Results and discussion

Seleninyl bis(trifluoromethanesulfonate)

Reaction of seleninyl chloride with trifluoromethanesulphonic acid anhydride yields seleninyl bis(trifluoromethanesulphonate) in quantitative yield according to:

$$SeOCl_2 + 2(CF_3)_2S_2O_5 = SeO(SO_3CF_3)_2 + 2CF_3SO_2Cl$$

This compound is highly sensitive to moisture, fumes in moist air, and is reduced to elemental selenium. It has a pungent smell, is soluble in most of the common organic solvents such as CCl_4, CH_3CN, CH_3NO_2, $C_6H_5NO_2$, and DMF, and decomposes in DMSO to give elemental Se. Its millimolar solution in acetonitrile is non-conducting, thereby suggesting the covalent nature of $SeO(SO_3CF_3)_2$. The ^{19}F nmr spectrum shows a single peak at −73.6 ppm from external $CFCl_3$. This resonance occurs in a region characteristic for trifluoromethanesulphonates (5).

The ir and Raman spectra of $SeO(SO_3CF_3)_2$ are given in Table 4. Earlier vibrational studies on trifluoromethanesulphonates have provided information on ionic SO_3CF_3 groups (6), covalently bonded monodentate OSO_2CF_3 groups (7) and bidentate bridging SO_3CF_3 groups (8). Problems exist for accurate assignments for the SO_3CF_3 group owing to the possibility of S—O and C—F vibrations of identical symmetry being observed in the same spectral region (9, 10). Some band assignments in Table 4 have been made assuming that the C_{3v} symmetry for an isolated CSO_3 moiety (or a tridentate trifluoromethanesulphonate group) which would be responsible for six fundamentals, three E [$\nu_{as}(SO_3)$, $\delta_{as}(SO_3)$, and $\delta_s(SO_3)$] and three A [$\nu_s(SO_3)$, ν(S—C), and $\delta_s(SO_3)$] modes of ir-active vibrations is lowered to C_s as may be the case for a monodentate type of coordination. In the latter case the three E modes are split to give six bands and a total of nine ir-active bands. In the vibrational spectrum of $SeO(SO_3CF_3)_2$ both ν_4 and ν_5 modes are split indicating that the CSO_3 symmetry is reduced below C_{3v} and is consistent with a SO_3CF_3 coordination in which one oxygen is more strongly bonded to the selenium than the other two as is evident from the X-ray diffraction data below. Similarly, the selenium–oxygen vibration of the seleninyl bond at 1024 cm^{-1} is higher than that for $SeOCl_2$ (955 cm^{-1}) (11), $SeOF_2$ (1012 cm^{-1}) (12), and SeO_2F_2 (1014 cm^{-1}) (13) but significantly lower than that observed for $SeO(SO_3F)_2$ (1055 cm^{-1}) (1).

The Lewis acid character of $SeOCl_2$ is well known (14). Similar behaviour of $SeO(SO_3CF_3)_2$ has not been demonstrated and it was also possible that two or more monodentate ligands could displace the trifluoromethanesulfonate ligand(s) from this compound. In order to distinguish between these two possibilities, we have investigated the reaction of $SeO(SO_3CF_3)_2$ with pyridine which results in the formation of a 1:2 addition complex, $SeO(SO_3CF_3)_2.2C_5H_5N$. Comparison of the infrared spectrum of this adduct with that of the original compound suggests that bands due to S—O and Se=O stretching modes are observed at frequencies very close to those observed in the parent compound. Bands due to C—C, C—N, ring-breathing frequencies, and the three in-plane C—H deformations are observed at considerably higher frequencies than in pure pyridine. This is consistent with coordination to selenium through the nitrogen of pyridine (15).

Seleninyl bis(acetate)

This compound is soluble in all common organic solvents, very hygroscopic, and on exposure to moist air undergoes decomposition. It has a pungent smell, typical of selenium compounds. The ir spectrum of **2** is reported in Table 4. Several ir studies of the acetate ion have been reported and band assign-

ments have been made (16, 17). In **2** two intramolecular Se...O contacts involving the second oxygen atoms of the acetate groups are observed so that the coordination of the acetate group to selenium may be classed as unsymmetrically bidentate (18). The difference $\Delta\nu$ ($\nu_1(COO^-)-\nu_s(COO^-)$) is suggested to be somewhat indicative of the mode of coordination of the acetate group in different complexes with the separation in the free ion values (ca. 1560 and 1416 cm^{-1}) increasing in unidentate complexes and when the acetate bridges two metal centres due to the increasing difference in the carbon–oxygen bond orders (18, 19). In the present compound the slight differences in the acetate coordination modes observed in the crystal structure (see below) are not apparent in the spectra and the large $\Delta\nu$ separation of 500 cm^{-1} is consistent with an unidentate mode in which the interaction of the second oxygen atoms of the acetates with the selenium is quite weak.

Another notable feature in the spectrum is the observation of a Se═O stretching band at 955 cm^{-1} in seleninyl bis(acetate). This band is observed at a much lower value than that in seleninyl bis(trifluoromethanesulfonate) (1024 cm^{-1}) although

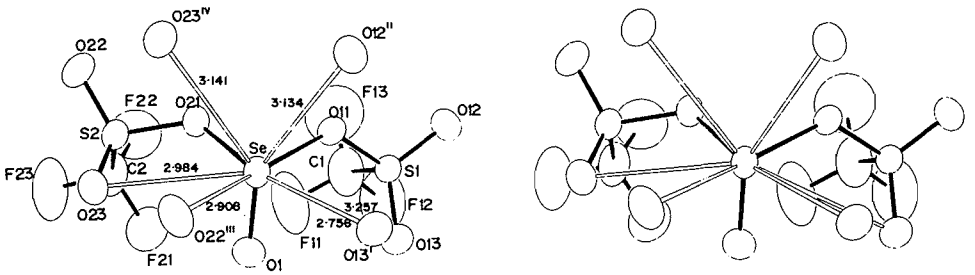

FIG. 1. Stereoscopic view of $SeO(O_3SCF_3)_2$ showing the complete coordination geometry of the Se atom. Secondary bonds are indicated by the unfilled bonds.

the selenium–oxygen distances (1.575 Å in $SeO(OOCCH_3)_2$ and 1.571 Å in $SeO(O_3SCF_3)_2$) are the same and do not suggest that there should be any shift towards higher wave numbers in the acetate. Such a correlation between Se—O bond distance and its stretching frequency is very difficult to draw without X-ray structures. The lowering in selenium–oxygen stretching frequency in $SeO(OOCCH_3)_2$ may be attributed to intermolecular interactions btween the oxygen of the Se=O group and the Se atom of another molecule.

Discussion of crystal structures

(1) Seleninyl bis(trifluoromethanesulfonate)

The primary geometry of the selenium atom in $SeO(O_3SCF_3)_2$ is AX_3E with a Se=O distance of 1.571(3) Å and Se—O bond lengths to the trifluoromethanesulfonate ligands of 1.902(3) and 1.922(3) Å. Completing the overall coordination geometry of this Se atom are two intramolecular and four further intermolecular Se...O contacts which are less than the sum of the neutral atom van der Waals radii for Se and O (3.35 Å). This overall Se coordination geometry is not easily described since the two triflate anions are significantly differently rotated about the Se—O(11) and Se—O(21) bonds so that the molecule has no overall molecular symmetry. This can be seen in the difference between the two torsion angles τ(Se—O(21)—S(2)—O(23)) = −1.4(3) and τ(Se—O(11)—S(1)—O(13)) = −16.5(3)° and the enlargement of the angle Se—O(11)—S(1) = 128.1(2)° over Se—O(21)—S(2) = 119.1(2)°. Similarly this results in the two atoms O(13) and O(23) forming the intramolecular contacts being 0.913(3) and −0.761(3) Å, respectively below and above the O(1)—O(11)—O(21) basal plane (Se is −0.860 Å above the plane). The long Se...O(13) intramolecular contact (3.257(3) Å) is however, compensated for by the fairly short intermolecular Se...$O(13)^I$ contact (2.758(3) Å). This latter contact and the intermolecular contact Se...$O(22)^{III}$ are approximately *trans* to the Se—O(11) and Se—O(21) bonds (O(11)—Se...$O(22)^{III}$ = 152.9(5)°; O(21)—Se...$O(13)^I$ = 169.0(1)°) and with the two remaining intermolecular contacts to $O(12)^{II}$ and $O(23)^{IV}$ clearly avoid and help define the position of the expected lone pair on Se (Fig. 1).

Secondary bonding is invariably present in seleninyl compounds and their related ions and adducts (14, 20) but it is rare to observe as large a number of contacts as that found for the present compound. By the use of a formalism proposed (21) for the description of the overall primary and secondary geometries of Sb(III) and related compounds the geometry in the present compound might be approximately denoted as $AX_3(Y')Y'_2Y_3E$ with O(23), O(13), and O(12) as the face capping [Y] contacts, $O(23)^{III}$ and $O(22)^{IV}$ the edge bridges [Y'] and the intramolecular contact to O(13) is considered to bridge the O(1)...O(11) edge of the polyhedron. The arrangement of the present intermolecular contacts is similar to the overall geometry of one of the Se atoms in the compound $(Se_4S_2N_4)(AsF_6)_2$ (see Fig. 3 in ref. 22) and has been observed in other compounds, e.g. the environment of the Sb(III) atom in $CsSbClF_3$ (21).

The strengths of these and other secondary bonding interactions can usually be approximately calculated using the bond valence curves of Brown and others (23). For Se(IV)—O interactions the curve has the form $S = S_0 (R/R_0)^{-N}$ with $S = 1.0$, $R = 1.796$ Å, and $N = 4.0$, and its application results in a bond valence sum Σs for all the selenium–oxygen distances indicated in Fig. 1 of 4.03, compared to the expected value of 4.0. The six longer intra- and intermolecular contacts account for 19% of this sum.

The primary and secondary bond lengths in $SeO(O_3SCF_3)_2$ are compared to values for other seleninyl compounds in Table 5. It is notable that the present Se=O distance has the same value as that in the $SeOCl_2$·dioxane solvate (14) although the O atom in the latter compound is also involved in Se...O secondary bonding (2.902(11) Å). Both of these values are somewhat shorter than other values in the table and nominally Se=O distances in compounds such as H_2SeO_3 (Se=O = 1.643 Å) (24). Similarly, the Se—O single bonds to the triflate anions are significantly different due to the different arrangement of the anions as noted above. Both distances are enlarged over distances observed in selenates or selenites (⟨Se—O⟩ = 1.641 and 1.704 Å respectively) (20*b*). The long weak Se—O(11), O(21) and short, strong Se—O(1) bonds explain the contracted small O(11)—Se—O(21) bond angle of 84.5(1)° and enlarged O=Se—O bond angles (102.3(2), 106.1(2)°). The significant 3.8° difference in the latter angles is consistent with the Se—O(11), O(21) bond lengths since the smaller angle involves the longer Se—O(21) bond, although the intermolecular contacts will also affect these angles slightly.

As a consequence of the intermolecular contacts, the crystal packing (Fig. 2) consists of layers of interacting molecules in the $(\bar{1},0,1)$ plane held together by F...F contacts between the CF_3 groups on the upper and lower surfaces of each layer.

In the trifluoromethanesulfonate groups the C—F and S—C bond lengths are normal (25). In ionic examples the lengths of the S—O bonds, however, are a function of hydrogen bonding and other contacts (26) but are typically ≤1.46 Å in length. Similarly, in two organometallic examples where the ligand is directly bonded to the metal the S—O distances of 1.456(6) Å (aquodimethyl(trifluoromethanesulfonato)gold(III)) (27) and 1.441(8) Å (trifluoromethanesulfonato)-(3-(diethylamino)-propionyl)(diethylamine)palladium(II)) (28) are still significantly shorter than the present S(1)—O(11) and S(2)—O(21) distances (1.535(3) and 1.541(3) Å). Moreover, these

distances and the short S(1)—O(12), O(13), and S(2)—O(22), O(23) distances as well as the OSO and CSO bond angles are more compatible with the dimensions of trifluoromethane sulfonic acid (S—OH = 1.531(4), S—O = 1.412, 1.424(3) Å) (29).

(2) Seleninyl bis(acetate)

There is some disorder in this compound involving a few residual peaks representing up to ca. 25% of an oxygen atom (Table 2). The peaks denoted O(4b), C(3a), and C(4a), along

with O(4a) appear to define an alternative arrangement of one acetate; those denoted O(1b) and O(1c) result in alternative bridging arrangements involving the seleninyl group or even possibly the presence of $SeOCl(OOCCH_3)$ in the lattice. The following discussion is, however, limited to the geometry and packing of the major component atoms. As with $SeO(O_3SCF_3)_2$ above, the primary geometry of the Se atom in $SeO(OOCCH_3)_2$ consists of a Se=O bond of length 1.575(9) Å and Se—O bonds to the acetate ligands of lengths 1.847(7) and 1.831(8) Å. Both of the latter distances are significantly shorter than the Se—O distances to the triflate ligands. Completing the overall geometry of the Se atom are two intramolecular contacts involving the acetate oxygen atoms O(2) and O(4a) of lengths 2.637(9) and 2.814(7) Å and two intermolecular contacts involving the seleninyl oxygen atom (2.862(10) Å) and O(2) (3.126(8) Å) of symmetry related molecules. Overall the packing consists of centrosymmetric dimeric units linked by the interactions involving O(2) which are further enchained by the bridging Se=O...Se interactions (Figs. 3 and 4).

The environment of the Se atom might be designated as $AX_3Y_3Y'E$ representing a monocapped octahedral arrangement of ligands and lone pair which is further distorted by the second intermolecular contact involving O(2). As with $SeO(O_3SCF_3)_2$, a bond valence calculation gives a Σs of 4.16 for all the selenium–oxygen interactions in $SeO(OOCCH_3)_2$ with the longer secondary interactions accounting for 15% of this sum.

Consistent with the stronger Se—O(Ac) bonding in the present compound it is notable that the O(1)—Se—O(3) angle between the acetate ligands is ca. 3° larger (87.5(4)°) and the O=Se—O(1),O(3) angles are ca. 3° smaller (102.7, 98.6(4)°) than corresponding values in $SeO(O_3SCF_3)_2$ above (84.5(1), 106.1, and 102.3(2)°). In the acetate groups it is notable that the interactions involving O(2) results in a smaller Se—O(1)—C(1) angle (108.1(6) cf.Se—O(3)—C(3)=114.4(7)°) and an apparent lengthening of the C(1)—O(2)=1.227(12) Å bond (cf. C(3a)—O(4a)=1.194(14) Å).

Prototropic reactions for 1-, 2-, and 4-fluorenamides in the ground and excited singlet states

RAMASAMY MANOHARAN AND SNEH K. DOGRA[1]
Department of Chemistry, I.I.T. Kanpur, Kanpur-208 016, India

Received November 26, 1987

RAMASAMY MANOHARAN and SNEH K. DOGRA. Can. J. Chem. **66**, 2375 (1988).

Absorption and fluorescence spectra of 1-, 2- and 4-fluorenamides (1-FAm, 2-FAm, 4-FAm) were studied in different solvents and at various acid concentrations. This study indicates that the long wavelength absorption band is long-axis polarised in 2-FAm whereas in 1-FAm and 4-FAm, it is composed of long- and short-axis polarised transitions. The —$CONH_2$ group in 1-FAm and 4-FAm is coplanar with the fluorene moiety, whereas the same group in 2-FAm is non-coplanar with the fluorene ring in non-polar solvents, both in S_0 and S_1 states, but attains coplanarity in the polar and hydrogen bonding solvents in the S_1 state. Hammett's acidity scale is not valid for the protonation reaction of amides and a medium effect is observed on the absorption spectra of the monocations in strong sulphuric acid. The prototropic equilibrium for the protonation of ring carbon atom is not established in the S_1 state, due to the slower rate of protonation reaction. Proton-induced fluorescence quenching of the monocations is followed before the monocations are being protonated.

RAMASAMY MANOHARAN et SNEH K. DOGRA. Can. J. Chem. **66**, 2375 (1988).

Utilisant différents solvents et des concentrations différentes d'acide, on a étudié les spectres de fluorescence des fluorénamides-1, -2 et -4 (FAm-1, FAm-2, FAm-4). Ces études indiquent que la grande longueur d'onde d'absorption est polarisée selon le grand axe dans le composé FAm-2 tandis que dans les composés FAm-1 et FAm-2 cette longueur d'onde est composée de transitions polarisées selon les deux axes. Le groupe —$CONH_2$ du compé FAm-1 et l'unité fluorène sont coplanaires, tandis que dans le composé FAm-2, cette coplanéarité n'existe pas dans les solvants non-polaires dans les états S_0 et S_1, mais on l'observe dans l'état S_1 dans les solvants polaires et dans les solvants contenant des liaisons hydrogènes. L'échelle d'acidité de Hammett n'est pas valable pour la réaction de protonation des amides et on observe un effet du milieu sur les spectres d'absorption des monocations dans l'acide sulfurique fort. On n'a pas pu déterminer l'équilibre prototropique de la protonation de l'atome de carbone du cycle dans l'état S_1, à cause de la vitesse plus lente de la réaction de protonation. On observe l'arrêt de fluorescence du monocation, induit par le proton, avant la protonation des monocations.

[Traduit par la revue]

Introduction

Many organic molecules possess more than one site of protonation or deprotonation and determining which of these is the main reaction is not always simple. Amides are one group of such molecules where the site of protonation can be either the carbonyl oxygen or the nitrogen atom of the amino group. Stewart (1) has recently reviewed this subject. Liler (2) favoured the site to be the amino-nitrogen atom. This was based on the fact that (*i*) the hydroxide-catalysed reaction is faster than the hydronium-catalysed one (3–5) and (*ii*) the pK_a values for the prototropic reactions (~−2) are not consistent with the pK_a values (~−7) of similar reactions of other carbonyl groups in carboxylic acids and esters (6, 7). Liler (2) also proposed that while in aqueous sulphuric acid the protonation occurs at the amino-nitrogen group, in concentrated or anhydrous sulphuric acid, it occurs at the carbonyl oxygen atom, indicating the presence of tautomerism.

However the vast majority of workers in this field have concluded that the site of protonation is the carbonyl oxygen atom and a large amount of evidence now exists in favour of oxygen protonation (8–16). Their studies also include (*i*) Hammett's acidity scale cannot be used to calculate the pK_a value for this prototropic reaction (8–11); thus a new scale, H_A, was developed to calculate the pK_a value in the real thermodynamic sense (10); (*ii*) the absorption spectra of the monocations of the amides depend on the environment and a regular red shift in the absorption spectrum is observed with an increase in acidity (11*c*, *d*).

Unfortunately, theoretical studies have not been able to solve this controversy. Although they favour oxygen protonation in the gas phase, they predict that increasing "pyramidization" of the —NH_2 group, which might occur in solution, increases the nitrogen basicity and decreases the oxygen basicity (17).

Our aim in the present study of 1-fluorenamide (1-FAm), 2-fluorenamide (2-FAm), and 4-fluorenamide (4-FAm) is to study the effect of solvents and acid concentration on the absorption and fluorescence spectra of these amides. At the same time, we have tried to assign the nature of the transition of the longest wavelength band and to calculate the pK_a values for the various prototropic reactions in the ground and excited singlet states.

Materials and methods

Acid chlorides of 1-fluorenecarboxylic acid (1-FA), 2-fluorenecarboxylic acid (2-FA), and 4-fluorenecarboxylic acid (4-FA) were prepared by the thionyl chloride method (18). After purification, these carbonyl chlorides were reacted with cold aqueous ammonia to give their corresponding amides. All the amides were recrystallised from ethanol and purity was checked by noting the melting points, elemental analysis, ir spectra, nmr spectra, and obtaining similar fluorescence spectra excited with different wavelengths. The data as listed in Table 1 agree reasonably well with the data of compounds containing similar functional groups. Analytical grade sulphuric acid, sodium hydroxide, *o*-phosphoric acid, and trifluoroacetic acid (TFA), all of BDH, were used as such. Analytical grade cyclohexane (SDS), dioxane (BDH), acetonitrile (E. Merck), and methanol (E. Merck) were further purified according to the procedure described in the literature (19). Triply distilled water was used for aqueous solutions. The modified Hammett's acidity scale (H_0) (20), as well as the H_A scale (10) for H_2SO_4–H_2O mixtures below pH 1 and Yagil's basicity scale (21) for NaOH–H_2O mixtures, above pH 13, were used.

Absorption spectra were recorded on a Shimadzu UV 190 spectro-

photometer, equipped with a U 135 recorder. Fluorescence measurements were made on a scanning spectrofluorimeter, fabricated in our laboratory, details of which are reported elsewhere (22). Both the excitation and emission monochromator were calibrated with a low pressure mercury lamp from time to time. The band width used for excitation is 8 nm. The quantum yields in different solvents were calculated for solutions with absorbance less than 0.1. The fluorescence spectra were corrected according to the procedure of Parker (23), and quinine sulphate in 0.1 N H_2SO_4 was used as a fluorescence standard (24). The excitation wavelength used for 1-FAm is 313 nm. 2-FAm and 4-FAm were excited at 300 nm. The fluorescence spectrum at 77 K was recorded in an aqueous medium with varying concentrations of acid. This system does not form a perfect glass and a lot of scattering was observed. The fluorescence spectrum of the different species at 77 K was obtained by scanning the solutions with and without fluorophore. The experiments in these solutions were designed to observe if the different prototropic species, which were non-fluorescent at 298 K, are fluorescent at 77 K. The concentrations of the solutions used were 2×10^{-5} M, containing no more than 1% (v/v) ethanol. For absorptiometric and fluorimetric titrations, the solutions were prepared just before taking measurements. The fluorescence intensity at any analytical wavelength was measured by exciting the solutions at their isosbestic points. The pH of the solutions in the range of 1–13 was measured on a Toshniwal pH meter model CL 44A.

Results

Effect of solvents

The absorption and fluorescence spectra of 1-FAm, 2-FAm, and 4-FAm were recorded in different solvents (shown in Fig. 1) and at various acid concentrations (shown in Fig. 2). The relevant data are compiled in Table 2. The data of Table 2 clearly show that the long wavelength absorption maximum of 1-FAm is more diffuse and largely red-shifted as compared to the maxima of 4-FAm, 2-FAm, and fluorene (25). In the case of 4-FAm, the absorption spectrum is broad and featureless. The absorption spectra of 2-FAm and 4-FAm resemble those of the respective carboxylic acids (26) but in case of 1-FAm, the spectrum is blue-shifted in comparison to 1-FA (1-fluorenecarboxylic acid) (27). In all cases, absorption spectra are unaffected by the nature of the solvent environment.

The fluorescence spectrum of 2-FAm is structured in cyclohexane but this structure is lost as the solvent polarity or proton donor/acceptor property of the solvent increases. The fluorescence spectral profile of 2-FAm resembles that of 2-FA (2-fluorene carboxylic acid) (26). On the other hand, the fluorescence spectra of 1-FAm and 4-FAm are broad and red-shifted, both with respect to fluorene (25) and to 2-FAm. Similar to 2-FAm, the fluorescence spectra of 1-FAm and 4-FAm are progressively red-shifted upon increasing the polarity and hydrogen bonding ability of the solvents. It can be noted from the data on Table 2 that the fluorescence band maxima of any one amide in any one solvent is blue shifted with respect to the corresponding acids, the blue shift being especially large for 1-FAm in water. The fluorescence quantum yield increases with increasing proton donor capacity of the solvents.

Effect of acid concentration

The absorption spectra of all the species remain unchanged in the range of H_- 16 to pH 0, except that a large red-shift is observed in the case of 4-FAm, after pH 14. Below pH 0, a red-shift is observed in all the amides. Clear isosbestic points are observed till $H_0 - 4$ followed by a continuous red-shift upto $H_0 - 7$ (Fig. 4). Similar behaviour is observed in other primary amides. The former behaviour is due to the formation of a monocation, whereas the latter behaviour is due to a medium effect (11*d*). A blue shift is observed after $H_0 - 7$, because of the dication species formed by protonating the ring carbon atom. Similar to the absorption spectra, the fluorescence spectra of the monocations are red shifted as compared to the neutral species, except that the monocation of 1-FAm is non-fluorescent in aqueous medium but fluorescent in cyclohexane + 2% TFA (v/v). Below $H_0 - 2$, the fluorescence intensities of monocations start decreasing without the appearance of any other new band. This has been assigned to the proton-induced fluorescence quenching of monocations as observed in naphthamides (28, 29). The blue-shifted fluorescence band below $H_0 - 4$ for 2-FAm is assigned to the dication, formed by the protonation of cabonyl oxygen atom and the ring carbon atom, but similar species of 1-FAm and 4-FAm are non-fluorescent at 298 K (*vide infra*). The fluorescence spectra of the neutral amides and monocations at H_0 0 and -6 (where the monocations are non-fluorescent at 298 K) and the dications at $H_0 - 10$ were recorded at 77 K. Unlike room temperature studies, all the species, are fluorescent and a normal blue shift is observed

TABLE 3. Acidity constants of fluorenamides in the ground and first excited singlet states[a]

Equilibrium	pK_a	pK_a^*	Förster cycle method (pK_a^*)		
			a	*f*	Average
1-FAmH$_2^{2+}$ ⇌ 1-FAmH$^+$ + H$^+$	−8.5				
1-FAmH$^+$ ⇌ 1-FAm + H$^+$	−1.87	2.1	−0.4	7.8	3.7
1-FAm ⇌ 1-FAm$^-$ + H$^+$	>16	13.8	—	—	—
2-FAmH$_2^{2+}$ ⇌ 2-FAmH$^+$ + H$^+$	−8.3	−7.8			
2-FAmH$^+$ ⇌ 2-FAm + H$^+$	−1.95	2.0	1.6	3.3	1.8
2-FAm ⇌ 2-FAm$^-$ + H$^+$	>16	13.6	—	—	—
4-FAmH$_2^{2+}$ ⇌ 4-FAmH$^+$ + H$^+$	−8.1	—			
4-FAmH$^+$ ⇌ 4-FAm + H$^+$	−2.2	1.8	1.8	5.6	3.0
4-FAm ⇌ 4-FAm$^-$ + H$^+$	>16	15.3	—	—	—

[a]pK_a^* (Förster) of 1-FAm and 4-FAm were calculated by using low temperature (77 K) fluorescence data.

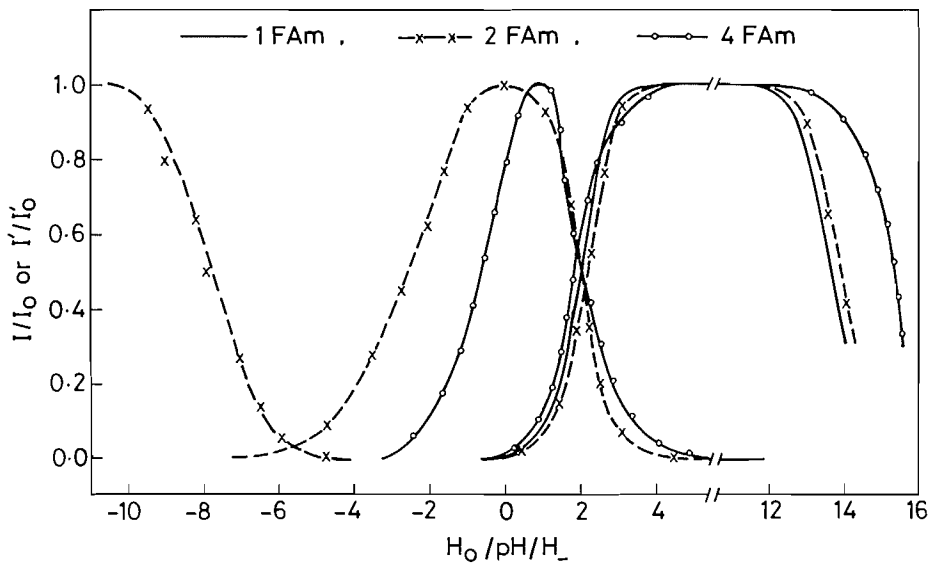

FIG. 3. Plot of I/I_0 vs. H_0/pH/H_-.

in the fluorescence spectra of each species as compared to those recorded at 298 K. Further at 77 K, the monocations are fluorescent at the acid concentration where they are non-fluorescent at 298 K. Under these conditions, the fluorescence spectra of the dications are blue shifted as compared to monocations. Similar behavior has also been observed for 2-FAm at 298 K. The fluorescence intensity of each amide also starts decreasing below pH 12, without the appearance of other new band.

The pK_a values for monocation–neutral and dication–monocation equilibria have been determined spectrophotometrically and are listed in Table 3, whereas the pK_a value for neutral–monoanion equilibrium cannot be determined as the formation of anion is not complete even in the highly basic medium used. The pK_a's in the excited state have been determined with the help of fluorimetric titrations (Fig. 3). The values are also listed in Table 3. The Förster-cycle method has been used wherever applicable to calculate the pK_a^* values listed in Table 3.

Discussion

Effect of solvents

It is well known that the moderately intense 300 nm and strong 265 nm absorption bands of fluorene are long-axis polarised, whereas the weak 287 nm band is short-axis polarised (30, 31). In 1-FAm and 4-FAm, the —$CONH_2$ group is along the shorter axis, whereas in 2-FAm, it is along the axis which predominantly affects the long-axis polarised transition. If the —$CONH_2$ group in any amide is coplanar with the fluorene moiety, the absorption transition of fluorene, polarised along that particular direction will be perturbed more than the other. The similarity of the spectral profile of 2-FAm and fluorene indicates that the conjugation between the π cloud of —$CONH_2$ group and fluorene moiety is minimal (Fig. 1). In other words, the —$CONH_2$ group is non-coplanar with the fluorene moiety in the S_0 state. The small red-shift of 3 to 4 nm observed in the long wavelength band of the fluorene molecule is due to the inductive effect of the —$CONH_2$ group. Whereas the large red-shift observed in the absorption spectrum of fluorene in 1-FAm and 4-FAm indicates that the —$CONH_2$ group is coplanar with the fluorene moiety. This is based on the following observations: (*i*) Unlike the fluorene spectrum, the long-wavelength bands of these compounds are broad and featureless. (*ii*) The long-wavelength absorption band is a mixture of the 300 nm band, which is not affected at all by the presence of the amide group and the weak 287 nm band, which is perturbed by the

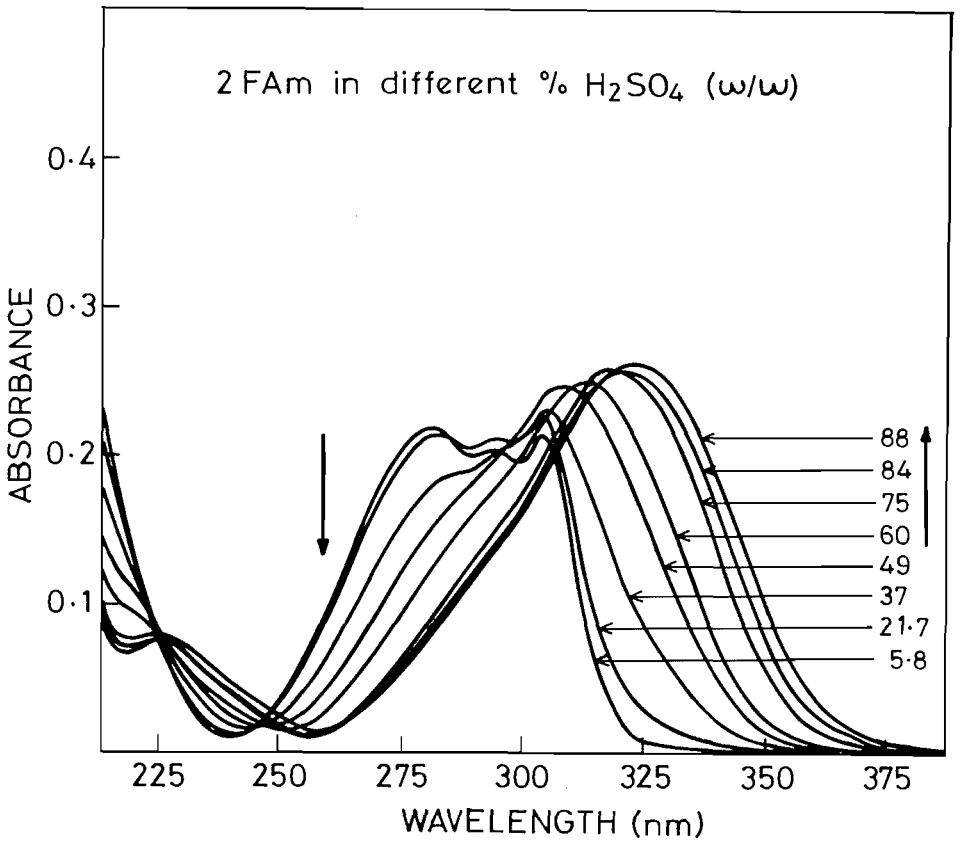

FIG. 4. Absorption spectra of 2-FAm in different wt.% H_2SO_4 acid.

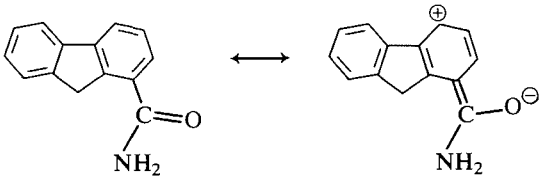
amide group. (*iii*) The molecular extinction coefficient data (25) of fluorene indicate that the first vibrational peak of the long wavelength band is more intense than the others toward the short-wavelength side, and than the 287 nm band. 4-FAm follows the same trend, therefore the 287 nm band is not stabilised enough to replace the 300 nm band.[2] However, the molecular extinction coefficient data of 1-FAm suggest that its short-axis polarised band (287 nm) is more stabilised than the long-axis polarised band (300 nm) and that it is of lower energy. This is explained by the fact that the molecular extinction coefficient of the first long-wavelength peak is less than that of the second peak in the 287 nm band. This may be due to more coplanarity of —$CONH_2$ group with the fluorene moiety and it may be due to the hydrogen bonding between the hydrogen atom at the 9-position and the amide group in 1-FAm. Similar behaviour is observed in 2-phenylbenzimidazole (33), where the phenyl group is coplanar with the benzimidazole moiety. On the other hand, the phenyl groups are non-coplanar in biphenyl (34). The higher pK_a value for the dissociation of 1-FA compared to the values for 2-FA, 3-FA, and 4-FA is due to hydrogen bonding from the hydrogen at the 9-position (35). The planarity of the phenyl and naphthalene rings in 1-fluoro-2-phenylnaphthalene in the S_0 and S_1 states have been explained on the basis of hydrogen bonding between the fluorine atom and the hydrogen atom of the C—H bond of the phenyl ring (34). The blue shift observed in the absorption spectra of 1-FAm and 4-FAm with respect to their respective carboxylic acids (26) is due to the presence of the amino group rather than to the presence of the hydroxy group. The amino group is a



I II

better charge donor than the hydroxy group and thus will increase the charge density at the carboxyl group. Due to the increased charge density at the carbonyl group, the canonical structure **II** is not very important in the resonance interaction as is observed in 1-FA. This consequently reduces the π electronic interaction between the two chromophores.

The fluorescence spectrum of 2-FAm in a non-polar solvent is different from that of 1-FAm or 4-FAm. The former shows a vibrational spacing $\sim 1420\,cm^{-1}$, whereas the latter are broad. The absorption and fluorescence spectra of fluorene are very complex and it has been shown that many vibrational modes are active in the long-wavelength electronic transition (30, 31) which is long-axis polarised. The absorption spectrum of 2-FAm illustrates this kind of behaviour and the vibrational frequencies observed in the absorption spectrum are close to 800, 500, and $1420\,cm^{-1}$. On the other hand, the fluorescence spectrum of 2-FAm shows only one vibrational mode with a frequency near $1400\,cm^{-1}$. This vibrational mode is one of the frequencies observed in the absorption spectrum indicating that fluorescence is taking place from the electronic state governing the absorption. This is also clear from the near-equivalence of the 0–0 transition observed in the absorption and fluorescence spectrum of 2-FAm.

The Stokes shifts ($\bar{\nu}_{max}$(abs) − $\bar{\nu}_{max}$(flu)) for 1-FAm, 2-FAm,

[2]This is based on the absorbance data as the molecular extinction coefficients could not be determined.

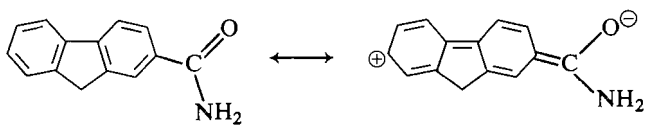
TABLE 4. Stokes shift (cm^{-1}) observed for 1-FAm, 2-FAm, and 4-FAm in different solvents and at various proton concentrations

Solvent	Stokes shift		
	1-FAm	2-FAm	4-FAm
Cyclohexane	1360	110	4515
Dioxane	2010	420	5160
Acetonitrile	2365	2020	5890
Methanol	3540	3310	7470
Water	5570	5120	8470
Monocation	—	6696	—
Dication	—	4764	—

and 4-FAm have been calculated in various solvents and recorded in Table 4. The long-wavelength maximum in the absorption spectrum matches the short-wavelength maximum in the fluorescence spectrum in non-polar solvents for 2-FAm. Very small Stokes shifts observed in non-polar solvents indicate that the geometry of the molecule (2-FAm) in the excited state is not different from that in the ground state and thus 2-FAm in non-polar solvents can be assigned to class-2 type molecules as suggested by Berlman (36). Molecular models demonstrate that the steric hindrance experienced by the amide group of 2-FAm from the adjacent hydrogen atoms is quite a bit less than that experienced by the amide group at the 1-position of 1-FAm. Substitution of the amide group at position 2 of fluorene should therefore be expected to impart more substantial changes in the absorption and fluorescence spectra of fluorene than substitution at position 1. Contrary to this, the absorption and fluorescence spectra of 2-FAm are structured compared to those of 1-FAm and 4-FAm, indicating that the amide group in 2-FAm is not coplanar with the fluorene ring in the ground and excited states. This is supported by the Stokes shift observed in cyclohexane for 2-FAm. This behaviour is similar to that observed for 2-FA (27), but quite different from that of many other carboxylic acids, where the —COOH group is not coplanar in the S_0 state but attains coplanarity with the parent aromatic molecule on excitation (37–39).

The vibrational structure is lost in more polar and hydrogen-bond forming solvents, indicating strong interaction between solute and solvent. Correspondingly large Stokes shifts are observed in more polar and better hydrogen-bonding solvents. The Stokes shifts observed in polar and hydrogen-bonding solvents (e.g. methanol and water) are so large for 2-FAm that this cannot be explained by simple solute–solvent interaction, especially where the amide group is not coplanar in a non-polar solvent. It seems that in polar and proton donor or proton acceptor solvents, the resonance form **II** becomes more favour-



I **II**

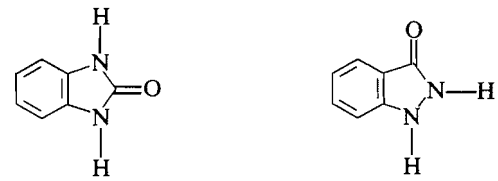
able in the excited state. This is due to a change in the electron density induced by the long-axis polarised transition dipole moment and is confirmed by the large Stokes shift observed in methanol and water as solvents. As might be expected, significant hydrogen bonding interaction with the solvent is better transmitted to the ring via coplanar configuration. The Stokes shift observed in the above environments for 1-FAm and 4-FAm are greater than those observed for 2-FAm, indicating that charge migration from the fluorene ring to the amide group of 1-FAm and 4-FAm is greater than that in 2-FAm in the first excited singlet state.

The increase in the fluorescence quantum yields of the amides in polar and hydroxylic solvents can be explained along the same lines as has been done by Lim and Yu (40) provided the $^1\pi\pi^*$ is the lowest singlet state and the energy gap between the $^1\pi\pi^*$ and the next singlet $^1n\pi^*$ is not too large, i.e., solvent dependent fluorescence from $^1\pi\pi^*$ singlet can be based on the assumption that efficient radiationless transition to the triplet states can occur through the vibronic interaction of the lowest excited singlet state with the $n\pi^*$ singlet state and the extent of this interaction depends upon the energy gap between these two states. In polar and hydroxyl solvents, the energy gap between $^1\pi\pi^*$ and $^1n\pi^*$ singlets will increase. This will decrease the vibronic interaction between these two states and thereby reduce the rate of intersystem crossing to triplet states. In other words, an increase in fluorescence intensity will be noticed in hydroxylic solvents. It has been shown that $^1\pi\pi^*$ is the lowest singlet state in benzoic acid and benzamide (41). It can also be speculated that $^1\pi\pi^*$ will be lowest energy singlet in the compounds studied here and based on our results it can be concluded that the energy gap between the $^1\pi\pi^*$ and $^1n\pi^*$ singlets is not very large.

Effect of acid concentration

Ground state

Monocations of primary amides can be obtained either by protonating the carbonyl oxygen or by protonating the nitrogen atom of the amino group, though more evidence exists for the former. It is very difficult from our study to locate the site of protonation, yet based on our study of the prototropic reactions of 2-benzimidazolone (42) (**1**) and 3-indazolinone (**2**) (43) we



1 **2**

conclude that the protonation in amides occurs on the carbonyl oxygen. In the case of molecule **1**, the first protonation in aqueous (where this structure is more stable) solutions should have occurred at pH ~ 4 and monocations should have been formed by protonating the >N—H group adjacent to benzene ring. On the other hand, the pK_a value observed for this reaction is −2.1. This pK_a is in the right region for carboxamide, which proves that the protonation has occurred at the carbonyl oxygen, rather than that at >NH group. Further protonation of the monocation of molecule **1** leads to a reorganization of bonds resulting in the benzimidazole structure as inferred from the absorption spectrum of the monocation. If the protonation had occurred at the >NH group, structural reorganization to the benzimidazole moiety would have also required the migration of proton from $>NH_2^+$ to the carbonyl oxygen atom, which is less favourable than simple charge migration in case

TABLE 5. Ground state pK_a of monocation–neutral equilibria of amides, using different data (see text)

of protonation at the carbonyl group. Similar results also exist for molecule **2**, as well as for *N*-methyl-2-benzimidazolone and *N*,*N*′-dimethyl-2-benzimidazolone (44, 45).

Two conclusions evident from the earlier studies on the prototropic reactions of the amides are (*i*) Hammett's acidity scale is not valid (10) and (*ii*) a continuous red-shift is observed with an increase in acid concentration (11*d*). As said earlier, the clear isosbestic points are observed up to $H_0 - 4$ to -5 but the red-shift in absorption spectra of the amides are observed up to $H_0 - 7$. If the red-shift in the absorption spectrum up to $H_0 - 7$ is because of the protonation of amides and the Hammett's acidity scale is valid, one should get a slope equal to -1 from the plot of H_0 vs. $\log [BH^+]/[B]$, where $[BH^+]$ and [B] are the concentration of the acid and its conjugate base, respectively. pK_a values have been calculated using H_0 and H_A scales and the relevant data are compiled in Table 5. It is clear from Table 5 that the H_0 acidity scale is not at all valid even for data up to $H_0 - 4$, whereas the H_A scale is followed when the data points are used up to $H_A - 4$. This clearly indicates that Hammett's acidity scale is not valid for these primary amides and that a medium effect is observed for the monocations. This is consistent with the literature, as said earlier.

Lovell and Schulman (46) have proposed that the failure of Hammett's acidity scale for the prototropic reactions of amides is because of the different hydration requirements of the prototropic reactions of the carboxamides relative to the hydration requirements of the dissociations of the primary amines, used as indicators to establish the H_0 scale. The following equation has been derived

$$H_0 - \log \frac{[B]}{[BH^+]} = pK_a - (n - r) \log a_w$$

where $(n - r)$ is the difference in the hydration number as described above and a_w is the activity of water. The slopes and intercepts from the plot of left hand side vs. $\log a_w$ are listed in Table 5. The a_w values were taken from a curve constructed from the data of Giauque *et al.* (47). The pK_a values obtained for each amide agree nicely with those calculated using the H_A scale. Slopes also indicate that two fewer water molecules are involved in the dissociation reactions of the protonated amides than in the dissociation reactions of ammonium ions used in the establishment of H_0 scale.

Acid hydrolysis of the amide group is possible. If the hydrolysis of the amide group had occurred, it would have yielded the monocations of the respective acids, formed by protonating the carbonyl group. This possibility is rejected on the ground that monocations of the respective acids are highly fluorescent and the fluorescence band maxima are at a longer wavelength (26, 27) than those of the neutral species. This indicates that even though acid hydrolysis of amides is possible, it is too slow to affect our results. The pK_a values for dication–monocation equilibrium are consistent with the value obtained for the prototropic reaction of fluorene (48). The pK_a for 4-FAm is the lowest and that for 2-FAm is the highest. In fluorene the electrophilic substitution takes place first at position 2 and then at positions 7 and 4 (25). In the case of 2-FAm, the second protonation will be at position 7 and the presence of an electron-withdrawing group at position 2 will decrease the charge density at position 7. On the other hand, in the case of 1-FAm and 4-FAm, the charge densities will be lowered at positions 2 and 3, respectively, i.e. *ortho* to each other. Thereby position 2 will be susceptible to attack by a proton in the case of 4-FAm, followed by 1-FAm and 2-FAm. Our results are also consistent with this argument.

First excited singlet state

Fluorimetric titrations clearly show that the amide group becomes more basic in the S_1 state. The pK_a^* for dication–monocation equilibrium has been calculated for 2-FAm, as the dications of the other amides are non-fluorescent at 298. The results obtained agree with similar protropic reactions of aromatic hydrocarbons (49–51) in the sense that the rate of protonation for aromatic hydrocarbon is so small that the prototropic equilibrium is not established during the lifetimes of the conjugate acid–base pair. The decrease in the fluorescence intensity of the neutral amide at pH > 12, could be due to either the base hydrolysis of the amides, hydroxyl-induced fluorescence quenching or formation of the monoanion, obtained either by deprotonation of the methylene group at posi-

For personal use only.

tion 9 or the $—NH_2$ group. The first possibility is rejected on the ground that the base hydrolysis of amides will lead to the formation of carboxylate anions and the anions of the respective carboxylic acids are fluorescent under these conditions (26, 27). Unfortunately, the monoanion obtained by the deprotonation of methylene group of fluorene and by the deprotonation of aromatic amines (52–54) (with few exceptions (55, 56)) are non-fluorescent. Further, pK_a^* obtained from the fluorimetric titrations for both the above equilibria nearly fall in the same region. This study indicates that it is not easy to find out whether the decrease in fluorescence intensity is due to hydroxyl-induced fluorescence quenching or to the formation of monoanions.

Lastly, fluorescence quenching of the monocations by protons is consistent with the results of Watkins (28) and Hussain and Wyatt (29). The quenching rate constants k_q cannot be calculated because of the unavailability of the lifetimes of the monocations. Strickler and Berg's (32) equation cannot be used because the appropriate absorption envelopes of the monocations are mixtures of two transitions, especially for 1-FAm and 4-FAm.

The fluorescence band maxima observed at 77 K are consistent with the earlier results that the blue-shift, observed as compared to the results at 298 K, is due to a reduced solvent interaction at low temperature. These results also indicate that the absence of fluorescence of the monocation of 1-FAm and the dications of 1-FAm and 4-FAm at 298 K is due to collisional quenching.

The formation of dication produces a blue shift, both in absorption and fluorescence relative to the monocation species. The pK_a values, calculated for the dication–monocation equilibrium, indicate that the protonation occurs at a ring carbon atom. As said earlier, the electrophilic attack on fluorene takes place first at position 2, then at positions 7 and 4 (25). In the case of 2-FAm, the protonation will occur at position 7. This will inhibit charge transfer, i.e., structure **II** will be unfavourable and hence the polarity of the dication will decrease. This will lead to a decrease in solvent interaction, thus increasing the gap between the two states. Similar arguments can be given for the other two amides. Similar results are also observed for the second protonation of fluorene carboxylic acids (26, 27).

Conclusions

The following conclusions can be drawn from this study. (*i*) The longest wavelength band in 2-FAm is long-axis polarised, whereas those of 1-FAm and 4-FAm are a mixture of long- and short-axis polarised transitions. (*ii*) The amide group in 1-FAm and 4-FAm is coplanar with the fluorene moiety, both in S_0 and S_1 states, whereas the same group in 2-FAm is not coplanar with fluorene, in both the S_0 and S_1 states in non-polar solvents, but attains coplanarity in polar and hydrogen bonding solvents in the S_1 state. (*iii*) Hammett's acidity scale is not valid for the prototropic reactions of the amides and a medium effect is observed in the absorption spectra of the monocations of the amides in concentrated sulphuric acid. (*iv*) The amide group becomes a stronger base in the S_1 state. (*v*) Proton-induced fluorescence quenching is observed for the monocations. (*vi*) The rate of protonation of the ring carbon atom is slow as compared to the rate of emissive decay.

MICHÈLE DARTIGUENAVE, YVES DARTIGUENAVE, ALAIN MARI, ANDRÉ GUITARD, MARC. J. OLIVIER, and ANDRÉ L. BEAUCHAMP. Can. J. Chem. **66**, 2386 (1988).

Two series of complexes have been prepared by reaction of 2,5-dimethyl-2,5-diisocyanohexane (TMB) with AgX (X = NO_3^-, BF_4^-, PF_6^-, ClO_4^-). Complexes of the first series, Ag(TMB)X, have been obtained with X = NO_3^-, BF_4^-, PF_6^-. The structures have been determined by X-ray diffraction for X = NO_3^- and BF_4^-. The crystals contain infinite chains of silver atoms alternating with bridging TMB ligands. When X = NO_3^-, the Ag atom is best described as (2 + 2)-coordinated, with two of the coordination sites filled by NO_3^- acting as a bidentate ligand. When X = BF_4^-, the Ag—TMB chain is of a different type and Ag can be considered two-coordinated and weakly interacting with a monodentate BF_4^- ion. The second series includes $Ag_2(TMB)_3X_2$ complexes whose structure consists of pairs of chains cross-linked by extra TMB ligands leading to a ladder-like pattern. A weak unidentate interaction involving ClO_4^- or PF_6^- is also apparent. The infrared data are in agreement with the X-ray results, since the highest $\nu(C{\equiv}N)$ value is obtained for $Ag(TMB)BF_4$, where Ag—CN distance is the shortest. The conformation of TMB is always *trans* about the central CH_2—CH_2 bond. The methyl groups render one of the staggered orientations of the —$C(CH_3)_2(NC)$ groups unfavorable, leaving two conformations for coordinated TMB, both of which are observed in the Ag complexes.

MICHÈLE DARTIGUENAVE, YVES DARTIGUENAVE, ALAIN MARI, ANDRÉ GUITARD, MARC. J. OLIVIER et ANDRÉ L. BEAUCHAMP. Can. J. Chem. **66**, 2386 (1988).

Deux séries de complexes ont été préparés par réaction du diméthyl-2,5 diisocyano-2,5 hexane (TMB) avec AgX (X = NO_3^-, BF_4^-, PF_6^-, ClO_4^-). Des complexes de la première série, de formule Ag(TMB)X, ont été obtenus avec X = NO_3^-, BF_4^- et PF_6^-. La structure a été déterminée par diffraction des rayons X pour X = NO_3^- et BF_4^-. Les cristaux contiennent des chaînes infinies d'atomes Ag alternant avec des ligands TMB pontants. Pour X = NO_3^-, l'atome Ag possède une coordination (2 + 2), deux des sites de coordination étant occupés par NO_3^- jouant le rôle de ligand bidentate. Lorsque X = BF_4^-, la chaîne Ag—TMB est d'un type différent, alors que Ag peut être considéré comme étant bicoordiné et participant à une faible interaction avec un ion BF_4^- monodentate. La deuxième série comprend des complexes $Ag_2(TMB)_3X_2$ dont la structure consiste en paire de chaînes Ag—TMB reliées entre elles par d'autres ligands TMB, qui donnent naissance à un motif en échelle. Il y a une faible interaction monodentate des ions ClO_4^- ou PF_6^- avec Ag. Les données infrarouges sont en bon accord avec les résultats cristallographiques, puisque la valeur la plus élevée de $\nu(C{\equiv}N)$ est obtenue pour $Ag(TMB)BF_4$, où la liaison Ag—CN est la plus courte. La conformation du TMB est toujours *trans* autour du lien CH_2—CH_2 central. Les groupes méthyles défavorisent l'une des orientations décalées des groupes —$C(CH_3)_2(NC)$, ce qui laisse pour le TMB coordiné deux conformations, qui sont toutes deux observées dans les complexes de l'argent.

Introduction

Although isonitriles are commonly used ligands, the potential of aliphatic diisonitriles has not been much explored as yet. End-on coordination at the terminal carbons and linear geometry at nitrogen impart to these molecules structural characteristics that have been used for developing unusual architectures in metal complexes of low nuclearity. For instance, a series of Rh(I) complexes containing Rh—Rh bonds have been shown by Gray, Mann, and their co-workers (1–3) to possess valuable photoredox properties. A mixed Rh—Mn compound has also been obtained (4). With Ni(II) and Pd(II), dinuclear species without direct metal–metal bonding show the interesting characteristic of being able to encapsulate halide ions (5). Aromatic diisonitriles, on the other hand, have been found to give rise to two-dimensional polymeric compounds which attracted attention for their potential use in heterogeneous catalysis (6).

Our research has been recently directed at assembling Ag atoms into complexes of low nuclearity. Diisonitriles were considered as potential ligands to bring together silver atoms, which do not usually form Ag—Ag bonds, but can be positioned side-by-side by trifluoroacetate (7), adenine (8), and other ligands (9). In a previous paper (10), we reported on the 2:3 $AgClO_4$ complex with 2,5-dimethyl-2,5-diisocyanohexane (TMB = "tetramethylbridge" (2)). This material was shown to be polymeric with the diisonitrile in an extended conformation and one ClO_4^- oxygen occupying a coordination site about silver. By using counter-anions whose Lewis basicity is either higher (NO_3^-) or lower (BF_4^-, PF_6^-), these compounds could show different coordinating characteristics. They are described in the present paper.

Experimental section

TMB (2,5-dimethyl-2,5-diisocyanohexane) was prepared as previously reported (10, 11). $AgNO_3$, $AgBF_4$, $AgPF_6$ (Fluka) were used as received. All the silver complexes were protected from light.

The infrared spectra were recorded on Perkin Elmer 577 or 983 spectrophotometers, as Nujol mulls between KBr disks or as KBr pellets.

Electrical conductivity of powdered samples was measured on compressed pellets with a Wayne and Kerr Model B 605 Automatic Com-

ponent Bridge. The resistance of the pressed pellet was measured directly in the "conductivity press" while applying a force of 700 kg on 2 mm diameter pistons moving in a glass capillary.

Ag(TMB)(NO$_3$), 3

TMB (2 mmol, 0.32 g) dissolved in acetonitrile (40 mL) was added to a stirred solution of $AgNO_3$ (0.34 g; 2 mmol) in methanol (20 mL). After 30 min, the solution was concentrated to 30 mL. A layer of ether (30 mL) was poured very delicately. White crystals appeared as the solvents diffused. They were filtered, washed with cold ether, and dried *in vacuo*. Yield: 80%. *Anal.* calcd. for $C_{10}H_{16}AgN_3O_3$: C 35.95, H 4.83, N 12.58; found: C 35.62, H 5.03, N 12.29.

Ag$_2$(TMB)$_3$(PF$_6$)$_2$·2CH$_3$CN, 2; Ag(TMB)(PF$_6$), 5

TMB (5 mmol, 0.82 g) dissolved in 50 mL of methanol was slowly added to 5 mmol (1.26 g) of $AgPF_6$ dissolved in 50 mL of methanol. Immediate precipitation of a white powder occurred, which was filtered, washed with ether, and dried *in vacuo*. Recrystallization overnight at −30°C in acetonitrile gave white crystals, which were filtered cold and washed with cold ether. They turned into a powder by drying *in vacuo* (ir, $\nu(C{\equiv}N) = 2235\ cm^{-1}$). *Anal.* calcd. for $C_{10}H_{16}AgF_6N_2P$, **5**: C 28.80, H 3.87, N 6.72; found: C 29.00, H 3.83, N 6.75. Recrystallization of **5** in acetonitrile gave, after 15 days at −25°C, white crystals of **2**, which were isolated following the same procedure, but not dried *in vacuo* (ir, $\nu(C{\equiv}N) = 2195\ cm^{-1}$). *Anal.* calcd. for $C_{34}H_{54}Ag_2F_{12}N_8P_2$, **2**: C 37.79, H 5.04, N 10.37; found: C 36.71, H 4.75, N 10.10.

Ag(TMB)(BF$_4$), 4

Same procedure as above using 11.8 mmol (2.30 g) of $AgBF_4$ in 25 mL methanol and 11.8 mmol (1.87 g) of TMB in 25 mL methanol/dichloromethane (40/10). Yield: 90%. *Anal.* calcd. for $C_{10}H_{16}AgBF_4N_2$: C 33.46, H 4.49, N 7.80; found: C 33.33, H 4.41, N 7.99. Recrystallization in methanol at 0°C yielded the crystals used for X-ray work (ir, $\nu(C{\equiv}N) = 2225\ cm^{-1}$). When recrystallized from a methanol/ether mixture, the microcrystalline precipitate consisted mainly of the above 1:1 complex ($\nu(C{\equiv}N) = 2225\ cm^{-1}$), together with a small amount of a compound whose $\nu(C{\equiv}N)$ vibration (2195 cm^{-1}) would be consistent with $Ag_2(TMB)_3(BF_4)_2$. However, this 2:3 complex, presumably similar to the PF_6^- compound, was not isolated in a pure form.

Crystallographic measurements and structure determination

An Enraf-Nonius CAD-4 diffractometer was used to obtain the cell dimensions, space group, and intensity data for compounds **2**, **3**, and **4**. A series of 20–25 randomly distributed reflections created by the automatic search procedure were centered in the counter. The reduced triclinic cell through these reflections was calculated by the autoindexing routine and checked by means of long-exposure oscillation photographs, which showed the expected layer line spacing about each of the crystallographic axes. Inspection of the Niggli matrix indicated that no higher symmetry was present for the PF_6^- compound, leaving *P*1 and $P\bar{1}$ as possible space groups. For the NO_3^- compound, Laue mirrors on the three oscillation photographs confirmed the orthorhom-

bic system suggested by the 90° angles of the reduced cell. The systematic absences ($0kl$, $k \neq 2n$, $h0l$, $l \neq 2n$; $hk0$, $h \neq 2n$) revealed by the full data set identified *Pbca* as the only possible space group. The Niggli matrix and the presence of a Laue mirror for oscillation about the 8.03 Å axis pointed to a *C*-centered monoclinic cell for the BF_4^- complex. The axes were redefined accordingly. Space groups *Cc* and *C2/c* were consistent with the systematic absences ($h0l$, $l \neq 2n$; $hk0$, $h + k \neq 2n$) noted in the data set.

The intensity data were collected following the method described earlier (10), using graphite-monochromatized MoKα radiation (λ = 0.71069 Å). The data were corrected for polarization and the Lorentz effect. They were not corrected for absorption owing to the low absorption coefficients.

The three structures were solved by the heavy-atom method and refined on $|F_o|$ by full-matrix least-squares procedures. For the BF_4^- and PF_6^- compounds, where two space groups were possible, resolution was first attempted in the centric space groups. This choice was confirmed by successful refinement. In each case, the Ag atom was located from a Patterson synthesis, and the remaining non-hydrogen atoms were found from a difference Fourier (ΔF) map phased on Ag. These atoms were refined isotropically, then anisotropically. All hydrogen atoms were visible in the subsequent ΔF map. They were introduced into the model and isotropically refined, simultaneously with the non-hydrogen atoms, which were anisotropically refined. The final ΔF map showed no significant electron density.

The conditions used for data collection and the results of the refinement are summarized in Table 1. The scattering curves were taken from Cromer and Waber (12), except for hydrogen (13). The anomalous dispersion contributions f' and f'' were included for Ag and P (14).

The refined positional parameters are listed in Table 2. The anisotropic temperature factors and the structure factor amplitudes are provided in the supplementary material.[2]

Results and discussion

All complexes are white solids, soluble in polar solvents such as methanol and acetonitrile. Two series of compounds are formed: $Ag(TMB)X$ ($X = NO_3^-$, BF_4^-, PF_6^-), *type 1*, and $Ag_2(TMB)_3X_2$ ($X = ClO_4^-$, BF_4^-, PF_6^-), *type 2*. With ClO_4^-, only a *type 1* complex has been obtained, and with NO_3^-, only a *type 2* complex. Both types were found to exist with PF_6^- and BF_4^-.

The infrared data are reported in Table 3 together with the Ag—C distances observed for the different complexes by X-ray diffraction (*vide infra*).

Coordination of the anion to silver is detected by infrared only for NO_3^-, which acts as a bidentate ligand ($\nu(NO_3^-)$ = 1470, 1275, 1030 cm^{-1}). These values are very similar to those reported for $Ni(dien)(NO_3)_2$: 1480, 1300, 1021 cm^{-1} (15, 16). Coordination of ClO_4^- is not apparent since only a broad ν_3 band is present at 1075 cm^{-1}. Similarly, only broad bands are observed for BF_4^- (ν_3 = 1075 cm^{-1}) and PF_6^- (ν_3 = 840 cm^{-1}).

Of particular interest is the $\nu(C\equiv N)$ vibration of the isonitrile ligand. Previous studies on the bonding in M—CNR groups have shown a direct correlation between $\nu(C\equiv N)$ and the strength of the M—CNR bond. Moreover, the decrease of the $\nu(C\equiv N)$ frequency was found to parallel the increase of the isonitrile/metal molar ratio and the charge on the metal (17–21). The experimental values in Table 3 are consistent with these trends. Higher values are observed for the *group 1* complexes **4** and **5** (TMB/Ag = 1) compared with the *group 2* species **1** and **2** (TMB/Ag = 1.5). Also, for *group 1* complexes, the greatest $\nu(C\equiv N)$ value is observed for complex **4**, that is, the one with the greatest Ag—C distance. Complex **3** behaves differently, which can be related to the higher Lewis basicity of NO_3^- compared to ClO_4^- or PF_6^-.

Electrical conductivity in the solid state was checked for **2** and **4**. As expected, both are insulators.

Crystal structure of $Ag_2(TMB)_3(PF_6)_2 \cdot 2CH_3CN$

Despite the presence of acetonitrile in $Ag_2(TMB)_3(PF_6)_2 \cdot 2CH_3CN$, this compound is structurally so close to $Ag_2(TMB)_3(ClO_4)_2$ (10) that they are virtually isomorphous. Comparison of Fig. 1 with the stereoview for the perchlorate analog (Fig. 2 in ref. 10) strikingly shows that the Ag—TMB frameworks are nearly superimposable. Both symmetry-independent TMB ligands exist as the extended conformer, with a *trans* conformation about the central C(3)—C(4) bond (see Fig. 2 for numbering scheme). This conformation invariably generates polymeric chains rather than dinuclear units. The —Ag—CN NC—Ag—CN NC—Ag— chains oriented along the ***b*** axis occur by pairs in the crystals. Junction is achieved by TMB molecules cross-linking corresponding Ag atoms in the two parallel chains, thereby defining a ladder-like pattern, in which the main chains of TMB ligands (type D) and silver atoms define the side arms, whereas the cross-linking ligands (type E) are the rungs.

Silver forms three coplanar Ag—C bonds of 2.135(5), 2.140(5), and 2.186(5) Å, respectively (Table 4). Departure from the ideal 120° values for the C—Ag—C angles (119.6, 110.5, 129.0, σ = 0.2°) is significant, but relatively small. Beside these three strong bonds, there is a long Ag—F(3) contact of 2.873(6) Å with the PF_6^- anion, which is found roughly at the same place as the ClO_4^- ion in the perchlorate analog (10). This Ag—F contact is weak compared with those of the bidentate PF_6^- ion (Ag—F = 2.668(14) Å) in the *t*-$Bu_3C_6H_2NC$ complex (22). In spite of the good affinity of Ag(I) for nitriles, the CH_3CN molecule is not coordinated to the metal, but simply fills space in the unit cell, interacting with its surroundings by normal van der Waals contacts. The intensity data for this compound were collected at 170 K. At this temperature, the PF_6^- ion and CH_3CN molecule have higher

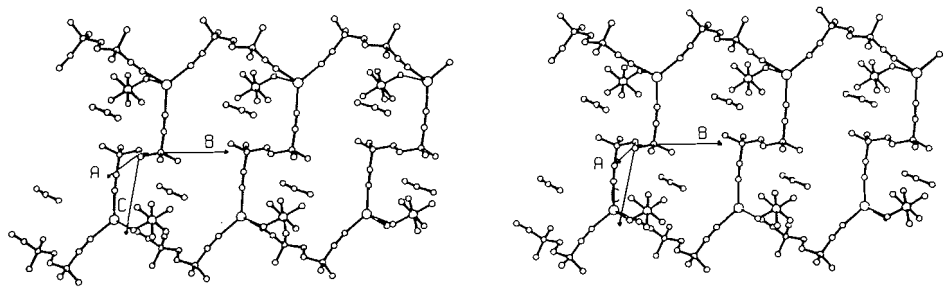

FIG. 1. Stereo view of molecular packing for $Ag_2(TMB)_3(PF_6)_2 \cdot 2CH_3CN$ down the a^* direction. Hydrogens are omitted for simplicity. The atoms are shown as spheres of arbitrary sizes, the larger ones corresponding to Ag. The anions, with thin bonds representing the contacts with Ag, are easily recognized.

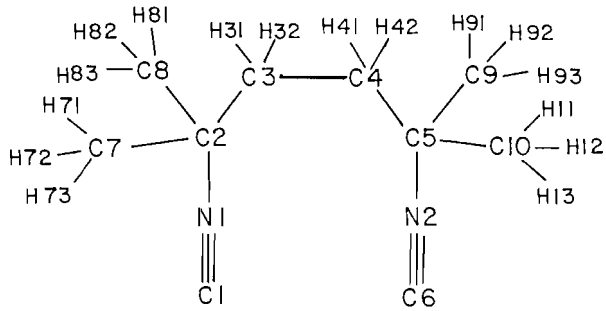

FIG. 2. Numbering scheme in the TMB ligand. Letters (A to G) are used to identify individual ligands in the various compounds.

thermal motion than the rest of the structure (Table 2), but they show no evidence for disorder, except for the methyl hydrogens of CH_3CN which were not located. At room temperature, however, the crystals remain stable only in sealed vials. In open air, they lose their crystallinity within a few minutes by evaporation of the lattice acetonitrile molecule.

Crystal structures of Ag(TMB)X, X = BF_4^- and NO_3^-

In contrast with the PF_6^- and ClO_4^- complexes, the BF_4^- and NO_3^- compounds contain one diisonitrile per metal. Again, the extended conformer of TMB alternating with Ag atoms generates infinite chains in both cases. However, these two compounds show different chain arrangement and metal–anion interaction.

The zigzag chains observed in the BF_4^- complex are shown in Fig. 3. These chains are built up from two symmetry-independent types of TMB ligands showing different relative orientations of their terminal $-CMe_2(NC)$ units. In type B ligands, the two roughly antiparallel $-N{\equiv}C$ groups bridge two silver atoms in the straight portion of the chain. Ligands of type C with their $-N{\equiv}C$ groups oriented ~60° apart define the bent portions. These interlocked chains generate layers parallel to the ***b*** axis and the cell ***ac*** diagonal. Layer thickness corresponds to the length of the extended TMB conformer, as the ligands C(2)—C(5) vectors are perpendicular to the layer surface. Cohesion between the layers is achieved by normal van der Waals forces.

In this BF_4^- compound, silver forms only two strong Ag—C bonds with a C—Ag—C angle of 167.8(3)°. Departure from the ideal 180° value is large, but not uncommon in silver chemistry. The Ag—C bonds (2.073(8) Å) are shorter than in the PF_6^- and ClO_4^- complexes, reflecting the reduction in coordination number from 3 to 2 (15). A long Ag—F(3) contact of 2.850(11) Å is also found. Thermal motion is very high for the BF_4^- anion in this crystal, whose intensities were collected at room temperature (see Fig. 5, supplementary material).

The nitrate compound contains a single type of diisonitrile (labelled A). Whereas the Ag—BF_4^- interaction is very weak, the better coordinating NO_3^- anion is found to interact to a much greater extent and in a bidentate manner via O(1) and O(2) (Fig. 4). The Ag—O distances (2.519(5) and 2.647(4) Å), although not the shortest known, are on the low side of the range for this type of interaction (23). The Ag—O contacts found here are definitely stronger than those observed in the ClO_4^- compound (Ag—O = 2.733(13) Å) (10). Greater donor ability of NO_3^- is also evidenced from the Ag—C bond lengths (2.123(5) and 2.091(5) Å) being greater than in the BF_4^- compound, and in the greater deviation of the C—Ag—C angle (144.9(2)°) from 180°. Thus, the Ag atom is best described here as (2 + 2)-coordinated, but the overall geometry around the metal does not fit a common polyhedron.

The NO_3^- ion is planar within 1σ (0.005 Å), but the metal lies at a large distance (0.23 Å) from this plane. This is probably due to intermolecular contacts involving the free O(3) atom. Coordination of O(1) and O(2) leaves the N—O bonds unchanged (1.245(6) and 1.250(6) Å) compared with the uncoordinated NO_3^- ion, but the distance to the free oxygen O(3) is shorter (1.224(7) Å). The O(1)—N(1)—O(2) angle (117.9(5)°) is also slightly reduced compared with those involving O(3) (120.8(5) and 121.3(5)°). Although these changes are significant only at the ~3σ level, they follow the trends noted for bidentate nitrate coordination (24).

The packing pattern (Fig. 4) shows layers of thickness ***c***/2, parallel to the ***ab*** plane. Cohesion between the layers is achieved by van der Waals contacts involving hydrogen atoms of TMB and the O(3) atom of the nitrate group. Within the layers, zigzag chains running roughly along the ***b*** direction are interlocked to fill space efficiently.

The structure of the ligand in the various complexes is compared in Table 5. The —C—N≡C portions of TMB should be linear and the lone pair should lie along this direction. There is a small, but significant, bend at nitrogen (C—N≡C = 173.6–179.1°) and a greater departure from linearity at the donor atom (Ag—C≡N = 169.3–176.8°, Table 4). These angles are likely to be very sensitive to crystal packing. The remaining distances and angles in TMB are normal (Table 5).

Conformation of the TMB ligand

The conformation of TMB in the complexes can be discussed from the torsion angles listed in Table 6. For all seven unequivalent ligands in four silver compounds, the diisonitrile adopts the *trans* conformation about the central C(3)—C(4) bond: deviation from 180° is less than 12°. Rotation about C(3)—C(4) toward a *trans–gauche* conformation is opposed by mutual repulsion between the substituents in the $-CMe_2(NC)$ terminal groups. On the other hand, each $-CMe_2(NC)$ group

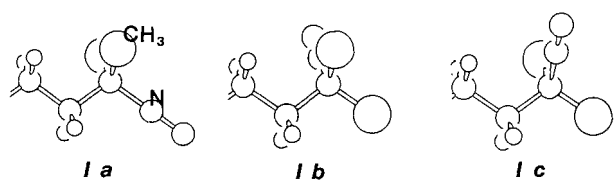
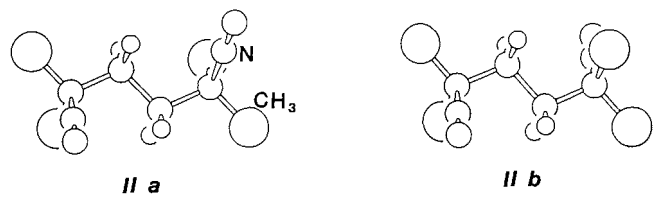


SCHEME 1



SCHEME 2

can adopt three possible staggered conformations (Scheme 1) with respect to the adjacent methylene group. However, Table 6 shows that only **I***b* and **I***c* are observed. A N(1)—C(2)—C(3)—C(4) angle of 180° (conformation **I***a*) would force both methyl groups close to the β methylene hydrogens. This is energetically unfavorable compared with **I***b* and **I***c*, where a methyl group is replaced by a less bulky isonitrile group in these β interactions. Combining the *trans* conformation about C(3)—C(4) with these two possible orientations for each of the $—CMe_2(NC)$ groups, four possible combinations (**II***a*, **II***b*, and their mirror images, see Scheme 2) are found for the relative orientations of the isonitrile groups in TMB. In conformer **II***b*, the —N≡C groups are oriented in opposite directions. This conformer is found for ligands B, E, and G (Table 6). For conformer **II***a*, the isonitrile groups are pointing 60° apart. This conformation occurs for ligands A, C, D, and F. Thus, these two conformations are found with roughly the same probability among the Ag compounds studied here. This reflects their probable similarity in energy.

These torsion angles (Table 6) can be compared with those found for $Rh_2(TMB)_4(PF_6)_2$, which are typical of systems where TMB is bridging two metal atoms in dinuclear species (2–4, 25). In the Rh complex, TMB conformation can be regarded as derived from **II***a*, by applying strain in the chain to bring the —N≡C groups closer together. This constraint changes only to a small extent the N(1)—C(2)—C(3)—C(4) and N(2)—C(5)—C(4)—C(3) angles, which are controlled by the steric effect of the methyl groups. Most of the distortion is absorbed by the central C(3)—C(4) region, where the system has moved from the *trans* conformation toward a less favorable *trans–gauche* orientation (C(2)—C(3)—C(4)—C(5) ~ 145°). In order to overcome this expense in energy, there must be a net im-

provement in overall isonitrile–metal binding energy in the dinuclear system, compared with the formation of the same number of bonds with two remote metal atoms. In the rhodium complexes, Rh—Rh bonding obviously overcomes this expense in energy. In the case of silver, the absence of Ag—Ag bonding leaves no energetically favorable alternative to the polymerized system. Therefore, TMB does not act as a dinucleating ligand for silver and it is unlikely to have marked potential to induce metal assembling in systems containing no otherwise preassembled metal atoms.

Received January 20, 1988

D. Larry Haire, Uwe M. Oehler, H. Duane Goldman, Robert L.Dudley, and Edward G. Janzen. Can. J. Chem. **66**, 2395 (1988).

We report the first ^1H and ^{14}N electron nuclear double resonance (ENDOR) spectra of oxygen-centered radical adducts (i.e., derived from the addition of *tert*-butoxyl radicals) of 5,5-dimethyl-1-pyrroline-*N*-oxide (DMPO) as well as the related cyclic nitrones: 4-phenyl-5,5-dimethyl-1-pyrroline-*N*-oxide (4-Ph-DMPO) and 3,3,5,5-tetramethyl-1-pyrroline-*N*-oxide (M_4PO). Features of the electron paramagnetic resonance (EPR) and ENDOR spectra of these cyclic (pyrrolidine) aminoxyl (nitroxide) species along with some deuterated analogues in liquid toluene solutions are highlighted. For instance, we found several long-range γ-H hyperfine splittings (HFS's) detectable by ENDOR that provide unique spectral signatures for these radical adducts. Conformational assignments of the pyrrolidine aminoxyl structures based upon the EPR and ENDOR findings are also discussed. Signs of the various hyperfine splittings (i.e., a^N, a_β^H, a_γ^H) investigated by cross-relaxation intensity sequence patterns (CRISP) in the ENDOR spectra are also presented.

D. Larry Haire, Uwe M. Oehler, H. Duane Goldman, Robert L.Dudley et Edward G. Janzen. Can. J. Chem. **66**, 2395 (1988).

On rapporte pour la première fois les spectres de résonnance double nucléaire électronique (RDNE) du ^1H et du ^{14}N d'un adduit radicalaire ayant un oxygène central c.-à-d. qui dérive de l'additon de radicaux *tert*- butoxyles), du diméthyl-5,5 pyrroline-1 *N*-oxyde (DMPO) aussi bien que ceux des nitrones cycliques apparentés : phenyl-4 diméthyl-5,5 pyrroline-1 *N*-oxyde (Ph-4 DMPO) et tétraméthyl-3,3,5,5 pyrroline-1 *N*-oxyde (M_4PO). On met en évidence les caractéristiques des spectres de RDNE et de résonnance paramagnétique électronique (RPE) de ces espèces cycliques (pyrrolidine) aminoxyle (nitroxide) ainsi que ceux de quelques analogues deutériés dans des solutions de toluène liquide. Nous avons trouvé, par exemple, plusieurs dédoublements hyperfins (DHF) à longue distance γ-H décelables par RDNE qui constituent des caractéristiques spectrales uniques de ces adduits radicalaires. On discute également des attributions conformationnelles des structures aminoxyle pyrrolidine à partir des spectres de RDNE et de RPE. On présente également les traces des divers dédoublements hyperfins (c.-à-d. a^N, a_β^H, a_γ^H) étudiés par relaxation croisée faisant appel au modèle d'intensité sequentielle (CRISP).

[Traduit par la revue]

Introduction

Cyclic nitrones were introduced in the mid 1970's (1–4) for the detection and identification of transient free radicals by EPR spin trapping (5) (eq. [1], below).[4] Since that time there has been a steady interest in these compounds as probes for free radicals in a variety of chemical and biochemical systems. Recently, the focus of attention has been on the trapping of oxygen-centered radicals such as hydroxyl, alkoxyls, and peroxyls (e.g., superoxide anion) (10–13).[5] For instance, these spin trapping studies have suggested that oxygen-centered radicals may be important intermediates in radiolysis (14) and sonolysis (15) reactions, ozone-related chemistry (16, 17), xanthine/xanthine oxidase systems (18), carcinogenesis (19), antitumour drug redox interactions (20–22), cigarette smoke (23), drug/skin phototoxicity (24, 25), neutrophil action (26*a*–*c*), peroxidation reactions (27–31), as well as myocardial ischemia/reperfusion injury (32*a*–*c*).

Solution ENDOR spectroscopy has proven to be a valuable tool for gleaning detailed structural and environmental information about aminoxyl (nitroxide) spin probes, spin labels, as well as radical spin adducts (33–67). There are a number of important advantages of studying aminoxyls by ENDOR (Electron Nuclear Double Resonance). These include the ability

[4]For a recent general review of EPR spin trapping see also ref. 6. For two recent reviews of EPR spin trapping in biochemical systems see refs. 7 and 8. For a compilation of EPR hyperfine splittings of spin adducts see ref. 9.

[5]It is noteworthy that the kinetics for spin trapping certain oxygen-centered radicals with cyclic nitrones is fast, e.g., 2.0×10^9 M^{-1} s^{-1} for hydroxyl with DMPO (ref. 10). Alkoxyl radicals are also efficiently trapped (e.g., $\sim 10^8$ M^{-1} s^{-1} for *tert*-butoxyl with DMPO): ref. 11. Resonance-stabilized oxygen-centered species such as superoxide and hydroperoxyl radicals are trapped considerably more slowly than alkoxyls (e.g., $\sim 10^1$ and $\sim 10^4$ M^{-1} s^{-1} respectively with DMPO), yet the relative persistence of these cyclic nitrone adducts enables spin trapping to be feasible (12). The sulfur analogues of alkoxyl radicals (thiyls) are also trapped at fast rate constants ($\sim 10^8$ M^{-1} s^{-1}) (13).

to detect long-range hyperfine splittings (HFS's) as well as the possibility of determining the signs of HFS's by CRISP (Cross Relaxation Intensity Sequence Pattern) (44) or Triple (51) modifications of the ENDOR experiment. Very recently aminoxyl ENDOR has also been applied to investigate heterogeneous systems such as micelles (33) and inverse micelles (39), as well as biological systems (e.g., imaging of plant stems with aminoxyl probes) (35).

In favourable cases the spin trapping of radicals by nitrones (e.g., phenyl-*N*-*tert*-butyl nitrones (PBN)) (34, 37, 44, 52, 59), or by C-nitroso compounds (e.g., 2-methyl-2-nitrosopropane (MNP)) (41, 46) leads to aminoxyl concentrations ($\sim 10^{-4}$–10^{-5} M) that are sufficient for analysis by ENDOR spectroscopy. To date, no ENDOR spectroscopic studies of radical adducts of "DMPO-type" nitrones, or any other 5-membered ring nitrogen heterocycle (e.g., pyrrolidine aminoxyls) with a β-hydrogen, has appeared in the literature. In this account we describe the first successful ENDOR experiments on these types of sytems. Specifically, ^{1}H and ^{14}N ENDOR spectra of *tert*-butoxyl radicals adducts of DMPO-type nitrones are reported.

Experimental

The *tert*-butoxyl radical adducts were produced by the thermolysis (25°C) of 50 mM di-*tert*-butylperoxalate (2, 3) in toluene solutions containing 50 mM nitrone.[6] Alternatively, these alkoxyl radical adducts were produced by the photolysis (low pressure 75-W Xenon lamp, Oriel model 6137) of 2-mL solutions of di-*tert*-butylperoxide (Lucidol–Penwalt) containing 50 mM nitrone in 13 × 100-mm borosilicate glass test tubes, followed by evaporation of this solvent and redissolution in toluene. Samples were deoxygenated by four freeze–pump–thaw cycles and sealed on a vacuum line prior to EPR and ENDOR analysis.

The EPR and ENDOR spectra were recorded with a Bruker ER-200D EPR spectrometer (ST 4102 and EN 801 X-band cavities, respectively) coupled to an ER-140 (Aspect 2000) computer system. The ENDOR spectra were obtained with an E-N A-300 amplifier with 12.5-kHz radiofrequency modulation. The EPR field was centered around 3400 gauss. Thus, the ENDOR doublets for ^{1}H and ^{14}N are centered about 14.47 and 1.046 MHz, respectively. The sample temperature was controlled with a Bruker ER 4111 VT unit. The *g* values were determined with Fremy's salt (sodium peroxylamine disulfonate, available from Sigma) in saturated sodium bicarbonate (a^N = 13.091 gauss, g = 2.00550) (70) in a capillary tube attached to the walls of the 4-mm o.d. quartz EPR and ENDOR cells.

All ENDOR spectra were generated from the $M_I = 0$ branch of the EPR line unless otherwise noted. The relevant settings during ordinary EPR and EPR for ENDOR were the following: modulation amplitude = 0.125 gauss, sweep time = 50 s, and time constant = 50 ms. Note, the microwave power was 20.4 mW for the former and 129.0 mW for the latter. Also, the spectrometer gain was generally 10 times higher during ENDOR. The settings for the full ENDOR spectrum (23 MHz) and the expanded view (4 MHz) were as follows: radiofrequency power = 102.0 mW and 65.0 mW, radiofrequency modulation depth = 100 kHz and 20 kHz, ENDOR start frequency = 4 and 12.5 MHz, ENDOR spectrum width = 23 and 4 MHz, ENDOR sweep time = 23 and 10 s.

The cyclic nitrones, 5,5-dimethyl-1-pyrroline-*N*-oxide (DMPO) (71, 72) and 3,3,5,5-tetramethyl-1-pyrroline-*N*-oxide (M_4PO) (72) were prepared by literature methods but are available commercially (e.g., Aldrich or Sigma). The phenylated nitrone, 4-phenyl-5,5-dimethyl-1-pyrroline-*N*-oxide (4-Ph-DMPO) was prepared by the procedure of Bapat and Black (73). The analogous deuterated nitrone required synthesis of *trans*-3-deuterio-cinnamaldehyde (available from a directed aldol reaction between benzaldehyde-1-*d* (available from MSD Isotopes) and acetaldehyde) (74). Addition of 2-nitropropane-d_6 (available from the reaction of acetone-d_6 (available from MSD Isotopes) and sodium nitrite) (75) to *trans*-3-deuterio-cinnamaldehyde gave 4-methyl-4-nitro-3-phenylpentanal-d_7. This nitroaldehyde was converted to the cyclic nitrone, 4-phenyl-5,5-dimethyl (d_6)-4-deuterio-1-pyrroline-*N*-oxide (4-Ph-DMPO-d_7), as described previously (73).

[6]Please note that di-*tert*-butylperoxybutylate is *shock-sensitive* (68). Professor L. R. C. Barclay (Mount Allison University) has suggested that di-*tert*-butylhyponitrite, $(CH_3)_3CON{=}NOC(CH_3)_3$, may be a better thermal source of *tert*-butoxyl radicals (69). The *trans*-sodium hyponitrite precursor may be obtained from G. D. Mendenhall at the Department of Chemistry and Chemical Engineering, Michigan Technical University, Houghton, MI 49931, U.S.A.

Results and discussion

Magnitudes and signs of the hyperfine splittings (HFS's) of the *tert*-butoxyl radical adducts of the DMPO-type nitrones are collected in Table 1. The HFS's are indicated by Greek subscripts to designate by the number of intervening bonds between the nucleus in question and the aminoxyl radical center (i.e., N-a_α-b_β-c_γ-d_δ-e_ϵ- etc.). EPR and ENDOR spectra of these radical adducts are provided in Figs. 1–3 and Figs. 4–6, respectively.

[a]All hyperfine splittings (HFS's) were determined in toluene solutions. ^1H and ^{14}N ENDOR values were obtained at 200 and 230 K, respectively. The EPR values are listed in gauss and the ENDOR values are given in MHz with the gauss values in brackets (conversion of MHz to gauss: division by 2.81).

[b]The numbering for the γ-HFS's follows that for the pyrrolidine ring shown in eq. [1].

[c]Signs of the HFS's were determined by examination of the relative intensities of the ENDOR lines (i.e., cross-relaxation intensity sequence patterns (CRISP) (37, 42, 44) as different branches of the EPR aminoxyl triplet ($M_I = +1$ vs. $M_I = 0$ vs. $M_I = -1$) were saturated). The signs of the γ-hydrogen hyperfine splittings (HFS's) are tentative because successful CRISP experiments required temperatures at or above 230 K where ENDOR resolution is not optimum. Sign information from TRIPLE resonance experiments proved to be inconclusive.

[d]N.R. indicates small long-range hyperfine splittings (HFS's), which contribute to the EPR linewidth but are not resolvable.

[e]The *tert*-butoxyl radical adducts of 4-Ph-DMPO and 4-Ph-DMPO-d_7 are diastereomeric. The EPR hyperfine splittings (HFS's) are: $a^N = 13.42$, $a_\beta^H = 14.99$ gauss for the *cis* isomer. ENDOR spectra of this isomer were not obtained. For the HFS's of the *trans* isomer, see the table.

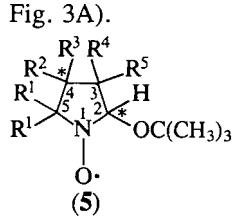
EPR spectra of the DMPO-type radical adducts

In contrast to carbon-centered radical adducts of DMPO (e.g., methyl, phenyl, etc.) (1), the EPR spectra of oxygen-centered radical adducts (e.g., *tert*-butoxyl, Fig. 1) in organic solvents usually exhibit a small extra doublet splitting (~2 gauss) in additon to the β-hydrogen doublet and nitrogen triplet hyperfine splittings (HFS's). Since this extra splitting is absent in comparable oxygen-centered adducts of M_4PO (76) (e.g., *tert*-butoxyl, Fig. 2) it is expected that this γ-hydrogen splitting originates from one of the hydrogen nuclei attached to the 3-position of the pyrrolidine ring (which may form a favourable geometric "W-type" arrangement with the aminoxyl p_π orbital) (77). It is noteworthy that of the oxyl family of DMPO spin adducts the hydroxyl adduct is anomalous in that it does not exhibit the characteristic small doublet splitting in organic (or aqueous) solvents (9).

The *tert*-butoxyl radical adduct of 4-phenyl-DMPO (Fig. 3) is a diastereomeric mixture of radical adducts due to the asymmetric centers (*) at the 2- and 4-positions of the pyrrolidine ring (**5**). One of these isomers exhibits an EPR hyperfine splitting pattern that is quite similar to that observed for the *tert*-butoxyl adduct of DMPO (i.e., $a^N = 13.12$, $a_\beta^H = 7.59$, $a_\gamma = 1.94$ vs. $a^N = 13.11$, $a_\beta^H = 6.41$, $a_\gamma = 1.99$ gauss, respectively, Table 1). Since the *trans*-2-*tert*-butoxyl-4-phenyl species should more closely resemble the analogous DMPO adduct (less perturbation of the pyrrolidine aminoxyl ring structure) the EPR pattern is assigned to this isomer. The other component (i.e., $a^N = 13.42$, $a_\beta^H = 14.99$ gauss) is attributed to the corresponding *cis* isomer.

When 4-Ph-DMPO is substituted with 4-Ph-DMPO-d_7 the resulting DMPO-like *tert*-butoxyl radical adduct exhibits one more γ-hydrogen hyperfine splitting (i.e., a 0.70-gauss doublet appears) due to the sharper EPR lines afforded by the deuterated nitrone (cf. Fig. 3B vs. Fig. 3A).



(**5**)

ENDOR spectra of the DMPO-type radical adducts

ENDOR spectra of a variety of 5-membered ring (i.e., pyrrolidine) aminoxyls have appeared in the literature. For instance, pyrrolidine spin labels and spin probes (33, 40, 45, 53, 54, 64) as well as the heteroatom substituted 3-aza (53), 3-oxa (53, 57), 3-aza-*N*-oxide (imidazole-type) (48), 3-aza and 2-oxa 4,5-aryl fused (36, 49) analogues have been successfully analyzed by ENDOR spectroscopy. It is noteworthy that all of the above studies have involved 2,2,5,5-tetra-α-substituted aminoxyls, which are indefinitely stable compounds. In contrast, the ENDOR spectra we present here deal with 2,5,5-tri-α-substituted pyrrolidine aminoxyls (**5**) (R^1 = CH_3 or CD_3, and R^5 = $OC(CH_3)_3$), which are known to be considerably less persistent (e.g., second-order decay rate constant for DMPO–$OC(CH_3)_3$ ~ 10^3 M^{-1} s^{-1}) (11).

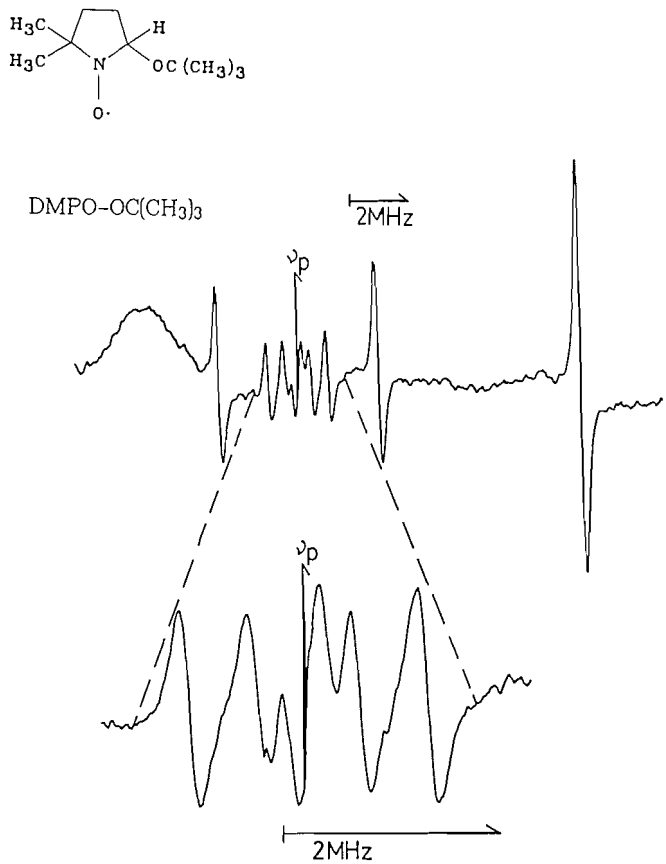

FIG. 4. ENDOR spectrum of the *tert*-butoxyl radical adduct of DMPO in toluene at 200 K. Note: The left side of the β-H ENDOR doublet is not shown due to instrumental noise in this low-frequency region (49).

ENDOR spectra of radical adducts of DMPO-type nitrones seem to be more difficult to obtain than from the related spin labels and spin probes alluded to earlier. Notwithstanding the problems of low spin adduct concentrations due to EPR spin trapping kinetics considerations (i.e., spin adduct formation and decay rate constants), the substitution around the pyrrolidine ring seems to affect the ease of obtaining ENDOR spectra. Of the *tert*-butoxyl radical spin adducts studied, M_4PO–$OC(CH_3)_3$ gave the strongest ENDOR response. The 4-substituted derivatives 4-Ph-DMPO–$OC(CH_3)_3$ and 4-Ph-DMPO-d_7–$OC(CH_3)_3$ provided slightly weaker spectra, with spectra from DMPO–$OC(CH_3)_3$ substantially (>5×) weaker than those from M_4PO–$OC(CH_3)_3$. To compensate for these intrinsically weaker ENDOR responses (e.g., as with DMPO–$OC(CH_3)_3$ these ENDOR spectra were accumulated accordingly longer. Thus, ring rigidity induced by pyrrolidine ring substitution may play a role in determining the ENDOR response, perhaps due to alteration of the electronic or nuclear relaxation behavior of the cyclic radicals.

DMPO–$OC(CH_3)_3$

There are at least seven types of magnetically distinct hydrogen nuclei in the *tert*-butoxyl radical adduct of DMPO (**6**). These include the β-H, the four H's at the 3- and 4-positions, the

For personal use only.

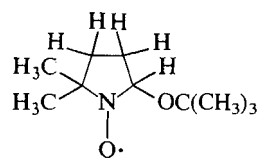
γ-H's of the methyl groups at the 5-position, and the ϵ-H's of the *tert*-butoxyl group at the 2-position. The numbering for the various γ-H HFS's will be indicated according to that shown in eq. [1]. In Fig. 4 the ^1H ENDOR spectrum in toluene at 200 K reveals five of them. Since the *tert*- butoxyl H's are too distant (ϵ with respect to the aminoxyl nitrogen) to be observable even by ENDOR spectroscopy, only one type of hydrogen nucleus remains unaccounted for. Thus, this hyperfine splitting is either below the ENDOR resolution limit or its magnitude accidentally coincides with that of another hydrogen HFS.

Assignment of the β-H is straightforward due to its very large magnitude (Table 1, Fig. 4). One of the H's at the 3-position generates $a^H_{\gamma 5}$ (for assignment arguments, see the EPR spectra of DMPO–$OC(CH_3)_3$ vs. M_4PO–$OC(CH_3)_3$). Additionally, one of the H's at the 4-position is assigned to a^{H2}_{γ} (see Table 1) due to the remarkable spectral similarities with *trans*-4-phenyl-DMPO–$OC(CH_3)_3$ (see later).

The observed isotropic EPR linewidth of only ~1.1 gauss (Fig. 1) should contain contributions from a 1:6:15:20:15:6:1 septet due to the six H's on the methyl groups at the 5-position. Thus, the HFS from these H's may correspond to a^{H1}_{γ} because six times this value (i.e., 6 × 0.12 gauss) yields a reasonable linewidth contribution. Six times any other γ-H value (i.e., 6 × 1.95 vs. 6 × 0.72 vs. 6 × 0.31 gauss) produces a contribution to the linewidth that by itself may be too large for the linewidth actually observed.

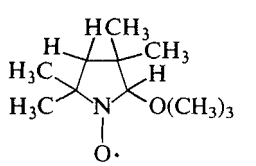
By elimination, $a^H_{\gamma 3,4}$ is assigned to one of the remaining hydrogen nuclei at the 3- and 4-positions. For the HFS assignments for DMPO–$OC(CH_3)_3$ (**6**), see Table 1.



DMPO–$OC(CH_3)_3$
(**6**)

M_4PO–$OC(CH_3)_3$

Assignment of the hydrogen HFS due to the methyls at the 5-position (a^{H1}_{γ}) is based on arguments analogous to those developed for DMPO–$OC(CH_3)_3$. The δ-H's of the methyls at the 3-position are expected to be too small to detect. The remaining HFS's (i.e., a^{H2}_{γ} and a^{H3}_{γ}) for M_4PO–$OC(CH_3)_3$ therefore may be due to H's at the 4-position (**7**), Table 1).



M_4PO–$OC(CH_3)_3$
(**7**)

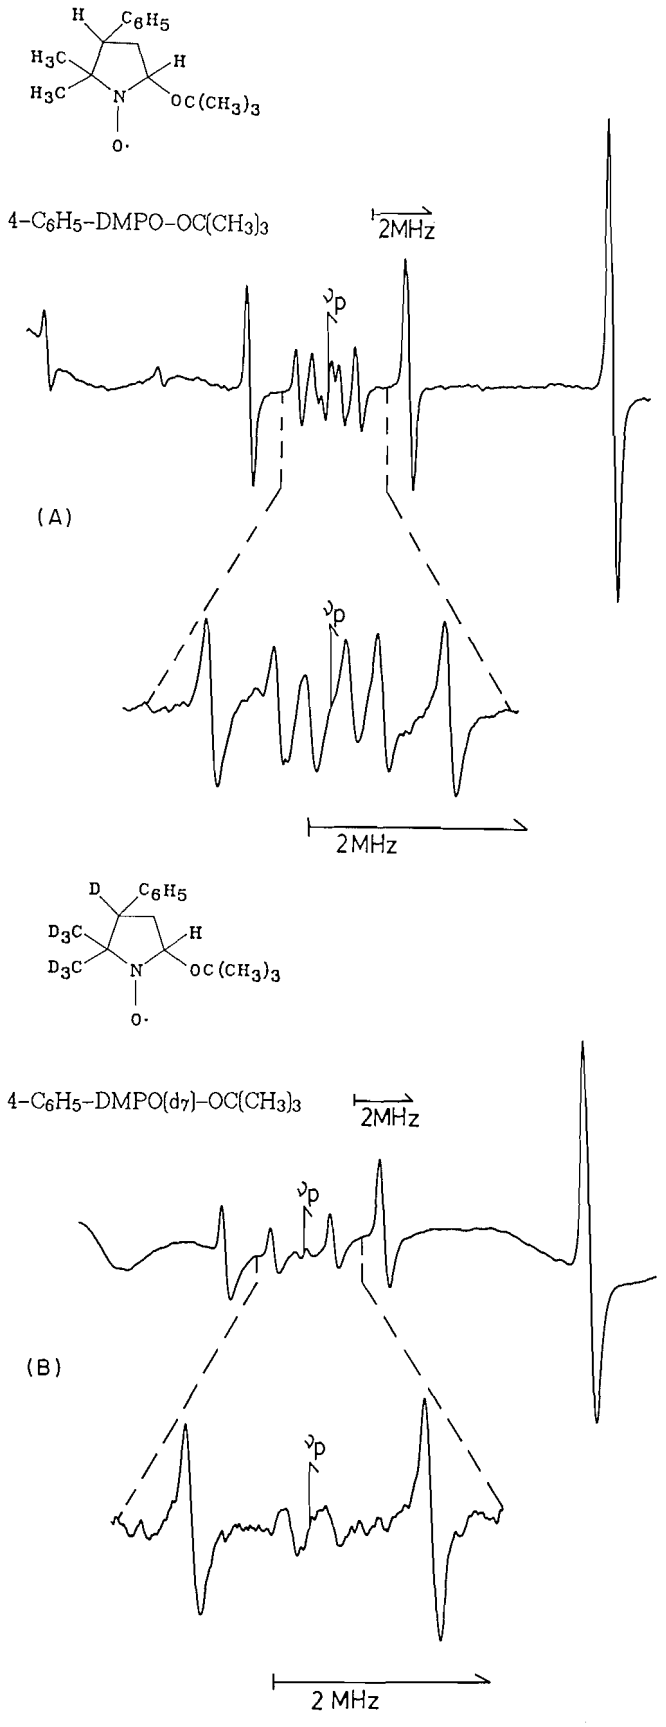

FIG. 6. (A) ENDOR spectrum of the *tert*-butoxyl radical adduct of 4-Ph-DMPO in toluene at 200 K. (B) ENDOR spectrum of the *tert*-butoxyl radical adduct of 4-Ph-DMPO-d_7 in toluene at 200 K. Note: The left side of the β-H ENDOR doublet is not shown due to instrumental noise in this low-frequency region (49).

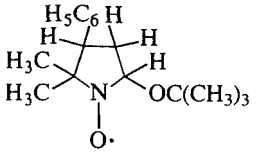
4-Ph-DMPO–$OC(CH_3)_3$ and 4-Ph-DMPO-d_7–$OC(CH_3)_3$

The hyperfine splitting for the γ-H at the 4-position can be definitively assigned because this HFS ($a_\gamma^{H_3}$) disappears upon deuteration (see Fig. 6A vs. 6B). The 1.99-gauss splitting is assigned (by analogy to DMPO–$OC(CH_3)_3$) to one of the H's at position 3 (i.e., $a_\gamma^{H_5}$). Long-range phenyl HFS's are not expected to contribute ENDOR signals because these nuclei are ϵ- or further away from the aminoxyl radical centre. Because deuteration of the methyl groups at the 5-position is only around 93% (according to mass spectroscopy) some residual ENDOR response may be detected ($a_\gamma^{H_1}$). The remaining HFS (i.e., $a_\gamma^{H_4}$) for *trans*-4-phenyl-DMPO–$OC(CH_3)_3$ (**8**) therefore may arise from the second hydrogen nucleus at the 3-position, see Table 1.



trans-4-Ph-DMPO–$OC(CH_3)_3$
(**8**)

Sign determination in the DMPO-type radical adducts

Signs of the HFS's were estimated by comparing the relative intensities of the ^1H and ^{14}N ENDOR peaks during saturation of different wings of the aminoxyl triplet (37, 42, 44) and are listed in Table 1. We have suggested the term CRISP (cross relaxation intensity sequence patterns) be used to describe this process (37, 44).

The *tert*-butoxyl radical adduct of M_4PO at 230 K in toluene solution was chosen to demonstrate the CRISP effect (Figs. 5B–5D). As the $M_I = +1$ branch of the EPR line is saturated the intensity ratio of high frequency to low frequency ^{14}N ENDOR lines decreases (Fig. 5B). Conversely, as the $M_I = -1$ wing is saturated this ratio increases (Fig. 5D). Because optimum temperatures for ^1H ENDOR are lower (i.e., ~200 K) than those for ^{14}N ENDOR (and CRISP) (i.e., ~230 K), sign determination (especially for the γ-H's) is tentative. Additional support for the negative γ-H HFS's for these DMPO-type spin adducts comes from the fact that other *N*,*N*-dialkylaminoxyls (e.g., spin adducts of α-phenyl *N*-*tert*-butyl nitrone (PBN)) (37, 44) also exhibit negative γ-H HFS's, as would be expected if a spin polarization mechanism of spin transfer from the aminoxyl nitrogen were operative. We have observed distinctly positive γ-H HFS's in certain *N*-acyl, *N*-alkylaminoxyls (nitroxones); however, the bonding characteristics in these species seem to be rather special compared to *N*,*N*-dialkylaminoxyls (78).

Summary

The first ^1H and ^{14}N ENDOR spectra of oxygen-centered radical adducts of DMPO-type nitrones (namely, the *tert*-butoxyl adducts) are shown to be useful because they can uncover extra diagnostic HFS's hidden in the EPR linewidth and also because the relative signs of the HFS's may be deduced by CRISP (37, 44) techniques. In addition to the hyperfine splittings from the β-H and ^{14}N nuclei, a number of γ-H splittings from the 3- and 4-positions as well as the methyls at the 5-position of the pyrrolidine aminoxyl are readily observable by ENDOR spectroscopy. Applications of these or other EPR resolution enhancement techniques (79–81)[7] to detect

[7]For "90° out-of-phase" resolution enhancement EPR see ref. 79. For "post-experiment" resolution enhancement by Fourier transform and related techniques see refs. 80 and 81.

characteristic long-range HFS's (either from the spin trap moiety or from the radical addend itself) appear to be viable new methodologies to assist in the confirmation of EPR spin adduct assignments. Additionally, we have found that deuteration of the cyclic nitrone nucleus (e.g., as in 4-Ph-DMPO-d_7) also leads to reduced linewidths and hence higher spectral resolution.

Acknowledgements

The authors would like to thank the Natural Sciences and Engineering Research Council of Canada (NSERC) for the purchase of the ENDOR spectrometer and for continuing support of this research.

Ion–dipole complexes in the unimolecular reactions of isolated organic ions. Fragmentation of protonated and cationated formate and acetate esters

ADAM W. MCMAHON AND ALEX. G. HARRISON
Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received March 14, 1988

ADAM W. MCMAHON and ALEX. G. HARRISON. Can. J. Chem. **66**, 2403 (1988).

The unimolecular fragmentation reactions occurring on the metastable ion time scale have been determined for protonated alkyl formates and acetates and for the adducts of CD_3^+ and $C_2H_5^+$ with these esters. The protonated esters, $R^1CO_2RH^+$, fragment to form $R^+ + R^1CO_2H$ or, by internal hydrogen transfer, $R^1CO_2H_2^+ + (R - H)$ with the relative yields depending on the identity of R^1 and R. Using deuterium labelling it has been shown that the added proton interchanges with hydrogens of the R group prior to fragmentation. The methyl-d_3-cationated esters, $R^1CO_2R.CD_3^+$, mostly fragment to give $R^1CO_2CD_3$, H^+ by elimination of (R − H), although R^+ formation is observed in a few cases. The ethyl-cationated esters fragment primarily to give $R^1CO_2C_2H_5.H^+$ by elimination of (R − H); specifically no elimination of C_2H_4 is observed. All of the results can be rationalized in terms of a step-wise mechanism of fragmentation involving initial formation of an ion–dipole complex of the alkyl ion R^+ with a carbonyl compound. This complex may either fragment to form R^+ or may proceed by way of an ion–dipole complex of a protonated carbonyl and an olefin to the protonated species plus (R−H). The results indicate that primary alkyl ions are not formed but rather that rearrangement to the more stable secondary or tertiary structure occurs. There is some evidence that *s*-butyl cations are not formed, but that these too rearrange to the *t*-butyl structure.

ADAM W. MCMAHON et ALEX. G. HARRISON. Can. J. Chem. **66**, 2403 (1988).

On a déterminé les réactions de fragmentation unimoléculaire se produisant à l'échelle de temps des ions métastables des formiates et des acétates d'alkyle protonés et des adduits du CD_3^+ et du $C_2H_5^+$ avec ces esters. Les esters protonés $R^1CO_2RH^+$ se fragmentent pour donner du $R^+ + R^1CO_2H$, ou par transfert d'hydrogène interne, du $R^1CO_2H_2^+ + (R - H)$ dont les rendements relatifs dépendent des groupes R^1 et R. L'utilisation du marquage au deutérium a permis de mettre en évidence un échange entre le proton ajouté et les hydrogènes du groupe R avant la fragmentation. Les esters cationiques méthyl-d_3, $R^2CO_2R.CD_3^+$, se fragmentent principalement surtout pour donner du $R^1CO_2CD_3.H^+$ par élimination de (R − H) en dépit du fait que dans certains cas on observe la formation du groupe R^+. Les esters éthyliques cationiques se fragmentent principalement pour donner le composé $R^1CO_2C_2H_5.H^+$ par élimination de (R − H) et on n'a pas observé d'élimination spécifique de C_2H_4. On peut rationnaliser tous ces résultats en terme d'un mécanisme de fragmentation par étapes impliquant la formation initiale d'un complexe ion-dipôle de l'ion alkyle R^+ avec le composé carbonylé. Ce complexe peut soit se fragmenter pour donner R^+ soit se transformer via un complexe ion–dipôle d'un carbonyle protoné et d'une oléfine en l'espèce protoné plus (R−H). Les résultats indiquent que les ions alkyle primaire ne se forment pas mais qu'ils se transposent de préférence en ions secondaire ou tertiaire plus stable. On a la preuve que les cations *s*-butyles ne se forment pas mais qu'ils se transposent en cations *t*-butyle.

Introduction

The reactions of isolated gaseous ions can be investigated conveniently using mass spectrometers (for a recent review, see ref. 1). Particularly useful information may be acquired from the study of the fragmentation reactions occurring on the metastable ion time frame where the excess energies in the transition state are similar to those involved in solution reactions (ref. 2, for reviews emphasizing the usefulness of metastable ion investigations, see ref. 3). For such reactions the relative rates are determined primarily by relative critical reaction energies and the results frequently can be understood in terms of potential energy profiles (3). Thus, the study of the unimolecular fragmentation reactions of metastable ions probes the fragmentation pathways of lowest critical reaction energy. The present study reports such a study of protonated, methyl-cationated and ethyl-cationated ethyl through butyl formates and acetates. The proton-transfer chemical ionization mass spectra of esters have received extensive study (4–11) and the major fragmentation pathways of higher energy protonated species have been delineated. However, the threshold fragmentation reactions which explore the potential energy profiles for fragmentation have not been examined. In addition, the fragmentation reactions of the methyl-cationated and ethyl-cationated species have not been studied systematically. Extensive studies have shown that species comprising an incipient cation and a neutral, held together by ion–dipole attractive forces frequently play a role in the chemistry of isolated ions (12–26). Much of the earlier evidence for these ion–dipole complexes derived from the behaviour of closed-shell "onium" ions generated by dissociative ionization of alcohols, ethers, and amines (12–16). More recently, such complexes have been shown to be involved in the fragmentation of closed-shell species produced by bimolecular ion/molecule reactions (18–26). The present results provide further examples of the role of ion–dipole complexes in the fragmentation of closed-shell species.

Experimental

The unimolecular fragmentation reactions of the protonated, deuteronated, and ethyl-cationated esters, which occur on the metastable ion time frame, were investigated by the MIKES technique (2) using a VG Analytical ZAB-2FQ mass spectrometer (27). Kinetic energy releases were evaluated from the peak widths at half-height after correction for the main beam width. The MIKES spectra of the methyl-cationated species were complicated by artifact peaks and by fragmentation of the MH^+ ion of the next higher homologous ester which was present as a low level impurity. To eliminate the latter complication the methyl-d_3-cationated esters were studied. To eliminate the first complication the appropriate ion was transmitted to the rf-only quadrupole cell of the instrument where unimolecular fragmentation occurred (in the absence of collision gas) with the products being analyzed by the final stage quadrupole mass analyzer; the extra stage of mass/energy selection eliminated the artifact peaks. The collision-induced dissociation mass spectra of the protonated esters were

determined over the collision energy range 5 to 100 eV by mass selecting the appropriate MH^+ ion by the double-focussing (BE) mass spectrometer, decelerating the ions to the appropriate energy and injecting them into the rf-only quadrupole cell with N_2 used as collision gas. The products of dissociation were analyzed with the final quadrupole mass analyzer.

For metastable ion studies the protonated esters were prepared by CH_4 chemical ionization in a combined EI/CI source operating in the CI mode. Substitution of CD_4 for the CH_4 reagent gas yielded the deuteronated ester. For the CID studies the protonated ester was prepared by isobutane chemical ionization to minimize unimolecular fragmentation. The methyl-d_3-cationated species were prepared by using CD_3Br as reagent gas while the ethyl-cationated species were prepared by using C_2H_5Br as reagent gas. The exact reaction(s) forming the cationated esters is (are) not known, however, in both systems the dialkyl bromonium ion R_2Br^+ (R = CD_3 or C_2H_5) was a major species and alkyl ion transfer by this species to the ester undoubtedly is occurring. The ion source was operated at ~200°C with 50 eV ionizing electron energy and 8 kV ion accelerating potential.

The esters either were commercially available or were prepared by standard methods.

Results and discussion

Fragmentation of protonated esters

Table 1 records the relative fragment ion intensities observed as a result of fragmentation of protonated formate esters as metastable ions while Table 2 records the similar data obtained for the fragmentation of protonated acetate esters. For metastable ions two fragmentation reactions are observed, elimination of a carboxylic acid forming an alkyl ion (reaction [1]) and elimination of an olefin forming the protonated acid (reaction [2]). Also included in the tables for each ester are the enthalpies of reactions [1] and [2] calculated from the thermochemical

$$[1]\quad R^1\text{-}C(OH^+)\text{-}OR \rightarrow R^1COOH + R^+$$

$$[2]\quad \rightarrow R^1CO_2H_2^+ + (R—H)$$

data listed in the Appendix. On the metastable ion time scale protonated ethyl formate fragments by reaction [2] while the protonated propyl and butyl formates fragment by reaction [1]. The protonated acetates fragment primarily by reaction [2] with the exception of protonated i-butyl and t-butyl acetates which fragment primarily by reaction [1]. These results are in accord with the proton-transfer chemical ionization mass spectra reported earlier (11) in that for each ester the dominant fragment ion observed in the CI mass spectrum is the same as that observed in the metastable ion mass spectrum.

The results obtained for the metastable ion fragmentation of the deuteronated esters are particularly relevant to a discussion of the mechanism of fragmentation of protonated esters. The MD^+ ion of ethyl formate forms HCO_2HD^+ exclusively in metastable ion fragmentation reactions. The MH^+ ions of the remaining formates fragment to form the appropriate alkyl ions; for the MD^+ ions this products was observed both as C_nH_{2n+1} and as $C_nH_{2n}D^+$, the observed $C_nH_{2n}D^+/C_nH_{2n+1}$ ratios

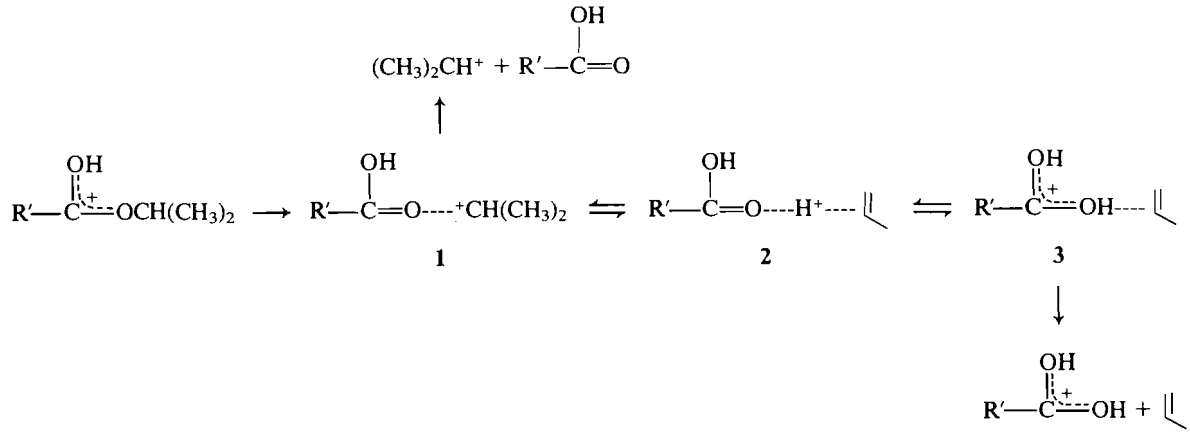

SCHEME 1

being given in Table 1. The protonated acetates fragment to give protonated acetic acid; for the deuteronated acetates both $CH_3CO_2HD^+$ and $CH_3COH_2^+$ were observed, the $CH_3CO_2HD^+/CH_3CO_2H_2^+$ ratios being given in Table 2. Note that only $CH_3CO_2HD^+$ is observed in the ethyl acetate system. In addition to these results the butyl ions produced from the *i*-butyl and *t*-butyl esters showed substantial deuterium incorporation: $C_4H_8D^+/C_4H_9^+ = 0.7$ (*i*-butyl) and 2.6 (*t*-butyl). Initial protonation/deuteronation of the esters presumably occurs at the carbonyl oxygen (the most basic site (28)) and the present results clearly show that, except for the ethyl esters, this added hydrogen/deuterium undergoes substantial interchange with the hydrogens of the alkyl group. Such interchange reactions have been observed previously for protonated ethanol (25) and protonated methyl isopropyl ether (29) and have been rationalized (25) in terms of partial equilibration between the ion–dipole complexes proposed as intermediates in the fragmentation of protonated molecules. This mechanism, applied to the case of protonated esters and using a protonated isopropyl ester as an example, is shown in Scheme 1. If partial equilibration between the intermediate complexes **1** and **3** occurs, hydrogen interchange between oxygen and the alkyl group will be observed. In line with earlier arguments (25), such equilibration should be observed as long as **1** is lower in energy than the final products $R^1CO_2H_2^+ + (R—H)$. The complex **1** should be stabilized, relative to $R^+ + R'CO_2H$, by ion–dipole interactions which may amount to as much as 40–60 kJ mol^{-1} (12), so that, as long as $\Delta H_1 - \Delta H_2 \leq 40$–60 kJ mol^{-1}, **1** will be lower in energy than $R^1CO_2H_2^+ + (R—H)$ and hydrogen interchange should occur. Perusal of the thermochemical data of Tables 1 and 2 shows that the protonated ethyl esters do not meet this requirement and, indeed, hydrogen interchange is not observed. Based on this criterion, hydrogen interchange is predicted for the remaining protonated acetates *provided* we assume relatively facile rearrangement of the incipient primary alkyl cations in **1** to the more stable secondary or tertiary structure. This point will be returned to below. Similarly, hydrogen interchange is predicted for the protonated propyl and butyl formate esters with the possible exception of *t*-butyl formate. In this case one would expect that the complex **3** is higher in energy than the products $t\text{-}C_4H_9^+ + HCO_2H$; consequently any complexes **1** which have energy to reach **3** will have more than enough energy to fragment. Nevertheless, hydrogen interchange is observed, although to a smaller extent than for the *n*-butyl and *s*-butyl esters. Clearly, the hydrogen interchange data provide strong evidence for the participation of ion–dipole complexes in the fragmentation of protonated closed-shell species.

It should be noted that the reaction enthalpies for [1] and [2] are the same, within experimental uncertainty, for the protonated propyl formates, yet $C_3H_7^+$ is the only product observed in metastable ion fragmentation reactions. This may indicate that there is a barrier in addition to the reaction endothermicity for formation of $R^1CO_2H_2^+$. Alternatively the results may be interpreted in tems of similar energy barriers, but with the reaction forming the alkyl ion being favoured entropically because it is a simple bond fission reaction with a loose transition state, while the reaction forming $R^1CO_2H_2^+$ involves H^+ transfer and has a tight transition state. Support for the latter hypothesis comes from low variable-energy collision-induced dissociation (ERMS) (30–32) studies. It is well established (33–37) that, in such low energy collisional experiments, the energy deposited in the ion as internal energy increases with increasing collisional energy; thus, by varying the collision energy, the energy dependence of the competing reactions can be examined over an extended range such that not only relative critical energies, but also relative frequency factors play a role in determining the relative rates. In the present study, it was observed that, for those systems where alkyl ion formation (reaction [1]) dominated the metastable ion mass spectrum, the same ion dominated the breakdown graph (fractional fragment ion intensities as a function of collision energy). Typical results are shown in Fig. 1 for the protonated *i*-propyl formate system. In these systems formation of $R^1CO_2H_2^+$ cannot compete with formation of R^+ at higher internal energies because of the lower frequency factor for the former reaction. By contrast, for those systems where rearrangement to form $R^1CO_2H_2^+$ is the energetically favoured reaction and this ion dominates the metastable ion spectrum, formation of the alkyl ion R^+ increases markedly in importance with increasing collision energy. Typical results are shown in Fig. 2 for the protonated *s*-butyl acetate system; similar results were obtained for the protonated propyl acetates and protonated *n*-butyl acetate. In these cases formation of R^+, although there is a higher critical reaction energy, there is also a more favourable frequency factor (loose transition state) and the reaction competes effectively with the formation of $R^1CO_2H_2^+$ at higher internal energies as the latter reaction has a lower frequency factor (tight transition state).

The results reported in Tables 1 and 2 have been rationalized above, in part, by assuming that the incipient primary alkyl ions undergo facile rearrangement to the more stable secondary or tertiary structure. There is substantial evidence that small

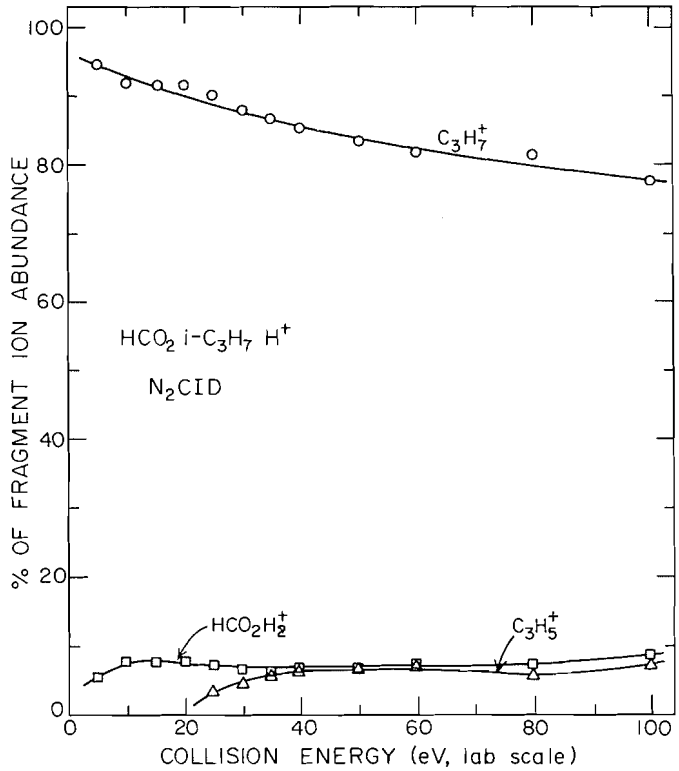

FIG. 1. Breakdown graph for protonated *i*-propyl formate.

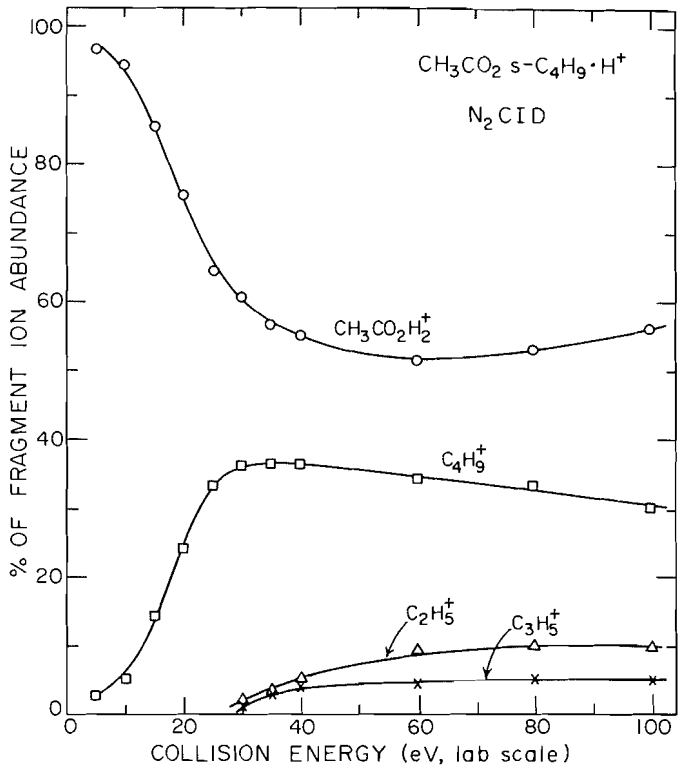

FIG. 2. Breakdown graph for protonated *s*-butyl acetate.

hydrocarbon ions undergo facile isomerizations prior to unimolecular dissociation in the gas phase (38) and under solvolytic conditions in condensed phases (39); indeed, it appears that free primary alkyl ions are not stable species (40). Further information relevant to the question of the rearrangement of the incipient alkyl ions comes from measurements of the kinetic energy releases associated with the fragmentation reaction [1] occurring on the metastable ion time scale. The results of such measurements are presented in Table 3. The results for the *t*-butyl and *i*-butyl esters are particularly informative. The kinetic energy release associated with reaction [1] is 2.0 meV for protonated *t*-butyl formate and 3.1 meV for protonated *t*-butyl acetate. These low kinetic energy releases are consistent with a reaction which is continuously endothermic along the reaction coordinate. By contrast, the corresponding protonated *i*-butyl esters show much larger kinetic releases (14.3 and 15.7 meV, respectively). These larger kinetic energy releases are inconsistent with a continuously endothermic reaction leading to formation of the *i*-butyl cation, but are consistent with an exothermic rearrangement of the incipient *i*-butyl cation to the *t*-butyl structure. There is ample evidence (18, 41) that dissociation of gaseous ions which are preceded or accompanied by an exothermic isomerization of the incipient cation are associated with an increased kinetic energy release. The isomerization from the *i*-butyl to the *t*-butyl structure presumably occurs by a hydride ion migration (42) in the *i*-butyl$^+$–R^1CO_2H complex. This complex should be 40–56 kJ mol^{-1} more stable than the separated *i*-$C_4H_9^+$ + R^1CO_2H products. However, since ΔH_f^0(*i*-$C_4H_9^+$) − ΔH_f^0(*t*-$C_4H_9^+$) = 134 kJ mol^{-1} (Appendix) it is clear that this complex is higher in energy than the final products, leading to an exothermic fragmentation reaction and an increased kinetic energy release. On the other hand, protonated *i*-propyl formate and protonated *n*-propyl formate show essentially identical kinetic energy releases in metastable ion fragmentation reactions to form $C_3H_7^+$, although it is probable that *i*-$C_3H_7^+$ is formed in both cases. However, ΔH_f^0 (*n*-$C_3H_7^+$) − ΔH_f^0 (*i*-$C_3H_7^+$) = 67 kJ mol^{-1} and it is likely that the stabilization energy in the *n*-$C_3H_7^+$–HCO_2H complex is of this order of magnitude so that the complex is not significantly higher in energy than the final products, *i*-$C_3H_7^+$ + HCO_2H, in this case; consequently no significant increase in kinetic energy release would be expected. Schwarz and Stahl (18) have observed that fragmentation of $C_3H_7OH_2^+$ to $C_3H_7^+$ + H_2O gave the same low kinetic energy release for both isomers but that fragmentation of $C_3H_7CO^+$ to $C_3H_7^+$ + CO gave a considerably higher kinetic energy release for the *n*-C_3H_7 isomer because of the decreased ion–dipole stabilization associated with interaction with CO compared to interaction with H_2O. Our system should be comparable to the $C_3H_7^+$–H_2O system.

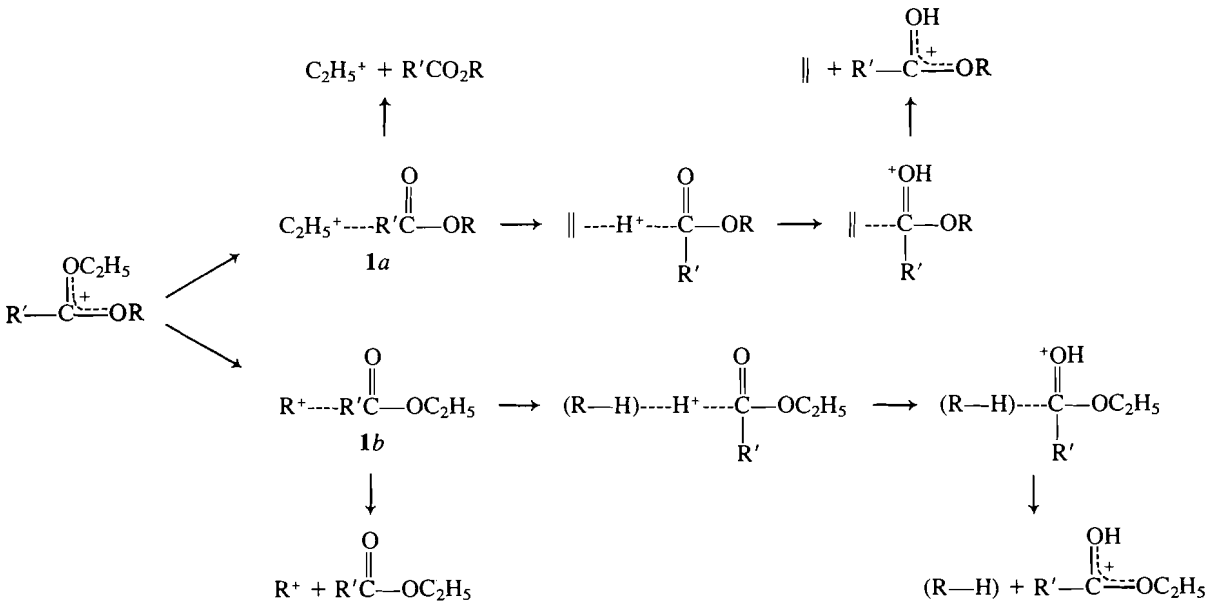

SCHEME 2

The most intriguing result in Table 3 is the relatively large kinetic energy release associated with reaction [1] for protonated *s*-butyl formate. Such a large kinetic energy release is not expected if simple bond fission to form *s*-$C_4H_9^+$ + HCO_2H occurs. It appears probable, therefore, that fragmentation of this protonated ester is accompanied by exothermic rearrangement to the *t*-butyl cation structure. Such a rearrangement has been proposed (43) to occur through the *i*-butyl$^+$ structure. It is interesting to note that the *s*-butyl$^+$ ion rearranges to the tertiary structure in the solution phase at −60°C (39). It is probable that fragmentation of the protonated *n*-butyl ester also involves rearrangement of the alkyl group to the *t*-butyl structure.

Fragmentation of methyl-cationated esters

Unimolecular fragmentation of the CD_3^+ adducts on the metastable ion time scale gave, with two exceptions, the protonated ester $R^1CO_2CD_3.H^+$ (reaction [3])

[3] $R^1CO_2RCD_3^+ \rightarrow R^1CO_2CD_3.H^+ + (R—H)$

The two exceptions were the *i*-butyl formate system where $C_4H_9^+$ was the only fragment ion observed and the *t*-butyl formate system where 73% $HCO_2CD_3.H^+$ and 27% $C_4H_9^+$ were observed; these latter data are uncertain because of the extremely low intensity of the adduction.

Calculation of the heats of formation of products reveals that reaction [3] is the thermochemically favoured reaction except for the adducts with *i*-butyl formate and *t*-butyl formate where formation of *t*-$C_4H_9^+$ becomes the thermochemically favoured reaction. (This, of course, assumes rearrangements from the *i*-butyl to the *t*-butyl structure). In effect, the proton affinities of the methyl esters are sufficiently high to direct the reaction to formation of this product in most cases. As examples, the proton affinity of methyl formate (797 kJ mol^{-1} (Appendix) is higher than that of 2-butene (761 kJ mol^{-1} (43)) (the conjugate base of *s*-butyl$^+$) but lower than that of *i*-butene (824 kJ mol^{-1} (43)) (the conjugate base of *t*-butyl$^+$). On the other hand, the proton affinity of methyl acetate (829 kJ mol^{-1} (Appendix)) is greater than that of *i*-butene.

Fragmentation of ethyl-cationated esters

Unimolecular fragmentation reactions of the $C_2H_5^+$ adducts with the propyl and butyl formates and acetates were examined, with the exception of the adduct with *t*-butyl formate where no significant adduct ion signal was observed. Earlier work (44) has shown that the $C_2D_5^+$ adduct of ethyl acetate fragments by loss of C_2D_4 and C_2H_4. Four fragmentation reactions, [4] to [7], are possible for fragmentation of these adducts.

[4] $R^1CO_2R{\cdot}C_2H_5^+ \rightarrow R^1CO_2R{\cdot}H^+ + C_2H_4$

[5] $\rightarrow R^1CO_2C_2H_5{\cdot}H^+ + (R—H)$

[6] $\rightarrow C_2H_5^+ + R^1CO_2R$

[7] $\rightarrow R^+ + R^1CO_2C_2H_5$

Thermochemical calculations show that the reactions enthalpies of [4] and [5] are the same within experimental uncertainty (±17 kJ mol^{-1}); in several cases reaction [5] appears to be thermochemically favoured. Despite this, no evidence was found for loss of C_2H_4 in the metastable ion fragmentation reactions. The dominant fragmentation reaction, with one exception, was elimination of (R—H), reaction [5]. The one exception was the adduct with *i*-butyl formate which formed both $HCO_2C_2H_5{\cdot}H^+$ (39%) and $C_4H_9^+$ (61%) in metastable ion fragmentation reactions; for this case the thermochemical data show that reactions [5] and [7] have very similar reaction enthalpies.

At first sight the domination of reaction [5] over reaction [4] is surprising given that the reaction enthalpies are very similar. However, the results are readily rationalized if olefin elimination occurs by a step-wise mechanism involving ion–dipole complexes (Scheme 2) rather than by a concerted mechanism. The ion–dipole complex, **1***a*, which leads to elimination of C_2H_4 will be of higher energy than the ion–dipole complex **1***b*, and higher in energy than the products $R^1CO_2C_2H_5.H^+$ + (R—H). This is illustrated by the following representative data

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 112.217.228.212 on 09/07/12
For personal use only.

		ΔH_f^0 (products) (kJ mol^{-1})
$HCO_2.i\text{-}C_4H_9.C_2H_5^+$	$\rightarrow HCO_2.i\text{-}C_4H_9.H^+ + C_2H_4$	343
	$\rightarrow HCO_2C_2H_5.H^+ + i\text{-}C_4H_9$	331
	$\rightarrow C_2H_5^+ + HCO_2.i\text{-}C_4H_9$	489
	$\rightarrow C_4H_9^+ + HCO_2C_2H_5$	460 (i-butyl$^+$)
		326 (t-butyl$^+$)
$CH_3CO_2.s\text{-}C_4H_9.C_2H_5^+$	$\rightarrow CH_3CO_2.s\text{-}C_4H_9.H^+ + C_2H_4$	238
	$\rightarrow CH_3CO_2C_2H_5.H^+ + 2\text{-}C_4H_8$	238
	$\rightarrow C_2H_5^+ + CH_3CO_2.s\text{-}C_4H_9$	414
	$\rightarrow s\text{-}C_4H_9^+ + CH_3CO_2C_2H_5$	322

The complexes **1***a* and **1***b* should have similar stabilization energies (40–60 kJ mol^{-1}) relative to the separated alkyl ion plus ester products and that leading to ethylene elimination will be considerably higher in energy because of the high enthalpy of formation of $C_2H_5^+$. This is particularly true if we assume facile rearrangement of incipient primary propyl and butyl ions to the more stable secondary and tertiary structures. Clearly these results also provide strong evidence for the role of ion–dipole complexes on the fragmentation of even-electron species. It should be noted that an explanation similar to the above has been presented to rationalize the elimination of C_3H_6 rather than C_2H_4 from protonated ethyl isopropyl amine activated by chemical means or by multi-photon absorption (19, 20).

Appendix

The thermochemical data relevant to the enthalpies of formation of protonated carboxylic acids and esters are summarized in Table 4. The proton affinities are taken from Kebarle (45) or are estimated and are adjusted to $PA(NH_3)$ = 857.7 kJ mol^{-1} as recommended by Aue and Bowers (46). The neutral enthalpies of formation are literature values (47, 48) or are estimated by group equivalent methods (49). Other relevant enthalpies of formation (kJ mol^{-1}) are $C_2H_5^+$, 916; *n*-$C_3H_7^+$, 870; *i*-$C_3H_7^+$, 803; *n*-$C_4H_9^+$, 841; *i*-$C_4H_9^+$, 833; *s*-$C_4H_9^+$, 766; *t*-$C_4H_9^+$, 699, all taken from ref. 50. Neutral enthalpies of formation, from refs. 47 and 48, are (in kJ mol^{-1}): C_2H_4, 52; C_3H_6, 21; 1-C_4H_8, −1; 2-C_4H_8, −8; −8; *i*-C_4H_8, −18. All data are for the temperature of 298 K.

Determination of the dissociation constant of D_2O_2 in D_2O by a conventional method and via muonium kinetics

JEAN-CLAUDE BRODOVITCH, PAUL W. PERCIVAL, AND DEREK POTERYKO
Department of Chemistry and TRIUMF, Simon Fraser University, Burnaby, B.C., Canada V5A 1S6

Received March 3, 1988

JEAN-CLAUDE BRODOVITCH, PAUL W. PERCIVAL, and DEREK POTERYKO. Can. J. Chem. **66**, 2410 (1988).

The dissociation constant of deuterium peroxide has been determined from measurements of the pH of mixtures of D_2O_2/NaOD in D_2O. At 25°C, $pK_a = 12.35$ (5), confirming the value previously deduced from a kinetic study of the reactions of muonium with H_2O_2 and D_2O_2. The enthalpy and entropy of dissociation of D_2O_2 are estimated to be 34.7 (8.8) kJ mol^{-1} and -120 (30) J K^{-1}, respectively.

JEAN-CLAUDE BRODOVITCH, PAUL W. PERCIVAL et DEREK POTERYKP. Can. J. Chem. **66**, 2410 (1988).

La constante de dissociation du péroxyde de deutérium déduite ailleurs à partir d'une étude de la cinétique des reactions des péroxydes d'hydrogène et de deutérium avec le muonium, a été confirmée en mesurant directement le pH d'une série de mélanges D_2O_2/NaOD en milieu D_2O. On a estimé l'enthalpie et l'entropie de dissociation de D_2O_2 à 34.7 (8.8) kJ mol^{-1} et -120 (30) J K^{-1} respectivement. A 25°C, on a obtenu $pK_a = 12.35$ (5).

We have recently completed an extensive study of the kinetics of the reactions Mu + H_2O_2 and Mu + D_2O_2 in aqueous solution. Muonium (Mu) is the exotic atomic system μ^+e^-, and behaves as a light radioactive isotope of H (see ref. 1 for a general introduction and references to the literature of Mu chemistry and the μSR technique). Muonium decay rates were measured for various conditions of peroxide concentration (0 to 3 m*M*), acidity of the medium (pH 3 to pH 12.4 for H_2O_2, pD 3 to pD 13.7 for D_2O_2) and temperature (0 to 50°C). A preliminary account and most of the data are to be found in a conference report (2). Full experimental details and interpretation of the results in terms of mechanism and isotope effects will be reported in a full publication elsewhere. This short note is intended to highlight a "spin-off" of the kinetics study, namely, the determination of the ionisation constant of D_2O_2, and to report an independent determination by more conventional means.

The H_2O_2 data are consistent with the following reaction scheme:

[1] $\mathrm{Mu} + \mathrm{H_2O_2} \xrightarrow{k_1} \text{products}$

[2] $\mathrm{Mu} + \mathrm{HO_2^-} \xrightarrow{k_2} \text{products}$

[3] $\mathrm{Mu} + \mathrm{OH^-} \xrightarrow{k_3} \text{products}$

[4] $\mathrm{H_2O_2} \overset{K_a}{\rightleftharpoons} \mathrm{HO_2^-} + \mathrm{H^+}$

[5] $\mathrm{H_2O} \overset{K_w}{\rightleftharpoons} \mathrm{OH^-} + \mathrm{H^+}$

For such a scheme, the first order decay rate for the disappearance of Mu is given by (1):

$$[6]\quad \lambda_{obs} = \frac{k_1[H^+] + k_2K_a}{[H^+] + K_a} \cdot [H_2O_2]_t + \frac{k_3K_w}{[H^+]} + \lambda_0$$

where $[H_2O_2]_t = [H_2O_2] + [HO_2^-]$ is the nominal peroxide concentration, and λ_0 is the decay rate measured for pure water. A similar reaction scheme and an analogous expression to [6] was assumed for the Mu + D_2O_2 system. The purpose of the kinetics study was to determine k_1 and k_2 and their equivalents in the D_2O_2 scheme. They may be obtained by fitting [6] to the experimental data, using k_1, k_2, and k_3 as adjustable parameters. In the case of the H_2O_2 system we used literature values of K_a (3). However, we were unable to find any reported values for the corresponding dissociation constant of D_2O_2. Therefore, we used the kinetic data to determine K_a by performing a fit to expression [6] with K_a as an extra adjustable parameter.

By processing the D_2O_2 data in this manner we have determined K_a to be $6.8(6) \times 10^{-13}$ *M* ($pK_a = 12.2(2)$) at 25°C. (For H_2O_2 $pK_a = 11.66$ at this temperature (4).) However, to obtain meaningful fits some constraints had to be imposed on K_a during the calculations. Specifically, the variation of pK_a with temperature was required to be equal for H_2O_2 and D_2O_2, in similar fashion to the temperature dependence of pK_w for H_2O and D_2O. In terms of the activation parameters for the dissociation of D_2O_2, this is equivalent to imposing the same ΔH^0 value as that of H_2O_2 while leaving ΔS^0 a free parameter. The pK_a value found for D_2O_2 is larger than that of H_2O_2, which seems reasonable given the relative dissociation constants of H_2O and D_2O: $pK_w(H_2O) = 14.0$ compared to $pK_w(D_2O) = 14.9$ at 25°C (5).

The determination of K_a by such a procedure suffers from some serious drawbacks. First, the results are imprecise due to the insensitivity of the fit to K_a; second, the value of K_a obtained is very much dependent on the model chosen to explain the kinetic data; third, the results are biased by the restriction imposed on the fit; fourth, the technique of μSR is not yet widely known, so a constant such as a pK_a derived in this manner warrants independent confirmation. Aside from these considerations, the parameters of principal interest to us are the rate constants associated with the various reaction channels, and their determination will be more reliable if we can reduce the number of degrees of freedom of the fit by employing definite values of K_a.

With this in mind, we decided to make an independent measurement of the pK_a of D_2O_2. We followed the procedure of Evans and Uri (6) in their determination of the pK_a of H_2O_2. It involves the measurement of the pH (more precisely here the pD $= -\log_{10}[D^+]$) of known mixtures of NaOD and D_2O_2 as a function of the ionic strength of the medium, which is adjusted with $NaClO_4$. The pK_a can be calculated from the pD value extrapolated to zero ionic strength.

A solution (~3 *M*) of D_2O_2 was prepared by reacting an excess of D_3PO_4 (obtained from D_2O + P_2O_5) with Na_2O_2, followed by vacuum distillation of the D_2O_2 evolved into a cold

TABLE 1. Results of pH analysis of D_2O_2 solutions*

t/°C	pH_0	pK_a	c
20.0	11.04(5)	12.44(6)	0.038(86)
35.0	10.75(2)	12.15(4)	0.035(38)

*Conditions: $[NaOD]_0$ = 0.051(2) M, $[D_2O_2]_0$ = 0.5592(11) M, I = 0.05 to 1.0 M.

trap (7). This solution was standardized by titration against $KMnO_4$ solution.

A CO_2-free solution of ~0.3 M NaOD was obtained by addition of D_2O to Na(Hg) amalgam prepared by the technique described by Vogel (8). It was standardized by titration against HCl solution.

To prepare a ~5 M solution of sodium perchlorate, commercially available $NaClO_4$ was recrystallized in H_2O, thoroughly dried in a vacuum oven, then the required amount dissolved in D_2O. This solution was determined by acid–base titration of the H^+ released after passing an aliquot through a REXYN-101 cation exchange column.

Wherever necessary, the solvent was D_2O (>99 atom% D) obtained from MSD ISOTOPES.

The test solution was contained in a jacketed flask attached to a circulating bath to control the temperature (±0.02°C). pH measurements were made with a digital pH-meter (Cole-Parmer model 5985-80) equipped with a saturated NaCl glass electrode. The pH-meter was calibrated with two buffer solutions (pH 7 and pH 10 from BDH). The effect of temperature on the electrode response was taken into account by using the built-in temperature compensator of the pH meter. No attempt was made to correct the reading for Na^+ activity.

Care was taken to exclude atmospheric CO_2 during sample manipulations by continuous bubbling with purified wet N_2.

We first checked our set-up and technique by repeating Evans and Uri's experiment with H_2O_2. The pH can be expressed by the Henderson buffer equation (6):

$$[7]\quad pH = pH_0 - 0.5I^{1/2} + cI$$

with

$$[8]\quad pH_0 = pK_a + \log_{10}\frac{[NaOH]_0}{[H_2O_2]_0 - [NaOH]_0}$$

where I is the ionic strength and c a small empirical constant. The conditions $[H_2O_2]_0$ = 0.55 M and $[NaOH]_0$ = 0.05 M are chosen such that the log term in eq. [8] is equal to −1(6). The pH was measured at four ionic strengths (I = 0.05 to 1.0 M) and two temperatures. The results were then fitted to eq. [7] in which pH_0 and c are the free parameters. The pK_a value is readily calculated from eq. [8].

