g of the activated samples in 2 mL of 99.9 mol% pure D_2O. The deuterated as well as undeuterated samples were sealed in 3 mm o.d. Suprasil quartz tubes for the ESR and ESEM experiments.

All the ESR spectra were recorded at X-band (~9 GHz) on a Varian E-4 spectrometer. Two- and three-pulse ESEM spectra were recorded at 4 K on a home-built spectrometer interfaced to a Nicolet 1280

computer with 293B pulse programmer. Three-pulse stimulated echoes were recorded as a function of time T between the second and third pulses to observe modulation from both ^{2}D and ^{27}Al. To observe deuterium modulation without interference from Al modulation, the time τ between the first and second pulses was selected to be 0.27 μs, which suppresses Al modulation at the magnetic field used. To record ^{27}Al modulation, τ was set at 0.4 s. To suppress any two-pulse interferences in the three-pulse spin echo envelope at times $T = \tau$ and $T = 2\tau$, as well as to correct for baseline drifts, a phase-cycling procedure was employed (16).

ESEM spectral simulations were performed on the basis of the spherical averaging model (17) discussed in previous publications (5, 18, 19). The simulation procedure compares experimental ESEM spectra with the calculated ones to give "best fit" values for the electron–nucleus distance, R, the number of interacting nuclei, N, and the isotropic hyperfine interaction A_{iso}. All calculated ESEM spectra were multiplied by a decay function (nonlinear least squares fitted to the experimental decay) of the form exp $(a_0 + a_1T + a_2T^2 + a_3T^3)$ to account for the magnetic relaxation.

Results

A. ESR spectra

The room temperature ESR spectrum of freshly prepared C1 cancrinite gives a broad isotropic line centered around $g = 2.159$, which is identified to arise from a hexa-hydrated complex (19) undergoing motional tumbling in the tubular cancrinite channel. As the sample is cooled to 77 K the rotational freedom becomes partially hindered and the resulting ESR spectrum becomes axially symmetric as shown in Fig. 1 (a). Mild dehydration at 100°C destroys this hexa-hydrated species and the Cu^{2+} then becomes coordinated to the zeolite framework. The resulting spectrum is now axially symmetric as shown in Fig. 1 (b). This spectrum yields values of $g_{\|} = 2.442$, $g_{\perp} = 2.068$, $A_{\|} = 83 \times 10^{-4}$ cm^{-1}, and $A_{\perp} = 18 \times 10^{-4}$ cm^{-1}, which are strikingly reminiscent of a variety of examples in the literature where Cu^{2+} is in tetrahedral coordination (20, 21). This point will be further discussed in the light of our ESE results for C1.

Following activation at the higher temperature of 400°C, C1 yields the ESR spectrum shown in Fig. 1 (c). Samples of C1 containing other Cu^{2+} concentrations, activated at 400°C, also yield spectra of similar intensity and resolution. From Fig. 1 (c) we find that the ESR parameters characterizing this site are $g_{\|} = 2.400$, $A_{\|} = 138 \times 10^{-4}$ cm^{-1}, and $g_{\perp} = 2.081$ with unresolved $A_{\perp}$ features. These values suggest a square-pyramidally coordinated Cu^{2+}. Such a coordination of Cu^{2+} to the four oxygens of one of the four-rings of the cancrinite structure is possible.

In Figs. 2 and 3 are given the ESR spectra of the low- and high-temperature activated forms of the carbonate-containing structure C2. The most characteristic feature here is that the two differently activated C2 samples show two sets of g values indicative of two Cu^{2+} species. Figure 2(a) is the room temperature ESR spectrum of C2 doped with 0.3 mol% Cu^{2+} after 100°C activation. The spectral analysis for one species, Cu^{2+}(A), gives $g_{\|} = 2.442$, $g_{\perp} = 2.090$, and $A_{\|} = 90 \times 10^{-4}$ cm^{-1}, which are typical of tetrahedrally coordinated Cu^{2+}. Analysis for the other species, Cu^{2+}(B), gives $g_{\|} = 2.340$, $A_{\|} = 147 \times 10^{-4}$ cm^{-1}, $g_{\perp} = 2.040$, and $A_{\perp} = 35 \times 10^{-4}$ cm^{-1}.

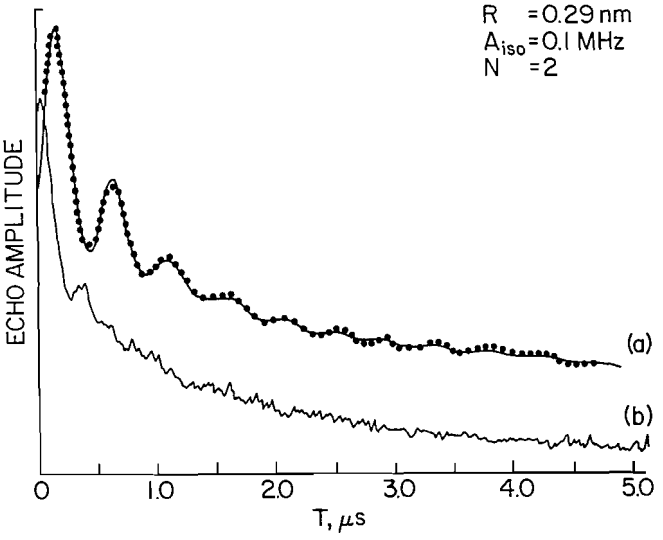

FIG. 5. Three-pulse ESEM spectra of Cu^{2+} in 100°C activated cancrinite C1: (a) Upper curve: experimental ^2D modulation at 4 K and 319 mT (———) and the simulation (····). The decay function used is exp $(2.465 - 0.753\ T + 0.181\ T^2 - 0.017\ T^3)$; (b) Lower curve: experimental ^{27}Al modulation at 4 K and 319 mT.

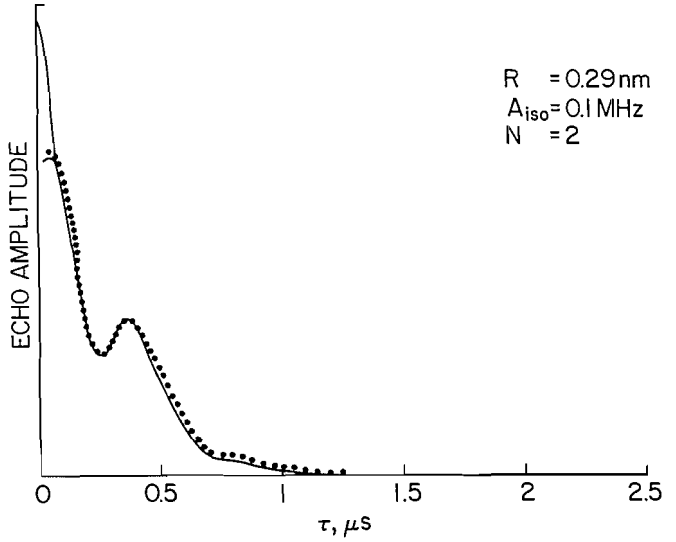

FIG. 6. Two-pulse ESEM spectrum of Cu^{2+} in 100°C activated cancrinite C1 at 4 K and 319 mT: (———) experimental spectrum, showing ^2D modulation, (····) simulation using the decay function exp $(-0.183 + 1.031\ \tau - 8.11\ \tau^2 + 2.81\ \tau^3)$.

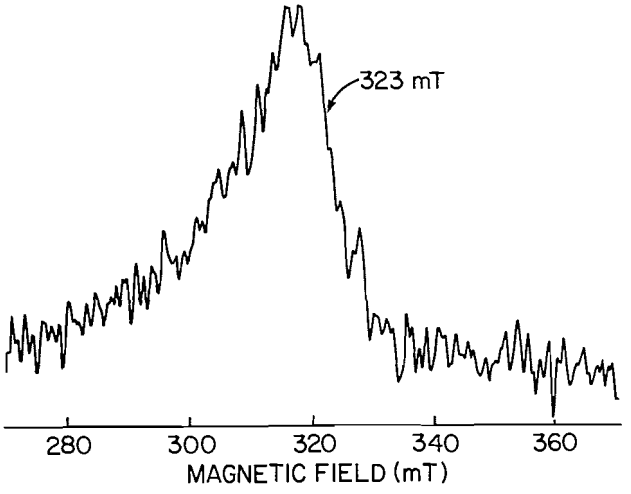

FIG. 7. Field-swept two-pulse ESE spectrum of Cu^{2+} in 100°C activated cancrinite C2 at 4 K, using $\tau = 0.58$ μs. Each field point was incremented after a delay of 193 ms, and the echo was accumulated 10 times during each increment.

Neither the anisotropy nor the g and A parameters of the above sites change when the ESR is recorded at 77 K, as shown in Fig. 2(b). However, after the 400°C activation of C2 the ESR lines of Cu^{2+}(B) become more prominent, as shown in Fig. 3(a). When the ESR spectrum is recorded at 77 K after 400°C activation of the C2 specimen with the highest Cu^{2+} concentration (0.5 mol%), the Cu^{2+}(B) is preponderant, while much weaker spectral features corresponding to Cu^{2+}(A) are barely discernible (see Fig. 3(b)).

On rehydrating the 400°C activated C2, an ESR spectrum corresponding mainly to Cu^{2+}(B) is obtained, as shown in Fig. 4. Long periods of exposure of the above activated samples to flowing oxygen did not change the above observations.

B. ESEM spectra

The three-pulse ^2D and ^{27}Al modulated ESEM spectra of a 100°C activated C1 sample after D_2O exchange are shown in Fig. 5. It is clearly seen that the ^2D modulation is much deeper than the ^{27}Al modulation. The best-fit simulation of the three-pulse deuterium modulated echo, showed by the dotted curve in Fig. 5, yields the result that the Cu^{2+} is interacting with two ($N = 2$) equivalent deuteriums (one water molecule), with a Cu^{2+}–$D(D_2O)$ distance of $R = 0.29$ nm and a small isotropic hyperfine constant A_{iso}. Assuming tetrahedral orbitals on the oxygen, this distance corresponds to a Cu—O bond length of 0.22 nm, which is a value typically observed in aluminosilicates. The shallow ^{27}Al modulation implies that the Cu^{2+} is displaced from a framework window that contains several aluminums.

These three-pulse simulation parameters are confirmed by a two-pulse ESEM spectrum for which simulation gives the same parameters as shown in Fig. 6.

The ESEM spectra of the 100°C activated carbonate-containing specimen C2 were next examined. To determine the magnetic field value for an optimum echo response, a field-swept two-pulse spin echo spectrum was first run on C2, with τ

set at 0.56 μs to suppress the ^{27}Al modulation. The magnetic field was swept over 100 mT. Each field point (512 per 100 mT) was incremented after a delay of 193 ms, and the echo was accumulated 100 times during each increment. The field-swept echo profile is presented in Fig. 7, and is seen to peak at 320 mT (a smilar field-sweep profile run for C1 peaked at 317 mT). Consequently, a field value of 323.3 mT (indicated by an arrow in Fig. 7) was chosen as the best setting for obtaining ESEM data for C2.

Figure 8 shows experimental three-pulse ^2D and ^{27}Al spin echo modulation results for C2. In contrast to C1 (Fig. 5) it is seen that the ^{27}Al modulation is deeper and the ^2D modulation is more shallow. Two observations may be made immediately. Firstly, the deeper Al modulation suggests that Cu^{2+} is closer to a framework Al in C2 if the ^{27}Al quadrupole interaction is not significantly changed. Secondly, although the deuterium-modulated echo was too weak to reliably simulate, one may interpret the weak ^2D modulation as suggesting that the Cu^{2+}–D distance is larger than in the C1 lattice.

Discussion

Our ESR and ESEM results for Cu^{2+} in 100°C activated C1 together establish that the active Cu^{2+} sites have tetrahedral symmetry. Although tetrahedral Cu^{2+} sites are somewhat less common than distorted octahedral Cu^{2+} sites, their preferential

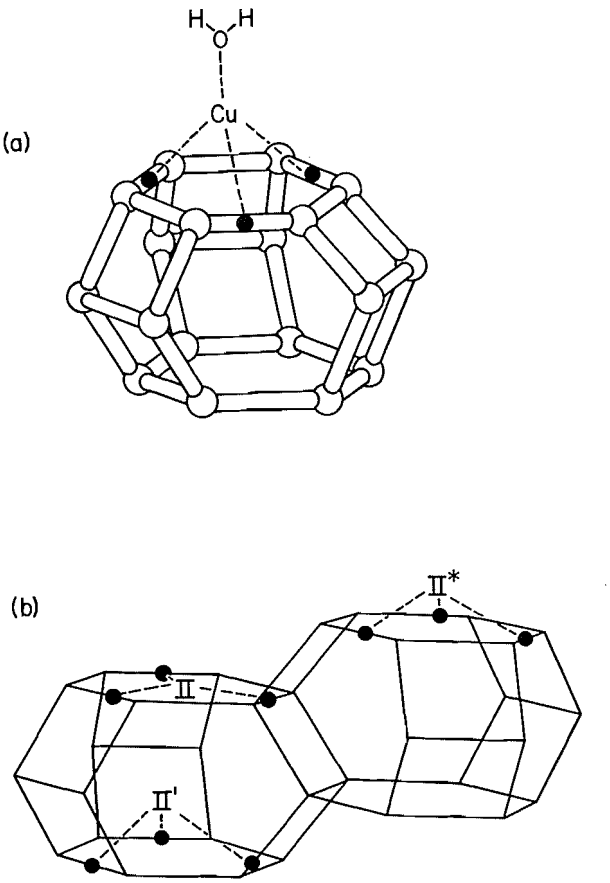

FIG. 9. Proposed sites for Cu^{2+} in the cancrinite framework: (a) tetrahedral site in C1, (b) trigonal sites II* and II′ in C2. The dark circles represent oxygen positions.

formation has been reported in a number of host structures where spatial constraints dominate (20, 21). Table 1 summarizes selected literature data on this point. It is proposed that this Cu^{2+} site in cancrinite C1 is situated as shown in Fig. 9 (a), where the Cu^{2+} ion is near a six-ring bonded to three oxygens of the ring and is located at a site *outside* the undecahedral cancrinite cage in the cancrinite channel. The fourth coordination position is a water molecule in the open cancrinite channel. This structure is consistent with the observed ESR parameters, and the cancrinite channel location can account for the shallow ^{27}Al modulation observed in the ESEM spectrum.

Such a Cu^{2+} site, which remains exposed in the cancrinite channel, should be easily accessible to adsorbate molecules. It is

suggested, therefore, that Cu^{2+} doped in the C1 structure is likely to be a potentially good catalytic site.

In the case of the carbonate-entrained cancrinite C2, it is significant that rehydration after 400°C activation gives exclusively the spectrum corresponding to the Cu^{2+}(B) species leaving the g and hyperfine parameters unaltered. It may be rationalized that high-temperature activation produces a Cu^{2+} species that is trigonally bound to three framework oxygens in a six-ring. Trigonal sites with similar g and A values have been characterized recently in Cu^{2+}-doped K-ZK4 zeolite (21). A comparison of the ESR parameters for species Cu^{2+}(B) in C2 with those reported for Cu^{2+} in trigonal sites of K-ZK4 is presented in Table 2.

The proposed Cu^{2+} sites in C2 are shown in Fig. 9 (b). Site II is trigonally coordinated at the center of a six-ring, and sites II* and II′ are displaced along the trigonal axis towards the cancrinite channel and into the cancrinite cage, respectively. Since there are two water molecules in the unit cell of cancrinite C2 at room temperature, a water molecule can coordinate with Cu^{2+} at II* to give the tetrahedral site, which is detected as species Cu^{2+}(A). Cu^{2+}(B) is suggested to be located in a trigonal site II or II′. Upon high-temperature activation most of the water is lost, and the Cu^{2+} ions originally at II* move into II or II′ to give trigonal sites. The somewhat stronger ^{27}Al modulation observed for Cu^{2+}(B) in C2 seems consistent with site II, which is within 0.3 nm of three framework Al atoms in a six-ring.

The weak deuterium modulation observed for C2 may be explained by the presence of distant hydroxyl (-OD) groups weakly interacting with Cu^{2+} sites but not directly coordinated to Cu^{2+}. It is known that hydroxyl groups capable of interacting with cation sites are generated during high-temperature activation of Ca^{2+}-containing zeolites (22–24). The presence of Ca^{2+} in the carbonate-entrained cancrinite may also generate hydroxyl groups, which can weakly interact with Cu^{2+}. It appears that "molecular" water is absent in high-temperature activated C2. In previous free-radical entrapment studies (6–8) in C2 cancrinite it has been suggested that the matrix is "water free".

Conclusions

ESR studies of two types of Cu^{2+}-doped cancrinite, one being more hydrated (C1) and the other being less hydrated with entrained carbonate (C2), reveal that upon activation C1 contains Cu^{2+} sites of tetrahedral symmetry while C2 contains mainly Cu^{2+} sites of trigonal symmetry. Two- and three-pulse ESEM studies show ^{2}D and ^{27}Al modulation patterns that corroborate the ESR assignments for the coordination symmetry of the Cu^{2+} sites in these two types of cancrinite.

The photochemistry of bichromophoric species containing nitroaromatic and arylamino moieties has been studied in the presence and absence of an external magnetic field. Photolysis products are an unsubstituted arylamine, a nitrosoaromatic species (Product 1), and a nitroaromatic compound (Product 2). On application of the magnetic field, the formation yield for Product 1 decreases and that for Product 2 correspondingly increases, whereas the consumption of the starting material and the release of the unsubstituted arylamine are independent of the magnetic field. Analysis of the magnetic field effects shows that the hyperfine coupling mechanism predominates and that the photoreaction takes place in the triplet manifold of the nitroaromatic moiety. Application of the magnetic field may cause an appreciable change in the relative yield of cage and escape products, i.e., the branching ratio of competitive processes.

RYOICHI NAKAGAKI, KIYOSHI MUTAI, MITSUO HIRAMATSU, HIDEYUKI TUKADA et SABURO NAKAKURA. Can. J. Chem. **66**, 1989 (1988).

On a etudié les effets du champ magnétique sur la photochimie des espèces bichromophoriques qui contiennent un groupement arylaminé et un noyau nitroaromatique. Les produits de photolyse sont l'amine aromatique nonsubstituée, le composé aromatique nitrosé (Produit 1), et le composé aromatique nitré (Produit 2). Sous un champ magnétique, le rendement du Produit 1 est diminué et celui de Produit 2 est augmenté, tandis que la consommation de l'espèce de départ ou la libération de l'amine aromatique nonsubstituée ne dépend pas de l'intensité du champ magnétique. De l'analyse des effets du champ magnétique, il résulte que le mécanisme du couplage hyperfin prédomine et la réaction photochimique a lieu dans un état triplet du noyau nitroaromatique. L'application du champ magnétique peut causer un changement manifeste dans la proportion des deux produits photochimiques de la réaction concurrente, c.-à-d., le produit de cage et celui de fuite.

1. Introduction

In our previous papers, we have shown that the photochemical behaviour of some bifunctional chain molecules, A-$(CH_2)_n$-D (A = nitroaromatic electron acceptor and D = arylamino electron donor) critically depends on excitation photon density (1), methylene chain length, n (2), and magnetic field strength (3, 4). Theoretical considerations given in our earlier publications (5, 6) predict that the magnetic field effect on cage product formation is quite opposite to that on escape product formation, when the same radical pair precursor is commonly involved as a reaction intermediate. Namely, when the cage product yield decreases, the escape product yield correspondingly increases and vice versa, irrespective of the factor governing the singlet–triplet transition (the hyperfine coupling or the Zeeman mechanism) or the precursor spin multiplicity. Therefore, it is possible by applying an external magnetic field to control the branching ratio between the cage and escape products formed through the common radical pair (or biradical) intermediate. The present paper is concerned with the magnetic field effects on the photodecomposition yield of bichromophoric species containing the 4-nitro-1-naphthoxyl moiety as an electron acceptor.

2. Experimental

2.1 General

Electronic absorption spectra were measured on a Hitachi U-3200 spectrophotometer. The ^1H nmr spectra were recorded on a Varian EM-390 spectrometer with CD_3Cl as solvent. An electromagnet (Tokin SEE-9G) was used. The magnetic field strength was monitored with a Densijiki Kogyo GM-1220 gaussmeter, and the residual field was 0.08 mT.

2.2 Material

Compounds **1**–**4**, the bifunctional species examined in this work, are shown in Chart 1. The following commercially available chemicals were used for intermolecular model photoreactions and identification

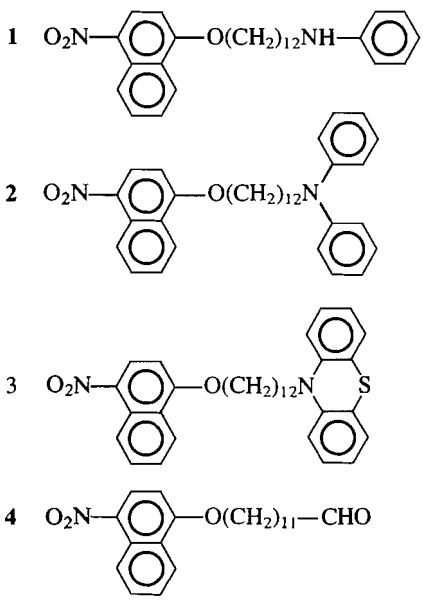

CHART 1

of photoproducts: 1-methoxy-4-nitronaphthalene (Aldrich), 10-methylphenothiazine (Eastman Kodak), phenothiazine, *N*-methylaniline, aniline, *N*-benzylaniline, benzaldehyde, and diphenylamine (Tokyo Kasei). 1-Methoxy-4-nitrosonaphthalene was prepared by procedures in the literature (7). γ-Cyclodextrin was purchased from Tokyo Kasei. The solvents listed below were used for steady-state photolysis and chromatographic analysis: acetonitrile, benzene, ethyl acetate (AcOEt), tetrahydrofuran (THF), *N*,*N*-dimethylformamide (DMF), and water. These were all of spectro or hplc grade.

12-(4-Nitro-1-naphthoxy)dodecyl bromide

A mixture of 1.37 g (10 mmol) of 4-nitro-1-naphthol, 3.94 g (12 mmol) of 1,12-dibromododecane, 1.38 g (10 mmol) of potassium carbonate, 0.3 g of tetrabutylammonium bromide, and 30 mL of water was heated overnight with stirring at 110°C. After the usual work-up, chromatography of the reaction mixture using a silica gel column with hexane–benzene (2:1) as eluent gave 1.96 g (45% yield) of pale yellow crystals, mp 71–72°C (EtOH); ^{1}H nmr δ: 1.33 (s, br, 16H, $-(CH_2)_8$), 1.65–2.1 (m, 4H, $2CH_2$), 3.37 (t, 2H, CH_2Br), 4.19 (t, 2H, CH_2O), 6.72 (d, 1H, Ar-2), 7.35–7.7 (m, 2H, Ar-6,7), 8.34 (two d, 2H, Ar-3,8), 8.74 (dd, 1H, Ar-5). *Anal.* calcd. for $C_{22}H_{30}NO_3Br$: C 60.55, H 6.93, N 3.21; found: C 60.42, H 7.11, N 3.25.

N-*[12-(4-Nitro-1-naphthoxy)dodecyl]aniline (1)*

A mixture of 405 mg (0.93 mmol) of 12-(4-nitro-1-naphthoxy)dodecyl bromide and 1.5 mL of aniline was heated at 90–95°C for 2 h. After the usual work-up and chromatography using a column (activated alumina) with hexane–benzene (1:1) as eluent, 322 mg (77%) of the amine was isolated as yellow crystals, mp 81.5–82°C; ^{1}H nmr δ: 1.32 (s, br, 16H, $-(CH_2)_8$), 1.4–2.1 (m, 4H, $2CH_2$), 3.06 (t, 2H, CH_2N), ca. 3.5 (s, br, 1H, NH), 4.17 (t, 2H, CH_2O), 6.45–6.7 and 7.0–7.25 (m, 5H, C_6H_5N), 6.72 (d, 1H, Ar-2), 7.4–7.8 (m, 2H, Ar-6,7), ca. 8.3 (two d, 2H, Ar-3,8), 8.71 (dd, 1H, Ar-5). *Anal.* calcd. for $C_{28}H_{36}N_2O_3$: C 74.97, H 8.08, N 6.24; found: C 74.85, H 8.22, N 6.23.

N-*(12-Bromododecyl)diphenylamine*

To a stirred solution of 1.69 g (10 mmol) of diphenylamine in 15 mL of dry DMF was added in one portion 0.44 g (11 mmol) of sodium hydride (60% dispersion in mineral oil) under nitrogen. After 30 min of stirring, 4.26 g (13 mmol) of 1,12-dibromododecane in 5 mL of dry DMF was added in one portion and stirring was continued for 2 h at room temperature and then for 1 h at ca. 50°C. After cooling the reaction mixture, the solvent was removed under reduced pressure, and the residue was triturated with chloroform. The extract was dried over magnesium sulfate and filtered. The solvent was removed, and the remaining liquid mass was charged on a column (activated alumina) and eluted with hexane–benzene (4:1). A crude eluate (1.36 g) containing ca. 15% of 1,12-bis(diphenylamino)dodecane was obtained; colorless liquid; ^{1}H nmr δ: 1.30 (s, br, 16H, $-(CH_2)_8$), 1.4–2.1 (m, 4H, $2CH_2$), 3.39 (t, 2H, CH_2Br), 3.66 (t, 2H, CH_2N), 6.7–7.3 (m, 10H, $2C_6H_5$).

N-*[12-(4-Nitro-1-naphthoxy)dodecyl]diphenylamine (2)*

A mixture of 1.25 g (3 mmol) of *N*-(12-bromododecyl)diphenylamine, further purified by hplc, 0.57 g (3 mmol) of 4-nitro-1-naphthol, 0.60 g (1.8 mmol) of cesium carbonate, and 10 mL of 2-methoxyethanol was heated at 120°C with stirring for 5 h. After cooling, the solvent was removed under reduced pressure, and the residue was triturated with chloroform. The extract was dried with magnesium sulfate and filtered. The remaining liquid mass was chromatographed on a silica gel column with benzene–dichloromethane (1:1) as eluent. The fraction (1.08 g) containing **2** was further purified by hplc. Yield 0.99 g (63%), mp 60–61°C (EtOH); ^{1}H nmr δ: 1.31 (s, br, 16H, $-(CH_2)_8$), 1.4–2.1 (m, 4H, $2CH_2$), 3.65 (t, 2H, CH_2N), 4.22 (t, 2H, CH_2O), 6.74 (d, 1H, Ar-2), 6.8–7.35 (m, 10H, $2C_6H_5$), 7.35–7.8 (m, 2H, Ar-6,7), ca. 8.35 (two d, 2H, Ar-3,8), 8.77 (dd, 1H, Ar-5). *Anal.* calcd. for $C_{34}H_{40}N_2O_3$: C 73.62, H 6.90, N 5.05; found: C 73.42, H 6.95, N 4.92.

10-(12-Bromododecyl)phenothiazine

This compound was prepared from 1,12-dibromododecane and phenothiazine, in a similar method to that applied to *N*-(12-bromododecyl)diphenylamine, as a crude liquid; ^{1}H nmr δ: 1.30 (s, br, 16H, $-(CH_2)_8$), 1.65–2.1 (m, 4H, $2CH_2$), 3.34 (t, 2H, CH_2Br), 3.76 (t, 2H, CH_2O), 6.7–7.2 (m, 8H, $N(C_6H_4)_2S$).

10-[12-(4-Nitro-1-naphthoxy)dodecyl]phenothiazine (3)

A mixture of 1.63 g (2.97 mmol) of 10-(12-bromododecyl)phenothiazine, 0.56 g (3 mmol) of 4-nitro-1-naphthol, 0.40 g (3 mmol) of potassium carbonate, 0.2 g of tetrabutylammonium bromide, and 15 mL of water was heated at 100°C for 40 h. After the usual work-up, chromatography using a column (silica gel) with hexane–benzene (1:1) as eluent gave 0.78 g (47% in yield) of **3** as pale yellow crystals, mp 82–83°C (EtOH–benzene); ^{1}H nmr δ: 1.28 (s, br, 16H, $-(CH_2)_8$), 1.4–2.1 (m, 4H, $2CH_2$), 3.77 (t, 2H, CH_2N), 4.15 (t, 2H, CH_2O), 6.6–7.2 (m, 9H, $N(C_6H_4)_2S$ and Ar-2), 7.35–7.75 (m, 2H, Ar-6,7), ca. 8.3 (two d, 2H, Ar-3,8), 8.74 (dd, 1H, Ar-5). *Anal.* calcd. for $C_{34}H_{38}N_2O_3$: C 77.83, H 7.68, N 5.34; found: C 77.68, H 7.55, N 5.25.

12-(4-Nitro-1-naphthoxy)-1-dodecanol

This compound was obtained from 12-bromo-1-dodecanol and 4-nitro-1-naphthol (70% yield), in a similar procedure to that used for the preparation of 12-(4-nitro-1-naphthoxy)dodecyl bromide, as yellow crystals, mp 85.5–86.5°C (EtOH); ^{1}H nmr δ: 1.30 (s, br, 16H, $-(CH_2)_8$), 1.7–2.1 (m, 4H, $2CH_2$), 3.57 (m, 2H, CH_2OH), 4.13 (t, 3H, CH_2OAr and OH), 6.62 (d, 1H, Ar-2), 7.2–7.8 (m, 2H, Ar-6,7), ca. 8.24 (two d, 2H, Ar-3,8), 8.66 (dd, 1H, Ar-5). *Anal.* calcd. for $C_{22}H_{31}NO_4$: C 70.75, H 8.37, N 3.75; found: C 70.83, H 8.53, N 3.80.

12-(4-Nitro-1-naphthoxy)dodecanal (4)

The alcohol was oxidized by chromium(III) oxide–pyridine complex as described by Collins *et al.* (8). Yield 84%, yellow crystals, mp 83–84°C (*n*-hexane–benzene); ^{1}H mr δ: 1.33 (s, br, 16H, $-(CH_2)_8$), 1.6–2.1 (m, 2H, CH_2CH_2OAr), 2.40 (dt, 2H, CH_2CHO), 4.19 (t, 2H, CH_2OAr), 6.73 (d, 1H, Ar-2), 7.35–7.8 (m, 2H, Ar-6,7), ca. 8.3 (two d, 2H, Ar-3,8), 8.68 (dd, 1H, Ar-5), 9.74 (t, 1H, CHO). *Anal.* calcd. for $C_{22}H_{29}NO_4$; C 71.13, H 7.87, N 3.77; found: 71.13, H 8.05, N 3.82.

2.3 Photolysis and chromatographic analysis

The concentration of the bichromophoric species was 1.2×10^{-4} M in all solvents unless otherwise indicated. Sample solutions were deaerated by several freeze–pump–thaw cycles and then sealed under vacuum before irradiation. The sample solution in a quartz cell of 1-cm path length was irradiated with uv light from an Ushio 500-W Xe arc filtered through an appropriate combination of coloured glass filters. For example, the combination of Hoya U-340 and Toshiba UV-35 shows a transmittance maximum at 363 nm with a 23-nm bandwidth

(full-width at half maximum), which enables the selective excitation of the acceptor moiety. The Xe arc intensity was monitored by a photosensor with a beam splitter (Toshiba glass filter UV-25). The accumulation of output signal from the sensor for a constant period indicated that the light intensity fluctuation was less than 0.6%. The quartz cuvette containing the sample solution was placed between the pole pieces of the electromagnet during photolysis at room temperature.

Reaction mixtures were analyzed by a Waters Model 510 high performance liquid chromatograph (hplc) equipped with a Waters Model 481 LC spectrophotometer. Reversed- and normal-phase columns were used for the hplc analysis of photoproducts in polar and nonpolar solvents, respectively. The photo-induced absorbance change or integrated intensity of a chromatographic peak due to a photoproduct was used for determining the reaction yield ratio Φ^H/Φ^0 where Φ^H and Φ^0 refer to the yields in the presence and absence of an external magnetic field, respectively. The relative yield was determined as an average value for six to eight separate measurements. Absorption spectra of labile photoproducts were measured by the lc–uv method, i.e., by the combined use of the Waters hplc and a spectrophotometer fitted with a diode array detector (Union Giken MCPD-350PC). The formation of nitrosoaromatic species was properly confirmed by the lc–uv method, although it could not be isolated from reaction mixtures in a conventional manner.

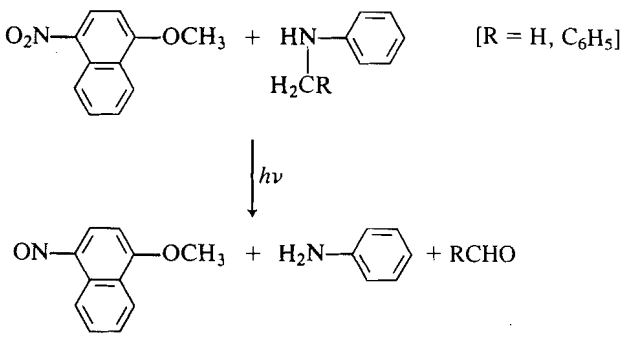
3. Results and discussion

3.1 Identification of photoproducts in intermolecular model photoreactions

To obtain preliminary information about the photolysis of **1–3**, we have studied intermolecular photoreactions between 1-methoxy-4-nitronaphthalene (MNN) and the model donor compounds. The intermolecular photoreaction products from MNN and *N*-methylaniline were identified as 1-methoxy-4-nitrosonaphthalene and aniline by means of hplc, when acetonitrile or benzene was employed as a solvent. When 10-methylphenothiazine was used instead of *N*-methylaniline, unsubstituted phenothiazine was detected in the reaction mixture. The formation of benzaldehyde was confirmed by an hplc analysis of the intermolecular photoreaction involving MNN and *N*-benzylaniline. Thus, the intermolecular photochemistry may be summarized as a redox reaction where deoxygenation of the nitro moiety is associated with oxidation of the methylene group adjacent to the arylamino nitrogen. Some of the intermolecular reactions are described in Scheme 1.

3.2 Characterization of reaction products in intramolecular photochemistry of 1–3

By analogy with the intermolecular model photoreactions mentioned above, it is anticipated that an oxidative *N*-dealkylation of the donor moiety takes place in the intramolecular photochemistry of **1–3**. Steady-state photolysis of **1–3** in benzene yields two major products and one minor product. A product analysis by hplc revealed that one of the major ones is an



SCHEME 1

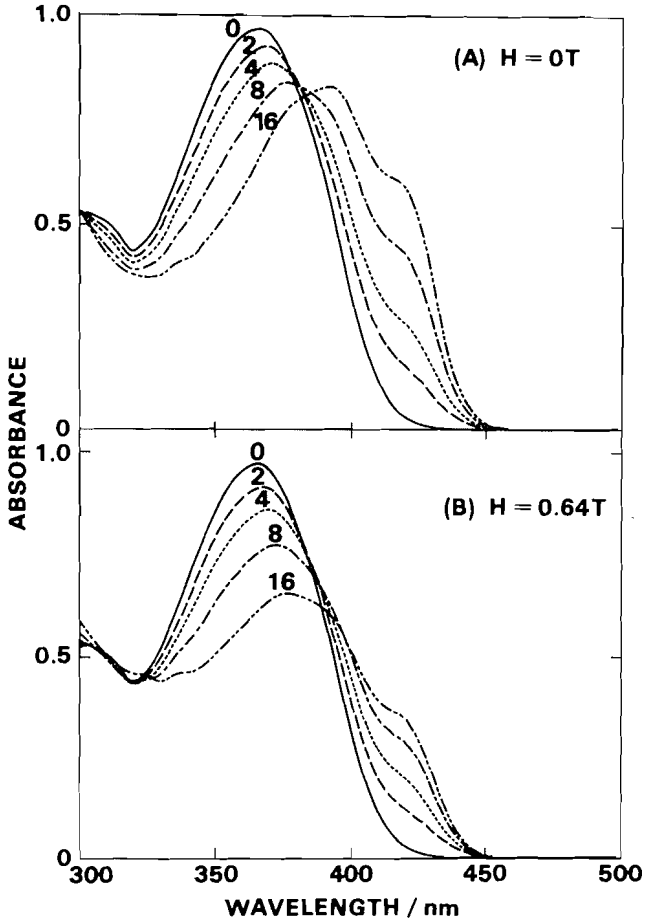


FIG. 1. Photoreaction of **1** in benzene as detected by uv-absorption spectroscopy (A) in the absence and (B) in the presence of an external magnetic field (0.64 T). The number refers to the irradiation time in min. Excitation source: 500-W Xe arc with coloured glass filters, Hoya U-340, Toshiba UV-25, and Toshiba UV-35.

unsubstituted aromatic amine, namely, aniline, diphenylamine, and phenothiazine, in photolysis of **1**, **2**, and **3**, respectively. The major products other than the arylamine (referred to hereafter as Product 1) and the minor product (referred to hereafter as Product 2) were commonly detected with reaction mixtures produced by photolysis of **1–3**.

The photoreaction of **1** in benzene was monitored by uv-absorption spectroscopy (see Fig. 1). Spectral changes observed in the region longer than 350 nm can be ascribed mainly to the disappearance of a 4-nitro-1-naphthoxyl chromophore and the appearance of the 4-nitroso-1-naphthoxyl group. Similar spectral changes have been observed for photoreactions of **2** and **3** in benzene, except for an absorption tail in the shorter wavelength region due to the donor moiety.

Aromatic chromophores in Product 1 and Product 2 were identified by comparison of their absorption spectra recorded by the lc–uv method with reference spectra for the authentic model compounds. The lc–uv spectrum of Product 1 shows an absorption maximum at 393 nm and is very similar to that of 1-methoxy-4-nitrosonaphthalene (see Fig. 2). Therefore, it is concluded that Product 1 contains a 4-nitroso-1-naphthoxyl group. The absorption band due to this chromophore in Product 1 is clearly seen in the spectrum recorded after 16-min irradiation in the absence of the magnetic field (see Fig. 1). In the same manner, the minor photoproduct was found to have a 4-nitro-1-

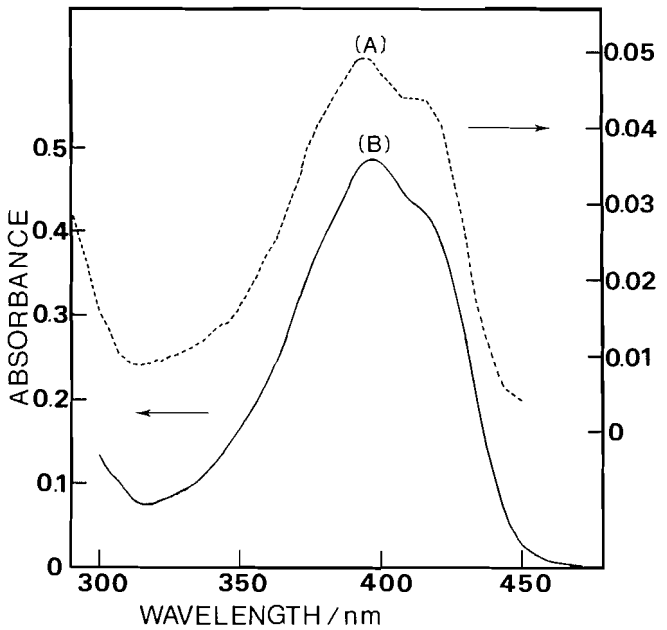

FIG. 2. Absorption spectra of Product 1 (A) and 1-methoxy-4-nitronaphthalene (B). (A): recorded by the lc–uv method for the reaction mixture obtained by 24-min photolysis of **1** in benzene with the concentration of 2.4×10^{-4} M. Excitation source, the same as that in Fig. 1. Normal-phase column, Merck Lichrosorb Si 60 (10 μm). (B): measured in benzene–acetonitrile mixed solvent (4:1) with the concentration of 4.7×10^{-5} M.

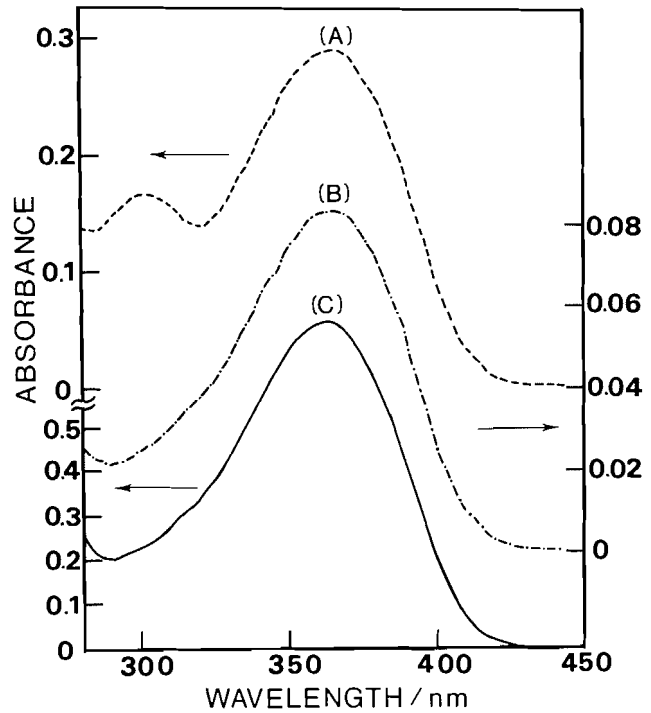

FIG. 3. Absorption spectra of **1** (A), Product 2 (B), and 1-methoxy-4-nitronaphthalene (C). (A) and (B): recorded by the lc–uv method for the reaction mixture obtained by 24-min irradiation of **1** in benzene. Experimental conditions are the same as those in Fig. 2. (C): MNN in benzene with the concentration of 9.5×10^{-5} M.

naphthoxyl chromophore (see Fig. 3). The lc–uv spectra indicate that neither Product 1 nor Product 2 has an arylamino moiety. From these findings, the photoractions of **1–3** in benzene can be characterized as follows:

$$4\text{-}O_2N\text{-}C_{10}H_6\text{-}1\text{-}O(CH_2)_{12}\text{-(Donor)} \xrightarrow{h\nu}$$

$$4\text{-}ON\text{-}C_{10}H_6\text{-}1\text{-}OR^1\text{(major)} + 4\text{-}O_2N\text{-}C_{10}H_6\text{-}1\text{-}OR^2\text{(minor)} + \text{H-(Donor)}$$

where (Donor) = NHC_6H_5, $N(C_6H_5)_2$, and $N{=}(C_6H_4)_2{=}S$.

In the photochemistry of **2** or **3** in benzene, the formation yield of Product 2 is much less than that in the photoreaction of **1**. Hence, ^1H nmr spectroscopy of the photoproducts of **2** or **3** in C_6D_6 may provide information about the structure of the side chain in Product 1, R^1. The observed nmr spectra show new signals attributable to the formyl methylene group, CH_2CHO, i.e., methylene protons at $\delta = 1.92$ ppm and aldehyde proton at $\delta = 9.31$ ppm.[2] This indicates that the terminal group in R^1 is CH_2CHO and suggests $R^1 = (CH_2)_{11}CHO$. The signals due to the formyl methylene group have been observed in the nmr spectra of the reaction mixture obtained by photolysis of 4-O_2N-C_6H_4-1-$O(CH_2)_{12}$-NHC_6H_5 (2). Product 2 is identified as **4** by an hplc analysis, i.e., from the agreement of the retention time and lc–uv spectra. It is concluded that R^2 is also $(CH_2)_{11}CHO$.

There was no indication of thermal reactions of **1–3** in solutions kept in the dark for 24 h at room temperature.

3.3 Magnetic field effects on the photochemistry of 1

3.3.1 Qualitative interpretation

Magnetic field effects on the photochemistry of **1** in benzene have been investigated by means of spectrophotometry. The observed results are given in Figs. 1 and 4. Figure 1 shows that the intensity of the absorption band peaking around 393 nm is reduced in the presence of the external magnetic field (0.64 T). This band is due to the 4-nitroso-1-naphthoxyl chromophore, and therefore the yield of Product 1 decreases on application of the magnetic field. Figure 4 illustrates two chromatograms recorded for the reaction mixtures obtained after 16-min irradiation of **1** in the presence and absence of the field. The peak intensity due to Product 1 decreases in the presence of the magnetic field, while that due to Product 2 increases.

Table 1 summarizes the magnetic field effects on photochemistry of **1**. We can see from this table that application of the external magnetic field (0.64 T) causes an appreciable change in the formation yields of Product 1 and Product 2, whereas neither the disappearance of **1** nor aniline formation is dependent on the magnetic field strength.

The magnetic field effects obtained in the present study suggest an intramolecular radical pair (biradical) in which two unpaired electrons are weakly coupled (3, 5, 6). The spin state of the reaction intermediate and the factor controlling the singlet–triplet mixing can be determined from analysis of the observed results on the basis of theoretical treatment of magnetic field effects upon chemical reactions via a radical pair (5, 6). The nitrosoaromatic species have been identified as cage products derived from the parent nitroaromatic compounds (3). Therefore, the following two cases can account for the observed magnetic field effects on the cage product formation: (*i*) a singlet biradical precursor is formed and the Zeeman mechanism is of dominant importance; (*ii*) a triplet biradical precursor is produced and the hyperfine coupling (HFC) mechanism predominates. The latter possibility is more likely, because the excited singlet state of the 4-nitro-1-naphthoxyl moiety undergoes a

[d]DMF–water mixed solvent (80:20 by volume ratio).

[e]DMF–water mixed solvent (80:20 by volume ratio) containing 6.9×10^{-3} M of γ-cyclodextrin.

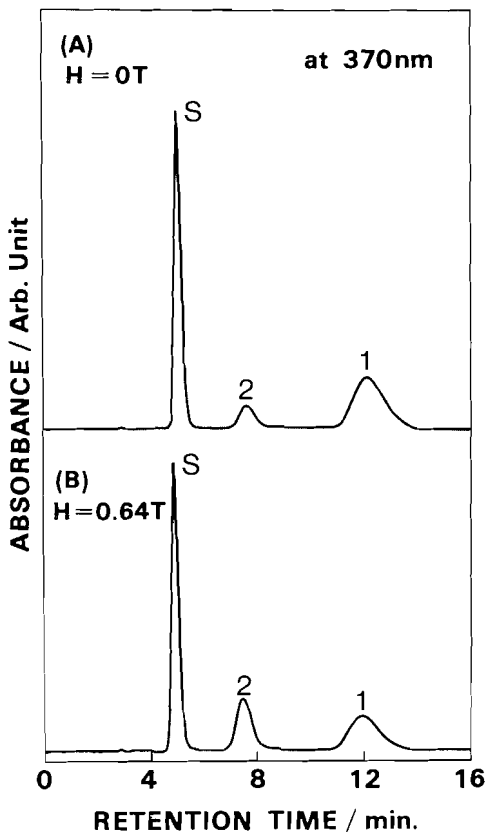

FIG. 4. Chromatograms recorded by monitoring absorbance at 370 nm for the reaction mixture obtained by 16-min irradiation of **1** in benzene (A) in the absence of (B) in the presence of an external magnetic field (0.64 T). Excitation source, the same as that in Fig. 1. S, starting material; 1, Product 1; and 2, Product 2. Normal-phase column, Merck Lichrosorb Si 60 (10 μm).

very rapid intersystem crossing (ISC) to the excited triplet state (10) and the initially prepared biradical must be of the triplet spin multiplicity. This conclusion is in accordance with the fact that the photo-redox reactions of 4-O_2N-C_6H_4-1-$O(CH_2)_{12}$-NHC_6H_5 (3) and related nitro compounds (11) occur mainly through the excited triplet state.

Figure 5 illustrates a reaction scheme proposed for the photochemistry of **1**. Since the HFC mechanism is of dominant importance, the ISC rate between ^{3}BR and ^{1}BR in Fig. 5 lowers in the presence of an external magnetic field (5, 6). The decrease in the ISC rate gives rise to the increase in the formation yield for escape products derived from the triplet precursor under the magnetic field. Therefore, Product 2 is identified as an escape product that may be formed through an intermolecular redox reaction. Because aniline is formed through both the cage and escape processes, its yield is insensitive to the magnetic field. Magnetic field effects on the consumption of **1** are hardly discernible from the experimental error.

3.3.2 Kinetic analysis

The observed magnetic field effects can be reasonably analyzed by a simple kinetic model based on the reaction scheme in Fig. 5. We measured magnetic field effects on the relative formation yield with changing field strength. Figure 6 shows the observed dependence of Φ^H/Φ^0 on H for Product 1 and Product 2 in the photochemistry of **1** in benzene. Since the relative yield becomes constant in the range higher than 0.5 T, the Zeeman mechanism is of no importance in the present case (5, 6). To analyze the magnetic field dependence of Φ^H/Φ^0, the following two kinetic parameters are introduced into the reaction scheme of Fig. 5: $K_{ISC}(X)$ for the ISC rate between ^{3}BR and ^{1}BR in the presence of the magnetic field of X T, and K_{esc} for the rate of escape process for ^{3}BR. The dependence of cage and escape product formations on H is described by eqs. [1] and [2], respectively[3]:

$$[1]\quad (\Phi^H/\Phi^0)_{cage} = K_{ISC}(H)\{K_{ISC}(0) + K_{esc}\}/K_{ISC}(0)\{K_{ISC}(H) + K_{esc}\}$$

$$[2]\quad (\Phi^H/\Phi^0)_{escape} = \{K_{ISC}(0) + K_{esc}\}/\{K_{ISC}(H) + K_{esc}\}$$

From the relative yield values for the cage and escape products given in Fig. 6, $Q(H) = (\Phi^H/\Phi^0)_{cage}/(\Phi^H/\Phi^0)_{escape} =$

[3]These equations were derived on the following assumptions: (*i*) Photostationary conditions are satisfied, i.e., $d[^3BR]/dt = d[^1BR]/dt = 0$. (*ii*) The cage process yielding Product 1 is much more rapid than other processes occurring from ^{1}BR, e.g., the ISC going back from ^{1}BR to ^{3}BR. Namely, K(cage product formation) $\gg K_{ISC}(X)$. (*iii*) The external magnetic field has no effects on K(cage product formation) or K_{esc}. The second assumption has usually been employed for the analysis of radical pair reactions involving triplet precursors: e.g., ref. 12.

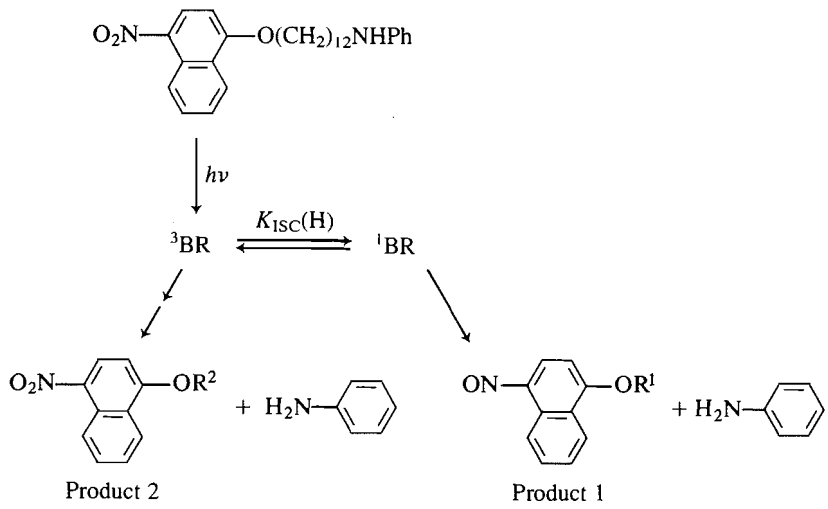

FIG. 5. Reaction scheme for the photochemistry of **1**. BR represents a biradical reaction intermediate. Superscripts 1 and 3 indicate the spin multiplicity.

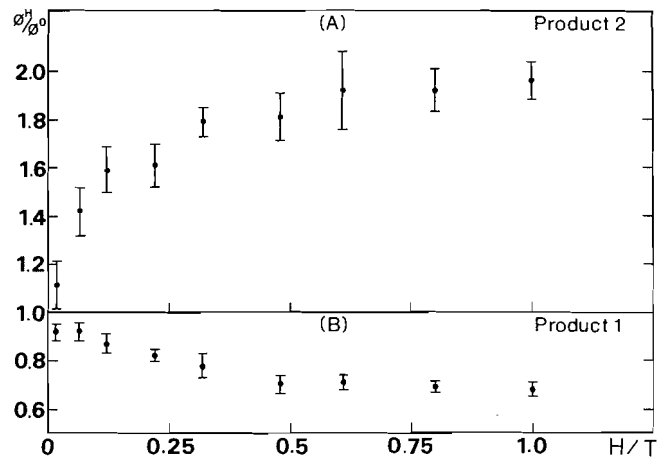

FIG. 6. Dependence of the relative yield, Φ^H/Φ^0 on the field strength, H, for photochemistry of **1** in benzene. The error bar represents the standard deviation. The relative yield was determined by hplc at 10% disappearance of **1**. Excitation source, the same as that in Fig. 1.

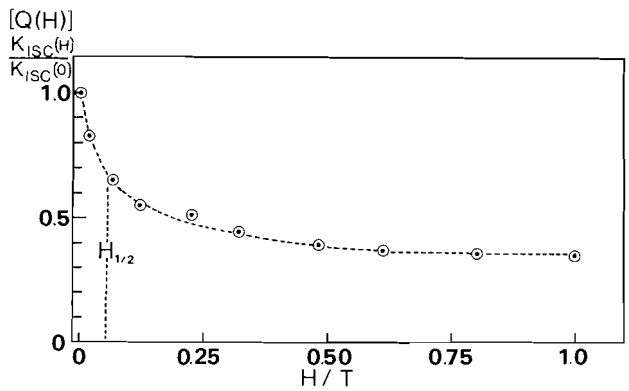

FIG. 7. Dependence of $Q(H) = K_{ISC}(H)/K_{ISC}(0)$ on the field strength, H.

$K_{ISC}(H)/K_{ISC}(0)$ was plotted in Fig. 7 as a function of the magnetic field strength, H. A magnetic field effect parameter, $H_{1/2}$, is defined as the field strength at which half the magnetic field effect in the saturation region is observed (13). The $H_{1/2}$ value was determined to be 55 mT from the plot of $Q(H)$ vs. H in Fig. 7 according to the relation, $Q(H_{1/2}) = [Q(0\ T) + Q(>0.5\ T)]/2 = [1 + Q(>0.5\ T)]/2$. The magnitude of this value is slightly larger than that usually observed in the magnetic field effects due to the HFC mechanism for the intramolecular photoreaction of polymethylene-linked chain molecules (14, 15), e.g., 20 mT for (1-pyrenyl)-$(CH_2)_{12}$-4-C_6H_4-1-$N(CH_3)_2$ (14). Consequently, there may be some contribution from other mechanisms, e.g., the relaxation mechanism (16).

3.4 Solvent effects and reaction mechanism of photochemistry of 1

The magnetic field effects upon the photochemistry of **1** have been studied in several solvents. We can see from the results in Table 1 that the effects have no systematic dependence on solvent polarity. However, the magnetic field effects on nitrosoaromatic formation depend appreciably on the irradiation time, especially in acetonitrile and tetrahydrofuran. This is due to the disappearance of the primary nitrosoaromatic product through a secondary process (3). Figure 8 shows that the formation yield of Product 2 becomes larger than that of Product 1 on prolonged photolysis of **1** in CH_3CN in the presence of a high magnetic field (0.64 T). On the other hand, the relation [Product 1] > [Product 2] holds when the consumption of **1** is low (see Table 2). Therefore, it is desirable to compare solvent effects on the relative yield, Φ^H/Φ^0, when the consumption of the starting material is still low (less than 40%). Benzene and ethyl acetate are much better than more polar solvents in that the secondary reaction is relatively slow.

In view of the rather low ionization potentials for *N*-alkylanilines (17), e.g., 7.65 eV for *N*-methylaniline, it is reasonable to assume photo-induced charge separation in polar media such as acetonitrile. Hence, the charge-separated biradical $A^{\cdot}$-$(CH_2)_n$-D^{+} formed by an electron transfer from the donor to the excited acceptor group can reasonably explain the observed magnetic field effects. In fact, the transient absorption due to the charge-separated biradical was recorded by laser photolysis of 4-O_2N-C_6H_4-1-$O(CH_2)_{12}$-NHC_6H_5 in acetonitrile (2). Magnetic field effects were observed for higher homologues with long methylene chains 4-O_2N-C_6H_4-1-$O(CH_2)_n$-NHC_6H_5 ($n \geq 8$) in CH_3CN and interpreted in terms of a change in the ISC

rate due to the HFC mechanism for the charge-separated biradical (3).

On the other hand, in nonpolar solvents, e.g., benzene, it is very unlikely that the charge-separated biradical is involved as a reaction intermediate, because solvation energy for a highly polar species is very small in solvents with low dielectric constants (18). By analogy with the intermolecular photo-redox reaction involving *N*-methylaniline and excited *m*-chloronitrobenzene (19), hydrogen abstraction from the alkyl chain by the nitro group is likely as a photochemical primary process in benzene. The charge-separated biradical formed after photoexcitation in benzene can be characterized as an exciplex or a contact ion pair (18) and, therefore, the interradical distance must be very small. The observation of pronounced magnetic field effects suggests a large separation (≥1 nm) between the two unpaired electrons (3, 15). It is reasonable to assume a neutral biradical as a reaction intermediate in benzene.

TABLE 3. Magnetic field effects on product formation of **1–3** in benzene[a]

Compound	Arylamine	Product 1	Product 2
1		0.71±0.03	1.92±0.16
2		0.88±0.03	1.37±0.10
3	1.01±0.04	0.91±0.06	[b]

[a] Determined by hplc as I^H/I^0 (H = 0.64 T). The quoted uncertainty represents the standard deviation.
[b] The precise determination was impossible, because the formation yield for Product 2 was very low.

A biradical intermediate in the reaction scheme of Fig. 5 may be the charge-separated species in CH_3CN and the neutral type of HA-$(CH_2)_{n-1}$-ĊHD in C_6H_6.

*3.5 Magnetic field effects on the competitive processes in photochemistry of **1***

A parameter for two competing reactions, R_b is defined as a yield ratio, R_b = Φ(escape product)/Φ(cage product). The value of R_b can be estimated from hplc data, namely, (*i*) measurement of chromatograms by monitoring absorbance at a particular wavelength, λ nm, and (*ii*) comparison of the integrated intensity of two peaks due to both products, on the assumption concerning the molar extinction coefficient at λ nm that ε(Product 2)/ε(Product 1) = ε(4-methoxy-1-nitronaphthalene)/ε(4-methoxy-1-nitrosonaphthalene). Table 2 lists the R_b values for photoreaction of **1**. The R_b value is sensitive to reaction environments, e.g., presence of γ-cyclodextrin (γ-CD). The escape product is considerably enhanced on addition of γ-CD, which suggests that the inclusion complexation of the donor and (or) the acceptor moieties by γ-CD depresses the intramolecular cage process forming Product 1.[4] The R_b value also increases on prolonged irradiation, because the denominator of R_b is reduced by the secondary decomposition of the primary cage product. On addition of γ-CD or on continuing photolysis for a long time, Product 2 becomes dominant over Product 1 under the magnetic field of 0.64 T (see Fig. 8). This fact implies that the magnetic field effect can be used for controlling chemical reactions that occur via a biradical or radical pair intermediate.

*3.6 Comparison of photochemistry of **1–3***

A photoreaction mechanism of **2** or **3** is closely related to that of **1** in Fig. 5, since they commonly undergo photo-induced oxidative *N*-dealkylation. Tables 3 and 4 list the magnetic field effects on photoproduct formation and on the competitive processes of **1–3** in benzene, respectively. On going from **1** to **3**, the magnitude of magnetic field effects on product formation shows a decreasing tendency and the R_b value is greatly diminished. These two findings can be explained in terms of eq. [1]. When the rate of escape process, K_{esc}, becomes negligibly small in comparison with $K_{ISC}(X)$, the relative yield, $(\Phi^H/\Phi^0)_{cage}$ approaches 1 as the limiting value. (Substitution of 0 for K_{esc} in eq. [1] gives $(\Phi^H/\Phi^0)_{cage}$ = 1.) Photochemistry of **3** can be classified as an example closest to this extreme case among **1–3**. There is an interesting correlation between the R_b values and the ionization potential of the donor moiety, IP(D) (see Table 6). When the electron-donating ability is increased, the cage product is formed more efficiently than the escape product.

[4] An inclusion complex formation has been known for an aqueous DMF solution: see ref. 20.

TABLE 4. Magnetic field effects on competitive processes in photochemistry of **1**–**3**[a]

Compound	R_b(0 T)	R_b(0.64 T)	IP(D) / eV
1	0.21±0.02	0.58±0.08	7.65[b]
2	0.10±0.02	0.16±0.04	7.44[c]
3	<0.04[d]	<0.04[d]	7.15[e]

[a] $R_b = \Phi$ (Product 2) / Φ (Product 1) determined based on the hplc data.
[b] A value for *N*-methylaniline taken from ref. 17.
[c] A value for *N*-methyldiphenylamine given in ref. 21.
[d] Since the Product 2 yield is too low to determine the R_b value precisely, the upper limit was estimated from the sensitivity of hplc analysis.
[e] A value for 10-methylphenothiazine reported in ref. 9.

4. Concluding remarks

The results reported in this work, as well as those presented in previous papers (3–6, 15, 16), show that the spin dynamics of radical pairs play one of the most important roles in the magnetic field effects on chemical processes or "spin chemistry". Although magnetic fields (≤1 T) generated by an ordinary electromagnet can cause rather small Zeeman splittings in a radical pair intermediate with triplet spin multiplicity, the relative ISC rate $K_{ISC}(H)/K_{ISC}(0)$ may change from 1 to ca. 1/3 in the case of magnetic field effects due to the HFC mechanism. Thus, magnetic field effects on radical reactions provide us with useful tools for elucidating the reaction mechanism (dynamical behaviour of the radical pair, spin states of biradical precursors, etc.), for controlling reaction rates and product yields, and for selecting reaction pathways.

The pyrazolylborate molybdenum tricarbonyl anions, $(HBpz_3)Mo(CO)_3^-$ and $(HBpz''_3)Mo(CO)_3^-$, have been utilized to prepare a number of heteronuclear bimetallic species containing Mo—Sn and Mo—Cu bonds. Crystals of [hydrotris(1-pyrazolyl)borato-*N*,*N*,*N*](triphenylstannyl)tricarbonylmolybdenum are monoclinic, a = 17.570(2), b = 14.077(2), c = 12.180(1) Å, β = 96.985(8)°, Z = 4, space group $P2_1/n$, those of [hydrotris(1-3,5-dimethylpyrazolyl)borato-*N*,*N*,*N*](chlorodimethylstannyl)tricarbonylmolybdenum are monoclinic, a = 11.044(3), b = 12.061(2), c = 20.218(4) Å, β = 100.43(1)°, Z = 4, space group $P2_1/c$, and those of [hydrotris(1-pyrazolyl)borato-*N*,*N*,*N*]tricarbonylmolybdenum(*N*,*N*,*N*′,*N*′-tetramethylethylenediamine)copper dichloromethane solvate are orthorhombic, a = 19.027(2), b = 16.995(2), c = 16.136(2) Å, Z = 8, space group *Pbca*. The structures were solved by conventional heavy atom methods and refined by full-matrix least-squares procedures to R = 0.044, 0.042, and 0.059 for 2084, 2502, and 1891 reflections, respectively. The two tin structures have a 3:3:1 capped octahedral structure with Mo—Sn bonds of 2.864(1) and 2.823(1) Å. The copper complex has a 3:4 piano stool arrangement of ligands about Mo with a Mo—Cu bond of 2.639(2) Å, two semibridging carbonyl ligands, and one terminal carbonyl ligand.

YAN-YUN LIU, ARTHUR MAR, STEVEN J. RETTIG, ALAN STORR et JAMES TROTTER. Can. J. Chem. **66**, 1997 (1988).

On a utilisé les anions pyrazolylborate de molybdène tricarbonyle, $(HBpz_3)Mo(CO)_3^-$ et $(HBpz''_3)Mo(CO)_3^-$, pour préparer un certain nombre d'espèces bimétalliques hétéronucléaires contenant des liaisons Mo—Sn et Mo—Cu. Les cristaux de l'[hydrotris(pyrazolyl-1)borato-*N*,*N*,*N*](triphénylstannyl)tricarbonylmolybdène sont monocliniques avec a = 17,570(2), b = 14,077(2) et c = 12,180(1) Å, β = 96,985(8)°, Z = 4 et groupe d'espace $P2_1/n$, ceux de l'[hydrotris(diméthyl-3,5 pyrazolyl-1)borato-*N*,*N*,*N*](chlorodiméthylstannyl)tricarbonylmolybdène sont monocliniques avec a = 11,044(3), b = 12,061(2) et c = 20,218(4) Å, β = 100,43(1)°, Z = 4 et groupe d'espace $P2_1/c$, et ceux de l'[hydrotris(pyrazolyl-1)borato-*N*,*N*,*N*]tricarbonylmolybdène(*N*,*N*,*N*′,*N*′-tétraméthyléthylènediame)cuivre solvaté par du dichlorométhane sont orthorhombiques avec a = 19,027(2), b = 16,995(2), c = 16,136(2) Å, Z = 8 et groupe d'espace *Pbca*. On a résolu ces structures par les méthodes conventionnelles aux atomes lourds et on les a affinées par la méthode des moindres carrés (matrice entière) jusqu'à des valeurs de R de 0,044, 0,042 et 0,059 respectivement pour 2084, 2502 et 1891 réflexions. Les deux structures contenant de l'étain possèdent des structures octaédriques cappées 3:3:1 avec des liaisons Mo—Sn de 2,864(1) et 2,823(1) Å. Le complexe de cuivre possède un arrangement des ligands autour du Mo qui prend la forme d'un banc de piano 3:4 avec une liaison Mo—Cu de 2,639(2) Å, deux ligands carbonyle agissant comme ponts et un ligand carbonyle terminal.

[Traduit par la revue]

Introduction

Earlier reports (1, 2) have detailed our findings on the complexation of the anion $(MeGapz_3)Mo(CO)_3^-$ with Rh, Cu, and Sn containing moieties. Structural studies revealed a novel 3:3:1 arrangement of the ligating atoms about the Mo centre, and carbonyl groups in a variety of bonding modes. In one of these reports (2), the pyrazolyl-borate containing complex, $(HBpz_3)Mo(CO)_3Rh(PPh_3)_2$, was described. The present paper describes the general utility of the pyrazolyl borate molybdenum tricarbonyl anions, $LMo(CO)_3^-$, in the synthesis of mixed metal complexes containing Mo—Cu and Mo—Sn bonds, and presents X-ray structural results for three of the complexes prepared.

Experimental

Starting materials

Air-sensitive materials were handled in a nitrogen atmosphere. Tetrahydrofuran (THF), benzene, CH_2Cl_2, and hexane were dried by refluxing over Na/benzophenone, potassium, CaH_2, and $CaSO_4$, respectively, followed by distillation. $[Cu(PPh_3)Cl]_4$ (3), $(MeCN)_3Mo(CO)_3$ (4), $K^+HBpz_3^-$ (5), and $K^+HBpz''_3$ (5) were prepared by literature methods. Me_3SnCl (Aldrich Chemicals), Ph_3SnCl (Alpha Chemicals), and Me_2SnCl_2 (PCA Chemicals) were used as supplied. $Me_2NCH_2CH_2NMe_2$ (tmed) was dried over CaH_2 and distilled before use.

Synthesis of $K^+LMo(CO)_3^-$ ligands (L= $HBpz_3$ or $HBpz''_3$)

A solution of the K^+L^- ligand (~0.4 mmol per 100 mL THF) was added to an equimolar amount of $(MeCN)_3Mo(CO)_3$ in the same solvent. The initial yellow coloration of the molybdenum complex in THF changed to an amber color on addition of the ligand solution. The reaction mixture was stirred for ~2 days to ensure complete formation of the $K^+LMo(CO)_3^-$ species as evidenced by ir measurements. The resulting solution was then reacted directly with equimolar amounts of the various tin and copper compounds as described below.

Synthesis of $(HBpz_3)Mo(CO)_3SnPh_3$

A solution of $K^+(HBpz_3)Mo(CO)_3^-$ in THF was prepared as described above and Ph_3SnCl (1.584 g, 4.11 mmol) in THF was added to this salt solution. The resulting reaction mixture was stirred for ~2 days after which the solvent was removed *in vacuo*. The dark yellow residue was extracted with CH_2Cl_2 and filtered. An equal amount of hexane was added to the filtrate and the mixed solvents allowed to evaporate slowly. Yellow crystals of the product in ~50% yield were obtained. Pertinent physical data for this complex are presented in Table 1. The mass spectrum of the complex displayed the parent ion signal, P^+, together with prominent signals due to the ions $(P - CO)^+$, $(P - 2CO)^+$, and $(P - 3CO)^+$.

The $(HBpz_3)Mo(CO)_3SnMe_3$ and the two complexes, $LMo(CO)_3$-

Values given for R, R_w, and S are based on those reflections with $I \geq n\sigma(I)$.

$SnMe_2Cl$, were prepared similarly. Table 1 lists selected physical data for these complexes. The X-ray structure analyses of the $(HBpz_3)Mo(CO)_3SnPh_3$ and $(HBpz''_3)Mo(CO)_3SnMe_2Cl$ compounds are described below.

Synthesis of $(HBpz_3)Mo(CO)_3CuPPh_3$

A solution of $K^+(HBpz_3)Mo(CO)_3^-$ in THF was added to a one-quarter molar amount of the tetramer $[Cu(PPh_3)Cl]_4$ (0.596 g, 1.65 mmol) in the same solvent. The reaction mixture was stirred for ~2 days after which the solvent was removed under vacuum. The residue was extracted with CH_2Cl_2, filtered, and hexane added. On slow evaporation of the mixed solvents, a yellow solid product was deposited in ~50% yield. Physical data for the complex are collected in Table 1.

Synthesis of $LMo(CO)_3Cu(tmed)$ complexes (L = $HBpz_3$ or $HBpz''_3$, tmed = N,N,N′,N′-tetramethylethylenediamine)

In a typical reaction the $K^+LMo(CO)_3^-$ salt (1–2 mmol) in ~200 mL THF was added to equimolar amounts of CuI and tmed in the same solvent. The reaction mixture was stirred for several hours and the solvent then removed under vacuum. The residue was extracted with CH_2Cl_2 and the mixture filtered. Slow evaporation of the solvent from the filtrate gave yellow orange crystals of the desired complexes. The crystal structure of the complex $(HBpz_3)Mo(CO)_3Cu(tmed)\cdot(1/2)CH_2Cl_2$ is described below. Physical data for both complexes are given in Table 1.

Spectra

The ir spectra were recorded on a Perkin-Elmer 598 spectrometer. The ^1H nmr spectra were recorded on Bruker WP-80 or Nicolet-Oxford H270 MHz instruments using FT techniques.

X-ray crystallographic analyses

Crystallographic data for $(HBpz_3)Mo(CO)_3SnPh_3$, $(HBpz''_3)Mo(CO)_3SnMe_2Cl$, and $(HBpz_3)Mo(CO)_3Cu(tmed)\cdot(1/2)CH_2Cl_2$ appear in Table 2. Unit-cell parameters were refined by least-squares on 2 sin θ/λ values for 25 reflections (2θ = 20–29, 14–23, and 20–29°, respectively) measured with Mo-$K\alpha_1$ radiation. The intensities of three standard reflections, measured each hour of X-ray exposure time, showed only small random variations for the two Sn compounds, and a uniform decay of 10.8% for $(HBpz_3)Mo(CO)_3Cu(tmed)\cdot(1/2)CH_2Cl_2$ (likely a result of surface decomposition). Data were corrected for Lp, absorption (numerical integration), and decay (where appropriate).[2]

All three data sets showed a relatively small number of reflections having significant intensity. High-angle washout is a contributing factor, very few reflections with $2\theta > 40°$ being classified as observed. The high-angle data were collected and retained in order to maximize the numbers of reflections used in the refinements at the expense of the overall fractions of significant data. This problem was particularly serious for $(HBpz_3)Mo(CO)_3Cu(tmed)\cdot(1/2)CH_2Cl_2$ where inter-

[2]The computer programs used include locally written programs for data processing and locally modified versions of the following: AGNOST, absorption corrections, by J. A. Ibers; ORFLS, full-matrix least-squares, and ORFFE, function and errors, by W. R. Busing, K. O. Martin, and H. A. Levy; FORDAP, Patterson and Fourier syntheses, by A. Zalkin; ORTEP II, illustrations by C. K. Johnson.

molecular cavities are occupied by disordered solvent molecules. The molecular structures themselves, which contain large groups of coplanar atoms, contribute to this problem, resulting in a small number of very intense reflections and large numbers of weak reflections.

All three structures were solved by conventional heavy-atom methods, the coordinates of the heavy atoms being determined from the Patterson functions and those of the remaining non-hydrogen atoms from subsequent difference Fourier syntheses. The dichloromethane molecule in $(HBpz_3)Mo(CO)_3Cu(tmed).(1/2)CH_2Cl_2$ was found to be

disordered about a crystallographic twofold axis. The single Cl atom in the asymmetric unit was found to occupy two different positions, related to one another by a 90° rotation about the twofold axis. The site occupancy factors for the two Cl positions were initially estimated from relative Fourier peak heights and subsequently adjusted to give equal equivalent isotropic thermal parameters for the two partially occupied sites. Non-hydrogen atoms were refined with anisotropic thermal parameters and hydrogen atoms were fixed in idealized positions (methyl group orientations based on observed positions, $C(sp^3)$—H = 0.98, $C(sp^2)$—H = 0.97, B—H = 1.08 Å, $U_H \propto U_{\text{bonded atom}}$). Neutral atom scattering factors and anomalous scattering corrections (Sn, Mo, Cu, and Cl) were taken from ref. 6. Final positional and equivalent isotropic thermal parameters (U_{eq} = (1/3) trace of diagonalized U) for the non-hydrogen atoms appear in Table 3. Bond lengths and bond angles are given in Tables 4 and 5, respectively. Calculated hydrogen atom parameters, anisotropic thermal parameters, complete lists of torsion angles, intra-annular torsion angles (Tables 6–9), and measured and calculated structure factor amplitudes have been placed in the Depository of Unpublished Data.[3]

Results and discussion

The ability of the tricarbonyl anion, $(MeGapz_3)Mo(CO)_3^-$, to form complexes with both transition metal and main group metal moieties in which heteronuclear metal–metal bonds are featured has been demonstrated in earlier publications (1, 2). The analogous tricarbonyl anions $(HBpz_3)Mo(CO)_3^-$ and $(HBpz''_3)Mo(CO)_3^-$ have now been utilized to synthesize a series of Mo—Cu and Mo—Sn complexes. The study was of interest to determine whether the incorporation of the $HBpz_3^-$ ligand in place of the $MeGapz_3^-$ ligand would have any effect on the geometry of the mixed metal complexes prepared. The cone angle (see Fig. 1) for $HBpz_3$ has been estimated to be ~180° (7–9), but unlike the 3:3:1 structures observed for a number of $(MeGapz_3)Mo(CO)_3X$ compounds (1, 2), only the 3:4 piano stool structure has been observed for $(HBpz_3)Mo(CO)_3X$ systems (10), an arrangement which is however ubiquitous in $CpMoL_4$ complexes. It has been pointed out, however, that the barrier for interconversion of ligands in the basal plane of the 3:4 structure is much lower in the $HBpz_3$ complexes than in the Cp complexes and further that the 3:3:1 isomers of $(HBpz_3)Mo(CO)_3X$ are viable intermediates in the observed fluxional processes (10). The cone angle for the $MeGapz_3^-$ ligand has been estimated to be ~180° from our structural data on "$(MeGapz_3)Mo$" systems (1, 2) (the longer Ga—N distance compared to the B—N distance being compensated for by a smaller N—Ga—N angle of ~100° *vis-à-vis* an N—B—N angle of ~108°), and thus any structural differences in the $(HBpz_3)Mo(CO)_3$"M" complexes would be attributable to

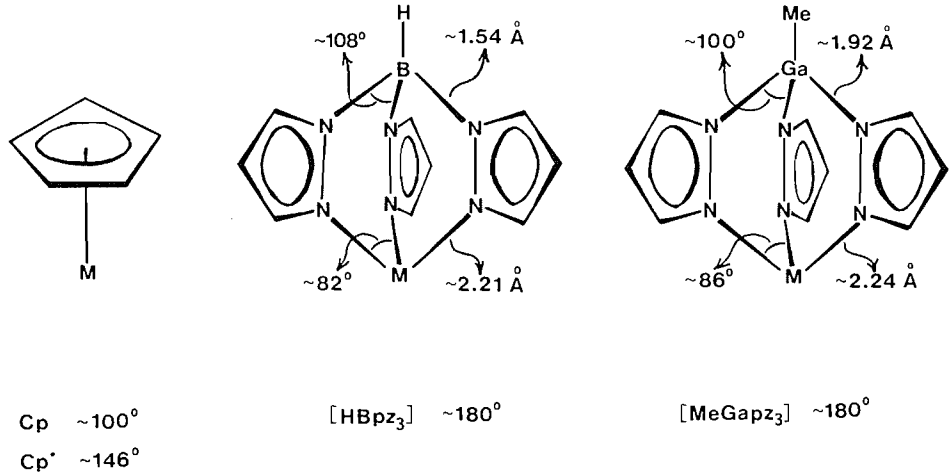

FIG. 1. Cone angles for the Cp, $HBpz_3$, and $MeGapz_3$ ligands.

electronic effects of substituting B for Ga in the compounds. Conversely, if similar 3:3:1 structures were observed with the boron analogs, then these would be a vindication of earlier arguments that the 3:3:1 arrangement represents a stable minimum in the potential energy surface for such $(HBpz_3)Mo(CO)_3X$ complexes (10, 11).

With the incorporation of the much more sterically demanding ligand $HBpz''_3{}^-$ (cone angle ~225° (7, 9)) in the molybdenum tricarbonyl anion, $(HBpz''_3)Mo(CO)_3{}^-$, it was anticipated that a crowded Mo centre might lead to different reactivity patterns. Precedents in the literature include the extensive chemistry of the $(HBpz''_3)Mo(NO)(X)_2$ (X = halogen), complexes (12), the oxo-molybdenum(V) complexes $(HBpz''_3)MoO(X)(Y)$, (X, Y = Cl^-, NCS^-, OR^-, SR^-, etc.) (13), and the efficient C—H activation properties of the $(HBpz''_3)Rh(CO)_2$ compound (14), all these examples relying on the steric properties the tris(3,5-dimethylpyrazolyl)borate ligand for their unique behavior.

The reaction of the $LMo(CO)_3{}^-$ anions (L = $HBpz_3$ or $HBpz''_3$) with organotin chlorides led to the yellow–orange crystalline products listed in Table 1. The complexes are moderately air-stable in the solid state but solutions deteriorate on exposure to air. A comparison with the analogous series of compounds involving the $CpMo(CO)_3{}^-$ ion (15) reveals that both series of compounds display only terminal ν_{CO} bands in their ir spectra, indicative of a Mo—Sn bond devoid of any bridging CO interactions. In the case of the cyclopentadienyl complexes three strong ν_{CO} bands were observed in each case, whereas the four compounds reported here show different patterns. Three of the complexes display two ν_{CO} bands much stronger than the third ν_{CO} band while the fourth complex exhibits one strong and two weak ν_{CO} bands. Structural differences between the two sets of complexes must be responsible and evidence presented below establishes a 3:3:1 structure for the "$LMo(CO)_3Sn$" complexes rather than the 3:4 structure suggested for the "$CpMo(CO)_3Sn$" compounds (15).

The ^1H nmr spectra of the $(HBpz_3)Mo(CO)_3SnMe_3$ and $(HBpz_3)Mo(CO)_3SnPh_3$ complexes indicate equivalent pyrazolyl rings in the compounds and are consistent with a 3:3:1 arrangement of ligating atoms about the Mo centre. This arrangement has been definitively established for the "$SnPh_3$" derivative by X-ray crystallography (see below). The two "$SnMe_2Cl$" compounds (Table 1) are of interest in that only the $(HBpz_3)Mo(CO)_3SnMe_2Cl$ derivative shows the presence of isomers in its ^1H nmr spectrum, a phenomenon observed and discussed for the analogous $(MeGapz_3)Mo(CO)_3SnMe_2Cl$ complex (1). The less symmetrical isomer B (3:4 piano stool) again disappears with time and produces isomer A (3:3:1 structure). The $(HBpz''_3)Mo(CO)_3SnMe_2Cl$ compound, by contrast, gave only one set of signals in its ^1H nmr spectrum, corresponding to the symmetrical 3:3:1 arrangement. This complex gave crystals suitable for X-ray analysis and the solid state structure reported below confirms our predictions of the molecular arrangement and provides a further example of the steric influence of the 3,5-methyl groups substituted on the pyrazolyl rings.

The reaction of the $(HBpz_3)Mo(CO)_3{}^-$ ion with the $[Cu(PPh_3)Cl]_4$ compound gave the Mo—Cu complex, $(HBpz_3)Mo(CO)_3Cu(PPh_3)$ in good yield, with properties similar to those described previously for the compound $(MeGapz_3)Mo(CO)_3Cu(PPh_3)$ (see Table 1 and ref. 2) and consequently we assign the 3:3:1 structure to the present system. The reactions of the $LMo(CO)_3{}^-$ ions with equimolar amounts of CuI and tmed (tmed = tetramethylethylenediamine) were investigated for two reasons. Firstly, would the tmed ligand chelate the copper centre as in the $CpMo(CO)_3Cu(tmed)$ derivative (16), or would the steric bulk of the pyrazolyl borate ligands prevent this, and secondly, if the latter, would the 3:3:1 or 3:4 structure about the Mo centre prevail. The complexes isolated showed, in their solution ^1H nmr, both the equivalence of the three pyrazolyl rings in the structure and also the equivalence of the "NMe_2" groups of the tmed ligand. The X-ray crystal structure of the $(HBpz_3)Mo(CO)_3Cu(tmed)$ complex shown in Fig. 2 clearly indicates a bidentate chelating tmed ligand and two semibridging carbonyl groups with one strictly terminal CO ligand. This arrangement is very comparable to both the $CpMo(CO)_3Cu(tmed)$ (16) mentioned above and also to the $CpW(CO)_3Cu(PPh_3)_2$ structures reported by Carlton *et al.* (17). The three strong bands in the solution ir spectra of the $LMo(CO)_3Cu(tmed)$ complexes are also similar to those reported for the above complexes. The solution ^1H nmr of the present compound can only be explained if fluxional processes are operative. A rotation of the $HBpz_3$ or $HBpz''_3$ moieties about the B···Mo axis might afford a rationale for the equivalence of the pyrazolyl rings but, in addition,

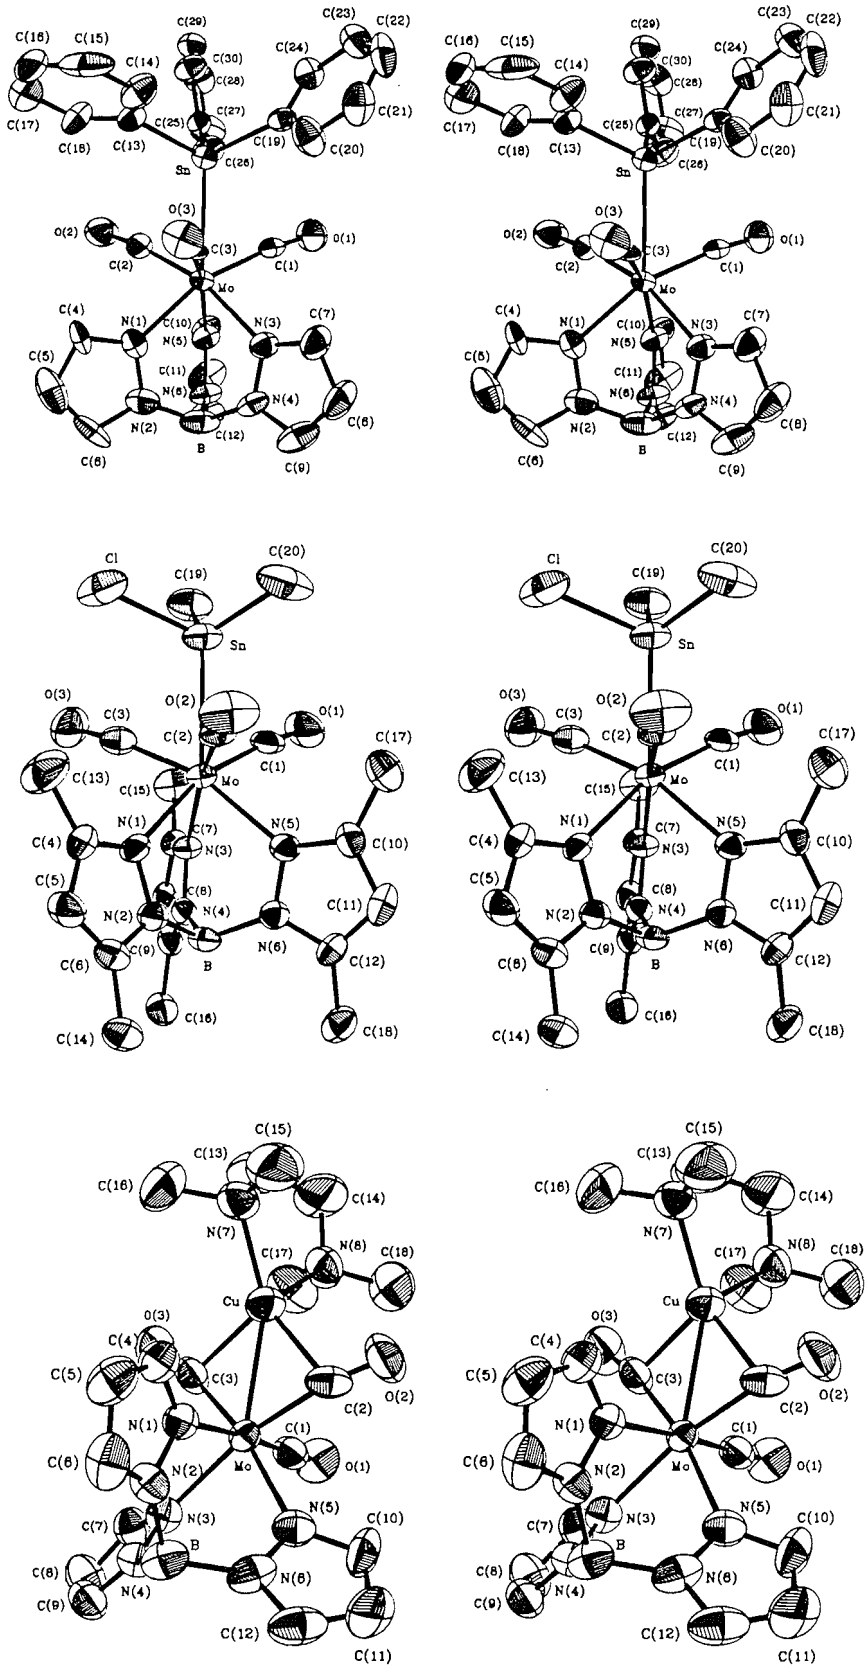

FIG. 2. Stereoscopic views of the $(HBpz_3)Mo(CO)_3SnPh_3$, $(HBpz''_3)Mo(CO)_3SnMe_2Cl$, and $(HBpz_3)Mo(CO)_3Cu(tmed)$ molecules; 50% probability thermal ellipsoids are shown for the non-hydrogen atoms. Hydrogen atoms have been omitted for the sake of clarity.

a rapid exchange of bridging and terminal CO groups, or a rotation of the tmed ligand, is necessary to explain the singlet observed for the "NMe_2" groups in the spectrum.

The structures of the $(HBpz_3)Mo(CO)_3SnPh_3$, $(HBpz''_3)Mo(CO)_3SnMe_2Cl$, and $(HBpz_3)Mo(CO)_3Cu(tmed)$ molecules are shown in Fig. 2. The two tin complexes have a 3:3:1 capped octahedral arrangement of ligands about the Mo atom as observed for the gallium analog $(MeGapz_3)Mo(CO)_3SnPh_3$ (1). The Mo—Sn, mean Mo—N, and mean Mo—C(O) distances are 2.864(1), 2.215, and 1.983 Å for $(HBpz_3)Mo(CO)_3SnPh_3$; 2.823(1), 2.239, and 1.981 Å for $(HBpz''_3)Mo(CO)_3SnMe_2Cl$; and 2.8579(3), 2.242, and 1.987 Å for $(MeGapz_3)Mo(CO)_3SnPh_3$. The major structural difference between the two "$SnPh_3$" complexes can be seen in the Mo—N distances and the N—Mo—N angles, the former being shorter (see above) and the latter being smaller for the "$HBpz_3$" compound than for the "$MeGapz_3$" analog (means of 82.0 and 86.0°, respectively). The reduced steric demands of the $SnMe_2Cl$ ligand relative to $SnPh_3$ are probably responsible for the significantly shorter Mo—Sn bond in $(HBpz''_3)Mo(CO)_3SnMe_2Cl$. Inspection of Fig. 2 shows that the sterically demanding $HBpz''_3$ ligand effectively imposes the 3:3:1 geometry, consistent with the observation of only one structural isomer of $(HBpz''_3)Mo(CO)_3SnMe_2Cl$ in solution (see above). The longer Mo—N distances in $(HBpz''_3)Mo(CO)_3SnMe_2Cl$, when compared with $(HBpz_3)Mo(CO)_3SnPh_3$, reflect both the electronic differences between the $HBpz_3$ and $HBpz''_3$ ligands and the stronger Mo—Sn interaction in the $SnMe_2Cl$ complex. The average C—O distances and M—C—O angles, 1.147 Å and 171.6° for $(HBpz_3)Mo(CO)_3SnPh_3$ and 1.154 Å and 172.6° for $(HBpz''_3)Mo(CO)_3SnMe_2Cl$, are as expected for terminal carbonyl ligands. In both of the tin complexes the slight nonlinearity of the Mo—C—O units represents a bending away from the capping Sn atom, as noted earlier for $(MeGapz_3)Mo(CO)_3SnPh_3$ (1).

The structure of $(HBpz_3)Mo(CO)_3Cu(tmed)$ features a Mo—Cu bond (2.639(2) Å), one terminal CO ligand (Mo—C = 1.90(1) Å, Mo—C—O = 178(1)°), and two semibridging CO ligands (Mo—C = 1.96(1) and 1.93(1) Å, Cu—C = 2.12(1) and 2.13(1) Å, Mo—C—O = 170(1) and 168(1)°, Cu—C—O = 109.5(9) and 111.1(9)°, Mo—C—Cu = 80.6(5) and 81.0(5)°). The complex has a 3:4 piano stool structure similar to those reported for $CpMo(CO)_3Cu(tmed)$ (16), $CpW(CO)_3Cu(PPh_3)_2$ (17), and $(MeGapz_3)Mo(CO)_3Rh(PPh_3)_3$ (2). Unlike the asymmetric $M(CO)_2M'$ units observed for the above-mentioned molecules, that in $(HBpz_3)Mo(CO)_3Cu(tmed)$ is symmetric with respect to the Cu atom. The CuN_2C_2 moiety in $(HBpz_3)Mo(CO)_3Cu(tmed)$ has an irregular tetrahedral geometry with equal Cu—C distances and significantly different Cu—N distances (2.07(1) and 2.20(1) Å), while the corresponding moiety in $CpMo(CO)_3Cu(tmed)$ has a distorted square planar geometry with effectively equal Cu—N distances (2.130(2) and 2.139(6) Å) and significantly different Cu—C distances (2.185(3) and 2.415(6) Å). The shorter Mo—Cu bond in the Cp compound (2.592 Å) is compensated for by a stronger interaction of the Cu atom with the semibridging CO ligands in the $HBpz_3$ complex. The Mo—N distance *trans* to the terminal CO ligand (2.264(9) Å) is longer than those *trans* to the semibridging carbonyls (2.245(9) and 2.246(9) Å), but the difference is not statistically significant.

Structural studies of organoboron compounds. XXXI.[1] (3-Benzoyl-(+)-camphorato)diphenylboron

WILLIAM R. CULLEN, STEVEN J. RETTIG, JAMES TROTTER, AND EUGENE B. WICKENHEISER
Department of Chemistry, University of British Columbia, 2036 Main Mall, Vancouver, B.C., Canada V6T 1Y6

Received December 4, 1987

This paper is dedicated to Professor Charles A. McDowell on the occasion of his seventieth birthday

WILLIAM R. CULLEN, STEVEN J. RETTIG, JAMES TROTTER, and EUGENE B. WICKENHEISER. Can. J. Chem. **66**, 2007 (1988).

Details of the synthesis and physical properties of the title compound are reported along with a new preparation of 3-benzoyl-(+)-camphor. Crystals of (3-benzoyl-(+)-camphorato)diphenylboron are triclinic, a = 9.0362(3), b = 9.4679(3), c = 14.2731(7) Å, α = 101.920(3), β = 100.086(3), γ = 93.251(3)°, Z = 2, space group $P\bar{1}$. The structure was solved by non-routine application of direct methods and was refined by full-matrix least-squares procedures to R = 0.036 and R_w = 0.039 for 4094 reflections with $I \geq 3\sigma(I)$. The unit-cell contains two crystallographically independent molecules, related to one another in the crystal lattice by a pseudo-inversion centre, and having the same configuration but different conformations. The structure analysis shows that the chiral, anionic, 1,3-diketonate ligand derived from 3-benzoyl-(+)-camphor is not symmetrically delocalized like most related ligands, resulting in significantly different O—B bond lengths. Bond lengths (corrected for libration) include: O—B = 1.514(4), 1.522(4); 1.568(4) and 1.567(4) Å; C—B = 1.594(5)–1.616(5) Å.

WILLIAM R. CULLEN, STEVEN J. RETTIG, JAMES TROTTER et EUGENE B. WICKENHEISER. Can. J. Chem. **66**, 2007 (1988).

On rapporte les détails de la synthèse et les propriétés du composé mentionné dans le titre ainsi qu'une nouvelle préparation du (+)-benzoyl-3 camphre. Les cristaux du ((+)-benzoyl-3 camphrato)diphénylbore sont tricliniques, avec a = 9,0362(3), b = 9,4679(3) et c = 14,2731(7) Å, α = 101,920(3), β = 100,086(3) et γ = 93,251(3)°, Z = 2 et groupe d'espace $P\bar{1}$. On a résolu la structure par une application qui n'est pas de routine des méthodes directes et on l'a affinée par la méthode des moindres carrés (matrice entière) jusqu'à des valeurs de R = 0,036 et R_w = 0,039 pour 4094 réflexions avec $I \geq 3\sigma(I)$. La maille contient deux molécules qui sont indépendantes d'un point de vue cristallographique, qui sont reliées entre elles dans le réseau cristallin par un centre de pseudo-inversion et qui possèdent la même configuration mais des conformations différentes. L'analyse de structure démontre que le ligand dicétonate-1,3, qui est chiral, anionique et dérivé du (+)-benzoyl-3 camphre, n'est pas délocalisé d'une manière symétrique comme c'est le cas avec la plupart des ligands apparentés; il en résulte que les longueurs des liaisons O—B sont très différentes. Parmi les longueurs de liaison observées et corrigées pour la libration, on note : O—B = 1,514(4), 1,522(4); 1,568(4) et 1,567(4) Å; C—B = 1,594(5)–1,616(5) Å.

[Traduit par la revue]

Introduction

Rhodium(I) complexes of 3-benzoyl-(+)-camphor have been found to be useful as homogeneous hydrogenation catalysts for the reduction of olefins. The catalytic species can be prepared *in situ* by the addition of the sodium salt of 3-benzoyl-(+)-camphor to a solution of bis(ethylene)rhodium(I) chloride dimer, or may be generated from the (3-benzoyl-(+)-camphorato)bis(ethylene)rhodium(I) complex, under an atmosphere of hydrogen in the presence of an olefinic substrate (1). The related diphenylboron chelate, (3-benzoyl-(+)-camphorato)diphenylboron, has now been synthesized, and an X-ray crystallographic analysis undertaken, to provide accurate geometrical parameters for the coordinated 3-benzoyl-(+)-camphorate ligand and also as part a continuing structural investigation of organoboron compounds.

Experimental

Preparation of 3-benzoyl-(+)-camphor, 4

A solution of lithium diisopropylamide was prepared by adding butyllithium (22.6 mL of 1.6 *M* solution in hexane, 36 mmol) to a solution of diisopropylamine (5.1 mL, 36 mmol) in 80 mL of dry diethyl ether. After 2 h, (+)-camphor (**1**, 5.0 g, 33 mmol) was added and the mixture was stirred overnight. The solution was cooled to 0°C and ethyl benzoate (6.2 mL, 43 mmol) was added dropwise. After 4 h the ether was removed by reduced pressure and the pinkish solid was washed with dry hexane. The solid was hydrolyzed with 25 mL of 20% HCl and the product extracted with diethyl ether. The ether extracts were dried over magnesium sulfate. Removal of the ether by reduced pressure yielded 3.4 g (40%) of 3-benzoyl-(+)-camphor, **4**. Melting point 83°C (lit. 84°C (2)). *Anal.* calcd. for $C_{17}H_{20}O_2$: C 79.65, H 7.86; found: C 79.90, H 7.88. Infrared (KBr, all strong): 1668, 1617 cm^{-1} (CO); 1600 (C=C).

Preparation of (3-benzoyl-(+)-camphorato)diphenylboron, 6

The sodium salt of 3-benzoyl-(+)-camphor, **5**, was prepared by the addition of sodium hydride (94 mg, 3.9 mmol) to a solution of 3-benzoyl-(+)-camphor (1.0 g, 3.9 mmol) in 30 mL of anhydrous diethyl ether. The mixture was stirred for 1 h at room temperature. A solution of diphenylborinic acid, prepared by the acid hydrolysis (40 mL, 0.1 *M* HCl) of (2-aminoethanolato)diphenylboron (0.88 g, 3.9 mmol) and extraction with diethyl ether (4 × 25 mL), was added dropwise to a solution of the sodium salt of 3-benzoyl-(+)-camphor and the mixture was stirred overnight. The solution was filtered, concentrated to 40 mL, and refrigerated to afford 1.2 g (73%) of yellow crystals. Melting point 167°C. *Anal.* calcd. for $C_{29}H_{29}BO_2$: C 82.86, H 6.95; found: C 82.60, H 6.94. Infrared (KBr, all strong): 1601, 1511 cm^{-1} (CO), 1597, 1501, 1483 (C=C). ^1H nmr (C_6D_6, 25°C, 300 MHz): δ 0.43 (s, 6H, unresolved $C(8)H_3$ and $C(10)H_3$), 0.93 (s, 3H, $C(9)H_3$), 1.10 (m, 2H, $C(5)H_2$), 1.32, 1.55 (m, 2H, $C(6)H_2$), 2.60 (m, 1H, C(4)H), 7.00–8.00 (m, 15H, aromatic protons). The multiplets due to the camphor protons were poorly resolved and accurate coupling constants were not obtained. The electron ionization mass spectrum showed the presence of a molecular ion peak as well as peaks due to the loss of a phenyl group, and peaks due to the presence of benzoylcamphor and diphenylboron ions.

The ir spectra were recorded on a Pye Unicam SP 1100 spectrophotometer, the ^1H nmr spectrum on a Varian XL-300, and the mass spectrum on a Kratos AES M50 spectrometer at 150°C and 70 eV.

X-ray crystallographic analysis

1 2 3 5 4a 4b 6

mm from a common origin): {0 1 1}, 0.22, {1 0 0}, 0.15, (0 1 −2), 0.26, and (0 −1 1), 0.26, was mounted in a general orientation. Unit-cell parameters were refined by least-squares on 2 sin θ/λ values for 25 reflections (2θ = 76–95°) measured on a diffractometer with Cu-$K\alpha$ radiation ($\lambda(K\alpha_1)$ = 1.540562, $\lambda(K\alpha_2)$ = 1.544390 Å). Crystal data at 22°C are as follows:

$C_{29}H_{29}BO_2$ f.w. = 420.36

Triclinic, a = 9.0362(3), b = 9.4679(3), c = 14.2731(7) Å, α = 101.920(3), β = 100.086(3), γ = 93.251(3)°, V = 1170.85(8) Å^3, Z = 2, ρ_c = 1.192 Mg m^{-3}, $F(000)$ = 448, μ(Cu-$K\alpha$) = 5.27 cm^{-1}. Absent reflections: none, space group $P1$ (C_1^1, No. 1, Buerger reduced cell).

Intensities were measured with nickel-filtered Cu-$K\alpha$ radiation on an Enraf-Nonius CAD4-F diffractometer. An ω-2θ scan at 1.2–10.0° min^{-1} over a range of (0.75 + 0.14 tan θ) degrees in ω (extended by 25% on both sides for background measurement) was employed. Data were measured to 2θ = 150°. The intensities of three check reflections, measured every 4000 s throughout the data collection, showed only small random variations. After data reduction,[2] an absorption correction was applied using the Gaussian integration method (3, 4). Transmission factors ranged from 0.768 to 0.864 for 96 integration points. Of the 4804 independent reflections measured, 4094 (85.2%) had intensities greater than or equal to $3\sigma(I)$ above background where $\sigma^2(I) = S + 2B + (0.04(S - B))^2$ with S = scan count and B = normalized background count.

Since the molecule is chiral it must crystallize in the noncentrosymmetric (and chiral) space group $P1$, thus there are two crystallographically independent molecules in the asymmetric unit. Attempts to solve the structure by direct methods in the space group $P1$ were not successful. The E-statistics were consistent with a centrosymmetric structure, implying that the two molecules in the unit-cell are related to one another by a pseudo-inversion centre. The structure was solved by direct methods in the centrosymmetric space group $P\bar{1}$, the coordinates of 24 of the 32 non-hydrogen atoms of the molecule (the three phenyl rings and the six-membered heterocyclic ring) being determined from an E-map. The refinement was then continued in $P1$, the coordinates of the second molecule being generated by inversion through the point (0, ½, ½) followed by a small translation to avoid a singular matrix. The positions of the remaining non-hydrogen atoms were determined from subsequent difference Fourier syntheses. In the final stages of refinement the non-hydrogen atoms were refined with anisotropic thermal parameters and the hydrogen atoms were fixed in idealized positions (methyl groups staggered, C(sp^2) = 0.97, C(sp^3)—H = 0.98 Å, $U_H \propto U_{\text{bonded atom}}$). Scattering factors for all atoms and anomalous scattering corrections for O, N, and C were taken from ref. 5. The weighting scheme $w = 1/\sigma^2(F)$, where $\sigma^2(F)$ is derived from the previously defined $\sigma^2(I)$, gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of both $|F_o|$ and sin θ/λ and was employed in the final stages of full-matrix refinement of 575 variables. Reflections with $I < 3\sigma(I)$ were not included in the refinement. An isotropic Type I extinction correction (Thornley–Nelmes definition of mosaic anisotropy with a Lorentzian distribution) was applied (6–8). The final value of g was 0.53(2) × 10^4. Convergence was reached at R = 0.036 and R_w = 0.039 for 4094 reflections with $I \geq 3\sigma(I)$. A parallel refinement of the mirror-image structure resulted in R and R_w ratios of 1.006, in agreement with the known absolute configuration of the starting material. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$, $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$ and $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$.

On the final cycle of refinement the mean and maximum parameter shifts corresponded to 0.03 and 0.16σ, respectively. The mean error in an observation of unit weight was 1.234. A final difference

[2]The computer programs used include locally written programs for data processing and locally modified versions of the following: MULTAN 80, multisolution program by P. Main, S. J. Fiske, S. E. map showed maximum fluctuations of −0.24 to +0.15 e Å^{-3}. The final positional and thermal parameters appear in Tables 1 and 6,[3] respectively.

The ellipsoids of thermal motion for the non-hydrogen atoms are shown in Fig. 1. The thermal motion has been analysed in terms of the rigid-body modes of translation, libration, and screw motion (9). The rms standard error in the temperature factors σU_{ij} (derived from the least-squares analysis) is 0.0023 Å^2. Analysis of the entire molecules indicated significant independent motion of the phenyl rings. Each molecule was broken down into four structural subunits (PhC(11), 2 PhB, and the 14-atom fragment consisting of the polycyclic skeleton and attached methyl carbons), which were separately analysed (rms ΔU_{ij} = 0.0019–0.0033, average 0.0024 Å^2). The appropriate bond distances have been corrected for libration (9, 10), using shape parameters q^2 of 0.08 for all atoms involved. Corrected bond lengths appear in Table 2 along with the uncorrected values; corrected bond angles do not differ by more than 1σ from the uncorrected values given in Table 3. Intra-annular torsion angles defining the conformations of chelate and other rings are listed in Table 4. Calculated hydrogen coordinates and thermal parameters (Table 5), a complete listing of torsion angles (Table 7), and measured and calculated structure factors have been placed in the Depository of Unpublished Data.[3]

Results and discussion

The crystal structure of (3-benzoyl-(+)-camphorato)diphenylboron, **6**, consists of well-separated molecules. The shortest intermolecular contacts between non-hydrogen atoms are O(1)···C(8′) ($x - 1, y, z$) = 3.510(5) Å and C(27)···C(27′) ($x - 2, y + 1, z$) = 3.516(5) Å. The two crystallographically independent molecules (Fig. 1) are related to one another in the crystal lattice by a pseudo-inversion centre at approximately (0, ½, ½), only the atoms of the chiral (+)-camphor moieties deviating significantly from this pseudosymmetry. Since the atoms of the six-membered heterocyclic rings are related by the pseudo-inversion centre, the two molecules have different conformations. This can be seen clearly in Fig. 1 where the molecules are both viewed in approximately the same direction with respect to the (+)-camphor moieties. The six-membered C_3O_2B rings in the unprimed and primed molecules have, respectively, *exo-* and *endo-B*-envelope conformations (see Table 4), similar to those observed for the acetylacetone complexes of "Ar_2B", where Ar = Ph (11) and *p*-tolyl (12), and the related compound (salicylaldehydato)diphenylboron (13). Bond lengths and angles in the two crystallographically independent molecules of **6**, presented side-by-side in Tables 2 and 3, are generally equal within experimental error. Significant differences between bond angles, in particular at C(1) and C(4), are probably the result of packing effects.

Unlike the fully delocalized and symmetric 1,3-diketonate moieties observed in the acetylacetone complexes of "Ar_2B" (11, 12) and in (benzoylacetonato)difluoroboron (14), those observed in **6** show a small but statistically significant bond length alternation within the O(1)—C(2)—C(3)—C(11)—O(2) fragments. The O(1)—C(2) (average 1.288 Å) and C(3)—C(11) (1.379 Å) bonds are significantly shorter than O(2)—C(11) (1.322 Å) and C(2)—C(3) (1.404 Å), respectively, indicating a significant O(1)=C(2)—C(3)=C(11)—O(2) contribution to the molecular structure. The ν_{CO} values for **6** (see Experimental section) are consistent with these findings. The average O—C and C—C distances[4] in these fragments (1.305 and 1.391 Å,

[3]Supplementary material mentioned in the text may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

[4]Libration corrected bond lengths (esd's assumed equal to those of the uncorrected values) are employed in the discussion and are compared with similarly treated (9) distances unless otherwise stated.

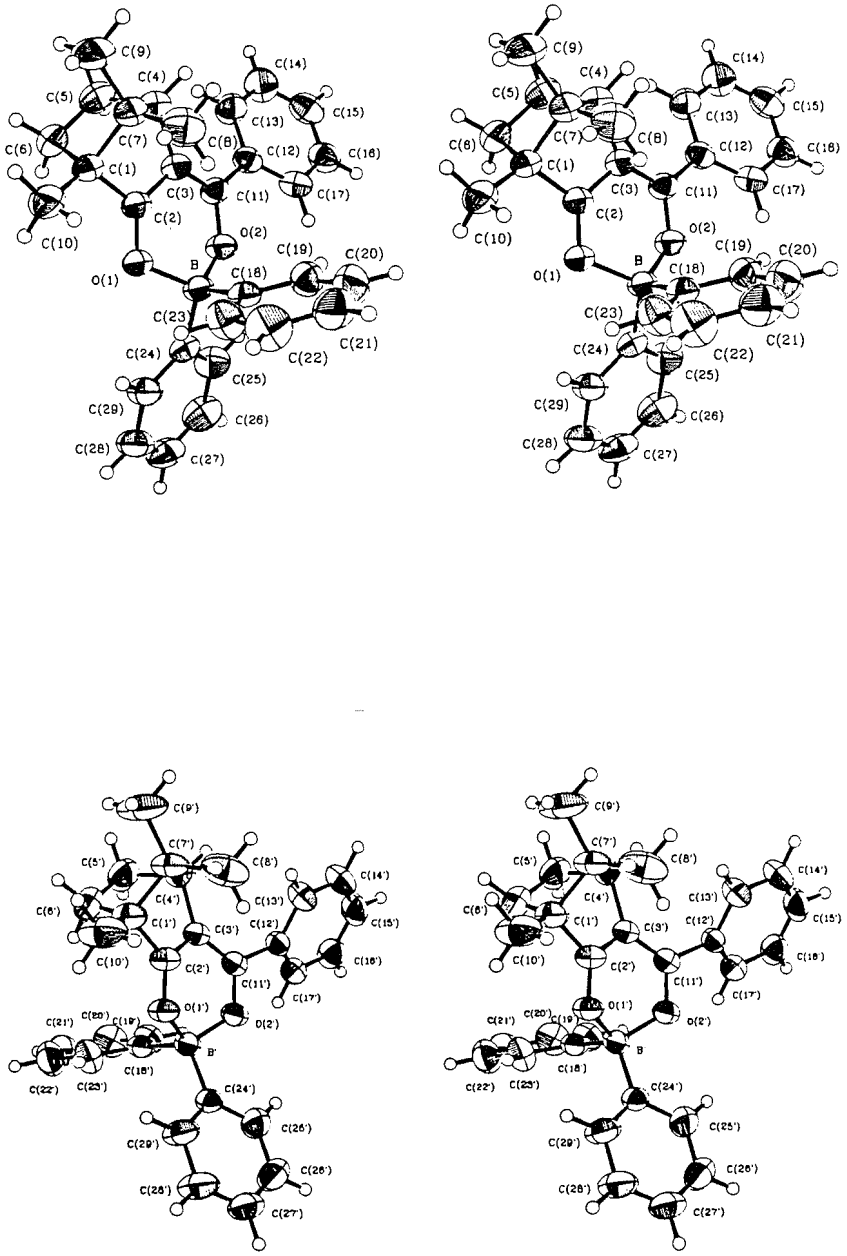

FIG. 1. Stereoscopic views of the two independent (3-benzoyl-(+)-camphorato)diphenyboron molecules; 50% probability thermal ellipsoids are shown for the non-hydrogen atoms. Hydrogen atoms have been assigned arbitrary thermal parameters for the sake of clarity.

respectively) may be compared with corresponding average values of 1.288–1.304 and 1.367(uncorr)–1.389 Å in the above-mentioned boron complexes (11, 12, 14), and with average uncorrected values of 1.274 and 1.391 Å observed for metal complexes of acetylacetone (15). The longer C—O distances observed for the boron complexes, when compared with the transition metal complexes, are consistent with the more covalent nature of the O—B interaction. The asymmetry of the 1,3-diketonate moiety in **6** leads to a significant difference between the two O—B bond lengths, those involving O(2) (average 1.518 Å) being about 0.05 Å shorter than those involving O(1) (1.568 Å). Transition metal complexes of 3-benzoyl-(+)-camphor would also be expected to show a significant difference between the two M—O bonds. A difference of 0.022 Å between the chemically equivalent O—B bonds in $(p\text{-tolyl})_2$B(acac) has been noted (12) while the O—B bonds in both crystal forms of Ph_2B(acac) are equal within experimental error. The asymmetric chelation observed for this chiral 1,3-diketonate ligand may play an important role in the catalytic properties of the Rh(I) complex mentioned in the Introduction.

The average O—B and C—B distances are 1.541 and 1.611 Å for the unprimed molecule and 1.545 and 1.605 Å for the primed molecule. These values are similar to the corresponding averages of 1.543 and 1.605 Å, and 1.533 and 1.607 Å observed for the two crystal forms of Ph_2B(acac) (11). Corresponding uncorrected values of 1.542 and 1.630 Å have been reported for $(p\text{-tolyl})_2$B(acac) (12). It has been shown that,

for a given chelate ring size, the sum of libration-corrected bond distances involving boron is essentially constant for *O,O*-chelates of diphenylboron (16). As a result, the average corrected O—B distance is a good indicator of the overall binding strength of the ligand with respect to the Ph_2B moiety. In order to compare structures for which libration corrections were either inappropriate, or were not made, with those for which the corrections were made, the ratio of the average C—B and O—B bond distances is a suitable parameter. The advantage of this parameter is that it is essentially the same whether it is calculated with corrected or uncorrected bond lengths. These C—B/O—B ratios for the ten structurally characterized *O,O*-chelates of diphenylboron containing six-membered chelate rings (11, 12, 17–21, this work) range from 1.039 to 1.088 with an average value of 1.058. The larger the value of this parameter, the stronger the O—B binding is in the molecule. The values of 1.039 and 1.045 for the two independent molecules of **6**, along with similar values of 1.040 and 1.048 for the two forms of Ph_2B(acac) (11) and 1.046 for (salicylaldehydato)diphenylboron (13) represent the weakest overall ligand binding observed for this type of compound. The differences between the average bond length ratios for the two molecules of **6** and also between the two crystal forms of Ph_2B(acac) are indicative of the extent to which packing forces, intramolecular steric effects, and resulting conformational differences can influence the molecular geometry.

Five of the six independent phenyl rings in the structure are planar within experimental error, while the other (containing C(18)) shows a statistically, but not chemically, significant deviation from planarity (maximum deviation from the mean plane 0.010(4) Å). The phenyl rings show the expected substituent-induced geometric distortions (22). The sp^2-hybridized C(3) atoms in both molecules are significantly displaced from the planes defined by their substituent atoms (C(3) by 0.070(4) Å and C(3′) by 0.059(4) Å), presumably a result of ring strain in the polycyclic ring system.

Received January 4, 1988

This paper is dedicated to Professor Charles A. McDowell on the occasion of his seventieth birthday

K. AKASAKA, K. TAKEGOSHI, T. TERAO, and S. GANAPATHY. Can. J. Chem. **66**, 2014 (1988).

Proton spin–lattice relaxation times (T_1) were measured on a protein *Streptomyces* subtilisin inhibitor, in the solid state, in the presence and the absence of adsorbed ^2H_2O in the temperature range between −170 and 100°C at 30 and 60 MHz. In both samples, a common relaxation process is attributed to the methyl group rotations of amino acid side chains which show minimum values of T_1 of 0.11 s at −105°C at 30 MHz and 0.23 s at −80°C at 60 MHz. In the presence of adsorbed ^2H_2O, another, effective relaxation process was found above 0°C, showing a minimum value of T_1 of 0.12 s at about 80°C at 60 MHz. The latter relaxation process was attributed to internal motions of exposed peptide segments, a large part of which is located in the crucial enzyme-binding region of the inhibitor.

K. AKASAKA, K. TAKEGOSHI, T. TERAO et S. GANAPATHY. Can. J. Chem. **66**, 2014 (1988).

Opérant dans un intervalle de température allant de −170 à 100°C, on a mesuré les temps de relaxation spin–réseau de la protéine *Streptomyces*, un inhibiteur de la subtilisine, à l'état solide, à 30 et à 60 MHz en présence et en l'absence de ^2H_2O adsorbée. Dans les deux cas, on attribue à la rotation du méthyle des chaines latérales des acides aminés, un processus commun de relaxation qui a des valeurs de T_1 de 0,11 s à −105°C à 30 MHz et de 0,23 s à −80°C à 60 MHz. On a trouvé un autre processus effectif de relaxation au-dessus de 0°C avec une valeur minimum de T_1 de 0,2 s à environ 80°C à 60 MHz. On attribue ce dernier processus de relaxation à des mouvements internes des segments de peptides exposés dont une grande partie se situe dans la zone cruciale d'encrage de l'enzyme de l'inhibiteur.

[Traduit par la revue]

Streptomyces subtilisin inhibitor (SSI) is a dimeric globular protein made up of two identical subunits of 113 amino acids (molecular weight 23 000 as dimer) (Fig. 1) (1). SSI inhibits a wide variety of proteases of subtilisin family, e.g., subtilisin BPN′ as well as those of chymotrypsin family, e.g., *Streptomyces griseus* proteases A and B (1). Unlike the trypsin inhibitors, SSI has a relatively long, enzyme-binding peptide segment consisting of about ten amino acid residues (Arg 65-Tyr 75) which are well exposed on the surface of the protein (1, 2). Moreover, a part of this segment, i.e., Arg 65-Met 70, is apparently flexible, as in the X-ray diffraction analysis the electron density corresponding to a part of the peptide segment is extremely low (1, 2) (see Fig. 1). This portion, however, rigidifies upon binding to the enzyme, as its electron density becomes very clear in the SSI–subtilisin BPN′ complex (1, 3). It has been suggested by one of the present authors that this flexibility is to make SSI capable of binding to a wide variety of target enzymes (4). It is in this connection that a special interest lies in the mobility of the surface segments of SSI.

In this report, we applied ^1H NMR spin–lattice relaxation measurements for the detection of internal motions of SSI in the solid state. The great advantage of measuring spin relaxation times in solids is that only the internal motions affect spin relaxation, whereas in solution one needs to take the overall rotation of the molecule into account in the analysis of relaxation data. Our results clearly indicated that in addition to the well-known methyl group rotations, there are other motions in the protein attributable to the exposed segments. The latter motions were found to be greatly enhanced when the dry protein sample was allowed to equilibrate with the water vapor.

Materials and methods

Lyophilized powders of SSI were obtained in high purity according to the previously described procedure (5). A fully dry sample of SSI was prepared by evacuating the lyophilized protein powder on a vacuum line at 25°C to approximately 10^{-3} mm Hg and sealed in an NMR sample tube. A hydrated sample was prepared by equilibrating the dry sample with the ^2H_2O vapor for a long enough time (17 h) at 25°C, and then sealed in an NMR sample tube. Proton longitudinal relaxation times were measured on a Bruker BKR 322S spectrometer operating at 30 MHz and on a home-built spectrometer operating at 60 MHz (59.525 MHz) using either the saturation recovery or the inversion recovery pulse sequence. The ^2H_2O content of the sample was measured on a JEOL GX-61D NMR spectrometer operating at 61 MHz.

Results

At all temperatures of measurement, the time dependence of magnetization of protons obeyed single exponential functions, giving single relaxation times T_1. This indicates that possible differences in spin–lattice relaxation rate among different protons are fully averaged out by extensive spin diffusion, as normally expected in solid.

Figure 2 shows the plots of T_1 values obtained for the dry sample of SSI at 30 and 60 MHz in the temperature range between −170 and 100°C. At the lower temperature side of the plot, the T_1 value decreases with increasing temperature, while at the higher temperature side, it increases with temperature until it reaches maxima at about 0°C. Clearly, minimum values of T_1 occur approximately at −80°C at 60 MHz ($T_{1\,\min}$ =

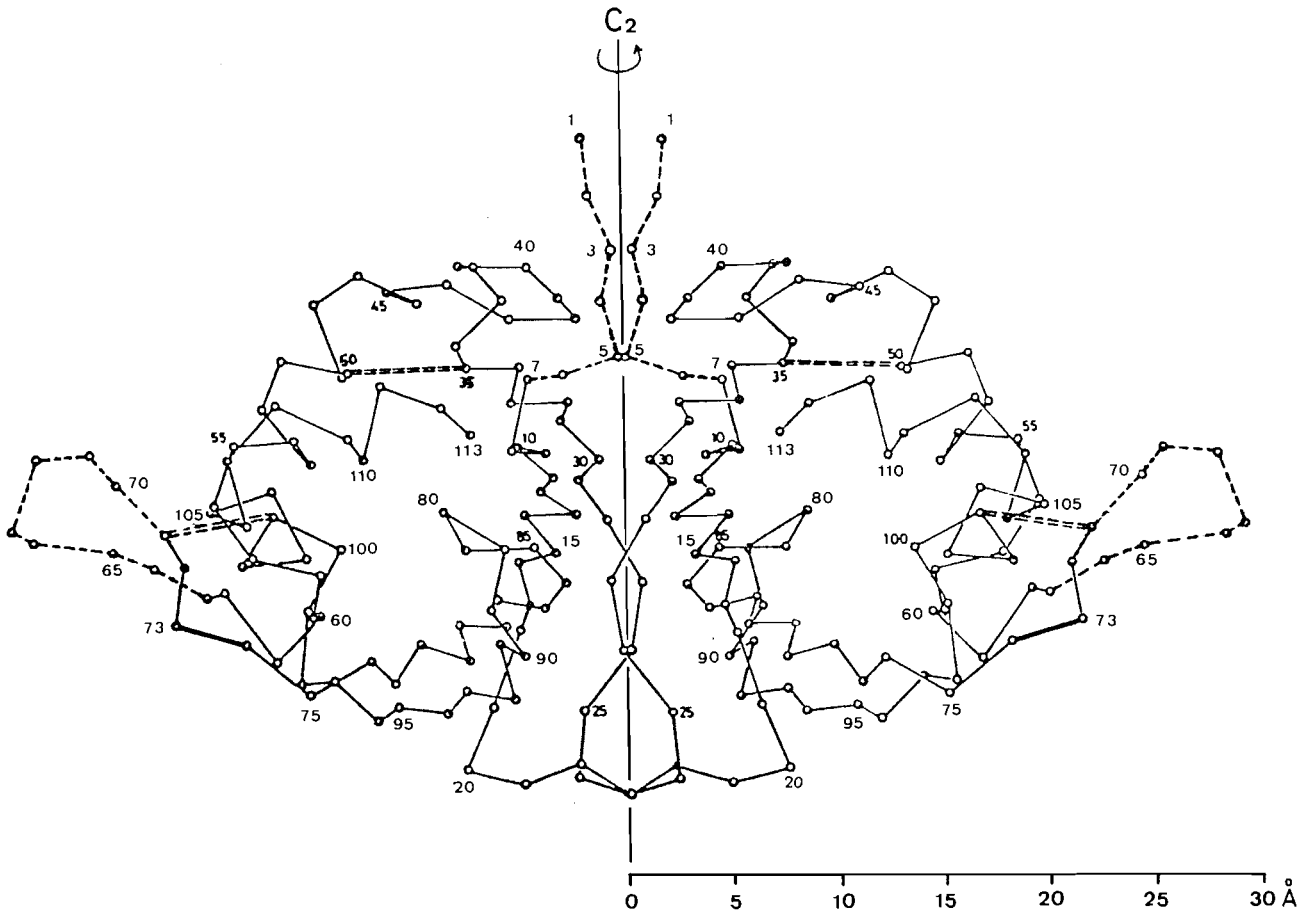

FIG. 1. The crystal structure of *Streptomyces* subtilisin inhibitor (after ref. 2). Two identical subunits are mutually related by a two-fold (C_2) axis. -○-, α-carbon backbone; ----, disulfide bridge. The dotted lines indicate where the electron density is dim or missing.

0.23 s) and at −105°C at 30 MHz ($T_{1\,\mathrm{min}} = 0.11$ s), indicating that there is a well-defined relaxation process (relaxation process I) in the temperature range between −170 and 0°C.

The experimental data could be fitted reasonably well for both frequencies by a Kubo–Tomita expression for longitudinal relaxation times (T_1) of protons (6), i.e.,

$$[1]\quad T_1^{-1} = C[\tau_c(1 + \omega^2\tau_c^2)^{-1} + 4\tau_c(1 + 4\omega^2\tau_c^2)^{-1}]$$

In this expression, the proton–proton dipolar interaction is assumed to fluctuate with the correlation time

$$[2]\quad \tau_c = \tau_0 \exp(E_a/RT)$$

in which a single set of parameters $C = 0.115 \pm 0.007 \times 10^{10}\,\mathrm{s}^{-2}$, $E_a = 1.14 \pm 0.07$ kcal/mol, and $\tau_0 = 0.653 \pm 0.152 \times 10^{-10}$ s are used for both frequencies (Fig. 2, solid lines).

Above 0°C T_1 values again show slight decrease with temperature (Fig. 2). This observation suggests that there may be another type of relaxation process (relaxation process II) in addition to the one observed at low temperature. This relaxation process was found to be greatly enhanced by introducing humidity to the protein sample. Ten hours after breaking the vacuum seal in the laboratory atmosphere at room temperature, T_1 decreased from 0.32 to 0.20 s at 30 MHz. When the sample was further exposed to an atmosphere saturated with water (^1H_2O) vapor for 30 min, T_1 further decreased to 0.083 s. These observations indicate that relaxation process II is strongly dependent on the adsorbed water. However, it was not clear

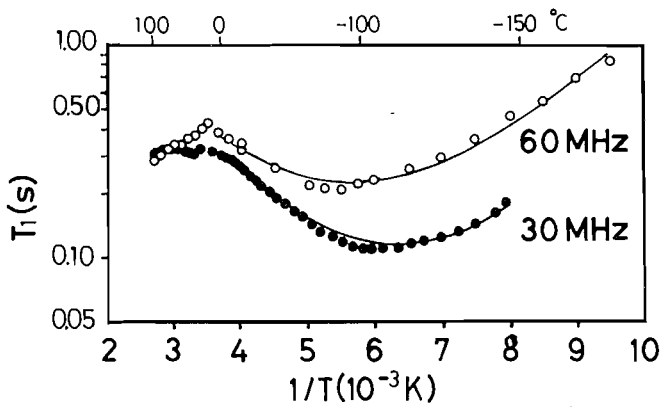

FIG. 2. The temperature dependence of the apparent ^1H spin–lattice relaxation times of *Streptomyces* subtilisin inhibitor in the dehydrated solid state, measured at 30 MHz (-●-) and at 60 MHz (-○-).

from the above experiment alone whether the protons of the adsorbed water molecules (^1H_2O) themselves act as relaxation sinks for the protons of the protein by way of spin diffusion among the protons or the adsorbed water protons induce new internal motions in the protein that have been largely quenched in the absence of adsorbed water.

In order to distinguish between the two cases, relaxation times were measured of solid protein samples equilibrated with a ^2H_2O vapor rather than with a ^1H_2O vapor. The water (^2H_2O)

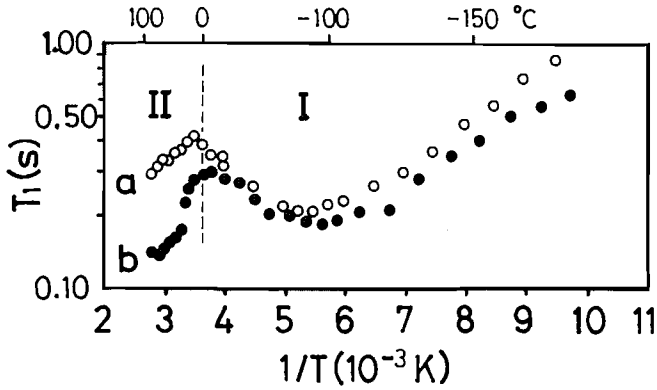

FIG. 3. The temperature dependence of the apparent ^1H spin–lattice relaxation times of *Streptomyces* subtilisin inhibitor measured at 60 MHz. (*a*) In dehydrated solid state (-○-) and (*b*) in hydrated solid state after exposure to the ^2H_2O vapor (-●-).

content in the ^2H_2O vapor-equilibrated sample was determined by dissolving it in a ^2H-depleted water and measuring the intensity of the ^2H_2O resonance in the high resolution ^2H NMR spectrum. The adsorption of ^2H_2O vapor by the dried protein was rapid, leading to a nearly final water (^2H_2O) content of approximately 50% of the total weight (protein plus water) within 10 h, which corresponds to about 1300 deuterons/subunit of SSI. The fraction of ^1H_2O within the water layer should be small, at most 5% even if all the labile protons of the protein after exchange with ^2H_2O remained adsorbed by the protein, and would give negligible contribution to the proton relaxation. On the other hand, cross relaxation caused by the flip–flop of the spins cannot take place effectively between the protons and the deuterons owing to a large difference in Larmor frequency of the two nuclei. Fluctuating dipolar field at the proton Larmor frequency produced by the deuterons of the mobile water molecules on the surface of the protein can still be a cause for relaxation of the protein protons. However, this contribution would not be appreciable, because of the small gyromagnetic ratio of the deuteron. After all, the bound ^2H_2O molecules would not themselves act as effective relaxation sinks for protons. Significant relaxation enhancement of the protons should arise only when the bound ^2H_2O molecules newly induced certain internal motions in the protein, which then would act as relaxation sinks.

Figure 3 compares T_1 values at 60 MHz of the solid SSI sample which had been equilibrated with a ^2H_2O vapor (-●-) with the T_1 values of the dry sample (-○-) at various temperatures. Clearly, the high temperature relaxation process (process II) was markedly enhanced by equilibrating the dry sample with the ^2H_2O vapor ($T_{1\,min} = 0.12$ s). The fact that the longitudinal magnetization in this sample also obeyed a single exponential function of time indicates that T_1's are averaged over all the protons by spin diffusion via proton–proton dipolar coupling. These observations clearly indicate that certain internal motions induced by the adsorbed water molecules act as new relaxation sinks in relaxation process II. In addition, a slight decrease in T_1 in the low temperature relaxation process (process I) is also noted in Fig. 3, which will be discussed later.

Discussion

Relaxation process I

The reasonable fit of relaxation process I to the Kubo–Tomita expression indicates that this relaxation process is due to a well-defined internal motion of the protein. The low activation energy (1.14 kcal/mol), together with C and τ_0 values, is analogous to the cases found in several other proteins by Andrew *et al.* (7). Through comparison of proton relaxation data of proteins with the corresponding data of polypeptides, they showed that the motion responsible for this relaxation process is mainly rotation of the methyl groups of amino acid side chains about their three-fold axes.

The subunit of SSI consists of 113 amino acids and contains 73 methyl groups, i.e., it has 219 methyl protons against 735 protons for the entire subunit when the proton content of the hydrogen atoms is 100% (1). The average values of the $T_{1\,min}$ for the methyl proton itself would therefore be 0.033 and 0.069 s for 30 and 60 MHz, respectively, should the protons other than the methyl protons make negligible contribution to the relaxation. These values may be compared with the $T_{1\,min}$ values calculated for the case when rotations of all the methyl groups of SSI were identical, using eq. [1] with $C = C_0 \times (219/735)$, where C_0 is the value of C for an isolated methyl group and is taken to be $0.8 \times 10^{10}\,s^{-2}$ (7). They are 0.053 and 0.10 s for 30 and 60 MHz, respectively. The difference between the experimental and the calculated $T_{1\,min}$ values would largely be explained by taking into consideration the distribution of temperatures of $T_{1\,min}$ for methyl groups of different amino acid residues (8).

A slight decrease in the observed T_1 values when the dry sample is equilibrated with ^2H_2O vapor can be explained reasonably well if one takes into account the fact that certain labile protons are replaced easily with deuterons (1). The percentage of replacement by deuterons in the present case can be estimated to be 10%, corresponding to approximately 70 protons/subunit, from the relative decrease of T_1.

Relaxation process II

The water content in the water vapor-equilibrated sample (approximately 50%) is comparable to that in the single crystal of SSI (about 45%). It is highly conceivable that, upon hydration in the ^2H_2O vapor-equilibrated powder sample, SSI largely regains its native conformation similar to that found in the single crystal, where ample segmental motions set in. The slight presence of relaxation process II in the dry sample (Fig. 2) could be either due to intrinsic motions that are present even in the absence of adsorbed water or due to a trace of water (^1H_2O) that could not be completely removed by evacuation.

The T_1 value for ^2H_2O vapor-equilibrated sample at 80°C (0.12 s at 60 MHz, Fig. 3) would have been as long as 1.9 s if only relaxation process I were present. It is noteworthy that $T_{1\,min}$ for relaxation process II is even shorter than the $T_{1\,min}$ for relaxation process I (0.23 s at 60 MHz at −105°C, Fig. 3), indicating that relaxation process II can be more efficient than in relaxation process I in SSI. Gaspar *et al.* (9) also found leveling off of T_{1D} (proton dipolar relaxation time) above 260 K in solid lysozyme, which they tentatively attributed to the effect of backbone and side chain motions. However, no such effect was found in their T_1 values.

The existence of the strong relaxation process at high temperature (relaxation process II) seems to be characteristic of SSI, and its origin must be sought in the unique structure of SSI (1, 2). SSI has unusually long exposed, peptide segment which acts as the binding segment towards the protease, i.e., Arg 65-Tyr 75 (3). In the absence of the protease, a part of this segment seems to be flexible, as they give only a dim electron density in the electron density map (1, 2). In addition, it has an *N*-terminal segment (residues 1–5) whose electron density is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 112.217.228.212 on 09/07/12
For personal use only.

completely missing (2) (see Fig. 1). Recent ^{1}H NMR studies in solution proved that the entire *N*-terminal segment undergoes rapid segmental motions of 10^{-9} s order (10–12).

Our present result (Fig. 3) indicates that even in solid, segmental motions with correlation times of similar magnitude take place in solid. We would not attempt to analyze the data of Fig. 3 (relaxation process II) quantitatively, because of the obvious complexity of the motions involved. However, their average value should be of the order of reciprocal Larmor frequency, i.e. ca 3×10^{-9} s at the temperature of $T_{1\,min}$ (80°C).

It has been often anticipated, but has been directly proved in very few cases, that the missing electron density in the X-ray crystallographic analysis be due to segmental motions of that part of the protein. Some direct proofs for the existence of internal motions in solids have been obtained by NMR investigations (7–9), but these have been restricted, in most cases, to those of the methyl group rotation. The present work not only demonstrated that segmental motions are present in the solid protein, but also that they occur predominantly in the hydrated state. The presence of ample segmental motions in SSI seems to be particularly important in view of the anticipation that segmental flexibility in the enzyme-binding region, particularly that of Arg 65 through Met 70, is a key to facilitate its binding with a variety of structurally different proteases (4, 11).

Conclusion

Although it has been generally accepted that in proteins proton spin relaxation is mainly dominated by methyl group rotations, the result of the present study has clearly indicated that other motions can be more important in causing spin relaxation. Since these motions were shown to be quenched in samples which had been vacuum-dried, they are likely to arise from surface segments that are mobilized by the adsorbed water molecules. Thus the water molecules appear to play essential roles in freeing those frozen segments on the surface and thereby bringing the protein in normal function.

The ion–molecule reactivity of the positive muon molecular ions $HeMu^+$ and $NeMu^+$

D. J. ARSENEAU, D. G. FLEMING, M. SENBA, I. D. REID, AND D. M. GARNER
TRIUMF and Department of Chemistry, University of British Columbia, Vancouver, B.C., Canada V6T 1Y6

Received March 24, 1988

This paper is dedicated to Professor Charles A. McDowell on the occasion of his 70th birthday

D. J. ARSENEAU, D. G. FLEMING, M. SENBA, I. D. REID, and D. M. GARNER. Can. J. Chem. **66**, 2018 (1988).

Thermal (300 K) ion–molecule reaction rates are measured, using the μSR (muon spin rotation) technique, for the muonated rare gas molecular ions $HeMu^+$ and $NeMu^+$ reacting with NO, O_2, N_2O, NH_3, CF_4, C_2H_4, TMS, and CH_3NO_2. In almost every case (excepting O_2), both charge transfer (k_e) and muon transfer (k_μ) contribute to the reaction rate. Reaction is believed to occur from ro-vibrational excited states, $[HeMu^+]^*$ and $[NeMu^+]^*$, due to the poor efficiency of He and Ne moderators for collisional deactivation. The total experimental rate constants, $k_{exp} = k_\mu + k_e$, are generally in excellent agreement with total capture rates predicted by the simple ADO theory, regardless of the degree of internal excitation. Comparisons with literature values for corresponding protonated ion reaction rates with O_2 and C_2H_4 reveal little or no isotope effect, although it is noted that these reactions are dominated by proton transfer, in contrast to the μSR results.

D. J. ARSENEAU, D. G. FLEMING, M. SENBA, I. D. REID et D. M. GARNER. Can. J. Chem. **66**, 2018 (1988).

Utilisant la technique du μSR, on a mesuré les vitesses thermiques (300 K) de réactions ions–molécules des ions moléculaires de gaz rares muonées ($HeMu^+$ et $NeMu^+$) avec le NO, le O_2, le N_2O, le NH_3, le CF_4, le C_2H_4, le TMS et le CH_3NO. Dans pratiquement chacun des cas (excepté avec le O_2), le transfért de charge (k_e) ainsi que le transfert de muon (k_μ) contribuent à la vitesse de la réaction. On croit que la réaction se produit à partir d'états excités ro-vibrationnels, $[HeMu^+]^*$ et $[NeMu^+]^*$, qui sont dûs à la mauvaise efficacité des modérateurs He et Ne dans la désactivation par collision. En général, les constantes de vitesse expérimentales totales, $k_{exp} = k_\mu + k_e$, sont en excellent accord avec les vitesses totales de capture qu'on peut prédire en se basant uniquement sur la théorie ADO, sans tenir compte du degré d'excitation interne. En se basant sur une comparaison avec des valeurs de la littérature concernant les vitesses de réaction correspondantes des ions protonés avec le O_2 et le C_2H_4, on peut en déduire qu'il n'y a que peu ou pas d'effet isotopique; on tire ces conclusions même si, par opposition avec les résultats de μSR, on note que ces réactions sont dominées par des transferts de proton.

[Traduit par la revue]

Introduction

There is currently widespread interest in a variety of both experimental and theoretical studies of gas phase molecular ions and ion–molecule reactivity (1), centered on the formation of molecular ion complexes (2, 3) and the effect of ro-vibrational excitation on reactivity (4–6), including now some detailed studies of the quenching process itself (5, 6). On the theoretical side (7–10), ion–molecule reactions are more amenable to a quantitative understanding than are atom–molecule reactions because ion–molecule reactivity is usually dominated by the long range (induced or permanent) electric dipole interaction. This attraction captures the reactants and holds them together until they can react, regardless of the details of the reaction. Sometimes though, short range "chemical" forces may be important, particularly in the case of open-shell ions where reactivity may be facilitated by the formation of long-lived molecular ion complexes (2, 3, 11), but this should not be the case for reactions of very simple molecular ions such as the protonated rare gases HeH^+ and NeH^+ (12–14).

In an earlier paper (15) we reported preliminary observations on the reactivity of the positive muon analog of protonated neon, $NeMu^+$. The present paper extends that work considerably to include results on both $NeMu^+$ and $HeMu^+$ ions reacting with a variety of molecules of widely differing polarizabilities and dipole moments. Like their proton counterparts, $HeMu^+$ and $NeMu^+$ represent the simplest molecular ions, being essentially point charges as well as closed electron shell systems: the best choice for comparisons with theoretical calculations of reactivity based entirely on ion–molecule capture. To date, relatively few experimental data have been reported on the reactivity of the corresponding protonated ions (12–14), almost no work at all on NeH^+, and very little in general on molecules with non-zero dipole moments (14). The present paper on the muonated rare gases extends this data base considerably, particularly in the area of charge transfer reactions.

Most measurements of thermal ion–molecule rate constants have been obtained with flowing afterglow (FA), (selected ion) drift tubes (SIFT), or ion cyclotron resonance (ICR) techniques, at pressures in the range from about 1 to 10^{-6} Torr (1 Torr = 133.3 Pa). Such low pressures leave open the possibility that reported rate constants for some "binary" collisions may in fact be due to termolecular processes (11, 16). Just the opposite limit is provided by the present μSR study of molecular ions, which are observed typically at pressures $\gtrsim$1 atm (1 atm = 101.3 kPa). A general comparison of rate constants for protonated molecules with those for their positive muon analogs could reveal the importance, if any, of total pressure in determining ion–molecule reactivity.

Another reason for the present study was the possibility that the very light μ^+, being only 1/9 as massive as a proton, might reveal interesting behaviour due to quantum tunneling, raised vibrational zero point energies, or more widely spaced ro-vibrational excitation energies. In fact this paper deals with a subset of a larger program, including also investigation of quenching processes (17).

Experimental technique

This paper is concerned with molecular ions containing a positive muon, μ^+. To a chemist, a μ^+ is just a light proton, especially since it forms an atom called muonium, denoted Mu, which is just like hydrogen but with 1/9 the mass. Muons and muonium are studied by the technique of μSR wherever muons are available in quantity, notably at meson facilities such as TRIUMF, where the present experiments were performed. The

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 112.217.228.212 on 09/07/12
For personal use only.

subject of μSR is well discussed elsewhere (18, 19), so only some main features will be briefly mentioned here.

Positive muons are produced 100% longitudinally spin polarized and have kinetic energies of ≳2.5 MeV as they enter the gas target in our experiment. This polarization is maintained as the μ^+ slows down in a moderator gas, although there can be appreciable loss through cyclic charge exchange ($\mu^+ + M \rightleftharpoons Mu + M^+$) at lower moderator pressures (19, 20). Depending on the moderator, M, the muon thermalizes within about 20 ns in a paramagnetic Mu atom, in some larger parmagnetic species (though not in these experiments), or in one of many diamagnetic species.

Regardless of its environment, the positive muon decays with a mean life $\tau_\mu = 2.2$ μs, emitting a positron preferentially along its spin axis ($\mu^+ \rightarrow e^+ \nu_e \bar{\nu}_\mu$), which is detected in the experiment by plastic scintillators. In a transverse magnetic field, muons in different magnetic environments precess with different Larmor frequencies, so their asymmetric positron decay patterns also precess, giving rise to a muon spin rotation (μSR) signal, in analogy with NMR and ESR spectroscopies (18). Like these other techniques, μSR can distinguish between paramagnetic environments and diamagnetic ones but, unlike the situation in NMR, muons in different diamagnetic environments (bare muons, molecular ions, neutral molecules) cannot easily be resolved; the frequency resolution of μSR is limited to ~0.5 MHz by the short muon lifetime.

In the present study, molecular ions are the only reasonable possibility for the observed diamagnetic signals (15), an example of which is shown in Fig. 1 for ~10 ppm NH_3 in He. As is clear from this figure, the precessing decay asymmetry, $A(t)$, undergoes a two-component relaxation, which is fitted to the equation

$$[1] \quad A(t) = (A_f e^{-\lambda_f t} + A_s e^{-\lambda_s t}) \cos(\omega_D t + \phi_D)$$

where A_f and λ_f represent the initial amplitudes and relaxation rates ($\lambda = 1/T_2$) for the fast-relaxing component of the signal, while A_s and λ_s apply to the slow- or non-relaxing component. All parameters apply to muons in diamagnetic environments, precessing with Larmor frequency ω_D, and initial phase ϕ_D. The total initial amplitude is indicative of processes that occur during the slowing down of the μ^+ in the gas, whereas λ corresponds to interactions of the μ^+ ensemble with its environment after thermalization; in μSR as in NMR, (T_2) relaxation is due to loss of phase coherence in the time ensemble of precessing muons. In the present study, this is a result of the formation of a paramagnetic species, either the Mu atom itself via charge exchange, or a radical ion via a muon transfer process. The first case is actually much more common and accounts for the fast-relaxing component, as will be discussed below.

The moderator gases used in this experiment (He and Ne) were of UHP grade and were further purified by passing them through a trap filled with molecular sieve and cooled by liquid nitrogen. The reactant gases were generally of research grade (>99% pure) and were used without further treatment. However, the low concentrations of reactant gases used (≲100 ppm) indicates that impurities in the moderator are of far more concern than reactant impurities.

The target vessel was a 200-litre aluminum cylinder with a thin Kapton beam entrance window at one end. The large volume is necessary because the low stopping power of helium would allow muons to reach the walls of a smaller vessel, giving rise to unwanted diamagnetic signals. Even with such a large vessel, however, the slight wall signals present in some data made subsequent analysis very difficult. The target was placed between a pair of 1.5 m diameter Helmholtz coils providing a magnetic field of ~300 gauss, and two sets of scintillation counters to detect decay positrons plus a thin counter placed before the entrance window to detect incoming muons. These provided, respectively, the "stop" and "start" signals to a high frequency time-digitizer, which maintained a histogram of decay times used to extract the signal of interest (Fig. 1).

Results and kinetic model

We have measured μSR spectra for reactants "X" = NO, NH_3, N_2O, C_2H_4, O_2, CF_4, CH_3NO_2, and $(CH_3)_4Si$ (TMS) in He and Ne gas at or above 1 atm pressure. All exhibit spectra similar to that shown in Fig. 1, with a two-component relaxation. This observation of both slow (λ_s) and fast (λ_f) relaxations indicates that there are two groups of muons in diamagnetic environments. However, rather than being distributed between these groups initially, we contend that all the initial diamagnetic signal comes from a single muonated molecular ion species formed in a ro-vibrationally excited state during the slowing down process (15), with muons subsequently entering differing environments through competing reactions. Specifically, in gas M = He or Ne, the diamagnetic $[MMu^+]^*$ reacts with the dopant, X, by charge (electron) transfer with rate constant k_e, yielding muonium, or by muon transfer with rate constant k_μ, to form diamagnetic XMu^+ according to the kinetic scheme

$$[2] \quad [MMu^+]^* + X \xrightarrow{k_e} Mu + X^+ + M$$
$$[MMu^+]^* + X \xrightarrow{k_\mu} XMu^+ + M$$
$$[MMu^+]^* + M \xrightarrow{k_q} MMu^+$$

where a third reaction channel is included to account for reactions with the moderator, with rate constant $k_q[M]$, indentified as quenching of excited MMu^+.

In a μSR experiment, as mentioned earlier, relaxation of the experimental signal is due to spin dephasing, which, in the majority of cases, is accomplished only via the electron transfer reaction forming Mu in the kinetic scheme above. Since the ground state binding energies of $HeMu^+$ and $NeMu^+$ are approximately 1.5 and 1.8 eV respectively (21), charge transfer between a ground state ion and most reactants is endothermic, indicating that the molecular ion must react from a ro-vibrationally excited state, $[MMu^+]^*$. The importance of including a quenching channel is indicated by the data to be discussed and is expected also from current studies on the effect of vibrational excitation on ion–molecule reactivity (4–6).

As only a few million muons are used per experiment, and only one muon at a time is permitted in the target, the X and M species are in vast excess, allowing a straightforward analysis to give the concentration at time t of all diamagnetic species of the reaction scheme [2] as

$$[3] \quad [D]_t = [MMu^+]^*_0 \left(\frac{k_e[X]}{\lambda} e^{-\lambda t} + \frac{k_\mu[X] + k_q[M]}{\lambda} \right)$$

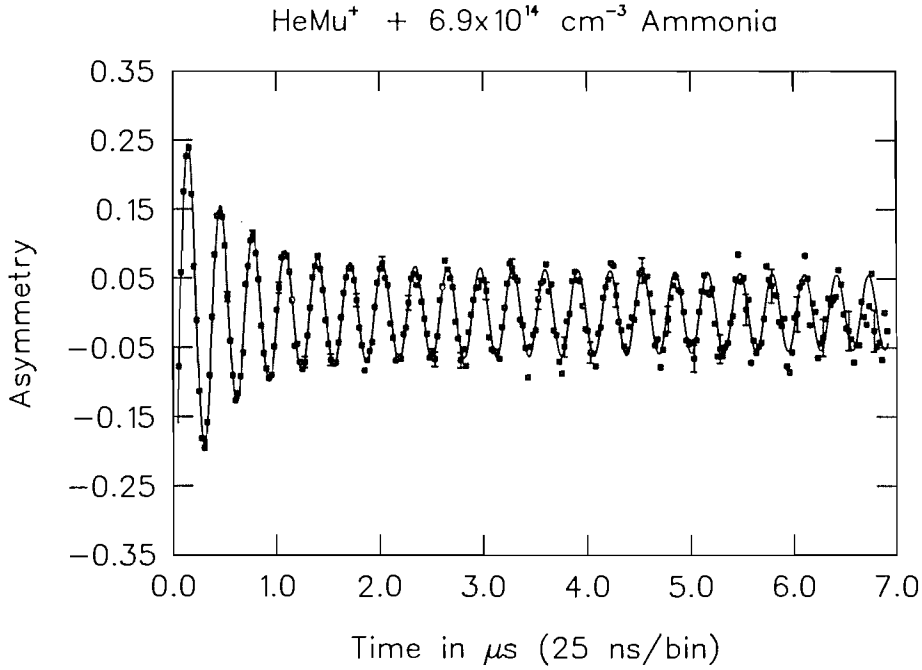

FIG. 1. A μSR "asymmetry" plot for ~10 ppm NH_3 added to He at 2280 Torr total pressure. The solid curve is a χ^2 fit of eq. [1] to the data, revealing the existence of two components: a quickly relaxing one and a very slowly relaxing one. The fast relaxation is due to charge exchange from a ro-vibrational excited state of a $[HeMu^+]^*$ molecular ion.

where λ is identified with the experimental λ_f and is given by $\lambda_f = (k_e + k_\mu)[X] + k_q[M]$. Thus a plot of λ_f vs. [X] gives a straight line with slope $k_e + k_\mu$ and intercept $k_q[M]$, which is indeed the case for all the gases investigated, as illustrated by Fig. 2, which shows the experimental values of λ_f for the reaction of $HeMu^+$ with nitromethane. Experimental values for $k_{exp} = k_e + k_\mu$ as well as values for k_q are listed in Table 1.

It may be noted that the rate constant for the reaction of NH_3 with $NeMu^+$ is much larger than that reported by us in ref. 15. At that time, the values reported for both X = CH_4 and NH_3 were based on earlier data of ref. 22, which were measured at much lower fields (~70 G) than used for the present measurements. Consequently, the two-component relaxations now observed were not resolved, leading to erroneously small ion–molecule relaxation rates in the case of NH_3. With improved apparatus and technique, the experimental errors in Table 1 are typically 10%, which are as good as or better than typical errors reported for related studies of ion–molecule reactivity (12–14).

Note that eq. [3] predicts a slow relaxation rate of exactly zero, but in fact there was always a finite slow relaxation observed, even in pure He or Ne. While this rate was usually ~0.05 μs^{-1}, commensurate with the inhomogeneity of the applied magnetic field, it was sometimes as high as 0.15 μs^{-1}. Such values for λ_s are indicative of additional relaxation processes affecting the products of muon transfer reactions, XMu^+ (15). They do not, however, interfere with the interpretation of λ_f and so will be ignored for the remainder of this paper.

Besides giving an interpretation for the relaxation λ_f, eq. [3] also shows that the ratio of the measured amplitudes from eq. [1] is $A_s/A_f = (k_\mu[X] + k_q[M])/k_e[X]$, indicating that a plot of A_s/A_f vs. $1/[X]$ should give a straight line with slope $k_q[M]/k_e$ and intercept k_μ/k_e. Such a plot for X = CF_4 is shown in Fig. 3, and the results of fitting such lines to the measured amplitudes are listed in Table 1 under the heading k_μ/k_e. This method of

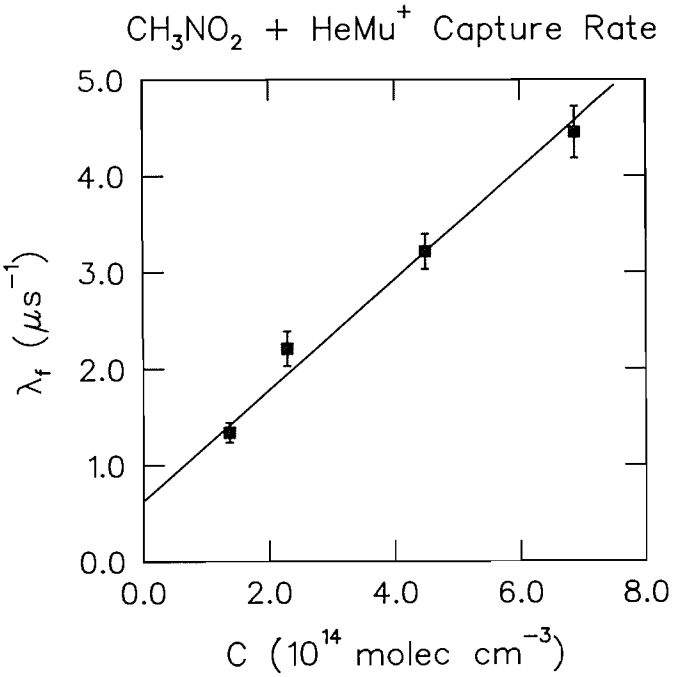

FIG. 2. A typical plot of the observed relaxation rate λ_f in nitromethane-doped helium vs. the concentration C of CH_3NO_2. The slope of the line gives the experimental capture rate constant $k_c = k_e + k_\mu$ for charge (k_e) and muon (k_μ) transfer reactions of the $[HeMu^+]^*$ molecular ion.

determining the relative importance of muon transfer and charge transfer fails in the case of X = NO in the present study, since the $NOMu^+$ ion formed is itself paramagnetic and leads to depolarization just as does the Mu formed by the electron transfer reaction. Thus, even though the amplitudes seem to indicate a value for $k_\mu/k_e = 0$, muon transfer may be quite prevalent in this particular case.

[a]First ionization points, in eV, taken from CRC Handbook of Chemistry and Physics, 1975 ed. Table E-74, except for CF_4, which was not given and was estimated from trends in the chloromethanes.
[b]Reaction endothermicities in eV; a negative value means that the reaction $MMu^+ + X \rightarrow M + Mu + X^+$ is exothermic from the *ground state* of the molecular ion.
[c]Experimental results from fits of eq. [1] to the data; k_{exp} in units of 10^{-10} cm^3 molec^{-1} s^{-1} and k_q in units of 10^{-15} cm^3 atom^{-1} s^{-1}.
[d]Charge exchange is endothermic for the bare μ^+.
[e]No relaxing component observed.
[f]Measured at a temperature of 125°C; all other measurements were made at room temperature, ~20°C.

Discussion and comparison with theory

What is not made clear in the kinetic scheme of [2] is that both charge transfer and muon transfer proceed from a single reaction in which the molecule, X, is captured by the molecular ion, MMu^+. For the case where the capture reaction is the limiting rate, the capture rate constant is given by $k_c = k_\mu + k_e$, which is exactly k_{exp} of the previous section. The capture rate is amenable to theoretical analysis (7–10), of which the most elementary treatment gives the Langevin rate constant (23), which is determined solely by the charge – induced dipole interaction and has the form

$$[4] \quad k_L = 2\pi q\sqrt{\frac{\alpha}{\mu}}$$

where α is the isotropic polarizability of the atom or molecule and μ is the reduced mass of the colliding pair. If the neutral molecule also possesses a permanent dipole moment, μ_D, the orientation of the dipole towards the charge adds a second term to the rate constant, the sum of both terms being conveniently written as

$$[5] \quad k_{ADO} = k_L\left(1 + c\mu_D\sqrt{\frac{2}{\alpha\pi k_B T}}\right)$$

where c is a "locking constant," frequently interpreted as some average orientation of the dipole, after the Average Dipole Orientation (ADO) theory of Su and Bowers (10). Although the ADO theory has been criticized for not taking angular momentum conservation properly into account (8, 9), it has been remarkably successful over the years at describing a wide variety of reactions in ion–molecule chemistry (1). Angular momentum conservation has been taken into account in an approximate way in the AADO version of the theory (8–10), which tends to increase the basic ADO rate constants by about 10%.

There have since been other, more advanced, treatments, including the classical derivations of Sakimoto and of Bates (9), in which total angular momentum transfer has been taken into account in a self consistent way, as well as TST (7) and trajectory calculations (24) of ion–molecule collision rates. In addition to these classical or semiclassical treatments, there are recent quantum calculations due to Clary (8), which, like the ADO and the AADO calculations, are based on a capture approximation (ACSA) with the potential again being dominated by the long range dipolar interaction. As pointed out by Troe (7), Clary's treatment is formally akin to a TST approach. Indeed, Troe's statistical theory in its high pressure limit and Clary's ACSA calculation give very similar results for ion–molecule reactivity, both agreeing with the simple ADO prediction of Su and Bowers at room temperature. That is the crucial point: while at low temperatures there can be marked differences between the different theories cited above, they give essentially the same results as the simpler ADO treatment at room temperature. Therefore, in this paper, our room temperature experimental capture rates are compared with ADO predictions. In a later publication we shall present results on the temperature dependence of these rates (17). In regard to comparisons with ADO, it is worth emphasizing that the theoretical ADO capture rate gives only the maximum possible (classical) rate, and subsequent reaction pathways may appreciably alter chemical reactivity with the result that k_{exp} may be considerably different from the theoretical maximum; the general expectation, then, is for $k_{exp} \leq k_{ADO}$.

[a]Experimental values taken from Table 1; all rate constants in units of 10^{-10} cm^3 molec^{-1} s^{-1}.
[b]Theoretical values calculated from eq. [5].
[c]Isotropic polarizabilities in Å^3, taken from several sources, including those in those in refs. 26 and 27; in some cases calculated from refractive indices using the Clausius–Mosotti equation.
[d]Electric dipole moments in debyes, taken from several sources, including those in ref. 27.
[e]Value for CF_4 not known to us and is therefore estimated from trends in the chloromethanes; likely uncertainty ~ ±30%.
[f]Measured at a temperature of 125°C; all other measurements were made at room temperature, ~20°C.

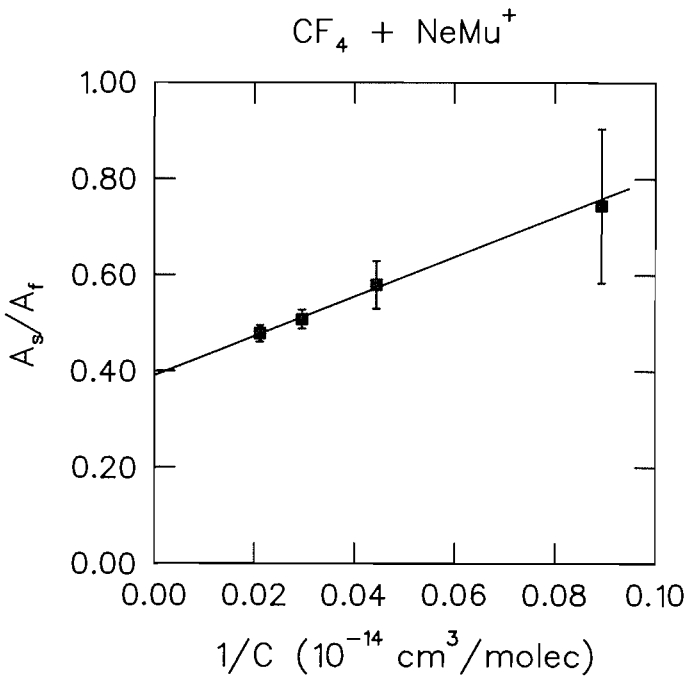

FIG. 3. A typical plot of the ratio of the observed amplitudes for the slow (A_s) and fast (A_f) relaxing components of the signal for CF_4 in 800 Torr neon vs. the inverse of the concentration of added CF_4. The slope of the line is related to a rate constant for quenching $[NeMu^+]^*$ and the intercept gives the ratio of rate constants for muon transfer to charge transfer, k_μ/k_e.

Table 2 shows the comparison between the experimental rate constants ($k_c = k_{exp} = k_e + k_\mu$) for $HeMu^+$ and $NeMu^+ + X$ taken from Table 1 with the values calculated from the polarizabilities and dipole moments (also listed in Table 2) using the ADO (or Langevin) theory of eqs. [4] and [5]. The entries in Table 2 are consistent with what is qualitatively expected based on current understanding of ion–molecule reactions. In every case the $[HeMu^+]^*$ reacts faster than $[NeMu^+]^*$, as expected from the reduced mass dependence of eq. [5]. The magnitudes of the polarizability α and the dipole moment μ_D of the target molecule seem to be the most important factors in determining the reactivity of these muon ions; e.g., TMS, with the largest polarizability, gives the fastest reaction rate among molecules with zero dipole moment, whereas CH_3NO_2, with the largest dipole moment (and also a large polarizability), gives the largest reaction rate seen. This dependence seems to be far more important generally than the ~1 eV variation in ionization potential, and thus in reaction exothermicity, between different reactant molecules.

The fact that the μSR results shown in Table 2 generally agree well with the ADO predictions means that the ion–molecule reactivity for these rare gas molecular ions is indeed dominated by the classical orbiting (dipole) radius and that other processes must play only a minor role. This conclusion is consistent with a wide body of other ion–molecule reactions (at 300 K) where the remarkable level of agreement frequently found between experiment and the ADO prediction is now well established (1, 8–10, 14). This level of agreement also verifies that the initial diamagnetic state in the present experiments is a $NeMu^+$ or $HeMu^+$ ion; were the initial ion a bare μ^+, for example, the measured rates would be faster by about a factor of 6 (He) to 13 (Ne) due to the lighter mass, and there would not be the observed consistent difference between He and Ne moderators.

Although the rate we measure experimentally is the overall capture rate, the presence of the charge transfer reaction is essential for the observation of any depolarization and, thus, for the measurement of the capture rate. Examination of the reaction exothermicities listed in Table 1, however, makes it clear that charge transfer occurs in cases where it is energetically disallowed for a ground state $NeMu^+$ or $HeMu^+$, namely O_2, N_2O, and CF_4, while it does not occur in the case of H_2 where charge exchange is endothermic even for a bare μ^+. This confirms the availability of extra excitation energy necessary for the reaction, which we have ascribed earlier to ro-vibrational excitation of $[HeMu^+]^*$ and $[NeMu^+]^*$. It can be noted that we have assumed charge exchange at thermal energies leads to a three-body final state (eq. [2]), which is favoured by phase space arguments, but a two-body final state formed by $[MMu^+]^* + X \rightarrow Mu + XM^+$ might also be possible: this could provide another source of reaction exothermicity, since XM^+ can be expected to be bound by a few electron volts (25). On the

other hand, the existence of this reaction channel is not indicated by results from the corresponding protonated ion studies (12–14), where the observation of charge exchange is the rare exception.

In regard to quenching of the excited states, we may expect that values of k_q[M] be independent of X. While this appears not to be the case at first glance from the values in Table 1, it should be noted that a large error in the intercept (~0.3 μs) can result from a relatively small error in the slope, making it particularly difficult to establish the value of small intercepts. Allowing for an error of this magnitude, one can indeed conclude that k_q is constant for essentially all X in Table 1 with an average value of $\bar{k}_q = (2.8 \pm 0.4) \times 10^{-15}$ cm^3 atom^{-1} s^{-1}, consistent with what would be expected for quenching by He and Ne (5, 6). The model we have used of a single excited state and a single quenching reaction is undoubtedly an oversimplification. For the more realistic case with a number of excitation levels it is quite reasonable to expect that different reactants, sensitive to different levels of excitation, would yield different values for "k_q". In the extreme case of a reactant such as NO, which can react with a ground state MMu^+ ion by either charge exchange or muon transfer, the measured k_q should be zero (i.e., quenching should have no effect.) The values tend to support this, but the scatter in the k_q values makes any conclusion uncertain. It is not entirely clear that our measured intercepts *are* due to quenching. Small concentrations of impurities that react predominantly via muon transfer would account for the observed values, and for their nonreproducibility. The meaning of the intercepts for λ_f must be left an open question.

As noted above, charge exchange is rarely seen in studies of the reactivity of protonated ions; proton transfer is the overwhelmingly dominant reaction channel. The present study of muonated ions indicates that both electron and muon (proton) transfer are prevalent. Using the ratios of k_μ/k_e listed in Table 1, as determined from the experimental amplitudes, values for k_μ and k_e were calculated, and are shown in Table 3 with relevant proton ion results from the literature. Such corresponding studies are few, as is made apparent by the sparseness of those columns in Table 3. Only the tandem ICR work of Smith and Futrell (13) has been sensitive to both charge exchange and proton transfer but, unfortunately, only their results for C_2H_4, reacting with HeH^+ and NeH^+, are comparable with the muonated ion results reported herein. Nevertheless, the agreement is exemplary: both the proton/muon transfer rates and the charge transfer rates are in agreement. While a difference in the charge transfer rates was not expected, some isotope effect on the proton/muon transfer rate could have been. The other protonated ion study cited in Table 3, due to Bohme and co-workers (12), measured the proton transfer rate constant for $O_2 + HeH^+$. Unfortunately, we have only measured the reaction of $O_2 + NeMu^+$ and have had to estimate a rate constant for the $O_2 + HeMu^+$ reaction from that result based on the difference in reduced mass. Even with the uncertainty due to this method, however, one feature is striking: Bohme observed only proton transfer while we saw *no* muon transfer, only charge exchange. While this may be due to differences between the $HeMu^+$ and $NeMu^+$ ions, it is more probably a result of differences in excitation; the muon ion results involve excited $NeMu^+$ while the proton ion results are for ground state ions, for which the charge exchange reaction is endothermic. The good agreement between the present work and both sets of proton ion data, considering the vastly different pressure regimes utilized, indicates that total pressure plays a negligible role in ion–molecule reactivity, in contrast to the suggestions of ref. 16. While these comparisons are useful, the relative lack of data for the corresponding

reactions of the HeH^+ and NeH^+ ions frustrates the potentially important broad comparisons that could otherwise be made with the present μSR results.

As noted, the present report is a subset of a larger body of data (17) for the formation, quenching, and ion–molecule reactivity of the muonated rare gases $[HeMu^+]^*$, $[NeMu^+]^*$, as well as $[ArMu^+]^*$, although fast relaxations are rarely seen in Ar. Some reactants are characterized by curved kinetic plots, pointing to more complex kinetic schemes than the one utilized here. Others, such as CH_4, give no fast relaxation when charge exchange is energetically allowed, indicating a dominant muon transfer channel. While, generally, agreement with the ADO theory remains good for this wider data set, there are notable exceptions that are still under consideration and will be discussed in a later paper. We have also measured temperature dependent reaction rates of $[NeMu^+]^*$ and $[HeMu^+]^*$ with a variety of reactants over the range ~100–500 K. In some cases there is good agreement with the ADO predictions, but others, such as $C_2H_4F_2$, react much faster than expected at lower temperatures. This work will also be reported in due course.

Photolysis of, and the reactions of H-atoms with, isopropanethiol

W. W. LAM, T. YOKOTA, I. SAFARIK, AND O. P. STRAUSZ[1]

Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received November 27, 1987

This paper is dedicated to Professor Charles A. McDowell on the occasion of his seventieth birthday

W. W. LAM, T. YOKOTA, I. SAFARIK, and O. P. STRAUSZ. Can. J. Chem. **66**, 2025 (1988).

Detailed investigation of the photolysis of i-C_3H_7SH has been carried out in the absence and presence of the inert gas, n-C_4H_{10}. A mechanism consisting of three primary photochemical steps: i-$C_3H_7SH \xrightarrow{[1]} i$-$C_3H_7S$ + H, $\phi_1 = 0.93 \pm 0.02$; i-$C_3H_7SH \xrightarrow{[2]} i$-$C_3H_7$ + SH, $\phi_2 = 0.057 \pm 0.024$; i-$C_3H_7SH \xrightarrow{[3]} H_2S + C_3H_6$, $\phi_3 = 0.009 \pm 0.001$; six hot reaction steps and seven thermal reaction steps adequately explains all the experimental observations. As in the case of hot H* atoms both the H-atom abstraction, H + i-$C_3H_7SH \xrightarrow{[7]} H_2 + i$-$C_3H_7S$, and the SH-displacement, H + i-$C_3H_7SH \xrightarrow{[8]} H_2S + i$-$C_3H_7$, reactions occur with thermalized H-atoms, with the rate constant ratio $k_7/k_8 = 19.2 \pm 4.3$ at 25°C. The Arrhenius expressions have been determined over the temperature range 25–145°C, to be: $k_7 = (4.0 \pm 0.7) \times 10^{12} \exp[(-1066 \pm 43)/RT]$ and $k_8 = (2.8 \pm 0.6) \times 10^{12} \exp[(-2597 \pm 114)/RT]$ cm^3 mol^{-1} s^{-1}. It was found that the overall mechanism for the photolytic decomposition of i-C_3H_7SH is analogous to that established for C_2H_5SH in previous investigations.

W. W. LAM, T. YOKOTA, I. SAFARIK et O. P. STRAUSZ. Can. J. Chem. **66**, 2025 (1988).

Opérant en présence et en l'absence du gaz inerte n-C_4H_{10}, on a effectué une étude détaillée de la photolyse du i-C_3H_7SH. On peut expliquer toutes les observations expérimentales en faisant appel à trois étapes photochimiques primaires : i-$C_3H_7SH \xrightarrow{[1]} i$-$C_3H_7S$ + H, $\phi_1 = 0{,}93 \pm 0{,}02$; i-$C_3H_7SH \xrightarrow{[2]} i$-$C_3H_7$ + SH, $\phi_2 = 0{,}057 \pm 0{,}024$; i-$C_3H_7SH \xrightarrow{[3]} C_3H_6 + H_2S$, $\phi_3 = 0{,}009 \pm 0{,}001$; à six étapes réactionnelles chaudes et à sept étapes réactionnelles thermiques. Comme on l'a observé avec les atomes de H*, les atomes de H thermalisés donnent aussi lieu à des réactions d'abstraction d'atomes de H, i-C_3H_7SH + H $\xrightarrow{[7]} i$-$C_3H_7S + H_2$ ainsi qu'à des réactions de substitution des SH, i-C_3H_7SH + H $\xrightarrow{[8]} i$-$C_3H_7 + H_2S$ à 25°C, le rapport des constantes de vitesse $k_7/k_8 = 19{,}2 \pm 4{,}3$. Aux températures allant de 25 à 145°C, on a déterminé que les expressions d'Arrhénius doivent être représentées par les expressions $k_7 = (4{,}0 \pm 0{,}7) \times 10^{12} \exp[(-1066 + 43)/RT]$ et $k_8 = (2{,}8 \pm 0{,}6) \times 10^{12} \exp[(2597 \pm 114)/RT]$ cm^3 mol^{-1} s^{-1}. On a trouvé que le mécanisme global de la décomposition photolytique du i-C_3H_7SH est analogue à celui qui avait été proposé antérieurement pour le C_2H_5SH.

[Traduit par la revue]

Introduction

The gas-phase photolytic decomposition of simple alkane thiols has already been utilized for generating hydrogen atoms and thiyl radicals long ago (1, 2). Their formation was explained by simple S—H cleavage

$$RSH + h\nu \rightarrow RS + H$$

which was followed by

$$H + RSH \rightarrow H_2 + RS$$

$$2RS \rightarrow R_2S_2$$

In later studies H_2S (3, 4), alkane, and the corresponding alkene (5–9) were also detected as photolysis products indicating a more complicated mechanism.

Systematic in depth studies of the gas-phase photolysis of C_2H_5SH by the research groups of Steer and Knight (5, 6), White *et al.* (7, 8), and Lam *et al.* (9) revealed that the formation and the distribution of all the photolysis products can be accounted for by three primary photochemical reactions:

$$C_2H_5SH + h\nu\ (254\ nm) \rightarrow H^* + C_2H_5S$$
$$\rightarrow HS + C_2H_5^*$$
$$\rightarrow H_2S + C_2H_4$$

It has also been proven that H atoms and C_2H_5 radicals are formed with substantial excess energy and enter into hot reactions

$$C_2H_5^* \rightarrow C_2H_4 + H$$
$$C_2H_5^* + C_2H_5SH \rightarrow C_2H_6 + C_2H_5S$$
$$C_2H_5^* + M \rightarrow C_2H_5 + M$$
$$H^* + C_2H_5SH \rightarrow H_2 + C_2H_5S$$
$$\rightarrow H_2S + C_2H_5$$
$$H^* + M \rightarrow H + M$$

Finally the following thermal reactions complete the mechanism:

$$C_2H_5 + C_2H_5SH \rightarrow C_2H_6 + C_2H_5S$$
$$H + C_2H_5SH \rightarrow H_2 + C_2H_5S$$
$$\rightarrow H_2S + C_2H_5$$
$$HS + C_2H_5S \rightarrow C_2H_5SSH$$
$$2C_2H_5SSH \rightarrow 2C_2H_5SH + S_2(wall)$$
$$C_2H_5S + C_2H_5S \rightarrow C_2H_5SSC_2H_5$$
$$\rightarrow C_2H_4S + C_2H_5SH$$

In our systematic studies of the photolysis of simple alkane thiols we have investigated the photolysis of isopropanethiol. Nothing has yet been reported on the mechanism of the photolysis of isopropanethiol in the literature and we hoped to reveal the effect, if any, of the methyl substitution on the primary or secondary reactions. The results of our investigations are summarized in this paper.

TABLE 1. Average product quantum yields in the photolysis of pure i-C_3H_7SH and C_2H_5SH[a]

Substrate	$\phi(H_2)$	ϕ(alkane)[b]	$\phi(H_2S)$	ϕ(alkene)[b]	ϕ(disulfide)[b]
i-C_3H_7SH	0.80 ± 0.03	0.21 ± 0.02	0.24 ± 0.02	0.042 ± 0.004	0.81 ± 0.07
C_2H_5SH	0.77 ± 0.02	0.22 ± 0.02	0.24 ± 0.03	0.030 ± 0.005	0.92 ± 0.05

[a]From ref. 9.
[b]Alkane = C_3H_8 or C_2H_6; alkene = C_3H_6 or C_2H_4; disulfide = $(i\text{-}C_3H_7)_2S_2$ or $C_2H_5SSC_2H_5$.

Experimental

Experiments were carried out in a grease-free conventional high vacuum system. The light source was a medium-pressure Hg lamp (Hanovia, Type SH, model 45078) equipped with a 253.7 nm interference filter (Baird Atomic). A cylindrical quartz reaction vessel, 5 × 10 cm, was employed and was enclosed in an aluminum block furnace heated by two pencil heaters. A 4-in. focal length quartz lens was placed between the lamp and the reaction vessel to collimate the light. The sample storage bulb was surrounded by a small temperature-controlled metallic jacket which could be cooled by tap water between experiments. The entire reaction system was fitted inside a thermostatted box and the temperature was monitored by standard Fe–constantan thermocouples. Reagent pressures were measured with a MKS Baratron absolute pressure gauge for 0–100 Torr and an absolute pressure Bourdon gauge (Matheson) for pressures greater than 100 Torr.

Research-grade i-C_3H_7SH (Aldrich) was purified by distillation in two stages at −88.5 and −95°C. The middle portion from the latter was retained and stored in the sample reservoir after purity test by GC/MS. Research-grade n-C_4H_{10} (Phillips), 99.97%, was used without further purification.

After a 60 min photolysis, H_2 was passed over traps at −196 and −210°C and was measured in a gas buret while H_2S, C_3H_6, C_3H_8, and $(i\text{-}C_3H_7)_2S_2$ were condensed at −196°C. H_2S, C_3H_6, and C_3H_8 were distilled at −95°C and analysed on a 6-ft Porapak Q:QS (1:1), 80/100 mesh, 6 mm o.d. glass column at 59°C. $(i\text{-}C_3H_7)_2S_2$ was analysed on a 6-ft, 12% tricresylphosphate, WAW–DMCS, 80/100 mesh column at 80°C.

When n-C_4H_{10} was present in the reaction mixture, the products condensable at −196°C were distilled in two stages at −117°C, for H_2S, C_3H_6, and C_3H_8. n-C_4H_{10} and substrate i-C_3H_7SH were distilled at −95°C.

Chemical actinometry was performed using H_2S as the actinometer on a separate set-up along an optical bench. The optical train consisted of a medium-pressure Hg lamp (Hanovia), a 1-cm aperture, a 253.7 nm interference filter (Baird Atomic), a quartz lens, a 5 × 10 cm, cylindrical quartz reaction vessel, a 5 × 10 cm, cylindrical quartz actinometer vessel, a monochromator (Bausch & Lomb; gratings = 2 700 grooves mm^{-1}), and a photocell connected to a readout meter, in this order. The aperture was employed to obtain better collimation of the light. The products from the reaction vessel were analyzed in the same manner as those in the main experiments. H_2 produced in the actinometry vessel was collected and measured in a gas buret while unreacted H_2S was kept in a trap at −196°C.

Results

The gas phase UV absorption spectrum of i-C_3H_7SH is a broad band in the 220–260 nm range with maximum absorbance located near 225 nm. The extinction coefficient at 254 nm is about 4.17×10^{-3} $Torr^{-1}$ cm^{-1} at 298 K, after the background for reflection by the quartz cell is taken into account.

In the photolysis total product conversion was maintained low, at 2–6%, in order to minimize secondary absorption by H_2S and $(i\text{-}C_3H_7)_2S_2$. Under these circumstances over 95% of the incident light was absorbed by i-C_3H_7SH.

H_2S actinometry

The absorbed light intensity in the reaction cell was determined experimentally by H_2S actinometry. The absorbed light intensity in the actinometric cell is equal to the rate of H_2 production since $\phi(H_2) = 1.00$ in the photolysis of H_2S (10–12).

From the results of the actinometric measurements the average value for $[R(H_2) + R(C_3H_8)]/I_a$ was found to be 1.01 ± 0.04. Therefore, the absorbed light intensity in the reaction cell, I_a, is equal to $0.99[R(H_2) + R(C_3H_8)]$. All the quantum yields obtained from the photolysis of i-C_3H_7SH were calculated by the relation $\phi_i = R_i/I_a$, where R_i (i = H_2, C_3H_8, H_2S, C_3H_6, and $(i\text{-}C_3H_7)_2S_2$) is the rate of product formation.

Photolysis of pure isopropanethiol

The major photolysis products were H_2 and $(i\text{-}C_3H_7)_2S_2$, while the minor products were C_3H_8, H_2S, and C_3H_6. The dark reaction runs at 25 and 145°C did not produce any measurable products, thus, i-C_3H_7SH is thermally stable within this temperature range. It was also observed that increasing reaction times up to 120 min did not affect the quantum yields. The quantum yields of these products from 60-min photolysis were observed to be independent of the substrate pressure in the range 5–50 Torr. The values of the product quantum yields averaged over the entire pressure range studied are listed in Table 1. The product yields of the photolysis of pure C_2H_5SH from our previous studies are also given in this table for comparison.

Photolysis of isopropanethiol with added thermalizer, n-C_4H_{10}

The effects of added thermalizer, n-C_4H_{10}, on the product quantum yields were investigated in this series of experiments. The pressure of i-C_3H_7SH was kept constant at 20 Torr while the pressure of n-C_4H_{10} was varied between 28 and 400 Torr. It was observed that with increasing pressure of the thermalizer $\phi(H_2)$ and $\phi[(i\text{-}C_3H_7)_2S_2]$ increased gradually along with a concomitant decline in the values of $\phi(C_3H_8)$, $\phi(H_2S)$, and $\phi(C_3H_6)$, but the sum of $R(H_2)$ and $R(C_3H_8)$ remained invariant at $(8.6 \pm 0.5) \times 10^{-2}$ μmol min^{-1}. The quantum yields of all products reach limiting values at approximately a fifteenfold excess of n-C_4H_{10} pressures over i-C_3H_7SH, that is, at a n-C_4H_{10} pressure of ≥300 Torr. This is shown in Table 2, along with the experimental product quantum yield at different n-C_4H_{10} pressures.

The photolysis of i-C_3H_7SH with added thermalizer, n-C_4H_{10}, was repeated at higher temperatures, 65, 105, and 145°C. Although the product quantum yields varied with increasing temperature, the effect of increasing n-C_4H_{10} pressure on these quantum yields was the same at each temperature as that observed at 25°C. With increasing temperature $\phi(H_2)$ and $\phi[(i\text{-}C_3H_7)_2S_2]$ decrease, while $\phi(C_3H_8)$, $\phi(H_2S)$, and $\phi(C_3H_6)$ increase, but the sum, $R(H_2)$ and $R(C_3H_8)$, remains invariant. The product quantum yields obtained at the

high n-C_4H_{10} pressure limit, 300–560 Torr, and at different temperatures are summarized in Table 3.

Discussion

Reaction mechanism

Because the photolysis products for i-C_3H_7SH and their dependence on the pressure and temperature are quite similar to those observed in the photolysis of C_2H_5SH, a reaction mechanism analogous to that established for C_2H_5SH (9) can also be postulated for i-C_3H_7SH.

The primary photochemical reactions are:

[1] $i\text{-}C_3H_7SH + h\nu\ (254\ nm) \rightarrow H^* + i\text{-}C_3H_7S$

[2] $\rightarrow HS + i\text{-}C_3H_7^{\ddagger}$

[3] $\rightarrow H_2S + C_3H_6$

These are followed by hot H* atom and i-$C_3H_7^{\ddagger}$ radical reactions:

[4]* $i\text{-}C_3H_7^{\ddagger} \rightarrow C_3H_6 + H$

[5]* $i\text{-}C_3H_7^{\ddagger} + i\text{-}C_3H_7SH \rightarrow C_3H_8 + i\text{-}C_3H_7S$

[6]* $i\text{-}C_3H_7^{\ddagger} + M \rightarrow i\text{-}C_3H_7 + M$

[7]* $H^* + i\text{-}C_3H_7SH \rightarrow H_2 + i\text{-}C_3H_7S$

[8]* $\rightarrow H_2S + i\text{-}C_3H_7$

[9]* $H^* + M \rightarrow H + M$

and the thermal reactions are as follows, in parallel with that established for C_2H_5SH:

[5] $i\text{-}C_3H_7 + i\text{-}C_3H_7SH \rightarrow C_3H_8 + i\text{-}C_3H_7S$

[7] $H + i\text{-}C_3H_7SH \rightarrow H_2 + i\text{-}C_3H_7S$

[8] $\rightarrow H_2S + i\text{-}C_3H_7$

[10] $HS + i\text{-}C_3H_7S \rightarrow i\text{-}C_3H_7SSH$

[11] $2i\text{-}C_3H_7SSH \rightarrow 2i\text{-}C_3H_7SH + S_2(wall)$

[12] $2i\text{-}C_3H_7S \rightarrow (i\text{-}C_3H_7)_2S_2$

[13] $\rightarrow i\text{-}C_3H_7SH + (CH_3)_2CS$

The reaction enthalpies for [1], [2], and [3] are the same as those for the analogous reactions with C_2H_5SH; namely, 88, 70, and 18 kcal mol^{-1}, respectively. The photon energy at 254 nm is equal to 113 kcal Einstein^{-1}, thus the hot H* atoms are formed in the primary step [1] with excess energy of 25 kcal mol^{-1}. The excess energy distribution for the second primary step [2] has not been studied. However, because of the great number of vibrational degrees of freedom in the i-C_3H_7 radical we expect a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 112.217.228.212 on 09/07/12
For personal use only.

greater part of the 43 kcal mol^{-1} excess energy to be localized on it. The thermal energy for the i-$C_3H_7^*$ radical is estimated from $0.5(sRT)$ (13) (where $s = 24$, the number of effective oscillators) to be 8–11 kcal mol^{-1} in the temperature range 25–145°C, thus raising its total excess energy to about 51 kcal mol^{-1}.

The unimolecular decomposition of i-$C_3H_7^*$ into H + C_3H_6 has a reaction enthalpy of 36–39 kcal mol^{-1}, estimated from available thermochemical data (14, 15). The critical energy for [4]* is given by Benson and O'Neal (16) to be about 41 kcal mol^{-1}. This is about 10 kcal mol^{-1} less than the assumed excess energy of the i-$C_3H_7^*$ radical, so its decomposition in reaction [4]* is energetically feasible. Unfortunately, no computations of the unimolecular rate constant and its energy dependence were carried out for i-C_3H_7 radicals. However, Rabinovitch and Setser (17) have calculated $k_4^* \approx 10^8$ s^{-1} for n-propyl radicals carrying an active energy content of ~10 kcal mol^{-1} above the critical energy. Thus, it can be postulated that the rate constant for Reaction [4]* will also be $\leq 10^8$ s^{-1} for isopropyl radicals.

The addition reaction, which is the reverse of Reaction [4]*,

[14] $H + C_3H_6 \rightarrow i\text{-}C_3H_7^*$

is known to have an activation energy of ~1.6 kcal mol^{-1} (18, 19). The alternative competitive reaction, which is the addition of H at the non-terminal carbon,

[15] $H + C_3H_6 \rightarrow n\text{-}C_3H_7^*$

requires a higher activation energy of about 4 kcal mol^{-1} (19) and is of relatively minor importance at ~5% (20–22). Cvetanovic and co-workers (20, 21) have reported that over 95% of the i-$C_3H_7^*$ radicals formed from [14] invariably dissociate back to the reactants at low, 20 Torr, C_3H_6 pressures. This is in contrast to hot n-C_3H_7 radicals, which dissociate predominantly into a methyl radical and ethylene:

[16] $n\text{-}C_3H_7^* \rightarrow CH_3 + C_2H_4$

We can conclude from the above that the major secondary source of C_3H_6 is reaction [4]*. On the other hand, the amount of C_3H_6 lost in [15] and [16] cannot be significant since the rate of step [15] is very small at low conversions and C_2H_4 was not found in the products. Other possible source of C_3H_6 is the disproportionation reaction of i-C_3H_7 radicals

[17] $2\,i\text{-}C_3H_7 \rightarrow C_3H_6 + C_3H_8$

for which the rate constant ratio for the disproportionation to combination reaction,

[18] $2\,i\text{-}C_3H_7 \rightarrow C_6H_{14}$

k_{17}/k_{18}, has been determined to be 0.60 ± 0.01 (23). However, [17] cannot be important, since no 2,3-dimethylbutane was found in the products.

The collisional deactivating molecules for the quenching of hot H* and i-$C_3H_7^*$ radicals in reactions [6]* and [9]*, may be either i-C_3H_7SH or n-C_4H_{10}. The possibility of extra H_2 being produced by the hot H* atom reactions with n-C_4H_{10} was ruled out because of the several orders of magnitude difference between the rate constants, $k(H + RSH) = 1.23 \times 10^{12}$ cm^3 mol^{-1} s^{-1} (24) and $k(H + n\text{-}C_4H_{10}) = 2.82 \times 10^8$ cm^3 mol^{-1} s^{-1} (25). Since alkanes absorb only in the vacuum UV region, below 200 nm (26), H atoms from direct photolysis of n-C_4H_{10} can also be excluded.

The scatter in $\phi[(i\text{-}C_3H_7)_2S_2]$ is observed to be more than that in $\phi(H_2S)$. This may be due to the increased difficulty in measuring the heavier isopropyldisulfide product quantitatively, and also to the reactions of thiyl radicals with Hg,

$$2\,i\text{-}C_3H_7S + Hg \rightarrow (i\text{-}C_3H_7S)_2Hg$$

$$(i\text{-}C_3H_7S)_2Hg \rightarrow (i\text{-}C_3H_7)_2S_2 + Hg$$

$$(i\text{-}C_3H_7S)_2Hg \rightarrow (i\text{-}C_3H_7)_2S + HgS$$

The following quantum yield expressions have been derived from the steady-state treatment of the proposed mechanism.

$$[19]\quad \phi(C_3H_6) = \phi_3 + \frac{k_4^*\phi_2}{k_4^* + k_5^*[i] + k_6^*[M]}$$

$$[20]\quad \phi(H_2) = \frac{k_7\phi_1}{k_7 + k_8} - \frac{(k_7k_8^* - k_7^*k_8)\phi_1[i]}{(k_7 + k_8)\{(k_7^* + k_8^*)[i] + k_9^*[M]\}} + \frac{k_4^*k_7\phi_2}{(k_7 + k_8)(k_4^* + k_5^*[i] + k_6^*[M])}$$

$$[21]\quad \phi(C_3H_8) = \frac{k_8\phi_1}{k_7 + k_8} + \phi_2 + \frac{(k_7k_8^* - k_7^*k_8)\phi_1[i]}{(k_7 + k_8)\{(k_7^* + k_8^*)[i] + k_9^*[M]\}} - \frac{k_4^*k_7\phi_2}{(k_7 + k_8)(k_4^* + k_5^*[i] + k_6^*[M])}$$

$$[22]\quad \phi(H_2S) = \frac{k_8\phi_1}{k_7 + k_8} + \phi_3 + \frac{(k_7k_8^* - k_7^*k_8)\phi_1[i]}{(k_7 + k_8)\{(k_7^* + k_8^*)[i] + k_9^*[M]\}} + \frac{k_4^*k_8\phi_2}{(k_7 + k_8)(k_4^* + k_5^*[i] + k_6^*[M])}$$

$$[23]\quad \phi[(i\text{-}C_3H_7)_2S_2] = \frac{k_{12}\phi_1}{k_{12} + k_{13}}$$

where ϕ_1, ϕ_2, and ϕ_3 are the quantum yields associated with the three primary photochemical reactions, [1]–[3]. M is the collisional deactivating molecule for hot H* and i-$C_3H_7^*$ radicals and may be either i-C_3H_7SH or n-C_4H_{10} molecules. The expressions for $k_6^*[M]$ and $k_9^*[M]$ are $k_{6i}^*[i] + k_{6n}^*[n]$ and $k_{9i}^*[i] + k_{9n}^*[n]$, respectively. [i] is the concentration or pressure of i-C_3H_7SH and [n] is that of added n-C_4H_{10}.

Quantum efficiencies of primary photochemical steps: quantum yield of C_3H_6

The effect of n-C_4H_{10} pressure on $\phi(C_3H_6)$ is shown in Fig. 1 at 25, 65, 105, and 145°C. At each temperature $\phi(C_3H_6)$ decreases very rapidly with increasing n-C_4H_{10} pressure and approaches a constant value at high pressures. This behavior indicates the existence of two different sources of C_3H_6. One is the pressure dependent unimolecular decomposition of hot i-$C_3H_7^*$ radicals to H and C_3H_6, the other is the primary photochemical step [3]. The unimolecular decomposition is completely suppressed at high n-C_4H_{10} pressures, therefore the high pressure limit of $\phi(C_3H_6)$ gives the quantum yield of reaction [3].

Equation [19] derived for $\phi(C_3H_6)$ consists of a constant and a pressure-dependent term reflecting the existence of the two different sources. ϕ_3 can be determined from its modified form:

$$[24]\quad [\phi(C_3H_6) - \phi_3]^{-1} = (1 + \alpha P_i)/\phi_2 + \beta P_n/\phi_2$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 112.217.228.212 on 09/07/12
For personal use only.

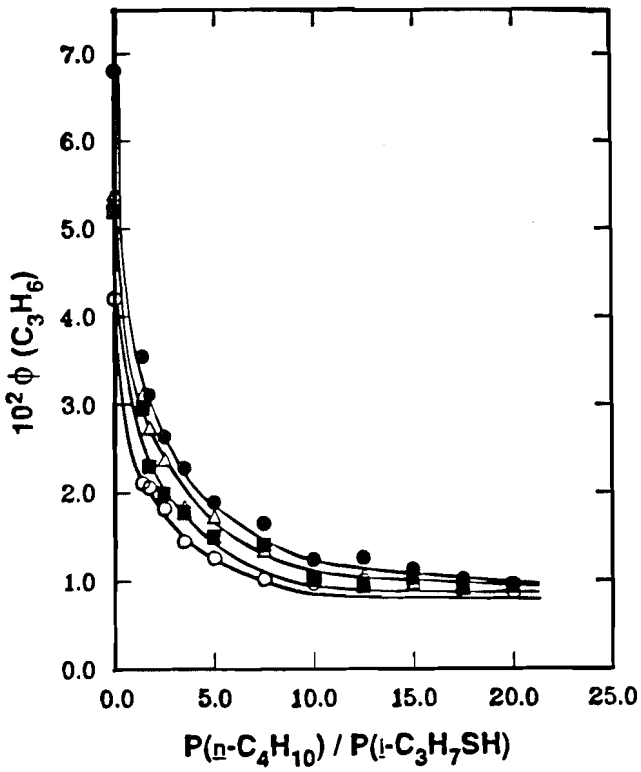

FIG. 1. Plots of quantum yield of C_3H_6 as a function of $P(n\text{-}C_4H_{10})/P(i\text{-}C_3H_7SH)$. ○, 25°C; ■, 65°C; △, 105°C; ●, 145°C.

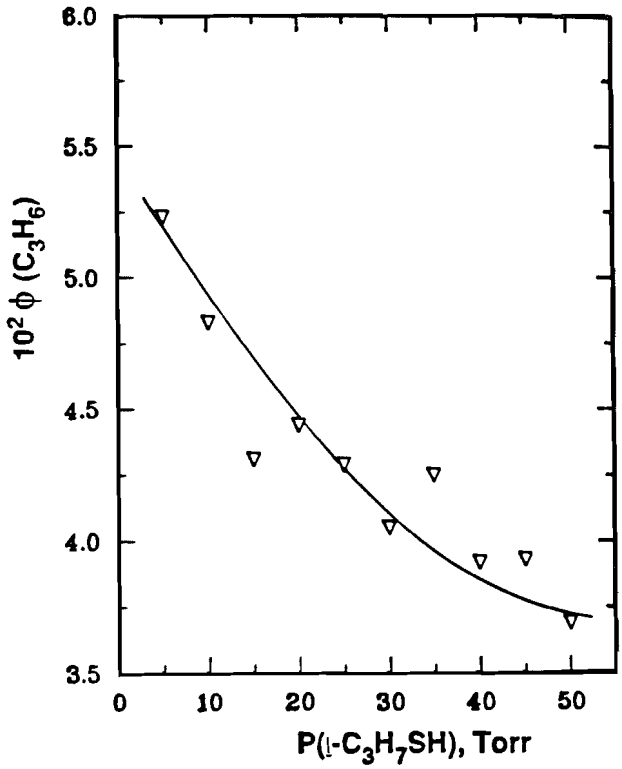

FIG. 2. Quantum yield ϕC_3H_6 versus $i\text{-}C_3H_7SH$ pressure.

where $\alpha = (k_5^* + k_{6i}^*)/k_4^*$, $\beta = k_{6n}^*/k_4^*$ and $[\phi(C_3H_6) - \phi_3]^{-1}$ is a linear function of P_n at constant P_i.

The linear correlation coefficient for eq. [24] was calculated, in the first approximation, for ten values of ϕ_3, ranging from 0.0081 to 0.0090. The results show that the highest correlation coefficient value is located at $\phi_3 = 0.0083$, which corresponds closely to the average experimental value $\phi(C_3H_6) = 0.009$ in the high (300–400 Torr) $n\text{-}C_4H_{10}$ pressure region at 25°C, Fig. 1.

Equation [24] becomes a linear function of P_i in the absence of thermalizer, i.e. $P_n = 0$,

$$[25]\quad [\phi(C_3H_6) - \phi_3]^{-1} = 1/\phi_2 + \alpha P_i/\phi_2$$

The plot of $\phi(C_3H_6)$ versus $P(i\text{-}C_3H_7SH)$ using a much expanded ordinate scale, Fig. 2, illustrates the marginal pressure dependence of $\phi(C_3H_6)$ on $P(i\text{-}C_3H_7SH)$. The values for $[\phi(C_3H_6) - \phi_3]^{-1}$ at $P_n = 0$ were calculated using $\phi_3 = 0.009$ and were plotted against $i\text{-}C_3H_7SH$ pressure in Fig. 3. The following linear relation was derived by the LMS method, for the condition $P_n = 0$;

$$[26]\quad [\phi(C_3H_6) - \phi_3]^{-1} = (23.5 \pm 0.9) + (0.24 \pm 0.03)P_i$$

Combining this equation with eq. [25], ϕ_2 and α were determined to be 0.043 ± 0.002 and $(1.03 \pm 0.14) \times 10^{-2}\,\text{Torr}^{-1}$, respectively.

The values of ϕ_2 at higher temperatures may now be determined from the intercepts of eq. [24]. The variations of $[\phi(C_3H_6) - \phi_3]^{-1}$ with pressure and temperature are plotted in Fig. 4, from which the derived intercepts are listed in Table 4. From the intercepts α appears to be little affected by temperature; the experimental observations (Table 3) show that changes in ϕ_3 up to 145°C are within experimental error. The derived values of ϕ_2 and subsequently ϕ_1 ($\phi_1 + \phi_2 + \phi_3 = 1.0$), are listed in Table 5. A slight increase in ϕ_2 (0.043–0.074) and consequently a decrease in ϕ_1 (0.95–0.92) are observed with increasing temperature. However, this variation is still within the experimental error. As a result, the quantum efficiencies of the primary photochemical reactions can be considered to be

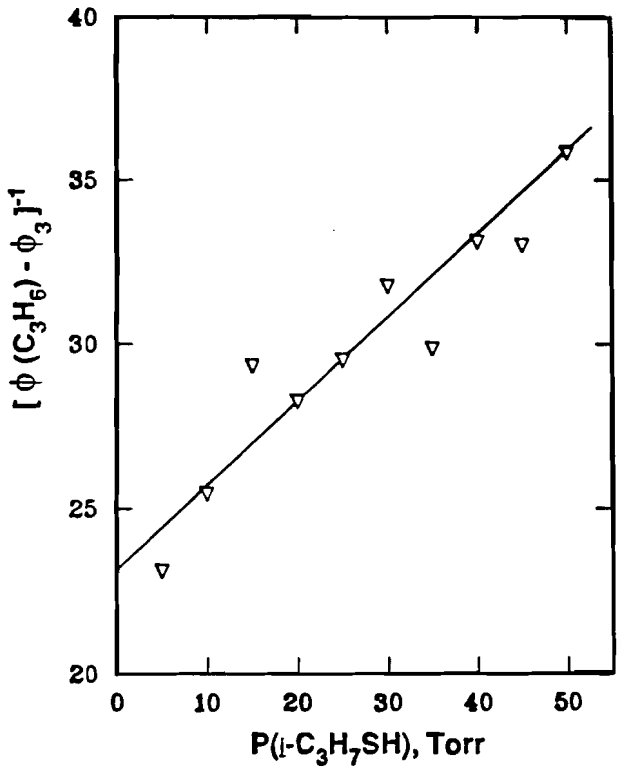

FIG. 3. $[\phi(C_3H_6) - \phi_3]^{-1}$ versus $i\text{-}C_3H_7SH$ pressure. The best fitted value of $\phi_3 = 0.009$ was used.

independent of temperatures within an experimental error of ±3%. The average values for ϕ_1, ϕ_2, and ϕ_3 from this work are then 0.93 ± 0.02, 0.057 ± 0.024, and 0.009 ± 0.001, respectively. When compared with the values obtained for C_2H_5SH (9), ϕ_1 is slightly lower, 0.96 ± 0.01, and ϕ_2 is higher, 0.029 ± 0.010, while ϕ_3 is almost the same, 0.010 ± 0.001, within experimental error. The similar ϕ-values are due to the same (S—H) and (C—S) bond energies for both C_2H_5SH and $i\text{-}C_3H_7SH$.

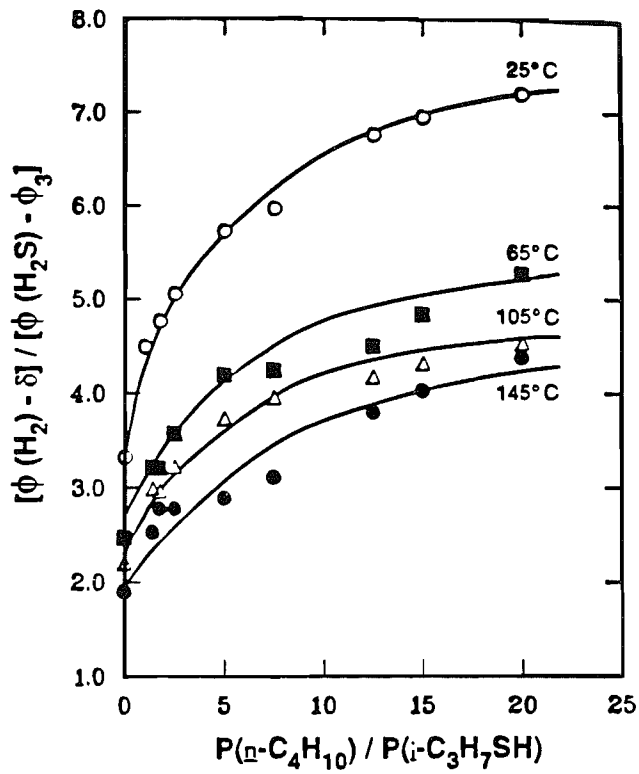

FIG. 5. Plots of $[\phi(H_2) - \delta]/[\phi(H_2S) - \phi_3]$ as a function of $P(n\text{-}C_4H_{10})/P(i\text{-}C_3H_7SH)$.

Hydrogen atom reactions with isopropanethiol: quantum yields of H_2 and H_2S

The variations of the H_2 and H_2S yields with pressure and temperature provide information on the relative rates of the hot and thermalized H-atom reactions with $i\text{-}C_3H_7SH$; [7]*, [7], [8]*, and [8]. The total $\phi(H_2S)$ comprises the H_2S formed in [8]* and [8] and in the molecular primary step [3], for which $\phi_3 = 0.009$. The H_2S yield contributed by the hot and thermalized H-atom reactions with $i\text{-}C_3H_7SH$, [8]* and [8], is thus $[\phi(H_2S) - \phi_3]$. The total $\phi(H_2)$ comes from reactions [7]* and [7], and from the unimolecular decomposition, [4]*. The contribution from [4]* is equal to the difference between the total C_3H_6 yield and that from the primary molecular step [3]. Thus, the H_2 yield from the hot and thermalized H-atom reactions with $i\text{-}C_3H_7SH$, [7]* and [7] is given by $[\phi(H_2) - \delta]$, where δ is the correction factor, $[\phi(C_3H_6) - \phi_3]$.

The variations of the ratio $[\phi(H_2) - \delta]/[\phi(H_2S) - \phi_3]$ with $n\text{-}C_4H_{10}$ pressure and temperature are plotted in Fig. 5. It is found that at each temperature $[\phi(H_2) - \delta]/[\phi(H_2S) - \phi_3]$ increases with increasing thermalizer pressure, indicating that thermalization of the H atoms favours the H-abstraction reaction, i.e. the displacement reaction [8] has a higher activation energy than the H-abstraction reaction [7]. Also, $[\phi(H_2) - \delta]/[\phi(H_2S) - \phi_3]$ decreases with increasing temperature, indicating that the rate of the displacement reaction increases faster than the H-abstraction reaction at higher temperatures, as expected.

Relative rate parameters for the H-atom reactions: quantum yields of H_2 and C_3H_8

The relative rate parameters for the thermalized H-atom reactions, [7] and [8], are determined from the H_2 and C_3H_8 yields. The quantum yield expressions for H_2 and C_3H_8 are given by eqs. [20] and [21], respectively. The plots of $\phi(H_2)$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 112.217.228.212 on 09/07/12

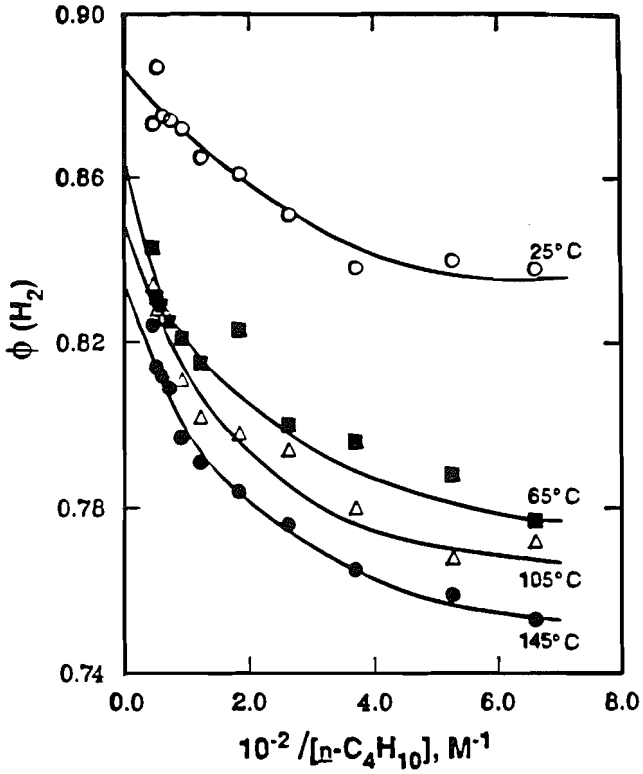

FIG. 6. Plots of $\phi(H_2)$ as a function of the reciprocal of n-C_4H_{10} concentration at $[i\text{-}C_3H_7SH] = 1.04 \times 10^{-3}\,M$.

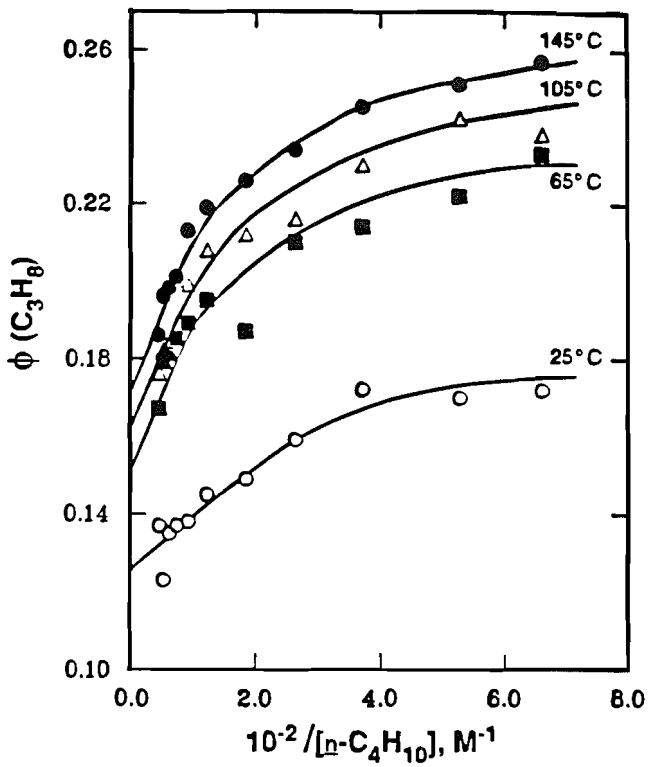

FIG. 7. Plots of $\phi(C_3H_8)$ as a function of the reciprocal of n-C_4H_{10} concentration at $[i\text{-}C_3H_7SH] = 1.04 \times 10^{-3}\,M$.

and $\phi(C_3H_8)$ against inverse n-C_4H_{10} concentration at each temperature are shown in Figs. 6 and 7. The variation with pressure observed in these plots can be correlated with the pressure-dependent terms in eqs. [20] and [21],

$$\frac{(k_7k_8^* - k_7^*k_8)\phi_1[\mathrm{i}]}{(k_7 + k_8)\{(k_7^* + k_8^*)[\mathrm{i}] + k_9^*[\mathrm{M}]\}}$$

and

$$\frac{k_4^*k_7\phi_2}{(k_7 + k_8)(k_4^* + k_5^*[\mathrm{i}] + k_6^*[\mathrm{M}])}$$

When $[n\text{-}C_4H_{10}]$ is large, deactivation of hot radicals by i-C_3H_7SH can be neglected and $k_9^*[\mathrm{M}]$ and $k_6^*[\mathrm{M}]$ become $k_{9\mathrm{n}}^*[\mathrm{n}]$ and $k_{6\mathrm{n}}^*[\mathrm{n}]$, respectively. Also, for the condition $P_\mathrm{n} \gg P_\mathrm{i}$, the terms $\{(k_7^* + k_8^*)[\mathrm{i}]\}$ and $\{k_4^* + k_5^*[\mathrm{i}]\}$ may be neglected from the pressure-dependent terms. After substituting for $k_9^*[\mathrm{M}]$ and $k_6^*[\mathrm{M}]$ and rearranging, the following linear relations are obtained for the high n-C_4H_{10} pressure condition;

$$[27]\quad \phi(H_2) = \frac{k_7\phi_1}{k_7 + k_8} - \frac{(k_7k_8^* - k_7^*k_8)k_{6\mathrm{n}}^*\phi_1[\mathrm{i}] - k_4^*k_7k_{9\mathrm{n}}^*\phi_2}{(k_7 + k_8)k_{6\mathrm{n}}^*k_{9\mathrm{n}}^*[\mathrm{n}]}$$

$$[28]\quad \phi(C_3H_8) = \frac{k_8\phi_1}{k_7 + k_8} + \phi_2 + \frac{(k_7k_8^* - k_7^*k_8)k_{6\mathrm{n}}^*\phi_1[\mathrm{i}] - k_4^*k_7k_{9\mathrm{n}}^*\phi_2}{(k_7 + k_8)k_{6\mathrm{n}}^*k_{9\mathrm{n}}^*[\mathrm{n}]}$$

The linear behaviour of $\phi(H_2)$ and $\phi(C_3H_8)$ at high n-C_4H_{10} pressures is illustrated in Figs. 6 and 7 for $P_\mathrm{n} > 100$ Torr, or $[n\text{-}C_4H_{10}]^{-1} < 0.02\,M^{-1}$. The intercepts of the linear portions of these plots are listed in Table 6 and are defined by [27] and [28] to be

$$[29]\quad \phi(H_2, P_\mathrm{n} \to \infty) = \frac{k_7\phi_1}{k_7 + k_8}$$

$$[30]\quad \phi(C_3H_8, P_\mathrm{n} \to \infty) = \frac{k_8\phi_1}{k_7 + k_8} + \phi_2$$

145	28.1	0.838±0.005	0.172±0.007

[a]Linear region from $[n\text{-}C_4H_{10}]^{-1} < 0.02\,M^{-1}$ or $P(n\text{-}C_4H_{10}) > 100$ Torr.

From the intercepts and the derived values of ϕ_1 and ϕ_2 (Table 5), the rate constant ratio, k_7/k_8, may be calculated at each temperature. Their values are listed in Table 7, along with another set of values for k_7/k_8 which were derived directly from the experimental H_2 and C_3H_8 yields at high total pressures (Table 3). It is observed that the latter set of k_7/k_8 values are lower than the former. This difference may be due to the fact that the experimental H_2 and C_3H_8 values have not yet reached the true limiting yields at 300–400 Torr.

The Arrhenius plot for the thermalized H-atom reactions [7] and [8], shown in Fig. 8, is constructed using the kinetically derived values of k_7/k_8 in Table 7. The Arrhenius expression from the plot is given by,

$$[31]\quad \ln k_7/k_8 = (0.35 \pm 0.10) + (770 \pm 36)/T$$

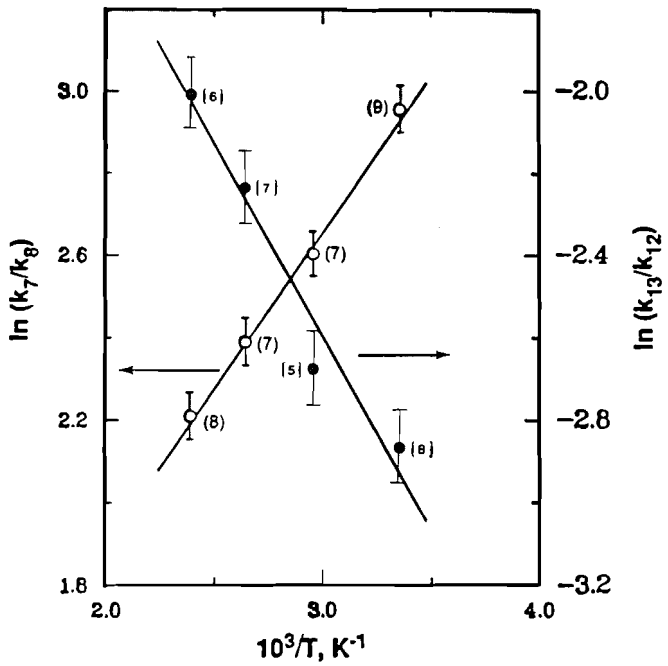

FIG. 8. Plots of ln k_7/k_8 and ln k_{13}/k_{12} versus the reciprocal of temperature. Figure in bracket indicates number of experiments.

TABLE 7. Temperature dependence of k_7/k_8 and k_{13}/k_{12}

Temperature (°C)	$(k_7/k_8)^a$	$(k_7/k_8)^b$	$(k_{13}/k_{12})^c$

[c]Calculated from the photolysis of i-C_3H_7SH with added n-C_4H_{10} at the high pressure limit.
[d]Standard error.

From eq. [31], the activation energy difference, $(E_7 - E_8) = -1.53 \pm 0.07$ kcal mol^{-1}, is slightly higher than that obtained for the H-atom reactions with C_2H_5SH (9), where $(E_7 - E_8) = -1.310 \pm 0.025$ kcal mol^{-1}. The ratio of the pre-exponential factors, A_7/A_8, derived from [31] is equal to 1.43 ± 0.06. Absolute rate parameters for k_7 and k_8 cannot be derived at this time due to the lack of available data in the literature. However, since the (S—H) bond strengths in C_2H_5SH and i-C_3H_7SH are the same, the rate constant, k_7, i-C_3H_7SH should be the same as, or close to the rate constant of the analogous reaction derived for C_2H_5SH (9):

$$[32] \quad k_7 \text{ (cm}^3 \text{ mol}^{-1} \text{ s}^{-1}) = (3.98 \pm 0.72) \times 10^{12} \exp [(-1066 \pm 43)/RT]$$

From this, the rate constant, k_8, for i-C_3H_7SH is then determined to be:

$$[33] \quad k_8 \text{ (cm}^3 \text{ mol}^{-1} \text{ s}^{-1}) = (2.78 \pm 0.56) \times 10^{12} \exp [(-2597 \pm 114)/RT]$$

The experimental entropy of activation, $S^{\ddagger}$, calculated from the A factor of k_8 is −27.6 eu for the standard state of 1 atm.

[a]T = 25°C, (k_7/k_8) = 19.2, ϕ_2 = 0.043, $\alpha = 1.03 \times 10^{-3}$ Torr^{-1}.

This value is similar to those obtained for the H + CH_3SCH_3 (27) and the H + $C_2H_5SC_2H_5$ (28) reactions, −24.1 and −22.1 eu, respectively, suggesting transition states with similar structures. Using Benson's method (29) for a transition state which involves an initial interaction between the H atom and the non-bonding 3p orbital of the sulfur atom:

$$H + i\text{-}C_3H_7SH \rightarrow [i\text{-}C_3H_7 \cdots \underset{\vdots}{\underset{H}{S}}\text{—}H]^{\ddagger} \rightarrow i\text{-}C_3H_7 + H_2S$$

we will obtain

$$\Delta S^{\ddagger} = S_0^{\ddagger} - S_0(i\text{-}C_3H_7SH) - S_0(H)$$
$$= S_0(i\text{-}C_3H_7SH) + R \ln 2 + x - S_0(i\text{-}C_3H_7SH) - S_0(H)$$
$$= 1.4 + x - 27.4 = -26.0 + x$$
$$x = -1.6 \text{ eu}$$

This low value for the vibrational contribution to $\Delta S^{\ddagger}$ indicates a very tight structure for the activated complex.

In the photolysis of pure i-C_3H_7SH, i.e. $P_n = 0$, the resulting expressions for H_2 and C_3H_8 yields are simplified from [20] and [21] as follows;

$$[34] \quad \phi(H_2) = \frac{k_7\phi_1}{k_7 + k_8} - \frac{(k_7k_8^{\ddagger} - k_7^{\ddagger}k_8)\phi_1}{(k_7 + k_8)(k_7^{\ddagger} + k_8^{\ddagger} + k_{9i}^{\ddagger})} + \frac{k_7\phi_2}{(k_7 + k_8)(1 + \alpha P_i)}$$

$$[35] \quad \phi(C_3H_8) = \frac{k_8\phi_1}{k_7 + k_8} + \phi_2 + \frac{(k_7k_8^{\ddagger} - k_7^{\ddagger}k_8)\phi_1}{(k_7 + k_8)(k_7^{\ddagger} + k_8^{\ddagger} + k_{9i}^{\ddagger})} - \frac{k_7\phi_2}{(k_7 + k_8)(1 + \alpha P_i)}$$

where α is the rate constant ratio, earlier derived to be $(k_5^{\ddagger} + k_{6i}^{\ddagger})/k_4^{\ddagger} \approx 1.03 \times 10^{-3}$ Torr^{-1}. The last term in both of the H_2 and C_3H_8 expressions indicates that $\phi(H_2, P_n = 0)$ and $\phi(C_3H_8, P_n = 0)$ are inverse functions of P_i. However, the predicted pressure dependence is not apparent and $\phi(H_2)$ and $\phi(C_3H_8)$ are approximately constant at 0.80 ± 0.01 and 0.21 ± 0.01, at 25°C, in the i-C_3H_7SH pressure range 5–50 Torr, Table 1. Thus, the magnitude of any changes in the pressure term in [34] and [35] is likely to be relatively small and should fall within the range of the experimental error. This prediction is again verified by evaluating the pressure term, using the already derived values of ϕ_2, α, and k_7/k_8. As shown in Table 8, this pressure term decreases with increasing i-C_3H_7SH pressure, and the net change is indeed small, being only 0.002 on going

For personal use only.

from 5 to 50 Torr. Therefore, increasing the i-C_3H_7SH pressure has negligible effects on $\phi(H_2)$ and $\phi(C_3H_8)$, and the pressure terms in [34] and [35] can be considered to be constant, indicating that i-C_3H_7SH is not an efficient deactivator.

Disproportionation–combination of thiyl radicals: quantum yield of (i-C_3H_7)$_2S_2$

The quantum yield expression for the formation of $(i\text{-}C_3H_7)_2S_2$,

$$[23] \quad \phi[(i\text{-}C_3H_7)_2S_2] = \frac{k_{12}\phi_1}{k_{12} + k_{13}}$$

predicts that $\phi[(i\text{-}C_3H_7)_2S_2]$ and ϕ_1 are equal to each other if no disproportionation of i-C_3H_7S radicals occurs,

$$[13] \quad 2i\text{-}C_3H_7S \rightarrow i\text{-}C_3H_7SH + C_3H_6S$$

However, the observation that $\phi[(i\text{-}C_3H_7)_2S_2]$ is less than ϕ_1 indicates that reaction [13] occurs in competition with the combination reaction,

$$[12] \quad 2i\text{-}C_3H_7S \rightarrow (i\text{-}C_3H_7)_2S_2$$

The products of disproportionation are the thiol substrate, i-C_3H_7SH, and the aliphatic thioketone, thioacetone. The latter is known to be unstable, although it can be isolated in the monomeric thione form as well as in the tautomeric enethiol form (30). Since, however, $\phi(i\text{-}C_3H_7)_2S_2$ is only slightly less than $\phi(H_2)$, from Tables 1–3, the disproportionation of i-C_3H_7S radicals should be a relatively minor reaction, in comparison with the combination reaction.

Equation [23] predicts no pressure dependence for $(i\text{-}C_3H_7)_2S_2$. This is verified by the $\phi[(i\text{-}C_3H_7)_2S_2]$ values obtained both in the absence and presence of n-C_4H_{10} (Tables 1 and 2). The disproportionation–combination ratio, k_{13}/k_{12}, is derived from [23] to be;

$$[36] \quad \frac{k_{13}}{k_{12}} = \frac{\phi_1}{\phi[(i\text{-}C_3H_7)_2S_2]} - 1$$

Their values, calculated from Table 4, are listed in Table 7. k_{13}/k_{12} increases with temperature, however, this increase must be viewed with caution since large errors are associated with the calculated k_{13}/k_{12} values due to the scatter in the measured yields of $(i\text{-}C_3H_7)_2S_2$. The Arrhenius plot, Fig. 8, is constructed using the high pressure values of the disproportionation–combination steps [13] and [12], respectively. The following rate expression is derived:

$$[37] \quad \ln k_{13}/k_{12} = (1.30 \pm 0.72) - (1339 \pm 251)/T$$

from which $(E_{13} - E_{12}) = 2.65 \pm 0.50$ kcal mol^{-1} and $A_{13}/A_{12} = 3.6 \pm 1.1$. Since the recombination step [12] requires negligible activation energy, E_{13} is therefore estimated to be ~2.65 kcal mol^{-1} and is smaller than that determined for the disproportionation of C_2H_5S radicals, 3.12 kcal mol^{-1} (9).

Conclusion

Our results show that the most important primary step in the photolysis of i-C_3H_7SH is the cleavage of the S—H bond forming hot H-atoms, with a quantum yield of 0.93 ± 0.02. The quantum yields of the two other primary steps, the cleavage of the C—S bond and the molecular formation of H_2S are substantially lower, 0.057 ± 0.024 and 0.009 ± 0.001, respectively. Subsequently, the hot H* atoms react either in a H-atom abstraction or a SH-displacement reaction with the substrate. Both the H-atom abstraction and the SH-displacement occur also with thermalized H-atoms, with the average rate constant ratio $k_7/k_8 = 19.2 \pm 4.3$ at 25°C. The proposed overall mechanism explains satisfactorily not only the formation and distribution of the products but also the observed pressure and temperature effects. It was found that methyl substitution did not have any noticeable effect on any mechanistic aspects of the photolytic decomposition of simple alkane thiols.

Ab initio molecular orbital studies of the potential energy curves for the low lying triplet states of Be_2 and Be_3

RATNAKAR K. GOSAVI AND OTTO P. STRAUSZ[1]

Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received November 30, 1987

This paper is dedicated to Professor Charles A. McDowell on the occasion of his seventieth birthday

RATNAKAR K. GOSAVI and OTTO P. STRAUSZ. Can. J. Chem. **66**, 2034 (1988).

Ab initio calculations with uniform quality gaussian basis set were carried out at the RHF-SCF and CI level on the potential energy curves of the low lying triplet states of Be_2 and Be_3. The lowest excited state, the $^3\Sigma_u^+$ state of Be_2 is 26.0 kcal/mol higher in energy than the ground $^1\Sigma_g^+$ state, and 39.4 kcal/mol lower than the separated Be($^1S_0$) + Be(^3P) atoms, with the *s*, *p*, *d* basis set. The next higher triplet state, the $^3\Pi_g$, is only 8.7 kcal/mol above the lowest $^3\Sigma_u^+$ state. The $^3\Sigma_g^-$ and $^3\Pi_u$ states lie comparatively much higher than the $^3\Sigma_u^+$ state. All the triplet state potential curves have a bonding nature. The lowest triplet state $^3\Sigma_u^+$ in Be_3 with $D_{\infty h}$ symmetry lies ~15 kcal/mol above the ground $^1A_1'$ state, and 48.2 kcal/mol lower than the separated atoms, 2Be($^1S_0$) + Be(^3P). The $^3\Sigma_u^+$ state has 1,3-diradical character and in all the higher triplet states α spin electrons are delocalized among the three Be atoms. The next higher triplet state $^3\Pi_u$ is 7.7 kcal/mol above the lowest $^3\Sigma_u^+$ state. The $^3\Sigma_g^-$ and $^3\Pi_g$ states lie much higher than the $^3\Sigma_u^+$ and $^3\Pi_u$ states. Like the triplet states of Be_2, all Be_3 triplet states have a bonding nature. Reaction path studies on the Be(^3P) energy transfer reactions, Be($^1S_0$) + Be(^3P) ⇄ Be_2($^3\Sigma_u^+$, $^3\Pi_g$) and Be_2($^1\Sigma_g^+$) + Be(^3P) → Be_2($^3\Sigma_u^+$) + Be($^1S_0$), show that these reactions do not feature any activation energy barrier.

RATNAKAR K. GOSAVI et OTTO P. STRAUSZ. Can. J. Chem. **66**, 2034 (1988).

On a réalisé des calculs *ab initio*, avec un ensemble de base de Gauss de qualité uniforme, au niveaux RHF-SCF et IC sur les courbes d'énergie potentielle des états triplets inférieurs du Be_2 et du Be_3. Dans l'état de plus faible excitation, l'énergie de l'état $^3\Sigma_u^+$ du Be_2 est de 26,0 kcal/mol supérieure à celle de l'état fondamental $^1\Sigma_g^+$ et de 39,4 kcal/mol inférieure à celle des atomes séparés Be($^1S_0$) + Be(^3P) avec l'ensemble de base *s*, *p*, *d*. L'état triplet suivant de plus haute énergie $^3\Pi_g$ n'est que de 8,7 kcal/mol plus élevé que l'état le plus faible $^3\Sigma_u^+$. Les états $^3\Sigma_g^-$ et $^3\Pi_u$ sont comparativement plus fortement liés que l'état $^3\Sigma_u^+$. Toutes les courbes de potentiel de l'état triplet sont de nature liante. L'énergie de l'état triplet le plus faible $^3\Sigma_u^+$ du Be_3 de symmétrie $D_{\infty h}$ est d'environ 15 kcal/mol au-dessus de celle de l'état fondamental $^1A_1'$ et de 48,2 kcal/mol inférieure à celle des atomes séparés Be($^1S_0$) + Be(^3P). L'état $^3\Sigma_u^+$ a un caractère de diradical-1,3 et les spins électroniques des états triplets supérieurs α sont délocalisés sur les trois atomes de Be. L'énergie de l'état triplet suivant le plus élevé $^3\Sigma_u$ est de 7,7 kcal/mol supérieure à celle de l'état le plus faible $^3\Sigma_u^+$. Les états $^3\Sigma_g^-$ et $^3\Pi_g$ sont plus fortement liés que les états $^3\Sigma_u^+$ et $^3\Pi_u$. Les états triplets du Be_3 sont de nature liante comme les états triplets du Be_2. L'étude du processus réactionnel des réactions de transfert d'énergie du Be(^3P) : Be($^1S_0$) + Be(^3P) ⇄ Be_2($^3\Sigma_u^+$, $^3\Pi_g$) et Be_2($^1\Sigma_g^+$) + Be(^3P) → Be_2($^3\Sigma_u^+$) + Be($^1S_0$) montre que ces réactions ne caractérisent aucune barrière d'énergie d'activation.

[Traduit par la revue]

Introduction

The electronic structure and properties of small metal clusters have gained considerable attention on account of their theoretical and experimental interest, as useful models for crystals (1–3), point defects (4), catalysis (5–7), and chemisorption (8–13). Among the various metal clusters that have been investigated theoretically, probably beryllium clusters of varying size have been studied most extensively (14–21). The smallest system, Be_2, has been used as a model in theoretical studies since 1931 (22, 23). The potential energy curve of the ground state of Be_2 has been the subject of a number of theoretical investigations (14–18) but in spite of the large number of calculations with various degrees of sophistication, it was only recently that reliable calculations on the potential energy curve for the ground state of Be_2 have been reported (14, 16, 17). The calculated values of R_e = 2.51 Å (16), 2.50 Å (17) and D_e = 2.23–2.34 kcal/mol (14), 2.04 ± 0.2 kcal/mol (17) are in good agreement with the experimentally determined values of R_e = 2.465 Å, and D_e = 2.29 kcal/mol (24–26).

Recently the Be atom has been used as a model in the molecular orbital studies of metal atom reactions with unsaturated hydrocarbons (27, 28) and with the hydrogen molecule (29). The reactions of Be(^3P) atoms have also been utilized in *ab initio* MO studies for the elucidation of the mechanism of electronic energy transfer reactions (28–30). As a simple model of Be(^3P) atom reactions, we studied the reaction of Be(^3P) with Be($^1S_0$) and Be_2($^1\Sigma_g^+$) giving rise to triplet Be_2 and Be_3, respectively. Even though a large number of theoretical studies with varying degrees of sophistication have been carried out on the ground state potential energy curve of Be_2 and Be_3, only relatively few studies on the excited states of Be_2 and Be_3 have been reported in the literature. The first study reported on the excited states of Be_2 by Furry and Bartlett (23) using the Heitler–London valence bond method indicated that the triplet state potential curves were repulsive for small values of internuclear distances and for larger separations, the method behaved erratically. Fraga and Ransil (31) calculated the potential energy curves for the lowest lying excited Σ states at the SCF level with best limited STO basis set. The low-lying electronic excited states of the Be_2 molecule have also been examined by Bender and Davidson (32) with the MO SCF CI method using a basis set of elliptical orbitals. Molecular binding energy curves for the low-lying states were also studied using the local spin-density functional formalism (33). Whiteside *et al.* (18) reported the optimized Be—Be distance for the $^3\Sigma_u^+$ state of Be_2 and Be_3 at the UHF-SCF level and total energy at the UHF-SCF and UMP4 (SDQ) level.

In our Be(^3P) reaction studies here we report the potential energy curves of the low-lying triplet states of Be_2 and Be_3 and

the reaction paths for the processes $Be(^1S_0) + Be(^3P) \rightleftarrows Be_2(^3\Sigma_u^+, {}^3\Pi_g)$ and $Be_2(^1\Sigma_g^+) + Be(^3P) \rightarrow Be_3(^3\Sigma_u^+) \rightarrow Be_2(^3\Sigma_u^+) + Be(^1S_0)$.

Methods

The uniform quality gaussian basis set of $10s$, $5p$ were contracted according to a "2.5 zeta" (double zeta for the core and triple zeta for the valence shell) contraction scheme reported earlier (34). A single set of 6, d polarization function with $\alpha_d = 0.255$ was added to the s, p basis set. Molecular parameters were optimized at the RHF-SCF level by the energy gradient method and by the stepwise method, fitting the parabola for the minimum energy at the CI level. CI calculations including all singly and doubly excited configurations (CISD) with respect to the SCF configuration were done using the direct CI method (35). Davidson's formula (36) was applied to the CI results to estimate the correction for the quadruple excitation (CISDQ). All electrons and all orbitals were used in the CI calculations of the Be atom and Be_2 with s, p basis set. In the s, p, d basis set CI computations of Be_2, four δ virtual orbitals were kept frozen, and in the Be atom, two d virtual orbitals were kept frozen.

In the case of the triplet states of Be_3, the three lowest occupied orbitals corresponding to $1s$ core orbitals were kept doubly occupied and frozen, and only the lowest $15\sigma + 12\pi$ orbitals were used in CI calculations. Correspondingly, to calculate relative energies with respect to separated entities the total CI energies of $Be(^1S_0)$ and $Be(^3P)$ were recalculated with only $5s$ and $4p$ orbitals and the lowest occupied orbital corresponding to the $1s$ core orbital was kept doubly occupied and frozen. All computations were carried out employing the modified version of the GAUSSIAN 80 Program (37), the MONSTERGAUSS Program (38).

Results and discussion

Triplet states of Be_2

Total energies calculated at the RHF-SCF and CI level for Be, $^1S_0$ and ^3P states are given in Table 1. The optimized Be—Be distance for the four lowest triplet electronic states of Be_2, $^3\Sigma_u^+$, $^3\Pi_g$, $^3\Sigma_g^-$, and $^3\Pi_u$ with electronic configuration, total energy, and relative energies with respect to the separated $Be(^1S_0) + Be(^3P)$ atoms, are summarized in Table 2. The corresponding potential energy curves with s, p basis set at the CISD level are plotted in Fig. 1. For comparison the ground state, $^1\Sigma_g^+$, potential energy curve is calculated at the same level as the triplet states and is also plotted in Fig. 1. As expected with simple molecular orbital methods the ground $^1\Sigma_g^+$ state turns out to be repulsive, but the most sophisticated calculations predict a weak binding energy of ≈ 2 kcal/mol (14, 16, 17). Recent experimental results from gas phase, laser-induced fluorescence spectral studies of Be_2 also predict a binding energy of ≈ 2 kcal/mol (24–26). Since the ground $^1\Sigma_g^+$ state of Be_2 has the electronic configuration $(1\sigma_g)^2(1\sigma_u)^2(2\sigma_g)^2(2\sigma_u)^2$, featuring two bonding and two antibonding electrons, the binding energy expected is very small. Electronic excitation by promoting one electron from the highest occupied antibonding $2\sigma_u$ orbital to the low-lying unoccupied $3\sigma_g$ or $^1\pi_u$ bonding orbital will produce more strongly bonded low-lying excited states of Be_2 with respect to the corresponding separated atoms. This has been deduced from spectroscopic constants and lifetime calculations for the low-lying excited states, obtained in gas phase laser induced fluorescence studies of Be_2 (24–26). Similar conclusions were also arrived at in the theoretical

calculations reported earlier on Be_2 (31–33). The lowest triplet state, $^3\Sigma_u^+$ has a diradical structure. At the RHF-SCF level, this state lies below the ground singlet state, $^1\Sigma_g^+$. This is mainly the consequence of the neglect of correlation energy, which is larger for the singlet than the triplet state. Inclusion of the correlation energy by CI calculations predict the correct order of the potential energy curves which can be seen in Fig. 1. The lowest triplet state, $^3\Sigma_u^+$, is 36.8 kcal/mol higher in energy than

[a]Valence electrons only, core is $(1\sigma_g)^2(1\sigma_u)^2$.
[b]Relative energy with respect to separated Be($^1S_0$) + Be(^3P) atoms, $\Delta E = E^3[Be_2] - E[Be(^1S_0) + Be(^3P)]$.

the ground state $^1\Sigma_g^+$ (in the present case the $^1\Sigma_g^+$ state total energy is taken as twice the total energy of Be($^1S_0$)), with the s, p basis set. Inclusion of the d polarization function brings this energy down to 26.0 kcal/mol. The next triplet state, $^3\Pi_g$, is very close to the $^3\Sigma_u^+$ state, with only 4.4 kcal/mol (with s, p basis set and 8.7 kcal/mol with s, p, d basis set at the CISDQ level) higher in energy. Single reference CI calculations at larger atomic separations (≥4 Å) does not give the complete representation of the state as seen by the coefficient of the root configuration ($C_0 \leq 0.90$). Thus, for the correct shape of the potential energy curve at larger separations ($R > 4$ Å) multi-reference CI calculations would be required. However, in the present studies this region was of no particular importance. The effect of addition of the d polarization function on the optimized Be—Be distance was not significant, Table 2, and inclusion of correlation energy by CI calculations slightly increased the optimized Be—Be distance in all cases, except in the case of s, p, d basis set calculations of the $^3\Sigma_u^+$ state, where it had a slightly decreasing effect on the computed distance. The optimized Be—Be distance in the $^3\Sigma_u^+$ state (2.144–2.161 Å) is close to the experimental value of 2.16 Å for the $^1\Sigma_u^+$ state (24, 26). Thus far triplet states of Be_2 have not been observed experimentally. The earlier reported optimized Be—Be distance of 2.182 Å for the $^3\Sigma_u^+$ state by STO basis set (31) and 2.20 Å by spin density functional calculations (33) are slightly longer than our optimized value. The recent UHF/6-31G optimized (18) value of 2.155 Å is close to the present optimized value. The Be—Be distance in the $^3\Pi_g$ state is slightly shorter than in the $^3\Sigma_u^+$ state (Table 2), and similar to the earlier reported optimized value of 2.03 Å (33). The optimized Be—Be distance in the $^3\Sigma_g^-$ state is much shorter than in the $^3\Sigma_u^+$ and $^3\Pi_g$ states (Table 2) and similar to the earlier reported value of 1.79 Å (33). The $^3\Pi_u$ state optimized Be—Be distance at the RHF-SCF level is close to the optimized distance of the $^3\Pi_g$ state (Table 2). The Be_2 $^3\Sigma_u^+$ state is 37.9 kcal/mol lower in energy at the RHF-SCF level with s, p basis set, than the separated Be($^1S_0$) and Be(^3P) atoms, which at the CISDQ level reduces to 31.1 kcal/mol.

These values are similar to the UHF/6-31G (39.8 kcal/mol) and UMP4(SDQ)/6-31G (33.5 kcal/mol) results reported by

Whiteside *et al.* (18). Addition of the *d* polarization function does not bring about a significant change in the relative energy (38.3 kcal/mol) at the SCF level. Inclusion of correlation energy by CI calculations at the *s*, *p* basis set at CISDQ level, however, decreases the relative energy compared to the SCF value. On the other hand, with the *s*, *p*, *d* basis set, the relative energy increases slightly to 39.4 kcal/mol as a result of CI calculations at the CISDQ level (Table 2). In the next higher-lying $^3\Pi_g$ state, the inclusion of correlation energy increases the relative energy by 10 kcal/mol with the *s*, *p* basis set, and 14 kcal/mol with the *s*, *p*, *d* basis set. The $^3\Pi_g$ state is 30.7 kcal/mol more stable than the separated Be($^1S_0$) + Be(^3P) atoms. A similar trend is observed in the $^3\Sigma_g^-$ and $^3\Pi_u$ state relative energies. These triplet states are slightly higher in energy than the separated Be($^1S_0$) + Be(^3P), and dissociate to higher excited Be atoms. The $^3\Sigma_u^+$, $^3\Pi_g$, and $^3\Sigma_g^-$ states potential energy curves have a bonding character. At shorter Be—Be distances ($\leq$1.5 Å) all three triplet states collapse into a single state.

Triplet states of Be_3

The ground state Be_3($^1A_1'$) with equilateral triangle (D_{3h}) has been studied in detail in recent years (14, 15, 18, 39, 40). The potential energy curve according to Whiteside *et al.* (18) at the RHF/6-31G level shows a shallow minimum of 0.5 kcal/mol at 4.706 Å with a close in maximum around 3.0 Å and a second minimum at 2.244 Å with an energy 1.6 kcal/mol above that of the three separated Be($^1S_0$) atoms. Addition of *d* functions (6-31G*) lowered this minimum by 3.3 kcal/mol at the optimized distance of 2.234 Å. Inclusion of correlation energy by MP_2, MP_3, MP_4(SDQ) level with 6-31G* basis set yielded binding energies of 24.7, 19.5, and 13.1 kcal/mol, respectively. This poor convergence of the perturbation series for the binding energy is associated with the isolated atoms rather than the Be_3 molecule. Whiteside *et al.* (18) estimate their best value at the CCD level, predicting 6.0 kcal/mol for the binding energy. Pacchioni and Koutecky (39) have also calculated the dissociation energy of 7.1 kcal/mol with 4*s*, 2*p*, 1*d* basis set at the MRSD CI level, for the distance of 2.223 Å. The most accurate results for the $^1A_1'$ ground state of Be_3, reported recently by Harrison and Handy (14), show that Be_3 is bound only at the full CI level of accuracy at 2.233 Å with 22–25 kcal/mol binding energy.

The closed shell $^1\Sigma_g^+$ and low lying $^3\Sigma_u^+$ and $^3\Sigma_g^-$ excited states for the linear ($D_{\infty h}$) structure have been studied by Whiteside *et al.* (18). The STO-3G basis set SCF level results predicted that the $^3\Sigma_u^+$ state has the lowest energy followed by the $^1A_1'$, $^1\Sigma_g^+$, and $^3\Sigma_g^+$ states. Their UHF/6-31G and UHF/6-31G* results also predicted that the $^3\Sigma_u^+$ state is lower than the $^1A_1'$ ground state, similar to that of Be_2. On inclusion of correlation energy by UMP computations, this order was reversed. Pacchioni and Koutecky (39) have also studied the $^1\Sigma_g^+$ and $^3\Sigma_u^+$ states with 4*s*, 2*p* and 4*s*, 2*p*, 1*d* basis set by an *ab initio* pseudopotential method followed by MRD CI calculations. The computed potential curves closely resembled those of diatomic Be, and the $^1\Sigma_g^+$ state was predicted to have a slight bonding character.

We studied the potential energy curves for the low-lying triplet states of Be_3, both at the RHF-SCF and limited CI levels, with linear $D_{\infty h}$ symmetry. The Be—Be distance for the lowest $^3\Sigma_u^+$ state has been optimized at the RHF-SCF, CISD and CISDQ level with both *s*, *p* and *s*, *p*, *d* basis set, whereas for the higher, $^3\Pi_u$, $^3\Sigma_g^+$, and $^3\Pi_g$ states, only the *s*, *p* basis set was used. The computed optimized Be—Be distance, with total and relative energies are given in Table 3. Relative energies were also calculated both with respect to separated atoms [2 × Be($^1S_0$) + Be(^3P)] and at 6.0 Å Be—Be separation. The corresponding potential energy curves with *s*, *p* basis set at the CISDQ level are plotted in Fig. 2. For comparison, the ground state equilateral triangle, D_{3h} symmetry $^1A_1'$ potential energy curve was also calculated at the same level as the triplet states and plotted in Fig. 2. Computed net atomic charges and atomic spin densities are summarized in Table 4. As predicted earlier (18), at the SCF level, the $^1A_1'$ potential energy curve goes through a local minimum at 2.240 Å, which is 3.7 kcal/mol higher in energy than the separated Be($^1S_0$) atoms, and a maximum around 2.75 Å, with 6.1 kcal/mol above the separated Be($^1S_0$) atoms, which disappears at the CI level calculations. At the present level of calculations the $^1A_1'$ ground state does not show much bonding. At the SCF level, the stability of the $^3\Sigma_u^+$ state is exaggerated and is predicted to be 25.6 kcal/mol more than the $^1A_1'$ ground state, which is due to the neglect of correlation energy. Inclusion of correlation energy, even with limited CI calculations gave the correct order of potential energy curves, Fig. 2. The lowest triplet state, $^3\Sigma_u^+$, lies ~15 kcal/mol above the ground $^1A_1'$ state. At the RHF-SCF level with *s*, *p* basis set, calculations showed that the $^3\Sigma_u^+$ state is the most stable triplet state being 64.3 kcal/mol lower in energy than the separated atoms, which is close to the earlier reported value of 68.3 kcal/mol with UHF/6-31G (18), and the optimized Be—Be distance of 2.161 Å is also similar to the UHF/6-31G optimized value of 2.172 Å (18). Addition of the *d* polarization function did not change much either the optimized Be—Be distance or the relative energy (Table 3). Inclusion of correlation energy slightly increased the bond distance and the relative energy with respect to the separated atoms. Values of relative energies with respect to the 6.00 Å distance of separation are much smaller than the values calculated by the separated atom values. This may be due to a poor convergence of the correlation energy in the separated atoms. Thus, if we take the 6.00 Å distance value as the lower limit, the $^3\Sigma_u^+$ state is 47.1 kcal/mol lower than the separated atoms at the CISDQ level computations with *s*, *p* basis set and 48.2 kcal/mol with the *s*, *p*, *d* basis set. From the calculated atomic spin density values (Table 4) and the localized molecular orbital (LMO) analysis, in its $^3\Sigma_u^+$ state the Be_3 molecule has a diradical character having one α spin electron on each of its terminal Be atoms.

The next lowest triplet state, the $^3\Pi_u$ state obtained by the promotion of an electron to the $1\pi_u$ orbital from $3\sigma_u$, is 36.8 kcal/mol higher in energy at the SCF level, than the $^3\Sigma_u^+$ state. With inclusion of correlation energy this value reduces to 7.7 kcal/mol at the CISDQ level, and lies 39.4 kcal/mol lower than the separated atoms at 6.00 Å separation. The optimized Be—Be distance of the $^3\Pi_u$ state is slightly shorter (~0.06 Å) than in the $^3\Sigma_u^+$ state. Computed atomic spin densities and the LMO analysis showed that the two α spin electrons are delocalized among the three Be atoms, with slightly more concentration at the central Be atom. Interaction between the three atoms takes place near 2.50 Å separation, above this distance the LMO analysis shows that all three atoms are separated. The lowest $^3\Sigma_u^+$ and $^3\Pi_u$ states dissociate to two Be($^1S_0$) and one Be(^3P), whereas the higher $^3\Sigma_g^-$ and $^3\Pi_g$ states dissociate to higher excited states. Both the $^3\Sigma_g^-$ and $^3\Pi_g$ states lie much higher than the low-lying $^3\Sigma_u^+$ and $^3\Pi_u$ states. The $^3\Sigma_g^-$ state is 51.1 kcal/mol at the SCF level (30.4 kcal/mol at CISDQ) and $^3\Pi_g$ state 61.1 kcal/mol at the SCF level

(28.8 kcal/mol at CISDQ) higher than the lowest $^3\Sigma_u^+$ state. At the SCF level the $^3\Pi_g$ state is higher than the $^3\Sigma_g^-$ state; the inclusion of correlation energy brings the $^3\Pi_g$ state slightly lower than the $^3\Sigma_g^-$ state (~1.6 kcal/mol). Optimized Be—Be distances (Table 3) for these states are slightly shorter than the $^3\Sigma_u^+$ and $^3\Pi_u$ states. Computed atomic spin densities (Table 4) and LMO analysis showed that in both cases the α spin electrons are delocalized among the three Be atoms, slightly concentrating more at the central Be atom. Relative energies with respect to separated atoms at 6.00 Å separations and $2Be(^1S_0)$ + $Be(^3P)$ are given in Table 3 for comparison purposes. Computed net atomic charges calculated by the Mulliken population analysis (Table 4) show that the central Be atom has more negative charge than the terminal Be atoms in all the triplet states studied.

Be(^{3}P) reaction paths

The reaction, $Be(^3P)$ + $Be(^1S_0)$ can produce the Be_2 molecule in the $^3\Sigma_u^+$ and $^3\Pi_g$ states, both being more stable than the separated atoms, the $^3\Sigma_u^+$ state, by 39.4 kcal/mol, and the $^3\Pi_g$ state by 30.7 kcal/mol at the CISDQ level with s,p,d basis set. It is also important to note that there is no activation energy barrier for either of these reactions. We have also studied the $Be(^3P)$ reaction with the ground state $Be_2(^1\Sigma_g^+)$, producing triplet Be_3 molecules in two states, namely $^3\Sigma_u^+$ and $^3\Pi_u$. Both of these states are more stable than the separated entities by 47.1 and 39.4 kcal/mol, respectively, relative to the 6.0 Å separation. We calculated the total energies both at the SCF and CI levels with the s,p basis set, as a function of the $Be_1—Be_3$ distance along both the $^3\Sigma$ and $^3\Pi$ reaction paths. The $Be_1—Be_2$ distance was optimized for each $Be_1—Be_3$ distance. Cross sections of each of the resulting potential energy surfaces for the $^3\Sigma$ and $^3\Pi$ states at the CISDQ level are plotted in Fig. 3. Along the $^3\Sigma$ path, until the $Be_1—Be_3$ distance reaches 4.00 Å, all three Be atoms remain separated and around 3.75 Å the energy transfer from $Be(^3P)$ to $Be_2(^1\Sigma_g^+)$ takes place giving $Be(^1S_0)$ and $Be_2(^3\Sigma_u^+)$. From here the reaction can go in two directions to yield either $Be_2(^3\Sigma_u^+)$ and $Be(^1S_0)$, or if the $Be_1—Be_3$ distance decreases, this will form $Be_3(^3\Sigma_u^+)$, along the surface below 3.75 Å distance. At the SCF level for the $Be_2(^1\Sigma_g^+)$ + $Be(^3P)$ → $Be_2(^3\Sigma_u^+)$ + $Be(^1S_0)$ reaction path calculations predict a small activation energy barrier of 0.7 kcal/mol around 4.00 Å, which, however, disappears at the CI level. Along the $^3\Pi$ reaction path all three Be atoms remain separated until the $Be_1—Be_3$ distance reaches 3.00 Å. Below this distance, one of the α spin electrons is

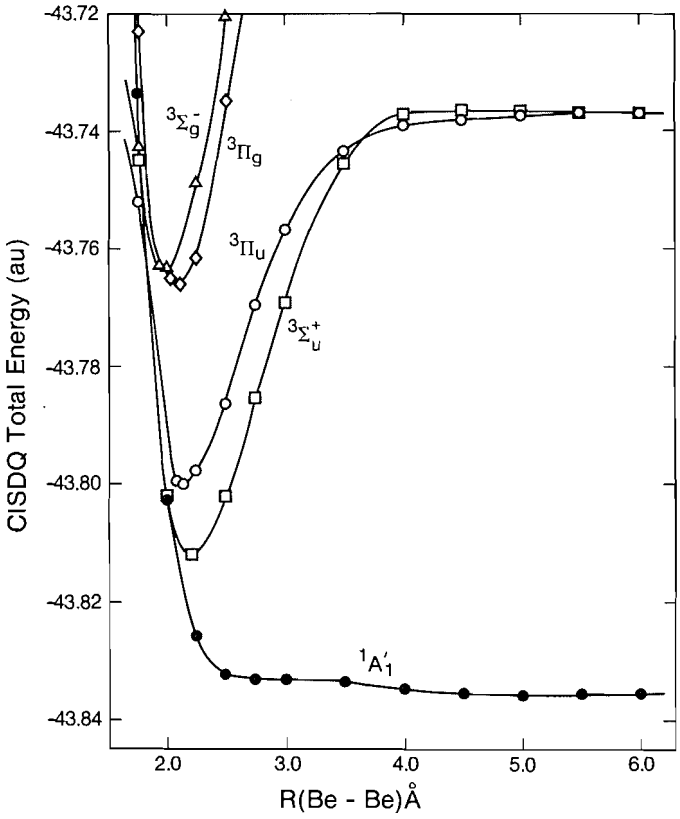

FIG. 2. Low lying triplet states potential energy curves of Be_3, with 10*s*, 5*p* basis set at the CISDQ level.

localized on the terminal Be_3 atom and the other α spin electron is delocalized between Be_1 and Be_2. Around a value of 2.0 Å for the distance of Be_1—Be_3, these electrons are switched, one localizing on Be_2 and the other delocalizing between Be_1 and Be_3. The fully optimized $^3\Pi$ state (with $C_{\infty v}$ symmetry) at the RHF-SCF level (Table 3) is 12.0 kcal/mol lower than the $^3\Pi_u$ (with $D_{\infty h}$ symmetry).

RHF-SCF geometry optimization of localized structures **I** and **II** with one short and one long bond length ($^3\Pi$, $C_{\infty v}$)

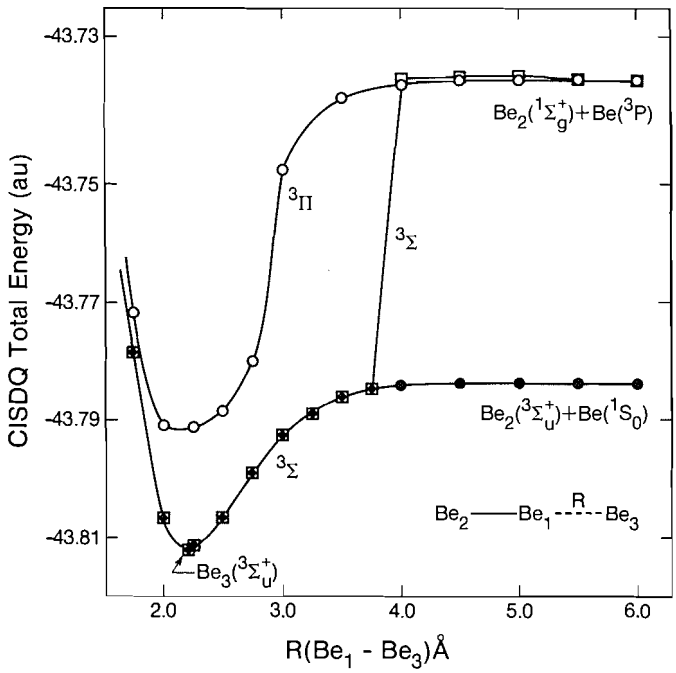

FIG. 3. $^3\Sigma$ and $^3\Pi$ Potential energy surface for the reaction of $Be_2(^1\Sigma_g^+)$ + Be(^3P) → $Be_3(^3\Sigma_u^+)$ → $Be_2(^3\Sigma_u^+)$ + Be($^1S_0$), with 10*s*, 5*p* basis set at the CISDQ level.

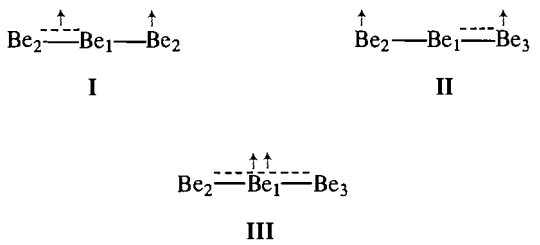
overestimates the stability relative to the delocalized structure **III** with intermediate equal bond lengths ($^3\Pi_u$, $D_{\infty h}$).



This type of symmetry dilemma has been observed for allyl and other carbon free radicals and is described in the literature (41–44), and the problem has been shown to be resolvable by inclusion of the correlation energy. The results of the CI computations predict the $^3\Pi_u$ state to be 4.5 kcal/mol lower in energy than the $^3\Pi$ state. The $^3\Pi$ reaction path does not show any activation energy barrier either at the SCF or at the CI level. This surface crosses over to the lowest $^3\Sigma$ or $^3\Sigma_u^+$ state at the early part of the reaction (~4.0 Å) or at shorter distances below 1.75 Å (Figs. 2 and 3). The $^3\Sigma$ reaction path for the $Be_3(^3\Sigma_u^+)$ → $Be_2(^3\Sigma_u^+)$ + Be($^1S_0$) was also computed at the SCF and CI level with *s*, *p* basis set as a function of $R(Be_1—Be_3)$ (Fig. 3). The $Be_3(^3\Sigma_u^+)$ state is 17.8 kcal/mol (at the CISDQ level) lower than that of $Be_2(^3\Sigma_u^+)$ + Be($^1S_0$) at 6.00 Å separation. Beyond 3.00 Å separation between Be_1 and Be_3, $Be_2(^3\Sigma_u^+)$ and Be($^1S_0$) remain as separated entities, with α spin electrons on Be_1 and Be_2. At the distance of 3.00 Å and below, the α electrons are localized on Be_2 and Be_3 and follow the $^3\Sigma$ path to the minimum at the $Be_3(^3\Sigma_u^+)$ state. At the SCF level there is a small energy barrier of 1.5 kcal/mol around 3.25 Å distance of Be_1—Be_3, for the reaction of $Be_2(^3\Sigma_u^+)$ + Be($^1S_0$) → $Be_3(^3\Sigma_u^+)$, which disappears at the CI level.

Thus, the energy transfer reaction of Be(^3P) to $Be_2(^1\Sigma_g^+)$ giving $Be_2(^3\Sigma_u^+)$ and Be($^1S_0$) suddenly goes through to the $^3\Sigma$

surface without any activation energy near 3.75 Å separation, or it can go through the $^3\Sigma$ path to form $Be_3(^3\Sigma_u^+)$ and dissociate without any activation energy barrier to $Be_2(^3\Sigma_u^+)$ and $Be(^1S_0)$. $Be_2(^1\Sigma_g^+)$ + $Be(^3P)$ can also give rise to the $Be_3(^3\Pi_u)$ state along the $^3\Pi$ reaction path, which in turn crosses over to the lowest $^3\Sigma_u^+$ state in the early stage of the reaction or at shorter distances in the molecular compression region ($R \geq 1.75$ Å) which subsequently can dissociate to give $Be_2(^3\Sigma_u^+)$ + $Be(^1S_0)$.

Ab initio calculations on tetramethoxymethane

R. J. McEachern, J. A. Weil, and P. G. Mezey
Department of Chemistry, University of Saskatchewan, Saskatoon, Sask., Canada S7N 0W0

Received September 27, 1987

This paper is dedicated to Professor Charles A. McDowell on the occasion of his 70th birthday

R. J. McEachern, J. A. Weil, and P. G. Mezey. Can. J. Chem. **66**, 2041 (1988).

Minimal basis set *ab initio* SCF-MO calculations were performed on the 21-atom system of tetramethoxymethane (tetramethyl orthocarbonate). The geometric configuration of this model was optimized in two conformations, one having quasi-S_4 symmetry and the other D_{2d} symmetry. The S_4 conformation was found to be 8 kJ mol^{-1} lower in energy than the D_{2d} conformation, at the STO-3G level. The calculated energy difference is consistent with the recently measured geometric configuration of crystalline tetrabenzyl orthocarbonate. The calculated values of the bond lengths and angles were compared to the results of an electron diffraction study of the methyl species, and agree well with experiment. The theoretical electric dipole moment was calculated to be 0.01 D.

R. J. McEachern, J. A. Weil et P. G. Mezey. Can. J. Chem. **66**, 2041 (1988).

Utilisant un ensemble de base minimal, on a effectué des calculs d'OM *ab initio* en champ auto-cohérent sur le système à 21 atomes du tétraméthoxyméthane (orthocarbonate de tétraméthyle). On a optimisé la configuration géométrique de ce modèle dans deux conformations, l'une possédant une symétrie quasi-S_4 et l'autre de symétrie D_{2d}. Au niveau STO-3G, on a trouvé que l'énergie de la conformation S_4 est 8 kJ mol^{-1} plus faible que celle de la conformation D_{2d}. La différence d'énergie calculée est en accord avec la configuration géométrique mesurée récemment pour l'orthocarbonate de tétrabenzyle à l'état cristallin. On a comparé les valeurs calculées pour les longueurs et les angles de liaison avec les données expérimentales obtenues par diffraction électronique sur l'espèce méthylée et elles sont en bon accord avec les expériences. On a calculé que le moment dipolaire électrique est de 0,01 D.

1. Introduction

Study of molecules in which a carbon atom has four oxygens as nearest neighbors, the so-called orthocarbonates, has been rather neglected. In particular, relatively little is known about molecules of type $C(OR)_4$, where R is an organic group. The simplest member of this family, tetramethoxymethane (tetramethyl orthocarbonate), $C(OCH_3)_4$, was first synthesized (1) in 1927, and has been employed in organic synthesis, particularly for the preparation of spiro-orthocarbonates (2, 3). However, despite this utility, the structure of this molecule has not been determined by X-ray diffraction, and spectroscopic studies have resulted in disagreement over its structure (4, 5). There are two low-energy conformations of the tetramethoxymethane model that must be considered (4): one has S_4 symmetry, while the other has D_{2d} symmetry. We retain this nomenclature even though the optimized S_4 conformation was found to have slight deviations from S_4 symmetry, and should be described as quasi-S_4 (see Results and Discussion). Both conformations of the tetramethoxymethane molecule can be visualized as having a (close to) tetrahedral arrangement of oxygen atoms around the central carbon atom, with the methyl groups placed so that the $C(OC)_4$ portion of the molecule has the appropriate (S_4 or D_{2d}) symmetry (see Fig. 1). The methyl groups each have a staggered conformation with respect to the C(central)—O bond. Mijlhoff *et al.* (6) did an electron diffraction study on tetramethoxymethane, and found that only the S_4 structure is present in the gas phase, with the molecule flattened so as to be oblate with respect to the S_4 axis. The central C—O bonds were found to be shorter than the peripheral C—O bonds; the relative lengths of the C—O bonds are important since this information provides insight into the anomeric effect (7–9), which is an important phenomenon in carbohydrate chemistry.

The present theoretical study was initiated to gain insight into the properties of orthocarbonates, since tetrabenzyl orthocarbonate has recently been synthesized in our laboratory, is crystalline, and has been shown[1] by X-ray diffraction to have central symmetry very close to S_4. *Ab initio* calculations on tetramethoxymethane serve as a tool to gain insight into the controversial and complex problem regarding the relative stability of the S_4 and D_{2d} conformations of this molecule. Other properties, such as bond lengths and the electric dipole moment, have been calculated herein and compared to experiment. Our study of tetramethoxymethane was also done because it is a useful model for simulation of a hypothetical carbon impurity in α-quartz[2] and in other silicates. In particular, the absence of reports in the literature of the occurrence of carbon

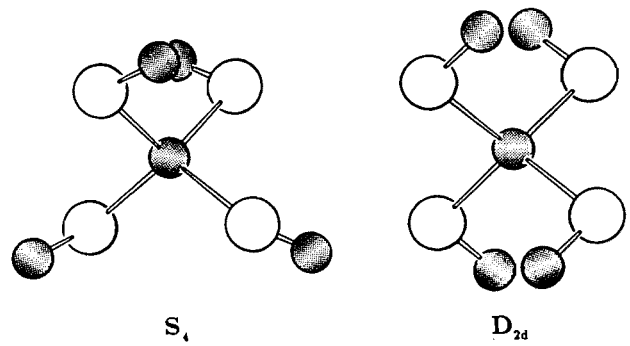

FIG. 1. The S_4 and D_{2d} conformations of the $C(OCH_3)_4$ model. The carbon and oxygen atoms are denoted by shaded and clear circles respectively. For clarity, the methyl protons are not shown. In the S_4 conformation, the S_4 axis lies vertically in the plane of the paper while, for the D_{2d} conformation, the S_4 axis lies horizontally in the plane of the paper; in both cases the axis threads the central carbon atom.

(in contradistinction to germanium) substituted for silicon merits investigation.

1.1 Models

The model used throughout this study has been the 21-atom cluster $C(OCH_3)_4$. Different conformations (S_4 and D_{2d}) of this model were considered by varying the starting configuration of the model; the two catchment regions on the energy hypersurface proved to be well separated, and there was no computational problem with conformations switching between the two regions in the process of geometry optimization.

1.2 Calculations

The calculations reported herein were performed using the program Gaussian 82 (12) on a VAX 8600/8650 computer cluster. The large size of the models and the need for geometry optimization constrained our choices for basis sets. In this study, the STO-3G minimal basis set (13–15) was used, and all calculations were carried out within the restricted Hartree–Fock (RHF) framework. No explicit symmetry restrictions were placed on the models in this study, i.e., all bond lengths and angles were allowed to vary independently. Optimizations were continued until the forces acting on all bond lengths and angles were reduced to less than 0.00045 hartree bohr^{-1} or hartree radian^{-1} respectively.

2. Results

The optimized Cartesian coordinates of the two conformations of the $C(OCH_3)_4$ system are given in Table 1. A diagram of the optimized configuration of the S_4 conformation of the $C(OCH_3)_4$ molecule is shown in Fig. 2. The net atomic charges on the optimized geometry of the S_4 conformation of the $C(OCH_3)_4$ molecule (obtained by Mulliken population analysis) are listed in Table 2. The energy differences between each of the models optimized in this study are presented in Table 3. The optimizations include those with methyl group rotation

TABLE 2. Net atomic charges q (in units of $|e|$) for the optimized S_4 conformation of the $C(OCH_3)_4$ model, as calculated by the Mulliken procedure

Atom	q
C(central)	+0.463
O	−0.265
C (peripheral)	−0.068
H	+(0.070 → 0.075)

TABLE 3. Total energy E_t (in hartree cluster^{-1}), and energy ΔE (in kJ mol^{-1}) relative to the lowest-energy S_4 conformation, for various conformations of the $C(OCH_3)_4$ model

Conformation symmetry	Methyl group rotation[a] (degrees)	E_t	ΔE
S_4	0[b]	−489.416175	1.0
S_4	8[c]	−489.416545	0.0
S_4	30[b]	−489.412642	10.3
S_4	60[b]	−489.407631	23.4
D_{2d}	0[d]	−489.413650	7.6
D_{2d}	30[b]	−489.411228	14.0
D_{2d}	60[b]	−489.407408	24.0

[a]Methyl group rotation is measured as the deviation from the antiperiplanar conformation, which is obtained when the dihedral H—C(peripheral)—O—C(central) angle is 180°. The positive direction is taken as counterclockwise, when viewed from the methyl group.

[b]Calculation was for a single geometric configuration using the program Monstergauss (26).

[c]S_4 conformation subjected to complete geometry optimization using Gaussian 82. The average deviation from the antiperiplanar conformation was 8°; however, there were slight deviations from S_4 symmetry, and the actual deviation varied for individual methyl groups from 7° to 10°.

[d]The complete geometry optimization of the D_{2d} conformation proved to have a 0° methyl group rotation.

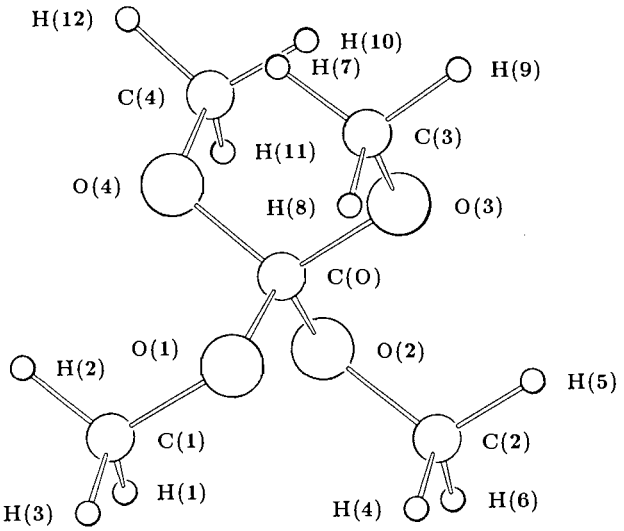

FIG. 2. The optimized S_4 conformation of the $C(OCH_3)_4$ model. The cluster shown here is enantiomorphic to the one shown in Fig. 1.

restricted (to 0, 30, or 60°) as well as complete geometry optimizations on both the S_4 and D_{2d} conformations.

3. Discussion

The results of this *ab initio* study support the view that the S_4 conformation is the most stable for the $C(OCH_3)_4$ molecule; the STO-3G calculations indicate that the energy difference between the two conformations is 8 kJ mol^{-1}. Among the factors that may be responsible for the conformation S_4 having lower energy than D_{2d}, increased repulsion between lone pairs (5) and unfavorable electric dipole–dipole interactions (16, 17) may be the most important. The calculated energy difference between the two conformations of tetramethoxymethane is somewhat larger than the estimate of 4.1 kJ mol^{-1} by Ypenburg and Gerding (4), but considerably smaller than the estimated value of 25.1 kJ mol^{-1} suggested by Mijlhoff *et al.* (6), based on a study of methanediol (18). The sizable difference (18.5 kJ mol^{-1}) may indicate that methanediol is not an appropriate model for tetramethoxymethane. It is known that although the STO-3G basis set generally predicts geometries reasonably well, it is usually less accurate with respect to energies. An *ab initio* study of similar compounds $X(OH)_4$, where X = C or Si, showed that the STO-3G basis set predicted energy differences between the S_4 and D_{2d} conformations that are appreciably too low as compared to the 6-31G* (19, 20) basis set values (21).

It should be noted that the optimized geometry of the S_4 model did not in fact show exact S_4 symmetry. Rather, there were small deviations from symmetry, particularly in the methyl groups, which reduced the formal symmetry to C_1. To see if the deviations from S_4 are significant, the model was reoptimized with S_4 imposed. The latter was found to be 4.1 kJ mol^{-1} higher in energy than the unconstrained model, with the STO-3G basis set. The difference in energy is small but significant, so that we feel that the symmetry of this model could appropriately be called quasi-S_4. The occurrence of slight deviations from S_4 symmetry encountered in this study is supported by the infrared spectrum of tetramethoxymethane (5).

Comparison of the net atomic charge data in Table 2 with the results of an *ab initio* study (22) of $(HO)_2Si(OSiH_3)_2$ illustrates clearly the more electronegative character of carbon as compared to silicon.

TABLE 4. Bond lengths (in Å) and angles (in degrees) for the two conformations of $C(OCH_3)_4$. Experimental values are from ref. 6. Values in parentheses represent the range (±) for parameters where there were slight deviations from symmetry for the theoretical results. For the experimental results, the values in parentheses are the estimated standard deviations

Parameter	D_{2d} (theor.)	S_4 (theor.)	S_4 (expt.)
r C—O (central)	1.429	1.429	1.396(3)
r C—O (peripheral)	1.438	1.437	1.423(3)
r C—H	1.092(2)	1.092(2)	1.114(3)
∠C—O—C	111.2	111.6	113.9(4)
∠O—C—O (sym)[a]	102.6	112.4	114.6(5)
∠O—C—O (non-sym)[a]	113.0	108.0	106.9(5)
∠O—C—H	110(4)	110(4)	112(1)
Methoxy torsion[b]	0.1	±4(2)[d]	+3(1)[e]
Methyl torsion[c]	0.3	∓8(2)[c,d]	+45(2)[e]

[a]For both conformations, there was a distortion of the CO_4 tetrahedron such that two types of O—C—O bond angles were formed: two (equivalent) O—C—O angles bisected by the symmetry axis ("O—C—O sym"), and the four other O—C—O angles ("O—C—O non-sym").

[b]Methoxy torsion is given as the deviation from the antiperiplanar configuration for the two pairs of methoxy groups related by two-fold symmetry along the S_4 or C_2 axis.

[c]Methyl torsion is given as the deviation from the antiperiplanar configuration for any one of the C(0)—O—C—H dihedral angles. Methyl group deviations from symmetry were reported using the range indicated in parentheses.

[d]For the methoxy carbon atom pairs (1,2) and (3,4) respectively (see Fig. 1).

[e]Results had been reported as deviations from the eclipsed periplanar configuration, and were converted to deviations from the antiperiplanar configuration.

We estimate that the energy barrier for simultaneous rotation of all four methyl groups in $C(OCH_3)_4$ is approximately 23 kJ mol^{-1}. From this, one may deduce that the barrier for rotation of a single methyl group is approximately 6 kJ mol^{-1}. It is recognized that this result is fairly crude, since the various methyl groups will interact with each other. Therefore, a calculation was done in which a single methyl group was rotated by 60° from the optimized configuration; with the STO-3G basis, the energy barrier was found to be 7.2 kJ mol^{-1}. This energy barrier for the rotation of the methyl groups is low enough to be consistent with the observed proton nmr spectra of this compound, which indicate that the methyl groups are not in different environments (23).

The data presented in Table 4 indicate that there is quite good agreement of the theoretically calculated optimum bond lengths and angles with the results of the electron diffraction study. The calculated values of the C—O bond lengths (average for the two types) are 0.024 Å longer than the experimental values. It is a well-known fact that the STO-3G basis set tends to produce theoretical bond lengths that are somewhat too large (24), so that the (small) difference between calculated and experimental values is not surprising. Other calculations on a similar model, $C(OH)_4$, showed that a change from the STO-3G to the 6-31G basis set caused a decrease of 0.036 Å in the C—O bond length.[3] Thus it seems reasonable to conclude that the major source of error in the present calculations is the basis set limitation. Mijlhoff *et al.* (6) noted that the central C—O bond lengths were 0.03 Å shorter than the peripheral C—O bond lengths; the results of our *ab initio* calculation confirm their findings with regard to the relative magnitude of the C—O bond lengths. The shortening of the central C—O bonds is consistent with the model of charge delocalization of oxygen lone-pair

electrons, proposed by Romers *et al.* (7) as a possible explanation of the anomeric effect. Essentially, this model states that, for a given O(j)—C(0)—O(i)—R fragment (Fig. 2), charge delocalization will occur when the O(j)—C(0)—O(i)—R dihedral angle is in the range 90 ± 30°. When the dihedral angle is in this range, the alignment of orbitals is advantageous, so that there is delocalization of electrons from the (essentially) p-type lone-pair orbital on O(i) into one of the C(0) $2p$ orbitals (partially emptied by the electronegative substituent O(j)). The delocalization of the O(i) lone pair thus gives the C(0)—O(i) bond some degree of double-bond character. This study is thus consistent with earlier works on similar models (18, 25) in supporting the theory of charge delocalization of oxygen lone-pair electrons. It should be noted, however, that work[3] on the $C(OH)_4$ model suggests that charge delocalization is not a major factor in the energy differences between the various conformations of this model.

The value 1.092 ± 0.002 Å determined in the C—H bond length calculation is 0.022 Å shorter than the experimental value. It is uncommon for the STO-3G basis set to predict bond lengths that are too short, but such results have been observed before (27). The agreement between theoretical and experimental results is within the range (0.03 Å) typically found for molecules consisting of first-row elements when using STO-3G (27). For acetaldehyde and methanol (28), the experimental results are in the range 1.09–1.10 Å.

The calculated distortion of the CO_4 tetrahedron (the structure is flattened in the direction of the S_4 axis) is in good agreement with the electron diffraction study. There are many possible qualitative explanations as to why the tetramethoxymethane model distorts in the manner it does; among these are repulsion between lone pairs on oxygen atoms (5), electric dipole interactions (29), and delocalization of lone pairs (as described above); probably a combination of all the above factors is responsible for the distortion. It should be noted that distortion of the CO_4 tetrahedron, in a manner similar to that seen in this model, was observed in the $C(OH)_4$ model with various basis sets.[2,3]

The electric dipole moment of the S_4 conformation of the $C(OCH_3)_4$ model was calculated to be 0.01 debye. The calculated dipole moment is consistent with the one available gas-phase measurement (<0.3 D), which is rather old and probably only represents an upper limit on the dipole moment of this molecule (30). Measurements of the dipole moment of $C(OCH_3)_4$ in the liquid phase were generally found to be in the range 0.7–0.9 D (10, 11, 16, 23). Whereas dipole moments calculated with basis sets of modest size are in general rather unreliable, the poor agreement between the calculated dipole moment and the experimental values determined in the liquid phase presumably is at least partly due to distortion of the $C(OCH_3)_4$ molecule by interaction with the solvent.

4. Conclusions

The results of *ab initio* calculations on a fully geometry-optimized model of $C(OCH_3)_4$ have been reported, using the STO-3G basis set for optimization. There is good agreement between the calculated and experimentally determined values of bond lengths and angles. The calculations provide support for the lone-pair delocalization model (25) since the calculated central C—O bonds are shorter than the peripheral C—O bonds. The results of the present study support the view that the quasi-S_4 conformation of the $C(OCH_3)_4$ molecule is more stable than the D_{2d} conformation; our results show that the theoretical energy difference is 8 kJ mol^{-1} with the STO-3G basis set.

Using electron paramagnetic resonance spectroscopy we have measured the temperature dependence of ionic rearrangements and domain nucleation around the antiferroelectric transition temperature T_c of $NH_4H_2AsO_4$, $ND_4D_2AsO_4$, $NH_4H_2PO_4$, and $ND_4D_2PO_4$. CrO_4^{3-} radicals, produced by γ-irradiation of K_2CrO_4-doped samples, were used as microscopic probes because their charge, size, and symmetry match those of the host anions. The use of high deuteration level and "monodomain" samples prepared by temperature cycling was found to be crucial in the signal assignment and line-shape analysis. The results show that as a sample approaches T_c from $T > T_c$, the hydrogen-bonded protons slow down anomalously, much more slowly than expected for Arrhenius behaviour. Simultaneously, the lattices develop "clusters" of antiferroelectrically ordered molecules. These clusters eventually ($T \ll T_c$) expand to occupy the whole lattice and thus complete the lattice ordering. The probe selection and sample preparation methodology discussed and the microscopic details of the ionic rearrangements reported appear to be highly significant for further studies of these phase transitions.

N. S. DALAL et A. H. REDDOCH. Can. J. Chem. **66**, 2045 (1988).

Utilisant la spectroscopie en résonance paramagnétique électronique, on a mesuré les réarrangements ioniques et la nucléation de domaine en fonction de la température qui se produit près de la température de transition antiferroélectrique, T_c, du $NH_4H_2AsO_4$, du $ND_4D_2AsO_4$, du $NH_4H_2PO_4$ et du $ND_4D_2PO_4$. Des radicaux CrO_4^{3-}, produits par l'action d'irradiations-γ sur des échantillons dopés au K_2CrO_4, ont été utilisés comme sondes microscopiques parce que leur charge, leur grosseur et leur symétrie sont comparables à celles des anions hôtes. Pour l'attribution des signaux et pour l'analyse de la forme des raies, il est crucial d'utiliser des échantillons à «domaines uniques» qui ont été préparés par des cycles de température et qui contiennent des niveaux élevés de deutération. Lorsque la température d'un échantillon approche de T_c, on observe que les protons liés par des ponts hydrogènes sont anormalement ralentis, beaucoup plus que ce que l'équation d'Arrhénius nous laisserait prévoir. En même temps, les réseaux forment des «agrégats» de molécules qui sont ordonnés d'un point de vue antiferroélectrique. Lorsque $T \ll T_c$, ces agrégats prennent de l'expansion et complètent sa mise en ordre. La méthode de sélection de la sonde ainsi que la méthodologie de préparation d'échantillons qui est discutée et les détails microscopiques des réarrangements ioniques rapportés semblent très significatifs pour des études ultérieures de ces transitions de phase.

Introduction

We report here probably the first observation via electron paramagnetic resonance (EPR) spectroscopy of atomic fluctuations and the growth of antiferroelectrically ordered domains in several disordered paraelectric lattices in the vicinity of their paraelectric–antiferroelectric phase transitions. As is well known (1), a paraelectric–antiferroelectric transition is defined to take place at a temperature (T_c) below which each molecule in the unit cell acquires an electric dipole moment oriented such that the net dipole moment of the unit cell is zero. The nature of interactions that lead to the antiferroelectric ordering is not yet understood (1) and is a topic of current activity (for recent reviews, see ref. 2), even after four decades of study (2, 3). We have now investigated the four KH_2PO_4-type of hydrogen-bonded antiferroelectrics: $NH_4H_2AsO_4$ (ADA), $ND_4D_2AsO_4$ (DADA), $NH_4H_2PO_4$ (ADP), and $ND_4D_2PO_4$ (DADP), where the letters inside the brackets form the commonly used abbreviations for the corresponding compound. The results obtained (see ref. 4 for a preliminary account) bear on the microscopic picture of an antiferroelectric sample as it approaches the phase transition ($2d$), and suggest guidelines for choosing a paramagnetic probe for studying atomic fluctuations in KH_2PO_4-type of ferroelectrics, antiferroelectrics, and perhaps other chemical systems.

Since all four compounds studied are normally diamagnetic, CrO_4^{3-} radicals (5), substituting for AsO_4^{3-} or PO_4^{3-} ions, were used as microscopic paramagnetic probes. CrO_4^{3-} was chosen over AsO_4^{4-} and SeO_4^{3-}, the two other probes used widely for such studies (2), because of the charge and symmetry requirements: an ideal probe must have approximately the same electronic charge, overall size, and symmetry as those of the substituted units in the host lattice. AsO_4^{4-}, formed (2) via γ-irradiation of an arsenate, has an extra negative charge compared to the substituted units (AsO_4^{3-} or PO_4^{3-}). This excess charge alters the electrostatic interactions in the vicinity of the AsO_4^{4-} center. Hence the motional fluctuations observed via this probe will not be expected to be the same as those of AsO_4^{3-} or PO_4^{3-} units in the unperturbed lattice. Of course SeO_4^{3-} has the same charge as the PO_4^{3-} or AsO_4^{3-} units, but electron nuclear double resonance (ENDOR) measurements have shown (6) that the disposition of the hydrogen-bonded protons around the SeO_4^{3-} center, and hence its observed site symmetry (D_{2d}) is quite different from that (7) (C_s) of a PO_4^{3-} unit below T_c. On the other hand, CrO_4^{3-} has the same charge and approximate size as a PO_4^{3-} or AsO_4^{3-} unit, and recent ENDOR studies have shown (8) that its proton arrangement and

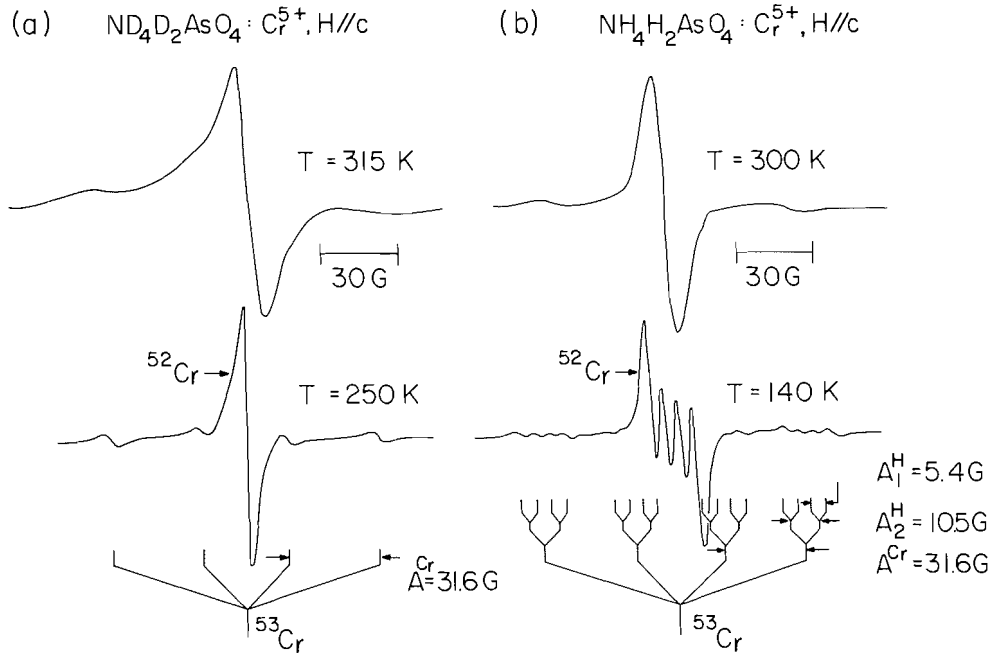

FIG. 1. EPR spectra of the CrO_4^{3-} center for H//c: (a) DADA, T = 315 K, paraelectric phase, and T = 250 K, antiferroelectric phase; (b) ADA, T = 300 K, paraelectric phase, and T = 140 K, antiferroelectric phase.

hence site symmetry approximate those of a host antiferroelectric lattice. We note that other probes such as Hg^+ ($6s^1$) also meet (9) the charge and symmetry requirements for these lattices, but those probes yield motional information on the cations, rather than the PO_4^{3-} or AsO_4^{3-} units. A fuller understanding of the role of the various chemical units in triggering the phase transition would benefit from motional and structural data obtained via the use of probes specific to different sites in the lattice.

After our initial study (4), Müller and Berlinger (10) reported an EPR study of CrO_4^{3-} in ADA and partially (~75%) deuterated ADA, as did Gaillard and Gloux (8) on the proton ENDOR of CrO_4^{3-} in ADA. The present work supplements the ENDOR study by employing specially prepared (monodomain) samples. Also, the present work includes ADP and DADP and focuses on the dynamical effects near T_c, not contained in the earlier work (8, 10).

Experimental

The single crystals used in this work were grown from aqueous solutions doped with ~1 mol% of K_2CrO_4 and γ-irradiated to a dose of about 1 Mrad at room temperature (4). Important differences from the earlier studies (8, 10) are (*a*) the growth of high isotopic purity (~99%) DADA and DADP crystals by vacuum line synthesis to obtain narrower EPR signals than before, since the earlier study (10) used only ~75% deuterated samples; (*b*) the annealing of samples at ~50°C to reduce the number of unwanted paramagnetic centers, which would interfere with the CrO_4^{3-} signals; (*c*) the growth of an essentially monodomain crystal in which the number of EPR signals was half that in a normal, polydomain crystal, thereby helping the assignment of signals to a given site and domain; and (*d*) the more detailed study of the angular and temperature dependence of the EPR spectra than before (10).

The EPR measurements were made at 9.5 GHz with the aid of a proton resonance fluxmeter and a frequency counter to read the fluxmeter and the microwave frequencies. The sample temperature was controlled to an accuracy of ±0.1 K.

Results and discussion

Characterization of the CrO_4^{3-} center

In all four cases the EPR spectra consist of strong central lines flanked by weak satellites. Typical spectra for ADA and DADA are shown in Fig. 1; those for ADP and DADP are very similar. From the intensity and the spin multiplicity considerations the central (strong) component can be identified with that from the ^{52}Cr (I = 0) isotope and the four satellites can be described in terms of the g tensor and the hyperfine interaction of the unpaired electron with the ^{53}Cr (I = 3/2) isotope. Figure 2 shows the angular dependence of the ^{52}Cr lines in the three crystallographic planes of DADA; those for the other compounds are essentially similar.

The paraelectric phase spectra (shown by the dashed lines) can be described by the spin Hamiltonian,

$$\mathcal{H} = \beta_e[g_\parallel H_z S_z + g_\perp (H_x S_x + H_y S_y)] + A_\parallel S_z I_z + A_\perp [S_x I_x + S_y I_y]$$

where the z direction coincides with the crystalline c-axis. The values of $g_\parallel$, $g_\perp$, $A_\parallel$, and $A_\perp$ obtained by fitting the experimental data are given in Table 1, wherein the results for other, related crystals (5, 11) are also included. The g and A parameters for ADA, DADA, ADP, and DADP compare well with those for KD_2AsO_4 and KD_2PO_4, implying that the CrO_4^{3-} centers have indeed substituted for the parent PO_4^{3-} or AsO_4^{3-} units. For all compounds, $g_\parallel < g_\perp$ and $A_\parallel > A_\perp$, implying (12) that the ground state of CrO_4^{3-} in all of these compounds uses mainly the Cr(V) $d_{x^2-y^2}$ orbital. Using the Maki–McGarvey (12) relationship between $g_\parallel$, $g_\perp$, $A_\parallel$, $A_\perp$ and the coefficients of $d_{x^2-y^2}$ and d_{z^2} in the wave function for CrO_4^{3-}, we find that the ground state has approximately 90% $d_{x^2-y^2}$ character, which is nearly the same as for Cr(V) in K_3CrO_8 (13).

A striking similarity is found also between the g-tensor results in the low temperature phases of the ammonium and the potassium salts. Detailed studies of the angular variation of the ^{52}Cr components of the CrO_4^{3-} center in all four ammonium compounds show that all have nearly identical variation. Figure 2 shows the results for DADA. A least-squares fitting of the lines in the three crystallographic planes yielded 16 tensors with nearly equal rms error of ~0.5 G. However, measurements in

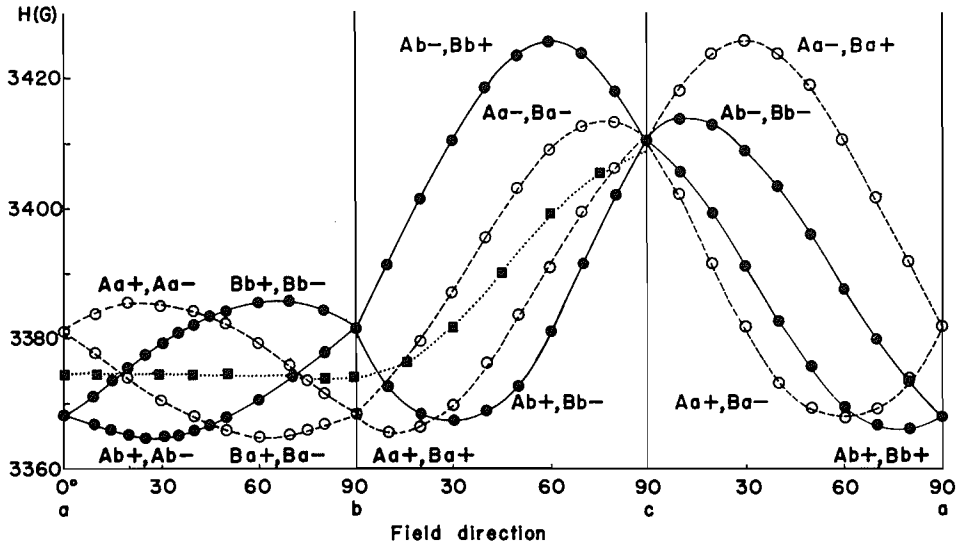

FIG. 2. Angular dependence of the central ($I = 0$) transitions for CrO_4^{3-} in DADA. The solid and the dashed lines belong to the different domains of polarization. The assignment of the lines to the various domains and sites has been made with the help of the monodomain samples and the symmetry analysis as explained in the text. The angular dependence in the paraelectric phase is that shown by the dotted lines.

the [1 1 0] (fourth) plane reduced them to a set of eight, which is the number expected from the crystal symmetry considerations, to be discussed in more detail in the next section. The g-tensor components for one of the eight tensors are given in Table 2, the other tensors being obtainable from this set by applying the crystal symmetry elements. The results for KD_2AsO_4 (DKDA) are also included therein, the comparison confirming the similarity between the ammonium and the potassium salts.

Further confirmation of the identification came from the analysis of the proton superhyperfine structure (shfs). Figure 3 shows the angular dependence of the shfs splitting from the two protons closest to the CrO_4^{3-} center in ADP. The high resolution necessary to obtain Fig. 3 was possible because of the use of the "monodomain" samples. The coupling constants obtained are in essential agreement with the ENDOR study of ADA by Gaillard and Gloux (8). The major outcome of the monodomain results is that they confirm the assignment of the ENDOR signals to the various antiferroelectric domains, which is not possible with the normal (polydomain) ADA crystals used in the ENDOR study (8), and that the proton shfs and hence the proton configuration around the CrO_4^{3-} center in ADP and ADA are essentially identical.

The finding of $d_{x^2-y^2}$ as the ground state of CrO_4^{3-} in the phosphates and arsenates is interesting, since the ground state of CrO_4^{3-} in nearly all other cases is found to be d_{z^2}, as discussed by Greenblatt (14). In fact, ligand field theory predicts (11, 12) that if the CrO_4^{3-} tetrahedron is compressed along the tetragonal distortion axis, then the ground state of Cr(V) would be d_{z^2} rather than $d_{x^2-y^2}$. The PO_4^{3-} and the AsO_4^{3-} tetrahedra in the compounds studied here are compressed (by ~2%) along the tetragonal (c)-direction. If some of these ions are substituted by CrO_4^{3-}, then the latter are also expected to be similarly compressed. Thus the observed $d_{x^2-y^2}$ ground state is in contradiction to the simple ligand field approach and differs from that (d_{z^2}) found in Li_3PO_4, Li_3AsO_4, and many other hosts (14). In an effort to reconcile these results, Müller and Berlinger (15) have suggested that electrostatic interaction of the hydrogen bonds (in these hosts) with the unpaired electron of CrO_4^{3-} stabilizes the $d_{x^2-y^2}$ as compared to d_{z^2}. However, we have recently carried out (13) detailed studies of the isoelectronic peroxy ion CrO_8^{3-} in K_3CrO_8, which of course has no hydrogen, and where the CrO_8^{3-} ion is similarly compressed. The ground state of the Cr(V) in K_3CrO_8 is also found to be $d_{x^2-y^2}$. Thus it is not clear why CrO_4^{3-} has $d_{x^2-y^2}$ as the ground state here and any further theoretical work to explain this discrepancy would be most welcome.

TABLE 1. Spin Hamiltonian parameters for the CrO_4^{3-} radical stabilized in the paraelectric phase of the KDP-type crystals. The error limits on $g_\parallel$ and $g_\perp$ are ±0.0005. The $A_\parallel$ and $A_\perp$ are in units of gauss, the ∥ direction is along the crystal c-axis

Domain and site assignment

To be able to utilize the CrO_4^{3-} center as a probe of the phase

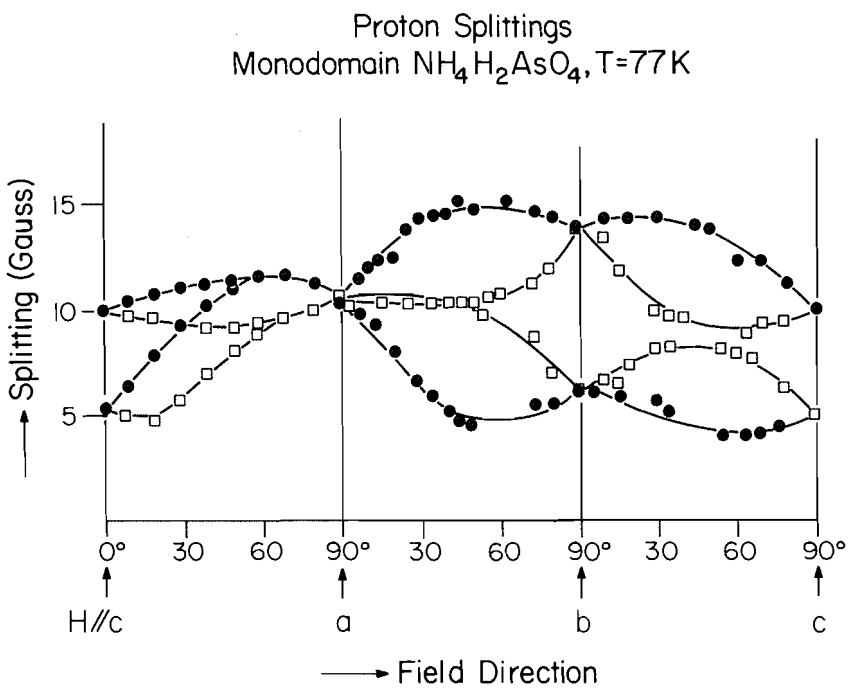

FIG. 3. Angular dependence of the proton superhyperfine (shfs) tensors for the close protons in the antiferroelectric phase of ADA. The use of monodomain samples was found to be essential for these measurements.

transition, it was important to be able to assign the observed signals to the various sites and domains in the crystal. Failure to do so in an earlier study (15) had led to erroneous interpretation of the motional correlation times for DKDA, as has been shown elsewhere (5).

The assignment was achieved by using the data on crystal symmetry (7). All of the four ammonium compounds crystallize in the space group $I\bar{4}2d$, which changes to $P2_12_12_1$ below T_c. There are two rotationally distinct crystallographic sites, say A and B, and each may be imbedded in domains with local polarization in the + or − directions along the a or b axes. These combinations yield 8 possible tensors, which may be labelled $Aa+$, $Bb-$, etc. in the notation of Dalal *et al.* (5). The crystallographic symmetry $P2_12_12_1$ implies twofold screw axes parallel to each crystallographic axis. In addition, the two domains can be related by introducing glide planes 110 and $1\bar{1}0$, which occur in the higher temperature structure. The application of these symmetry elements leads to the assignments indicated in Fig. 2.

These assignments predict that a domain effect, in the form of different line intensities, may be expected in the ab, bc, and ac planes but not in the 110 and $1\bar{1}0$ planes. This prediction was in complete agreement with the results on the monodomain crystals. It also supports the earlier assignment (5) of the domain structure for KD_2AsO_4 and KD_2PO_4.

The facts that the CrO_4^{3-} EPR shows the domain effect and that the effect conforms to the above analysis suggest that the Cr centers are coupled to the antiferroelectric domains, and can thus be used as sensitive probes of the long-range order that sets in around and below T_c.

Temperature dependence of the EPR spectra: evidence for dynamic clusters

Striking changes in line shapes and positions were observed near T_c in the EPR spectra of the CrO_4^{3-} centers in ADA, DADA, ADP, and DADP. The changes were reversible with a hysteresis of 2 K. Figure 4 shows the spectra for ADA and DADA. Similar effects were observed for ADP and DADP. The temperature dependence of g_c, the component of the g tensor along the c-axis, is shown in Fig. 5. A sudden change in g_c can be seen to occur at T_c in all three compounds. Similar changes were noted in the ^{53}Cr hyperfine couplings, as shown in Fig. 6. Even more interesting was the observation that in the temperature interval of about 5° around T_c, the observed line shape was a superposition of the signals characteristic of those from the high temperature, labeled P, and the low temperature phase, labeled A. The assignment of the P and the A-type signals to paraelectric and antiferroelectric phases respectively was achieved through detailed angular variation studies, such as shown in Fig. 2. As the temperature is lowered through T_c, the P-type signals are rapidly replaced by the A-type signals, although no line broadening or shifting is observed. It is seen that the position of the P signals is *not* that expected from a rapid averaging of all the A-type signals. This conclusion is evident from Fig. 5, and more clearly from Fig. 2 where the dashed line shows the angular dependence of the P-type signals.

These results disagree with those of Müller and Berlinger (10) who concluded that for ADA and DADA the high temperature spectra are the "averages" of the low temperature ones. Müller also used this result as a basis for concluding that the CrO_4^{3-} is a Halperin–Varma center, defined (10, 15, 16) as an impurity that has an activated motion of its own, not related to the intrinsic host fluctuations. Our results thus do not support this conclusion either.

The temperature dependence of the intensity of the A-type signals for ADA is shown in Fig. 7. Similar results were observed for DADA. To correlate the intensity of the A-type signals with the long-range order in this material, the dielectric loss and the EPR signal changes were simultaneously measured for several samples. This was achieved by using a standard EPR spectrometer but employing a dual-sample microwave cavity, containing the ADA sample in one part and a paramagnetic

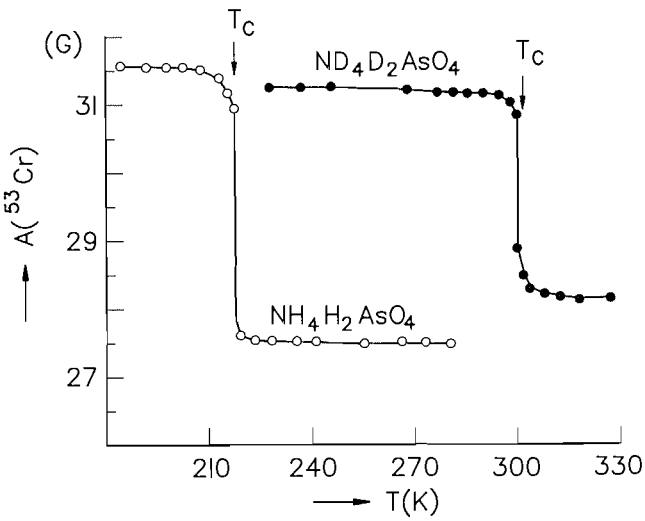

FIG. 6. Temperature dependence of the ^{53}Cr splitting for H//c in ADA and DADA.

reference salt ($CuSO_4 \cdot 5H_2O$) in the other. The latter was maintained at room temperature. The dielectric response of the sample was studied by following the change in the Q-factor of the microwave cavity, as monitored by observing the change in the intensity of the EPR signal from the reference salt. The dielectric loss and the CrO_4^{3-} signals could be studied independently at a given temperature. Alternatively, for a given magnetic field H_0, the dielectric loss could be recorded as a function of the sample temperature. Such a plot for ADA is shown in Fig. 8. The temperature dependence of the static dielectric constant was also measured with a capacitance bridge, as discussed elsewhere (17). Excellent quantitative agreement was found between the static and the microwave dielectric measurements. In particular, a thermal hysteresis of about 2° was found for the dielectric as well as the CrO_4^{3-} EPR measurements (17).

The role of the inhomogeneity in the sample temperature, arising from thermal gradients in the gas flow system, in causing

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 112.217.228.212 on 09/07/12

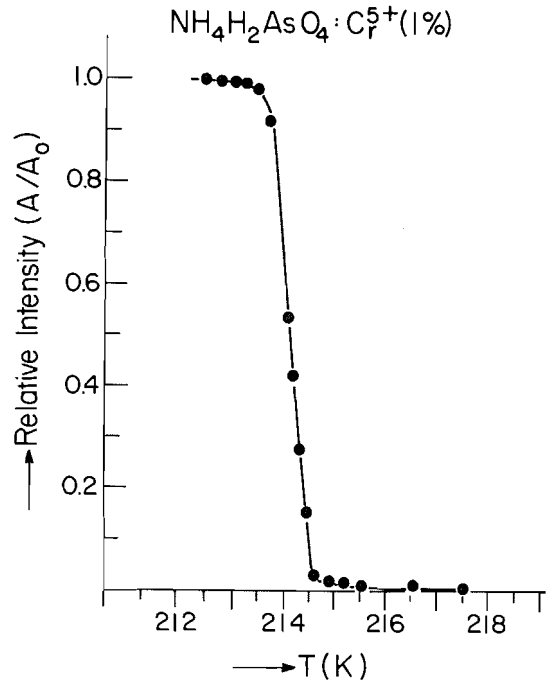

FIG. 7. Temperature dependence of the intensity of the A-type signals in ADA. A_0 is the intensity well below T_c.

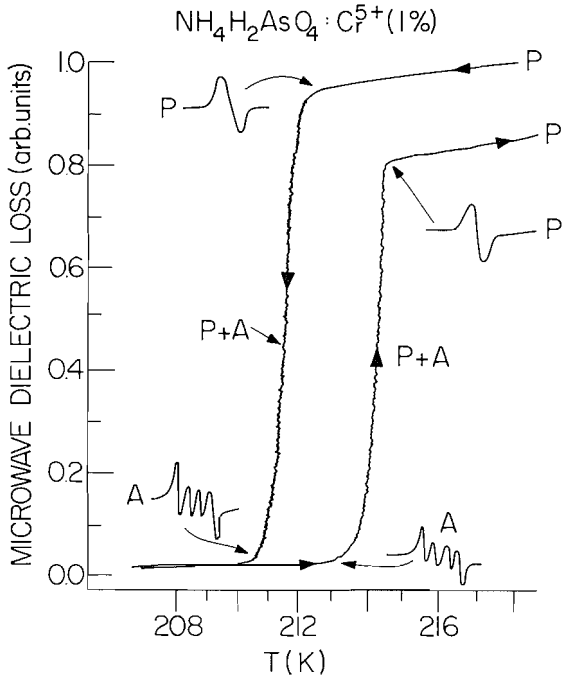

FIG. 8. Temperature variation of the dielectric loss (L) at 9.5 GHz for ADA. A sharp change in the dielectric loss is seen to occur at T_c and a hysteresis of $\sim 2.6 \pm 0.2$ K is noted. The microwave dielectric loss measurements agree with the static dielectric constant measurements.

the observed coexistence of the high temperature and the low temperature spectra was checked by reducing the sample size. No significant effect of the sample size on the spectral coexistence was observed. In addition, runs made with temperature sensors above and below the crystal indicate that the inhomogeneity does not exceed 0.1 K, a value smaller than the coexistence range. We thus conclude that the spectral coexistence is inherently related to the sample behavior near the phase transition, although the presence of the paramagnetic probe might cause some (perhaps small) perturbation.

The detection of A-type signals above T_c, the rapid growth of these signals as T approaches T_c (from $T > T_c$), and the fact that these are the only signals well below T_c imply the following picture of a lattice undergoing antiferroelectric transition. As $T \rightarrow T_c + 3°$ from above, molecular "islands" are formed in the "sea" of the paraelectric host lattice. The symmetry of molecules in these islands corresponds to that of the low-temperature (antiferroelectric) phase. As $T \rightarrow T_c$, these islands rapidly grow in size, and below $T_c - 3°$ they grow to occupy the whole crystal, thus setting up the long-range ordered domains in the whole sample.

The detection of the ordered regions above T_c is analogous to the ^{75}As NQR-perturbed NMR results (18) for $T > T_c$ in the ferroelectric KH_2AsO_4. The present study, however, constitutes the first detection of the "ordered clusters" in the paraelectric phases of the antiferroelectric compounds, and thus shows that the ferroelectric and the antiferroelectric phase changes involve essentially similar macroscopic transformations near T_c. Moreover, the corresponding NQR (nuclear quadrupole resonance) detection cannot be made for the phosphates, since ^{31}P has no quadrupole moment. There is no such restriction on EPR.

Proton dynamics in ADP and ADA

To measure the changes in the motion of the protons near T_c, the temperature dependence of the proton shfs was investigated for ADP and ADA. Figure 9 shows the temperature dependence for ADP, H//c. It is seen that well above T_c, the shfs is a 1:4:6:4:1 quintet, indicative of equal coupling to the four H-bond protons surrounding the CrO_4^{3-} probe. As $T \rightarrow T_c$, the motion of the protons slows down on the EPR time scale and the spectra change to a 1:1:1:1 quartet, showing that the CrO_4^{3-} has lost its $\bar{4}$ symmetry, that the four H-bond protons are now chemically distinct, and that the couplings of two of the protons are too small to be resolved by EPR. These two protons can thus be labeled as the "far" protons and the other two protons, causing the quartet of lines, are the "close" protons. The measured close proton couplings are $a_1 = 11.3$ and $a_2 = 6.1$ G and the far proton couplings were taken as $a_3 = -1.6$ and $a_4 = -1.0$ G for H//c, in accordance with the ENDOR measurements on ADA (8). The relative magnitudes and signs of (a_1, a_2) and (a_3, a_4) were also deduced from our observation that the high-temperature quintet was $(16 \pm 1)\%$ narrower than the low-temperature quartet as measured by the distance between the centers of the outermost lines. This conclusion follows because the width of the quintet is $a_1 + a_2 + a_3 + a_4$ while that of the quartet is $a_1 + a_2$. Thus $a_3 + a_4$ must have the sign opposite to that of $a_1 + a_2$. It may be noted here that while this relative sign information is implicit in the ENDOR data (8), the ENDOR results were obtained at 1.4 K and on ADA. The procedure used here gives the signs for ADP and ADA at the temperatures of interest to this study.

The temperature-dependent spectra were analyzed by employing the modified Bloch equations for a 4-site exchange process, as discussed previously (5). The actual calculated spectra are shown in Fig. 9. These are the results of adjusting the parameters τ and T_2, where τ is the correlation time for the protonic motion and T_2 is the inverse linewidth parameter. The agreement between the calculated and the observed spectra (also shown in Fig. 9) was found to be good except in the vicinity of T_c, perhaps due to the superposition of the high temperature and the low temperature spectra.

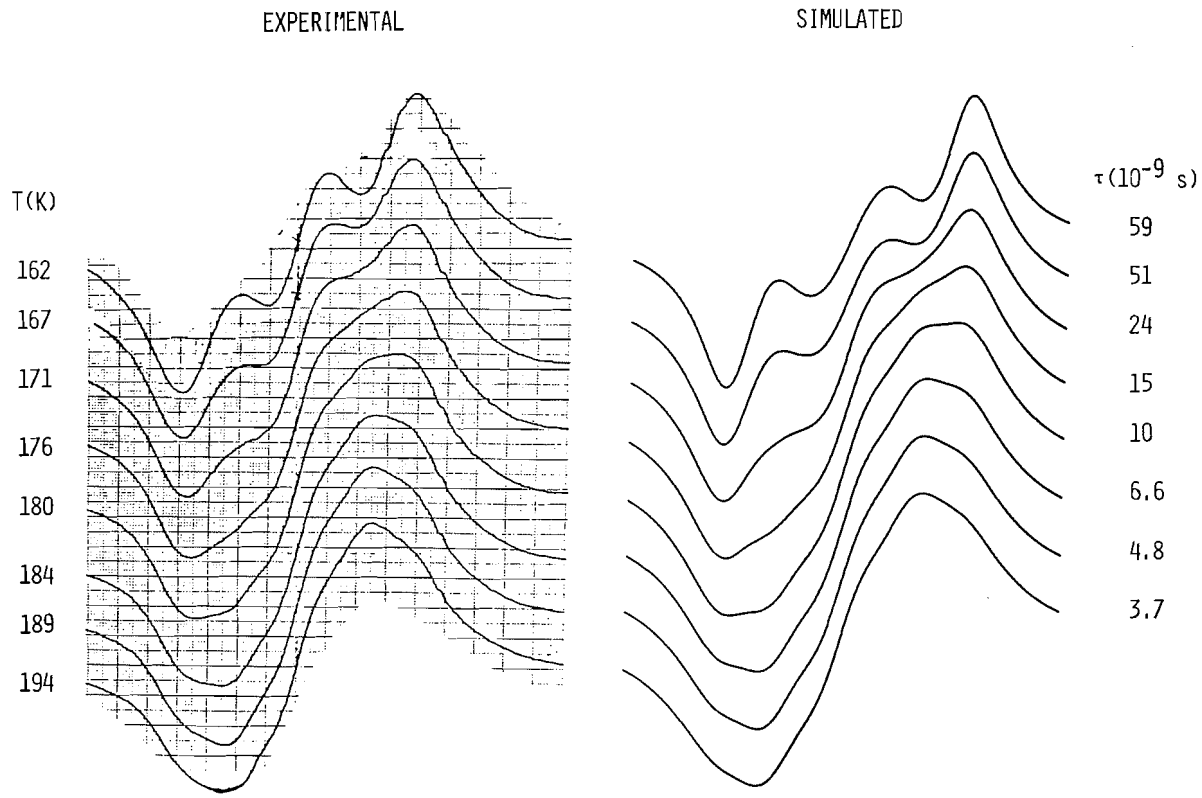

FIG. 9. Temperature dependence of proton superhyperfine splittings for CrO_4^{3-} in ADP, H//c: left, observed, and right, computer simulated.

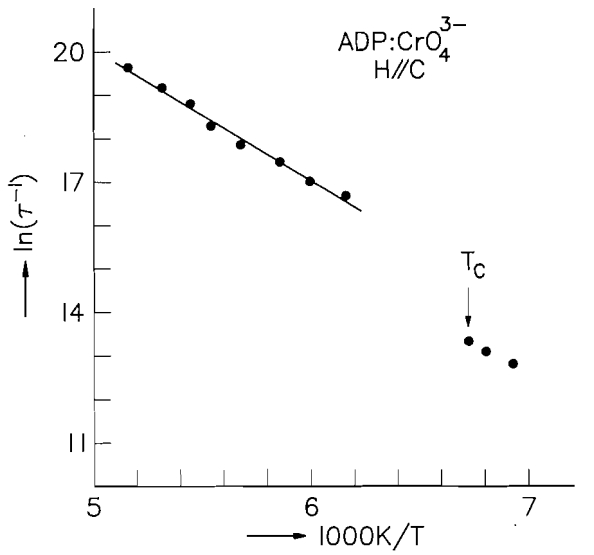

FIG. 10. Temperature dependence of the correlation time (τ) for the motion of protons around the CrO_4^{3-} center in ADP, H//c.

The derived values of τ are plotted as a function of temperature in Fig. 10. It is seen that τ varies rapidly in this temperature range with a larger increase at T_c. The average value of the slope, i.e., the Arrhenius activation energy, and the preexponential factors are (0.27 ± 0.05) eV and 2.2×10^{-16} s for $T > T_c$ and (0.23 ± 0.05) eV and 4.1×10^{-14} s for $T < T_c$, respectively, for ADP.

Unfortunately, it was not possible to obtain more values of τ close to T_c. Thus the nature of the non-Arrhenius behavior remains unclear. Non-Arrhenius behavior has been reported previously for AsO_4^{3-} in ADA (19) and KDA (19) (KH_2AsO_4), CrO_4^{3-} in KDP (20) (KH_2PO_4), and SeO_4^{3-} in KDP (21, 22)[2] but this has been far from T_c. Where results were obtained close to T_c no distinct unusual behavior was evident. However proton spin-lattice relaxation times (23) for NH_4^+ in $NH_4H_2PO_4$ show a sharp discontinuity at T_c reflecting a first-order phase transition. It may be that the present measurements for the hydrogen-bonded protons arise from similar effects.

Finally, the temperature dependence of the proton shfs in ADA is shown in Fig. 11. It was noted that here the quintet–quartet transition takes place within 2° of T_c (~216 K), and in the same region where the high and the low temperature spectra coexist, and the proton dynamics could be observed over only a few degrees. However, a comparison of the observed spectra with the calculated spectra shows that for ADA, $\tau = 5 \times 10^{-7}$ s at 218 K, which is of the same order of magnitude as that for ADP near T_c, thereby showing the similarity in the microscopic behavior of ADP and ADA near T_c.

Conclusions

This study establishes the following:

(a) CrO_4^{3-} can serve as sensitive probes of the antiferroelectric order in $NH_4H_2AsO_4$, $NH_4H_2PO_4$, and their deuterated analogs. Earlier failure (2) to observe similar changes via EPR of AsO_4^{4-} and SeO_4^{3-} can be ascribed to the fact that these probes do not have the same charge and site symmetry as those of the units they replace (PO_4^{3-} or AsO_4^{3-}). This important point does not seem to have been emphasized and (or) demon-

[2]This paper (22) also discussed the results for SeO_4^{3-} in KDP, but the activation data near T_c, as reported in ref. 21 could not be verified: R. Blinc, private communication.

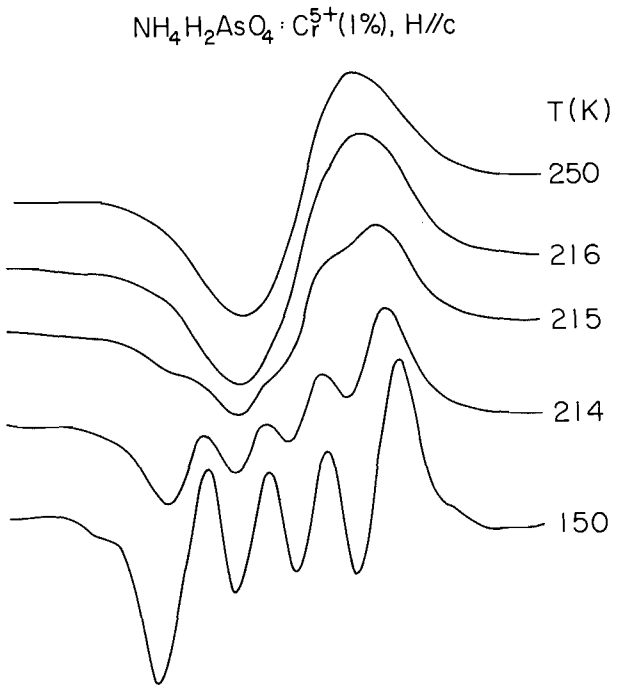

FIG. 11. Temperature dependence of the proton superhyperfine splittings for CrO_4^{3-} in ADA, H//c.

strated earlier, as also the use of monodomain antiferroelectric samples.[3]

(b) As the temperature is lowered to approach T_c, the paraelectric phase lattice starts to develop clusters of molecules that exhibit the symmetry and dynamics of the antiferroelectric phase. These clusters then grow rapidly below T_c and fill the whole lattice, leading to the antiferroelectric order in the sample.

(c) The motion of the hydrogen bonds around CrO_4^{3-} shows a strong deviation from Arrhenius behavior near T_c. Such behavior in the activation energy has been observed (23) for the NH_4^+ motion by NMR, ^1H T_1 measurements. The corresponding ^{31}P data would be important to obtain, since their comparison with the Cr EPR would show how faithful the CrO_4^{3-} probe is in representing the PO_4^{3-} unit. These results can provide experimental data for recent theoretical models (22) of the motion of paramagnetic probes in lattices undergoing order–disorder transitions.

(d) An important corollary from the above results is that the SeO_4^{3-} center should detect critical effects near T_c of the corresponding ferroelectric compounds (such as KH_2PO_4 and KD_2PO_4) but CrO_4^{3-} and AsO_4^{4-} should not, as pointed out here in the introduction. Of course, CrO_4^{3-} and AsO_4^{4-} do not show (2) marked changes near T_c of the ferroelectrics. Some evidence for changes in the EPR of SeO_4^{3-} in KH_2PO_4 has been reported (21) but the extensive proton superhyperfine structure makes the results hard to interpret. KD_2PO_4:SeO_4^{3-} could be a much better example, in particular because externally applied electric fields could be used to verify that the clusters observed above T_c do indeed represent a long-range order within the cluster, and are not due to a frozen molecular motion of the probe. Such experiments are in progress in our laboratory[4] and elsewhere (25)[5] as are also efforts to study the effects of applied pressure in the antiferroelectric case since there an electric field will have little or no effect.

(e) The ground state of CrO_4^{3-} has been found to derive mainly (~90%) from the Cr $d_{x^2-y^2}$ orbital, rather than the d_{z^2} orbital expected from a ligand field theoretical approach. Further theoretical calculations to explain this discrepancy would be helpful to understand the stabilization process of new paramagnetic probes.

[3]While the exact mechanism that causes the samples to be monodomain is not understood, the samples can be prepared by a rapid crystallization over a few hours, as against a few days for normal crystal growth of these compounds. It was also observed that temperature cycling of the samples through T_c enhances the monodomain character. Further studies are in progress to understand the mechanism of this intriguing (and spectroscopically useful) phenomenon.

[4]A preliminary report of the observation of ferroelectric clusters in paraelectric KD_2PO_4 via electric field effects on the EPR of SeO_4^{3-} was presented at the Fifth International Meeting on Ferroelectricity, College Park, Pennsylvania (1981). See ref. 24.

[5]Those authors report on the coexistence of high-temperature and low-temperature spectra of SeO_4^{3-} in KD_2PO_4. However, electric field effects were not studied.

LEED crystallographic studies for the chemisorption of oxygen on the (100) surface of copper

H. C. ZENG, R. A. MCFARLANE, R. N. S. SODHI, AND K. A. R. MITCHELL

Department of Chemistry, University of British Columbia, 2036 Main Mall, Vancouver, B.C., Canada V6T 1Y6

Received January 16, 1988

This paper is dedicated to Professor Charles A. McDowell on the occasion of his seventieth birthday

H. C. ZENG, R. A. MCFARLANE, R. N. S. SODHI, and K. A. R. MITCHELL. Can. J. Chem. **66**, 2054 (1988).

Intensity analyses with low-energy electron diffraction (LEED) are reported for surface structures obtained by adsorbing submonolayer amounts of oxygen on the (100) surface of copper. It is found for chemisorption on the four-coordinate hollow sites that the correspondence between experimental and calculated intensity-versus-energy curves, for 10 diffracted beams, is slightly better for coplanar adsorption than for adsorption about 0.75 Å above the surface (the latter model is essentially as proposed previously by both SEXAFS and photoelectron diffraction). Nevertheless, in neither of these contrasting situations is the agreement sufficient to conclude that the structural analysis is complete. Evidence is presented that nearly coplanar chemisorption, in combination with a missing row model, can accommodate a number of structural features for this system, including the existence of the $(2\sqrt{2} \times \sqrt{2})45°$–O phase, beam splittings resulting from antiphase domain boundaries, and the structural analogy noted in other studies between the $(2\sqrt{2} \times \sqrt{2})45°$–O phase and the stepped nature of the (410) copper surface which can form by faceting in oxygen. Considerations of O–Cu surface bond lengths, guided by those in bulk Cu_2O, suggest that additional lateral relaxations are likely in the topmost copper layer. This study provides no support for the O chemisorption occurring in tetrahedral-type sites.

H. C. ZENG, R. A. MCFARLANE, R. N. S. SODHI, et K. A. R. MITCHELL. Can. J. Chem. **66**, 2054 (1988).

On a effectué les analyses d'intensité de diffractions électronique de basse énergie (DEBE) pour des structures de surface obtenues par l'adsorption de quantités ne correspondant pas à des monocouches d'oxygène sur la surface (100) du cuivre. Pour la chemisorption sur les sites vides de coordination-4, examinée à l'aide de 10 faisceaux de diffraction, on a trouvé que la correspondance entre les courbes expérimentales et les courbes calculées de l'intensité vs l'énergie est légèrement meilleure pour l'adsorption coplanaire que pour l'adsorption à environ 0,75 Å au-dessus de la surface (ce dernier modèle est essentiellement celui qui avait été proposé antérieurement tant par SEXAFS que par diffraction électronique). Toutefois, ni l'une ni l'autre de ces situations pourtant très différentes ne conduit à une concordance suffisante pour conclure que l'analyse de structure est complète. On présente des données suggérant que de la chemisorption coplanaire, combinée avec un modèle impliquant une couche manquante, peut accommoder un certain nombre de caractéristiques de structure de ce système, y compris l'existence de la phase $(2\sqrt{2} \times \sqrt{2})45°$–O ainsi que la nature en escalier de la surface (410) du cuivre qui peut se former lorsqu'elle est facettée dans de l'oxygène. Des considérations concernant les longueurs des liaisons Cu–O de surface, basées sur celles que l'on retrouve dans du Cu_2O, suggèrent que les relaxations latérales additionnelles sont probables dans la couche supérieure du cuivre. Cette étude ne fournit accun support pour l'hypothèse selon laquelle la chemisorption des O se fait sur des sites de type tétraédriques.

Introduction

It is a special pleasure to contribute to this issue honouring Professor C. A. McDowell, particularly since he provided much encouragement to the setting up of our surface science laboratory in 1975. That same year Professor McDowell organized a Faraday Discussion Meeting titled "Electron Spectroscopy of Solids and Surfaces", and a perusal of the presentations at that meeting (1) shows several associated with the chemisorption of oxygen on the (100) surface of copper. Over the years this system has been subjected to numerous investigations, especially for the chemisorption phases which are designated as $(\sqrt{2} \times \sqrt{2})45°$ (or $c(2 \times 2)$) and $(2\sqrt{2} \times \sqrt{2})45°$ according to the diffraction patterns observed with low-energy electron diffraction (LEED).[1] These phases are often reported to form sequentially, with increasing oxygen coverage, prior to the onset of bulk oxide formation (3, 4). However, another view of the chemisorption regime is that the $(2\sqrt{2} \times \sqrt{2})45°$ structure is always the stable form, and $c(2 \times 2)$ patterns are only observed when the ordering is insufficient to establish measurable intensities for the quarter-order beams (5).

Information on the chemisorption phases has been provided by a range of techniques including LEED (5–14), X-ray photoelectron spectroscopy (XPS) (15), work function measurements (10, 11), ion scattering (16, 17), secondary ion mass spectrometry (18), high-resolution electron energy loss spectroscopy (19, 20), photoelectron diffraction (21), and surface extended X-ray absorption fine structure (SEXAFS) (22). Several studies have suggested that oxygen penetrates below the top copper layer, especially for the $(2\sqrt{2} \times \sqrt{2})45°$ surface (6, 8, 10, 11) but other evidence has pointed to the $(\sqrt{2} \times \sqrt{2})45°$ and $(2\sqrt{2} \times \sqrt{2})45°$ surfaces as having related structures (12, 21). Attempts at quantitative structural analyses have not yet supported the model of oxygen penetration; nevertheless the structural models reported are wide-ranging. For example, determinations by SEXAFS (22) and photoelectron diffraction (21) indicate that O atoms adsorb close to 0.7 and 0.8 Å, respectively, above hollow sites of four-fold coordination (hereafter referred to as 4*f* sites), whereas an analysis with angular resolved XPS suggests O is coplanar with the topmost metal layer (15). Some preliminary support for a nearly-coplanar structure was provided by LEED (12), although an earlier study, in combination with ion scattering measurements, proposed that bridge bonding may occur (13, 16), a view that received indirect support from observations of beam splitting associated with antiphase domain boundaries (14).

Methods such as SEXAFS, photoelectron diffraction, and angular resolved XPS apparently emphasise the immediate

[1]The notations conventionally used in surface crystallography were introduced by Wood (2).

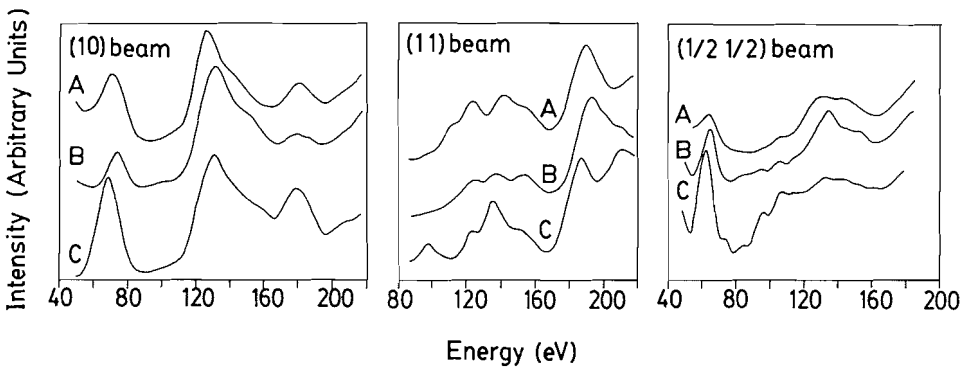

FIG. 1. Comparisons of $I(E)$ curves for the (1,0), (1,1), and (1/2,1/2) beams measured at normal incidence from the three surfaces Cu(100)–($\sqrt{2} \times \sqrt{2}$)45°–N (curves designated A), Cu(100)–($\sqrt{2} \times \sqrt{2}$)45°–O (curves designated B) and Cu(100)–($2\sqrt{2} \times \sqrt{2}$)45°–O (curves designated C).

neighbourhood of the adsorbate, while giving only limited information about any relaxations or reconstructions of the metal surface. By contrast, the latter contributions can perhaps be assessed more directly with LEED, and this provides a motivation for our undertaking the current work. A LEED crystallographic analysis involves measuring intensity-versus-energy ($I(E)$) curves for the set of diffracted beams which emerge from the surface, and making comparisons with the corresponding curves calculated for various structural models. The surface geometry is then determined by the conditions for which the calculated curves give the best match to the set of experimental $I(E)$ curves (23–25).

New LEED crystallographic analyses have been undertaken for the oxygen on Cu(100) system with the hope of clarifying some conflicting information which has emerged recently for this surface. This paper also addresses some associated points. The first relates to the tendency for oxygen to form the ($2\sqrt{2} \times \sqrt{2}$)45° structure on Cu(100), and this suggests that there should be some emphasis on those structural models which can naturally generate this particular translational symmetry. A second point, which also distinguishes this surface from the corresponding structure formed on Ni(100), concerns the tendency for the Cu(100) surface to roughen in the presence of oxygen (26), and ultimately to form (410) facets (27). In this regard, a structural similarity has been noted between the ($2\sqrt{2} \times \sqrt{2}$)45° superstructure formed by oxygen on Cu(100) and the stepped nature of the (410) surface (28, 29).

Experimental

The sample preparation, cleaning procedures, and analysis chamber used in this work were the same as those detailed in an earlier LEED study from this laboratory for the clean (311) surface of copper (30). The prepared Cu(100) surface, which showed a sharp (1 × 1) LEED pattern after cleaning and annealing, was exposed to reagent grade oxygen with continued pumping according to two alternative procedures which were used to form structures which manifests ($\sqrt{2} \times \sqrt{2}$)45° LEED patterns. The first procedure involved exposing the clean surface to 1×10^{-6} Torr of oxygen for 5 min while heating the surface to 300°C, followed by annealing at the same temperature for a further 5 min. In the second procedure the adsorption was done at room temperature for 5 min, while exposing the surface to 8×10^{-6} Torr of oxygen activated with the ion gun at 200 V, followed by a short anneal at 400°C. Most often this latter procedure gave the sharpest ($\sqrt{2} \times \sqrt{2}$)45° LEED patterns. LEED patterns corresponding to two orthogonal domains of ($2\sqrt{2} \times \sqrt{2}$)45°-type formed on exposing to oxygen at the above pressures for longer times, typically around 8 min, although there could be some variability in the conditions that gave the ($2\sqrt{2} \times \sqrt{2}$)45° patterns in particular cases.

Diffracted beam $I(E)$ curves were measured with a video LEED analyser (31) as detailed in a previous paper from this laboratory (32). For the Cu(100)–($\sqrt{2} \times \sqrt{2}$)45°–O surface structure, a total of 10 independent $I(E)$ curves were measured over the energy range 50–220 eV for the beams (1,0), (1,1), (1/2,1/2) at normal incidence, (0,0), (1,0), (0,1), (−1,1), (1/2,1/2), (−1/2,1/2), (1/2,3/2) at an off-normal direction where the polar angle is 15° and the azimuthal direction is [01$\bar{1}$] with respect to the crystal axes (i.e. the LEED pattern shows reflection symmetry about the [10] line). Corresponding data have also been measured from a Cu(100)–($2\sqrt{2} \times \sqrt{2}$)45°–O surface structure. Some comparisons are shown in Fig. 1 between these $I(E)$ curves measured at normal incidence and those similarly measured from the Cu(100)–($\sqrt{2} \times \sqrt{2}$)45°–N surface structure (33).

Calculations

Methods used

The LEED intensity calculations were made with the multiple scattering programs provided by Van Hove and Tong (34), and the procedures used are similar to those described in our recent structural analysis for the Cu(100)–($\sqrt{2} \times \sqrt{2}$)45°–N surface (33). The potential in each structural model was approximated with the muffin-tin form, and the scatterings of individual atoms were summed to give the layer scatterings. Layers were then stacked to form each structural model considered, the method for combining the layers being dependent on the interlayer spacings involved (23, 25). Briefly, layers were combined with the renormalised forward scattering method when interlayer spacings are 0.9 Å or greater, the full matrix inversion procedure was used to form "composite" layers where spacings are less than 0.6 Å, and the layer-doubling method was applied in intermediate situations (34).

The atomic potential in the substrate was characterized by phase shifts (up to $\ell = 7$) derived from a band structure potential for copper (35), and the real part of the constant potential (V_{or}) between the muffin-tin spheres was initially set at −10.0 eV for both the surface layer and the bulk. However values of V_{or} could be effectively refined later during the comparisons of experimental and calculated beam intensities. The oxygen phase shifts used were those derived by Demuth *et al.* (36) from a superposition potential, and the imaginary part (V_{oi}) of the potential between all atomic spheres was kept constant at −5.0 eV. The Debye temperatures were taken as 343 and 684 K for copper and oxygen, respectively. Appropriate domain averag-

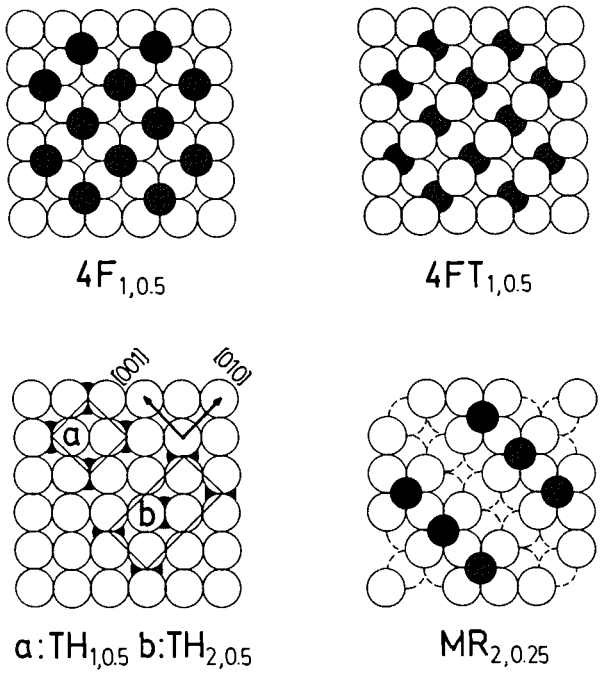

FIG. 2. Schematic indications of some models discussed in text. The dark filled circles represent oxygen atoms and the open circles formed by continuous and dashed lines correspond to copper atoms respectively in the topmost layer and the second layer of the ideal clean metal surface.

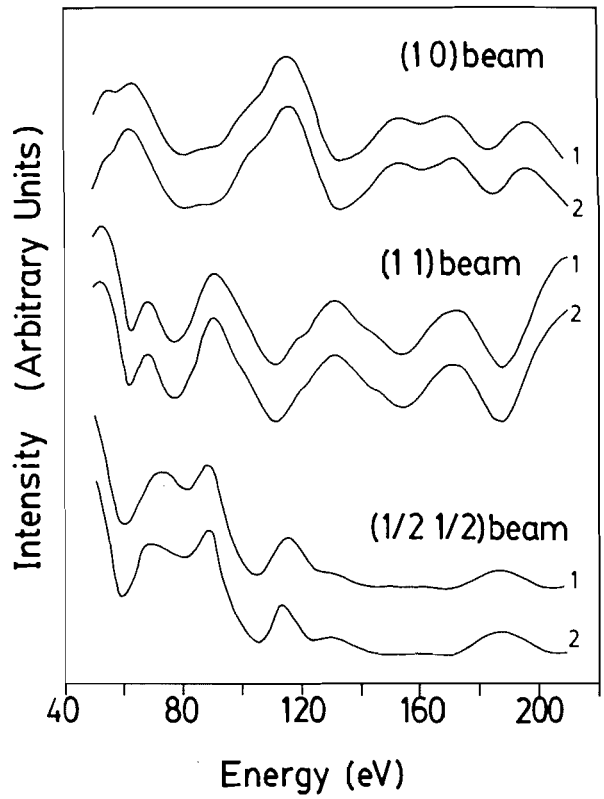

FIG. 3. Comparison of $I(E)$ curves at normal incidence for the (1,0), (1,1), and (1/2,1/2) beams calculated for the O on Cu(100) models designated $TH_{1,0.5}$ (curves identified by 1) and $TH_{2,0.5}$ (curves identified by 2) with d_{O-Cu} = 1.05 Å.

ing was done to the calculated $I(E)$ curves prior to comparing with those from experiment.

Models investigated

Figure 1 indicates that the $I(E)$ curves measured for the Cu(100)–$(\sqrt{2} \times \sqrt{2})45°$–O and Cu(100)–$(2\sqrt{2} \times \sqrt{2})45°$–O surfaces are relatively similar to those measured previously for Cu(100)–$(\sqrt{2} \times \sqrt{2})45°$–N (33). Further, since O and N have similar scattering factors (37), these three surfaces are likely to have structural features in common. The models considered for the $(\sqrt{2} \times \sqrt{2})45°$–O surface therefore start from the premiss that, as for N, adsorbed O atoms occupy 4f hollow sites. From this starting point other models can be produced involving lateral and vertical relaxations of copper atoms, as well as missing rows of copper atoms as indicated in Fig. 2. Missing-row models merit consideration since they can naturally yield $(2\sqrt{2} \times \sqrt{2})45°$ structures, and their involvement may help the rearrangement to the stepped Cu(410) surface formed during faceting. In addition, because oxygen atoms in crystalline Cu_2O and CuO are surrounded tetrahedrally by four copper atoms (38), other models are considered where O atoms occupy tetrahedral holes between the first and second layers of the Cu(100) surface, as well as relaxed models with distorted tetrahedral holes for the O atoms. Consideration is not given here to models with mixed 4f and bridge-site adsorption, as proposed by Onuferko and Woodruff (13), because they are not strongly supported by the $I(E)$ curves calculated in that work.

The basic structures considered in this study are distinguished by designations of the types $X_{n,m}$. In this notation, X identifies the type of model and is represented by 4F for O adsorption in regular 4f hollow sites, by TH for adsorption in tetrahedral holes between the first and second copper layers, by MR when O adsorbs in 4f sites but with missing rows of copper atoms, and by 4FT when the 4F structure with O initially coplanar with the neighbouring copper atoms is subjected to a tetrahedral-type distortion. The subscript n has a value 1,2 for the $(\sqrt{2} \times \sqrt{2})45°$, $(2\sqrt{2} \times \sqrt{2})45°$ structures respectively, while m indicates the O coverage as a fraction of a monolayer (i.e. ratio of number of O atoms to number of Cu atoms in the top layer for the ideal metal surface). Finally, a prime is added to the model designation (e.g. TH′) when additional lateral relaxations are included for the copper atoms in the vicinity of the surface. These relaxations act to increase the neighbouring O–Cu bond lengths. For example, for the models designated MR′, half the atoms in the top copper layer are laterally displaced perpendicular to the line of the missing row; similarly for the TH′ models copper atoms in the top two layers are displaced in the [010] and [001] directions. The specific models examined in this work are detailed in Table 1; the headings d_{O-Cu} and d_{Cu-Cu} are respectively the topmost O–Cu interlayer spacing and the first Cu–Cu spacing.

Results and discussion

Initial comparisons of experiment and calculation

Comparisons of $I(E)$ curves measured from Cu(100)–$(\sqrt{2} \times \sqrt{2})45°$–O, for normal incidence, with those calculated for the range of models considered for tetrahedral hole adsorption (i.e. the models TH and TH′ in Table 1) showed no reasonable levels of correspondence as assessed both by visual inspection and by use of the reliability index (R_p) introduced by Pendry (39). Therefore this model does not appear relevant to this chemisorption system, an observation which is in general agreement with the previous observations (3, 4) that bulk oxide formation occurs at much higher oxygen exposures than considered here. Nevertheless Fig. 3 reports $I(E)$ curves calculated for the $TH_{1,0.5}$ and $TH_{2,0.5}$ models, with a constant

*This model has 1/2 monolayer each of inequivalent O atoms designated O_1 and O_2.

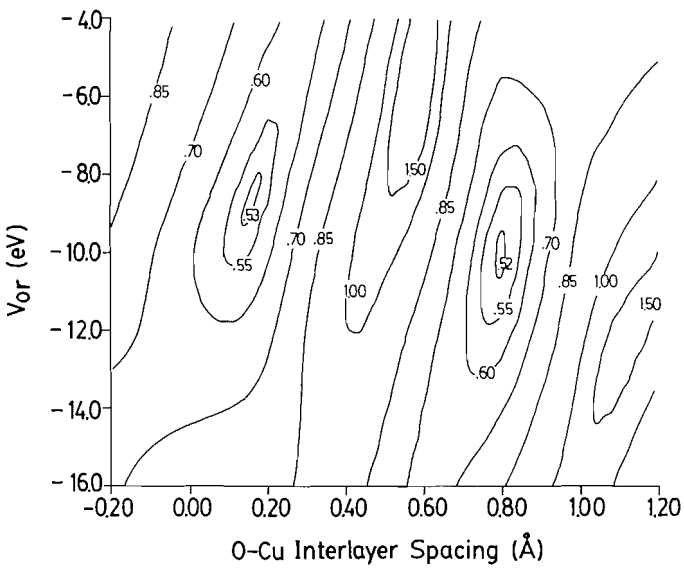

FIG. 4. Contour plot of R_p versus V_{or} and the O–Cu interlayer spacing for normal incidence data and $4F_{1,0.5}$ models of O on Cu(100). All neighbouring Cu–Cu interlayer spacings in the calculations equal 1.81 Å.

local geometry, using the approach applied previously for the CO on Pd(100) system (40). The close similarity of the curves for each beam designation reinforces arguments of Yang *et al.* (12) regarding the stability of $I(E)$ curves for corresponding beams when the local coordination is constant but the overall translational symmetry varies. The original observations of this behaviour emphasized the constancy of $I(E)$ curves for fractional-order beams, but in this case it is clear that the curves for corresponding integral beams are also closely similar.

The reliability index R_p is defined (39) so that the closer the correspondence between the sets of $I(E)$ curves being compared the smaller its value. Figure 4 shows for the $4F_{1,0.5}$ model type a contour plot of R_p versus V_{or} and d_{O-Cu}, the topmost O–Cu interlayer spacing, for the normal incidence data when the first Cu–Cu spacing (d_{Cu-Cu}) is held at the bulk value (1.81 Å). Two local minima are apparent with almost equal values. For one the oxygen atoms are held close to coplanarity with the topmost copper layer, while for the other the adsorbed atoms are about 0.75 Å above the 4f sites. Interestingly these two minima occur for conditions similar to the conclusions, noted in the Introduction, from studies with angular resolved XPS (O close to coplanar) and with photoelectron diffraction and SEXAFS (O close to 0.75 Å above surface). Nevertheless the comparison in Fig. 4 is not sufficient for distinguishing these two situations, one reason being that with coplanarity some vertical relaxation in the topmost Cu–Cu spacing would likely occur. Accordingly the contour plot of R_p in Fig. 5, made for the normal incidence data with O nearly coplanar with the topmost copper layer, suggests that the optimal value of d_{Cu-Cu} is close to 1.84 Å. The contour plot of R_p shown in Fig. 6 is calculated for both normal and off-normal incidence data with O held between 0.7 and 1.5 Å above the 4f sites. In this case R_p is minimized with d_{O-Cu} equal to 0.85 Å. Figure 7 compares some representative $I(E)$ curves from experiment, for both normal and off-normal incidence, with those calculated for three $4F_{1,0.5}$ models, namely: (*i*) d_{O-Cu} = 0.0, d_{Cu-Cu} = 1.88 Å; (*ii*) d_{O-Cu} = 0.7 Å, d_{Cu-Cu} = 1.81 Å; (*iii*) d_{O-Cu} = 0.9 Å, d_{Cu-Cu} = 1.81 Å. The minimum value of R_p calculated for the coplanar model for all 10 beams is 0.69; the corresponding values for models (*ii*) and (*iii*) are 0.76 and 0.75, respectively. Insofar as the best agreement between the experimental and calculated $I(E)$ curves corresponds to the smallest value of R_p, the coplanar model appears favoured. A similar conclusion may be reached from a visual comparison of the individual $I(E)$ curves shown in Fig. 7, although the correspondence remains far from ideal. We also made multiple-scattering calculations for one-monolayer ($\sqrt{2} \times \sqrt{2}$)45° models in which all the O atoms are held in 4f sites, but where half are coplanar with the topmost copper layer while the other half are held between 0.55 and 0.95 Å above the surface. These calculations showed much lower levels of correspondence with the experimental $I(E)$ curves, than those in Fig. 7, and so it seems safe to discount this type of inequivalent O adsorption.

Comparisons of ($\sqrt{2} \times \sqrt{2}$)45°–O and ($2\sqrt{2} \times \sqrt{2}$)45°–O structures

Overall the corresponding $I(E)$ curves measured in this work for the ($\sqrt{2} \times \sqrt{2}$)45°–O and ($2\sqrt{2} \times \sqrt{2}$)45°–O structures are quite similar (Fig. 1), and there is a broad agreement, at least

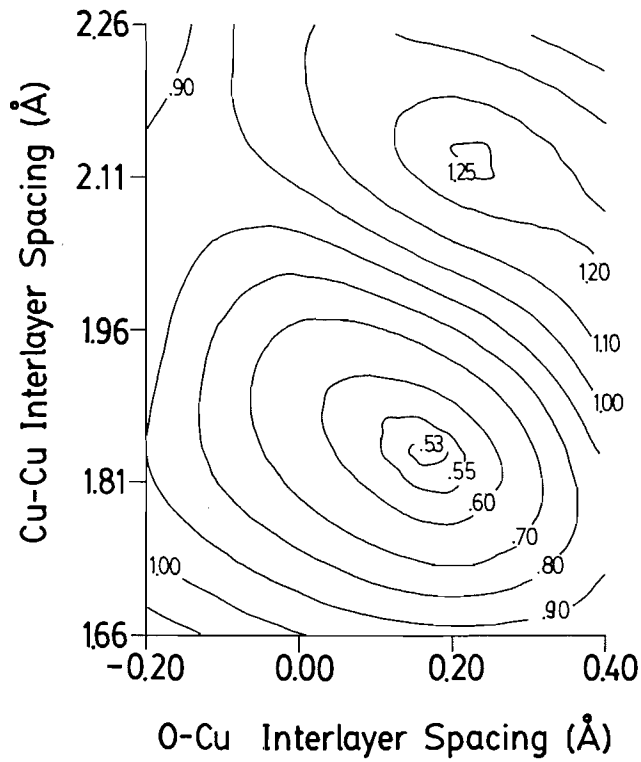

FIG. 5. Contour plot of R_p versus the topmost Cu–Cu interlayer spacing and the O–Cu interlayer spacing for normal incidence data and $4F_{1,0.5}$ models of O on Cu(100). V_{or} is fixed equal to −8.0 eV for these comparisons.

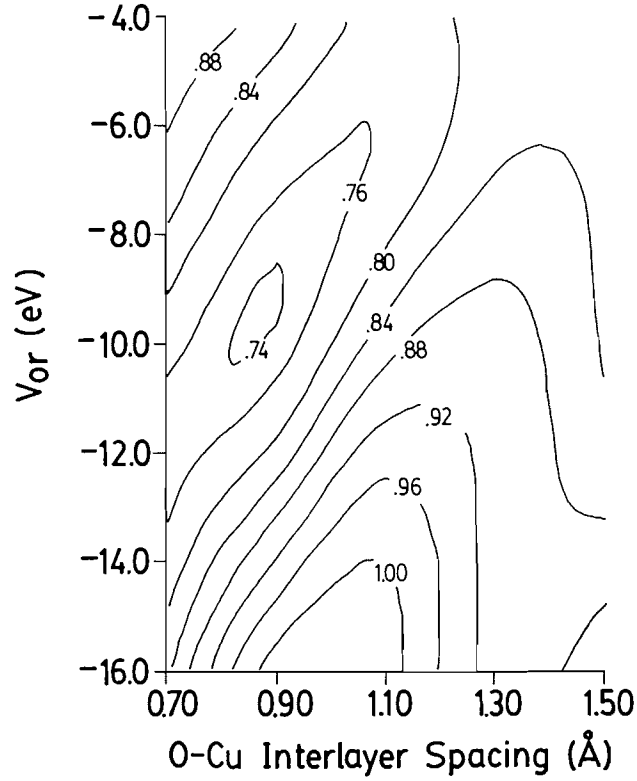

FIG. 6. Contour plot of R_p versus V_{or} and the O–Cu interlayer spacing for ten beams measured and for $4F_{1,0.5}$ models of O on Cu(100). All neighbouring Cu–Cu interlayer spacings in the calculations equal 1.81 Å.

in peak positions, with curves reported previously by Onuferko and Woodruff (13) and by Yang *et al.* (12). Certainly there is some variation in relative intensities, but we find such variations ourselves when making measurements from independently prepared surfaces which show a particular type of LEED pattern. Onuferko and Woodruff reported the existence of identical $I(E)$ curves from surfaces with the different translational symmetries, an observation that could be taken to support the contention of Mayer *et al.* (5) that only one structure, of $(2\sqrt{2} \times \sqrt{2})45°$ type, is produced throughout the oxygen exposure regime. Yang *et al.* (12), in contrast, report very similar $I(E)$ curves for the (1/2,1/2) beam, but somewhat different (1,0) and (1,1) beams, a situation similar to that found in the present work. Some evolution of $I(E)$ curves occurs with increasing coverage, particularly for the integral beams, although this appears more as a second-order effect.

The general similarity in peak positions for the half-order beams with changing translational symmetry (or perhaps just increasing surface order) suggests, in concert with the views of Yang *et al.* (12), that the environment of the chemisorbed O is essentially constant with the evolution (a conclusion that has also been reached from the photoelectron diffraction studies (21)). Whatever the initial situation, there is no doubt that ultimately chemisorbed O forms the $(2\sqrt{2} \times \sqrt{2})45°$ structure on Cu(100), and therefore it is important that consideration be given to structural models with this translational symmetry. Nevertheless, while emphasizing the basic aspects of the surface structures, as we do in this paper, and while recognizing that there is a general similarity in the $I(E)$ curves calculated for related $(\sqrt{2} \times \sqrt{2})45°$ and $(2\sqrt{2} \times \sqrt{2})45°$ models (e.g. Fig. 3), $I(E)$ curves measured from $(\sqrt{2} \times \sqrt{2})45°$ LEED patterns are compared here with $I(E)$ curves calculated for structural models with both types of translational symmetries.

Analysis of bond lengths

The contour plot in Fig. 5 suggests that the correspondence between experimental and calculated $I(E)$ curves is optimized with $d_{O-Cu} = 0.17$ Å and $d_{Cu-Cu} = 1.84$ Å. In this situation each O is bonded to one Cu atom (directly below) at 2.01 Å and the four Cu atoms at 1.81 Å, with the average of the five O–Cu bond lengths equalling 1.85 Å. This appears quite inconsistent with the structure of bulk CuO (38), for which each O is bonded to four Cu atoms in a distorted tetrahedral arrangement at an average distance of 1.92 Å. Even for the structure of bulk Cu_2O (38), in which the metal oxidation state is lower and therefore is more likely to be relevant to the low-coverage chemisorption situation, each O is bonded tetrahedrally to four Cu atoms at 1.85 Å. With the Brown–Altermatt expression (41)

$$[1] \quad r = r_o - 0.85 \log s$$

as used in an earlier report from this laboratory (42), the O–Cu distance for a unit bond valence (r_o) equals 1.59 Å. Therefore, when O (valency $v = 2$) is bonded to 5 neighbours ($n = 5$), the average bond valence is $s = v/n = 0.4$ and the corresponding average O–Cu bond distance is estimated to equal 1.93 Å. This suggests that further relaxations beyond those considered above may occur in the surface region for O on Cu(100) to make the average of the local O–Cu distances greater than 1.85 Å and closer to 1.93 Å.

The analysis in Fig. 5 uses just three beams and therefore the data base is insufficient to assert at this point whether the d_{O-Cu} spacing is really 0.17 Å as opposed, for example, to a smaller

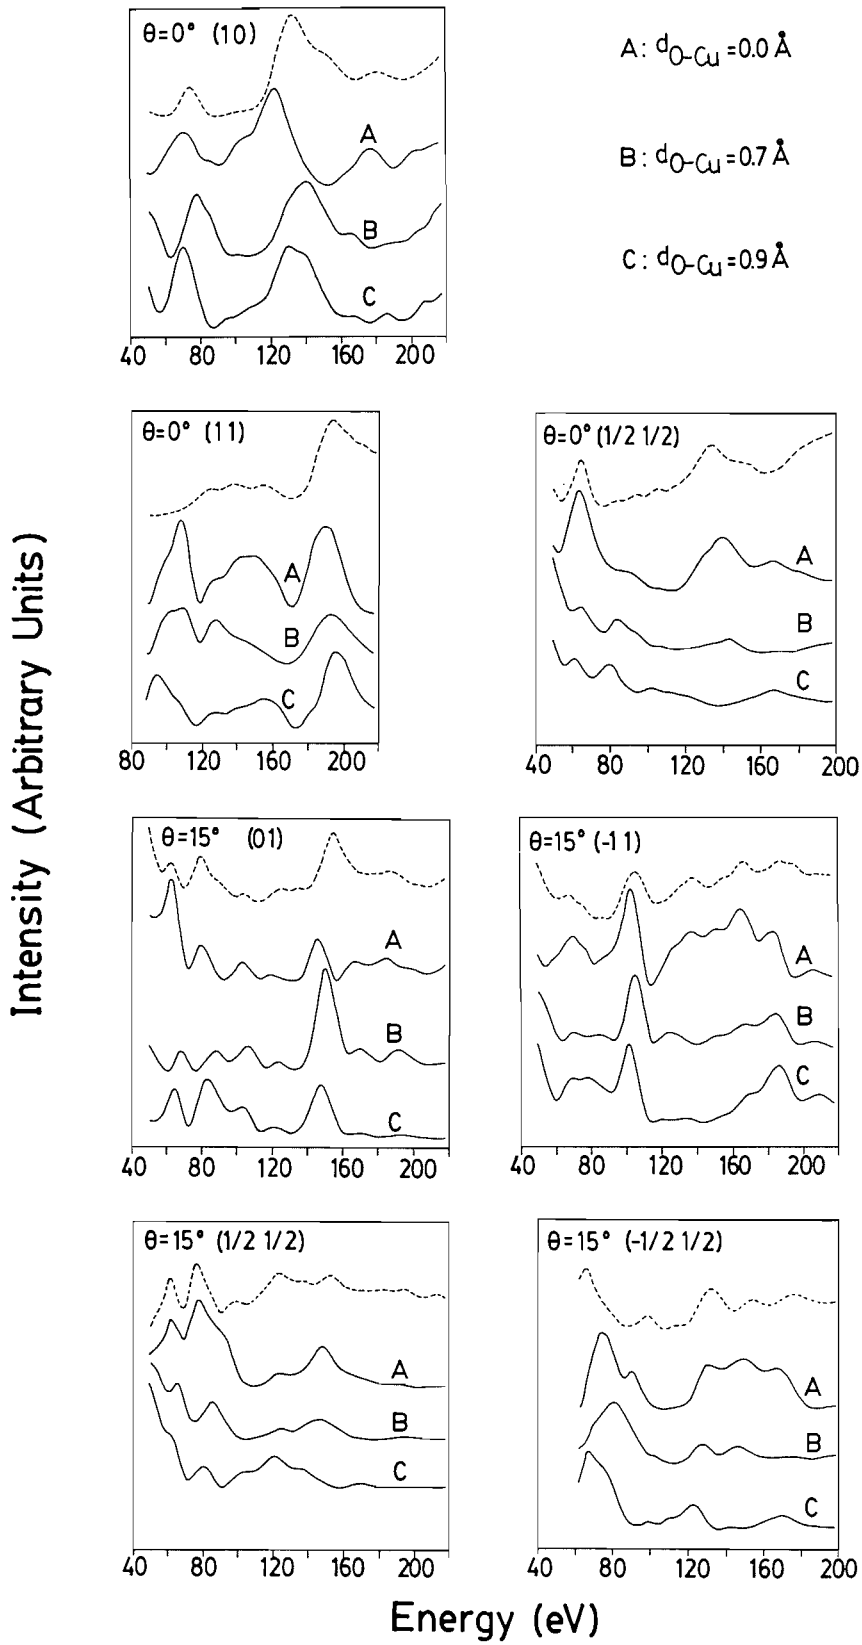

FIG. 7. Comparison of representative experimental $I(E)$ curves (dashed) from Cu(100)–($\sqrt{2} \times \sqrt{2}$)45°–O with those calculated for three 4F models: (*i*) $d_{O-Cu} = 0.0$, $d_{Cu-Cu} = 1.88$ Å (curves designated A); (*ii*) $d_{O-Cu} = 0.7$ Å, $d_{Cu-Cu} = 1.81$ Å (curves designated B); (*iii*) $d_{O-Cu} = 0.9$ Å, $d_{Cu-Cu} = 1.81$ Å (curves designated C). For these comparisons V_{or} is kept at the initial value of -10.0 eV.

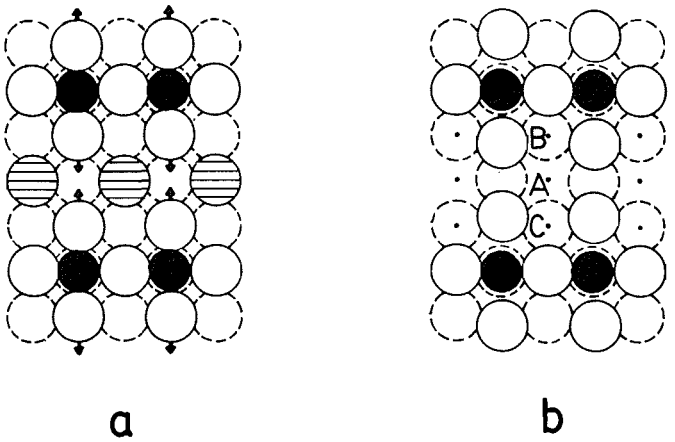

FIG. 8. Schematic illustration of formation of missing-row model of Cu(100) surface for 1/4 monolayer coverage of O atoms represented by dark filled circles. (*a*) With O atoms in coplanar 4f sites, some top layer Cu atoms are displaced laterally (indicated by arrows) and the Cu atoms represented by hatched circles are displaced to form the missing row. (*b*) Shows top layer and second layer Cu atoms after forming the missing row, and identifies sites designated A, B, C for further possible O chemisorption.

value. Since this paper aims just to assess the broader aspects of this surface structure, the current discussion will consider models with the chemisorbed O atoms coplanar with the topmost copper layer (this increases the layer symmetry with a consequent reduction in computing cost). Given the basic coplanar 4F model as a starting point, the average O–Cu bond distance may in principle be increased by vertical and lateral relaxations, either individually or in combination.

Variations on coplanar models

The 4FT model derives from the coplanar 4F model by having, for each O atom, two diagonally-related Cu atoms displaced vertically upwards while the other two are displaced downwards by the same amount (Fig. 2). This allows the O–Cu bond length to increase, although the rearrangement for the topmost metal structure can be substantial for only a small increase in the adsorbate bond length. For example, with the Cu atoms vertically displaced by 0.3 Å, the O–Cu distance increases by less than 0.03 Å. As judged both by R_p and visual comparisons, the $I(E)$ curves calculated for the 4FT models showed no improved correspondence with the experimental $I(E)$ curves relative to the situation for the coplanar 4F model. Therefore the 4FT models are not considered further in this paper.

In general with O chemisorption in coplanar 4f sites, lateral relaxations of the Cu atoms can provide an efficient route to increasing the average O–Cu bond length, although that may occur at the expense of strain in the metal structure. An exception is if the lateral relaxations are accompanied by removal of rows of Cu atoms. Missing row (MR) models have been postulated in other examples of O chemisorption, including that on the (110) surface of copper (43), and Fig. 8 outlines a possible scheme for the Cu(100) surface starting with a 1/4 monolayer coverage. The MR model shown naturally develops the $(2\sqrt{2} \times \sqrt{2})45°$ translational symmetry for the O chemisorption structure.

Missing row models

Figure 9 shows $I(E)$ curves calculated for normal incidence for some MR models, and it also allows comparisons with curves calculated for the corresponding coplanar 4F model. In all these models, the O atoms are in coplanar 4f sites and the topmost Cu–Cu interlayer spacings are fixed at 1.88 Å. Following the behaviour established in Fig. 3, and in other studies (12, 44), the $I(E)$ curves calculated for the $4F_{1,0.5}$ model are expected to be essentially identical to the corresponding model of $4F_{2,0.25}$ type. Then Fig. 9 indicates the trends in peak shapes and positions in calculated $I(E)$ curves on adding a missing row ($MR_{2,0.25}$), and on making two further independent changes, namely doubling the surface coverage, as in $MR_{2,0.5}$ where the extra O atom per unit mesh occupies the coplanar site A (Fig. 8), and introducing a lateral shift to the topmost copper layer ($MR'_{2,0.25}$). These changes can effect an improvement in the comparison with the experimental $I(E)$ curves, although some changes are quite subtle. For the (1,0) beam, the basic shape of the calculated $I(E)$ curves is relatively constant, although there is a systematic shift towards more favourable peak positions as the changes in surface structure are made (i.e. calculated peaks shift to higher energies). More substantial changes are found in the (1,1) and (1/2,1/2) beams.

Overall the best correspondence found so far is for the $MR'_{2,0.25}$ model, although no claim can be made that this corresponds to the actual surface structure. More detailed investigations are needed, in part because a systematic variation of geometrical parameters in the calculations has not yet been made. Also there is still a significant discrepancy between calculation and experiment for the (1,1) beam with regard to the strong peak which is calculated at around 110 eV. This peak is found in all curves calculated so far (including for models with O held close to 0.75 Å above the 4f site), but it is absent in curves measured from surfaces which show $(\sqrt{2} \times \sqrt{2})45°$ LEED patterns. By contrast, measurements from the $(2\sqrt{2} \times \sqrt{2})45°$ structure (Fig. 1) show a smaller peak at around 100 eV, although so far it remains unclear whether this discrepancy is one that can be primarily related to disorder at the surface, or whether it indicates that substantial changes in the basic structure are still needed. The trends in Fig. 9 suggest that an improved correspondence with the experimental $I(E)$ curves may occur for $MR'_{2,0.5}$ models with a larger lateral shift than the value of 0.26 Å used. That this lateral shift (Fig. 8) could be larger is suggested by the following considerations. With the O atoms in coplanar 4f sites, and with the value of d_{Cu-Cu} equal to 1.88 Å, there are two O–Cu distances at 1.81 Å and one at 1.88 Å. Equation [1] then requires the other two O–Cu distances to equal 2.15 Å in order that the sum of bond valences to the chemisorbed species equals the conventional valency. This corresponds to a lateral shift of 0.34 Å.

Some further points may be noted for the missing row model. First, other adsorption sites are available for oxygen, as indicated in Fig. 8 where three such sites are labelled A, B, and C. Presumably any energetic penalty in forming the missing rows can be counterbalanced by the extra possibilities for Cu–O bond formation. Most probably sites of the A type would fill first beyond the 1/4 monolayer coverage situation. Then, with eq. [1] and the assumptions above, such O atoms are predicted to chemisorb at about 0.65 Å above the *second* copper layer, assuming both that the interlayer spacing between the second and third copper layers equals the bulk value, and that there are no lateral relaxations at the second copper layer. Such an environment is noticeably closer to that reported from SEXAFS and photoelectron diffraction, although we have not yet had the opportunity to make the LEED intensity calculations for this more complicated model. Superficially this model

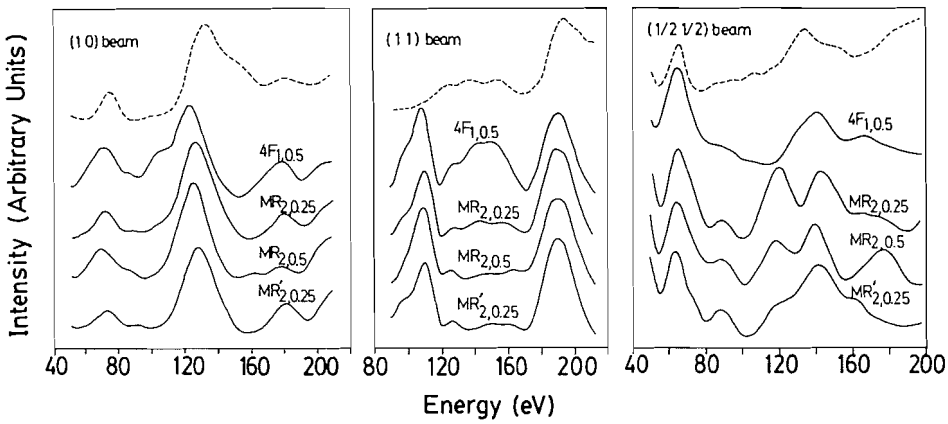

FIG. 9. $I(E)$ curves measured at normal incidence for the (1,0), (1,1), and (1/2,1/2) beams from Cu(100)–$(\sqrt{2} \times \sqrt{2})45°$–O (shown as dashed lines) and compared with calculated curves for the four models designated $4F_{1,0.5}$, $MR_{2,0.25}$, $MR_{2,0.5}$, $MR'_{2,0.25}$. In each model O is held in coplanar 4f sites and the topmost Cu–Cu interlayer spacing equals 1.88 Å (all other Cu–Cu interlayer spacings are fixed at 1.81 Å).

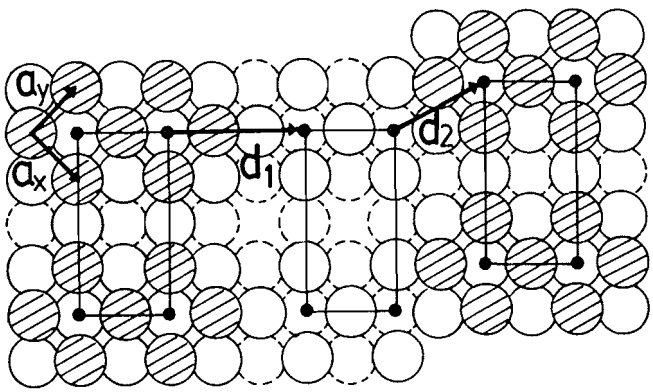

FIG. 10. Illustration of two types of antiphase boundaries with the missing row model. The parallel vectors shown satisfy $\boldsymbol{d}_1 = (3/2)\boldsymbol{a}_x + (3/2)\boldsymbol{a}_y$ and $\boldsymbol{d}_2 = (1/2)\boldsymbol{a}_x + (3/2)\boldsymbol{a}_y$. The dots represent oxygen atoms, and the first, second and third copper layers are represented by hatched circles, open continuous circles and dashed circles, respectively.

appears consistent with the reports that oxygen ultimately incorporates below the first copper layer (10, 11, 45).

If O can additionally adsorb in the sites of types B and C then the $(2\sqrt{2} \times \sqrt{2})45°$ translational symmetry could be maintained over the complete range of coverage from quarter monolayer to one monolayer. Further, with two copper layers involved in the ideal structure, antiphase domain boundaries can occur across atomic steps, as indicated by the examples in Fig. 10. Beam splittings, as a result of antiphase scattering, are determined by the parallel component of the vector which links related positions across the domain boundary (i.e. of the type $\boldsymbol{d} = d_x\boldsymbol{a}_x + d_y\boldsymbol{a}_y$ shown in Fig. 10). The (hk) beam is split according to the antiphase scattering mechanism, in directions perpendicular to the domain boundaries, whenever

$$hd_x + kd_y = (1/2)(2n + 1)$$

for n integral (46). Several domain boundaries are possible, but Fig. 10 shows the two different types of vector $\boldsymbol{d}$ that can occur. With these, the missing row model predicts splittings for the beams (1/2,1/2) and (1,0), but not (1,1), as reported by Richter and Gerhardt (14). However, the present analysis does not follow these other authors in concluding that the splittings reported indicate that the O chemisorption occurs on bridge sites.

Concluding remarks

This paper should be seen as a progress report of current LEED crystallographic investigations for the O on Cu(100) surface structure. A new feature introduced here concerns the proposal that a missing row model may be able to accommodate many observations reported previously for this system. With further possible surface relaxations, this structure may be more complicated than has previously been considered. A full resolution of the structural details for the $(2\sqrt{2} \times \sqrt{2})45°$ models could be aided by a combined investigation with other techniques including high-energy ion scattering and scanning tunneling microscopy. Disorder contributions apparently significantly affect this system. Frequently 1/4 order beams could not be detected on our conventional LEED screen, but we have no basis to disagree with the report of Mayer *et al.* (5) that, with appropriate ordering, $(2\sqrt{2} \times \sqrt{2})45°$ diffraction patterns always dominate. Nevertheless we do note that with the missing row model the $(2\sqrt{2} \times \sqrt{2})45°$ translational symmetry could be maintained over a range of O coverage. Incidentally, although they did not explicitly consider the missing row model, Boulliard and Sotto (29) proposed a 3/4 monolayer structure for the Cu(100)–$(2\sqrt{2} \times \sqrt{2})45°$–O surface which is closely analogous to the model in Fig. 8 with additional O adsorption on sites of types B and C. Whether there could be some change over of O adsorption sites between 1/2 and 3/4 monolayer coverage is a topic for further surface structural investigation.

Received November 29, 1987

This paper is dedicated to Professor Charles A. McDowell on the occasion of his 70th birthday

TILAK P. WIJESEKERA, SHANTHA DAVID, JOHN B. PAINE III, BRIAN R. JAMES, and DAVID DOLPHIN. Can. J. Chem. **66**, 2063 (1988).

The synthesis of porphyrins having a fully hydrophobic cavity capped by a durene moiety is described. The size of the cavity is adjusted by varying the number of methylene $-(CH_2)_n-$ groups linking the tetramethylphenylene cap with the diametrically opposite β-positions of the porphyrin. Bis(chloromethyl)durene (**1**) was first converted to durene-bisalkanoic acids **11** (n = 4), **13** (n = 5), and **18** (n = 7) using standard chain extension methods. The diacid chlorides were then used to acylate two equivalents of a β-unsubstituted pyrrole to give a chain-linked bispyrrole. Each pyrrole, following appropriate manipulation of the α substituents, was condensed with an α-unsubstituted pyrrole and the resulting chain-linked dipyrromethane dimer was cyclized *intramolecularly* under high dilution to give the capped porphyrin **34** (n = 4, 5, or 7).

TILAK P. WIJESEKERA, SHANTHA DAVID, JOHN B. PAINE III, BRIAN R. JAMES et DAVID DOLPHIN. Can. J. Chem. **66**, 2063 (1988).

On décrit la synthèse de porphyrines portant une cavité complètement hydrophobe et qui sont cappées par une portion de durène. On ajuste la grandeur de la cavité en faisant varier le nombre de groupements méthylènes $-(CH_2)_n-$ reliant le tétraméthylphénylène servant de cap avec les positions β diamétralement opposées de la porphyrine. Dans la première étape, on transforme le bis(chlorométhyl)durène (**1**) en acides durène-bis-alcanoïques (**11**, n = 4; **13**, n = 5 et **18**, n = 7) en utilisant des méthodes standards pour l'extension de la chaîne. On utilise alors les chlorures de diacides pour acyler deux équivalents d'un pyrrole substitué en position β afin d'obtenir un bispyrrole lié par une chaîne. Après une manipulation appropriée des substituants en α, on a condensé chacun des pyrroles avec un pyrrole substitué en α et, utilisant la technique des grandes dilutions, on a ensuite procédé à une cyclisation *intramoléculaire* du dipyrrométhane lié par une chaîne qui en résulte afin d'obtenir la porphyrine cappée désirée (**34**, n = 4, 5 ou 7).

[Traduit par la revue]

Introduction

Synthetic heme models all necessarily incorporate an active site comparable to that of deoxymyoglobin that has an iron(II) atom coordinated to the four nitrogen atoms of a porphyrin dianion and an axial imidazole. The use of simple ferrous porphyrins as models for reversible oxygen-carrying hemoproteins has been thwarted for two main reasons. First, the addition of a nitrogen-donor base to four coordinate ferrous porphyrins in solution usually leads to a six-coordinate complex incapable of binding oxygen (1). Second, coordination of oxygen to the five coordinate species at room temperature leads rapidly and irreversibly to the formation of bridged oxo-iron(III) species (2, 3). Autoxidation of the iron centre proceeds via the initial formation of a monomeric iron-dioxygen adduct, followed by the reaction with a second iron(II) porphyrin unit (4).

Attempts to achieve reversible dioxygen binding at ambient temperature gave rise to model designs incorporating steric bulk on one face of the porphyrin. This not only retards the ligation of the nitrogenous base at the sixth site, thus facilitating dioxygen binding, but also prevents "dimerization" of the initially formed dioxygen adduct which leads to oxidation of the metal centre. The best known sterically hindered porphyrins are the "picket-fence" (5) and "pocket" (6) porphyrins of Collman *et al.*, the "capped" (7) porphyrins of Baldwin and co-workers, and the "cyclophane hemes" (8) of Traylor *et al.* Model systems with steric hindrances on both faces of the porphyrin (the "basket-handle" porphyrins (9) of Momenteau *et al.*), as well as those with protective structures on one and appended imidazole on the other face have also been prepared (10, 11). This area has recently been reviewed (12) and a survey of the synthesis and structure of these systems has been presented (13).

Two basic synthetic strategies have been used to obtain these hindered porphyrins. The first involves the condensation of a benzaldehyde derivative with pyrrole in a manner analogous to the synthesis of *meso*-tetraphenylporphyrin (14). The protective structure is introduced either by the modification of an appropriate *ortho*-substituent on the phenyl group (5, 6) or by carrying it in the aldehyde component prior to condensation with pyrrole (7, 9, 10). The second and the more widely used strategy is to condense, via ester or amide linkages, a diagonally β-disubstituted porphyrin with a terminally bifunctional molecule carrying the required protective structure (8, 11).

Differentiation between CO and O_2 in model systems arises from electronic, polar, and steric effects (12). Porphyrins synthesized by the above methods are limited in the size of the cavity produced and, in addition, do not provide a truly hydrophobic environment for small molecule binding. The durene-capped porphyrins described here provide a simple reference series where the influence of the distal steric effects on CO and O_2 binding may be evaluated in the absence of stabilizing electronic or polar interactions (12). An early attempt at the preparation of such a hydrophobic system resulted in a very low yield for the cyclization step due to the use of rigid and unreactive dipyrromethene precursors (15). However, the synthetic route originally developed by some of us to construct permanently deformed porphyrins (16–18), which utilizes more flexible and reactive dipyrromethane intermediates, appeared ideally suited for the synthesis of sterically hindered porphyrins having small fully hydrophobic cavities.

A preliminary communication outlining the synthesis of the durene-capped parent porphyrin and the crystallographic characterization of a chloroiron(III) derivative has appeared (19).

Results and discussion

The bis(chloromethyl)durene (**1**) was used as starting material for the introduction of the tetramethylphenylene protecting

SCHEME 1

group for the porphyrin. The synthetic strategy involved the elaboration of **1** into durene bisalkanoic acids (Scheme 1; **11**, **13**, and **18**), which could be employed to acylate, simultaneously, two β-unsubstituted pyrroles. Such chain-linked bispyrroles could then be transformed efficiently into the durene-capped porphyrins using the chemistry perfected for the synthesis of deformed porphyrins (16–18).

It was uncertain as to how reactive compound **1** might be, given a significant potential for steric hindrance by the *ortho*-methyl groups. However, in absolute ethanol containing excess sodium ethoxide and diethyl malonate, bis(chloromethyl)durene reacted rapidly and exothermically to give durene-bismethylene malonic ester (**2**) nearly quantitatively. Compound **2** could be isolated as a crystalline solid by aqueous dilution of the reaction mixture. However, we found it convenient to saponify the tetra ester *in situ*, by the addition of water and further alkali. The resulting durene-bismethylene malonic acid (**3**) was isolated by acidification of the reaction mixture. Its decarboxylation to the

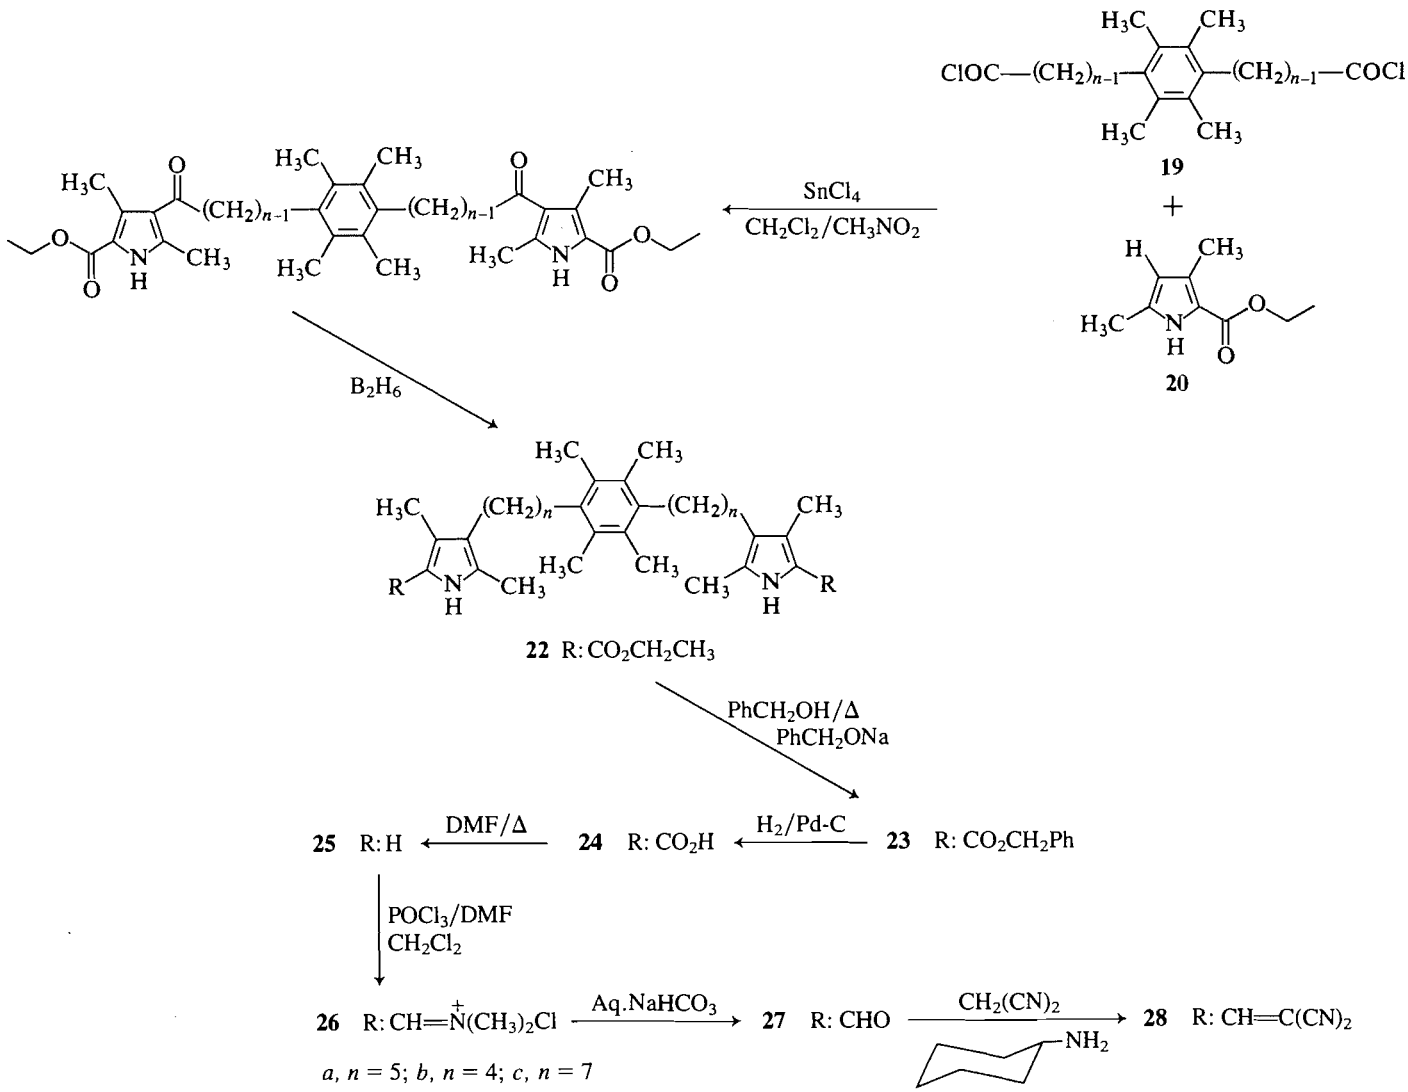

SCHEME 2

durene-bispropanoic acid (**4**) was initially effected by the addition of **3** to boiling quinoline, but *N*,*N*-diethylformamide was subsequently found to be an equally effective solvent.

Although diborane reduction of the diacid **4** was effective on a small scale, solubility problems were encountered upon scale-up, which led to incomplete reduction of the carboxyl groups, thus producing, in addition to the bis(hydroxypropyl)-durene (**5**), the monohydroxypropylmonocarboxyethyldurene (**6**). The use of this incompletely reduced material in the subsequent bromination reaction with 48% aqueous HBr led to the formation of an ester-linked durene dimer **7** as a significant by-product that was difficult to separate from the desired bis(bromopropyl)durene (**8**). However, these problems were avoided by prior esterification of the diacid **4**, which improved the solubility of both the starting material and intermediates of the diborane reduction. The bis(hydroxypropyl)durene (**5**) isolated in greater than 95% yield was converted to the bis(bromopropyl)durene (**8**) in over 90% yield. Had these problems been anticipated in the diborane reduction of **4**, the tetramethyl ester could have been isolated and its direct conversion to the diester **9** attempted. Decarbalkoxylations of similar geminal diesters have been reported by Krapcho *et al.* (20).

To generate the durene-bisbutanoic acid (**11**), bis(bromopropyl)durene (**8**) was reacted with KCN in ethanol and the resulting durene-bisbutyronitrile **10** hydrolyzed with alkali. The bispentanoic acid **13** and the bisheptanoic acid **18** were prepared by similar malonate syntheses and functional group modifications as shown in Scheme 1.

Examination of space-filling models suggested that two five-carbon chains would allow a durene moiety to be held close to the macrocycle, without significant deformation of the porphyrin core. It was to this species that we first directed our efforts (series a). The reaction sequence was then repeated using the bisbutanoic acid **11** (series b) and the bisheptanoic acid **18** (series c). The experimental methods and yields for all the intermediates in both series b and c were entirely comparable and are provided as supplementary material.[1]

The subsequent synthetic strategy involved the intramolecular cyclization of the chain-linked 5′-unsubstituted-5-formyldipyrromethane dimers. Only two basic pyrroles were used in this synthesis. 2-Ethoxycarbonyl-3,5-dimethylpyrrole (**20**) was pre-

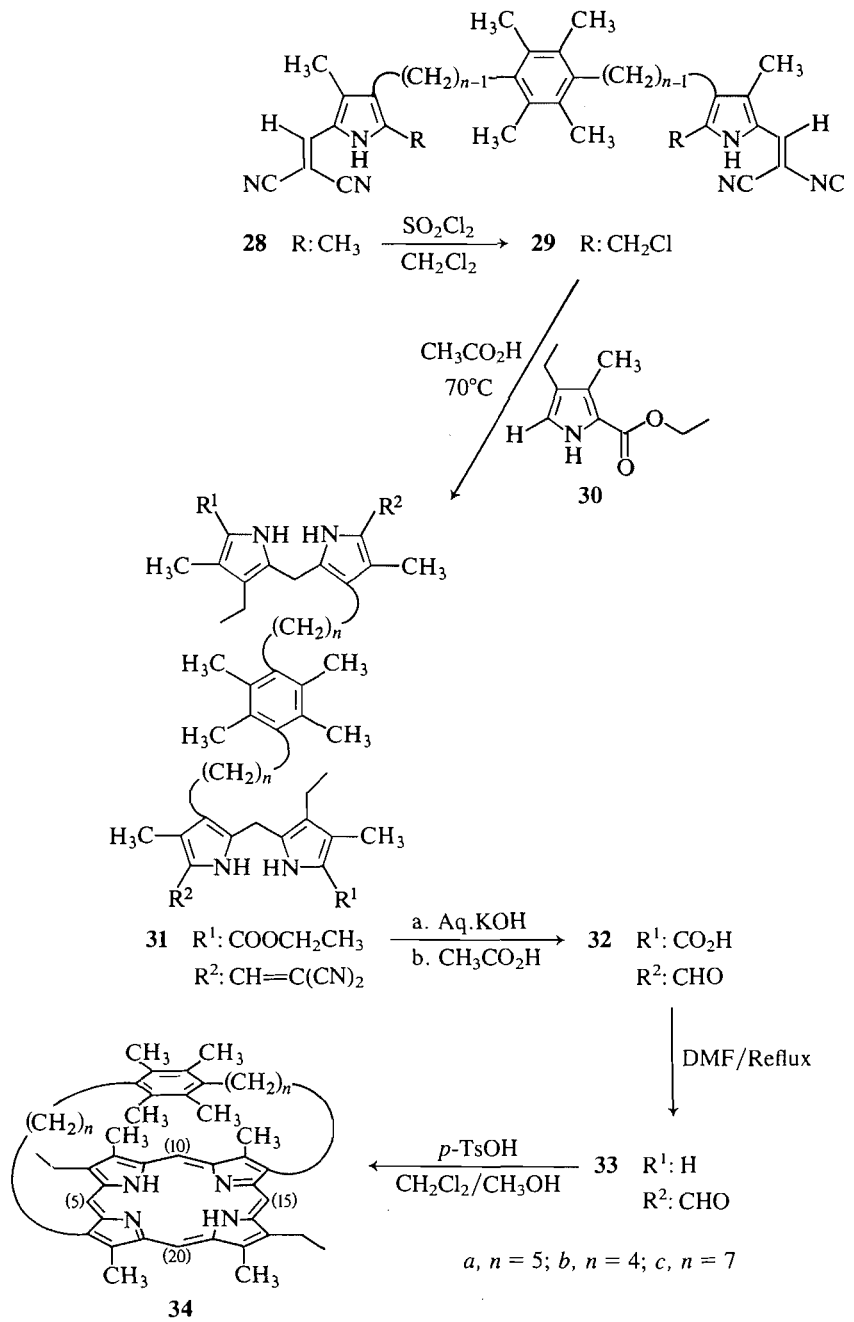

SCHEME 3

pared by the reductive condensation (21) of diethyloximinomalonate with 2,4-pentanedione in the presence of zinc and acetic acid. The other pyrrole, 2-ethoxycarbonyl-4-ethyl-3-methylpyrrole (**30**), was prepared by improved procedures (16) of standard degradations (22) of 2-ethoxycarbonyl-4-ethyl-3,5-dimethylpyrrole.

The synthesis of the durene-capped porphyrin was initiated by the acylation of the pyrrole **20** with the diacid chloride **19** in methylene chloride – nitromethane using stannic chloride as catalyst (Scheme 2). The resulting durene-bisoxoalkylidene pyrrole **21** was subjected to the usual diborane reduction, to convert the ketonic carbonyl to methylene groups. For ease of manipulation, the bispyrrole ethyl ester **22** was transbenzylated (18) to give the bispyrrole benzyl ester **23**, which was then transformed into the synthetically useful bisformylpyrrole **27** by standard methods (18). The benzyl ester **23** was cleaved by catalytic hydrogenation in tetrahydrofuran and, after removal of the catalyst and the solvent, the acid **24** was decarboxylated in refluxing dimethylformamide. Vilsmeier formylation with phosphorus oxychloride was effected in dimethylformamide without isolation of the bis α-free pyrrole **25**, and the resulting iminium salt **26** was hydrolyzed in aqueous bicarbonate to produce the formylpyrrole **27**. This was converted to its dicyanovinyl (23) derivative **28** primarily for the purpose of protecting the formyl group during the subsequent oxidation of the α-methyl group. This also served as a method of purification by chromatography, which was essential at this stage since none of the intermediates **24**–**27** was isolated.

Modification of the α-methyl groups of **28** to monochloromethyl groups was now required in order to condense them with the α-unsubstituted pyrrole **30** to produce the dipyrromethane dimers (Scheme 3). The possibility that the durene-methyl

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 112.217.228.212 on 09/07/12

groups might compete with the pyrrole α-methyl groups for the oxidant, sulfuryl chloride, made this reaction the most crucial step in the entire reaction sequence. However, in practice, sulfuryl chloride reacted exclusively with the pyrrole α-methyl groups, and the chloromethyl derivative **29** so produced gave the desired dipyrromethane dimer **31** in the excellent yield of ca. 90% overall for two reactions. The deprotection of the formyl groups and the saponification of the esters of **31** were effected in a single step using aqueous alkali. The 5-carboxy-5′-formyldipyrromethane dimer **32** was subsequently decarboxylated in refluxing dimethylformamide (monitored by the disappearance of the uv absorpion band at λ_{max} = 280 nm), but the product **33** was not isolated. Instead, the solution was concentrated *in vacuo*, diluted with methylene chloride, and most of the remaining dimethylformamide removed by extraction with water. The dried methylene chloride solution of the 5′-unsubstituted-5-formyldipyrromethane dimer **33** was added (by means of a syringe pump) to a solution of *p*-toluenesulfonic acid in methanol/methylene chloride to effect the intramolecular cyclization. The monomeric capped porphyrin **34** was the only porphyrin present in the reaction mixture and was isolated and purified by chromatography. The overall yield for the decarboxylation–cyclization reactions was dependent on the purity of the starting material **32**. In the pentamethylene series (n = 5), the yield of the porphyrin **34***a* varied from 22 to 31% while the tetramethylene and heptamethylene series produced the porphyrins **34***b* and **34***c* in 11–16% and 9–13% yield, respectively.

The ^{1}H nmr spectra of **34***a–c* exhibit significant upfield shifts for the durene methyl and chain -CH_2- resonances, resulting from the shielding effect of the porphyrin diamagnetic ring current. The durene methyl protons, usually observed at δ 2.2, are shifted, for example for **34***c*, to δ −0.20 ppm, and the chain -CH_2- resonances for **34***a–c* are spread over the range δ = +4 to −2 ppm.

The porphyrin methine protons appear as two singlets in the ^{1}H nmr, because of the asymmetry introduced into the molecule by the strap. A significant nuclear Overhauser effect was observed in the upfield methine resonance on irradiation of either the CH_2 resonance of the ethyl groups or the chain CH_2 at the porphyrin terminus. This allows for an unambiguous assignment of the upfield resonance to the 5- and 15-methine protons.

Work describing the formation of Fe(III) and Fe(II) derivatives of these durene-capped porphyrins and some data on the binding of amines, isocyanides, CO, and O_2 to the latter have already been published (12, 24). Further details on these systems (25) will be published elsewhere.

Experimental

The nmr spectra were obtained in the indicated solvents, using a Varian HA-100 or XL-100 instrument for proton (5-mm tube) or a Varian CFT-20 (at 25.2 MHz) or Bruker WH-400 (at 100.6 MHz) instrument for carbon-13 (10-mm tube). Melting points were obtained using a Thomas Hoover Unimelt oil bath/capillary tube or a Thomas Kofler Micro Hot Stage apparatus, and are uncorrected. Microanalyses were performed by P. Borda of this department. Reagents were employed as obtained, unless otherwise noted.

1,4-Bis(2,2-dicarboxyethyl)-2,3,5,6-tetramethylbenzene (3)

Freshly cut metallic Na (12.85 g, 0.56 mol) was dissolved under N_2, in anhydrous ethanol (600 mL) in a 2-L Erlenmeyer flask. Diethyl malonate (152 mL, 160.4 g, 1.0 mol) was stirred in followed by 1,4-bis(chloromethyl)-2,3,5,6-tetramethylbenzene (bis(chloromethyl)-durene) (**1**) (57.8 g, 0.25 mol), which was washed down with another 50 mL of anhydrous ethanol. The mixture was refluxed on a stirrer hot plate for 0.5 h; the starting material dissolved on reaction, with precipitation of NaCl.

Ethanol (approximately 200 mL) was distilled off, the reaction mixture cooled to room temperature, and a solution of KOH (200 g, 3.04 mol) in water (400 mL) added. Distillation of ethanol was continued until the temperature reached 100°C, more water (ca. 1 L) added until all of the solid dissolved, and the solution reheated to boiling. This was treated, dropwise, with concentrated HCl (ca. 300 mL). The white solid that precipitated out was collected by filtration, washed well with water, and dried in air to give 86.8 g (94.9%) of analytically pure material, mp 278.0–280.0°C (dec.); ^{1}H nmr (δ, DMSO-d_6): 2.13 (s, 12H, durene -CH_3), 3.13–3.22 (m, 4H, side-chain 1,1′-CH_2), 3.22–3.33 (m, 2H, -C*H*(CO_2H)$_2$); ms *m/e*: 278 (72) (*M*−2 CO_2), 219 (100), 205 (54). *Anal.* calcd. for $C_{18}H_{22}O_8$: C 59.01, H 6.05; found: C 58.95, H 5.92.

1,4-bis(2-carboxyethyl)-2,3,5,6-tetramethylbenzene (4)

Durene-bismethylenemalonic acid **3** (86.5 g; 0.24 mol) was added in portions to boiling quinoline (150 mL) over 20 min. The resulting thick mixture was heated until gas evolution ceased and then poured into 6 M HCl (400 mL). The product that crystallized out was collected by filtration and washed well with water under suction.

The crude solid was purified by dissolving in hot saturated aqueous $NaHCO_3$, filtering through Celite, and reprecipitating with concentrated HCl. Yield, 62.9 g (94.7%); mp 284.0– 286.0°C; ^{1}H nmr (δ, DMSO-d_6): 2.13 (s, 12H, durene CH_3), 2.06–2.39 (m, 4H, side-chain 2,2′-CH_2), 2.72–3.02 (m, 4H, side-chain 1,1′-CH_2). *Anal.* calcd. for $C_{16}H_{22}O_4$: C 69.04, H 7.97; found: C 68.48, H 7.93.

1,4-Bis(2-ethoxycarbonylethyl)-2,3,5,6-tetramethylbenzene (9)

1,4-Bis(2-carboxyethyl)-2,3,5,6-tetramethylbenzene(**4**) (158.9 g, 0.57 mol) was esterified with ethanol (400 mL) and concentrated H_2SO_4 (27 mL) using toluene (200 mL) to azeotrope out the water (Dean–Stark trap). Yield, 170.5 g (89.4%); mp: 118.5–120.0°C; ^{1}H nmr (δ, $CDCl_3$): 1.25 (t, 6H, J = 7 Hz, -OCH_2CH_3), 2.18 (s, 12H, durene CH_3), 2.28–2.50 (m, 4H, side-chain 2,2′-CH_2), 2.90–3.12 (m, 4H, side-chain 1,1′-CH_2), 4.14 (q, 4H, J = 7 Hz, -OCH_2CH_3); ^{13}C nmr (δ, $CDCl_3$): 173.10 (C=O), 135.25 (2C, durene 1,4), 132.39 (4C, durene 2,3,5,6), 60.41 (2C, -OCH_2CH_3), 34.21 (2C, side-chain 2,2′), 26.15 (2C, side-chain 1,1′), 16.30 (4C, durene CH_3), 14.28 (2C, OCH_2CH_3); ms m/*e*: 334 (M^+, 86), 289 (16), 247 (100), 233 (38). *Anal.* calcd. for $C_{20}H_{30}O_4$: C 71.82, H 9.04; found: C 72.10, H 9.11.

1,4-Bis(3-hydroxypropyl)-2,3,5,6-tetramethylbenzene (5)

1,4-Bis(2-ethoxycarbonylethyl)-2,3,5,6-tetramethylbenzene **9** (16.7 g, 0.05 mol) dissolved in dry THF (200 mL) was treated under N_2 with $NaBH_4$ (8.5 g, 0.22 mol), followed by $BF_3 \cdot Et_2O$ (45 mL, 0.36 mol). The reaction was monitored by tlc and, on completion, the excess diborane was destroyed with acetic acid (50 mL) and water (100 mL). The solvent was evaporated under reduced pressure causing the product to separate out as a white solid. More water (300 mL) was added and the solid was collected by filtration. The crude product was recrystallized by dissolving in warm ethanol (350 mL) and reprecipitating with water. Two crops of the recrystallized bis(hydroxypropyl)durene amounted to 11.2 g, an overall yield of 89.6%; mp 158.0–159.5°C; ^{1}H nmr (δ $CDCl_3$): 1.50 (s, 2H,-OH), 1.58–1.94 (m, 4H, side-chain 2,2′-CH_2), 2.26 (s, 12H, durene CH_3), 2.66–2.90 (m, 4H, side-chain 1,1′-CH_2), 3.78 (t, 4H, -C*H*$_2$OH); ^{13}C nmr (δ, $CDCl_3$): 136.16 (2C, durene 1,4), 132.23 (4C, durene 2,3,5,6), 63.14 (2C, CH_2OH), 32.82 (2C, side-chain 1,1′), 26.96 (2C, side-chain 2,2′), 16.38 (4C, durene CH_3); ms *m/e*: 250 (M^+, 87), 205 (94), 191 (47), 161 (63), 147 (100). *Anal.* calcd. for $C_{16}H_{26}O_2$: C 76.75, H 10.47; found: C 77.02, H 10.64.

1,4-Bis(3-bromopropyl)-2,3,5,6-tetramethylbenzene (8)

1,4-Bis(3-hydroxypropyl)-2,3,5,6-tetramethylbenzene (**5**) (7.5 g, 0.03 mol) and 48% aqueous HBr (24 mL) were heated at reflux under N_2. The starting material did not dissolve, but turned into a pale yellow oil, resulting in an overall emulsion. Thin-layer chromatographic

analysis of the reaction mixture after 30 min indicated that the reaction was complete.

The solution was cooled to room temperature, CH_2Cl_2 (100 mL) added, and the acid extracted out with saturated aqueous $NaHCO_3$ (2 × 30 mL) and water (30 mL). The organic layer was dried (Na_2SO_4) and evaporated *in vacuo* after adding CH_3OH. The product crystallized out as silvery white needles, yield 9.4 g (83.3%). The mother liquors were concentrated to give a second crop of 0.90 g (7.9%), mp 113.0–114.0°C; ^1H nmr (δ, $CDCl_3$): 1.84–2.10 (m, 4H, side-chain 2,2′-CH_2), 2.17 (s, 12H, durene CH_3), 2.68–2.92 (m, 4H, side-chain 1,1′-CH_2), 3.45 (t, 4H, J = 6.5 Hz, CH_2Br); ^{13}C nmr (δ, $CDCl_3$): 135.39 (2C, durene 1,4), 132.33 (4C, durene 2,3,5,6), 33.92 (CH_2Br), 32.69 (2C, side-chain 1,1′), 29.37 (2C, side-chain 2,2′), 16.44 (4C, durene-CH_3); ms *m/e*: 374–376–378 (M^+), 267–269 (30–30), 173 (15), 161 (26), 145 (27). *Anal.* calcd. for $C_{16}H_{24}Br_2$: C 51.09, H 6.43, Br 42.48; found: C 50.95, H 6.49, Br 42.28.

*1,4-Bis(3-cyanopropyl)-2,3,5,6-tetramethylbenzene (**10**)*

1,4-Bis(3-bromopropyl)-2,3,5,6-tetramethylbenzene (**8**) (20.0 g, 0.05 mol), KCN (13.0 g, 0.20 mol), and ethanol (250 mL) were refluxed under N_2 for 4 h. Water (300 mL) was then added to the cooled solution causing crystallization of the product, which was filtered off and washed with more water. Yield: 13.0 g (97%); mp 139.0–141.5°C; ^1H nmr (δ, $CDCl_3$): 1.57–2.05 (m, 4H, side-chain 2,2′-CH_2), 2.29 (s, 12H, durene CH_3), 2.48 (t, 4H, J = 7 Hz, side-chain 1,1′-CH_2), 2.72–3.00 (m, 4H, CH_2CN); ^{13}C nmr (δ, $CDCl_3$): 135.07 (2C, durene 1,4), 132.39 (4C, durene 2,3,5,6), 119.57 (2C, CN), 29.60 (2C, side-chain 1,1′), 25.37 (2C, side-chain 2,2′), 17.33 (2C, side-chain 3,3′), 16.44 (4C, durene CH_3); ms *m/e*: 268 (M^+, 90), 214 (100), 200 (60). *Anal.* calcd. for $C_{18}H_{24}N_2$: C 80.55, H 9.01, N 10.44; found: C 80.46, H 9.06, N 10.15.

*1,4-Bis(3-carboxypropyl)-2,3,5,6-tetramethylbenzene (**11**)*

1,4-Bis(3-cyanopropyl)-2,3,5,6-tetramethylbenzene (**10**) (12.5 g, 0.047 mol), KOH (21 g, 0.38 mol), and ethanol (250 mL) were refluxed under N_2 until the evolution of NH_3 (g) ceased (ca. 5 h). The ethanol was distilled off and replaced with water. The resulting clear solution was refluxed for another 1 h. The solution was cooled, carefully acidified with concentrated HCl, and the white diacid product was collected and washed with water to give 14.1 g (98%), mp 265.0–267.0°C; ^1H nmr (δ, 10% TFA/$CDCl_3$): 1.60–2.10 (m, 4H, side-chain 2,2′-CH_2), 2.32 (s, 12H, durene CH_3), 2.48–2.97 (m, 8H, side-chain 1,1′,3,3′-CH_2);ms *m/e*: 306 (M^+, 40), 233 (100), 219 (30). *Anal.* calcd. for $C_{18}H_{26}O_4$: C 70.56, H 8.55; found: C 70.86, H 8.53.

*1,4-Bis(4,4-dicarboxybutyl)-2,3,5,6-tetramethylbenzene (**12**)*

The bis(bromopropyl)durene **8** (15 g, 40 mmol) was treated with diethyl malonate (25 mL, 26.4 g, 165 mmol) and Na (2.4 g, 104 mmol) in anhydrous ethanol (200 mL) in a manner analogous to that described for the preparation of **3**. The tetraethyl ester so obtained was saponified *in situ* using KOH and acidified with concentrated HCl to give 15.9 g (94.9%) of the desired product, mp 193.5–195.0°C (dec.); ^1H nmr (δ, DMSO-d_6): 1.14–1.98 (m, 8H, side-chain 2,2′,3,3′-CH_2), 2.07 (s, 12H, durene CH_3), 2.38–2.74 (m, 4H, side-chain 1,1′-CH_2), 3.25 (t, 2H, J = 7 Hz, C*H*(CO_2H)$_2$); ms *m/e*: 334 ($M-2CO_2$, 20), 247 (100), 147 (70). *Anal.* calcd. for $C_{22}H_{30}O_8$: C 62.55, H 7.16; found: C 62.32, H 7.20.

*1,4-Bis(4-carboxybutyl)-2,3,5,6-tetramethylbenzene (**13**)*

1,4-Bis(4,4-dicarboxybutyl)-2,3,5,6-tetramethylbenzene (**12**) (15.5 g, 36.7 mmol) was decarboxylated in boiling quinoline (50 mL) and purified as described for the bismalonic acid (**3**). Yield 11.6 g (94.6%), mp 210.0–211.0°C; ^1H nmr (δ, DMSO-d_6): 1.10–1.82 (m, 8H, side-chain 2,2′, 3,3′-CH_2), 2.13, 2.06–2.38 (s, m, 16H, durene CH_3, side-chain 4,4′-CH_2), 2.42–2.76 (m, 4H, side-chain 1,1′-CH_2); ms *m/e*: 334 (M^+, 30), 247 (100), 233 (20), 147 (50).

*1,4-Bis(4-ethoxycarbonylbutyl)-2,3,5,6-tetramethylbenzene (**14**)*

The dicarboxylic acid **13** (37.5 g, 110 mmol) was esterified as described for the diacid **4** to produce the diester **14** in 95% yield, mp 55.0–56.0°C; ^1H nmr (δ, $CDCl_3$): 1.25 (t, J = 7 Hz, 6H, OCH_2CH_3), 1.35–1.95 (m, 8H, side-chain 2,2′,3,3′-CH_2), 2.20 (s, 12H, durene CH_3), 2.25–2.80 (m, 8H, side-chain 1,1′4,4′-CH_2), 4.13 (q, 4H, J = 7 Hz, OCH_2CH_3); ^{13}C nmr (δ, $CDCl_3$): 173.54 (C=O), 136.65 (2C, durene 1,4), 131.95 (4C, durene 2,3,5,6), 60.14 (2C, OCH_2CH_3), 34.24 (2C, side-chain 4.4′), 30.36 (2C, side-chain 3,3′), 29.37 (2C, side-chain 2,2′), 25.49 (2C, side-chain 1,1′), 16.28 (durene CH_3), 14.23 (OCH_2CH_3); ms *m/e*: 390 (M^+, 40), 275 (50), 129 (100). *Anal.* calcd. for $C_{24}H_{38}O_4$: C 73.81, H 9.81; found: C 73.89, H 9.89.

*1,4-Bis(5-hydroxypentyl)-2,3,5,6-tetramethylbenzene (**15**)*

The diethyl ester **14** (41.0 g, 0.1 M) was reduced by diborane as described for the analogous compound **9** to give 32.1 g (99%) of **15**, mp 109.5–111.0°C; ^1H nmr (δ, $CDCl_3$): 1.35–1.80 (m, 14H, OH and side-chain 2,2′,3,3′,4,4′-CH_2) 2.27 (s, 12H, durene CH_3), 2.50–2.88 (m, 4H, side-chain 1,1′-CH_2), 3.71 (t, 4H, CH_2OH); ^{13}C nmr (δ, $CDCl_3$): 136.71 (2C, durene 1,4), 131.90 (4C, durene 2,3,5,6), 62.85 (2C, CH_2OH), 32.66 (2C, side-chain 1,1′), 30.71 (2C, side-chain 2,2′), 29.73 (2C, side-chain 3,3′), 26.37 (2C, side-chain 4,4′), 16.34 (durene CH_3); ms *m/e*: 306 (M^+, 80), 233 (100), 161 (20), 147 (30). *Anal.* calcd. for $C_{20}H_{34}O_2$: C 78.38, H 11.18; found: C 78.47, H 11.40.

*1,4-Bis(5-bromopentyl)-2,3,5,6-tetramethylbenzene (**16**)*

The bis(hydroxypentyl)durene **15** (31,6 g, 100 mmol) was brominated as described for **5** to give 38.3 g (86%) of the dibromo compound **16**, mp 100–102.0°C; ^1H nmr (δ, $CDCl_3$): 1.40–1.65 (m, 8H, side-chain 2,2′,3,3′-CH_2), 1.75–2.07 (m, 4H, side-chain 4,4′-CH_2), 2.20 (s, 12H, durene CH_3), 2.50–2.85 (m, 4H, side-chain 1,1′-CH_2), 3.43 (t, 4H, -CH_2Br); ^{13}C nmr (δ, $CDCl_3$): 136.58 (2C, durene 1,4), 131.98 (4C, durene 2,3,5,6), 33.69 (2C, CH_2Br), 32.71 (2C, side-chain 1,1′), 30.60 (2C, side-chain 2,2′), 29.07 (2C, side-chain 3,3′), 28.79 (2C, side-chain 4,4′), 16.37 (durene -CH_3); ms *m/e*: 430–432–434 (M^+, 55), 295–297 (100); *Anal.* calcd. for $C_{20}H_{32}Br_2$: C 55.70, H 7.46, Br 36.97; found: C 55.82, H 7.45, Br 36.76.

*1,4-Bis(6,6-dicarboxyhexyl)-2,3,5,6-tetramethylbenzene (**17**)*

This compound was prepared in 96% overall yield, starting from the bis(bromopentyl)durene **16** (37.3 g, 86 mmol) in the manner described for the preparation of the analogous compound **12**, mp 160.5–162.5°C (dec.); ^1H nmr (δ, 10% TFA/$CDCl_3$): 1.35 (br, 12H, side-chain 2,2′,3,3′,4,4′-CH_2), 1.58–1.93 (m, 4H, side-chain 5,5′-CH_2), 2.12 (s, 12H, durene CH_3), 2.33–2.73 (m, 4H, side-chain 1,1′-CH_2), 2.97 (t, 2H, J = 7 Hz, C*H*($COOH$)$_2$); ms *m/e*: 390 ($M-2CO_2$, 45), 275 (100).

*1,4-Bis(6-carboxyhexyl)-2,3,5,6-tetramethylbenzene (**18**)*

The bismalonic acid **17** was decarboxylated in refluxing diethylformamide to give the diacid **18** in near quantitative yield, mp 147–149.0°C (dec.); ^1H nmr (δ, 10% TFA/$CDCl_3$): 1.35 (br, 16H, side-chain 2,2′,3,3′,4,4′,5,5′-CH_2), 2.13 (s, 12H, durene CH_3), 2.20 (bs, 4H, side-chain 6,6′-CH_2), 2.35–2.70 (m, 4H, side-chain 1,1′-CH_2); ms *m/e*: 390 (M^+, 30), 275(30), 161(60), 147(50). *Anal.* calcd. for $C_{24}H_{38}O_4$: C 73.81, H 9.81; found: C 73.77, H 9.72.

Chain-linked bispyrroles

*1,4-Bis[5-(5-ethoxycarbonyl-2,4-dimethylpyrrol-3-yl)-5-oxopentyl]-2,3,5,6-tetramethylbenzene (**21**a)*

Durene-bispentanoic acid (**13**) (16.7 g, 0.05 mol) and $SOCl_2$ (23.8 g, 0.2 mol) were refluxed on a steam bath until the mixture was homogeneous and gas evolution had ceased (ca. 30 min). The excess $SOCl_2$ was removed by evaporation *in vacuo* and by codistillation with CCl_4 (4 × 30 mL). The resulting crude diacid chloride (**19***a*) and 2-ethoxycarbonyl-3,5-dimethylpyrrole (**20**) (18.0 g, 0.11 mol) were dissolved in CH_2Cl_2 (175 mL); CH_3NO_2 (100 mL) and anhydrous $SnCl_4$ (38.9 g, 0.15 mol) were added dropwise at room temperature under moisture-exclusion conditions.

After being stirred for 1 h, the reaction mixture was poured into water (300 mL) acidified with concentrated HCl (10 mL), stirred for 15 min, and filtered to collect the solid product (18.3 g, 57.9%). Evaporation *in vacuo* of the organic phase from the filtrate afforded a second crop of 2.7 g (8.5%).

An analytical sample was obtained by adding ethanol to a concentrat-

For personal use only.

ed solution of the crude solid in CH_2Cl_2 and minimum trifluoroacetic acid; mp 207.5–209.0°C; ^{1}H nmr (δ, 10%, TFA/$CDCl_3$): 1.46, 1.38–2.10 (t, br, 14H, OCH_2CH_3, chain 2,2′,3,3′-CH_2), 2.24 (s, 12H, durene CH_3), 2.39 (s, 6H, pyrrole 4-CH_3), 2.42 (s, 6H, pyrrole 2-CH_3), 2.58–2.85 (m, 4H, chain 1,1′-CH_2), 2.96 (t, 4H, J = 7.5 Hz, chain 4,4′-CH_2), 4.47 (q, 4H, J = 7 Hz, OCH_2CH_3), 10.20 (bs, 2H, NH); ^{13}C nmr (δ, 10% TFA/$CDCl_3$): 204.11 (2C, ketonic C=O), 164.25 (2C, ester C=O), 142.50 (2C, pyrrole 2), 136.59 (2C, durene 1,4), 132.37 (6C, pyrrole 4, durene 2,3,5,6), 123.03 (2C, pyrrole 3), 118.61 (2C, pyrrole 5), 62.57 (2C, -OCH_2CH_3), 42.27 (2C, chain 4,4′), 30.62, 29.88 (4C, chain 1,1′,2,2′), 26.12 (2C, chain 3,3′), 16.41 (4C, durene CH_3), 15.44 (2C, pyrrole 2-CH_3), 14.26 (2C, -OCH_2CH_3), 13.03 (2C, pyrrole 4-CH_3); ms m/*e*: (M^+, 19), 209 (100), 194 (71), 148 (62). *Anal.* calcd. for $C_{38}H_{52}N_2O_6$: C 72.12, H 8.28, N 4.43; found: C 72.10, H 8.08, N 4.63.

*1,4-Bis[5-(5-ethoxycarbonyl-2,4-dimethylpyrrol-3-yl)pentyl]-2,3,5,6-tetramethylbenzene (**22**a)*

The diketone **21***a* (17 g, 0.027 mol) and $NaBH_4$ (3 g, 0.079 mol) were suspended in dry THF (400 mL) under N_2 and treated dropwise (ice-bath) with $BF_3{\cdot}Et_2O$ (14 mL, 0.11 mol). When tlc examination showed the absence of starting material or intermediates (more $NaBH_4$ and $BF_3{\cdot}Et_2O$ were added if necessary), the reaction mixture was quenched by careful dropwise addition of glacial acetic acid (100 mL). Water (1.5 L) was added causing the separation of the product, which was filtered and washed with water. The solid was redissolved by heating in THF (500 mL), the undissolved impurities were removed by filtration, and the filtrate was then diluted with CH_3OH and concentrated *in vacuo* to give 14.3 g (88.3%) of a white powdery solid, in two crops, mp 198.0–199.0°C; ^{1}H nmr (δ, $CDCl_3$): 1.35, 1.32–1.62 (t, br, 18H, OCH_2CH_3, chain 2,2′,3,3′4,4′-CH_2), 2.20, 2.22, 2.28, 2.24–2.50 (s,s,s,m, 28H, pyrrole 2-CH_3, durene CH_3, pyrrole 4-CH_3, chain 5,5′-CH_2), 2.50–2.80 (m, 4H, chain 1,1′-CH_2), 4.32 (q, 4H, J = 7 Hz, OCH_2CH_3), 8.73 (bs, 2H, NH); ms m/*e*: 688 (M^+, 62), 558 (29), 180 (100), 134 (90). *Anal.* calcd. for $C_{38}H_{56}N_2O_4$: C 75.46, H 9.33, N 4.63; found: C 75.18, H 9.32, N 4.72.

*1,4-Bis[5-(5-benzyloxycarbonyl-2,4-dimethylpyrrol-3-yl)pentyl]-2,3,5,6-tetramethylbenzene (**23**a)*

The diethyl ester **22***a* (13.1 g, 21.5 mmol) and benzyl alcohol (125 mL) (redistilled from K_2CO_3 at 1 atm) were heated to boiling under N_2, and a fresh solution of Na in dry benzyl alcohol was added in ca. 1-mL portions until the exchange was complete. The hot solution was quenched by pouring (cautiously) into a solution of acetic acid (25 mL) in CH_3OH (500 mL) when the solid product appeared immediately. Water (400 mL) was stirred in, the mixture was allowed to stand for 5 min, and the solid filtered and washed with 50% aqueous CH_3OH. Yield 15.5 g (98.1%). A sample was recrystallized from THF–CH_3OH for analysis; mp 171.0–172.0°C; ^{1}H nmr (δ, $CDCl_3$): 1.46 (br, 12H, chain 2,2′,3,3′,4,4′,-CH_2), 2.19, 2.22, 2.30, 2.22–2.50 (s,s,s,m, 28H, pyrrole 2-CH_3, durene CH_3, pyrrole 4-CH_3, chain 5,5′-CH_2), 2.50–2.78 (m, 4H, chain 1,1′-CH_2), 5.31 (s, 4H, $OCH_2C_6H_5$), 7.30–7.52 (m, 10H, C_6H_5), 8.60 (bs, 2H, NH); ^{13}C nmr (δ, 10% TFA/$CDCl_3$): 164.53 (2C, C=O), 137.17 (2C, durene 1,4), 135.81 (2C, benzene 1), 134.25 (2C, pyrrole 2), 132.35 (4C, durene 2,3,5,6), 131.03 (2C, pyrrole 4), 128.91, 128.69, 128.39 (10C, benzene 2,3,4,5,6), 123.96 (2C, pyrrole 3), 115.57 (2C, pyrrole 5), 67.37 (2C, -$OCH_2C_6H_5$), 30.96, 30.82, 30.24, 30.07 (8C, chain, 1,1′,2,2′,3,3′,4,4′), 24.20 (2C, chain 5,5′), 16.49 (4C, durene CH_3), 11.69, 11.34 (4C, pyrrole 2-CH_3, 4-CH_3); ms m/*e*: 728 (M^+, 88), 620 (36), 242 (32), 108 (100), 91 (68). *Anal.* calcd. for $C_{48}H_{60}N_2O_4$: C 79.08, H 8.30, N 3.84; found: C 78.91, H 8.47, N 3.83.

*1,4-Bis[5-(5-formyl-2,4-dimethylpyrrol-3-yl)pentyl]-2,3,5,6-tetramethylbenzene (**27**a)*

This compound was prepared from the foregoing dibenzyl ester **23***a* in three steps without the isolation and characterization of the intermediates.

(*i*) *Debenzylation*. The dibenzyl ester **23***a* (10.0 g, 13.8 mmol) and 10% Pd/C (0.9 g) were stirred under H_2 (1 atm, room temperature), in THF (250 mL) containing triethylamine (5 drops). When the H_2 uptake ceased (ca. 3 h), the solution was checked by tlc for the absence of starting material and the catalyst was filtered. The solvent was then removed *in vacuo* below 40°C, affording the crude biscarboxypyrrole as a pale yellow solid.

(*ii*) *Decarboxylation*. The above yellow solid was dissolved in DMF (100 mL) and refluxed under N_2 until the uv absorption maximum at 284 nm was reduced to a minor shoulder (ca. 2.5 h).

(*iii*) *Formylation*. The decarboxylation mixture above was added dropwise to an ice-cooled solution of the Vilsmeier reagent (prepared by adding $POCl_3$ (30 mL) in CH_2Cl_2 (10 mL) to DMF (25 mL) in CH_2Cl_2 (80 mL)); the reaction mixture was stirred for 30 min, when the CH_2Cl_2 was removed *in vacuo* and the remaining solution poured onto crushed ice (500 g).

Solid $NaHCO_3$ was added cautiously (with effervescence) until the solution was weakly basic. The solution was heated on a steam bath (further bicarbonate being added if the solution became acidic) until the remaining CH_2Cl_2 evaporated, and a clear brown single-phase solution was formed (pH should remain around 8).

The solution was suction filtered to remove minor insoluble tars, the volume adjusted to ca. 1 L with water, and heating continued for a further 30–60 min. The bisformylpyrrole **27***a* separated out as a grey solid and was filtered, washed with water, and dried to give 7.1 g. The crude solid was reacted with malonitrile to afford the bisdicyanovinylpyrrole **28***a* (*vide infra*). After purification by chromatography, a sample of this was deprotected with KOH in aqueous propanol to produce **27***a* for analysis; mp 233.0–234.0°C; ^{1}H nmr (δ, $CDCl_3$): 1.46 (br, 12H, 2,2′,3,3′,4,4′-CH_2), 2.20 (s, 12H, durene CH_3), 2.22, 2.26 (s,s 12H, pyrrole 2,4-CH_3), 2.30–2.43 (m, 4H, 5,5′-CH_2), 2.56–2.69 (m, 4H, 1,1′-CH_2), 8.99 (bs, 2H, NH), 9.44 (s, 2H, CHO); ms m/*e*: 516 (M^+, 42), 488 (33), 473 (18), 136 (100), 108 (76). *Anal.* calcd. for $C_{34}H_{48}N_2O_2$: C 79.02, H 9.36, N, 5.42; found: C 78.87, H 9.47, N 5.43.

*1,4-Bis{5-[5-(2,2-dicyanovinyl)-2,4-dimethylpyrrol-3-yl]pentyl}-2,3,5,6-tetramethylbenzene (**28**a)*

The crude bisformylpyrrole **27***a* (6.5 g) and malononitrile (2.0 g, 30.3 mmol) were refluxed in toluene (300 mL) in the presence of cyclohexylamine (2 mL). Thin-layer chromatographic analysis of the reaction mixture indicated the completion of the reaction in 2 h. Toluene was evaporated *in vacuo*, CH_3OH added, and the crude product isolated in two crops. The combined solid was chromatographed on silica (activity I, 150 g) using CH_2Cl_2 initially, and 0.2–0.5% CH_3OH in CH_2Cl_2 later, for elution. The yellow solution was concentrated *in vacuo* and the bisdicyanovinylpyrrole crystallized out analytically pure, as a lemon yellow solid (4.82 g, 62.6% overall from the bisbenzyl ester **23***a*) by the addition of CH_3OH; mp 228.5–229.5°C; ^{1}H nmr (δ, $CDCl_3$): 1.44 (br, 12H, chain 2,2′,3,3′,4,4′-CH_2), 2.13 (s, 6H, pyrrole 4-CH_3), 2.20 (s, 12H, durene CH_3), 2.31 (s, 6H, pyrrole 2-CH_3), 2.34–2.45 (m, 4H, chain 5,5′-CH_2), 2.56–2.69 (m, 4H, chain 1,1′-CH_2), 7.28 (s, 2H, C(*H*)=$C(CN)_2$), 9.29 (bs, 2H, NH); ^{13}C nmr (δ, 10% TFA/$CDCl_3$): 145.09 (2C, pyrrole 2), 140.97 (2C, *C*(H)=$C(CN)_2$), 138.80 (2C, pyrrole 4), 136.85 (2C, durene 1,4), 132.19 (4C, durene 2,3,5,6), 126.94 (2C, pyrrole 3), 125.04 (2C, pyrrole 5), 117.24 (2C, C≡N), 116.29 (2C, C≡N), 58.77 (2C, C(H)=*C*$(CN)_2$), 30.83 (2C, chain 1,1′), 30.11 (6C, chain 2,2′,3,3′,4,4′), 24.04 (2C, chain 5,5′), 16.45 (4C, durene CH_3), 12.59 (2C, pyrrole 2-CH_3), 9.81 (2C, pyrrole 4-CH_3); ms m/*e*: 612 (M^+, 94), 597 (12), 226 (17), 184 (100). *Anal.* calcd. for $C_{40}H_{48}N_6$: C 78.39, H 7.89, N 13.71: found: C 78.49, H 7.77, N 13.63.

*1,4-Bis{5-[2-(5-ethoxycarbonyl-3-ethyl-4-methylpyrrol-2-yl)methyl]-5-(2,2-dicyanovinyl)-4-methylpyrrol-3-yl]pentyl}-2,3,5,6-tetramethylbenzene (**31**a)*

(*i*) *Monochlorination of the α-methyl substituents*. The bisdicyanovinylpyrrole **28***a* (1.23 g, 2.01 mmol) in dry CH_2Cl_2 (180 mL) was treated dropwise, at room temperature, with 20 mL of a stock solution of SO_2Cl_2 (2.85 g, 21.1 mmol; redistilled) in CH_2Cl_2 (100 mL). The solvent was carefully displaced with anhydrous diethyl ether, causing

For personal use only.

the bischloromethyl derivative **29***a* to crystallize as a lemon yellow powdery solid. This was collected by filtration, washed with 10% CH_2Cl_2 in ether, air dried, and used in the following reaction without further purification.

(*ii*) *Formation of the bisdipyrromethane*. The above bischloromethyl derivative **29***a* and 2-ethoxycarbonyl-4-ethyl-3-methylpyrrole **30** (1.2 g, 6.6 mmol) were warmed (water bath) in glacial acetic acid (600 mL), under N_2 to 80°C. The yellow starting material dissolved with reaction and the solution turned orange-red. Thin-layer chromatographic analysis indicated that the reaction was complete in 1 h.

The solution was cooled to room temperature, concentrated to ca. 25 mL *in vacuo*, CH_3OH (100 mL) was added, and it was allowed to stand overnight under refrigeration. The product crystallized as a dark yellow solid, which was collected by filtration and washed with CH_3OH; yield 1.74 g (89.2%). An analytical sample was recrystallized from CH_2Cl_2–CH_3OH, mp 186.0–190.0°C; ^{1}H nmr (δ, $CDCl_3$): 1.02 (t, 6H, J = 7.5 Hz, 3′-CH_2CH_3), 1.32 (t, 6H, J = 7 Hz, -OCH_2CH_3), 1.44 (br, 12H, chain 2,2′,3,3′,4,4′-CH_2), 2.13 (s, 6H, pyrrole 4-CH_3), 2.20 (s, 12H, durene CH_3), 2.26 (s, 6H, pyrrole 4′-CH_3), 2.33–2.48 (m, 8H, 4′-CH_2CH_3, chain 5,5′-CH_2), 2.56–2.69 (m, 4H, chain 1,1′-CH_2), 3.94 (s, 4H, *meso* CH_2), 4.23 (q, 4H, J = 7 Hz, OCH_2CH_3), 7.28 (s, 2H, C(*H*)=$C(CN)_2$), 8.75 (br, 2H, 1′-NH), 9.17 (br, 2H, 1–NH); ^{13}C nmr (δ, 10% TFA/$CDCl_3$): 164.74 (2C, C=O), 142.93 (2C, *C*(H)=$C(CN)_2$), 141.89 (2C, pyrrole 2), 138.78 (2C, pyrrole 4), 136.89 (2C, durene 1,4), 132.21 (4C, durene 2,3,5,6), 129.82, 128.98, 126.51, 126.11 (8C, pyrrole 3,2′,3′,4′), 125.19 (2C, pyrrole 5), 118.09 (2C, pyrrole 5′), 116.75 (2C, C≡N), 115.67 (2C, C≡N), 61.97 (2C, -OCH_2CH_3), 60.99 (2C, C(H)=*C*$(CN)_2$), 30.82 (2C, chain 1,1′), 30.19, 29.97 (4C, 2C, chain 2,2′,3,3′,4,4′), 24.20 (4C, *meso* CH_2, chain 5,5′), 17.44 (2C, pyrrole 3′-*C*H_2CH_3), 16.42 (4C, durene CH_3), 15.29 (2C, pyrrole 3′-CH_2CH_3), 14.24 (2C, -OCH_2CH_3), 10.85 (2C, pyrrole 4′-CH_3), 9.76 (2C, pyrrole 4-CH_3); ms *m/e*: 970 (0.2), 924 (1.6), 878 (2.6), 745 (26). *Anal.* calcd. for $C_{60}H_{74}N_8O_4$: C 74.20, H 7.68, N 11.54; found: C 73.99, H 7.51, N 11.60.

*1,4-Bis{5-[2-[(5-carboxy-3-ethyl-4-methylpyrrol-2-yl)methyl]-5-formyl-4-methylpyrrol-3-yl]pentyl}-2,3,5,6-tetramethylbenzene (**32**a)*

The dimeric dicyanovinyl dipyrromethane ester **31***a* (1.21 g, 1.25 mmol) was suspended in a solution of KOH (7.5 g) in water (100 mL) and the mixture heated under N_2. At reflux, *n*-propanol (60 mL) was added; the yellow starting material dissolved promptly giving a pale brown solution. Reflux was continued and the reaction was monitored by uv–visible spectroscopy. The starting material absorbed strongly at 407 nm, and moderately at 275 nm, while the product absorbed strongly at 270 nm and 320 nm. Propanol was then boiled off while replenishing with water (total volume 300 mL) until the reflux temperature reached 100°C. The solution was cooled to room temperature under N_2, acidified with acetic acid, and the product isolated and dried to give 1.01 g (99%) of analytically pure material, mp 158.0–160.0°C (dec.); ^{1}H nmr (δ, DMSO-d_6): 0.84 (t, 6H, 3′-CH_2-CH_3), 1.32 (br, 12H, chain 2,2′,3,3′,4,4′-CH_2), 1.96–2.44 (m, br, 36H, durene CH_3, pyrrole 2,4-CH_3, chain 1,1′,5,5′-CH_2, 3′-CH_2CH_3), 3.78 (br, 4H, *meso* CH_2), 9.48 (s, 2H, CHO), 10.94 (bs, 2H, 1-NH), 11.48 (bs, 2H, 1′-NH); ms *m/e*: 818 (M^+, 5), 816 (15), 730 (40). *Anal.* calcd. for $C_{50}H_{66}N_4O_6$: C 73.32, H 8.12, N 6.84; found: C 73.28, H 8.22, N 6.80.

*7,17-Diethyl-2,8,12,18-tetramethyl-3,13-[2,3,5,6-tetramethylphenylene-1,4-bis(pentamethylene)]porphyrin (**34**a)*

(*i*) *Decarboxylation*. The chain-linked bisdipyrromethane **32***a* (901 mg; 1.1 mmol) was decarboxylated in refluxing DMF (100 mL) under N_2. The reaction was monitored by uv spectroscopy; the absorption band at 280 nm decayed relative to the band at 320 nm and the reaction was complete in 2–2.5 h.

The solution was cooled under N_2, concentrated *in vacuo* to approximately 50 mL, and diluted with CH_2Cl_2 (200 mL). This was washed with water (3 × 60 mL) to remove most of the remaining DMF, dried (Na_2SO_4), filtered, and diluted to 500 mL with CH_2Cl_2 in preparation for the next step.

(*ii*) *Intramolecule 2 + 2 coupling*. The cyclization was carried out in two 2-L Erlenmeyer flasks (covered with aluminum foil to exclude light) each containing *p*-toluenesulfonic acid (4.0 g) in CH_3OH (25 mL) – CH_2Cl_2 (600 mL). The CH_2Cl_2 solution from the above decarboxylation step was added to the catalyst solution by means of a syringe pump; the entire addition was complete in 6 days.

The reddish violet solution was concentrated *in vacuo* to approximately 150 mL, extracted with saturated aqueous $NaHCO_3$ (3 × 50 mL) to remove the acid catalyst, and then taken to dryness *in vacuo*. The residue was taken up in minimal CH_2Cl_2 and chromatographed as described below.

(*iii*) *Chromatographic purification of porphyrin*. The crude porphyrin was initially chromatographed on silica gel (Woelm, act. I, 70–150 mesh, 100 g) using CH_2Cl_2 to elute most of the nonfluorescent impurities. The porphyrin was eluted with 2% CH_3OH in CH_2Cl_2 and rechromatographed on activity IV silica gel (35 g). The impurities were removed with CH_2Cl_2 and the porphyrin was eluted cleanly using 1% CH_3OH in CH_2Cl_2, and crystallized from CH_3OH to give a yield of 239 mg (31.4% overall for decarboxylation–cyclization). Typically, the yield varied between 22 and 31% and appeared to depend to a large extent on the particular sample of the starting material **32***a*; mp 273.0–274.5°. Visible spectrum (CH_2Cl_2), λ_{max}(nm) (log ε): 400.7 (5.16), 500.8 (4.04), 537.0 (3.98), 569.8 (3.76), 623.9 (3.64); ^{1}H nmr (δ, $CDCl_3$): 9.94 (s, 2H, 10-H and 20-H), 9.86 (s, 2H, 5-H and 15-H), 4.09 (m, 6H, CH_2CH_3 and one proton each at chain termini), 3.84 (m, 2H, one proton each at chain termini), 3.64 (s, 6H, CH_3), 3.48 (s, 6H, CH_3), 1.90, 1.87 (t, m, 10H, CH_2CH_3 and four chain protons), 1.40 (t, 4H, chain-durene termini), 0.91 (m, 2H, chain protons), 0.69 (m, 2H, chain protons), 0.41 (s, 12H, durene CH_3), −1.06 (m, 4H, chain protons), −3.81 (bs, 2H, N–H); ^{13}C nmr (δ, 10% TFA/$CDCl_3$): 146.07, 143.08, 142.90, 142.71, 141.25, 140.31, 139.17 (16C, α- and β-pyrrolic carbons), 134.79 (2C, durene 1,4), 130.25 (4C, durene 2,3,5,6), 99.87, 98.91 (4C, *meso* 5,10,15,20), 30.80, 29.46, 27.20 (10C, chain carbons), 20.16 (2C, CH_2CH_3), 16.67 (2C, CH_2CH_3), 14.65 (4C, durene CH_3), 12.28, 11.68 (4C, 2,8,12,18-CH_3). Mol Wt. found by high resolution mass spectrometry: 692.4866; $^{12}C_{48}{}^1H_{60}{}^{14}N_4$ required 692.4818. *Anal.* calcd. for $C_{48}H_{60}N_4 \cdot CH_3OH$: C 81.22, H 8.84, N 7.73; found: C 81.50, H 8.90, N 7.72.

*7,17-Diethyl-2,8,12,18-tetramethyl-3,13-[2,3,5,6-tetramethylphenylene-1,4-bis(tetramethylene)]porphyrin (**34**b)*

The bisdipyrromethane **32***b* was decarboxylated as described for **32***a*. Because of the lower solubility of the intermediate **33***b*, the DMF solution was concentrated, diluted with THF instead of CH_2Cl_2, and cyclized under high dilution, as described earlier. The crude porphyrin was chromatographed initially on activity I silica gel as before but the partially purified porphyrin was rechromatographed on activity III neutral alumina. Toluene was used initially as the eluant, which was later changed to CH_2Cl_2. Yields varied between 11 and 16%; mp 272.0–273.0°C. Visible spectrum (CH_2Cl_2), λ_{max} (nm) (log ε): 400.7 (5.22), 502.0 (4.04), 538.0 (4.07), 571.5 (3.76), 626.0 (3.64); ^{1}H nmr (δ, $CDCl_3$): 9.83 (s, 2H, 10-H and 20-H), 9.61 (s, 2H, 5-H and 15-H), 4.06 (m, 4H, -CH_2CH_3), 3.82 (m, 2H, chain protons), 3.62 (m, 8H, two CH_3 and 2 chain protons), 3.32 (s, 6H, two CH_3), 1.88 (t, J = 7.5 Hz, 6H, -CH_2CH_3), 1.71 (s, 2H, chain protons), 1.43 (m, 4H, chain protons), 1.30 (m, 2H, chain protons), 0.29 (s, 6H, durene CH_3), 0.21 (s, 6H, durene CH_3), −1.51 (m, 2H, chain protons), −1.72 (m, 2H, chain protons), −3.54 (bs, 2H, N–H); ^{13}C nmr (δ, 10% TFA/$CDCl_3$): 146.54, 144.87, 143.00, 140.94, 140.31, 139.57, 139.42, 138.62 (16C, α- and β-pyrrolic carbons), 135.69, (2C, durene 1,4), 129.49, 129.17 (4C, durene 2,3,5,6), 99.93, 98.84 (4C, *meso* 5,10,15,20), 28.66, 28.00, 27.55, 25.20 (8C, chain carbons), 20.07 (2C, CH_2CH_3), 16.38 (2C, CH_2CH_3), 14.46 (4C, durene CH_3), 12.00, 11.59 (4C, 2,8,12,18-CH_3). Mol. Wt. found by high resolution mass spectrometry: 664.4495; $^{12}C_{46}{}^1H_{56}{}^{14}N_4$ requires 664.4509. *Anal.* calcd. for $C_{46}H_{56}N_4 \cdot H_2O$: C 80.99, H 8.56, N 8.20; found: C 81.06, H 8.20, N 8.20.