For H_2O_2, we obtained pK_a values of 11.80(11) at 20°C and 11.44(7) at 30°C; at these temperatures the literature values range from 11.75 to 11.85 and 11.48 to 11.58, respectively (4).

The experiment was then repeated with D_2O_2 under essentially identical conditions and following the same procedure. The pH extrapolated to zero ionic strength was converted to pD_0 using (9):

$$[9]\quad pD = pH + 0.40$$

and the pK_a value was calculated from [8]. The results are summarized in Table 1. From these two data points, we derive the following values of the thermodynamic parameters for the ionisation of D_2O_2: ΔH^0 = 34.7(8.8) kJ mol^{-1}, ΔS^0 = −120(30) J K^{-1}, and ΔG^0 = 69.8(3) kJ mol^{-1} at 20°C; the corresponding quantities for H_2O_2 are 34.3 kJ mol^{-1}, −107.4 J K^{-1}, and 69.04 kJ mol^{-1}, respectively (6). At 25°C, pK_a = 12.35(5), in agreement with the value (12.2(2)) deduced from our kinetic measurements. The restriction imposed in our fitting procedure appears to be justified; the values of ΔH^0 are very similar (i.e. same slope of plot of pK_a vs. $1/T$) for both peroxides as is the case for H_2O and D_2O (55.76 kJ mol^{-1} vs. 58.4 kJ mol^{-1}, respectively (5). Further discussion on the values of these thermodynamic parameters is not warranted in view of the large uncertainties of the present determination.

In conclusion, we have obtained values for the pK_a of D_2O_2 directly from pH measurements and indirectly from kinetics data. The determinations agree within experimental errors, which we interpret as evidence to support our reaction scheme. This is the first example of the use of μSR data in the determination of an ionisation constant, but we do not advocate it as a general method.

Enhanced nucleophile selectivity in the photoaddition to styrene. Comparison with the thermal addition

STEVEN W. ANDERSON[1] AND KEITH YATES[2]

Lash Miller Chemical Laboratories, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received January 29, 1988

This paper is dedicated to Professor John T. Edward on the occasion of his 65th birthday

STEVEN W. ANDERSON and KEITH YATES. Can. J. Chem. **66**, 2412 (1988).

The reactivity–selectivity properties of the *sec*-phenethyl carbenium ion and its analogues have been examined in binary-aqueous solutions of alcohols (ROH; R = Me, Et, CF_3CH_2, *n*-Bu, *t*-Bu, *n*-Pr, *i*-Pr), acetic acid, and in solutions containing external nucleophiles such as thiophenol, ethanethiol, acetate, and benzenesulfinate. Selectivity ($S = k(\text{Nuc})/k(H_2O)$) is observed to be a function of the nucleophile, the ring substituent, thermal or photochemical conditions, irradiation time, and medium acidity. In the case of styrene, the photochemically generated (usually 254 nm, 1 h) species exhibits greater selectivity (up to two orders of magnitude) than its thermal counterpart, generated (usually 80°C, 2–4 d) in identical media, particularly in aqueous-rich solvent compositions. A rationale for these differences, supported by fluorescence quenching experiments, and the other effects upon selectivity will be discussed.

STEVEN W. ANDERSON et KEITH YATES. Can. J. Chem. **66**, 2412 (1988).

On a étudié les propriétés de réactivité–sélectivité de l'ion *sec*-phénéthyl carbenium et de ses analogues dans des solutions aqueuses binaires d'alcool (ROH; où R = Me, Et, CF_3CH_2, *n*-Bu, *t*-Bu, *n*-Pr, *i*-Pr), et acide acétique et dans des solutions contenant des nucléophiles externes tels le thiophénol, l'éthanethiol, l'acétate et le benzènesulfinate. On a observé que la sélectivité ($S = k(\text{Nuc})/k(H_2O)$) dépend du nucléophile, du substituent sur le cycle, des conditions thermiques et photochimiques, du temps d'irradiation et de l'acidité du milieu. Dans le cas du styrène, les espèces générées photochimiquement (généralement 254 nm, 1 h) montrent une plus grande sélectivité (jusqu'à deux ordres de grandeur) que celles générées thermiquement (généralement 80°C, 2–4 d) dans un milieu identique; particulièrement dans des solvants binaires riches en eau. On discute de la rationalisation de ces différences, que supporte des expériences d'extinction de fluorescence, et des autres effets sur la sélectivité.

[Traduit par la revue]

Previous studies in our laboratories (1, 2) have shown that the photohydrations of ring-substituted styrenes are generally subject to acid catalysis, the reaction proceeding via a polarized S_1 state (eq. [1] (R = H, OMe, F, 3,4(C_4H_4)).

[1] 
The nitrostyrenes, however, exhibit anomalous behavior leading to *anti*-Markownikov addition products, which were shown to arise from a reverse-polarized T_1 state. It is conceivable that the *sec*-phenethyl carbenium ion generated by acid catalysis, photochemically or thermally, could be intercepted by a nucleophile other than water. Such attack could occur on carbenium ions that, intrinsically, would be expected to exhibit different reactivity, e.g., those in an electronically excited state, a vibrationally "hot" ground (electronic) state, or an electronic (and vibrational) ground state. To test this hypothesis we have investigated the acid-catalyzed photoaddition of various nucleophiles to styrene. Several compositions of binary-aqueous alcohols and aqueous solutions containing charged and neutral species of greater or less nucleophilicity than water were employed. A comparison with the acid-catalyzed thermal reaction has also been carried out. Factors influencing the observed selectivity, such as acid concentration, ring substitution (Chart 1), nucleophilicity, steric bulk, solvating ability of the nucleophile, solvent composition, and irradiation time, have also been explored.

Although the literature is replete with studies of thermal- and photo-addition reactions of nucleophiles (frequently with a sensitizer or catalyst present) to alkenes and alkynes, very few papers have examined reactivity–selectivity relationships and, in these instances, only indirectly. It is therefore appropriate that we briefly summarize these now, since they will have an important bearing on our later discussion.

Nozaki and co-workers observed (3) that both direct and acetophenone sensitized irradiation of 1-phenyl-cyclohexene or -cycloheptene (eq. [2]) with solvent of 0.003 mole fraction

[2] 
$n = 1$	direct yield, %	26 (23)	19 (14)

acetic acid in methanol gave more than one-third yield of the acetate in comparison to the ether. Selectivities ($S = k(\text{MeOH})/k(\text{AcOH})$) for both conditions are essentially invariant and independent of the ring size. The average is approximately 0.005, reflecting a strong preference for reaction with acetic acid. Nozaki has reasoned that the intermediate (the *trans* alkene) is sufficiently long-lived to capture the more favorable partner (carboxylic acid) and form a benzyl carbocation and

carboxylate anion pair, which ultimately recombine to give the ester.

The photolysis of 2-phenylnorborn-2-ene in aqueous methanol containing 0.72 mole fraction of methanol was found by Kropp (4) to give predominantly the methyl ether adduct (eq. [3]). A selectivity value ($S = k(\text{MeOH})/k(H_2O)$) of 0.62

[3] 
32%(51%)

can be calculated based upon these results. This reaction apparently involves a singlet excited state. Use of *tert*-butanol gave only the reduction product. Similarly, irradiation of (+)-carene in aqueous solvent of 0.19 mole fraction *tert*-butanol with benzene as sensitizer gave only isomerization and alcohol products (5). Presumably the latter results are largely a consequence of the steric bulk of *tert*-butanol.

Results

Acid-catalyzed photo and thermal addition of binary-aqueous organic solvents to styrene

Selectivity values for the competitive reaction between a nucleophile and water with the intermediate were calculated (6) by eq. [4] (where R = 1-phenethyl-, 1-(4-methoxyphenyl)ethyl-, and 1-(3-nitrophenyl)ethyl-),

[4] $S = k(\text{Nuc})/k(H_2O) = ([\text{RNuc}][H_2O]/[\text{ROH}][\text{Nuc}])$

the product ratio being determined by glc analysis.

Selectivity values for the photochemical and thermal reactions are listed along with product ratios for 28 solvent compositions in Table 1. It is readily seen that the S values remain relatively constant up until 10% of the organic cosolvent and then increase proportionally with water content, this increase being most pronounced in aqueous ethanol. It is also apparent that the photochemically generated carbenium ion exhibits greater selectivity than its thermal counterpart generated in identical media at 80°C. At 50.1°C, for 10–1% aqueous methanol (footnote *c*, Table 1), the observed selectivity for the thermal reaction was much lower. In sharp contrast, regardless of the solvent composition, the S values in aqueous acetic acid remained essentially constant, independent of the solvent composition or conditions. We also found that there was no correlation of mass balance (i.e., the percentage of recovered styrene and solvent adducts) with solvent composition or conditions. Ideally, we would have preferred to compare solvent nucleophilicities with the obtained S values. The greatest changes in selectivity, however, occur for solvent compositions less than 10% (by volume) of the organic component, for which solvent nucleophilicity data are not currently available. N_{OTs} values decrease only by 7% in going from 10% cosolvent (acetone, ethanol, methanol) to pure water (Table 2 and ref. 7). To accommodate this gap we have calculated weighted nucleophilicities, which take into account the nucleophilicities of the pure components and their proportion (mole fraction) in various solvent compositions. In eq. [5] we define C_i as the weighted

[5] $C_i = x_i n_i$

nucleophilicity of the ith component where x and n are the corresponding mole fraction and antilog of the nucleophilicity (N_{OTs}) of the pure solvent. It follows that, for a binary mixture, $S_n = C_A + C_B$, where S_n is defined as the sum-weighted nucleophilicity of a mixture of A and B. If the intermediate (or substrate) reacts with the solvent components according to their effective (or relative) concentration and nucleophilicity (taken together), then S should be a 1:1 function of C_A/S_n and a plot of S vs. C_A/S_n should pass through the origin, where as C_A/S_n approaches zero (or $-\infty$ for a logarithmic plot), S does also. Four important assumptions inherent in this analysis are (1) the intermediate (or substrate) reacts with solvent components according to their effective (or relative) concentrations and nucleophilicities, (2) ground-state nucleophilicities are applicable to excited-state reactions, (3) catalytic acid equally perturbs the effective nucleophilicities of both solvent components, and (4) side reactions of the products are negligible. Logarithmic plots of C_{MeOH}/S_n vs. S are depicted in Figs. 1 and 2 for the thermal and photochemical reactions, respectively. The correlation between C_{MeOH}/S_n is quite reasonable for the photochemical reactions in aqueous ethanol, methanol, and TFE ($r > 0.970$), yet the thermal reactions (and the photochemical reaction in acetic acid) give a very poor correlation ($r < 0.770$).

Structural, nucleophilic, and solvation effects upon selectivity

In an attempt to ascertain whether S values are controlled predominantly by one factor of the nucleophile (e.g., steric bulk, nucleophilicity, or solvation effects) we have examined the photoaddition reaction, at constant acidity and irradiation time, in six binary-aqueous compositions of seven alcohols. The results are listed in Table 3. In general, S values decrease in the order MeOH, EtOH > *n*-PrOH > *i*-PrOH > *n*-BuOH, *t*-BuOH > TFE. Of particular interest is the observation that the

photochemical reaction has a distinct preference for the organic component, independent of N_{OTs} values (Table 2).

Selectivity as a function of acid concentration

The photoaddition of 1 and 10% aqueous methanol to styrene as a function of added sulfuric acid (0–25% by volume) concentration was studied. Except for the acid concentration, the conditions for these reactions were identical to those listed in Table 1. No systematic behavior was evidenced at either concentration of methanol. In 1% methanol, the S values ranged from a minimum of 33 (at 15% H_2SO_4) to a maximum of 423 (at 3% H_2SO_4) with significant fluctuations at the other points. In 10% methanol, the S values spanned from a maximum of 21 (at 5% H_2SO_4) to a minimum of 2 (at 3% H_2SO_4). Similar fluctuations were observed here. However, the range of S values was much smaller. There is no direct correspondence between medium acidity and selectivity nor between the selectivity trends in the two methanol compositions. This lends support to our third assumption (*vide supra*), that catalytic acid equally perturbs the effective nucleophilicities of both solvent components.

Irradiation time/product stability

The photoaddition of 10% aqueous methanol to styrene in the presence of 5% sulfuric acid (same conditions as outlined in Table 1, except for the irradiation time) was found to increase in selectivity with irradiation time from a minimum of 7 at 10 and 20 min, to 16 at 40 min, and a maximum of 21 at 60 min. Irradiation for a longer period (80 min) gave a corresponding drop in the selectivity to 11. We also studied the variation in

selectivity with irradiation time for four different compositions of aqueous methanol (Table 4) at the concentrations where fluctuations in selectivity are significant. The most pronounced selectivity changes (ca. two orders of magnitude) are manifested only at 60 min; at shorter irradiation times the changes in selectivity (ca. one order of magnitude) are attenuated. When the data are extrapolated back to zero time, where secondary photochemistry is presumably excluded, the selectivity trend is still in the same direction. That is, the selectivity still increases proportionally with the water content of the mixed solvent.

We have also studied the decomposition of authentic samples of the ether (**2**) and alcohol (**1**) products under the same conditions used for the photo and thermal addition reactions to styrene (Table 5). Use of both "uncorrected" and "corrected" selectivity values indicates that the alcohol reacts slightly faster (1–1.5 times) than the ether in both the photo and thermal reactions.

Reactions with neutral and anionic external nucleophiles

Extensive secondary photochemistry was observed when thiols were employed as nucleophiles. The photolysis of styrene

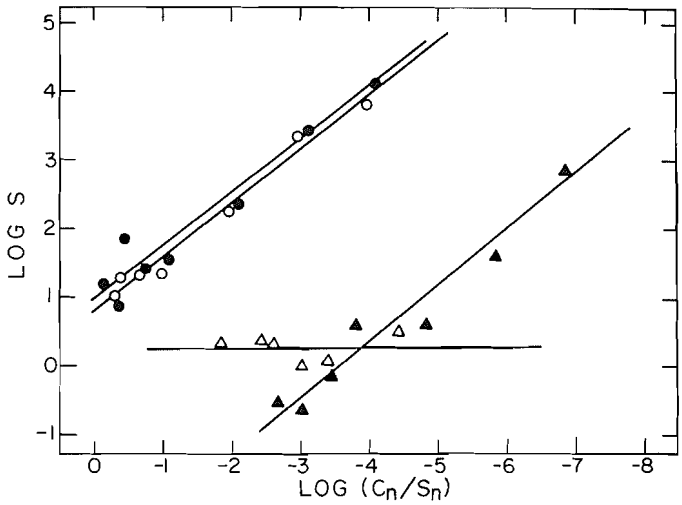

FIG. 2. Logarithmic plot of selectivity vs. weighted nucleophilicity for photoadditions to styrene. (Closed circles are for EtOH–H_2O, open circles for MeOH–H_2O, closed triangles for AcOH–H_2O, and open triangles for TFE–H_2O.)

with thiophenol or ethanethiol under a variety of conditions afforded between 0.5 and 11% of the expected thioethers (**10** and **11**), trace amounts of the alcohol (**1**), and variable amounts of unreacted styrene. The bulk of the reaction mixtures consisted of several unidentified products and intractable polymer. Lower limits for selectivity values were calculated and gave 380 with thiophenol and 1.4×10^5 for ethanethiol.

The photoaddition of aqueous solutions of the benzenesulfinate anion to styrene (same conditions as given in Table 1 except without acid catalyst) gave the expected adduct (**12**), with calculated S values of ca. 33,000 for a 2.4-fold molar excess and ca. 2900 for a 28-fold molar excess. The amount of unreacted styrene varied from zero up to ca. 80% and no major by-products were detected. It was found that the thermal addition (80°C, 7 d, 0.1% H_2SO_4, 2.4-fold molar excess of $PhSO_2^-$) gave an S value of 1420. Sodium acetate, present in a 37-fold molar excess, gave a lower selectivity value of 281.

Ring substitution

The effects upon the selectivity of introducing either a *p*-methoxy or *m*-nitro substituent to the styrene ring are summarized in Table 6. The thermally generated carbenium ion from *p*-methoxystyrene (at 40°C) exhibits greater selectivity than that from styrene in the same compositions of aqueous methanol. In contrast, the photochemically generated species is less selective than for styrene. However, similar dichotomy in selectivity between the photo and thermal reactions is observed, as with styrene (except for the crossover at 0.01% MeOH). In other words, the photochemical reaction still exhibits greater selectivity than its thermal counterpart.

The photochemically generated species from *m*-nitrostyrene is decidedly less selective than either styrene or *p*-methoxystyrene. In fact, no methyl ether was detected at methanol compositions of 0.1 and 0.01% by volume. In line with the photohydrations *m*- and *p*-nitrostyrene (1, 2), the *anti*-Markownikov addition products (**15** and **16**) were observed. No products resulting from Markownikov addition were detected.

photolyses, were measured for possible fluorescence quenching. These and data for other binary-aqueous organic solvents are listed in Table 7. In proceeding from 80 to 0.01% methanol a 41% drop in the fluorescence quantum yield occurred. Fluorescence quenching was also observed in aqueous ethanol (a 19% reduction from 80 to 0.01%), the isomeric propanols, and in 2,2,2-trifluorethanol (TFE). In aqueous acetic acid, the trend was reversed with Φ_{fl} increasing from 0.012 to 0.14 from 80 to 0.01% of the organic component. Only two emission bands, centered at 294 and 305 nm, could be detected for styrene. No others could be found at longer wavelengths with maximum instrument sensitivity.

Discussion

Selectivity trends in thermal and photochemical solvent addition

We can propose two different explanations for the observed trends. Symon's theory of water reactivity (8) can accommodate our results if we consider that addition of a basic cosolvent (e.g., MeOH, MeCN) to water will free lone pairs on the water molecules, thereby increasing their bulk nucleophilicity (eq. [6]). Therefore, as we increase the concentration of the

$$(H_2O)_{bulk} \rightleftharpoons (OH)_{free} + (\text{lone pairs})_{free} \quad (4\text{–}8\%)$$
$$\text{Base} + (OH)_{free} \rightleftharpoons \text{Base----(HO)} \qquad [6]$$

basic cosolvent, water molecules can compete more effectively in trapping the intermediate and the observed selectivity will be lower. Alternatively, as the water concentration of the mixed solvent is increased, the medium polarity will simultaneously increase, thereby stabilizing the developing carbenium ion. Of the solvents investigated, water has the largest Y value (Table 2) and its high polarity will best stabilize the developing carbenium ion by dipole–dipole interactions. Either of these explanations could account for the observed trends. The anomalous behavior in aqueous acetic acid (nearly constant selectivity) is primarily due to competitive photosolvolysis of the addition products (demonstrated by control experiments) or the result of the lower availability of "free" acetic acid by virtue of its known self-association in monomer–dimer equilibria (9–11), which favors the dimer. The latter argument does not appear to be supported, however, by the fluorescence quenching data (Table 7) where the greatest total quenching is observed in 80% acetic acid and varies by a factor of 12 from 0.01%. It is difficult to see why the correlation between the weighted nucleophilicity (C_{MeOH}/S_n) and S (Figs. 1 and 2) is very good for the photochemical reactions, yet poor for the thermal reactions in light of the fact that the weighted nucleophilicity is derived from thermal kinetic data. These results suggest that some other factors than nucleophilicity are operative. Even if the nucleophilicity values could be modified for the photochemical reactions, all of the results could still not be explained. As we shall discuss shortly, secondary photochemistry of the addition products also occurs in the other solvent systems, but is much slower. Nonetheless, the fact that selectivity trends are in the same direction in aqueous methanol for four different irradiation times (Table 4), even when extrapolated back to zero time, sugests that *we can make qualitative predictions, despite this secondary photochemistry*. We could not resort to irradiation of styrene at longer wavelengths because its molar absorptivity approaches zero at 300 nm. The methyl ether (**2**) and alcohol (**1**) adducts possess molar absorptivities of ca. 300 at this wavelength. At 254 nm, however, styrene is the principal absorber (ϵ_{max} (243 nm) = 13,360) while the alcohol and ether products have lower (<4900) molar absorptivities. Since selectivity changes were most pronounced at 60 min, all irradiations were conducted for this duration. Trends might have otherwise been indistinguishable in the less nucleophilic TFE–H_2O mixtures. It remains for us to delineate why the photochemical reaction should exhibit much higher selectivity than its thermal counterpart.

Fluorescence quenching

Our results (Table 7) indicate that there is preferential solvation of styrene by the organic component in the binary-aqueous solvent. We believe that this is due to a pre-association step involving hydrogen bonding, which is retained or enhanced in the excited state. The latter effect is possibly due to the increase in π-bond basicity in the excited state for styrenes, ca. 8–10 pK_a units (1). An alternative explanation considered, involving a HOMO–LUMO interaction between styrene and the nucleophile in the excited state, is unlikely to be correct since Whitten and co-workers (12) could not spectrally detect exciplexes in the photoaddition of nucleophiles to electron-deficient alkenes, substrates ideally suited for such an interaction. Furthermore, scanning of our solutions of aqueous methanol with styrene at longer wavelengths and maximum instrument sensitivity did not reveal an emission band (usually broad), characteristic of an exciplex. Fluorescence quenching due to hydrogen bonding has previously been observed with 9-trimethylsilylanthracene in methanol (13) and 1-aminopyrene in pyridine/hexane (14).

Structural, nucleophilic, and solvation effects upon selectivity

styrene, just alluded to, might also be due in part to other factors. A lower than expected nucleophilicity for water in acetonitrile has been explained (15) in terms of solvent clusters held together by weak hydrogen bonds that diminish the nucleophilic character of water, in accord with Symon's theory (8). A similar rationale has been proposed by Jencks and co-workers (16) for aqueous TFE mixtures. From thermochemical measurements (by mass spectroscopy) of mixed water–methanol cationic clusters ($(H_2O)_n(MeOH)_mH^+$), Meot-Ner (17) has found that the H^+ (charged) center will be preferentially solvated by methanol molecules. In other words, the most stable isomers will have the methanol molecules situated near the charged center. It is not unreasonable to presume that this line of argument could be extended to conclude that styrene molecules would prefer to reside within such a cluster, if the hydrophobic nature of styrene is considered. On the basis of solubility alone, styrene would be expected to be better solvated by the organic solvent component. Moreover, we would anticipate that the selectivity should increase with better solvating organic solvents (e.g., propanol vs. methanol). The only consistent trend in this particular study (Table 3) is that the *sec*-phenethyl carbenium ion reacts preferentially with the organic solvent component. The approximate order of selectivity we observed does not correlate with ground-state solvent nucleophilicity values, the solvatochromatic parameters α and β, pK_a, or *Y* values (Table 2). Kobayashi *et al.* observed (15) a similar disparity between the ground-state and "apparent" excited-state nucleophilicity order (MeOH > EtOH > *i*-PrOH > H_2O > *t*-BuOH) in the decay of vinyl cations generated via flash photolysis. Our results imply that selectivity is governed by an interplay of steric bulk, solvating ability, and solvent composition, with all other variables remaining equal. It is quite remarkable that a preference is shown even for weakly nucleophilic TFE in the presence of water. Clearly, its solvating power as well as superior hydrogen-bonding ability must be factors in this behavior.

Medium acidity

The discordant results obtained in 1 and 10% aqueous methanol are not easily interpreted. One likely possibility is that the thermal addition is competitive at higher acid concentrations (>15% H_2SO_4). Even though precautions were taken (cooling during mixing of components and use of a cold finger during irradiation) this still seems to be a viable explanation. Wan has noted (1, 18) that the ground-state hydration of styrene becomes significant at $H_0 < -1.4$ (ca. 15% H_2SO_4). In addition to this, acid-catalyzed photosolvolysis and (or) suppression of solvent autoionization (particularly in 1% MeOH–H_2O) could be occurring.

Irradiation time/product stability

At first it was speculated the results (a parabolic increase and decrease in selectivity with irradiation time) might be due to selective photosolvolysis of the alcohol adduct. Initially, this seemed unlikely since the leaving groups (methanol and water) differ by only 2 pK_a units (Table 2) and are of approximately the same pK_a ($\Delta pK_a = 0.3$) when methanol is in dilute solution (19, 20). At other compositions of aqueous methanol, it was found that *S* does not always increase from 20 to 40 min (Table 4), yet the most significant changes are at 60 min and later. The most reasonable explanation for this trend is that there is another, completely different reaction of the primary photoaddition (photosolvolysis) product(s), which has a much lower quantum yield, or which requires one of the initially formed products to react with it. Our decomposition study, however, does reveal that the alcohol (**1**) reacts 1–1.5 times faster than the ether (**2**) during a comparable time period (60 min) in various compositions of aqueous methanol. This rate variation, in itself, does not make a significant enough contribution to explain the time dependent irradiation behavior.

Reactions with external nucleophiles

The results with thiophenol and ethanethiol (<11% of the thioether adduct) imply that competitive photochemistry of the thiol and (or) adduct is occurring. One inherent problem is that styrene and thiophenol have comparable molar absorptivities (21). A competitive radical pathway initiated by homolytic dissociation of the thiols is consistent with earlier photochemical studies by Sivertz and co-workers (22, 23). This may explain why the observed selectivity is greater with ethanethiol, which does not absorb light as strongly.

The benzenesulfinate anion was the most potent nucleophile (24) we examined. The molar absorptivity of $PhSO_2^-$ was found to be very low (ϵ_{max} (269 nm) = 1004 in water) thus mitigating against competitive absorption with styrene. Our observed fluctuation in selectivities with nucleophile concentrations, for both the acetate and benzenesulfinate ions, suggests an interplay between substrate/nucleophile solubility at higher

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 112.217.228.212 on 09/07/12
For personal use only.

nucleophile concentrations. At lower nucleophile concentrations, the barrier to desolvation of acetate to allow it to approach the developing carbenium ion must be of higher energy than that required for the benzenesulfinate ion, which parallels an argument set forth by Richard and Jencks for carboxylate anions (25). Polymerization of styrene is not likely to compete at such low concentrations; i.e., 10^{-4} M. It would be hazardous to speculate upon the selectivity difference in the photo and thermal addition of $PhSO_2^-$ to styrene, due to the difference in medium acidity.

Ring substitution

On the basis of simple resonance effects, it was anticipated that *p*-methoxystyrene might exhibit greater selectivity than styrene in both the thermal and photochemical addition reactions. On the other hand, we expected *m*-nitrostyrene to give lower selectivity and *anti*-Markownikov addition products for the photoaddition. Addition at the carbinol carbon, in light of partial diradicaloid character (1), could also conceivably compete. The increased selectivity of *p*-methoxystyrene over styrene in the thermal addition of aqueous methanol (Table 6) is clearly consistent with resonance stabilization of the developing carbenium ion by the *p*-methoxy substituent. Results from the photoaddition were initially puzzling; they are in direct contradiction to the reactivity–selectivity principle (RSP; 6, 26). Excitation of styrenes (analogous to normal alkenes) presumably leads to an S_1 state where a weakening of the π-bond results in a preferred nonplanar conformation of the *p*-orbitals (1, 27, 28). This partial disruption of the extended π-system might explain the attenuation in resonance stabilization. Alternatively, introduction of a ring substituent may also contribute to a shorter lifetime by providing an energy sink for the excited-state species, i.e., additional vibrational degrees of freedom afforded by a "free rotor" effect. Previous measurements in our laboratories (1, 2, 18) gave fluorescence lifetimes of 7.5 and 1 ns for styrene and *p*-methoxystyrene, respectively, in acetonitrile–water at pH 7. It was found that these lifetimes decreased with increasing medium acidity. Hence, the lower selectivity of *p*-methoxystyrene as compared to styrene is quite reasonably explained either by attenuated resonance effects and (or) a shorter intermediate lifetime. The *sec*-phenethyl carbenium ion has also been generated in a photosolvolytic reaction. McKenna and co-workers observed (29) that both the thermal- and photo-solvolysis of (−)-1-(4-methoxyphenyl)-ethyltrimethylammonium iodide in aqueous methanol (containing 0.31 mole fraction methanol) gave a strong preference for formation of the methyl ether rather than the alcohol (eq. [7]).

[7] 
From the yield of the ether product, it was calculated that the capture ratio (k(MeOH)/H_2O)) is at least 20. The similarity of capture by methanol under both conditions indicates the photochemically generated carbenium ion is most likely thermally equilibrated prior to coordination with the solvent molecule(s). The large selectivity (e.g., S values of 1.5–2.8 were found for the benzyl analogues in the same solvent) was ascribed to stabilization of the ion pair by the *p*-methoxy group. It is not entirely clear why our photochemical results, but not the thermal, agree with McKenna's (29) solvolytic data. Ion pairs in the solvolysis reaction might be one significant point of departure. The thermal S values are also close to the previously described results of Richard and Jencks (25). The fact that our observations differ from those of McKenna demonstrates that there is no appreciable thermal equilibration of the photochemically generated carbenium ion from *p*-methoxystyrene prior to coordination with the solvent molecule(s).

m-Nitrostyrene, which reacts via a T_1 state, has a considerably longer lifetime of ca. 460 ns (18). The very low selectivity that we have observed with the *meta* derivative appears to be the result of largely one effect. It could be due to the reverse-polarized or diradicaloid character of the intermediate, which would render it less susceptible to nucleophilic attack. This is consistent with the previous observation (1, 2) that photohydration of the nitrostyrenes was not subject to acid catalysis. As we anticipated, no products that would arise from attack at the carbinol carbon (**17** and **18**) were detected.

Conclusions

Our study has demonstrated that selectivity in the acid-catalyzed addition of nucleophiles to styrene is a function of several variables. While the selectivities we have measured are not absolute by any means, the results do indicate a marked difference between the photochemically and thermally generated carbenium ions. Our data further argue against proton transfer to styrene (or *p*-methoxystyrene) leading to an intermediate that funnels from the excited-state energy surface to the corresponding ground-state surface. Indeed, the results suggest that the photochemical reaction involves either a hot cation, an excited state, or a blend of these possibilities. Some of our observations have also raised further questions as to the validity of the RSP (30). Fluorescence quenching measurements in aqueous methanol mixtures have supported our hypothesis that the difference in selectivity between the photochemical and thermal reaction is due to retention or enhancement of hydrogen bonding of the organic solvent to styrene in the excited state. This also might be attributed to a "local" concentration effect as a result of the rapid intermediate generation in the photochemical reaction. The longer time period for the thermal reaction allows for greater solvent reorganization.

Experimental

Instrumentation

Infrared (ir) absorption spectra were recorded using a Nicolet 5DX FT-IR grating spectrophotometer, in a potassium bromide matrix or neat. The ^1H nmr spectra were measured using a Varian T-60 spectrometer at 60 MHz with deuterochloroform as solvent and tetramethylsilane as an internal standard. Capillary melting points (mp) were determined on a Gallenkamp apparatus. Both melting points and boiling points (bp) are uncorrected. Ultraviolet (uv) absorption spectra were measured using a Varian 2300 uv–vis spectrometer with 1-cm cells. Analytical glc analyses were performed on either a Varian 3400 gas chromatograph (using a 15 m × 0.25 mm fused silica (0.25 μm) capillary column packed with OV-101) or on a Varian Aerograph 2700 gas chromatograph (using a 6 ft × 2 mm column packed with either 3% OV-101 on 80/100 mesh Chromosorb G or 3% OV-17 on 80/100 mesh Chromosorb W) with a Varian 4270 integrator (error estimated at ±5%). *m*-Dimethoxybenzene was employed in nearly all cases

as an internal standard for response calibration to the detectors. Fluorescence spectra were recorded on Perkin Elmer MPF-44B or MPF-66 fluorescence spectrophotometers at 20°C using argon degassed solutions. Unless otherwise specified, all preparative irradiations were conducted with 525-mL solutions using a Rayonet RPR-100 reactor equipped with 254-nm lamps. Solutions were outgassed with argon for at least 20 min prior to irradiation. A 0.6-L Vycor quartz tube was employed with a cold finger connected to tap water. During irradiations, the outlet water temperature was found to be ca. 5°C. Stirring of the reaction mixture was effected with a magnetic bar. Thermal runs were carried out in either tightly stoppered volumetric flasks or in sealed ampoules placed in a constant temperature bath maintained within ±0.2°C.

Materials

Benzene and acetonitrile were Caledon ACS reagent grade and used as received. All of the alcohol solvents, except for 2,2,2-trifluoroethanol (TFE, Aldrich Gold Label) and *tert*-butanol (Fisher), were Caledon ACS reagent grade. The alcohols and acetic acid (Baker glacial, ACS reagent grade) were used as received without further purification. All of these solvents were used together with distilled water to prepare binary solutions on a volume/volume basis at 21°C. The appropriate volume of sulfuric acid (BDH or Fisher) was then added. Styrene (Fisher), *p*-methoxystyrene (K & K), and *m*-nitrostyrene (Fairfield) were distilled from hydroquinone under reduced pressure prior to use. Substrates **1** and **15** were purchased from Aldrich Chemical Company. Other substrates, except for those described specifically below, were prepared following literature procedures. Compound **10** was prepared by the reaction of thiophenol and **1** according to the method of Scretas and Scretas (31). Substrate **11** was synthesized from the reaction of ethanethiol (Aldrich) and **1** by the procedure of Guindon *et al.* (32). 1-Phenethyl bromide and 1-(4-methoxyphenyl)ethyl bromide were prepared from the corresponding alcohols by treatment with constant boiling hydrobromic acid as described by McKenna and co-workers (29). Substrates **2**, **4**, **6**, **7**, **8**, and **14** were synthesized from the appropriate alkyl bromide and the corresponding alcohol by the method of McKenna (29). Compound **13** was prepared by sodium borohydride reduction of *p*-methoxyacetophenone (Aldrich) in ethanol. Substrate **3** was synthesized according to the method of Dauben *et al.* (33) by reaction of ethyl iodide with **1**. Compound **9** was prepared by a Fischer esterification of acetic acid and **1**. The above synthesized compounds were purified and identified by their melting or boiling points and spectroscopic data, which were, in all cases, in good agreement with the literature values.

1-Phenethylbenzenesulfinate (12)

In a manner analogous to the preparation of 1-adamantyl methyl sulfide (34), *sec*-phenethyl bromide (2.00 g) and sodium benzenesulfinate (3.55 g, Aldrich) were reacted in refluxing acetonitrile for 24 h. The reaction mixture was concentrated (rotary evaporator) and gave, upon standing overnight at room temperature, yellow platelets. Recrystallization from benzene gave a pale yellow solid and repeated washing with ether and pentane afforded 0.7 g (26% yield) of a fine white powder, mp 112–114°C; ir (KBr) ν_{max}: 1299 and 1286 (asym. SO_2), 1142 and 1139 (sym. SO_2); uv λ_{max} (H_2O): 269 nm (ϵ 1044), 228 nm (ϵ 2419); ^{1}H nmr ($CDCl_3$) δ: 1.82 (d, CH_3, 3H, J = 7 Hz), 4.27 (q, CH, 1H, J = 7 Hz), 7.28 (m, 2 Ph, 10H).

3-Nitrophenethyl methyl ether (15)

Following the procedure of Merz (35), a solution of **15** (1.99 g, Aldrich) and tetra-*n*-butylammonium iodide (0.072 g) in dry benzene (20 mL) and 50% aqueous NaOH (7.5 mL) was equilibrated by vigorous stirring for 30 min. Dimethylsulfate (4.4 mL) was then added dropwise, with cooling during a 15-min period at a rate such that the temperature did not exceed 45°C. The whole was next brought to reflux and stirred for 6 d whereupon glc analysis (OV-101 column) showed complete disappearance of starting material. This was followed by quenching with concentrated NH_4OH (40 mL), extraction with ether (3 × 30 mL), and drying of the combined extracts over $MgSO_4$. Removal of solvent followed by distillation of the crude product under reduced pressure afforded 1.3 g (60% yield) of a pale, clear yellow liquid, bp 112–114°C (0.65 Torr; 1 Torr = 133.3 Pa); ir (neat) ν_{max}: 1529, 1525 (asym. N=O), 1349 (sym. N=O), 1115 (C—O—C); ^{1}H nmr ($CDCl_3$) δ: 2.92 (t, CH_2OH, 2H, J = 6 Hz), 3.32 (s, CH_3O, 3H), 3.64 (t, $PhCH_2$, 2H, J = 6 Hz), 7.23–8.18 (m, Ph, 4H).

Irradiations

The following experiment was representative of the procedure employed. A solution of styrene (34 mg in 25 mL of MeCN and 500 mL of 1% aqueous ethanol containing 5% H_2SO_4) was outgassed with argon for 20 min and then irradiated for 1 h at 254 nm in a Vycor tube equipped with a cold finger. The solution was then saturated with NaCl and extracted with CH_2Cl_2 (3 × 100 mL). The combined organic extracts were neutralized with saturated aqueous $NaHCO_3$ solution. Subsequent drying over $MgSO_4$, solvent removal (rotary evaporator), and response-calibrated glc analysis (OV-17 column) of the crude product revealed the presence of 0.5% styrene, 41.1% of **3**, and 58.9% of **1**. These components comprised approximately 62% of the total reaction mixture, the remainder consisting of several unidentified higher boiling by-products.

Thermal runs

In a typical experiment, a solution of *p*-methoxystyrene (10 mg in 5 mL of MeCN and 95 mL of 0.1% aqueous methanol containing 5% H_2SO_4) in a 250-mL volumetric flask was placed in a constant temperature bath thermostatted at 40.6°C for 28.5 h. The solution was then saturated with NaCl, extracted with CH_2Cl_2 (3 × 30 mL), the combined extracts neutralized with saturated aqueous $NaHCO_3$, and then dried over $MgSO_4$. Removal of solvent (rotary evaporator) followed by response-calibrated glc analysis (OV-101 column) revealed the presence of peaks corresponding to starting material (1.6%), **13** (95.4%), and **14** (3.0%). These components made up approximately 29% of the total reaction mixture, the remainder again consisting of numerous by-products possessing longer retention times.

Fluorescence quenching

Solutions for fluorescence quenching studies were prepared by injecting 10 μL of a stock solution of styrene (4.00×10^{-4} M in CH_3CN) into the appropriate mixed solvent (3 mL), which had been degassed for 1 min, in a quartz cuvette. The resulting styrene concentration was 1.33×10^{-6} *M*. Corrected fluorescence spectra of these solutions were then recorded under identical conditions employing Rhodamine-B as a standard.

Solvation properties in iso-acidic media involving phosphoric acid

C. Louis, A. Bebba, and J. Bessière

Laboratoire de Chimie et Electrochimie Analytique, Faculté des Sciences, Université de Nancy 1, B.P. 239, 54506 Vandoeuvre Les Nancy CEDEX, France

Received October 23, 1987[1]

C. Louis, A. Bebba, and J. Bessière. Can. J. Chem. **66**, 2422 (1988).

Concentrated solutions of mineral acids (phosphoric, hydrochloric, perchloric, sulfuric) are characterized, for an equal value of their water activity, by an equal R_0(H) acidity level (iso-acidic solutions). By mixing them, we prepare what we call iso-acidic mixtures which keep the same acidity level as the constitutive solutions whatever the proportions; their redox and solvating properties depend both on the nature and on the ratio of the constitutive solutions. Reactivity variations for ionic species: Cl^-, Br^-, I^-, diethyldithiophosphate (LET^-), $Si(W_3O_{10})_4^{4-}$, $Si(W_3O_{10})_4^{5-}$, Cu^{2+}, Cu^+, Pb^{2+}, Sn^{2+}, Cd^{2+}, Zn^{2+}, Ag^+, Fe^{3+}, Fe^{2+}, UO_2^{2+}, U^{4+} in the iso-acidic mixtures are characterized by their f solvation-transfer activity coefficients. Relations between f coefficient values and complexation properties are established and it is shown that phosphoric acid has comparatively weak solvating properties toward most species. The possibility for anticipating reaction changes with the iso-acidic mixture composition by using the f coefficients is demonstrated in the case of cadmium ionic flotation with diethyldithiophosphate and silver extraction with dithizone in carbon tetrachloride.

C. Louis, A. Bebba et J. Bessière. Can. J. Chem. **66**, 2422 (1988).

On a caractérisé des solutions concentrées d'acides minéraux (phosphorique, chlorhydrique, perchlorique, sulfurique), ayant la même activité dans l'eau et le même niveau d'acidité R_0(H) (solutions iso-acides). En les mélangeant, on a préparé ce que l'on peut appeler des mélanges iso-acides qui gardent le même niveau d'acidité que les solutions qui les constituent quelles que soient les proportions. Leurs propriétés de solvatation et redox dépendent à la fois de la nature et du rapport des solutions de départ. On a caractérisé les variations de réactivité des espèces ioniques Cl^-, Br^-, I^-, diethyldithiophosphate (LET^-), $Si(W_3O_{10})_4^{4-}$, $Si(W_3O_{10})_4^{5-}$, Cu^{2+}, Cu^+, Pb^{2+}, Sn^{2+}, Cd^{2+}, Zn^{2+}, Ag^+, Fe^{3+}, Fe^{2+}, UO_2^{2+}, U^{4+}, des mélanges iso-acides en se basant sur leur coefficient d'activité de transfert de solvatation f. On a établi des relations entre les valeurs du coefficient f et les propriétés de complexation et on montre que de tous les acides, c'est l'acide phosphorique qui solvate moins bien la plupart des espèces. Utilisant la flottation de l'ion cadmium par le diethyldithiophosphate d'éthyle et l'extraction à l'argent avec la dithizone dans le tétrachlorure de carbone, on démontre qu'il est possible de se servir du coefficient f, pour prévoir le comportement des réactions en fonction de la composition du mélange iso-acide.

[Traduit par la revue]

Introduction

It has been shown recently that concentrated solutions of mineral acids (phosphoric, hydrochloric, perchloric, sulfuric) having the same water activity, are characterized by an equal value of the R_0(H) acidity function (1). By mixing these solutions, we prepare what we call iso-acidic mixtures which have the same acidity level as the constitutive solutions, whatever the proportions (2). Nevertheless, their solvation and redox properties are assumed to be different, depending both on the nature and the proportions of the constitutive solutions.

The concept of iso-acidity is important to anticipate changes of equilibria with the composition of concentrated acid mixture. We intend to apply it in particular to the analysis of the acidic dissolution processes of minerals (apatites, mineral fluorides ...) which generally lead to complex acid mixtures. As we did in the case of concentrated phosphoric acid solutions (3), we characterize the variation of ionic species reactivity in iso-acidic solutions involving phosphoric acid with their solvation-transfer activity coefficients (f) and analyze these data to find out if ionic species having weak chemical interactions with the solvent anions keep the same reactivity when the composition of the iso-acidic mixture is changed.

We consider binary iso-acidic mixtures involving phosphoric acid on the one hand and hydrochloric acid, sulfuric acid, or perchloric acid on the other. Hydrochloric and sulfuric acids have been selected for their complexing properties and perchloric acid for its lack of complexing properties.

Changes in the precipitation reaction of cadmium with diethyldithiophosphate (LET^-) and the extraction reaction of silver with dithizone (acidic extractant H_2Dz) are then analyzed taking into account variations of the solvation characteristics of the involved species.

Variations of solute solvation: theoretical aspects

Variations of solute solvation are characterized by means of the solvation-transfer activity coefficients (f). They are calculated from normal potential values of the corresponding redox systems according to the relations [1]–[4].

M^{n+}/M system

[1] $$\log f_{M^{n+}} = n(E_0^a - E_0^w)/0.058$$

$M^{n+}/M^{(n-m)+}$ system

[2] $$\log f_{M^{n+}}/f_{M^{(n-m)+}} = m(E_0^a - E_0^w)/0.058$$

$MO_p^{n+}/MO_q^{[n+2(p-q)-m]+}$ system

[3] $$\log f_{MO_p^{n+}}/f_{MO_q^{[n+2(p-q)-m]+}} = m(E_0^a - E_0^w)/0.058 + 2(p-q)R_0(H) + (p-q)\log a_{H_2O}$$

AX_n/A system

[4] $$\log f_{X^-} = (E_0^w - E_0^a)/0.058$$

E_0^w represents the normal potential of the considered redox system in water, E_0^a its value in an iso-acidic medium characterized by its acidity level, R_0(H) (4–7), and its water activity, a_{H_2O} (8). Both are referred to the ferricinium/ferrocene (Fc^+/Fc) comparison system (9, 10).

The f coefficients have been alternatively determined from

*Precipitation in mixtures containing H_2SO_4.

solubility product values according to the relation [5]

MX compound

$$[5] \quad pK_s^a - pK_s^w = \log f_{M^+} + \log f_{X^-}$$

where K_s^a represents the solubility product of the MX compound in the iso-acidic medium and K_s^w its value in water.

In the case of cadmium ionic flotation with diethyldithiophosphate as a collector, there is a direct relationship [6] between the precipitation of cadmium with the LET^- collector and the cadmium ionic flotation yield (R) (6, 11).

$$[6] \quad K_s = (1 - R)(\Phi - 2R)^2 C_0^3$$

where K_s is the solubility product and C_0 the initial concentration of cadmium. R represents the ratio of collected Cd^{2+} to initial Cd^{2+} and Φ the ratio of initial concentration of the collector to initial concentration of cadmium.

The precipitation reaction of Cd^{2+} with LET^-

$$[7] \quad Cd(LET)_2 \downarrow \leftrightarrow Cd^{2+} + 2LET^-$$

is characterized in water and in an acidic mixture, respectively, by the constants:

$$[8] \quad K_s^w = [Cd^{2+}][LET^-]^2$$

$$[9] \quad K_s^a = [Cd^{2+}]_a[LET^-]_a^2$$

which are related according to

$$[10] \quad pK_s^a = pK_s^w + \log f_{Cd^{2+}} + 2 \log f_{LET^-}$$

with $pK_s^w = 9.9$.

Extraction constants are related to the activity coefficients of the extracted species. If the extraction of a metallic cation (Ag^+) with an acidic extractant (dithizone H_2Dz) in an organic solvent (CCl_4) is considered (12), the extraction equilibrium

$$[11] \quad Ag^+ + H_2Dz^* \leftrightarrow AgHDz^* + H^+$$

*X = X species in the organic phase

is generally characterized by the constant

$$[12] \quad K = a_{H^+} a_{AgHDz} / a_{H_2Dz} a_{Ag^+}$$

If the concentrations of both the extracted species and the extractant are low and with an aqueous phase at pH = 0, the extraction constant is

$$[13] \quad K = K_{app}^w = [AgHDz]/[Ag^+][H_2Dz]$$

with $\log K_{app}^w = 7.0$ at pH = 0.

with an acidic aqueous phase (acidity level $R_0(H)$),

$$[14] \quad K_{app}^a = [AgHDz]/[Ag^+]_a[H_2Dz] = f_{Ag^+}[AgHDz]/a_{Ag^+}[H_2Dz] = Kf_{Ag^+}/a_{H^+}$$

$$[15] \quad \log K_{app}^a = \log K + \log f_{Ag^+} + R_0(H)$$

This relationship is valid in any acidic mixture provided the extraction equilibrium remains unchanged and the nature of the organic phase does not change when the composition of the acidic aqueous phase is modified.

Experimental

The normal potentials of some redox systems were determined directly by classical electrochemical methods: dc polarography and zero current potentiometry.

Direct current polarography was used in the case of Cd^{2+}/Cd, Pb^{2+}/Pb, Zn^{2+}/Zn, Cu^{2+}/Cu, Sn^{2+}/Sn, Fe^{3+}/Fe^{2+}, $Si(W_3O_{10})_4^{4-}/Si(W_3O_{10})_4^{5-}$ (6, 13, 14). Normal potentials and half-wave potentials of rapid systems are equal as long as the diffusion coefficients of cations in solution and in the amalgam are the same. In concentrated media, diffusion coefficient variations are determined and the correction is calculated, the correction is significant in iso-acidic media with an $R_0(H)$ acidity level lower than −5.9.

Normal potentials were determined by potentiometry at the silver electrode (Nernst law verification) in the case of the redox systems: $AgCl\downarrow/Ag\downarrow$, $AgBr\downarrow/Ag\downarrow$, $AgI\downarrow/Ag\downarrow$, $AgLET\downarrow/Ag\downarrow$. The potentials were all measured at 20°C by reference to the following electrode: aqueous SCE in a separate compartment containing 0.1 M H_3PO_4.

Normal potentials of uranium were calculated from the equilibrium constants of the reaction

$$[16] \quad U(VI) + 2Fe(II) \leftrightarrow U(IV) + 2Fe(III)$$

in acidic media with an $R_0(H)$ acidity level higher than −2.0.

These equilibrium constants were determined from vis-spectrophotometric measurements on U(IV) species at 660 nm (15, 16).

Determinations involving ionic flotation were carried out in the following way: the acidic solution containing the cadmium and the collector (Φ ratio) is introduced in the Hallimond flotation cell (6). Air under controlled pressure is passed through. The foam which contains the cadmium-collector species is collected at the top and diluted in dimethylsulfoxide. The Cd^{2+} concentration is determined polarographically.

The extraction of AgHDz in CCl_4 is realized in the following conditions: shaking, 15 min; phase separation, 2 h; Ag species concentrations are calculated from [AgHDz]; spectrophotometric measurements at 463 nm (6).

The normal potentials (referred to the ferricinium/ferrocene system) are given in Tables 1, 2, 3, 7, 8. The solvation transfer activity coefficients ($\log f$) are given in Tables 4, 5, 6, 9, 10.

Discussion

1. Ion solvation

Solvation of Cl^-, Br^-, I^-, LET^- anions which are monovalent and have no basic properties except for the last one, does not change significantly when the composition of the iso-acidic mixture is modified (Tables 4, 5, 6, 9, 10). Consequently, reducing properties of metals which oxidize in the form of an insoluble halogenide and oxidizing properties of Cl_2, Br_2, I_2 species in gas or solid state or in solution in an immiscible solvent, do not change when the composition of the iso-acidic mixture is modified. In addition, the variation of the halogenide solubility product depends only on the variation of the cation solvation.

The normal potential of the redox system $Si(W_3O_{10})_4^{4-}/Si(W_3O_{10})_4^{5-}$ remains constant although large anions with several charges are involved. So far, we cannot generalize such a result. Some cations do not have the same reactivity in the various iso-acidic mixtures. Some others hold the same solvation characteristics (Tables 4, 5, 6, 9, 10). Solvation variations are summarized in Table 11.

Perchloric acid is said to have little complexing properties. It is then this medium which, for an equal water activity value, should have presented the weakest affinity toward metallic cations. Nevertheless, phosphoric solutions are generally the less solvating toward most cations.

Complexation phenomena can explain the variations observed in the $\log f$ values.

The effect of Cl^- on Ag^+, Pb^{2+}, Cd^{2+}, Cu^+ cations is apparent in the phosphoric–hydrochloric iso-acidic mixtures as soon as HCl is added to H_3PO_4. Ag^+, Pb^{2+}, Cu^+ are probably in the form of the soluble complexes $AgCl_2^-$, $PbCl_3^-$, $CuCl_2^-$. It has been shown (17) that $CdCl^{(n-2)2+}$ complexes exist in the phosphoric mixtures. Their stability is approximately the same as the one they have in water. Cd^{2+} and Zn^{2+} cations are less solvated in phosphoric acid than in perchloric acid. This can be explained by the formation of $CdClO_4^+$ and $ZnClO_4^+$ complexes. In water, $ZnClO_4^+$ pK_c value is 1.3. Since ClO_4^- has no basic properties, the interaction between zinc and perchlorate anion is possible in concentrated solutions as well. Zinc and cadmium have close chemical properties so that their similar behaviour appears logical.

SO_4^{2-} anions have basic properties ($pK_a = 1.9$), then their reactivity decreases as the acidity increases, nevertheless the higher the H_2SO_4 concentration in the iso-acidic medium, $R_0(H) = -1.9$, the stronger the Ag^+, Zn^{2+}, and Cd^{2+} solvation. Such a behaviour is analogous to the one of organic cations (Hammett indicator cations) which have no interaction with the solvent anions. In both cases, cations are more solvated

in the more ionized acid. In particular, solvation variations of Ag^+ and 4-nitro-2-aniline cations are very close in the mixture 5.5 M H_3PO_4 − 3.25 M H_2SO_4 (6). This analysis is also valid in the R_0(H) = −5.9 iso-acidic mixtures.

Cu^{2+} and Sn^{2+} cations are less solvated in the perchloric medium than in the phosphoric medium. These cations are characterized in 2.0 M phosphoric medium by negative log f values (15, 18) indicating a specific interaction with phosphoric acid at a low concentration. One can understand that the other iso-acidic media can be less solvating toward these cations as it is for Cu^{2+} in perchloric acid and for Sn^{2+} in sulfuric and perchloric acids.

The correlation which exists between complexation and solvation variations explains that log f cannot be calculated according to recently developed models (19–22) which assume no specific interaction between the particles, taking uniquely into account electrostatic interactions (short and mean distances) and not complexation.

2. Reaction evolution analysis

The LET^- anion is equally solvated in the various iso-acidic mixtures (Tables 4, 5), then according to relation [10], the less solvating the iso-acidic mixture toward Cd^{2+}, the easier the $Cd(LET)_2$ separation. The pK_s^{exp} values calculated from flotation experiments according to relation [6] and pK_s^{calc} values calculated according to relation [10] are fairly consistent (Table 12). Cd^{2+} ionic flotation yield is the higher in the phosphoric medium.

+1) when the aqueous phase is 5.5 M H_3PO_4, 3.25 M H_2SO_4 or 3.4 M $HClO_4$ iso-acidic solutions ($R_0(H) = -1.9$). Conditions are then fulfilled for the calculation of the partition constants according to relation [15]. It is shown on Table 13 that K_{app}^{calc} partition constants calculated according to relation [15] and K_{app}^{exp} determined from extraction experiments are in good agreement. Ag^+ cation is less extracted in the acidic solutions than in water because lesser solvation Ag^+ in these solutions does not compensate for the acidity increase. When the iso-acidic solutions are compared, the extraction efficiency depends uniquely on Ag^+ solvation variations, then Ag^+ extraction in more efficient in the case of phosphoric medium.

Density measurements in the succinonitrile–water system

LEE HONG NG AND DONALD ROBERT SADOWAY

Department of Materials Science and Engineering, Massachusetts Institute of Technology, Cambridge, MA 02139, U.S.A.

Received March 31, 1988

LEE HONG NG and DONALD ROBERT SADOWAY. Can. J. Chem. **66**, 2428 (1988).

The variation of density with temperature and composition in the succinonitrile–water system was measured by the direct Archimedean method. At fixed composition, density was found to vary linearly with temperature. At constant temperature, density was found to vary linearly with composition. Along the phase boundary there is a density reversal: at temperatures above 45°C the water-rich phase is denser; below 45°C the succinonitrile-rich phase is denser.

LEE HONG NG et DONALD ROBERT SADOWAY. Can. J. Chem. **66**, 2428 (1988).

Utilisant la méthode directe d'Archimède, on a mesuré la variation de la densité du système eau–succinonitrile en fonction de la température et de la composition du mélange. On a trouvé que pour une composition déterminée, la densité varie linéairement avec la température, tandis qu'à température constante la densité varie linéairement avec la composition. Il y a une inversion de la densité le long de la frontière des phases : la phase riche en eau est plus dense à une température supérieure à 45°C. En dessous de cette température c'est la phase riche en succinonitrile qui est plus dense.

1. Introduction

Miscibility gaps are present in many technologically important systems. In order to attain microstructural goals in these systems it is imperative that phase separation phenomena be strictly controlled during materials processing operations. This requires a knowledge of the kinetics of phase transformation.

Classical studies of phase separation were restricted to solids where it is effectively impossible to observe microstructural evolution as it occurs. However, conclusions based on the final morphologies can be misleading (1–6). It is clear that the transformation must be studied in real time.

The novelty of the present work is that for the first time a liquid system was made the subject of a phase transformation study. The succinonitrile–water system was chosen because it is liquid at ambient temperature and transparent to visible light. The latter allows the use of noninvasive optical techniques for real time measurement of microstructure. However, this requires a knowledge of the variation of the index of refraction. Such data have not been reported for the succinonitrile–water system. As the index of refraction is related to density, the purpose of the present study was to measure the dependence of density on temperature and composition in this system.

2. Experimental

Density was measured by the direct Archimedean technique in which one monitors the weight change of a calibrated bob upon immersion in the solution under study (7). The apparatus is shown in Fig. 1. The upper limb is 66 cm long and houses the fused quartz spring; the lower limb is 16 cm long and holds the sample which is heated by circulating water. Water temperature is regulated by a constant temperature circulator.[1] The spring is centered by the ball and socket joint at the top of the upper limb and is raised and lowered by the pulley mechanism. During the experiment the sample is kept under an atmosphere of argon.

The density bob is made of borosilicate glass and weighs about 3 g. The bob is connected to the spring by means of a stainless steel wire, 0.5 mm in diameter. The fused quartz spring[2] has a sensitivity of 0.05 g cm^{-1} and extremely good linearity. Spring displacement was measured by cathetometer[3] which read to the nearest 0.1 mm and can measure a maximum length of 40 cm. In order to minimize calibration errors, an effective "cell constant" which relates spring displacement to the density of the sample was determined by measuring the temperature dependence of the density of water and comparing these results with those in the literature (8).

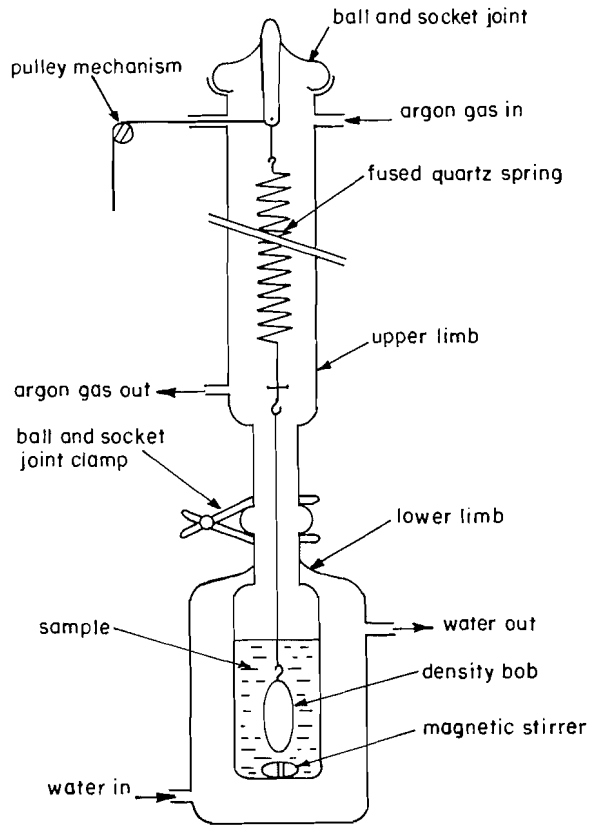

FIG. 1. Apparatus for the measurement of density.

Reagent grade succinonitrile[4] was vacuum distilled several times until a clear residue remained. The melting point of the distillate was measured by cryoscopy and taken to be a further indication of purity. Binary solutions of succinonitrile-water were prepared by adding high purity water to succinonitrile and heating the mixture to obtain a

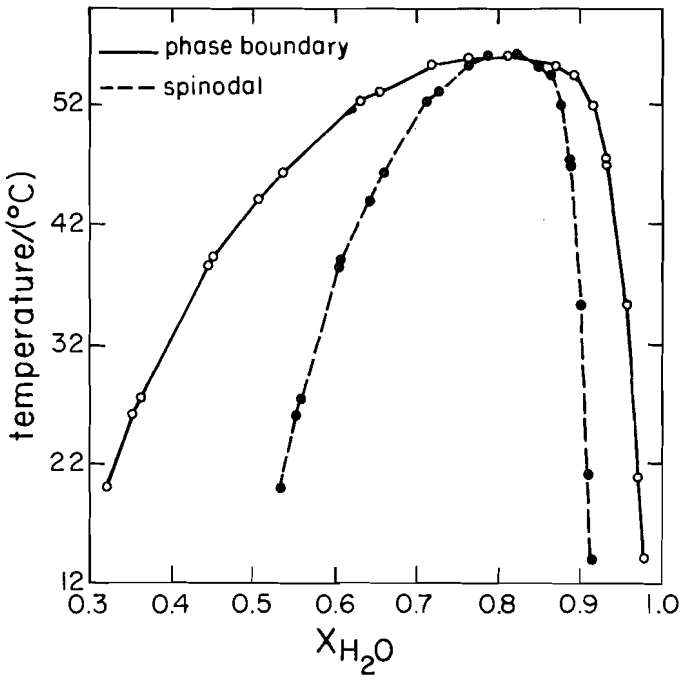

FIG. 2. Phase diagram of the succinonitrile–water system. Spinodal calculated by the "root three" rule.

homogeneous solution which was then transferred to the apparatus. The composition of the sample was then checked once again by comparing the temperature of the phase boundary as reported in the phase diagram (9) to the homogenization temperature as determined by heating the sample and visually inspecting for the presence of any second phase particles. The phase diagram is reproduced for the convenience of the reader in Fig. 2 which also gives the spinodal as calculated by the "root three" rule (10).

In a typical experiment the temperature of the sample, which weighed about 30 g, was varied from approximately 2 K above the solubility limit to a maximum temperature of 80°C. Once the temperature of the sample was set, it was mixed for 10 min by magnetic stirrer. Next, the bob was lowered into the solution, and the extension of the spring was measured by cathetometer. The bob was raised and lowered into the sample again, and another reading was taken. This was repeated at least four times before the temperature was changed. Care was taken to ensure that the immersion depth of the bob was constant in all measurements. The results were checked for reproducibility by performing the experiment on at least two different samples at every composition. The range of composition in this study was 0.3 to 0.97 mole fraction of water. In addition, the density of pure succinonitrile was measured between 60 and 80°C.

3. Results and discussion

At each composition the density measurements were fitted to the following linear function of temperature:

$$[1] \quad \rho/(\text{g cm}^{-3}) = a - bT$$

where T is in Kelvins. Equation [1] is valid only in the single-phase region outside the miscibility gap. The results are shown in Table 1. The fit was extremely good for all compositions, including that of pure succinonitrile. In consideration of the experimental errors associated with this technique, the accuracy of all the density measurements is assessed to be 0.2%.

There are no reports of the density of binary solutions of succinonitrile–water. However, Timmermans and Hennaut-Roland have measured the density of pure succinonitrile (11), and their results differ by less than 0.2% from the present work.

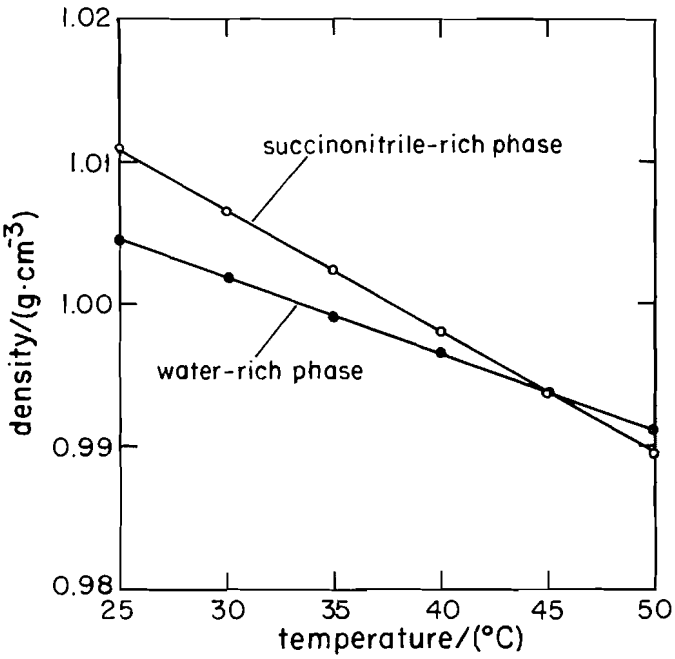

FIG. 3. Variation of density with temperature at compositions along the phase boundary.

The molar volume was calculated from the density data through the use of the equations in Table 1. The molar volume at a given composition is defined as the molar mass of the solution divided by its density. In a binary system the molar mass refers to the mass of one mole of solution and is calculated by adding the molar masses of the pure components weighted by their mole fractions. The molar volume isotherm was found to be a linear function of composition at any given temperature. At temperatures below the consolute the solutions separate into two phases, and the molar volume is undefined in this two-phase region. However, molar volume isotherms of the water-rich solutions and succinonitrile-rich solutions were piecewise linear and appear to lie on the same line when projected across the miscibility gap.

Equation [2] represents the variation in molar volume with composition at a constant temperature of 60°C.

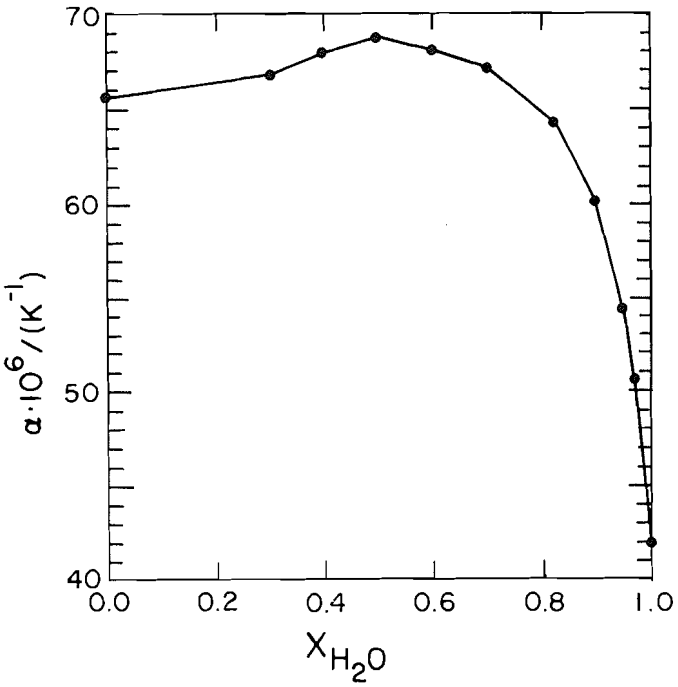

FIG. 4. Variation of thermal expansivity, α, with composition at a temperature of 60°C.

$$[2] \quad V_m/(cm^3) = 81.70 - 63.42X_{H_2O}$$

Equation [2] was constructed by computing the values of molar volume at 60°C from the least squares fits of density versus temperature at different compositions as measured in this study. For the molar volume of pure succinonitrile eq. [2] gives a value of 81.70 cm^3 which differs by less than 0.1% from the value calculated directly from the measured density of succinonitrile at this temperature.

Figure 3 shows the variation in density with temperature along the phase boundary. At each composition the density was calculated from the least-squares fit of density versus temperature evaluated at the corresponding phase boundary. There are two lines, one for the water-rich phase and one for the succinonitrile-rich phase.

This system exhibits density reversal. During the course of experiments the liquid phases were observed to exchange position at temperatures near 45°C. This is consistent with Fig. 3 which shows that at temperatures above 45°C the water-rich phase is denser and below 45°C the succinonitrile-rich phase is denser.

Figure 4 shows the isothermal variation of the thermal expansivity, α, with composition at 60°C. This temperature was chosen because it is above the consolute and thus provides access to the full compositional range. Furthermore, while the absolute magnitude of α changes with temperature, the relative magnitude of α across an isotherm is comparatively insensitive to temperature, i.e., the shape of the isotherm does not change much with temperature.

Figure 4 shows that α is effectively invariant with composition spanning the interval between pure succinonitrile and the consolute composition, 82.7 mol% water. At higher water contents the value of α drops sharply to that of pure water, which is only about half that of succinonitrile. Thus, as the temperature of a two-phase mixture within the miscibility gap is made to decrease, there is a more pronounced variation in density of the succinonitrile-rich phase. The result is that at temperatures below 45°C the succinonitrile-rich phase becomes denser in spite of the fact that at higher temperatures the water-rich phase is denser.

Iodination and deuteration of catechin derivatives[1]

E. KIEHLMANN, N. LEHTO, AND D. CHERNIWCHAN
Department of Chemistry, Simon Fraser University, Burnaby, B.C., Canada V5A 1S6

Received March 1, 1988

E. KIEHLMANN, N. LEHTO, and D. CHERNIWCHAN. Can. J. Chem. **66**, 2431 (1988).

The preparation and ^1H and ^{13}C nuclear magnetic resonance spectra of ten monoiodocatechin derivatives are described. The iodination of catechin with *N*-iodosuccinimide (NIS) takes place regiospecifically at C-6 in acetone but preferentially at C-8 in dimethylformamide; both products can be derivatized at oxygen in alkaline medium but lose iodine in the presence of acid. 3′,4′,5,7-Tetra-*O*-methylcatechin reacts with NIS regiospecifically at C-8 while catechin pentaacetate resists iodination. The debromination of 6-bromo- and 6,8-dibromocatechin with sodium sulfite in CD_3CN/D_2O is accompanied by H/D-exchange at C-6 and C-8. The synthesis of catechin pentaacetate from partially deuterated catechin and its conversion to tetra-*O*-methylcatechin proceed without H/D-exchange and permit distinction between the H-6 and H-8 chemical shifts.

E. KIEHLMANN, N. LEHTO et D. CHERNIWCHAN. Can. J. Chem. **66**, 2431 (1988).

On décrit la préparation et les spectres de résonance magnétique nucléaire du ^1H et du ^{13}C de dix dérivés de la monoiodocatéchine. L'iodation de la catéchine avec la *N*-iodosuccinimide (NIS), dans l'acétone, est régiospécifique au niveau du carbone en position 6 mais se fait préférentiellement au niveau du carbone en position 8 dans le diméthylformamide. En milieu alcalin, on peut transformer les deux produits en dérivés oxygénés, mais en milieu acide, l'iode est éliminé. La tétra-*O*-méthyl-3′,4′,5,7 catéchine réagit de façon régiospécifique avec la NIS au niveau du carbone en position 8 tandis que le pentaacétate de catéchine résiste à l'iodation. La débromation des dérivés bromo-6 et dibromo-6,8 catéchines par le sulfite de sodium dans un mélange de CD_3CN/D_2O s'accompagne d'un échange de H/D au niveau des carbones en positions 6 et 8. La synthèse du pentaacétate de catéchine à partir de la catéchine partiellement deutérée et sa transformation en tétra-*O*-méthylcatéchine se font sans échange de H/D et permettent de discriminer les déplacements chimiques des protons H-6 et H-8.
[Traduit par la revue]

Introduction

In continuation of our studies of halogen as protecting group in flavanoid synthesis (1), we have investigated the iodination of catechin derivatives, the protodeiodination of iodocatechins, the deuteration of catechin, and the debromination of bromocatechins with sodium sulfite in deuterated solvents. A better understanding of the halogenation (2, 3), dehalogenation (4, 5), and deuteration mechanisms (6) is essential for the regiospecific introduction and removal of protecting groups prior to interflavanoid coupling at the unprotected nucleophilic centre (C-6 or C-8) of flavans. It was hoped that the large size and low electrophilicity of iodine might improve the regioselectivity of the halogenation step and facilitate subsequent dehalogenation. A recently published paper (7) on the coupling of mollisacacidin with 6-iodocatechin prompts us now to report our results.

Results and discussion

More than 80 years ago, Kostanecki and Lampe (8) prepared the first two iodocatechin derivatives, 8-iodotetra-*O*-methylcatechin (**3***f*) and its 3-acetate (**5***f*), by direct iodination of tetra-*O*-methylcatechin (**3***a*) with molecular iodine in ethanol and subsequent acetylation (eq. [1]). Repeating this procedure or using *N*-iodosuccinimide (NIS) in dimethylformamide (DMF) as more convenient iodinating agent, we obtained the same compounds in high yields, although **3***f* started to decompose (loss of iodine) at a lower temperature than quoted in the original paper. In sharp contrast to the analogous bromination of **3***a*, the use of two molar equivalents of iodine or NIS does not result in diiodination, indicating unfavourable steric interactions between a large halogen substituent at C-6 and two bulky *ortho*-methoxy groups. The structure assignments of **3***f* and its acetate **5***f*, especially the position of attachment of iodine to ring A (C-8 rather than C-6), are based on a comparison of their proton and carbon chemical shifts (Tables 1 and 2) with those of the 6-iodo isomers (**3***e* and **5***e*, *vide infra*) and the corresponding bromocatechins (1, 9), and on the nuclear Overhauser enhancement (nOe) of two methoxy signals when the aromatic ring A proton of **5***f* is saturated. Most of our ^1H nmr and mass spectrometry data for **5***f* (see Experimental) agree with those reported by Roux and co-workers (7) who obtained the compound in less than 1% yield from catechin by successive iodination, methylation, chromatographic purification of the intermediate tetramethyl ester, and acetylation. Methylation of the aliphatic hydroxy group (at C-3) of **3***f* with methyl iodide in DMF gives 8-iodo-3,3′,4′,5,7-penta-*O*-methylcatechin (**4***f*) in high yield.

The corresponding 6-iodo isomers are accessible by regioselective iodination of catechin and subsequent derivatization of the OH groups (eq. [2]). The medium for the reaction of catechin with NIS controls the regiochemistry: dimethylformamide leads primarily to 8-substitution (**2***f*/**2***e* ratio 4:1) while acetone yields almost exclusively 6-iodocatechin; 6,8-diiodocatechin is formed when two molar equivalents of NIS are used. Contrary to recently published data (7), we identified 8-iodocatechin (rather than the 6-iodo compound) as major reaction product in mixtures of the two solvents. The two regioisomers are readily distinguished by the characteristically different chemical shifts of their residual ring A aromatic protons (see Table 1), and by the nOe difference spectra of their tetramethyl ether acetates: saturation of H-8 of **5***e* enhances only one methoxy signal while saturation of H-6 of **5***f* enhances two. Additional verification of our structure assignments is provided by the excellent correlation of the nmr chemical shifts for all ten monoiodocatechin derivatives (Tables 1 and 2) with those for the corresponding bromo compounds (1, 9).

The discrepancies between our results and those of Roux and co-workers warrant detailed comment. In part 14 of their series on the synthesis of condensed tannins (7), Roux and co-workers

[c]Chemical shifts deviate significantly from those reported in the literature (7).

have stated (on p. 2522):

> ... some progress towards regiospecific synthesis of [4,8]-isomers was possible through quantitative reaction of (+)-catechin with 1 mol. equiv. of NIS to give predominantly 6-iodo-(+)-catechin as intermediate. The point of substitution was established by the chemical shift of the residual 8-proton (8-H, δ 6.24) (cf. ref. 10), and also by reaction of an excess of the crude product of iodination with (+)-mollisacacidin in an acid medium (0.1 M HCl, 25°C) which led almost exclusively to a 1:1 ratio of [4,8]-3,4-*trans*- and [4,8]-3,4-*cis*-(−)-fisetinidol-(+)-catechins in a 44% combined yield. The sequence of 8-substitution and de-iodination at C-6 (during work-up) is supported by formation of only trace amounts of [4,6]-isomers and recovery of some 50% unsubstituted (+)-catechin.

Unfortunately, the literature reference (10) cited in support of their incorrect peak assignment does not contain ^{1}Hmr data on substituted catechins in their free phenolic form. Although a nearly quantitative reaction of catechin with NIS (1:1 molar ratio) is possible, as verified by recording the ^{1}Hmr spectrum of the crude product mixture shortly after sample preparation, both 6- and 8-iodocatechin are labile compounds that we were unable

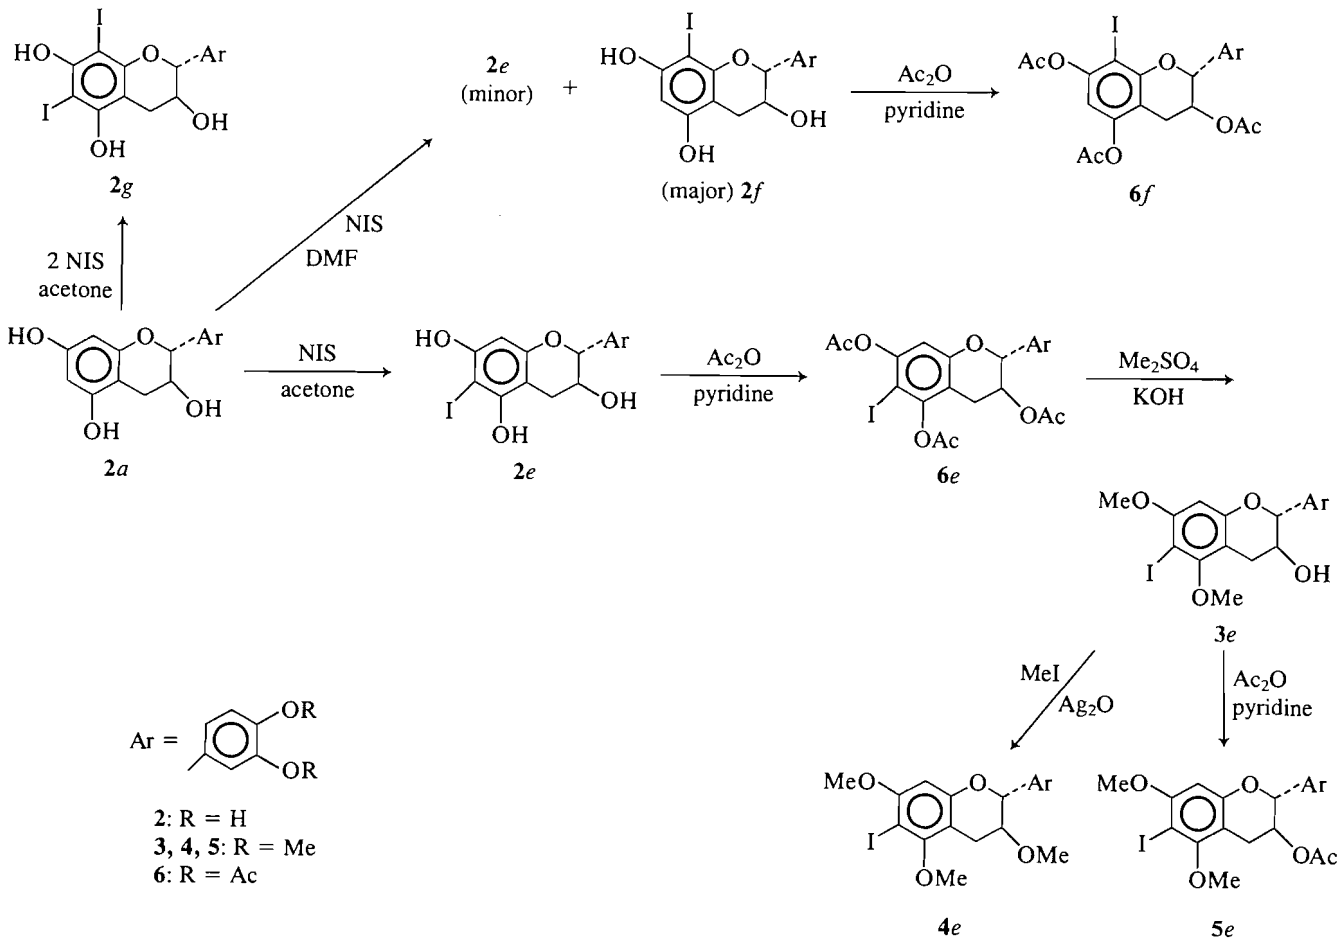
[2]



to isolate in pure form. Mixtures with the iodination by-product succinimide may be stored for several days in a desiccator with little decomposition but undergo slow deiodination (red colouration) on standing in acetone, more rapidly in the presence of acid (the most likely reason for the poor product yields obtained in the reaction of catechin with molecular iodine). A sample of **2***e* in acetone-d_6 was quantitatively converted to catechin 20 min after the addition of 2 μL concentrated HCl.

Since protodeiodination competes efficiently with (slow) interflavanoid coupling, the exclusive formation of the two diastereomeric [4,8]-fisetinidolcatechins observed by Roux must be attributed to the reaction of mollisacacidin with nonhalogenated catechin (preferential attack at C-8) rather than with 6-iodocatechin. The recovery of a large quantity of unsubstituted (+)-catechin, which cannot be explained by sequential substitution and deiodination at C-6, is indeed consistent with this interpretation. Clearly, Roux and co-workers also obtained 8- rather than 6-iodocatechin as major product of the initial halogenation step, as evidenced by the reported chemical shift of 6.24 ppm (our values: 6.25 ppm for **2***f*, 6.12 ppm for **2***e*). Therefore, the authors' claim of progress toward regiospecific synthesis of 4,8-coupled diflavanoids appears premature. We consider it a risky proposition to establish the point of substitution (by iodine) by reference to two subsequently formed interflavanoid coupling products (11) whose structures have never been unambiguously proved. The previously proposed criteria for the distinction between 6- and 8-substituted catechins are strictly limited to a few pairs of regioisomeric monoflavanoid methyl ethers (10). They do not apply to the corresponding free phenols (1), nor can they be indiscriminately extrapolated to diflavanoid derivatives without additional experimental structure proof.

The iodocatechin pentaacetates (**6***e* and **6***f*) are accessible only by acetylation of the respective free phenols (**2***e* and **2***f*) since catechin pentaacetate (**6***a*) is inert toward iodinating agents. However, it can be brominated to yield a 3:2 mixture of 6- and 8-bromocatechin pentaacetate (**6***c* and **6***d*) in quantitative yield (eq. [3]); no dibromination is observed even when more than two molar equivalents of *N*-bromosuccinimide are used.

(X = H, Br or I) (Y = H or Br)

FIG. 1

In view of the aforementioned regiospecific 8-halogenation of catechin methyl ethers, the predominance of the 6-isomer (**6***c*) in the product mixture is at first surprising. However, an analysis of the most likely transition state geometries provides an explanation. Flavanyl ethers prefer to react at C-8 because this is the least crowded position in the crablike planar conformation A (Fig. 1), which permits maximum resonance stabilization of the initially formed cationic adduct and prevents electrophilic attack at C-6 for steric reasons. The alternate "paddle-wheel" conformation B should be less reactive, due to steric interference of the bulky methyl groups with the attacking electrophile, and is assumed to be the species leading to dibromination (Fig. 1, Y = Br). A large iodine atom at C-8 forces the 7-methyl carbon to rotate out of the ring plane; this relief of steric strain is accompanied by a loss of conjugative interaction between the oxygen lone pairs and the aromatic π-electrons that reduces the nucleophilicity of ring A sufficiently to prevent a second electrophilic substitution at C-6. In the preferred conformations of aryl acetates, on the other hand, the acetyl groups are oriented at 45–90°C angles relative to the ring plane (Fig. 1C), as shown by X-ray diffraction studies (12),[2] CNDO calculations (13), and dipole moment measurements (14). The oxygen lone pairs interact strongly with the electron-withdrawing carbonyl group instead of enhancing the reactivity of the *ortho* and *para* carbons (15). As a consequence, the weak electrophile iodine does not react at all, and bromination at C-6 is slightly favoured over C-8. van der Waals repulsion between AcO-7 and the first bromine leads to a reorientation of the bulky acetyl group toward the second nucleophilic centre, making the latter sterically inaccessible and thereby preventing dibromination.

This interpretation agrees with the results of our recent studies of stereoelectronic substituent effects on the carbon-13 chemical shifts of bromocatechin derivatives (9) and is confirmed by the ^{13}Cmr spectra of the corresponding iodo compounds (Table 2). The individual resonance lines were assigned as described for the bromo compounds. Except for the expected strong shielding of the ipso carbon (by 30.3 ± 1.1 ppm), the effect of iodination at C-6 or C-8 on the electron densities at the remaining ring A carbons is similar to that of bromination. This can be seen best by calculating the substituent chemical shifts (SCS) for transhalogenation (Table 3). The (hypothetical) replacement of bromine by iodine deshields the *ortho* (by 2.1–3.2 ppm) and *para* carbons (by 1.4–1.7 ppm) and shields (by 0.3–0.8 ppm) the *meta* carbons. The relatively large downfield shifts (by 3.1–3.2 ppm) measured for C-5 of **6***e* and C-7 of **6***f* are indicative of significant conformational changes of the

[2]A search of the CRYSTOR data base (CAN/SND, National Research Council of Canada, Ottawa) revealed 86 additional aryl acetate crystal structures (1935–1986) with a mean value of 75 ± 13° for the C—C—O—CO torsion angle.

[d] Average of 3 values.

acetoxy group (rotation toward C-4 and C-6, respectively) resulting from steric interference with the adjacent iodine atom. The (hypothetical) isomerization of 6- to 8-iodo compounds is accompanied by the expected upfield shift of the C-8 signals (by 30.2–32.3 ppm), correspondingly large downfield shifts for C-6 of **2** (by 29.4 ppm) and **6** (31.4 ppm), and negligible changes in the absorption positions for C-5 and C-7, but unusually large upfield (by 4.7–5.1 ppm) and small downfield shifts (by 15.4–15.8 ppm) for C-4a and C-6, respectively, of the three methyl ethers (**3**, **4**, and **5**). When iodine is moved from C-6 to C-8, the relief of van der Waals strain at C-5 permits the 5-methoxy carbon to rotate into the ring plane, and the resulting interaction of the oxygen lone pairs with the aromatic π-electrons leads to shielding of the *ortho* carbons. Thus, as in the case of the bromo analogues, steric inhibition of resonance (which is insignificant in the free phenols and their acetates) explains the deshielding of the *meta* carbons and the exceptionally low shielding of the ipso carbon when iodine is introduced at C-6 of catechin methyl ethers (16). The same effect is observed for the 5-methoxy carbon of **3***e*, **4***e*, and **5***e*, which resonates at considerably lower field (60.1 ppm) than expected because the presence of two bulky *ortho* substituents (CH_2-4 and I-6) forces it to rotate out of coplanarity with the ring (17).

The absorption positions of the 5-methoxy protons, on the other hand, undergo little change on iodination (by −0.04 to +0.03 ppm) while the 7-methoxy proton signals shift significantly downfield when iodine is introduced at C-6 (by 0.06–0.07 ppm) or at C-8 (by 0.13–0.14 ppm). These trends parallel those observed previously (1) for bromocatechins and, in conjunction with nOe difference spectra, permit assignment of the methoxy peaks. The protons attached to the skeletal carbons of iodocatechins were generally found to resonate within ±0.03 ppm of the corresponding bromo compounds,[3] and 6-halogenation has again a larger deshielding effect on H-8 (by 0.19–0.20 ppm) than 8-halogenation on C-6 (by 0.03–0.04 ppm). The consistency of the ^{1}Hmr and ^{13}Cmr chemical shift values of the ten iodocatechin derivatives listed in Tables 1 and 2 and their more thoroughly studied bromo analogues (1) firmly establishes the point of halogen substitution in each molecule.

The unexpected regioselectivity of the reaction of catechin with NIS in different solvents suggested sequential iodination at C-6 (in acetone), bromination at C-8, and deiodination at C-6 as possible synthetic route to 8-bromocatechin. However, 6,8-dibromocatechin was formed as the major product of bromination of 6-iodocatechin with *N*-bromosuccinimide, together with minor quantities of iodobromo- and monohalocatechins. This result shows that iodine is weakly bonded to carbon, especially in dihalogenated molecules, and readily replaced by stronger electrophiles such as protons or bromonium ions. Only by recording a ^{13}Cmr spectrum within half an hour of sample preparation could we establish the presence of 8-iodo-6-bromocatechin (**2***h*), in addition to some unreacted starting material, in the crude reaction mixture obtained from 6-bromocatechin and NIS.

Our search for selective dehalogenation agents also led to a further investigation of the mechanism of debromination of bromocatechins by sodium sulfite (2). We reasoned that the replacement of Br-6 of 6-bromocatechin (**2***c*) by deuterium, monitored by ^{1}Hmr, should be accompanied by a shift of the H-8 resonance from 6.06 to 5.82 ppm (in CD_3CN) if dehalogenation is faster than hydrogen/deuterium exchange via keto/enol tautomerization. This would verify by chemical means the H-8 assignment in the ^{1}Hmr spectrum of catechin, which was previously determined by the enhancement of the aromatic ring A proton signals on gated decoupling of OH-5 and OH-7, respectively, in the presence of cadmium nitrate (1). In the event, the very slow replacement by deuterium of H-6 and H-8 of catechin in CD_3CN/D_2O (pH ~ 6) was speeded up by sodium sulfite (pH ~ 7.5), but during the debromination of **2***c* the ^{1}Hmr signals for *both* protons (δ 5.92 and 5.82 ppm) appeared simultaneously (equal intensities) before gradually fading away. When the amount of sulfite is insufficient for complete monodebromination of 6,8-dibromocatechin (**2***b*), i.e., less than two molar equivalents, dehalogenation stops as the pH drops below 7 (due to the formation of $NaHSO_4$), and the composition of the product mixture shows that the ease of bromine removal decreases in the order 8-Br of **2***b* > Br of **2***c* ≫ 6-Br of **2***b*; no 8-bromocatechin is formed but the initially produced 6-bromocatechin (**2***c*) is partially converted to catechin before the starting material has been completely 8-debrominated. Fortunately, the extent of catechin formation can be minimized by running the reaction at low temperature (2). Thus, H/D-exchange is accelerated by base, and complete H-6/H-8 scrambling accompanies rapid debromination. Similar results have been obtained for other polyhydric phenols: Furlong and Nudelman (6) investigated the rates of base-catalyzed deuteration of resorcinol and phloroglucinol at C-2, C-4, and C-6 (H-5 of resorcinol is not exchanged) in D_2O/MeOD; Äryä and Widén (19) attributed the slow disappearance of the C-5 signal

[3] In ref. 1 (Table 2), the chemical shifts for H-5′ and H-6′ of **5***d* in $CDCl_3$ were inadvertently exchanged; the correct assignments are δ 6.805 (H-5′) and 6.858 ppm (H-6′).

in the ^{13}Cmr spectrum of 2,4,6-trihydroxy-3-methylbutyrophenone in acetone-d_6/D_2O to H/D-exchange; Davis and Harrington (4) described the debromination of 2,4,6-tribromoresorcinol with sulfite in basic solution; and we have confirmed the replacement of H-2 (but not H-5) by deuterium when sodium carbonate is added to a solution of 4,6-dibromoresorcinol in acetone-d_6/D_2O.

In all cases, including a recent kinetic study of the epimerization of catechin (20), ketone structures have been invoked as intermediates. We conclude from these results that the reactive species is an α-bromoketone ("ketobromide", cf. refs. 4 and 21) that, for its formation in significant concentration, requires the presence of two *meta*-oriented OH groups on the aromatic ring. (In contrast to 4,6-dibromoresorcinol, 4,6-dibromo-3-methoxyphenol does not react with sodium sulfite.) Nucleophilic attack by sulfite at the carbonyl carbon yields an α-hydroxysulfonate that undergoes oxidation at sulfur and halide elimination at the α-carbon (eq. [4], route a). Alternatively, the product may be formed in a single step by nucleophilic displacement at halogen (route b). Analogous mechanisms have been proposed for the dehalogenation of 4-bromo-3-arylsydnones (22) and of α-haloketones (23) with sodium dithionite. In view of the isolation and characterization of several sulfite addition products to resorcinols and phloroglucinols in the past (24, 25, 33), we favour route a: Rapid intramolecular proton transfer from C-8 to C-6 (and vice versa) via the hydroxysulfonate function at C-7 (eq. [4], structure E) may be responsible for the observed scrambling of the aromatic ring A protons.

The reactivity differences exhibited by C-6 and C-8 of catechin toward halogen electrophiles and the slow H/D-exchange observed in neutral and acidic medium suggested the possibility of regioselective deuteration by recrystallization of catechin hydrate from heavy water. Integration of the ^{1}Hmr spectrum of a catechin sample kept for 2 h in D_2O solution at 90°C revealed the presence of 20% 8-deutero- (H-6 singlet at 6.01 ppm), 10% 6-deutero- (H-8 singlet at 5.86 ppm), 50% 6,8-dideuterocatechin, and 20% unreacted (protonated) starting material, i.e., preferred substitution at C-8. None of the B-ring aromatic protons had been replaced by deuterium, and exchange of the OH protons was incomplete. H-6 and H-8, whose chemical shifts have been previously identified by nOe difference spectroscopy (see before), could now be distinguished by their different peak areas. The invariance of the H-6 and H-8 peak area ratio (4:3) on conversion of the partially deuterated catechin to its tetramethyl ether **3***a* (H-6 at 6.12, H-8 at 6.03 ppm, solvent acetone-d_6) via the pentaacetate (**6***a*) intermediate (H-6 at 6.55, H-8 at 6.65 ppm, solvent CD_3CN) confirms that in the acetate, contrary to free catechin and its tetramethyl ether, H-6 resonates upfield from H-8 (1, 26). More importantly, it demonstrates that neither the acetylation with acetic anhydride and pyridine nor the reaction of **6***a* with dimethyl sulfate and 50% aqueous potassium hydroxide in methanol is accompanied by H/D-exchange at C-6 or C-8. It appears that the ester transmethylation in strongly alkaline medium involves nucleophilic aromatic substitution rather than sequential ester hydrolysis and etherification by phenoxide attack at the methyl carbon (27). Further studies of this mechanism are currently in progress.

In summary, the regioselectivity of electrophilic aromatic substitution in ring A of catechin depends strongly on the medium: both 6- and 8-iodocatechin (also 6,8-diiodocatechin) are accessible by direct iodination with *N*-iodosuccinimide but undergo protodeiodination in neutral or weakly acidic solution. The large size and low electrophilicity of iodine prevent iodination of tetra-*O*-methyl-8-iodocatechin at C-6 and of catechin pentaacetate. Catechin slowly exchanges H-6 and H-8 in heavy water (pH 6) but not during acetylation and methylation in alkaline medium.

Experimental

The ^{1}Hmr spectra of 0.02–0.04 M substrate solutions in acetone-d_6 (free phenols) or chloroform-*d* were recorded on a Bruker 400-MH FT spectrometer (unless specified otherwise) at a probe temperature of 30°C, ^{13}Cmr spectra of 0.3–0.7 M solutions at 21°C. Chemical shifts are reported in ppm downfield from TMS. Samples for nOe difference spectra were degassed immediately prior to the experiment. Melting points (uncorrected) were determined on a Fisher–Johns apparatus, elemental analyses with a Carlo Erba elemental analyzer model 1106. Anhydrous catechin (**2***a*) was obtained by drying commercial catechin hydrate (Sigma) under vacuum (12 h at 110°C) and converted to 6-bromocatechin (**2***c*) and 6,8-dibromocatechin (**2***b*) as previously described (2). Standard literature procedures were followed to derivatize the halogenated catechins:

(a) Acetylation (**2** → **6**, **3** → **5**, ref. 28): The free phenol or its tetramethyl ether (70–100 mg) is dissolved in a mixture of 0.5 mL acetic anhydride and 0.3 mL pyridine, allowed to stand at 25°C for 24 h, pipetted into 5 mL ice water, and refrigerated for 12 h. The product is isolated and purified by filtration, recrystallization from ethanol, and vacuum drying (P_2O_5).

(b) Acetate transmethylation (**6** → **3**, ref. 29): Three millilitres of 50% aqueous potassium hydroxide are added dropwise to a solution of the pentaacetate (1 mmol) in 3 mL methanol and 1 mL dimethyl sulfate. After brief boiling, the mixture is poured into ice water, and the product

is filtered, washed free of alkali, and vacuum dried. Preparative tlc (benzene/acetone 4:1) and recrystallization from ethanol gives the pure tetramethyl ether.

(c) Exhaustive methylation (**3** → **4**, ref. 30): To a magnetically stirred solution of the tetramethyl ether (0.2 mmol) in dry dimethylformamide (1.0 mL) are added silver oxide (150 mg) and methyl iodide (0.44 mL, added in 5 portions over a period of 4 days). After 5 days, the mixture is poured into water (50 mL) and extracted with chloroform (5 × 25 mL). The pentamethyl ether is obtained by solvent evaporation and vacuum drying (P_2O_5).

*8-Iodo-3′,4′,5,7-tetra-*O*-methylcatechin (**3**f)*

N-Iodosuccinimide (225 mg, 1.00 mmol) in 3 mL dimethylformamide (DMF) was added dropwise to a stirred solution of 3′,4′,5,7-tetra-*O*-methylcatechin (**3***a*) (348 mg, 1.00 mol) in 4 mL DMF (70 min). Filtration of the beige precipitate formed on pouring the reaction mixture into ice water (50 mL) and recrystallization (95% ethanol) gave **3***f* (63% yield), mp 173–175°C (lit. (8) mp 192–193°C (dec.); sinters and turns brown at 160°C). The nmr spectral parameters (Tables 1 and 2) are identical to those of the products formed (*i*) from **3***a* and 2 mol. equivs. NIS (quant. yield), and (*ii*) from **3***a* and molecular iodine (with trace of iodic acid) in ethanol (according to ref. 8); no 6,8-diiodo-3′,4′,5,7-tetra-*O*-methylcatechin was detected in either experiment. *Anal.* calcd. for $C_{15}H_{21}IO_6$: C 48.32, H 4.48; found: C 48.61, H 4.54%.

*8-Iodo-3-*O*-acetyl-3′,4′,5,7-tetra-*O*-methylcatechin (**5**f)*

Acetylation of **3***f* (procedure a) gives **5***f* (92% yield), mp 193–195°C (lit. (8) mp 189°C); ^{1}Hmr (nOe difference): saturation at 6.13 ppm (H-6) enhances signals at 3.80 (MeO-5) and 3.90 ppm (MeO-7). *Anal.* calcd. for $C_{21}H_{23}IO_7$: C 49.04, H 4.51; found: C 48.65, H 4.24%.

*8-Iodo-3,3′,4′,5,7-penta-*O*-methylcatechin (**4**f)*

From **3***f* by exhaustive methylation (procedure c) in 91% yield, mp 159–160°C (dec.). *Anal.* calcd. for $C_{20}H_{23}IO_6$: C 49.40, H 4.77; found: C 49.45, H 4.74%.

*Iodination of catechin (**2**a)*

(i) In acetone

Dropwise addition (10 min) of NIS (225 mg, 1.00 mmol) in 6 mL reagent acetone to a solution of catechin (290 mg, 1.00 mmol) in 10 mL acetone at 25°C, continued stirring (1 h), and solvent evaporation gave a fluffy beige solid that was shown by ^{1}Hmr to consist of 6-iodocatechin (**2***e*, >95%, H-8 at 6.12 ppm), 8-iodocatechin (**2***f*, <5%, H-6 at 6.25 ppm), succinimide (CH_2 at 2.67 ppm), and a trace of catechin. After 2 weeks of storage at 4°C, an ^{1}Hmr sample in acetone-d_6 had turned red-brown and contained approximately 5 mol% catechin. The addition of acid accelerated deiodination (acid/time/catechin percentage): 2 μL CF_3COOH/18 h/40%, 2 μL conc. HCl/15 min/90%, 14 μL 0.1 N HCl/24 h/25%.

(ii) In dimethylformamide

A solution of NIS (225 mg, 1.00 mmol) in 3 mL dry DMF was added dropwise (7 min) to a stirred solution of dry catechin (290 mg, 1.00 mmol) in 4 mL DMF. After 1 h of continued stirring at 25°C, the mixture was poured into 80 mL carbon tetrachloride and the layers were allowed to separate (12 h). Drainage of the CCl_4 layer and suspension of the remaining red oil in dichloromethane gave a beige solid that, after vacuum drying (P_2O_5), weighed 168 mg and contained (by ^{1}Hmr) 75% 8-iodocatechin (**2***f*), 15% 6-iodocatechin (**2***e*), 10% catechin (**2***a*), and traces of DMF and succinimide. Chromatographic separation of the iodocatechins from catechin was attempted but unsuccessful. When the *N*-iodosuccinimide was dissolved in acetone (rather than DMF), the acetone evaporated under nitrogen before work-up with CCl_4 and CH_2Cl_2, and the crude product immediately acetylated (procedure a), the molar ratio of the three pentaacetates **6***f*, **6***e*, and **6***a* (94% overall yield) was found to be 6:1:2 by integration of the ^{1}Hmr spectrum.

*6,8-Diiodocatechin (**2**g)*

The iodination of catechin (124 mg, 0.43 mmol) with 2 molar equivs. NIS in acetone (see above, procedure *i*), solvent evaporation under nitrogen, and vacuum drying (KOH) gave 316 mg of a brown solid containing **2***g* and catechin in the approximate molar ratio 13:1. The product underwent slow deiodination in acetone solution (^{1}Hmr sample), which was accelerated by the addition of CF_3COOH (**2***g*/**2***a* ratio 1:1 after 91 h); ^{1}Hmr of **2***g* (red solution in acetone-d_6) δ: 6.86 (H-2′), 6.74–6.77 (H-5′ and H-6′), 4.88 (d, *J* 6.5 Hz, H-2), 4.10 (m, H-3), and 2.88 (dd, *J* 5.3 and 16.2 Hz, H-4a) ppm.

*6-Bromo-8-iodocatechin (**2**h)*

The iodination of 6-bromocatechin (**2***c*, 0.5 mmol, ref. 2) with NIS (0.5 mmol) in acetone (see above, procedure *i*) gave 294 mg of a reddish-brown product containing **2***h* and **2***c* in the appropriate molar ratio 7:2 (by ^{1}Hmr).

*6-Iodocatechin pentaacetate (**6**e)*

Acetylation (procedure a) of the crude product of iodination of catechin (0.50 mmol) in acetone (>95% **2***e*) gave **6***e* (90% yield), mp 90–92°C (from 50% ethanol). *Anal.* calcd. for $C_{25}H_{23}IO_{11}$: C 47.94, H 3.70; found: C 47.79, H 3.75%.

*3′,4′,5,7-Tetra- and 3,3′,4′,5,7-penta-*O*-methyl-6-iodocatechin (**3**e and **4**e)*

Transmethylation (procedure b) of **6***e* (0.45 mmol) gave 93 mg (44% yield) of a yellow powder, which was subjected to preparative tlc (benzene/acetone 4:1): **3***e* (R_f 0.44, 74 mg), mp 129.5–130.5°C (from 95% EtOH), and **4***e* (R_f 0.64, 13 mg). *Anal.* calcd. for $C_{19}H_{21}IO_6$ (**3***e*): C 48.32, H 4.48; found: C 48.35, H 4.45%; calcd. for $C_{20}H_{23}IO_6$ (**4***e*): C 49.40, H 4.77; found: C 49.44, H 4.42%.

*6-Iodo-3-*O*-acetyl-3′,4′,5,7-tetra-*O*-methylcatechin (**5**e)*

Acetylation (procedure a) of **3***e* (0.14 mmol) gave **5***e* (83% yield), mp 64–71°C (after preparative tlc, benzene/acetone 9:1); ^{1}Hmr (nOe difference): saturation at 6.37 ppm (H-8) enhances the signal at 3.88 ppm (MeO-7). *Anal.* calcd. for $C_{21}H_{23}IO_7$: C 49.04, H 4.51; found: C 49.14, H 4.65%. Previously reported analytical data (7) are incorrect and apply to **2***e* ($C_{15}H_{13}IO_6$).

*8-Iodocatechin pentaacetate (**6**f)*

Acetylation (procedure a) of the crude product of iodination of catechin in DMF (see above, procedure *ii*) gave a beige solid, which was separated by preparative tlc (toluene/ethyl acetate 7:3) into two fractions: R_f 0.55 (**6***e*) and R_f 0.48 (**6***f* and **6***a*). Pure **6***f* was obtained from the latter by recrystallization from ethanol and aqueous methanol, mp 114–116°C. *Anal.* calcd. for $C_{25}H_{23}IO_{11}$: C 47.94, H 3.70; found: C 47.91, H 4.08%.

*Bromination of catechin pentaacetate (**6**a)*

A solution of catechin pentaacetate (500 mg, 1.00 mmol) and *N*-bromosuccinimide (356 mg, 2.00 mmol) in 7 mL DMF was magnetically stirred for 16 h, then poured into 40 mL water and filtered. The white precipitate was washed with water and vacuum dried (P_2O_5) to give 515 mg (89% yield) of a mixture (H-8/H-6 ^{1}Hmr peak area ratio 3:2) of 6-bromo- and 8-bromocatechin pentaacetate (**6***c* and **6***d*; see refs. 1 and 9 for nmr data) from which small samples of the pure components were obtained by fractional crystallization from ether (**6***c* is less soluble), and by repeated preparative tlc (poor separation) using toluene and ethyl acetate (7:3). No 6,8-dibromocatechin pentaacetate was detected by tlc or nmr. Repetition of the experiment with one molar equivalent NBS gave the same mixture in 80% yield, and ^{1}Hmr monitoring showed that the ratio of **6***c*/**6***d* does not change as a function of time.

*Debromination of 6-bromocatechin (**2**c) and 6,8-dibromocatechin (**2**b) in CD_3CN/D_2O*

The ^{1}Hmr spectra of catechin (**2***a*), 6-bromocatechin, and 6,8-dibromocatechin were recorded on an XL-100 spectrometer (CW mode) before and at various time intervals after the addition of sodium sulfite. Because of the limited miscibility of acetonitrile-d_3 and heavy water at the required substrate concentration levels, a rigorous kinetic study was not feasible. However, the observed variations in the relative

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 112.217.228.212 on 09/07/12
For personal use only.

peak areas of the H-2 (ring C, δ 4.5–4.6 ppm), H-6/8 (ring A, δ 5.8–6.1 ppm), and H-2′/5′/6′ (ring B, δ 6.7–6.8 ppm) signals, designated below by the capital letters C, A, and B, gave a good indication of the reaction progress. Catechin (75 mg, 0.26 mmol) was dissolved in a mixture of 0.5 mL CD_3CN and 0.5 mL D_2O. After 16 h at 25°C the A:B:C ratio was essentially the same (2:3:1) as at time zero (no exchange). Forty minutes after the addition of 0.1 mL 2.2 M Na_2SO_3 in D_2O and vigorous shaking (several minutes) of the resultant two-phase system, the top layer was withdrawn by pipette and analyzed by ^{1}Hmr: the A/C ratio had decreased to one third of its original value, and 4 h later the H-6/8 signals had completely vanished.

Starting from a solution of 0.22 mmol 6-bromocatechin (**2***c*) in 0.4 mL CD_3CN and 0.2 mL D_2O (A/C ratio 1:1), the reaction with 0.1 mL 5 M Na_2SO_3 (excess) led initially (when the H-2 peak areas indicated debromination of one third of the starting material) to the appearance of both the H-6 and the H-8 doublet of catechin at the expense of H-8 of **2***c*, and after additional shaking (debromination half-complete) to their disappearance due to H/D-exchange. In the second series of experiments, a solution of **2***c* (92 mg, 0.25 mmol) in 0.6 mL CD_3CN and 0.2 mL D_2O was vigorously shaken with 0.1 mL 1.6 M Na_2SO_3, and the top layer analyzed by ^{1}Hmr (time: 6 min). Additional spectra of the top layer were recorded after recombination of the layers and continued shaking (times: 25, 44, and 61 min). A second portion of 0.1 mL 1.6 M Na_2SO_3 was added before the final analysis (time: 81 min). As the amount of sulfite was insufficient for complete debromination (0.25 mmol **2***c* requires 0.50 mmol Na_2SO_3), only one third of the organic substrate was initially converted to catechin: H-2 (**2***c*)/H-2 (**2***a*) peak area ratios 5:1 (6 min), 3:1 (25 min), 2:1 (44 min), and 2:1 (61 min). Relative to H-2, the area of the H-8 peak of **2***c* decreased from 0.75 to 0.50 over the same period, while the H-6/8 (**2***a*):H-8 (**2***c*) ratio increased substantially from 1:3 (6 min) to 1:1 (61 min), and finally to 2:1 after 81 min (rapid debromination). Twenty minutes after addition of the second sulfite portion, the reaction mixture contained equal amounts of **2***a* and **2***c* (equal H-2 areas), but the total aromatic ring A proton area was only half as large as would be expected in the absence of H/D-exchange.

Treatment of a solution of 6,8-dibromocatechin (**2***b*, 112 mg, 0.25 mmol) in 0.6 mL CD_3CN and 0.2 mL D_2O with sodium sulfite and monitoring by ^{1}Hmr (as described above for **2***c*, second series) gave the following results (mmol Na_2SO_3, time, product composition): 0.19 mmol, 6 min, 75% **2***b*/25% **2***c*; 0.38 mmol, 24 min, 50% **2***b*/50% **2***c*; 0.38 mmol, 84 min, 30% **2***b*/45% **2***c*/25% **2***a*; 0.57 mmol, 136 min, 25% **2***b*/40% **2***c*/35% **2***a*.

Debromination and deuteration of 4,6-dibromoresorcinol

To a stirred solution of 5.36 g (20.0 mmol) 4,6-dibromoresorcinol (31) in 20 mL methanol and 40 mL water were added 40 mL 1 M Na_2SO_3 during the first 15 min and 10 mL 1 N NaOH after 6.5 h. After 21 h the reaction mixture was acidified to pH 3 with 10% HCl, the methanol evaporated, and the aqueous solution extracted with ether (6 × 60 mL). The white powder (2.34 g, 62% yield) obtained after drying ($MgSO_4$), solvent evaporation, and recrystallization from benzene was washed with ice water (5 × 5 mL) and vacuum dried to give pure 4-bromoresorcinol, mp 97–100°C (lit. (32) mp 100–102°C); ^{1}Hmr (acetone-d_6) δ: 8.64 (OH), 7.24 (d, *J* 8.6 Hz, H-5), 6.52 (d, *J* 2.7 Hz, H-2), and 6.31 (dd, H-6) ppm; ^{13}Cmr (acetone-d_6) δ: 157.8 (C-1), 154.8 (C-3), 133.5 (C-5), 108.9 (C-6), 104.0 (C-2), and 99.4 (C-4) ppm. When 4,6-dibromoresorcinol was treated with 2 molar equivs. Na_2SO_3 and 2 molar equivs. NaOH under similar conditions, the product mixture was found (by ^{1}Hmr) to contain 52 mol% 4-bromoresorcinol, 24% resorcinol, and 12% unreacted starting material. A solution of 50 mg 4,6-dibromoresorcinol in 0.5 mL acetone-d_6 and 0.3 mL D_2O showed no evidence of ring deuteration (equal ^{1}Hmr peak areas for H-2 and H-5) over a period of 7 weeks. On addition of 5 mg K_2CO_3, H/D-exchange at C-2 started within 15 min and was 90% complete after 54 h (50% after 24 h) as measured by the decrease in the H-2 peak area relative to H-5.

Attempted debromination of 4,6-dibromo-3-methoxyphenol

A solution of 4,6-dibromo-3-methoxyphenol (282 mg, 1.00 mmol), prepared by bromination of 3-methoxyphenol as described in the literature (18), in 40 mL 50% aqueous methanol was treated with 2 mL 1 M Na_2SO_3 and 2 mL 1 N NaOH and stirred for 9 h at 25°C (pH 10–11). Acidification (10% HCl), flash evaporation of the methanol, extraction with ether (4 × 20 mL), drying ($MgSO_4$), and ether evaporation gave an oily residue (235 mg) that solidified on standing and was shown to be identical to the starting material; ^{1}Hmr (acetone-d_6) δ: 7.59 (H-5), 6.74 (H-2), and 3.82 (OMe) ppm; ^{13}Cmr (acetone-d_6) δ: 157.2 (C-3), 155.3 (C-1), 136.0 (C-5), 101.9 (C-2), 101.7 (C-4), 100.9 (C-6), and 56.8 (OMe) ppm. Refluxing the reagent mixture for 24 h, or doubling the amounts of Na_2SO_3 and NaOH, or omitting the NaOH addition (pH 7.5–8) had little effect: in all cases, 82–85% of the starting material was recovered.

Preparation of partially deuterated catechin and its derivatives

Catechin hydrate (1.54 g, 4.25 mmol) was dissolved in 12 mL hot D_2O. After 2 h at 90°C, the solution was cooled to 20°C and the white crystals were filtered and vacuum dried (110°C/5 h, P_2O_5) to give 1.17 g partially deuterated catechin. The product composition was determined by integration of the ^{1}Hmr spectrum (acetone-d_6 with trace of cadmium nitrate): the measured peak area ratio of 22:6.5:9:66 for H-2 (δ 4.54 ppm):H-8 (δ 5.86 ppm):H-6 (δ 6.01 ppm):H-2′/5′/6′ (δ 6.73–6.89 ppm) corresponds to approximately 10% 6-deutero-, 20% 8-deutero-, 50% dideuterocatechin, and 20% unreacted starting material. The integral of the OH signals (OH-5 at 8.28, OH-7 at 8.09, OH-3′/4′ at 7.99 and 7.93 ppm) indicated incomplete deuterium exchange (42%). Acetylation (procedure a) of this product gave partially deuterated catechin pentaacetate (81% yield) with the relative intensities of the downfield (H-8: 6.65 ppm in $CDCl_3$ and CD_3CN, 6.67 ppm in acetone-d_6) and upfield (H-6: 6.59 ppm in $CDCl_3$, 6.56 ppm in CD_3CN, 6.60 ppm in acetone-d_6) ^{1}Hmr signals for the aromatic ring A protons in the ratio 3:4. In all three solvents the singlets caused by the two monodeuterated compounds were found to overlap the upfield components of the H-6 and H-8 doublets of nondeuterated catechin. Transmethylation (procedure b) of this pentaacetate mixture (67% deuterated at C-6 and C-8) gave a mixture of 3′,4′,5,7-tetra- and 3,3′,4′,5,7-penta-*O*-methylcatechin (molar ratio 11:1) in 91% overall yield, which was 68% deuterated in ring A (H-6/8:H-2 peak area ratio 20:31), and contained more 8- than 6-deuterated product (intensity ratio of 25:19 for the H-6 and H-8 ^{1}Hmr signals at δ 6.12 and 6.03 ppm, respectively, in acetone-d_6).

The solvent deuterium isotope effect on the hydroxide-ion-catalyzed conversion of acetaldehyde to its enolate ion

J. R. KEEFFE[1] AND A. J. KRESGE

Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received March 2, 1988

J. R. KEEFFE and A. J. KRESGE. Can. J. Chem. **66**, 2440 (1988).

Rates of proton transfer from acetaldehyde to the hydroxide ion were measured by iodine scavenging in H_2O and in D_2O solution at 25°C; the results give the solvent isotope effect $k_{HO^-}/k_{DO^-} = 0.73 \pm 0.02$. This value is somewhat more consistent with an estimate, made using fractionation factor theory, for hydron transfer directly from the substrate to the hydroxide ion than with another estimate, made similarly, for hydron transfer through an intervening water molecule.

J. R. KEEFFE et A. J. KRESGE. Can. J. Chem. **66**, 2440 (1988).

On a mesuré les vitesses de transfert du proton de l'acétaldéhyde à l'ion hydroxyde en utilisant l'iode comme piège dans l'eau et dans une solution de D_2O à 25°C. On obtient dans ces conditions un effet isotopique du solvant de $k_{HO^-}/k_{DO^-} = 0{,}73 \pm 0{,}02$. Cette valeur se rapproche davantage de l'évaluation faite, selon la théorie du facteur de fractionnement, pour le transfert direct de l'hydron du substrat vers l'ion hydroxyde, que d'une autre évaluation faite de la même façon, pour le transfert de l'hydron via la participation d'une molécule d'eau.

There is much current interest in simple enols (for reviews, see ref. 1) and, in our recent examination of some of the chemistry of the simplest enol of all, vinyl alcohol, we determined the solvent deuterium isotope effect on the hydronium-ion-catalyzed formation of this substance from acetaldehyde, eq. [1] (2). We now wish to report the results of a companion

[1] 
study, which provides the solvent isotope effect on the reaction of acetaldehyde with hydroxide ion to give the enolate ion, eq. [2].

[2] 
Experimental

Rates of reaction of acetaldehyde with hydroxide ion were measured as before (2) by using iodine to scavenge the enolate ion product as it formed. Initial stoichiometric aldehyde and iodine concentrations in the reaction mixtures were ca. 2×10^{-4} M and 1×10^{-3} M respectively. Reactions were followed to completion; the data obeyed the first-order rate law well, and observed first-order rate constants were calculated by least-squares fitting to an exponential function (3). Hydroxide ion concentrations were determined by acidimetric titration of spent reaction solutions.

Results

Acetaldehyde in aqueous solution is in rapidly established equilibrium with appreciable amounts of its hydrate, eq. [3],

[3] 
and, at the hydroxide ion concentrations used here, the hydrate is ionized to a significant extent, eq. [4].

TABLE 1. Rate data for reaction of acetaldehyde with hydroxide ion in H_2O and D_2O at 25°C[a]

$[LO^-]/10^{-2}$ M	$k_{obs}/10^{-2}$ s^{-1}	k_{LO^-}/M^{-1} s^{-1}
H_2O		
9.38	4.33	1.07
8.88	4.15	1.07
D_2O[b]		
8.14	4.75	1.45
8.93	5.19	1.46

[a]Ionic strength = 0.1 M.
[b]Deuterium content of reaction mixtures was 98 at.%.

All of these species are consumed in the reaction studied here, but only the aldehyde is the reactive form. Corrections to observed rate constants allowing for this may be made according to eq. [5] where K_h is the hydration equilibrium constant,

$$[5] \quad k_{corr} = k_{obs}\{1 + K_h(1 + K_a[LO^-]/K_w)\}$$

K_a is the acidity constant of the hydrate, and K_w is the autoprotolysis constant of water.

For H_2O solution, $K_h = 1.06$ (4) and $K_a = 2.53 \times 10^{-14}$ M (5), both at 25°C. An isotope effect $K_{H_2O}/K_{D_2O} = 0.89$ is available for K_h at 15°C (4); it is unlikely that this would change very much over the short temperature interval 15–25°C, and use of the same value for 25°C leads to $(K_h)_{D_2O} = 1.19$. The isotope effect on K_w at 25°C has been measured: $K_{H_2O}/K_{D_2O} = 7.3$ (6). No isotope effect on K_a is available, but a reasonable value for an acid as weak as acetaldehyde hydrate would be $K_{H_2O}/K_{D_2O} = 6$ (7); the correction to k_{obs}, at any rate, is not a sensitive function of this constant.

Use of these values with the experimental data listed in Table 1 gives $k_{HO^-} = 1.07$ M^{-1} s^{-1}, in good agreement with $k_{HO^-} = 1.17$ M^{-1} s^{-1} measured before (2), and $k_{DO^-} = 1.46$ M^{-1} s^{-1}. The latter value refers to D_2O containing 2 at.% protium, and linear extrapolation to 100% D_2O leads to the isotope effect $k_{HO^-}/k_{DO^-} = 0.73$ with an estimated uncertainty of ±0.02. This result is consistent with $k_{HO^-}/k_{DO^-} = 0.68$ reported for acetone (8).

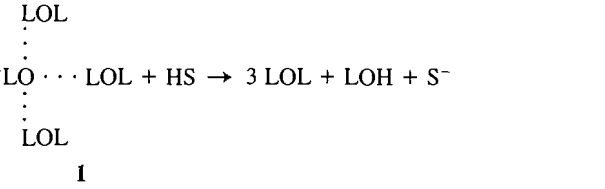
Discussion

Hydroxide-ion-consuming reactions, such as that investigated here, generally show inverse solvent deuterium isotope effects, $k_{HO^-}/k_{DO^-} < 1$. It is believed that this is because the hydroxide ion is strongly solvated in aqueous solution through hydrogen bond formation to three water molecules, as shown in **1** (9). Hydrogen bonding is known to lower the vibrational frequencies of bonds to the hydrogens involved, and these solvating water molecules consequently have weaker bonds, with less isotopically sensitive zero-point energy, than do ordinary water molecules in the bulk solvent (10). Destruction of the hydroxide ion, e.g., by hydron transfer from a substrate (eq. [6]), converts these solvating molecules into ordinary



[6]

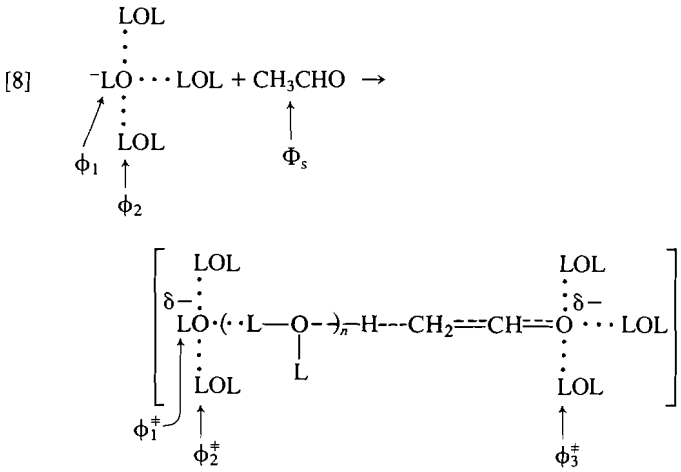
1

water, and that raises their isotopically sensitive zero-point energy and gives an inverse solvent isotope effect.

This picture of hydroxide ion solvent isotope effects can be used to make a quantitative prediction for the presently examined reaction. It is convenient to do this using fractionation factor theory, which expresses a kinetic isotope effect as the product of fractionation factors for all exchangeable hydrogens in the initial state, ϕ_i, divided by a like product for the transition state, $\phi_j^{\ddagger}$, eq. [7] (11). Application of this formalism to the

$$[7] \quad k_H/k_D = \pi_i\phi_i/\pi_j\phi_j^{\ddagger}$$

present system, eq. [8], leads to eq. [9], in which Φ_s is



[8]

the fractionation factor of the water molecules solvating the acetaldehyde substrate.[2]

$$[9] \quad k_{HO^-}/k_{DO^-} = \phi_1(\phi_2)^3\Phi_s/\phi_1^{\ddagger}(\phi_2^{\ddagger})^{2+n}(\phi_3^{\ddagger})^3$$

If hydron transfer from acetaldehyde to the hydroxide ion takes place indirectly through one of the water molecules originally solvating the hydroxide ion, n in eqs. [8] and [9] will be equal to 1. If, on the other hand, hydron transfer is direct, then one of the solvating molecules must be lost before the transition state is reached, and $n = 0$. It has recently been shown that hydron transfer from a carbon acid to amines and alkoxide ions is direct, but it is not known whether this applies to hydron transfers involving the hydroxide and hydronium ions as well (12). Estimates will therefore be made for $n = 0$ and $n = 1$.

The more remote hydrogens of the water molecules solvating the hydroxide ion are believed to have fractionation factors similar to those of bulk water, $\phi = 1.00$; the other two kinds of hydrogen have been assigned the values $\phi_1 = 1.15$ and $\phi_2 = 0.72$ (9). In the transition state these latter hydrogens are on the way to becoming bulk water molecules and their fractionation factors, $\phi_1^{\ddagger}$ and $\phi_2^{\ddagger}$, should therefore lie between the corresponding initial state values and that for bulk water, i.e., unity. It would seem reasonable to assume that these fractionation factors will differ from unity in proportion to the amount of negative charge remaining on the oxygen atom they are solvating, and that this charge may be estimated as $1 - \beta$ where β is the Brønsted exponent for the system; it follows then that $\phi_1^{\ddagger} = (\phi_1)^{1-\beta}$ and $\phi_2^{\ddagger} = (\phi_2)^{1-\beta}$. A Brønsted exponent has not been measured for the ionization of acetaldehyde, but $\beta = 0.53$ is available for hydron transfer from isobutyraldehyde to a series of aryloxide ions (13), and use of the rounded value $\beta = 0.50$ leads to $\phi_1^{\ddagger} = 1.07$ and $\phi_2^{\ddagger} = 0.85$.

Fractionation factors for the hydrogens of water molecules solvating the oxygen atoms of enolate ions have not been determined, but a reasonable estimate might be $\phi_{E^-} = 0.75$; this is slightly greater than $\phi_1 = 0.72$ mentioned above for the more basic hydroxide ion and is consistent with $\phi = 0.75$ measured for the methoxide ion in methanol solution (14). A transition state value may be derived from this estimate, as before, by using the relationship $\phi_3^{\ddagger} = \phi_{E^-}^{x}$ where x is an index denoting the amount of negative charge developed on the enolate oxygen atom at the transition state. Because of transition state imbalance (15), x is not simply equal to β; rather, it has been estimated at $x = 0.38$ (2), and use of the rounded value $x = 0.40$ gives $\phi_3^{\ddagger} = 0.89$.

The substrate fractionation factor Φ_s has also not been determined directly, but an estimate may be made from the solvent isotope effect on the hydration of simple aldehydes and ketones (cf. eq. [3]). This isotope effect may be expressed as $K_{H_2O}/K_{D_2O} = \Phi_s/\phi_h^2$, and, on the assumption that $\Phi_s = 1.00$, $\phi_h = 1.08$ has been calculated for the hydroxyl hydrogens of the hydrates (16). It is not clear, however, that the fractionation factor of such hydrogens should be different from unity, which is the value usually found for uncharged hydroxyl groups. On the other hand, Φ_s could be significantly less than unity because carbonyl oxygen atoms of simple aldehydes or ketones bear an appreciable negative charge, and water molecules solvating such oxygens will be hydrogen bonded to them and will consequently have lowered fractionation factors. Taking $\phi_h = 1.00$ then leads to $\Phi_s = 0.86$; this estimate is consistent with the approximate value $\Phi_s = 0.83$ recently determined for isobutyrophenone.[3]

Use of these values in eq. [9] gives $k_{HO^-}/k_{DO^-} = 0.68$ for direct hydron transfer ($n = 0$) and $k_{HO^-}/k_{D_2O^-} = 0.80$ for transfer through a bridging water molecule. The experimentally determined value, $k_{HO^-}/k_{DO^-} = 0.73 \pm 0.02$ lies between these two estimates, but somewhat closer to that for direct transfer. This suggests that direct transfer is the more likely reaction mechanism, and it is interesting in this connection that analysis of our previously determined solvent isotope effect on the hydronium-ion-catalyzed enolization of acetaldehyde supported direct transfer for that reaction as well (2).

[2]In accord with ref. 11*b*, we use Φ to denote the aggregate isotopic fractionation produced by m sites with identical individual fractionation factors ϕ, i.e., $\Phi = \phi^m$.

Halogen and pseudohalogen substitution of some adamantanoid chalcogenate clusters $[(\mu\text{-EPh})_6(MEPh)_4]^{2-}$ using methylmercury and triphenyltin derivatives. A multinuclear nuclear magnetic resonance study[1]

PHILIP A. W. DEAN[2] AND JAGADESE J. VITTAL
Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received March 15, 1988

PHILIP A. W. DEAN and JAGADESE J. VITTAL. Can. J. Chem. **66**, 2443 (1988).

Multinuclear nmr (^1H, ^{77}Se, $^{111/113}Cd$, ^{119}Sn, ^{199}Hg, as appropriate) has been used to study $Y^- - EPh^-$ exchange in Me_2CO or MeCN between $R_nM'Y$ (R_nM' = Ph_3Sn or MeHg; Y = Cl, Br, I, NCO, or NCS) and the adamantane-like anions $[(\mu\text{-EPh})_6(MEPh)_4]^{2-}$ (E = S, M = Zn, Cd, or Co; E = Se, M = Zn or Cd), as their tetraalkylammonium salts. Quantitative terminal substitution of the clusters occurs in most cases, giving $[(\mu\text{-EPh})_6(MEPh)_{4-x}(MY)_x]^{2-}$ (x = 1–4). However, reaction is incomplete for M = Cd, E = S or Se, $R_nM'Y$ = Ph_3SnNCO or Ph_3SnNCS and for M = Zn or Co, E = S, $R_nM'Y$ = MeHgI. Differences in the extents of reaction for Ph_3SnY and MeHgY are consistent with the position of equilibrium in MeHgY:Ph_3SnEPh mixtures.

Group interchange provides a convenient alternative synthesis of the known halogen-substituted clusters $[(\mu\text{-EPh})_6(MY)_4]^{2-}$ (M = Zn or Cd, Y = Cl, Br, or I; M = Co, Y = Cl), and the first syntheses of $[(\mu\text{-SPh})_6(CoY)_4]^{2-}$ (Y = Br or I) and various pseudohalogen-substituted adamantanoid anions. The nuclei used for full direct nmr characterization of the new clusters in solution were: ^{77}Se and ^{113}Cd for $[(\mu\text{-SePh})_6(CdSePh)_{4-x}(CdY)_x]^{2-}$ (x = 1–4; Y = NCO or NCS); ^{77}Se for $[(\mu\text{-SePh})_6(ZnSePh)_{4-x}(ZnY)_x]^{2-}$ (x = 1–4, Y = NCO or NCS); ^{113}Cd for $[(\mu\text{-SPh})_6(CdSPh)_{4-x}(CdY)_x]^{2-}$ (x = 1–4; Y = NCO or NCS); ^1H for $[(\mu\text{-SPh})_6(CoY)_4]^{2-}$ (Y = Br, I, NCO, or NCS). The first solution ^1H nmr spectrum of $[(\mu\text{-SPh})_6(CoCl)_4]^{2-}$ is also reported.

PHILIP A. W. DEAN et JAGADESE J. VITTAL. Can. J. Chem. **66**, 2443 (1988).

Faisant appel à la rmn multinucléaire (^1H, ^{77}Se, $^{111/113}Cd$, ^{119}Sn, ^{199}Hg selon le cas) on a étudié l'échange $Y^- - EPh^-$, dans le Me_2CO ou le MeCN, entre le $R_nM'Y$ (R_nM = Ph_3Sn ou MeHg; Y = Cl, Br, I, NCO ou NCS) et les anions du type adamantane $[(\mu\text{-EPh})_6(MEPh)_4]^{2-}$ (E = S, M = Zn, Cd ou Co; E = Se, M = Zn ou Cd) sous forme de sels de tétraalkylammonium. Dans la plupart des cas il se produit une substitution terminale quantative des aggrégats qui conduit à la formation de $[(\mu\text{-EPh})_6(MEPh)_{4-x}(MY)_x]^{2-}$ (x = 1–4). La réaction est cependant incomplète dans lorsque M = Cd, E = S ou Se, $R_nM'Y$ = Ph_3SnNCO ou Ph_3SnNCS et pour M = Zn ou Co, E = S et $R_nM'Y$ = MeHgI. Les différences constatées dans les réactions sont en accord avec la position d'équilibre dans les mélanges de MeHgY:SnEPh.

L'échange mutuel entre les groupes fournit une méthode de synthèse alternative des aggrégats connus ayant un halogène comme substituant $[(\mu\text{-EPh})_6(MY)_4]^{2-}$ (M = Zn ou Cd, Y = Cl, Br ou I; M = Co, Y = Cl) et la première synthèse du $[(\mu\text{-SPh})_6(CoY)_4]^{2-}$ (Y = Br ou I) et de divers anions de type adamantane ayant des substituants pseudohalogénés. On a utilisé les noyaux suivants pour caractériser les nouveaux composés en solution par rmn : le ^{77}Se et le ^{113}Cd pour $[(\mu\text{-SePh})_6(CdSePh)_{4-x}(CdY)_x]^{2-}$ (x = 1–4, Y = NCO ou NCS); le ^{77}Se pour $[(\mu\text{-SePh})_6(ZnSePh)_{4-x}(ZnY)_x]^{2-}$ (x = 1–4, Y = NCO ou NCS); le ^{113}Cd pour $[(\mu\text{-SPh})_6(CdSPh)_{4-x}(CdY)_x]^{2-}$ (x = 1–4, Y = NCO ou NCS); le ^1H pour $[(\mu\text{-SPh})_6(CoY)_4]^{2-}$ (Y = Br, I, NCO ou NCS). On rapporte également la première solution du spectre de rmn du $[(\mu\text{-SPh})_6(CoCl)_4]^{2-}$.

[Traduit par la revue]

Introduction

Adamantane-like anions, $[(\mu\text{-SPh})_6(MSPh)_4]^{2-}$, with a [4M-6S] core of (idealized) T_d symmetry, are known for various divalent metal ions including Mn(II), Fe(II), Co(II), Zn(II), and Cd(II) (1). For M = Zn and Cd, the related selenolate complexes, $[(\mu\text{-SePh})_6(MSePh)_4]^{2-}$, have also been reported (2). The $[(\mu\text{-EPh})_6(MEPh)_4]^{2-}$ clusters should have an interesting ligand substitution chemistry, but to date there has been very little work in this area.[3] In previous papers from these laboratories we have described substitution of the Zn_4 and Cd_4 clusters with halogens (2*b*, 5) and R'E' (2*a*, 2*b*).

Halogen substitution of $[(\mu\text{-EPh})_6(MEPh)_4]^{2-}$ (M = Zn or Cd; E = S or Se) according to eq. [1], allows complete terminal

[1] $[(\mu\text{-EPh})_6(MEPh)_4]^{2-} + 2X_2 \rightarrow [(\mu\text{-EPh})_6(MX)_4]^{2-} + 2Ph_2E_2$

[1a], X = Cl; [1b], X = Br; [1c], X = I

substitution (2*b*, 5). For incorporation of chlorine, $PhICl_2$ (6) acts as a useful alternative to the halogen itself (2*b*, 5), as shown in eq. [2]. So far as we are aware, these are the only studies

[2] $[(\mu\text{-EPh})_6(MEPh)_4]^{2-} + 2PhICl_2 \rightarrow [(\mu\text{-EPh})_6(MCl)_4]^{2-} + 2Ph_2E_2 + 2PhI$

in which halogen-substituted clusters have been made from the parent $[(\mu\text{-EPh})_6(MEPh)_4]^{2-}$ anions. At the outset of our work, the only other tetrahalo-anions that had been reported were $[(\mu\text{-SPh})_6(FeX)_4]^{2-}$ (X = Cl or Br), assembled from $FeCl_2$, Cl^- and SPh^-, or from $Fe(SPh)_4^{2-}$ and FeX_2, rather than by substitution of pre-formed $[(\mu\text{-SPh})_6(FeSPh)_4]^{2-}$ (7). Up to that time, attempts to build up tetrahalo-anions of Zn(II) (8) and Co(II) (9) in a similar manner had been unsuccessful, leading only to doubly terminally substituted products. Since the completion of our study, the synthesis of $(Bu_4N)_2[(\mu\text{-SPh})_6(CoCl)_4]$ from $(Bu_4N)[CoCl_3(PPh_3)]$ and $PhSSiMe_3$ has been reported, with characterization of the new tetranuclear anion by X-ray analysis (10).

Reaction [1c] is convenient to carry out, but there are drawbacks to [1a], [1b], and [2]. Quantitative addition of Cl_2 [1a] or Br_2 [1b] is difficult, and for [2] $PhICl_2$ must be freshly

[1]Presented in part at the 70th Canadian Chemical Conference, Quebec City, Quebec, June 1987.

[2]Author to whom correspondence should be addressed.

[3]Several groups have investigated *metal* substitution of such adamantanoid clusters (2*a*, 3, 4).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 112.217.228.212 on 09/07/12
For personal use only.

made for each synthesis. Further, the syntheses of reactions [1] and [2] cannot be extended straightforwardly to other substituents such as the common pseudohalogens, nor are they suitable for clusters of readily-oxidizable metals. Alternative methods of substitution clearly deserve exploration.

In this paper we have used multinuclear nmr to make a systematic investigation of substitution of the representative anions $[(\mu\text{-EPh})_6(\text{MEPh})_4]^{2-}$ (M = Zn or Cd, E = S or Se; M = Co, E = S) via interchange of groups with $R_nM'Y$ (R_nM' = MeHg or Ph_3Sn), as in eq. [3].

$$[3]\quad [(\mu\text{-EPh})_6(\text{MEPh})_4]^{2-} + 4R_nM'Y \rightarrow [(\mu\text{-EPh})_6(\text{MY})_4]^{2-} + 4R_nM'EPh$$

The organo-mercury and -tin compounds possess several features making them promising reagents for the interchange reaction of interest: (*i*) the "soft" organometallic centres bind the chalcogenate group strongly with a 1:1 stoichiometry;[4] (*ii*) a wide range of stable $R_nM'Y$ is readily available so that Y groups other than halides can be tried; (*iii*) the fate of R_nM' can be followed using ^{199}Hg or ^{119}Sn nmr;[5] and (*iv*) in future synthetic studies, the solubility of the organometallic reagents and products in non-polar solvents should allow easy separation from the ionic clusters. In addition, since [3] involves ligand exchange rather than oxidation by halogens (eqs. [1] and [2]), it reduces the possibility of problems due to metal oxidation.

Experimental

Materials

Literature syntheses without significant variation were used for $(Me_4N)_2[(\mu\text{-EPh})_6(\text{MEPh})_4]$ (E = S, M = Zn (3), Cd (13), or Co (9); E = Se, M = Zn (*5b*) or natural or ^{113}Cd-enriched Cd (*2a*)) and $(Et_4N)_2[(\mu\text{-SePh})_6(\text{ZnSePh})_4]$ (*2b*, *5b*). The synthesis of $(Pr_4N)_2[Cd_4(SPh)_{10}]$ paralleled that of the Me_4N^+ salt. MeHgNCS was prepared from MeHgI and AgSCN (14). The analogous synthesis using AgN_3 gave $MeHgN_3$, which was recrystallized from $CHCl_3$. Reported methods gave Ph_3SnY (Y = N_3 (15), NCO (16), or I (17)). Following ref. 17, Ph_3SnBr was prepared by the stoichiometric reaction of Sn_2Ph_6 with Br_2 in $CHCl_3$; it was recrystallized from dry propanol. The method of ref. 11, but with NaOMe (produced *in situ*) in place of Et_3N, yielded $Ph_3SnSePh$, which was recrystallized from $CHCl_3$. Two synthetic methods were used to produce Ph_3SnNCS: (*i*) reaction of Ph_3SnI and AgSCN in refluxing Et_2O, with subsequent solvent removal and recrystallization from toluene; or (*ii*) reaction of Ph_3SnCl with KSCN in refluxing MeOH, followed by precipitation with water, drying, and recrystallization from toluene (18). The compounds Ph_3SnSPh and MeHgEPh (E = S or Se) were obtained as the by-products of appropriate completely reacted mixtures of $R_nM'Y$ and $[(\mu\text{-EPh})_6(\text{MEPh})_4]^{2-}$ (M = Zn or Cd) (see below): following solvent removal from a completely reacted $[(\mu\text{-EPh})_6(\text{MEPh})_4]^{2-}$–$R_nM'Y$ mixture, $R_nM'EPh$ was extracted into C_6H_6. The crude products obtained by evaporation of C_6H_6 were recrystallized from $CHCl_3$. Ph_3SnCl (Aldrich) was recrystallized from dry propanol. MeHgY (Y = Cl, Br, or I) (all from Alfa) were used as received. All solvents were dried over 3A molecular sieves before use. Before preparation of solutions containing any of the chalcogenate clusters, solvents were also thoroughly de-oxygenated in a flow of Ar.

The purities of the organometallic reagents were checked using nmr: ^{119}Sn nmr[5] (together with ^{77}Se nmr[5] for $Ph_3SnSePh$) was used for the triphenyltin compounds and ^{1}H and/or ^{199}Hg nmr[5] for the organomercury compounds. Our nmr data are consistent with literature values, where available (19–21). We could find no published ^{119}Sn nmr data for several of the triphenyltin compounds. Metal nmr data for these, as solutions in inert solvents, are given in Table 1. Similarly, no ^{199}Hg nmr data seem to have been reported for $MeHgN_3$; we find $\delta_{Hg} = -904$ (relative to external $HgMe_2$), $^2J(^{199}Hg—^1H) = 191 \pm 3$ Hz at 293 K for a $CHCl_3$ solution containing 0.05 mol/L of solvent. The compound MeHgNCO has been only partially characterized in the literature (23). The synthesis and further characterization of this compound are described below.

Synthesis

MeHgNCO. An earlier brief report (23) of this substance described its synthesis from MeHgCl and ClNCO and characterization by osmometry and vibrational spectroscopy. From a ^{119}Hg nmr[5] study, we find the compound to be formed quantitatively when a 1:1 mixture of MeHgI and AgNCO is stirred for 12–18 h at room temperature in acetone. The crude product is obtained by removal of the solvent from the filtrate. On recrystallization from $CHCl_3$, pure MeHgNCO is isolated as white flakes. Isolated yield: 51%. Pmr (0.05 mol/L of $CDCl_3$): $\delta_H = 1.04$ ppm, $^2J(^{199}Hg—^1H) = 199 \pm 1$ Hz. In the ^{199}Hg nmr spectrum of this sample at 294 K, $\delta_{Hg} = -852$ ppm. *Exact mass* calcd. for $C_2H_3{}^{202}HgNCO$: 258.9921; found (ms at 70 eV): 258.9925.

Solid MeHgNCO deteriorates over a period of days on standing at room temperature, becoming gradually insoluble in $CHCl_3$. Because of this instability, as well as the high volatility of the compound (23), after our initial synthesis MeHgCO was not normally isolated. Instead, it was prepared *in situ* in acetone, as outlined above, with removal of AgI by filtration before use.

Nuclear magnetic resonance spectra

All samples were prepared on the basis of (mass of solute/volume of solvent). For solutions of the chalcogenate clusters, solvents were de-oxygenated in a flow of Ar.

Nuclear magnetic resonance spectra were measured using a Varian XL-200 or -300 spectrometer system. Conventional methods were used to obtain ^{1}H and ^{13}C nmr spectra, using samples in 5 mm od nmr tubes. For ^{199}Hg, ^{77}Se, $^{111/113}$Cd, and ^{119}Sn nmr spectroscopy[5] samples were prepared in 10 mm od nmr tubes. In these cases measurements of temperature, instrumental operating conditions and external referencing were generally similar to those used in earlier reports from this laboratory (*2a*, *2b*, *5b*, 13, 24). However, during the current work we made an inversion-recovery measurement of T_1 for ^{77}Se in $(Me_4N)_2[(\mu\text{-SePh})_6(\text{ZnI})_4]$ (*2b*) as a solution in deoxygenated acetone (0.05 mol/L of Me_2CO). At 57.20 MHz and 297 K, $T_1 = 0.75 \pm 0.02$ s, a much shorter T_1 than presumed[6] in our earlier work on PhSe-bridged clusters (*2b*, *5b*, *24a*). The conditions used here to collect ^{77}Se nmr spectra assume T_1 values of *ca.* 1–2 s, e.g. tip angles of *ca.* 60° with an acquisition (and repetition) time of 1 s, so that ^{77}Se data collection is more efficient than earlier.

Results and discussion

Anion exchange between methylmercury and triphenyltin compounds

Of interest in connection with the reaction shown in eq. [3] is a study of equilibrium [4] for various combinations of EPh and Y. To our knowledge, there are no literature data for this

$$[4]\quad MeHgY + Ph_3SnEPh \underset{}{\overset{K_4}{\rightleftharpoons}} MeHgEPh + Ph_3SnY$$

[4]We note, however, that organotin chalcogenates have sometimes been used as a source of the chalcogenate ion in synthesis (e.g. ref. 11), just as Me_3SiSPh is used as a *source* of SPh^- in the synthesis of $[(\mu\text{-SPh})_6(CoCl)_4]^{2-}$.

[5]The nuclei ^{199}Hg, ^{119}Sn, ^{111}Cd, ^{113}Cd, and ^{77}Se all have spin $I = 1/2$. Their % natural abundances and receptivities relative to ^{13}C are, respectively, 16.84 and 5.57, 8.58 and 25.6, 12.75 and 6.97, 12.26 and 7.67, and 7.58 and 3.01 (12).

[6]T_1 values of ^{77}Se are typically long for small molecules. For larger molecules that tumble more slowly, shorter relaxation times can occur (e.g. ref. 25).