*7,17-Diethyl-2,8,12,18-tetramethyl-3,13[2,3,5,6-tetramethylphenylene-1-4-bis(heptamethylene)]porphyrin (**34**c)*

This was synthesized in a manner similar to that described for its analogue **34***a*. The second chromatographic purification of this material was performed on activity III neutral alumina. Some forerunning brown impurities were removed by using 25% hexane–toluene initially. The porphyrin product was then eluted cleanly using 20% CH_2Cl_2–toluene and was crystallized from CH_2Cl_2–CH_3OH. Yields varied between 9 and 13%, mp 314.5–315.5. Visible spectrum (CH_2Cl_2), λ_{max} (nm) (log ϵ): 397.0 (5.16), 495.5 (4.12), 528.5 (3.98), 565.0 (3.81), 618.5 (3.72); ^{1}H nmr (δ, $CDCl_3$): 10.04 (s, 2H, 10-H and 20-H), 10.02 (s, 2H, 5-H and 15-H), 4.41 (m, 2H, chain protons), 4.16 (m, 2H, chain protons), 3.97 (m, 4H, -CH_2CH_3), 3.60 (s, 6H, two CH_3), 3.57 (s, 6H, two CH_3), 2.31 (m, 2H, chain protons), 2.05 (m, 2H, chain protons), 1.84 (t, J = 7.5 Hz, 6H, -CH_2CH_3), 1.57 (m, 2H, chain protons), 1.38 (m, 2H, chain protons), 1.30–0.95 (m, 12H, chain protons), −0.01 to −0.16 (m, 4H, chain protons), −0.20 (s, 12H, durene CH_3), −3.71 (bs, 2H, N–H); ^{13}C nmr (δ, 10% TFA/$CDCl_3$): 145.45, 143.45, 142.68, 142.46, 141.65, 140.85, 139.71, 138.78 (16C, α- and β-pyrrolic carbons), 135.52 (2C, durene 1,4), 130.60 (4C, durene 2,3,5,6), 99.28 (4C, *meso* 5,10,15,20), 31.19, 29.85, 29.26, 28.44, 28.37, 27.76, 26.82 (14C, chain carbons), 20.15 (2C, CH_2CH_3), 16.43 (2C, CH_2CH_3), 15.20 (4C, durene CH_3), 12.19, 11.66 (4C, 2,8,12,18-CH_3). Mol Wt. found by high resolution mass spectrometry: 748.5446; $^{12}C_{52}{}^{1}H_{68}{}^{14}N_4$ requires 748.5444. *Anal.* calcd. for $C_{52}H_{68}N_4 \cdot 1/2H_2O$: C 82.38, H 9.17, N 7.39; found: C 82.58, H 9.34, N 7.30.

Received February 26, 1988

This paper is dedicated to Professor Charles A. McDowell, on the occasion of his seventieth birthday

RAMESH M. BELANI, BRIAN R. JAMES, DAVID DOLPHIN, and STEVEN J. RETTIG. Can. J. Chem. **66**, 2072 (1988).

The complex (5,10,15,20-tetraphenylporphinato)bis(tri-*n*-butylphosphine)iron(II), **1**, has been isolated in a triclinic crystal form, $a = 12.499(3)$, $b = 12.528(2)$, $c = 12.039(2)$ Å, $\alpha = 116.39(1)$, $\beta = 109.79(1)$, $\gamma = 98.13(1)°$, $Z = 1$, space group $P\bar{1}$. The structure was solved by conventional heavy atom methods and was refined by full-matrix least-squares procedures to $R = 0.060$ and $R_w = 0.070$ for 3551 reflections with $I \geq 3\sigma(I)$. The molecule, which has crystallographic 1-C_i symmetry, displays a relatively undistorted pseudo-octahedral coordination geometry with Fe—P = 2.346(1) and Fe—N = 1.998(3) and 1.993(3) Å. In CH_2Cl_2 solution, **1** reacts with CO and aldehydes to generate the carbonyl(phosphine) derivative, and decarbonylation of phenylacetaldehyde to toluene becomes catalytic under an Ar stream. The aldehyde decarbonylations involve radical pathways via carbonyl loss from $PhCH_2\dot{C}O$. The hydrogen abstraction/initiation reaction probably utilizes trace O_2 (and possibly trace (water); speculative mechanisms are discussed.

RAMESH M. BELANI, BRIAN R. JAMES, DAVID DOLPHIN et STEVEN J. RETTIG. Can. J. Chem. **66**, 2072 (1988).

On a isolé le complexe (tétraphényl-5,10,15,20 porphinato)bis(tris-*n*-butylphosphine)fer(II), **1**, sous la forme de cristaux tricliniques avec $a = 12,499(3)$, $b = 12,528(2)$ et $c = 12,039(2)$ Å, $\alpha = 116,39(1)$, $\beta = 109,79(1)$ et $\gamma = 98,13(1)°$, $Z = 1$ et groupe d'espace $P\bar{1}$. On a résolu la structure par les méthodes conventionnelles aux atomes lourds et on l'a affinée par la méthode des moindres carrés (matrice entière) jusqu'à des valeurs de $R = 0,060$ et $R_w = 0,070$ pour 3551 réflexions avec $I \geq 3\sigma(I)$. La molécule, qui possède une symétrie cristallographique 1-C_i, se présente sous une géométrie de coordination pseudo-octaédrique qui n'est pas déformée, avec Fe—P = 2,346(1) et Fe—N = 1,998(3) et 1,993(3) Å. En solution dans le CH_2Cl_2, le composé **1** réagit avec le CO et avec les aldéhydes pour donner le dérivé carbonyl (phosphine) et la décarbonylation du phénylacétaldéhyde en toluène devient catalytique sous un jet d'Ar. Les décarbonylations d'aldéhydes impliquent des voies radicalaires par le biais de la perte du carbonyle du $PhCH_2CO$. La réaction d'initiation par enlèvement d'hydrogène utilise probablement des traces de O_2 (et possiblement des traces d'eau); on spécule sur divers mécanismes possibles.

[Traduit par la revue]

Introduction

Carbonylation reactions provide key steps in a range of homogeneously catalyzed processes of industrial importance (1, 2). Decarbonylation (for example, of aldehydes: RCHO → RH + CO) might appear unattractive commercially, but is of potential, *if done catalytically*, in terms of (*a*) recycling of a branched aldehyde side-product formed in hydroformylation of olefins (ref. 2, Chapt. 4), and (*b*) in organic synthesis of fine chemicals, where conversion of a formyl substituent to hydrogen is required. Further, nature has learned how to effect catalytic decarbonylation at ambient conditions, for example, within (*a*) an uncharacterized metal-containing decarbonylase that generates from aldehydes less prevalent hydrocarbons containing odd numbers of carbon atoms (3), and (*b*) a nickel–zinc–iron–sulfur cluster containing carbon monoxide dehydrogenase that *reversibly* decarbonylates acetyl coenzyme A (4). It should be noted that reports on the enzymatic systems appeared subsequent to the rhodium and ruthenium catalysts discussed below.

Stoichiometric decarbonylation of aldehydes (and acid chlorides) by platinum metal complexes is well documented (5), but it is generally difficult to remove the coordinated carbonyl from the resulting complex either thermally (5) or photolytically (6). However, effective thermal catalysts (in refluxing toluene) for such decarbonylation were first provided by $Rh(P—P)_2^+$ complexes, because the $Rh(CO)(P—P)_2^+$ species generated lose CO quite readily (7). Then, early observations on stoichiometric decarbonylation of acetic acid (8) and dimethylformamide (9) by ruthenium(II) porphyrin complexes led us to develop an efficient catalytic system for decarbonylation of aromatic and aliphatic aldehydes at ambient conditions (10): the system, a purely thermal one, required the presence of tertiary phosphines, which were considered necessary to displace coordinated carbonyl via established, labile equilibria such as shown in eq. [1] (10).

[1] $Ru(porp)(CO)(PR_3) + PR_3 \rightleftharpoons Ru(porp)(PR_3)_2 + CO$

(R = Ph, ^{n}Bu)

The studies led to a "recipe" for a practical procedure for decarbonylation of aldehydes starting with solutions containing $Ru(porp)(PR_3)_2$ complexes, but the mechanism remained poorly defined, although radical pathways have been established (10). An obvious follow-up to this ruthenium work was extension to the first-row, cheaper iron(II) systems and at the time this work was initiated in 1982 (11), bis(tertiary phosphine)(porphyinato)iron(II) complexes had not been isolated in the solid state.

Of note, there have been recent developments in the use of tertiary phosphines as structural probes for heme environments (12), and indeed the first published work on isolation of $Fe(porp)(PR_3)_2$ and $Fe(porp)[P(OR)_3]_2$, which appeared in 1984, was motivated by this bioinorganic interest (13). We first made such complexes at the same time (11), and report here on the full characterization of $Fe(TTP)(P^nBu_3)_2$ including an X-ray structural analysis, and use of the complex for catalytic decarbonylation of aldehydes. The data have been reported at

[1] ABBREVIATIONS. P—P = the chelating ditertiaryphosphines $PPh_2(CH_2)_nPPh_2$ n = 1–4; porp = a porphyrin dianion; TPP = 5,10,15,20-tetraphenylporphyrin dianion; pip = piperidine.

meetings (14), and the structure appears to be the first reported for a hemephosphine complex.[2]

Experimental

All solvents were distilled, stored, and handled under argon, the purification methods being outlined in the literature (15). Liquid aldehydes were distilled under N_2 at reduced pressures, while solid aldehydes were recrystallized from appropriate solvents (15). The phosphines were from Strem Chemicals, the P^nBu_3 being fractionally distilled under vacuum and the purity checked by ^{31}P nmr ($\delta(C_6H_6)$ 31.8). C.P. grade CO, N_2, and Ar were obtained from Canada Liquid Air Ltd. All manipulations, including preparation of the complexes, were carried out under Ar using Schlenk techniques. General procedures used for recording optical, infrared, nmr, and mass spectra have been given elsewhere (16, 17) (^{31}P nmr shifts are relative to 85% H_3PO_4, downfield being positive). Gas chromatography (thermal conductivity) was performed on a Hewlett-Packard 5830A instrument using 6 ft. × 0.125 in. 6% OV101 and OV17 packed columns. Gas chromatography/mass spectrometry was carried out on a Carlo-Erba Fractovap 4160-Kratos MS80RFA instrument.

The compounds H_2TPP (18), Fe(TPP)Cl (19), $[Fe(TPP)]_2O$ (20), and $Fe(TPP)(pip)_2$ (21), were made according to the literature procedures.

Synthesis of $Fe(TPP)(PR_3)_2$ complexes; R = ^{n}Bu (1), Ph (2)

To Fe(TPP)Cl (140 mg, 0.2 mmol) in 30 mL CH_2Cl_2 under Ar was added P^nBu_3 (3 mL), and the solution refluxed for 20 min. The volume was then reduced to about 5 mL by bubbling Ar through the solution; addition of MeOH (10 mL) precipitated purple crystals of **1** that were filtered off, washed with methanol, and dried under Ar (95% yield). *Anal.* calcd. for $C_{68}H_{82}N_4P_2Fe$: C 76.14, H 7.65, N 5.22; found: C 75.9, H 7.7, N 5.1. λ_{max} nm (log ϵ), CH_2Cl_2: 358(4.69), 455(5.11), 562(4.20), 603(4.37), in good agreement with the literature (13). Nuclear magnetic resonance (C_6D_6, 20°C, *in vacuo*): δ_H −2.0 (br, CH_2P, 12H), −0.87(br, CH_2CH_2P, 12H), 0.5 (t, CH_2CH_3, 18H), 0.6 (m, CH_2CH_3, 12H), 7.5–7.6 (m, *m*-H, *p*-H, 12H), 8.32 (m, *o*-H, 8H), 8.74 (s, pyrrole-H, 8H). δ_P 5.65(s).

To Fe(TPP)Cl (140 mg, 0.2 mmol) in 20 mL CH_2Cl_2 under Ar were added PPh_3(210 mg, 0.8 mmol), and $Na_2S_2O_4$ (70 mg, 0.4 mmol) dissolved in 5 mL degassed water, and the mixture stirred at 30°C for 30 min. The organic layer was syringed out, evaporated to about 5 mL, and MeOH (10 mL) added. The resulting solid (**2**) was collected and dried under vacuum (60% yield). *Anal.* calcd. for $C_{80}H_{58}N_4P_2Fe\cdot CH_3OH$: C 79.42, H 5.06, N 4.57; found: C 79.4, H 5.7, N 3.8. λ_{max} nm, CH_2Cl_2, in the presence of added PPh_3: 590, 550, 450, and 345.

Procedure for catalytic aldehyde decarbonylation

The reactions were carried out in a side-armed flask, fitted with a reflux condenser connected to a dry ice/acetone trap. The system was continually flushed with Ar, that could be deoxygenated by passage through a BASF catalyst maintained at 45°C, and be dried by passage through P_2O_5, KOH, and Drierite columns. The aldehyde (10^{-1}–10^{-2} *M*) was added to the Fe(II) porphyrin complex dissolved at 10^{-3}–10^{-5} *M* in chosen solvents and temperatures, and the reaction monitored (uv/vis and gc) by withdrawing samples with a gas-tight syringe. Organic reactants and products collected also in the cold trap, the amounts depending on the reaction time and temperature. Quoted conversions and turn-overs include total concentration detected in the reaction vessel and cold-trap.

X-ray crystallographic analysis of $Fe(TPP)(P^nBu_3)_2$

A crystal bounded by the ten faces (followed by the distances in mm between parallel faces): {0 1 0}, 0.18, {1 0 0}, 0.30, {1 0 − 1}, 0.50, {0 1 −1}, 0.52, {0 0 1}, 0.51 was mounted in a general orientation. Unit-cell parameters were refined by least-squares on 2 sin θ/λ values for 25 reflections (2θ = 30–37°) measured on a diffractometer with Mo-$K\alpha$ radiation ($\lambda(K\alpha_1)$ = 0.70930, $\lambda(K\alpha_2)$ = 0.71359 Å). Crystal data at 22°C are:

$C_{68}H_{82}FeN_4P_2$ f.w. = 1073.2

Triclinic, a = 12.499(3), b = 12.528(2), c = 12.039(2) Å, α = 116.39(1), β = 109.79(1), γ = 98.13(1)°, V = 1492.3(6) Å^3, Z = 1, ρ_c = 1.194 Mg m^{-3}, F (000) = 574, μ(Mo-$K\alpha$) = 3.5 cm^{-1}. Absent reflections: none, space group $P\bar{1}$ (reduced cell, Donnay convention) from structure analysis.

Intensities were measured with graphite-monochromatized Mo-$K\alpha$ radiation on an Enraf-Nonius CAD4-F diffractometer. An ω–2θ scan at 0.9–10.0° min^{-1} over a range of (0.85 + 0.35 tan θ) degrees in ω (extended by 25% on both sides for background measurement) was employed. Data were measured to 2θ = 55°. The intensities of three check reflections, measured every 3600 s throughout the data collection, showed only small random variations. Of the 6835 independent reflections measured and processed,[3] 3551 (52%) had intensities greater than or equal to 3σ(I) above background where $\sigma^2(I) = S + 2B + (0.04(S - B))^2$ with S = scan count and B = normalized background count. No absorption correction was made in view of the low value of μ.

The E-statistics and the Patterson function were consistent with the centrosymmetric space group $P\bar{1}$. The coordinates of the P atoms were determined from the Patterson function, the iron atom being constrained by space group symmetry to lie at a crystallographic inversion centre; the coordinates of the remaining non-hydrogen atoms were determined from a subsequent difference map. An attempt to refine the structure in the non-centrosymmetric space group $P1$ resulted in a singular matrix. Non-hydrogen atoms were refined with anisotropic thermal parameters and hydrogen atoms were fixed in idealized positions (staggered methyls, C(sp^2)—H = 0.97, C(sp^3)—H = 0.98 Å, $U_H \propto U_{bonded\ atom}$). Scattering factors for all atoms and anomalous scattering corrections for Fe and P were taken from ref. 22. The weighting scheme $w = 1/\sigma^2(F)$, where $\sigma^2(F)$ is derived from the previously defined $\sigma^2(I)$, gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of both $|F_o|$ and sin θ/λ and was employed in the final stages of full-matrix refinement of 340 variables. Reflections with $I < 3\sigma(I)$ were not included in the refinement. Convergence was reached at R = 0.060 and R_w = 0.070 for 3551 reflections with $I \geq 3\sigma(I)$. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$, $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$ and $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$.

On the final cycle of refinement the mean and maximum parameter shifts corresponded to 0.03 and 0.20σ, respectively. The mean error in an observation of unit weight was 2.681. The final difference map showed no unusual features. The final positional and thermal parameters appear in Tables 1 and 5,[4] respectively. Measured and calculated structure factors have been placed in the Depository of Unpublished Data. Bond lengths and angles appear in Tables 2 and 3, respectively. Calculated hydrogen parameters (Table 4), torsion angles (Table 6), and intra-annular torsion angles (Table 7), are also included as supplementary material.

[2]Professor Simonneaux and his group at the Université de Rennes have recently isolated several $Fe(TPP)(PR_3)_2$ species and characterized structurally the bis(dimethylphenylphosphine) complex (private communication).

[a]Here and elsewhere primed atoms have coordinates related to those in Table 1 by the symmetry operation (1 − x, 1 − y, 1 − z).

Results and discussion

Synthesis and characterization of the complexes

The Fe(TPP)(P^{n}Bu$_3$)$_2$ complex **1** is easily prepared by treating Fe(TPP)Cl with excess of the free phosphine, which presumably acts as the reducing agent; the nature of the redox process has not been elucidated but it may be akin to the well documented H-atom abstraction radical process involved in a corresponding reaction of Fe(TPP)Cl with piperidine to give Fe(TPP)(pip)$_2$ (21). Formation of the bis(triphenylphosphine) complex **2** requires addition of dithionite (or borohydride) as reductant. The synthesis of **1** parallels that discovered independently and reported earlier by Ohya *et al.* (13); this group has already discussed the "hyper" uv/visible spectra (i.e. the presence of a split Soret bond) generated by the bis(tertiary phosphine) and bis(tertiary phosphite) complexes. The uv/visible spectrum obeys Beer's Law and is independent of added P^{n}Bu$_3$, showing that dissociation of a phosphine to give a five-coordinate species is negligible; the same behaviour with this strongly basic phosphine has been noted earlier for the corresponding Ru(II) complex (16). The ^{1}H nmr spectrum of **1**, not studied previously (13), is very typical of that of a six-coordinate, diamagnetic porphyrin complex, and resembles closely that of the Ru(TPP)(P^{n}Bu$_3$)$_2$ complex, resonances of the butyl groups being shifted upfield because of the porphyrin ring current (16).

The crystal structure of Fe(TPP)(P^{n}Bu$_3$)$_2$ consists of well-separated molecules (Fig. 1) having crystallographic $\bar{1}$-C_i symmetry. As a result of this imposed symmetry, the FeN_4 unit is rigorously planar. The iron atom has a tetragonally distorted octahedral coordination geometry. Bond angles at the metal are essentially undistorted from the "ideal" values of 90 and 180°, the largest deviation being 0.42(9)°. The Fe—N distances are equal within the experimental error, the mean Fe—N distance of 1.996(4) Å agreeing well with the value of 2.000(1) Å for Fe(TPP)(PMe$_2$Ph)$_2$[2] and values of 1.98(3)–2.02(3) Å observed for other low-spin Fe(II) TPP complexes (23–27). The Fe—P bond length of 2.346(1) Å is significantly longer than the corresponding distance of 2.284 Å in Fe(TPP)(PMe$_2$Ph)$_2$, as well as those in other (non-porphyrin) octahedral, low-spin Fe(II) complexes with *trans* phosphine ligands, the longest, to our knowledge, being 2.312(8) Å in *trans*-Fe[PPh$_2$(CH$_2$)$_2$PPh$_2$]Cl$_2$ (28). The present Fe—P distance, however, is still substantially shorter than those reported for high-spin complexes which are typically 2.5–2.7 Å (29). The longer Fe—P bond in **1** compared to that in Fe(TPP)(PMe$_2$Ph)$_2$ is almost certainly steric in origin; within **1**, the hydrogens on carbons 27, 28, 31, and 32 are 2.50, 2.49, 2.71, and 2.44 Å respectively, from the porphyrin, less than the normal packing distance of 2.9 Å (30).

The porphyrin core is not rigorously planar, the maximum deviation from the mean plane being 0.045 Å. The pyrrole and phenyl rings are either planar within experimental error or are slightly, but significantly, non-planar (maximum deviation

from the mean plane = 0.03(7) Å). The dihedral angles between the normals to the porphyrin and phenyl mean planes are 91.7 and 92.9°. The mean bond lengths and angles in the porphyrin core are normal (31). Anomalous bond distances are noted within two of the *n*-butyl groups and may be ascribed to high thermal motion and/or minor unresolved disorder.

The $Fe(TPP)(PPh_3)_2$ complex **2** is probably not isolated in a pure state. Associated methanol is observed (the mass spectrum shows a 31 peak (CH_3O^+) as well as the 668 and 334 peaks of $Fe(TPP)^+$ and $Fe(TPP)^{2+}$), and although the C, H elemental analysis is satisfactory, that for N is not. In solution, **2** is very air-sensitive and also dissociates a phosphine ligand, at least at $\sim 10^{-5}$ *M*, because excess phosphine has to be added to generate the uv/visible spectrum typical of a six-coordinate bis(phosphine) species. The degrees of air-sensitivity, and ligand dissociation to give a five-coordinate species, are almost certainly related properties (32). The more basic and less sterically demanding P^nBu_3 ligand does not measurably dissociate from complex **1** at 10^{-5} *M*, which is more readily handled in solution than **2**, although is still air-sensitive (see below). The ^1H nmr spectrum of **2** is complicated by phosphine dissociation and exchange, and the tendency of **2** to oxidize. More careful, detailed studies are required on this system, although it is clear that the hydrogens of the coordinated PPh_3 are shifted upfield, as in $Ru(TPP)(PPh_3)_2$ (16). Attempts to purify **2** via recrystallization were unsuccessful.

Carbonylation/decarbonylation studies using CO

Solutions of $Fe(TPP)(P^nBu_3)_2$ react rapidly and reversibly with CO according to eq. [2].

$$[2]\quad \underset{\mathbf{1}}{Fe(TPP)(P^nBu_3)_2} + CO \overset{K}{\rightleftharpoons} \underset{\mathbf{3}}{Fe(TPP)(CO)(P^nBu_3)} + P^nBu_3$$

The Soret band of **1** (455 nm) is replaced by that of the (carbonyl) phosphine species **3** (438 nm). That the reaction follows the stoichiometry of equation [2] is readily demonstrated by a standard spectrophotometric titration technique (33, 34). The analysis of the data gives $K = 0.65$ at 23°C in toluene (11), which is comparable to that determined by Stynes *et al.* (34) for the corresponding protoporphyrin IX dimethylester system (K = 1.7, 25°C in toluene). The ir spectrum of **3** formed in situ in CH_2Cl_2 reveals ν_{CO} at 1993 cm^{-1}. The equilibrium constant for reaction [2] shows that **1** and **3** are readily interconvertible at easily attainable concentrations of added phosphine and CO, whose solubility in toluene, for example, is 7.6×10^{-3} *M* atm^{-1} at 25°C (35), thus making **1** an appropriate complex to test for catalytic decarbonylation. The K value for reaction [2] involving the Ru analogues of **1** and **3** is 0.054 at 26°C in toluene (36), showing that thermodynamically CO is more readily replaced by P^nBu_3 in the Ru system, although it should be noted that the Ru-catalyzed aldehyde decarbonylation reactions involve a mixed P^nBu_3/PPh_3 system (10). Complex **1** was indeed found to effect such catalysis, but the contribution of these K equilibria reactions within the overall mechanism (free radical in nature — see below) is not clear. Nevertheless, an equilibrium for a reaction comparable to [2], but with $Fe(TPP)(pip)_2$ as reactant, has $K = 15\,000$ (23°C, toluene) (33), showing much higher CO affinity, and the amine system was not an effective catalyst. The K value does serve as a qualitative guide for catalytic potential. The presence of the relatively strong *trans*-effect ligands CO and P^nBu_3 in **3** (compared to CO and pip) is consistent with a higher K value for the amine system, but differences in the labilities of the axial L ligands in the $Fe(TPP)L_2$ complexes (L = P^nBu_3, pip) may also be a factor (34).

Decarbonylation of aldehydes

Treatment of **1** at 10^{-4}–10^{-5} *M* in CH_2Cl_2 at room temperature with a variety of aromatic aldehydes (at $\sim 10^{-3}$ *M*): benzaldehyde and substituted ones (*p*-dimethylamino-, *p*-nitro-, 2,6-dichloro-, 3-methoxy-4-hydroxy-, 2,4,6-trimethoxy-, salicyaldehyde, piperonal), and phenylacetaldehyde, generated the (carbonyl)phosphine species **3** as detected by uv/vis spectroscopy; the reaction times were not reproducible for any one aldehyde, and varied from $t_{1/2}$ values of a few hours to several days. Heptanal-1 and 2-ethylbutanal similarly with **1** gave "irreproducible" formation of **3**. Vacuum pumping (or Ar flushing) the optical cells containing a solution of **3** and excess aldehyde regenerated **1** (eq. [2]), thus establishing the plausibility of catalytic decarbonylation of the aldehydes.

The most extensive studies were carried out using phenylacetaldehyde as substrate because the decarbonylation reaction always proceeded with this substrate and at a reasonable rate; further, the gc retention times for this aldehyde and toluene (the decarbonylation product) were well separated (typically in the 15 and 4 min range), respectively, with a temperature programmed OV101 separation (60°C/5 min and the 5°C/min to 180°C). Samples of catalytically active solutions taken during Ar flushing (see Experimental) revealed the 455 nm band of **1**, while discontinuation of the Ar flow allowed for growth of the 438 nm band of **3**. At room temperature using $PhCH_2CHO$ at $\sim 10^{-3}$ *M* and **1** at $\sim 10^{-5}$ *M* in CH_2Cl_2, essentially complete conversion to toluene occurred with turnovers in the range of 5–20 min^{-1}; at 40°C (refluxing CH_2Cl_2) turnovers a high as 100 min^{-1} were recorded. Of importance, a small amount of bibenzyl was sometimes detected by gc/ms. Flushing with a CO atmosphere (instead of Ar), or addition of $\geq$ 1.0 equivalent of P^nBu_3/Fe, inhibited the decarbonylation completely. All the necessary control experiments were done, and decarbonylation does require the presence of **1**. Addition of a radical inhibitor such as hydroquinone or 2,6-ditertiarybutyl-*p*-cresol at $\sim 10^{-4}$ *M* (which show no reactivity with **1**) prevented any decarbonylation, even stoichiometric, of the aldehyde.

Addition of air or oxygen to CH_2Cl_2 (or toluene) solutions containing $Fe(TPP)(P^nBu_3)_2$, either in the presence or absence of aldehydes, caused a rapid, irreversible colour change (red to greenish red); the Soret was shifted from 455 to 415 nm (log ϵ 4.95 based on [**1**]), while the visible maxima remained essentially unchanged in position but increased slightly in intensity. Such solutions containing the 415 nm band did not effect aldehyde decarbonylation; indeed, if sufficient O_2 gets into the active catalytic solutions to generate the "415 nm species" (e.g. during sampling), and only small amounts are necessary, the catalysis is suppressed. We have been unable to isolate any characterizable complex. One plausible oxidation product $[Fe(TPP)]_2O$ (20, 37) is ruled out because the Soret maximum of the μ-oxo species in CH_2Cl_2 is seen at 403 nm; a less likely product Fe(TPP)Cl exhibits the Soret maximum at 418 nm in CH_2Cl_2. The "oxidized" solution may well contain the five-coordinate phosphine oxide complex $Fe(TPP)(O{=}P^nBu_3)$; the corresponding triphenylphosphine oxide species is said to result from treatment of *in situ* $Fe(TPP)(PPh_3)_2$ with O_2, but no characterization details were presented (37). The 415 nm species could be readily reconverted to **1** by treatment with P^nBu_3. This could be a ligand substitution reaction, although a redox reaction comparable to that seen in the

synthesis of **1** from Fe(TPP)Cl cannot be ruled out; however, the visible spectral changes do not indicate changes in oxidation state of the iron. As noted above, excess phosphine inhibits decarbonylation and so cannot be used to protect against adventitious oxygen.

It should be emphasized that with substrates other than phenylacetaldehyde, catalytic decarbonylation occurred rarely and when catalysis was not observed the 415 nm band was always evident, even though every effort had been made to exclude trace O_2. It is possible that trace impurities in the aldehydes were problematic (either promoting reactivity for the phenylacetaldehyde substrate, or deactivating the other systems). Benzaldehyde was sometimes decarbonylated (the maximum turn-over at 20°C being 0.2 min^{-1}); salicylaldehyde and piperonal were never catalytically decarbonylated. Our earlier catalytic Ru systems were most efficient in MeCN or PhCN solution (10), but use of these solvents was not effective for the Fe(TPP)(P^nBu_3)$_2$/phenylacetaldehyde system; with neat aldehyde as solvent/substrate, temperatures of 200°C and reaction times of 1 h were necessary before decarbonylation products were detected.

Speculation on mechanisms

An attempt to rationalize the general findings can be made only in terms of radical mechanisms, and the evidence for such processes is strong (irreproducibility, inhibition experiments, and detection of bibenzyl with the phenylacetaldehyde substrate). Further, the "standard" decarbonylation mechanism (5, 7) involving oxidative-addition of aldehyde, CO migration (with subsequent elimination), and reductive elimination of hydrocarbon product, seems unlikely at a metalloporphyrin site (10), where one-electron, radical processes more generally are becoming increasingly well documented (38).

It is possible that trace dioxygen initiates a radical mechanism for the Fe-catalyzed decarbonylations, although there is no direct evidence for this; any attempts to add small amounts of O_2 led to formation of the "415 nm species" and inactivity. The irreproducibility in the data, especially within the stoichiometric reactions, certainly suggests that trace O_2 (air) is involved, and there is precedent for O_2 playing a role in assisting hydrogen abstraction from an aldehyde to give an acyl radical in the presence of, for example, a cobalt complex (39). Organic peroxides, whose formation can be catalyzed by metal ions in the presence of O_2 (40*a*), can also generate acyl radicals by reaction with aldehydes (41). Once the acyl radical is formed, catalytic decarbonylation may be accommodated by the processes shown in [3]:

[3] $R\dot{C}O \rightarrow R^{\cdot} + CO;\ R^{\cdot} + RCHO \rightarrow RH + R\dot{C}O$

The decarbonylation of acyl radicals is well known (40*b*), and the sometimes detected bibenzyl must come from the $PhCH_2\cdot$ radical.

That the catalysis is completely inhibited by addition of small, measured amounts of O_2 tends to suggest that initiation via Fe(III) as in eq. [4] (40*c*) is unlikely. Oxygenated species such as trace amounts of $Fe^{II}O_2$ ($Fe^{III}O_2^-$) could act as a chain initiator; H atom abstraction would then give coordinated

[4] $RCHO + Fe^{III} \rightarrow R\dot{C}O + Fe^{II} + H^+$

or free $HO_2^-\cdot$, and such a reaction has been suggested previously (42). The O_2-oxidation of Fe(II) porphyrin phosphine species involves bridged-peroxo and oxo intermediates (37), and H-abstraction by either of these seems plausible (37, 43). Trace protons (from water) can promote formation of superoxide (stabilized as $HO_2\cdot$) from reaction of O_2 with hexacoordinate metalloporphyrins via a one-electron outer-shere process (44, 45), and H-abstraction by $HO_2\cdot$ could also be envisaged. Our findings that isolated 5-coordinate Ru(porp)(PR_3) complexes in benzene do not react with rigorously purified benzaldehyde in the absence or presence of dry O_2, or with dry O_2 alone (32), suggest that the radical mechanism for aldehyde decarbonylation by the Ru system perhaps follows a different initiation pathway to that of the Fe system. Further, some unpublished work on the stoichiometric decarbonylation of phenylacetaldehyde by Ru(TPP)(P^nBu_3)$_2$ in CH_2Cl_2 had shown that the reaction rate increased generally with increasing O_2 at least up to 0.4 atm (36), but this O_2 had not been rigorously dried.

Further work is in progress in an attempt to unravel the complexities of these free-radical initiated catalytic decarbonylations. The studies, however, are difficult and frustrating because of the irreproducible data obtained. Trace impurities seem to be of key importance, and findings are leaning toward the conclusion that if the various ingredients for the recipes are "really highly purified", reactivity may cease. Nevertheless, effective catalytic systems have been discovered, and a search for their understanding continues to expand the coordination chemistry of five- and six-coordinate metalloporphyrins of the iron sub-group metals containing tertiary phosphine ligands. The relation, if any, of these free-radical type decarbonylations to the more recently discovered enzymatic systems (see Introduction) remains to be established.

Received

This paper is dedicated to Professor Charles A. McDowell on the occasion of his seventieth birthday

HAYNES, J. S., SAMS, J. R., and THOMPSON, R. C. 1988. Can. J. Chem. **66**, 2079 (1988).

Six new pyrazine-bridged complexes of iron(II) have been prepared and studied using magnetic susceptibility, differential scanning calorimetry, and vibrational, electronic, and Mössbauer spectroscopic methods. $Fe(pyz)(CF_3SO_3)_2$ exhibits a susceptibility maximum at 4.4 K and analysis of the magnetic data according to a two-dimensional $S = 2$ system in the (isotropic) Heisenberg limit yields best-fit values of $J = -0.26 cm^{-1}$ and $g = 2.20$. Variable temperature Mössbauer spectra between 4.2 and 1.6 K are also reported for this compound and show the onset of magnetic hyperfine splitting below ~3.8 K. Analysis of magnetic data for $Fe(pyz)_2(CH_3SO_3)_2$ and $Fe(pyz)_2(CF_3SO_3)_2 \cdot CH_3OH$ according to the two-dimensional Heisenberg model also indicates the presence of weak antiferromagnetic exchange in these complexes ($J = -0.18$ and $-0.20 cm^{-1}$, respectively). No clear evidence for magnetic concentration was obtained from our studies on $Fe(pyz)_2(ClO_4)_2$, $Fe(pyz)(p\text{-}CH_3C_6H_4SO_3)_2$, and $Fe(pyz)(p\text{-}CH_3C_6H_4SO_3)_2.2CH_3OH$; any antiferromagnetic coupling in these complexes must be considerably weaker than in the other complexes studied.

HAYNES, J. S., SAMS, J. R., et THOMPSON, R. C. 1988. Can. J. Chem. **66**, 2079 (1988).

On a préparé six nouveaux complexes du fer (II) contenant un pont pyrazine et on les a étudié en faisant appel à la suceptibilité magnétique, à la calorimétrie de balayage différentiel et à des méthodes de spectroscopies vibrationnelle, électronique et de Mössbauer. Le $Fe(pyz)(CF_3SO_3)_2$ présente une susceptibilité maximale à 4,4 K et une analyse des données magnétiques à l'aide d'un système bidimensionnel $S = 2$, dans la limite isotrope d'Heisenberg, conduit à des valeurs de $J = -0{,}26 cm^{-1}$ et $g = 2{,}20$. Sur ce composé, on a aussi déterminé les spectres de Mössbauer à températures variables entre 4,2 et 1,6 K; il commence à présenter un couplage magnétique hyperfin en dessous d'environ 3,8 K. Une analyse des données magnétiques du $Fe(pyz)_2(CH_3SO_3)_2$ et du $Fe(pyz)_2(CF_3SO_3)_2 \cdot CH_3OH$ à l'aide du modèle bidimensionnel d'Heisenberg indique aussi la présence de faibles échanges antiferromagnétiques dans ces complexes ($J = -0{,}18$ et $-0{,}20 cm^{-1}$, respectivement). Nos études sur le $Fe(pyz)_2(ClO_4)$, le $Fe(pyz)(p\text{-}CH_3C_6H_4SO_3)_2$ et le $Fe(pyz)(p\text{-}CH_3C_6H_4SO_3)_2 \cdot 2CH_3OH$ n'ont pas permis de mettre en évidence la présence d'une concentration magnétique; dans ces complexes, les couplages antiferromagnétiques doivent être beaucoup plus faibles que ceux observés dans les autres complexes étudiés.

[Traduit par la revue]

Introduction

A recent report describing magnetic susceptibility and Mössbauer studies on $Fe(pyz)_2(NCS)_2$ and $Fe(pyz)(NCO)_2$ (1) demonstrated clearly that bridging pyrazine (1,4-diazine, pyz) ligands are capable of transmitting significant magnetic exchange effects between iron(II) centres. The thiocyanate compound has a two-dimensional layer structure with sheets consisting of a square array of iron atoms bridged by pyrazine and axially coordinated by —NCS groups; it exhibits a maximum in magnetic susceptibility at ~8 K, indicating a transition to a magnetically ordered state. The cyanate derivative contains bridging bidentate >NCO groups forming linear chains cross-linked by pyrazine ligands; it exhibits a broad susceptibility maximum at ~38 K.

Not all pyrazine-bridged complexes of iron show such strong magnetic concentration, however. Magnetic susceptibility studies on $Fe(pyz)_2X_2$ (X = Cl, Br, I) from 300 to 4.2 K and on $Fe(pyz)Cl_2$ from 300 to 1.9 K gave no conclusive evidence for exchange coupling in these complexes (2, 3). Mössbauer studies provide some evidence for incipient magnetic ordering in $Fe(pyz)_2Cl_2$ below 0.5 K, while no evidence of ordering was observed for $Fe(pyz)Cl_2$ down to 0.33 K (4, 5).

As part of a general search for and study of magnetic exchange effects in pyrazine-bridged iron compounds, we have investigated the complexes formed between pyrazine and some iron(II) sulfonates. Two types of complexes were obtained: mono(pyrazine) derivatives of the type $Fe(pyz)(RSO_3)_2$, where R is CF_3 and $p\text{-}CH_3C_6H_4$, and bis(pyrazine) complexes $Fe(pyz)_2(RSO_3)_2$, where R is CH_3 and CF_3 (the latter being obtained as a methanol solvate).

Since none of the complexes described here was obtained in a form suitable for structure determination by single crystal X-ray diffraction studies we have had to rely on indirect methods including vibrational, electronic and Mössbauer spectroscopy and differential scanning calorimetry. Comparisons with related compounds are also useful and we report here our investigation of two such complexes, $Fe(pyz)_2(ClO_4)_2$ and the pyridine complex, $Fe(py)_2(CF_3SO_3)_2$. A preliminary report of low temperature Mössbauer studies on $Fe(pyz)(CF_3SO_3)_2$ has appeared elsewhere (7).

Experimental section

Materials and syntheses

All chemicals used in this study were of at least reagent grade quality and obtained from commercial sources. Solvents were dried prior to use as follows: methanol was refluxed in the presence of magnesium methoxide; diethyl ether was refluxed over sodium benzophenone ketyl; pyridine was refluxed over barium oxide. After drying, solvents were distilled under a dry nitrogen atmosphere. The iron(II) complexes prepared are air- and moisture-sensitive; thus all manipulations were carried out either using standard vacuum-line techniques, or in a nitrogen atmosphere glove box.

The complexes were prepared either by a solution or a thermolytic route. The choice of temperature for preparative scale thermolysis was found to be quite critical and was determined by heating at gradually increasing temperature and monitoring changes in both the infrared spectrum and microanalytical data.

Bis(pyridine)iron(II) trifluoromethanesulfonate, $Fe(py)_2(CF_3SO_3)_2$

Heating of $Fe(pyz)_4(CF_3SO_3)_2$ (7) *in vacuo* at a temperature of approximately 360 K for 22 h resulted in loss of 2 mol of pyridine and production of $Fe(py)_2(CF_3SO_3)_2$. Further heating at this temperature caused no additional loss of pyridine. *Anal.* calcd. for $FeC_{12}H_{10}N_2F_6S_2O_6$: C 28.14, H 1.97, N 5.47; found: C 28.15, H 2.04, N 5.63.

Bis(pyrazine)iron(II) trifluoromethanesulfonate methanol solvate, $Fe(pyz)_2(CF_3SO_3)_2 \cdot CH_3OH$

A solution of pyrazine (0.55 g, 6.9 mmol) in methanol (5 mL) was added to iron(II) trifluoromethanesulfonate (8) (0.741 g, 2.09 mmol) dissolved in methanol (5 mL). A yellow solution resulted and after 24 h, precipitation of a yellow solid was facilitated by the addition of diethyl ether (30 mL). The product was removed by filtration and washed with diethyl ether (yield, 72%). *Anal.* calcd. for $FeC_{11}H_{12}N_4F_6S_2O_7$: C 24.19, H 2.21, N 10.26; found: C 24.12, H 2.34, N 10.27.

Bis(pyrazine)iron(II) methanesulfonate, $Fe(pyz)_2(CF_3SO_3)_2$

Pyrazine (1.28 g, 16.0 mmol) was dissolved in methanol (5 mL) and this solution was added to a solution of iron(II) methanesulfonate (8) (1.09 g, 4.43 mmol) in methanol (20 mL). A yellow precipitate formed immediately. The product was isolated in 83% yield after filtration and washing with methanol and diethyl ether. *Anal.* calcd. for $FeC_{10}H_{14}N_4S_2O_6$: C 29.56, H 3.48, N 13.79, O 23.63; found: C 29.47, H 3.66, N 13.50, O 23.95.

Bis(pyrazine)iron(II) perchlorate, $Fe(pyz)_2(ClO_4)_2$

The preparation of the dihydrate, $Fe(pyz)_2(ClO_4)_2 \cdot 2H_2O$, has been reported recently (9). The method involved the addition of a solution of hydrated iron(II) perchlorate to a solution of the ligand, both reagents being dissolved in the minimum amount of water. In the previous report, it was noted that drying the product over silica gel at reduced pressure failed to produce the anhydrous species. The same procedure was followed here and the dihydrate was isolated; this was subsequently dehydrated by applying more stringent conditions. The dihydrate was heated in an Aberhalden drying pistol at a temperature of approximately 390 K for a period of 46 h at reduced pressure, in the presence of P_4O_{10}. The anhydrous compound was isolated in 72% yield. *Anal.* calcd. for $FeC_8H_8N_4Cl_2O_8$: C 23.16, H 1.94, N 13.50, O 30.85; found: C 23.13, H 1.92, N 13.46, O 31.00.

Mono(pyrazine)iron(II) trifluoromethanesulfonate, $Fe(pyz)(CF_3SO_3)_2$

$Fe(pyz)_2(CF_3SO_3)_2 \cdot CH_3OH$, prepared as described above, was heated *in vacuo* for 15 h at 380 K in the presence of P_4O_{10} in an Aberhalden drying pistol. The infrared spectrum of the product shows significant changes from that of the starting material, and the analytical data are consistent with the formation of the unsolvated mono(pyrazine) complex. Heating for longer periods of time at the same temperature resulted in no further loss of pyrazine. *Anal.* calcd. for $FeC_6H_4N_2F_6S_2O_6$: C 16.60, H 0.93, N 6.45; found: C 16.85, H 0.98, N 6.38.

Mono(pyrazine)iron(II) p-toluenesulfonate bis(methanol) solvate, $Fe(pyz)(p\text{-}CH_3C_6H_4SO_3)_2 \cdot 2CH_3OH$

Iron (II) *p*-toluensulfonate (8) (0.87 g, 2.2 mmol) was dissolved in methanol (10 mL). Pyrazine (0.77 g, 9.6 mmol) dissolved in methanol/diethyl ether (12 mL, 1:5v/v) was then added to this solution. Small orange–yellow crystals formed after 0.5 h, and after 3 days the solid was removed by filtration and the product washed with a small amount of diethyl ether (yield 66%). *Anal.* calcd. for $FeC_{20}H_{26}N_2S_2O_8$: C 44.29, H 4.83, N 5.16; found: C 44.05, H 4.71, N 4.93.

Mono(pyrazine)iron(II)p-toluenesulfonate, $Fe(pyz)(p\text{-}CH_3C_6H_4SO_3)_2$

The unsolvated compound was prepared by heating the solvate, prepared as described above, at approximately 340 K *in vacuo* for 16 h. *Anal.* calcd. for $FeC_{18}H_{18}N_2S_2O_6$: C 45.20, H 3.79, N 5.85, O 20.07; found: C 44.98, H 3.77, N 5.77, O 19.86.

Physical measurements

Electronic and infrared spectra and differential scanning calorimetry data were obtained using equipment and procedures described previously (8). ^{57}Fe Mössbauer spectra were recorded at 78 and 293 K in transmission mode, with a constant acceleration spectrometer of conventional design. For $Fe(pyz)(CF_3SO_3)_2$ spectra were also obtained in the 1.6–4.2 K range. The Doppler velocity scale was calibrated with an iron foil absorber, and isomer shifts are quoted relative to the centroid of the iron spectrum.

Magnetic susceptibility measurements between 80 and 300 K employed the Gouy technique (8); a vibrating sample magnetometer (10) was used for measurements between 1.9 and 120 K. Magnetic susceptibilities were also measured at room temperature with a Faraday magnetic balance (11) at three different values of $H \cdot dH/dx$. No field dependence was observed. Molar magnetic susceptibilities were corrected for the diamagnetism of the metal ion and ligands. Corrections used were: Fe^{2+}, −13; $CF_3SO_3^-$, −46; $CH_3SO_3^-$, −35; $p\text{-}CH_3C_6H_4SO_3^-$, −89; CH_3OH, −34; pyridine, −49; pyrazine, −45 (in units of $10^{-6}cm^3mol^{-1}$).

Analyses for C, H, N, and O were performed by P. Borda of this department.

Results and discussion

Thermal studies

Thermolysis of tetrakis(pyridine) and bis(pyrazine) complexes often occurs by stepwise loss of neutral ligand, allowing convenient preparation of the corresponding bis(pyridine) and mono(pyrazine) derivatives. Previous studies of the thermal stabilities of tetrakis(pyridine) complexes of iron(II) sulfonates by differential scanning calorimetry (DSC) (7) suggested the possibility of a thermolytic route to the corresponding bis(pyridine) complexes. Long and co-workers (12, 13) have also used thermolysis as a preparative technique for obtaining bis(pyridine) derivatives.

We have succeeded in preparing $Fe(py)_2(CF_3SO_3)_2$ and $Fe(pyz)(CF_3SO_3)_2$ by thermolysis of $Fe(py)_4(CF_3SO_3)_2$ and $Fe(pyz)_2(CF_3SO_3)_2 \cdot CH_3OH$, respectively. In the former case the DSC curve showed an endothermic event at 465 K ($\Delta H = 95$ kJ mol^{-1}), with a weight loss corresponding to the removal of two pyridines (7). In the preparative thermolysis reported here, this same change was accomplished by heating at 360 K *in vacuo*. Similarly, for $Fe(pyz)_2(CF_3SO_3)_2 \cdot CH_3OH$ there is a thermal event at 415 K ($\Delta H = 104$ kJ mol^{-1}), the weight loss of 21% corresponding to the removal of the methanol of solvation and 1 mol of pyrazine; the same change was accomplished *in vacuo* at 380 K. The DSC results for $Fe(py)_2(CF_3SO_3)_2$ and $Fe(pyz)(CF_3SO_3)_2$ show thermal events at 557 K and 606 K respectively, due to the removal of the remaining neutral ligands to yield $Fe(CF_3SO_3)_2$. The thermal analysis of $Fe(pyz)_2(CH_3SO_3)_2$ shows two endothermic events at 503 and 583 K due to the successive loss of pyrazine ligands. Although it should be possible to obtain the mono(pyrazine) derivative of this sulfonate by preparative thermolysis, this has not yet been achieved.

The DSC curve for $Fe(pyz)(p\text{-}CH_3C_6H_4SO_3)_2 \cdot 2CH_3OH$ is more complex than that for the unsolvated species. Two thermal events at relatively low temperatures (329 and 367 K) are observed for the solvated species, probably associated with the consecutive loss of the two methanol molecules. The ΔH values, 13 and 33 kJ mol^{-1}, respectively, indicate that one methanol molecule is more strongly held than the other. After removal of solvent molecules from $Fe(pyz)(p\text{-}CH_3C_6H_4SO_3)_2 \cdot 2CH_3OH$, the thermogram is similar to that of $Fe(pyz)(p\text{-}CH_3C_6H_4SO_3)_2$, as expected. One broad endothermic peak occurs at approximately 545 K in both instances, probably associated with the removal of the pyrazine ligand.

Spectroscopic studies

Mössbauer spectra were recorded for all complexes at liquid nitrogen and room temperatures, and the results are given in

TABLE 1. ^{57}Fe Mössbauer parameters[a]

Compound	T (K)	δ (mm s^{-1})	ΔE_Q (mm s^{-1})	Γ_1 (mm s^{-1})	Γ_2 (mm s^{-1})

	78	1.16	3.74	0.35	0.33

[a]Estimated precision of parameters is ±0.01 mm s^{-1}.

Table 1. At 78 K and above, all the spectra consist of symmetric quadrupole-split doublets, with isomer shift (IS) and quadrupole splitting (QS) values typical of pseudooctahedral high-spin iron(II) complexes. The three bis(pyrazine) complexes have QS values in excess of 3 mm s^{-1} at both temperatures studied, values which are diagnostic of orbitally non-degenerate ($^5B_{2g}$) ground states. Thus, our results indicate ground states with the d_{xy} orbital lying lowest in energy, corresponding to a tetragonal compression of the octahedron and a positive value of V_{zz}, the principal component of the electric field gradient (EFG). The close similarity between these results and those for the tetrakis(pyridine)iron(II) sulfonates (7), where X-ray crystallography shows axially compressed octahedra of approximately D_{4h} symmetry, suggests a similar tetragonal compression of the FeN_4O_2 chromophores formed by bridging pyz ligands and axially coordinated anions in the bis(pyrazine) derivatives, with V_{zz} presumably directed along the pseudo-tetragonal O—Fe—O axis.

The room temperature IS values for the two bis(pyrazine)iron(II) sulfonate complexes are slightly higher than those of the corresponding tetrakis(pyridine) compounds (7). This suggests a somewhat greater degree of covalency in the pyridine derivatives, consistent with the relative base strengths of pyridine and pyrazine.

Similar Mössbauer spectra are observed for the bis(pyridine) and mono(pyrazine) complexes, although the QS values are somewhat smaller for $Fe(py)_2(CF_3SO_3)_2$ and $Fe(pyz)(p\text{-}CH_3C_6H_4SO_3)_2$ than for the other derivatives reported here. In all cases, however, the QS at 78 K is substantially greater than 2 mm s^{-1}, indicative of a ground state that is orbitally non-degenerate. We assume that in all these complexes V_{zz} is positive, as previously found for $Fe(pyz)Cl_2$ (2) and $Fe(pyz)(NCO)_2$ (1), and confirmed below for $Fe(pyz)(CF_3SO_3)_2$. Thus, the ground state can be described approximately as $^5B_{2g}$ in these complexes also.

The electronic spectra of the complexes are also consistent with high-spin distorted octahedral complexes of iron(II). The complexes exhibit, in the near infrared region, broad absorption bands (Table 2) which may be assigned to unresolved electronic transitions from the $^5B_{2g}$ ground state to the $^5A_{1g}$ and $^5B_{1g}$ levels derived from ^5E_g in octahedral symmetry. The energies of the band maxima of the three bis(pyrazine) derivatives lie in a range (10 800 – 11 600 cm^{-1}) comparable to that reported earlier for the tetrakis(pyridine)sulfonates (7), thus supporting an FeN_4O_2 chromophore for the former group of compounds with bridging pyrazine ligands and monodentate anion coordination.

For the bis(pyridine) complex and the three mono(pyrazine) complexes the position of the absorption maximum occurs at approximately the same frequency (~10 800 cm^{-1}), which is strong evidence to suggest the same chromophore in all instances. A likely structure for these would involve an FeN_2O_4 chromophore with a bidentate bridging pyrazine ligand (or two monodentate pyridine ligands) and bidentate sulfonate anions. The modes of anion coordination proposed here are supported by infrared studies.

Vibrational assignments for the complexes were made on the basis that the absorption bands originate from two constituent parts, namely, the neutral ligands and the anions. Partial infrared data with assignments (8, 14, 15) are given in Table 3. The anion bands tend to be intense and broad, particularly in the S—O (or Cl—O) stretching regions, and to some extent mask the neutral ligand vibrations. The anion bands are considered first.

The spectrum of $Fe(py)_2(CF_3SO_3)_2$ gives clear evidence for reduction in anion symmetry below C_{3v}, i.e., below that of the free ion. A clear indication of this reduction of anion symmetry is the splitting of the asymmetric SO_3 stretching mode ν_4. Importantly, the magnitude of this band splitting is different from that observed in $Fe(py)_4(CF_3SO_3)_2$ (7), suggesting different modes of anion coordination. In $Fe(py)_4(CF_3SO_3)_2$, where the anions are monodentate and *trans*-disposed, the ν_4 splitting is only 85 cm^{-1} (7). For $Fe(py)_2(CF_3SO_3)_2$, the splitting of this band is 111 cm^{-1}. The degree of splitting of the ν_4 band has been used to suggest bidentate bridging anion coordination in $(CH_3)_2Sn(FSO_3)_2$ (16), a situation subsequently confirmed by X-ray crystallography (17). It was noted that the ν_4 splitting was substantially larger in this tin complex than in complexes where the anion is coordinated in a unidentate fashion. The large splitting seen here for the bis(pyridine) derivative suggests a bidentate bridging mode of anion coordination, to give a linear

[b]Sulfonate assignments (CSO_3 part, C_{3v} symmetry) from ref. 8; perchlorate assignment (C_{3v} symmetry) from ref. 19.
[c]Pyridine bands correspond to strong bands at 1580 and 405 cm^{-1} in the free ligand. Pyrazine bands correspond to a strong band at 804 cm^{-1} and a medium-intensity band at 417 cm^{-1} in the free ligand.

chain or two-dimensional sheet structure with trans pyridine ligands. The infrared data clearly eliminate the possibility that the product of the thermolysis of $Fe(py)_4(CF_3SO_3)_2$ is an equimolar mixture of this compound and $Fe(CF_3SO_3)_2$. In particular, infrared spectroscopy would detect the unsolvated sulfonate compound through the presence on an intense band at 1239 cm^{-1} (8), and this is not observed in the spectrum of $Fe(py)_2(CF_3SO_3)_2$.

The infrared spectra of the other triflate complexes are also informative. The spectrum of $Fe(pyz)(CF_3SO_3)_2$ is virtually identical (in regard to anion vibrations) to that of $Fe(py)_2(CF_3SO_3)_2$, consistent again with bidentate, likely bridging, triflate anions. In contrast, the spectrum of $Fe(pyz)_2(CF_3SO_3)_2 \cdot CH_3OH$ is almost identical to that of $Fe(py)_4(CF_3SO_3)_2$, where monodentate anion coordination is known to occur (7). In this bis(pyrazine) complex the six-fold coordination about iron is likely filled by two bridging pyz ligands and two monodentate anions, with the methanol present as solvent of crystallization.

The methanesulfonate anion spectra are virtually identical for $Fe(py)_4(CH_3SO_3)_2$ and $Fe(pyz)_2(CH_3SO_3)_2$ and we conclude the presence of monodentate anions in both, proven by X-ray studies (7) in the case of the former. The spectrum of $Fe(pyz)(p\text{-}CH_3C_6H_4SO_3)_2$ is, on the other hand, different from that of the pyridine complex $Fe(py)_4(p\text{-}CH_3C_6H_4SO_3)_2$. In particular, the splitting of ν_4 is greater (116 cm^{-1} vs. 90 cm^{-1} for the pyridine complex), supporting the assignment of a bidentate bridging mode of coordination in this complex. The spectrum of the bis(methanol) solvate of this complex differs from that of its ansolvated counterpart principally in regard to the ν_4 region. The splitting here is comparable to that of the pyridine analogue. This may be a consequence of the effects of H-bonding between methanol molecules and the anions; however, in this case we cannot rule out the possibility that the methanol molecules are, in fact, coordinated to iron with monodentate anions and bridging pyrazine molecules completing the coordination sphere.

Turning now to $Fe(pyz)_2(ClO_4)_2$, it is relevant to note that for the free perchlorate ion (point group T_d) there are four normal modes, of which only ν_3 and ν_4, the asymmetric stretching and bending modes, respectively, are infrared active. In ionic perchlorates these infrared active bands generally occur at approximately 1110 and 630 cm^{-1}, respectively (18), the former appearing as a very broad strong band which is occasionally split. Upon coordination through a single oxygen atom, the symmetry is reduced at least to C_{3v}; a splitting of the two triply degenerate normal modes results, the two symmetric modes become infrared active, and six bands may appear in the infrared spectrum. The infrared spectrum of $Fe(pyz)_2(ClO_4)_2$ shows splitting of both ν_3 and ν_4 (in T_d symmetry) and a strong absorption at 918 cm^{-1}, indicating a lowering of anion symmetry. If we assume C_{3v} symmetry for the anion in $Fe(pyz)_2(ClO_4)_2$, the assignments given in Table 3 are obtained. These assignments are very similar to those made for some $M(py)_4(ClO_4)_2$ complexes where unidentate anion coordination has been proposed (19), and indicate a similar coordination mode in $Fe(pyz)_2(ClO_4)_2$.

Selected neutral ligand vibrations are given in Table 3 for each complex. The pyridine bands listed for $Fe(py)_2(CF_3SO_3)_2$ are shifted to higher frequencies from those of the free ligand as expected for coordinated pyridine (7). Free pyrazine exhibits two bands of medium to strong intensity below 900 cm^{-1}, at 804 and 417 cm^{-1}. It was noted previously (2) that the 417 cm^{-1} band in particular shifts to higher frequencies (~470 cm^{-1}) upon coordination. In the complexes studied here both of these bands are shifted and, in addition, some band splitting is observed particularly in the case of the bis(pyrazine) derivatives, where both bands are split by 10 to 20 cm^{-1}. Such band splitting is not uncommon in pyrazine complexes and it has been suggested that it may arise from interactions between adjacent pyrazine rings or from different orientations of pyrazine rings giving rise to slightly different environments (2). It seems doubtful the splitting arises from significantly different structural environments for pyrazine rings as occurs in, for example, $Cu(pyz)_2(CH_3SO_3)_2$ (20). In this complex bridging pyrazine groups are of two types, one occupying equatorial positions and the other axial positions in the copper coordination sphere. This gives rise to band splittings of 33 and 54 cm^{-1} for the ~800 and ~470 cm^{-1} bands, respectively. In principle, it should be possible to prove the absence of unidentate pyrazine in these complexes since such ligands would give rise to bands at approximately 1230, 920, and 750 cm^{-1} (1, 2, 21, 22). Unfortunately, these regions are largely obscured by rather broad and intense anion absorptions.

In summary, the spectroscopic studies have shown that all the compounds under consideration here are pseudo-octahedral complexes of high-spin iron(II). The bis(pyrazine) complexes contain bridging pyrazine ligands and unidentate anions, with structures very probably similar to that of $Cu(pyz)_2(CH_3SO_3)_2$ (20) in which metal ions are bridged in a square array by neutral ligands and anions occupy trans-axial positions. The sulfonate anions in the bis(pyridine) and the three mono(pyrazine) complexes are coordinated in a bidentate fashion yielding chromophores of the type FeN_2O_4. Although it is possible the anions are coordinated in a chelating fashion, this is considered unlikely given the strain that accompanies four membered chelate rings. This point has been made previously in a review article on coordinated fluorosulfate and trifluoromethanesulfonate (23). It seems more likely that the anions are bridging to form either linear chains or sheet-like structures (**2** and **3** in ref. 1). For the mono(pyrazine) complexes the chains or sheets formed by the bridging anions will be cross-linked by pyrazine ligands. These chains or sheets will be effectively isolated in $Fe(py)_2(CF_3SO_3)_2$.

Magnetic measurements

Magnetic susceptibility and magnetic moment data as functions of temperature (4.2–300 K) are given in Table 4.[1] Magnetic moment data at three selected temperatures are given in Table 2. As we are interested in magnetic exchange effects, it will be useful in discussing these data to refer to the magnetic properties of the $Fe(py)_4(RSO_3)_2$ complexes (7). X-ray crystallography has shown that these compounds are monomeric, there is no evidence for magnetic concentration, and the temperature dependence of the magnetic moment arises solely from single-ion effects. Thus these complexes can serve as a benchmark from which magnetic exchange effects in the present sulfonate derivatives can be measured.

The magnetic properties of the bis(pyrazine) complexes $Fe(pyz)_2(CF_3SO_3)_2 \cdot CH_3OH$ and $Fe(pyz)_2(CH_3SO_3)_2$ are significantly different from those of the $Fe(py)_4(RSO_3)_2$ compounds. The differences are not significant at room temperature, where the magnetic moments for all these compounds are within the range 5.1–5.5 μ_B, typical of high-spin iron(II) derivatives. The bis(pyrazine) complexes, however, exhibit much stronger temperature dependencies in their moment values than do the tetrakis(pyridine) complexes, and at 4.2 K the magnetic moments for the two groups of compounds diverge by about 1.3 μ_B. A comparison of the temperature dependence of magnetic moment for $Fe(py)_4(CH_3SO_3)_2$ and $Fe(pyz)_2(CH_3SO_3)_2$ is shown in Fig. 1. A similar divergence exists for the tetrakis(pyridine) and bis(pyrazine) triflate derivatives. Unlike $Cu(pyz)_2(CH_3SO_3)_2$, which shows a maximum in its magnetic susceptibility vs. temperature plot at 6.9 K (20), the bis(pyrazine)iron(II) species do not exhibit susceptibility maxima down to 4.2 K. There is thus no conclusive evidence of this type for antiferromagnetic exchange interactions in these iron complexes.

It is often possible to analyze the temperature dependence of the magnetic moment as a function of distortion from O_h symmetry, spin–orbit coupling, and electron delocalization (24, 25). For the tetrakis(pyridine)iron(II) sulfonates this approach gave reasonable fits to the experimental data above

[1]Table 4 may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

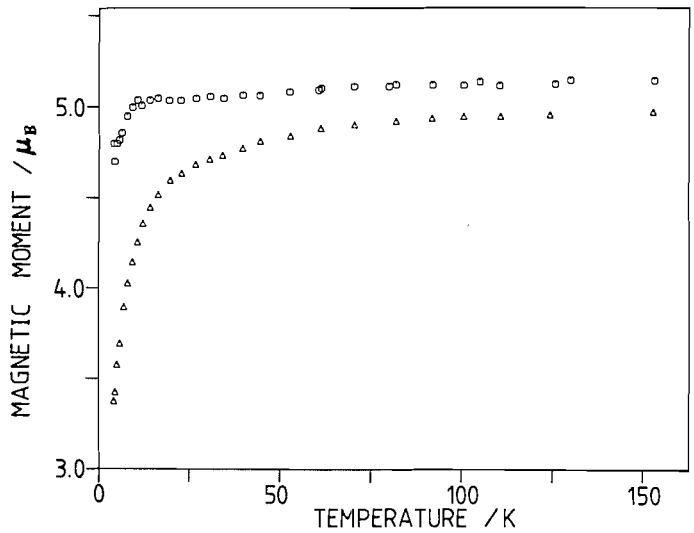

FIG. 1. Magnetic moment versus temperature for $Fe(py)_4(CH_3SO_3)_2$ (□) and $Fe(pyz)_2(CH_3SO_3)_2$ (△).

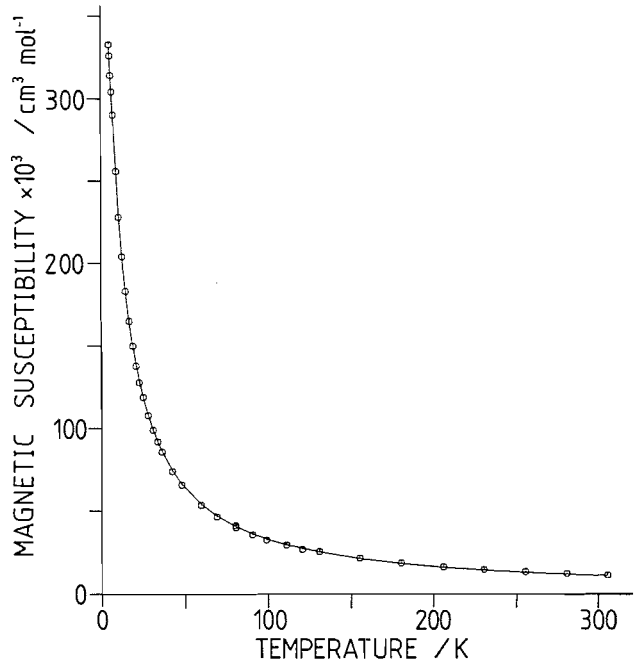

FIG. 2. Magnetic susceptibility versus temperature for $Fe(pyz)_2(CH_3SO_3)_2$. Two-dimensional model; solid line generated with $J = -0.18$ cm^{-1} and $g = 2.07$.

about 20 K, although there was disagreement at low temperatures between observed moments and those calculated from the simple crystal field model (7). For the bis(pyrazine)iron(II) sulfonates on the other hand, such a model is entirely unsatisfactory and quite incapable of reproducing the observed magnetic moment behaviour. The experimental values are always substantially below any values which the model generates. We therefore conclude that the strong temperature dependence of the magnetic moments for the bis(pyrazine) complexes arises either from a large zero-field splitting of the spin quintet ground state or from weak antiferromagnetism.

To see if zero-field splitting effects could account for the magnetic properties of these two complexes, we have analyzed the data using the magnetic susceptibility equation for zero-field splitting of the $S = 2$ ground multiplet (26). By least-squares fitting of the temperature dependence of the molar magnetic susceptibilities, we have obtained the zero-field splitting parameters D and isotropic g values given in Table 5. There is insufficient information in the powder susceptibility data to determine the sign of D; we have assumed $D > 0$, so that the $M_s = 0$ state lies lowest. To reproduce the magnetic susceptibility data for the bis(pyrazine) complexes it is necessary to employ D values that are approximately three times larger than those used for the analogous tetrakis(pyridine) complexes. (The standard deviations of the fits are about three times larger for the bis(pyrazine) complexes as well.) As both groups of compounds contain FeN_4O_2 chromophores and would be expected to have similar single-ion effects, it would seem very difficult to rationalize the extremely large D values suggested by this treatment for the bis(pyrazine) complexes, and we consider them unrealistic.

In view of the proposed two-dimensional structure of the bis(pyrazine) complexes, we have analyzed the magnetic susceptibility data using Lines' high-temperature series expansion for a two-dimensional square-planar $S = 2$ system in the (isotropic) Heisenberg limit (27). Excellent agreement between calculated and observed data was obtained with the parameter values given in Table 5. The agreement between experiment and theory for $Fe(pyz)_2(CH_3SO_3)_2$ is illustrated in Fig. 2. The small negative values of the exchange coupling constant J indicate that any exchange interactions present are of a weak antiferromagnetic nature. This is consistent with our previous results for $Fe(pyz)_2(NCS)_2$ and $Cu(pyz)_2(CH_3SO_3)_2$, where antiferromagnetic phase transitions were observed. The excellent fits obtained here using the two-dimensional exchange model provides strong support for the conclusion that weak exchange effects are present in these complexes, and that it is the bridging pyrazine ligands that provide the pathway for antiferromagnetic coupling of the Fe centres.

For $Fe(pyz)_2(ClO_4)_2$ a weaker temperature dependence of the magnetic moment is found, the value at 4.2 K being 4.31 μ_B, compared to about 3.36 μ_B for the bis(pyrazine) sulfonate derivatives. Although we have not analyzed the suspectibility data for $Fe(pyz)_2(ClO_4)_2$ in terms of Lines' model, it seems clear that any exchange effects in this complex are even weaker than in the sulfonates. Spectroscopic evidence suggests a structure for the perchlorate that is similar to that of the copper analogue (28), which shows a maximum in the magnetic susceptibility at 12.1 K (29), and we might have expected stronger magnetic exchange interactions in $Fe(pyz)_2(ClO_4)_2$.

Of the mono(pyrazine) and bis(pyridine) complexes studied here, $Fe(pyz)(CF_3SO_3)_2$ exhibits the most interesting magnetic properties. The room temperature magnetic moment is 5.4 μ_B, but decreases to 1.6 μ_B at 2 K, and there is a maximum in the magnetic susceptibility vs. temperature curve at approximately 4.4 K. This is a clear indication of antiferromagnetic exchange interactions; however, these interactions are considerably weaker in the triflate than in $Fe(pyz)(NCO)_2$, where the susceptibility maximum occurs at approximately 38 K (1).

The presence of a complex bridging network involving both the pyrazine ligands and triflate anions would seem to complicate the analysis of the susceptibility data for $Fe(pyz)(CF_3SO_3)_2$, as it is likely the exchange mechanisms through the two types of groups are different. At one extreme, if a single exchange mechanism is dominant, the magnetic susceptibility may be best represented by a one-dimensional linear chain model. On the other hand, if exchange proceeds nearly equally through both

bridging ligands, a two-dimensional Heisenberg model is more appropriate. In the case of $Fe(pyz)(NCO)_2$, we found that on the low-temperature side of the susceptibility maximum the experimental data fell between the curves predicted by these two treatments, consistent with the anisotropic (Ising-like) two-dimensional characteristics of the complex (1).

For $Fe(pyz)(CF_3SO_3)_2$ we have analyzed the susceptibility data in terms of both a linear chain model and a two-dimensional model for $S = 2$ in the Heisenberg limit. Two approximation methods have been developed for an antiferromagnetic Heisenberg chain with $S = 2$. Weng (30) developed an interpolation scheme, and we have employed the coefficients given by Hiller *et al.* (31) to reproduce Weng's numerical results. The other approach is that of Wagner and Friedberg (32) who have scaled the exact results of Fisher (33) to the series expansion of Rushbrooke and Wood (34) to develope an equation for the temperature dependence of the susceptibility. Both these models produce similar curves and neither gives a satisfactory fit to the experimental data in the region of the maximum. Results obtained from the Weng model are shown in Fig. 3*a*.

On the other hand, agreement between experimental and calculated magnetic susceptibility data from Lines' square-planar Heisenberg model is excellent for $Fe(pyz)(CF_3SO_3)_2$ (Fig. 3*b*), with $J = -0.26\ cm^{-1}$ and $g = 2.20$. The success of the two-dimensional Heisenberg model in this case is interesting. If the structure consists of a linear chain in which the Fe centres are bridged by anions with the chains being cross-linked through pyrazine (which is clearly the case for $Fe(pyz)(NCO)_2$), then the present results suggest that pyrazine and triflate groups are essentially equal in their ability to propagate superexchange effects. On the other hand, if $Fe(pyz)(CF_3SO_3)_2$ adopts a sheet-like structure with bridging triflate anions in the equatorial plane and axial pyrazine groups bridging the sheets, our results may imply that exchange through the anions predominates, with the pyrazine ligands assisting to bring about long range three-dimensional ordering. In the absence of an X-ray structural determination, the susceptibility data are not able to distinguish between these possibilities.

The magnetic moment data for $Fe(py)_2(CF_3SO_3)_2$, $Fe(pyz)(p\text{-}CH_3C_6H_4SO_3)_2$, and $Fe(pyz)(p\text{-}CH_3C_6H_4SO_3)_2 \cdot 2CH_3OH$ all decrease with decreasing temperature, but none of these complexes shows a maximum in the magnetic susceptibility, so there is no conclusive evidence for magnetic interactions. It is clear that if such interactions are indeed present, they are considerably weaker in these derivatives than in $Fe(pyz)(CF_3SO_3)_2$.

Spectroscopic evidence indicates a close structural similarity between $Fe(pyz)(p\text{-}CH_3C_6H_4SO_3)_2$ and $Fe(pyz)(CF_3SO_3)_2$, i.e., bridging pyrazine and bridging anions. The magnetic properties of the two materials, however, are quite distinct, the *p*-tosylate derivative exhibiting a much weaker temperature dependence

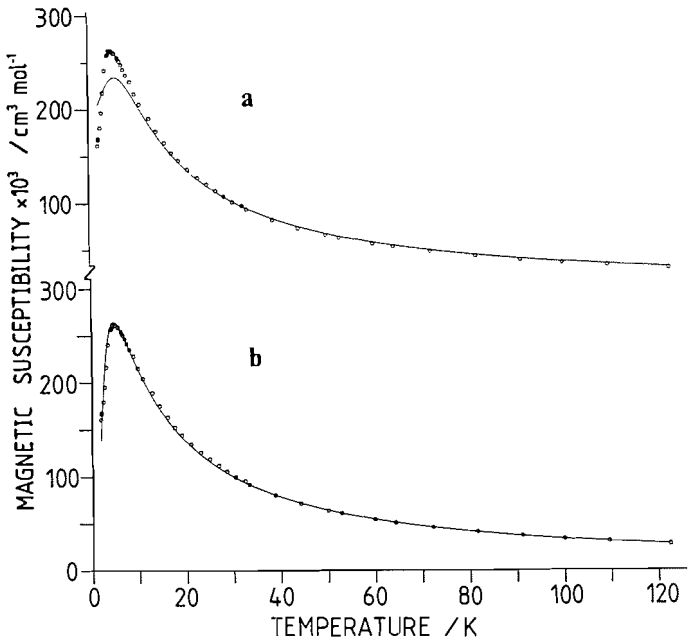

FIG. 3. Magnetic susceptibility versus temperature for $Fe(pyz)(CF_3SO_3)_2$. (*a*) Weng linear chain model; solid line generated with $J = -0.76\ cm^{-1}$, $g = 2.25$. (*b*) Two-dimensional model; solid line generated with $J = -0.26\ cm^{-1}$ and $g = 2.20$.

of the magnetic moment. As there is no X-ray structural evidence for the complexes it is difficult to rationalize these differences, but a possible explanation may lie in the more weakly basic nature of the triflate relative to the *p*-tosylate anion. This could result in a stronger iron–pyrazine interaction in the triflate derivative and an enhanced exchange effect via pyrazine.

The four iron(II) triflate derivatives containing pyridine or pyrazine that we have now prepared and studied provide an interesting comparison (Table 2 and ref. 7). For each compound the magnetic moment at 300 K lies in the narrow range 5.3–5.5 μ_B, whereas at 4.2 K a significant spread in moment values occurs. At 4.2 K the magnetic moment values are in the order: $Fe(py)_4(CF_3SO_3)_2 > Fe(py)_2(CF_3SO_3)_2 > Fe(pyz)_2(CF_3SO_3)_2 \cdot CH_3OH > Fe(pyz)(CF_3SO_3)_2$. This order indicates an increase in antiferromagnetic interactions from the tetrakis(pyridine) complex to the mono(pyrazine) complex, which appears to be in agreement with the proposed nature of the bridging system in each complex: the absence of a bridging network in $Fe(py)_4(CF_3SO_3)_2$, bridging triflate only in $Fe(py)_2(CF_3SO_3)_2$, bridging pyrazine in $Fe(pyz)_2(CF_3SO_3)_2 \cdot CH_3OH$, and both bridging pyrazine and bridging triflate in $Fe(pyz)(CF_3SO_3)_2$. No magnetic interactions are observed in the complex which lacks bridging ligands and

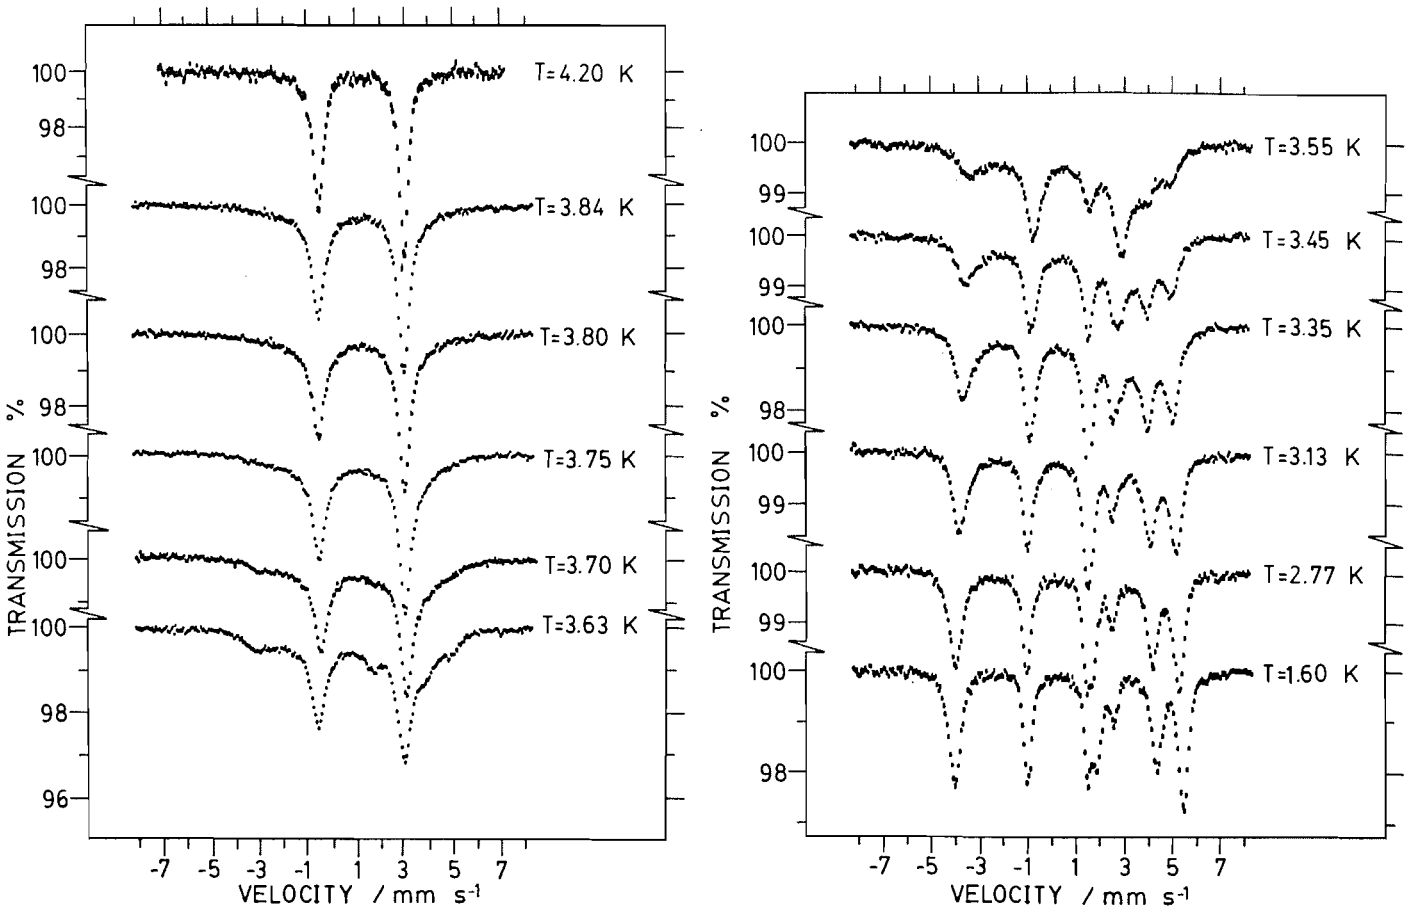

FIG. 4. Low-temperature Mössbauer spectra of $Fe(pyz)(CF_3SO_3)_2$.

the magnetic interaction increases with increasing number of bridging ligands. Clearly the combination of bridging triflate and bridging pyrazine groups provides the most facile magnetic exchange pathway in this series of complexes.

In view of the 4.4 K susceptibility maximum observed for $Fe(pyz)(CF_3SO_3)_2$, and the consequent possibility of observing magnetic ordering in the Mössbauer spectra below this temperature, additional spectra were measured for this complex between 4.2 and 1.6 K. These spectra are shown in Fig. 4.

The spectrum at 4.2 K shows considerable asymmetry, mainly in intensity, which may be attributable to a texture effect, to relaxation effects occurring within the Mössbauer frequency window ($\sim 10^7$ s^{-1}), or to some combination of these. As the lines are also substantially broadened, and as no significant asymmetry was observed at 78 K, we favour an explanation in terms of relaxation effects. Between 3.84 and 3.70 K further line broadening is seen, as well as the development of a magnetic hyperfine pattern. Below 3.70 K the spectra clearly show the combined effects of magnetic and quadrupolar interactions, but with some line broadening persisting down to 1.60 K.

The nature of these low-temperature spectra makes it impossible to estimate the Neel temperature precisely, nor can the spectra be simulated accurately by a static molecular field model (35). In principle, the line broadening seen between 4.2 and 1.6 K could be due either to soliton dynamics (36, 37) or to slow single-ion spin relaxation. We plan to carry out detailed analysis of these spectra employing methods discussed by de Jongh *et al.* (38), in an attempt to distinguish between these two possibilities.

Preliminary simulations of the spectrum obtained at 1.60 K using a static model (35) indicate that the line positions can be reproduced quite well, although there are discrepancies in intensities due presumably to dynamic effects. Although the parameter values obtained by this process must clearly be considered tentative, they are still of some interest. Specifically, they indicate that V_{zz} is positive, that the EFG is effectively axially symmetric, and that the internal hyperfine field at the iron nucleus is approximately 25 T. Of the polar angles θ and ϕ that specify the orientation of the hyperfine field with respect to the EFG principal axis system, the indications are that θ is approximately 77° and ϕ is indeterminate because of the axial symmetry.

These results are very different from those obtained for $Fe(pyz)(NCO)_2$ (1), where both angles were found to be approximately 90° (i.e., the hyperfine field H_{eff} is pinned along the y-axis of the EFG), and the asymmetry parameter was 0.47. In this complex, we have argued (1) that the most reasonable choice of EFG axes is to take the *y*-axis along the linear chain direction in **2** of ref. 1, the *x*-axis along the pyz—Fe—pyz direction, and the *z*-axis normal to the sheets of cross-linked linear chains. If a similar cross-linked linear chain structure obtains for $Fe(pyz)(CF_3SO_3)_2$, then the axial symmetry would require that the EFG *z*-axis now lies along the pyz—Fe—pyz direction. On the other hand, it is possible that $Fe(pyz)(NCO)_2$ and $Fe(pyz)(CF_3SO_3)_2$ are not isostructural, and that the latter adopts the cross-linked sheet structure **3** of ref. 1, where it would be entirely natural to take V_{zz} along the N—Fe—N direction. In either case the positive V_{zz} would require some-

what shorter Fe—N distances than Fe—O distances. In view of the X-ray crystallographic evidence for the tetrakis(pyridine)-iron(II) sulfonates, where the Fe—N bonds are at least 0.1 Å *longer* than the Fe—O bonds, such a structure would be unusual. However, a final resolution of these questions must await a satisfactory treatment of the dynamic effects.

Received January 24, 1988

This paper is dedicated to Professor Charles A. McDowell on the occasion of his 70th birthday

H. M. JEMSON, W. LEWIS-BEVAN, and M. C. L. GERRY. Can. J. Chem. **66**, 2088 (1988).

The infrared spectrum of gas phase aminodifluoroborane, NH_2BF_2, has been observed for the first time. A partial assignment to the fundamental vibrations has been made. The 2_0^1 band has been recorded at high resolution, and the rotational and centrifugal distortion constants of $NH_2{}^{11}BF_2$ have been obtained in both the ground and 2^1 levels. A small rotational perturbation in the 2^1 level has been attributed to a perpendicular Coriolis interaction. Using a newly written least-squares fitting program, spectroscopic constants of the unseen level have been evaluated, including its band origin and the Coriolis coupling coefficient. Possible identities of the unseen level are suggested.

H. M. JEMSON, W. LEWIS-BEVAN et M. C. L. GERRY. Can. J. Chem. **66**, 2088 (1988).

On a déterminé le spectre infrarouge de l'aminodifluoroborane, NH_2BF_2, en phase gazeuse pour la première fois. On a effectué une attribution partielle des vibrations fondamentales. On a enregistré la bande 2_0^1 à haute résolution et on a obtenu les constantes de distorsion de rotation ainsi que de centrifugation du $NH_2{}^{11}BF_2$ tant à l'état fondamental qu'au niveau 2^1. On a attribué une faible perturbation au niveau 2^1 à une interaction de Coriolis perpendiculaire. Utilisant un nouveau programme développé récemment pour ajuster les moindres carrés,on a évalué les constantes spectroscopiques du niveau qui n'est pas visible, y compris sa bande d'origine ainsi que son coefficient de couplage de Coriolis. On suggère des identités possibles pour le niveau qui n'est pas visible.

[Traduit par la revue]

Introduction

The aminoboranes, of general formula $R_2N—BR'_2$, can often be prepared by the pyrolysis of borane–amine complexes:

$$R_3NBR'_3 \longrightarrow R_2N—BR'_2 + RR'$$

For example, the parent compound, aminoborane, H_2NBH_2, the inorganic analog of ethylene, is prepared by pyrolysis of NH_3BH_3 (1). Similarly, gaseous aminodifluoroborane, NH_2BF_2, the inorganic analog of $CH_2 = CF_2$, may be prepared by heating ammonia boron trifluoride, NH_3BF_3. Early studies (2) of this reaction above 125°C suggested that it takes place according to:

$$4NH_3BH_3 \longrightarrow 3NH_4^+ BF_4^- + BN$$

However, it was shown later that no BN is present in the decomposition products, which do, however, contain several HNBF species (3). The mass spectrum of the volatile decomposition products of the pyrolysis of NH_3BF_3 at 185°C was monitored carefully by Rothgery *et al.* (4), and showed that primarily NH_2BF_2 is formed, along with some trifluoroborazine, $(HNBF)_3$. The vapour can also be condensed to form polymeric aminodifluoroborane (4, 5).

Lovas and Johnson (6) have studied the microwave spectrum of NH_2BF_2, which was produced in this case in a simple gas phase reaction of a mixture of NH_3 and BF_3, and later by the revaporization of the condensation products of this reaction by heating to 140°C. The measurement of the rotational constants of six isotopic species confirmed the ethylene-like planar structure of the molecule. The work also produced ground state centrifugal distortaion constants and a value for the dipole moment.

No infrared data are available in the literature for NH_2BF_2. The aim of this study was therefore to measure the infrared spectrum of this molecule in the gas phase, and to evaluate the wavenumbers of the fundamental vibrations. The rotational structure of the 2_0^1 band was also investigated at high resolution to improve the accuracy of the ground state constants, and to measure for the first time rotational parameters of the 2^1 level. A newly written Coriolis least-squares fitting program has been used to account for a small perturbation in the band.

Experimental

NH_2BF_2 was prepared by heating solid NH_3BF_3:

$$NH_3BF_3(s) \xrightarrow[125–140°C]{\Delta} NH_2BF_2(g) + HF(g)$$

The adduct had previously been prepared by passing a stream of NH_3 gas over a stirred solution of boron trifluoride etherate (Aldrich) diluted with twice its volume of diethyl ether. The white precipitate of NH_3BF_3 that was formed was filtered off, washed with diethyl ether, and dried under vacuum. Care was taken to keep the reaction flask flushed with nitrogen because NH_3BF_3 hydrolyses easily.

The spectrum of NH_2BF_2 was recorded with a Bomem DA3.002 interferometer equipped with a multiple reflection Wilks-type cell with flat KBr windows. The path length used was 8.25 m. Because the compound is unstable it was observed using a flow system. Solid NH_3BF_3 was loosely packed in a 20-cm Pyrex tube and heated to between 125 and 140°C; the reaction products were flowed through the cell. Initially only residual solvent, diethyl ether, was produced, but gradually the spectrum of NH_2BF_2 was detected, although some diethyl ether was still present, contaminating the spectrum. When the NH_3BF_3 was heated to higher temperatures the more stable trifluoroborazine, $(HNBF)_3$, started to appear; above 180°C the sample decomposed rapidly and the spectrum diasappeared. In any case very little vapour pressure could be maintained, probably because NH_2BF_2 was polymerizing in the cell, and the spectra obtained were not very intense.

The spectrum was recorded between 400 and 3700 cm^{-1}, using a globar light source. A KCl beamsplitter was used above 550 cm^{-1} and a

Mylar beamsplitter below. The detectors were InSb above 1900 cm^{-1}, HgCdTe from 700 to 1800 cm^{-1}, both cooled with liquid nitrogen, and Ge:Cu below 700 cm^{-1}, cooled with liquid helium. Digital and optical filters were used to restrict the amplified band width so that only data in the range of interest were collected. Portions of the spectrum were recorded at 0.05 and 0.01 cm^{-1} resolution to identify the fundamentals.

The 2_0^1 band near 1608 cm^{-1} was recorded at 0.004 cm^{-1} resolution. For this band, after every 10 high-resolution scans, a low-resolution survey spectrum was obtained to ensure continued presence of NH_2BF_2. Ninety high-resolution scans were coadded for the final spectrum, which took about 5 h to record. The interferogram was transformed with no apodization (boxcar truncation); the resulting spectrum was ratioed against the spectrum of the empty cell and finally converted to absorbance units. The Bomen software peak-find routine, which differentiates the peaks, was used to determine line positions. The absolute calibration was checked against the absorption spectrum of H_2O (7). The accuracy of the line centers is estimated as follows: relative accuracy, ±0.0002 cm^{-1}, absolute accuracy, ±0.0005 cm^{-1}, for the stronger lines.

A deuterated sample, ND_2BF_2, was obtained by heating ND_3BF_3 that had been prepared as above using gaseous ND_3 (MSD isotopes, 99.2 at.% D). Low-resolution (0.05 cm^{-1}) spectra were recorded, as above.

Assignment and analysis

(a) Assignment of fundamentals

NH_2BF_2 is a planar, oblate, near-symmetric rotor (κ = 0.8326) having C_{2v} symmetry; the symmetry axis is the *a*-inertial axis. The 12 normal modes transform as $5A_1 + A_2 + 2B_1 + 4B_2$ (Mulliken's convention (8)). The fundamentals with A_1, B_2, and B_1 symmetry give rise to type A, type B, and type C bands, respectively; the A_2 mode, the torsion, is infrared inactive.

Unfortunately only a partial assignment of the normal modes could be made in this study. While some bands could be clearly identified, many were too weak to be observed or were overlapped. The chief criteria for assignment were the contours of the bands (9), in combination with the line spacings in their P and R branches. For a planar oblate rotor the spacings in a parallel (type C) band are ~$(A + B)$, while those in perpendicular (type A or B) bands are ~$(1/2)$ $(A + B)$ (assuming only small differences in rotational constants between vibrational states). Extra information was provided by comparison with the wavenumbers of the fundamentals of NH_2BH_2, (1)[4] and HBF_2 (10, 11), and from the wavenumbers obtained from an *ab initio* SCF calculation (12). The spectrum of the deuterated species was very weak, and provided only a little information.

The spectrum of NH_2BF_2 at low resolution, from 800 to 3800 cm^{-1}, is shown in Fig. 1. The pair of fundamentals at ~3500 cm^{-1} is assigned to the NH stretching vibrations by analogy with NH_2BH_2: the band at 3468 cm^{-1} has a type A contour and thus corresponds to ν_1, while the band at 3576 cm^{-1} has a type B contour and is thus ν_9. The band near 1608 cm^{-1} is also of type A; it is shown at 0.05 cm^{-1} resolution in Fig. 2. It is assigned to ν_2, largely the NH symmetric bend, again following NH_2BH_2.

In the range 1300–1460 cm^{-1} the spectrum is very complex and clearly contains several bands, though there is considerable likelihood of overlap with bands of residual diethyl ether. In an attempt to make an assigmnent it was investigated at 0.01 cm^{-1} resolution. A very weak type B band could be seen near 1339 cm^{-1}, and is tentatively assigned to ν_{10}, the BF_2 asymmetric stretch. Between 1360 and 1460 cm^{-1} the complexity is such that no clear assignment could be made, though there are what appear to be Q branches near 1396, 1419, 1445, and 1459 cm^{-1}. One or more could correspond to ν_3, the BN stretch. No properly resolved fine structure was observed.

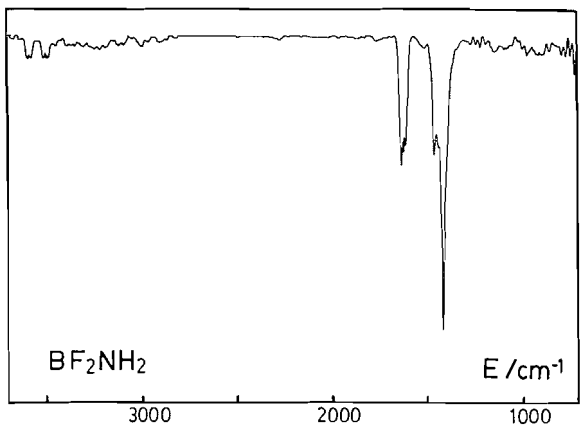

FIG. 1. Low resolution transmittance spectrum of NH_2BF_2 in the region 750–3700 cm^{-1}.

Two bands were observed for NH_2BF_2 between 400 and 700 cm^{-1}. The first, a type C band at 661 cm^{-1} (Fig. 3) is assigned to ν_7, the BF_2 out-of-plane bend, following the theoretical calculations. Very weak absorptions were also found nearby, with similar boron isotope shifts, for ND_2BF_2; these would seem to confirm the assignment, though it is interesting that corresponding wavenumbers of the deuterated species are slightly higher than those of the normal species. The band at 439 cm^{-1} (Fig. 4) is seemingly, from the apparent structure of its P branch, also a type C band, presumably the NH_2 out-of-plane bend. The spike at 464 cm^{-1} might then result from the ^{10}B species. It is curious, though, that if this is the case both type C bands would have the same boron isotopic dependence. Another possible assignment of this spike is to ν_5, the lowest frequency A_1 mode. It is interesting that vibrational satellites were observed in the microwave spectrum suggesting that the lowest frequency mode is near 450 cm^{-1} (6).

Three further bands were observed in searches for the spectrum of ND_2BF_2; they were centered near 2990, 1043, and 963 cm^{-1}. All showed PQR contours. Of these, only the band near 1043 cm^{-1} can be confidently assigned to this molecule. It has the correct spacing in its P and R branches for a perpendicular (type A) band. Its *B* isotopic shift is very small (~1 cm^{-1}); its assignment is unclear. There is a good chance that the other two bands were due to impurities. Their rotational structures are not so easily accounted for, and indeed the band near 2990 cm^{-1} shows no structure at all. Because only a very small amount of ND_3BF_3 was available, it was heated for much longer than the NH_3BF_3, thus increasing the probability of producing impurity gases.

A summary of the assignments is given in Table 1, along with those of any $NH_2{}^{10}BF_2$ band centres that could be identified. They are compared with the *ab initio* calculated wavenumbers, which are consistently higher than the measured values for both NH_2BF_2 and NH_2BH_2 (for which wavenumbers were also calculated (12)). Table 1 also contains a comparison of the

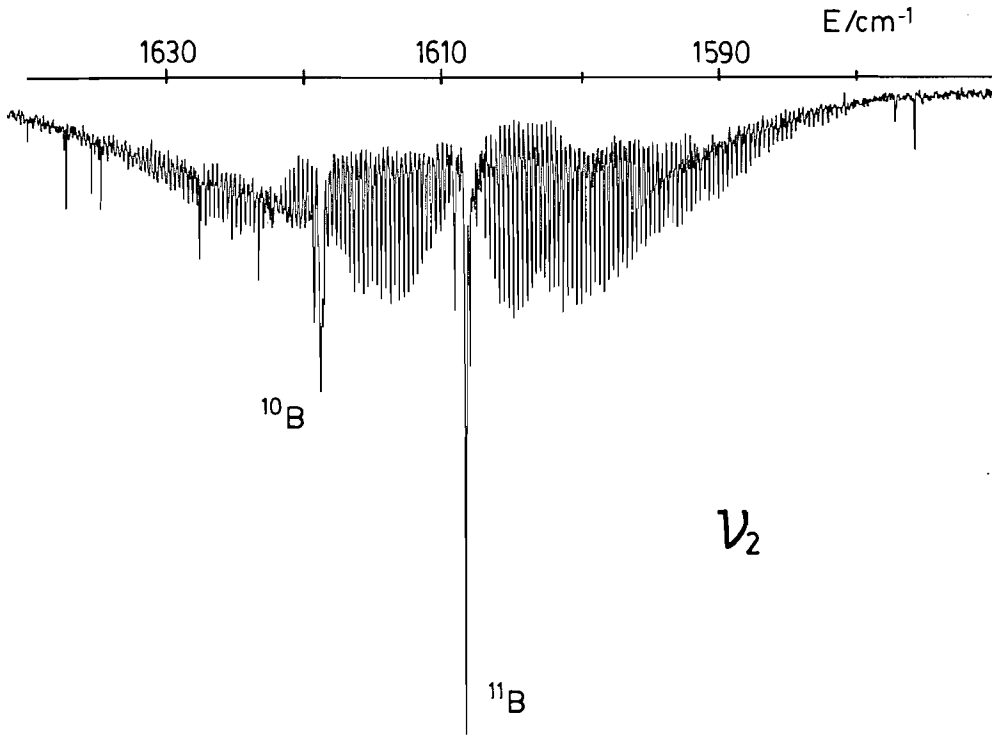

FIG. 2. The 2_0^1 band of NH_2BF_2, recorded as transmittance at 0.05 cm^{-1} resolution. The band origins due to $NH_2{}^{10}BF_2$ and $NH_2{}^{11}BF_2$ are indicated.

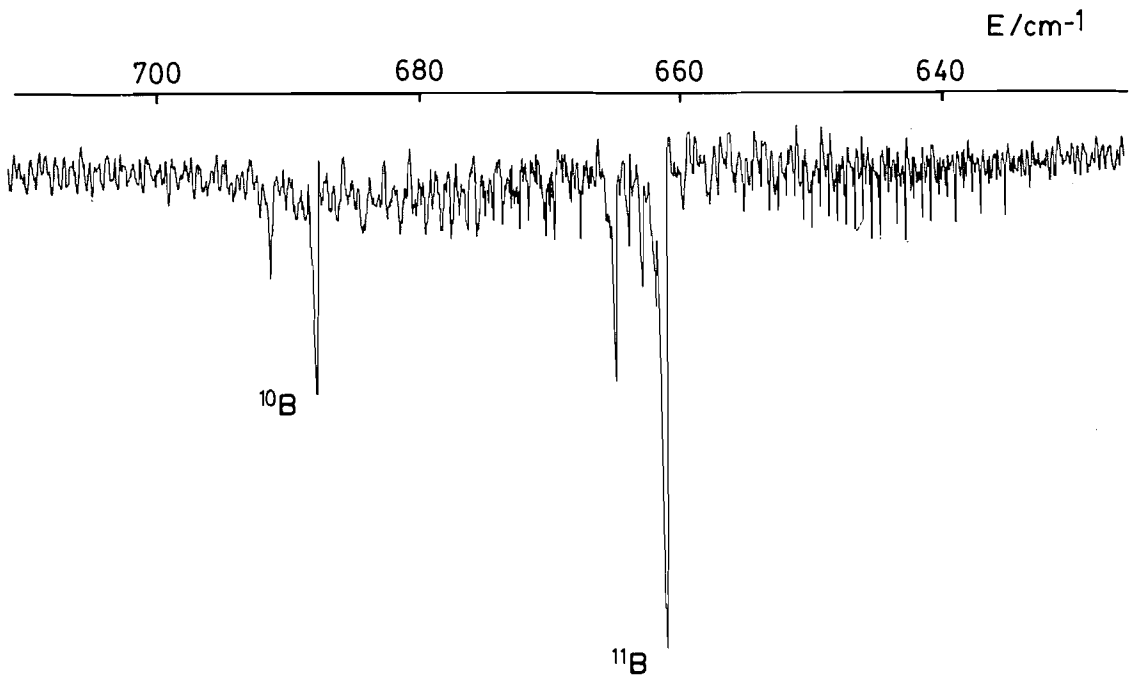

FIG. 3. The 7_0^1 band of NH_2BF_2, recorded at 0.05 cm^{-1} resolution. The band origins due to $NH_2{}^{10}BF_2$ and $NH_2{}^{11}BF_2$ are indicated.

assigned fundamentals of NH_2BF_2 with the corresponding values of NH_2BH_2 and HBF_2.

(b) Analysis of the 2_0^1 band

The 2_0^1 band near 1608 cm^{-1} (Fig. 2) is a type A band of an oblate near-symmetric rotor, following the rotational selection rules $\Delta J = 0, \pm 1$; $\Delta K_a = 0, \pm 2, \ldots$; and $\Delta K_c = \pm 1, \pm 3, \ldots$ It shows two intense central Q-branch features belonging to the overlapping Q-branch lines of $NH_2{}^{11}BF_2$ and $NH_2{}^{10}BF_2$. On either side of the band center lie clusters of R- and P-branch transitions; this clustering is common in planar oblate near-symmetric rotors when the rotational constants do not change much on vibrational excitiation, and $C \sim (\frac{1}{4})(A + B)$ (13). Each cluster has a different value of $(2J - K_c)$; they alternate between even and odd K_c. Within a given cluster the lower state quantum numbers of the transitions are $(J, K_c = J)$, $(J - 1, K_c = J - 2), \ldots$

[a]Reference 12.
[b]Footnote 4.
[c]Several possible Q branches were observed, at 1396, 1419, 1445, and 1459 cm^{-1}.
[d]The spike observed at 464 cm^{-1} (Fig. 4) may be the origin of this band.

down to $((J + 1)/2, K_c = 1)$ or $(J/2, K_c = 0)$. The spectrum consequently becomes more dense away from the band center, both to high and low wavenumbers. A section of the P branch is shown in Fig. 5. In some cases asymmetry splitting was observed, and showed the 5:3 intensity ratio predicted from the spin statistics of two pairs of equivalent Fermions.

Initial assignments of the quantum numbers of the ^pP and ^rR branch transitions, which were the strongest lines of the spectrum, were made using ground state Δ_2F combination differences calculated from the microwave constants of Lovas and Johnson (6). Once correct assignments had been made in this way the remaining assignments were clear from the spectral patterns.

A global fit of 229 ground state combination differences and the 32 microwave measurements (6) of $NH_2{}^{11}BF_2$ was made to the ground state rotational and quartic centrifugal distortion constants, using Watson's *A*-reduced Hamiltonian in its I^r representation (14). The microwave data were given uncertainties 100 times smaller than those of the combination differences; the weights were proportional to $(\text{uncertainty})^{-2}$. The results are in Table 2, along with a comparison with the microwave constants. Clearly a significant improvement has been made in the precision of the constants; two of the distortion constants have been measured for the first time.

Finally, a least-squares fit was made using measured wavenumbers to the constants of $NH_2{}^{11}BF_2$ in the 2^1 state. In the fit the ground state constants were held fixed at the values calculated above. All measured ^pP, ^pQ, and ^rR branch transi-

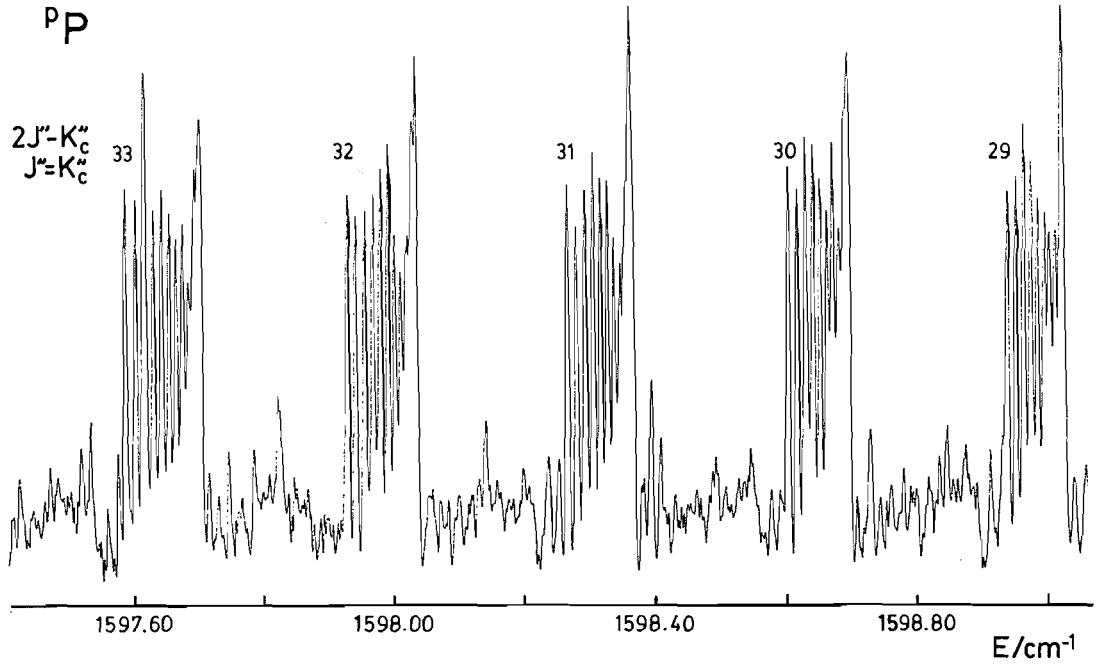

FIG. 5. A portion of the PP branch of the 2_0^1 band of gaseous NH_2BF_2, recorded as absorbance at 0.004 cm^{-1} resolution. The value of $2J - K_c$ for the *ground* state of each cluster of lines is indicated. This is also the value of J'' and K''_c for the line at the lowest wavenumber side of each cluster; in a given cluster J decreases by 1 and K_c by 2 for adjacent lines moving to higher wavenumbers.

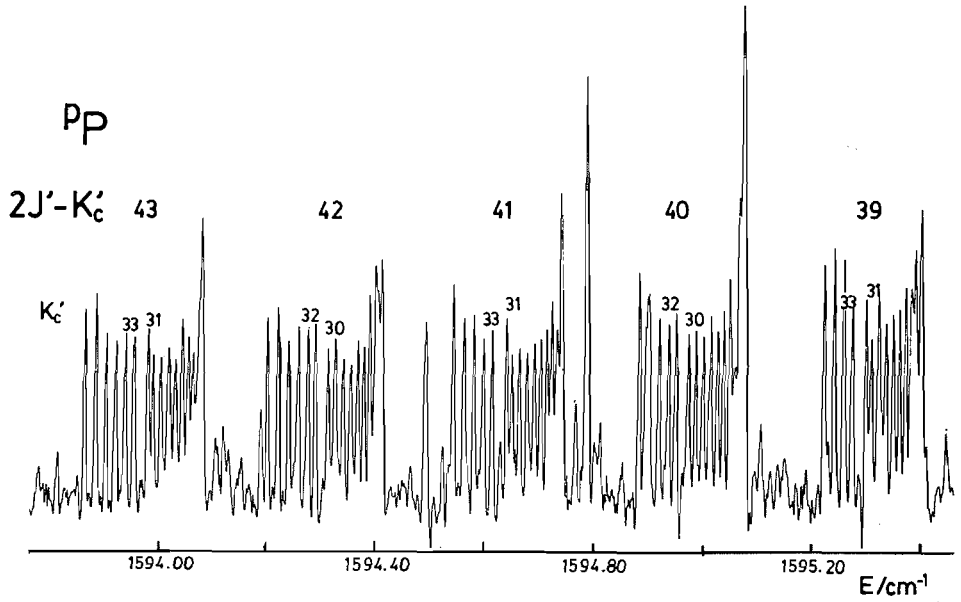

FIG. 6. A portion of the PP branch of the 2_0^1 band of NH_2BF_2, recorded as absorbance, showing a small Coriolis perturbation. The value of $2J - K_c$ for the 2^1 *level* is indicated for each cluster, as well as the value of K'_c for the lines on each side of the gap in the rotational structure.

tions were included, up to $J' = 53$ and $K'_c = 50$, with the exception of lines with $K'_c = 29$–33, for which a small perturbation was observed. Watson's *A*-reduced Hamiltonian in its I^r representation (14) was again used, and the results are also in Table 2. Once again accurate values have been obtained for the rotational and quartic distortion constants, all for the first time for this level, along with an accurate value for the band origin, T_0. Table 3 contains all the measured wavenumbers with their assignments and weights; the goodness of fit is also indicated.

(c) Perturbations in the 2^1 level

Some of the rotational structure of the 2_0^1 band is significantly perturbed by a Coriolis interaction. This is clearly shown in Fig. 6: a gap appears in both the PP- and RR-branch clusters at the same value of K'_c. Rotational levels in the region $K'_c = 29$–33 are shifted, with the largest shifts for $K'_c = 31$ and 32. These shifts, which are evaluated from the differences between the observed and calculated frequencies in the upper state, are indicated in Table 3; they are relatively small ($<\sim 0.01$ cm^{-1}) and are roughly proportional to $(J(J + 1)$–

[a]Calculated from combination differences of the 2_0^1 band and microwave data of ref. 6.
[b]Values of ref. 6 converted to the A-reduction I^r representation (14), and to cm^{-1} using $c = 2.99792458 \times 10^8$ m s^{-1}.
[c]Calculated from observed cm^{-1}, omitting transitions with $K_c' = 29$–33, and with ground state constants fixed at the value of column 1.
[d]Numbers in parentheses are one standard deviation in units of the last significant figures.

$K_c'(K_c' \pm 1)$) for values of $K_c' = 29$–33. This implies a perpendicular Coriolis interaction in the symmetric rotor limit. Since NH_2BF_2 is an oblate rotor the interaction would be about the a- or b-inertial axis, and the interacting mode should thus be of species A_2 or B_1, respectively.

The directions of the shifts indicate that the interaction is probably $\Delta K_c' = -1$, with a vibrational level lying just below the 2^1 level. Since the levels involving $K_c' = 31$ and 32 have been pushed to higher and lower energies respectively, by similar amounts, one can deduce that the unseen vibrational state has K_c values of 30 and 31 lying between the $K_c' = 31$ and 32 levels of the 2^1 state. Figure 7 shows a plot of the rotational energies of the 2^1 level (solid lines) and those of the unseen level (dashed lines) vs. $J(J + 1)$. A rough estimate of ξ^α (with $\xi^x \equiv X\zeta^x$ etc.) using second order perturbation theory gave a value of $\xi^\alpha \sim 0.004$, and the origin of the unseen band at $\sim 1598.4\ cm^{-1}$.

With this information, least-squares Coriolis fits, using a newly written program, were undertaken to refine these constants. As before, the I^r representation was used, and fits were carried out assuming both x- and z-axis (b- and a-axis, respectively) Coriolis type interactions. (An attempted fit assuming a y-axis interaction failed.) The fits were made to the energy *levels* of the 2^1 state; these had been calculated by adding the measured infrared wavenumbers to the ground state energy levels calculated from the ground state fit. The levels were weighted according to the number of times they were measured in the infrared spectrum. All the constants obtained earlier for the 2^1 level were included in the fits, along with ξ^α, and T_0 and $(A + B)$ of the unseen level. The remaining constants of the unseen level were held at the ground state values. $(A + B)$ was floated because it determines the relative spacing of the K_c states.

The results of the Coriolis fits are summarized in Table 4, which includes the derived constants for both fits, along with the energies of the levels of the 2^1 state with $K_c' = 29$–33 (the levels where the perturbation is clearly evident) and the standard deviations of the fits. The constants of the unseen state are completely uncorrelated with those of the 2^1 state.

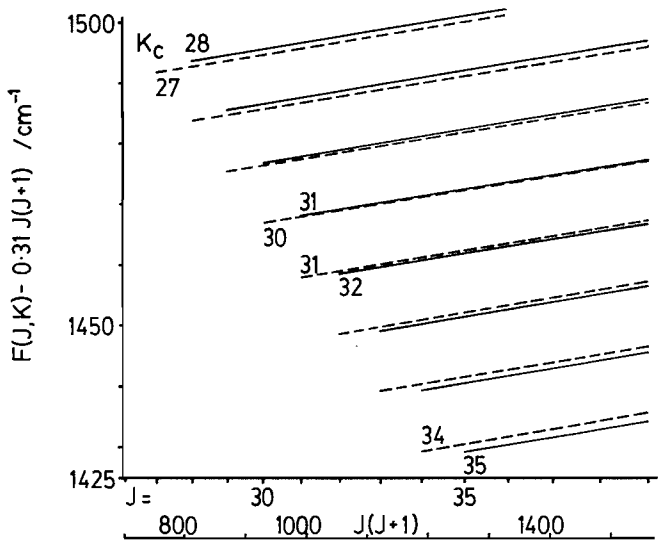

FIG. 7. A plot of energy levels (minus a factor of 0.31 $J(J + 1)$) vs. $J(J + 1)$ for the observed 2^1 vibrational state (solid lines) and the unseen state (dashed lines). $K_c' = 30$ and 31 of the unseen state are sandwiched between $K_c' = 31$ and 32 for the 2^1 state, allowing an unique solution of the position of the unseen vibration to be obtained.

From a comparison of Tables 2 and 4, it is clear that the perturbation is equally well accounted for by an a- or b-type Coriolis interaction. Even the value of ζ^α derived from the constants is essentially the same for both interactions (Table 4). Consequently, the identity of the perturbing level is rather obscure. It cannot be a fundamental, because the shifts are too small, there are no bands overlapping the 2_0^1 band, and it is highly unlikely that the torsion would lie at such a high energy. Also, since it cannot be an overtone level, which must be of species A_1, it must thus be a combination, of which there are several possibilities. On the basis of the calculated wavenumbers (11), one candidate is $\nu_7 + \nu_{11}$ (species A_2); another is $\nu_4 + \nu_7$ (species B_1). There are several others in which three

[a]All measured transitions are included. Weights given are those used to obtain the 2^1 state constants given in Table 2.
[b]The deviation is the observed frequency minus that calculated using the constants obtained (Table 2) in the analysis omitting the Coriolis interaction.

modes are combined. If it is $\nu_7 + \nu_{11}$ or $\nu_4 + \nu_7$, this would set ν_{11} or ν_4 at $1598-661 = 937\,cm^{-1}$; no band was seen clearly here, however.

Discussion and conclusions

Good progress has been made in assigning for the first time the infrared spectrum of NH_2BF_2. It is somewhat of a pity that not all the normal modes could be accounted for. A major contributing factor to this difficulty was the rather low yield of desired product in the face of many competing reactions. This is entirely in keeping with the complex known chemistry of the system (4). Difficulties in removing all residual diethyl ether did not help either.

Of the bands that could be definitely assigned, the agreement

between the observed wavenumbers and those predicted from theory (Table 1) is rather poor (12). It is rather better for NH_2BH_2 (1),[4] but it seems that some new calculations would be in order.

The assignments and analysis of the 2_0^1 band are clear, however. This is one of the relatively rare examples of a perpendicular band of an oblate near-symmetric rotor from which spectroscopic constants have been obtained, others being OCF_2 (13) and CH_2CF_2 (15). The results of three analyses are presented; all give excellent constants. The rotational and distortion constants found when the perturbations are omitted (Tables 2 and 3) are very comparable to those found when they are included (Table 4); in the latter cases the Coriolis constant seems properly determined, although it is a pity we could not distinguish between *a*- or *b*-type interactions. The molecule is one of several (10) for which we have observed Coriolis effects in the rotational fine structure. It was to analyze these that our Coriolis fitting routine was written; results of the other analyses will appear in due course.

Received February 7, 1988

This paper is dedicated to Professor Charles A. McDowell on the occasion of his 70th birthday

NEIL H. DRYDEN, PETER LEGZDINS, FREDERICK W. B. EINSTEIN, and RICHARD H. JONES. Can. J. Chem. **66**, 2100 (1988).

The compound $(\eta^5\text{-}C_5Me_5)W(NO)I_2$ has been prepared by treating $(\eta^5\text{-}C_5Me_5)W(NO)(CO)_2$ with I_2. A single crystal X-ray crystallographic analysis establishes that the formally 16-electron complex possesses a monomeric, three-legged piano stool molecular structure in the solid state. Solution molecular weight measurements also indicate no significant degree of association of the compound.

NEIL H. DRYDEN, PETER LEGZDINS, FREDERICK W. B. EINSTEIN et RICHARD H. JONES. Can. J. Chem. **66**, 2100 (1988).

On a préparé le $(\eta^5\text{-}C_5Me_5)W(NO)I_2$ en faisant réagir du $(\eta^5\text{-}C_5Me_5)W(NO)(CO)_2$ avec du I_2. Faisant appel à une analyse par diffraction des rayons-X, on a établi que, à l'état solide, ce complexe comportant formellement 16 électrons possède une structure moléculaire monomère en forme de banc de piano à trois pieds. Des mesures de poids moléculaire effectuées sur des solutions indiquent que ce composé ne conduit pas à beaucoup d'association.

Metal halide complexes serve as useful starting materials for the synthesis of many organometallic compounds (1). Indeed, the availability of the complexes

$$[(\eta^5\text{-}C_5R_5)M(NO)X_2]_n$$

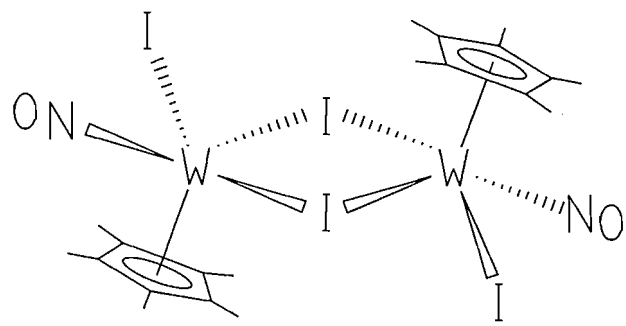
R = Me, H

M = Mo, W

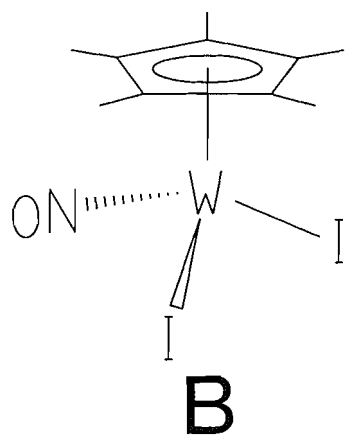
X = Cl, Br, I

n = 1 or 2

has enabled us to prepare various classes of Group 6 nitrosyl compounds (2–4). Although the dihalo species have been known for a long time, their molecular natures both in solution and in the solid state are still very uncertain. They have generally been formulated as halo-bridged dimers in the solid state (5) on the basis of satisfying an 18-electron, filled valence shell configuration for each metal centre. However, to the best of our knowledge, none of them has been structurally characterized. In this paper we wish to report the optimized synthesis of the title complex and to describe its solution and solid state physical characteristics, which clearly indicate that rather than being the dimer **A** it is the novel monomer **B**.



A



B

Experimental

All reactions and subsequent manipulations were performed under anaerobic and anhydrous conditions. General procedures employed in these laboratories have previously been described in detail (4). The solution molecular weight determination was effected by the Signer method (6) with azobenzene as the reference compound. A published procedure for the preparation of LiC_5Me_5 was used (7). All other chemicals were used as received from commercial suppliers.

Caution: Due to the evolution of CO gas during all of these syntheses, all reactions should be properly vented to a fumehood.

Preparation of $(\eta^5\text{-}C_5Me_5)W(NO)(CO)_2$

The complex was previously prepared (8) using NaC_5Me_5 as the permethylcyclopentadienyl source. In our opinion, a more efficient and convenient synthesis (especially for larger scale preparations) is the one described below.

A 1-L, 3-necked flask was charged with LiC_5Me_5 (17.5 g, 123 mmol) and was connected to a vacuum line. Then $W(CO)_6$ (44.0 g, 125 mmol) and THF (300 mL) were added. The initial pale yellow solution was refluxed gently with stirring for 4 days. The final

red solution was cannulated into a 1-L sublimation flask. A yellow solution of Diazald (26.4 g, 123 mmol, Aldrich) in THF (150 mL) was added dropwise to the red solution via a pressure-equalized dropping funnel over a period of 30 min. Vigorous gas evolution occurred, and the reaction mixture was stirred for an additional 3 h after the Diazald addition was complete. Solvent was removed from the reaction mixture *in vacuo* to obtain an orange-tan solid. Initial sublimation of the solid material onto a water-cooled probe (10^{-3} Torr (1 Torr = 133.3 Pa), static vacuum, 60°C) for 3 h removed any unreacted W $(CO)_6$. Sublimation of the remaining solid onto a water-cooled probe (10^{-3} Torr, dynamic vacuum, 110–115°C) over 24 h yielded $(\eta^5\text{-}C_5Me_5)W(NO)(CO)_2$ as an orange crystalline solid (40.5 g, 81% yield based on LiC_5Me_5). The product was characterized by its distinctive nitrosyl and carbonyl infrared absorptions (CH_2Cl_2: ν(CO), 1992, 1912 cm^{-1}; ν(NO), 1633 cm^{-1}) and used without further purification.

Preparation of $(\eta^5\text{-}C_5Me_5)W(NO)I_2$

The synthesis of this compound has previously been described (9, 10). The method presented here is a modification of these earlier procedures.

An orange solution of $(\eta^5\text{-}C_5Me_5)W(NO)(CO)_2$ (8.1 g, 20 mmol) in toluene (100 mL) was rapidly cannulated into a stirred, dark red-purple solution of I_2 (5.0 g, 20 mmol) in toluene (150 mL). The reaction mixture evolved copious quantities of gas and became green in colour. After vigorous gas evolution ceased, the reaction mixture was warmed to 30–35°C, and the pressure in the flask was reduced. The flask was periodically reevacuated over 3 h to remove the remaining slowly evolving CO. Then the volume of solvent was reduced *in vacuo* to approximately 30 mL, resulting in the formation of a bright green, microcrystalline precipitate. Hexanes (50 mL) were added, and the mixture was cooled overnight at −15°C. Isolation of the resulting bright green microcrystals from the pale green supernatant by filtration on a glass frit and washing with hexanes (3 × 10 mL) afforded analytically pure $(\eta^5\text{-}C_5Me_5)W(NO)I_2$ (9.9 g, 83% yield); ir (CH_2Cl_2) ν: 1630 (NO) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 2.18 (s, C-CH_3); $^{13}C\{^1H\}$ nmr ($CDCl_3$) δ: 117.5 (*C*-CH_3), 12.8 (C-*C*H_3). *Mol. Wt.* (20°C, CH_2Cl_2) calcd. for $C_{10}H_{15}NOI_2W$: 603 g/mol; measured: 606 g/mol. *Anal.* calcd. for $C_{10}H_{15}NOI_2W$: C 19.92, H 2.51, N 2.32; found: C 19.94, H 2.52, N 2.27.

Crystals suitable for X-ray crystallographic analysis were obtained from a toluene solution at −15°C.

Crystal structure analysis

Crystal data:

$C_{10}H_{15}NOWI_2$ fw = 602.89

Monoclinic, $P2_1/m$ (confirmed by refinement), a = 7.148(2), b = 13.073(10), c = 8.563(3) Å, β = 111.63(2)°, V = 743.81 Å^3, Z = 2, D_c = 2.692 g cm^{-3}, μ(MoKα) = 12.02 mm^{-1}, (MoKα$_1$) = 0.7093 Å.

A suitable crystal (0.21 × 0.17 × 0.16 mm) was mounted in a thin-walled glass capillary and transferred to an Enraf–Nonius CAD4F diffractometer equipped with graphite monochromated MoKα radiation. The unit-cell parameters were obtained from the accurate setting angles of 24 reflections ($21 < 2\theta < 33^0$). Data were collected in the range $4 < 2\theta \leq 50^0$, $h,k, \pm l$, using the θ–2θ scan technique. The scan width was 1.0 + 0.35 tan θ^0, and the scan speed varied between 0.75 and 2.75° min^{-1}. Two standard reflections measured every hour showed a marked decline in intensity with time (24%), and these standards were used to scale the data. The data were corrected for Lorentz polarization effects and analytically for absorption (11) (with transmission factors varying between 0.152 and 0.248). A total of 1395 reflections were collected, of which 990 having $I \geq 3\sigma(I)$ were used in the crystal structure analysis.

Models in both $P2_1$ and $P2_1/m$ were considered. Ultimately, the best justified model was that in $P2_1/m$ with disorder allowing the molecule to achieve site symmetry m. The disorder involved one iodine atom and the nitrosyl group. To achieve convergence, restraints were applied to the W—N, N—O, and the C—C(methyl) lengths together with the along-bond component of the anisotropic motion of the atoms in the pentamethylcyclopentadienyl group (12, 13). The hydrogen atoms of the methyl groups were geometrically placed and allowed to "ride" on the carbon atoms to which they were bonded. The variables included in the final cycles of refinement were scale, positional, and anisotropic thermal parameters for the non-hydrogen atoms, except for isotropic variables for the disordered nitrogen and oxygen atoms, and one isotropic thermal parameter for all the hydrogen atoms. Although an even more sophisticated model that would split all atom sites according to the disorder could be developed, our estimate of the displacements involved would be less than 0.05 Å for the tungsten atom splitting (since it is presumably mainly dependent on the difference between the W—I and W—"NO" bond lengths).

TABLE 1. Atomic coordinates (fractional × 10^4) and U_{eq} or U_{iso} ($U \times 10^4$ Å^2) for non-hydrogen atoms

Atom	x/a	y/b	z/c	U_{eq}/U_{iso}
W(1)	948(1)	2500	2041(1)	527
I(1)	2333(3)	2500	−442(3)	904
I(2)	2942(5)	3860(4)	4252(5)	911
N(1)	2385(48)	3582(20)	3125(43)	934(98)
O(1)	2928(93)	4331(35)	3934(68)	1736(299)
C(1)	−1827(36)	2500	2765(26)	715
C(2)	−1977(25)	3355(14)	1805(31)	787
C(3)	−2260(20)	3012(15)	146(22)	632
C(11)	−1725(71)	2500	4562(32)	1614
C(12)	−2116(37)	4450(18)	2310(54)	1289
C(13)	−2689(38)	3719(30)	−1333(37)	1351

The final residuals were R = 0.047, and R_w = 0.064, and the goodness of fit was 1.034. Refinement was by full-matrix least-squares minimization of the function $\Sigma w(|F_o| - |F_c|)^2$, where w was calculated from the three-term Chebyshev series, $w = [304.5t_o(x) + 397.3t_1(x) + 128.8t_2(x)]^{-1}$, where $x = F_o - F(\max)$ (14). The refinement was considered complete when the ratio of all shifts to esd's was less than 0.1. The highest peak in the final difference map was 3.10(17) e Å^{-3} and was situated 0.95 Å from the tungsten atom. Complex neutral atom scattering factors were taken from International tables for crystallography (15). Calculations were carried out on a Microvax II computer with use of the NRC VAX crystal structure system (16) and the CRYSTALS suite of programs (17). Positional parameters are given in Table 1. Selected bond distances and angles are listed in Table 2. Anisotropic thermal parameters, hydrogen atom coordinates, and tables of calculated and observed structure factors have been deposited as supplementary material.[2] A view of the molecule is given in Fig. 1 (18).

Results and discussion

The preparation of the title compound can be effected by the sequential transformations summarized in eq. [1]–[3] below.

[1] $W(CO)_6 + Li(C_5Me_5) \xrightarrow[-3\ CO]{THF,\ reflux} Li[(\eta^5\text{-}C_5Me_5)W(CO)_3]$

[2] $Li[(\eta^5\text{-}C_5Me_5)W(CO)_3] \xrightarrow[Diazald]{THF} (\eta^5\text{-}C_5Me_5)W(NO)(CO)_2$

[3*a*] $(\eta^5\text{-}C_5Me_5)W(NO)(CO)_2 \xrightarrow[I_2,\ -CO]{Toluene} (\eta^5\text{-}C_5Me_5)W(NO)(CO)I_2$

[3*b*] $(\eta^5\text{-}C_5Me_5)W(NO)(CO)I_2 \xrightarrow[35°C,\ in\ vacuo\ -CO]{Toluene} (\eta^5\text{-}C_5Me_5)W(NO)I_2$

C(2)—C(3)—C(13)	123.6(24)
C(3)—C(3)—C(13)	127.9(19)

The I_2 addition (eq. [3]) proceeds via a relatively stable intermediate complex, i.e., $(\eta^5\text{-}C_5Me_5)W(NO)(CO)I_2$, thereby making it necessary to warm the toluene solution under reduced pressure to induce the complete decarbonylation of this intermediate compound.

The final $(\eta^5\text{-}C_5Me_5)W(NO)I_2$ product is a bright green, crystalline solid. It is interesting that at approximately 25°C it displays reversible thermochromism, changing from bright green to golden yellow. This colour change is evident in both the solid state and in solution. To the best of our knowledge, this phenomenon is unique to this member of the family of compounds having the empirical composition $(\eta^5\text{-}C_5R_5)M(NO)X_2$. However, since the ^1H nmr spectrum of $(\eta^5\text{-}C_5Me_5)W(NO)I_2$ in $CDCl_3$ is invariant from 0 to 40°C, no inference concerning the physical basis for the observed thermochromism may be drawn at present.

Previous attempts to grow crystals of the analogous cyclopentadienyl tungsten diiodide complex suitable for X-ray crystallographic analysis were unsuccessful.[3] This was attributed to the low solubility of the cyclopentadienyl compounds in organic solvents (5). The replacement of the cyclopentadienyl ligand with its permethylcyclopentadienyl analogue can lead to marked increases in solubility and crystallizability (20), and this is indeed the case in this instance. In fact, the increased solubility of $(\eta^5\text{-}C_5Me_5)W(NO)I_2$ allows its solution molecular weight to be determined, something not possible for its cyclopentadienyl analogue (5). We measured the molecular weight of the diiodo complex in dichloromethane to be 606 g/mol. This value quite clearly indicates that there is no significant amount of association of the molecular units even in a non-coordinating solvent such as dichloromethane (21). Fortunately, the permethylated species also forms single crystals suitable for X-ray crystallographic analysis.

[3]J. T. Martin. Personal communication.

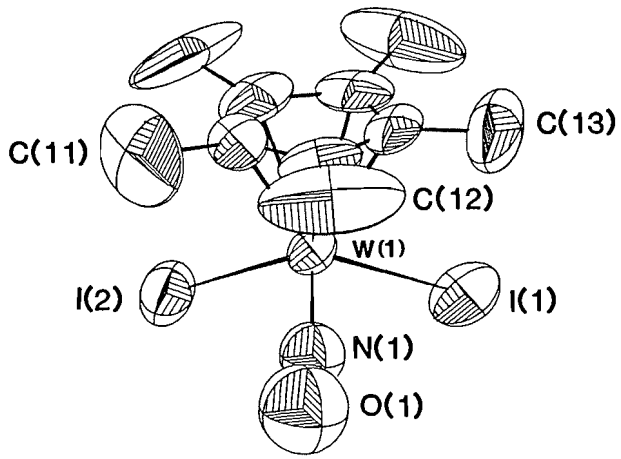

FIG. 1. SNOOPI plot of the molecular structure of $(\eta^5\text{-}C_5Me_5)W(NO)I_2$.

The crystal structure of $(\eta^5\text{-}C_5Me_5)W(NO)I_2$ consists of a closely packed array of monomeric molecular units, with normal van der Waals contacts between the units. Hence, the structure establishes unambiguously the monomeric nature of $(\eta^5\text{-}C_5Me_5)W(NO)I_2$ (Fig. 1). Discussion of the detailed intramolecular geometry of the monomer is unfortunately limited by the disorder of the nitrosyl group and one of the iodine atoms. Nevertheless, the unrestrained bond lengths in the $(\eta^5\text{-}C_5Me_5)W$ fragment are in good agreement with previously determined structures. Thus, the W—$(\eta^5\text{-}C_5Me_5)$–centroid distance of 2.006 Å is comparable to that found in $(\eta^5\text{-}C_5Me_5)W(NO)(CO)_2$ (2.008 Å)(8). The most noteworthy bond lengths are the W—I bonds (W—I(1) = 2.655(2) Å and W—I(2) = 2.605(3) Å (disordered)), which are significantly shorter than those seen in related 18-electron compounds, e.g., 2.803(1) Å in $(\eta^5\text{-}C_5H_5)W(NO)(\eta^3\text{-}C_3H_3)I$ (22), 2.864(av) Å in $(t\text{-}C_4H_9NC)_3W(CO)_2I_2$ (23), 2.845(2) Å in $W(CO)_4(PMe_3)I_2$ (24). A possible explanation for this may be the occurrence of some $W(d\pi)$–$I(p\pi)$ bonding in $(\eta^5\text{-}C_5Me_5)W(NO)I_2$. A similar inference can be drawn for $[WI(NEt_2)_2]_2$ where similar W—I bond lengths are observed (W—I = 2.682(av)) Å (25). Furthermore, similar multiple bonding has also been invoked in analogous electronically unsaturated, formally 16-electron molybdenum complexes. For instance, $Mo(d\pi)$–$N(p\pi)$ bonding has been suggested for the shortening of the Mo—N amido bonds in the pyrazolylborate complex $[\{Mo(NO)[HB(Me_2pz)_3]Cl\}_2(NC_4H_3N)]$ (26), and theoretical calculations have supported the existence of $Mo(d\pi)$–$S(p\pi)$ bonding in $(\eta^5\text{-}C_5He_5)Mo(NO)(SPh)_2$ to account for the observed shortening of the Mo—S bonds (27).

A formal 16-electron configuration for monomeric $(\eta^5\text{-}C_5Me_5)W(NO)I_2$, while novel for an organometallic halide, is not unreasonable. In our experience, the related 16-electron species

$(\eta^5\text{-}C_5H_5)M(NO)R_2$

M = Mo, W; R = CH_2SiMe_3

M = W ; R = SCH_2SiMe_3

are stable, isolable monometallic complexes (4, 27). Indeed, in the case of the thiolate complex, an 18-electron intermediate preferentially converts to the formally 16-electron product (19). It is possible, however, that the thiolate complex may also owe its thermal stability to the existence of some $W(d\pi)$–$S(p\pi)$ bonding (*vide supra*) (27).

The knowledge obtained from this study should prove useful in helping to understand the mechanisms by which the derivatives of $(\eta^5\text{-}C_5Me_5)W(NO)I_2$ are formed. In closing, it should be emphasized that the results presented in this paper do not imply anything about the degrees of association of the other $(\eta^5\text{-}C_5R_5)M(NO)X_2$ family members. Rather, they simply indicate that care should be taken when invoking the familiar 18-electron rule to deduce molecular structures without any other supporting evidence.

Received December 24, 1987

This paper is dedicated to Professor Charles A. McDowell on the occassion of his seventieth birthday

ISHII, I., MCLAREN, R., HITCHCOCK, A. P., JORDAN, K. D., CHOI, Y., and ROBIN, M. B. Can. J. Chem. **66**, 2104 (1988).

Absolute oscillator strength spectra in the C 1*s* (280–340 eV) and F 1*s* (680–740 eV) regions of the perfluoro-*n*-alkanes from C_2 to C_6 and perfluorocycloalkanes from C_3 to C_6 have been determined from inner-shell electron energy loss spectra recorded under electric-dipole scattering conditions. The spectral features are interpreted in terms of spatially localized transitions terminating at orbitals of predominantly σ*(C—F) and σ*(C—C) character. When compared to the spectra of the perfluoro-*n*-alkanes, both the C 1*s* and F 1*s* spectra of the perfluorocycloalkanes exhibit additional low-lying bands which are assigned to transitions terminating at σ*(C—C) orbitals which are shifted to low energy by the combination of the strain of cyclization and the inductive effect of the fluorination. The electron transmission spectra of selected perfluorocycloalkanes (which provide information on their anion states) show as well that the electron affinities of the cyclic systems are substantially lower than those of the corresponding perfluoro-*n*-alkanes, again as a result of a low-lying σ* orbital in the cyclic species. Quantum chemical calculations of the alkane and perfluoroalkane ground-state orbital structures support the experimental results. The localized character of the inner-shell excitations, indicated by the constancy of both term values and oscillator strengths with increasing chain length, contrasts with the more delocalized character of the states accessed in ultraviolet excitation or negative ion formation.

ISHII, I., MCLAREN, R., HITCHCOCK, A. P., JORDAN, K. D., CHOI, Y., et ROBIN, M. B. Can. J. Chem. **66**, 2104 (1988).

Utilisant les spectres de pertes d'énergie électronique des couches internes enregistrés dans des conditions de diffraction du dipôle électrique, on a déterminé les spectres de force absolute de l'oscillateur des régions C 1*s* (280 à 340 eV) et F 1*s* (680 à 740 eV) des perfluoro-*n*-alcanes (C_2 à C_6) et des perfluorocycloalcanes (C_3 à C_6). On interprète les caractéristiques spectrales en fonction de transitions qui sont localisées dans l'espace et qui se terminent avec les orbitales possédant des caractéres σ*(C—F) et σ*(C—C) prédominants. Lorsqu'on les compare aux spectres des perfluoro-*n*-alcanes, les spectres tant C 1*s* que F 1*s* des perfluorocycloalcanes présentent de faibles bandes additionnelles que l'on a attribuées à des transitions se terminant au niveau des orbitales σ*(C—C) qui sont déplacées vers les basses énergies par une combinaison de tensions de cycle et d'effet inductif des fluors. De plus, les spectres de transminnion électronique des ions négatifs de perfluorocycloalcanes choisis montrent que les affinitiés électroniques des systèmes cycliques sont beaucoup plus faibles que celles des perfluoro-*n*-alcanes correspondants; ces résultats sont encore une fois expliqués par la présence d'orbitales σ* basses dans les systèmes cycliques. Des calculs de chimie quantique effectués sur les structures des orbitales des états donsamentaux d'alcanes et de perfluorocycloalcanes sont en accord avec les résultats expérimentaux. Le caractère localisé des excitations de couches internes, tel qu'indiqué par la constance de chacun des termes des valeurs ainsi que des forces d'oscillation avec une augmentation de la longueur de la chaîne, est en opposition avec le caractère plus délocalisé des états atteints par les excitations ultraviolettes ou par la formation d'ions négatifs.
[Traduit par le revue]

1. Introduction

The fate of electronic transitions terminating at σ* MO's in the outer-shell (5–50 eV) and inner-shell (50–1000 eV) spectra of large organic molecules remains very much an open question. At first sight, the problem would seem to be that the transitions to σ* are rather high lying, and so are difficult to identify either because they fall among the clutter of transitions to Rydberg (R) orbitals or because they are autoionized in the ionization continua. However, the problem is more complex, for there is a very real possibility that a particular valence (V) σ* MO is mixed more or less with the R MO's of the same symmetry so that its valence identity becomes clouded; in extreme cases a σ* MO can dissolve in the Ryberg sea to such an extent as to lose its valence character completely (1, 2). Though valence transitions to σ* in the ionization continuum do appear as shape resonances (3, 4) and cannot be confused with transitions to R orbitals, assignment still can be ambiguous here as well, for other phenomena such as two-electron excitation, shake-up, and EXAFS interference also can contribute structure in this region (5). Finally, because the nature of the transitions to σ* MO's in the outer-shell and inner-shell spectra of the same molecule may be quite different, conclusions about σ* MO's reached in one type of study would not necessarily apply to the other.

In the present work, we have studied the inner-shell excitation energies and oscillator strength distributions of a series of perfluoro-*n*-alkanes (C_2—C_6) and perfluorocycloalkanes (C_3—C_6) as well as perfluoroneopentane. For certain of these compounds, we also have determined the negative-ion electron transmission spectra and performed *ab initio* ground state calculations. In our discussion of the spectral results, we address the following questions: (*1*) What are the energies and

relative R/V characters of the σ* MO's accessed in the inner-shell and negative-ion spectroscopies of the perfluoroalkanes? (*2*) To what extent are σ* orbitals stabilized by perfluorination and/or ring strain? (*3*) Are the inner-shell and negative-ion excitations terminating at σ* in the perfluoroalkanes localized or delocalized?

Identification of transitions terminating at σ* is most readily approached through the study of inner-shell spectra, for in this case though the terminating MO manifold may be complex, at least the originating inner-shell MO manifold is simpler than the occupied valence MO manifold involved in outer-shell excitations. In addition, because of the smaller number of configurations of similar core-excitation energies, a one-electron orbital model is expected to be more applicable to inner-shell than to outer-shell excitation. Given the inner-shell ionization potential, usually from X-ray photoelectron spectroscopy, one knows that the corresponding R excitations will fall in a certain region below this limit (1). The energy difference between the ionization potential and the corresponding discrete excitation is called the term value. Term values for R states are usually between 0 and 5 eV. On the other hand, transitions to σ* orbitals can occur over a much wider spectral range; in this case, term values as large as 14 eV (F_2) and as small as −22 eV (C_2H_2) have been reported (4).

Recently it has been shown that the term value of a $1s \rightarrow \sigma^*$(A—B) transition can be estimated from empirical considerations of the atomic numbers of atoms A and B involved in forming the σ* MO and the A–B internuclear distance (3, 4). This correlation assumes that the σ* MO reached in an inner-shell excitation is strongly localized in the region of a localized core hole, even in systems of large size containing several equivalent and adjacent bonds. The localization of the $1s \rightarrow$ V(σ*) excitation could arise from a local character of the σ* orbital and/or spatial localization of the core hole.

In the case where inner-shell excitations to σ* and R orbitals are nearly degenerate, term value arguments are less compelling and the question arises as to the separate existence of near-degenerate R and V levels (1, 2). Although the answer to this is ambiguous in many cases, clear evidence for the coexistence of distinct V and R levels in the same spectrum has been presented for F_2O (6).

In addition to the term-value criteria, there are a number of effects that can assist in the determination of the relative R/V character of a particular spectroscopic feature. First, in the condensed phase, transitions to R levels are generally broadened significantly and shifted to higher energies so as to make the transitions effectively disappear (1, 7). In contrast, the transitions to V states persist virtually unchanged in a condensed phase. Second, there is a well-known upper limit to the oscillator strength of transitions to R states (1), whereas many transitions to V states have oscillator strengths which exceed the R limit. Third, the transition energies and oscillator strengths exhibit systematic variations through a homologous series of molecules which may help to distinguish transitions to R states from those to V states.

In a specific class of molecules, it has been found that σ* MO's can lie so low that their identification is not comprised by problems of congestion or orbital mixing. Thus, if a molecule has a bond between atoms A and B which has a strength of 60 kcal/mol or less, then the σ–σ* splitting will be abnormally small and the σ*(A—B) MO will be relatively low lying, as will inner-shell transitions such as A $1s \rightarrow \sigma^*$(A—B) and outer-shell transitions such as B $2p \rightarrow \sigma^*$(A—B). This lowering of the inner-shell and outer-shell energies for excitations to σ* has been called the weak-bond effect (2, 6).

In addition to the questions listed above, we also raise the question as to whether an *overall* molecular strain energy which weakens several bonds simultaneously also can result in a small σ–σ* split. If so, then such strained systems also will show unambiguous low-lying excitations to σ* with unusually large term values. In this regard, it is pertinent to note that C $1s \rightarrow \sigma^*$ transitions at lower-than-expected energies already have been observed in the spectra of cyclopropane and cyclobutane (8).

The opportunities for observing transitions to low-lying σ* MO's may be heightened yet again by perfluorinating the strained cyclic hydrocarbons. This could arise both from the introduction of strain energy due to F—F repulsions (9), and from the fact that fluorination of a molecule acts to lower both σ and σ* MO's due to the strong inductive effect of the F atom (6, 10). That the perfluoroalkanes may prove to be a rich hunting ground for low-lying transitions to σ* MO's was mentioned earlier following a comparison of the vacuum ultraviolet (VUV) spectra of alkanes and their perfluoro derivatives (1); related ideas can be found in discussions of the inner-shell spectra of the fluoromethane (1, 11–13) and chloromethane series (14).

In hydrocarbons consisting of several C—C bonds, the C $1s$ AO's on equivalent sites form a narrow band of width *ca.* 0.01 eV. It is generally believed that because of the narrow bandwidth, mobility of the $1s$ hole is so low that the originating orbital in the core-excited state can be localized at a single atomic site during the very short lifetime of the hole state (15–18). However, see the work of Schwartz *et al.* (19) for possible exceptions to this point of view. There clearly is a question at present as to the degree of localization of the core hole in the core excited states of molecules having the excited atoms in equivalent sites. Related aspects to this problem are the degree of delocalization of the σ* MO's populated in the core states, and the fact that the degree of delocalization of the optical orbital may differ depending upon the spectroscopy by which it is examined (20). That is, the potential experienced by the optical electron in a ($1s$, σ*) hole-localized excited state in the X-ray region of a given molecule is quite different from that appropriate to a delocalized (σ, σ*) state in the VUV excitation of that molecule. In these situations, the σ* MO's may be quite different both in spatial extent and term value.

The presence of low-lying, strain-induced σ* MO's in the perfluorocycloalkanes could be revealed not only in the inner-shell spectra but in their negative-ion spectra as well (21). Though the potential experienced by an electron in a σ* orbital is very different in the case of a negative-ion and inner-shell excitation in a neutral molecule, this avenue was felt to be worth exploring in spite of the possible differences. Inner-shell and negative-ion comparisons of this type have been found useful in studying the unoccupied orbitals of the fluorobenzenes (10) and fluoroethylenes (6).

In the present work, we have measured the negative-ion transmission spectra of the perfluoro-*n*-alkanes and the corresponding perfluorocycloalkanes. These results are compared with virtual-orbital calculations of the successive electron affinities of the linear and cyclic perfluoroalkanes. Negative-ion resonances in saturated molecules may involve not only σ* resonances, but Feshbach resonances as well, in which two electrons occupy a single R orbital. For purposes of assigning

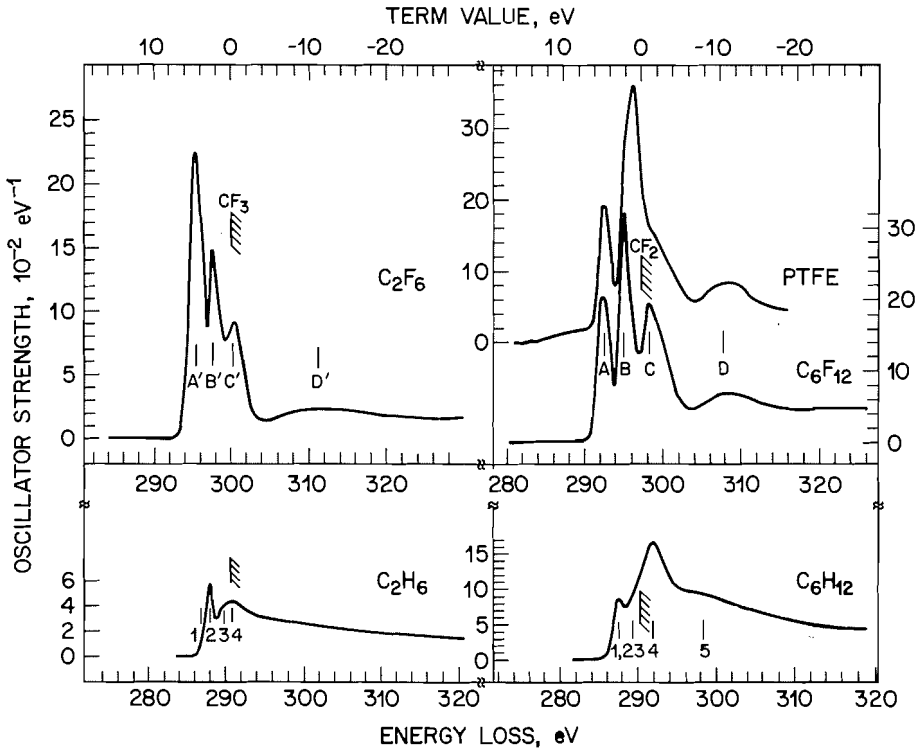

FIG. 1. Comparison of the oscillator strength spectra of C_2H_6 and C_6H_{12} with those of C_2F_6 and C_6F_{12}, as derived from energy-loss spectra recorded with 2.5 keV final electron energy, 2° scattering angle and 0.6 eV FWHM resolution. The spectra have been shifted so as to bring the C 1*s* ionization potentials into alignment. Also shown is the optical spectrum of PTFE, as recently reported by Ohta *et al.* (32), plotted on the same absolute energy scale as that of C_6F_{12}.

the negative-ion resonances, the strategy used here is to first assign the Feshbach resonances, using the well-known energy criteria for such excitations (1, 20, 22), and then assume that the remaining resonances involve occupation of the σ* MO's.

In this paper, we consider successively the C 1*s* spectra of the linear and branched perfluoroalkanes (sect. III) and compare these with the C 1*s* spectra of the cyclic perfluoroalkanes (sect. IV). Similar comparisons are drawn for the F 1*s* spectra of the same series of compounds (sect. V). The ordering of the virtual orbitals and their R/V characters as derived from these spectra are then compared with the conclusions deduced from the negative-ion spectra, as supported by *ab initio* calculations (sect. VI). These comparisons lead to a discussion of excitation localization/delocalization in these spectra (sect. VII).

II. Experimental

The C 1*s* and F 1*s* inner-shell spectra of the perfluoro-*n*-alkanes from C_2F_6 to C_6F_{14}, perfluoroneopentane, and the cyclic compounds from C_3F_6 to C_6F_{12} were recorded by electron energy loss spectroscopy using the McMaster inner-shell electron energy loss (ISEEL) spectrometer. Operating under conditions chosen to accentuate electric-dipole transitions (2.5 keV final electron energy and scattering angles less than 2°), a resolution of 0.6 eV FWHM was achieved. Further details of the spectrometer and operating procedures are presented elsewhere (3, 23). Each of the perfluoroalkanes was a commercial product except for perfluorocyclopropane, perfluorocyclopentane, and perfluoroneopentane which were gifts from Professor J. L. Adcock. Sample purity within the spectrometer cell was monitored mass spectrometrically and the energy loss spectra calibrated by the addition of appropriate gases of known transition energies. In all cases, the energy loss spectra reported here have had the underlying continuum intensity subtracted and have been converted to approximate absolute oscillator strength distributions (±20%) using corrections for kinematic effects and normalization to calculated atomic 1*s* photoionization oscillator strengths (24).

Negative-ion resonance energies were determined using an electron transmission spectrometer operating in the derivative mode. The technique is described in ref. 21. Negative-ion spectra were determined for selected members of both the linear and cyclic perfluoroalkanes, as well as for certain alkanes.

III. Inner-shell spectra of perfluoro-*n*-alkanes

The discrete transitions below the C 1*s* ionization potentials in the inner-shell spectra of the alkanes are of mixed R/V character (3, 8, 25). Since the general effect of fluorination is to accentuate the V character of the lower excitations, we must expect to see much stronger R/V mixing in the perfluoroalkanes or even low-lying transitions to relatively pure σ* MO's. In the latter case, the V levels may rest among the R levels or even precede them. Indeed, it is clear from earlier work (1, 12, 13, 26–30) that the C 1*s* spectrum of CF_4 involves comingling of transitions to both R MO's and to V σ*(C—F) levels. However, there is no *a priori* way of knowing how this will be reflected in the perfluoroalkane spectra.

Because the separation between the C 1*s*(CF_2) and C 1*s*(CF_3) ionization potentials is nearly 2 eV (31) in the perfluoro-*n*-alkanes, one has two partially overlapped inner-shell spectra and difficulties therefrom for perfluoro-*n*-alkanes larger than C_2F_6. In this case, it is best to first focus on a molecule containing only CF_3 groups (CF_3CF_3) and a molecule containing only CF_2 groups [$(CF_2)_6$], and then to apply this information toward interpreting the spectrum of $CF_3(CF_2)_xCF_3$, x = 1–4, which can be considered as a mixture of more or less weakly interacting CF_3 and CF_2 chromophores. The spectra of the molecular pair C_2H_6 and C_2F_6 and the pair C_6H_{12} and C_6F_{12} are

presented on common term value and oscillator strength scales (Fig. 1) to facilitate interpretation of the mixed chromophore systems. The spectrum of another possible CF_2 prototype, polytetrafluoroethylene (PTFE) $(CF_2)_x$ taken from the work of Ohta *et al.* (32) also appears in this figure.

III.1. The CF_3 spectrum

We consider CF_3CF_3 to be the prototypical CF_3 chromophore. This molecule has a spectrum in the C 1*s* region, Fig. 1 and Table 1, which not only is deeper by about 8 eV than that of CH_3CH_3, but also has a dramatically different oscillator strength distribution. Based on term values, analogy can be made between band *A'* of C_2F_6 (295.4 eV, 4.50 eV term value) and band 1 of C_2H_6 (286.9 eV, 3.69 eV term value) (25). In C_2H_6, this band has been assigned as terminating at a mixed $3s/\sigma^*$ MO with predominantly R character (1, 25). The increased term values of the transitions to $3s/\sigma^*$ upon fluorination of a wide variety of systems is well known (1, 2). What is more interesting here is that in C_2H_6 the C $1s \rightarrow 3s/\sigma^*$ transition is relatively weak and seems to be following the quasiatomic propensity rule forbidding $1s \rightarrow 3s$ transitions, whereas what appears to be the corresponding transition in C_2F_6 has more than 10 times the oscillator strength and is the most prominent band in the spectrum! Since the most intense Rydberg transitions in VUV spectroscopy have oscillator strengths of only 0.08 per degree of degeneracy (1) and R transitions in the inner-shell region will be much weaker still, both the 0.15 oscillator strength of the *A'* band of C_2F_6 and the increased term value indicate that the F atoms of C_2F_6 are strongly perturbing the $3s/\sigma^*$ orbital, acting to make it increasingly valence shell. In light of this, it follows that the 295.4 eV feature of C_2F_6 (band *A'*) can be considered as predominantly C $1s \rightarrow \sigma^*$(C—F). The spectral intensification and change of character from $3s/\sigma^*$-(C—H) to σ^*(C—F) on going from C_2H_6 to C_2F_6 has its parallels, for these changes also are observed on going from C_2H_4 to C_2F_4 (22, 24) and throughout the fluoromethane series (1, 12, 13, 26, 29).

Band *B'* of C_2F_6 with a term value of 2.09 eV has its counterpart in C_2H_6 (band 2), thought to be mixed $1s \rightarrow 3p$ and $1s \rightarrow \sigma^*$(C—H) (25, 33) with a term value of 2.70 eV. In this case, band *B'* has an oscillator strength which is threefold larger than that of band 2 in C_2H_6. Note that the observed increase of the *A'* term value, decrease of the *B'* term value and intensification of both transitions in C_2F_6 all follow naturally from a strong mixing of *3s* and *3p* orbitals among themselves along with further strong mixing with σ^* V orbitals. See sect. III.2 for further discussion of excitations to σ^*(C—F) in the CF_3 group.

The assignment of both *A'* and *B'* as transitions terminating at σ^*(C—F) is consistent with the bond length/term value correlation (4) which predicts a term value of 2.3 eV for the 1.326 Å C—F bond length in C_2F_6. This predicted value lies between the term values observed for features *A'* (4.5 eV) and *B'* (2.1 eV). Although the splitting of the σ^*(C—F) intensity into two peaks contradicts the bond-localized excitation assumption of the bond length correlation, this splitting (2.4 eV) is relatively small and the two observed lines straddle the predicted C $1s \rightarrow \sigma^*$(C—F) position. More dramatic examples of this type of deviation from the most simple implementation of the bond length correlation have been noted in the σ^*(C—C) resonances of benzene and the fluorobenzenes (10), as well as the σ^*(C—O) resonances of CO_2 (5).

Band *C'* of C_2F_6 (300.5 eV, 0.7 eV beyond the ionization potential) has its counterpart in C_2H_6 as band 4 (290.8 eV, 0.2 eV beyond the ionization potential). As in the CH_4/C_2H_6 comparison (3, 25), we see on comparing the CF_4 (26–30) and C_2F_6 (Fig. 1 and Table 1) inner-shell spectra, that the *C'* shape resonance of C_2F_6 does not appear in CF_4 and so must terminate at σ^*(C—C). The doubling of the C $1s \rightarrow \sigma^*$(C—C) oscillator strength upon perfluorinating C_2H_6 can be rationalized in terms of the potential barrier localization of the σ^*(C—C) orbital (34).

In C_2F_6, band *D'* can be assigned as either an unusually strong first EXAFS feature or alternatively, feature *D'* may represent the energy at which the C 1*s* photoelectron energy exceeds the height of the potential barrier associated with the large number of electronegative F atoms in this molecule (34). Within the framework of group-localized core excitations, the *D'* excitation energy is much too large to terminate at σ^*(C—C) or σ^*(C—F) (4). In the potential barrier interpretation, the spectral feature of interest is not the *D'* maximum, but rather the depressed C 1*s* continuum intensity between 302 and 310 eV which reaches a minimum value of 0.01 eV^{-1} at 305 eV compared to a value of 0.03 eV^{-1} at an equivalent photoelectron energy in C_2H_6 (Fig. 1). A strong suppression of the C 1*s*

near-continuum intensity of CF_4 relative to that in CH_4 was found in recent quantitative optical studies (29). If one follows the continuum intensity backward from high energy loss to the ionization potential, the slow rise in continuum begins to fall off approximately at the maximum of the apparent peak. If this is interpreted as the energy at which a potential barrier begins to depress the ionization cross section, then one arrives at an estimate of approximately 11 eV for the height of the centrifugal barrier in C_2F_8. It is interesting that this estimate is slightly greater than the estimate of 8 eV for the centrifugal barrier in C_2F_4 reached using slightly different arguments (24). That the potential barrier becomes larger as the number of electronegative F atoms surrounding the central C atom increases is intuitively acceptable. The depressed continuum intensity between 302 and 310 eV is found not only in C_2F_6 but also throughout all of the perfluoroalkanes. This is shown in Table 2, which compares on a per-C-atom basis the near-continuum intensity (from −4 to −12 eV term value) for all of the compounds studied in this work with those of the representative alkanes C_2H_6, C_6H_{12}, and C_6H_{14}.

Based on the above considerations, and with due allowance for the effects of fluorination on term values (1) and relative intensities (34), it is concluded that the A' and B' transitions of C_2F_6 are superficially related to those of C_2H_6 labelled 1 and 2 in Fig. 1, but whereas those of the latter are largely R in character, those of C_2F_6 are largely V. Shape resonances which closely resemble one another in energy and width are seen in C_2F_6 (band C') and C_2H_6 (band 4); both terminate at σ^*(C—C).

III.2. The CF_2 spectrum

We use perfluorocyclohexane $(CF_2)_6$ as a model of the CF_2 inner-shell spectrum and compare its spectrum with that of $(CH_2)_6$ in Fig. 1. As an alkane is lengthened, the term values for the excitations to $3s/\sigma^*$ and to $3p/\sigma^*$ orbitals converge upon one another at *ca.* 2.6 eV (1, 25). Accordingly, in C_6H_{12} (8), the transitions from C 1s to $3s/\sigma^*$ and $3p/\sigma^*$ no longer can be resolved, and instead form a single sharp feature (bands 1 and 2) with a term value of 2.60 eV. This coincidence is not expected in C_6F_{12}, for a large $3s/\sigma^*$–$3p/\sigma^*$ splitting (2–4 eV) often is observed in heavily fluorinated molecules. Indeed, the lowest two sharp bands (A and B) in the inner-shell spectrum of C_6F_{12} have term values of 4.8 and 2.11 eV, in the range characteristic of R transitions terminating at $3s$ and $3p$ orbitals, respectively. However, as with the bands of C_2F_6, these bands of C_6F_{12} when compared to those of C_6H_{12} are seen to have the greatly increased oscillator strengths more characteristic of valence transitions. The V bands in $(CF_2)_6$ are sufficiently broad that the C 1s → 4p transition (band 3 of the alkanes) does not appear. The dominance of C 1s → σ^*(C—F) and the relative weakness of C 1s → R transitions also is consistent with the potential barrier model for core excitation in perfluoro compounds (34). Features C (C 1s → σ^*(C—C)) and D appear in C_6F_{12} with term values close to those observed in C_2F_6. Feature C in C_6F_{12} has a high-energy shoulder and is broadened with respect to that in C_2F_6, consistent with contributions from several overlapping C 1s → σ^*(C—C) transitions in this region, as noted as well for the transitions to σ^*(C—C) in the longer alkanes.

If one considers the peak heights or oscillator strengths of bands A/A' and B/B' in C_6F_{12}/C_2F_6, one finds that, per carbon atom, the sum of the A' and B' oscillator strengths of C_2F_6 is roughly twice that of the A and B bands of C_6F_{12}, Table 2. This is somewhat larger than but similar to the relative numbers of C—F bonds in the CF_3 and CF_2 groups, for which C_2F_6 and C_6F_{12} are taken as prototypes. The oscillator strength per carbon atom of bands B and B' are approximately the same in the two species, whereas that for band A' in C_2F_6 is 2–3 times greater

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 112.217.228.212 on 09/07/12
For personal use only.

than that for band A in C_6F_{12}. If one considers a local C_{2v} symmetry for the CF_2 group and local C_{3v} symmetry for the CF_3 group, the oscillator strengths then suggest that peaks B and B' correspond to C $1s$ excitations to the nondegenerate local σ^*(C—F) MO in both cases (a_1 in CF_3; a_1 or b_1 in CF_2). On the other hand, peaks A and A' then correspond to C $1s$ excitations to σ^*(C—F) levels of e symmetry in CF_3 groups but b_1 or a_1 symmetry in CF_2 groups. Thus in C $1s(CF_3)$ spectra, we label the A' band as $\sigma^*(C—F)_\pi$ and the B' band as $\sigma^*(C—F)_\sigma$. It should be noted that in this assignment scheme for CF_3, the A' and B' bands do not necessarily have the same symmetries as the $3s$ and $3p$ R orbitals, and so we are not dealing with the intensification of R transitions by mixing with V transitions, but rather with the overlapping of intense V transitions upon R transitions. It also should be noted that there is not necessarily a general one-to-one relationship between relative degeneracies and relative intensities. However, such a relationship is not unexpected when orbitals of similar character are involved.

Further support for a $\sigma^*(C—F)_\pi$ below $\sigma^*(C—F)_\sigma$ ordering of the CF_3 group orbitals in the C $1s$ excitation spectrum is found in the *ab initio* calculations for CF_3H and CF_2H_2 reported by Snyder and Basch (35). The C $1s$ spectra of CF_3H (14) and C_2F_6 are very similar except that the C_2F_6 spectral intensities are twice as large and there is additional intensity at the C $1s$ ionization potential associated with the C $1s \rightarrow \sigma^*$(C—C) promotion in C_2F_6. In the CF_3H ground state, a nondegenerate MO of σ^*(C—F) character ($8a_1$) is calculated to lie 1.8 eV above a degenerate pair of $\sigma^*(C–F)_\pi$ orbitals (*11, 12e*), in agreement with the $\sigma^*(C—F)_\pi$ below $\sigma^*(C—F)_\sigma$ ordering we assign for C_2F_6 on the basis of intensities.

Similarly, the discrete portion of the C $1s$ spectrum of CF_2H_2 resembles that of C_6F_{12}, although additional sharp structures associated with C $1s \rightarrow \sigma^*$(C—H) transitions are observed in CF_2H_2, the second σ^*(C—F) feature is much weaker, and the C $1s \rightarrow \sigma^*$(C—C) transition is absent. This provides further justification for our use of these compounds to model the C $1s(CF_3)$ and C $1s(CF_2)$ excitations in perfluoro-*n*-alkanes.

The ground-state virtual orbital eigenfunctions of CF_3H and CF_2H_2 calculated by Snyder and Basch (35) also can be used to estimate the relative intensities of C $1s(CF_3) \rightarrow \sigma^*$(C—F) and C $1s(CF_2) \rightarrow \sigma^*$(C–F) transitions and thus to provide further support for our spectral interpretation. In the absence of strong distortions by the core hole, the intensity of C $1s$ (F $1s$) excitations to a virtual orbital are expected to be proportional to the squares of the C $2p$ (F $2p$) atomic orbital coefficients on the core excited atom. This approach has been used recently to compare calculated and experimentally derived spatial distributions of the π^*(C—O) orbital in substituted carbonyls (36). According to the double-zeta GTO calculations (35), the ratio of the squared coefficients in the $\sigma^*_\pi/\sigma^*_\sigma$ orbitals of CF_3H is 1.5 (using the diffuse component) and 1.0 (using the compact component) (35), while the ratios of the squared C $2p$ coefficients in the first two virtual orbitals in CF_2H_2 are 0.8 (diffuse) and 1.2 (compact). Thus the ground state calculation suggests that the C $1s(CF_3) \rightarrow \sigma^*(C—F)_\pi$ transition should be more intense than the C $1s(CF_3) \rightarrow \sigma^*(C—F)_\sigma$ transition while the two C $1s(CF_2) \rightarrow \sigma^*$(C—F) excitations should be of similar magnitude. This is consistent with our interpretation of the virtual orbital ordering in C_2F_6 since the ratio of the areas of the first two peaks in the C $1s$ spectra is 2.7 in C_2F_6 and 0.7 in C_6F_{12}.

Further support for a $\sigma^*(C—F)_\pi$ below $\sigma^*(C—F)_\sigma$ ordering of the CF_3 group orbitals in the C $1s$ excitation spectrum is found in the *ab initio* calculation for C_2F_6 (see sect. VI). In this, we find the lowest virtual orbital to be C—F antibonding with overall e_u symmetry in the molecular point group; this corresponds to $\sigma^*(C–F)_\pi$. The virtual orbital corresponding to $\sigma^*(C–F)_\sigma$ is a_{2u} in the molecular point group, an orbital which is 2.92 eV higher in energy.

III.3. Condensed phase spectra

It is generally acknowledged (1, 7) that R states are very susceptible to perturbation by adjacent molecules in a condensed phase, whereas valence excitations are much less so. The R excitations of a solute molecule in a condensed phase of low electron mobility generally are shifted to higher energies and broadened so greatly as to make the transitions effectively disappear, whereas a valence transition to σ^* in the same molecule will suffer a much weaker perturbation, shifting slightly to lower energy. It is of great interest to use this difference to further illuminate the R/V characters of the inner-shell excitations in perfluoroalkanes. Possible problems which one might encounter using this approach are the effect due to a matrix/solvent of high electron mobility (rare gases, metal surfaces, matrices/solvents of near spherical symmetry, etc.) and the deperturbation which might be wrought by the matrix/solvent on a transition which in the gas phase is of mixed R/V character (37).

The electron yield spectrum of a thin film of PTFE recorded by Ohta *et al.* (32) using synchrotron radiation is plotted in Fig. 1 for comparison with that of C_6F_{12} in the vapor phase. A very similar spectrum of PTFE has been recorded by Fink *et al.* using inelastic electron scattering (38). There is a remarkably close correspondence between the bands of the $(CF_2)_x$ and $(CF_2)_6$ systems in spite of the fact that one of them is in the vapor phase and the other is a solid of low electron mobility. One argues from this that since the spectra of $(CF_2)_x$ and $(CF_2)_6$ are in one-to-one correspondence and since all of the observed bands of PTFE are necessarily valence, that all of the resolvable features of C_6F_{12} also are predominantly valence shell. It follows as well that since we are taking C_6F_{12} as prototypical of the CF_2 group excitation spectrum, all of the excitations attributed to the CF_2 group in whatever molecule are also strongly valence shell.

As with the PTFE/C_6F_{12} pair, comparison of the C $1s$ spectra of the analogous pair polyethylene (PE)/C_6H_{12} also shows a remarkably close correspondence of excitations (33). Further, these spectra bear close resemblance to those of the much smaller vapor phase *n*-alkanes (C_2H_6–C_6H_{14}). In the case of PE, polarization studies have been performed on the oriented material, leading to confirmation of the assignments of the two lowest energy features as valence excitations terminating at σ^*(C—H) and σ^*(C—C) MO's, respectively (32, 33). By analogy with the situation in PE, the B and C bands of oriented PTFE (292.7 and 296.0 eV), Fig. 1, should be polarized respectively perpendicular and parallel to the C—C direction.

III.4. The spectra of $CF_3(CF_2)_xCF_3$

It appears from the work quoted above that the inner-shell excitations in the CF_2 and CF_3 groups are very much localized. Working further in this approximation, one expects in zeroth order that the C $1s$ inner-shell spectrum of a perfluoro-*n*-alkane will be the sum of the spectra of its constituent CF_2 and CF_3 groups. Deviations from this may be due to inter-group interactions which spread the excitation over two or more CF_x groups. Thus, within the localization model, consideration of the C_2F_6 and C_6F_{12}/PTFE spectra leads to certain expectations

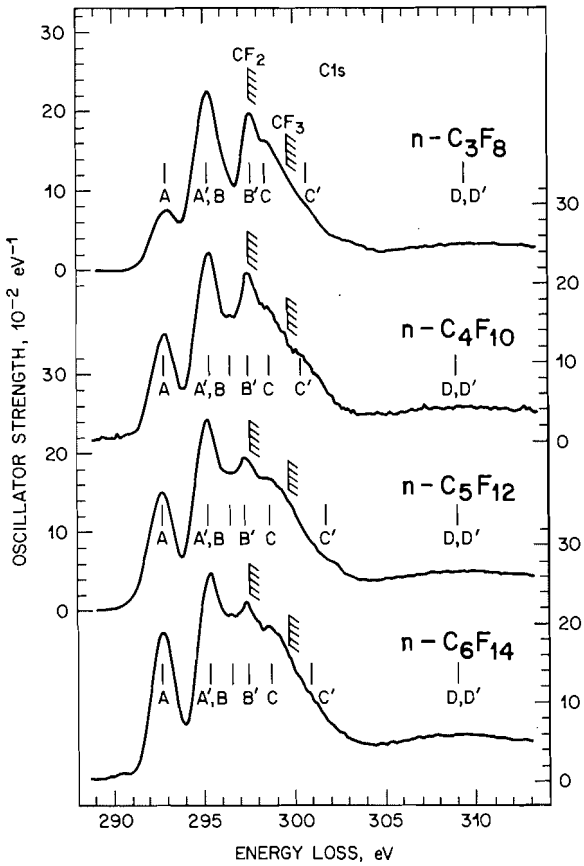

FIG. 2. Oscillator strength spectra of the perfluoro-*n*-alkanes in the C 1*s* region as derived from energy loss spectra (for details, see caption to Fig. 1). Inner-shell ionization potentials are shown by hatched areas. The unprimed transitions originate at CF_2 groups whereas the primed transitions originate at CF_3 groups.

in regard the spectra of perfluoro-*n*-alkanes: (*1*) On the term value scale, essentially the same spectral pattern is observed for CF_2 and CF_3 groups, although the relative intensities of the component transitions differ for the CF_2 and CF_3 chromophores. Thus the same transitions to σ*(C—F) and σ*(C—C) considered in sects. III.1 and III.2 will dominate the discrete structure of the perfluoro-*n*-alkane C 1*s* spectra, but with oscillator strengths proportional to the numbers of CF_2 and CF_3 groups in the molecule. (*2*) Spectra originating at CF_2 and CF_3 groups will be offset by the difference in the ionization potentials of these groups, typically 1.2–1.8 eV. Although the *A*/*B* and *A*′/*B*′ features are well separated in the spectrum of each chromophore, confusion may arise because their splitting in the perfluoro-*n*-alkanes will very nearly equal the splitting of the CF_2 and CF_3 ionization potentials. This leads to unavoidable coincidences of bands, e.g., the C $1s(CF_3) \rightarrow$ σ* *A*′ transitions will be accidentally degenerate (or nearly so) with C $1s(CF_2) \rightarrow$ σ* *B* transitions in all perfluoro-*n*-alkanes larger than C_2F_6. The characteristic relative intensities of bands *A* and *B* in the CF_2 and *A*′ and *B*′ in the CF_3 group spectra may assist in resolving this overlap.

Spectral analysis of the perfluoro-*n*-alkanes as a sum of CF_2 and CF_3 group excitations originating at C 1*s* is summarized in Table 1 and in Fig. 2; one sees a facile resolution of the spectra provided one accepts the unresolved coincidence of the *A*′ and *B* transitions in the C_3F_8–C_6F_{14} series. The (C 1*s*, σ*) term values of the lowest excitations increase very slowly with the size of the molecule, being 4.5 eV in C_2F_6 and reaching only 5.0 eV in C_6F_{14}. The term values for excitations originating at C $1s(CF_3)$ appear systematically smaller than those of the corresponding transitions originating at C $1s(CF_2)$. As expected from the localization model, the spectra of the perfluoro-*n*-alkanes can be interpreted as combinations of the spectra of the CF_2 and CF_3 groups. Only the transitions to σ* levels are seen. To some extent, this situation may result from the rather limited resolution (0.6 eV) of the present spectra, so that weak but discrete R features may be revealed with higher resolution studies. However, we expect them to be weaker and/or more congested than in CF_4 since the R structure in CF_4 is detected by our present apparatus.

The dramatic differences in the oscillator strength distributions for C 1*s* excitation in the perfluoro-*n*-alkanes as compared to the *n*-alkanes is emphasized by comparing the ratio of the sum of the discrete oscillator strengths to that obtained by integrating from the ionization potential to a point 25 eV beyond, Table 2. It is interesting to note that whereas the ratio of discrete to continuum oscillator strength values is 1.2 ± 0.1 for all of the perfluoro-*n*-alkanes (including CF_4), it is significantly lower for the *n*-alkanes (0.20 ± 0.05). It is clear as well that the oscillator strengths in the discrete regions of the C 1*s* spectra of the perfluoro-*n*-alkanes are many times larger than those in the corresponding *n*-alkanes, and much larger than expected solely from Rydberg excitations. This supports our interpretation of the discrete features in the perfluoro-*n*-alkanes as excitations to virtual orbitals of predominantly valence character. This also is consistent with the potential barrier model (34) since the intensities of transitions to inner-shell valence type orbitals are expected to be enhanced strongly in the core excitation spectrum of an atom surrounded by many highly electronegative atoms.

Our simplified view of the inner-shell spectra of the perfluoro-*n*-alkanes as sums of the CF_2 and CF_3 group excitations predicts that the intensity of a band such as *A* should scale linearly with the number of CF_2 groups in the molecule. In fact, if the C 1*s* spectra of C_2F_6 and C_6F_{12} are truly good models for the perfluoro-*n*-alkane spectra, then the oscillator strength of the *A* peak in a given $CF_3(CF_2)_xCF_3$ species should be predictable from the oscillator strength of the *A* peak in C_6F_{12}, scaled by $x/6$. As shown in Table 2, the oscillator strength of the first peak does increase systematically with x, but is almost twice as large as that predicted from C_6F_{12}. Our comparison of the C 1*s* oscillator strengths among these molecules must be treated with caution. The extrapolation of the background was made from a relatively short pre-edge region in some cases, and in all species the continuum intensity is very small relative to that of the discrete structure. Both factors contribute to the uncertainty in our determination of the C 1*s* continuum intensity at 25 eV beyond the ionization potential and thus to the estimated 20% uncertainty in the oscillator strength for peak A. If our results are confirmed by more precise measurements, it would appear that C_6F_{12} is not a perfect model for the C $1s(CF_2)$ excitations in the perfluoro-*n*-alkanes.

In our intensity analysis of band *A* in the perfluoro-*n*-alkanes, we have assumed that all of band *A* in C_6F_{12} corresponds to a transition to σ*(C—F). However, closer examination of this feature and comparison with the spectra of other perfluorocycloalkanes strongly suggest that there is a second transition to this band which terminates at σ*(C—C) and is common to all perfluorocycloalkanes (see sect. IV). In this regard, the spectrum of PTFE might be a better model for the perfluoro-*n*-alkanes than C_6F_{12}, especially if intensity information were available on it. Caution is therefore needed in applying an

For personal use only.

independent-systems model to inner-shell spectra. Although this approach has worked well in the past (chloroethane (14) and methyl formate (39)), in the present case quantitative problems appear when comparing expectations with experiment. In view of the near degeneracy of the σ*(C—F) MO's within the CF_2 and CF_3 groups, mixing of these levels is not unexpected, and in part may be the reason behind the inconsistency between the observed and the predicted scaling of the *A*-band oscillator strengths with increasing numbers of CF_2 groups.

We similarly expect the peak at *ca.* 295 eV in the perfluoro-*n*-alkanes to grow in intensity with increasing chain length according to our assignment of it as overlapping *A'* and *B* transitions. However, the peak intensity of this feature is relatively constant at *ca.* 0.25 eV^{-1} in all species, contrary to the approximate doubling expected on going from C_3F_6 to C_6F_{12}. This suggests that the *A'* and *B* transitions possibly are not exactly aligned, but rather displaced so that the feature broadens rather than heightens as the chain length increases. This broadening is evident in Fig. 2, particularly on the high energy side.

III.5. Branched isomers

It is known from previous work (25) that there is little or no difference between the inner-shell spectra of the isomers *n*-pentane and neopentane, the reason being that at the present level of resolution there is no difference between the spectra of CH_2 and CH_3 groups. Because this is not true for CF_2 and CF_3 groups, it is anticipated that there will be significant differences between the C 1*s* spectrum of perfluoro-*n*-pentane and that of its isomer perfluoroneopentane since the latter contains no CF_2 groups. On the other hand, both contain CF_3 groups which should add their characteristic pattern to both spectra. There should be smaller differences in the F 1*s* spectra of these isomeric pentanes (see sect. V.2). The C 1*s* spectra of the two compounds appear in Figs. 2 and 3 and are summarized in Tables 1 and 3. Though C 1*s* ionization potentials are not known for $C(CF_3)_4$, the X-ray photoelectron spectra of other molecules (31) suggest ionization potentials of 293 eV for C 1*s*(C) and 300 eV for C 1*s*(CF_3). These reasonable values for the C 1*s* ionization potentials in turn result in quite reasonable term values for the observed transitions, Table 3.

The C 1*s* spectra of the C_5F_{12} isomers are similar in that they both show the *A'*, *B'*, *C'*, *D'* patterns of bands which correspond to transitions originating at the CF_3 groups. On the other hand, the four bands of perfluoro-*n*-pentane corresponding to transitions originating at the CF_2 groups (*A*, *B*, *C*, *D*) are replaced in perfluoroneopentane by only two relatively weak bands, *A* and *D*, which must originate at the central C atom of that molecule. The dominance of CF_3 group excitations in perfluoroneopentane leads to a remarkable similarity between its C 1*s* spectrum and that of C_2F_6 (Fig. 3), in spite of their very different symmetries. This similarity is reasonable if the C 1*s* holes are localized in the core excited states of each molecule, resulting in an effective C_{3v} symmetry at the core hole in each case.

Band *D* of $C(CF_3)_4$ originating at the central C atom has been assigned to a shape resonance or a delayed onset continuum feature, analogous to that discussed previously (see sect. III.1). The *A* band, while appearing relatively weak in the $C(CF_3)_4$ spectrum nonetheless has an oscillator strength of 0.095; though its term value of 2.6 eV is appropriate for a Rydberg upper state, the oscillator strength is too large for such an assignment. Thus the transition in question is assigned as C 1*s*(C) → σ*(C—F)$_\pi$.

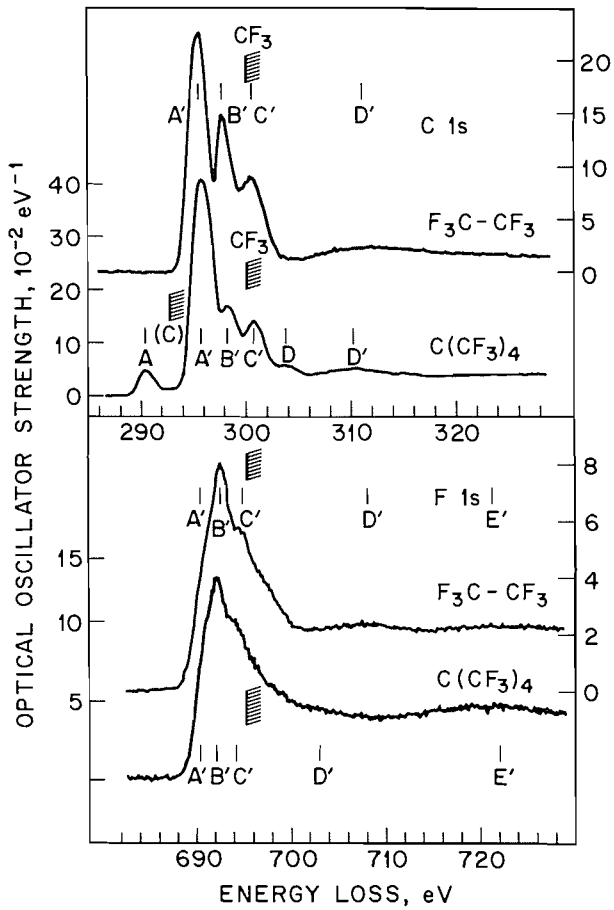

FIG. 3. Comparison of the oscillator strength spectra of C_2F_6 and $C(CF_3)_4$ in the C 1*s* (*upper panel*) and F 1*s* regions (*lower panel*). Primed and unprimed transitions originate with the CF_3 and C groups, respectively.

The term values of the C 1*s*(CF_3) → σ*(C—F)$_\pi$ and C 1*s*(CF_3) → σ*(C—F)$_\sigma$ transitions are 4.5 and 2.1 eV in C_2F_6 and 4.3 and 1.9 eV in $C(CF_3)_4$, respectively. The assignment of band *A* to C 1*s*(C) → σ*(C—F)$_\pi$ thus may seem strange based on the relatively low term value of 2.6 eV. However, it recently has been observed for a few well-defined cases (6) that transitions to highly localized molecular orbitals from the inner shells of atoms which are one atom removed from the localized bond show a decrease of 1–4 eV in their term value as compared to those in which the excitation involves a hole on an atom within the localized bond. A similar reduction of the term value also can be observed for valence excitations to the same σ* orbital. For example, inner-shell transitions to the local σ*(O—F) orbital of CF_3OF have term values of 11.1 and 11.0 eV in the O 1*s* and F 1*s*(OF) spectra, and are the dominant features of the spectra (6). Here the originating orbital has strong overlap with the terminating orbital and is highly localized. However, the C 1*s* → σ*(O—F) transition has a term value of only 7.0 eV and its oscillator strength is reduced by a factor of approximately 6 compared to the transition terminating at the same orbital in the O 1*s* and F 1*s*(OF) spectra. Similar discrepancies in term values and intensities also have been reported for inner-shell transitions to π* orbitals from local and distant sites in various carbonyls (36) and the fluoroethylenes (24).

The phenomenon of widely differing term values for transitions to a highly localized orbital when originating at atoms

which are distant rather than close to that orbital can be rationalized in terms of an energy penalty which must be paid when significant charge transfer is involved in the excitation.

IV. Low-lying σ* MO's in perfluorocycloalkanes

To this point, there is no evidence in the inner-shell spectra of the perfluoro-*n*-alkanes for a distinct transition to σ* which lies below the normal Rydberg region, although there is evidence for intense C 1*s* → σ* transitions overlapping the R transitions and most likely mixing with them. However, the C 1*s* excitations in several perfluorocycloalkanes, Fig. 4 and Table 4, are distinctly different from those of their linear counterparts in this regard, Fig. 2. Consider perfluorocyclopropane C_3F_6, as an example. The lowest-energy band in the C 1*s* spectrum of C_3F_6, Fig. 4 and Table 4, has a very large term value of 6.1 eV. Inasmuch as the lowest energy band of the corresponding linear system C_3F_8 has a term value of only 4.7 eV, Table 1, it is clear that the first band in the C 1*s* spectrum of C_3F_6 is unusually low lying due to the cyclization. We conclude that it is an additional transition to a σ* valence MO lying below those of C_3F_8 in the 293–300 eV region, with an enhanced term value due to molecular strain.

The C 1*s* → σ* transition is a prominent low-lying feature in the inner-shell spectrum of cyclopropane (8). According to X-α (8) and SCF-MO calculations (40), the lowest σ* MO in cyclopropane is a_2', an MO which is strictly C—C antibonding and has no C—H contribution whatsoever. Presumably, the additional band which is so low lying in C_3F_6 is a C 1*s* → a_2' σ*(C—C) transition. On the other hand, a virtual orbital calculation of C_3F_6 (sect. VII) shows that the a_2'(C—C) level is only second lowest, with a_2' σ*(C—F) being lower by *ca.* 1.2 eV.

The next band in the C 1*s* spectrum of C_3F_6 has a term value of 4.4 eV and so is assignable as C 1*s* → σ*(C—F), i.e., on the basis of its term value it corresponds to the *A* band for C 1*s* (CF_2) excitation. The *B*-band transition in C_3F_6 falls at 294.1 eV with a term value of 3.1 eV. This term value is unexpectedly high for a *B* band (Table 1), however, the upward shift of this spectral feature relative to its position in the perfluoro-*n*-alkanes may be a consequence of σ*(C—C) mixing with σ*(C—F).

The assignment of the lowest band of C_3F_6 to a transition to σ*(C—C) follows from the very high strain energy of 54 kcal/mol estimated for this molecule (9). In this regard, it is interesting then that Liebman *et al.* (9), have estimated the strain energy in perfluorocyclobutane, C_4F_8, as 14.5-18 kcal/mol, this being due in part to F—F repulsions. We argue that bond strain can be a significant factor in a four-membered ring such as C_4F_8, and as with C_3F_6, again may lead to a transition to a low-lying σ*(C—C) MO.

The *A* band in C_4F_8 at 293.1 eV (C 1*s* → σ*(C—F), 4.2 eV term value) is preceded by a prominent band which has a term value of 6.0 eV, Fig. 5. This term value is much larger than that expected for a transition to σ*(C—F) (Table 1), and thus the transition is assigned as terminating at a σ*(C—C) valence orbital which is shifted down due to molecular strain. The abnormal nature of the lowest excitation from C 1*s* in C_4F_8 (Table 4) is obvious when compared to the C 1*s* spectrum of C_4H_8 and the other cycloalkanes (8). Similarly, there is no complement of the low-lying σ* band of C_4F_8 to be found in C_4F_{10}. The narrow shape resonance at 302 eV in C_4F_8, Fig. 4, having a term value of −4.6 eV also is unique when compared with the spectra of the perfluoro-*n*-alkanes, and again suggests that there is something unusual going on in the σ* manifold of this compound.

Though the idea that molecular strain can lead to a low-lying transition to σ*(C—C) is an attractive one in view of the support

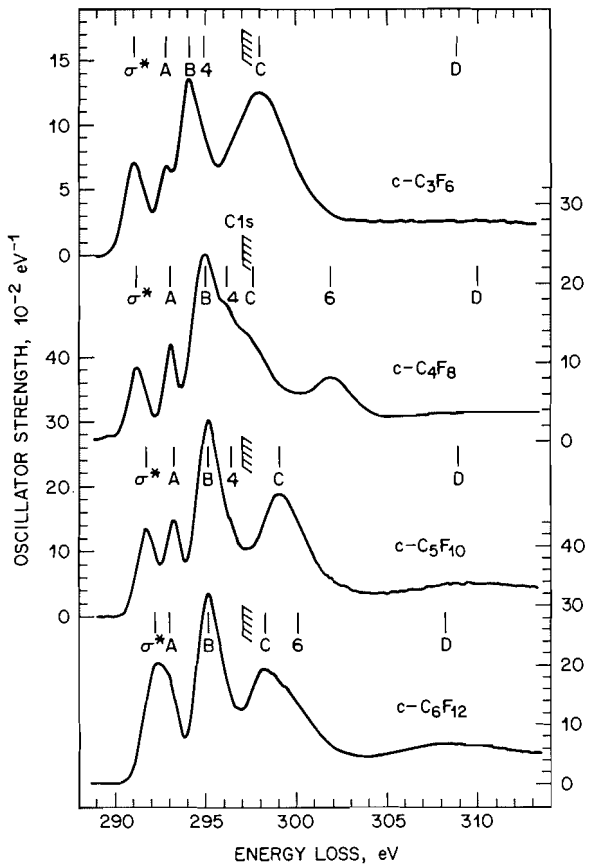

FIG. 4. Oscillator strength spectra of the perfluoro-*n*-alkanes in the C 1*s* region.

it receives from the C 1*s* spectra of C_3F_6, C_3H_6 (8) and C_4F_8, note too that the strain energy in C_4H_8 is 6 kcal/mol *higher* than in C_4F_8, yet there is no prominent, low-lying transition to σ*(C—C) in its inner-shell spectrum (8). Perhaps the low-lying position of the σ*(C—C) MO in C_4F_8 is due in part to its mixing with the low-lying σ*(C—F) levels. Note that an empirical analysis of the outer-shell spectrum of C_4H_8 (1) did lead to the suggestion of a valence excitation to σ* preceding the lowest R transition.

To this point, the role of strain in lowering σ* seems reasonable, with low-lying σ*(C—C) MO's appearing in the strained molecules C_3F_6 and C_4F_8, but not in the open chain relatives C_3F_8 and C_4F_{10}, nor apparently in C_6F_{12}. Though there is no data on molecular strain in C_5F_{10}, data on C_5H_{10} (41) shows it to be almost strain-free. Thus for C_5F_{10}, one might expect a C 1*s* spectrum much like that of C_6F_{12}. How surprising then to see, Fig. 6, that C_5F_{10} also shows a low-lying transition to σ*(C—C)!

The presence of an "extra" low-lying band in the spectra of the perfluorocycloalkanes is graphically illustrated in Figs. 5 and 6, where the C 1*s* spectra of the corresponding cyclic and linear perfluoroalkanes are compared on the basis of energy and intensity. One sees clearly from these comparisons that the lowest energy feature in the C_3, C_4, and C_5 linear compounds correspond to the second lowest in the cyclic compounds. The term values of the lowest bands in the cyclic systems, Table 4, are far too large for excitations to σ*(C—F) MO's, and so must terminate at σ*(C—C). A careful examination of the "C 1*s* → σ*(C—F)" transition of C_6F_{12} (Fig. 4) at 292.4 eV in fact shows that it too consists of two strongly overlapped transitions, the lower one of which is presumably a transition to σ*(C—C). With this feature in place, one sees a monotonic trend of the (C 1*s*, σ*(C—C)) term value from 6.1 to 4.8 eV as the ring strain decreases from C_3F_6 to C_6F_{12}.

It is at first sight anomalous that C_5F_{10} and C_6F_{12} would show low-lying excitations to σ*(C—C) due to strain (Fig. 6) when the C_5H_{10} and C_6H_{12} rings have strain energies of only 6.2 and 0.0 kcal/mol, respectively (41). However, it must be remembered that this argument neglects the F—F repulsions undoubtedly present in the perfluoro derivatives. The possibility that the σ*(C—C) level is low-lying in the perfluorocycloalkanes because the C 1*s* and σ* levels are delocalized around the rings leads to the expectation that, all other factors being equal, the (C 1*s*, σ*) term value will be largest in C_6F_{12} and smallest in C_2F_6, whereas the opposite is observed. The persistence of a low-lying σ*(C—C) level up to C_6F_{12} in the perfluorocycloalkanes may be due to mixing with low-lying σ*(C—F) levels (symmetry allowing) which amplifies the strain shift.

One can imagine that the $(CF_2)_x$ ring is formed by removing a CF_2 group from $(CF_2)_{x+1}$ and rejoining the terminal CF_2 groups. If this exercise is performed on perfluorocyclopropane, the result is tetrafluoroethylene, which we take for our purposes as a two-membered ring. In this two-membered ring, the MO conventionally taken as the "π" MO is the one that closes the ring; this MO is here relabelled σ′, while its antibonding counterpart (π*) is relabelled σ′*. Of course, the "two-membered ring" is extremely strained and so will have an unusually small σ′–σ′*

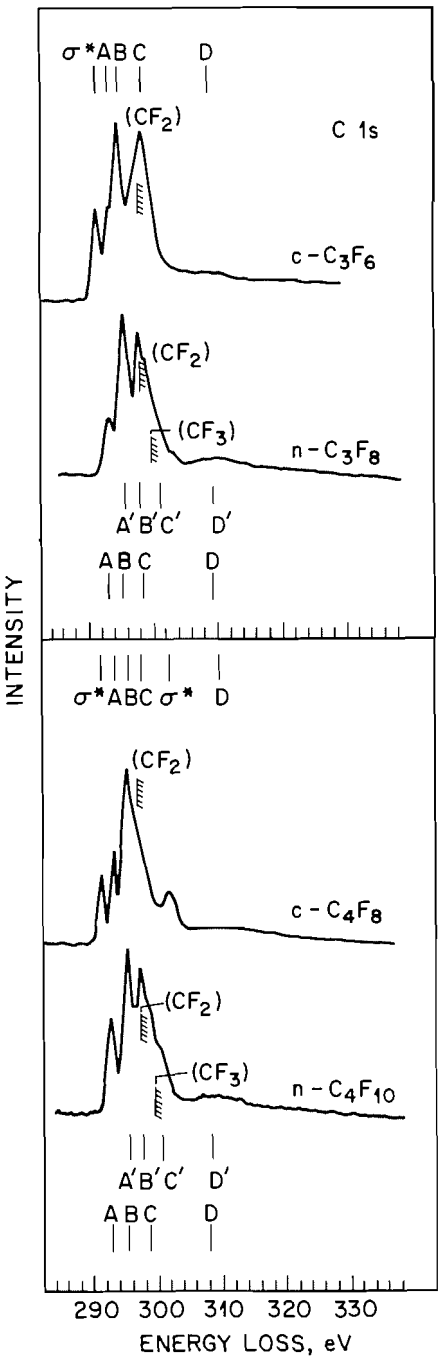

FIG. 5. Comparison of the C 1*s* spectra of the C_3 and C_4 perfluorocycloalkanes with those of corresponding perfluoro-*n*-alkanes.

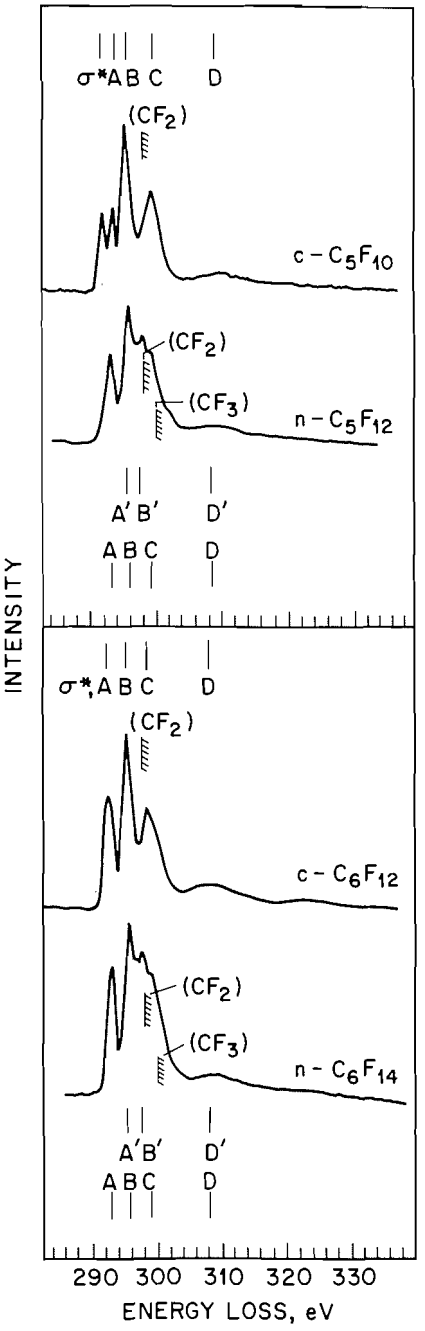

FIG. 6. Comparison of the C 1*s* spectra of the C_5 and C_6 perfluorocycloalkanes with those of the corresponding perfluoro-*n*-alkanes.

split. As anticipated from this, the C $1s \rightarrow \sigma'^*$ excitation of tetrafluoroethylene (conventionally written as C $1s \rightarrow \pi^*$) falls well below the lowest Rydberg excitation, having a term value of 6.47 eV (24). In this brief discussion, it is not our aim to propose a new nomenclature for olefins in which π/π^* and σ/σ^* are interchanged, but rather to show how the inner-shell spectra of unsaturates can be related to those of saturated compounds by virtue of the high strain in the former when considered as "cyclic" systems. If C_2F_4 is added to the list of strained perfluorocycloalkanes, then the term value trend for the C $1s \rightarrow \sigma^*$(C—C) transition stretches monotonically from 6.47 to 4.8 eV.

V. F 1*s* spectra of the perfluoroalkanes

Although not as well structured as those from C 1*s*, the F 1*s* spectra of the perfluoroalkanes also are of use when investigating low-lying transitions to σ^*. Note however, that ionization from F 1*s* in CF_4 is unusually broad (FWHM *ca.* 1.5 eV) due to dissociation of the F $1s^{-1}$ molecular ion (15). The strongly dissociative nature of F $1s^{-1}$ states is easily understood within the $Z + 1$ equivalent core model whereby the F 1*s* ionized atom is replaced by a Ne atom. This dissociation leads to very broad features in the F 1*s* inner-shell spectra of all of the perfluoroalkanes. In a previous study of the F 1*s* spectra of the

For personal use only.

fluoromethanes, the first broad bands below the F 1*s* ionization potentials were assigned as terminating at antibonding V levels (42).

*V.1. The perfluoro-*n*-alkanes*

Our experience from earlier work on perfluorinated systems (10, 22, 24, 43) is that many of the transitions appearing in the C 1*s* spectra also appear in the F 1*s* spectra, though with poorer resolution and often with somewhat smaller term values. This is the case as well in the perfluoroalkanes. The F 1*s* spectra of the perfluoro-*n*-alkanes are plotted in Fig. 7, in comparison with those of the perfluorocycloalkanes. The spectral energies, term values and assignments are tabulated in Tables 3, 5, and 6. The poorly resolved character of the F 1*s* spectra is due not only to the large linewidths of the transitions to dissociative excited states (15), but also to the fact that the F 1*s*(CF_3) and F 1*s*(CF_2) ionization potentials are separated by only 1.5 eV (assuming that the measured ionization potentials of C_3F_8 (31) apply as well to the higher members of the perfluoro-*n*-alkanes series). Nonetheless, certain aspects of the F 1*s* spectra are clear:

(*1*) In the case of C_2F_6 (see Fig. 3), the F 1*s*(CF_3) $\rightarrow$ σ^*(C—F) *A'* band is expected to have a term value of *ca.* 4.3–5.0 eV, which fits for the barely perceptible shoulder at 690 eV having a 5.3 eV term value. In C_3F_8 the *A'* shoulder is more easily seen (689.9 eV) and is probably at 690–691 eV in the F 1*s* spectra of the other compounds in this series. Note too, there is an F 1*s*(CF_2) ionization in the C_3F_8–C_6F_{14} series which is *ca.* 1.5 eV lower than that from F 1*s*(CF_3), yet there are no signs whatever of the F 1*s*(CF_2) $\rightarrow$ σ^*(C—F) transitions! Since we are confident where these missing transitions should appear, we are led to conclude that the F 1*s*(CF_2) $\rightarrow$ σ^*(C–F) *A* band transitions are unusually weak. The 689.9 eV band of C_3F_8 is predominantly F 1*s*(CF_3) $\rightarrow$ σ^*(C—F). As in the C 1*s* spectra, there is nothing in the F 1*s* spectra of the perfluoro-*n*-alkanes to suggest a distinct σ^* MO lying below the R levels.

(*2*) Although the F 1*s* $\rightarrow$ σ^* *A* and *A'* transitions appear to be strongly electric-dipole forbidden, the F 1*s* $\rightarrow$ σ^* transitions *B* and *B'* should be strongly dipole allowed and thus the spectra should show two intense bands separate by *ca.* 1.5 eV, the difference of F 1*s* (CF_2) and F 1*s*(CF_3) ionization potentials. Indeed, the first two intense peaks in the F 1*s* spectra of C_3F_8 to C_6F_{14} are separated by *ca.* 1.5 eV.

(*3*) What appear to be high-energy shape resonances in the F 1*s* spectra of the perfluoro-*n*-alkanes from CF_4 to C_6F_{14} (features *D* and *D'*) have term values of *ca.* −14 eV, and seem to parallel those observed in the C 1*s* spectra with nearly the same term values (−11 eV). However, EXAFS or delayed continuum onset assignments also are possibilities here. The minima between *C* and *D* in the F 1*s* spectra are much less pronounced than the corresponding minima in the C 1*s* spectra. This is consistent with a potential barrier, delayed continuum onset interpretation of band *D*, since the F atoms are on the periphery of the molecule and thus should experience a smaller barrier.

(*4*) There are peaks in the F 1*s* spectra at 694–695 eV (*C'*) which are just at the F 1*s*(CF_3) ionization potential. It seems likely that these are F 1*s*(CF_2) $\rightarrow$ σ^*(C—C) shape resonances corresponding to band *C*, *C'* in the C 1*s* spectra.

(*5*) A very broad feature (*E*, *E'*) has a term value of *ca.* −28 eV in CF_4 to C_6F_{14}, and does not appear in any of the C 1*s* spectra. This is likely to be an EXAFS oscillation associated with backscattering from an F atom bonded to the same C atom as that to which the core-excited F atom is attached.

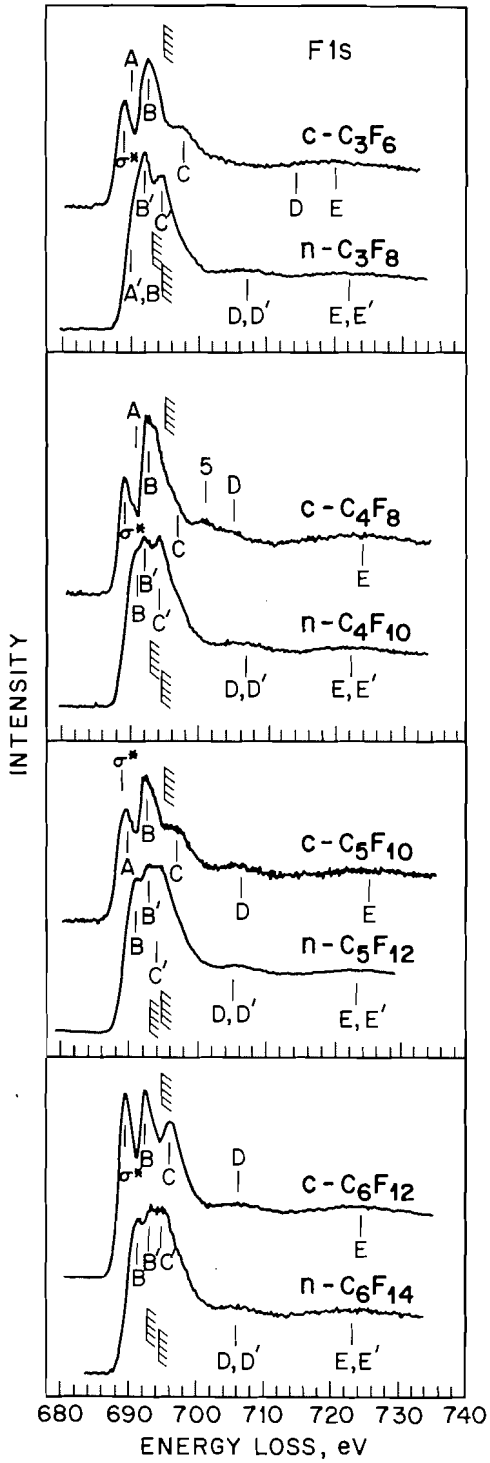

FIG. 7. Oscillator strength spectra of the perfluoro-*n*-alkanes and perfluorocycloalkanes in the F 1*s* region as derived from energy-loss spectra. Inner-shell ionization potentials are shown by hatched areas. The unprimed transitions originate at CF_2 groups whereas the primed transitions originate at CF_3 groups.

V.2. Branched perfluoroalkanes

Even more than with the C 1*s* spectra, the F 1*s* spectra of C_2F_6 and $C(CF_3)_4$ show a remarkable match, Fig. 3 and Tables 3 and 4. This close similarity arises not only because all of the F atoms in the two molecules are in CF_3 groups and thus are spectroscopically equivalent at our resolution, but also because of the apparent localization of the excitations to the CF_3 groups. This

[a]Taken as equal to that of C_4F_8 (31).

similarity includes not only spectral shape and peak positions but also intensities. The region below the F 1*s* ionization potential in $C(CF_3)_4$ has an integrated oscillator strength which is 1.7 times that of the corresponding region in C_2F_6, in reasonable agreement with the ratio of 2.0 between the number of F atoms in the two molecules. Indeed, on a per-F-atom basis, the oscillator strength in the discrete region of the F 1*s* spectra is remarkably constant, having a value of 0.53 (5) when averaged over all perfluoro species studied.

One dramatic difference between the F 1*s* spectra of C_2F_6 and $C(CF_3)_4$ is that band *D'* around 705 eV is not detected in $C(CF_3)_4$. This suggests that *D'*, a feature common to all of the perfluoroalkane F 1*s* spectra, may be a shape resonance or the first EXAFS oscillation associated with backscattering from an F atom on an adjacent C atom. These types of F—F distances do not exist in $C(CF_3)_4$. The presence of band *E'* with similar intensities in both C_2F_6 and $C(CF_3)_4$ is consistent with an EXAFS oscillation associated with backscattering from an F atom bonded to the same C atom as that to which the core-excited F atom is attached.

V.3. Perfluorocycloalkanes

The anomalous behavior of the C 1*s* spectra of the perfluorocycloalkanes (when compared with the linear species) persists in the F 1*s* spectra. Figure 7 compares the F 1*s* spectra of the cyclic and linear systems. One sees similar features in each case except for the addition of low-lying transitions to $\sigma^*(C—C)$ orbitals in the cyclic species. The (F 1*s*, σ^*) term values, Table 6, are esentially the same as those for the C $1s \rightarrow \sigma^*$ bands, Table 4. The observation of the low-lying excitations to $\sigma^*(C—C)$ in the F 1*s* spectra suggest that there is considerable interaction between the $\sigma^*(C—C)$ and $\sigma^*(C—F)$ orbitals on a single center. This implies that the MO induced to be so low-lying by strain and the inductive effect has both C—C and C—F antibonding character and is thus somewhat delocalized on its center.

VI. Negative-ion resonances

We now attempt to apply the lessons learned from the inner-shell excitation spectra of the alkanes and perfluoroalkanes in the 280–740 eV region to the interpretation of their negative-ion spectra in the 0–8 eV region. The thread connecting these two very different spectroscopies is a set of virtual orbitals assumed to be common to the transitions in each.

The electron affinities of selected perfluoroalkanes were determined by the electron transmission (ETS) technique (21), with results as shown in Fig. 8 for the linear species and in Table 7 for both linear and cyclic species. These data in some cases differ substantially from those of Christophorou *et al.* (44–46), who used the less direct technique of dissociative electron attachment (DEA) for determining the energetics of negative-ion formation. One major difference between ETS and DEA is that corresponding peaks generally appear at lower energy in

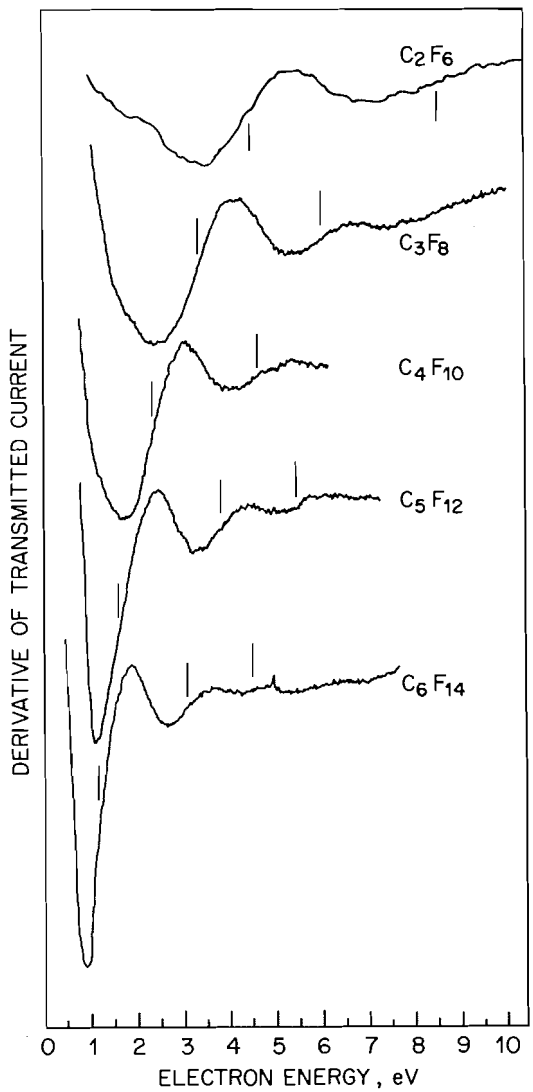

FIG. 8. Electron transmission spectra of the perfluorinated ethane, propane, *n*-butane, *n*-pentane, and *n*-hexane. Negative-ion resonance energies are indicated by the vertical bars.

DEA than in ETS because the attachment process is dissociative and so the survival probability of the anion decreases as the resonance energy increases from one end of the band to the other.

In each of the perfluoroalkanes investigated, two or more negative-ion resonances were observed. Since the target molecules are saturated, the negative ions must result either from electron capture into σ^* MO's or by formation of Feshbach resonances. In the latter, the incident electron excites a bound electron into an R orbital and is itself captured in an R orbital. Usually, but not always, the two electrons occupy the same R orbital. In the case where the R orbital in question is the $3s$ MO, it is known that the Feshbach resonance energy is very nearly 0.5 eV below the corresponding R excitation to $3s$ in the neutral molecule (1, 10, 22). That is to say, the $^1(\phi_i, 3s)$ R state has an electron affinity of +0.5 eV in forming the $^2(\phi_i, 3s^2)$ negative ion.

Referring to the uppermost valence ionization potentials in the perfluoro-*n*-alkanes as determined by photoelectron spectroscopy (1), one sees that the term values of the lowest transitions to $3s$ fall in the range 3.71–4.42 eV in the series CF_4 to C_6F_{14}. The corresponding transition energies to the $3s$ MO's are in the range 12.48–8.33 eV, thus placing the lowest possible Feshbach resonances for these compounds in the 12.0–7.8 eV range. For the *n*-alkanes CH_4 to C_6H_{14}, the corresponding limit below which negative-ion Feshbach resonances will not form is 9.2–7.2 eV. Any negative-ion states observed below these ranges necessarily must involve the occupation of σ^* MO's rather than R orbitals. If the qualitative conclusions of the inner-shell spectroscopic study carry over to the negative ions, then the σ^* resonances in the perfluoro-*n*-alkanes should lie considerably below those of the corresponding *n*-alkanes, and the σ^* negative ions should be particularly low lying in the highly strained perfluorocycloalkanes.

Negative-ion energies as determined by the electron transmission technique are summarized in Table 7. One sees that the negative-ion energies of the perfluoro-*n*-alkanes decrease as the size of the molecule increases. However, the incremental effect of each CF_2 group is diminished as the molecular chain is lengthened. All of the observed resonances are well below the region in which the lowest Feshbach resonances are expected, and so terminate at σ^*. Such behavior of the σ^* resonances is just that expected for delocalized σ^* valence MO's of large bandwidth, uncomplicated by the presence of R orbitals. Indeed, R MO's are irrelevant to the discussion of the binding of an electron to a neutral molecule because the electron does not experience a $-1/r$ potential. Unlike the electron transmission spectra of the perfluorinated alkanes, those of methane and *n*-hexane (47) provide no evidence of σ^* anion states below 6 eV. Thus the electron transmission spectra clearly show the strong stabilization of certain alkane σ^* MO's upon fluorination.

The lowest energy feature in the electron transmission spectrum of C_3F_6 occurs 1.27 eV above the ground state of the neutral molecule and is presumably due to the formation of the ground-state anion. Thus the lowest anion state of C_3F_6 is 2.17 eV more stable than that of acyclic C_3F_8. The electron transmission spectrum of C_3F_6 also shows structure due to anion states at 5.7 and 7.2 eV.

The electron transmission spectra of C_4F_8 and C_6F_{12} do not show structures due to anion formation below 3.7 eV. However, for each of these two compounds there is a feature just above the beam zero, the position of which varies with the retarding voltage. Experience shows that this often occurs when there is an anion state energetically slightly below the ground state of the neutral molecule. If the lowest anion states of these two molecules are indeed bound, this would imply that the ground-state anion of the cyclic C_4F_8 molecule is at least 2.37 eV more stable than that of the corresponding acyclic C_4F_{10}, and that the ground-state anion of the cyclic system C_6F_{12} is at least 1.20 eV more stable than that of acyclic C_6F_{14}. That the energy differences between the ground-state anions of the cyclic and acyclic compounds could be this large is clear from the above-mentioned results for the C_3 species. In light of the results discussed above for the inner-shell spectra, it is surprising that the drop in the electron affinity on going from C_4F_{10} to C_4F_8 is greater than that on going from C_3F_8 to C_3F_6. Perhaps this is due to the fact that the σ^* orbitals involved in the inner-shell spectra are localized while those in the electron transmission spectra are delocalized.

To aid in the assignments of the temporary-anion states, we have performed HF calculations on the ground states of the neutral molecules. In these calculations, the STO-3G basis set was employed and the geometries were fully optimized at the HF level. The virtual orbitals from these calculations are uniformly too high by about 9 eV as compared to the experimental electron

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 112.217.228.212 on 09/07/12

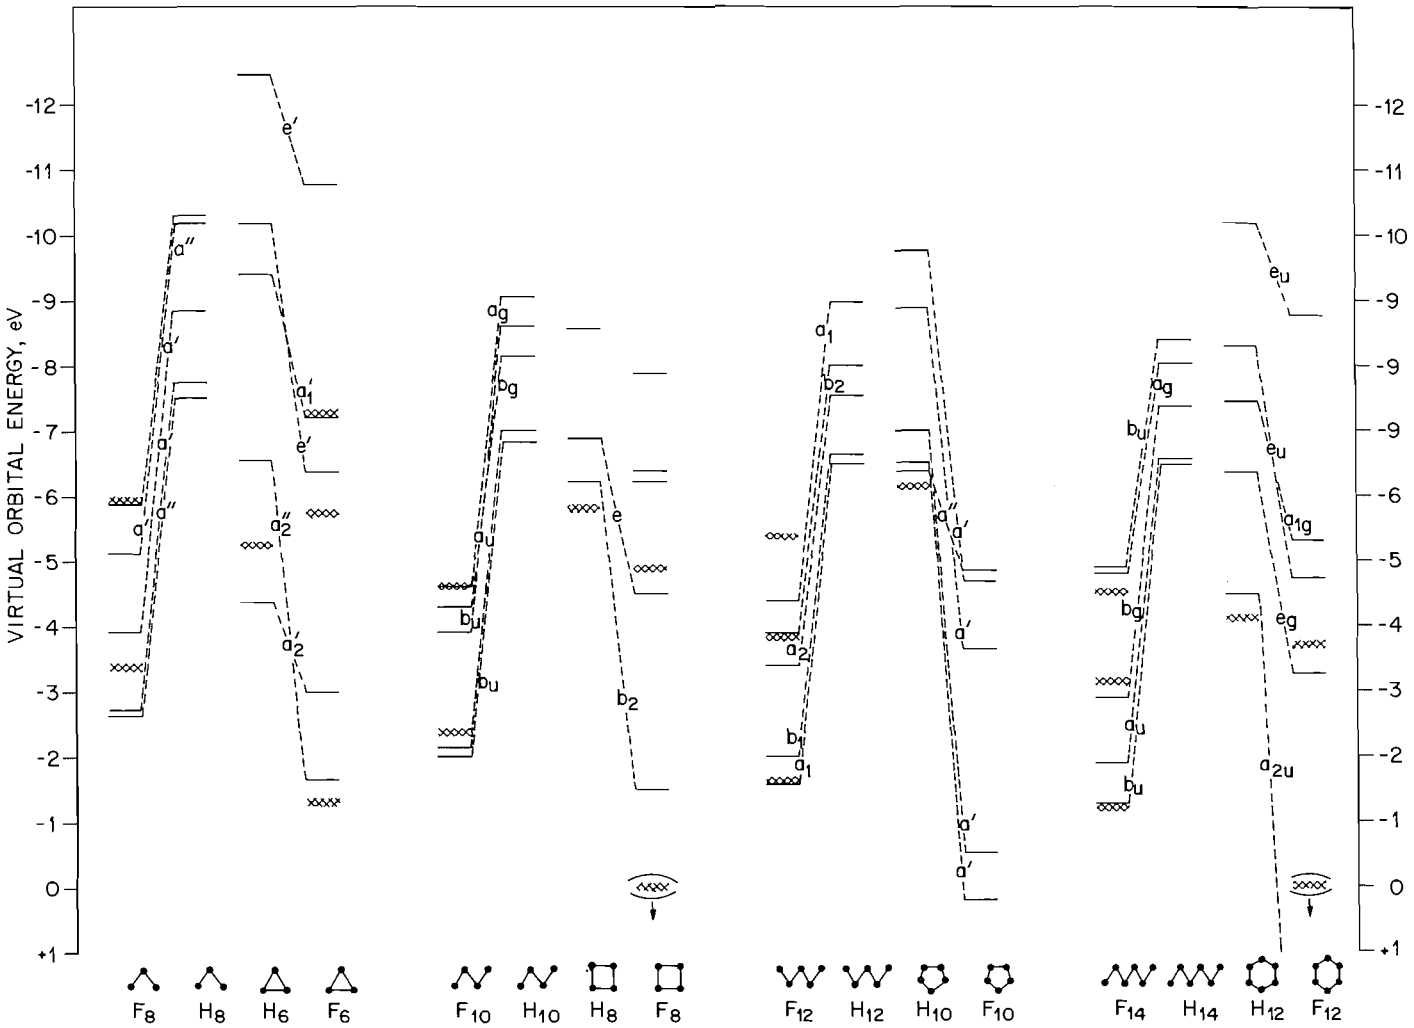

FIG. 9. Correlation of the computed virtual orbital energies of the linear and cyclic alkanes and perfluoroalkanes. All of the calculated energies have been shifted downward by 9 eV to improve agreement with experiment. The cross-hatched lines represent measured electron transmission resonance energies, with those in vertical parentheses being at energies greater than 0.0 eV, but otherwise of unknown magnitude.

affinities, and this quantity has been subtracted from the calculated eigenvalues. We note that this approach is quite crude, however more rigorous calculations would require introduction of continuum states for electron-molecule scattering, which is not yet practical for molecules of the complexity studied here.

One sees in Table 7 and Fig. 9 that the virtual MO approximation, naive though it is, does quite well in assigning the negative-ion features. In the perfluoro-*n*-alkanes series, the lowest resonance is observed to drop monotonically from 4.6 eV in C_2F_6 to 1.2 eV in C_6F_{14}, a trend which is semiquantitatively mirrored by the lowest predicted ngative-ion energies, which drop from 5.4 to 1.25 eV in the same series. The virtual MO calculations also predict that the lowest resonances in the perfluorocycloalkanes C_3F_6 and C_6F_{12} will be substantially below those of the corresponding perfluoro-*n*-alkanes, as observed. However, these calculations predict similar energies for the lowest anion states of C_4F_8 and C_4F_{10}, in contrast to the experimental evidence.

We also have performed calculations on selected hydrocarbons and the results are compared in Fig. 9 and Table 7 with the electron transmission results found in the literature (47, 48). In the *n*-alkane series C_2H_6 to C_6H_{14}, the lowest negative-ion resonance is predicted to drop by 2.39 eV, paralleling the drop of 2.49 eV observed for the corresponding perfluoro-*n*-alkanes. However, there is an almost uniform offset of 5 eV between the lowest anion energies in the two series of compounds, which would appear to be due to an inductive effect of the F atom.

As our electron transmission spectra of CH_4 and *n*-C_6H_{14} did not provide evidence for σ^* states below 6 eV, we presume that the transmission spectra of the intermediate *n*-alkanes also lack low-energy features due to anion formation. According to the calculations, Table 6, the lowest σ^* anion states in CH_4 through C_6H_{14} should fall between 6.5 and 7.0 eV above the neutral molecule ground states. Although this is indeed quite high in energy, it is interesting to observe that a peak due to anion formation shows clearly at 6.4 eV in the transmission spectrum of C_5H_{10} (this work). There are several factors which could cause the resonance in a cyclic system such as C_5H_{10} to be more visible than in the *n*-alkanes. First, the partial wave expansions of the lowest σ^* MO's of cyclic compounds are expected to contain greater contributions from high *l* values than are those of linear compounds. Second, at room temperature a significant

[c]Calculated in C_s geometry.
[d]Experimental values for *n*-pentane are not available, however, a resonance energy of -6.14 eV is reported for neopentane (48).
[e]Experimental values from Howard and Staley (47).

fraction of the molecules in the vapor phase of an *n*-alkane will have geometries considerably removed from that of the lowest energy conformation. This will tend to broaden the electron-transmission peaks of alkanes, both due to the thermal motion and due to the fact that the empty σ* MO will tend to have more *s* wave character in the higher energy conformer. In general, resonance lifetimes are expected to decrease with symmetry lowering and with the accompanying increase in importance of low-*l* partial waves. If the resonance lifetimes become too short, the resonances are difficult to detect in the total scattering cross sections. The observation by Giordan and Moore (48) of a relatively sharp resonance in neopentane is compatible with the rules stated above.

A far more substantial difference between hydrocarbon and perfluorocarbon is seen in the cyclic compounds, where the lowest negative-ion resonance energy in the $(CF_2)_x$ series decreases monotonically with increasing x, whereas for the $(CH_2)_x$ compounds the trend is strongly upward for $x = 3$ to $x = 5$ and then downward at $x = 6$, as calculated.

Though the virtual orbital calculations would seem to give a satisfactory simulation of the observed negative-ion resonance energies in the perfluoroalkanes, a look at the wavefunctions raises some questions. The delocalized virtual orbital wavefunctions are inappropriate to a discussion of the localized inner-shell excitations (sect. VII), but may be better suited to a discussion of negative-ion states. Note however, Fig. 9, that on cyclizing C_3F_8 to C_3F_6, the virtual orbital which is predicted to be stabilized is the LUMO a'_2. This orbital is $\sigma^*(C—F)_\pi$ rather than σ*(C—C) as deduced from the inner-shell spectra. More sophisticated calculations on inner-shell excitation and negative-ion formation are needed to clarify some of the band assignments.

VII. Core hole and optical σ* orbitals; localization versus band formation

The two electron impact techniques used in this paper (inelastic electron scattering and electron transmission) were chosen because each should yield a clear picture of the role of σ* MO's in the virtual orbital manifolds of the perfluoroalkanes. However, we find that in the inner-shell spectra of unstrained systems, the excitations to σ* MO's have very nearly constant energies irrespective of the molecular size (Tables 1 and 5), whereas when studied by electron transmission, the σ* MO's have energies which decrease substantially with increasing molecular size (Table 7). Only in the strained molecules C_4F_8 and C_6F_{12} do the two techniques agree in placing a σ* MO at anomalously low energy. Yet a third technique, that of VUV spectroscopy (1), suggests that the σ* MO's in the perfluoro-*n*-alkanes descend with increased molecular size, in support of the trend displayed by the electron transmission spectra.

In order to rationalize the apparent contradiction between the trends in the inelastic electron impact and electron transmission data in regard to the behavior of σ* MO's in the perfluoroalkanes, one must recognize that the σ* MO's in the excited states of the two spectroscopies are very different. In the case of the σ* negative ions, the σ* MO is a global one, spanning the length of the molecule and having an orbital energy which decreases particle-in-a-box-like with increasing molecule size. In contrast, the energies for inner-shell excitations to the same σ* MO are very weakly dependent upon molecular size, suggesting to us that the 1*s* hole in the inner-shell excited states is localized which in turn localize the σ* MO. There is at the same time evidence in the inner-shell spectra for mixing of the σ*(C—C) and σ*(C—F) bond orbitals; we suggest that this only occurs

For personal use only.

between such bond orbitals bonded to a common center, thus preserving the local character of the excitation.

It is relevant here to note the close similarity of the number of bands, their intensities and separations for the excitations to σ*(C—C) and σ*(C—F) in the perfluoroalkanes and in PTFE. The saturation of electronic band formation at relatively short chain lengths is consistent with the effective localization of the excitation during the lifetime of the core hole. Just such a conclusion was reached as well in regard the (1*s*, π*) localization in unsaturated hydrocarbons of increasing length (22). Paralleling the situation in the perfluoroalkanes, the spectra of the short-chain alkanes closely resemble those of PE, which again is understandable in terms of localized excitations to (1*s*, V) states (33). In addition, Hutson and Ramaker (49) conclude on the basis of comparisons of calculated and experimental Auger spectra that the (C 1*s*, σ*(C—C)) states in PE are appreciable localized. Although in these two cases we argue from saturation of band formation with chain length in favor of localized core hole excited states, it should be noted that the width of the occupied C 2*p* band of the alkanes is essentially constant above C_4H_{10} (50), yet the 2*p* orbitals are generally considered to be delocalized. Thus there are aspects to this problem yet to be understood.

VIII. Summary[3]

In summary, our interpretation of the inner-shell and negative-ion spectra of the perfluoroalkanes lead to the following qualitative picture of their σ* MO structures. In these species, the σ* levels are inherently lower and the inner-shell transitions to them more intense than in the corresponding alkanes; in the perfluoro-*n*-alkanes the lowest σ* MO has dominant (C—F) character. This valence character is confirmed by the lack of spectural perturbation observed on going into a condensed phase. On cyclizing the perfluoro-*n*-alkanes, a σ*(C—C) MO appears at yet lower energies. Its very large term value is related to molecular strain in the cyclic compounds. The uniquely low energy of the σ*(C—C) MO in the perfluorocycloalkanes is qualitatively confirmed by negative-ion spectroscopy and *ab initio* calculations, as is the relative stabilization of σ*(C—F) MO's in relation to σ*(C—H). However, the differences among inner-shell, negative-ion and VUV spectral shifts with chain length suggest that the core hole excited states are far more localized whereas the negative-ion states span the entire molecule.

IX. Acknowledgements

We are indebted to Professor J. L. Adcock for the generous gift of several perfluorinated hydrocarbons, to Professor J. Fink and to Professor T. Ohta and their students for access to their unpublished spectra of PTFE, and to K. Raghavachari for numerous discussions. Financial support in the form of research grants and a University Research Fellowship (APH) was provided by NSERC (Canada). A grant from the National Science Foundation to KDJ is gratefully acknowledged.

[3]NOTE ADDED IN PROOF: In this work and in earlier work as well (22), it was concluded on the basis of experiment that fluorination strongly increases the valence character of what are otherwise Rydberg upper levels. Just such an effect has recently been reported in theoretical calculations on the fluoroethylene series (51).

Received January 27, 1988

I. B'SHARY, C. GUIMON, M. GRIMAUD, G. PFISTER-GUILLOUZO, and D. LIOTARD. Can. J. Chem. **66**, 2123 (1988).

A dimer of HCN, *N*-cyanomethanimine **6**, was prepared by flash pyrolysis (gas phase, 10^{-2} mbar) from 3-azido-1,2,4-triazole **1***a* and detected by ultraviolet photoelectron spectroscopy (HeI). Its ionization potentials were measured and the ionic states sequence proposed, with the aid of *ab initio* – CI (configuration interaction) calculations. The study of the MNDO potential hypersurface enabled us to propose a mechanism of the thermal reorganization of the precursor **1***a*. It is shown that the reaction path passes through the formation of the protomer **1***b* before thermal decomposition and the generation of the nitrene **2***b*.

I. B'SHARY, C. GUIMON, M. GRIMAUD, G. PFISTER-GUILLOUZO et D. LIOTARD. Can. J. Chem. **66**, 2123 (1988).

Un dimère de HCN, la *N*-cyanomethanimine **6**, a été préparé par flash thermolyse en phase gazeuse (10^{-2} mbar) à partir de l'azido-3 triazole-1,2,4 **1***a* et détecté par spectroscopie photoélectronique ultraviolette (HeI). Nous avons mesuré ses premiers potentiels d'ionisation et déterminé l'ordre de ses premiers états ioniques à l'aide de calculs *ab initio* avec interaction de configuration. L'analyse de l'hypersurface de potentiel MNDO nous a permis de proposer un mécanisme de la décomposition thermique du précurseur **1***a*. Ainsi nous avons pu montrer que le chemin de réaction passe par la formation du protomère **1***b* avant toute decomposition et avant la génération du nitrène **2***b*.

Introduction

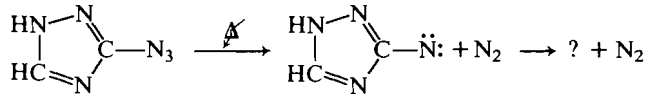
In the chemistry of transient or highly reactive molecules, hydrocyanic acid dimers have created considerable interest both because of their probable presence in interstellar space (1) and as precursors in the prebiotic synthesis of amino acids (2–4).

Theoretical studies (5–9) have shown that only three forms have a sufficient stability to be detected in the gas phase. They are, in order of decreasing stability, iminoacetonitrile (HN=CH—C≡N), the linear hydrogen bonded complex (HC≡N···HC≡N), and *N*-cyanomethanimine (H_2C=N—C≡N). The first and third have been generated from various precursors by photolysis or thermolysis. Iminoacetonitrile, whose *N*-butyl derivative was prepared as early as 1970 (10), could be characterized by its infrared spectrum, by photolysis of azidoacetonitrile N_3CH_2CN at 308 nm in argon matrix (9), and by thermal degradation (1300 K) in a saturated atmosphere (2 Torr; 1 Torr = 133.3 Pa) (11) of dimethylcyanamide. The existence of *N*-cyanomethanimine, deduced from the analysis of the mass spectrum of the decomposition products of trimethylenetetrazole (12), was also generated by pyrolysis of dimethylcyanamide (13). This compound and its deuterated derivative (14, 15) have been the object of several detailed microwave spectrometry studies. In addition, a very recent photoelectron study (16) showed that the decomposition of trimethylenetetrazole yields *N*-cyanomethanimine and ethylene.

In the context of our work on the analysis of the electronic structure of transient molecules, using the combined techniques of photoelectron spectroscopy and quantum mechanical calculations, we have investigated the thermal decomposition of different azides (17, 18). These molecules lose a nitrogen molecule relatively easily (17–19) and form an unstable nitrene, which can undergo various rearrangements. We report the results obtained with 3-azido-1,2,4-triazole. Flash thermolysis of this compound leads to *N*-cyanomethanimine, which we have characterized from observed ionization potentials and for which we propose a mechanism of formation.

1. Thermal rearrangements of triazolonitrene

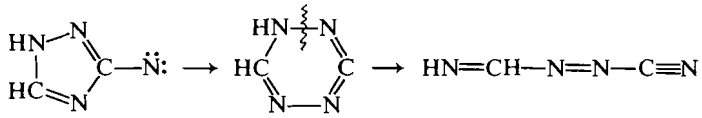
As we stated in the introduction, 3-azido-1,2,4-triazole loses a nitrogen molecule above a certain temperature and can undergo various rearrangements.



1*a* **2***a*

According to the results of Wentrup (20, 21) in the case of conjugated heterocyclic compounds and in addition to the nitrene rearrangement products in the triplet state leading to 3-amino-1,2,4-triazole, three main intramolecular mechanisms in the singlet state may occur (the hypothesis of spin conservation is generally admitted):

(a) Ring extension, already observed for 6-member rings (22, 23), would lead to a 6-member cyclic carbodiimide, which could open to yield linear compound **4**.



2*a* **3** **4**

In parallel, we determined the respective stability of the rearrangement products with MNDO calculations (Table 1).

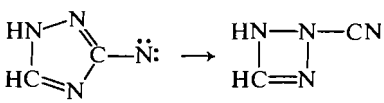
TABLE 1. MNDO relative energies after optimization of all structural parameters

	1*a*	**1***b*	**2***a* + N_2	**2***b* + N_2	**3** + N_2	**4** + N_2	**5** + N_2	**6** + 2 N_2
Relative energy kJ mol^{-1})	0	29.9	117.3	164.4	155.4	−34.1	64.1	−160.3

Considering the low stability of **3** (the corresponding 7-member ring for which the carbodiimide group is less bent can be observed only at low temperature in an argon matrix), this possibility can be rejected in our experimental conditions (gas phase and high temperature).

(b) Ring opening has been postulated or demonstrated for other heterocyclic compounds such as 5-azido-1,2,4-triazole (24) and azido pyrazole (25, 26). In our case, this reaction would require the 1–3 migration of a hydrogen atom to form also **4**, which renders it improbable in spite of the relative stability of **4** (Table 1).

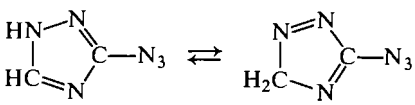
(c) Ring contraction occurs relatively easily in such 6-member heterocyclic compounds as the azido pyridines and azido pyrimidines (17, 20, 27–29). When the precursor heterocycle is a 5-member ring, this process generates a 4-member heterocycle (5) with an obviously reduced stability.



2*a* **5**

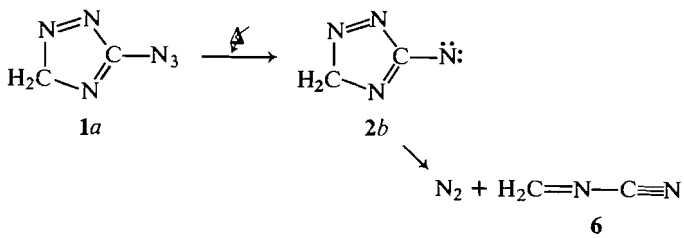
This instability, confirmed by MNDO calculations (30) (Table 1), thus renders this reaction highly improbable in our experimental conditions.

The last possibility, rarely suggested, is a sigmatropic rearrangement of the precursor by the 1–5 migration of a hydrogen even before the formation of the nitrene. This prototropic equilibrium **1***a* ⇄ **1***b* is possible if the associated activation barrier is of the same order as the energy required to form the nitrene **2***a*. In the opposite case, the 1–5 sigmatropic rearrangement of the nitrene is very improbable as a result of the thermodynamic instability of this species.



1*a* **1***b*

In addition to the decomposition of the azido group, the protomer **1***b* can lose the interacyclic N_2 fragment (12, 31) to yield *N*-cyanomethanimine **6**, a compound that is by far the most thermodynamically stable among the various possibilities proposed (Table 1).



1*a* **2***b* **6**

2. Experimental results: photoelectron spectrum and structure of H_2CNCN

Figures 1 and 2 are the photoelectron spectra (HeI) of 3-azido-1,2,4-triazole before (380 K) and after pyrolysis (800 K). At this temperature (Fig. 2), there is first a very weak band around 9.4 eV, corresponding to the initial compound (Fig. 1), as well as bands (hatched) characteristic of hydrocyanic acid HCN and nitrogen (32, 33). Beginning at 1200 K, the spectra contain only the bands of these two molecules (Fig. 3).

If we refer to the photoelectron spectra of methanimine (34, 35) and its alkyl (36–38) and phenyl derivatives (39, 40), as well as acrylonitrile (41, 42), the remaining bands correspond to the expected spectrum of *N*-cyanomethanimine (Table 2). As is the case for simple imines, the first band, associated principally with the nonbonding orbital with σ symmetry of imino nitrogen (n_N) interacting with the $\pi'_{C=N}$ (π orbital in the σ plane of imine), is relatively broad and poorly resolved. The shift of the corresponding ionization potential (1 P) (11.25 eV) compared to that of the simple imine (10.52 eV) is explained by the considerable inductive effect of the C≡N group, which is not compensated by the interaction of the localized n_N and $\pi'_{C\equiv N}$ orbitals.

The shape of the second band is characteristic of the π system of imines, where we encounter a very pronounced vibrational structure. The main vibrational frequency of the ion (2000 cm^{-1}) is very close to that of acrylonitrile (42) (2080 cm^{-1}). In spite of the inductive effect of the cyano group, this second ionization potential (11.75 eV) is lower than that of methanimine. This results from a pronounced conjugation due to the strong interaction of $\pi_{C=N}$ and $\pi_{C\equiv N}$ orbitals. As a result of the substantial localization of the $\pi_{C=N}$ orbital on the nitrogen atom, this interaction is stronger than in the case of acrylonitrile, where we observe a stabilization of the corresponding orbital (11.1 eV) in comparison to ethylene (10.50 eV) (43).

The third band, which in light of its intensity could cover two ionizations, and the fourth band are associated with two bonding combinations, $\pi'_{C\equiv N} + n_N$, $\pi_{C\equiv N} + \pi_{C=N}$, and a σ type orbital delocalized on the skeleton of the molecule.[2]

This spectrum is confirmed by that obtained by subtraction between the spectrum of trimethylene tetrazole pyrolysis products and that of ethylene (16) (published during this study).

We wished to confirm this qualitative attribution and define the sequence of ionic states by calculating ionization potentials. In addition to the semi-empirical MNDO method used subsequently to follow reaction paths, two types of *ab initio* "beyond Koopmans" calculations were performed. The first (PSHONDO) considers only a portion of the polarization and specific

[2]It is possible that the band of HCN at 13.6 eV hides a band of H_2CNCN about 13.9 eV as suggested by HAM/3 calculations (made by D. T. Chong of Vancouver). The IP's calculated by this method are indeed very close to experimental IP's: 11.19, 12.00, 13.20, 13.92, and 14.61 eV.

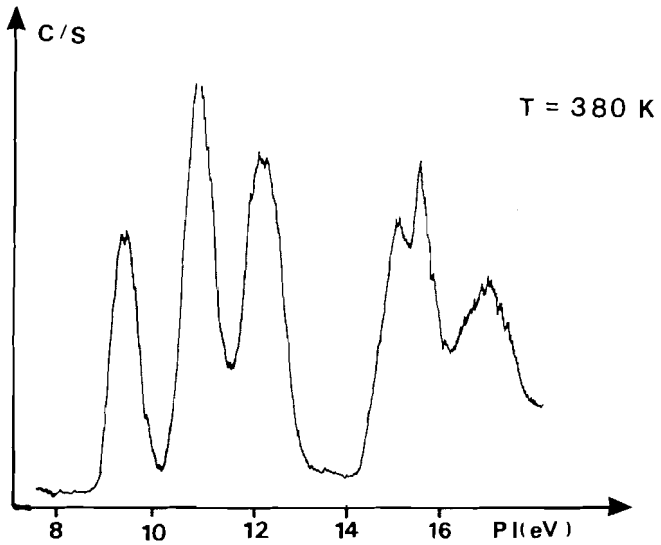

FIG. 1. Photoelectron spectrum (HeI) of 3-azido-1,2,4-triazole before pyrolysis.

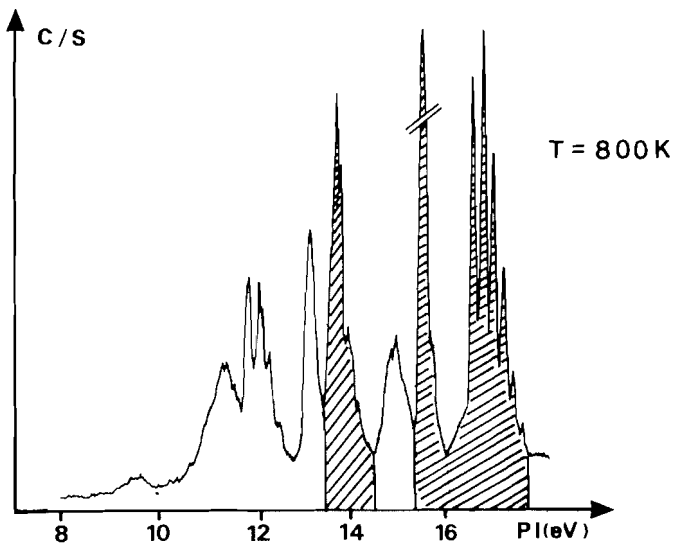

FIG. 2. Photoelectron spectrum (HeI) of 3-azido-1,2,4-triazole after pyrolysis (800 K).

correlation effects of the ions. The second (CIPSI) uses configuration interaction (CI) (see theoretical part). The results (Table 3) were obtained with optimized geometry (Fig. 4) using the MONSTERGAUSS program (see theoretical part).

It should first be noted that in contrast to the empirical MNDO method, the *ab initio* calculation furnishes an inversion of the first two ionization potentials at the level of the Koopmans approximation (IP $\sim -\epsilon_i$) (44). The sequence is reestablished by taking into account the specific correlation terms of the ions (reflected in the CI calculation by double excitations not invoking the ionic state considered) and above all the polarization terms (double excitations in which the determinant associated with this ionic state participates). The latter correction appears overestimated by the CI calculation at the level of the first ionization potential. This observation had already been mentioned in the theoretical study of other conjugated molecules (45). In contrast, the following four ionization potentials

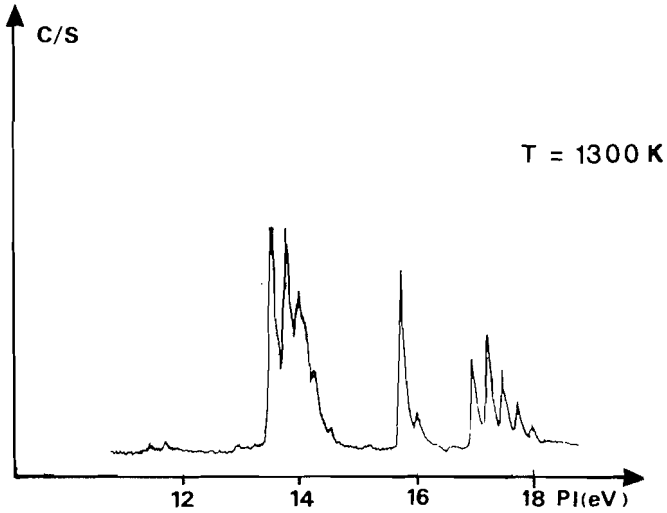

FIG. 3. Photoelectron spectrum (HeI) of 3-azido-1,2,4-triazole after pyrolysis (1300 K).

calculated with CIPSI are in good agreement with the experimental values, in contrast to the $-\epsilon_i$ values. In particular, the important polarization effect in the fourth ionic state should be noted, associated primarily with the σ orbitals of the skeleton, bringing the corresponding ionization potential to a value close to that associated with the third ionic state for which the main correction term is from specific correlation. Thus, in contrast to the proposal for acrylonitrile (42) (Table 2), the ionization potential characterizing the most stable π molecular orbital is much higher (1.8 eV) than that associated with the first bonding σ orbital, while the corresponding eigenvalues (ϵ_i) in the SCF calculations are of the same order (Table 3).

3. Reaction path

In parallel to these experimental data, we have carried out a theoretical analysis of the mechanism of *N*-cyanomethanimine formation from 3-azido-1,2,4-triazole. The reaction profile (MNDO) is shown in Fig. 5. We will analyze the different steps in this path, each corresponding to a saddle point, i.e., an activation energy barrier. We note that the first two steps (prototropic equilibrium and nitrene formation) require similar energies, supporting the hypothesis of a preliminary step involving a 1–5 prototropic migration.

3.1 1st step:3-azido-1,2,4-triazole(1H) 3-azido-1,2,4-triazole(5H) equilibrium

This step is a 1–5 migration of the hydrogen atom bound to a nitrogen. 1–5 Sigmatropic shifts are described in the literature in the cases of triazole (46, 47), pyrazole (48), and 1,2,4-diazaphosphole (49). They occur easily in solution, although we cannot speak of true unimolecular reactions. In the vapor phase and under low pressure the migration should be more difficult if we consider the barrier of 258 kJ mol^{-1} calculated in MNDO, a result confirmed by the temperature at which the change of 3-azido-1,2,4-triazole begins (700 K). The transition state TS_1 (Fig. 6) corresponds to what can be expected after applying Woodward–Hoffmann rules (50) for sigmatropic reactions (51, 52). The highest occupied orbitals of the ring and the corresponding radical are π type, and so in the transition state the migrating hydrogen atom is practically midway between the nitrogen and carbon atoms and above the plane (its ordinate with reference to the plane of the molecule is 1.08 Å).

3.2 2nd step: formation of 1,2,4-triazole(5H) nitrene

Whether the reaction by photolysis (53–55) or pyrolysis (56) of conjugated azides, the presence of an intermediate nitrene has often been proposed if not demonstrated. As a result of the energy proximity of the HOMO and LUMO frontier orbitals (degenerated in NH), the most stable state of these entities is a triplet (57, 58). Nevertheless, as we stated in the discussion of possible nitrene rearrangements, the thermal decomposition of azides preferentially yields a singlet nitrogen molecule (59) accompanied also by nitrene in the singlet state (20, 60). If we follow the changes in the frontier orbitals along the path **1***b* → **2***b* (Fig. 7), we observe a crossing between the HOMO and LUMO, leading to a relatively high activation barrier. In light of this crossing, it was necessary to search for the saddle point in the calculations by carrying out CI limited to the essential (frontier) orbitals.

Following this, it was found that the most stable singlet state of nitrene is not a closed shell state but rather open shell, i.e., presenting one electron on each orbital, schematically shown in Fig. 7. The same is true for the transition state TS_2, which is structurally close to nitrene (Fig. 6) according to the criterion of Hammond (61).

3.3. 3rd step:decomposition of 1,2,4-triazole(5H) nitrene

Nitrene **2***b* is metastable and easily loses nitrogen molecule to yield *N*-cyanomethanimine (Fig. 5). Contrary to the preceding step, there is no crossing between the occupied and virtual orbitals, explaining the low activation energy (57 kJ mol^{-1}). The corresponding transition state TS_3 is also close to the structure of nitrene, since it also presents a basic singlet state with two open shells. From its structure (Fig. 6) it appears that the departure of N_2 begins by a ring opening, which is consistent with general trends of cyclic nitrenes (see Sect. 1).

Passage of a singlet ground state with closed shells (more stable for the forms **1***a*, TS_1, **1***b*, and **6**) to a configuration with two open shells (more stable for TS_2, **2***b*, and TS_3) is shown in Fig. 8 by the dotted lines. In the crossing regions of the both S_0 and S_1 states, the slope of curve S_0 is much steeper than that of S_1, which shifts the maxima of the dotted curve (associated with TS_2 and TS_3) toward the intermediate minimum (**2***b*). This explains the structure of the two transition states TS_2 and TS_3, relatively close to that of nitrene **2***b*.

Conclusion

In this study, we have shown that the thermal decomposition (gas phase flash pyrolysis under low pressure) of 3-azido-1,2,4-triazole differs from the reaction paths usually proposed for this type of reaction of the heterocyclic series (extension, opening, or contraction of the ring). The formation of *N*-cyanomethanimine **6**, demonstrated by photoelectron spectroscopy, requires passage of the initial form via a tautomer (NH form → CH form). This tautomer then loses a nitrogen molecule to form a conjugated cyclic nitrene, which then splits into **6** + N_2. During this reaction, MNDO calculations have shown the

existence of crossing between the singlet states S_0 and S_1 due to the particular order of stability of nitrene (T_0, S_1, S_0).

The generation of *N*-cyanomethanimine in the ionization chamber of the photoelectron spectrometer also enabled us to determine the value of its first ionization potentials and to propose the sequence of the corresponding ionic states.

Experimental and computational details

As for most heterocyclic azides (62), 3-azido-1,2,4-triazole was obtained by the reaction of sodium azide with the diazonium chloride of 3-amino-1,2,4-triazole at 270 ± 2 K (mp 377 K, 80% yield).

The HeI photoelectron spectra were recorded on a PE spectrometer 0078 of Photoelectron Laboratories Ltd. with argon and xenon used as internal calibrants (12.126 and 13.443 eV for $^2P_{1/2}$ and $^2P_{3/2}$ of Xe; 15.755 and 15.93 eV for $^2P_{1/2}$ and $^2P_{3/2}$ of Ar). Flash pyrolysis was carried out with a variable-temperature probe (63) allowing us to heat the vapor above 1300 K in a ceramic tube during a few tenths of a second. The short pathway of about 5 cm between the end of the heating zone and the target chamber of the PE spectrometer allows recording of photoelectron spectra of transient compounds (ca. 0.1 s) or rearrangement derivatives.

The potential energy hypersurface of the $C_2N_6H_2$ system was calculated with the MNDO method (30), which gives for a reasonable price a quality of results close to *ab initio* double zeta results (64, 65). A saddle point search algorithm (66–68) was used in these calculations, enabling us to find the lowest saddle point on the pathway between two minima on the potential energy hypersurface.

The spectroscopic data were compared to the theoretical ionization potentials calculated with two different methods. We used the HONDO program (69) in which polarization and correlation effects are included after the SCF calculations by using a procedure based on a partial perturbative treatment (71, 72),[3] which calculates the energetic contributions of second-order corrective terms for the fundamental and ionic states. The basis set was of the 4-31 G type with *d* polarization orbitals on nitrogen. Several tests have shown the calculated IP were little influenced by polarization functions on carbon and hydrogen. We also performed a more rigorous calculation of the first ionization potentials by means of a program (73) using the CIPSI algorithm (74) (CI calculation on the ground states and the first ionic states).

A variational zeroth-order wave function was built in an iterative selection of the most important single and double excited determinants formed from the former reference subspace, the other ones being taken into account through a second-order Moller–Plesset perturbation. The configuration selection was based on the determinant coefficients in the correction of the zeroth-order function in the first order of the perturbation. In our case, the cutoff threshold was 0.02. So the reference subspace contained between 50 and 60 determinants. The number of determinants taken into account in the perturbative treatment was about 4×10^6.

The molecular geometries were fully optimized with respect to all structural parameters (bond lengths and angles) by the Broyden–Fletcher–Goldfard–Shanno gradient method (75) included in the MONSTERGAUSS program (70, 76) (same basis set as for HONDO calculations).

Tetracyclic triterpenes. X.[1] Solvent effect in reactions of tetrasubstituted triterpenoidal olefins with ozone. An allylic oxidation

ZDZISLAW PARYZEK[2] AND JACEK MARTYNOW
Faculty of Chemistry, A. Mickiewicz University, 60-780 Poznań, Poland

Received August 24, 1987[3]

ZDZISLAW PARYZEK and JACEK MARTYNOW. Can. J. Chem. **66**, 2130 (1988).

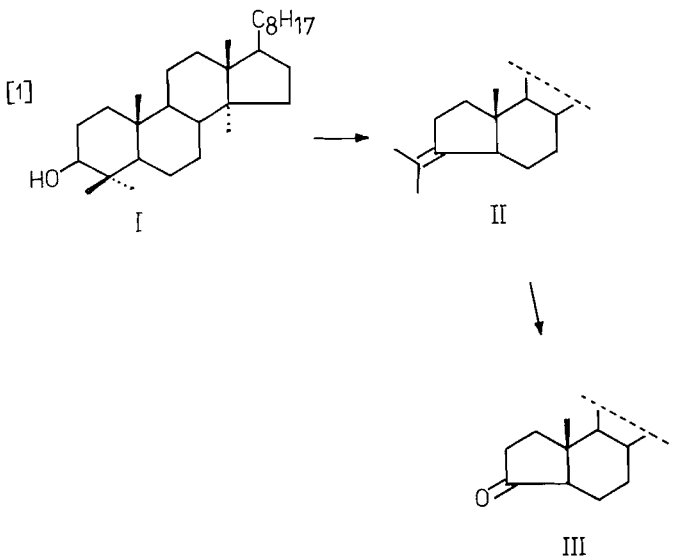
The highly hindered 8,9 double bond in lanostane derivatives was found susceptible to oxidation with ozone. The reaction depends on the polarity of the solvent. It is proposed that the structure of the initial complex formed between the olefin and ozone is influenced by the reaction medium. Reaction of 3β-acetoxy-5α-lanost-8-ene with ozone gives 8α,9α-epoxide in methylene chloride, while 3β-acetoxy-5α-lanost-8-en-7-one, an allylic oxidation product, is the main compound formed in ethyl acetate.

ZDZISLAW PARYZEK et JACEK MARTYNOW. Can. J. Chem. **66**, 2130 (1988).

On a trouvé que la double liaison très empêchée que l'on retrouve dans les positions 8,9 des dérivés du lanostane est très susceptible aux oxydations par l'ozone. La réaction est influencée par la polarité du solvant. On suggère que la structure du complexe qui se forme initialement entre l'oléfine et l'ozone est influencée par le milieu réactionnel. Dans le chlorure de méthylène, la réaction de l'acétoxy-3β 5α-lanostène-8 avec l'ozone conduit à l'époxyde 8α,9α; par ailleurs, dans l'acétate d'éthyle, le produit principal est l'acétoxy-3β 5α-lanostène-8 one-7, un produit provenant d'une oxydation allylique.

[Traduit par la revue]

Retropinacolic rearrangement of a triterpene 3-alcohol, for example 5α-lanostan-3β-ol (I), under the action of phosphorus pentachloride leads to the ring A contracted isopropylidene compound (II). Treatment of the olefin (II) with ozone provides a simple method of preparation of *A*-nor steroids (III). The sequence shown in eq. [1] has been described for pentacyclic (1)



and tetracyclic (2) triterpenes, their derivatives possessing a degraded side chain (3), and for 4,4-dimethyl steroids (4). In the lanostane series, 14α-methyl-*A*-nor-steroids were prepared by this simple degradation route (5).

The literature search revealed, however, that ozonolysis of 3-izopropylidene-*A*-nor-steroids was only rarely performed on substrates possessing an additional olefinic double bond in the molecule. In these cases the reported yields of the degraded compounds were low (15–45%) (1*a*, 6).

In our approach to 14α-methyl-*A*-nor-5α-cholest-8-en-3-one (**9**), the isopropylidene compound **4**, which was prepared from dihydrolanosterol (**1**), was subjected to oxidative degradation with ozone. The reaction carried out in methylene chloride at −78°C gave the keto-diene **5**, which isomerized during work-up to the 5β-isomer **6** (2*b*). Thin-layer chromatographic monitoring of the reaction showed that the epoxy-ketone **7** was the primary product of the reaction. Dehydration of **7** to the diene **5** was catalyzed by an acid[4] formed from the solvent under ozonolysis conditions (7). This was evidenced by the isolation of the epoxy-ketone **7** (51% yield) and the enone **9** (5%) from the reaction of **4** carried out in the same solvent containing a small amount of pyridine (8). In the course of the ozonolysis of **4** in CH_2Cl_2 the reaction sample was analyzed after approximately 0.1 molar equivalent of ozone had reacted. It contained, besides the substrate, 7% of the diene **5** (uv test). This indicates that the reactivity of both the double bonds in **4** toward ozone is similar and the formation of the epoxide **7** was not a result of over-ozonation. Interestingly, the reactivity of the trisubstituted 24,25 double bond in 3β-acetoxy-5α-lanosta-8,24-diene exceeds significantly that of the tetrasubstituted olefinic linkage, thus making it possible to stop the ozonolysis at the stage of 24,25-ozonide, leading to the acid **11**.[5] In the light of these results it seemed of interest to study the reaction of ozone with other 8,9-olefins, both in the *A*-nor and in the "normal" lanostane series.

In the *A*-nor series, keto-olefin **9** gave the dienone **6** (48%) under acidic[4] conditions, while in methylene chloride–pyridine solution it was epoxidized to give **7**(34%). Similar epoxidation occurred when the olefin **12** (as a mixture of 3α- and 3β-epimers) was ozonized. The same reaction of 3β-acetoxy-5α-lanost-8-ene (**2**) and of 5α-lanost-8-en-3-one (**3**) gave the respective epoxides **13** (47%) and **14** (56%). Compound **2** gave 3β-acetoxy-5α-lanosta-7,9(11)-diene (65%) under acidic[4] conditions. In the course of all ozonations carried out in methylene chloride a remarkable destruction of the substrate was observed. This was probably a result of the attack of ozone on unactivated C—H bonds being more pronounced in the strained *A*-nor compounds.

Diverse results were obtained when ozonations were carried out in nonpolar and unreactive solvent, *n*-hexane. The diene **4** was transformed to the enone **9** (78% yield) and only traces of the epoxide **7** could be detected in the reaction product. The two epimeric ozonides **15**, detected on tlc plates, were quite stable. One of them was isolated and characterized by its ^{1}H nmr and ir spectra. Ozonide **15** was stable toward reductive action of dimethyl sulfide and its decomposition was achieved by treatment with zinc in acetic acid or with potassium hydroxide in methanol–benzene solution. Olefin **2** was recovered unchanged after prolonged reaction with ozone in *n*-hexane.

The *trans* hydrindane-type ketone **9** isomerized easily in basic solution to the thermodynamically more stable 5β-ketone **10** (1*b*, 10). We found that epimerization at C(5) in *A*-nor-3-ketones was distinctly slower in the case of 8,9-olefins if compared with the 7,9(11)-dienes, which isomerized during the work-up and chromatography on silica gel. The characteristic spectral differences between 5α- and 5β-*A*-nor-3-ketones are summarized in Table 1. The 5β-configuration in **4** and **6** was confirmed by the positive Cotton effect associated with the $n \rightarrow \pi^*$ transition of the carbonyl group. High optical activity of the ketone **6** is determined by the asymmetry of the overlap between the 7,8 double bond and the carbonyl orbitals, which are in close proximity to each other in this γ,δ-unsaturated ketone.

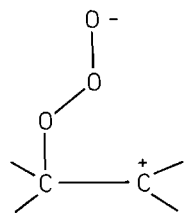
*For the discussion of C-19 carbon shielding differences between 5α and 5β steroids see ref. 11.

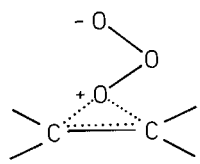
studied here prompted the investigation of the reaction in more polar solvent. When olefin **2** dissolved in ethyl acetate reacted with ozone a mixture of two compounds formed. These were identified as the epoxide **13** (40%) and the enone **16** (46%). In similar conditions, compound **3** gave a mixture of the epoxide **14** (22%) and the enone **17** (57%). In another experiment epoxide **13** was excluded as a precursor of the enone **16**.

In spite of the large amount of work devoted to the elucidation of ozone reaction with alkenes and with olefins containing other functional groups, many aspects of the mechanism of ozonolysis (12) are still unclear. There are many reported cases where ozone is likely to be the epoxidation agent (12*b*). Formation of epoxides was observed in reactions of ozone with hindered triterpenoidal (13) and steroidal (14) olefins. These reactions do not conform with the concerted Criegee mechanism of ozonolysis (12*a*,*c*), which proceeds with the formation of 1,2,4-trioxolane as a final ozonide. In the case of crowded olefins, 1,2,3-trioxolanes as primary ozonides seem also to be excluded. Instead, open σ-complex, π-complex, and peroxy-epoxide are proposed as precursors from which epoxides may be formed (12*a*, 15).

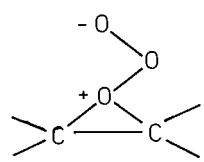
[2]



σ-complex



π-complex



peroxy epoxide

Recently an intermediate primary ozonide, a diradical or zwitterion derived from the primary ozonide, and carbonyl oxide, which is the primary ozonide cleavage product, were evaluated as potential epoxidizing agents for the unreacted olefin (16). Experimental evidence was presented that epoxidation of olefins can be caused by carbonyl oxide (16*c*). However, considering activation energies (16*a*,*b*) and steric requirements for oxygen transfer, these intermediates have to be excluded as an effective source of oxygen in the epoxidation of crowded, triterpenoidal olefins.

Solvent effects in ozonolysis of alkenes were discussed in terms of the *cis–trans* ozonide ratio (12*c*, 15, 17) rather than the structure of the complex formed initially between ozone and an alkene. The effect of solvent on decomposition of the initial ozonide has also been reported (18). The observed influence of the solvent on reactions examined in this study suggests that the initial complex formed between ozone and the crowded triterpenoidal olefin may be stabilized by dipole–dipole interactions. On the basis of this assumption it is proposed that in methylene chloride (ε 8.93, μ5.17 × 10^{-30} $C \times m$) the structure of the ozone–olefin complex is of the π-complex type or rather the peroxy-epoxide **18**, stabilization of which is achieved by the elimination of oxygen molecule with formation of the α-epoxide **13**. In hexane (ε 1.88, μ 0.0), a complex of type **18** is not formed due to the lack of solvent stabilization. Thus no epoxide was isolated in reactions of **2** or **4** in *n*-hexane. In ethyl acetate (ε 6.02, μ 6.27 × 10^{-30} C·m), more effective solvent stabilization may result in formation of a complex with more pronounced charge separation, with structure similar to σ-complex **19**. Polar solvent stabilization would enhance the stability and increase the lifetime of **19**, thus increasing the opportunity for intramolecular oxygen transfer. This complex might rearrange to trioxolane **20**, which, due to steric congestion, eliminates an oxygen molecule with formation of the allylic alcohol, subsequently oxidized with excessive ozone to the enone **16** (Scheme 1).

Formation of the enone **16** might be explained assuming direct allylic oxidation and the intermediacy of hydrotrioxides. These have been postulated (19) in reactions proceeding with the 1,3-dipolar insertion of ozone into activated C—H bonds in ethers (20). However, these processes are of low regioselectivity.

The epoxide **13** was found stable toward ozone in ethyl acetate; therefore its isomerization to allylic alcohol as a possible pathway leading to the enone **16** could also be excluded.

Another possibility that might be considered is the oxidation of the olefin with the participation of singlet oxygen. In oxidations of olefins with ozone leading to epoxides, singlet oxygen is a by-product (21). Although $^1O_2$ is known to attack the unsaturated systems (22), this process may not be regarded as operating here for two reasons. First, singlet oxygen reactions are rather low yield processes, while the first oxidation step would require the effective transfer of $^1O_2$ to the unreacted olefin. Second, in the reaction of **3** with ozone the epoxide-to-enone ratio was approximately 1:2.5, thus excluding the epoxide as a source of singlet oxygen. Photooxygenation of 3β-acetoxy-5α-lanost-8-ene gave a low yield of several products among which 8-en-7-one and 7-hydroperoxy-8-ene were isolated in 16 and 6% yield (23).

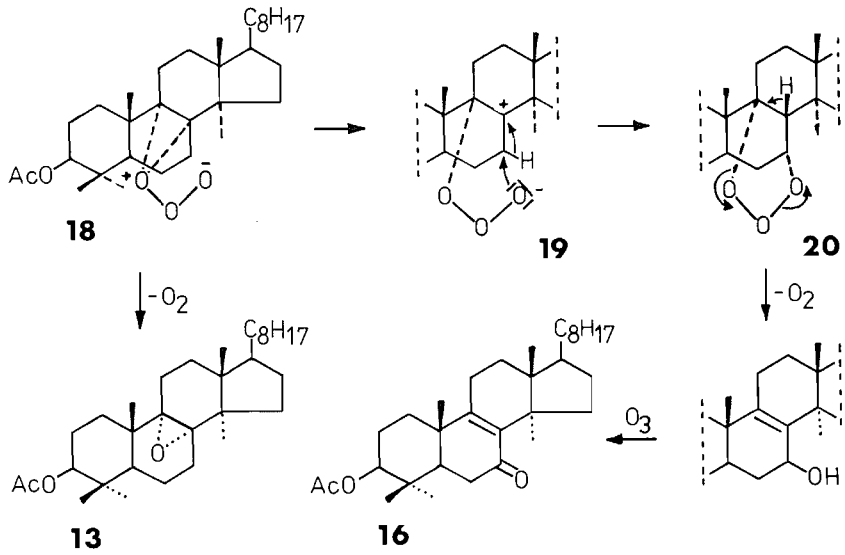
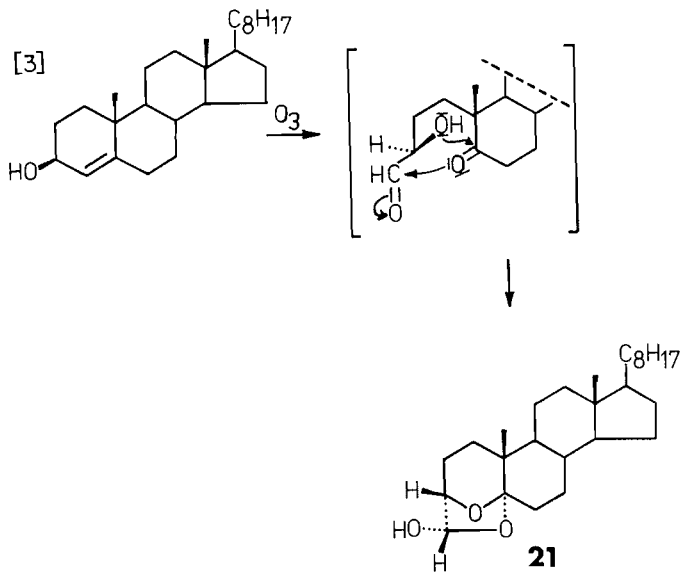


SCHEME 1

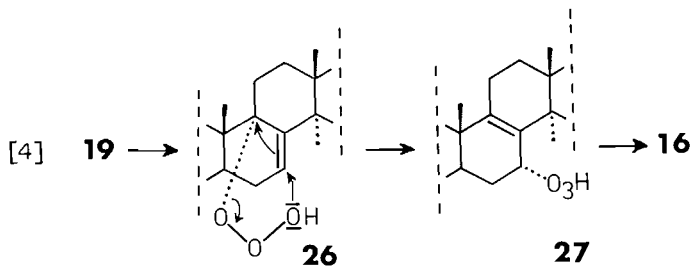
The oxidation of secondary alicyclic alcohols with ozone is known (24). Therefore, in view of the proposed intermediacy of allylic alcohol in ozonations under study, it was of interest to investigate the reaction of a model steroidal allylic alcohol with ozone in ethyl acetate at −78°C. Cholest-4-en-3β-ol was chosen as the model compound. However, the only product of this reaction (eq. [3]) had the structure **21**, which is in agreement with the Criegee mechanism of ozonolysis and is inconsistent with the abnormal ozonolysis pathway reported for allylic derivatives (25).



Identity of **21** obtained as a crystalline compound, was established by spectral data (Experimental) and by oxidation to the lactone **22**. Configuration *S* of C(4) in **21** was assigned on the basis of vicinal coupling (J = 8.8 Hz) between protons at C(4) and C(3) observed in the ^{1}H nmr spectrum. The structure of **21** was further supported by a ^{13}C nmr spectrum that revealed three deshielded signals recognized as arising from carbon atoms adjacent to one or two oxygen atoms. A singlet signal at 112.9 ppm and doublet signals at 81.4 and 96.4 ppm ascribed to C-5, C-3, and C-4, respectively, established the assigned structure definitively. Similar spontaneous (26) or acid catalyzed (27) intramolecular double acetalization has been reported.

The result of ozonolysis of cholest-4-en-3β-ol indicates that the allylic hydroxy group is not susceptible to oxidation with ozone, which preferably attacks the double bond. This evidence suggests that the most probable transformation of the postulated transient allylic alcohol (Scheme 1) is via the second oxidation step with formation of a complex similar to **19**, not necessarily involving formation of the 8,9-epoxy-7α-alcohol as an intermediate product.

The mechanistic proposal shown in Scheme 1 was supported by the following experiment. 3β-Acetoxy-5α-lanost-8-en-7-one was quantitatively reduced with lithium aluminum hydride to the mixture of 3β,7β- and 3β, 7α-diols **23** and **24** in the ratio 1.1:1. The assignment of the configuration of carbon 7 in **23** and **24** was based on the coupling pattern of the 7-H signal in the ^{1}H nmr spectra and on the characteristic up-field shift (4.5 ppm) of C-5 (28) in the ^{13}C nmr spectrum[6] of the pseudoaxial 7α alcohol **24**. The diol **24** was entirely transformed to the enone **25** upon treatment with ozone in ethyl acetate at −78°C.



However, on the basis of the evidence presented, a reaction pathway involving the rearrangement of **19** (via the trioxide **20**, or alternatively via **26**) to the transient hydrotrioxide **27**, from which 8-en-7-one **16** may be formed directly (eq. [4]), cannot be excluded.

The reactions reported in this paper appear to be the first examples of solvent-dependent ozone oxidation of crowded olefins to the α-,β-unsaturated ketones.

[6]The full details of the ^{13}C nmr spectra of compounds described in this work will be discussed elsewhere.

Experimental

Melting points were determined on a Kofler hot-stage apparatus and are uncorrected. The ir spectra were determined with a Perkin Elmer 580 spectrophotometer for solutions in chloroform. The uv spectra were recorded with a Shimadzu 160 spectrophotometer for solutions in ethanol. The ^1H and ^{13}C nmr spectra were recorded with a JEOL FX 90Q spectrometer operating in the Fourier transform mode using solutions in deuteriochloroform. Mass spectra were recorded with a JEOL JMS-D 100 spectrometer using electron impact. The cd spectra were recorded with a Jobin–Yvon Dichrograph Mark III for solutions in dioxane.

Reactions of olefins with ozone. General procedure

The following solvents were used in ozonation reactions: procedure A: methylene chloride; procedure B: methylene chloride containing 1.5–3 molar equiv. of pyridine; procedure C: *n*-hexane; procedure D: ethyl acetate containing 1.5–3 molar equiv. of pyridine.

The olefin was dissolved in the solvent to get a 5–10% solution. Oxygen–ozone mixture was passed through this solution, cooled to −78°C and kept in the dark, until all the substrate disappeared (30–180 min, tlc test). Excessive ozone was removed with the stream of oxygen. An excess of dimethyl sulfide was added to the reaction mixture and it was left for 2 h at room temperature. Evaporation of the solvent under reduced pressure gave the crude product, which was purified by chromatography and crystallization.

Ozonation of ***4*** (procedure A)

The diene **4** (350 mg) gave an oily crude product (356 mg), which was chromatographed on silica gel to give pure 14α-methyl-*A*-nor-5β-cholesta-7,9(11)-dien-3-one (**6**) (170 mg, 52%), mp 85.5–86.5°C (methanol–water – diethyl ether) (lit. (*2b*) mp 85–87°C); ir ν_{max}: 1733 cm^{-1}; uv λ_{max} (ε): 237 nm (10 400) and 251 nm (h,7 700); cd Δε(λ): +4.11 (265), +5.22 (286), +6.41 (296), +5.96 (305), and +3.02 (316); ^1H nmr δ: 5.66 (1H, m), 5.39 (1H, m), 1.33, 0.90, 0.83, 0.79, and 0.56 (methyl signals); mass spectrum *m/z*: 382(M+,100%), 367, 349, 227, 157, and 43. *Anal.* calcd. for $C_{27}H_{42}O$: C 84.75, H 11.06; found: C 84.58, H 11.21.

Ozonation of ***9*** (procedure A)

The enone **9** (410 mg) gave a crude product, which was chromatographed on silica gel to give **6** (196 mg, 48%) identical in all respects with the compound described above.

Ozonation of ***2*** (procedure A)

Dihydrolanosteryl acetate **2** (400 mg) gave a crude product, which was chromatographed on alumina to give 3β-acetoxy-5α-lanosta-7,9(11)-diene, mp 167–168°C (methanol – methylene chloride) (lit. (*29a*) mp 164–166°C) and gave spectra in agreement with those of an authentic sample (*29b*).

Ozonation of ***4*** (procedure B)

Zinc (0.8 g) was added to the crude product obtained from the diene **4** (300 mg) and dissolved in a mixture of *n*-hexane (10 mL) and acetic acid (10 mL), and the mixture was stirred at room temperature for 1 h. After work-up the oily residue (305 mg) was chromatographed on silica gel. First compound **9** (15 mg, 5%) was eluted. This was an oil, which gave ir and ^1H nmr spectra identical with those obtained for the product of ozonation of **4** in hexane (*vide infra*). The further fractions contained epoxide **7**, as an oil (149 mg, 51%); ir ν_{max}: 1731, 1280, 1242, 1145, and 975 cm^{-1}; cd Δε(λ): −2.77(297), −2.71(290); ^1H nmr δ: 2.68 (1H, m, 5α-H), 2.21 (2H, m, 2α- and 2β-H), 1.02, 0.92, 0.90, 0.83, and 0.80 (methyl signals); mass spectrum *m/z*: 400 (M^+), 385, 382, 367 (100%), 259, 95, and 43. *Anal.* calcd. for $C_{27}H_{44}O_2$: C 80.94, H 11.07; found: C 80.62, H 10.94.

Ozonation of ***9***(procedure B)

The enone **9** (300 mg) gave a crude product (yellow oil), which after chromatography on silica gel afforded epoxy-ketone **7** (oil, 106 mg, 34%), identical (^1H nmr, ir) with **7** obtained in the previous experiment.

Ozonation of 3β-acetoxy-5α-lanost-8-ene (2) (procedure B)

The crude product obtained from **2** (400 mg) was purified on a short column of alumina and crystallized twice from methanol – diethyl ether mixture to give 3β-acetoxy-8α,9α-epoxy-5α-lanostane (**13**) (197 mg, 48%), which had mp 135–138°C (diethyl ether – methanol) (lit. (30) mp 140–142°C); this compound was identical in all respects with the original sample obtained from **2** upon epoxidation with *m*-chloroperbenzoic acid.

Ozonation of 5α-lanost-8-en-3-one (3) (procedure B)

The crude reaction product obtained from **3** (400 mg) was chromatographed on a column of silica gel to give 8α,9α-epoxy-5α-lanostan-3-one (**14**) (231 mg, 56%), which had mp 102–104°C (methanol); ir ν_{max}: 1702, 1235, 1119, and 970 cm^{-1}; ^1H nmr δ: 2.49 (2H,m), 1.25, 1.03, 1.01, 0.90, 0.82, and 0.79 (methyl signals); mass spectrum *m/z*: 442 (M^+), 427, 424, 409, 291 (100%), 152, and 43. *Exact Mass* calcd. for $C_{30}H_{50}O_2$: 442.3810; found: 442.3811.

Ozonation of ***4*** (procedure B)

The crude product obtained from **4** (400 mg) was dissolved in a solution of potassium hydroxide in methanol (5%) and left at room temperature for 18 h. The usual work-up and chromatography on a silica gel column gave **10** (30 mg, 8%), and 14α-methyl-8α,9α-epoxy-*A*-nor-5β-cholestan-3-one (**8**) (180 mg, 46%), which had mp 72–74°C (heptane); ir ν_{max}: 1728, 1155, 1118, and 970 cm^{-1}; cd Δε (λ): +2.60 (286 nm), +2.56 (292), and −0.08 (323); ^1H nmr δ: 2.33 (3H, m), 1.30, 0.90, 0.86, 0.83, and 0.79 (methyl signals); mass spectrum *m/z*: 400 (M^+), 385 (100%), 287, 180, and 44. *Anal.* calcd. for $C_{27}H_{44}O_2$: C 80.94, H 11.07; found: C 80.69, H 11.22.

Ozonation of ***12*** (procedure B)

Lithium aluminum hydride (100 mg) was added to the ketone **9** (100 mg) dissolved in tetrahydrofuran (5 mL) and the mixture was stirred under argon at room temperature for 25 min. The usual work-up gave an oil (78 mg), which was a mixture of epimeric alcohols **12** as evidenced by ^1H nmr signals at δ: 4.26 (1H, m, OH), 3.85, (0.2H, m), 3.72 (0.6H, m) and 3.60 (0.2H, m). This mixture was ozonized (procedure B) and the crude product was chromatographed on a silica gel column to give the oil (34 mg, 41%). This had ν_{max} 3360 cm, *m/z* 402 (M^+), and gave ^1H nmr signals at δ: 4.16 (1H, m, OH) and 3.90 (1H, bm, 3α- and 3β-H). Brief treatment of this material (18 mg) dissolved in chloroform with hydrogen bromide (0.2 mL, 40%) gave the product (an oil, 16 mg), which had spectral characteristics in accordance with the 7,9(11)-dien-3-ol structure: uv λ_{max} (ε): 243 (8 600); ^1H nmr δ: 5.45 (2H, m), 4.23 (1H, m, OH), 3.75 (1H, bm, 3α- and 3β-H); mass spectrum *m/z*: 384 (M^+), 366, 351, 197, 83 (100%), and 43.

Ozonation of ***4*** (procedure C)

Acetic acid (10 mL) and zinc (0.4 g) were added to the crude product obtained from the diene **4** (600 mg) and the mixture was stirred at room temperature for 1 h. The usual work-up gave an oily residue (596 mg), which was chromatographed on a silica gel column. First, starting material (51 mg) was eluted. The main fractions contained 14α-methyl-*A*-nor-5α-cholestan-3-one (**9**) as an oil (441 mg, 78%), which crystallized at −20°C as needles, mp 36–37°C (watered methanol); ir ν_{max}: 1732 cm^{-1}; cd Δε (λ): −2.51 (294) and −2.63 (302); ^1H nmr δ: 2.30–2.07 (7H, m), 0.90, 0.83, and 0.73 (methyl signals); mass spectrum *m/z*: 384 (M^+), 369 (100%), 215, 203, and 44. *Anal.* calcd. for $C_{27}H_{44}O_2$: C 84.31, H 11.53; found: C 84.21, H 11.63.

Isolation of the ozonide ***15*** (procedure C)

The crude product obtained from the diene **4** (1.0 g) was treated with dimethyl sulfide (2 mL) at room temperature for 16 h. The solvent was evaporated and the residue dissolved in *n*-hexane. After addition of methanol (5 mL) a white precipitate formed. This was filtered (347 mg) and the filtrate was evaporated to give an oily residue (600 mg), which was chromatographed on a silica gel column. The two compounds obtained, in order of their elution, were (1) ozonide **15** (oil, 101 mg), ir ν_{max}: 1250, 1220, 1180, 1115, and 980 cm^{-1}; ^1H nmr δ: 2.23–2.05 (5H, m), 1.49 (6H, s, 2 × CH_3), 0.95, 0.90, 0.87, 0.83, and 0.72; (2)

compound **9** (317 mg), identical with the sample obtained in the previous experiment.

Base catalyzed isomerization of the ketone 9

To the solution of ketone **9** (80 mg) in benzene (10 mL) a solution of potassium hydroxide in methanol (3 mL, 5%) was added and the mixture stirred at room temperature for 1 h. The benzene solution was washed with water, dried with sodium sulfate, and evaporated to yield 14α-methyl-*A*-nor-5β-cholestan-3-one (**10**) (72 mg), which had mp 81–82°C (watered methanol) (lit. (2*a*) mp 82–83.5°C); ir ν_{max}: 1728 cm^{-1}; cd $\Delta\epsilon$ (λ): +0.97 (267), +2.42 (287), +3.14 (296), +3.16 (306), and +1.75 (316); ^1H nmr δ: 1.22, 0.90, 0.83, 0.81, and 0.73 (methyl signals); mass spectrum *m/z*: 384 (M^+), 369 (100%), 203, 189, 105, and 44.

Ozonation of olefin 2 (procedure C)

Dihydrolanosteryl acetate (**2**) (100 mg) dissolved in hexane (50 mL) was ozonized at −78°C for 2.5 h. Thin-layer chromatography of the reaction mixture showed some polar material. The crude product was filtered through a short column of alumina (2 g). The pure fractions were combined, evaporated, and crystallized from methanol to give the substrate **2** (61 mg), which had mp 117–121°C (chloroform–methanol) and was identical with the original sample.

Ozonation of olefin 2 (procedure D)

The crude product obtained from **2** (400 mg) was chromatographed on a silica gel column. Two compounds obtained, in order of their elution, were 3β-acetoxy-8α,9α-epoxy-5α-lanostane (**13**) (166 mg, 40%), with mp 135–138°C (methanol) (lit. (30) mp 140–142°C) and spectra (ir, ^1H nmr, ms) in agreement with those of the original sample; and 3β-acetoxy-5α-lanost-8-en-7-one (**16**) (188 mg, 46%), with mp 149–150°C (*n*-heptane) and 145–146°C (diethyl ether – methanol) (lit. (31) mp 145–146°C) and spectra (^1H nmr, ir, uv, ms) in agreement with those of the original sample.

Ozonation of olefin 3 (procedure D)

The crude product obtained from **3** (420 mg) was chromatographed on a column of silica gel. Three compounds were obtained in order of their elution: the substrate **3** (36 mg, 8.5%); 8α,9α-epoxy-5α-lanostan-3-one (**14**) (94 mg, 22%), which had mp 102–104°C (methanol) and spectra (^1H nmr and ir) in accordance with those of the sample obtained in ozonation of **3** according to procedure B (above); and 5α-lanost-8-en-3,7-dione (**17**) (248 mg, 57%), which had mp 145–147°C (methanol) (lit. (32) mp 145–147°C); ir ν_{max}: 1704, 1652, and 1586 cm^{-1}; uv λ_{max} (ε): 253 nm (11 000) (lit. (32) λ_{max} (ε): 254 nm (12 600)); ^1H nmr δ: 2.52 (2H, m), 2.43 (2H, m), 1.12, 1.10, 0.94, 0.90, 0.83, and 0.68; mass spectrum *m/z*: 440 (M^+), 425 (100%), 327, 259, 149, and 44. *Anal.* calcd. for $C_{30}H_{48}O_2$: C 81.76, H 10.98; found C 81.58, H 11.12.

Ozonation of 13 (procedure D)

Treatment of **13** (35 mg) dissolved in ethyl acetate (20 mL) with ozone at −78°C for 1 h gave no reaction. Starting material was recovered and crystallized from methanol to give **13** (29 mg), which had mp 136–138°C and was identical (^1H nmr) with the authentic sample.

Ozonation of cholest-4-en-3β-ol

The crude product obtained from ozonolysis (procedure D) of cholest-4-en-3β-ol (320 mg) was dissolved in acetic acid (10 mL) and stirred with zinc powder (800 mg) at room temperature for 1 h. The reaction mixture was filtered and the filtrate was evaporated to dryness, purified by chromatography on an alumina column, and evaporated to give a white solid. This was crystallized from methanol – ethyl acetate mixture to give **21** (247 mg, 71%), which had mp 155–157°C. Recrystallization from acetonitrile gave white needles, mp 157–158°C; ir ν_{max}: 3570, 3425, 1137, 1095, 1072, 1049, 1029, 988, 937, and 868 cm^{-1}; ^1H nmr δ: 5.20 (1H, bd, J = 8.8 Hz, 4β-H), 4.20 (1H, d, J = 2 Hz, OH), 3.21 (1H, bd, J = 8.8 Hz, 3β-H), 1.02, 0.89, 0.82, and 0.64 (methyl signals); ^{13}C nmr δ: 112.9 (C-5), 96.4 (C-4), and 81.4 (C-3); mass spectrum *m/z*: 418 (M^+), 403, 372 (100%), 149, 95, and 44. *Anal.* calcd. for $C_{27}H_{46}O_3$: C 77.46, H 11.08; found: C 77.21, H 11.09.

Oxidation of bis-acetal 21 with Jones reagent

Compound **21** (25 mg) dissolved in acetone (15 mL) was oxidized with Jones reagent. After the substrate had reacted (tlc), methanol (0.5 mL) was added and the solvents evaporated. The residue was dissolved in benzene and this solution was filtered through an alumina (1 g) column. The product was compound **22** (22 mg, 88%). It had mp 130–131°C (acetonitrile); ir ν_{max}: 1783, 1278, 1250, 1195, 1060, 996, 987, 908, and 878 cm^{-1}; ^1H nmr δ: 4.44 (1H, m, $W_{\frac{1}{2}}$ = 4.8 Hz, 3β-H), 1.13, 0.93, 0.90, 0.86, 0.83, and 0.66 (methyl signals); mass spectrum *m/z*: 416 (M^+, 100%), 401, 372, 261, 149, and 44. *Anal.* calcd. for $C_{27}H_{44}O_3$: C 77.84, H 10.64; found: C 77.79, H 10.91.

Lithium aluminum hydride reduction of 3β-acetoxy-5α-lanost-8-en-7-one (16)

$LiAlH_4$ (600 mg) was added in portions to compound **16** (560 mg) dissolved in diethyl ether (80 mL) and the mixture was stirred at room temperature for 1 h. To this mixture, cooled to −78°C, was added a saturated aqueous solution of magnesium sulfate (20 mL). After warming up, the ether layer was separated and evaporated to give a white crystalline residue (474 mg), which was chromatographed on a column of silica gel. Two compounds were obtained: (1) 5α-lanost-8-en-3β,7β-diol (**23**) (202 mg, 39%), which had mp 167–168°C (acetonitrile); ir ν_{max}: 3610, 3440, 1240, 1027, 995, 980, 945, and 884 cm^{-1}; ^1H nmr δ: 4.35 (1H, m, $W_{\frac{1}{2}}$ = 23 Hz, 7α-H), 3.20 (1H, m, 3α-H), 1.07, 0.99, 0.90, 0.84, and 0.76 (methyl signals); ^{13}C nmr δ: 78.6 (C-3), 68.4 (C-7), and 49.5 (C-5); mass spectrum *m/z*: 444 (M^+), 426 (100%), and 411. *Anal.* calcd. for $C_{30}H_{52}O_2$: C 81.02, H 11.79; found: C 80.93, H 11.61; and (2) 5α-lanost-8-en-3β,7α-diol (**24**) (177 mg, 35%), which had mp 144–146°C (acetonitrile); ir ν_{max}: 3610, 3410, 1238, 1045, 1020, 1005, and 925 cm^{-1}; ^1H nmr δ: 4.20 (1H, m, $W_{\frac{1}{2}}$ = 10 Hz, 7β-H), 3.26 (1H, m, 3α-H), 1.03, 0.95, 0.90, 0.82, and 0.60 (methyl signals); ^{13}C nmr δ: 78.1 (C-3), 67.5 (C-7), and 45.0 (C-5); mass spectrum *m/z*: 444 (M^+), 426 (100%), and 411. *Anal.* calcd. for $C_{30}H_{52}O_2$: C 81.02, H 11.79: found: C 80.74, H 11.55.

Ozonation of 24 (procedure D)

The crude product obtained from **24** (100 mg) was a white solid (103 mg), which gave one spot on tlc. After crystallization from methanol 3β-hydroxy-5α-lanost-8-en-7-one (**25**) (63 mg) was obtained, which had mp 132–134°C (lit. (33) mp 135–136°C). This material was identical (ir, ^1H nmr, tlc) with an authentic sample.

The thermodynamics of zinc sulphide transport in hydrogen chloride by modified entrainment

PETER J. GARDNER AND PETER PANG

Royal Holloway and Bedford New College, University of London, Egham Hill, Egham, Surrey, TW20 0EX, U.K.

Received December 1, 1987

PETER J. GARDNER and PETER PANG. CAN. J. CHEM. **66**, 2137 (1988).

The equilibrium ZnS(c,sphalerite) + 2HCl(g) = $ZnCl_2$(g) + H_2S(g) was studied by modified entrainment in the temperature range 1023 to 1263 K and the free energy equation, ΔG^0/J mol^{-1} = (95060 ± 2700) − (38.7 ± 2.4)T, was obtained. A free energy equation for the corresponding equilibrium, ZnS(c,sphalerite) + 2HCl(g) = $ZnCl_2$(l) + H_2S(g), was derived using ancillary thermodynamic data, ΔG^0/J mol^{-1} = (−28340 ± 2800) + (85.6 ± 2.4)T, (638–978 K).

PETER J. GARDNER et PETER PANG. CAN. J. CHEM. **66**, 2137 (1988).

Opérant dans l'intervalle de température allant de 1023 à 1263 K et faisant appel à une méthode modifiée d'entraînement, on a étudié l'équilibre ZnS(c, sphalérite) + 2HCl(g) = $ZnCl_2$(g) + H_2S(g) et on a déterminé que l'équation d'énergie libre est la suivante : ΔG^0/J mol^{-1} = (95060 ± 2700) − (38,7 ± 2,4)T. Utilisant des données thermodynamiques accessoires, on a déterminé que l'équation d'énergie libre de l'équilibre correspondant, ZnS(c,sphalérite) + 2HCl(g) = $ZnCl_2$(l) + H_2S(g) est la suivante : ΔG^0/J mol^{-1} = (−28340 ± 2800) + (85,6 ± 2,4)T, (638–978 K).

Introduction

Molten zinc chloride is a selective catalyst for the hydrocracking of both coal and heavy crude oil residues to produce gasoline in good yield (1). A major problem encountered in the commercial exploitation of the process is the steady accumulation of ZnS in the melt, the sulphur arising from heteroatoms in the feedstock. Several regeneration procedures have been proposed (2) including passing hydrogen chloride through the melt so regenerating the chloride via eq. [1]

[1] $\quad ZnS(c) + 2HCl(g) = ZnCl_2(l) + H_2S(g)$

Reliable data for the temperature variation of K_1 and hence the likely efficiency of this regeneration route are scarce. Britske and Kapustinskii (3) have measured K_1 directly at 565 and at 635 K using a closed tube reactor. Jona and Mandel (4) have studied the kinetics of the corresponding vapour transport reaction, [2], over a wide range of HCl pressures at one temperature, 1268 K.

[2] $\quad ZnS(c) + 2HCl(g) = ZnCl_2(g) + H_2S(g)$

Equilibrium [2] has been examined between 1023 and 1263 K by modified entrainment to yield K_2 as a function of temperature. These results when combined with free energy data for the vaporization of zinc chloride (5) yield a definitive free energy equation for [1] within the liquid range of zinc chloride, 591 to 1005 K.

Experimental

The modified entrainment ring has been described in detail (6–8). Briefly, the zinc sulphide was contained in a spherical fused silica capsule suspended on one arm of a recording microbalance. The capsule was positioned in the central region of a vertically-mounted tube furnace and the carrier gas (argon) mixed with the transporting gas (hydrogen chloride) passed downwards over the capsule. The orifice of the capsule is a capillary (ca. 20 mm long × 1 mm internal diameter) which acts as a diffusive resistance to the transporting gas diffusing in and the reaction products diffusing out. Temperature (to ±2 K) was measured with a calibrated Pt – 13% Rh/Pt thermocouple mounted axially immediately below the capsule. Two separate capsules were used with diffusive resistances (l/r^2; l = length, r = internal radius) of 6.699 × 10^4 m^{-1} and 6.006 × 10^4 m^{-1}. The experimentally-determined quantity is the rate of mass loss of ZnS from the capsule at a known temperature, $\dot{\omega}(T)$. Four doping ratios of hydrogen chloride in argon (between 0.0602 and 0.0968) were used and are quoted as pressure fractions ($p_{HCl}/(p_{Ar} + p_{HCl})$) determined from a ratio of flow rates of Ar and HCl from calibrated mass flow controllers reading in cm^3(stp) min^{-1}. The total flow rate (Ar + HCl) was ca. 100 cm^3(stp) min^{-1} and 145 data points were recorded from 1023 K ($\dot{\omega} \approx 3.1 \times 10^{-11}$ kg s^{-1}) to 1263 K ($\dot{\omega} \approx 1.2 \times 10^{-10}$ kg s^{-1}). The ZnS transition (sphalerite → wurtzite) temperature is 1293 ± 10 K (9).

Materials

Argon was purified by passage through a commercial rare gas purifier (Model RGP-4, BOC Ltd.) which includes a titanium getter operating at 700°C to remove O_2 and N_2, copper oxide at 450°C to remove H_2, hydrocarbons, and CO, and molecular sieves to remove CO_2 and H_2O. Hydrogen chloride (electronic grade, 99.99%, Air Products Ltd.) was dried by passage through columns containing anhydrous magnesium perchlorate. Hydrogen was purified in a palladium diffuser (model H28/1, Johnson Matthey Ltd.).

Zinc sulphide (Aldrich Chemical Co., Gold Label, 99.99%, batch 0301 JK), a finely-divided pale yellow polycrystalline material, was characterized by X-ray diffraction (XRD), spectrographic and elemental analyses. Spectrographic analysis showed < 25 ppm of metallic impurities. Batches of stock ZnS were pretreated in flowing Ar or H_2 for at least 24 h, quenched rapidly, and subdivided in a dry box for XRD and elemental analysis. Hydrogen was selected for pretreatment as it is produced in small quantities from H_2S decomposition during entrainment, and it has been suggested (10) that its presence depresses the sphalerite → wurtzite conversion temperature (1293 ± 10 K). Sample sizes and irradiation times for XRD were such that the level of discrimination between the phases was about 5%. The results are collected in Table 1. This evidence confirmed that the material examined by modified entrainment was stoichiometric and was 95+% sphalerite (or β).

Results and discussion

Reaction stoichiometry

The H_2S produced in reaction [2] is significantly dissociated (K_5(1200 K) ≈ 500) in the experimental temperature range (1023–1263 K). The H_2 from the dissociation participates in reductive sublimation of ZnS. Further, $ZnCl_2$ undergoes slight dimerization below 1200 K (5, 11–13). The dissociative sublimation (eq. [4]) is known to be congruent (14) and the concentration of molecular ZnS in the vapour in our temperature range is negligible (15). Also, there is insignificant contribution from S_n(g) ($n > 2$ or $n = 1$) in the gas phase in this temperature range (16). Consequently, the eqs. [2]–[5] were considered as

Printed in Canada / Imprimé au Canada

For personal use only.

the participating equilibria during entrainment

[2] $ZnS(c, \beta) + 2HCl(g) = ZnCl_2(g) + H_2S(g)$

[3] $2ZnCl_2(g) = Zn_2Cl_4(g)$

[4] $ZnS(c, \beta) = Zn(g) + \frac{1}{2}S_2(g)$

[5] $H_2(g) + \frac{1}{2}S_2(g) = H_2S(g)$

Notice that the reductive sublimation referred to above arises from the combination of [4] and [5] so is not included explicitly. The experimental temperature range overlaps with the liquid range of Zn(693–1186 K). However, the partial pressure of Zn in the modified entrainment experiments (see Table A3) is several orders of magnitude less than the corresponding saturation vapour pressure of zinc (17) and consequently it is correct to write zinc as Zn(g) in equilibrium [4].

Assumptions

The central assumption of the modified entrainment method (MEM) is that the diffusive resistance offered by the capillary above the sample is sufficiently high so that equilibrium partial pressures of all the gaseous species in [2] to [5] obtain within the capsule (6, 18). This condition is met provided the surface area of the condensed phase (ZnS here) is large compared with the cross-sectional area of the channel and that unfavourable surface kinetic effects do not intervene (18). Unfavourable surface kinetics may arise from (*i*) physical effects, e.g. a surface film of oxide may form on a liquid metal so hindering its vaporization or (*ii*) structural effects, e.g. the vaporization coefficient for *P*(red) is exceptionally small ($\approx 10^{-8}$) due to the structural reorganization in the solid → gas transition (8, 19). Liquids, most metals, and isotropically bonded solids have vaporization coefficients close to unity (20). Kinetic inhibition for reaction [2] at low partial pressures of HCl has been suggested (4) but this was in a closed tube reactor for which the diffusive resistance is five times smaller than in the MEM experiments. The equilibrium assumption is usually verified experimentally, as in this work, by conducting experiments with capsules having different channel dimensions and showing the results are self-consistent.

Equilibrium constants are written in terms of partial pressures and not fugacities. The standard state pressure is 101325 N m^{-2}. Non-ideality corrections are rarely available for the gaseous components of heterogeneous equilibria and such data that do exist suggest that at ca. 1000 K and 1 atm pressure, the correction will be small. For example, for $H_2O(g)$ at 1300 K and 10000 atm the non-ideality correction is ca. 10% (21).

The partial pressure (p_i^0) of any species depends on its flux (j_i) and diffusivity (D_i) in the channel and temperature (22).

$$[6] \quad \frac{p_i^0}{P} = \frac{j_i}{J} - \left[\frac{j_i}{J} - \frac{p_i^l}{P}\right]e^{-\xi_i}$$

$$[7] \quad \xi_i = \frac{JRTl}{D_iP}$$

In [6] and [7], J is the total flux, P is the total pressure (about 3 Torr above ambient pressure), p_i^l is the partial pressure of i at the open end of the channel, and D_i is a multicomponent diffusion coefficient of i into the mixture of the other species. The application of this equation and the estimation of the diffusion coefficients is outlined in the Appendix.

Ancillary data

In order to derive K_2 (or ΔG_2^0) and its temperature coefficient from the flux equations outlined in the Appendix it is necessary to know corresponding results for K_3, K_4, and K_5. Zinc chloride vaporization has been studied (5) by MEM and the results interpreted in terms of monomeric and dimeric species in the vapour. The free energy expression [8] was derived.

$$[8] \quad \Delta G_3^0/\text{J mol}^{-1} = -(162000 \pm 8000) + (202 \pm 11)T \qquad 638\text{–}978 \text{ K}$$

Although the temperature ranges of the zinc chloride work and these studies are not coincident, the zinc chloride dimer makes little contribution to the transport above 1000 K (see values of β in Table A1 and partial pressures in Table A3) so the non-coincidence is not a source of serious error. The dissociative sublimation of sphalerite (eq. [4]) has also been studied (23) by modified entrainment and eq. [9] obtained

$$[9] \quad \Delta G_4^0/\text{J mol}^{-1} = (374200 \pm 1100) - (190.4 \pm 1.0)T \qquad 1010\text{–}1270 \text{ K}$$

The free energies from this equation are within 2% of the free energies obtained from a recent independent study of [4] using a high temperature solid electrolyte cell (24). The thermodynamic parameters for the components in equilibrium [5] have been critically assessed by the compilers of the JANAF tables (25) and values of ΔG_5^0 were calculated at 100 K intervals from 900 to 1500 K using $\Delta G^0(T) = \Delta H_{298}^0 - T\Delta(\text{fef})$ where fef = $-(G_T^0 - H_{298}^0)/T$ and with the JANAF results for fef and ΔH_{298}^0. Regression of $\Delta G^0(T)$ with T gave

$$[10] \quad \Delta G_5^0/\text{J mol}^{-1} = -(90333 \pm 110) + (49.3 \pm 0.1)T \qquad 900\text{–}1500 \text{ K}$$

A recommended expression (26) for ΔG_5^0 over a much wider temperature range (298–1750 K) gave values for ΔG_5^0 within 0.3% of corresponding values from [10] in the experimental temperature range.

MEM results

The results from the MEM experiments with different channel sizes were first processed separately yielding two regression lines of the form $\Delta G_2^0 = a - bT$. Analysis of covariance showed there was no significant probability that the input data arose from different populations; this test confirms that equilibrium partial pressures obtain within the capsules. The results (145 data pairs, $\dot{\omega}(T)$) from the two different capsules and four different HCl doping levels (see Experimental) were then pooled and eq. [11] obtained by regression

$$[11] \quad \Delta G_2^0/\text{J mol}^{-1} = (95060 \pm 2700) - (38.7 \pm 2.4)T \qquad 1023\text{–}1263 \text{ K}$$

The uncertainty intervals in eqs. [8]–[11] are standard deviations of the regression coefficients. The equilibrium of central importance to this study is eq. [1]. The coefficients of eq. [11] were scaled to refer to 808 K (the mean temperature of the $ZnCl_2$ vaporization study, see below) using C_p results for HCl and H_2S from JANAF tables (25), for $ZnCl_2(g)$ from Givan and Loewenschuss (27) and for ZnS(β) from Pankratz and King (28)

TABLE 1. Zinc sulphide pretreatment regimes, XRD results and elemental analyses

Pretreatment	β(XRD)	α(XRD)	Zn:S ratio
973 K/24 h/H_2	Dominant	<5%	0.998±0.002
1073 K/24 h/H_2	Dominant	<5%	—
1173 K/24 h/H_2	Dominant	≈5%	0.999±0.002
1173 K/32 days/Ar + 1173 K/10 min/H_2	Dominant	5–10%	—

TABLE 2. Comparison of K_1 calculated from eq. [15] with literature results

Source	K (565 K)	K (635 K)
Bristske *et al.* (3)	0.072	0.021
This work	0.014±0.008	0.0072±0.0041

and Stuve (29). Thus,

$$[12] \quad \Delta G_2^0/\text{J mol}^{-1} = (98260 \pm 2700) - (42.0 \pm 2.4)T \quad \langle 808\ \text{K}\rangle$$

An independent study (5) of zinc chloride vaporization (eq. [13]) by modified entrainment in the range 638–978 K gave eq. [14].

$$[13] \quad ZnCl_2(l) = ZnCl_2(g)$$

$$[14] \quad \Delta G_{13}^0/\text{J mol}^{-1} = (126600 \pm 500) - (127.6 \pm 0.5)T \quad 638\text{–}978\ \text{K}$$

The mean temperature for the zinc chloride vaporization study was 808 K and combining eqs. [12] and [14] gives

$$[15] \quad \Delta G_1^0/\text{J mol}^{-1} = (-28340 \pm 2800) + (85.6 \pm 2.4)T \quad \langle 808\ \text{K}\rangle$$

which is valid over a temperature range of 638–978 K which is within the liquid range of $ZnCl_2$ (591–1005 K). Equilibrium constants calculated from eq. [15] are compared in Table 2 with the literature results of Britske and Kapustinskii (3). Although the proportional error in our K_1 is ca. 60%, the values are significantly different from those of Britske *et al.*

Third law and second law treatments

The free energy values for eq. [2] were analysed by the third law method. Free energy functions were taken from the literature (25, 27–29). Using values of $(H_{1143}^0 - H_{298}^0)$ from these same sources, the corresponding second law estimate of ΔH_{298}^0 was obtained from ΔH_2^0 (1143 K) = +95.1 ± 2.7 kJ mol^{-1} (from eq. [11]):

$$\Delta H_2^0(298\ \text{K}), \text{ second law} = 103.9 \pm 5.4\ \text{kJ mol}^{-1}$$

$$\Delta H_2^0(298\ \text{K}), \text{ third law} = 100.8 \pm 0.4\ \text{kJ mol}^{-1}$$

(uncertainty intervals in these and subsequent thermodynamic results are ± 2 (standard deviations of the mean)). The contribution to ΔH_2^0 from the $T\Delta$(fef) term in the third law analysis is ca. 50% and the coincidence between the second and third law results suggests the free energy functions for the components in eq. [2] are in good order.

Appendix

The partial pressures of the gaseous species in eqs. [2]–[5] are calculated from eqs. [6] and [7]. As four interdependent equilibria are involved, three coupling parameters (β, δ, and θ) are defined,

$$[A1] \quad \beta = \frac{j(Zn_2Cl_4)}{j(ZnCl_2)}; \delta = \frac{j(Zn)}{j(S_2)}; \theta = \frac{j(H_2)}{j(H_2S)}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/07/12

TABLE A1. Typical values of the coupling parameters (eq. [A1])

T/K	$10^5\beta$	θ	$10^4\delta$
1024	1.14	1.28	0.336
1159	0.278	2.60	11.5
1252	0.119	4.03	97.8

where j is the flux of the species in the channel. The net elemental fluxes are written in terms of the fluxes of the participating species, e.g.

[A2] $\text{Flux(Zn)} = j(ZnCl_2) + 2j(Zn_2Cl_4) + j(Zn)$

Combining the elemental flux equations with mass conservation equations permits the ratio of any individual flux to the total flux to be written in terms of a function (F_i) of the coupling parameters (22)

[A3] $$\frac{j_i}{J} = F_i(\beta, \theta, \delta)$$

There is mass conservation of both hydrogen and chlorine in this system in that there is zero net flux of each. For example, for hydrogen,

[A4] $j(HCl) + 2j(H_2S) + 2j(H_2) = 0$

For HCl in eq. [6],

[A5] $$\frac{p_i'}{P} = \epsilon$$

where ϵ is the pressure fraction of the transporting gas (HCl) in the carrier gas (Ar) plus HCl mixture — see Experimental. For all other species the ratio p_i'/P is zero as the carrier gas flushes these species away from the open end of the channel. The exponential term in [6] is expanded and truncated at O(2) — the error in this approximation is $\leq 5\%$ when the transport function, $\xi_i < 0.1$. Hence

[A6] $$\frac{p_i^0}{P} \approx \frac{j_i}{J}\xi_i$$

and

[A7] $$\frac{p^0(HCl)}{P} \approx \epsilon + \frac{j(HCl)}{J}\xi_{HCl}$$

assuming $\epsilon\xi_{HCl} \ll 1$.

The transport functions. (eq. [7]) are written in terms of the experimental parameter, $\dot{\omega}$(ZnS), and take the form

[A8] $$\xi_i = \frac{\dot{\omega}RTl}{AD_iMP}G(\beta, \theta, \delta)$$

where G is a universal function of the coupling parameters, M is the molecular mass of ZnS, and A is the cross-sectional area of the channel. Combining eqs. [A6] to [A8], the partial pressures are formed

[A9] $$p_i^0 = \frac{\dot{\omega}RTl}{AD_iM}F_iG \qquad (i \neq HCl)$$

[A10] $$p_{HCl}^0 = P\epsilon - \frac{\dot{\omega}RTl}{AD_{HCl}M}F_{HCl}G$$

Next, the equilibrium constants K_2 to K_5 are written in terms of the partial pressures and K_3 to K_5 are equated to analytical expressions taken from the literature (see Results and discussion — ancillary data). The resulting expressions for K_3 to K_5 are manipulated so as to solve for the three unknown coupling parameters (θ, δ, and β) which are then evaluated at each experimental temperature. These values are then back-substituted in the equation for K_2.

As more than two gaseous components are present in the channel at any time the effects of multicomponent diffusion (30) are taken into account. A second order treatment (31) of this effect permits the multicomponent diffusion coefficients (D_i) to be written in terms of the corresponding binary diffusion coefficient ($\mathcal{D}_{ij}$) when j is the majority component (in this work, Ar),

[A11] $$D_i = \frac{\mathcal{D}_{iAr}}{\gamma_i} = \frac{\mathcal{D}_{iAr}}{(1 + A_i\epsilon + B_i\xi_i)}$$

where A_i and B_i are functions of j_i, J, and $\mathcal{D}_{ij}$. Notice that γ_i in [A11] contains Σ_{j_i} which itself is a function of D_i. Hence a

[a]Experimental results (32).

reiterative procedure is employed, initializing all γ_i to unity and terminating when successive values of γ_i differ by less than 1 in 10^4. Some typical values of the coupling parameters, the multicomponent diffusion correction coefficients and partial pressures are collected in Table A1 to A3. All transport functions (ξ_i) were less than 0.007, so validating the exponential approximation ([A6] and [A7]).

Seven binary diffusion coefficients ($\mathcal{D}_{i\mathrm{Ar}}$) and their variation with temperature are required to complete the calculation (eq. [A11]). Experimental data are available for the Zn/Ar (32) and H_2/Ar (33) systems only. Kinetic theory for binary diffusion is well-established (34) and binary diffusion coefficients may be estimated (35) to a precision of ca. 7% if Lennard–Jones (L–J) potential parameters are available; such parameters exist (35) for Ar, H_2S, HCl, and H_2. Svehla's estimates (36) for L–J parameters were used for S_2. For $ZnCl_2$ and Zn_2Cl_4 a scaling procedure recommended by Mason and Kronstadt (37) was used. This requires a system of structural similarity (Ar/CO_2 was chosen) for which reliable experimental results are available (33). Estimates obtained in this manner have proved satisfactory in a study of zinc chloride vaporization by the MEM (5). Six estimated binary diffusivities each with a possible maximum error of $\approx 7\%$ are not the serious source of error as would initially appear. The coefficients usually occur in ratios and error cancellation is likely. The estimated values were regressed to equations of the form

$$[\mathrm{A12}]\quad \mathcal{D}_{i\mathrm{Ar}} = \mathcal{D}^0_{i\mathrm{Ar}} \left[\frac{T}{273.15}\right]^{1+s}$$

at 1 atm pressure over the temperature range 1020 to 1450 K; the constants for [A12] are collected in Table A4.

Étude expérimentale et modélisation théorique de la décomposition du radical éthyle

YVES SIMON, JEAN FRANÇOIS FOUCAUT ET GÉRARD SCACCHI[1]

Département de chimie physique des réactions, Unité associée n° 328 du Centre national de la recherche scientifique, Institut-national polytechnique de Lorraine – École nationale supérieure des industries chimiques, 1, rue Grandville, 54042 Nancy CEDEX, France

Reçu le 8 février 1988

YVES SIMON, JEAN FRANÇOIS FOUCAUT et GÉRARD SCACCHI. Can. J. Chem. **66**, 2142 (1988).

Une étude bibliographique sur la décomposition thermique du radical éthyle montre une assez grande dispersion des paramètres cinétiques pour les conditions limites haute et basse pression. C'est la raison pour laquelle nous avons repris une étude de ce processus élémentaire dans la pyrolyse de l'éthane, vers 800 K, en réacteur fermé et pour des pressions d'hydrocarbure pur comprises entre 1 et 300 Torr. Les résultats expérimentaux sont traités grâce à trois approches théoriques : la théorie RRKM et deux méthodes proposées par Troe. On obtient, chaque fois, un excellent ajustement des courbes théoriques aux points expérimentaux, ainsi que des expressions d'Arrhenius pour les constantes de vitesse à haute et basse pression. Une analyse critique détaillée de nos propres résultats et de ceux de la littérature montre qu'il n'existe pas encore une très bonne compatibilité entre les travaux les plus récents sur ce sujet. Néanmoins il est possible de donner deux expressions d'Arrhenius pour les constantes limite haute et basse pression qui représentent un bon compromis entre les résultats des divers auteurs :

$$k_\infty(s^{-1}) = 10^{13,2} \exp\left(-\frac{38\,000}{RT}\right)$$

$$k_0(cm^3 \cdot mol^{-1} \cdot s^{-1}) = 10^{18,3} \exp\left(-\frac{34\,900}{RT}\right)$$

YVES SIMON, JEAN FRANÇOIS FOUCAUT, and GÉRARD SCACCHI. Can. J. Chem. **66**, 2142 (1988).

A bibliographical study of the thermal decomposition of the ethyl radical shows that the kinetic parameters for the upper and lower limits of the pressure are rather scattered. This observation explains why we have carried out a new study of this elementary process in the pyrolysis of ethane, around 800 K, in a closed vessel and at pressures of the hydrocarbon varying from 1 to 300 Torr. The experimental results have been treated according to three theoretical approaches: the RRKM theory and two methods proposed by Troe. In each case, an excellent fit of the theoretical curves with the experimental data is obtained, as well as Arrhenius expressions for the reaction rate constants at high and low pressures. A detailed critical analysis of our results as well as those found in the literature shows that as yet there is no good agreement between recent studies on this subject. However, it is possible to present two Arrhenius expressions for the reaction rate constants at high and low pressures; these expressions represent a good compromise for the results obtained by various authors:

$$k_\infty(s^{-1}) = 10^{13,2} \exp\left(-\frac{38\,000}{RT}\right)$$

$$k_0(cm^3 \cdot mol^{-1} \cdot s^{-1}) = 10^{18,3} \exp\left(-\frac{34\,900}{RT}\right)$$

[Journal translation]

Introduction

La décomposition thermique du radical éthyle en éthylène et hydrogène atomique est une réaction élémentaire omniprésente dans les réactions en phase gazeuse d'hydrocarbures : pyrolyses, oxydations, chlorations, etc... Une bonne connaissance des paramètres thermochimiques et cinétiques de ce processus est donc nécessaire si l'on désire modéliser les réactions complexes précédentes. C'est la raison pour laquelle un certain nombre d'études expérimentales ont été consacrées, en particulier, à la variation de la constante de vitesse du processus avec la pression. Ce phénomène («fall-off»), observé d'abord dans la pyrolyse du butane (1), a été confirmé par des travaux sur la pyrolyse (2) et sur la décomposition photosensibilisée par le mercure (3) de l'éthane, ceci à des températures inférieures à 1000 K. Cette même réaction thermique a été étudiée plus récemment en tube à onde de choc entre 1200 et 1600 K (4) et vers 1000 K dans un réacteur «sans paroi» (5). Les différents auteurs de ces travaux proposent des expressions d'Arrhenius pour la constante de vitesse limite à haute pression (et parfois pour la constante bimoléculaire, à très basse pression) en utilisant des méthodes d'extrapolation ou de simulation théorique variées. On observe une assez grande dispersion des paramètres cinétiques et c'est la raison pour laquelle nous avons repris une étude expérimentale de la pyrolyse de l'éthane vers 800 K, en réacteur fermé.[2]

Pendant ce travail deux travaux importants, l'un sur le processus qui nous intéresse (7), l'autre sur le processus inverse (8, 9), ont été menés à bien. Une comparaison détaillée de ces nouveaux résultats et de ceux de notre étude sera présentée à la fin du présent article.

Conditions expérimentales

La pyrolyse de l'éthane a été étudiée en réacteur fermé, isotherme, à volume constant. L'éthane utilisé a été préparé par la Société l'Air Liquide. Il contient moins de 10 ppm d'éthylène et moins de 1 ppm d'oxygène. Par suite de la grande sensibilité de la réaction aux traces d'oxygène (10, 11), nous avons pris soin de dégazer soigneusement

1. Auteur à qui adresser toute correspondance.

2. Ce travail a été résumé dans le mémoire de Thèse de Doctorat de Troisième Cycle présenté par l'un d'entre nous (Y.S.) en mai 1986 à Nancy (6). Les principaux résultats ont fait l'objet d'une communication-poster au «IXth International Symposium on Gas Kinetics», Bordeaux (France), 20–25 juillet 1986.

le réactif avant chaque expérience par piégeage dans l'air liquide et pompage. Pour la même raison toute l'installation était équipée en robinets à soufflets métalliques, étanches à l'air. Il a été observé (12–15) que la décomposition thermique de l'éthane était sensible aux effets de parois, en particulier dans des réacteurs en silice. On pense (12, 14–16) que ce phénomène est dû aux terminaisons hétérogènes d'atomes d'hydrogène aux parois. Pour limiter l'importance de ce facteur nous avons choisi de pyrolyser l'éthane dans un réacteur en «Pyrex» où les effets de parois et les irreproductibilités sont moindres qu'avec la silice (15), de rapport surface/volume le plus faible possible. Un volume de un litre nous a paru un bon compromis entre un faible s/v (0,48 cm^{-1}) et une bonne homogénéité de température à l'intérieur du réacteur (moins facile à obtenir avec un réacteur plus gros). Les parois du réacteur ont été, de plus, traitées successivement à la soude puis à l'acide nitrique (17) pour diminuer encore ces effets perturbateurs.

L'utilisation du Pyrex à la place de la silice a limité la température maximale d'étude vers 540°C (813 K). La mesure du méthane, produit de transfert en faibles quantités, a imposé la température plancher vers 520°C (793 K). Le plus grand soin a été apporté au contrôle et à la mesure de la température. L'enregistrement continu de ce paramètre n'a jamais montré des variations de plus de 0,1 degré, ce qui correspond à une modification de l'avancement de 0,6% maximum.

Pour les raisons précédentes, nous avons donc mené à bien une étude de la pyrolyse de l'éthane entre 793 et 813 K (4 températures) et pour 13 pressions initiales d'éthane pur, comprises entre 1 et 300 Torr (1 Torr = 101 325/760 Pa). Les produits de la réaction, en particulier le méthane et l'éthylène, ont été suivis par chromatographie en phase gazeuse (colonne de 1,5 m de Carbo Sieve 100/120 mesh, à 135°C).

Principe de la mesure de la constante de vitesse et résultats expérimentaux

Il est généralement bien admis que la pyrolyse de l'éthane, vers 800 K, et à très faible avancement, relève d'un mécanisme radicalaire en chaînes (18) :

[1] $C_2H_6(+M) \rightarrow 2CH_3\cdot(+M)$

[x] $\cdot CH_3 + C_2H_6 \rightarrow CH_4 + \cdot C_2H_5$

[2] $C_2H_5\cdot(+M) \rightarrow C_2H_4 + H\cdot(+M)$

[3] $H\cdot + C_2H_6 \rightarrow H_2 + C_2H_5\cdot$

[4] $2C_2H_5\cdot \rightarrow n C_4H_{10}$ ou $C_2H_4 + C_2H_6$

On déduit de ce mécanisme les relations suivantes :

[5] vitesse d'amorçage = vitesse de terminaison :

$$k_1(C_2H_6)_0 = k_4(C_2H_5\cdot)^2$$

[6] vitesse initiale de production de C_2H_4 :

$$r^0_{C_2H_4} = k_2(C_2H_5\cdot)$$

[7] vitesse initiale de production de CH_4 : $r^0_{CH_4} = 2k_1(C_2H_6)_0$

Ces expressions amènent les commentaires suivants :

L'expression [5] suppose que l'unique processus de terminaison est [4]. Une étude détaillée (6) des rapports $(H\cdot)/(C_2H_5\cdot)$ et $(CH_3\cdot)/(C_2H_5\cdot)$, s'appuyant sur nos propres résultats et sur ceux de Pacey et Purnell (19), montre que les vitesses des processus de terminaison en $H\cdot + C_2H_5\cdot$, $2CH_3\cdot(+M)$ ou $H\cdot + CH_3\cdot(+M)$ sont toujours négligeables devant celle de [4]. En revanche, à très basse pression (1 Torr) il se peut que le processus

[8] $CH_3\cdot + C_2H_5\cdot \rightarrow C_3H_8$ ou $CH_4 + C_2H_4$

représente 3 ou 4% des terminaisons.

La relation [6] n'est correcte que si C_2H_4 provenant de [4] ou de [8] est négligeable devant C_2H_4 venant de [2], c'est-à-dire si les chaînes sont suffisamment longues. L'expérience (6) montre que la longueur de chaîne n'est jamais inférieure à 120 dans tout le domaine de pression et température exploré, ce qui justifie [6].

La relation [7] suppose que les radicaux $CH_3\cdot$ sont essentiellement produits par l'amorçage [1] et consommés par le transfert [x]. Là aussi une étude détaillée (6), utilisant nos propres résultats et des constantes de vitesse de la littérature, permet de montrer que les processus $H\cdot + C_2H_6 \rightarrow CH_4 + CH_3\cdot$ et $H\cdot + C_2H_5\cdot \rightarrow 2CH_3\cdot$ sont, dans tout le domaine expérimental couvert, négligeables devant l'amorçage [1]. Les processus : $CH_3\cdot + H\cdot(+M) \rightarrow CH_4(+M)$ et $2CH_3\cdot(+M) \rightarrow C_2H_6(+M)$ qui tendent à consommer des $CH_3\cdot$ sont également d'importance négligeable devant le transfert [x]. En revanche, comme il a été signalé plus haut, le processus [8] peut intervenir, très légèrement, à très basse pression pour concurrencer [x].

Des trois relations [5], [6] et [7] on tire :

[9] $$k_2 = (2k_4)^{1/2} r^0_{C_2H_4} (r^0_{CH_4})^{-1/2}$$

Cette expression est valable dans tout le domaine de pression et de température, à l'exception peut-être de la pression P_0 = 1 Torr. Il faudrait alors remplacer [9] par :

[10] $$k_2 = (2k_4)^{1/2} r^0_{C_2H_4} (r^0_{CH_4} - r_8)^{-1/2}$$

Si [8] représente environ 4% des terminaisons, donc 2% de $r^0_{CH_4}$, on voit que la correction sur k_2 est extrêmement faible, de l'ordre de grandeur des erreurs expérimentales sur les vitesses initiales.

En revanche il n'est pas possible de savoir quelle est l'importance et quelles sont les conséquences d'un processus de terminaison hétérogène du type :

[11] $H\cdot \rightarrow$ parois

signalé plus haut.

Vers 800 K et $P_0 \simeq 50$ Torr il a été montré (10, 15) que, dans un réacteur en Pyrex vide, [11] était complètement négligeable devant [4] mais ce travail n'a pas été fait pour P_0 = 1 Torr. Le fait que les courbes de formation de CH_4 et C_2H_4 pour P_0 = 1 Torr soient parfaitement régulières et que nous n'ayons pas observé d'irreproductibilité semble montrer que même à cette faible pression on peut négliger [11]. Dans son dernier article, Trenwith (7) pense, au contraire, que la variation qu'il observe du rapport dismutation/combinaison du processus [8] avec la pression ne peut s'expliquer que par la participation de [11]. Peut-être la nature des parois (silice) de son réacteur est-elle à l'origine du phénomène?

La figure 1 montre qu'à 813 K, les courbes de formation d'éthylène sont des fonctions linéaires du temps, à faible avancement (toujours inférieur à 1%). À plus fort avancement la courbure vers le bas deviendrait visible. Aux trois autres températures (793, 801 et 807 K) il en est de même. Seules les courbes correspondant aux deux pressions extrêmes sont montrées. Les pressions intermédiaires conduisent également à des droites. Les vitesses initiales $r^0_{C_2H_4}$ sont ainsi déterminées avec grande précision. Les courbes de formation de méthane (fig. 2) sont linéaires à très faible avancement mais on note, pour P_0 = 300 Torr, l'allure autoaccélérée au-delà de t = 2 min ($\simeq$0,2% d'avancement), due à la formation de méthane secondaire (20). Ce phénomène, visible uniquement à haute pression dans notre échelle de temps, ne perturbe pas la mesure des vitesses initiales $r^0_{CH_4}$.

En adoptant $k_4 \simeq 10^{13}$ $cm^3\cdot mol^{-1}\cdot s^{-1}$ (21–23), la relation [9] fournit les valeurs de k_2 (s^{-1}) du tableau 1.

1	—	—	13	16,3

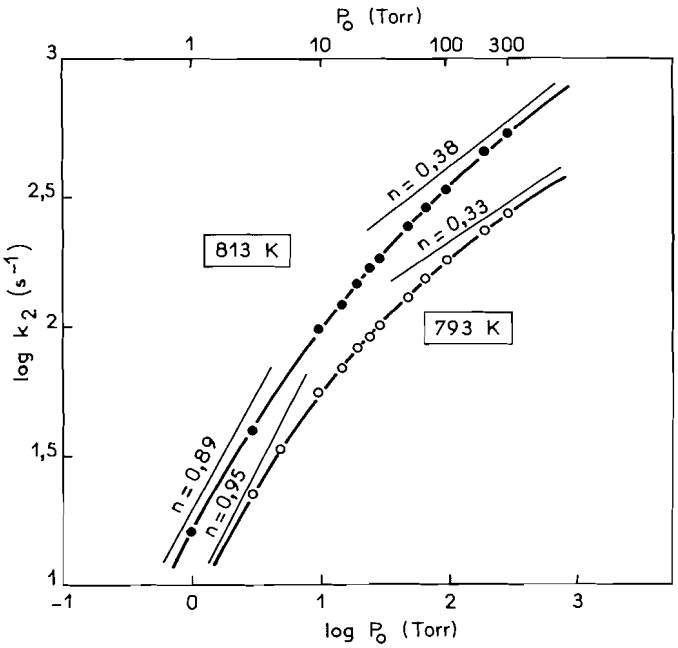

FIG. 3. Courbes de «fall-off» expérimentales aux deux températures extrêmes : 793 et 813 K.

La figure 3 montre les deux courbes de «fall-off», en coordonnées logarithmiques, pour les deux températures extrêmes 793 et 813 K. On voit qu'à 1 Torr l'ordre de k_2 est environ 0,90–0,95 : k_2 est très proche de la constante limite basse pression. En revanche, pour P_0 = 300 Torr, l'ordre est encore environ 0,35, donc assez éloigné de l'ordre théorique limite 0 à haute pression.

Exploitation des résultats expérimentaux

L'exploitation des résultats expérimentaux a été faite grâce à la théorie RRKM et à deux approches dues à Troe.

1. Théorie RRKM

Nous avons utilisé le programme mis au point par Gilbert (24).

Paramètres choisis pour le radical $C_2H_5\cdot$: fréquences (25, 26) en cm^{-1} : 2995 (5), 1432 (4), 1037 (2), 988 (2), 540 (1); rotation

TABLEAU 2. Méthode RRKM : valeurs de $k_{2,\infty}$, $k_{2,0}$ et des paramètres d'Arrhenius à pression infinie, aux différentes températures

T(K)	$k_{2,\infty}$ (s^{-1})	log $A_{2,\infty}$ (s^{-1})	$E_{2,\infty}$ (kcal·mol^{-1})	$k_{2,0}$ ($cm^3 \cdot mol^{-1} \cdot s^{-1}$)
793	516	14,00	40,97	$4,5 \times 10^8$
801	681	14,02	41,00	$5,55 \times 10^8$
807	824	14,02	41,02	$6,55 \times 10^8$
813	1030	14,04	41,04	$7,70 \times 10^8$

interne : $B = 14,1\ cm^{-1}$ ($I_{red} = 1,3$ uma Å^2); symétrie externe : $\sigma_{ext} = 1$; nombre d'isomères optiques : $n = 1$; symétrie interne : $\sigma_{int} = 6$.

Paramètres choisis pour le complexe activé : fréquences (25) en cm^{-1} : 3047 (4), 1466 (3), 1023 (2), 933 (3) plus *400* (2) cm^{-1}, fréquence ayant servi à obtenir le meilleur ajustement avec les points expérimentaux; symétrie externe : $\sigma^{\neq}_{ext} = 1$; nombre d'isomères optiques : $n^{\neq} = 1$.

Autres paramètres : énergie seuil à 0 K : $E^0 = 38,8$ kcal·mol^{-1}; diamètre «apparent» de collision : $\sigma = 2,9$ Å; rapport des moments d'inertie : $I^{\neq}/I = 1,14$–$1,20$ selon la température.

Le programme fournit, pour chaque température, les paramètres à pression infinie : $k_{2,\infty}$, $E_{2,\infty}$, et log $A_{2,\infty}$. L'ajustement entre les courbes théoriques et expérimentales se fait essentiellement, après que l'on s'est fixé E^0, grâce à la fréquence la plus basse du complexe activé (400 cm^{-1} ici), au rapport $I^{\neq}/I$ et au diamètre apparent de collision σ. En réalité c'est le facteur d'efficacité de désactivation λ, dans le produit $\lambda\sigma^2$, qui est le paramètre ajustable. Ainsi, si l'on admet pour $C_2H_5\cdot$ un diamètre de collision proche de celui de C_2H_6 : $\sigma_d = 4,45$ Å (valeur viscosimétrique (27)) l'adoption d'un diamètre apparent de 2,9 Å correspond à $\lambda \simeq 0,4$.

La figure 4 présente, pour les deux températures extrêmes, les courbes théoriques comparées aux points «expérimentaux» (ces points tiennent compte, dans cette représentation, de la valeur k_∞ donnée par le programme RRKM. Ils sont donc modifiés à chaque essai d'ajustement). L'accord est très bon, quelle que soit la température, la qualité de l'ajustement étant comparable pour les deux températures intermédiaires.

Le programme a permis le calcul de k_2 pour des pressions très basses : 0,01–0,1 Torr, en conservant les valeurs des paramètres ajustables précédents. La variation, linéaire, de k_2 dans ce domaine fournit la valeur de la constante bimoléculaire $k_{2,0}$.

Le tableau 2 regroupe les valeurs des paramètres à pression infinie données directement par le programme ainsi que les valeurs de la constante bimoléculaire $k_{2,0}$.

2. Première méthode de Troe (notée Troe 1)

Dans cette première méthode, Troe (28, 29) propose une expression modifiée de l'intégrale de Kassel :

$$[12]\quad I = \frac{k}{k_\infty} = \frac{1}{\Gamma(S_K)} \int_0^\infty \frac{x^{S_K - 1} \exp(-x)\, dx}{1 + \frac{k_\infty}{k_0 P_0} I_0(S_K, B_K) \left(\frac{x}{x + B_K}\right)^{S_K - 1}}$$

avec :

$$I_0(S_K, B_K) = \frac{1}{\Gamma(S_K)} \int_0^\infty (x + B_K)^{S_K - 1} \exp(-x)\, dx$$

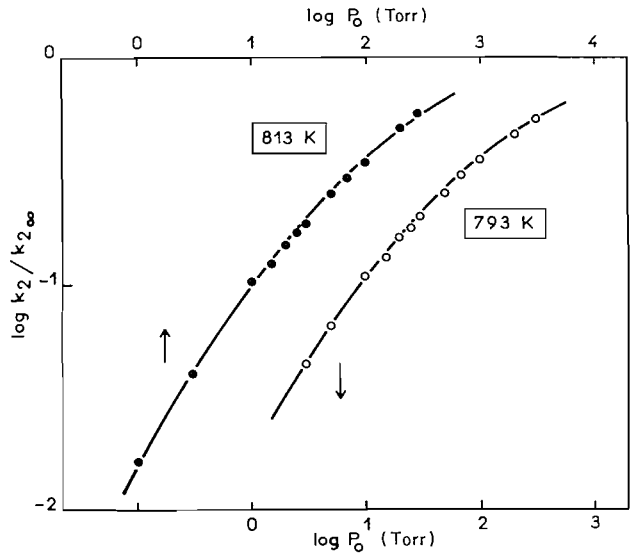

FIG. 4. Ajustement des courbes théoriques RRKM aux points expérimentaux, pour les deux températures extrêmes : 793 et 813 K.

où :

$$x = \frac{E - E^0}{k_B T}$$

E, énergie courante; E^0, énergie seuil à 0 K.

S_K et B_K sont les valeurs effectives des paramètres de Kassel S (paramètre ajustable dans la théorie RRK) et B ($= E^0/k_B T$ dans l'intégrale de Kassel). S_K et B_K sont calculables a priori à partir uniquement de E^0 et des fréquences de la molécule de réactif (28). On peut alors calculer l'intégrale I en fonction du paramètre $k_\infty/k_0 P_0$ où intervient la pression P_0 du réactif.

La méthode de détermination de k_∞ et k_0 à partir des résultats expérimentaux que nous avons mise au point est la suivante.

L'expression [12] se réécrit :

$$\log I = \log k - \log k_\infty$$

et

$$\log \frac{k_0 P_0}{k_\infty} = \log P_0 + \log \frac{k}{k_\infty} + \log \frac{k_0}{k}$$
$$= \log P_0 - \log k + \log k_0 + \log I$$

On peut alors tracer la courbe *théorique* : log I vs. log $(k_0 P_0/k_\infty)$ − log I en prenant $k_0 P_0/k_\infty$ comme paramètre soit encore log k − log k_∞ vs. log P_0 − log k + log k_0.

Les mesures expérimentales de k en fonction de P_0 peuvent être représentées par la courbe dite «*expérimentale*» : log k vs. log P_0 − log k.

Alors la courbe théorique se déduit de cette courbe expéri-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/07/12
For personal use only.

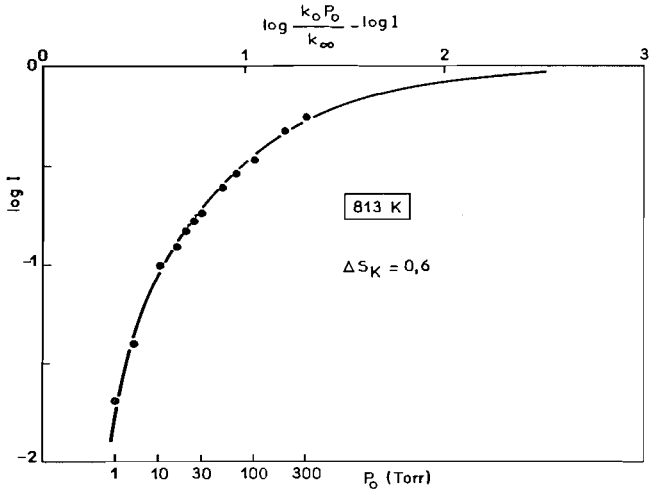

FIG. 5. Première méthode de Troe : ajustement de la courbe théorique transformée aux points «expérimentaux», permettant la détermination de $k_{2,\infty}$ et $k_{2,0}$ (cf. texte). Température : 813 K.

mentale par une translation selon l'axe des abscisses de $\log k_0$ et une translation selon l'axe des ordonnées de $-\log k_\infty$, ce qui permet l'évaluation de k_0 et k_∞.

Les valeurs de E^0 et des 14 fréquences de vibration de $C_2H_5\cdot$ sont les mêmes que pour le traitement RRKM et la rotation interne est ici remplacée par une vibration de fréquence 350 cm^{-1}. Les valeurs des paramètres efficaces sont alors, à 813 K : $S_K = 4{,}76$ et $B_K = 11{,}66$.

L'évaluation de k_0 et k_∞ se fait par optimisation au sens des moindres carrés, c'est-à-dire que l'on cherche le couple k_0, k_∞ qui donne la valeur minimale de la somme des carrés des distances entre les deux courbes expérimentales translatée et théorique, cette distance étant calculée pour chaque point expérimental.

Pour tenir compte de l'efficacité de désactivation (correspondant au facteur λ dans la théorie RRKM) Troe propose de modifier légèrement la valeur de S_K obtenue a priori par la formule qu'il préconise (28). Ainsi divers essais ont montré que le meilleur ajustement possible, à 813 K, de la courbe théorique aux points expérimentaux était obtenu pour $\Delta S_K = +0{,}6$. Ceci est illustré sur la figure 5. Le tableau 3 regroupe les valeurs de $k_{2,0}$ et $k_{2,\infty}$ obtenues par ajustement pour les quatre températures.

La courbe théorique de «fall-off» calculée, à 813 K, par la formule [12], à partir des valeurs $k_{2,\infty}$ et $k_{2,0}$ du tableau précédent est représentée, avec les points expérimentaux, sur la figure 6. Comme pour la théorie RRKM l'ajustement est de très bonne qualité. Il en est de même aux trois autres températures.

3. Deuxième méthode de Troe (notée Troe 2)

Troe et collaborateurs (29–33) ont proposé une représentation des courbes de «fall-off» en double échelle réduite, de la forme :

$$[13]\quad \log\frac{k}{k_\infty} = \log\frac{(k_0P_0/k_\infty)}{1+(k_0P_0/k_\infty)} + \frac{\log F_{cent}}{1+\left(\dfrac{\log(k_0P_0/k_\infty)}{0{,}75-1{,}27\log F_{cent}}\right)^2}$$

Le paramètre F_{cent} représente l'écart par rapport à la courbe de Lindemann–Hinshelwood (broadening factor) au centre de

TABLEAU 3. Première méthode de Troe : valeurs de $k_{2,\infty}$ et $k_{2,0}$ aux différentes températures

T (K)	$k_{2,\infty}$ (s^{-1})	$k_{2,0}$ ($cm^3\cdot mol^{-1}\cdot s^{-1}$)
793	385,5	$9{,}37 \times 10^8$
801	525,4	$1{,}16 \times 10^9$
807	646,4	$1{,}33 \times 10^9$
813	882,6	$1{,}55 \times 10^9$

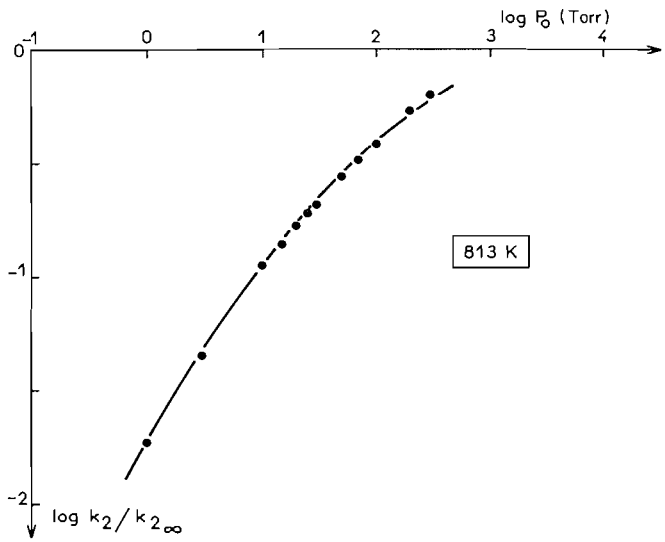

FIG. 6. Première méthode de Troe : courbe théorique, calculée à partir de $k_{2,\infty}$ et $k_{2,0}$ obtenus grâce à la figure 5, et points expérimentaux. Température : 813 K.

cette courbe (lorsque la variable réduite $y = k_0P_0/k_\infty$ vaut 1). F_{cent} se met sous la forme : $F_{cent} = F^{s.c.}{}_{cent} \times F^{w.c.}{}_{cent}$.

Le facteur $F^{s.c.}{}_{cent}$, correspondant à l'hypothèse des collisions fortes dans la désactivation de $C_2H_5\cdot$ activé, peut être estimé à partir des paramètres effectifs S_K et B_K évoqués dans la méthode précédente. Ceux-ci sont calculés (33) à partir de l'énergie seuil E^0 (= 38,8 $kcal\cdot mol^{-1}$) et des 14 fréquences de vibration du radical éthyle, la rotation interne étant prise en compte séparément (les 14 fréquences sont celles choisies dans la théorie RRKM).

À 813 K on obtient ainsi : $S_K = 4{,}76$ et $B_K = 12{,}29$ (formule un peu différente de celle utilisée dans la première méthode de Troe), d'où $F^{s.c.}{}_{cent} = 0{,}51$.

Le facteur $F^{w.c.}{}_{cent}$ est la correction à apporter lorsque les collisions sont faibles.

$F^{w.c.}{}_{cent} = \beta_c^{0,14}$ où β_c est l'efficacité de collision qui dépend de la température selon :

$$[14]\quad \frac{\beta_c}{1-\sqrt{\beta_c}} \simeq -\frac{\langle\Delta E\rangle}{F_E kT}$$

$\langle\Delta E\rangle$ est l'énergie moyenne échangée par collision. F_E, facteur statistique rendant compte de la dépendance de la densité d'états vibrationnels (harmoniques) $\rho_{vib.,h}$ vis-à-vis de l'énergie, est calculable (32) à partir de E^0 et des fréquences de vibration du radical éthyle.

Si l'on se donne $\langle\Delta E\rangle$ (cf. par exemple, réf. 31), la courbe $\log k/k_\infty$ vs. $\log k_0P_0/k_\infty$ peut ainsi être calculée a priori à partir de S_K, B_K et β_c. Si l'on désire comparer cette méthode aux deux précédentes, il est nécessaire de pouvoir passer de la

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/07/12
For personal use only.

variable réduite $\log k_0P_0/k_\infty$ à la variable $\log P_0$, donc de connaître k_0 et k_∞. Troe propose l'expression factorisée de k_0 suivante :

[15] $$k_0 = \frac{\beta_c Z_{LJ} \rho_{vib,h}(E^0) k_B T}{Q_{vib}} \exp\left(-\frac{E^0}{k_B T}\right) F_E F_{anh} F_{rot} F_{rot.int.}$$

On indique ci-dessous la signification de ces différents termes, les grandeurs nécessaires à leur évaluation et leur valeur numérique à 813 K calculée à partir des formules de réf. 32. Z_{LJ} : fréquence de collision de Lennard–Jones; $\rho_{vib,h}(E^0)$: densité d'états vibrationnels (oscillateurs harmoniques) pour l'énergie seuil E^0; $Q_{vib.}$: fonction de partition vibrationnelle du réactif (oscillateurs harmoniques); F_E défini précédemment; F_{anh} : tient compte de l'anharmonicité des vibrations; $F_{rot.}$: rend compte du changement de moments d'inertie (rotations externes) entre réactif et complexe activé; $F_{rot.int.}$: représente la contribution des rotations internes du réactif.

Grandeurs nécessaires à l'évaluation des termes précédents : énergie seuil E^0 (38,8 kcal·mol^{-1}), nombre $S = 14$ et valeurs des fréquences vibrationnelles du réactif (celles de RRKM), diamètre de collision : $\sigma = 4{,}4$ Å (27); énergie d'interaction de Lennard–Jones : $\varepsilon_{A\text{-}M} = 1{,}79 \times 10^3$ J·mol^{-1} (27); nombre de rotations internes dans le réactif : $r = 1$; nombre d'oscillateurs qui disparaissent durant la réaction : $m = 3$; rapport des moments d'inertie I^*/I entre le complexe activé et le réactif : $I^*/I = 1{,}14$–$1{,}20$ selon la température. À 813 K on calcule ainsi : $Z_{LJ} = 3{,}96 \times 10^{11}$ cm^3·mol^{-1}·s^{-1}; $\rho_{vib.,h}(E^0) = 33{,}66$; $Q_{vib} = 4{,}80$; $F_E = 1{,}40$; $F_{anh} = 1{,}125$; $F_{rot} = 1{,}16$; $F_{rot.int.} = 1{,}79$.

Pour exploiter les résultats expérimentaux, plusieurs méthodes sont envisageables :

(*i*) On peut évaluer k_∞ par une méthode d'extrapolation comme celle de Oref et Rabinovitch (34), k_0 directement à partir des résultats expérimentaux à basse pression, en admettant que l'on se trouve dans le domaine bimoléculaire, et calculer F_{cent} par S_K, B_K et β_c (en se donnant une valeur, a priori, de $\langle \Delta E \rangle$; par exemple 10 kJ·mol^{-1} (31)). Dans cette méthode, adoptée par Trenwith (7), il n'y a pas de paramètre ajustable et la courbe théorique, calculée a priori, est comparée aux résultats expérimentaux.

(*ii*) Dans une étude du processus inverse $H\cdot + C_2H_4 \rightarrow C_2H_5\cdot$, Lightfoot et Pilling (9) envisagent une autre approche. Ils calculent F_{cent} a priori par S_K, B_K et en se donnant β_c et ils ajustent courbe théorique et points expérimentaux en prenant comme paramètres ajustables k_∞ et k_0. En revanche ils ne comparent pas, ensuite, la valeur de k_0 ainsi obtenue avec l'expression théorique [15] de Troe. On ne sait donc pas s'il y a ou non compatibilité.

(*iii*) Une autre méthode a été retenue. Nous calculons S_K et B_K a priori (33) et nous ajustons d'abord courbe expérimentale et points théoriques en prenant comme paramètres k_∞ et β_c et en déduisant k_0 de β_c par la formule [15]. Ce travail d'optimisation, aux quatre températures, permet de constater que β_c reste toujours voisin de 0,45 (entre 0,45 et 0,48). La valeur de β_c à 813 K (0,45) a alors été choisie pour calculer la valeur supposée indépendante de la température de $\langle \Delta E \rangle$ par la formule [14]. Cette valeur $\langle \Delta E \rangle = 13$ kJ·mol^{-1} permet de calculer β_c aux trois autres températures par [14] et k_0 par la formule [15]. L'ajustement, repris à 793, 801 et 807 K avec k_∞ comme unique paramètre, a conduit aux résultats du tableau 4.

La figure 7 montre l'excellente qualité de l'ajustement aux deux températures extrêmes. Il en est de même à 801 et 807 K.

TABLEAU 4. Deuxième méthode de Troe : valeurs de $k_{2,\infty}$, $k_{2,0}$, de l'efficacité de collision β_c et du paramètre F_{cent} («broadening factor») aux différentes températures

T(K)	β_c	F_{cent}	$k_{2,\infty}$(s^{-1})	$k_{2,0}$(cm^3·mol^{-1}·s^{-1})
793	0,459	0,463	530	$5{,}87 \times 10^8$
801	0,456	0,459	710	$7{,}43 \times 10^8$
807	0,453	0,457	860	$8{,}73 \times 10^8$
813	0,45	0,454	1100	$1{,}05 \times 10^9$

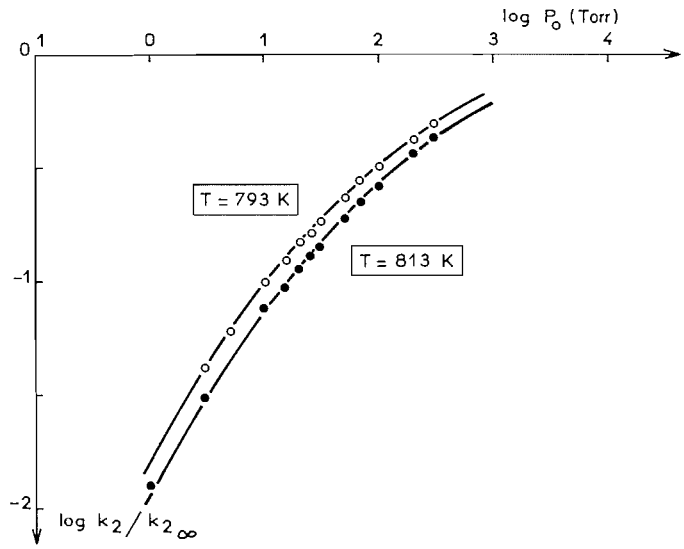

FIG. 7. Seconde méthode de Troe : ajustement des courbes théoriques aux points expérimentaux, pour les deux températures extrêmes : 793 et 813 K.

Discussion et comparaison avec les résultats de la littérature

Comme on vient de le voir, les trois méthodes précédentes permettent un très bon ajustement des courbes théoriques aux points expérimentaux. Parmi les différents travaux sur la décomposition du radical éthyle, seul le traitement RRKM, par Lin et Laidler (35), des résultats de Lin et Back (2) et de Loucks et Laidler (3), conduit à un ajustement de qualité comparable (pour des pressions supérieures à 30 Torr). Il a déjà été signalé (32, 36) que la détermination de k_∞ et k_0 à partir des courbes de «fall-off» est délicate et relativement peu précise, à moins de disposer de points expérimentaux dans un très grand domaine de pression, ce qui est rarement le cas. En particulier nous pensons, comme Clark et Quinn (36), que les méthodes d'extrapolation purement empiriques comme celle de Oref et Rabinovitch (34) ne conduisent pas à des valeurs précises de k_∞.

Néanmoins la comparaison des tableaux 2, 3 et 4 montre qu'en ce qui concerne $k_{2,\infty}$, la deuxième méthode de Troe fournit des valeurs qui ne diffèrent que de 5–6% de celles données par RRKM. Ce pourcentage est de 15–25% pour la première méthode de Troe. Dans le cas de $k_{2,0}$ la dispersion est plus importante : 30–35% pour Troe 2 par rapport à RRKM et un facteur 2 pour Troe 1. La cohérence entre les trois méthodes et en particulier entre RRKM et Troe 2 est donc très correcte.

Il est difficile de proposer des expressions d'Arrhenius précises, pour $k_{2,\infty}$ et $k_{2,0}$, lorsque les points expérimentaux ne couvrent qu'un domaine restreint de température (20°C). Un traitement d'Arrhenius sur les résultats des tableaux 2, 3 et 4 conduit aux paramètres figurant en bas du tableau 5, les valeurs

[a]Valeurs obtenues par un traitement d'Arrhenius (par nos soins) des résultats RRKM de l'article.
[b]Le traitement RRKM porte sur les résultats expérimentaux des réfs. 2 et 3 et sur ceux des auteurs lors de l'étude de l'activation chimique $H\cdot + C_2H_4 \rightarrow C_2H_5\cdot$. Le traitement d'Arrhenius a été fait par nos soins.

log $A_{2,\infty}$ et $E_{2,\infty}$ pour RRKM étant celles calculées directement par le programme (moyenne sur le tableau 2).

Le tableau 5 rassemble les paramètres proposés par les différents auteurs ainsi que les méthodes d'exploitation utilisées. Il faut noter que les expressions originales figurant dans les références 2, 3, 4, 25 et 35 ont été modifiées en prenant $k_4 = 10^{13}\,cm^3 \cdot mol^{-1} \cdot s^{-1}$ (au lieu de 2×10^{13}).

Comparaison des paramètres à pression infinie

Si l'on écarte les valeurs de $E_{2,\infty}$, manifestement trop élevées, données par les deux méthodes de Troe, on s'aperçoit que les autres se regroupent en deux domaines : l'un aux environs de 38 kcal·mol^{-1}, l'autre autour de 41 kcal·mol^{-1}. La valeur $\Delta H^0_f(C_2H_5\cdot) = 25{,}8$ kcal·mol^{-1} (300 K) couramment admise (38) conduisait à $\Delta H^0_{2(800\,K)} \simeq 40{,}0$ kcal·mol^{-1} soit $E_{2,\infty} - E_{-2,\infty} \simeq 38{,}4$ kcal·mol^{-1} donc $E_{2,\infty} \simeq 40{,}6$ kcal·mol^{-1}, compatible avec les valeurs expérimentales élevées. Mais il semble que des travaux (39–43), confirmés par l'étude récente de l'équilibre $H\cdot + C_2H_4 \rightleftarrows C_2H_5\cdot$ par Pilling et coll. (8), tendent à attribuer à $\Delta H^0_f(C_2H_5\cdot)$ une valeur plus élevée : $\simeq$28,4 kcal·mol^{-1} qui conduit à $E_{2,\infty} - E_{-2,\infty} \simeq 35{,}8$ kcal·mol^{-1} à 800 K. La valeur $E_{-2,\infty} = 2{,}16$ kcal·mol^{-1} proposée par Lightfoot et Pilling (9) vers 600 K donne alors : $E_{2,\infty} \simeq 38{,}0$ kcal·mol^{-1} en accord avec les faibles valeurs expérimentales, en particulier celle de Trenwith (7), ainsi qu'avec la valeur admise par Tsang (43) : 38,4 kcal·mol^{-1}, à 600 K.

En revanche, dans un article très récent, Grela et Colussi (44) estiment l'énergie d'activation $E_{2,\infty}$ à 0 K à 39,7 kcal·mol^{-1}, ce qui, compte-tenu des fréquences qu'ils adoptent pour le radical éthyle et le complexe activé (45), conduit à : $\Delta U_2^{0\neq} \simeq 40{,}2$ kcal·mol^{-1} à 800 K donc à une valeur élevée de $E_{2,\infty} \simeq 41{,}8$ kcal·mol^{-1} à 800 K. Il est à noter que ces auteurs admettent, dans leurs calculs, la nouvelle valeur de $\Delta H^0_f(C_2H_5\cdot) \simeq 28{,}2$ kcal·mol^{-1} et un jeu de fréquences qui leur permet de retrouver certaines caractéristiques de l'état de transition obtenues par les calculs «*ab initio*» de Schlegel (45) ainsi qu'un facteur de fréquence de $10^{13,5}\,s^{-1}$ à 600 K, très voisin de celui ($10^{13,4}\,s^{-1}$ à 600 K) retenu par Tsang (43). Malgré cela, il semble y avoir une incohérence interne dans ce travail puisque la nouvelle valeur de $\Delta H^0_f(C_2H_5\cdot)$ conduit, comme on l'a vu, à $E_{2,\infty} - E_{-2,\infty} \simeq 35{,}8$ kcal·mol^{-1} à 800 K, ce qui donnerait $E_{-2,\infty} \simeq 6$ kcal·mol^{-1}, valeur manifestement trop élevée.

Dans le tableau 6 on a rassemblé nos valeurs expérimentales de $k_{2,\infty}$ et $k_{2,0}$ à 813 K et celles, calculées, à 813 et 902 K, de ces mêmes grandeurs à partir des paramètres cinétiques du tableau 5. Figurent également les valeurs déduites des travaux de Pilling et coll. sur la thermochimie (8) et sur la cinétique de la réaction inverse (9). Enfin on y trouve les valeurs proposées à la seule température de 902 K par Pacey et Wimalasena (23) ainsi que celles calculées à partir des expressions de Tsang (43) et Grela et Colussi (44).

Compte-tenu de l'incertitude indiquée par Pilling, on voit qu'à 813 K, l'accord est excellent entre nos valeurs $k_{2,\infty}$ et la sienne. En particulier l'écart par rapport à notre valeur RRKM n'est que de 5%, ce qui est remarquable. Les résultats obtenus à partir de l'expression de Tsang sont également compatibles avec les précédents. Compte-tenu des incertitudes, la valeur proposée par Pacey est très voisine des précédentes à 902 K.

TABLEAU 6. Comparaison des valeurs numériques de $k_{2,\infty}$ et $k_{2,0}$ à 813 et 902 K, tirées des expressions du tableau 5 (à 813 K les valeurs du présent travail sont les valeurs «expérimentales»)

Références		$T = 813$ K		$T = 902$ K	
		$k_{2,\infty}$ (s^{-1})	$k_{2,0} \times 10^{-8}$ ($cm^3 \cdot mol^{-1} \cdot s^{-1}$)	$k_{2,\infty} \times 10^{-4}$ (s^{-1})	$k_{2,0} \times 10^{-9}$ ($cm^3 \cdot mol^{-1} \cdot s^{-1}$)

43		1200		1,3	
44		420		0,54	

Il n'en est pas de même pour les résultats de Trenwith, systématiquement trop bas, vraisemblablement à cause du faible facteur préexponentiel. Même remarque pour les valeurs récentes de Grela et Colussi, la raison étant cette fois la trop forte énergie d'activation.

Compte-tenu de ce qui précède on peut donc proposer une expression d'Arrhenius de la forme :

$$k_{2,\infty}(s^{-1}) = 10^{13,2} \exp\left(-\frac{38\,000}{RT}\right)$$

compatible avec les expressions fournies par Trenwith (7), Pilling (8, 9) et Tsang (43) et avec les valeurs expérimentales de Pacey (23) et les nôtres.

Comparaison des paramètres à basse pression

Comme le montre le tableau 5 il n'y a pas d'expression d'Arrhenius récente pour $k_{2,0}$ dans la littérature. On peut toutefois déduire des deux articles de Pilling et coll. (8, 9) l'expression : $k_{2,0} \simeq 10^{18,5} \exp(-37\,000/RT)\ cm^3 \cdot mol^{-1} \cdot s^{-1}$ vers 800 K. La valeur $E_{2,0} \simeq 37$ kcal·mol^{-1} correspond très exactement à celle obtenue, dans notre travail, par la méthode Troe 2. Rappelons que Pilling et coll. ont utilisé cette même méthode pour le traitement de leurs résultats sur la réaction inverse. Il y a donc là une excellente cohérence des deux travaux.

Néanmoins cette valeur est probablement trop forte. En effet, l'écart entre les valeurs $E_{2,\infty}$ et $E_{2,0}$ déduites de l'étude de Pilling est environ 1 kcal·mol^{-1}. Or il a été montré (32, 33) que $E_\infty - E_0 \simeq S_K RT$ soit ici environ 7,5 kcal·mol^{-1} (à 813 K). Même si l'incertitude sur S_K est 1, cette différence est encore de l'ordre de 5–6 kcal·mol^{-1}. Ce problème est encore aggravé par le fait que la valeur $E_{2,0} = 37$ kcal·mol^{-1} est déduite de travaux sur la réaction inverse utilisant l'hélium comme gaz inerte. Cette valeur correspondrait donc à la décomposition du radical éthyle dans le cas de collisions faibles. L'éthane étant un partenaire de choc plus efficace que l'hélium on devrait observer une valeur $E_{2,0} > 37$ kcal·mol^{-1}. On aurait alors une valeur $E_{2,0}$ voisine, ou même supérieure, à l'énergie critique E^0, ce qui n'est pas raisonnable (46).

Nous pensons que des valeurs $E_{2,0}$ de l'ordre de 34–35 kcal·mol^{-1} sont plus vraisemblables. Notons que notre valeur RRKM (34,9 kcal·mol^{-1}) est compatible avec la valeur correspondante $E_{2,\infty} = 41$ kcal·mol^{-1} et l'écart $E_{2,\infty} - E_{2,0}$ signalé plus haut. Il en est de même avec les expressions de Lin et Laidler (35) et également de Lin et Back (2), compte-tenu des incertitudes.

Comme le montre le tableau 6, il existe un facteur 2, à 813 K, entre notre valeur $k_{2,0}$ (RRKM) et la valeur obtenue à partir des travaux de Pilling. Ce facteur se retrouve à 902 K mais les deux résultats sont compatibles avec la valeur ponctuelle proposée par Pacey et coll. (23), ce qui est remarquable.

La cohérence des résultats entre le traitement RRKM effectué par Lin et Laidler (35) (sur les travaux de Lin et Back et Loucks et Laidler) et notre propre traitement RRKM nous amène à proposer, pour $k_{2,0}$, une expression du type :

$$k_{2,0}(cm^3 \cdot mol^{-1} \cdot s^{-1}) = 10^{18,3} \exp\left(-\frac{34\,900}{RT}\right)$$

qui conduit à une valeur à 902 K en très bon accord avec celle de Pacey.

Conclusion

L'analyse des résultats les plus récents sur la décomposition thermique du radical éthyle montre qu'il existe maintenant un assez bon accord entre les valeurs numériques de $k_{2,\infty}$ et $k_{2,0}$ obtenues, ponctuellement, à certaines températures. En revanche les expressions d'Arrhenius de ces deux constantes limites diffèrent encore sensiblement les unes des autres. Si l'on tient compte de la nouvelle valeur de $\Delta H^0_f(C_2H_5\cdot)$ et de la différence prévue théoriquement entre $E_{2,\infty}$ et $E_{2,0}$, il nous semble que les deux expressions :

$$k_{2,\infty}(s^{-1}) = 10^{13,2} \exp\left(-\frac{38\,000}{RT}\right)$$

$$k_{2,0}(cm^3 \cdot mol^{-1} \cdot s^{-1}) = 10^{18,3} \exp\left(-\frac{34\,900}{RT}\right)$$

représentent au mieux l'ensemble des résultats expérimentaux.

L'efficacité de désactivation λ ou β_c de la molécule d'éthane

semble être voisine de 0,4 vers 800 K (0,4 par RRKM et 0,45 par Troe 2), en parfait accord avec les travaux de Trenwith (7), ce qui correspond à $\langle \Delta E \rangle \simeq 13\ \text{kJ}\cdot\text{mol}^{-1}$. La valeur $\langle \Delta E \rangle \simeq 20\ \text{kJ}\cdot\text{mol}^{-1}$ (31), adoptée par Lightfoot et Pilling (9) paraît trop élevée et conduirait à une valeur $\beta_c \simeq 0{,}55$ vers 800 K, incompatible avec nos résultats et ceux de Trenwith.

Cobalt(II) and nickel(II) thiolates, $M(SR)_2$, can be prepared in high yield by the electrochemical oxidation of a metal anode in an acetonitrile or acetone solution of RSH (R = C_6H_5, *o*-$CH_3C_6H_4$, 2-$C_{10}H_7$, 2,3,4,5-C_6F_4H; not all combinations). When 2,2-bipyridine or 1,10-phenanthroline (=L) is added to the electrolyte phase, the products are the adducts $M(SR)_2L_2$. In the case of $Co(SC_6H_5)_2(phen)_2$, aerial oxidation leads to the formation of the cobalt(III) cation $[Co(SC_6H_5)_2(phen)_2]^+$, isolated as the perchlorate salt. X-ray crystallographic analysis showed that this cation has a *cis*-$CoS_2(N_2)_2$ kernel.

RAJ K. CHADHA, RAJESH KUMAR, JAIME ROMERO LOPEZ-GRADO et DENNIS G. TUCK. Can. J. Chem. **66**, 2151 (1988).

Opérant avec des solutions de RSH (R = C_6H_5-, *o*-$CH_3C_6H_4$-, $C_{10}H_7$-2, F_4-2,3,4,5-C_6H-; pas toutes les combinaisons) dans l'acétonitrile ou l'acétone et faisant appel à une oxydation électrochimique d'une anode métallique, on peut préparer les thiolates de cobalt(II) ou de nickel(II), $M(SR)_2$, avec d'excellents rendements. Lorsqu'on ajoute de la bipyridine-2,2 ou de la phénanthroline-1,10 (=L) à la phase électrolytique, les produits qui se forment sont les adduits $M(SR)_2L_2$. Dans le cas du $Co(SC_6H_5)_2(phen)_2$, l'oxydation par l'air conduit à la formation du cation Co(III), $[Co(SC_6H_5)_2(phen)_2]^+$, qui est isolé sous la forme d'un perchlorate. Une analyse par diffraction des rayons-X a démontré que le noyau de ce cation est formé de $CoS_2(N_2)_2$-*cis*.

[Traduit par la revue]

Introduction

The thiolato derivatives of transition metal elements have been the subject of considerable recent interest, in large measure because a number of these compounds are believed to serve as models for active metal–sulphur sites in metalloproteins (1). In previous papers from this laboratory, we have shown that the technique of direct electrochemical synthesis can be used to prepare thiolato compounds of d^{10} metal ions in high yield by a simple one-step room temperature reaction (2–6). The present paper describes the successful application of this method to the synthesis of various $Co(SR)_2$ and $Ni(SR)_2$ compounds, and of a number of neutral adducts. In the course of working up one of the preparations, we obtained crystals of $[Co(SC_6H_5)_2(phen)_2]ClO_4$ (phen = 1,10-phenanthroline), and the crystal structure of this compound is also discussed.

Experimental section

Materials

Solvents were distilled from and stored over drying agents (acetonitrile – calcium hydride; acetone – anhydrous sodium sulphate). Thiols, and neutral ligands, were used as supplied (Aldrich). Cobalt was used as sheets 0.5 mm thick, and nickel as a wire (0.5 mm diameter), or better, as a rod (0.5 cm diameter). These metals were washed with dilute aqueous nitric acid and then distilled water, dried, and finally abraded with fine sandpaper.

Analysis and spectroscopy

Metal analysis was performed by atomic absorption spectrophotometry, using an IL 151/251 instrument. Microanalysis on selected compounds was performed by Guelph Chemical Laboratories Ltd. Infrared spectra were recorded on a Nicolet 5DX instrument. The magnetic susceptibility measurements were determined by the Gouy method using a Newport instrument with a VR3 power source.

Electrochemical procedures

The electrochemical syntheses utilized the methods described elsewhere (4,7). The cells were of the general type

$$Pt_{(-)}/CH_3CN(\text{or acetone}) + RSH\,(+\text{ ligand})\text{-}/M_{(+)}\,(M = Co, Ni)$$

using a 100-mL tall form beaker to contain the solution, with the anode suspended in the solution via a platinum wire. All experiments were carried out under an atmosphere of dry nitrogen, which also served to stir the reaction mixture as it bubbled gently through the solution. Details of solution composition, and the electrochemical conditions, are given in Table 1; isolation procedures are outlined below. Analytical results are reported in Table 2. Yields were generally in excess of 90%, based on the quantity of metal dissolved from the anode.

$M(SR)_2$ (M = Co, Ni; R = C_6H_5, 2,3,5,6-C_6F_4H, o-$CH_3C_6H_4$, 2-$C_{10}H_7$)

The brown–red products precipitated from the anode as the reaction proceeded, and were collected, washed with CH_3CN, or acetone (15 mL) and then *n*-pentane or diethyl ether (10 mL), and dried *in vacuo*. The products are all insoluble in aromatic solvents, acetonitrile, dimethylsulphoxide, and dimethylformamide, but are slightly soluble in pyridine; this latter solubility increases with temperature.

$M(SR)_2L_2$ (L = 2,2'-bipyridine, 1,10-phenanthroline)

As the electrolysis proceeded, the colour of the solution changed from pale brown to deep red–brown for cobalt, and to green for nickel. After the end of the electrolysis, the flow of nitrogen through the solution was continued for periods of 2–16 h during which time crystals deposited in the cell as the solvent slowly evaporated. These crystals were collected, washed with cold solvent and then diethyl ether, and dried *in vacuo*. The compounds are soluble in acetonitrile or dimethylsulphoxide, but insoluble in aromatics.

With chloroform, there is evidence of reaction, since colour changes were generally observed. In a brief study, $Ni(SC_6H_5)_2(phen)_2$ (0.61 g) was suspended in chloroform (60 mL) and the mixture stirred for 3 days at 20°C under nitrogen. The green solid gradually dissolved to give a yellow solution which slowly deposited a green–yellow solid which was collected, washed with $CHCl_3$ (10 mL) and dried *in vacuo*. Yield 0.51 g. Analysis Ni 9.8, Cl 11.3; c.f. $NiCl_2(phen)_2$: calcd. Ni 12.0, Cl 14.5; $NiCl(SC_6H_5)(phen)_2$: calcd. Ni 10.4, Cl 6.3. The filtrate from this reaction was taken to dryness, and the resultant red–yellow solid extracted with diethyl ether (100 mL). This extract contained $(C_6H_5)_2S_2$;

mp 55°C (c.f. 58°C for a genuine sample), ^1H nmr spectrum identical with that of a genuine sample (7.07–7.63 m ppm from Me_4Si). The residue from this ether extraction (80 mg) had Ni 8.5%. This evidence does not allow us to identify the reaction unambiguously, but it appears to be similar to that observed with $CuSC_6H_5(phen)$, where $(C_6H_5)_2S_2$ and a copper(I) chloride derivative were identified (5).

[Co(SC$_6$H$_5$)$_2$(phen)$_2$]ClO$_4$(1)

In investigating the Co/C_6H_5SH/phen system, we observed a colour change from red–brown to green when the solution was exposed to air. In a subsequent experiment, oxygen was bubbled through a solution prepared in the way described above; green crystals deposited on slow evaporation of the cooled solution. These were collected,

washed with *n*-pentane (10 mL) and dried *in vacuo*. *Anal.* calcd. for $C_{36}N_{26}N_4S_2CoClO_4$: C 58.7, H 3.6, N 7.6, Co 8.0; found: C 59.3, H 3.4, N 7.6, Co 7.9.

The uv/visible spectrum of **1** had λ_{max} = 395 nm, $\epsilon = 2.2 \times 10^4$ mol^{-1} L cm^{-1}. A prominent feature of the infrared spectrum was a broad strong band at 1070 cm^{-1}, identified as ν_3 of ClO_4^-.

Crystallographic analysis

A suitable crystal of $[Co(SC_6H_5)_2(phen)_2]ClO_4$ (**1**), prepared by the method described above, was sealed in a capillary tube and mounted along the largest dimension in a Syntex $P2_1$ diffractometer. The cell dimensions (Table 3) were obtained from the least squares refinement of the setting angles of 15 high angle reflections ($15° > 2\theta > 30°$). The density was determined by flotation in carbon tetrachloride/benzene mixtures.

Relevant information on the X-ray crystallographic experiment is given in Table 3. The intensities of three mounted reflections did not change significantly during the data collection. Details of the collection and reduction of the experimental data, and the sources of the scattering factors and computer programmes used, have been described previously (8, 9).

The intensity statistics suggested a centric space group, and the space group $P\bar{1}$ was assumed, and subsequently confirmed by a successful refinement. The position of the cobalt atom was determined by a sharpened Patterson synthesis using SHELX, and the remaining atoms were revealed by subsequent difference maps. The cobalt, sulfur, nitrogen, chlorine, and oxygen atoms of **1** were refined anisotropically, and the remainder isotropically. Hydrogen atoms were included in the final refinements in ideal positions (C—H = 0.95 Å, CCH = 120°), with isotropic U-values set at 0.1 Å^2 greater than those of the corresponding carbon atoms. The function minimized in the least squares refinement was $(|F_o| - |F_c|)^2$, and a weighting scheme of the form $\omega = 1/[\sigma^2(F) + \rho f^2]$ was used, with a final ρ-value of 0.0001. No evidence of secondary extinction was found. The refinement converged at R = 0.0995, and R_w = 0.101. These high values are apparently related to the high thermal parameters of the oxygen atoms of the perchlorate anion and to an unresolved disorder problem in the anion; neither of these affect the details of the structure of the cation.

The final coordinates for the non-hydrogen atoms are given in Table 4 and important bond distances and angles in Table 5. Tables of fractional coordinates and thermal parameters for hydrogen atoms, of anisotropic thermal parameters, and of observed and calculated structure factors have been deposited, as has a packing diagram of the unit cell.[4]

Results and discussion

Preparative

As with other direct electrochemical syntheses developed in this laboratory, the anodic oxidation of cobalt or nickel in the presence of a thiol is a simple efficient one-step route to $Co(SR)_2$ and $Ni(SR)_2$ species. The present experiments involved the preparation of only small quantities of product in short experiments, but larger cells, or cells run in series, are easily operated for the synthesis of gram quantities of product. The characterization of these substances depended on elemental analysis, and on infrared spectroscopy which confirmed the presence of the appropriate SR and neutral donor ligands.

The average E_F value (defined as moles of metal dissolved per Faraday of charge) for the formation of $M(SR)_2$ (see Table 1) is 0.50 mol F^{-1} for Co, and 0.44 mol F^{-1} for Ni, although in the latter case the average is significantly affected by the result for *o*-$CH_3C_6H_4SH$, where the product adhered to the electrode thereby lowering the efficiency of the anode reaction. The overall average of ~0.50 mol F^{-1}, and the formation of H_2 at the cathode, is in keeping with the mechanism proposed previously (1):

$$\text{cathode: } 2RSH + 2e \rightarrow H_2 + 2RS^-$$

$$\text{anode: } 2RS^- + M \rightarrow M(SR)_2 + 2e$$

We may note here that this same E_F, and hence the same mechanism, applies to the formation of $M(SR)_2L_2$ adducts (L = bpy, phen), confirming that adduct formation follows the anodic oxidation process. A number of E_F values below 0.5 were observed, and in each case this was associated with the formation of materials adhering to the anode.

The insolubility of $M(SR)_2$ in common organic solvents other than pyridine for M = Co or Ni is similar to the behavior of other simple metal thiolates (2, 5, 10), and is most likely due to extensive secondary coordination, linking together $M(SR)_2$ units by S→M donation, which would be in keeping with the known ability of both Co^{II} and Ni^{II} to form four-coordinate $M(SR)_4^{2-}$ complexes (11, 12), and with the physical properties of these and other $M(SR)_2$ compounds.

All the cobalt(II) and nickel(II) $M(SR)_2$ compounds prepared form adducts with the bidentate donors bpy and phen. Surprisingly such compounds do not appear to have been reported previously. Given their solubility in organic solvents, and the known coordination chemistry of the two elements, these compounds can all be reasonably classified as monomeric species, with *cis*-$MS_2(N_2)_2$ coordination kernels. Magnetic studies on two such compounds, namely $Co(SC_6H_5)_2(phen)_2$ and $Ni(SC_6H_5)_2(phen)_2$, gave corrected values of μ_{eff} = 2.70 and 3.30 BM, respectively. For the nickel(II) compound, the magnetic moment is at the high end of the range of values reported for octahedral d^8 species (13), which is explicable in

[a] U_{eq} for the non hydrogen atoms is calculated from the refined anisotropic thermal parameters ($U_{eq} = 1/3\ \Sigma_i\Sigma_j U_{ij} a_i^* a_j^* a_i \cdot a_j$).

terms of a strong distortion from O_h symmetry in the NiS_2N_4 kernel, plus a significant orbital contribution. The result for the cobalt complex shows that this is an example of the unusual low-spin d^7 state, arising from the presence of the high field 1,10-phenanthroline ligands and the low symmetry (13), which persists on oxidation as shown in the next section. The redox chemistry of such compounds might prove interesting, given the ease with which the cobalt(III) species **1** is formed by aerial oxidation.

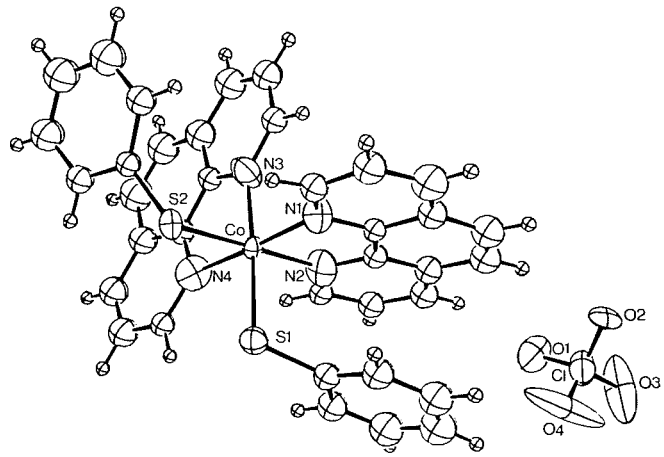

FIG. 1. Molecular structure of $[Co(SC_6H_5)_2(phen)_2]ClO_4$ showing the atomic numbering scheme. Ortep diagram, with 50% probability ellipsoids.

Structure of $[Co(SPh)_2(phen)_2]ClO_4$

The X-ray crystallographic results show unambiguously that **1** is indeed the 1:1 salt of a cobalt(III) complex, with the cation balanced by a perchlorato anion whose origin must be in the Et_4NClO_4 added to the electrolyte solution as part of our standard technique to enhance the initial conductivity (see Table 1). There is little doubt that the formation of this compound is the result of aerial oxidation, which is a common feature of the chemistry of cobalt(II). The structural features of the ClO_4^- anion in **1** are those of a slightly distorted tetrahedral anion, with r(Cl—O) = 1.35(3) Å (av) and O—Cl—O = 110(4)° (av), values which call for no special comment.

The cation (see Fig. 1), with its *cis*-CoS_2N_4 kernel of distorted octahedral geometry, is one of the few examples of a cobalt(III)–thiolato complexes, although several cobalt(II) compounds have been studied crystallographically (11, 12). Both mononuclear and polynuclear cobalt (III) structures with such ligands have been identified. The square-planar $[Co(S\text{-}2,4,6\text{-}i\text{-}Pr_3C_6H_2)_4]^-$ anion (**2**) has been investigated (14), as have polymeric $Co(SR)_3$ compounds (15, 16) and the square-planar $[Co(S_2\text{-}1,2\text{-}C_2H_4)_2]^-$ anion (17), and these provide a limited basis against which to compare the present results. The average Co—S bond distance in **1** is 2.297(4) Å, while in **2** the average is 2.207(3) Å, and this contraction is explicable in terms of the lower coordination number. The average Co—S distance in octahedral $Co^{III}S_6$ complexes has been given (18) as 2.27 Å, although there are no structures which are directly comparable with **1**. In the cation $[Co(ttcn)_2]^{3+}$ (ttcn = 1,4,7-trithiacyclononane, $C_6H_{12}S_3$), the average Co—S bond length in the CoS_6 octahedral kernel is 2.253(3) Å (19), and the analogous values in the cobalt(III)–thiosulphate complexes $[(en)_2Co(NO_2)(S_2O_3)]$ and $[(en)_2Co(S_2O_3)_2]^+$ are 2.281(3) and 2.263(3) Å, respectively (20), but such molecules are obviously different in ligand type from **1**, and the overall conclusion can only be that the present value is compatible with those in the literature as far as the comparisons can be made at present.

The Co^{III}—N bond distances in **1** give an average value of 1.97(1) Å. There are many reports of crystallographic studies of Co^{III}—N donors, but the most relevant and direct comparison is

Dérivés hydrosilylés des complexes (η-arène) tricarbonylchrome, de type (η C_6R_6)$(CO)_2$Cr(H)$SiHPh_2$; liaison à 2 électrons/3 centres, Cr—H—Si

ELISABETH MATARASSO-TCHIROUKHINE ET GÉRARD JAOUEN

École nationale supérieure de chimie de Paris, Unité Associée 403, 11, rue Pierre et Marie Curie, 75231 Paris CEDEX 05, France

Reçu le 26 octobre 1987

ELISABETH MATARASSO-TCHIROUKHINE et GÉRARD JAOUEN. Can. J. Chem. **66**, 2157 (1988).

L'action photochimique, à basse température, du diphénylsilane sur les complexes (η arène) tricarbonylchrome conduit à des dérivés hydrosilylés instables, de type (η C_6R_6)$(CO)_2$Cr(H)$SiHPh_2$, qui possèdent une liaison à 2 électrons/3 centres, Cr—H—Si. Le degré de cette liaison est supérieur à celui de la liaison Mn—H—Si dans les complexes isoélectroniques du manganèse, (η C_5R_5)L_2Mn(H)$SiHPh_2$, d'une part, et à celui de la liaison Cr—H—Si dans le complexe permethylé, (η C_6Me_6)$(CO)_2$Cr(H)$SiHPh_2$, d'autre part. La variation de $|^2J$(Cr—H—Si)| est discutée en fonction de la densité électronique sur le métal.

ELISABETH MATARASSO-TCHIROUKHINE and GÉRARD JAOUEN. Can. J. Chem. **66**, 2157 (1988).

Diphenylsilane reacts photochemically, at low temperature, on the η(tricarbonylchromium) arenes, to give unstables hydrosilylcomplexes, (η-C_6R_6)$(CO)_2$Cr(H)$SiHPh_2$ with a three-center two-electron bond, Cr—H—Si; according to ^{29}Si NMR data, the degree of this bond is higher than both the degree of the Mn—H—Si bond in isoelectronic manganese compounds, (η-C_5R_5)L_2Mn(H)$SiHPh_2$, and the degree of the three-center Cr—H—Si bond in the permethylated complex, (η-C_6Me_6)$(CO)_2$Cr(H)$SiHPh_2$, of chromium. The variation of $|^2J$(Si—Cr—H)| depending on the electron density of the metal is discussed.

Introduction

L'addition oxydante des silanes sur les métaux de transition se rattache à un problème qui a suscité beaucoup d'intérêt au cours des deux dernières décennies (1, 2); en effet, elle conduit à des complexes qui jouent un rôle d'intermédiaires important dans les hydrosilylations catalysées par ces métaux. Il a été suggéré que ces réactions procèdent en faisant intervenir une liaison à 2 électrons/3 centres (3–5) (cf. schéma 1).

Les complexes du manganèse de type (η $C_5R'_5$)L_2Mn(H)-$SiR^1R^2R^3$, décrits déjà en 1970–1971 (6, 7), ont été, depuis, l'objet d'études exhaustives (8, 9). En effet, la mise en évidence dans ces complexes d'une liaison à 2 électrons/3 centres Mn—H—Si, comparable à la liaison agostique C—H—M (10), permet de les considérer comme des états « gelés » des coordonnées de la réaction d'addition oxydante des silanes (11).

Afin d'étudier *l'influence sur le degré 2e/3c de la liaison M—H—Si* de la *nature du métal*, d'une part, et de la *densité électronique sur le métal*, d'autre part, nous avons étendu l'étude de l'addition oxydante du diphénylsilane aux complexes (η arène) tricarbonylchrome.[1]

Résultats et discussion

Les complexes (η arène) tricarbonylchrome **1**(*a–d*) réagissent sur le diphénylsilane, par irradiation UV à basse température et sous atmosphère inerte, pour conduire aux complexes **2**(*a–d*) (cf. schéma 2), caractérisés par spectroscopie RMN des ^{1}H, ^{29}Si et ^{13}C.

Les complexes **2**(*a–d*) présentent, d'une part, *une très grande instabilité à l'air* et, d'autre part, *une très grande instabilité thermique*. Sous atmosphère inerte, à température ambiante, **2***a* est décomposé en quelques jours, **2**(*c* et *d*) instantanément et ils le sont rapidement au-dessus de −20°C.

Les complexes **2**(*a,b*) ont été isolés cristallisés; seul **2***a* a pu être purifié par recristallisation (**2***b* subit une décomposition).

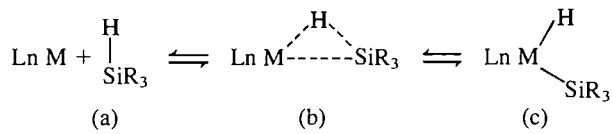

SCHÉMA 1

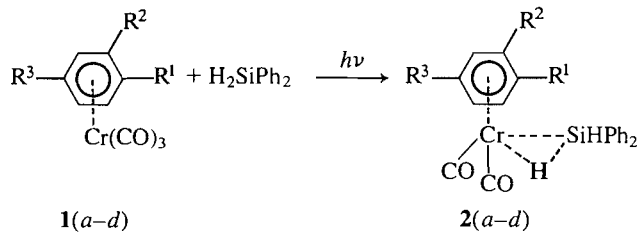

1(*a–d*) **2**(*a–d*)

1*a*, **2***a* $R^1 = R^2 = CH_3$; $R^3 = H$
1*b*, **2***b* $R^1 = CH_2N(CH_3)_2$; $R^2 = R^3 = H$
1*c*, **2***c* $R^1 = COOCH_3$; $R^2 = R^3 = H$
1*d*, **2***d* $R^1 = R^3 = COOCH_3$; $R^2 = H$

SCHÉMA 2

Les complexes **2**(*c,d*) très instables n'ont pu être cristallisés; les résultats obtenus, par specroscopie RMN des produits bruts, ont été confirmés par leur action sur PPh_3 qui conduit dans de bonnes conditions, par élimination réductrice du silane, aux complexes (η $R^1R^2C_6H_4$)$(CO)_2CrPPh_3$ (schéma 3).

Les complexes **2**(*a–d*) (cf. tableau 1) possèdent un proton lié au chrome (δ^1 H ~ −12 ppm) et un proton lié au silicium (δ^1 H ~ 6–7 ppm) dont le couplage $|^2J$(Si—Cr—H)| élevé, de l'ordre de 80 Hz, témoigne d'une liaison à 2 électrons/3 centres, Cr—H—Si. En effet, on sait (8) qu'une valeur élevée de $|^2J$(Si—M—H)|, comme $|^2J$(C—M—H)| pour la liaison agostique M—H—C (10), est caractéristique d'une liaison à 2 électrons/3 centres, M—H—Si, et sert de sonde pour la détermination du degré d'intéraction du silicium et de l'hydrogène: sa valeur absolue est en fonction croissante de cette

1. Pendant la dernière phase de ce travail est paru un article de U. Schubert *et al.* (12), concernant la structure et les propriétés du complexe (η Me_6C_6)$(CO)_2$Cr(H)$SiHPh_2$.

SCHÉMA 3

intéraction, c.a.d. du degré 2e/3c de la liaison à 2 électrons/3 centres M—H—Si.

Le degré 2e/3c de la liaison Cr—H—Si est supérieur à celui de la liaison Mn—H—Si dans les complexes du manganèse, de type (η $C_5R'_5$)(CO)LMn(H)(SiR_3) (8), pour lesquels ^2J(Mn—Si—H) ≤ 69 Hz; *^2J(Si—Cr—H) et ^1J(Si—H) sont fonction décroissantes de la densité électronique sur le métal* (cf. tableaux 1 et 2).[2]

L'accroissement de $|^1J$(Si—H)| a pour origine l'accroissement de l'électro-négativité du substituant au silicium (η C_6R_6)$(CO)_2$Cr (13).

L'accroissement de $|^2J$(Si—Cr—H)| peut avoir pour origine deux facteurs: (*a*) l'accroissement de l'électronégativité du substituant (η C_6R_6)$(CO)_2$Cr, au silicium, et (*b*) l'accroissement du degré de la liaison à 2 électrons/3 centres, Cr—H—Si.

Si l'on compare (cf. tableau 1) la variation, $\Delta|^2J|$ du couplage ^2J(Si—Cr—H) à la variation, $\Delta|^1J|$, du couplage ^1J(Si—H), il apparaît que :

1. *Lorsqu'on passe du dérivé perméthylé au complexe* **2**a $\Delta|^2J|$ *(~13%) est important par rapport à* $\Delta|^1J|$ *(~2%)*, ce qui permet de conclure à un *accroissement du degré de la liaison à 2 électrons/3 centres, Cr—H—Si.*

2. Lorsqu'on passe *du complexe* **2**a *au complexe* **2**d $\Delta|^2J|$ *(~2%) est faible par rapport à* $\Delta|^1J|$ *(~10%)* et peut avoir pour origine aussi bien la diminution de la densité électronique sur le métal que l'accroissement du degré de la liaison 2e/3c Cr—H—Si.

Toutefois, *l'instabilité thermique des complexes* **2**(*a–d*), également fonction décroissante de la densité électronique sur le métal, témoignerait en faveur de cette dernière hypothèse. En effet, on sait que l'instabilité thermique de ce type de complexes est liée à la tendance du silane à une élimination réductrice d'autant plus aisée que le degré d'intéraction Si—H est grand, nous avons montré par action de PPh_3 que l'élimination réductrice du silane dans le cas du complexe **2***c*, très lente à −40°C, devient aisée à 0°C, la vitesse de la réaction étant déterminée par la dissociation du complexe (14, 15) (cf. schéma 3).

La très faible variation de ^2J (dans les limites des erreurs expérimentales) observée (cf. tableau 1) en dépit d'une variation consistante de la densité électronique sur le métal, comme l'indique en spectroscopie IR la variation des fréquences $\nu(CO)_{Cr}$ (cf. tableau 2), suggère que la densité électronique sur le métal n'a qu'une influence très faible, sinon nulle, sur le caractère 2e/3c de la liaison Cr—H—Si pour les complexes **2**(*a–d*) de la série (η C_6R_6)$(CO)_2$Cr(H)$SiHPh_2$ étudiée.

Le dérivé perméthylé (η C_6Me_6)$(CO)_2$Cr(H)$SiHPh_2$ (12) se situe à part dans la série, avec un degré 2e/3c de la liaison Cr—H—Si, $|^2J$(Si—Cr—H)| = 70,8 Hz (12), relativement faible par rapport à ceux des autres complexes de la série $|^2J$(Si—Cr—H)| ~ 80 Hz, qui représenteraient des états gelés des coordonnées de l'addition oxydante du silane moins avancés, en d'autres termes, des états plus proche de (b) (cf. schéma 1).

Le déplacement chimique $\delta\,^{29}Si$ évolue vers les champs forts, lorsque la densité électronique sur le métal décroit. Un résultat analogue a été observé pour les complexes isoélectroniques du manganèse (η C_5R_5)(CO)LMn(H)$SiHPh_2$ (8).

L'addition oxydante du diphénylsilane aux complexes (η arène) tricarbonylchrome **1**(*c,d*), s'accompagne, dans les conditions expérimentales mises en jeu, d'une réaction secondaire non négligeable, qui conduit à des composés renfermant l'entité (SiH), mis en évidence dans le milieu réactionnel, en particulier, par la RMN du ^{29}Si.

Une première approche conduit à penser que ce sont des produits d'hydrosilylation, dont les complexes **2**(*c,d*) seraient les espèces précurseurs. Leur étude est en cours et fera l'objet d'une publication ultérieure.

Partie expérimentale

Toutes les manipulations concernant les produits sensibles à l'air ont été conduites en atmosphère inerte (argon) en utilisant la technique de Schlenk. Tous les solvants ont été distillés sur benzophénone Na avant usage. H_2SiPh_2 est préparé au laboratoire selon la réf. 16; il est distillé et conservé sous argon. $C_6H_5(COOCH_3)$, débarrassé de l'acide qu'il pouvait contenir, a été distillé sous argon sur hydrure de calcium et gardé sous argon. $C_6H_4(COOCH_3)_2$ et $Cr(CO)_6$, commerciaux, ont été dégazés sous pression réduite (environ 0,1 Torr; 1 Torr = 133,3 Pa) et gardés sous argon.

Complexes (η-arène) tricarbonyle chrome

Les complexes **1***a,b* ont été fournis par Monsieur G. Jaouen; les complexes **1***c,d* ont été préparé au laboratoire par action de $Cr(CO)_6$ sur l'arène correspondant avec une modification des techniques décrites (17, 18).[3]

$CH_3COOC_6H_5Cr(CO)_3$ ***1****c*: Une solution de $C_6H_5(COOCH_3)$ (6 mL) et de $Cr(CO)_6$ (2 g, 42) dans de l'oxyde de butyle (75 mL) à 10% de THF est portée à reflux à l'aide d'un bain d'huile à 130°C pendant 62 h. Le solvant est éliminé au rotavapor. Le solide résiduel est dissout dans du benzène et chromatographié sur colonne de silice, éluant hexane/benzène/éther (5:1:1); trois fractions sont isolées: I (têtes) (produits secondaires et $C_6H_5(COOCH_3)$ n'ayant pas réagit; II (**1***c*, produits secondaires et traces de $C_6H_5(COOCH_3)$; III (orangée), qui conduit au $C_6H_5(COOCH_3)Cr(CO)_3$ (**1***c*) par élimination du solvant au

2. Une conclusion identique a été émise (8) dans le cas des dérivés du manganèse, de type (η $C_5R'_5$)(CO)LMnHSiR_3, L = CO, PR_3, $P(OR)_3$, CNR. L'effet inverse observé dans le cas des composés (η C_5Me_5)$(CO)_2$Mn(H)$SiHPh_2$, ^2J = 65,4 Hz, et (η C_5H_4Me)$(CO)_2$-Mn(H)$SiHPh_2$, ^2J = 63,5 Hz, a été attribué à un effet stérique du noyau permethylé (8).

3. Les réactions sont délicates à conduire du fait de réactions secondaires et, à notre connaissance, non signalées dans la littérature, conduisant, en particulier à $C_6H_6Cr(CO)_3$, **1**′*c*, et $CH_3C_6H_5Cr(CO)_3$, **1**″*c*. Les vitesses de la complexation, ainsi que de la formation des complexes secondaires (qui atteint rapidement 100%), sont fonctions croissantes de la température de la réaction; il existe un rapport optimum *t*°C)/temps de la réaction.

Le tableau 3 rassemble les conditions expérimentales de la réaction photochimique. De façon générale, on irradie par une lampe Hanovia-450W, refroidie par une gaine à ciculation d'eau en quartz et placée à 5–10 cm du mélange réactionnel, une solution du complexe arène tricarbonyle chrome et de diphényle silane en excès, contenue dans un réacteur en Pyrex à double paroi, qui permet de refroidir le mélange

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/07/12
For personal use only.

réactionnel par la circulation d'un liquide approprié maintenu à basse température. Durant l'irradiation on fait passer un faible courant d'argon dans le mélange réactionnel agité. La réaction est suivie par spectroscopie infra-rouge, dans la région 2200–1700 cm^{-1} (cf. tableau 2). La réaction terminée, le traitement du mélange réactionnel varie légèrement suivant le complexe **2**(*a*–*d*) obtenu.

Dans le cas du composé **2***a*, qui est obtenu cristallisé dans le mélange réactionnel, le solvant est siphoné et le solide résiduel lavé plusieurs fois au 3-Me-pentane. Il est recristallisé à −40°C par addition de 3-Me-pentane, jusqu'à un léger trouble, à sa solution dans le minimum de toluène. Dans le cas du complexe **2***b* le mélange réactionnel est réduit à 1–2 mL en éliminant les solvants sous pression réduite, 20 mL de 3-Me-pentane sont ajoutés à la solution (formation d'un précipité flaconneux jaune) qui est maintenue à −40°C pendant 48 h. Un produit cristallisé, jaune-orangé, est ainsi obtenu; il est lavé plusieurs fois avec du 3-Me-pentane; les traces de solvant sont éliminées sous pression réduite à −40°C. Le produit brut ne se prête pas à la recristallisation selon la technique mise en jeu pour le composé **2***a* (décomposition). Dans le cas des complexes **2**(*c*,*d*), l'élimination du solvant à basse température conduit à un produit rouge-brun cristallisé pâteux.[5] Les tentatives de recristallisation ayant échoué (décomposition), les études spectroscopiques ont été réalisées sur les produits bruts.

Les spectres IR ont été enregistrés soit sur appareil Bomem-Michelson 100, soit sur appareil Bruker FT–IR 45.

Les spectres RMN ont été enregistrés sur appareil Bruker AM 250; les déplacements chimique de ^{29}Si ont été déterminés par rapport au diphénylsilane, pris comme référence interne, et reconvertis par rapport au TMS en prenant δ ^{29}Si diphenylsilane/TMS = −33,254 ppm, obtenu sur le même appareil avec le TMS comme référence interne.

5. Dans le cas du complexe **2***d*, en opérant comme dans le cas du complexe **2***b*, une seule et unique fois on a pu isoler des cristaux rouge vif se décomposant instantanément par élévation de *t* ou au contact de l'air. Il est vraisemblable que des traces d'impuretés accélèrent considérablement la décomposition.

Remerciements

Nous remercions Madame Hélène Le Pesant et Monsieur Yvon Besace pour leur assistance technique en spectroscopie IR–FT et RMN.

Symmetries of configurations of charges on a sphere

R. H. FRICKEL AND B. V. BRONK

Chemical Research Development and Engineering Center, Aberdeen Proving Ground, Maryland 21010-5423, U.S.A.

Received June 1, 1987[1]

R. H. FRICKEL and B. V. BRONK. Can. J. Chem. **66**, 2161 (1988).

New equilibrium figures are obtained for finite numbers of point charges confined to a sphere and interacting via a Coulomb potential. The symmetries of the configurations are classified for all cases up to a charge number of forty. Features of the geometry of the configurations are discussed and shown on equal area projections. The substantial number of configurations now available permit study of frequency of occurrence of various symmetries and persistence of certain geometries over a range of charge numbers, as well as detailed comparison of similarities and differences of the present global minimum energy figures with corresponding close packed structures.

R. H. FRICKEL et B. V. BRONK. Can. J. Chem. **66**, 2161 (1988).

On a obtenu de nouvelles valeurs pour les équilibres de charges ponctuelles à nombres finis, confinées a une sphère et qui interagissent par le biais d'un potentiel de Coulomb. Pour tous les cas jusqu'à quarante charges, on a pu établir une classification des symétries de configuration. On discute des caractéristiques de la géométrie des configurations et on les présente sur des aires de projection qui sont égales. Le très grand nombre de configurations qui sont maintenant disponibles permet d'étudier la fréquence d'apparition de diverses symétries et la persistance de certaines géométries pour des valeurs très différentes de nombres de charges ainsi que de faire une comparaison détaillée des similarités et des différences qui existent entre les valeurs actuelles de l'énergie globale minimale avec les structures correspondantes fermées.

Introduction

The problem of arranging points on a sphere subject to extremal conditions is well-known to relate to many problems in physical chemistry. These include applications as basic as using minimal configurations to predict the polyhedral shapes of molecules as in the lone electron-pair model (1, 2). Further, many more contemporary problems such as arrangements of molecules on the surface of microdroplets, atoms in clusters (3), self-assembly of virus particles into macromolecular polyhedra, and examples of structural phase changes (4) are related to such configurations (see also refs. 5, 6, and 7).

In the present paper we examine the symmetries and changes of symmetry which occur when charged particles interact with each other via coulomb forces but are constrained to remain on the surface of a sphere. We reexamine the early examples studied by Foeppl (8) as well as more recent tabulations of the Coulomb case (9) and extend that case for n up to 40. We present several new equilibrium figures with lower Coulomb energy than that previously presented for the same charge number. We also present tabulations which allow one to see which symmetries recur most often and note the persistence of certain patterns for configurations. The present problem is a special case of the more general problem of finding the minimum energy configuration on a sphere for n particles interacting with energy

$$[1] \quad E = \tfrac{1}{2} \sum_{i=1}^{n} \sum_{\substack{j=1 \\ j \neq i}}^{n} \left| \bar{r}_i - \bar{r}_j \right|^{-m}$$

where $\bar{r}_i$ is the position of the i^{th} particle and m is arbitrary. Melnyk *et al.* (10) reviewed the relationship among equilibrium figures for various values of m for n between 3 and 16. The closest packing of hard spheres or inflexible circles ($m = \infty$) was recently extended for values of n up to 40 by Clare and Kepert (11).

[1]Revision received February 25, 1988.

2. Approach

In our calculations we fix the center of the sphere at the origin, set $r_i = 1$ and minimize the energy as defined in eq. [1] for $m = 1$, starting from arbitrarily specified initial charge positions on the sphere's surface. The charges are recursively moved, each by a small displacement proportional to the tangential force on it due to all the other charges, until the positions converge to an equilibrium configuration. We will subsequently use the abbreviation CCn to refer to the lowest-energy coulomb-equilibrium charge configurations (MCEC's) that we have computed (or recomputed) in this way.

Each configuration produced by this scheme was computed at least twice from independent initial configurations. Except in one instance for $n = 16$ and one for $n = 32$, discussed below, only one lowest-energy equilibrium configuration was found for each charge number.

We examined the symmetries using equal area projections, different edge lengths in each configuration being represented by different line types. As seen in Figs. 1–3, this representation allows configuration symmetries as well as similarities and differences between different configurations to be much more readily visualized than do more commonly encountered symmetry diagrams.

3. Discussion and results

The results of the present study and comparison with previous studies are presented in Tables 1 and 2. The total coulomb energy, point group, and the number of sets of equivalently situated charges suffice to identify the configuration. (Specific angular coordinates for most of the cases presented here are available in ref. 12.) Sources for previously reported MCEC's are listed in Table 1; data for other coulomb equilibrium configurations of interest are displayed at the end of the table. The point group classifications are summarized in Table 2.

3.1. Previous work

The symmetry and general structure of MCEC's presented by

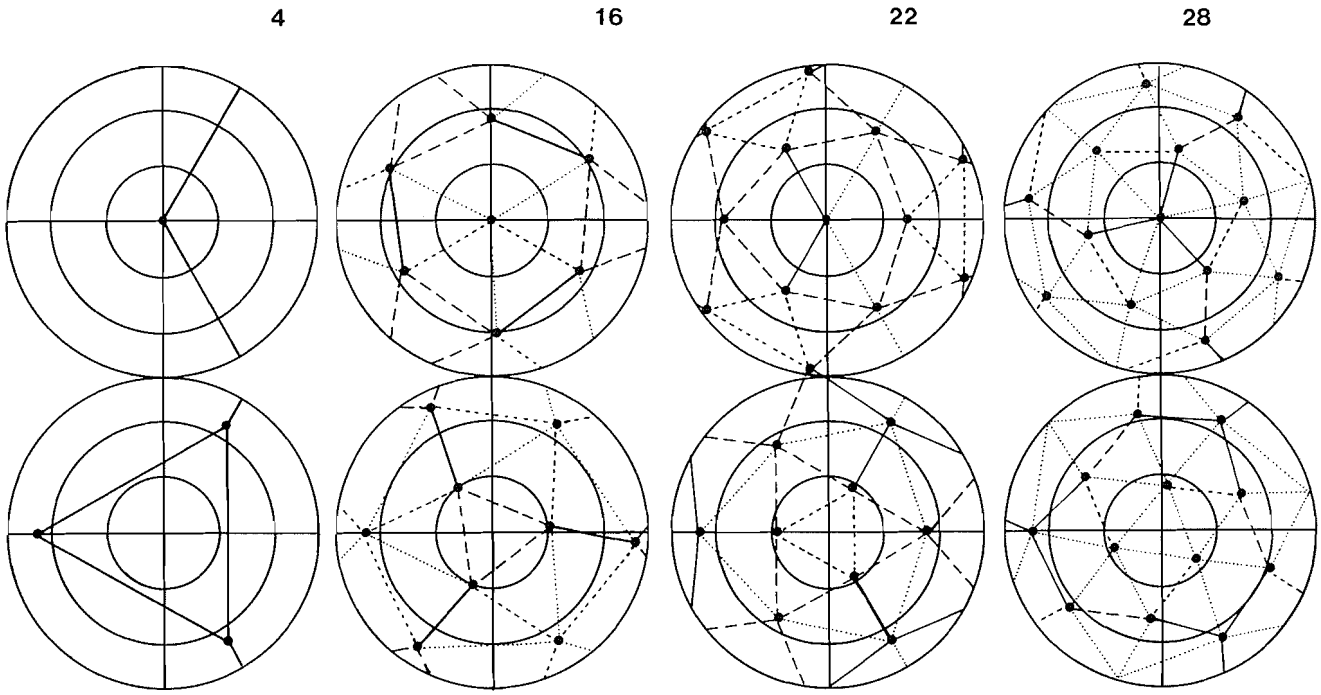

FIG. 1. Equal-area projections of the four tetrahedral configurations (CC4, CC16, CC22, and CC28). Both hemispheres are shown as seen from above. The four corners of the tetrahedron are shown in the same positions in all four configurations. For each configuration the edges of shortest length are shown as solid lines, the next shortest as long-dashed lines, and the next as short-dashed lines. Edges of greater length are shown as dotted lines. These edge-length keys also apply to the Figs. 2 and 3.

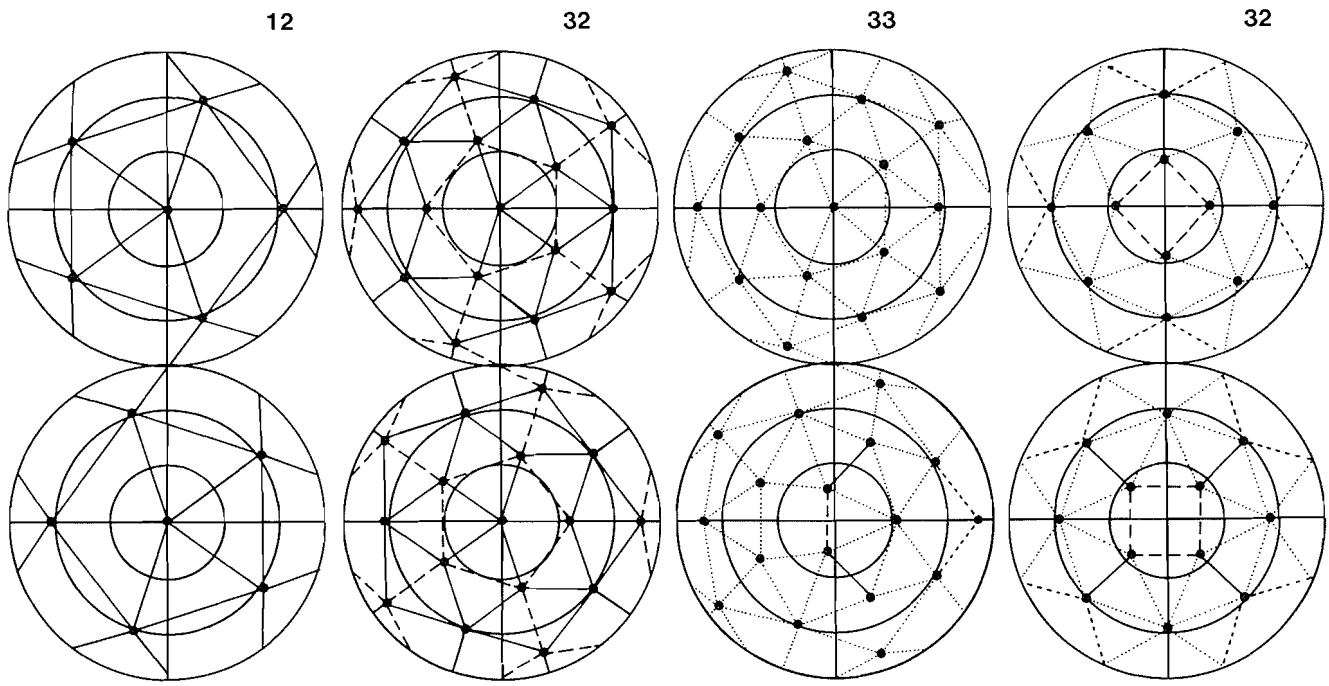

FIG. 2. CC12, CC32, and CC33. CC12 (the icosahedron) and CC32 (which has all the points of both the icosahedron and the dodecahedron) belong to the I_h group. CC33 has only a reflection plane (the horizontal axis in the diagram) but one can see that the upper hemisphere almost retains the structure and the C_5 symmetry of CC32. In the lower hemisphere the 33rd point appears to have been inserted near the pole, altering the structure. The anomalous D_{4d} 32-charge configuration is also shown.

Foeppl (8) for $n = 2$ through 8, 10, 12, and 14, by Cohn (13) for $n = 9$ and 11, and by Melnyk (10) for $n = 13$ and 15 were confirmed (or reconfirmed) by us. We also confirmed the coulomb energies as well as the structures presented by Munera (9) for $n = 4$ through 10, 12, 14, 17, and 18. The configurations presented by Munera for $n = 11$, 13, and 15 have higher coulomb energies than those computed by Melnyk. Munera's configurations for $n = 19$ and 20 have higher energies than those we computed. Our first computation (12) for $n = 16$ produced the D_{4d} double antiprism offered by both Melnyk and Munera.

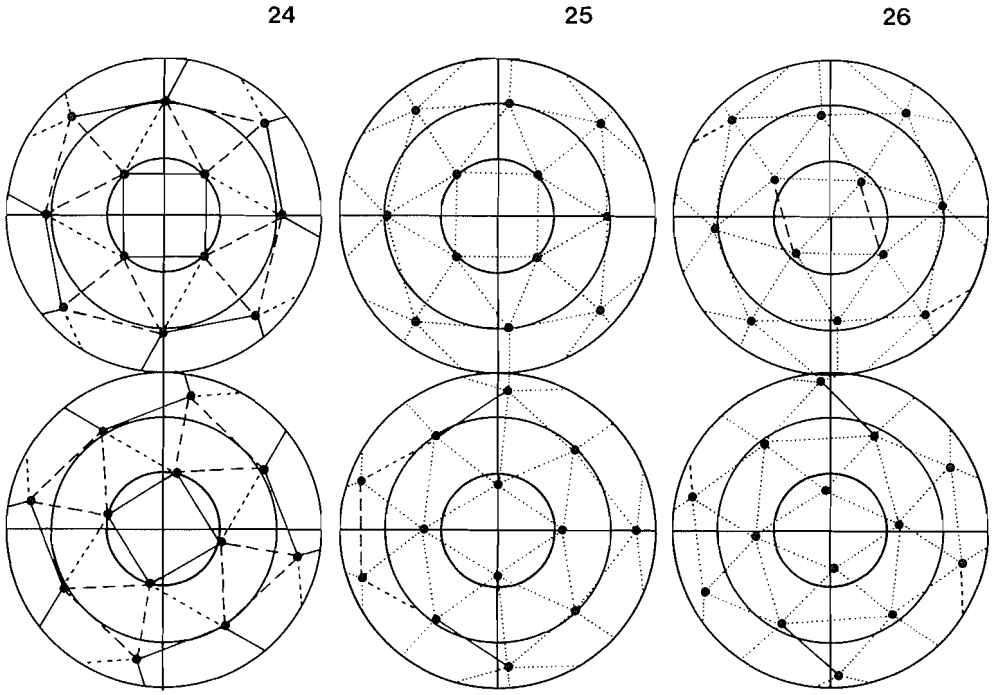

FIG. 3. Configurational continuity (CC24, CC25, and CC26). CC24 belongs to point group O. It has a square at each pole and four squares around the equator. CC25 is only C_s and CC26 only C_2. In the upper hemisphere the structure of CC24 is somewhat retained in CC25 and CC26. In the lower hemisphere the structure has been altered by the apparent insertion of the 25th and then the 26th charge.

*PG is the point group; PS is the number of sets of equivalent points; Ref. number cites earlier reference; "m" indicates same symmetry and a similar looking polyhedron to a closest packed configuration cited by Mackay *et al.* (14) but present figure is congruent to close packed figure only in cases labeled with a "c". All figures labeled with both m and c satisfy the Leech (15) criteria for equilibrium. "L" indicates a figure which meets the Leech criteria but is of different symmetry from the closest packed solution.

Subsequent computation produced the new tetrahedrally symmetric configuration we present in Table 1, which has a lower energy (92.9117 vs. 92.9204) than the D_{4d} configuration.

Melynk proffered a bicapped square prism + 4 configuration for $n = 14$ as having lower energy for small m than Foeppl's bicapped pentagonal antiprism (the latter was also presented by Munera); however, the coulomb energy for Melnyk's configuration, which we computed to be minimal when the square prism is a cube and the structure is hence O_h, is higher (69.3424 vs. 69.3064) than that for Foeppl's D_{6d} structure.

3.2. *New configurations*

In addition to CC16, the tetrahedral $n = 16$ configuration, we have computed new equilibrium configurations for $n = 19$ through 40, for which we have not found any previous references (Table 1). The symmetry groups for these configura-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/07/12
For personal use only.

tions range from C_s and C_2 to T_d and I_h. No completely unsymmetrical minimum-energy configuration was found for $n \leq 40$.

CC21 is C_{2v}, but the angular position of the charges varies from C_{4v} symmetry by fractions of a degree. An effort was made to force the configuration into C_{4v} symmetry, but the charges always returned to the C_{2v} configuration.

CC16 and CC28 belong to point group T and CC22 to T_d. They are displayed in Fig. 1, along with CC4, the regular tetrahedron.

CC24 (Fig. 3) is a slightly distorted snub cube (see Sect. 3.3); it belongs to point group O. CC32 (point group I_h) is a rhombic triacontahedron distorted by bending each of its faces into two triangles so as to make it inscribable in a sphere. CC32 is shown in Fig. 2, along with CC12, the regular icosahedron, and CC33 (see Sect. 3.4). Our first computation for $n = 32$ produced a C_{4d} configuration having a higher coulomb energy than the spherical triacontahedron, but subsequent computations done from a variety of initial configurations always produced CC32.

Almost all the faces of the convex polygons defined by the charge configurations are triangles. CC8 (a square antiprism) and CC24 have some square faces. CC19 has a rectangular face at one of the poles. CC25 and CC33 are C_s and each has a quadrilateral face lying across the reflection plane. CC25 had five and CC33 has seven single charges scattered irregularly on the reflection-plane great circle.

3.3. *Relationship to the close-packing solutions*

A few of these newly computed minimum-coulomb-energy configurations have been previously presented as solutions (CPS's) for the close-packing problem, to wit, maximizing the minimum distance between charges (i.e., $m = \infty$). Indeed, structures in the same symmetry groups and having the same structural type as the corresponding MCEC's have been presented as CPS's for $n = 2$ through 6, 8, 9, 12, 15, 17, 18, 20, 24, 27, and 32 (10, 14). However, except for the structures demonstrated by Leech (15) to be in equilibrium independently of the nature of the interaction force (equatorial polygons with or without charges at the poles and certain figures related to the regular polyhedra), the CPS's are not congruent with the corresponding MCEC's. Melynk (10), for instance, points out that for $n = 8$ the CPS square antiprism is not congruent with the MCEC square antiprism; the former is equilateral, while in the latter the edges of the square faces are shorter than the edges connecting the square faces. Similarly the CPS for $n = 24$ is a snub cube (14, 16), which must be distorted to produce the MCEC CC24.[2] The CPS's are congruent with the corresponding MCEC's only for $n = 2$ through 6, 12, and 32 in agreement with Leech's criteria. (Tarnay and Gaspar (17) have produced a closer packing for $n = 32$ by distorting the spherical triacontahedron, and also new closer packings for $n = 17$ and 18.)

[2]The snub cube itself is a CPS and not a coulomb-equilibrium configuration. It does not satisfy Leech's criterion and is in equilibrium only for $m = \infty$. Construction of CC24 from the snub cube (which is equilateral) can be visualized as follows: The square faces are moved slightly closer to the center of the sphere; this lengthens their edges and shortens the edges connecting their corners. Each square face is then rotated slightly (through 1.0113°) within its plane, further altering the lengths of the connecting edges. The minimum edge length of the resulting MCEC (CC24) is 42.0653° compared with 43.6908 for the snub cube; its coulomb energy is 223.3471 vs. 223.4551 for the snub cube.

TABLE 2. Summary of point group classifications

O	24	T_d	4,22		

*This symbol indicates an additional equilibrium configuration with higher energy.

3.4. *Other equilibrium configurations*

A number of configurations in equilibrium under coulomb forces but not lowest-energy configurations are listed at the end of Table 1. The CPS configuration for $n = 7$, a C_{3v} capped modified triangular antiprism, is not in electrostatic equilibrium. The C_{3v} structure listed in Table 1 is the corresponding coulomb-equilibrium configuration; the minimum interval between particles is 73.2823° vs. 77.8659° for the CPS (and 72° for the D_{5h} MCEC). The CPS for $n = 11$ is the regular icosahedron minus one particle — a C_{5v} capped pentagonal antiprism. This structure is modified to achieve electrostatic equilibrium by moving both pentagonal faces of the antiprism away from the polar charge; they are then no longer congruent. The $n = 14$ and $n = 16$ non-minimum configurations are discussed above. The 30-particle I_h configuration is the vertex-figure derivative of the icosahedron. The 32-particle configuration is a D_{4d} figure achieved once during our computations, subsequent trials producing the spherical triacontahedron. This configuration is shown in Fig. 2.

3.5. *Relationships between adjacent configurations*

Similarities between configurations with adjacent charge numbers can sometimes be observed even when the symmetries are very different. In Fig. 2, for example, CC33 is shown beside CC32. We recall that CC32 displays very high (icosahedral) symmetry, while CC33 has only a reflection plane. Nevertheless, the C_5 symmetry of CC32 is almost retained in the upper hemisphere of CC33. The 33rd charge of CC33 appears to have been inserted near the lower pole of CC32, obliterating the C_5 symmetry in the lower hemisphere. It should be noted that CC32 and CC33 were independently derived from arbitrary initial conditions.

Figure 3 shows CC24, CC25, and CC26. Although CC24 displays octahedral symmetry, while CC25 and CC26 have only a reflection plane and a C_2 axis, respectively, the upper hemispheres of these three figures correspond point for point and almost edge for edge; the quadrilateral at the pole of CC24 is retained in CC25 (though no longer a square), and also appears, now bent into two triangles, at the pole of CC26. In the lower hemisphere one can see in CC25 where the 25th charge appears to have been inserted near the left-hand edge of the configuration, destroying the C_4 symmetry of CC24 and breaking the polar square into two triangles. The lower hemispheres of CC25 and CC26 also correspond closely; one can see where the 26th charge appears to have been inserted near the right-hand edge of CC26. Again we note that CC24, CC25, and CC26 were computed independently.

3.6. *Energy vs. symmetry*

The energy of a charge of magnitude n uniformly distributed

For personal use only.

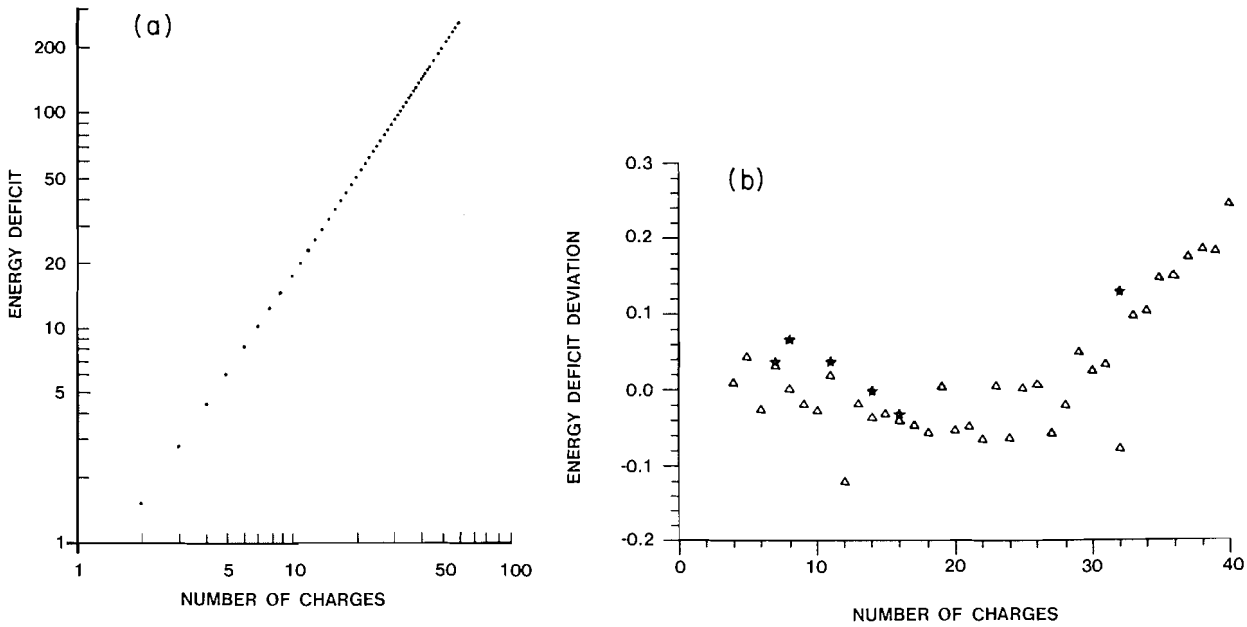

FIG. 4. (*a*) The energy deficit $n^2/2 - E(n)$ vs n. (*b*) The deviation of the calculated energy deficit from a least squares straight-line through the log-log plot in 4*a*. Higher-energy configurations have higher deviation values. The values for minimal-energy configurations are displayed as triangles. Those for the non-minimal-energy configurations are shown as stars. The values for the dodecahedron and the icosadodecahedron are out of the scale of the plot.

over the surface of a unit sphere is $n^2/2$. The excess of this quantity over the energy E_n of the minimum-energy configuration for n unit charges

[2] $E_0 = n^2/2 - E_n$

is shown in Fig. *4a* plotted against n. Figure *4b* shows the deficit of E_0 with respect to a least squares straight-line fit to the previous plot. Higher values of this excess correspond to higher values of E_n. Configurations of higher symmetry tend to have lower values than their neighbors, but this comparison cannot be made globally over the whole range of n. For the most part, a high degree of symmetry tends to be associated with low configuration energy (see Sect. 3.5), but this is not a general rule. The cube ($n = 8$) and the regular dodecahedron ($n = 20$) are neither MCEC's nor CPS's despite being regular polyhedra, nor is the O_h configuration for $n = 14$. The CC20 polyhedron has four sets of equivalent points and edges of seven different lengths, as compared with one each for the regular dodecahedron, but nevertheless CC20 has a lower configuration energy.

4. Conclusion

We have determined a number of new equilibrium configurations for a small number of charged particles confined to the surface of a sphere and interacting with a Coulomb force. These are zero temperature equilibrium configurations. We note that many of these configurations are closely related to solutions to the close-packing problem. A problem of interest to us is the behavior of objects interacting with realistic forces at finite temperatures on the surface of a spherical particle. An attractive initial step to the study of this problem would be to set up computer programs for calculating the molecular dynamics of the system. This computational system can be checked thermodynamically in the ideal gas case and can later be related to situations with more complex interactions and also to the symmetrical configurations studied here as the temperature is reduced sufficiently to induce phase changes.

A comparative study on the dynamics of epimeric 1-hydroxymethyl quinolizidines: II. The solvent and concentration dependence of the association properties

K. KULIŃSKA AND M. WIEWIÓROWSKI

Institute of Bioorganic Chemistry, Polish Academy of Sciences, Noskowskiego 12,61-704 Poznan, Poland

Received December 11, 1987

K. KULIŃSKA and M. WIEWIÓROWSKI. Can. J. Chem. **66**, 2166 (1988).

The homo and heteroassociation patterns of lupinine and epilupinine in different solvents and at various concentrations have been studied. In *n*-hexane, *n*-heptane, CCl_4, and $C_2H_4Cl_2$ solvents, lupinine monomers with an intramolecular OH...N hydrogen bond dominate over homoassociates with an OH...O′ intermolecular hydrogen bond even in concentrated solutions. Homoassociation of lupinine by intermolecular OH...N′ hydrogen bonding is observed only in saturated solutions. In chloroform solution any intermolecular homoassociation is effectively blocked because of significant affinity of chloroform molecules acting as a weak acid toward the free electron pairs of the oxygen atom from the hydroxyl group that would be otherwise engaged in intramolecular OH...N hydrogen bonding. Epilupinine in *n*-hexane, *n*-heptane, CCl_4, $C_2H_4Cl_2$, and chloroform solutions forms possible homoassociates both by OH...N′ and OH...O′ intermolecular hydrogen bonding. In dioxane-d_8, DMSO, and D_2O solvents both lupinine and epilupinine form heteroassociates with solvent molecules.

K. KULIŃSKA et M. WIEWIÓROWSKI. Can. J. Chem. **66**, 2166 (1988).

On a étudié les modèles d'homoassociation et d'hétéroassociation de la lupinine et de l'épilupinine dans différents solvants et à différentes concentrations. Dans le *n*-hexane, le *n*-heptane, le CCl_4 et le $C_2H_4Cl_2$ les monomères de la lupinine ayant des liaisons hydrogènes OH...N intramoléculaires dominent les composés homoassociés ayant des liaisons hydrogènes OH...O′ intermoléculaires même en solutions concentrées. On observe l'homoassociation de la lupinine par des liaisons hydrogènes intermoléculaires OH...N'uniquement dans des solutions saturées. En solution dans le chloroforme, toute homoassociation intermoléculaire est effectivement bloquée à cause de la très grande affinité des molécules de chloroforme agissant comme un acide faible en présence de la paire d'électrons libres de l'atome d'oxygène du groupe hydroxyle qui, par ailleurs, peut-être impliqué dans une liaison hydrogène intramoléculaire OH...N. L'epilupinine en solution dans le *n*-hexane, le *n*-heptane, le CCl_4, le $C_2H_4Cl_2$ et le chloroforme forme les deux types possibles de composés homoassociés par des liaisons hydrogènes intermoléculaires OH...N'et OH...O′. La lupinine et l'épilupinine dans le dioxanne-d_8, le DMSO, et le D_2O forment toutes deux des composés d'hétéroassociation avec les molécules de solvant.

[Traduit par la revue]

Introduction

The similarity of the conformations of biologically active molecules in water solution and as crystals is a crucial problem of structural study. Many proposed mechanisms of interaction on the molecular level are based on identical conformations in solution and in crystals. In effect, the preferred solution conformation of biomolecules seems to be generally similar to its crystal structure (1). Lupinine molecule (1-hydroxymethyl-quinolizidine) belongs to those rare biomolecules whose crystal structure deviates significantly from its structure in solution (2). Its epimer, epilupinine, differs from lupinine in the configuration of the exocyclic hydroxymethyl group, but this relatively small structural change has a great influence on the molecular and intermolecular dynamism of both epimers. Epilupinine retains in its crystal structure the preferred conformation from solution. Conformational dynamics in CCl_4, $CDCl_3$, and D_2O solutions, and in the liquid as compared with the solid state of both epimers, has been elucidated from spectroscopic ir and nmr data in the previous paper of this series (2). In this paper we attempt to determine the homo and heteroassociation patterns of lupinine and epilupinine in different solvents and at various concentrations to explain why the predominant tendency of lupinine to intramolecular self-association does not lead to crystals with a similar structure, but always to the homopoly-associated form, which is rarely present even in a concentrated solution and is very similar to that existing in crystalline epilupinine. The observations presented may be useful for a proper understanding of very important equilibrium processes between intra and intermolecular hydrogen bonds.

Experimental

Infrared spectra were measured on a Perkin–Elmer ir spectrometer, type 180. The ^1H nmr spectra were recorded on JEOL FX-90Q Fourier transform impulse equipment by a standard method. For details refer to our previous paper (2).

Results and discussion

Lupinine and epilupinine possess analogous proton-donor and -acceptor centres. There are two main possible modes of intermolecular hydrogen bonding formation: (*i*) between the hydroxyl group of one molecule and the nitrogen atom of another: OH...N′; (*ii*) between the hydroxyl group of one molecule and the oxygen atom of another: OH...O′. Moreover, intramolecular OH...N self-association is possible in lupinine in the *syn*/−60° conformation, as opposed to epilupinine where the equatorial position of the CH_2OH group renders this interaction impossible (2).

In effect, inter and intramolecular interactions of this type are fully or partially manifested in the ir spectra in the region of the stretching vibrations of the hydroxyl groups (Table 1 and Figs. 2–6). In dilute CCl_4 lupinine solutions two forms of monomers occur: 90% of the monomers, with the OH group engaged in intramolecular hydrogen bonds, are manifested in the ir spectra by ν(OH...N) at 3295 cm^{-1} (L_1 in Figs. 1 and 2) and about 10% of the monomers, with a free OH group, are manifested by the ν(OH) band (L_2 in Figs. 1 and 2) (2, 3). In dilute CCl_4 epilupinine solutions 100% of the monomers possess a free OH group (E in Figs. 1 and 2) and vibrate with the same frequency as the L_2 lupinine monomers at ν(OH) of 3640 cm^{-1} (2, 3).

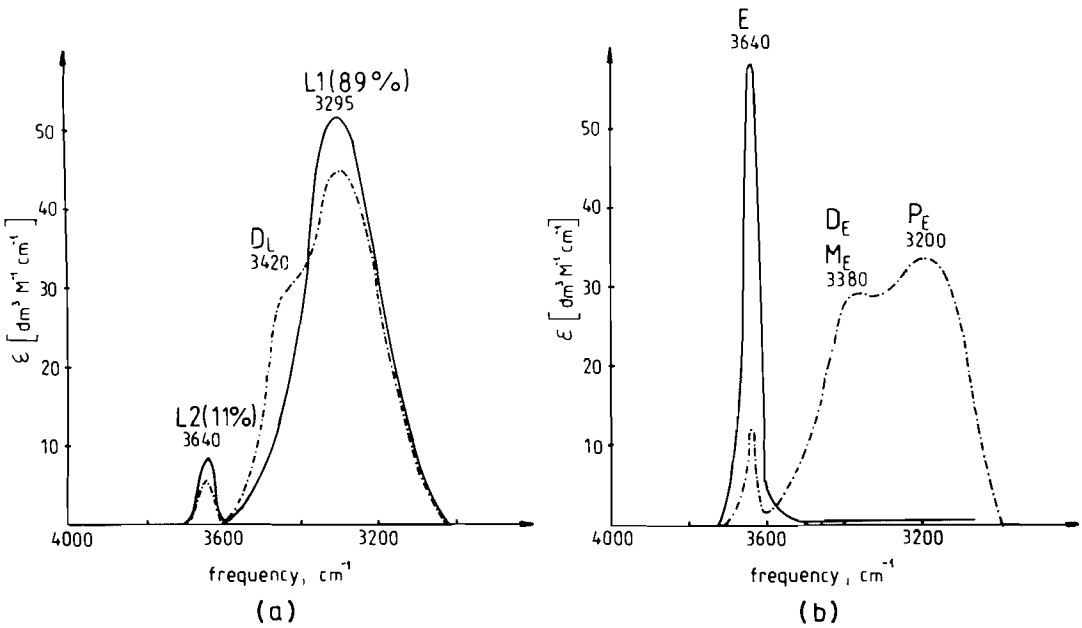

FIG. 2. Infrared spectra of lupinine (a) and epilupinine (b) in carbon tetrachloride (CCl_4) solutions of different concentrations: c = 0.03 M (————); c = 1.0 M (—·—·—·—).

Upon increased lupinine concentration only one new band, ν(OH...O'), appears at about 3420 cm^{-1} in the stretching vibration region of the ir spectra (Fig. 2, Table 1). This band has been assigned to homoassociates by an intermolecular OH...O' hydrogen bonding involving two lupinine molecules, one with an intramolecular hydrogen bonding L_1 and the other with a free OH group L_2 (D_L in Figs. 1 and 2). The assignment is deduced from a simultaneous intensity decrease of both monomer bands ν(OH) and ν(OH...N) and the growth of intensity of the homoassociate band ν(OH...O'), which is due to increasing lupinine concentration in solution. The integrative absorption rate of both monomer bands ν(OH) and ν(OH...N) as a function of concentration remains constant.[1] The position and intensity of the absorption band ν(OH...N) originating from the stretch-

[1]The integrative absorption rate was calculated from the concentration effect on the ir spectra of CCl_4 and $C_2H_4Cl_2$ lupinine solutions in the concentration ranges 0.003–1.5 M and 0.03–1.5 M, respectively (2).

ing vibration of the hydroxyl groups engaged in intramolecular hydrogen bonds depend on the concentration (concentration increase leads to a decrease of integrative absorption of the ν(OH...N) band —see Fig. 2), and solvent (the position of the ν(OH...N) band changes from 3325 cm^{-1} in *n*-hexane to 3220 cm^{-1} in chloroform—see Table 1). Due to the presence of two free electron pairs at the oxygen atom, lupinine monomer L_1 may act as a proton acceptor both for lupinine monomers L_2 forming dimers D_L (Figs. 1 and 2) and for proton-donor solvent molecules like 1,2-dichloroethane and chloroform. These interactions of the proton-donor group with free electron pairs at the oxygen atom partially reduce its negative charge, thus increasing the acidity and donor properties of the OH group. The intramolecular OH...N hydrogen bond becomes stronger, as indicated by the shifts of the ν(OH...N) bands to shorter wavenumbers (see Table 1). As one can see in Table 1, band ν(OH...N) shows the greatest shift to shorter wavenumbers in chloroform, being located at 3220 cm^{-1}. This indicates that in chloroform solutions the intramolecular OH...N hydrogen bond is the strongest. Acidic C—H hydrogen from chloroform molecules can stabilize the intramolecular OH...N hydrogen bond by acting as a proton donor with a free electron pair at the oxygen atom. In this way, intermolecular homoassociation is effectively blocked in chloroform solution and no homoassociate band is present in the ir spectra. Only at a saturated concentration, when crystallization processes start, homoassociates by intermolecular OH...N' hydrogen bonding similar to those in the crystal structure appear.

The intensity of the D_L dimer ν(OH...O')and in *n*-hexane, *n*-heptane, CCl_4, and $C_2H_4Cl_2$ solutions never exceeds that of monomers L_1 with an intramolecular ν(OH...N) hydrogen bond even in saturated solutions, where processes of crystallization start. The band of lupinine homoassociates by intermolecular OH...N' hydrogen bonding is observed only in the ir spectra of *n*-hexane and *n*-heptane saturated lupinine solutions at about 3220 cm^{-1}.

The intermolecular OH...N' hydrogen bond is stronger than the OH...N intramolecular one (ν(OH...N) − ν(OH...N') = 125 cm^{-1} in *n*-hexane lupinine solution), but it is not sufficiently strong to bind two lupinine molecules in solution into a stable dimer. The intramolecular OH...N hydrogen bond does not repress the diffusive movements of lupinine molecules in solution. Although the intramolecular hydrogen bond is weaker than the intermolecular OH...N' hydrogen bond it is kinetically more favourable. Probably this is the reason why homoassociates by intermolecular OH...N' hydrogen bonding are not observed in an unsaturated lupinine solution.

The homoassociation pattern of epilupinine is drastically different from that of lupinine. As the concentration of epilupinine increases, several new homoassociate bands appear in the stretching vibration region of the ir spectra. First of all a band appears at 3190 cm^{-1} in $C_2H_4Cl_2$ solution, at 3200 cm^{-1} in CCl_4 solution, and at 3230 cm^{-1} in *n*-hexane and *n*-heptane (see Table 1). This band is attributed to intermolecular OH...N' hydrogen bonding due to the formation of homoassociates, linear polymeric structures like those in the solid state (P_E in Fig. 1). At higher concentration another band of homoassociates appears at about 3500 cm^{-1}. The position of this band is concentration dependent and shifts towards shorter wavenumbers (3500 cm^{-1} → 3380 cm^{-1} in CCl_4, 3470 cm^{-1} → 3360 cm^{-1} in $C_2H_4Cl_2$; see Fig. 3) with increasing concentration. This band is attributed to the OH...O' intermolecular interaction. At lower concentrations linear dimers (D_E in Fig. 1) are probably formed, which at higher concentration transform into a linear multimer (M_E in Fig. 1) affecting the shift of the ν(OH...O') band as in other alcohols (4).

The pattern of epilupinine homoassociation presented above is similar for *n*-hexane, *n*-heptane, CCl_4, $C_2H_4Cl_2$, and even chloroform epilupinine solutions. Solvation of epilupinine molecules by chloroform proceeds similarly to the case of lupinine molecules, but does not hinder homoassociation because of the absence of intramolecular hydrogen bonding in epilupinine. The free OH groups of both epimers interact with the chlorine atom of solvent molecules to form very weak hydrogen bonds. The position of band ν(OH) = 3630 cm^{-1} is identical in lupinine and epilupinine chloroform solutions (see Fig. 4). The CH proton-donor group from chloroform (or CD from deuterochloroform) interacts with the free acceptor centres

of both epimers, i.e., the free electron pairs of oxygen atoms, but this interaction does not hinder epilupinine homoassociation.

In more polar solvents such as dioxane, DMSO, and D_2O, lupinine and epilupinine form heteroassociates with the molecules of the solvents (Table 1, Fig. 5). In dioxane, oxygen atoms with free electron pairs possess strong proton acceptor abilities and a majority of lupinine and epilupinine molecules form heteroassociates with the solvent molecules (ν(OH...O'$_{solv}$) = 3490 cm^{-1}). However, a significant percentage of lupinine molecules (about 40%) retain the monomeric form L_1 with an intramolecular hydrogen bond. In epilupinine dioxane solutions about 20% of epilupinine molecules form homoassociates by OH...N' hydrogen bonding (ν(OH...N') = 3190 cm^{-1}). In DMSO and D_2O both epimers form only heteroassociates with molecules of the solvents (ν(OH...O'$_{solv}$) = 3445 and 3400 cm^{-1} respectively).