TABLE 1. Tin-119 nmr data for some compounds Ph_3SnY at 294 ± 2 K[a]

Y	Solvent	δ_{Sn}[b]	$\Delta\nu_{1/2}$ (approx) (Hz)	Other
Br	CH_2Cl_2	−47.2	8	
SePh	CH_2Cl_2	−81.4	19	$^1J(^{119}Sn—^{77}Se) = 1167 \pm 5$ Hz $\delta_{Se} = -27.1$[c]
N_3	$CHCl_3$	−88.1	90	
NCO	$CHCl_3$	−118.0	75	
NCS	$CHCl_3$	−134.8	50	$^1J(^{119}Sn—^{14}N) = 88 \pm 3$ Hz[d]

[a]Measured at 74.61 MHz (38.16 MHz for ^{77}Se) for solutions with concentrations 0.05 mol per L of solvent.

[b]Relative to external pure $SnMe_4$; estimated error in measurement ±0.1 ppm.

[c]Relative to external pure Me_2Se; estimated error in measurement ±0.1 ppm; $\Delta\nu_{1/2} \approx 6$ Hz.

[d]For comparison, $^1J(^{119}Sn—^{14}N) = 136$ Hz for $(c\text{-}C_6H_{11})_3SnNCS$ in toluene (22*a*). Also $^1J(^{119}Sn—^{15}N) = 307.0$ Hz for Bu_3SnNCS (22*b*); from this, the calculated value of $^1J(^{119}Sn—^{14}N)$ in Bu_3SnNCS = 218.9 Hz.

particular equilibrium. However, Kravtsov *et al.* (26), have studied the position of equilibrium for $OAc^- - ArS^-$ exchange in mixtures of phenylmercury and triphenyltin derivatives. They found that the preference for ArS^- over OAc^- in $PhHg^+ > Ph_3Sn^+$, concluding that the organomercury centre is the softer acceptor. Also, Grant and Wardell (27) have shown that complete anion exchange occurs in mixtures of $Me_3SnSePh$ and PhHgCl.

Overall, Me_2CO was used most widely in the studies of reaction [3] described below. Accordingly, Me_2CO was also the solvent chosen to study [4].[7] As probes of the position of equilibrium[8] both ^{119}Sn and ^{199}Hg nmr were used.

In mixtures of MeHgY and MeHgEPh, there is rapid exchange of the MeHg group between sites (see, for example, ref. 28). Thus with a prior knowledge of δ_{Hg} for MeHgY and MeHgEPh separately,[9] the position of the exchange-averaged ^{119}Hg nmr signal can be used to indicate the position of [4]. This method will be least accurate when K_4 is very large or very small. Under these conditions the value found for K_4 will be most sensitive to the (comparatively small) variation of δ_{Hg}(MeHgEPh/Y) with concentration and with small changes in ambient probe temperature.

Our ^{119}Sn nmr studies show that on this nmr timescale there is no exchange of the Ph_3Sn group between sites in mixtures of Ph_3SnEPh (E = S or Se) and Ph_3SnY (Y = Cl, Br, I, N_3, NCO, or NCS) in acetone, with or without added methylmercury compound. Here the relative intensities of the separate ^{119}Sn signals[10,11] can be used to quantitate equilibrium [4], complementing the results of ^{199}Hg nmr. The intensity ratios, and hence the calculated values of K_4, are once more expected to be least accurate for extreme values of K_4.

TABLE 2. Equilibrium constants for [4] at 295 ± 2 K in Me_2CO[a]

	log K_4[b]	
Y	E = S	E = Se
Cl	2.2±0.2	2.5±0.2
Br	0.3±0.1	−1.0±0.2
I	−1.5±0.3	−1.3±0.2
NCO	>2.7[c]	>2.7[c]
NCS[d]	>2.7[c]	>2.7[c]
N_3	>2.7[c]	>2.7[c]

[a]Total concentrations of methylmercury and triphenyltin compounds are 0.05–0.2 mol/L of solvent.

[b]Estimated errors are quoted.

[c]K_4 was too large to be measured accurately.

[d]The thiocyanate group is S-bound in MeHgSCN and N-bound in Ph_3SnNCS (see text).

The values found for K_4 are given in Table 2. When E = S or Se and Y = NCO, NCS,[12] or N_3, the value of K_4 is too large to be measured accurately ($K_4 > 500$). For Y = halide, the values found using the two different metal nmr probes are in reasonable agreement; the average value is given. The data in Table 2 show that equilibrium [4] favours Ph_3SnEPh strongly for E = S, Y = I and for E = Se, Y = I or Br. Conversely, MeHgEPh is favoured strongly for E = S or Se and Y = Cl, NCO, N_3, or NCS, and slightly for E = S, Y = Br. In general then, MeHgY should be the more potent reagent for substitution of chalcogenate clusters when Y = Cl, NCO, NCS, or N_3, while Ph_3SnI should be more potent when Y = I. For Y = Br an

[7]Qualitatively similar results were found using MeCN as solvent.

[8]The equilibria are rapidly established compared with the rate at which the nmr spectra can be obtained.

[9]At 293 K, for Me_2CO solutions containing 0.05 mol/L of solvent, δ_{Hg} = −847, −958, −1147, −979, −918, −787, −615, and −682 for Y in MeHgY = Cl, Br, I, N_3, NCO, SCN, SPh, and SePh, respectively.

[10]At 295 K, for Me_2CO solutions containing 0.05 mol/L of solvent, δ_{Sn} = −103.7, −103.7, −121.6, −161.0, −185.8, −234.3 ($^1J(^{119}Sn—^{14}N)$ = 120 ± 10 Hz), −65.9 and −81.0 ($^1J(^{119}Sn—^{77}Se) = 1150 \pm 5$ Hz, $\delta_{Se} = -31.6$) for Y in Ph_3SnY = Cl, Br, I, N_3, NCO, NCS, SPh, and SePh, respectively.

[11]The large changes in δ_{Sn} for Ph_3SnY (Y = N_3, NCO, or NCS) and in $^1J(^{119}Sn—^{14}N)$ for Ph_3SnNCS that occur on change of solvent from $CHCl_3$ to Me_2CO (compare Table 1 and footnote 10) indicate coordinate of Me_2CO. The acceptor properties of these neutral pseudohalides are well established from other work, e.g. ref. 18*b* and references therein. Also it appears that Ph_3SnCl and Ph_3SnBr are ionized to $Ph_3Sn(OCMe_2)_x^+$ in Me_2CO: in this solvent the two compounds have identical ^{13}C as well as ^{119}Sn nmr spectra.

[12]It should be noted that S-bonded thiocyanate occurs in MeHgSCN (14, 28), and N-bonded thiocyanate in Ph_3SnNCS (29).

experimental determination of the better reagent would be safest.

Reaction of $[(\mu\text{-}EPh)_6(MEPh)_4]^{2-}$ and $R_nM'Y$

Relative extent of reaction must obviously be an important factor in the choice of a reagent, Ph_3SnY or MeHgY, for a particular reaction [3]. However, practical considerations also influence the choice. From the point of view of handling, the Ph_3SnY reagents are preferable: they are less volatile and therefore less hazardous. Also solid Ph_3SnNCO is thermally stable whereas solid MeHgNCO is not (see Experimental Section). A disadvantage of the MeHg(II) reagents is that MeHgY:$[M_4(EPh)_{10}]^{2-}$ mixtures give broader nmr signals in spectra measured at ambient probe temperature than do Ph_3SnY:$[M_4(EPh)_{10}]^{2-}$ mixtures (see below). This is not a problem in low temperature spectra however, and here the organomercury reagents have the advantage of generally greater solubility in Me_2CO.

Just as described above for MeHgY:Ph_3SnEPh mixtures, ^{119}Sn or ^{199}Hg nmr spectra of mixtures of $[(\mu\text{-}EPh)_6(MEPh)_4]^{2-}$ and $R_nM'Y$ in Me_2CO at ambient probe temperature can be used to obtain the $R_nM'EPh/R_nM'Y$ ratio and so obtain an initial indication of the extent of reaction. The *cleanness* of reaction must be found by other means. The two organometallic azides certainly undergo reaction with $[M_4(EPh)_{10}]^{2-}$, as judged by $^{119}Sn/^{119}Hg$ nmr, but we could not identify the non-organometallic products, though they are certainly not those expected from [3]. Accordingly, the azides are not considered further in the following discussion.

*(i) $[(\mu\text{-}SePh)_6(CdSePh)_4]^{2-}$ (**1**)*

On the basis of $^{119}Sn/^{199}Hg$ nmr, there is complete reaction of **1** with MeHgY (Y = Cl, Br, I, NCO, or NCS) and with Ph_3SnY (Y = Cl, Br, or I) up to $R_nM'Y/\mathbf{1} = 4$.[13] Reaction of **1** with Ph_3SnNCO and Ph_3SnNCS is incomplete. Detailed ^{77}Se and ^{113}Cd nmr studies of those reactions that appear complete by $^{119}Sn/^{199}Hg$ nmr confirm the completeness and show that all these reactions occur cleanly in accordance with eq. [3].

We have previously reported that ^{77}Se nmr spectra of **1** in Me_2CO or MeCN at ambient probe temperature show a single broad exchange-averaged signal (*2a*, *5b*), while for MeCN solutions at 234 K well-separated resonances, assignable to bridging and terminal PhSe groups ($PhSe_t$ and $PhSe_{br}$), are found at 18 and −62 ppm, respectively (*5b*). As part of the current work we have obtained more definitive low temperature ^{77}Se nmr spectra of **1**. At 213 K, a sample of **1** in Me_2CO (concentration 0.01 mol/L of solvent) showed sharp resonances with $\delta_{Se} = 26.4$ and −64.3 ppm, and relative intensities approximately 2 and 3. These signals can be assigned to $PhSe_t$ and $PhSe_{br}$ groups, respectively (*5b*). Satellites from one-bond coupling to $^{111/113}Cd$ can be picked out readily. In a sample with partial ^{113}Cd enrichment, $^1J(^{113}Cd—^{77}Se_t) = 144 \pm 3$ Hz, while $^1J(^{113}Cd—^{77}Se_{br}) = 165 \pm 3$ Hz. From the $^{111/113}Cd$ nmr[5] spectra of this sample, $^2J(^{113}Cd—Se—^{111}Cd) = 66 \pm 3$ Hz.

Addition of 4 mol equiv. of $R_nM'Y$ (R_nM' = Ph_3Sn or MeHg; Y = Cl, Br, or I) to **1**, leads to the tetrahalo anions $[(\mu\text{-}SePh)_6(CdY)_4]^{2-}$, which we have described earlier (*5*). Low temperature ^{77}Se and ^{113}Cd nmr spectra are in general agreement with those already reported (*5*) for these species. It is somewhat surprising that sharper spectra were obtained in the present work, using samples prepared *in situ*, than could be obtained previously using analytically pure samples (*5*). Hence it was possible to measure some couplings here that were previously obscured by the linewidth. At 237 K[14] in Me_2CO or MeCN $^1J(^{111/113}Cd—^{77}Se_{br})$ (from ^{77}Se nmr) and $^2J(^{113}Cd—^{111}Cd)$ (from ^{113}Cd nmr) are 58 ± 3 and *ca.* 33 Hz, and 80 ± 2 and *ca.* 38 Hz, for the tetrachloro and tetrabromo complexes, respectively. Only the two couplings for the tetraiodo complex (120 ± 10 and 52 ± 2 Hz, which we confirmed here) and an approximate value of $^1J(^{113/111}Cd—^{77}Se)$ for the tetrabromo complex were obtained previously (*5b*). Since $^1J(^{111/113}Cd—^{77}Se)$ and $^2J(^{113}Cd—^{111}Cd)$ share a common coupling pathway, they are expected to change in concert, as found here for the series of **1** and its tetrahalo-substituted derivatives.

When MeHgY (Y = NCO or SCN) is added stepwise to **1** in Me_2CO, ^{77}Se and ^{113}Cd nmr spectra of samples at 213 K[14] provide clear evidence for stepwise substitution of the pseudohalide into **1** to give $[(\mu\text{-}SePh)_6(CdSePh)_{4-x}(CdY)_x]^{2-}$ as components of equilibrium mixtures.[15] A typical ^{77}Se nmr spectrum, that of a mixture with MeHgNCO/**1** = 2, is shown in Fig. 1*a*. The first new cluster formed in the MeHgY:**1** mixtures is characterized by one new ^{77}Se nmr signal (relative intensity 1) in the $PhSe_t$ region and two new signals (each of relative intensity 1) in the $PhSe_{br}$ region. This spectrum reaches its maximum intensity with the concentration of addition of 1 mol equiv. of MeHgY. Following previous work (*2b*), the spectrum can be assigned to the anion with $x = 1$. The concentration of $[(\mu\text{-}SePh)_6(CdSePh)_2(CdY)_2]^{2-}$ reach a maximum at MeHgY/**1** = 2. This species has a ^{77}Se nmr spectrum consisting of a $PhSe_t$ signal (relative intensity 2) and three $PhSe_{br}$ signals (two of relative intensity 1, one of relative intensity 4), as expected (*2b*) for species of time-averaged C_2 symmetry. The anion $[(\mu\text{-}SePh)_6(CdSePh)(CdY)_3]^{2-}$, which has maximum concentration at MeHgY/**1** = 3, gives one ^{77}Se resonance (relative intensity 1) in the $PhSe_t$ region and two (both of relative intensity 3) in the $PhSe_{br}$ region, consistent (*2b*) with time-averaged C_3 symmetry. At MeHgY/**1** = 4, the major species is $[(\mu\text{-}SePh)_6(CdY)_4]^{2-}$. This anion is not the sole species present, however. Significant amounts of the species with $x = 3$ still exist at this ratio. The products corresponding to $x > 4$, which must also exist in the equilibrium mixture, remain unidentified. A similar redistribution equilibrium has been noted earlier for $[(\mu\text{-}SePh)_6(ZnCl)_4]^{2-}$ (*2b*).

The occurrence of a total of nine ^{77}Se nmr signals in the $PhSe_{br}$ region of the series $[(SePh)_6(CdSePh)_{4-x}(CdY)_x]^{2-}$ (Y = NCO or NCS), as exemplified in Fig. 1*a*, shows that the ^{77}Se resonances of $PhSe_{br}$ are sensitive to both geminal and more distant substitution, and assignments can be made on this basis (*2b*). The ^{77}Se nmr spectra of the two pseudohalide-substituted series so assigned are given in Table 3. The data for the two series of spectra are sufficiently similar to allow the conclusion that NCS^-, like NCO^-, is N-bonded in the Cd_4 anions. N-bound NCS^- also occurs in discrete[16] mononuclear cadmium complexes (e.g. ref. 31).

The low temperature[14] ^{113}Cd nmr spectra of mixtures of **1** and MeHgY (Y = NCO or SCN) give results consistent with

[13]Complete reaction occurs to higher $R_nM'Y/[M_4(EPh)_{10}]^{2-}$ ratios, but we have been unable as yet to characterize the products beyond the 4/1 ratio.

[14]At ambient probe temperature very broad lines are found.

[15]The distribution of the species $[(\mu\text{-}EPh)_6(MEPh)_{4-x}(MY)_x]^{2-}$ is close to statistical.

[16]Most Cd^{2+}–thiocyanate species are polymeric (e.g. ref. 30).

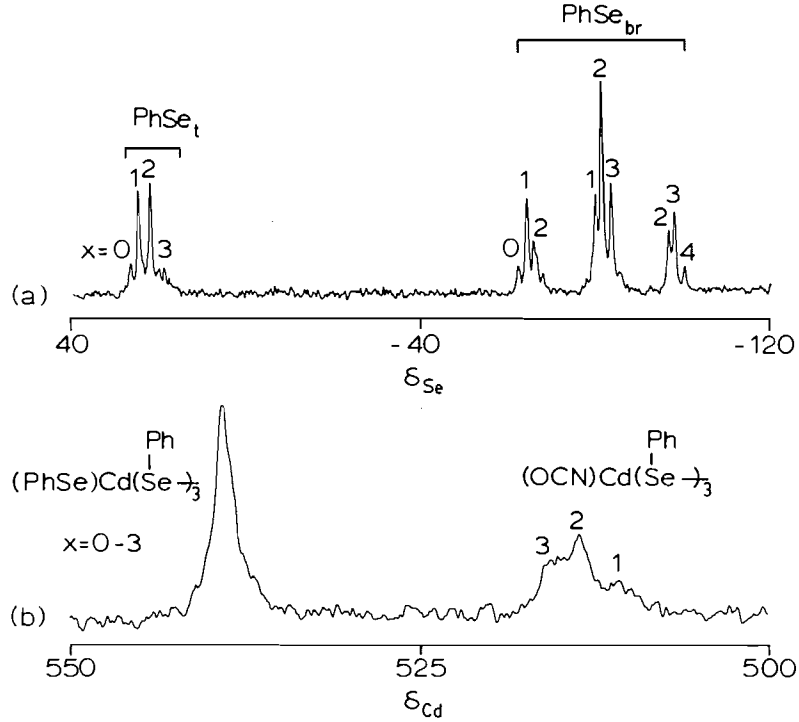

FIG. 1. Nuclear magnetic resonance spectra at 213 K of the supernatant liquid from a mixture of $(Me_4N)_2[(\mu\text{-SePh})_6(CdSePh)_4]$ (**1**):MeHgNCO = 1:2 in acetone, showing the formation of $[(\mu\text{-SePh})_6(CdSePh)_{4-x}(CdNCO)_x]^{2-}$. (*a*) ^{77}Se nmr spectrum at 38.15 MHz. (*b*) ^{113}Cd nmr spectrum at 44.37 MHz. The mixture was prepared using 0.05 mol of **1**/L of Me_2CO.

those from ^{77}Se nmr, though the ^{113}Cd nmr spectra with their larger linewidths were less well resolved. The ^{113}Cd nmr spectra of the series $[(\mu\text{-SePh})_6(CdSePh)_{4-x}(CdY)_x]^{2-}$ (Y = NCO or NCS; x = 0–4) give rise to signals in two regions, as illustrated in Fig. 1*b* for a mixture with MeHgNCO/**1** = 2. The two regions in the spectra must correspond to the two different first coordination spheres, $PhSeCd(\mu\text{-SePh})_3$ and $YCd(\mu\text{-SePh})_3$, that occur in these series (5, 32). The higher frequency region contains the signal of **1** itself and so can be assigned to the $PhSeCd(\mu\text{-SePh})_3$ grouping. Thus the more shielded region is due to $YCd(\mu\text{-SePh})_3$. The thiocyanate series shows further fine structure in both these regions and from the order of appearance of the signals and their relative intensities, the ^{113}Cd spectra of the five individual complexes can be assigned. For the species with x = 1, 2, and 3, the relative intensities in the $PhSeCd(\mu\text{-SePh})_3$ and $SCNCd(\mu\text{-SePh})_3$ regions are 3 and 1, 2 and 2, and 1 and 3, respectively. The anion $[(\mu\text{-SePh})_6(CdNCS)_4]^{2-}$ gives a signal in the $SCNCd(\mu\text{-SePh})_3$ region only. Similar spectra occur for the cyanato complexes (Fig. 1*b*) though these give resolved signals only in the $OCNCd(\mu\text{-SePh})_3$ region. Details of the ^{113}Cd nmr spectra of these new Cd_4 complexes are given in Table 4. The data confirm that N-bonding of the pseudohalide occurs in both series. Attachment of an S-bound thiocyanate to ^{113}Cd is expected (33) to produce *deshielding* relative to attachment of an N-bound cyanate. This is the reverse of what we observe.

Unlike the reactions of **1** with MeHgNCO and MeHgNCS, reactions with Ph_3SnNCO and Ph_3SnNCS do not proceed to completion. After addition of two equivalents of Ph_3SnNCO to **1** (0.01 mol/L of Me_2CO), ^{77}Se nmr at 213 K shows that the major species at equilibrium is still **1**; a smaller amount of $[(\mu\text{-SePh})_6(CdSePh)_3(CdNCO)]^{2-}$ is also evident, as is the co-produced $Ph_3SnSePh$. An identical experiment using Ph_3SnNCS shows that the major Cd_4 species present in this case is $[(\mu\text{-SePh})_6(CdSePh)_3(CdNCS)]^{2-}$. Even here though, less than 50% of the Ph_3SnNCS is converted to $Ph_3SnSePh$ at equilibrium. The different behaviours of methylmercury and triphenyltin pseudohalides towards **1** are consistent with results of MeHgSePh:Ph_3SnY (Y = NCO or NCS) mixtures.

*(ii) $[(\mu\text{-SePh})_6(ZnSePh)_4]^{2-}$ (**2**)*

From $^{119}Sn/^{199}Hg$ nmr there appears to be complete reaction of **2** with $R_nM'Y$ (R_nM' = Ph_3Sn or MeHg; Y = Cl, Br, I, NCO, or NCS) up to $R_nM'Y/2 = 4$.[13] Using ^{77}Se nmr, it can be shown that the reactions occur cleanly. In Me_2CO solution at ambient probe temperature, the anion **2** itself gives two well-separated ^{77}Se resonances at 46 and −7 ppm, that can be assigned to $PhSe_t$ and $PhSe_{br}$, respectively (2*b*). From ^{77}Se nmr spectra obtained at 298 K on stepwise addition of Cl_2 or $PhICl_2$, Br_2, or I_2 to **2**, we have earlier characterized the series $[(SePh)_6(ZnSePh)_{4-x}(ZnY)_x]^{2-}$ (Y = Cl, Br or I; x = 1–4) (2*b*). Under the same conditions, essentially identical spectra, with additional resonances from $Ph_3SnSePh$, are obtained here on stepwise addition of the corresponding Ph_3SnY. These results show that reaction [3] occurs cleanly as well as completely with the organotin halides. Using methylmercury halides very similar results are obtained except that the ^{77}Se nmr spectra, of species containing $PhSe_t$ in particular, are significantly broader. Sharp clean spectra can be obtained at reduced temperature, but it is clear that a new, as yet unidentified, exchange process occurs in the presence of methylmercury salts. The same phenomenon was observed whenever MeHgY was used.

Incremental addition of Ph_3SnY (Y = NCO or NCS) to **2** in Me_2CO at 298 K, causes ^{77}Se nmr spectral changes indicative of the formation of the new anions $[(\mu\text{-SePh})_6$-

[a]In equilibrium mixtures produced from $(R_4N)_2[(\mu\text{-SePh})_6(MSePh)_4]$ and $R_nM'Y$, with 0.05 mol of cluster per L of Me_2CO at room temperature. Some mixtures were saturated.

[b]Relative to external pure Me_2Se at 298 K.

[c]In $(Me_4N)_2[(Cd_4(SePh)_{10}]$–MeHgY mixtures.

[d]In a solution where $[M_4(SePh)_{10}]^{2-}$:$R_nM'Y$ = 1:1.

[e]In a solution of $(Me_4N)_2[Cd_4(SePh)_{10}]$ (0.01 mol per L of Me_2CO, enriched with ^{113}Cd to *ca.* 40 atom%) at 213 K, δ_{Se} and $^1J(^{113}Cd—^{77}Se)$ = 26.4 and 144 ± 3 Hz, and −64.3 and 165 ± 3 Hz, for terminal and bridging PhSe, respectively.

[f]In a solution where $[M_4(SePh)_{10}]^{2-}$:$R_nM'Y$ = 1:2.

[g]$^1J(^{111/113}Cd—^{77}Se) \approx 144$ Hz.

[h]$^1J(^{111/113}Cd—^{77}Se) \approx 164 \pm 10$ Hz.

[i]$^1J(^{111/113}Cd—^{77}Se) \approx 152 \pm 6$ Hz.

[j]$^1J(^{111/113}Cd—^{77}Se) \approx 151$ Hz.

[k]$^1J(^{111/113}Cd—^{77}Se) \approx 180$ Hz.

[l]$^1J(^{111/113}Cd—^{77}Se) \approx 178$ Hz.

[m]$^1J(^{111/113}Cd—^{77}Se) \approx 154$ Hz.

[n]$^1J(^{111/113}Cd—^{77}Se) \approx 162$ Hz.

[o]In a solution where $[M_4(SePh)_{10}]^{2-}$:$R_nM'Y$ = 1:3.

[p]In $(Me_4N)_2[Zn_4(SePh)_{10}]$–$Ph_3SnY$ mixtures; these mixtures also contain $Ph_3SnSePh$ (δ_{Se} = −30.3 to −30.8; $^1J(^{119}Sn—^{77}Se)$ = 1150 ± 5 Hz, at 298 K).

[q]In a $(Et_4N)_2[Zn_4(SePh)_{10}]$–MeHgNCO mixture; this solution also contains MeHgSePh (δ_{Se} = 156, $\Delta\nu_{1/2} \approx 45$ Hz, at 253 K).

$(ZnSePh)_{4-x}(ZnY)_x]^{2-}$ (Y = NCO or NCS) in equilibrium mixtures.[15] The ^{77}Se nmr spectral patterns of the individual clusters and the equilibrium mixtures are qualitatively similar to those of the series $[(\mu\text{-SePh})_6(CdSePh)_{4-x}(CdY)_x]^{2-}$ (Y = NCO or NCS) (see above) and $[(\mu\text{-SePh})_6(ZnSePh)_{4-x}(ZnY)_x]^{2-}$ (Y = Cl, Br, or I) (2*b*), and can be assigned in the same manner. At $Ph_3SnY/\mathbf{1}$ = 4, the major species is $[(\mu\text{-SePh})_6(ZnY)_4]^{2-}$, but the anion is in equilibrium with detectable amounts of the species with x = 3 and products corresponding to x > 4, which remain unidentified. The Cd_4 analogues and $[(\mu\text{-SePh})_4(ZnCl)_4]^{2-}$ redistribute similarly, as discussed above. Assigned ^{77}Se nmr spectra of the two pseudohalide-substituted series are given in Table 3. The similarity between the ^{77}Se nmr spectra of the two series shows that in these tetranuclear Zn_4 anions NCS^-, like NCO^-, is N-bonded. This is the case in mononuclear zinc complexes also (e.g. refs. 31*a*, 34).

Table 3 also contains data for a representative series of clusters formed using the methylmercury method. The spectra of MeHgNCO:**2** mixtures are broad at ambient probe temperature, but sharp at reduced temperature. Apart from expected

[p]Using $(Pr_4N)_2[Cd_4(SPh)_{10}]$.
[q]$^2J(^{113}Cd—^{111/113}Cd) \approx 56$ Hz.
[r]Poorly resolved.
[s]At 297 K, $\delta_{Cd} \approx 536$, $\Delta\nu_{1/2} \approx 370$ Hz.

(2*b*) temperature shifts, and the absence of the signals of $Ph_3SnSePh$, the ^{77}Se spectra of the complexes formed from MeHgNCO are identical to those formed from Ph_3SnNCO.

(iii) $[(\mu\text{-SPh})_6(CdSPh)_4]^{2-}$ (3)

When 4 mol equiv. of $R_nM'Y$ (R_nM' = Ph_3Sn or MeHg; Y = Cl, Br, or I) are added to **3** in Me_2CO or MeCN, ^{113}Cd nmr shows that the tetrahaloanions $[(\mu\text{-SPh})_6(CdY)_4]^{2-}$ are formed cleanly. Cadmium-113 nmr data have already been reported on these species (5), **3** (3, 12, 35), and the partially-substituted species $[(\mu\text{-SPh})_6(CdSPh)_{4-x}(CdY)_x]^{2-}$ (Y = Cl, Br, or I; x = 1–3) (5).

On incremental addition of up to 4[13] mol equiv. of MeHgNCO or MeHgNCS to **3** in Me_2CO, the changes occurring in the ^{113}Cd nmr spectra of the mixtures at 213 K[14] can be interpreted in terms of the formation $[(\mu\text{-SPh})_6(CdSPh)_{4-x}(CdY)_x]^{2-}$ (Y = NCO or NCS; x = 1–4). The spectra are generally similar to those of the corresponding $PhSe^-$ complexes discussed above, and can be assigned in the same way. The ^{113}Cd nmr spectra are summarized in Table 4. For the thiolate clusters, the linewidths are generally smaller than for the $PhSe^-$ analogues, and in several cases partially resolved cadmium satellites are evident. Whereas only $^2J(^{113}Cd—^{111}Cd)$ coupling is expected over the pathway PhS—Cd—S(Ph)—Cd—SPh in these tetranuclear complexes (12, 35), both ^{113}Cd–^{111}Cd and ^{113}Cd–^{113}Cd coupling can occur in the fragment PhS—Cd—S(Ph)—Cd—Y. The partially-resolved couplings observed (Table 4) will be a superimposition of these. As expected, the values of ^2J are similar to those of **3** (e.g. 47 ± 2 Hz at 295 K in Me_2CO (13)). From the data for $[(\mu\text{-SPh})_6(CdSPh)_{4-x}(CdY)_x]^{2-}$ (Y = NCO or NCS) in Table 4, it is again clear that in the thiocyanate complexes N-bonding of the ligand occurs.

Comparison of the ^{113}Cd nmr spectra of **3**:Ph_3SnY (Y = NCO or NCS) mixtures with those of the analogous **3**:MeHgY mixtures shows that reaction of the triphenyltin pseudohalides occurs cleanly but is incomplete. With 4 mol equiv. of $Ph_3Sn(IV)$ reagent added to **3** (0.05 mol/L of Me_2CO) only *ca.* 33% of the cadmium ions have been substituted at equilibrium. This is in agreement with the results of ^{119}Sn nmr. As noted above, the corresponding reactions with **1** are also incomplete.

The different behaviours of the triphenyltin and methylmercury pseudohalides towards **3** are consistent with the position of equilibrium [4] when E = S and Y = NCO or NCS.

(iv) $[(\mu\text{-SPh})_6(ZnSPh)_4]^{2-}$ (4)

Substitution of this cluster cannot be followed directly by nmr methods. The properties of the quadrupolar ^{67}Zn nucleus[17] make this an unattractive probe (see, for example, ref. 36), and the ^{13}C and ^1H nmr spectra of the PhS_{br} groups are insensitive to changes in the terminal substituents of the cluster (see, for example, ref. 5*b*). In this case, then, the cleanness of reaction cannot be assessed by nmr. The extent of reaction can be followed by ^{119}Sn or ^{199}Hg nmr, as above. From ^{119}Sn nmr of mixtures with $0 < Ph_3SnY/4 \leq 4$,[13] reaction [3] appears complete for Y = Cl, Br, I, NCO, and NCS. Similarly, from ^{199}Hg nmr, complete reaction seems to occur up to MeHgY/**4** for Y = Cl, Br, NCO, and SCN. In contrast, MeHgI does not react completely with **4**. The supernatant fraction of a mixture of **4** (0.05 mol/L of Me_2CO) with 4 mol equiv. of MeHgI at 295 K gives an exchange-averaged ^{199}Hg nmr signal at $\delta_{Hg} = -660$. This chemical shift shows that *ca.* 10% of the MeHgI remains unreacted at equilibrium. Thus Ph_3SnI is a better reagent for iodide-substitution of **4** than MeHgI. This is as expected from the position of equilibrium [4] when E = S and Y = I (see Table 2 and discussion above).

(v) $[(\mu\text{-SPh})_6(CoSPh)_4]^{2-}$ (5)

Earlier workers (3) have shown that at or below 346 K this paramagnetic complex gives six separate isotropically-shifted ^1H nmr signals, consistent with slow exchange between PhS_t and PhS_{br} groups. Assignments were made using deuterium labelling. In agreement with the earlier work, our spectra of **5** (0.02 mol/L of MeCN) at 294 K show six well-resolved signals (see Fig. 2*a* and Table 5).

Stepwise addition of Ph_3SnY (Y = Cl, Br, I, NCO, or NCS) to **5** (0.02 mol/L of MeCN) causes both the generation of new signals in each of the six regions of the ^1H nmr spectrum of **5**

[17] ^{67}Zn: 4.11% natural abundance; spin, I = 5/2; quadrupole moment 0.16 Q/m^2; receptivity relative to ^{13}C 0.670 (12).

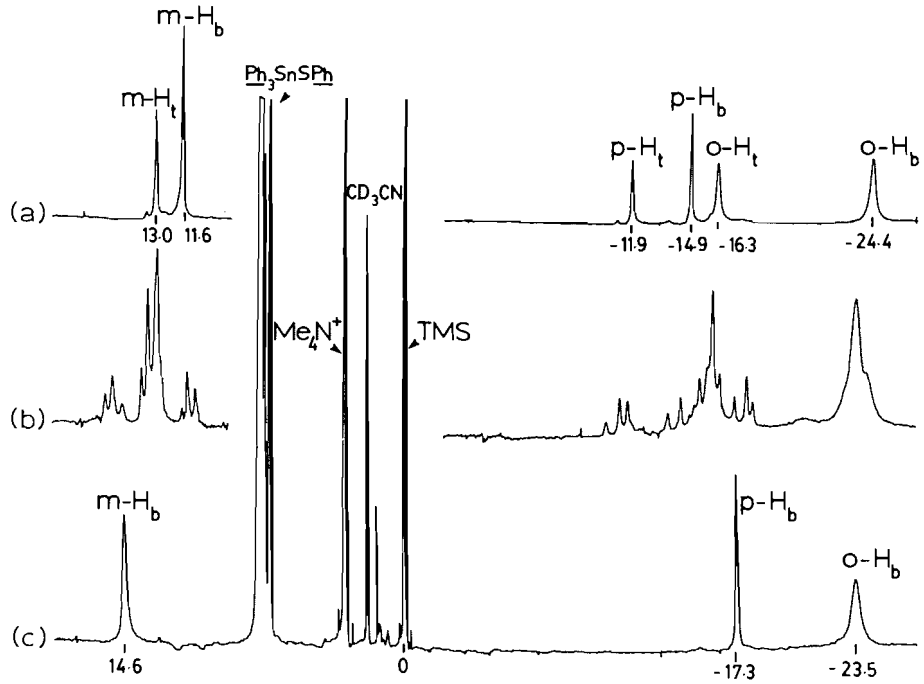

FIG. 2. Proton nmr spectra at 200.06 MHz and 294 K of $(Me_4N)_2[(\mu\text{-SPh})_6(CoSPh)_4]$ (**5**):Ph_3SnI mixtures in CD_3CN showing formation of $[(\mu\text{-SPh})_6(CoSPh)_{4-x}(CoI)_x]^{2-}$. (*a*) **5** alone. (*b*) Ph_3SnI:**5** = 2:1. (*c*) Ph_3SnI:**5** = 4:1. The mixtures were prepared using 0.02 mol of **5**/L of CD_3CN.

TABLE 5. Proton nmr spectra of some complexes $[(\mu\text{-SPh})_6(CoY)_4]^{2-}$ in MeCN at 294 ± 2 K[a]

Y	δ_H[b] ($\Delta\nu_{1/2}$ (approx)[c])		
	o-H[d]	*m*-H[d]	*p*-H[d]

NCS	−22.2 (85)	15.08 (17)	−16.73 (17)

[a]In an equilibrium mixture with $(Me_4N)_2[(\mu\text{-SPh})_6(CoSPh)_4]$:$Ph_3SnY$ = 1:4, prepared starting from a solution containing 0.02 mol of $[Co_4(SPh)_{10}]^{2-}$ per L of MeCN; see text.
[b]Relative to internal TMS.
[c]In Hz.
[d]Assignments are based on those of ref. 3.
[e]Data for $[(\mu\text{-SPh})_6(CoSPh)_4]^{2-}$ have been reported previously (3).
[f]Terminal SPh groups.

and a stepwise diminution in the Ph_t/Ph_{br} intensity ratio. A representative series of ^1H nmr spectra, from the system **5**–Ph_3SnI, are shown in Fig. 2. Overall, the results for the systems **5**–Ph_3SnY are quite consistent with the production of equilibrium mixtures of $[(\mu\text{-SPh})_6(CoSPh)_{4-x}(CoY)_x]^{2-}$. We have not attempted assignment of the spectra of all the individual members of the several series. Many lines are expected[18] and there is significant signal overlap (e.g. Fig. 2*b*).

However, assignment of the relatively simple spectra of all the fully terminally substituted complexes $[(\mu\text{-SPh})_6(CoY)_4]^{2-}$ was straightforward. Details of these spectra are given in Table 5. The complex $[(\mu\text{-SPh})_6(CoI)_4]^{2-}$ is the sole species present in Ph_3SnI:**5** mixtures at Sn/Co = 4 (see Fig. 2*c*). At this same ratio, a small amount of $[(\mu\text{-SPh})_6(CoSPh)(CoY)_3]^{2-}$ is present in the equilibrium mixtures when the other Ph_3SnY are used. Probably $[(\mu\text{-SPh})_6(CoY)_4]^{2-}$ exists in equilibrium with its redistribution products in these cases, since ^{119}Sn nmr shows no detectable amount of unreacted Ph_3SnY.

This is the first characterization of the tetra-substituted complexes with Y = Br, I,[19] NCO and NCS.[20] As noted in the Introduction, $[(\mu\text{-SPh})_6(CoCl)_4]^{2-}$ has been characterized in the solid state very recently (10). In the same work, an attempt to characterize this complex in solution using ^1H nmr was unsuccessful. We find that the ^1H nmr spectrum of $[(\mu\text{-SPh})_6(CoCl)_4]^{2-}$ is not unusually broad (see Table 5) and can offer no explanation for the earlier lack of success.

When MeHgY is used to substitute **5**, the ^1H nmr spectral changes observed are generally similar to those obtained using Ph_3SnY. However, noticeable broadening of the spectra is induced by the methylmercury compounds, and the ^1H nmr spectrum of MeHgSPh is also broad in these mixtures. Again these results suggest an intermolecular exchange process in the presence of MeHg(II). The broadness of the ^1H nmr lines in **5**:MeHgY mixtures makes it difficult to quantify the extent of reaction by pmr. However, judged by ^{199}Hg nmr, reaction is complete for Y = Cl, Br, NCO, or SCN up to MeHgY/**5** = 4.

[18]For $1 \leq x \leq 3$, every new member of the series should give rise to a new signal in each of the *o*-H_t, *m*-H_t, and *p*-H_t regions. For x = 1, 2, 3, and 4, there should be two, three, two, and one new signal(s), respectively, in each of the *o*-H_{br}, *m*-H_{br}, and *p*-H_{br} regions (c.f. discussion of the ^{77}Se nmr spectra of $[(\mu\text{-SePh})_6(MSePh)_{4-x}(MY)_x]^{2-}$ (M = Cd or Zn) above).

[19]We find that this complex can also be synthesized cleanly by treatment of **5** with 2 mol equiv. of I_2 in MeCN, as described earlier (5) for the Cd_4 and Zn_4 analogues.

[20]The bonding mode of NCS^- in $[(\mu\text{-SPh})_6(CoY)_4]^{2-}$ (Y = NCS) cannot be determined unambiguously from the ^1H nmr spectrum of the cluster. N-bonding seems most probable, since this bonding mode is well-established for Co(II) (e.g. ref. 34).

For personal use only.

In contrast, reaction of **5** with MeHgI is incomplete. For example, when 4 mol equiv. of MeHgI are added to **5** (0.01 mol/L of MeCN), approximately 40% of the MeHgI reacts. As noted above, incomplete reaction with MeHgI is also observed for **4**.

Acknowledgments

We thank the Natural Sciences and Engineering Research Council of Canada for financial support of this work. We are grateful to Mrs. V. M. Richardson and Ms. S. Wilson, both of this Department, for expert technical assistance in obtaining some of the nmr spectra, and to Dr. Ivor Wharf of Dawson College, Montreal, P.Q., for helpful discussions about triphenyltin pseudohalides.

The effects of aggregation, counterion binding, and added NaCl on diffusion of aqueous methylene blue

DEREK G. LEAIST
Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received April 5, 1988

DEREK G. LEAIST. Can. J. Chem. **66**, 2452 (1988).

A simplified version of the Harned conductimetric technique is used to measure binary diffusion of the self-associating dye methylene blue chloride in water at 25°C. As the dye concentration is increased from 0.0006 to 0.02 mol dm^{-3}, aggregation of the dye monomers and binding of the chloride counterions cause the dye's binary diffusion coefficient to drop from 0.83×10^{-9} to 0.63×10^{-9} $m^2 s^{-1}$. Ternary diffusion coefficients for aqueous methylene blue chloride + NaCl solutions are also reported. These results show that small amounts of added NaCl (0.005 or 0.01 mol dm^{-3}) sharply reduce the diffusivity of the dye component, and that each mole of diffusing dye cotransports 0.2–0.7 mol NaCl. Diffusion of trace amounts of the dye in the presence of a large excess of an inert supporting electrolyte is discussed briefly.

DEREK G. LEAIST. Can. J. Chem. **66**, 2452 (1988).

On a utilisé une version simplifiée de la technique de conductimétrie de Harned pour mesurer la diffusion binaire du colorant auto-associé, le chlorure du bleu de méthylène dans l'eau à 25°C. Lorsque la concentration du colorant passe progressivement de 0,0006 à 0,02 mol dm^{-3}, l'aggrégation des monomères du colorant et la fixation des ions contraires du chlorure provoquent une chute du coefficient de diffusion binaire du colorant de $0,83 \times 10^{-9}$ à $0,63 \times 10^{-9}$ $m^2 s^{-1}$. On rapporte également les coefficients de diffusion ternaire des solutions aqueuses de chlorure de bleu de méthylène + NaCl. Ces résultats indiquent que l'addition de petites quantités de NaCl (0,005 ou 0,01 mol dm^{-3}) réduisent sensiblement la diffusibilité du colorant, et que la diffusion de chaque mole de colorant entraine celle de 0,2 à 0,7 mole de NaCl. On discute brièvement de la diffusion du colorant à l'état de traces en présence d'un grand excès d'un electrolyte agissant comme support inerte.

[Traduit par la revue]

1. Introduction

Methylene blue (1–13), like many other dyes (14, 15) and biochemicals (16), self-associates in aqueous solutions. The flat methylene blue cations stack like plates to form dimers, trimers, and larger aggregates. In this paper diffusion coefficients are reported for methylene blue chloride in water and in aqueous sodium chloride solutions. The work was undertaken to study the effects of aggregation, added salt, and counterion binding on the diffusion behavior of an ionic dye.

When methylene blue chloride diffuses in pure water, an electric field is generated to speed up the methylene blue aggregates and to slow down the smaller, relatively mobile chloride counterions, thereby preventing charge separation. If a supporting electrolyte such as NaCl is added, the electric field will produce a coupled flow of Na^+ ions at the expense of speeding up the methylene blue cations. As a result, the dye will diffuse more slowly (17, 18) and it will cotransport sodium ions. These features have practical implications for dyeing operations that use baths containing supporting electrolytes.

The aggregation of methylene blue has been the subject of numerous previous investigations. Sedimentation (1–3) and solvent extraction (5–9) techniques, for example, have been used with success to determine the stepwise association constants. Absorption spectroscopy (1, 4, 10, 11), osmometry (4), polarography (12), and electrical conductivity (13) measurements have also been used to study the speciation of the aqueous dye.

2. Experimental

Methylene blue chloride, 3,7-bis[dimethylamino]phenazothionium chloride (Sigma Chemical Co.), was recrystallized from ethanol (1) and dried in a vacuum oven at 80°C. Potentiometric titration against silver nitrate indicated a purity of 98%. Sodium chloride (BDH reagent grade) was dried at 110°C and used without further treatment. Solutions were made up with distilled deionized water in calibrated volumetric flasks.

The intense optical absorbance of the dye and its tendency to adsorb onto glass surfaces would complicate interferometric or diaphragm-cell diffusion measurements. Accordingly, diffusion coefficients were determined by using a simplified Harned conductimetric procedure (19–21). The initial concentration gradients were prepared by injecting electrolyte into the lower ends of columns of solution. The rate of diffusion was followed by measuring changes in electrical conductivity with pairs of small platinum electrodes positioned near the top and bottom of the columns. Plots of the logarithm of the difference between the upper and lower conductivity against time for binary diffusion of the dye (no added NaCl) were linear. This indicated that the dye sample was adequately pure for our experiments (19).

In the ternary diffusion experiments on methylene blue chloride + NaCl solutions, separate experiments were run with initial gradients in the methylene blue chloride component or the NaCl component. Moments analysis (22) of the conductivity versus time data was used to evaluate the ternary diffusion coefficients. The diffusion cells used in the present work had cylindrical diffusion channels (4.57 cm height, 1.27 cm diameter) that were milled from high-density polyethylene or polypropylene and fitted with 0.1 cm diameter electrodes.

3. Results

Methylene blue chloride (1) + water

Diffusion of the methylene blue chloride component transports chloride ions together with dye monomers, dimers, trimers, etc. Conveniently, electroneutrality and local equilibrium of the association reactions ensure that only one solute flow is independent (23, 24). Consequently, diffusion of the dye obeys the simple binary transport equation

$$[1] \quad -J_1 = D_{11}\nabla C_1$$

Here, C_1 stands for the concentration of the methylene blue chloride component in moles of total dye monomer (free plus aggregated monomers) per unit volume and J_1 is the flux density of the dye component in moles of total dye monomer per unit area per unit time.

Values of D_{11}, the binary diffusion coefficient of the dye, were determined at 25.00 ± 0.01°C and mean cell concentrations of dye from 0.00057 to 0.0197 mol dm^{-3}. The measured

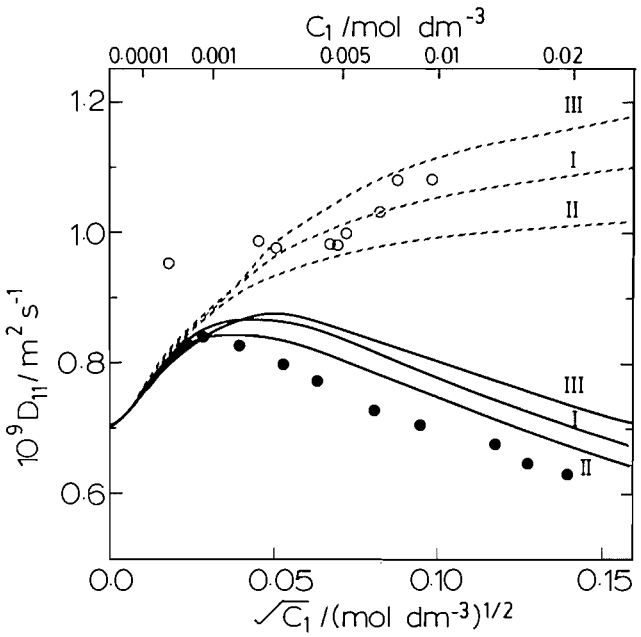

FIG. 1. Measured and predicted binary diffusion coefficients for aqueous dyes at 25°C. Methylene blue chloride: ●, measured D_{11} values; solid curves, predicted D_{11} values with chloride binding constant K_L = 45 dm^3 mol^{-1} and non-attenuated (I), attenuated (II), and isodesmic (III) association constants; dashed curves, predicted D_{11} with counterion binding omitted (K_L = 0). Methyl orange: ○, measured D_{11} values.

values of D_{11} drop from 0.83 × 10^{-9} to 0.63 × 10^{-9} m^2 s^{-1} with increasing concentration. The results of the experiments are summarized in Table 1.

Conductimetric diffusion data were reported recently for aqueous solutions of the sodium salt of methyl orange (25), a self-associating anionic azo dye. In contrast to the methylene blue diffusivities, the D_{11} values for methyl orange increase with concentration. The diffusion data for the two dyes are compared in Fig. 1.

The dye monomers become more extensively associated as the concentration rises. A qualitative analysis of the effect of aggregation on the diffusion behavior can be formulated by treating the dye as an n-univalent electrolyte, where n designates the mean aggregation number, the average number of dye monomers per aggregate. Methylene blue chloride, for example, may be assumed to dissolve as follows: MBCl = $(1/n)(MB)_n^{n+}$(aq) + Cl$^-$(aq). For this type of electrolyte, the mobility, U, and the thermodynamic driving force per mole of MBCl are given by (26)

$$[2] \quad U \cong \frac{1}{RT}\frac{nD_pD_{Cl}}{nD_p + D_{Cl}}$$

$$[3] \quad -\nabla\mu_1 \cong \frac{RT}{C_1}\left(1 + \frac{1}{n}\right)\nabla C_1$$

where D_p is the diffusion coefficient of the polyion that contains n dye monomers, D_{Cl} is the diffusion coefficient of the chloride counterions, and μ_1 is the chemical potential of the dye component. The factor $1 + (1/n)$ appearing in eq. [3] equals the number of moles of free solute particles per mole of dissolved dye. According to Stokes law, D_p should vary with n approximately as $n^{-1/3}$ (27). Therefore, as n increases with concentration, the mobility of the dye component should also increase and approach the mobility of the counterions.

Equations [2] and [3] lead to the following approximate expression for the binary diffusion coefficient (26)

$$[4] \quad D_{11} = C_1 U\frac{\partial\mu_1}{\partial C_1} \cong \frac{(n+1)D_pD_{Cl}}{nD_p + D_{Cl}}$$

which is identical to the expression for the limiting diffusion coefficient of an n-univalent electrolyte. It predicts that D_{11} should increase with n since, for large values of n, the predicted values of D_{11} for methylene blue chloride approach the diffusivity of the chloride counterions, about 2.0 × 10^{-9} m^2 s^{-1} at 25°C (28). The fact that the measured values of D_{11} actually decrease with concentration suggests that the simple model of free counterions diffusing with dye aggregates may require modification in the case of methylene blue. This point will be discussed later.

Methylene blue chloride (1) + NaCl (2) + water

Ternary diffusion in aqueous methylene blue chloride solutions with added NaCl is described by the coupled transport equations

$$[5] \quad -J_1 = D_{11}\nabla C_1 + D_{12}\nabla C_2$$

$$[6] \quad -J_2 = D_{21}\nabla C_1 + D_{22}\nabla C_2$$

where J_1 and J_2 are the molar flux densities of the methylene blue (1) and NaCl (2) components, and C_1 and C_2 are the respective concentrations of the components. Cross-diffusion coefficient D_{21} measures the flux of NaCl produced by the gradient in the concentration of the dye, and vice versa for D_{12}.

The ternary diffusion coefficients were determined in triplicate at the mean cell concentrations 0.002, 0.005, or 0.010 mol dm^{-3} methylene blue chloride and 0.005 or 0.01 mol dm^{-3} NaCl. The measured values of D_{ik} were reproducible within ±0.03 × 10^{-9} m^2 s^{-1}. The results of the ternary experiments are listed in Table 1.

As shown in Fig. 2, added NaCl sharply reduces the dye's diffusivity (D_{11}). The positive values of D_{21} confirm that the gradient in the concentration of the dye produces a significant co-current coupled flow of NaCl. It is evident from the values of the ratio D_{11}/D_{21} that each mole of diffusing dye cotransports 0.2 to 0.7 mol NaCl. The coupled flow of dye produced by the gradient in the concentration of NaCl is relatively small in the solutions that were studied. These and other features of the ternary diffusion behavior can be interpreted by treating the solutes as a simple mixture of $P_{1/n}$Cl + NaCl electrolytes. Extending eq. [4] to solutions with added NaCl gives (21, 30)

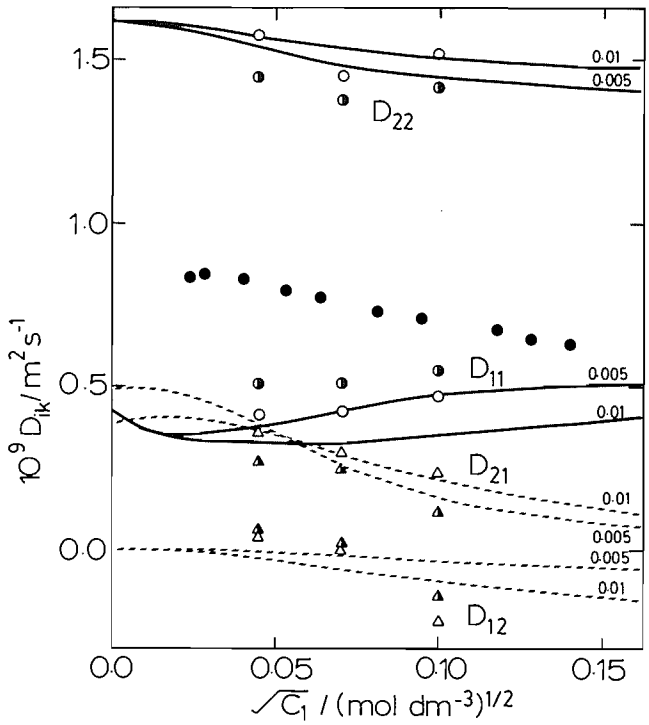

FIG. 2. Measured and predicted ternary diffusion coefficients for aqueous methylene blue chloride (1) + NaCl (2) solutions at 25°C. Measured values: △, ○, in 0.010 mol dm^{-3} NaCl; ▲, ◑, in 0.005 mol dm^{-3} NaCl; ●, binary diffusion coefficient D_{11} for NaCl-free methylene blue chloride solutions. Predicted values calculated with K_L = 45 dm^{-3} mol^{-1} and non-attenuated association constants (set I): solid curves, D_{11} and D_{22}; dashed curves, D_{12} and D_{21}.

[7] $D_{11} \cong D_p + t_p(D_{Cl} - D_p)$

[8] $D_{12} \cong t_p(D_{Cl} - D_{Na})/n^2$

[9] $D_{21} \cong t_{Na}(D_{Cl} - D_p)n^2$

[10] $D_{22} \cong D_{Na} + t_{Na}(D_{Cl} - D_{Na})$

Here t_i stands for the transference number of ion i

[11] $$t_i = c_i z_i^2 D_i \Big/ \sum_{k=1}^{3} c_k z_k^2 D_k$$

and c_i and z_i are the ionic concentrations and charges: $c_p = C_1/n$, $z_p = n$, $c_{Na} = C_2$, $z_{Na} = 1$, $c_{Cl} = C_1 + C_2$, $z_{Cl} = -1$. As the ratio of NaCl to methylene blue chloride increases, the transference number t_p of the methylene blue polyion drops to zero, and the predicted ternary diffusivity of the methylene blue chloride component, D_{11}, drops to D_p. As the NaCl:dye ratio increases, t_{Na} and hence D_{21} also increase.

4. Discussion

Aggregation

A more realistic treatment of diffusion in the methylene blue solutions with allowance for the polydispersity of the dye aggregates will now be attempted. Stepwise association of the dye cations will be described by using the series of reactions

$$MB^+ + (MB)_{i-1}^{(i-1)+} = (MB)_i^{i+}$$

with the association constants

[12] $K_i = c_i/c_1 c_{i-1}$

for the formation of an aggregate of i methylene blue monomers from an aggregate of $i - 1$ monomers. The concentration of the aggregate of i monomers is denoted by c_i.

Given the total dye concentration and values for the association constants (1, 6), the concentration of the free dye monomers, c_1, can be obtained by solving the mass balance equation

[13] $$C_1 = \sum_{i=1}^{\infty} i c_i = c_1 + 2K_2 c_1^2 + 3K_2 K_3 c_1^3 + \ldots$$

The concentrations of the methylene blue polymers can then be evaluated from $c_2 = K_2 c_1^2$, $c_3 = K_3 c_1 c_2$, etc. For the special case of isodesmic association (1, 6, 24), the various stepwise association constants are identical, $K_2 = K_3 = K_4 = \ldots = K$, and $C_1 = c_1/(1 - Kc_1)^2$.

Added NaCl

The diffusion coefficients for the solute components are most easily estimated (31) by first evaluating the Onsager L_{ik} transport coefficients defined by the flow equations

[14] $$-J_i = \sum_{k=1}^{2} L_{im} \nabla \mu_m$$

and then using the identity

[15] $$D_{ik} = \sum_{m=1}^{2} L_{im} \partial \mu_m / \partial C_k$$

Small electrophoretic interactions between the diffusing ions may be neglected for dilute solutions to give (26, 31)

[16] $L_{11} = (c_{Na} D_{Na} + c_{Cl} D_{Cl})A/B$

[17] $L_{12} = L_{21} = -c_{Na} D_{Na} A/B$

[18] $L_{22} = c_{Na} D_{Na}(c_{Cl} D_{Cl} + A)/B$

where A and B are abbreviations for

[19] $$A = \sum_{i=1}^{\infty} i^2 c_i D_i$$

[20] $B = RT(c_{Cl} D_{Cl} + c_{Na} D_{Na} + A)$

The values of $\partial \mu_m/\partial C_k$ required to estimate values of D_{ik} can be obtained by differention of eq. [13] together with the expressions

[21] $\mu_1 = \mu_1^0 + RT \ln [c_1(C_1 + C_2)]$

[22] $\mu_2 = \mu_2^0 + RT \ln [C_2(C_1 + C_2)]$

for the chemical potentials of the solute components.

In Fig. 1 the binary values of D_{11} for methylene blue chloride (no added NaCl) predicted by eqs. [12] and [22] are compared with the measured values. The association constants used in the calculations were taken from the solvent extraction study of Mukerjee and Ghosh (6). Three of their sets of recommended K_i values were used: I, "non-attenuated" association, K_2 = 2090 dm^3 mol^{-1} for the dimerization constant and $K_i (i > 2)$ = 2000 $(i - 1)/(i - 2)$ dm^3 mol^{-1} for the subsequent association constants; II, "attenuated" association, K_2 = 2160 dm^3 mol^{-1} and the slowly decreasing values $K_i (i > 2)$ = 8700/$(i - 1)$ dm^3 mol^{-1}; isodesmic association, $K_i (i > 1)$ = 2500 dm^3 mol^{-1}. The predicted values of D_{11} (dashed curves) and the measured values show poor agreement. The former increase with concentration whereas the latter decrease. The data in Fig. 1 are plotted against the square root of the dye concentration to help visualize the behavior at very low concentrations.

The value of the chloride ion diffusivity used in the calculations, 2.03×10^{-9} m^2 s^{-1}, was estimated from the limiting molar ionic conductance (28) $\Lambda_m^0(Cl^-) = 0.00763$. Although a precise value for the limiting conductance of the methylene blue cation is not known, extrapolation of Robinson's data for methylene blue chloride (13) gives the approximate value 0.0016 ($\pm$0.0002) for $\Lambda_m^0(MB^+)$, and hence $D_1 = 0.43 \times 10^{-9}$ m^2 s^{-1} for the methylene blue monomer. In order to estimate the diffusion coefficient of the dimer, we assumed that the dimer's volume is twice the volume of the monomer. Shape effects were taken into account by assuming that the monomer and dimer were oblate ellipsoids with minor axis:major axis ratios 1:4 and 2:4, respectively. Application of the well-known expression for the friction factor of an ellipsoid (32, 34) gave 0.38×10^{-9} m^2 s^{-1} for the diffusivity of the dimer, D_2. The trimer was assumed to have an axial ratio of 3:4, and so on for the higher polymers. This estimation procedure gave 0.34, 0.31, 0.29, 0.27, 0.25, 0.24, and 0.23 m^2 s^{-1} for $10^9 D_3$ through $10^9 D_9$.

It is conceivable that the large discrepancy between the measured and predicted values of D_{11} shown in Fig. 1 results from the neglect of activity coefficients which allow for departures from ideal solution behavior. However, these terms were thought to be relatively unimportant for the dilute solutions under consideration. As a check, the predicted values of D_{11} were recalculated by including ionic activity coefficients, y_i, estimated from the semi-empirical relation (35) $\ln y_i = -1.17 z_i^2 I^{1/2} (I + I^{1/2})^{-1}$. Significant improvement in the agreement between the measured and predicted values of D_{11} was not obtained. Terms for electrophoresis and changes in the solution viscosity can also be neglected in view of the low concentrations that were used.

Counterion binding

Up to this point in the analysis the simplifying assumption has been made that the chloride counterions do not bind to the stacks of the aggregated methylene blue cations. However, Braswell's sedimentation studies (3) have shown that the aqueous methylene blue chloride component is essentially unionized in solutions containing a large excess of NaCl. In a study of the protonation equilibria of methylene blue, Ghosh (8) was able to estimate the value 2.6 dm^3 mol^{-1} for the association constant for the reaction in which chloride ions pair with methylene blue dimers, $Cl^- + (MB)_2^{2+} = (MB)_2Cl^+$. The tendency of chloride ions to bind to the higher methylene blue polymers, which have larger positive charges, might be stronger.

These pieces of evidence suggest that the neglect of counterion binding might be a poor approximation. To include the chloride ions in the aggregation reactions, suppose that each $(MB)_i^{i+}$ species has i sites for chloride binding. The methylene blue dimers, for example, may then diffuse as the chloride-free $(MB)_2^{2+}$ species or as the $(MB)_2Cl^+$ and $(MB)_2Cl_2$ species. As a first approximation valid for small extents of binding, the various binding sites may be considered identical, regardless of whether the neighbouring sites are occupied. If this assumption holds, the fraction of the total sites that are filled, θ, followed the Langmuir isotherm (32)

$$[23] \quad \theta = K_L c_{Cl}/(1 + K_L c_{Cl})$$

where K_L is the binding equilibrium constant and c_{Cl} is the concentration of free chloride ions. Braswell's sedimentation data for dilute methylene blue chloride in 0.1 mol dm^{-3} NaCl solution indicate that approximately 82% of the chloride ions were bound to the dye cations (3). Substitution of $\theta = 0.82$ and $c_{Cl} = 0.1$ mol dm^{-3} into eq. [23] gives 45 dm^3 mol^{-1} for K_L.

*In mol dm^{-3}.
†In m^3 s^{-1}.

For each aggregate of i methylene blue monomers, $\theta^j(1 - \theta)^{i-j}$ gives the probability that a particular set of j sites will be occupied by chloride ions ($j \leq i$) and the remaining $i - j$ sites will be unoccupied. Since there are $i!/j!(i - j)!$ ways to distribute j chloride ions among the i sites, the concentration of the species consisting of i dye monomers and j chloride ions, c_{ij}, is given by

$$[24] \quad c_{ij} = [i!/j!(i - j)!]\theta^j(1 - \theta)^{i-j} c_i$$

where, as before, c_i is the total concentration of species containing i dye monomers, $c_i = \sum_{j=0}^{i} c_{ij}$. Counterion binding reduces the concentration of the free methylene blue cations, MB^+, from c_1 to c_{10}

$$[25] \quad c_{10} = (1 - \theta)c_1$$

Similarly, the concentration of the free chloride ions drops from $C_1 + C_2$ to the value given by

$$[26] \quad c_{Cl} = (1 - \theta)C_1 + C_2$$

To estimate the effects of counterion binding on the diffusion behavior of methylene blue solutions, the expressions for the L_{ik} transport coefficients were elaborated to include the $(MB)_iCl_j^{(i-j)+}$ species, as shown in the Appendix. Each $(MB)_iCl_j^{(i-j)+}$ species was assumed to have the same diffusivity as the $(MB)_i^{i+}$ species. The values of $\partial\mu_m/\partial C_k$ were obtained by differentiation of the modified expressions

$$[27] \quad \mu_1 = \mu_1^0 + RT \ln [(1 - \theta)C_1((1 - \theta)C_1 + C_2)]$$

$$[28] \quad \mu_2 = \mu_2^0 + RT \ln [C_2((1 - \theta)C_1 + C_2)]$$

In Fig. 1 the recalculated binary diffusion coefficients for methylene blue chloride (solid curves) are compared with the measured values. When the terms for counterion binding are included, the predicted values of D_{11} increase initially then decrease as the concentration is raised. This brings the predicted and measured values of D_{11} into good qualitative agreement. The counterion binding reduces the number of free solute particles per mole of dye, which in turn reduces the driving force and slows the rate of diffusion. For the solutions that were studied, the calculated fraction of bound chloride ions ranged from 0.024 for the most dilute solution to 0.35 for the most concentrated solution.

The remaining small discrepancies between the measured and predicted values of D_{11} shown in Fig. 1 may well be due to the approximations that were made in the model, such as the

assumption of identical ion binding sites and ideal solution behavior. Another likely source of error in the predictions are errors in the estimated values of the diffusivities of the dye aggregates.

In view of the uncertainties in the predicted values of D_{11}, it is not possible to decide here which of Mukerjee and Ghosh's sets of recommended association constants gives the most accurate description of the dye's aggregation. Nevertheless, it may be noted that sets I and II, which they regarded as more reliable than the isodesmic set III, lead to better agreement with the experimental results.

In Fig. 2 the measured D_{ik} values for the solutions with added NaCl are compared with the predicted ternary coefficients. (To emphasize the reduction in the dye's diffusivity caused by the added NaCl, the measured values of D_{11} for the NaCl-free solutions are also plotted (filled circles).) Although qualitative agreement is obtained, it is not as good as the agreement obtained for binary diffusion. The sodium ion diffusivity 1.33×10^{-9} m^2 s^{-1} (28) together with the diffusivities of the chloride ions and the methylene blue species quoted previously were used in the calculations.

Intradiffusion

Hillson and McKay (12) have used a polarographic technique to measure intradiffusion coefficients (36–39) for several dyes in aqueous solutions containing a large excess of KCl and other supporting electrolytes. They found that methylene blue's intradiffusion coefficient, designated here by D^*_{MB}, dropped by 40(±10)% as the total dye concentration was increased from 10^{-5} to 0.003 mol dm^{-3}. Absolute values of D^*_{MB} were not reported.

To test whether the polarographic result is consistent with the model of dye diffusion developed in the present report, values of D^*_{MB} were estimated by weighting the diffusivities of each dye-containing species in proportion to the fraction of the total dye it transports (36–39).

$$[29] \quad D^*_{MB} = \sum_{i=1}^{\infty} \sum_{j=0}^{i} ic_{ij}D_i/C_1 = \sum_{i=1}^{\infty} ic_iD_i/C_1$$

As shown in Fig. 3, the predicted values of D^*_{MB} drop from about 0.42×10^{-9} to 0.31×10^{-9} m^2 s^{-1} in the concentration range from 10^{-5} to 0.003 mol dm^{-3}. This 30% drop agrees reasonably well with the polarographic result.

Also shown in Fig. 3 are intradiffusion coefficients for the chloride counterions calculated according to the expression

$$[30] \quad D^*_{Cl} = \sum_{i=1}^{\infty} \sum_{j=0}^{i} jc_{ij}D_i/C_1$$

As the dye concentration increases, a higher proportion of the chloride ions is attached to the slowly-diffusing dye aggregates which causes a drop in the values of D^*_{Cl}. In order to measure D^*_{Cl} it would be necessary to use solutions containing small amounts of methylene blue chloride and an excess of an inert supporting electrolyte, such as $NaClO_4$.

5. Conclusions

Despite the myriad of different solute species, the simple binary diffusion equation can be used to describe diffusion of methylene blue chloride in water. The concentration dependence of the dye's binary diffusion coefficient can be understood in terms of aggregation of the dye ions and counterion binding. Aggregation and counterion binding tend to respectively increase and decrease the rate of diffusion. As a result, the binary diffusion coefficient of the dye is not sensitive to concentration. On the other hand, small amounts of added NaCl lead to a sharp reduction in the diffusivity of the dye in the ternary solutions.

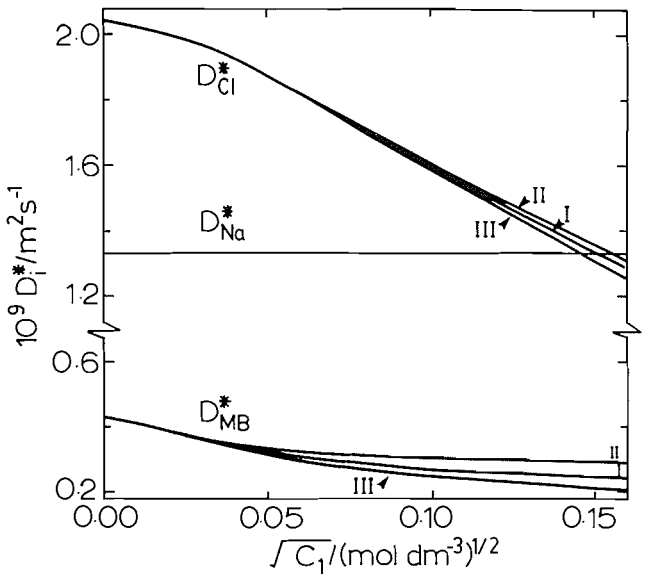

FIG. 3. Calculated tracer diffusion coefficients for aqueous methylene blue and chloride ions at 25°C. Non-attenuated association constants (set I) and $K_L = 45$ dm^3 mol^{-1} were used.

Appendix

Multicomponent transport coefficients for diffusion of incompletely dissociated mixed electrolytes can be estimated by using the identity (31)

$$[A1] \quad \mathbf{L} = (\boldsymbol{\nu}^t(\hat{\boldsymbol{\nu}}\hat{\mathbf{l}}\hat{\boldsymbol{\nu}}^t)^{-1}\boldsymbol{\nu})^{-1}$$

where $\hat{\mathbf{l}}$ is the matrix of Onsager $\hat{l}_{ik}$ transport coefficients for the solute species, $\hat{\boldsymbol{\nu}}$ is the matrix of stoichiometric coefficients $\hat{\nu}_{ik}$ which give the number of moles of constituent ion i per mole of species k, and $\boldsymbol{\nu}$ is the matrix of stoichiometric coefficients ν_{im} which give the number of moles of constituent ion i per mole of electrolyte component m. $\boldsymbol{\nu}^t$ and $\hat{\boldsymbol{\nu}}^t$ denote the transpose of $\boldsymbol{\nu}$ and $\hat{\boldsymbol{\nu}}$. For dilute solutions, it is a good approximation to write $\hat{l}_{ii} = c_i D_i/RT$ and to assume the off-diagonal elements $\hat{l}_{ik}(i \neq k)$ are zero (31).

For the solutions of methylene blue chloride (component 1) + NaCl (component 2), the constituent ions were numbered as follows: 1 = MB^+, 2 = Na^+, 3 = Cl^-. For calculation purposes, the solute species were numbered as follows: 1 = MB^+, 2 = Na^+, 3 = Cl^-, 4 = $(MB)_2^{2+}$, 5 = $(MB)_2Cl^+$, 6 = $(MB)_2Cl_2$, 7 = $(MB)_3^{3+}$, 8 = $(MB)_3Cl^{2+}$, etc., and hence

$$[A2] \quad \boldsymbol{\nu} = \begin{pmatrix} 1 & 0 \\ 0 & 1 \\ 1 & 1 \end{pmatrix}$$

$$[A3] \quad \hat{\boldsymbol{\nu}} = \begin{pmatrix} 1 & 0 & 0 & 2 & 2 & 2 & 3 & 3 & \dots \\ 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & \dots \\ 0 & 0 & 1 & 0 & 1 & 2 & 0 & 1 & \dots \end{pmatrix}$$

In practice, the speciation was truncated at $(MB)^{50+}$. The concentrations of the higher aggregates were negligible.

Methylmercury(II) complexes with tryptophan and its *N*-acetyl derivative

MARIE-CLAUDE CORBEIL AND ANDRÉ L. BEAUCHAMP[1]

Département de chimie, Université de Montréal, C.P. 6128, Succ. A, Montréal (Québec), Canada H3C 3J7

Received January 13, 1988

MARIE-CLAUDE CORBEIL and ANDRÉ L. BEAUCHAMP. Can. J. Chem. **66**, 2458 (1988).

CH_3HgOH reacts with tryptophan in aqueous ethanol to form a 2:1 neutral complex in which CH_3Hg groups are bound to the terminal amino group and to the deprotonated indole nitrogen. When this complex is dissolved in water, ^1H and ^{13}C nuclear magnetic resonance show that the indole CH_3Hg group hydrolyzes, leading to an amino-bound 1:1 species. Under the same conditions, *N*-acetyltryptophan forms a neutral 1:1 compound where the metal is bound to a carboxylate oxygen, and a neutral 2:1 complex in which an extra CH_3Hg group is fixed to the deprotonated indole ring. It is shown by ^1H and ^{13}C nuclear magnetic resonance that the 1:1 species is stable in DMSO-d_6, but that the 2:1 compound is readily hydrolyzed to the 1:1 compound by traces of water. The solid-state infrared and Raman spectra are discussed. In the crystal structure of the 2:1 tryptophan complex, the ligand adopts a conformation favoring a short intramolecular π interaction between Hg and the indole ring. No such π interaction is found in the crystal structure of the 1:1 carboxylate-bonded complex with acetyltryptophan.

MARIE-CLAUDE CORBEIL et ANDRÉ L. BEAUCHAMP. Can. J. Chem. **66**, 2458 (1988).

CH_3HgOH réagit avec le tryptophane dans l'éthanol aqueux pour former un complexe 2:1 neutre, dans lequel les groupes CH_3Hg sont liés à la fonction amino terminale et à l'azote déprotoné de l'indole. Quand ce complexe est dissous dans l'eau, les spectres de résonance magnétique nucléaire ^1H et ^{13}C indiquent que le groupe CH_3Hg lié à l'indole s'hydrolyse pour conduire à un composé 1:1 neutre, où la coordination se fait seulement à la fonction amine. Dans les mêmes conditions, le *N*-acétyltryptophane forme un composé 1:1 neutre où le métal est lié à un oxygène carboxylate, ainsi qu'un composé 2:1 neutre dans lequel le groupe CH_3Hg supplémentaire est fixé au cycle indole déprotoné. On montre par résonance magnétique nucléaire ^1H et ^{13}C que l'espèce 1:1 est stable dans DMSO-d_6, alors que le composé 2:1 s'hydrolyse en espèce 1:1 en présence de traces d'eau. Les spectres infrarouges et Raman des composés solides sont discutés. Dans la structure cristalline du complexe 2:1 du tryptophane, le ligand adopte une conformation qui favorise une interaction π intramoléculaire courte entre le mercure et le cycle indolique. Il n'y a pas d'interaction semblable dans la structure cristalline du complexe 1:1 de l'acétyltryptophane.

Introduction

The reactions of the methylmercury cation with S-containing amino acids have been thoroughly studied (1–5), because the major step in mercury poisoning involves soft sulfhydryl groups in proteins acting as primary targets for the soft mercury species (6). Much less effort has been devoted to sulfur-free amino acids, although the side chains of such residues in proteins may play an important part, for instance, by forming secondary bonds to stabilize the Hg-sulfhydryl complex and shield it from the surroundings, or by providing migration pathways in a detoxification process.

Our recent work with glycine, alanine, and glycylglycine (7, 8) confirmed earlier studies (9, 10) by showing that the methylmercury group remains bonded to the $-NH_2$ end of simple amino acids over a wide pH range. However, no evidence could be obtained from Raman spectroscopy for the presence of mercury-carboxylate species in water solution, even in the case of the $[(CH_3Hg)_2(\text{glycylglycinate})]^+$ ion, which was shown to contain a carboxyl-bonded methylmercury group in the solid state (8).

In a previous paper dealing with serine (11), the methylmercury ion was found not to form a primary bond with the weakly coordinating $-CH_2OH$ side chain. However, X-ray work revealed the presence of an intramolecular Hg...O contact in the NH_2-bonded complex, and this secondary interaction is strong enough to make the same conformation the most abundant one in aqueous solution.

In the present paper, we are reporting on the reactions with the tryptophan residue, whose side chain attracted our attention for two main reasons: (*i*) it contains an aromatic group, and interactions of aromatic units with the coordinated methylmercury group have been previously reported (9, 10, 12, 13); (*ii*) an endocyclic N-H group is also present, and it was of interest to determine the relative affinities of mercury for this potential coordination site and for oxygens. To account for both carboxylate and amide oxygens, we looked at *N*-acetyltryptophan as well.[2]

Experimental

Reagents

DL-Tryptophan (J. T. Baker) and *N*-acetyl-DL-tryptophan (Aldrich) were used without further purification. The source of CH_3Hg^+ ions was the hydroxide CH_3HgOH (1 M aqueous solution from Alfa Inorganics).

Nuclear magnetic resonance spectroscopy

The ^1H and ^{13}C nmr spectra were recorded on a Bruker WH-400 (^1H, 400.13 MHz; ^{13}C, 100.62 MHz) spectrometer at the Laboratoire Régional de RMN Haut Champ, located at the Université de Montréal.

The concentrations of the solutions were in the range 0.01–0.03 M, except for $(CH_3Hg)_2$(DL-Trp), for which the maximum concentration obtained was 0.005 M. The samples were prepared by dissolving the solids in 0.5 or 2.0 mL of either D_2O (Cambridge Isotope Laboratories or Aldrich) or Me_2SO-d_6 (Aldrich). For D_2O solutions, DSS (^1H, δ = 0.00 ppm from TMS) and 1,4-dioxan (^{13}C. δ = 63.4 ppm from TMS) were used as external references. For Me_2SO-d_6 solutions, the residual solvent signal was used as internal reference (^1H, δ = 2.50 ppm from TMS; ^{13}C, δ = 39.6 ppm from TMS).

Raman spectroscopy

The Raman spectra, excited by the 514.5-nm line from a Spectra Physics model 165 argon ion laser, were recorded on a Spex model 1400 microcomputer-controlled spectrometer. The samples were contained in capillary tubes that were mounted on a motor shaft and rotated at high speed in the laser beam. The laser power at the sample was ~200 mW for free tryptophan, and was kept very low for all

other compounds (25–50 mW). For the highly light-sensitive acetyltryptophan complexes, the spectra were recorded using the back scattering Raman technique. All spectra were typically recorded with a 5 cm^{-1} spectral slit width, and a 2 s integration time at each 2 cm^{-1} frequency increment.

Infrared spectroscopy

The infrared spectra were recorded as KBr pellets on a Nicolet 7199 FTIR spectrometer equipped with a HeNe class II laser. The spectral resolution was 1 cm^{-1} and a typical spectrum required 200 scans.

Preparations

In the following procedures, the filtered crystalline solids were dried *in vacuo* at room temperature.

$(CH_3Hg)_2$(DL-Trp)

DL-Tryptophan (1 mmol, 204 mg) was suspended in a mixture of distilled water (15 mL) and 1 M CH_3HgOH (2 mL), and heated until complete dissolution. Ethanol (25 mL) was then added to the solution. After a few days at room temperature in a vented hood, the volume had reduced to ~30 mL and platelets had deposited. Yield: 120 mg (19%). *Anal.* calcd. for $C_{13}H_{16}Hg_2N_2O_2$: C 24.65, H 2.55, Hg 63.33, N 4.42; found: C 24.67, H 2.63, Hg 64.12, N 4.61.

(CH_3Hg)(N-Ace-DL-HTrp)

Acetyl-DL-tryptophan (1 mmol, 246 mg) was dissolved in absolute ethanol (50 mL) and 1 M CH_3HgOH (1 mL). Platelets formed after a few days, in the same conditions as above. Yield: 239 mg (52%). *Anal.* calcd. for $C_{14}H_{16}HgN_2O_3$: C 36.48, H 3.50, Hg 43.52, N 6.08; found: C 36.40, H 3.66, Hg 43.53, N 5.91.

$(CH_3Hg)_2$(N-Ace-DL-Trp)

One millimole of acetyl-DL-tryptophan was dissolved in propanol (25 mL) and 1 M CH_3HgOH (2 mL). Crystals precipitated within a few days. Yield: 304 mg (45%). *Anal.* calcd. for $C_{15}H_{18}Hg_2N_2O_3$: C 26.67, H 2.69, Hg 59.39, N 4.15; found: C 27.06, H 2.76, Hg 60.06, N 4.01.

Crystal structure of (CH_3Hg)(N-Ace-DL-HTrp)

$C_{14}H_{16}HgN_2O_3$ fw = 460.88

Monoclinic, $P2_1/c$, a = 8.330(2), b = 19.324(3), c = 9.380(3) Å, β = 96.76(2)°, V = 1499.4 $Å^3$, Z = 4, D_c = 2.041 g cm^{-3}, $\lambda(MoK\bar{\alpha})$ = 0.71069 Å (graphite monochromator), $\mu(MoK\alpha)$ = 102.6 cm^{-1}, T = 293 K.

A specimen of dimensions (mm) 0.18 (between the 100 and $\bar{1}00$ faces) × 0.19 (010 and $0\bar{1}0$) × 0.66 (001 and $00\bar{1}$) was used for X-ray work. Cell parameter determination and data collection were carried out with an Enraf–Nonius CAD4 diffractometer, as described elsewhere (14). Axial photographs were recorded about the three axes as a check for cell dimensions and Laue symmetry. Seven standard reflections monitored during the experiment showed random fluctuation within ±2.5%. A total of 2036 hkl and $hk\bar{l}$ reflections were measured, within a sphere limited by 2θ = 45°. Space group $P2_1/c$ was uniquely defined from the systematic absences ($0k0$, $k \neq 2n$; $h0l$, $l \neq 2n$). After rejection of the systematic absences, the data set consisted of 1955 independent reflections, of which 1528 were used to solve the structure ($I > 3.0\sigma(I)$). The data were corrected for the Lorentz effect, polarization, and absorption (Gaussian integration, grid 8 × 8 × 8, transmission ranges: 0.15–0.21).

The structure was solved by the heavy-atom method and refined on $|F_o|$. The mercury atom was located from a Patterson map and the non-hydrogen atoms were found from a difference Fourier (ΔF) map phased on Hg. The structure was refined isotropically by full-matrix least squares. Refinement was completed by block-diagonal least squares. All hydrogen atoms (except those of the two methyl groups, which were neglected) were fixed at ideal positions (C—H = 0.95 Å, N—H = 0.87 Å, B_{iso} = 4 $Å^2$). Their parameters were not refined, but their coordinates were recalculated after each least-square cycle. Anisotropic refinement of all non-hydrogen atoms converged to $R = \Sigma||F_o| - |F_c||/\Sigma|F_o| = 0.040$ and $R_w = [\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2]^{1/2} = 0.046$, and a goodness-of-fit ratio of 2.11. The highest residuals on the final ΔF map (±|1.2 − 1.4| e $Å^{-3}$) were around the Hg atom and the general background was below ±0.9 e $Å^{-3}$.

Crystal structural of $(CH_3Hg)_2$(DL-Trp)

$C_{13}H_{16}Hg_2N_2O_2$ fw = 633.47

Triclinic, $P\bar{1}$, a = 5.508(4), b = 9.497(5), c = 14.064(8) Å, α = 77.70(4), β = 87.62(6), γ = 80.83(5)°, V = 709.6 $Å^3$, Z = 2, D_c = 2.965 g cm^{-3}, $\lambda(MoK\bar{\alpha})$ = 0.71069 Å (graphite monochromator), $\mu(MoK\alpha)$ = 216.1 cm^{-1}, T = 143 K.

This compound gave crystals of poor quality. Several crystals were tried and the data from an untwinned specimen of dimensions (mm) 0.04 (010–$0\bar{1}0$) × 0.08 (001–$00\bar{1}$) × 0.68 (100–$\bar{1}00$) were retained. Cell parameters and data collection were done as above. The reduced triclinic cell obtained was checked with oscillation photographs, and the Niggli parameters indicated no symmetry higher than triclinic. The seven standards showed random fluctuation within ±5%. A set of 2500 hkl, $hk\bar{l}$, $h\bar{k}l$, and $h\bar{k}\bar{l}$ reflections ($2\theta \leq 50°$) was collected. A total of 1949 reflections was retained ($I > 3\sigma(I)$) for structure determination. The data were corrected for the Lorentz effect, polarization, and absorption (Gaussian integration, grid 8 × 8 × 8, transmission range: 0.19–0.46).

The structure was solved by the heavy-atom method and anisotropically refined. The final residuals were R = 0.073, R_w = 0.094, goodness-of-fit ratio = 3.39. The poor quality of the crystals is reflected in the rather high residuals. Other crystals from the same or different batches yielded data of comparable quality. Although the esd's on distances and angles are slightly higher than for the other compound, it is clear that the connectivity and the chemically significant features of this structure are reliably defined. The general background in the final ΔF map was ±1.0 e $Å^{-3}$, with a few peaks above background near the Hg atoms.

The scattering curves were from standard sources (15). The f' and f'' contributions of Hg to anomalous dispersion were included in the structure factor calculation (15). The refined coordinates and equivalent isotropic temperature factors are listed in Table 1.[3]

Results and discussion

In the absence of soft thiolate groups, amino acids usually bind the CH_3Hg^+ ion via the $-NH_2$ end. Our X-ray work (see below) shows that tryptophan follows this trend. However, the simple 1:1 complex could not be isolated. The solid precipitating from alcohol-rich water–ethanol mixtures contained an extra CH_3Hg^+ group bound to the deprotonated nitrogen of the indole ring. Even when lower metal:ligand ratios were used to favor the 1:1 (CH_3Hg)(HTrp) compound, the material isolated consisted of the 2:1 $(CH_3Hg)_2$(Trp) complex, sometimes containing unreacted tryptophan. Thus, despite the high pK_a (16.8) (16) of the indole N-H proton, substitution takes place under mild conditions and at low methylmercury concentration in this water-poor medium. Other cases are known of CH_3Hg^+ ions replacing very weakly acidic N-H protons under similar conditions (17).

[1] $2(CH_3Hg)(HTrp) \rightarrow (CH_3Hg)_2(Trp) + H_2Trp$

That a 1:1 complex was not obtained seems to originate mainly in its solubility being greater than those of either the

2:1 complex or free tryptophan, so that the disproportionation reaction [1] is shifted to the right. However, on the basis of the nmr spectra, a 1:1 species results when the 2:1 complex is dissolved in water.

Both ^1H and ^{13}C nmr spectra have been reported for aqueous solutions of tryptophan (18), but the pH used is not known. The solutions were probably acidic, since the authors indicated in the experimental section that "the samples were pD adjusted with DCl". It may be assumed that tryptophan is present as the monocation in these samples. In contrast, our ^1H data listed in Table 2 correspond to D_2O solution whose pD was not adjusted, and the amino acid is present almost exclusively in the zwitterionic neutral form. This explains the small chemical shift differences between our results and those obtained in acidic solutions. Solubility at that pD was too low to obtain the ^{13}C spectrum.

The ^1H and ^{13}C data for the 2:1 complex dissolved in D_2O are given in Tables 2 and 3. Complexation to the NH_2 end is evidenced from the downfield shift (0.76 ppm) of the methine proton, also noted for the serine (11) complex. On the other hand, the ^1H indole signals do not differ significantly from those of free tryptophan. Since greater differences are expected for a mercurated indole unit (see below), it must be concluded that the CH_3Hg^+ group has been displaced by a proton to generate the amino-coordinated 1:1 complex. Thus, in water, formation of the 1:1 complex by hydrolysis (reaction [2]) becomes favorable. Nevertheless, all attempts to isolate the 1:1 species from aqueous solution yielded only a mixture containing free tryptophan, the 2:1 complex, and perhaps a small amount of a 1:1 complex.

[2] $(CH_3Hg)_2Trp + H_2O \rightarrow (CH_3Hg)HTrp + CH_3HgOH$

When the amino end of tryptophan is blocked by an acetyl group, the ligand exists as a normal carboxylic acid. The X-ray work discussed below shows that in the neutral 1:1 complex, the CH_3Hg^+ group has substituted the carboxylic proton and formed a Hg—O bond. By reacting two equivalents of CH_3HgOH per ligand, a 2:1 compound was isolated, which was shown, by infrared and Raman spectroscopy (see below), to be carboxylate and indole coordinated. As these compounds are insoluble in water, the nmr data (Tables 2 and 3) were obtained in DMSO-d_6, where solubility is still low, but acceptable.

Complexation via a carboxylic oxygen in the 1:1 complex is retained in DMSO. The low-field ^1H signal at 12.6 ppm for the carboxylic proton disappears in the complex, whereas the amide proton at 8.15 ppm is shifted to high field by 0.16 ppm. The methine and methylene protons remain virtually unmoved, whereas very small shifts are found for the corresponding ^{13}C signals. The methine and carboxylate ^{13}C resonances, however, have moved downfield by 2 ppm upon complexation. The CH_3Hg^+ signal is found at 0.73 ppm with a coupling constant of 226 Hz with ^{199}Hg, which is consistent with Hg—O coordination (9).

Coordination of the extra CH_3Hg^+ group to the indole ring of acetyltryptophan is detected by the disappearance of the indole N-H signal of the 1:1 complex and free ligand at 10.8 ppm, and by shifts on the ^1H signals for the protons near the complexation site (0.18 ppm on H4). Solubility was too low to obtain the ^{13}C spectrum. Just like the 2:1 tryptophan complex, the indole-bonded CH_3Hg^+ group is readily displaced by hydrolysis: small residual peaks for the 1:1 compound are detected in the baseline as a result of a reaction with the traces of water in DMSO-d_6, unless special care is taken to thoroughly dry the solvent.

Structure of [$(CH_3Hg)_2$(DL-Trp)]

The structure of the 2:1 complex with DL-tryptophan is shown in Fig. 1 with the atom numbering scheme. Selected interatomic distances and bond angles are listed in Table 4.

In addition to coordinating to the amino group as commonly observed with amino acids (1, 7, 10, 11), the CH_3Hg^+ ion is found to bind to the deprotonated N(1) site of the indole ring. The Hg—N and Hg—C distances are normal. Departure from linearity is significant, but small, at the amino-bonded Hg atom (C(13)—Hg(2)—N(2) = 173(1)°). For the other methylmercury group, the coordination is almost perfectly linear (179(1)°), but it does not take place exactly along the ideal direction of the indole nitrogen lone pair, as evidenced from the

difference of 14° between the two Hg(1)—N(1)—C angles. The distances and angles in the ligand (supplementary material) show no unusual features.

The amino-bonded Hg atom makes an intramolecular contact of 2.60(2) Å with the carboxylate oxygen O(1) atom. In this respect, the present complex compares well with those of other amino acids (1, 7, 10, 11). However, the present compound is peculiar in that the methylmercury group sits above the indole ring; more precisely, the methyl group is just above the middle of the six-membered ring, whereas the ring C(1) and C(6) atoms are at ~3.05 Å from Hg(2), and close to the plane through Hg(2) and perpendicular to the N(2)—Hg(2)—C(13) direction (Table 4). It is very likely that some Hg-ring π interaction is taking place, of the type proposed for the complexes of tyrosine (10) and other aromatic ligands (13), in which the methylmercury group is similarly positioned with respect to the phenyl ring.

This π interaction is responsible for the particular conformation adopted by the amino acid in the complex. For free DL-tryptophan in the solid state (19), the amino group is *trans* relative to the indole ring (N(2)—C(10)—C(9)—C(7) torsion angle = 169°), whereas the carboxylate group is *gauche*

Hg(1)—O(1)	2.085(9)	C(14)—Hg(1)—O(1)	178.1(5)
Hg(1)—C(14)	2.07(1)	Hg(1)—O(1)—C(11)	109.9(7)

(C(11)—C(10)—C(9)—C(7) = −68°). In the $(CH_3Hg)_2$(DL-Trp) molecule, these torsion angles have become −70(3)° and 53(3)°, respectively, which corresponds to the carboxylate and amino groups both being *gauche* to the indole ring. Thus complexation induces a 120° rotation about the C(9)—C(10) bond, which makes it possible for a carboxylate oxygen and the aromatic ring to make simultaneous contacts with mercury: these interactions can take place simultaneously only if the amino, carboxylate, and indole units are in the same region of space, as in the observed conformation.

Cohesion in the unit cell is achieved mainly by intermolecular Hg...O contacts and N—H...O hydrogen bonds.

Structure of [(CH_3Hg)(N-Ace-HTrp)]

The complex is represented in Fig. 2. Interatomic distances and bond angles are listed in Table 4.

In this 1:1 compound where the tryptophan NH_2 end has been blocked by an acetyl group, the CH_3Hg^+ ion is bound to a carboxylate oxygen, and the indole unit retains its N-H proton.

The Hg(1)—O(1) distance (2.085(9) Å) is similar to the one observed for the 2:1 glycylglycine complex (8). Mercury shows the usual linear coordination (C(14)—Hg(1)—O(1) = 178.1(5)°). Considering the esd's, the interatomic distances and bond angles in the acetyltryptophan ligand do not differ

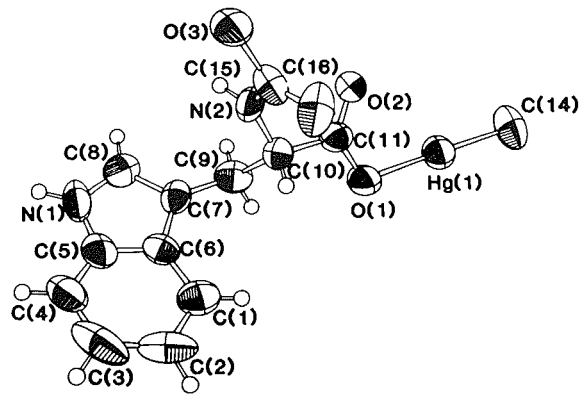

FIG. 2. Structure and numbering scheme for (CH_3Hg)(*N*-Ace-HTrp). Ellipsoids correspond to 50% probability.

significantly from those of its free form (20). However, the torsion angles around the C(10)—C(11) and C(10)—N(2) bonds are changed by ~20°.

Beside normal van der Waals contacts between organic groups, the lattice contains only hydrogen bonds (Fig. 3). Surprisingly, mercury is not involved in intra- or intermolecular Hg---O contacts, as commonly observed for other methylmercury – amino acid structures (1, 2, 7, 10, 11). The mercury cannot participate in a π interaction with the indole ring, as found in the crystal structure of $(CH_3Hg)_2$(DL-Trp), without inducing drastic perturbation in bond angles. The same situation was observed in the crystal structure of the [L-(2-amino-4-phenylbutanoato)]methylmercury(II) complex (10), where mercury is also five bonds away from the aromatic ring. However, in (CH_3Hg)(*N*-Ace-DL-HTrp), the oxygen-bonded mercury is located above the aromatic ring of a neighboring molecule.

Vibrational spectroscopy

H_2Trp and $(CH_3Hg)_2$(Trp)

The infrared and Raman frequencies are provided in Table 5 (supplementary material). Our assignments are based on those proposed by other groups (21–24) and on our previous work on methylmercury complexes with simple amino acids (7, 11).

The infrared spectrum of the $(CH_3Hg)_2$(DL-Trp) complex shows characteristic bands of the methylmercury group: ν(2915 cm^{-1}), δ(1198 cm^{-1}), and ρ(805 cm^{-1}). The ν and δ modes are also Raman active and give intense lines at 2918 and 1198 cm^{-1}, respectively. The vibrations involving the metal (ν Hg—C and ν Hg—N) are weak in infrared, but give rise to the most intense Raman lines. The ν Hg—C mode occurs at 560 cm^{-1}, while ν Hg—N is located at 484 cm^{-1}. These two bands are broader than those observed on the spectra of 1:1 complexes of alanine, glycine, and serine. This indicates that the frequencies of the two distinct CH_3Hg groups are close, but not exactly coincident, as noted by Alex and Savoie (25).

The infrared spectrum of free tryptophan shows a broad absorption, centered around 3000 cm^{-1} and assigned to ν NH_3^+. It is flanked by a sharp peak at 3406 cm^{-1} due to the indole NH stretching mode. This mode is Raman active and gives a strong line at 3350 cm^{-1}. Substitution of this NH proton by methylmercury removes this band from the infrared and Raman spectra. The broad ν NH_3^+ absorption is replaced by bands at 3110 and 3000 cm^{-1} corresponding to ν NH_2 vibrations of the -$NH_2(HgCH_3)$ group. The δ NH_3^+ bands (1665 and 1554 cm^{-1}) are replaced by a single δ NH_2 band at 1598 cm^{-1},

but some intensity remains at $\sim 1530\ cm^{-1}$ because of coincidence with an indole ring vibration. The NH_3^+ group also has two rocking modes normally located between 1260 and $1100\ cm^{-1}$. The first one occurs at $1251\ cm^{-1}$ and disappears by complexation. The second mode probably produces one of the components in the $1166/1135\ cm^{-1}$ pair, the other originating from in-plane bending of the indole N-H group. Although both of these absorptions should be removed in the complex, this spectral region for the complex still shows bands, which are probably due to ω and (or) $\tau\ NH_2$ vibrations. The $\rho\ NH_2$ mode is believed to contribute to the band at $825\ cm^{-1}$, because of its characteristic broad shape. The indole NH group also produces an out-of-plane (γ) deformation mode. According to Lautié and co-workers (22), it occurs as a broad and intense band at $487\ cm^{-1}$ for indole. The infrared spectrum of tryptophan shows two such bands at 529 and $504\ cm^{-1}$. Upon complexation, they are replaced by a narrow peak at $532\ cm^{-1}$. One of these bands can be assigned to γ NH.

As noted for other methylmercury – amino acid complexes, the carboxylate vibrations are not greatly affected by complexation.

N-Ace-DL-H_2Trp and its methylmercury complexes

The spectra of acetyltryptophan and its methylmercury complexes are analyzed by comparison with the above discussion. The ν NH (amide and indole) and ν COOH modes were assigned by Battaglia *et al.* (26). The spectra of the methylamide have also been discussed by Matsuura *et al.* (27). The frequencies and tentative assignments are listed in Table 6 (supplementary material).

Carboxylate protonation and replacement of the NH_3^+ group of tryptophan by an acetyl group introduce changes in the high frequency region. There is a second sharp peak at $3340\ cm^{-1}$ for the amide ν NH band. The carboxylic ν OH mode produces a band at $2980\ cm^{-1}$, considerably narrower than the NH_3^+ absorption, which also occurred in this region for tryptophan.

The ν_a COOH mode appears as a strong doublet at $1722/1711\ cm^{-1}$, whereas the ν_s counterpart is located at $1236\ cm^{-1}$ (26). The very strong band at $1633\ cm^{-1}$ is broad and includes two indole ring vibrations, plus the amide I mode. The amide II and III bands are located at 1551 and probably $1249\ cm^{-1}$, respectively. The amide IV and V bands normally occur below $800\ cm^{-1}$. They are found at 663 and $711\ cm^{-1}$, respectively, for glycylglycine (8), but their frequencies are lower (602 and $684\ cm^{-1}$) for acetylglycine (28). The $682\ cm^{-1}$ band could be assigned to the amide V mode, this band being absent from the spectrum of tryptophan. However, the amide IV mode could not be identified.

The first methylmercury group reacts by substitution of the carboxylic proton, which removes the ν OH band from the spectrum. The ν_a and ν_s COO bands now occur at 1608 and $1381\ cm^{-1}$, respectively. The frequency difference between these two bands is thus reduced, as expected for carboxylate coordination to the metal (29). The observed frequencies are in good agreement with those reported by Battaglia *et al.* for acetyltryptophan chelates of copper (26).

Again, the presence of methylmercury is confirmed by its characteristic infrared (2923, 1191, and $806\ cm^{-1}$) and Raman bands (2934 and $1190\ cm^{-1}$). The Raman spectrum shows a strong ν Hg—C band at $554\ cm^{-1}$. The ν Hg—O band is located at $539\ cm^{-1}$ and coincides with the ρ COO mode, which usually produces a weak Raman line. The ν Hg—O band for the 2:1 glycylglycine complex was observed at $536\ cm^{-1}$ (8).

The spectral features described above for the 1:1 compound are also present for the 2:1 complex. In addition, spectral changes reflecting the deprotonation of the indole NH group are observed. The ν NH band disappears. The γ NH band, located at $565\ cm^{-1}$ in the infrared spectra of acetyltryptophan and its 1:1 complex, is removed from the spectrum of the 2:1 complex. The δ NH mode could not be reliably assigned.

The Raman spectrum of the 2:1 complex shows two sets of ν Hg—C and ν Hg—X (X = O and N) lines. The oxygen-bonded CH_3Hg group produces the ν Hg—C and ν Hg—O bands at 558 and $542\ cm^{-1}$, respectively. The CH_3Hg group bonded to the indole nitrogen atom gives rise to ν Hg—C and ν Hg—N bands located at 553 and $488\ cm^{-1}$, respectively. The frequency of the ν Hg—N band is almost the same as observed for the 2:1 tryptophan complex ($484\ cm^{-1}$).

Conclusion

The methylmercury complex with tryptophan incorporates two structural characteristics generally found for sulfhydryl-free amino acids, namely mercury coordination to the NH_2 end and an intramolecular secondary Hg...O bond with a carboxylate oxygen. The most interesting feature of the complex, however, is the side chain conformation that positions an indole ring C—C bond just above the methylmercury group. The Hg-ring π contact is probably strong enough to make this conformation the most favorable in solution, judging from the relatively deshielded positions of the ^1H and ^{13}C methylmercury nmr signals. Substitution of the indole N-H proton is found to

take place under mild conditions for both tryptophan and its *N*-acetylated derivative. In the latter case, blocking the NH_2 end by an acetyl group displaces the primary binding to a carboxylate oxygen. However, when methylmercury binds at this end, no low-energy conformation can bring the aromatic ring near mercury to produce π interactions.

Acknowledgments

We wish to thank the Natural Sciences and Engineering Research Council of Canada and the Fonds FCAR (Ministère de l'Éducation du Québec) for financial support. We are also grateful to M. J. Olivier who collected the X-ray data, and to S. Alex, M. Pigeon, and M. Savoie, who provided the Raman spectra.

A 6-31G* chemistry of isoelectronic tetrahedral XL_4^{ϵ} and YL_4^{ϵ} (X = Li to F; Y = Na to Cl; L = H, F, Cl) species. Part 2. Energies, bond lengths, and critical radii[1]

S. C. Choi, Russell J. Boyd, and Osvald Knop

Received January 20, 1988

S. C. Choi, Russell J. Boyd, and Osvald Knop. Can. J. Chem. **66**, 2465 (1988).

The 6-31G* *ab initio* treatment of isoelectronic tetrahedral species now covers the complete XL_4^{ϵ} and YL_4^{ϵ} series (X = Li to F; Y = Na to Cl; L = H, F, Cl). The optimized equilibrium molecular parameters comprise the total electronic energy E, bond lengths, critical radii r_c, MO energy levels, net charges, and electron densities at the bond critical points; only the first four are discussed in this part. The stability in terms of E, of the tetrahedral species relative to some competing systems, is examined. The energy requirements associated with the transfer of electronic charge from L to the central atom are reflected in the variation of the critical radii with the oxidation state m of X and Y, with important differences between the first- and the second-row elements. In an appendix it is shown that the $E_{\sim\text{HF limit}}$ energies of isoelectronic He-core (Li^+ ff.), Ne-core (Na^+ ff.), and Ar-core (K^+ ff.) series of ions can be represented analytically by quadratic polynomials in m to an accuracy of ~0.0023% of the $E_{\sim\text{HF limit}}$ range or better, and that these approximations for the three series are *qualitatively* of the type $E = -a(Z - b)^2$.

S. C. Choi, Russell J. Boyd et Osvald Knop. Can. J. Chem. **66**, 2465 (1988).

Le traitement *ab initio* au niveau 6-31G* des espèces tétraédriques isoélectroniques s'étend maintenant aux séries XL_4^{ϵ} et YL_4^{ϵ} (X = Li à F; Y = Na à Cl; L = H, F, Cl). Les paramètres optimisés de l'équilibre moléculaire comprennent : l'énergie électronique totale E, les longueurs de liaison, les rayons critiques r_c, les niveaux d'énergie OM, les charges nettes et les densités électroniques au niveau des points critiques de liaison. La discussion, dans cette étude, ne porte que sur les quatre premiers paramètres. On étudie la stabilité des espèces tétraédriques, en fonction de l'énergie électronique totale E, par rapport à quelques systèmes concurrents. Les énergies nécessaires au transfert de la charge électronique de l'atome L à l'atome central se réflètent dans la variation du rayon critique en fonction de l'état d'oxydation m de X et de Y, avec une différence importante entre les éléments de la première et de la deuxième période. On montre dans un appendice que les énergies $E_{\sim\text{HF limite}}$ des systèmes isolélectroniques suivants : He-squelette (Li^+ ff.), Ne-squelette (Na^+ ff.) et Ar-squelette (K^+ ff.) des ions peuvent être représentées analytiquement par des polynômes quadratiques de degré m avec une précision de l'ordre de ~0,0023% de $E_{\sim\text{HF limite}}$ ou mieux, et que ces approximations dans le cas de ces trois séries sont *qualitativement* de type $E = -a(Z - b)^2$.
[Traduit par la revue]

In Part 1 (1)[2] we dealt with the results of *ab initio* calculations at the 6-31G* level of isoelectronic tetrahedral YF_4^{ϵ} (Y = Na, Mg, S, Cl) and $YF_{4-n}Cl_n^{\epsilon}$ (Y = Al, Si, P; n = 0–4) species. This investigation has now been extended to the entire set XH_4^{ϵ}, $XF_{4-n}Cl_n^{\epsilon}$, $XF_{4-n}H_n^{\epsilon}$, YH_4^{ϵ}, and $YF_{4-n}Cl_n^{\epsilon}$, where X is an element of the first row (Li to F), Y an element of the second row (Na to Cl), and n = 0–4. In the following we compare the results on the homoligand species XL_4^{ϵ} and YL_4^{ϵ} (L = H, F, Cl); results on the mixed species will be communicated in subsequent papers. The notation, abbreviations, and the method of calculation are the same as in Part 1, to which the reader is also referred for a discussion of the validity of the 6-31G* treatment.[3]

Table 1 supplements the electronic energies (au) listed in Table 4 of Part 1 by the $E_{6\text{-}31G^*}$ and $E_{\sim\text{HF limit}}$ values for X = Li to Ne and for a few other ions. The differences for the 6-31G* and ~HF-limit pairs of values are on the average ten times smaller than for Y^{m+}, i.e., the 6-31G* basis set yields much better energies for X^{m+} than for Y^{m+}, as would be expected. Observations on analytic representations of the $E(X^{m+})$ and $E(Y^{m+})$ values are discussed in the appendix.

[3]The only departure from the optimization procedure employed earlier involves FF_4^{3+}, for which attempts to obtain SCF convergence with GAUSSIAN 80 failed. Convergence was achieved with GAUSSIAN 86 (2), but as this program has not yet been interfaced with the AIMPAC set of programs (cf. ref. 1), the molecular parameters of FF_4^{3+} related to the bond critical point (r_c(F), $\rho(r_c)$, ϵ(F), electron-density contours) are not available at present.

[a]For previously presented results on YF_4^{ϵ} (Y = Na to Cl) and YCl_4^{ϵ} (Y = Al, Si, P) see Tables 2 and 3 of ref. 1.

Results and discussion

The values of the molecular parameters for the tetrahedral XL_4^{ϵ} and YL_4^{ϵ} species not reported in Part 1 are listed in Table 2. For a chemist to draw full benefit from these and additional results, their analysis must be reasonably complete and therefore of necessity somewhat lengthy. In order not to lose sight of the main conclusions and to keep our account manageable for the reader, the analysis presented in this paper is confined to the energies, bond lengths, and critical radii, all at the 6-31G* level unless stated otherwise. A sequel will deal with net charges, electron densities at the bond critical points, and electron-density distributions.

The discussion that follows is an extension of that in Part 1, in a similar format. However, some of the conclusions in Part 1 concerning trends in the molecular parameters have to be modified to take account of the much more complete present set of results. The curves in the figures are visual fits unless stated otherwise.

Stability relative to competing species

The sum $E(BeF_3^{-}, D_{3h}) + E(F^{-})$ was discovered to be lower than $E(BeF_4^{2-}, T_d)$. This would point to instability of the T_d ion relative to the two simpler species. However, crystalline salts of BeF_4^{2-} are well known,[4] whereas crystals containing discrete BeF_3^{-} units do not appear to have been reported. Comparisons of $E(T_d$ species) with E(competing system) values are therefore of limited usefulness for predicting the stability of as yet unobserved T_d species under ordinary conditions, except where the difference of the two values is large. In that case a large positive difference, E(competing system) − $E(T_d$ species), would indicate that the tetrahedral species is stable relative to the given alternative; a *large negative* difference would point to instability. Where the difference is negative but small, the tetrahedral species, if ionic, stands a good chance of being stabilized in a crystal by Coulombic energy, and the same would apply to small positive differences, for the sign of the difference is of uncertain significance when the difference is numerically small, especially where fluorine is involved (cf. ref. 1).

Although the stability, in terms of E, of the XL_4^{ϵ} and YL_4^{ϵ}

[4]Discrete BeF_4 tetrahedra occur, for example, in the orthorhombic A_2BeF_4 of the K_2SO_4 (A = Na, K, Rb, Cs, NH_4, Tl) and Al_2BeO_4 (A = Cs, $Li_{1/2}Na_{1/2}$) types, the hexagonal Na_2BeF_4 ($LiKSO_4$ type), the trigonal Li_2BeF_4 (Be_2SiO_4 type), and the orthorhombic $ABeF_4$ (A = Ba, Pb; $BaSO_4$ type).

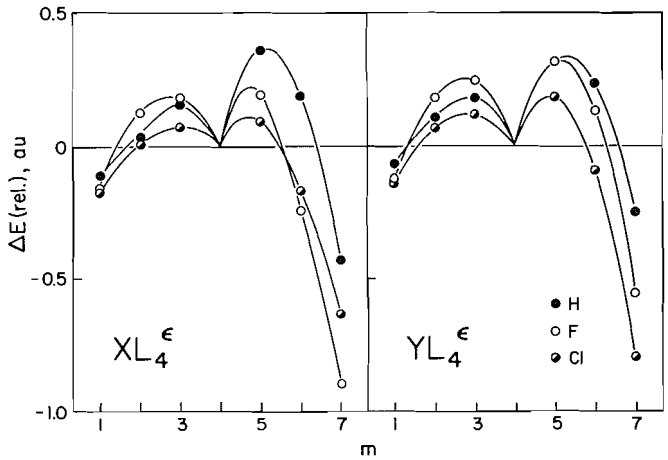

FIG. 1. Stability of the tetrahedral XL_4^{ϵ} and YL_4^{ϵ} species relative to the competing systems $XL_{4-|\epsilon|}^{0} + |\epsilon|L^{\epsilon/|\epsilon|}$ or $YL_{4-|\epsilon|}^{0} + |\epsilon|L^{\epsilon/|\epsilon|}$ (cf. Table 3). ΔE(rel.) = $E(XL_{4-|\epsilon|}^{0}) + |\epsilon|E(L^{\epsilon/|\epsilon|}) - E(XL_4^{\epsilon})$ and similarly for the Y species.

species relative to competing systems was not the subject of this work and has not been investigated systematically, a few dissociative schemes are listed in Table 3. The 6-31G* energies and geometric parameters of the pertinent product species will be found in Table 4. In the particular case of competing systems that involve the lower-coordinated neutral species, $XL_{4-|\epsilon|} + |\epsilon|L^{\epsilon/|\epsilon|}$ and $YL_{4-|\epsilon|} + |\epsilon|L^{\epsilon/|\epsilon|}$, it is found (Fig. 1) that gross instability occurs only with FL_4^{3+} and ClL_4^{3+}. The species OH_4^{2+}, SH_4^{2+}, and SF_4^{2+} might therefore be capable of being stabilized in the presence of suitable counter anions in crystals; for SCl_4^{2+} and OCl_4^{2+} the probability of this happening would seem much smaller (Table 3).

In fact, an account of an investigation of the stability of OH_4^{2+} relative to $H_3O^+ + H^+$ appeared while the present work was in progress (10). From a 6-31G* treatment (as well as from MP2/6-31G**, MP3/6-31G**, and MP4SDTQ/6-31G** refinements) the authors concluded that, although the thermodynamic stability (in terms of E) of the isolated OH_4^{2+} ion is unfavourable, the *kinetic* stability should be substantial. They suggest, from the results of their ^{17}O nmr experiments in $HF:SbF_5$, that OH_4^{2+} under such conditions might be stabilized by solvation. Since Coulombic energy in crystals containing divalent ions would provide at least as much stabilization, the possibility of existence of crystalline OH_4^{2+} salts cannot be dismissed.

Bond lengths

None of the calculated bond lengths is shorter than 1 Å, in agreement with observation. A comparison of the calculated and observed bond lengths can be made with reference to Table 5 and to Tables 1 and 2 of Part 1. Where experimental values are available, they are seen to agree with the calculated values to about 0.02 Å for the neutral and the singly charged species except AlH_4^-; in making these comparisons for the hydrogenic cations one must consider the lengthening effect of hydrogen bonding in crystals. For the higher-charged anionic species the extent of agreement is difficult to estimate, as such species have only been observed in crystals, where the bond length is invariably shorter (in the hydrogenic species especially so). This is the expected consequence of Coulombic compression as well as of the fact that species like LiH_4^{3-} or LiF_4^{3-} in crystals cannot be properly regarded as autonomous ionic units. No examples have been found of the doubly charged cationic species.

The trends reported in Part 1 for the variation with m of the internuclear distances Y—L in YF_4^{ϵ} (Y = Na to Cl) and YCl_4^{ϵ} (Y = Al, Si, P) are present in all six series (Fig. 2). In the XL_4^{ϵ} series the turn upward in the X—L vs. m curve occurs roughly at m = 5, whereas in the YL_4^{ϵ} series the corresponding change occurs at m = 6. The minima of the curves are quite flat and the shapes at large m give the impression of asymptotic

convergence (X,Y)—L → ∞ (or at any rate a large increase in the bond length) as $m \rightarrow 8$.

Assuming, as in Part 1, that the variation of (X,Y)—L with m can be represented as a sum of a bond-shortening (attractive) and a bond-lengthening (repulsive) term, and further that the internuclear distance tends to infinity as $m \rightarrow 8$, the (X,Y)—L distances were fitted to a function $a(m - b)^c + d(8 - m)^e$. The initial estimates of a, b, and c were obtained by fitting the (X,Y)—L values for $m = 1$–3 to a simple power function, and d and e were estimated from a power fit to the differences between (X,Y)—L and the $a(m - b)^c$ values calculated from the initial estimates of a, b, and c. All five parameters were then optimized by iterative least squares (Table 6). The goodness of fit σ ranges from ~0.4% of the observed Y—L range for YF_4^{ϵ} to ~2.4% for YCl_4^{ϵ} and appears adequate for our purposes.

Examination of the m_{eq} values at which $a(m - b)^c = d(8 - m)^e$ reveals that the repulsive interaction sets in later in the three Y series than in the three X series, but $m_{eq} > 7$ in all six series. The positions of m_{min} obtained from the analytic approximations confirm what is observed visually, viz. in the three X series the minimum occurs near $m = 5$, whereas in the three Y series it occurs near $m = 6$, although for YCl_4^{ϵ} the minimum is closer to Y = P than to Y = S.

Critical radii

Going from $m = 1$ to $m = 7$ the oxidation state and the nuclear charge Z of the central atom of XL_4^{ϵ} and YL_4^{ϵ} increase. As a result there is a progressive transfer of electronic charge from L to the central atom, i.e., $L^- \rightarrow L^0 \rightarrow L^+$ as $m \rightarrow 8$. These factors would be expected to decrease the effective size of X and Y as well as of L (as measured by r_c), thus progressively shortening the (X,Y)—L bond, reducing the positive charge on X and Y by $m - \epsilon(X,Y)$ and the negative charge on the ligand atom by $-1 - \epsilon(L)$.

These consequences are in fact observed, but not necessarily over the entire m range (Table 2, Fig. 3). The $r_c(X)$ and $r_c(L)$ vs. m curves for the X series fall from $m = 1$ to a minimum at $m = 3$ (at $m = 4$ for L = F), and the $r_c(Y)$ and $r_c(L)$ vs. m curves for the Y series fall from $m = 1$ to a minimum at $m = 5$ (at $m = 6$ for L = F). Beyond these minima the $r_c(X,Y)$ values increase with increasing m and the $r_c(L)$ values decrease, indicating that eventually enough electronic charge is transferred from L to the

central atom to start increasing the effective size of the latter whilst r_c(L) decreases further. The tendency of the central atom to acquire electronic charge from L increases steadily with m, but $L^- \rightarrow L^0$ and $L^0 \rightarrow L^+$ represent two stages of the charge transfer process from L with different energy requirements: for free atoms the second stage involves an approximately tenfold expenditure of energy over the first. It is therefore not surprising to find that the resulting compromise between the charge acquisition by X and Y and the charge surrender by L is reflected in the r_c vs. m or ϵ(L) curves, even though the course of the variation of r_c with m, ϵ(L), or ϵ(X,Y) cannot be predicted in detail.

Between $m = 1$ and the minimum the r_c(X) and r_c(Y) vs. m curves for L = H and Cl practically coincide and the curves for L = F parallel the respective curves for the hydrides and chlorides. This is also largely true of the r_c(H) and r_c(Cl) vs. m curves in the XL_4^{ϵ} and YL_4^{ϵ} series; the shapes of the corresponding curves for L = F are somewhat different. The increase in r_c(X,Y) for m values to the right of the minima is considerable: by $m = 7$ the r_c(X,Y) values in both the L = H

[a] m_{eq}, the value of m at which $a(m - b)^c = d(8 - m)^e$; m_{min}, the value of m at which the equilibrium distance is a minimum. The above optimized parameter values are believed to correspond to the absolute σ minima, but the possibility that they correspond to local minima close to the global minimum cannot be completely ruled out.

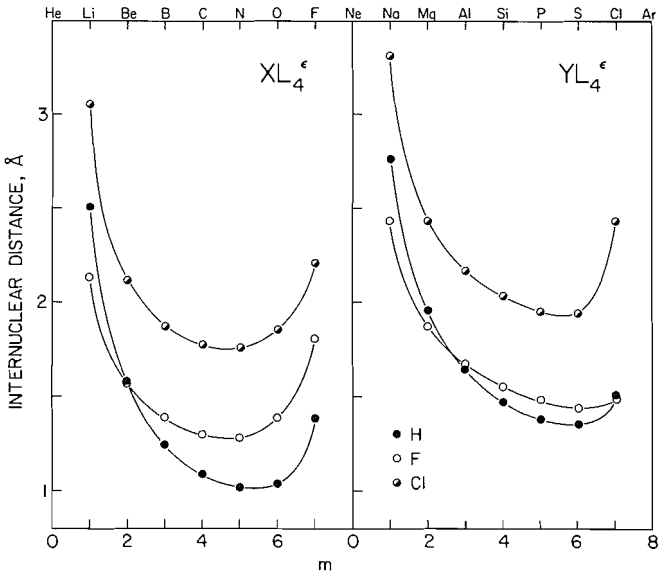

FIG. 2. Variation of the X—L and Y—L bond lengths in XL_4^{ϵ} and YL_4^{ϵ} (L = H, F, Cl) with the oxidation state m of X and Y.

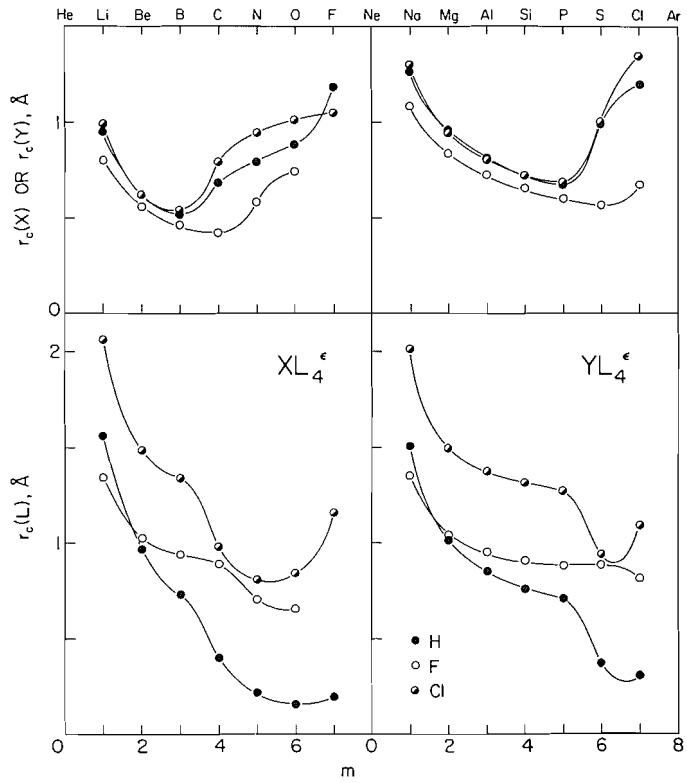

FIG. 3. Variation of the critical radii $r_c(L)$, $r_c(X)$, and $r_c(Y)$ in XL_4^{ϵ} and YL_4^{ϵ} with m.

and Cl series have reached or exceeded the corresponding values for $m = 1$. For L = F the trend is the same, although here the $r_c(X,Y)$ values do not regain, at high m, the values for $m = 1$.

The minima in the $r_c(X,Y)$ vs. m curves correspond to points of inflection in the $r_c(L)$ vs. m curves, and the minimum in the $r_c(H)$ vs. m curve for XH_4^{ϵ} corresponds to a point of inflection in the $r_c(X)$ curve for those hydrides. Such a correspondence might also exist in the curves for the other series, but the cutoff at $m = 7$ does not permit this to be verified. The rise, toward the end of the range, in the $r_c(H)$ and $r_c(Cl)$ values for XH_4^{ϵ}, XCl_4^{ϵ}, and YCl_4^{ϵ} must be considered together with the simultaneous increase in the bond length.

The electronic charge transfer from L to X and Y is more difficult for F than for H and Cl, especially in the YF_4^{ϵ} series; hence the $r_c(X,Y)$ vs. m curves for the fluorides reach their minima at higher values of m than is the case for H and Cl. The progress of the transfer is illustrated more dramatically by plotting the difference $r_c(L) - r_c(X,Y)$ against m or, more informatively, against $\epsilon(L)$ (Fig. 4). In the plot for the Y series in particular the uniformity of the features of these curves is clearly evident. Up to $\epsilon(L) \sim 0$ the r_c difference varies only slightly, i.e., $r_c(Y)$ and $r_c(L)$ for a given m decrease by the same amount (this is not quite true for Li). At $\epsilon(L) \sim 0$, however, further charge transfer from L produces a substantial drop in the value of the difference. This sudden drop, for $m = 6$ in the YH_4^{ϵ} and YCl_4^{ϵ} series and $m = 7$ in the YF_4^{ϵ} series, is caused by a simultaneous decrease in $r_c(L)$ and an increase in $r_c(Y)$, whereas for $m = 7$ the $r_c(Cl = L)$ value increases even though the value of the r_c difference drops.

In the X series (Fig. 4) the $r_c(L) - r_c(X)$ difference varies with $\epsilon(L)$ more gradually; for XH_4^{ϵ} from X = B to F the variation is almost linear. The turn downward occurs at $m = 4$ for L = F and at $m = 3$ for L = Cl, and for both at $\epsilon(L) \sim -0.2$. For X = H the turn at $m = 3$ and $\epsilon(H) \sim -0.2$ is less well

defined. The earlier onset of the charge transfer from L in the X series may be attributed to the lower shielding of the nuclear charge on X.

The relative variation of $r_c(X,Y)$ and $r_c(L)$ is displayed even more clearly when these quantities are plotted against each other (Fig. 5). Implicit in this plot, unlike in Fig. 4, is the length of the (X,Y)—L bond. The $r_c(L)$ vs. $r_c(X,Y)$ curves therefore display an additional feature, viz. the onset of a repulsive interaction responsible for the bond lengthening that is observed toward the end of the m range in all six $(X,Y)L_4^{\epsilon}$ series (Fig. 2). This is best seen in the curves for XCl_4^{ϵ} and XH_4^{ϵ}, each of which contains unmistakably two turning points. The first, at a lower m, is consistent with the turning point of the curve in Fig. 4; the second, at a higher m, corresponds approximately to the minimum of the bond length. Although allowance must be made for the uncertainties of the visual fits of the points in Fig. 5, the *qualitative* similarity of the six curves cannot be denied. Further support for the existence of the repulsive interaction at high m will be presented in Part 3.

Position of the bond critical point

The relative position of the critical point in the Y—L bonds, $r_c(L)/(Y—L)$, in YL_4^{ϵ} varies little with m up to $m = 5$, after which the point moves suddenly toward the ligand nucleus (Fig. 6A). This shift is quite abrupt for L = H and Cl but less pronounced for L = F. The variation observed for XL_4^{ϵ} is similar except that the drop in $r_c(L)/(X—L)$ occurs already after $m = 3$. These trends are consolidated when the relative position of the critical point is plotted against $\epsilon(L)$ (Fig. 6B), in which case the plot resembles closely that of Fig. 4.

The internal consistency of the parameters involved is confirmed in Fig. 7, where the curves representing the visual fits carry more conviction.

Difference between X and Y elements

The variation of $r_c(X)$ with m is significantly different from that of $r_c(Y)$. The $r_c(Y)$ vs. m curves resemble those for $r_c(X)$ vs. m but are stretched along the m axis in such a way that the m_{min} values increase roughly by two units (Fig. 3). The maximum difference between the corresponding $r_c(X)$ and $r_c(Y)$ curves thus falls in the $m = 3$–5 region and reflects the difference in the bonding properties of the elements of the first and the elements of the second row. Figure 8 brings out this

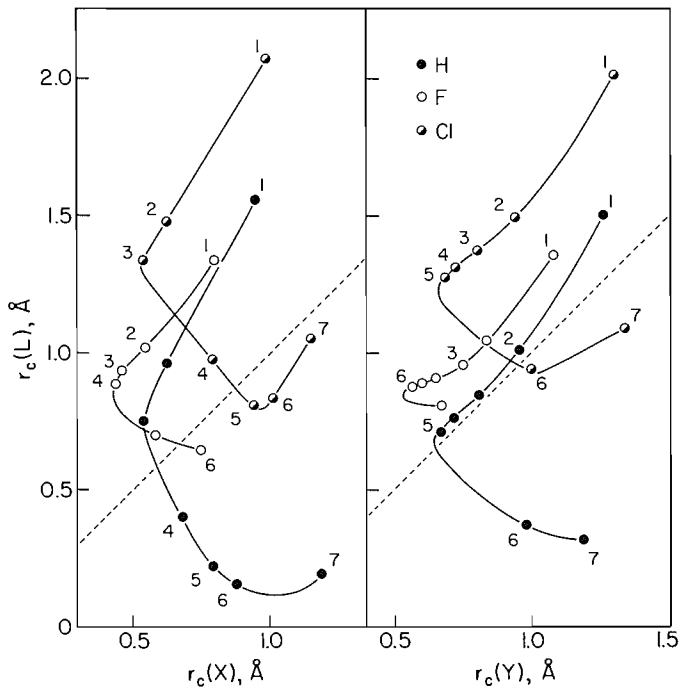

FIG. 5. Variation of the critical radii $r_c(L)$ in XL_4^{ϵ} and YL_4^{ϵ} with $r_c(X,Y)$.

difference more dramatically. In the $r_c(L)^X$ vs. $r_c(L)^Y$ plot the points for $m = 1$–2 and L = H, $m = 1$–4 and L = F, and $m = 1$–3 and L = Cl all lie, perhaps not surprisingly, close to the $r_c(L)^X = r_c(L)^Y$ line. For higher m values, however, there is a significant divergence due to $r_c(L)^X < r_c(L)^Y$; for the chloride series the points are situated on a loop, which for $m = 7$ returns to the 45° line. This behaviour seems to suggest association with a factor that intensifies with increasing m to a maximum and falls off again as $m \rightarrow 8$. The differences $\epsilon(L)^X - \epsilon(L)^Y$ and $[\epsilon(X) - \epsilon(L)^X] - [\epsilon(Y) - \epsilon(L)^Y]$ (i.e., the difference of bond "polarity") both have, qualitatively, this property, although lack of close *numerical* agreement indicates that these quantities alone do not account for the difference between $r_c(L)^X$ and $r_c(L)^Y$ for a given m. The F atoms would thus carry about the

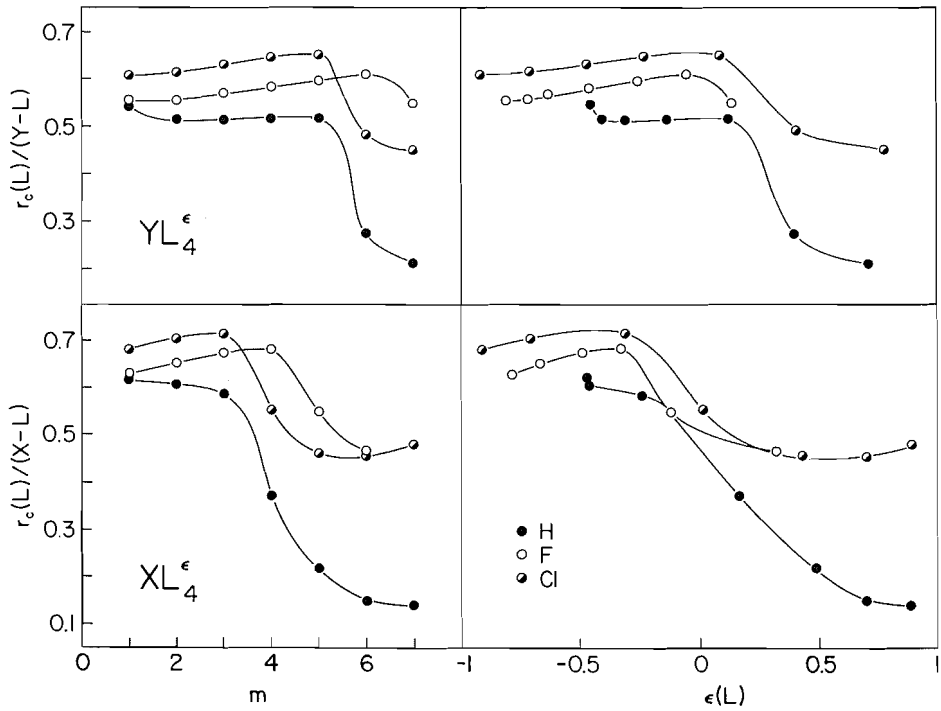

FIG. 6. Variation, with m (A, *left*) and ϵ(L) (B, *right*), of the relative position of the critical point in the X—L and Y—L bonds of XL_4^ϵ and YL_4^ϵ.

same net charge in CF_4 and SiF_4, but the Cl and H atoms in CL_4 would have significantly more electronic charge than in SiL_4, and the difference in the bond polarity between CL_4 and SiL_4 would be much larger for Cl and H than for F.

A somewhat analogous, and even more uniform, behaviour is observed in the plot of $r_c(X)_m$ vs. $r_c(Y)_m$ (Fig. 8). Here, however, $r_c(X)_m$ becomes larger than $r_c(Y)_m$ for $m > 4$. In the fluorides $r_c(Y)_m$ differs from $r_c(X)_m$ by a constant amount of ~0.3 Å up to $m = 4$, after which $r_c(Y)$ decreases only slightly with increasing m but $r_c(X)$ shows a rapid increase. Similar behaviour is observed in the chlorides and hydrides already after $m = 3$.

Critical vs. empirical radii

The $r_c(X^{m+})$ values for X = Li to B in the fluorides are, on the average, 0.054 Å smaller than those for L = H and Cl, and the $r_c(Y^{m+})$ values for Y = Na to P and L = F are 0.070 Å smaller than those for the corresponding hydrides and chlorides. For these m ranges the critical radii of X^{m+} and Y^{m+} in the fluorides correlate very well ($r^2 = 1.00$) with Shannon's effective covalent $r^{iv}(X^{m+})$ and $r^{iv}(Y^{m+})$ radii: $r^{iv}(X^{m+}) = -0.376 + 1.392 r_c(X^{m+})^F$ and $r^{iv}(Y^{m+}) = -0.698 + 1.691 r_c(Y^{m+})^F$. For YCl_4^ϵ and YH_4^ϵ the linear correlation is somewhat less good, while for XH_4^ϵ and XCl_4^ϵ the correlation is nonlinear. Since Shannon's set of effective radii was devised for use with oxides and fluorides (cf. ref. 1), the poorer agreement for L = Cl and H is not unexpected, but the difference between the $r_c(X^{m+},Y^{m+})$ values for L = F and those for L = Cl and H demonstrates the limitations of any quasi-universal additive set of effective radii.

If the sets of $r_c(X^{m+})$ and $r_c(Y^{m+})$ values correlate with Shannon's empirically derived additive set of effective radii only within a limited range of m values, Fig. 3 shows that there is little prospect of arriving at a self-consistent set of effective radii for the ligand atoms L. The critical radius $r_c(L)$ varies with m so widely that it would be meaningless to single out particular $r_c(L)$ values as representative except where L can be regarded

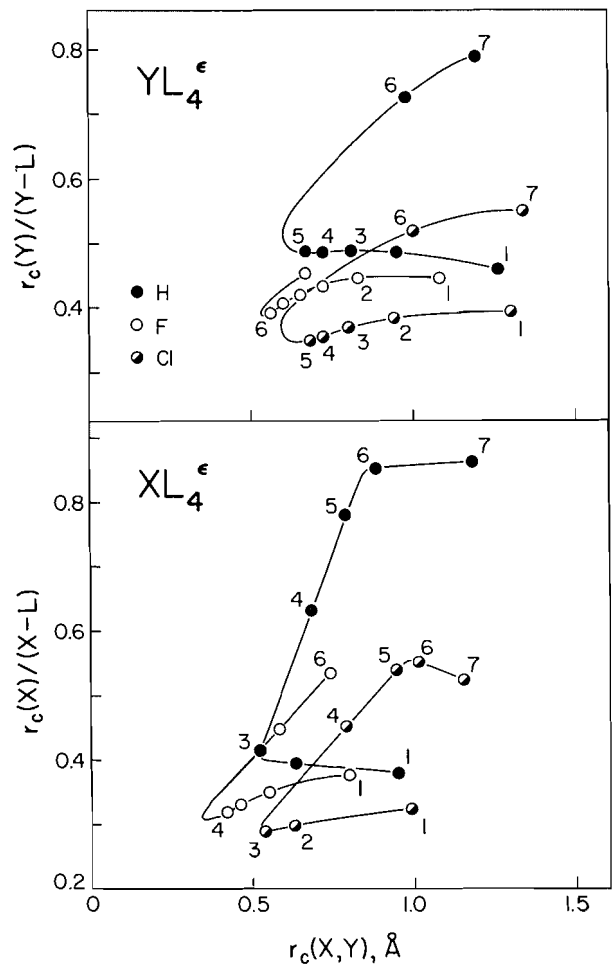

FIG. 7. Variation of the relative position of the bond critical point $r_c(X,Y)/[(X,Y)—L]$ in XL_4^ϵ and YL_4^ϵ with the critical radius $r_c(X,Y)$.

as largely ionic, i.e., for $m = 1$–2. In that case the ratio $r_c(Cl)/r_c(F)$ is ca. 1.48(4), which approaches the values 1.40 and 1.36 for Shannon's covalent and ionic L radii, respectively, in six-coordination.

MO energy levels

In an attempt to discover the reasons for the minima in the bond length vs. m curves we have examined the individual MO energy levels (Figs. 9–11; Tables 7–9).[5] However, if such reasons are implicit in the MO levels, they are not self-evident in the gross features of Figs. 9–11. The steady decrease in energy with increasing m is the consequence of the increasing nuclear charge. For all three L the top occupied level in the YL_4^ϵ series is below that in the XL_4^ϵ series, but as m increases this order is preserved for L = F but reversed for L = H and Cl. Similarly, the lowest a_1 level is higher in the YL_4^ϵ than in the XL_4^ϵ series for L = H and Cl but not for L = F, where $4a_1$ is considerably below $3a_1$ of XF_4^ϵ.

For $m = 1$ the top five bonding levels of the fluorides and

[5]Copies of these tables can be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

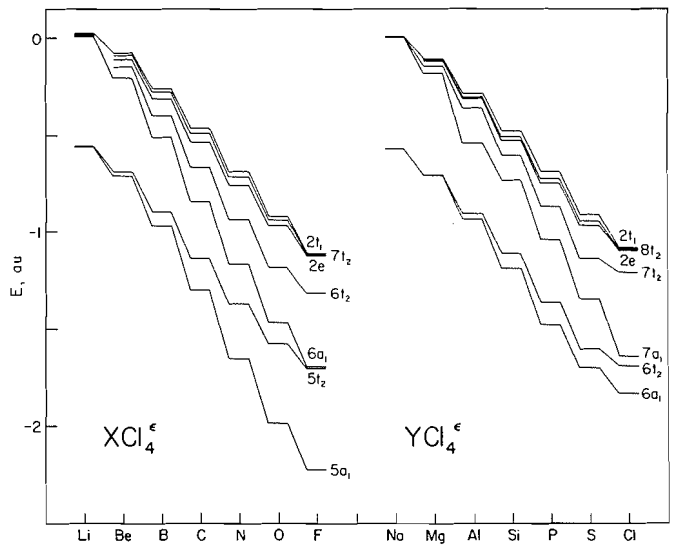

FIG. 11. MO energy levels in XCl_4^ϵ and YCl_4^ϵ (cf. Table 9 for numerical values).

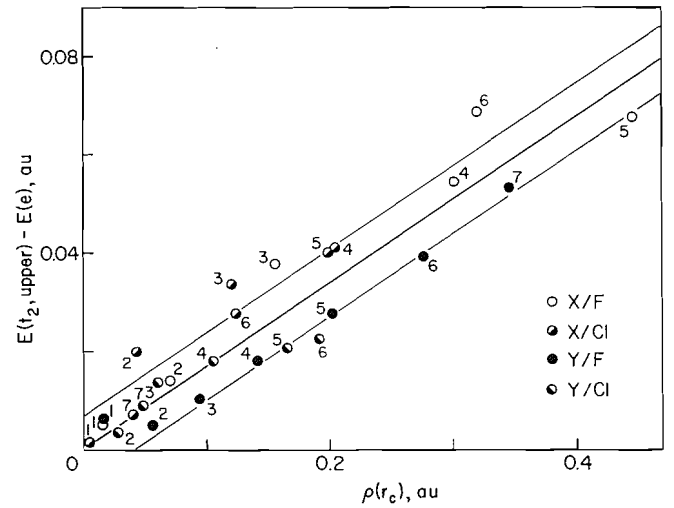

FIG. 12. Correlation of the MO energy difference $E(t_2, \text{upper}) - E(e)$ with the electron density $\rho(r_c)$ at the bond critical point in XF_4^ϵ, XCl_4^ϵ, YF_4^ϵ, and YCl_4^ϵ.

chlorides are very closely spaced. With increasing m their splitting increases but eventually decreases again, with the result that in the fluorides the upper t_2 and t_1 levels are again closely spaced, and in the chlorides the upper t_2, t_1, and e levels tend to coalesce. There is also a crossover of the $4t_2$ and $1t_1$ levels in the XF_4^ϵ series between N and O, and of the $5t_2$ and $1t_1$ in the YF_4^ϵ series between Na and Mg. In the hydrides the splitting of a_1 and t_2 increases steadily with m. The MO diagrams suggest that, in the $m \rightarrow 0$ limit, the bonding-orbital levels would coalesce to a single, 15-fold degenerate level, and for $m \rightarrow 8$ possibly to a 6-fold degenerate level in the fluoride species and an 8-fold degenerate level in the chlorides.

Further, more detailed, analysis would be required to determine how these progressive changes in the energy levels affect the equilibrium bond lengths of the tetrahedral species.

As a preliminary observation we note that the magnitude of the upper $t_2 - e$ splitting appears to correlate (roughly linearly, $r^2 = 0.88$, $\sigma = 0.00715$ au) with the electron density at the bond critical point, $\rho(r_c)$ (Fig. 12).

Conclusions

A complete set of equilibrium molecular geometries optimized at the 6-31G* level is now available for the isoelectronic T_d species XL_4^ϵ and YL_4^ϵ (X = Li to F; Y = Na to Cl; L = H, F, Cl). Analysis of the total electronic energies E, bond lengths, critical radii r_c, and MO energy levels brings to light the following main trends in the six series:

1. In each series the bond length decreases with the increasing formal oxidation state m of the central atom to a local minimum at $m \geq 4$ (Fig. 2). This variation can be approximated quite closely by the sum of a bond-contracting and a repulsive term: (X,Y)—L = $a(m - b)^c + d(8 - m)^e$, where $c, e < 0$.

2. The gross variation of r_c(X,Y) and r_c(L) with m resembles that of (X,Y)—L but the detail is more complex (Fig. 3). The r_c vs. m minimum in a particular series does not occur at the same m for r_c(X,Y) as for r_c(L), i.e., an increase in (X,Y)—L = r_c(X,Y) + r_c(L) with m may be produced by an increased r_c(X,Y) and a *decreased* r_c(L). The r_c values reflect the manner in which the electronic charge is progressively transferred from the ligand to the central atom as m increases.

3. The position r_c(L)/[(X,Y)—L] of the critical point in the bond remains at first relatively constant with m but then shifts suddenly toward L. This shift occurs in the vicinity of the zero net charge, ϵ(L) = 0, on the ligand in the YL_4^ϵ and at ϵ(L) ~ −0.3 in the XL_4^ϵ series (Fig. 6).

4. There are significant differences in the r_c vs. m variation between the first- and the second-row series after $m = 3$ (Fig. 8).

The net charges ϵ(X,Y) and ϵ(L), the electron densities at the bond critical points $\rho(r_c)$, and the geometry of the electron-density contours in XL_4^ϵ and YL_4^ϵ will be discussed in Part 3, in which we also intend to present more complete conclusions from this investigation.

Appendix

Analytic representation of $E(X^{m+})$ *and* $E(Y^{m+})$

While examining the energies of formation $E_f(XL_4^{\epsilon})$ and $E_f(YL_4^{\epsilon})$ we made the following observations, which we think worth reporting.

1. The total electronic energies $E(X^{m+})_{\sim\text{HF limit}}$ and $E(Y^{m+})_{\sim\text{HF limit}}$ $(m = 0\text{–}8)$ can be represented to a high accuracy by simple quadratic functions of m, and so can the $E_{\sim\text{HF limit}}$ of the third-row isoelectronic ions from Ar^0 to Ni^{10+}:

He-core ions, $E_{\sim\text{HF limit}} = -2.861616 - 3.374838m - 1.0000129m^2$, $\sigma = 0.00005$ au $\sim 5 \times 10^{-5}$% of range;

Ne-core ions, $E_{\sim\text{HF limit}} = -128.537413 - 31.141118m - 2.0048218m^2$, $\sigma = 0.00773$ au ~ 0.0023% of range;

Ar-core ions, $E_{\sim\text{HF limit}} = -526.786812 - 69.787000m - 2.4540177m^2$, $\sigma = 0.02019$ au ~ 0.0023% of range.

The listed $E_{\sim\text{HF limit}}$ values for the Ne- and Ar-core ions (3) are somewhat less accurate than those for X^{m+}. It is therefore possible that an improved accuracy of these two sets might result in quadratic expressions of even lower σ values. The accuracy of these simple representations is so high as to suggest that a simple polynomial is the proper functional representation of $E_{\sim\text{HF limit}}$ for such isoelectronic series. Similar representations, of lower accuracy, are obtained for the $E_{6\text{-}31G^*}$ sets.

2. The quadratic representations can be rewritten as $E_{\sim\text{HF limit}} = -a(Z - b)^2 - R$, where Z is the atomic number:

He-core ions, $a = 1.0000129$ au, $b = 0.312603 \sim 5/16$, $R = 0.01417$ au ~ 0.016% of range;

Ne-core ions, $a = 2.0048218$ au, $b = 2.233445$, $R = 7.607809$ au ~ 0.22% of range;

Ar-core ions, $a = 2.4540177$ au, $b = 3.781072$, $R = 30.638634$ au ~ 3.2% of range.

The form of this function suggests that the b term may be regarded as a shielding parameter, and the relative smallness of the R term suggests that the $E_{\sim\text{HF limit}}$ values could be approximated by a two-constant function to an accuracy probably no worse than 1%. Regressing $E_{\sim\text{HF limit}}$ on $-a(Z - b)^2$ and taking a(He-core ions) = 1 and a(Ne-core ions) = 2 gave these results:

He-core ions, $a = 1$ au, $b = 0.311539$, $\sigma = 0.00512$ au ~ 0.006% of range;

Ne-core ions, $a = 2$ au, $b = 2.068103$, $\sigma = 1.58170$ au ~ 0.46% of range;

Ar-core ions, $a = 2.4462$ au, $b = 3.4352$, $\sigma = 5.00$ au ~ 0.53% of range.