The concentration effect observed in the ^{1}H nmr spectra confirms the association pattern of lupinine and epilupinine in

CCl_4, $CDCl_3$, and DMSO solutions (Fig. 6). The chemical shift of the hydroxyl proton signal of lupinine or epilupinine reflects the different average magnetic environments of those protons, between which a quick chemical exchange takes place. Every turbulence of conformational and association equilibrium in solution results in a change of position of the hydroxyl proton signal. Positions of the hydroxyl proton signals in ^1H nmr spectra of lupinine and epilupinine CCl_4 solutions undergo shifts induced by changes in solution concentration. In the case of epilupinine the dependence is monotonic throughout the concentration range investigated (0.2–2.0 M), whereas the hydroxyl signal of lupinine is independent of concentration below 1 M. This is most probably due to a very low percentage of associates in these solutions. The signal of the hydroxyl proton in the ^1H nmr spectrum of lupinine solution in $CDCl_3$ is located in a field lower by approximately 1 ppm with respect to its position in CCl_4 and DMSO solutions. It is almost concentration independent in the whole range investigated. The insensitivity of δ (OH) of lupinine in chloroform solutions of different concentrations is evidence of the stability of the lupinine conformational and association equilibrium in this solution. A weaker screening of the hydroxyl proton of lupinine in $CDCl_3$ confirms that the intramolecular hydrogen bonds are stronger in chloroform than in other solvents. The signal of the hydroxyl proton of epilupinine in chloroform solutions is sensitive to

concentration changes just as in the case of epilupinine solutions in CCl_4. In the entire range of concentrations investigated the dependence is linear. In the ^1H nmr spectra of lupinine and epilupinine solutions in DMSO the chemical shift of the hydroxyl protons is concentration independent in the range of 0.2–2.0 M, which could mean that basic DMSO molecules solvate both epimeric amino alcohols in a very similar manner.

Summary

In spite of the fact that lupinine and epilupinine possess analogous proton-donor and -acceptor centres, the different configurational and conformational dynamics of those molecules are responsible for their different capabilities of homo and heteroassociation.

In nonpolar solvents lupinine closes its active groups, N and OH, by forming an intramolecular hydrogen bond. This type of intramolecular interaction probably also exists in isolated molecules of the argon matrix but is always in equilibrium with monomers weakly solvated by molecules of nonpolar solvents. Even in concentrated solutions these monomers dominate over dimeric lupinine molecules associated by an intermolecular OH...O′ hydrogen bonding. Polyassociation of lupinine with an intermolecular OH...N′ hydrogen bonding is blocked up to saturated solutions. The blocking of homoassociation processes in lupinine chloroform solution is caused by significant affinity of chloroform molecules acting as a weak acid toward the free electron pairs of the oxygen atom from the hydroxyl group engaged in intramolecular OH...N hydrogen bonding. This interaction causes an additional strengthening of the intramolecular OH...N hydrogen bond in lupinine.

In polar solvents such as dioxane, DMSO, and D_2O, the intramolecular hydrogen bond in lupinine is partly or totally broken, and OH groups of lupinine interact specifically with the proton-acceptor centres of solvent molecules forming heteroassociates. In dioxane, a significant number of lupinine molecules form an intramolecular OH...N hydrogen bonding, whereas none in H_2O solution and very few in DMSO do so.

On the other hand, in all nonpolar solvents, chloroform included, epilupinine forms both types of homoassociates by OH...N′ and OH...O′ intermolecular hydrogen bonding. In polar solvents epilupinine behaves similarly to lupinine and forms heteroassociates with the solvent molecules.

Received January 4, 1988

EDOUARD LAURENT LOUFOUILOU and JEAN PAUL GISSELBRECHT. Can. J. Chem. **66**, 2172 (1988).

The polarographic reduction of samarium(III) cryptates with cryptands 222, 221, and 22 was investigated in propylene carbonate. The samarium(III) cryptates are reduced in two consecutive steps, the first step was reversible and corresponded to the reduction of the Sm(III) to the Sm(II) cryptate. The Sm(III)/Sm(II) redox potential of the cryptates depended on the anion used in the complex and, in the case of the cryptate with chloride anions, a stable mixed complex was observed in propylene carbonate. The Sm(III)/Sm(II) redox potentials of the cryptates were more cathodic than the redox potential of the uncomplexed Sm(III)/Sm(II) couple, which is typical of a lower stability of the reduced cryptate. Propylene carbonate does not stabilize low oxidation states of lanthanides by cryptation. This is at variance with behavior observed previously in other media like water and methanol. Variations of redox potentials as a function of increasing amounts of water were accounted for by solvent shielding of samarium(III) upon encapsulation in cryptands.

EDOUARD LAURENT LOUFOUILOU et JEAN PAUL GISSELBRECHT. Can. J. Chem. **66**, 2172 (1988).

La réduction polarographique de cryptates de samarium(III) en utilisant les cryptands 222, 221 et 22 a été étudiée dans le carbonate de propylene. Les cryptates de samarium(III) sont réduits en deux étapes consécutives dont la première était réversible et correspondait à la réduction du cryptate de samarium(III) en cryptate de samarium(II). Le potentiel rédox du couple Sm(III)/Sm(II) pour les cryptates étudiés dépendait énormément de la nature de l'anion du cryptate étudié et, dans le cas des cryptates dont l'anion était l'anion chlorure, un complexe mixte et stable a été mis en évidence dans le carbonate de propylène. Les potentiels rédox du couple Sm(III)/Sm(II) des cryptates étudiés était plus cathodique que le potentiel rédox du couple Sm(III)/Sm(II) non complexé, ce qui est caractéristique d'une plus faible stabilité du cryptate réduit par rapport à la forme oxydée. Dans le carbonate de propylène la complexation d'ions lanthanides par les cryptands ne permet pas de stabiliser leurs bas degrés d'oxydation comme cela a été observé antérieurement dans d'autres solvants tel l'eau et le méthanol. D'autre part, l'évolution des potentiels rédox des cryptates en fonction de la teneur en eau du carbonate de propylène, a montré clairement que ceux-ci évoluaient de manière plus conséquente pour le samarium(III) non complexé que pour les cryptates, confirmant l'effet d'écran du cryptand vis à vis de la solvatation.

Introduction

Up to now the encapsulation of lanthanide ions by macrocycles has been much less explored than that of alkaline, earth-alkaline, and transition metals ions (1). A recent review (2) on rare earth complexes with neutral macrocyclic ligands showed that the electrochemical studies on these species are still scarce in the literature.

The published electrochemical studies on such cryptates aimed mainly at stabilizing low oxidation states. It has been shown in water (3, 4) and methanol (5) that the complexation of lanthanides ions by cryptands stabilized low oxidation states, especially for Eu, Sm, Yb, whereas this stabilization was not observed in propylene carbonate (5). In propylene carbonate low oxidation states were stabilized with crown ethers (2, 5, 6).

The aim of the present work was to investigate the electrochemical properties of samarium(III) cryptates involving the cryptands 222, 221, and 22, to understand why these samarium(II) cryptates are not stabilized in propylene carbonate as indicated electrochemically by the observed cathodic shift of the redox potential of the Sm(III)/Sm(II) couple in the cryptate with respect of the uncomplexed couple, and to assess solvent shielding effects when samarium ions become complexed with macrocycles. While this research was in progress (7) Tabib *et al.* (8) reported that redox potentials of europium, samarium, and ytterbium cryptates with 222 and 221 in different solvents may be used as probe of solvent shielding effects in lanthanide cryptates (8).

Experimental

All electrochemical measurements were carried out in propylene carbonate (PC) (Merck) purified according to the method proposed by Gosse and Denat (9). Tetraethylammonium perchlorate (TEAP) (Fluka) was used as supporting electrolyte and was recrystallized in methanol before use (10).

Electrochemical measurements were performed with a multipurpose PRG4 device (SOLEA, Tacussel), on a dropping mercury electrode as working electrode (m = 0.085 mg/s; h = 40 cm). The reference electrode was a saturated calomel electrode (SCE) electrically connected to the electrolysis cell by a bridge filled with CP + 0.1 *M* TEAP.

The ligands 222, 221, 22 (Kryptofix, Merck) were used without further purification.

The samarium(III) trifluoromethanesulfonate was prepared according to the procedure described by Massaux and Duyckaerts (11) and dried under vacuum at 60°C for 24 h.

The complexes [222 Sm]Cl_3, [221 Sm]Cl_3, [22 Sm]Cl_3 were prepared as described by Seminara and Musumeci (12).

For the cryptates with trifluoromethanesulfonate (triflate) as anions an original synthetic route was used: 1 mmol of $Sm(CF_3SO_3)_3$ in 10 mL methanol was dried by trimethyl orthoformate — $CH(OCH_3)_3$ — (Jansen Chemica) according to Massaux and Musumeci (11). Acetonitrile (20 mL) was added and the methanol was removed by distillation. Then, a solution of 1.1 mmol of ligand in 10 mL acetoni-

trile was added to the samarium(III) solution in a dry box. The mixture was heated under reflux for half an hour at 40°C. White crystals precipitated. After filtration the solid was washed with hexane and dichloromethane and dried under vacuum at 40°C for 48 h. The complexes were slightly hygroscopic but they were easier to dry than the perchlorate salts.

To introduce chloride or water into the solutions we always added a precise volume of a stock solution containing tetraethylammonium chloride (TEACl) or water, of which concentration was exactly known.

Results

Reduction of samarium(III) triflate in CP

The polarographic reduction of samarium(III) occurs in two consecutive diffusional waves at − 1.14 V/SCE and −2.0 V/SCE corresponding, respectively, to the reduction of Sm(III) to Sm(II) and Sm(II) to Sm(0). This reduction behaviour was described previously (5, 11, 13, 14). The log plot (log $(I/I_d - I)$ versus E) was linear and the slopes were equal to 66 and 29 mV per log unit, respectively. The wave heights were proportional to the concentration over the range 2×10^{-4} M to 2.5×10^{-3} M, the slopes of the $I = f(C)$ plot being 0.23 and 0.45 μA/mM under our experimental conditions, respectively. Cyclic voltammetry performed between −0.5 to −2.0 V/SCE (Fig. 1) showed a reversible reduction of Sm(III) to Sm(II) and an irreversible reduction from Sm(II) to Sm(0). The samarium was reoxidized around −0.7 V/SCE. Cyclic voltammetry on the first reduction step between −0.9 and −1.4 V/SCE showed that this reduction occurs quasireversibly: $I_{p_c} = f(v^{1/2})$ linear and crossing the origin (I_{p_c} = reduction peak current), $E_{p_c} = f(\log v)$ non-linear and E_{p_c} shifted cathodically with increasing scan rate (Ep_c = reduction peak potential), the peak potentials difference $E_{p_c} - E_{p_a}$ increasing from −130 mV at 2 V/s to −380 mV at 100 V/s. At low scan rates (10 to 100 mv/s) (5) the difference $E_{p_c} - E_{p_a}$ was equal to −70 mV. From the evolution of the peak potential difference $E_{p_c} - E_{p_a}$, with scan rate, it was possible, according to Nicholson (15), to determine the charge transfer rate constant $k_s = (8.3 + 0.3) \times 10^{-2}$ cm s^{-1}.

Reduction of samarium in propylene carbonate with increasing water content

Increasing amounts of water added to a solution of $Sm(CF_3SO_3)_3$ shifted cathodically the Sm(III)/Sm(II) reduction potential but had no effect on the wave height. The redox potential moved up to −1.40 V/SCE (from −1.14 V/SCE) for a water concentration equal to 0.56 M (the value observed in water was −1.78 V/SCE (13, 14)). The limit of water solubility in propylene carbonate is approximately 4.5 M (16).

By cyclic voltammetry, like in polarography, the redox potential of the Sm(III)/Sm(II) couple became also more negative with increasing water concentration as shown on Fig. 1. Analysis of the voltammetric curves related to the first reduction (from −0.4 to −1.4 V/CE), proved that the system remained reversible, after addition of water. The ratio I_{p_a}/I_{p_c} remained constant and close to unity over the scan range 2 to 100 V/s, as water was added to the solution. Also the peak potentials difference $|E_{p_c} - E_{p_a}|$ increased, with scan rate, but the rate of the charge transfer slowed down against dry PC. Indeed, the calculated rate constant, according to Nicholson (15), became $k_s = (5.4 + 0.3) \times 10^{-2}$ cm s^{-1} for a water concentration in PC equal to 0.48 ML^{-1}.

Thus, the electrochemical behaviour of samarium(III) in the presence of water indicated that the redox potential of the

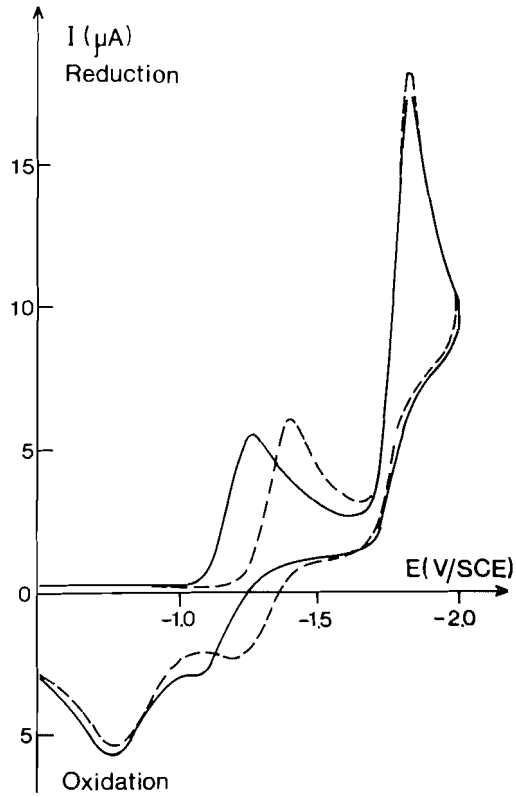

FIG. 1. Cyclic voltammogram of $Sm(CF_3SO_3)_3$ ($C = 2.52 \times 10^{-3}$ M) in PC + 0.1 M TEAP (v = 10 V/s). ——— Anhydrous CP; --------- PC + H_2O ($C_{H_2O}/C_{Sm} = 68$).

Sm(III)/Sm(II) couple depended very much on the water concentration in the propylene carbonate. As the redox potential of Sm(II)/Sm(0) remained unaffected by water concentration, it may be expected that only Sm(III) was strongly hydrated. This result was not surprising taking into account the very high hydration energy of about 800 kcal/mol for Sm(III) (17) whereas it is only 200 kcal/mol for calcium(II) which has about the same ionic radius. It explains why the reduction potential of Sm(III) was not water independent, like the reduction potential of Ca(II).

On the other hand, the high hydration energy of samarium(III) might explain why no significant encapsulation occurred by adding a cryptand to the samarium(III) solution. In fact, in interaction between samarium–cryptand indeed occurred. When cryptand was added to a samarium(III) solution, the Sm(III)/Sm(II) wave decreased and vanished as soon as the cryptand samarium ratio reached unity. Simultaneously, a new irreversible wave appeared at −1.85 V/SCE (5) who could be attributed to the reduction of an exclusive complex, the inclusive cryptate being reduced reversibly at a more anodic potential as demonstrated hereafter.

Reduction of samarium cryptates with [222], [221], [22] cryptands

Each of the different cryptates studied was dissolved in propylene carbonate. In the case of the [22 Sm]Cl_3 the solubility limit was about 5×10^{-3} M and for higher concentrations the solution became opalescent. Each cryptate was reduced in two distinct steps whose polarographic characteristics are summarized in Table 1.

The limiting current of each two reduction waves was

TABLE 1. Characteristics of the polarographic reduction of samarium cryptate in propylene carbonate

Cryptates	$E_{1/2}$ (III/II) (V/SCE)	$\log (I/I_d-I)$ (mV)	$E_{p_c} - E_{p_a}$ (mV)(10 V/s)	$E_{1/2}$ (II/0) (V/SCE)
[222 $SmCl_3$]	−1.46	69	− 88	<−2.6
[221 $SmCl_3$]	−1.62	61	−100	−2.6
[22 $SmCl_3$]	−1.74	95	−139	−2.36
[222 $Sm(CF_3SO_3)_3$]	−1.12	61	− 68	−2.40
[221 $Sm(CF_3SO_3)_3$]	−1.34	63	− 80	−2.30
[22 $Sm(CF_3SO_3)_3$]	−1.46	59	− 90	−2.35

proportional to the concentration on the range 0.2 to 3×10^{-3} M. We checked, using the chronoamperometric criterion developed in this aim (18) that the reduction limiting currents were diffusion controlled. Also, the slope of $\log (I/I_d - I) = f(E)$ indicated that the first reduction step was a reversible monoelectronic reduction step, except for [22 Sm]Cl_3. As the half-wave potential of the first reduction was independent on cryptate concentration, the reduction occurred without change in the metal/ligand stoichiometry. Thus the first step corresponded to the reduction of the complexed samarium(III) to the complexed samarium(II). The second reduction observed at more negative potentials corresponded to the reduction of the samarium(II) cryptate to free ligand and zerovalent samarium.

Another remarkable characteristic in these reductions was that the half wave potential of the first step depended upon the nature of the anion in the cryptate (Table 1): the $SmLCl_3$ cryptates were reduced at more cathodic potentials — about 0.3 V — than the corresponding $SmL(CF_3SO_3)_3$ cryptates. That behaviour will be discussed later on.

Cyclic voltammetry performed on the two reduction steps showed that the first step was a reversible one — presence of an anodic peak — whereas the second step was irreversible. The reduction parameters of the first reduction step were obtained from cyclic voltammetry performed on this first step only: $Ip_c = f(v^{1/2})$ was linear and crossing the origine, $Ep_c = f(\log v)$ was not linear (Ep_c shifting cathodically with increasing scan rate), the difference $|Ep_c - Ep_a|$ increased with scan rate, Ip_a/Ip_c was equal to unity. These parameters clearly indicated that the first reduction step of the studied Sm(III) cryptates was a quasi reversible monoelectronic reduction.

The reduction of [22 Sm]Cl_3 was also chemically reversible, as shown by the observed anodic peak in cyclic voltammetry (Fig. 2). However, the slope of the log plot and the peak potentials difference (Table 1) denoted a non Nernstian process. Cyclic voltammetry performed on the first reduction step showed that the evolution of the reduction parameters were similar to those described above, however the difference $|E_{p_c} - E_{p_a}|$ was higher, ranging from 100 mV at 50 mV/s to 160 mV at 20 V/s. These parameters indicated that the rate determining step was a slow charge transfer in this first reduction. Figure 2 shows also clearly the second reduction peak, as well as the reoxidation peak of the samarium(0) at −0.7 V/SCE.

Water concentration effects on the redox behaviour of samarium cryptate, in propylene carbonate

Adding increasing amounts of water to propylene carbonate had different effects on the first reduction potentials of the samarium(III) cryptates, depending on the anions used. For $SmLCl_3$ the redox potential shifted anodically as the water

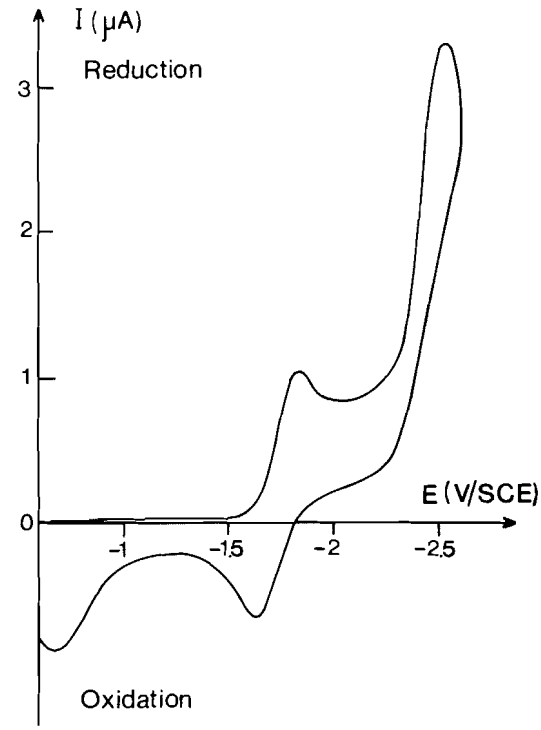

FIG. 2. Cyclic voltammogram of Sm 22 Cl_3 ($C = 5 \times 10^{-3}$ M) in PC + 0.1 M TEAP (v = 10 V/s).

content increased whereas a cathodic shift was observed with $SmL(CF_3SO_3)_3$. In other words, $SmLCl_3$ and $SmL(CF_3SO_3)_3$ cryptates exhibited closer reduction potentials after addition of water (Table 2).

It shall be noticed that addition of water shifted cathodically the Sm(III)/Sm(II) redox potential for derivatives having triflates as anions, when Samarium ions were complexed and when they were not complexed as well. However, the cathodic shift with water concentration was much smaller for the cryptates than for the uncomplexed samarium(III). On the other hand, the observed anodic shift in the derivatives with chloride anions was probably due to the dissociation of the chloride from the cryptate by water. This explanation will be discussed hereafter, but we have also checked that, in water and with a given cryptand involved, $SmLCl_3$ and $SmL(CF_3SO_3)_3$ cryptates have the same reduction potential, as expected for a total dissociation of these salts in water.

This behaviour led us to studying the changes in the redox potential of $SmL(CF_3SO_3)_3$ cryptates dissolved, in dry propylene carbonate, when increasing amounts of chloride were added to this solution.

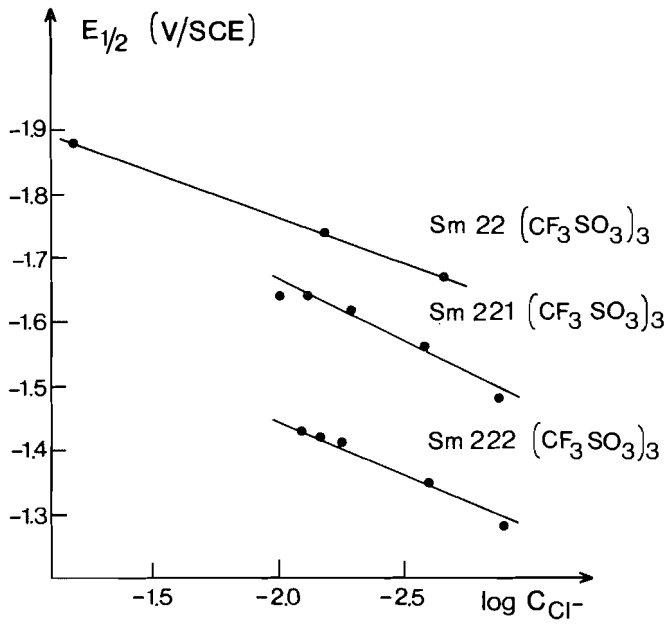

FIG. 3. Plot of half-wave potentials as a function of chloride concentration.

TABLE 3. Effect of the chloride concentration on the redox potential of the couple Sm(III)/Sm(II), in solutions of $Sm(CF_3SO_3)_3$ cryptates[b]

Ligand	$E_{1/2}$ (V/SCE)	Slope $\Delta E_{1/2}/\Delta \log (C_{Cl-})$	$p - q$
222	−1.12	180±10	3
221	−1.34	190±20	3
22	−1.46	110±10	2

[b]Solvent: PC + 0.1 *M* TEAP; *p* and *q* denote the number of chlorides coordinated with Sm(III) and Sm(II), respectively.

Changes in the redox potential of triflated Sm(III)/Sm(II) cryptates, in the presence of added chloride

Upon addition of tetraethylammonium chloride to the solution, the Sm(III)/Sm(II) redox potential in the different cryptates shifted cathodically with increasing chloride concentration. Also, the reduction potential measured in the presence of stoechoimetric amount of chloride added to the triflate solution (i.e. 3 Cl/1 Sm) was the same as the potential measured, in the same solvent, after dissolution of the corresponding $SmLCl_3$ cryptate. From the plots of the potential versus the logarithm of the chloride concentration (Fig. 3 and Table 3), the relation established by Stackelberg (19) led to calculate the stoechiometry change of coordinated chloride during the reduction of Sm(III) to Sm(II). Also, the stability constant of the mixed complex corresponding to the equilibrium $SmL + nCl^- \rightleftharpoons SmLCl_n$ was determined (Table 4).

TABLE 4.

Overall stability constants $\beta = \dfrac{(SmLCl_n)}{(SmL)\,(Cl^-)^n}$ of $SmLCl_n$ complexes

Ligand	Stoichiometry M^{3+}	: L :	nCl^-	log β
222	1	1	3	11.6
221	1	1	3	11.5
22	1	1	2	9.1

The values obtained for log β (Table 4) illustrated that the $SmLCl_n$ cryptates are very stable in solution, thus explaining why the redox behaviour of the $SmLCl_n$ cryptates, were so different from that of the corresponding $SmL(CF_3SO_3)_3$ cryptates.

Discussion

The present results obtained in propylene carbonate may be compared with previous studies in water (3, 4) and in methanol (5), where divalent lanthanides became stabilized by complexation by cryptand, as documented electrochemically for samarium(III) by the observed anodic shift of the redox potential of Sm(III)/Sm(II) in the cryptate with respect to the measured potential of the uncomplexed Sm(III)/Sm(II) couple. The present results clearly indicate that no stabilization of samarium(II) occurred by complexation with cryptand in propylene carbonate, with the exception of [222 Sm]$(CF_3SO_3)_3$, for which the 20 mV anodic shift of the redox potential indicated a very small stabilization of Sm(II) compared to Sm(III).

On the other hand, the addition of water to propylene carbonate shifted cathodically the redox potential of Sm(III)/Sm(II) in species with triflate anions. The effect was much greater for uncomplexed samarium(III) — from −1.12 to −1.40 V/SCE for 0.56 *M* of water, i.e. about +280 mV — than for the samarium cryptate: about 100 mV for 0.6 *M* of water. For example, for a 0.56 *M* water concentration the redox potential of Sm(III)/Sm(II) in $Sm(CF_3SO_3)_3$ became more cathodic ($E_{1/2}$ = −1.40 V/SCE) than the potential of Sm(III)/Sm(II) in [222 Sm]$(CF_3SO_3)_3$ ($E_{1/2}$ = −1.16 V/SCE). Therefore, in PC + 0.56 *M* H_2O, the uncomplexed Sm(III)/ Sm(II) potential was much less positive relative to 221 Sm(III)/221 Sm(II) than in anhydrous PC. It was expected that further addition of water will invert the sequence. This was actually observed in pure water and in methanol (3, 5). These results are consistent with the donor numbers of PC and water (20). It shall

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/07/12

also be noticed that, in anhydrous PC, it was possible to obtain stable complexes of Sm(III) with cryptand and chloride, which were dissociated in the presence of water. Such mixed complexes have previously been obtained in water with europium(III) and ytterbium(III) with fluoride and hydroxide in excess, but not with chloride (3). Our results are in agreement with the solvating properties of propylene carbonate according to Gutmann (20). The above results illustrate clearly the shielding effect of complexation by cryptand towards solvation. This shielding effect of the cryptand towards the cation-solvent interactions was assessed in one of our previous studies on cryptates in PC, where a levelling effect of complexation by cryptand was observed on the stokes radii of diffusing alkali ions in presence of 222 (21). That result was interpreted assuming that the 222 ligand replaced the first solvation shell around the complexed cation.

From the redox potentials obtained in the present paper and from the stability constants of lanthanide(III) cryptates determined by Loufouilou and co-workers (22), in PC, it was possible to calculate the stability constants of the corresponding samarium(II) cryptates, using Stackelberg's relationship (19) applied to the present reduction scheme:

$$ML_p^{n+} + (n\text{-}m)\ e \rightleftharpoons ML_q^{n+} + (p\text{-}q)\ L$$

(p and q correspond to the number of ligands attached to Sm^{n+} and Sm^{m+}, respectively).

The relationship has the form

$$\Delta E_{1/2} = [0.059/(n\text{-}m)] \times \log \beta_{red}/\beta_{ox} - (p\text{-}q) \times [0.059/(n\text{-}m)] \times \log L$$

(where β denotes the stability constant).

In the present case, the stoichiometry of the oxidized and of the reduced species is the same. Thus, $p\text{-}q = 0$ and the above relationship become

$$\Delta E_{1/2} = [0.059/(n\text{-}m)] \times \log \beta_{red}/\beta_{ox}$$

From Table 1 and from the stability constants of samarium(III) cryptates given in Table 5, we calculate the corresponding stability of samarium(II) cryptates (Table 5).

These results show, for the 22 ligand, that the highest stability is not attained as soon as the ionic radius of the metal cations fits the radius of the cavity, as observed for alkali and earth alkaline cryptates. This is probably due to the fact that the complexation in lanthanides is not only due to electrostatic interactions but also to covalent bonding.

If we compare the complexing properties of cyclic polyethers like 18-crown-6 (18-C-6) reported in Table 5 with the 22 cryptand which has the same ring size, it is well established that cryptates form more stable complexes than crown-ethers. However, there is no satisfactory explanation why cyclic polyethers stabilize Sm(II), whereas the 22 cryptand does not.

The complexing mechanisms between Sm(III) on the one hand and the ligand 22 and 18-C-6 on the other hand are likely to be different: the complexation of Sm(III) by 18-C-6 occurred easily in PC while the complexation of Sm(III) by the 22 cryptand had to be carried out in dry solvating media such as CH_3CN or ethanol–acetonitrile mixtures. A very crucial step in the complexation reaction of lanthanides is the desolvation of the cation to be complexed. As the desolvation of a cation is facilitated by a polar surrounding of the complexation site (27), the above results would indicate that the crown ether is more polar than the cryptand. Thus, the complexation with 18-C-6 is facilitated.

DL-γ-Carboxyglutamic acid (Gla) reacts easily and quantitatively with aldehydes to give the racemic diastereoisomers of 5-substituted-4,4-dicarboxyprolines. After heating at 100°C for 30 minutes these amino acids lose a carboxyl group from C-γ of Gla and C-4 of the proline ring to give glutamic acid and the racemic diastereoisomers of cyclic analogs of glutamic acid respectively. This paper reports a study of the above-mentioned compounds by using FAB mass spectrometry in comparison with CI analysis. FAB turned out to be an adequate ionization technique for dealing with such nonvolatile and thermolabile amino acids, and may thus allow the development of a rapid and sensitive method for detecting γ-carboxyglutamic acid in urine and in other biological matrices in pathological cases (i.e., renal stones and blood serum).

R. CAPASSO, P. PUCCI, G. RANDAZZO et A. MALORNI. Can. J. Chem. **66**, 2177 (1988).

L'acide γ-carboxyglutamique (Gla) réagit facilement et quantitativement avec les aldéhydes pour donner des diastéréoisomères racémiques des dicarboxy-4,4 prolines substitués en position 5. Par chauffage à 100°C pendant 30 minutes ces acides aminés perdent un groupe carboxyle à partir du carbone en position γ du Gla et du carbone en position 4 du cycle de la proline pour donner respectivement l'acide glutamique et les diastéréoisomères des analogues cycliques de l'acide glutamique. On rapporte une étude de ces composés en faisant appel à la spectrométrie de masse BFA conjointement avec l'analyse par IC. Le BFA se révèle être une technique adéquate d'ionisation pour acides aminés non volatils et thermolabiles. Il peut ainsi constituer une méthode sensible de détection de l'acide γ-carboxyglutamique dans l'urine et dans d'autres matrices biologiques dans des cas pathologiques (c.-à.-d. calculs rénaux, serum sanguin).

[Traduit par la revue]

Introduction

γ-Carboxyglutamic acid (Gla) has been found in proteins involved in blood clotting (1–4). Gla-containing proteins have also been identified in calcified tissues such as the organic matrix of bone (5), renal stones (6), and atherosclerotic plaque (7). Free Gla has been found in human urine (8) as a metabolic product of the catabolism of Gla-containing proteins (8, 9). In pharmacological therapy with warfarin (10) and in diseases such as osteoporosis (11), abnormal levels of Gla have been detected in the urine.

In this regard an analytical method to determine Gla in the urine, based on the quantitative and simple reaction of the amino acid with acetaldehyde, has been proposed (12).

Recently it has been shown, mainly by ^{1}H nmr (13), that DL-Gla generally reacts with aldehydes to give the racemic diastereoisomers of the 5-substituted-4,4-dicarboxyprolines. With the ultimate aim of finding a sensitive mass spectrometric method to detect Gla in the urine in pathological cases, the CI and FAB behaviour of the compounds mentioned has been investigated. The CI technique, which was successfully applied to the analysis of naturally occurring amino acids (14), failed in studying these derivatives on account of the high temperature required at the ms source to vaporize such nonvolatile and thermolabile tricarboxyamino acids. The FAB technique, on the contrary, proved to be very suitable in dealing with such polar compounds. Furthermore, the behaviour of these compounds after exposure at 100°C for 30 min in H_2O has been studied: they lose a carboxyl group from C-γ of Gla and from C-4 of proline derivatives, giving rise to glutamic acid and racemic diastereoisomers of the cyclic analogs of glutamic acid (13) respectively.

Experimental

FAB mass spectra were recorded on a Kratos MS 50 double focusing mass spectrometer, equipped with an M-scan source and an M-scan gun, using xenon as bombarding gas. Spectra were recorded at 8-kV acceleration potential, at 100 s/decade scan rate on Kodak paper Linagraph direct print. Samples were dissolved in 5% AcOH and loaded (0.1–10 μg) into a glycerol-coated probe tip. A significant improvement in the FAB spectra of some compounds was obtained by adding concentrated hydrochloric acid to the sample.

Linked scans at constant B/E (B/E linked scan) were performed by scanning the magnetic sector field-strength B and the electrostatic sector field-strength E simultaneously, holding the accelerating voltage constant. The B/E ratio is maintained at a constant value determined by the ratio of the two field-strengths, which transmit the selected precursor ion whose fragment-ion spectrum is required.

The CI mass spectra were obtained on a Kratos MS 80 mass spectrometer, using isobutane or ammonia as reagent gas, at a pressure of 0.8 Torr (1 Torr = 133.3 Pa) and at 350–400 eV. The sample (5–10

μg) was placed in a glass capillary tube, inserted into the probe of the mass spectrometer, and heated at 250–300°C.

Glu was purchased from Sigma and Gla from Bachem Biochemicals. The amino acid 4,4-dicarboxy-5-methylproline **3** (Fig. 1) was prepared by reaction of γ-carboxyglutamic acid with acetaldehyde as previously described (13), but the purification was performed as follows. The product (4.5 mg) was chromatographed on a DEAE-cellulose column, (1.5 × 10 cm) equilibrated and eluted with 0.3 M pyridine-acetate buffer pH 4.75. The fractions were analyzed by thin-layer chromatography (tlc) (Kieselgel Merck 0.25 mm 60 F_{254}, *n*-butanol – acetic acid – water 60:15:25, as eluent) and those giving a yellow spot with ninhydrin were pooled and lyophilized at least three times before the ms analyses. The amino acids 4,4-dicarboxyproline **2**, 4,4-dicarboxy-5-phenylproline **4**, -5-(*p*-OCH_3-phenyl)-proline **5**, and -5-(*p*-NO_2-phenyl)-proline **6** (Fig. 1) were prepared by reaction of carboxyglutamic acid with formaldehyde, benzaldehyde, *p*-methoxybenzaldehyde, and *p*-nitrobenzaldehyde respectively, as previously reported (13). The normal and C-4 deuterated amino acids were prepared by heating the parent amino acids **1–6** for 30 min at 100°C in H_2O or D_2O (99%). The solutions were cooled at room temperature, lyophilized, and the residue was directly analyzed by mass spectrometry.

The amino acids considered were identified by ^1H nmr analysis as already published (13).

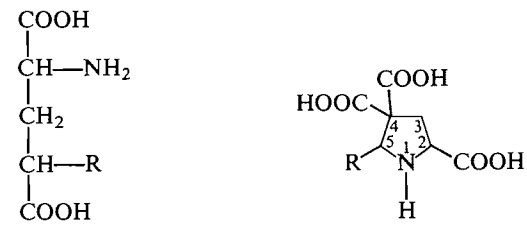
Results and discussion

The FAB mass spectrum of γ-carboxyglutamic acid **1** (Fig. 1 and Table 1) shows a strong protonated molecular ion at *m/z* 192. The CI spectra (with isobutane and ammonia), of the same compound **1** and its monodecarboxy derivative, obtained by heating at 100°C for 30 min display the same characteristic fragmentation pattern as that of glutamic acid (14) (Table 2).

Furthermore, the FAB spectrum of glutamic acid **1***a* and the decarboxy derivative of Gla are identical (Table 1). These results strongly suggest that during CI experiments decarboxylation of Gla occurs in the mass spectrometer source, probably due to the high temperature (250°C) required to vaporize the nonvolatile and thermolabile Gla, according to the malonic acid nature of the carboxyl groups.

The data of positive FAB spectra of amino acids **3–5** are reported in Table 1. All the spectra, with the exception of product **2**, show two signals with different intensities, corresponding to MH^+ and $MH^+ - 44$ (Table 1). The latter refers to the monodecarboxy derivative formed by loss of CO_2 from C-4 of the proline ring as discussed below.

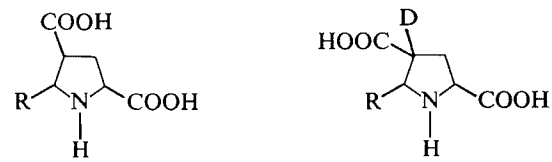
The 4,4-dicarboxyproline **2** (Fig. 1) does not afford signals,



1 R = -COOH
1*a* R = -H

2 R = -H
3 R = -CH_3
4 R = -C_6H_5
5 R = -$C_6H_4OCH_3$
6 R = -$C_6H_4NO_2$

FIG. 1. Structure of Gla, Glu, 4,4-dicarboxyproline, and 5-substituted-4,4-dicarboxyprolines.



3*a*$_1$ R = -CH_3
4*a*$_1$ R = -C_6H_5
2*a*$_1$ R = -H

3*a*$_2$ R = -CH_3
4*a*$_2$ R = -C_6H_5
2*a*$_2$ R = -H

FIG. 2. Structure of 4-carboxyproline and 5-substituted-4-carboxyprolines with a hydrogen or deuterium atom on C-4.

while the 4,4-dicarboxy-5-methlyproline **3** does not show any CO_2 loss from the molecular ion. The reason for this behaviour remains unclear.

All the samples were heated at 100°C for 30 min in H_2O and D_2O and the resulting derivatives were analyzed by FAB mass spectrometry. The sample heated in D_2O showed a protonated molecular ion shifted up one mass unit in comparison to the derivatives obtained in H_2O. The statistical replacement of one of the carboxyl groups on C-4 by a deuterium atom provides 5-substituted-4-carboxy-4-D-prolines, as already demonstrated by ^1H nmr data (13). As examples, the data of the FAB spectra of 4-carboxyproline **2***a*$_1$, -4D-proline **2***a*$_2$, 4-carboxy-5-methylproline **3***a*$_1$, -4-D-5-methylproline **3***a*$_2$, 4-carboxy-5-phenylproline **4***a*$_1$, and -4-D-5-phenylproline **4***a*$_2$ (Fig. 2) are reported for

1	148 (1)* (6)†	130 (100)* (68)†	102 (1)* (17)†	84 (30)* (100)†	$\mathbf{1}a$‡	148 (1)†	130 (55)†	102 (3)†	84 (100)†
2	—	—	—	—	$\mathbf{2}a_1$	160 (42)†	142 (100)†	—	—
4	236 (18)* (25)†	218 (17)* (12)†	190 (100)* (100)†	172 (70)* (60)†	$\mathbf{4}a_1$	236 (24)*	218 (14)*	190 (100)*	172 (75)*

*Relative intensity data with ammonia gas.
†Relative intensity data with isobutane gas.
‡This kind of fragmentation is identical to that of glutamic acid.

comparison in Table 1. The mass difference between the two MH^+ ions is clearly detectable.

Finally, B/E-linked scan experiments performed on 4,4-dicarboxy-5-phenylproline **4** demonstrate that the CO_2 loss originates from the protonated molecular ion, as shown by the presence of the peak at m/z 236 in the corresponding spectrum (Fig. 3). Moreover the FAB spectrum of **4** is reported as an example in Fig. 4. In this spectrum smaller peaks at m/z 262 and 244 appear in addition to m/z 280 and 236 and are attributed to the loss of H_2O, as indicated in the B/E-linked scan spectrum (Fig. 3). This kind of fragmentation (the loss of H_2O) is not observed in the FAB spectra of the other amino acids.

Compounds **2–6** were analyzed by CI technique in the same way as compound **1**. Samples **2**, **3**, **5**, and **6** did not give reproducible spectra, while the decarboxy derivative $\mathbf{2}a_1$ gave a clear and reproducible spectrum (Table 2). The spectrum of 4,4-dicarboxy-5-phenylproline **4** did not show the molecular ion at m/z 280 because of the thermolability of the carboxyl group on the C-4. The fragmentation pattern showed peaks at m/z 236 ($MH^+ - CO_2$), 218 ($MH^+ - CO_2$—H_2O), 190 ($MH^+ - CO_2$—$COOH_2$), and 172 (MH^+—H_2O). This spectrum is identical to that displayed by the compound $\mathbf{4}a_1$, obtained by heating sample **4** at 100°C for 30 min. All the data are summarized in Table 2.

These results confirm the failure of this method in analyzing such very polar, nonvolatile, and thermolabile compounds; the CI technique provides limited information only on a few samples, and therefore it does not seem the ideal technique for

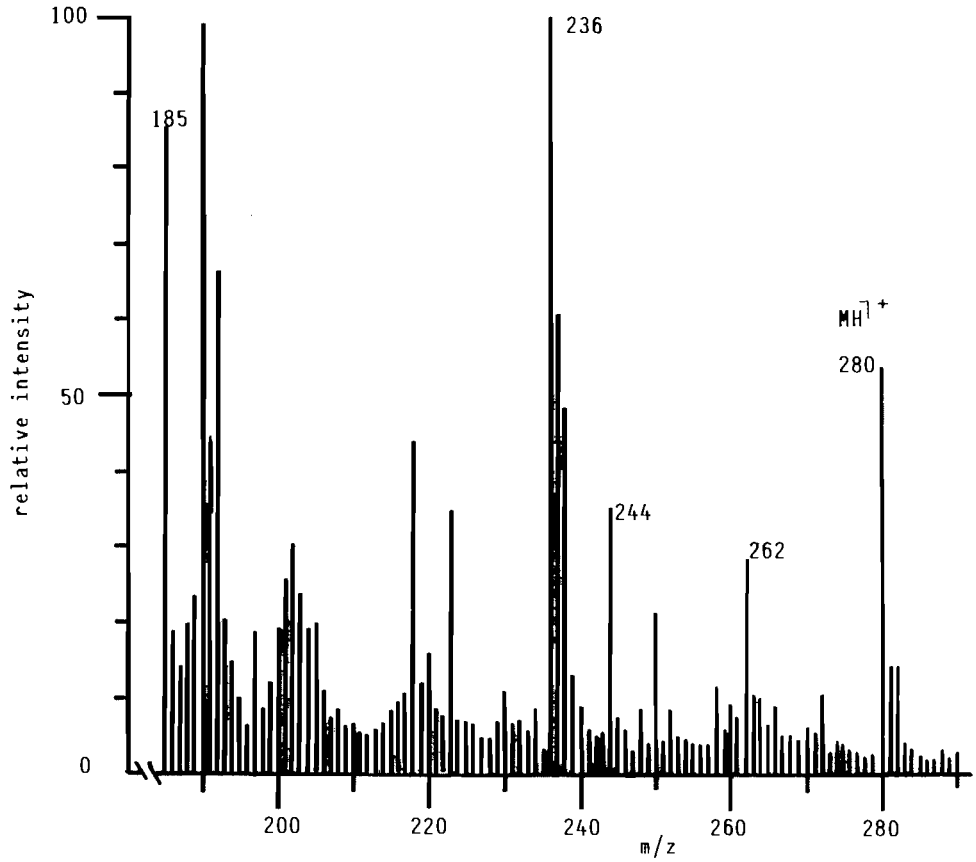

FIG. 4. Positive ion FAB spectrum of 4,4-dicarboxy-5-phenylproline **4**.

dealing with such compounds, as it has been in studies on naturally occurring amino acids (14).

The FAB ionization mode allows the mass spectrometric analysis of both the tricarboxyamino acids Gla and those formed by reacting Gla with aldehydes, and the decarboxy derivatives obtained by heating, permitting their detection at low levels. These findings suggest that FAB mass spectrometry could be used for quantitative analysis of the above-stated compounds, as already shown for other polar molecules (15–18), and we have therefore been encouraged in developing a FAB mass spectrometric method to detect Gla in biological matrices.

Acknowledgements

We are grateful to Mr. Antonio Cantilena of the Dipartimento di Chimica Organica e Biologica, Università di Napoli, for the CI mass spectra. The authors thank Professor G. Marino for helpful discussions. This work was supported by grants from the "Ministero della Pubblica Istruzione."

Constant composition study of crystal growth of dicalcium phosphate dihydrate. The influence of polyphosphates, phosphonates, and phytate

ZAHID AMJAD

The BF Goodrich Company, Avon Lake Technical Center, Avon Lake, OH 44012, U.S.A.

Received September 29, 1987

ZAHID AMJAD. Can. J. Chem. **66**, 2181 (1988).

The influence of inhibitors of varying functional groups on the crystal growth of calcium phosphate dihydrate ($CaHPO_4 \cdot 2H_2O$, DCPD) on DCPD seed crystals at pH 6.00, 37°C, has been studied using the constant composition technique. The inhibitors studied include: (*a*) polyphosphate (sodium pyrophosphate, sodium hexametaphosphate, SHMP), (*b*) phosphonates (nitrilotris(methylene phosphonic acid), NTMP; 1-hydroxyethylidene-1,1-diphosphonic acid, HEDP; ethylenediaminetetra (methylene phosphonic acid), ETMP; hexamethylenediaminetetra(methylene phosphonic acid), HMDP); and (*c*) myoinositol hexaphosphoric acid (phytic acid). The effect of these inhibitors on the growth kinetics have been studied at several inhibitor concentrations. The retarding effect of these inhibitors is discussed in relation to calcium–inhibitor complex formation on the DCPD seed crystals and the structural features of the inhibitor molecules. The fit of the Langmuir adsorption to experimental data supports a mechanism of inhibition through molecular adsorption of the inhibitor ions on the surface of growing crystals. Based upon the kinetic data, the overall order of inhibitors effectiveness is

ETMP > HMDP > phytic acid > hexametaphosphate > HEDP > pyrophosphate

ZAHID AMJAD. Can. J. Chem. **66**, 2181 (1988).

Opérant à un pH de 6,0, à une température de 37°C et utilisant la technique de la composition constante, on a étudié l'influence des inhibiteurs portant divers groupements fonctionnels sur la croissance cristaux de phosphate de calcium dihydrate ($CaHPO_4 \cdot 2H_2O$, DCPD) sur des cristaux de DCPD ensemences. Les inhibiteurs examinés comportent; (*a*) des polyphosphates (pyrophosphate de sodium, hexamétaphosphate de sodium, HMPS), (*b*) des phosphonates (nitrilotris(acide méthylène phosphonique), NTMP; acide hydroxy-1 éthylidène diphosphonique-1,1, HEDP; éthylènediaminetétra(acide méthylène phosphonique), HMDP; et (*c*) l'acide hexaphosphorique du myoinositol (acide phytique). On a étudié l'effet de ces inhibiteurs sur la cinétique de la croissance à plusieurs concentrations d'inhibiteurs. On discute de l'effet retardant de ces inhibiteurs en relation avec la formation d'un complexe calcium–inhibiteur sur les cristaux de DCPD ensemencés et en relation avec les caractéristiques des structures des molécules d'inhibiteurs. L'ajustement de l'adsorption de Langmuir aux données expérimentales supporte un mécanisme d'inhibition impliquant l'adsorption moléculaire des ions inhibiteurs sur la surface des cristaux en croissance. En se basant sur les données cinétiques, l'ordre d'efficacité globale des inhibiteurs est le suivant :

ETMP > HMDP > acide phytique > hexamétaphosphate > HEDP > pyrophosphate

[Traduit par la revue]

Introduction

The importance of calcium phosphates as the main inorganic constituents of biological hard tissue (1–3) and urinary calculi (4,5) has stimulated the extensive research on the precipitation of these compounds. In addition, calcium phosphate compounds are involved in wastewater treatment processes, in agriculture as fertilizers, and in industrial water systems as hard deposits on heat exchanger surfaces. During the precipitation process at ambient temperature, the following calcium phosphate phases have been shown to be formed depending upon the level of supersaturation, pH, and ionic medium: dicalcium phosphate dihydrate ($CaHPO_4 \cdot 2H_2O$, DCPD), octacalcium phosphate ($Ca_8H_2(PO_4)_6 \cdot 5H_2O$, OCP), tricalcium phosphate ($Ca_3(PO_4)_2$, TCP), hydroxyapatite ($Ca_5(PO_4)_3OH$, HAP), and amorphous calcium phosphate, ACP (6–9). Results of previous studies have shown that the kinetically favored precursor phases such as ACP, DCPD, OCP, and TCP are formed prior to the formation of the thermodynamically stable HAP phase. Moreover, it has been suggested that such precursor phases can be stabilized by the presence of certain additives (10, 11).

The influence of naturally occurring substances such as pyrophosphate and polyphosphates on the precipitation of calcium phosphates at physiological conditions has also been the subject of numerous investigations (12–14). The results of these studies suggest that these substances, when present at low concentrations, greatly inhibit the precipitation of calcium phosphates from supersaturated solutions. Polyphosphates have been known much longer for their inhibitory role and they are commercially in use, preventing scale formation on heat exchanger surfaces in industrial water systems. Physical and chemical studies by Francis (13) and Varsanik (15) on the organophosphonates, a series of compounds similar to polyphosphates, led to their use as biological mineralization inhibitors and industrial scale control agents. The diphosphonates are characterized by —P—C—P— bonds in place of —P—O—P bonds of polyphosphates and have the advantage of being resistant to hydrolysis.

Phytic acid is another constituent of cells and cereals that may be involved in calcium metabolism (16). Excessive phytates in the diet may precipitate calcium in the intestine and cause calcium deficiency disease (17–19). Phytates may also adsorb to tooth surfaces and reduce cavities (20, 21). The inhibitory effect of phytate and HEDP on the crystal growth of HAP at low supersaturation has been studied recently using the constant composition technique (22). Results of this investigation indicate that phytate is about 25 times less effective than HEDP in reducing the rate of crystallization of HAP. A surface adsorption mechanism involving a simple Langmuir isotherm model was proposed to explain marked inhibitory action of these inhibitors.

Results of previous crystal growth studies (2, 22–25) on sparingly soluble salts in the presence of inhibitors have shown that the constant-composition technique is particularly useful in evaluating the effectiveness of inhibitors since their effect on the

TABLE 1. Structures of inhibitors

Inhibitor	Structure
Sodium pyrophosphate	$Na_4P_2O_7 \cdot 10H_2O$
Sodium hexametaphosphate	$(NaPO_3)_6$
Myo-inositol hexaphosphoric acid (phytic acid)	$C_6H_6(OPO_3H_2)_6$
Nitrilotri(methylene phosphoric acid) (NTMP)	$N(CH_2PO_3H_2)_3$
1-Hydroxyethilidine-1,1-diphosphonic acid (HEDP)	$CH_3C(OH)(PO_3H_2)_2$
Hexamethylenediaminetetra(methylene phosphonic acid) (HMDP)	$(CH_2PO_3H_2)_2N(CH_2)_6N(CH_2PO_3H_2)_2$
Ethylenediaminetetra(methylene phosphonic acid) (ETMP)	$CH—N(CH_2PO_3H_2)_2$ | $CH—N(CH_2PO_3H_2)_2$

crystal growth process can be accurately studied. The advantages of using the constant-composition technique, in which the concentration of the solution species is kept constant by the stoichiometric addition of reactants, to study the crystal growth of DCPD have been discussed previously (23).

In the present work, the constant-composition technique has been used to investigate the influence of a variety of inhibitors at constant supersaturation upon the kinetics of crystal growth of DCPD. The inhibitors tested include: (*a*) polyphosphate: sodium pyrophosphate, $Na_4P_2O_7$; sodium hexametaphosphate, $(NaPO_3)_6$; (*b*) phosphonates: nitrilotris(methylenephosphonic acid), NTMP; 1-hydroxyethylidine-1,1-diphosphonic acid; HEDP; hexamethylenediaminetetra (methylene phosphonic acid), HMDP; ethylenediaminetetra (methylenephosphonic acid), ETMP; and (*c*) phytic acid. The structures of these inhibitors are shown in Table 1.

Experimental

Reagent grade chemicals and grade A glassware were used. Potassium hydroxide solutions were prepared from Dilut-it reagents (J. T. Baker Co.) which were standardized by titration with potassium hydrogen phthalate using phenolphthalein as indicator. Phosphate solutions were prepared from potassium dihydrogen phosphate (J. T. Baker Co., Ultrex) and were standardized both by potentiometeric and by titration with standard potassium hydroxide solutions with thymolphthalein blue as indicator. Calcium chloride solutions were standardized by ion-exchange and atomic absorption spectroscopy. Sodium pyrophosphate and sodium hexametaphosphate solutions were prepared from reagent grade chemicals, and the phosphonates used in this study were prepared from samples that were kindly donated by Monsanto Chemical Co., St. Louis, MO. The DCPD seed crystals were prepared and characterized as previously described (23). After aging, DCPD crystals were filtered and dried to a constant weight in a desiccator over silica gel and used in subsequent experiments as seed materials.

Crystal growth experiments were made in a double-walled Pyrex cell at 37°C using the constant composition technique. The stable supersaturated solutions of calcium phosphate with a molar ratio of total calcium, T_{Ca}, to total phosphate, T_P = 1.00, were prepared by adjusting the pH of the premixed solution of calcium chloride and potassium dihydrogen phosphate to a value of 6.00 by slow addition of 0.1 *M* potassium hydroxide. Hydrogen ion measurements were made with a glass/Ag–AgCl electrode pair equilibrated at 37°C. The electrode pair was standardized before and after each experiment using NBS standard buffer solutions. The solutions were continuously stirred (325 rpm) while nitrogen gas, presaturated with water at 37°C, was bubbled through the solution to exclude carbon dioxide. Following the addition of DCPD seed crystals, the crystal growth reaction was monitored by the addition of titrant solutions from mechanically coupled automatic burettes mounted on a modified pH stat (pH meter model 632; dosimet model 655; impulsomat model 614, Brinkmann Instruments, Westbury, NY). The titrant solutions in the burettes consisted of calcium chloride, potasssium phosphate, potassium hydroxide, and inhibitor. The molar concentration ratio of the titrants corresponded to the stoichiometry of DCPD. Potassium chloride was added to the calcium phosphate supersaturated solutions in order to maintain the ionic strength to within ±1%. The constancy of solution composition was verified by analyzing the filtered samples which were withdrawn at various time intervals, for total calcium and total phosphate by a combined spectrophotometric method (26). The rates of crystallization were determined from the rates of addition of mixed titrants, and corrected for surface area changes (23).

[c]DCPD = 32 mg.

Results and discussion

Concentrations of ionic species in solutions were calculated from previously reported dissociation constants for phosphoric acid, phosphonic acids, phytic acid, and association constants of calcium-inhibitor complex formation (2, 22, 27–30). An iterative computational procedure for the ionic strength, involving mass balance and electroneutrality expressions, was used

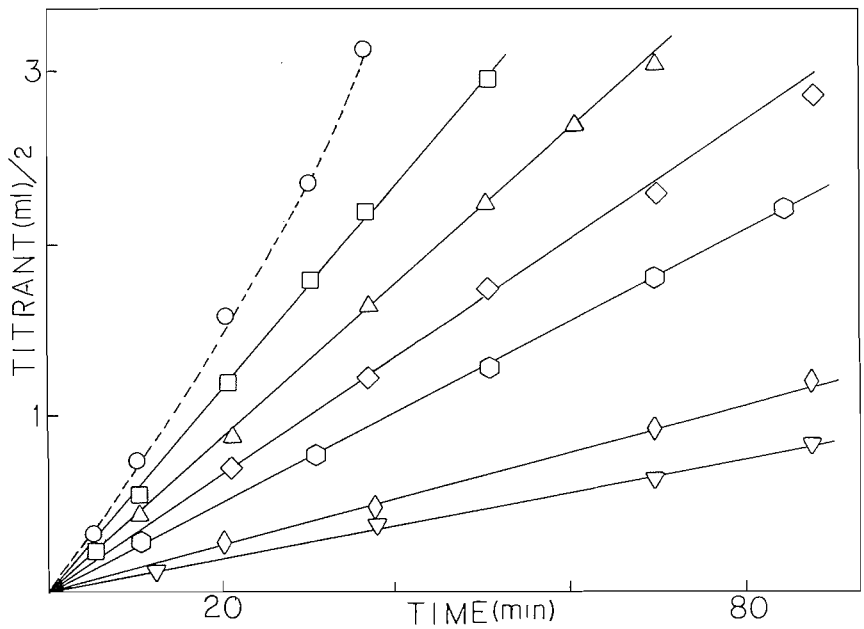

FIG. 1. Crystal growth of DCPD at constant supersaturation. Plots of volume of titrants added as a function of time in the presence of pyrophosphate (10^{-6} *M*). (□), ○; (△), 0.20; (◇), 0.30; (⬡), 0.50; (◇), 1.00; (▽), 2.00. Dotted line corresponds to experiment 3, uncorrected for surface area changes.

(22). The free energy term is computed from the equation:

[1] $\Delta G = -RT \ln (IP/K_s)^{1/n}$

in which n is the number of ions in a formula unit, IP is the activity product, and K_s, the thermodynamic solubility product for the precipitated calcium phosphate phase. The ΔG values obtained by using the above equation for various calcium phosphate phases indicate the thermodynamic instability of the experimental solutions compared to solutions in thermodynamic equilibrium with that particular phase.

The results of crystal growth experiments are summarized in Table 2. Typical plots of titrant volume needed to maintain the calcium and phosphate concentrations constant during DCPD seeded growth crystallization in experiment 5 are illustrated in Fig. 1. It can be seen in Fig. 1 that crystal growth began immediately upon the addition of seed crystals. Changes in surface area were calculated from these data, assuming the crystallites to be perfect spheres and the ordinate values, normalized to initial seed surface area (23), are also shown as corrected curves in Fig. 1. The slopes of the lines are used to calculate the growth rates expressed as mol of DCPD in Table 2. The excellent reproducibility is illustrated by the agreement between the results of experiments 3 and 5, respectively. In experiments 5 and 6 the weight of seed used to initiate the reaction was varied. It can be seen in Table 2 that the rate of crystallization is directly proportional to the amount of seed crystals added initially. This confirms that crystallization occurred only on seed crystals, without any secondary nucleation or spotaneous precipitation.

The effect of pyrophosphate on the crystal growth of DCPD from calcium phosphate supersaturated solutions was studied by a series of experiments summarized in Table 2. The analytical data of a typical crystal growth experiment in the presence of pyrophosphate (2.95×10^{-7} *M*, experiment 14) are summarized in Table 3. It can be seen that the stochiometry of the precipitating phase (Table 3) was constant with a calcium to phosphate molar ratio of 1.00 ± 0.02 for more than 70 min of reaction. The amount of newly grown DCPD phase was more than 170% of the original seed materials. Plots of moles of newly grown DCPD as a function of time for crystal growth experiments in the presence of pyrophosphate are shown in Fig. 1 and rate data summarized in Table 2. It can be seen that pyrophosphate at a concentration of 2.5×10^{-8} *M* (experiment 8) did not exhibit any significant inhibition on the crystal growth of DCPD. However, increasing the pyrophosphate concentration to 5.00×10^{-7} *M* (experiment 13) resulted in ~70% reduction in the rate of crystallization.

[a] T = 37°C, pH = 6.00, $[P_2O_7] = 3.00 \times 10^{-7}$ *M*, experiment 14.

The influence of the —P—O—P chain length in polyphosphate on crystal growth of DCPD is shown in Table 2. Under conditions used in the present work, sodium hexametaphosphate, at a concentration of 5.0×10^{-8} *M* (experiment 21) retarded crystal growth of DCPD to a greater degree than pyrophosphate ion at a concentration of 2.50×10^{-7} *M* (experiment 11). Results of crystal growth experiments in the presence of polyphosphates shown in Table 2 reveal that the inhibition by polyphosphate ion increases as the chain length increases. It should be noted that similar inhibitory effect of these polyphosphates has been recently reported (31) for HAP crystal growth from aqueous solution. In agreement with these results, it has been shown that polycarboxylic acids of high

molecular weight are much more effective as $CaSO_4 \cdot 2H_2O$ crystal growth inhibitors than the simple uni-, di-, or tricarboxylic acids (32).

Another class of inhibitors that has proved to be effective in inhibiting calcification and mineral scale formation is the organic phosphonates. These inhibitors are characterized by the relatively inert P—C—P and P—C—N—C linkages which substitute for the hydrolyzable P—O—P bond of polyphosphate (Table 1). Crystal growth experiments made in the presence of phosphonates are summarized in Table 3 and mol DCPD grown as a function of time in the presence of NTMP are shown in Fig. 2. It can be seen that the presence of low concentrations of phosphonates markedly reduce the rate of DCPD crystallization. Analytical data of crystal growth experiment in the presence of NTMP (2.50 × 10^{-8} *M*, experiment 24) are summarized in Table 4. The observed T_{Ca}/T_P molar ratio of 1.00 ± 0.02 suggests that despite the marked inhibition, DCPD is the exclusively grown phase in the presence of NTMP.

The influence of other phosphonates such as HEDP, HMDP, and ETMP on the crystallization of DCPD was also studied by a series of experiments summarized in Table 2. Figure 3 shows the plots of mol of newly grown DCPD on DCPD seed crystals as a function of time in the presence of 2.5 × 10^{-8} *M* of each phosphonate present initially in the supersaturated solution. Based upon the rate data (Table 2) the order of effectiveness for phosphonates as crystal growth inhibitors is as follows:

ETMP > HMDP > NTMP > HEDP

The rate data for phytic acid as DCPD crystal growth inhibitor is summarized in Table 2. Plots of the mol of DCPD grown in the presence of phytic acid of varying concentrations are shown in Fig. 4. It can be seen (Table 2) that the presence of low concentrations of phytic acid markedly reduces the rate of DCPD crystallization. For example, rates of DCPD crystal growth obtained in the presence of 1.0 × 10^{-8} and 1.0 × 10^{-7} *M* phytic acid are 0.865 × 10^{-6} and 0.175 × 10^{-6} mol min, respectively, compared to 1.24 × 10^{-6} mol min obtained in the absence of phytic acid.

The results summarized in Table 2 indicate that the striking effect of the inhibitors, i.e. polyphosphates, phosphonates, phytate, etc. at low concentrations in reducing the rate of DCPD crystal growth cannot be attributed simply to the change in supersaturation due to calcium-inhibitor complex formation (the percent calcium complexed at the highest inhibitor concentration accounts for less than 5% of total calcium).

If we assume that the reduction in rate of DCPD crystal growth results from the adsorption of inhibitor at the DCPD crystal surface, then some form of adsorption model should be applicable. In many instances the Langmuir adsorption model, which was developed for the adsorption of ideal gases onto solid surfaces, has been used to describe empirically the reduction in crystal growth rates of sparingly soluble salts due to the adsorption of a wide variety of inhibitors. If the adsorbed inhibitor of concentration [C] covers a fraction α of the total available surface, then the rate of adsorption may be expressed as $k_a[C](1 - \alpha)$ and the rate of desorption as $k_d\alpha$, where k_a and k_d are the corresponding rate constants. At equilibrium it can be shown that:

$$[2] \quad R_0/(R_0 - R_i) = 1 + k_a/k_d[C]^{-1}$$

where R_0 and R_i are the growth rate constants in the absence and presence of inhibitors, respectively. Equation [2] shows that

this model predicts a linear relationship between $R_0/(R_0 - R_i)$ and $[C]^{-1}$. The constant k_a/k_d, can be calculated from the slope of the resulting straight line. The ratio k_a/k_d, can be called "affinity constant", but it should be noted that it is not an equilibrium constant. If k_a is large or k_d is small, then the apparent affinity is of the adsorbing molecule to the substrate will be high.

Plots of $R_0(R_0 - R_i)^{-1}$ against $[C]^{-1}$ are shown in Fig. 5 for DCPD crystal growth in the presence of polyphosphates and phosphonates. The linear plots shown in Fig. 5 suggest that the inhibitor effect is due to the adsorption on the seed crystals. Application of the Langmuir model in this case is an oversimplification, because the prerequisites for the application of such a model are not valid. However, plots like that of Fig. 5 are useful for comparative purposes, since the slope of such plots is a measure for the affinity of a certain inhibitor for the particular solid substrate (22, 23). The values of "affinity constant" for polyphosphates, phosphonates, and phytic acid, as calculated from kinetic data shown in Table 2, are summarized in Table 5.

Based upon the kinetic data (Table 2), the order in terms of decreasing effectiveness for P—O—P bond containing inhibitors such as pyrophosphate, hexametaphosphate, and phytic

acid is:

phytic acid > hexametaphosphate > pyrophosphate

It may be pointed out that in the case of HAP seeded growth (31) in the presence of polyphosphates, the order of effectiveness suggested was:

hexametaphosphate > phytic acid > pyrophosphate

The differences observed in the effectiveness of polyphosphates for HAP (31) and for DCPD as found in the present study, may be due to several factors including different rates of adsorption/desorption of polyphosphates on the two different types of calcium phosphate substrates namely, HAP and DCPD.

Varsanik (15) studied the spontaneous precipitation of calcium phosphates in the presence of phosphonates and concluded that the two most effective inhibitors were NTMP and HEDP, whereas ETMP and HMDP showed lower effectiveness as inhibitors for calcium orthophosphate. This is in contrast to the results obtained in the recent study (31) where only HAP exclusively grew on HAP seed crystals in the presence of phosphonates compared to the formation of calcium phosphate precursor phase(s) under spontaneous precipitation (15). Thus it is likely that phosphonates may have a different effect on the formation and subsequent transformation of the precursor phase (15) than on the formation of the thermodynamically stable HAP phase.

The effect of low levels of phosphonates on the crystal growth on calcium carbonate has also been investigated (33). Results of this study indicate that the effectiveness of the various phosphonates at a fixed weight concentration of 0.50 ppm, is in the order:

HEDP > HMDP > ETMP > NTMP

It is of interest to note that in the case of calcium oxalate monohydrate precipitation in the presence of phosphonates (34) the relative abilities of the phosphonates in retarding the precipitation was found to vary with varying experimental conditions. At 4.0×10^{-6} M phosphonate concentrations the order of effectiveness reported was:

HMDP > HEDP > ETMP and ETMP > HMDP > HEDP

for spontaneous and seeded growth, respectively. The observed results were interpreted in terms of both adsorption and complexation phenomena.

The differences in the ability of the various inhibitors, (viz., pyrophosphate, NTMP, HEDP, HMDP, ETMP, phytic acid, etc.) to retard or inhibit crystallization of DCPD could be rationalized in terms of their abilities to form a complex with the calcium ion. Table 5 summarizes the comparative data on the calcium-inhibitor complexation constant K_{ML} and the "affinity constant" for a variety of inhibitors. It can be seen that on the basis of "affinity constant" values, the order of effectiveness for the polyphosphate and phosphonates is:

ETMP > HMDP > NTMP > HEDP > pyrophosphate

whereas the values of the complexation constants follows the order:

ETMP > HEDP > NTMP > HMDP > pyrophosphate

A better assessment could only be gained by comparing the structural arrangement of phosphonate groups. The most effective of the inhibitors, ETMP, is structurally similar to the strong complexing agent EDTA (ethylenediamine tetraacetic acid) and would also be expected to be a strong complexing agent for calcium ion situated at DCPD crystal surface sites. The relative weakness of HMDP, containing four additional methylene groups compared to ETMP, as a potential inhibitor may be

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/07/12
For personal use only.

attributed to the difficulty in grouping all the phosphonates groups around one calcium site. The higher "affinity" value (21.4×10^5) for DCPD obtained in the present study for pyrophosphate at 37°C may be compared with 5.5×10^5 obtained at 25°C (14).

Results summarized in Table 2 for the inhibitory effect of phytic acid indicate that low levels (2.0×10^{-7} *M*) of PA completely inhibits DCPD crystal growth for at least 20 h. The value of the "affinity constant" (Table 5) for phytic acid is 4.10×10^7 which can be compared with 1.7×10^7 obtained for HEDP. It is of interest to note that values of "affinity constant" of phytic acid and HEDP for HAP crystal growth (31) were 8.4×10^5 and 208×10^5, respectively. The change in order of inhibitor effectiveness of PA and HEDP for DCPD and HAP crystallization may be due to several factors including different rates of adsorption and desorption of these inhibitors on two different types of substrates, i.e. DCPD and HAP crystals.

Summary

In the present work it has been shown that the presence of inhibitors viz. polyphosphates, phosphonates, and phytic acid, at low concentration can significantly inhibit the crystal growth of DCPD on DCPD seed crystals from calcium phosphate supersaturated solution maintained at constant supersaturation. The marked inhibitory influence of the inhibitors may be explained by adsorption of inhibitor molecules at the active growth sites. Based upon the kinetic data effectiveness of the inhibitors follows the order:

polyphosphates: phytic acid > hexametaphosphate > pyrophosphate

phosphonates: ETMP > HMDP > NTMP > HEDP

Étude thermodynamique du mélange chlore – acide isocyanurique en milieu aqueux

BERNARD SOLASTIOUK ET XAVIER DEGLISE[1]

Laboratoire de photochimie appliquée (Unité associée n° 238 du Centre national de la recherche scientifique), Université de Nancy I, Boite postale 239, 54506 Vandoeuvre-les-Nancy CEDEX, France

Reçu le 8 février 1988

BERNARD SOLASTIOUK et XAVIER DEGLISE. Can. J. Chem. **66**, 2188 (1988).

Nous présentons un mode de calcul permettant d'obtenir les concentrations à l'équilibre en solution aqueuse, de l'acide cyanurique et de ses dérivés chlorés en fonction du pH, du rapport chlore/acide cyanurique et de la concentration en ions chlorures. Une étude de l'influence de chacun de ces paramètres sur les différents équilibres est présentée, dans des conditions proches de celles de l'utilisation de ces composés dans les eaux de piscines.

BERNARD SOLASTIOUK and XAVIER DEGLISE. Can. J. Chem. **66**, 2188 (1988).

A method of calculation of the equilibrium concentrations in aqueous solution of cyanuric acid and its chlorinated derivatives as a function of pH, molar ratio of chlorine/cyanuric acid, and chloride ion concentration is presented. The influence of each of these parameters is studied in conditions close to those used for these compounds in swimming pools.

Introduction

Les dérivés *N*-chlorés de la triazine-1,3,5 trione-2,4,6 ou acide cyanurique(Cy) sont des produits couramment utilisés comme sources de chlore dans les détergents et les eaux de piscines. En effet ces produits solides représentent une source de chlore plus facilement transportable et utilisable par exemple que l'eau de javel ou le chlore gazeux. Ils empêchent surtout la photolyse rapide du chlore car les molécules mono-, di-, et trichlorées de l'acide cyanurique ($CyCl$, $CyCl_2$, $CyCl_3$) tout en conservant un pouvoir chlorant efficace pour la désinfection des eaux sont d'une relative stabilité vis à vis du rayonnement solaire.

Les constantes d'équilibres entre ces composés ont été déterminées par O'Brien *et al.* (1, 2) et c'est à partir de ces valeurs que nous déterminons la composition d'une solution aqueuse de ces produits. Dans ces équilibres il n'est pas tenu compte des différentes formes tautomères que peuvent prendre ces molécules (voir figure 1).

1. Le chlore en solution aqueuse

Le chlore moléculaire dissous dans l'eau est soumis à différents équilibres et forme de façon rapide et réversible différentes espèces (acide hypochloreux, hypochlorites, et ions trichlorures) dont les proportions sont régies par les équilibres suivants :

$$Cl_2 + H_2O \rightleftarrows ClOH + H^+ + Cl^-$$

$$K_1 = \frac{[ClOH][Cl^-][H^+]}{[Cl_2]} = 3{,}94 \times 10^{-4}\ M^2 \text{ à } 298\ K$$

$$ClOH \leftrightarrows ClO^- + H^+$$

$$K_2 = \frac{[ClO^-][H^+]}{[ClOH]} = 2{,}88 \times 10^{-8}\ M \text{ à } 298\ K$$

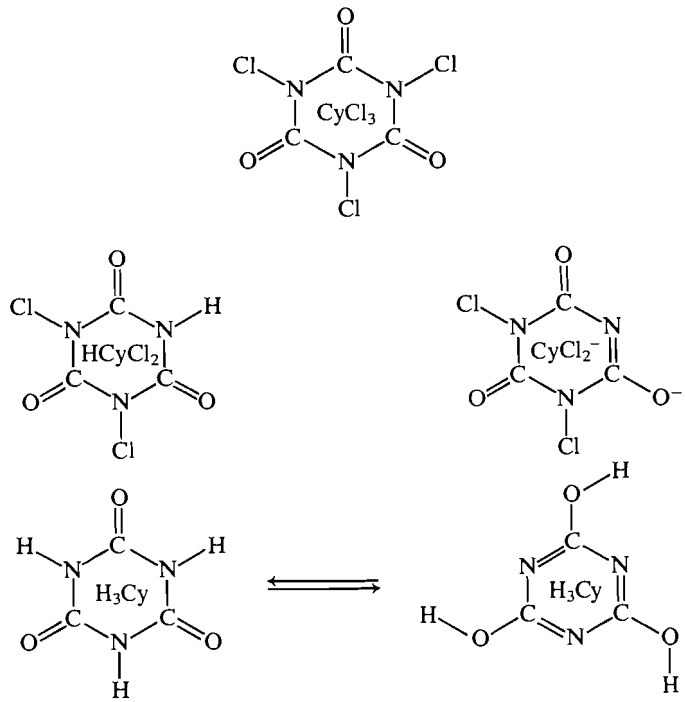
$$Cl_2 + Cl^- \leftrightarrows Cl_3^-$$

$$K_3 = \frac{[Cl_3^-]}{[Cl_2][Cl^-]} = 0{,}18\ M^{-1} \text{ à } 298\ K$$

Bell et Gells (7) ont étudié la stabilité en solution aqueuse du cation Cl^+ et du cation solvaté $H_2O{\cdot}Cl^+$. Eigen et Kustin (8) quant à eux ont estimé celle de Cl_2OH^-. Ces espèces restant dans toutes conditions très minoritaires, sinon inexistantes, en solution aqueuse; nous n'en tenons donc pas compte.

Nous regroupons sous le terme générique de «chlore libre» indifféremment les quatre espèces Cl_2, $ClOH$, ClO^- et Cl_3^-, par opposition au chlore lié aux atomes d'azote.

Les ions chlorures sont pris en excès par rapport au chlore actif total en sorte que leurs concentrations puissent être considérées comme invariantes aux cours des différentes mises à l'équilibre considérées ($[Cl^-] \gg [Cl]_{total}$).



s Triazine trione — *s* Triazine triol

FIG. 1. Structures moléculaires des dérivés concernés. $CyCl_3$: acide trichlorocyanurique (*N*-trichloro-2,4,6 *s* triazine trione-1,3,5); $HCyCl_2$: acide dichlorocyanurique (*N*-dichloro-2,4 *s* triazine trione); $CyCl_2^-$: ion dichlorocyanurates; H_3Cy : acide cyanurique (*s* triazine-2,4,6 trione-1,3,5 et *s* triazine-2,4,6 triol-1,3,5).

2. Le mélange chlore – acide cyanurique en solution aqueuse

Lorsqu'on mélange chlore et acide cyanurique en solution aqueuse chaque azote du cycle triazinique est susceptible de fixer un atome de chlore (1–4).

Pour décrire ce système, les valeurs des constantes d'équilibre seront données pour les équilibres types suivants (où x est compris entre 0 et 2) :

$$Cl_{(3-x)}CyH_x + H_2O \rightleftarrows HOCl + Cl_{(2-x)}CyH_{(x+1)}$$

De plus les propriétés acido-basiques de ces dérivés imposent de tenir compte d'espèces supplémentaires plus ou moins ionisées.

Le schéma suivant (schéma 1) présente ces différents produits et les équilibres dans lesquels ils interviennent :

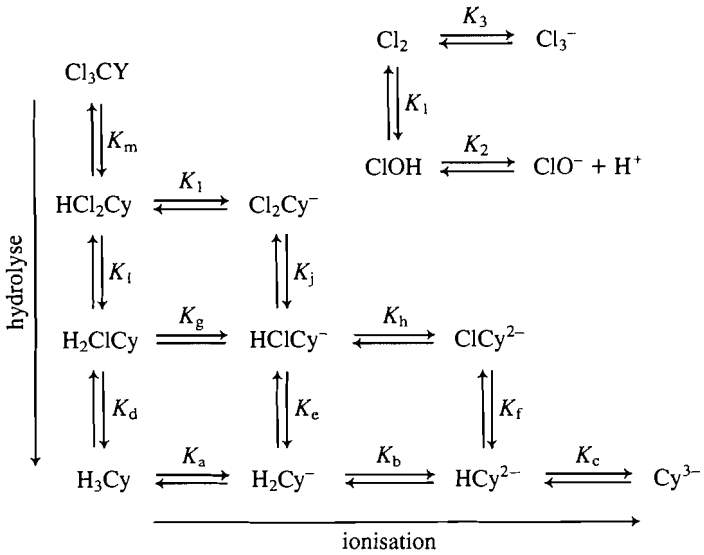

SCHÉMA 1

Les dix espèces comprenant un noyau cyanurique ($C_3N_3O_3$), et les quatre formes de chlore libre, sont susceptibles d'échanger protons et atomes de chlore.

3. Mode de calcul

Nous voulons étudier le devenir à l'équilibre d'une solution aqueuse d'un mélange d'acide cyanurique (H_3Cy) et de chlore en tenant compte :

- de la concentration initiale en acide cyanurique : $C_0 = [H_3Cy]_0$;
- de la concentration initiale en chlore considérée comme multiple de C_0 $[Cl_2]_0 = G \cdot C_0$;
- du pH : $h = [H^+] = 10^{-pH}$;
- de la concentration en chlorure : $Cl = [Cl^-]$;
- des valeurs des constantes d'équilibres;
- de la température supposée constante et égale à 25°C.

Nous utilisons les notations suivantes pour les différentes sommes des concentrations molaires

des dérivés du chlore libre (Chl) :

$$\Sigma_{Chl} = [ClOH] + [ClO^-] + [Cl_2] + [Cl_3^-]$$

des dérivés non-chlorés :

$$\Sigma_{(0)} = [H_3Cy] + [H_2Cy^-] + [HCy^{2-}] + [Cy^{3-}]$$

des dérivés monochlorés :

$$\Sigma_{(I)} = [H_2ClCy] + [HClCy^-] + [ClCy^{2-}]$$

des dérivés dichlorés :

$$\Sigma_{(II)} = [HCl_2Cy] + [Cl_2Cy^-]$$

et pour le dérivé trichloré :

$$\Sigma_{(III)} = [Cl_3Cy]$$

La concentration de chacune des 14 espèces présentes en solution est une inconnue. Pour résoudre ce système nous disposons de deux bilans (bilan en chlore et bilan en noyaux cyanuriques) et de 15 lois d'action de masse, il suffit d'en choisir arbitrairement 12 qui soient indépendantes.

Avec nos notations les bilans s'écrivent :

$$C_0 = \Sigma_{(0)} + \Sigma_{(I)} + \Sigma_{(II)} + \Sigma_{(III)}$$

(Bilan en noyaux cyanuriques)

$$G \cdot C_0 = \Sigma_{Chl} + \Sigma_{(I)} + 2\Sigma_{(II)} + 3\Sigma_{(III)}$$

(Bilan en chlore)

Et à partir de l'expression des constantes d'équilibre on peut exprimer les sommes en fonction de la concentration de l'espèce non ionisée de la série :

$$\Sigma_{(0)} = [H_3Cy]\{1 + K_a/h + K_aK_b/h^2 + K_aK_bK_c/h^3\} = [H_3Cy]\alpha$$

$$\Sigma_{(I)} = [H_2ClCy]\{1 + K_g/h + K_gK_h/h^2\} = [H_2ClCy]\beta$$

$$\Sigma_{(II)} = [HCl_2Cy]\{1 + K_1/h\} = [HCl_2Cy]\gamma$$

$$\Sigma_{(III)} = [Cl_3Cy]$$

La somme des concentrations des espèces de chlore libre peut s'exprimer à partir de celle de ClOH

$$\Sigma_{Chl} = [ClOH](1 + (Cl \cdot h/K_1) + (K_3 \cdot Cl^2 \cdot h/K_1) + (K_2/h)) = [ClOH]\delta$$

Les coefficients α, β, γ et δ sont évidemment facilement calculables et constants pour un pH et une concentration en chlorures donnés.

Les bilans s'écrivent alors :

bilan en noyaux cyanuriques :

$$C_0 = \alpha[H_3Cy] + \beta[H_2ClCy] + \gamma[HCl_2Cy] + [Cl_3Cy]$$

bilan en chlore :

$$G \cdot C_0 = \delta[ClOH] + \beta[H_2ClCy] + 2\gamma[HCl_2Cy] + 3[Cl_3Cy]$$

et sont exprimés en fonction de [ClOH] et $[H_3Cy]$:

$$C_0 = [H_3Cy]\left(\alpha + \beta\frac{[ClOH]}{K_d} + \gamma\frac{[ClOH]^2}{K_dK_i} + \frac{[ClOH]^3}{K_dK_iK_m}\right)$$

$$G \cdot C_0 = \delta[ClOH] + [H_3Cy]\left(\beta\frac{[ClOH]}{K_d} + 2\gamma\frac{[ClOH]^2}{K_dK_i} + 3\frac{[ClOH]^3}{K_dK_iK_m}\right)$$

En remplaçant dans la seconde équation la valeur de $[H_3Cy]$ par celle obtenue à partir de la première on trouve, après simplification et regroupement des différents termes, l'équation :

$$[1]\quad \left\{\frac{\delta}{K_dK_iK_m}\right\}[ClOH]^4 + \left\{\frac{\delta\gamma}{K_dK_i} + (3\text{-}G)\frac{C_0}{K_dK_iK_m}\right\}[ClOH]^3 + \left\{\frac{\delta\beta}{K_d} + (2\text{-}G)\frac{\gamma C_0}{K_dK_iK_m}\right\}[ClOH]^2 + \left\{\delta\alpha + (1\text{-}G)\frac{\beta C_0}{K_d}\right\}[ClOH]^2 - G\alpha C_0 = 0$$

équation du quatrième degré qui, résolue numériquement, nous

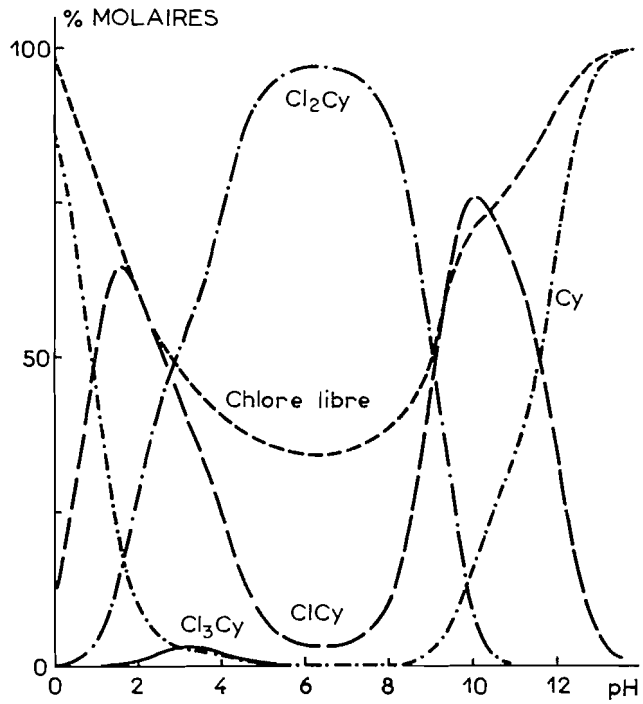

FIG. 2. Influence du pH sur la composition du mélange chlore – acide cyanurique en solution aqueuse. $[H_3Cy]_0 = 10^{-3}$ M; $[Cl_2]_0 = 3 \times 10^{-3}$ M équivalent à $[CyCl_3]_0 = 10^{-3}$ M (232 mg/L); $[Cl^-] = 10^{-1}$ M. (——) Cl_3Cy; (—·—·) Cl_2Cy somme des composés dichlorés; (— —) ClCy somme des composés monochlorés; (·····) Cy somme des composés non-chlorés; (----) chlore libre (Cl_2, ClOH, ClO^-, Cl_3^-).

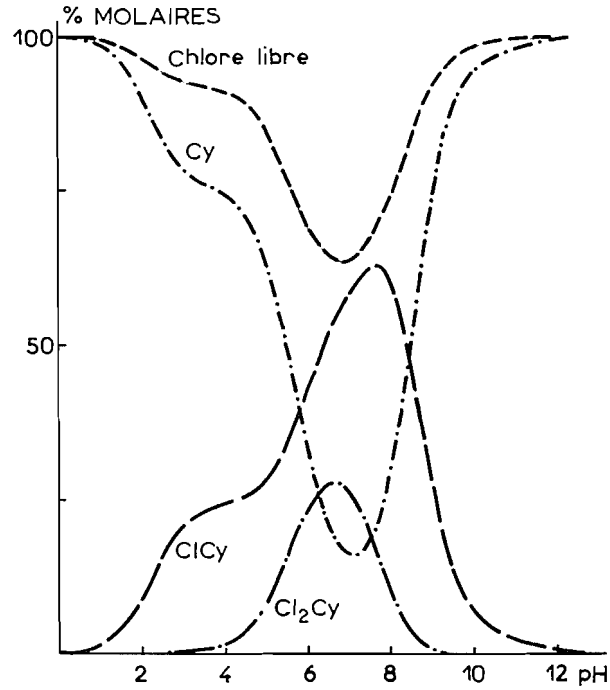

FIG. 3. Influence du pH sur la composition du mélange chlore – acide cyanurique en solution aqueuse. $[H_3Cy]_0 = 10^{-5}$ M; $[Cl_2]_0 = 3 \times 10^{-5}$ M équivalent à $[CyCl_3]_0 = 10^{-5}$ M (2,32 mg/L); $[Cl^-] = 10^{-1}$ M. (—·—) Cl_2Cy somme des composés dichlorés; (——) ClCy somme des composés monochlorés; (·····) Cy somme des composés non-chlorés; (----) chlore libre (Cl_2, ClOH, ClO^-, Cl_3^-).

donnera la valeur de [ClOH] pour les conditions fixées. La résolution de cette équation ne présente pas de difficulté particulière, en effet la racine recherchée $[ClOH]_{eq}$, prend une valeur forcément comprise entre 0 et la concentration en chlore initiale soit $G \times C_0$. Il est d'ailleurs facile de vérifier que pour $C = 0$ la fonction prend la valeur négative $-\alpha G \cdot C_0$ alors que pour $C = G \times C_0$ elle prend la valeur :

$$\frac{G^4(\delta-1)+G^3}{K_iK_dK_m}C_0^4 + \gamma\frac{G^3(\delta-1)+2G^2}{K_iK_d}C_0^3 + \beta\frac{G^2(\delta-1)+G}{K_i}C_0^3 + \alpha G(\delta-1)C_0$$

qui est positive, les coefficients δ étant toujours supérieurs ou égaux à 1. Un simple calcul informatique permet d'extraire rapidement cette racine.

Les concentrations des autres espèces se déduisent linéairement de la valeur de [ClOH]. Nous avons mis au point un logiciel bâti autour de ce calcul qui nous donne, pour une composition et un pH donnés, toutes les concentrations recherchées.

Les valeurs des différentes constantes d'équilibres que nous avons utilisées sont reportées dans le tableau 1.

4. Résultats

4.1 Influence du pH

Les figures 2 et 3 sont obtenues par le calcul précédent

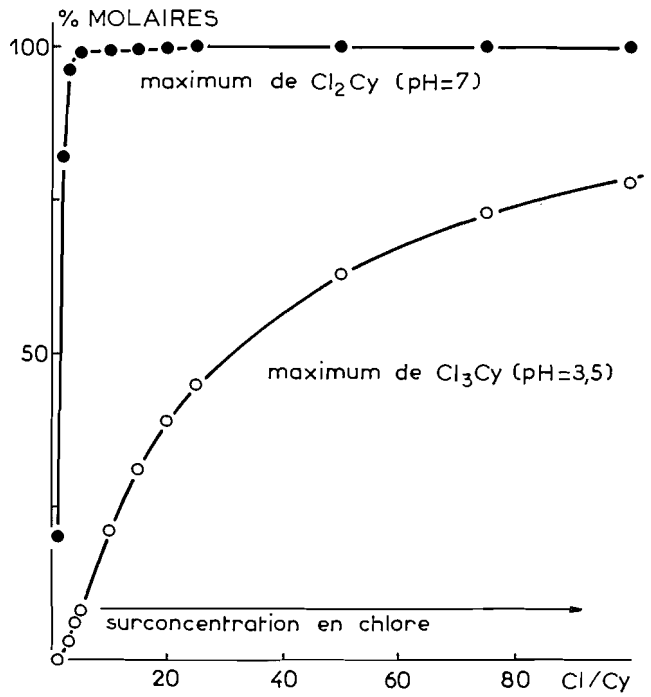

FIG. 4. Influence de la surconcentration en chlore; ● : proportion maximale de Cl_2Cy; ○ : proportion maximale de Cl_3Cy. $[H_3Cy]_0 = 10^{-3}$ M; $[Cl^-] = 10^{-1}$ M.

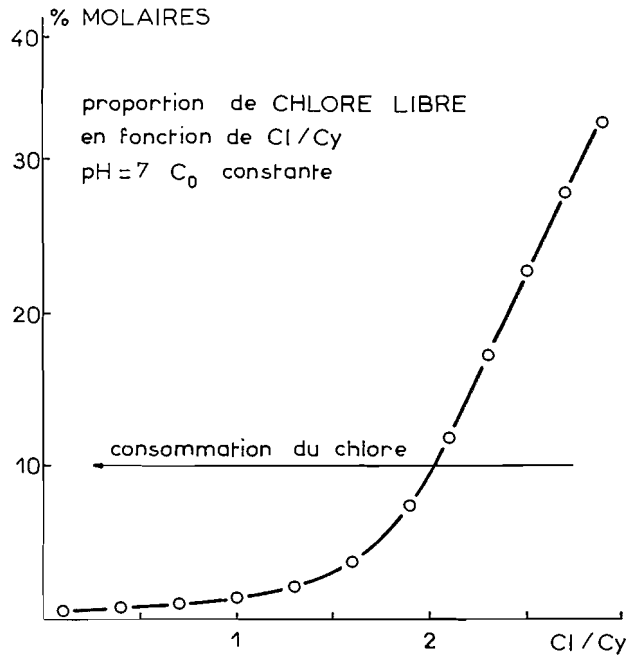

FIG. 5. Influence de la baisse du rapport Cl/Cy (dispariton du chlore) : proportion de chlore libre. $[H_3Cy]_0 = 10^{-3}$ M; $[Cl^-] = 10^{-1}$ M.

effectué dans tout le domaine de pH d'une solution aqueuse. Elles correspondent à deux dilutions différentes de Cl_3Cy, respectivement 10^{-3} M (232 mg/L) et 10^{-5} M (2,3 mg/L).

Les courbes qui y apparaissent représentent les pourcentages molaires pour chaque catégorie de composés, chlore libre ($\Sigma_{Chl}/(G \times C_0)$), mono, di, et trichloré ($\Sigma_{(i)}/C_0$) en fonction du pH.

La figure 2 montre une certaine symétrie, avec au centre (de pH 4–8) une large zone de prédominance du composé dichloré, cette plage correspond aussi au minimum de chlore libre en solution. Notons que les pH d'utilisation des dérivés chlorés de l'acide cyanurique se situent dans cette zone proche de la neutralité (eau de piscine par exemple) et à un minimum de chlore libre en solution correspond un minimum de la vitesse de disparition du chlore actif par photolyse.

De part et d'autre de cette plage apparaissent deux zones de prédominance du composé monochloré en milieu acide (pH 1–3) et milieu basique (pH 9–12) et pour des solutions très acides ou très basiques l'*hydrolyse* est totale.

Dans les conditions de calcul de cette figure, c'est à dire trois chlores pour un noyau cyanurique, la proportion maximale de trichlorocyanurique en solution ne dépasse pas 4 ou 5%. Par dissolution de Cl_3Cy on obtient donc dans des pH proches de la neutralité principalement Cl_2Cy, le tiers de chlore restant étant libéré sous forme d'acide hypochloreux.

Pour la figure 3 la symétrie précédente est conservée avec une baisse très sensible de la proportion des formes les plus chlorées, Cl_3Cy n'y apparait plus en quantité notable et Cl_2Cy n'est plus majoritaire à pH 7. Ceci est général, pour un même rapport Cl/Cy, plus la dilution est grande plus le chlore libre est abondant par rapport au chlore lié aux atomes d'azote des cycles cyanuriques.

4.2 Influence de la surconcentration en chlore

Il est évident à priori que plus le chlore sera en excès dans le milieu (plus le rapport Cl/Cy sera grand) plus la chloration relative de ces composés sera forte.

La figure 4 montre l'évolution des maxima en acide dichloro et trichlorocyanurique en fonction de ce rapport.

Il apparait que pour une faible surconcentration de chlore on obtient facilement au pH adéquat une proportion proche de 100% en Cl_2Cy alors qu'il est très difficile d'obtenir une grande proportion de Cl_3Cy.

La figure 5 montre la quantité de chlore libre par rapport au chlore actif total pour des valeurs du rapport chlore/acide cyanurique comprises entre 0 et 3. La baisse de Cl/Cy peut représenter la consommation du chlore dans une eau où l'on aurait dissous Cl_3Cy.

Cette figure montre que la dissolution du dérivé dichloré (rapport Cl/Cy = 2) amène moins de chlore libre, donc moins de chlore sensible à une photodégradation rapide en solution.

Pour mieux illustrer ce fait la figure 6 montre, à quantité de chlore actif total constant, l'influence directe du rapport Cl/Cy sur la proportion de chlore libre.

$$[\text{Cl actif}] = [\text{Cl lié à Cy}] + [\text{Cl libre}]$$

Nous avons pris dans cet exemple [Cl actif] = 1,5 mg/L, ce qui est de l'ordre de grandeur requis dans l'eau d'une piscine. (La quantité de chlore résiduel conseillé après surchloration et stabilisation d'une eau de piscine est de 1 à 1,5 ppm.)

4.3 Influence de la dilution (C_0)

Il existe un effet de dilution pour un même rapport Cl/Cy; la chloration est plus complète à concentration élevée en noyaux cyanurique.

La figure 7 représente la proportion maximale du dérivé dichloré en fonction du logarithme de $[H_3Cy]_0$ pour un rapport Cl/Cy constant et égal à 3.

4.4 Influence des ions chlorures

Hormis l'influence de la force ionique, les ions chlorures ont un effet sur la composition du mélange en milieu acide, plus la

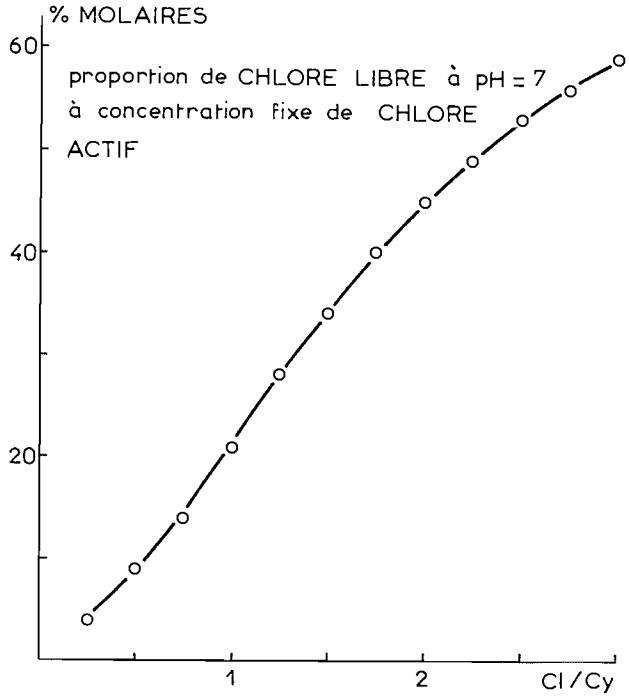

FIG. 6. Influence du rapport Cl/Cy sur la proportion de chlore libre à quantité de chlore actif constante : proportion de chlore libre. $[Cl_2]_0 = 1.5$ mg/L; $[Cl^-] = 10^{-1}$ M.

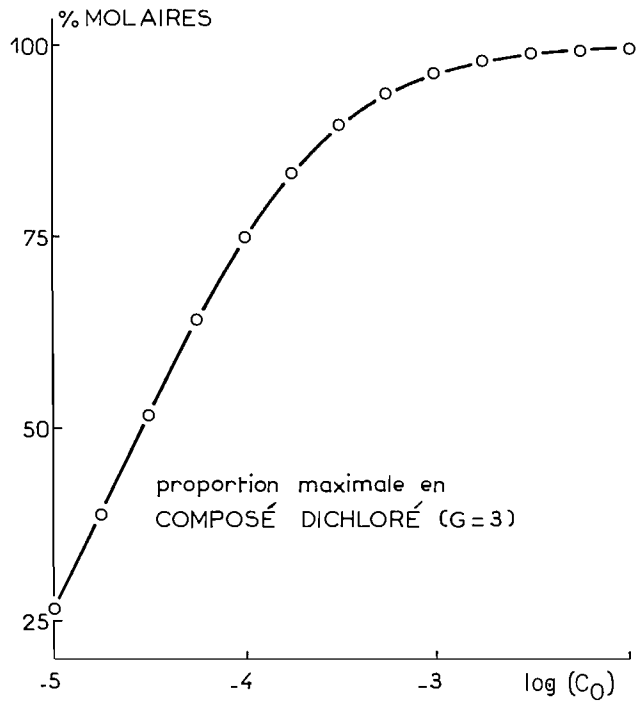

FIG. 7. Influence de la dilution globale : proportion maximale de dichlore versus $\log_{10}$ (C_0). Rapport Cl/Cy = constante = 3. $[H_3Cy]_0$ (C_0) variant de 10^{-5} à 10^{-2} M; $[Cl^-] = 10^{-1}$ M.

concentration en ions chlorures augmente plus la formation du dérivé trichloré est défavorisée.

Sur la figure 8 les concentrations en ions chlorures variant de 0,1 à 1 M; nous avons représenté le pourcentage maximum de $CyCl_3$ par rapport à la concentration initiale de noyaux cyanuriques en fonction de $[Cl^-]$, ceci en négligeant l'effet de

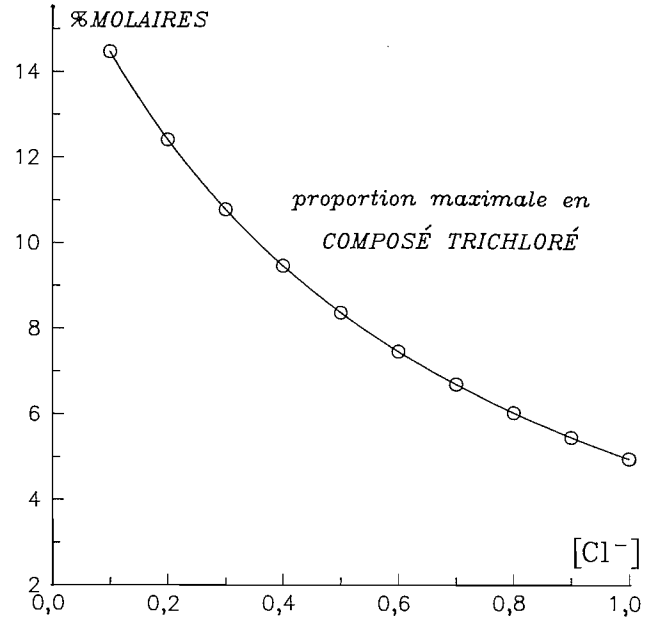

FIG. 8. Influence des ions chlorure : proportion maximale de trichlore versus $[Cl^-]$. Rapport Cl/Cy = 5. $[H_3Cy]_0 = 2 \times 10^{-3}$ M; $[Cl^-]$ variant de 0,1 à 1 M.

la force ionique du milieu sur les coefficients d'activités et les déplacements d'équilibres susceptibles d'en résulter.

Ces précautions étant prises, il apparait clairement qu'une forte concentration en ions chlorures favorise l'hydrolyse de $CyCl_3$.

En milieu basique les ions chlorures n'influencent pas directement la composition de la solution.

Conclusions

Le calcul utilisé ici permet de trouver facilement par la résolution de l'équation [1] les concentrations de toutes les espèces en solution aqueuse du système chlore/acide isocyanurique dans toutes les conditions de pH et de dilution voulues. Ceci est du au fait que nous tenons compte de toutes les espèces de chlore libre qu'il est possible de trouver en équilibre rapide et réversible sur toute la gamme de pH alors qu'habituellement la plupart des auteurs ne tiennent compte que des espèces ClOH et ClO^-. Le fait de prendre en compte la formation éventuelle de Cl_2 et Cl_3^- permet l'étude du milieu acide ce qui peut présenter un intérêt vis-à-vis de problèmes de synthèse (de Cl_3Cy en particulier).

Nous avons pu constater que l'acide trichlorocyanurique n'était majoritaire en solution qu'en présence d'un large excès de chlore, soit dans des conditions très différentes de celles des eaux de piscines; dans les conditions normales d'utilisation la dissolution des dérivés chlorocyanuriques conduit principalement à la formation d'acide dichloro et monochlorocyanurique.

Les résultats obtenus rejoignent les conclusions de O'Brien *et al.* (2) qui corrèlent la plus forte inhibition de la photodécomposition du chlore au minimum de chlore libre par rapport au chlore total entre pH 6 et 8, et celles de Pinsky et Hu (3) qui relie logiquement cette inhibition à la surconcentration en acide cyanurique.

Dans la mesure où le chlore lié aux noyaux isocyanurates reste actif en ce qui concerne son rôle désinfectant, il s'avère, pour gérer la composition d'une eau de piscine que à une teneur en chlore donnée, qu'il est préférable de maintenir un rapport

Synthesis and X-ray crystal structure of the novel Mo—Cu complex, $(Ph_2PCH_2CH_2PPh_2)_2Cu^+[(HBpz''_3)Mo(CO)_3]_2Cu^-$ (where pz'' = 3,5-dimethylpyrazolyl, $N_2C_5H_7$)

STEVEN J. RETTIG, ALAN STORR, AND JAMES TROTTER

Department of Chemistry, University of British Columbia, 2036 Main Mall, Vancouver, B.C., Canada V6T 1Y6

Received March 3, 1988

RETTIG, S. J., STORR, A., and TROTTER, J. 1988. Can. J. Chem. **66**, 2194 (1988).

The novel complex, $(Ph_2PCH_2CH_2PPh_2)_2Cu^+[(HBpz''_3)Mo(CO)_3]_2Cu^-$ (where pz'' = 3,5-dimethylpyrazolyl), has been synthesized by reacting the $(HBpz''_3)Mo(CO)_3^-$ anionic ligand with CuI in the presence of a stoichiometric amount of $Ph_2PCH_2CH_2PPh_2$. Crystals of $(Ph_2PCH_2CH_2PPh_2)_2Cu^+[(HBpz''_3)Mo(CO)_3]_2Cu^- \cdot 3.5C_6H_6 \cdot CH_2Cl_2$ are triclinic, a = 13.421(1), b = 14.931(3), c = 28.523(5) Å, α = 90.41(2), β = 90.19(1), γ = 104.65(1)°, Z = 2, space group $P\bar{1}$. The structure was solved by heavy atom methods and was refined by full-matrix least-squares procedures to R = 0.047 and R_w = 0.049 for 8779 reflections with $I \geq 3\sigma(I)$. The crystal structure consists of $(Ph_2PCH_2CH_2PPh_2)_2Cu^+$ cations having irregular tetrahedral coordination geometry about the copper atom (Cu—P = 2.263(2)–2.304(2) Å and P—Cu—P = 88.30(7)– 134.62(8)°) and novel $[(HBpz''_3)Mo(CO)_3]_2Cu^-$ anions having exact C_i and approximate D_{3d} symmetry. The central Cu atom of the anion is bonded to two Mo atoms in a linear fashion and also interacts with six semi-bridging carbonyl ligands, three from each $(HBpz''_3)Mo(CO)_3^-$ ligand. Average bond lengths and angles for the anion are Mo–Cu = 2.565, Mo—C = 1.955, Mo—N = 2.256, Cu—C = 2.309, C—O = 1.174 Å, Mo—C—O = 171.7° and Cu—C—O = 114.7°.

RETTIG, S. J., STORR, A., et TROTTER, J. 1988. Can. J. Chem. **66**, 2194 (1988).

On a synthétisé le nouveau complexe, $(Ph_2PCH_2CH_2PPh_2)_2Cu^+[(HBpz''_3)Mo(CO)_3]_2Cu^-$ (où pz'' = diméthyl-3,5 pyrazolyl), en faisant réagir le ligand anionique $(HBpz''_3)Mo(CO)_3^-$ avec le CuI en présence de quantités stochiométriques de $Ph_2PCH_2CH_2PPh_2$. Les cristaux de $(Ph_2PCH_2CH_2PPh_2)_2Cu^+[(HBpz''_3)Mo(CO)_3]_2Cu^- \cdot 3.5C_6H_6 \cdot CH_2Cl_2$ sont tricliniques et appartiennent au groupe d'espace $P\bar{1}$ avec a = 13,421(1), b = 14,931(3), c = 28,523(5) Å, α = 90.41(2), β = 90,19(1), γ = 104.65(1)°, Z = 2. On a résolu la structure par la méthode des moindres carrés (matrice complète) jusqu'à des valeurs de R = 0.047 et de R_w = 0.049 pour 8779 réflexions avec $I \geq 3\sigma(I)$. La structure du cristal consiste en des cations $(Ph_2PCH_2CH_2PPh_2)_2Cu^+$ ayant une géométrie de coordination irrégulière autour de l'atome de cuivre (Cu—P = 2,263(2)–2,304(2) Å et P—Cu—P = 88,30(7)–134.62(8)°) et des nouveaux anions $[(HBpz''_3)Mo(CO)_3]_2Cu^-$ ayant exactement C_i et une symmétrie approximative D_{3d}. L'atome de cuivre central de l'anion est lié de façon linéaire à deux atomes de Mo et est en interaction avec six ligands carbonyles en position de demi-pont, chaque ligand $(HBpz''_3)Mo(CO)_3^-$ fournissant trois unités de ce demi-pont. Les longueurs moyennes de liaison et les angles moyens de l'anion sont Mo—Cu = 2,565, Mo—C = 1,955, Mo—N = 2,256, Cu—C = 2,309, C—O = 1,174 Å, Mo—C—O = 171,7° et Cu—C—O = 114,7°.

Introduction

Earlier publications (1, 2) have described a number of complexes of the type (RE"pz"$_3$)Mo(CO)$_3$CuL (where R = Me when E = Ga and "pz" = $N_2C_3H_3$, L = PPh_3; where R = H when E = B and "pz" = $N_2C_3H_3$ for L = PPh_3 or tmed, or "pz" = $N_2C_5H_7$ for L = tmed). In these complexes a Mo—Cu bond is complimented by semi-bridging CO groups and the Cu centre is further ligated by a monodentate Ph_3P ligand or by the bidentate tmed molecule. The complexes where L = Ph_3P are unusual in their coordinative unsaturation about the copper centre, especially when compared to complexes of the type CpM(CO)$_3$Cu-$(Ph_3P)_2$ where M = Mo or W (3).

The Cp^- ligand has been likened to the trispyrazolylborate and -gallate ligands, RE"pz"$_3^-$, in that all three ligand systems are six-electron donors, facially tridentate chelating and uninegative. Consequently many "isoelectronic" series of complexes incorporating these ligands have been reported (4–7). The different compositions of the triphenylphospine complexes produced with the $CpMo(CO)_3^-$ and $(RE"pz"_3)Mo(CO)_3^-$ anions are thought to be manifestations of the different steric requirements of the two ligand types. The present study was an attempt to exploit this steric effect to produce a Cu diphos complex with a "dangling" diphenylphosphino functionality, viz, $(HBpz''_3)Mo(CO)_3CuPh_2PCH_2CH_2PPh_2$ (where pz'' = 3,5-dimethylpyrazolyl, $N_2C_5H_7$). The complex isolated did indeed display this stoichiometry but the novel molecular arrangement observed was unexpected and totally without precedent.

Experimental

Starting materials

Air-sensitive materials were handled in a nitrogen atmosphere. Tetrahydrofuran (THF), benzene, CH_2Cl_2, and hexane were dried by refluxing over Na/benzophenone, potassium, CaH_2, and $CaSO_4$, respectively, followed by distillation. A THF solution of the ligand $K^+[(HBpz''_3)Mo(CO)_3]^-$ was prepared as described previously (2).

Preparation of $(Ph_2PCH_2CH_2PPh_2)_2Cu^+[(HBpz''_3)Mo(CO)_3]_2Cu^-$

To a solution of $K^+[(HBpz''_3)Mo(CO)_3]^-$ (1.494 mmol) (2) in 200 mL THF was added a slurry of CuI (0.284 g, 1.494 nmol) and $Ph_2PCH_2CH_2PPh_2$ (0.594 g, 1.494 mmol) in CH_2Cl_2/THF. The mixture was stirred for ~16 h at room temperature and then the solvents were removed under vacuum. The residue was extracted with CH_2Cl_2 and filtered. Hexane and benzene were added to the clear filtrate and the mixed solvents allowed to evaporate slowly. Golden yellow crystals of the product were solvated with 3.5 C_6H_6 and one CH_2Cl_2 solvate molecules per ion pair. Yield ~60%. *Anal.* calcd. for $(Ph_2PCH_2CH_2PPh_2)_2Cu^+[(HBpz''_3)Mo(CO)_3]_2Cu^- \cdot 3.5C_6H_6 \cdot CH_2Cl_2$: C 59.07, H 5.15, N 7.52; found: C 58.60, H 5.08, N 7.64. ^{1}H nmr

Spectra

The ir spectra were recorded on a Perkin-Elmer 598 spectrometer. The ^1H nmr spectrum was recorded on a Varian 300 MHz instrument using FT techniques.

X-ray crystallographic analysis of bis[1,2-bis(diphenylphosphino)ethane]copper(I) bis[(hydrotris(3,5-dimethylpyrazolyl)borato)tricarbonylmolybdenum]copper(2Mo—Cu) benzene dichloromethane solvate

A crystal bounded by the six faces (followed by the distances in mm between parallel faces): {0 0 1}, 0.22, {0 1 1}, 0.09, {1 0 1}, 0.65, was mounted in a general orientation. Unit-cell parameters were refined by least squares on 2 sin θ/λ values for 25 reflections (2θ = 35–38°) measured on a diffractometer with Mo–$K\alpha$ radiation ($\lambda(K\alpha_1)$ = 0.70930, $\lambda(K\alpha_2)$ = 0.71359 Å). Crystal data at 22°C are as follows:

$C_{88}H_{92}B_2Cu_2Mo_2N_{12}O_6P_4 \cdot 3.5C_6H_6 \cdot CH_2Cl_2$ f.w. = 2236.59 Triclinic, a = 13.421(1), b = 14.931(3), c = 28.523(5) Å, α = 90.41(2), β = 90.19(1), γ = 104.65(1)°, V = 5530(1) Å^3, Z = 2, ρ_c = 1.343 Mg m^{-3}, $F(000)$ = 2306, μ(Mo-$K\alpha$) = 18.7 cm^{-1}. Absent reflections: none, space group $P\bar{1}$ (C_i^1, No. 2, reduced cell) from structure analysis.

Intensities were measured with graphite-monochromated Mo-$K\alpha$ radiation on an Enraf-Nonius CAD4-F diffractometer. An ω scan at 2.0–20.1° min^{-1} over a range of (0.90 + 0.35 tan θ) degrees in ω (extended by 25% on both sides for background measurement) was employed. Data were measured to 2θ = 50°. The intensities of three check reflections, measured every 6000 s throughout the data collection, showed only small random variations (<4%). After data reduction, an absorption correction was applied using the Gaussian integration method. Transmission factors ranged from 0.820 to 0.939 for 96 integration points. Of the 19350 independent reflections measured, 8779 (45.4%) had intensities greater than or equal to $3\sigma(I)$ above background where $\sigma^2(I) = S + 2B + (0.04(S-B))^2$ with S = scan count and B = normalized background count. Pseudo-I-centering of the crystal lattice is partially responsible for the relatively small fraction of significant data, half of the total number being systematically weak.

The structure analysis was initiated in the centrosymmetric space group $P\bar{1}$ (which was confirmed by subsequent calculations). The structure was solved by heavy atom methods, the metal atom coordinates being determined from the Patterson function. The solution was complicated by the fact that there are two independent, centrosymmetric, $[(HBpz''_3)Mo(CO)_3]_2Cu^-$ anions located about the lattice points (0,0,0) and (1/2,1/2,1/2), and having the linear Mo—Cu—Mo moieties parallel. This results in considerable overlapping of the Patterson function peaks. The remaining non-hydrogen atoms of the cation and anion were positioned from a subsequent difference Fourier map. After further refinement the solvent molecules were located (three benzene molecules in general positions and one at a centre of symmetry and one molecule of dichloromethane). In the final stages of refinement the non-hydrogen atoms were refined with anisotropic thermal parameters and hydrogen atoms were fixed in idealized positions (B—H = 1.09, (C(sp^2)—H = 0.97, C(sp^3)—H = 0.98 Å, $U_H \alpha U_{\text{bonded atom}}$, methyl orientations based on observed hydrogen positions). Scattering factors for all atoms and anomalous scattering corrections for Mo, Cu, Cl, and P were taken from ref. 8. The weighting scheme $w = 1/\sigma^2(F)$, where $\sigma^2(F)$ is derived from the previously defined $\sigma^2(I)$, gave uniform average values of $w(|F_o|-|F_c|)^2$ over ranges of both $|F_o|$ and sin θ/λ and was employed in the final stages of full-matrix refinement of 1264 variables. Reflections with $I < 3\sigma(I)$ were not included in the refinement. Convergence was reached at R = 0.047 and R_w = 0.049 for 8779 reflections with $I \geq 3\sigma(I)$. The function minimized was $\Sigma w(|F_o|-|F_c|)^2$, $R = \Sigma(||F_o|-|F_c||/\Sigma|F_o|$ and $R_w = (\Sigma w(|F_o|-|F_c|)^2/\Sigma w|F_o|^2)^{1/2}$.

On the final cycle of refinement the mean and maximum parameter shifts corresponded to 0.04 and 0.83 σ, respectively. The mean error in an observation of unit weight was 1.763. The final difference map showed maximum fluctuations of −1.0 and 0.6 e Å^{-3} in the vicinity of the Mo atoms and was essentially featureless elsewhere. The final positional and thermal parameters appear in Tables 1 and 6[2], respectively. Measured and calculated structure factors have been placed in the Depository of Unpublished Data.[1] Selected bond lengths and bond angles appear in Tables 2 and 3, respectively. Intra-annular torsion angles, calculated hydrogen atom parameters, anisotropic thermal parameters, and complete lists of bond lengths, bond angles, and torsion angles (Tables 4–9) have also been deposited.[1]

Results and discussion

The ability of the tricarbonyl anions $(RE''pz''_3)Mo(CO)_3^-$ to form complexes with both transition metal and main group metal moieties in which heteronuclear metal–metal bonds are featured has been demonstrated in earlier publications (1, 2, 9). That the steric requirements of these anions are much greater than those of the comparable $CpMo(CO)_3^-$ anion is evidenced by the two different formulations for the Cu triphenylphosphine complexes, viz. $(RE''pz''_3)Mo(CO)_3CuPPh_3$ (1, 2) vs. $CpMo(CO)_3Cu(PPh_3)_2$ (3). Cognizant of this phenomenon, we have investigated the reaction of $(HBpz''_3)Mo(CO)_3^-$ with $CuI/Ph_2PCH_2CH_2PPh_2$ with the expectation that steric effects would prevent chelation of the diphos ligand at the Cu centre and a complex with a dangling "Ph_2P" moiety would result, viz. $(HBpz''_3)Mo(CO)_3$-$CuPh_2PCH_2CH_2PPh_2$. The golden yellow crystals isolated in moderate yield did in fact have the above stoichometry with additional benzene and dichloromethane solvate molecules. Surprisingly, however, the molecular arrangement was unique and totally unexpected, consisting of a $(Ph_2PCH_2CH_2PPh_2)_2Cu^+$ cation together with a trimetallic anion $[(HBpz''_3)Mo(CO)_3]_2$-Cu^-, the latter displaying a linear arrangement for the Mo_2Cu unit and six semi-bridging carbonyls around the Cu centre.

The solution ^1H nmr spectrum of the complex in d^6-acetone shows all the pyrazolyl rings to be in equivalent environments, as established in the solid state (see below). The ir spectra in both the solid state and in solution displayed three strong ν_{CO} bands, somewhat surprising considering the threefold symmetry of the complex which would be expected to give two ν_{CO} vibrations (a and e modes). Perhaps, as was noted earlier in the solid state spectrum of the complex $(MeGapz_3)Mo(CO)_3CuPPh_3$

[1]The structure factor table, Table 6 (anisotropic thermal parameters) and other material mentioned in the text may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

(ν_{CO} = 1890, 1805, and 1780 cm^{-1}) (1), a splitting of the *e* mode is occurring due to packing or solvent effects.

The crystal structure of $(Ph_2PCH_2CH_2PPh_2)_2Cu^+[(HBpz''_3)Mo(CO)_3]_2Cu^- \cdot 3.5C_6H_6 \cdot CH_2Cl_2$ consists of $(Ph_2PCH_2CH_2PPh_2)_2Cu^+$ cations, $[(HBpz''_3)Mo(CO)_3]_2Cu^-$ anions, and solvated molecules of benzene and dichloromethane. The shortest distance between structural entities involving non-hydrogen atoms is the cation–anion contact O(2′)...C(48)($x-1$, $y-1$, $-z$) = 3.213(9) Å. There are four cation–anion C—H...O interactions of possible significance: C(40)—H(40)...O(2), C(57)—H(57)...O(3′)($1-x$, $1-y$, $-z$), C(58)—H(58)...O(2′)($1+x,1+y,z$), and C(67)—H(67)...O(3) ($1-x,1-y,-z$); H...O = 2.52, 2.52, 2.56, and 2.51 Å; C...O = 3.28(1), 3.34(1), 3.515(9), and 3.48(1) Å; C—H...O = 136, 143, 168, and 177°, respectively. The solvate molecules are fairly well resolved, but generally display a high degree of thermal motion. This factor combined with possible unresolved disorder leads to some anomalous geometrical features; a significant non-planarity of the C(80)—C(85) benzene ring has been noted in addition to other features apparent in Tables 7 and 8. All of the solvate molecules occupy spaces in the crystal lattice between anions.

The $(Ph_2PCH_2CH_2PPh_2)_2Cu^+$ cation (Fig. 1) has a highly irregular tetrahedral coordination geometry about the Cu(I) centre with P—Cu—P bond angles (88.30(7) to 134.62(8)°) similar to those reported for the Cu(I) species $[Cu(1,2\text{-}(Me_2As)_2C_6H_4)(pz_4B)]$ and $[Cu(1,2\text{-}(Me_2As)_2C_6H_4)_2]^+$ (10). As noted for the above complexes, steric factors are most likely responsible for the irregular geometry, which in the present example includes significant differences between the Cu(2)—P distances, two of which (Cu(2)—P(1) = 2.304(2) and Cu—P(4) = 2.296(2) Å) are significantly longer than the other two (Cu(2)—P(2) = 2.263(2) and Cu(2)—P(3) = 2.270(2) Å). The average Cu(2)—P distance of 2.283 Å is similar to the corresponding average value of 2.299 Å reported for $CpW(CO)_3Cu(PPh_3)_2$ (3).

The most interesting feature of the structure is the novel $[(HBpz''_3)Mo(CO)_3]_2Cu^-$ anion. The asymmetric unit contains two crystallographically independent centrosymmetric anions. One of these is shown in Fig. 2 while the second is essentially identical and is labelled in the same way, the atoms of the second anion being denoted by primed atom labels. The anions have exact C_i and approximate D_{3d} symmetry. The deviations from D_{3d} symmetry as well as the differences between the two independent half-ions are statistically, but not chemically, significant and are probably the result of packing effects. The central Cu atom is bonded to two Mo atoms in a linear fashion and also interacts with six semi-bridging carbonyl ligands to form a 1:3:3:1 bicapped octahedron. The Ω values ($\Omega = \exp[D(Cu—C)/D(Cu—O)]$) for $[(HBpz''_3)Mo(CO)_3]_2Cu^-$ range from 2.144 to 2.185 and average 2.16, consistent with a semi-bridging interaction (11). The 3:3:1 capped octahedral coordination geometry about the Mo atoms is similar to that reported for $(MeGapz_3)Mo(CO)_3CuPPh_3$ (1), which has three semi-bridging carbonyl groups, and for the complexes $(MeGapz_3)Mo(CO)_3SnPh_3$ (9), $(HBpz''_3)Mo(CO)_3SnMe_2Cl$ (2), and $(HBpz_3)Mo(CO)_3SnPh_3$ (2), which all have three terminal carbonyl ligands.

The $[(HBpz''_3)Mo(CO)_3]_2Cu^-$ anion is closely related to the $(MeGapz_3)Mo(CO)_3CuPPh_3$ molecule where the triphenylphosphine ligand has been replaced by a second $(RE"pz"_3)Mo(CO)_3^-$ ligand. The average Mo—Cu, Mo—C, Mo—N, Cu—C, and C—O bond lengths and Mo—C—O and Cu—C—O bond angles of 2.565, 1.955, 2.256, 2.309, and 1.174 Å, 171.7 and 114.7° are similar to the corresponding values of 2.513, 1.967, 2.257, 2.320, and 1.164 Å, 170.9 and 117.7° observed for $(MeGapz_3)Mo(CO)_3CuPPh_3$ (1). The M—Cu bond lengths in related molecules having a 3:4 piano stool geometry about the M atom (M = Mo or W) with two semi-bridging carbonyl ligands and one terminal carbonyl ligand are significantly longer: 2.592 Å in $CpMo(CO)_3Cu(tmed)$ (12), 2.639 Å in $(HBpz_3)Mo(CO)_3Cu(tmed)$ (2), and 2.721 and 2.771 Å in two crystalline modifications of $CpW(CO)_3Cu(PPh_3)_2$ (3).

Introduction

The transformation of resin acids and their derivatives into biologically active steroid intermediates has attracted the attention of several research groups over the past three decades (1).

Although much of the attention has been focused on the transformation of diterpene derivatives with a podocarpane (2) and abietane (3) type of skeleton, several recent contributions have led to the conversion of pimaradienic diterpenes into androstane derivatives by acid-catalyzed cyclization (4), intramolecular carbon–hydrogen insertion (5), and radical cyclization (6) processes.

Since the closure of acylium and carbonium ions from 4,5- and 5,6-unsaturated acids (7), aldehydes (8), and alcohols (9) are well-known reactions, we envisaged that the selective functionalization of the vinyl portion of sandaracopimaric acid derivatives would lead to substrates that could undergo acid-promoted cyclizations.

In the present work we describe the preparation of several of these substrates (**3**, **4**, **5**, **6**, **7**, and **10**) and the results obtained under acid-promoted cyclization conditions.

Results and discussion

(a) Preparation of the substrates

The methyl ketone **2** was prepared by a previously described procedure (10): oxymercuriation of methyl sandaracopimarate **1** followed by $NaBH_4$ reduction and further Jones oxidation led to **2** (62%, from **1**).

Treatment of **2** with vinyl magnesium bromide in refluxing THF led to a mixture of epimeric allylic alcohols **3** (74%) (Scheme 1), according to the evidence obtained from the ^1H nmr spectrum.

Reformatsky reaction of **2** with ethyl bromoacetate under standard conditions (11) led to a mixture of epimeric hydroxyesters **4**, with 76% isolated yield (flash chromatography).

Selective saponification of **4** with aqueous KOH in refluxing ethanol yielded a mixture of β-hydroxy acids **5** (83%), whose structure is based on ir and ^1H nmr evidence.

Treatment of **4** with $POCl_3$ in pyridine at 100°c afforded the diester **6** (64%). The presence of an α,β-unsaturated ester **6** (Fig. 1) is substantiated by the uv spectrum (CH_3OH); λ_{max}: 220 nm (log ε: 4.1). Furthermore, the ir and ^1H nmr spectra corroborated the structure corresponding to **6**. The δ value obtained for the methyl on the side chain (δ 2.02 ppm) confirms the *E* configuration of the double bond according to accurate nmr studies (12).

Selective saponification of **6** with 2 N methanolic KOH at room temperature yielded the α,β-unsaturated acid **7** (81%) whose structure was established from the uv, ir, and ^1H nmr spectra.

Preparation of the α,β-unsaturated aldehyde **10** (Fig. 1) from diester **6** was accomplished by a three-step sequence: (*i*) Reduction of **6** with $LiAlH_4$ in refluxing ether yielded diol **8** (93%). (*ii*) MnO_2 oxidation of the allylic alcohol **8** led to hydroxy aldehyde **9** (92%). The uv, ir, and ^1H nmr spectra confirm the proposed structure for the oxidation product. (*iii*) Treatment of **9** with acetic anhydride in pyridine led to the corresponding acetate **10** (82%) whose structure is apparent from the spectroscopic data.

(b) Cyclization attempts

The ring-forming reaction of a 5,6-unsaturated cation or an acylium ion in a pimarane diterpene derivative requires that the side chain have sufficient freedom of motion to attain the necessary transition state. The nucleophilic attack of the double bond on the electrophilic center must achieve the required trajectory to form the final bond (8, 13).

We found that the presence of a 2,3 double bond on the side chain led to failure in the ring-forming reaction, even when the existence of a *cis-trans* isomerization of the type shown in Scheme 2 could make the *E* configuration of the double bond (substrates **3**, **6**, **7**, and **10**) completely irrelevant.[2]

Treatment of allylic alcohol **3** with formic acid at room temperature led to the isolation of the rearranged formate **11** in quantitative yields. Increases in the reaction temperature did not change our first result.

Attempts to cyclize **6** with $ZnBr_2$, either in THF or in benzene at room temperature and under refluxing conditions, led to recovery of the starting material. The same result was obtained when the α,β-unsaturated acid **7** was treated with polyphosphoric acid in sulfolane under the cyclization conditions described by Nakatani and Kawashima (15).

Charge delocalization of the cationic cyclization intermediate

[1]Author to whom correspondence may be addressed.

[2]Presumably, the acid-catalyzed interconversion of the *trans* and *cis* derivatives **A** and **C** is faster than the cyclization because of the charge delocalization possible in the allylic cation **B**, which gives this intermediate a sufficiently long lifetime to permit *cis–trans* isomerization (14).

SCHEME 2

(Scheme 2) and the decreased cationic character due to the positive inductive effect of the ethoxy group might account for our discouraging results.

Treatment of the acetoxy aldehyde **10** with $SnCl_4$ (8) in either CH_3NO_2 or CH_2Cl_2 at room temperature led to recovery of starting material. An increase in the reaction temperature (refluxing CH_2Cl_2) yielded a rearranged aldehyde **12** whose structure is currently undetermined since the position of the internal double bond ($\Delta^{8,9}$ in **12***a*, or $\Delta^{5,10}$ in **12***b*) requires further spectroscopic evidence.

The above disappointing results prompted us to try the cyclization on a substrate with a completely saturated side chain. Presumably, the unsaturated character of the side chain in pimarane derivatives such as **6**, **7**, and **10** restricts the relative motion of the terminal carbonium ion (or equivalent) for undergoing efficient overlap with the π system of the internal double bond.

Treatment of the β-hydroxy acid **5** with *p*-toluenesulfonic acid in acetic anhydride at room temperature for 20 h gave **13** (76%), mp 128–130°C (hexane); $C_{23}H_{32}O_3$ (M^+ 356).

The location of an α,β-unsaturated ketone in **13** follows from uv spectroscopic evidence (CH_3OH): λ_{max}: 231 nm (log ε: 4.03); ir (ν_{max}: 1680, 1630 cm^{-1}). Inspection of the ^1H nmr spectrum reveals the presence of an olefinic proton (δ 5.70 (s,1H)) coupled to a methyl on the double bond (δ 2.00 (d, J = 1.5 Hz,3H)).

The optical rotatory dispersion (ord) curve of **13** showed a negative Cotton effect ($\Delta\varepsilon_{225}$: −48.13), which, according to Djerassi and co-workers (16), could correspond to an α,β-unsaturated 15-ketosteroid with a 14β-H configuration. However, according to the same authors the Cotton effect shown by this type of chromophore is highly dependent on the configuration of the adjacent rings. The 2D nOe (bidimensional nuclear Overhauser enhancement) technique was used for assigning the 14-H configuration. Thus, irradiation at δ 1.15 (13-Me) affected the signal at δ 2.39 (14-H), showing the spatial proximity of the 13-Me to the 14-H. This observation revealed that 13-Me and 14-H are oriented on the same plane.

We believe that the mechanism of formation of **13** involves the mixed anhydride, which collapses to an acylium

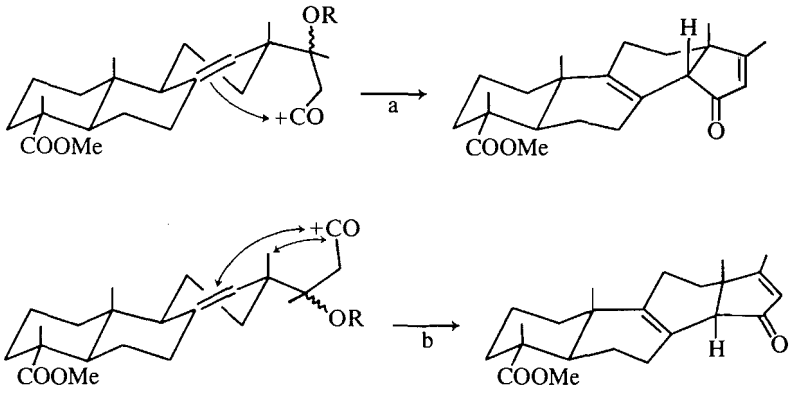

SCHEME 3

intermediate by acid catalysis. Ring closure takes place and dehydration occurs, giving **13** as the final product.

Nucleophilic attack at the α-face (pathway a, Scheme 3) should be favoured because attack at the β-side would have to overcome the strain due to the 1,3-diaxial interaction between the C-18 methyl and the acylium portion of the molecule (pathway b).

Experimental

Organic extracts were dried with commercially dried Na_2SO_4 and evaporated under reduced pressure below 40°C. Melting points were determined on a Kofler hot-stage apparatus. Optical rotations were determined on a digital Perkin Elmer 241 polarimeter in a 1-dm cell. The ^1H nmr spectra were recorded on a Hitachi Perkin Elmer R-24 60-MHz spectrometer and on a Bruker WP-200-SY spectrometer operating at 200 MHz. Nuclear Overhauser enhancements (nOe's) were obtained as described previously. The ir spectra were determined on a Beckman 33-IR spectrophotometer as indicated in each case. The uv absorptions were measured on a digital Varian 8-654 spectrophotometer. Optical rotatory dispersion curves were measured on a Jobin–Ybon Dichrograph III. Mass spectra were measured on a V.G. TS-250 apparatus. Microanalyses were performed using a Carlo Erba 1106 elemental analyser. All compounds discussed in this paper were obtained in a chromatographically homogeneous state.

Methyl 15-ethenyl-15-hydroxy-8(14)-isopimar-en-18-oate (3)

A solution of vinyl bromide (1 mL, 14.3 mmol) in dry THF (2 mL) was slowly added under nitrogen to a 100-mL flask containing Mg turnings (243 mg, 10 mmol) and freshly distilled THF (3 mL). Addition proceeded with a gentle reflux of the reaction mixture and, at the end of the addition, temperature was maintained at 60°C for 30 min. The reaction mixture was allowed to cool to 0°C and a solution of **2** (500 mg, 1.5 mmol) in freshly distilled THF (3 mL) was added. The reaction was stirred overnight. Following this an aqueous saturated NH_4Cl solution (5 mL) was added and the reaction mixture was extracted with ethyl acetate. The combined organic layers were washed with brine, dried (Na_2SO_4), filtered, and evaporated to afford crude material (500 mg). Partition of the crude by silica gel chromatography afforded **3** (400 mg, 74%), eluted with hexane-ether (8:2) as a colorless gum; $[\alpha]_D^{20}$ +24.3° (*c* 2.72, $CHCl_3$); ν_{max} (film): 3500, 1740, 940, 915 cm^{-1}; ^1H nmr (60 MHz, $CDCl_3$) δ : 0.80 (s, 3H), 1.00 (s, 3H), 1.20 (s, 6H), 3.60 (s, 3H); ABX system: 4.96 (dd, J_1 = 6 Hz, J_2 = 3 Hz, 1H), 5.18 (dd, J_1 = 13 Hz, J_2 = 3 Hz, 1H), 6.00 (dd, J_1 = Hz, J_2 = 6 Hz, 1H), 5.40 (s, 1H) ppm. *Anal.* calcd. for $C_{23}H_{36}O_3$: C 76.66 H 10.00; found: C 76.81, H 10.06.

Methyl 15-(ethoxycarbonyl)methyl-15-hydroxy-8(14)-en-18-isopimarate (4)

A solution of **2** (19 g, 5.7 mmol) in a benzene-ether (1:1) mixture (20 mL) and ethyl bromoacetate (1.7 mL, 15.3 mmol) was added dropwise, with stirring and under nitrogen, to a gently refluxing suspension of activated Zn powder (4.1 g, 63 mmol) in a benzene–ether (1:1) mixture (43 mL) with iodine. Stirring was continued for 5 h. The mixture was allowed to cool to room temperature and 10% H_2SO_4 (6 mL) was added. The Zn was decanted and the two layers separated. The aqueous layer was washed with ether, and the combined organic layers were washed with $NaHCO_3$ (5%) and brine, dried (Na_2SO_4), filtered, and evaporated to afford crude product (2.2 g). Chromatography of the crude on silica gel (30 g) afforded **4** (1.8 g, 70%), eluted with hexane–ether (90:10); ν_{max} (film): 3000, 1730, 1260 cm^{-1}; ^1H nmr ($CDCl_3$, 60 Mhz) δ :0.80 (s, 3H), 1.00 (s, 3H), 1.12 (s, 3H), 1.15 (s, 3H), 1.23 (t, J = 7 Hz, 3H), 3.56 (s, 3H), 4.18 (q, J = 7 Hz, 2H), 5.45 (s, 1H) ppm. *Anal.* calcd. for $C_{25}H_{40}O_5$: C 71.42, H 9.52; found: C 71.63, H 9.56.

Methyl 15-carboxymethyl-15-hydroxy-8(14)-en-18-isopimarate (5)

A stirred mixture of **4** (1.8 g, 4.3 mmol), KOH (0.5 g, 9.2 mmol), and H_2O (2 mL) was refluxed under nitrogen for 1 h. The reaction mixture was allowed to cool to room temperature and evaporated to dryness. The residue was dissolved in water, acidified with 4 N HCl, and extracted with ether. The extract was dried (Na_2SO_4), filtered, and evaporated to afford **5** (1.5 g, 90%); ν_{max} (film): 3250, 1715, 1695, 1240 cm^{-1}; ^1H nmr ($CDCl_3$, 60 MHz) δ : 0.80 (s, 3H), 1.00 (s, 3H), 1.20 (s, 3H), 1.25 (s, 3H), 3,60 (s, sH), and 5.40 (s, 1H) ppm.

Methyl 15-(ethoxycarbonyl)methylidenyl-8(14)-en-18-isopimarate (6)

Phosphorus oxychloride (0.2 mL, 2.14 mmol was added to a stirred solution of **4** (330 mg, 0.78 mmol) in dry pyridine (1 mL) at 0°C. The mixture was kept at room temperature for 1 h and then heated at 100°C for 1 h. The mixture was allowed to cool to room temperature and extracted with ether. The combined organic layers were washed with 2 N HCl, $NaHCO_3$ (5%) and brine, dried (Na_2SO_4), filtered, and evaporated to afford **6** (230 mg, 64%); $[\alpha]_D^{20}$ −10.5° (*c* 2.28, $CHCl_3$); ν_{max} (film): 1735, 1635, 860 cm^{-1}; ^1H nmr (60 MHz, CCl_4) δ : 0.85 (s, 3H), 1.12 (s, 3H), 1.15 (s, 3H), 1.23 (t, J = 7 Hz, 3H), 2.02 (s, 3H), 3.55 (s, 3H), 4.00 (q, J = 7 Hz, 2H), 5.20 (s, 1H), 5.50 (s, 1H) ppm. *Anal.* calcd. for $C_{25}H_{38}O_4$: C 74.63, H 9.45; found: C 74.69, H 9.50.

Methyl 15-carboxymethylidenyl-8(14)-en-18-isopimarate (7)

A 2 N methanolic solution (2 mL) was added to a stirred solution of **6** (92 mg, 0.25 mmol) in MeOH (2 mL) at room temperature. After 18 h, the MeOH was evaporated and the residue was dissolved in water. The aqueous solution was acidified and extracted with ether. The extract was washed with brine, dried (Na_2SO_4), filtered, and evaporated to afford **7** (77 mg, 80%); ν_{max} (film): 3500–3000 (br), 1730, 1690, 870 cm^{-1}; ^1H nmr (60 MHz, $CDCl_3$) δ : 0.85 (s, 3H), 1.15 (s, 3H), 1.20 (s, 3H), 2.10 (s, 3H), 3.65 (s, 3H), 5.25 (s, 1H), 5.75 (s, 1H) ppm. *Anal.* calcd. for $C_{23}H_{34}O_4$: C 73.80, H 9.09; found: C 73.87, H 9.05.

15-(2'-Hydroxy)ethylidenyl-8(14)-en-isopimar-18-ol (8)

Lithium aluminium hydride (76 mg, 2 mmol) was added to a solution of **6** (400 mg, 1 mmol) in dry ether (2 mL). The mixture was stirred at room temperature for 2 h. Then, H_2O (1 mL) and aqueous NaOH (15%) (0.1 mL) were successively added. The mixture was extracted with

ether. The combined organic layers were washed with brine, dried (Na_2SO_4), filtered, and evaporated to afford **8** (330 mg, 90%); ν_{max} (film): 3350, 1050 cm^{-1}; ^1H nmr (60 MHz, $CDCl_3$) δ : 0.80 (s, 3H), 0.85 (s, 3H), 1.10 (s, 3H), 1.60 (s, 3H), 3.20 (AB system, 2H), 4.15 (d, J = 7 Hz, 2H), 5.30 (s, 1H), 5.40 (m, 1H) ppm. *Anal.* calcd. for $C_{22}H_{36}O_2$: C 79.52, H 10.84; found: C 79.59, H 10.53.

15-(2'-Oxo)ethylidenyl-8(14)-en-isopimar-18-ol (9)

Activated MnO_2 (1 g, 11.50 mmol) was added to a solution of **8** (100 mg, 0.30 mmol) in acetone (5 mL). The mixture was stirred at room temperature under nitrogen for 7 h. The solid was then filtered and washed with acetone. Distillation of the solvent of the combined organic layers afforded crude **9** (91 mg). Partition of the crude material by chromatography on silica gel afforded **9** (61 mg, 60%), eluted with hexane–ether (40:60); $[\alpha]_D^{20}$ +59.8° (*c* 3.04, $CHCl_3$); ν_{max} (film): 3400, 2780, 1680, 880, 860 cm^{-1}; ^1H nmr (60 MHz, $CDCl_3$) δ : 0.75 (s, 3H), 0.85 (s, 3H), 1.15 (s, 3H), 2.12 (s, 3H), 3.18 (AB system, 2H), 5.25 (s, 1H), 5.85 (d, J = 8 Hz, 1H), 9.95 (d, J = 8 Hz, 1H) ppm. *Anal.* calcd. for $C_{22}H_{34}O_2$: C 80.00, H 10.30; found: C 80.08, H 10.38.

Acetate of 15-(2'-oxo)ethylidenyl-8(14)-en-isopimar-18-ol (10)

A solution of **9** (180 mg, 0.54 mmol) in Ac_2O (2 mL) and pyridine (1 mL) was allowed to stand overnight at room temperature. Ice was then added and the mixture was extracted with ether. The combined organic layers were washed with 2N HCl, aqueous $NaHCO_3$ (5%) and brine, dried (Na_2SO_4), filtered, and evaporated to afford the crude material (175 mg). Partition of the crude by chromatography over silica gel gave **10** (80 mg, 39%) eluted with hexane–ether (80:20); $[\alpha]_D^{20}$ −21.1° (*c* 1.03, $CHCl_3$); ν_{max} (film): 2750, 1745, 1670, 1630, 1245, 880, 860 cm^{-1}; ^1H nmr (60 MHz, $CDCl_3$) δ : 0.85 (s, 6H), 1.15 (s, 3H), 1.98 (s, 3H), 2.05 (s, 3H), 3.68 (AB system, 2H), 5.18 (s, 1H), 5.75 (d, J = 8 Hz, 1H), 9.82 (s, 1H), ppm. *Anal.* calcd. for $C_{24}H_{36}O_3$: C 77.42, H 9.68; found: C 77.49, H 9.73.

Methyl 15-(2'-formyloxy-ethylidenyl-8(14)-isopimaren-18-oate (11)

A solution of **3** (50 mg, 0.14 mmol) in formic acid (98%) (1 mL) was stirred for 30 min at room temperature. The reaction mixture was then poured over an aqueous saturated $NaHCO_3$ solution and extracted with chloroform. The combined organic layers were washed with brine, dried (Na_2SO_4), filtered, and evaporated to afford the crude material (60 mg). Filtration of the crude fraction through a silica gel column afforded **11** (53 mg, 98%) as a colorless gum; $[\alpha]_D^{20}$ −27.5° (*c* 2.32, $CHCl_3$); ν_{max} (film): 2680, 1740, 1665 cm^{-1}; ^1H nmr (60 MHz, CCl_4) δ : 0.85 (s, 3H), 1.08 (s, 3H), 1.18 (s, 3H), 1.65 (s, 3H), 3.57 (s, 3H), 4.52 (d, J = 7 Hz, 1H), 5.15 (m, 24), 7.85 (s, 1H), ppm. *Anal.* calcd. for $C_{24}H_{36}O_4$: C 74.22, H 9.28; found: C 74.43, H 9.45.

α,β-Unsaturated aldehyde (12)

Freshly distilled stannic choride (0.2 mL, 1.7 mmol) was slowly added to a stirred solution of **10** (80 mg, 0.21 mmol) at 0°C under nitrogen. After 18 h, 1 N HCl (10 mL) was added and the reaction mixture was extracted with CH_2Cl_2. The combined organic layers were washed with 2N HCl, aqueous $NaHCO_3$ (5%) and brine, dried (Na_2SO_4), filtered, and evaporated to afford the crude material (64 mg). Partition of the crude fraction by chromatography on silica gel gave **12** (44 mg, 56%) eluted with hexane–ether (90:10); $[\alpha]_D^{20}$ +76.9° (*c* 1.1, $CHCl_3$); ν_{max} (film): 2780, 1740, 1670, 1620, 1240 cm^{-1}; ^1H nmr (60 MHz, $CDCl_3$) δ : 0.75 (s, 3H), 0.90 (s, 3H), 1.00 (s, 3H), 1.96 (s, 3H), 2.05 (s, 3H), 3.65 (AB system, 2H), 5.45 (d, J = 8 Hz, 1H), 9.85 (s, 1H), ppm. *Anal.* calcd. for $C_{24}H_{36}O_3$: C 77.42, H 9.68; found: C 77.49, H 9.73.

4 β,-17-Dimethyl-4α-methoxycarbonyl-8,16-androstadien-14 β-15-one (13)

A mixture of **5** (1.2 g, 2.9 mmol), acetic anhydride (7 mL), and *p*-toluenesulfonic acid (722 mg, 3.8 mmol) was stirred under nitrogen for 24 h. Then brine (25 mL) was added and the mixture was stirred for 1 h. The two phases were separated and the aqueous layer was extracted with ether. The combined organic layers were washed with brine, dried (Na_2SO_4), filtered, and evaporated to afford the crude product (1 g). Partition of the crude by column chromatography on silica gel gave **13** (722 mg, 73%) eluted with hexane-ether (80:20); mp 128–130°C (hexane); $[\alpha]_D^{20}$ +238.2° (*c* 1.3, $CHCl_3$); λ_{max} (film): 1740, 1710, 1640, 1260 cm^{-1}; uv (CH_3OH) λ_{max}: 210 (ε 11 500), 231 (10 700); cd (CH_3OH) $\Delta\varepsilon_{205}$: +42.8, $\Delta\varepsilon_{225}$: −48.13, $\Delta\varepsilon_{320}$: +1.20; ^1H nmr ($CDCl_3$, 200 MHz) δ : 0.96 (s, 3H), 1.15(s, 3H), 1.19 (s, 3H), 2.01 (d, J = 1.2 Hz, 3H), 2.39 (s, 1H), 3.62 (s, 3H), 5.83 (d, J = 1.2 Hz, 1H) ppm; irradiation of the signal at δ 1.15 ppm gave a 10.96% nOe at δ 2.39 ppm; ^{13}C nmr ($CDCl_3$, 200 MHz) δ: 13.96, 16.38, 17.92, 19.07,20.69, 21.16, 27.10, 30,60, 32.80, 35.02, 36.17, 37.53, 46.04, 46.87, 47.29, 51.46, 60.49, 123.76, 130.37, 140.57, 178.32, 181.02, 204.85 ppm; ms (E.I)) *m/e* (%) :356 (M^+, 58), 296 (19), 282 (23), 281 (100), 110 (18), 105 (18), 91 (20), 55 (22), 41 (43). *Anal.* calcd. for $C_{23}H_{32}O_3$: C 77.53, H 8.99; found: C 77.46, H 8.90.

Lithum ion complexation effects on stereochemical dynamics of 14-crown-4 ethers in solution as studied by ^{13}C nuclear magnetic resonance

G. W. BUCHANAN, R. A. KIRBY, K. BOURQUE, AND C. MORAT[1]

Ottawa–Carleton Chemistry Institute, Department of Chemistry, Carleton University, Ottawa, Ont., Canada K1S 5B6

Received December 2, 1987

G. W. BUCHANAN, R. A. KIRBY, K. BOURQUE, and C. MORAT. Can. J. Chem. **66**, 2204 (1988).

The barrier to ring inversion for the *cis–syn–cis* isomer of dicyclohexano-14-crown-4 has been determined via ^{13}C nuclear magnetic resonance coalescence temperature measurements to be 42.3 ± 0.8 kJ/mol. For the LiNCS complex of this isomer, the inversion barrier increases by ca. 5 kJ/mol. For the Li^+ complex of the *cis–anti–cis* isomer, evidence for two dynamic conformational processes in solution is presented, with Li complexation inducing an increase in the barrier to degenerate cyclohexane ring inversion similar to that found in the *cis–syn–cis* isomer. ^{13}C T_1 measurements indicate a substantial decrease in the mobilities of both isomers in the presence of Li^+ ions in solution.

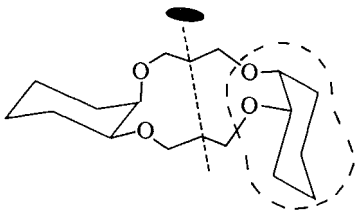
G. W. BUCHANAN, R. A. KIRBY, K. BOURQUE et C. MORAT. Can. J. Chem. **66**, 2204 (1988).

Faisant appel à des mesures de températures de coalescence des bandes de la résonance magnétique nucléaire du ^{13}C, on a déterminé que la barrière à l'inversion de cycle de l'ismère *cis–syn–cis* du dicyclohexano-14-éther-4 est de 42,3 ± 0,8 kJ/mol. La formation de complexes entre cet isomère et des ions lithium (LiNCS) augmente la barrière à l'inversion par environ 5 kJ/mol. Pour le complexe entre l'ion Li^+ et l'isomère *cis–anti–cis*, on présente des données suggérant que, en solution, deux processus conformationnels dynamiques sont impliqués; on observe que la complexation avec le lithium induit une augmentation de la barrière à la dégénérescence de l'inversion du noyau cyclohexane qui est semblable à celle observée avec l'isomère *cis–syn–cis*. Des mesures de T_1 dans les spectres rmn du ^{13}C indiquent que, lorsque chacun des isomères est mis en solution, leurs mobilités diminuent d'une façon importante lorsqu'ils sont placés en présence d'ions Li^+.

[Traduit par la revue]

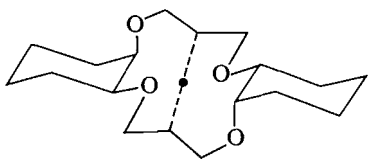
Introduction

A recent communication from these laboratories (1) has dealt with the nature of conformational equilibria present in solution for the *cis–anti–cis* isomer, **1**, of dicyclohexano-14-crown-4. Using 100.6-MHz ^{13}C nmr at low temperature, the existence of two unequally populated conformations was demonstrated. These conformations appear to be present in a ratio of ca. 2:1 at 173 K and are interconvertible by inversion of just one of the two



1A

$K \approx 2$

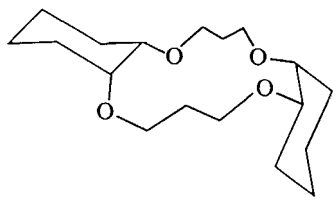


1B

cyclohexane rings present in the molecule, accompanied by a reorganization of the 14-membered ring geometry. This process is depicted above.

[1]Permanent address: LEDSS, Université scientifique, technique et médicale de Grenoble, B.P. 68, St-Martin d'Hères, France.

Presently we wish to report results regarding conformational equilibria for the previously unavailable *cis–syn–cis* isomer, **2** (below), as well as its LiNCS complex. Also, although it has not been possible to isolate a Li^+ complex of **1**, strong evidence for its existence in solution has been obtained from the T_1 measurements and low temperature spectra.



2

Results and Discussion

The structures and numbering schemes for **1** and **2** and the LiNCS complex of **2** are depicted in Fig. 1. The dispositions of the cyclohexane rings in each case are consistent with the recently obtained X-ray data (2).

Chemical shifts and coalescence data

These data are collected in Table 1. The chemical shift assignments at 293 K are made as a result of several considerations. Initially distinction between resonances for CH vs. CH_2 carbons bearing oxygen is made on the basis of the APT experiment (3). The resonance for C-4,15 is evident from its low relative intensity in nOe suppressed experiments, while distinction between C-8,11,19,22 and C-9,10,20,21 can be made on the basis of the known β-deshielding substituent effect of oxygen (4) on cyclohexyl ring carbon resonances.

The conformational equilibrium for free **1** in solution has been studied previously (1). The preferred conformation, **1*B***, (K ~ 2), at low temperatue appears to be the form with a centre of symmetry, which is also the structure found in the crystal (2).

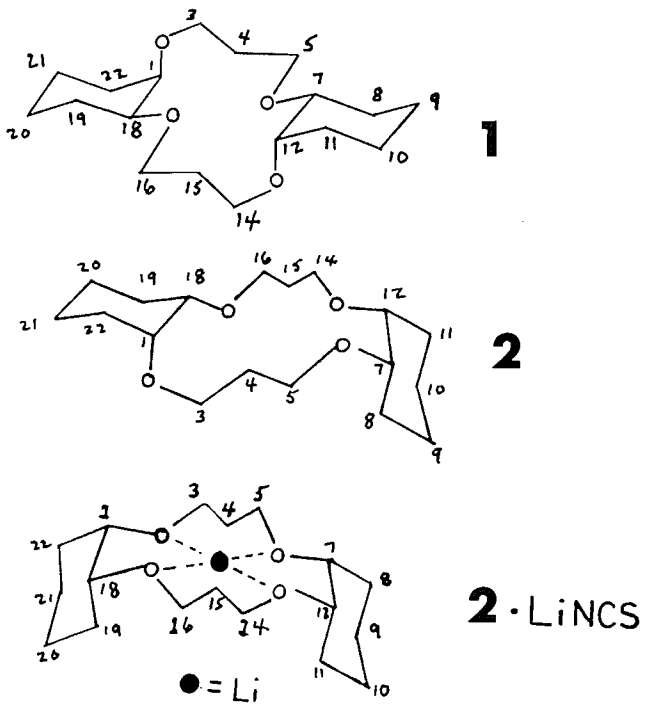

FIG. 1. Structures and numbering schemes.

All attempts to isolate LiNCS and $LiClO_4$ complexes of **1** have failed; however, there is strong evidence for its existence in solution. The 75.4-MHz spectra of a 1:1 mixture of **1** and LiNCS in CD_2Cl_2 as a function of temperature are presented in Fig. 2. At the low temperature limit of 165 K, eight resonances of approximately equal intensity are observed in the 64–80 ppm range for the oxygenated carbons. This suggests that there is only one conformation present in which no elements of symmetry are present. In the 18–30 ppm region for non-oxygenated carbon, one would expect to observe ten ^{13}C resonances in the low temperature limit for the case of a single asymmetric conformation. In fact, eight signals appear of which two are double intensity, specifically those at 16.87 and 21.98 ppm.

A detailed analysis of the temperature dependence of the spectra indicates that there exist two dynamic conformational processes, which have substantially different free energies of activation. To aid in the analysis of the spectra, the changes with temperature are depicted in a simplified way in Fig. 3. The five-line ^{13}C spectrum at room temperature is represented in the figure by the designation A, B, C, D and E. The A line represents the carbinyl carbons bearing oxygen i.e., C-1, 7, 12, and 18 appears at δ_C 77.17 and are depicted by B. The C-4, 15 carbons appear at δ_C 28.99 and are represented by C in the line spectra. Similarly the D line at 24.91 ppm depicts C-8, 11, 19, 22 while the most shielded resonance at δ_C 20.99 is represented by E and arises from the C-9, 10, 20, and 21 sites.

As the temperature is lowered gradually the lines A, B, D, and E each split into equal intensity components represented by A_1, A_2, B_1, B_2, D_1, D_2, E_1, and E_2 respectively. These four coalescence phenomena provide four independent measurements of the free energy of activation for this degenerate process. The coalescence temperatures and chemical shift differences are listed in Table 1. From these data the average value for $\Delta Gs5^{\ddagger}$ is calculated to be 47.2 ± 0.5 kJ/mol. We attribute this process to the degenerate double cyclohexane ring inversion since the observed shift differences at individual carbon sites are very similar to those found for cyclohexane ring inversion in related molecules (5). For example, the chemical shift difference for the carbinyl carbons at 230 K is 4.2 ppm (i.e., $A_1 - A_2$), which is consistent with expectations for carbons bearing axial and equatorial oxygenated substituents, the carbon bearing the axial function being the more shielded. The cyclohexyl carbons, which are γ to the oxygen atoms, also show large chemical shift differences at 230 K, i.e., $E_1 - E_2 = 5.06$ ppm. The more shielded resonance can be assigned to C-10, 21, which bear *gauche*-γ relationships to the axial oxygen atoms O-13 and O-2 respectively (1). For the methylene carbons bearing oxygen, the chemical shift difference at 230 K, i.e., $B_1 - B_2$, is 2.30 ppm. In the absence of an X-ray structure, it is difficult to make unambiguous assignments for these sites. If one employs uncomplexed **1** as a model, however, one could tentatively assign the more shielded resonance to C-5, 16, i.e., the carbons bonded to equatorial oxygen (1, 2). The smallest resolvable chemical shift difference, $D_1 - D_2 = 0.96$ ppm, at 230 K occurs for the cyclohexyl ring carbons β to oxygen. Due to the number of factors contributing to the ^{13}C shift at these carbons, no attempt will be made at this point to distinguish the C-8, 19 vs. the C-11, 22 pairs.

Comparison of the barrier to degenerate ring inversion in free **1** (1) with the LiNCS complex studied herein indicates an increase of ca. 4 kJ/mol in the barrier for the complex.

Temperature reduction below 230 K causes further spectral changes until a "limiting slow exchange" spectrum is obtained at 165 K. Figure 3 depicts the additional splitting of resonances that occurs in the $A_1, A_2, B_1, B_2, C, D_1$, and D_2 lines respectively. From the coalescence data in Table 1, $\Delta G^{\ddagger}$ for this second process can be calculated to be 39.6 ± 1.4 kJ/mol. The magnitude of this barrier is ca. 4 kJ/mol lower than that found for cyclohexane inversion in simple disubstituted cyclohexanes (5). Hence it is tempting to suggest that this second barrier represents the free energy of activation for 14-membered ring conformational change, which is taking place after the cyclohexanes are stereochemically "locked" on the nmr time scale. Support for this hypothesis comes from the lack of further splitting of the C-9, 10, 20, 21 lines below 230 K. Since these carbons are the most remote from the 14-membered ring, it is reasonable to expect that they would be least affected by stereochemical changes in that region of the molecule. Interestingly, the C-4, 15 site, whose resonance at δ_C 28.99 did not decoalesce as a result of ring inversion becoming slow on the nmr time scale, is split into two equal-intensity components with a chemical shift dif-

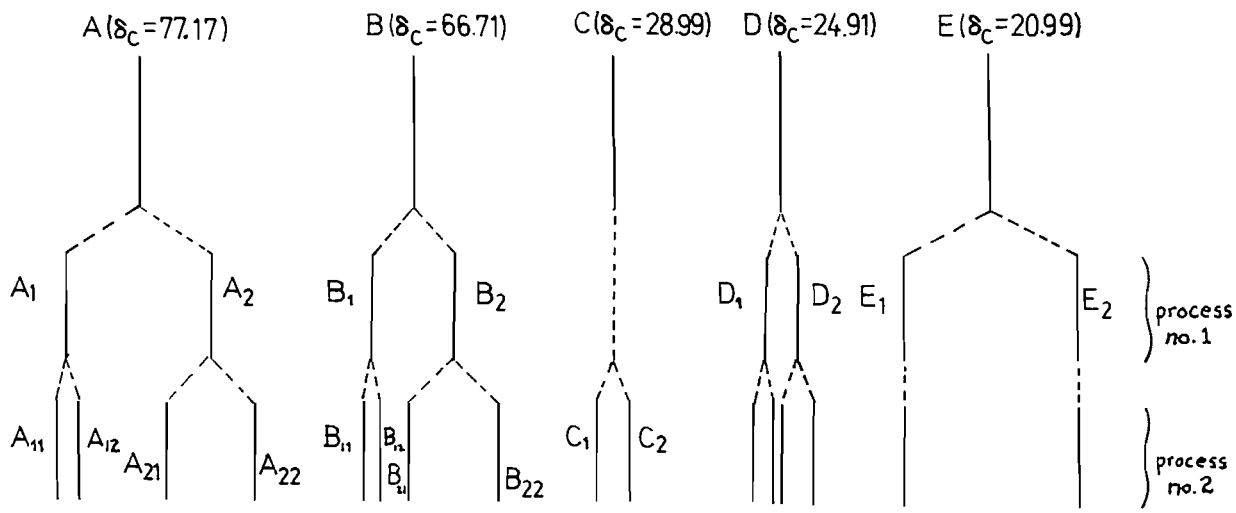

FIG. 3. Schematic analysis of the temperature dependent processes occurring in the ^{13}C nmr spectra of **1** + 1 equivalent LiNCS.

ference of ca. 1 ppm as a result of the 14-membered ring conformational process being retarded.

For **2**, reduction of the temperature produces ^{13}C nmr spectral changes consistent with a single degenerate conformational process becoming slow on the nmr time scale. The five-line spectrum at 293 K shows nine lines in the slow exchange limit, there being one position, C-4, 15, whose chemical shift differences are insufficient for resolution.

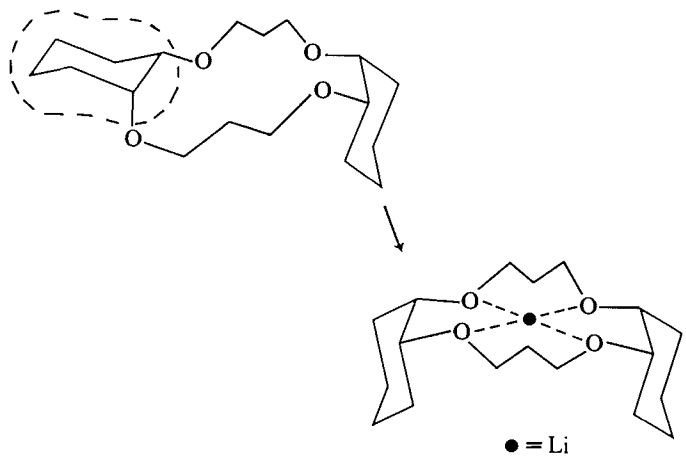
From the coalescence temperatures (T_C) and the limiting chemical shift differences ($\Delta\nu$) in Table 1, one can use the Eyring equation to calculate $\Delta G^{\ddagger}$, the free energy of activation for the process. For **2**, the average of the results for four sites is

42.3 ± 0.8 kJ/mol. This is nearly identical to values obtained for ring inversion in simple 1,2-disubstituted cyclohexanes (5). Hence we attribute the present results to degenerate ring inversion of both cyclohexane rings of **2**, accompanied by a reorganization of the 14-membered ring geometry as depicted below.

The simple degenerate conformational equilibrium for **2** is in contrast to the situation for its isomer **1** (1).

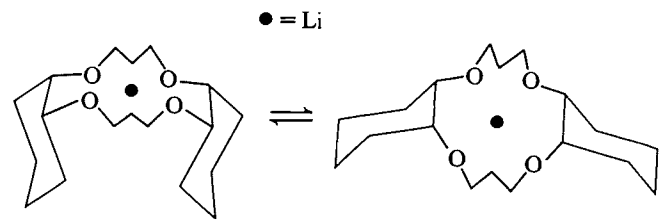
For the complex of **2** with LiNCS, the coalescence data are included in Table 1. In this case the five-line ^{13}C spectrum at 293 K becomes, in the low temperature limit, five pairs of equal-intensity doublets indicative of a single degenerate conformational process becoming slow on the nmr time scale. For each of the five exchanging pairs, the chemical shifts are sufficiently large to give five indepenent measures of the free energy of activation for the conformtional interconversion. The average value for $\Delta G^{\ddagger}$ is 47.0 ± 0.9 kJ/mol, i.e., ca 5 kJ/mol *higher* than for free **2**.

From X-ray data (2) the structure of **2**·LiNCS is as illustrated below. It is interesting to note that one of the cyclohexane rings has undergone an inversion in the complex, compared to the structure for free **2**. The four oxygens are found to be in a plane and bind to the lithium cation, which is situated 0.53 Å out of the plane of the ethereal oxygens.



For ring inversion to occur, some disruption of this Li--O binding phenomenon must take place, and hence an increase in the free energy of activation for the degenerate double ring inversion process depicted below is intuitively reasonable.

Interestingly, the observed increase in the barrier in the present case is almost identical to the increase in the ring inversion barrier for the corresponding dicyclohexano-18-crown-6 systems upon complexation with the K^+ ion (6).



Spin-lattice relaxation times (T_1)

These data were determined by the inversion–recovery method (7) and are presented in Table 2. Measurement of nuclear Overhauser enhancements indicated that spin-lattice relaxation in these molecules is dominated by the dipole–dipole mechanism to the extent of over 90% for all carbon sites. For systems of molecular weight of less than 1000, it is reasonable to assume that the motional narrowing limit conditions apply, and hence the correlation time τ_C for the C–H vector is proportional to $1/T_1$.

TABLE 2. ^{13}C Spin-lattice relaxation times (T_1)

Compound	Site	T_1(s)
1	1,7,12,18	2.08±0.38
1 + 1 equiv. LiNCS		1.27±0.02
2		2.68±0.31
2·LiNCS		1.24±0.15
1	3,5,14,16	1.19–±0.09
1 + 1 equiv. LiNCS		0.75±0.02
2		1.60±0.08
2·LiNCS		0.75±0.04
1	4,15	1.33±0.05
1 + 1 equiv. LiNCS		0.77±0.02
2		1.27±0.08
2·LiNCS		0.88±0.06
1	8,11,19,22	1.39±0.12
1 + 1 equiv. LiNCS		0.82±0.01
2		1.45±0.06
2·LiNCS		0.88±0.02
1	9,10,20,21	1.22±0.04
1 + 1 equiv. LiNCS		0.75±0.02
2		1.39±0.05
2·LiNCS		0.73±0.10

Initially it is of interest to compare the T_1 data for uncomplexed **1** and **2**. Within the limits of uncertainty, results for the C-4, 15 and C-8, 11, 19, 22 sites are identical while those for the C-9, 10, 20, 21 sites are very nearly so. By contrast, the T_1's for the oxygenated carbons are substantially longer for **2** than for **1**. The greatest difference, ca. 34%, is found between the C-3, 5, 14, 16 sites, implying that the increase in mobility in **2** relative to **1** is most pronounced at this position. For the C-9, 10, 20, 21 carbon, the T_1 for **2** is ca. 29% longer than that of **1**. It is noteworthy that **2**, which appears to have a greater degree of segmental motion than **1** in the oxygenated portion of the molecule, is the isomer that more readily forms the LiNCS complex. Indeed X-ray data (2) indicate that one cyclohexane ring of **2** inverts its conformation upon complex formation.

In the LiNCS complex of **2** the T_1's at all sites are considerably reduced relative to the free crown ether. the most pronounced differences occur at the oxygenated carbons, however, a result that is consistent with the observed binding of the lithium by the four coplanar oxygen atoms in the complex (2).

Although we have not been able to isolate the complex of **1** with LiNCS, the T_1 data for **1** + 1 equivalent of LiNCS indicate very substantial specific interactions beteen these two species in solution. Indeed, the reductions in mobility of **1** upon addition of the LiNCS are comparable to those present in the LiNCS complex of **2** relative to free **2**.

Our present X-ray results (2) indicate that the effective 14-membered ring cavity diameter for **2** is 1.88 Å. This is too small to fit even the Li cation (effective diameter 1.18–1.52 Å (8) within the plane of the four oxygen atoms.

Experimental

(a) Spectra

The ^{13}C spectra were obtained at 50.3 MHz using a Varian XL-200 nmr spectrometer. Sample concentrations were 0.2 M in CD_2Cl_2 contained in 5 mm o.d. tubes. Routinely spectra were recorded with

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/07/12
For personal use only.

complete ^1H noise decoupling. Normal conditions were as follows: sweep width = 10 kHz with 32K data points; pulse width = 7 μs (45°) and a repetition rate of 1.0 s. The number of accumulations for the low temperature spectra was typically 2000. Temperatures were calibrated using a copper–constantan thermocouple.

The ^{13}C spectra at 75.5 MHz were recorded on a Bruker MSL-300 instrument. For the low temperature experiments a sweep width of 7 kHz was employed using 8K data points. Resonances due to the solvent were eliminated via the DEPT (9) sequence using a 60° sorting pulse. The sequence was carried out assuming a J value of 140 Hz. An acquisition time of 0.6 s and a pulse delay of 2.0 s were employed. Typically, under these conditions, 400 accumulations provided adequate signal-to-noise ratios. The $\pi/2$ ^1H and ^{13}C pulses were 19 and 9.2 μs respectively.

^{13}C spin-lattice relaxation times were determined at 50.3 MHz via the inversion–recovery sequence (7) on 0.2 M solutions. Data were processed using the standard XL-200 software.

(b) Materials

Synthetic procedures for all materials employed herein have been described previously (2).

Ion chemistry of transition metals in hydrocarbon flames. I. Cations of Fe, Co, Ni, Cu, and Zn

QUANG TRAN, NICHOLAS S. KARELLAS, and JOHN M. GOODINGS
Department of Chemistry, York University, 4700 Keele Street, North York, Ont., Canada M3J 1P3

Received February 19, 1988

QUANG TRAN, NICHOLAS S. KARELLAS, and JOHN M. GOODINGS.. Can. J. Chem. **66**, 2210 (1988).

A fuel-rich, premixed, conical, methane–oxygen flame at 2200 K and atmospheric pressure is doped with approximately 1 ppm of the transition metals Fe, Co, Ni, Cu, and Zn. Metallic ions of these metals and their compounds formed by chemical ionization reactions with H_3O^+ are observed by sampling the flame through a nozzle into a quadrupole mass spectrometer. Concentration profiles of individual and total cations are measured as a function of distance along the flame axis, and also mass spectra at a fixed point in the burnt gas. For a given metal A, the mass spectra are dominated by the atomic ion A^+ with smaller amounts of the molecular ions AH^+, AOH^+, $A(OH)H^+$, $A(OH)_2H^+$, and ACO^+ and their hydrates. The spectra for Fe, Co, Ni, and Cu are very similar, but no ions are observed for Zn. The ion chemistry is dominated by proton transfer reactions from H_3O^+ to A and to the metallic compounds AO, AOH, and $A(OH)_2$ which exist in the flame. In addition, A^+ can be formed from the reaction of H_3O^+ with A by a charge transfer process. Also, some ions are formed by three-body association and free radical stripping reactions. The chemistry is discussed in detail to explain the relative magnitudes of the ion signals observed. In particular, when the atomic A^+ ion is dominant, its concentration can reach a superequilibrium level early in the burnt-gas region before it slowly decays downstream; the phenomenon is similar to the free radical overshoot which occurs in hydrogen flames.

QUANG TRAN, NICHOLAS S. KARELLAS et JOHN M. GOODINGS.. Can. J. Chem. **66**, 2210 (1988).

Opérant à 2200 K et à la pression atmosphérique, on a dopé une flame méthane–oxygène, conique, pré-mélangée et riche en carburant, avec environ 1 ppm des métaux de transition Fe, Co, Ni, Cu et Zn. En faisant un échantillonage de la flamme par le biais d'un spectromètre de masse quadripolaire, on a pu observer les ions métalliques de ces métaux ainsi que leurs composés qui se sont formés par des réactions d'ionisation avec le H_3O^+. On a mesuré les profils de concentration des cations individuels et totaux en fonction de la distance le long de l'axe de la flamme ainsi que les spectres de masse à un point fixe dans les gaz d'échappement. Pour un métal donné A, le spectre de masse est dominé par l'ion atomique A^+ accompagné de quantités plus faibles des ions moléculaires AH^+, AOH^+, $A(OH)H^+$, $A(OH)_2H^+$ et ACO^+ ainsi que leurs hydrates. Les spectres obtenus avec le Fe, le Co, le Ni et le Cu sont très semblables; on n'a toutefois pas observé d'ions avec le Zn. La chimie des ions est dominée par les réactions de transfert de protons de H_3O^+ vers A et vers les composés métalliques AO, AOH et $A(OH)_2$ qui existent dans la flamme. L'ion A^+ peut aussi se former par la réaction de H_3O^+ avec A par un processus de transfert de charge. En plus, quelques ions se forment par une association de trois composantes et par des réactions de dépossession de radicaux libres. On discute de cette chimie en détail afin d'expliquer les amplitudes relatives des signaux des ions. En particulier, lorsque l'ion atomique A^+ domine, sa concentration peut atteindre un niveau de super-équilibre très tôt dans les gaz d'échappement et sa concentration diminuer lentement alors qu'on évolue plus loin; le phénomène est semblable dépassement qui se produit avec les radicaux libres dans les flammes d'hydrogène.

Introduction

We recently had occasion to consider the ion chemistry of alkali and alkaline earth metals in a premixed, fuel-rich, CH_4–C_2H_2–O_2 flame (1). This arose in the context of soot suppression by metallic additives involving an ionic mechanism (2, 3). We have now extended these studies to include chemical ionization (CI) processes for the first row of ten transition metals, Sc to Zn (atomic numbers 21–30). The last five including Fe, Co, Ni, Cu, and Zn are described here; the first five including Sc, Ti, V, Cr, and Mn present some different features, and are the subject of a second paper.

A premixed, fuel-rich, CH_4–O_2 flame doped with metallic additive is sampled into a mass spectrometer to ascertain what metallic cations are present and where in the flame they occur. The interest in the problem stems from the considerable variety of oxidation states known for these metals, and the bond formation and structural configurations which they may exhibit at high temperature.

Basically two mass-spectrometric flame studies involving cations of some of these transition metals have appeared in the past. In hydrogen flames, Hayhurst and Telford (4) observed ions for Cr, Mn, Fe, and Cu, and also other metals, in the course of measuring rate constants attributed to the charge transfer reaction

[1] $$H_3O^+ + A \rightarrow A^+ + H_2O + H$$

where A is the metal atom. In a CO/H_2 diffusion flame doped with benzene and containing $Fe(CO)_5$ as an impurity, Ham and McAllister (5) observed a considerable variety of iron molecular ions in addition to Fe^+. In this kind of flame having a relatively low temperature, molecular metallic ion signals are enhanced although their identification is complicated by the simultaneous observation of many C—H—O, non-metallic ions. The metallic ion chemistry is discussed in some detail.

A large and impressive body of research on organometallic ion chemistry involving transition metals in the gas phase has been published during the past few years. This work has been carried out near room temperature in many laboratories making use of ion cyclotron resonance (ICR), Fourier-transform mass spectrometry (FTMS), laser desorption/ionization (LDI), photodissociation and guided ion beams. The scope and versatility of FTMS, LDI, and photodissociation for metallic ion studies have been reviewed with excellent examples by Freiser (6). Only a small part of this work is applicable to the present flame studies since metal–carbon bond formation, except for carbonyl coordination, was not observed even when the flame is fuel-rich. Nevertheless, data obtained near room temperature for "inorganic" species are relevant involving metal–oxygen and metal–hydrogen bond formation in metallic oxides, hydroxides, hydrides, and their hydrates, both ionic and neutral. These thermodynamic data include proton affinities, bond dissociation energies, gas-phase basicities, ligand (e.g. hydrate)

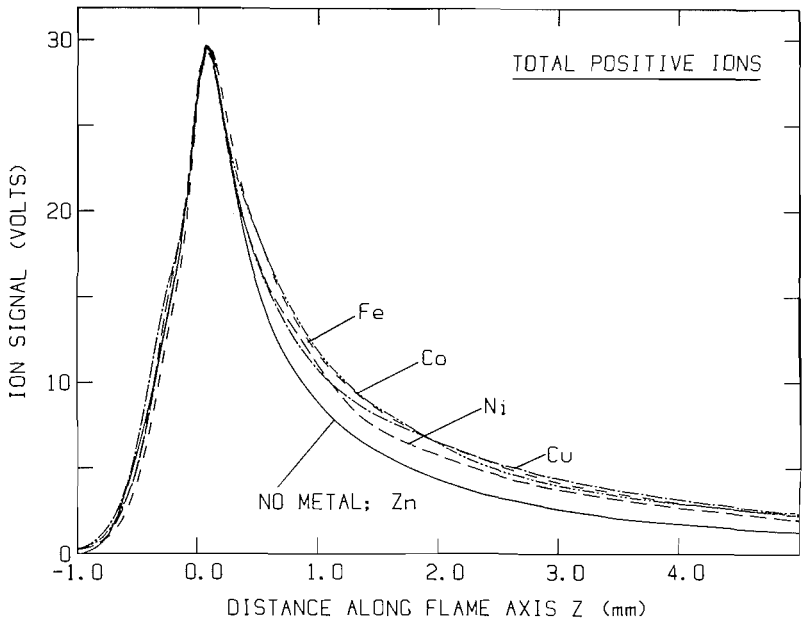

FIG. 1. Total ionization profiles along the flame axis with metal absent, and with the flame doped with equal molar concentrations (~1 ppm) of Fe, Co, Ni, Cu, and Zn. The luminous reaction zone is located upstream of $z = 0$.

binding energies, etc. They are assembled and referenced below.

Experimental

The flame employed for these studies was a premixed, laminar, CH_4–O_2 flame of fuel-rich composition (equivalence ratio $\phi = 2.15$) whose natural cation chemistry we have studied extensively in the past (7). It has a burnt-gas temperature of 2200 K and rise velocity of approxiamtely 1 m s^{-1}. Its small, conical, luminous, reaction zone (height 5 mm, base diameter 3 mm, thickness 0.3 mm) facilitates sampling along the flame axis into the mass spectrometer. The flame is stabilized at atmospheric pressure on a simple, tubular, quartz burner (2.3 mm i.d.) and surrounded by a flowing argon shield to minimize the entrainment of atmospheric air.

Transition metals (Fe, Co, Ni, Cu, and Zn) were introduced by spraying a 0.25 *M* aqueous solution of the metallic chloride into the premixed flame gas as an aerosol derived from a pneumatic atomizer (8). The atomizer was operated by part of the burner's oxygen supply. Alternatively, Fe was also introduced as $Fe(CO)_5$ vapour in a small flow of argon using a gas saturator technique. The use of flowing oxygen was not suitable since a brown deposit, presumably Fe_2O_3, was produced on the walls of the interconnecting tubing. The small argon flow, amounting to 2% of the total premixed gas, did not noticeably alter the flame characteristics. In fact, the whole range of ion signals observed with iron introduced as $FeCl_3$ aerosol or as $Fe(CO)_5$ vapour was remarkably similar. Moreover, the $Fe(CO)_5$ gas saturator technique provided a means of calibrating the tiny atomizer used with this flame. Spraying a 0.25 *M* solution introduced very nearly 1 ppm (8.7×10^{-7} mole fraction) of metal into the unburnt flame gas.

The burner was mounted on a motor-driven carriage and the flame axis was accurately aligned with the sampling orifice of the mass spectrometer. The calibrated burner drive provided spatial resolution of ±0.02 mm along the flame axis (designated *z*) for measurements of ion concentration profiles. The flame-ion mass spectrometer has been described previously in detail (7). The flame burned against a 60° conical, chromium, sampling nozzle of orifice diameter ca. 0.1 mm mounted in a water-cooled flange of the type described by Hayhurst and Telford (9). The sampled ions pass through two stages of differential pumping into a quadrupole mass filter. The mass-analyzed ions are detected with a parallel-plate Faraday collector connected to a vibrating reed electrometer having a grid-leak resistance of 10^{10} ohms.

The ion signals given in the figures have been corrected at low resolution for mass discrimination in the filter against ions of high *m/e* measured at high resolving power. The dynamic range of sensitivity of the apparatus is five orders of magnitude. A method has been described (7) involving a relatively sharp minimum in the pressure profile of the sampled gas for locating a reproducible origin ($z = 0$) in the flame (not referred to the burner). It corresponds to the downstream edge of the luminous reaction zone on the flame axis. In this way, a family of ion profiles at different mass numbers *m/e* can be accurately overlaid on the distance scale *z*. It is also an important consideration, when comparing mass spectra at a fixed point on the flame axis, to be able to return to the same point reproducibly.

Some ion signals are subject to distortion during sampling by the mass spectrometer. The flame gas is cooled in passing through the thermal boundary layer surrounding the sampling orifice, and again during the expansion to supersonic velocity which proceeds for a few orifice diameters just inside the sampling nozzle. This can affect the signal ratio of two ionic species participating in a fast ion–molecule reaction having a reaction time (relaxation time) comparable to, or less than, the sampling time (of order 1 μs). In these circumstances, the ratio will change in favour of the product ion in the exothermic direction of the reaction. These sampling effects for flames have been discussed in a series of papers by Hayhurst and co-workers of which refs. 10–12 are particularly relevant. A common case is the production of hydrate ions since a high water concentration in the burnt gas of the flame produces a high rate of hydration. Thus, Knewstubb and Sugden (13) concluded that the hydrate ions $H_3O^+.nH_2O$ ($n = 1$–4) are formed largely during sampling in contrast to H_3O^+ ($= H^+.H_2O$) which is a genuine flame ion. For metallic ions in cases where most of the hydrate is formed during sampling, the hydrate ion signal only amounts to a few percent of the parent ion signal (10). A larger ratio of hydrate/parent may indicate that the hydrate is a genuine flame ion. A notable example occurs for lithium where $Li^+.H_2O = Li(OH)H^+$ is relatively large, arising from protonation of the hydroxide which is a major metallic species in the flame (1, 10, 12). Similar cases will be encountered for the transition metal ions discussed below.

Results and discussion

Figure 1 shows total positive ion profiles measured as a function of distance along the flame axis in the absence of metal and with Fe, Co, Ni, Cu, and Zn present. The profiles are obtained with the d.c. voltages to the quadrupole mass filter

[a]Energy values for the gas phase are quoted in kJ mol^{-1} at 0 K unless otherwise noted.
[b]Referred to 298 K.
[c]The temperature T is sometimes unspecified but usually refers to an experimental temperature near 298 K. In general, the correction to 0 K will lie within the experimental error.
[d]Many of these values are given in the evaluated compilation of proton affinities by Lias *et al.* (29) and its supplements (in preprint form, not yet published).
[e]Quoted in eV. In a few cases, the temperature is unspecified.

switched off. The luminous flame reaction zone is located upstream of $z = 0$ (negative z). No change of the total ion signal is observed in the reaction zone, nor at the profile peak. The signal is enhanced downsteam throughout the burnt gas for Fe, Co, Ni, and Cu, but no enhancement is observed for Zn. These observations imply that the metals do not participate in any new chemi-ionization process, at least in the flame reaction zone. Certainly thermal ionization is an unlikely process since these metals, and their compounds which might exist in the flame, all have relatively high ionization energies (IE) > 7 eV. Known thermochemical data for the metals, their compounds, and associated cations are assembled in Table 1.

Downstream in the burnt gas with metal absent, the ion signal is overwhelminghly H_3O^+ and its first hydrate, $H_3O^+.H_2O$ (1, 7), most of which is formed on sampling (13). Thus, it is logical that the enhanced ion profiles observed downstream with metal present result from chemical ionization (CI) reactions of H_3O^+ with the metal or its compounds. Evidence that H_3O^+ serves as a reagent cation is given in Fig. 2 where it is shown that the H_3O^+ profile magnitude decreases when Fe, Co, Ni, or Cu are present in the flame; no change is observed for Zn, however. It is not necessary to invoke a new chemi-ionization source to explain the enhanced signal observed downstream in Fig. 1 with metal present. In the absence of metal, H_3O^+ disappears by the relatively fast, two-body, dissociative, electron–ion recombination reaction

$$[2] \quad H_3O^+ + e^- \rightarrow H + H + OH \text{ (or } H + H_2O)$$

With metal present, if H_3O^+ reacts to form metallic ions and an appreciable fraction of the product ions is the atomic ion A^+ of the metal, the A^+ ions disappear by relatively slow, three-body, atomic recombination

$$[3] \quad A^+ + e^- + M \rightarrow A + M$$

where M is a third body. For Fe, Co, Ni, and Cu, the atomic ion signals A^+ are much larger than any of those observed for molecular metallic ions. Atomic ion profiles are given in Fig. 3, whose signal magnitudes decrease in the order $Fe^+ > Co^+ > Ni^+ > Cu^+$; although the profile for the isotope of major natural abundance (see Table 1) was measured for each of Fe^+, Ni^+, and Cu^+, the signal magnitudes have been corrected to include the natural abundances of the other isotopes. For each profile,

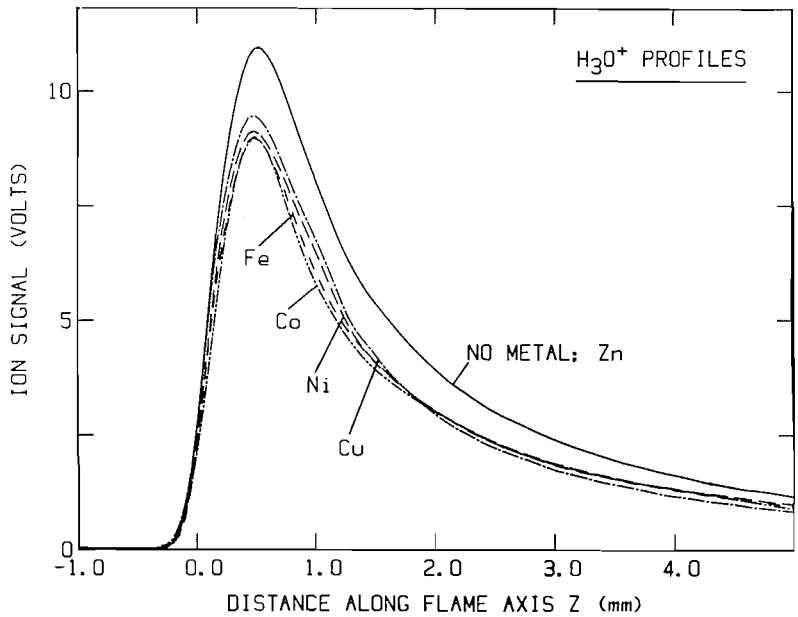

FIG. 2. Axial H_3O^+ profiles with metal absent, and with the flame doped with equal molar concentrations (~1 ppm) of Fe, Co, Ni, Cu, and Zn. The luminous reaction zone is located upstream of $z = 0$.

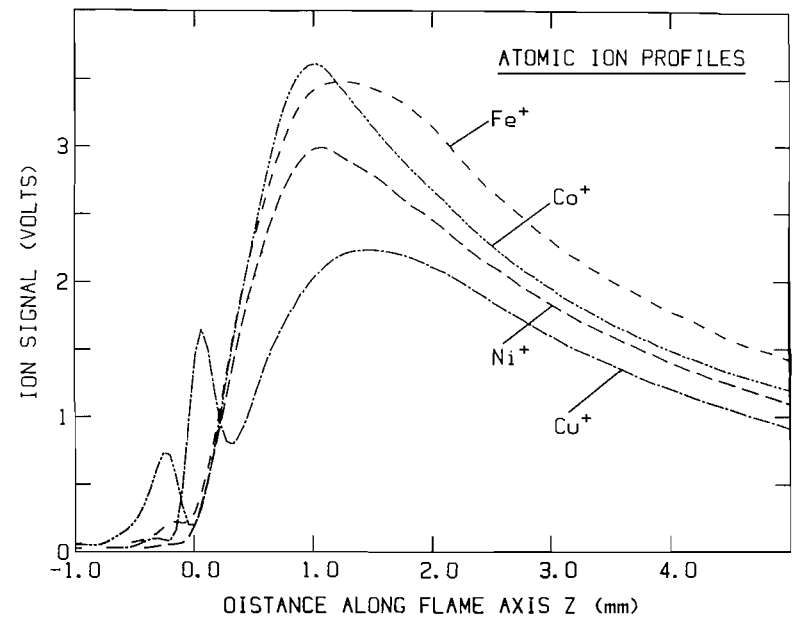

FIG. 3. Axial profiles of the dominant atomic ions A^+ observed when the flame is doped with equal molar concentrations (~1 ppm) of Fe, Co, Ni, and Cu. The luminous reaction zone is located upsteam of $z = 0$.

the small peak or peaks in and around the reaction zone near $z = 0$ stem from natural C—H—O ions at the same mass number as A^+. No signal was detected for Zn^+. Thus, the increased total ion signal observed downstream appears to result from a decreased overall loss rate rather than a new source term for ion formation.

In addition to A^+, a maximum of nine molecular ions including hydrates could be observed for Fe, Co, Ni, and Cu below 120 u. We were unable to observe any metallic ions with Zn. Profiles for the metallic ions of Co are given in Figs. 4 and 5. The profile peaks around the reaction zone near $z = 0$ stem from natural C—H—O ions at the same mass numbers as the metallic ions, but this is not the case downstream.

Cobalt offers the least ambiguity in the assignment of ions since ^{59}Co has a natural abundance of 100%. Similar sets of profiles were obtained for Fe, Ni, and Cu (not shown). Apart from profiles, mass spectra were measured at a fixed point in the flame. These are given in Fig. 6 for (*a*) Fe, (*b*) Co, (*c*) Ni, and (*d*) Cu measured at $z = 1.25$ mm downstream. From these spectra and the known isotopic abundances, the relative contributions of the various metallic ions for Fe, Ni, and Cu could be sorted out with reasonable certainty. The relative contributions for the four metals at $z = 1.25$ mm downstream are given in Table 2 as percentages of the total metallic ions present. Various structures are suggested for some of these ions in Table 2. In some cases at least, it is probable that only one isomeric structure is involved.

For example, the general designation AOH_2^+ refers to the same ionic structure whether formed by protonation of AOH represented by $A(OH)H^+$, or by hydration of A^+ represented by $A^+.H_2O$.

It should be emphasized that the ions shown in Fig. 6 and given in Table 2, apart from H_3O^+ and its hydrates, represent all of the ion signals observable at 1.25 mm downstream. That is, all of the signals logically correspond to metallic ions. This is in contrast to the observations of Ham and McAllister (5) using a diffusion flame doped with Fe at a considerably lower temperature where many C—H—O ions were observed in addition to metallic species. Also, their experimental conditions appear to enhance hydrate ions which may be formed largely during sampling. On the other hand, our premixed flame at higher temperature tends to enhance the atomic A^+ ion such that many of the molecular metallic ion signals are small.

Consideration is now given to the metallic neutral species which might be present in the the flame at 2200 K. Thermodynamic data are available (18, 31–33) for Fe and Co to calculate the approximate equilibrium distribution of total metal amongst the species A, AOH, AO, and $A(OH)_2$. The values are given as percentages of total metal in Table 3. However, the table may well be incomplete since gas-phase data for other possible neutrals are not known; e.g., $Fe(OH)_3$ as invoked by Ham and McAllister (5). Both Jensen and Jones (34) and Farber *et al.* (35) identified the presence of FeO, FeOH, and $Fe(OH)_2$ in addition to Fe in flames. Also for Fe (and Cr), the situation may be complicated by the presence of solid oxide particles detected

	100.00	100.00

[a]Jensen and Jones (33) attach large uncertainty factors ≥ 10 to the equilibrium constants from which these relative concentrations are calculated.

by Padley (36). For a premixed, fuel-rich, H_2—O_2—N_2 flame at 2025 K doped with Cu, Hayhurst and Telford (4) have done a statistical mechanical calculation using the data of Bulewicz and Sugden (37, 38) and Gaydon (39) which gives equilibrium concentrations for CuO, CuH, and CuOH of 3, 2, and 0.2%, respectively.

With this background, it remains to discuss the ion chemistry of these metals in hydrocarbon flames where H_3O^+ is the primary reagent cation. There are basically two reaction mechanisms of A with H_3O^+ to form A^+ involving charge transfer and proton transfer. The charge transfer reaction [1] might easily be dismissed on the grounds that it is endothermic for all five metals Fe–Zn; however, it is considered further in the discussion of signal magnitudes given below. With regard to the proton transfer mechanism, only recently has it been recognized that metallic atoms can have high proton affinities (see Table 1) such that

$$[4] \quad H_3O^+ + A \rightleftharpoons AH^+ + H_2O$$

is exothermic for Fe, Co, and Ni, and only somewhat endothermic for Cu and Zn. The observed AH^+ signals given in Table 2 for Fe, Co, and Ni are small, and an obvious route back to the atomic ion is provided by the radical reactions

$$[5a] \quad AH^+ + H \rightleftharpoons A^+ + H_2$$

$$[5b] \quad AH^+ + OH \rightleftharpoons A^+ + H_2O$$

which are exothermic for all five metals. In the equilibrium burnt gas of this fuel-rich flame, the mole fractions of H and OH amount to 3.63×10^{-3} and 3.05×10^{-4}, respectively.

Reaction [4] would seem to be an improbable CI source for Cu ions; certainly CuH^+ was not detected. Although its endothermicity is only slight, it is comparable to that for Zn for which no metallic ions of any kind could be detected. The existence of CuH in flames (37, 38) raises the possibility of the proton transfer reaction

[6] $H_3O^+ + CuH \rightarrow CuH_2^+ + H_2O$

followed by thermal decomposition of the product ion in one step

[7] $CuH_2^+ + M \rightarrow Cu^+ + H_2 + M$

or, more likely, in two steps involving dehydrogenation by radical attack

[8] $CuH_2^+ + H, OH \rightarrow CuH^+ + H_2, H_2O$

[9] $CuH^+ + H, OH \rightarrow Cu^+ + H_2, H_2O$

The energetics of the overall reaction [6] + [7]

[10] $H_3O^+ + CuH \rightarrow Cu^+ + H_2 + H_2O$

(or similarly for [6] + [8] + [9]) yield the relationship $\Delta H^0_{10} = PA^0(H_2O) - PA^0(CuH) + D^0(HCu^+—H) + D^0(Cu^+—H) - D^0(H—H)$; that is, $PA^0(H_2O) - PA^0(CuH) = 317 - D^0(HCu^+—H)$ kJ mol^{-1} at 298 K. This means that reaction [6] will be exothermic only if $D^0(HCu^+—H)$ exceeds 317 kJ mol^{-1}. Although possible, the $HCu^+—H$ bond is unlikely to be so strong, such that the proton affinity of CuH is probably less than 697 kJ mol^{-1}, the proton affinity of water. In corroboration, we were unable to detect any ion signal downstream in the flame at 67 u, the mass number of $^{65}CuH_2^+$.

In common with the alkali and alkaline earth metals (1), the oxides and hydroxides of Fe, Co, Ni, and Cu might be expected to have high PA's greater than that of H_2O. Certainly this is the case for FeO and CoO whose PA values of 916 ± 21 kJ mol^{-1} have been measured (17). These componds will chemically ionize in proton tranfer reactions with H_3O^+

[11] $H_3O^+ + AO \rightleftharpoons H_2O + AOH^+$

[12] $H_3O^+ + AOH \rightleftharpoons H_2O + A(OH)H^+$ or $A^+.H_2O$

[13] $H_3O^+ + A(OH)_2 \rightleftharpoons H_2O + A(OH)_2H^+$ or $AOH^+.H_2O$

The pairs of alternative formulae given in reactions [12] and [13] almost certainly refer to the same ionic structure. For all of these molecular ions, reaction paths back to the atomic ion A^+ occur by way of thermal dissociation or radical attack by H atoms

[14] $A(OH)_2H^+$ or $AOH^+.H_2O + M \rightleftharpoons AOH^+ + H_2O + M$

[15] $AOH^+ + H \rightarrow A^+ + H_2O$

[16] $A(OH)H^+$ or $A^+.H_2O + M \rightleftharpoons A^+ + H_2O + M$

Finally, higher hydrates of any of these ions may form in consecutive three-body reactions with H_2O; e.g.,

[17] $A^+.H_2O + H_2O + M \rightleftharpoons A^+.2H_2O + M$

where the calculated equilibrium mole fraction of H_2O in the burnt gas of this flame amounts to 0.251. As mentioned above, hydrates tend to be enhanced when the flame gas cools during sampling, and may not represent genuine flame ions (10–13). Typically, such hydrates give signals amounting to a few percent of the parent ion signals (1) depending on the quality of the sampling technique. When they are appreciably larger than this, it is an indication that the hydrate ions are truly present in the flame. An obvious example occurs in Table 2 for $AOH^+.H_2O = A(OH)_2H^+$ compared with AOH^+; evidently the dihydroxide really is involved in the proton transfer equilibria. In addition, it is not surprising that "hydration" also occurs with CO in this fuel-rich flame where the mole fraction of CO is large, amounting to 0.298

[18] $A^+ + CO + M \rightleftharpoons ACO^+ + M$

followed by further hydration with water to form $ACO^+.H_2O$. Whether metal–carbon bond formation is involved rather than AOC^+ formation is not clear from these experiments.

The relative signal magnitudes for the five metals require further discussion; namely, why the total ion signals observed with Fe, Co, Ni, and Cu are similar, but no ions are observed for Zn (see Fig. 1). Relevant data for a comparison of the charge transfer reaction [1]

[1] $H_3O^+ + A \rightleftharpoons A^+ + H_2O + H$

with the overall proton transfer mechanism [4] + [5a] or [4] + [5b]

[19a] $H_3O^+ + A + H \rightleftharpoons A^+ + H_2O + H_2$

[19b] $H_3O^+ + A + OH \rightleftharpoons A^+ + 2H_2O$

are given in Table 4. From the $PA^0_{298}(A)$ values in Table 1 and $PA^0_{298}(H_2O) = 697$ kJ mol^{-1} (29), the proton tranfer step [4] of reactions [19a] or [19b] to form AH^+ is exothermic for Fe, Co, and Ni, but slightly endothermic for Cu and Zn (see Table 4). Also from Table 4, the overall reactions [19a] or [19b] at 2200 K are exothermic and exoergic for all five metals. If the proton transfer mechanism and the endothermic reaction [4] are operative for Cu, why not for Zn as well for which no ions were observed? A possible solution to this dilemma comes from a further consideration of the charge transfer reaction [1]. The enthalpy of reaction is not a good criterion; from Table 4, ΔH^0_1 at 2200 K is considerably endothermic for all five metals. The proper criterion is ΔG^0_1 which is exoergic for Fe, Co, Ni, and Cu but slightly endoergic for Zn. The large entropy term in reaction [1] is not surprising since two reagent particles form three products. Thus, both reaction mechanisms for the production of Zn^+ are energetically unfavourable. However, for Cu where no CuH^+ was observed because reaction [4] is endothermic, presumably reaction [1] becomes the dominant path for the chemical ionization of copper.

This does not mean that reaction [19] is inoperative for the other metals since AH^+ was observed for Fe, Co, and Ni (see Table 2). In addition, for a metal like iron where FeOH is a major neutral species in the flame (see Table 3), production of Fe^+ can also proceed by reaction [12] to form $Fe(OH)H^+$ (or $Fe^+.H_2O$) followed by the dehydration reaction [16]. Reactions [11] + [15] provide yet another path to A^+ via the oxide AO which is appreciable in the case of Co (see Table 3). Presumably zinc exists in the flame entirely as Zn atoms such that these other production reactions for Zn molecular ions are not possible.

It is further necessary to explain why the ion signals for Fe, Co, Ni, and Cu have similar magnitudes fairly early in the burnt-gas region (see Figs. 1–3). The concentration data given in Table 4 show that this will not be the case far downstream when full thermodynamic equilibrium is attained. The equilibrium concentrations have been calculated at 2200 K on the assumption that the only ions present are A^+ and H_3O^+; quasi-neutrality requires that $[e^-] = [A^+] + [H_3O^+]$. Note that the total ionization levels represented by $[e^-]$ vary by a factor of 30. The equilibrium value for $[Zn^+]$ is much smaller than $[A^+]$ for

the other metals, stemming ultimately from the high ionization energy of Zn (see Table 1). A large variation of $[A^+]/[H_3O^+]$ at equilibrium is evident, and yet the observed ratio is comparable for Fe, Co, Ni, and Cu (from Figs. 1–3).

Fairly early in the burnt gas, the explanation comes from chemical kinetic rather than thermodynamic considerations. The ion ratio is determined by the difference of the rates of production and loss of metallic ions. The rate of production, given by $k[H_3O^+][A]$, will be approximately constant if the rate constants k_1 and k_4 are similar for all four metals. (The same will be true if k_{12} and k_{11} are comparable when hydroxides and oxides are involved, respectively.) It is important to recognize that the increase in *total* ion signal shown in Fig. 1 with Fe, Co, Ni, and Cu present reflects the degree to which reaction [3] contributes to the overall rate of ion loss. Reaction [3] involves the slow, three-body recombination of e^- with A^+. For $k_3 = 10^{-27}$ mL^2 $molecule^{-2}$ s^{-1} (taken from ref. 33 which lists similar rate constants for alkali metal recombination) and $[e^-] < 10^{10}$ mL^{-1}, the relaxation time for reaction [3] amounts to $\tau_3 \simeq 1/k_3[e^-][M] > 30$ ms, corresponding to more than 30 mm of flame for a burnt-gas velocity of 1 m s^{-1}. Since $[A^+]$ (including a fraction of $[A^+.H_2O]$ formed during sampling) has similar values for Fe, Co, Ni, and Cu, and since their k_3 values should be roughly equal, it is reasonable that the profiles given in Figs. 1–3 are similar for the four metals. The overall chemical picture is interesting. In general, A^+ is produced by relatively fast, two-body processes, but is ultimately lost by a slow, three-body reaction. Thus, $[A^+]$ may achieve a superequilibrium level early in the burnt gas, but subsequently takes a long time downstream to fall to the equilibrium concentration given in Table 4. This situation for ions resembles the phenomenon of neutral radical overshoot which occurs for H, OH, and O in hydrogen flames (40).

Hayhurst and Telford (4) measured rate coefficients k for the rate of dissappearance of H_3O^+ in fuel-rich, H_2–O_2–N_2 flames doped with Fe and Cu as well as other metals. For example, in a flame of composition 4.0–1.0–4.0 at 2025 K, they measured k_{Fe} and k_{Cu} to be 1.2×10^{-9} and 4.1×10^{-10} mL $molecule^{-1}$ s^{-1}, respectively. They suggest that k_{Fe} and k_{Cu} represent a weighted mean for reaction [11] with AO and the reaction

[20] $H_3O^+ + A \rightleftharpoons AOH^+ + H_2$

which is exothermic for both metals. We do not favour reaction [20] because, in contrast to the transfer of a single particle (H^+, H, or e^-), a good deal of chemical rearrangement is involved; namely, the simultaneous breaking of two bonds and the formation of two others. More probably, k_{Fe} represents a weighted average (in approximate decreasing order; see Table 3) of reactions [12], [1], [4], [13], and [11], all of which are exothermic. For Cu, reactions [1], [11], and [12] would seem to be involved. Hayhurst and Telford (4) rejected reaction [1] for Fe and Cu because it is endothermic; they were unaware that it is exoergic for both metals because the thermodynamic data were not available at the time of their study. Similarly, the proton affinities of metallic atoms involved in reaction [4] were not known at that time.

It is of interest to compare our results for a premixed flame at 2200 K with those of Ham and McAllister (5) for a CO/H_2 diffusion flame at much lower temperature. In both flames, H_3O^+ is the primary CI source ion. In decreasing order of magnitude, they observed $Fe(OH)_2H^+$, $Fe(OH)_3H^+$, $Fe(OH)H^+.H_2O$, $Fe(OH)H^+$, and $Fe(OH)_2H^+.H_2O$, all of which involve proton transfer from H_3O^+. Of these, only $Fe(OH)_3H^+$ was not observed by us; presumably appreciable $Fe(OH)_3$ can only exist in a flame at lower temperature. In decreasing order, they next observed the curious ion $FeO(OH)_2^+$ (or $FeO_2^+.H_2O$) having an Fe oxidation state of 5 (not observed by us), followed by Fe^+. Finally, they observed $Fe(OH)_3^+$ and a small $Fe(OH)_2^+$ signal which we did not detect.

For these latter two ions of the type $Fe(OH)_n^+$, Ham and McAllister (5) hypothesize a CI source reaction analogous to reaction [1]

[21] $H_3O^+ + Fe(OH)_n \rightarrow Fe(OH)_n^+ + H_2O + H$

which is exothermic only if IE $[Fe(OH)_n] < 6.4$ eV. That is, reaction [21] is expected to be very endothermic for $Fe(OH)_2$ and $Fe(OH)_3$ (see, for example, $IE^0_O(FeOH)$ in Table 1). Since proton transfer to these compounds by H_3O^+ is probably exothermic, we would favour a two-step mechanism

[22] $H_3O^+ + Fe(OH)_n \rightarrow Fe(OH)_nH^+ + H_2O$

[23] $Fe(OH)_nH^+ + H, OH \rightarrow Fe(OH)_n^+ + H_2, H_2O$

[24] $H_3O^+ + Fe(OH)_n + H, OH \rightarrow Fe(OH)_n^+ + H_2O + H_2, H_2O$

The overall net reaction [24] is less endothermic than reaction [21] by 103 (for H) or 118 (for OH) kJ mol^{-1}. In summary, the results for Fe ions in these two flames are surprisingly different, both as to relative magnitude and type.

Conclusions

Equal concentrations (~1 ppm) for Fe, Co, Ni, Cu, and Zn are introduced into a fuel-rich, premixed, CH_4–O_2 flame at 2200 K and atmospheric pressure in which CO is a major component of the burnt gas (0.298 mole fraction). These metals exist in flames as atoms A and the metallic compounds AO, AOH, and $A(OH)_2$ in varying amounts. Most of these species appear to possess high proton affinities. The metallic ions observed include A^+ which is predominant, and the molecular ions AH^+, AOH^+, $A(OH)H^+$, $A(OH)_2H^+$, ACO^+ together with their hydrates. These ions are formed mainly by proton transfer reactions of H_3O^+ to the metallic neutral species including A, supplemented by three-body association and free radical stripping reactions. Also, A^+ can be formed by the reaction of H_3O^+ with A in a charge transfer process. In general, the hydrate ion signals are enhanced when the flame gas is cooled during sampling by the nozzle into the mass spectrometer. In some cases, however, the ion hydrates have the same structure as protonated metallic neutrals, and are genuine flame ions; examples include $A^+.H_2O = A(OH)H^+$ and $AOH^+.H_2O = A(OH)_2H^+$. The only flame ion observed to exhibit the possible formation of a metal–carbon bond is the carbonyl compound ACO^+ in contrast to studies of ion–molecule reactions near room temperature. The ion profiles for Fe, Co, Ni, and Cu are very similar as to relative magnitude and shape. No ions are observed for Zn, however. If the atomic A^+ ion is dominant, its concentration can reach a superequilibrium level early in the burnt-gas region before it slowly decays downstream; the phenomenon is similar to the free radical overshoot which occurs in hydrogen flames. Finally, the ion chemistry is surprisingly different from that observed by Ham and McAllister (5) for Fe in a diffusion flame at lower temperature.

Ion chemistry of transition metals in hydrocarbon flames. II. Cations of Sc, Ti, V, Cr, and Mn

JOHN M. GOODINGS, QUANG TRAN, AND NICHOLAS S. KARELLAS
Department of Chemistry, York University, 4700 Keele Street, North York, Ont., Canada M3J 1P3

Received February 19, 1988

JOHN M. GOODINGS, QUANG TRAN, and NICHOLAS S. KARELLAS. Can. J. Chem. **66**, 2219 (1988).

The same fuel-rich, premixed, conical, methane–oxygen flame at 2200 K and atmospheric pressure used for studies of Fe, Co, Ni, Cu, and Zn in Part I (1) is doped with the same concentration (~1 ppm) of Sc, Ti, V, Cr, and Mn to complete the first row of ten transition metals. Metallic ions of these metals and their compounds formed by chemical ionization reactions with H_3O^+ are observed by sampling the flame through a nozzle into a quadrupole mass spectrometer. Concentration profiles of individual and total cations are measured as a function of distance along the flame axis, and also mass spectra at a fixed point in the burnt gas. If A is the metal atom, the observed ions can be represented by four hydrate series including (*a*) $A^+.nH_2O$, (*b*) $AOH^+.nH_2O$, (*c*) $AO^+.nH_2O$, and (*d*) $AO_2H^+.nH_2O$ with $n = 0$–3 or 4, giving a maximum of four ligands around the metal atom. However, alternative isomeric structures are possible for each of the four basic series (e.g. $AO^+.2H_2O \sim A(OH)_2{}^+.H_2O \sim A(OH)_3H^+$). The ions observed with Cr and Mn, in common with those of Fe, Co, Ni, and Cu, strongly favour series (*a*). On the other hand, Sc is completely different; the ions of series (*c*) are dominant. All four series are observed with each of Ti and V. Series (*b*) dominates for Ti and series (*c*) for V; ions from series (*d*) were observed for the first time. The ion chemistry of these metals is discussed in detail with emphasis on the probable chemical ionization reactions responsible for metallic ion formation. The pre-eminent role of proton transfer processes is apparent.

JOHN M. GOODINGS, QUANG TRAN et NICHOLAS S. KARELLAS. Can. J. Chem. **66**, 2219 (1988).

Opérant dans les mêmes conditions que celles utilisées alors qu'on avait dopé une flamme méthane–oxygène, conique, pré-mélangée et riche en carburant, avec environ 1 ppm des métaux de transition Fe, Co, Ni, Cu et Zn (1), on a dopé cette flamme avec la même concentration (~1 ppm) des métaux Sc, Ti, V, Cr et Mn et on a ainsi complété l'examen de la première rangée des dix métaux de transition. Utilisant un échantillonnage de la flamme dans un spectromètre de masse quadripolaire, on a observé la formation des ions métalliques de ces métaux ainsi que celle de leurs composés formés par des réactions d'ionisation chimique avec le H_3O^+. On a mesuré les profiles de concentration des cations individuels et totaux en fonction de la distance le long de l'axe de la flamme ainsi qu'à un point fixe dans les gaz d'échappement. Si A est l'atome métallique, les ions observés peuvent être représentés par quatre séries d'hydrates comprenant; (*a*) $A^+.nH_2O$, (*b*) $AOH^+.nH_2O$, (*c*) $AO^+.nH_2O$ et (*d*) $AO_2H^+.nH_2O$ avec $n = 0$ à 3 ou 4 et conduisant à un maximum de quatre ligands autour des atomes métalliques. Toutefois, d'autres structures isomères peuvent exister pour chacune des quatre séries de base (par exemple, $AO^+.2H_2O \sim A(OH)_2{}^+.H_2O \sim A(OH)_3H^+$). Les ions observés avec le Cr et le Mn, de même qu'avec le Fe, le Co, le Ni et le Cu, favorisent fortement la série (*a*). Par ailleurs, le Sc est complètement différent; les ions de la série (*c*) dominent. Les quatre séries sont observées avec le Ti ainsi que le V. La série (*b*) domine avec le Ti et la série (*c*) avec le V; on a observé des ions de la série (*d*) pour la première fois. On discute en détail de la chimie ionique de ces métaux en mettant de l'emphase sur les réactions d'ionisation chimique qui sont probablement responsables de la formation d'ions métalliques. Le rôle prépondérant des processus de transfert de protons est apparent.

[Traduit par la revue]

Introduction

In the preceding paper designated Part I (1), we considered the ion chemistry of Fe, Co, Ni, Cu, and Zn in a fuel-rich, premixed, CH_4–O_2 flame at 2200 K and atmospheric pressure. This work follows on from our previous studies of chemical ionization reactions of alkali and alkaline earth metals in hydrocarbon flames in which the role of proton transfer reactions was emphasized (2). The present paper is a continuation of Part I for Sc, Ti, V, Cr, and Mn in order to complete the first row of ten transition metals.

We are not aware of any previous observations of flame ions for Sc, Ti, and V. Soundy and Williams (3) measured the reaction of H_3O^+ with Cr and Mn (and also Li, Cu, and Pb) in one flame at 2368 K but their electrostatic probe technique without mass analysis leaves the nature of the ions in doubt. Hayhurst and Telford (4) introduced Cr and Mn as well as a number of other metals into fuel-rich, H_2–O_2–N_2 flames containing natural flame ions, principally H_3O^+, arising from small amounts of hydrocarbon impurities. Using a mass spectrometer, they measured rate constants for the disappearance of H_3O^+ reacting with metallic atoms A, or with oxides AO, hydroxides AOH and $A(OH)_2$, or even hydrides AH if these compounds exist in flames for a particular metal. The ion–molecule reactions involved are discussed in detail below.

Part of the interest in these metals stems from the considerable number of common oxidation states which they exhibit in their chemistry at room temperature. It is, therefore, not surprising that a corresponding variety of different metallic ions are observed in flames. Broadly speaking, the ions of Cr and Mn show much in common with each other, and with those of Fe, Co, Ni, and Cu discussed in Part I in which the atomic ion A^+ is heavily favoured. In contrast, the ions observed for Sc with its single oxidation state of +3 are quite different. Finally, the ions of Ti and V are the most varied, show nearly all of the aspects observed for the other transition metals, and exhibit certain new features in addition.

Experimental

Exactly the same experimental procedures described in Part I were used in the present study. Equal concentrations (8.7×10^{-7} mole fraction; i.e., ~1 ppm) of the metals were introduced into the same conical, fuel-rich, premixed, CH_4–O_2 flame at 2200 K and atmospheric pressure by spraying a 0.25 *M* aqueous solution of the metallic chloride from an atomizer into the premixed gas feeding the burner. The single exception was Ti which was introduced as $TiCl_3$ vapour using a gas saturator technique. An equivalent concentration was assured by making the molar flow rate of $TiCl_3$ equivalent to that of $Fe(CO)_5$ vapour from the same saturator; the flow of Fe as $Fe(CO)_5$ was, in turn, made equivalent to that introduced by spraying a 0.25 *M*

aqueous solution of $FeCl_3$ in the atomizer. Ion concentration profiles were measured along the flame axis z and also mass spectra at a fixed point $z = 1.25$ mm downstream of the flame reaction zone. This was done by sampling the flame along its axis through a chromium nozzle into a quadrupole mass spectrometer as described in Part I.

Results and discussion

Figure 1 shows total positive ion profiles measured as a function of distance along the flame axis in the absence of metal and with equal concentrations of Sc, Ti, V, Cr, and Mn present. The profiles were obtained with the d.c. voltages to the quadrupole mass filter rods switched off. Essentially no change of the total ion signal is observed at the profile peak nor in the flame reaction zone ($z < 0$, upstream). The signal is enhanced downstream in the burnt gas for all five metals, very slightly for Sc, Ti, and V, and very considerably for Cr and Mn. These observations imply that the metals do not participate in any new chemi-ionization process, at least in the flame reaction zone. Certainly thermal ionization is unlikely since all of these metals and their compounds which might exist in the flame have high ionization energies, IE > 6 eV. Known thermochemical data for the metals, their compounds, and associated cations are assembled in Table 1. These data come from the many studies of the gas-phase ion chemistry of transition metals carried out near room temperature using a variety of techniques: ion cyclotron resonance (ICR) and Fourier-transform mass spectrometry (FTMS), laser desorption/ionization (LDI), photodissociation, and guided ion beams. These various studies are referenced in Table 1.

The logical source of the metallic ions observed in the flame begins with the classic chemi-ionization reaction for hydrocarbons

$$[1] \qquad CH + O \rightarrow HCO^+ + e^-$$

In our flame where water is a major product in the burnt gas (equilibrium mole fraction 0.251), HCO^+ undergoes exothermic proton transfer to H_2O

$$[2] \qquad HCO^+ + H_2O \rightleftharpoons H_3O^+ + CO$$

In the absence of a metallic additive, H_3O^+ and its first hydrate, most of which is formed during sampling (see Part I), are by far the most abundant ionic species present downstream in the flame. With a metal present in the form of atoms or compounds, H_3O^+ serves as a chemical ionization (CI) source for the formation of metallic ions. The resulting depletion of H_3O^+ is shown for the five metals in Fig. 2. The depletion is small for Sc, Ti, and V, but large for Cr and Mn in correspondence with Fig. 1. Normally ions are lost in the burnt gas by the two-body, electron–ion recombination reaction

$$[3] \qquad H_3O^+ + e^- \rightarrow H + H + OH \text{ (or } H_2O + H)$$

It is evident in Fig. 1 that the loss rate for total ions is considerably reduced with Cr or Mn present. This is explained by the partial replacement of reaction [3] by the much slower three-body process involving atomic ion–electron recombination

$$[4] \qquad Cr^+, Mn^+ + e^- + M \rightarrow Cr, Mn + M$$

where M is a third body. Clearly, Cr^+ and Mn^+ must be the major metallic ions formed with these metals to affect the total ion loss rate so markedly. But even for Sc, Ti, and V, Fig. 1 is explicable in terms of a slightly decreased ion loss rate in the burnt gas; there is no evidence for any new chemi-ionization source reaction akin to reaction [1] involving metallic neutral species.

The results and discussion of the five metals will be presented in groups based on similarities of the ion chemistry. First, Cr and Mn are much the same, and have many features in common with Fe, Co, Ni, and Cu discussed in Part I. Secondly, the ion chemistry of Sc is markedly different. Thirdly, Ti and V show most of the features of all the other metals and present some new aspects in addition. To serve as a sort of index, percentages of the total metallic ions for each metal are given in Table 2, observed on the flame axis at a fixed point $z = 1.25$ mm downstream in the burnt gas. For Ti and Cr (and V to a small extent), the percentages have been corrected to allow for the contributions to a given ion of the various isotopes of the metal whose natural abundances are given in Table 1. For many of the

ions, more than one chemically reasonable isomer is possible corresponding to the same empirical formula.

Chromium and manganese

Profiles along the flame axis of the major metallic ions observed for Mn are given in Fig. 3. The subsidiary peaks in the flame reaction zone upstream of $z = 0$ stem from natural C—H—O ions at the same mass numbers. The profiles of Mn are straightforward because the isotope ^{55}Mn has a natural abundance of 100%. Mass spectra of the metallic ions measured at a fixed point on the flame axis $z = 1.25$ mm downstream are given in Fig. 4 (*a*) for Cr and (*b*) for Mn; the various isotopes of Cr are apparent.

The next consideration involves the metallic neutral species present in the flame which are available for chemical ionization by H_3O^+. Spectroscopic studies of H_2—O_2—N_2 flames doped with manganese revealed the presence of appreciable MnO such that [MnO]/[Mn] = 0.3 for a near-stoichiometric flame at 2200 K (14); a very small amount of MnOH was also detected (14, 18). In our flame at 2000 K, the amounts of total manganese present as Mn, MnO, and MnOH on a molar percentage basis are approximately 83, 17, and <1%, respectively. A similar and very detailed study of chromium revealed the presence of solid Cr_2O_3 particles which, however, amounted to <10% of the total chromium added (19). Of the gaseous chromium present, hydroxides appeared to be negligible. Using data from the JANAF Tables (8) for our flame at 2200 K, the relative amounts of Cr, CrO, CrO_2, and CrO_3 on a molar percentage basis are 63, 31, 6, and ≪1%, respectively. Bulewicz and Padley (7) also present evidence for the presence of $HCrO_3$ with $[HCrO_3]/[Cr] \geq 0.2$, but little information is available other than its estimated atomization energy of 1940 ± 40 kJ mol^{-1}. In summary, appreciable fractions of both metals are present as strongly-bound, gaseous oxides in the burnt gas of the flame (see Table 1).

The ion chemistry for chromium and manganese has many aspects in common with that of Fe, Co, Ni, and Cu already discussed in Part I. Proton transfer from H_3O^+ to the metallic atoms is exothermic for the first eight transition metals, Sc–Ni (see Table 1, and Table 1 in Part I; proton affinity of water $PA^0_{298}(H_2O)$ = 697 kJ mol^{-1})

$$[5] \qquad H_3O^+ + A \rightleftharpoons AH^+ + H_2O$$

although a small, steady-state signal for the AH^+ intermediate

was detected only for Mn. Presumably the same exothermicity is valid for the monoxides as well

[6] $H_3O^+ + AO \rightleftharpoons AOH^+ + H_2O$

The preponderance of Cr^+ and Mn^+ in Table 2 implies the subsequent occurence of fast stripping reactions with radicals

[7a, b] $AH^+ + H, OH \rightleftharpoons A^+ + H_2, H_2O$

[8] $AOH^+ + H \rightleftharpoons A^+ + H_2O$

The latter reaction has been previously suggested by Schofield and Sugden (20) for the AOH^+ ions of the alkaline earth metals, particularly Mg (2). In Table 2 for Cr, there is the hint of an alternative channel for reaction [8] to produce the oxide ion, AO^+

[9a, b] $AOH^+ + H, OH \rightleftharpoons AO^+ + H_2, H_2O$

although the detected signal is small.

Any of these ions can undergo subsequent hydration in a three-body process, particularly as a consequence of cooling during sampling as discussed in Part I; for example

[10] $A^+ + H_2O + M \rightleftharpoons M + A^+.H_2O$ or $A(OH)H^+$

[11] $AO^+ + H_2O + M \rightleftharpoons M + AO^+.H_2O$ or $A(OH)_2^+$

Using our conical, sharp-edged, chromium sampling nozzles, a

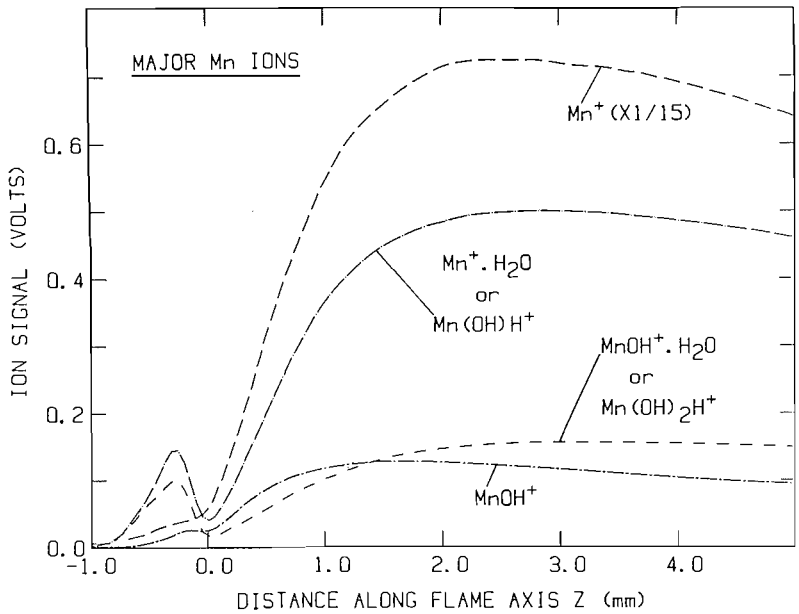

FIG. 3. Axial profiles of the major metallic ions observed when the flame is doped with ~1 ppm of Mn. The luminous reaction zone is located upstream of $z = 0$.

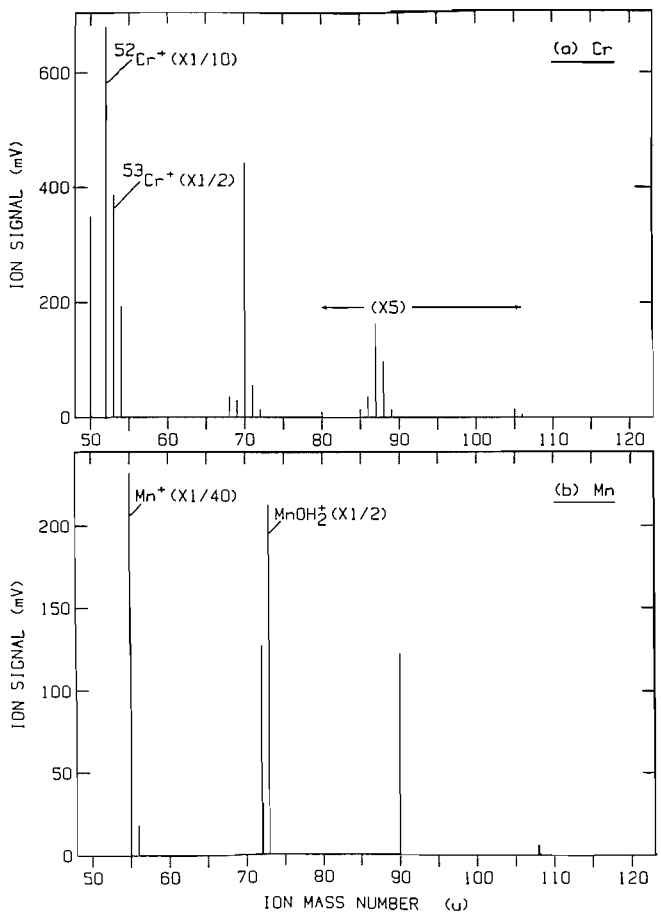

FIG. 4. Mass spectra observed at a fixed point on the flame axis at $z = 1.25$ mm downstream in the burnt gas when the flame is doped with equal molar concentrations (~1 ppm) of (*a*) Cr and (*b*) Mn.

typical hydrate ion signal is generally observed to be a few % of the parent ion signal. This ratio appears to have been exceeded in the present observations such that proton transfer to the monohydroxide cannot be ruled out

[12] $H_3O^+ + AOH \rightleftharpoons H_2O + A(OH)H^+$ or $A^+.H_2O$

and possibly to the dihydroxide as well

[13] $H_3O^+ + A(OH)_2 \rightleftharpoons H_2O + A(OH)_2H^+$ or $AOH^+.H_2O$

All of these ion–molecule reactions have been written above showing both the forward and reverse directions because the ion signals tail out a long way through the burnt gas as in Fig. 3 for the Mn profiles.

Hayhurst and Telford (4) also detected $[AOH^+]$ in amounts up to approxiately 5% of the $[A^+]$ ion signal for Cr and Mn. They invoke the chemical ionization reaction [6] and also

[14] $H_3O^+ + A \rightarrow AOH^+ + H_2$

followed by reaction [8], as well as

[15] $H_3O^+ + MnO \rightarrow Mn^+.H_2O + OH$

as an additional possibility for manganese. However, at the time of their study, it was not known that metallic atoms and oxides could possess high PA values. We believe that it is not necessary to invoke reactions as complicated as [14] and [15] from a point of view of chemical rearrangement in order to explain the ion signals observed.

It remains to discuss why the total ion signals detected with Cr and Mn present are so large compared with those of the other transition metals (see Fig. 1, and also the similar Fig. 1 in Part I for Fe, Co, Ni, and Cu). As explained in Part I, the overall mechanisms responsible for the production of A^+ involve proton transfer by [5] + [7] when A is the reagent

[16a, b] $H_3O^+ + A + H, OH \rightleftharpoons A^+ + H_2O + H_2, H_2O$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 112.217.228.212 on 09/07/12

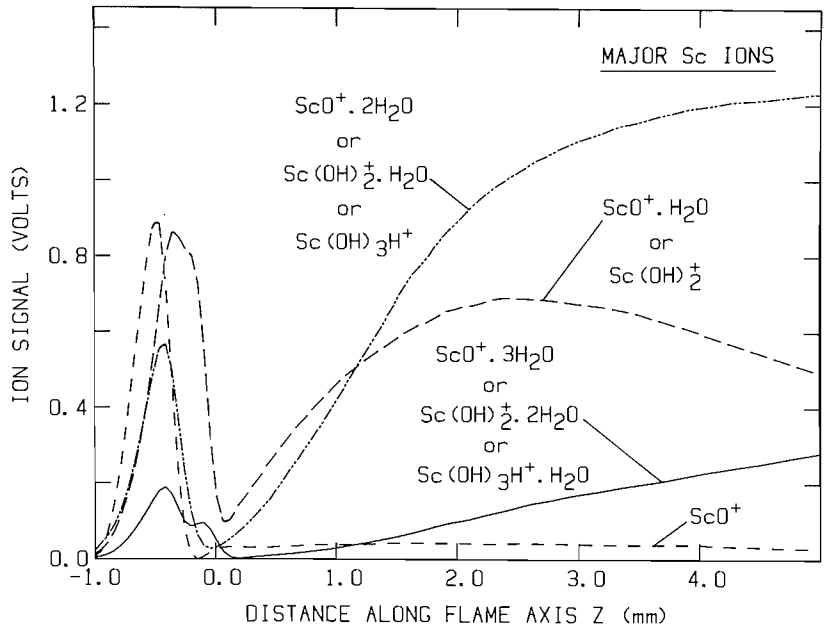

FIG. 5. Axial profiles of the major metallic ions observed when the flame is doped with ~1 ppm of Sc. The luminous reaction zone is located upstream of $z = 0$.

or by [6] + [8] with the oxide AO as reagent

[17] $H_3O^+ + AO + H \rightleftharpoons A^+ + 2H_2O$

or may involve charge transfer in a single step

[18] $H_3O^+ + A \rightleftharpoons A^+ + H_2O + H$

The detection of MnH^+ indicates that reaction [5] followed by [7a], [7b] (i.e., the overall reaction [16]) is operative, at least for manganese; presumably reaction [18] occurs as well. The reactions are all energetically favourable. Using data from the JANAF Tables (8) at 2200 K, the ΔG^0 values for reactions [16a], [16b], [17], and [18] are −408, −443, −411, and −218 kJ mol^{-1} for Cr, respectively. With Mn, the ΔG^0 values for reactions [16a], [16b] and [18] are −349, −384, and −159 kJ mol^{-1}, respectively; reaction [17] will certainly be exoergic but $\Delta G^0_{f,2200}(MnO)$ is not available. At full thermodynamic equilibrium under these flame conditions, $[Cr^+]/[H_3O^+] = 144$ and $[Mn^+]/[H_3O^+] = 5.82$; the calculated equilibrium concentrations of $[A^+]$, $[H_3O^+]$, and $[e^-] = [A^+] + [H_3O^+]$ are 6.22×10^8, 4.33×10^6, and 6.26×10^8 mL^{-1} for Cr, respectively, and 1.16×10^8, 1.99×10^7, and 1.36×10^8 mL^{-1} for Mn, respectively.

Chromium and manganese represent an extreme case of the behaviour already discussed in Part I for Fe, Co, Ni, and Cu. The enhancement of the total ion profiles in Fig. 1 with Cr and Mn present reflects the degree to which slow, three-body, atomic recombination of A^+ replaces the faster, two-body, dissociative recombination of H_3O^+ with e^- by reaction [3]. Since Cr^+ and Mn^+ are formed rapidly by reactions [16] and [18] with a corresponding loss of H_3O^+, reaction [4] soon dominates reaction [3]. That is, $[Cr^+]$ and $[Mn^+]$ reach superequilibrium levels early in the burnt gas, and take a long time to decrease to their equilibrium values much further downstream. A similar enhancement of the profiles in Fig. 1 for Sc, Ti, and V was not observed because the atomic A^+ ions, if present, are minor species (see Table 2). In general, molecular metallic ions will recombine with free electrons by fast, two-body, dissociative processes just like reaction [3] for H_3O^+. The fact that the total metallic ion signals for Sc, Ti, and V are not large (this is evident from Fig. 2 since the decrease in $[H_3O^+]$ is small) means that the formation reactions are not very exoergic, leading to small values of the equilibrium constants.

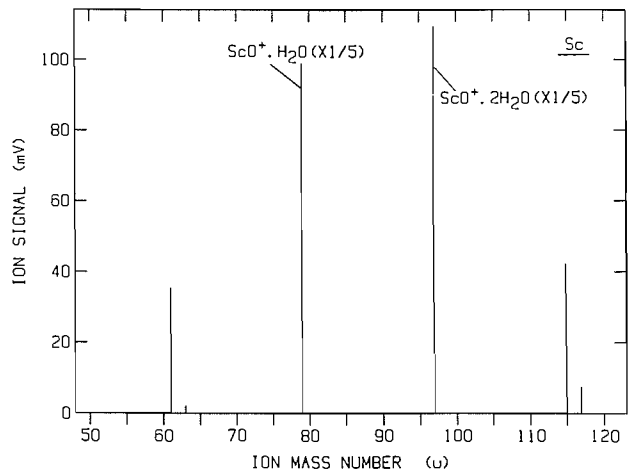

FIG. 6. Mass spectrum observed at a fixed point on the flame axis at z = 1.25 mm downstream in the burnt gas when the flame is doped with ~1 ppm of Sc.

Scandium

Axial concentration profiles for the major scandium ions are shown in Fig. 5. The upstream peaks in the reaction zone ($z < 0$) arise from natural C—H—O ions which are present when no metal is added to the flame. A mass spectrum measured at z = 1.25 mm downstream showing six metallic ions for ^{45}Sc which has a natural abundance of 100% is given in Fig. 6. These signals are represented in Table 2 as percentages of the total metallic ion signal observed.

We are not aware of any available information about scandium neutral species present in flames. Since no Sc^+ nor ScH^+ ions were observed, and since Sc has the highest PA of any first-row transition metal (see Table 1), it is unlikely that an

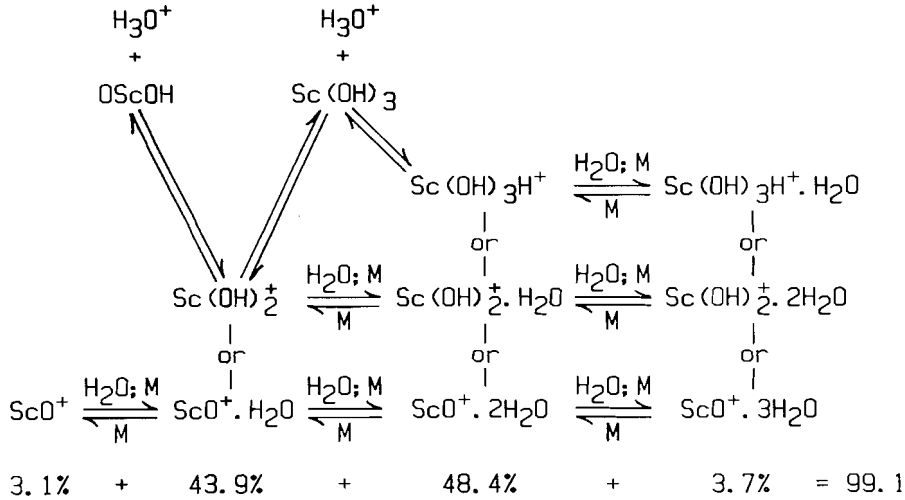

FIG. 7. Reaction flow diagram showing the dominant flame-ion chemistry for Sc. Three hydrate series involving isomeric ion structures are apparent.

appreciable quantity of the metal exists in the flame as Sc atoms. Near room temperature in solutions and solids, Sc exhibits only the single oxidation state of +3. Certainly this same oxidation number is favoured in the gas phase as flame temperature. The four major Sc ions in Figs. 5 and 6 or Table 2 can be interpreted as $ScO^+.nH_2O$ (n = 0–3), the series ending when Sc is surrounded by an electron octet, although the octet stability may have little significance for a transition metal. The octet occurs with four ligands around the metal atom, and the steric effect of a tetrahedral structure against further ligand addition is probably the more important consideration. Alternatively, the last three members of the series can be represented by $Sc(OH)_2^+.nH_2O$ (n = 0–2), or the last two by $Sc(OH)_3H^+.nH_2O$ (n = 0, 1) based on the protonated trihydroxide. In addition, two very small signals shown in Table 2 were observed for just two members of the series $Sc^+.nH_2O$ (n = 1, 4) or, alternatively, $Sc(OH)H^+.nH_2O$ (n = 0, 3) based on the protonated monohydroxide. In the last member, the Sc atom is surrounded by 10 electrons.

An insight into the chemistry leading to the formation of these ions comes from the profiles given in Fig. 5. The shapes of these profiles indicate that $Sc(OH)_2^+$ and perhaps $Sc(OH)_3H^+$ are formed first, which then dehydrate and hydrate, respectively, to form the other two members of the $ScO^+.nH_2O$ (n = 0, 3) series. Plausible Sc neutral species present in the flame which maintain the Sc(III) oxidation state are O=Sc—OH (the oxyhydroxide) and $Sc(OH)_3$. These could react with H_3O^+ to form the two major ions by the reactions

[19] $H_3O^+ + OScOH \rightleftharpoons Sc(OH)_2^+ + H_2O$

[20a] $H_3O^+ + Sc(OH)_3 \rightleftharpoons Sc(OH)_3H^+ + H_2O$ proton transfer

[20b] $\rightleftharpoons Sc(OH)_2^+ + 2H_2O$ charge transfer

Reaction [19] is preferred to form $Sc(OH)_2^+$ because reaction [20b] must be rather endothermic in the forward direction. This $ScO^+.nH_2O$ (n = 0–3) series of four ions accounts for 99% of the total Sc ions observed. A convenient summary of the ion chemistry is given in Fig. 7. Recall from Figs. 1 and 2 that the total metallic ion signal for Sc was small compared with those for Cr and Mn. If reactions [19] and [20a] are dominant and not very exoergic, their equilibrium constants may be close to unity giving low values for the $[Sc(OH)_2^+]/[H_3O^+]$ and $[Sc(OH)_3H^+]/[H_3O^+]$ ratios.

It is difficult to be definitive about formation processes for the minor ions $Sc^+.H_2O$ and $Sc^+.4H_2O$ recorded in Table 2. If a small amount of atomic Sc is present, the proton transfer reaction [5]

[5] $H_3O^+ + Sc \rightleftharpoons ScH^+ + H_2O$

invoked above for Cr and Mn, and also for Fe, Co, Ni, and Cu in Part I, is a logical starting point. The reactive radical cation ScH^+ might be expected to lose H by reaction [7] to form Sc^+, but the latter ion was not observed. Conceivably, it might react with water to form the first hydrate directly according to

[21] $ScH^+ + H_2O \rightleftharpoons H + Sc^+.H_2O$ (or $HScOH^+$)

The alternative structure given in parentheses indicates that reaction [21] is not necessarily a simple H/H_2O switching reaction. Written as the hydrate, $Sc^+.H_2O$ would constitute an unusual example of the Sc(I) oxidation state. The same ion could be produced by proton transfer to :ScOH if the monohydroxide were present in the flame. The structure of the observed ion depends on the protonation site; i.e., whether the O atom or the lone pair of electrons on Sc is the more basic. The former gives the hydrate $:Sc^+.H_2O$ involving Sc(I), while the latter amounts to hydride formation giving $H—Sc—OH^+$ which retains the common Sc(III) oxidation state.

Alternatively, $Sc^+.H_2O$ (or $HScOH^+$) could be produced from the large $Sc(OH)_2^+$ ion identified as primary in Fig. 5; e.g.

[22] $HOScOH^+ + H_2 \rightleftharpoons HScOH^+ + H_2O$

The reaction is attractive because of the high mole fraction (0.412) of H_2 in the burnt gas of this fuel-rich flame. The mechanism would seem to favour $HScOH^+$ rather than the hydrate structure. Once formed, the ion could undergo further hydration to form $Sc^+.4H_2O$ (or $HScOH^+.3H_2O$), the other tiny signal given in Table 2. The intermediate hydrates were not observed; the relative signal size merely depends on the values of the equilibrium constants for the various steps in the hydration sequence.

In summary, it is possible to interpret all of the Sc ions observed as members of various series of hydrates based on ScO^+, $HOScOH^+$, or $HScOH^+$, all of which maintain the Sc(III) oxidation state.

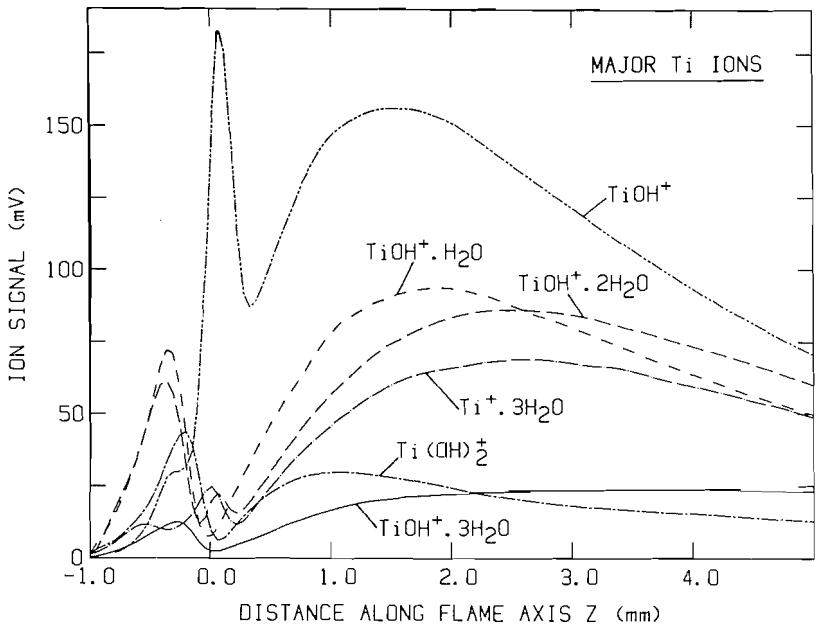

FIG. 8. Axial profiles of the major metallic ions observed when the flame is doped with ~1 ppm of Ti. The luminous reaction zone is located upstream of $z = 0$.

Titanium and vanadium

Axial profiles for the six major ions observed with titanium additive are given in Fig. 8, corrected to include contributions from the five stable Ti isotopes listed in Table 1. The various isotopes are evident in the mass spectrum of Ti ions measured at $z = 1.25$ mm downstream given in Fig. 9(*a*). A similar mass spectrum for V ions is shown in Fig. 9(*b*). These ion signals are presented in Table 2 as percentages of the total metallic ion signal observed for each metal.

Little is known about the chemistry of either of these metals in flames. Several common oxidation states are known for them near room temperature, and certainly they give rise to the greatest variety of flame ions of any of the first-row transition metals. On this basis, a considerable variety of neutral compounds of these metals in flames would not be surprising. A perusal of Table 2 indicates that much of the ion chemistry already discussed for Cr and Mn on the one hand, and for Sc on the other, will also be applicable to Ti and V; it will not be repeated here. The exception is the series of $AO_2H^+.nH_2O$ ions observed for the first time with Ti and V. However, it is of interest to consider why particular members of the various hydrate series give rise to uncommonly large signals.

For titanium, the $TiOH^+.nH_2O$ ($n = 0$–3) series, which includes the $Ti(OH)_2H^+.nH_2O$ ($n = 0$–2) as a sub-series, accounts for 80.0% of the Ti ions and emphasizes the Ti(II) oxidation state. The first member is explained by the protonation of TiO via reaction [6], and the second member by protonation of $Ti(OH)_2$ involving reaction [13]. The inference is that most of the Ti is present in the flame as TiO and/or $Ti(OH)_2$, both of which may have PA values > $PA(H_2O)$. The third member must be formed by hydration but its signal is exceptionally large for a hydrate. Since Ti has four valence electrons, this ion may have a special stability associated with the metal atom surrounded by an inert-gas octet of electrons. As with the Sc example discussed above, it is not clear whether protonation occurs on the lone pair of Ti to give $H:Ti(OH)_2^+.H_2O$ or on an O atom giving $:TiOH^+.2H_2O$. Further hydration produces the fourth and last member of the series in which the Ti atom is surrounded by 10 electrons.

For vanadium having five valence electrons, the same chemistry is in evidence but to a much smaller extent. Only the first two members of the $VOH^+.nH_2O$ ($n = 0$, 1) series were observed, both of which are radical cations, and the V(II) oxidation state is less prominent. The emphasis shifts to the $VO^+.nH_2O$ ($n = 0$–3) series involving the V(III) oxidation state. Similarities with the Sc ion chemistry are expected; the large ion signals are down-shifted to the next lower member of the series since V contains an extra electron pair compared with Sc. The major ion chemistry for V is essentially the same as that shown for Sc in Fig. 7. The third member of the series has a relatively large magnitude compared with the second, and completes an electron octet around the V atom. The fourth member terminates the series with 10 electrons surrounding V. The inference for vanadium neutral compounds present in the flame is that much of the V is present as $V(OH)_3$ and/or OVOH; presumably HVO_2 is a much less probable entity.

Similar reasoning indicates why this same series of ions is much less prominent for titanium involvng the Ti(III) oxidation state. The first four members are observed but amount to only 5.7% of the total Ti ions. All the members are, of course, radical cations; even if they were to be formed at appreciable rates, presumably the relatively high reactivity of such species mitigates against high steady-state concentrations. The second member of the series, $Ti(OH)_2^+$, is relatively prominent. Its profile given in Fig. 8 peaks early in the burnt gas, probably because of its subsequent reactivity further downstream. It might be formed by radical attack on the major $Ti(OH)_2H^+$ ion according to

$$[23a, b] \quad Ti(OH)_2H^+ + H, OH \rightleftharpoons Ti(OH)_2^+ + H_2, H_2O$$

which is similar to reaction [7] involving the dehydrogenation of the metallic hydride ions.

The $AO_2H^+.nH_2O$ ($n = 0$–2) series of ions, which includes the $A(OH)_3^+.nH_2O$ ($n = 0$, 1) sub-series, was observed for the first time with Ti and V. If the flame with Ti additive contains a small amount of TiO_2 involving the Ti(IV) oxidation state, it can protonate according to

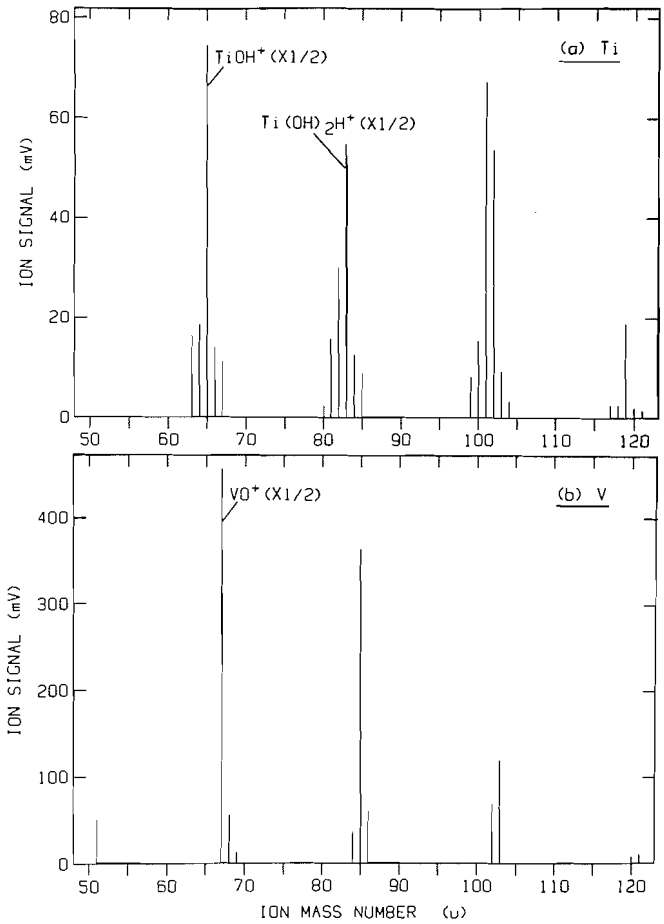

FIG. 9. Mass spectra observed at a fixed point on the flame axis at z = 1.25 mm downstream in the burnt gas when the flame is doped with equal molar concentrations (~1 ppm) of (*a*) Ti and (*b*) V.

[24] $H_3O^+ + TiO_2 \rightleftharpoons TiO_2H^+ + H_2O$

with subsequent hydration of the parent ion. The same production mechanism may also apply to V, although alternative reactions can be envisaged involving the major $VO^+.nH_2O$ ions as precursors. For example, to produce the one ion $VO_2H^+.H_2O$ (or $V(OH)_3^+$), possible reactions include

[25] $VO^+.H_2O$ or $V(OH)_2^+ + H_2O \rightleftharpoons H + VO_2H^+.H_2O$ or $V(OH)^+$

[26a, b] $V(OH)_2^+.H_2O$ or $V(OH)_3H^+ + H, OH \rightleftharpoons V(OH)_3^+ + H_2, H_2O$

with similar reactions for other members of the series. All the vanadium ions in this series are free radicals. In particular, the comparatively large signal obtained for the second member, assumed to be $V(OH)_3^+$ with 7 electrons around the metal atom, is remarkable. Whether the ion structure is pyramidal or planar trigonal and the character of the odd electron are not clear but the symmetry of the possible structures is noteworthy. Another strikingly similar example for Ti will be encountered below.

The last $A^+.nH_2O$ ion series includes the $A(OH)H^+.nH_2O$ ions as a sub-series. Only the first two members were observed for vanadium in Table 2 and probably arise by protonation of V atoms followed by H-atom abstraction and subsequent hydration in the manner already discussed for Cr and Mn via reactions [5], [7], and [10]. The uncommon V(I) oxidation state is involved in V^+ but V(III) can be invoked for its first hydrate if it is $HVOH^+$. The chemistry for Ti must be different because the first four hydrates were observed but not Ti^+ (see Table 2). One obvious explanation is protonation of TiOH by reaction [12] with subsequent hydration. The major $AOH^+.nH_2O$ ions could be involved as precursors in reactions such as

[27a, b] $TiOH^+.nH_2O + H_2, H_2O \rightleftharpoons H, OH + HTiOH^+.nH_2O$ or $Ti^+.(n+1)H_2O$

[28] $TiOH^+.nH_2O + H \rightleftharpoons Ti^+.nH_2O + H_2O$

All of the ions are odd-electron species. A remarkably large signal is obtained for one member of the series, assumed to be $Ti^+.3H_2O$ with 9 electrons around the metal atom in the unusual Ti(I) oxidation state. The considerations already noted for $V(OH)_3^+$ involving structure, character of the odd electron and molecular symmetry apply equally in the present case. That these two radical cations are particularly stable against chemical attack in the burnt gas of the flame is noteworthy. In general, if chemical reactivity is enhanced by irregularities in the electron density distribution around a molecule, surely such irregularities are reduced when the molecular symmetry is increased.

Summary and conclusions

The same fuel-rich, premixed, CH_4–O_2 flame at 2200 K and atmospheric pressure was doped with the same concentration (~1 ppm) of Sc, Ti, V, Cr, and Mn as was employed in Part I (1) for similar studies of Fe, Co, Ni, Cu, and Zn. Chemical ionization by H_3O^+ of these metal atoms A and a number of their compounds which may exist in flames including AOH, AO, OAOH (oxyhydroxide), $A(OH)_2$, $A(OH)_3$, and AO_2 produces series of metallic ions in the burnt-gas region which were observed by sampling the flame into a mass spectrometer. Apart from MnH^+, the observed ions can be described by four hydrate series, each of which contains one or two isomeric sub-series; namely, (*a*) $A^+.nH_2O$ (containing $A(OH)H^+.(n-1)H_2O$ as a sub-series), (*b*) $AOH^+.nH_2O$ (containing $A(OH)_2H^+.(n-1)H_2O$ as a sub-series), (*c*) $AO^+.nH_2O$ (containing $A(OH)_2^+.(n-1)H_2O$ as a sub-series, which contains $A(OH)_3H^+.(n-2)H_2O$ as a second sub-series), and (*d*) $AO_2H^+.nH_2O$ (containing $A(OH)_3^+.(n-1)H_2O$ as a sub-series, which contains $A(OH)_4H^+.(n-2)H_2O$ as a second sub-series). The value of n ranges from 0 to 4 for (*a*), 3 for (*b*) and (*c*), and 2 for (*d*). Thus, the observed series all terminate with four ligands around the central metal atom, and not five or six as is often the case for solutions and solids of transition metals near room temperature. This limited number of ligands may be caused by the high temperature, and also by the gas phase; in condensed phases, the ligands' electrons will be more delocalized by hydrogen bonding. All of the series of observed ions terminate with a maximum of 10 electrons around the metal atom with the single exception of $Ti^+.4H_2O$ which has 11. Not all metals exhibit all of the series. Some of the higher hydrates are undoubtedly enhanced by cooling during sampling into the mass spectrometer.

The ion chemistry of Cr and Mn has much in common with that of Fe, Co, Ni, and Cu discussed in Part I. It is dominated by series (*a*) involving proton transfer to A followed by dehydrogenation to form A^+ with subsequent hydration. The preponderance and slow electron–ion recombination of A^+ for Cr and Mn are responsible for the comparatively large metallic ion signal obtained for these two metals in the burnt gas. Series (*b*) involving proton transfer to AO and/or $A(OH)_2$ is much less prominent. In contrast, the ion chemistry of Sc is completely different; series (*c*) accounts for 99% of the observed ions. The major ions appear to involve proton transfer to OScOH and $Sc(OH)_3$. This

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 112.217.228.212 on 09/07/12
For personal use only.

interpretation maintains Sc(III) as the single oxidation state exhibited by all of the ions and neutral species. It is even true for the minor ions of series (*a*) if $Sc^+.H_2O$ does, in fact, have the $HScOH^+$ structure formed by protonation of HScO.

For Ti and V, ions were observed from all four series. Ions from series (*d*) involving proton transfer to AO_2 were encountered for the first time. The major Ti ions in series (*b*) appear to arise by protonation of TiO and $Ti(OH)_2$; the Ti(II) oxidation state is favoured. For V, like the ion chemistry for Sc with two additional electrons, the major ions in series (*c*) appear to form by protonation of OVOH and $V(OH)_3$; the V(III) oxidation state is favoured. Series (*a*) and (*c*) for titanium emphasizing Ti(III), and series (*a*) and (*b*) for vanadium emphasizing V(I) and V(II) are less prominent. Two radical cations interpreted as $Ti^+ \cdot 3H_2O$ and $V(OH)_3^+$ yield unexpectedly large signals. Their stability against chemical attack in the burnt gas region of the flame is attributed to their high degree of symmetry, whether pyramidal or planar trigonal.

Received November 9, 1987

ANNA M. RITCEY, GÉRARD CHARLET, and DEREK G. GRAY. Can. J. Chem. **66**, 2229 (1988).

The apparent circular dichroism arising from the selective reflection of circularly polarized light by cholesteric films of (hydroxypropyl)cellulose is extremely sensitive to residual linear orientation. The introduction of a uniaxially oriented film in the spectropolarimeter beam in front of a liquid crystalline sample may change both the intensity and the sign of the observed mesophase reflection band. The results can be understood by a simple consideration of the way in which the polarization state of light is altered as it traverses the birefringent film. These observations emphasize a potential problem in the use of circular reflectivity as a method to characterize the reflection properties of polymeric cholesteric liquid crystals. The presence of linear orientation in such samples can give rise to artifacts.

ANNA M. RITCEY, GÉRARD CHARLET et DEREK G. GRAY. Can. J. Chem. **66**, 2229 (1988).

Lorsque des films cholestériques d'(hydroxypropyl)cellulose réfléchissent sélectivement de la lumière polarisée d'une façon circulaire, on observe un dichroïsme circulaire apparent qui est très sensible à l'orientation linéaire des résidus. Lorsqu'on introduit un film orienté dans un seul axe dans le faisceau d'un spectropolarimètre, devant un échantillon de cristal liquide, il peut se produire un changement tant de l'intensité que du signe de la bande observée pour la réflexion de la mésophase. On peut comprendre facilement les résultats en faisant appel à une considération simple impliquant le façon dont l'état de polarisation de la lumière est altérée lorsqu'elle traverse le film biréfringent. Ces observations suggèrent que des problèmes peuvent surgir lors de l'utilisation de la réflectivité circulaire pour caractériser les propriétés de réflexion des cristaux liquides cholestériques de polymères. La présence d'orientations linéaires dans de tels échantillons peut donner lieu à des artéfacts.

Introduction

Since the initial report (1) of the formation of a cholesteric liquid crystalline phase in concentrated aqueous solutions of (hydroxypropyl)cellulose (HPC), many other cellulose derivatives have been found to form similar ordered phases (2, 3). These liquid crystals possess unique optical properties arising from the selective reflection of light by the helicoidal arrangement of molecules found within them. This twisted supramolecular structure, illustrated schematically in Fig. 1, is characterized by its handedness and by the pitch, P, which is the distance through which a vector representing the average molecular orientation completes a 360° rotation. DeVries (4) formulated a theory for the optical properties of the cholesteric mesophase, predicting the reflection of circularly polarized light. For an incident beam parallel to the helicoidal axis, the wavelength of reflected light corresponds to the pitch. In addition to being selective with respect to wavelength, this reflection is also selective with respect to handedness: right-handed cholesteric liquid crystals reflect only right circularly polarized light and, similarly, left-handed cholesterics reflect only left circularly polarized light. At wavelengths within the reflection band, the intensity of light transmitted by a cholesteric mesophase will therefore be different for incident light of the two circular polarizations and the reflection properties can be monitored as apparent circular dichroism (CD) or "circular reflectivity".

The optical properties of dry HPC films cast from mesophase solution have recently been reported (5). When heated, these HPC films reflect circularly polarized light, indicating that the cholesteric order present in the lyotropic solution is retained on drying. This is the case for the films cast from a mesophase sample in the unperturbed cholesteric state. We would like to report here an additional optical effect, which is observed if the mesophase solution is sheared and then dried before the system can relax to the equilibrium cholesteric structure. Such samples sometimes show a reversal in sign of the CD peak. Normally this would indicate a reversal of the cholesteric structure from a right- to a left-handed helicoidal arrangement. This is physically improbable. The molecular orientation (6, 7) induced by shear and frozen-in during rapid drying may, however, drastically affect the circular reflectivity spectra of these films, and the presence of linear orientation in such samples can give rise to major artifacts.

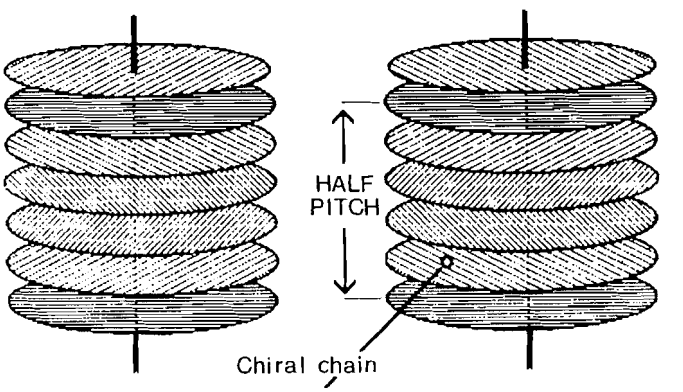

FIG. 1. Schematic representation of the molecular order found in cholesteric liquid crystals. The cholesteric phase can be pictured as consisting of a series of molecular layers perpendicular to the cholesteric axis. The molecules within each layer point in the same general direction and each layer is twisted relative to the next so as to generate a helicoidal supramolecular structure.

The problems associated with circular dichroism measurements of optically active chromophores in the presence of linear orientation have been treated in the literature (8–10). This paper illustrates that similar considerations are very significant in the

[1]Present address, Max-Planck Institute for Polymer Research, Postfach 3148, D-6500 Mainz, West Germany.

[2]Present address, Departement de chimie, Université Laval, Québec (Québec), Canada G1K 7P4.

characterization of the cholesteric reflection properties of polymeric liquid crystals. In these systems linear orientation is promoted by the ease with which molecular alignment is achieved under shear and the relatively high viscosities that restrict relaxation.

A theoretical analysis of the optical properties of samples that exhibit both linear and circular birefringence is complex since these two properties cannot be treated separately. The required Mueller matrix formalism is well described in the literature (9) and no attempt will be made to apply this approach in the present case. However, since the characterization of cholesteric liquid crystals by apparent circular dichroism is rapid and convenient, but subject to artifacts introduced by linear birefringence, a brief quantitative discussion is presented of results for a simplified model system consisting of a birefringent film and a cholesteric liquid crystal placed separately in the spectrometer beam. This provides a simple illustration of the observed artifacts.

Experimental

Sample preparation

Dry films were prepared from aqueous mesophase solutions of (hydroxypropyl)cellulose (Aldrich Chemical Co., nominal molecular weight 100 000) having a concentration of ~65% polymer by weight. The mesophase samples were pressed between two glass slides and allowed to relax to the equilibrium cholesteric structure, characterized by the appearance of a uniform reflection colour. The two slides were then separated by sliding lengthwise. The resulting thin HPC films dry rapidly at ambient conditions. Complete drying was achieved under vacuum.

Banded textures were observed with a Reichert polarizing microscope equipped with a rotating stage.

Reflectivity spectra

Circular reflectivity (CR) spectra were recorded with a Jasco J-500C spectropolarimeter. Temperature control was achieved by placing samples in a microscope hot stage (Mettler FP52) mounted in the spectrometer beam. All heating experiments were performed at a rate of 0.2°C/min.

Results and discussion

Optical properties

HPC films cast from mesophase solutions that have been sheared and then dried before relaxation to the equilibrium cholesteric structure is complete unexpectedly show a *positive* circular reflection band. At room temperature this reflection band is situated below 300 nm but, as is the case for cholesteric HPC films, moves to longer wavelengths on heating. Spectra recorded for this type of sample when heated at 150°C are shown in Fig. 2. This behaviour is very similar to that observed for the cholesteric films cast under equilibrium conditions, indicating that the peaks shown in Fig. 2 are cholesteric reflection bands. However, the reflection bands for sheared and equilibrium films are of opposite signs.

The lyotropic cholesteric liquid crystals formed by HPC (11), as well as the thermotropic mesophases formed by ester derivatives of HPC (12, 13), are right-handed and therefore preferentially reflect right circularly polarized light and give negative CR spectra. It is unlikely, however, that the positive reflection band observed here arises from the selective reflection of left circularly polarized light from a left-handed cholesteric arrangement. The method of sample preparation suggests that these films are uniaxially oriented and this is confirmed by the linear birefringence observed when the films are viewed between crossed polars. The polarization state of light will therefore be altered as it traverses such a sample and this change in polarization will in turn affect the recorded CR spectrum. In some cases, as shown below, the result can be a reversal in the sign of a CR spectrum.

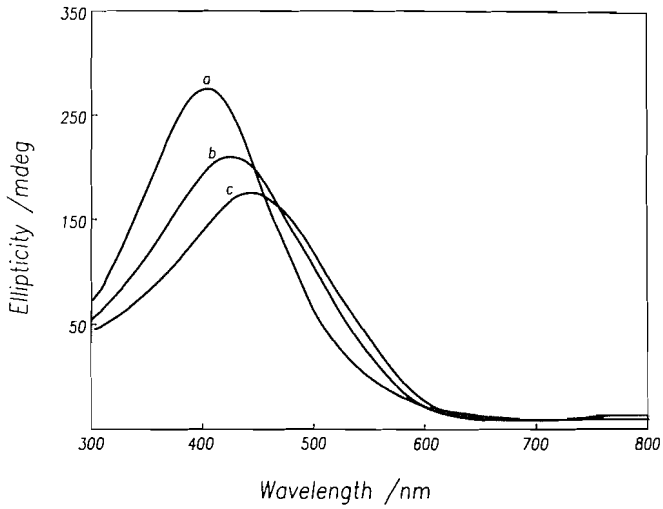

FIG. 2. Circular reflectivity spectrum of an HPC film cast from aqueous mesophase solution under shear recorded (a) 2, (b) 12, and (c) 40 minutes after heating from room temperature to 150°C.

The structure of the films cast under shear is quite complex in that the molecular orientation varies across the thickness of the sample. In addition to being linearly oriented, such a film must also possess the cholesteric component responsible for the observed reflection band. This cholesteric component can be eliminated by the preparation of very thin (<5 μm) samples, which dry almost immediately after shear. The composite nature of films that give positive reflection spectra can be modeled by placing one or more of these thin uniaxially oriented samples in the spectrometer beam along with a well-ordered lyotropic cholesteric mesophase.

The CR spectra obtained for such a combination of samples are shown in Fig. 3. The bottom curve (a) is the reflection band of the lyotropic liquid crystal alone. In this case the sample is an aqueous HPC mesophase and the reflection band is negative as expected. The presence of a birefringent HPC film, placed in the spectrometer beam in front of the mesophase sample, significantly reduces the intensity of the reflection band (curve b). The introduction of a second piece of the same film affects the spectrum differently, depending on the orientation of its shear direction relative to that of the first. Two oriented films placed so that the shear direction of one is perpendicular to that of the other have no effect on the mesophase spectrum, while the introduction of a second oriented film parallel to the first reverses the sign of the peak (curve c). If the samples are placed so that the spectrometer beam first passes through the mesophase sample and then the oriented film, the reflection spectrum is unchanged from that recorded for the mesophase alone.

These CR spectra can be understood through the following simple consideration of the polarization state of the light incident on the mesophase sample. The spectropolarimeter monitors the intensity of light transmitted by a sample as the incident radiation is modulated between left and right circularly polarized light. This cirularly polarized light can be decomposed into two perpendicular plane-polarized waves that are 90° out-of-phase. As these two perpendicular waves pass through a birefringent sample an additional phase difference, δ, develops between them. If the sheared sample has a birefringence such that $\delta = \pm 90°$ (i.e., the oriented sample is a quarter-wave plate),

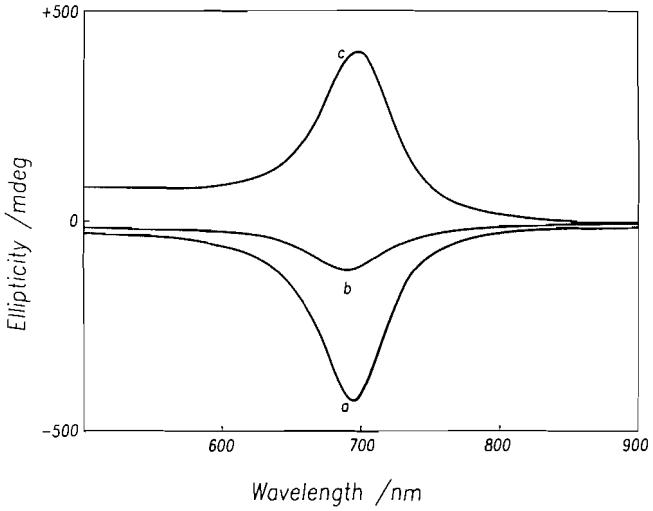

FIG. 3. Circular reflectivity spectrum of an aqueous HPC mesophase: (a) alone in the spectrometer beam; (b) with one HPC oriented film in beam; (c) with two oriented HPC films in the beam.

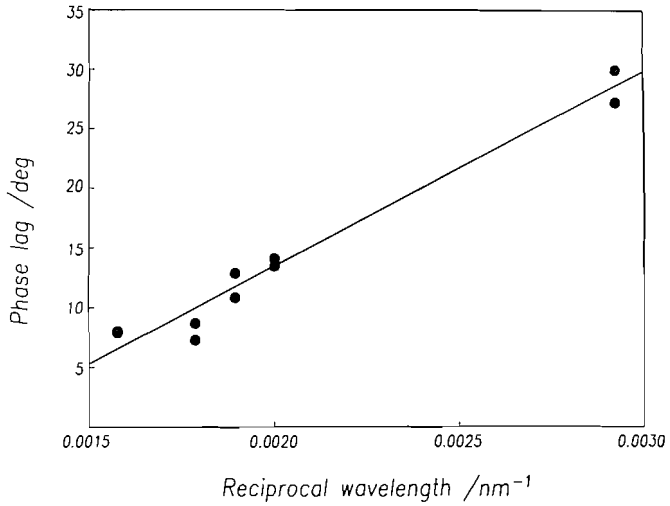

FIG. 4. Wavelength dependence of the phase lag introduced between two perpendicular waves on traversing an oriented HPC film. The phase lag was calculated from the observed decrease in the ellipticity of the reflection band of various HPC aqueous mesophases.

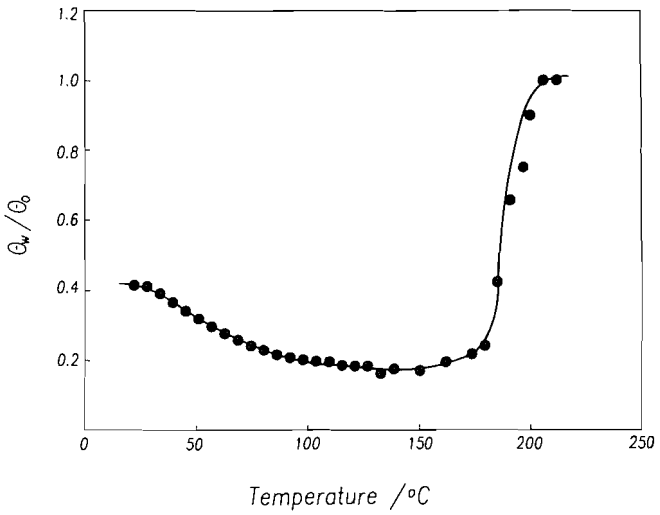

FIG. 5. Effect of waveplate temperature on the observed maximum of a CD spectrum of an HPC aqueous mesophase. θ_0 and θ_w are the ellipticity at the peak maximum in the absence and presence of the waveplate, respectively.

the resultant of the two waves after traversing the birefringent film will be plane polarized. The mesophase sample will then reflect the same intensity of light regardless of the handedness of the circularly polarized light being produced by the CD modulator, and the CR reflection band will therefore vanish. If, on the other hand, $\delta = \pm 180°$ (i.e., the oriented sample is a half-wave plate), the birefringent film will reverse the handedness of each of the circular polarizations produced by the CD modulator. In this case the recorded CR peak of the mesophase probe is reversed in sign.

In the intermediate cases the incident circularly polarized light is converted to elliptically polarized light as it passes through the birefringent film. It may be shown (see Appendix) that the observed maximum intensity of the reflection peak, θ_w, is related to that of the mesophase alone, θ_0, by

$$[1] \quad \theta_w/\theta_0 = 1 - \sin\delta$$

for $0° \leq \delta \geq 90°$. (Since the handedness of the radiation was not considered in the deviation, these limits for δ restrict eq. [1] to cases that do not involve a change in the sign of the observed peak.)

The phase shift δ is related to the birefringence, $n_1 - n_2$, of the oriented sample by

$$[2] \quad \delta = \frac{2\pi\,\Delta z}{\lambda}(n_1 - n_2)$$

where Δz is the film thickness, λ is the wavelength of the incident light, and n_1 and n_2 are the refractive indices parallel and perpendicular to the orientation direction.

For a given oriented film, δ can be determined as a function of wavelength by measuring θ_w/θ_0 for a number of lyotropic mesophase samples of various concentrations and therefore different wavelengths of maximum reflection. Values of δ determined in this way are plotted against reciprocal wavelength in Fig. 4. The film birefringence is calculated as 0.009 from the slope when the film thickness is taken as 5 μm. This value is of the same order of magnitude as the birefringence measured for several HPC cholesteric mesophases (14).

The molecular orientation responsible for the retardation plate behaviour of these HPC films persists to relatively high temperatures. The ratio of the observed maximum (θ_w) to the true intensity (θ_0) of a mesophase reflection band is plotted in Fig. 5 as a function of the temperature of the oriented HPC film. The true reflection band of the mesophase is observed only when the temperature of the oriented sample reaches 200°C. The light intensity transmitted by the sample between crossed polars also decreases sharply near this temperature, indicating a loss of birefringence.

Banded texture

When viewed between crossed polars, oriented films of HPC cast from a sheared mesophase exhibit the banded texture that has been reported for HPC films prepared in a similar manner (6, 7), for shear oriented films prepared from the thermotropic melt (15), and as an intermediate structure in the relaxation of HPC lyotropic mesophases after shear (16). The general behaviour of these bands when the sample is rotated agrees with previous observations (6, 17). However, the material and molecular

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 112.217.228.212 on 09/07/12
For personal use only.

relaxation processes that cause the bands to form after a liquid crystalline polymer has been sheared remain obscure.

Like the birefringence of the oriented films, the banded texture persists to relatively high temperatures. The bands are difficult to discern in samples heated at 185°C since the field begins to darken as the birefringence vanishes. The bands and the birefringence, however, reappear when such samples are cooled.

Conclusions

Residual shear-induced orientation in cholesteric liquid crystals complicates the interpretation of the circular reflectivity spectra of such samples. However, the optical properties of partially oriented films indicate a potential use in the preparation of single component optical devices possessing the necessary properties for applications both as filters or circular polarizers and as waveplates (18).

Appendix

Derivation of equation [1]

The Jasco J-500C spectropolarimeter monitors the intensity of light transmitted by a sample while an incident radiation of constant intensity, I_0, is modulated between left and right circularly polarized states. If the sample preferentially absorbs or reflects light of one of these polarizations, the intensity reaching the detector will depend on the polarization of the incident beam. If we choose as the sample a right-handed cholesteric mesophase, the time dependence of the intensity reaching the detector will be as illustrated in Fig. A1. Assuming that right circularly polarized light is reflected with a reflectivity R, and that all left circularly polarized light is transmitted, the intensity reaching the detector for incident right and left circularly polarized light is $I_R = I_0 - RI_0$ and $I_L = I_0$ respectively.

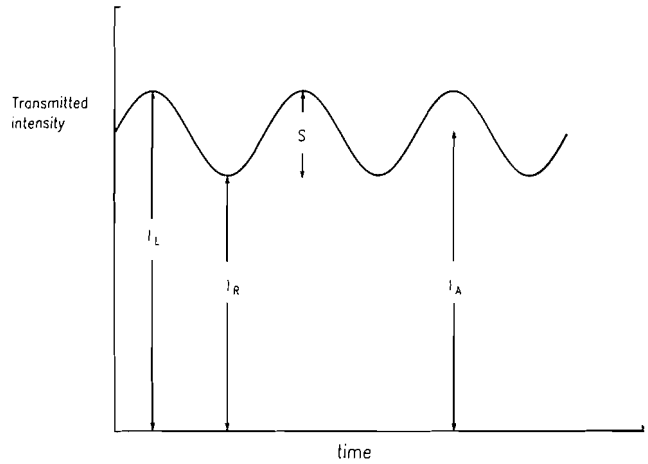

FIG. A1. Intensity of light reaching the detector of the spectropolarimeter as a function of time when a sample that preferentially reflects right circularly polarized light is placed in the beam. I_L and I_R are the transmitted intensities when the CD modulator is producing left and right circularly polarized light, respectively. S is the difference between these two intensities and I_A is their average.

The spectropolarimeter reports the spectrum as ellipticity, θ, as a function of wavelength. The recorded ellipticity is directly proportional to the parameters S and I_A:

$$[3] \quad \theta = C S/I_A$$

where C is a constant (19) and S and I_A are defined in Fig. A1.

The relationship between the observed ellipticity at the wavelength of maximum reflection and the reflectivity of the mesophase is then

$$[4] \quad \theta = \frac{-CR}{(1-R/2)}$$

Circularly polarized light can be decomposed into two linearly polarized components out-of-phase by 90°. The electric vector, $\boldsymbol{E}$, of right circularly polarized light propagating along the z-axis is given by

$$[5] \quad \boldsymbol{E} = E_0 \sin(\omega t)\,\boldsymbol{i} + E_0 \cos(\omega t)\,\boldsymbol{j}$$

where ω is angular frequency, t is time, and $\boldsymbol{i}$ and $\boldsymbol{j}$ are the unit vectors along the x- and y-axes, respectively. As these waves traverse the birefringent film where $n_i \neq n_j$, an additional phase lag, δ, develops between them, and now

$$[6] \quad \boldsymbol{E} = E_0 \sin(\omega t + \delta)\,\boldsymbol{i} + E_0 \cos(\omega t)\,\boldsymbol{j}$$

Therefore, at any point along the beam path

$$[7] \quad E_x = E_0 \sin(\omega t + \delta)$$

and

$$[8] \quad E_y = E_0 \cos(\omega t)$$

These equations can be combined to give

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 112.217.228.212 on 09/07/12
For personal use only.

[9] $E_x^2 - 2E_xE_y \sin \delta + E_y^2 = E_0^2 \cos^2 \delta$

This is the equation of an ellipse with major axis tilted at 45° to the x- and y-axes. After rotation of the axes by 45° the general form of an ellipse is obtained:

[10] $$\frac{E_x^2}{E_0^2(1 + \sin \delta)} + \frac{E_y^2}{E_0^2(1 - \sin \delta)} = 1$$

for $-90° \leq \delta \leq 90°$.

The birefringent film therefore serves to change the light reaching the mesophase sample from alternating right and left *circularly* polarized light to alternating right and left *elliptically* polarized light. The selective reflection of elliptically polarized light from the cholesteric mesophase can be evaluated by considering this polarization as the sum of a circularly polarized component and a plane-polarized component. The intensities of these two components, I_{cir} and I_{pl} respectively, are given by

[11] $I_{cir} = 2E_0^2 (1 - \sin \delta)$

[12] $I_{pl} = 2E_0^2 (1 - \cos \delta)$

for $0° \leq \delta \leq 90°$. When the instrument is producing right circularly polarized light the sample will reflect R times the circularly polarized component and $\frac{1}{2}R$ times the plane-polarized component:

[13] $I_R = I_0 - RI_0(1 - \sin \delta) - \frac{1}{2}I_0R(1 - \cos \delta)$

When the instrument is producing left circularly polarized light the same proportion of the linearly polarized component is reflected, but all of the circularly polarized component is transmitted:

[14] $I_L = I_0 - \frac{1}{2}I_0R(1 - \cos \delta)$

The presence of the waveplate therefore serves to increase I_R and decrease I_L. For relatively low reflectivities it is reasonable to assume that I_A is unaffected by the waveplate, and that the major effect on the observed spectrum is through S. S in the presence of the waveplate, S_W, will be given by

[15] $S_w = I_0R(1 - \sin \delta)$

Therefore the ratio of the observed ellipticity in the presence of the waveplate, θ_w, to the observed ellipticity in the absence of the waveplate, θ_0, is

[16] $\theta_w/\theta_0 = (1 - \sin \delta)$

for $0° \leq \delta \leq 90°$.

This derivation treats only the simplified case when the linear birefringence and the circular reflectivity are physically separated. Consideration of the optical behaviour of birefringent cholesteric films, where a single polymer sample displays simultaneously these two optical properties, requires a more complex approach (9).

Ozonolysis of tetramethoxyethene[1]

KARL R. KOPECKY, JOSÉ MOLINA,[2] AND RODRIGO RICO[3]
Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received December 1, 1987

KARL R. KOPECKY, JOSÉ MOLINA, and RODRIGO RICO. Can. J. Chem. **66**, 2234 (1988).

Ozonolysis of tetramethoxyethene **1** produces 20–40% of dimethyl carbonate **3**, 35–60% of methyl trimethoxyacetate **7**, and 20–35% of the dioxetane **8** of **1**. Yields vary with initial concentration of **1**, temperature, and solvent. Singlet oxygen is produced, which reacts with **1** to form **8** and can be trapped with 2,5-dimethylfuran. No evidence for the formation of the molozonide of **1** was obtained. Up to 2.5 moles of **1** are consumed per mole of ozone. Ozonolysis of a mixture of **1** and 2,3-dimethyl-2-butene **12** gave the epoxide of **12** and three times the expected amount of the allylic hydroperoxide of **12**. A competing radical chain oxidation reaction is proposed to account for these products and the stoichiometry of the ozonolysis. The initial reaction in the ozonolysis of **1** is proposed to be an electron transfer reaction that is calculated to be exothermic by >35 kcal/mol. The resulting radical ions initiate the radical chain oxidation and combine to form the oxygenated epoxide **9** of **1**. Loss of singlet oxygen from **9** forms the epoxide **10**, which rearranges to **7**. At −95°C the zwitterion from **10** is trapped by CD_3OD to produce a mixture of **7** with one α OCD_3 group and pentamethoxyethanol with one β OCD_3 group from which a CH_3OD group is lost at ~ −10°C to form more deuterated ester.

KARL R. KOPECKY, JOSÉ MOLINA et RODRIGO RICO. Can. J. Chem. **66**, 2234 (1988).

L'ozonolyse du tétraméthoxyéthène (**1**) fournit de 20 à 40% de carbonate de diméthyle (**3**), de 35 à 60% de triméthoxyacétate de méthyle (**7**) et de 20 à 35% du dioxétane **8** du composé **1**. Les rendements varient avec la concentration initiale du composé **1**, avec la température et avec le solvant. Il se produit de l'oxygène singulet qui réagit avec le composé **1** pour donner du produit **8**; on peut le piéger avec du diméthyl-2,5 furanne. On n'a pas obtenu de résultats suggérant qu'il se forme du molozonide du composé **1**. Pour chaque molécule d'ozone, il y a 2,5 moles du composé **1** qui sont consommées. L'ozonolyse d'un mélange du composé **1** et du diméthyl-2,3 butène-2 (**12**) fournit l'époxyde **12** ainsi que de l'hydroperoxyde allylique de **12** qui se forme en quantités trois fois plus grandes que ce qu'on avait prévu. On suggère l'existence d'une réaction compétitive d'oxydation radicalaire en chaîne pour expliquer la formation de ces produits ainsi que la stoechiométrie de l'ozonolyse. On suggère que la réaction initiale, lors de l'ozonolyse du composé **1**, est une réaction de transfert électronique qui, d'après nos calculs, serait exothermique par >35 kcal/mol. Les ions radicaux qui en résultent initient la réaction d'oxydation radicalaire en chaîne et se combinent pour former l'époxyde oxygéné **9** du composé **1**. Par perte d'oxygène singulet, le composé **9** fournit l'époxyde **10** qui se transpose en composé **7**. À −95°C, le zwitterion provenant du composé **10** est piégé par le CD_3OD pour conduire à un mélange du composé **7** portant un groupement OCD_3 en α et de pentaméthoxyéthanol portant un groupement OCD_3 en β qui, par perte de CH_3OD à ~ −10°C, forme d'autre ester deutéré.

[Traduit par la revue]

Introduction

A general synthesis of tetraalkoxy-1,2,4,5-tetroxanes was required as part of a search for new luminescent molecules. There appear to be no examples of this class of compound but it would seem to be possible to prepare them by ozonolysis of tetraalkoxyethenes, which are readily available (1).

Studies were thus initiated with the simplest of these alkenes, tetramethoxyethene **1**. According to the commonly accepted mechanism of ozonolysis (2), treatment of **1** with ozone should result, via the molozonide **2**, in the formation of dimethyl carbonate **3** and tetramethoxy-1,2,4,5-tetroxane **5**, Scheme 1. In the participating solvent, methanol, dimethyl carbonate oxide **4** should be trapped to yield trimethoxymethyl hydroperoxide **6**.

In fact the ozonolysis of **1** was studied some time ago (3). Only 70% of the theoretical amount of ozone was consumed. The only products identified, by gas chromatography, were **3** and methyl trimethoxyacetate **7**. Both of these products were formed in the participating solvent, methanol, as well as in the inert solvents, chloroform and hexane. A 15% yield of peroxidic material, as determined by iodometric titration, was formed in methanol. These results indicate that peroxidic products are formed to only a minor extent.

Since compounds as sensitive as **5** and **6** might not survive the conditions of the gas chromatographic analysis used, the ozonolysis of **1** was reinvestigated using nmr spectroscopy at low temperature as a nondestructive method of analysis. The reaction proved to be more complex than anticipated. The dioxetane of **1** is a major product along with **3** and **7**, and there is evidence that a radical chain reaction contributes to product formation.

Results and discussion

Identification of dioxetane 8

Initially, ozonolyses were carried out at −78°C in nmr tubes and the reaction mixtures analyzed immediately by ^1H nmr spectroscopy at −70°C. Actually, the products were found to be stable for several hours at 20°C in inert solvents, but not in CD_3OD, if all traces of acid were removed from solvent and glassware. In addition to signals due to **3** and **7**, the nmr spectrum of the reaction mixture also exhibited a strong signal at δ 3.50 (CD_2Cl_2). This was originally thought to be due to the desired tetroxane **5**. However, the solution had only 49% of the

active oxygen content expected, as determined by iodometric titration. This suggested that the third product might be tetramethoxy-1,2-dioxetane **8**, and, in fact, the ^1H and ^{13}C nmr spectra of this product were identical with those of authentic **8** (4), which was prepared by oxidation of **1** with singlet oxygen. The dioxetane **8** is also formed upon ozonolysis of **1** in CD_3OD. The presence of a dioxetane was further confirmed by observation of bright luminescence upon addition of some of the reaction mixtures in CD_2Cl_2 or CD_3OD to hot toluene containing 9,10-dibromo- and 9,10-bis(phenylethynyl)anthracene. More evidence for the dioxetane structure was obtained by observation of the very rapid disappearance of the ^1H nmr signal attributed to **8** upon addition of a trace of $CuCl_2$ to an ozonolysis mixture in CD_3OD at $-60°C$. The intensity of the signal due to carbonate increased by a corresponding amount. Dioxetanes have been shown to be cleaved rapidly to carbonyl compounds by transition metal ions (5).

The yields of products formed in inert solvents vary with temperature, the initial concentration of **1**, and a little with solvent. They range from 20 to 40% **3**, 35 to 55% **7**, and 20 to 35% **8**, Table 1. Amounts of dioxetane formed are thus quite significant. There is no evidence that any other products are formed in the ozonolysis of **1** in inert solvents or, above $-50°C$, in CD_3OD. Higher temperatures and low initial concentrations of **1** result in increased yields of carbonate **3**. Highest yields of dioxetane occur at low temperature and higher initial concentrations of **1**. Under a given set of conditions product yields are quite reproducible. There is only a small change in product distribution when a stream of ozone in argon is used rather than a stream of ozone in oxygen.

Possible reaction pathways

Initial attempts to understand how the products are formed were based on reactions for which there was already precedent, Scheme 2. Formation of the ester **7** and dioxetane **8** could occur via the oxygenated epoxide **9**. Such species have been postulated on numerous occasions, mainly to rationalize epoxide formation in ozonolysis of very hindered alkenes (2), which **1** is not. Thus, **9** would fragment to the epoxide **10** and singlet oxygen (6). Rearrangement of **10** would result in ester **7** and the singlet oxygen would react with a second molecule of **1** to form **8**.

Evidence in favor of the formation of **8** by reaction between **1** and singlet oxygen was obtained by conducting the ozonolysis of **1** in the presence of 2,5-dimethylfuran **11**, an efficient singlet oxygen scavenger. No (<5%) dioxetane was formed when a 6:1 mixture of **11**:**1** was ozonized to 25% consumption of **1** although **3** and **7** were still formed in the normal ratio, eq. [1].

Essentially complete scavenging of singlet oxygen under these conditions would be expected since tetraethoxyethene and 2,3-dimethyl-2-butene **12** show similar reactivities toward this species, the rate constants for the reactions are 4.5×10^7 (acetone) (7) and 4.7×10^7 (methanol) (8), respectively, at room temperature, and **11** has been shown to be 11 times as reactive as **12** at −78°C (9). This was confirmed by carrying out competitive oxygenations of **1** and **12** sensitized by rose bengal at −78°C. These show that the latter alkene is more reactive toward singlet oxygen by a factor of 1.3 in CD_3COCD_3 and 1.6 in CD_3OD, in excellent agreement with the room temperature reactivities of **12** and tetraethoxyethene. Thus, **11** is 14–16 times as reactive as **1** toward singlet oxygen.

The formation of **3** and **7** in the normal ratio in ozonolysis of **1** in the presence of excess **11** shows that the reactions by which these two materials are formed are unaffected by the presence of **11**. The endoperoxide **13** of **11**, identified by its ^1H nmr spectrum (9), was present in about twice the expected amount, based on the relative yield of **8** formed in the absence of **11**. The reason for the larger than expected amount of **13** is unknown. Control experiments show that none is formed as a result of ozonolysis of **11** alone. It appears that **11** is much less reactive toward ozone than is **1**. At least 50% of the measured amount of ozone that was delivered was consumed by **1** based on the amount of **3** and **7** that were formed. Only weak signals were present in the ^1H nmr spectrum of the reaction mixture that could be attributed to ozonolysis products from **11**.

This evidence that **8** is formed by the reaction between **1** and singlet oxygen eliminates another conceivable route to **7** and **8**. The formation of **8** upon ozonolysis of **1** is reminiscent of earlier reports (10) that dioxetanes can be prepared by ozonolysis of alkenes under certain conditions. A peroxydioxetane intermediate was proposed to be the initial ozonolysis product that could transfer an oxygen atom to a suitable acceptor or rearrange to form the conventional molozonide. While these reports of

dioxetane formation were soon shown to be incorrect (11), the possibility that peroxydioxetanes could be intermediates in ozonolysis of alkenes has not been excluded in a general way. Applying this concept to the present work, the alkene **1** would serve as an oxygen atom acceptor from the peroxydioxetane **14**, eq. [2]. However, it is very unlikely that such a route to **7** and

[2]  + 1 → 8 + 10 → 7

14

8 would be affected by the presence of **11**. Thus, while the formation of **14** would provide an economical route to **7** and **8** according to eq. [2], these products are not formed in this way.

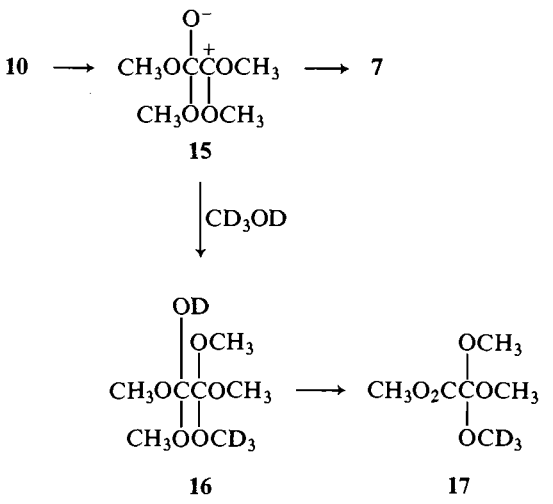
Lack of evidence for carbonyl oxide 4

The formation of **7** and **8** can be rationalized on the basis of the intermediate formation of the oxygenated epoxide **9**, but an additional reaction is required to account for the formation of the carbonate **3**. An obvious route to **3** would involve an initial competing reaction to form the molozonide **2**, followed by its cleavage to **3** and the carbonyl oxide **4**, the reaction that was anticipated at the outset. If **3** were formed by this sequence, the lack of formation of **5**, the dimer of **4**, in inert solvents might be attributed to the transfer of an oxygen atom from **4** to **1**, a reaction of carbonyl oxides that has been proposed in other systems (12). This would result in an additional molecule of **3** and the epoxide **10**, which would then undergo rearrangement to **7**. However, this oxygen atom transfer would have to be especially efficient because no sign of any product in addition to **3**, **7**, and **8** could be detected even in experiments when the initial concentration of **1** was as low as 10^{-3} M and when **1** was added to excess ozone in CD_2Cl_2. In this inverse addition reaction **1** should never be present in any appreciable amount in solution, thus enhancing the possibility of dimerization of any **4** that might be formed. The amount of dioxetane **8** that was formed in the inverse addition experiments was always lower than in the other experiments and became insignificant when the addition of **1** was slow. The lack of formation of **8** under these conditions could be due to the rapid reaction between ozone and **1**, which greatly depletes the amount of **1** available to react with singlet oxygen, and a possible reaction between singlet oxygen and ozone.

Trapping a precursor of 7 in CD_3OD

Carbonyl oxides are efficiently scavenged by alcohols (2) but attempts to confirm the presence of **4** by conducting the ozonolysis reaction in solvent CD_3OD were unsuccessful.

Only **3**, **7**, and **8** are formed on ozonolysis of **1** in CD_3OD above −50°C and the relative intensities of the ^1H nmr signals of the CH_3O_2C and $C(OCH_3)_3$ groups of **7** are 1:3.0. This ratio decreases as the temperature at which the reaction is carried out is decreased from −50°C. At −95°C it is 1:2.1. Also three additional signals appear in the ^1H nmr spectra of the reaction mixtures when the reactions are conducted below −50°C and become more intense as the temperature of the reaction is lowered. One of these signals, 32 Hz downfield from that of the $C(OCH_3)_3$ group of **7** (−60°C), is due to CH_3OD. Its intensity corresponds to the missing intensity of the $C(OCH_3)_3$ group. The other signals are 17 and 41 Hz downfield from that of the $C(OCH_3)_3$ group and are of similar intensity. These signals remain upon warming the reaction mixture until about −10°C. At this temperature both signals disappear simultaneously.



SCHEME 3

Those due to CH_3OD and **7** increase in intensity. The signals of **3** and **8** do not change in intensity. These observations show that a precursor to **7** is trapped by CD_3OD in a reaction that becomes competitive with rearrangement of the precursor to **7** below −50°C. A mixture of the relatively stable hemiorthoester **16** and the partially deuterated ester **17** result, Scheme 3. The amount of **16** formed increases as the temperature of the ozonolysis reaction decreases, but is not reproducible at any given temperature. At −95°C the yield of **16** varies from 7 to 14%. Since **16** is formed in neutral solution it is much longer lived than previously observed molecules of this class, which were not prepared in neutral solution (13).

The scheme depicts the zwitterion **15** as arising from **10**, but there is no evidence that any **10** is ever formed in ozonolysis of **1**, and the zwitterion may arise in another way. Attempts to detect **10** by ^1H nmr were unsuccessful. Samples of **1** were injected rapidly into ozone in CD_2Cl_2 at −90°C in the probe of the nmr spectrometer. The ^1H nmr spectra taken within 2 s contained signals of **7** that increased little in intensity with time. If any **10** is formed in the reaction it must have a half-life of less than 2 s at −90°C.

No evidence for the formation of any adduct **6** could be detected by ^1H nmr even when initial concentrations of **1** were 10^{-3} M. Thus, if any **4** were formed and it could not be trapped by CD_3OD because of a more rapid oxygen transfer reaction with **1**, the rate constant for the latter reaction would have to be $\sim 10^5$ that for the reaction between **4** and 24 M CD_3OD. While **4** might be less reactive than other carbonyl oxides toward CD_3OD, such a great lack of reactivity appears to be unprecedented. It is thus difficult to avoid the conclusion that no **4** is ever formed during ozonolysis of **1** and, further, that the molozonide **2** is not formed either.

Evidence for a radical chain reaction

Additional difficulties arise when attempting to account for the ozonolysis of **1** in terms of the reactions in Scheme 2. According to this scheme the ester **7** is formed in two ways. One mole of **7** would be formed for each mole of **8** produced, and another mole of **7** would result for each 2 moles of carbonate formed. Thus, the amount of **7** formed would be equal to the sum of the amounts of **3** and **8**. The results of the initial experiments, carried out at −95 to −65°C and ~0.1 M **1** in inert solvents, were tantalizingly close to this. However, at different temperatures and concentrations of **1** the product distribution deviates significantly from this expectation.

CD_3OD	81	76	21	118[a]	14	73	77	>15	<77[b]
	33	33	6	25[a]	8	23	13	>5	<13[b]

[a]The sum of 4/3 the area of the signals of **17** and twice the area of the signal of a $(CH_3O)_2C$ group of **16**.

[b]The signals of **19** and **20** are superimposed. The area due to **20** is taken to be equal to the area due to acetone. The area due to **19** is taken to be the difference between those observed for **19** plus **20** and acetone. The areas given for **19** and **20** are minimum and maximum values, respectively, since some acetone is formed by a radical chain reaction that does not form **20**.

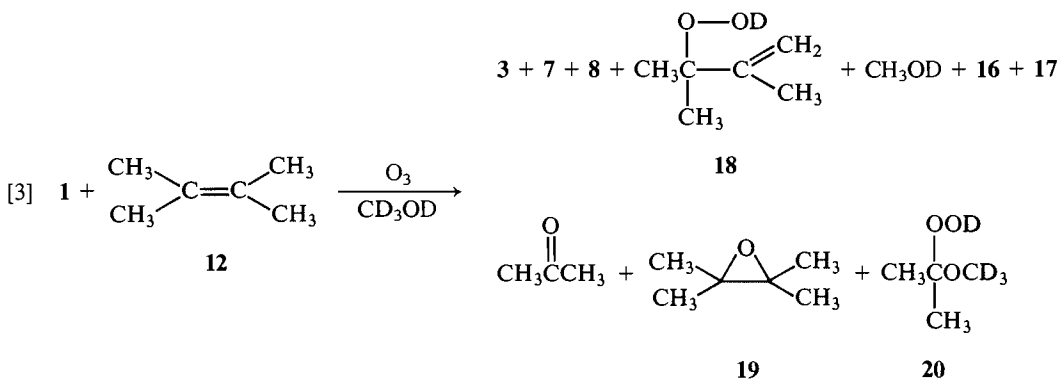
According to Scheme 2 each mole of ozone should consume 2 moles of **1**. The actual amount of **1** consumed varies with the initial concentration of **1** and ranges from 1.5 moles per mole of ozone at 0.1 M **1**, in agreement with the original work (3), to 2.5 in saturated solutions of **1** (~1 M) in CD_3COCD_3 at −78°C, Table 1, when a stream of ozone in oxygen is used. The consumption of **1** is lower with a stream of ozone in argon. These results point to a contribution from a radical chain oxidation reaction with both oxygen and ozone.

Further evidence for a radical chain contribution was obtained from ozonolysis of mixtures of **1** and **12**. The object of these experiments was to confirm the formation of singlet oxygen upon ozonolysis of **1** by observing the formation of 3-hydroperoxy-1-butene **18**, the product of reaction between **12** and singlet oxygen. Equimolar mixtures of **1** and **12** were treated with a limited amount of ozone in CD_3COCD_3 and CD_3OD at −95°C. The products of the reaction in CD_3OD are shown in eq. [3]. Based on the relative reactivities of **1** and **12** toward singlet oxygen, somewhat more **18** than **8** would be expected to be formed. Actually, more than twice as much of **18** as of **8** was formed in CD_3COCD_3 and between 3 and 5 times as much in CD_3OD, Table 2.

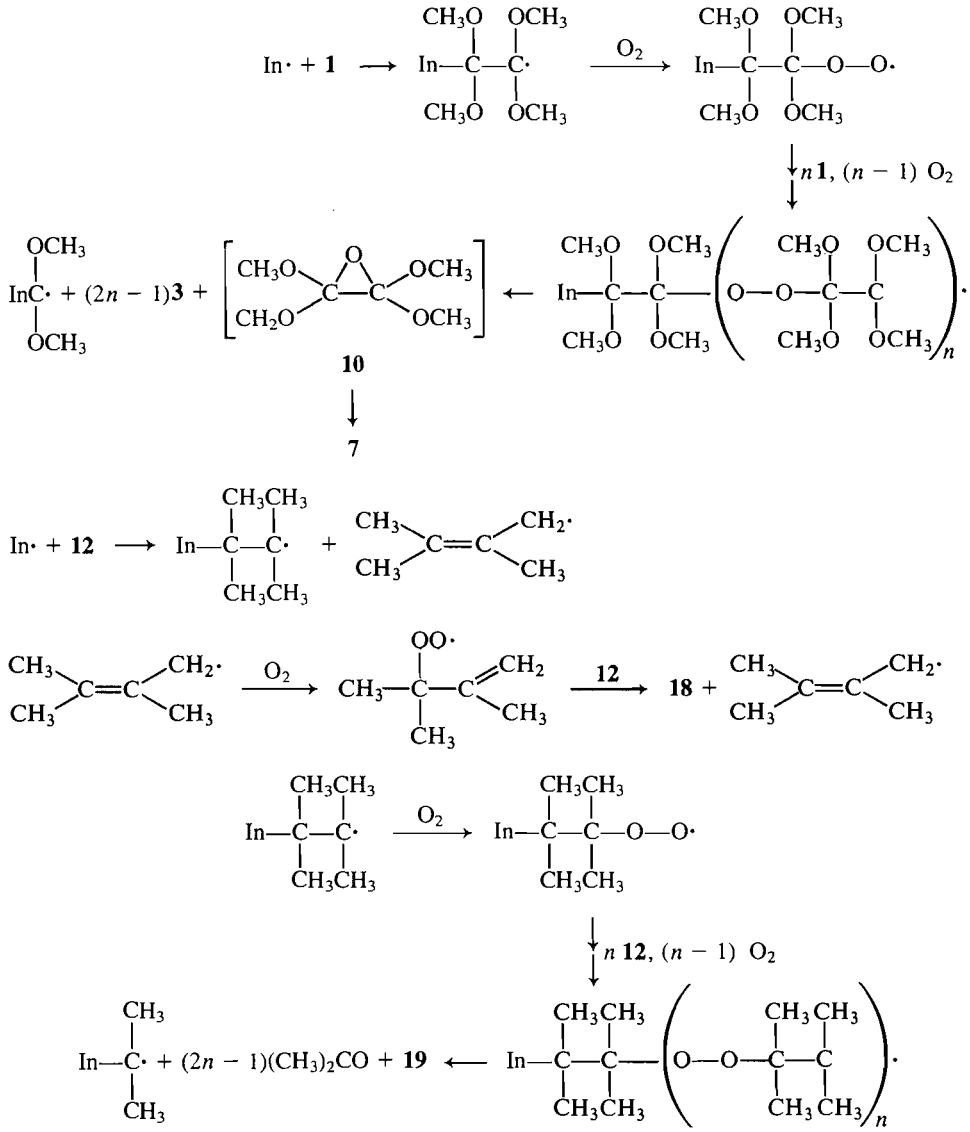
Another unexpected result from the ozonolysis of mixtures of **1** and **12** is the formation of significant amounts of 2,3-epoxy-2,3-dimethylbutane **19** in both solvents. In the reaction in CD_3COCD_3 this is evidenced by the presence of a sharp singlet 5 Hz upfield from the signal of the *gem*-dimethyl group of **18** in the ^{1}H nmr spectrum. Addition of some authentic **19** enhanced the intensity of this signal. The signals of the products formed from the carbonyl oxide of acetone (14) do not interfere with the signals of the other products. In CD_3OD the ^{1}H nmr signals of **19** and the acetone carbonyl oxide – CD_3OD adduct **20** coincide exactly and the amount of **19** formed was estimated from the difference in the areas of the signals due to acetone and to **19** and **20**. The areas of the signals due to acetone and **20** are exactly equal when **12** alone is ozonized in CD_3OD. Control experiments showed that neither **18** nor **19** was formed upon ozonolysis of **12** alone in either solvent.

The formation of the epoxide **19** together with excess allylic hydroperoxide **18** points to a contribution from a radical chain oxidation when **1** and **12** are ozonized together. Since **18** and **19** are not formed on ozonolysis of **12** alone, the presence of **1** is required to initiate the radical reaction. Thus, a radical chain reaction very likely contributes to product formation in ozonolysis of **1** alone. This would provide a route for the formation of carbonate **3**, Scheme 4, and account for the consumption of more than 2 moles of alkene per mole of ozone delivered to high initial concentrations of **1**. This radical reaction would also result in the formation of some ester **7**, which is always formed in higher yield than dioxetane **8** in ozonolysis of **1**. The nature of the initiator in Scheme 4 will be addressed later.

The free radical auto-oxidation of alkenes not having allylic hydrogen atoms results in epoxide formation and cleavage to carbonyl compounds (15). It has been shown that **3** and **7** do result from **1** (3). The auto-oxidation of neat **12** to low conversion at 50°C under 4 atmospheres of oxygen (1 atm = 101.3 kPa) results in the formation of allylic hydroperoxides, **19**, and acetone in a 8.6:3.1:2.1 ratio (16). The 3° allylic hydroperoxide **18** was found to predominate over the 1° isomer by a factor of 18 to 1. These oxidations of **1** and **12** were carried out under conditions much different from those used in the present ozonolysis studies. To assess the magnitude of the contribution of the radical chain oxidation to the ozonolysis



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 112.217.228.212 on 09/07/12
For personal use only.



SCHEME 4

reactions the product distributions were determined for the auto-oxidation reactions alone by photolysis of solutions of **1** and **12** in CD_3COCD_3 containing azoisobutyronitrile at −78°C while oxygen was passed through, Table 3. Surprisingly, a small amount (~12% of the total of **3**, **7**, and **8**) of dioxetane **8** was formed from **1**. It was identified by the position of its ^{1}H nmr signal and by the observation of luminescence upon addition of the reaction mixture to hot toluene containing 9,10-dibromo- and 9,10-bis(phenylethynyl)anthracene. It is not clear how **8** is formed. Perhaps some singlet oxygen is generated during the photolysis. Several other unidentified products were formed but **3** and **7** and **8** made up about 80% of the total product. Some minor unidentified products were formed during auto-oxidation of **12** but **18**, **19**, and acetone predominated greatly. These were formed in a ratio of about 18:4:1. This ratio is not greatly different from that at higher temperature and oxygen pressure. When mixtures of **1** and **12** were oxidized this product ratio was 5.5:3.5:1. The change is probably due to the participation of **1** in the chain. The ratio **3**:**7**:**8** was about 4:3:1 when **1** was oxidized either alone or in the presence of **12**. The ratios cited here are the ratios of the areas of the ^{1}H nmr signals of the products.

It should be possible to estimate the yield of ester **7** formed in the ozonolysis of **1** by applying the results of the auto-oxidation experiments. If all the carbonate **3** were produced by the radical chain oxidation and all the dioxetane **8** were formed by the reaction between **1** and singlet oxygen, which, in turn, results from the oxygenated epoxide **9**, then the yield of **7** should be equal to the yield of **8** plus about 2/3 the yield of **3**. The agreement between the experimentally found and calculated quantities of **7** is only fair. There is almost always more **7** found than calculated. Perhaps not all the oxygen formed from **9**, or a precursor of **9**, see below, is singlet oxygen. On the other hand the formation of relatively large amounts of allylic hydroperoxide **18** in the ozonolysis of mixtures of **1** and **12** is well accounted for by the inclusion of a contribution from a radical chain oxidation reaction. The yield of **18** should be equal to about the yield of **8** (from singlet oxygen) plus about twice the yield of epoxide **19**. For the one experiment in which a mixture of **1** and **12** were ozonized in CD_3COCD_3 the agreement

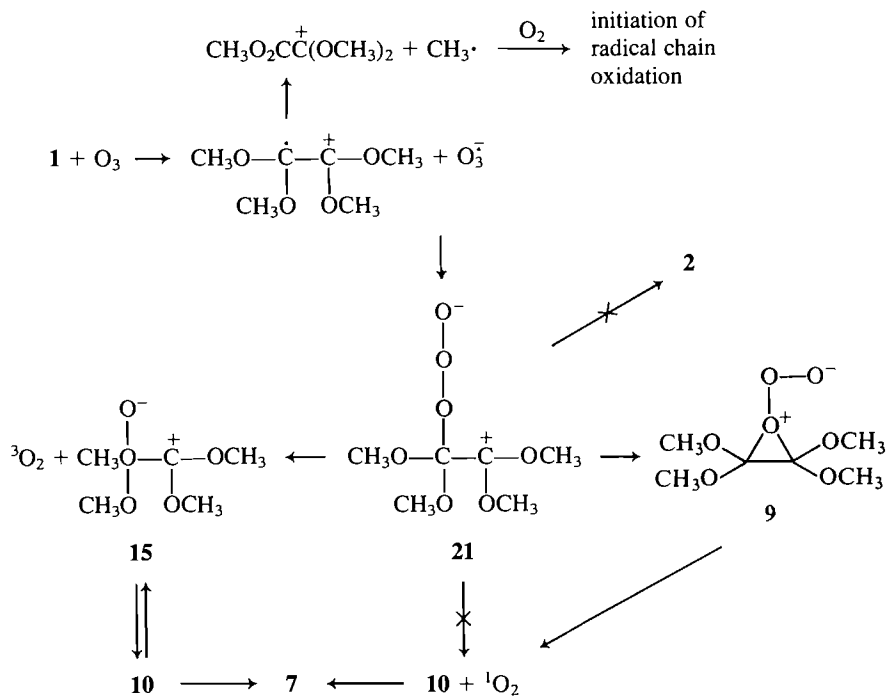


SCHEME 5

between the observed, 44, and calculated, 47, relative amounts of **18** formed is quite good.

A different attempt to verify a contribution from a radical chain oxidation in the ozonolysis of **1** was inconclusive. The product distribution was affected by the presence of the inhibitor 2,6-di-*tert*-butylphenol, but the effect was relatively small, less than might be expected for a long chain length reaction.

Initial electron transfer

All the products from the reaction between ozone and **1** can be accounted for without requiring the initial formation of any molozonide **2**. There appear to be no steric or energetic impediments to the formation of **2**: all the available evidence indicates that the reaction between ozone and **12** forms the molozonide; the methoxy group is considered to be less sterically demanding than the methyl group (17, 18); and the reaction to form **2** can be calculated, using group additivity values (18–20), to be exothermic by 71 kcal/mol. Thus, there must be another reaction that intervenes as the molecules of ozone and **1** approach each other. A likely candidate for this reaction, which can lead to a series of reactions to give all the observed products, is electron transfer to produce the ozone radical anion and the radical cation of **1**, Scheme 5. Formation of the radical ion pair provides a path for the initiation of the radical chain oxidation reaction. There is no evidence on the nature of the initiating species but a possible one might be methyl radical formed by fragmentation of the radical cation. Competing with this, or another, radical forming reaction would be collapse of the pair to give the zwitterion **21**. A rapid reaction of **21** should be cyclization to the molozonide **2**. This should be an irreversible reaction since the dioxetane **8**, which has much more ring strain, is stable in methanol to 10°C. Since there is no evidence that any **2** is ever formed, **21** must be produced in a conformation from which direct ring closure cannot occur and which allows another rapid reaction that forms singlet oxygen and ultimately the ester **7** to compete effectively. Several reactions could occur: cyclization to **9**, which would then undergo fragmentation to form singlet oxygen and the epoxide **10**; a concerted fragmentation and ring closure to form these products; and a fragmentation without ring closure to form

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 112.217.228.212 on 09/07/12
For personal use only.

triplet oxygen and the zwitterion **15**. This last reaction could account for the excess of ester **7** formed, which was noted above.

The paths to singlet oxygen suggested here are preferred to the fragmentation of **21** to **15** and singlet oxygen on energetic grounds. The reaction of eq. [4] has been calculated to be endothermic by 11 kcal/mol, while the corresponding, spin forbidden, reaction to form triplet oxygen is exothermic by 11 kcal/mol (19). The energetics of the fragmentation of **21** to **15** and oxygen should be similar. The fragmentation of **9** with the neutral **10** as the leaving group should be exothermic enough to produce singlet oxygen.

[4] $HOOO^- \longrightarrow HO^- + {}^1O_2$

[5] $HOOO^- \longrightarrow HO^- + {}^3O_2$

The reactions of Scheme 5 are identical to those suggested some time ago (21) to explain luminescence during ozonolysis of 10,10′-dimethyl-9,9′-biacridylidene. A radical chain oxidation with oxygen was also discussed.

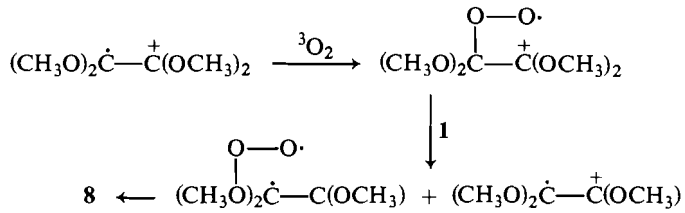
The electron transfer reaction would have to be quite exothermic to compete with molozonide formation. The enthalpy of the electron transfer reaction, eq. [6], depends on the ionization potential IP of **1**, the electron affinity EA of the

[6] $\Delta H^0_{et} = \mathrm{IP}(\mathbf{1}) - \mathrm{EA}(O_3) - \underset{\text{attraction}}{\text{Coulombic}} - \underset{\text{energy}}{\text{solvation}}$

$= \mathrm{IP}(\mathbf{1}) - 2.2\ \mathrm{eV} - 5.4\ \mathrm{eV} + 1\ \mathrm{eV}$

ozone, the coulombic attraction of the ion pair and the difference between the solvation energies of the neutral molecules and the ion pair. The values of the last two terms are taken to be equal to those used to calculate the energy of reaction between ozone and alkanes or alcohols (19) that leads initially to ion pairs. The IP of **1** is unknown but it should be considerably less than that of **12**, which is 8.45 eV (22). Replacement of a methyl group in propene or 2-methyl-2-butene or of an isobutyl group in 4-methyl-1-pentene by an alkoxy group results in a decrease of about 0.6 eV in the πIP (23). The effect of four such substitutions on **12** would probably not be additive, but it is unlikely that the πIP of **1** is greater than 7 eV. An IP of this magnitude would result in the ΔH^0 of the electron transfer reaction to be about −35 kcal/mol. This might be exothermic enough to compete with molozonide formation since electron transfer can occur at a greater separation of reactants than molozonide formation.

The radical chain reaction oxidation initiated by the electron transfer reaction here appears to be quite different from the cation radical catalyzed chain oxygenation of alkenes that has recently received intensive study (24). In particular, according to this type of reaction, dioxetane **8** would be formed as shown in Scheme 6. However, dimethylfuran would not be expected to interfere so effectively with dioxetane formation if **8** were formed in this way. Also, this reaction results in the formation of considerable acetone and pinacolone with **12** as the substrate. In the present study, ozonolysis of mixtures of **1** and **12** gives acetone as a minor product and no evidence for the presence of any pinacolone was found. Oxidation of **1** alone with oxygen at −78°C in CD_2Cl_2 catalyzed with a trace of $(4\text{-}BrC_6H_4)_3\dot{N}^+$ resulted mainly in carbonate. Only a little **7** and a trace of dioxetane **8** were formed. Significant amounts of several other,



SCHEME 6

unidentified, compounds were formed, presumably products of an acid-catalyzed reaction of **1**.

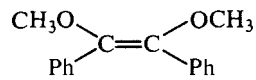
A reaction between ozone and **1** to form the zwitterion **21** directly without initial electron transfer seems unlikely since the reaction between the alkenes **22**, **23**, and **24** and ozone, which could form zwitterions where the positive charge is similarly stabilized as in **21**, results in exclusive molozonide formation as judged from product distribution. Carbonate **3** and aldehyde or ketone carbonyl oxide products are formed in quantitative yield.[4] There is no evidence for formation of any epoxide or dioxetane from these materials.

$CH_2{=}C(OCH_3)_2$ **22** $CH_3CH{=}C(OCH_3)_2$ **23** $(CH_3)_2C{=}C(OCH_3)_2$ **24**

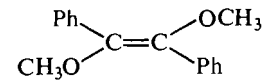
Electron transfer in other ozonolyses

Ozonolysis of the *Z*-dimethoxystilbene **25** produces about 20% of dioxetane and about 40% of an unidentified product, which may be an epoxide or a rearrangement product analogous to **7**, in addition to methyl benzoate. Also, 1.3 moles of **25** are consumed by 1 mole of ozone.[4] These results suggest that a process similar to that in ozonolysis of **1** is occurring. No dioxetane is formed on ozonolysis of the *E*-isomer **26**, one molecule of **26** is consumed by 1 mole of ozone and, in CD_3OD solvent, methyl benzoate and the CD_3OD adduct of the carbonyl oxide of methyl benzoate are the only products formed in equal amount.[4] Clearly this reaction proceeds via the molozonide.

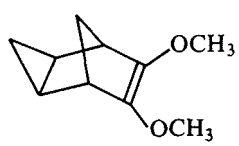
Ozonolysis of other electron-rich alkenes may also proceed according to Scheme 5. The ozonolysis of 10,10′-dimethyl-9,9′-biacrildylidene (21) has already been noted. Recently, direct evidence of dioxetane formation in an acenaphthylene derivative oxygenated at the 1 and 2 positions has been obtained (25). Ozonolysis of the dimethoxynorbornene derivative **27** forms ~50% of **28** (26), a product analogous to **7**.



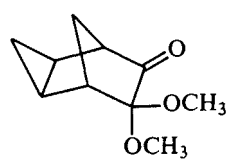
25



26



27



28

A variety of hindered alkenes containing two or three alkyl groups on the double bond give epoxides, sometimes in quite high yield, upon ozonolysis (27). The πIP of such materials

should be 8.8–9.0 eV and electron transfer with ozone would be endothermic. In these reactions oxygenated epoxides corresponding to **9** were proposed to be formed directly and evidence for the formation of singlet oxygen was reported.

Experimental

Tetramethoxyethene 1

The procedure using dimethoxyethane as solvent (1) resulted in material that could be obtained in a high state of purity, >99%, by recrystallization from isopentane followed by distillation. The procedure using diglyme as solvent (28) resulted in material that contained 4–5% of impurities despite repeated attempts at purification. These impurities gave ^{1}H nmr signals in the region where the ozonolysis products of **1** absorbed.

Ozonolysis of 1

The ozonolysis reactions were carried out in nmr tubes. The product distributions were determined by ^{1}H nmr on a Bruker WH 200 spectrometer. Initially, the effluent stream from an ozonizer was divided and one portion of the stream passed through the solutions of **1**. The ^{1}H nmr chemical shifts of the compounds formed in the various reactions are shown in Table 4. Most reactions were carried out by taking up the ozone–oxygen mixture from the effluent stream of the ozonizer into a 50- to 200-mL gas syringe and then delivering the gas into the solution through a 1-mm Teflon tube that reached to the bottom of the nmr tube. The plunger fell of its own weight at a rate that delivered the required amount of gas over about a 5-min period. The ozone–oxygen mixture could be stored in the syringe for several hours at room temperature with no loss in ozone content. The nmr tubes were freed of acid by soaking in ammonia solution, draining, and drying at 120°C. Syringes used to deliver solvent were similarly treated except that they were dried with an air stream. Halogenated solvents were filtered slowly through a plug of powdered potassium carbonate. Even with these precautions by-products were formed in numerous runs that interfered with the ^{1}H nmr analysis. These were probably the result of acid-catalyzed reactions of **1** because they were formed quickly during the ozonolyses and did not build up in concentration as the ozonolyses progressed.

The amount of **1** consumed by ozone was measured as follows. Known volumes of the ozone–oxygen mixtures were delivered into excess 2,3-dimethyl-2-butene **12** in CD_3OD at −78°C. The reaction mixtures were analyzed by ^{1}H nmr, measuring the areas of the signals due to remaining **12**, acetone, and **20**. Solutions containing known amounts of **1** were then treated with the calibrated ozone–oxygen mixtures.

Ozone in argon mixtures were made by taking up ozone that had been adsorbed on silica gel with a stream of argon into a syringe. The ozone–argon mixture was passed back and forth between two syringes about 10 times to ensure uniform mixing.

Identification of tetramethoxy-1,2-dioxetane 8

A solution of 0.26 g **1** in 5 mL CD_2Cl_2 was ozonized at −90°C until all of **1** was consumed. The resulting solution was shaken with aqueous sodium hydroxide at 0°C until all **3** and **7** had been removed and only the signal of **8** was present in the ^{1}H nmr spectrum at δ 3.50. The ^{13}C nmr spectrum had signals at δ 51.37 and 118.64. Iodometric titration (29) showed 98% of the active oxygen content expected for **8**.

Authentic **8** was prepared by photooxygenation (4) of **1** in CD_3OD or in CD_2Cl_2. The ^{1}H and ^{13}C nmr signals of **8** prepared in this way in CD_2Cl_2 were identical to those of the sample prepared by ozonolysis; ^{1}H nmr (CD_2Cl_2): 3.50; ^{13}C nmr (CD_2Cl_2): 51.51, 118.66.

Competitive photooxygenation of 1 and 12

Mixtures of **1** and **12**, each 0.1 M, in CD_3COCD_3 or CD_3OD that contained some rose bengal adsorbed on silica gel were irradiated with a 200-W incandescent bulb while kept in a glass Dewar flask at −78°C. A slow stream of oxygen was bubbled through the mixtures. The resulting solutions were analyzed by ^{1}H nmr and the relative reactivities toward singlet oxygen calculated as described (30).

Auto-oxidation of 1 and 12

Solutions of **1** and **12** and mixtures of **1** and **12** in CD_3COCD_3 that contained 3.0×10^{-2} M azoisobutyronitrile, in nmr tubes kept in a Dry Ice – acetone bath, were removed and irradiated for 2-s intervals with light from a 200-W Hanovia mercury lamp. Intermittent irradiation followed by cooling was continued until several per cent of the alkenes were oxidized. The product distributions were determined by ^{1}H nmr. The signal for CH_3COCH_3 is 2 Hz downfield from the downfield peak of CHD_2COCD_3. Its area could be determined quite accurately.

Search for 18 and 19 in ozonolysis of 12

Solutions 1 M in **12** in CD_3OD and CD_3COCD_3 were ozonized at −78°C so that about 30% of **12** was consumed. The solutions were examined by ^{1}H nmr. In particular, no peaks due to the *gem*-dimethyl group of **18** could be detected in either solvent, no peak due to **19** could be detected in the CD_3COCD_3 solution, and the peaks due to acetone and **20** had exactly the same integral in CD_3OD.

Molar volumes and refractivities of highly concentrated solutions of ammonium and potassium thiocyanates in water and dimethylsulphoxide

PETR PACÁK AND ZDENĚK KODEJŠ

Institute of Inorganic Chemistry, Czechoslovak Academy of Sciences, Majakovského 24, 160 00 Prague 6, Czechoslovakia

Received December 11, 1987

PETR PACÁK and ZDENĚK KODEJŠ. Can. J. Chem. **66**, 2244 (1988).

Densities and refractive indices of highly concentrated solutions of ammonium and potassium thiocyanates in water and dimethylsulphoxide have been measured at 333.2 K in the composition range from $x_s = 0.01$ up to saturated solutions. Molar volumes and apparent molar volumes have been calculated from density measurements and their concentration dependences are discussed. All the systems are volumetrically non-ideal and exhibit negative deviations from additivity. The molar refractivities were calculated from the refractive indices using the Lorentz–Lorenz equation. The refractivity values of individual ions were estimated in infinitely dilute solutions and were used for discussion of ion–solvent interactions.

PETR PACÁK et ZDENĚK KODEJŠ. Can. J. Chem. **66**, 2244 (1988).

Opérant à 333,2 K et à des composition en x_s allant de 0,01 à des solutions saturées, on a mesuré les densités et les indices de réfraction de solutions très concentrées de thiocyanates d'ammonium et de potassium, dans l'eau et le diméthylsulfoxyde. A partir des mesures de densité, on a calculé les volumes molaires ainsi que les volumes molaires apparents et on discute de leurs dépendances sur la concentration. D'un point de vue volumétrique, aucun système n'est idéal et chacun présente des déviations négatives par rapport à l'additivité. Utilisant l'équation de Lorentz–Lorenz, on a calculé les réfractivités molaires à partir des indices de réfraction. On a calculé les valeurs de réfractivité des ions individuels à dilution infinie et on les a utilisées pour discuter des interactions ion–solvant.

[Traduit par la revue]

Introduction

One of the reasons for studying the volumetric properties of electrolyte solutions is to formulate and to test models and equations useful both for experimental data fitting and for extrapolation of the volumetric properties into experimentally inaccessible concentration regions.

In our previous studies (1–4), water was used as a solvent and, of the ionic salts, mainly nitrates have been studied because of their high solubility. The relation between the deviation from ideal volumetric behaviour of binary salt + molecular solvent systems and parameters characterizing solute–solvent interactions were studied and an equation was derived for the dependence of the molar volume on composition of the solution from the concept of the apparent molar volume of water (3, 4). Experimental data on systems with dimethylsulphoxide (DMSO) as a solvent (5) were used to test the general validity of our model. Alternative approaches to the problem have been described by several authors (6–10).

The refractive index and molar refractivity yield valuable information on the electronic polarizability of individual ions in solutions. The molar refractivity corresponds to the actual volume of the ions (molecules) in one mole of the substance and thus it can be compared with the volumetric properties calculated from density measurements. The dependence of the refractivity on the salt concentration was investigated in the previous paper (11) for solutions of some univalent chlorides and nitrates in water and dimethylsulphoxide. The results can serve as a basis for discussions on the interactions of other ions with the two solvents.

In the present paper, the results of experimental study of volumetric and refractometric properties of highly concentrated solutions of thiocyanates in water and DMSO are presented to form a basis for consideration of ion–ion and ion–solvent interactions in dependence on the composition of electrolyte solutions. Dimethylsulphoxide was used as an alternative solvent for its capability to dissolve many inorganic salts. It is an aprotic solvent with a boiling point of 462 K. The solvation ability of DMSO and water can be compared on the basis of the concept of the donor number, D_N. The scale proposed by Gutmann (12) gives values of 18 and 30 for water and DMSO, respectively, indicating much stronger interaction of DMSO with electrolytes. The strength of ion–solvent interactions depends also on the solvent permanent dipole moment. The values for water and DMSO are 1.83 D and 3.96 D, respectively. Thiocyanates were chosen for their high solubility in both solvents.

Experimental

Reagent-grade NH_4SCN and KSCN ("pro analysi", Merck) were vacuum desiccated and stored over P_2O_5. Reagent-grade dimethylsulphoxide ("pro analysi", Merck) containing less than 0.03 mass% of water was used as received. Mixtures for measurements were prepared by weighing.

The density of the solutions was measured at 333.2 K using a DMA 40 digital vibration densimeter (Paar). The accuracy of the measured density values was estimated to be better than $\pm 4 \times 10^{-4}$ g cm^{-3} from analysis of the calibration method and the precision of temperature control.

The density of molten NH_4SCN was measured by the pycnometric method at 428 K, the pycnometer (approximately 25 cm^3) was calibrated at 298.2 K with water and the thermal expansion coefficient of glass was used for calculation of the volume of the pycnometer at 428 K. The uncertainty in the density value of molten NH_4SCN does not exceed $\pm 4 \times 10^{-3}$ g cm^{-3}.

The refractive index was determined with a Pulfrich refractometer (type PR-2, Zeis, Jena) at a wavelength of $\lambda = 587.6$ nm (helium D-line) with an accuracy of $\pm 5 \times 10^{-5}$ units. The molar refractivity values were calculated from the refractive index with an accuracy of ± 0.02 cm^3 mol^{-1}.

Results and discussion

Molar volumes

The measured values of the density, d, of the solutions of NH_4SCN and KSCN in H_2O and DMSO at different salt concentrations, x_s, at 333.2 K are reported in Table 1 together with the refractive index values, n.

Molar volumes, V_m, i.e. volume of the solution containing 1 mol of the components (salt + solvent), were calculated from the density data by means of the equation

$$[1] \quad V_m = \frac{x_s M_s + (1 - x_s)M}{d}$$

where x_s is the salt mole fraction, M_s and M are the molecular weights of the salt and solvent, respectively, and d is the density of the solution.

Theoretically an electrolyte solution can be prepared by isothermal mixing of the solvent and liquid (molten) salt. In our case, i.e. at 333.2 K, the liquid salt would be in a hypothetical undercooled state. There is some uncertainty in the value of the molar volume of both salts at this temperature as it was obtained by extrapolation from the literature (13) and our experimental data. We found the density of the melt of NH_4SCN as d = 1.175 g cm^{-3} at 428 K; the uncertainty in this value is given mainly by the slow decomposition of the melt at the temperature of measurement.

For extrapolation of the density of KSCN from the experimental temperature range (473–537 K) to 333.2 K, the value of thermal coefficient for the density $b = 5 \times 10^{-4}$ g cm^{-3} K^{-1} was calculated from the literature data (13). The value of b for NH_4SCN melt cannot be determined experimentally as the melt decomposes above its melting point. The density of the solutions $NH_4SCN + H_2O$ and NH_4SCN + DMSO was measured in the temperature range from 298 to 333 K and the value of b were calculated for individual solutions. The value of b for NH_4SCN melt was estimated from the composition dependence of the thermal coefficients for the density, b, of the $NH_4SCN + H_2O$ solutions by extrapolation to the molten salt. The value of $b = 5 \times 10^{-4}$ g cm^{-3} K^{-1} was used for molten NH_4SCN and the values 58.9 and 62.5 cm^3 mol^{-1} for the molar volume of KSCN and NH_4SCN, respectively, were calculated by extrapolation to a temperature of 333.2 K. The uncertainty in the values of the molar volumes of the pure salts is estimated to be about ±0.4 cm^3 mol^{-1}. The value of the molar volume of pure KSCN is in a reasonable agreement with the value of 57.5 cm^3 mol^{-1} reported in the literature (14). The value has been obtained by the extrapolation of molar volume isotherm of $Ca(NO_3)_2.4H_2O$ + KSCN melt to the molten KSCN at 323 K.

The calculated values of the molar volumes are plotted against the salt mole fraction in Fig. 1. It is evident that all the systems are volumetrically non-ideal; the deviations from ideality, i.e. from purely additive behaviour, are negative and are more pronounced when DMSO is used as a solvent (Fig. 2). This conclusion is in agreement with earlier results (5) and the difference in the solvent permanent dipole moment can be invoked to explain this fact.

A relation between the type of anion and the magnitude of the deviations from ideality can be deduced from their numerical values at a fixed salt concentration, e.g. at x_s = 0.2. For NH_4NO_3, we found the deviations to be −0.1 and −1.0 cm^3 mol^{-1} at 333.2 K in H_2O and DMSO, respectively (4, 5), while for NH_4SCN the deviations are −0.12 and −0.9 cm^3 mol^{-1}, respectively. At this salt concentration, the effect of the SCN^- anion on the molar volume of the solution is similar to that of the NO_3^- anion.

An interesting insight into the problem of volumetric properties can be obtained from the concept of the apparent molar volume of the salt, Φ. This value is defined by the relation

$$[2] \quad V_m = x_s\Phi + (1 - x_s)V_1^0$$

where V_1^0 is the molar volume of the pure solvent. Even if the value of Φ is evaluated mainly at infinite dilution, where the partial molar volume and the apparent molar volume of the electrolyte are equal, it can also be used to discuss ion–solvent interactions in concentrated solutions.

The dependence of Φ on the composition of the solution for

the studied systems is depicted in Fig. 3. The apparent molar volume concept is based on the value of the molar volume of the solvent, V_1^0, which is experimentally accessible, in contrast to the value of the molar volume of the molten salt, V_2^0, which is mostly a hypothetical value. In this concept, all the deviations from additivity between V_1^0 and V_2^0 are included in the value of the apparent molar volume of the salt. It may seem natural to discuss the deviations in terms of changes in the molar volume of the salt, but this approach is probably acceptable only in dilute solutions of electrolytes where the solvent molecules form a "continuum", but even then it is preferable to speak about the "mode of accommodation" of the ions in the solvent structure. Different modes of "ion accommodation" can be employed to explain, e.g. a difference between the values of Φ of a salt in H_2O and DMSO. Dimethylsulphoxide molecule is larger than water and thus there is also a larger intermolecular space in the structure of DMSO and only small expansion with respect to the original solvent structure is necessary to form "holes" for accommodation of ions. Utilization of the free volume in the solvent structure is reflected in lower value of Φ for both salts in DMSO than in water (Fig. 3). The effective molar volume of solvent molecules that are in contact with ions is lower than V_1^0. This is another, even if not so significant, contribution to the negative deviation from additivity between V_1^0 and V_2^0.

In salt-rich systems the above explanation of deviations from additivity is not applicable. In this range all solvent molecules are distinctly affected by ions and are accommodated in a quasi-lattice structure of ions. The difference between the effective molar volume of solvent molecules and V_1^0 is responsible for the deviations from additivity beween V_1^0 and V_2^0. A contribution of interionic space can explain the differences in the effective molar volume of solvent in different salt + solvent systems.

The shape of the experimental dependences in Fig. 3 is completely in agreement with the above assumptions. The difference between the straight line (ideal behaviour) and the experimental curves is smaller for aqueous than for

DMSO solutions, indicating higher deformability of the DMSO molecules.

There is another aspect of coordinate system used in Fig. 3. It can be used for the extrapolation of Φ to $x_s = 1$ and to estimate a value for the molar volume of the pure molten salt, V_2^0, at this temperature. The precision of this estimation is influenced by rather long extrapolation to the molten salt end and there is no simple model for mathematical form (shape) of the isotherm Φ vs. x_s. It means that the method can be used only as a rough test of the value obtained from the density data of molten salt.

Molar refractivity

Aqueous solutions

The molar refractivity of the solution, defined by the Lorentz–Lorenz equation

$$[3] \quad [R]_{soln} = \frac{n^2 - 1}{n^2 + 2} V_m$$

(V_m is the molar volume of the solution, n is the refractive index for a given wavelength) reflects the changes in the properties of the ions due to polarization or deformation of their electron shells under the influence of the electric field of the neighbouring ions. It is assumed that the refractivity of a system can be calculated in a strictly additive manner from the individual refractivities of the components. Every deviation from additivity is regarded as an indication of interactions between the components.

According to Fajans (15), the refractivity of anions is decreased by neighbouring cations. The stronger the electric field of a cation and, thus, the stronger the interactions between the cation and an anion, the more the refractivity of the anion is lowered. On the other hand, anions should increase the refractivity of cations. The joining of ions into molecules or crystals is then accompanied by a net decrease in the refractivity, $\Delta[R]$, when the effect of the cation on the anion outweighs the effect of the anion on the cation.

As the solution becomes more concentrated, the ions displace the solvent molecules and unite to form complex ions or ion pairs. These effects appear as a change in the refractivity of the ions. The refractivity values of the individual ions in the free gaseous state $[R]_g$, calculated by Pauling (16) and Fajans (17), can be used as a measure of their respective deformabilities. The change in the refractivity of a salt accompanying transition from the gaseous state to an infinitely dilute solution, $\Delta[R^0]$, is then expressed as

$$[4] \quad [R^0_{salt}] = [R_{cat}]_g + [R_{an}]_g + \Delta[R^0]$$

We subtracted the refractivity of the pure solvent (taken from ref. 18) from the refractivity of the solution, $[R]_{soln}$, containing 1 mole of the salt. This procedure is analogous to the calculation of the apparent molar volume of the salt. The molar refractivity values of the salt, $[R_x]$, thus obtained at various concentrations, were plotted as a function of the salt concentration (Fig. 4) and the refractivity of the salt in infinitely dilute solution, $[R^0]$, was obtained by extrapolation to the concentration, $x_s = 0$ (Table 2). The ionic refractions in infinitely dilute solutions were found to be additive both in aqueous (19) and in DMSO solutions (11). The refractivity values, $[R^0]_{H_2O}$, of NH_4^+ and K^+ cations in infinitely dilute aqueous solutions were estimated by Fajans (19) (Table 3), so that refractivity of the SCN^- anion can be estimated: $[R^0_{SCN^-}] = [R^0_{salt}] - [R^0_{cat}]$. The values of 17.84 and 17.89 calculated from KSCN and NH_4SCN, respectively, are in good agreement and the average value of $[R^0_{SCN^-}] = 17.86$ was adopted and is given in Table 3.

Cations and anions not only influence one another, but also affect the solvent molecules surrounding them in the solution. It was estimated earlier that the K^+ cation has no polarizing effect on water (19) and its refractivity value in the gaseous state is the same as in infinitely dilute solution, whereas the NH_4^+ cation

Cl^-	8.61[a]	−0.45

[a]Values taken from ref. 11.

lowers the refractivity of water by 0.3 (11). The effect of the SCN^- anion on water cannot be estimated using eq. [4] because the refractivity value of SCN^- anion in the free gaseous state is not known. We can, however, compare the refractivity change accompanying dissolution of the crystalline salts in water: $[R_{salt}]_{c\text{-}H_2O} = [R^0_{salt}]_{H_2O} - [R_{salt}]_c$ (Table 2). The value for NH_4SCN is by 0.33 lower than that for KSCN. Since the NH_4^+ cation lowers the refractivity of water by 0.33 (11), it seems that the SCN^- anion has no polarizing effect upon water and thus $[R^0_{SCN^-}]_{H_2O} = [R_{SCN^-}]_g$. This result is reasonable considering the high refractivity value of SCN^-.

With increasing salt concentration, water molecules are replaced by cations and anions which approach more closely to each other. Cations have a stronger polarizing effect on the SCN^- anions than on water as follows from comparison of the refractivity values of the salts in infinitely dilute aqueous solutions with those for crystals (Table 2). Thus, a decrease in the salt refractivity with increasing salt concentration was observed (Fig. 4). The refractivity changes linearly with changing concentration and extrapolation to the concentration of $x_s = 1$, i.e. the pure salt, yields a value which is the same as that given in Table 2 for the refractivity of the crystal. This behaviour is considered to be additive and no formation of complexes or ion pairs is expected.

DMSO solutions

The refractivities of the salts in infinitely dilute solutions are lower than those for aqueous solutions. The DMSO molecule is more polarizable than the water molecule (18) and is influenced more strongly by cations and anions. The concentration dependence of the salt refractivities is depicted in Fig. 4 and the values extrapolated to infinite dilution ($x_s = 0$), $[R^0_{salt}]_{DMSO}$, are listed in Table 2. The refractivities of the SCN^- anion and K^+ cation in infinitely dilute DMSO solution were evaluated from these values and the known value of $[R^0_{NH_4^+}]_{DMSO} = 4.38$ (11) ($[R^0_{SCN^-}] = [R^0_{salt}] - [R^0_{NH_4^+}]$, etc.) and are given in Table 4. The effect of the ions on the DMSO molecule, $\Delta[R^0]_{g\text{-}DMSO}$, can be estimated by comparing the $[R^0]_{DMSO}$ values of ions with their refractivities in the gaseous state, $[R]_g$ (see Table 4). The K^+ cation decreases the refractivity of DMSO by 0.36, the effect being stronger than that of the NH_4^+ cation. The SCN^- anion lowers the refractivity of DMSO by 0.86, which is more than for nitrate and chloride anions (11).

As the DMSO solutions become more concentrated, the salt refractivity increases and positive deviations from the additivity between $[R^0]$ and $[R]_c$ were observed. This behaviour is explained by the formation of complex solvates of the cations with the DMSO. The cations are surrounded by DMSO molecules, preventing approach by anions. Consequently, interactions between the ions are limited. The actual content of DMSO decreases with increasing salt concentration, so that the relative effect of the cation on DMSO also decreases. A positive term is thus introduced into the concentration dependence of the salt refractivity. The SCN^- anions have a similar effect as they also influence the DMSO molecule. The positive deviations from additivity are higher for K^+ than for NH_4^+ salt because of the stronger effect of the K^+ cation on DMSO which introduces a higher positive component into the refractivity change (Fig. 4). It is assumed that, if a higher concentration of the salt in the solution can be attained, the refractivity would decrease toward the refractivity value for the crystal.

Conclusions

Solutions of NH_4SCN and KSCN in water and dimethylsulphoxide are volumetrically non-ideal. Deviations from additivity are negative in both solvents.

The strength of the solute–solvent interactions that depends among others on the value of the solvent dipole moment and easier deformability of the DMSO molecules can be used to explain the more distinct deviations from volumetric ideality in solutions of both salts in DMSO than in water and the positive deviations from additivity in the concentration dependence of the salt refractivity.

The effect of K^+ cations on the DMSO molecule was found to be stronger than the effect of NH_4^+, both from refractometric and volumetric measurements. The effect of the SCN^- anion on DMSO is stronger than the effect of NO_3^- or Cl^-, but SCN^- has no effect on the water molecules. A similar conclusion was drawn on the basis of the solvent activity data in solutions of KSCN and KNO_3 in DMSO (20). The stronger interaction of the DMSO molecule with SCN^- than with NO_3^- is not unexpected for the stronger solvation of voluminous and polarizable anions in dipolar aprotic solvents.

Received October 26, 1987

MARIOLA SZPAKOWSKA and OTTÓ B.NAGY. Can. J. Chem. **66**, 2250 (1988).

A simple second order intermolecular perturbation theory is proposed in the Fukui approximation to account for the electronic spectral behavior of electron acceptor solutes dissolved in pure *n*-donor solvents. This double perturbation theory considers explicitly both the solvating and complexing effects of the solvent. Using the electronic spectral data of mono- and binuclear copper acetate and chloride complexes obtained in pure pyridine derivatives it is shown that the predicted shifts brought about by increasing *n*-donor ability of solvent are fully corroborated by experiment. The sensitivity of mononuclear copper complexes to steric effects is also confirmed and it is shown that binuclear ones are not sensitive to this effect. New ionization potential values have also been determined using a simple interpolation–standardization procedure.

MARIOLA SZPAKOWSKA et OTTÓ B.NAGY. Can. J. Chem. **66**, 2250 (1988).

Une théorie simple de perturbation intermoléculaire d'ordre deux est proposée dans l'approximation de Fukui afin d'interpréter le comportement spectroscopique de solutés accepteurs d'électrons dissouts dans des solvants purs *n*-donneurs. Cette théorie de double perturbation considère explicitement les effets solvatants et complexants du solvant. En utilisant les données de la spectroscopie électronique de complexes d'acétate et de chlorure de cuivre mono- et binucléaires obtenues dans des dérivés purs de pyridine, il est démontré que les déplacements prédits, provoqués par le pourvoir *n*-donneur croissant du solvant, sont complètement corroborés par l'expérience. La sensibilité de complexes de cuivre mononucléaires aux effets stériques est aussi confirmée et il est démontré que les complexes binucléaires ne sont pas sensibles à ces effets. De nouvelles valeurs de potentiel d'ionisation ont été aussi déterminées en utilisant une simple procédure d'interpolation et de standardisation.

Introduction

In analyzing medium effects on physico-chemical properties of molecules it seems useful to distinguish between general (caused by polarity and polarizability) and specific (*n*-donor, π-donor, and hydrogen bond forming ability) solvent effects (1, 2). When the latter are present they usually dominate the overall medium effect (1–5). An immediate consequence of this situation is that aprotic solvents cannot be treated the same way but rather should be divided into several solvent classes (1, 2). The discovery of these classes (1, 2) lead to a better understanding of medium effects and allowed the interpretation of the seemingly anomalous behavior of *n*-donor solvents (1, 6).

A first successful explanation could be found in a particular solvation shell structure stemming from the presence of free electron pairs and the asymmetric charge distribution in solvent molecules (1). Another explanation was obtained from intermolecular perturbation theory (7). It has been shown that a simple intermolecular second order perturbation theory developed in the Fukui molecular orbitals (FMO) approximation (8, 9) can account successfully for the specific solvent effects observed for 2 + 4 cycloaddition reactions. The same theoretical method has also been used to study the behavior of *n*-donor solvents (7). It was predicted that in the case of π–π donor–acceptor molecular complexes the first electronic transition energy should increase with increasing *n*-donor ability of solvents (7), in full agreement with the previous explanation (1) and experimental observations (1, 2, 7).

An important limiting case is obtained when the electron acceptor molecule is dissolved in pure *n*-donor solvent. In this case the solvent is not only solvating but also complexing the acceptor solute, i.e. it takes over the role played by the electron donor complexing partner. In the present paper this specific complexing–solvating property of *n*-donor solvents will be studied using mono- and binuclear copper complexes (10, 11) as electron acceptor solutes, and substituted pyridine derivatives as *n*-donor solvents. Our choice was guided by the fact that these copper complexes proved to be very useful in realizing an extreme situation of microscopic partitioning according to the competitive preferential solvation (COPS) theory (3, 12), i.e. a full coordination of the competing solvent molecules. When copper acetate $[Cu(CH_3CO_2)_2H_2O]$ is dissolved in pure pyridine derivatives (L) a new complex is formed, $[Cu(CH_3CO_2)_2L_2]$, in which two molecules of the solvation shell are singled out by coordination (10). This mononuclear complex may also be in equilibrium with its binuclear form (10).

On the other hand, copper chloride may complex three or four pyridine molecules ($[Cu(Cl)_2L_n]$ with $n = 3, 4$).

Theoretical part

According to the previously proposed perturbation theory (7, 9) the *n*-donor solvent molecule (S) interacts with the lowest unoccupied orbital ($|l_A\rangle$, energy E_{lu}^{A}) of the electron acceptor solute (A) mainly through its highest occupied molecular orbital ($|h_S\rangle$, energy E_{ho}^{S}) (8). This solvating interaction leads to a new species AS, having the following Fukui energy levels:

$$[1] \quad E_{lu}^{AS} = E_{lu}^{A} + \frac{\langle l_A|H^S|h_S\rangle^2}{E_{lu}^{A} - E_{ho}^{S}}$$

[1]To whom all correspondence should be addressed.

Printed in Canada / Imprimé au Canada

and

$$[2] \quad E_{ho}^{AS} = E_{ho}^{S} + \frac{\langle h_S|H^S|l_A\rangle^2}{E_{ho}^{S} - E_{lu}^{A}}$$

as can be shown easily by standard perturbation theory (H^S represents the interaction Hamiltonian). In particular, second order calculation is needed here since the perturbation is intermolecular. The lowest unoccupied orbital of AS has the form

$$[3] \quad |l_{AS}\rangle = \left[1 + \left(\frac{\langle l_A|H^S|h_S\rangle}{E_{lu}^{A} - E_{ho}^{S}}\right)^2\right]^{-1/2}\left(|l_A\rangle + \frac{\langle l_A|H^S|h_S\rangle}{E_{lu}^{A} - E_{ho}^{S}}|h_S\rangle\right)$$

The solvent is also complexing the solute. This complexing interaction can be taken into account by admitting that the lowest unoccupied orbital of AS ($|l_{AS}\rangle$) in turn interacts with the highest occupied orbital of the complexing solvent molecule. Again, the Fukui energy levels of the resulting solvated-complexed solute (SAS) will be

$$[4] \quad E_{lu}^{SAS} = E_{lu}^{AS} + \frac{\langle l_{AS}|H^C|h_S\rangle^2}{E_{lu}^{AS} - E_{ho}^{S}}$$

$$[5] \quad E_{ho}^{SAS} = E_{ho}^{S} + \frac{\langle h_S|H^C|l_{AS}\rangle^2}{E_{ho}^{S} - E_{lu}^{AS}}$$

with the usual notations.

Let us note that in this simple perturbational calculation the Hamiltonian operators are not considered explicitly. Their matrix elements H_{ij}^C and H_{ij}^S are taken as parameters as in the simple Hückel approximation of molecular orbital theory. It should only be remembered that in general $H_{ij}^C > H_{ij}^S$ for obvious physico-chemical reasons. In more detailed calculations H^C is taken as the usual Hamiltonian of molecular systems containing electronic kinetic and potential energies as well as electronic and nuclear repulsion terms. H^S may be either constructed in the same way as H^C or one may use some alternative formulation based on current models of medium effects (point dipole approximation, reaction field effect, ...) (27).

The variation of energy levels brought about by the solute–solvent interaction is depicted in Fig. 1. The first electronic transition energy of species SAS will have the value: $\Delta E = E_{lu}^{SAS} - E_{ho}^{SAS}$. A more explicit expression can be obtained by substituting eqs. [1] and [3] into eqs. [4] and [5]. By adopting the zero differential overlap (ZDO) approximation (i.e., S—S interaction is neglected) and neglecting the small fourth order term which appears in the denominator of eqs. [4] and [5], we obtain, after some algebra, the following expression:

$$[6] \quad \Delta E = (E_{lu}^{A} - E_{ho}^{S}) + \frac{\langle l_A|H^S|h_S\rangle^2}{E_{lu}^{A} - E_{ho}^{S}} + 2\langle l_A|H^C|h_S\rangle^2\left[(E_{lu}^{A} - E_{ho}^{S}) + 2\frac{\langle l_A|H^S|h_S\rangle^2}{E_{lu}^{A} - E_{ho}^{S}}\right]^{-1}$$

It appears that this equation represents the limiting case of a more general expression obtained for the donor–acceptor complex – n-donor solvent interaction by similar double perturbation treatment (7). Equation [6] shows that the electronic transition energy depends on the energy gap separating the interacting orbitals in a rather complicated way. When the n-donor ability of the solvent increases, $E_{lu}^{A} - E_{ho}^{S}$ will decrease and the interaction matrix element increases. As a result, the last two terms in eq. [6] increase. However, the first term is the dominating one (24) as it can also be verified easily by numerical simulation. Therefore, it can be predicted that *with increasing* n*-donor ability of the solvent the electronic transition energy of the solute decreases.* This conclusion is just opposite to that obtained for the n-donor solvent effect on the electronic excitation energy of π–π complexes where a blue shift was predicted (7) and confirmed experimentally (1, 7).

In the case of a transition metal complex solute the complexing action of the solvent is strongly controlled by symmetry restrictions. As a matter of fact, the coordination of solvent molecules to the central metal ion takes place according to a well-defined geometry. Consequently, only those solute–solvent orbitals can interact which belong to the same irreducible representation of the actual symmetry point group. On the other hand, the solvating action of the solvent is not subject to such limitations because of the dynamic character of the solvation shell structure.

All the complexes considered here have a tetragonally distorted octahedral geometry and therefore they belong to the D_{4h} symmetry point group.

In both mono- and binuclear copper acetate complexes with n-donor solvents such as pyridine derivatives, the complexing solvent molecules occupy the axial positions along the z-axis (25). Molecular orbital calculations show (25, 26) that the highest occupied and the lowest unoccupied orbitals are mainly centered on the metal, receiving only slight contributions from the ligands. They have essentially the character of metal d orbitals and will be designated by $|h_M\rangle$ (energy E_{ho}^{M}) and $|l_M\rangle$ (energy E_{lu}^{M}), respectively (Fig. 1; note that for clarity, the metal is designated by F instead of M for chloride complexes). This result is in full agreement with the experimental observation that the electronic transitions considered here are essentially of d–d type. A potential field of D_{4h} symmetry splits the d orbital energy levels in such a way that the orbital d_{z^2} becomes the highest occupied (occupation number: 2), while the orbital d_{xy} becomes the lowest unoccupied (occupation number: 1) orbital of the complex (25). d_{z^2} and d_{xy} belong to the a_{1g} and b_{2g} irreducible representations of D_{4h}, respectively. Considering only σ-type metal–pyridine interactions (π-type interactions can influence neither $|l_M\rangle$ nor $|h_M\rangle$ for symmetry reasons), it can be seen that the pyridine lone pair electron orbital ($|h_S\rangle$, symmetry: a_{1g}, energy E_{ho}^{S}) can interact only with d_{z^2}, leading to the new highest occupied orbital $|h_{MS}\rangle$ (energy: E_{ho}^{MS}). Solvating action of pyridine affects both $|h_{MS}\rangle$ and $|l_{MS}\rangle$ ($\equiv |l_M\rangle$) (see above) and the final energy level positions are given in Fig. 1. Using the same procedure and applying the same approximations as for the derivation of eq. [6], the following expression is obtained for the metal d–d transition energy perturbed by the complexing–solvating ability of the n-donor solvent ($\Delta E_a = E_{lu}^{SMS} - E_{ho}^{SMS}$):

$$[7] \quad \Delta E_a = (E_{lu}^{M} - E_{ho}^{M}) + \frac{\langle l_M|H^S|h_S\rangle^2}{E_{lu}^{M} - E_{ho}^{S}} - \frac{\langle h_M|H^C|h_S\rangle^2}{E_{ho}^{M} - E_{ho}^{S}} - \langle h_M|H^S|h_S\rangle^2\left[(E_{ho}^{M} - E_{ho}^{S}) + 2\frac{\langle h_M|H^C|h_S\rangle^2}{E_{ho}^{M} - E_{ho}^{S}}\right]^{-1}$$

Again, if the n-donor ability of solvent increases, i.e. $E_{lu}^{M} - E_{ho}^{S}$ (and $E_{ho}^{M} - E_{ho}^{S}$) decreases, all terms, except the first one, increase. But, since the negative contribution (3rd and 4th terms) is greater than the positive one (2nd term), the overall

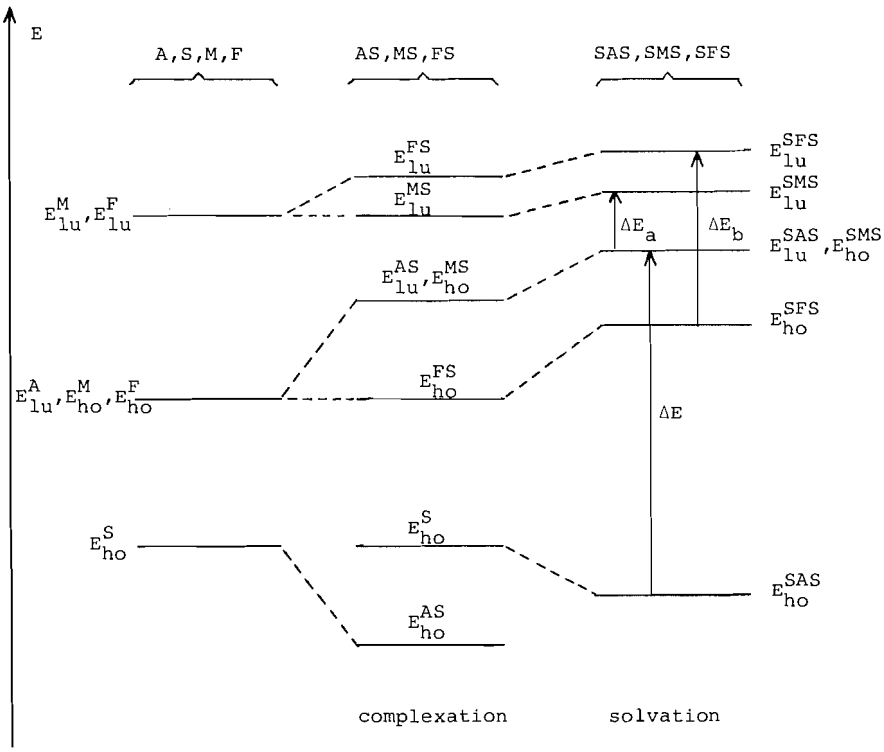

FIG. 1. Effect of complexing–solvating perturbation on the electronic levels of electron acceptor solutes.

transition energy will decrease and a *red shift* must be observed. It will be seen that this prediction is fully borne out by experiment.

In those copper chloride – pyridine complexes where four pyridine molecules are present, the latter occupy the equatorial xy plane of the distorted octahedron. Therefore the complexing solvent molecules interact mainly with the singly occupied d_{xy} metal orbital pushing it to higher energies, while the highest occupied orbital (d_{z^2}) remains unaffected for symmetry reasons. Here also solvation effect is not submitted to symmetry restrictions (Fig. 1). The same perturbational treatment as applied before to the acetate complexes results in the following expression for the metal d–d transition energy ($\Delta E_b = E^{SFS}_{lu} - E^{SFS}_{ho}$):

$$[8]\quad \Delta E_b = (E^F_{lu} - E^F_{ho}) - \frac{\langle h_F|H^S|h_S\rangle^2}{E^F_{ho} - E^S_{ho}} + \frac{\langle l_F|H^C|h_S\rangle^2}{E^F_{lu} - E^S_{ho}} + \langle l_F|H^S|h_S\rangle^2\left[(E^F_{lu} - E^S_{ho}) + 2\frac{\langle l_F|H^C|h_S\rangle^2}{E^F_{lu} - E^S_{ho}}\right]^{-1}$$

Here the positive contributions (3rd and 4th terms) will dominate and an increase of n-donor ability of solvent (i.e. $E^F_{lu} - E^S_{ho}$ decreases) provides a *blue shift* of the d–d metal transition. The opposite predictions of eqs. [7] and [8] show clearly that the same n-donor ability of solvent can influence differently the electronic spectrum of a given transition metal complex solute depending on the geometry and electronic structure of the latter.

Results and discussion

The electronic transition energies obtained for the mono- and binuclear forms of copper acetate complexes in pure n-donor solvents are collected in Table 1. Since the ionization potential (I_S) of the solvent represents in fact the energy of its highest occupied molecular orbital (i.e. $I_S = -E^S_{ho}$, Koopman's theorem), it was taken as an experimental parameter to express the n-donor power of the solvent molecules. The paucity of I_S values in the literature prompted us to work out a simple approach to determine the lacking data either by interpolation or by standardization. The basic principle is the existence of possible linear relationship between basicity (pK_a) and ionization potential.

As a starting point a standard series was chosen using only I_S values which have been well established both theoretically and experimentally (13). Using the ionization potentials of pyridine derivatives 3, 4, 7, and 8 from Table 1, of 3-methyl- (pK_a = 5.68; I_S = 9.68 eV), 4-methyl- (pK_a = 6.02; I_S = 9.63 eV), 2,5-dimethyl- (pK_a = 6.40; I_S = 9.57 eV), 2,3-dimethyl- (pK_a = 6.57; I_S = 9.57 eV), and 2,4,6-trimethyl- (pK_a = 7.59; I_S = 9.42 eV) pyridines (13), and of 4-cyano- (pK_a = 1.90; I_S = 10.25 eV) and 3-fluoro- (pK_a = 2.97; I_S = 10.09 eV) pyridines (14), the following linear relationship could be established between pK_a and I_S values (all acidity constants are from ref. 15):

$$[9]\quad pK_a = 71.12(\pm 1.13) - 6.76(\pm 0.12)I_S \qquad (r = 0.9987;\ \sigma = 0.093)$$

This equation was taken as standard and it was used to determine unknown ionization potentials by direct interpolation. On the other hand, it was noted that other ionization potential values (14) also lay on a line parallel to that given by eq. [9]. The average distance between the two parallel lines is 0.2 eV. This observation suggests that if the ionization potentials situated on this parallel line are corrected by increasing their values by +0.2 eV, useful estimates can be obtained for unknown I_S values. The results arrived at by this standardization procedure are collected in Table 2 (see also Table 1).

As it was shown above, eq. [7] predicts that when the n-donor ability of the solvating-complexing solvent molecules increases

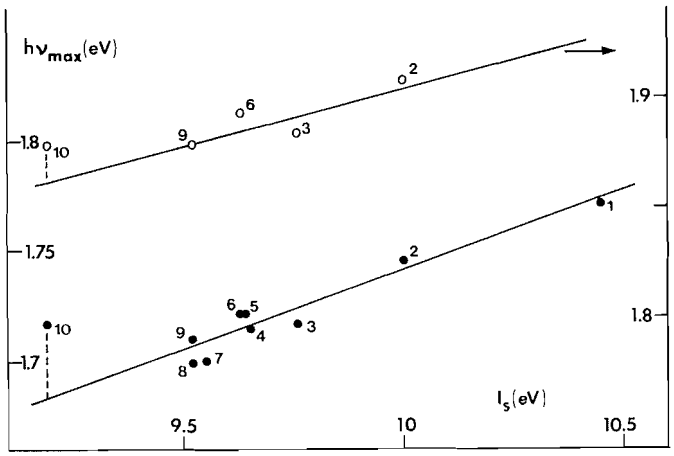

FIG. 2. Influence of n-donor power of solvent on the first electronic transition energy of mononuclear (○) and binuclear (●) copper acetate complexes (Table 1).

the first excitation energy of the solute should decrease. Figure 2 shows that this is indeed the case. The linear relations governing this correlation for both mono- and binuclear copper acetate complexes are given by eqs. [10] and [11] respectively:

$$[10] \quad h\nu_{max}\,(\text{eV}) = 1.384(\pm 0.218) + 0.052(\pm 0.022)I_S \qquad (r = 0.8543;\ \sigma = 0.008)$$

$$[11] \quad h\nu_{max}\,(\text{eV}) = 1.012(\pm 0.077) + 0.073(\pm 0.007)I_S \qquad (r = 0.9615;\ \sigma = 0.006)$$

It should be remembered, however, that these relationships are linear only in first approximation.

It can be seen that the slopes of eqs. [10] and [11] are very similar, showing that both mono- and binuclear complexes are sensitive to n-donor properties of solvent in a rather similar extent. It is important to note that the actual values of the slopes are much smaller than unity. It is well known that unit slopes are characterizing weak molecular interactions (22, 23). On the other hand, it has been suggested that the smaller the value of the slope, the stronger is the interaction between the donor–acceptor partners (24). As a matter of fact, full coordination of the donor to the acceptor represents the case where the interaction is very strong, i.e. considerably stronger than in loose molecular complexes. Therefore, according to the above suggestion (24), a slope much smaller than unity is expected in the present case when the first electronic transition energy is plotted vs. the ionization potential of the n-donor molecules. It can be seen that this is fully borne out by experiment (Fig. 2 and eqs. [10] and [11]).

Let us note that the points representing the complexes with isoquinoline do not fall on the straight lines obtained for pyridine derivatives. This is a natural consequence of the fact that in perturbation theory only the members of a given homologous series can be compared.

[a]See notes of Table 1.
[b]Reference 18.
[c]Reference 19.
[d]Reference 20.
[e]Reference 21.

On the other hand, it is well known (10, 16) that mononuclear species are very sensitive to steric effects. This is why points representing pyridine derivatives able to provoke strong steric effect (numbers 4, 7, and 8 in Table 1) fall completely off the line obtained for mononuclear complexes (not shown on Fig. 2). Interestingly enough, the same points follow closely eq. [11], showing that binulcear copper complexes are not sensitive to steric effects. As a matter of fact, the particular geometrical structure of these complexes neutralizes in a large extent the influence of steric crowding. It should be noted that all the interpolated and standardized ionization potentials behave in a coherent way with known I_S values, i.e. they obey the same perturbational relationship (eq. [7]). This allows to consider the new I_S values given in Tables 1 and 2 as a good first approximation to the unknown ionization potentials. It also supports the validity of the present standardization–interpolation procedure.

Some copper chloride complexes have been also reinvestigated and the new experimental results are given in Table 3 (the older, less accurate data are also included in parentheses for comparison).

It can be seen that increasing *n*-donor ability of solvent molecules brings about a blue shift as predicted by eq. [8], with isoquinoline falling again out of the homogeneous series of pyridine derivatives as it has been observed already for copper acetate complexes. Unfortunately, the data in Table 3 cannot be compared directly on account of the existing structural differences. While the complexes with pyridine and 2,4-dimethylpyridine contain four pyridine molecules, the complex with 4-ethylpyridine has only three (19, 20). Thus, only the cases of pyridine and 2,4-dimethylpyridine really corroborate the theoretical predictions. Further investigations are therefore necessary to establish definitively whether copper chloride complexes obey eq. [8] or show different behavior.

The above analysis shows that simple second order intermolecular perturbation theory developed here in the Fukui approximation can account successfully for the spectroscopic behavior of solutes which enter into solvating-complexing interactions with *n*-donor solvent molecules. The presently proposed theory is based on a double perturbation taking into account explicitly the two roles played by the solvent: complexation and solvation. The predicted spectral shifts brought about by increasing *n*-donor ability of solvent are fully borne out by experiment. This should also be compared to the blue shift predicted by this same theory for donor–acceptor molecular complex solutes in complete agreement with experimental observations (7).

Experimental

Solid copper acetate and chloride complexes with pyridine derivatives were obtained as described previously (10, 18, 21). The pyridine derivatives were dried by standing over KOH and distilled from molecular sieves (4 Å) *in vacuo*.

Electronic spectra (340–800 nm) were recorded on a Beckmann U.V. 5270 spectrophotometer in thermostatted stoppered cells at 298 ± 0.1 K. The experimental error of the band maxima is about ±0.5 nm.

All the measured electric conductivities of the various solutions were less than $10^{-7}\,\Omega^{-1}\,cm^{-1}$ at copper concentrations of $10^{-3}\,M$.

Copper analysis were realized by the standard EDTA titration procedure.

All manipulations were carried out in a dry box in the presence of P_2O_5.

Alkylation of *tert*-butyl lithiohydrazones of aldehydes and ketones

SHAO-FANG WANG[1] AND JOHN WARKENTIN[2]
Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received December 9, 1987

SHAO-FANG WANG and JOHN WARKENTIN. Can. J. Chem. **66**, 2256 (1988).

Treatment of the *tert*-butylhydrazones of formaldehyde, acetaldehyde, and acetone with butyllithium afforded the corresponding *tert*-butyl lithiohydrazones, which were alkylated with alkyl, allyl, and benzyl halides. Fourteen new *tert*-butylazo compounds were prepared in yields ranging from 38 to 86%.

SHAO-FANG WANG et JOHN WARKENTIN. Can. J. Chem. **66**, 2256 (1988).

La réaction des *tert*-butylhydrazones du formaldéhyde, de l'acétaldéhyde et de l'acétone avec le butyl-lithium conduit aux *tert*-butylhydrazones lithiées correspondantes qui peuvent être alkylées par les halogénures d'alkyle, d'allyle et de benzyle. On a préparé 14 nouveaux composés *tert*-butylazo, avec des rendements variant de 38 à 86%.

[Traduit par la revue]

Introduction

The alkylation of hydrazone salts of aldehydes and ketones (1–5) occurs primarily at carbon rather than at nitrogen, if the substituent at N is a large one, such as *tert*-butyl (reaction [1]).

[1] $R^1CH{=}N{=}NC(CH_3)_3^- Li^+ + R^2X \rightarrow R^1R^2CHN{=}NC(CH_3)_3 + LiX$

That selectivity has been used for a variety of useful synthetic purposes (1–5) including the overall conversion of aldehydes into ketones (reactions [1], [2]). The latter conversion is achieved by taking advantage of the fact that the azo/hydrazone equilibrium lies very much to the hydrazone side.

[2] $R^1R^2CHN{=}NC(CH_3)_3 \xrightarrow{F_3CCO_2H} R^1R^2C{=}NNHC(CH_3)_3 \xrightarrow{H^+,\ H_2O} R^1R^2CO$

We were interested in the azo compounds themselves, as substrates for intramolecular radical cyclizations to form heterocycles (6), and we therefore sought to apply the method of reaction [1] to their synthesis. We report the syntheses of 14 new azo compounds, including six prepared from formaldehyde *tert*-butylhydrazone, which had been used only once before to prepare two ketones by sequential anion formation, alkylation, isomerization, anion formation, and alkylation (3).

Methods, results, and discussion

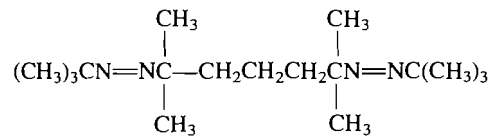
Tetrahydrofuran (THF) was used as solvent throughout. One equivalent of tetramethylethylenediamine (TMEDA) enhanced the yields from reactions with formaldehyde *tert*-butylhydrazone and in reactions of hydrazone salts with 1-chloro-3-iodopropane.

The order of mixing of the reactants was not important in many cases but, for alkylation with 1-bromo-3-iodopropene, the preferred method involved addition of a solution of the preformed lithiohydrazone to a solution of the alkylating agent. Significantly lower yields were obtained for that case if the alkylating agent was added gradually to a solution of the lithiohydrazone. Reaction conditions and yields for the preparation of some *tert*-butylazo compounds, according to reaction [3], are given in Table 1.

[3] $R^1R^2C{=}NNHC(CH_3) \xrightarrow[2.\ R^3X]{1.\ BuLi,\ THF} R^1R^2R^3CN{=}NC(CH_3)_3 + LiX$

1 **2** **3**

1,3-Dibromopropane and 1,3-diiodopropane did not afford the expected azo compounds from reactions with the lithio derivative of **1***a*. Major products from 1,3-diiodopropane were the bis substitution product **4** (~20%) and the allyl derivative



4

3*i* (~15%). The latter was the major product isolated from treatment of 1,3-dibromopropane with the lithium salt of **1***a*. We were unable to find reaction conditions to circumvent the double substitution and (or) elimination reactions that afford those products, and the only azo compounds of type $X(CH_2)_3CR^1R^2N{=}NC(CH_3)_3$ that we were able to prepare in good yield were **3***k* and **3***l* (X = Cl) from the dihalide 1-chloro-3-iodopropane.

The azo compounds (**3**) of Table 1, all of which are new,[3] were purified by vacuum distillation or by chromatography as described in the experimental section. They are identified from their ^1H nmr and high resolution mass spectra (Table 2).

Experimental

The tetrahydrofuran solvent was freshly distilled from sodium and benzophenone. Tetramethylethylenediamine and butyllithium (2.5 or 10.1 M, in hexanes) were used as received from Aldrich. Halides **2** were used as received from Aldrich except for **2***b* and **2***d*, which were prepared.

tert-*Butylhydrazone of acetone*, *1*a

A suspension of *tert*-butylhydrazine hydrochloride (30 g, 0.24 mol) and sodium carbonate (13 g, 0.12 mol) in a solvent made from 40 mL of acetone, 2 mL of water, and 60 mL of benzene was heated for 3 h at the reflux temperature. It was cooled to room temperature and dried over $MgSO_4$. The solid was removed by filtration and washed twice with benzene. The combined filtrate was distilled and the fraction boiling at

[a]All products were oils at room temperature. Yields are average values from two to four runs.
[b]Abbreviations: *o*-BrBz = *ortho*-bromobenzyl; *o*-IBz = *ortho*-iodobenzyl; Bz = benzyl.
[c]One equivalent of TMEDA present.
[d]The starting material (R^3X) was a mixture of *cis*/*trans* isomers, as was the corresponding product.
[e]Yields from runs with one equivalent of TMEDA. Lower yields were obtained without TMEDA.

128–134°C was collected. The yield of **1***a* was 18.1 g (44%); ^{1}H nmr ($CDCl_3$) δ: 1.16 (s, 9H), 1.68 (s, 3H), 1.90 (s, 3H).

tert-*Butylhydrazone of acetaldehyde,* ***1****b*

A suspension of *tert*-butylhydrazine hydrochloride (30 g, 0.24 mol) and sodium carbonate (13.5 g, 0.13 mol) in a solution prepared from acetaldehyde (11.8 g, 0.27 mol), water (5 mL), and ether (50 mL) was stirred at 0°C for 2.5 h. Enough water was then added to bring all the suspended solid into solution. The organic layer was separated and the aqueous layer was extracted (2 × 25 mL) with ether. The combined organic layers were dried and the solvent was removed with a rotatory evaporator to leave 23.1 g (84%) of **1***b*. Distillation at 32–36°C (14 Torr; 1 Torr = 133.3 Pa) gave pure **1***b* as a mixture of *E* and *Z* isomers, *E*/*Z* ratio ≃ 1.4, assignments (7) and ratio by ^{1}H nmr spectroscopy of the mixture; ^{1}H nmr ($CDCl_3$) *E* isomer, δ: 1.11 (s, 9H), 1.84 (d, *J* = 5.5 Hz, 3H), 5.08 (s, br), 7.16 (q, *J* = 5.5 Hz, 1H); *Z* isomer, δ: 1.10 (s, 9H), 1.68 (d, *J* = 6.0 Hz, 3H), 5.08 (s, br), 6.64 (q, *J* = 6.0 Hz, 1H).

Hydrazone **1***b* was not distillable at atmospheric pressure. A sample of **1***b* solidified on heating to 100°C.

tert-*Butylhydrazone of formaldehyde,* ***1****c*

A solution of *tert*-butylhydrazine hydrochloride (6.04 g, 0.048 mol) and sodium carbonate (2.64 g, 0.025 mol) in water (30 mL) and methanol (20 mL) was cooled to −22(±2)°C with a Dry Ice – acetone bath. Formaldehyde (6 mL of 37% aqueous solution, 0.074 mol) was dropped in and the resulting solution was aged at −22(±2)°C for 30 min before it was extracted with ether. The ether extract was washed with water and dried over $MgSO_4$.

The ether solvent was evaporated with a rotatory evaporator, with the flask containing **1***c* in ice water. The residue was distilled, bulb-to-bulb, at room temperature in a closed system at ca. 0.06 Torr, to afford 2.2 g (40%) of **1***c*; ^{1}H nmr ($CDCl_3$), δ: 1.00 (s, 9H), 4.95 (s, br, 1H), 6.08 (d, *J* = 13.5 Hz, 1H), 6.62 (d, *J* = 13.5 Hz, 1H). Compound **1***c* could be stored for several days at the temperature of Dry Ice.

o-*Iodobenzyl bromide,* **2**b

Bromination of *o*-iodotoluene with *N*-bromosuccinimide (8) afforded **2***b*; ^{1}H nmr (90 MHz, $CDCl_3$), δ: 4.58 (s, 2H), 6.8–8.2 (m, 4H).

1-Bromo-3-iodopropene, **2**d

To 1,3-dibromopropene (3.7 g, 18.5 mmol, isomer ratio 1.6, *trans*:*cis*), prepared by the procedure of Hatch (5), was added a solution of sodium iodide (3.7 g, 29 mmol) in acetone (25 mL). The reaction mixture was stirred overnight at room temperature before evaporation of most of the acetone, addition of water, and extraction with ether. The ether extract was dried over $MgSO_4$ and the solvent was evaporated. Kugelrohr distillation (50°C, 0.06 Torr) afforded 2.7 g of the *trans*/*cis* isomers of **2***d*; ^{1}H nmr ($CDCl_3$), δ: 3.8–4.0 (m, 2H), 6.2–6.5 (m, 2H). Isomer ratio by integration of the ^{1}H nmr spectrum ca. 1.6.

Alkylation of lithiohydrazones

The following procedure is typical of those in which the *tert*-butylhydrazone of formaldehyde or 1-chloro-3-iodopropane was one reactant.

A 3-necked, 50-mL flask fitted with a magnetic stirrer, a pressure-equalizing addition funnel, a condenser topped with an inlet for N_2, and a septum was charged with THF (6 mL). The flask was cooled to between −20 and −25°C with a bath of acetone to which Dry Ice had been added. Formaldehyde *tert*-butylhydrazone (1.23 g, 12.3 mmol) was added to the THF, followed by butyllithium (5 mL of 2.5 M solution, 12.5 mmol) and TMEDA (1.4 mL, 9.3 mmol). The reaction mixture was left under N_2 at −20 to −25°C for 15 min before the temperature was allowed to rise to −5°C. *ortho*-Bromobenzylbromide (2.71 g, 10.8 mmol) was then added during 5 min. When addition was complete, the reaction mixture was kept for 3 h at a temperature between 0 and 10°C. Work-up involved acidification of the slurry with dilute aqueous HCl, extraction with ether, washing of the ether extract successively with dilute potassium carbonate solution and with water, and, finally, drying of the ether layer with $MgSO_4$. Evaporation of the ether left **3***d* (2.5 g, 86%) containing a minor impurity that was removed by column chromatography on silica gel, using ether (1.5%) in petroleum ether (bp 40–60°C). Spectra of pure **3***d*, an oil, are in Table 2.

The following procedure is typical of those used to prepare azo compounds from the *tert*-butylhydrazone of acetone, with the exception of **3***k*.

In a three-necked flask, equipped as described above, was placed **1***a* (2.5 g, 19.5 mmol) in 15 mL of THF. The flask was cooled with ice water before BuLi (2.15 g, 21.5 mmol, 10.1 M solution in hexane) was added by syringe through the septum. After the resulting solution had aged for 15 min, benzyl bromide (**2***c*, 2.36 g, 19.5 mmol) in THF (10 mL) was added and the resulting solution was kept at 60°C for 20 h. The work-up, analogous to that described above, afforded 4.77 g (67%) of slightly impure **3***e*. It was distilled to afford pure **3***e*, bp 63–64°C, 0.5 Torr, as an oil.

The following procedure is typical of those used to prepare allylic compounds such as **3***g*.

[a]High resolution. The numbers are given in the order calcd. followed by found.
[b]EI.
[c]CI(NH_3).
[d]CI(CH_4).

In a three-necked flask, described above, were placed **1***a* (0.71 g, 5.5 mmol) and THF (6 mL). The solution was cooled to ice temperature before BuLi (5.5 mmol, 2.2 mL of 2.5 M solution) was injected from a syringe. After 10 min, the resulting solution of lithium salt was withdrawn from the flask into the syringe. A solution of 1-bromo-3-iodopropenes (**2***d*, 1.08 g, 4.4 mmol) in THF (6 mL) was introduced into the flask and the contents of the syringe were then added over a 17-min interval. The solution so formed was kept at 10–15°C for 1 h. Work-up, as described above, afforded **3***g* (0.78 g, 69%) containing traces of impurities that were removed by column chromatography on silica gel using ether (2%) in petroleum ether (bp 40–60°C). The *trans*/*cis* isomer ratio, estimated from the ^{1}H nmr spectrum, was 1.8.

The three procedures described above serve as models for the 14 syntheses reported. Additional information can be found in Table 1.

Bis substitution product **4** *(2,2,5,5,9,9,12,12-octamethyl-3,4,10,11-tetraazatrideca-3,10-diene)*

To the three-necked flask, described above, was added **1***a* (0.70 g, 5.5 mmol) in 7 mL of THF. The solution was cooled with ice and BuLi (5.5 mmol, 2.2 mL of 2.5 M solution) was added during 10 min. After 15 min more at 0°C, 1,3-diiodopropane (1.7 g, 5.7 mmol) in THF (5 mL) was dropped in over 10 min. The temperature was allowed to rise to ambient and the mixture was worked up after stirring overnight. Work-up afforded a residue containing mostly 1,3-diiodopropane and **4**, which were separated by tlc on silica gel plates using ether (3%) in petroleum ether (bp 40–60°C) as the developing solvent; ^{1}H nmr ($CDCl_3$), δ of **4**: 0.98 (s, 12H), 1.10 (s, 18H), 1.38–1.80 (m, 6H).

Mixing the reactants in the inverse order afforded **3***i* and unreacted 1,3-diiodopropane, but not **4**. Analogous reactions with 1,3-dibromopropane instead of 1,3-diiodopropane gave **3***i* and unreacted 1,3-dibromopropane from both the normal addition mode and the inverse addition mode.

Voltammetric stabilization of electrofaceted (100)-type platinum electrodes in acidic solutions

SARA ALFONSINA DORA ALDABE DE BILMES, MARÍA CRISTINA GIORDANO, AND ALEJANDRO JORGE ARVIA

Instituto de Investigaciones Fisicoquímicas Teóricas y Aplicadas (INIFTA), Facultad de Ciencias Exactas, Universidad Nacional de La Plata, Sucursal 4, Casilla de Correo 16, (1900) La Plata, Argentina

Received June 23, 1987[1]

SARA ALFONSINA DORA ALDABE DE BILMES, MARÍA CRISTINA GIORDANO, and ALEJANDRO JORGE ARVIA. Can. J. Chem. **66**, 2259 (1988).

The voltammetric stabilization of electrofaceted (100)-type Pt electrodes prepared from polycrystalline Pt by fast repetitive triangular potential cycling are followed by conventional voltammetry in the H-electroadsorption/electrodesorption potential range in either 1 *M* H_2SO_4 (0 to 35°C) or 0.5 *M* $HClO_4$ (−2 to 35°C). The influence of CO adsorption on the stabilized voltammetric profile is also considered. Depending on the potential cycling used in conventional voltammetry, two well-defined stabilized profiles at 0.1 V/s in the H-electroadsorption/electrodesorption range can be obtained, namely, that corresponding to the H-adsorption stabilized electrofaceted (100)-type Pt, and that related to the O-adsorption stabilized electrofaceted (100)-type Pt.

The changes in the conventional voltammetric profiles can be interpreted in terms of surface modifications basically associated with either adsorption or electroadsorption processes. The influence of the anion (electrolyte composition) prevailing in solution is accounted for in terms of a competitive adsorption between anions and H-adatoms. The influence of temperature in the range covered by this work is smaller than that of the structure of the solution at the electrode/solution interface.

SARA ALFONSINA DORA ALDABE DE BILMES, MARÍA CRISTINA GIORDANO et ALEJANDRO JORGE ARVIA. Can. J. Chem. **66**, 2259 (1988).

Opérant soit dans du H_2SO_4 1 *M* (0 à 35°C) ou dans du $HClO_4$ 0,5 *M* (−2 à 35°C) et faisant appel à la voltamétrie conventionnelle dans l'écart de potentiel d'électroadsorption/électrodésorption du H, on a examiné la stabilisation voltamétrique d'électrodes de Pt du type (100) qui ont été facettées d'une façon électrochimique et qui ont été préparées à partir de Pt polycristallin par un cyclage rapide et répétitif d'un potentiel triangulaire. On a aussi considéré l'influence de l'adsorption de CO sur le profil voltamétrique stabilisé. Suivant le potentiel de cyclage utilisé lors de la voltamétrie conventionnelle, on a obtenu deux profils stabilisés bien définis, à 0,1 V/s, dans l'écart de potentiel d'électroadsorption/électrodésorption du H; il s'agit, d'une part, de celui qui correspond au Pt de type (100) facetté d'une façon électrochimique et stabilisé par adsorption de H et, d'autre part, à celui du Pt de type (100) facetté d'une façon électrochimique et stabilisé par adsorption de 0.

On peut interpréter les changements dans les profils voltamétriques conventionnels en fonction de modifications de surface qui sont essentiellement associées avec des processus soit d'adsorption ou d'électroadsorption. On explique l'influence de l'anion (composition de l'électrolyte) prédominant en solution en fonction d'une adsorption compétitive entre des anions et des atomes de H. L'influence de la température dans la zone couverte par notre travail est beaucoup plus faible que celle de la structure de la solution à l'interface électrode/solution.

[Traduit par la revue]

Introduction

It has been recently found that the voltammetric characteristics of polycrystalline Pt can be modified by applying fast potential cycling in acid electrolytes (1–3). Results obtained at present show that those electrodes exhibiting (100)-type preferred orientations behave in a very reproducible way and exhibit a very clear faceting (3–5). Nevertheless, the stabilized voltammetric response of these electrodes can be achieved only after they have been potential cycled under certain conditions within the potential range of bulk water stability. In this potential range the H-electroadsorption/electrodesorption in the 0 to ca. 0.45 V range, and the O-electroadsorption/electrodesorption in the 0.7 to 1.4 V range take place. The voltammetric features of both processes depend on the electrolyte composition (4–13), electrode treatment (14–16), and particularly, on the surface crystallographic orientation and defects (11–19).

The present work is devoted to study the stabilization of (100)-type preferred oriented Pt electrodes resulting after the electrochemical faceting treatment (1–3). The different stabilization stages are followed by conventional voltammetry and they depend on the potential cycling programme, electrolyte composition, temperature and adsorption/electroadsorption of foreign species. The voltammetric changes observed with electrofaceted (100)-type Pt are, in principle, comparable to those resulting from Pt(100) single crystal electrodes (12, 17–20). In both types of electrodes the voltammetric changes resulting from the potential cycling before the stable voltammogram is obtained can be associated with electrode surface modifications which are influenced by the proper potential cycling and the electrolyte solution composition adjacent to the electrode.

Experimental

The experimental work can be divided into two parts, namely, the preparation of the electrofaceted Pt electrodes and the voltammetric stabilization by means of repetitive triangular potential cycles at 0.1 V/s.

The electrofaceted (100)-type Pt electrodes were prepared from polycrystalline Pt wires (0.20 cm^2 apparent area) by applying a repetitive triangular potential cycling (RTPS) between 0.08 and 1.42 V, at 1.9×10^4 V/s, for 8 h in 1 *M* H_2SO_4 at 25°C. The experimental setup which was extensively used in previous works (1, 2) consisted of an about 10 mL capacity cell with the virgin pc Pt wire electrode (0.5 mm diameter, Johnson Matthey Chemicals Co., spectroscopically pure) symmetrically surrounded by a spiral shaped platinized platinum wire of about 5 cm^2 geometric area. The potential

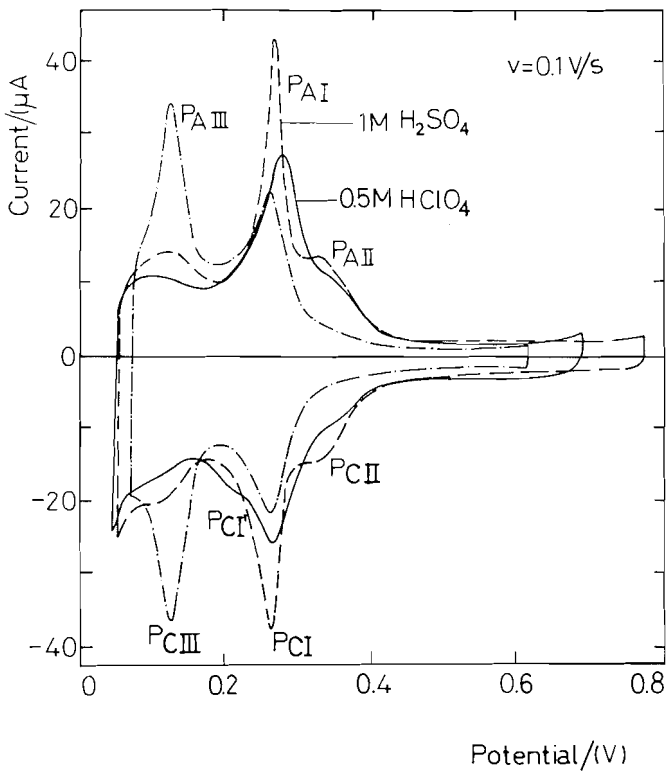

FIG. 1. Stable voltammograms obtained with polycrystalline Pt and HASE electrodes in acidic solutions at 0.1 V/s and 25°C: (···) polycrystalline Pt in 1 *M* H_2SO_4; (---) (100)-type Pt in 1 *M* H_2SO_4; (—) (100)-type Pt in 0.5 *M* $HClO_4$; $E_{s,c}$ = 0.07 and 0.05 V; $E_{s,a}$ = 0.61, 0.77, and 0.68 V.

of the working electrode was measured against a reversible hydrogen electrode in the same solution placed in a separate compartment provided with a Luggin tip passing through the counterelectrode spiral. The electrode arrangement assured the best current distribution compatible with the simplest cell design. A M-5 LYP potentiostat coupled to a LYP square wave generator was used. The characteristics of the potentiostat were as follows: output potential, ±30 V; output current, ±1 A; resolution, ±1 mV; slew rate, 2 V/μs; accuracy, 0.2%; linearity, 0.25%; ohmic drop compensation, up to 100 kΩ; and rise time, 5 μs. The SEM micrographs of the electrode surface were in agreement with those already published for this type of faceted Pt surfaces (4, 5).

The voltammetric stabilized studies of the electrofaceted electrodes were performed at a sweep rate of 0.1 V/s. These runs were made in a conventional three compartment Pyrex glass cell of about 50 mL with a jacket for thermostatic liquid circulation. Solutions, 1 *M* H_2SO_4 and 0.5 *M* $HClO_4$, were prepared from 98% Merck p.a. H_2SO_4 and 70% Merck Suprapure $HClO_4$, respectively. The triply distilled water satisfied the purity requirements usually accepted for electrocatalysis (21). Experiments were performed between −2 to 35°C with the temperature controlled to ±0.1°C. The voltammogram of the electrofaceted (100)-type Pt electrodes in 1 *M* H_2SO_4 in the 0.06–0.7 V range (Fig. 1) reproduces exactly the one previously reported in the literature (1–4) and is also very similar to the voltammogram of a Pt(100) single crystal electrode under the same conditions (12, 17–20). The roughness factor of electrofaceted (100)-type Pt electrodes was 1.1 as determined by comparing the experimental H-adatom voltammetric charge density to that of the H-adatom monolayer calculated for a Pt(100) single crystal surface (15).

$E_{s,c}$ = 0.05 V, and the anodic switching potential, $E_{s,a}$ = 0.78 V in either 1 *M* H_2SO_4 or 0.5 *M* $HClO_4$ at 25°C with a polycrystalline Pt and an electrofaceted (100)-type Pt electrode. The latter type of electrode is denoted as HASE (hydrogen adsorption stabilized electrode).

The voltammetric response of a HASE shows a main pair of conjugated current peaks at ca. 0.26 V (PAI/PCI) and two satellite pairs of conjugated current peaks at each side, namely (PAII/PCII) at 0.35 V and (PAIII/PCIII) at 0.12 V. The pair of peaks PAI/PCI becomes sharper in 1 *M* H_2SO_4 than in 0.5 *M* $HClO_4$ probably due to the difference in the adsorbabilities of HSO_4^- and ClO_4^- ions (22). In 0.5 *M* $HClO_4$ a shoulder (PCI′) at 0.2 V is also recorded during the negative potential going scan.

The voltammetric response of HASE closely resembles that previously reported by several authors for a Pt(100) single crystal electrode under comparable sweep rate conditions (12, 17–20), except for small differences in the pair of peaks PAII/PCII. The contribution of peaks PAIII/PCIII can be attributed to residual Pt(111) faces remaining on the electrofaceted (100)-type Pt electrode after the preparation of the oriented surface from a polycrystalline Pt.

The evolution of the H-adatom electroadsorption profile under cycling, starting from that of a freshly prepared electrofaceted electrode is depicted in Fig. 2*a*,*b* for both 1 *M* H_2SO_4 and 0.5 *M* $HClO_4$ at 25°C. The first voltammogram (Fig. 2*a*) swept cathodically from 0.58 V in 1 *M* H_2SO_4 shows an asymmetric pair of peaks PCI′/PAI at 0.21 and 0.26 V, respectively, as major current contributions. The height of PAII is greater in the first cycle than that of HASE. The H-electroadsorption current peak PCI′ gradually moves to PCI after 9 min RTPS to achieve the voltammogram of the HASE in 1 *M* H_2SO_4. The interconversion of PCI′ to PCI is better defined in 1 *M* H_2SO_4 than in 0.5 *M* $HClO_4$ (Fig. 2*b*). For the latter, the corresponding HASE voltammogram after a prolonged RTPS still shows a remaining contribution of PCI′.

Isopotential values ($E_{i,c}$) at 0.24 V in 1 *M* H_2SO_4 and at 0.25 V in 0.5 *M* $HClO_4$ are observed during the accomplishment of the stable H-electroadsorption voltammogram for HASE. These isopotentials suggest an intra/interconversion of at least two states of H-adatoms promoted during cycling. Hence, the pair of conjugated peaks PCI/PAI can be ascribed to the stable H-adatom adsorption configuration for HASE. The HASE configuration emerges from the first voltammogram only when the potential step, E_{ad} preceding the RTPS is more negative than $E_{i,c}$ as seen from the comparison of Figs. 3*a*, *b*, and *c* for $E_{ad} < E_{i,c}$, $E_{ad} \simeq E_{i,c}$, and $E_{ad} > E_{i,c}$, respectively. Likewise, a voltammogram similar to that of the HASE in 0.5 *M* $HClO_4$ can be accomplished after the electrooxidation of adsorbed CO on freshly prepared electrofaceted Pt (Fig. 4*a*). In this case, CO adsorption was performed from a CO saturated solution at E_{ad} = 0.58 V (23) using a microflow cell (24), and then the solution was replaced by 0.5 *M* $HClO_4$. The voltammogram run immediately after the electrooxidation of adsorbed CO (Fig. 4*b*) becomes similar to that depicted in Fig. 3 in the H-adatom potential range for a HASE (25). These results demonstrate that the initial energy distribution in the freshly prepared electrofaceted (100)-type Pt surface is gradually changed through adsorbate–substrate interactions. The stronger the interaction the shorter the time to reach a stable surface configuration.

2. Data for $E_{s,a} > 0.8$ *V at 25°C*

The voltammogram in the H-electroadsorption/electrodesorption region substantially changes when the RTPS applied to the HASE in 1 *M* H_2SO_4 or in 0.5 *M* $HClO_4$ extends over the oxygen electroadsorption potential region (Fig. 5*a*,*b*). Similar changes are also observed just by extending $E_{s,a}$ towards increasingly positive potentials. In any case, after several RTPS in the 0.03–1.37 V range another stabilized voltammogram is obtained. The resulting electrode is denoted as OASE (oxygen adsorption stabilized electrode). The first potential excursion up to 1.4 V exhibits a rather poor definition of the O-electroadsorption current peaks (Fig. 5). Nevertheless, the electrooxidation current at ca. 1.2 V decreases progressively during the RTPS in both acids, whereas the O-electroadsorption at ca. 0.8 V increases. Finally, two oxidation current peaks are recorded in the O-electroadsorption range when the OASE voltammogram is achieved. The voltammetric changes observed in the O-electroadsorption/electrodesorption potential range are accompanied by simultaneous modifications in the H-electroadsorption/electrodesorption potential range. Thus, peaks PAI/PCI become wider than those already described for the HASE; the heights of peaks PAIII/PCIII increase considerably and, peak PCII is no longer observed.

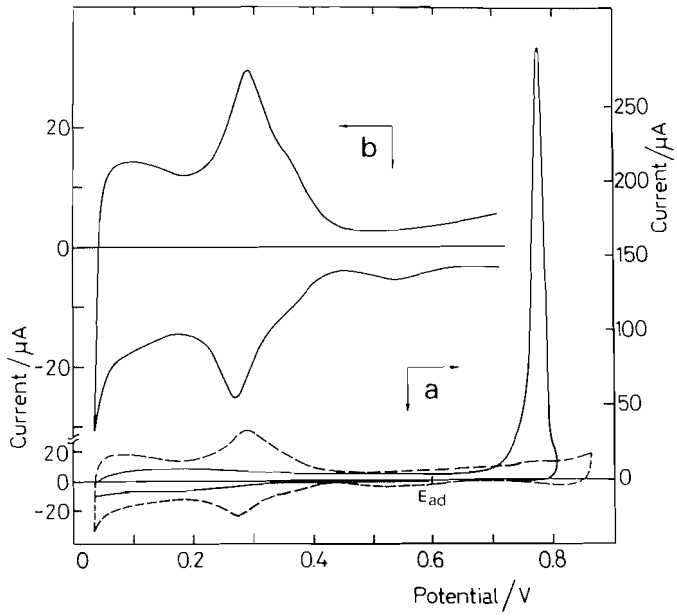

FIG. 4. Voltammogram run with a (100)-type Pt electrode after CO adsorption and electrooxidation: 0.1 V/s, *T* = 25°C, 0.5 *M* $HClO_4$. (*a*) (—) CO electrooxidation (microflow cell) (24), (---) 2nd cycle; (*b*) 3rd cycle expanded scale (equivalent to a HASE).

The voltammetric changes above described which are followed in 0.5 *M* $HClO_4$ better than in 1 *M* H_2SO_4, indicate that the O-electroadsorption/O-electrodesorption produces a partial rearrangement of the HASE surface structure.

Comparable results can be drawn from runs made by stepwise increasing $E_{s,a}$ from 0.70 to 1.4 V. As $E_{s,a}$ moves within the 0.7 to 0.9 V range the changes observed in the H-electroadsorption/electrodesorption process in 0.5 *M* $HClO_4$ are comparatively greater than in 1 *M* H_2SO_4. This difference can be assigned to the delay of O-electroadsorption due to HSO_4^- ion adsorption (9, 13, 15).

3. The influence of temperature in the conventional voltammograms

The variation of temperature from 0 to 35°C in 1 *M* H_2SO_4 and from −2 to 35°C in 0.5 *M* $HClO_4$ (Figs. 6 and 7) produces

For personal use only.

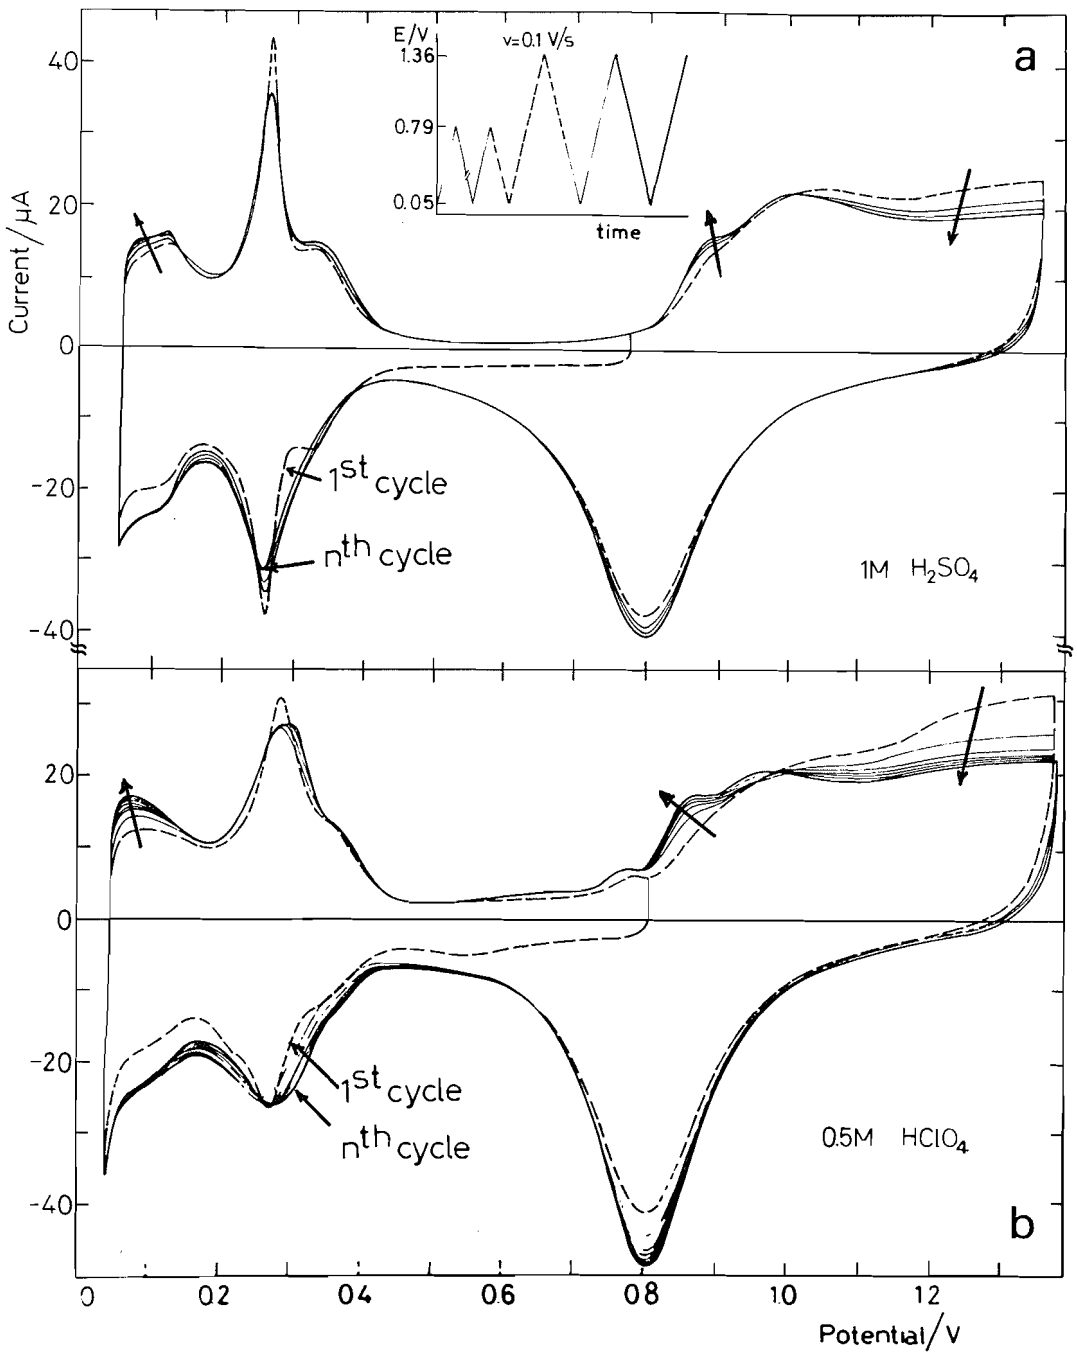

FIG. 5. Stabilized voltammogram from a HASE after RTPS between 0.05 and 1.4 V at 0.1 V/s; T = 25°C. (*a*) 1 *M* H_2SO_4, *n*th cycle = 5th cycle. (*b*) 0.5 *M* $HClO_4$, *n*th cycle = 10th cycle.

voltammetric changes qualitatively similar to those already described at 25°C. The higher the temperature, the lower the number of RTPS at 0.1 V/s required to get the voltammetric response of HASE, although the influence of temperature in 1 *M* H_2SO_4 is considerably greater than in 0.5 *M* $HClO_4$, that is, the time required for the voltammetric stabilization in each acid is different, although for both acids the potential difference between PCI′ and PCI decreases as the temperature increases.

The effect of O-electroadsorption/electrodesorption in the development of the OASE voltammogram is little influenced by temperature in both electrolytes. Although as it can be seen in Fig. 7 for 0.5 *M* $HClO_4$, the increase in temperature produces a considerable decrease of the O-electroadsorption threshold potential. This effect cannot be observed in 1 *M* H_2SO_4 at least in the potential range covered in Fig. 6.

Discussion

The initial voltammetric response of an electrofaceted (100)-type Pt electrode is very sensitive to the electrolyte composition, potential cycling conditions and temperature. Two different stabilized voltammetric profiles are obtained depending whether the value of $E_{s,a}$ is lower or greater than the threshold potential for the O-electroadsorption process. The two types of stabilized voltammetric profiles are denoted as HASE and OASE depend-

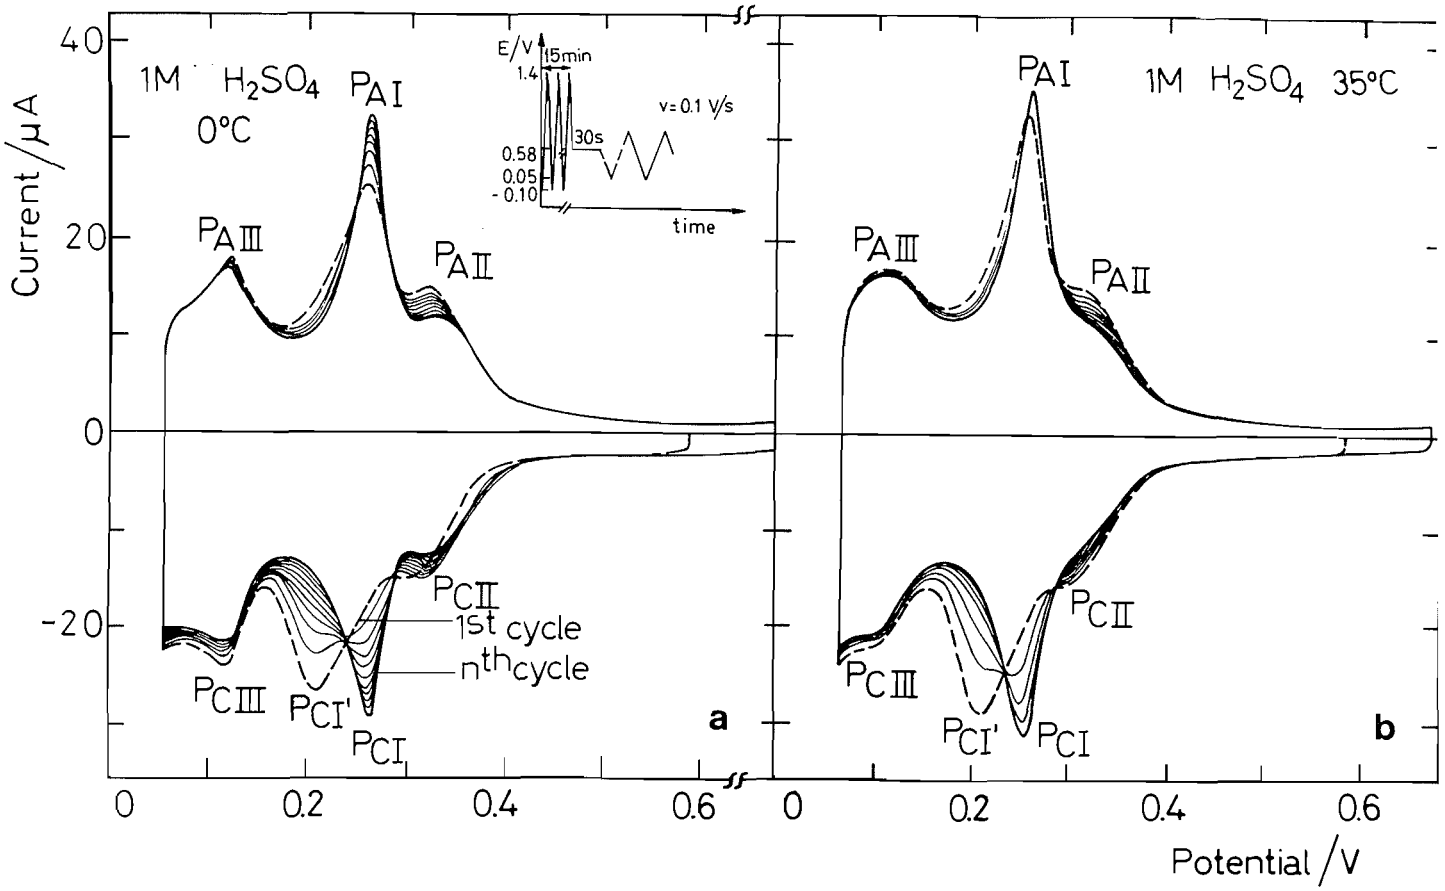

FIG. 6. Influence of temperature on the voltammetric evolution of H-adatom electroadsorption/electrodesorption peaks from (100)-type Pt to a HASE after RTPS in 1 *M* H_2SO_4 at 0.1 V/s. (*a*) 0°C; (*b*) 35°C.

ing whether stabilization is performed by H-electroadsorption/electrodesorption or O-electroadsorption/electrodesorption processes.

The changes observed on an electrofaceted (100)-type Pt electrode by H-electroadsorption/electrodesorption could be associated with an order-forming surface modification. This conclusion is supported by the fact that the definition of the pair of peaks PAI/PCI, which is considered as a fingerprint for a Pt(100) plane, is certainly improved in a HASE.

On the other hand, the pair of peaks PAI/PCI becomes broader and more poorly defined with an OASE. This fact indicates that the irreversible O-electroadsorption/electrodesorption process actually distorts in some way the surface order found with a HASE. For the latter, the substrate–adsorbate interaction energy must be of outmost importance in defining the type of surface modification suffered by the initial electrofaceted Pt electrode, such as the displacement of some metal atoms from their original positions in the polycrystalline surface during the adsorption/electroadsorption halfcycle. For low adsorption energies, the metal atom displacement is probably less than the average atom-to-atom distance at the metal surface. The metal atoms can be restored to their rest position in the lattice during the desorption/electrodesorption halfcycle which for most atoms is different from the original one (3, 26). Furthermore, for a small substrate–adsorbate interaction energy (<20 kJ/mol) such as that of H atoms or H_2O species on Pt (27), the adsorbate interferes the metal surface atom rearrangement by promoting a less dence crystallographic packing of metal atoms at the surface. This can be the case of HASE where the voltammetric characteristics of the (100) crystallographic plane is enhanced. The changes in the voltammogram occurring during the RTPS before attaining the HASE response are mainly observed in the H-electroadsorption region.

The electroadsorption of OH from water is the primary stage for the O-electroadsorption reaction. The adsorbed OH species may participate in various different reactions, such as the platinum electrodissolution and surface oxide electroformation, including place exchange reactions (9, 13, 15). For either a partial or a complete O-electroadsorption coverage the substrate–adsorbate interaction energy becomes greater than that corresponding to H-electroadsorption/electrodesorption, hence larger surface modifications should be expected. The initial electrofaceting would tend to be smeared out since during O-electrodesorption the partially "bare" Pt surface lasts a sufficiently long time ($>10^{-3}$ s) to rearrange in different ways. This leads to a poorly defined voltammetric response. In the long term a structure approaching polycrystalline Pt free from residual strains (16, 26) would be expected.

The H-atom electroadsorption/electrodesorption on both HASE and OASE electrofaceted (100)-type Pt is characterized by three pairs of conjugated peaks PAI/PCI; PAII/PCII, and PAIII/PCIII. Recent results (28) have shown that each process has a different time constant. Peaks PAI/PCI and PAII/PCII correspond closely to the H-adsorption peaks observed on a

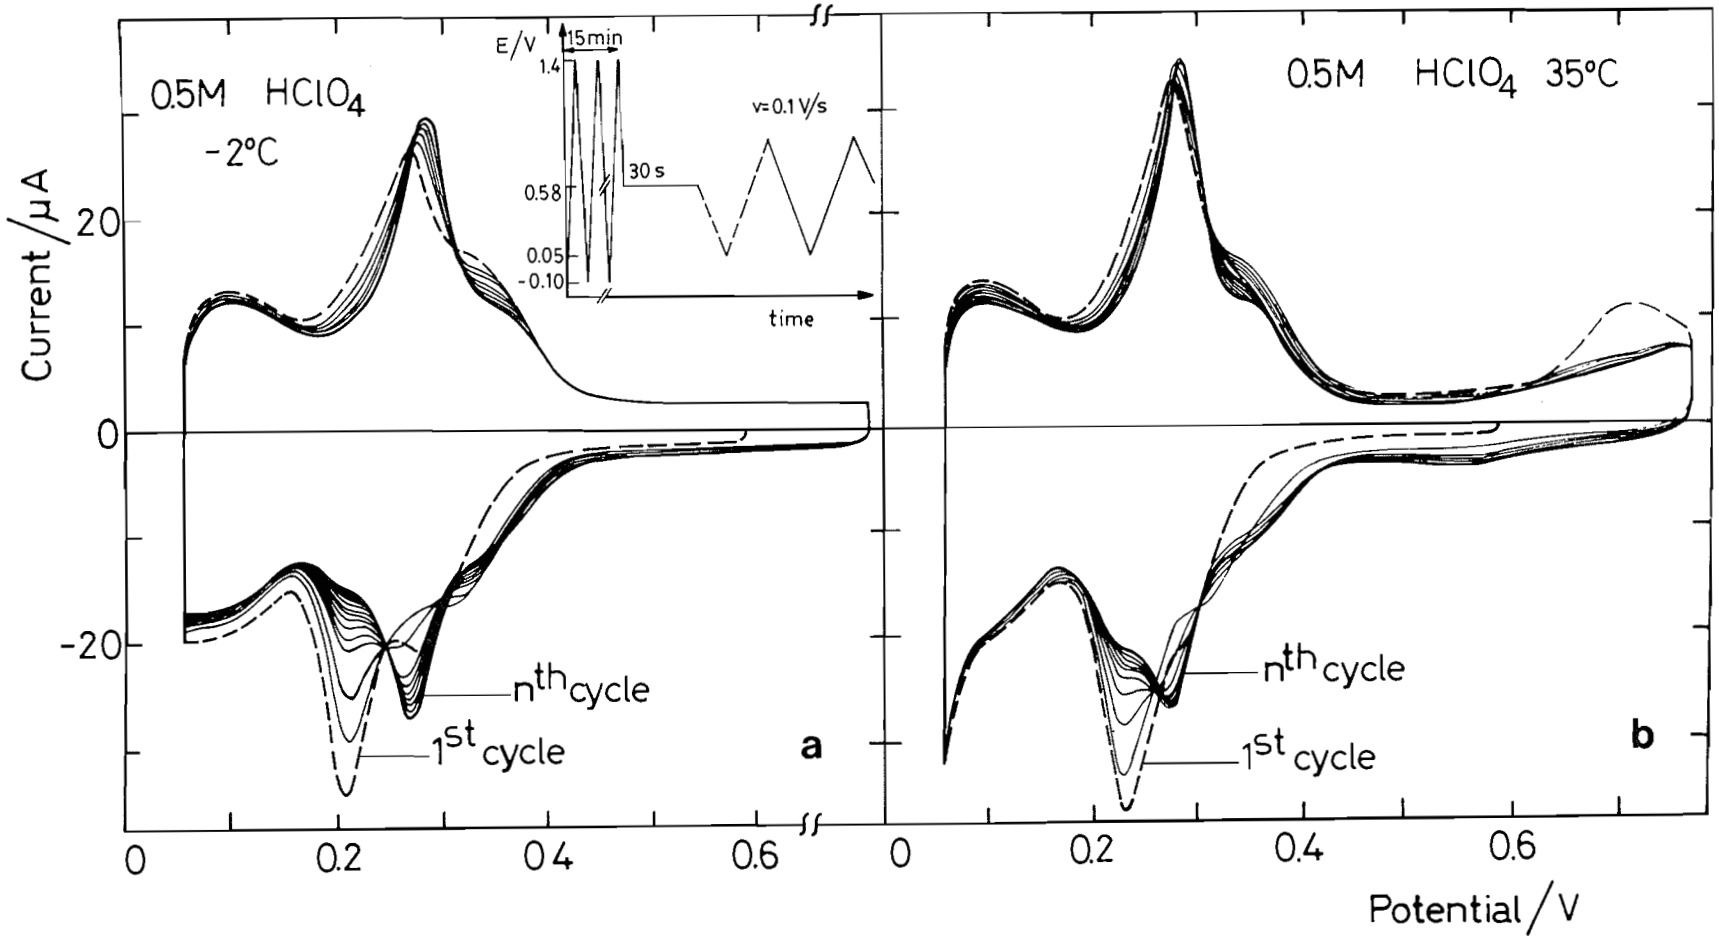

FIG. 7. Influence of temperature on the voltammetric evolution of H-adatom electroadsorption/electrodesorption peaks from (100)-type Pt to a HASE after RTPS in 0.5 *M* $HClO_4$ at 0.1 V/s. (*a*) −2°C; (*b*) 35°C.

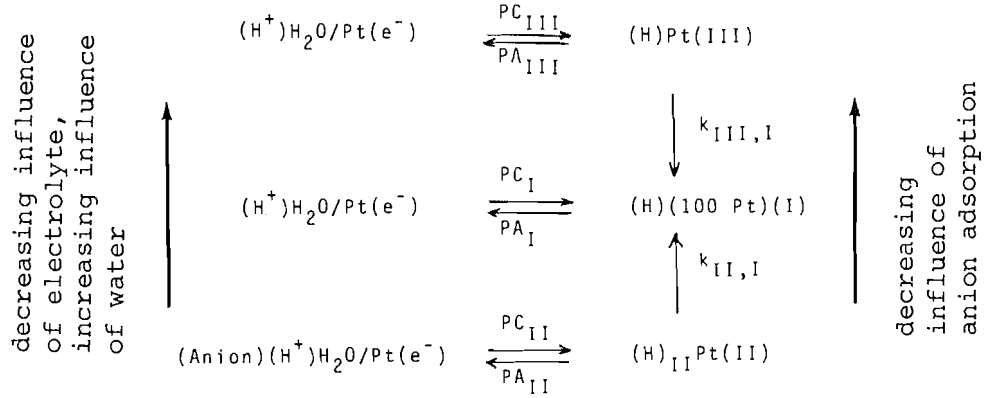

FIG. 8. Reaction scheme related to the different H-electroadsorption/electrodesorption voltammetric peaks. $k_{II,I}$ and $k_{III,I}$ denote the rate constants of adatom surface reactions.

Pt(100) single crystal electrode in 1 *M* H_2SO_4 (12). The electrolyte composition has little influence on the conjugated electrochemical reaction related to the pair of peaks PAIII/PCIII located at the negative potential side of the potential of zero charge of Pt in the acid electrolyte. This suggests that a relatively rapid electron–proton transfer should take place without requiring some previous slow rearrangements of the water–electrolyte structure. This agrees, in principle, with the structure of water in contact with Pt as recently discussed (29). Conversely, the largest influence of anions on the reaction should be expected in the potential range of peaks PAII/PCII as quite likely they are located at the positive potential side of the potential of zero charge of any crystallographic plane of a Pt single crystal (30). The influence of anion adsorption on the H-electroadsorption process related to PCII and PCI is accounted for in terms of a competitive adsorption between anions and H-adatoms as a sweep rate of 0.1 V/s is not sufficiently fast to suppress anion adsorption. This competitive adsorption can explain the change in the voltammogram from PCI′ to PCI on potential cycling (Figs. 2 and 3). The influence of anion adsorption should become increasingly important as the anion–metal interaction energy increases. All these effects are qualitatively summarized in the diagram for the H-adatom electroadsorption/electrodesorption depicted in Fig. 8, consisting of three electron transfer steps in parallel.

The number of cycles required to turn the voltammogram of a freshly prepared electrofaceted (100)-type Pt electrode into that of a HASE, or the latter into the voltammogram of OASE decreases on increasing the temperature. The resulting stable voltammograms exhibit a voltammetric response which depends on the electrolyte composition. The influence of the solution composition becomes more remarkable in the region where the strongest H-metal adsorption interaction is expected. The temperature affects the whole H-electroadsorption/electrodesorption profile, and in particular influences the pair of peaks PAIII/PCIII and PAI/PCI. The electrolyte composition and temperature are variables both acting simultaneously on the electrochemical system making it difficult to deal with each effect independently.

Conclusions

The voltammetric response at 0.1 V/s in 1 *M* H_2SO_4 and in 0.5 *M* $HClO_4$ of a freshly electrofaceted (100)-type Pt electrode cycled in the H-electroadsorption potential range approaches a first stable level which corresponds to an electrode surface denoted as HASE. The voltammogram of the latter is similar to that reported in the literature for Pt(100) single crystal electrode at 0.1 V/s in the same electrolyte. The rate of the voltammetric change to achieve the HASE response depends on both the electrolyte composition and the temperature. The HASE voltammetric response is also obtained from either H-adatom electroadsorption/electrodesorption or CO adsorption followed by adsorbate electrooxidation on the freshly electrofaceted electrode surface.

Surface rearrangements produced on the electrofaceted (100)-type Pt electrodes after O-electroadsorption–electrodesorption in both 1 *M* H_2SO_4 and 0.5 *M* $HClO_4$ turn the voltammogram of HASE into a second stable level denoted as OASE.

Bridged-ring steroids. V. The total synthesis of 1,4-methano steroids by a modified Torgov sequence[1]

PETER YATES, STEPHEN P. DOUGLAS, SUSHIL K. DATTA, AND JEFFREY F. SAWYER
Lash Miller Chemical Laboratories, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received February 23, 1988

PETER YATES, STEPHEN P. DOUGLAS, SUSHIL K. DATTA, and JEFFREY F. SAWYER. Can. J. Chem. **66**, 2268 (1988).

The Diels–Alder adduct, **17**, of cyclopentadiene and 2-methoxy-5-methyl-1,4-benzoquinone was reduced with sodium borohydride to the ketol **18**, whose acetate **19** was further reduced with zinc amalgam to the monoketone **20**. Reaction of **20** with vinyllithium gave the allylic alcohol **21**, which underwent very ready dehydration with rearrangement to give the tricyclic enol ether **27**, which was hydrolyzed to ketone **28***a*. Hydrogenation of **19** gave the dihydro product **30**, which was reduced with zinc amalgam to the ketone **31**. Treatment of the latter with vinyllithium gave the allylic alcohol **32**. This was more stable than its analogue **21**, but underwent hydrolysis and dehydration to the dienone **33**. Treatment of **32** with 2-methyl-1,3-cyclopentanedione (**5**) in the presence of Triton B gave the tricyclic intermediate **35**, its hydrolysis product **36**, and the hydroxy derivative of the latter, **37**. In the absence of base, **32** and **5** gave largely product **36**. Hydrogenation of **36** gave the dihydro product **38**, which on treatment with methanolic potassium hydroxide gave (±)-(1β,4β,5β,8α,9β,10β,13β,14β)-14-hydroxy-1,4-methanoandrostane-7,17-dione (**39**). Dehydration of **39** with *p*-toluenesulfonic acid gave first (±)-(1β,4β,5β,9β,10β,13β)-1,4-methanoandrost-8(14)-ene-7,17-dione (**40**), which was converted in turn to (±)-(1β,4β,5β,8α,9β,10β,13β,14β)-1,4-methanoandrost-15-ene-7,17-dione (**41**). Similar dehydration of **36** gave (±)-(1β,4β,5β,10β,13β,14β)-1,4-methanoandrosta-8,15-diene-7,17-dione (**45**).

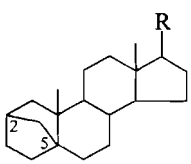
PETER YATES, STEPHEN P. DOUGLAS, SUSHIL K. DATTA et JEFFREY F. SAWYER. Can. J. Chem. **66**, 2268 (1988).

Sous l'action du borohydrure de sodium, l'adduit **17** provenant de la condensation de Diels–Alder du cyclopentadiène sur la méthoxy-2 méthyl-5 benzoquinone-1,4 conduit au cétol **18**; son acétate **19**, par réduction à l'aide de l'amalgame de zinc, conduit à la monocétone **20**. La réaction du composé **20** avec le vinyllithium fournit l'alcool allylique **21** qui se déshydratate facilement, avec une transposition concomitante, pour conduire à l'éther énolique tricyclique **27** qui donne naissance, par hydrolyse, à la cétone **28***a*. L'hydrogénation du composé **19** fournit le composé dihydrogéné **30** qui, par réduction par l'amalgame de zinc, conduit à la cétone **31**. Par réaction avec le vinyllithium, cette dernière donne naissance à l'alcool allylique **32**. Celui-ci est plus stable que son analogue **21**; toutefois, son hydrolyse et sa déshydratation conduisent à la diénone **33**. Le composé **32**, par réaction avec la méthyl-2 cyclopentanedione-1,3 (**5**) en présence de Triton B, fournit l'intermédiaire tricyclique **35** ainsi que son produit d'hydrolyse **36** et le dérivé hydroxylé **37** de ce dernier. En l'absence de base, la réaction des composés **32** et **5** conduit principalement au produit **36**. L'hydrogénation du produit **36** fournit le dérivé dihydrogéne **38** qui, par traitement avec de l'hydroxyde de potassium en milieu méthanolique, conduit à la (±)-(1β,4β,5β,8α,9β,10β,13β,14β)-hydroxy-1,4 méthano-1,4 androstanedione-7,17 (**39**). La déshydratation du composé **39** par de l'acide *p*-toluènesulfonique conduit en premier lieu à la (±)-(1β,4β,5β,9β,10β,13β)-méthano-1,4 androstène-8(14) dione-7,17 (**40**) qui est ensuite transformée en (±)-(1β,4β,5β,8α,9β,10β,13β,14β)-méthano-1,4 androstène-15 dione-7,17 (**41**). Soumis à une déshydratation semblable, le composé **36** fournit de la (±)-(1β,4β,5β,10β,13β,14β)-méthano-1,4 androstadiène-8,15 dione-7,17 (**45**).

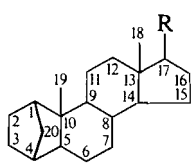
[Traduit par la revue]

Introduction

In our previous work on the synthesis of bridged-ring steroids (2–4) the routes have involved partial synthesis from other steroids. For example, 2,5-carbon-bridged steroids of type **1** have been obtained by introduction of the bridge into a steroid precursor via an ene reaction (3). We now report on the total synthesis of 1,4-carbon-bridged steroids of type **2** via a modified Torgov reaction sequence.



1



2

The conventional Torgov sequence (5, 6) provides a short and efficient route for the synthesis of steroids with an aromatic ring A. Thus treatment of 6-methoxy-1-tetralone (**3**) with vinylmagnesium bromide followed by condensation of the resulting allylic alcohol **4** with 2-methyl-1,3-cyclopentanedione (**5**) in the presence of benzyltrimethylammonium hydroxide (Triton B) gave the dione **6** (Scheme 1), which underwent acid-catalyzed cyclization to the steroid **7**; this was reduced to (±)-estrone methyl ether (**8**) (6). Kuo, Taub, and Wendler (7) showed subsequently that a basic catalyst was not required for the reaction of **4** with **5** to give **6** and that this conversion could best be effected via the isothiuronium salt **9**.[2] Wiechert (8) and Valenta (9) and their co-workers modified the Torgov sequence to make it applicable to the synthesis of non-aromatic ring A steroids; thus dione **10** was converted to the steroid **13** via the allylic halide **11** and trione **12**.

There appeared to us to be two critical features of the original Torgov sequence (5–7): (*i*) ready formation of a cationic intermediate of type **14** that leads to C-12—C-13 bond[3] formation and (*ii*) ready formation of a cationic intermediate of type **15** that results in C-8—C-14 bond formation in the acid-catalyzed cyclization of **6**. In both cases cation formation would be expected to be facilitated by the *p*-anisyl ring. In Valenta's modified sequence (9), the closure of ring C was effected by base-catalyzed aldol condensation involving the anion formed from the trienone system in **12**. It was clear that neither of these

[1]For Part IV see ref. 1*a*; for a preliminary communication concerning part of this work see ref. 1*b*.

[2]The use of such salts is limited, however, because of their insolubility in organic solvents.

[3]Steroid numbering is used throughout this account (cf. **2**).

enabling features could be called into play in the synthesis of a bridged ring A system of type **2**.[4] We therefore devised a further modification of the Torgov synthesis, involving the cation **16** as an intermediate. It was anticipated that this would be readily formed from the allylic alcohol **21** analogous to **4** and that subsequent closure of ring C could be effected by either acid- or base-catalyzed processes.

Results and discussion

Synthesis and rearrangement of the allylic alcohol 21

We synthesized **21** by the route shown in Scheme 2. Compound **17**, the Diels–Alder adduct of 2-methoxy-5-methyl-1,4-benzoquinone (10) and cyclopentadiene (11), was reduced chemospecifically to the alcohol **18** with sodium borohydride in methanol buffered with ammonium chloride, conditions that had previously been used by Cavill and Quinn (12) for the chemoselective reduction of **22** to **23**. The presence of only 13 signals in its ^{13}C nmr spectrum showed that the alcohol **18** was formed as a single diastereomer. The *endo* nature of the hydroxyl substituent was established by the ^{1}H nmr signal arising from the proton at C-6, a broad doublet (J = 10 Hz) at δ4.80. The dihedral angle measured from a model of **18** between the *exo* C-5—H bond and the *exo* C-6—H bond is approximately 0°, indicating that there would be a large coupling between protons with these orientations. Since there is a coupling constant of 10 Hz between the C-5 and C-6 protons the hydroxyl group must have the *endo* configuration. The stereochemistry of **18** was confirmed by its cyclization to an iodo ether (13).

Cavill and Quinn (12) acetylated **23** to form **24** and then removed the acetyloxy group with calcium and liquid ammonia to give **25**. We acetylated **18** to give **19**, which was then treated with calcium and liquid ammonia. However, in the present case the reaction was found to be very capricious, with the yield of **20** varying from 0 to 40%; the low yields appear to result from over-reduction. Attempted reduction of **19** with aluminum amalgam (14), chromous chloride or acetate (15), or zinc in acetic acid (16) was fruitless. Aluminum amalgam gave results similar to those with calcium and liquid ammonia, chromous salts did not effect reduction, and zinc in acetic acid led to hydrolysis of the enol ether function. The chromous salts were prepared by treatment of chromic chloride with an acidic slurry of zinc amalgam. This led us to compare the reduction potentials of Zn(0), Cr(II), and Ca(0). These are in the order Ca > Zn > Cr^{2+} (17), which suggested that zinc amalgam might have a reactivity intermediate between the reactivities of the other two reductants.

We were gratified to find that reaction of **19** with zinc amalgam in mildly acidic aqueous acetone consistently furnished **20** in >95% yield. This reagent could also be used to reduce the alcohol **18** to **20**, but in reduced yield (70%).

The ir, ^{1}H nmr, and ^{13}C nmr spectra of compounds **17**–**20** are compared in Tables 1 and 2 and their relationship may be seen to be in accord with the structural assignments.

Our next goal was the conversion of **20** to the allylic alcohol **21**, by reaction with a suitable vinyl anion equivalent. The original Torgov procedure utilized vinylmagnesium bromide (6). This reagent was found to be completely unreactive with **20**, although it reacted with the enol methyl ether of 1,3-cyclohexanedione. Valenta and co-workers found, in the case of

[4]Although the Wiechert modification (8) might be applicable, the yields reported for this method are very low.

dione **10**, that vinylmagnesium bromide was also unreactive and they devised a modification using lithium acetylide followed by catalytic hydrogenation (9). However, this reagent proved to be completely unreactive with **20**, although the reaction with the enol methyl ether of 1,3-cyclohexanedione proceeded smoothly. We next investigated the use of vinyllithium and, after extensive experimentation, found conditions (see Experimental) under which **20** was quantitatively converted to **21**.

The gross structure of **21** was apparent from its spectra. In its ^{1}H nmr spectrum, the C-methyl and O-methyl signals at δ1.19 and 3.42, respectively, were shifted upfield relative to those of compounds **17**–**20**. The low-field region of the spectrum showed the retention of the norbornene ethylenic proton signals (δ6.03 (m, 2H)) together with signals characteristic of a vinyl group. The product appears to be very largely a single diastereomer. The stereochemistry at C-9 is considered to be that shown in **21**, with attack from the less-hindered *exo* face (cf. the *exo* attack in the reduction of **17** to **18** with sodium borohydride).

The allylic alcohol **21** proved to be very unstable and did not survive even mild heating. A solution of the alcohol in deuterochloroform was left to stand at room temperature; the solution had separated into two phases (aqueous and organic) after 1 day. A new methoxyl signal appeared in the ^{1}H nmr spectrum of the organic product in addition to new vinylic proton signals. Also, a new C-methyl signal appeared at δ1.95, downfield from that of the starting material, indicative of the situation of the methyl group on a double bond or adjacent to a carbonyl group. After several days the methoxyl signal was absent and the spectrum remained constant. A structure, **27**, for the initially formed product consistent with the spectroscopic data and a route leading to its formation are shown in Scheme 3.

It is postulated that **21** is protonated by traces of adventitious acid and that loss of water occurs with cleavage of the bicyclo[2.2.1]heptene system. Reaction of the resulting allylic cation **26** with the enol methyl ether system and loss of a proton would furnish the enol ether **27**.

The ir spectrum (5.80 μm) and the ^{1}H nmr[5] and ^{13}C nmr spectra (Table 3) of the final rearrangement product are in accord with the assignment to it of structure **28***a*. Salient peaks in its mass spectrum are also in consonance with this assignment (Scheme 4). Its formation would result from hydrolysis of the enol ether **27**.

Hydrogenation of **28***a* over 5% palladium on carbon in ethyl acetate gave tetrahydro-**28***a*, in accord with the presence in **28***a* of three ethylenic double bonds, one of which is tetrasubstituted. The product, which is assigned structure **29**, featured only signals for C(sp^3) protons in its ^{1}H nmr spectrum: these included signals attributable to a vinylic methyl group (δ1.79) and the methyl group of a C-ethyl moiety (δ0.95 (t, J = 8 Hz)). A strong band at 5.83 μm was present in its ir spectrum. Its ^{13}C nmr spectrum showed two olefinic carbon signals (both singlets in the SFORD spectrum) instead of the six in the spectrum of **28***a*, and two C-methyl carbon signals corresponding to the methyl proton signals observed in the ^{1}H nmr spectrum.

The formation from **21** of an alternative rearrangement product, **28***b*, can also be envisaged. This could arise from the allylic cation **26**, postulated as an intermediate in the formation of **28***a* (Scheme 5). However, structure **28***a* is favored over **28***b* because of the similarity of the splitting patterns of the signals of the two cyclopentene ethylenic protons in the ^{1}H nmr spectrum of the product.

Our perception that the facile rearrangement of **21** involved the intermediacy of the allylic cation **26** led us to synthesize and investigate the utilization of the allylic alcohol **32**, a dihydro derivative of **21** that would not be expected to undergo such facile opening of the bicyclo[2.2.1]heptane system.

Synthesis of the allylic alcohol 32 and its conversion to 1,4-methano steroids

Acetate **19** was hydrogenated over 10% palladium on carbon to give **30**, which was treated with zinc amalgam to produce **31** (Scheme 6). The ir spectrum of **30** showed strong absorption bands at 5.73 and 6.18 μm, which are assigned to the ester and enone carbonyl-stretching frequencies, respectively. The ^{1}H nmr spectrum of **30** displayed the signal of the proton under the acetoxyl group as a multiplet at δ5.91. The enol ether vinyl proton gave rise to a doublet (J = 2 Hz) at δ5.35 and the signal of the methoxyl protons was little changed from its position in **19** at δ3.70. The signal for the acetyl methyl protons appeared at δ2.15 and the C-methyl protons gave rise to a singlet at δ1.22.

[5] Spin-decoupling experiments at 200 MHz confirmed many of the assignments (13).

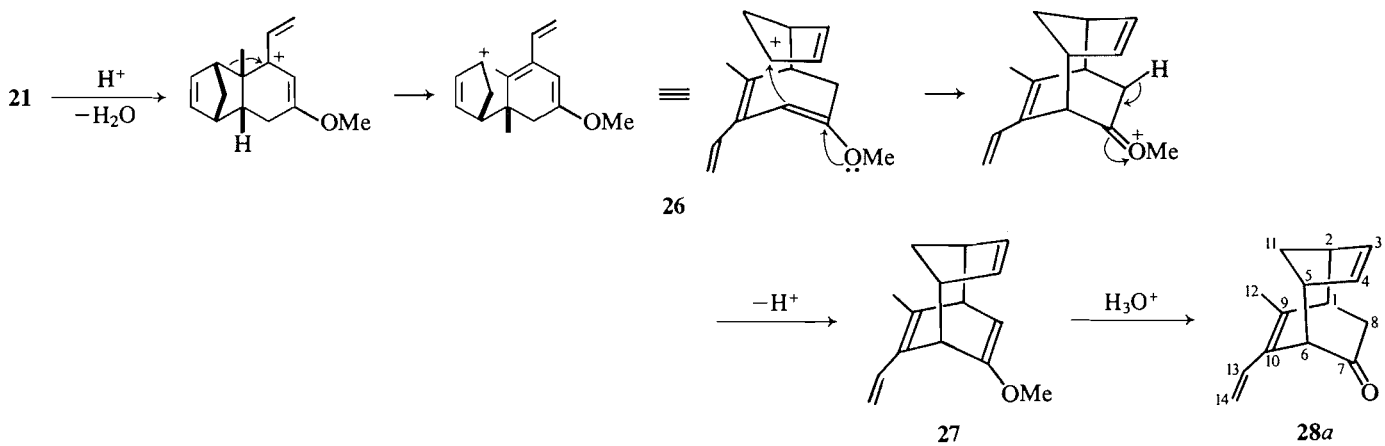
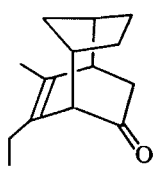
[b]Bands are strong unless otherwise indicated.
[c]Signals are multiplets unless otherwise indicated, and their relative areas are in accord with the assignments; overlapping signals within a given spectrum are indicated with asterisks; *J* values are in Hz.