The accuracy of these two-constant regressions is considerably poorer than for the unconstrained quadratic fits. However, it is sufficiently good to suggest that the "effective" charge, which for the He-core ions involves a shielding parameter appropriate to the s electrons, in the case of the Ne- and Ar-core ions can similarly, to a first approximation, be expressed as $Z - b$, where b represents an overall shielding parameter due to *all* the *s and p* electrons.

Étude structurale de l'amino-5 dibenzyl-4,4 one-3 2*H*-thiadiazine-1,2,6 dioxyde-1,1

La structure à l'état solide de l'amino-5 dibenzyl-4,4 one-3 2*H*-thiadiazine-1,2,6 dioxyde-1,1 a été déterminée par diffraction des rayons X. La structure montre que la molécule correspond au tautomère amino et qu'il y a disposition en feuillets des cycles aromatiques et hétérocycliques. Le noyau hétérocyclique non conjugué présente ici une structure plane alors qu'il est généralement plié chez les substances homologues. Les résultats obtenus en solution par spectroscopie en résonance magnétique nucléaire ^1H et par mesure du moment dipolaire sont compatibles avec cette géométrie.

PIERRE BROUANT, JACQUES BARBE, PILAR GOYA, and CARMEN OCHOA. Can. J. Chem. **66**, 2477 (1988).

5-Amino-4,4-dibenzyl-3-one-2*H*-1,2,6-thiadiazine-1,1-dioxide was structurally characterized in the solid state by X-ray diffraction. The structure shows that the title compound exists in the solid in a sheet-packed form and as the amino tautomer. The unconjugated heterocyclic ring, which in the structures of related compounds is usually folded, is planar in the present structure. ^1H nuclear magnetic resonance and dipole moment data indicate that the title compound has the same structure in the solid state and in solution.

Introduction

La configuration des hétérocycles thiadiaziniques-1,2,6 a été largement étudiée par radiocristallographie. Leur caractère non aromatique s'accorde avec les structures pliées qui sont décrites dans la littérature (1–8). Pour ce qui concerne plus particulièrement les dérivés de la 2*H*-thiadiazine-1,2,6 dioxyde-1,1, plusieurs activités biologiques différentes ont été mentionnées. Ainsi, on a décrit chez ces substances des propriétés bactéricide (9), antifongique (10–12) et antiparasitaire (12, 13). Cependant, si leur analogie apparente avec les bases pyrimidiniques planes se confirmait sur le plan topographique, ceci permettrait d'orienter les recherches vers l'élaboration et l'élucidation de nouvelles activités biologiques. C'est pourquoi, on a entrepris l'étude structurale de la molécule schématisée sur la figure 1 : l'amino-5 dibenzyl-4,4 one-3 2*H*-thiadiazine-1,2,6 dioxyde-1,1.

Partie expérimentale

1. Radiocristallographie

Les données cristallographiques sont rapportées dans le tableau 1. Le composé, préparé selon le mode opératoire décrit dans la référence 14, a été recristallisé dans le chloroforme. La densité a été mesurée par flottaison dans le mélange toluène – tétrachlorure de carbone. La détermination de la maille et l'enregistrement des intensités diffractées ont été effectués sur un diffractomètre automatique 4 cercles CAD-4 Enraf Nonius à monochromateur de graphite : $\lambda(\text{Mo K}\bar{\alpha}) = 0{,}7107$ Å. Les dimensions de la maille ont été obtenues par moindres carrés à partir des positions angulaires de 25 réflexions. Le groupe spatial a été déterminé par analyse des extinctions systématiques sur clichés de diffraction effectués en chambre en précession avec la radiation Cu Kα.

On a utilisé la technique de balayage θ–2θ. On a réalisé des contrôles d'orientation toutes les 300 mesures et des contrôles d'intensité toutes les 10 000 secondes. La déviation angulaire maximum tolérée a été de 0,12 et les variations d'intensité ont été inférieures à 1%.

Les intensités mesurées n'ont pas été corrigées pour l'absorption. La structure a été déterminée par méthode directe (15) avant d'être précisée par une succession de synthèses de Fourier-différences et de cycles d'affinements par moindres carrés.

Les atomes d'hydrogène, construits géométriquement à l'exception des trois hydrogènes portés par les atomes d'azote qui ont pu être localisés sur les cartes de Fourier-différences, ont été inclus et affinés dans les derniers cycles d'affinement qui ont eu lieu en matrice entière. Tous les atomes ont été affinés avec des coefficients d'agitation thermique anisotropes à l'exception des atomes d'hydrogène affectés d'un facteur d'agitation thermique isotrope. La fonction à minimiser est $\Sigma w(|F_o| - |F_c|)^2$. Le facteur d'accord R et le facteur d'accord pondéré Rw sont donnés par $R = \Sigma||F_o| - |F_c||/\Sigma F_o$ et $Rw = \Sigma\sqrt{w}||F_o| - |F_c||/\Sigma\sqrt{w}F_o$. Dans ces expressions $w = 1{,}6084/\sigma^2(F_o)$. Les facteurs de diffusion atomique proviennent de la référence 16. Tous les calculs ont été effectués sur ordinateur DEC PDP 11/44 sous logiciel SDP (17).

L'enregistrement des intensités diffractées et les calculs ont été réalisés dans le Service de Cristallochimie de l'Université d'Aix-Marseille III.

Le tableau 2 donne les coordonnées atomiques et les tableaux 3, 4 et 5 donnent les distances interatomiques, les angles de valence et de torsion les plus significatifs.[2]

La configuration cristalline est rapportée sur la figure 2.

2. Dipôlemétrie

Le moment dipolaire de l'espèce en solution dans le dioxanne a été mesuré à 10°C, 20°C, 25°C, 30°C, 35°C, 40°C, 45°C et 50°C. Les valeurs de la constante diélectrique et de l'indice de réfraction des solutions ont été extrapolés à dilution infinie selon la méthode de Guggenheim (18) et Smith (19). La pente à la concentration molaire $C = 0$, de la courbe donnant $(\varepsilon_{12} - n_{12}^2) - (\varepsilon_1 - n_1^2)fC$, permet alors le calcul du moment selon la relation :

$$\mu^2 = \frac{9kT}{4\pi N} \cdot \frac{3}{(\varepsilon_1 + 2)(n_1^2 + 2)} \cdot \frac{(\varepsilon_{12} - n_{12}^2)(\varepsilon_1 - n_1^2)}{C}$$

1. Auteur à qui la correspondance doit être adressée.

2. Les tableaux des facteurs thermiques anisotropes, des coordonnées des atomes d'hydrogène et des facteurs de structure calculés et observés sont disponibles. On peut les acheter en s'adressant au Dépôt de données non publiées, ICIST, Conseil national de recherches du Canada, Ottawa (Ontario), Canada K1A 0S2.

Facteur d'accord pondéré, R_w :	0,033
Variation sur erreur maximum, $(\lvert\Delta/\sigma\rvert)_{max}$:	0,027

où K est la constante de Boltzmann, N le nombre d'Avogadro, T la température absolue, ε et n les permittivités et les indices de réfraction du solvant (indice 1) et des solutions (indice 12). Les résultats sont schématisés sur la figure 3.

Les moments dipolaires ont, par ailleurs, été calculés tant par addition vectorielle d'incréments moléculaires et (ou) de liaison que par CNDO/2 (20). Les valeurs suivantes des moments dipolaires furent employées lors des calculs : aniline, 1,53 D; diméthylsulfone, 4,52 D; pyridine, 2,20 D; pyrrole, 1,81 D; toluène, 0,40 D; aziridine, 1,74 D (21); C=O, 2,35 D (22). Tous les calculs ont été effectués sur l'ordinateur MicroVax II du Service Commun d'Infographie de la Faculté de Pharmacie de Marseille.

Les résultats, dans les diverses hypothèses conformationnelles d'énergies précisées dans le tableau 6 et construites selon une géométrie idéale, à l'exception des angles O(11)S(1)O(12) : 115°, C(41)C(4)C(42) : 112°, C(4)C(41)C(411) et C(4)C(42)C(421) : 114°, sont présentés dans le tableau 7.

3. Résonance magnétique nucléaire ^1H

Le spectre du produit en solution dans l'acétone-d_6 a été enregistré à 20°C sur un spectrophotomètre Bruker AM 200.

Discussion

De l'étude par diffraction des rayons X, il ressort que l'hétérocycle est pratiquement plan. En effet, les atomes S(1) et C(4) sont respectivement à 0,085(1) Å et 0,010(4) Å du plan moyen formé par les atomes N(2), C(3), C(6) et N(6) ($\chi^2 = 86$). D'autre part, ces mêmes atomes sont respectivement à 0,040(1) Å et 0,022(4) Å du plan moyen formé par les six atomes du noyau hétérocyclique ($\chi^2 = 2260$). Enfin, S(1) est à 0,089(1) Å d'un plan moyen formé par les atomes N(2), C(3), C(4), C(5) et N(6) ($\chi^2 = 87$). Certes, d'un strict point de vue cristallographique, il ne s'agit pas là de plans véritables; néanmoins, on est ici loin des formes réellement pliées des composés homologues. En effet, les dérivés thiadiaziniques

possédant une ou deux doubles liaisons dans le cycle se présentent tous avec une configuration de type «enveloppe» dans laquelle l'atome de soufre, avec une élévation variant de 0,171 Å à 0,753 Å, est largement hors du plan N(2), C(3), C(4), C(5) et N(6) (1–5). De même, les espèces qui n'ont pas de double liaison intracyclique présentent une configuration de type «bateau», au demeurant plus ou moins applatie selon les substituants portés par les atomes d'azote en positions 2 et 6, dans lesquelles les atomes S et C(4) sont, en moyenne, à 0,46 Å et 0,35 Å du plan N(2), C(3), C(5) et N(6) (6–8). D'autre part, on doit noter que le plan moyen formé par les six atomes du noyau hétérocyclique est un pseudo-plan de symétrie pour toute la molécule. En effet, les substituants benzyles sont disposés

symétriquement de part et d'autre de l'hétérocycle pour former ainsi un triple feuillet avec des angles dièdres de valeur moyenne 56°.

Il convient de souligner que cette configuration symétrique s'accorde avec le spectre rmn ^1H sur lequel on remarque, d'une part, l'équivalence des protons aromatiques (7,23 ppm; 10H) impliquant une conformation identique pour les groupements phényles et, d'autre part, le couplage AB avec une constante J_{gem} = 13,8 Hz pour les protons des deux groupements méthylènes (3,65 ppm, 2H; 3,47 ppm, 2H). Ainsi, les deux protons d'un même groupement méthylène ne sont pas équivalents, ce qui s'explique par un environnement différent, l'un étant soumis au champ de la fonction amine primaire, l'autre à celui de la fonction carbonyle. Ceci ne se conçoit qu'en admettant une conformation moléculaire en phase dissoute qui soit analogue à la configuration observée à l'état solide.

Néanmoins, le tableau 6 donnant l'énergie calculée par CNDO/2 de différentes conformation-limites possibles fait apparaître d'autres minimums que celui correspondant à la configuration décrite dans l'état solide. On a donc calculé par

N(6)—S(1)	0,227

moments mesurés et calculés qui sert à la description structurale de la molécule, ne peut être valablement faite qu'après une étude en température. En effet, les associations soluté–solvant rendent, lorsqu'elles existent, la mesure du moment dipolaire dépendante de la température. Pour éviter alors, de considérer indûment le moment électrique d'une association comme celui du seul soluté, il est nécessaire de mesurer le moment dipolaire de l'espèce en solution à des températures croissantes et ce jusqu'à valeur constante (fig. 3). On peut ainsi extrapoler la valeur expérimentale du moment dipolaire de la molécule étudiée. De plus, à ce propos, on doit, ici, souligner la surévaluation des moments dipolaires calculés par CNDO/2, ce qui a d'ailleurs déjà été observé (4) chez des substances structuralement apparentées.

En revanche, le calcul par CNDO/2 des indices de liaison rassemblés dans le tableau 8 révèle une conjugaison partielle sur les fragments NH_2—C=N et NH—C=O. Il n'y aurait donc pas de conjugaison s'étendant sur l'ensemble de l'hétérocycle comme, d'ailleurs, les valeurs des longueurs de liaison obtenues par radiocristallographie (tableau 3) le laissaient effectivement penser mais contrairement à ce que la planéité du noyau aurait pu laisser croire.

Enfin, toutes les méthodes utilisées, que ce soit la résolution de la structure cristalline—où, en particulier, les deux hydrogènes du groupement amino ont pu être localisés sur les cartes de Fourier-différences—ou encore la comparaison du moment dipolaire expérimental avec les moments calculés pour les différentes fonctions (tableau 7), s'accordent avec l'existence du seul tautomère amine.

Conclusion

Étudiée dans divers états et sous diverses conditions expérimentales, l'amino-5 dibenzyle-4,4 one-3 2*H*-thiadiazine-1,2,6 dioxyde-1,1 montre une structure moléculaire constante, de forme générale globulaire avec un noyau hétérocyclique plan, non conjugué et fonctionnalisé en tant qu'amine. Cette géométrie diffère ainsi notablement des formes pliées antérieurement décrites pour des substances homologues.

Air-stable binuclear alkoxytungsten complexes as catalyst precursors for olefin metathesis

JACQUES SAVARD AND HOWARD ALPER[1]

The Ottawa–Carleton Chemistry Institute, Department of Chemistry, University of Ottawa, Ottawa, Ont., Canada K1N 9B4

Received February 10, 1988

JACQUES SAVARD and HOWARD ALPER. Can. J. Chem. **66**, 2483 (1988).

The use of the air-stable complexes tetrachlorobis(μ-methoxy)bis(methanolo)dimethoxyditungsten (**1**) and tetrachlorobis(μ-ethoxy) tetraethoxyditungsten (**2**) as catalyst precursors for the metathesis of 1-octene is described. Using mild conditions, the latter was converted to 7-tetradecene (**4**) in fair yields when diethylaluminum chloride (**3**) was used as a cocatalyst. Product stereoselectivity was 4/1 in favor of the *trans* isomer. The reaction was also shown to be efficient for the production of 2-nonenes.

JACQUES SAVARD et HOWARD ALPER. Can. J. Chem. **66**, 2483 (1988).

Les tetrachlorobis(μ-methoxy)bis(methanolo)dimethoxyditungsten (**1**) et tetrachlorobis(μ-ethoxy)tetraethoxyditungsten (**2**), des complexes stables à l'air, ont été utilisés comme précurseurs de systèmes catalytiques pour la métathèse de l'octène-1. Ce dernier a ainsi été converti en tetradecène-7 (**4**), sous des conditions douces et avec de bons rendements, en utilisant le chlorure de diéthylaluminium (**3**) comme cocatalyseur. La stéréosélectivité des liaisons doubles est de 4 à 1 en faveur de l'isomère *trans*. La réaction s'est aussi avérée utile pour la préparation des nonènes-2.

Introduction

Olefin metathesis has been extensively investigated in recent years. Although many metal complexes have been examined with respect to metathesis activity, those of molybdenum and tungsten, including tungsten hexachloride and molybdenum pentachloride, have drawn the most attention (1).

The synthesis and chemistry of binuclear complexes containing metal–metal multiple bonds is another subject of considerable interest (2). Those complexes possessing metal–metal double bonds can, in principle, undergo metathesis reactions with olefins (like metal–metal triple bonds with alkynes). Such an approach may generate metal carbene complexes, which are known to readily undergo metathesis with alkenes (1). There are no publications, to our knowledge, of olefin metathesis using metal–metal double bond complexes as catalysts. We now describe the utilization of such a complex, and a related single bonded complex, as catalysts for the metathesis reaction.

A feature common to many known catalysts as well as to complexes containing metal–metal multiple bonds is the high reactivity to both oxygen and moisture. An exception is the double bonded tungsten–tungsten alkoxide dimers **1** which are quite air-stable, as are the W—W single bond species **2** (Fig. 1) (3). Complexes of type **1**, which can be prepared directly from tungsten tetrachloride, readily undergo alcohol exchange reactions, thus providing an entry into several higher homologues (3).

The use of **1** and **2** as catalysts for the metathesis of 1-octene is the subject of this paper. 1-Octene was chosen as the model compound because, if successful, tetradecene would be formed as one of the products: long chain systems, suitably functionalized, are of value in the areas of biophysics, polymers, and pharmaceuticals (e.g. liposomes, vesicles (4), prepolymers, synthons).

Results of discussions

No reaction occurred on exposure of 1-octene to **1** (R = methyl), in benzene at reflux for 24 h. A cocatalyst is therefore required. While tetralkyltin compounds (R_4Sn, R = CH_3, C_2H_5, C_4H_9) and triethylaluminum were inactive, both diethylaluminum chloride **3** and ethylaluminum dichloride induced metathesis of 1-octene by **1**. However, ethylaluminum dichloride was unsuitable for use due to its ability to catalyse Friedel–Crafts reaction of benzene. Consequently, diethylaluminum chloride **3** was the most useful of the cocatalysts which were screened for the metathesis process.

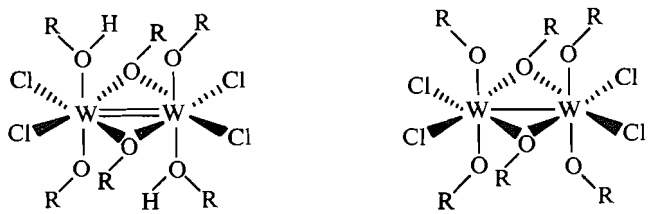

FIG. 1. Structures of **1** and **2**.

The proportion of cocatalyst to catalyst required to induce the formation of an active species is 4/1, in contrast to most cases where it is 1/1 (ref. 1, for analogous systems, see ref. 5). This difference may be a consequence of the presence of two alcohol molecules bound to the binuclear complex as ligands.

Conversion rate

Reacting **1** (R = methyl) in benzene with Et_2AlCl (**3**), followed by the addition of 1-octene, gave a dark brown suspension. The latter induced the conversion of the starting material to metathesis products (24 h at 80°C). Figure 2 shows the effect of temperature and time on conversion. It is also noteworthy that equilibrium is apparently reached within 6 to 7 h even at low temperature (20°C). No significant improvement could be obtained with longer reaction times. 1-Heptene and 1-hexene exhibited similar behavior to 1-octene.

Identical results were obtained when the red complex **2** (R = ethyl) was used instead of **1** (R = methyl) as the catalyst (Table 1), the conversion being 80% although the equilibrium was not reached for 24 h. However, an improvement of the conversion rate was observed when the reaction was run for 120 h at 50°C (56% to 71%). The yield of 7-tetradecene (**4**) did not significantly improve (34% to 42%). After 24 h, one could see lower molecular weight by-products becoming much more important.

Running reactions in boiling benzene while decreasing the

[a]Reactions done in boiling benzene except when mentioned. Other conditions are described in the table. Conversion is defined here as the summation of the yields of all metathesis products. The selectivity is defined as the ratio of the amount of compound to the % conversion. Compounds lighter than 1-octene were not monitored. For **1**: R = Me; **2**: R = Et.

[b]Reactions run without cocatalyst.

[c]Reactions run at 20°C.

[d]Reactions run at 35°C.

[e]Reactions run at 50°C.

[f]Reactions run under nitrogen for the complete reaction time.

[g]Reactions run in pentane.

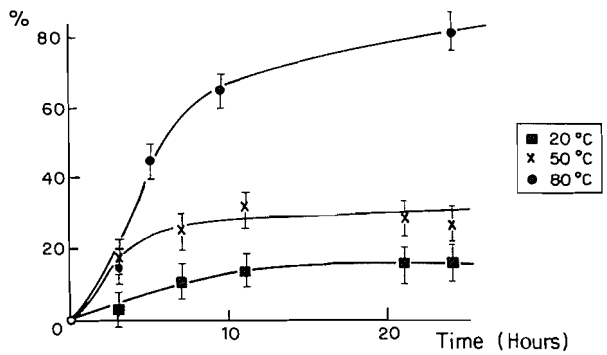

FIG. 2. Conversion rates induced by **1** in benzene as a function of time and temperature.

ratio of catalyst to olefin to 0.6% induced a major drop in the conversion rates (Table 1). Doubling the amount of catalyst provided no further improvement of the conversion rate. However, when the reaction was run at 50°C with 5 mol% the conversion rate increased from 28 to 68%. At this temperature a decrease of the catalyst concentration showed the same deleterious effect on the conversion as was observed in boiling benzene.

Chemoselectivity

A mixture of several octene isomers could undergo cometathesis with 1-octene and produce a complex mixture of lower molecular weight metathesis by-products. The normal metathesis products for 1-octene are 7-tetradecene (**4**) and ethylene. But if 2-octene is also present in the mixture, 6-tridecenes, 2-nonenes, 1-heptene, and propylene could also form. Other isomers of 1-octene could undergo similar pathways to produce a large number of different low molecular weight cometathesis by-products (from C3 to C13). Because very few systems are known to be selective for terminal olefins in long chain metathesis reactions (1), the effect of each parameter on the yields was examined for these lower molecular weight by-products (C9 to C13). It is interesting to note that internal alkenes hardly reacted with the catalyst to undergo metathesis. The use of both *cis*- and *trans*-2-nonene gave only 2% conversion to 7-tetradecene (**4**) using the more severe conditions. So the reaction of internal alkenes formed in the mixture may be regarded as coming from the interaction of the complex formed by a terminal double bond and the catalyst.

The isomerization process for terminal to internal olefins may be induced mainly by the cocatalyst since no isomerization occurs in the absence of any cocatalyst. It was reasoned that an

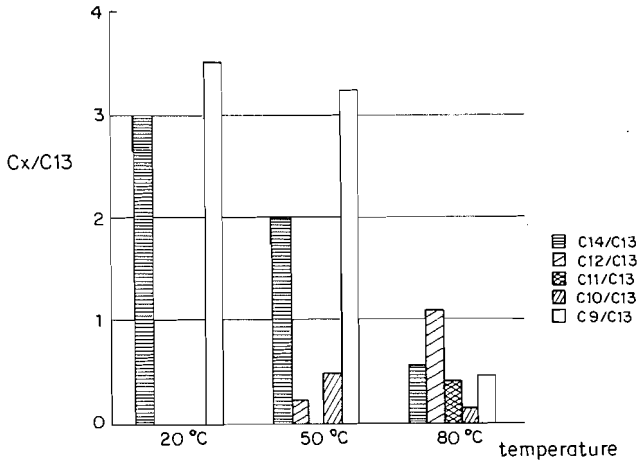

FIG. 3. Distribution of products with temperature after 24 h (from entries #6, 7, 9).

exact ratio of cocatalyst had to be used and that the generation of the active species had to be complete prior to the introduction of the substrate.

For both catalytic systems (**1** and **2**), product selectivity was dependent on the temperature as shown by the results in Fig. 3. Despite the increase in conversion rates at higher temperatures the expected reaction product (C14) is formed in low yields compared with lower molecular weight analogues (C12–C13). With **1** (R = methyl) room temperature reactions proved to be more useful as they provided higher selectivity and easily separable mixtures of 1-octene, 2-nonenes, and 7-tetradecene (**4**) (Fig. 3). For the reactions induced by **2**, 20°C was obviously the temperature of choice since after 24 h, the mixture showed almost exclusively 7-tetradecene **4** along with residual 1-octene.

It is also noteworthy that almost all reactions (including room temperature ones) gave around 25% of 2-nonenes. This corresponds to the coupling of the longer carbon chain of one olefin with the shorter chain of a second isomerized alkene (2-octene). The coupling of two long moieties which should lead to the formation of 6-tridecenes was always lower in yields than the former. This observation is similar to the well described, favored interchanges of methylenes in the degenerative metathesis of terminal olefins (6), such a phenomenon is probably also occurring in the selective production of 2-nonenes and 7-tetradecenes (**4**) under the less severe conditions (see Fig. 3) using the system described herein.

The reaction is sensitive to concentration effects. Using a more dilute solution (3×) of benzene to generate the catalytic system improved the selectivity at the expense of the conversion (2%) while a more concentrated solution (neat) was shown to be impracticable because the poor solubility of the catalyst in octene (0.5 mL) prevented good interaction between **1** and the cocatalyst. The solvent had no influence on either the selectivity or the conversion, as long as it was a non-polar one (benzene, pentane). Any traces of polar solvents (trichloroethylene, acetonitrile) or additives (propyl acetate) totally inhibit reaction.

An induction period was needed to allow the formation of the catalytic species. In this manner, the cocatalyst is transformed to the active species strong interaction with the substrate is thus prevented. Extensive olefin isomerization occurred using **1** (R = methyl) with a short induction period (0 and 5 min). A minimum of 10 min was required to observe a slight increase in the selectivity of the reaction. Similarly, a higher temperature (80°C), while generating the catalyst, increased the amount of isomerization by-products. It also reduced the total conversion of 1-octene and the actual yield of tetradecene. With **2**, the selectivity was best using an induction period of three minutes.

Stereoselectivity

Each reaction product was present as a mixture of *cis* and *trans* isomers, the relative composition of which was not determined except for 7-tetradecene (**4**). The stereochemistry of the double bond in the latter case was approximately 4/1 in favor of the *trans* isomer in all cases. This ratio appeared to be constant from the beginning of the reaction. Isomers of 2-nonenes were formed in equal amounts.

Conclusion

In conclusion complex **2** and, to some extent, **1**, are useful catalyst precursors for the metathesis of 1-octene to tetradecene and ethylene. These processes occur under mild conditions, although the conversion to tetradecene is not high.

Experimental section

1-Octene, purchased from Aldrich Chemical Co., was distilled and stored over molecular sieves. The other alkenes (Wiley Organics) and solutions of Et_2AlCl (**3**) (Aldrich Chemical Co.) were used as received. Tungsten chloride was synthesized according to procedures described elsewhere (7). Benzene was dried, distilled (over benzophenone ketyl), and degassed (nitrogen) prior to use. The analysis of product mixtures was performed on a Varian 3300 Gas Chromatograph equipped with a 4-m DB-1 capillary column (butylbenzene as internal standard).

Synthesis of catalysts

(a) Tetrachlorobis(μ-methoxy)bis(methanolo)dimethoxyditungsten (1)

Although the catalyst can be synthesized from the direct reaction of cooled methanol and WCl_4 a two-step procedure involving alcohol exchange was used because **1** was more readily isolated in high yield and purity (3, 8). Ethanol was reacted in the cold with WCl_4 and the dark green solid obtained by filtration under nitrogen was recrystallized from chloroform/ethanol (37%). The pure ethoxy complex was then refluxed in degassed methanol from which the light green compound **1** precipitated (57%). It was dried under vacuum for several hours and then stored under nitrogen.

(b) Tetrachlorobis(μ-ethoxy)tetraethoxyditungsten (2)

The precursor of **1** can be easily oxidized to the red complex **2** by simply bubbling O_2 through a room temperature solution of **1** (R = ethyl) in ethanol at room temperature. This complex was also prepared by the use of a mild oxidizing agent (3).

General procedure

The catalytic system was generated under a nitrogen stream at room temperature by adding four equivalents of Et_2AlCl (1.8 *M* solution in toluene) to a benzene suspension (3–4 mL) of either **1** or **2** (0.1 mmol). The mixture was then stirred at the desired temperatures for 10 min (except otherwise noted). The degassed alkene (≈0.5 g containing the internal standard and 0.5 mL of solvent) was then introduced with a syringe and the flask was placed in an oil bath preheated to the reaction temperature (or at room temperature). The nitrogen flow was turned off after several minutes to avoid loss of materials. Acetone (10 mL) was added, the solution was filtered, dried ($MgSO_4$), and the filtrate was analyzed by gas chromatography.

Received February 9, 1988

KEITH VAUGHAN, HARTFORD W. MANNING, MARCUS P. MERRIN, and DONALD L. HOOPER. Can. J. Chem. **66**, 2487 (1988).

Reaction of 3-acetoxymethyl-1-aryl-3-methyltriazenes with sodium thiophenolate or thiocresolate in anhydrous dimethylformamide affords a new series of 3-arylthiomethyltriazenes (**2**), Ar-S-CH_2-NMe-N=N-Ar′. These triazenes are remarkably labile in aqueous buffer and may be good pro-drugs for the active metabolite of the antitumour dimethyltriazenes. The reaction of arenediazonium fluoroborates with 1,3-thiazolidine in aqueous acetone affords a new series of *N*-arylazo-1,3-thiazolidines (**4**); the arylazothiazolidines represent a new class of triazene in which the N3 nitrogen is incorporated into a heterocyclic unit, in this case a 1,3-thiazolidine. Nuclear magnetic resonance spectra of the arylazothiazolidines show evidence for rotational isomerism of the exocyclic N2—N3 bond in the triazene moiety.

KEITH VAUGHAN, HARTFORD W. MANNING, MARCUS P. MERRIN et DONALD L. HOOPER. Can. J. Chem. **66**, 2487 (1988).

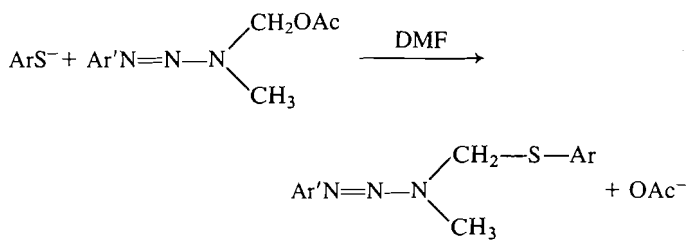
La réaction des acétoxyméthyl-3 aryl-1 méthyl-3 triazènes avec le thiophénolate ou le thiocrésolate de sodium, dans le diméthylformamide anhydre, fournit une nouvelle série d'arylthiométhyl-3 triazènes (**2**), Ar-S-CH_2-NMe-N=N-Ar′. Dans des tampons aqueux, ces triazènes sont remarquablement labiles et, pour cette raison, ils peuvent être de bons précurseurs de drogues pour le métabolite actif des diméthyltriazènes antitumoraux. La réaction des fluoroborates d'arènediazonium avec la thiazolidine-1,3, dans de l'acétone aqueuse, fournit une nouvelle série de *N*-arylazothiazolidines-1,3 (**4**); les arylazothiazolidines correspondent à une nouvelle classe de triazène dans laquelle l'azote N3 est incorporé dans un hétérocycle; dans ce cas, il s'agit d'une thiazolidine-1,3. Les spectres en résonance magnétique nucléaire des arylazothiazolidines suggèrent l'existence d'une isomérie de rotation autour de la liaison exocyclique N2—N3 de la portion triazène.

[Traduit par la revue]

1-Aryl-3,3-dimethyltriazenes (**1***a*) are an important class of antitumour agents (1), which have been shown to undergo metabolic activation to the short-lived 3-hydroxymethyltriazene (**1***b*) (2). Because of the inherent instability of hydroxymethyltriazenes under physiological conditions (they lose formaldehyde rapidly in aqueous buffer), it has been suggested (3) that a stable derivative of the hydroxymethyltriazene might be a suitable pro-drug for the active metabolite of the dimethyltriazene, the monomethyltriazene (Ar-N=N-NHMe) formed by loss of formaldehyde from **1***b*. To this end several derivatives of **1***b* have been reported and do indeed have antitumour activity in animal models. Examples of such derivatives are the chemically reactive 3-acetoxymethyltriazenes (**1***c*; "acetates") and the relatively inert 3-methoxymethyltriazenes (**1***d*) (4).

Previous attempts to synthesize 3,3-dialkyltriazenes with an α-situated sulfur functionality in one of the alkyl groups have met with mixed success. Hemens and Vaughan (5) have found that the acetoxymethyltriazenes (**1***c*) reacted smoothly with methanol to give the methoxymethyltriazenes (**1***d*) but not at all with a pure thiol; the lack of reactivity of the thiol was accounted for by the poor ionizing ability of the thiol as solvent. More recently, Iley *et al.* (6) discovered that the hydroxymethyltriazene (**1***b*) can be converted directly to the methyl ether (**1***d*) by reaction in methanol with an acid catalyst; surprisingly, the acid treatment leaves the triazene unit unaffected and furthermore can be applied to catalyze the reaction of **1***b* with an alkane thiol to give the first reported example of an alkanethiomethyltriazene (**1***e*).

In this paper, we report a different approach to the synthesis of α-sulfur containing alkyltriazenes; the method is specific for *S*-aryl, rather than *S*-alkyl thioethers. In our method, the hydroxymethyltriazene (**1***b*) is first converted to the acetate (**1***c*), which is then reacted with the sodium thiophenolate in anhydrous dimethylformamide:



2

This reaction affords good yields of the 3-arylthiomethyltriazenes (**2**).

Identification of the new 3-arylthiomethyltriazenes is based on ir and nmr spectroscopic analysis, molecular weight determination by mass spectrometry, and elemental analysis of representative compounds (Table 1). The ir spectra show the expected absorption bands of the aryl substituent (X) and the absence of absorption from OH or acetate-carbonyl groups. The ^{1}H nmr spectra of **2** show the overlapping patterns of two aromatic nuclei in addition to N-Me resonance at δ 3.22–3.27, Ar-S-CH_2 resonance at δ 5.16–5.24, and the anticipated resonance from protons (when present) in the X and Y substituents.

We were initially perplexed at the relatively low-field

resonance of the S-CH_2 protons in **2**, which occurs at almost exactly the same chemical shift as the methylene protons of the hydroxymethyltriazene (**1***b*) (7); an upfield shift might have been anticipated when replacing -OH by -SPh. However, in comparison with the nmr data of the 3-alkanethiomethyltriazenes (**1***e*) (6) the shift looks reasonable, since the CH_2 resonance in the *S*-alkyl compounds occurs at ca. δ 4.95. Additive chemical shift parameters for methylene protons (8) predict a downfield shift of 0.29 ppm for CH_2SAr compared to CH_2SR, consistent with our observations of compounds of type **2**.

The new 3-arylthiomethyltriazenes are, with one exception (**2***i*), crystalline solids. An important consideration for the possible pro-drug use of these new triazenes is their stability in buffer solution and their consequent facility to release a cytotoxic species in the cell. Other α-substituted triazenes show quite marked differences in stability in aqueous buffer, the facility for hydrolysis being influenced by the leaving group capacity of Z. Thus the methyl ethers (**1***d*), where Z is a poor leaving group, show no tendency to hydrolyse in buffer and are consequently not cytotoxic in vitro (3). In contrast, the acetates (**1***c*) possess a good leaving group (acetate ion), they hydrolyse rapidly in aqueous buffer, and are cytotoxic to tumour cells in vitro (3). It is intriguing to note that the 3-alkanethiomethyltriazenes (**1***e*) are stable in aqueous buffer, showing no apparent hydrolysis over a 24-h period.[3] Apparently the *O*-alkyl and *S*-alkyl groups, of **1***d* and **1***e* respectively, are similarly inert as leaving groups, within the 24-h time period studied.

In contrast, the 3-arylthiomethyltriazenes described here are remarkably labile in aqueous buffer (pH 7.2, 0.05 M phosphate), with half-lives, measured by following uv spectral decay, in the range 4–16 min. The comparison of stability of the *S*-alkyl and *S*-aryl compounds is quite striking and must reflect the enhanced leaving group ability of ArS^- over RS^-. The facility of hydrolysis of compounds of type **2** suggests that they may indeed be potential pro-drugs for the cytotoxic monomethyltriazene and the results of in vivo antitumour tests with representative compounds of this series are presented in Table 2. Compounds **2***a* and **2***f* were tested against the ADJ/PC6 solid tumour (3) and do indeed show activity comparable with other α-substituted alkyltriazenes (3). However, although comparable percent inhibition of tumour growth was achieved, much higher doses of the triazenes **2***a* and **2***f* were required to achieve the same percent inhibition as with compounds of type **1***c* (see Table 2). Thus the therapeutic index of compounds of type **2** is not as high as that of other triazenes tested by us.

The preparation of these 3-arylthiomethyltriazenes represents a further illustration of the usefulness of the acetoxymethyltriazenes (**1***c*) as synthetic intermediates for α-substituted triazenes. In previous studies we have shown that the acetates react with methanol to give the methyl ethers (**1***d*) (4) and with azide ion in aqueous acetone to afford the 3-azidomethyltriazenes (**1***f*) (10). Whereas reaction of the acetate with the pure thiol

(RSH) failed to produce any alkanethiomethyltriazene (**1***e*) (5), we have now shown that conversion of the acetate to the thioether can be achieved by reaction with the stronger nucleophile, $Ar\text{-}S^-$. The requirement for the strong nucleophile and the polar aprotic solvent suggests that the conversion **1***c* → **2** may be an S_N2 process, but further work needs to be carried out with these nucleophiles to establish the mechanism clearly.

A heterocyclic analogue of the 3-hydroxymethyltriazene (**1***b*) is the arylazooxazolidine (**3**), in which the α-situated oxygen

is incorporated into the five-membered heterocyclic ring. In a previous report (11), we described the synthesis of the 3-arylazo-1,3-oxazolidines (**3**) by diazonium coupling with 1,3-oxazolidine (**5**). The oxazolidine was generated *in situ* from 2-ethanolamine and formaldehyde and coupled directly with the diazonium salt (eq. (*i*)). *In situ* generation of **5** was used because of the tendency of oxazolidines without an *N* substituent to polymerize (12). In the work described here, we sought to extend this approach to the sulfur analogues, the 3-arylazo-1,3-thiazolidines (**4**), which are the heterocyclic analogues of the 3-alkanethiomethyltriazenes (**1***e*).

Unlike oxazolidine (**5**), the 1,3-thiazolidine (**6**) is not readily polymerized and is commercially available (Aldrich 14969-1). However, the commercial product is more expensive by a factor of three, compared to its precursor, 2-aminoethanethiol. We therefore attempted the synthesis of compounds of type **2** by diazonium coupling with 1,3-thiazolidine (**6**) generated *in situ* in an aqueous medium from 2-amino ethanethiol and formaldehyde (eq. (*ii*)), as described in Method "A" in the experimental. This reaction did indeed afford the 3-arylazo-1,3-thiazolidines in low yield, but the products were not pure and did not respond well to conventional purification procedures. A low yield of a pure sample of the 3-(*p*-nitrophenylazo)-1,3-thiazolidine (**4***b*) was obtained by Method A, which also gave a moderate yield of the *p*-bromo analogue. However, recrystallization of the latter product failed to produce a sample with a sharp melting point. Thus, although the *in situ* thiazolidine method does give the expected products, the method does not show much promise for general synthetic application.

An alternative method in which the diazonium salt was coupled in aqueous solution with commercial thiazolidine was less successful. The initial products of these reactions were bright yellow solids but they proved to be unstable and were found to decompose to intractable tars within hours of preparation. The identity of the initially formed yellow solids has not been established.

A successful method (Method B) for the preparation of the 3-arylazo-1,3-thiazolidines (**4**) was developed using the diazonium salt as the fluoroborate, which was reacted with 1,3-thiazolidine in aqueous acetone. The solid products of these reactions required repeated crystallization and (or) column chromatography to achieve analytical purity, but the final products are apparently stable. Yields and physical data are given in Table 3; the yields of arylazothiazolidines are of the same order as those of the arylazooxazolidines previously reported (11). Analytical data for representative compounds are given in Table 4 and spectroscopic data in Tables 5 and 6.

The infrared spectra of the arylazo-1,3-thiazolidines show predictably no functional group distinguishing features other than those expected to arise from the Y substituent in the aryl moiety. However the nmr spectra are very diagnostic. The ^1H nmr spectra (Table 5) show aromatic AA′BB′ patterns and a 2 proton singlet at ca. 4.8 ppm arising from the methylene protons at C2. The other methylene protons attached to C4 and C5 give rise to triplets at ca. 4.1 ppm and ca. 3.1 ppm respectively; the assignments are based on the assumption that the chemical shift of the $N\text{-}CH_2$ protons at C4 will be shifted to lower field than those at C5, and on a comparison of the ^1H nmr spectrum with that of thiazolidine itself (H-2, 4.09; H-4, 3.11, and H-5, 2.79 ppm). All the thiazolidine ring protons in **4** are shifted downfield compared to the analogous protons in thiazolidine itself.

A significant feature of the ^1H nmr spectrum of the *p*-nitro derivative (**4***b*) is the extensive broadening of the signals of the C2 and C4 methylene protons, both of which are attached to nitrogen. The most logical explanation of this phenomenon is

the restricted rotation around the N2—N3 bond in the triazene unit, i.e., **4***b*′ ⇌ **4***b*″; hindered rotation of this sort is well known for other 1-aryl-3,3-dialkyltriazenes (13). Further evidence for this hindered rotation is seen in the ^{13}C nmr spectra of the *p*-nitrophenylazo-1,3-thiazolidine (**4***b*) and the *p*-chloro analogue (**4***d*) (Table 6). In the spectrum of the *p*-chloro derivative, the signals of the carbon atoms at C2 and C4 are broadened, but not that from the carbon atom at C5, which is well removed from the site of rotational isomerism. In the case of the *p*-nitro compound (**4***b*), the spectrum was recorded at low temperature, which resolved the signals of the C4 and C5 carbon atoms into two signals from each. However, the signal from the C2 carbon of **4***b* was still broadened and unresolved at −30°C.

The lack of resolution of the C2 signals of **4***b* at −30°C may need further explanation. The resolution of such signals depends on two factors: (*a*) the rate of interconversion of the two forms; (*b*) the chemical shift difference between the two signals. Presumably in the case of compound **4***b* the signals of C2 in the two forms are much closer in chemical shift than those of C4 or C5. Thus the signals of C4 and C5 are resolved at −30°C whereas those of C2 are not.

In conclusion, the new compounds reported here represent an important addition to the spectrum of derivatives of 3,3-dialkyltriazenes with α-substituents in one of the alkyl groups. The sulfur containing triazenes described here (**2** and **4**) and those reported by Iley *et al.* (6) (**1***e*) are of potential interest pharmacologically because of their close structural relationship to the 3-hydroxymethyltriazene (**1***b*), a metabolite of the antitumour 3,3-dimethyltriazene (7). Further studies are being undertaken to determine the pharmacological properties of these new triazenes.

acetoxymethyltriazene (**1***c*) (0.004 mol) was dissolved in anhydrous dimethylformamide (6.0 mL) and treated with a twofold excess of the sodium thiophenolate solution (4.0 mL). After stirring at room temperature for 2 h, the red reaction mixture was poured into water (25 mL), extracted with ether (3 × 20 mL), and the washed (water, aqueous $NaHCO_3$, water again) ether extracts were dried ($CaCl_2$) and evaporated. The residue was purified by column chromatography on silica gel with 1:1:1 hexane/ethyl acetate/carbon tetrachloride as eluant, followed by recrystallization from hexane/chloroform mixture, to afford the 1-aryl-3-arylthiomethyl-3-methyltriazenes (**2***a–j*). Yields and physical data are given in Table 1.

3-Arylazo-1,3-thiazolidines (4)

General procedure

Method A: The aniline (0.01 mol) was diazotized in 2 M hydrochloric acid (50 mL) with sodium nitrite (0.011 mol). The resulting diazonium salt solution was added dropwise to a cold (0°C) solution containing 2-aminoethanethiol (0.02 mol), formaldehyde (7.8 g of 40% aqueous solution), and sodium carbonate (5.24 g) in water (40 mL), acidified to pH 3 with 2 M hydrochloric acid. The resulting yellow solution was neutralized to pH 7.5 with sodium bicarbonate. A bright yellow precipitate forms (when Y = CN or NO_2) and is removed by filtration to afford the crude 3-arylazo-1,3-thiazolidine. These crude products did not respond well to recrystallization.

However, the *p*-nitrophenyl analogue (**4***b*) was purified by column chromatography and then recrystallized from hexane/methylene chloride to give a low yield (6%) of the pure *N*-arylazothiazolidine.

Method B: The arenediazonium fluoroborate (0.011 mol) was dissolved in acetone (15.0 mL). A solution of thiazolidine (0.011 mol) in water (10 mL) was added slowly to the diazonium salt solution at 0°C. A coloured (usually yellow to orange) precipitate formed immediately and was removed by filtration after stirring the mixture for a further 0.5 h. The product was purified by recrystallization or by column chromatography as follows:

*3-(*p*-Cyanophenylazo)-1,3-thiazolidine (4*a*)*. The crude product was an orange solid, which was treated with a boiling mixture of hexane/toluene (1:1). The insoluble dark greasy oil was discarded, but the mother liquor afforded a crystalline product on cooling. Further recrystallization from hexane/toluene afforded the pure arylazothiazolidine as reported in Table 3.

*3-(*p*-Methoxycarbonylphenylazo)-1,3-thiazolidine (4*c*)*. The crude product was a yellow-orange solid, which was purified by successive column chromatography, with alumina as the solid support and toluene as the eluant in the first column and 1:1 hexane/toluene as the eluant in the second. Further purification by two recrystallizations from hexane/toluene gave analyticallu pure material.

*3-(*p*-Chlorophenylazo)-1,3-thiazolidine (4*d*)*. The crude product was a red oily precipitate which was extracted into dichloromethane. The residue from the dried (Na_2SO_4) dichloromethane extracts was purified by column chromatography using alumina and 1:1 hexane/toluene in the first column and pure hexane as eluant in the second column. The product was purified further by recrystallization from *n*-pentane.

The ^{15}N and ^{13}C chemical shifts of the sodium salt of deoxycytidylyl-(3′,5′)-guanosine have been measured in dimethylsulfoxide in the presence of variable amounts of CF_3COOH. N3(cyt) is protonated first, followed by N7(gua) and the phosphate anion. These results vary from those reported for the binding of the methylmercuric cation to d(CpG).

GIOVANNA BARBARELLA, MASSIMO LUIGI CAPOBIANCO, ANTONIO CARCURO, FRANCESCO PAOLO COLONNA, ANNA GARBESI et VITALIANO TUGNOLI. Can. J. Chem. **66**, 2492 (1988).

Opérant dans le diméthylsulfoxyde, en présence de quantités variables de CF_3COOH, on a mesuré les déplacements chimiques du ^{15}N et du ^{13}C du sel de sodium de la désoxycytidylyl-(3′,5′)-guanosine. Le N3(cyt) est le premier à se protoner, suivi du N7(gua) et de l'anion phosphate. Les résultats diffèrent de ceux publiés pour la liaison du cation méthylmercurique au d(CpG).

[Traduit par la revue]

Extensive work on nucleosides and mononucleotides has shown that ^{15}N nmr is the more direct and powerful method for establishing the sites of proton and metal-ion binding to DNA bases (1). ^{15}N chemical shifts of "pyridine-like" nitrogens of purine bases are considerably affected by the mean molecular excitation energy contribution to the paramagnetic shielding (2, 3). Since this term is dominated by the low energy $n \rightarrow \pi^*$ transitions, it increases and an upfield shift occurs (2, 3) when the lone pair of a pyridine-like nitrogen becomes involved in bonding, or even in weaker associations with electrophiles. Upfield shifts up to 100 ppm are found for proton or platinum binding to nitrogen (1, 4), while smaller but significant chemical shift changes are observed for nitrogen association to other "soft" metals such as Hg^{2+} (5). Unfortunately, owing to the high concentrations required to observe ^{15}N nmr signals at natural abundance (6), ^{15}N nmr data on DNA constituents beyond the mononucleotide level are very few.

A number of ^{13}C nmr studies on association of nucleobases with metals playing a biological role have shown that carbon chemical shifts as well as carbon–proton coupling constants are also very sensitive probes of binding sites (7). However, ^{13}C nmr data on oligonucleotides are also limited in number. A recent paper (8) on the interactions of d(CpG) with the methylmercuric cation shows that quite significant chemical shift changes are observed in the carbons flanking the binding site, N7(gua).

As a part of a program aimed to characterize the acid–base equilibria of deoxydinucleotides and their interactions with electrophiles in different solvents, we have investigated the protonation of these compounds in dimethylsulfoxide by means of ^{15}N and ^{13}C nmr. DMSO was chosen as the solvent to begin with, since work on nucleosides and mononucleotides has shown that a qualitative estimate of the relative basicities of protonation sites can be made in this solvent, owing to the lack of base–solvent proton exchange (1, 7). As well, the data in DMSO can be useful as a guideline for understanding the acid–base equilibria in water. Indeed, data obtained by potentiometry and calorimetry show that, although DMSO solutions are very different systems from aqueous ones, the pK values of several nitrogen bases in this solvent (including purines and related compounds) are only slightly smaller than in water (9).

We give here the initial results for the protonation of deoxycytidylyl-(3′,5′)-guanosine sodium salt (Fig. 1) in dimethylsulfoxide.

Results and discussion

The conformational features of d(CpG) have been investigated by proton nmr (10). A study of the X-ray structure of d(CpG) sodium salt has just been published (11). According to studies based on proton (10) and ^{13}C (8) nmr, d(CpG) gives significant stacking interactions in water. No data are available regarding d(CpG) in DMSO. Base stacking is not likely to occur in DMSO (12) where, however, hydrogen-bonded base pairs can be formed (13). Earlier studies based on ^{1}H (13) and ^{15}N (14) nmr in DMSO indicate that guanosine and cytidine associate to give Watson–Crick base pairs in DMSO. When hydrogen bonds are formed between guanosine and cytidine, the protons involved in bonding are shifted downfield, and a linear relationship between the magnitude of the downfield shifts and the concentration of the nucleoside is observed (13). We have found[2] that NH(gua), NH_2(gua), and NH_2(cyt) protons of d(CpG) show the same behavior when the concentration of d(CpG) in DMSO increases, a result that is consistent with the formation of intermolecular base pairs between the cytidylyl and guanosine residues of d(CpG) in this solvent.

To test the sensitivity of ^{13}C nmr to the variations of stacking and hydrogen-bonding interactions following a temperature

increase, we measured the ^{13}C chemical shifts of 0.02 M solutions of d(CpG) in water and DMSO at 22–25°C (probe T) and 80°C. The results are given in Table 1. It is apparent that only very small chemical shift changes are found in both solvents. The ^{13}C nmr is not very sensitive, at least in dilute solutions, to the conformational adjustments arising from variations in the interactions that occur in DMSO and water on temperature increase. In DMSO solution chemical shift changes within the experimental error (±0.1 ppm) are found. In aqueous solution the variations are slightly larger, though never exceeding 0.5 ppm, and are indicative of a higher degree of order in water compared to DMSO. Most of the carbons are *deshielded* at 80°C compared to probe temperature. Due to ring currents from the electrons of the bases, stacking generally leads to upfield shifts of near atoms (16*a*). Thus, the downfield shifts observed in the aqueous solution at 80°C are consistent with a decrease in the stacking interactions at high temperature.

The ^{15}N chemical shifts of a 0.35 M solution of d(CpG) in dimethylsulfoxide at varying amounts of added CF_3COOH are given in Table 2. Signal assignment is straightforward, as the chemical shifts of the neutral solution are nearly the same as those of cytidine and guanosine in DMSO (1*a*), also reported in Table 2 for comparison. The fact that N3 and NH_2 of the cytidylyl residue are *shielded* by 4.5 ppm and *deshielded* by 0.6 ppm, respectively, compared to the corresponding nitrogens of free cytidine, supports the hypothesis that Watson–Crick base-pairs are formed in dimethylsulfoxide (14).

Figure 2 is a plot of ^{15}N chemical shifts of d(CpG) vs. the molar equivalents of added acid. The chemical shift variations observed are proportional to the concentration of the protonated form, since for each acid addition the chemical shifts are weighted averages between the δ values for the neutral and the protonated species.

Several basic sites are present in d(CpG). There is a lot of evidence to show that in water as well as DMSO the most basic site of free cytidine and deoxycytidine is N3, whereas the most basic center of free guanosine and deoxyguanosine is N7 (16*b*). The pK_{BH^+} values assigned for ionization of the corresponding protonated bases (BH^+, first protonation step), are 4–4.5 for N3 and 2–2.5 for N7 (17), i.e., the N3 nitrogen of cytidine is more basic than the N7 nitrogen of guanosine by more than 2 pK units.

Figure 2 shows that, in line with the pK values for the free nucleosides, addition of up to 1.2 molar equivalents of CF_3COOH to d(CpG) perturbs essentially the cytidylyl residue. A progressive *shielding* of N3 (about −10 ppm for each 0.2 molar equiv. of added acid) is found, indicating that protonation at this site takes place. Chemical shift increments of N3 of nearly the same magnitude are found for free cytidine in DMSO.

Table 2 and Fig. 2 show that, parallel to the upfield shift observed for N3, a smaller but quite important *deshielding* of the amino group of the cytidylyl residue (about +2 ppm for each 0.2 molar equiv. of added acid) occurs, almost the same as that observed for cytidine in the same conditions.

[a]In ppm, with respect to NH_3.
[b]0.35 M in DMSO-d_6.
[c]Not observed.
[d]Reference 1*a*.

As already known, in free cytidine there is delocalization of the lone pair belonging to the amino nitrogen over the ring system, leading to a partial double bond character of the C4—NH_2 bond (cf. resonance structure **B** of Fig. 3), and resulting in a shift of the amino nitrogen to lower fields (18). Comparison of the chemical shift for the amino nitrogen of cytidine with that of guanosine, in which there is no lone-pair delocalization, shows that the first resonates 20 ppm further downfield than the latter. Table 2 shows that in d(CpG) the same chemical shift difference between NH_2(cyt) and NH_2(gua) is found.

According to an X-ray study (19), delocalization of the lone pair of the amino nitrogen occurs also in protonated cytidine. Moreover, the contribution of the resonance structure **D** to the protonated form of cytidine is more important than that of **B** to the neutral form. If the same is true for d(CpG) in DMSO, the progressive deshielding of NH_2(cyt) upon protonation at N3(cyt) can be explained by the fact that contribution of **D** to the protonated cytidylyl residue is more important than that of **B** to the corresponding neutral form.

It is worth noting that a contribution of form **B** to the cytidylyl residue in neutral d(CpG) in DMSO implies a large distribution of negative charge at N3 and O2 and that this favours the formation of Watson–Crick base pairs (14).[2] On the other hand, protonation at N(3) should have an effect on the hydrogen-bonding capabilities of d(CpG) and lead to variations in the chemical shifts of NH(gua) and NH_2(gua) nitrogens. Unfortunately, guanosine nitrogens are much less sensitive to changes in hydrogen-bonding interactions (14) than those of cytidine. Consequently, the shielding variations in NH(gua) and NH_2(gua) for protonation of the cytidylyl residue at N3 are too small to give any useful information on this point.

Further addition of CF_3COOH to d(CpG) begins to affect the guanine residue of d(CpG). While only minor variations are found in NH_2(gua) on addition of acid, N7 is progressively *shielded* by several ppm. However, contrary to that observed in N3(cyt), the upfield shift of N7(gua) following addition of acid (roughly 4 ppm each 0.2 molar equivalents of added acid) is much smaller than that observed for guanosine under the same conditions (nearly 10 ppm for each 0.2 molar equiv. of added acid). Clearly, after addition of 2.6 molar equiv. of CF_3COOH, N7 is far from being fully protonated. Table 2 shows that the chemical shift of N7(gua) reaches the same value as that of protonated guanosine only after a large excess of added acid.

Table 3 gives the ^{13}C chemical shifts of a 0.19 M solution of d(CpG) in DMSO-d_6 at varying amounts of added CF_3COOH, together with those of the free nucleosides for comparison. Table 4 reports the variations of the significant carbon–proton coupling constants of d(CpG) upon addition of acid. That N(3) protonates first is clearly shown by the variation in the one-bond couplings of the cytidylyl moiety ($^1J_{C5H5}$ and $^1J_{C6H6}$), while the one-bond ($^1J_{C8H8}$) and the long-range ($^3J_{C5H8}$) coupling of the guanosine residue are unaffected. After addition of an excess of acid, $^1J_{C8H8}$ *increases* by 3.5 Hz and $^3J_{C5H8}$ *decreases*

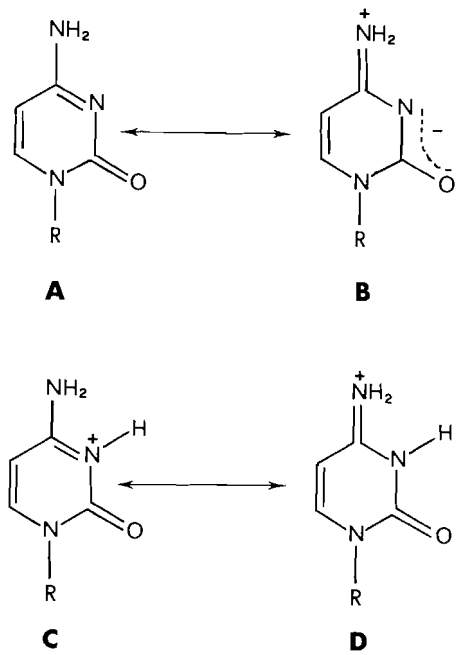

FIG. 3. Resonance forms of cytidine and N3 protonated cytidine.

by 4.9 Hz, as would be expected for protonation at N7 of purine bases (20).

As expected according to Grant's pioneering work on the protonation of purines (21), ^{13}C chemical shift variations on addition of acid are one order of magnitude smaller than those found for ^{15}N.

Examination of Table 3 shows that the trend of $\delta(^{13}C)$ upon addition of acid is similar to that found in $\delta(^{15}N)$.

It is seen that on addition of the first equivalent of CF_3COOH nearly the same variations as those observed for cytidine are found in the carbons flanking N3(cyt). In contrast, further addition of acid up to more than 3 molar equivalents does not affect the carbon atoms of the guanine moiety to the extent to which they are affected in guanosine upon protonation at N(7). Protonation of guanosine shields C5 by nearly 7 ppm, whereas C8, the other carbon next to the protonation site, is unchanged, probably due to cancelling effects. After addition of more than 3 molar equiv. of acid to d(CpG), C5(gua) is shifted upfield by only 3.6 ppm and the chemical shifts found in protonation of guanosine are reached only after addition of a large excess of acid.

Both ^{15}N and ^{13}C nmr results suggest that protonation at N7(gua) is competitive with protonation at another basic site, which is not a nitrogen atom, i.e., the phosphate group. Indeed, since it is reasonable to assume that the pK value for the first ionization step of $(HO)_3PO$ is close to that of a phosphate diester, its value, 2.2–2.5 (22), appears to be in the same range as that of N7(gua). Unfortunately, the chemical shift variations upon protonation found in the carbons near the phosphate center, namely C3′(cyt) and G5′(gua), are not very significant, not only because they are small, but also because it is impossible to distinguish between the contributions arising from protonation of the phosphate group and small perturbations in the distribution of conformers of the deoxyribose ring or minor adjustments of the sugar phosphate backbone. For the same reasons it would be difficult to get more direct evidence of protonation of the phosphate group by ^{31}P nmr. Determination of the pK_{BH^+} values of N3(cyt), N7(gua), and the phosphate group by other techniques such as uv spectroscopy (23), which would take into account the variations of ionic strength or the presence of competitive ions such as Na^+, is required.

The results of protonation of d(CpG) in dimethylsulfoxide vary from those of metallation of the same compound by the methylmercuric cation in water (8), which, for less than one molar equivalent of CH_3Hg^+ added, occurs at N7(gua).

It is generally considered that in cytosine and guanine protonation and metal ion coordination sites are the same (1*c*, 18). In agreement with this, mercuriation occurs at N3 in cytidine and cytidine-3′-monophosphate (5*a*, *c*, 24) and at N7 in guanosine and guanosine-5′-monophosphate (5*a*, *c*), in water and DMSO as the solvents.

[b]0.2 M in DMSO-d_6.

Since the reversal of the relative basicities of N3(cyt) and N7(gua) in water in respect to DMSO is unlikely (9, 17), it would have been expected that addition of less than one equivalent of CH_3Hg^+ would have brought about preferential binding at N3(cyt).

However, although in both processes the relative basicities of the potential binding sites play a crucial role, protonation and metallation are quite different reactions in terms of steric requirements and activation energies. Thus, the question arises whether the different results found for proton and CH_3Hg^+ addition to d(CpG) are due to steric reasons (the binding of CH_3Hg^+ at N3 being hindered by the presence of the flanking amino and keto groups) or are in some way related to the mini-helix structure of d(CpG) in water (10), or both. The question is not only in itself of obvious chemical interest but is especially relevant to the problem of the mutagenic action of several metals (25) or the activity of anticancer drugs such as cisplatin (26).

Experimental

The dinucleoside monophosphate, d(CpG), was prepared according to a published procedure (15). The sodium salt was obtained from the corresponding ammonium derivative by treatment with Dowex 50W8 (Na^+ form).

Natural abundance ^{15}N nmr spectra were obtained at 30.408 MHz with a Bruker CXP-300 spectrometer. A 10-mm dedicated probe was employed and the spectra run with inverse-gated decoupling to suppress the unfavorable $\{^{15}N-^{1}H\}$ nuclear Overhauser enhancement. Typical conditions were sweep width, 10 kHz; pulse width, 40°; repetition time, 7 s; data points, 16K. The free induction decays were zero-filled to 32K before transformation. The chemical shifts were measured with respect to an external 1 M solution of HNO_3 and converted to the NH_3 scale using the conversion factor $\delta_{NH_3}(HNO_3)$ = 376 ppm (2).

The ^{13}C spectra were run at 75.458 with the same instrument. The assignments were based on ref. 8. C1′(cyt), C4′(cyt), and C4′(gua) resonate at nearly the same frequency. The two signals showing a $^{13}C-^{31}P$ coupling were assigned to C4′(cyt) and C4′(gua); however, these could be interchanged. For the solutions in DMSO the chemical shifts were measured with respect to TMS as internal reference. For the solution in water the chemical shifts were measured with respect to internal dioxane and converted to the TMS scale using the conversion factor δ_{TMS} = 67.4 ppm.

ANDRÉ G. MICHEL, M. PROULX, G. EVRARD, E. MILCHERT, and B. NORBERG. Can. J. Chem. **66**, 2498 (1988).

The crystal structures of two 16-alkyl thebaine and oripavine analogues are described, in an attempt to put forward the particular requirements of these compounds to interact with the opiate receptor. Conformational congruencies accounting for the very high potency of these compounds are also emphasized.

In light of the crystal structures, the influence of the 16-alkyl substitution is discussed, as well as the differentiation in the agonist activity observed between diastereomers at C(19) characterizing these classes of opioids.

Significant distortions in the condensed ring system and the existence of an intramolecular hydrogen bonding are the main geometrical observations. They are invoked to account for particular modulations in the analgesic activity.

ANDRÉ G. MICHEL, M. PROULX, G. EVRARD, E. MILCHERT et B. NORBERG. Can. J. Chem. **66**, 2498 (1988).

Les structures cristallines de deux analogues 16-alkylés de la thébaine et de l'oripavine sont décrites, afin de mettre en évidence les propriétés conformationnelles caractérisant leurs intéractions spécifiques avec le récepteur opiacé.

L'influence du substituant 16-alkyl sur la conformation est discutée, ainsi que la différentiation dans l'activité agoniste observée pour les diastéréoisomères 19-*R* et 19-*S*, particularité propre à ces deux familles de composés.

Des déformations significatives dans le noyau polycyclique et la présence d'une liaison hydrogène intramoléculaire constituent les principaux éléments d'ordre structurel invoqués pour tenir compte des modulations particulières de l'activité analgésique de ces composés.

Introduction

In the past decade, crystal structure analysis of opiate alkaloids has proven to be extremely useful to probe the opiate receptor topography: more than 45 crystal structures have been reported. Nevertheless, very few of these are semi-rigid narcotic alkaloids of the oripavin and thebain families; their particular interest derives from the presence of a C(6)—C(14) etheno bridge, bearing various C(7) substituents.

In early attempts to establish structure–activity relationships of opiate multi-ring compounds, three interaction sites were postulated at the receptor level; an anionic center interaction with the nitrogen atom, and hydrophobic site, in relation with the aromatic ring A and finally a "hole" where C(15) and C(16) had to fit (1). This model had to be updated to explain the tremendous increase in the analgetic activity for 6,14-*endo*-ethenotetrahydrothebaine where not only is activity as much as 2200 times higher than that of morphine (2), but also the *R* diastereoisomers are much more potent than the *S* diastereoisomers.

In this study we have addressed two structure–activity questions; the influence of the alkyl substitution at the C(16) position and the differentiation in agonist activity between diastereomers at C(19) (2). Compounds **1** and **2** were chosen accordingly; they belong to the oripavin and thebain family respectively and differ by the C(16) substitution.

The effect of this alkyl substitution relates to the size of the particular "C(15)—C(16) hole" as mentioned in the opiate receptor model proposed by Beckett and Casy (1): all the 16-alkyl-6,14-*endo*-ethenotetrahydrothebaines are less active as analgetics than the unsubstituted compounds (2). In particular, a group larger than methyl (compound **2**) eliminates almost completely the analgesic activity. We were also interested in the effect of substitution on the distortion of the multi-ring system as an alternative hypothesis to take into account the loss of activity.

Concerning C(7) substitution and its stereospecificity, conformational studies of a series of oripavine suggested the formation of an intramolecular hydrogen bonding (4). These results were consistent with the crystallographic data available (7). In our study, a similar intra-hydrogen bonding also exists in compounds **1** and **2** this would be useful to explain the stereospecificity at C(7) and determine the size and the orientation of corresponding subsite to be taken into account in the opiate receptor modelisation.

Experimental

The preparations and pharmacological properties of the title compounds have been reported earlier (2).

Crystals of **1** were obtained by slow evaporation from a solution in methanol, kept at 5°C. Colourless transparent plates were prepared to be suitable for X-ray analysis. Crystals of **2** were obtained from an aqueous isopropanolic solution in a 1:1 ratio. Prismatic, colourless transparent crystals grew slowly at 5°C.

The cell constants and space groups were obtained with film

techniques and were confirmed using the diffractometer data. A total of 18 (compound **1**) and 25 (compound **2**) reflections were used to refine the cell dimensions. Independent reflections were collected on a Nonius CAD-4 automatic diffractometer. Experimental conditions related to the data acquisitions are given in Table 1.

Absorption corrections were not applied because of the small sizes of the crystals and the small values of linear absorption coefficients for CuKα. Lorentz and polarization corrections were applied.

The positions of the non-hydrogen atoms of both molecules were obtained from the E-map computed subsequently to the direct methods application (MULTAN programs) (5). The structure refinement of compound **1** was performed by isotropic and anisotropic refinements by full-matrix least squares applied to F's using the NRCVAX program (12). Counting statistics weights were used, H atoms located on difference Fourier maps and isotropically refined in subsequent calculations. The "y" coordinate of atom O(1) has been fixed during the refinements, $P2_1$ being a polar space group. The structure refinement of compound **2** has been achieved by isotropic and anisotropic refinements by full-matrix least squares; using the XTAL83 program (6) lowered the R value to 0.070. A Fourier difference synthesis revealed the coordinates of the H atoms, which were given the isotropic thermal parameters of their adjacent atoms. Counting statistics weights

were used. Although not refined, the H atoms parameters were included in the subsequent calculations. High values for (displacement/σ) may be attributed to the relatively important mosaïcity of the crystals and resulting low quality of the measurements. The O(5) atom lies in a position very close to the 2-fold axis. Its factor of occupancy has been assigned to 0.5. For both compounds, the final refinement undertaken under the conditions listed in Table 2 yielded the atomic coordinates of the non-hydrogen atoms as given in Table 3. The positional parameters of the H atoms together with their isotropic temperature factors, as well as the lists of structure factors and anisotropic thermal parameters have been deposited as supplementary material.[3]

Results

The atomic numbering used for compounds **1** and **2** is indicated in Fig. 1, which shows the crystal structure of **2**. The atoms C(25) and C(26) are not present in **1**.

The numbering of the carbon atoms in the crystal structure corresponds to the commonly accepted conventions for the morphine class of molecules. The T shape of the rigid morphine-like part is displayed by both compounds. The bond distances for the two compounds are listed in Table 4 and bond angles in Table 5.

The molecular structures are similar to those of 19-propylthevinol hydrobromide described earlier (7). The piperidyl system is in the chair conformation with the *N*-methyl equatorial, in spite of the presence of the 16-β-alkyl substituent. In both compounds the O(4) hydroxyl oxygen forms an intramolecular hydrogen bond with the ether oxygen O(3), as observed in early X-ray studies (7) as well as predicted by conformational analysis (4).

[3]Tables of observed and calculated structure factor amplitudes, of anisotropic temperature factors for non-hydrogen atoms, of fractional coordinates and temperature factors for hydrogen atoms, and of torsional angles may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

[a] $B_{eq} = \frac{8\pi^2}{3}\sum_i\sum_j U_{ij}a_i^*a_j^*a_ia_j$.

To evaluate the distortions on the molecule structures induced by the 16-β-alkyl substituent, we have superimposed both compound **1** and compound **2** on compound **5**, propylthevinol, the unsubstituted thebaine derivative (7). Its activity is about 100 times more potent than morphine in tail pressure test in rats (10). The best molecular fittings have been made by exact superposition of the phenyl rings (ring A) constraining the six pairs of equivalent atoms to match perfectly. Resulting pictures are shown in Fig. 2. The "fit" option of the SYBYL molecular modelling system has been used (8).

In compound **1**, the crystal packing is assured by one intermolecular hydrogen bond between the O(2) hydroxyl oxygen and the O(4) 19-hydroxyl oxygen of another molecule, and by Van der Waals contacts. In compound **2**, the packing in the crystal is mainly achieved by hydrogen bonds between the O(5) atom of water and the hydroxyl O(4) atom, the corresponding values are given in Table 6. The H_2O molecule (O(5) atom) bridges two symmetry-related molecules, as can be seen in Fig. 3.

Although very different one from each other, the packings of compounds **1** and **2** do not induce significant modifications at the molecular level. Even the intramolecular hydrogen bond is conserved, although the O(4) hydroxyl atom of compound **2** is shared between an intra- and an intermolecular H-bond: donor to O(3) (intra) and acceptor from O(5) of the water (inter). Intervening protons have been represented in Fig. 3.

Discussion

Essential molecular characteristics for thebaine and oripavine narcotics appear from the present study and can be related to their specific agonist properties.

The presence of the 16-methyl (compound **1**) and 16-ethyl (compound **2**) as R^3 substituents has been shown to have minor effects on the N-lone pair orientation and cannot be invoked to justify the loss of activity (9). The argument of the steric hindrance as postulated in former models (1) remains the most plausible. Nevertheless, the examination of Figs. 2*a* and *b* shows that the distortion on the orientation of the C(7)—C(19) bond is in the order of 30° compared to the unsubstituted propylthevinol compound **5** (7). This observation might be reconsidered when the contribution of the R^2 to the pharmacophore would be precised. Particularly its relative position and orientation with respect to the tyramine part of the molecule would be of interest in the description of the opiate receptor.

This statement is corroborated by the presence of intramolecular hydrogen bonding O(3)...O(4) corresponding to O-methoxy and hydroxyl groups, respectively. This observation confirms NMR, IR, and quantum calculations predictions, reported earlier (3). The protons involved were located on Fourier-difference maps for both compounds. The geometrical characteristics are given in Table 6. Also observed for com-

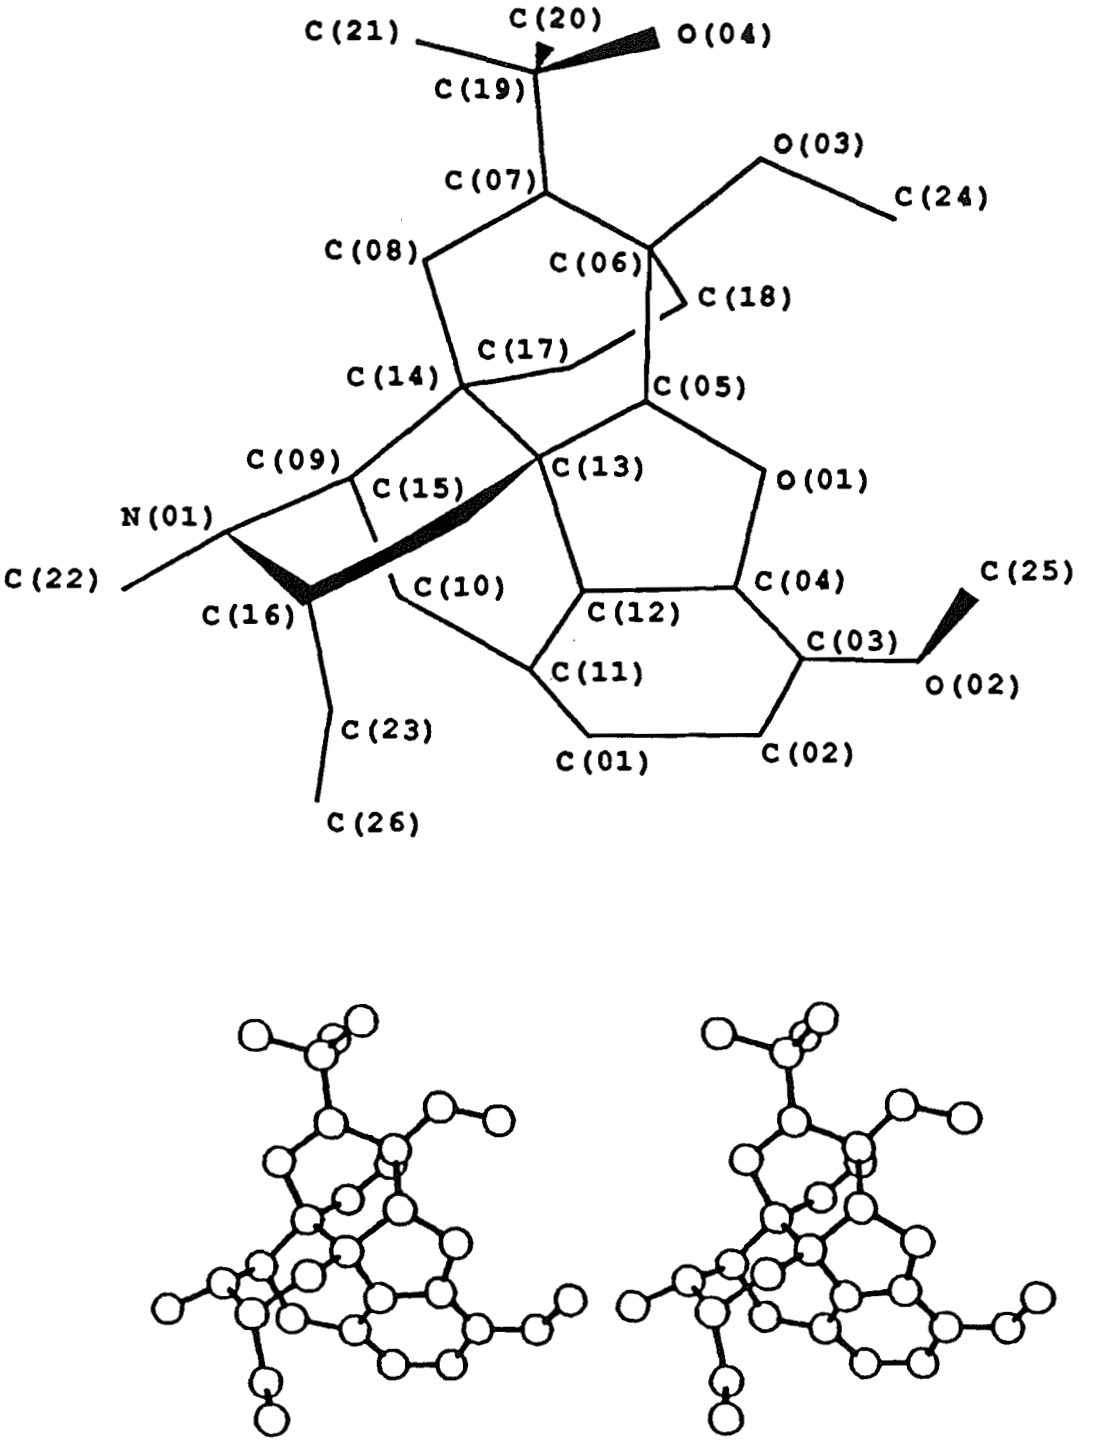

FIG. 1. Atoms numbering for **1** and **2**: represented by using the crystal structure of **2**: C(25) and C(26) are not present in **1**. The numbering corresponds to the chemical conventions.

pound **5**, this intramolecular constraint differentiates the *R* and *S* isomers at C(19), in consequence of the hindered rotation around the C(7)—C(19) bond. As a result, the torsional angles C(6)—C(7)—C(19)—O(4) are very similar: −60.3° for compound **1**, −70.0° for compound **2** and −66.2° for compound **5** (7). Molecular similarities are evident from Fig. 2: excellent molecular fits were obtained between compound **1** and compound **5** (Fig. 2*a*) as well as between compounds **2** and **5** (Fig. 2*b*) and between **1** and **2** (Fig. 2*c*). Similarities are also reflected by equivalent distances between atoms involved in the interaction with the opiate receptor. N(1)—O(3): 6.8 Å for compound **1**, 6.6 Å for compound **2**, to be compared with 6.7 Å in compound **5** (7). This finding may also explain the observed differentiation in the narcotic activity between the diastereoisomers at C(19). According to the Becket and Casy (1) receptor model, the C(7) substituents interact with a lipophilic receptor site. The presence of the hydrogen bond allows the *R* isomers to orient the C(7) substituent in the proper region of space and, hence, increase the agonist potency.

Computer modelling techniques demonstrated the similari-

Received March 28, 1988

SIMONETTA FORNARINI and MAURIZIO SPERANZA. Can. J. Chem. **66**, 2506 (1988).

Free, unsolvated phenylium ions formed by the spontaneous decay of 1,4-ditritiobenzene have been allowed to react with gaseous cyclic ethers (oxirane, propene oxide, and oxetane) and acetaldehyde in the pressure range 30–250 Torr and in the presence of a thermal radical scavenger (O_2, 4 Torr). The effects of a gaseous base (NMe_3, 20 Torr) and of an energy moderator (He, 630–720 Torr) were also investigated. Phenylium ion confirms its considerable site selectivity, demonstrated by the distinct preference for the *n*-type center of the substrate, although appreciable insertion into the carbocyclic structure of propene oxide and oxetane is observed as well. The stability features of the ionic intermediates from addition of phenylium ion to selected substrates have been evaluated as well as their fragmentation and isomerization mechanisms. The behavior of gaseous phenylium ion toward cyclic ethers, in particular its ability to formally abstract an oxygen atom from the ether to give the phenoxenium ion, a reaction first observed in the present study, is discussed and compared with previous mechanistic investigations carried out in the gas phase and in solution.

SIMONETTA FORNARINI et MAURIZIO SPERANZA. Can. J. Chem. **66**, 2506 (1988).

Opérant à des pressions allant de 30 à 250 Torr et en présence d'un piège à radicaux thermiques (O_2, 4 Torr), on a laissé réagir les ions phényliums libres et non-solvatés qui se forment par la décomposition spontanée du ditritio-1,4 benzène avec des éthers cycliques à l'état gazeux (oxiranne, oxyde de propène et oxétanne) ainsi qu'avec de l'acétaldéhyde. On a aussi évalué les effets de la présence d'une base gazeuse (NMe_3, 20 Torr) ainsi que d'un modérateur d'énergie (He, 630–720 Torr). L'ion phénylium confirme sa haute sélectivité qui est démontrée par sa préférence marquée pour le centre de type *n* du substrat même si on observe aussi une quantité appréciable d'insertion dans la structure carbocyclique de l'oxyde de propène et de l'oxétanne. On a évalué les caractéristiques de stabilité ainsi que les mécanismes de fragmentation et d'isomérisation des intermédiaires ioniques obtenus par l'addition de l'ion phénylium sur des substrats choisis. On discute du comportement de l'ion phénylium gazeux vis-à-vis des éthers cycliques, en particulier de sa facilité d'arracher formellement un atome d'oxygène de l'éther pour donner l'ion phénoxénium, une réaction qui a été observée pour la première fois dans cette étude; on compare ce comportement avec celui observé dans des études mécanistiques rapportées antérieurement et effectuées soit en phase gazeuse soit en solution.

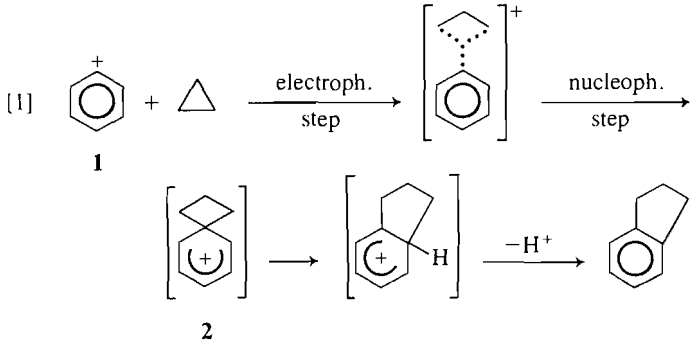
Introduction

Unsaturated carbenium ions are reactive intermediates in which the electron-deficient carbon is an integral part of a π-unsaturation. In the singlet configuration, the formally positive carbon atom has a nominally vacant orbital, which is orthogonal to a strongly polarized π system (1). As a consequence, the positive carbon center tends to acquire the character of a substituted singlet carbene (2), thus conferring on the unsaturated species a marked tendency for insertion into σ-bonds and π-bonds and addition to *n*-type electrons (3).

Experimental confirmation of this ability is provided by the pronounced reactivity of gaseous vinyl and aryl cations toward essentially all kinds of organic substrates. Of special interest is the mode of insertion of these ions into π- and σ-bonds of hydrocarbons (4), which is thought to proceed via two distinct consecutive steps (2). The first step is the electrophilic insertion of the vacant orbital of the ion into the hydrocarbon bond to yield a two-electron three-center bond. The second step is the nucleophilic coupling of the antibonding orbital of the hydrocarbon with the π system of the unsaturated ion to form a second σ-bond (2). This mode of attack accounts for the formation of indane from gas-phase insertion of singlet phenylium ion **1** into the C—C bonds of cyclopropane via the spiro



intermediate **2**, reaction [1] (5). In the same way, isomeric dihydronaphthalenes are produced in fair yields from gas-phase addition of **1** to the terminal carbons of 1,3-butadiene (6).

Simple addition to the *n*-type center is observed in the attack of **1** on molecules such as alkyl halides, alcohols, and ethers to yield the corresponding onium intermediates (7). In all circumstances an internal nucleophilic step, such as the one shown in reaction [1] involving alkyl group migration from the heteroatom to the π system of the onium intermediates, is hardly observed. Rather, the onium ions undergo unimolecular fragmentation with loss of an alkene in competition with a bimolecular displacement by an external nucleophile, whose

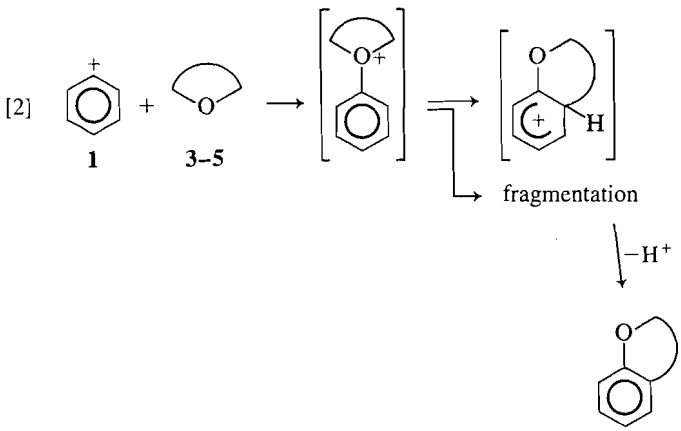
Printed in Canada / Imprimé au Canada



relative extent depends primarily upon the experimental conditions adopted (7).

To ascertain whether this is a general behavior of *n*-type molecules toward **1** or whether other mechanisms, similar to the one shown in reaction [1], are operative, the investigation is now extended to strained cyclic ethers, such as oxirane **3**, propene oxide **4**, and oxetane **5**. In this way, while we broaden our knowledge of the site selectivity of **1** in the gas phase, we expect to gain information about the relative stability of the oxonium intermediates from the gas-phase O-phenylation of **3–5** as well as on their propensity to relieve the strain energy via O-to-ring alkyl group migration, reaction [2]. The different strain energy and structural features of the selected cyclic ethers **3–5** might be expected to lead to remarkable differences in both extent and mechanism of fragmentation of the corresponding phenylated oxonium intermediates, and to influence the possibility of intramolecular isomerization to a ring alkylated structure.

Experimental

Materials

1,4-Ditritiobenzene, used as a precursor of the tritiated phenylium ion **1**, was synthesized and purified as previously described (8). He, NMe_3, and O_2 were obtained from Matheson Gas Products, Inc.; their stated purity exceeded 99.9 mol%.

Aldrich Chemical Co. and Fluka AG provided all the products used as glc standards or as components in the gas-phase experiments. Other aromatic compounds, not available commercially, such as α- and β-methyldihydrobenzofuran (9), phenyl vinyl ether (10), and all isomeric phenyl propenyl ethers (10, 11) were prepared according to established synthetic procedures. 2-Methylbenzodioxane was prepared by the reaction of *o*-dihydroxybenzene with 1,2-dibromopropane in aqueous KOH. The identity of the synthesized products was checked by conventional ir and nmr spectroscopy.

Decay experiments

The decay samples were prepared by introducing sealed glass capillaries containing ca. 1 mCi of tritiated benzene (specific activity: 80 mCi $mmol^{-1}$) into 300-mL Pyrex ampoules. The ampoules were connected to a vacuum line and thoroughly degassed. The organic substrate was then introduced, together with minor amounts (ca. 4 Torr; 1 Torr = 133.3 Pa) of oxygen, which was used as a scavenger of the radical species that could be formed by the passage of the energetic β-particle from the nuclear decay of tritiated benzene through the gaseous mixture. In some cases, either He (630–720 Torr) or NMe_3 (20 Torr) was added to the mixture. The ampoules were finally sealed and the capillary tube containing benzene broken with a glass hammer.

The decay mixtures were stored for about a year in the dark, at room temperature. The vessels were then opened under airtight conditions and their content analyzed by radio glc, using a C. Erba Fractovap 4200 gas chromatograph equipped with a high-sensitivity hot-wire detector (HWD), coupled in series with a Berthold proportional counter tube, kept at 180°C. The identity of the tritiated products was established by coincidence of the radiochemical peaks with the HWD signals from authentic reference compounds on both the following columns: (*i*) 2 m 5% SP 1200/5% Bentone-34 on 80–100 mesh Supelcoport, operated at 120°C; (*ii*) 5 m 15% 550 Silicone Oil on 60–80 mesh Chromosorb W-AW, operated at 130°C.

Over 40 reference compounds were tested, including those described in the previous section, arenes (e.g., styrene), aldehydes (e.g., phenylacetaldehyde), ketones (e.g., ethylphenylketone), cyclic (e.g., phenyloxirane) and acyclic ethers (e.g., cinnamyl methyl ether), alcohols (e.g., cinnamyl alcohol), phenols (e.g., *o*-allyl phenol), esters (e.g., phenyl acetate), and a variety of benzocyclic compounds (e.g., 1,3-dihydroisobenzofuran, 3,4-dihydro-1*H*-2-benzopyran, 3,4-dihydro-2*H*-1-benzopyran).

As the tritium-labelled products are formed in extremely small amounts (picogram level), their routine analysis can be performed only by radioanalytical methods. In some cases a further check on the identity of a product was sought by a derivatization procedure. An inactive carrier corresponding to the product of interest was added to the mixture of the decay experiment. A chemical reaction was then carried out (typically an electrophilic substitution on our aromatic compounds) and it was carefully noted whether the derived product possessed the expected fraction of radioactivity from its precursor.

Fourier-transform mass spectrometric (FT–MS) experiments

Phenylium-ion attack on oxirane and acetaldehyde was investigated by the FT–MS technique. All the mass spectrometric experiments were performed on a Nicolet FT–MS 1000 ICR spectrometer equipped with a 2.54-cm cubic trapping cell situated between the poles of a superconducting magnet operated at 2.0 T.

Sample pressures (uncorrected) were measured with a Granville–Phillips 280 Bayard–Alpert ion gauge. The FT–MS resolution was typically 1000 fwhh (full width half height) at mass 100. Inlet system and trapping cell were kept at room temperature. Ions were trapped in the cell by a differential trapping voltage of about 1.0 V. Typical operating conditions were as follows: nominal electron beam energy, 20 eV; electron beam pulse, 3 ms; emission current, 400 nA; total pressure, 10^{-7}–10^{-6} Torr. The reaction sequences involved attack of either phenylium ions (from EI (electron impact) on chlorobenzene) or phenoxenium ions (from EI on nitrobenzene) on the selected substrates and were investigated by multiple resonance experiments on the appropriate ionic species with variable reaction times up to 200 ms.

Results

Tables 1–3 show the relative and absolute yields of tritiated products recovered from the gas-phase attack of the 1,4-ditritiobenzene decay ions on oxirane, propene oxide, and oxetane, respectively. To extend the investigation of structural factors on the tritiated product distribution, decay runs were also carried out using an isomer of oxirane, namely acetaldehyde **6**, whose results are reported in Table 4. In all systems, reaction conditions were chosen to span a factor of over 7 in the substrate partial pressure (30–250 Torr). In some cases, He gas (630–720 Torr) was used as moderator of the energetic species. A powerful base, such as NMe_3 (20 Torr) was also introduced in the decay experiments carried out at the highest partial pressure of the substrate.

At variance with the results of related decay experiments carried out using alkyl halides, alcohols, and acyclic ethers (7), analysis of Tables 1–4 reveals comparatively limited absolute yields of tritiated products from the decay runs, never exceeding 30%. Radio glc analysis showed that low-boiling fragmentation products account for only a small fraction of the missing activity (<2%). We therefore proceeded in the quantitative measurement of the total activity of the crude reaction mixture as well as of the inner surface of the reaction vessel by liquid scintillation

counting. We observed that it largely exceeds the combined activity of the individual products identified by radio glc, thus indicating that most of the missing activity resides in high-boiling labeled products, i.e., polymers.

In conclusion, the activity balance is mostly accounted for by polymerization products, accompanied by minor yields of fragmentation products and monotritiated benzene, whose activity cannot be discriminated from that contained in the undecayed 1,4-ditritiobenzene, arising from possible hydride-ion transfer from **3**–**6** to phenylium ion **1**. The identity of a few radioactive products is left undefined, since it could not be safely assessed by comparison with authentic standard compounds. However, according to their retention volumes on the selected glc columns, these unknown products are most likely aromatic oligomers of the substrate and (or) their unimolecular fragmentation derivatives.

Analysis of Tables 1–4 reveals the formation of five different families of aromatic products from all decay experiments, namely benzofuran derivatives, benzodioxane derivatives, phenol, benzaldehyde, and acyclic alkenyl phenyl ethers. Their occurrence and relative yields depend on many factors, including the nature of the substrate, the presence of the base NMe_3, and the total pressure of the system. Thus, while benzofuran and benzodioxane derivatives are major products from the oxirane and propene oxide decay runs carried out in the absence of base, they are absent among the products from the oxetane and acetaldehyde decay experiments. Here, phenol is the predominant product at any system pressure in the absence of NMe_3. In the presence of base, the relative yields of the acyclic alkenyl phenyl ethers are increased significantly (by a factor greater than 2). This effect is consistent with the role of inhibitor of a cationic polymerization sequence.

In the oxirane set of experiments (Table 1), the increase of the ether pressure leads to an increase of the relative yield of dihydrobenzofuran (from 21 to 37%) and to a decrease of the relative yield of benzodioxane (from 61 to 33%). Formation of phenol is favored as well (from 15 to 30%). In contrast, phenol is absent from the products recovered in the propene oxide runs (Table 2). Here, the relative yields of 3-methyldihydrobenzofuran (21–28%) and 2-methylbenzodioxane (22–26%) are rather unaffected by large variations of the partial pressure of the ether.

In the absence of NMe_3, formation of cyclic and acyclic ethers in the propene oxide and oxetane decay experiments is accompanied by variable amounts of benzaldehyde, i.e., a tritiated product apparently derived from formal insertion of phenylium ion into the C—H and (or) C—C bonds of the ethers (Tables 2 and 3). Formation of benzaldehyde appears prevented in the phenylium-ion attack on oxirane and acetaldehyde (Tables 1 and 4). Finally, it should be pointed out that the same set of acyclic alkenyl phenyl ethers is generated from the decay experiments with isomeric substrates. Thus, while oxirane and acetaldehyde give rise only to phenyl vinyl ether, propene oxide and oxetane yield isomeric phenylpropenyl ethers and allyl phenyl ether, in proportions that are very similar in the presence of NMe_3 and significantly different in the absence of base.

To obtain independent information on the mechanism of formation of the decay products, phenylium ion was produced by 20-eV electron impact on chlorobenzene, and its reaction pattern towards oxirane and acetaldehyde was examined by Fourier-transform mass spectrometry (FT–MS). The adduct between phenylium ion and the substrate was not observed under the mass spectrometric conditions (source pressure: 10^{-7}–10^{-6} Torr), nor was it expected, but significant abundances of ionic species at masses 43, 91, and 93 (3:3:1) were produced from phenylium ion. These ions seem to be rather stable intermediates under FT–MS conditions since their relative abundances do not change much by increasing their residence time in the FT–MS cell up to 200 ms. The ionic fragment at $m/z = 43$ is presumably acetyl cation or some isomeric species arising from formal hydride-ion transfer from the substrate to phenylium ion.

The peak at $m/z = 91$ is probably the benzyl cation or some other isomeric species, whose formation indicates the possibility of formal attack of phenylium ion on the σ-bonds of the substrate. Unexpectedly, minor amounts of a fragment with $m/z = 93$ invariably accompany the above-mentioned species. This ionic intermediate does not display any Bronsted-acid properties toward the substrate, thus excluding its possible identification as protonated toluene.[2]

As a consequence, we are inclined to attribute to the $m/z = 93$ fragment the structure of the phenoxenium ion PhO^+, arising from attack of phenylium ion on the *n*-type center of the substrate and subsequent fragmentation of the ensuing excited phenyloxonium intermediate with loss of a C_2H_4 moiety.

To increase our knowledge of the reactivity properties of a gaseous phenoxenium ion, the known procedure (12) for preparing it in high yields by electron impact on nitrobenzene was exploited in our FT–MS cell, and its reactivity toward oxirane and acetaldehyde was examined by multiple resonance experiments. Phenoxenium ions from 20-eV electron bombard-

[2]In spite of the slightly higher proton affinity of toluene (P.A. = 189.9 kcal mol^{-1}) with respect to that of oxirane (P.A. = 187.9 kcal mol^{-1}) and acetaldehyde (P.A. = 186.6 kcal mol^{-1}), the enormous excess of neutral substrate vs. neutral toluene in the FT–MS cell would lead to the slow disappearance of a conceivable protonated toluene peak ($m/z = 93$) and increase of the $m/z = 45$ ion abundance at long reaction times, i.e., under conditions approaching thermodynamic equilibrium. The essential unreactivity of the $m/z = 93$ toward oxirane and acetaldehyde observed even at rather long reaction times (200 ms) excluded any significant contribution of the protonated toluene structure to the $m/z = 93$ peak. Consistent with these conclusions is the absence of any labelled toluene in all decay experiments involving the same substrates.

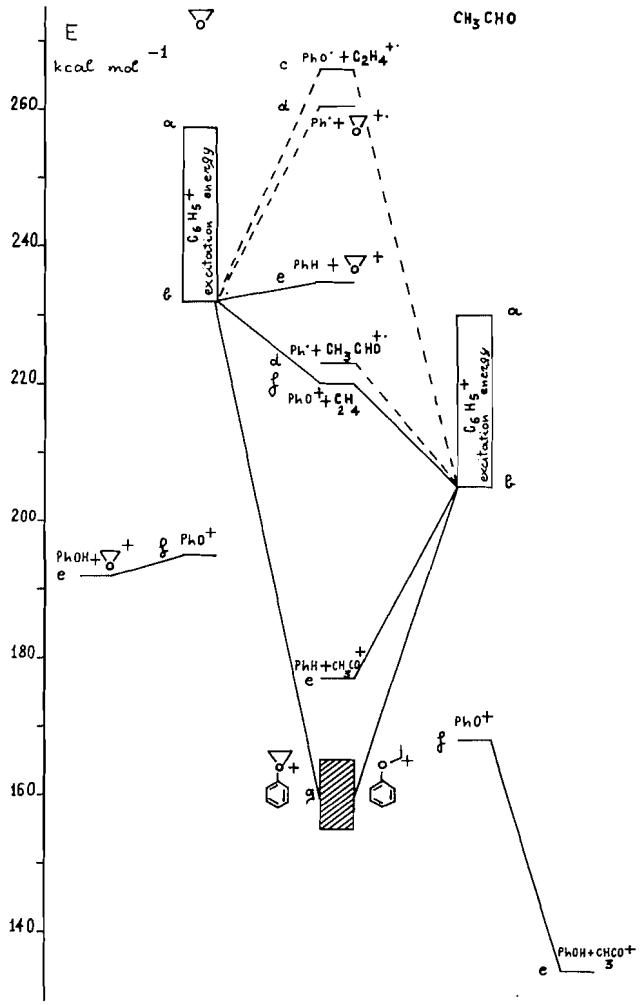

FIG. 1. Energetics of several relevant ion–molecule reactions involved in the gas-phase attack of phenylium ion on oxirane and acetaldehyde. (a) According to *ab initio* calculations (21), the ΔH_f^0 of a phenylium ion with the geometry of benzene is ca. 32 kcal mol^{-1} higher than that of a phenylium ion in a vibrational ground-state. Thus, the maximum formation enthalpy available to a phenylium ion formed by nuclear decay **1** is computed to be ca. 277 kcal mol^{-1}, which is in satisfactory agreement with the experimental value (ΔH_f^0 = 266–270 kcal mol^{-1}; ref. 22) derived from the ionization potential of the phenyl radical. (b) The ΔH_f^0 of a phenylium ion in a vibrational ground state has been calculated to be 244.8 kcal mol^{-1} (13). (c)–(f) Formation enthalpy data taken from ref. 14; (d) Ionization potential data taken from ref. 15; (e) Formation enthalpy data taken from refs. 14*b* and 16; (g) the ΔH_f^0's of **7** and **13** were estimated as several kilocalories per mol higher than that of dimethylphenyloxonium ion, ref. 7*d*.

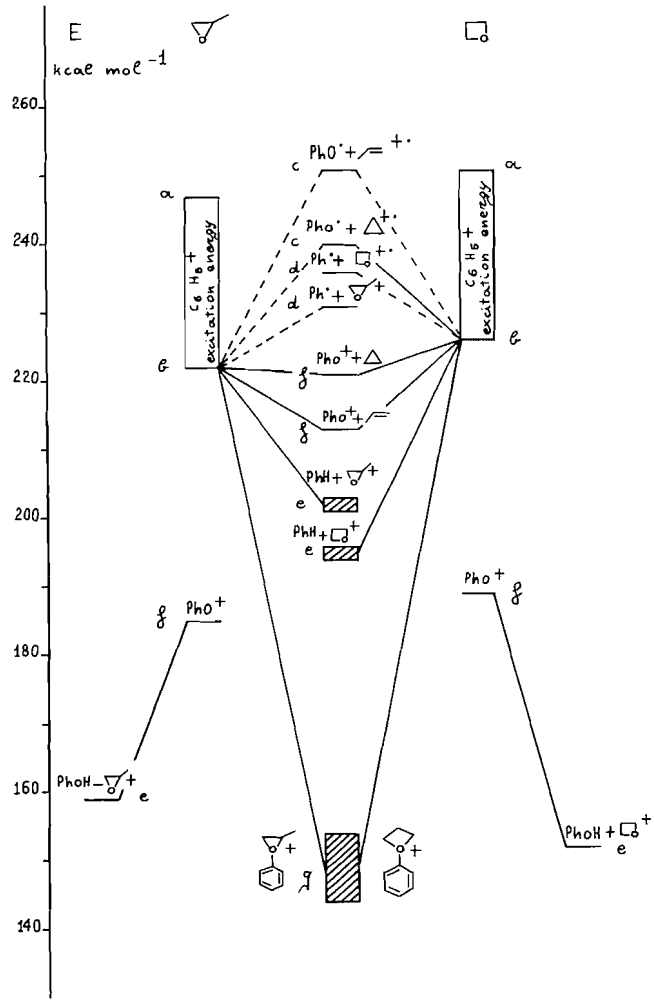

FIG. 2. Energetics of several relevant ion–molecule reactions involved in the gas-phase attack of phenylium ion on propene oxide and oxetane. (a)–(f) See (a)–(f) of Fig. 1; (g) The ΔH_f^0's of **14** and of the O-phenyloxetanium intermediate were estimated as several kilocalories per mol lower than that of dimethylphenyloxonium ion, ref. 7*d*.

ment on nitrobenzene display essentially the nature of a hydride-ion acceptor from acetaldehyde yielding efficiently the acetyl cation m/z = 43. The same reaction does not occur appreciably when oxirane is used as the neutral substrate.

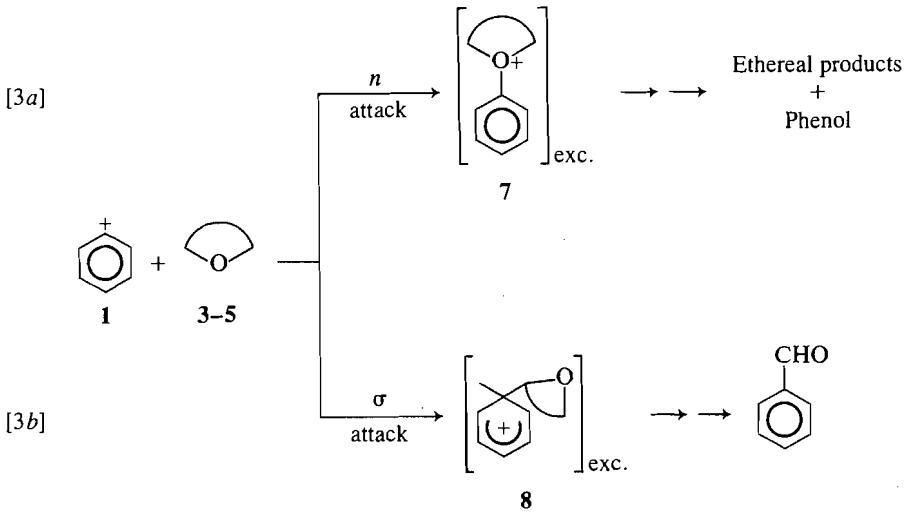
Discussion

The attack of the phenylium ion

The nature and the properties of free phenylium ion **1** produced by nuclear decay in tritiated benzene and used in the present study as the electrophilic reactant have been previously described in detail (7).

Several reaction channels are open to phenylium ion **1** formed by nuclear decay, in its attack on the selected substrates, as illustrated in Figs. 1 and 2. The figures give approximate reaction enthalpies for the relevant gas-phase processes. For the sake of clarity, other plausible reaction pathways are not reported in the figures, either because they are highly endothermic or because they are not observed under FT–MS and nuclear-decay conditions. For instance, charge exchange (paths (d) of Figs. 1, 2) as well as O^- transfer between **1** and the substrate (paths (c) of Figs. 1, 2) to yield the molecular ion of the substrate or a $C_2H_4^+/C_3H_6^+$ fragment, respectively, are rather endothermic processes and, therefore, very inefficient reactions, as confirmed by the absence of m/z = 44 and m/z = 28 peaks among the daughter species of phenylium ion in the FT–MS runs with oxirane and acetaldehyde.

A significant exothermicity characterizes all the remaining processes of Figs. 1 and 2, namely (*i*) the addition of **1** to the *n*-type center of the substrate to yield the corresponding primary phenyloxonium intermediates (paths (g)); (*ii*) the subsequent fragmentation of these intermediates to give a phenoxenium ion and a neutral alkene moiety (paths (f)), allowed by the substantial excess energy of the phenyloxonium precursors from the preceding highly exothermic process; (*iii*) the hydride-ion transfer from the substrate to **1** to yield benzene and the



[substrate-H]$^+$ fragment (paths (e)). The latter two paths have been directly observed by FT–MS experiments. All the above exothermic processes, therefore, may be considered as potential ionic sources of radioactive products in the decay experiments, although the hydride-ion transfers (e) are "blind" (i.e., not leading to identifiable labeled products, other than the tritiated benzene precursor) reaction channels, which could partly account for the activity loss (over 70%) observed in all decay systems.

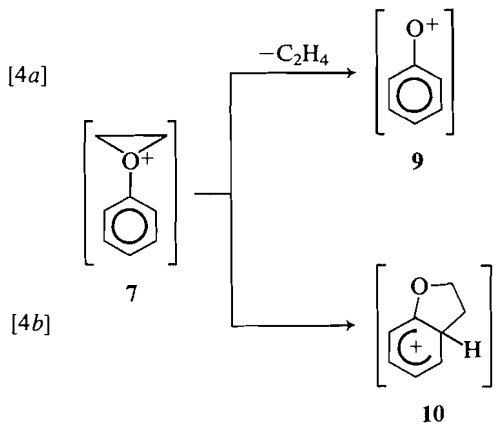
The results reported in Tables 1–4 confirm the remarkable affinity of **1** toward the *n*-center of the substrate, as inferred from the relatively high yields of cyclic and acyclic phenyl ethers and phenol (overall relative yield, 82–100%).

It is therefore suggested, in analogy with the conclusion reached in previous studies (7), that the phenylation process occurring in the decay systems involves competitive attack of **1** on the *n*- and σ-type centers of the substrate, to give the corresponding onium intermediate **7** in predominant yields, reaction [3], and minor, if any, amounts of arenium ions (e.g., **8** in reaction [3*b*]), respectively, with the latter responsible for the formation of benzaldehyde. It should be noted, in this connection, that measurable amounts of benzaldehyde are observed only among the labeled products from propene oxide and oxetane, namely from those isomeric cyclic ethers with the highest ratio of σ- vs. *n*-type centers.

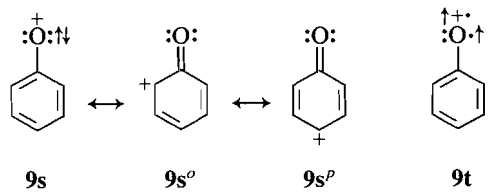
In addition, the distinct site selectivity of **1** is extended to the different σ-bonds of propene oxide and oxetane as well. In fact, no measurable amounts of 1,3-dihydroisobenzofuran, 1,3-dihydro-1-methylisobenzofuran, and 3,4-dihydro-1*H*-2-benzopyran were recovered among the labeled decay products from these systems, thus confirming previous experimental evidence pointing to **1** as attacking exclusively the σ_{C-H} bonds of a saturated hydrocarbon chain, while ignoring the σ_{C-C} bonds (4*e*).

Isomerization and fragmentation of phenyloxonium intermediates 7

The fate of the phenyloxonium intermediates **7**, excited by the exothermicity of their formation processes [3*a*], appears to be highly sensitive to the nature of the parent oxygenated substrate and of the reaction environment. In the oxirane systems without added NMe_3 (Table 1), predominant formation of benzodioxane, dihydrobenzofuran, and phenol is observed, whose relative yields are dependent upon the total pressure of the system. Thus, while the relative yield of benzodioxane increases at low pressure (30 Torr), formation of both dihydrobenzofuran and phenol appears more favored at high ether pressure (220 Torr). Taking into account the FT–MS results for the same system, recovery of benzodioxane in significant yields, increasing at low pressure, i.e., under conditions favoring high-energy fragmentation processes, is attributed to the formation of a phenoxenium intermediate **9** from unimolecular fragmentation of the corresponding excited *O*-phenyloxiranium intermediate **7**, reaction [4*a*].

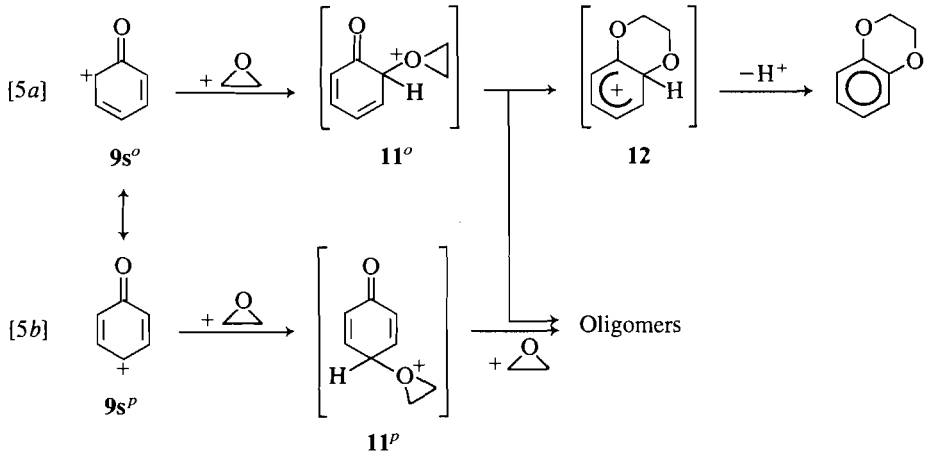


As for the isoelectronic phenylcarbenes and nitrenes, free phenoxenium ion **9** may exist in the singlet (**9s**) or a triplet (**9t**) state, but neither experimental nor theoretical data are available to date with regard to their relative stability and interconversion rate.



In the singlet state configuration, phenoxenium **9** can be represented by resonance structures, with the oxocyclohexadienylium canonical structures **9s**^{o} and **9s**^{p} reasonably contributing more than the **9s** one. As a consequence, singlet phenoxenium ion should act as a typical carbocationic electrophile adding to the high-electron density center of a nucleophilic substrate, with formation of *ortho* and *para* substituted phenols. On the contrary, triplet phenoxenium ion **9t** should formally

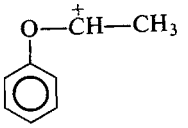
Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/07/12
For personal use only.



maintain most of the positive charge at the O center. Therefore it is expected that **9t** would attack predominantly the C and H centers of a substrate, yielding essentially phenyl ethers and phenol, respectively, as neutral end products.

On these grounds, formation of benzodioxane in the oxirane decay systems is attributed to the addition of a singlet phenoxenium intermediate to the *n*-type center of a second oxirane molecule to yield the oxocyclohexadienyl oxonium intermediates $\mathbf{11}^o$ and $\mathbf{11}^p$ (or their hydroxyphenyl oxonium tautomers), reactions [5*a*,*b*]. The subsequent fate of these intermediate species depends essentially on their structure. Thus, while both isomers $\mathbf{11}^o$ and $\mathbf{11}^p$ (or their tautomers) would proceed in undergoing further nucleophilic addition of oxirane at the side-chain carbon centers to give oligomeric structures, a competitive isomerization pathway [5*a*] is opened exclusively to the *ortho* isomer $\mathbf{11}^o$ (or its tautomer), involving internal nucleophilic attack of the ketonic (or phenolic) oxygen on one of the side-chain carbons and yielding directly a protonated benzodioxane structure, e.g., **12**.[3] In this perspective, sequence [4*a*] → [5*a*] in the oxirane decay systems is favored at the lowest ether partial pressure (30 Torr), because collisional quenching of excited **7**, competing with the fragmentation step [4*a*], is minimized, and because the extent of the secondary oligomerization process [5*b*] is proportionally reduced in favor of the parallel isomerization channel [5*a*].

A lower-energy process, competing with the high-energy fragmentation path [4*a*], is the isomerization of excited **7** to a protonated dihydrobenzofuran structure **10**, reaction [4*b*]. Intermediacy of open-chain transients in reaction [4*b*] appears unlikely on the following grounds. Extensive collisional activation analysis excludes that open-chain isomers of **7** may undergo significant cyclization even at relatively long ion lifetimes (17). This conclusion agrees with the absence of detectable yields of benzocyclic products from the acetaldehyde decay systems (Table 4), wherein only the open-chain 1-phenoxyethyl cations **13** are generated by attack of **1** on the O of the substrate. Hence, it is concluded, in analogy with the two-step mechanism of insertion of unsaturated carbenium ions into σ- and π-bonds (2), that the isomerization step [4*b*] is promoted by the intramolecular nucleophilic interaction of the π system of the phenyl group with the electrophilic C—O Walsh orbitals of the oxirane moiety



13

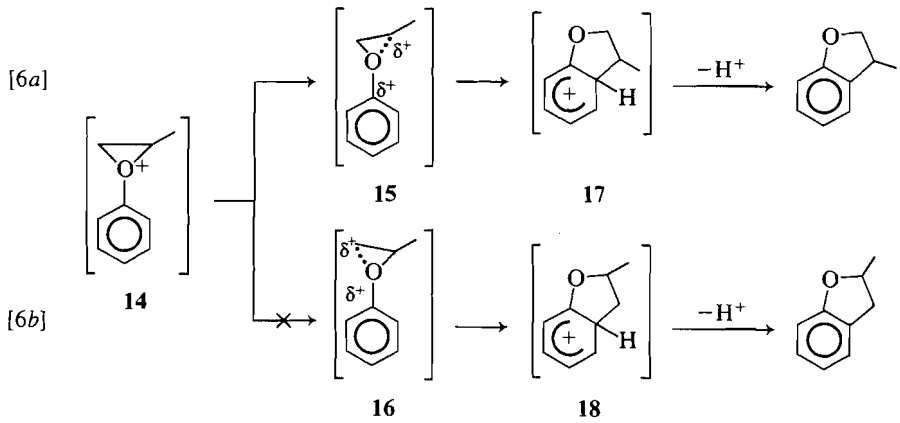
A reaction network similar to [4] → [5] appears operative in the propene oxide decay systems as well (Table 2). In fact, both 2-methylbenzodioxane and 3-methyldihydrobenzofuran represent the most abundant labeled products, in the absence of added NMe_3, whose yields slightly increase by lowering the ether partial pressure from 250 to 30 Torr. This observation is only consistent with a comparable efficiency of the two competing processes analogous to [4*a*,*b*]. In these cases, in fact, an O-phenylated propene oxide intermediate (**14**) is involved, which isomerizes exclusively to the protonated 3-methyldihydrobenzofuran structure (**15**), reaction [6*a*], the alternative isomerization pathway leading to 2-methyldihydrobenzofuran being essentially prevented. Following the previous conclusion concerning isomerization of **7**, this observation is consistent with an isomerization transition state wherein a partial positive charge is developed at the side-chain carbon center before significant interaction with the phenyl ring π orbital is established. It follows that the presence of an electron-releasing methyl substituent at the carbon center renders its migrating rate substantially higher than that of an unsubstituted carbon center. Therefore, it can be expected that the isomerization pathway [6*a*], involving the O-phenylated propene oxide intermediate **14**, is inherently faster than that involving **7**, to the point of becoming comparable to the rate of the competing fragmentation channel, analogous to [4*a*].

No benzocyclic products are recovered from the oxetane decay systems (Table 3). Here, in the absence of NMe_3, most of the activity resides in the aromatic ring of phenol. No simple rationale for the formation of phenol is presently available.[4]

[3] In the absence of NMe_3, neutralization of protonated intermediates such as **12** may occur by several mechanisms, including proton transfer to the substrate itself, to the walls of the reaction vessel, or to traces of nucleophiles invariably present or radiolytically formed in the gaseous decay system.

[4] A possible explanation of these results involves actual formation of O-phenylated oxetane, excited enough to dissociate to phenoxenium and a C_3H_6 moiety, much like the analogous intermediates **7** and **14**, reaction [4*a*]. Here, however, a phenoxenium ion **9t** with the triplet configuration would be preferentially formed, which reacts by hydride-ion abstraction from oxetane yielding preferentially phenol. However, the results obtained in the oxirane systems (Tables 1 and 2) indicate a distinct increase in the formation of products from phenoxenium intermediates with decreasing pressure. This behavior is not paralleled

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/07/12
For personal use only.



The peculiar behavior of oxetane with respect to the oxiranes **3** and **4** following attack of **1** is further shown by the absence of formation of any benzocyclic products. In fact, no observable amounts of 3,4-dihydro-2*H*-1-benzopyran or isomeric methyldihydrobenzofurans were recovered among the tritiated products from oxetane, in spite of specific search (Table 3). It is therefore concluded that O-phenylated oxetane, at variance with the more strained **7** and **14** analogues, has no tendency to fragment to **9** or to isomerize to protonated benzocyclic structures, but it is sufficiently long lived to undergo nucleophilic attack by an external oxetane molecule at a side-chain carbon center, initiating an oligomerization process.

The effect of the NMe_3 base

Addition of 8–9 mol% of a powerful base, such as NMe_3 (P.A. = 225.1 kcal mol^{-1}) (14*b*), to the gaseous mixtures leads to a pronounced increase of the absolute yield of alkenylphenyl ethers (over 3 times) and a profound modification of their isomeric composition (Tables 1–4). In fact, comparative analysis of Tables 2 and 3 reveals a substantially different distribution of alkenylphenyl ethers from propene oxide and oxetane in the absence of NMe_3, whereas, in the presence of base, a similar composition is observed, i.e., *cis*-propenylphenyl ether (43–51%) > *trans*-propenylphenyl ether (33–35%) > isopropenylphenyl ether (15–16%) > allylphenyl ether (0–6%). A rationalization of these results can be attempted by starting from the observation that addition of NMe_3 causes a 3-fold increase of the absolute yield of alkenylphenyl ethers from propene oxide, which is counterbalanced by a greater than 5-fold decrease of the overall yield of benzocyclic products (Table 2). In the oxetane systems, instead, the pronounced 6-fold increase of the absolute yield of alkenylphenyl ethers is accompanied by only a halving of the absolute yield of phenol. It follows that the main path responsible for the formation of alkenylphenyl ethers in the propene oxide/NMe_3 systems involves an NMe_3-induced β-elimination in the phenyloxonium intermediate **14**, although a contribution from deprotonation of its open-chain isomers cannot be excluded.[5] An analogous process is responsible for the formation of phenylvinyl ether in the oxirane/NMe_3 and acetaldehyde/NMe_3 systems (Tables 1, 4).

In the oxetane/NMe_3 systems, on the other hand, a number of ionic species may be involved in the base-induced formation of isomeric alkenylphenyl ethers, including the long-lived O-phenylated oxetane and its open-chain isomers, as well as the progeny of their oligomerization intermediates. Hence, it is suggested that the similar distribution of alkenylphenyl ether observed in the propene oxide/NMe_3 and oxetane/NMe_3 systems does not arise from the interaction of the base with a common intermediate or family of intermediates, but rather can be regarded as an accidental coincidence.

However, restricting the analysis to the relative yields of alkenylphenyl ether from the propene oxide/NMe_3 systems (Table 2), a hint into the regioselectivity of NMe_3 toward the phenyloxonium intermediate **14** can be obtained from the olefin distribution. The observed trend suggests that interaction of the base occurs preferentially with the most acidic hydrogens. In fact the positively charged oxirane ring hydrogens are highly favored over the methyl ones. Among the ring hydrogens the interaction of NMe_3 is mostly directed to the methylene hydrogens rather than to the methine one, due to the presence of the electron-releasing methyl group.

Conclusions

The present investigation confirms the view that the phenylium ion **1** may act essentially as a Lewis acid attacking both σ- and *n*-type bonds. As expected, it displays a large preference for the *n*-type centers as compared to the σ-type ones, as demonstrated by the product distribution of Tables 1–4. In the meantime, the reaction pattern following the attack of **1** at the *n*-center of the selected strained cyclic ethers is significantly different and appears to be related to the stability of the ensuing phenyloxonium intermediates. Thus, while the primary intermediate from O-phenylation of oxetane appears so stable as to undergo further oligomerization processes, intermediates **7** and **14** from O-phenylation of oxirane and propene oxide are rather unstable and readily isomerize to the corresponding benzocyclic isomers **10** and **17**, respectively.

Intramolecular nucleophilic interaction of the π-phenyl orbitals with the electrophilic C—O Walsh orbitals of the oxirane moiety promotes an isomerization process that is analogous to the nucleophilic step involved in the insertion of unsaturated carbenium ions into σ- and π-bonds of hydrocarbons. A high-energy unimolecular fragmentation process, competing with the isomerization pathway, leads to the forma-

by the yield of phenol from oxetane, thus casting doubts on a common reaction pathway.

A unified view may be obtained if, at low ether pressure, **9t** has partly converted to the conceivably more stable singlet configuration (**9s**). In this case, however, benzocyclic products containing two oxygen atoms are expected to be formed, contrary to experimental data.

[5]Deprotonation of open-chain isomers of **14** is probably the predominant source of alkenylphenyl ethers in the absence of added NMe_3.

tion of singlet phenoxenium ion from both **7** and **14** excited intermediates, both under FT–MS and nuclear decay conditions.

By analogy with the results of related solvolytic studies (18), singlet phenoxenium ion is able to attack its parent ether with the formation of a C—O bond, as demonstrated by the recovery of benzodioxane derivatives among the labeled product from these systems.

Thus, the present results have not only extended our knowledge of the reactivity of phenylium ion **1** toward *n*-type organic molecules, but have also opened up a way to investigating the intimate nature and the kinetic behavior of phenoxenium ions in the dense gas state and to compare them with those observed in solution.

In view of the considerable interest in the chemistry of phenoxenium ions, particularly in connection with phenol oxidation in general (19) and biosynthetic-type oxidative coupling reactions in particular (20), development of alternative procedures to generate and investigate singlet and triplet phenoxenium ions, such as those reported in the present study, deserves further attention.

Received January 25, 1988

MICHAEL P. MURCHIE, JOHN W. BOVENKAMP, ANDRÉ RODRIGUE, KIMBERLEY A. WATSON, and SUZANNE FORTIER. Can. J. Chem. **66**, 2515 (1988).

The syntheses, in ethereal solvents, of the complexes of 15-crown-5 and cyclohexano-15-crown-5 with lithium, sodium, and potassium phenoxide are described. The two macrocycles form complexes with lithium and sodium phenoxide with host:guest ratios of 1:2. Potassium phenoxide, however, was complexed by the two macrocycles to give products with macrocycle:salt ratios of 1:1. Crystals of 15-crown-5·2LiOPh were obtained for X-ray diffraction structure determinations. In fact, the crystal structures of two co-crystallizing polymorphs of this complex (**1***a* and **1***b*) have been determined. Polymorph **1***a* crystallizes in space group $P\bar{1}$ with $a = 11.386(4)$, $b = 11.901(4)$, $c = 10.654(4)$ Å, $\alpha = 106.53(3)$, $\beta = 112.60(3)$, $\gamma = 106.52(3)°$, and $Z = 2$. Polymorph **1***b* crystallizes in space group $P2_1/n$ with $a = 15.355(4)$, $b = 11.642(2)$, $c = 13.595(6)$ Å, $\beta = 104.56(3)°$, and $Z = 4$. Both structures were solved by direct methods, and refined by full-matrix least-squares calculations to residuals, R, of 0.053 and 0.055 for polymorphs **1***a* and **1***b*, respectively. The structures of the two polymorphs differ only in the orientation of the phenoxides. The structures show a dimer, $(15\text{-crown-5}\cdot 2\text{LiOPh})_2$, which consists of an aggregate of four lithium phenoxide molecules complexed by two 15-crown-5 macrocycles. The two lithiums of each monomeric unit of this dimer have different crystallographic and chemical environments. One lithium is coordinated to all five oxygens of the macrocycle and to one of the phenoxide oxygens while the other lithium is coordinated to only one oxygen of the macrocycle and to three phenoxide oxygens.

MICHAEL P. MURCHIE, JOHN W. BOVENKAMP, ANDRÉ RODRIGUE, KIMBERLEY A. WATSON et SUZANNE FORTIER. Can. J. Chem. **66**, 2515 (1988).

On décrit les synthèses, dans des solvants éthérés, des complexes de la 15-couronne-5 et de la cyclohexano-15-couronne-5 avec les phénolates de lithium, de sodium et de potassium. Les deux macrocycles forment des complexes avec les phénolates de lithium et de sodium avec des rapports 1:2. Toutefois, le phénolate de potassium est complexé par les deux macrocycles et il donne des produits possédant des rapports de macrocycle à sel de 1:1. On a pu obtenir des cristaux du complexe 15-couronne-5·2LiOPh d'une qualité appropriée pour la diffraction des rayons-X. En fait, on a déterminé les structures cristallines de deux polymorphes de ce complexe (**1***a* et **1***b*) qui co-cristallisent. Le polymorphe **1***a* cristallise dans le groupe d'espace $P\bar{1}$, avec $a = 11{,}386(4)$, $b = 11{,}901(4)$ et $c = 10{,}654(4)$ Å, $\alpha = 106{,}53(3)$, $\beta = 112{,}60(3)$ et $\gamma = 106{,}52(3)°$ et $Z = 2$. Le polymorphe **1***b* cristallise dans le groupe d'espace $P2_1/n$, avec $a = 15{,}355(4)$, $b = 11{,}642(2)$ et $c = 13{,}595(6)$ Å, $\beta = 104{,}56(3)°$ et $Z = 4$. On a résolu les deux structures par des méthodes directes et on les a affinées par la méthode des moindres carrés (matrice entière) jusqu'à des valeurs résiduelles de R de 0,053 et de 0,055 respectivement pour les polymorphes **1***a* et **1***b*. Les structures des deux polymorphes ne diffèrent que par l'orientation des groupements phénolates. Les structures présentent un dimère, $(15\text{-couronne-5}\cdot 2\text{LiOPh})_2$, qui consiste en un agrégat de quatre molécules de phénolate de lithium qui sont complexées par deux macrocycles 15-couronne-5. Les deux lithiums de chacune des unités monomères de ce dimère possèdent des environnements cristallographique et chimique différents. Un des lithiums est coordonné à chacun des cinq oxygènes du macrocycle et à un oxygène de phénolate alors que l'autre lithium est coordonné à un seul oxygène du macrocycle et à trois oxygènes de phénolate.

[Traduit par la revue]

Introduction

In 1967, Pedersen (1) showed that crown ethers form stable complexes with alkali metal salts. Since then, crown ether complexes have been extensively studied. Several reviews (2–9) have been written on this topic. A large number of alkali metal salt complexes with 15-crown-5 (10–13), benzo-15-crown-5 (14–16), and cyclohexano-15-crown-5 (1) have been prepared and isolated in the solid state. The structures of several complexes of benzo-15-crown-5 and 15-crown-5 with alkali metal salts have been determined by X-ray crystallography; e.g. benzo-15-crown-5·X (X = Li(Pic)·$2H_2O$ (17), Na(Pic) (18), (1/2)(K(Pic)) (19), and Cs(Pic) (20); Pic = 2,4,6-trinitrophenolate) and 15-crown-5·Y (Y = NaSCN·(1/2)H_2O (10) and Na(ethylacetoacetate) (11)).

Complexes of 15-crown-5, benzo-15-crown-5, and cyclohexano-15-crown-5 with alkali metal salts have been shown to have macrocycle:salt stoichiometries of only 1:1 (for lithium and sodium salts) and 2:1 (for potassium salts); e.g. butylbenzo-15-crown-5·LiNCS (1), 15-crown-5·Na(ethylacetoacetate) (11) and $(\text{benzo-15-crown-5})_2\cdot$K(Pic) (19). The complexation of a cation by a macrocycle and the stoichiometry of the resulting macrocycle salt complex are dependent upon a number of factors; including (*i*) compatibility of cavity size and cation diameter, (*ii*) anion effects, and (*iii*) solvent effects (2–9). Recently, Rodrigue *et al.* (21) demonstrated the importance of solvent effects in the formation of 18-crown-6 macrocycle salt complexes. Using ethereal solvents such as 1,2-dimethoxyethane, tetrahydrofuran, and diethyl ether, complexes were isolated which exhibited novel macrocycle:salt ratios of 1:2 and 1:3; e.g. dicyclohexano-18-crown-6(isomer B)·2KOPh,

TABLE 1. The complexes, their host:guest ratios, the solvents used, and the yields obtained for the complexes

Complex number	Macrocycle[a] (mmol)	Salt[a] (mmol)	Macrocycle:salt[b] ratio	Solvent used[c] (mL)	% Yield of complex
1	15C5(5.43)	LiOPh(11.30)	1:2	Hexane(70) + Et_2O(90)	94
2	15C5(9.99)	NaOPh(20.83)	1:2	THF(50) + Et_2O(85)	70
3	15C5(10.19)	KOPh(10.18)	1:1	THF(50) + Et_2O(43)	80
4	C-15C5(2.10)	LiOPh(4.25)	1:2	Et_2O(30)	89
5	C-15C5(2.52)	NaOPh(5.11)	1:2	THF(2) + Et_2O(35)	78
6	C-15C5(5.50)	KOPh(2.73)	1:1	Et_2O(45)	57

[a]15C5 and C-15C5 represent 15-crown-5 and cyclohexano-15-crown-5, respectively.
[b]With the exception of **6**, the macrocycle:salt ratio remains unchanged when an excess or deficit of phenoxide salt is used (see Experimental).
[c]The solvent or solvent mixture in which the complex was formed. Et_2O and THF are used to designate diethyl ether and tetrahydrofuran. See Experimental for isolation and purification procedures.

dicyclohexano-18-crown-6(isomer A)·2NaOPh and 18-crown-6·3NaOPh. In each case, only 1:1 complexes would have been expected. X-ray crystal structures (22) have been obtained for dicyclohexano-18-crown-6(isomer B)·2KOPh and dicyclohexano-18-crown-6(isomer A)·2NaOPh.

The above results led to the present study in which the complexes of lithium, sodium, and potassium phenoxide with 15-crown-5 and cyclohexano-15-crown-5 have been isolated from the ethereal solvents tetrahydrofuran and diethyl ether. The preparation and characterization of six complexes that exhibit novel 1:2 (macrocycle:salt) ratios with lithium and sodium salts, and 1:1 ratios with potassium salts are described. These six complexes are as follows:

1 15-crown-5·2LiOPh

2 15-crown-5·2NaOPh

3 15-crown-5·KOPh

4 cyclohexano-15-crown-5·2LiOPh

5 cyclohexano-15-crown-5·2NaOPh

6 cyclohexano-15-crown-5·KOPh

The X-ray crystal structure of the complex formed between 15-crown-5 and lithium phenoxide (**1**) is reported and discussed.

Experimental

Anhydrous diethyl ether was dried over sodium wire. Hexane was dried over molecular sieves (Type 3A). Reagent grade tetrahydrofuran and 1,2-dimethoxyethane were distilled from lithium aluminum hydride and stored over molecular sieves. Lithium, sodium, and potassium phenoxides were prepared as described in refs. 21 and 23. Commercially obtained 15-crown-5 was stored over molecular sieves. Cyclohexano-15-crown-5 (*cis* isomer) was prepared and purified according to the procedure described in ref. 24.

Great care was taken throughout this work to protect the samples from atmospheric moisture. All complexation reactions, the preparation of samples for elemental analysis and the preparation of infrared, ultraviolet, and nmr spectroscopic samples were carried out in a Dri-Lab (Vacuum Atmospheres Corp.) under an argon atmosphere.

*Standard synthetic method used for complexes **1–5***

In this procedure, 1 equiv. of the macrocycle was added to a solution containing 2 equiv. of the salt in the cases of LiOPh and NaOPh, and 1 equiv. of the salt in the case of KOPh.

In a typical reaction, LiOPh (11.30 mmol) was dissolved in a mixture of diethyl ether (90 mL) and hexane (40 mL). The 15-crown-5 (5.43 mmol), dissolved in hexane (30 mL), was added to the LiOPh solution. A white precipitate was formed immediately upon addition of the 15-crown-5. The reaction mixture was stirred for 1.5 h at room temperature. The precipitate was isolated by suction filtration and then dried under high vacuum (<0.001 Torr) in a drying pistol at 56°C for 16 h. The white solid was identified by proton NMR spectroscopy and elemental analysis as 15-crown-5·2LiOPh, and the yield obtained was 5.12 mmol, which corresponds to a 94% yield based on 15-crown-5 (see Table 1).

In Table 1 are listed the amounts of reactants, the solvent (or solvent mixture) used and its volume, and the % yield for each of the complexes. Table 2 gives the melting point and elemental analysis obtained for each complex. The complexes were further characterized by ^1H nmr, infrared, and ultraviolet spectroscopy. Complex **1** was also characterized by single crystal X-ray diffraction techniques.

*Other methods used for complexes **1–5**. Reactions using an (a) excess or (b) deficit of phenoxide salt*

(a) Excess of phenoxide. A procedure similar to that described above was used (see below for details) except that 1 equiv. of the macrocycle was added to a solution containing at least 3 equiv. of the phenoxide salt in the cases of LiOPh and NaOPh, and 2 equiv. of the salt in the case of KOPh. In all cases, the macrocycle:salt ratios of the complexes formed were the same as those of the complexes formed by the standard method previously described and listed in Table 1.

In a typical reaction, LiOPh (3.98 mmol) was dissolved in a mixture of anhydrous solvents (diethyl ether (20 mL) and hexane (10 mL)). A solution of 15-crown-5 (1.00 mmol) dissolved in hexane (10 mL) was added to the LiOPh solution. A large quantity of white precipitate was formed immediately upon addition of the 15-crown-5. The reaction mixture was stirred for 2 h at room temperature. The white solid was isolated by suction filtration and then dried under vacuum (0.001 Torr) at 56°C for 16 h. The white solid was identified as 15-crown-5·2LiOPh, and the yield obtained was 0.98 mmol which corresponds to a 98% yield based on 15-crown-5.

(b) Deficit of phenoxide. Again, the procedure used was similar to that described for the standard synthetic method except that 1 equiv. of the macrocycle was added to a solution containing 1 equiv. of the salt in the cases of LiOPh and NaOPh, and half of an equivalent of the salt in the case of KOPh. The macrocycle:salt ratio of the complexes formed were the same as those of the complexes formed by the standard synthetic method, and listed in Table 1.

In a typical reaction, NaOPh (1.80 mmol) was dissolved in a mixture of tetrahydrofuran (1 mL) and diethyl ether (10 mL). A solution of cyclohexano-15-crown-5 (1.89 mmol) dissolved in diethyl ether (5 mL) was added to the NaOPh solution. After stirring at room temperature for 15 min, a white precipitate formed. The mixture was stirred at room temperature for a further 2 h. The solid was isolated by suction filtration and then dried under vacuum at 56°C for 17 h. The white solid was identified as cyclohexano-15-crown-5·2NaOPh, and the yield obtained was 0.74 mmol which corresponds to an 83% yield based on NaOPh.

*Synthesis of complex **6***

Diethyl ether (10 mL) was added to solid potassium phenoxide (2.73 mmol) forming a colorless solution over a white solid (potassium

TABLE 2. Melting points and elemental analyses of the complexes

Complex number	Melting point (°C)	Calculated					Found				
		C	H	Li	Na	K	C	H	Li	Na	K
1	196.0–197.0	62.84	7.19	3.30			63.02	7.26	3.58		
2	151.0–152.0	58.40	6.68		10.16		58.12	6.66		9.80	
3	169.0–170.5	54.52	7.15			11.09	54.30	7.36			11.30
4	185.0–185.6	65.81	7.65	2.92			66.10	7.90	2.95		
5	136.0–137.0	61.65	7.16		9.08		61.35	7.43		8.80	
6[a]	83–87	59.09	7.69			9.62	55.39	7.78			9.91

[a]A satisfactory elemental analysis could not be obtained for complex **6**. Several attempts were made but, although the integrated proton magnetic resonance spectra were in agreement with the 1:1 ratio shown in Table 1, the complex was too unstable to give either a sharp melting point or a satisfactory elemental analysis. The elemental analysis shown was the best result obtained.

phenoxide is essentially insoluble in diethyl ether). Cyclohexano-15-crown-5 (5.50 mmol), dissolved in diethyl ether (35 mL), was added to the potassium phenoxide – diethyl ether mixture. After stirring for less than 5 min, a light brown – cloudy solution over a very small quantity of light-colored precipitate was observed. A powdery grey–brown precipitate at the bottom of a translucent yellow–brown solution was obtained after 24 h. The solution was concentrated to approximately 50% of its original volume, and the solid was isolated by suction filtration. The powder turned a purple colour while under vacuum (0.001 Torr) at 56°C for 20 h. The powder had the proton NMR spectrum expected for cyclohexano-15-crown-5·KOPh, and the yield obtained was 1.54 mmol which corresponds to a 57% yield based on KOPh. This compound is discussed further in the Results and discussion section.

X-ray crystal structures of polymorphs **1***a and* **1***b of 15-crown-5·2LiOPh*

Suitable crystals of 15-crown-5·2LiOPh were obtained from a solution of the complex (0.128 g) in a mixture of diethyl ether/dimethoxyethane (3 mL/5 mL). The solution was slowly evaporated to dryness in an argon atmosphere. Crystals of both polymorphs, **1***a* and **1***b*, were obtained from this sample. The discovery of the two polymorphs was by serendipity and was due to the fact that more than one crystal was selected for analysis. The proportion of the two polymorphs in the mixture is not known. The mixture of the crystalline polymorphs had a melting point of 196.5–197.0°C.

Pertinent data about the crystals used and the measurement of diffraction intensities are summarized in Table 3. The crystals used in the diffraction experiments were mounted inside glass capillaries in a moisture-free environment. The intensity data were collected on an Enraf-Nonius CAD-4 diffractometer using graphite monochromated MoKα (λ = 0.71073 Å) radiation. In each case, intensities were collected by the ω/2θ scanning procedure and three reflections were measured after every 7200 s of exposure time to check on the stability of the crystal. No evidence of crystal decay was detected in either case. The data were corrected for Lorentz and polarization effects; absorption corrections were not considered necessary. The structure of **1***b* was solved routinely by direct methods using the program

MULTAN 80 (25). For **1***a*, a reasonable fragment could be found in the top MULTAN solution but it was not possible to extend it through standard Fourier techniques. As this suggested proper orientation but incorrect position of the fragment in the unit cell, the space group was relaxed to $P1$, and the partial structure was used for Karle recycling. After one cycle, all of the atoms were identified in the *E*-map and the correct position in $P\bar{1}$ was determined. The positions of all the hydrogen atoms for **1***a* were found in the difference Fourier map. For **1***b*, 28 of the total of 30 hydrogen atoms were located in the difference Fourier maps, the remaining two were calculated. The structures were refined by full-matrix least-squares using all reflections with $I \geq 3\sigma(I)$. Anisotropic temperature factors were used for the non-hydrogen atoms. The hydrogen atoms were assigned isotropic temperature factors equal in magnitude to the equivalent isotropic temperature factors of their parent atoms. They were included in the calculations but they were not refined. The function minimized was $\Sigma w||F_o| - |F_c||^2$, where $w = 1/\sigma^2(|F_o|)$. A correction for isotropic secondary extinction effect was included in each refinement. The scattering factors were taken from Cromer and Waber (26). The fractional coordinates and equivalent isotropic temperature factors of the non-hydrogen atoms are presented in Tables 4 and 5. All calculations were done on a PDP 11/23 computer using the Enraf-Nonius SDP program package (27).

Nuclear magnetic resonance spectra

Integrated proton magnetic resonance spectra of the complexes were obtained using a Varian XL-200 (at 200.058 MHz using a 5 mm computer switchable probe) spectrometer. Chemical shifts were referenced relative to internal TMS. Typically, 20–50 mg samples of the complexes were dissolved in CD_3OD (0.5 mL). The spectra were in agreement with the structure of the complexes shown in this paper.

Ultraviolet spectra of complexes 1–6 and the alkali metal phenoxides

The ultraviolet spectra were obtained using a Varian Cary 2300 spectrophotometer. The complexes and salts were dissolved in anhydrous 1,2-dimethoxyethane to concentrations of ca. 2×10^{-3} *M*. Samples of the resulting solutions were loaded into ultraviolet cells (0.1 cm). The reference cell contained anhydrous 1,2-dimethoxyethane.

Infrared spectra and elemental analyses of the complexes

Infrared spectra were obtained on a Perkin Elmer (model 283) infrared spectrophotometer using Nujol mulls of the complexes and ZnSe optically flat windows. The spectra obtained were in agreement with the structure of the complexes shown in this paper.

Elemental analyses for complexes **1–6** (see Table 2) were carried out by Guelph Chemical Laboratories Ltd., Guelph, Ontario.

Results and discussion[2]

Synthesis of complexes 1–6 and the novel macrocycle:salt ratios

Pure samples of complexes **1–5** were prepared in good yield by the addition of 15-crown-5 or cyclohexano-15-crown-5 to solutions of lithium, sodium, or potassium phenoxide in ethereal solvents. With the exception of complex **6**, the macrocycle:salt ratio in each complex was invariant regardless of the proportions of the reactants used in the synthesis.

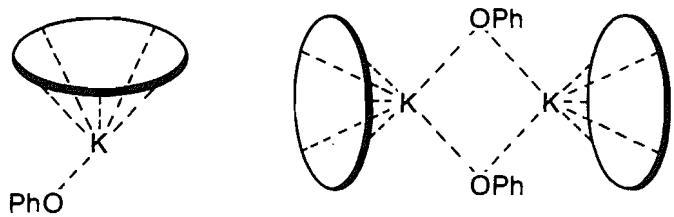
Complex **6** was isolated only from the reaction of cyclohexano-15-crown-5 and potassium phenoxide in a proportion of 2:1, respectively. Reactions of cyclohexano-15-crown-5 and potassium phenoxide at stoichiometries less than 2:1 led to tars. All attempts to isolate pure products from these tars were unsuccessful. Table 1 gives the amounts of reactants and solvents and the yields of the complexes obtained. Infrared spectra obtained on Nujol mulls of the complexes showed the absence of uncomplexed macrocycle and phenoxide. The macrocycle:salt ratios in complexes **1–6** were determined by dissolving the complexes in CD_3OD, obtaining the ^1H nmr spectra, and comparing the integrated areas of the aromatic protons with the 15-crown-5 resonances in the case of complexes **1–3**, and the aromatic protons with the macrocyclic ring and cyclohexano resonances in the case of complexes **4–6**. Complexes **1–5** gave good melting point ranges (Table 2). The macrocycle:salt ratios of complexes **1–5** were confirmed by elemental analysis (Table 2). Complex **6** could not be isolated in a pure state although several attempts were made. Integrated proton magnetic resonance spectra of **6** showed a 1:1 ratio, however, the complex was too unstable to give either a sharp melting point or a satisfactory elemental analysis. The elemental analysis result shown in Table 2 for **6** was the best result obtained.

Many alkali metal salts form aggregates in ethereal solvents such as tetrahydrofuran, diethyl ether, and dimethoxyethane. The degree of association of ion pairs is dependent on the solvent, and the size, charge density, and the hardness of both the cation and anion (28, 29). In Jackman and Lange's review (28), solvents are separated into four classes with respect to the occurrence of free ions, ion pairs, and aggregates of ion pairs. Weakly polar solvents like tetrahydrofuran and diethyl ether were termed class B solvents. In this class of solvents, lithium, sodium, and potassium phenoxide are expected to form hexamers, tetramers, and (or) dimers similar to those observed in the X-ray crystal structures of several alkali metal enolates; e.g. the hexameric species $[Li^+(pin^-)]_6$ and $[K^+(pin^-)\cdot THF]_6$ (30) (where pin^- = the enolate of pinacolone); the tetrameric species $[Na^+(pin^-)\cdot pinacolone]_4$ (30) and $[Li^+(methyl\text{-}3,3\text{-}dimethylbutanoate^-)\cdot THF]_4$ (31); and the dimeric species $[Li^+(tert\text{-}butylpropionate^-)\cdot TMEDA]_2$ and $[Li^+(tert\text{-}butyl\text{-}2\text{-}methylpropionate^-)\cdot TMEDA]_2$ (31) (where TMEDA = *N,N,N',N'*-tetramethylethylenediamine). In more polar solvents (class C and D) the phenoxide salts are expected to exist as more highly solvated monomers.