SCHEME 3

The conversion of **30** to **31** was made apparent by the absence of the acetyl methyl signal in the ^{1}H nmr spectrum of the latter. The enol ether vinyl proton signal appeared as a broad singlet at δ5.41, the methoxyl protons gave rise to a singlet at δ3.71, and the signal for the C-methyl protons appeared as a singlet at δ1.21. The ir spectrum of **31** displayed a strong band at 6.17 μm.



29

Reaction of **31** with vinyllithium under the same conditions as those used with **20** gave allylic alcohol **32** in excellent yield. The ^{1}H nmr spectrum of **32** established the completeness of the reaction by the absence of the signal of the methoxyl group at δ3.71 and its replacement with a methoxyl signal at δ3.50. Other assignable signals included a doublet of doublets (J_{AX} ~ 16 Hz, J_{MX} ~ 10 Hz) at δ5.70 arising from the X proton of the vinyl AMX system, a doublet of doublets (J_{AM} ~ 2 Hz) at δ5.01 from the A proton, a doublet of doublets at δ4.80 from the M proton, a doublet (J = 2 Hz) at δ4.54 arising from the

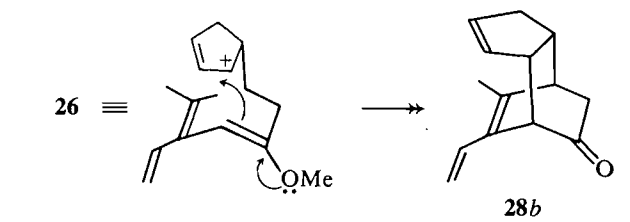
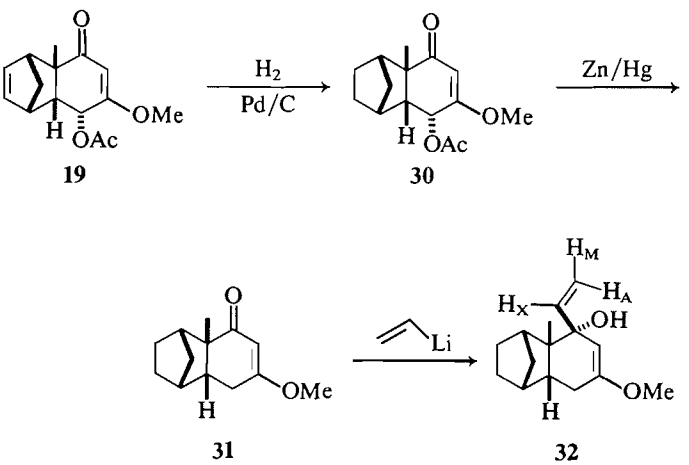
enol ether vinyl proton, and a singlet at δ0.95 from the C-methyl group. Medium absorption at 5.99 μm in the ir spectrum of **32** is assigned to the double bond stretching vibrations.

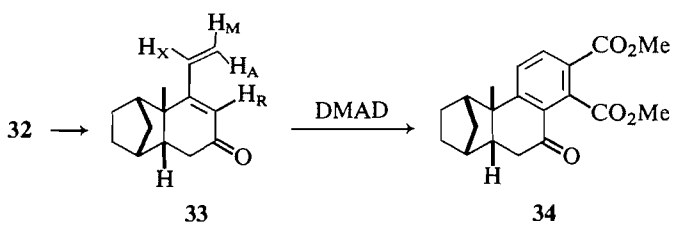
We were happy to find that allylic alcohol **32** was not only more stable than **21** but that it reacted as desired with dione **5** (*vide infra*). However, **32** was readily converted to dienone **33**



SCHEME 5



SCHEME 6



SCHEME 7

upon attempted purification (Scheme 7). The ^1H nmr spectrum of **33** displayed a complex olefinic region from which could be extracted the signal for H_X at δ6.35 (J_{AX} ~ 16 Hz, J_{MX} ~ 10 Hz), H_A at δ5.68 (J_{AM} = 2 Hz), H_M at δ5.34, and H_R at δ6.19. A C-methyl singlet at δ1.12 was the only other assignable peak. Its ir spectrum displayed a carbonyl-stretching band at 6.04 μm with a shoulder at 6.17 μm. The ultraviolet spectrum of **33** indicated that the unsaturated system was in the *s-cis* conformation, based on the magnitude of the extinction coefficient (18) of the maximum at 244 nm (ε = 5800); the n → π* absorption band appeared at 332 nm (ε = 120).

Heating a mixture of **33** with dimethyl acetylenedicarboxyl-

ate (DMAD) in benzene at 100°C for 15 h gave the aromatic product **34** in low yield together with several other compounds that were not isolated (Scheme 7). Compound **34** must arise by oxidation of the initially formed cycloadduct of the 1,3-diene **33**.

In view of the poor yield obtained in this Diels–Alder reaction of **33** we elected not to investigate an approach to steroid synthesis (19) that utilizes this method. We did explore the possibility of a Michael addition reaction of dione **5** to the dienone **33** as the key reaction to form an ABD steroid skeleton, a type of reaction for which precedent exists (20). However, attempts to catalyze the reaction with bases (21) and with potassium fluoride (22) were uniformly unsuccessful, as was the titanium(IV) chloride-mediated reaction (23) with the trimethylsilyl enol ether of **5**.

We therefore returned to the Torgov-type reaction and treated alcohol **32** with a slight excess of dione **5** in boiling toluene in the presence of a trace of Triton B, and obtained **35** and its hydrolysis product **36** in poor yield, together with a third product (**37**, *vide infra*) (Scheme 8). When the reaction was carried out in *tert*-butyl alcohol and xylenes in the absence of Triton B the main product isolated was **36**, which was obtained in 73% overall yield from **31**.

The ^{1}H nmr spectrum of **35** featured a one-proton, broad singlet at δ5.55 assigned to the C-8 proton. The C-11 proton gave rise to a triplet (J = 8 Hz) at δ4.82. The signal for the methoxyl protons appeared at δ3.73 and the signals for the two C-methyl groups at δ1.16 and 1.14. The four cyclopentanedione methylene protons are accidentally equivalent at δ2.67. The ir spectrum of **35** displayed a strong carbonyl-stretching band at 5.80 μm and a medium dienol ether band at 6.08 μm.

The ^{1}H nmr spectrum of the trione **36** displayed a signal for the vinyl proton as a broad singlet at δ5.85, a singlet for the cyclopentanedione protons at δ2.77, and a six-proton C-methyl singlet at δ1.16. Its ir spectrum showed strong stretching bands for the enone and the cyclopentanedione carbonyl groups at 6.02 and 5.80 μm, respectively.

The third product from the reaction carried out in the presence of Triton B is considered to have structure **37**. Exact mass measurement showed that it differed in composition from compound **36** by the presence of an additional oxygen atom. This fact and comparison of its ir and ^{1}H nmr spectra (see Experimental) and its ^{13}C nmr spectrum with those of **36** (Table 4) led to the conclusion that it was a hydroxy derivative of **36**. The presence of the hydroxyl group was confirmed by its conversion to an acetate. A heteronuclear correlation (HETCOR) nmr experiment (24) was performed[6] to determine the position of the hydroxyl group. The direct correlation chart established the direct ^{1}H–^{13}C connectivity ($^1J_{CH}$) of the proton signal at δ4.0, arising from attachment to the carbon atom bearing the hydroxyl group, and the carbon signal at δ70.0. The indirect correlation chart established the indirect ^{1}H–^{13}C connectivity ($^2J_{CH}$ or $^3J_{CH}$) of the carbonyl carbon signal at δ200.4 and the proton signal at δ4.0. Thus the hydroxyl group is located on C-6, next to the carbonyl carbon C-7.

The origin of **37** is problematic. It cannot arise from "carry through" of the hydroxyl group in **18**, since intermediates in the sequence were purified. Thus it must arise via oxidation during the reaction of **31**, but the nature of the oxidation process is uncertain. In the absence of Triton B no **37** was formed. Since the hydrolysis product **36**, which is needed for the next step, is the major product under the latter conditions, these are clearly to be preferred.

[6]We thank Mr. N. Plavac and Professor W. F. Reynolds for their assistance in this experiment.

[b]See footnote *b* in Table 2.
[c]See footnote *d* in Table 3.

Hydrogenation of **36** gave a dihydro compound that is assigned structure **38** on the basis of spectroscopic data and the fact that a molecular model indicates that the less-hindered side of the cyclohexene ring is the β face. The ^{1}H nmr spectrum of **38** featured the cyclopentanedione proton signal at δ2.77 and the signals of the two C-methyl groups at δ1.14 ppm and 1.05. Its ir spectrum displayed bands for the carbonyl groups at 5.79 μm (cyclopentanedione) and 5.84 μm (cyclohexanone).

A methanolic solution of compound **38** was stirred at 70°C overnight in the presence of a catalytic amount of potassium hydroxide. Upon work-up, compound **39** (Scheme 9), the first 1,4-methano bridged steroid to be synthesized, was obtained as a white crystalline solid. The prominent features of the ^{1}H nmr spectrum of **39** were the singlets for the two methyl groups at δ1.00 and 1.09. Its ir spectrum showed a hydroxyl stretching band at 3.00 μm, and carbonyl-stretching bands at 5.76 μm (cyclopentanone) and 5.90 μm (cyclohexanone). The spectra of **39** and related compounds are compared in Tables 5 and 6 (*vide infra*).

Examination of molecular models suggested that of the four possible transition states for carbon–carbon bond formation in the aldol reaction leading from **38** to the steroid, the one giving the diastereomer depicted as **39** is freest of steric interactions (13). Since this diastereomer also appears to be thermodynamically favored, we tentatively assigned the relative configura-

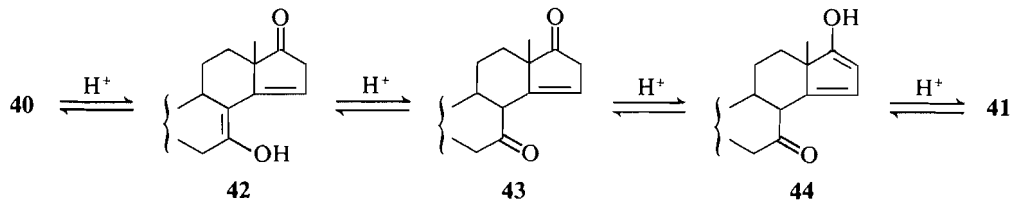
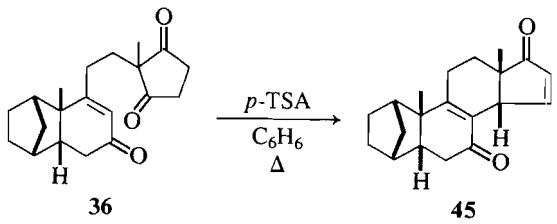


SCHEME 11



SCHEME 12

systems. The single, carbonyl-stretching band in the spectrum of **41**, which is very strong, can be attributed to overlap of bands arising from the cyclohexanone and 2-cyclopentenone systems. Both compounds show ethylenic stretching bands, with that of **40** being unusually strong as expected for an *s-cis*-2-enone (26). Prominent features in the ^{1}H nmr spectra of **40** and **41** are given in Table 5. The former shows the presence of the two angular methyl groups and the absence of vinyl protons. The latter again shows the presence of the two angular methyl groups and also two vinyl protons with signals at δ6.11 and 8.13, assigned to the C-16 and C-15 protons, respectively. The unusually low-field position of the latter is attributable to anisotropic deshielding by the carbonyl group at C-7. The vicinal coupling constant ($J_{15,16}$) of the vinyl protons is 5.8 Hz, while the values for $J_{14,15}$ and $J_{14,16}$ are 2.7 and 1.7 Hz, respectively (cf. the corresponding values for 2-cyclopentenone (5.5, 2.7, and 1.5 Hz)). The ^{13}C nmr spectra of **40** and **41** are compared with the spectrum of **39** in Table 6, and corroborate the structural assignments (*vide infra*).

The conversion of **39** to **40** clearly involves conventional acid-catalyzed dehydration of an aldol via the α-enol of the β-hydroxy ketone system. The subsequent conversion of the $\Delta^{8(14)}$ 7-keto compound **40** to the Δ^{15} 17-keto compound can readily be interpreted as involving acid-catalyzed isomerization of the enol **42** of **40** to the 3-ene-1,6-dione **43** followed by isomerization of this via the enol **44** to **41** (Scheme 11). It is of interest that the 2-cyclopentenone **41** with a disubstituted ethylenic double bond is favored over the 2-enone **40** with a tetrasubstituted ethylenic double bond.

It may be noted that there is no facile acid-catalyzed route for the isomerization of **40** to the corresponding $\Delta^{8(9)}$ 7-keto steroid.

Finally, we investigated the acid-catalyzed cyclization of the enetrione **36**, the immediate precursor of the trione **38**. Treatment with *p*-toluenesulfonic acid in boiling benzene gave a product that is assigned structure **45** (Scheme 12). Its uv spectrum showed a single maximum at 235 nm, which is considered to result from overlap of maxima arising from the two 2-en-1-one systems. As expected for such overlap, the band is exceptionally wide with the width at half-height ($W_{1/2}$) equal to 50 nm (for compound **40**, $W_{1/2}$ = 30 nm).[7] In its ir spectrum **45** shows 2-cyclopentenone and 2-cyclohexenone carbonyl-stretching bands at 5.84 and 6.04 μm, respectively, together with two weak ethylenic double bond stretching bands at 6.14 and 6.24 μm. Its ^{1}H nmr spectrum shows prominent signals analogous to those observed in the spectrum of **41**. These are again assigned to the two angular methyl groups and the unsubstituted 2-cyclopentenone system. In the present case the interpretation of the coupling pattern of the vinyl protons (Table 6) was corroborated by a decoupling experiment. Irradiation at the frequency of a one-proton multiplet at δ3.93, which is assigned to the C-14 proton, led to the collapse of each of the vinyl proton signals to a doublet with J = 5.6 Hz, confirming that the fine splitting of each vinyl proton signal in the original spectrum arises from coupling with the C-14 proton. The relative stereochemistry of **45** has not been established unambiguously since it cannot be excluded that the relative configurations at C-13 and C-14 are different from those in **39**.

Compound **45** is considered to arise via enolization of **36** to **46** and acid-catalyzed cyclization of this to the aldol **47** (Scheme 13); dehydration would then lead to the dienedione **48**, which could lead as in Scheme 11 to the 3-cyclopentenone **49**. Two acid-catalyzed enolizations of this would lead to the bis 3-enone system of **45**. In this case the $\Delta^{8,15}$ 7,17-diketo steroid is preferred to the $\Delta^{8,9}$ 7,17-diketo steroid **48**. This can be attributed at least in part to the greater degree of conjugation in **45**. It may be noted that here there is no facile route for the acid-catalyzed conversion of the $\Delta^{8(9)}$ 7-keto system of **45** to the corresponding $\Delta^{8(14)}$ 7-keto system.

The bridged steroids **39–41** and **45** we have described all have an "unnatural" *syn* relationship between the C-19 methyl group (at C-10) and the C-9 hydrogen atom. This, combined with the *cis* A/B ring fusion and the ring A bridge, results in an unusually compact stereostructure (cf. **50** ≡ **39**). It seems probable that our general method can be adapted in its later stages for the synthesis of other types of stereoisomer. Thus, for example, reduction of **36** with reducing metals rather than by hydrogenation could lead to products with an *anti* relationship between the C-19 methyl group and the C-9 hydrogen atom.

Experimental

Melting points were determined with a Thomas Hoover capillary melting point apparatus and are uncorrected.

Infrared (ir) spectra were obtained from solutions in chloroform, unless otherwise specified. Band positions in microns (μm) are reported relative to the 6.24-μm band of polystyrene; unless denoted as medium (m) or weak (w), their intensities are strong. Ultraviolet (uv) spectra were recorded in 95% ethanol. Proton magnetic resonance (^{1}H nmr) spectra of solutions in deuterochloroform (unless otherwise specified) were acquired at 60 MHz and at 200 MHz. Signal positions are reported on the delta (δ) scale in parts per million (ppm) downfield from tetramethylsilane as internal standard; coupling constants, J, are reported in hertz (Hz). Carbon-13 magnetic resonance (^{13}C nmr) spectra were acquired from deuterochloroform solutions, unless otherwise specified, on a Varian CFT-20, XL-200, or XL-400 spectrometer. The chemical shifts, obtained in the proton noise-decoupled mode, are reported on the delta scale in ppm and are referenced to the signal

[7]The value for the extinction coefficient is lower than might be expected for the overlap of the two chromophores; this is attributable to deviation from coplanarity of the 2-cyclohexen-1-one system.

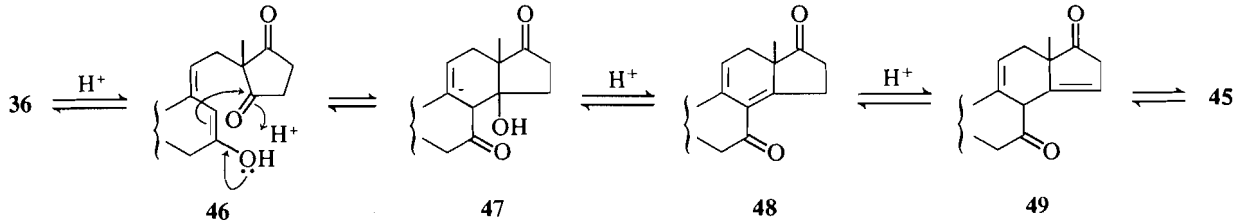
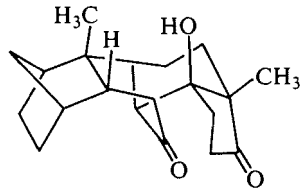


SCHEME 13



50

for the middle line of $CDCl_3$ at 77.9 ppm. Signal multiplicities were determined from the single-frequency off-resonance decoupled (SFORD) spectra (CFT-20) or from APT or DEPT experiments (XL-200 and XL-400).[8]

Low resolution mass spectra were recorded at 70 eV with a Bell and Howell CEC 21-490 single focussing mass spectrometer. Peak positions are reported in mass-to-charge units (m/z) followed by the relative abundances in parentheses. Exact mass measurements were determined from high resolution mass spectra obtained on a AEI MS-3074 double focussing mass spectrometer with a DS-50 data system.

The apparatus for reactions performed under anhydrous conditions was either oven-dried for at least 24 h at 110°C or flame-dried and then cooled in a desiccator prior to assembly. Argon (99.99%, supplied by Canox) was used as an inert atmosphere.

Analytical thin-layer chromatography was carried out on aluminum-backed plates that had been pre-coated with 0.20 mm of silica gel 60 containing a fluorescent indicator (Merck). Preparative thin-layer chromatography was performed on 20 × 20 cm plates coated with 2 mm of silica gel 60 containing a fluorescent indicator (Merck). Compound visualization was effected by ultraviolet light. On the preparative scale, bands were scraped off the plate and stirred with methanol for at least 0.5 h, and the extracts were filtered and concentrated. The compounds were isolated from the residue by solution in dichloromethane followed by filtration and concentration. Silica gel (grade 923, 100–200 mesh, Grace Davison) was used for column chromatography. Flash chromatography was carried out on 40–60 μm silica gel (Merck grade 60, 230–400 mesh, 60 Å mean pore diameter).

2-Methoxy-5-methyl-1,4-benzoquinone

The title compound was synthesized by the method of Woodward *et al.* (10); mp 175–177°C (lit. (10) mp 174–175.5°C); ir λ_{max}: 5.98, 6.08, 6.26 μm; ^{1}H nmr δ: 2.07 (d, J = 2 Hz, 3H), 3.83 (s, 3H), 5.91 (s, 1H), 6.53 (q, J = 2 Hz, 1H).

Diels–Alder reaction of cyclopentadiene with 2-methoxy-5-methyl-1,4-benzoquinone. Formation of ***17***

A solution of cyclopentadiene (100 mL, 1.21 mmol) and 2-methoxy-5-methyl-1,4-benzoquinone (35.0 g, 0.23 mmol) in hexanes (1000 mL) and ethyl acetate (500 mL) was boiled under reflux for 24 h. Additional cyclopentadiene (20 mL) was added and the mixture was heated for another 24 h. The mixture was concentrated and dicyclopentadiene was removed by high vacuum pumping at 40°C. The crude solid product was recrystallized from ethyl acetate/hexanes to give **17** in 87% yield; mp 118–120°C (lit. (11) mp 119–120°C).

When the reaction was carried out in boiling chloroform for 24 h and the reaction mixture was worked up in similar fashion, **17**, mp 119–120°C, was obtained in 93% yield.

[8]Spectroscopic data for many of the products are given in the Discussion or the tables.

Reduction of ***17*** *with sodium borohydride. Formation of ketol* ***18***

Sodium borohydride (1.10 g, 26.8 mmol) was added in small portions to a chilled (ice bath), stirred solution of diketone **17** (15.00 g, 68.7 mmol) and ammonium chloride (1.51 g, 28.2 mmol) in methanol (250 mL). The cooling bath was removed after the completion of addition and the mixture was stirred for an additional 30 min. Water (1500 mL) was added and multiple extractions with dichloromethane yielded, after concentration, ketol **18** as a white solid (14.86 g, 98%), which was recrystallized from acetone; mp 121–123°C. *Anal.* calcd. for $C_{13}H_{16}O_3$: C 70.89, H 7.32; found: C 70.77, H 7.32.

Acetylation of ***18****. Formation of acetate* ***19***

A mixture of alcohol **18** (6.50 g, 29.5 mmol) and freshly distilled acetic anhydride (3.82 mL, 40.5 mmol) in pyridine (25 mL) was treated with a crystal of 4-(dimethylamino)pyridine and stirred for 24 h. High vacuum pumping removed all unconsumed reagent and solvent to leave a solid, which was recrystallized from acetone/hexanes to give **19** (6.50 g, 90%) as colorless rods, mp 74–76°C. *Anal.* calcd. for $C_{15}H_{18}O_4$: C 68.68, H 6.92; found: C 68.36, H 6.88.

Reduction of ***19*** *with zinc amalgam. Formation of enone* ***20***

To a rapidly stirred solution of mercuric chloride (1.60 g, 5.89 mmol) in water (40 mL) was added concentrated hydrochloric acid (2 mL) and then zinc dust (20.9 g) in small portions (0.25 g). The cloudy mixture resulting after each addition was allowed to clarify and the resulting solid was crushed with a glass rod to prevent aggregation. After half the zinc was added the quantity of each addition could be doubled and the solid amalgam was checked periodically for the formation of large particles. The suspension was stirred for 15 min; the aqueous layer was decanted and the fluffy amalgam was washed several times with water. Water (50 mL) and hydrochloric acid (1.75 mL, 21.0 mmol) were added to the amalgam and the mixture was chilled in an ice bath. A solution of acetate **19** (1.40 g, 5.35 mmol) in acetone (50 mL) was added, the cooling bath was removed, and the reaction mixture was stirred for 20 min. The liquid phase was decanted, the amalgam was washed with acetone, and the combined liquid phases were concentrated. The product was isolated from the resulting concentrate by extraction with dichloromethane. The dichloromethane was evaporated giving **20** (1.01 g, 93%) as an oil, which crystallized from hexanes; mp 64.5–65.5°C. *Anal.* calcd. for $C_{13}H_{16}O_2$: C 76.44, H 7.90; found: C 76.06, H 7.90.

Addition of vinyllithium to ***20****. Formation of* ***21***

To a magnetically stirred solution of vinyl bromide (1 mL, ~14 mmol) in ether (30 mL) at −78°C in a Dry Ice/acetone bath was added dropwise 2.0 M *tert*-butyllithium (10.0 mL, 20 mmol). The mixture was stirred for 40 min and a solution of ketone **20** (0.403 g, 1.97 mmol) in ether (25 mL) was added slowly. The Dry Ice/acetone bath was replaced with a Dry Ice/carbon tetrachloride bath and the reaction mixture was stirred for 1 h at −23°C. The temperature of the mixture was lowered again to −78°C with a Dry Ice/acetone bath, and acetic acid (1.2 mL, 21 mmol) was added slowly. The cooling bath was removed after 30 min and the mixture was allowed to warm up. At ~0°C saturated aqueous sodium bicarbonate (20 mL) was added and the layers were separated. The aqueous phase was extracted with ether (2 × 5 mL) and the combined organic phases were concentrated after the addition of benzene (100 mL) to give the allyl alcohol **21** as an oil; ^{1}H nmr δ: 1.0–2.8 (m, 8H), 1.19 (s, 3H), 3.42 (s, 3H), 4.37 (s, 1H), 4.85 (dd, J = 14, 2 Hz, 1H), 5.06 (dd, J = 10, 2 Hz, 1H), 5.86 (dd, J = 14, 10 Hz, 1H), 6.03 (m, 2H).

*Rearrangement of **21**. Formation of **27** and **28**a*

A solution of allylic alcohol **21** in deuterochloroform on standing for 1 day gave an initial product, **27**, as an oil, showing new C-methyl, methoxyl, and vinyl proton signals in its ^{1}H nmr spectrum. On standing for several days this gave the final product, ***28a***, in quantitative yield as a viscous oil; this was also obtained on treatment of **21** with wet silical gel in methanol; ms *m/z*: 200 (31), 135 (100). *Exact Mass* calcd. for $C_{14}H_{16}O$: 200.1201; found: 200.1205.

*Hydrogenation of **28**a. Formation of **29***

A solution of triene ***28a*** (0.036 g, 0.18 mmol) in ethyl acetate (10 mL) was hydrogenated over 5% palladium on carbon (0.008 g) at atmospheric pressure until uptake of hydrogen ceased. The mixture was filtered through Celite and concentrated to give **29** (tetrahydro-***28a***) as an oil; ms *m/z*: 204 (M; 22), 162 (98), 133 (100).

*Hydrogenation of acetate **19**. Formation of **30***

A stirred mixture of acetate **19** (4.46 g, 17.0 mmol) and 10% palladium on carbon (0.22 g) in ethyl acetate (200 mL) was hydrogenated at atmospheric pressure until no more hydrogen was taken up. The solution was filtered through Celite and concentrated to give **30** (4.40 g, 98%) as a solid, which was recrystallized from acetone/hexanes; mp 76–78°C. *Anal.* calcd. for $C_{15}H_{20}O_4$: C 68.16, H 7.63; found: C 68.31, H 7.63.

*Reduction of **30** with zinc amalgam. Formation of enone **31***

The amalgam was prepared as described above by adding zinc dust (44.0) to mercuric chloride (3.55 g, 13.1 mmol) in water (150 mL) containing concentrated hydrochloric acid (4.4 mL). To the freshly prepared amalgam was added water (60.0 mL) and concentrated hydrochloric acid (2.23 mL, 26.8 mmol). The stirred mixture was chilled (ice bath) and a solution of the acetate **30** (2.98 g, 11.3 mmol) in acetone (40 mL) was added. The cooling bath was removed and the reaction mixture was stirred vigorously for 30 min. The reaction mixture was filtered and the amalgam was washed with acetone (25 mL). The combined liquid phases were concentrated and enone **31** was recovered (2.00 g, 86%) as an oil from the resulting solution by multiple extraction with dichloromethane followed by concentration. *Exact Mass* calcd. for $C_{13}H_{18}O_2$: 206.1307; found: 206.1303.

*Addition of vinyllithium to **31**. Formation of **32***

To a stirred solution of vinyl bromide (2.1 mL, 30 mmol) in ether (20 mL) under argon cooled in a Dry Ice/acetone bath was added dropwise 1.7 M *tert*-butyllithium (5.88 mL, 10 mmol). After 70 min a solution of ketone **31** (0.538 g, 2.56 mmol) in ether (40 mL) was added slowly. The Dry Ice/acetone bath was removed and replaced with a Dry Ice/carbon tetrachloride bath and the mixture was stirred for 1 h. The Dry Ice/acetone bath was restored and after 5 min acetic acid (2.06 mL, 46 mmol) was added. The cooling bath was removed after the reaction mixture had been stirred for 0.5 h and, when the temperature of the solution was between −20 and 0°C, saturated aqueous sodium bicarbonate (10 mL) was added. The aqueous layer was extracted with ether and the combined organic phases were dried (Na_2SO_4). Removal of the solvent gave **32** as an oil (0.40 g), which was used without further purification.

*Hydrolysis of **32**. Formation of **33***

Attempted purification of the above product **32** by chromatography on silica gel with elution with ethyl acetate/hexanes led to the formation of dienone **33** as an oil. *Exact Mass* calcd. for $C_{14}H_{18}O$: 202.1353; found: 202.1339.

*Diels–Alder reaction of **33** and dimethyl acetylenedicarboxylate. Formation of **39***

A mixture of dienone **33** (0.176 g, 0.87 mmol) and dimethyl acetylenedicarboxylate (0.214 mL, 1.74 mmol) in benzene (10 mL) was sealed in a glass-lined stainless steel reaction vessel with a Teflon-lined bronze screw-cap and heated for 15 h at 95°C. Solvent and unconsumed dienophile were removed under high vacuum to give a mixture of compounds, which were separated on a preparative tlc plate with elution with 30% ethyl acetate in hexanes. The fraction with R_f 0.3–0.4 was collected to give **34** (0.03 g, 10%) as an oil; ir λ_{max}: 5.77, 5.89 μm; ^{1}H nmr δ: 1.0–2.8 (m, 11H), 1.37 (s, 3H), 3.85 (s, 3H), 3.95 (s, 3H), 7.39 (d, *J* = 8 Hz, 1H), 8.10 (d, *J* = 8 Hz, 1H). *Exact Mass* calcd. for $C_{20}H_{22}O_5$: 342.1461; found: 342.1450.

*Torgov reaction of **32** and 2-methyl-1,3-cyclopentanedione (**5**). Formation of **35**, **36**, and **37***

(i) In the presence of Triton B

To a mixture of crude allylic alcohol **32** (0.23 g, 1.0 mmol) and dione **5** (0.171 g, 1.5 mmol) in toluene (30 mL) was added 40% methanolic Triton B (55 μL; 0.1 mmol). The mixture was boiled gently under reflux for 15 h, cooled, and then washed with aqueous 5% potassium hydroxide (5 mL) and water (5 mL). After concentration the residual reaction product was chromatographed (silica gel, 30% ethyl acetate in hexanes) to give first dienol ether **35** as an oil (0.060 g, 18%) with R_f 0.48.

Trione **36** was next eluted as an oil (0.082 g, 26%) with R_f 0.16. *Exact Mass* calcd. for $C_{20}H_{26}O_3$: 314.1882; found: 314.1841.

The third component, **37**, of the reaction mixture was the most polar fraction; it was recovered as an oil (0.042 g, 14%); ir λ_{max}: 2.89 (w), 5.81, 5.98 μm; ^{1}H nmr δ: 1.1–2.6 (m, 13H), 1.14 (s, 3H), 1.18 (s, 3H), 2.78 (s, 4H), 3.22 (m, 1H, OH), 4.04 (d, *J* = 7 Hz, 1H), 5.81 (br s, 1H). *Exact Mass* calcd. for $C_{20}H_{26}O_4$: 330.1831; found: 330.1824.

(ii) In the absence of Triton B

To a mixture of crude allylic alcohol **32** (0.508 g, 2.17 mmol) and dione **5** (0.359 g, 3.2 mmol) were added dry *tert*-butyl alcohol (4 mL) and dry xylene (4 mL) and the mixture was boiled under reflux for 40 h under argon. The reaction mixture was cooled, diluted with ether, and washed with aqueous 5% potassium hydroxide. The organic solution was dried (Na_2SO_4) and the solvent was evaporated to afford a thick, pale yellow oil (0.620 g, 91%). Purification by preparative thin-layer chromatography with elution with hexane/ethyl acetate (7:3 v/v) gave **36** (R_f 0.16; 0.500 g, 73%).

*Acetylation of **37**. Formation of **37**-acetate*

A mixture of alcohol **37** (0.20 g, 0.605 mmol) and acetic anhydride (5 mL) in pyridine (10 mL) was treated with a crystal of 4-(dimethylamino)pyridine and was stirred for 15 h. Unconsumed acetic anhydride and pyridine were removed under high vacuum and the resulting oil was dissolved in dichloromethane. The solution was washed with dilute hydrochloric acid and concentrated to give ***37-acetate*** as an oil; ir λ_{max}: 5.77 μm; ^{1}H nmr δ: 1.2–2.7 (m, 13H), 1.19 (s, 6H), 2.10 (s, 3H), 2.79 (s, 4H), 5.11 (d, *J* = 7 Hz, 1H), 5.81 (br s, 1H).

*Hydrogenation of **36**. Formation of **38***

A mixture of enone **36** (0.314 g, 1.00 mmol) and 10% palladium on carbon (0.02 g) in ethanol (100 mL) was hydrogenated at atmospheric pressure until the calculated amount of hydrogen had been taken up (16 h). The catalyst was removed by filtration through Celite and the solution was concentrated to give **38** in quantitative yield as an oil; ms *m/z*: 316 (M; 23), 204 (100).

*Base treatment of **38**. Formation of (1β,4β,5β,8α,9β,10β,13β,14β)-14-hydroxy-1,4-methanoandrostane-7,17-dione[9] (**39**)*

To a solution of **38** (0.316 g, 1.00 mmol) in methanol (150 mL) was added potassium hydroxide (0.060 g, 1.1 mmol) and the mixture was heated to 75°C for 15 h under argon. The solvent was evaporated and water was added to the residue. The mixture was extracted with benzene. The combined extracts were washed with aqueous potassium bicarbonate, dried, and concentrated to give **39** as a white solid (0.316 g, 100%), mp 209–211°C, which was crystallized from methanol; mp 210–212°C. *Anal.* calcd. for $C_{20}H_{28}O_3$: C 75.91, H 8.92; found: C 75.65, H 9.02.

[9]Formally, compounds **39–41** and **45** should be named as cyclopentaphenanthrene derivatives. We consider it preferable, however, to expand the meaning of "androstane" to include variations in configuration at all of its chiral centers and to use this expanded version as a basis for naming steroids of the type synthesized in the present work.

Dehydration of ***39***

*(i) Formation of (±)-(1β,4β,5β,9β,10β,13β)-1,4-methanoandrost-8(14)-ene-7,17-dione (**40**)*

A solution of **39** (0.143 g, 0.45 mmol) and anhydrous *p*-toluenesulfonic acid (0.0774 g, 0.45 mmol) in dry benzene (15 mL) was boiled at reflux under argon for 24 h. The reaction mixture was cooled to room temperature and poured into water (10 mL). The layers were separated and the aqueous phase was extracted with ether (3 × 10 mL). The combined organic layers were washed with water (3 × 10 mL), saturated aqueous sodium bicarbonate (10 mL), and saturated aqueous sodium chloride (10 mL). The solution was dried (Na_2SO_4) and concentrated to give a thick semisolid residue (0.130 g), which on trituration with ether gave **40** as a white solid (0.060 g), mp 153–154°C. Preparative thin-layer chromatography on silica of the solid from the ethereal extract with hexanes/ethyl acetate (7:3 v/v) as eluent provided additional product (0.21 g; total yield 60%), mp 153–154°C. Recrystallization from aqueous methanol afforded **40** as white crystals, mp 155–156°C. *Anal.* calcd. for $C_{20}H_{26}O_2$: C 80.49, H 8.78; found: C 80.25, H 9.08.

A small amount of a second product could be detected in the ^1H nmr spectrum of the crude product. This was subsequently identified as **41** (*vide infra*).

*(ii) Formation of **40** and (±)-(1β,4β,5β,8α,9β,10β,13β,14β)-1,4-methanoandrost-15-ene-7,17-dione (**41**)*

A solution of **39** (0.100 g, 0.316 mmol) and anyhydrous *p*-toluenesulfonic acid (0.172 g, 1.00 mmol) in dry benzene (15 mL) was boiled under reflux for 48 h under argon. Work-up as in (*i*) gave a pale yellow semisolid residue (0.090 g). Purification by preparative thin-layer chromatography on silica with elution with hexanes/ethyl acetate (7:3 v/v) gave **41** (R_f 0.31), which was crystallized from aqueous methanol to give white needles (0.045 g, 48%), mp 170–171°C. *Anal.* calcd. for $C_{20}H_{26}O_2$: C80.49, H 8.78; found: C 80.49, H 8.80.

Compound **40** (0.035 g, 37%) crystallized out from the mother liquor on standing at room temperature as white crystals, mp 154–155°C. The ir and nmr spectra of this product were identical with those of the product that was obtained by procedure (*i*).

*Acid treatment of **36**. Formation of (±)-(1β,4β,5β,10β,13β,14β)-1,4-methanoandrosta-8,15-diene-7,17-dione (**45**)*

A solution of **36** (0.50 g, 1.59 mmol) and anhydrous *p*-toluenesulfonic acid (0.11 g) in dry benzene (50 mL) was boiled under reflux for 24 h under argon. After cooling to room temperature, the solution was poured into water (25 mL). The aqueous phase was extracted with ether (3 × 20 mL). The combined organic layers were washed with water (3 × 15 mL), saturated aqueous sodium bicarbonate (20 mL), and saturated aqueous sodium chloride (15 mL). The solution was dried (Na_2SO_4) and evaporated to give a light brown oil (0.43 g). Preparative thin-layer chromatography on silica with hexanes/ethyl acetate (7:3 v/v) as eluent gave crystalline **45** (R_f 0.28; 0.25 g, 53%), mp 147–149°C. Recrystallization from methanol gave **45** as white crystals, mp 149–150°C. *Anal.* calcd. for $C_{20}H_{24}O_2$: C 81.04, H 8.16; found: C 80.69, H 8.29.

Ab initio molecular orbital and Møller–Plesset perturbation theory calculations have been carried out on two model dithiatriazines RCN_3S_2 (R = H, NH_2). With geometry optimization and the inclusion of electron correlation both of these dithiatriazines are predicted to be ground state singlets. Both molecules have low-lying triplet excited states, with energy gaps of 6.6 (R = H) and 13.0 (R = NH_2) kcal mol^{-1}. The singlet dithiatriazines distort from high (C_{2v}) to low (C_s) symmetry, and these changes are important in determining the relative energies of the singlet and triplet molecules. The structural distortions experienced by these molecules are related to Hartree–Fock and Jahn–Teller instabilities in other thiazene heterocycles.

R. E. HOFFMEYER, W.-T. CHAN, J. D. GODDARD et R. T. OAKLEY. Can. J. Chem. **66**, 2279 (1988).

On a effectué des calculs d'orbitales moléculaires *ab initio* et d'autres calculs suivent la théorie des perturbations de Møller–Plesset sur deux dithiatriazines modèles, RCN_3S_2 (R = H, NH_2). Si on introduit une optimisation de la géométrie et qu'on inclut une corrélation électronique, les calculs prédisent que, dans leur état fondamental, chacune de ces dithiatriazines existera sous forme de singulet. Pour chacune de ces molécules, les états triplets excités sont à des niveaux relativement bas; les différences d'énergies sont respectivement de 6,6 (R = H) et de 13,0 (R = NH_2) kcal mol^{-1}. Les dithiatriazines à l'état singulet adoptent des symétries déformées allant d'élevée (C_{2v}) à basse (C_s); ces changements sont importants lorsqu'on détermine les énergies relatives des molécules dans les états singulet et triplet. On a établi une corrélation entre les distorsions de structure que subissent ces molécules et les instabilités de Hartree–Fock et de Jahn–Teller observées dans d'autres thiazènes.

[Traduit par la revue]

Introduction

Since the inception of the Hückel $4n + 2$ rule (1) chemists have been intrigued by molecular systems that violate it. Traditionally the concepts of aromaticity and anti-aromaticity (2) have been associated with organic chemistry, but the ideas are no less relevant to inorganic frameworks. Studies of the chemistry of heterocyclic thiazenes have, in particular, provided considerable conceptual and experimental information as to the relative stabilities, both kinetic and thermodynamic, of $4n$ and $4n + 2$ π-systems constructed from inorganic units. The empirical analyses of binary sulphur–nitrogen (SN) rings by Banister in the early 1970's (3) stressed the importance of the Hückel rule as a guideline for molecular stability, and correctly predicted the existence of the planar 10π-electron $S_3N_3^-$ anion. The degree of aromatic character in this, and other binary SN rings, with both $4n + 2$ and $4n$ π-electron counts, has recently been probed by Gimarc, Jurić, and Trinajstić (4), who extended the concept of Dewar resonance energies (5) to these "electron-rich" π-systems.

While adherence to the $4n + 2$ rule is the norm in SN chemistry, there are both old and new examples of exceptions. The cage-like structure of S_4N_4 (6) itself has long been used to demonstrate, in a somewhat *a posteriori* way, one possible fate of a high symmetry anti-aromatic (12π) system, i.e. to distort to lower symmetry (7). Heterocycles of the general formula EN_3S_2 have also attracted attention. Generically, these dithiatriazine rings (E = R_2P, SO_2^-, RC) can all be considered as derivatives of the anti-aromatic 8π-electron $S_3N_3^+$ cation. *Ab initio* molecular orbital (MO) studies have confirmed a triplet ground state for this latter species (in D_{3h} symmetry), by virtue of the "high spin" occupancy of the degenerate e'' orbitals (see Fig. 1) (8). This degeneracy is lifted by the replacement of one (charged) sulphur atom with an isoelectronic fragment E; the two e'' orbitals transform, in C_{2v} symmetry, as b_1 and a_2 representations. With an electropositive perturbation the b_1 MO energy is raised relative to the a_2, which is nodal at the heteroatom site. With large perturbations, as expected for E = R_2P **1** (9) and SO_2^- **2** (10), the b_1–a_2 splitting is sufficient to favour a "low spin" singlet ground state. In the solid state these compounds are monomeric, albeit with structures quite distorted from ideal C_{2v} symmetry; their intense low energy absorption bands (*ca.* 550 nm) have been assigned to a b_1–a_2 excitation.

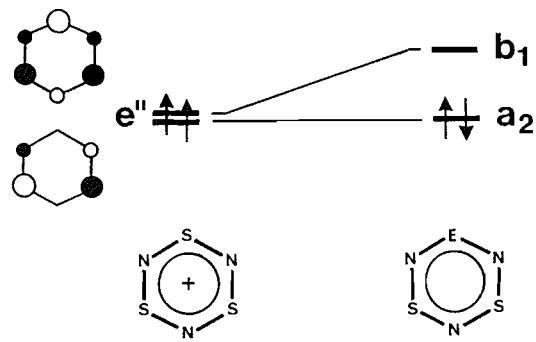

FIG. 1. Splitting of the degenerate e'' orbitals of $S_3N_3^+$ by the incorporation of a less electronegative atom E, and its effect on ground state multiplicity.

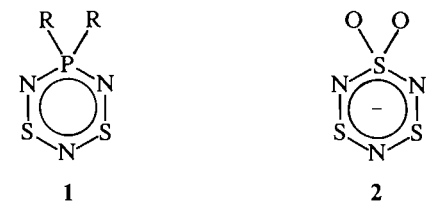

1 **2**

In the case of an S^+/CR replacement, the orbital electronegativity difference is less acute, and the energetic separation between the high (triplet) and low (singlet) spin states cannot be anticipated readily from purely one-electron arguments. MNDO calculations on a variety of model RCN_3S_2 derivatives **3** (R = H, NH_2, F, Ph) favour the triplet by 12–15 kcal mol^{-1} (11).

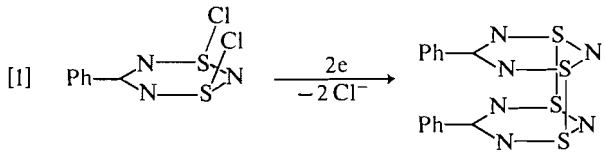
3 4

Interestingly, analogous calculations on the isoelectronic thiatriazine anion $H_2C_2N_3S^-$, **4** (R = H) predict the singlet to be considerably more stable than the triplet (by 28 kcal mol^{-1}) (12). Hartree–Fock–Slater (HFS) results on **3** have been far from definitive (13); convergence to a singlet ground state could only be achieved for R = NH_2, and no data on the corresponding triplet was provided.

Efforts to prepare discrete RCN_3S_2 species have had mixed success. The reduction of $RCN_3S_2Cl_2$ (R = CF_3 (14) and NMe_2 (13*b*)) has afforded red solid materials with the anticipated (for **3**) elemental and/or mass spectral analysis, but no structural or molecular weight data were reported. The reduction of $PhCN_3S_2Cl_2$, **5**, also leads to a compound with the correct empirical composition (eq. [1]) (11). In this case, however, the structure of the product has been established crystallographically as the cofacial dimer **6**, in which two $PhCN_3S_2$ are fused through two long S---S contacts (mean length 2.527 Å).



[1]

5 6

As part of ongoing studies of heterocyclic thiazenes, in particular the electronic and molecular structures of $4n$ π-systems, we have been anxious to remove some of the uncertainties surrounding the electronic structures of monomeric dithiatriazines, **3**. In the present paper we provide the results of a series of *ab initio* MO and electron correlation calculations, the latter using Møller–Plesset (MP) perturbation theory, on two model compounds **3** (R = H and NH_2). Our purpose has been to study the relative stabilities of the singlet and triplet states of these models, and also to ascertain what kind of internal structural changes might alter the energetic balance between the two multiplicities.

Computational methods

Ab initio calculations were carried out with the MONSTERGAUSS (15) version of GAUSSIAN80 adapted to the UNIX operating system of a SUN 3/160 workstation and with GAUSSIAN82 (16) running on a VAX 11/785. Geometries for the lowest closed shell singlet and triplet states were optimized at the SCF level (UHF for the triplets) employing gradient methods. The STO-3G* basis set (17) was used in the geometry optimizations as it has been found to give reasonable geometries for such molecules as $S_3N_3^-$ (18) and for cyclic phosphazenes (19). Stationary point geometries were checked as to their nature (minima, transition structures) by analytic evaluation of the harmonic vibrational frequencies. The effects of basis set extension were examined by use of the 3-21G* basis (20) at the STO-3G* geometries. The effects of electron correlation which are expected to be crucial in determining the relative stabilities of any pair of singlet and triplet species were included by Møller–Plesset perturbation theory through third order (MP2, MP3) (21, 22). Tests of stability of the STO-3G*

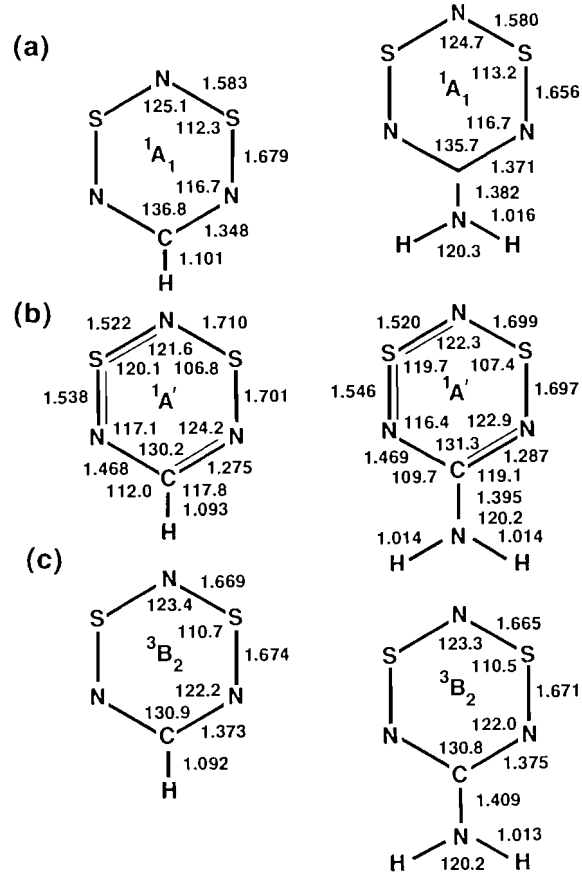


FIG. 2. STO-3G* SCF optimized geometries of HCN_3S_2 and $H_2NCN_3S_2$: (*a*) C_{2v} $^1A_1$, (*b*) C_s $^1A'$, (*c*) C_{2v} $^3B_2$.

wavefunctions for the singlet state H-substituted dithiatriazine, **3** (R = H) at the STO-3G* optimized equilibrium geometries (C_{2v} and C_s) were performed using the codes of Seeger and Pople (23) available as a part of GAUSSIAN82.

Results

Geometries and vibrational frequencies

The STO-3G* SCF optimized geometries for **3** (R = H and NH_2) are presented in Fig. 2. In $S_3N_3^-$, assuming D_{3h} symmetry, the STO-3G* basis predicts an SN distance of 1.616 Å (18), in very reasonable agreement with experimental values (range 1.584–1.626 Å) (24). Thus, although the optimized geometries for **3** (R = H and NH_2) originate from relatively small basis sets, they can be inferred to be reasonably accurate relative to the (unknown) experimental geometries of monomeric dithiatriazines.

The harmonic vibrational frequencies for the dithiatriazines are reported in Tables 1 and 2. These frequencies are not so much predictions of experimental results as they are conclusive demonstrations that at the STO-3G* SCF level both of the singlet dithiatriazines are unstable to geometrical distortions (note the imaginary b_2 frequencies) from C_{2v} to C_s nuclear frameworks. In the case of singlet $H_2NCN_3S_2$ (C_{2v}), a second imaginary frequency (b_1) is associated with pyramidalization of the tricoordinate nitrogen of the NH_2 group. Such a distortion is plausible but is not of energetic consequence. Further geometry optimization was thus performed with a planarity constraint.

Clearly the most interesting geometrical results are the rather

large changes in ring bond lengths which accompany the distortions of both the H- and NH_2-substituted singlet structures. The C_s geometries are highly suggestive of two SN double bonds, two SN single bonds, one conjugated CN single, and one CN double bond around the ring, i.e. reminiscent of the valence bond formulation **7** (eq. [2]). In the C_{2v} structures the

[2] 
3 7

CN distances must be equal by symmetry and, at 1.348 or 1.371 Å are nicely intermediate between the distances in the C_s form (H, 1.468, 1.275, mean 1.372 Å; NH_2, 1.469, 1.287, mean 1.378 Å). The short SN distances of 1.52 to 1.54 Å and the long distances of 1.70 to 1.71 Å in the C_s minima average to ca. 1.67 while the SN distances in the C_{2v} transition structures are 1.58 Å to the unique nitrogen and 1.656 or 1.679 Å on the sides.

The triplet electronic state C_{2v} minima have geometries which are somewhat "looser" (longer SN and CN ring bond lengths) than the singlet C_{2v} structures. The bond distances in the H- and NH_2-substituted triplet models are remarkably similar.

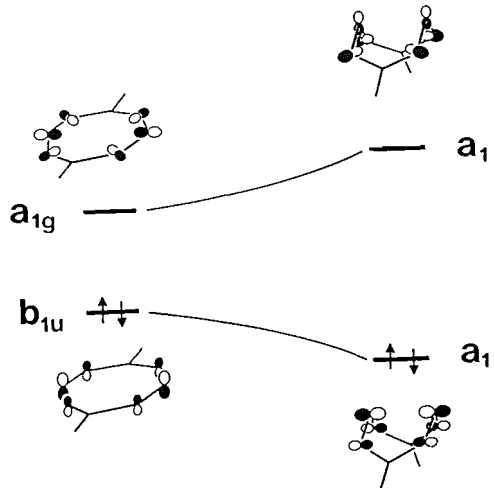

FIG. 3. The a_{1g}–b_{1u} orbital mixing that drives the second order Jahn–Teller distortion of dithiatetrazocines from D_{2h} to C_{2v} symmetry.

The singlet–triplet energy gap in dithiatriazines

Table 3 summarizes the total energies and energies relative to the C_s singlet minima for both dithiatriazine models at four levels of computation, STO-3G* SCF, 3-21G* SCF, 3-21G* MP2, and 3-21G* MP3. The geometries correspond to those specified in Figs. 2 and 3, i.e. STO-3G* SCF optimized structures.

Basis set limitations and truncation of the perturbation series at third order notwithstanding, the localized (C_s) singlet is more stable than the delocalized (C_{2v}) version. The relative energies vary with the level of calculation, the C_s form being favoured by 13 to 18 kcal mol^{-1} for R = H and by 7 to 11 kcal mol^{-1} for R = NH_2. The best predictions are 14.3 (R = H) and 11.3 (R = NH_2) kcal mol^{-1} for the exothermicities of the distortions from C_{2v} to C_s symmetry. These differences were slightly reduced, e.g. from 14.3 to 11.4 kcal mol^{-1} for R = H, when the STO-3G* harmonic frequencies were used to calculate the zero point energies of the C_{2v} and C_s forms.

Of considerable interest is the ground state multiplicity of simple monomeric dithiatriazines. With the inclusion of electron correlation by MP2 and MP3 calculations, which is essential in comparing states with different numbers of unpaired electrons, both dithiatriazine models are predicted to be singlet stable. The singlet/triplet separation is 6.6 kcal mol^{-1} for R = H (4.0 kcal mol^{-1} if zero point energies are used), and increases to 13.0 kcal mol^{-1} for R = NH_2; the difference can be attributed to the π-donor properties of the NH_2 group, which lead to conjugative destabilization of the b_1 MO (Fig. 1) and hence double occupancy of the a_2 MO.

Discussion

The term "electron-rich", which pervades many discussions of the electronic structures of heterocycles comprised of catenated —S=N— units, emphasizes the importance of π-electron count on overall molecular stability; increased occupation of anti-bonding π^*-levels reduces overlap populations. At the same time π-electron repulsion is increased, but since the extent of these interactions is not easily extracted from the total electronic energy, explicit discussion of their involvement tends to be avoided. There is another, also often overlooked, aspect of the electronic structures of SN heterocycles that contributes to their fragility, and that is the extent of electron repulsion between the in-plane non-bonding orbitals, the "lone pairs" on sulphur and nitrogen. The destabilizing influence of such lone

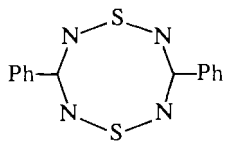
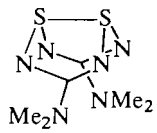
pair interactions in molecules constructed from the later first and second row elements (e.g. nitrogen halides) has long been recognized (25). The large endothermic heats of formation of SN compounds, e.g. 110 kcal mol^{-1} for S_4N_4 (26), are direct manifestations of this effect. It is prudent, therefore, to remember that thiazine heterocycles are σ-electron-rich as well as π-electron-rich; the associated electronic instabilities in both systems can influence molecular structure.

Frequently, however, it is more appealing to ascribe major structural changes to π-effects. The structural dichotomy observed for 1,5-dithiatetrazocines provides a useful example. These compounds can be planar, e.g. **8**, or puckered, e.g. **9**,



8



9

depending on the nature of the exocyclic ligand (27). The distortion is conveniently rationalized as being driven by a second order Jahn–Teller (SOJT) instability (28) in the π system. Accordingly ring puckering is precipitated by the destabilizing influence of π-donor ligands at the 1,5-positions (29), and consequent mixing of the high lying π-HOMO with a low-lying virtual σ-orbital (Fig. 3) (30).

In the case of the dithiatriazine system HCN_3S_2, the observed slippage from C_{2v} into C_s symmetry (eq. [2]) maintains the σ/π distinction. The interpretative problem that arises is to decide whether the symmetry lowering is driven by instabilities in the σ-system, the π-system, or a combination of both. These issues have been highlighted by several recent papers by Bénard, Laidlaw, and Paldus (31) in which they have probed the symmetry breaking (32) of the Hartree–Fock (HF) wavefunctions of several binary rings (e.g. $S_3N_3^-$, $S_4N_4^{2+}$, S_2N_2) when all the SN bonds are stretched to a length about 20% greater than their equilibrium values. They concluded that the mixing of occupied and unoccupied σ-orbitals was at least as important as the more easily anticipated π*/π* process.

As in the dithiatetrazocine system noted above, the π-instability rationalization in **3** is conceptually appealing. The conventional SOJT description for the C_{2v} to C_s distortion involves a mixing of the frontier π*-orbitals, specifically the a_2 HOMO and b_1 LUMO to yield two a'' orbitals (Fig. 1). This view is supported by analysis of the changes in these two orbitals as the distortion proceeds (Fig. 4). Of particular note is (*i*) the large change in the orbital eigenvalues as the two orbitals mix, i.e. $\Delta < \Delta'$, and (*ii*) the change in the eigenvector coefficients, in particular those of the lower orbital, whose bonding and antibonding properties reflect, broadly speaking, the bond localization apparent in the valence bond representation **7**.

In order to relate our results to those of Bénard, Laidlaw, and Paldus (31), we tested the STO-3G* HF wavefunctions of HCN_3S_2 at both the C_{2v} and C_s calculated equilibrium geometries for instabilities by following the methods of Seeger and Pople (23). In both geometries the wavefunctions were singlet stable. Such a result is in complete agreement with the earlier work on $S_3N_3^-$, $S_4N_4^{2+}$, and S_2N_2 (31), where the wavefunctions were always stable at the optimized *equilibrium* geometries, and showed broken symmetry solutions only when the SN bond lengths were increased.

In the light of these results the HF stability of the C_{2v} wavefunction of HCN_3S_2 was further examined by uniformly increasing all bond lengths by 20% and retesting the wavefunction. The wavefunction was still stable. In assessing the significance of this result it is important to recall from the earlier work that symmetry breaking was only observed from a high symmetry point group, i.e. D_{3h}, D_{4h}, or D_{2h}, down to C_{2v} (31). Instabilities involving a C_{2v} to C_s symmetry loss could not be induced, even at large SN separations. In the dithiatriazines studies here we have "chemically" broken the symmetry relative to $S_3N_3^+$ by introducing the CR group in place of S^+. Viewed in this way it is not surprising that a HF instability in HCN_3S_2 leading to a C_s wavefunction appears difficult to obtain.

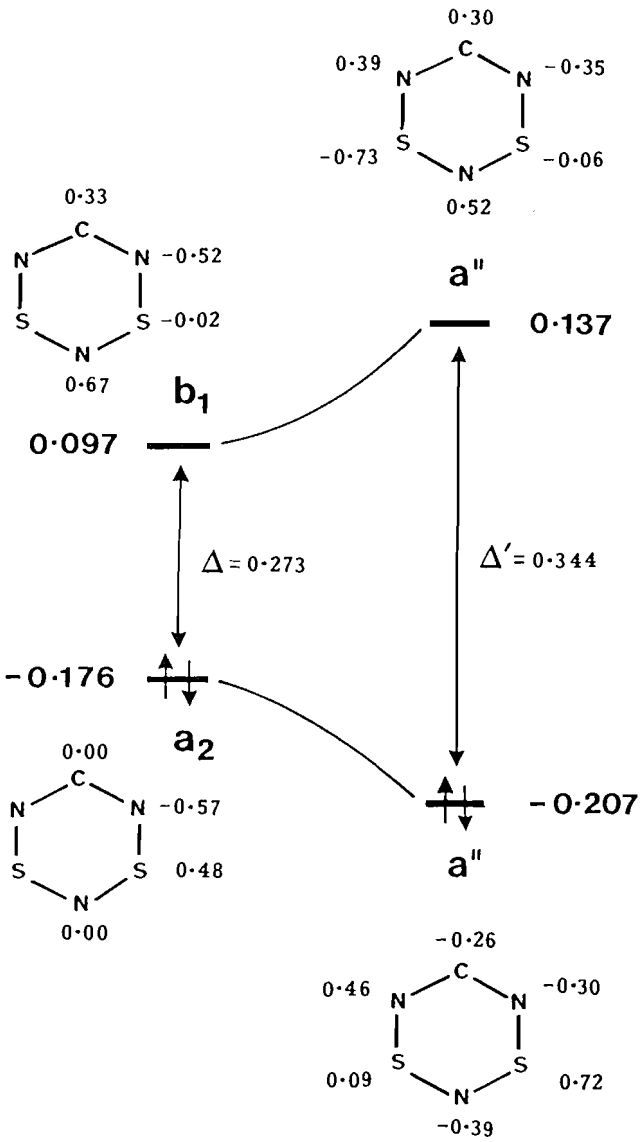

FIG. 4. Orbital energy (in Hartree au) and distribution changes in the a_2 HOMO and b_1 LUMO of HCN_3S_2 accompanying a distortion from C_{2v} to C_s symmetry. The eigenvector coefficients shown are the largest $p\pi$ components (STO-3G*).

Conclusion

Singlet C_{2v} dithiatriazines have been demonstrated to be unstable with respect to a distortion of the nuclear framework to C_s symmetry. There has been speculation that in any system a HF symmetry breaking instability in the electronic wavefunction may drive a nuclear framework distortion (33). Indeed a formal relationship between the relaxation component of the negative force constant in the SOJT distortion mechanism and the HF stability matrix has been derived (34). However, it would appear from both the results of this work and the distinctions drawn earlier (31) between HF instabilities and Jahn–Teller effects that a nuclear distortion conventionally rationalized by the SOJT model need not require a HF instability, nor does a HF instability imply a SOJT distortion.

There is, to date, no evidence for monomeric dithiatriazines **3**. The structural characterization of the dimer **6** shows that, at least for this derivative, the formation of two weak interannular S---S bonds is energetically preferred to a valence bond "slump" (10), i.e. slippage of delocalized rings **3** into the low symmetry form **7**. Such a conclusion would perhaps not be too surprising to an organic chemist; the dimerization of **3** (R = Ph) represents the fate of many strongly anti-aromatic species, i.e. to self-associate.

The synthesis and unimolecular decomposition of four novel Δ^1-1,2,4-triazolines[1]

ADRIAN L. SCHWAN[2] AND JOHN WARKENTIN[3]

Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received December 4, 1987

ADRIAN L. SCHWAN and JOHN WARKENTIN. Can. J. Chem. **66**, 2285 (1988).

Treatment of 4-*tert*-butyl-3,3-dimethyl-5-methylene-Δ^1-1,2,4-triazoline (**3**) with benzonitrile oxide (**9**), diphenylnitrile imine (**10**), phenyl azide, and *p*-nitrophenyl azide led, in each case, to 1,3-dipolar cycloaddition. The products, Δ^1-1,2,4-triazolines that are spiro-fused to another 5-membered ring, could be isolated in pure form in three of the four cases. All four are thermally unstable and decompose by loss of N_2 from the Δ^1-1,2,4-triazoline moiety to form an azomethine ylide. Subsequent reactions of those ylides are described.

ADRIAN L. SCHWAN et JOHN WARKENTIN. Can. J. Chem. **66**, 2285 (1988).

La réaction de la *tert*-butyl-4 diméthyl-3,3 méthylène-5 Δ^1-triazoline-1,2,4 (**3**) avec l'oxyde du benzonitrile (**9**), l'imine du diphénylnitrile (**10**), l'azoture de phényle ou de *p*-nitrophényle conduit, dans chaque cas, à une cycloaddition dipolaire-1,3. Les produits, des Δ^1-triazolines-1,2,4 qui sont spiro-condensées à un autre cycle à cinq chaînons, ont pu être isolés à l'état pur dans trois cas sur quatre. Les quatre sont instables d'un point de vue thermique et ils se décomposent par perte de N_2, de la part de la portion Δ^1-triazoline-1,2,4, pour conduire à un ylure d'azométhine. On décrit des réactions subséquentes de ces ylures.

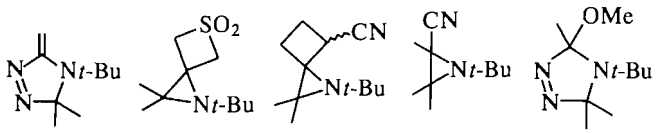
Although there are now a variety of methods available for the generation of azomethine ylides (**2**) (1–3), a very attractive route, the extrusion of N_2 from Δ^1-1,2,4-triazolines (**1**) as proposed by Kellogg (4) (reaction [1]), has still not been developed.

Our efforts toward the synthesis of Δ^1-1,2,4-triazoline (**1**) precursors of azomethine ylides have led to the synthesis of triazoline **3** (5, 6), the first Δ^1-1,2,4-triazoline without heteroatom substituents, and to aziridines **4**, **5**, and **6**, obtained by treating **3** (an enamine as well as a triazoline) with the appropriate electrophilic substrates. Presumably those aziridines arise from azomethine ylides derived from very thermolabile triazolines such as **7** (7) (reaction [2]). Thus, although triazolines of type **1** have been prepared as transient intermediates (e.g., **7**), none have been isolated.

[1] 
1 **2**



3 **4** **5** **6** **8**

[2] 
3 **7** **4**

We have, however, obtained evidence that triazolines with a heteroatom attached to one of the two sp^3 ring carbons (e.g., **8**) may have more inherent stability than those with all carbon substituents (7). Thus, methoxytriazoline **8** was observed by ^{13}C and ^1H nmr spectroscopy when **3** was dissolved in acidified methanol. The persistence of **8** in that medium indicated a resistance to N_2 extrusion substantially greater than those associated with triazolines such as **7**.

Although **8** was thermally stable in methanol solution, attempts to isolate **8** were unsuccessful. We reasoned that analogues of **8**, in which the heteroatom substituent was itself part of a ring, might be isolable. To test that hypothesis we treated **3** with 1,3-dipoles bearing a heteroatom at one of their termini.

Results and discussion

The first two 1,3-dipoles chosen for reaction with **3** were benzonitrile oxide, Ph—C≡$\overset{+}{N}$—O^- (**9**) and diphenylnitrile imine, PhC≡$\overset{+}{N}$—$\overset{-}{N}$Ph (**10**). They were selected not only because they provided a heteroatom at the desired position but also because both are known to react with enamines at ambient or lower temperatures (8). Indeed such a cycloaddition between **3** and both **9** and **10** was achieved. Treatment of **3** with benzoyl chloride oxime (**11**) (9) and triethylamine at −30°C for 10 min afforded **12** in 75% yield (reaction [3]). Benzoyl chloride phenylhydrazone (**14**) (10) together with triethylamine and **3** provided **15** in 84% yield after 40 h at room temperature (reaction [4]).

Structures **12** and **15** were assigned as the triazolines resulting from 1,3-dipolar cycloaddition of **11** and **14** to **3** on the basis of spectroscopic data. In the ^1H nmr spectra both **12** and **15** showed two magnetically nonequivalent methyl groups and the methylene protons appeared as an AB quartet, demonstrating their nonequivalence.[4] The ^{13}C nmr spectra provided evidence that the cycloaddition proceeded with the expected regiochemistry (8) and that the azo function was still present in the products. The triazoline ring carbons resonated at 128.63 and 104.68 ppm for **12** and at 119.58 and 102.68 ppm for **15**. These values are in keeping with expectations based on the number of

adjacent heteroatoms (cf. the values for **4**, **5**, and **6** (7)). Moreover, the presence of a strong band in the 1590–1600 cm^{-1} region of the Raman spectra of **12** and **15** is indicative of a *cis* azo function (11).

The mass spectral data for **12** and **15**, although less informative, are in keeping with the assignments. Molecular ions from neither **12** nor **15** were observable under electron impact (ei) conditions. Weak signals at $m/z = (M - N_2)^+$ and strong signals corresponding to $m/z = (M - N_2 - CH_3)^+$ fragments were observed. Under chemical ionization (ci) conditions, the expected $(M + 1)^+$ ions were observed. All spectroscopic data can be found in the Experimental.

Triazolines **12** and **15** are the first isolable Δ^1-1,2,4-triazolines with sp^3 ring carbons. With those in hand, we proceeded to investigate their thermolysis chemistry, with the hope that they would be useful precursors of azomethine ylides.

Thermolysis of **12** and **15** in benzene afforded isoxazole **13** (89%) and pyrazole **16** (94%) respectively, in high yield (reactions [3], [4]). Unfortunately those were also the products when the thermolyses were done in methyl acrylate or in dimethyl acetylenedicarboxylate (DMAD), two efficient dipolarophiles (8). Heterocycles **13** and **16** were identified on the basis of the spectroscopic data, which correspond well with those of similar known aromatic heterocycles (Table 1) (12–20). A significant feature of the nmr data is that the two methyl groups that are not part of the *t*-Bu substituent are magnetically equivalent, providing strong evidence that the 1,2,4-triazoline ring of **12** and **15** is not present in **13** and **16**.

The infrared spectra showed NH stretching bands at 3355 (**13**) and 3378 cm^{-1} (**16**). The mass spectra of **13** and **16** showed a weak signal at $m/z = M^+$ under ei conditions. A signal at $m/z = (M - CH_3)^+$ was significant in both instances. Under ci conditions the expected $m/z = (M + 1)^+$ peaks were observed. Finally, the background in the spectra of **12** and **15** contained the characteristic spectra of **13** and **16**, respectively. This is presumably due to some thermolysis of **12** and **15** in the heated inlet system of the mass spectrometer.

The mechanism of the transformation of **12** to **13**, and similarly of **15** to **16**, can be rationalized as outlined in Scheme 1. As we have observed with more thermolabile triazolines (6, 7), loss of N_2 to yield an azomethine ylide **17** is probably the first step. Ylide **17** would be expected to close quickly to aziridine **18** due to the large nonbonding interactions of the five ylide substituents. Electrocyclic ring closures of ylides are common and sterically congested ylides such as **17** are known to form 3-membered rings with rate constants large enough to prevent cycloaddition to a dipolarophile (7, 21–23). Thus the failure of methyl acrylate or DMAD to trap **17** (or its analog from **15**) is not surprising.

Ring opening of **18** (Scheme 1) may occur by an intramolecular dipolar mechanism leading to **19**. Finally, proton transfer from the ring to the negatively charged nitrogen forms the aromatic heterocycle **13**.

Other mechanisms may be possible but two features must be part of any proposal. The carbon bearing two methyl groups in **12** must end up attached to the ring in **13** and the bond that held

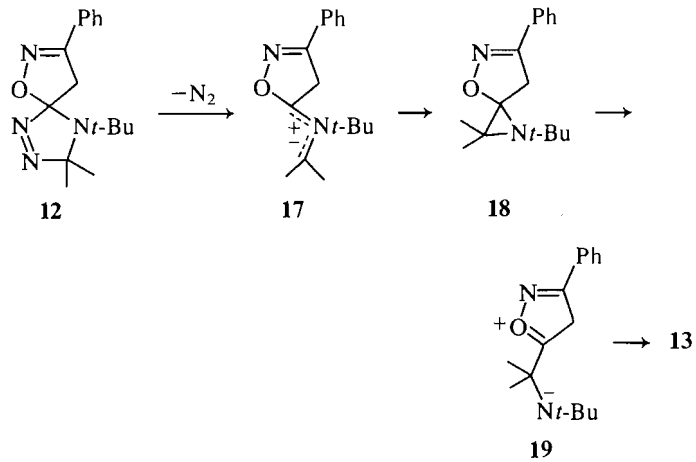
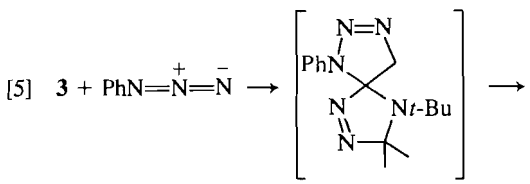


SCHEME 1

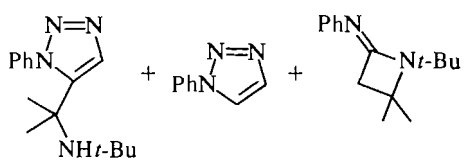
the N(*t*-Bu) group to the spiro atom of **12** must be broken. Precedent for the C—N cleavage can be found in the commonplace conversion of 5-aminoisoxazolines to deaminated isoxazoles (24). The transformation of 5-aminopyrazolines to deaminated pyrazoles, known to proceed readily (25), serves as a model for the analogous steps from **15** to **16**.

To estimate activation parameters for thermal decomposition of **12** and **15**, degassed solutions of the triazolines in benzene were sealed into nmr tubes, which were immersed in a constant temperature bath. Periodic integration of the ^{1}H nmr spectra gave first-order rate constants. The activation parameters, from data for the range 40–80°C, were $\Delta H^{\ddagger}$(**12**) = 26, $\Delta H^{\ddagger}$(**15**) = 26 kcal mol^{-1}, $\Delta S^{\ddagger}$(**12**) = −2, and $\Delta S^{\ddagger}$(**15**) = 0 eu. Although the nmr method for measuring reaction rate constants is rough, the values of $\Delta S^{\ddagger}$ obtained are in good agreement with values from the literature (26) for concerted unimolecular extrusions of N_2. The kinetic parameters are therefore supportive of the proposed mechanism (Scheme 1), with the first step irreversible and rate limiting. All the rate constants are compiled in Table 2.

Two other 1,3-dipoles were treated with **3**. Phenyl azide would not react with **3** at room temperature in a variety of solvents. Heating to 80°C was sufficient but heating reduced the chances of isolating spirotriazoline **20**, and only compounds believed to be derived from **20** were isolated (reaction [5]).



20



Triazoline **3** is also an enamine and therefore the 1,3-dipolar cycloaddition with azides is predicted to be controlled by the energy gap between the HOMO of the dipolarophile and the LUMO of the dipole. Since a *para*-nitro group is known to lower the LUMO of phenyl azide and to render it more reactive

TABLE 2. Decomposition rates of **12** and **15** (benzene)

T(°C)	k/s^{-1} for **12**[a]	k/s^{-1} for **15**[a]
40	3.8×10^{-6}	2.1×10^{-6}
50.5[b]	1.5×10^{-5}	8.2×10^{-6}
60	4.7×10^{-5}	2.4×10^{-5}

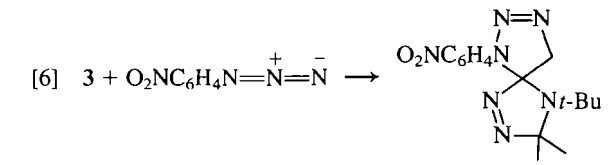
toward π-excessive double bonds (8), *p*-nitrophenyl azide was treated with **3**. An isolable triazoline (**22**) was obtained as a solid (reaction [6]).

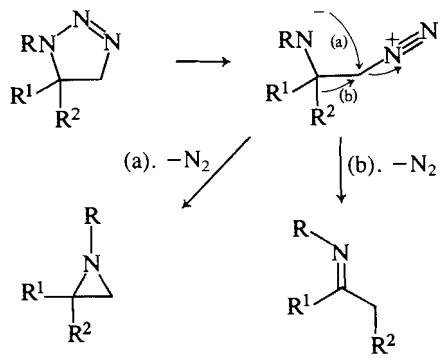


22

The spectroscopic properties of **22** were similar to those of **12** and **15**. In the ^{1}H nmr spectrum the *gem*-dimethyl group furnished two singlets while the methylene protons appeared as an AB quartet. The ^{13}C nmr spectrum was supportive of the assignment, with triazoline ring carbon signals (at δ114.12 and 104.11) comparable to those of **12** and **15**.

The ei mass spectrum of **22** provided a peak at m/z = $(M - N_4)^+$ while the ci (CH_4) spectrum gave the expected peak at $m/z = (M + 1)^+$. The Raman spectrum of **22** showed a band at 1596 cm^{-1} along with intense nitro group signals.

Cycloadduct **22** is a unique spiro species containing both a Δ^2-1,2,3-triazoline and a Δ^1-1,2,4-triazoline ring. Whereas the background regarding the thermolysis chemistry of Δ^1-1,2,4-triazolines is limited to that from this laboratory (5–7, 27), very much is known about N_2 loss from Δ^2-1,2,3-triazolines (28, 29). Those triazolines are known to decompose via a zwitterion, rather than an ylide, to give aziridines via ring closure and (or) imino species by means of an alkyl group shift (Scheme 2).



SCHEME 2

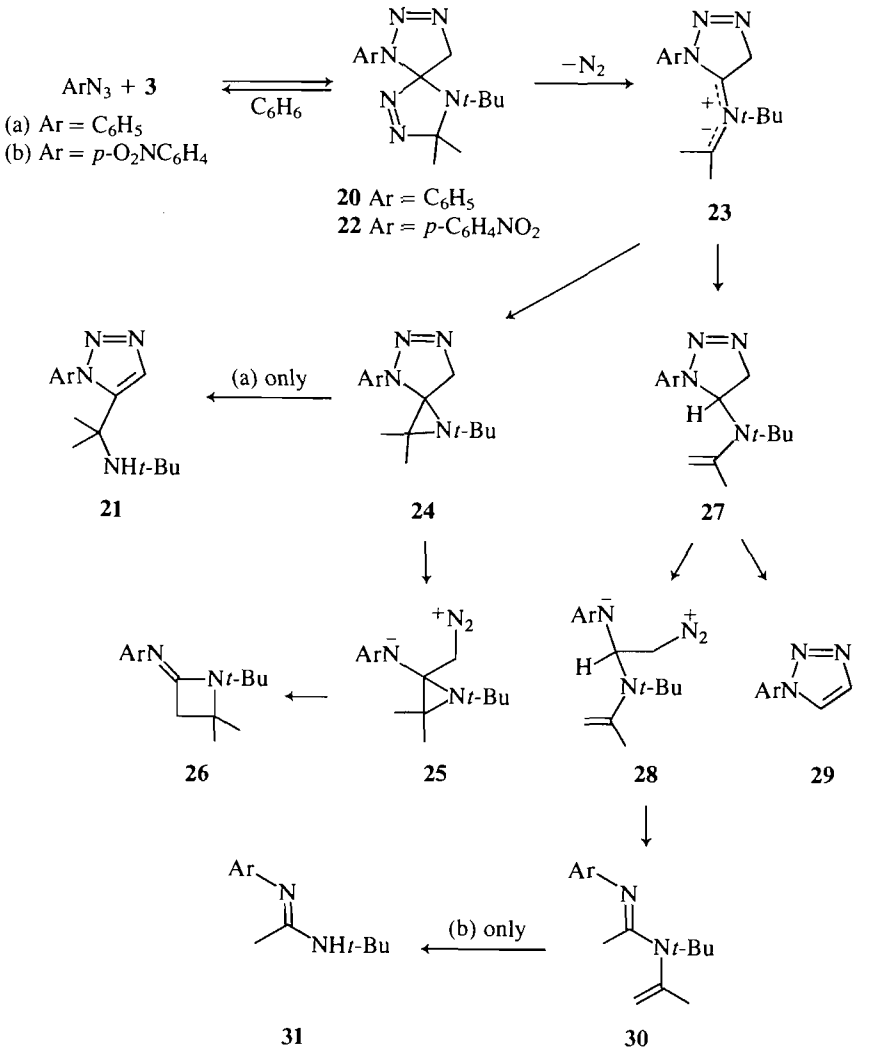

SCHEME 3

One would expect the Δ^1-1,2,4-triazoline ring of **25** to be the more labile of the two rings due to the conjugatively stabilized azomethine ylide that results from loss of molecular nitrogen. Breakdown of the 1,2,3-triazoline portion to yield the nonstabilized zwitterion, as depicted in Scheme 2, could follow extrusion of N_2 from the 1,2,4-triazoline ring. That sequence was assumed. It is known that aziridines rarely result from the breakdown of 5-amino-1,2,3-triazolines[5] (28), most of which decompose to 1,2,3-triazoles via loss of amine. When the 1-position of the 5-amino triazolines bears an electron-withdrawing group, loss of N_2 leading to an amidine (Scheme 2, $R^1 = NR_2^3$), becomes significant and may compete with deamination to the triazole (28). Finally, spiro Δ^2-1,2,3-triazolines tend to give ring-expanded imino compounds.

With these trends in mind, the thermal decomposition products of the assumed intermediate **20** and of **22** could be identified and rationalized readily (Scheme 3). Unfortunately the decomposition of **22** did not proceed with clean loss of one or two molecules of N_2. Cycloadduct **25** also reverts to **3** and *p*-nitrophenyl azide. There is precedent for this cycloreversion reaction and the equilibrium favours azide at higher temperatures (32). This complication prevented the straightforward acquisition of a unimolecular decomposition rate constant for **22**.

The decomposition of **22** was usually carried out without its isolation, and thermolysis of **20** was necessarily performed in this manner since it could not be isolated in pure form.

Refluxing a solution of phenyl azide and **3** in benzene followed by chromatographic separation provided products **21**, **26***a*, and **29***a*, in the yields indicated in Table 3. Analogous treatment of *p*-nitrophenyl azide with **3** in benzene afforded compounds **26***b*, **27***b*, **29***b*, **30***b*, **31***b*, and *p*-nitroaniline. Of these **29***b* was not isolated. Its presence in the crude mixture (in ca. 1% yield) was inferred from an ^{1}H nmr spectrum at 500 MHz.

Triazole **21** was identified by comparison of its spectra to those of similar heteroaromatic compounds including those of 1-phenyl-5-(isopropylaminomethyl)-1,2,3-triazole (20) (Table 1). Triazoles **29** are known species and the spectral data and physical properties for **29** were totally consistent with those reported previously (19, 32, 33).

Amidines **26** were identified by way of comparison of their spectroscopic data with those of amidine **33** (20). The C=N stretching frequency in the infrared spectra of **26***a* and **26***b* appeared at 1674 and 1652 cm^{-1}, respectively. The ^{1}H nmr

[5]For two exceptions to this general rule, the reader is referred to refs. 30 and 31.

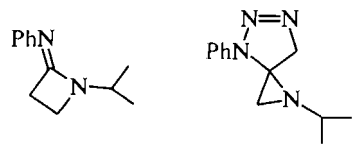
[b]60 MHz.
[c]500 MHz.

spectra showed singlets for the methylene groups of **26***a* and **26***b* and for their geminate methyl substituents. The ^{13}C nmr spectra showed signals at 156.66 ppm (**26***a*) and 157.49 ppm (**26***b*) for the amidine carbons. Both values are in the range expected for amidines (20, 35). Although the geometry about the C=N bond cannot be determined from the spectroscopic data, amidines **20** were assigned the *E* geometry on the basis of the fact that amidines with the *Z* configuration are rare and are known to isomerize readily to the *E* form (35, 36).



33 **32** **34**

Amidines **30***b* and **31***b* showed spectroscopic characteristics quite similar to those of **26**. The ^{1}H nmr spectrum of **30***b* permitted assignment of the signals from the two sp^2-bound methyl groups. The acetamidine methyl signal at 1.88 ppm is very sharp while the isopropylidene methyl peak at 1.97 ppm is broader due to allylic coupling. The nmr data and the mass spectrum of **31***b* indicated that it did not have the N-isopropenyl moiety of **30***b* but an NH moiety instead, as evidenced by the presence of an N—H stretching band at 3422 cm^{-1} in the ir spectrum.

Finally Δ^2-1,2,3-triazoline **27***b* was identified by way of its ^{1}H nmr spectrum. The ABX pattern of the ring protons of 5-dialkylamino-Δ^2-1,2,3-triazolines is a readily recognizable feature (Table 4) (37). The other spectral data of **27***b* were totally consistent with the assignment.

An ^{1}H nmr spectrum of the crude reaction mixture from phenyl azide and **3** also showed the distinctive ABX pattern and this is ascribed to the presence of **27***a* in the crude mixture. Only small amounts of **29***a* could be detected in this crude mixture and, because **29***a* was obtained in higher yield as the ultimate product, it follows that **27***a* is deaminated to **29***a* during chromatography.

Scheme 3 offers a series of pathways that rationalize the formation of the observed products. Cycloaddition between **3** and azide yields **20** or **22**, which should break down with rate constants similar to those for the decay of **12** or **15**. Such cycloreversions would generate azomethine ylides **23**. Two reactions of **23** then lead to the series of products obtained. A [1,4]-hydrogen shift leads to Δ^2-1,2,3-triazolines **27**. This sigmatropic rearrangement is a known reaction of azomethine ylides (6, 27, 38, 39). 1,2,3-Triazoline **27***a* deaminates to **29***a* upon chromatography. Analogue **27***b* survives chromatography but does decompose to *p*-nitroaniline and other products with prolonged manipulation. Presumably the nitro group of **27***b* renders the sp^3 nitrogen of the triazoline ring less nucleophilic, thereby reducing the rate of deamination.

Triazolines **27** also break down thermally by a mechanism different from that of deamination to **29**. Zwitterion **28***b*, from heterocyclic cleavage of the triazoline ring, is postulated. A hydride shift and loss of N_2 affords amidine **30***b* from **27***b*. Amidine **31***b* is the product of enamine hydrolysis of **30***b*. When the thermolysis mixture from **20** was heated for long periods of time, **30***a* was detected and lower yields of **29***a* were obtained even after chromatography. Identification of **30***a* followed from the similarity of its spectra to those of **30***b*. Extended refluxing of the mixture from **22** led to greater yields of *p*-nitroaniline and **30***b* at the expense of **27***b*. Presumably **27***b* is decomposed gradually to **30***b*, which is hydrolyzed slowly to **31***b*. The latter is apparently hydrolyzed more rapidly, to *p*-nitroaniline.

The other unimolecular reaction of ylides **23** is the ring closure to **24**. Crandall *et al.* (20) have proposed spiroaziridine **32** as an intermediate in the reaction of phenyl azide and *N*-isopropylmethyleneaziridine (20). Species **32** decomposed rapidly to 1-phenyl-5-(isopropylaminomethyl)-1,2,3-triazole and amidine **33**. The proposed decomposition pathway of **33** is analogous to that displayed in Scheme 3 for the breakdown of **24**. Only **24***a* gives the deaminated triazole (**21**). When **24***a* is generated in CH_3CN, **21** becomes the major product, most likely because the dipolar intermediate involved in the process is stabilized in that solvent. Presumably the mechanism suggested for the formation of heterocycles **13** and **16** is also suitable for rationalizing the presence of **21**.

Amidines **26** are formed by cleavage of the 1,2,3-triazoline (**24**) to **25**, which undergoes an alkyl shift and loss of molecular nitrogen to afford the ring-expanded species (**26**). In view of the known greater thermal stability of 1-phenyl-1,2,3-triazolines over their 1-*p*-nitrophenyl counterparts, it is not surprising that **24***a* forms **21** as well as **26***a*, whereas **24***b* does not lead to the analogue of **21**.

When a pure sample of **22** was decomposed in methyl acrylate, an efficient trap for azomethine ylides (1), no new products arising from **23***b* were detected.

On the whole, all of the products obtained from **3** and aryl azides can be rationalized with ample precedent. The pathways of Scheme 3 are fairly secure because **27***a* can be detected and **27***b* can be isolated. As well, the likelihood that **32** is an intermediate in the reaction of phenyl azide with *N*-isopropyl methyleneaziridine (20) lends credence to the proposal that **24** lies on the pathway to **21** and **26**. Although the mechanism of Scheme 3 is sufficient, the possibility that there is another concurrent decomposition pathway cannot be ruled out. Scheme

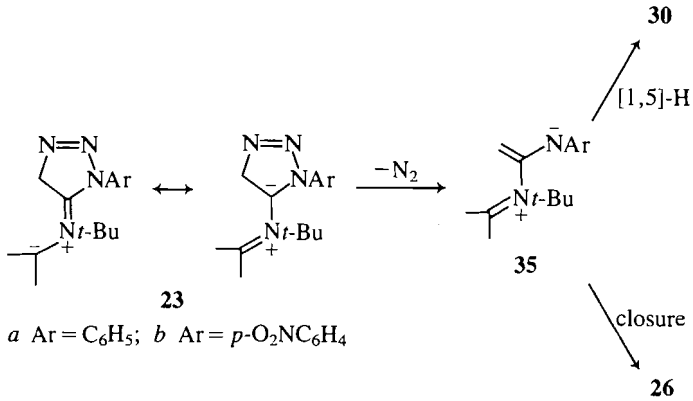
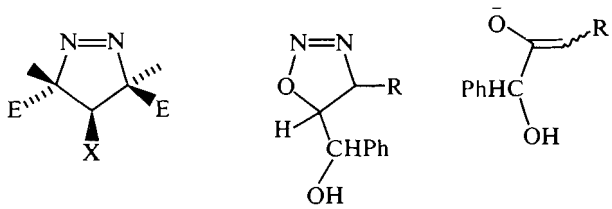


SCHEME 4

4, for example, depicts an alternative pathway from **23** to **26** and to **30**. In that mechanism, ylide **23** loses N_2 from the 1,2,3-triazoline ring to form zwitterionic species **35**, which then closes to **26** or transfers a proton intramolecularly from a methyl group, affording **30**. This latter step can also be perceived as a [1,5]-hydrogen transfer, assisted, at least in part, by the polarity of **35**. Species **35***b* would be more stable than **35***a* due to the conjugative effects of the *p*-nitro group. The pathway of Scheme 4, if it competes at all, may therefore be more important for the decay of **23***b* than of **23***a*. Unfortunately there is no model system with which the reactivity of **23**, with respect to loss of N_2, can be assessed. Deprotonations of Δ^2-1,2,3-triazolines that have been carried out have occurred from C-4 (40). Two examples are supportive of the proposal depicted in Scheme 4. Deprotonation from the 4-position of pyrazolines **36** enhances the rate of nitrogen loss by a factor of 10^{12} for X = CO_2Me (41) and by a factor of 10^{29} for X = CN (8, 42).

A closer analogy is the mechanism suggested by Padwa *et al.* to account for the decomposition of heterocycle **37** (43). Deprotonation from the 5-position of **37** yielded enolate **38** via anionic cycloreversion of the type that follows deprotonation from the 2-position of THF with formation of ethylene and acetaldehyde enolate (44).

Based on the examples above, some credibility can be given to the alternative mechanism for the formation of **26** and **30** as



36 **37** **38**

depicted in Scheme 4, even if there is not a full negative charge at the 4-position of the 1,2,3-triazoline ring of **23**.

The fact that triazolines **12** and **15** can be isolated is truly surprising in light of the thermal instability of triazolines such as **7**. Intuitively, one would expect the additional heteroatom substituent at the spiro carbon atom to have a destabilizing effect. Analysis of all the examples from this and previous papers (6, 7, 26) allows one to conclude that the ring size of the spiro ring, if present, has little effect on the stability of the triazoline.

The observed stability of triazolines **12**, **15**, and **22** could be attributed to the relative energies of the ground state triazolines or of the corresponding ylides. Considering the ylide energy levels, ylides **17** and **23** are unlikely to be destabilized relative to those resulting from triazolines represented by **7**, based on the calculated substituent effects on carbonyl ylides (45). Addition of the amino substituent to a terminus of an unsubstituted carbonyl ylide provides 5 kcal mol^{-1} of stabilization (45). The corresponding stabilization of azomethine ylides is probably somewhat lower since they are considered to be more π-excessive than carbonyl ylides (1, 8) and therefore have less to gain from a donor substituent.

By process of elimination it seems necessary to postulate a ground state effect for the observed stability of **12**, **15**, and **22**, although the origin of such an effect is obscure.

Experimental

Melting points were determined on a Thomas Hoover capillary melting point apparatus and are uncorrected. Proton nuclear magnetic resonance (^{1}H nmr) spectra were recorded on a Varian EM 390 or a Bruker AM-500 instrument using TMS as the internal standard. Carbon-13 nuclear magnetic resonance (^{13}C nmr) spectra were obtained with either a Bruker WM-250 (62.90 MHz), WP-80/90 (22.62 MHz), or AM-500 (125.26 MHz) machine. Samples for nmr analysis were dissolved in $CDCl_3$ in all instances. Infrared spectra (ir) were obtained with a Perkin–Elmer model 283 instrument and are calibrated against the 1601.4 cm^{-1} band of polystyrene. Ultraviolet spectra (uv) were taken with a Hewlett–Packard model 8451A diode array spectrometer. Mass spectra (ms) were recorded on either a VG 70-70F or a VG ZAB-E spectrometer.

For Raman spectra, a Coherent model Innova 90 argon laser giving up to 3.5 W at 5145 Å was used for excitation. The spectrometer was a Spex Industries model 14018 double monochromator equipped with 1800 grooves/mm holographic gratings. Slit widths were set at 100 or 200 μm. The power setting was 50 or 100 mW. The scan rate was set at 1 or 2 cm^{-1} s^{-1}. Raman shifts quoted are believed to be accurate to ±2 cm^{-1}.

Centrifugal chromatography was carried out on a Chromatotron 7924T instrument equipped with silica-coated glass plates (coating 2 mm thick, 12 cm in radius, Merck Kieselgel 60 PF_{254}, using distilled solvents. Plastic-backed, Merck Kieselgel 60 PF_{254} 0.2 mm silica plates or plastic-backed polygram ALOX, N/UV_{254}, 0.2 mm neutral alumina plates were used for analytical thin-layer chromatography (tlc).

All reaction solvents were distilled from P_2O_5 before use.

The synthesis of **3** has been published (6).

Reaction of 3 with benzonitrile oxide

A flask containing 4 mL of dry CH_2Cl_2 and benzoyl chloride oxime (9) (162 mg, 1.14 mmol) was stirred at −30°C (alcohol – Dry Ice). A solution of **3** (162 mg, 0.97 mmol) and Et_3N (150 mg, 1.49 mmol) in 4 mL CH_2Cl_2 was added all at once. After 15 min, 4 volumes of ether were added and the solution was filtered. The filtrate was concentrated (aspirator) and applied to a basic Al_2O_3(II) column. Elution was with 40% ether in light petroleum. The fraction eluting with R_f 0.28 (40% ether) contained **12** (193 mg, 0.75 mmol) 77%. Recrystallization from light petroleum provided white crystals, mp 120–122°C (dec.). Spectral data for **12**: uv ($CHCl_3$), λ_{max} (log ε): 264 nm (3.88), 317 nm (2.95); ir (film), cm^{-1}: 1596 (vw), 1580 (vw), 1450, 1420, 1399, 1366, 1310, 1258, 1208; Raman, cm^{-1}: 1600, 1592 (N=N), 1564; ^{1}H nmr (90 MHz) δ: 1.36 (s, 9H), 1.58 (s, 3H), 1.67 (s, 3H), 3.59 (s, 2H, (ab q, J = 18 Hz in C_6H_6)), 7.38–7.58 (m, 3H), 7.67–7.82 (m, 2H); ^{13}C nmr (62.90 MHz), δ: 26.85, 27.88 (Me's), 31.99 (*t*-Bu), 42.63 (CH_2), 53.08 (CMe_3) 104.68 (ring C), 128.63 (spiro C), 126.61, 128.95, 129.99, 130.47 (Ph C's), 157.59 (C=N); ms (ei), *m/z* (%): 258(5), 257(4), 244(18), 243(89), 187(58), 186(62), 159(31), 103(30), 77(27), 58(100), 57(47); ms (ci, CH_3), *m/z* (%): 287(19), 259(22), 243(48), 203(29), 201(30), 186(31), 159(56), 118(70), 114(100), 104(86), 99(50), 84(36); ms (ei, high resolution), *m/z* calcd. for $C_{16}H_{22}N_2O$ [$M^+ - N_2$]: 258.1732; found: 258.1748; calcd. for $C_{15}H_{19}N_2O$ [$M^+ - N_2 - CH_3$]: 243.1497; found: 243.1503.

Reaction of 3 with diphenylnitrilimine

A flask containing **3** (236 mg, 1.41 mmol), benzoyl chloride phenyl-

hydrazone (10) (326 mg, 1.41 mmol), Et_3N (300 mg, 2.87 mmol), and 5 mL of dry CH_2Cl_2 was stirred at room temperature for 44 h. At this time, 4 volumes of ether were added and the solution was filtered. After concentration of the filtrate, the residue was applied to a basic Al_2O_3(II) column. Development with 10% ether in light petroleum afforded **15** (425 mg, 1.18 mmol) 84%, as a solid, mp 110°C (dec.), R_f 0.10 (10% ether). Spectral data for **15**: uv (hexanes), λ_{max} (log ε): 240 nm (4.14), 298 nm (3.93), 326 nm (4.18), 352 nm (4.10); ir (film), cm^{-1}: 1599, 1581(w), 1563(w), 1493, 1445(w), 1384, 1378, 1365, 1313, 1273, 1232, 1218; Raman, cm^{-1}: 1595 (N=N), 1562; ^1H nmr (90 MHz), δ: 1.28 (s, 9H), 1.49 (s, 3H), 1.70 (s, 3H), 3.42 (AB q, 2H, J = 18.3 Hz), 6.83–7.86 (m, 10H); ^{13}C nmr (125.76 MHz), δ: 26.85, 27.16 (Me's), 31.99 (*t*-Bu), 43.30 (CH_2), 52.72 (CMe_3), 102.68 (ring C), 119.58 (spiro C), 117.80, 121.80, 125.61, 128.47, 128.75, 128.93, 132.88, 143.15 (Ph C's), 146.51 (C=N); ms (ei), *m/z* (%): 333(1), 318(26), 262(32), 261(31), 143(26), 117(21), 77(100), 58(45); ms (ci, NH_3), *m/z* (%): 362(85), 334(100), 261(92), 74(46); ms (ei, high resolution), *m/z* calcd. for $C_{21}H_{24}N_3$ [$M^+ - N_2 - CH_3$]: 318.1970; found: 318.1974.

*Conversion of **12** to **13***

Triazoline **12** (104 mg, 0.36 mmol) was heated in 5 mL of benzene at 80°C for 3 h. After cooling and concentration, centrifugal chromatography of the residue (10% ethyl acetate in light petroleum) afforded **13** (83 mg, 0.32 mmol) 89%, obtained as a solid, mp 56–58°C (light petroleum), R_f 0.65 (25% EtOAc in petroleum, Al_2O_3). Spectral data for **13**: uv (MeOH), λ_{max} (log ε): 240 nm (4.04); ir (film), cm^{-1}: 3352 (br), 3121, 1597, 1576, 1508, 1467, 1438, 1405, 1391, 1379, 1362, 1214 (br); ^1H nmr (90 MHz), δ: 1.08 (s, 9H), 1.60 (s, 6H), 1.85 (s, br, 1H), 6.37 (s, 1H), 7.43–7.55 (m, 3H), 7.79–7.92 (m, 2H); ^{13}C nmr (125.76 MHz), δ: 30.64 (di-Me), 31.77 (*t*-Bu), 52.05, 52.76 (quat. C's), 98.10 (C-4), 126.63, 129.04, 129.57, 130.02 (Ph C's), 162.36 (C-3), 181.20 (C-5); ms (ei), *m/z* (%): 258(1), 243(79), 187(36), 186(38), 77(13), 58(100); ms (ci, CH_4), *m/z* (%): 259(8), 243(43), 186(26), 114(100), 74(9); ms (ei, high resolution), *m/z* calcd. for $C_{15}H_{19}N_2O$ [$M^+ - CH_3$]: 243.1497; found: 243.1503.

*Conversion of **15** to **16***

Triazoline **15** (95 mg, 0.25 mmol) was heated in benzene at 80°C for 3 h. After cooling and concentration, centrifugal chromatography (10% EtOAc in petroleum) afforded **16** (82 mg, 0.25 mmol) 94%, as a solid, mp 104–105°C (petroleum), R_f 0.63 (25% EtOAc in petroleum, Al_2O_3). Spectral data for **16**: uv (hexane), λ_{max} (log ε): 258 nm (4.24); ir (film), cm^{-1}: 3378 (br), 3063, 1599, 1538(w), 1498, 1460, 1421(w), 1389, 1377, 1363, 1213 (br); ^1H nmr (90 MHz), δ: 0.99 (s, 9H), 1.47 (s, 6H), 1.92 (s, br, 1H), 6.57 (s, 1H), 7.20–7.76 (m, 8H), 7.81–7.98 (m, 2H); ^{13}C nmr (125.76 MHz), δ: 31.71 (*t*-Bu), 32.28 (di-Me), 51.70, 52.80 (quat. C's), 102.50 (C-4), 125.57, 127.51, 128.49 (br), 128.54, 128.65, 133.28, 142.33 (Ph C's), 149.98 (C-3), 154.16 (C-5); ms (ei), *m/z* (%): 333(2), 318(61), 262 (80), 261(100), 77(18), 58(26); ms (ei, high resolution), *m/z* calcd. for $C_{22}H_{27}N_3$: 333.2205; found: 333.2210.

*Decomposition kinetics of triazolines **12** and **15***

Medium-walled nmr tubes were charged with the substrate and with sufficient benzene to give solutions with the concentrations indicated in Table 2. The solutions were degassed by means of three "freeze–pump–thaw" cycles before the tubes were sealed and immersed in constant temperature baths controlled to ±0.1°C.

Progress of the decomposition was monitored by ^1H nmr spectroscopy. Integration of the *tert*-butyl and *gem*-dimethyl signals of all components provided the normalizing integrals. Decompositions were followed to at least 85% conversion. Good fits of the data to the first-order rate law were obtained. The activation parameters listed in Table 2 were calculated from the Eyring equation.

*Synthesis of triazoline **22***

A flask was charged with **3** (171 mg, 1.03 mmol), *p*-nitrophenyl azide (46) (168 mg, 1.01 mmol), and 5 mL of dry CH_3CN. The contents were stirred at room temperature for 5 days. At this time the contents were concentrated (aspirator) and applied to a basic Al_2O_3(II) column. Elution was with 33% ether in light petroleum. The fraction with R_f 0.20 (33% ether) was collected and concentration afforded **22** (220 mg, 0.66 mmol) 65% as a yellow solid, mp 80°C (dec.) (light petroleum). Spectral data for **22**: uv ($CHCl_3$), λ_{max} (log ε): 280 nm (3.75), 332 nm (4.19); ir (film), cm^{-1}: 1604, 1524, 1502, 1400(w), 1382(w), 1370, 1341, 1328, 1300(w), 1290, 1272, 1172; Raman, cm^{-1}: 1596 (C—N=N—C), 1589, 1329, 1290, 1113; ^1H nmr (90 MHz), δ: 1.12 (s, 9H), 1.64 (s, 3H), 1.88 (s, 3H), 4.63 (AB q, 2H, J = 18.6 Hz), 7.40 (d, 2H, J = 9.3 Hz), 8.30 (d, 2H, J = 9.3 Hz); ^{13}C nmr (125.76 MHz), δ: 26.82, 27.05 (Me's), 31.60 (*t*-Bu), 53.04 (CMe_3), 73.03 (CH_2), 104.11 (sp^3 ring C), 114.12 (spiro C), 116.62, 125.13, 143.64, 144.48 (Ph C's); ms (ei), *m/z* (%): 275(16), 218(24), 163(50), 138(42), 117(21), 98(38), 82(73), 58(44), 57(100); ms (ci, NH_3), *m/z* (%): 332(8), 276(48), 246(47), 168(100), 140(38), 113(75), 111(40), 109(81); ms (ei, high resolution), *m/z* calcd. for $C_{15}H_{21}N_3O_2$ [$M^+ - N_4$]: 275.1634; found: 275.1633.

*Reaction of **3** and phenyl azide in benzene*

Triazoline **3** (384 mg, 2.30 mmol) and phenyl azide (47) (375 mg, 3.15 mmol) were heated together in 30 mL of benzene at 80°C for 43 h. After cooling, the benzene was removed (aspirator) followed by the excess phenyl azide (vacuum line). The residue was applied to a neutral Al_2O_3(II) column. Development with 2% ether in petroleum afforded **26** (85 mg, 0.37 mmol) 16% as a white solid, mp 52–54°C (light petroleum), R_f 0.28 (2% ether). Increasing the solvent polarity to 20% ether gave **21** and **29*a*** as a mixture (R_f 0.10, 20% ether). Centrifugal chromatography of this mixture (5% EtOAc in petroleum) gave pure **29*a*** (107 mg, 0.74 mmol) 32%, obtained as a solid, mp 52–53.5°C (light petroleum) (lit. (33) mp 55–56°C). Product **21** could not be recovered. The yield of **21** (7%) was estimated from the ^1H nmr spectrum of the crude reaction mixture. Spectral data for **26*a***: uv (MeOH), λ_{max} (log ε): 246 nm (4.01); ir (film), cm^{-1}: 1674 (vs), 1594, 1489, 1368, 1271, 1251, 1230, 1131; ^1H nmr (90 MHz), δ: 1.41 (s, 9H), 1.42 (s, 6H), 2.52 (s, 2H), 6.78–7.28 (m, 5H); ^{13}C nmr (125.76 MHz), δ: 28.27 (di-Me), 28.39 (*t*-Bu), 44.14 (CH_2), 55.30 (CMe_3), 61.01 (sp^3 ring C), 121.65, 122.71, 128.79, 150.66 (Ph C's), 156.42 (C=N); ms (ei), *m/z* (%): 230(38), 173(18), 139(28), 118(100), 98(25), 82(60), 57(77); ms (ei, high resolution), *m/z* calcd. for $C_{15}H_{22}N_2$: 230.1783; found: 230.1780. Partial ^1H nmr data for **27*a***, from ^1H nmr spectrum of crude reaction mixture (500 MHz), δ: 1.24 (s, 9H), 1.53 (s, 3H), 4.08 (dd, 1H, J = 10.5 and 17.4 Hz), 4.54 (s, br, 1H), 4.58 (dd, 1H, J = 3.2 and 17.4 Hz), 4.83 (s, br, 1H), 5.47 (dd, 1H, J = 3.2 and 10.5 Hz).

*Extended heating of **3** and phenyl azide*

Triazoline **3** (354 mg, 2.12 mmol) and phenyl azide (140 mg, 3.48 mmol) were heated in 30 mL of benzene at 80°C for 30 h. After removal of the benzene and the phenyl azide as described above, toluene (20 mL) was added. This solution was refluxed for 22 h before cooling and removal of the toluene by vacuum distillation. The residue was applied to a neutral Al_2O_3(II) column. Elution was with 1% ether in petroleum and afforded **30*a*** (24 mg, 0.10 mmol) 5%, R_f 0.48 (1% ether), followed by **26*a*** (68 mg, 0.30 mmol) 14%. Increasing the solvent polarity provided **21** and **29*a*** as a mixture. Centrifugal chromatography of this mixture provided **29*a*** (43 mg, 0.30 mmol) 14%. The yield of **21** was estimated to be 3%. Spectral data for **30*a***: uv (hexanes), λ_{max} (log ε): 236 nm (4.23); ir (film), cm^{-1}: 3061, 1610 (vs), 1592, 1482, 1370, 1345, 1267, 1223; ^1H nmr (90 MHz), δ: 1.53 (s, 9H), 1.79 (s, 3H), 1.93 (s, br, 3H), 4.91 (s, br, 1H), 5.20 (s, br, 1H), 6.61–7.17 (m, 5H).

*Reaction of **3** and phenyl azide in CH_3CN*

Triazoline **3** (176 mg, 1.05 mmol) and phenyl azide (317 mg, 2.66 mmol) were heated in 5 mL of CH_3CN at 65°C for 3 days. After cooling the CH_3CN was removed (aspirator), followed by the phenyl azide (vacuum line). Centrifugal chromatography (10% EtOAc in petroleum) of the residue provided pure **21** (109 mg, 0.42 mmol) 40%, obtained as a solid, mp 55–56°C (light petroleum), R_f 0.17 (Al_2O_3, 10% EtOAc). Product **26*a*** was detected by analytical gc in <1%

yield. Spectral data for **21**: uv (MeOH) λ_{max} (log ε): 262 nm (3.43); ir (film), cm^{-1}: 3340(br), 3158, 1600, 1537(w), 1581, 1471(w), 1452, 1413(w), 1390, 1380, 1363, 1311, 1230, 1220, 1201, 1180, 1169, 1164, 1127; ^1H nmr (90 MHz), δ: 1.02 (s, 9H), 1.50 (s, 6H), 7.57–7.63 (m, 5H), 7.64 (s, 1H); ^{13}C nmr (125.76 MHz), δ: 32.01 (di-Me), 32.15 (*t*-Bu), 51.91, 52.01 (sp^3 C's), 127.99, 128.71, 129.85, 147.21 (Ph C's), 132.04 (4-C), 138.58 (5-C); ms (ei), *m/z* (%): 258(2), 243(25), 186(21), 158(16), 114(24), 77(20), 58(100); ms (ei, high resolution), *m/z* calcd. for $C_{15}H_{22}N_4$: 258.1844; found: 258.1839.

Reaction of ***3*** *and* p*-nitrophenyl azide in benzene*

Triazoline **3** (260 mg, 1.56 mmol) and *p*-nitrophenyl azide (260 mg, 1.58 mmol) were heated together in 15 mL of benzene at 80°C for 20 h. After cooling, the benzene was removed (aspirator) and the residue was triturated with 3 × 30 mL of hot 30–60°C petroleum ether. The petroleum extracts were combined and put in a freezer at −20°C for 12 h. The liquid was decanted from the solid film that had fallen from solution. The liquid was concentrated and applied to a neutral Al_2O_3(II) column. Development with 2% ether in light petroleum provided *p*-nitrophenyl azide (R_f 0.39, 2% ether) followed by amidine **30***b* (82 mg, 0.30 mmol) 19%, as a yellow solid, mp 90–92°C (light petroleum), R_f 0.57 (10% ether). Gradual increase of the polarity to 10% ether afforded amidine **26***b* (128 mg, 0.47 mmol) 30%, mp 93–94°C (petroleum), R_f 0.32 (10% ether), followed by **31***b* (15 mg, 0.06 mmol) 4%, as a yellow solid, mp 137–138°C (from $CHCl_3$ in light petroleum), R_f 0.12 (10% ether).

The solid that fell from the cold petroleum ether solution was taken up in a small amount of solvent and applied to a neutral Al_2O_3(II) column. Development with 33% ether in light petroleum provided 1,2,3-triazoline **27***b* (99 mg, 0.33 mmol) 21%, mp 120–122°C, R_f 0.61 (33% ether), followed by *p*-nitroaniline (4 mg, 0.03 mmol) 2%, R_f 0.09 (33% ether). Spectral data for **26***b*: uv ($CHCl_3$), λ_{max} (log ε): 372 nm (4.52); ir (film), cm^{-1}: 1652(br), 1578(br), 1502, 1381, 1369, 1327, 1260, 1219, 1168, 1131, 1104, 1073; ^1H nmr (90 MHz), δ: 1.51 (s, 9H), 1.57 (s, 6H), 2.66 (s, 2H), 6.91 (d, 2H, J = 9.3 Hz), 8.13 (d, 2H, J = 9.3 Hz); ^{13}C nmr (22.62 MHz), δ: 27.94 (di-Me), 28.21 (*t*-Bu), 44.39 (CH_2), 55.97 (CMe_3), 62.18 (sp^3 ring C), 122.48, 125.10, 141.96, 157.62 (Ph C's), 157.49 (C=N); ms(ei), *m/z* (%): 275(32), 218(26), 204(17), 163(41), 139(49), 98(30), 82(67), 58(38), 57(100); ms (ei, high resolution), *m/z* calcd. for $C_{15}H_{21}N_3O_2$: 275.1634; found: 275.1633. Spectral data for **27***b*: uv (hexanes), λ_{max} (log ε): 220 nm (3.66), 3.38 nm (3.79), ir (film), cm^{-1}: 3042, 1578(br), 1502, 1383, 1370, 1329, 1208; ^1H nmr (500 MHz), δ: 1.31 (s, 9H), 1.53 (s, 3H), 4.19 (dd, 1H, J = 10.0 and 17.7 Hz), 4.53 (s, br, 1H), 4.72 (dd, 1H, J = 2.9 and 17.7 Hz), 4.85 (s, br, 1H), 5.50 (dd, 1H, J = 2.9 and 10.0 Hz), 7.56 (d, 2H, J = 9.2 Hz), 8.23 (d, 2H, J = 9.2 Hz); ^{13}C nmr (125.76 MHz), δ: 25.12 (Me), 29.78 (*t*-Bu), 55.17 (CMe_3), 66.90 (CH), 71.71 (CH_2), 116.82 (=CH_2), 114.87, 125.57, 140.75, 146.02 (Ph C's), 145.96 (vinyl C); ms, (ei), *m/z* (%): 275(7), 204(11), 177(33), 121(87), 82(60), 57(100), 41(72). Spectral data for **31***b*: uv ($CHCl_3$), λ_{max} (log ε): 350 nm (3.90); ir (film), cm^{-1}: 3422(br), 1644, 1584, 1526, 1487, 1323, 1261, 1202, 1611, 1102; ^1H nmr (90 MHz), δ: 1.46 (s, 9H), 1.79 (s, 3H), 4.38 (s, br, 1H), 6.78 (d, 2H, J = 9.0 Hz), 8.16 (d, 2H, J = 9.0 Hz); ^{13}C nmr (22.62 MHz), δ: 18.81 (Me), 28.74 (*t*-Bu), 51.84 (CMe_3), 122,21, 125.09, 142.03, 159.08 (Ph C's), 153.21 (C=N); ms (ei), *m/z* (%): 235(44), 179(24), 178(100), 163(38), 138(100), 108(38), 76(36), 57(57); ms (ei, high resolution), *m/z* calcd. for $C_{12}H_{17}N_3O_2$: 235.1320; found: 235.1324. ^1H nmr data for **29***b* obtained from crude reaction mixture (34) (500 MHz), δ: 7.92 (s, 1H), 8.00 (d, 2H, J = 9.1 Hz), 8.13 (s, 1H), 8.43 (d, 2H, J = 9.1 Hz).

Extended heating of ***3*** *and* p*-nitrophenyl azide*

Triazoline **3** (219 mg, 1.31 mmol) and *p*-nitrophenyl azide (220 mg, 1.34 mmol) were heated in benzene at 80°C for 24 h. After cooling, concentration, and trituration of the mixture into 3 × 30 mL of hot 30–60°C petroleum, the petroleum was concentrated (aspirator) and the residue was taken up in 10 mL of toluene. This solution was heated for 12 h at 110°C. After cooling and removal of the toluene by vacuum distillation, the residue was triturated with 3 × 30 mL of hot petroleum ether. The combined petroleum ether extracts were put in a freezer for 12 h.

Chromatography of the components remaining in solution was done as described above and afforded **30***b* (94 mg, 0.34 mmol) 26%, **26***b* (115 mg, 0.42 mmol) 32%, and **31***b* (15 mg, 0.07 mmol) 5%.

Chromatography of the solid that fell from the cold petroleum solution afforded *p*-nitroaniline (27 mg, 0.20 mmol) 15%.

Partial decomposition of ***22*** *in benzene*

Triazoline **22** (20 mg in 3 mL of benzene) was heated at 80°C for 2 h. After cooling, tlc indicated the presence of **26***b*, **27***b*, **30***b*, **31***b*, and *p*-nitroaniline as well as starting material **22**, *p*-nitrophenyl azide, and triazoline **3**.

Vanadium(V) oxyanions. The dependence of vanadate alkyl ester formation on the pK_a of the parent alcohols

ALAN S. TRACEY, BRUNO GALEFFI, AND SOROUSH MAHJOUR
Department of Chemistry, Simon Fraser University, Burnaby, B.C., Canada V5A 1S6

Received January 22, 1988

ALAN S. TRACEY, BRUNO GALEFFI and SOROUSH MAHJOUR. Can. J. Chem. **66**, 2294 (1988).

The interaction of vanadate ($VO_4H_2^{1-}$) with a variety of alkyl alcohols (ROH) covering about seven pK_a units of acidity have been studied in aqueous solution by ^{51}V nuclear magnetic resonance spectroscopy. A linear free energy relationship between the equilibrium constant for the formation of the vanadate monoester ($HOVO_3R^{1-}$) and the acidity of the alcohol was established at 23°C. The correlation was found to be log $1/K = -(0.09 \pm 0.02)pK_a^{ROH} + 2.1 \pm 0.3$ where $K = [HOVO_3R^{1-}]/[VO_4H_2^{1-}][ROH]$. This correlation was shown not to extend to ligands with π-bonding capability such as phenols or phosphates, where the products are highly favoured relative to the alkyl esters. An interesting correlation between pK_a values of the product esters and the pK_a of the parent alcohols was also observed. It was found that below a pK_a^{ROH} of about 15 the pK_a values of the esters were essentially constant. However, above this value of 15 the pK_a of the ester was found to increase rapidly with an increase in pK_a of the alcohol. This result may indicate that the electron accepting ability of the metal is exhausted with the higher pK_a alcohols, and the extra electron density is transferred to the oxygens, thus causing an increase in pK_a of the ester.

ALAN S. TRACEY, BRUNO GALEFFI et SOROUSH MAHJOUR. Can. J. Chem. **66**, 2294 (1988).

Operant en solution aqueuse et utilisant la spectroscopie rmn du ^{51}V, on a étudié l'interaction du vanadate ($VO_4H_2^{1-}$) avec un grand nombre d'alcools aliphatiques (ROH) couvrant sept unités de pK_a. À 23°C, on a pu établir une relation linéaire d'énergie libre entre la constante d'équilibre pour la formation du monoester de vanadate ($HOVO_3R^{1-}$) et l'acidité des alcools. On a trouvé que la corrélation prend la forme de log $1/K = -(0{,}09 \pm 0{,}02)pK_a^{ROH} + 2{,}1 \pm 0{,}3$, dans laquelle $K = [HOVO_3R^{1-}]/[VO_4H_2^{1-}][ROH]$. On a démontré que cette corrélation ne s'étend pas aux ligands présentant une capacité de liaison par des électrons π, comme les phénols ou les phosphates; dans ces cas, les produits sont très favorisés par rapport aux esters d'alkyles. On a aussi observé une corrélation intéressante entre les valeurs des pK_a des esters qui se forment comme produits et les pK_a des alcools qui leur donnent naissance. On a trouvé qu'en-dessous d'une valeur de 15 pour le pK_a^{ROH}, les valeurs des pK_a des esters augmentent rapidement avec une augmentation du pK_a des alcools. Ce résultat semble indiquer que la facilité du métal à accepter des électrons est épuisée avec les alcools de pK_a élevé et que la densité électronique additionnelle est transférée aux oxygènes; ceci provoque une augmentation du pK_a de l'ester.

Introduction

The aqueous chemistry of the higher oxidation states of vanadium is attracting increasing attention in chemistry and biochemistry. There is considerable evidence that vanadium is an essential element for animals (1, 2). Vanadium is found in the enzyme systems of some nitrogen-fixing bacteria (3, 4) and is apparently utilized in the halogenation processes of a variety of seaweeds (4). Vanadium(V) (vanadate) and vanadium(IV) (vanadyl) oxyanions can have a large effect on the function of a variety of enzymes either as an activator or inhibitor of the enzyme function (1, 5). The ability of vanadate to affect enzyme function seems to arise, at least in part, from the ability of vanadate to act as a phosphate analogue.

The condensation of phosphate with hydroxylic compounds to form a phosphate derivative is, to a significant extent, dependent on the acidity of the hydroxyl group. Thus, the formation constant for phosphate esters of alkyl alcohols is comparatively favourable, comparable in fact to the formation constant for alkyl vanadates as for instance in the case of formation of phosphate and vanadate esters of ethanol (6). The formation of phosphate esters of phenols is, by comparison, highly unfavourable when compared with those for ethyl phosphate and phenyl vanadate (7). An investigation of this phenomenon has shown that there is a direct relationship between the acidity constant, K_a, of the parent hydroxylic compound and the formation or hydrolysis constant for the phosphate ester (8).

The equilibrium constant for hydrolysis of the phosphate ester dianion is related to the pK_a of the parent hydroxyl group by eq. [1],

$$[1] \quad \log K = -1.35pK_a^{ROH} + 7.50$$

where K is the hydrolysis constant defined by eq. [2] and pK_a^{ROH} is the pK_a of the hydroxyl group of interest (8). In eq. [2]

$$[2] \quad HOPO_3^{2-} + H^+ + RO^- \underset{K}{\rightleftharpoons} ROPO_3^{2-}$$

$$K = [HOPO_3^{2-}][H^+][RO^-]/[ROPO_3^{2-}]$$

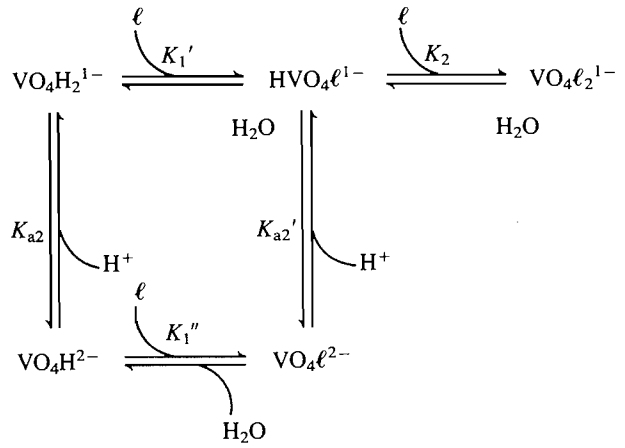
the formation of water is not explicitly considered. In view of the linear free energy relationship between product formation and the pK_a of the hydroxyl group expressed by eq. [1] for phosphate, it was decided to investigate the vanadate system in more detail, particularly in view of the fact that the available information suggested that the vanadate system showed much more complex behaviour.

^{51}V nuclear magnetic resonance (NMR) spectroscopy allows direct measurement of the equilibria since separate signals from the vanadium products and precursors, in general, are observed in the NMR spectra. Simple correlations, determined as a function of ligand or vanadate concentration, or of pH provide the requisite information.

Experimental

Materials

Reagent grade chemicals were used without further purification. Proton NMR spectra indicated that all the alkyl alcohols used in this



SCHEME 1

study were greater than 97% pure. Preparation of stock solutions and final solutions followed procedures previously described (6, 9).

Spectroscopy

All ^{51}V NMR spectra were obtained at ambient temperature from a Bruker WM-400 NMR spectrometer operating at the vanadium frequency of 105.2 MHz. Spectral widths of 40 kHz, 50° pulse widths and 0.05 s acquisition times were used for all spectra. Relative signal intensities were obtained using the integration routine supplied by the instrument manufacturer. No effort to obtain more accurate integrals through use of line-fitting or other methods was made. Chemical shifts are reported relative to that of $VOCl_3$ at 0.0 ppm.

Methods

The methods employed for determination of equilibrium constants for formation of the vanadate esters have been described in detail elsewhere as have the procedures employed for the determination of the pK_a values for those compounds with ionizable protons (6). No significant changes have been made to those methods in this study.

Results and discussion

The vanadate ion spontaneously and reversibly condenses with a variety of molecules containing hydroxyl groups to provide esterified vanadate derivatives (6, 7, 9, 10). This condensation has been shown to be reasonably favourable both for the ions VO_4H^{2-} and $VO_4H_2^-$ with the individual condensations apparently occurring in the manner indicated in Scheme 1 where l refers to the ligand.

In Scheme 1 the esterification reactions tend to be slow on the NMR time scale and as a consequence separate NMR signals can generally be observed for vanadate and its mono- and diesters. Proton exchange, on the other hand, is fast and because of the rapid proton exchange it is not possible to measure K_1' and K_1'' independently of each other in an NMR experiment but, rather, only an observed equilibrium, K_1, which is dependent on K_{a2} and K_{a2}', can be measured, K_1 is defined by eq. [3], and water formation is not explicitly considered. In eq. [3], T_i refers to tetrahedral vanadate, $VO_4H_2^-$ plus VO_4H^{2-}, and Tl to the product esters.

$$[3] \quad T_i + l \overset{K_1}{\rightleftharpoons} Tl \quad [T_i][l]K_1 = [Tl]$$

Expressing K_1 in terms of K_1', K_{a2} and K_{a2}' of Scheme 1 yields eq. [4].

$$[4] \quad K_1 = \frac{K_1'(1 + K_{a2}'/[H^+])}{1 + K_{a2}/[H^+]}$$

It is evident that if K_1 is determined for a variety of pH values near K_{a2} and K_{a2}', then all the constants of eq. [4] can be determined and as well K_1'' of Scheme 1. In practice, it is easier to measure K_{a2} and K_{a2}' directly since these values can be determined by the effect of pH on the chemical shifts of the ^{51}V NMR signals corresponding to T_i and Tl. A change in protonation state of vanadate or its monoester has a substantial effect on the shielding of the vanadium nucleus. At a pH well below the pK_{a2} of vanadate, the vanadate species in solution is $VO_4H_2^{1-}$, which is characterized by a chemical shift δ_l at a pH well above pK_{a2}, the species in solution is VO_4H^{2-} with the chemical shift δ_h. At intermediate pH values the observed shift, δ, is related to the pH and pK_a by eq. [5],

$$[5] \quad pH = pK_a + \log \frac{\delta - \delta_l}{\delta_h - \delta}$$

It is useful to note that when the logarithmic term is plotted against pH the slope of the straight line should be 1. This provides a convenient test of the applicability of eq. [5] to the system being studied. Equation [5] is also applicable to the vanadate monoester but not the diester $VO_4l_2^{1-}$, since the diester has no proton to lose. In this case the ^{51}V chemical shift should be pH-independent. This has been demonstrated for the vanadate/ethanol system (6) and has been observed here. Table 1 gives the chemical shifts and pK_a values for vanadate and its esters for a variety of alcohol solutions.

Knowledge of the K_{a2} and K_{a2}' values for vanadate and its esters then provides K_1' simply by determining K_1 of eq. [2] at any pH and applying eq. [4]. Of course K_1 must be determined within a pH range much lower than the pK_a for the alcohol or pK_{a3} of vanadate and well above pK_{a1} for vanadate or its ester. If this is not done, Scheme 1 must be expanded appropriately. Fortunately the pK_{a1} values are low, about 3.0 for vanadate (11, 12), while pK_{a3} of vanadate and the pK_a of the alcohols except for hexafluoroisopropanol are quite high (pK_a for CF_3-$CHOHCF_3$ = 9.3, pK_a (VO_4H^{2-}) ~ 13 (12)). From the various equilibrium constants measured at a pH near 7 and the known K_a values the respective K_1' and K_1'' were calculated and collected into Table 2.

From the entires of Table 2 it can be seen that the K_a values for the alcohols of this study range over about 7 orders of magnitude from pK_a = 9.3 for $(CF_3)_2CHOH$ to ~16.8 for *t*-butanol. Despite this large change in pK_a values, the formation constants of the various esters ranges only from about $0.20\,M^{-1}$ for the higher pK_a values to $0.06\,M^{-1}$ for the lower values. The decrease in formation constants, although small, follows the decrease in pK_a of the alcohols. This result does show that ester formation is not particularly sensitive to the pK_a of the alcohol. It can, however, be shown that, with the exception of the methyl and *t*-butyl vanadate esters, there is a linear free energy relationship between the pK_a of the alcohol and the hydrolysis (or formation) constant of the ester as can be seen by plotting $\log(1/K_1')$ versus the pK_a of the parent alcohol. When this was done a straight line of slope -0.09 ± 0.02 and intercept $+2.1 \pm 0.3$ as shown in Fig. 1 was obtained. The very small slope of this correlation illustrates the insensitivity of ester formation to the electron withdrawing ability of the ligand, RO^-.

This line has a slope of -1.09 ± 0.02 when cast into the form of eq. [1], for which a slope of -1.0 indicates that ester formation is independent of the pK_a of the parent alcohol. It is

[a] Equilibrium constants are those defined by Scheme 1 and were determined as discussed in the text. Estimated errors for all equilibrium constants are about 10% of the reported values except for the K_2 values where the errors are about ±0.01 M^{-1} for all measurements.
[b] Alcohol pK_a values were taken from tabulations in ref. 17.
[c] The pK_a for this alcohol was estimated from values for related compounds tabulated in ref. 17.
[d] The statistical factor of two is removed from reported formation constants (ref. 16) to give the formation constants K'_1 and K''_1.

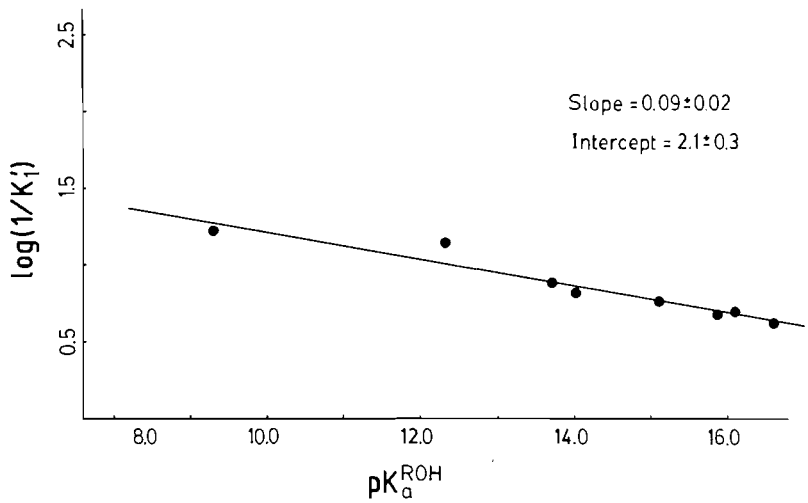

FIG. 1. The linear free energy relationship between the vanadate ester hydrolysis constants and the acidity constants of the product alcohols is shown. The experimental points are taken from the data of Table 2.

evident then, that phosphate alkyl ester formation is considerably more sensitive than vanadate alkyl ester formation to the pK_a of the alcohol. In fact the formation of vanadate alkyl esters shows a sensitivity to neighbouring substituents which is comparable to that attributable to electron withdrawal or donation as is evident for the formation of *t*-butyl vanadate, $K'_1 = 0.095 \pm 0.005 M^{-1}$ (10), 1-vanado-3-hydroxybutane, $K'_1 = 0.25 \pm 0.01 M^{-1}$ (10), 1-hydroxy-3-vanadobutane, $K'_1 = 0.29$

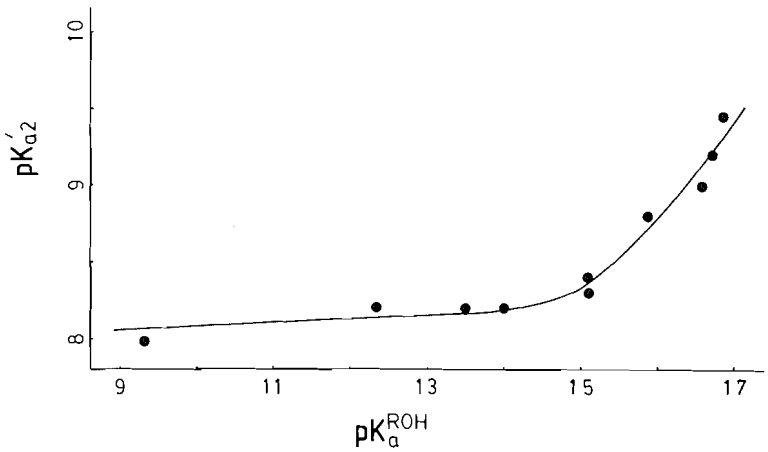

FIG. 2. The free energy relationship between the acidity constant of the vanadate esters, $HOVO_3R$, and those of the parent alcohols, ROH. The experimental points are taken from Table 1. (Note that the pK'_{a2} of this figure corresponds to the pK''_{a2} of Table 1.)

$\pm 0.02 M^{-1}$ (10) and 2-vanadopropionate, $K'_1 = 0.54 \pm 0.05 M^{-1}$ (13).

Interestingly enough, when an attempt was made to expand the considerations of pK_a to include hydroxylic compounds other than the alkyl alcohol systems of Table 2, no simple relationship between the pK_a of the parent hydroxyl and product formation was found. For instance, phosphate ($PO_4H_2^-$) with a pK_a of 6.70 readily forms a phosphovanadate anhydride, from $VO_4H_2^-$, with a formation constant of $64 \pm 3 M^{-1}$ (9). This value is much larger than the formation constants for vanadate esters from alkyl alcohols (Table 2) and clearly shows the presence of strong product stabilizing interactions which oppose the destabilizing interactions of electron withdrawal. Such stabilizing interactions apparently are much less significant for the case of formation of pyrophosphate from phosphate since pyrophosphate is a high energy phosphate product.

Somewhat similar behaviour is observed in the case of phenol. Phenylvanadate is formed with a formation constant of $1.0 M^{-1}$ (7), a value about 15 times larger than that expected for alkyl vanadates formed from alkyl alcohols of a similar pK_a^{ROH}, but about 4 orders of magnitude larger than phenyl phosphate formation (7). Behaviour such as this may indicate that the enhanced stabilization arises from vanadium *d*-orbital interactions with the π-system of the ligand. A variety of substituted phenols is currently being studied in an attempt to obtain more information concerning the factors influencing vanadate condensation reactions.

An additional point to be made from the information of Table 2 is that as the pK_a of the parent alcohol increases, the formation (K''_1) of $ROVO_3^{2-}$ from VO_4H^{2-} becomes increasingly favoured relative to the formation (K'_1) of $ROVO_3H^-$ from $VO_4H_2^-$. For example, for the very high pK_a alcohols such as *t*-butanol and *s*-butanol the proportion $K'_1 : K''_1$ is about 20:1 whereas with the low pK_a alcohols this proportion is about 1:1.

The effect that the aqueous solutions of the different alcohols have on the pK_{a2} of vanadate is rather small but significant. In general, the alcohol tends to increase the pK_a thus favouring the least ionized form of vanadate. Similar considerations also apply to the vanadate ester. If the effects of alcohol on the pK_a of $VO_4H_2^{1-}$ and on the pK_a of the ester $ROVO_3H^{1-}$ are similar, then the pK_a of the ester in dilute solution can be estimated by applying a correction factor obtained by comparing the pK_a of $VO_4H_2^{1-}$ in water ($pK_{a2} = 8.2$) to that observed for the aqueous alcoholic solutions in which the pK_a was measured (Table 1). The ester pK_a values estimated by this procedure are tabulated in Table 1 under pK''_{a2}. Corrections obtained by this type of procedure have been shown to be valid from studies of the effect of solvent on acid/base equilibria where it was concluded that solvent does not affect the relative strengths of acids as long as they are the same charge and same chemical type (14).

An interesting point of this study is revealed when the pK''_{a2} values of the alkyl esters and their parent alcohols are compared as shown in Fig. 2. From this graph it is seen that for alcohols with a pK_a below about 15, the pK''_{a2} values of the product esters are essentially constant; however, at a pK_a^{ROH} of about 15, the pK''_{a2} of the esters rise rapidly with increase in pK_a of the parent alcohols. The reason for this is not clear, but the behaviour indicates that the vanadium centre becomes saturated with electrons and any further electrons inductively introduced to the coordination centre are redistributed to the oxygens of the vanadate thus increasing pK''_{a2}. Below the critical pK_a^{ROH} the electron density may be localized to the vanadium centre. This behaviour is reminiscent of that observed for a homologous series of bidentate ligands where it was found that the coordination geometry and protonation state of the product vanadium(V) derivative depended in a rather subtle manner on the oxidation state of the ligand (13).

Fungal biotransformation of 1,3-oxathiolanes

HERBERT L. HOLLAND AND BENITO MUNOZ
Department of Chemistry, Brock University, St. Catharines, Ont., Canada L2S 3A1

Received January 14, 1988

HERBERT L. HOLLAND and BENITO MUNOZ. Can. J. Chem. **66**, 2299 (1988).

A series of 2,2-disubstituted 1,3-oxathiolanes has been incubated with fungi known to be capable of efficient asymmetric oxidation of sulfides to sulfoxides. In three cases (2-phenyl-1,3-oxathiolane, 2-methyl-2-phenyl-1,3-oxathiolane, and 2-*tert*-butyl-2-phenyl-1,3-oxathiolane), sulfoxidation occurred to give a single diastereomer of sulfoxide, whose relative stereochemistry has been assigned by ^{1}H nuclear magnetic resonance analysis. The sulfoxides were obtained as racemates or had low enantiomeric enrichment. In some cases ketones, assumed to be formed by spontaneous hydrolysis of oxathiolane sulfoxides, were obtained, together with their reduction products, secondary alcohols.

HERBERT L. HOLLAND et BENITO MUNOZ. Can. J. Chem. **66**, 2299 (1988).

On a soumis une série d'oxathiolanes-1,3 disubstitués en position-2,2 à une incubation avec des champignons qui sont connus pour leur capacité de provoquer une oxydation asymétrique des sulfures en sulfoxydes. Dans trois cas (phényl-2, méthyl-2 phényl-2 et *tert*-butyl-2 phényl-2 oxathiolanes-1,3), la réaction de sulfoxydation se produit pour conduire à un seul sulfoxyde diastéréomère dont la stéréochimie relative a été déterminée par une analyse du spectre en résonance magnétique nucléaire du ^{1}H. Les sulfoxydes ont été obtenus sous la forme de racémates ou de mélanges pour lesquels l'enrichissement énantiomérique est faible. Dans quelques cas, on a obtenu des cétones, qui se sont vraisemblablement formées par une hydrolyse spontanée des sulfoxydes d'oxathiolanes, ainsi que les alcools secondaires qui proviennent de leur réduction.

The use of actively growing or resting cultures of fungi to convert organic sulfides of type R^1—S—R^2 to the corresponding sulfoxides, with introduction of chirality at the sulfur atom, represents, in many cases, the most efficient method for the preparation of such chiral molecules (1–3). Not only can this enzymatic reaction occur with selective oxidation of the enantiotopic electron pairs of sulfur (1–3), but, with appropriate substrates such as the 1,3-dithianes (**1**), enzymic sulfoxidation can also result in enantioenrichment at C-2 by selection between the two enantiotopic sulfur atoms (4, 5).

We have studied a range of substituted 1,3-oxathiolanes (**2**) as substrates for sulfoxidation by four fungi known to be capable of efficient asymmetric sulfoxidation of sulfides, namely *Mortierella isabellina* (2, 6) *Helminthosporium* species (6), *Aspergillus niger* (1), and *Rhizopus arrhizus* (5). These substrates, readily prepared from the corresponding ketones by treatment with 2-mercapto ethanol, offer the possibility of induction of chirality at C-2 concomitant with selective oxidation at the single sulfur atom. Neither 1,3-oxathiolanes nor the corresponding dithiolanes, dithio ethylene ketals, have been previously studied as substrates for fungal biotransformation.

Of the range of oxathiolane substrates studied, only three (**2***a*–**2***c*) were converted to sulfoxides (**3***a*–**3***c*, respectively) by *M. isabellina*, in a low yield (see Table 1). Of the other fungi studied, only *R. arrhizus* gave a sulfoxide product, **3***c*. In some cases (**2***a*–**2***d* and **2***g* with *M. isabellina*, and **2***c* and **2***d* with *R. arrhizus*), products were obtained that were identified as the corresponding ketones **5** and (or) the secondary alcohols **6**. Since these fungi are known to be capable of reducing a carbonyl group (7, 8), the latter products were presumably produced by the enzymic reduction of the corresponding ketones (**5**). In two cases (**5***a* → **6***a* and **5***c* → **6***d*) this was confirmed by the use of the ketones as substrates for *M. isabellina*; the alcohols produced in this way had the same enantiomeric enrichments and predominant absolute stereochemistries as those isolated from the use of oxathiolane substrates, strongly suggesting the intermediacy of ketones in the production of alcohols from oxathiolanes.

The ketones **5** could be produced as the hydrolysis products of either the oxathiolane **2** or the corresponding sulfoxide, **3**. We favour the intermediacy of the latter for the following reasons: control experiments with inactivated enzymes (auto-

*Normal (see Experimental) unless otherwise stated.

claved fungus) suggest that the oxathiolanes are stable to non-enzymic hydrolysis under the conditions of the incubation. Thus **2***b*, **2***d*, and **2***g* were recovered unchanged, and unaccompanied by ketone, from incubation with inactivated *M. isabellina* (Table 1). Furthermore, oxathiolane sulfoxides, as discussed below and noted by others,[1] are hydrolytically labile. These observations suggest that, in cases where ketone and (or) alcohol products were observed in the absence of isolated sulfoxide (e.g., from **2***d* and **2***g*), the latter may have been formed but subsequently hydrolysed in the aqueous incubation medium.

The oxathiolane sulfoxides **3***a*–**3***c* were all characterized by spectral means. All were racemic ($[\alpha]_D$ 0°) with the exception of **3***c* produced by *M. isabellina*, which had an enantiomeric excess determined by ^{1}H nmr in the presence of chiral shift reagent to be less than 10%. In no case, however, was any evidence found either chromatographically or spectroscopically for the presence of more than one diastereomer of sulfoxide. The compounds were all hydrolytically labile, rapidly producing the corresponding ketone together with unidentified lower molecular weight species on standing on the bench or in wet organic solvents. The stability is in the order **3***c* ≫ **3***b* > **3***a*: the former compound can be stored for weeks under a dry argon atmosphere at −20°C, the latter surviving no more than a few days even under these conditions, and only a few hours in chloroform solution. In view of the rapid decomposition of **3***a* under analytical conditions (e.g., during acquisition of nmr and optical rotation data), the incubation of **2***a* was performed only with *M. isabellina*.

The relative stereochemistry of the oxathiolane sulfoxides was determined by ^{1}H nmr analysis of the spectrum of **3***b*, and then correlation of this spectrum with those of **3***a* and **3***c* (see Table 2). The ^{1}H nmr spectrum of **3***b* showed, in addition to signals attributed to the phenyl and methyl groups, a clearly defined set of four multiplet signals assigned to H-1–H-4 of **3***b* as follows: of the S-methylene proton signals centred at δ 2.8 and 3.0 ppm, the lower field set were assigned to H-2, *cis* to the sulfoxide oxygen, with the signals of H-1 assigned at 2.8 ppm. The downfield shift of signals from hydrogens *cis* to sulfoxide oxygen has previously been used for the assignment of relative stereochemistry of substituted dithiane sulfoxides derived from **1** (4, 5).

TABLE 2. The ^{1}H nmr data for **2***a*–**2***c*

Protons	δ, ppm **2***a*	**2***b*	**2***c*
H-1	2.8	2.8	2.5
H-2	3.0	3.0	2.9
H-3	4.5	4.4	4.2
H-4	4.7	4.7	4.8
	Coupling constants, Hz		
$J_{1,2}$	13.5	14.7	13.6
$J_{1,3}$	7.1	6.4	7.3
$J_{1,4}$	6.8	6.6	6.4
$J_{3,4}$	9.6	10.5	8.9
$J_{2,4}$	7.0	7.5	6.9
$J_{2,3}$	5.4	5.3	5.2

The other two sets of methylene signals in the spectrum of **3***b* belonged to the O-methylene protons, and appeared as multiplets centred at δ 4.4 and 4.7 ppm. They were assigned to H-3 and H-4 respectively, on the grounds of the expected downfield shift in the presence of a 1,3 phenyl substituent, and on the basis of 2-D COSY and selective proton decoupling experiments that gave the following coupling constants, consistent with the resonance assignments: $J_{1,2(gem)}$ = 14.7 Hz, $J_{1,4}$ = 6.6 Hz, $J_{1,3}$ = 6.4 Hz, $J_{2,4}$ = 7.5 Hz, $J_{2,3}$ = 5.3 Hz, and $J_{3,4(gem)}$ = 10.5 Hz.

Irradiation at δ 1.7 ppm (C-CH_3) caused a nuclear Overhauser enhancement (nOe) of the signals assigned to H-2 (45%) and H-3 (10%), but no effect on the signals of H-1 or H-4, confirming the *cis* placement of methyl and H-2, and therefore indirectly the *cis* arrangement of methyl and sulfoxide oxygen shown in structure **3***b*.

The methylene proton signals of **3***b* could be closely simulated by Intercal or NMRcal programs, and were almost identical with those observed for **3***a* and **3***c*, with minor chemical

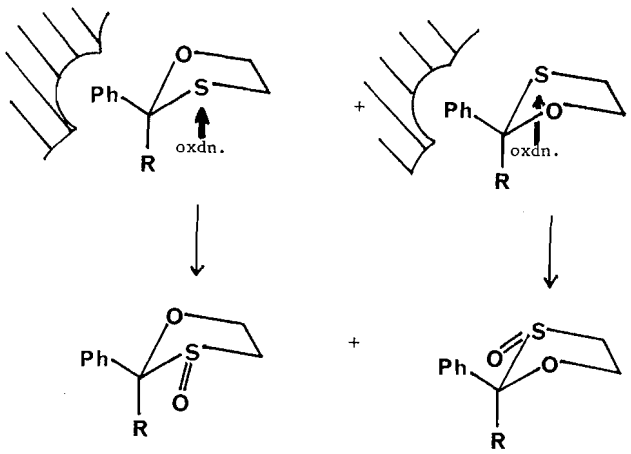

FIG. 1. Binding and sulfoxidation of 2-phenyl-1,3-oxathiolanes.

shift and J differences (see Table 2). No nOe enhancements were observed between the C-2 substituent and methylene hydrogens of **3***c*, and the experiment was not carried out on **3***a* because of instability problems, but the close correspondence between the methylene splitting patterns of **3***a*–**3***c* confirm that all three compounds have the same relative configuration.

Diastereomeric sulfoxides derived from chemical oxidation of **2***b* under modified Sharpless conditions have recently been reported, but without assignment of any relative or absolute stereochemistry (9). In our hands, routine chemical methods of sulfoxidation of **2***b* (*m*-chloroperoxybenzoic acid in methylene chloride or two-phase buffered systems, sodium metaperiodate, or hydrogen peroxide) all resulted in the isolation of acetophenone as the only reaction product.

The chemical oxidation of **2***b* referred to above (9) produces a close to racemic mixture of diastereomers (diastereomeric ratio 78:22, ee 3% by nmr) (9). Although the enzymic oxidations described herein produce only a single diastereomer, with one exception (see above), **3***a*–**3***c* were also obtained as racemates. This is surprising in view of the apparent specific aryl binding capability of the sulfoxidizing enzyme(s) of *M. isabellina* (3), but can be explained by the hypothesis outlined in Fig. 1, in which random but phenyl-dependent binding is followed by diastereospecific oxidation from the side opposite to the aromatic substituent. *Mortierella isabellina* is capable of sulfoxidation of benzyl thioethers in 10–40% yield (10), but nothing is known about the stereochemistry of the reaction.

To investigate the possibility that racemization of **3** may occur by reversible ring opening, the open-chain oxathiolane analogue **4** was used as substrate for *M. isabellina*. The only biotransformation product, the corresponding sulfoxide, was produced in 12% yield and was stable under normal conditions, but close to racemic ($[\alpha]_D^{20}$ −0.85°), suggesting an intrinsic lack of stereoselectivity in the sulfoxidation of benzyl thioethers. In the absence of a sample of oxathiolane sulfoxide of moderate to high optical purity, however, the possibility of racemization by ring opening cannot be eliminated from consideration, nor can other possible routes for racemization. Selective further metabolism of one sulfoxide enantiomer, as reported for some 1,3-dithiane sulfoxides (4, 5), may be occurring, but the hydrolytic lability of the oxathiolane sulfoxides precludes their use as substrates for biotransformation, so no data are available on this possibility.

It is therefore apparent that, although the fungal sulfoxidation of 2-phenyl-1,3-oxathiolanes produces racemic or nearly racemic material, the method does, unlike the only successful chemical method of oxidation (9), produce a single diastereomer of product in a consistent manner.

Experimental

Apparatus, materials, and methods

Melting points were determined on a Gallenkamp apparatus and are uncorrected. Infrared spectra were recorded with an Analect FX-6260 FTIR interfaced with a MAP-66 data system. The ^{1}H nmr spectra were obtained at 200 MHz and ^{13}C nmr at 50.3 MHz using a Bruker AC-200 FT instrument, $CDCl_3$ as solvent, and TMS as internal standard. Fast atom bombardment (FAB) mass spectra were obtained with a Kratos MS30 instrument with a saddle field gun (Ion Tech), operating at 7 keV using a glycerol sample matrix and argon beam. Electron impact (EI) mass spectra were recorded on a Kratos/AEI MS30 at 70 eV. Optical rotation measurements were obtained with a Rudolph Autopol III using a 10-cm cell and ethanol as solvent.

Computer simulated ^{1}H nmr spectra were generated using an Iteration of Calculated NMR Spectrum using Least Squares Criteria (ITRCAL) or a Nuclear Magnetic Resonance Spectrum Calculation (NMRCAL) program.

Flash column chromatography was performed using Merck silica gel 9385 (230–400 mesh), and thin-layer chromatography on Merck silica gel 60F 254.

Enantiomeric excesses were determined by ^{1}H nmr in CCl_4 solution in the presence of tris[3-(trifluoromethylhydroxymethylene)-(+)-camphorato], europium III derivative, at a relative concentration of 0.8–1.2 M, as previously described by us (7).

Mortierella isabellina NRRL 1757, *Aspergillus niger* ATCC 9142, and *Rhizopus arrhizus* ATCC 11145 were grown at 28°C and maintained at 4°C on malt agar slopes. *Helminthosporium* species NRRL 4671 was grown at 28°C and maintained at 4°C on V-8 juice agar slopes (ATCC medium 343).

Preparation of substrates

1,3-Oxathiolanes **2**a–**2**h

These were prepared from the corresponding ketone or aldehyde in 83–92% yield using the method of Djerassi and Gorman (11). All compounds gave satisfactory spectral and analytical data. The procedure is outlined below for the case of **2***b*.

A solution of acetophenone (17 g), 2-mercaptoethanol (10 g), and *p*-toluenesulfonic acid monohydrate (1 g) in anhydrous benzene (100 mL) was refluxed in a flask fitted with a Dean–Stark trap until no more water appeared in the separator (3 h). The solution was then cooled, washed ($NaHCO_3$, H_2O), and dried (Na_2SO_4). Evaporation yielded 2-methyl-2-phenyl-1,3-oxathiolane (**2***b*), (21.5 g); oil; ir, no CO stretch; ^{1}H nmr, δ: 1.9 (3H, s, CH_3), 2.4–3.1 (2H, m, —CH_2—S—), 3.8–4.5 (2H, m, —CH_2—O—), and 7.0–7.5 (5H, m, phenyl H) ppm; EI ms *m/z* (%): 180(10), 165(2), 120(3), 78(100). *Anal.* calcd. for $C_{10}H_{12}OS$: C 66.63, H 6.71, S 17.78%; found: C 66.42, H 6.61, S 17.92%. Other physical properties were identical with those reported (12).

1-Phenylethyl 2′-hydroxyethyl sulfide (4)

2-Mercaptoethanol (5 g) was added slowly to a stirred suspension of sodium hydride (2.5 g) in anhydrous benzene (25 mL), and the resulting mixture refluxed gently during subsequent addition of 1-chloro-1-phenylethane (9 g). The reaction mixture was refluxed for a further 24 h, then poured onto water (50 mL), and extracted with ether. The combined ethereal extract was dried (Na_2SO_4) and evaporated to give **4** (5.2 g). Purification by flash column chromatography using ethyl acetate:hexane (4:1) as solvent gave pure **4** (2.8 g), whose physical properties were identical with those reported (12); ir ν_{max}: 3300 (OH), but absence of 2650 (SH) cm^{-1}; ^{1}H nmr, δ: 1.5 (3H, d, —CH_3), 2.0 (1H, br s, —OH), 2.5 (2H, t, —CH_2—S—), 3.5 (2H, t, —CH_2—O—), 3.9 (1H, q, CH), and 7.1 (5H, br s, phenyl H) ppm.

Growth of microorganisms

Mortierella isabellina

The growth medium used in the cultivation of *M. isabellina* con-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 112.217.228.212 on 09/07/12

For personal use only.

sisted of a mixture of glucose (40 g), soy grits (5 g), yeast extract (5 g), sodium chloride (5 g), and dibasic potassium phosphate (5 g) per litre of distilled water. The growth medium (150 mL) was transferred to 1-L flasks, and the flasks were stoppered with sponge plugs and sterilized at 15 psi (1 psi = 6.9 kPa) and 121°C for 15 min, following which they were allowed to cool to room temperature. The fungus was transferred from slopes into the growth medium under sterile conditions, and the flasks placed on a rotary shaker (180 rpm) for 3 days at 26°C.

After 3 days, the mycelial growth was isolated by filtration, and washed with distilled water. The resulting fungal growth was divided into equal parts and resuspended in distilled water (150 mL/flask). The substrate was dissolved in 95% ethanol in the ratio of 1.0 g of substrate to 10 mL of solvent, and to each flask was added 1 mL of substrate solution. Incubations were carried out for 72 h, and the medium and fungal growth then separated by filtration.

The medium was continuously extracted over a 72-h period with dichloromethane, dried over anhydrous sodium sulfate, and evaporated. The medium residue was chromatographed either by using a benzene–ether stepwise gradient or by using mixtures of hexane and ethyl acetate as eluants. The fractions were analyzed by tlc and appropriate fractions pooled and subjected to ^{1}H nmr, ^{13}C nmr, ir, optical rotation, and mass spectrometric analysis.

The filtered fungus was blended twice in a Waring Blender with dichloromethane (200 mL) and the filtrate dried and evaporated.

Aspergillus niger

Aspergillus niger was grown in a Czapek Dox broth medium (35 g/L). The growth medium (150 mL) was transferred to 1-L flasks. Standard sterilization, filtration, incubation, extraction, and analysis procedures as outlined above were then followed.

Helminthosporium *species*

A procedure similar to that described above was followed for this fungus, using a growth medium consisting of V-8 juice (200 mL) and calcium carbonate (3 g) per litre of distilled water, adjusted to a pH of 7.2.

Rhizopus arrhizus

The procedure was similar to those previously described with two alterations: firstly, the growth medium consisted of a mixture of glucose (40 g), peptone (20 g), and corn steep liquor (5 mL) per litre of distilled water. Secondly, prior to incubation with the substrate, the fungus was blended in a Waring Blender for approximately two 1-s periods.

Incubation of substrates

The results are summarized in Table 1.

*2-Phenyl-1,3-oxathiolane (2*a)

Incubation of **2***a* (1 g) with *M. isabellina* gave extracts from the medium (0.09 g) and fungus (0.12 g). The latter extract contained only **2***a*. Chromatography of the medium extract yielded benzyl alcohol (**6***e*) (0.04 g), followed by the sulfoxide, **3***a* (0.08 g), as an unstable oil; $[\alpha]_D^{20}$ +0.008 ± 0.05°; ir ν_{max}: 1050 (S=O) cm^{-1}; ^{1}H nmr, δ: 2.5–2.9 (2H, m, —CH_2—S(O)—), 4.4–4.8 (2H, m, —CH_2—O—), 5.4 (1H, s, —CH), and 7.4 (5H, br s, phenyl H) ppm. Details of assignments and coupling constants are in Table 2; ^{13}C nmr, δ: 52.7 (—CH_2—S(O)—), 69.8 (—CH_2—O—), 111.65 (C(O)S), 125.9 and 128.9 (aromatic *o*- and *m*-C's), 129.4 (aromatic *p*-C), and 133.3 (aromatic C-1) ppm; EI ms *m/z* (%): 182 (16, M^+), 154(27), 126(12), 105(100), 77(65).

*2-Methyl-2-phenyl-1,3-oxathiolane (2*b)

(*i*) Incubation of 1 g of **2***b* with *M. isabellina* gave medium and fungal extracts of 0.26 g and 0.2 g respectively. The latter contained only **2***b*; chromatography of the former extract gave, in order of elution, **2***b* (0.01 g), acetophenone (**5***a*) (0.02 g), 1-phenylethanol (**6***a*) (0.02 g) ($[\alpha]_D^{20}$ −21.1°, ee 51%), and the sulfoxide **3***b* (0.05 g), mp 77–79°C; $[\alpha]_D^{20}$ +0.08 ± 0.1°; ir ν_{max}: 1040 (S=O) cm^{-1}; ^{1}H nmr δ: 1.7 (3H, s, CH_3), 2.7–3.0 (2H, m, —CH_2—S(O)—), 4.3–4.8 (2H, m, —CH_2—O—), and 7.3 (5H, br s, phenyl H's) ppm. Details of assignments and coupling constants are in Table 2; ^{13}C nmr, δ 22.2 (CH_3), 51.1 (—CH_2—S(O)—), 68.1 (—CH_2—O—), 106.7 (C(O)S), 125.2 and 128.9 (aromatic *o*- and *m*-C's), 128.5 (aromatic *p*-C), and 139.0 (aromatic C-1) ppm; FAB ms *m/z* (%): 197 (13, M + 1), 196 (19, M^+), 126(6), 121(34), 105(21), 97(14), 77(71).

(*ii*) Incubations of **2***b* with *R. arrhizus*, *H.* species, or *A. niger* resulted only in the recovery of **2***b* from either medium or fungal extracts.

(*iii*) Incubation of **2***b* with *M. isabellina* in 0.1 M phosphate buffer, pH 7.1, under conditions otherwise identical with those described above, afforded a medium extract (0.2 g) from which only acetophenone (0.03 g) was recovered. The fungal extract contained **2***b* as the only exogenous material.

(*iv*) Incubation of **2***b* (1 g) with autoclaved cells of *M. isabellina* gave extracts from the fungus (0.86 g) and medium (0.26 g) from which a total of 0.88 g of **2***b* was recovered as the only exogenous material.

*2-*tert*-Butyl-2-phenyl-1,3-oxathiolane (2*c)

(*i*) Incubation of **2***c* (1 g) with *M. isabellina* gave a medium extract (0.22 g) that upon chromatography gave recovered **2***c* (0.015 g), 2,2-dimethylpropiophenone (**5***b*) (0.01 g), 2,2-dimethyl-1-phenyl-1-propanol (**6***b*) (0.03 g), and the sulfoxide **3***c* (0.03 g), mp 64–66°C; $[\alpha]_D^{20}$ −13.3 ± 0.1°, ee 4%; ir ν_{max}: 1050 (S=O) cm^{-1}; ^{1}H nmr, δ: 1.12 (9H, s, CH_3), 2.4–2.9 (2H, m, —CH_2—S(O)—), 4.2–4.8 (2H, m, —CH_2—O—), 7.4 (5H, br s, phenyl H) ppm; ^{13}C nmr δ: 27.0 (CH_3), 39.4 ($C(CH_3)_3$), 50.7 (—CH_2S(O)—), 67.7 (—CH_2—O—), 112.9 (C(O)S), 126.9 and 128.4 (*o*- and *m*-aromatic C's), 128.2 (*p*-aromatic C), and 136.1 (C-1 aromatic C) ppm; FAB ms *m/z* (%): 238 (50, M^+), 195(6), 163(93), 146(24), 119(31), 105(67), 77(100).

(*ii*) Incubation of **2***c* (1 g) with *R. arrhizus* gave a medium extract (0.22 g) that afforded **5***b* (0.01 g), **6***b* (0.03 g), and **3***c* (0.03 g), mp 63–67°C, identical with the sample described above except that $[\alpha]_D^{20}$ = 0.5 ± 0.1°.

(*iii*) Incubation of **2***c* with *H.* species or *A. niger* resulted in the recovery of **2***c* as the only exogenous material.

*2,2-Diphenyl-1,3-oxathiolane (2*d)

(*i*) Incubation of 1 g of **2***d* with *M. isabellina* or *R. arrhizus* gave medium extracts that contained diphenyl methanol **6***c* as the only exogenous materials in yields of 20% and 5%, respectively. Incubation of **2***d* with the other fungi used in this study resulted only in the recovery of unchanged substrate.

(*ii*) Incubation of **2***d* with autoclaved *M. isabellina* gave medium and fungal extracts from which a total of 82% of **2***d* was recovered as the only exogenous material.

*2-*tert*-Butyl-2-methyl-1,3-oxathiolane (2*g)

(*i*) Incubation of **2***g* (1 g) with *M. isabellina* gave a medium extract (0.25 g) that upon chromatography afforded **2***g* (0.015 g), *tert*-butyl methyl ketone (**5***c*) (0.01 g), and 2,2-dimethyl-3-butanol (**6***d*) (0.02 g); $[\alpha]_D^{20}$ +0.5 ± 0.1°. Only unchanged substrate was recovered following incubation of **2***g* with *R. arrhizus*, *H.* species, or *A. niger*.

(*ii*) Incubation of **2***g* (0.5 g) with autoclaved *M. isabellina* gave a total recovery of 70% of unchanged substrate from medium and fungal extracts.

*2-Ethyl-2-methyl-1,3-oxathiolane (2*e), *2-methyl-2-*n*-propyl-1,3-oxathiolane (2*f), *and 2-cyclohexyl-2-methyl-1,3-oxathiolane (2*h)

The above substrates were recovered unchanged in yields of 50–80% following incubation with any of the fungi used in this study.

*Acetophenone (5*a)

Incubation of **5***a* with *M. isabellina* to yield *S*-(−)-1-phenylethanol in a yield of 87% and ee of 54% has previously been described (7).

*tert-Butyl methyl ketone (5*c)

Incubation of **5***c* (2 g) with *M. isabellina* gave extracts from the fungus (0.26 g) and medium (1.52 g). The latter extract afforded 2,2-dimethyl-3-butanol (1.45 g, 72%), with $[\alpha]_D^{20}$ +0.6 ± 0.1°.

EPR study of the long-range effect of a β-carbon chiral center on the magnetic equivalence of β-methylene protons[1]

PETER SMITH[2] AND WILLIAM HARLEY DONOVAN

Received February 25, 1988

PETER SMITH and WILLIAM HARLEY DONOVAN. Can. J. Chem. **66**, 2304 (1988).

Using aqueous $TiCl_3$-based continuous-flow, radical-generating methods at 25°C we have carried out a comprehensive EPR study of hydroxyl- and aminyl-radical addition to eight alkene substrates that yielded radicals of general formula XCH_2—$\dot{C}Y$—C*HR^1R^2, where C* is a chiral center, to investigate the magnetic inequivalence of β-CH_2 protons arising from a nonadjacent β-C chiral center. We attribute the observed nonequivalence to the long-range influence of the chiral center in these radicals, and note that our results are consistent with the reasonable expectation that the presence of bulky groups in the radicals is likely to favor particular conformations, leading to more easily observed inequivalence of the β-CH_2 proton splittings.

PETER SMITH et WILLIAM HARLEY DONOVAN. Can. J. Chem. **66**, 2304 (1988).

Opérant à 25°C et utilisant des méthodes de production de radicaux basées sur des écoulements continus de solutions aqueuses de $TiCl_3$, on a réalisé une étude rpe détaillée d'additions des radicaux hydroxyle et aminyle sur huit alcènes conduisant à des radicaux de formule générale XCH_2—CY—C*HR^1R^2 dans lesquels C* est un centre chiral; ces expériences ont été réalisées afin d'évaluer si les protons CH_2 en β, qui sont soumis à l'influence d'un centre chiral qui n'est pas adjacent, sont équivalents. On a observé qu'ils ne sont pas équivalents et on attribue ce résultat à l'influence à longue distance du centre chiral présent dans ces radicaux; de plus, on note que nos résultats sont en accord avec les attentes qu'on peut raisonnablement avoir si on admet que la présence de groupements volumineux dans les radicaux devrait favoriser des conformations particulières et ainsi conduire à une inéquivalence plus facilement observable des couplages des protons CH_2 en β.

[Traduit par la revue]

Introduction

Recently (1), we presented the results of an EPR study of three XCH_2—$\dot{C}H$—$CH(OH)CH_2X$ radicals, with -X = -CN, -COOH, and -OH, formed from symmetrical 1,2-disubstituted alkenes in aqueous solution at ca. 25°C with use of the $TiCl_3$–H_2O_2, continuous-flow, radical-generating method (2). Two of these radicals showed magnetic inequivalence of their β-CH_2 protons due to the presence of a nonadjacent β-chiral carbon, an EPR phenomenon that has received little attention (3–7) and, in the case of acyclic C-centered radicals, no systematic study (5–7). Similar long-range effects of molecular asymmetry are numerous in the NMR literature (8–12), and the adjacent chiral effect, namely, magnetic inequivalence of β-CH_2 protons adjacent to a γ-C chiral center or of γ-CH_2 protons adjacent to a β-C chiral center, is common in EPR spectroscopy (13–23).

Previously (1), we stressed the importance to spectral interpretation of recognizing the possibility of there being inequivalent β-CH_2 protons in radicals with a nonadjacent chiral center. The present investigation successfully extends our previous study of the nonadjacent chiral effect; specifically, to determine how often inequivalence of β-CH_2 protons can occur in radicals of general structure XCH_2—$\dot{C}Y$—CHR^1R^2, derived from mono-, di-, and tri-substituted alkenes employing the $TiCl_3$–H_2O_2 and –NH_2OH reaction systems. With this larger body of data now available, we are able to substantially reinforce and extend the major conclusions of the earlier, more limited study (1).

Experimental

The experimental arrangements and procedures were essentially as before (15). However, the spectrum-simulation program was that of Oehler and Janzen (24). The field-modulation amplitude was normally 0.50×10^{-1} to 2.00×10^{-1} G and all reported results refer to that range. The substrates examined were 2-acetoxy-3-butenenitrile, **1** (97%), 3-butene-2-ol, **2** (99%), *cis*-2-butene-1,4-diol, **3** (91%), *cis*-1,4-diacetoxy-2-butene, **4** (92%), 1,4-dicyano-2-butene, **5** (97%), *trans*-β-hydromuconic acid, **6** (98%), and 3-butene-1,2,3-tricarboxylic acid **7** (97%), all from Aldrich, except **4** (American Tokyo Kasei) and **7** (Lancaster Synthesis), and used as received; and (*E*)-propene-1,2,3-tricarboxylic acid, **8**, which we synthesized via a standard procedure (25).

When employing the $TiCl_3$–H_2O_2 method, the reducing stream was 0.004 M in $TiCl_3$, the oxidizing stream 0.1 M in H_2O_2, and both streams 0.1 M in H_2SO_4 and 0.02–0.10 M in substrate; also, the total flow rate (4–6 mL s^{-1}) was equally distributed between the two streams. When using the $TiCl_3$–NH_2OH system, the reaction conditions were as for the $TiCl_3$–H_2O_2 work except that we replaced the H_2O_2 in the oxidizing stream by 0.5 M $NH_2OH \cdot HCl$ (96%, Eastman) and made the total flow rate 2 mL s^{-1}. All results presented refer to 25.0 ± 1.0°C, unless otherwise noted. In any case where line broadening was evident or suspected at 25°C, we also ran spectra at 15 and 40 ±1.0°C. In an effort (20, 26) to reduce the linewidths of spectra obtained with both radical-generating systems using **7** and **8**, we made both streams 1.0 M in H_2SO_4, with no perceptible improvement in resolution.

Results and discussion

Table 1 summarizes the EPR spectroscopic data for all radicals characterized in the present study and includes results obtained previously in our laboratory (1, 15). All radicals listed that were generated in the present work resulted from individual studies of **1**, **4**, **7**, and **8** in the $TiCl_3$–H_2O_2 system, and of **1**–**8** in the $TiCl_3$–NH_2OH system, and there was no evidence for the formation of species other than those shown. To illustrate the quality of the spectra obtained in this study, Fig. 1 presents the higher-field half of the spectrum from **15** and a matching computer-generated plot.

In general, our results were consistent with expectation on three counts (31, 32). First, when reacting **1** and **8**, for example, we were able to add the hydroxyl radical to both carbons in their

double bonds, while, with the aminyl radical, there was evidence only for addition to the less hindered carbon (31, 32). Secondly, in the spectrum from a particular aminyl-radical adduct, the ΔH_{pp} values of the lines not broadened by restricted rotation were equal to or larger than those from the corresponding hydroxyl-radical adduct (31). Finally, relative to the $TiCl_3$–H_2O_2 system, the $TiCl_3$–NH_2OH system was less effective in yielding an observable signal from hydrogen-atom abstraction radicals (31, 32).

Considering those hydroxyl-radical adducts not already reported in the literature, namely, **9**, **10**, and **16**, we assigned the splittings for **9** and **10** by comparison with those of similar radicals (1, 15, 31, 33–36). Also, the splittings for **16** are analogous to those for **9**. However, while the assignment of the α-CH proton splitting in **16** was straightforward, there were two conceivable assignments for the β-CH and -CH_2 protons, which were very close in size, namely, (A) the β-CH_2 protons were nonequivalent, with splittings 18.8 and 19.3 G, requiring the $\alpha_{\beta\text{-H}}$(CH) value to be 19.5 G, and (B) the β-CH_2 protons were equivalent, 19.3 G, making $\alpha_{\beta\text{-H}}$(CH) equal to 18.8 G. The latter alternative seems more probable as $\alpha_{\beta\text{-H}}(CH_2) > \alpha_{\beta\text{-H}}(CH)$ for all radicals of structure similar to that of **9** in this study.

The assignments of the *a*-values for the aminyl-radical adduct **11** were analogous to those in **9** except that the β-CH_2 protons were equivalent (within the linewidth) and there was an expected (31) γ-nitrogen splitting. In the case of the other

For personal use only.

aminyl-radical adducts in Table 1, the assignments of the splittings for **13**, **15**, **17**, **19**, and **21** were essentially as for **11**, and likewise for **23** and **26**, bearing in mind their lack of an α-CH proton.

In general, we would expect the β-CH_2 protons in the radicals with a nonadjacent chiral carbon center, namely, **9**, **11–24**, and **26**, to be nonequivalent. However, for **11–13**, **16**, **17**, **19**, and **20** the nonequivalence was too small to be observable. Likewise, the γ-CH_2 protons in the radicals bearing an adjacent chiral carbon center, namely, **14–23**, should also be nonequivalent. Indeed, in **14**, **16**, **18**, and **21**, our observations fitted this expectation as only one γ-CH_2 proton splitting was resolvable, the other being within the linewidth. In **17**, the γ-CH_2 proton splittings were nonequivalent and measurable. However, for **15** and **19**, the difference between the $a_{\gamma\text{-H}}$ (CH_2)-values was undetectable, so that we observed small (1:2:1)-triplets. For **20**, **22**, and **23**, no γ-CH_2 proton splittings were discernible.

The results in Table 1 show that $a_{\alpha\text{-H}}$(CH) for each aminyl-radical adduct of type $H_2NCH(X)—\dot{C}HY$ is slightly larger than that for the corresponding hydroxyl-radical adduct, a relationship that is true in all analogous cases in the literature of which we are aware (31, 32, 37–39). That the aminyl-radical adducts do display a greater α-CH proton splitting than the corresponding hydroxyl-radical adducts is in line with the relative sizes of the Fischer Δ-functions for $-CH_2OH$ and $-CH_2NH_2$ and the reasonable assumption that the effect stems primarily from changes in the unpaired π-electron spin density at the α-C in these species (31). This observation supports our earlier assignments (1), as it is reasonable to expect the α-CH proton splittings to vary over a much smaller range than those of the β-CH and $-CH_2$ protons for a series of radical adducts as presented here.

The spectra of **13–17**, **22**, **24**, and **26** displayed selective line broadening (40) to some degree. We can attribute this phenomenon to hindered interconversion between equilibrium conformations, a view supported by our finding that in each case the degree of the broadening decreased with increase in temperature. However, the effect manifested itself spectroscopically in three qualitatively different ways.

Radicals **13**, **24**, and **26** showed selective broadening of their $M_\beta = 0$ lines, a phenomenon treated in detail elsewhere (13, 14). The spectra of **24** and **26** both showed broadening of the inner relative to the outer lines in each (1:1:1:1)-quartet, consistent with out-of-phase modulation of the β-CH_2 protons during interconversion between conformations. The spectrum from **13** was similar except that the inequivalence of the β-CH_2 protons was unobservable due to the line broadening. Presumably, in all three cases, the small magnetic inequivalence of the β-CH_2 protons renders the $M_\beta = 0$ line more susceptible to exchange broadening than would be the case were there no asymmetry in these radicals.

Radicals **14–17** showed a small degree of line broadening seemingly unrelated to the β-CH_2 protons. Rather, we find this feature to be consistent with restricted rotation about the $C_\beta—C_\gamma$ bond, resulting in a modulation of the hyperfine splittings of the β-CH and the detectable γ-CH_2 protons. For the radicals in which the nuclear-spin orientation of these protons is the same, either αα or ββ, no field shift of the corresponding lines results from $C_\beta—C_\gamma$ bond rotation (41). Hence, half of the lines in the spectrum of **14** and **16** remained sharp and the rest displayed minor broadening. A similar effect also appeared to be present in **15** and **17**, although it was even less noticeable and, consequently, a definitive analysis was not possible.

For **22**, the line broadening was as described recently (5), where the outer rather than the inner lines of the (1:1:1:1)-quartet from the β-CH_2 protons were broadened, consistent with in-phase modulation of the β-CH_2 protons during interconversion between conformations (42).

Previous comprehensive EPR investigations of the adjacent chiral effect in nitro-anion and nitroxyl radicals of the forms $R^1R^2R^3CCH_2—NO_2^{\cdot-}$ (13) and $R^1R^2R^3CCH_2—N(t\text{-Bu})O\cdot$ (14), respectively, and of the nonadjacent chiral effect in 1,3-dioxolan-4-yl radicals of the type $\dot{C}H_2—CH—OCR^1R^2O$ (3), suggest that the magnitude of the Δ(β-CH_2) values, see Table 1, corresponds directly to the steric constraints imposed by the R groups attached to the chiral carbon. Our results for $XCH_2—\dot{C}Y—CHR^1R^2$ radicals are in general agreement with this size-inequivalence relationship, and illustrate the magnitude of methylene-proton inequivalence that we can expect in typical radicals of this sort. The Δ(β-CH_2) values in the radicals derived from the monosubstituted alkenes tended to be so small as to be seldom detectable, while those of the radicals produced by the disubstituted alkenes were usually, but not always, resolvable, and the trisubstituted alkenes gave rise to radicals with large Δ(β-CH_2) values. However, within this general trend, there are instances where it is impossible to predict what the size of Δ(β-CH_2) will be, see Table 1. Hence it follows that one must apply the general rule relating substituent size and number to the magnetic inequivalence with caution. That this is so is in line with the recognized complex nature of factors that influence nonequivalence (11).

Our results combined with relevant examples in the literature (5–8) show that the nonadjacent chiral effect is capable of rendering methylene protons detectably inequivalent in high-resolution EPR spectra of a variety of acyclic carbon-centered radicals. This effect appears to be somewhat more pronounced in cyclic carbon-centered radicals (3, 4). As far as we are aware, all reported cases of the nonadjacent chiral effect in EPR spectroscopy involve a separation of the methylene protons and the chiral center by only two single C—C bonds. Based on the attenuation of Δ(β-CH_2) values observed when comparing radicals with γ-C chiral center adjacent to a β-methylene group (13–23) to those we present here, we may reasonably speculate that methylene-proton inequivalence is not likely to be detectable in an acyclic radical with a chiral carbon three or more single C—C bonds removed from the methylene protons. This result contrasts with NMR findings where, for example, in an acyclic molecule, chemical shift nonequivalence of CH_3 protons can arise from asymmetry as far as six single C—C bonds away (9).

Protium–deuterium exchange of styrenes in dilute acid at elevated temperatures

NICK HENRY WERSTIUK AND GEORGE TIMMINS
Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received February 25, 1988

NICK HENRY WERSTIUK and GEORGE TIMMINS. Can. J. Chem. **66**, 2309 (1988).

A modified high temperature – dilute acid method is used to synthesize phenylethene-2,2-d_2 ("styrene-2,2-d_2") (**1***b*), 2-phenylpropene-1,1,3,3,3-d_5 ("α-trideuteriomethylstyrene-2,2-d_5") (**2***b*), and *E*-1-phenylpropene-2-*d* ("*trans*-β-methylstyrene-2-*d*") (**3***b*) from phenylethene ("styrene") (**1***a*), 2-phenylpropene ("α-methylstyrene") (**2***a*), and *E*-1-phenylpropene ("*trans*-β-methylstyrene") (**3***a*), respectively. The deuteriated substitution product *E*-1,3-diphenyl-1-butene-2,4,4,4-d_4 (**4***b*) is also obtained from **1***a*. Labelled substitution products 1,3,3-tri-trideuteriomethyl-1-phenylindane-2,2-d_{11} (**5***b*), 4-trideuteriomethyl-2,4-diphenyl-1-pentene-1,1,3,3,5,5,5-d_{10} (**6***b*), and *E*-4-trideuteriomethyl-2,4-diphenyl-2-pentene-1,1,1,3,5,5,5-d_{10} (**7***b*) are obtained from 2-phenylpropene.

NICK HENRY WERSTIUK et GEORGE TIMMINS. Can. J. Chem. **66**, 2309 (1988).

On a utilisé une méthode modifiée impliquant une température élevée et de l'acide dilué pour synthétiser le phényléthène-d_2-2,2 (« styrène-d_2-2,2 ») (**1***b*), le phényl-2 propène-d_5-1,1,3,3,3 (« α-trideutérométhylstyrène-d_5-2,2 ») (**2***b*) et le phényl-1 propène-*d*-2-(*E*) (« β-méthylstyrène-d2-*d*-*trans* ») (**3***b*) à partir respectivement du phényléthène (« styrène ») (**1***a*), du phényl-2 propène (« α-méthylstyrène ») (**2***a*) et du phényl-1 propène-(*E*) (« β-méthylstyrène-*trans* ») (**3***a*). On a aussi obtenu le diphényl-1,3 butène-1-d_4-2,2,4,4-(*E*) (**4***b*) à partir du composé **1***a*. Utilisant le phényl-2 propène, on a aussi préparé les produits marqués suivants : tri-trideutérométhyl-1,3,3 phényl-1 indane-d_{11}-2,2 (**5***b*), trideutérométhyl-4 diphényl-2,4 pentène-1-d_{10}-1,1,3,3,5,5,5 (**6***b*) et trideutérométhyl-4 diphényl-2,4 pentène-2-d_{10}-1,1,1,3,5,5,5-(*E*) (**7***b*).

Introduction

In continuing to detail the scope and limitations of the high temperature – dilute acid (HTDA) method for hydrogen-isotope labelling of alkenes and aromatic compounds (1–10), we have studied the H–D exchange of phenylethene (**1***a*), 2-phenylpropene (**2***a*), and *E*-1-phenylpropene (**3***a*). To reduce the extent of substitution (polymerization) of these substrates, a modified HTDA method (7, 9) was used. An inert cosolvent was added to "dilute" the water-insoluble substrate and the reaction mixture was shaken to facilitate phase transfer. The results of our studies on **1***a*, **2***a*, and **3***a*, which are summarized in Table 1, establish that the HTDA mehod provides a simple, inexpensive route to phenylethene-2,2-d_2 (**2***b*), 2-phenylpropene-1,1,3,3,3-d_5 (**2***b*), *E*-1-phenylpropene-2-*d* (**3***b*), as well as *E*-1,3-diphenyl-1-butene-2,4,4,4-d_4 (**4***b*), 1,3,3-tri-trideuteriomethyl-1-phenylindane-2,2-d_{11} (**5***b*), 4-trideuteriomethyl-2,4-diphenyl-1-pentene-1,1,3,3,5,5,5-d_{10} (**6***b*), and *E*-4-trideuteriomethyl-2,4-diphenyl-2-pentene-1,1,1,3,4,4,4-d_{10} (**7***b*).

Results and discussion

H–D exchange of phenylethene (1a)

When **1***a* was heated in 0.26 M HCl/H_2O at 170°C with decalin as a cosolvent, 54.3% of **1***a* remained and 39.3% of **4***a* was obtained along with 6.4% of five other minor components that were not identified. Substituted butene **4***a* was identified as the major substitution product by its ^{1}H nmr and mass spectrum. When the reaction was carried out in deuteriated medium (entry 2, Table 1), ^{1}Hmr, ^{2}Hmr, and mass spectrometry indicated that **1***a* at C-2 was equilibrated with the deuterium pool. Mass spectrometry established that **4***b* contained 3.35 D atoms in excess of natural abundance and consisted of 8.91% d_2, 18.1% d_3, 59.8% d_4, 2.7% d_5, and 0.4% d_6 species. Signals at δ 6.4 and δ 1.5 in the ^{2}Hmr spectrum of deuteriated **4***b* corresponded to C2-D and the CD_3 group, respectively. There was a weak signal at δ 2.6, but no detectable peaks in the aromatic region. At a lower temperature (entries 3 and 4), more starting material remained, and, after 7.5 h at 145°C, 1.54 D atoms are incorporated into **1***a*. Additional studies were carried out in nondeuteriated medium. When the cosolvent decalin was used as an internal standard for the gc analysis, it was established that 25% of **1***a* and 50% of **4***a* were present relative to the amount of **1***a* present initially. It is conceivable that higher molecular weight products are formed that do not pass through the gc column and that **1***a* polymerizes in the gc injector block. When the reaction was carried out with pentane as the cosolvent, to facilitate recovery of the deuteriated compound, **1***b* was isolated in 21% yield. Although the yield is quite low, the method does provide a simple inexpensive route to **1***b* and **4***b*. It is noteworthy that H–D exchange of **1***a* competes with polymerization. This is probably due to the fact that the concentration of the styrene in the aqueous phase is kept low.

H–D exchange of 2-phenylpropene (2a)

When **2***a* was reacted in 0.26 M HCl/H_2O (entry 5), in addition to a short-retention-time product, which was **2***a* according to its ^{1}Hmr and mass spectrum, three higher molecular weight products were present. The components were separated by preparative gc and 250-MHz ^{1}Hmr spectra were

[a]H indicates 0.26 M HCl/H_2O, D indicates 0.26 M DCl/D_2O, dec indicates decalin and cyc indicates cyclohexane as the cosolvent. The reactions were agitated using a rocking motion of the pressure vessel. The temperatures were controlled to ±3°C.

[b]The products are listed in order of increasing gc retention time. Dimers refers to substitution products, which were not identified.

[c]Determined mass spectrometrically at low ionizing voltage (12–15 eV).

[d]Deuterium content was not determined.

obtained. The higher molecular weight component obtained in lowest yield exhibited signals at δ 1.03 (s, 3H), δ 1.35 (s, 3H), δ 1.69 (s, 3H), δ 2.19 (d, 1H), δ 2.42 (d, 1H), and δ 7.1–7.3 (m, 9H) in keeping with the spectrum expected for **5***a*. The other two products were assigned structures **6***a* (signals at δ 1.23 (s, 6H), δ 2.48 (s, 2H), δ 4.79 (d, 1H), δ 5.14 (d, 1H), and δ 7.2–7.3 (m, 10H)) and **7***a* (signals at δ 1.53 (s, 6H), δ 1.58 (s, 3H), δ 6.14 (s, 1H), and δ 7.2–7.4 (m, 10H)) on the basis of their ^{1}Hmr, ^{2}Hmr, and mass spectra. While **5***a* is formed by cyclization of the 4-methyl-2,4-diphenyl-2-pentyl cation (Scheme 1), **6***a* and **7***a* result from loss of protons from C-1 and C-3, respectively.

Treatment of **2***a* in 0.26 M DCl/D_2O/cyclohexane at 170°C for 12 h (entry 6) followed by distillation of the cyclohexane yielded a product consisting of **2***b* (32.2%), **5***b* (8.9%), **6***b* (28.4%), and **7***b* (28.7%) from which **2***b* (0.48 g, 27%) was isolated by distillation at reduced pressure. Mass spectral analysis indicated that **2***b* incorporated 4.91 D atoms and consisted of 11.6% d_4, 85.7% d_5, and 2.7% d_6 species. The ^{2}Hmr spectrum of **2***b* exhibited intense signals at δ 2.1 (CD_3), δ 5.05, and δ 5.35 (vinyl C-Ds); a weak signal (<5%) in the aromatic region established that only a small amount of deuterium was incorporated in the ring while the side chain was equilibrated with the deuterium pool. As established by ^{2}Hmr, even at 205°C (entry 7), there was little exchange (<5%) of the aromatic ring. The labelled substitution products **5***b*, **6***b*, and **7***b* were separated by preparative gc and their 250-MHz ^{1}Hmr spectra showed only weak signals (<5% relative to the arene protons), due the aliphatic and vinylic protons, thereby indicating essentially complete deuteriation of the aliphatic portions of these molecules. Thus, the reactions of **1***a* and **2***a* in deuteriated medium provide unique routes to **4***b*, **6***b*, and **7***b*.

H–D exchange of E*-1-phenylpropene (***3***a)*

When **3***a* was reacted under the same conditions as **2***a* (entries 5 and 8), very little substitution occurred, in contrast to the reaction of **2***a*. That the major component was **3***a* was established by ^{1}Hmr. Analytical gc analysis established that 8% of *Z*-1-phenylpropene was present. Mass spectral analysis of **3***b* isolated in 73% yield by preparative gc from a reaction in deuteriated medium (entry 9) established that **3***a* incorporated 0.88 D atoms and that it consisted of 22.4% d_0, 67.4% d_1, 9.6% d_2, and 0.5% d_3 species. Its ^{2}Hmr spectrum exhibited a strong signal at δ 6.2 with a shoulder and two weak signals (<5%) in the aromatic region, indicating that the deuterium was located predominantly at C-2. At 205°C (entry 10), 2.37 D atoms (0.4% d_0, 21.7% d_1, 37.3% d_2, 26.2% d_3, 10.4% d_4, 3.3% d_5, and 0.8% d_6) are incorporated into **3***a*. It was established by ^{2}Hmr

spectroscopy (Fig. 1) that deuterium is located at C-2 (0.93 D), C-1 (0.20 D), in the benzene ring (1.06 D), and in the methyl group. Although additional nmr studies were not carried out, the relative intensities (2:1) of the peaks in the aromatic region indicate that exchange occurs predominantly at the *ortho* and *para* positions; this is expected on the basis of the activating effect of the 1-propenyl substituent. It is interesting to note that the phenyl group of **3***a* undergoes exchange significantly faster than the phenyl group of **2***a* (*vide supra*). This observation establishes that vinyl cyclohexadienyl cations **8***a* and **9***a* are more stable than isomers **8***b* and **9***b*, a point that cannot be established easily by any other study because the double bond is substantially more reactive towards electrophiles than the benzene ring. Under more forcing conditions (entry 11), **3***a* incorporated 7.16 D atoms of deuterium (0.3% d_3, 1.2% d_4, 6.3% d_5, 18.5% d_6, 32.7% d_7, 31.1% d_8, 8.8% d_9, and 1.0% d_{10} species). Analysis by ^{1}Hmr and ^{2}Hmr spectroscopy established that the vinylic positions were equilibrated with the deuterium pool and that there were approximately three and two

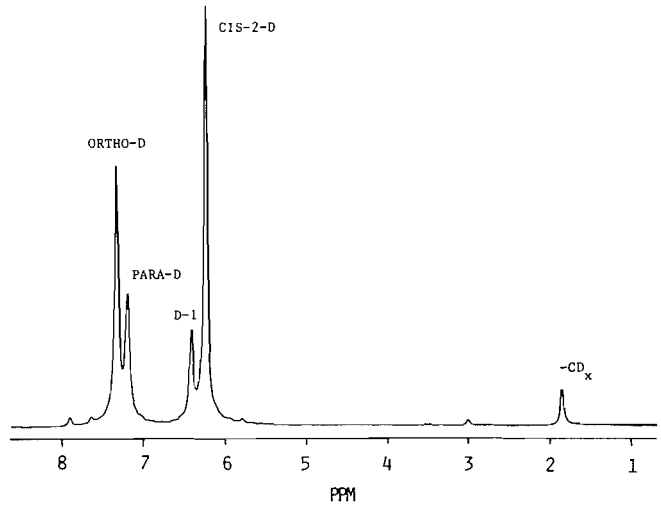

FIG. 1. The ^{2}Hmr spectrum (38.4 MHz, CCl_4) of *E*-1-phenylpropene-$d_{2.37}$.

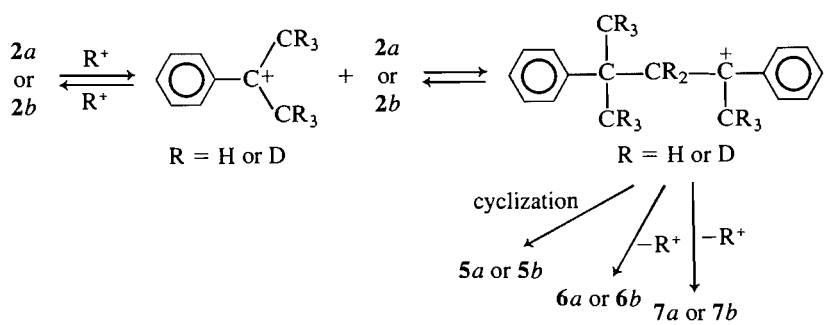
deuterium atoms located in the ring and the methyl group, respectively. Although additional nmr studies were not carried out, based on the relative intensities of the signals in the aromatic region, we expect that the deuterium in the ring is located at the *ortho* and *para* positions. Gas chromatographic analysis established that there was substantial conversion (73%) to other products, which were not identified.

Computation studies on cations **9**a *and* **9**b

AM1 calculations (11) were carried out to probe the structures of cations **9***a* and **9***b*. According to AM1 the heats of formation of **9***a* and **9***b* are 867.4 and 901.5 kJ/mol, respectively. That AM1 predicts **9***a* to be lower in energy than **9***b* by 34.1 kJ/mol is in keeping with the fact that **3***a* undergoes H–D exchange of the aromatic ring faster than **2***a*. The difference in stability is due to two factors: steric interactions twist the double bond of **9***b* away from coplanarity with the cyclohexadienyl π-system. According to AM1, the twist angle is 29.5°C in this case. In the case of **9***a*, the double bond is almost complanar with the cyclohexadienyl π-system; the twist angle is 11.5°C. Furthermore, the methyl group at C-2 of **9***a* provides additional stabilization not available in the case of **9***b*.

Conclusions

This study established that a modified high temperature – dilute acid method provides a simple, inexpensive route to deuterium labelled phenylethene ("styrene"), 2-phenylpropene ("α-methylstyrene"), and *E*-1-phenylpropene ("*trans*-β-methylstyrene") as well as several substitution products. It should be a



SCHEME 1

simple matter to tritiate these substrates by substituting tritiated water of the appropriate activity for the D_2O and to label other substituted derivatives with this methodology.

Experimental

Analyses were carried out on a Tracor model 560 chromatograph equipped with a Varian Aerograph model 485 electronic integrator using a 6 ft × 4 mm i.d. 3% OV-1 on 100/120 mesh Supelcoport column. Preparative collections were performed on a Varian A-700 gas chromatograph equipped with a 5 ft × 1/4 in. 15% SE-30 on 80/100 Chromosorb W column. The yields were not corrected for collection losses. Products were characterized by ^{1}Hmr and ^{2}Hmr spectroscopy (Varian EM-390 and Bruker WM-250 spectrometers). Deuterium analyses were carried out on a VG Micromass 7070F mass spectrometer at low ionizing voltage (12–15 eV).

*H–D exchange of phenylethene (**1**a)*

In a typical reaction, **1***a* (0.20 g), 0.27 M HCl/H_2O or 0.27 M DCl/D_2O (5 mL), and decalin (1 mL) were sealed under vacuum in a medium-walled Pyrex tube after the solution was degassed via three freeze–pump–thaw cycles. Tubes were heated in a 600-mL Parr pressure vessel containing water to equalize the pressure. Mixing was accomplished by a rocking motion of the vessel. The tubes were cooled, opened, the decalin layers were withdrawn, analyzed by analytical gc, and the products were isolated by preparative gc. The results are given in Table 1.

In a large scale preparation, six tubes each containing **1***a* (0.25 g), pentane (1.5 mL), and 0.27 M DCl/D_2O (5 mL) were prepared in the usual manner and heated with agitation at 137 ± 3°C for 24 h in a Parr pressure vessel. The tubes were opened, the pentane layers were withdrawn, and the combined aqueous layers were saturated with NaCl and extracted with pentane (3 × 10 mL). The extracts were dried, filtered, and the pentane was removed on a rotatory evaporator. Several crystals of hydroquinone were added to the residue and **1***b* (0.31 g, 21%) was flash distilled under vacuum through a short-path apparatus; ms: 5.8% d_6, 27.7% d_2, 66.9% d_2, 1.2% d_3, and 9.3% d_4 species; 1.64 D atoms per molecule.

*H–D exchange of 2-phenylpropene (**2**a)*

In a typical reaction **2***a* (0.20 g), 0.27 M DCl/D_2O or 0.27 M HCl/H_2O (5 mL), and decalin or cyclohexane (1 mL) were reacted and the products isolated as described for the case of **1***a*.

For a larger scale reaction, three tubes each containing **2***a* (0.60 g), cyclohexane (3 mL), and 0.27 M DCl/D_2O (10 mL) were heated at 175 ± 3°C for 12 h with agitation. The organic layers were withdrawn and washed with aqueous $NaHCO_3$ saturated with NaCl. The $NaHCO_3$ solution was extracted with cyclohexane (2 × 5 mL) and the combined cyclohexane layers were dried over Na_2SO_4. Most of the cyclohexane was taken off on the rotatory evaporator. The residue was kept under rotatory pump vacuum for several minutes, several crystals of hydroquinone were added, and **2***b* (0.43 g, 27%) was isolated by rapid distillation at approximately 4 Torr (1 Torr = 133.3 Pa) using a short path distillation apparatus; ms: 11.6% d_4, 85.7% d_5, and 2.7% d_0 species; 4.91 D atoms per molecule.

H–D exchange of E*-1-phenylpropene (**3**a)*

In a typical reaction **3***a* (0.20 g), 0.27 M DCl/D_2O or 0.27 M HCl/H_2O (5 mL), and decalin or cyclohexane (1 mL) were reacted and the products isolated as described for **1***a*.

For a larger scale reaction, three tubes each containing **3***a* (0.50 g), cyclohexane (3 mL), and 0.27 M DCl/D_2O (10 mL) were heated for 12 h at 175 ± 3°C with agitation. The organic layers were withdrawn and washed with aqueous $NaHCO_3$ saturated with NaCl. The $NaHCO_3$ solution was extracted with cyclohexane (2 × 5 mL) and the combined cyclohexane layers were dried over Na_2SO_4. Most of the cyclohexane was taken off on the rotatory evaporator. The residue was kept under rotatory pump vacuum for several minutes, several crystals of hydroquinone were added, and **3***b* (0.99 g, 65.2%) was isolated by rapid distillation at 1 Torr using a short path distillation apparatus; ms: **3***b*, 16.4% d_0, 71.7% d_1, and 0.7% d_2 species; 0.96 D atoms per molecule.

N. EL KHATIB, B. BOUDJEMA, M. MAITROT, H. CHERMETTE, and L. PORTE. Can. J. Chem. **66**, 2313 (1988).

The electronic structure of zinc phthalocyanine is investigated through MSXα computations and XPS experiments. Reasonable argeement is found between the qualitative structure of the molecular orbital diagram and the XPS spectrum. The visible spectrum is also discussed and the calculation is compared to previous semi-empirical computations. On the other hand, it is shown that a similar calculation on the zinc tetraazaporphyrin — selected as a model molecule — cannot be used to interpret the electronic properties of the phthalocyanine.

N. EL KHATIB, B. BOUDJEMA, M. MAITROT, H. CHERMETTE, et L. PORTE. Can. J. Chem. **66**, 2313 (1988).

La structure électronique de la phtalocyanine de zinc a été étudiée au moyen de la méthode MSXα et par spectrométrie XPS. Un bon accord est trouvé entre la structure qualitative du spectre et le diagramme d'orbitales moléculaires. Le spectre visible est aussi discuté et le calcul est comparé aux calculs semi-empiriques connus. D'autre part, il est montré qu'un calcul similaire sur la tétraazaporphyrine de zinc, qui pourrait être considérée comme une molècule modèle de celle étudiée, ne peut pas être utilisée pour interpéter les propriétés électroniques de la phtalocyanine.

1. Introduction

Zinc phthalocyanine (ZnPc) is a well-known compound first prepared in the thirties (1). If its use as a paint pigment is quite old, it has been more recently studied for its electrical properties. In fact, its thermal stability (up to 500°C, no chemical degradation is observed) and its ability to sublime are remarkable. High purity can be obtained by successive sublimations, so it would be possible to use ZnPc as a molecular electronic components: although its conductivity is rather low ($\sigma = 10^{-9}$, 10^{-10} (ohm cm)$^{-1}$) for a thin evaporated layer at room temperature, it is not much lower than the conductivity of usual disordered mineral electronic components like SiH. Moreover, doping agents are available with a very high efficiency(2). Firstly, some dopants like oxygen and iodine were introduced into the ZnPc layers by gas or vapour diffusion (3). However, larger molecules, more stable in the phthalocyanine, can be used as p or n dopant: for instance by using the coevaporation method (3*b*) it was predicted that at low dopant concentration, pn junctions could probably be made, and perhaps some other electronic components such as field effect transistors or diodes. On the other hand, the contact properties of ZnPc have been thoroughly studied: diode effects were tested with Al or Ni electrodes, the photovoltaic effect was also studied in Schottky diodes, but up to now, a low efficiency has been obtained.

Moreover, numerous properties of metallophthalocyanines (1*b*) are well known for metallophthalocyanine structures from X-ray diffraction measurements, the macrocycle being planar to within 0.03 nm, so that the symmetry of the molecule is approximately D_{4h}. The spectroscopic properties like MCD spectra, electronic absorption spectra or photoemission spectra, can be used as tests of theoretical models (4). Some other properties, such as redox potentials or ESR measurements, important to characterize the electronic structure of ZnPc (5, 6), are also available. Thus, in spite of the large dimensions of the molecule (diameter equal to 1.5 nm), a fully theoretical calculation of the electronic structure of this compound should be interesting both for experimentalists (for instance, to assign electronic spectra) and for theoreticians to investigate what degree of confidence can be obtained in such "first principles" calculations at the one-electron level.

2. Experimental

Preparation

Linstead and co-workers in the 1930's (1) have given several methods to synthesize the metâllophthalocyanines. ZnPc is obtained by reacting 1,2-dicyanobenzene with the finely dispersed metal at 250–300°C. Many sublimations are used in a nitrogen atmosphere to purify the phthalocyanine.

The impurities still present in the powder consist mostly of hydrogen phthalocyanine (ca. 0.1%) which is eliminated in the evaporation step by using a cache to hide the plate, since the sublimation temperature of H_2Pc is slightly lower than that of ZnPc.

The film polycrystallinity is rather small and depends mainly on the temperature of the target. At low temperature (we used −70°C) the film is totally amorphous, and this is much better for electronic applications since interfaces between the crystallites are avoided. To obtain thin layers of ZnPc (100 to 1000 nm), the powder is evaporated onto a glass plate (10^{-7} Torr) (electrical or optical studies) in a strict absence of oxygen or onto a conducting plate (XPS measurements); the evaporation rate is kept low and constant (0.1–0.5 nm s^{-1}) during all the evaporation process.

Photoemission spectrum

The sample of about 300 nm thickness has been evaporated on a copper support. The X-ray photoelectron (XPS) spectrum was taken in a "Hewlett-Packard 5950 A" electron spectrometer, using the monochromatized AlKα X-ray (1487 eV) with a resolution equal to 0.85 eV.

Spectra were recorded at room temperature and the base pressure in the analysis chamber was in the 10^{-9} Torr range. Neither radiation damage nor outgassing was observed and measurements recorded on different samples were reproducible. No charging effects or peak deformation were observed and the spectra were recorded without flood gun compensation. Binding energies (BE) were measured taking the AU 4*f* 7/2 core line as reference (BE = 84.0 eV).

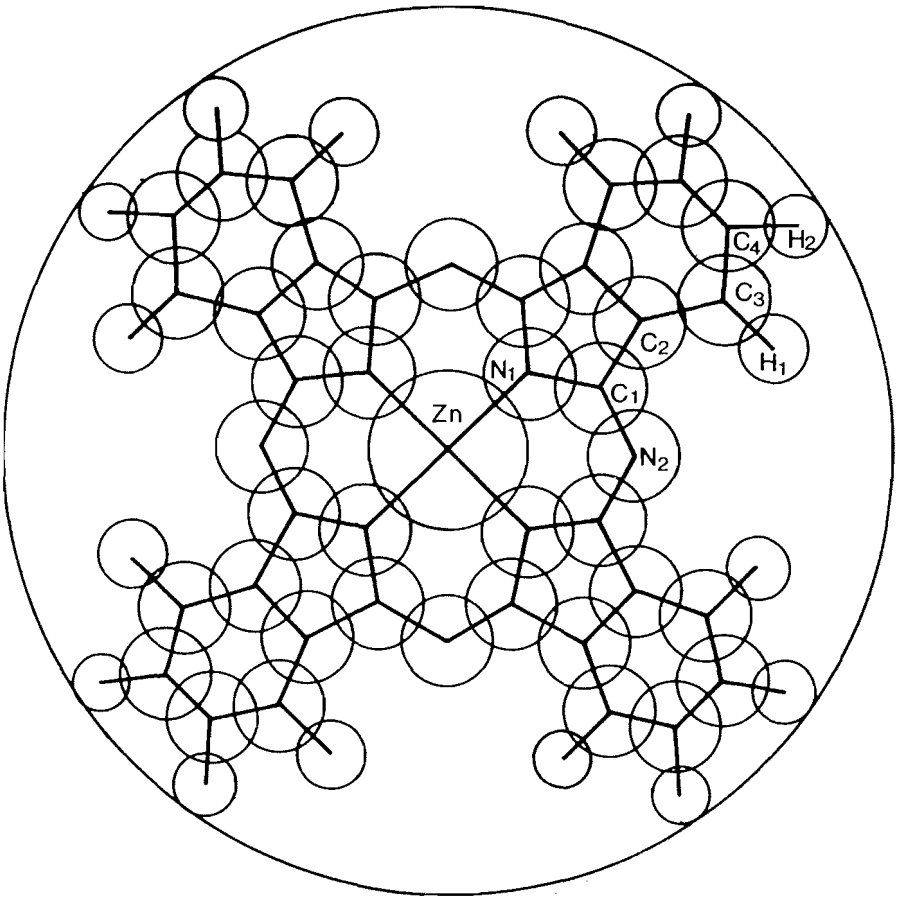

FIG. 1. Zinc phthalocyanine in the muffin-tin approximation.

3. Theoretical calculations

Calculations have been performed with the MS-Xα method with standard parameters. Although the muffin-tin approximation may be rather severe for such a molecule with a planar structure, quite good results have been obtained in the past for calculations on TCNQ and other planar molecules (7), so that we were confident to obtain at least semiquantitative results. The crudeness of the muffin-tin approximation is related here to the large volume of the intersphere region in which the potential is approximated as constant.

Computational details

D_{4h} symmetry was retained for a geometry deduced from the data of Scheidt and Dow (8). Slightly overlapping spheres were used, with radii obtained partly by Norman's criterion (9) along with the requirement to keep the same radii for similar atoms (10). The selected overlapping ratios were taken equal to 1.15 and 1.25 for C—N bonds, to 1.10 for Zn—N bonds, between 1.10 and 1.15 for C—C bonds, and equal to 1.30 for C—H bonds. Parameters were taken from Schwarz's compilation (11) and the basis set was limited to f waves ($l = 3$) for Zn, to p waves ($l = 1$) for N, C, and H atoms, and g waves ($l = 4$) for the outersphere. The coordinates, the α values, and the radii of unique atoms are displayed in Table 1.

4. Results and discussion

Ground state

The phthalocyanine is a neutral 294 electron system that consists of one Zn, 8 N, 32 C, and 16 H. Figure 1 depicts the inequivalent atoms in the molecule. On the other hand, the 294 electrons can be divided into two sets: the first one consists of 98 core electrons, namely $1s$, $2s$, $2p$, $3s$, and $3p$ for Zn, and $1s$ for nitrogen and carbon atoms. The second group gathers the valence electrons which are classically $1s$ for hydrogen, $4s$ and

$3d$ for zinc, $2s$ and $2p$ for nitrogen, and $2s$ and $2p$ for carbon, for a total of 196 electrons.

In the Xα ground state there are 50 doubly occupied orbitals and 24 quadruply occupied orbitals. Table 2 lists all these molecular orbitals (MO) with their eigenvalues; the atomic character of the most important valence orbitals is also indicated in the energy diagram (Fig. 2). In Table 3 are mentioned the core energy levels. One can notice the characteristics of two frontier MO's:

The LUMO: (Lowest Unoccupied Molecular Orbital) belongs to the e_g irreducible representation which mainly exhibits carbon character with small nitrogen contributions.

The HOMO: (Highest Occupied Molecular Orbital) belongs to the a_{1u} irreducible representation; it exhibits only carbon character since nitrogen character is symmetry forbidden in the a_{1u} irreducible representation.

It appears that the Zn(d) band is spanned mainly in four irreducible representations, namely $6a_{1g}$, $4b_{1g}$, $6b_{2g}$, and $1e_g$ with an atomic d character varying from 56% (b_{2g}) to 99% (e_g). Then the d bandwidth equals 0.8 eV and the d band is only slightly mixed with the other orbitals of the valence band VB. However, a slight, but significant, mixing involves levels as far as 3 eV from the center of the d band. This is clearly apparent in Fig. 2.

Comparison between Xα and EHT calculations

To our knowledge, only one Extended Huckel (EHT) calculation (12) and one PPP calculation (13) have so far been performed on the ZnPc molecule. In Fig. 3 are given the energy diagram from Xα (present work) and EHT calculations (the diagram is limited to the upper MO's).

Let us recall that the Xα eigenvalues (and more generally local spin-density eigenvalues) do not have the same significance as the EHT energies, as already pointed out by Case and Karplus (14). The EHT energies do not take explicitly the electronic repulsion into account, while the Xα eigenvalues contain a spurious self-energy interaction which can be extracted through a straightforward calculation (one shot iteration) as depicted in ref. 15. This self-interaction is strongly related to the localization of MO's exhibiting a similar delocalization over the molecule. This term is responsible for the apparently non satisfied Fermi statistics of the ground state of some molecules like Cu porphyrin (14) and possibly lithium phthalocyanine (16).

However, a qualitative comparison can be made between the two kinds of calculations, and it shows the following points:

(*1*) The calculated Xα levels are deeper than the corresponding Huckel ones. This effect is mainly due to the muffin-tin approximation in our calculation: to be more precise, the effect is due to the large size of the outersphere (required to be tangent to the outermost atomic spheres) leading to a large intersphere zone for which the potential is assumed constant. This effect is discussed in detail in a recent work (17).

(*2*) The LUMO levels are found to belong to the same irreducible representation (e_g) in both calculations but the HOMO is (a_{1u}) in Xα and (b_{1g}) in EHT. The authors of the EHT calculation pointed out, however, that their calculation leads to an erroneous result for the nature of the HOMO which should be of (a_{1u}) symmetry to agree with experimental properties such as the optical spectrum. Our result is then in accord with what the authors were expecting, i.e. the experimental conclusions.

(*3*) The two methods give almost the same gap value (0.6 eV). However, the gap in Xα calculations should be calculated through a Slater transition state calculation, in order to remove the self-interaction energy and take the electronic relaxation into account. But since both the HOMO and LUMO exhibit a similar π or π* character, their self-interactions are rather similar and the electronic relaxation has to be small (no charge transfer involved). Consequently the theoretical gap should not reach a value far from 0.6 ± 0.1 eV.

(*4*) The pattern of the first unnoccupied levels is rather similar if one excludes the $13a_{1g}$ level we found which has no equivalent in the EHT calculation. This MO exhibits a strong (for a virtual level) Zn ($4s$) atomic character (50%). Its exact position among the virtual levels may be subject to discussion because of the muffin-tin approximation involved in the calculation. In silver chloride calculations, the Ag ($5s$) level was found (with a smaller atomic $4s$ character) about 2 eV lower than required by the experimental spectrum (18).

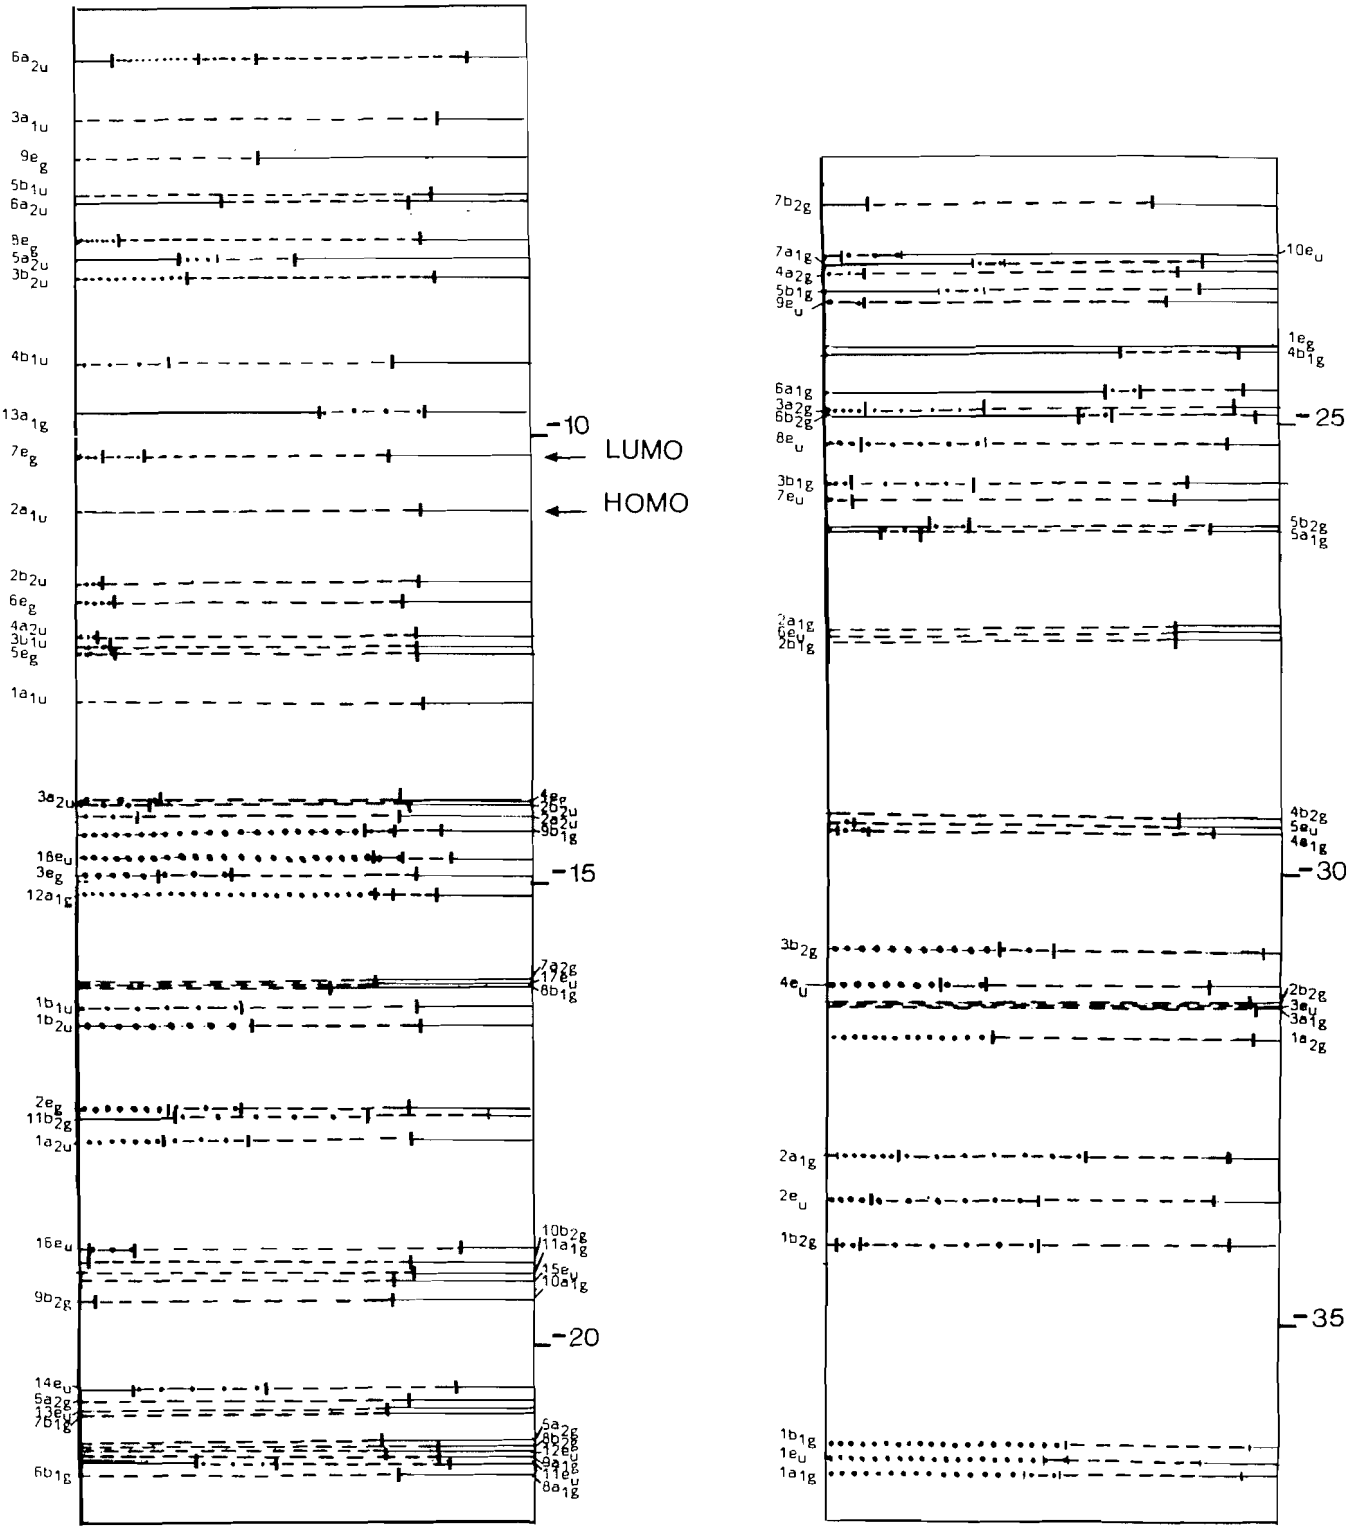

FIG. 2. Xα energetic diagram of ZnPc. ---, Zn contribution; . . . . . , N1 contribution; -·-·-·, N2 contribution; – – –: all carbon contribution.

(5) The order of the occupied levels is very different, between the two calculations and no one-to-one correspondence can be made since the authors did not give the full list of them (and the VB width).

Comparison between ZnPc and a similar smaller molecule zinc tetraazaporphyrin (ZnTAP)

This kind of molecule has also been the subject of several experimental determinations and theoretical calculations (19), however, to our knowledge no calculation has been performed on the zinc complex. One should emphasize that the geometry used for our calculation is that of ZnPc from which the benzo groups have been removed and after having saturated the dangling bonds by hydrogen atoms. This is not the experimental geometry which should, however, not be very different. Consequently, the same parameter set has been retained for the

TABLE 3. Theoretical core energy levels (eV)

Zn:	1*s*	2*s*	2*p*	3*s*	3*p*	
	9414.0	1148.0	1015.0	138.5	96.32

	391.1	392.1	285.6	282.6	281.1	279.5

calculation, the outersphere radius excepted, since it is taken tangent to the most external atomic spheres in both cases.

The experimental spectrum of this kind of molecule is known to be quite different from the ZnPc spectrum (19): however, this calculation should be compared to both experimental and theoretical ZnPc spectram.

We did not find a ZnTAP photoemission spectrum in the literature but some qualitative features should be derived from the other transition elements TAP spectra described by Koch (19).

The experimental valence band width amounts to 24.0 eV, which is smaller than the calculated one. This is due to the geometry retained for the calculation, which is neither optimized in the calculation, (since the calculation aimed to mimic the phthalocyanine molecule) nor the experimental one.

If one compares now the ZnTAP to the ZnPc molecules, a smaller valence band width is expected because of a smaller π cloud over the molecule. the HOMO–LUMO gap is also expected to be found rather different since it involves orbitals belonging (in part) to peripheral atoms. On the other hand, the frame could be expected to be not significantly different from the previous one. In fact we found the two frontier MO's (HOMO, LUMO) belonging to the irreducible representations $5a_{2g}$ (10.08 eV, carbon character) and $5a_{2u}$ (9.875 eV, nitrogen character) respectively. This leads to a forbidden gap equal to 0.22 eV, much smaller than the gap of ZnPc. On the other hand, the valence band width is larger than the VB of ZnPc, since it is equal to 39.74 eV instead of 25.76 eV.