It has been shown that 15-crown-5, or its derivatives, generally react with alkali metal salts containing Li^+, Na^+, and K^+ to form complexes with macrocycle:salt ratios of 1:1 (Li^+ and Na^+) and 2:1 (K^+) (1, 6, 7, 9, 16). These ratios are often attributed to how well the cation fits into the cavity of the macrocycle. The cation diameters of Li^+ (1.52 Å) and Na^+ (2.04 Å) are compatible with the diameter of the 15-crown-5 cavity (1.72–1.84 Å) (9) and consequently, 1:1 complexes are formed; e.g. butylbenzo-15-crown-5·LiSCN (1) and 15-crown-5·NaSCN·(1/2)H_2O (10). On the other hand, the K^+ cation (diameter = 2.76 Å) (9) is too large to fit into the cavity of 15-crown-5, thus allowing 2:1 macrocycle:salt sandwich complexes to be formed; e.g. $(benzo\text{-}15\text{-}crown\text{-}5)_2\cdot KX$ (X = I^-, Pic, and Dnb·2HDnb; where Pic = picrate and Dnb = dinitrobenzoate) (16).

The present work clearly shows that, in weakly polar solvents, complexes of 15-crown-5 and cyclohexano-15-crown-5 with lithium and sodium phenoxide (i.e. complexes **1**, **2**, **4**, and **5**) are obtained with macrocycle:salt ratios of 1:2. The 1:2 ratio is attributed to the tendency of the alkali metal phenoxides to form aggregates in ethereal solutions. The complexing abilities of 15-crown-5 and cyclohexano-15-crown-5 are not sufficient to break up the alkali metal phenoxide aggregates into contact ion pairs.



I II

FIG. 1. Possible orientations for the complexes with potassium phenoxide. The ovals represent the macrocycles.

The complexes with potassium phenoxide (i.e. **3** and **6**), which were expected to have the 2:1 macrocycle:salt ratio of a sandwich complex, had a 1:1 stoichiometry. Such a stoichiometry indicates that the structures of these complexes may consist of a contact ion pair complexed to the macrocycle (**I**) or a dimeric structure containing a potassium phenoxide aggregate (**II**) (see Fig. 1). We feel that the latter structure is the correct one and are attempting to prove this by obtaining suitable crystals of **3** for an X-ray diffraction structure determination (see section on ultraviolet spectra for further discussion).

*Crystal structures of 15-crown-5·2LiOPh (**1**a and **1**b)*

The 15-crown-5·2LiOPh complex crystallized to give two polymorphs (**1***a* and **1***b*). The ORTEP diagrams of **1***a* and **1***b* are shown in Figs. 2 and 3, respectively. Polymorphs **1***a* and **1***b* exhibit structures which differ only in the orientation of the phenoxides. The structures may simply be described as an aggregate of four lithium phenoxide units complexed by two crown ethers. Lithium–oxygen bond distances and angles appear in Table 6; average and range of bond distances and angles of the macrocycles and of the phenoxides are given in Table 7; and macrocyclic ring torsion angles are presented in Table 8.

The structures of **1***a* and **1***b* are very similar. The differences between them (Tables 6, 7, and 8) are very minor and therefore, discussion of the crystal structures will be limited to the former. In **1***a*, there is a center of a symmetry situated midway between O(16) and O(16′). There are two different chemical environments for the lithium atoms. Li(1) is coordinated to only one of the pentaether oxygens (i.e. O(1)) at a distance of 2.155(4) Å and to three phenoxide oxygens (i.e. O(16), O(16′), and O(23)) at an average distance of 1.90(3) Å. Figure 2 and the values in Table 6 indicate that the geometry around Li(1) is roughly tetrahedral. Li(2) lies 0.63(1) Å (0.65(1) Å in **1***b*) out of the mean plane defined by the five oxygens of the crown. It is coordinated to all five of the pentaether oxygens at distances ranging from 2.210(4)–2.531(5) Å with an average value of 2.3(1) Å. In addition, Li(2) is coordinated to one phenoxide oxygen, O(23), located at a distance of 1.866(4) Å. It is worth noting that the distance between the Li^+ ions and the phenoxide oxygens are all significantly shorter than those between the Li^+ ions and the crown oxygens. Thus, stronger interactions exist between the Li^+ cations and the phenoxide oxygens of the aggregate than the Li^+ ions and the crown oxygens.

The average lithium – pentaether oxygen distance for Li(2) in

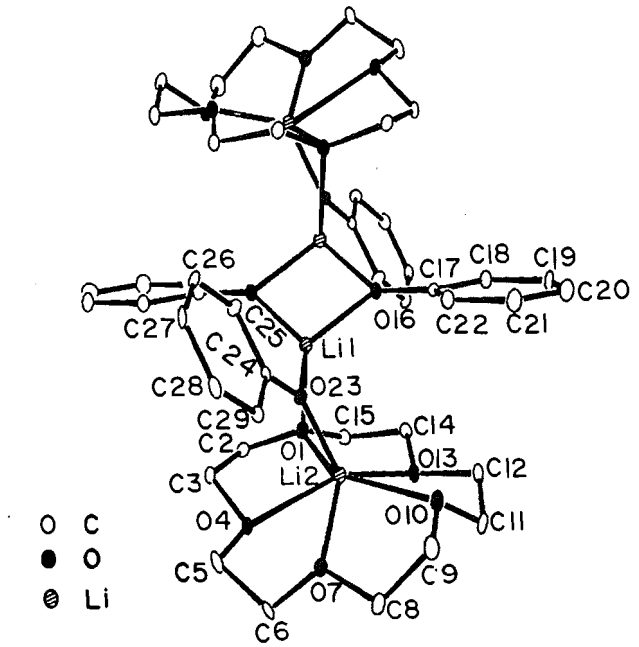


FIG. 2. ORTEP diagram and atom numbering scheme for 15-crown-5·2LiOPh (**1***a*).

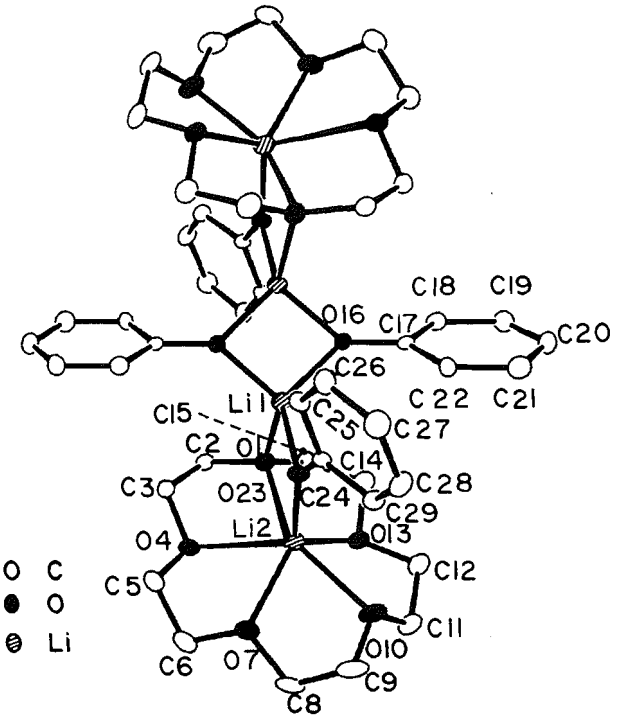

FIG. 3. ORTEP diagram and atom numbering scheme for 15-crown-5·2LiOPh (**1***b*).

15-crown-5·2LiOPh is longer than other lithium – crown ether oxygen distances found in the literature. For example, the average lithium – crown ether oxygen distance is 2.10 Å for 18,18′-spirobi-(19-crown-6)·2LiI·4H_2O (32), 2.10 Å for 18-crown-6·$LiClO_4$·2H_2O (33), 2.03 Å for 18-crown-6·2LiSCN·2H_2O (33), 2.07 Å for benzo-13-crown-4·LiNCS (34), and 2.04 Å for dibenzo-14-crown-4·LiNCS (35). This shows that for 15-crown-5·2LiOPh the $Li(2)^+$ – phenoxide oxygen interactions are stronger than the $Li(2)^+$ – pentaether oxygen interactions. This results in the $Li(2)^+$ ion being pulled out of the crown ether pocket with a subsequent lengthening of the Li(2) – pentaether oxygen distances. The lithium – phenoxide oxygen distances in 15-crown-5·2LiOPh are consistent with the lithium – enolate oxygen distances of 1.90–1.95 Å in lithium-*tert*-butylpropionate·TMEDA and lithium-*tert*-butyl-2-methylpropionate·TMEDA (31), and 1.849 Å in lithium-2,6-di-*tert*-butylphenoxide (36).

The 15-crown-5·2LiOPh dimer (Fig. 2) contains an Li_2O_2 four-membered ring comprised of Li(1), O(16), Li(1′), and O(16′). In this four-membered ring, the Li(1)—Li(1′) distance of 2.55(1) Å in **1***a* (2.58(1) Å in **1***b*) is shorter than the lithium–lithium bond distance of 2.67 Å in Li_2 (37, 38). Other complexes that exhibit short lithium–lithium distances are known. For example, lithium–lithium distances of 2.34 Å in [(*N*-(2-lithiocyclohexenyl)-*N*,*N*′,*N*′-trimethyl-1,3-propanediamine]$_2$ (39, 40), 2.37 Å in $(\eta^5\text{-}C_5H_4)_2Fe(N_3C_9H_{23})Li_2]_2$ (40, 41), 2.40 Å in cyclohexyl lithium (40, 42), and 2.57 Å in tetrameric methyllithium (40, 43) have been reported.

The structure of the phenoxide aggregate in the 15-crown-5·2LiOPh complex has many similarities to that described for dicyclohexano-18-crown-6(isomer A)·2NaOPh (22). In dicyclohexano-18-crown-6(isomer A)·2NaOPh, four sodium phenoxides form an aggregate, and the four sodium ions are complexed by two dicyclohexano-18-crown-6(isomer A) macrocycles. In addition, dicyclohexano-18-crown-6(isomer A)·2NaOPh contains two unique sodium ions, one of which is coordinated to one crown oxygen and three phenoxide oxygens; the other of which is coordinated to all six of the crown oxygens and only one phenoxide oxygen.

The bond lengths and angles of the 15-crown-5 ring (Table 7) are similar to those observed in other complexes such as 15-crown-5·NaSCN·(1/2)H_2O (10), 15-crown-5·$SnCl_4$·2H_2O (44), and 15-crown-5·$CuBr_2$·2H_2O (45). The C—C bond lengths in **1***a* show the characteristic shortening with an average value of 1.500(5) Å (1.46(3) Å in **1***b*). An unusually short carbon–carbon distance of 1.376(9) Å was observed for the C(8)—C(9) bond in **1***b*, however, the reason for such a short carbon–carbon bond distance is not apparent. The C—O bond lengths have an average value of 1.43(1) Å, and the O—C—C and C—O—C angles have averaged values of 108(1)° and 113(2)°, respectively. In undistorted cyclic polyethers the torsion angles about the C—C bonds are synclinal and those about C—O bonds are antiperiplanar. As can be seen from Table 8, these values are found in the present structures of **1***a* and **1***b* with the exception of the torsion angle around the C(9)—O(10) bond. This conformation of the 15-crown-5 ring is also present in the structures of 15-crown-5·Na(ethylacetoacetate) (11), 15-crown-5·NaSCN·(1/2)H_2O (10), and 15-crown-5·$SnCl_4$·2H_2O (44) (see Table 8).

Ultraviolet spectra of the complexes

The λ_{max} values from the ultraviolet spectra of the phenoxide anion in the complexes **1–6** and the alkali metal phenoxides in 1,2-dimethoxyethane are given in Table 9. The λ_{max} values for lithium, sodium, and potassium phenoxides themselves, which are expected to exist as dimers and (or) higher aggregates of ion pairs in this solvent, are similar to those reported previously by Zaugg and Schaeffer (46) and Rodrigue *et al.* (21). The λ_{max} values for the phenoxide in **1**, **2**, **4**, and **5**, all of which have 1:2 macrocycle:salt ratios, are essentially identical with those found for lithium and sodium phenoxide themselves. This indicates that the Li^+ and Na^+ ions are not being complexed strongly and

that the LiOPh and NaOPh salt molecules are associated more strongly with each other than with the macrocycles. In the case of 15-crown-5·2LiOPh, the X-ray crystal structure shows that the LiOPh molecules are associated more strongly with each other than with the macrocycles (*vide supra*). As found for 15-crown-5·2LiOPh (**1**), the ultraviolet data suggest that the 15-crown-5 macrocycles in **2**, **4**, and **5** form complexes with aggregates of lithium and sodium phenoxide. Therefore complexes **2**, **4**, and **5** may have structures similar to that of **1**. Work is underway to obtain crystal structures of these complexes.

A similar situation was observed for the 1:2 and 1:3 host:guest complexes of sodium and potassium phenoxide with 18-crown-6 and its derivatives (21). The λ_{max} value of dicyclohexano-18-crown-6(isomer A)·2NaOPh in dimethoxyethane was identical to the value obtained for NaOPh itself (21), indicating that the macrocycle very likely was complexed to an aggregate of NaOPh. The crystal structure of dicyclohexano-18-crown-6(isomer A)·2NaOPh (22) confirmed this and showed two macrocycles complexed to an aggregate of four NaOPh molecules.

The λ_{max} values for the 1:1 macrocycle:salt complexes **3** and **6** are also essentially identical to that obtained for potassium phenoxide itself. This indicates that, similar to the situation for LiOPh and NaOPh, the K^+ ions are not being complexed strongly and that the KOPh units are associated more strongly

TABLE 9. λ_{max} from the ultraviolet spectra of the phenoxide anion in the complexes **1–6** and the phenoxide salts dissolved in dimethoxyethane

Complex number	Complex	λ_{max} (nm)
1	15-crown-5·2LiOPh	290
2	15-crown-5·2NaOPh	300
3	15-crown-5·KOPh	312
4	C-15-crown-5·2LiOPh	290
5	C-15-crown-5·2NaOPh	300
6	C-15-crown-6·KOPh	310
	LiOPh	293
	NaOPh	301
	KOPh	311

with each other than with the macrocycles. In contrast, the λ_{max} for the 1:1 KOPh complexes with 18-crown-6, its derivatives and cryptand [2.2.2] (21) were significantly greater than the value for the KOPh itself. This indicates that, very likely, the macrocycles were complexed to single ion pairs rather than associated ion pairs. Therefore, this suggests that aggregates of KOPh are to be expected in the 1:1 complexes with 15-crown-5 and cyclohexano-15-crown-5. One possible structure for complexes **3** and **6** is a KOPh dimer sandwiched between two macrocycles (see **II** in Fig. 1).

The dimeric structure depicted for **II** (Fig. 1) has been observed in the crystal structure of (18-crown-6·$RbNCS)_2$ (47), (18-crown-6·$CsNCS)_2$ (48), and [benzo-15-crown-5·Ba(3,5-dinitrobenzoate)$_2]_2$ (49).

Kinetics of hydride transfer between nitrogen heteroaromatic cations

JOHN W. BUNTING AND MARK A. LUSCHER
Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received March 14, 1988

JOHN W. BUNTING and MARK A. LUSCHER. Can. J. Chem. **66**, 2524 (1988).

The kinetics of the reduction of the 3-cyano-1-methylquinolinium, 4-cyano-2-methylisoquinolinium, and 2-methyl-5-nitroisoquinolinium cations by 9,10-dihydro-10-methylacridine, and also the reduction of these same three cations as well as the 10-methylacridinium cation by 5,6-dihydro-5-methylphenanthridine, have been investigated in 20% acetonitrile – 80% water, ionic strength 1.0, 25°C. The reactions of the 2-methyl-5-nitroisoquinolinium cation with both reductants, and also of the 4-cyano-2-methylisoquinolinium cation with 9,10-dihydro-10-methylacridine, display kinetic saturation effects in the pseudo-first-order rate constants as a function of heterocyclic cation concentration. These effects are consistent with the formation of 1:1 association complexes between hydride donor and acceptor prior to the rate-determining step of the reduction. The second-order rate constants for these reactions, and also those for analogous heterocyclic cation reductions by 1,4-dihydronicotinamides, show systematic variations as a function of the hydride donor and acceptor species.

JOHN W. BUNTING et MARK A. LUSCHER. Can. J. Chem. **66**, 2524 (1988).

Opérant à 25°C, à une force ionique de 1,0, dans une solution d'acétonitrile dans l'eau 20:80, on a étudié la cinétique de la réduction des cations cyano-3 méthyl-1 quinolinium, cyano-4 méthyl-2 isoquinolinium et méthyl-2 nitro-5 isoquinolinium par la dihydro-9,10 méthyl-10 acridine ainsi que la réduction de ces trois même cations ainsi que celle du cation méthyl-10 acridinium par la dihydro-5,6 méthyl-5 phénanthridine. Les réactions du cation méthyl-2 nitro-5 isoquinolinium avec chacun des réactifs ainsi que celle du cation cyano-4 méthyl-2 isoquinolinium avec la dihydro-9,10 méthyl-10 acridine présentent des effets de saturation cinétique des constantes de vitesse du pseudo premier ordre en fonction de la concentration de cation hétérocyclique. Ces effets sont en accord avec la formation de complexes d'association 1:1 entre le donneur et l'accepteur d'hydrure avant l'étape qui détermine la vitesse de la réduction. Les constantes de vitesse du deuxième ordre de ces réactions, ainsi que celles des réductions analogues de cations hétérocycliques par les dihydro-1,4 nicotinamides, présentent des variations systématiques en fonction des espèces qui donne ou qui accepte l'hydrure.

[Traduit par la revue]

The rates of reduction of nitrogen heteroaromatic cations (Q^+) by the dihydro derivatives of various nitrogen heteroaromatic species (i.e., derivatives of dihydropyridines (RH in eq. [1])) have been extensively investigated as part of the general exploration of non-enzymic hydride transfers that are relevant to the redox reactions of the nicotinamide coenzymes (1–32).

[1] $Q^+ + RH \rightarrow QH + R^+$

Many of these investigations have utilized 1,4-dihydronicotinamides for the reduction of a variety of pyridinium (1–9), quinolinium (10–14), isoquinolinium (15, 16), and acridinium (11, 13, 17–28) cations, since such reducing agents are most closely related to the biological NADH and NADPH species. However, a variety of 1,4-dihydroquinolines (11, 13, 24, 25, 29), 9,10-dihydroacridines (11, 13, 24, 25, 30, 31), and 5,6-dihydrophenanthridines (11, 13, 30, 32) have also been used as hydride donors in the continuing investigations of "model nicotinamide–coenzyme reactions". These reactions have also attracted interest as vehicles for the evaluation of some fundamental principles of physical organic chemistry (11, 13, 31, 32).

Some form of association complex between the hydride donor and acceptor species would be expected to precede the hydride transfer process between these relatively large organic species. In actual fact, such complexation has rarely been observed in reactions of the general class described by eq. [1] (14–16, 19), although evidence for the formation of association complexes is readily obtainable in the reactions of 1,4-dihydronicotinamides and their derivatives with flavins (33–36), quinones (37–42), and related species (43, 44). Such complexation between the two reactants becomes obvious in the form of a "kinetic saturation" for the dependence of pseudo-first-order rate constants upon the concentration of the excess reactant, or by the spectral observation of transient charge-transfer complexes. While lack of evidence for complexation between Q^+ and RH of eq. [1] might be simply ascribable to very small association constants for complex formation, the cases in which kinetic saturation has been reported imply that this phenomenon should be more widely encountered, especially in predominantly aqueous solutions.

The most extensive examples of complexation between hydride donor and acceptor species have been reported for the reduction of isoquinolinium (15, 16) and quinolinium (14) cations by 1,4-dihydronicotinamides in aqueous solutions containing 20% acetonitrile cosolvent. Pronounced kinetic saturation effects are found in the pseudo-first-order rate constants for these reactions, and these effects are consistent with the presence of 1:1 complexes between the two reactant species. As usual, the interpretation of complexation is complicated by the well-known kinetic conundrum, in which the formation of productive and (or) nonproductive complexes produces kinetically equivalent reaction mechanisms.

Weak complexation between these organic species is consistent with either weak π–π^* electronic interactions of the charge-transfer type or hydrophobic interactions between the reactant species. Either of these weak interactions would be expected to be significantly stronger for larger, and less polar, hydride donor species than for 1,4-dihydronicotinamides. That such complexation has not been reported when 1,4-dihydroquinolines, 9,10-dihydroacridines, or 5,6-dihydrophenanthridines have been used as the hydride donors, may be simply attributable to the fact that these reactions have usually been investigated in relatively nonpolar solvent systems, in which the minimization of aqueous interactions with large organic molecules is less of a factor in favour of complexation between organic species.

In the current work, we report an extension of our earlier

studies (in 20% acetonitrile in water) of the kinetics of the 1,4-dihydronicotinamide reduction of isoquinolinium (15, 16), quinolinium (14), and acridinium (24) cations to the reduction of some examples of these cations by 9,10-dihydro-10-methylacridine and 5,6-dihydro-5-methylphenanthridine in this same solvent (eqs. [2]–[8]). We have found that the expectations mentioned above, regarding the importance of complexation using these large hydride donors in a predominantly aqueous solvent, are justified. Furthermore, the current data allow a comparison of relative reactivities of hydride donor and acceptor species in our own solvent system, and in the less polar 80% 2-propanol – 20% water solvent, which has been extensively used by Kreevoy and co-workers (11–13, 30–32) in studies that parallel our own work in this area.

Experimental

10-Methylacridinium chloride dihydrate (45) and 4-cyano-2-methylisoquinolinium bromide (46) were available from earlier studies in this laboratory. These materials, as well as all other heterocyclic salts described below, were recrystallized and characterized by ^{1}H nmr spectroscopy prior to use.

5-Methylphenanthridinium iodide was prepared by stirring phenanthridine (2 g) in iodomethane (15 mL) in a pressure bottle for 3 days at room temperature. Since this iodide salt is air sensitive, it was converted to the corresponding chloride monohydrate by stirring with freshly prepared silver chloride in methanol, followed by recrystallization from aqueous acetone; mp 211–213°C (lit. (47) mp 215°C).

10-Methylacridinium iodide was prepared by stirring acridine (3.95 g) in acetone (3 mL) with iodomethane (3.4 mL) in a pressure bottle at room temperature for 3 weeks. The red powder was used for synthetic purposes without further purification.

3-Cyano-1-methylquinolinium iodide was prepared by stirring 3-cyanoquinoline (3 g) with iodomethane (20 mL) for 2 days. After the addition of diethyl ether (50 mL), the crude product was recrystallized several times from ethanol to give brown crystals of mp 243–244°C (dec.) (lit. (48) mp 207°C (?)).

2-Methyl-5-nitroisoquinolinium iodide was prepared by stirring 5-nitroisoquinoline (2 g) with iodomethane (20 mL) for 3 days. The crude product was treated with diethyl ether, and recrystallized from a methanol–2-propanol mixture; mp 165°C (dec.).

9,10-Dihydro-10-methylacridine

10-Methylacridinium iodide (2.17 g) was dissolved in 2:1 methanol–water (100 mL) and cooled to 10°C. An aqueous solution (10 mL) of sodium borohydride (310 mg) was added dropwise with stirring. The yellow solution turned black, then dark green, followed by light green, and finally deposited a creamy white precipitate. Water was added (100 mL), and the mixture was then extracted with dichloromethane. After evaporation of the solvent the crude product was recrystallized several times from aqueous methanol; mp 101–102°C (lit. (49) 102–103°C).

5,6-Dihydro-5-methylphenanthridine

5-Methylphenanthridinium iodide (2 g) was dissolved in 2:1 methanol–water (80 mL) and cooled to 10°C. An aqueous solution (7.9 mL) of sodium borohydride (185 mg) was added dropwise, to give a pale green solution. Water (200 mL) was added, and the mixture was stored in the dark under nitrogen for 30 min to allow the product to crystallize. After suction filtration, the crystals were dissolved in methanol (15 mL) under nitrogen. Water was added dropwise until the solution became slightly cloudy, whereupon a single crystal from the crude product was added to seed crystallization. When crystallization appeared complete, more water (150 mL) was added dropwise over a period of 1–2 h. The crystalline product was filtered off, and recrystallized again by the same procedure to give fine white crystals of mp 44–46°C (lit. (50) mp 48°C). This material was stored in the vacuum desiccator in the dark, and recrystallized biweekly to maintain purity.

Kinetic studies

Stock solutions of dihydropyridine derivatives (RH) in spectroscopic grade acetonitrile were freshly prepared each day, while neutral aqueous solutions of salts of the heterocyclic cations (Q^+) were replaced weekly, with refrigeration while not in active use. All kinetic and spectral studies were done at 25°C using a Cary 210 spectrophotometer in 20% acetonitrile – 80% water, at ionic strength 1.0 (potassium chloride), and buffered at pH 7.0 with 5 mM phosphate unless indicated otherwise. Reactions of the 4-cyano-2-methylisoquinolinium cation were studied at pH 5.0 (5 mM acetate) to avoid competing pseudobase formation by this cation (pK_{R^+} 7.80 (46)). This pH 5.0 buffer was also used for reactions of the 3-cyano-1-methylquinolinium cation to avoid a very slow decomposition of the 1,4-dihydroquinoline reaction product that was observed at higher pH.

The time dependence of the absorbance was recorded at appropriate wavelengths as discussed in the Results. These data were digitized by a microprocessor controlled by a Commodore 4048 computer into 75 data points usually covering at least 95% of the overall reaction. For pseudo-first-order kinetic studies, the rate constants were calculated from the appropriate logarithmic relationship by linear least-squares analysis. In a few cases when a poor correlation was obtained, or competing reactions were obvious (e.g., eq. [7] as discussed in the Results), the rate constant was calculated by fitting the absorbance (A_t) at time t to the relationship, $A_t = A_f + (A_0 - A_f) \exp(-k_{obs} \cdot t)$, via the Marquardt algorithm treating the initial absorbance (A_0), the final absorbance (A_f), and k_{obs} as parameters to be evaluated. This same algorithm was also used for parameter evaluation from the k_{obs} vs. $[Q^+]$ kinetic saturation curves (eq. [9]).

Results

Spectral observations

We have used spectrophotometric techniques to measure the rates of reduction of the 3-cyano-1-methylquinolinium cation (CQ^+), the 4-cyano-2-methylisoquinolinium cation (CIQ^+), and the 2-methyl-5-nitroisoquinolinium cation (NIQ^+) by 9,10-dihydro-10-methylacridine (AH) (eqs. [2]–[4]), and the reduction of these three cations and also the 10-methylacridinium cation (A^+) by 5,6-dihydro-5-methylphenanthridine (PH) (eqs. [5]–[8]) in 20% acetonitrile in water, buffered at an appropriate pH as described in the experimental section, at ionic strength 1.0 and 25°C. In initial experiments, the time dependences of the electronic absorption spectra of equimolar mixtures of the reactants were obtained for each of the reactions in eqs. [2]–[8]. In all cases, as indicated below, the spectral observations were consistent with the reaction products of eqs. [2]–[8].

The reduction of the 3-cyano-1-methylquinolinium cation by either AH (eq. [2]) or PH (eq. [5]) has been shown to occur exclusively at C-4 rather than at C-2 of this quinolinium cation (11, 13). Our spectral observations confirm this result. For the reaction of eq. [2], the appearance of the 10-methylacridinium cation reaction product is clear from its characteristic spectrum consisting of an intense sharp maximum at 357 nm and a less intense series of three peaks at 397, 416, and 439 nm. Superimposed upon this acridinium cation spectrum is a shoulder in the vicinity of 333 nm, which is derived from the absorption maximum of 3-cyano-1,4-dihydro-1-methylquinoline (CQH) (51). The product spectrum from the reaction of eq. [5] displayed a very broad absorption maximum in the vicinity of 330 nm and a shoulder at about 355 nm. The difference spectrum between this product mixture and an equimolar concentration of the 5-methylphenanthridinium cation displayed the characteristic spectrum of the 1,4-dihydroquinoline derivative. For each of these reactions, the time-dependent spectra show clean isosbestic points, which indicate that there is no significant formation of intermediate species in these reactions.

The product spectra from the reduction of the 4-cyano-2-methylisoquinolinium cation by either AH (eq. [3]) or PH (eq. [6]) were characterized by the spectra of the 10-methylacridinium and 5-methylphenanthridinium cations, respectively, superimposed upon the spectrum of 4-cyano-1,2-dihydro-2-methylisoquinoline (CIQH), which has also been shown to be the product of the reduction of this isoquinolinium cation by 1-benzyl-1,4-dihydronicotinamide (16). Clean isosbestic points indicate the absence of significant concentrations of intermediates in either of these reactions.

The spectra of the reaction mixtures containing the 2-methyl-5-nitroisoquinolinium cation (eqs. [4] and [7]) are complicated by the relative instability of the 1,2-dihydro-2-methyl-5-nitroisoquinoline (NIQH) reaction product (λ_{max} = 440 nm) over the lengthy periods required to observe these extremely slow reactions. In the reduction of this isoquinolinium cation by PH (eq. [7]) (both 0.06 mM), a broad absorbance centered near 440 nm, as expected for the NIQH reaction product, appears during the first few hours of the reaction. However, the lack of clean isosbestic points, and the subsequent decrease in the absorbance from the 440 nm maximum, suggest the decomposition of this product in competition with its formation in the reduction reaction. Similar observations have been reported (15) for the reduction of this cation by 1,4-dihydronicotinamides, and are attributable to the aerobic oxidation of the 1,2-dihydro product to 2-methyl-5-nitro-1-isoquinolinone, which does not absorb at $\lambda > 400$ nm.

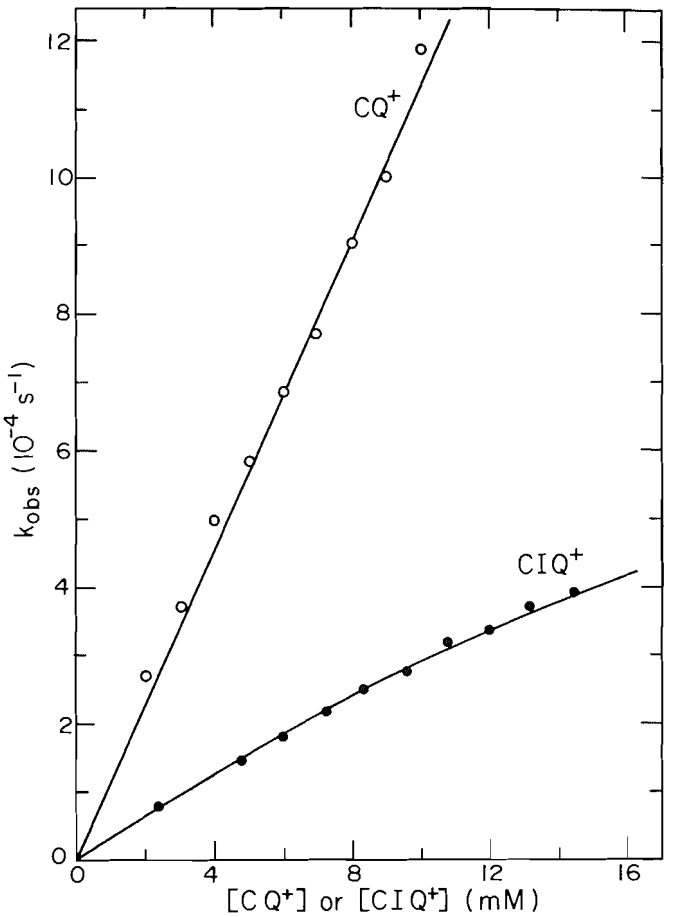

FIG. 1. Pseudo-first-order rate constant as a function of cation concentration for the reduction of CQ^+ and CIQ^+ by AH (eqs. [2] and [3]).

The reaction of equimolar concentrations of the 2-methyl-5-nitroisoquinolinium cation and AH is about 100 times slower than the reaction described above for the reduction of this cation by PH. Consequently, in this case decomposition of the immediate NIQH product is much faster than its formation, so that spectral observation shows only the clean formation of the characteristic 10-methylacridinium cation spectrum at $\lambda > 400$ nm. The reaction shows clean isosbestic points, indicating that there is no significant buildup of the NIQH reduction product as an "intermediate" prior to its aerial oxidation. Superimposed upon the 10-methylacridinium cation spectrum in the reaction product is an additional absorption of $\lambda_{max} \approx 340$ nm, which we attribute to 2-methyl-5-nitro-1-isoquinolinone.

The reaction of 5,6-dihydro-5-methylphenanthridine and the 10-methylacridinium cation (eq. [8]) is known to give 9,10-dihydro-10-methylacridine and the 5-methylphenanthridinium cation. The spectrum of our product mixture is consistent with this result. This product spectrum is identical to that of an equimolar mixture of the predicted reaction products, displaying an intense absorption maximum at 285 nm characteristic of AH, and absorption in the vicinity of 355 nm characteristic of the 5-methylphenanthridinium cation.

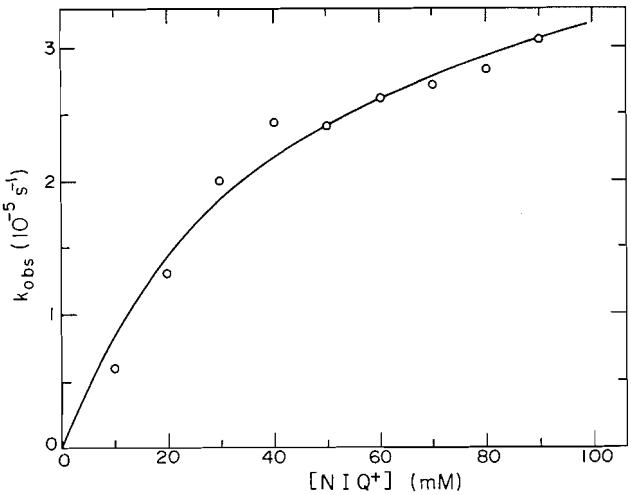

FIG. 2. Pseudo-first-order rate constant as a function of cation concentration for the reduction of NIQ^+ by AH (eq. [4]).

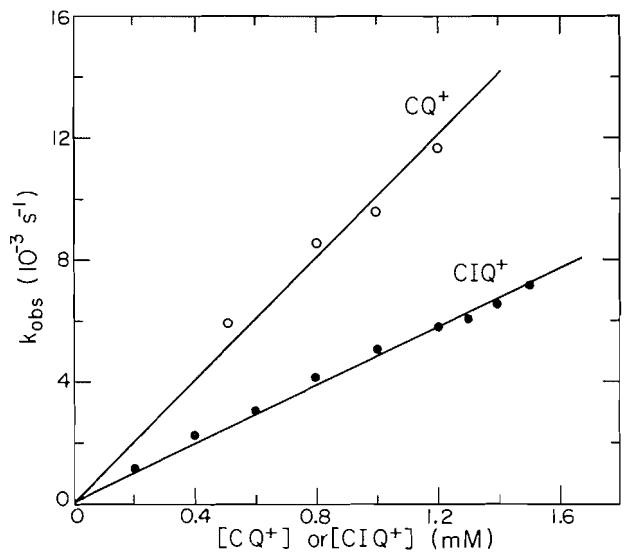

FIG. 3. Pseudo-first-order rate constant as a function of cation concentration for the reduction of CQ^+ and CIQ^+ by PH (eqs. [5] and [6]).

Kinetic studies

(i) Reactions of 9,10-dihydro-10-methylacridine (eqs. [2]–[4])

The rates of the reactions in each of eqs. [2]–[4] were followed by monitoring the appearance of the 10-methylacridinium cation at 416 nm (eqs. [2] and [3]) or 435 nm (eq. [4]) using an initial concentration of 0.06 mM for AH, and large excesses of the heteroaromatic cations. Pseudo-first-order rate constants (k_{obs}) were evaluated at a number of cation concentrations, and are displayed in Figs. 1 and 2. For the reduction of the 3-cyano-1-methylquinolinium cation (eq. [2]), k_{obs} is linear in cation concentration over the limited concentration range that is accessible. However, for each of the isoquinolinium cations in eqs. [3] and [4], k_{obs} is less than linearly dependent upon cation concentration. While the curvature in Fig. 1 is only slight for the 4-cyano-2-methylisoquinolinium cation, the curved dependence for the 2-methyl-5-nitroisoquinolinium cation in Fig. 2 is quite dramatic, with k_{obs} tending to a limit at high concentrations of isoquinolinium cation.

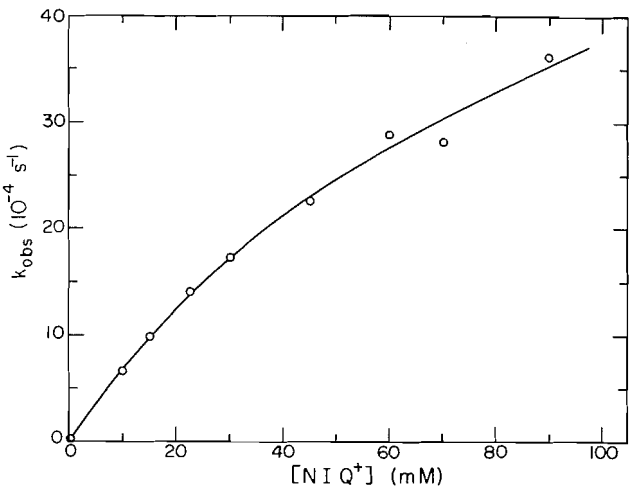

FIG. 4. Pseudo-first-order rate constant as a function of cation concentration for the reduction of NIQ^+ by PH (eq. [7]).

(ii) Reactions of 5,6-dihydro-5-methylphenanthridine (eqs. [5]–[8])

The reactions of eqs. [5] and [6] are characterized by extensive overlap between the spectra of reactant and product species at all wavelengths. Consequently, only limited concentration ranges of the heterocyclic cations were accessible for pseudo-first-order kinetic studies (at 365 nm for eq. [5], and 370 nm for eq. [6]). Within these regions, k_{obs} was strictly linear for the reduction of each of the cations in eqs. [5] and [6] (Fig. 3).

The formation of 1,2-dihydro-2-methyl-5-nitroisoquinoline in eq. [7] can be conveniently monitored in the vicinity of 440 nm; however, as described above, this species undergoes subsequent decomposition prior to completion of the reduction. Consequently, the absorbance due to this species as a function of time passes through a maximum. Fortunately, the decomposition reaction occurs sufficiently slowly, relative to the reduction, that accurate pseudo-first-order rate constants were accessible by analyzing the absorbance vs. time data over the first 70% of the reaction, during which complications from decomposition are insignificant. Values of k_{obs} for this reaction show a clear saturation effect (Fig. 4). From the time dependence of the disappearance of NIQH at long reaction times, we have estimated an apparent first-order rate constant of about 10^{-4} s^{-1} for the decomposition of the dihydroisoquinoline product under the current reaction conditions (20% CH_3CN – 80% H_2O, pH 7.0 phosphate buffer (5 mM), ionic strength 1.0, 25°C).

It is not possible to investigate the reaction of eq. [8] under pseudo-first-order conditions, because of the long wavelength absorbance by the 10-methylacridinium cation and the limited solubility of the 5,6-dihydro-5-methylphenanthridine in the predominantly aqueous solvent. Consequently, we have followed the disappearance of the acridinium cation at 416 nm, at similar concentrations of the two reactant species. Second-order kinetic plots ($1/[A^+]$ vs. time) are linear for approximately the first 50–60% of the reaction. However, during the second 50% of the reaction, curvature of the type shown in Fig. 5 becomes obvious. Such curvature, which implies an increase in apparent

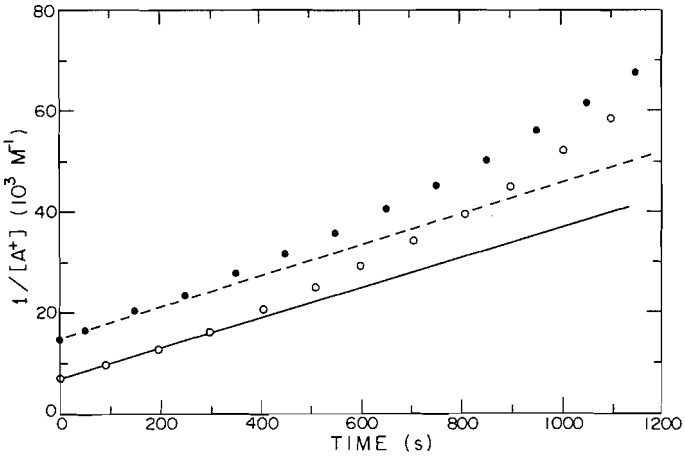

FIG. 5. Second-order kinetic plots for the reduction of A^+ by PH (eq. [8]). Initial reaction concentrations: ●, $[A^+]$ = [PH] = 0.167 mM; ○, $[A^+]$ = [PH] = 0.30 mM. Both lines represent second-order rate constants of $30\ M^{-1}\ s^{-1}$.

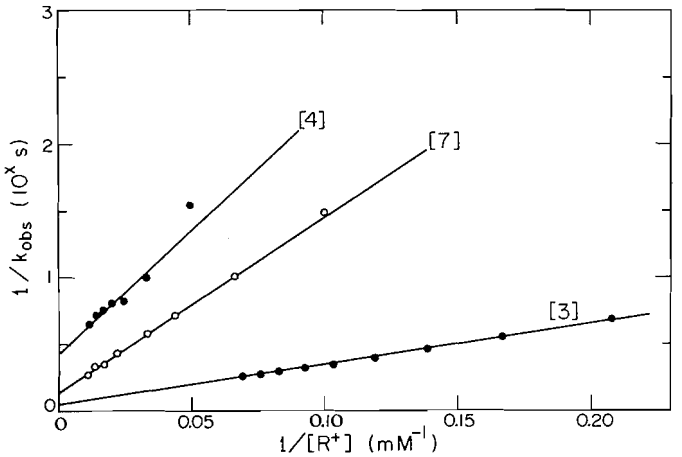

FIG. 6. Double reciprocal plots of pseudo-first-order rate constants for the reactions of eq. [3] ($x = 4$), eq. [4] ($x = 4.7$), and eq. [7] ($x = 5$) as indicated on the figure. Data from Figs. 1, 2, and 4.

second-order rate constant as the reaction progresses, is unchanged even after extensive repurification of both reactants, and is independent of the presence of significant added concentrations of either reaction product (up to at least 0.17 mM AH and 9 mM P^+). We have no ready explanation for this curvature at the present time. Second-order rate constants evaluated from the linear region of these kinetic plots during the first 50% of the reaction were found to be independent of either reactant or product concentration. It is this second-order rate constant that is reported for this reaction in Table 2.

Discussion

Kinetic saturation effects of the type shown in Figs. 1, 2, and 4 have previously been reported for the reduction of quinolinium (14) and isoquinolinium (15, 16) cations by 1,4-dihydronicotinamides. This phenomenon was shown to be consistent with the formation of a 1:1 association complex between hydride donor and acceptor, with complex formation being rapid relative to the hydride transfer process. Such a kinetic scheme predicts that $1/k_{obs}$ should be linearly dependent upon $1/[Q^+]$ where k_{obs} is the pseudo-first-order rate constant in the presence of a large excess of heterocyclic cation (Q^+). Double reciprocal plots of the nonlinear dependences in Figs. 1, 2, and 4 are shown in Fig. 6. These plots are clearly linear, and so indicate that these kinetic saturation effects are consistent with the formation of a 1:1 complex between the hydride donor and acceptor species.

We feel that an alternative possibility, that the kinetic saturation effects may arise from self-aggregation of ion pairs of the acceptor organic salt, can be ruled out on two different grounds. Firstly, the measured association constants for three different donors with NIQ^+ vary by more than fivefold (Y_{int}/slope of Table 1). These parameters should be independent of the hydride donor if they reflect self-aggregation of NIQ^+Cl^- ion pairs. Secondly, kinetic saturation effects in these reactions are only commonly observed in predominantly aqueous reaction media, and are rarely (if ever) reported for more hydrophobic solvents. This result is as expected for the association of neutral hydride donors with heteroaromatic cations since such complexes should be favoured by more polar solvents, whereas the reverse would be expected to be true for ion pairs.

The slope and ordinate intercept (Y_{int}) parameters that characterize the plots in Fig. 6 were evaluated from regression analyses of the kinetic saturation curves in Figs. 1, 2, and 4, according to the relationship in eq. [9]. These parameters are collected in Table 1, which also includes literature data for the reaction of 1-benzyl-1,4-dihydronicotinamide with the 2-methyl-5-nitroisoquinolinium cation, the 2-methylisoquinolinium cation, and the 1-methylquinolinium cation under the same reaction conditions.

$$[9] \quad k_{obs} = ([Q^+]/\text{slope})/(1 + Y_{int}[Q^+]/\text{slope})$$

The interpretation of these empirical parameters depends upon which of several kinetically equivalent reaction schemes is chosen (see below). However, independent of reaction scheme, the ratio Y_{int}/slope represents the overall association constant for 1:1 complex formation, and 1/slope has units of a second-order rate constant. These second-order rate constants are equivalent to the initial slopes of the curves in Figs. 1, 2, and 4 at low concentrations of heterocyclic cation, and are collected in Table 2, along with second-order rate constants evaluated from the slopes of the linear relationships in Figs. 1 and 3.

Clear trends are evident across each row and down each column in Table 2. These trends are quantified more clearly in Table 3, where the data are expressed as relative rate constants referenced to 5,6-dihydro-5-methylphenanthridine as a common reductant, or alternatively to the 3-cyano-1-methylquinolinium cation as a common oxidant. In both comparisons of relative rate constants, the value for the 1-benzyl-1,4-dihydronicotinamide reduction of the 2-methyl-5-nitroisoquinolinium cation appears to be somewhat anomalous and has not been included in the calculation of the following relative reactivities. This case will be considered further below. The relative reactivities of NH:PH:AH towards heteroaromatic cations are close to 10:1:0.01, while the relative reactivities of A^+:CQ^+:ClQ^+:NIQ^+ are approximately 3:1:0.3:0.008 for the oxidation of dihydro nitrogen heterocycles. These ratios should have useful predictive value in future studies in this area.

The association constants in Table 1 for HA with ClQ^+ and NIQ^+ and also PH with NIQ^+ are somewhat smaller than that for NH with NIQ^+, but are clearly much larger than those for NH with the parent *N*-methyl quinolinium and isoquinolinium cations. Extensive analysis (15, 16) of the association complexes

TABLE 1. Parameters describing kinetic saturation of pseudo-first-order rate constants according to eq. [9]

Reaction[a]	$1/Y_{int}$ (s^{-1})	1/slope ($M^{-1}\,s^{-1}$)	Y_{int}/slope (M^{-1})
AH + NIQ^+	$4.5\ (\pm0.4)\times10^{-5}$	$1.0\ (\pm0.1)\times10^{-3}$	23 (±4)
PH + NIQ^+	$7.2\ (\pm0.8)\times10^{-3}$	$7.4\ (\pm0.2)\times10^{-2}$	10 (±2)
NH + NIQ^+	2.1×10^{-3}	0.12	56[b]
AH + CIQ^+	$2.4\ (\pm0.3)\times10^{-3}$	$3.3\ (\pm0.1)\times10^{-2}$	14 (±2)
NH + IQ^+	3.9×10^{-4}	8.0×10^{-4}	2.1[c]
NH + Q^+	9.5×10^{-3}	5.0×10^{-3}	0.5[d]

[a]NH = 1-benzyl-1,4-dihydronicotinamide; IQ^+ = 2-methylisoquinolinium cation; Q^+ = 1-methylquinolinium cation (this table only); other reactants are defined by eqs. [2]–[8]. All data in 20% acetonitrile – 80% water; ionic strength 1.0; 25°C.
[b]Data from ref. 15.
[c]Data from ref. 16.
[d]Data from ref. 14.

TABLE 2. Second-order rate constants for reactions of eq. [1][a]

Reductant (RH)	Oxidant (Q^+)			
	A^+	CQ^+	CIQ^+	NIQ^+
NH	400[b]	121[c]	29[d]	0.12[e]
PH	30 (±4)	10 (±1)	4.6 (±0.2)	$7.4\ (\pm0.2)\times10^{-2}$
AH		0.103 (±0.003)	$3.3\ (\pm0.1)\times10^{-2}$	$1.0\ (\pm0.1)\times10^{-3}$

[a]Units: $M^{-1}\,s^{-1}$; reactants are defined by eqs. [2]–[8]; NH = 1-benzyl-1,4-dihydronicotinamide.
[b]Data from ref. 27.
[c]Data from ref. 14.
[d]Data from ref. 16.
[e]Data from ref. 15.

between 1,4-dihydronicotinamides and isoquinolinium cations has shown that the relatively large association constant observed between NH and NIQ^+ can only be simply interpreted as being due to the formation of a nonproductive complex between these two species. It has been established (16) that this complexation involves a specific interaction between the 5-NO_2 substituent of NIQ^+ and the 3-$CONH_2$ unit of NH. Since the AH and PH species lack such a carboxamide substituent, it seems unlikely that the association complexes between either of these species and NIQ^+ are structurally analogous to the NH–NIQ^+ complex. This view is supported by the similar association constants that are found for AH with NIQ^+ and CIQ^+.

These considerations are the basis for our suggestion above that the data in Table 3 for the NH reduction of NIQ^+ are not directly comparable with the other relative rate data in this table. The two simplest reaction schemes that generate kinetic saturation effects of the type observed in this work are shown in Scheme 1 (productive complex) and Scheme 2 (nonproductive complex). These two schemes represent the simplest cases from several, more general, kinetically equivalent schemes involving productive and nonproductive complexes. Detailed algebraic analyses of five schemes of this type have been previously presented (15).

$$Q^+ + RH \underset{}{\overset{K}{\rightleftharpoons}} C \xrightarrow{k_c} QH + R^+$$

$$\frac{-d[RH]}{dt} = \frac{k_c K[Q^+][RH]}{1 + K[Q^+]} = k_{obs}[RH] \qquad (\text{for } [Q^+] \gg [RH])$$

SCHEME 1

$$Q^+ + RH \overset{K_{NP}}{\rightleftharpoons} C_{NP}$$

$$Q^+ + RH \xrightarrow{k_2} QH + R^+$$

$$\frac{-d[RH]}{dt} = \frac{k_2[Q^+][RH]}{1 + K_{NP}[Q^+]} = k_{obs}[RH] \qquad (\text{for } [Q^+] \gg [RH])$$

SCHEME 2

Scheme 2, which was previously used (15) for the NH + NIQ^+ reaction, predicts that 1/slope for the double reciprocal plot should be the true second-order rate constant for a bimolecular reaction. On the other hand, Scheme 1 requires that 1/slope = $k_c \cdot K$ is an apparent rate constant containing contributions from both the association constant for productive complex formation and also a first-order rate constant for hydride transfer within such a complex. Thus if the saturation effects observed in the AH and PH reductions arise predominantly from productive complex formation as in Scheme 1, then the apparent second-order rate constants in Table 2 have different definitions for these species than for the NH + NIQ^+ reaction. Significantly, the NH reductions of A^+, CQ^+, and CIQ^+, which do not show observable saturation effects, seem to fit the general patterns discerned for the AH and PH reductions in Table 3, and this again points to the strong complexation observed between NH and NIQ^+ being of a quite different nature than that found for the other species.

If one accepts the productive complexation of Scheme 1 as a reasonable interpretation of the reactions in the current study, then one must also interpret the second-order rate constants

TABLE 3. Relative reactivities for reactions according to eq. [1][a]

Reductant (RH)	Oxidant (Q^+)			
	A^+	CQ^+	CIQ^+	NIQ^+
NH	13	12	6.3	1.6
PH	1	1	1	1
AH		0.010	0.0072	0.0135
NH	3.3	1	0.24	0.00099
PH	3.0	1	0.46	0.0074
AH		1	0.32	0.0097
NH[b]	17 (0.5)[c]			
PH[b]	1 (0.4)[c]	1 (0.13)[c]		
AH[b]	0.0036	0.0062 (0.08)[c]		

[a]Calculated from data in Table 2 (in 20% acetonitrile – 80% water, ionic strength 1.0, 25°C), unless indicated otherwise.

[b]Calculated from data in ref. 11 for 80% 2-propanol – 20% water.

[c]Ratio of second-order rate constant in 80% 2-propanol – 20% water (ref. 11) to that in 20% acetonitrile – 80% water (current work).

evaluated from the linear relationships of Figs. 1 and 3 in terms of $k_c \cdot K$ as defined by Scheme 1, with K being too small to produce significant nonlinearity in the accessible concentration ranges. It is certainly reasonable that such large organic species should be significantly associated in predominantly aqueous solutions, since there are numerous precedents for the association of neutral aromatic molecules with heteroaromatic cations, to form complexes that have been attributed to hydrophobic, charge-transfer, or $\pi-\pi^*$ donor–acceptor interactions. To a first approximation one might expect that the k_c and K parameters of Scheme 1 would both vary in a similar way upon changing the reactant species, since both hydride transfer and charge-transfer or $\pi-\pi^*$ interactions involve the redistribution of electron density from the formal hydride donor to the hydride acceptor species. In fact a weak charge-transfer complex has been shown (19) to be formed immediately upon mixing 1-benzyl-1,4-dihydronicotinamide and the 10-methylacridinium cation, with the rate of disappearance of this complex being identical to the rate of hydride transfer between these two species. A fuller exploration of the association of neutral aromatic species with the various heteroaromatic cations of this study is reported in the accompanying paper (52).

The earlier examples of complexation between 1,4-dihydronicotinamides and isoquinolinium (15, 16), quinolinium (14), or acridinium (19) cations have now been extended to include 9,10-dihydroacridines and 5,6-dihydrophenanthridines as hydride donors towards these heteroaromatic cations. Experimental limitations precluded the investigation of some of the current reactions at high enough concentrations to demonstrate the kinetic consequences of complexation between hydride donor and acceptor. Nevertheless, it is now clear that such association complexes must be seriously considered in all quantitative studies of hydride transfer according to eq. [1].

Table 3 includes data from Kreevoy and co-workers for those reactions which are common to their studies in 80% 2-propanol – 20% water and our own studies in 20% acetonitrile – 80% water. It is clear that the same qualitative relative reactivities are found in the two solvent systems, although the selectivities seem to be somewhat enhanced in the less polar medium. All reactions are slower in the less polar solvent than in our predominantly aqueous medium, with an indication that the solvent effect is somewhat dependent upon the cation involved. Thus, in 80% 2-propanol, acridinium cations are reduced at 40–50% of the rate in 20% acetonitrile, while the 3-cyano-1-methylquinolinium cation is reduced at only about 10% of the rate in the more aqueous medium. In the light of the general conclusions of the current study, the detailed interpretation of such comparisons will require quantitative information of the solvent dependences of both k_c and K of Scheme 1 as a function of hydride donor and acceptor.

Charge transfer complexation of *N,N*-dimethyl-*p*-toluidine with nitrogen heteroaromatic cations as a model for association complexes in hydride transfer reactions

JOHN W. BUNTING AND MARK A. LUSCHER
Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received March 14, 1988

JOHN W. BUNTING and MARK A. LUSCHER. Can. J. Chem. **66**, 2532 (1988).

Charge-transfer complexation of *N,N*-dimethyl-*p*-toluidine (DMT) with each of the following *N*-methyl cations has been investigated in acetonitrile solution at 25°C: acridinium; phenanthridinium; 3-X-quinolinium and 4-X-isoquinolinium (X = H, Br, $CONH_2$, CN); 5-nitroisoquinolinium; 3-X-pyridinium (X = $CONH_2$, CN) (also the *N*-benzyl pyridinium cations); *N,N'*-dimethyl-4,4'-dipyridylium dication. Charge-transfer absorption maxima are reported, and extinction coefficients (ε_{max}) at these maxima and association constants (K) for 1:1 complex formation have been evaluated from the dependence of absorbance upon [DMT]. In general, the longest wavelength absorption maximum increases with increasing association constant. There is a strictly linear relationship between ε_{max} and $1/K$. These observations are considered in the context of theories of charge-transfer spectra. Such charge-transfer species are considered as models for the association complexes that are believed to exist upon the reaction pathway for hydride transfer between heteroaromatic cations. Although some significant qualitative relationships are apparent, variations in susceptibility of heteroaromatic cations to charge-transfer complexation are much smaller than variations in the reactivity of these cations towards hydride donor species.

JOHN W. BUNTING et MARK A. LUSCHER. Can. J. Chem. **66**, 2532 (1988).

Opérant dans une solution d'acétonitrile, à 25°C, on a examiné la complexation par transfert de charge de la *N,N*-diméthyl *p*-toluidine (DMT) avec chacun des cations *N*-méthylés suivants : acridinium, phénanthridinium, X-3 quinolinium et X-4 isoquinolinium (X = H, Br, $CONH_2$, CN), nitro-5 isoquinolinium, X-3 pyridinium ainsi que les cations *N*-benzyl pyridinium (X = $CONH_2$, CN) et le dication *N,N'*-diméthyl dipyridinium-4,4'. On rapporte les maxima d'absorption des transferts de charge; en se basant sur la relation qui existe entre l'absorbance et la [DMT], on a évalué les coefficients d'extinction (ε_{max}) à ces maxima ainsi que les constantes d'association (K) pour la formation des complexes 1:1. Il existe une relation strictement linéaire entre le ε_{max} et $1/K$. On considère ces observations dans le contexte des théories des spectres de transfert de charge. On considère que de telles espèces de transfert de charge sont de bons modèles pour les complexes d'association qui existeraient lors du cheminement réactionnel des hydrures au cours de leur transfert entre des cations hétéroaromatiques. Même s'il semble exister des relations qualitatives importantes, les variations dans la susceptibilité des cations hétéroaromatiques à la complexation de transfert de charge sont beaucoup plus faibles que les variations observées dans la réactivité de ces cations vis-à-vis des espèces donneurs d'hydrure.

[Traduit par la revue]

The transfer of a hydride ion to a nitrogen heteroaromatic cation from a dihydro derivative of another heteroaromatic cation (eq. [1]) has been extensively investigated in recent years. Such studies, which are summarized in the accompanying paper (1), are of interest because of their relevance to the reactions of the biologically important hydride sources NADH and NADPH in a wide range of enzymic redox reactions.

[1] $A^+ + DH \rightarrow AH + D^+$

In general, one would expect (2–4) that the reaction of eq. [1] would be preceded by the formation of an association complex between A^+ and DH, and a minimal description of such reactions would be that shown in Scheme 1.

$$A^+ + DH \rightleftharpoons [A^+ \cdot DH]$$
$$[A^+ \cdot DH] \rightleftharpoons [AH \cdot D^+]$$
$$[AH \cdot D^+] \rightleftharpoons AH + D^+$$

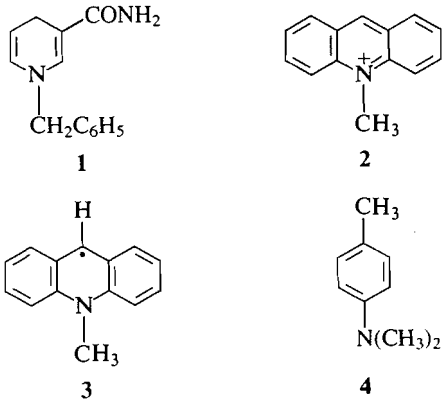
SCHEME 1

From the observation of saturation kinetics for pseudo-first-order rate constants for reactions of the type shown in eq. [1], evidence is beginning to accumulate (1, 5–8) for the presence of 1:1 association complexes between the reactants in such reactions. Many such association complexes appear to be quite weak, and it is clear that, at least for predominantly aqueous solutions, limited solubilities of the reactants will often not permit studies at sufficiently high reactant concentrations to allow the observation of complexation and the evaluation of association constants. We have therefore sought an indirect method of estimating the likely extent of complexation of a variety of heteroaromatic cation hydride acceptors (A^+) with a common hydride donor (DH).

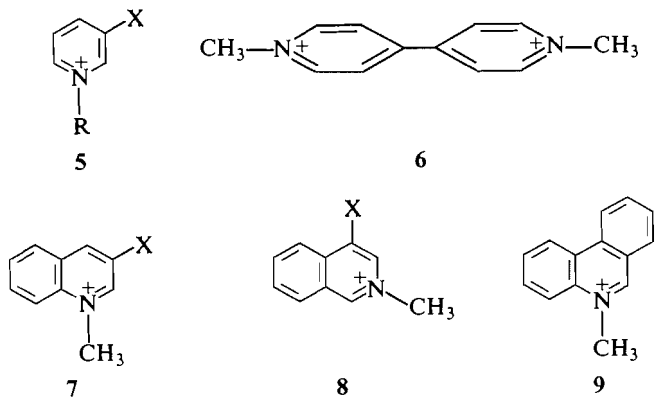
To a first approximation, one may characterize the $[A^+ \cdot DH]$ association complex as a charge-transfer complex between the DH electron donor and the A^+ acceptor (4). In fact, the formation of a charge-transfer complex between 1-benzyl-1,4-dihydronicotinamide (**1**) and the 10-methylacridinium cation (**2**) has been spectroscopically observed (5). This complex has λ_{max} in the vicinity of 550 nm in methanolic solution, which is quite similar to that reported (9) (λ_{max} = 555 nm) for the complex formed between *N,N*-dimethylaniline and this same cation. It is also intriguing that both of these charge-transfer spectra are quite similar to the spectrum reported (10–12) for the *N*-methylacridanyl radical (**3**) (λ_{max} = 520 nm), since one interpretation of the electronic structure of the $[A^+ \cdot DH]$ charge-transfer complex is in terms of a resonance contribution from the species $[A^{\cdot} \cdot DH^{\cdot +}]$. These considerations suggest that the complexation of aniline derivatives with heteroaromatic cations may be a reasonable simulation of the complexation of 1,4-dihydronicotinamides with such cations. There are a number of reports in the literature of the spectral observation of complexes between aniline derivatives (9, 13–16), or other π-excessive electron donors (17–26), and heteroaromatic cations. However, we have been unable to find any report of a systematic quantitative study of this phenomenon.

We now present an investigation of the charge-transfer complexation of *N,N*-dimethyl-*p*-toluidine (**4**) with many of the heterocyclic cations that have been used as hydride acceptors

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/07/12
For personal use only.



in recent investigations of reactions of the type described in eq. [1]. We present data upon the spectral characterization of such complexes, and also equilibrium constants for their formation, as a function of cation structure and substitution, for a variety of pyridinium (**5** and **6**), quinolinium (**7**), isoquinolinium (**8**), acridinium (**2**), and phenanthridinium (**9**) cations. The choice of *N*,*N*-dimethyl-*p*-toluidine as donor species was made so as to minimize interference from coupling reactions of the type described by Ballard *et al.* (15). In this initial study, acetonitrile was chosen as a solvent, rather than an aqueous or alcoholic medium, to minimize complications that may arise from nucleophilic addition to these cations. Such hydroxide or alkoxide adducts would also be potential donors in charge-transfer complexation with these heteroaromatic cations.



Experimental

Materials

Most of the *N*-methyl heteroaromatic cations were available as their chloride or bromide salts from recent or concurrent (1) studies in our laboratory. In all cases, these were recrystallized several times, and their identities were confirmed by ^{1}Hmr spectroscopy. The dibromide salt of the *N*,*N*′-dimethyl-4,4′-dipyridylium dication (**6**) was prepared by stirring 4,4′-dipyridyl with excess methyl bromide in a pressure bottle for several days at room temperature. The yellow solid was recrystallized several times from a 1:1 mixture of methanol and ethanol and characterized by ^{1}Hmr spectroscopy.

N,*N*-Dimethyl-*p*-toluidine (Aldrich Chemical Co.) was distilled several times under vacuum to give a very pale yellow liquid. Stock samples of this compound were redistilled weekly to ensure purity. All acetonitrile solutions were made from the hplc grade solvent supplied by Aldrich Chemical Co.

Spectroscopic studies

The charge-transfer absorbance spectrum was measured for each cation in a solution (3 mL) containing acetonitrile (2 mL) and *N*,*N*-dimethyl-*p*-toluidine (1 mL) and the chloride or bromide salt of the heterocyclic cation (usually 2 mM). Absorbance maxima (λ_{max}) were evaluated from these curves, but extinction coefficients were calculated from the subsequent spectrophotometric determination of the association constants. Studies of several cations, which were available as both the chloride and bromide salts, gave identical results for these two counterions.

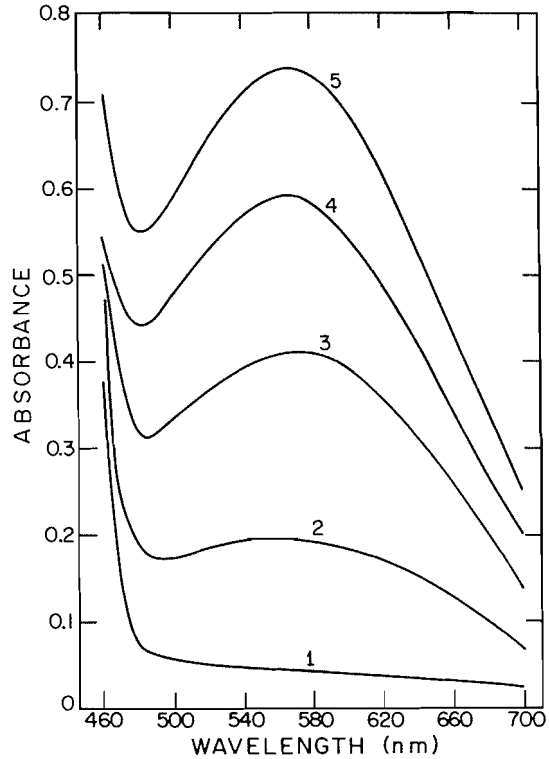


FIG. 1. The absorption spectrum (1-cm path) of 10-methylacridinium chloride (5 mM) in acetonitrile solution in the presence of the following concentrations (M) of *N*,*N*-dimethyl-*p*-toluidine: 1, 0; 2, 0.077; 3, 0.189; 4, 0.309; 5, 0.540.

All equilibrium constants were evaluated spectrophotometrically (Cary 210 spectrophotometer) in acetonitrile solution at 25°C. Absorbances were read at a wavelength in the vicinity of λ_{max} immediately upon preparation of solutions that were made by mixing appropriate volumes of a stock solution of the heterocyclic salt in acetonitrile, *N*,*N*-dimethyl-*p*-toluidine, and acetonitrile to give a final total volume of 3 mL. Each of these components was individually stored in a vial thermostatted at 25°C. Absorbances were measured at a constant concentration of the heterocyclic salt (usually 2 mM), and at about ten different concentrations of *N*,*N*-dimethyl-*p*-toluidine, covering at least a tenfold range in the concentration of this aniline. Equilibrium constants (K) and extinction coefficients (ε_{max}) of the complexes were evaluated as described below.

Results

Figure 1 shows the electronic absorption spectrum as a function of the concentration of *N*,*N*-dimethyl-*p*-toluidine (DMT) immediately upon mixing DMT with 10-methylacridinium chloride in acetonitrile solution. These spectra are somewhat unstable, and undergo small changes over a period of time; nevertheless the formation of a species of $\lambda_{max} \approx 572$ nm, having an absorbance that is dependent upon [DMT], is quite clear. The formation of this species absorbing at 572 nm appears to occur "instantaneously" upon mixing these solutions, with slight decreases in absorbance in this region usually accompanying the subsequent slow process mentioned above. All absorbance measurements used in the calculation of equilibrium

[c]By direct fitting to eq. [2] using the Marquardt algorithm iterative method.
[d]From least-squares analysis of Benesi–Hildebrand plots.
[e]Stock solution was a saturated solution of uncertain concentration. *K* is not influenced by this concentration; however, accurate ε_{max} are not obtainable.
[f]No discrete maximum observable (see text).
[g]*N*-Benzyl cation.
[h]Absorption maximum is obscured by absorption from the high [DMT] required.
[i]Calculated from eq. [8] as described in text.

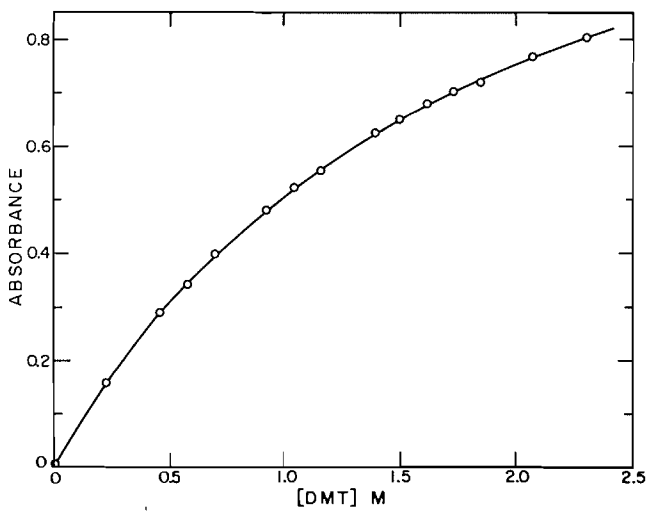

FIG. 2. Variation of the absorbance (1-cm path) of acetonitrile solutions of 10-methylacridinium chloride (2 mM) at 550 nm as a function of the concentration of *N*,*N*-dimethyl-*p*-toluidine (DMT).

constants were obtained within 30 s of mixing temperature-equilibrated solutions of the reactants. Studies of the time dependence of the absorbance at fixed wavelength indicated that extrapolations to "zero time" produced less than 1% change in these absorbances.

The variation of absorbance as a function of [DMT] is shown in Fig. 2 for mixtures of DMT with a fixed concentration of the 10-methylacridinium cation. This concentration dependence of the absorbance (A) is consistent with eq. [2], which is derived for 1:1 complexation between donor and acceptor, with the donor (D) being present in large excess (>10-fold) over the acceptor cation (total concentration $[A^+]_T$ of complexed and free cation), and the complex being the only species with a significant extinction coefficient (ε_c) at the wavelength under study. Fitting eq. [2] to the experimental data in Fig. 2 allows the evaluation of the association constant (K) and ε.

$$[2] \qquad A = \frac{\varepsilon K[D][A^+]_T}{1 + K[D]}$$

Similar spectral observations were made for solutions containing mixtures of DMT and a variety of other nitrogen heteroaromatic cations. The absorption maximum of the association complex is sensitive to the structure of the cationic acceptor (Table 1). Most cations show significant curvature in absorbance vs. [DMT] (e.g., Figs. 2 and 3) and equilibrium constants for 1:1 complex formation could be evaluated according to eq. [2]. For the *N*-methyl pyridinium cations, association with DMT appears to be so weak that absorbance vs. [DMT] is linear (Fig. 4), and consequently only lower limits for the association constants are accessible in these cases.

All absorption maxima (λ_{max}), extinction coefficients (ε_{max} at λ_{max}), and association constants (K) measured for DMT in the current study are collected in Table 1. In several cases, the charge-transfer absorption maximum is at sufficiently short wavelength that it is not readily accessible because of the absorbance by DMT at these wavelengths. A brown charge-transfer complex is formed immediately upon addition of DMT to solutions of the 2-methyl-5-nitroisoquinolinium cation;

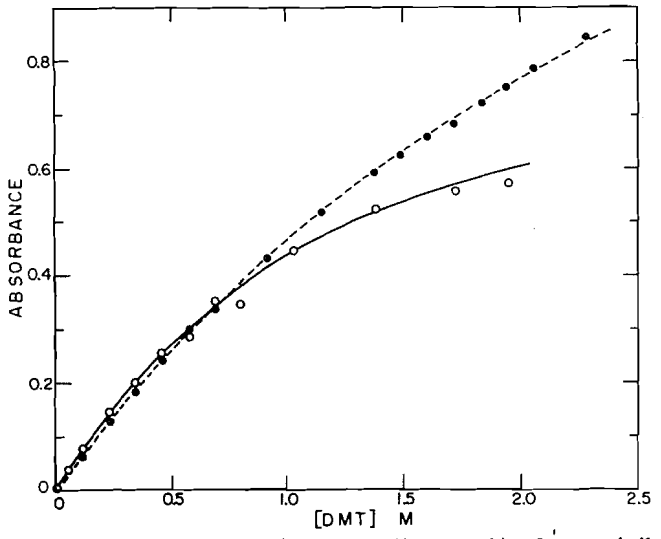

FIG. 3. Variation of the absorbance (1-cm path) of acetonitrile solutions of 3-cyano-1-methylquinolinium chloride (2 mM) (○) at 525 nm and 3-bromo-1-methylquinolinium chloride (2 mM) (●) at 482 nm as a function of the concentration of *N*,*N*-dimethyl-*p*-toluidine (DMT).

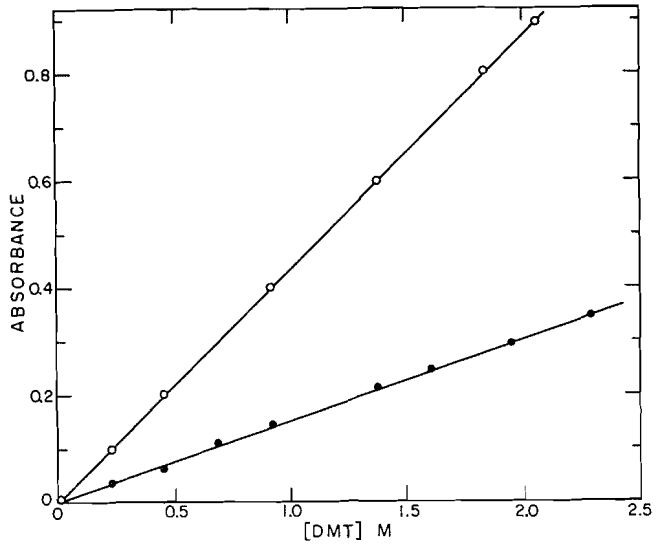

FIG. 4. Variation of the absorbance (1-cm path) of acetonitrile solutions of 3-cyano-1-methylpyridinium chloride (2 mM) (○) at 440 nm and 3-carbamoyl-1-methylpyridinium chloride (2 mM) (●) at 430 nm as a function of the concentration of *N*,*N*-dimethyl-*p*-toluidine (DMT).

however, the spectrum of this charge-transfer species appears to be very broad and featureless, with a tail extending to >700 nm, and a definitive absorbance maximum is not observed. Observation of λ_{max} for the charge-transfer species in this case is also complicated by the absorption spectrum of this cation, which shows a weak shoulder in the vicinity of 425 nm ($\varepsilon \approx 100\ M^{-1}\ cm^{-1}$) and a broad tail extending out to >550 nm at the concentrations used in the current study.

Methods for the evaluation of equilibrium constants for charge-transfer complex formation in studies of the current type have been reviewed on several occasions (27, 28). In Table 1 we present three values for each equilibrium constant. These values were obtained using three different methods of data analysis: (*i*) the classical Benesi–Hildebrand technique (29) using a plot of $1/A$ vs. $1/[D]$ in which K is given by the Y-intercept:slope ratio; (*ii*) evaluation of the parameters K and ε_{max} by directly fitting A as a function of [D] to eq. [2] using an iterative technique (30) based upon the Marquardt algorithm; and (*iii*) by using the weighted nonlinear regression iterative method developed by Wilkinson (31) for fitting steady-state rate data in enzyme kinetic studies to the Michaelis equation, which has the same analytical form as eq. [2]. In general there is good agreement for values of K evaluated by each of these techniques, with almost exact agreement from methods (*ii*) and (*iii*), although the latter of these methods is preferable since consecutive iterations converge upon a final set of parameters much more quickly when small equilibrium constants (<0.1) are involved. The upper limits for K that are given for several complexes in column 5 of Table 1 are the values obtained after arbitrarily stopping the iterative technique after 50 cycles of the Marquardt algorithm, which was begun using the Benesi–Hildebrand parameters as the initial estimates. Convergence in the Wilkinson method using these same data was complete after only four iterative cycles. We have used the parameters evaluated by Wilkinson's method (column 4 of Table 1) in all comparisons in the discussion that follows. While all Benesi–Hildebrand plots are quite linear for the current data sets ($r > 0.999$ in most cases), this method appears to significantly overestimate K for the weakest complexes ($K < 0.1$).

Discussion

All of the nitrogen heteroaromatic cations listed in Table 1 form charge-transfer complexes in the presence of *N*,*N*-dimethyl-*p*-toluidine in acetonitrile solution. In most cases plots of absorbance vs. [DMT] show saturation with increasing [DMT]. The [DMT] varies as high as 1 mL in a total solution volume of 3 mL (i.e., 2.31 M) suggesting that significant solvent effects may influence the absorbance vs. [DMT] curves of Figs. 2 and 3. However, the plots in Fig. 4 are clearly linear. These data cover the highest concentration ranges of DMT in any of these studies, and represent cases where complexation is expected to be weakest. The linearity of the plots in Fig. 4 can be taken as an indication that solvent effects are not an important influence in these studies, and this conclusion is also supported by the fact that curvature in the other plots is very dependent upon cation structure. We therefore confidently attribute the saturation effects in Figs. 2 and 3 to complexation that is consistent with 1:1 interaction between DMT and the heterocyclic cation. In all cases eq. [2], which is derived upon this assumption, gives a close fit to the experimental data.

From a perusal of the data in Table 1, it can be concluded that the charge-transfer absorption maxima (λ_{max}), the extinction coefficients (ε_{max}) at these maxima, and the equilibrium association constants (K) for charge-transfer complex formation all vary systematically with the structure and the substitution of the heterocyclic cation. In general, as discussed in more detail below, strong complexation (large K) is associated with the longest wavelength absorption maxima, but the weakest absorbance intensities at these maxima.

Quinolinium and isoquinolinium cations

We first consider substituent effects within the series of C-3 substituted (H, $CONH_2$, Br, CN) quinolinium cations (**7**), and also the corresponding series of C-4 substituted isoquinolinium cations (**8**). Within each of these two series of cations, K increases in the order $H < CONH_2 < Br < CN$, and λ_{max} also increases in this same order. The intensities (ε_{max}) of the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/07/12
For personal use only.

charge-transfer absorbance maxima in these series seem to decrease in this same order; i.e., ε_{max} decreases with increasing λ_{max}. In all cases, K is slightly larger, and the charge-transfer maximum (λ_{max}) is somewhat longer, for the quinolinium cation than for the correspondingly substituted isoquinolinium cation.

Within each of these two series of cations, the substituent effects upon K and λ_{max} follow closely the substituent Hammett σ_m values defined for the ionization of *meta*-substituted benzoic acids in aqueous solutions. The dependence of log K upon σ_m appears to be essentially linear, with a Hammett ρ value of 1.8 ($\pm$0.1) for the quinolinium cations (r = 0.993) and ρ = 1.90 ($\pm$0.05) for the isoquinolinium cations (r = 0.999). These ρ values are considerably smaller than are found (ρ = 5.9 (32)) for the pK_a values (which also correlate with σ_m) for deprotonation of the 3-X-quinolinium and 4-X-isoquinolinium cations. However, the sign and magnitude of these ρ values for log K clearly indicate significant transfer of fractional negative charge (electron density) to these cationic acceptors upon charge-transfer complexation with this donor.

Benzylogous heteroaromatic cations

Variations in λ_{max} for charge-transfer spectra in the order acridinium > phenanthridinium $\approx$ quinolinium > isoquinolinium > pyridinium for cationic acceptors with a constant donor have been reported several times in the literature (9, 15, 17, 19), and are again found in the current study (Table 1). Although individual λ_{max} are quite donor and solvent dependent, this order does not change and, as discussed by other workers, can be correlated with the energies of the LUMO's (9, 24) or the electron affinities (25) of these cationic acceptors. The relatively strong complex observed for the *N,N'*-dimethyl-4,4'-dipyridylium dication (also known as the methyl viologen or paraquat dication) is consistent with its ready susceptibility to one-electron reduction to the radical cation (33, 34). This observation stresses the importance of the relationship between the ability of a heteroaromatic cation to accept a single electron (35), and its susceptibility to charge-transfer complexation with an appropriate donor species such as DMT.

Literature data on equilibrium constants for charge-transfer complexation by these cationic acceptors are quite sparse. We have been unable to locate any report of equilibrium constants for complexation of the *N*-methyl acridinium, phenanthridinium, quinolinium, isoquinolinium, and pyridinium cations with a common donor. Kampar and Neiland (22) have reported K in the order quinolinium > isoquinolinium > pyridinium for complexation of the anions of several 2-(substituted phenyl)-1,2-indandiones with these *N*-methyl cations in ethanolic solution. These complexes are much stronger (K in the range 24–172 M^{-1}) than those investigated in the current study, although the relative values of K for the quinolinium and isoquinolinium cations are similar to those reported in Table 1. The only other K that we have located for these cationic acceptors are the data of Shinitzky (36) for association between acridine, quinoline, and isoquinoline and their corresponding cations. Although the acridinium cation does form the strongest of these complexes, these data cannot be simply related to the current study since they do not refer to a common donor species interacting with these various cations.

In Fig. 5, the relationship between log K for charge-transfer complexation with DMT and the pK_{R^+} value (37) for hydroxide ion addition to these heterocyclic cations is explored, with the thermodynamically more stable hydroxide adducts (C-2 or C-4 as the case may be) being considered for the quinolinium cations (38). For this purpose we have considered the cations of Table 1 in two distinct groups. The *N*-methyl acridinium, phenanthridinium, 3-bromoquinolinium, 4-bromoisoquinolinium, quinolinium, and isoquinolinium cations appear to describe a reasonably linear relationship between log K and pK_{R^+}:

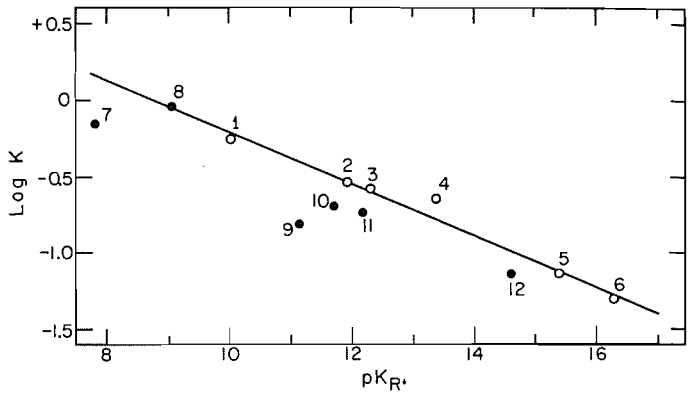

FIG. 5. Dependence of log K (from Table 1) upon pK_{R^+} for the following *N*-methyl cations: 1, acridinium; 2, phenanthridinium; 3, 3-bromoquinolinium; 4, 4-bromoisoquinolinium; 5, quinolinium; 6, isoquinolinium; 7, 4-cyanoisoquinolinium; 8, 3-cyanoquinolinium; 9, 4-carbamoylisoquinolinium; 10, 5-nitroisoquinolinium; 11, 3-carbamoylquinolinium; 12, 1-benzyl-3-carbamoylpyridinium. Correlation line is calculated for cations 1–6 only (see text).

[3] $$\log K = -0.17\ (\pm 0.02)\ pK_{R^+} + 1.5\ (\pm 0.2) \qquad (r = 0.982)$$

The remaining cations bear cyano, carboxamido, or nitro substituents, which are known (38, 39) to stabilize the hydroxide adducts via resonance effects that are not expected to be applicable to charge-transfer complexes. Consistent with this expectation, each of these cations is less efficient (although the 3-cyano-1-methylquinolinium cation is apparently an exception) as a charge-transfer acceptor than predicted by the correlation line (eq. [3]) for other cations in which such resonance effects are not present. That such cyano and carboxamido cations would deviate from eq. [3] is actually predictable from the correlations of log K with σ_m that are noted above, since pK_{R^+} is known (38, 39) to correlate with σ_p^- for 4-substituted isoquinolinium cations and 3-substituted quinolinium cations. The weak dependence of log K upon pK_{R^+} that is expressed by eq. [3] is presumably a reflection of the fact that hydroxide ion addition results in complete charge neutralization upon these cations, whereas charge-transfer complexation results in only a fractional transfer of electron density.

A general tendency for K to increase with λ_{max} while ε_{max} decreases with increasing λ_{max} seems to be apparent for the data in Table 1. A detailed analysis of these trends indicates that there is no simple general relationship between λ_{max} and either K or ε_{max}. However, a general relationship between ε_{max} and K, covering all examples in Table 1 for which both of these parameters are available, is apparent in Fig. 6. Least-squares analysis indicates that this relationship is linear (r = 0.998), and corresponds to eq. [4]:

[4] $$\varepsilon_{max} = 175\ (\pm 4)(1/K) + 330\ (\pm 30)$$

From quantum mechanical considerations, Mulliken's theoretical treatment of charge-transfer complexation (42, 46), and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/07/12
For personal use only.

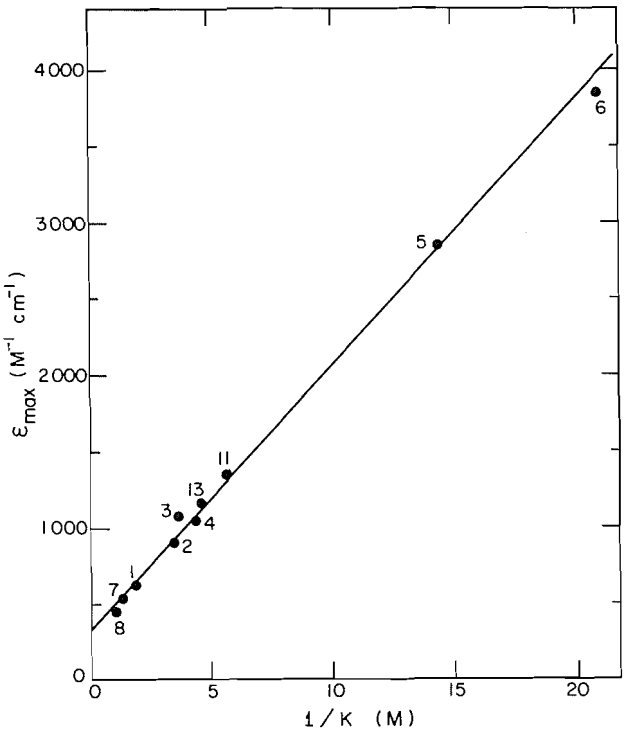

FIG. 6. Dependence of ε_{max} upon $1/K$ for *N*-methyl cations. Data points are as indicated in legend to Fig. 5; 13, *N*,*N*′-dimethyl-4,4′-dipyridylium dication.

its extension by Murakami (43), leads to a prediction that the intensity of the charge-transfer absorption band should increase with increasing complex strength within a series of structurally related complexes. However, the usual experimental result is actually the reverse of this prediction; i.e., ε_{max} is usually observed to decrease as the association constant increases. McGlynn (40) has commented upon this situation in detail, and we note this commonly observed trend is also reproduced by the data from our current study, and is expressed by eq. [4] above. The only earlier attempt at such a quantitative relationship seems to be the report of Tamres *et al.* (41) who found that ε_{max} is linearly dependent upon $1/\sqrt[3]{K}$ for the association of a series of five methylbenzenes with molecular iodine. The current relationship of eq. [4] appears to be the first reported for a common donor with a series of different acceptors, and also is the most extensive quantitative relationship of this type of which we are aware.

Since Mulliken's ideas form the basis of most modern theoretical considerations of charge-transfer complexation (44, 45), a rationalization of this divergence between theory and experimental result is essential. Two such rationalizations have been reported (46, 47), and these make use of two essentially independent hypotheses. The current data, and in particular eq. [4], will now be considered briefly in the context of each of these hypotheses.

Orgel and Mulliken (46) introduced the concept of contact charge-transfer absorption during random encounters between donor and acceptor molecules. Such contact species are assumed to contribute to the observed intensity of the charge-transfer band, but are such weak complexes that the association constants for their formation approach zero. In a system in which measurable association complexes exist in equilibrium with the donor, acceptor, and contact species, Orgel and Mulliken showed (46) that the experimentally determined extinction coefficient (ε_{max} in Table 1) is given by

$$[5] \quad \varepsilon_{max} = \varepsilon_c(1 + \rho/K)$$

where ε_c is the true extinction coefficient of a stable 1:1 charge-transfer complex formed with association constant K, and ρ is a function of the average number of possible contact sites for a donor molecule around an acceptor molecule under conditions of loose thermal contact. This model predicts that the evaluation of data according to eq. [2] gives the correct association constant for stable complexes, even though the apparent extinction coefficient is exalted by the presence of contact charge-transfer absorption. Combination of eqs. [4] and [5] gives

$$[6] \quad \varepsilon_c(1 + \rho/K) = 175/K + 330$$

An obvious solution to eq. [6] is $\varepsilon_c = 330$ and $\rho = 0.53$, which would require that the extinction coefficient of the charge-transfer species be independent of K.

An alternative hypothesis is due to Carter, Murrell, and Rosch (47), who emphasize the role played by solvation, and ignore any contribution from contact charge-transfer species. These workers assume an equilibrium of the form:

$$[7] \quad A{\cdot}S_n + D{\cdot}S_m \rightleftharpoons AD{\cdot}S_p + qS$$

where $q = (n + m - p)$ is the difference in the number of solvent molecules in the first solvation shells of the solvated complex ($AD{\cdot}S_p$) and the solvated donor and acceptor species, i.e., the number of solvent molecules "liberated" upon formation of one molecule of the complex. According to this model, the experimentally evaluated constants K and ε_{max} (according to eq. [2]) are given by

$$[8] \quad K = K_c - q(m + 1)/S_0$$

$$[9] \quad \varepsilon_{max} = \varepsilon_c K_c/K$$

where K_c is the equilibrium constant for eq. [7], ε_c is the extinction coefficient for the solvated charge-transfer complex, and S_0 is the molar concentration of the pure solvent. Equations [8] and [9] imply that analysis of experimental data according to eq. [2] underestimates the association constant, and overestimates the extinction coefficient for the complex. Combination of eqs. [8] and [9] leads to

$$[10] \quad \varepsilon_{max} = \varepsilon_c + \varepsilon_c q(m + 1)/(K_c S_0)$$

which in the light of eq. [4] requires $\varepsilon_c = 330$ and $q(m + 1) = 10$ ($S_0 = 19.2$ for acetonitrile). This value for $q(m + 1)$ is similar to values for this function obtained in other analyses of this type (47).

This solvation model, like the contact species model discussed above, gives an extinction coefficient that is independent of the acceptor species in the current study. The analysis according to eq. [8] requires that the true association constants defined by eq. [7] are given by $K_c = K + 0.53$. Values of K_c calculated in this way are included in the final column of Table 1. It is important to note that the same relative order is obtained for the susceptibilities of the various heteroaromatic cations to charge-transfer complex formation, irrespective of the model assumed in the evaluation of the association constants.

Complexation in hydride transfer reactions

The presence of association complexes (as described by Scheme 1) in hydride transfer reactions between heteroaromatic cations is supported by the observation (1, 5–8) of kinetic

saturation effects in some of these reactions, and also by the spectroscopic observations (5) of a charge-transfer complex (λ_{max} = 550 nm) in the reaction between the *N*-methylacridinium cation and 1-benzyl-1,4-dihydronicotinamide. However, it is not easy to demonstrate that such species are productive complexes upon the reaction coordinate. In fact, we have argued (6) that the strong complexation observed (K = 10–1800 M^{-1}) in the reduction of 5-nitroisoquinolinium cations by 1,4-dihydronicotinamides is only readily interpretable in terms of nonproductive species that lie off the reaction coordinate for hydride transfer. This conclusion is supported by the data in Table 1, which indicate that the 2-methyl-5-nitroisoquinolinium cation does not form unusually stable charge-transfer complexes relative to related heterocyclic cations. However, in the accompanying paper (1), we present data for other hydride transfers that can be sensibly interpreted in terms of productive 1:1 complexation between the hydride donor and acceptor species.

For a reaction according to eq. [1], which actually proceeds via a weak productive 1:1 complex between A^+ and DH, the apparent second-order rate constant (k_2) is equal to the product $k_c \cdot K$, where k_c is the first-order rate constant for hydride transfer within a complex formed with association constant K. It is well established that for the reduction of individual series of substituted quinolinium (8) and isoquinolinium cations (7) by 1-benzyl-1,4-dihydronicotinamide, the experimentally determined log k_2 is linearly correlated with pK_{R^+} for hydroxide ion addition to these cations. For a hydridic transition state (6, 48), one also would expect that, to a first approximation, log k_c would also be related to pK_{R^+}, and relationships such as eq. [3] now also predict a similar dependence upon pK_{R^+} for log K. The relatively small slope of this correlation line suggests that the deviations observable for some cations in Fig. 5 would only appear as a small experimental scatter in a log k_2 vs. pK_{R^+} correlation.

Acridinium cations are well established as being intrinsically more reactive in their reduction by hydride donors than are related phenanthridinium, quinolinium, isoquinolinium, or pyridinium cations. Such enhanced reactivity is apparent if one compares (49) the relative rates of reduction and of hydroxide ion addition to such cations. This enhanced reactivity for acridinium cations also emerges in terms of a lower intrinsic barrier towards reduction when the rate data are treated (4) in terms of the Marcus theory. One possible interpretation of such enhanced reactivity would be in terms of a much greater susceptibility of acridinium cations towards formation of productive complexes with the hydride donor species. The complex between the 10-methylacridinium cation and DMT is one of the more stable species in Table 1; however, the differences in the relative susceptibilities to complex formation by the various cations in this table are not large. While it may be that DMT is not a good model for 1,4-dihydronicotinamide and related hydride donor species, we feel that at the present time the equilibrium constants in Table 1 should be accepted as representative relative association constants for the various heteroaromatic cations, and alternative reasons shoud be sought for their observed differences in reactivity with hydride donors.

Acridinium cations show enhanced reactivity relative to other heteroaromatic cations even in degenerate hydride transfer processes (2). The relative rates of such degenerate hydride transfers vary over a range of 66-fold under constant experimental conditions, with the relative rates of such degenerate reactions following the order (9,10-dihydroacridine + acridinium) > (5,6-dihydrophenanthridine + phenanthridinium) > (1,4-dihydroquinoline + quinolinium) > (1,4-dihydropyridine + pyridinium). Again, in terms of Scheme 1, one would predict that variations in overall rate might be attributable to variations in the strength of complex formation between donor and acceptor pairs. Of course, in such degenerate reactions, one now also has the complication that both the donor and the acceptor species vary from one reaction to the next, and the association constant for complex formation depends both upon the donor and the acceptor species. If the relative abilities of the donors to form complexes vary in the same order as their cationic acceptors (Table 1), then, in the context of Scheme 1, the relative rates of such degenerate reactions are predicted to be in the order that is experimentally observed. In this regard, it is intriguing that the largest association constants that we have attributed (1) to productive complex formation are for 10-methyl-9,10-dihydroacridine and 5-methyl-5,6-dihydrophenanthridine as the hydride donor species. As indicated above, these donor species are also the most reactive in degenerate hydride transfers.

While the current study is not conclusive, it does further implicate the association complexes of Scheme 1 as important intermediates to be considered in hydride transfer reactions between heteroaromatic cations. The extension of this work to the quantitative evaluation of the charge-transfer complexation of other donors, which more closely resemble the structures of typical hydride donor species, should provide further insights into the role of association complexes in determining the rates of hydride transfer between heteroaromatic cations.

Received November 20, 1987[4]

MAREK SLEBIODA, MARC A. ST-AMAND, FRANCIS M. F. CHEN, and N. LEO BENOITON. Can. J. Chem. **66**, 2540 (1988).

The kinetics of racemization of 2,4-disubstituted-5(4*H*)-oxazolones obtained from *N*-acetyl, *N*-benzoyl, and *N*-benzyloxycarbonylglycyl-L-leucine, -valine, and -phenylalanine have been studied in several solvents alone and in the presence of tertiary amines. The influence of the nature of the substituents on the rate of the reaction has been evaluated, and the values of the activation parameters $\Delta H^{\neq}$ and $\Delta S^{\neq}$ for the base-catalyzed reactions have been determined. The racemization process is governed by electronic effects of the C(2)-substituents and steric effects of the C(4)-substituents of the oxazolones. The thermodynamic data suggest that the 2-substituted-4-benzyl-5(4*H*)-oxazolones racemize more readily than the 4-alkyl analogues (alkyl ≠ benzyl) because of the unique conformation assumed by the benzyl substituent. The rate of the base-catalyzed reaction depends on the extent of hindrance about the nitrogen atom of the tertiary amine as well as on its basicity. The data suggest that the relative rates of racemization of oxazolones are not a true reflection of the relative tendencies to racemize of the pertinent residues during couplings of the parent acids.

MAREK SLEBIODA, MARC A. ST-AMAND, FRANCIS M. F. CHEN et N. LEO BENOITON. Can. J. Chem. **66**, 2540 (1988).

Opérant dans divers solvants seuls ainsi qu'en présence d'amines tertiaires, on a étudié la cinétique de la racémisation de 4*H*-oxazolones-5 disubstituées en positions 2,4, qui ont été obtenues à partir des *N*-acétyl, *N*-benzoyl et *N*-benzyloxycarbonyl-glycyl-L-leucine, -valine et -phénylalanine. On a évalué l'influence de la nature des substituants sur la vitesse de la réaction et on a déterminé les valeurs des paramètres d'activation $\Delta H^{\neq}$ et $\Delta S^{\neq}$ pour les réactions catalysées par les bases. Le processus de racémisation est gouverné par les effets électroniques des substituants en C(2) et par les effets stériques des substituants en C(4) des oxazolones. Les données thermodynamiques suggèrent que les benzyl-4 (4*H*)-oxazolones-5 substituées en position 2 se racémisent plus facilement que leurs analogues alkylés en position 4 (alkyle ≠ benzyle); la cause de cette différence serait la conformation unique qu'adopte le substituant benzyle. La vitesse de la réaction catalysée par les bases dépend de l'empêchement stérique autour de l'atome d'azote de l'amine tertiaire ainsi que de sa basicité. Les données suggèrent que les vitesses relatives de racémisation des oxazolones ne reflètent pas nécessairement les tendances relatives à se racémiser des résidus correspondant au cours des couplages des acides parents.

[Traduit par la revue]

Introduction[5]

The main side-reaction which accompanies the activation and peptide-bond forming reactions which are used in peptide synthesis is racemization. The stereomutation results from the formation and tautomerism of the 2,4-dialkyl-5(4*H*)-oxazolone **2** (1–3). The degree of racemization and the factors contributing thereto during peptide synthesis have been extensively investigated (2, 3). However, few data on direct measurements of the rates of racemization of oxazolones can be found in the literature (4–6). This is undoubtedly due to the difficulties encountered in preparing pure oxazolones. Recognition that oxazolones survive washing a solution of the oxazolone with water has allowed us to obtain them in pure form using a soluble *N*,*N*′-dialkylcarbodiimide (7, 8). In the present article, we describe a study of the kinetics of the racemization which oxazolones undergo through an autocatalytic process (7, 9, 10), as well as the kinetics of their racemization in the presence of tertiary amines.

Results and discussion

Racemization was monitored by observing the change in optical rotation of a solution of the oxazolone. To demonstrate the validity of the approach, the stability of the oxazolones under the same conditions was examined by ^{1}H-nuclear magnetic resonance spectroscopy. Oxazolones exhibit a characteristic C(4)-proton signal which is different from that of the α-H in the precursor acid or any product generated by ring-opening, thus allowing the detection of 3–5% of impurity. Compounds **2***e*, **2***f* and **2***g* in deuteriochloroform, tetrahydrofuran-D_8 or dimethylformamide-D_7 showed no change for at least 6 h after the addition of 1% of triethylamine. In fact, there was no apparent change in the compounds kept for 18 h in tetrahydrofuran-D_8 in the presence of 0.5 equiv. of triethylamine. That oxazolones are relatively stable to hydrolysis is attested to by the fact that **2***c* could be isolated in near-quantitative yield 2 h after dissolution in tetrahydrofuran–water (1:1). We conclude that the change in optical activity of a solution of oxazolone in the presence of tertiary amines is due solely to the racemization process resulting from abstraction of the C(4)-proton (2).

In the cases studied, in aprotic solvents the racemization process involved parallel reactions [1] to [6]:

$$[1]\quad Ox_S \xrightarrow{k_1} Ox_R$$

$$[2]\quad Ox_R \xrightarrow{k_1} Ox_S$$

$$[3]\quad Ox_S + Ox_S \xrightarrow{k_2} Ox_R + Ox_S$$

$$[4]\quad Ox_R + Ox_R \xrightarrow{k_2} Ox_S + Ox_R$$

$$[5]\quad Ox_S + Ox_R \xrightarrow{k_2'} Ox_S + Ox_S$$

$$[6]\quad Ox_R + Ox_S \xrightarrow{k_2'} Ox_R + Ox_R$$

1 2 3

	1	R^1	R^2
a	Ac-Phe	CH_3	$C_6H_5CH_2$
b	Ac-Leu	CH_3	$(CH_3)_2CHCH_2$
c	Bz-Phe	C_6H_5	$C_6H_5CH_2$
d	Bz-Leu	C_6H_5	$(CH_3)_2CHCH_2$
e	Bz-Val	C_6H_5	$(CH_3)_2CH$
f	Z-Gly-Phe	$ZNHCH_2$	$C_6H_5CH_2$
g	Z-Gly-Leu	$ZNHCH_2$	$(CH_3)_2CHCH_2$
h	Z-Gly-Val	$ZNHCH_2$	$(CH_3)_2CH$
i	Z-Gly-Ala	$ZNHCH_2$	CH_3

Combining these reactions one can obtain the rate equation [7]:

$$[7]\quad \frac{d[Ox_S]}{dt} = k_1\{[Ox_R] - [Ox_S]\} + k_2\{[Ox_R]^2 - [Ox_S]^2\}$$

or

$$[8]\quad \frac{d[Ox_S]}{dt} = -\{k_1 + k_2[Ox_T]\}\{[Ox_S] - [Ox_R]\}$$

where $[Ox_T] = [Ox_S] + [Ox_R]$.

Since the observed optical rotation of the solution of oxazolone is equal to:

$$[9]\quad \alpha = \frac{\phi l}{10}\{[Ox_S] - [Ox_R]\} = \frac{\phi l}{10}\{2[Ox_S] - [Ox_T]\}$$

where l is the length of the polarimeter tube (dm) and ϕ is the molecular rotation which is equal to the specific rotation times the molecular weight divided by 100. One can note that:

$$[10]\quad \frac{d}{dt}\{[Ox_S] - [Ox_R]\} = \frac{d}{dt}\{2[Ox_S] - [Ox_T]\}$$
$$= 2\frac{d}{dt}[Ox_S]$$

Uniting [8], [9], and [10] gives

$$[11]\quad \frac{d\alpha}{dt} = -2\alpha\{k_1 + k_2[Ox_T]\}$$

This is a pseudo first-order reaction, in which

$$[12]\quad k_{obs} = 2\{k_1 + k_2[Ox_T]\}$$

and k_1 and k_2 may be found by plotting k_{obs} against $[Ox_T]$.

It is seen in Table 1 that the values of the rate constants for the racemization of a series of oxazolones in dichloromethane depend on the nature of the C(2) as well as the C(4)-substituents. There was an inverse relationship between the steric hindrance caused by the C(4)-substituent and the reaction rate, the rate diminishing over 70 times (at $[Ox_T] = 0.1$ mol dm^{-3}) in the order (R^2) benzyl > isobutyl >> isopropyl. In the extreme case of the isopropyl analogue, the first-order reaction rate was below the limit of detection. The relatively high rate constant of reaction of the 4-benzyl analogue in comparison to the 4-isobutyl analogue is probably due to the unique conformation

TABLE 1. Reaction rate constants for the autoracemization of oxazolones **2** in dichloromethane: $[Ox_T] = 0.05$–0.90 mol dm^{-3}, temperature = 23°C[a]

2	R^1	R^2	$k_1 \times 10^6$ (s^{-1})	$k_2 \times 10^5$ ($dm^{-3}mol^{-1}s^{-1}$)

e	C_6H_5	$(CH_3)_2CH$	0.05	0.34

[a]Relative mean error in k_1 and k_2 is $< \pm 4\%$.

assumed by the phenyl ring of the benzyl substituent (see below). The nature of R^1 affected the racemization rate to a similar extent, due to electronic rather than steric effects. The data substantiate the reports that oxazolones **2** undergo a chiral inversion process which is autocatalytic (7, 9, 10). Autoracemization, however, is unlikely to occur in the course of peptide synthesis, because of the relatively high concentration of bases present. Instead, the base-catalyzed reaction will predominate.

As seen in Table 2, the rate of racemization of oxazolone **2***f* in the presence of tertiary amines was markedly affected by the nature of the amine. There was no discernable correlation between the apparent rate constants and the accessibility of the nitrogen atom of the acyclic bases (DIEA < Bu_3N < Et_3N) in the two solvents, and also of the cyclic bases (<NMM/NMP) in dimethylformamide. The reasons for the differences in catalytic effects between NMM and NMP remain obscure.

The base-catalysed racemization of oxazolones **2** in tetrahydrofuran obeys simple pseudo first-order kinetics.

$$[13]\quad Ox_S + B \underset{k_4}{\overset{k_3}{\rightleftharpoons}} Ox^- + BH^+ \underset{k_3}{\overset{k_4}{\rightleftharpoons}} Ox_R + B$$

where B is the base, and Ox^- is the deprotonated oxazolone. Under steady-state conditions $d[Ox^-]/dt = 0$, the rate equation

$$[14]\quad -\frac{d[Ox_S]}{dt} = k_3[B][Ox_S] - k_4[Ox^-][BH^+]$$

becomes equal to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/07/12
For personal use only.

$$[15] \quad -\frac{d[Ox_S]}{dt} = k_3[B_T]\left\{[Ox_S] - \frac{[Ox_T]}{2}\right\}$$

where $[B_T] = [B] + [BH^+]$ is the total concentration of base. If $[Ox^-]$ is much less than $[Ox_T]$, the observed optical rotation of a solution of oxazolone can be expressed in terms of $[Ox_S]$ and $[Ox_T]$ (see eq. [9]) and eq. [15] can be written as

$$[16] \quad -\frac{d\alpha}{dt} = k_3[B_T]\alpha$$

which can be integrated to give

$$[17] \quad \ln\frac{\alpha_0}{\alpha} = k_3[B_T]t$$

On the basis of the dependence of the apparent rate constants, $k_{obs} = k_4[B_T]$ on the concentration of base, $[B_T]$, and the reaction temperature, the values of the catalytic rate constant, k_4, and the activation parameters of the reaction in the presence of several tertiary amines were obtained (Table 3). The values of the enthalpy of activation, $\Delta H^{\neq}$, of the reaction increased in the order $Et_3N < Bu_3N < NMM \simeq NMP \simeq DIEA$, which can be attributed not only to changes in the basicities of the amines but also to changes in the energetic expense required for the amine to approach the reaction centre, i.e., to steric interactions. On the other hand, despite the same values of $\Delta H^{\neq}$ for reactions in the presence of *N*-methylmorpholine and *N*-methylpiperidine, the catalytic rate constant of the NMP-catalysed reaction is unexpectedly high. This results from the relatively small entropy of activation of the latter reaction, which is probably due to solvation effects.

The influence of the nature of the substituents R^1 and R^2 on the reaction parameters for the base-catalysed racemization of oxazolones **2** in tetrahydrofuran was examined. It is seen in Table 4 that the effect was exerted mainly in changes in the values of enthalpy of activation. Thus, the enthalpy of activation of oxazolone **2***b* (oxazolone from Ac-Leu) was about 50% higher than that of **2***d* (oxazolone from Bz-Leu). However, racemization of the oxazolone from Z-Gly-Phe (**2***f*) was twice as rapid as that of the oxazolone from Z-Gly-Leu (**2***g*) due to the entropy effect. This could be caused by the folding of the side-chain phenyl ring over the oxazolone ring, a phenomenon observed for 4-oxazolidinones (12) and other heterocyclic compounds (13, 14). In fact, such a conformation has been suggested for 2-methyl-4-benzyl-5(4*H*)-oxazolone (**2***a*) on the basis of its ^{1}H-nmr spectrum (15) and is indicated when one compares the nmr spectra of the oxazolones **2***a–h* (16). Such a feature of the oxazolone molecule should diminish the steric interaction of the 4-benzyl substituent with the approaching tertiary amine, and the rotation around the C(4)—CH_2Ph bond should be frozen in the ground and transition states. On the other hand, the transition state of the 4-isobutyl analogue should be more restricted than its ground state because of the base–C(4)-substituent steric interactions. Indeed, the racemization of 2-$ZNHCH_2$-4-benzyl-5(4*H*)-oxazolone is favoured by 8 J mol^{-1} K^{-1} in entropy. Moreover, there would be almost no difference in rotation around the C(4)—CH_3 bond in the ground and transition states of the 4-methyl analogue, and the values of $\Delta S^{\neq}$ between the 4-benzyl and 4-methyl analogues differ only by 2 J mol^{-1} K^{-1}.

The influence of the C(2)-substituents on the rate of racemization is mainly of mesomeric and/or inductive nature (compare $\Delta H^{\neq}$ values in Table 4), and the reaction rate decreased in the order phenyl > $ZNHCH_2$ ≫ methyl. Nevertheless, small long-distance steric interactions between the C(2)- and C(4)-substituents are still possible, and the entropy of activation of the 2-$ZNHCH_2$ analogue is 5 J mol^{-1} K^{-1} lower than that of the 2-methyl analogue.

TABLE 2. Apparent rate constants of the base-catalyzed racemization of 2-($ZNHCH_2$)-4-benzyl-5(4*H*)-oxazolone (**2***f*): $[Ox_T] = 0.10$ mol dm^{-3}, $[B_T] = 4 \times 10^{-4}$ mol dm^{-3}

In relation to the influence of the C(2)-substituent, it is of interest to note that although *N*-acetylamino acids undergo more racemization than the corresponding *N*-protected peptides when coupled with an amino group (3), the rate of racemization of the oxazolone from Ac-Leu (**2***b*) was almost 17 times less than that of the oxazolone from Z-Gly-Leu (**2***g*) (Table 4). Thus the relative rates of racemization of oxazolones are not a true reflection of the relative susceptibilities to racemization of residues during coupling. Other variables implicated in determining the stereomutation observed in a coupling are the rates of oxazolone formation, coupling, and aminolysis, as well as asymmetric induction.

Conclusions

2,4-Disubstituted-5(4*H*)-oxazolones **2** in solution undergo solvent-promoted and/or autocatalyzed racemization, both reactions being governed by electronic effects of the C(2)-substituents and steric effects of the C(4)-substituents. In the presence of tertiary amines, the base-catalyzed reaction takes place. The rate of this reaction depends on the steric interactions between the oxazolone and the amine molecules, and the basicity of the amine. Again, the influence of the C(2)-substituents of the oxazolone on the rate of reaction is mainly mesomeric and/or inductive in nature, whereas that of the C(4)-substituents is steric. The relatively rapid racemization of 2-substituted-4-benzyl-5(4*H*)-oxazolones compared to the 2-substituted-4-alkyl-5(4*H*)-oxazolones is due to the entropy

effect and it is probably caused by folding of the phenyl ring over the oxazolone ring.

Experimental

General

Amino acid derivatives and the carbodiimide were obtained from Sigma Chemical Co. (St. Louis, MO), tertiary amines were Aldrich products obtained from Terochem Labs (Edmonton, AL), solvents were HPLC-grade obtained from Fisher Scientific. Dimethylformamide was freshly distilled under reduced pressure before use. Optical rotations were measured with a Rudolph Research (Flanders, NJ) Autopol III automatic polarimeter using a 2-dm thermostated tube.

Kinetic determinations

Oxazolones were weighed in 10-mL volumetric flasks. Solvents and amine solutions at the appropriate temperatures were added and the solutions were immediately transferred to the polarimeter tube. The changes in optical rotation were recorded until an 80% decrease in the initial value had been reached. Experiments were carried out using the bivariable plan, i.e., the temperature and concentration of one of the reactants or the concentrations of the two reactants were varied at the same time according to the latin squares method. The ranges of values for the variables are given in the tables. Any results which are compared are from experiments carried out with the same batch of solvents.

*2,4-Disubstituted-5(4*H*)-oxazolones 2*

These were prepared by a slight modification of the published procedure (7). *N*-Ethyl-*N'*-(3-dimethylaminopropyl)-carbodiimide hydrochloride (1 mmol) was added to a solution of the *N*-substituted amino acid or dipeptide **1** (1 mmol) in 20 mL of dichloromethane at 0°C and the mixture was washed successively with cold 10% aqueous citric acid, water, 5% aqueous $NaHCO_3$ and water, the solution was dried ($MgSO_4$), and the solvent was removed with a rotary evaporator (bath temperature 35°C). The yields, mp's, and specific rotations of the products were in agreement with previous data (7). In some cases, the stereochemical purity of the oxazolones was verified by converting them into hydrazines **3** (7, 8, 17) by leaving the oxazolone (1 mmol) in 10 mL of methanol containing 85% hydrazine hydrate (1 mL) for 10 min. After removal of the solvent, the specific rotations of the products were compared with those of the same compounds prepared from the corresponding esters (7, 18) (Table 5).

Data handling and presentation

All the kinetic data are reported to within the last significant figure (at confidence level 0.05) and the confidence intervals are omitted in order to simplify the presentation of data. The values of the apparent rate constants were found for each pair of measurements (t_{i-1}, α_{i-1}), (t_i, α_i) according to:

$$[18] \quad k_{obs} = \frac{1}{t_i - t_{i-1}} \ln \frac{\alpha_{i-1}}{\alpha_i}$$

and the mean values are reported. The values of the enthalpy and entropy for the transition state reaction rate theory, and the catalytic rate constants were computed using the weighted least-squares technique (19) with a Sharp mini-computer, type PC-1401.

The effect of substitution on the conformation in *para*-substituted ethylene glycol dibenzoate molecules

SUZANNE DEGUIRE AND FRANÇOIS BRISSE

Département de chimie, Université de Montréal, C.P. 6128, Succ. A, Montréal (Québec), Canada H3C 3J7

Received February 22, 1988

SUZANNE DEGUIRE and FRANÇOIS BRISSE. Can. J. Chem. **66**, 2545 (1988).

The series of ethylene glycol di-*para*-X-benzoates, where X = Me, OMe, CN, and NO_2, has been studied by infrared spectroscopy and solid state CP/MAS ^{13}C nuclear magnetic resonance. The crystal structures were established for X = Me and OMe. Bond distances, bond angles, and torsion angles were compared to those of related molecules (X = H, Ph, Cl). It was found that the conformation of the CO—O—CH_2—CH_2—O—CO sequence is either *trans-trans-trans* or *trans-gauche-trans*. (*trans* = *t*, *gauche* = *g*). The CH_2—CH_2 bond distance ranging from 1.471(2) to 1.499(3) Å is always very short. The O—CH_2—CH_2 bond angle is around 105° for the *ttt* conformation and 107° for the *tgt* conformation. It was confirmed that the infrared frequencies for the CH_2 bending, CH_2 wagging, C–C stretching, and CH_2 rocking modes are observed at 1470–1485, 1335–1340, 975–980, 845–855 cm^{-1} and at 1460, 1370–1375, 1040, 895–900 cm^{-1} for the *ttt* and *tgt* conformations respectively. The substitution effect on the nmr chemical shifts, both in solution and the solid state, can be rationalized in terms of induction and resonance contributions. On the basis of the ir and nmr spectra, it is proposed that for both the *p*-NO_2 and *p*-CN substituted molecules, for which no crystal structure has been established, the conformation of the methylenic sequence is *trans-trans-trans*.

SUZANNE DEGUIRE et FRANÇOIS BRISSE. Can. J. Chem. **66**, 2545 (1988).

Faisant appel à la spectroscopie infrarouge et à la résonance magnétique nucléaire CP/MAS du ^{13}C à l'état solide, on a étudié une série de di-*para*-X-benzoates de l'éthylène glycol dans laquelle X = Me, OMe, CN et NO_2. Pour les cas où X = Me et OMe, on a établi les structures cristallines. On a comparé les longueurs des liaisons, les angles des liaisons ainsi que les angles de torsion avec les valeurs correspondantes observées dans des molécules apparentées (X = H, Ph et Cl). On a trouvé que la conformation de la séquence CO—O—CH_2—CH_2—O—CO est soit *trans-trans-trans* soit *trans-gauche-trans* (*trans* = *t* et *gauche* = *g*). La longueur de la liaison CH_2—CH_2, qui varie de 1,471(2) à 1,499(3) Å, est toujours très courte. L'angle de la liaison O—CH_2—CH_2 est d'environ 105° pour la conformation *ttt* et de 107° pour la conformation *tgt*. Dans l'infrarouge, les vibrations des modes de déformation angulaire du CH_2, de vibration de balancement du CH_2, d'élongation C–C et de vibration de rotation du CH_2 sont observées 1470–1485, 1335–1340, 975–980 et 845–855 cm^{-1} et 1460, 1370–1375, 1040 et 895–900 cm^{-1} respectivement pour les conformations *ttt* et *tgt*. On peut rationaliser l'effet de substitution des déplacements chimiques en rmn, tant en solution qu'à l'état solide, en faisant appel à des contributions de l'induction ainsi que de la résonance. En se basant sur les spectres ir et rmn, on suggère que les molécules substituées tant par un *p*-NO_2 que par un *p*-CN, pour lesquelles les structures cristallines n'ont pas été établies, existent dans la conformation impliquant une séquence méthylénique *trans-trans-trans*.

[Traduit par la revue]

Introduction

Daubeny, Bunn, and Brown (1) were the first to determine the structure of the crystalline region of poly(ethylene terephthalate) or 2GT. The fiber repeat was found to be 0.15 Å shorter than expected for an all-*trans* conformation. The departure from planarity was mostly localized in the glycol group. Tomashpol'skii and Markova (2) and Arnott and Wonacott (3) reinvestigated the structure of 2GT. Their structures are in general agreement with that proposed earlier by Daubeny *et al.* However, there remains some puzzling discrepancies between the three structures. More accurate information about the geometry of the repeat unit had to be provided.

Pérez and Brisse (4, 5) tackled this problem by the model compound approach. They undertook a systematic study of ethylene glycol dibenzoates and *para*-substituted dibenzoates. The crystal structure of ethylene glycol dibenzoate, 2DBO (C_6H_5—CO—O—$(CH_2)_2$—O—CO—C_6H_5), showed some unusual geometrical features (4). The CH_2—CH_2 bond distance of 1.499(3) Å was significantly shorter than the expected $C(sp^3)$—$C(sp^3)$ distance of 1.535(3) Å (6). Simultaneously, the two C—C—O angles involving this CH_2—CH_2 bond were not as open as expected. Using these geometrical parameters, the distance between the centers of the aromatic rings of ethylene glycol dibenzoate was identical to the fiber repeat, *c*, reported by Daubeny *et al.* for poly(ethylene terephthalate).

The crystal structure of ethylene glycol di-*para*-chlorobenzoate, 2DBO-*p*-Cl (Cl—C_6H_4—CO—O—$(CH_2)_2$—O—CO—C_6H_4—Cl), was also determined (5). The same significant shortening of the ethylene part of the molecule was observed. The CH_2—CH_2 distance was only 1.493(2) Å. Unlike ethylene glycol dibenzoate, for which the O—CH_2—CH_2—O sequence was shown to be in the *trans* conformation, the same sequence was found to be in the *gauche* conformation in the case of 2DBO-*p*-Cl.

Since these two molecules, which differ only by the *para* substituent, have two different conformations, we undertook to study the *para*-substitution effect on the conformation. To do this, we chose substituents of different size, geometry, and electronegativity: methyl, methoxy, phenyl (7), nitro, and cyano groups.

Structural information about this series of model compounds was collected by means of X-ray structure determinations. Infrared spectroscopy was used to gain additional structural information on certain model compounds, for which no crystal suitable for X-ray structure determination could be obtained.

Solid-state CP/MAS ^{13}C nmr spectroscopy was also investigated. It has been shown previously that the γ-*gauche* effect and molecular packing interactions both affect the chemical shift to different degrees. By studying this series of model compounds we tried to quantify the factors influencing the chemical shift.

Experimental

Ethylene glycol di-*para*-methylbenzoate, 2DBO-*p*-Me, ethylene glycol di-*para*-methoxybenzoate, 2DBO-*p*-OMe, ethylene glycol di-*para*-cyanobenzoate, 2DBO-*p*-CN, and ethylene glycol di-*para*-nitrobenzoate, 2DBO-*p*-NO_2, were prepared according to the method described by Heim and Poe (8), by reacting, in pyridine, solutions of ethylene glycol and of the *para*-methyl, *para*-methoxy, *para*-cyano, or *para*-nitro substituted benzoyl chlorides. Crystals of 2DBO-*p*-Me and 2DBO-*p*-OMe were obtained by slow evaporation from a chloroform solution.

X-ray diffraction

The orientation of the well-developed single crystals of 2DBO-*p*-Me and 2DBO-*p*-OMe and their unit-cell dimensions were obtained by a least-squares fit to the angular settings of 25 well-centered reflections on a Nonius CAD-4 diffractometer. Graphite monochromatized CuKα radiation was used ($\lambda CuK\bar{\alpha}$ = 1.54178 Å). Crystal data of interest are given in Table 1. The data collections were performed by the ω–2θ scan method. The orientation of the crystal was monitored every 100 reflections. The intensities of three reference reflections in both cases, measured every hour, showed a maximum random variation of 1.0% for 2DBO-*p*-Me and 1.6% for 2DBO-*p*-OMe over the duration of the data collection. The diffracted intensities were corrected for Lorentz and polarization effects. No absorption correction was applied since the absorption coefficients were small.[1]

The structures were solved by direct methods using MULTAN. All non-hydrogen atoms were revealed in the first computed E-map. The hydrogen atoms were located on subsequent difference Fourier syntheses. The weighted least-squares refinements of the atomic coordinates, minimizing $\Sigma w(|F_o| - |F_c|)^2$, were conducted with anisotropic temperature factors for C and O atoms and isotropically for H atoms. The details of the least-squares refinement of the two compounds are given in Table 2.

The scattering curves for C and O atoms were taken from ref. 13 and those for H atoms from ref. 14.

Infrared spectroscopy

The ir spectra were recorded from KBr pellets on a FTIR Nicolet 7199 equipped with a He–Ne class II laser with a resolution of 2 cm^{-1} and 200 scans per spectrum, while the background noise spectra were signal-averaged with 100 scans. The FTIR spectra of 2DBO and of the *p*-X-substituted derivatives where X = Me, OMe, Ph, Cl, CN, and NO_2 were thus recorded.

Nuclear magnetic resonance

The ^{13}C nmr solution spectra were measured on a Bruker 80 MHz spectrometer at a frequency of 20.11 MHz. Each compound (0.1 g) was dissolved in 2 mL of $CDCl_3$, and tetramethylsilane was used as reference. ^{13}C CP/MAS spectra were taken with a Varian CXP 300 MHz at a frequency of 75.31 MHz. An averaged contact time of 1.9 μs was used with a delay of around 5.0 s between sequences. An averaged number of 5138 contacts was used.[2]

Chemical shifts are given with respect to powdered hexamethylbenzene whose aromatic signal is at 132.1 ppm.

Results and discussion

Structural considerations

For 2DBO-*p*-Me, both the Cc or $C2/c$ space groups are compatible with the observed systematic absences. Since the refinement proceeded normally in $C2/c$, this choice was retained. Furthermore, the density indicated that there are only four molecules per unit cell and these lie about the twofold symmetry axes. In the case of 2DBO-*p*-OMe, the space group is $P\bar{1}$ and the density indicates two molecules in the unit cell. However, instead of having two centrosymmetrically related molecules, we find here that each molecule (A and B) has a crystallographic center of symmetry.

The final positional parameters and their standard deviations are presented in Table 3. The atomic numbering is shown in Fig. 1 and the molecular structures are presented as stereopairs in Fig. 2. The packing of the molecules is shown in Fig. 3. The bond distances and angles of 2DBO-*p*-Me and 2DBO-*p*-OMe are given in Table 4 where they are compared to the corresponding quantities for 2DBO-*p*-Ph, 2DBO-*p*-Cl, and 2DBO.

The benzoate groups

The C(sp^2)—C(sp^2) bond distances in the phenylene rings average 1.384 Å for 2DBO-*p*-Me, 2DBO-*p*-OMe, and 2DBO-*p*-Cl, 1.389 Å for 2DBO-*p*-Ph, and 1.379 and 1.384 Å for 2DBO. They are very close to the mean bond length of 1.379 Å computed from 78 C(sp^2)—C(sp^2) distances by Brisse and Sygusch (15). The average angle in each of the benzene rings is 120.0°.

There are some slight deviations from a perfect hexagonal symmetry. The angles affected by substitution, at C(1) and C(4), have been underlined in Table 4. They can be accounted for and confirm the rules established by Domenicano, Vaciago, and Coulson (16).

As usual the angles around the carbon atom C(7) of the ester groups are unequal. This disymmetry tends to open the C(1)—C(7)—O(1) angle while the C(1)—C(7)—O(2) angle is lowered. The mean value of the C(1)—C(7)—O(1) angle is 124.5°, the mean value of C(1)—C(7)—O(2) is 112.1°, while the angle O(1)—C(7)—O(2) has a mean value of 122.2°.

The methylenic sequence

As noted for 2DBO and 2DBO-*p*-Cl, the observed CH_2—CH_2 bond lengths are always significantly shorter than the expected C(sp^3)—C(sp^3) distance of 1.535(3) Å (6). The mean bond length is 1.490 Å. It varies from 1.471(3) to 1.499(3) Å. Bocelli

[1]The programs used here are modified versions of NRC-2, data reduction; NRC-3, absorption correction; NRC-10, bond distances and angles; and NRC-22, mean planes; FORDAP, Fourier and Patterson maps (A. Zalkin); MULTAN, multisolution program; NUCLS, least-squares refinement; and ORTEP, stereodrawing (9–12).

[2]^{13}C CP/MAS experimental details have been deposited together with H-atom coordinates, anisotropic thermal parameters, and structure factor tables of the X-ray determinations. Copies may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

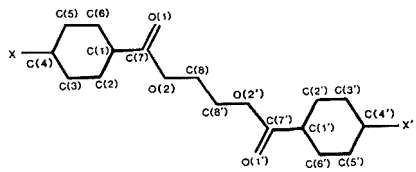

FIG. 1. Schematic representation of the molecules and atomic numbering.

and Grenier-Loustalot have observed a similar short distance for 2,3-butenediyl dibenzoate (17) and 1,2-propanediyl di(*p*-chlorobenzoate) (18). The C(8)—C(8′) distance measures 1.511(3) and 1.471(9) Å respectively in the above two compounds. All this justifies, after the fact, the short C—C distance that was adopted, without justification, by Daubeny *et al.* (1) in the structure of poly(ethylene terephthalate). Note also that the angle O(2)—C(8)—C(8′), involving the CH_2—CH_2 bond, has a mean value of 105.5° (it varies from 104.9(2) to 107.3(2)°). This angle is strikingly smaller than is usually accepted for molecules with no apparent strain. In 2,3-butanediyl dibenzoate this angle has a value of 103.6(2)°, and its values are 103.7(4) and 104.2(5)° in 1,2-propanediyl bis(*p*-chlorobenzoate). It seems that the value taken by this O—C—C angle depends upon the conformation (see below). We observe an angle of about 105° or less when the conformation is all-*trans*. When the conformation is *trans-gauche-trans*, the angle is slightly larger, about 107°.

Conformation

The conformational angles for the dibenzoates correspond to the calculated conformations, which are energetically stable. The torsional angles that characterize the methylenic sequence are defined by ϕ_1 = C(7)—O(2)—C(8)—C(8′), ϕ_2 = O(2)—C(8)—C(8′)—O(2′), and ϕ_1' = C(8)—C(8′)—O(2′)—C(7′). The values taken by these torsional angles are given in Table 5. We observe two types of conformation: *trans-trans-trans* and *trans-gauche-trans*. Bocelli and Grenier-Loustalot (17, 18) have observed a conformation relatively far from all-*trans* for the two compounds. The angle values of the methylenic sequence are −156.6, −179.0, and 146.4° for 2,3-butanediyl dibenzoate. In 1,2-propanediyl bis(*p*-chloro-

benzoate), the corresponding angle values are 152.1, −169.8, and −174.6°. It is the bulk of the methyl groups which is responsible for the deviation from the *trans* conformation. Poulin-Dandurand (19) calculated the conformational energy of an isolated molecule of ethylene glycol dibenzoate, 2DBO. The (ϕ_1, ϕ_2) pairs of torsion angles corresponding to the five lowest energy minima, all within 1 kcal/mol, are compared in Table 5 with the actual torsion angles of the dibenzoates.

Mean planes

The carboxylic groups are tilted by about 5° with respect to the corresponding phenyl plane. This is in good agreement with the systematic study of benzoate groups (7) in which it is found that the dihedral angle between the carboxylate group and the phenylene ring is in the interval of 0–10° with the most frequently observed value around 5°.

Relation to the parent polyester

The equivalent fiber repeat, p_c, is measured by the distance between the centers of the aromatic rings. In 2DBO, 2DBO-*p*-OMe, and 2DBO-*p*-Ph, p_c is very close to the observed fiber repeat, c = 10.75 Å, reported by Daubeny *et al.* (1) in

poly(ethylene terephthalate). In 2DBO-*p*-Me and 2DBO-*p*-Cl, p_c is 10.27 and 9.27 Å respectively, values much lower than the observed fiber repeat of 2GT.

For a planar chain, i.e., for the polyester in a fully extended conformation, the calculated fiber repeat is 10.9 Å. It is interesting to note that for the three model compounds with various combinations of bond distances, angles, and torsion angles, the equivalent fiber repeat is always shorter than that for an all-*trans* conformation and nearly matches the observed fiber repeat of poly(ethylene terephthalate).

Packing of the molecules

In all the molecules, none of the intermolecular contacts is less than 3.30 Å; therefore, the molecules are held in the crystal by van der Waals forces only.

In 2DBO, 2DBO-*p*-Ph, and 2DBO-*p*-OMe, the molecules are packed in a herringbone manner. In 2DBO-*p*-Me, the molecules are in an interlocking herringbone type of arrangement.

Infrared spectra

Since our interest was in the conformation of the methylenic sequence, the relevant absorption bands are those of the methylene groups. The FTIR bands observed for these vibrational modes for the dibenzoates are compared in Table 6.

The band assignment follows the work of Schneider *et al.* (20), Boitsov and Gotlib (21), and Ward and Wilding (22). They established a series of bands for the *trans* and the *gauche* conformations of a O—CH_2—CH_2—O segment. They assigned the absorption bands at 1470, 1340, 975, and 845 cm^{-1} to the *trans* conformation while the absorption bands at 1450, 1370, 1040, and 898 cm^{-1} were assigned to the *gauche* conformation. This assignment is confirmed in the case of the dibenzoates whose structures were determined in this work. We propose that in both 2DBO-*p*-CN and 2DBO-*p*-NO_2, for which compounds no crystal structure has been determined, the O—CH_2—CH_2—O sequence is in the *trans* conformation. All the absorption bands of 2DBO-*p*-CN and 2DBO-*p*-NO_2 fit very well with the assignment corresponding to a *trans* conformation. In the case of 2DBO-*p*-NO_2, the band at 1340 cm^{-1} is absent. It is probably hidden in the strong absorption of the symmetric stretching of the nitro group at 1336 cm^{-1}.

Another relevant absorption band is the ν(C=O) band of a benzoate group, normally observed at 1720 cm^{-1} (23). It is the resonance between the aromatic ring and the ester group which lowers the frequency with regard to that of a saturated ester whose band ν(C=O) is at 1735 cm^{-1} (24). The resonance between the aromatic ring and the ester group is influenced by the nature of the substituent on the six-membered ring. The effect of the substitution on the resonance between the phenylene ring and the ester group is qualitatively evaluated in Table 7 by taking into account the inductive effect and the resonance effect of the substituents (25). In the case of the methyl, phenyl, cyano, and nitro groups, there is no ambiguity in interpreting the observed shifts since both the inductive and resonance effects act in the same direction. In the case of 2DBO-*p*-Me and 2DBO-*p*-Ph, we observe an increase of the resonance between the aromatic ring and the ester group, and this is characterized by a ν(C=O) band observed at 1715 and 1708 cm^{-1} respectively. However, when the substituents are nitro or cyano groups, the ν(C=O) band is observed in both cases at 1724 cm^{-1}, as the resonance between the six-membered ring and the ester group is lowered. As for the methoxy and chloro groups, the two contributions have opposite effects. It is then difficult to evaluate their combined effect. We observe two ν(C=O) bands at 1715 and 1709 cm^{-1} for 2DBO-*p*-OMe, and one at 1714 cm^{-1} for 2DBO-*p*-Cl, thus indicating an increase of the resonance between the phenylene ring and the ester group. Therefore, the contribution of the resonance between the methoxy group and the aromatic ring is then larger than the contribution of the inductive effect.

TABLE 7. Contributions of the substituents on the resonance between the aromatic ring and the ester group

	Contributions*		Effect of the substituent on the resonance	
Substituent	Induction	Resonance	Predicted	Experimental
Me	+I	+R	Increase	Increase
OMe	−I	+R	?	Increase
Cl	−I	+R	?	Increase
Ph	—	+R	Increase	Increase
NO_2	−I	−R	Decrease	Decrease
CN	−I	−R	Decrease	Decrease

*−I: group takes on a negative charge by induction. +I: group takes on a positive charge by induction. −R: group takes on a negative charge by resonance. +R: group takes on a positive charge by resonance.

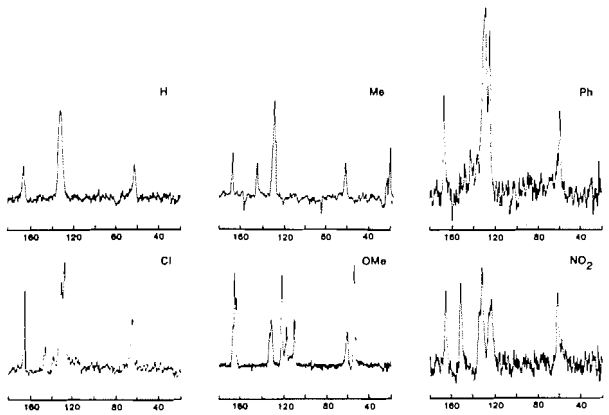

FIG. 4. ^{13}C nuclear magnetic resonance spectra of model compounds of polyethylene terephthalate.

^{13}C solid-state nuclear magnetic resonance

The ^{13}C solid-state nmr spectra of 2DBO, 2DBO-*p*-Me, 2DBO-*p*-OMe, 2DBO-*p*-Ph, 2DBO-*p*-Cl, and 2DBO-*p*-NO_2 are shown in Fig. 4. The chemical shifts in both the solid and liquid phases are given in Table 8.

In the cases of 2DBO-*p*-Me, 2DBO-*p*-Cl, and 2DBO-*p*-Ph, we observe only one peak for each pair of symmetrically related carbon atoms. This is because 2DBO-*p*-Me and 2DBO-*p*-Cl have a twofold axis of symmetry lying at the midpoint of the aliphatic chain while there is a center of symmetry in 2DBO-*p*-Ph.

Aliphatic region

These symmetry elements make the C(8), C(8′) and C(7), C(7′) atoms crystallographically equivalent in 2DBO-*p*-Me, -Cl, and -Ph. Thus, for these three compounds, only one peak is observed for C(8) and C(7). However, since there are two distinct centrosymmetrical molecules in the crystals of 2DBO-*p*-OMe, we observe two peaks for each of the C(8) and C(7) atoms. Finally, since there is no symmetry element in 2DBO there are also two peaks for each of the C(8) and C(7) atoms.

It has been shown that the γ-*gauche* effect and the molecular packing interactions both affect the chemical shift to different degrees. For the *para*-substituted dibenzoates, atoms C(8) and C(8′) are not affected by the γ-*gauche* effect since all the torsion angles (ω, ϕ_1) that could influence the chemical shift are *trans*. ω is the torsion angle C(7)—O(2)—C(8)—C(8′). However, the molecular packing interactions may still influence the chemical shift.

The averaged value of the chemical shift of C(8) in solution is 62.7 ppm and in the solid state it is 62.0 ppm. In both phases, the chemical shift does not vary significantly with the substitution. In solution, the extreme values are 62.4 and 63.2 ppm while in the solid phase they range from 60.2 to 62.5 ppm, except for 2DBO-*p*-Cl for which the chemical shift is 65.0 ppm. This value is out of the range observed here but it is quite similar to those obtained by Grenier-Loustalot and Bocelli for the ^{13}C solid-state nmr chemical shift of C(8) in butylene-1,4 dibenzoates substituted by chlorine in *ortho*, *meta*, and *para*, and in butylene-1,4 dibenzoate (28).

Aromatic ring

In solution, the chemical shift of the C(7) atom is influenced by the substitution of the aromatic ring, since the ester group is in resonance with the aromatic ring. Indeed, if the substituent is

*The values given in parentheses are for chemical shift calculated for the corresponding "methylbenzoate" (26, 27).
†In 2DBO-*p*-Me, *or* indicates that the assignment of C2/C6 could be interchanged.

strongly electron withdrawing, it will decrease the conjugation between the aromatic ring and the ester group, and thus C(7) will be shielded. In the case of the methyl, methoxy, chloro, and phenyl groups, their inductive and resonance effects increase the resonance between the aromatic ring and the ester group. For these substituents, the extreme values of the chemical shift of C(7) range from 165.5 to 166.3 ppm and their average is 166.0 ppm, a value quite similar to the chemical shift of C(7) in 2DBO (166.2 ppm). However, the nitro group is strongly electron withdrawing and it decreases the conjugation between the six-membered ring and the ester group. As expected, C(7) is shielded and its chemical shift is 164.3 ppm.

For the ^{13}C solid-state nmr, this effect is less remarkable. Indeed, the chemical shift of the C(7) atom ranges from 163.9 to 166.0 ppm and averages 164.7 ppm. In the solid state, the chemical shift of C(7) is also influenced by the γ-*gauche* effect related to the ϕ_1 torsion angle as well as by the molecular packing. In the case of the γ-*gauche* effect, this is negligible because, in all the compounds, the torsion angle of interest is always *trans*. The fluctuations of the chemical shift are then probably due to packing interactions.

As can be seen in Table 8, the observed chemical shifts of the aromatic ring carbons are quite similar to those calculated for the corresponding "methylbenzoate" in both solution and solid phase. In the case of 2DBO-*p*-OMe, the region of the aromatic carbons is more complicated in the solid-state spectra than in the solution spectra because the nuclei that are equivalent in solution (C(2), C(6) and C(3), C(5)) become nonequivalent in the solid. Indeed, the C(3) and C(5) atoms give rise to a doublet (see Table 8) separated by 7.3 ppm, while C(2) and C(6) are separated by 1.7 ppm although they are coincident in the liquid state. This is due to the nonsymmetric orientation of the methoxy group with respect to the aromatic ring. This has already been encountered in the study of *p*-alkoxybenzoic acids (29). Whereas free rotation about the methoxy bond may occur in solution, the molecule is locked in the solid state such that the C(3) and C(5) and the C(2) and C(6) atoms are no longer equivalent.

Conclusions

The study of these dibenzoates has served to establish that the CH_2—CH_2 bond length, whose average is 1.490 Å, is shorter than the expected C(sp^3)—C(sp^3) distance. The O—CH_2—CH_2 bond angles are not open as expected. It seems that this angle depends upon the value of the O—CH_2—CH_2—O torsion angle. We observe two types of conformation for the CO—O—CH_2—CH_2—O—CO sequence: all-*trans* and *trans-gauche-trans*. When the conformation is all-*trans* we observe an angle value of 105°, and when the conformation is *trans-gauche-trans* the angle value is 107°. No matter what the substituents are, the equivalent fiber repeat of those models in the all-*trans* conformation is always very close to that of the parent polyester.

The absorption bands in infrared spectroscopy confirm the conformation of the O—CH_2—CH_2—O sequence for the dibenzoates whose structures have been solved. For the two compounds for which no crystal structure has been determined, 2DBO-*p*-CN and 2DBO-*p*-NO_2, the observed absorptions allow us to propose, in both cases, a *trans* conformation.

For the molecules that have a twofold axis or a center of symmetry lying at the midpoint of the aliphatic chain, we observe in the nmr spectra only one peak for each pair of symmetrically related carbon atoms.

Palladium phthalocyanine and its polymorphic forms

ARNOLD KEMPA AND JAN DOBROWOLSKI

Institute of Inorganic Chemistry and Technology, Technical University of Gdańsk, 80-952 Gdańsk, Majakowski Str. 11/12, Poland

Received July 6, 1987[1]

ARNOLD KEMPA and JAN DOBROWOLSKI. Can. J. Chem. **66**, 2553 (1988).

Pd(II) phthalocyanine (PdPc) was obtained by reaction of $PdCl_2$ with phthalimide and urea in the presence of ammonium molybdate in boiling nitrobenzene, resulting in a good yield equal to 68%. This method has not been used previously. The following polymorphic forms were obtained: metastable α- and γ-PdPc, not previous described in the literature, and stable β-PdPc. The IR spectra and X-ray powder diffraction spectra of these phases were measured and interpreted. The results were compared with the literature data on polymorphic forms of other phthalocyanines. At this time we do not know if any of the PdPc polymorphs are isomorphous with the various forms of nickel, copper, and platinum phthalocyanine.

ARNOLD KEMPA et JAN DOBROWOLSKI. Can. J. Chem. **66**, 2553 (1988).

Faisant appel à une méthode qui n'avait pas été utilisée jusqu'à maintenant, on a préparé le phtalocyanure de Pd(II) (PdPc) avec un rendement de 68% en faisant réagir du $PdCl_2$ avec de la phtalimide et de l'urée en présence de molybdate d'ammonium, dans du nitrobenzène bouillant. On a obtenu les formes polymorphes suivantes : les formes métastables α- et γ-PdPc qui ne sont pas décrites dans la littérature ainsi que le forme stable β-PdPc. On a déterminé les spectres ir et les spectres de diffraction des rayons-X des poudres de ces phases et on les a interprétés. On a comparé les résultats avec ceux retrouvés dans la littérature pour des formes polymorphes d'autres phtalocyanures. Sur la base de ces données, on ne peut pas affirmer que des formes polymorphes du PdPc sont isomorphes avec diverses formes de phtalocyanures de nickel, de cuivre ou de platine.

[Traduit par la revue]

Introduction[2]

Our investigations on synthesis and properties of PdPc complexes with iodine required preparation and examination of certain physical properties of various polymorphic forms of PdPc. No data on PdPc polymorphs are available from the literature. From the group of phthalocyanines of the d^8 ions of the VIII group metals, viz. Ni, Pd, and Pt, PdPc was the least examined. This is probably due to difficulties associated with its synthesis. In a reaction of $PdCl_2$ with phthalonitrile Cl-PdPc is formed (1–3). PdPc can be obtained from palladium black and phthalonitrile, but the product contains a mixture of H_2Pc and colloidal palladium which are very difficult to remove (4, 5). Other methods of preparation also yield PdPc mixed with H_2Pc (1, 6). We therefore decided to synthesize PdPc by reaction of $PdCl_2$ with phthalimide in the presence of urea and a catalyst. PdPc has not been prepared by this method up to now, while according to Moser and Thomas (7), under such conditions no H_2Pc is formed and the chlorination of phthalocyanines does not occur. Following synthesis and purification of PdPc, its polymorphic forms were synthesized. The terms α, β, γ were used, similar to the polymorphic forms of CuPc (7). X-ray powder diffraction spectra of α-, β-, and γ-PdPc were taken to reveal similarities with the known diffraction spectra of α-PtPc (8), β-NiPc (9), α-CuPc (8, 10–14), and β-CuPc (11, 12, 14), γ-CuPc (8, 13, 14), and α- and β-H_2Pc (15). Another technique used to differentiate between polymorphic forms of phthalocyanines is their IR spectra (16). Infrared spectra of α-, β-, and γ-PdPc were taken to find out if they are identical. For isomorphous forms of the same compound (PdPc) the IR spectra should be identical, while for non-isomorphous forms the IR spectra should be different.