In order to compare the two VB of ZnPc and ZnTAP we begin with the two spectra Fig. 4 (*a*) and (*b*) where the total densities of state of ZnPc and ZnTAP are respectively given. These densities of states are obtained by convolution of the discrete levels by gaussian of 0.6 eV HWHM. The intensity of each level is given by its occupation number, while in partial or local densities of states, this intensity is weighted by the partial charges (*s*, *p*, *d*) of the selected atoms (Table 4). Finally the theoretical spectra are sums of partial densities of states weighted by atomic cross sections. As just mentioned, the valence band is narrower in ZnPc than in ZnTAP. On the (*a*) spectrum the characteristics of some peaks (purely 2*s* or *d* peaks) are given, the other peaks corresponding to mixed orbitals. The lack of C3(2*s*) and C4(2*s*) peaks in ZnTAP spectrum can be observed, and so the two peaks N1(2*s*) and N2(2*s*) are pulled nearer the Zn(3*d*) peak when the two atoms C3 and C4 are removed (i.e. going from ZnPc to ZnTAP). Moreover, a wide shift of the whole spectrum towards the lower energies is observed when going from ZnPc to ZnTAP. This is related to the size of the outersphere (i.e. the volume of the intersphere region), as previously stated. The order of magnitude of this shift can be deduced from the two spectra (*c*) and (*d*). On (*c*), the ZnPc molecule is given after setting to 0 the cross section of C3, C4, H1, and H2 atoms. On (*d*) a spectrum of ZnPc is given with a null cross section for H atoms, so that theoretically, the same molecules should be obtained. Although

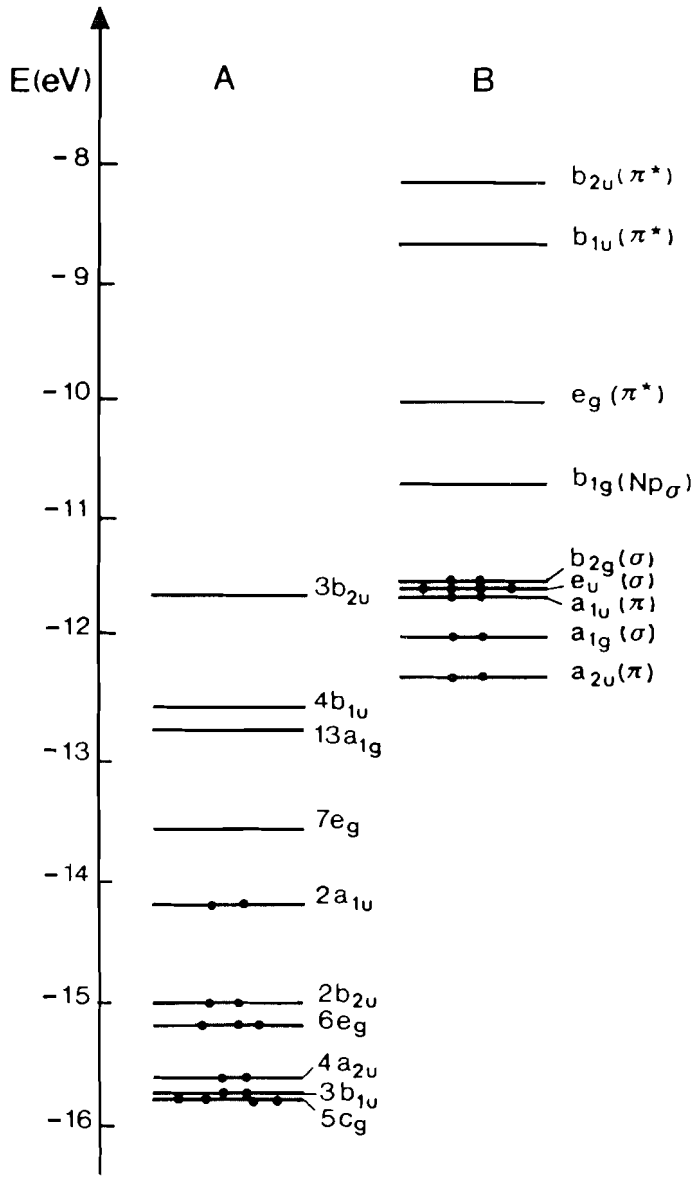

FIG. 3. Comparison between Xα and EHT calculations of the electronic structure of ZnPc.

the two spectra compared exhibit a similar shape, it can be deduced that the N1(2*s*) and N2(2*s*) peak shift amounts to 13 eV while the Zn(3*d*) peak shift is only about 4 eV.

Two spectra (not displayed here) can be calculated for ZnPc and ZnTAP with the usual atomic cross sections taken from Scofield's table (2). These two spectra do not differ significantly from the (*c*) and (*d*) spectra because the cross sections of the other orbitals N(2*p*), C(2*p*), and H(1*s*) are very weak in comparison to 3*d* (3*d*) cross section.

Extending this comparison to the C1(2*s*) and C1(2*p*) spectra, it clearly appears that these electrons are delocalized over all the MO's in both ZnPc and ZnTAP. However, the C2(2*s*) electrons localized at one place on the (*g*) spectrum (ZnPc) become localized at two places in the (*h*) spectrum (ZnTAP): this is not true for C2(2*p*) electrons which are delocalized over the whole spectrum in both cases. Therefore, the "truncation" of the ZnPc not only affects the qualitative distribution of these electrons, it also leads to a quantitative difference in the relative positions of the different peaks.

5. Valence band photoemission spectra of ZnPc

Figure 5(*a*) reproduces the XPS spectrum of ZnPc in the valence band region; one notices the peak with the highest intensity lying at 11.0 eV BE, which is the Zn 3*d* peak. This peak shows that the energy of the (*d*) orbitals is concentrated in a narrow band.

Figure 5(*b*) gives a theoretical XPS spectrum obtained after having weighted the partial DOS (Fig. 5(*c*) by atomic cross sections, and a convolution with gaussians of 0.6 eV FWHM. The last two spectra show that the role of the cross section is dominant so that we cannot make direct comparisons between experiment and the DOS. On the other hand, the use of Scofield's values (20) allow a good agreement between the theoretical spectrum and the experimental one.

However, the theoretical photoemission spectrum should involve the transition state energies of all the MO's rather than the ground state eigenvalues, in order to take into account the electronic relaxation during the ionisation process and to remove the self-interaction, as already stated. This is hardly possible for reasons of computational cost, but we know that for orbitals exhibiting the same atomic character, the relaxation is similar (21). Accordingly, we can gather the VB MO's in three groups: the π orbitals, the (C,N)2*s orbitals and the Zn(3d)* orbitals. Therefore, we computed a transition state for one MO of each group in order to determine semi-quantitatively the shift to apply to each group. We found "relaxations" (i.e. self-

TABLE 4. Electronic sphere charges

out	int	Zn	N1	N2	C1	C2	C3	C4	H1	H2

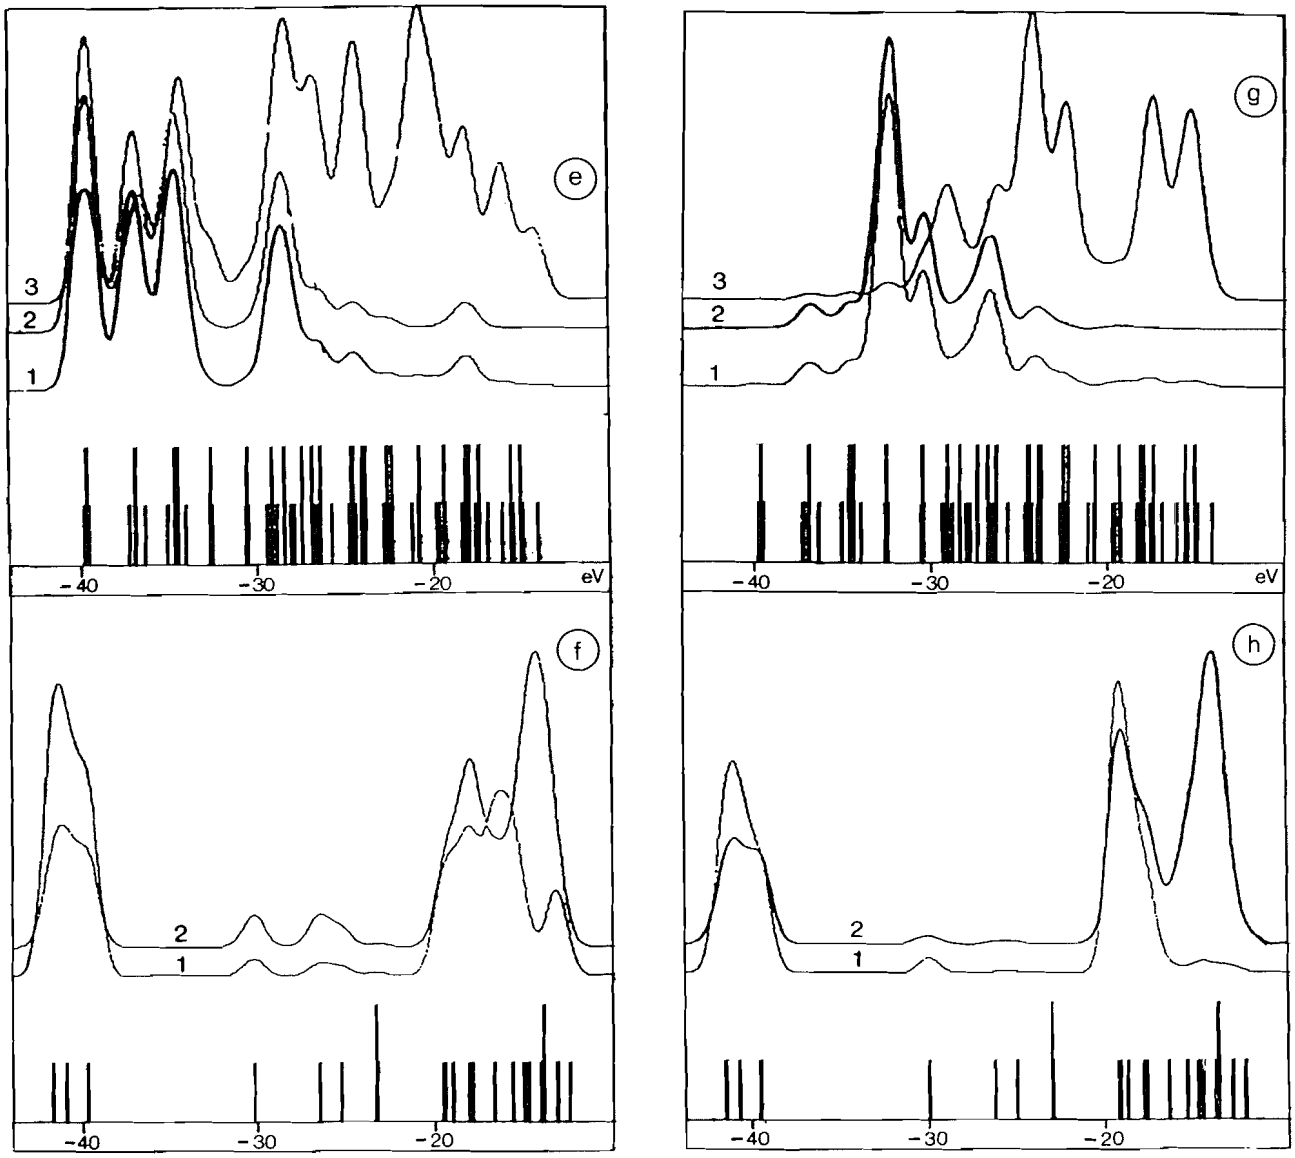

FIG. 4. (*Concluded*)

interaction energies + relaxation energies) as large as 5.8 eV for Zn(3*d*) MO's (calculated on the $1e_g$) and 1.7 eV for π^* MO's (HOMO). An intermediated value probably equal to 4 to 5 eV should be obtained for the 2*s* peaks since these orbitals are localized on one kind of symmetry-equivalent atoms. We did not compute it since a correct calculation should be performed in C_1 symmetry to let the ionization hole localize over one of the (4 or more- symmetry-equivalent atoms of the molecule in D_{4h} symmetry. These values compare well to the relaxation shift found by Tossell (22) for ZnS or Zn halides. On the other hand, the relaxation found for π orbitals is much larger than the 0.5 eV relaxation found by Ellis *et al.* in a DV-SCC calculation of SiTAP (23).

Therefore, the theoretical spectrum given in Fig. 5(*b*) may be discussed and compared to experiment if one keeps in mind that the Zn peak has to be shifted (by 4 eV) towards larger binding energies, as well as the left part of the spectrum (2s peaks, by ca. 3 eV) relatively to the π peaks.

The theoretical and experimental spectra given in Fig. 5(*a*) and (*b*) are rather similar if one performs a shift of 13 eV towards the lower energies in the theoretical spectrum with respect to the experimental one, and if one takes this shift to align the peaks of Zn(3*d*) we can observe the correspondence between the two peaks which are found at 24.0 eV and 20.5 eV BE in the experimental spectrum and the orbitals N1(2*s*) and N2(2*s*) peaks, respectively; an analogous correspondence can be established for the peaks which are found at 17.75 eV and 13.95 eV Be corresponding to the orbitals C4(2*s*) and C(2*s*), respectively.

The comparison between the experimental and theoretical values once this shift is performed, is summarized in Table 5. These values show that the differences between theoretical and experimental peak energies amounts to values as small as 0.5 eV, which are rather small, since a part of them can be attributed to the difference in the relaxation energies of the different oribtals through the ionization process.

In the experimental spectrum, the first peak lies at 3.7 eV below the Fermi level: it corresponds to the first peak of the DOS

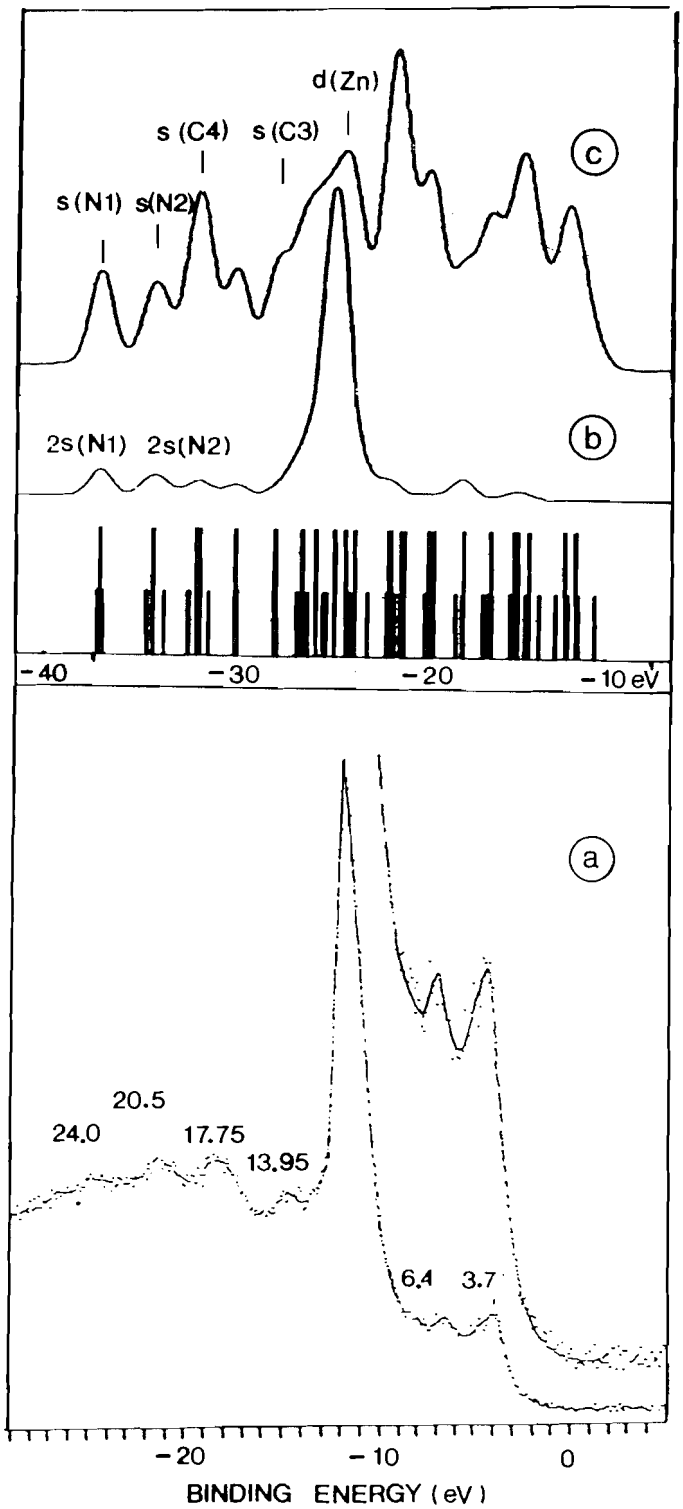

FIG. 5. (*a*) Experimental XPS spectrum of ZnPc, (*b*) theoretical XPS spectrum of ZnPc, (*c*) DOS of ZnPc.

and it arises essentially from the photoionization of the π electrons which are delocalized over the carbons.

Finally, let us recall that the shift of 13.9 eV is related to the too large value for the outersphere radius, or more precisely, to the large size of the intersphere volume in the muffin-tin representation of the potential. As already stated, this effect of increased binding energies of large (planar) molecules has been studied in detail in a forthcoming paper (17).

6. Absorption spectrum

Figure 6 gives the experimental spectrum of a thin layer obtained in the laboratory by evaporation under vacuum. We have compared in this figure this absorption spectrum to that obtained in the vapor phase by Eastwood *et al.* (24), in solution by Lever (25), and more recently by Nyokong *et al.* (4*a*).

The absorption spectrum of a metal-phthalocyanine usually composes of two intense bands in the 300–400 nm zone (the Soret band) and the 600–700 nm zone (the Q band) (26). The absorption coefficient in these bands is very large. Thin film (300 nm) spectra have been recorded in the 0.2–2 μm range and exhibit no absorption in the 800 nm–2 μm range, therefore the first electronic transition does not lie in the infrared region and should be found in the visible spectrum.

Edward and Gouterman (21) have studied the absorption spectrum of the ZnPc and other phthalocyanines in the vapour phase between 800 nm and 300 nm. Generally, the metal effect is relatively weak in the 300 to 800 nm zone, since the specific band of the metal is found in the infrared range. In the uv a wide band exists at 180–160 nm. On the other hand, these authors have also compared the spectra in the vapor phase and in the solution state. These spectra differe slightly. However, more important changes occur when one goes from solution to solid state: one observes a widening of the Q band with the appearance of the Davidov splitting (27) which is clearly apparent in the thin film spectrum (Fig. 6). We notice the widening of the peak when one goes from the solution state to the solid state. On the other hand, the peaks are not of the same intensity ratio. The Q band is thus modified: the peak at 880 nm in the vapor phase is found at 707 nm in the solid phase spectrum, the peak at 600 nm which represents a shoulder is more intense than the band at 707 nm, and is shifted to 617 nm. This last peak also exhibits a shoulder. On the other hand, the Soret band lies at lower energies and is more intense than the Q peak, slightly wider, and has a shoulder at 380 nm.

In the literature some interpretations of the absorption spectra by molecular orbital theories can be found. The EHT method used by Gouterman *et al.* allowed to interpret the Q band as a $\pi \rightarrow \pi^*$ transition of $a_{1u} \rightarrow e_g$ type, the Soret band being also a $\pi \rightarrow \pi^*$ transition of $a_{2u} \rightarrow e_g$ symmetry. This would also be in agreement with PPP calculations.

The most detailed analysis of the absorption spectrum of ZnPc is given in Nyokong's paper (4*a*) in which the assignment is obtained through a correlated analysis of the absorption and the MCD spectra.

The energy diagram of ZnPc given in the previous paragraph shows for the forbidden gap ($2a_{1u}$–$7e_g$) an energy at 0.6 eV, which is at variance with the experimental electrochemical gap of about 1.7 eV (25–31). This discrepancy cannot be attributed only to the solvation of the molecule used for the experiment, and which is not taken into account in the calculation. On the other hand, solid state effects like the stacking of the ZnPc rings cannot be invoked since the vapor uv spectrum is rather similar

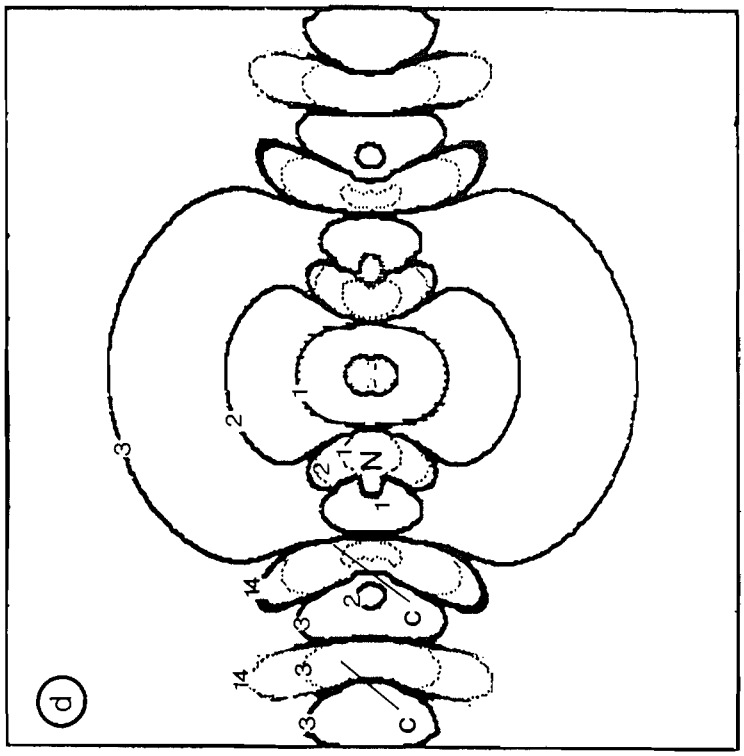

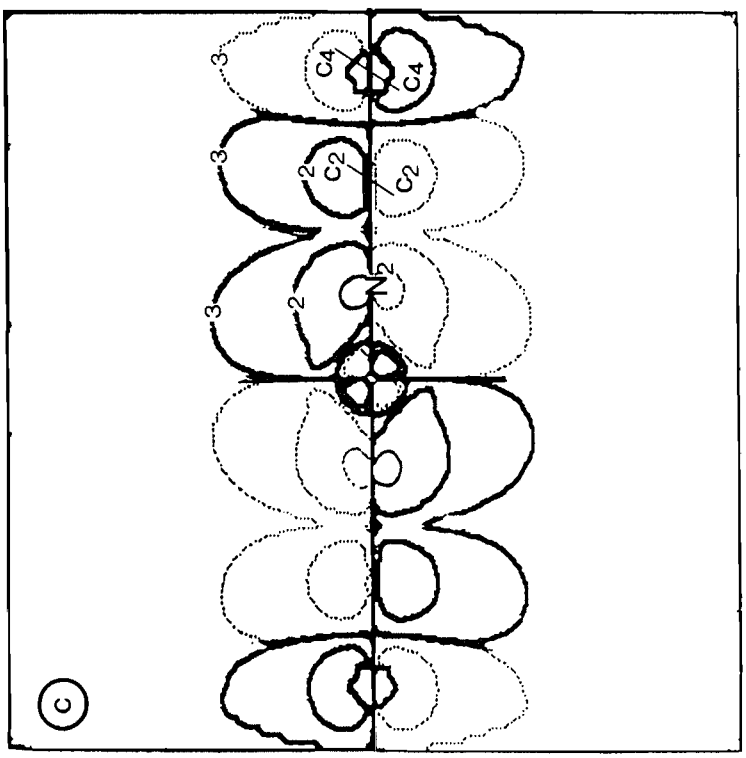

FIG. 7. (*Concluded*)

to the solid state one. The electronic gap and the electronic transitions are definitely underestimated, but if one adds 1.2 eV to the virtual level eigenvalues one obtains the optically allowed transition energies which are listed in Table 6. With this shift the HOMO–LUMO $2a_{1u}$–$7e_g$ transition corresponds well to the Q band which lies at 1.8 eV, i.e., 690 nm while the Soret $4a_{2u}$–$7e_g$ transition lies near 390 nm. Indeed, the correlation with Nyokong's assignment (4*a*) becomes surprisingly good since the four QBNL bands are found to agree within 5% (Table 6).

In order to get a better view of the MO's in the optical transitions some contour maps have been plotted in Fig. 7 for frontier orbitals $2a_{1u}$, $7e_g$, and the $13a_{1g}$ MO's. Their π or π^* character is clearly apparent in the views which are taken either in the *y*O*z* or the *xy*/O*z* planes. One also clearly sees the strong Zn(4*s*) character in the $13a_{1g}$ MO. The overlap between these π and π^* MO's is quite large, leading to high absorption coefficients. One should also expect in the far uv region, intense transitions involving the $13a_{1g}$ MO which exhibits a Zn(4*s*) character as already indicated.

Finally one can conclude that the energy level diagram allows the correct interpretation of the electronic absorption spectrum, as well as the XPS spectrum. This lead us to expect that it may be used with success to calculate the doping of this material by donor or acceptor molecules of similar shape. This work is now in progress.

The kinetics of gas phase reactions studied in a "homogeneous reactor"

JOHN M. ROSCOE
Department of Chemistry, Acadia University, Wolfville, N.S., Canada B0P 1X0

Received January 28, 1988

JOHN M. ROSCOE. Can. J. Chem. **66**, 2325 (1988).

The use of a "well-stirred" or "homogeneous" reactor in kinetic studies of gas phase reactions has been examined to assess the sensitivity of the method to the criteria upon which its use is based. The effects of heterogeneous and homogeneous secondary reactions are considered and the validity of the assumption of homogeneity has been examined experimentally for conditions similar to those which have been used elsewhere. The atom sink presented by the excess reagent under pseudo first order conditions results in failure of the homogeneity assumption. However, it is found that homogeneity is not required for successful use of the method provided the analytical measurements have good spatial resolution and the reaction volume is well-defined. The method is illustrated by using it to study some reactions of $O(^3P)$.

JOHN M. ROSCOE. Can. J. Chem. **66**, 2325 (1988).

On a examiné l'utilisation d'un réacteur "bien agité" ou "homogène" dans les études cinétiques des réactions en phase gazeuse, dans le but d'établir la sensibilité de la méthode face à ses critères d'utilisation. On a considéré les effets des réactions secondaires hétérogènes et homogènes et on a examiné expérimentalement la validité de l'hypothèse d'homogénéité dans des conditions semblables à celles déjà utilisées. Le puits d'atomes présenté par l'excès de réactifs dans des conditions de pseudo ordre 1 est dû à l'insuffisance de l'hypothèse d'homogénéité. On a trouvé que l'homogénéité n'est pas nécessaire pour une utilisation fructueuse de la méthode en admettant que les mesures analytiques ont une bonne résolution spatiale et que le volume réactionnel est bien défini. On applique la méthode à l'étude de quelques réactions du $O(^3p)$.

Introduction

The principles of kinetic measurements in a "well-stirred" or "homogeneous" reactor, first developed by Denbigh (1, 2), have had sporadic application to the study of gas phase reactions of atoms and radicals (3–15). While considerable success has been attained at the relatively low pressures of the VLPP method of Benson and co-workers (10, 11), the validity of the homogeneity assumption at the higher pressures used in other work (3–9, 12–15) is unclear and has not been examined directly. The criteria for efficient mixing have received some attention (4, 9, 12), but the effect on the use of homogeneous reactors of the homogeneous atom sink represented by the excess reactant has been largely neglected in this higher pressure region. On the other hand, there are several theoretical and experimental evaluations of the relative importance of diffusive and convective mass transport in conventional flow systems operated at pressures of a few Torr (1 Torr = 133.3 Pa) and containing both homogeneous and localized heterogeneous atom sinks (16–20).

Homogeneous reactors operated at pressures above about 0.1 Torr represent a potentially simple and convenient way to study the kinetics of atom and free radical reactions. Although much of the work in the literature which uses this method has employed relatively expensive instrumentation (4–9), it has also been used successfully with much less costly apparatus (12–14). We were surprised, then, when our initial efforts to apply the homogeneous reactor method gave results which were in very poor agreement with data reported in the literature. Our results suggested that the criterion of homogeneity was not satisfied in our apparatus even though the physical criteria for homogeneity (9) were met and the homogeneous reactor equation relating concentrations of reactants to the rate constant for the reaction was evidently obeyed. This led us to investigate the implications at these pressures of a homogeneous atom sink for the principles upon which the method is based. The validity and necessity of the assumption of homogeneity were examined directly over a range of conditions encompassing most of those used in previous work (4–9, 12–15) and the reliability of the method was examined by using it to study the kinetics of some reactions of $O(^3P)$ for which good agreement exists among recent results in the literature.

Theory

Neglecting radial concentration gradients, the steady-state balance of atoms (A) entering and leaving a cross-section of a cylindrical gas kinetics flow reactor is

$$[1] \quad D\frac{\partial^2[A]}{\partial x^2} - v\frac{\partial[A]}{\partial x} - \sum_i k_i [A]^{n_i}[S]^{m_i} = 0$$

where D is the diffusion coefficient for A, v is the velocity of gas flow through the reactor, S is the substrate with which A reacts, x is the axial distance in the direction of flow, and k_i, n_i, and m_i are the rate constant and appropriate reaction orders for the ith reaction removing A. For simplicity, consider the removal of atoms by a single reaction which is first order in both S and A and which occurs under conditions which are pseudo first order in A (excess S). Equation [1] then becomes

$$D\frac{\partial^2[A]}{\partial x^2} - v\frac{\partial[A]}{\partial x} - k_1[A] = 0$$

where $k_1 = k[S]$ is the pseudo first order rate coefficient. Solution of this equation for [A] at any point x along the axis of the flow tube gives

$$[2] \quad [A]_x = [A]_0 e^{Rx}$$

where $[A]_0$ and $[A]_x$ are the atom concentrations at the inlet of the flow reactor and at some point x downstream from the inlet and R is given by

$$R = \frac{v}{2D} - \left[\left(\frac{v}{2D}\right)^2 + \frac{k_1}{D}\right]^{1/2}$$

It may be easily shown that, under the conditions encountered in conventional flow experiments (large v and small D), the second derivative term in eq. [1] becomes negligible and $R = -k_1/v$ as required.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/07/12
For personal use only.

Two methods of using homogeneous reactors have appeared in the literature. In the first method (4–7, 12–15), the inlet and exit atom concentrations are measured and are related to the rate constant for the reaction by

$$[3] \quad [A]_0 - [A]_L = k[S][A]_L V/\dot{V}$$

where $[A]_0$ and $[A]_L$ are the inlet and exit atom concentrations respectively, $\dot{V}$ is the volumetric flow rate through the reactor and V is the reactor volume. The assumption is made that diffusional mixing is so fast that the exit atom concentration equals the bulk (homogeneous) atom concentration.

The second method (9) measures an average atom concentration within the reactor and again uses eq. [3] on the assumption that diffusional mixing is so fast that the measured atom concentration equals the exit atom concentration. Since it is uncertain how much of the reactor was sampled in these experiments, the relationship of the measured atom concentration to the volumetric average atom concentration within the reactor is also uncertain.

Because it is desired to test the assumptions outlined above, two additional equations will be developed. If the reactor is sufficiently short, axial homogeneity can, in principle, be achieved to an arbitrarily good degree of approximation. Under such conditions eq. [3] can be differentiated, for a cylindrical reactor with constant [S] and of radius r, to give

$$-\mathrm{d}[A] = \frac{k[S]\pi r^2}{\dot{V}}\,\mathrm{d}([A]x)$$

where x is the axial distance from the reactor inlet. Substituting eq. [2] for [A] on the right hand side avoids the necessity of assuming axial homogeneity and leads to

$$\int_{[A]}^{[A]_0} \mathrm{d}[A] = \frac{k[S][A]_0\pi r^2}{\dot{V}} \int_0^x (1 + Rx)\mathrm{e}^{Rx}\mathrm{d}x$$

Integration gives on rearrangement

$$[4] \quad \left[\frac{[A]_0}{[A]} - 1\right] = \frac{k[S]V}{\dot{V}}$$

which is equivalent to the homogeneous reactor eq. [3] but does not rely in its derivation upon rapid diffusional mixing. It does, however, assume good spatial resolution in measuring [A] so that the volume defined by the limits of integration is the same as that to which $[A]_0 - [A]$ applies.

When the spatial average concentration is measured, the following approach applies. The volumetric average concentration of A up to a point at a distance L from the reactor inlet is given by

$$\langle[A]\rangle = \frac{1}{L}\int_0^L [A]_0\mathrm{e}^{Rx}\mathrm{d}x$$

This gives

$$\frac{\langle[A]\rangle}{[A]_0} = \frac{\mathrm{e}^{RL} - 1}{RL}$$

If we define $\langle x\rangle$ as the axial distance at which $[A] = \langle[A]\rangle$, use of eq. [2] gives

$$[5] \quad \langle x\rangle = \frac{1}{R}\ln\left\{\frac{(\mathrm{e}^{RL} - 1)}{RL}\right\}$$

Equation [4] may now be used with the realization that use of $\langle[A]\rangle$ requires integration between 0 and $\langle x\rangle$ so that V is replaced by $\langle V\rangle = \pi r^2\langle x\rangle$. The result is

$$[6] \quad \frac{[A]_0}{\langle[A]\rangle} - 1 = \frac{k[S]V}{\dot{V}}\frac{\langle x\rangle}{L}$$

The homogeneous reactor assumption, using the geometric volume, will give an apparent rate constant which is too small and which varies with $\langle x\rangle$ unless the pressure is sufficiently small that $\langle x\rangle = L$.

Experimental

Two reaction vessels of similar design were used in this work. The basic design is shown in Fig. 1. The reactor used to examine homogeneity differed from that used for the rest of the work in having a reactant inlet approximately in the center of the reactor, as shown in Fig. 1(*a*), and in having only the observation port used for viewing along the axis of the reactor. This reactor was not enclosed in a furnace so that measurements could be made at any point along its axis with a movable photomultiplier tube. The reactors used for most of the kinetic measurements had observation ports viewing the reactor at right angles to the direction of flow. In one reactor, these were located between the inlet and exit tubes as shown in Fig. 1(*a*). In the other reactor, shown in Fig. 1(*b*), the observation ports were located just outside the reaction volume at the inlet and exit. These reactors were also enclosed in a furnace to provide temperature control.

Most of the experiments were made at pressures ranging from 0.8 to 1.7 Torr and at room temperature. The flowrates of the carrier gases, N_2 and He, were measured with calibrated capillary flowmeters. Flowrates of the other components were determined by measuring the increase in pressure when the gas whose flowrate was required was allowed to enter a bulb of known volume for a measured length of time.

Atomic oxygen was produced by adding NO to $N(^4S)$ atoms formed in a microwave discharge through N_2 or a mixture of a few percent of N_2 in He. The purification procedures used for these gases are standard and have been described elsewhere (17, 18). This method of producing $O(^3P)$ has the advantage of minimizing interference by ground state or electronically excited molecular oxygen. The concentration of $O(^3P)$ was controlled by adjusting the composition of the gas passing through the discharge or by varying the ratio of gas flowrates through the discharge and through a bypass around the discharge while maintaining a constant total flowrate. This made it possible to achieve ratios of reactant concentration to $O(^3P)$ concentration of as much as several thousand. This was necessary in some cases to avoid interference by secondary reactions and to ensure both pseudo first order disappearance of $O(^3P)$ and constant stoichiometry.

The concentration of $O(^3P)$ was monitored by measuring the chemiluminescence produced by the reaction between $O(^3P)$ and a small amount of NO (less than about 10% of $[O(^3P)]$). The titration of $N(^4S)$ with NO was used to calibrate the chemiluminescence signal in terms of $[O(^3P)]$. When two photomultipliers were used to measure this chemiluminescence at two positions the signals produced by them in the absence of a second reactant were made equal by adjusting the high voltage applied to each detector. In all cases, the dark currents produced by these detectors were within 30% of each other and were no greater than 10% of the smallest signal recorded in the kinetic measurements. In most measurements the dark current was less than 1% of the signal produced by the NO_2 chemiluminescence. In all the kinetic measurements the ratio of substrate concentration to $O(^3P)$ concentration was at least 200 and in most cases was several thousand. This should have ensured pseudo first order loss of $O(^3P)$ and, except in the reaction of $O(^3P)$ with NO, a stoichiometric coefficient of unity.

Results and discussion

The reaction of $O(^3P)$ with CH_3OH was selected as the test reaction because its rate constant is known with reasonable accuracy (22–25) and is of a convenient magnitude at room temperature for use in evaluating the performance of the available apparatus. Two other reactions were subsequently

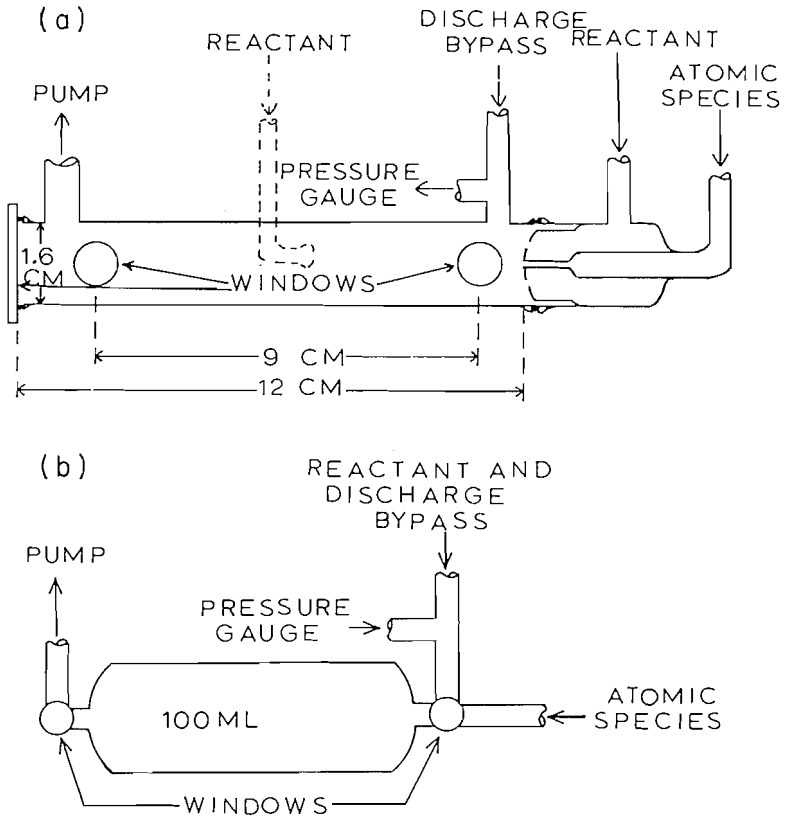

FIG. 1 (*a*). Basic reactor design for investigation of homogeneity; (*b*). Design of the reactor used in the kinetic measurements.

examined in the same system to provide additional information about its reliability and the useful range of operating conditions.

Experimental test of homogeneity:

Radial homogeneity was examined in the reactor shown in Fig. 1(*a*) by adding a small amount of NO to the $O(^3P)$ stream before it entered the reactor. The intensity of the resulting NO_2 chemiluminescence was observed at several points across the diameter of the window mounted on the end of the reactor. Uniform intensity was found both in the presence and absence of methanol indicating that efficient radial mixing had occurred by the time the gas stream had reached the downstream end of the reactor. No variation in this behaviour was found for residence times in the range 30 to 400 milliseconds.

Axial homogeneity was examined by generating NO_2 chemiluminescence as above but using a movable photomultiplier tube to observe the intensity at various positions along the axis of the reactor. In the absence of methanol, the intensity of the NO_2 chemiluminescence was uniform along the full length of the reactor indicating good axial homogeneity. However, when methanol was added through the central inlet the intensity of the NO_2 chemiluminescence remained constant from the atom inlet to within about a centimeter of the central inlet. It then decreased steadily from the central inlet to the reactor outlet. This behaviour is illustrated in Fig. 2. The criterion for efficient mixing in the absence of an atom sink is (9) $t_D/t_R \simeq r^2\dot{V}/2DV << 1$ where r is a characteristic distance over which diffusion occurs in maintaining homogeneity, t_R is the residence time in the reactor, t_D is the time required for diffusion over a distance r, and the other symbols are as defined earlier. The value of r for a cylindrical reactor has been taken as the radius in other work (9) and this practice is followed here as well to provide a consistent means of comparison with the conditions used by others. For the least favourable conditions (largest $\dot{V}$) in our experiments $r^2\dot{V}/2DV = 0.016$ which is smaller than the value attained in much of the work in the literature. The data of Fig. 2 show that the homogeneity criterion clearly fails in the presence of a homogeneous atom sink although homogeneity was observed experimentally in the absence of the sink.

It is clear from the foregoing that kinetic data calculated from eq. [6] using average concentrations or from eq. [4] on the assumption that [A] is constant throughout the reactor and equal to the exit concentration will be incorrect. One may, however, test the applicability of eq. [4] using atom concentrations measured at various points along the reactor as outlined above. Equation [4] predicts that a plot of $(I_0/I - 1)\dot{V}$ against $[CH_3OH]$ should be linear, passing through the origin. Figure 3 indicates that such plots are linear and that, within the scatter of the experimental points, they pass through the origin. Equation [4] also predicts that the slopes of the lines of Fig. 3, divided by the rate constant for the reaction, should give the reactor volume up to the observation point. These experiments were made at substantially larger concentrations of $O(^3P)$ than those described later in this work with the result that the accessible values of $[CH_3OH]/[O(^3P)]$ were less than required for a stoichiometric coefficient of unity (22–25). The stoichiometric coefficient has been measured for $[CH_3OH]/[O(^3P)]$ ratios comparable to those used here (22) and the product of this stoichiometric coefficient and the absolute rate constant was used in obtaining the results presented in Table 1. The data of Table 1 indicate that in all cases the volume calculated from eq. [4] is much greater than the corresponding geometric volume. Although the volumes calculated from eq. [4] vary linearly with distance from the reactant inlet, as required for a cylindrical

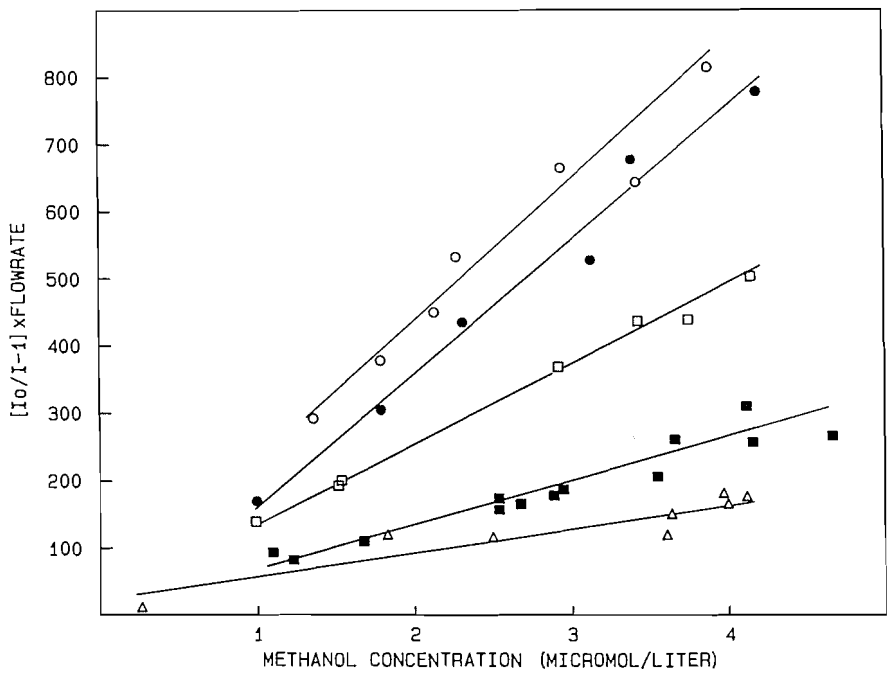

FIG. 3. Analysis of the data of Fig. 2 in terms of eq. [4] at different distances L from the reactant inlet. ○, L = 6.04 cm; ●, L = 4.84 cm; □, L = 2.64 cm; ■, L = 0.84 cm; △, L = 0.44 cm.

reactor, the intercept is not at the origin and the slope (3.12 cm^2) is significantly greater than the value of πr^2 (2.01 cm^2) appropriate to the cylindrical reactor used in these experiments.

A possible source of the difficulty with this application of eq. [4] could stem from the ability of a substrate such as CH_3OH to quench the emission from excited NO_2 (see, for example, ref. 26). This would make the effective sensitivity of the $O(^3P)$ measurement less in the presence of CH_3OH than in its absence and would make the ratio I_0/I larger than it would be in the absence of quenching. Moreover, this effect would become more severe as the concentration of CH_3OH increased. For Stern–Volmer quenching, it may be shown that, for a constant total flowrate through the reactor,

$$[7] \quad \left[\frac{I_0}{I} - 1\right]\frac{\Sigma \dot{V}}{[CH_3OH]} = a[CH_3OH] + b$$

where a depends on both the rate constant and the Stern–Volmer

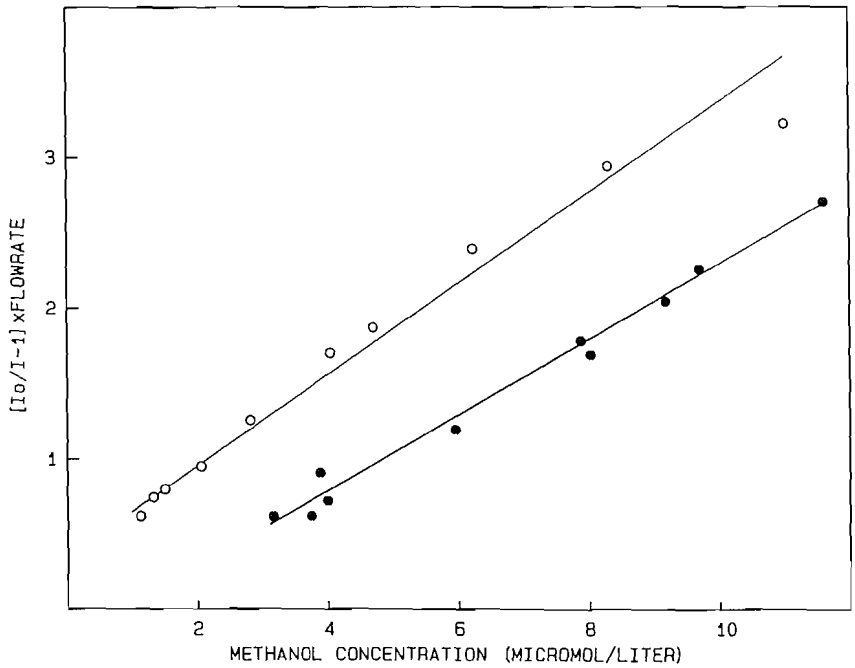

FIG. 4. Representative results of experiments designed to correct for quenching of the NO_2 chemiluminescence by methanol at 298 ± 1 K. ○, Pressure = 1.11 Torr ± 2%, $[O(^3P)] = 9.24 \times 10^{-8}$ mol L^{-1}; ●, pressure = 1.02 Torr ± 2%, $[O(^3P)] = 9.20 \times 10^{-10}$ mol L^{-1}.

TABLE 1. Evaluation of the use of eq. [4] with the reactor described in Fig. 1(*a*) and the reaction $O + CH_3OH \rightarrow OH + CH_2OH$[a]

Distance from reactor inlet (cm)	*kV* {eq. [4]} ($cm^3 L s^{-1} mol^{-1}$)	"Experimental" volume (cm^3)	Geometric volume (cm^3)
0.44	4.31×10^7	4.4	0.88
0.84	6.49×10^7	6.4	1.69
2.64	1.24×10^8	12.7	5.31
4.84	1.87×10^8	19.2	9.73
6.04	2.13×10^8	21.9	12.1

[a]Temperature = 299 K, pressure = 0.46 Torr ± 2%, total volumetric flowrate = 190 $cm^3 s^{-1}$ ± 10%. Experimental volumes were calculated from the values in the second column using the following expression for the rate constant of the reaction (23) combined with the stoichiometric coefficient, 1.9 ± 0.2 (22), measured with comparable values of $[CH_3OH]/[O(^3P)]$: $k = 9.79 \times 10^9 \exp(-2267/T)$ L mol^{-1} s^{-1}.

quenching constant while *b* depends only on the rate constant. This would produce upward curvature in plots such as those of Fig. 3 when a sufficiently wide range of concentrations of substrate is used. Such behaviour was, in fact, observed in experiments in which the CH_3OH concentration covered an order of magnitude or more and plots of the left hand side of eq. [7] against $[CH_3OH]$ were linear as expected. This leads to the conclusion that at least a significant part of the difficulty in applying the homogeneous reactor equations was a result of quenching of the NO_2 chemiluminescence by methanol.

Quenching does not affect the accuracy of rate constants measured under conditions of pseudo first order atom loss in a conventional flow tube reactor because the atom signals which are used in the calculation are all obtained with an effectively constant substrate concentration. This ensures that the sensitivity of the atom signal is reduced by the same fraction over the entire length of the reactor. The two-window versions of the reactor indicated in Fig. 1 take advantage of this by comparing the atom signals at the two windows in the presence of identical concentrations of CH_3OH, the excess reactant. The ratio I_0/I is then unaffected by quenching and it should now be possible to use eq. [4]. In these experiments, the signals from the photomultipliers viewing the two observation ports were made equal in the absence of methanol by adjusting the high voltage applied to them. These signals remained equal over a wide range of NO concentrations and varied linearly with [NO] verifying that loss of $O(^3P)$ in the reactor was either negligible or constant in the absence of CH_3OH. In these and subsequent experiments with CH_3OH the ratio $[CH_3OH]/[O(^3P)]$ was in the range 200 to 10^4 to avoid the stoichiometric complications of the earlier experiments. The effects of this ratio on the stoichiometric coefficient have been fully discussed elsewhere (22–25).

Experiments were first made in the two-window version of the reactor indicated in Fig. 1(*a*). This provides data under experimental conditions which differ from those above only in providing a means of compensating for quenching. While it is clear that the concentrations in the reactor are not homogeneous, it is equally certain that diffusional mixing is significant under the flow conditions used in these experiments and the time resolution at the two windows at which $O(^3P)$ concentrations were measured is likely to be poor. These experiments should indicate the effect of this poor resolution. The reaction of $O(^3P)$ with CH_3OH was again used as the test reaction. Representative results of these experiments are shown in Fig. 4 and these indicate that good linearity was obtained over a range of values of $[CH_3OH]$ which gave distinct curvature in the experiments using a single window at the end of the reactor. The effect of quenching seems, then, to have been eliminated. The slopes of the lines in Fig. 4 should give the volume of the portion of the reactor between the windows if good time resolution has been achieved. The experiments gave an average volume of 51 cm^3 ± 4% which is much larger than the geometric volume of 20 cm^3 between the windows. The effect of diffusional mixing, while not sufficient to produce homogeneity along the axis of the reactor, is clearly substantial and prevents adequate time

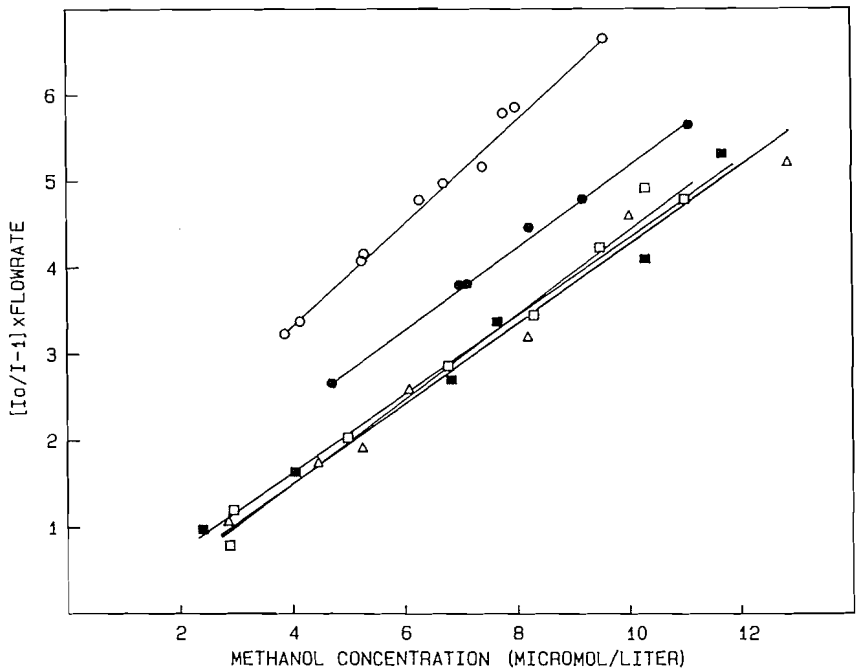

FIG. 5. "Calibration" of the effective reaction volume of the reactor of Fig. 1(*b*) using the reaction of $O(^3P)$ with methanol. Temperature = 299 ± 2 K. ○, pressure = 1.51 Torr ± 2%, residence time = 0.170 s ± 3%; ●, pressure = 1.34 Torr ± 2%, residence time = 0.185 s ± 3%; □, pressure = 1.47 Torr ± 2%, residence time = 0.175 s ± 3%; ■, pressure = 1.42 Torr ± 2%, residence time = 0.195 s ± 3%; △, pressure = 1.33 Torr ± 1%, residence time = 0.200 s ± 3%.

resolution for accurate kinetic measurements based on concentration measurements within the reactor.

Kinetic measurements

It is clear from the foregoing that conditions adequate for accurate application of eq. [4] require a two-window reactor to eliminate the effect of quenching and a design which provides good temporal resolution at the inlet and exit of the reactor. The reactor illustrated in Fig. 1(*b*) was constructed with these requirements in mind. Figure 5 and Table 2 show the data obtained on the test reaction of $O(^3P)$ with CH_3OH. As noted earlier, the ratio $[CH_3OH]/[O(^3P)]$ was kept in the range 200 to 10^4 to avoid the need for stoichiometric corrections. The pseudo first order rate constants calculated from eq.[4] may represent the sum of a homogeneous pseudo first order rate constant and a heterogeneous first order rate constant representing the efficiency of oxygen atom loss at the wall. This is represented as

$$k_{obs}\, V = kV[CH_3OH] + k_0$$

The values of k_0 represent a correction to be applied to the experimental pseudo first order rate constants and are included in Table 2. They were always small and were frequently zero within the accuracy of the measurements. As Fig. 5 indicates, linearity of these plots was good. The slopes of these lines, divided by the value of k, gives the effective volume of the reactor. The value of k used for this purpose was calculated from the Arrhenius expression reported in ref. 23. The average reactor volume obtained with these measurements was 107 cm^3 ± 11% which compares favourably with the geometric volume, including an estimate of the volume at the window locations, of 100 cm^3 ± 5%. No dependence of the calculated volume on the ratio $[CH_3OH]/[O(^3P)]$ was discernable.

In experiments such as these there is always the possibility of fortuitous agreement between experiment and theory as a result of selection of a specific value of a rate constant from among those available in the literature. To examine the validity of our use of the kinetic data of ref. 23 as a basis for the "calibration" of the reactor, two other reactions were studied. These were selected for (*a*) reliability of the reported rate constants and (*b*) coverage of a sufficient range of reaction rates to delineate the range of application of the 100 cm^3 reactor.

The reaction

$$[8] \quad O(^3P) + NO + M \rightarrow NO_2 + M$$

has been studied extensively (27) with specific evaluation of the rate constant for M = He in two cases with good agreement (28, 29). Since the above reaction is followed by the comparatively rapid reaction

$$[9] \quad O(^3P) + NO_2 \rightarrow NO + O_2$$

the experimental rate constants are related to the absolute rate constant for reaction [8] by

$$[10] \quad k_{obs} = 2\, k_8\, [NO]P/RT + k_0$$

The results calculated for a reactor volume of 107 cm^3 are indicated in Table 3 and Fig. 6 and give a rate constant of 2.48×10^{10} $L^2\ mol^{-2}\ s^{-1}$ ± 13% at 298 K. This agrees well with the values of refs. 28 (2.1×10^{10}) and 29 (2.24×10^{10}) and provides encouraging support of the calibration procedure for the reactor. Linearity of the plot of k_{obs} against $[NO]P/RT$ is good. Although there appears to be some gentle upward curvature at high NO concentrations, one cannot be certain of this within the scatter of the measurements. The intercepts are again small. Although it is tempting to interpret these intercepts as heterogeneous loss terms, they may also include an accumulation of other effects such as approximately constant absolute errors in pressure or in the concentration of NO. The origin of the negative values of these intercepts is therefore not clear and they are probably best regarded simply as empirical correction terms.

It seemed useful to examine the reliability of the homogeneous reactor method with a reaction having a more complex mechanism than the reaction of $O(^3P)$ with NO and in which secondary reactions of $O(^3P)$ are known to have an important effect on the kinetics of the reaction if a sufficient excess of the second reactant is not maintained. The reaction of $O(^3P)$ with acetone satisfies these criteria. The rate constant for this reaction has been measured as a function of temperature by two quite different methods (30, 31). The Arrhenius parameters obtained in the two studies are in excellent agreement and lead to numerical values of the rate constants at 298 K which agree within some 20%. The results of one set of experiments (30) cover conditions in which $O(^3P)$ was in large excess of the acetone and the rate constant was based on the measured decrease in acetone concentration with time. The other experiments (31) were made in the presence of a large (as much as 1000-fold) excess of acetone and the rate constant was based on the measured decrease in $O(^3P)$ concentration with time. Both studies indicated that when one or other of the reactants was not in sufficient excess substantial stoichiometric corrections were required to obtain a value for the absolute rate constant of the reaction. These potential mechanistic complications have been discussed elsewhere (30, 31) and the experiments reported here were made with $[(CH_3)_2CO]/[O(^3P)]$ ratios which had been found in other work (31) to be large enough to avoid stoichiometric corrections. The results obtained with the homo-

geneous reactor, based on a reaction volume of 107 cm^3, are presented in Table 4 and Fig. 7. Agreement with the results of refs. 30 (4.04×10^5 L mol^{-1} s^{-1}) and 31 (5.33×10^5 L mol^{-1} s^{-1}) is not as good as with the other reactions examined. The slopes of plots of the data according to the equation

$$[11] \quad k_{obs} = k[(CH_3)_2CO] + k_0$$

lead to a rate constant of 8.13×10^5 L mol^{-1} s^{-1} ± 6% which is nearly double the reference values cited above. Linearity of the plots is again good and, although there is some indication of upward curvature at large acetone concentrations, one cannot be certain of this within the scatter of the data. The values of k_0 are again negative and are of the same order of magnitude as they were in the experiments with NO. If the data are fitted to a quadratic, as suggested by eq. [7], rather than a straight line, the correlation coefficient is virtually the same as for the linear fit.

However, the value of the rate constant is now 5.3×10^5 L mol^{-1} s^{-1}. While this is much closer to the reference values, the distribution of the residual errors is not significantly different from the linear fit and the standard deviation in the rate constant is much worse, largely as a result of fitting the additional coefficient. The y-intercept is somewhat smaller but is still negative and of the same order of magnitude as before. This indicates the sensitivity of the results to the method selected for analyzing the data. Use of eq. [4] in this case leads to a rate constant which is evidently almost a factor of two too large. Use of eq. [7], on the assumption that correction for quenching is incomplete, leads to a rate constant which is in better agreement with those in the literature. However, a statistical analysis by itself would provide no indication whether the linear fit or the quadratic fit is a better description of the data. It is clear that the method can only provide reliable results if extraneous effects such as quenching are absent and there is no ambiguity concerning the method of analyzing the data.

Conclusions

The experiments described here indicate that the type of reactor used can provide accurate kinetic information. However, the reactors are not accurately described as homogeneous at the pressures at which they are most commonly used and should be described by some alternative term such as "fixed residence time" or "plug flow". The reactor designs used in conjunction with mass spectrometers (4–7) seem to have incorporated sampling into the mass spectrometer with good spatial resolution at the inlet and exit from the reactor. The use of eq. [4] was therefore appropriate. The reactor designs used in conjunction with esr spectrometers (8, 9) cannot be treated as easily. Particularly in the experiments of ref. (9), the volume to which the measured atom concentrations apply is uncertain. In fact, some difficulty was noted in that work with respect to the rate constants obtained for several of the reactions that were examined. It may be that at least some of this difficulty can be traced to a lack of homogeneity within the reactor. The nature of their experiments made it impossible to directly examine homogeneity. Finally, the reactor design used in the most recent application of such reactors (12–14) and which also used a chemiluminescent method to measure the atom concentration was quite similar to that of Fig. 1(*b*) although it was of substantially greater volume. While the atom concentrations were measured at the entrance and exit of the reactor, evidently with good spatial resolution, the other reactants were added through a separate inlet. This may have led to some interference due to quenching but the extent to which this was a problem is not clear. Successful use of such reactors for measurement of rate constants clearly requires careful attention to provision of good spatial resolution and avoidance of extraneous effects such as quenching.

Acknowledgments

Financial support for this work was provided by the Natural Sciences and Engineering Research Council of Canada. The author is indebted to Mr. Timothy D. Locke and Mr. Dennis Curran for their assistance in some of the initial experiments with "homogeneous" reactors.

Catalytic polarographic waves of cobalt(II) in the presence of sodium sulfide (SH^- form) in borax – ammonium chloride

DOLORES MARIN AND CARMEN TEIJEIRO

Departamento de Química Física, Química Analítica e Ingeniería Química, Universidad de Alcalá de Henares, Alcalá de Henares (Madrid), Spain

Received January 14, 1988

DOLORES MARIN and CARMEN TEIJEIRO. Can. J. Chem. **66**, 2335 (1988).

The presence of SH^- ions in a medium containing ammonia (borax–NH_4Cl) and cobalt(II) gives rise to a catalytic cobalt(II) prewave and a catalytic hydrogen wave, both of which manifest more positive potentials than the cobalt(II) reduction wave. The effects of time, sulfide and cobalt concentrations, mercury column height, and gelatine and neutral salts addition are discussed. In addition, the characteristics of the current–time and electrocapillary curves are shown. The results obtained suggest a mechanism whereby a cobalt(II) prewave is produced by a cobalt(II) complex with SH^- in the 1:2 relationship. Hydrogen catalytic evolution is attributed to the reduction of a protonated complex.

DOLORES MARIN et CARMEN TEIJEIRO. Can. J. Chem. **66**, 2335 (1988).

La présence d'ions SH dans un milieu contenant de l'ammoniaque (borax–NH_4Cl) et du cobalt(II) donne lieu à une pre-vague catalytique du cobalt et à une vague due à l'hydrogène catalytique qui toutes deux ont des potentiels plus positifs que le vague de réduction du cobalt(II). On discute des effets du temps, des concentrations en sulfide et en cobalt, de la hauteur de la colonne de mercure, et de la gélatine et des sels neutres. De plus, on montre les courbes caractéristiques du courant en fonction du temps et les courbes d'électrocapillarité. Les résultats obtenus suggèrent un mécanisme par lequel un complexe de cobalt(II) avec SH dans la proportion 1:2, produit une pre-vague de cobalt(II). On attribue le dégagement catalytique de l'hydrogène la réduction du complexe protoné.

Introduction

In the presence of certain complexing substances, cobalt and nickel ions give rise to catalytic currents (1–3). Complexing substances have specific active groups and generally, the —SH group is considered the most characteristic for catalytic processes in the presence of cobalt. One of the principal reasons limiting our understanding of the phenomenon is the fact that the structure of these substances, which give rise to catalysis, is usually organic and extremely complicated (4, 5). Calusaru and Kuta (6) state: "The most favorable case would be represented by the simplest molecule, the one with the smallest number of functional groups. It can be noted that even as the catalytic process is considered to be appreciably tied to the sulfide groups in the molecule, they alone are not enough for the activity to be expressed, and it can be manifested with the presence of other groups like amino or carboxilic groups".

This paper studies catalytic waves of cobalt(II) and a simple inorganic ligand, free SH^- ion.

Experimental technique

Polarograms and i–t curves were obtained with an Amel 473 Polarographic Analyzer using a polarographic cell equipped with three electrodes, one of which, a saturated calomel electrode (SCE), was used as the reference electrode. At a mercury reservoir height of 45 cm, the dropping mercury electrode (DME) used in these experiments had the following characteristics: $m = 2.08$ mg s^{-1} and $t = 3.86$ s at -700 mV (vs. SCE) in 0.06 M borax – 0.70 M NH_4Cl. The pH values were measured with a Model 62 Radiometer pH-meter.

The hexamminocobalt trichloride employed was Fluka purum grade and all other chemicals were Merck reagent grade. The mercury used in the DME was first purified chemically and subsequently distilled twice.

The stock sulfide solution was freshly prepared every week from $Na_2S.xH_2O$ ($x = 7$–9) in doubly-distilled water with enough ammonium hydroxide for pH > 12 and de-aerated before each set of experiments. The $Na_2S.xH_2O$ concentration was tested with iodometry. The sulfide solution is lifted to its SH^- form at alkaline pH.

Since an ammonium medium is necessary for prewave appearance, a borax–NH_4Cl (0.06–0.70 M) buffer was used (pH = 8.4).

As stated in the Introduction, this paper aims to study the cobalt(II)–SH^- system; however, cobalt(II) sulfides are very insoluble. On the other hand, catalytic waves need an ammoniacal medium to appear but cobalt(II) aquo-ammoniacal complexes are very unstable. As a result, only very diluted sulfide concentrations can be used with cobalt(II) in ammoniacal medium.

Cobalt(III) is reduced in two steps. The first step is cobalt(III) reduction to cobalt(II) at -0.20 V and the other is cobalt(II) reduction to cobalt(0) at -1.15 V. Cobalt(II) is reduced in a step that, at equal cobalt(III) and cobalt (II) concentrations, it is identical to the second cobalt(III) step (Fig. 1(*I*)).

The first cobalt(III) wave is unaltered and the other behaves the same as the cobalt(II) wave in presence of SH^- (Fig. 1(*II*)).

From the above we conclude that cobalt(III) can be substituted for cobalt(II) to study the cobalt(II)–SH^- system, since cobalt(III) electrogenerates cobalt(II) at -0.20 V. Since aquo-ammoniacal cobalt(III) complexes are very stable, the sulfide concentrations that can be used with cobalt(III) are much higher that the ones that can be used with cobalt(II).

Given the foregoing and even though we use cobalt(III) in the solutions, we speak of cobalt(II) reduction wave — second cobalt(III) step — and cobalt(II) catalytic wave.

The intensity of the catalytic waves diminishes over time, thus every polarogram was made at the same time: 2 min from mixing the solutions.

Results

Cobalt(III) in the presence of sulfide in a borax–NH_4Cl medium presents two waves at more positive potentials than those of cobalt(II) reduction (Fig. 1). The first is a catalytic prewave of cobalt(II) and the second a hydrogen catalytic wave, as we will demonstrate in this paper.

As can be seen in Fig. 2, catalytic wave intensity diminishes with time. The decrease is more noticeable in the first catalytic wave than in the second. For both waves, the decreases deepen as the cobalt(III) concentration increases.

The effect of the sulfide concentration on the catalytic waves has been studied between 3×10^{-6} and 1.5×10^{-4} M at a constant cobalt(III) concentration, 5×10^{-4} M (Fig. 3). The

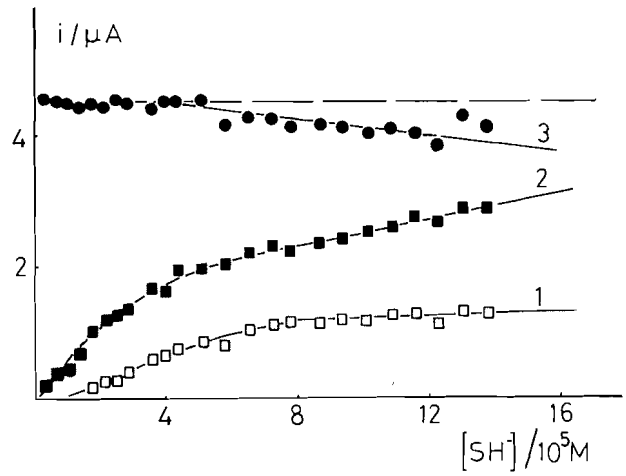

FIG. 3. SH^- concentration effect: 0.06 *M* borax – 0.70 *M* NH_4Cl; 5×10^{-4} *M* Co(III). (*1*) First catalytic wave; (*2*) second catalytic wave; (*3*) Co(II) reduction wave.

first catalytic wave was studied with a sulfide concentration higher than 2.5×10^{-5} *M* since the wave is not observable at lower concentrations. The intensity of this wave increases with sulfide concentration tending toward a limiting value which is approximately 30% of the value of the cobalt(II) reduction current. The second catalytic wave, which also presents a maximum, increases continually with sulfide concentration. At sulfide concentrations greater than 5×10^{-5} *M* the solution is darkened by cobalt(II) sulfides and as a result, cobalt(II) reduction current decreases. In spite of the turbidity, it was necessary to increase the sulfide concentration in order to find the limit of these waves.

The half-wave potential for the first catalytic wave is constant with the sulfide concentration. However, the peak potential of the second wave changes toward more negative potentials reaching a limit of −1100 mV.

At constant sulfide concentration, the intensity of the two catalytic waves varies linearly with cobalt(III) concentration (Fig. 4).

In order to establish the character of the catalytic waves, the *i–t* curves, the effect of the mercury column height, the electrocapillary curves, and the effect of neutral salt additions have been studied.

The dependence of the second catalytic wave height on

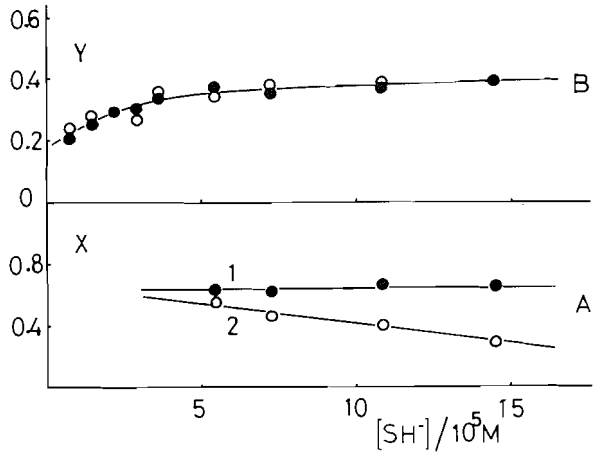

FIG. 5. Exponent variation of the equations (*A*) $i = f(H^x)$, (*B*) $i = f(t^y)$ on SH^- concentration: 5×10^{-4} *M* Co(III) in 0.06 *M* borax – 0.70 *M* NH_4Cl. (*1*) First catalytic wave; (*2*) second catalytic wave.

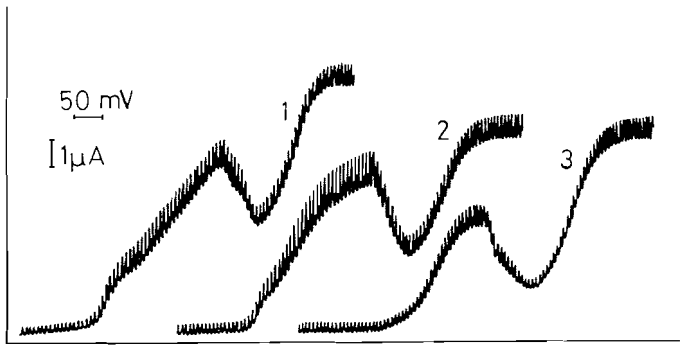

FIG. 6. Polarograms of 5×10^{-4} *M* Co(III) and 5.4×10^{-5} *M* SH^- in 0.06 *M* borax – 0.70 *M* NH_4Cl containing different gelatine concentrations: (*1*) 0; (*2*) 0.005; (*3*) 0.010%. Start potential −700 mV.

mercury column height, *H*, changes with the sulfide concentration. In Fig. 5*A* the exponent *x*, from the $i = f(H^x)$ equation, is plotted vs. the sulfide concentration at a constant cobalt(III) concentration. The *x* exponent remains constant for the first catalytic wave at a value of 0.65, and for the second it ranges from 0.5 to 0.2.

Logarithmic analysis of the *i*–*t* curves obtained at the limiting current potential of the first catalytic wave and the peak potential of the second wave gives the exponent for the $i = f(t^y)$ equation. This exponent increases with sulfide concentration and tends to a limiting value of 0.4 in both waves (Fig. 5*B*).

The electrocapillary curves obtained in the absence and in the presence of sulfide and cobalt(III) do not show adsorption phenomena.

The effect of neutral salts on the catalytic waves has been studied by adding several amounts of different chlorides to a 5×10^{-4} *M* cobalt(III) and 3.62×10^{-5} *M* sodium sulfide in 0.06 *M* borax – 0.70 *M* NH_4Cl solution. An increase in the ionic strength due to the addition of a salt is accompanied by a decrease in the catalytic currents. The decreasing effect is $(C_4H_9)_4N^+ > K^+ \simeq Na^+ \simeq Li^+$, that is, the effect grows with cation size and, consequently, when the absolute value of the ψ potential is smaller. The half-wave potential of the first catalytic wave and the peak potential of the second do not change with neutral salt addition.

Figure 6 shows the effect of gelatine on the catalytic waves. The first catalytic wave decreases with gelatine addition until it disappears. Gelatine on the second catalytic wave only rounds the maximum.

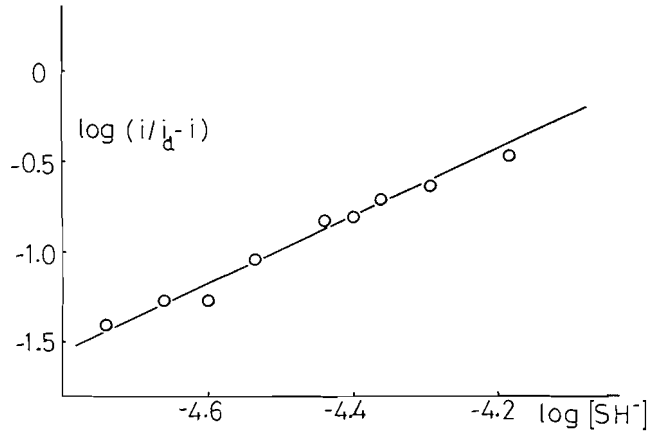

FIG. 7. Log $i/(i_d - i)$ vs. log $[SH^-]$ plot for the first catalytic wave, where *i* and i_d are respectively the average limiting currents of the prewave and the Co(II) reduction wave; 5×10^{-4} *M* Co(III) in 0.06 *M* borax – 0.70 *M* NH_4Cl.

Discussion

The catalytic character of the waves under study is clear since their intensities are higher than the intensity expected from the low sulfide concentration in the solution.

It was thought that both waves were cobalt(II) prewaves. However, the second wave presents a maximum which does not disappear with gelatine addition and reaches a higher intensity than do cobalt(II) reduction wave intensity. Electrolysis at the peak potential of this wave results in the appearance of bubbles on the DME. So, the first wave is a cobalt(II) prewave and the second a catalytic hydrogen wave.

The cobalt catalytic prewave is produced by a cobalt(II) complex with SH^-, discharged before the reduction cobalt(II) wave. The composition of the complex is not known, but it is obvious, as was remarked above, that ammonia is necessary to form the complex which produce the prewave. Therefore, we can express the catalytic complex as $[Co(II)(SH^-)_z(NH_3)_w]^{2-z}$, although it may include some other ligand. The variation in the prewave intensity (tending to a limit value) with sulfide concentration is characteristic of catalytic processes. In the electrodic process the ligand is regenerated and so the prewave current is larger than the diffusion current expected from the cobalt-sulfide complex. The SH^-:cobalt(II) relationship in the complex can be calculated using an approximate method for catalytic current (7). If the electrodic process takes place on the surface of the electrode, the catalytic current and the ligand concentration are related by the following equation $\log i/(i_d - i) = \text{constant} + z \log [SH^-]$ where *i* is the average cobalt(II) limiting catalytic current of the prewave, i_d the average cobalt(II) reduction limiting current, $[SH^-]$ the sulfide concentration, and *z* the complex stoichiometric coefficient. Figure 7 shows that this equation is valid, and the resulting slope is close to two (1.83). The catalytic complex is then formed between SH^- and cobalt(II) in the relationship of 2:1.

The catalytic hydrogen wave appears at a potential of −1100 mV, which means that hydrogen overvoltage has diminished substantially. Under some conditions an ill-defined new wave is observed together with the hydrogen wave. When this wave is not observed, it may be that it has been overlapped by the hydrogen wave. This kind of overlapping is found frequently in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/07/12
For personal use only.

the literature (1, 7). The catalytic hydrogen wave may be attributed to the reduction of a protonated complex of cobalt(II or 0) and sulfide. We think that the second prewave is due to a complex of cobalt(II) and sulfide which catalyses hydrogen evolution before electroreduction. Taking into account values of x and y, which range from 0.5 to 0.2 and 0.2 to 0.4, respectively, the character of this wave changes with sulfide concentration from a diffusion control to a mixed diffusion–kinetic control.

There are no adsorption phenomena in any of these waves since, (*a*) the electrocapillary curves did not change with sulfide addition, (*b*) the half-wave potential and the peak potential did not change with ionic strength, and (*c*) gelatine did not change the intensity of the hydrogen catalytic wave; the prewave intensity decreased with gelatine and, therefore, we attribute a surface character to this wave.

Conversion of some azaheterocyclic-acetic esters and -acetonitriles into fused heterocycles

DAVID M. MCKINNON, PERRY SPEVACK, AND GRAHAM TIPPLES
Chemistry Department, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received August 6, 1987[1]

DAVID M. MCKINNON, PERRY SPEVACK, and GRAHAM TIPPLES. Can. J. Chem. **66**, 2339 (1988).

Various heterocyclic acetic esters and nitriles of the pyridine, thiazole, and imidazole series react with 3-methylthio-4-phenyl-1,2-dithiolium perchlorate to form fused pyridinethiones or dithiolylidene esters. These esters or nitriles also react with trichloromethanesulfenyl chloride to form fused isothiazoles.

DAVID M. MCKINNON, PERRY SPEVACK et GRAHAM TIPPLES. Can. J. Chem. **66**, 2339 (1988).

Divers esters et nitriles acétiques hétérocycliques de la pyridine, du thiazole et de l'imidazole réagissent avec le perchlorate du méthylthio-3 phényl-4 dithiolium-1,2, pour former des pyridinethiones condensés ou des esters dithiolylidène. Ces esters ou ces nitriles réagissent également avec le chlorure de trichlorométhanesulphényle pour former des isothiazoles condensés.

[Traduit par la revue]

Introduction

The possession by azaheterocyclic acetic acid derivatives of both a reactive methylene group and a reactive nitrogen atom allows many fruitful syntheses of fused heterocyclic systems with bridgehead nitrogen atoms, by cyclocondensation with numerous substrates. Two useful additions to this repertoire have been investigated: the reaction with 3-methylthio-4-phenyl-1,2-dithiolium perchlorate (**1**) and with trichloromethanesulfenyl chloride (**2**).

In an earlier paper (1), the reaction of methyl pyridine-2-acetate (**3***a*) with 1,2-dithiolium salts was reported. While most reacted to form 1,2-dithiolylidenepyridine-2-acetate derivatives, the salt **1** reacted by an alternative mechanism to form a quinolizinethione derivative. This suggested that related azaheterocyclic acetic esters might react analogously to form a number of nitrogen fused pyridinethione analogues (Scheme 1). Likewise, it appeared likely that these compounds could react with trichloromethanesulfenyl chloride, which, providing a suitable carbon–sulfur unit, would form other sulfur-containing fused five-membered rings. In its reaction with certain amino-pyridine and -pyrimidines such chemistry is observed (2, 3), and it is suggested that the reaction of some thiazoleacetamides with the related chlorothioformyl chloride forms thiazolothiazoles (4).

Results and discussion

The starting esters or nitriles were either available commercially, or synthesized by literature methods or by modifications. The benzimidazole **4***a* was made by reaction of methyl cyanoacetate with 2-methylaminoaniline, and the benzothiazole and benzimidazole (**5***a*, **4***b* respectively) were made by reaction of ethyl malonate with 2-mercaptoaniline or 2-methylaminoaniline respectively. The benzothiazole **5***a* had been reported (5) to decompose on distillation but no difficulties were encountered on distillation at 1.5 Torr (1 Torr = 133.3 Pa). In these reactions small amounts of di(benzothiazol-2-yl)methane **6***a* and di(1-methylbenzimidazol-2-yl)methane **6***b* respectively were also obtained.

Reactions of these esters or nitriles with the dithiolium salt **1** were carried out in acetonitrile/dioxane mixtures. In the case of the benzimidazoles **4***a*, *b*, better results were obtained in the presence of triethylamine.

The reaction of pyridine-2-acetonitrile (**3***b*) with **1** gave two products. The major product had properties consistent with the cyanoquinolizinethione **7***a* formed by initial reaction of **3***b* at

SCHEME 1

the unsubstituted 5-position of the dithiole ring, followed by ring opening and recyclization. This compound exhibits a strong absorption at 1129 cm^{-1}, tentatively assigned to the thiocarbonyl group. A related quinolizinethione absorbs in this region (1110 cm^{-1}) (6) and 3-phenylquinolizine-4-thione, prepared earlier (1), absorbs at 1084 cm^{-1}. The compound **7***a* exhibited a λ_{max} at 423 nm, while that of 3-phenylquinolizine-4-thione was at 440 nm. The other product is tentatively assigned the structure **8**, or a tautomer. It exhibits an ion in the mass spectrum at $M^+ = 296$ and a broad band in the nmr at $\delta = 8.6$ ppm, consistent with this structure. A plausible scheme for its formation would involve attack of the nitrile at the 3-position of the dithiolium salt, forming 2-(1,2-dithiolylidene)-2-pyridylacetonitrile by elimination of methanethiol, which further reduces the 1,2-dithiole ring to form **8**.

The reaction of **1** with the thiazoleacetic ester **5***b* gave two products. One of these was the desired fused system **9***b*. The other product was a material that had a consistent mp, nmr, and mass spectrum even after many recrystallizations, but on the basis of its nmr spectrum, especially from the appearance of two singlets at δ 2.93 and 3.80 ppm, appears to be a mixture of two compounds. The nmr spectrum indicates that these are two geometrical isomers **10***b* and **11***b* of a 1,2-dithiolylidenethiazoleacetic ester. In the isomer **10***b*, which has a phenyl group close to the ester function, the latter experiences shielding effects by the aromatic ring and absorbs at relatively high field. In the isomer **11***b*, no such shielding is possible and the methyl group absorbs in a normal range. The relative intensities of the peaks indicate that the predominant isomer is that with the more shielded methyl group. When the ester **5***c* was treated with the dithiolium salt, related compounds were obtained, the pyrido[2,1-*b*]thiazole ester **9***c*, and what appear to be the geometrical isomers **10***c*, **11***c* of a 1,2-dithiolylidenethiazoleacetic ester, with once more the shielded isomer **10***c* formed in greater amount. However, these compounds were accompanied by a dark violet material that also appears to be a mixture of two components. Mass spectral and analytical data were consistent with a formula of $C_{26}H_{21}NS_5O_2$, thus this material is formed by a reaction of the ester **5***c* with two molecules of dithiole. The structures **12**, **13** are tentatively assigned to these on the following basis. In the spectra of **10***c*, **11***c* above, two nmr signals at $\delta = 6.45$ and 6.75 ppm are assigned to their respective thiazole protons, as the compounds **10***b*, **11***b* lack signals in this range. In the violet material above, no signals in this range are evident; thus it appears that the hitherto free position of the thiazole ring is involved in a further reaction. Also the mass spectrum showed a large ion at $M^+ = 290$, which is consistent with a cleavage at the bond adjacent to the 2-carbon of thiazole ring in **12** or **13**. Significantly, no violet material could be isolated from the reaction of the ester **5***b*, which lacks a free thiazole position.

The reaction of the ester **5***a* with **1** gave the pyridobenzothiazole **9***a* as a major product. No products corresponding to **10***a* or **11***a* could be isolated. Likewise the benzimidazoles **4***a*,*b* gave the pyridobenzimidazoles **9***d*, *e* respectively as major products. No material corresponding to dithiolylidenebenzimidazole esters was isolated, yet curiously the reaction of the 2-quinolineacetic ester **3***c* under standard conditions gave only a dithiolylidenequinolineacetic ester. As the nmr of this indicates that it is a single compound, and the methylene protons of the ethyl group are evident as a quartet centered at δ = 3.40 ppm, it thus appears that this is the isomer **14**, i.e., that in

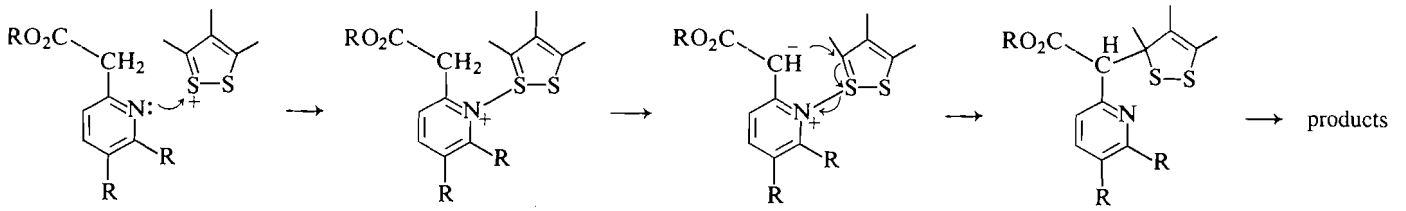

SCHEME 2

which the ester function is shielded by the phenyl group. When the ester **3***c* reacted with **1** in the presence of triethylamine, the ester **14** was still formed as the major product but it was accompanied by the benzoquinolizinethione **7***b*.

Surprisingly the benzisothiazole and benzisoxazoleacetic esters **15***a*,*b* failed to react.

While the above reactions show that there are two modes of reaction of the azaheterocyclic esters and the dithiolium salt, and product formation may be rationalized in terms of which position of the dithiolium salt is preferentially attacked, the reason for the substantial differences in the products from the different substrates is not clear. The difference in products between methyl pyridine-2-acetate and ethyl quinoline-2-acetate is especially striking.

Steric factors do not provide a suitable explanation, as there appears to be little difference in steric accessibility of the reactive groups in **3***a* or **3***c*.

Also, the results do not correlate in terms of attack of anions derived from **3***a*, **3***c* on the 3- or 5-position of **1**, using hard–soft acid–base theory, using data from pK_a's of 2-picoline and 2-methylquinoline (7), and calculated electron densities of the 2-mercapto-1,2-dithiolium ion (8) taken as models. However, if the reactions involve prior attack of the heterocyclic nitrogen at a ring sulfur (Scheme 2), with subsequent reaction as shown, there is a correlation of results with basicities of 2-picoline and 2-methylquinoline (9). Relative nucleophilicities of pyridine and quinoline nitrogen atoms are more extreme (10) and it is reasonable that thiophilicities will show large differences. Thus the former would initially attack S-1 of the salt, the latter, S-2. The results of the reaction of **3***c* in the presence of triethylamine may be interpreted as attack of a more strongly nucleophilic resonant anion from **3***c* attacking at the ring sulfur (S-1) bearing the greater positive charge.

Reactions of the esters or nitriles with trichloromethanesulfenyl chloride were carried out in acetonitrile.

With the ester **3***a*, using an equivalent quantity of halide **2**, a complex mixture was obtained, from which were isolated in low yield what appear to be the pyrido[1,2-*b*]isothiazoles **16***a*,*b*,*c*, and the ester **4***b*. Chlorination of pyridine side chains by **2** is reported (11). For the formation of **16***a*,*b*,*c*, it is likely that a dichloro compound **16***d* is the initial product, which by reaction with water or more ester forms **6***a* or *c* respectively. Further halogenation on sulfur, and hydrolysis, would form **16***b*. While it is possible that these compounds have the isomeric fused pyridothiazole system, **17**, we favour isothiazole formulation on the basis of ^{13}C studies of a benzothiazole ester product below. Also in β-aminocrotonic esters, whose tautomeric form has structural relationship to the pyridine esters, reaction with trichloromethanesulfenyl chloride produces isothiazoles (12, 13). With two equivalents of sulfenyl halide the compound **16***c* was obtained in a higher yield, along with another compound to which the dithietane structure **18** is tentatively assigned, arising by dimerization of a thioketene **19**. This was also obtained from the reaction of **3***a* with thiophosgene.

17

Although the compound **17***c* has potential for exhibiting hypervalency of the sulfur atom, and thereby becoming symmetrical like structure **20**, for example, similarly to related compounds (14, 15), the nmr spectrum of **17***c* exhibited two methyl peaks, consistent with an unsymmetrical structure. This lack of symmetry may be due to steric interference, preventing planarity and hence utilization of sulfur *d* orbitals, or it may be an electronic effect, as the electron-withdrawing ester functions reduce electron density on the rather weak S—N bonds.

Reaction of pyridine-2-acetonitrile **3***b* with trichloromethanesulfenyl chloride gave similar products (**18***b*, **16***e*). While the nitrile group in **16***d* should exhibit much less steric interference, its colour was not consistent with a hypervalent sulfur formulation. It was too insoluble for nmr studies. The reaction of the benzothiazole-2-acetate **5***a* with **2** gave as the main product a pale yellow compound, whose properties were consistent with the ketone **21***a*. This is probably formed by a 1:1 reaction of **5***a* with **2** to form a dichloro compound, which during work-up forms the ketone by hydrolysis. This structure, rather than the isomeric thiazolothiazole **22**, is favoured on the basis of its ^{13}C nmr spectrum, which exhibited two peaks at

δ = 161.6 and 165.7 ppm, consistent with two rather similarly situated carbonyl groups. Data for thiazolinone structures such as **22** indicate that these absorb around δ = 172 ppm (16). The only other major component in this reaction was a reddish solid that failed to give a sharp mp. Mass spectra and nmr data suggest that it is a mixture of the two geometrical isomers of a 2:1 reaction product **23**.

The thiazole ester **5***c* reacted with **2** similarly. The only product isolated was the thiazoloisothiazolone **21***b*. However, ethyl 1-methylbenzimidazole-2-acetate **4***b* failed to give new heterocyclic rings. Instead the dichloro ester **4***c* was obtained as the sole isolable product, arising by halogenation of the side chain.

Ethyl quinoline-2-acetate (**3***c*) reacted to give the fused isothiazoles **16***f* and **16***g* in rather poor yield.

Experimental

The ^{1}H nmr spectra were obtained in deuteriochloroform solution using tetramethylsilane as an internal standard, on Varian model EM360 or AM300 spectrometers. The ^{13}C spectra were obtained on a Bruker WH90 spectrometer and mass spectra were obtained on a VG 7070E spectrometer. Thick-layer chromatography was performed on Merck-type 60PF_{254} silica gel. Infrared (ir) spectra were performed as mulls in liquid paraffin using a Perkin–Elmer model 881 spectrometer.

Starting esters, trichloromethanesulfenyl chloride, and thiophosgene were purified by distillation prior to use. Where necessary, solutions were dried over anhydrous magnesium sulfate.

Reactions of heterocyclic acetic esters or acetonitriles with 3-methylthio-4-phenyl-1,2-dithiolium perchlorate

General procedure

Equimolar quantities of the reagents in the approximately tenfold weight of a 50:50 acetonitrile:dioxane mixture were heated under reflux for 2 h. In the case of imidazole reagents an equivalent quantity of triethylamine was also added. Products were isolated by dilution with water, neutralization with sodium bicarbonate, and chloroform extraction. Evaporation gave oils that were separated by chromatography using varying amounts of chloroform in benzene. The fastest running bands, dark red and orange, were decomposition products of the dithiolium salt and were not examined. Products of type **7** or **9** were usually evident as yellow bands, and those of type **10**, **14** were as reddish bands.

Reaction of 2-pyridine acetonitrile

Chromatography indicated a complex mixture, but with yellow and red bands formed in the greatest amounts. Work-up of the yellow band gave **7**. It recrystallized from nitromethane as yellow needles, mp 170–172°C (41%). The ir spectrum: 2230 (C≡N), 1129 (C=S) cm^{-1}. The uv spectrum in ethyl acetate, λ_{max}: 433, 318, 287, 263. The ^{1}H nmr spectrum of **7***a*, δ: 7.34–7.56 (6H, complex m, the aromatic and one pyridine ring protons), 7.81 (1H, s, H2), 7.89 (1H, dd, tentatively H7), 8.23 (1H, d, H8), 10.81 (1H, d, H5) ppm. The ^{13}C nmr spectrum, δ: 175.85 (C=S), 114.52 (C≡N) ppm. The mass spectrum, M^+ 262; M calcd.: 262. Ions at 261 ($M^+ - 1$), 218 (M^+ – (C=S)), and 149 (M^+ – CNC—CH=C—Ph) were also evident. *Anal.* calcd. for $C_{16}H_{10}N_2S$: C 73.28, H 3.82, N 10.68, S 12.21; found: C 73.31, H 3.62, N 10.80, S 12.08.

Work-up of the red band gave **8** as a solid that crystallized from nitromethane as red needles, mp 204°C (19%). The nmr spectrum of **8** indicated only a series of bands, δ 7.15–8.48 ppm, and a broad band at δ 8.6 ppm. The latter disappeared on shaking with D_2O. The mass spectrum, M^+ 296; M calcd.: 296. *Anal.* calcd. for $C_{16}H_{12}NS_2$: C 64.86, H 4.05, N 9.46, S 21.62; found: C 64.77, H 4.11, N 9.63, S 21.53.

Reaction of methyl 4,5-dimethylthiazole-2-acetate

Chromatography of the reaction mixture gave two main bands isolated as yellow and red semicrystalline solids.

The yellow material crystallized from ethanol giving **9***b* as yellow needles, mp 126–128°C (48%). The nmr spectrum of **9***b*, δ: 2.40, 2.97 (two, 3H, s, the thiazole methyls), 3.93 (4H, s, the O-methyl), 7.20–7.67 (5H, bands, the aromatic protons), 7.71 (1H, s, the heterocyclic proton) ppm. The mass spectrum, M^+ 329; M calcd.: 329. *Anal.* calcd. for $C_{17}H_{15}NS_2O_2$: C 62.01, H 4.56, N 4.26, S 19.45; found: C 61.77, H 4.28, N 4.04, S 19.23.

The red material crystallized from acetonitrile giving **10***b*, **11***b* as small red prisms, mp 152–154°C (18%). The nmr spectrum indicated that this was an approximately 55:45 mixture of the two components, **10***b*, **11***b* respectively, tentatively assigned; for isomer **10***b*, δ: 2.07, 2.43 (two 3H, s, the thiazole methyls), 2.93 (3H, s, the shielded O-methyl), 7.43 (5H, s, the aromatic protons), 7.70 (1H, s, the dithiole proton) ppm. For isomer **11***b*, δ: 1.90, 2.37 (two 3H, s, the thiazole methyls), 3.80 (3H, s, the O-methyl), 7.08 (5H, br s, the aromatic protons), 7.75 (1H, s, the dithiole proton) ppm. The mass spectrum, M^+ 361; M calcd.: 361. *Anal.* calcd. for $C_{17}H_{15}NS_3O_2$: C 56.51, H 4.16, N 3.88, S 27.59; found: C 56.77, H 4.03, N 4.01, S 27.32.

Reaction of methyl 4-methylthiazole-2-acetate

Chromatography of the reaction mixture gave three main reaction products, visible as yellow, violet, and red bands in order of elution.

The yellow material crystallized from ethanol giving **9***c* as yellow needles, mp 148°C (30%). The ir spectrum, 1690 (C=O), 1140 (C=S) cm^{-1}. The nmr spectrum of **9***c*, δ: 3.17 (3H, s, the thiazole methyl), 3.93 (3H, s, the O-methyl), 6.93 (1H, s, the thiazole proton), 7.28–7.65 (5H, br, the aromatic protons), 7.87 (1H, s, the pyridyl proton) ppm. The mass spectrum, M^+ 315; M calcd.: 315. *Anal.* calcd. for $C_{16}H_{13}NO_2S_2$: C 60.95, H 4.13, N 4.44, S 20.32; found: C 61.11, H 4.21, N 4.50, S 20.04.

The violet material crystallized from nitromethane giving **12** and **13** as fine dark red needles with a green reflex, mp 175°C (17%). The nmr spectrum indicated that these were present in approximately 70:30 amounts, respectively. These are tentatively assigned; for **12**, δ: 2.65, 2.70 (two 3H, s, the thiazole and S-methyls), 2.86 (3H, s, the O-methyl), 7.78 (1H, s, the dithiole proton), 8.50 (1H, s, the side-chain proton) ppm. For **13**, δ: 2.16, 2.64 (two 3H, s, the thiazole and S-methyl protons), 3.69 (3H, s, the O-methyl), 7.67 (1H, s, the dithiole proton), 8.14 (1H, s, the side-chain proton) ppm. All other protons in both isomers gave complex bands between δ 6.90 and 7.55 ppm. The mass spectrum, M^+ 539; M calcd.: 539. *Anal.* calcd. for $C_{26}H_{21}NO_2S_5$: C 43.25, H 3.90, N 2.60, S 29.68; found: C 43.55, H 4.01, N 2.63, S 29.52.

The red material crystallized from acetonitrile giving **10***c*, **11***c* as reddish brown prisms, mp 130°C (32%). The nmr spectrum indicated that it was a mixture of the two components in approximately 60:40 amounts, respectively. These are tentatively assigned; for **10***c*, δ: 2.57 (3H, s, the thiazole methyl), 2.91 (3H, s, the O-methyl), 6.75 (1H, s, the thiazole proton), 7.70 (1H, s, the dithiole proton) ppm. For isomer **11***c*, δ: 2.01 (3H, s, the thiazole methyl), 3.79 (3H, s, the

O-methyl), 6.45 (1H, s, the thiazole proton), 7.03 (1H, s, the dithiole proton) ppm. For both isomers other protons were evident as bands, δ 6.95–7.45 ppm. The mass spectrum, M^+ 347; M calcd.: 347. *Anal.* calcd. for $C_{10}H_{13}NO_2S_3$: C 55.33, H 3.75, N 4.03, S 27.67; found: C 55.07, H 3.81, N 4.17, S 27.92.

Reaction of ethyl benzothiazole-2-acetate

Chromatography gave two main products, evident as yellow and red bands in order of elution. The yellow material crystallized from a toluene:ethanol 1:1 mixture giving **9***a* as golden yellow needles, mp 181–182°C (68%). The ir spectrum: 1686 (C=O) and 1131 (C=S) cm^{-1}. The nmr spectrum of **9***a*, δ: 1.20, 4.19 (3H, t, and 2H, q, resp., the ethyl protons), 7.32–7.75 (9H, bands, the aromatic protons), 7.91 (1H, s, the pyridyl proton) ppm. The mass spectrum, M^+ 365; M calcd.: 365. *Anal.* calcd. for $C_{20}H_{15}NO_2S_2$: C 65.75, H 4.11, N 3.84, S 17.53; found: C 66.01, H 4.32, N 3.72, S 17.44.

The red band could not be purified satisfactorily, but its nmr spectrum displayed two ethyl groups at δ 0.90 and 3.32 ppm (3H, t, and 2H, q, resp.), and δ 1.25 and 4.22 ppm (3H, t, and 2H, q, resp.), consistent with the isomers **10***a*, **11***a*.

Reaction of 1-methylbenzimidazole-2-acetonitrile

Evaporation of the solvent and dilution with water gave an oily solid, which was collected and crystallized from nitromethane giving **9***d* as yellow needles, mp 240°C (76%). The ir spectrum: 2208 (C≡N), 1117 (C=S) cm^{-1}. This was too insoluble in chloroform for a satisfactory nmr spectrum. The mass spectrum, M^+ 315; M calcd.: 315. *Anal.* calcd. for $C_{19}H_{13}N_3S$: C 72.38, H 4.13, N 13.30, S 10.16; found: C 72.28, H 4.07, N 13.22, S 9.95.

Reaction of ethyl 1-methylbenzimidazole-2-acetate

Chromatography of the reaction mixture indicated only one yellow band as a main product. Isolation gave a yellow solid that crystallized from nitromethane giving **9***e* as lemon yellow needles, mp 183°C (62%). The nmr spectrum of **9***e*, δ: 1.42, 4.40 (3H, t, and 2H, q, resp., the ethyl protons), 3.89 (3H, s, the N-methyl), 7.95 (1H, s, the pyridyl proton) ppm. *Anal.* calcd. for $C_{21}H_{18}NO_2S$: C 69.61, H 4.97, N 7.73, S 8.34; found: C 69.54, H 5.07, N 7.72, S 8.96.

Reaction of ethyl quinoline-2-acetate

Chromatography of the crude reaction product gave a strongly absorbed red band as a major reaction product. Work-up gave **14** as a red oil (82%). The nmr spectrum of **14**, δ: 1.06 and 3.40 (3H, t, and 2H, q, resp., the ethyl protons), 7.36–8.55 (12H, bands, the aromatic and heterocyclic protons) ppm. The mass spectrum, M^+ 391; M calcd.: 391. *Anal.* calcd. for $C_{22}H_{17}NS_2O_2$: C 67.52, H 4.35, N 3.58, S 16.98; found: C 67.55, H 4.41, N 3.68, S 17.10.

When the reaction was carried out using one equivalent of triethylamine as a catalyst, the ester was accompanied by another deep red material, which was separated by repeated chromatography. A red oil was obtained, which crystallized under ethanol. It was recrystallized from acetonitrile as dark red prisms, mp 171–172°C (13%). The nmr spectrum of **7***b*, δ: 1.41, 4.42 (3H, t, and 2H, q, the ethyl protons), 7.35–7.91 (9H, bands, the aromatic protons), 7.90 and 8.91 (2H, d, the pyridine ring protons) ppm. The mass spectrum, M^+ 359; M calcd.: 359. *Anal.* calcd. for $C_{22}H_{17}NSO_2$: C 73.54, H 4.74, N 3.90, S 8.91; found: C 73.01, H 4.83, N 3.77, S 8.82.

Attempted reactions of methyl 1,2-benzisoxazole-2-acetate and methyl 1,2-benzisothiazole-2-acetate

No apparent reaction products could be isolated under a variety of reaction conditions.

Reactions of heterocyclic esters or nitriles with trichloromethanesulfenyl chloride

General procedure

Equimolar quantities of reagents (≈10 mmol); were heated under reflux in acetonitrile (20 mL) for 2 h. Solutions were worked up by dilution with water, neutralization with sodium bicarbonate, and chloroform extraction. The dried chloroform extracts were treated with charcoal and evaporated. In some cases the products crystallized on evaporation. In others chromatography was necessary.

Reactions with methyl pyridine-2-acetate

A complex mixture was obtained. Examination by chromatography of the major bands gave, in order of elution, a yellow solid, a colorless oil, a yellow oil, a pale yellow solid, and an orange solid.

The yellow solid crystallized from ethanol giving **16***b* as amber needles, mp 126–127°C (8%). The nmr spectrum of **16***b*, δ: 3.87 (3H, s, the methyl protons), 8.22–8.90 (4H, m, the pyridine ring protons) ppm. The mass spectrum M^+ 225; M calcd.: 225. *Anal.* calcd. for $C_9H_7NSO_4$: C 48.00, H 3.11, N 6.22, S 14.22; found: C 48.26, H 3.09, N 6.21, S 14.07.

The colorless oil **3***d* failed to crystallize. It was purified by rechromatography (3%). The nmr spectrum of **3***d*, δ: 3.91 (3H, s, the methyl protons), 7.34–8.80 (4H, bands, the pyridine protons) ppm. The mass spectrum showed M^+ ions at 219, 221, 223; M calcd.: 219, 221, 223. This material was not analyzed.

The yellow oil crystallized under methanol and was recrystallized from methanol, giving **16***a* as yellow needles, mp 81–82°C (6%). The nmr spectrum of **16***a*, δ: 3.86 (3H, s, the methyl protons), 6.51 (1H, t), 7.10 (1H, t), 7.89 (1H, d), 8.08 (1H, d, the pyridine ring protons) ppm. The mass spectrum, M^+ 209; M calcd.: 209. *Anal.* calcd. for $C_9H_7NSO_3$: C 51.67, H 3.35, N 6.70, S 15.31; found: C 51.82, H 3.64, N 6.29, S 15.07.

The pale yellow solid recrystallized from nitromethane, giving **18***a* as pale yellow needles, mp 214–218°C (5%). The nmr spectrum, of **18***a*, δ: 3.96 (two 3H, s, the ester methyls), 8.61–7.02 (8H, bands, the pyridine protons) ppm. The mass spectrum, M^+ 386; M calcd.: 386. *Anal.* calcd. for $C_{18}H_{14}N_2S_2O_4$: C 55.96, H 3.63, N 7.25, S 16.58; found: C 56.13, H 3.88, N 7.03, S 16.49.

The orange material recrystallized from toluene, giving **16***c* as orange prisms, mp 217–218°C (8%). The nmr spectrum of **16***c*, δ: 3.76, 3.89 (two 3H, s, the ester methyls), 5.91–8.82 (8H, bands, the pyridine protons) ppm. The mass spectrum, M^+ 342; M calcd.: 342. *Anal.* calcd. for $C_{17}H_{14}N_2SO_4$: C 59.63, H 4.13, N 8.18, S 9.36; found: C 59.71, H 4.22, N 8.16, S 9.51.

When this reaction was performed with a 2:1 ratio of ester to sulfenyl halide, work-up gave a dark red solid. Recrystallization from toluene after a charcoal treatment gave the ester **16***c* as orange prisms (18%).

Reactions of pyridine-2-acetonitrile

Reagents here were heated for 10 min. Work-up gave a brown solid that was chromatographed using chloroform as an eluent. A yellow and an orange band, in order of elution, were evident.

The yellow band gave **18***b* as a yellow solid that crystallized from dioxane as a yellow powder, mp 350°C, darkening above 330°C (31%). The ir spectrum: 2214 (C≡N) cm^{-1}. It was too insoluble for a satisfactory nmr spectrum. The mass spectrum, M^+ 320; M calcd.: 320. *Anal.* calcd. for $C_{16}H_8N_4S_2$: C 60.00, H 2.50, N 17.50, S 20.00; found: C 60.33, H 2.65, N 17.21, S 19.85.

The orange band gave an orange powder that crystallized from dioxane, giving **16***e* as an orange microcrystalline powder, mp 288–294°C (42%). It was too insoluble for a satisfactory nmr spectrum. The mass spectrum, M^+ 276; M calcd.: 276. *Anal.* calcd. for $C_{15}H_8N_4S$: C 65.22, H 2.90, N 20.29, S 11.59; found: C 65.26, H 2.97, N 20.14, S 11.73.

Reaction of ethyl benzothiazole-2-acetate

Work-up gave a red oil, which was separated by chromatography into a pale yellow band and a more strongly adsorbed red band.

The pale yellow band gave a yellow solid that crystallized from micromethane, giving **21***a* as pale yellow needles, mp 139–140°C (41%). The ^1H nmr spectrum of **21***a*, δ: 1.36, 4.34 (3H, t, and 2H, q, resp., the ethyl protons), 7.20–8.32 (4H, m, the aromatic protons) ppm. The ^{13}C spectrum, δ: 161.32 and 165.52 ppm, the two carbonyl carbons. The mass spectrum, M^+ 279; M calcd.: 279. *Anal.* calcd. for $C_{12}H_9NS_2O_3$: C 51.61, H 3.23, N 5.02, S 22.94; found: C 51.90, H 3.15, N 5.11, S 23.08.

The red band on work-up gave an orange powder that recrystallized from nitromethane, giving **23** as red prisms, mp 168–172°C (9%). The nmr spectrum of **23**, δ: 0.95 and 4.01 (3H, t, and 2H, q, resp.,

the ethyl group), 7.01–7.78 (8H, bands, the aromatic protons) ppm. The mass spectrum, M^+ 482; M calcd.: 482. *Anal.* calcd. for $C_{23}H_{18}N_2S_3O_4$: C 57.26, H 3.73, N 5.81, S 19.92; found: C 57.51, H 3.82, N 5.66, S 20.20.

When the reaction was allowed to reflux for 24 h the ester **23** was the major product (22%).

Reaction of methyl 4-methylthiazole-2-acetate

The crude dark red oil gave a faster running yellow band and a slower red band on chromatography. The yellow band on elution and evaporation gave a yellow oil that crystallized under ethanol. It was crystallized from acetonitrile, giving **22***b* as yellow needles, mp 214°C (19%). The nmr spectrum of **22***b*, δ: 2.53 (3H, s, the thiazole methyl), 4.07 (3H, s, the ester methyl), 6.90 (1H, s, the thiazole proton) ppm. The mass spectrum, M^+ 229; M calcd.: 229. *Anal.* calcd. for $C_8H_7NS_2O_3$: C 41.92, H 3.05, N 6.11, S 27.95; found: C 42.06, H 3.11, N 5.95, S 27.64.

Further chromatography of the red band indicated that it was very complex and it was not further examined.

Reaction of ethyl 1-methylbenzimidazole-2-acetate

A work-up gave a thick yellow oil, which gave only one major band on chromatography. It was further purified by rechromatography, giving **4***c* as a pale yellow oil (31%). The nmr spectrum of **4***c*, δ: 1.13 (3H, t, the ester methyl), 3.72 (3H, s, the N-methyl), 4.27 (2H, q, the ester methylene), 6.95–7.75 (4H, bands, the aromatic protons) ppm. The mass spectrum, M^+ ions at 286, 288, 290; M calcd.: 286, 288, 290. *Anal.* calcd. for $C_{12}H_{12}Cl_2N_2O_2$: C 50.17, H 4.18, Cl 24.74, N 9.76; found: C 50.33, H 4.21, Cl 24.43, N 9.73.

Reaction of ethyl quinoline-2-acetate

Reaction gave a dark red oil, which separated on chromatography into a yellow and a more strongly adsorbed red band. These were isolated and purified by rechromatography.

The yellow band gave a dark yellow crystalline solid that crystallized from acetonitrile, giving **16***f* as dark yellow needles, mp 138–140°C (3%). The nmr spectrum of **16***f*, δ: 1.45, 4.41 (3H, t, and 2H, q, resp., the ethyl group), 7.07–8.13 (6H, bands, the heterocyclic and aromatic protons) ppm. The mass spectrum, M^+ 273; M calcd.: 273. *Anal.* calcd. for $C_{14}H_{11}NO_3S$: C 61.40, H 4.03, N 5.13, S 11.72; found: C 61.66, H 4.07, N 4.98, S 11.64.

The red band gave a red solid that recrystallized from nitromethane, giving **16***g* as fine red prisms, mp 285–290°C (dec.) (2%). It was too insoluble for a satisfactory nmr spectrum. The mass spectrum, M^+ 470; M calcd.: 470. *Anal.* calcd. for $C_{27}H_{22}N_2O_4S$: C 68.94, H 4.68, N 5.96, S 6.81; found: C 68.67, H 4.43, N 6.02, S. 6.76.

Reaction of methyl pyridine-2-acetate with thiophosgene

The ester **3***a* (3.2 g, 0.02 mol) and thiophosgene (2.3 g, 0.02 mol) in acetonitrile (20 mL) were refluxed for 1 h. The mixture was cooled, diluted with saturated sodium bicarbonate solution, and extracted with chloroform. Evaporation gave a dark yellow oil that gave two main bands on chromatography. Separation gave the dithietane **18***a* (11%) and pyridoisothiazole **16***c* (12%) identical to those obtained above.

Preparation of ethyl benzothiazole-2-acetate (5a)

2-Aminobenzenethiol (12.5 g, 0.1 mol) and ethyl malonate (16 g, 0.1 mol) in toluene (100 mL) were refluxed for 24 h. The evaporated solution was cooled for 1 day, crystalline material removed, and the liquid distilled *in vacuo*. The fraction, bp 145°C at 1.5 Torr (1 Torr = 133.3 Pa), was collected, giving **5***a* as a pale yellow oil (55%). The crystalline precipitate was recrystallized from ethanol, giving **6***b* as fine pale yellow plates, mp 82°C (5%). The nmr spectrum of **6***b*, δ: 5.03 (2H, s, the methylene protons), 7.45–8.20 (8H, bands, the aromatic protons) ppm. The mass spectrum, M^+ 282; M calcd.: 282. *Anal.* calcd. for $C_{15}H_{10}N_2S_2$: C 63.83, H 3.55, N 9.93, S 22.70; found: C 63.77, H 3.46, N 10.09, S 22.84.

Preparation of 1-methylbenzimidazole-2-acetonitrile (4a)

2-Methylaminoaniline (2.44 g, 0.02 mol) and methyl cyanoacetate (3 g, 0.03 mol) were refluxed gently for 3 h and cooled for 16 h. The crystalline product was collected and recrystallized from ethanol as colorless needles, mp 132–134°C (lit. (17) mp 132–134°C) (62%).

Preparation of ethyl 1-methylimidazole-2-acetate (4b)

2-Methylaminoaniline (2.44 g, 0.02 mol) and ethyl malonate (1.6 g, 0.01 mol) were heated gently under reflux for 24 h. The boiling point, initially 150°C, had decreased to 100°C. The mixture was cooled, allowed to stand for 1 day, and filtered to remove the crystalline precipitate of **6***a*. The liquid was distilled *in vacuo* and the fraction, bp 170–180°C at 1.5 Torr, was collected. This crystallized on standing and was recrystallized from ethanol as colorless needles, mp 66–67°C (lit. (18) mp 66–67°C) (63%).

The solid **6***a* recrystallized from nitromethane as colorless needles, mp 196°C (11%). The nmr spectrum of **6***a*, δ: 3.90 (6H, s, the N-methyl protons), 4.71 (2H, s, the methylene protons), 7.11–7.73 (8H, bands, the aromatic protons) ppm. The mass spectrum, M^+ 276; M calcd.: 276. *Anal.* calcd. for $C_{17}H_{16}N_4$: C 73.91, H 5.80, N 20.29; found: C 73.88, H 5.67, N 20.02.

Orientation specific Diels–Alder addition of isoprene to an activated 4,4-dimethylcyclohexenone. An improved route to himachalenes

HSING-JANG LIU, ERIC N. C. BROWNE,[1] AND SEW YEU CHEW
Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received February 29, 1988

HSING-JANG LIU, ERIC N. C. BROWNE, and SEW YEU CHEW. Can. J. Chem. **66**, 2345 (1988).

Diels–Alder addition of isoprene to enone-ester **3** proceeds exclusively to the *para*-addition product **6**. The specificity of this route constitutes a significant improvement in the previously reported total synthesis of himachalenes via **6**. The mechanistic significance of the observed specificity of addition is discussed.

HSING-JANG LIU, ERIC N. C. BROWNE et SEW YEU CHEW. Can. J. Chem. **66**, 2345 (1988).

L'addition de Diels–Alder de l'isoprène sur l'ester énonique **3** conduit exclusivement au produit d'addition en *para* **6**. La spécificité de cette voie d'accès constitue une amélioration significative des synthèses totales connues des himachalènes par l'intermédiaire du composé **6**. On discute de l'importance du mécanisme de cette addition spécifique observée.

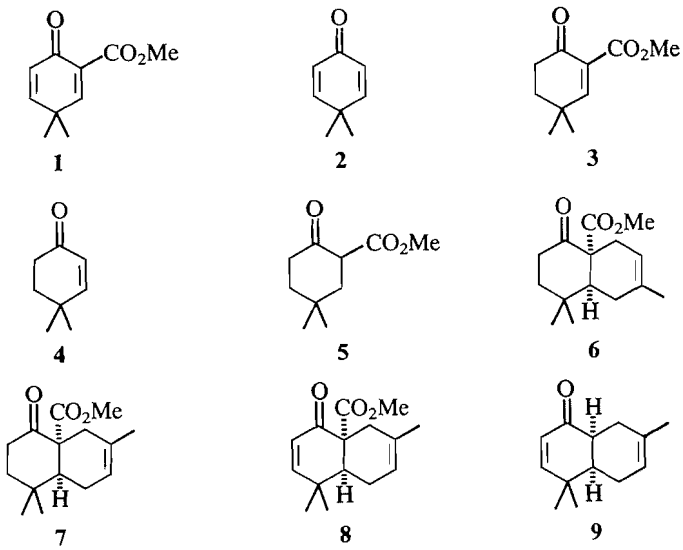
Introduction

We previously reported on the Diels–Alder reactions of dienone-ester **1** and dienone **2** with various dienes (1–3). In particular, we described, and provided a mechanistic rationale for, the unusual regioselectivity observed in additions of isoprene (2–5) to these dienophiles. We used an isoprene adduct of **1** in the total synthesis of himachalenes (4). We now report on additions of isoprene to the enone-ester **3** that contrast with the regiochemical outcome of additions to **1** and **2** but very clearly complement the mechanistic rationale we presented for regiochemical effects in this dienophile system. The new results constitute a formal improvement of the total synthesis of himachalenes.

Results and discussion

The enone-ester **3** was prepared in three steps (78% overall yield) from 4,4-dimethyl-2-cyclohexen-1-one **4** (6). Catalytic hydrogenation of **4** (H_2, Pd/C, EtOAc) gave 4,4-dimethylcyclohexanone, which was carbomethoxylated with dimethyl carbonate (NaH, 1,2-dimethoxyethane (DME), reflux). Dehydrogenation of the product, saturated keto-ester **5**, in one pot, by phenylselenenylation (PhSeCl, pyridine, CH_2Cl_2) and oxidative elimination (aqueous H_2O_2) gave the target dienophile **3**.

The Diels–Alder reaction of **3** with isoprene was examined using three Lewis acid catalysts and a variety of conditions, which are summarized in Table 1. Exclusive generation of the "*para*"-addition product **6**[2] was observed in all cases regardless of catalyst or temperature. This is in striking contrast to the high selectivity of **2** for the "*anti-para*"-addition product **9** (2, 3) and the catalyst dependent selectivity of **1** in which the formation of the *anti-para*-addition product **8** cannot be completely excluded (3, 4). The effect of catalyst selection on the relative order of reaction rates for **3** ($FeCl_3 > SnCl_4 > BF_3 \cdot Et_2O$) and of reaction yields ($SnCl_4$ best, $BF_3 \cdot Et_2O$ poorest) corresponds to



that observed for dienophile **1**, although in general the rates are slower and yields poorer for **3**. With increased proportion of catalyst the yields are seen to improve for $BF_3 \cdot Et_2O$ and $SnCl_4$ catalysis, and reaction rates increased for all three cases.

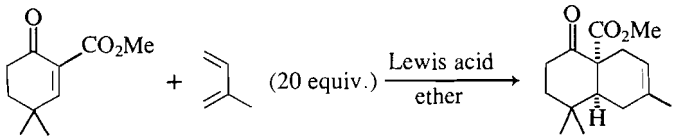
The regiochemical result of these additions implies that the preference for transition states **A**, having secondary orbital interaction with the ketone carbonyl observed in additions to **1** (3), is not present in additions to **3**. The difference in behavior of **1** and **3** under these reaction conditions would arise from a relative reduction in secondary orbital effect stabilization of the **A**-type transition states due to chemical reduction of the C5—C6 double bond and loss of its contribution to the cross-conjugated π-orbital system. Potential steric interaction between the quasi-axial proton of the C5 methylene of **3** and the diene would also contribute to the observed effect. Likely, these two effects combine to completely eliminate any addition by **A**-type transition states. In the **B**-type transition states, the usual directing effects are unmodified and the *para*-addition product via **6B** is formed exclusively. The retained specificity of orientation in the product, even under low temperature conditions (Entries 6–8) where the product of the most stable transition state would be more favoured, confirms this conclusion.

The observed high selectivity for adducts arising from secondary orbital overlap with the ethyl ester group in the case of the related dienophile **10** (8) follows similarly from combined

[1]Present address: Ayerst Laboratories, 1025 Laurentian Blvd., St. Laurent, P.Q., Canada H4R 1J6.

[2]The structure of adduct **6** derived from Diels–Alder addition to **1** has been conclusively demonstrated (4, 5). The adduct derived from **3** is identical in its ^{1}Hmr, ir, and ^{13}Cmr spectra. The regioisomer **7** has been prepared from the enone-ester **8** and shows spectral characteristics (7) distinctly different from those of **6**; ^{1}Hmr for **7**, δ:5.40 (br s, 1H, =CH—), 3.72 (s, 3H, $-OCH_3$), 1.65 (br s, 3H, $=\overset{|}{C}CH_3$), 1.00 (s, 3H, $-CH_3$), and 0.90 (s, 3H, $-CH_3$).

TABLE 1. Lewis acid catalyzed Diels–Alder addition of isoprene to enone-ester **3**



3 **6**

Entry	Lewis acid	(equiv.)	Temperature (°C)	Time (h)	Yield (%)
1	$BF_3 \cdot Et_2O$	(0.5)	20	140	< 5[a,b]
2	$BF_3 \cdot Et_2O$	(1.0)	20	29	33
3	$SnCl_4$	(0.5)	20	44	58
4	$SnCl_4$	(1.0)	20	18	87
5	$FeCl_3$	(0.5)	20	2	52
6	$FeCl_3$	(0.5)	0	18	67[a,c]
7	$FeCl_3$	(1.0)	0	9	59
8	$FeCl_3$	(0.5)	−20	48	49[a,d]

[a]Based on the consumed starting material. The starting material was recovered as indicated:

[c]In 14%.
[d]In 49%.

changes in steric and secondary orbital effects and likewise gives exclusively the *para*-addition product with isoprene. The enone-aldehydes **11** (9) and **12** (10) can be predicted to show a similar reversal of regioselectivity. Indeed **12** has already been shown (11) to give Diels–Alder addition products specifically via secondary orbital overlap of the ketone carbonyl. In contrast, in the addition to unactivated enones **4** and **13** the only possible secondary orbital effect stabilized transition states overlap the ketone carbonyl and consequently the product

mixtures contain *para* and *anti-para* adducts of isoprene in equal or nearly equal amounts (12, 13).[3]

The preparation of **6**, the key intermediate in the synthesis of himachalenes in 68% yield (four step) from **4** is a significant improvement over the previous approach (4), which accomplished the conversion of **4** to **6** in 37% yield (five steps). This improved approach, formally giving the key intermediate **16** in 58% yield (five steps) from **4**, remains superior in both its regiospecificity and in overall yield to a recently reported direct approach to this intermediate (12), which gives a 38% yield of the correct regioisomer (as a *cis*/*trans* mixture) contaminated with an equal amount of the difficultly separable incorrect regioisomer.

Conclusion

Further to our previous illustration of the role of catalyst selection in the regiochemistry of Diels–Alder additions, the effect of a remote structural feature such as the cross-conjugated double bond in this dienophile system has been shown to play a significant role in the regiochemical and stereochemical outcome of the Diels–Alder reaction. That such an effect may occur through slight modifications of steric and electronic environments of the substrate serves to draw increased attention to the importance of secondary orbital effects in cycloadditions.

Experimental

General

Melting points were determined on a Kofler hot stage apparatus and are uncorrected. Elemental analyses were performed by the microanalytical laboratory of this department. The ir spectra were recorded on a Nicolet 7199 FT-IR spectrophotometer and were obtained in neat film. The ^{1}Hmr and ^{13}Cmr spectra were recorded on a Bruker AM 300 spectrometer and were obtained on solutions in deuteriochloroform using tetramethylsilane as internal reference. Mass spectra (ms) were recorded using an A.E.I. model MS 50 mass spectrometer. Unless stated otherwise, anhydrous magnesium sulfate was used for drying organic solutions.

4,4-Dimethylcyclohexanone

A solution of 13.026 g (0.105 mol) of enone **4** (6) in ethyl acetate

[3]The specificity of the dehydro derivatives of **4** and **13**, **2** and **14** respectively, for *anti-para* addition and generation of equal mixtures of *para* and *anti-para* adducts of ketals **15** (R = Me or Et or R,R = $-CH_2CH_2-$), has already been demonstrated (2, 14, 15).

(200 mL) was hydrogenated using palladium on activated carbon (260 mg) as catalyst at 15 psi (1 psi = 6.9 kPa) for 3 h. Filtration (with a layer of Celite) and concentration of the reaction mixture gave the product (12.772 g, 96% yield) as a white solid; mp 44–45°C (lit. (16) mp 38–40°C); ir: 1706 (C = O) cm^{-1}; ^{1}Hmr δ:1.10 (s, 6H, 2 × CH_3), 1.67 (t, 4H, J = 7 Hz, 2 × -CH_2-), and 2.35 (t, 4H, J = 7 Hz, 2 × -CH_2CO-). *Exact Mass* calcd. for $C_8H_{14}O$: 126.1045; found (ms): 126.1046.

4,4-Dimethyl-2-carbomethoxycyclohexanone (5)

Sodium hydride (80% dispersion in oil, 3.108 g, 0.103 mol, washed with petroleum ether and DME (freshly distilled over sodium/benzophenone)) was suspended in DME (40 mL) under an atmosphere of argon, and dimethyl carbonate (21.998 g, 0.244 mol) was added. The suspension was heated at reflux while stirring with a mechanical stirrer. A solution of 5.967 g (0.047 mol) of 4,4-dimethylcyclohexanone in DME (15 mL) was added dropwise. Heating was continued for 3 h and then the mixture was cooled to 0°C. An aqueous 10% acetic acid solution (100 mL) was added dropwise with stirring and the mixture was extracted with ether (3 × 50 mL). The extracts were washed with water, saturated aqueous sodium bicarbonate, water and saturated aqueous sodium chloride, dried, filtered, and concentrated. Flash chromatography of the residue on silica gal, eluting with 3–14% ether in petroleum ether, gave keto ester **5** (7.778 g, 85% yield) as a light yellow liquid. This compound existed mostly (~94% by ^{1}Hmr integration) in the corresponding enol form. The following ir and ^{1}Hmr data were attributed to the enol form: ir: 1659 (ester) and 1620 (enol) cm^{-1}; ^{1}Hmr δ:0.95 (s, 6H, -CH_3), 1.44 (t, 2H, J = 6 Hz, —CH_2—CH_2—C(OH)=), 2.03 (t, 2H, J = 1 Hz, —CH_2—C=), 2.29 (tt, 2H, J = 6, J' = 1 Hz, —CH_2—C(OH)=), 3.75 (s, 3H, -OCH_3), and 12.15 (s, 1H, =C—OH). The following ir and ^{1}Hmr data were attributed to the keto form: ir: 1750 (ester) and 1720 (ketone) cm^{-1}; ^{1}Hmr δ:1.07 (s, 3H —CH_3), 1.19 (s, 3H, —CH_3), and 3.75 (s, 3H, —OCH_3). *Exact Mass* calcd. for $C_{10}H_{16}O_3$: 184.1100; found (ms): 184.1101.

4,4-Dimethyl-2-carbomethoxy-2-cyclohexen-1-one (3)

At 0°C, pyridine (2.82 g, 0.036 mol) was added to a solution of phenylselenenyl chloride (6.89 g, 0.036 mol) in dichloromethane (200 mL) under an argon atmosphere. After stirring for 10 min, keto-ester **5** (5.529 g, 0.03 mol) in 30 mL of dichloromethane was added. After 4 h, the reaction mixture was washed with 1 M aqueous hydrochloric acid (2 × 100 mL). The organic solution was placed in a flask and cooled to 0°C. A 30% aqueous hydrogen peroxide solution (6 mL) was added. After stirring for 10 min, an additional 6 mL of 30% aqueous hydrogen peroxide was added. After 1.5 h, water was added and the layers separated. The organic layer was washed with saturated aqueous sodium bicarbonate, dried, filtered, and concentrated. The residue was distilled in a Kugelrohr apparatus at reduced pressure (aspirator) and enone-ester **3** (5.246 g, 96% yield) was obtained as a yellow oil; ir: 1747 (ester), 1719 (conjugated ester and ketone), and 1698 (conjugated ketone) cm^{-1}; ^{1}Hmr δ:1.24 (s, 6H, 2 × -CH_3), 1.90 (m, 2H, -CH_2-), 2.54 (m, 2H, -CH_2—C-), 3.80 (s, 3H, -OCH_3), and 7.36 (t, 1H, J = 1 Hz, =CH—). *Exact Mass* calcd. for $C_{10}H_{14}O_3$: 182.0943; found (ms) 182.0943.

8a-Carbomethoxy-4,4,6-trimethyl-3,4,4a,5,8,8a-hexahydro-1(2H)-naphthalenone (6)

At 0°C, anhydrous tin(IV) chloride (0.18 mL, 1.5 mmol) was added to a solution of enone-ester **3** (0.273 g, 1.5 mmol) and isoprene (3 mL, 30 mmol) in ether (11 mL; freshly distilled over sodium and benzophenone). The reaction mixture was stirred at room temperature under an atmosphere of argon for 18 h. Saturated aqueous sodium bicarbonate (6 mL) was added and the resulting mixture was extracted with ether. The extracts were washed with water, dried, filtered, and concentrated. Flash chromatography of the residue on silica gel, eluting with 10–20% ether in Skelly B, gave keto-ester **6** (0.329 g, 87% yield) as a colourless oil; ir: 1744, 1730 (ester), and 1709 (ketone) cm^{-1}; ^{1}Hmr δ:5.38 (m, 1H, -CH=), 3.72 (s, 3H, -OCH_3), 1.64 (d, 3H, =C—CH_3), 1.11 (s,3H, -CH_3), and 1.01 (s, 3H, -CH_3); ^{13}Cmr δ: 209.3 (C1), 173.7 (-COO-), 132.0 (C6), 117.6 (C7), 59.6 (C8a), 52.5 (-OCH_3), 44.8 (C4a), 38.5, 35.6, 33.4 (C2, C3, C4), 30.7 (-CH_3), 29.6, 28.6 (C5, C8), 23.8, and 23.5 (2 × -CH_3). *Exact Mass* calcd. for $C_{15}H_{22}O_3$: 250.1569; found (ms): 250.1571. *Anal.* calcd. for $C_{15}H_{22}O_3$: C 71.97, H 8.86; found: C 72.09, H 8.77.

Using the same procedure, Diels–Alder reactions of enone-ester **3** and isoprene were carried out with different Lewis acid catalysts. The results are summarized in Table 1.

Electron microprobe studies of chemical reactions in ancient painted murals: The Beni Hasan Tombs, Egypt[1]

K. M. WILSON-YANG AND GEORGE BURNS
Lash Miller Chemical Laboratories, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received August 31, 1987[2]

K. M. WILSON-YANG and GEORGE BURNS. Can. J. Chem. **66**, 2348 (1988).

The Egyptian tombs at Beni Hasan (ca. 2100 B.C.) have developed an ubiquitous, progressive grey surface layer which disfigures their painted surfaces. Recently, we published a series of X-ray photoelectron spectra of samples from these tombs and proposed a mechanism for surface layer formation. It involves CO_2-saturated condensed water which gradually erodes the mural substrate. However, no direct evidence for this erosion was available. To test the proposed mechanism, light microscopy was used to study cross-sections of the murals. Areas of repeated solution and precipitation, in the form of dendritic structures were discovered in the subsurface regions, especially in yellow pigmented samples. In red pigmented samples, this degradation is not seen to the same extent. A series of electron microprobe analyses of the surface and subsurface regions of small painted fragments also were performed. Porous, heterogenous subsurface regions with pockets of phosphates have been found, predominantly in the yellow samples. These findings support the mechanism proposed earlier. Pore size measurements, estimated by photographic measurements, indicate that subsurface alteration took place before the bulk of the surface deposit layer had formed and that the existing surface deposit protects, as well as obscures, the painted walls. The surface layer development described here has some aspects common to other natural systems, i.e. the interaction of CO_2 in water with carbonate-bearing rocks and deposits. However, at Beni Hasan there is effectively no source of groundwater and the painted surfaces are sheltered from direct exposure to the environment. Therefore the Beni Hasan deterioration has unique mechanistic features.

K. M. WILSON-YANG et GEORGE BURNS. Can. J. Chem. **66**, 2348 (1988).

Les tombes égyptiennes à Beni Hasan (environ 2100 B.C.) ont développées une couche superficielle grise qui défigure progressivement les surfaces peintes. Récemment, on a publié une série de spectres photo-électroniques des rayons-X effectués sur des échantillons provenant de ces tombes et on a proposé un mécanisme pour expliquer la formation de ces couches superficielles. Il implique de l'eau saturée par du CO_2 qui provoque une érosion graduelle des murales. Toutefois, on ne possédait aucune donnée directe concernant cette érosion. Afin de vérifier le mécanisme proposé, on a utilisé la microscopie lumineuse pour étudier des sections droites des murales. Sous la surface, on a découvert des surfaces ayant subi des solutions et précipitations répétées, sous la forme de structures dendritiques et particulièrement dans les échantillons pigmentés avec du jaune. Dans les régions pigmentées en rouge, on n'a pas observé un tel degré de dégradation. On a aussi effectué une série d'analyses par micro-sondes électroniques à la surface et dans les régions sous la surface de petits fragments peints. Dans les échantillons pigmentés en jaune, on a observé sous la surface des régions poreuses et hétérogènes qui forment des poches de phosphates. Ces résultats sont en accord avec le mécanisme proposé antérieurement. Des mesures faites à l'aide de photographies ont permis de déterminer la grosseur des pores; elles indiquent que les modifications qui se sont produites sous la surface sont antérieures au dépôt de la couche que l'on retrouve en surface et que les dépôts qui se sont faits sur la surface existante protège, et en même temps obscurcissent, les peintures murales. Le développement de la couche superficielle qui est décrit ici ressemble à d'autres systèmes naturels comme l'interaction du CO_2 de l'eau avec les roches et les dépôts contenant du carbonate. Toutefois, à Beni Hasan il n'y a effectivement pas de source d'eau dans le sol et les surfaces peintes sont protégées d'une exposition directe à l'environnement. La détérioration observée à Beni Hasan possède donc des caractéristiques mécanistiques unique.

[Traduit par la revue]

Introduction

The Beni Hasan tombs are man-made structures, cut in the cliffs overlooking the east bank of the Nile River. Their environment is essentially desert, although irrigation and agriculture are practised in the plain below them. The walls of these tombs are obscured by an opaque deposit (1) consisting of calcite ($CaCO_3$) and sand components (2, 3). Earlier studies (4) indicate that this deposit is recent, accelerating and progressive. Such deterioration is often evidence of environmental disturbances. This paper is concerned with the development of this surface degradation.

Several mechanisms for the formation of the disfiguring layer at Beni Hasan have been proposed (1–3). A recent X-ray photoelectron spectroscopic (XPS) study (5) indicated that none of these mechanisms is complete: neither the recent formation of the surface layer nor the consequences to the subsurface regions had been previously recognized or predicted. It was possible to propose a mechanism which predicted subsurface deterioration. However, this mechanism was based on information from XPS analyses which provides information only at the nanometer level on the painted surfaces.

To assess this new mechanism it was necessary to look beyond the nanometer level into the regions of the bulk surface deposit and into the subsurface structure of the painted walls. In studies below, electron microprobe analyses and light microscopy have been used to establish the elemental compositions and structural characteristics, respectively, of small, authentic fragments of the painted walls. These procedures provide cross-sectional information from the first few micrometers of the surface deposit into the rock substrate to a depth of several hundred micrometers.

TABLE 1. Sample descriptions, origins, sampling heights above tomb floor and surface layer thickness

Sample designation	Origin	Sampling height (m)	Surface layer thickness (μm)
15-I[a]Y	Tomb 15, yellow	1.8	50–60[b]
15-IR[c]	Tomb 15, red	2.3	20–25
17-IY	Tomb 17, yellow	2.3	60–65[b]
33-IR[c]	Tomb 33, red	1.5	20–70
33-IRY(a)	Tomb 33,[d] red, ca. 600 A.D./ yellow, ca. 2150 B.C.	1.5	30–50
33-IRY(b)	Tomb 33, red, ca. 2150 B.C.	1.5	30–50
33-IRY(c)	Tomb 33, red, ca. 600 A.D.	1.5	30–50
2-M[e]RC[c]	Tomb 2, red, cleaned	1.8	20–35
3-MY[c]	Tomb 3, yellow	1.2	—
3-MR[c]	Tomb 3, red	1.2	15–20
3-MRC	Tomb 3, red,[f] cleaned	1.2	25–45[b]
2-MR	Tomb 2, red	0.9	15–20
2-MY	Tomb 2, yellow	2.1	50–75[b]
23-MY(a)[c]	Tomb 23, yellow	2.3	30–75[b]
23-MY(b)	Tomb 23, yellow	2.3	50–70[b]

[a]First intermediate period: I.
[b]Surface layer and apparent pigment.
[c]XPS sample, see ref. 5.
[d]The sample was taken near the edge of a Coptic cross which had been incised into a wall of Tomb 33 and then outlined in red. The surfaces of Tomb 33 are uniformly blackened and are assumed to have suffered smoke damage.
[e]Middle Kingdom: M.
[f]Sample presentation allows the analysis of the subpigment and rock regions only.

Experimental

Sampling

Samples were selected on the basis of the appearance of the surface layer and the historical importance of the tomb of origin. Since surface degradation processes and underlying transport phenomena were to be investigated, only red and yellow pigmented samples were assembled. This reduced the number of variables involved in the interpretation of results. The samples were removed from the wall surfaces with a stainless steel scalpel, handled with disposable plastic gloves. Care was taken not to remove any archaeological information and/or unique painted features. Samples were stored in pre-cleaned, plastic, screw-topped vials (PROVIAL and NALGENE) packed with glass wool and sealed with strips of PARAFILM (American Can).

Table 1 provides descriptions of the samples. The sample number is built up from four pieces of information: the number of the tomb of origin (as assigned in the Egyptological literature (6)), the period in which the tomb was constructed (6, 7) and the sample's apparent colour. Thus, sample 15-IY is from Tomb 15, which was constructed in the First Intermediate Period "I", and the sample's colour is yellow, "Y". Middle Kingdom tombs are designated "M" and red samples are denoted with "R". The designation "C" indicates that the sample had been cleaned, on site, by conservators. Cleaning of mural surfaces has taken place intermittently for the last 20 years and has involved the use of HCl. Subsamples with identical sample numbers after all designations were made, are further noted by (a), (b), or (c).

Photography

Specimens were photographed under reflected light using a Wild-Leitz 160959 Microscope and also by plane-polarized light using a Leitz petrographic microscope with and without crossed-nicols. Both black and white film (Kodak PANATOMIC X) and colour slide film (Kodak EKTACHROME W) were employed. Measurements of layer thicknesses, particle-size estimates and pore-size estimates were made using graticules photographed on the same film as were the samples.

Electron microprobe analyses

Samples were grain-mounted in discs of epoxy resin (METSET SW, Metaserv). Cross-sections were exposed by cutting perpendicular to the painted surface with a diamond saw (Buehler ISOMET). The cross-sections were polished with alumina powders and diamond polishing preparations and then coated with a layer of carbon approximately 10 μm thick to minimize charging effects during analysis.

All analyses were performed on an ETEC electron microprobe controlled by a PDP-11 computer at the University of Toronto. Samples were fitted into a moveable stage and were observed directly by an off-angle refracting optics microscope (8) fitted on the sample chamber. Spectra were collected using a focussed beam 1 μm in diameter at an energy of 20 keV for a fixed time of 100 s. The analyzed spot size was approximately 2 μm in diameter due to electron beam spreading in the sample, as estimated from the cathodoluminscence of a willamite standard. The coordinates of the focussed beam were known at all times. No element with $Z < 11$ can be detected by electron microprobe.

Results

Photography

The cross-sectional photographs show that in general, the Beni Hasan samples have four layer structures: a surface deposit layer or encrustation, a pigmented layer, a subpigment region, and a rock substrate. This is unusual in that only two or three layer structures should have been observed.

On the whole, the surface deposit layer appears as a heterogeneous coating ranging in thickness from 15 to 70 μm. Individual grains, ranging in diameter from 5 to 20 μm can be seen (Fig. 1). This suggests that sediments are of wind-borne origin which are typically ≤50 μm (9) in size. The estimated pore width in the surface deposit layer ranges from ≤5 to 10 μm in all samples. Ranges of surface deposit layer thicknesses are given in Table 1 for each sample.

Pigmented layers are seen below the surface encrustation in all red samples (Fig. 1). These pigment layers have an average thickness of 30 ± 10 μm. In the yellow samples, the distinc-

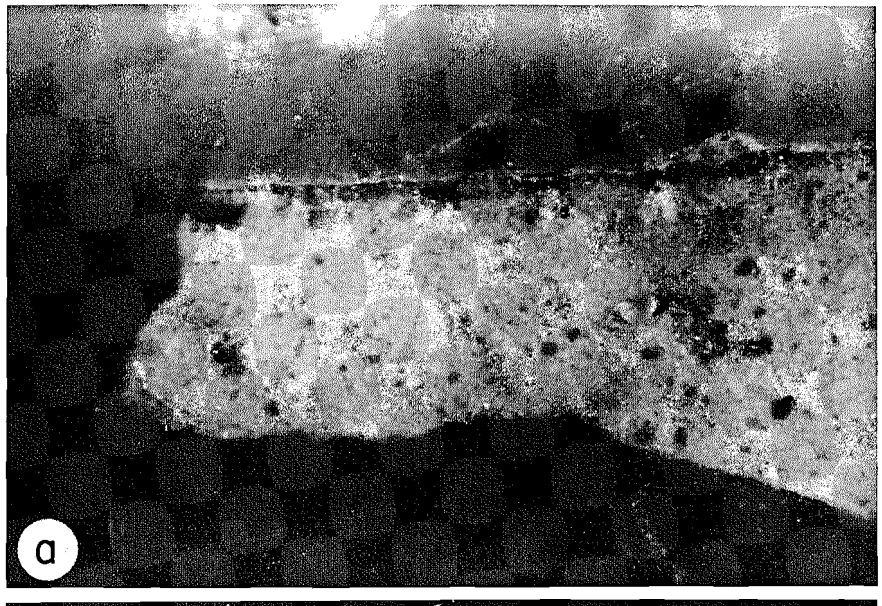

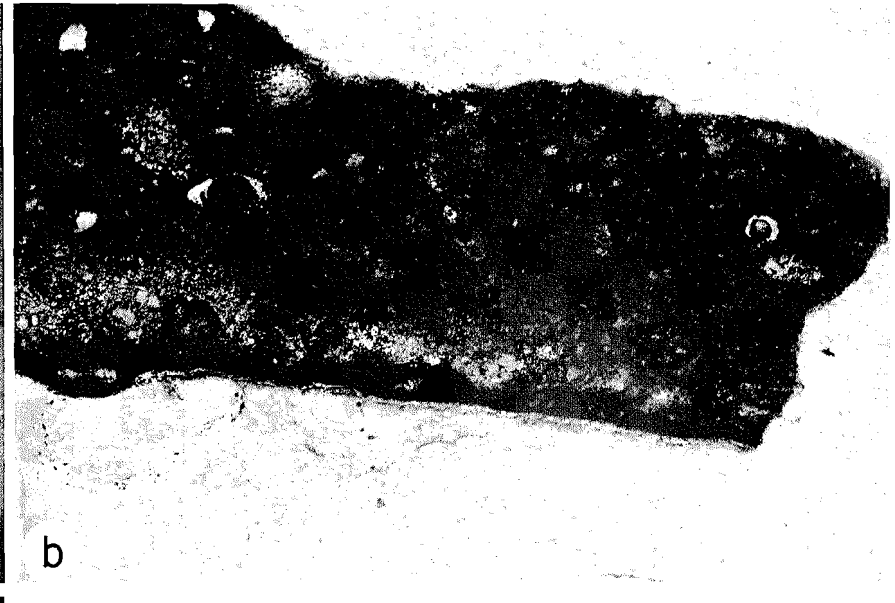

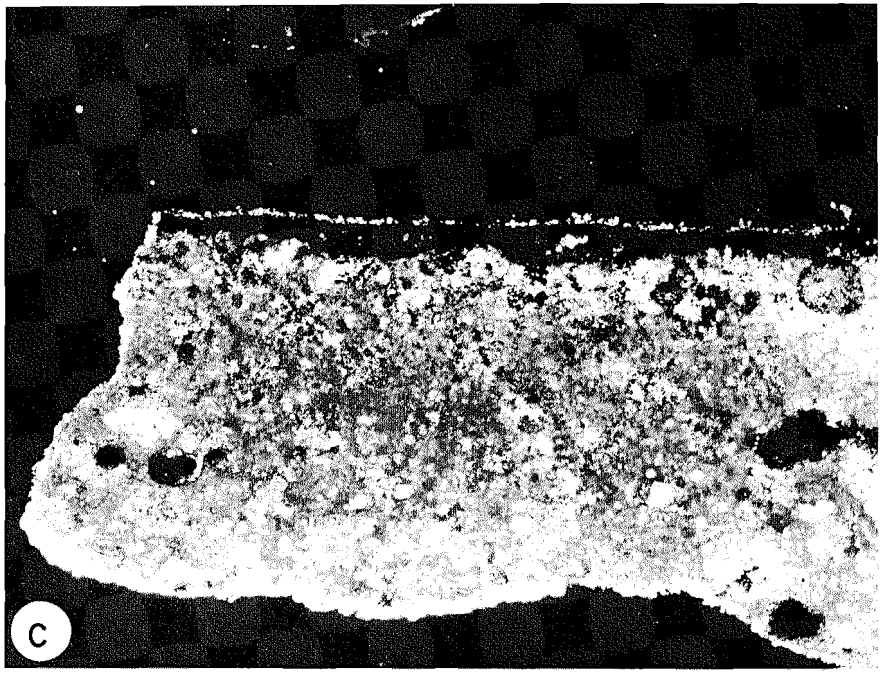

FIG. 1. Sample 2-MRC in cross-section: this sample has a red pigment layer which is visible under a granular surface deposit. The sample was removed from a portion of a painting in Tomb 2 which had been cleaned approximately 20 years ago. The sample cross-section is 700 μm in width at its widest point. (*a*) Photograph taken under reflected light; magnification 50× on 35 mm negative; three layers are visible: surface deposit, pigment, and substrate rock. (*b*) Photograph taken under plane-polarized light; magnification is 63× on a 35 mm negative. (*c*) Photograph taken under crossed-nicols; magnification is 63× on a 35 mm negative.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 112.217.228.212 on 09/07/12
For personal use only.

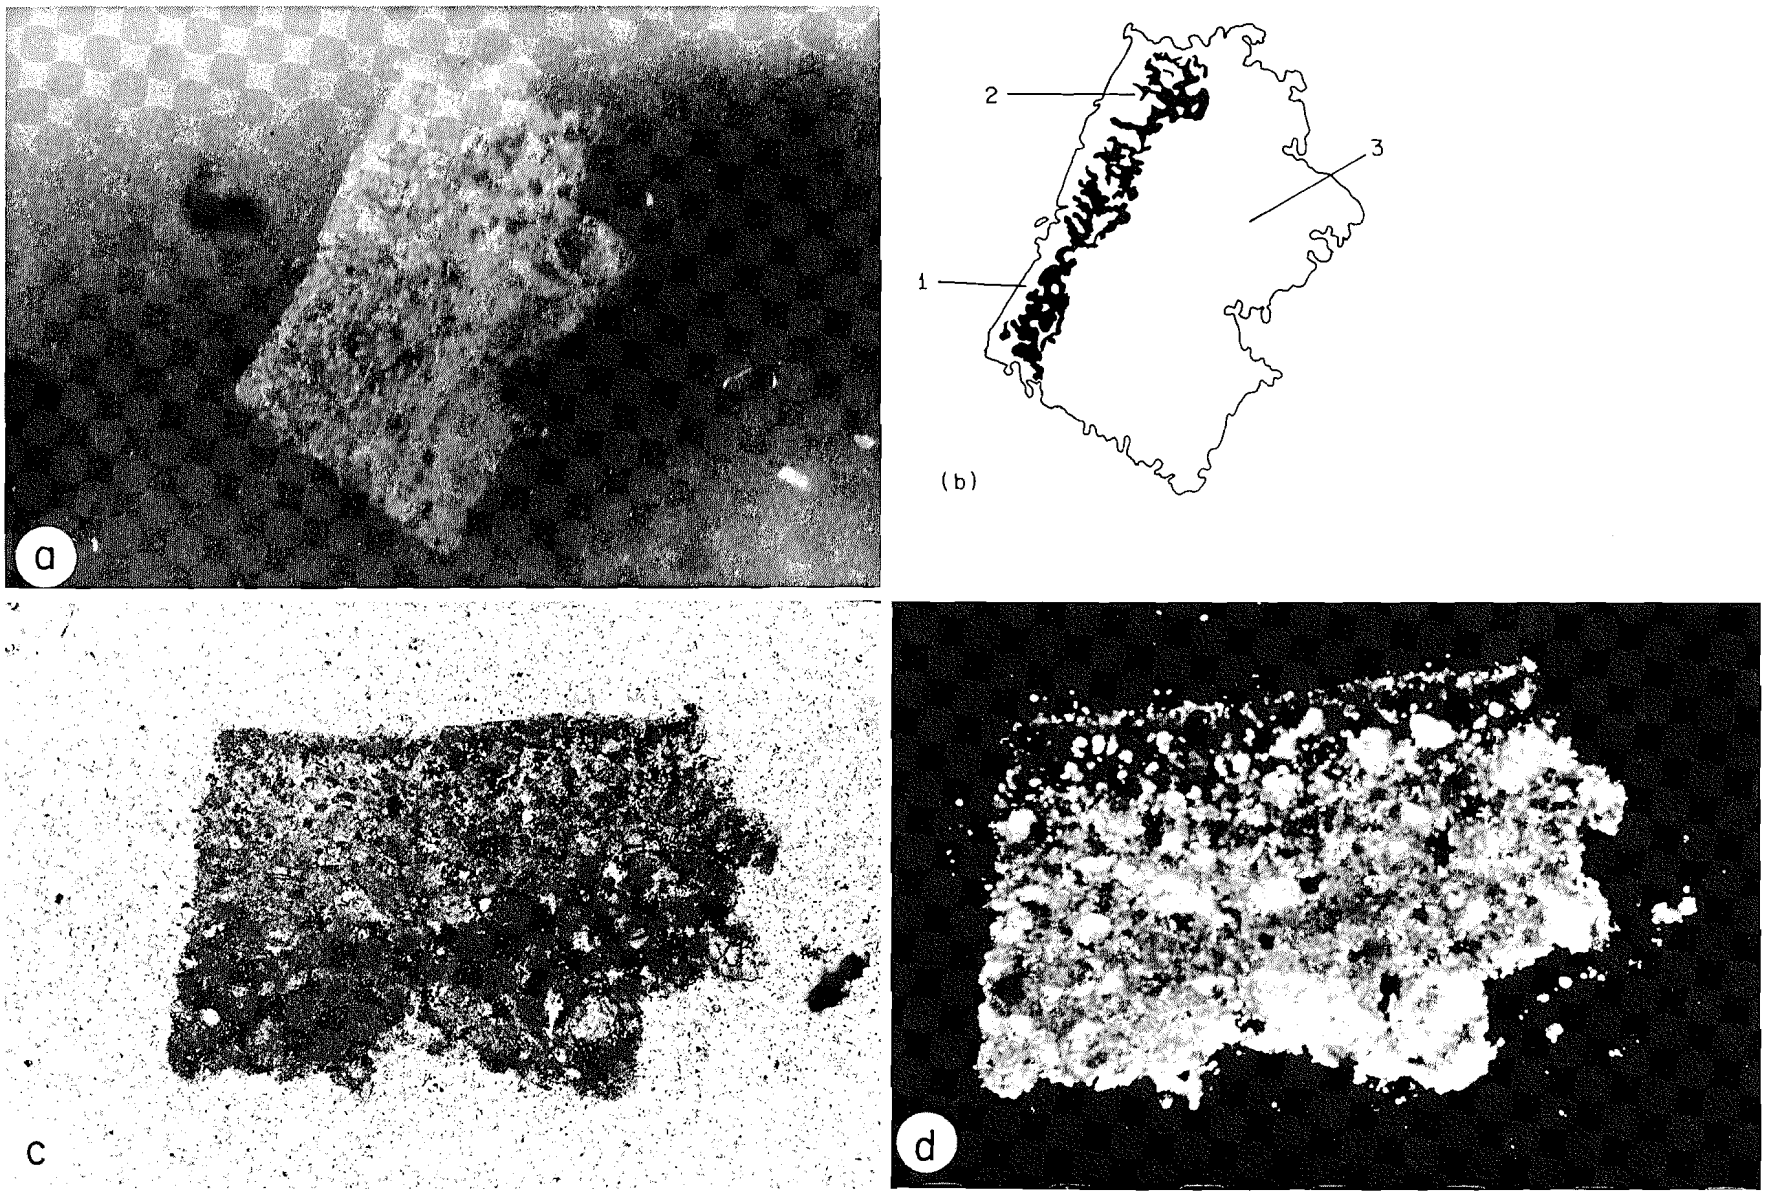

FIG. 2. Sample 23-MY(a) in cross-section: this sample is a yellow pigmented fragment from Tomb 23. A clearly defined pigment layer is not seen, instead a visually inhomogeneous, dendritic, subsurface region appears under magnification. (*a*) Photograph taken under reflected light; magnification 50× on a 35 mm negative; the sample cross-section is 620 μm in width at its widest point. (*b*) Schematic of (*a*) showing surface: *1*; dendritic layer: *2*; and substrate rock: *3*. (*c*) Photograph is taken under plane-polarized light; magnification is 63× on a 35 mm negative. The dendritic region is dark. (*d*) Photograph is taken under crossed-nicols; magnification is 63× on 35 mm negative. The dendritic layer remains dark thus indicating a region of porosity or microcrystalline material.

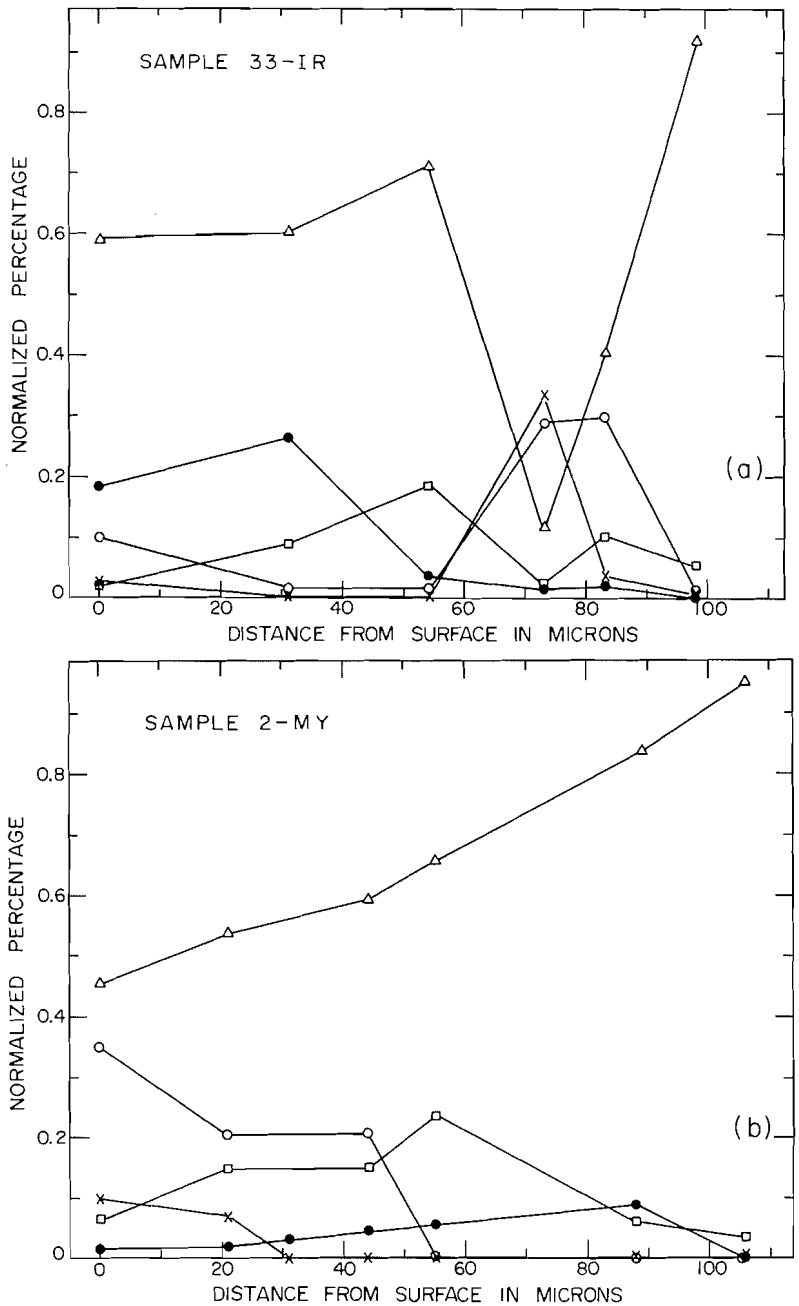

FIG. 3. Cross-sectional scans of Beni Hasan fragments. The abscissa is measured in microns from the beginning of the surface deposit. The ordinate is normalized elemental weight percent. The elements are identified as follows:

△, Ca; ○, Si; □, P; ×, Fe; ●, S.

Errors are estimated as 1 s.d. based on the sample-average s.d. (Table 3). (*a*) Sample 33-IR. The pigment layer is identified by the Fe peak between 70 and 80 μm. Ca and S both drop in this region. (*b*) Sample 2-MY. No Fe maximum is seen. Phosphorus attains a plateau above rock levels between 20 and 60 μm.

tion between the surface layer, the pigment layer and the subpigment region is not as well defined.

In five of the red-pigmented samples, 2-MRC, 2-MR, 3-MRC, 3-MR, and 15-IR, and in two of the six yellow-coloured samples, 15-IY and 3-MY, the surface deposit is found directly upon the pigment layer which in turn appears to be placed directly on the rock substrate. The rock substrate has a pore width of ≤5 μm. In sample 33-IR, a dark subpigment layer 35 to 70 μm thick with an estimated pore width of 40 μm is visible under crossed-nicols and, in sample 33-IRY(b), a white opaque layer 50 to 100 μm in thickness is seen below the pigment by reflected light. Three of the yellow samples, 2-MY, 23-MY(a), and 23-MY(b) display a region with irregularly branched or dendritic features with a pore or dendrite width range of 20–90 μm extending 55 to 230 μm under the surface encrustation. By reflected light, this dendritic region is opaque white and grey; it is dark when observed under plane-polarized light as well as through crossed-nicols (Fig. 2). The dark regions seen under crossed-nicols can indicate (*a*) a total lack of material, (*b*) a region of high porosity, (*c*) the presence of microcrystalline or amorphous material, i.e., with particle size <5 μm. Because of the white appearance of these regions under reflected

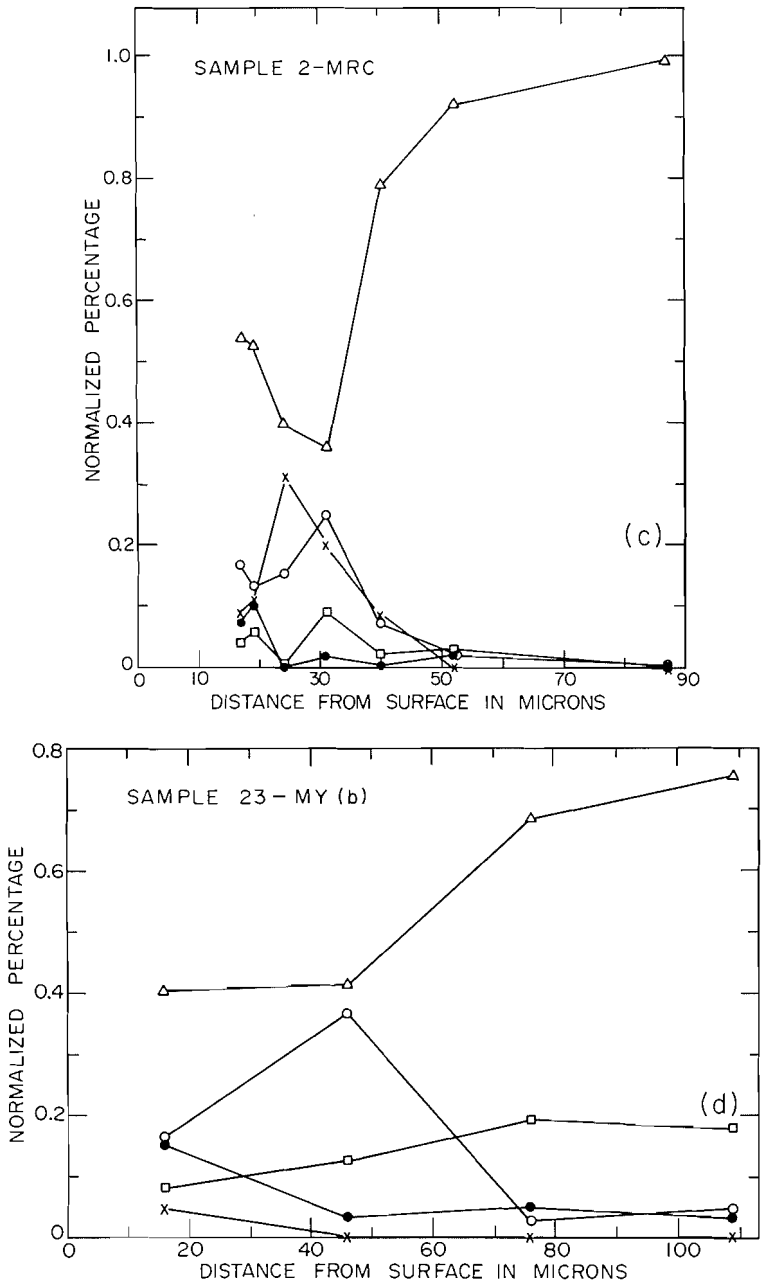

FIG. 3. (*c*) Sample 2-MRC. This scan shows similar features to 33-IR. The Fe peak is situated between 20 and 30 μm. (*d*) Sample 23-MY(b). Si peaks between 40 and 50 μm. There is a high phosphorus plateau extending past 100 μm from the surface. This indicates movement of soluble phosphates downward under the action of solvent with movement of soluble substrate material upward. Ca at 100 μm is lower than that in Fig. 3 (*a*)–(*c*).

light, either one of the latter two explanations is probable. The remaining yellow sample, 17-IY, has granular, dendritic subpigment region, but it did not appear dark under crossed-nicols. The significance of these dendritic regions is discussed in detail below.

Electron microprobe

Peak areas from the electron microprobe spectra were reduced to elemental weight-percentages by a ZAF procedure (10, 11) which uses calibration data from standard minerals.[3] If samples and standards are well-matched both in composition and homogeneity, accurate elemental analysis of the sample can be obtained. However, because the samples studied were both multilayered and heterogeneous, standards cannot match the samples well. None the less, it is possible to establish the error associated with the method of analysis using the ZAF procedure and standard minerals of known composition containing the same elements as the unknowns but in different matrices. The inherent error due to this method of quantification is 10% for major elements and 50 to 100% for elements near the detection limit. The detection limit is estimated as 0.5% by weight which translates as 0.01 normalized percent.

Samples were analyzed to establish (*i*) the average elemental compositions of each identifiable layer in each sample, referred

[3]The standard minerals were apatite: $Ca_5F(PO_4)_3$, pyrite: FeS, diopside: $CaMgSi_2O_6$ and scapolite: a silicate mineral without a well-defined composition which includes sodium, calcium, chlorine, sulphur and CO_3^{2-}.

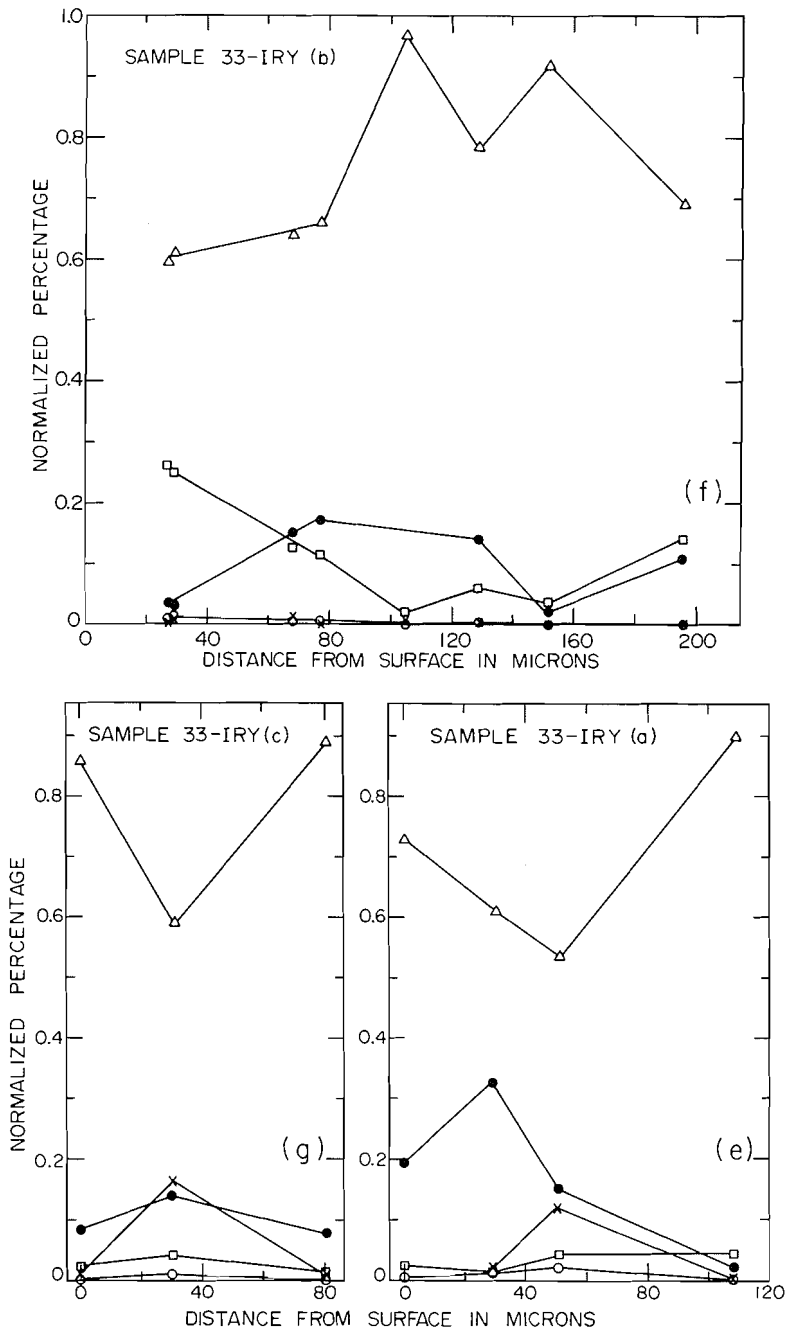

FIG. 3. (*e*) Sample 33-IRY(a) shows a Fe maximum from a Coptic (600 A.D.) red pigment. (*f*) Sample 33-IRY(b) appeared red. It has a high phosphorus content between 30 and 80 μm but has no indication of a red pigment. (*g*) Sample 33-IRY(c) has an Fe maximum from a Coptic (600 A.D.) red pigment.

herein as sample-averages and (*ii*) the average elemental composition of all four layers throughout the site as a whole, referred to as site-averages. Individual analyses performed at known distances were assembled to obtain elemental composition as a function of depth in the sample (Fig. 3).

The elemental weight percentages were normalized by dividing them by the total percentage of analyzed elements in each analysis. The analysis totals are indicators of the density of matter, excluding elements which have $Z < 11$, in the analysis region. The analysis totals are affected by surface roughness and by inherent porosity. Analysis totals have been correlated to porosity (12) and to degree of vitrification (13) in ceramic ware. Elemental weight-percentages have been normalized by dividing them by the analysis totals to obtain elemental normalized percentages. This normalization procedure removes variations between samples as well as fluctuations in instrument conditions during analysis. It does not remove the effects of inhomogeneous elemental spatial distributions. The elemental normalized percentages form the body of the data used for comparisons among samples and among layer structures.

Site-averages

The sample-average values for each element were used to calculate averages for each element for the whole site. These site-averages, their pooled standard deviations (14), and 95% confidence limits for Ca, P, S, Si, Fe, Al, Cl, Na, Mg, and K

[a]Total analysed elements in percent ± 95% C.I. for elements with $Z > 11$.

[b]Error is reported as a 95% confidence limit based on the compound standard deviation:

$$((s)^2_{\text{norm. percent}} + (s)^2_{\text{total}})^{1/2}$$

the normalized percentages were reconverted to elemental percentages before use in the calculation of compound percentage composition.

[c]The percentage $CaCO_3$ was calculated by first calculating the percentage $Ca_3(PO_4)_2$ and then $CaSO_4 \cdot 2H_2O$ and assigning the remainder of Ca to $CaCO_3$.

[d]Total number of analyses is denoted "n".

[e]Total number of samples is denoted "k".

are given in Table 2. Only red sample data were used to calculate site-averages for the pigment layer. The percentage composition as compounds are also given in Table 2 as a general guide only. The nature of the compounds is suggested by evidence from previous XPS analyses (5).

As a preliminary check, a one-way analysis of variance (14) was performed on the site-average values. A one-way analysis of variance is a statistical method for the simultaneous comparison of more than one mean to establish the existence of significant differences. In the current application, a one-way analysis of variance tests if the expected variance of the elemental site-average between layers is greater than the expected variance within layers. Here, the large variances contributed by individual sample-averages to the site-averages removed any significant differences between layers at the 95% level except in the cases of Fe and Ca. A pairwise t-test (14) at the 95%

[a]L signifies that the sample-average lies outside the lower confidence limit.
[b]H signifies that the sample-average lies outside the higher confidence limit.
[c]No. of analyses is denoted "n".
[d]Standard deviation is denoted "s.d.".

level was used to identify the layers which were the source of these differences in Fe and Ca contents. It was found that the rock is significantly higher in Ca than all other layers: this finding provides additional proof, over and above that provided in the photographs, that rock was indeed sampled in these thin (<1 mm thick) specimens. The red pigment layer is significantly higher in Fe than all other layers. Furthermore, in these samples, the surface layer has a higher Fe content than the rock and the pigment layer has a lower Ca content than the subpigment regions.

Sample-averages

To examine the replicate analyses, and any single analysis, of each sample, a reference distribution function estimated by the elemental site-average (Table 2) and its pooled standard deviation (14) is constructed for each element. The 95% confidence band of the elemental site-average (Table 2) is used to identify values which lie outside the estimated reference distribution at this level of probability. The sample-averages are presented in Table 3 and the samples which lie outside the confidence bands on both the high and low sides are identified. As one expects, the more heterogeneous is the layer, the more samples are found outside the confidence limits.

The surface and subpigment regions have the greatest number of results which lie outside their respective confidence limits (Table 3). The red pigment layer was found to be the most homogeneous. The rock, although exhibiting some data outside the 95% confidence limits, is not as heterogeneous, overall, as the surface and subpigment layers.

The sulphur site-average for the subpigment regions is dominated by one high sample-average, that of 15-IY. Nine of the remaining twelve samples are below the site-average sulphur content. When this obvious disparity is removed from the site-average, the site-average sulphur content drops to 0.06 ± 0.05

(95% C.I.) normalized percent or about 10% $CaSO_4 \cdot 2H_2O$ in the subpigment regions. A one-way analysis of variance again does not indicate significant differences between layers.

Sample 2-MY is noteworthy because of the existence of pockets of phosphorus and sulphur enrichment in its subpigment dendrites which have sample-averages outside the 95% confidence limits of the respective elements. The estimated size of these pockets is 20 μm. In addition, the opaque white subpigment layer seen in 33-IRY(b) (see previous section) was found to be phosphate-rich.

Analysis totals

A one-way analysis of variance of the site-averages for the elemental-analysis totals (Table 2) indicates that a significant difference in these averages does not exist between the four layers.

One can compare the sample-average values of the elemental-analysis totals (Table 3) with the elemental-analysis totals reference distribution at a 95% confidence level. It is found that samples 33-IR and 15-IR have high surface layer average totals. The pigmented layer of 2-MRC has the lowest total of all the red pigmented regions and 33-IRY(a) has the highest. The subpigment totals of 2-MRC, 3-MR, 23-MY(a), 23-MY(b), and the sulphate-rich dendrite of 2-MY are below the site-average and the high sulphate subpigment region of 15-IY is well above it. The samples 23-MY(a) and 23-MY(b) have low rock totals as do 2-MRC and 2-MR whereas the samples 33-IRY, 33-IR, 3-MRC, and 3-MY have high totals.

Cross-sectional scans

Cross-sectional scans were performed on all samples which had well-defined, parallel layers: 2-MRC, 2-MY, 23-MY(b), 33-IRY(a), (b), and (c), and 33-IR. Scans were assembled in steps starting at zero distance defined at the outside edge of the surface layer and preceding at known distances across the sample. One analysis per step was performed. These scans are presented in Fig. 3. Data are entered as normalized percentages. Only Ca, P, Si, S, and Fe are shown. The error associated with these normalized percentages is estimated as one standard deviation where the best available estimate of the standard deviation is the respective sample-average standard deviation. The error in distance is ±1 μm.

Trends that appear in the sample-averages presented above (Table 3) are also found in the cross-sectional scans. It can be seen from the cross-sectional scans that: (*i*) with the exception of 33-IRY(b), only the red-pigmented samples have Fe maxima, the depth of which depends on the thickness of the surface deposited layer, (*ii*) no sulphur maxima are seen in the subpigment regions, and (*iii*) the subpigment regions contain noticeable contributions from P and Si in the samples with dendritic or altered regions as seen in the photographs, these being 23-MY(b), 2-MY, 33-IRY(b), and to a lesser extent, 33-IR. These alterations are not seen in samples 2-MRC, 33-IRY(c), and 33-IRY(a).

Discussion

The surface deposits at Beni Hasan are, on average, 30 μm thick. They contain, in order of decreasing abundance based on the site-average (see previous section) Ca, S, P, Si, Fe, Al, Cl, and traces of Na, Mg, and K (Table 2). Egyptian desert sand consists primarily of silicates and aluminosilicates. However, it has been found that, in some cases, it may contain up to 35% soluble material, mostly gypsum, NaCl, and KCl in the particle-size fraction ≤74 μm (15). It is recognized that the proportion of soluble material can be site-specific. The Si component of the surface deposits as well as some soluble material likely arise from wind-blown sand. Bats are known to inhabit these calcitic tombs and their deposits are seen on the walls, hence soluble phosphates (16) and calcium phosphates are expected in the local tomb dust as is some $CaCO_3$. Iron occurs in the surface layer, originating in part from iron silicates in the sand; its surface deposit site-average abundance is greater than that of the rock. Correlations between surface deposited layer thicknesses or composition with sampling height (Table 1) have not been found in this sample population.

Aside from the above general description, one cannot say that there is a fixed composition of the surface deposit layer, as studied by the electron microprobe, in all tombs. Every sample has at least one sample-average which lies outside its respective reference distribution at the 95% level. Based on the information given in Table 3, there are six samples which have three or more elemental sample averages lying outside the 95% bands. A high Ca, low Si and P surface is found in samples 33-IRY(a), (c), and 17-IY; samples 2-MRC and 2-MY have a surface type which is high in Si and Fe but low in S. Sample 2-MY is also significantly low in Ca; the cleaned sample, 2-MRC, has a Ca content that lies just inside the lower bound. Sample 15-IR exhibits, in a single analysis, a surface which is high in P and low in S and Si. By considering the surface deposits of the remaining samples to have an intermediate composition, three and possibly four surface compositions are seen by the electron microprobe. The surface deposit layer types seen by the electron microprobe are representative of the surface layer growth and deterioration process integrated over time.

Earlier XPS results (5) indicated the presence of three distinct surface types detected the point of growth of the surface deposit i.e. at the nanometer level: a high Si – low Ca surface, a low Si – high Ca surface, and surfaces which were intermediate in the abundances of these elements. The observation of these surface types by XPS has lead to the suggestion (5) that there are two ways to initiate surface layer growth, one involving deposition of silica-containing dust and sand and a resulting increase in surface area and the increased possibility of capillary condensation of CO_2-enriched water vapour, and a second involving direct deposition of dew-point condensation. Subsurface attack and movement of soluble components of the substrate, including $CaCO_3$, was proposed as a consequence of the action of solvent water (5). The electron microprobe surface deposit layers represent the end products in these cumulative processes and their compositions may indicate the dominant mode of surface layer growth at localized spots.

We now have evidence, both from photographs and from bulk analyses, that subsurface depletion or alteration of the soluble components of rock and subpigment regions has occurred indeed under the inward movement of solvent (Fig. 2). The dendritic regions seen in the yellow pigmented fragments and the samples from the severely disfigured Tomb 33, on top of the calcite-rich rock, are direct evidence of alteration in particle size due to repeated solution from above and subsequent reprecipitation. The attack of acid rain on urban marbles has been found to produce a similar type of alteration in subsurface particle size (17, 18). Porosity (see Table 3 and previous section) is seen in the subpigment layers of these samples and also in the rock regions of three of the yellow samples. Pockets of phosphates in the altered regions are observed also. The exis-

For personal use only.

tence of phosphate pockets is significant since the movement and subsequent immobilization of soluble phosphate deposits can be considered a marker for inward movement of solvent water.

A cohesive pigment layer is not seen in the yellow samples. The pigment yellow ochre is expected at this site. The yellow pigment orpiment, As_2S_3, is not seen in wall paintings until the 18th dynasty (ca. 1560 B.C.) (19). Yellow ochre is hydrated Fe_2O_3 admixed with silica, clay, and sometimes gypsum (20) (see also Table 3, pigment layer, sample 15-IY). However, the iron abundance of yellow iron pigments can be close to the detection limit of the microprobe and still be sufficient to yield colouration in the pigment layer visible to the human eye. Furthermore, it is known that the yellow, hydrated iron oxides are more soluble in acids and water than are the anhydrous iron oxides (21, 22) on which the red pigment at this site is based (19, 23). The differences seen in the red and yellow pigmented samples suggest that solvent water does not penetrate through the red pigment layers but does penetrate the more soluble and porous yellow pigment layer.

The effects of stronger acids may be evident in sample 2-MRC. This sample was cleaned approximately 20 years ago with HCl. However, Cl was not detected in the surface deposit or the rock layer of sample 2-MRC and was just detected in pigment and subpigment regions. However, sample 2-MRC has been found to have significantly low pigment layer, subpigment layer and rock totals at the 95% level based on the analysis-totals reference distribution (see previous section) even though these layers appear unaltered in photographs (Fig. 1). Material depletion from these layers may be a possible result of the application of strong acid. Further detailed analyses are on-going to investigate the effects of acid-cleaning.

No sulphate plaster layer exists in this tomb system. The significantly high sulphate sample-averages of 15-IY arise from the analyses of an inclusion approximately 450 μm in diameter below the surface and *not* from a continuous layer. The use of $CaCO_3$-based whitewash for preparing the rock wall for the execution of mural paintings is a possible alternative to the use of gypsum. Its employment has been cited and the presence of gypsum impurities in the whitewash noted (20). It is also possible that the rock walls were painted directly without a final wall preparation or polishing. The mechanistic consequence of the lack of a sulphate-rich plaster is that the surface layer is not dominated by sulphate even though subsurface attack and removal of soluble components, including sulphate, has occurred.

In natural limestone caves, water in the form of groundwater is almost always present. Calcite, in these situations, precipitates when CO_2 is degassed from the solvent water when the solvent water moves from high P_{CO_2} to low P_{CO_2} regions or to regions of higher temperature (24, 25). This is the case in the painted caves at Lascaux where groundwater enriched in CO_2 from biological soil processes (25, 26) has formed surface deposits. These deposits range in appearance from "cauliflower-like" concentrations to thin translucent films (26). In Beni Hasan there is no evidence for subsurface water flow or water flow over entire walls although a very few fissures, stained with iron-oxides, do appear in some Beni Hasan tombs. Stalactites and stalagmites are not seen by us anywhere in these tombs. The most probable source of water is condensation, both the dew-point and the capillary type (27, 28). Hence, we have a deposit which has formed in the presence of *atmospheric* CO_2 and in the absence of continuous excess solvent water.

Other deposits in which rain or dew provide solvent action have been described. Many open-air North American petroglyph and rock art sites have layers of silcrete and calcrete[4] deposited under the action of rain and groundwater (29, 30). These layers often form both substrate and surface deposit on these carved or painted rock faces (31, 32). The thin (<1 mm thick) dark coloured deposit known as rock or desert varnish is also formed on exposed outcrops from the dissolution of rock and dust rich in Fe and Mn silicates (33, 34) by dew and rain. Desert varnish can contain up to 30% Mn and Fe oxides (33). In the formation of coastal deposits known as aeolinites (35) on coastal outcrops and dunes, windborne materials such as SiO_2, Fe_2O_3, and $CaSO_4 \cdot 2H_2O$ are cemented in place by $CaCO_3$. At Beni Hasan, the deteriorating surfaces are in relatively enclosed spaces, the surface deposit layer compositions show the effects of material originating from the immediate tomb surroundings and subsurface attack as well as windborne sand. The recent formation (during the past 150 years) of the surface deposit indicates an environmental change which most likely involves the availability of solvent. It is unlikely that these tombs have been exposed to regular dew-fall such as occurs in the open desert (15) over the first four millennia of the tombs' existence. Therefore, although it has some features in common with other deposits, the Beni Hasan phenomenon has aspects which are unique and which have general significance in the understanding of the degradation processes of ancient painted surfaces.

The system CO_2–H_2O–$CaCO_3$ provides, to a first approximation, a description of the physical chemistry in the limestone-walled tombs of Beni Hasan. The solubility of $CaCO_3$ may be calculated (25, 35), for illustrative purposes, by considering the equilibria for carbonate dissolution in neutral water in the presence of CO_2. Continuous contact with an atmospheric source of CO_2, as is the case at Beni Hasan, is also assumed.

$$2CO_2(g) + H_2O \rightleftharpoons CO_2(aq) + H_2CO_3 \quad K_H K_0$$
$$H_2CO_3 \rightleftharpoons H^+ + HCO_3^- \quad K_1$$
$$HCO_3^- \rightleftharpoons CO_3^{2-} + H^+ \quad K_2$$
$$CaCO_3 \rightleftharpoons Ca^{2+} + CO_3^- \quad K_{sp}$$
$$H_2O \rightleftharpoons OH^- + H^+ \quad K_w$$

Amounts of dissolved Ca^{2+} calculated on the basis of concentration have been found. Experimental solubility data (36) for the Henry's law constant, K_H, and a value of 600 for the equilibrium constant for the hydration of CO_2, K_0, (37) were used. The amounts found are 53 ppm Ca^{2+} at 20°C at a P_{CO_2} of 3.0×10^{-4} atm and at a partial pressure of CO_2 comparable to that in human breath, 5.5×10^{-2} atm (38), 6400 ppm at 20°C. Thus, although the high levels of CO_2 typically seen in ground waters in cave environments (5×10^{-3} to 2×10^{-2} atm (25)) are not available at Beni Hasan, the influence of human activity may compensate. More exhaustive calculations of calcite solubilities based on activities, and including contributions from ion pairs and molecular species, have been cited in the literature (25) for temperatures and pressures expected in cave environments.

The kinetics of the dissolution and precipitation of $CaCO_3$ have been investigated (25, 39–44). At Beni Hasan, we are most interested in these processes in porous media (42, 43) and in thin films (41, 44).

The dissolution mechanism of calcite within the rock matrix has been investigated both experimentally and by solving transport equations in pores at varying flow velocities (42, 43).

[4]Silcrete typically has an SiO_2 content of 87–98% (29); calcrete typically has a $CaCO_3$ content of 80% (30).

Within the assumption that chemical reactions in the system are instantaneous (42), the rate of dissolution was found to depend on transport processes, i.e., the ability of the solute to diffuse away or be carried, from the dissolving pore-walls. When the rates of chemical surface reactions are also considered (43), it has been shown that for high flow rates (or short residence times of solvent water) surface reaction kinetics and chemical reaction kinetics become rate determining. In stagnant or low-flow regimes, the rate of dissolution again becomes dependent upon transport processes. In both the model which ignores surface reactions and the model which includes them, the incoming solution will become saturated within a distance comparable to the radius of a pore in a low-flow situation (42, 43). The extent of structural alteration in porous limestone is then just the distance that CO_2-saturated water will travel through the pore-network before becoming saturated with $CaCO_3$. The attainment of saturation may take a few minutes or several hours depending on the thickness or depth of the water film in the porous surface and below. In films approximately 500 μm thick, diffusion of CO_2 in the solvent is the rate-determining step (41, 44). In very thin films, such as are expected at Beni Hasan, i.e. $\leq$30 μm, the rate-determining step (44) for the dissolution of calcite is the slow (45) hydration of CO_2.

At Beni Hasan, the surface-layer pore width, estimated from photographic measurements, is approximately 5 μm and the rock pore width is $\leq$5 μm. The current depth limit of alteration in a single exposure to unsaturated solvent can be estimated at 5 μm in the surface layer. The width of the dendrites in the depleted region, however, is $\geq$20 μm. This is roughly four times as large as the surface pore size. Individual samples, notably 33-IR, show larger differences between surface layer pore sizes and subsurface dendrite widths. This difference in pore and dendrite width is evidence that there has been repeated dissolution caused by solvent entering from the surface in the initial stages of surface layer growth. The existing surface deposit, which at present disfigures the painted surfaces, is concurrently acting as a barrier to further substrate attack. The kinetics of the multistep degradation process on-going at this site is currently being modelled by us.

Acknowledgements

The authors wish to thank the Egyptian Antiquities Organization and its Permanent Committee for Archaeology for their permission, given in 1980, to take samples from the tombs at Beni Hasan. Special thanks are extended to Dr. Ali el Khouli, Mr. Mottawi Balboosh, and Mr. Gamal M. Amin for their advice and assistance. Drs. M. Gorton and C. Cermignani and Mr. George Taylor, Department of Geology, University of Toronto, provided advice on the electron microprobe analyses. Dr. J. M. Allen, also of the Department of Geology, made available a petrographic microscope for photography. Dr. D. Spanel, Virginia Museum, Richmond, VA., provided valuable discussions on the Egyptological aspects of these investigations. Dr. Jean Vouvé, Dr. M. del Monte, Dr. el Goresy, and Mr. Ian Wainwright provided reprints of their articles.

Received May 6, 1987[2]

BASHEIR A. EL-SHETARY, SHAKER L. STEFAN, MOHAMED S. ABDEL-MOEZ, and MAHMOUD M. MASHALY. Can. J. Chem. **66**, 2362 (1988).

A new series of hydrazone β-diketone organic ligands were prepared: 3-(2-acetylphenylhydrazone)pentane-2,4-dione (2-APHA), 2-(2-acetylphenylhydrazone)-1-phenyl-1,3-butane dione (2-APHB), 2-(2-acetylphenylhydrazone)-1,3-diphenyl-1,3-propane dione (2-APHDB), 3-(2-acetylphenylhydrazone) 1,1,1-trifluoropentane-2,4-dione (2-APHTA) and 2-(2-acetylphenylhydrazone)-5,5-dimethyl-1,3-cyclohexane dione (2-APHDm). The step formation constants of their 1:1 and 1:2 rare-earth complexes were determined at 30°C by pH titration in 75% (v/v) dioxane–water solvent. The ionization constant of ligands were also measured. A curious odd–even stability differential was apparent in the (2-APHDm) ligand with the heavier rare earths Gd–Lu. The differential was apparent in both log K_1 and log β values and may be sufficient to cause reversal of the usual ion-exchange elution sequence.

BASHEIR A. EL-SHETARY, SHAKER L. STEFAN, MOHAMED S. ABDEL-MOEZ et MAHMOUD M. MASHALY. Can. J. Chem. **66**, 2362 (1988).

On a préparé une nouvelle série de ligands organiques dérivés d'hydrazones de β-dicétones : (acétyl-2 phénylhydrazone)-3 pentanedione-2,4 (2-APHA), (acétyl-2 phénylhydrazone)-2 phényl-1 butanedione-1,3 (2-APHB), (acétyl-2 phénylhydrazone)-2 diphényl-1,3 propanedione-1,3 (2-APHDB), (acétyl-2 phénylhydrazone)-3 trifluoro-1,1,1 pentanedione-2,4 (2-APHTA) et (acétyl-2 phénylhydrazone)-2 diméthyl-5,5 cyclohexanedione-1,3 (2-APHDm). Opérant à 30°C, dans un mélange dioxanne/eau à 75% (v/v), on a déterminé les constantes de formation par étape de leurs complexes 1:1 et 1:2 avec des terres rares. On a aussi mesuré la constante d'ionisation des ligands. On a déterminé qu'il existe une curieuse de stabilité différentielle dans les complexes pair et impair du ligand 2-APHDm avec les terres rares plus lourdes de la série Gd à Lu. On peut remarquer les différences tant dans les valeurs du log K_1 que du log β et ces différences sont telles qu'elles peuvent être suffisantes pour renverser la séquence habituelle d'élution lors de l'échange d'ions.

[Traduit par la revue]

β-Diketones are well-known chelating agents, capable of forming stable complexes with metal ions. Lanthanide β-diketones have also been found to have wide application (2), including chromatographic separation of the lanthanide series (3). Azo compounds are also used as complexing agents (4), and the combination of azo compounds and β-diketones are good ligands (5). The chelation between similar ligands and lanthanide metal has been studied (6, 7).

The coupling product of the diazonium salt of 2-aminoacetophenone with different β-diketones such as acetylacetone, benzoylacetone, dibenzoyl methane, trifluoroacetylacetone, and 5,5-dimethylcyclohexane-1,3-dione (dimedone) produces a series of 3-(2-acetylphenylhydrazone)diketone ligands. The present study determined the acid dissociation constants of these ligands and the formation constants of their trivalent lanthanide complexes. The structure and basicity effects of the ligands on the stability of the formed complexes are discussed and some correlations attempted. These complexing agents may be useful in the separation of the lanthanides.

Experimental

(i) Materials and methods

Stock solutions of lanthanide nitrates were prepared from their metal oxides (BDH 99.9%) as mentioned previously (7). The acidity of the metal ion solutions was adjusted to between pH 4.0 and 4.5. The exact concentration was determined by titration with EDTA using xylenol orange as indicator (7). Dioxane was freshly purified by refluxing with $LiAlH_4$ and sodium metal for 8 h and then distilled. Oxygen-free nitrogen gas was passed through the solutions during the titrations.

Titrations of 5×10^{-3} *M* free ligands, as well as mixtures of the free ligands and 1×10^{-3} *M* lanthanide ions, were carried out against standard KOH in 75% dioxane – water (v/v) to avoid precipitation. Dilute solutions (10^{-3} *M*) were used to reduce the possibility of formation of polynuclear species. All titrations were done in duplicate; the curves agreed within 0.03 pH units in all cases. The formation of lanthanide–nitrate complexes was assumed negligible.

The ligands used in this study did not undergo hydrolysis under the above experimental conditions. This was indicated by rapid attainment of equilibrium during titration and by the absence of any significant drift in the pH even after a half hour (8). pH titrations were carried out using a WTW digital pH meter 520 fitted with combination electrode at 30°C and <0.025 ionic strength in 75% (v/v) dioxane – water solvent.

The dissociation constants pK_H were calculated as mentioned before (9). As 75% dioxane – water (v/v) was used as a solvent, a correction value of 0.28 pH unit was added as recommended by Irving and Mahnot (10). The adopted method by Irving and Rossotti (11) was employed to determine the parameters $\bar{n}$ and pL. Linear plots of $\bar{n}/(1 - \bar{n})$ and $\log [(\bar{n} - 1)/(2 - \bar{n})]$ vs. pL were drawn to obtain the best values of stepwise formation constants. Also correlation coefficients were calculated and found to be equal to or better than 98%.

(ii) Preparation of ligands

The organic ligands used in this investigation were prepared by coupling the diazonium salt of 2-aminoacetophenone with different diketones in sodium acetate medium (12). The crude materials were crystallized twice from acetic acid to obtain pure products.

The purity of the ligands was checked by infrared, thin layer chromatography, and elemental analysis.

3-(2-Acetylphenylhydrazone)pentane-2,4-dione (2-APHA), I

This compound was obtained as yellow crystals from acetic acid, mp 159.0–159.5°C; ir (KBr) ν: 3080–3020 (NH) (mb), 1663 (C=O) (s), 1570 (C=N) (s) cm^{-1}. *Anal.* calcd. for $C_{13}H_{14}N_2O_3$: C 63.41, H 5.69, N 11.38; found: C 63.60, H 5.80, N 10.67.

Results and discussion

(i) Dissociation constants

The titration curves of free ligand in 75% dioxane – water (v/v) reveals that the ligands behave as weak monoprotic acids. The pK_H values of the different ligands were observed to be affected by the terminal groups of the β-diketone in the ligands.

2-APHA ligand has the highest value of dissociation constant (pK = 14.43). This may be attributed to the increase in electron density on the hydrazone moiety caused by the electron repelling property of the methyl group, which retards removal of the ligand proton and increases its basicity. For 2-APHB ligand the presence of one electron-withdrawing phenyl group in the β-diketone branch decreases its basicity (pK = 13.99). The effect of phenyl group substitution on the basicity of ligand becomes more obvious in the 2-APHDB ligand since the value of the dissociation constant is 12.54. The effect of the electron-withdrawing group on the basicity of ligands is clear in comparing the pK_H values of 2-APHA (pK_H = 14.43) and 2-APHTA (pK_H = 12.5). The decreased value of the latter is attributed to the presence of fluorine atoms. The order of

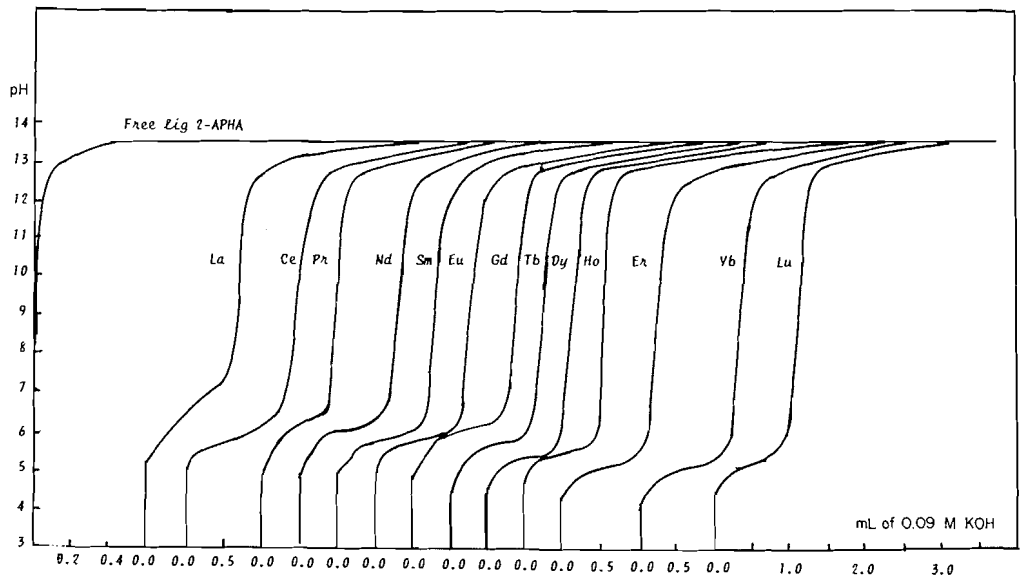

FIG. 1. Potentiometric titration curves for 5×10^{-3} *M*, 3-(2-acetylphenylhydrazone)pentane-2,4-dione in the absence and presence of 1×10^{-3} *M* lanthanide ion, $T = 30°C$, 75% (v/v) dioxane – water, $V^0 = 40$ mL.

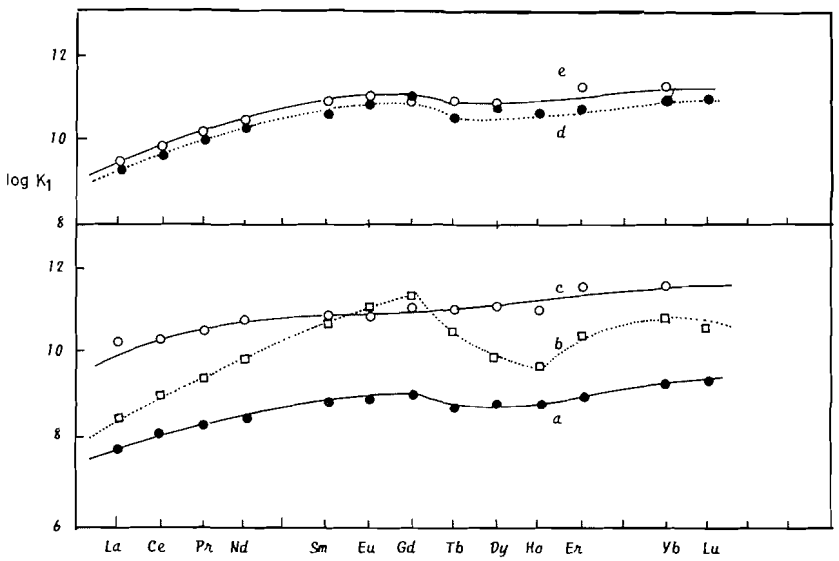

FIG. 2. log K_1 as a function of atomic number for lanthanide(III) complexes at 30°C in 75% (v/v) dioxane – water mixture. (*a*) Ln(III)–2-APHTA, (*b*) Ln(III)–2-APHDm, (*c*) Ln(III)–2-APHA, (*d*) Ln(III)–2-APHB, and (*e*) Ln(III)–2-APHDB.

dissociation constants of the studied ligands decreases in the same manner as that of the β-diketone themselves (1). The decreased basicity of the 2-APHDm ligand ($pK_H = 13.13$) relative to the 2-APHA ligand ($pK_H = 14.43$) may be due to both the cyclic structure and the distant location of the methyl groups from the hydrazone moiety. Considering substitution effects, the investigated ligands can be arranged according to increased basicity in the following order: 2-APHTA < 2-APHDB < 2-APHDm < 2-APHB < 2-APHA.

(ii) Formation constants

Titration curves of the 2-APHA ligand (Fig. 1) are greatly altered in the presence of Ln^{3+} ion (Lu = La, Ce, Pr, Nd, ..., Lu) as a result of complex formation.

The lanthanide ions (1×10^{-3} *M*) and organic ligand mixtures in a ratio of 1:5 were titrated with KOH at 30 ± 0.5°C and <0.025 *M* ionic strength in 75% dioxane – water (v/v) solvent. A sharp inflection was observed at $m = 2$, where m = mole of base per mole of ligand, indicating that the highest complex formation ratio is 1:2 metal-to-ligand. The lighter and heavier lanthanides all form ML and ML_2 complexes. Therefore, stepwise formation constants (log K_1 and log K_2) can be evaluated (Table 1). A plot of the formation constants (log K_1) for these complexes vs. atomic number of lanthanide elements shows a regular increase from lanthanum (La) to europium (Eu) with a break after gadolinium (Fig. 2). The increase in formation constant values of the light lanthanide complexes La^{3+} to Gd^{3+}) may be attributed mainly to electro-

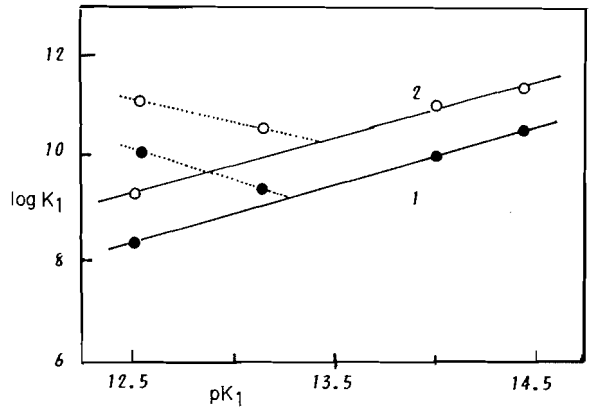

FIG. 3. Comparison of stabilities of 1:1 Ln–chelate reagent complexes. (*1*) Pr^{3+} complexes. (*2*) Lu^{3+} complexes.

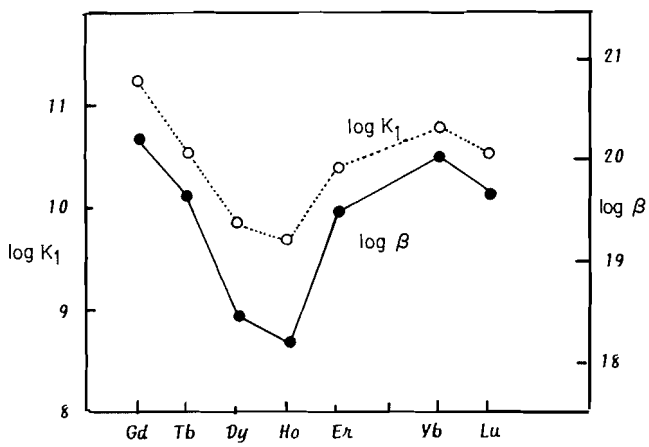

FIG. 4. Apparent odd–even effect in chelate stabilities noted with the heavier rare-earth–2-APHDm species.

static attraction. The behaviour observed in these ligands agrees very well with that of other chelating agents (13–15). On the other hand, the formation constants (log K_1) of the heavier lanthanide complexes (Tb^{3+} to Lu^{3+}) show a very slight increase (Fig. 2). The latter increase is 0.27, 0.35, 0.02, and 0.09 units for 2-APHTA, 2-APHDB, and 2-APHB, respectively. However, differences between consecutive log K_1 values for lanthanide complexes from La to Gd (light lanthanides) was 0.12, 0.16, and 0.23, and 0.24 units for the same order of ligands. The smaller increase in the formation constants for the heavier lanthanide complexes cannot be explained by electrostatic bond interactions. In terms of electrostatic considerations, the gadolinium break may be attributed to the discontinuity of the crystal radius at gadolinium (16). The deviation of the ligand stability constants from linearity is not peculiar, but seems to be common for most rare earth complexes with several chelating agents, such as 2,4-pentanedione (17), 1-phenyl-1,3-butane dione (18) and *N*-hydroxyethylenediamine triacetic acid (14). This agreement in behaviour of the studied ligands with those cited in literature (17–20) may be due to the similarity of the coordination sites of the ligands.

The plots of stability constants of the 2-APHDm lanthanide chelates vs. the atomic number of the lanthanides in Fig. 2 suggests the presence of ionic interaction through the light lanthanide elements. However, the stability values of the heavier lanthanide complexes decrease to Ho^{3+} and then increase to Lu^{3+}. Figure 3 shows the relationship between the acid dissociation constant pK_H and the formation constant log K_1 of the Ln chelates (Pr^{3+} and Lu^{3+} are given as examples). The stabilities of the complexes of the flexible ligands exhibit a dependance on the acid dissociation constant while the stabilities of the complexes of the rigid 2-APHDm ligand do not follow the trend. The stability constant values of the Ln(III) complexes (Table 1) for the different ligands have been found to be related to their basicities and structures. The general trend observed is that by increasing the basicity of the organic ligands, the formation constants of the lanthanide complexes are increased in the order: 2-APHDm > 2-APHA > 2-APHB > 2-APHDB > 2-APHTA.

Formation constants of the Ln–(2-APHDm) complexes have been found to deviate from the general trend. This deviation may be due to the rigid structure of the 2-APHDm ligand with respect to the other ligands. The effect of ligand structure is obvious in the stability values of the Ln complexes (Table 1). Values for the flexible branches 2,4-pentanedione, 1-phenyl-1,3-butane dione, and 1,3-diphenyl-1,3-propane dione decreased gradually. This may be due to the bulky methyl and phenyl groups present. The results obtained agree with those cited in the literature (21, 22).

A literature (14, 17, 23) survey showed that the lanthanides can form 1:1, 1:2, and 1:3 complexes with β-diketones, but in this study only 1:1 and 1:2 types were obtained. This may be due to steric effects of the ligands which hinder interaction of the ligands around the metal ions.

The 2-(2-acetylphenylhydrazone)-5,5-dimethyl-1,3-cyclohexanedione–lanthanide complexes (Fig. 4) show a curious odd–even effect from Gd^{3+} and Lu^{3+} for both log K_1 and log β. The difference in both log K_1 and log β between the pairs of lanthanide series is outside the experimental error (Fig. 4, Table 1). We conclude that the 2-APHDm ligand might be valuable for the separation of rare earth mixtures by ion exchange techniques.

RAMESH KAPOOR, POONAM WADHAWAN, PRATIBHA KAPOOR, and JEFFERY F. SAWYER. Can. J. Chem. **66**, 2367 (1988).

The compounds seleninyl bis(trifluoromethanesulphonate) (**1**) and seleninyl bis(acetate) (**2**) have been prepared and characterized by elemental analysis, ir and Raman spectroscopy, and X-ray crystallography. Crystals of **1** are monoclinic, space group $P2_1/n$ with $a = 12.735(1)$ Å, $b = 5.163(4)$ Å, $c = 16.133(2)$ Å, $\beta = 96.426(8)°$, $U = 1054$ Å^3, $D_x = 2.48$ g cm^{-3} for $Z = 4$, $R = 0.038$ for 1745 observed reflections with $I > 2.5\sigma(I)$. Those of **2** are orthorhombic, space group $Pcab$ with $a = 6.845(3)$ Å, $b = 8.992(2)$ Å, $c = 23.560(9)$ Å, $U = 1450$ Å^3, $D_x = 1.95$ g cm^{-3} for $Z = 8$, $R = 0.074$ for 1073 observed reflections with $I > 3.0\sigma(I)$. The primary geometry of the Se atom in $SeO(O_3SCF_3)_2$ is AX_3E with a Se═O distance of 1.571(3) Å and Se—O bond lengths to the CF_3SO_3 ligands of 1.902(3) and 1.922(3) Å. Completing the overall coordination geometry of the Se atom are 2 intramolecular and 4 intermolecular Se...O contacts which are less than van der Waals limits. The overall coordination geometry is somewhat irregular since the two triflate anions are significantly differently arranged with respect to the SeO_3E tetrahedron. The crystal packing consists of layers of interacting molecules. In **2** there is some disorder. However, the major arrangement of the molecule has Se═O and Se—O(1), Se—O(3) distances to the acetate ligands of lengths 1.575(9), 1.847(7), and 1.831(8) Å respectively. The overall geometry of the Se atom in this compound is completed by two intramolecular secondary Se...O contacts involving the second O atoms of both acetates and two intermolecular contacts involving the seleninyl oxygen atom and atom O(2) of an acetate group in two different symmetry related molecules. Overall, the crystal packing consists of essentially centrosymmetric dimeric units linked together through Se═O—Se bridges. A 1:2 adduct of **1** with pyridine has also been prepared and characterised.

RAMESH KAPOOR, POONAM WADHAWAN, PRATIBHA KAPOOR et JEFFERY F. SAWYER. Can. J. Chem. **66**, 2367 (1988).

On a préparé les composés séléninyl bis(trifluorométhanesulfonate) (**1**) et séléninyl bis(acétate) (**2**) et on les a caractérisés par des analyses élémentaires, des spectres ir et Raman et par diffraction des rayons-X. Les cristaux du composé **1** sont monocliniques, groupe d'espace $P2_1/n$, avec $a = 12,735(1)$, $b = 5,163(4)$ et $c = 16,133(2)$ Å, $\beta = 96,426(8)$, $V = 1054$ Å^3, $D_x = 2,48$ g cm^{-3}, $Z = 4$ et $R = 0,038$ pour 1745 réflexions observées avec $I > 2,5\sigma(I)$. Ceux du composé **2** sont orthorhombiques, groupe d'espace $Pcab$, avec $a = 6,845(3)$, $b = 8,992(2)$ et $c = 23,560(9)$ Å, $U = 1450$ Å^3, $D_x = 1,95$ g cm^{-3}, $Z = 8$ et $R = 0,074$ pour 1073 réflexions observées avec $I \geq 3,0\sigma(I)$. La géométrie primaire de l'atome de Se dans $SeO(O_3SCF_3)_2$ est AX_3E avec une distance Se═O de 1,571(3) Å et des longueurs de liaison Se—O dans les ligands CF_3SO_3 de 1,902(3) et 1,922(3) Å. Pour compléter la géométrie globale de coordination de l'atome de Se, il existe deux contacts intramoléculaires et quatre contacts intermoléculaires Se...O qui sont à l'intérieur des limites de van der Waals. La géométrie globale de coordination est assez irrégulière puisque deux anions triflates sont arrangés d'une façon assez différente par rapport au tétraèdre du SeO_3E. L'empilement cristallin comporte des couches de molécules qui interagissent. Dans le composé **2**, il y a un peu de désordre. Toutefois, l'arrangement principal de la molécule comprend des distances Se═O, Se—O(1) et Se—O(3) avec les ligands acétates qui sont respectivement de 1,575(9), 1,847(7) et 1,831(8) Å. La géomètrie globale de l'atome de Se de ce composé cet complétée par deux contacts intramoléculairer secondaires Se...O impliquant les deuxièmes atomes de O de chacun des acétates et deux contacts intermoléculaires impliquant l'oxygène d'atome du séléninyle et l'atome O(2) d'un groupement acétate qui sont situés dans deux molécules qui sont différentes du point de vue de la symétrie. Dans l'ensemble, l'empilement cristallin comprend essentiellement des unites dimères centrosymétriques qui sont liées entre elles par le bias de ponts Se═O—Se. On a aussi préparé un adduit 1:2 du composé **1** avec la pyridine et on l'a caractérisé.

[Traduit par la revue]

Introduction

Earlier studies on seleninyl compounds included the synthesis of $SeO(SO_3F)_2$ (1), $SeO(C_2O_4)$ and $SeO(OOCCH_3)_2$ (2). Ionic dissociation into $SeOSO_3F^+$ and SO_3F^- was proposed to account for the high electrical conductivity of $SeO(SO_3F)_2$ (1). On the basis of infrared measurements alone a trigonal pyramidal SeO_3 group with a planar covalently bonded oxalate and planar covalently bonded acetate groups to Se has been proposed for $SeO(C_2O_4)$ and $SeO(OOCCH_3)_2$. In this paper we report the syntheses of $SeO(SO_3CF_3)_2$ and $SeO(OOCCH_3)_2$, their X-ray crystal structures and other spectral measurements. The complex of **1** with pyridine, $SeO(SO_3CF_3)_2.2C_5H_5N$, has also been isolated.

[1]Revision received April 15, 1988.

Experimental methods

Seleninyl chloride (Alfa) and trifluoromethanesulfonic acid anhydride (Aldrich) were used without further purification. All the reagents involved were highly hygroscopic and required handling in a nitrogen atmosphere dry box. Selenium was determined in its elemental form by reduction of the compounds with hydrazine hydrochloride and SO_2 solution in water. Sulphur was determined as $BaSO_4$. C, H, and N were determined microanalytically.

Preparations

Seleninyl bis(trifluoromethanesulfonate), $SeO(SO_3CF_3)_2$

Reaction was carried out in a two-bulb glass vessel incorporating a Rotoflow valve and a teflon covered stirring bar. In a typical experiment, 1.52 g (9.2 mmol) of $SeOCl_2$ was distilled into one arm of the double ampule vessel followed by 3.1 mL (5.2 g, 18.4 mmol) of trifluoromethanesulfonic acid anhydride with the help of a calibrated

[e]Weights given by $[\sigma^2(F) + pF^2]^{-1}$.

glass syringe in the dry-box. The contents were stirred in a warm water bath at ca. 60°C, while keeping the other arm of the ampule in an ice–water bath. After a few hours, a colourless liquid distilled over to the other side and a yellow crystalline (needle-shaped) product separated out. After about 8–10 h, the mother liquor was distilled into the other arm by cooling it in a dry ice – acetone bath. The arm containing the yellow crystalline product was then flame sealed.

The product was analysed to be $SeO(SO_3CF_3)_2$. *Anal.* calcd. for $SeC_2F_6S_2O_7$: C 6.11, Se 20.09. S 16.29; found: C 6.02, Se 20.2, S 16.1. The mother liquor distilled at 31–32°C and was identified as CF_3SO_2Cl by its Raman spectrum (3). The following bands were observed (cm^{-1}): 1454(m), 1269(vs), 1236(w), 1123(m), 782(vs), 702(s), 640(w), 592(w), 564(m), and 546(m). The band at 702 cm^{-1} is assigned to a S—Cl stretch.

The adduct of $SeO(SO_3CF_3)_2$ with pyridine was prepared by adding an excess amount of pyridine to the suspension of the compound in light petroleum ether at 0°C. The pale-white product was filtered under vacuum and dried *in vacuo*. *Anal.* calcd. for $SeC_{12}H_{10}N_2F_6S_2O_7$: C 26.13, N 5.08, S 11.62, Se 14.33; found: C 26.02, N 5.20, S 11.3, Se 14.0.

Seleninyl bis(acetate)

This was prepared by the literature method (2). In a typical experiment seleninyl chloride (2.45 g, 0.0148 mol) was stirred with anhydrous sodium acetate (2.44 g, 0.0298 mol) in dry diethylether (30 mL) for about 8 to 10 h and the precipitated silver chloride was filtered off. The solution was reduced to one-third of its volume by pumping off the solvent. The solution gave colourless needle-shaped crystals on cooling to about 3–4°C. The crystals were removed by vacuum filtration and dried. *Anal.* calcd. for $SeC_4H_6O_5$: C 22.54, H 2.82, Se 37.08; found: C 22.36, H 2.67, Se 38.0.

The infrared spectrum of $SeO(SO_3CF_3)_2$ was recorded as a neat sample on silver chloride plates and that of $SeO(OOCCH_3)_2$ as a KBr pellet by the use of a Perkin-Elmer model 283 spectrophotometer. Raman spectra were recorded with a Spex Industries Model 1400 spectrometer equipped with a double monochromator, an RCA C31034 phototube detector, an electrometer amplifier and a recorder. The exciting radiation was the green 5145 Å line of a Spectra-Physics Model 140 Ar^+ laser. Both solid and liquid samples were sealed in 1/4 in. o.d. Pyrex tubes. A ^{19}F nmr spectrum was recorded on a Bruker WM 250 spectrometer operating at 235.35 MHz.

X-ray crystallography

Crystals of **1** and **2** as thin colorless needles or blocks were selected and sealed in 0.2–0.3 mm Lindemann capillaries in a dry box under a N_2 atmosphere. Further work on an Enraf-Nonius CAD4 diffractometer gave the crystal data summarized in Table 1, which also contains a summary of the intensity measurements and structure refinements undertaken. Lorentz and polarization corrections were applied to all data collected. Absorption corrections were made at a

later stage of the refinements by the use of the progam ABSORB of the Enraf-Nonius SDP package (4). Least-squares refinement minimizing $\Sigma w\Delta F^2$ and including extinction corrections for **1** then converged to the indicated residuals. The final atomic positional and equivalent isotropic thermal parameters are given in Table 2, bond lengths, bond angles, and information about the secondary bonding in Table 3. Tables of anisotropic thermal parameters and final structure factor amplitudes for both compounds have been deposited.[2]