Experimental

Materials

Analytical grade $PdCl_2$, urea, ammonium molybdate, isopropanol, NaOH, HCl, pyridine, methanol, xylene, and purum grade phthalimide made in Poland. Analytical grade nitrobenzene and acetone were obtained from Reactivul Bucuresti, and analytical grade H_2SO_4 was of Polish production.

Syntheses

PdPc was obtained using a method typical for synthesis of CuPc (7), adapted in a suitable way. $PdCl_2$, phthalimide, and urea (1:4:14 molar) were heated in boiling nitrobenzene for 4 h in the presence of ammonium molybdate (2% of mass of phthalimide) as a catalyst. A large amount of greasy impurities is formed during the reaction, probably because the formed PdPc catalyzes a number of side reactions (17). The resulting product was purified by washing in succession with isopropanol, 2–3% NaOH, and 2–3% HCl. PdPc was subsequently recrystallized four times from concentrated H_2SO_4. Usually during recrystallization the solution of phthalocyanine in concentrated H_2SO_4 is poured into distilled water (18). In this case the resulting particles are very fine, difficult to filter and to decant. As a result we used our method of precipitation. Since the use of pure water for precipitation results in an irreversible formation of very small crystallites, we used sulphuric acid of concentration decreasing gradually from 96 to nearly 0%. This proved to be a very convenient precipitation agent. A solution of H_2SO_4 was added slowly to a stirred solution of PdPc in concentrated H_2SO_4. PdPc precipitated this way consists of larger crystallities that are easy to filter and to decant. After complete recrystallization the PdPc obtained (γ-form) was further purified by Soxhlet extraction using in succession: py – water 1:9 by volume, methanol, and acetone. Yield, 68%. *Anal.* calcd. for PdPc: C 62.10, H 2.61, N 18.10, Pd 17.19; found: C 61.97, H 2.41, N 18.36, Pd 17.14.

α-PdPc, not previously known, was obtained by a method typical for synthesis of α-phthalocyanines (7). The solution of PdPc in concentrated H_2SO_4 was poured into a large amount of vigorously stirred distilled water. The product was filtered, the remaining acid washed out, and the phthalocyanine dried at 150°C.

β-PdPc was obtained by a method typical for synthesis of β-phthalocyanines (7), by heating PdPc for several hours in boiling xylene, subsequent filtration, and drying at 150°C.

[1]Revision received May 13, 1988.

[2]Abbreviations used in this article are as follows: PdPc, Pd(II) phthalocyanine; NiPc, Ni(II) phthalocyanine; CuPc, Cu(II) phthalocyanine; PtPc, Pt(II) phthalocyanine; H_2Pc, metal-free phthalocyanine; Cl-PdPc, Pd(II) monochlorophthalocyanine.

We prepared γ-PdPc using a modification of Knudsen's method of synthesis of γ-CuPc (13). A solution of H_2SO_4 of concentration decreasing gradually from 96 to nearly 0% was added slowly to the solution of PdPc in concentrated H_2SO_4 in such a manner that the final concentration of H_2SO_4 was lower than 60%. The product was filtered, the remaining acid washed out, and the phthalocyanine dried at 130°C.

The IR spectra were recorded in Nujol suspension using NaCl plates and a Carl Zeiss Jena Specord 75 IR spectrophotometer. Polystyrene and indene served as standards.

X-ray spectra

Powder diffraction spectra were recorded using a DRON-2 X-ray diffractometer: CuK_α 35/20 radiation; slit arrangement 2, 2, 0.5. Range of pulse counter 4×10^3 pulses/s, gain 128, time constant 1 s, goniometer rate 2°/min. External standards β quartz, $Ca(H_2PO_4)_2 \cdot H_2O$. Angular range 5–50°.

Results and discussion

(*1*) It was found that the present method produced a 68% yield of PdPc (hence better than that in literature (5)), free of mixtures of Cl-PdPc and H_2Pc. The crude product, however, requires quite laborious purification. New α and γ phases of PdPc, not described in the literature, were synthesized; the stable β-PdPc was also obtained. The products are fine coloured crystalline powders with α reddish, β pale blue, and γ dark blue.

[a]In Å.

(*2*) Table 1 presents our IR absorption spectra; together with Kobayashi's results for high temperature (550°C) sublimed PdPc (19) and Keen's results for α Cl-PdPc (3). All peaks of the α form have been found in the spectrum of the γ polymorph which has several additional peaks. The phenomenon suggests a similarity in the crystalline structure of α- and γ-PdPc, which on the other hand differs from that of β-PdPc.

(*3*) Well developed X-ray powder diffraction spectra were obtained for β- and γ-PdPc. The spectrum of the α-phase, however, consists of only four low, insufficiently developed, broad peaks. Hence it is concluded that α-PdPc consists of crystallites smaller than 0.1 μm (8, 20–22). Using the Debye–Scherer equation (22), taking into account the broadening of peaks (including correction), the average size of crystallites of α-PdPc was calculated to be equal to 0.008 μm. Crystallites of β- and γ-PdPc must be much bigger, because spectra of these forms are well developed. Table 2 shows our diffraction spectra. The diffraction spectrum of β-PdPc is entirely different from the spectra of the remaining two polymorphs, which indicates that its crystalline structure is totally different from those of α and γ forms. All the peaks which occur in the spectrum of α-PdPc are also present in the spectrum of the γ form, which has several additional peaks. Hence, it can be supposed that the structure of α and γ polymorphs are similar, although small differences in structure are not excluded. By comparing literature data with our results, we find no similarity between the diffraction spectra of the PdPc phases and those of α-PtPc, α-, γ-CuPc, β-CuPc, and β-NiPc. Hence, we have no basis to correlate the isomorphism of the obtained α-, β-, and γ-polymorphic forms of PdPc with any of the above listed crystal phases.

Conclusions

It follows from our investigations that we obtained PdPc in one stable β-PdPc form and two metastable α and γ forms which are different from the β form on the basis of IR and X-ray diffraction. Further research is required to determine if the α and γ polymorphs are isomorphous or are somewhat different in structure, and to determine the structure of the stable β form.

The intermediates in the interaction of phenols with *N*-bromosuccinimide

YUAN L. CHOW,[1] DA-CHUAN ZHAO, AND CARL I. JOHANSSON
Department of Chemistry, Simon Fraser University, Burnaby, B.C., Canada V5A 1S6

Received March 17, 1988

YUAN L. CHOW, DA-CHUAN ZHAO, and CARL I. JOHANSSON. Can. J. Chem. **66**, 2556 (1988).

Phenols react with *N*-bromosuccinimide to generate 2-bromocyclohexadienone-type intermediates that enolize to 2-bromophenols thermally or photolytically with a wide range of rate constants depending on the parent phenol. A trace amount of acids not only accelerates the rates of the formation and decomposition of the 2-bromodienones, it also promotes the rearrangement of the 2-bromodienones to cross-conjugated 4-bromocyclohexadienones. The enolization of these last compounds affords 4-bromophenols. The occurrence of autocatalysis in dienone decompositions arising from more acidic bromophenols is also established. The reaction is assumed to occur by a bromophilic attack of phenols on the N—Br bond to form unstable hypobromites that rapidly rearrange to the 2-bromocyclohexadienone intermediates. The quantum yield of the photodecomposition of 2-bromo-(2*H*)-naphthalene-1-one in the vicinity of 365 nm was determined to be unity.

YUAN L. CHOW, DA-CHUAN ZHAO et CARL I. JOHANSSON. Can. J. Chem. **66**, 2556 (1988).

Les phénols réagissent avec le *N*-bromosuccinimide pour conduire à des intermédiaires du type bromo-2 cyclohexadiènones, qui s'énolisent en bromo-2 phénols d'une façon thermique ou photochimique et avec des constantes de vitesse très variables suivant la nature des phénols de base. L'addition de traces d'acides n'accélère pas uniquement les vitesses de formation ou de décomposition des bromo-2 diènones, elle provoque aussi la transposition des bromo-2 diènones en bromo-4 cyclohexadiènones avec une conjugaison croisée. L'énolisation de ces derniers composés conduit à des bromo-4 phénols. On a aussi démontré que des décompositions des diénones se produisent sous l'effet d'une autocatalyse qui est dûe aux bromophénols qui sont plus acides. On suppose que la réaction se produit par une attaque bromophile des phénols sur la liaison N—Br qui conduit à la formation d'hypobromites instables qui se transposent rapidement en intermédiaires bromo-2 cyclohexadiènones. On a établi que le rendement quantique de la photodécomposition de la bromo-2 (2*H*)-naphtalènone-1, autour de 365 nm, est égal à un.

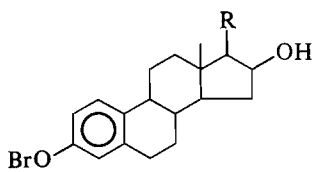
N-Bromosuccinimide (NBS) is a versatile brominating agent and has been used extensively in radical and ionic brominations (1–3).[2] We have observed that NBS reacts with phenols in aprotic solvent cleanly with second-order kinetics to form unstable intermediates that are shown to have dienone-type structures. The kinetics of formation and the behavior of these intermediates are described in this paper. Bromination of phenols with bromine has been studied extensively as a prototype electrophilic reaction (4–8). NBS has been used as an analytical reagent for phenols such as vanillin and thymol (9, 10), but its mechanistic aspects have scarcely received any attention. Semistable intermediates obtained from the reaction of NBS with estradiols have been suggested, such as the hypobromites **1** (11), although their nmr spectroscopic data are



1

equally compatible with a hexadienone structure, i.e., structures analogous to those of **3** and **4** (*vide infra*) (4, 12, 13). Since the reaction of NBS with phenols is a simple and clean method of preparing monobromo derivatives of phenols, and some of their intermediates can be developed as secondary actinometers, we undertook mechanistic studies of this reaction.

Results

Upon admixing dilute solutions of 1-naphthol (1-NpOH) and NBS in methylene chloride at room temperature in the dark, the mixture immediately revealed a pale yellow colour and rapidly developed an absorption peak at 357 nm with two isobestic points at 269 and 323 nm (Fig. 1a). The absorption peak of the new product was confirmed further by a differential ultraviolet spectroscopic method in which the mixture was scanned against a reference containing solutions of the starting materials (1-NpOH and NBS in double concentrations) separately placed in a double-compartment cell (Fig. 1b). Under the dark, ambient conditions, the new product from 1-NpOH decomposed slowly, and completely in a few days, to give 2-bromo-1-naphthol **5** and a small amount of the 4-bromo isomer **6**. Other phenols also reacted with NBS under similar conditions to afford the corresponding intermediates, whose uv absorptions were determined (Table 1). Some of these spectral patterns are shown in Fig. 2. The decomposition of these intermediates gave the corresponding bromophenols, which were isolated (see Experimental). The mechanistic studies were carried out primarily using 1-NpOH as a model compound.

The nmr parameters of the intermediates derived from naphthols and NBS were obtained from solutions prepared from substrates without isolation and are shown in Table 2. While these data, as well as the uv absorption parameters (Table 1), were consistent with the intermediates possessing dienone-type structures (12, 13), they failed to exclude the possibility of hypobromite intermediates, since alkyl hypobromites are reported to show absorptions near 340 nm (14, 15). The ir spectrum of the intermediates formed *in situ* from 1-NpOH and NBS was obtained by subtracting the absorption due to residual NBS (Fig. 3). The absorption band at 1701 is in agreement with those reported for the extended dienone, 2-bromo-(2*H*)-naphthalene-1-one (**3**). The carbonyl stretching frequency was shifted to a higher wave number than usual owing to the 2-equatorial C—Br bond orientation in **3**. Extensive studies of these spectra failed to show conclusively the presence of corresponding hypobromite absorptions. The intermediates

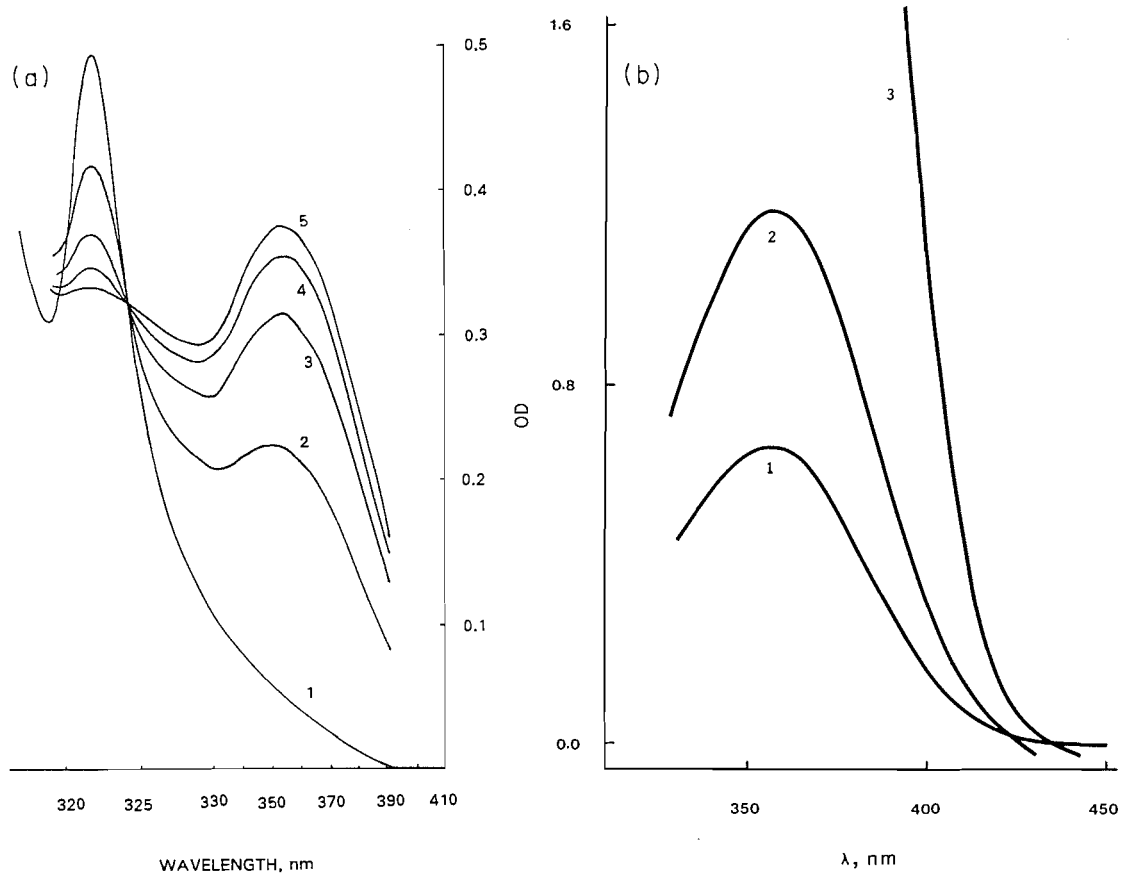

FIG. 1. Time-elapsed absorption spectra of the mixture of 1-NpOH (2.7×10^{-4} M) and NBS (2.0×10^{-2} M) in CH_2Cl_2 at 22 ± 2°C; (a) 10, 110, 210, 310, and 410 s after mixing. (b) Differential absorption spectra; the reference is a double-compartment cell, each compartment containing twice the concentration of the components in the solutions; curve 3, [1-NpOH] = 2.5×10^{-3} M, [NBS] = 2.0×10^{-3} M; curve 2, [1-NpOH] = 7.6×10^{-4} M, [NBS] = 1.6×10^{-3} M; curve 1, [1-NpOH] = 7.6×10^{-4} M, [NBS] = 3.2×10^{-4} M.

from other phenols were also assigned dienone structures by analogy with the 1-NpOH reaction as shown in Tables 1 and 2. As the intermediate solution decomposed to give a small amount of 4-bromo-1-naphthol **6**, 4-bromo-(4*H*)-naphthalene-1-one (**4**) could be present as a minor component. The failure to detect the ir absorptions corresponding to **4** suggested that **4** as well as **6** might be formed in a later stage by an autocatalytic process of phenolic products **5** and **6**, which are more acidic than 1-NpOH (*vide infra*). These dienone intermediates possessed reasonable thermal stability but were sensitive to light as well as acid catalysis. These properties precluded our effort to isolate the intermediates, but allowed us to study their photochemistry *in situ*.

The order of the reaction of 1-NpOH with NBS was determined under experimental conditions in which [1-NpOH] and [NBS] were in the vicinity of the $(2.7–5.4) \times 10^{-4}$ M range: doubling of the concentration of either reactant increased the absorbance at 365 nm by a factor of 2 ± 0.3 at 20 and 50 s after the mixing of reactant solutions. Since second-order reaction rate constants calculated from these traces were comparable and agreed within experimental error with those k_2 shown in Table 3 (*vide infra*), the reaction is first order in both reactants. The reaction order was further confirmed by experiments under pseudo-first-order conditions, i.e., an excess of 1-NpOH (3.74×10^{-3} M) in methylene chloride was allowed to react with increasing concentration of NBS ($2.5 \times 10^{-5} – 3.9 \times 10^{-4}$ M); the absorbance at 365 nm after the completion of the

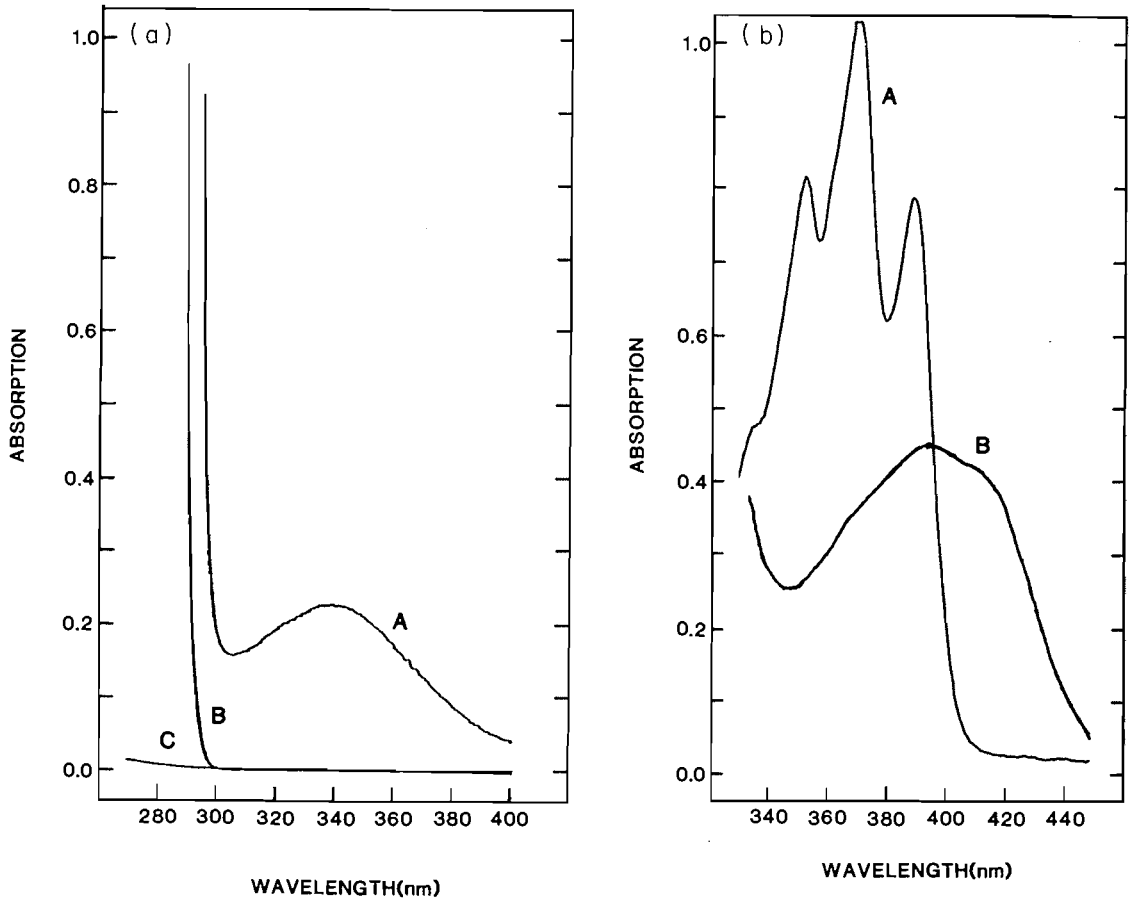

FIG. 2. Absorption spectra in CH_2Cl_2. (a) Curve A contains [NBS] = 4.63×10^{-4} M, [4-*tert*-butylphenol] = 1.34×10^{-2} M; curve B, [4-*tert*-butylphenol] = 1.34×10^{-2} M; curve C, [NBS] = 4.63×10^{-4} M. (b) Curve A contains [1-anthrol] = 5.0×10^{-5} M; curve B, [1-anthrol] = 5.0×10^{-5} M and [NBS] = 5.0×10^{-5} M.

reaction (~10 min) was plotted against NBS concentrations (Fig. 4) to give a straight line; the slope ($\epsilon = 1900$) represents the molar absorptivity of dienone **3** at 365 nm. Note that 365 nm was chosen since both reactants show nil absorption at this wavelength, which is not λ_{max} of the absorption peak.

In some of these experiments, a small amount of an olefin, either cyclohexene or 1,1-dichloroethene (10^{-4}–10^{-5} M), was added to scavenge bromine or bromine atom (16) in order to suppress radical pathways. However, it was found that if these reactions were conducted in the dark and completed in a matter of 10–30 min, the omission of olefins did not cause any observable difference in the kinetic curves and data. The concentrations of the reactants could be adjusted so that the kinetics of the dienone formation and (or) that of the decay could be followed readily. Usually, the reactions were carried out under pseudo-first-order reaction conditions using excess phenols, and the pseudo-first-order rate constants (k_{obs}) were obtained from kinetic traces such as shown in Fig. 5 and were converted to bimolecular rate constants (k_2 in Table 3). The rate constants of the formation of intermediate from other phenols and NBS were also determined and given in Table 3. Since the dienone intermediate derived from 1-anthrol decomposed relatively quickly, the kinetic measurement of the formation was carried out at higher substrate concentrations to avoid complications from the decomposition. The decomposition of the dienone intermediates derived from naphthols took more than 10 h. The decay curves monitored at a wavelength near the dienone λ_{max} did not afford a straight line according to second- or first-order kinetic analysis; the latter plots showed upward curvature, hinting at an autocatalytic process most likely arising from increased acidity of the brominated phenolic products. In Table 1 the times required for the absorptivity to decrease to its half-value are listed; these $t_{1/2}$ are not true half-life times because of kinetic complications.

The kinetics of the interaction of NBS with phenols as well as those of the decomposition of the intermediates were sensitive to impurities present in substrates and solvents; in particular, the presence of trace amounts of hydrochloric acid ($<10^{-5}$ M) could accelerate rates enormously (Table 3). The substrates and solvents must be carefully purified to ensure reproducible results as those given in this paper. The use of unpurified NBS and methylene chloride in the reaction with 2-NpOH gave rapid formation of the intermediate as well as the decay (Fig. 6). However, the decay curve of **7** as well as that of **3** in the presence of a trace amount of HCl gave good straight lines according to first-order analysis: The portion of acid catalysis arising from the phenolic products was apparently relatively unimportant under these conditions but the rate constants obtained did not represent the true unimolecular decomposition.

The reactions of other phenols with NBS under comparable conditions also showed a similar type of spectral changes and kinetic traces; two representative spectra are shown in Fig. 2.

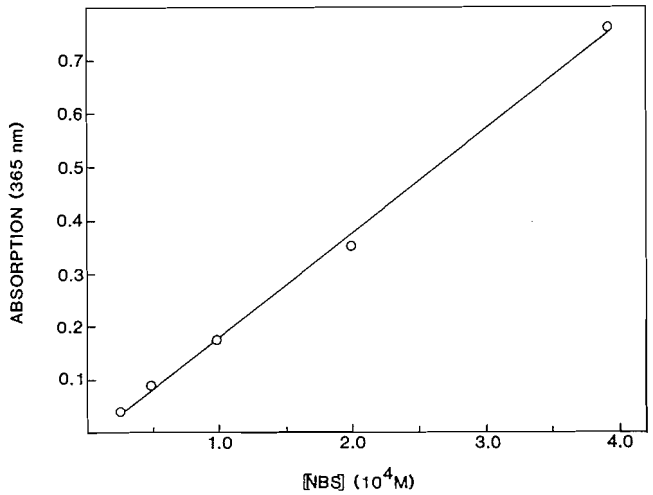

FIG. 4. The plot of the absorbance at 365 nm against the concentration of NBS in CH_2Cl_2 in the presence of [1-NpOH] = 3.74×10^{-3} M and [cyclohexene] = 1/5 [NBS]; the maximum absorbances were obtained after 5–10 min of mixing.

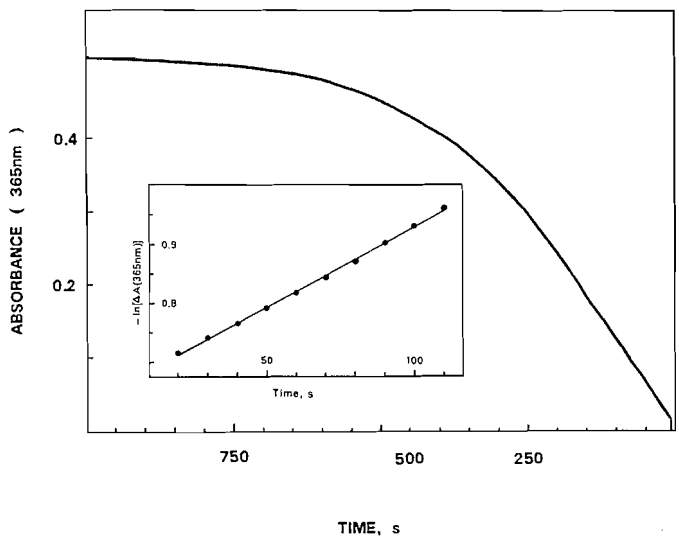

FIG. 5. The kinetic trace of the reaction of 1-NpOH (8.06×10^{-3} M) and NBS (2.80×10^{-4} M) in CH_2Cl_2 at 25 ± 1°C monitored at 360 nm.

For kinetic runs, a wavelength near the peak of the intermediate and where the starting materials showed no absorption was selected as the monitoring wavelength. The absorption maxima and extinction coefficients can be calculated from appropriate spectra in each case (Table 1). For 1-anthrol and *tert*-butylphenol, where the dienone intermediates underwent rapid decompositions, the ε-values were calculated from the highest optical density of kinetic runs (see Fig. 2), but these values must be smaller than the true values. The ε-values of the dienone intermediates derived from naphthols were determined more accurately using a plot similar to Fig. 2. Neither 4-nitro nor 4-cyano-phenol, on interaction with NBS, showed transient absorption under comparable conditions. Since no ring-brominated product was obtained after prolonged incubation in the dark (*vide infra*), it was concluded that the corresponding dienones were not formed from these phenols.

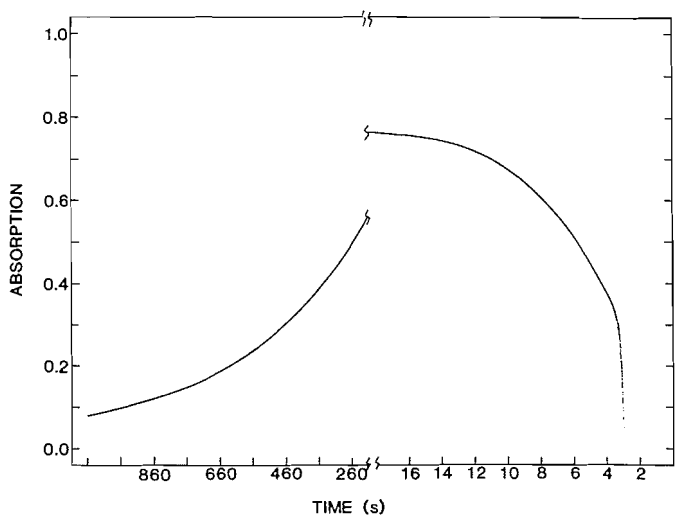

FIG. 6. Kinetic traces of the reaction of 2-NpOH with unpurified NBS in CH_2Cl_2 at 20 ± 1°C monitored at 335 nm; [NBS] = 2.75×10^{-4} M, [2-NpOH] = 9.73×10^{-4} M. The calculated rate constant of the formation is 100 M^{-1} s^{-1}, and that of the decomposition, 2.98×10^{-3} s^{-1}.

A methylene chloride solution of dienone **3** prepared *in situ* in quartz cuvettes was exposed to laboratory room light, unfiltered or filtered with a GWV filter (cutoff at <380 nm), and the absorbance at 365 nm was recorded at intervals. The plots of the absorbances, corrected for those due to thermal decomposition, against times of irradiation gave straight lines indicating a zero-order reaction up to 85% conversions. The quantum yield of the photoreaction of dienone **3** was measured using methylene chloride solutions prepared *in situ* and monochromatic light of 365 nm; benzophenone–benzhydrol actinometry was used as the secondary reference (19). The *observed* quantum yield of 0.66 was obtained for a solution of dienone **3** showing an absorbance change of 0.56–0.47: extrapolation to the total absorbance of incident light by the dienone gave the *actual* quantum yield of 0.9–1.0. For a methylene chloride solution of the dienone with the OD higher than unity, the observed quantum yield was 1.0 ± 0.1.

The product distribution in the photoreaction was studied in various solvents using a GWV filter to photoexcite the dienones alone at >380 nm. The dienone intermediate solutions were prepared *in situ* with an excess of 1-NpOH and the products were analysed by gc. The results are tabulated in Table 4. The percentage of 4-Br-1-NpOH **6** increased significantly as polarity of solvent increased, and also did so with unpurified NBS, obviously because of the presence of a trace amount of HBr. These solvent polarity effects are similar to that observed in bromination of phenols (17, 18). When the thermal decomposition of dienone was allowed to proceed for a longer time, the yield of **6** was also slightly increased. In certain photoreactions, 1-naphthyl methyl ether (1-$NpOCH_3$) was added to the intermediate solutions as a competing substrate. The amount of 4-bromo-1-methoxynaphthalene was negligibly small, indicating that dienone **3** is a poor brominating agent. NBS failed to react with 1-$NpOCH_3$ under prolonged incubation.

Some control and reference experiments were also carried out and results are shown in Table 5. They were competitive bromination of 1-NpOH and 1-$NpOCH_3$ in the absence and presence of K_2CO_3 and either in the dark or under illumination.

[a]Heterogeneous reaction because of low solubility of NBS in CCl_4; the photolysate was washed with $NaHSO_3$ solution to destroy remaining NBS before gc analysis.
[b]For these two experiments the reaction was allowed to proceed for 1 h before photolysis; for other experiments the reaction was allowed for 10 min before photolysis.
[c]1-Methoxynaphthalene (8.65×10^{-3} M) was added and 4-bromo-1-methoxynaphthalene was detected in <1%.
[d]Decomposed in the dark as comparison.
[e]1-Methoxynaphthalene (4.35×10^{-3} M) was added and 4-bromo-1-methoxynaphthalene was detected in <1%.
[f]An unpurified NBS reagent was used.
[g]Dichloroethane (3.1×10^{-3} M) was added.

TABLE 5. Competitive bromination of 1-naphthol and 1-naphthyl methyl ether in CH_2Cl_2

10^2[1-NpOH], M	10^2[1-NpOCH$_3$], M	10^2[XBr], M[a]	Relative yields[a] 2-Br-1-NpOH	4-Br-1-NpOH	4-Br-1-NpOCH$_3$
1.2[b]	1.1	0.7	1.0	0.62	0.77
1.2[c]	1.1	0.7	1.0	0.57	0.87
1.3[d]	1.0	0.6	1.0	0.57	0.78
1.3[e]	1.0	0.6	1.0	0.62	0.50
0.9[a]	0.87	0.6	12	1.0	0.0

[a]The last experiment uses NBS; other experiments use Br_2.
[b]A bromine solution was added while the substrate solution was irradiated with 410 ± 6 nm light (200-W Xe/He lamp, Kratos intensive monochromator).
[c]This experiment was carried out in the dark for 30 min, at which time the solution became colourless.
[d]The solution containing $K_2CO_3/Br_2 \geq 5$ was exposed to room light.
[e]A bromine solution was added while the substrate solution was irradiated with a 450-W Hanovia lamp.

The results show that bromination by bromine on 1-NpOH occurred very rapidly, and more rapidly than that on 1-NpOCH$_3$ in the dark or under illumination, to give nearly the same product ratio. The trend of this reactivity is known (20). In contrast NBS reacted exclusively with 1-NpOH, showing no trace of reaction with 1-NpOCH$_3$.

Discussion

Using 1-NpOH as a model compound, we have demonstrated that NBS is a useful reagent to monobrominate 1-NpOH cleanly via the intermediacy of dienones **3** and **4** to give 2-bromo-1-naphthol **5** and 4-bromo-1-naphthol **6**. While the preparation can be simply executed, the mechanism is more complicated than had been expected. The overall reaction can be conveniently separated into two steps for discussion, namely: (*i*) the interaction of NBS with 1-NpOH to form the dienones, and (*ii*) the rearrangement of the dienones, induced either by thermolysis or photolysis, to give the brominated phenols. Though these dienones are reasonably stable in the dark, as shown in Table 1, they were not isolated owing to their sensitivity towards acid and light catalysis. Their rearrangements are essentially a carbon-to-oxygen prototropy accompanied by aromatization and should be irreversible reactions; i.e., **3** → **5** and **4** → **6**. As externally added 1-NpOCH$_3$ was not brominated (Table 4) in the photolysis (or thermolysis), there exists no other competing pathway. Photoexcitation of **3** and **4** obviously results in their prototropic reaction with the quantum yield of unity.

The presence of acid catalysis in the thermal rearrangement of dienone intermediates is confirmed by kinetic studies, which also indicate the presence of autocatalysis of the rearrangement arising from the production of more acidic bromophenols in the carefully controlled bromination reaction. It is known that brominated phenols are more acidic, by ca. one pK_a unit, than the parent phenols and that an acid could catalyse (17, 18) the rearrangement of an extended dienone such as **3** to a cross-conjugated dienone such as **4**. The results described above are consistent with the occurrence of the acid-catalysed process of the **3** → **4** rearrangement.

At the onset of the interaction of NBS with 1-NpOH, *only one intermediate, that of dienone 3, is formed as the initial product*, as indicated by (*i*) the occurrence of two isobestic points at 269 and 323 nm, and (*ii*) the lack of the ir bands of **4**. If dienone **4** were also formed concurrently, the isobestic points could not be obtained since **4** should absorb strongly in the 250–310 nm region (12, 13). Since the prototropy of **4** cannot give anything but **6**, and that of **3** but **5**, the yields of **6** in Table 4 must mean that **4** is formed at a certain point in the reaction: the high percentage yields of **6** in experiments no. 10, 13, and 14, where an unpurified NBS is used, clearly indicate that indeed a trace amount of acid impurities catalyses the rearrangement of **3** → **4**. Slightly higher percentage yields of **6** in experiments 8, 9, and 12 support the presence of autocatalysis to form **4** by more acidic bromonaphthols; prolonged thermal decompositions in these experiments allow the involvement of acid catalysis.

Bromination of phenols to give dienone intermediates has been recognized previously (5–8, 17, 18) and, with some 2- and 4-substituted phenols and naphthols, the corresponding dienones have been isolated and identified (5, 17). However, bromine as the reagent generally leads to uncontrollable bromination for two reasons: (*i*) a secondary bromination of dienones, and (*ii*) the generation of HBr, which catalyses the rapid rearrangement of dienones as well as their formation. Indeed we have found that 10^{-4} M HCl catalyses both reactions so rapidly that kinetic measurements become impossible. From this viewpoint, NBS is an excellent reagent to generate extended dienones such as **3** *in situ* and (or) to monobrominate at the *ortho* positions of phenols, provided that care is taken to eliminate trace amounts of acids.

We now turn to the question on hypobromite **2** as a short-lived precursor of dienones. The immediate question is the location of the attack of NBS on phenolic species; i.e., whether it is an attack at the O-centre or C-centre. NBS is formally regarded as a source of positive bromine, and its N—Br bond may be polarized but not dissociated to provide a bromonium ion in nonpolar media. Though we have failed to detect the O—Br stretching absorption by FT-IR spectroscopy, there is evidence to suggest that the primary product from NBS and 1-NpOH is hypobromite **2**, which rearranges rapidly to dienone **3**. The failure of NBS to brominate 1-$NpOCH_3$ in a competitive reaction between 1-NpOH and 1-$NpOCH_3$ (Table 5) suggests that the reaction might have occurred at the oxygen but not at the carbon at the 2-position. This is a reasonable conclusion in view of the fact that in contrast to the facile addition of bromine to a carbon–carbon double bond, NBS showed no such reactivity. It should be mentioned that the latter reaction at the C2 position may not lead to the dienone intermediate but should give the *ortho*-brominated product eventually if the bromination occurs at all. Indeed Br_2 does brominate 1-$NpOCH_3$, as shown in Table 5. In the bromination of phenol with NBS, bromine has been proposed as the actual reagent; i.e., NBS is the reservoir of a low concentration of Br_2 by HBr scavenging (18). This conclusion is obviously untenable, at least in aprotic nonpolar solution, for the same reason.

The rearrangement of hypobromite **2** to dienone **3** therefore must be very fast, and the observed rate constants (k_2 in Table 2) represent the slower rate-determining step of the formation of **2**. The latter conclusion has been supported by the comparable rate constants of the disappearance of 1-NpOH to that shown in Table 1; this kinetic trace is run with 1-NpOH as the limiting reagent and by following the decrease of the absorption of 1-NpOH at 322 nm. Although we do not have additional information to offer, **1** possesses nmr data as well as stability properties that are more consistent with a dienone structure. The formation of hypobromites from phenols and NBS in aprotic solvent can be regarded as an electrophilic attack of the polarized N—Br bond on the phenol or a nucleophilic attack of phenolic oxygen on the bromine atom of NBS. The latter mechanism is essentially a halophilic reaction (21). Whatever interpretation is used, the failure of *p*-nitro- and *p*-cyano-phenols to react with NBS clearly indicates that a low electron density at the O-center retards the reactivities.

The solutions of dienones derived from naphthols as shown in Table 1 can be used as secondary actinometric solutions for the region of 300–400 nm. These solutions are easily prepared and have a sufficient lifetime. The concentrations of dienones are readily determined by uv spectroscopy. The efficient and clean photorearrangement of these dienones (e.g., the quantum yield of unity for the case of 1-NpOH) makes them excellent compounds for actinometry.

Experimental

Chemicals and equipment

NBS (BDH, reagent grade) was recrystallized from hot water and dried over $CaCl_2$ under vacuum. Bromine (Anachemia, reagent grade) was used as supplied. Dichloromethane, dioxane, acetonitrile, carbon tetrachloride, and benzene were distilled after being dried with $CaCl_2$. Anhydrous K_2CO_3 (BDH, analytical grade) was ground to a powder and pumped in a vacuum line at 150°C for 24 h. Nitrogen (Union Carbide, 99.998%) was used as supplied. 1-NpOH, 4-chloro-1-naphthol (mp 117.5–118.5°C), and 2-NpOH (Anachemia) were recrystallized from toluene and sublimed. Other compounds were purified by distillation or recrystallization followed by sublimation. Gas chromatographic (gc) analysis used a Hewlett-Packard 5792A equipped with an OV-1 capillary column; nmr spectra were recorded with a Bruker SY100 spectrometer, and uv spectra with a Cary 210 spectrophotometer.

Kinetic measurements

A solution of phenol placed in a uv cell was set in the Cary 210 compartment at 25 ± 1°C under dark conditions. A solution of NBS thermostated at the same temperature was injected with a syringe equipped with plastic tubes. The scanning of OD against time or against wavelengths commenced immediately. To obtain reproducible results, (*i*) phenols must be sublimed; (*ii*) solvent must be freshly redistilled; (*iii*) an NBS solution should be prepared within a few hours and kept in the dark; and (*iv*) syringe and cells should be rinsed thoroughly with distilled solvent. Under the pseudo-first-order reaction conditions, the traces of the increases of new absorbance were analysed by plotting ln ($A_\infty - A$) vs. time, where A_∞ and A are the absorbance at the completion of and during the reaction. For the unstable dienone intermediate from 4-*tert*-butylphenol, only an initial portion of the curve was analysed using computer-assisted fitting to obtain the best A_∞ value (22).

Irradiation of the dienone solutions

Solutions of the required concentrations in 1-NpOH and NBS were prepared in a test tube or uv cuvette in the dark and purged with nitrogen for 10 min; by this time dienones were formed as shown by uv spectra. The solutions were irradiated with a 200-W Hanovia medium-pressure mercury lamp filtered through a GWV filter (cutoff < 380 nm). In 5 min the yellow solutions were bleached but irradiation was continued for another 5–10 min. The products were analysed by gc using anthracene as the internal standard (Table 3), and in some cases were isolated. 2-Bromo-1-naphthol (**5**) and 4-bromo-1-naphthol (**6**) were recrystallized from ethanol to afford crystals, mp 44–45°C (lit. (23) mp 44°C) for the former and mp 127–128°C (lit. (24) mp 129°C) for the latter. Other products were also purified similarly: 1-bromo-2-naphthol, mp 82–83°C (lit. (25) mp 84°C); 2-bromo-4-chloro-1-naphthol, mp 92.5–93.5°C (lit. (26) mp 96°C); 2-bromo-4-*tert*-butylphenol, mp 50–51°C (lit. (27) mp 52°C); and 2-bromo-1-anthrol, mp 98–99°C.

Quantum yield measurements

Irradiation was carried out with a 200-W Hg/Xe lamp and Kratos high intensity monochrometer. At 365 nm, the emission was determined to be $(2.3 \pm 0.1) \times 10^{-7}$ Einstein/min in a 1-cm quartz uv cell using benzophenone–benzhydrol actinometry ($\Phi = 0.74$ in benzene) (19). Two methylene chloride solutions 1.2×10^{-3} M in NBS and 1.9×10^{-3} M in 1-NpOH and each containing dichloroethene 1.28×10^{-3} M were mixed in a uv cell in the dark. The resulting solution showed an absorbance of 0.56, and was irradiated for 1.5 min to give a value of 0.47. The thermal reaction was run simultaneously as the control reaction: the subtraction of the absorbance due to the thermal reaction gave that due to photoreaction. This absorbance decrease gave an apparent quantum yield of 0.66. This figure was normalized to 99% absorption of light (OD = 2) to give the actual quantum yield of 0.95–1.0.

When similar solutions with OD of 1.95 and 1.89 were irradiated for 1.5 min, the OD decreased to 1.74 and 1.66, respectively. The quantum yields were calculated to be 0.96 and 1.05.

Spectroscopic determinations of dienone 3

NBS and naphthol concentrations of $\sim 5 \times 10^{-2}$ M in $CDCl_3$ were mixed in an nmr tube and nmr signals were obtained with single scan after 10 min (Table 3).

NBS solution (200 μL, 5.17×10^{-2} M) in CH_2Cl_2 was placed in an ir cell (0.2 mL) and sealed with a septum. 1-NpOH solution (50 μL, 2.22×10^{-1} M) was injected with a syringe and the solution was mixed. The ir cell was placed in the sample compartment of a Bruker IFS-85 FT-IR spectrophotometer that had been flushed with N_2 for 10 min. The ir spectra of the solution were recorded at intervals.

The dependence of vanadate phenyl ester formation on the acidity of the parent phenols

BRUNO GALEFFI AND ALAN S. TRACEY[1]

Department of Chemistry, Simon Fraser University, Burnaby, B.C., Canada V5A 1S6

Received February 25, 1988

BRUNO GALEFFI and ALAN S. TRACEY. Can. J. Chem. **66**, 2565 (1988).

The condensation of vanadate ($VO_4H_2^{1-}$) with a variety of substituted phenols in aqueous acetone solution has been studied by ^{51}V nuclear magnetic resonance spectroscopy. The formation constants for the various product esters were determined, as were their respective pK_a values. Inductive and resonance contributions to vanadate ester formation were investigated using the dual substituent parameter approach. This procedure did not succeed particularly well, although trends were clearly observed. Correlations with Hammett constants were compared with those of the dual parameter approach. The observation of some linear free-energy relationships was interpreted to mean that the inductive and resonance parameters generally ascribed to the various phenols are not directly applicable to vanadate ester formation where *d* orbitals are probably involved. The results did indicate that resonance effects have a significantly greater influence on ester formation than do inductive effects.

BRUNO GALEFFI et ALAN S. TRACEY. Can. J. Chem. **66**, 2565 (1988).

Opérant en solution dans de l'acétone aqueuse et faisant appel à la résonance magnétique nucléaire du ^{51}V, on a étudié la condensation du vanadate ($VO_4H_2^{1-}$) avec divers phénols substitués. On a déterminé les constantes de formation des divers esters ainsi que les valeurs respectives de leurs pK_a. Utilisant l'approche du paramètre à double substituant, on a étudié les contributions relatives de l'induction et de la résonance sur la formation des esters du vanadate. Cette méthode n'est pas très appropriée, même si on peut clairement observer des tendances. On a comparé les corrélations avec les constantes de Hammett avec celles obtenues par l'approche du paramètre à double substituant. On a observé des relations linéaires d'énergie libre; on croit que ce résultat signifie que les paramètres d'induction et de résonance qui sont généralement attribués à divers phénols ne sont pas directement applicables à la formation des esters du vanadate qui implique probablement des orbitales *d*. Les résultats indiquent que les effets de résonance influencent beaucoup plus la formation de l'ester que les effets inductifs.

Introduction

The aqueous chemistry of vanadium(V) oxyanions is highly complex with a variety of oligomeric products arising as a function both of concentration and of pH. Various studies have succeeded in unravelling many of the details of this system (1, 2). These studies are of increasing importance as it has become evident from recent work that vanadium has an important biological role both in nitrogen fixation (3, 4) and in halogenation reactions (4, 5). Earlier work had suggested that vanadium is an essential element but this has not been unequivocally established (6, 7). Vanadium oxyanions have a significant effect on the function of many enzymes, activating some and inhibiting others (6–8). Some of this biological activity derives from the ability of vanadate to act as a phosphate analogue.

In the presence of hydroxylic compounds, such as alcohols and acids, condensation with vanadate spontaneously occurs to form vanadate esters or anhydrides (9–11). An interesting facet of such condensations, in the case of alkyl alcohols, is that a decrease in pK_a of the parent alcohol to a small extent disfavours the formation of vanadate esters (12). This behaviour does not extend to include ligands such as phosphate ($PO_4H_2^{1-}$), vanadate ($VO_4H_2^{1-}$), and phenol. In fact, condensation with these ligands is favoured well over that with the alkyl alcohols.

The behaviour exhibited by vanadate ester formation with the alkyl alcohols is similar to that found for phosphate ester formation; however, in the case of phosphate, the correlation extends to include condensation with phenols and other oxygen donors, including phosphate itself (13). It seems evident that for vanadate, as opposed to phosphate, there are stabilizing interactions that arise from certain types of ligands, which override the destabilizing interactions of electron withdrawal that disfavour condensation. These interactions may have their source in the unoccupied *d* orbitals of the vanadate ion, which can accept electron density from the π system of the ligand, thus favouring product formation.

In an effort to evaluate the effects of electron release or withdrawal on the esterification process, the interaction of vanadate with a variety of substituted phenols has been studied. Somewhat similar studies have been carried out by other workers for the Fe(III)–phenolate system where a linear relationship between the pK_a of the phenol and the formation constant for the product was observed (14). In the present study, an analogous free-energy relationship for the condensation of vanadate with phenols has not been observed.

Experimental

Materials

The various phenols used in this study were purchased from a variety of chemical supply companies, and their purity checked by proton magnetic resonance spectroscopy. Those which were discoloured or impure by ^1H nmr spectroscopy were recrystallized or, in the case of 3-chlorophenol, distilled under vacuum. Vanadium(V) oxide 99.99% (Aldrich "Gold Label") and TRIS (Tris[hydroxymethyl]aminomethane) 99.9% (Aldrich "Gold Label") were used as supplied. Reagent quality acetone was used without further purification. Sodium vanadate stock solutions were prepared by combining vanadium(V) oxide with two molar equivalents of 1.0 M aqueous NaOH in sufficient water to provide a final vanadium atom concentration of a little over 0.1 M. The orange material was stirred overnight during which time all of the vanadium pentoxide dissolved and a colourless product was obtained. The solution was then diluted with sufficient water to give a 0.1 M vanadium atom concentration.

Solutions

Aqueous acetone solutions were prepared by dissolving the required weight of phenol in a 42% v/v acetone/H_2O solution of near the final volume. Sufficient TRIS base to give the desired final concentration of 20 mM was added, and the pH was adjusted to slightly below the desired value by adding a few drops of either aqueous HCl or aqueous NaOH. Sufficient sodium vanadate stock solution to provide the

TABLE 1. Phenyl vanadate formation constants for a variety of substituted phenols in aqueous acetone solution

Phenol	pK_a[a]	K_1[b]	K_2[b]
2,4,6-Trichlorophenol	6.35	29±5	
4-Nitrophenol	7.50	3.3±0.2	
2,4-Dibromophenol	8.10	4.5±0.2	
3-Nitrophenol	8.71	3.0±0.2	
2-Chlorophenol	8.91	2.6±0.1	2.9±0.2
3-Chlorophenol	9.47	2.7±0.1	
4-Carboxyphenol	9.72	2.2±0.2	
4-Chlorophenol	9.76	2.0±0.1	2.4±0.2
3-Aminophenol	10.17	1.4±0.1	1.3±0.2
3-Carboxyphenol	10.20	1.6±0.3	
4-Fluorophenol	10.24	1.6±0.1	1.9±0.2
Phenol	10.34	1.8±0.1	1.1±0.1
4-Methylphenol	10.61	1.9±0.1	1.6±0.2
4-Aminophenol	10.65	2.4±0.2	1.2±0.2
2,6-Dimethylphenol	10.95	7.6±0.1	3.3±0.2
2,4-Diisopropylphenol	11.25	10±2	

[a]The pK_a values are for the various phenols in 42% v/v acetone/water and were corrected from the values for aqueous solution as discussed in the experimental section.

[b]These formation constants are defined in eq. [1], and were determined as described in the experimental section.

desired final concentration of vanadate was added, and the solution brought to the final volume by addition of 42% v/v acetone/H_2O. Final pH adjustment was made by addition of small amounts of NaOH. All samples were freshly prepared.

Nuclear magnetic resonance spectroscopy

All ^{51}V nmr spectra were obtained at 105 MHz from a Bruker WM-400 nmr spectrometer operating at ambient temperature in the broadband mode. Spectral widths of 20 kHz, 0.05-s acquisition times, and 45° pulse widths were used throughout. Spectra were zero-filled and a 35-Hz line broadening factor was applied before transforming the data to the frequency domain. All spectra were baseline corrected before signal intensities were determined using the instrument manufacturer's software. Chemical shifts are reported relative to an external reference of $VOCl_3$ at 0.0 ppm.

Proton nmr spectra were obtained at 100 MHz from a Bruker 100-SY nmr spectrometer.

pH and pK_a values

Measurements of pH in the acetone/water solvent solutions were made with a standard pH meter equipped with a combination electrode. The meter was standardized against aqueous buffer solutions prior to sample preparation and rechecked periodically. The pH of a mixed solvent system such as that employed here is not well defined; however, for the purposes of this study, it is important only that the *difference* between the hydrogen ion concentration and the measured pH not change significantly throughout the pH range employed, that is, pH 5.7–10.5.

The pK_a values of the phenols utilized in this study are also influenced by the solvent. Investigation of the *meta* and *para* nitrophenols by uv/visible spectroscopy showed that the pK_a value of the phenol in 42% aqueous acetone was 0.35 ± 0.1 unit higher than that for water. It has been shown that the relative pK_a values for phenols are essentially independent of the solvent (15), so the correction factor of 0.35 to the literature values (16–18) for the various phenols has been applied in the tabulation of Table 1.

Calculations

All the equilibrium constants were determined from at least five data points. Hydrogen ion concentration enters into the measured equilibrium constants via the pathway indicated in eq. [1]. The values of K_1 and K_2 are then pH-independent equilibrium constants as long as the phenol is not ionized. In eq. [1] water requirements are not explicitly considered.

$$\begin{array}{ccccc} H_2VO_4^- + ArOH & \overset{K_1}{\rightleftharpoons} & ArOVO_3H^- + ArOH & \overset{K_2}{\rightleftharpoons} & (ArO)_2VO_2^- \\ \Big\downarrow\uparrow K_{a2} & & \Big\downarrow\uparrow K'_{a2} & & \\ HVO_4^{2-} + H^+ & & ArOVO_3^{2-} + H^+ & & \end{array} \quad [1]$$

By working at sufficiently low pH, it was possible in most cases to avoid the ionization of the phenol itself. For the phenols having the lowest pK_a (4-nitrophenol and 2,4,6-trichlorophenol), the concentration of ionized phenol was easily determined by using the appropriate ionization constant, and the appropriate correction was made to K_1 and K_2.

The values of K_1 and K_2 can be calculated if pK_{a2} and pK'_{a2} are known. Deprotonation of both $H_2VO_4^-$ and $ArOVO_3H^-$ leads to substantial change in chemical shift of the ^{51}V nmr signal corresponding to the particular species. If δ_l and δ_h are the limiting chemical shifts at low and high pH for the monoanion and dianion, respectively, and δ_{obs} is the observed average chemical shift, then a simple calculation shows that the pK_a of the entity of interest is related to the chemical shifts and the pH by eq. [2].

$$[2] \quad pH = pK_a + \log \frac{\delta_{obs} - \delta_l}{\delta_h - \delta_{obs}}$$

A plot of the logarithm term versus pH then gives a straight line of unit slope and a y-intercept equal to the pK_a.

At a given pH, the total concentration of vanadate, of monoester, and of diester is provided by the respective signal intensities (at room temperature, ligand exchange is usually sufficiently slow to enable distinct resonances to be obtained for vanadate and its esters). The concentrations of $VO_4H_2^-$ and $ArOVO_3H^-$ can therefore be calculated at the considered pH using eqs. [3] and [4]. These values were used to obtain the equilibrium constants K_1 and K_2.

$$[3] \quad pH - pK_{a2} = \log \left(\frac{[\text{vanadate}]}{[VO_4H_2^-]} - 1 \right)$$

$$[4] \quad pH - pK'_{a2} = \log \left(\frac{[\text{monoester}]}{[ArOVO_3H^-]} - 1 \right)$$

Results and discussion

Vanadate reacts spontaneously with all of the phenols that were studied to form the corresponding phenyl vanadates. The condensation in all cases was a favourable one as is evident by comparing the formation constants, K_1, compiled in Table 1, for which K_1 is defined in eq. [1]. Of some note, as can be seen from this table, is the finding that the formation of phenyl

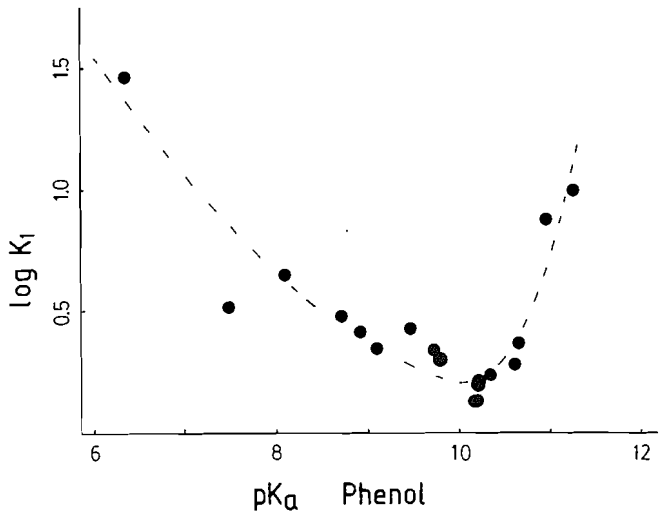

FIG. 1. The variation of the formation constant (K_1) for phenyl vanadate as a function of the pK_a of the parent phenol; K_1 = $[ArOVO_3H^-]/[VO_4H_2^-][ArOH]$.

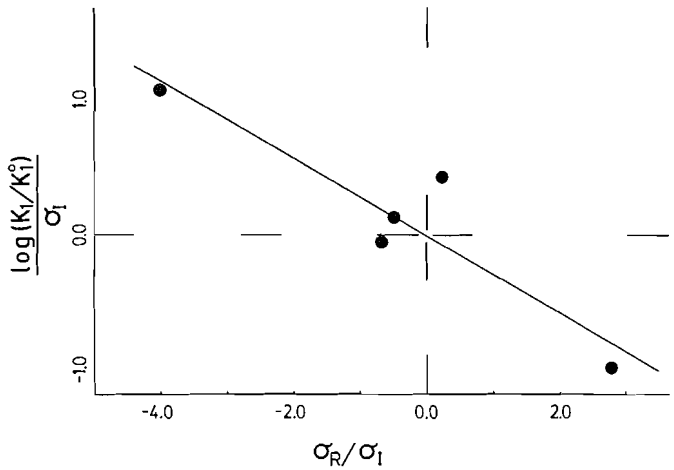

FIG. 2. The relationship between the inductive and resonance contributions to the formation of *para*-substituted phenyl vanadate esters is depicted.

vanadate from phenol and vanadate is among the least favoured reactions, while phenols of either higher or lower pK_a values more readily condense with vanadate to provide the ester. Figure 1 graphically depicts this behaviour and, since log K_1 is plotted in this figure, it is clear that there is no linear free-energy relationship between the formation constant of the product and the pK_a of the parent phenol. This result contrasts markedly with those of a similar study for which the interaction between phenols and iron(III) was studied (14). In this latter study, a very good linear free-energy relationship was observed, a behaviour also observed for the formation of alkyl vanadates (12).

The results of Table 1 suggest very strongly that there are at least two important substituent electronic contributions to vanadate ester formation. It is difficult to clearly identify these contributions. Attempts to correlate the observed ester formation constants with substituent inductive and resonance parameters via the Hammett constants did not succeed. The dual substituent parameter approach (19) was then utilized in an effort to separate the inductive and resonance contributions to the ester formation constants. The resonance and inductive electronic effects are related to the formation constants by eq. [5],

$$[5] \quad \log (K_1/K_1^0) = \rho_I\sigma_I + \rho_R\sigma_R$$

where σ_I and σ_R are the inductive and resonance factors determined from a variety of studies and ρ_I and ρ_R are the respective transmission factors for the system of interest. K_1 is the formation constant for the particular ester, and K_1^0 is that for the parent phenyl vanadate. Equation [5] can be rewritten as eq. [6], and the term on the left plotted versus σ_R/σ_I to give a line of intercept ρ_I and slope ρ_R.

$$[6] \quad \frac{\log (K_1/K_1^0)}{\sigma_I} = \rho_I + \frac{\rho_R\sigma_R}{\sigma_I}$$

From the values for σ_I and σ_R of ref. 19 and the measured equilibrium constants for the formation constants of the *para*-substituted products of Table 1, Fig. 2 was obtained.

It is evident from Fig. 2 that the *y*-intercept of the line must be near zero and also that the slope of the line is small, the least-squares values being 0.0 ± 0.2 and -0.3 ± 0.1, respectively. The small slope accounts for much of the apparent scatter in the plot of Fig. 2 but even so the correlation is rather poor. The fact that the intercept of this graph, which corresponds to ρ_I, is near zero means that vanadate ester formation is insensitive to inductive withdrawal or donation of electrons. A similar conclusion has previously been reached from a study of the formation of a number of alkyl vanadates (12). The slope of the line in this figure is quite small, -0.3, but its negative value indicates that resonance donation of electrons favours formation of vanadate esters, perhaps by allowing electron delocalization into the empty *d* orbitals of the vanadate moiety. Clearly this does not answer all questions since one must query why the formation of the 4-nitrophenyl, 2,6-dimethylphenyl, and 2,4-diisopropylphenyl vanadate esters is so highly favoured relative to what might be expected from the above considerations.

It does seem evident, however, that if electronic effects provide a dominating influence on ester formation, then those effects may be reflected in the pK'_{a2} values of the product vanadate esters as defined in eq. [1]. The pK_a values of vanadate and its esters were determined for the various reaction conditions of the different solutions by the procedure outlined in the experimental section and collected in Table 2. There is a significant variation in the values determined for the pK_a of $H_2VO_4^-$ from the solutions with different phenols. It has been shown (15) that relative strengths of acids of the same chemical type and same charge are essentially independent of solvent. On this basis, all pK_a values were corrected to the value for vanadate in 40% aqueous acetone and then plotted against the pK_a of the parent phenol (also determined for the aqueous acetone solvent). This plot is shown in Fig. 3 where two very good linear correlations are obtained. One correlation is between the pK_a of phenols substituted in the *meta* and *para* positions with slope = 0.19 and intercept = 7.52. The second correlation is with *ortho*-substituted phenols, and the slope and intercept are 0.28 and 7.01, respectively.

The observation of a good linear relationship between the pK_a values for the phenyl vanadates and the parent phenols (Fig. 3), and the lack of a similarly good correlation between vanadate ester formation constants and the polar and π-delocalization constants indicates that the dual substituent parameter approach employed here for investigation of the factors influencing vana-

[a]The pK_a values were determined for a 42% v/v acetone/water solution of the appropriate phenol using the procedure described in the experimental section.

[b]Estimated errors in δ_l, δ_h, pK_{a2}, and pK'_{a2} values are ±0.10, ±1.0, ±0.05, and ±0.10, respectively. δ_l is the chemical shift of $ROVO_3H^-$; δ_h, the chemical shift for $ROVO_3^{2-}$ where R = H or Ar.

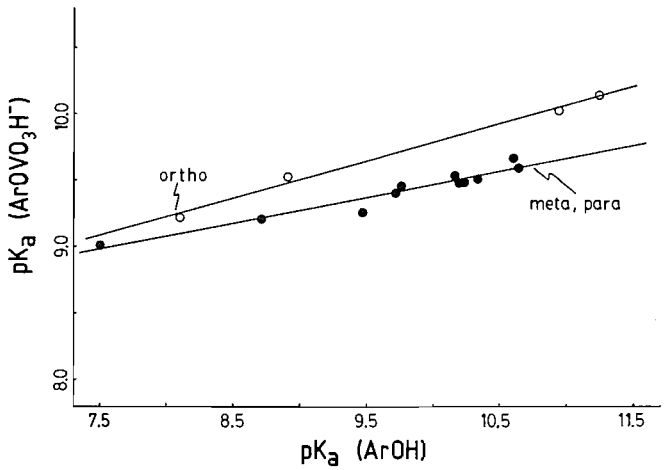

FIG. 3. The linear relationships between the pK_a of $ArOVO_3H^-$ and the parent phenols, ArOH, is revealed by this graph. The top plot is for *ortho*-substituted phenols, the bottom for a combination of *meta* and *para* substituents.

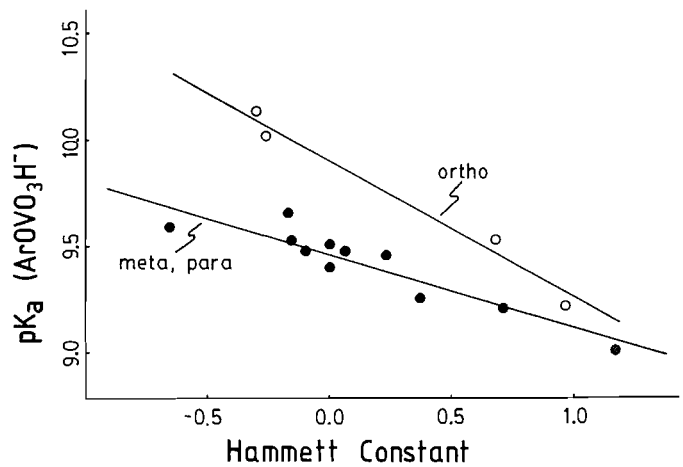

FIG. 4. Linear relationships between the pK_a values of a variety of substituted phenyl vanadates, $ArOVO_3H^-$, and the corresponding Hammett constants of the phenol precursors are depicted in this graph. The top plot is for *ortho*-substituted phenols, the bottom for *meta*- and *para*-substituted phenols.

date ester formation is not adequate. This view is reinforced if $(pK_a^{Tl} - pK_a^0)/\sigma_I$ is plotted against σ_R/σ_I, where pK_a^{Tl} is the pK_a of the individual vanadate esters and pK_a^0 is that for phenyl vanadate. This plot does not give a particularly good straight line, although a behaviour analogous to that of Fig. 2 is clearly observed. Interestingly enough, a plot of pK_a^{Tl} versus the Hammett constants for the various phenols does give a good straight line for the *meta*- and *para*-substituted phenols, and similarly a straight line for the *ortho*-substituted products as seen in Fig. 4. The Hammett constants represent some averaged value describing the electronic properties of the phenol. The linearity of pK_a^{Tl} versus the Hammett constants and the lack of a correspondingly good linearity in the dual substituent parameter approach means that, although the σ_I and σ_R values commonly employed (19) may not be adequate for a description of ester formation with vanadate where *d* orbitals are involved, a good separation of the electronic effects into inductive and resonance factors should be attainable.

An interesting facet of this investigation is the linear relationship between the pK_a values of the *meta*- and *para*-substituted phenyl vanadates ($ArOVO_3H^-$) and their respective vanadium chemical shifts. This relationship is depicted in Fig. 5. From the slope (5.03×10^{-2}) and intercept (37.9), the pK_a values for all the phenols studied here can be predicted to better than 0.1 pK_a unit, except for the *p*-aminophenyl vanadate ester, which is ~0.3 pK_a units from the line. It is not clear why parameters describing this latter compound deviate from the described line, or even if this linear relationship is a general one. It certainly does not apply to the *ortho*-substituted products.

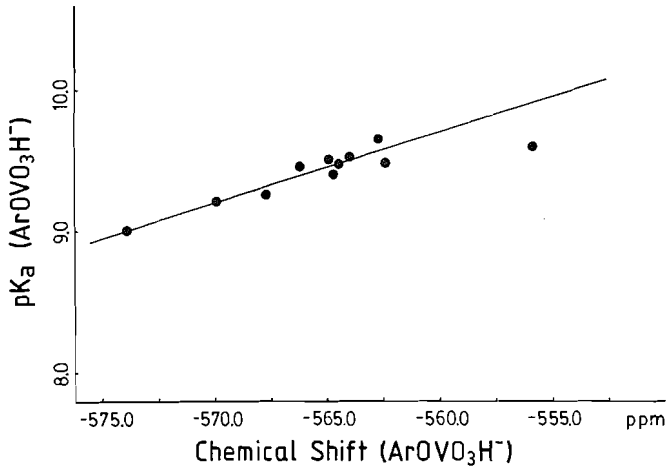

FIG. 5. The relationship between the chemical shifts of the vanadate ester monoanions ($ArOVO_3H^{1-}$) and their respective pK_a values is shown for *meta*- and *para*-substituted products.

The results of this study provide considerable insight into some of the factors governing vanadate ester formation and their acidity, but clearly much more work is necessary to obtain a good understanding of this system.

The characterization of primary, secondary, and tertiary vanadate alkyl esters by ^{51}V nuclear magnetic resonance spectroscopy

ALAN S. TRACEY AND MICHAEL J. GRESSER
Department of Chemistry, Simon Fraser University, Burnaby, B.C., Canada V5A 1S6

Received March 29, 1988

ALAN S. TRACEY and MICHAEL J. GRESSER. Can. J. Chem. **66**, 2570 (1988).

A variety of alkyl vanadates has been studied by ^{51}V nuclear magnetic resonance spectroscopy. It was found that the equilibrium constant for condensation of vanadate with alcohols is insensitive to whether the hydroxyl group is primary, secondary, or tertiary. These products, however, have characteristic vanadium chemical shifts that allow assignment of nmr signals to the appropriate ester. It was also found that chemical shifts are additive in the sense that the chemical shifts of the esters $ROVO_3H^-$ are one half the chemical shift of the diesters $(RO)_2VO_2^-$ when those shifts are given relative to −559 ppm. This effect is independent of whether the signals are to high or low field of −559 ppm and the additivity extends to mixed ligand systems. This value of −559 ppm is close but not equal to the chemical shift of the vanadate monoanion, $H_2VO_4^{1-}$, which is at −561 ppm. These results are at variance with arguments concerning the effects of ligand bulkiness on chemical shifts of vanadium(V) complexes.

ALAN S. TRACEY et MICHAEL J. GRESSER. Can. J. Chem. **66**, 2570 (1988).

On a étudié un certain nombre de vanadates d'alkyles en faisant appel à la résonance magnétique nucléaire du ^{51}V. On a trouvé que la constante d'équilibre pour la condensation du vanadate avec les alcools n'est pas sensible au caractère primaire, secondaire ou tertiaire des groupements hydroxyles. Toutefois, ces produits possèdent des déplacements chimiques du vanadium qui sont caractéristiques et qui permettent d'attribuer les signaux rmn aux esters appropriés. On a trouvé que les déplacements chimiques sont additifs dans le sens que les déplacements chimiques des esters $ROVO_3H^-$ correspondent à la moitié des déplacements chimiques des diesters $(RO)_2VO_2^-$ lorsque ces déplacements sont donnés par rapport à −559 ppm. Cet effet ne dépend pas de la position de ces signaux par rapport à −559 ppm et cette additivité s'étend aux systèmes comportant des ligands mixtes. La valeur de −559 ppm s'approche du, mais elle n'est pas égale au, déplacement chimique du monoanion de vanadate, $H_2VO_4^{1-}$, qui est égal à −561 ppm. Ces résultats sont en opposition avec les arguments concernant les effets d'encombrement des ligands sur les déplacements chimiques des complexes de vanadium(V).

Introduction

The aqueous chemistry of vanadium(V) oxyanions has, over recent years, become an area of considerable interest in chemistry and biochemistry, not only because vanadate has a significant effect on the function of many enzymes (1–4) but also because it is involved in nitrogen fixation (5, 6), in biological halogenation reactions (6–8), and may be useful in enzymic synthesis since vanadate esters can be accepted by some enzymes in lieu of the biological substrate, the analogous phosphate ester (9). There is also a potential use for vanadium in the treatment of the symptoms of diabetes and sickle-cell anemia (10–12).

Vanadate spontaneously and rapidly condenses with hydroxylic compounds to provide the corresponding vanadate ester derivatives (13–17). Previous work with aliphatic compounds has concentrated on primary alcohols. However, our studies of some systems have indicated that reaction with secondary alcohols to form the vanadate ester proceeds as readily as that for primary esters. These observations have been confirmed by this work and, as well, condensation of vanadate with the tertiary alcohol, *tert*-butanol, has been studied.

Studies of the condensation reactions of vanadate have utilized to a large extent ^{51}V nuclear magnetic resonance (nmr) spectroscopy (13–15, 18–20). Vanadium nmr offers the sensitivity to work conveniently at vanadate concentrations between 0.1 and about 4 mM, which, for many studies of condensation reactions, includes the optimum vanadate concentration range. It has become evident from nmr studies of vanadate complexes with alkyl alcohols (14, 16), vicinal diols (21), α-hydroxy acids (22, 23), and oxalate (18, 22) that the ^{51}V nmr signals from tetrahedral, octahedral, and pentacoordinate complexes containing these ligands tend to occur within rather restricted chemical shift regions of the ^{51}V nmr spectral range. Of these coordination geometries the vanadate products with tetrahedral coordination show a comparatively wide range of chemical shifts.

The chemical shifts of tetrahedral products are very sensitive to the state of protonation and the number of substituents. Beyond this, the nmr studies have indicated that the ^{51}V chemical shifts of vanadate esters of aliphatic alcohols have specific stereochemical dependencies that can be useful in structural assignments. In this work the results from previous studies have been utilized, together with those from some new systems, to obtain a cohesive picture of the effects of substitution and charge state on the ^{51}V nmr chemical shifts of alkyl vanadate esters.

Experimental

Materials

Vanadium pentoxide, 99.999% (Aldrich "Gold Label") and HEPES (N-2-hydroxyethylpiperazine-N'-2-ethanesulphonic acid, Sigma Chemical Co.) buffer were used as supplied. The purity of the various alcohols used in this study was checked by ^1H or ^{13}C nmr spectroscopy before use: all were used as supplied.

Methods

The procedures utilized in this study differed little from those of previous studies of other systems (14, 21). They have been recently described in detail in ref. 24 with the exception that no KCl was incorporated into the solutions. All ^{51}V nmr spectra were obtained at ambient temperature (21°C) using the broadband facility of a Bruker WM-400 nmr spectrometer. Signal intensities were determined using the instrument manufacturer's software. No attempt to obtain more accurate integrals was made.

The results of vanadium and alcohol concentration studies were analyzed according to Scheme 1 using the concentrations of the various

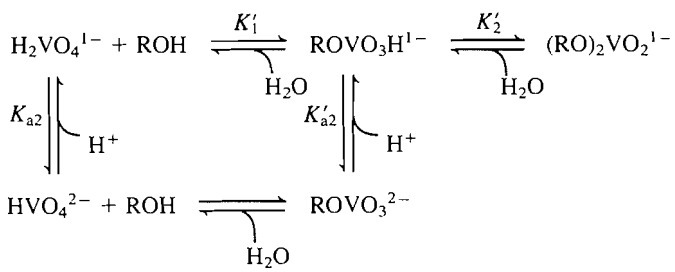
species given by the nmr spectra. The pK_a values for vanadate and the vanadate esters were determined by application of eq. [2] to the observed chemical shifts, which were determined relative to $VOCl_3$ at 0.0 ppm.

pH, as utilized in this study, refers specifically to the value provided by a standard pH meter equipped with a calomel electrode and calibrated with pH 4.00 and pH 10.00 buffer solutions. No effects resulting from the presence of alcohol in the aqueous solutions have been considered. As discussed in ref. 14, such effects are small except at high alcohol concentrations.

Results and discussion

The condensation of vanadate with alkyl alcohols to form the alkyl vanadate ester and water is a facile reaction which, at least for the case of ethanol, occurs in the millisecond time scale (14). The product can undergo a further condensation with a second alcohol to form the diester. Both vanadate and its monoester have the possibility of gaining or losing a proton since the second pK_a for these compounds has values within the range of pH utilized in this study. The dialkyl vanadate ester has no proton to lose since the first pK_a of vanadate is about 3.2 (25), and the first pK_a of its mono- and diesters should be similar to this. For the work described here, the pH was varied from about 6.5 to 10.5.

From the above discussion it is clear that the reactions of vanadate with alkyl alcohols are very simple. They are summarized in Scheme 1 where ROH refers to the alkyl alcohol



SCHEME 1

of interest. As a general rule, K_1' is not measured directly but rather K_1 as defined by eq. [1] is determined,

$$[1]\quad T_i + \ell \underset{H_2O}{\overset{K_1}{\rightleftharpoons}} T\ell \qquad [T_i][\ell]\,K_1 = [T\ell][H_2O]$$

where T_i refers to total tetrahedral vanadate ($H_2VO_4^{1-}$ + HVO_4^{2-}), $T\ell$ to its ester ($ROVO_3H^{1-}$ + $ROVO_3^{2-}$), and ℓ to the ligand. The chemical shift of tetrahedrally coordinated vanadate is quite sensitive to the protonation state, and consequently, by varying the pH, the changes in the observed chemical shift, δ_o, can be related to the shift of $ROVO_3H^{1-}$ (δ_l) and $ROVO_3^{2-}$ (δ_h) by eq. [2], and the pK_a values for vanadate

$$[2]\quad pH = pK_a + \log\left(\frac{\delta_o - \delta_l}{\delta_h - \delta_o}\right)$$

and its esters are therefore readily determined (14). The observed equilibrium constants, K_1, measured at any pH are related to the pH-independent K_1' of Scheme 1 and the K_{a2} values for vanadate and its esters by eq. [3].

$$[3]\quad K_1' = \frac{K_1(1 + K_{a2}/[H^+])}{(1 + K_{a2}'/[H^+])}$$

In practice, K_1 has generally been determined at a pH of 7.5 so that the correction to give K_1' is small since this pH is well below the pK_a of vanadate and its monoester.

As for K_1', the formation constant K_2' of Scheme 1 is, in general, not directly measured. K_2 as defined by eq. [4] is determined. This value is related to K_2'

$$[4]\quad T\ell + \ell \underset{}{\overset{K_2}{\rightleftharpoons}} T\ell_2 + H_2O \qquad [T\ell][\ell]K_2 = [T\ell_2][H_2O]$$

by eq. [5].

$$[5]\quad K_2' = K_2(1 + K_{a2}'/[H^+])$$

In this study the equilibrium constants for formation of vanadate esters from isopropanol, *sec*-butanol, *tert*-butanol, and 1,3-butane diol have been determined, and the pK_{a2} values for vanadate and the vanadate ester determined for each of the various solutions following procedures previously described for the formation of ethyl vanadate (14) as outlined below. The equilibrium constants K_1 and K_2 were readily obtained from the ^{51}V nmr spectra by first observing the appearance of the nmr signals corresponding to the vanadate ester and diester, respectively, then monitoring the changes in signal intensities as a function of alcohol concentration. The results of the concentration studies were then analyzed according to eqs. [1] and [4]. Variation of the hydrogen ion concentration at fixed ligand and total vanadate concentration allowed application of eq. [2] to provide the acidity constants and the limiting chemical shifts for low and high pH. These formation constants and the pK_a values are collected, together with values selected from other studies, in Table 1, which also tabulates the limiting chemical shifts, δ_l and δ_h of eq. [2], for each derivative. In Table 1, the formation constants are reported according to the formulation that the activity of liquid water is unity, so that the water concentration of eqs. [1] and [4] are not specifically considered. The pK_a values and formation constants for these and other vanadate esters have been discussed in detail elsewhere (26–28).

The formation constants listed in Table 1 are, however, of interest here. It is clear from this table that vanadate monoesters are formed, essentially, equally well, independent of whether the hydroxyl group being substituted is primary, secondary, or tertiary. It is particularly interesting to note that methyl vanadate has a formation constant almost identical to that for *tert*-butyl vanadate. The values for these two esters are approximately one half to one third those for most primary and secondary esters. The smaller formation constant for *tert*-butyl vanadate might be rationalized on steric grounds, but it is not clear why that for methanol is similar.

Except for methanol, vanadate ester formation is insensitive to whether the hydroxyl is secondary or primary. This is perhaps exemplified best in vanadate ester formation at the primary and secondary hydroxyls of 1,3-butane diol where, in fact, ester formation at the secondary position is slightly favoured over that at the primary position.

The insensitivity of ester formation to steric effects is evident also in the formation of vanadate diesters. Only with *tert*-butanol is there evidence of a steric effect on diester formation, since with this alcohol at concentrations up to 1.6 M no diester was observed. However, a low intensity signal ascribed to the di-*tert*-butyl vanadate was observed in a 50% acetone solution where higher concentrations of alcohol were obtainable.

It is evident from this work that in studies of systems containing a variety of hydroxyl groups, vanadate ester formation constants will not, in general, provide a reliable diagnostic

[b]50% acetone solution.

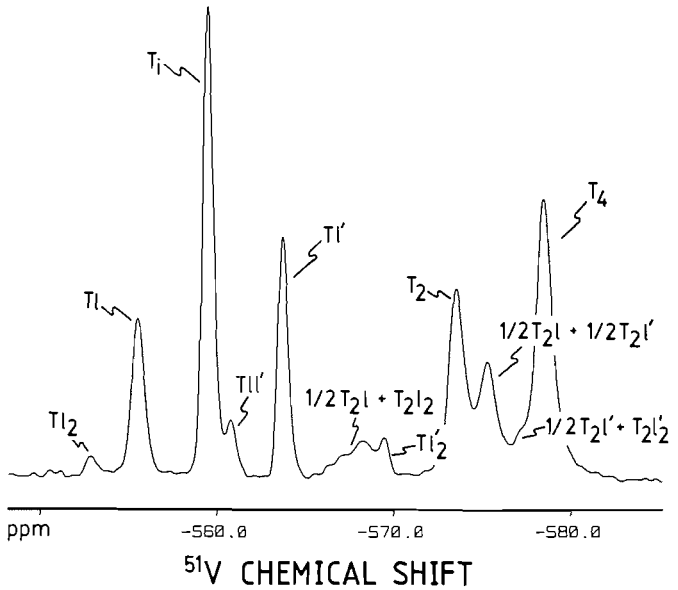

FIG. 1. ^{51}V nuclear magnetic resonance spectrum showing the products of the spontaneous condensation of vanadate with 1,3-butane diol in aqueous solution. In this figure the T represents the tetrahedrally coordinated vanadate; T_i, vanadate; T_2, divanadate; T_4, tetravanadate; ℓ, ligand complexed through the primary hydroxyl; ℓ', ligand complexed through secondary hydroxyl. The conditions of the experiment were 4.0 mM total vanadate, 1.11 M 1,3-butane diol, 20 mM HEPES buffer, and pH 7.5.

tool. It should be mentioned at this point that alkyl esters of divanadate are also formed. In general, a quantitative examination of their formation is difficult because the nmr signals are often not resolved from the signal of divanadate, T_2. A detailed study for the case of methanol has been reported (16). Signals in the nmr spectrum of 1,3-butane diol can be ascribed to the formation of divanadate esters, not only with the primary but also the secondary hydroxyls of the ligand, which are represented as ℓ and ℓ', respectively, in Fig. 1 where T is used to represent tetrahedral coordination about the vanadium nucleus. Other signals have been assigned to the esters of vanadate itself. A point to be made about the nmr spectrum of this system is that no signal ascribable to the product resulting from butane diol acting as a bidentate ligand is observed. This is in keeping with our observations with other 1,3-diol systems (27).

The assignment of ^{51}V nmr signals to vanadate products formed from 1,3-butane diol as depicted in Fig. 1 follows from the comparison of the chemical shifts reported in Table 1, from the study of methanol (16) and of 1-butanol, 2-butanol, and mixtures of the latter two. In this regard it should be mentioned that 1:1 mixtures of 1- and 2-butanol with vanadate provided ^{51}V nmr spectra virtually identical to spectra obtained from 1,3-butane diol. It is relevant to note that although the pK_{a2} for the vanadate monoanion, $H_2VO_4^{1-}$ (the predominant species at pH 7.5), is sensitive to the aqueous alcoholic solution in which it was measured, the ^{51}V nmr chemical shifts at low (δ_l) and high (δ_h) pH are remarkably constant near -561 ppm and -535 ppm, respectively. The pK_a values for the vanadate esters are also sensitive to solvent as well as to other effects such as the pK_a of the parent alcohol (28). However, as for vanadate itself, their chemical shifts are not sensitive to solvent, at least in the predominantly aqueous solutions employed here and for other studies. It is evident, however, from Table 1 that both the chemical shifts for $ROVO_3H^{1-}$ and $(RO)_2VO_2^{1-}$ vary considerably from one product to another. There does appear to

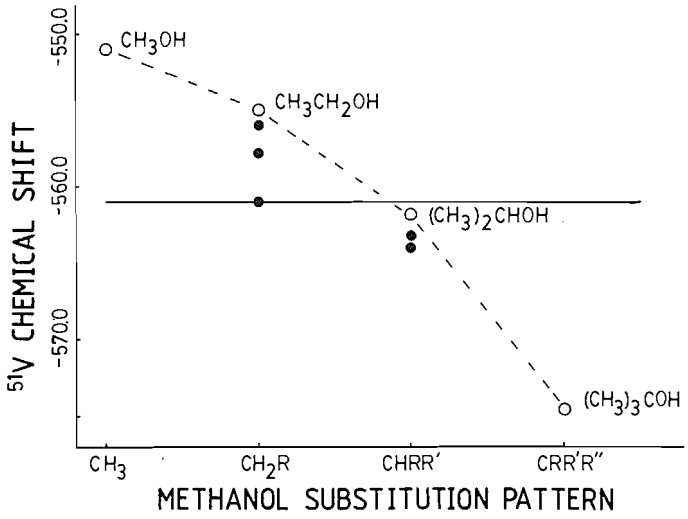

FIG. 2. A graphical representation of ^{51}V chemical shifts for $ROVO_3H^{1-}$ depicted as a function of the number of hydrogens of the methyl group of methanol replaced by alkyl substituents. The dashed line connects the chemical shifts for the products formed from the substituents CH_3OH, CH_3CH_2OH, $(CH_3)_2CHOH$, and $(CH_3)_3COH$. The solid line represents the chemical shift for $VO_4H_2^{1-}$ at −561 ppm. The open circles represent the specified alkyl alcohol, the solid circles, derivatives substituted at a methyl group. All chemical shifts are from Table 1.

be a systematic variation in these shifts, and this is exemplified in Fig. 2 where the chemical shift for $ROVO_3H^{1-}$ is compared to the number of methanol methyl hydrogens replaced by substituents and to the chemical shift of $H_2VO_4^{1-}$ (solid line at −561 ppm). It is seen from this figure that the chemical shifts of primary esters tend to be more positive than that of vanadate itself, while secondary esters are more negative. The only overlap of these ranges that we have observed to date is that of the fluorocarbon, 1,1,1-trifluoroethyl vanadate, which, with a δ_1 of −562.8 ppm, has a chemical shift to a slightly higher field than that of isopropyl vanadate (28). Certain other primary alkyl vanadates have chemical shifts very close to that of vanadate, such as 2-cyanoethyl vanadate (28). The chemical shifts from a variety of other compounds not explicitly considered here fall within the ranges depicted in Fig. 2.

In addition to the above finding, there also appears to be an additive property associated with ester and diester formation in that the ^{51}V chemical shifts of the diester monoanions for all the primary and secondary alcohols of Table 1 are close to twice as far away from −559.0 ppm as the chemical shifts of the corresponding monoester monoanions. This additivity of chemical shifts extends to mixed ligand species and can be used to calculate the chemical shift of the mixed diester formed from 1,3-butane diol T$\ell\ell'$ of Fig. 1. The value calculated is −561.0 ppm as compared to the observed value of −560.9.

It is interesting to speculate on the meaning of this unique chemical shift of −559 ppm. This shift, although close to that of the anion $H_2VO_4^-$ (−561 ppm) cannot be said to correspond to that value. It seems possible that it actually corresponds to the chemical shift of an $H_2VO_4^{1-}$ species that has some of the water of hydration removed or rearranged, similar to what would happen when an -OH is replaced by an -OR. This ion, which is not observable and indeed may not even exist under the conditions of these experiments, provides a reference frequency for the chemical shifts of the mono- and diesters. It is not possible to know if an analogous situation exists for the dianion HVO_4^{2-} since a diester cannot form with this ion. It is evident, though, from Table 1 that there is a systematic change in chemical shifts of the ester dianions, $ROVO_3^{2-}$, which parallels that of the monoanions, $ROVO_3H^{1-}$.

The dependence of chemical shift on the bulkiness of the alkyl group has been reported for vanadate esters in nonaqueous solution (29–31). An explanation (30) for this shift dependence, which invokes an increasing V—O bond length with increasing ligand bulkiness, and the associated effects on the paramagnetic term of the chemical shielding equation does not appear to provide an explanation for the results obtained here. The problem arises from considerations of the chemical shifts of the diesters relative to the monoesters. The incremental shifts, as we have seen above, are actually in opposite directions, dependent on whether the monoester, $ROVO_3H^-$, has a shift more positive or less positive than −559 ppm. Since incorporation of a second ligand necessarily increases total substituent bulkiness, it is clear that such an explanation is somewhat limited. An adequate description of chemical shielding should incorporate into it an explanation for a chemical shift of the special character of the −559 ppm observed here.

The characteristics of the chemical shift dependence of vanadate esters provide a useful diagnostic tool for analyzing ^{51}V nmr spectra. If the nmr spectra are obtained at a pH of 7.5 or less, where vanadate and its monoester are predominantly monoanions, then primary esters will, in general, resonate under, or to low field of, the vanadate signal, whereas signals from secondary or tertiary vanadates will generally occur to high field of the vanadate esters. Some consideration must also be given to rates of chemical exchange. Ethyl vanadate exchanges with vanadate in the millisecond timescale at 328°C. Other equilibration reactions could be faster than this so that, even at room temperature, signal coalescence might occur, particularly in cases where the chemical shifts of vanadate and its esters are close to each other. In this case some line broadening may be observable. Because of the additivity of the chemical shifts of mono- and diester vanadates, assignments of signal positions to either the monoester or the diester when one or the other signal is observed will be greatly facilitated. If the possibility for mixed diesters exists, then the chemical shift of the mixed species can be predicted from the chemical shifts of the two monoester precursors. Furthermore, as is evident from Fig. 1 and from a study of methanol/vanadate interactions (16), somewhat similar considerations apply to the chemical shifts of ester divanadates. In this case, it is the signal from the substituted vanadate moiety of the ester divanadate that is shifted by substitution, while the signal from the second vanadium nucleus shifts, at best, only a small amount. Esterification on the second vanadate to form the diester divanadate provides a symmetrical product with a resultant superposition of chemical shifts.

Linear oligopeptides. 188.[1] Crystallographic characterization of the conformation of the 1-aminocyclopentane-1-carboxylic acid residue in simple derivatives

GIOVANNI VALLE, MARCO CRISMA, AND CLAUDIO TONIOLO[2]

Biopolymer Research Centre, C.N.R., Department of Organic Chemistry, University of Padova, 35131 Padova, Italy

Received November 6, 1987[3]

GIOVANNI VALLE, MARCO CRISMA, and CLAUDIO TONIOLO. Can. J. Chem. **66**, 2575 (1988).

The crystal structures of six derivatives of the $C^{\alpha,\alpha}$-dialkylated α-aminoacid residue 1-aminocyclopentane-1-carboxylic acid (Acc^5) have been determined. These are Z-Acc^5-OH, Z-Acc^5-OH acetone hemi-solvate, Fmoc-Acc^5-OH, mClAc-Acc^5-OH, *p*BrBz-Acc^5-OH, and the 5(4*H*)-oxazolone from *p*BrBz-Acc^5-OH. The values determined for the torsion angles about the N—C^α (ϕ) and C^α—CO (ψ) bonds correspond to folded, potentially $\alpha/3_{10}$-helical conformations for the Acc^5 residue of Z-Acc^5-OH, Z-Acc^5-OH acetone hemi-solvate, mClAc-Acc^5-OH, and *p*BrBz-Acc^5-OH. The structure of Fmoc-Acc^5-OH, however, is unusual in having a semi-extended conformation for the ϕ, ψ angles, accompanied by a *cis* arrangement of the amide group of the secondary urethane moiety. The dependence of the N—C^α—C′ bond angle on the ψ torsion angle and the asymmetry at the C^α atom are relevant features of the Acc^5 residues. The position of the cyclopentyl ring relative to the peptide chain and its puckering parameters for the six compounds are also discussed.

GIOVANNI VALLE, MARCO CRISMA et CLAUDIO TONIOLO. Can. J. Chem. **66**, 2575 (1988).

On a déterminé les structures cristallines de six dérivés $C^{\alpha,\alpha}$-dialkylés du résidu d'acide α-aminé, amino-1 cyclopentane-carboxylique-1 (Acc^5). Il s'agit du Z-Acc^5-OH, du Z-Acc^5-OH hémisolvaté par l'acétone, du Fmoc-Acc^5-OH, du mClAc-Acc^5-OH, du *p*BrBz-Acc^5-OH et de la (4*H*)-oxazolone-5 préparée à partir du *p*BrBz-Acc^5-OH. Les valeurs qui ont été obtenues pour les angles de torsion autour des liaisons N-C^α (ϕ) et C^α-CO (ψ) du résidu Acc^5 du Z-Acc^5-OH, du Z-Acc^5-OH hémisolvaté par l'acétone, du mClAc-Acc^5-OH et du *p*BrBz-Acc^5-OH correspondent à des conformations repliées qui sont possiblement $\alpha/3_{10}$-hélicoïdales. Toutefois, la structure du Fmoc-Acc^5-OH est inhabituelle; sur la base des angles ϕ et ψ elle possède une conformation semi-étendue qui est accompagnée par un arrangement *cis* du groupement amide de la portion secondaire de l'uréthane. Le fait que l'angle de la liaison N—C^α—C′ varie en fonction de l'angle de torsion ψ et de l'asymétrie du C^α et sont caractéristiques importantes des résidus Acc^5. On discute aussi de la position du cyclopentane par rapport à la chaîne peptidique ainsi que des paramètres de plissement des six composés.

[Traduit par la revue]

Introduction

The use of uncommon α-amino acid residues in the synthesis of peptides with restricted conformational flexibility has acquired increasing importance in the design of analogs of bioactive peptides (2). $C^{\alpha,\alpha}$-dialkylated α-amino acid residues have proven to be valuable in the construction of conformationally constrained peptide backbones (3–5).

While considerable attention has been paid to the crystal-state conformational preferences of $C^{\alpha,\alpha}$-dialkylated residues with linear substituents, like $C^{\alpha,\alpha}$-dimethylglycine or α-aminoisobutyric acid (Aib) (3–16), $C^{\alpha,\alpha}$-diethylglycine (Deg) (5, 10, 17), and $C^{\alpha,\alpha}$-di-*n*-propylglycine (Dpg) (5, 10, 18), relatively few studies have been reported on peptides containing 1-aminocycloalkane-1-carboxylic acids (Acc^n, where *n* is the number of carbon atoms in the cycloalkane ring). Recent X-ray diffraction investigations in our laboratory suggest that both 1-aminocyclohexane-1-carboxylic acid (Acc^6) (19–22) and 1-aminocyclopentane-1-carboxylic acid (Acc^5), earlier referred to as cycloleucine and abbreviated as Cle, Cyl, cycloLeu or *c*Leu (23) strongly prefer folded backbone conformations in the $3_{10}/\alpha$-helical region of the conformational space ($\phi \simeq \pm 60 \pm 20°$, $\psi \simeq \pm 30° \pm 20°$) (24).

As a part of a program aimed to a detailed investigation of the conformational properties of the Acc^5 residue (23), in this report we describe the X-ray diffraction structures of six Acc^5 derivatives, namely Z-Acc^5-OH (**1**) (Z, benzyloxycarbonyl), Z-Acc^5-OH acetone hemi-solvate (**2**), Fmoc-Acc^5-OH (**3**) (Fmoc, fluoren-9-ylmethyloxycarbonyl), mClAc-Acc^5-OH (**4**) (mClAc, monochloracetyl), *p*BrBz-Acc^5-OH (**5**) (*p*BrBz, *para*bromobenzoyl), and the 5(4*H*)-oxazolone from *p*BrBz-Acc^5-OH (**6**). In particular, the results permit a definition of the Acc^5 ϕ, ψ torsion angles (24) and the conformational features of the cyclopentyl side chain. X-ray diffraction structures of H-Acc^5-OH monohydrate (25), H-Acc^5-OH hydrobromide (26), and the 2,5-dioxopiperazine from Acc^5 and Ser (27) have already been published by other groups.

This study was expected to provide information on the structural effect produced by Acc^5 when inserted in analogs of bioactive peptides. To our knowledge, Acc^5-containing peptides synthesized so far range from analogs of the formyl-methionyl tripeptide chemoattractant (28–31) to the sweetening agent aspartame (32–34), from angiotensin II (35) to enkephalins (36, 37), from the antitumor and antiviral agents 2,5-dioxopiperazines (38) to angiotensin-converting enzyme (39), peptidyltransferase (40), and γ-glutamyl transpeptidase (41, 42) inhibitors, from penicillin (43) and somatostatin (44) to oxytocin (45, 46) and vasopressin (47).

Experimental

Materials

Z-Acc^5-OH (**1**) (48) and mClAc-Acc^5-OH (**4**) (48) were prepared by published procedures.

Fmoc-Acc^5-OH (**3**) was prepared as described by Paquet (49). Mp 187–188°C (from ethyl acetate). *Anal.* calcd. for $C_{21}H_{21}NO_4$ (351.4): C 71.8, H 6.0, N 4.0; found: C 71.6, H 6.1, N 3.9.

*p*BrBz-Acc^5-OH (**5**) was prepared as described by Toniolo *et al.* (8). Mp 236–237°C (from ethyl acetate). *Anal.* calcd. for $C_{13}H_{14}NO_3Br$ (312.2): C 50.0, H 4.5, N 4.5, Br 25.6; found: C 49.8, H 4.5, N 4.4, Br 25.4.

5(4*H*)-Oxazolone from *p*BrBz-Acc^5-OH (**6**) was prepared as des-

cribed by Toniolo *et al.* (8). Mp 120–121°C (from toluene – petroleum ether). *Anal.* calcd. for $C_{13}H_{12}NO_2Br$ (294.2): C 53.1, H 4.1, N 4.8, Br 27.2; found: C 52.9, H 4.0, N 4.7, Br 27.0.

X-ray diffraction

Colorless crystals of Z-Acc^5-OH (**1**) were obtained from a diethyl ether solution by slow evaporation. Crystal data are as follows:

$C_{14}H_{17}NO_4$ fw = 263.3

Triclinic, a = 12.833(2), b = 8.580(2), c = 6.605(1) Å, V = 673.1 Å^3, α = 98.24(10), β = 103.58(10), γ = 103.22(10), ρ_o = 1.39(1), Z = 2, ρ_c = 1.396 g cm^{-3} (20°C; MoK$_\alpha$, λ = 0.7107 Å). Space group $P\bar{1}$.

Colorless crystals of Z-Acc^5-OH acetone hemi-solvate (**2**) were obtained from an acetone solution by slow evaporation. Crystal data are as follows:

$C_{14}H_{17}O_4.(1/2)(C_3H_6O)$ fw = 292.3

Orthorhombic, a = 31.282(3), b = 10.596(2), c = 9.621(2) Å, V = 3189.0 Å^3, ρ_o = 1.29(1), Z = 8, ρ_c = 1.30 g cm^{-3} (20°C; MoK$_\alpha$, λ = 0.7107 Å). Space group *Pbcn*.

Colorless crystals of Fmoc-Acc^5-OH (**3**) were obtained from an ethyl acetate solution by slow evaporation. Crystal data are as follows:

$C_{21}H_{21}NO_4$ fw = 351.4

Orthorhombic, a = 26.136(5), b = 13.854(4), c = 9.842(3) Å, V = 3563.7 Å^3, ρ_o = 1.30(1), Z = 8, ρ_c = 1.31 g cm^{-3} (20°C; MoK$_\alpha$, λ = 0.7107 Å). Space group *Pbca*.

Colorless crystals of mClAc-Acc^5-OH (**4**) were obtained from an acetone – petroleum ether mixture by slow evaporation. Crystal data are as follows:

$C_8H_{12}NO_3Cl$ fw = 205.6

Orthorhombic, a = 11.012(3), b = 9.541(3), c = 9.277(3) Å, V = 974.7 Å^3, ρ_o = 1.38(1), Z = 4, ρ_c = 1.39 g cm^{-3}, μ = 3.2 cm^{-1} (20°C; MoK$_\alpha$, λ = 0.7107 Å). Space group $P2_12_12_1$.

Colorless crystals (0.5, 0.5, 0.6 mm) of *p*BrBz-Acc^5-OH (**5**) were obtained from an ethyl acetate solution by slow evaporation. Crystal data are as follows:

$C_{13}H_{14}NO_3Br$ fw = 312.2

Orthorhombic, a = 21.313(5), b = 10.004(3), c = 12.158(3) Å, V = 2592.3 Å^3, ρ_o = 1.59(1), Z = 8, ρ_c = 1.60 g cm^{-3}, μ = 30.8 cm^{-1} (20°C; MoK$_\alpha$, λ = 0.7107 Å). Space group *Pccn*.

Colorless crystals (0.15, 0.15, 0.7 mm) of the 5(4*H*)-oxazolone from *p*BrBz-Acc^5-OH (**6**) were obtained from a toluene – petroleum ether mixture by slow evaporation. Crystal data are as follows:

$C_{13}H_{12}NO_2Br$ fw = 294.2

Triclinic, a = 12.635(3), b = 9.568(3), c = 5.490(2) Å, V = 615.5 Å^3, α = 100.1(3), β = 93.0(3), γ = 108.5(3), ρ_o = 1.57(1), Z = 2, ρ_c = 1.58 g cm^{-3}, μ = 32.4 cm^{-1} (20°C; MoK$_\alpha$, λ = 0.7107 Å). Space group $P\bar{1}$.

A total of 2368, 2811, 3139, 1718, 2288, and 2161 independent reflections for **1**, **2**, **3**, **4**, **5**, and **6**, respectively, were collected on a Philips PW 1100 four-circle diffractometer, using graphite-monochromatized MoK$_\alpha$ radiation at $4° < 2\theta < 50°$ with the θ–2θ scan mode. During data collection three standard reflections were measured every 180 min to check the stability of the crystal and the electronics. Intensities were corrected for Lorentz and polarization factors; no absorption corrections was applied.

The six structures were solved by direct methods using MULTAN 80 (50) and refined by block-diagonal least-squares (**1**, **2**, **3**, **5**, and **6**) or by full-matrix least-squares (**4**) with anisotropic thermal parameters for all non-hydrogen atoms with the exception of those of the acetone molecule of **2**. The hydrogen atoms of **1** and **2** were found on the difference Fourier map, but not refined; those of **3**, **4**, and **6** were found and refined isotropically. Part of the hydrogen atoms of **5** were found on the difference Fourier map while the others were calculated, and all were refined isotropically. All calculations were performed on the IBM 370/158 computer of the University of Padova, using SHELX 76 (51).

The final R values for the 745, 746, 1118, 1605, 1404, and 1432 observed reflections with $I \geq 3.0\sigma(I)$ of **1**, **2**, **3**, **4**, **5**, and **6**, respectively, were 0.077, 0.070, 0.064, 0.039, 0.052, and 0.052, respectively. For **1** and **2** the low percentages (31.5 and 26.5) of observed reflections might tentatively be attributed to the tiny crystals obtained in both cases and to the internal disorder existing particularly in the oxygen atom of the acetone molecule of **2**.

Tables of final atomic coordinates with esd's and thermal parameters, of bond lengths, bond angles, and torsion angles, and lists of observed and calculated structure factors are available from the Depository of Unpublished Data.[4]

Results and discussion

Perspective views of molecules **1** to **6** are shown in Figs. 1–6 with the atom numbering schemes. Average values of bond lengths and bond angles for the Acc^5 residue are listed in Fig. 7.

The Acc^5 residue

The Acc^5 residue of compounds **1**, **2**, **4**, and **5** is folded, the sets of ϕ, ψ_T torsion angles (24) falling in the region of the conformational energy map where both α- and 3_{10}-helices are found. The pertinent values are 60.9(13), 29.4(13)° for **1**, −58.2(11), −31.4(11)° for **2**; −62.6(4), −23.4(4)° for **4**; −61.9(8), −34.4(8)° for **5**. Conversely, the Acc^5 of **3** is semi-extended [−65.5(9), 160.9(6)°], as observed in Fmoc-Aib-OH, where the ϕ, ψ_T values are −78.6, 158.6° (52). In *t*-Boc-(Acc^5)$_2$-NHMe (*t*-Boc, *tert*-butyloxycarbonyl; NHMe, methylamino (23) the ϕ, ψ values for the two Acc^5 residues are −57.6, −38.1° and −60.2, −31.1° for the folded N- and C-terminal residues, respectively.

In general, bond lengths and bond angles of the Acc^5 residue agree well with those reported for the *trans* peptide unit (53, 54) and the Aib (54–57) and Acc^6 (21) residues. The average value for the N—C$^\alpha$—C′ (τ) bond angle is higher than the regular tetrahedral value, but the known dependence of this angle on the ψ torsion angle is found also in this study: in particular, the Acc^5 residue in the semi-extended conformation (compound **3**) shows a value closer to 109.5° than the Acc^5 residues in the helical conformation (compounds **1**, **2**, **4**, and **5**). The asymmetry at the C$^\alpha$ atom (bond angles involving the C$^{\beta L}$ as compared to those involving the C$^{\beta D}$ atom), already reported for the Aib and Acc^6 residues, stands out clearly also from the values of the Acc^5 residue listed in Fig. 7. As expected for a cyclopentyl ring (58), the endocyclic bond angles have values significantly lower than 109.5°.

As for the torsion angles relating the cyclopentyl ring to the peptide chain, N—C$^\alpha$—C$^{\beta L}$—C$^{\gamma L}$ and N—C$^\alpha$—C$^{\beta D}$—C$^{\gamma D}$, the sets of values observed (deposited) are half-way between the ideal *gauche* (g^+, g^-, or ±60°) and *skew* (s^+, s^-, or ±120°) conformations, with the single exception of the 5(4*H*)-oxazolone from *p*BrBz-Acc^5-OH (**6**), the values of which are reasonably close to the s^+, s^- conformation.

The endocyclic cyclopentane ring torsion angles of compounds **1** to **6** are listed in Table 1. As expected (58), the absolute values range from 0.3 (planar) to 41.0°. The values of ϕ, the phase angle of puckering (59), are 179.4(21), −42.5(21), 173.2(27), 171.6(7), 6.3(16), and 75.0(17)° for compounds **1**–**6**, respectively. In terms of the original cyclopentane model (60), values of ϕ = 0, 36, 72, 108, 144, 180° correspond to envelope conformations with C_s symmetry, while ϕ = 18, 54, 90, 126, 162° give half-chair (or twist) conformations with C_2 symmetry.

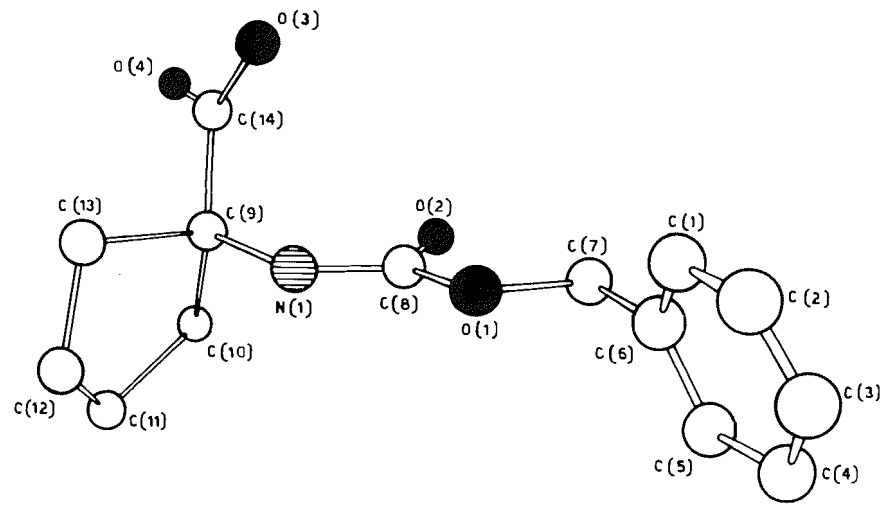

FIG. 2. Molecular structure of Z-Acc^5-OH acetone hemi-solvate (**2**) with numbering of the atoms.

N-terminal groups

The values of bond lengths and bond angles for the urethane group of the benzyloxycarbonyl compounds **1** and **2** (Figs. 1 and 2) are in agreement with literature data (61). In particular, the decrease of the bond angle at the carbonyl carbon, O(1)—C(7)—N(1) in **1** (110.4(9)°) and O(1)—C(8)—N(1) (109.2(8)°) in **2**, by about 5°, as compared with the corresponding bond angle C^{α}—C′—N in the peptide group (53, 54), must be ascribed to the reduced repulsion between the O(1) atom and the nearest substituent on the N-atom in urethane, compared with a corresponding repulsion involving the C^{α} atom of the peptide group. The θ_2 and θ_3 angles, giving the orientation of the phenyl ring relative to the urethane moiety (61), C(7)—O(1)—C(8)—C(14) and O(1)—C(8)—C(14)—C(13) in **1**, and C(8)—O(1)—C(7)—C(6) and O(1)—C(7)—C(6)—C(1) in **2**, have values of −162.5(9) and −45.9(14)° in **1**, and −173.2(9) and −76.6(14)° in **2**. Interestingly, in the observed distribution of θ_2 in crystalline Z-derivatives, the values are concentrated in three regions, close to 90, −90, and 180°, respectively; conversely, the distribution of θ_3 values is broad, extending over its entire range (61). The angle between normals to the average planes of the phenyl and urethane groups is 44.9° in **1** and 70.3° in **2**. The secondary urethane linkage is found in the usual *trans* conformation (61–63) in both **1** and **2**, the values of the ω_0 torsion angle (O(1)—C(7)—N(1)—C(2) in **1** and O(1)—C(8)—N(1)—C(9) in **2**) being −178.5(9)° in **1** and 179.3(7)° in **2**. This structural property, accompanied by the *trans* θ_1 torsion angle (179.1(9)° for N(1)—C(7)—O(1)—C(8) in **1**, while −178.3(9)° for N(1)—C(8)—O(1)—C(7) in **2**), allows us to classify the urethane moieties of **1** and **2** as the common type *b* (61–63).

Bond lengths and bond angles for the fluoren-9-ylmethyloxycarbonyl group of compound **3** (Fig. 3) compare well with those found in other Fmoc (52) and urethane (61, 62) derivatives. In particular, we note the following points: (*i*) The C(6)—C(7), C(12)—C(13), and C(1)—C(13) bond lengths of the fluorene system are 1.484(12), 1.535(13), and 1.511(13) Å, respectively. (*ii*) The tetrahedral bond angles about the C(13) atom are considerably spread (from 101.2(7) to 115.3(8)°) to help relieve the unfavorable interactions between the tricyclic moiety and the methyloxycarbonylaminoacyl chain. (*iii*) The C(13)—C(14) bond length (1.516(11) Å) is shorter than that quoted as standard for a paraffinic C—C single bond, 1.541 Å (64); by contrast, the C(14)—O(1) bond length (1.468(12) Å) is larger than that quoted as standard for an ether C—O single bond, 1.430 Å (64). The fluorene ring system, and the urethane and carboxylic acid groups are close to planarity. The angle between normals to the average planes of the two aromatic rings of the fluorene system is 3.8°. The angles between normals to the average plane of the urethane group and the average planes

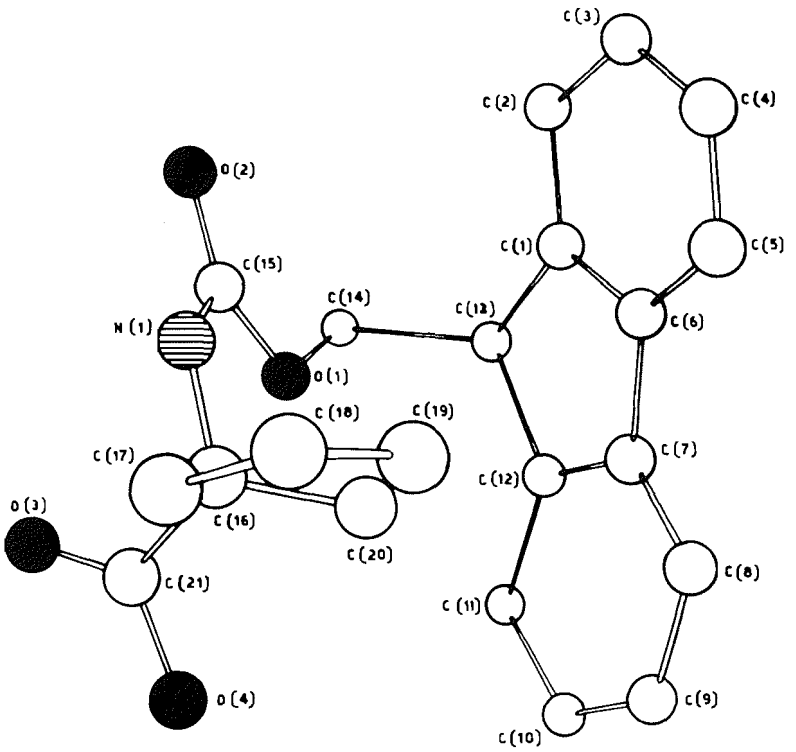

FIG. 3. Molecular structure of Fmoc-Acc^5-OH (**3**) with numbering of the atoms.

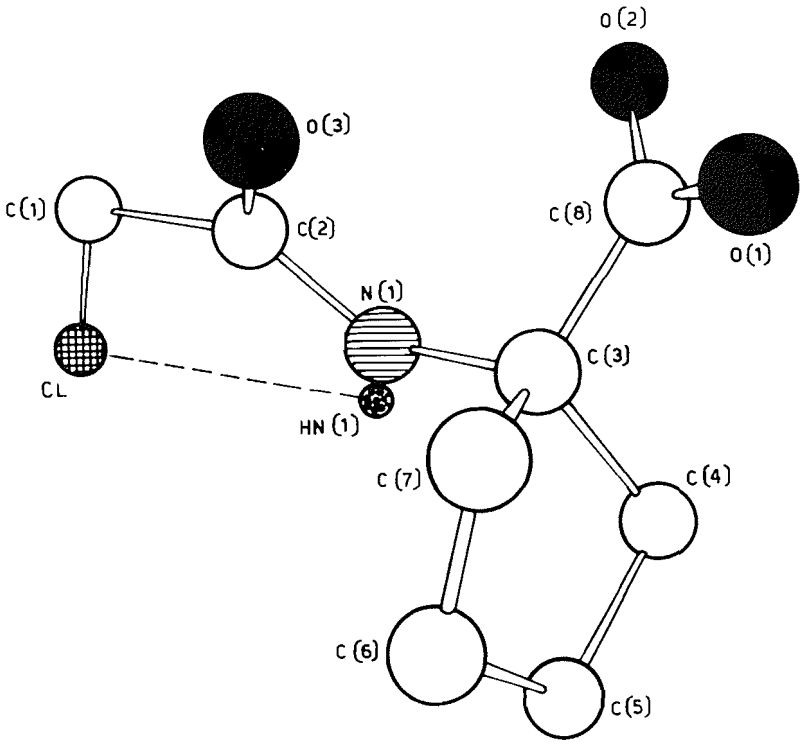

FIG. 4. Molecular structure of mClAc-Acc^5-OH (**4**) with numbering of the atoms. The intramolecular H-bond is shown as a dashed line.

of the central ring of the fluorene system and the carboxylic acid group are 116.9° and 104.6°, respectively. The secondary urethane moiety is in the relatively unusual type *a* (*trans*, *cis*) conformation (61–63), the two pertinent θ_1 and ω_0 torsion angles having values of −172.4(7) and −3.4(10)°, respectively. In Fmoc-Aib-OH (52), however, the urethane conformation is *trans*, *trans* (type *b*).

The dihedral angle δ between normals to the average planes of the amide and carboxylic acid groups of compound **4** (Fig. 4) is 107.8°. In *N*-acylamino acids this angle is known to have a preference for values near 20° or 90° (65). The alignment of the C(1)—Cl and the amide N(1)—H bonds is suggested by the value of the Cl—C(1)—C(2)—N(1) torsion angle (5.0(5)°). The presence of the intramolecularly H-bonded "C_5" conforma-

TABLE 1. Torsion angles (deg) in the cyclopentane rings of compounds **1** to **6**

Compound	Torsion angle									
	$C^{\beta D}$—C^{α}—$C^{\beta L}$—$C^{\gamma L*}$	C^{α}—$C^{\beta L*}$—$C^{\gamma L}$—$C^{\gamma D}$	$C^{\beta L}$—$C^{\gamma L}$—$C^{\gamma D}$—$C^{\beta D}$	$C^{\gamma L}$—$C^{\gamma D}$—$C^{\beta D}$—C^{α}	$C^{\gamma D}$—$C^{\beta D}$—C^{α}—$C^{\beta L}$
Z-Acc^5-OH (**1**)	37.1(10)	−22.8(12)	−0.3(13)	23.7(12)	−37.7(11)
Z-Acc^5-OH acetone hemi-solvate (**2**)	−17.1(11)	−4.8(13)	25.7(14)	−35.7(12)	32.7(11)
Fmoc-Acc^5-OH (**3**)	−31.6(10)	22.5(12)	−4.2(13)	−15.3(11)	28.6(9)
mClAc-Acc^5-OH (**4**)	36.7(4)	−19.3(4)	6.3(5)	29.6(4)	−41.0(3)
*p*BrBz-Acc^5-OH (**5**)	34.5(8)	−18.9(9)	−4.5(10)	26.1(9)	−37.1(7)
*p*BrBz-Acc^5-OH oxazolone (**6**)	−2.3(11)	25.2(12)	−39.1(12)	36.6(11)	−21.4(11)

*The C^{β} carbon atom in the Acc^5 residue that occupies the same position as C^{β} in an L-amino acid is designated as $C^{\beta L}$, and the other C^{β} atom is $C^{\beta D}$. Furthermore, the carbon atoms bonded to $C^{\beta L}$ and $C^{\beta D}$ are designated as $C^{\gamma L}$ and $C^{\gamma D}$, respectively.

tion (66) is corroborated by the following additional observations: (*i*) The secondary amide torsion angle, C(1)—C(2)—N(1)—C(3) is −178.1(3)°, the usual *trans* conformation (67). (*ii*) The intramolecular Cl···N(1) and Cl···HN(1) distances are 3.001(3) and 2.531(20) Å (22, 68–70).

Bond lengths and bond angles of the *p*BrBz moiety of compounds **5** (Fig. 5) and **6** (Fig. 6) agree well with those found in other *p*BrBz derivatives (8, 22, 71). The dihedral angle between normals to the average planes of the phenyl and amide groups in **5** is 36.3°, while the δ angle (65) is 77.8°. The phenyl and 5(4*H*)-oxazolone groups of **6** are nearly coplanar (the angle between normals to the average planes of these two groups being 8.2°), whereas the phenyl and cyclopentyl groups are nearly perpendicular to each other (the pertinent dihedral angle has a value of 78.8°). The secondary amide bond of **5** is *trans* (−175.4(6)°) (67), as found in *p*BrBz-Aib-OH (71).

C-terminal groups

In compounds **1**, **2**, **4**, and **5** the —COOH group adopts a conformation with respect to the C—N bond intermediate between the *anticlinal* and *antiperiplanar* conformations (72), the N—C^{α}—C′—O (carbonyl oxygen) torsion angles being −153.7(11), 156.3(9), 160.6(3), and 149.6(7)°, respectively. Conversely, this angle is −20.4(11) (intermediate between the *synperiplanar* and *synclinal* conformations) in **3**.

The N(1)—C(7) bond length, 1.271(12) Å, of the heterocyclic moiety of the 5(4*H*)-oxazolone from *p*BrBz-Acc^6-OH (**6**) is appropriate for a C—N double bond. This finding confirms the results obtained in the analysis of the amino acid and peptide 5(4*H*)-oxazolones the structures of which have been solved so far (22, 71, 73, 74), namely that this bond is not conjugated with the lactone moiety C(7), O(2), C(8), O(1), C(9). The O(2)—C(7) and O(2)—C(8) bond lengths are 1.384(11) and 1.392(11) Å, respectively, characteristic for an O—C(sp^2) bond (75). The exocyclic bond angles about the carbonyl C(8)—O(1) of the lactone moiety differ by 7.6°, with a larger value for the O(1)—C(8)—C(9) bond angle, 130.4(10)°. This latter value is probably the result of intramolecular interactions between O(1) and the two C(sp^3) substituents on the C(9). Again, this finding is in agreement with published data on other 5(4*H*)-oxazolones (22, 71, 73, 74). An additional result, common to all 5(4*H*)-oxazolones, is the widening of the N(1)—C(7)—C(4) exocyclic bond angle to >127°. The 5(4*H*)-oxazolone ring is nearly planar. The displacement of the atoms in the five-membered ring from its mean plane varies from −0.0074 to 0.069 Å (σ(m) = 0.0054 Å). The C(10) and C(13) atoms are displaced by nearly equal amounts on the opposite sides of the average plane of the 5(4*H*)-oxazolone ring (1.262 and −1.234 Å, respectively) (22, 71, 73, 74).

Crystal packing

The molecules of Z-Acc^5-OH (**1**) are held together across a crystallographic centre of symmetry by the formation of two intermolecular H-bonds of the N—H···O—C (acid) type, giving rise to a ten-membered cyclic dimer. The N(1)···O(3) $(1-x, 1-y, 1-z)$ distance is 3.085(12) Å, falling close to the most probable range for a length of a (peptide) N—H···O=C (peptide) H-bond, 2.9–3.0 Å (76, 77). There is an additional short distance involving heteroatoms in the crystals of **1**, namely O(2)···O(3) $(1-x, 1-y, -z)$ 2.644(10) Å (78, 79); however, the O(3)—*H*···O(2) separation is 2.726(20) Å. These findings are not in keeping with the principle that the maximum number of proton donors and acceptors will participate in the H-bonding scheme, recently put forward in a study of carboxylic acids and amides (80).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/07/12
For personal use only.

The packing mode of the molecules of Z-Acc^5-OH acetone hemi-solvate (**2**) is, however, completely different. We find an eight-membered cyclic dimer formed by two intermolecular H-bonds of the O—H···O=C (acid) type, the most commonly observed interlinking motif in carboxylic acids (81). The O(3)···O(4) ($-x$, $-y$, $1 - z$) separation is 2.652(10) Å (78, 79). In the crystal packing of this compound additional intermolecular H-bonds of the N—H···O=C (urethane) type are seen, ultimately producing chains of dimers along the z direction. The N(1)···O(2) (x, $-y$, $1/2 + z$) distance is 2.868(9) Å (76, 77). No interactions are seen between the acetone and the N-protected amino acid molecules.

The molecules of Fmoc-Acc^5-OH (**3**) are held together across a crystallographic centre of symmetry via two intermolecular H-bonds of the N—H···O=C (acid) type, forming a ten-membered cyclic dimer. The N(1)···O(3) ($1 - x$, $-y$, $2 - z$) separation is 3.035(8) Å (79, 80). Chains of dimers are produced along the y direction by the formation of O—H···O=C (urethane) intermolecular H-bonds. The O(2)···O(4) ($1 - x$, $1/2 + y$, $3/2 - z$) distance is 2.589(7) Å (78, 79).

In the crystals of mClAc-Acc^5-OH (**4**) rows of molecules are held together along the y direction through O—H···O=C (amide) intermolecular H-bonds. The O(2)···O(3) ($-x$, $1/2 + y$, $1/2 - z$) distance is 2.618(4) Å (78, 79). Chains of molecules are also observed along the z direction via N—H···O=C (acid) intermolecular H-bonds. The N(1)···O(1) ($1/2 - x$, $1 - y$, $-1/2 + z$) separation is 3.055(3) Å (76, 77). This is the most common packing motif of *N*-acyl amino acids (82). However, it is worth remembering that the N—H group is also participating in the intramolecular H-bond with the Cl atom (see above).

The packing mode of the *p*BrBz-Acc^5-OH (**5**) molecules involves cyclic dimer formation via two intermolecular H-bonds of the N—H···O=C (acid) type. The N(1)···O(1) ($-x$, $1 - y$, $-z$) distance is 3.118(7) Å (76, 77). Chain of dimers are eventually produced along the y-direction through O—H···O=C (amide) intermolecular H-bonds. The O(1)···O(3) ($-x$, $1/2 + y$, $-1/2 - z$) distance is 2.632(7) Å (78, 79).

Obviously, there are no intermolecular H-bonds connecting the molecules of the 5(4*H*)-oxazolone from *p*BrBz-Acc^5-OH (**6**) in the crystals, owing to the absence of potential H-bonding donors in this compound.

^{99}Tc-thiocyanate complexes: their extractions as ionic associations with Adogen 464

J. G. MARCH AND F. GRASES
Chemistry Department, Balearic Islands University, 07071-Palma de Malorca, Spain

Received June 23, 1987[1]

J. G. MARCH and F. GRASES. Can. J. Chem. **66**, 2583 (1988).

The extraction of the ionic species formed between two reduced Tc–SCN anionic complexes and trioctylmethyl ammonium cation has been studied spectrophotometrically in both oxygenated and deoxygenated media. The distribution ratio for each reduced complex has been determined as a function of tin(II) and Adogen 464 concentrations. The results indicate that, depending on the concentration of the Sn(II) reducing agent, a red Tc(IV) or a yellow Tc(III) complex can be formed.

J. G. MARCH et F. GRASES. Can. J. Chem. **66**, 2583 (1988).

Opérant tant dans des milieux tant oxygéné que désoxygéné et faisant appel à la spectrophotométrie, on a étudié l'extraction des espèces ioniques qui se forment entre deux complexes anioniques Tc–SCN réduits et le cation trioctylméthyl ammonium. On a déterminé le rapport de distribution de chacun des complexes réduits en fonction des concentrations de l'étain(II) et de l'Adogène 464. Les résultats indiquent que, suivant la concentration de l'étain(II) comme agent réducteur, il peut se former soit un complexe Tc(IV) rouge ou un complexe Tc(III) jaune.

[Traduit par la revue]

Introduction

The complex formation between reduced technetium and thiocyanate ion in aqueous media has been reported previously (1). The exact nature of that system has been examined by several workers (2–4). Depending on reaction conditions, either a red or yellow species are formed. Initially, the 500 nm band (red) was assigned to a Tc(V) complex, and the 400 nm band (yellow) to a Tc(IV) complex.

Subsequently, a thorough investigation (5) led to the proposal that the above two complexes formed a redox couple (eq. [1]).

[1] $[Tc(NCS)_6]^{2-} \leftrightharpoons [Tc(NCS)_6]^{-} + e^{-}$
yellow red

That study included the isolation of the two species. A red one, formulated as a Tc(V) compound $(Me_4N)[Tc(NCS)_6]$, and a yellow one, formulated as a Tc(IV) compound $(Me_4N)_2[Tc(NCS)_6]$.

More recently, the same system has been reinvestigated (6). Voltammetric studies in acetonitrile indicated that the two species were linked via electron transfer between $[Tc(NCS)_6]^{3-}$ (yellow technetium(III) complex) and $[Tc(NCS)_6]^{2-}$ (red technetium(IV) complex) (eq. [2]).

[2] $[Tc(NCS)_6]^{3-} \leftrightharpoons [Tc(NCS)_6]^{2-} + e^{-}$
yellow red

These conclusions agreed with the authors' potentiometric results which were obtained in aqueous media (9).

It should be noted that in most of the cases studied to date, the resulting technetium(V) complexes have either one or two oxo-groups remaining bonded to the metal (7). In fact, the oxo-technetium(V) thiocyanate complex, formulated as $[TcO(NCS)_5]^{2-}$, was prepared by ligand substitution on $[TcOCl_4]^{-}$ and characterized as tetraphenylarsonium salt (8).

Both thiocyanate species, the red and the yellow, were easily extractable from acid media in polar organic solvents (ether, butyl acetate, octanol). The extraction was assumed to take place through the formation of an ionic association between the complex (anion) and protonated molecules of the organic solvent (cation). The anion complex did not extract into non-polar organic solvents (e.g. chloroform, toluene, benzene).

According to the literature (5, 6, 9, 10), the molar ratio of Tc to NCS for both red and yellow species was 1:6. Therefore, the charge on the resulting thiocyanate complexes would appear to be directly related to the oxidation state of technetium in accordance with eq. [3].

[3] Tc oxidation state = 6 − negative charge on complex

The purpose of this work is to study the extraction of the Tc–NCS complexes into a non-polar organic solvent (toluene), using a liquid resin for anionic exchange (Adogen 464), through the formation of a ternary complex. Thus, the technetium oxidation state in the reduced complex can be determined by measuring the $Tc(NCS)_6$:resin molar ratio which corresponds to the charge on the complexes. In addition, this work proposes a new procedure for the extraction of technetium, which can be helpful in technetium purification processes.

Experimental

Chemicals and apparatus

^{99}Tc in solution form as ammonium pertechnetate (34.0 mg Tc/mL, 4.46 MBq/mL), was purchased from Amersham Searle Co., Arlington Heights, IL. A 10^{-3} *M* $^{99}TcO_4^-$ solution was prepared by dilution of the stock standard with water. A 0.1 *M* Sn(II) solution was prepared from reagent grade $SnCl_2 \cdot 2H_2O$ (Merck) in 6 *M* HCl; this solution was prepared daily and standardized by titration with KIO_3 (12). Stock solutions of reagent grade 4.2×10^{-3} *M* KSCN (Panreac) and 1.1×10^{-3} *M* trioctylmethyl ammonium chloride, commercially known as Adogen 464 (Serva), were prepared in water and in toluene, respectively. The Adogen 464 solution was deoxygenated before use.

A Perkin-Elmer 552 spectrophotometer equipped with 1-cm cell was used for taking absorbance measurements.

A Crison 517 potentiometer provided with a platinum indicator electrode and a calomel reference electrode was used for potential measurements.

The β-activity was determined by liquid scintillation counting (Beckman LS 1800) using a PPO/POPOP solution in xylene as fluor solution and a surfactant solution supplied by Aldabó & Juliá, Barcelona (Spain).

Method

A typical extraction procedure was as follows. In a separatory funnel, 1 mL of 10^{-3} *M* Tc(VII) solution, 5 mL of 4.2×10^{-2} *M* SCN^- solution, 4 mL of 6 *M* HCl solution, and enough water to ensure a final volume of 15 mL were placed. The mixture was deaerated by bubbling N_2 for 15 min. Then 15 μL of 0.1 *M* Sn(II) and 10 mL of $1:1 \times 10^{-3}$ *M* Adogen toluene solution were added. The system was shaken 45 min in a nitrogen atmosphere with a mechanical shaker. After phase separation, spectrophotometric measurements of the organic layer or

For personal use only.

potentiometric measurements of the aqueous phase were carried out. The extractions were carried out at room temperature.

To obtain distribution ratio values the organic layer was oxygenated for 3 h, then absorbance measurements at 506 nm were made (as described below this transforms reduced Tc species to the red Tc(IV) thiocyanate complex). The technetium concentration in the organic phase was evaluated from the absorbance value by using a calibration graph obtained with an amount of Sn(II) that guaranteed reduction to the +4 oxidation state. The technetium concentration in the aqueous phase was obtained from the difference between the total concentration and the organic phase concentration.

Results and discussion

A systematic study showed that, in the presence of a large excess of ligand (Tc:SCN molar ratio 40 or higher), within the range 2.0 to 0.3 *M* hydrochloric acid concentration, and working in anaerobic conditions, the colour of the organic phase was either red or yellow, depending on the amount of reducing agent added. Thus, the solution was red if the amount of tin(II) added was less than or equal to the theoretical stoichiometric amount necessary to reduce Tc(VII) to Tc(IV). The solution was yellow when the amount of Sn(II) added was greater than or equal to the theoretical stoichiometric amount necessary to reduce Tc(VII) to Tc(III). Both Tc complexes were quantitatively extracted into toluene that contained an adequate excess of Adogen 464 (Tc:Adogen molar ratio 15 or higher for both red and yellow species). The quantitativeness of the extractions (99.99%) was determined by measuring the ^{99}Tc radioactivity remaining in the aqueous phase after extraction. On the other hand, it was shown that following the procedure described in the Experimental section, Tc(VII) was not reduced by the thiocyanate ligand at the above mentioned hydrochloric acid concentrations because, in the absence of tin(II), there was no visible reaction; moreover, the solution showed typical reactions corresponding to Tc(VII) (13–16). It was interesting to note that if the reaction was carried out in the absence of oxygen, no significant changes in the spectra took place during the extraction.

From these observations, the extraction equilibria can be represented by eq. [4]

$$[4]\quad Tc(NCS)_6^{n-} + nR_4N^+_{org} \rightleftharpoons [Tc(NCS)_6(R_4N)_n]_{org}$$

(R_4N^+ = Adogen 464). This is supported by the fact that only slight changes in the spectra of the aqueous species were observed, from which it is assumed that extraction is due to ion-pair formation. Consequently,

$$[5]\quad K = \frac{[Tc(NCS)_6(R_4N)_n]_{org}}{[Tc(NCS)_6^{n-}][R_4N^+]_{org}^n}$$

The distribution ratio is defined as follows

$$[6]\quad D = \frac{[Tc]_{org}}{[Tc]_{aq}} = \frac{[Tc(NCS)_6(R_4N)_n]_{org}}{[Tc(NCS)_6^{n-}]}$$

Combining [5] and [6], and taking the logarithm of both sides, yields

$$[7]\quad \log D = \log K + n \log [R_4N^+]_{org}$$

Therefore, the slope of a plot of log D versus log $[R_4N^+]_{org}$ gives the charge on the technetium thiocyanate complex.

The absorption spectrum of the extracted ion-pair when tin(II) was present in a molar excess of 1.5, as can be seen in Fig. 1(*a*), shows only one maximum at 506 nm (red). Figure 2(*a*) shows the variation of the absorbance at that wavelength as a function of the tin(II) concentration. The curve shows a pronounced maximum for a Sn(II):Tc(VII) molar ratio equal to 1.5, which corresponds to a Tc(IV) final oxidation state, assuming Sn(II) to Sn(IV) oxidation to be quantitative and technetium to be reduced to only one final oxidation state. The stoichiometry found for the extracted red ternary complex, as can be seen in Fig. 3(*a*), is 1:2 technetium-complex:resin. The value of the slope found by plotting log D against log $[R_4N^+]$

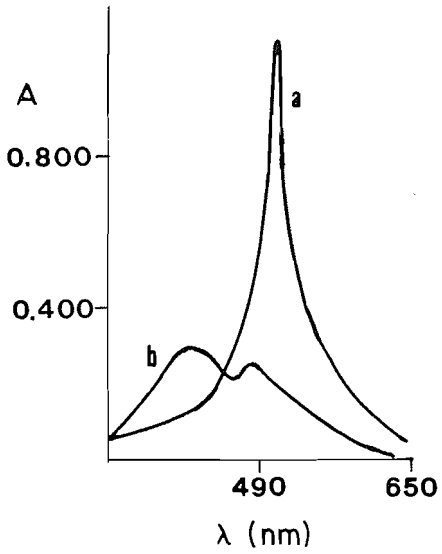

FIG. 1. Absorption spectra of Tc–NCS–Adogen ternary complex extracted in toluene corresponding to two different Sn(II):Tc(VII) molar ratios. [Tc(VII)] = 6.6×10^{-5} *M*, [SCN$^-$] = 1.4×10^{-2} *M*, [HCl] = 1.6 *M*, [Adogen]$_{org}$ = 1.1×10^{-3} *M*, V_{aq} = 15 mL, V_{org} = 10 mL, shaking time = 45 min. (*a*) [Sn(II)] = 1.0×10^{-4} *M*. (*b*) [Sn(II)] = 1.3×10^{-4} *M*.

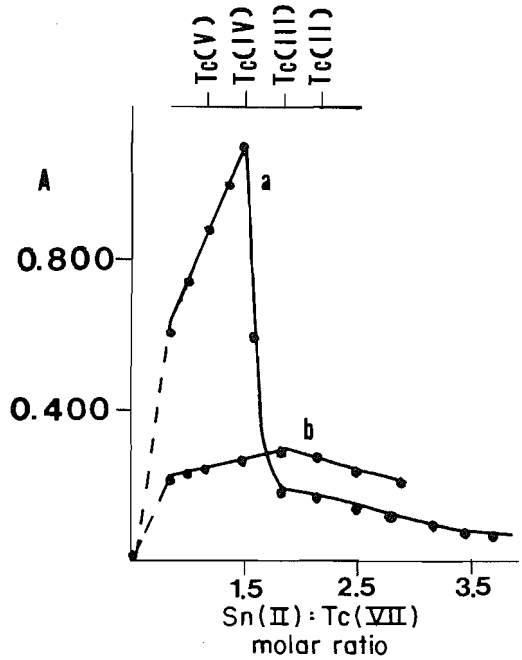

FIG. 2. Absorbance of the toluene phase at (*a*) λ = 506 nm, (*b*) λ = 414 nm, as a function of Sn(II):Tc(VII) molar ratio for [Tc(VII)] = 6.6×10^{-5} *M*, [SCN$^-$] = 1.4×10^{-2} *M*, [HCl] = 1.6 *M*, [Adogen]$_{org}$ = 1.1×10^{-3} *M*, V_{aq} = 15 mL, V_{org} = 10 mL, shaking time = 45 min. The figure includes an auxiliary axis denoting the final Tc oxidation state assuming complete oxidation of Sn(II) to Sn(IV).

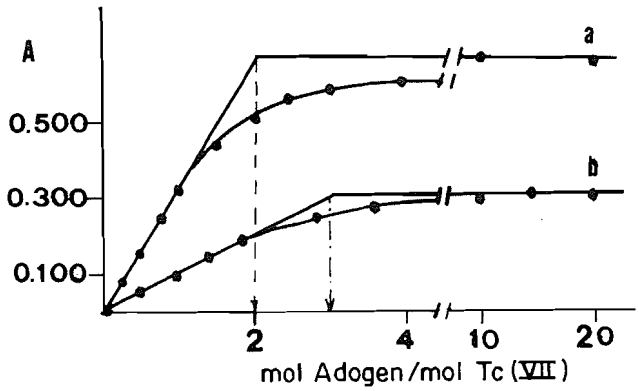

FIG. 3. Extraction of the two [Tc-SCN^-]–[Adogen] species as a function of Adogen/technetium molar ratio for two Sn(II):Tc(VII) molar ratios. [SCN^-] = 1.4×10^{-2} *M*, [HCl] = 1.6 *M*, V_{aq} = 15 mL, V_{org} = 10 mL, shaking time = 45 min. (*a*) [Sn(II)] = 6.0×10^{-5} *M*, [Tc(VII)] = 4.0×10^{-5} *M*, λ = 506 nm. (*b*) [Sn(II)] = 1.3×10^{-4} *M*, [Tc(VII)] = 6.6×10^{-5} *M*, λ = 414 nm.

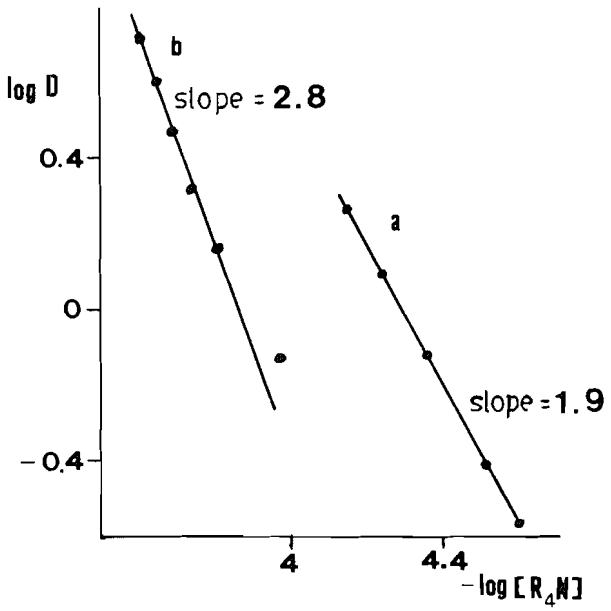

FIG. 4. Extraction ratio as a function of Adogen 464 (R_4N) concentration corresponding to two Sn(II):Tc(VII) molar ratios. Conditions: [SCN^-] = 1.4×10^{-2} *M*, [HCl] = 1.6 *M*, V_{aq} = 15 mL, V_{org} = 10 mL, shaking time = 45 min. (*a*) [Sn(II)] = 8.0×10^{-5} *M*, [Tc(VII)] = 5.3×10^{-5} *M*. (*b*) [Sn(II)] = 1.3×10^{-4} *M*, [Tc(VII)] = 6.6×10^{-5} *M*.

(see Fig. 4(*a*)), for that amount of reducing agent, was 1.9. These results indicate clearly that the oxidation state of technetium in the red ion-pair corresponds to Tc(IV).

The absorption spectrum obtained when tin(II) was present in a molar excess of 2, as can be seen in Fig. 1(*b*), shows maxima at 482 and 414 nm (yellow). A plot of A_{414} vs. Sn(II):Tc(VII) molar ratio (Fig. 2(*b*)) shows a maximum for a Sn(II):Tc(VII) molar ratio equal to 2. The stoichiometry found for the yellow ionic association was 1:3 technetium-complex:Adogen (Fig. 3(*b*)). The value of the slope of the curve log *D* vs. log [R_4N^+] (see Fig. 4(*b*)) was 2.8. Therefore the oxidation state of technetium in the yellow extracted ternary complex corresponds to Tc(III). As mentioned, in this case the absorption spectrum shows two maxima, suggesting two different species. In fact, an orange species was previously mentioned

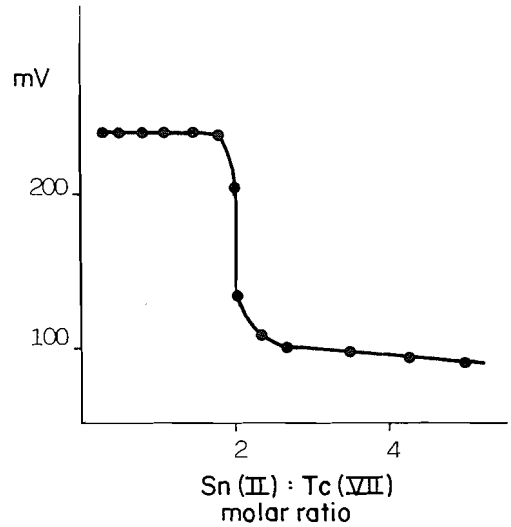

FIG. 5. Potential as a function of Sn(II):Tc(VII) molar ratio for [Tc(VII)] = 1.2×10^{-4} *M*, [SCN^-] = 2.6×10^{-2} *M*, [HCl] = 1.6 *M*, $[Adogen]_{org}$ = 2.0×10^{-3} *M*, V_{aq} = 15 mL, V_{org} = 10 mL, shaking time = 45 min.

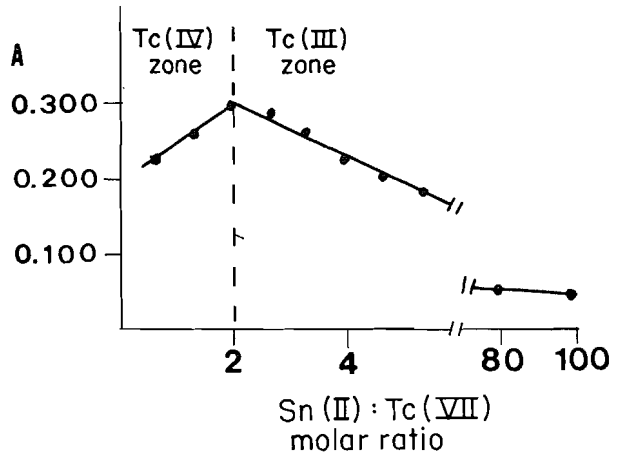

FIG. 6. Absorbance of the toluene phase at 414 nm as a function of Sn(II):Tc(VII) molar ratio. [Tc(VII)] = 6.6×10^{-5} *M*, [SCN^-] = 1.4×10^{-2} *M*, [HCl] = 1.6 *M*, $[Adogen]_{org}$ = 1.1×10^{-3} *M*, V_{aq} = 15 mL, V_{org} = 10 mL, shaking time = 45 min.

in the literature (6). A potentiometric study in aqueous media assigned to that compound a Tc(III) oxidation state (9).

In both water and toluene, exposure of the yellow complex to oxygen caused the absorption maxima at 414 and 482 nm to decrease as a function of time, and a corresponding increase in absorption at 506 nm. The red species was also obtained with the same yield under aerobic conditions, with a Sn(II):Tc(VII) molar ratio higher than 1.5. Under these conditions the yellow species is formed first but, during the extraction, the excess reducing agent is oxidized by oxygen, and the initial Tc(III) yellow complex is oxidized to the Tc(IV) red complex. This permitted establishment of a standard curve independent on Sn(II) concentration, and allowed determination of the distribution ratio spectrophotometrically.

The potentiometric data are summarized in Fig. 5, where the measured potential of the aqueous phase after extraction is plotted against the Sn(II):Tc(VII) molar ratio. As can be seen, the amount of tin(II) remaining in the aqueous phase increased abruptly when the Tc(III) oxidation state was reached. No

For personal use only.

reduction of Tc(III) to lower oxidation states was detected under the conditions employed in this study.

In summary, we present here results indicating that the reduction of Tc(VII) by Sn(II) takes place stoichiometrically. A more interesting point is that, after Tc(III) was obtained with the Sn(II) stoichiometric amount, any excess (Fig. 6) produced a negative effect on the yield of the complex. The potentiometric study indicates no further Tc(III) reduction, thus indicating the possibility of Sn–thiocyanate interactions. This point should be considered in technetium-radiopharmacy research, where reductions are normally carried out in the presence of a high molar excess of reducing agent (11). We believe that a non-controlled excess of reductant (Sn(II)) can produce variability in tissue distribution of some ^{99m}Tc imaging agents in nuclear medicine (17). Thus it is necessary to keep in mind the Sn(II) concentration when optimizing chemical procedures for Tc-radiopharmaceutical preparations.

Received August 31, 1987[2]

HANS VAN DER WEL, NICO M. M. NIBBERING, and MARGARET M. KAYSER. Can. J. Chem. **66**, 2587 (1988).

Gas phase ion/molecule reactions in a Fourier transform ion cyclotron resonance mass spectrometer have been carried out for reductions of isotopically labelled citraconic (methylmaleic), phenylmaleic, and ethoxymaleic anhydrides by BH_4^-. In citraconic anhydride the carbonyl group neighbouring the methyl substituent is reduced preferentially in agreement with the *ab initio* calculations, which show the higher LUMO coefficients at this site. Hydride ion transfer to the olefinic double bond occurs as well; however, in that case no preference for either of the carbon atoms is observed. In phenylmaleic anhydride strong indications are found for a theoretically unexpected hydride ion transfer to the phenyl ring. For ethoxymaleic anhydride experimental evidence is presented showing hydride ion transfer to the carbon atom carrying the ethoxy group, which is in agreement with the "best overlap" consideration predicting that this carbon atom bears the highest LUMO coefficient.

Most of the hydride transfers from BH_4^- to the molecules studied seem, therefore, to take place under orbital control rather than under control of long-range ion-induced dipole interactions between reactants.

HANS VAN DER WEL, NICO M. M. NIBBERING et MARGARET M. KAYSER. Can. J. Chem. **66**, 2587 (1988).

On a effectué des réactions ion/molécule en phase gazeuse dans un spectromètre de masse à résonance ionique par transformation de Fourier pour les réductions des anhydrides citraconique (méthylmaléique), phénylmaléique et éthoxymaléique par le BH_4^-. Dans le cas de l'anhydride citraconique, le groupement carbonyle adjacent du groupement méthyle subit une réduction préférentielle; ce résultat expérimental est en accord avec les calculs *ab initio* qui démontrent que le coefficient d'OM basse vacante se situe sur ce site. Il se produit aussi un transfert d'hydrure vers la double liaison oléfinique; toutefois, dans ce cas, on n'observe aucune préférence pour l'un ou l'autre des atomes de carbone. Dans le cas de l'anhydride phénylmaléique, on relève de fortes indications à l'effet qu'il se produirait un transfert d'hydrure vers le cycle aromatique; ce transfert est inattendu d'un point de vue théorique. Pour l'anhydride éthoxymaléique, on présente des données expérimentales démontrant qu'il se produit un transfert d'hydrure vers le carbone portant le groupement éthoxy; ce résultat est en accord avec les considérations de «meilleur recouvrement» qui prédisent que ce carbone porte le coefficient le plus élevé d'OM basse vacante.

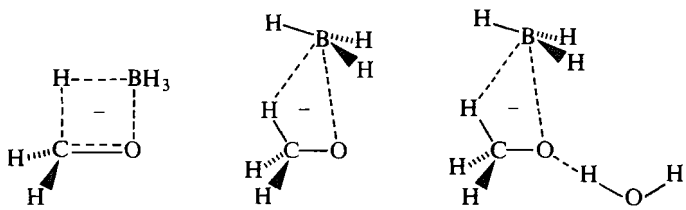
Il semble donc que la plupart des transferts d'hydrure de BH_4^- vers les molécules étudiées ont lieu sous un contrôle orbitalaire plutôt que sous un contrôle d'interactions dipolaires à longue distance entre les réactifs, qui seraient induites par les ions.

[Traduit par la revue]

Introduction

Previously performed *ab initio* calculations for borohydride addition to formaldehyde to give a $CH_3OBH_3^-$ species have suggested a one-step process as the least energy demanding route (1). The calculated transition state is not a symmetrical four-center arrangement in which B—H bond-breaking and C—H and B—O bond-making occur simultaneously (structure **A**), but rather a nonsynchronous structure in which the BH_3^- group is transferred from the almost completely formed C—H bond to the oxygen atom (structure **B**). The energy of this transition state relative to the reactants was calculated to be 127 kJ/mol, thus suggesting that the noncatalyzed reaction is energetically unfavourable. The calculations carried out with a single molecule of water, hydrogen bonded to the formaldehyde oxygen atom (structure **C**), showed the activation energy to be only 38 kJ/mol. These results are in accord with the experimental findings (2, 3) and confirm the hypothesis that the simultaneous or prior association of the carbonyl oxygen with a counterion, proton, or protic solvent facilitates hydride transfer (4).

In view of the above it was predicted that in the gas phase a one-step formation of the $CH_3OBH_3^-$ species from BH_4^- and a "naked" formaldehyde, although calculated to be highly exothermic, should not occur, as the energy of the transition state of 127 kJ/mol is too high to be compensated by the stabilizing effect of the $BH_4^-...CH_2O$ complexation, calculated to be 31 kJ/mol (1). Similarly, a hydride transfer from BH_4^- to CH_2O to give free CH_3O^- and BH_3, which would be the first in a two-step formation of $CH_3OBH_3^-$, should not occur either since, according to the calculations, this highly endothermic step requires 149 kJ/mol (1). It was, therefore, not surprising that the ion cyclotron resonance study of the reaction between BH_4^- and CH_2O showed that no hydride transfer could be detected (5) even upon increasing the translational energy of BH_4^-. However, when one or more electron-withdrawing substituents are attached to the carbonyl function, the activation energy for hydride transfer should be lowered, thus facilitating the reaction.



A **B** **C**

In solution chemistry the experimental evidence pointing in this direction was provided by Loupy *et al.*, who demonstrated

that a cation and (or) a protic solvent was not "essential" for the reduction of aromatic or conjugated ketones (6). The same trend appears to be true also in the gas phase. Although a recently reported list (7) of hydride affinities[3] shows that carbonyl compounds substituted with electron-withdrawing groups such as C_6H_5CHO, CF_3COCH_3, or CF_3CHO have a considerably lower hydride affinity than BH_3 (affinities ranging from 122 to 66 kJ/mol (7), we have found that hydride transfer from BH_4^- to hexafluoroacetone (reaction [1]) or to F_2CO (reaction [2]) *does occur*, with the relative abundance of the corresponding product ions approximately 90% and 5%, respectively.

[1] $BH_4^- + (CF_3)_2CO \rightarrow (CF_3)_2CHO^- + BH_3$
m/z 15 m/z 167

[2] $BH_4^- + CF_2O \rightarrow CF_2HO^- + BH_3$
m/z 15 m/z 67

Interestingly, preliminary experiments carried out on maleic and phthalic anhydrides showed that the gas phase hydride transfer from BH_4^- to these substrates did occur as well. This prompted us to examine further these reductions, particularly the question of regioselectivity of the hydride transfer. In solution, reductions of cyclic anhydrides by $NaBH_4$ yield lactones. These reductions are frequently highly selective, leading to preferential formation of one of the isomeric lactones in the case of unsymmetrical substituted anhydrides. Several factors influence the regioselectivity of these reactions (8). One of the effects appears to be the difference in the "intrinsic reactivity" (9) of the two carbonyl functions vis-a-vis a nucleophile. The difference in reactivity of the two carbonyl groups in cyclic anhydrides has been associated with the difference in the size of LUMO coefficients at the carbon atoms of the two carbonyl functions. At a short distance of approximately 2 Å the orbitals of the nucleophile and the substrate begin to merge. The best overlap between the nucleophile's HOMO and the carbonyl's LUMO leads to the more favourable lower energy transition state. Such a relationship between intrinsic reactivity and the regioselectivity of reductions of metal hydrides appears to hold for all succinic, maleic, and phthalic anhydrides studied (9–11). Yet, it is not possible to estimate the extent to which this effect is responsible for the control of regioselectivity, since in solution, counterions and (or) solvent also play an important role.

On the other hand, in the gas phase, solvent effects and counterions are absent; hence a gas phase study of the reduction of unsymmetrically substituted maleic anhydrides by BH_4^- should shed some light on the importance of intrinsic reactivity in the control of regioselectivity. For that purpose we carried out a Fourier transform ion cyclotron resonance (FT-ICR) mass spectrometric study (for recent reviews see ref. 12) of isotopically labelled maleic anhydrides, in combination with the *ab initio* calculations for a few model compounds.

Experimental

Ion cyclotron resonance spectra were measured with the FT-ICR instrument at the University of Amsterdam. The basic hardware (13*a*), software (13*b*), and general operation procedure (13*c*,*d*) of the instrument have been described previously. The partial pressures were kept around 4×10^{-5} Pa except for the anhydrides ($\sim 1 \times 10^{-5}$ Pa) and for the collision gas N_2O ($\sim 1 \times 10^{-4}$ Pa) during the collision induced dissociation (CID) experiments. These pressures were measured on an ionization gauge placed in a side arm of the main pumping line. The ionization gauge was calibrated against an MKS Baratron (type 170M, head type 94 AH-1) placed in the same side arm using N_2 as calibrant in the 10^{-1}–10^{-3} Pa pressure range.

Negative ions were trapped in the cubic FT-ICR cell (15.6 cm^3) at a magnetic field of 1.4 T by application of a small negative potential (~ -1.6 V) to the trapping plates.

General procedure

The BH_4^- ions were prepared by reaction of $O^{-\bullet}$ (generated from N_2O by electron impact with ~0.6 eV electrons) with B_2H_6.

In a typical experiment $^{11}BH_4^-$ ions were isolated in the cell by application of the so-called notch ejection technique (14) and the reactions with the anhyrides were studied as a function of the reaction time.

In some experiments, to confirm accurate mass measurements, the reactions of the $^{10}BH_4^-$ ions with the anhydrides were studied while the $^{11}BH_4^-$ isotopic ions were removed continuously from the cell.

Collision induced dissocation (CID) experiments (12)

CID experiments were performed with N_2O as collision gas. First the $(M + H)^-$ and $(M + BH_4)^-$ ions (M = anhydride) were isolated in the cell by application of the so-called notch-ejection technique (14) after 0.5–1 s reaction time, following isolation of the $^{11}BH_4^-$ ions in the cell. Then a short, but intense, radio-frequency pulse at the cyclotron frequency of the ions was used (0.02–0.03 ms duration, 10 V peak to peak) to excite the ions translationally. The fragment ions were detected 50–100 ms after the CID pulse (i.e., the "CID interaction time", during which time ion fragmentation occurred as a result of collisions with the target gas molecules).

Materials

B_2H_6 was prepared by reaction of KBH_4 with H_3PO_4 (15).

B_2D_6 (~85% D_6) was prepared by reaction of $NaBD_4$ with D_3PO_4 (made from D_2O and P_2O_5) (15).

Maleic and phthalic anhydrides were commercially available. The ^{13}C labelled substrates were prepared by few-step synthetic sequences (16).

Results and discussion

As mentioned in the introduction, preliminary experiments have shown that maleic and phthalic anhydrides **1** and **2** can be reduced by BH_4^- in the gas phase. These substrates react with BH_4^- essentially via two channels, as can be concluded from the product ions given in Table 1.

The major process is reduction of the anhydrides, while BH_4^- addition followed by elimination of either CO_2 or HBO or (HBO + H_2) plays a minor role. Although not only one of the carbonyl functions but also the double bond may be reduced, it is especially the CO_2 loss following BH_4^- addition that has given the impetus to study a possibly regioselective reduction in the case of unsymmetrically substituted maleic anhydrides. For the latter, citraconic (methylmaleic) anhydride **3**, phenylmaleic anhydride **4**, and ethoxymaleic anhydride **5** have been chosen, partly because these molecules could be labelled with ^{13}C rather easily at the carbonyl function indicated with an asterisk (16), partly because they are amenable to *ab initio* calculations.

5

[3]The anhydride affinity of a neutral compound, HA(X), is defined as the enthalpy of dissociation of the corresponding anion HX^- to free hydride and the neutral compound X:

$$HX^- \xrightarrow{\Delta H} H^- + X$$

$$HA(X) = \Delta H = \Delta H_f(H^-) + \Delta H_f(X) - \Delta H_f(HX^-)$$

TABLE 1. Primary product ion distributions[a] for the reactions of BH_4^- with maleic and phthalic anhydrides **1** and **2**

Anhydride	$(M + H)^-$	$(M + BH_4 - CO_2)^-$	$(M + BH_4 - HBO)^-$	$(M + BH_4 - HBO/H_2)^-$
 **1**	65	9	11	15
 **2**	81	9	4	6

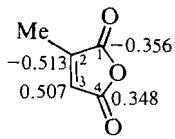
[a]The percentages were obtained after a reaction time of about 500 ms and correction for the secondary product ion formation (i.e., formation of the [primary product ion + BH_3]$^-$ ions) on the basis of double resonance experiments. Conversion into products was 50–80% and the error on the percentages is estimated to be around 15%.

Before presenting the results of the gas phase measurements and associated mechanistic interpretations, the relevant data from the *ab initio* calculations will be given.

Ab initio *calculations*

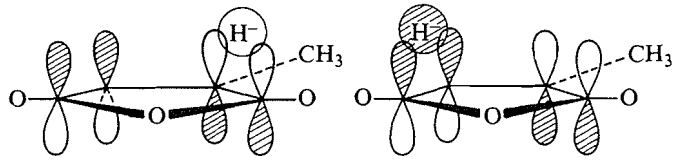
Citraconic anhydride

The *ab initio* calculations for citraconic anhydride show that the higher LUMO coefficient is located on the carbon of the carbonyl group neighbouring the substituent (9), see structure **6**. Hence, the citraconic anhydride – H^- supermolecule **7***a* is of lower energy than the isomeric complex **7***b* (10).



ϵ_{LUMO} = 0.16397 au

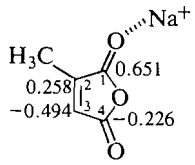
6



7*a* **7***b*

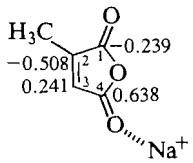
E = −7.5 kcal/mol E = 0 kcal/mol

Experimentally, the reductions of citraconic anhydride by a variety of metal hydrides in THF occur with a high regioselectivity at the carbonyl function next to the methyl substituent. The match between the forecast based on calculations and the experimental findings is only partially satisfactory. On the basis of "the best overlap" argument, the preferred hydride transfer should occur to the carbon atom with the LUMO coefficient of the highest absolute value; in citraconic anhydride it is C-2. The result of such a reaction would be the reduction of the double bond. For $NaBH_4$ reductions in solution, however, this is only a minor pathway, probably due to the interference of the Na^+ cation. The *ab initio* calculations for maleic anhydride – cation complexes show that the association of the cation with the oxygen atom of the carbonyl function modifies the LUMO coefficients, as shown in **8***a* and **8***b*.



8*a*

ϵ_{LUMO} = − 0.10372 au



8*b*

ϵ_{LUMO} = −0.09943 au

Thus, the influence of the cation not only facilitates hydride transfer (LUMO lowered: compare **6** vs. **8***a* or **8***b*), but also favours the reaction at the C atom of the CO group next to the substituent (compare ϵ_{LUMO} **8***a* < ϵ_{LUMO} **8***b*; and C1 coefficient **8***a* > C4 coefficient **8***b*). In the gas phase, in the absence of cation or protic solvent, BH_4^- encounters naked anhydride molecules whose LUMO orbital coefficients are shown in structure **6**. In terms of the best overlap, we should expect considerable H^- transfer to the double bond. If, however, H^- is transferred to the carbon of the carbonyl function, C-1 should be preferred over C-4.

Phenylmaleic anhydride

The phenyl substituent on a double bond extends conjugation, hence lowering the energy of the LUMO and causing polarization similar to that observed for acrolein and cyanomaleic anhydride (Fig. 1(b)).

It should be noted here that the reaction of phenylmaleic anhydride with $NaBH_4$ in THF solution results principally in the reduction of the double bond. The yield of lactonic products with the *untouched* double bond is low, 30% (17).

Ethoxymaleic anhydride

Ab initio calculations were carried out for methoxymaleic anhydride, which is an excellent model for ethoxymaleic anhydride. Here, as in other maleic anhydrides, the LUMO coefficients are higher on the carbon atoms of the double bond (the highest being on the substituent-bearing C-2, see Fig. 1). Of the two carbonyl functions C-1 has a higher LUMO coefficient than C-4. Here it should be noted that ethoxymaleic anhydride is reduced by $NaBH_4$ in THF solution entirely at the carbonyl group adjacent to the substituent,[4] similarly to the methoxymaleic anhydride (10).

The regiospecificity of methoxymaleic anhydride reductions

 **4**	90	—	—	—
 **5**	20	—	—	59

[a]See note *a*, Table 1.
[b]The percentages have been corrected for incomplete ^{13}C-labelling of the anhydrides (see experimental part).
[c]In small amounts m/z 98 ions are generated (~3% of the total product ion distribution), their exact origin being unknown.
[d]The origin of the $(M - C_2H_5)^-$ may be due to either a β-elimination reaction on the ethoxy group or an electron transfer reaction to the anhydride and loss of $C_2H_5^\cdot$ (the m/z 114 ions can easily be generated by electron impact on anhydride **5** with ~0.5 eV electrons and subsequent loss of $C_2H_5^\cdot$).

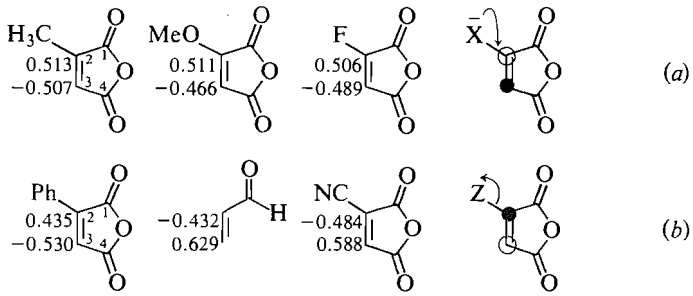

FIG. 1. (a) LUMO coefficients on the double bond for a series of maleic anhydrides bearing an electron-releasing substituent. (b) LUMO coefficients for a series of compounds with a conjugated double bond, including cyanomaleic anhydride. Here, the absolute values of the two LUMO coefficients are reversed compared to the (a) series.

in solution has been interpreted in terms of the important chelating effect by the reagent (19) or counterion (9) reinforced by various electronic effects (8).

Gas phase ion/molecule reactions

Citraconic anhydride

The primary product ions generated by reaction of BH_4^- with the ^{13}C-labelled citraconic anhydride **3** and also with the ^{13}C-labelled phenylmaleic and ethoxymaleic anhydrides **4** and **5**, which will be discussed below, have been summarized in Table 2.

As can be seen in this table, there is a minor $(M - H)^-$ formation, which is probably due to proton abstraction from the methyl group. Two other products, for which no mechanisms are given, result from the addition of BH_4^- and subsequent elimination of HBO and (HBO + H_2). The most relevant, however, to the problem of regioselectivity of BH_4^- attack on the anhydride is the observation that following BH_4^- addition $^{13}CO_2$ and CO_2 are lost in the ratio of 16:9. It is significant to note that in the corresponding product ions BH_4^- is retained, in contrast with the most abundant $(M + H)^-$ ion formation. This points, in our opinion, to a boron–oxygen bond formation, which is known to be very strong (>800 kJ/mol) (20). It seems therefore not unreasonable to suppose that the eliminations of $^{13}CO_2$ and CO_2 following BH_4^- addition are due to attack of BH_4^- upon the unlabelled and ^{13}C-labelled carbonyl groups, respectively, as visualized by reactions [3*a*] and [3*b*].

Although the structures of the final product ions of reactions [3*a*] and [3*b*] have not been proven experimentally, it has been demonstrated recently that vinylic anions can readily be generated as long-lived, stable species in the gas phase by CO_2 loss from carboxylate anions (21). It is gratifying to see that the preferential loss of $^{13}CO_2$ versus CO_2, i.e., a preferential attack of BH_4^- upon the carbonyl group neighbouring the substituent, is in line with the predictions made on the basis of the *ab initio* calculations (*vide supra*).[3]

Additional support for this interpretation is provided by collisionally induced dissociation (CID) experiments on the $(M + H)^-$ ions. Although the formation of these ions as such does not provide information on the site within the anhydride molecule to which the hydride ion has been transferred, the CID experiments show that the loss of $^{13}CO_2$ and CO_2 is in a 1:1 ratio (see Table 3), thus quite different from the 19:6 ratio following BH_4^- addition.

It seems likely, therefore, that in the long-lived $(M + H)^-$ ions, the double bond rather than one of the carbonyl groups has been reduced by BH_4^-, albeit without noticeable preference for H^- addition to one or the other carbon atom of the double bond (reactions [4*a*] and [4*b*]). This is further corroborated by the observation that the $(M + BH_4^-)$ ions, generated via reaction of

reactions of BH_4^- with the ^{13}C-labelled anhydrides **3**, **4**, and **5**

$(M + BH_4 - C_2H_4O/*CO_2)^-$	$(M + BH_4 - HBO)^-$	$(M + BH_4 - HBO/H_2)^-$	$(M - H)^-$	$(M - C_2H_5)^-$

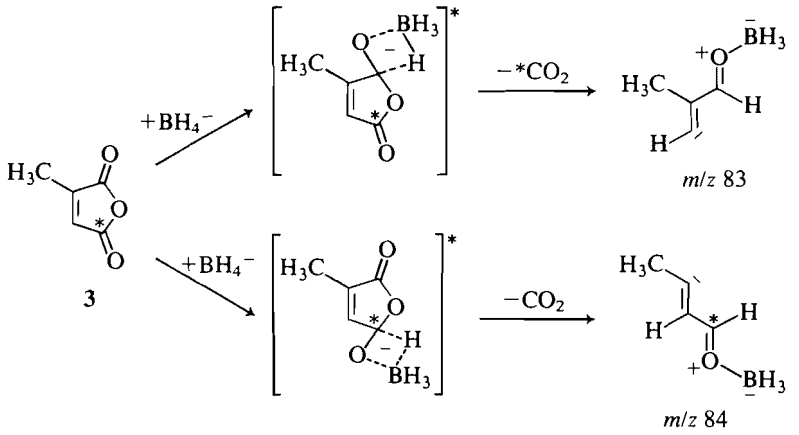
[3a] [3b]



[4a] [4b]

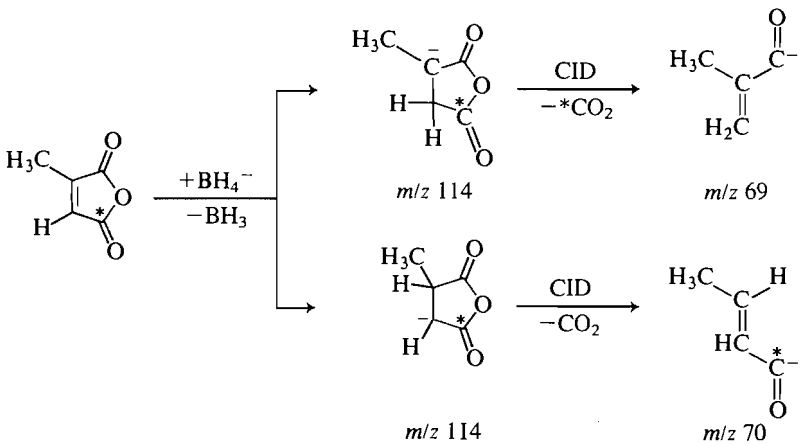


TABLE 3. Percentages of collisionally induced losses of $^{13}CO_2$, CO_2, and BH_3 from the $(M + H)^-$ and $(M + BH_4)^-$ ions of ^{13}C-labelled citraconic anhydride **3**

Ion	$^{13}CO_2$ loss (%)	CO_2 loss (%)	BH_3 loss (%)
 **3**	50	50	—
 **3**	30	30	40

the $(M + H)^-$ ions with B_2H_6 according to eq. [5], eliminate upon CID $^{13}CO_2$ and CO_2 in a 1:1 ratio as well (see Table 3).

[5] $(M + H)^- + B_2H_6 \rightarrow (M + BH_4)^- + BH_3$

These eliminations can be visualized in the same way as suggested for the $(M + H)^-$ ions in reactions [4*a*] and [4*b*] with the modification that in the $(M + H)^-$ ions a BH_3 molecule is bonded to the oxygen atom of the carbonyl group that eventually is retained in the product ion.

In summary, the carbonyl group reduction of citraconic anhydride by BH_4^- seems to take place predominantly in a regioselectively controlled manner, but such selectivity is not observed for the BH_4^- reduction of the olefinic bond.

Phenylmaleic anhydride

Reaction of BH_4^- with phenylmaleic anhydride **4** yields a very abundant $(M + H)^-$ ion, but loss of carbon dioxide following BH_4^- addition as in the case of citraconic anhydride is not observed here (see the data in Table 2).

CID experiments on the $(M + H)^-$ ions of **4** show specific losses of $^{13}CO_2$ and $^{13}CO_2/CO$ occurring in a ratio of about 2:1. These observations seem to indicate that neither of the carbonyl groups has been reduced by BH_4^-. It is then logical to suppose that the hydride ion has been transferred to one of the carbon atoms of the olefinic bond, which should be C-3 according to the *ab initio* calculations (*vide supra*). However, such $(M + H)^-$ ions are expected to eliminate $^{12}CO_2$ and $^{12}CO_2/^{13}CO$ upon CID, as visualized by reaction [6], which is just opposite to the observations made.

Another possibility is that the hydride ion is transferred to C-2, which could explain the observed $^{13}CO_2$ and $^{13}CO_2/CO$ losses from the corresponding $(M + H)^-$ ion upon CID via routes similar to those given in reaction [6]. However, it is important to note that the $(M + H)^-$ ions of phenylmaleic anhydride react only slightly with B_2H_6 to give $(M + BH_4^-)$ ions, in contrast with the $(M + H)^-$ ions of citraconic anhydride, which do react to a large extent in this way (*vide supra*, reaction [5]). Such observation casts doubts on the importance of hydride ion transfer to either of the carbon atoms of the olefinic bond, as such transfer would enable the localization of the negative charge at the carbonyl oxygen atoms and thus promote the formation of an O—BH_3 bond during collision with B_2H_6.

[6] 
The last possibility for $(M + H)^-$ ion formation is that the hydride ion is transferred to the phenyl ring, which at first glance might seem peculiar but which permits delocalization of the negative charge over a large part of the ion, which contributes to stabilization of charged species in the gas phase. Assuming that the hydride ion is attached to the *para* position of the phenyl ring, reaction [7] can then account very well for the observed specific losses of $^{13}CO_2$ and $^{13}CO_2/CO$.

[7] 
Support for such a route is provided by the observed exclusive losses of $^{12}CO_2$ and $^{12}CO_2/^{13}CO$ from the $(M - H)^-$ ions of citraconic anhydride **3** upon CID as summarized in reaction [8].

[8] 
Finally, the reactions of methoxide and ethoxide ions with 2-phenylmaleic anhydride **4** should be mentioned. These ions both transfer a hydride ion (22) to generate $(M + H)^-$ ions, which upon CID show specific losses of $^{13}CO_2$ and $^{13}CO_2/CO$ and react via an addition–elimination channel where again specifically $^{13}CO_2$ and $^{13}CO_2/CO$ are lost from the corresponding collision complexes. Even the long-lived adduct between methoxide and 2-phenylmaleic anhydride **4**, generated by

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/07/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/07/12
For personal use only.

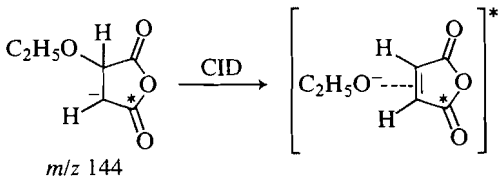
reaction with methanol-solvated methoxide ion, shows specific losses of $^{13}CO_2$ and $^{13}CO_2/CO$ upon CID. The addition of a nucleophile to the phenyl ring, as suggested above for the hydride transfer reaction from BH_4^-, seems therefore to be rather general.

Ethoxymaleic anhydride

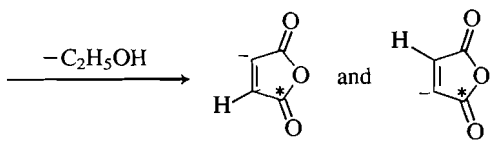
One of the major primary product ions that is formed upon reaction between BH_4^- and 2-ethoxymaleic anhydride **5** is the $(M + H)^-$ ion, as shown by the data in Table 2. CID experiments on this ion show losses of C_2H_5OH (~90%), C_2H_4/H_2 (~5%), and a neutral molecule of 44 daltons (~5%), which could be CO_2 and (or) C_2H_4O. The latter are both feasible in view of the fact that CID experiments on the corresponding $(M + H)^-$ ions of 2-methoxymaleic anhydride have shown both CO_2 and CH_2O loss together with CH_3OH and CH_4 loss in a ratio of 6:6:78:10, respectively.

The abundant loss of ethanol from the $(M + H)^-$ ion of **5** upon CID, which for the $(M + D)^-$ ions generated by reaction with BD_4^- becomes 65% C_2H_5OD loss and 35% C_2H_5OH loss, has been visualized by reaction [9] and is a strong argument for

[9]



m/z 144



m/z 98

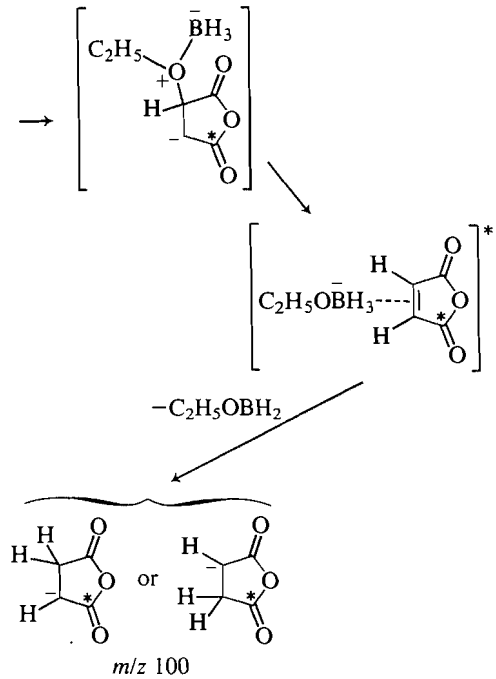
hydride ion transfer to C-2. This is in agreement with the results of *ab initio* calculations, which have indicated that C-2 has indeed the highest LUMO coefficient (*vide supra*).

The most abundant primary ion formed from reaction of BH_4^- with **5** (see Table 2) formally corresponds to elimination of $C_2H_5OBH_2$ from the collision complex, according to accurate mass measurements. In principle, this ion could also arise from the $(M + BH_4)^-$ collision complex by loss of C_2H_4O and BH_3, but this possibility is not likely because of the formation of $(M + BD_4 - C_2H_5D_2BO)^-$ ions in a much larger abundance than $(M + BD_4 - C_2H_4D_3BO)^-$ ions (~95:5%) when BD_4^- is used instead of BH_4^-. This indicates that mainly two deuterium atoms from BD_4^- are transferred to the anhydride. A possible route to explain the $(M + BH_4 - C_2H_5OBH_2)^-$ product formation might be that during the hydride transfer to C-2, BH_3 becomes bonded to the ether oxygen atom and that the energy released upon the boron–oxygen bond formation (bond strength > 800 kJ/mol; ref. 20) assists in the generation of an intermediate $C_2H_5OBH_3^-$/maleic anhydride complex. A subsequent hydride ion transfer in this complex would then result eventually in the formation of the most abundant primary $(M + BH_4 - C_2H_5OBH_2)^-$ ion (reaction [10]).

At any rate the elimination of $C_2H_5OBH_2$ from the collision complex points to hydride ion transfer to C-2, which is in line with the highest LUMO coefficient at that position.

Finally, a low abundant primary ion with *m/z* 69, which shifts to *m/z* 73 when BD_4^- is used, corresponds to expulsion of C_2H_4O and $^{13}CO_2$ from the BH_4^-/**5** collision complex

[10] $BH_4^- + \mathbf{5} \rightarrow$ *m/z* 15



m/z 100

(see Table 2). The observation that boron is retained in the product ion and that $^{13}CO_2$, but not $^{12}CO_2$, is lost, points to boron–oxygen bond formation at the C-1 carbonyl group. Irrespective of the details of the expulsion of C_2H_4O and $^{13}CO_2$ from the BH_4^-/**5** collision complex, the attack upon the C-1 rather than the C-4 carbonyl group is again in agreement with the *ab initio* calculations, which have indicated that C-1 has a higher LUMO coefficient than C-4 (*vide supra*).

Conclusions

Most of the gas phase hydride-ion transfer reactions from BH_4^- to the unsymmetrically substituted maleic anhydrides studied appear to proceed under orbital control. That is, the hydride ion is transferred predominantly to those carbon atoms of the anhydride that on the basis of the *ab initio* calculations have the higher LUMO coefficients. In other words, the regioselectivity of these reactions appears to be under orbital rather than charge control. In view of that we may conclude that the lifetimes of the corresponding collision complexes are relatively long, which has been shown to be the case in many other gas phase reactions (18, 23).

A reinvestigation of the interaction between triplet states of cyclohexenones and amines[1]

D. WEIR, J. C. SCAIANO, and D. I. SCHUSTER. Can. J. Chem. **66**, 2595 (1988).

Laser flash photolysis studies lead to the conclusion that the short-lived triplet states of cyclohexenones are readily quenched by amines. For example, in the case of 2-cyclohexen-1-one (**I**) its triplet state (τ_T = 40 ns in acetonitrile) is quenched by triethylamine with a rate constant of (9.0 ± 0.8) × 10^7 M^{-1} s^{-1}. Cyclohexenone triplets are also quenched efficiently by DABCO and by triphenylamine leading to the formation of the corresponding amine radical cations. The new evidence reported rules out the involvement of long-lived detectable exciplexes.

D. WEIR, J. C. SCAIANO et D. I. SCHUSTER. Can. J. Chem. **66**, 2595 (1988).

Sur la base d'études de photolyse éclair au laser, on peut conclure que les états triplets de courtes vies des cyclohexènones sont facilement piégés par les amines. Par exemple, dans le cas de la cyclohexène-2 one-1 (**1**), sont état triplet (τ_T = 40 ns, dans l'acétonitrile) est piégé par la triéthylamine avec une constante de vitesse de (9,0 ± 0,8) × 10^7 M^{-1} s^{-1}. Les triplets des cyclohexènones sont aussi piégés d'une façon efficace par le DABCO ainsi que la triphénylamine; dans chacun des cas, il y a formation des radicaux cations des amines correspondantes. Les données obtenues éliminent la possibilité d'intervention d'exciplex à longues vies qui seraient détectables.

[Traduit par la revue]

Introduction

Triplet excited states of ketones are known to be quenched directly by amines, as demonstrated by nanosecond flash techniques as well as steady state studies (for a review, see ref. 1). Cohen and Peters and their co-workers have studied this process with benzophenone and related ketones, and have demonstrated convincingly that the quenching process involves electron transfer to give initially amine radical cations and ketone radical anions (2). Schuster and Brisimitzakis demonstrated that reactive 2,5-cyclohexadienone triplets are quenched by amines of appropriate ionization potential to give a set of products not observed in the absence of amines. In all cases, the amine interacts directly with ketone triplet (3).

Reactions of photoexcited α,β-unsaturated carbonyl compounds with amines are known to give 1:1 adducts, presumably via the enone triplet states (4). Dunn *et al.* have reported results of nanosecond flash studies on excitation of cyclohexanone **I** and analogues such as **II** (see Chart I) in the presence of 1,4-diazabicyclo[2.2.2]octane (DABCO) which demonstrate that long-lived DABCO radical cations (λ_{max} 450 nm) are formed from an intermediate which has the same lifetime (ca. 25 ns) as the transient species (λ_{max} 280 nm) generated on laser excitation of the enone in the absence of amines (5). This transient has been suggested by Bonneau (6) and by Schuster *et al.* (7) to be a highly twisted triplet excited state of these cyclohexenones. In the presence of even small amounts of DABCO, long-lived absorption is observed which interferes with analysis of the fast component of the decay curve at wavelengths in the range 270–300 nm; at the DABCO concentrations required for observation of the growth of the radical cation at 450 nm, the fast decay at 280 nm cannot be monitored (5, 8).

In contrast to the above findings, Pienta and McKimmey reported results of product analyses from excitation of **I** in the presence of triethylamine as a function of enone and amine concentrations which they interpreted in terms of a mechanism in which triplets of **I** do not interact directly with amines but rather react with ground state enone to give a dimeric species (excimer?) which is the species intercepted by triethylamine (9). Pienta later reported that on laser flash excitation of **I** in acetonitrile at 355 nm in the presence of triethylamine, the lifetime of the transient decay observed at 280 nm increases with increasing amine concentration (10). This was interpreted in terms of reversible formation of a long-lived enone–amine exciplex, which also absorbs at 280 nm, from the twisted π,π* state of the enone (the short-lived transient observed in the absence of amines). Equilibrium constants for formation of the triplet enone–amine exciplexes were calculated for **I** as well as for **II** and several other methylated analogs of **I** from the decays measured as a function of amine concentration (10). It was noted that components with microsecond rates become measureable at even the lowest concentrations of amines used in this study (36 m*M*); attempts to fit these slow decays to second order kinetics were unsuccessful. As in our later studies using DABCO (5, 8), the slow components increase with amine

concentration at the expense of the fast decays and eventually the latter are obliterated. Mechanistically, these data were interpreted (in light of the product studies) to mean that the monomeric enone triplet interacts with amines to give a detectable exciplex which does *not* result in formation of products, in competition with formation of a dimeric enone triplet from which enone dimers as well as enone–amine adducts are derived (10).

Pienta's conclusions conflict with previous studies of interactions between amines and photoexcited ketones (1–5), as well as nanosecond flash data on **I**, **II**, and related compounds (5–8). Furthermore, we have observed that triethylamine, DABCO, and other amines quench the unimolecular photorearrangement of **II** and other cyclohexenones, as well as photocycloaddition to alkenes, with efficiencies (given by the Stern–Volmer slopes $k_q\tau_T$, where k_q is the bimolecular quenching rate constant and τ_T is the lifetime of the enone triplet) that depend inversely on the ionization potential of the amine (7, 8). Adducts of enone **II** and triethylamine were also formed under these conditions. In the case of **II** and DABCO, enone–amine adducts are not formed, but there is good agreement between the flash and steady-state quenching data (8). These results are readily rationalized by a mechanism involving electron transfer from the amines to the chemically reactive monomeric enone triplets.

As part of a detailed study of transient phenomena in cyclohexenone photochemistry, we have reexamined the interaction between triethylamine and other amines with the "280 nm transient" derived from **II** and other enones. This study was also prompted by examination of the decay curves from the earlier study (10) which were generously provided by Professor Pienta; we believe the conclusion from this study should be revised. Indeed, as detailed below, we now find that the fast decay rates measured at 280 nm on laser flash excitation of **II** and other enones at 337 nm are accelerated by low concentrations of triethylamine, and we find no evidence to support the prior claim for equilibration of these enone triplets with an enone–amine exciplex.

Experimental

Laser flash photolysis experiments were performed using the pulses from a Molectron UV-24 nitrogen laser (337.1 nm, ~8 ns, ≤10 mJ/pulse) for excitation. The monitoring system includes an arrangement of monochromator and photomultiplier, a Tektronix R7912 transient digitizer and a PDP11/23 computer which controls the acquisition, processing and display of the data. Other details on the system have been reported elsewhere (11). Samples of **I** and **II** were obtained from Aldrich and vacuum distilled before use. Triethylamine was refluxed over NaOH then fractionally distilled. DABCO (Aldrich) was recrystallized twice from ethanol before use.

The solvents acetonitrile, methanol, heptane, and cyclohexane were Aldrich Gold label and were used as received. The sources and purification of **III**, **IV**, and **V** were the same as in earlier work (7, 8).

Results

I. Quenching of enone triplets

A. Triethylamine

The quenching of the triplet of **I** with triethylamine (TEA) was carried out under conditions as identical as possible to those of Pienta (10). The solvent, concentration of **I** and concentration range of TEA additions were duplicated. Laser excitation wavelengths were slightly different (355 nm in Pienta's study, 337 nm in this study) but both wavelengths are encompassed in the same broad absorption band of **I**. Our measurements always include an emission correction. This correction is simply the subtraction of the signal recorded by the detector when the laser is incident on the sample with the analysing beam blocked. This correction takes into account a variety of emissive sources within the system, such as fluorescence, delayed fluorescence, scattered laser light, Raman emission, and monophotonic or multiphotonic emissions from optical components.

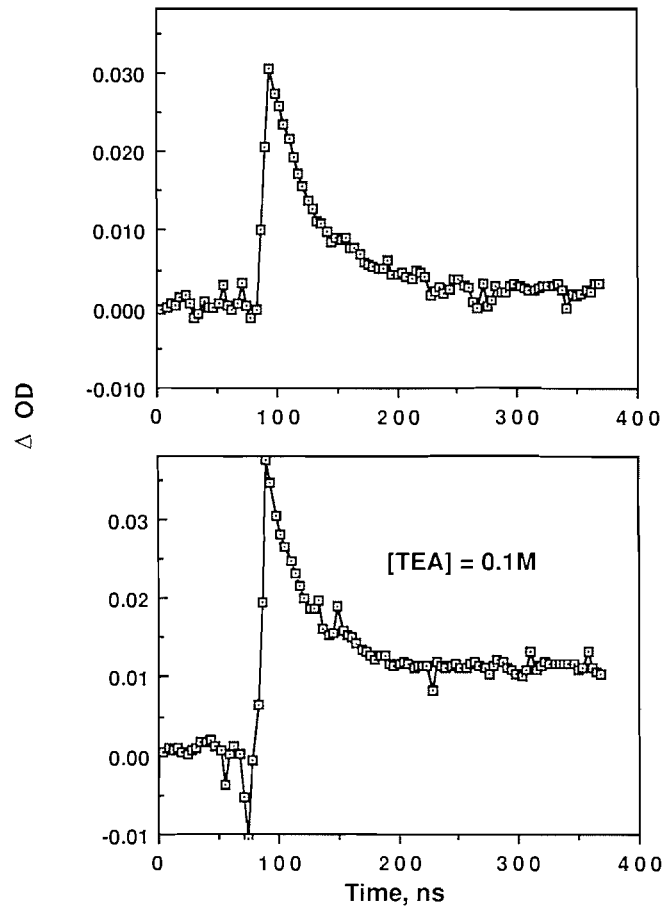

FIG. 1. Transient decay traces monitored at 280 nm following laser excitation of **I** in acetonitrile in the absence (top) and presence of 0.1 *M* triethylamine.

In the absence of quencher **I** gives a transient decay at 280 nm after 337 nm laser excitation, with lifetimes of 40, 28, and 27 ns in acetonitrile, cyclohexane, and methanol, respectively. These values agree well with those in the literature (7, 10), and specifically with the 36.7 ns lifetime in acetonitrile given by Pienta (10). The small difference between the two reported values is within the experimental error. It should be noted that both these values are significantly longer than a previous value of 24 ns estimated from the Stern–Volmer analysis of the kinetics for the growth of naphthalene triplet absorption at 413 nm upon quenching of triplet **I** (5).

We have also observed a long-lived residual signal of intensity 5–10% of the initial transient absorbance. This long-lived species is most likely a triplet-derived product (*vide infra*). The addition of triethylamine has two effects on the transient kinetic traces. The first is a definite shortening of the triplet lifetime. The second is an increase in the signal size (and thus concentration) of the long-lived species. Figure 1 shows two kinetic decay traces; the top trace with no TEA present and the bottom one with 0.1 *M* TEA. The quenching follows pseudo first order kinetics and can be represented by eq. [1].

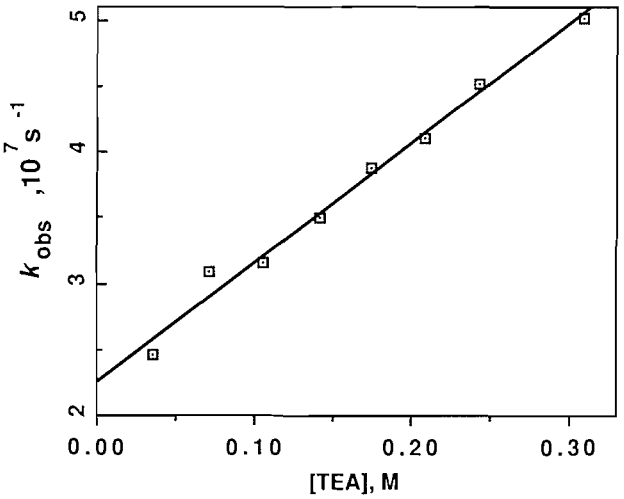

FIG. 2. Quenching of triplet **I** by triethylamine in acetonitrile, according to eq. [1].

TABLE 1. Triethylamine quenching of cyclohexenone triplets

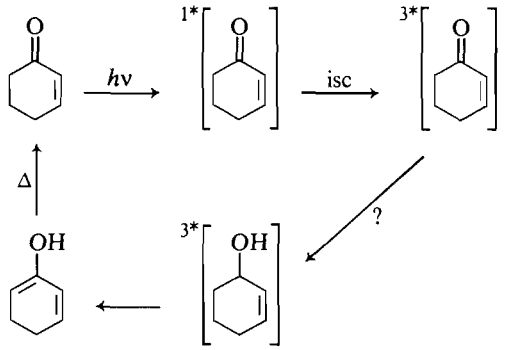
Compound	Solvent	k_q (M^{-1} s^{-1})
I	Acetonitrile	$(9.0 \pm 0.8) \times 10^7$
	Cyclohexane	$(9.2 \pm 4.6) \times 10^7$
II	Methanol	$(1.1 \pm 0.4) \times 10^8$
	Acetonitrile	$(3.7 \pm 0.5) \times 10^7$
III	Cyclohexane	$(1.3 \pm 0.5) \times 10^8$
IV	Acetonitrile	$(2.0 \pm 0.6) \times 10^6$

[1] $k_{obs} = k_0 + k_q[TEA]$

The rate constants k_{obs}, k_0, and k_q correspond to the observed triplet decay, the decay in the absence of quencher (i.e. τ^{-1}) and the second order quenching constant, respectively. Equation [1] leads to a linear quenching plot (Fig. 2) from which we obtain $k_q = (9.0 \pm 0.8) \times 10^7\ M^{-1}\ s^{-1}$ (errors as $\pm 2\sigma$ throughout). A similar value was obtained in cyclohexane (see Table 1). The long-lived species does not decay in the time scale of these experiments and a straightforward offset of the data is sufficient to adequately analyze the kinetics.

Triethylamine quenching of some other enones was also examined. The triplet of **II** gave lifetimes of 40 ns and 28 ns in methanol and cyclohexane. The T–T absorption spectrum shows a maximum at 275–280 nm. **II** showed a much smaller residual absorbance than **I**, which increases upon addition of triethylamine. The triplet of **II** is quenched by TEA with $k_q = (1.1 \pm 0.4) \times 10^8\ M^{-1}\ s^{-1}$ in methanol. A slower quenching was observed in acetonitrile (Table 1).

One possibility that has not been previously tested is that the short-lived transients observed in these experiments are not due to the lowest triplet state of these enones but rather to short-lived triplet enols which are produced by a route such as that shown in Scheme 1 for cyclohexenone. To explore this possibility we examined compound **III** in which methyl groups block the 6-position, thus cutting off the possibility of photoenolization. When **III** is excited with a 337 nm laser pulse a species with $\lambda_{max} \sim 275$ nm with a lifetime of 34 ns in acetonitrile is observed. The presence of this transient shows that the species observed in the laser flash photolysis of **I**–**III** are all of the same



SCHEME 1

origin and must be assigned to the ketone triplet states and not the enols. The TEA quenching of **III** was also interesting in that, although it gave a quenching rate similar to **I** and **II**, it did not, even at the highest amine concentrations, give any significant residual absorbance.

B. Quenching with other amines

In a previous study the effect of adding 1,4-diazabicyclo-[2.2.2]octane (DABCO) to quench the triplet of **I** and **II** was examined and the resulting quenching rate constants in acetonitrile (derived from kinetics of appearance of DABCO radical cations) were $3.7 \times 10^8\ M^{-1}\ s^{-1}$ and $2.7 \times 10^8\ M^{-1}\ s^{-1}$, respectively (5). We have examined the direct quenching of triplet **IV** by DABCO, and obtained $k_q = (7.7 \pm 0.9) \times 10^7\ M^{-1}\ s^{-1}$ in acetonitrile. All DABCO quenching rates are significantly higher than the corresponding TEA values, which is reasonable given the lower oxidation potential of DABCO vs. TEA. Using the lifetime of **II** in ACN of 40 ns and the DABCO quenching rate of $2.7 \times 10^8\ M^{-1}\ s^{-1}$ one obtains $k_q\tau_T = 10.8\ M^{-1}$. This value is in very good agreement with a product study of DABCO quenching of the photocycloaddition of **II** to tetramethylethylene (TME) which gave a Stern–Volmer slope of $11.6\ M^{-1}$ (12). It should be noted that the triplet lifetime of **II** is not affected by TME (13), so these data can be compared.

The triplet of **V** was quenched with diphenylamine. The quenching could not be followed at 280 nm but the growth of the diphenylaminyl radical cation could be observed. The spectrum, with a maximum at 680 nm in the visible region is in good agreement with literature values (14–16). The quenching plot with a representative trace showing diphenylaminyl radical cation growth kinetics is shown in Fig. 3. The resulting quenching rate constant was $3.9 \times 10^9\ M^{-1}\ s^{-1}$.

II. Residual transient absorbance experiments

With the amine quenching of the triplets of these enones now well established, we also wished to identify the long-lived species which are observed in these experiments. The most important question is whether this species is a direct product of the triplet or whether it is created by a separate reaction pathway, possibly via the singlet manifold or by reactions of products built up during the laser experiment. To this end a Stern–Volmer analysis of the triethylamine quenching data of **I**, **II**, and **IV** was made according to eq. [2].

$$[2] \quad \frac{1}{\Delta OD_{obs}} = \chi + \frac{\chi k_0}{k_q[TEA]}$$

In this treatment ΔOD_{obs} is the concentration of the long-lived species as measured by its transient absorbance after the triplet signal has fully decayed, χ is an experimental parameter which includes a measure of the efficiency of the reaction, k_0 is the

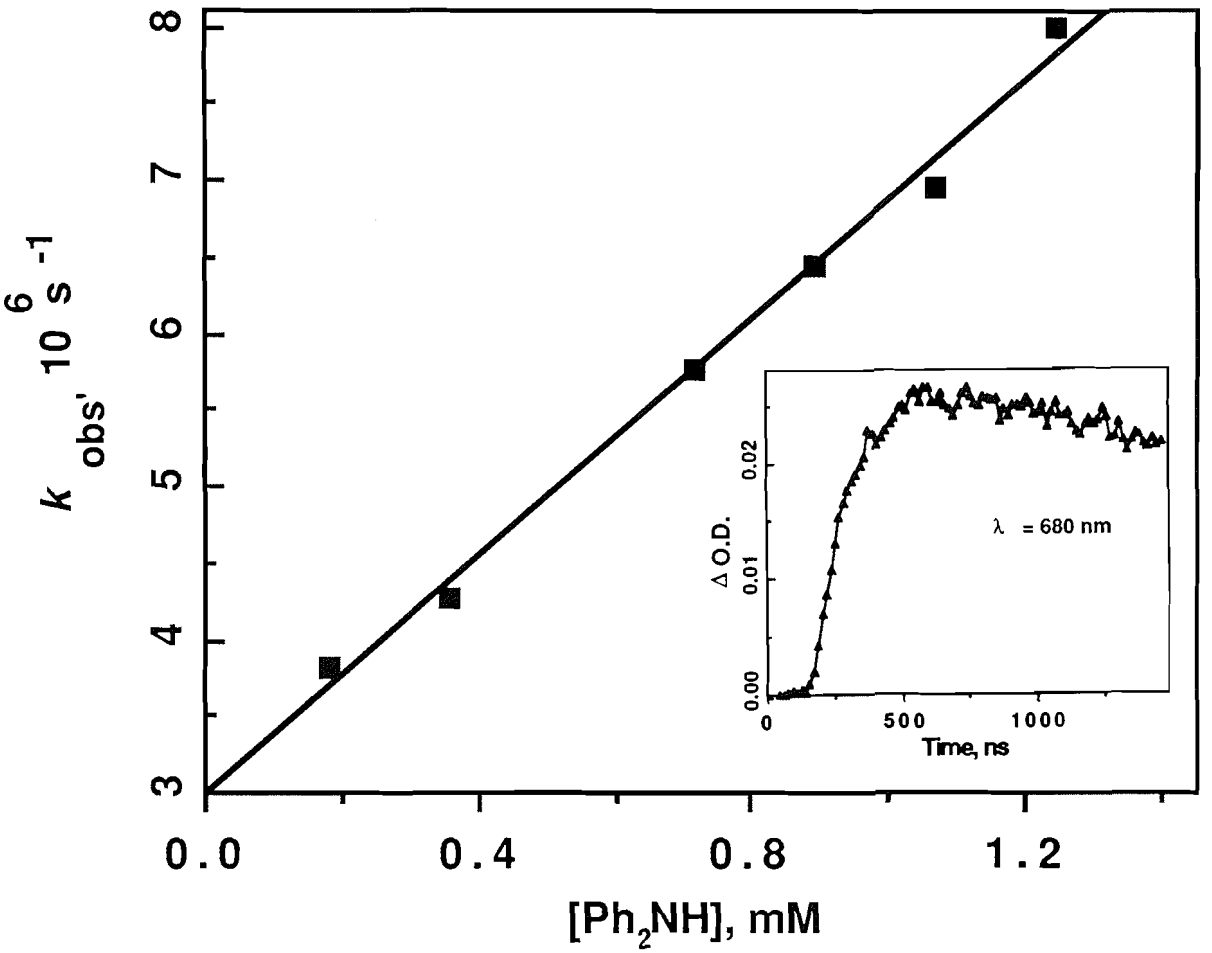

FIG. 3. Quenching of triplet **V** by diphenylamine in methanol, according to eq. [1]. *Insert*: Build-up of the diphenylamine radical cation obtained by reaction of triplet **V** with the amine present in 7.14×10^{-4} *M* concentration.

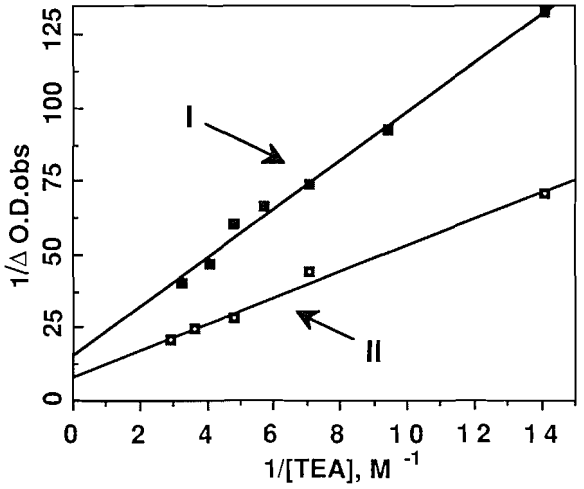

FIG. 4. Double reciprocal plots according to eq. [2] for the quenching of triplet **I** and **II** by triethylamine.

triplet decay rate in the absence of quencher, and k_q is the amine quenching rate constant. A plot of $(\Delta OD_{obs})^{-1}$ vs. $([TEA])^{-1}$ should be linear if the transient product is produced from only one state which is quenched by the amine. The intercept/slope ratio gives the Stern–Volmer constant, $k_q\tau_T$.

The plots for **I** and **II** according to eq. [2] are shown in Fig. 4. The values of $k_q\tau_T$ for the formation of the long-lived species in acetonitrile are 1.9, 1.8, and 0.13 M^{-1} for **I**, **II**, and **IV** (not shown), respectively. These values can be compared with independent values of k_q and τ_T also obtained in this study (*vide supra*) which give $k_q\tau_T$ values of 4.0 ± 0.6 for **I**, 1.2 ± 0.2 for **II** and 0.27 ± 0.05 M^{-1} for **IV**. Given the inherent error in trying to measure the residual OD in these experiments (especially at lower amine concentrations), as well as the large error in extrapolation to the intercept in plots of this type, the agreement within a factor of two is satisfactory and suggests that the long-lived species is a direct product of the triplet state. No Stern–Volmer plot could be produced for **III** since no residual ΔOD was observed upon amine addition.

Finally, the effect of solvent on the residual absorption of **V** was studied. The residual ΔOD was found to be present in both *n*-heptane or acetonitrile in the absence of amine. In protic solvents such as methanol or ethanol, however, little or no residual ΔOD was observed. If we assume that the extinction coefficients of these transient species are unlikely to change dramatically in going from acetonitrile to methanol, the likely explanation is that either the lifetime or the yield of this species is drastically reduced in protic solvents.

Discussion

Our results with compounds **I**–**III** clearly confirm that the short-lived transients observed at 270–280 nm upon laser

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/07/12
For personal use only.

excitation of cyclic enones are due to the triplets of these molecules. The similarity of the lifetime and quenching rates of **III**, which cannot form an enol, to the results with **I** and **II** shows that enols do not play a role at the triplet manifold level. This seems to be true also for **IV** and **V** since they show similar behavior.

Pienta (10) has suggested that these triplets form detectable exciplexes, with lifetimes longer than the triplet, upon the addition of triethylamine. He reported no amine quenching of the triplets of **I** and **II**. Our study, which closely duplicates the conditions of those experiments, shows this conclusion to be incorrect. The triplet states of **I–IV** are quenched by triethylamine at rates comparable to amine quenching of other carbonyl triplets. We cannot fully explain the reasons for Pienta's observation of lifetime lengthening upon amine addition; however, we found that we can closely reproduce his observations if we exclude the emission correction from our measurements. However, Professor Pienta has indicated that a similar correction was also employed in his experiments (17).

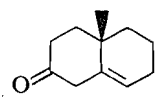
The quenching by amines is likely to involve an electron transfer mechanism. This is supported by the observation of DABCO radical cation when DABCO is used to quench the triplets of **I**, **II**, and **IV** (5), as well as by the fact that the amine quenching rates follow the trend of amine oxidation potentials. While the quenching of the triplet of **V** by TEA could not be followed, quenching by diphenylamine was measurable. Again, the results showed simple bimolecular amine quenching. All these results are consistent with previous product studies which examined the effect of TEA and DABCO addition on the rearrangement of **II** (7, 12). The agreement of the $k_q\tau_T$ values of those studies and the independently obtained values of this study further confirm that amines quench the triplet of **II**. Thus, only simple amine quenching occurs in these systems and there is no evidence for the formation of long-lived ketone–amine exciplexes.

It should be noted that our results do not rule out the possible involvement of an exciplex. They simply establish that if involved, it is not directly detectable by this technique. Kelly *et al.* (18) recently reported that self-quenching plays a role in the decay of triplet 3-phenylcyclopent-2-enone which has a triplet lifetime of 2.9 μs at room temperature. In the case of ketones **I–III** their triplet lifetimes are much shorter and as a result self-quenching is unlikely to be of importance.

The residual ΔOD observed for ketones **I**, **II**, **IV**, and **V** is proposed to be due to the corresponding enols. For isophorone (reaction [3]) the enol has been implicated as the intermediate

[3] 
in the observed deconjugation reaction in heptane (19), while enol formation has also been suggested to play a role in the photochemistry of **VI** (20, 21), i.e.

[4] 
VI



In the systems studied here the most efficient enol production would be via a hydrogen shift from the 6-position. In the case of **III** where the α-position is methyl substituted, no enol can be formed (22). This is consistent with the fact that no residual long-lived absorption was observed with **III** while it was with **I** and **II**. Upon the addition of amines this residual ΔOD increases. Since there is no evidence to suggest that different products are formed upon amine addition, and since the spectral and kinetic features are essentially the same whether TEA, DABCO, or diphenylamine is used as the quencher, it seems likely that the long-lived species observed in the amine quenching experiments is the same as that observed in the absence of amine. The effect of solvent on the residual ΔOD values also supports the assignment to the enol since in other systems some enols have reduced lifetimes in alcohols as opposed to alkanes or acetonitrile (10, 23).

Conclusion

Thus, our study demonstrates that there is nothing peculiar above the interaction of triplet states of cyclohexenones with amines, but rather that the dynamics of this interaction are similar to those observed with other carbonyl triplets (1–3). Mechanistic problems associated with Pienta's product analysis (9) remain to be resolved. Our results also illustrate the interpretative pitfalls that can arise in situations where complex decay kinetics are observed following flash excitation.

Acknowledgments

Thanks are due to Mr. S. E. Sugamori for technical assistance and to Professor N. J. Pienta for kindly providing some of the original traces obtained in his work. This work was supported in part by a grant (to D.I.S.) from the U.S. National Science Foundation (CHE-8320154).

Received March 29, 1988

PHOTIS DAIS, KEVIN R. HOLME, and ARTHUR S. PERLIN. Can. J. Chem. **66**, 2601 (1988).

The binding selectivities of univalent counterions for heparin in the systems $Ca^{2+}/M^+/HEP$, where $M^+ = Li^+$, Na^+, K^+, Cs^+, TMA^+, have been studied by ^{13}C nuclear magnetic resonance spectroscopy. Chemical shift displacements of the various ^{13}C nuclei of heparin in these systems clearly indicate that the binding selectivity of the polymer for univalent counterions increases with an increase in the radius of the hydrated cation form, namely $Li^+ > Na^+ > K^+ > Cs^+ > TMA^+$. An explanation for this binding preference is offered on the basis of electrostatic and entropic terms, whereby the latter is reflected in changes in the hydration volumes of the univalent cations. Differences in the magnitude of these hydration volumes, in relation to the free energies of hydration, may account for a binding selectivity that favours the more highly hydrated ions.

PHOTIS DAIS, KEVIN R. HOLME et ARTHUR S. PERLIN. Can. J. Chem. **66**, 2601 (1988).

Faisant appel à la résonance magnétique nucléaire du ^{13}C et opérant dans les systèmes $Ca^{2+}/M^+/HEP$ dans lesquels $M^+ = Li^+$, Na^+, K^+, Cs^+ et TMA^+, on a évalué les sélectivités de liaison de contre-ions univalents pour l'héparine. Les déplacements chimiques des divers noyaux ^{13}C de l'héparine dans ces systèmes indiquent clairement que la sélectivité de liaison du polymère pour les contre-ions univalents augmente avec une augmentation du rayon de la forme hydratée du cation, soit $Li^+ > Na^+ > K^+ > Ca^+ > TMA^+$. On offre une explication pour cette préférence de liaison; elle est basée sur des termes électrostatiques et entropiques et ce dernier est le reflet de changements dans les volumes d'hydratation des cations univalents. Les différences dans l'amplitude de ces volumes d'hydratation, par rapport aux énergies libres d'hydratation, pourraient expliquer une sélectivité de liaison qui favorise les ions les plus hydratés.

[Traduit par la revue]

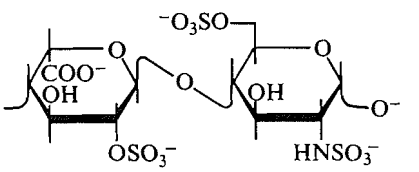
Introduction

^{13}C nuclear magnetic resonance spectroscopic studies on metal ion interactions with the biological polyelectrolyte heparin have been reported (1, 2) recently. The binding data for mixed counterion systems were correlated in a satisfactory manner with the two-variable theory of Manning (3, 4). A preliminary examination (2) of the binding selectivity of univalent counterions for heparin in the systems $Ca^{2+}/Na^+/HEP$ and $Ca^{2+}/K^+/HEP$ showed that Ca^{2+} binds to a greater extent in the presence of K^+ than of Na^+. This binding preference for Na^+ as compared with K^+, which is opposite to that observed in other experiments with heparin (5), invited clarification based on a systematic study using various alkali metal counterions.

In this report we present results obtained for the interaction of beef lung heparin with Ca^{2+} in the presence of a series of counterions covering a wide range of radii, namely, Li^+, Na^+, K^+, Cs^+, and also tetramethylammonium ion (TMA^+), all as chloride salts. The ^{13}C chemical shift displacements of the various carbons of heparin in these $Ca^{2+}/M^+/HEP$ systems show clearly that the binding selectivity of heparin for the univalent counterions increases as the radii of the cations in their hydrated forms increase.

Results and discussion

Table 1 summarizes the ^{13}C chemical shift displacements for all carbons of the main disaccharide unit (**1**) of heparin for the systems $Ca^{2+}/M^+/HEP$, where $M^+ = Li^+$, Na^+, K^+, Cs^+, TMA^+, at a total ionic strength of 0.4 M and constant ratio ($X = C_2/C_p = 1.0$) of Ca^{2+} ion (C_2) to heparin (C_p) concentration. In general, the chemical shift displacements for all carbons



1

in these systems, reflecting the extent of binding of Ca^{2+} to heparin in the presence of the univalent counterion M^+, increase in the order $TMA^+ > Cs^+ > K^+ > Na^+ > Li^+$. This trend corresponds to a stronger binding of heparin by Ca^{2+} in the presence of ions Li^+ through TMA^+, and indicates that the binding selectivity of heparin for these univalent counterions follows in the order of an increase in the size of the hydrated ion. The same trend as shown in Table 1 was observed for all chemical shift displacements obtained by varying the X-ratio from 0.0 to 1.0 at constant total ionic strength.

Manning's theoretical (6) and experimental (7) studies on species selectivity suggest that site-binding mechanisms play no role in the association between univalent counterions and polyelectrolytes, and that counterion selectivity may be attributed to the local dielectric constant of the medium surrounding the polyelectrolyte. This dielectric constant is equivalent, perhaps, to a 1 M aqueous ionic solution (the local concentration of territorially bound univalent counterions is estimated (3, 6) to be of the order of 1 M for polyanions of typical charge densities). Using the Born approximation, Manning calculated the contribution of the molar free energy of transfer of a counterion from the bulk dilute solution of dielectric constant $D_{H_2O} = 78.3$ to the local polyanion environment with dielectric constants (8)

[a]Negative values denote upfield shift.
[b]In D_2O at 70°C.
[c]At $X = C_2/C_p = 1$ and total ionic strength 0.4 M. C_2 is $[Ca^{2+}]$ and C_p is $[M^+/HEP]$.

$D_{Cs^+} = 70.6$ and $D_{Na^+} = 66.7$, corresponding to their respective 1 M ionic solution. His results indicated that the polyelectrolyte is more selective for the larger Cs^+ counterion than the smaller Na^+ (in terms of their *non*-hydrated radii), because the positive free energy of transfer to an environment of lower dielectric constant was less for the larger ion. Alternatively, it is possible to express this selectivity in terms of the size of their hydrated forms, because hydrated Na^+ is larger than hydrated Cs^+. Although the use of crystal radii in the Born equation (6) seems justified for ions in solution, there are other pitfalls (9) in employing the Born-type model: (*a*) The radius of an ion, or even an uncharged species, changes on transfer from the gas to the liquid phase, where it is subject to compressional forces. (*b*) The radius of the dissolved species depends on its surface charge density. Hence any model of solvation that uses a continuous charging process to evaluate the electrostatic energy must include a variable parameter for the ion size. (*c*) The radius depends on the degree of dielectric saturation induced by the ion in the solvent. (*d*) Realistic functions must be used to represent the dielectric constants in the vicinity of the ions, rather than of the bulk solution. (*e*) By considering the dielectric continuum model, structural effects on the electrical interactions of ions and solvent molecules are omitted.

In view of the very small changes in the free energies of hydration accompanying the binding of monovalent counterions to heparin, as suggested earlier (6, 10), the aforementioned factors questioning the validity of the simple Born approximation may play a decisive role in determining the correct order of binding selectivity.

Although this assessment of size selectivity is supported by a number of experiments (5, 7, 10–14), the converse order of specificity has been observed in others (15–18), as well as the present ones, i.e., increased binding with an increase in the hydrated radius ($Li^+ > Na^+ > K^+$). These diverse findings raise the possibility that, apart from free energy changes accompanying the transfer of an ion from the bulk solution to the surface of the polyanion, entropy effects accounting for the relative space in which territorial binding occurs also play an important role in determining binding selectivity.

Some qualitative predictions can be made, on the basis of Manning's selectivity rule (6). In his treatment of binding selectivity, Manning derived the following thermodynamic equation:

$$[1] \quad \alpha = \frac{\theta_2/X_2}{\theta_1/X_1} = \frac{V_2}{V_1} e^{-(\delta\mu_2^0 - \delta\mu_1^0)/RT}$$

where θ_1 and θ_2 are the fractions of ions 1 and 2, respectively, bound to the polyanions, X_1 and X_2 are the ratios of the concentrations of free counterions 1 and 2, respectively, to the total concentration ($C_t = C_i + C_p$, $i = 1, 2$) of the solution, V_1 and V_2 are the volumes in which counterions 1 and 2 are considered bound, and $\delta\mu_1^0$ and $\delta\mu_2^0$ have the meaning of free energy of transfer from the bulk solution to the environment near the polyanion. Moreover (4, 6),

$$[2] \quad \delta\mu_i^0 = \mu_{ib}^0 - \mu_{if}^0, \quad i = 1, 2$$

where μ_{ib}^0 and μ_{if}^0 represent the free energy of hydration of ion i in the bound and free state, respectively. This means that $\delta\mu_i^0$ primarily measures the change in hydration free energy as a counterion passes from the free to the bound state.

In eq. [1], when $\alpha > 1$, then counterion 2 binds the polyanion more selectively than counterion 1. The value of α depends both on the relative magnitudes of V_1 and V_2, and of $\delta\mu_1^0$ and $\delta\mu_2^0$. There are several choices for the parameters $V_i e^{-\delta\mu_i^0/RT}$, some of which have been discussed in ref. 6:

(*i*) $V_1 e^{-\delta\mu_1^0/RT} = V_2 e^{-\delta\mu_2^0/RT}$ leads to $\alpha = 1$, which is contrary to the experimental observations on selectivity.

(*ii*) $V \neq V_2$ and $e^{-\delta\mu_1^0/RT} = {}^{-\delta\mu_2^0/RT}$ leads to $\alpha \gtrless 1$, depending on the relative magnitudes of V_1 and V_2. Although variations in the condensed volumes, depending on the nature of the counterion, have been suggested by many authors (14, 19, 20), equality in the ΔG values for the bound and free ions seems improbable because, then, the determining factor is not the electrostatic interaction, as the polyelectrolyte theories imply, but an entropic change accompanying a change in ion hydration.

(*iii*) $V_1 = V_2$ and $e^{-\delta\mu_1^0/RT} \neq e^{-\delta\mu_2^0/RT}$, according to the "monolayer condensation" model by Iwasa (21). In this case, selectivity is purely electrostatic in nature and depends solely on the relative magnitude of the free energy terms in eq. [1].

(*iv*) $V_1 \neq V_2$ and $e^{-\delta\mu_1^0/RT} \neq e^{-\delta\mu_2^0/RT}$; then, selectivity must depend on the relative magnitude of differences between volumes and free energies of hydration. If there are minute changes in the free energies $\delta\mu_2^0 - \delta\mu_1^0$ in the range of −0.2 to −0.5 kcal (at 25°C), as suggested in the literature (6, 10), and assuming that the less hydrated ion 2 binds to heparin in preference to ion 1, then

$$[3] \quad \alpha = \frac{V_2}{V_1} \times (e^{+0.2/RT} \text{ to } e^{+0.5/RT}) = \frac{V_2}{V_1} \times (1.4 \text{ to } 2.3)$$

If $V_1 > V_2$ (1.4 to 2.3), then α becomes less than unity and a reversal of binding selectivity is to be expected, favoring the more hydrated ion 1.

In the monolayer condensation model represented by case (*iii*), the condensation volumes for both ions 1 and 2 are taken to be equal. This choice of a constant condensation volume, which is a general hypothesis in the counterion condensation model (3, 4), has been criticized by many authors (11, 14, 19, 20), as already mentioned. If one has to assume territorial binding in which the counterions bound to the polyanion retain their primary hydration sheath, then the condensation volume, which may be approximated by the volume of the hydrated ion, must be different for each cation, and decrease from Li^+ through

[d]Based on entropy measurements (ref. 22, p. 57).
[e]Based on transference numbers (ref. 31).

Cs^+. According to eq. [3] and the aforementioned inequality $V_1 > V_2$ (1.4–2.3), this may account for the binding selectivity observed.

A possible way to evaluate these considerations in a quantitative, although simplified manner, is to calculate the hydration volumes, $V_h(M^+)$, of the various cations studied. In principle, hydration volumes can be calculated through empirical equations, using the parameters of the hydration number (h) determined experimentally, and the effective volume (V_h) taken up by one water molecule in the primary hydration sheath. The latter quantity is indefinite, but it can be approximated (22) by the volume occupied by a water molecule in liquid water at 25°C, which is 30 Å^3. According to Robinson and Stokes (22), the volume of the hydrated cation is

$$[4] \quad V_h(M^+) = 30h + V^+$$

where V^+ is the apparent molal volume of the cation in Å^3. V^+ can be either estimated from the apparent molal volume of the salt, V_{app}, in solution by means of the equation (22)

$$[5] \quad V^+ = V_{app} - 6.47Z_1 \cdot r_-^3$$

where Z_1 is the cation valency and r_- the crystal radius of the anion (in Å), or it can be equated with the intrinsic volume (V_{in}), which can be identified with the actual volume occupied by the unhydrated cation in solution (23). The latter volume will be used in eq. [4], since it has been determined experimentally from the concentration dependence of the compressibility of the solution (24, 25).

The selection of the hydration number is quite uncertain, as there is a broad range of values in the literature (26, 27) for the hydration number of each cation, depending on methods and assumptions used. Nevertheless, a general pattern of hydration numbers, decreasing steadily from Li^+ to Cs^+, has been observed experimentally (26, 27). For our calculations, we have used the results of methods that determine strongly bound water molecules in the primary hydration sheath, and also those solvent molecules more distant but still under the attractive influence of the cation.

Table 2 summarizes the intrinsic volumes, the hydration numbers from various sources, and the calculated hydration volumes of cations Li^+ through Cs^+. The hydration volumes decrease steadily from the former to the latter, following the decreasing order of the number of the water molecules bound to the cations. Although these data are only an approximation and lack the degree of accuracy necessary for physical relevance, they clearly indicate that the hydration volumes (eq. [1]) influence the binding selectivity according to their relative magnitude, as well as the magnitude of the free energy change accompanying the transfer of counterions from the free to the bound state.

Of all the cations studied, TMA^+ ion binds the least strongly to heparin. This is in accord with earlier findings (2, 13, 15, 32), in which tetraalkylammonium ions showed a much smaller affinity for polyelectrolytes than do metal ions. TMA^+ is considered to be unhydrated or sparingly so, as are other tetraalkylammonium salts (ref. 23, pp. 77–83; ref. 26, Chaps. 2, 3, 4), although its unhydrated form has a relatively large molecular volume (95.9 Å^3) (33). Presumably, the energetic factors in eq. [1] must be large enough to compensate for entropy changes in the binding process. Although the inclusion of entropic effects on binding selectivity in terms of hydration volumes appears to be valid, the absolute magnitude of these volumes requires an accurate determination of the hydration numbers of the ions in solution. Due to the wide disparity among literature values (23, 26, 27), the present results may serve more as a reflection of the trend in counterion binding selectivity than as a definitive statement.

Other factors to be considered in interpreting binding data are the nature of the functional groups of the polyanion, and the degree of uniformity in their distribution. Structural differences among polymers represent variations in the local environments of the functional groups and, hence, in their standard free energies, which may lead to differences in binding selectivity. This is clearly a possibility with heparin, because specimens of this polymer may differ widely in structure, depending on their origin and method of isolation. Although, usually, the major type of repeating sequence consists of (1→4) linked residues of α-L-iduronic acid 2-sulfate and 2-deoxy-2-sulfamino-α-D-glucose 6-sulfate (**1**), such constituents as β-D-glucuronic acid and 2-acetamido-2-deoxy-α-D-glucose are relatively more prominent in heparin from hog mucosa than from beef lung (34). The latter type has been used in our studies on counterion binding, by choice, because of its higher degree of structural homogeneity with respect to disaccharide unit **1**. As heparin of the hog mucosal type is much more readily available commercially, it is likely to have been used in some of the other studies on counterion binding. This may help to account for some disagreement on ion selectivity in the literature, such as between Na^+ and K^+, for which differences in binding affinities are relatively small. To facilitate quantitative studies on binding, a synthetic polyelectrolyte having carboxyl and sulfate groups distributed uniformly in a known pattern should serve as a useful model.

Experimental

Sodium heparin, isolated from beef lung, was supplied by Upjohn

Co. of Canada. Purified by dialysis against distilled water, the heparin gave an equivalent weight of 178, and a sulfate to carboxylate ratio of 2.4 (1). To prepare the required univalent salts of heparin, a 2.5% w/v solution of sodium heparin was passed through a column of Amberlite IR 120 (H^+) ion-exchange resin, and the acid eluate was divided into five equal portions. The eluate fractions were then immediately neutralized with 1.0 M solutions of LiOH, NaOH, KOH, CsOH, and tetramethylammonium (TMA) hydroxide, respectively, and freeze-dried to give the Li^+, Na^+, K^+, Cs^+, and TMA^+ salts of heparin.

For ^{13}C nmr spectroscopy, solutions were prepared by weighing appropriate amounts of the heparin salts, $CaCl_2$, and the respective chloride salt of the univalent counterion into the nmr tube, followed by 0.50 mL of deuterium oxide. The polymer concentration in all samples was 0.10 M (0.40 equiv./L) based on the equivalent weight of heparin, and the ionic strength (I) was 0.4 M. For each of the five univalent counterions, samples containing calcium ion concentrations of 0.00, 0.02, 0.05, 0.07, and 0.10 M were prepared. The ^{13}C nmr spectra were acquired at 70°C with a Varian XL300 spectrometer operating at 75.4 MHz, and the chemical shifts were referenced to internal DMSO at δ 39.6.

Atrazine hydrolysis in aqueous suspensions of humic acid at 25.0°C[1]

DONALD S. GAMBLE[2] AND SHAHAMAT U. KHAN
Land Resource Research Centre, Agriculture Canada, Ottawa, Ont., Canada K1A 0C6

Received August 5, 1987[3]

DONALD S. GAMBLE and SHAHAMAT U. KHAN. Can. J. Chem. **66**, 2605 (1988).

The acidic properties of a Chernozemic humic acid were determined by equilibrium titration. The number of carboxyl groups is 2.828 (mmol/g) ± 0.5%. The results were used for an investigation of Brönsted acid catalysis of atrazine hydrolysis by a suspension of the humic acid. There is sufficient sorption so that the rates of change of atrazine and product hydroxyatrazine in solution differ both from each other and form the rate of atrazine conversion on the catalytic sites. An important objective of this work was the separate determination of the sorption equilibrium constants for atrazine and hydroxyatrazine, and the rate constant for atrazine conversion on the catalytic sites. All three constants are relevant to environmental research. The apparent rate constants for changes in solution are experimental artifacts however, not useful for such research. Calculated in terms of carboxyl sorption sites in the free acid form, the sorption equilibrium constants were 1.74×10^2, $\sigma = 0.03 \times 10^2$ and 8.5×10^2, $\sigma = 2.3 \times 10^2$, for atrazine and hydroxyatrazine, respectively. The rate constant for conversion on catalytic sites ranges from 1.8×10^{-1} day^{-1} ± 20% to 2.9×10^{-1} day^{-1} ± 20%, for atrazine coverage of sites from 9.0 (μmol/g) to 1.0 (μmol/g).

DONALD S. GAMBLE et SHAHAMAT U. KHAN. Can. J. Chem. **66**, 2605 (1988).

Faisant appel à une titrage à l'équilibre, on a déterminé les propriétés acides d'un acide humique Chernozémique. Le nombre de groupements carboxyliques est de 2,828 (mmol/g) ± 0,5%. On a utilisé ces résultats pour réaliser une étude de la catalyse acide de Brönsted sur l'hydrolyse de l'atrazine par une suspension de l'acide humique. La sorption est telle que, en solution, les taux de changement de l'atrazine et de son produit l'hydroxyatrazine diffèrent les uns des autres et qu'ils forment le taux de conversion de l'atrazine sur les sites catalytiques. Un objectif important de ce travail était de déterminer séparément les constantes d'équilibre de sorption de l'atrazine et de l'hydroxyatrazine ainsi que la constante de vitesse de conversion de l'atrazine sur les sites catalytiques. Les trois constantes sont importantes pour les recherches sur l'environnement. Toutefois, les constantes apparentes de vitesse pour les changements en solution sont des artéfacts qui ne sont pas utiles pour ces recherches. Si on les calcule en fonction des sites carboxyliques de sorption sous la forme d'acide libre, les constantes d'équilibre de sorption sont de $1{,}74 \times 10^2$, $\sigma = 0{,}03 \times 10^2$ et $8{,}5 \times 10^2$, $\sigma = 2{,}3 \times 10^2$ respectivement pour l'atrazine et pour l'hydroxyatrazine. La constante de vitesse pour la conversion des sites catalytiques varie de $1{,}8\ 10^{-1}$ jours^{-1} ± 20% à $2{,}9 \times 10^{-1}$ jours^{-1} ± 20% pour des couvertures des sites par l'atrazine allant de 9,0 (μmol/g) à 1,0 (μmol/g).

Introduction

In general, chemical reactions and microbiological processes both contribute to the degradation of organic chemical pesticides in soils. For some pesticides, microbiological processes are dominant. In the case of atrazine, chemical reaction can be quite important. Because of their ion exchange properties, acid soils can have higher concentrations of acid catalysts inside of the soil particles than they do in the external soil solutions. If the ionic strength is sufficiently low, a nearly neutral soil solution pH might not indicate a lack of catalytic activity. The general importance of sorption processes and hydrolysis reactions is indicated by the fact that pesticide regulatory agencies in Canada, the United States and Europe require sorption and hydrolysis tests as part of the documentation for commercial pesticide registration.

Rao and Davidson have commented that multiple regression equations could not be developed from the available literature because the information for physical, chemical, and microbiological properties of soils was inadequate (1). Some information is available, however. Statistical correlations in the literature generally implicate humic materials as an important factor. A review of Stevenson for example (2), presents evidence for this accumulated since 1962 (3–13). A number of authors have consequently investigated the interactions of organic pesticides with humic materials (5, 7, 14–33). The acidic functional groups of humic materials are an important factor (32, 34–38), and Perdue has examined their effects from the point of view of Brönsted acid–base catalysis theory (39).

Atrazine sorption by soils has been reported to be not only pH dependent, but also reversible (40, 41). Previous work with atrazine in fulvic acid solutions has demonstrated interactions between atrazine and unionized carboxyl groups and hydrogen ions (42–45). The atrazine – fulvic acid solution phase work has indicated that unionized carboxyl groups are hydrogen bonding sites. In addition, the only two catalysts for atrazine hydrolysis identified were hydrogen ions and unionized carboxyl groups (44–47). Under field conditions, some atrazine could be sorbed from solution into water swollen particles, encountering an internal gel solution containing unionized carboxyl groups and free hydrogen ions. The stoichiometrically exact investigation of such a system will require a humic acid for which the acid properties have been standardized in a way comparable to that of the fulvic acid. Unlike some fulvic acids, however, no humic acid standardizations of this type have yet been reported.

Humic acid titration curves have been in the literature for many years (46–52). A new investigation is required however, for at least four reasons. (*1*) Every humic acid has its own numerical values for its acidic, solubility, and other polyelectrolyte properties. (*2*) A humic acid is a carboxylic type cation exchanger. Marinsky's work (53) has shown that a titration of such a system is affected by intraparticle diffusion and governed by the Donnan potential, as discussed by Helffrich (54). Simple solution phase calculations are therefore not applicable. (*3*) The pH dependent dissolution of the humic acid must be accounted for during the calculation and interpretation of titration data. (*4*) H^+ molarity measurements are

more useful for chemical calculations than conventional pH measurements are.

Heterogeneous catalysis experiments do not all have the same purposes. They therefore do not all have the same experimental design or the same calculation procedures. In particular, pesticide persistence and movement problems in soil create a need for the separate determination of sorption equilibrium constants and kinetic rate constants. For an atrazine–humic system, the mixture of chemically different catalytic sites and the possibility of catalyst poisoning by hydroxyatrazine product must be accounted for. It is also important that true rate constants be determined, and not just apparent rate constants which are experimental artifacts. Measurements which are confined to initial rate measurements and to the conventional determination of the algebraic products of a rate constant and a sorption equilibrium constant are not adequate for practical purposes.

A consideration of the above factors, the types of correlations referred to by Rao and Davidson (1), and the availability of an analytical chemical method for the simultaneous determination of atrazine and hydroxyatrazine in the solution phase led to two specific research objectives. (*1*) Acid–base standardization of the humic acid, with its pH dependent solubility accounted for. (*2*) Use of the standardized humic acid, for the separate determination of sorption equilibrium constants for atrazine and hydroxyatrazine and the conversion rate constant of atrazine on the catalytic sorption sites.

Theory[4]

I. Standardization of the humic acid

By definition, a humic acid is a humic fraction that is insoluble in the free acid form but soluble in the Na^+ salt form. Undissolved humic acid in an aqueous system can therefore be expected to behave as a carboxylic-type cation exchanger having pH dependent solubility. The important equilibria, such as cation exchange and solubility, are governed by the acidic functional groups. They especially include the carboxyl groups. The carboxyl groups are, however, distributed over the polymer molecules of polydisperse polyelectrolyte. At a given point in an acid–base titration curve, the most general case is that a particular polyelectrolyte molecule will have some of its carboxyl groups protonated and some of them unprotonated. When the mole fraction of its unprotonated carboxyl groups becomes sufficiently great, the polyelectrolyte molecule will go into solution. The numerical value of this mole fraction is not known, and the possibility of it being less than 1 must be allowed. The reason for this might include hydrogen bonding and high charge density. The most general possible postulate is that each of the two physical phases will have both unionized carboxyl groups and carboxylate anions. Whether or not unionized carboxyl groups can be detected and measured in the external solution and whether or not carboxylate anions can be detected and measured in the undissolved humic acid are analytical chemistry questions. The sorption of water creates an internal gel solution in the particles of undissolved humic acid, just as it does with other cation exchanges (42, 45, 54).

Equation [1] describes the acid dissociation equilibrium for the mixture of chemically nonidentical carboxyl groups in the internal gel phase.

$$[1] \quad HA \overset{\overline{K}_{GA}}{\rightleftharpoons} H^+ + A^-$$

$$\overline{K}_{GA} = \frac{M_{GH} M_{GA}}{M_{GAH}}$$

The subscripts designate the molarities of the carboxyl groups AH, free protons H^+, and carboxylate anions A^- in the gel solution. Because it is defined for a mixture of carboxyl groups, $\overline{K}_{GA}$ is known to be a weighted average equilibrium function (49, 55–60). In terms of the effects of humic acid on atrazine, this equilibrium is important for at least two reasons. One is that unionized carboxyl groups and free protons both act as catalysts for the hydrolysis of atrazine (39, 45, 58, 64). Since their catalytic effects are different, net hydrolysis rates should depend on the gel phase concentrations of both of them. The acid dissociation equilibrium function $\overline{K}_{GA}$ is therefore very relevant to the Brönsted acid catalysis of atrazine. Marinsky has demonstrated methods for estimating the gel phase K_A values of carboxylic cation exchangers (53). It is found, however, that pH dependent solubility prevents the proper use of Marinsky's method for humic acid. The detailed proof is available.[4] The acid–base standardization of the humic acid is therefore confined to a Gran's function method for the equivalence point, and a titration curve for total gel phase acid. Equation [2] gives the Gran's function in terms of the measured H^+ molarity.

$$[2] \quad Y = VM_H$$

V is sample solution volume in L. The total gel phase acid Q_{GH} is obtained from the simple material balance eqs. [3] and [4].

$$[3] \quad Q_{GH} = Q_H - (M_H - K_W/M_H)V$$

$$[4] \quad Q_H = Q_A - Q_B$$

where Q_A and Q_B are moles of initial acid and added base, respectively.

II. The heterogeneous catalysis system

Figure 1 shows the overall scheme for atrazine in a sample having undissolved humic acid and water. During the reaction, both atrazine and hydroxyatrazine have equilibrium distributions between sorption sites within the interior gel solutions of the humic acid particles, and the external solution. Assuming reversible labile equilibria, the sorption and desorption processes are expected to be quite fast relative to the chemical reaction that might have half lives of days or weeks.

The sorption sites are assumed to be unneutralized carboxyl groups —COOH, which act as catalytically active hydrogen bonding sites. The experimental evidence for this postulate has been provided by recent investigations of atrazine complexing by fulvic acid (42–44). The collection of chemically nonidentical carboxyl groups is expected to have a spectrum of weak acid K_a values (39, 46, 47, 51). According to Brönsted acid catalysis theory and the work of Perdue, this is expected to cause the reaction rate constant to vary with site coverage (39).

In a realistic experiment, the site coverage will be small so that site saturation will not occur. Atrazine and hydroxyatrazine might nonetheless compete for sorption sites. Since usually no two compounds will be equally strongly sorbed, it cannot be assumed that site coverage will remain constant during the course of an experiment. For the most general case, it is therefore seen from simple material balance arguments that

[4]The detailed development of the heterogeneous kinetics, accounting for variable site coverage below saturation, catalyst poisoning, and separate calculation of sorption equilibrium functions is available from the Depository of Unpublished Data. A complete set of data may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

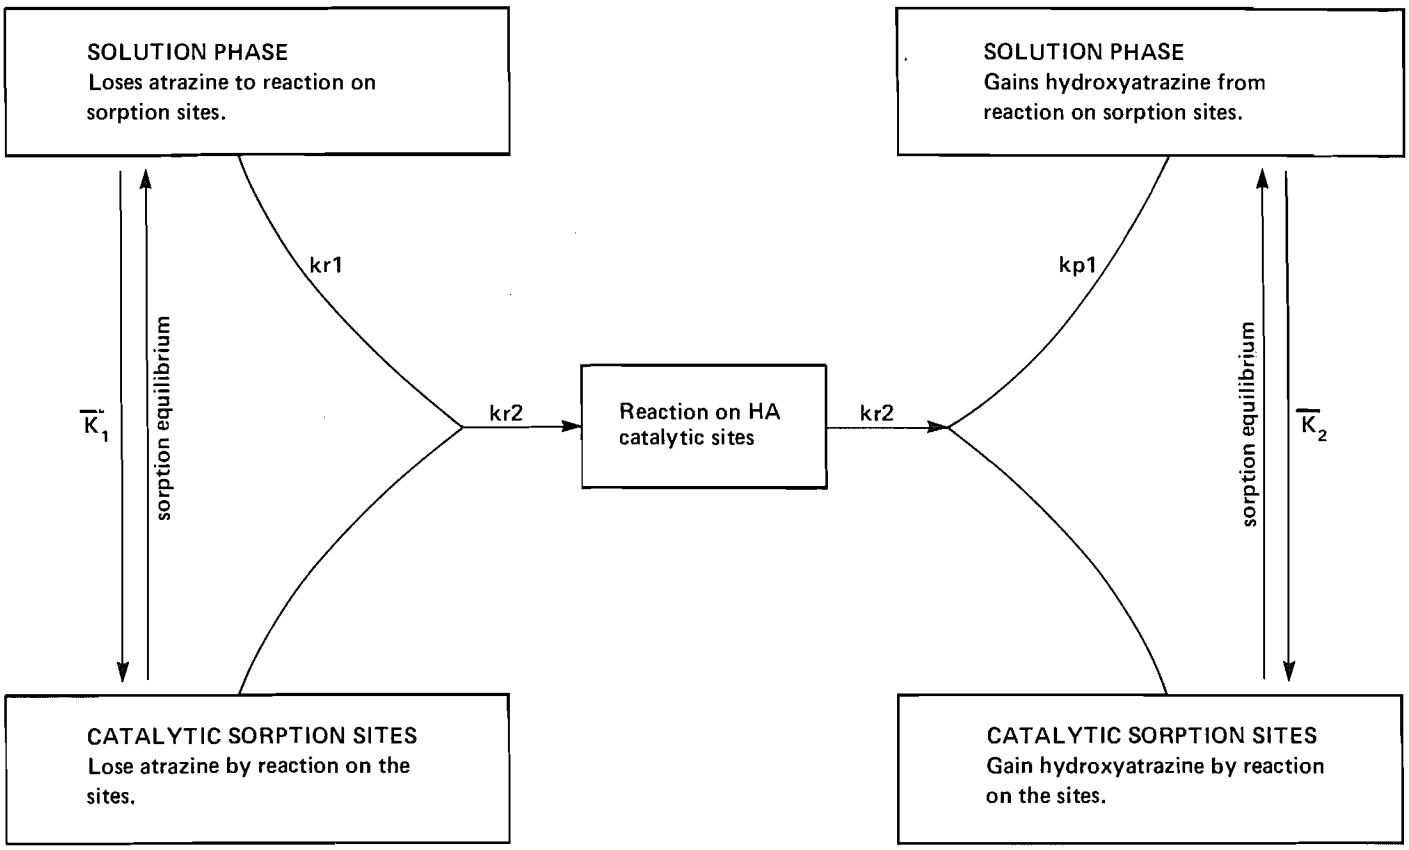

FIG. 1. Heterogeneous catalysis systems: a suspension of humic particles in an aqueous atrazine solution. The catalytic sorption sites are carboxyl groups in the H^+ form, in the ion exchange gel phase.

there are three processes for atrazine: (*i*) the conversion of atrazine to hydroxyatrazine on the catalytically active sorption sites; (*ii*) the net removal of atrazine from the sorption sites; (*iii*) the net removal of atrazine from the external solution. There are three corresponding processes for the accumulation of hydroxyatrazine. A direct consequence of these processes is that the rate at which atrazine disappears from solution and the rate at which hydroxyatrazine appears in solution cannot be assumed to be the same. From an environmental point of view, it is important to recognize that the apparent reaction rate constants and half lives measured directly in the solution could be quite different from the real reaction rate constants and half lives for the whole system. Misleading predictions could result if this is not clearly understood. The kinetic rate laws must therefore be formulated in a way that accounts for the phenomena described.

III. Sorption equilibria

Reversible labile equilibria are assumed to exist for the sorption of atrazine and of hydroxyatrazine from solution. The atrazine and hydroxyatrazine are also expected to compete for protonated carboxyl groups as sorption sites. Equation [5] defines the equilibrium function $\bar{K}_1$ for the sorption of atrazine. In the most general case, $\bar{K}_1$ will be a weighted average equilibrium function (47).

$$[5] \quad \mathrm{At} + \mathrm{HA} \overset{\bar{K}_1}{\rightleftharpoons} \mathrm{At.HA}$$

$$\bar{K}_1 = \frac{\theta_{At}}{M_{At}\theta_0}$$

M_{At} is the molarity of atrazine in the solution. θ_{At} is the moles of atrazine sorbed per g of humic acid. θ_0 is the moles of carboxyl groups unoccupied by sorbed molecules, per g of humic acid. In the same way, eq. [6] described the equilibrium sorption of hydroxyatrazine.

$$[6] \quad \mathrm{AtOH} + \mathrm{HA} \overset{\bar{K}_2}{\rightleftharpoons} \mathrm{AtOH.HA}$$

$$\bar{K}_2 = \frac{\theta_{AtOH}}{M_{AtOH}\theta_0}$$

where M_{AtOH} is the molarity of hydroxyatrazine in the solution and θ_{AtOH} is the moles of sorbed hydroxyatrazine per g of humic acid. The coverage of catalytic sorption sites might be important for two reasons. One is that the most strongly catalytic sites may be preferentially occupied. The other is that hydroxyatrazine sorption might cause catalyst poisoning. There is no available method however, for directly measuring the separate site coverages by atrazine and hydroxyatrazine. It is therefore important to estimate $\bar{K}_1$ and $\bar{K}_2$ by an indirect method. Because both compounds can be simultaneously monitored in the external solution throughout kinetics runs, this can be done. The calculation is based on eq. [7], which has been obtained from material balance relationships combined with eqs. [5] and [6].

$$[7] \quad Y_c = \bar{K}_1 M_{At} + \bar{K}_2 M_{AtOH}$$

$Y = (\theta_c/\theta_0)$ is the mole ratio of occupied to free carboxyl sorption sites. It is also an experimental quantity. The most general possible postulate for a system having a mixture of sorption sites is that $\bar{K}_1$ and $\bar{K}_2$ will depend on sorption site

For personal use only.

coverage and hence on solution composition (47). Apparently constant values of the atrazine – fulvic acid binding equilibrium function have been observed experimentally however, by Haniff *et al.* (44). A possible reason for this result was that only a small fraction of the carboxyl binding sites was occupied by atrazine. For the same reason it is postulated that $\bar{K}_1$ and $\bar{K}_2$ will be experimentally indistinguishable from constants. This permits the use of the partial derivatives in eqs. [8] and [9].

$$[8] \quad \bar{K}_1 = \left(\frac{\partial Y_c}{\partial M_{At}}\right)_{M_{AtOH}}$$

$$[9] \quad \bar{K}_2 = \left(\frac{\partial Y_c}{\partial M_{AtOH}}\right)_{M_{At}}$$

Once $\bar{K}_1$ and $\bar{K}_2$ values are available, it is then possible to estimate θ_{At} and θ_{AtOH}, the site coverages by atrazine and hydroxyatrazine.

IV. Hydrolysis in solution

The two catalysts for atrazine hydrolysis that have been identified in humic materials are protons and unionized carboxyl groups (61). In the present case, the investigation of catalytically active sorption sites in the undissolved humic acid requires that proton catalysis in the solution phase be accounted for. This is easily done with the reported half-life relationship (61) in eq. [45].

$$[10] \quad t_{1/2} = \left[8.796\left(\frac{1.777 \times 10^{-2} \times 10^{-pH}}{2.45 \times 10^{-2} + 10^{-pH}} + M_{AH}\right)\right] \text{days}$$

The experiment was run at a pH of 4.0. With no carboxyl groups in solution, this gives a half life for atrazine in solution of 333.5 years. It would therefore not be possible to detect solution phase hydrolysis during the course of a 14 day experimental run. Catalysed hydrolysis will consequently only be determined for the undissolved humic acid phase.

V. Hydrolysis on catalytically active sorption sites

A. Atrazine disappearance

The total rate of change of atrazine coverage on the catalytic sorption sites is given by eq. [11].

$$[11] \quad -W_{HA}\left(\frac{d\theta_{At}}{dt}\right)_t = -W_{HA}\left(\frac{d\theta_{At}}{dt}\right)_r + V_s\frac{dM_{At}}{dt}$$

In the left hand term, W_{HA} is g of humic acid, and the subscript "t" indicates total change. The first term on the right is the rate of atrazine conversion on the catalytic sorption sites, as explained by eq. [12].

$$[12] \quad \left(\frac{d\theta_{At}}{dt}\right)_r = -k_{r2}\theta_{At}$$

When sorption equilibrium is accounted for with eq. [5], the differential rate law is obtained as eq. [13]. It has been simplified by the absence of solution phase hydrolysis.

$$[13] \quad \frac{dM_{At}}{dt} = -k_{r1}M_{At} - \left(\frac{W_{At}}{V_s}\right)\left(\frac{d\theta_{At}}{dt}\right)_t$$

Unlike the true rate constant k_{r2} to which it is related, the apparent rate constant k_{r1} is an experimental artifact dependent on the relative amounts of humic acid and solution. Equation [14] shows the relationship.

$$[14] \quad k_{r1} = \left(\frac{W_{HA}}{V_s}\right)\bar{K}_1 k_{r2}\theta_0$$

The integral rate law required for calculations is eq. [15].

$$[15] \quad \ln(M_{At}) + A_{At}\ln(\theta_{At}) = -k_{r1}t + B_{At}$$

The constants A_{At} and B_{At} are defined by eqs. [16] and [17].

$$[16] \quad A_{At} = \left(\frac{W_{HA}}{V_s}\right)\bar{K}_1\theta_0$$

$$[17] \quad B_{At} = \ln(M^0_{At}) + A_{At}\ln(\theta^0_{At})$$

The apparent rate constant k_{r1} may therefore be calculated from linear fits of $[\ln(M_{At}) + A_{At}\ln(\theta_{At})]$ vs. t.

B. Hydroxyatrazine appearance

A similar examination of hydroxyatrazine production yields the differential rate law, eq. [18].

$$[18] \quad \frac{dM_{AtOH}}{dt} = -\left(\frac{k_{p1}}{A_{AtOH}}\right)M_{AtOH} + B_{AtOH}\theta_c$$

M_{AtOH} is the hydroxyatrazine molarity in the external solution. Equations [19] to [21] define the three constants.

$$[19] \quad k_{p1} = -\left(\frac{W_{HA}}{V_s}\right)\bar{K}_2 k_{r2}\theta_0$$

$$[20] \quad A_{AtOH} = 1 + \left(\frac{W_{HA}}{V_s}\right)\bar{K}_2\theta_0$$

$$[21] \quad B_{AtOH} = \frac{(W_{HA}/V_s)k_{r2}}{A_{AtOH}}$$

k_{p1} is also an apparent rate constant related to the real rate constant k_{r2}. Equation [22] is the corresponding integral rate law, calculated over the time interval t_1 to t_2.

$$[22] \quad \ln(M_2/M_1) = -(k_{p1}/A_{AtOH})(t_2 - t_1) + B_{AtOH}\int_{t_1}^{t_2} X(t)dt$$

M_1 and M_2 are the integration limits for M_{AtOH}, and the function $X(t)$ is explained by eq. [23].

$$[23] \quad X(t) = (\theta_c/M_{AtOH})$$

The evaluation of the apparent rate constant is more difficult for hydroxyatrazine than it is for atrazine. The reasons are that eq. [22] must be rearranged, and numerical integration is required for the last term on the right.

C. Key parameters

Equations [14] and [19] for the experimental parameters k_{r1} and k_{p1} not only have exactly the same form, but also mostly the same constants. A consequence of this is that the ratio (k_{r1}/k_{p1}) gives the useful relationship in eq. [24].

$$[24] \quad \frac{k_{r1}}{k_{p1}} = \frac{\bar{K}_1}{\bar{K}_2}$$

The two ratios (k_{r1}/k_{p1}) and $(\bar{K}_1/\bar{K}_2)$ might be used either to test the quality of experimental data, or to determine whether the data are consistent with theory.

Because k_{r1} and k_{p1} depend on experimental design, they cannot be used directly for practical applications. It is therefore necessary to evaluate the rate constant k_{r2}. This is easily done with data for both atrazine and hydroxyatrazine, by using eqs. [25] and [26].

$$[25] \quad k_{r2} = (V_s/W_{HA})(k_{r1}/\bar{K}_1\theta_0)$$

$$[26] \quad k_{r2} = (V_s/W_{HA})(k_{p1}/\bar{K}_2\theta_0)$$

The rate constant k_{r2} probably depends on the acid strengths of the occupied carboxyl groups. It is, however, the only rate constant that should be used for the comparison of samples or experiments, or for the modelling of field phenomena. In addition, eqs. [25] and [26] could be used for testing data or theory. It is therefore important to have equilibrium and kinetics data for both atrazine and hydroxyatrazine.

Experimental

Reagents

The humic acid was obtained from the Ah horizon of an Alberta black Chernozem soil which had a pH of 6.5. Its preparation and analysis have been reported by Khan and Schnitzer (62–65) and by Schnitzer and co-workers (66). Atrazine and hydroxyatrazine were crystalline solids which were prepared and analysed as previously described (58). Orthophosphoric acid and sodium chloride were reagent grade. Water redistilled under N_2 was used for the preparation of all standard stock solutions, standards, and samples. Chromatography grade acetonitrile was used for HPLC work.

Standard stock solutions

HCl and NaOH solutions were 0.1 *N* analytical standard solutions. Other standard stock solutions were 1.5×10^{-4} *M* HCl, 1.0×10^{-4} *M* atrazine, 1.0×10^{-4} *M* hydroxyatrazine, and 1.5×10^{-4} *M* atrazine.

Analytical standards

The standardization of a pH meter was done with an orthophosphoric acid solution that was 1.0×10^{-3} *M*, containing 0.01 *M* NaCl. HPLC analyses employed mixed standards which ranged from 3.0×10^{-5} *M* atrazine and 0.0 *M* hydroxyatrazine, to 0.0 *M* atrazine and 3.0×10^{-5} *M* hydroxyatrazine.

Experimental samples

Each reaction sample consisted of about 25.0 mg of standardized Chernozem humic acid, suspended in 25.0 mL of reaction solution. The solutions contained 1.0×10^{-4} *M* HCl to prevent dissolution of the humic acid. Initial atrazine concentrations, before sorption or reaction, ranged from 0.5×10^{-5} *M* to 5.0×10^{-5} *M*.

Equipment

An Orion 801 digital pH meter was used with an Orion Ross type micro combination glass electrode, and a 5.00 mL microburett. Jacketed reaction vessels for titrations and kinetics samples were connected to a circulating constant temperature bath.

The HPLC consisted of two Altex Model 100 pumps and a Beckman Model 164 variable wavelength detector. The reverse phase column was an Altex Ultrasphere – ODFS with 5 μm particles size, 4.6 mm ID, and 25 cm length. A corresponding 2 cm guard column had the same diameter and packing.

Humic acid titrations

Each titration sample consisted of 0.05 g of humic acid in 20.0 mL of 0.1 *N* NaCl solution. Equilibrium titrations were conducted with 0.05 mL increments of standard base at 25.00°C. The samples were stirred so that suspensions were titrated. Volts vs. mL data points were recorded 10.0 min after the addition of standard base, when the dissolution and mass transfer processes had been replaced by the much slower electrode drift. An instrument calibration titration was run for each sample titration, for the preparation of H^+ molarity curves. The calibration runs used 100.00 mL aliquots of a standard stock solution containing 1.0×10^{-3} *M* H_3PO_4 and 0.01 *M* NaCl. The use of orthophosphoric acid titrations for H^+ molarity calibrations and the related calculations have been previously described (58, 59). Five replicate titrations were run. A single H^+ molarity vs. mL curve was produced by averaging the five replicate runs. This was done by applying least squares polynomial fits to decade ranges of H^+ molarity data.

The Gran's function $Y = VM_H$ was fitted to a quadratic equation, which was found to give the best least squares fit. Since the equivalence point V_{el} is found at $Y = 0$, the quadratic equation may be rearranged to give eq. [27].

$$[27] \quad V_{el} = \frac{C_0}{C_1 + C_2 V_{el}}$$

C_0, C_1, and C_2 are the quadratic constants. V_{el} was obtained by iterative calculations using eq. [27]. This was checked against graphical calculations. The results are presented in Fig. 2.

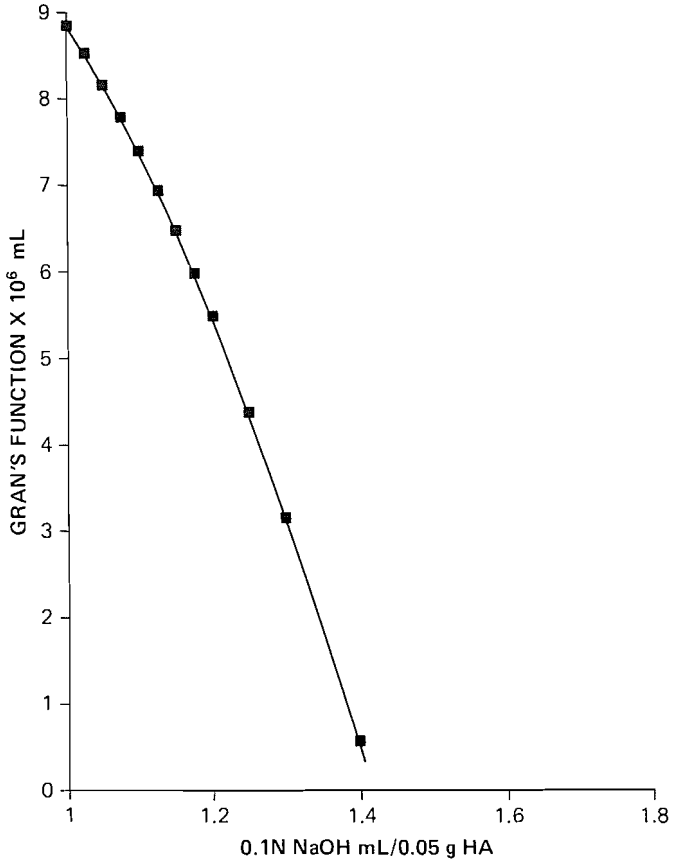

FIG. 2. The Gran's function, $Y = VM_H = -6.0006 \times 10^{-16} + 3.02446 \times 10^{-5} V - 2.13882 \times 10^{-5} V^2$. At $Y = 0$, $V = V_{el} = 1.414$ mL ± 0.5%.

A separate titration was carried out independently for an investigation of Na^+ uptake by undissolved humic acid. It was conducted in essentially the same way except that the external solution was monitored by 200 mm–300 mm UV scans for dissolved humate, and aliquots were drawn off at regular intervals for Na^+ analysis by atomic absorption spectroscopy.

Chemical kinetics runs

Each kinetics sample was kept in suspension by stirring, at a reaction temperature of 25.00°C. Air and light were excluded to prevent oxidation and photochemistry. Each sample was analysed daily at various recorded times for atrazine and hydroxyatrazine, during the course of a 12 day run. The analyses were done by HPLC with a mobile phase consisting of 50.0 vol% acetonitrile–H_2O containing 1.58×10^{-3} *M* HCl. The flow rate was 1.0 mL/min. Analysis aliquots were withdrawn from the reaction solutions through syringe tip filters. Every sample injection was bracketed by two standard injections, with atrazine and hydroxyatrazine peaks both being read from each injection. The atrazine and hydroxyatrazine peaks were read at 222.0 nm and 240.0 nm, respectively. The reaction solutions were examined by gas chromatography, to determine whether or not any products of dealkylation side reactions could be detected.

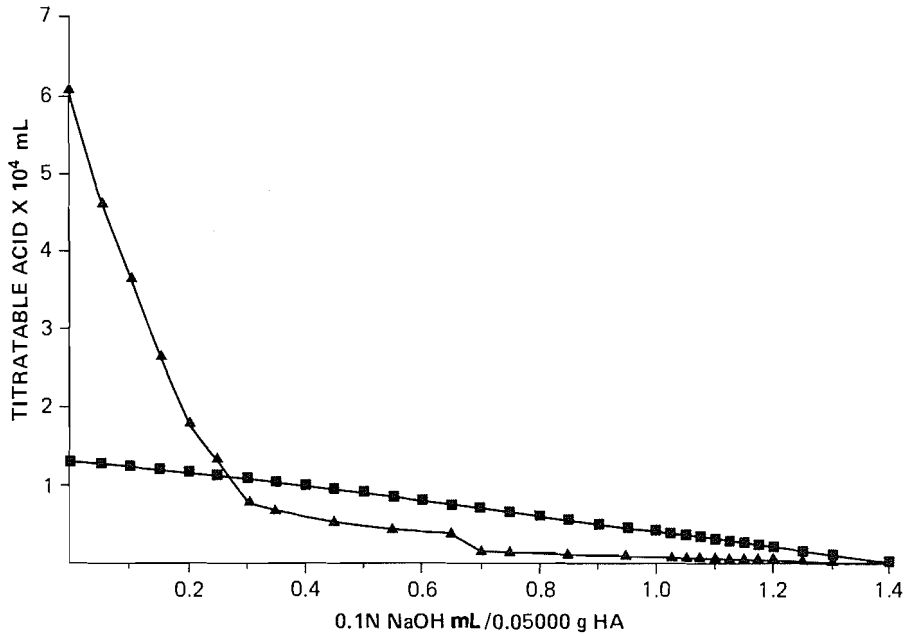

FIG. 3. The effects of titration on the quantities of acid remaining in the two physical phases of the sample. ▲, molarity of H^+ in the external solution; ■, (moles of acid/0.0500 g) in the gel phase. 25.0°C.

Results and discussion

I. Standardization of the humic acid

The Gran's function shown as the plot in Fig. 2 was quite conveniently used in the form $M_H V$ instead of the customary form $K10^{-kE_V}$, because the M_H data were available from the calibration. The data gave a very close least square fit to a quadratic equation. The titration equivalence point was calculated iteratively from the fitted constants, as indicated in Fig. 2. The simple graphical method gave the same equivalence point as did the Gran's plot in Fig. 2, to within the analytical error. A plot of M_H vs. mL of base gave a curve having the same general appearance of nearly the same extrapolation. The equivalence point value made it possible to calculate the amount of titratable acid remaining in the gel phase at each titration point. A titration scan curve for each of the two physical phases is consequently plotted in Fig. 3. These two curves represent a calibration of the acidic properties of the humic acid. The discontinuity in the gel phase at about 0.65 mL is probably a mathematical artifact caused by experimental scatter. About 0.6 mmol/g of carboxyl groups are more strongly acidic than the rest, which look rather similar to each other.

An important feature of Fig. 3 is that it shows the relationship between titratable acid found in the two phases. Atrazine, if present, would be affected differently by the protons in the external solution, and the combination of unionized carboxyl groups and free protons in the undissolved humic gel phase. Any attempts to make quantitative predictions of the atrazine sorption and hydrolysis must account separately for the amounts of acid species in both phases. At 0.28 mL of base, M_H is 1.0×10^{-4}. An examination of Fig. 4 and the titration curve shows that with an external solution pH of about 4, 85% of the original gel phase acid still remains. A pH of 5 is more common in soils. At 0.96 mL of base, the external solution has M_H equal to 1.0×10^{-5}. With the solution pH now approximately 5, solution phase hydrolysis of atrazine would be very slow (45). In the undissolved particles of humic acid, however, about 30 mol% of the original gel phase acid still remains to act as catalytically active sorption sites for atrazine. They are, however, the most weakly acidic fraction of the mixture of carboxyl groups. The most strongly acidic fraction of them were titrated by the first 0.3 mL of standard base. Not only can the fate of atrazine not be predicted by measuring the simple bulk mass of humic material present, it also cannot be predicted by measuring only the pH of the external solution. All of the information in Fig. 3 is required.

A polynomial least squares fit was produced for the gel phase curve in Fig. 3, so that it can be computerized for experimental design or for predictions. The polynomial constants are tabulated in Table 1. It should be noted that extra digits beyond the number of significant figures are recorded so that rounding off and truncation errors can be minimized. This calibration curve is only strictly valid for the experimental conditions actually used. Since it is the unneutralized acid functional groups that cause catalysis and control solubility and sorption, it is necessary to know what mol% of them remain unneutralized at any point in the acid–base titration curve. Figure 4, which was constructed for this reason, permits the mol% gel phase acid to be related to solution phase pH.

Humic acid solubility was monitored during titration with photometric absorbance measurements at 260 nm. The resulting A_{260} vs. mL curve is seen in Fig. 5. The solubility increased substantially between 0.3 and 1.0 (mL/0.05) g. This corresponds to the solution phase H^+ molarity range of 7.7×10^{-5} to 8.9×10^{-6}. Any changes in solubility that exist outside that range appear to be small. There would be an important practical advantage in monitoring the dissolution of carboxylate anions instead of monitoring the dissolution of chromophores, if an experimental method were available. The advantage would be that the amount of free protons in the humic gel phase could be estimated. Unfortunately, the dissolution of carboxylate anions could not be neglected and no successful method was found for measuring it in these experiments. Although it might be possible to use the approximation

$$M_A \approx N_B V_B$$

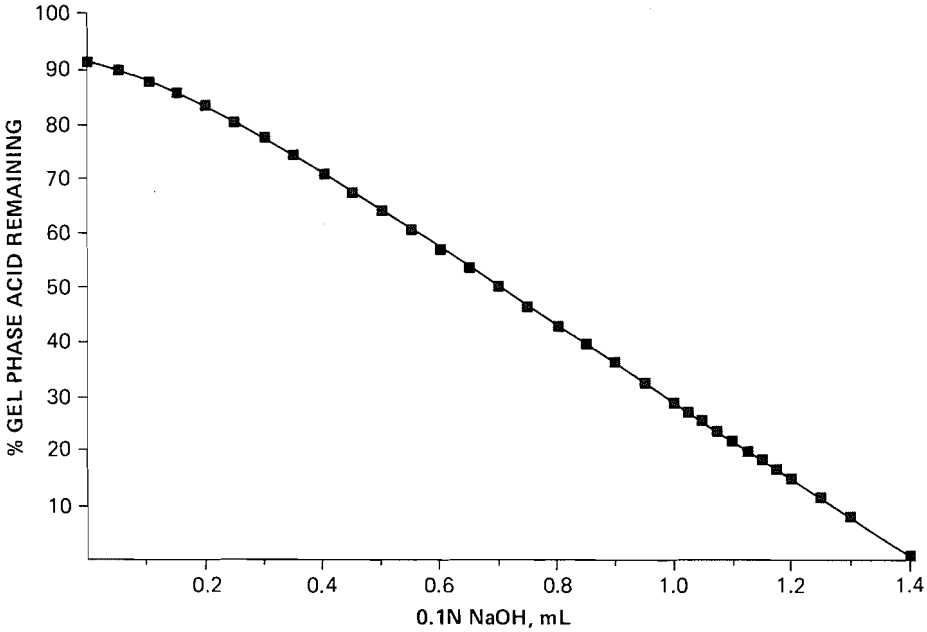

FIG. 4. Mol% of the titratable acid remaining in the gel phase during titration with standard base. Relative standard deviation, ±5%. 25.0°C.

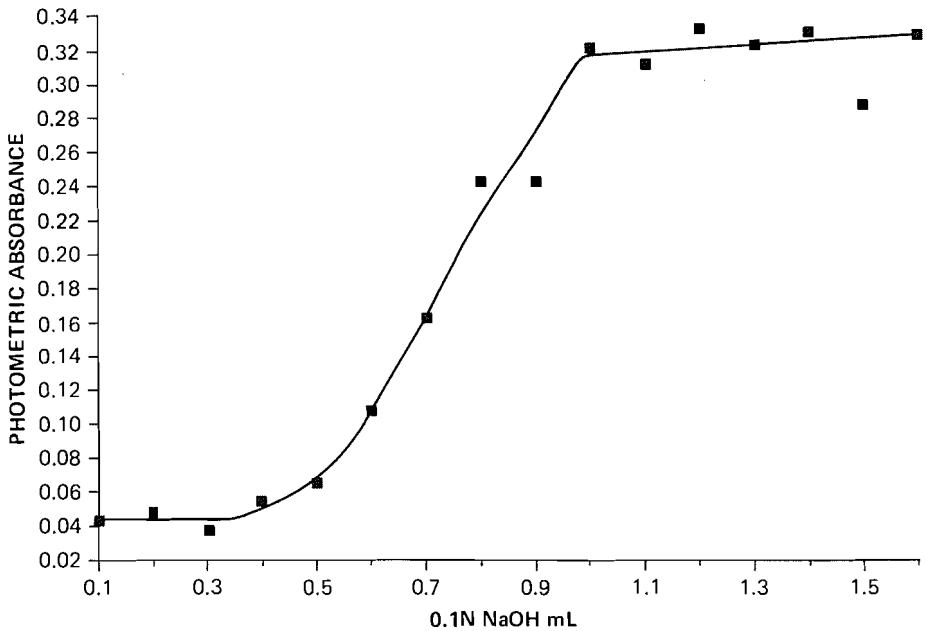

FIG. 5. Dissolution of the humic acid during titration, monitored by photometric absorbance at λ 260 nm.

it is not known how valid such an approximation would be, and it was not attempted. The errors in R found in Table 4 imply relatively large errors in values for the amount of free protons in the gel phase, near the equivalence point. Since the amounts of free gel phase protons should be small in this region of the titration curve, the errors may be less important than they seem. The best available option for atrazine – humic acid experiments is to correlate sorption and rate constant data with the total amounts of titratable gel phase acid.

Because it is important to have the calibration data in Tables 5 to 7 available for future calculations, they have been stored in numerical form[1]. The experimental errors found there are typical for glass electrode measurements (49, 58, 60).

Solution phase results obtained previously with a calibrated fulvic acid have demonstrated that a large reduction in experimental scatter may be achieved by correlating atrazine interaction parameters with numbers or concentrations of protons and protonated carboxyl groups (46, 56). A similar result is anticipated for two phase aqueous systems containing humic acid and atrazine.

II. Heterogeneous catalysis of the hydrolysis reaction

A. Sorption equilibria

Figure 6 shows a typical set of solution phase atrazine data. The top curve shows the loss of atrazine from solution. The bottom curve is the experimental plot of eq. [15] from which the apparent rate constant k_{r1} was calculated. The linearity of the plots indicates that atrazine attained sorption equilibrium quite

quickly. In chemical kinetics terms, the atrazine established a steady state condition. A separate sorption experiment used for extrapolations to zero time has provided supporting evidence of this. The hypothetical sorption site coverages at zero time have been plotted against initial atrazine concentrations, in Fig. 7. Because no plateau was reached, the sorption was evidently well below saturation so that no sorption capacity was observed. While it is reasonable to assume that such a capacity exists, it must be somewhat greater than the atrazine complexing capacity of dissolved fulvic acid (43, 44). A possible reason for this is that the internal gel solution of the water swollen humic acid has a much higher concentration of carboxyl groups than dilute fulvic acid solutions. At least in principle, the mixture of chemically nonidentical carboxyl groups would be expected to give nonlinear sorption curves. The apparent linearity may simply reflect the fact that the total site coverage attained amounted to less than 6%. Each kinetics run covered such a small range of acidities that the change in catalytic activity could not be observed outside experimental error.

Hydroxyatrazine curves typically had the shape seen in Fig. 8. This contrasts sharply with the observed behaviour of atrazine in Fig. 6. Generally about 4 days were required for the establishment of sorption equilibrium. Sorption equilibrium calculations and steady state kinetics calculations were therefore confined to the region beyond 4 days. The measurements made during the first 4 days lacked the quality and quantity required for interpretive calculations. Only one kinetics sample had a fast equilibration of hydroxyatrazine sorption. Sample No. 1, which was prepared with about 25.0 mg of humic acid in 24.9 mL of 5.09×10^{-6} *M* atrazine solution, had a linear ln plot for hydroxyatrazine just about down to zero reaction time. The curve resembled that of Fig. 8 except that the initial fast rise was missing. The reason for this was that the atrazine sorption was sufficiently small so that the reaction rate was too small for large concentration gradients to develop.

$\bar{K}_1$ was calculated according to eqs. [7] and [8], by least squares fitting and interpolation. Y_c vs. M_{AtOH} and $M_{At}.M_{AtOH}$ curves were fitted by least squares for each of several experimental runs. Y_c vs. M_{At} data points were then obtained by interpolation, for selected values of M_{AtOH} as a parameter. $\bar{K}_1$ values were then obtained as the slopes of linear Y_c vs. M_{At} fits with constant values of M_{AtOH}. The calculated $\bar{K}_1$ values are listed in Table 2, together with the corresponding M_{AtOH} values. The relative standard deviation is only 1.8%, but there could also be a systematic error in $\bar{K}_1$. Because it is intended that the $\bar{K}_1$ value be available for subsequent calculations, an extra figure beyond the significant figures has been retained for the purpose of limiting errors from computer truncation. In principle, $\bar{K}_1$ should decrease with increasing coverage of protonated carboxyl groups. The values in Table 2 do not show such an effect outside the limits of error, however. The sorption equilibrium function for hydroxyatrazine, $\bar{K}_2$, was calculated in a similar way using eq. [9]. According to Table 3, the equilibrium function for hydroxyatrazine has a much larger standard deviation. It is also evident that hydroxyatrazine is somewhat more strongly sorbed, with an equilibrium function about five times as great as that of atrazine. If $\bar{K}_2$ has any of the expected dependence on site coverage, it is also obscured by experimental error.

Once the values of $\bar{K}_1$ and $\bar{K}_2$ were available in Tables 2 and 3, it became possible to estimate separately the sorption site coverages of atrazine and hydroxyatrazine during the course of an experiment. Because the total sorption could be calculated

by material balance and because $\bar{K}_2$ has a relatively large error, the hydroxyatrazine coverage was actually calculated by difference. The three sorption curves in Fig. 9 present some very important information. The maximum site coverage was only a few percent of the carboxyl groups. This means that the total range of weak acid K_a values encountered by the sorbed molecules was too small for the sorption equilibrium function to vary to any extent visible outside experimental error. The changes are, however, significant mole percentages of the maximum atrazine sorption. This implies that the experimental data should be calculated with the variable coverage rate laws in

eqs. [15] and [22]. If the changes in site coverage are neglected, then the pseudo first order rate constants for hydroxyatrazine is not obtained.

B. Apparent rate constants in the solution phase

The apparent rate constant k_{r1} for the disappearance of atrazine from solution was calculated from the slopes of linear least squares fits, using eq. [15]. The apparent rate constant k_{p1}, for the appearance of hydroxyatrazine in solution, was more difficult to calculate. It was necessary to rearrange eq. [22] for least squares fitting, and to numerically evaluate the integral on the right hand side.

C. Tests for parameters against theory

The ratios (k_{p1}/k_{r1}) and $(\bar{K}_2/\bar{K}_1)$ were used for testing experimental results against theory, in accordance with eq. [24]. The calculated values and test results have been tabulated in Table 4. The relative amounts of humic acid and reaction solution are also indicated for the samples, since the observed values of k_{r1} and k_{p1} depend on them. The experimental results are consistent with theory, within the limits of the estimated experimental error. The errors are contributed by at least two factors. One is that the quantity and quality of the hydroxyatrazine data are not as good as those for atrazine. The measurements are more difficult to make. The other factor is that the partial derivative calculations for $\bar{K}_1$ and $\bar{K}_2$ tend to produce systematic errors from the original errors of measurement. Once the validity of the experimental parameters k_{r1} and k_{r2} had been tested, the final step was their use for the calculation of k_{r2}, the pseudo first order rate constant for hydrolysis on the catalytic sorption sites.

D. Calculation of pseudo first order rate constants

Three different methods were found for calculating k_{r2}, the pseudo first order rate constant for hydrolysis on the catalytic sorption sites. (*a*) The k_{r1} values obtained from atrazine measurements were used with eq. [25], for each of several chemical kinetics samples. (*b*) The k_{p1} values obtained from the slopes of fitted hydroxyatrazine measurements as previously described, were used with eq. [26] for various chemical kinetics samples. (*c*) The intercepts of fitted hydroxyatrazine measurements from various chemical kinetics samples were used in accordance with eq. [21] and the rearranged form of eq. [22].

The best quality k_{r2} data have been obtained from the atrazine calculations (*a*), and these have been tested and tabulated in Tables 4 and 8 for future use.[4] The hydroxyatrazine calculations (*b*) and (*c*) gave k_{r2} values of similar quality, which was inferior to that of the atrazine values. The hydroxyatrazine slope and intercept values have been listed in Table 9 for comparison with the atrazine slope values in Fig. 10 and Table 8. The hydroxyatrazine values for k_{r2} are too scattered for useful correlations, but within the limits of experimental error they are consistent with the atrazine data. This judgement takes into account the fact that they are averages whose numerical values are weighted by the spectrum of K_a values of the sorption sites covered.

Figure 9 documents the competition between atrazine and hydroxyatrazine for the catalytic sorption sites. No indication of a sorption limit was found, and without site saturation the atrazine sorption and hydroxyatrazine sorption are not additive. None the less, the more strongly sorbed hydroxyatrazine selectively preempts the most strongly catalytic sites. The anticipated "catalyst poisoning" is seen as a decrease in the k_{r2} in the experimental results of Fig. 11. This is also consistent with Brönsted acid catalysis theory.

[a]Average $(k_{p1}/k_{r1}) = 6.82$; $\sigma = 2.93$; $(K_2/K_1) = 4.90$, $\sigma = 1.39$.

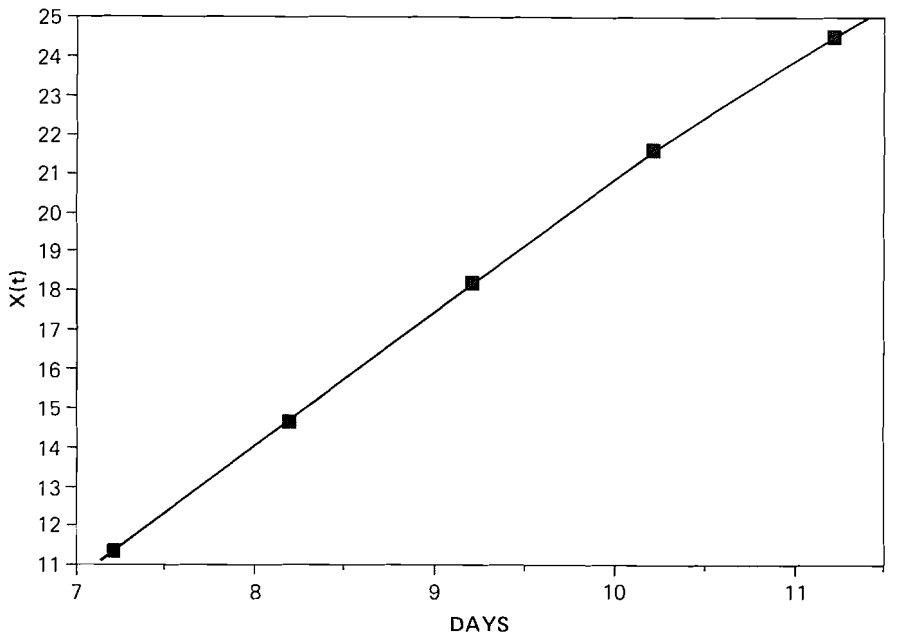

FIG. 10. The hydroxyatrazine site coverage function, $X(t) = (\theta_c/M_{At})$. See eq. [72]. Sample 4.

In practice it was found, however, that the change in site coverage during a kinetics run was not sufficiently great relative to the number and precision of the measurements, for any change in the rate constant to be detected. The expected dependence shows up instead when a chord plot is made with a whole set of kinetics runs, as has been done in Fig. 11. There are several conclusions to be drawn from this chord plot. (*1*) The rate constant k_{r2} decreases with decreasing acid strength of carboxyl groups, as predicted by Brönsted acid catalysis theory (39). (*2*) The k_{r2} values obtained are no better than ±20%, and improved data sets should be available before any attempt is made to calculate correlations between k_{r2} and the K_a values of a humic carboxyl groups. (*3*) Correlations of k_{r2} vs. K_a will continue to require the use of chord plots because changes in k_{r2} will not be detected within individual kinetics run. (*4*) Future correlations of k_{r2} vs. K_a should be calculated with two or three times as many chords. Each of these should have a statistically sound set of data points confined to chords that are only 1/3 to 1/2 the lengths of those in Fig. 10. This would require two or three times as many kinetics samples, each run for 1/3 to 1/2 the length of time. (*5*) The emergence of chord plots implies that the k_{r2} value obtained from each kinetics run is some sort of average value, corresponding to a set of occupied carboxyl groups that has a range of K_a values. Assuming that the carboxyl groups have a continuum of K_a values, then there should be a corresponding continuum of k_{r2} values. From the point of view of future modelling, it would be useful to know this continuous k_{r2} spectrum. Its calculation from the experimental averages would require, however, more and better data.

Calculated values for the pseudo first order rate constant, k_{r2}, are listed for future use, in the Depository of Unpublished Data.[4]

E. The comparison of humic acid and fulvic acid catalysts

An equation has been published for fulvic acid solutions, which describes the atrazine hydrolysis rate constant in terms of

both pH and the molarity of protonated carboxyl groups. If one assumes that the ion exchange particles of the aqueous humic acid suspension have internal gel solutions (52, 53), then it should be possible to compare k_{r2} with the rate constants in equivalent fulvic acid solutions.

Catalysed hydrolysis reactions are commonly expected to be fast. This expectation must be qualified, however, by a consideration of the number of catalytically active binding sites occupied, and their catalytic activities. This has been demonstrated by the solution phase fulvic acid catalysis of atrazine (45, 58).

While it was not possible to determine the spectrum of K_a values for the Chernozem humic acid used here, the carboxyl groups of a typical humic acid would have K_a values in about the range of 1.0×10^{-4} to 1.0×10^{-5}. Considering that peat soils quite commonly contain 80 wt% water, it seems reasonable to assume this value for the Chernozem humic acid. Using these values and the measured value for the carboxyl content, a corresponding range of k_{r2} values can be calculated for the internal gel solution. The calculations allow for the constraint on the movement of H^+, imposed by the Donnan potential in the absence of inorganic salts. For the internal gel solution, $K_A = 1.0 \times 10^{-4}$ gives $M_{AH} = 0.138\,M$ and pH = 2.46. Likewise, $K_A = 1.0 \times 10^{-5}$ gives $M_{AH} = 0.140\,M$ and pH = 2.94. The published fulvic acid equation predicts $k_{r2} = 1.1\ day^{-1}$ over this whole range. This is four to six times larger than the values actually found for the Chernozem humic acid. The difference between humic acid and fulvic acid primarily reflects the fact that humic acids generally have more weakly acidic carboxyl groups than fulvic acids do.

It is conventional practice to calculate rate constants from initial rates for the following types of experiments: (*a*) those complicated by a back reaction; (*b*) those which do not permit the estimation of equilibrium constants and site coverages for both reactant and product during the course of a kinetics run; (*c*) those which must relate to practical systems in which only the most strongly catalytic sorption sites will be occupied by the reactants.

As shown, none of these conditions applies to the present work.

Conclusions

Hydroxyatrazine is more strongly sorbed than atrazine is, and this caused the sorption equilibria to shift during the course of chemical kinetics runs. The reaction rate laws must account for this effect in order for correct rate constants to be calculated. The apparent rate constants for the disappearance of atrazine from solution and for the appearance of hydroxyatrazine in solution are different from each other and from the pseudo first order rate constant for the hydrolysis reaction on the catalytic sorption sites. The apparent rate constants are only empirical experimental parameters that depend directly on experimental conditions. Because they have no direct chemical meaning, they cannot be used for comparing experiments or samples, and cannot be used for the modelling of practical field problems. Any attempts to use these parameters in this way would cause serious misjudgements and general confusion. Health risks or crop damage could result. The correct chemical kinetics reaction rate constant can be calculated, however, for future use in comparisons, predictions, and modelling. The correct rate constant depends on the acid strength of catalytically active carboxyl groups as predicted by the Brönsted acid catalysis theory. The quantitative investigation of this effect would make an important contribution to future modelling.

Excess properties of mixtures of some *n*-alkoxyethanols with organic solvents. V. Excess enthalpies of 2-butoxyethanol with normal alkanes at 298.15 K[1]

JOSE CARLOS COBOS, ISAIAS GARCIA, AND CARLOS CASANOVA
Departamento de Física Aplicada II, Universidad de Valladolid, 47071-Valladolid, Spain

Received March 3, 1988

JOSE CARLOS COBOS, ISAIAS GARCIA, and CARLOS CASANOVA. Can. J. Chem. **66**, 2618 (1988).

The excess molar enthalpy H^E has been determined as a function of mole fraction x at 298.15 K and atmospheric pressure for five (2-butoxyethanol + *n*-alkane) mixtures. The *n*-alkanes were *n*-heptane, *n*-octane, *n*-decane, *n*-dodecane, and *n*-tetradecane. The mixtures show positive and unsymmetrical H^E, skewed towards low mole fractions of 2-butoxyethanol, and whose value increases with the chain length n of the alkane.

JOSE CARLOS COBOS, ISAIAS GARCIA et CARLOS CASANOVA. Can. J. Chem. **66**, 2618 (1988).

Opérant à 298,15 K et à pression atmosphérique, on a mesuré l'enthalpie molaire en excès, H^E, de cinq mélanges (butoxy-2 éthanol + *n*-alcane) en fonction de la fraction molaire, x. Parmi les *n*-alcanes, on a utilisé le *n*-heptane, le *n*-octane, le *n*-décane, le *n*-dodécane et le *n*-tétradécane. Avec une augmentation de la longueur de la chaîne n de l'alcane, tous les mélanges présentent un H^E qui est à la fois positif, asymétrique et déplacé vers les basses fractions molaires de butoxy-2 éthanol.

[Traduit par la revue]

Introduction

The study of alkoxyalkanols is of interest not only because of their wide use as industrial solvents, but also from the more theoretical point of investigating the effect of the simultaneous presence of etheric and hydroxyl groups on the interactions of such molecules.

In spite of the potential applications of *n*-alkoxyethanols there are relatively few experimental thermodynamics studies on this class of substances with organic solvents; the most studied medium is water (1). In particular, for mixtures with *n*-alkanes, to our knowledge, data only exist for excess enthalpies and isobaric vapor–liquid equilibria of 2-ethoxyethanol + *n*-octane (2); isobaric vapor–liquid equilibria of 2-butoxyethanol + *n*-octane (3); isobaric vapor–liquid equilibria of 2-ethoxyethanol + *n*-hexane (4); mutual solubilities of alkanes and 2-methoxyethanol (5); infinite-dilution activity coefficients of *n*-heptane with 2-methoxyethanol (6); excess volumes and isentropic compressibilities of 2-ethoxyethanol + *n*-heptane (7); heats of solutions of some poly-alkoxyalkanols with *n*-dodecane (8); excess enthalpies of 2-butoxyethanol + *n*-heptane (9), and excess enthalpies of some alkoxyalkanols with *n*-heptane (10). Therefore there is no systematic study on the behaviour of *n*-alkoxyethanols where the chain length of the *n*-alkanes is varied.

In this paper we extend our previous investigations on the excess molar functions (H^E, V^E, and C_p^E) of binary liquid mixtures of *n*-alkoxyethanols with organic solvents (11–15) to the excess molar enthalpies of 2-butoxyethanol (1) + *n*-alkane (2) mixtures. Measurements with *n*-heptane, *n*-octane, *n*-decane, *n*-dodecane, and *n*-tetradecane at 298.15 K and atmospheric pressure are reported.

Experimental

Liquid components

All chemicals used were from Fluka. *n*-Heptane (puriss p.a., with purity >99.5 mol%), *n*-octane (purum olefin-free, with purity >99 mol%), *n*-decane (purum olefin-free, with purity >99 mol%), *n*-dodecane (purum olefin-free, with purity >98 mol%), and *n*-tetradecane (puriss olefin-free, with purity >99 mol%), were used without further purification. 2-Butoxyethanol (purum, stated purity >98 mol%), was fractionally distilled many times in a glass 100 theoretical plates column, at a reflux ratio of approximately 25:1 at 3 kPa of reduced pressure, until no measurable impurities were observed in a vapor-phase chromatography trace analysis. The final purity was estimated to be 99.9%. Prior to the experimental measurements, all liquids were carefully dried over molecular sieves beads (Union Carbide type 4A) from Fluka.

Excess enthalpy measurements

A standard Calvet type microcalorimeter, equipped with a batch mixing cell with small (<2%) gas phase and the experimental technique of Paz Andrade *et al.* (16) was used to determine the excess molar enthalpies over the entire mole fraction range, x, of 2-butoxyethanol. Details of the experimental technique and of the accuracy attainable have been described previously (11, 12, 17).

Binary mixtures were prepared by mass. All weighings were corrected for buoyancy effects, and the error on the final mole fraction is estimated to be less than 0.0001. Conversion to molar quantities is based on the relative atomic mass table of 1975, issued by IUPAC.

Results

Experimental densities and refractive indices at 298.15 K of the pure *n*-alkanes were in good agreement with published values (18, 19). For the purified 2-butoxyethanol our observed density at 298.15 K $\rho = 896.0\ \mathrm{kg\ m^{-3}}$, determined in a SODEV densimeter (Model 02D), is in good agreement with available literature values (9, 20).

The results of our measurements of H^E as a function of x at 298.15 K and atmospheric pressure are summarized in Table 1. An equation of the type:

$$[1]\quad H^E(\mathrm{J\ mol^{-1}}) = x(1-x)\sum_{i=0}^{n} A_i(x)^{i/2}$$

was fitted to each set of results by least-squares regression with all points weighted equally. The coefficients A_i and the corresponding standard deviations $s(H^E)$ are given in Table 2. For all mixtures $s(H^E)/H^E(\mathrm{max}) < 0.01$, where $H^E(\mathrm{max})$ denotes the maximum value of the excess molar enthalpy with respect to mole fraction x, in accord with the precision attainable with the instrument used. A graphical representation of the experimental points together with the smoothing curves is shown in Fig. 1.

For mixtures with *n*-heptane our results differ by less than 1% in the range $0.3 < x < 0.7$ from those of the Kimura *et al.* (10), who used an isothermal displacement calorimeter. Their experi-

mental values, those that do not appear in the ref. 10, may be found in ref. 21. Outside this range of mole fraction the differences are slightly greater. On the other hand, the results of Villamañán *et al.* (9) measured with a Picker microcalorimeter are 5% lower than ours for $x < 0.7$; showing better agreement at high concentrations of 2-butoxyethanol. For other systems there are no available literature data for comparison.

Discussion

For all the mixtures studied H^E is positive over the whole composition range and as expected the endothermic mixing shows a higher intensity as the chain length of the n-alkane increases. This increase is approximately linear at equimolecular composition, $x = 0.5$, and can be estimated to be of the order of 50 J/mol for each —CH_2— group added to the n-alkane, beginning with n-heptane.

Both previous ir and microwave spectroscopic (23–29) and calorimetric (8, 10, 30) studies indicate that the molecules of n-alkoxyethanol are self-associated and form intermolecular and, more interesting, intramolecular hydrogen bonds. This second possibility is due to the simultaneous presence of both oxygen and hydroxyl groups in the same molecule, and it can be used to study the intramolecular heteroproximity effect in theoretical models of liquid mixtures based on the method of group contributions.

Our present results confirm this behaviour on the n-alkoxyethanol molecules and allow us to rationalize the results of the previous studies. Firstly, they suggest that the 2-butoxyethanol molecules form intermolecular H-bonds as in the alkanols. In fact, we observed similar characteristics between the data reported here and the data on mixtures formed with n-alkanols and solvents like alkanes or ethers (21, 22): large positive value and unsymmetrical excess enthalpy, skewed towards low mole fractions of 2-butoxyethanol or n-alkanol. Our previous work on mixtures of n-alkoxyethanols with ethers (9, 12) are in agreement at this point.

Secondly, the significantly higher H^E values found here on 2-butoxyethanol + n-alkane mixtures in comparison with the well-known values for homomorphic mixtures of n-alkanol + n-alkane (21) suggest that the intermolecular self-association of the n-alkoxyethanols are lower than those of n-alkanols. This may be due to the possible existence of intramolecular H-bonds in these molecules, which effectively decreases the alcohol self-association capability. Previous data of H^E on n-alkoxyalkanol + n-heptane mixtures (10), and the large excess molar

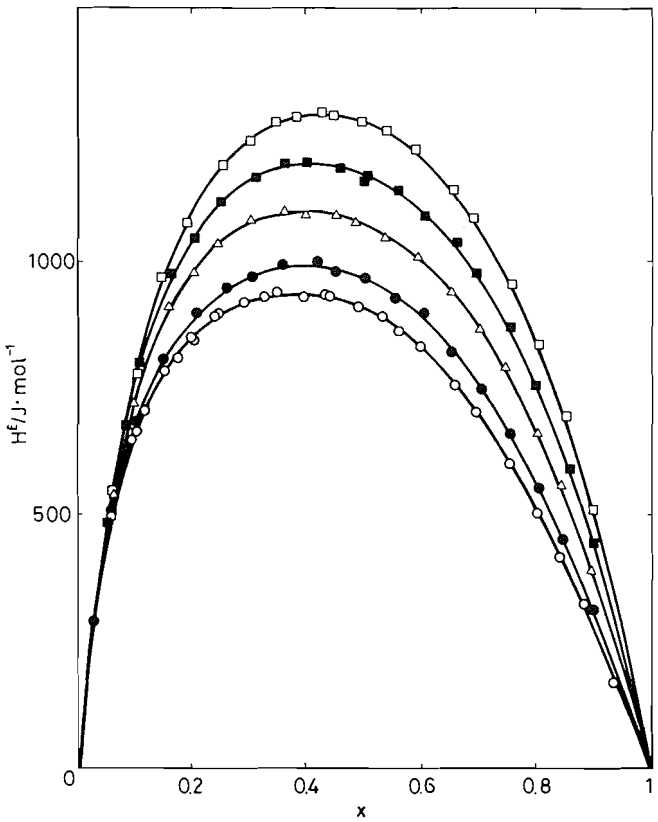

FIG. 1. Experimental excess molar enthalpies, H^E, for $x C_4H_9O(CH_2)_2OH + (1 - x)C_nH_{2n+2}$ at 298.15 K: (○), $n = 7$; (●), $n = 8$; (△), $n = 10$; (■), $n = 12$, and (□), $n = 14$. Full curves represent the smoothing eq. [1] with the coefficients of Table 2.

volume V^E of 2-ethoxyethanol + *n*-heptane (7), also confirm that the hydroxyl terminal group into 2-butoxyethanol becomes hindered by possible formation of intramolecular H-bonds.

On the other hand, it is important to note which dipole moments of the *n*-alkoxyethanols are greater than those of the *n*-alkanols (18, 31). Although in this work we were able to measure H^E for mixtures of 2-butoxyethanol with long *n*-alkanes without any signs of partial miscibility, it is well-known (5, 6, 32) that other *n*-alkoxyethanols have upper critical solution temperatures (UCST) when mixed with linear and cyclic alkanes at temperatures over 298.15 K, and that the UCST of 2-butoxyethanol with long alkanes are near 282 K.

These large UCST compared with those of homomorphic *n*-alkanol mixtures using the same alkanes can be interpreted in terms of a smaller intermolecular self-association. The existence of intramolecular H-bonds in *n*-alkoxyethanols may enhance the dipolar interactions between the more anisotropic molecules. In this work we can see this effect in the composition dependence of H^E. This dependence is unsymmetrical and skewed towards low mole-fractions of 2-butoxyethanol, but less than that in the corresponding *n*-alkanol + *n*-alkane mixtures.

One last remark is on the H^E values of the *n*-alkoxyethanols in mixtures with non-polar but polarizable solvents such as benzene or ethylbenzene (2, 30). These H^E values are lower than those with *n*-alkanes. This contrasts with the behaviour of *n*-alkanols, where the H^E values of benzene mixtures are greater than those of *n*-alkanes.

Received May 5, 1988

WOLFGANG KLIEGEL, MAHMOOD TAJERBASHI, STEVEN J. RETTIG, and JAMES TROTTER. Can. J. Chem. **66**, 2621 (1988).

Details of the syntheses, physical properties, and crystal structures of the title compounds are reported. Crystals of 5,5-difluoro-2,2-pentamethylene-1,4,6-trioxa-3*a*-azonia-5-borata-1,2,3,4,5,6-hexahydrobenzo[*h*]azulene are triclinic, a = 6.1576(3), b = 11.2651(3), c = 10.8118(3) Å, α = 109.747(3), β = 105.807(4), γ = 92.976(4)°, Z = 2, space group $P\bar{1}$, and those of 2,2-pentamethylene-5,5-diphenyl-1,4,6-trioxa-3*a*-azonia-5-borata-1,2,3,4,5,6-hexahydrobenzo[*h*]azulene are monoclinic, a = 9.8549(6), b = 10.9242(6), c = 41.263(2) Å, β = 92.717(6)°, Z = 8, space group $P2_1/n$. Both structures were solved by direct methods and were refined by full-matrix least-squares procedures to R = 0.045 and 0.042 for 2344 and 4248 reflections with $I \geq 3\sigma(I)$, respectively. The molecules were both found to possess a seven-membered chelate structure, the *O,O*-chelating ligand being strongly bound to the X_2B moiety. Two conformational isomers of the X = Ph compound were found in the solid state. The 2-oxazoline *N*-oxide moieties present in both compounds are the first to be structurally characterized. Important mean libration-corrected bond lengths are: O—B = 1.491 and F—B = 1.387 Å for X = F; O—B = 1.511 and C—B = 1.620 Å for X = Ph.

WOLFGANG KLIEGEL, MAHMOOD TAJERBASHI, STEVEN J. RETTIG et JAMES TROTTER. Can. J. Chem. **66**, 2621 (1988).

On rapporte les détails relatifs à la synthèse, aux propriétés physiques et à la structure cristalline des composés mentionnés dans le titre. Les cristaux du difluoro-5,5 pentaméthylène-2,2 trioxa-1,4,6 azonia-3*a* borata-5 hexahydro-1,2,3,4,5,6 benzo[*h*]azulène sont tricliniques, avec a = 6,1576(3), b = 11,2651(3) et c = 10,8118(3) Å, α = 109,747(3), β = 105,807(4) et γ = 92,976(4)°, Z = 2 et groupe d'espace $P\bar{1}$ alors que ceux du pentaméthylène-2,2 diphényl-5,5 trioxa-1,4,6 azonia-3*a* borata-5 hexahydro-1,2,3,4,5,6 benzo[*h*]azulène sont monocliniques avec a = 9,8549(6), b = 10,9242(6) et c = 41,263(2) Å, β = 92,717(6)°, Z = 8 et groupe d'espace $P2_1/n$. On a résolu les deux structures par des méthodes directes et on les a affinées par les méthodes des moindres carrés (matrice entière) jusqu'à des valeurs respectives de R = 0,045 et 0,042 pour 2344 et 4248 réflexions avec $I \geq 3\sigma(I)$. On a trouvé que les deux molécules possèdent des structures comportant un chélate à sept chaînons dans lesquels le ligand qui se chélate en *O,O* est fortement lié à la portion X_2B. A l'état solide, on a observé les deux isomères conformationnels du composé avec X = Ph. Les portions *N*-oxyde de l'oxazoline-2 qui sont présentes dans chacun des composés sont les premiers à être caractérisés d'un point de vue structural. Les longueurs de liaison moyennes corrigées pour la libration sont les suivantes : O—B = 1,491 et F—B = 1,387 Å dans le composé avec X = F; O—B = 1,511 et C—B = 1,620 Å pour le composé avec X = Ph.

[Traduit par la revue]

Introduction

In the course of our investigations of the formation, structure, and reactivity of *N*-substituted hydroxamic acids (1–4) we attempted to synthesize the difluoroboron chelate **2** by reaction of the β-hydroxyalkylated salicylhydroxamic acid **1** with trifluoroborane in diethyl ether solution. A crystalline reaction product was obtained which not only possesses the expected difluoroboron group (as a result of HF elimination), but has also lost a water molecule as shown by elemental analysis and ir and nmr spectroscopy. There are no OH bands in the ir spectrum nor are any OH signals present in the ^{1}H nmr spectrum that could arise from alcoholic, phenolic, or hydroxamic hydroxyl groups.

The condensation product could be an intramolecular alkylation product derived from an intermediate **2** by the formation of the cyclic ether **3** which features the BF_2 hydroxamate grouping. The alkylation of phenols with alkanols in the presence of Lewis acids like BF_3 is well documented (5). Less probable, but not excludable spectroscopically, are the alternative structures **4**, featuring a seven-membered BF_2 chelate ring containing a bidentate *N*-(2-hydroxyalkyl)amide ligand, and **5**, with a phenolic hydroxyl oxygen atom and an amide carbonyl oxygen atom as ligands in a six-membered chelate ring system. Structure **4** would require the formation of a 3-hydroxy-1,2-benzisoxazole ring by cyclodehydration, possible in the presence of BF_3. Comparable cyclocondensations of 2-hydroxybenzohydroxamic acids have been conducted with thionyl chloride (6) or carbonyldiimidazole (7) as dehydrating reagents. A ring closure to the four-membered oxazetidine system in **5** seems very unfavorable under the applied conditions. An intramolecular alkylation of the hydroxamic acid function by the *N*-(2-hydroxyalkyl) group is more likely. This would lead to the structure **6** with boron being chelated by the phenolic and hydroxylamine oxygen atoms. The seven-membered difluoroboron chelate **6** with a B—O—N—C—C—C—O ring system resembles the difluoroboron chelates of salicylaldehyde nitrones **7** (8).

For further elucidation of the chelate structure and of the chelate formation pathway, **1** was also reacted with oxybis(diphenylborane), a well-suited reagent for trapping hydroxamic acid ligands (2–4). A crystalline condensation product was obtained which contains a diphenylboron grouping and as in the reaction of **1** with BF_3, a water molecule has been eliminated. The crystal structures of both of these condensation products have been determined.

Experimental

N-Hydroxy-N-(1-hydroxycyclohexyl)methyl-salicyloylamide, 1

Compound **1** was prepared by an acylating method reported for *N*-phenylsalicylhydroxamic acid (9) with slight modifications (10). Melting point 155°C (crystallized from diethyl ether). *Anal.* calcd. for $C_{14}H_{19}NO_4$ (fw 265.3): C 63.38, H 7.22, N 5.28; found: C 63.16, H 7.55, N 5.22. Infrared (KBr): 3600–2400 (broad O—H), 1610 cm^{-1} (C=O). ^1H nmr (d_6-DMSO/TMS): δ (ppm) = 1.0–2.1 (m, 10 H of $—(CH_2)_5—$), 3.65 (s, CH_2N), 4.11 (s, broad, exchangeable, alkyl OH), 6.7–7.5 (m, C_6H_4), 9.79 (s, broad, exchangeable, N—OH and aryl OH).

5,5-Difluoro-2,2-pentamethylene-1,4,6-trioxa-3a-azonia-5-borata-1,2,3,4,5,6-hexahydrobenzo[h]azulene, 6

1 (0.30 g, 1.13 mmol) and diethyl ether – trifluoroborane (0.32 g, 2.26 mmol) were dissolved in 70 mL dry diethyl ether and refluxed for 20–30 min. During evaporation of the solvent *in vacuo*, boric acid (32 mg) precipitated and was separated. The remaining oil was treated with diethyl ether until crystallization began after 2 days at room temperature. Yield: 0.22 g (66%) of colorless crystals, mp 150°C (from ether). *Anal.* calcd. for $C_{14}H_{16}BF_2NO_3$: C 56.98, H 5.46, N 4.75; found: C 56.94, H 5.60, N 4.64. Infrared (KBr): 1660 cm^{-1} (C=N). ^1H nmr (d_6-DMSO/TMS): δ (ppm) = 1.20–2.25 (m, 10 H of $—(CH_2)_5—$), 4.23 (s, CH_2N), 6.8–7.7 (m, C_6H_4). Crystals suitable for X-ray analysis were obtained by recrystallization from diethyl ether.

2,2-Pentamethylene-5,5-diphenyl-1,4,6-trioxa-3a-azonia-5-borata-1,2,3,4,5,6-hexahydrobenzo[h]azulene, 8

1 (0.53 g, 2 mmol) and oxybis(diphenylborane) (0.35 g, 1 mmol) were refluxed in 80 mL of benzene for 15 min. After evaporation of the solvent and the addition of diethyl ether, crystallization started. Yield: 0.50 g (60%) of colorless crystals, mp 159–160°C (from ether). *Anal.* calcd. for $C_{26}H_{26}BNO_3$: C 75.92, H 6.36, N 3.40; found: C 76.30, H 6.52, N 3.42. Infrared (KBr): 1645 cm^{-1} (C=N). ^1H nmr ($CDCl_3$/TMS): δ (ppm) = 1.2–2.0 (m, 10 H of $—(CH_2)_5—$), 3.89 (s, CH_2N), 6.6–7.6 (m, 14 H of Ph_2B and C_6H_4). The substance gives a blue color reaction with diphenylcarbazone (11) in methanolic solution, indicating the presence of a Ph_2B moiety. Crystals suitable for X-ray analysis were obtained by recrystallization from diethyl ether.

X-ray crystallographic analyses of 6 and 8

Crystallographic data for the two compounds are presented in Table 1. Unit-cell parameters were refined by least-squares on 2 sin θ/λ values for 25 carefully centered reflections with 2θ = 80–96° for **6** and 50–92° for **8**. The intensities of three standard reflections, measured each hour of X-ray exposure time throughout the data collections,

[a]Temperature 295 K, Enraf-Nonius CAD4-F diffractometer, Cu-K$_\alpha$ radiation (λK_{α_1} = 1.540562, λK_{α_2} = 1.544390 Å), nickel filter, takeoff angle 2.7°, aperture (2.0 + tan θ) × 4.00 mm at a distance of 173 mm from the crystal, scan range extended by 25% on both sides for background measurement, $\sigma^2(I) = C + 2B + [0.04(C - B)]^2$ (C = scan count, B = normalized background count), function minimized: $\Sigma w(|F_o| - |F_c|)^2$ where $w = 1/\sigma^2(F)$, $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$, $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$, $S = (\Sigma w(|F_o| - |F_c|)^2/(m - n))^{1/2}$. Values given for R, R_w, and S are based on those reflections with $I \geq 3\sigma(I)$.

showed only small random variations. The data were reduced[2] and, for **8**, corrected for absorption (numerical integration). No absorption correction was applied for **6** due to irregularity of the crystal surface. Both structures were solved by direct methods, the positions of all non-hydrogen atoms being determined from E-maps and those of the hydrogen atoms from subsequent difference Fourier syntheses. The non-hydrogen atoms were refined with anisotropic thermal parameters. Hydrogen atoms in **6** were refined with isotropic thermal parameters and those in **8** were fixed in calculated positions with C(sp^2)—H = 0.97, C(sp^3)—H = 0.98 Å, and $U_H \propto U_{\text{bonded atom}}$. Neutral atom scattering factors for all atoms and anomalous dispersion corrections (F, O, N, and C) were taken from ref. 12. Isotropic Type I extinction corrections were applied (13–15), the final values of g being 0.36(4) × 10^4 for **6** and 0.73(9) × 10^4 for **8**. Final positional and anisotropic thermal parameters appear in Tables 2 and 7[3], respectively. Measured and calculated structure factors have been placed in the Depository of Unpublished Data.[3]

The thermal motion in both structures has been analysed in terms of the TLS model (16). The rms errors in the temperature factors U_{ij} (derived from the least-squares analyses) are 0.0009 and 0.0020 Å^2 for **6** and **8**, respectively. Analyses of the entire molecules indicated significant independent motion. The structural subunits O_2BF_2, O(3)C(3)—C(8), O(1)C(1)C(2)C(10)—C(14), and O(1)O(2)NC(2)-C(8)C(9) (Fig. 1) were separately analysed for **6** (rms ΔU_{ij} = 0.0011–0.0018 Å^2); and for each of the two independent molecules of **8** the subunits PhB, O(3)C(3)—C(9), O(1)C(1)C(2)C(10)—C(14), and the fused-ring systems were analysed (rms ΔU_{ij} = 0.0019–0.0040 Å^2). The appropriate bond distances have been corrected for libration (16, 17), using shape parameters q^2 of 0.08 for all atoms involved. Corrected bond lengths appear in Table 3 along with the uncorrected values; bond angles appear in Table 4 and intra-annular torsion angles in Table 5. Hydrogen atom parameters (Table 6), bond lengths and angles involving hydrogen, and a complete listing of torsion angles (Tables 8–10) have been deposited.[3]

[2]The computer programs used include locally written programs for data processing and locally modified versions of the following: MULTAN 80, multisolution program by P. Main, S. J. Fiske, S. E. Hull, L. Lessinger, G. Germain, J. P. Declercq, and M. M. Woolfson; AGNOST, absorption corrections, by J. A. Ibers; ORFLS, full-matrix least-squares, and ORFFE, function and errors, by W. R. Busing, K. O. Martin, and H. A. Levy; FORDAP, Patterson and Fourier syntheses, by A. Zalkin; ORTEP II, illustrations, by C. K. Johnson.

*U_{eq} = (1/3) trace of diagonalised U.

Results and discussion

The structure analyses confirm the boron chelate structures **6** and **8**. Surprisingly, in both cases the hydroxamic acid function does not serve as a bidentate ligand but rather has been transformed into an imidate *N*-oxide group by intramolecular alkylation. This imidate *N*-oxide function is bound to the boron atom only via the *N*-oxide oxygen atom, the second donor atom of the resulting bidentate chelating ligand being the phenolate oxygen atom.

The cyclocondensation of the *N*-(2-hydroxyalkyl)hydroxamic acid, leading to a 2-oxazoline *N*-oxide, is obviously not only possible in the presence of BF_3 but also proceeds under the influence of diphenylborinic anhydride, $(Ph_2B)_2O$, which should be a poorer acceptor (18) and therefore act as a weaker Lewis acid. Syntheses of 2-oxazolines by the cyclocondensation of *N*-(2-hydroxyalkyl)amides are well-known (19), whereas 2-oxazoline *N*-oxides have been reported only sporadically in the recent literature, prepared either by *N*-oxidation of the corresponding 2-oxazoline (20) or by condensation of *N*-(2-hydroxyalkyl)hydroxylamines and *ortho*-esters/amides (21).

The crystal structures of **6** and **8** both consist of discrete molecules, the shortest intermolecular distances between non-hydrogen atoms being F(1)···C(9) ($x - 1, y, z$) = 3.254(2) Å for **6** and O(1)···C(25) ($1/2 - x, 1/2 + y, 1/2 - z$) = 3.394(4) Å for **8**. Molecules are associated in the solid state by possible weak interactions: C(10)—H(10b)···F(1) ($1 + x, y, z$) and C(2)—H(2b)···O(2) ($1 - x, -y, 1 - z$) for **6** and C(4)—H(4)···O(2) ($1/2 - x, y - 1/2, 1/2 - z$) for **8** (H···O/F = 2.56(3), 2.51(3), and 2.54 Å; C···O/F = 3.371(3), 3.487(3), and 3.451(3) Å; C—H···O/F = 145(2), 168(2), and 156°, respectively). The two crystallographically independent molecules of **8** are, in fact, conformational isomers; in the unprimed molecule O(1) occupies an equatorial position of the cyclohexane ring while in the primed molecule O(1′) is in an

axial position at C(1′). In **6**, only the equatorial conformer is present (see Fig. 1).

In the formation of the boron chelates, **6** and **8**, the seven-membered chelate ring system is preferred over a five-membered (like **3**) or a six-membered chelate system (like **5**), in spite of the fact that five- and six-membered boron chelates are very stable and frequently reported. Seven-membered boron chelates are rare in the literature (8). The boron chelates of salicylaldehyde nitrones like **7** or **9**, however, do possess the same seven-membered ring skeleton as observed for **6** and **8** (8, 22). The structural dimensions of the chelate ring BONCCCO of **9**, established by X-ray analysis (22), are strikingly similar to those observed for **6** and **8** (especially so for the latter as expected). The seven-membered chelate ring in **8** has a distorted envelope-like conformation very similar to that observed for **9** while that in **6** has a different conformation, best described as a "twist-envelope" (see Table 5). The bulkier phenyl substituents at boron and the longer intracyclic B—O

distances in **8**, relative to those in **6**, are believed to be primarily responsible for the differences between the chelate ring conformations.

The C(9)—N bond distances[4] of 1.294(2) Å in **6** and an average of 1.303(4) Å in **8** are comparable to the C=N$^+$ double bond length of 1.290(2) Å in **9** (22) and demonstrate the iminium salt character within the *B*,*N*-betaine structure of **6** and **8**. A typical iminium salt like *N*,*N*-dimethylisopropylidenimminium perchlorate (23) shows an uncorrected C=N$^+$ bond length of 1.302 ± 0.043 Å. Similar C=N$^+$ distances have been observed in difluoroboron (X = F) and diphenylboron (X = Ph) chelates of *N*-methylacetohydroxamic acid **10** (1, 2), which are also best described as cyclic *B*,*N*-betaines (24). To our knowledge no imidate *N*-oxide groups have been structurally characterized by X-ray analysis. The 2-oxazoline *N*-oxide moieties in **6** and **8** therefore represent the first such examples. The structure of a thioimidate *N*-oxide **11** has recently been reported (25) and shows an uncorrected C=N$^+$ bond distance of 1.303 Å, essentially the same as that observed for the functionally related imidate *N*-oxide group in **8**.

In both compounds, **6** and **8**, the (sp^2)C—O single bonds C(9)—O(1) and C(3)—O(3) are relatively short (1.323(2)–1.347(2), mean 1.337 Å) with an estimated π-bond order (26) of about 0.35, indicative of an interaction with the adjacent π-bond systems. The significant difference between the C(9)—O(1) bond lengths in **6** (1.323(2) Å) and **8** (mean 1.341(3) Å) might result from distortions of the 2-oxazole ring. The sum of the C(9)—O(1) and O(1)—C(1) bonds in both compounds is nearly identical (~2.835 Å). The C(3)—O(3) bond distances correspond to similar phenolate C—O bonds in chelates like **9** (22) or corresponding salicylaldoxime derivatives (27, 28). The N—O bond distances in **6** and **8** (1.369(2) and 1.368(4) Å, respectively) are similar to that observed for the nitrone group in **9** (1.364(3) Å) and, as mentioned above for the nitrone C=N$^+$ bond in **9** (22), indicate the increased iminium salt character of the imidate *N*-oxide group within the *B*,*N*-betaine complexes **6** and **8**.

As in other boron chelates with one *N*-oxide and one phenolate (or alcoholate) ligand (ref. 22 and references therein), the two O—B bond lengths in **6** and **8** are significantly different from one another. As is generally the case, the O—B bonds to the *N*-oxide oxygen atoms are longer than those to the phenolate (or alcoholate) oxygen atoms. The shorter O—B distances in **6** (average 1.491 Å) compared with those in **8** (average 1.511 Å) demonstrate both the better acceptor qualities of the chelated difluoroborenium ion (BF_2^+) relative to the diphenylborenium ion (BPh_2^+) and the dependence of the boron covalent radius on the electronegativity of its substituents. These effects have been noted for the difluoroboron chelate **10** (X = F) (1) and its diphenylboron analog **10** (X = Ph) (2) with average O—B distances of 1.497 and 1.550 Å, respectively. For "Ph_2BO_2" compounds such as **8** the ratio of the average C—B and O—B bond lengths is a good indicator of the overall binding strength of the *O*,*O*-chelating ligand with respect to the "BPh_2^+" moiety (29). These mean C—B/mean O—B ratios range from 1.039 to 1.093 with an average value of 1.061 for 16 "Ph_2BO_2" compounds having six-, seven-, and eight-membered chelate rings (ref. 29 and references therein). The values of 1.080 and 1.063 observed for the two independent molecules of **8** are both indicative of above average binding strength for the ligand. The difference between the bond length ratios for the two molecules of **8**, which are conformational isomers (see above), is a result of significantly longer O—B and shorter C—B distances in the primed molecule (O(1′)-axial isomer). It is possible that the equatorial isomer is a slightly better donor than the axial isomer, consistent with the fact that only the former is observed in the structure of **6**. Differences in mean bond length ratios of up to 0.008 have been noted earlier for conformational isomers, structural polymorphs, and essentially equivalent crystallographically independent molecules (ref. 29 and references therein). The only other "Ph_2BO_2" compound having a seven-membered chelate ring, **9** (22), has a bond length ratio of 1.054.

The uncorrected O—B and F—B distances in **6** lie within the ranges 1.439–1.526 (mean 1.489 Å) and 1.314–1.401 (mean 1.366 Å) observed for "F_2BO_2" compounds having the boron atom in a six-membered ring (30). Compound **6** is the first example of a compound of this type having a seven-membered chelate ring. The ratios of the mean F—B and mean O—B distances in the six-membered "F_2BO_2" chelates range from 0.884 to 0.949 with an average value of 0.915. The value of 0.930 observed for **6** represents a relatively strong ligand binding to the "F_2B^+" moiety, as was also noted for the diphenylboron analog **8**.

The cyclohexane rings in **6** and **8** all have nearly undistorted chair conformations while the oxazoline rings display flattened C(1)-envelope conformations (see Table 5). The oxazoline rings, qualitatively, are nearly planar, the largest deviation from the mean plane being 0.140(3) Å for C(1) of **8**. The

[4]Libration corrected bond lengths (esd's assumed equal to those of the uncorrected values) are employed in the discussion and are compared with similarly treated (16) distances unless otherwise stated.

Charge distributions and chemical effects. XLV. Graphite

ANDREA PELUSO AND SÁNDOR FLISZÁR

Département de Chimie, Université de Montréal, C.P. 6128, Succ. A, Montréal (Qué.), Canada H3C 3J7

Received February 11, 1988

ANDREA PELUSO and SÁNDOR FLISZÁR. Can. J. Chem. **66**, 2631 (1988).

The zero point energy of graphite, ZPE = $(2/3)R\theta_{\parallel} + (1/4)R\theta_{\perp}$, is deduced from Debye's theory by separating the lattice vibrations into two approximately independent parts, with Debye temperatures $\theta_{\parallel}$ (in plane) and $\theta_{\perp}$ (perpendicular). A balanced evaluation gives ZPE $\simeq$ 3.68 kcal mol^{-1}. The bond energies of graphite in its potential minimum are derived from those of polynuclear benzenoïd hydrocarbons using a formula describing bond energies in terms of the charges at the bond-forming atoms. These energies plus a consideration of (*i*) van der Waals interactions between layers ($\sim$1.2 kcal mol^{-1}), (*ii*) ZPE = 3.68, and (*iii*) the experimental heat content, $H_T - H_0$ = 0.25 kcal mol^{-1}, lead to a theoretical enthalpy of atomization, $\Delta H_a(298.15)$ = 174.6, which is $\sim$2% larger than its experimental counterpart, 170.9 kcal mol^{-1}. Exploiting the fact that the carbon atoms are electroneutral in graphite and not so in benzenoïd hydrocarbons, the results obtained for graphite support the approximate validity of bond energies deduced for polynuclear benzenoïd hydrocarbons and of the net charge, 14.8 $\times$ 10^{-3} e, deduced for the carbon atom of benzene.

ANDREA PELUSO et SÁNDOR FLISZÁR. Can. J. Chem. **66**, 2631 (1988).

On a déduit l'énergie au point zéro du graphite, EPZ = $(2/3)R\theta_{\parallel} + (1/4)R\theta_{\perp}$, à l'aide de la théorie de Debye en séparant les vibrations du réseau en deux parties approximativement indépendantes avec les températures de Debye $\theta_{\parallel}$ (dans le plan) et $\theta_{\perp}$ (perpendiculaire au plan). Une évaluation balancée conduit à une valeur de EPZ de 3,68 kcal mol^{-1}. On a déduit les énergies de liaison du graphite à son potentiel minimum à partir de celles d'hydrocarbures benzénoïdes polynucléaires et en faisant appel à une formule décrivant les énergies de liaison en fonction des charges au niveau des atomes conduisant à la formation de liaisons. Ces énergies prises de concert avec (*i*) les interactions de van der Waals entre les couches ($\sim$1,2 kcal mol^{-1}), (*ii*) une valeur de EPZ de 3,68 et (*iii*) l'enthalpie expérimentale, $H_T - H_0$, de 0,25 kcal mol^{-1}, conduit à une enthalpie théorique d'atomisation, $\Delta H_a(298,15)$ = 174,6, qui est environ 2% plus élevée que sa contrepartie expérimentale, 170,9 kcal mol^{-1}. En exploitant le fait que les atomes de carbone sont électriquement neutres dans le graphite alors qu'ils ne le sont pas dans les hydrocarbures benzénoïdes, les résultats qui sont obtenus pour le graphite apportent donc un support à l'hypothèse établissant une validité approximative des énergies de liaison déduites d'hydrocarbures benzénoïdes polynucléaires et de la charge nette de 14,8 $\times$ 10^{-3} e qui a été déduite pour l'atome de carbone du benzène.

[Traduit par la revue]

Introduction

Here we submit an energy analysis of graphite covering (*i*) its vibrational energy and (*ii*) its energy when all the atoms are stationary in their equilibrium positions. Neither aspect is trivial. The first centers, in essence, on an estimate of the zero point energy while the second involves a calculation of bond energies. A comparison with experiment sheds light on the approximate validity of the two components evaluated in this analysis. The final result is instructive as regards the nature of the carbon–carbon bonds in benzenoïd hydrocarbons.

Zero point energy, ZPE

A crystal containing N atoms can be considered as a giant oscillating molecule with $3N$ normal modes of vibration, each with its own frequency, ν_i, and

$$\text{ZPE} = \frac{1}{2}\sum_{i=1}^{3N} h\nu_i$$

Since the frequencies are many and close together, this sum is conveniently replaced by the integral

$$[1] \qquad \text{ZPE} = \frac{1}{2}\int_0^{\nu_{max}} h\nu\rho(\nu)d\nu$$

where $\rho(\nu)d\nu$ is the number of frequencies in the range ν to $\nu + d\nu$ and ν_{max} is the highest allowable frequency. The problem thus rests with the evaluation of the density of states, $\rho(\nu)$.

Our approach follows Debye's model (1, 2) although, in spite of its success in numerous applications, it is unclear how it would perform in the evaluation of ZPE. The point is that the density of states function is not smooth, particularly in the region of high frequencies, as it exhibits occasional peaks corresponding to modes with different polarizations and velocities.[1] With these reservations in mind, we examine as follows the possibility of retrieving an acceptable estimate of ZPE in a simple manner.

Graphite has a layer-like structure. Each carbon is bonded to three other carbon atoms forming a framework of planar benzenoïd rings, with bond distances of 1.42 Å. The planes are separated by $\sim$3.4 Å. The atomic displacements perpendicular to a plane have restoring forces which are much weaker than for displacements in the plane. Briefly, the forces between the atoms in graphite are extremely anisotropic: high frequencies correspond to displacements in a plane, whereas modes in which the basal planes move essentially as rigid units have low frequencies. It is thus reasonable to separate the lattice vibrations into two approximately independent parts (5–16), with distinct Debye temperatures $\theta_{\parallel}$ (in plane) and $\theta_{\perp}$ (perpendicular) (Table 1).

Applying Debye's arguments to a graphite crystal containing N = Avogadro's number of atoms, we obtain after normalization (Appendix) the following expressions for the density of states:

$$[2] \qquad \rho_{\parallel}(\nu) = \frac{4N}{\nu_{max\parallel}^2}\nu$$

[1]Lattice dynamics (and a reasonable sampling of representative frequencies in the first Brillouin zone) gives access to $\rho(\nu)$ (3). This approach is plagued by errors largely due to force constants which, even in refined theoretical calculations, are usually overestimated by up to 20% (4) — a circumstance which would impair any definite assessment regarding the precision of the final result deduced in this way.

TABLE 1. Debye temperatures of graphite (K)

Method	$\theta_\parallel$	$\theta_\perp$	Reference
Calorimetry	2280	760	6
Calorimetry	2300	800	9
LEED	2300	780	10
LEED	2046	774	14
X-ray		700	11
Lattice dynamics	2500	950	8
Semi-continuum theory	2480		16*a*, *b*

$$[3] \qquad \rho_\perp(\nu) = \frac{N}{\nu_{\max\perp}}$$

where $\rho_\parallel$, $\nu_{\max\parallel}$ refer to the modes in the plane and $\rho_\perp$, $\nu_{\max\perp}$ to the perpendicular modes, with

$$[4] \qquad \theta_\parallel = \frac{h\nu_{\max\parallel}}{k} \qquad \theta_\perp = \frac{h\nu_{\max\perp}}{k}$$

Finally, it follows from eqs. [1]–[4] that

$$[5] \qquad \mathrm{ZPE} = \tfrac{3}{8}R\theta_\parallel + \tfrac{1}{4}R\theta_\perp$$

where $R = Nk$ is the gas constant.

Our description of $\rho_\parallel(\nu)$ is just an alternate form of a result given earlier by Komatsu and Nagamiya (16*a*), deduced from a semi-continuum treatment of graphite. Its quality is difficult to assess, however; $\rho_\parallel(\nu)$ is certainly not as smooth a function as suggested by eq. [2]. On the other hand, our $\rho_\parallel(\nu)$ benefits from a normalization offsetting at least part of the error due to the neglect of local departures from eq. [2]. Supporting evidence is offered by the following result due to Komatsu and Nagamiya. The force constants between the carbon atoms of benzene, determined by infrared and Raman spectroscopy, were used with appropriate modifications to permit a reasonable estimate of those of a graphite layer. On this basis, the authors arrive at $\theta_\parallel = 2440°$, which is realistic (Table 1). The point is that eq. [2] is part of this evaluation. Thus we may infer that eq. [2], if not taken on a point-by-point basis, behaves like an acceptable approximation in problems involving its use to cover the entire range from 0 to $\nu_{\max\parallel}$.

The distribution function for the vibrations perpendicular to the layers, eq. [3], differs from Komatsu's results (16*a*, *b*) only in the low frequency range, $\nu < \nu_z' = 3.76 \times 10^{12}\ \mathrm{s}^{-1}$, i.e., below $\theta_z' = h\nu_z'/k \simeq 180$ K. While these low frequencies play a leading role in the calculation of specific heats, they contribute little to the "perpendicular part" of ZPE. As a consequence, the error introduced by using eq. [3] in the entire range 0 to $\nu_{\max\perp}$ is minimal, all the more as the overall contribution of perpendicular vibrations represents only ~10% of the total ZPE.

Hence, within the framework of a simple Debye approach applied to a non-isotropic system, eq. [5] emerges as a reasonably viable first approximation. Of course, the difficulty now rests with the selection of the appropriate Debye temperatures. For internal consistency, we select $\theta_\parallel = 2480$ K, which is Komatsu's revised result (16*b*) obtained from his semi-continuum theory, and (somewhat arbitrarily) $\theta_\perp = 800$ K (Table 1). Our estimate is thus

$$\mathrm{ZPE} = 3.68\ \mathrm{kcal\ mol^{-1}}$$

which is tentatively used in the forthcoming analysis involving the enthalpy of atomization of graphite.

Bond energies of vibrationless graphite

For a molecule in its hypothetical vibrationless state we apply the energy formula (17)

$$[6] \qquad \epsilon_{ij} = \epsilon_{ij}^0 + a_{ij}\Delta q_i + a_{ji}\Delta q_j$$

where ϵ_{ij}^0 is for a bond formed by atoms i and j whose net charges are q_i^0 and q_j^0, respectively, and ϵ_{ij} for the same bond with charges $q_i = q_i^0 + \Delta q_i$ and $q_j = q_j^0 + \Delta q_j$. The a_{ij} and a_{ji} parameters measure the effect of unit charge variations at atom i (bonded to j) and atom j (bonded to i), respectively. This equation was successfully applied to a variety of organic systems (17), namely benzenoïd hydrocarbons (18), in calculations of their atomization energies, $\Delta E_a^* \simeq \Sigma\epsilon_{ij}$. Here we apply eq. [6] in a straightforward manner by treating graphite as a giant polycyclic aromatic system and temporarily postpone the discussion of imperfections associated with this simplified model. We use the theoretical a_{CC} value determined earlier (18) for benzenoïd hydrocarbons, namely $a_{CC} = -0.358\ \mathrm{kcal\ mol^{-1}\ me^{-1}}$ (1 me = 10^{-3} e), and the reference net charge, $q_C^0 = 14.8$ me, of the benzene carbon atom. The graphite carbon atoms being electroneutral, it follows that $\Delta q_C = -14.8$ me and, from eq. [6],

$$\epsilon_{CC} = \epsilon_{CC}^0 + 10.60\ \mathrm{kcal\ mol^{-1}}$$

The construction of the carbon skeleton of a planar polynuclear benzenoïd hydrocarbon, leaving all carbons with $q_C^0 = 14.8$ me, involves two types of ϵ_{CC}^0 energies. The aromatic carbon–carbon bond, $\epsilon^0(\mathrm{C}\cdots\mathrm{C}) = 114.21\ \mathrm{kcal\ mol^{-1}}$, represents, so to speak, the average between a single and a double bond as they are found in benzenoïd structures: it is the CC bond of benzene. This type of bond occurs twice as often as the number of double bonds one can write using classical Kékulé structures (e.g., six times in benzene, ten times in naphthalene, etc.). In addition, except for benzene, there is a number of single CC bonds "in excess" (e.g., 1 in naphthalene, 2 in anthracene, etc.) which are treated as such, i.e., as $C(sp^2)$—$C(sp^2)$ single bonds with $\epsilon^0(\mathrm{C—C}) = 91.56\ \mathrm{kcal\ mol^{-1}}$ (18). With zero net charges we thus obtain $\epsilon(\mathrm{C}\cdots\mathrm{C}) = 124.81$ and $\epsilon(\mathrm{C—C}) = 102.16\ \mathrm{kcal\ mol^{-1}}$.

In graphite, each carbon atom is engaged in one double and two single bonds, i.e., two bonds with energy 124.81 and one bond with energy 102.16, for a total of $351.78\ \mathrm{kcal\ mol^{-1}}$. The cleavage of these three bonds frees two carbon atoms. The atomization energy of graphite in its potential minimum at 0 K is thus

$$\Delta E_a^*(\mathrm{graphite}) = \tfrac{1}{2}\Sigma\epsilon_{CC} = 175.89\ \mathrm{kcal\ mol^{-1}}$$

This theoretical result can now be compared with experiment.

Discussion

The energy of atomization at $T = 298.15$ K, $\Delta E_a = \Delta H_a - RT$ (where ΔH_a is the corresponding enthalpy), is deduced from ΔE_a^* by subtracting ZPE as well as the heat content, $H_T - H_0$, gained between 0 and T and by adding the translational energy, $(3/2)RT$, of the carbon atoms formed during the atomization of graphite, i.e.,

$$[7] \qquad \Delta H_a = \Delta E_a^* - \mathrm{ZPE} - (H_T - H_0) + \tfrac{5}{2}RT$$

Using the experimental result (7), $H_T - H_0 = 0.25\ \mathrm{kcal\ mol^{-1}}$ (which consists, in essence, of thermal vibrational energy), our calculation gives

$$\Delta H_a(\mathrm{graphite}, 298.15) = 173.44\ \mathrm{kcal\ mol^{-1}}$$

The commonly accepted experimental value is $170.9\ \mathrm{kcal\ mol^{-1}}$

(19). Although our calculation appears to be in reasonable accord with the latter, the discrepancy is unusually large in comparison with what is generally obtained from eq. [6] (17, 18). Moreover, our model neglects the interactions between layers — a circumstance which adds approximately 1.2 kcal mol^{-1} to the error (20).

At best, only a minor part of the discrepancy can be blamed on possible errors associated with our evaluation of ZPE. The bond energies are certainly overestimated. Let us first examine the $a_{CC}\Delta q_C$ part of eq. [6]. In the evaluation of ΔE_a^*, a total of $\frac{1}{2}(3 \times 10.60) = 15.90$ kcal mol^{-1} comes from the charge neutralization, $\Delta q_C = -14.8$ me. This Δq_C is based on the carbon net charge in benzene, 14.8 ± 1 me (18). Hence, if the discrepancy in the calculation of ΔH_a (of the order of 3.7 kcal mol^{-1}) was to be *entirely* attributed to a misrepresentation of the benzene carbon, the charge of the latter should be reduced to ~11.4 me. This extreme, however, is probably not justified, as suggested by an examination of the ϵ_{CC}^0's. Those used here are for CC bonds with carbons 1.40 Å apart (18). In graphite, the bond distances are 1.42 Å (21). Our simple model cannot account for this change in geometry but it should be anticipated that longer bonds correspond to smaller bond energies. It is thus reasonable to advocate that at least a good part of the error made in our calculation should be blamed on too large ϵ_{CC}^0 reference energies.

Graphite represents a severe test for the simple approach describing bond energies in terms of the charges of the bond-forming atoms, eq. [6], and provides a fresh insight into the approximate validity of the charge, 14.8 ± 1 me, estimated for the benzene carbon atom. The results vividly support the approximate validity of the energies associated with the two types of carbon–carbon bonds occurring in polynuclear benzenoïd structures.

Appendix

Debye's approximation (1, 2) is based on a consideration of $\rho(\nu)$ at low frequencies and an extrapolation therefrom. Whether a given wave can persist, and hence be included among the normal oscillations, depends on whether it reinforces itself upon reflection from the surfaces of the solid. Reinforcement depends on the relation between the wavelength and the dimensions of the solid, only certain wavelengths being permitted. The wave velocity u may, for long wavelengths, be taken as constant for any type of wave. Since the wavelength λ and the frequency ν are related by the relation

[A1] $$u = \lambda\nu$$

this will determine the allowed frequencies. For a three-dimensional wave, with a slab of lengths a, b, and c, we have

[A2] $$\frac{\lambda}{\cos\alpha} = \frac{2a}{k_x} \qquad \frac{\lambda}{\cos\beta} = \frac{2b}{k_y} \qquad \frac{\lambda}{\cos\gamma} = \frac{2c}{k_z}$$

where k_x, k_y, and k_z are integers. The number of frequencies in any given range of frequencies is given by the number of integral triplets k_x, k_y, and k_z in that range; $\cos\alpha$, $\cos\beta$, and $\cos\gamma$ are the direction cosines of the direction of propagation in the directions of space.

Treating the problem of two-dimensional vibrations in a layer just as in Debye's theory of a three-dimensional continuum, it follows that (16*a*)

[A3] $$\rho_{\parallel}(\nu) = 2\pi ab\left(\frac{1}{u_l^2} + \frac{1}{u_t^2}\right)\nu$$

where u_l and u_t are the velocities of the longitudinal and transverse waves, respectively. Similarly, assuming parallel propagation and polarization vectors, we obtain for the perpendicular vibrations that $\lambda = u'/\nu = 2c/k_z$, i.e., $k_z = 2c\nu/u'$, and

[A4] $$\rho_{\perp}(\nu) = 2c/u'$$

Equations [A3] and [A4] are conveniently simplified with the introduction of the following normalizations

[A5] $$\int_0^{\nu_{\max\parallel}} \rho_{\parallel}(\nu)\,d\nu = 2N$$

[A6] $$\int_0^{\nu_{\max\perp}} \rho_{\perp}(\nu)\,d\nu = N$$

Equation [2] is obtained from eqs. [A3] and [A5], whereas eqs. [A4] and [A6] give eq. [3].

Molecular conformation of 2′-deoxy-3′,5′-di-*O*-acetyl guanosine. Crystal structure and high resolution proton nuclear magnetic resonance investigations

LEO H. KOOLE, HENK M. BUCK, JAN A. KANTERS, and ARIE SCHOUTEN. Can. J. Chem. **66**, 2634 (1988).

2′-Deoxy-3′,5′-di-*O*-acetyl guanosine crystallizes in the triclinic space group $P1$ (C_1^1, No. 1), and the cell dimensions are $a = 8.643(1)$ Å, $b = 10.122(1)$ Å, $c = 10.391(1)$ Å, $\alpha = 87.04(1)°$, $\beta = 73.58(1)°$, $\gamma = 72.37(1)°$, $V = 830.4(2)$ Å^3; $Z = 2$ molecules per cell. Least-squares refinement converged at $R = 0.031$ for 3450 observed reflections. The asymmetric unit consists of two independent molecules. The guanine bases are linked via N(1)—H...N(7) and N(2)—H...O(6) hydrogen bonds to form a virtually planar system. Moreover, the conformational preferences of the title compound in DMSO-d_6 solution have been determined with 300 MHz ^{1}H NMR. It is found that the X-ray structure and the solution conformation are essentially similar. The C(4′)—C(5′) linkage resides in the *gauche*$^+$ (g^+) or *trans* (t) rotamers in the solid state, while an approximately equal distribution over g^+, t, and *gauche*$^-$ is found in solution.

LEO H. KOOLE, HENK M. BUCK, JAN A. KANTERS et ARIE SCHOUTEN. Can. J. Chem. **66**, 2634 (1988).

La désoxy-2′ di-*O*-acétyl-3′,5′ guanosine cristallise dans le groupe d'espace triclinique $P1$ (C_1^1, No. 1) avec $a = 8,643(1)$, $b = 10,122(1)$ et $c = 10,391(1)$ Å, $\alpha = 87,04(1)$, $\beta = 73,58(1)$ et $\tau = 72,37(1)°$, $V = 830,4(2)$ Å^3 et $Z = 2$. La structure a été résolue par la méthode des moindres carrés (matrice entière) jusqu'à une valeur de R de 0,031 pour 3450 réflexions observées. L'unité asymétrique comporte deux molécules indépendantes. Les bases guanines sont liées par le biais de liaisons hydrogènes N(1)—H...N(7) et N(2)—H...O(6) et elles forment un système virtuellement plan. De plus, opérant en solution dans le DMSO-d_6 et faisant appel à la RMN du ^{1}H à 300 MHz, on a déterminé les préférences conformationnelles du composé mentionné dans le titre. On a trouvé que la structure déterminée par diffraction des rayons-X possède essentiellement la même conformation qu'en solution. A l'état solide, la liaison C(4′)—C(5′) se retrouve dans les rotamères *gauche*$^-$ (g^+) ou *trans* (t); en solution, on retrouve une distribution approximativement égale des rotamères g^+, t et *gauche*$^-$.

[Traduit par la revue]

Introduction[3]

Recent literature covers a substantial number of X-ray crystallographic studies on acetylated DNA or RNA nucleosides (1–9). The interest in these compounds stems primarily from their remarkable structural features. It has been found that acetylated nucleosides can serve as unique models to study different modes of hydrogen-bonded base pairing, which must be considered as alternatives for the conventional antiparallel coupling of complementary bases according to the Watson and Crick (10) model (adenine (A) – thymine (T), or guanine (G) – cytosine (C)). For example, it was found that 3′,5′-di-*O*-acetyl thymidine crystallizes in a *parallel* base-paired conformation, in which the T bases are linked via two N(3)—H...O(4) hydrogen bonds (6, 11, 12). We have recently shown that the possibility of parallel T–T base-pair formation may have a more general significance. Exclusive methylation of the phosphate groups in the mononucleotide d(pTp), and in the oligonucleotides d(T_2), d(T_3), d(T_4), d(T_6), and d(T_8) results in the formation of a remarkably slim parallel double helical structure in aqueous solution (11–13). The parallel strands in this structure are linked via T–T base pairs as first observed in the crystal structure of 3′,5′-di-*O*-acetyl thymidine. Very recent UV hyperchromicity experiments with unmodified d(T_8) have provided preliminary evidence for the formation of an analogous double helix, if one equivalent of the cationic protein polylysine is present (13). Most likely, complexation of polylysine with the negatively charged phosphodiester groups in d(T_8) leads to a substantial reduction of the effective negative charge on the phosphate groups. This is essential for the formation of T–T base pairs (11–13).

To investigate self association of the other DNA bases, we have previously studied the structure of 2′-deoxy-3′,5′-di-*O*-acetyl adenosine (1). It was observed that the A base does not form parallel A–A base pairs but, instead, any array of one-dimensional ribbons in which the bases are linked via two crystallographically-independent hydrogen bonds: N(6)—H...N(1) and N(6)—H...N(7). A highly comparable hydrogen bonding scheme was found by Wilson *et al.* for the crystal structure of the acetylated RNA counterpart structure, 2′,3′,5′-tri-*O*-acetyl adenosine (3).

In this paper we wish to report a structural study on the acetylated DNA nucleoside 2′-deoxy-3′,5′-di-*O*-acetyl guanosine (Fig. 1). The X-ray structure reveals that the asymmetric unit consists of two independent molecules, **I** and **II**. The planar guanine fragments of **I** and **II** are connected via N(1)—H...N(7) and N(2)—H...O(6) hydrogen bonds to form a nearly planar system with the two guanine rings at an angle of 5.0(1)°. Furthermore, a comparison is made of the X-ray data of the title compound, and the solution conformation as determined with 300 MHz ^{1}H NMR spectroscopy.

Experimental section

Preparation

Acetic anhydride (1.83 g, 17.92 mmol) was added to a stirred suspension of dry 2′-deoxyguanosine (2.00 g, 7.49 mmol) and

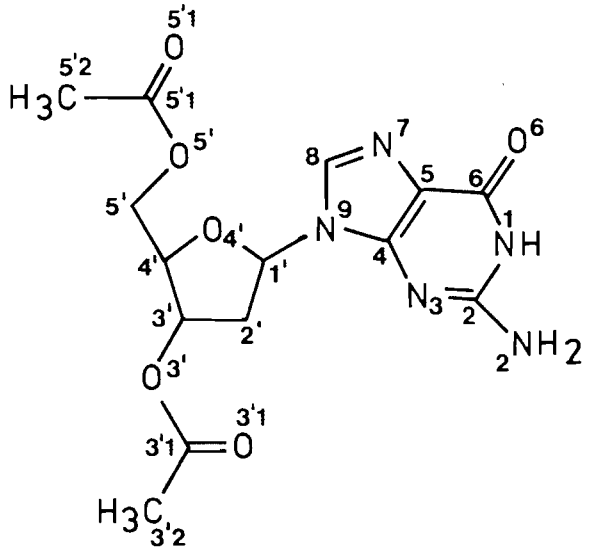

FIG. 1. Structural formula and atomic labelling of the 2′-deoxy-3′,5′-di-*O*-acetyl guanosine molecule.

4-*N*,*N*′-dimethylaminopyridine (0.15 g, 1.23 mmol) in a mixture of dry acetonitrile (100 mL) and 2.00 g (19.71 mmol) of triethylamine (14). After 2 h, methanol (2 mL) was added, and stirring was continued for 5 min. The reaction mixture was then filtered. 2′-Deoxy-3′,5′-di-*O*-acetyl guanosine was obtained as a white powder, which was purified by washing with ethanol and diethylether. Yield: 2.55 g (96%). Recrystallization from ethanol yielded plate-shaped colorless crystals. ^{1}H NMR (DMSO-d_6): δ 1.94 (3H, s, CH_3), 1.97 (3H, s, CH_3), 2.33 (1H, m, H(2″)), 2.81 (1H, m, H(2′)), 4.11 (2H, m, H(4′/5″), 4.15 (1H, m, H(5′)), 5.19 (1H, m, H(3′)), 6.03 (1H, dd, H(1′)), 6.40 (2H, bs, NH_2), 7.80 (1H, s, H(8)).

Crystallographic measurements and structure resolution

$C_{14}H_{17}N_5O_6$ fw = 351.32

Triclinic, a = 8.643(1) Å, b = 10.122(1) Å, c = 10.391(1) Å, α = 87.04(1)°, β = 73.58(1)°, γ = 72.37(1)°, V = 830.4(2) Å^3, Z = 2, D_c = 1.405 g cm^{-3}, λ(MoKα) = 0.71073 Å, t = 20°C, μ(MoKα) = 1.21 cm^{-1}, F(000) = 368; space group $P\bar{1}$ (C_i^1, No. 1).

A plate-shaped colorless crystal with dimensions (mm) 1.3 × 0.4 × 0.3 was mounted on a Nonius CAD4 diffractometer. Unit-cell dimensions were determined by least-squares refinement of the setting angles of 25 reflections in the θ range 17.1–22.0°. Intensities of 3795 reflections were measured within the sphere of reflection limited by 2θ = 55° and $-11 \leq h \leq 11$, $-12 \leq k \leq 12$, and $0 \leq l \leq 13$, using Zr-filtered MoKα radiation. The ω/2θ scan technique was applied with ω = (0.60 + 0.35 tan θ)°. The intensities of three reference reflections (014, 104, and 140), measured every 60 reflections, showed an average deviation less than 1% during the duration of the data collection. The intensities were corrected for Lorentz polarization effects, but not for absorption. A total of 3450 reflections that satisfied the criterion $I \geq 2.5\sigma(I)$ were retained for the structure determination and refinement. $\sigma(I)$ was derived from counting statistics. The structure was solved with the direct methods program of SHELXS84 (15), the coordinates of all non-hydrogen atoms being determined from an *E*-map. The hydrogen atoms were located on subsequent difference maps. The overall thermal parameter of the non-methyl hydrogen atoms refined to 0.054(4) Å^2. The hydrogen atoms of the methyl groups were placed at idealized positions (C—H 1.00 Å, H—C—H 109.5°). In the refinement the hydrogen atoms of the methyl groups were riding on their bonded atoms. The overall thermal parameter of the hydrogen atoms of the methyl groups refined to 0.14(1) Å^2. Anisotropic blocked full-matrix refinement (8 blocks) on F of 552 parameters converged at R = 0.031 and R_w = 0.034 with $w = 2.6552/\sigma^2(F_o) + 0.00012F_o^2$. The quantity minimized was $\Sigma w\Delta F^2$, the goodness of fit $s = \Sigma w\Delta F^2/(m - n)^{1/2}$, was 2.21 and the average and maximal shift to error ratio's 0.01 and 0.08, respectively. A final ΔF showed maximal fluctuations of +0.14 and −0.14 e Å^{-3}. Scattering factors were those of Cromer and Mann (16), and for hydrogen of Stewart, Davidson, and Simpson (17). Programs used include SHELX76 (18) (refinement) and EUCLID (19) (geometry and illustrations).

Nuclear magnetic resonance spectroscopy

One-dimensional spectra were recorded in the FT mode at 300.1 MHz on a Bruker CXP 300 NMR spectrometer, interfaced with an ASPECT 2000 computer (NMR facility at the Eindhoven University of Technology). An internal $(CD_3)_2SO$ field-frequency lock, and a spectral window of 3000 Hz (16 K data points) were used. Prior to Fourier transformation, the spectra were zero-filled to 32 K, and resolution enhanced by an appropriate Gaussian multiplication. A computer simulation-iteration routine was used in order to accurately extract chemical shifts and *J*-coupling constants. This proved to be of great value, especially for the non-first order pattern that corresponds to the nearly isochronous protons H(4′), H(5′), and H(5″) (*vide infra*).

Results and discussion

Crystal structure[4]

The fractional coordinates, along with equivalent isotropic temperature factors are summarized in Table 1. Bond distances between non-hydrogen atoms are given in Table 2. Table 3 lists bond angles between non-hydrogen atoms for the molecules **I** and **II**. Table 4 contains a selected set of torsion angles, describing the geometry of the furanose ring, the acetylated backbone, as well as the conformation around the glycosidic (C(1′)—N(9)) bond.

Furanose and backbone conformation

The 2′-deoxyribofuranose rings in the molecules **I** and **II** are found in the C(2′)-*endo* puckered form. A more precise description of the sugar ring conformations can be given with the pseudorotation concept (20), which relates the five endocyclic torsion angles mathematically to a phase angle of pseudorotation (P), which actually indicates which part of the ring is bent, and a puckering amplitude (ν_{max}), which identifies the deviation from planarity of the ring. For the title compound, P values of 167° and 164° are found for **I** and **II**, respectively. The puckering amplitudes amount to 30.6° and 35.6° for **I** and **II**, respectively. The bond distances and angles within the furanose unit are in agreement with other known C(2′)-*endo* puckered nucleosides (21, 23). The ring C—O bond distances are unequal, in such a way that C(4′)—O(4′) is approximately 0.03 Å longer than C(1′)—O(4′) (molecule **I**: C(1′)—O(4′) = 1.408(3) Å, C(4′)—O(4′) = 1.432(3) Å; molecule **II**: C(1′)—O(4′) = 1.415(2) Å, C(4′)—O(4′) = 1.442(2) Å). The difference in observed bond length is due to the anomeric effect, which is known to cause a slight shortening of C(1′)—O(4′) in nucleosides (22). The anomeric effect essentially stems from the proclivity of the heterocyclic base ring, as transmitted through N(9). The conformation around the exocyclic C(4′)—C(5′) bond shows a marked difference for molecules **I** and **II**. The *trans* (*t*) conformation (*trans* location of O(5′) and C(3′)) with γ(O(5′)—C(5′)—C(4′)—C(3′)) = 165.7(2)° is found for **I**. The C(4′)—C(5′) conformation is *gauche*$^+$ (g^+) (O(5′) *gauche* with respect to O(4′) and C(3′)), for **II**, γ = 57.8(2)°. The acetyl geometries are as previously noted (1–9), showing short C=O bonds. For molecule **I**, it is found that

C(3′1)—O(3′1) = 1.190(4) Å, C(5′1)—O(5′1) = 1.206(4) Å, and for **II**, C(3′1)—O(3′1) = 1.188(4) Å, C(5′1)—O(5′1) = 1.200(4) Å.

Geometry and orientation of the base

The glycosyl bond length C(1′)—N(9) and bond angle O(4′)—C(1′)—N(9) are 1.461(3) Å, 107.9(2)° for **I**, and 1.458(3) Å, 107.0(2)° for **II**. The guanine rings are approximately planar, the r.m.s. deviation of the 9 atoms from the least-squares plane is 0.010(4) Å, for **I** and **II**. The orientation of the base falls in the *anti* range, with values of χ(O(4′)—C(1′)—N(9)—C(4)) of −130.3(2)° for **I**, and −159.4(2)° for **II**. These data are indicated as spokes *1* and *2* in the conformational wheel of Fig. 2, showing the distribution of the glycosidic torsion angle χ in the crystal structures of acetylated nucleosides. Figure 2 clearly indicates that the χ values for acetylated nucleosides have a bimodal distribution. Nine *anti* conformations occur in the range χ = −148 ± 33°, and three *syn* conformations have been found in the range χ = 63 ± 11°. The favored *anti* and *syn* domains of acetylated nucleosides

are in close agreement with the structural data set of Altona *et al.* (21).

Hydrogen bonding and molecular stacking

The N—H and NH_2 groups of the purine fragment of molecules **I** and **II** are hydrogen-bond donors in seven intermolecular hydrogen bonds (Table 5). Two hydrogen bonds between molecules **I** and **II** form a dimer-type ribbon typical for guanosine derivatives. These bonds, N(1)...N(7) and N(2)...O(6), connect molecules **II** and **I**, and the same interaction exists between molecule **I** and a translationally related molecule **II** at $(-1 + x, y, 1 + z)$. This repeated pattern gives rise to an infinite chain of paired bases running in the $\bar{1}\,0\,1$ direction. Each molecule has an additional hydrogen bond between the NH_2 group and O(5′1) of the acetyl group at C(5′) of a translationally related molecule, also at $(-1 + x, y, 1 + z)$. The seventh hydrogen bond is between the NH_2 group of **II** and the ester oxygen $O_{5'}$ of the acetyl group at $C_{5'}$ of **I** at $(-1 + x, 1 + y, z)$. This implies that one N—H bond of the NH_2 group of **II** is involved in a bifurcate interaction, which is planar as follows from the sum of angles (359.5°), having the H atom as apex. The bifurcation results in weak hydrogen bonds as may be seen from their geometries (Table 5). Like in other acetylated pyrimidine and purine nucleosides (1–9), the acetyl groups play an important role in the stacking, in that the polar carbonyl group is oriented toward the base ring of neighbouring molecules. As Table 4 shows, the two carbonyl oxygen atoms O(3′1) and O(5′1) of both **I** and **II** have close contacts with atoms of the guanosine ring. The greater part of these contacts and also the shortest ones involve the carbonyl groups of molecule **II**.

Conformation in solution

The set of experimental *J*-coupling constants, determined at 298 K, are summarized in Table 6. The data refer to the solvent DMSO-d_6, since 2′-deoxy-3′,5′-di-*O*-acetyl guanosine was found to be virtually insoluble in D_2O. An iterative computer simulation procedure was used in order to obtain accurate NMR spectral data (Fig. 4). The structure of the 2′-deoxyribose ring can be described in terms of a rapid C(2′)-*endo* ⇄ C(3′)-*endo* conformational equilibrium (25, 26):

$$x(\text{C(2′)-}endo) = (17.8 - J(1'2'') - J(2''3''))/10.9 = 0.88$$

A similar preference for the C(2′)-*endo* conformation is

for *t* over g^+ and *gauche*$^-$ (g^-) is observed. It should be noted that 3′,5′-di-*O*-acetyl thymidine and 2′-deoxy-3′,5′-di-*O*-acetyl adenosine exhibit a clear preference for g^+ in solution.

Conclusion

The crystal structure of 2′-deoxy-3′,5′-di-*O*-acetyl guanosine consists of two independent molecules **I** and **II** in the asymmetric unit. The guanine bases are connected via two N(1)—H...N(7), and two N(2)—H...O(6) hydrogen bonds. The hydrogen donating base in this structure in fact mimics the C base in the Hoogsteen C—G base pair (27). Two hydrogen bonds N(2)—H...O(5′1) connect pairs of molecule **I** and pairs of molecule **II**. An additional N(2)—H...O(5′) interaction between **I** and **II** gives rise to a bifurcate hydrogen bond. Highly comparable hydrogen bonding patterns (except for the bifurcated hydrogen bond) have been found for the acetylated RNA counterpart structure 2′,3′,5′-tri-*O*-acetyl guanosine, both in the monoclinic (5) and orthorhombic (2) form. The conformational properties of the furanose unit and the acetylated backbone show a close correspondence between the solid state and the DMSO solution. The molecules **I** and **II** both have C(2′)-*endo* type furanose rings in the solid state, while a clear preference for C(2′)-*endo* is also observed in solution. With respect to the C(4′)—C(5′) conformation, it is found that an approximately equal distribution over the rotamers g^+, *t*, and g^- exists in solution. Both *t* (molecule **I**) and g^+ (molecule **II**) are encountered in the crystal structure. The crystal structure of 2′-deoxy-3′,5′-di-*O*-acetyl guanosine differs substantially from the structures of other acetylated DNA nucleosides, i.e., 2′-deoxy-3′,5′-di-*O*-acetyl adenosine (in which the A bases are linked in one-dimensional chains via N(6)—H...N(1) and N(6)—H...N(7) hydrogen bonds), and 3′,5′-di-*O*-acetyl thymidine, for which a parallel T–T base pair was found. Work is in progress to solve the X-ray structure of the fourth acetylated DNA nucleoside, 2′-deoxy-3′,5′-di-*O*-acetyl cytidine.

Received April 28, 1988

JERZY STRZELBICKI, WITOLD CHAREWICZ, JORG BEGER, and LUTZ HINZ. Can. J. Chem. **66**, 2640 (1988).

The influence of the length of an *n*-alkyl chain incorporated into the molecule of an *n*-alkyltri(oxyethylene) carboxylic acid of a general formula $C_nH_{(2n+1)}(OCH_2CH_2)_3OCH_2CO_2H$ (n = 6, 8, 10, and 12, respectively) on transfer of the zinc group element ions into chloroform was investigated. Metal ions were transferred from the aqueous solutions of $ZnCl_2$, $CdCl_2$, and $HgCl_2$ at initial concentrations of 0.835 m*M* and 1.67 m*M* with, and without, added NaCl. From the aqueous solutions to which no NaCl was added, the selectivity of transfer of divalent metal ions into the organic phase was low.

The selectivity of transfer of the divalent metal ions improved remarkably when NaCl was added to the aqueous phase due to the chemical equilibria involving complexation of the divalent metal ions by Cl^-, OH^-, and *n*-alkyltri(oxyethylene) carboxylic acid. In most systems (with NaCl added), Zn(II) was separated from Cd(II) and Hg(II). Less lipophilic *n*-alkyltri(oxyethylene) carboxylic acids (with a shorter *n*-alkyl chain incorporated) exhibited higher selectivity and efficiency as divalent metal ion carriers.

JERZY STRZELBICKI, WITOLD CHAREWICZ, JORG BEGER et LUTZ HINZ. Can. J. Chem. **66**, 2640 (1988).

On a étudié l'influence de la longueur de la chaîne *n*-alkyle, incorporée dans des molécules d'acide *n*-alkyl(oxyéthylène) carboxylique de formule générale $C_nH_{(2n+1)}(OCH_2CH_2)_3OCH_2CO_2H$ (n = 6, 8, 10 et 12 respectivement), sur le transfert des ions des éléments du groupe du zinc vers le chloroforme. On a examiné le transfert des ions métalliques à partir de solutions aqueuses de $ZnCl_2$, de $CdCl_2$ et de $HgCl_2$ à des concentrations initiales de 0,835 et 1,67 m*M* avec, et sans, addition de NaCl. Pour des solutions aqueuses auxquelles on n'a pas ajouté de NaCl, la sélectivité pour le transfert des ions métalliques bivalents vers la phase organique est faible.

Cette sélectivité augmente considérablement lorsqu'on ajoute du NaCl à la phase aqueuse; cette différence est dûe à l'équilibre chimique impliquant la complexation des ions métalliques bivalents par les ions Cl^- et OH^- ainsi que par l'acide *n*-alkyltri(oxyéthylène)carboxylique. Dans la plupart des systèmes (lorsque du NaCl a été additionné), on a pu séparer le Zn(II) du Cd(II) et du Hg(II). Les acides *n*-alkyltri(oxyéthylène) carboxyliques moins lipophiles (incorporant des chaînes *n*-alkyles plus courtes) présentent une plus grande sélectivité et une plus grande efficacité comme transporteurs d'ions métalliques bivalents.

[Traduit par la revue]

Introduction

The open chain polyethylene glycols (OCPGs) and their derivatives have been found to be capable of forming complexes with different metal cations in organic solvents in a manner similar to the macrocyclic polyethers. Due to their complexing abilities and relative inexpensiveness these compounds are of increasing interest in various areas of chemistry. The metal complexes of OCPGs and their derivatives have been mostly studied in homogenous systems (e.g. alcoholic solvents) or/and the crystal structure of these complexes has been investigated (1, 2). Much less is known about OCPGs and their derivatives as metal ion carriers from an aqueous solution into and/or through an organic phase (3–12), in particular, in systems containing transition and posttransition metal ions (5, 8, 12).

In the previous paper (12), we have reported the results on extraction of Zn(II), Cd(II), and Hg(II) using a series of dodecyloligo(oxyethylene) carboxylic acids. When NaCl was not added to the aqueous phase, the extractability of Hg(II) increased with an increasing number of oxyethylene units incorporated into the molecule of an extractant. For Zn(II) and Cd(II) no ionic size polyoxyethylene chain length dependence was found and the selectivity of extraction was low in those systems.

The selectivity of extraction of Zn(II), Cd(II), and Hg(II) improved dramatically in the extraction systems with NaCl added to the aqueous solution. The extractability of Hg(II) was always very low. The region of the high extractability of Cd(II) was shifted into the more basic region of the pH compared to that of Zn(II). The selectivity was apparently produced by the chemical equilibria involving divalent metal ions complexation by Cl^- and OH^- anions in the aqueous phase and by the dodecyloligo(oxyethylene) carboxylic acid in the organic phase.

Above pH 8, concentration of the divalent metal in the organic phase decreased as the pH was raised, and the precipitates of $Zn(OH)_2$ and/or $Cd(OH)_2$ appeared. This finding was in contrast with earlier reported results on extraction of Co(II) and Ni(II) by the dodecyltetra(oxyethylene)oxyacetic acid (8) because these metal ions were transferred efficiently into the chloroform phase also in the basic region of the pH.

The $M(OE)_2$ type of stoichiometry (OE = dodecyloligo(oxyethylene carboxylate anion) has been anticipated for the extraction complex (12).

The complexing abilities and extractabilities of crown carboxylic acids have been found as strongly dependent on an alkyl chain (or an aromatic component) incorporated into the molecule of a complexone (8, 13–15). Also, complexation of metal ions by neutral OPGs depends strongly on the end-group substitutions in the molecule of a complexone and the lipophilicity of a complexone (4, 10, 11, 16).

In this paper, the results on transfer of the divalent metal ions

Experimental

Apparatus

Concentrations of metals in aqueous and organic phases were determined radiometrically (^{65}Zn, ^{115m}Cd, and ^{203}Hg) with a Nuclear Data Inc. (Model 1200) multichannel spectrometer and a Canberra Industries (Model 7228) Ge/Li γ-radiation semiconductor probe. Measurements of the equilibrium pH in the aqueous phases were made with an ELPO (Model N-512) pH-meter and an Energopomiar (Model SAgP-209W) glass body combination electrode. ^{1}H NMR spectra were determined with a Tesla BC 487 nuclear magnetic resonance spectrometer. Melting points, which were corrected, were measured using a Carl Zeiss Jena micromelting point Boethius apparatus.

Reagents

Radioisotopes were from the isotope Production and Reactor Center of the Institute of Atomic Energy, Swierk, Poland (^{65}Zn, ^{115m}Cd), and from the Central Institute of Nuclear Research, Dresden, GDR (^{203}Hg). Reagent grade sodium, hydrochloric acid, sulphuric acid, $ZnCl_2$, $CdCl_2$, $HgCl_2$, NaCl, NaOH, sodium chloroacetate, diethyl-ether, *n*-hexane, xylene, and chloroform were obtained from POCh (Gliwice, Poland). $ZnCl_2$, $CdCl_2$, and $HgCl_2$ were first dried at 120°C and then kept in a desiccator containing a drying agent. 1-Bromohexane, 1-bromooctane, 1-bromodecane, and triethylene glycol were obtained from Fluka (FRG). Glycol was converted into the corresponding α-alkyl-ω-hydroxytri(oxyethylene) according to published procedure (17). The procedure of the synthesis of *n*-dodecyltri(oxyethylene) carboxylic acid (**4**) was described previously (12). The synthetic routes to *n*-alkyltri(oxyethylene) carboxylic acids **1**–**3** were analogous. Physical properties, elemental analysis data, yields, and spectral data for **1**–**3** are presented in Table 1.

Procedure

The phases were equilibrated at room temperature (19–21°C). The organic phase (5 mL) was a solution of an oligoether carboxylic acid in chloroform and the aqueous phase (5 mL) was an aqueous solution of zinc, cadmium, and mercury chlorides (labelled with ^{65}Zn, ^{115m}Cd, and ^{203}Hg radioisotopes), NaOH (pH regulator), and NaCl (in two series of experiments).

Both organic and aqueous phases were placed in a separatory funnel and shaken vigorously for 15 min. Usually, the phases separated just after shaking was stopped (in particular, in the systems with acidic or neutral aqueous solutions) or they could be separated by centrifuging for several minutes (15–20 min) in case if an emulsion appeared (usually in the systems with the basic aqueous solution). However, most often the separatory funnel was allowed to stand for 18 h to provide complete separation of the organic and aqueous phases. Samples (1.0 mL of 2.0 mL) from each phase were removed for the γ-spectrometric determination of metal ion concentrations. The metal concentrations were determined only in the clear organic and aqueous phases. Finally, the equilibrium pH of the aqueous phase was measured.

To determine the complexing agent concentration in the chloroform phase after the equilibration, the organic phase was shaken with equal volume of 1.0 *M* aqueous hydrochloric acid to remove metal ions. After stripping, the organic phase (1 mL) was diluted to 5 mL with methanol and titrated, using a 5.0 m*M* methanolic solution of NaOH, to the phenolphthalein end point.

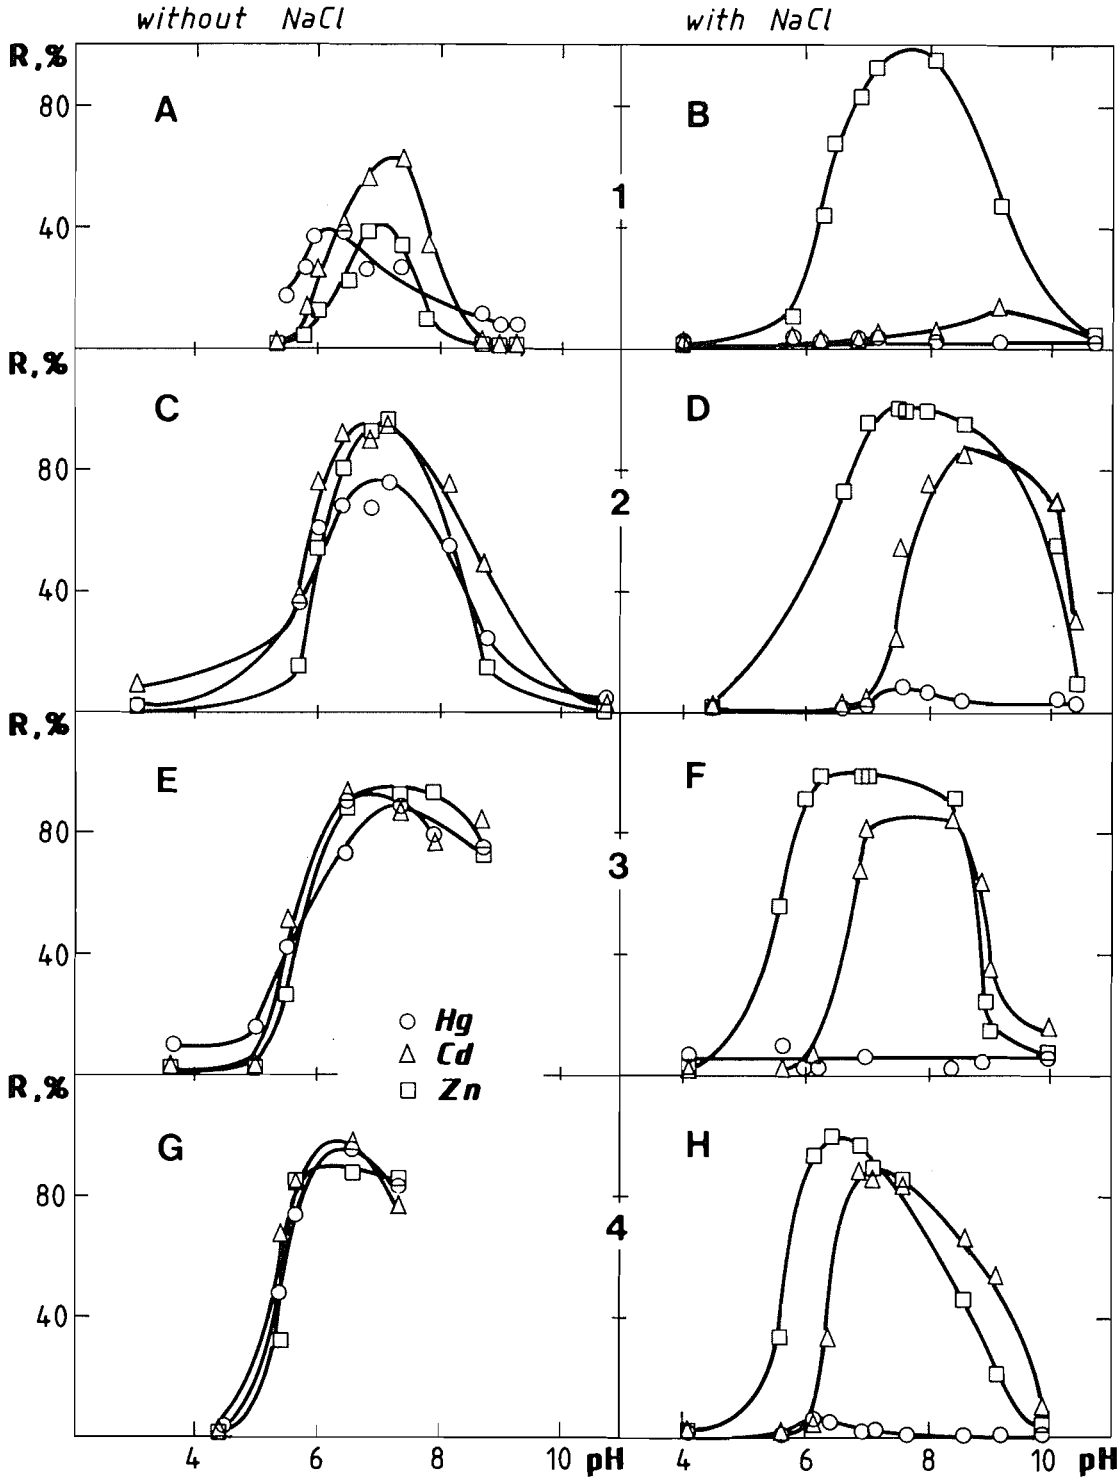

FIG. 1. Fraction of metal ions transferred (R) from aqueous solutions of 0.835 m*M* $ZnCl_2$, $CdCl_2$, and $HgCl_2$ (each) (*A*, *C*, *E*, *G*) and from aqueous solutions of 0.835 m*M* $ZnCl_2$, $CdCl_2$, and $HgCl_2$ (each) and 1.17 *M* NaCl (*B*, *D*, *F*, *H*) into 10 m*M* solutions of **1** (*A*, *B*), **2** (*C*, *D*), **3** (*E*, *F*), and **4** (*G*, *H*) (12) in chloroform vs. equilibrium pH of the aqueous phase.

At high equilibrium pH of the aqueous phase, an emulsion was formed and was often so stable that separation of the phases was impossible even by centrifuging. The results of experiments are presented only for those regions of the equilibrium pH of the aqueous phase, in which the organic and aqueous phases could be well separated and clear, before metal ion concentrations were determined. Thus, the end of the extraction curves in the figures indicates the pH values for which the emulsification process was too strong to continue experiments (Figs. 1*E*, *G* and 2*B*, *D*).

In the basic region of the equilibrium pH, Zn(II) and/or Cd(II) hydroxides precipitates appeared in the systems. Because the metal ion concentrations were determined in the clear organic and aqueous phases after the phases were fully equilibrated, the experimental data are included in the paper.

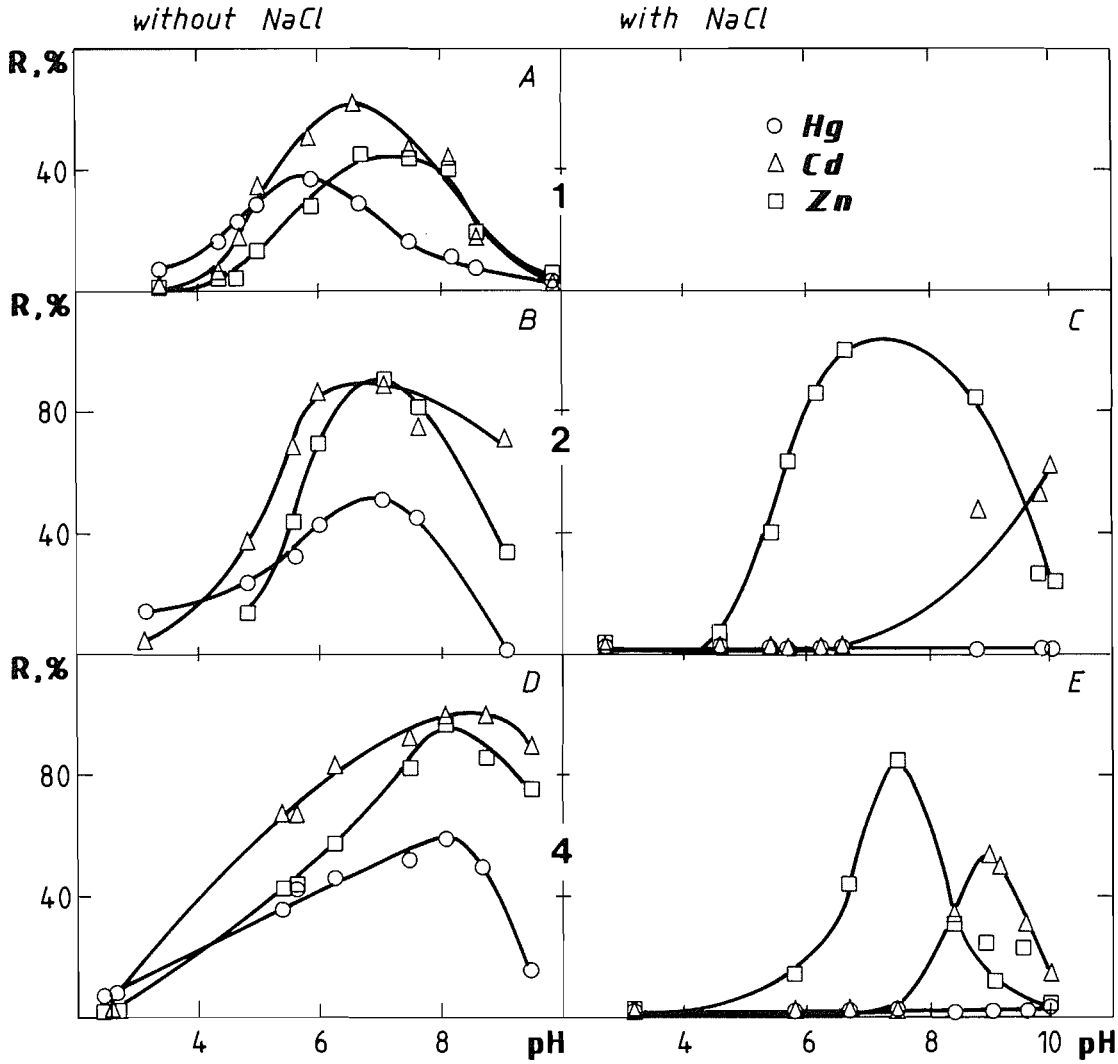

FIG. 2. Fraction of metal ions transferred (R) from aqueous solutions of 1.67 m*M* $ZnCl_2$, $CdCl_2$, and $HgCl_2$ (each) (*A*, *B*, *D*) and from aqueous solutions of 1.67 m*M* $ZnCl_2$, $CdCl_2$, and $HgCl_2$ (each) and 2.34 *M* NaCl (*C*, *E*) into 10 m*M* solutions of **1** (*A*), **2** (*B*, *C*), and **4** (*D*, *E*) (12) in chloroform vs. equilibrium pH of the aqueous phase.

Results and discussion

The results of experiments on transfer of Zn(II), Cd(II), and Hg(II) from aqueous solutions of $ZnCl_2$, $CdCl_2$, and $HgCl_2$ at an initial concentrations of 0.835 m*M* into a 10 m*M* solution of oligoether carboxylic acids **1**–**4** in chloroform are presented in Fig. 1 and Table 2. Two series of experiments were done, without (Figs. 1*A*, *C*, *E*, *G*), and with (Figs. 1*B*, *D*, *F*, *H*), added NaCl (at a concentration of 1.17 *M*). The results of experiments on transfer of Zn(II), Cd(II), and Hg(II) from 1.67 m*M* initial aqueous solutions of divalent metal chlorides into a 10 m*M* chloroform solution of **1**, **2**, and **4** are presented in Fig. 2 and Table 3. Experiments were done without (Figs. 2*A*, *B*, *D*), and with (Figs. 2*C*, *E*), added NaCl (at a concentration of 2.34 *M*). The sodium concentration in the initial aqueous solutions, which resulted from the pH regulation using a NaOH solution, did not exceed 20 m*M* (for the highest pH values).

Transfer of the divalent metal cations into chloroform was enhanced when the equilibrium pH of the aqueous phase increased up to pH of about 7. In the acidic pH region, there were "clean" solvent extraction systems composed of two liquid phases containing metal ions and/or their complexes with a complexing agent. Further increase of the pH usually produced a decrease of concentrations of the divalent metal ion in the organic phase and the precipitates of Zn(II) and/or Cd(II) hydroxides appeared (Tables 2 and 3). Hg(II) formed a precipitate (presumably Hg(II) oxide) usually at pH above 8.5. When precipitation occurs, there is not "clean" solvent extraction but yet the basic region of the equilibrium pH values in the systems under investigation is interesting because: (*i*) Formation of metal hydroxides approximately indicates the stability of complexes of the zinc group element with an *n*-alkyltri(oxyethylene) carboxylic acid. In the basic region of the pH, hydroxides were formed since they were thermodynamically more stable than complexes of the metal ion with an alkyltri(oxyethylene) carboxylic acid. (*ii*) Formation of hydroxide precipitates and a decrease of the metal ion concentrations in the organic phase provide possibility of removing the divalent metal ions from the organic phase in contact with the basic aqueous phase, without contamination of the aqueous phase with the divalent metal ions. (*iii*) The experimental data

points in the basic region of the pH values also indicate how "clean" solvent extraction systems function in that pH region.

Transfer of the divalent metal ions from the aqueous solutions in the systems to which no NaCl was added

The results of experiments are presented in Figs. 1*A*, *C*, *E*, *G*, and Table 2 (for the initial aqueous solution of 0.835 m*M* $ZnCl_2$, $CdCl_2$, and $HgCl_2$), and in Figs. 2*A*, *B*, *D* and Table 3 (for the initial aqueous solution of 1.67 m*M* $ZnCl_2$, $CdCl_2$, and $HgCl_2$).

The divalent metal ions investigated were complexed and transferred into the organic phase unselectively, in particular from a 0.835 m*M* aqueous solution of divalent metal chlorides (Figs. 1*A*, *C*, *E*, *G*). It indicated that the stabilities of Zn(II), Cd(II), and Hg(II) complexes with alkyltri(oxyethylene) carboxylic acids were the same or very similar. The selectivity of transfer of the metal ions improved slightly in the systems with a 1.67 m*M* solution of divalent metal chlorides (Figs. 2*A*, *B*, *D*). The Hg(II) concentration in the organic phase decreased, probably due to higher concentration of Cl^- and formation of chloride complexes of Hg(II).

The effectiveness of transfer of the metal ions into the organic phase by **1** was the lowest (Figs. 1*A* and 2*A*) due to low lipophilicity of that complexone and its solubility in the slightly acidic, neutral, and basic aqueous solutions (Table 2). The maximal divalent metal ion concentrations in the organic phase raised, when **2** was employed as the complexone, though its solubility in the aqueous phase was still high (Table 2). Thus, an overall lipophilicity of metal ion complexes with **2** was higher than those with **1**. It can be understood taking into account that in case of the $M(OE)_2$ type of complexes (12), the complex molecule formed by **1** contained two methylene units less than the complex molecule formed by **2**.

3 and **4** were highly lipophilic complexones and they were not lost from the organic phase even in contact with the very basic aqueous solutions. Also, the maximal divalent metal ion concentrations in the organic phase in the system with **3** and **4** were high (Figs. 1*E*, *G*).

For **4**, the $M(OE)_2$ stoichiometry type of complexes transferred into the organic phase was reported (12). When **2** was employed as the complexone, the total metal and the complexone concentrations ratio in the highest loaded organic phase was 2.6 (equilibrium pH 7.1, Fig. 2*B*). This ratio in the system with **1** was even higher — 4.4 (equilibrium pH 6.6 — Fig. 2*A*). Therefore, other stoichiometries of the extraction complex are possible depending on a complexone.

*Transfer of the divalent metal ions from aqueous solutions containing 0.835 m*M *$ZnCl_2$, $CdCl_2$, $HgCl_2$ and 1.17* M *NaCl*

The results of experiments are presented in Figs. 1*B*, *D*, *F*, *H* and Table 2.

The selectivity of transfer of the zinc group element ions into chloroform improved remarkably when NaCl was added to the aqueous phase. Due to formation of very stable chloride complexes of Hg(II) (18, 19), Hg(II) was not transferred into the organic phase or the percentage of Hg(II) transferred was very low (no more than 12%). In the system with **1**, also the percentage of Cd(II) transferred into chloroform was very low (the maximal amount was 14% at pH 9.2 — Fig. 1*B*). It indicated that chloride complexes of Cd(II) and Cd(II) hydroxide were enough stable to prevent complexation of Cd(II) by **1** and its transfer into chloroform. Thus, only Zn(II) was transferred efficiently by **1** into the organic phase and good separation of Zn(II) from other divalent metal ions was achieved in that phase. In the pH region of 5.8–7.1, 11 to 94% of Zn(II), respectively, was transferred by **1** into chloroform while transfer of Cd(II) and Hg(II) did not exceed 3% (Fig. 1*B*).

In the system with **2** employed as the complexone, also good separation of Zn(II) from Cd(II) and Hg(II) was found. In the pH region of 6.6–7.0, 74 to 97% of Zn(II), respectively, was transferred into the organic phase while transfer of Cd(II) and Hg(II) did not exceed 2.5% (Fig. 1*D*). When the pH was raised above 7.0, transfer of Cd(II) into chloroform by **2** increased and reached its maximal value (87%) at pH 8.6. Thus, **2** (with the *n*-octyl chain incorporated into the molecule) was a stronger complexone of Cd(II) than **1** (with the *n*-hexyl chain incorporated).

The curve portions illustrating concentrations of Zn(II) and Cd(II) in the organic phase in the acidic pH region were closer to each other if a complexone with a longer *n*-alkyl chain incorporated into the molecule was used (Figs. 1*D*, *F*, *H*). Thus, a difference in complexation of Zn(II) and Cd(II) decreased when lipophilicity of the complexone was raised. In other words, higher lipophilic *n*-alkyltri(oxyethylene) carboxylic acids were less selective.

*Transfer of the divalent metal ions from aqueous solutions containing 1.67 m*M *$ZnCl_2$, $CdCl_2$, $HgCl_2$, and 2.34* M *NaCl*

The results of experiments are presented in Figs. 2*C*, *E* and Table 3.

No metal concentrations were measured in the system with **1** because a stable emulsion was formed in chloroform in the pH region of 2.6–9.0.

In the system with **2**, good separation of Zn(II) from Cd(II) and Hg(II) was found. In the pH region of 4.6–6.6, 9.7 to 100% of Zn(II) was transferred into chloroform, respectively, while Cd(II) and Hg(II) remained entirely in the aqueous phase (Fig. 2*C*).

In the system with **4**, the efficiency of transfer of Zn(II) was lower (Fig. 2*E*) than in case of **2** (Fig. 2*C*). Only 83.5% (the maximal amount) of Zn(II) was transferred by **4** at pH 7.45. However, still good separation was achieved in that system because neither Cd(II) nor Hg(II) were transferred into chloroform in the pH region of 3.3–7.45 (Fig. 2*E*).

Again, less lipophilic **2** was found to be a better (more selective and more efficient) ion carrier than **4** which has two more methylene units incorporated into its molecule.

n-*Alkyloligo(oxyethylene) carboxylic acids (APOs) as selective complexones of the zinc group element ions*

APOs were found to be selective complexones of the zinc group metal ions when NaCl was added to the aqueous phase. In fact, the selectivity of separation was produced by the chemical equilibria involving complexation of those metal ions by Cl^-, OH^-, and an APO. Thus, the separation was strongly dependent on the aqueous phase composition.

The selectivity and efficiency of separation of the zinc group metal ions by APOs depend on the length of a poly(oxyethylene) chain (12) and on the length of a *n*-alkyl chain incorporated into their molecule.

The complexing abilities of APOs improved gradually when more oxyethylene units were incorporated into their molecule (12). This was in contrast with complexing abilities of poly(oxyethylene) dicarboxylic acids toward alkaline-earth cations because their selectivities changed remarkably but disorderly when a poly(oxyethylene) chain was lengthened (11).

Less lipophilic APOs (with a shorter poly(oxyethylene) chain incorporated into their molecule) were more selective and efficient carriers of the zinc group metal ions. This time, it was in contrast with the properties of both crown carboxylic acids and poly(oxyethylene) dicarboxylic acids because complexing abilities (the selectivity among them) of those compounds usually improved if their lipophilicity was raised (9, 13, 20).

Concentrations of the zinc group metal ion in the organic phase decreased in the basic region of the equilibrium pH of the aqueous phase due to formation of Zn(II) and Cd(II) hydroxides

and Hg(II) oxide precipitates, even if an APO was enough highly lipophilic to remain entirely in the aqueous phase. Apparently, these hydroxides were thermodynamically more stable than complexes of the metal ion with an APO.

At high Cl^- concentration, chloride complexes of Hg(II) were also enough strong to prevent Hg(II) complexation by an APO and its transfer into chloroform.

$(Ph_3P)_2Rh(SPCy_2)$: A complex containing a side-on bonded η^2-secondary phosphine sulfide anion

LUCIO GELMINI[1] AND DOUGLAS W. STEPHAN[2]

Department of Chemistry and Biochemistry, University of Windsor, Windsor, Ont., Canada N9B 3P4

Received March 29, 1988

LUCIO GELMINI and DOUGLAS W. STEPHAN. Can. J. Chem. **66**, 2647 (1988).

The reaction of $Cp_2Zr(SPCy_2)_2$ with either $(Ph_3P)_3RhH(CO)$ or $(Ph_3P)_4RhH$ led not to the expected heterobimetallic species but rather to a novel Rh species $(Ph_3P)_2Rh(SPCy_2)$, **4**. The $^{31}P\{^1H\}$ NMR spectrum of this complex is an ABCX pattern. The molecular geometry of **4** was confirmed by a crystallographic study. Compound **4** crystallizes in the space group $P2_1/c$ with $a = 10.912(1)$ Å, $b = 12.335(2)$ Å, $c = 32.346(7)$ Å, $\beta = 96.17(1)°$, $V = 4328(1)$ Å^3, and $Z = 4$. The coordination sphere about Rh in **4** is pseudo-square planar, containing three phosphorus and a sulfur atom from the two coordinated phosphines and a side-on bonded $SPCy_2$ moiety. This structural study confirms that the secondary phosphine chalcogenide is bonded to Rh in an η^2 fashion. The complex **4** is only the fourth example in which this mode of binding has been crystallographically confirmed and is the first such species to involve one of the Pt group metals.

LUCIO GELMINI et DOUGLAS W. STEPHAN. Can. J. Chem. **66**, 2647 (1988).

La réaction du $Cp_2Zr(SPCy_2)_2$ avec soit le $(Ph_3P)_3RhH(CO)$ ou le $(Ph_3P)_4RhH$ ne conduit pas aux espèces hétérobimétalliques attendues mais plutôt à une nouvelle espèce de Rh, le $(Ph_3P)_2Rh(SPCy_2)$, **4**. Le spectre rmn du $^{31}P\{^1H\}$ de ce complexe se présente sous la forme d'un arrangement ABCX. On a confirmé la géométrie moléculaire du composé **4** par une étude cristallographique. Le composé **4** cristallise dans le groupe d'espace $P2_1/c$ avec $a = 10{,}912(1)$, $b = 12{,}335(2)$ et $c = 32{,}345(7)$ Å, $\beta = 96{,}17(1)°$, $V = 4328(1)$ Å^3 et $Z = 4$. La sphère de coordination autour du Rh dans le composé **4** est pseudo plan carré et elle contient trois phosphores et un atome de soufre provenant de deux phosphines coordonnées et une portion de $SPCy_2$ liée sur le côté. Cette étude structurale permet de confirmer que la phosphine chalcogène secondaire est liée au Rh d'une façon η^2. Le complexe **4** n'est que le quatrième exemple dans lequel ce mode de liaison a pu être confirmé d'une façon cristallographique et il s'agit de la première espèce de ce type à incorporer un des métaux du groupe du Pt.

Introduction

Our interest in early/late heterobimetallics (1–12) has led us to investigate the use of functionalized early transition metal complexes as metalloligands for later transition metals. In a recent paper we described syntheses, structures and chemistry of some Ti, Zr, and Hf complexes of secondary phosphine sulfides and selenides (9). In these Ti, Zr, and Hf complexes, bonding of XPR_2 anions through chalcogenide was observed. However, secondary phosphine chalcogenides or their conjugate bases are known to exhibit at least six different bonding modes (Fig. 1) (13–35). One of these modes involves bonding in which the chalcogen and phosphorus nuclei are bound to different metal atoms (Fig. 1(*e*)); however, this type of ligand system has not been employed to synthesize mixed metal species. Thus, the complex $Cp_2Zr(SPCy_2)_2$, **1**, seemed a suitable synthon for the preparation of Zr/M heterobimetallics. In this paper, we describe some initial investigations that show that reactions of **1** with two Rh-hydride species result in the cleavage of the Zr—S bond, yielding the monometallic species $(Ph_3P)_2Rh(SPCy_2)$, **4**. The species, **4**, has been characterized crystallographically. The results show that the secondary phosphine sulfide moiety is side-on bonded in an η^2 fashion. Although this form of binding is known, this report is only the fourth in which this form of bonding has been structurally confirmed.

Experimental section

All preparations were done under an atmosphere of dry, O_2-free N_2. Solvents were reagent grade, distilled from the appropriate drying agents under N_2, and degassed by the freeze–thaw method at least three times prior to use. $^{31}P\{^1H\}$ NMR spectra were recorded on a Bruker AC-200 spectrometer, using external 85% H_3PO_4 as the reference. The chemical shifts are reported in ppm relative to this reference. Melting points are reported uncorrected. The complex $Cp_2Zr(SPCy_2)_2$, **1**, $(Ph_3P)_3RhH(CO)$, **2**, and $(Ph_3P)_4RhH$, **3**, were prepared by published methods (9, 36).

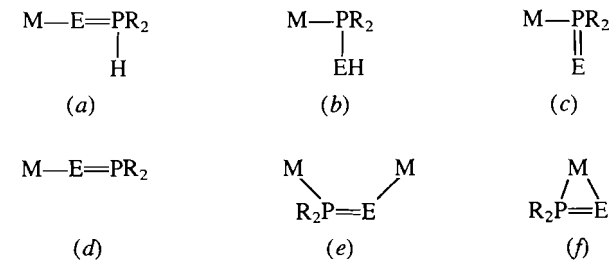

FIG. 1. Bonding modes of secondary phosphine chalcogenides.

Preparation of $(Ph_3P)_2Rh(SPCy_2)$, 4

To a benzene solution (5 mL) of 38 mg of **1** was added 50 mg of **2** in 5 mL of benzene. The solution was stirred for 12 h. The product precipitated from solution upon addition of hexane. The orange–red crystalline material was recrystallized from benzene/hexane. Replacement of **2** with an equivalent of **3** also affords the isolation of **4** via an identical work up procedure. Yield 35 mg (75%). ^1H NMR (δ, C_6D_6): 7.1–7.4 (m, 30 H), 2.2–2.8 (m, 22 H). $^{31}P\{^1H\}$ NMR (C_6H_6, δ, J (Hz)): 40.80 (P3, d of d of d, 1P), 48.20 (P2, d of d of d, 1P), 87.38 (P1, d of d of d, 1P), $|J_{P1—Rh}| = 87.9$, $|J_{P2—Rh}| = 215.6$, $|J_{P3—Rh}| = 168.7$, $|J_{P1—P2}| = 28.4$, $|J_{P1—P3}| = 231.6$, $|J_{P2—P3}| = 30.1$.

X-ray data collection and reduction

Orange–red crystals of **1** were obtained by vapour diffusion of hexane into a benzene solution of **2**. Diffraction experiments were performed on a four-circle Syntex $P2_1$ diffractometer with graphite-monochromatized Mo Kα radiation. The initial orientation matrix was obtained from 15 machine-centred reflections selected from a rotation photograph. These data were used to determine the crystal system. Partial rotation photographs around each axis were consistent with a monoclinic crystal system. Ultimately, 37 reflections ($4.7° < 2\theta <$

TABLE 1. Crystallographic parameters

Formula	$C_{48}H_{52}P_3SRh$
Crystal colour, form	Orange–red blocks
a (Å)	10.912(1)
b (Å)	12.335(2)
c (Å)	32.346(7)
β (deg)	96.17(1)
Crystal system	Monoclinic
Space group	$P2_1/c$
Volume (Å^3)	4328(1)
Density (g cm^{-3})	1.31
Z	4
Crystal dimensions (mm)	0.40 × 0.30 × 0.40
Absorption coefficient, μ (cm^{-1})	5.10
Radiation λ, (Å)	Mo Kα (0.71069)
Temperature (°C)	24
Scan speed (deg/min)	2.0–5.0 (θ/2θ scan)
Scan range (deg)	1.0 below $K\alpha_1$ 1.0 below $K\alpha_2$
Background/scan time ratio	0.5
Data collected	3002
No. of unique data $F_o^2 > 3\sigma(F_o^2)$	2088
No. of variables	166
R (%)	4.53
R_w (%)	5.32
Largest Δ/σ in the final least squares cycle	0.001
Maximum residual electron density (e/Å^3) (atom associated)	0.49 (C84—C85)

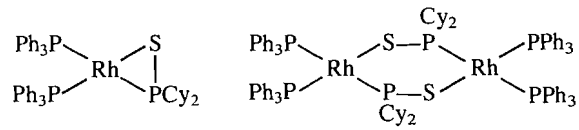
25°) were used to obtain the final lattice parameters and the orientation matrix. Machine parameters, crystal data, and data collection parameters are summarized in Table 1. The observed extinctions were consistent with the space group $P2_1/c$. All $\pm h$, $+k$, $+l$ data were collected in one shell ($4.5° < 2\theta < 35.0°$) and three standard reflections were recorded every 197 reflections. Their intensities showed no statistically significant change over the duration of the data collection. The data were processed using the SHELX-76 program package on the computing facilities at the University of Windsor. A total of 3002 reflections with $F_o^2 > 3\sigma F_o^2$ were used in the refinement. The absorption coefficient was small (μ = 5.10 5.10 cm^{-1}) and thus no absorption correction was applied to the data.

Structure solution and refinement

Non-hydrogen atomic scattering factors were taken from the literature tabulations (37–39). The Rh atom position was determined using the heavy atom (Patterson) method. The remaining non-hydrogen atoms were located from successive difference Fourier map calculations. The initial refinements were carried out by using full-matrix least-squares techniques on F, minimizing the function $\Sigma w(|F_o| - |F_c|)^2$ where the weight, w, is defined as $4F_o^2/\sigma^2(F_o^2)$ and F_o and F_c are the observed and calculated structure factor amplitudes. In the final cycles of refinement the Rh, P and S atoms were assigned anisotropic temperature factors. The carbon atoms of the phenyl and cyclohexyl rings were described by isotropic thermal parameters. The phenyl ring geometries were constrained to that of a hexagon with a carbon–carbon distance of 1.39 Å. Hydrogen atom positions were calculated and allowed to ride on the carbon to which they are bonded, assuming a C—H bond length of 0.95 Å. Hydrogen atom temperature factors were fixed at 1.10 times the isotropic temperature factor of the carbon atom to which they are bonded. In all cases the hydrogen atom contributions were calculated, but not refined. The final values of R and R_w are given in Table 1. The maximum Δ/σ on any of the parameters in the final cycles of the refinement and the location of the largest peaks in the final difference Fourier map calculation are also given in Table 1. The residual electron densities were of no chemical significance. The following data are tabulated: positional parameters (Table 2) and selected bond distances and angles (Table 3). Thermal parameters (Table S1), hydrogen atom parameters (Table S2), bond distances and angles associated with the cyclohexyl rings (Table S3) and values of $10|F_o|$ and $10|F_c|$ (Table S4) have been deposited as supplementary material.[3]

Results and discussion

The reaction of **1** with either $(Ph_3P)_3RhH(CO)$ or $(Ph_3P)_4RhH$ resulted in the immediate formation of an orange–red product, **4**. This material exhibits a ^1H NMR spectrum that shows only phenyl and cyclohexyl proton resonances, indicating the loss of the Cp_2Zr fragment. The $^{31}P\{^1H\}$ NMR spectrum contains three distinct resonances each comprised of a doublet of doublets of doublets. This ABCX spectrum (Fig. 2) is consistent with three inequivalent phosphorus nuclei about a pseudo-square planar Rh atom. The resonances were assigned to P1 (the phosphorus of the $SPCy_2$ moiety), P2 (the phosphorus of the PPh_3 *cis* to P1) and P3 (the phosphorus of the PPh_3 *trans* to P1) on the basis of chemical shifts and coupling constants. The expectation of square planar coordination geometry for Rh suggests that the S of the $SPCy_2$ moiety is also bound to Rh. This is consistent with either a monometallic species containing an η^2 bound secondary phosphine sulfide, **4**, a dimeric, **5**, or an oligomeric



4 **5**

complex. The magnitude of the P1—Rh coupling constant suggests the incorporation of P1 in a three-membered ring, thus suggesting a monometallic species (15, 29). Such η^2 binding of SPR_2 moieties to Rh has been previously postulated on the basis of spectroscopic data (17, 29) and is herein confirmed by X-ray crystallography (*vide infra*). This mode of binding of a secondary phosphine sulfide has also been confirmed for Mo (15, 35) and Fe (34) complexes. Complexes in which SPR_2 moieties are bound in a η^2 fashion have been postulated as intermediates in a number of reactions and are generally considered to be unstable (19–21, 26, 27, 34).

The mechanism of formation of **4** is not known nor is the nature of the Zr-containing product. It is clear, however, that cleavage of a Zr—S bond must occur in the process of the formation of **4**. Such lability of Zr—S bonds has been noted in other Zr—S chemistry (9).

Structure description

The crystallographic investigation of **4** revealed that the unit cell is monoclinic with a single discrete molecule in the asymmetric unit. The closest non-bonded distance between discrete molecules is 2.380 Å (H15B---H73). An ORTEP drawing of the molecule is shown in Fig. 3. The coordination sphere of Rh is pseudo-square planar containing three phos-

[3]A complete set of data, including thermal parameters (Table S1), hydrogen atom parameters (Table S2), and bond distances and angles associated with the cyclohexyl rings (Table S3) (6 pages); values of $10|F_o|$ and $10|F_c|$ (Table S4) (8 pages), may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

phorus atoms and a sulfur atom. The Rh—P1 bond distance is 2.248(3) Å. In comparison, the Rh—P bonds involving the PPh_3 moieties are 2.219(3) and 2.287(3) Å. All of these Rh—P distances are typical of those seen in other Rh–phosphine complexes (39). The Rh—P3 distance is longer than the Rh—P2 distance reflecting the *trans* influence of the basic phosphorus atom of the $SPCy_2$ moiety. The Rh—S bond distance of 2.399(3) Å is slightly longer than the Rh—S distance found in $[Rh(MeSCH_2CH_2PPh_2)_2]BF_4$ (2.353(3) and 2.342(3) Å) (40). Poorer donor ability of the sulfur of a $SPCy_2$ anion compared to that of the thioether sulfur of $MeSCH_2CH_2PPh_2$ may arise from the presence of P—S multiple bonding. In addition, the strain associated with the three-membered ring may result in poor orbital overlap between S and Rh.

The P1—Rh—P2 and P3—Rh—S angles of 108.4(1) and 95.8(1)° are consistent with the pseudo-square planar geometry about Rh. The P2—Rh—P3 angle of 103.6(1)° compares with the angle of 92.9(1)° found between the phosphine groups in $[Rh(COD)(PPh_2(C_4H_4S))_2]^+$ (40). Steric interactions between the phenyl rings on P2 with the cyclohexyl groups on P1 are apparently minimized by the orientation of the rings, such that only ring 5 (C51—C56) is directed towards the cyclohexyl groups. Steric interactions with the phenyl rings on P2 with

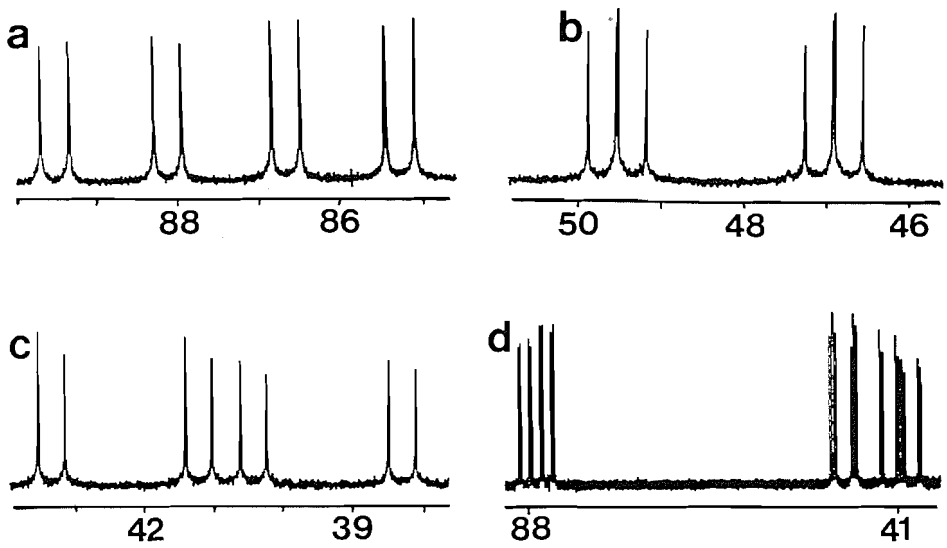

FIG. 2. $^{31}P\{^{1}H\}$ NMR Spectrum of **4**, scales are given in ppm. Expansion of the signals arising from P1, P2, and P3 are shown in (*a*), (*b*), and (*c*) respectively; (*d*) full spectrum.

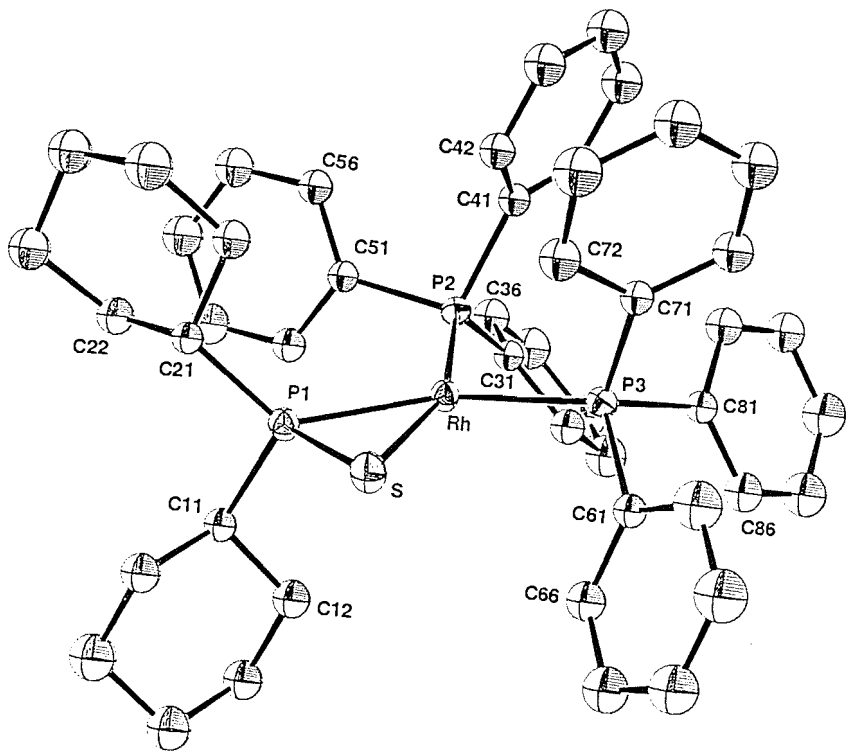

FIG. 3. ORTEP drawing of **4**, hydrogen atoms are omitted for clarity, 30% thermal ellipsoids are shown.

those on P3 are relived by the relatively large P2—Rh—P3 angle. These steric constraints are also reflected in the fact that the S—Rh—P3 angle (95.8(1)°) is smaller than the P1—Rh—P2 angle (108.4(1)°). The P1—Rh—S angle is 51.6(1)°. This is similar to the P—Fe—S angle of 51.13(3)° found in $(C_3F_7)Fe(CO)_3(SPEt_2)$, **6**, (34) and in contrast to the P—Mo—S angles of 47.11(5) and 46.91(5)° found in $Mo(CO)_2(PPh_3)(SPPh_2)_2$, **7** (15) and 47.5(1)° found in $(MeC_5H_4)Mo(CO)_2(\eta^2\text{-}SPPh_2)$, **8** (35). The larger angle at the metal center in **4** is consistent with the shorter M—P and M—S distances.

The P1—S bond distance of 2.028(4) Å is considerably longer than the typical P—S double bond length of 1.95 Å and shorter than P—S single bond lengths of 2.18 Å (15). The observed P—S distance in **4** is comparable to the P—S bond distances in the complexes containing η^2-bound SPR_2 units **6** (2.011(1) Å) (34), **7** (2.008(2), 2.013(2) Å) (15), and **8** (2.003(2) Å) (35). Thus, the P—S bond distance reflects a considerable degree of π bonding between phosphorus and sulfur.

Summary

The reaction of **1** with two Rh hydrides does not lead to the formation of stable heterobimetallics. Rather, the monometallic species **4** is formed. The structural study described herein, confirms the η^2 bonding mode of the secondary phosphine

sulfide anion. The complex **4** is only the fourth example in which this mode of binding has been crystallographically confirmed and is the first such species to involve one of the Pt group metals.

D. W. SHOESMITH and M. G. BAILEY. Can. J. Chem. **66**, 2652 (1988).

The anodic oxidation of lead has been studied using rotating disk electrodes, under voltammetric and potentiostatic conditions, in aqueous carbonate solutions at pH = 12. The solid films formed on the electrode surface have been identified by X-ray diffractometry. Two distinct surface layers are formed: a compact layer composed of two separate phases, plumbonacrite ($Pb_{10}O(OH)_6(CO_3)_6$) and hydrocerussite ($Pb_3(OH)_2(CO_3)_2$); and a more dispersed layer of hydrocerussite. The plumbonacrite in the compact layer is formed directly on the electrode surface by a solid-state growth process. The hydrocerussite component of this compact layer appears to form by conversion of the outer layers of plumbonacrite. The dispersed layer is formed by deposition from solution. The extent of deposition is controlled by the rate of transport of soluble Pb^{2+} species to the bulk of solution.

D. W. SHOESMITH et M. G. BAILEY. Can. J. Chem. **66**, 2652 (1988).

Opérant dans des solutions aqueuses de carbonate, à un pH de 12, dans des conditions voltamétriques ainsi que potentiostatiques et faisant appel à des électrodes à disque tournant, on a étudié l'oxydation anodique du plomb. Utilisant la diffraction des rayons-X, on a identifié les films solides qui se forment à la surface de l'électrode. À cette surface, il se forme deux couches distinctes : une couche compacte composée de deux phases séparées, de la plumbonacrite (Pb_{10})$(OH)_6(CO_3)_6$) et de l'hydrocérussite ($Pb_3(OH)_2(CO_3)_2$) ainsi qu'une couche plus dispersée d'hydrocérussite. La plumbonacrite présente dans la couche compacte se forme directement sur la surface de l'électrode par un processus de croissance à l'état solide. Il semble que la composante hydrocérussite de cette couche compacte se forme par la conversion des couches extérieures de plumbonacrite. La couche dispersée se forme par une déposition à partir de la solution. Le taux de déposition est contrôlé par la vitesse de transport des espèces Pb^{2+} à partir de la solution.

Introduction

The proposed Canadian method for the disposal of high-level nuclear waste, in the form of either irradiated fuel or reprocessed waste, is to bury it 1 km below the surface of a stable rock formation (1). A number of engineered barriers have been suggested to prevent access of groundwater to the wasteform and to impede the subsequent release of radionuclides. One proposal is that the wasteform be invested in lead and placed inside a titanium canister. The corrosion performance of titanium has been studied in detail (2) but little work has been done on lead (3).

Besides acting as a corrosion barrier, there appear to be a number of other chemical advantages in having lead present: (*a*) The lead could act as a redox scavenger by removing dissolved oxidants from the groundwater, thereby slowing down the oxidative dissolution of the uranium dioxide fuel (4). (*b*) The corrosion of lead could lead to the formation of basic lead compounds with a number of anions expected in the groundwater (5). The solubility of such compounds is generally low, and the anion concentration in the groundwater would be significantly reduced. This would be of particular advantage in the case of carbonate that strongly complexes UO_2^{2+}, the product of UO_2 dissolution ($UO_2(CO_3)_2^{2-}$, $UO_2(CO_3)_3^{4-}$), thereby increasing its solubility and accelerating the dissolution process (6, 7).

To evaluate the efficacy of lead as a barrier, it is necessary to have a good understanding of the chemical processes occurring under the redox and chemical conditions possible in a nuclear waste repository. The interaction of lead oxide (PbO, litharge) with aqueous carbonate solutions has been studied in detail (8), and the stability fields for a number of solids in the $PbO–CO_2–H_2O$ system have been determined. The infrared and Raman spectra for the various solids have been published (9). In this paper, we present results on the electrochemistry of lead in aqueous carbonate solutions. Since the Pb^{4+} state will not be achieved under natural corrosion conditions, we have concentrated on the study of the Pb/Pb^{2+} system.

Experimental

Experiments were performed in a conventional three-electrode cell, degassed with nitrogen. Solutions were made up with Fisher Scientific certified reagents. The lead was supplied by the Canadian Metal Company and was 99.99% pure. The electrodes were constructed as rotating disks with an exposed surface area of 1.6 cm^2. Electrodes were polished with wet 600 grit SiC, and washed with triply distilled water. The results were found to be very dependent on electrode preparation, and the preparation used gave reproducible results. Unless otherwise stated, all experiments were conducted in 1.0 mol L^{-1} potassium carbonate. All potentials are quoted against the saturated calomel electrode (vs. SCE).

Electrochemical experiments were performed using an EG and G model 173 potentiostat/galvanostat coupled to a model 179 coulometer and a model 175 Universal programmer. Electrodes were rotated using a Pine Instrument Company ASR rotator. Data were recorded using a Phillips model PM 8132 XY recorder.

The phases formed on the electrode surface were identified using a Philips PW-1150 diffractometer with Cu K_α radiation and a diffracted beam monochromator. The relative amounts of the different phases present were measured by comparing the heights of single diffraction peaks for the various phases. The particular peaks used were chosen so that they were of comparable intensities and did not significantly overlap with other peaks in the X-ray pattern. Thus, the peaks used for the various phases were as follows: plumbonacrite (*d*-spacing = 3.36 Å); hydrocerussite (3.29 Å); cerussite (3.498 Å); litharge (3.115 Å). Such a comparison is only semiquantitative.

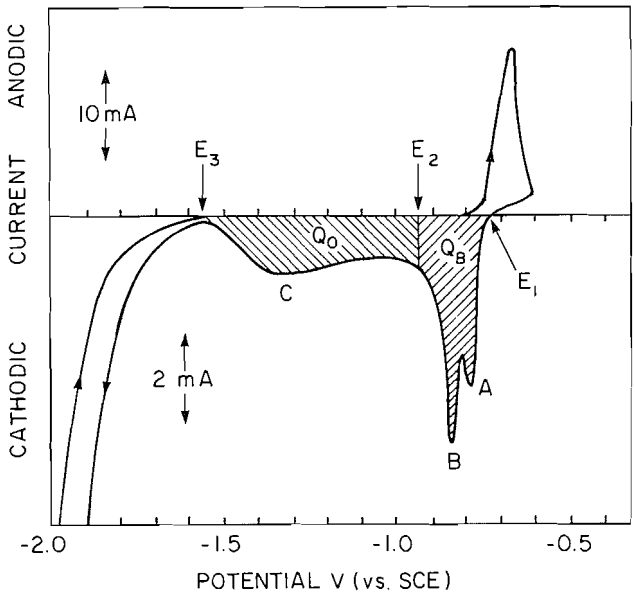

FIG. 1. Cyclic voltammogram recorded in 1.0 mol L^{-1} K_2CO_3 (pH = 12.0) at v = 20 mV s^{-1} and ω = 1.67 Hz. The various cathodic peaks are marked A, B, and C. The hatched areas show the sections of the plots integrated to obtain the charges Q_B and Q_O.

Results

Cyclic voltammetry

Figure 1 shows a cyclic voltammogram recorded in 1.0 mol L^{-1} K_2CO_3 (pH = 12) on a rotating disk electrode (ω = 1.67 Hz) at a scan rate of 20 mV s^{-1}. A single anodic peak is observed around −0.660 V (vs. SCE) with a shoulder at more negative potentials (~ −0.700 V). If the potential scan is reversed immediately after the main anodic peak, Fig. 1, three distinct reduction peaks (A, B, and C) are observed on the reverse cathodic scan. The existence of three reduction peaks suggests that three distinct films or phases are formed on the anodic scan. The sharpness, symmetry, and position of peaks A and B indicate the reduction of two compact adherent films. The broadness of peak C suggests that the second process (around E = ~ −1.300 V) is the reduction of a more dispersed film. If the process occurring at peak C is the reduction of an outer layer of deposit, it will be taking place on a possibly porous metal layer formed by the reduction of the base layer at peaks A and B. Further justification for our claim that peak C is due to the reduction of a deposited outer layer is offered below.

Figure 2 shows a series of voltammograms reversed at various anodic limits. The electrode rotation rate (ω) is an order of magnitude greater than for Fig. 1. The effect of this increase is to reduce the extent of formation of the film reduced at peak C. Potential scans limited to the cathodic side of the anodic peak show that the film reduced at peak B is formed in this region. This is clearly demonstrated by the data of Fig. 7, to be discussed below. The film reduced at peak A forms at more positive potentials, and becomes dominant as the scan progresses down the anodic side of the peak. Both peaks grow as the scan progresses to more positive potentials in the passive region beyond the main anodic peak. Although not shown in Fig. 2, the film reduced at peak C forms on the cathodic side of the anodic peak, and does not thicken significantly as the scan progresses to more positive potentials.

Figure 3 shows the effect of potential scan rate (to an anodic limit of −610 mV) on the anodic and cathodic charges, Q_A and

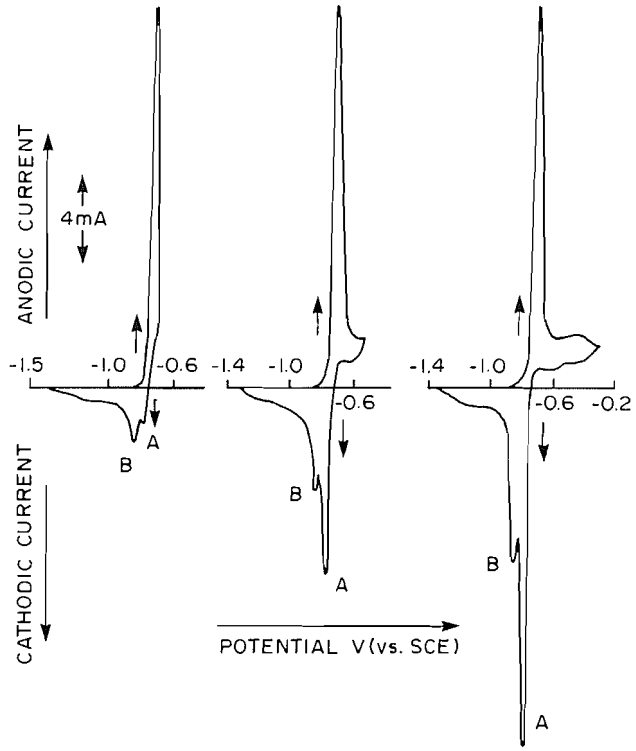

FIG. 2. Voltammetric scans to various anodic limits recorded in 1.0 mol L^{-1} K_2CO_3 (pH = 12.0) at v = 20 mV s^{-1} and ω = 16.7 Hz.

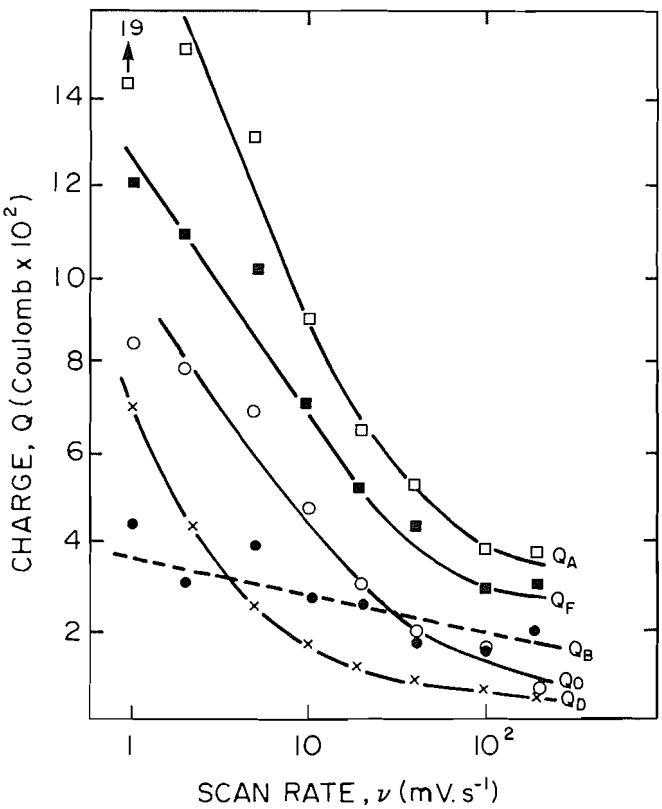

FIG. 3. Anodic and various cathodic charges, as a function of the scan rate (v), obtained by integration of voltammetric scans (to an anodic limit of −610 mV) recorded in 1.0 mol L^{-1} K_2CO_3 (pH = 12.0) at ω = 1.67 Hz; Q_A, Q_F, and Q_D are defined by eqs. [1] and [2] of the text, and Q_B and Q_O are defined in Fig. 1.

Q_F, and on the distribution of charges between base-layer formation (Q_B), outer-layer formation (Q_O), and the charge, Q_D, given by the expression

[1] $Q_D = Q_A - Q_F$

with

[2] $Q_F = Q_B + Q_O$

The charges are obtained by the integration of voltammograms of the form shown in Fig. 1: Q_A is the total anodic charge consumed during the anodic scan plus the small amount consumed at the start of the reverse scan; Q_F is the total charge measured by integration of the current between potentials E_1 and E_3 (Fig. 1), and is taken as the charge due to the reduction of all films; Q_B and Q_O are obtained by integration of the current between E_1 and E_2, and E_2 and E_3, respectively; Q_D is taken to be the charge due to dissolution to Pb^{2+} species.

By contrast, the charge associated with the reduction of the base layer, Q_B, changes only slightly with scan rate. This behaviour suggests that the thickness of the base layer is determined by kinetic parameters that are potential dependent, but large enough to be independent of scan rate. The passivating nature of this layer is the cause of the anodic peak observed in Fig. 1 and the rapid fall in current at potentials positive to the peak. By contrast to Q_B, both Q_A and Q_F decrease as the scan rate increases. This can be attributed to decreases in the extent of dissolution (Q_D) and in the thickness of the deposited layer (proportional to Q_O). As the scan rate increases, the potential spends less time in the potential region where dissolution occurs, i.e., less time on the cathodic side of the peak. Consequently, less dissolution and deposition are observed.

The parallel decrease in the thickness of the outer layer (Q_O) and the extent of dissolution (Q_D) indicate that these two processes are related. It is possible that the extent of dissolution determines the thickness of the outer layer, suggesting that this layer is formed by deposition of dissolved Pb^{2+} species. As discussed above, this deposited layer only forms on the cathodic side of the anodic peak.

Figure 4 shows the effect of electrode rotation speed on the form of the cyclic voltammograms. The height of the anodic peak is increased, but the size of the cathodic peaks is reduced. The major impact is on the size of peak C, which almost disappears at high electrode rotation rates. The relative heights of reduction peaks A and B do not vary consistently with changes in rotation rate.

Figures 5A and 5B show the effect of electrode rotation rate (ω) on the various charges, calculated as described above. The total anodic charge increases by ~40% over the range of rotation rates investigated (0.83–33.3 Hz), attributable to an increase in the extent of dissolution (Q_D). The extent of film formation (Q_F), Fig. 5B, decreases with increasing rotation rate. The thickness of the base layer (proportional to Q_B) is almost independent of rotation rate. However, there is a redistribution of charge between dissolution (Q_D), which increases, and film deposition (Q_O), which decreases. This redistribution demonstrates that the dissolution and deposition processes are competing for the same soluble material, and confirms that the outer layer of film is formed by deposition from solution. The extent of formation of this film is determined by the concentration of dissolved Pb^{2+} species close to the electrode surface. This concentration will decrease as the electrode rotation rate increases and the rate of transport of soluble species away from the electrode increases. In this manner, the solution transport and deposition processes compete for the soluble Pb^{2+} species, with transport predominating at higher electrode rotation rates. The Pb^{2+} species lost to the bulk of solution are not reduced on the subsequent cathodic scan. Hence, Q_F ($= Q_A - Q_D$, eq. [1]) decreases with increasing electrode rotation rate.

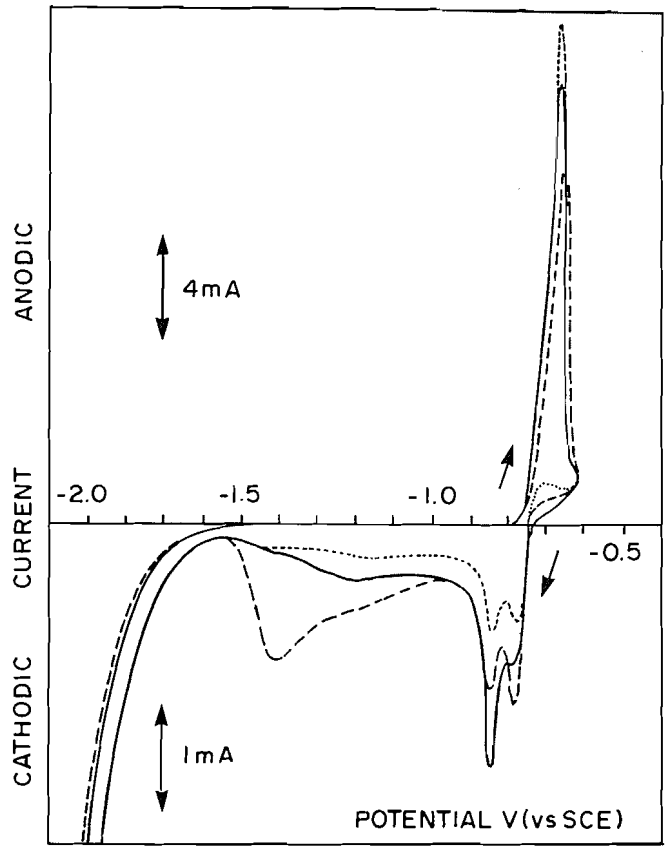

FIG. 4. Voltammetric scans recorded in 1.0 mol L^{-1} K_2CO_3 (pH = 12.0) at 20 mV s^{-1} and various electrode angular velocities (ω, in Hz); (---) 1.67 Hz; (—) 16.7 Hz; (····) 50 Hz.

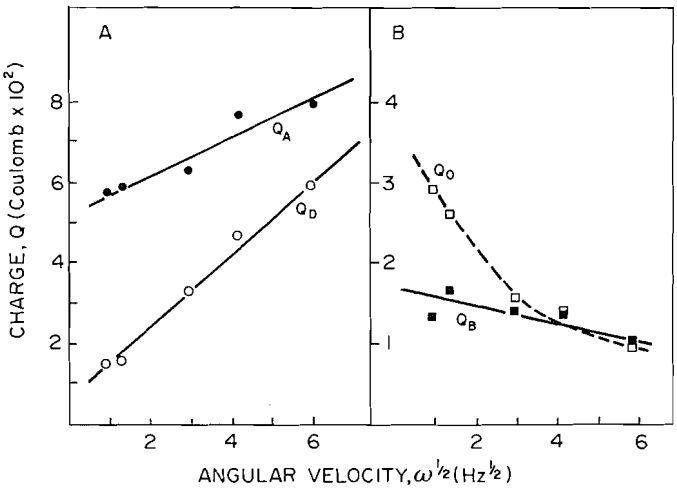

FIG. 5. Anodic and various cathodic charges, as a function of angular velocity (ω), obtained by integration of voltammetric scans recorded in 1.0 mol L^{-1} K_2CO_3 (pH = 12.0) at $v = 20$ mV s^{-1}; Q_A and Q_D are defined by eqs. [1] and [2] of the text, and Q_B and Q_O are defined in Fig. 1.

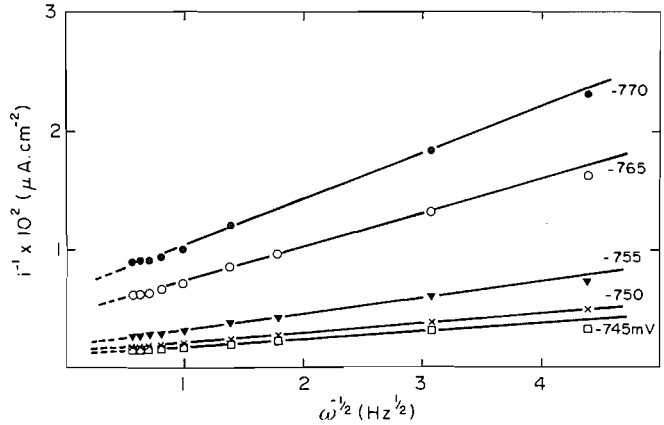

FIG. 6. Plot of steady-state currents (as i^{-1}) against $\omega^{-1/2}$ (Hz) recorded under potentiostatic conditions at various potentials in 1.0 mol L^{-1} K_2CO_3 (pH = 12.0).

Potentiostatic experiments

A series of potentiostatic experiments was performed under stagnant conditions ($\omega = 0$) at potentials in the vicinity of the foot of the main anodic peak (−0.790 to −0.740 V). Rapidly falling transients were obtained with the current (i) decreasing from >1 mA cm^{-2} to <15 $\mu A \cdot cm^{-2}$ in times (t) from 20 to 30 s. Steady-state currents were achieved after ~6–7 min. The form of the current (i) versus time (t) plot was dependent on electrode preparation. No consistent linear relationship between i and t was obtained. Also, no peak was observed in the current transient, indicating that a phase nucleation and growth process was not involved.

The steady-state currents are dependent on electrode rotation rate (ω) and are plotted according to the Levich theory (6) in Fig. 6. Extrapolation of these plots to infinite rotation speeds ($\omega^{-1/2} \rightarrow 0$) yields values for the dissolution current free from transport, confirming that the dissolution process is under mixed electrochemical/transport control. Further analysis according to this theory (6) did not yield consistent results.

From these data it can be concluded that a surface film is formed at potentials as negative as −0.790 V, and that there appears to be no potential region where dissolution of Pb^{2+} species occurs from a clean metal surface. Dissolution of this surface film occurs via a field-assisted process partially controlled by transport of Pb^{2+} species away from the electrode surface. Since the maximum Pb^{2+} concentration in equilibrium with hydrocerussite, the predominant surface phase, is $<10^{-3}$ mol L^{-1}, control by OH^- (10^{-2} mol L^{-1}) or carbonate (1.0 mol L^{-1}) transport to the electrode surface is ruled out.

XRD analyses of potentiostatically grown films

A series of potentiostatic oxidations was performed for various durations at different potentials. The films formed were subsequently analyzed by X-ray diffraction (XRD), or cathodically stripped using a voltammetric scan (CSV) from the oxidation potential to −2.0 V.

Figure 7 shows a series of cathodic stripping voltammograms (CSVs) recorded after oxidations at −0.726 V, a potential negative to the shoulder on the main anodic oxidation peak, Fig. 1. The XRD data obtained on a second series of experiments at this potential are shown in Fig. 8. For short oxidations, Fig. 7A, only peak B is observed. A corresponding XRD analysis detects only plumbonacrite, $Pb_{10}O(OH)_6(CO_3)_6$. After 10 min of oxidation, peak C is observed in the CSV, Fig. 7B, but, again,

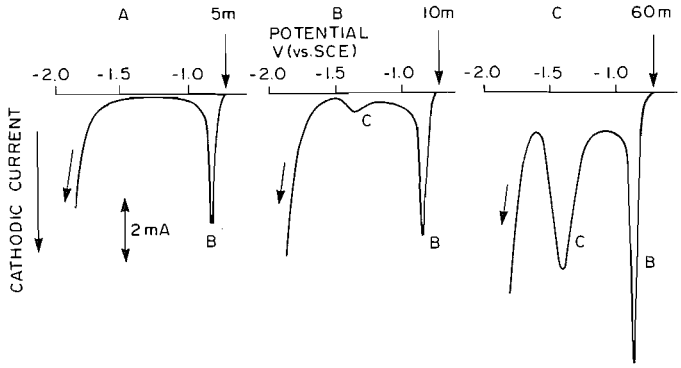

FIG. 7. Cathodic stripping voltammograms recorded after potentiostatic oxidation at −0.726 V (vs. SCE) for various times in 1.0 mol L^{-1} K_2CO_3 (pH = 12.0) at $v = 20$ mV s^{-1} and $\omega = 1.67$ Hz.

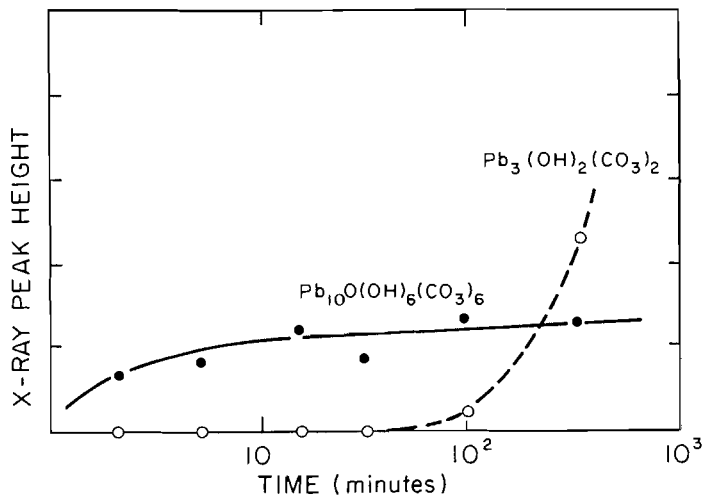

FIG. 8. X-ray peak heights for plumbonacrite and hydrocerussite recorded on electrodes oxidized at −0.726 V for various times in 1.0 mol L^{-1} K_2CO_3 (pH = 12.0) at $\omega = 1.67$ Hz.

only plumbonacrite is detected by XRD. At longer times of oxidation, Fig. 7C, peak C predominates in the CSV and hydrocerussite ($Pb_3(OH)_2(CO_3)_2$) is the dominant phase, Fig. 8. Since an XRD analysis and a CSV cannot be performed on the same sample it proved difficult to demonstrate unequivocably that peak B is due to the reduction of plumbonacrite and peak C is due to the reduction of hydrocerussite. However, repeating these two series of experiments four times showed that hydrocerussite was never observed by XRD when only peak B was present in the CSV, and after long times of oxidation, when peak C was much larger than peak B, hydrocerussite always predominated in the XRD pattern. These observations give us some confidence in our assignment of peaks B and C. Our results over a wider pH range help substantiate this claim.[3]

The amount of plumbonacrite required to yield a detectable XRD signal appears to be much smaller than for hydrocerussite, suggesting an enhanced X-ray sensitivity for plumbonacrite. An examination of the diffraction patterns for the two phases shows: (*i*) no evidence of a preferred orientation for the plumbonacrite layer that would confer an enhanced X-ray sensitivity; (*ii*) no evidence for a lower degree of crystallinity

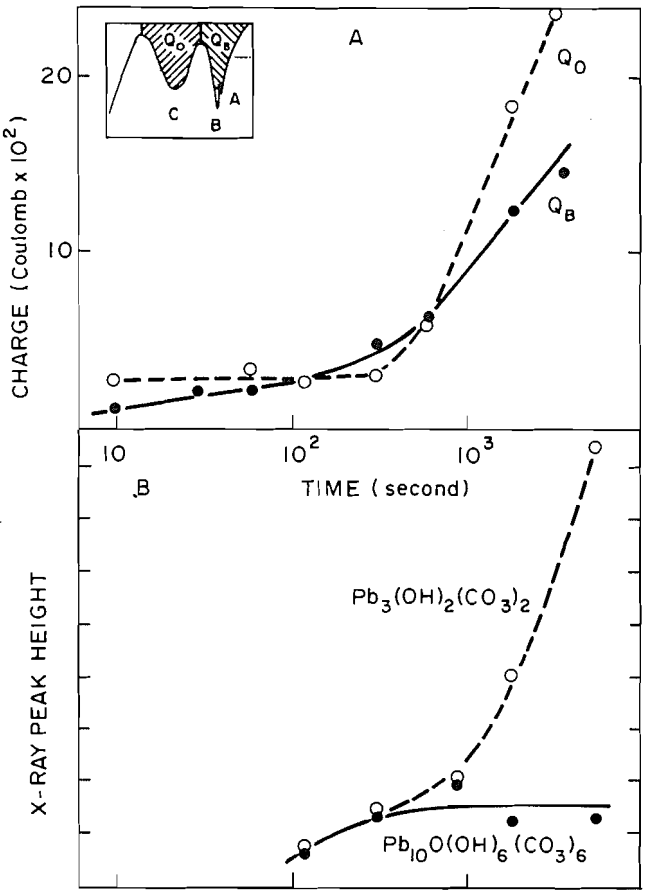

FIG. 9. (A) Charges Q_B and Q_O (obtained as indicated in the inset and outlined in Fig. 1) as a function of the time of potentiostatic oxidation at −0.640 V (vs. SCE) in 1.0 mol L^{-1} K_2CO_3 (pH = 12.0) at ω = 1.67 Hz. (B) X-ray peak heights for plumbonacrite and hydrocerussite as a function of the time of oxidation at −0.640 V (vs. SCE) in 1.0 mol L^{-1} K_2CO_3 (pH = 12.0) at ω = 1.67 Hz.

in hydrocerussite (as opposed to plumbonacrite) that would confer on this phase a lower sensitivity.

A possible explanation for this apparent difference in sensitivity is that the hydrocerussite is formed at local sites on the plumbonacrite surface and does not form a complete, coherent surface layer. Such a situation is consistent with the deposition of hydrocerussite from the solution, a process that would be expected to involve nucleation and growth at widely dispersed sites on the surface.

When oxidation is performed at −0.640 V (i.e., anodic to the main oxidation peak of Fig. 1), we obtain the data of Fig. 9. The charges due to reduction of the two layers (peaks A + B, Q_B, and peak C, Q_O), obtained by integration of the CSVs, increase with the duration of oxidation. Also the peak in the CSV for the reduction of the base layer contains both peaks A and B (as indicated in the inset to Fig. 9A), even for the shortest oxidation (10 s). The XRD results, Fig. 9B, show that plumbonacrite and hydrocerussite are both formed at short oxidation times. As the two films thicken, Fig. 9A, the amount of hydrocerussite increases substantially, whereas the XRD peak height for plumbonacrite levels off at approximately the same value as observed at −0.726 V. This behaviour suggests that both phases are formed initially, but the thickening of both layers involves mainly hydrocerussite formation. We conclude that the base layer formed at −0.640 V is composed of two

TABLE 1. Phases observed on a lead electrode by X-ray diffraction after potentiostatic oxidation in 1.0 mol L^{-1} K_2CO_3 (pH = 12, ω = 1.67 Hz) for 30 min at various potentials

P = Plumbonacrite ($Pb_{10}O(OH)_6(CO_3)_6$); HC = Hydrocerussite ($Pb_3(OH)_2(CO_3)_2$).

phases: plumbonacrite, reduced at peak B, and hydrocerussite, reduced at peak A. Again, peak C is attributed to hydrocerussite deposited from solution.

This conclusion is supported by the data of Table 1, which shows the nature of the predominant phase (based on XRD) after oxidations for 30 min at four separate potentials within the anodic peak region. The composition of the surface film changes from totally plumbonacrite, at the foot of the anodic peak, to mainly hydrocerussite on the anodic side of the peak. The presence of PbO was not detected in any of our diffractograms.

Discussion

The electrochemical and XRD data show that two distinct layers are formed: a base layer composed of two separate phases, plumbonacrite and hydrocerussite (depending on the potential), and a deposited layer of hydrocerussite. Our evidence for the formation of a deposited layer is supported by the response of the reduction peak C to variations in scan rate and, in particular, electrode rotation rate. The decrease in size of peak C with increasing electrode rotation rate demonstrates that the extent of formation of this film is determined by the concentration of Pb^{2+} species close to the electrode surface. Solution transport and deposition processes compete for soluble Pb^{2+} with film deposition predominating at the lower electrode rotation rates.

The formation of a dual-phase base layer was also claimed by Buchanan *et al.* (10) for lead oxidation in 0.1 mol L^{-1} $Na_2B_4O_7$ at pH = 9.0. The nature of these phases was not determined, but lead metaborate ($Pb(BO_2)_2$) and lead tetraborate (PbB_4O_7) were mentioned as two possibilities. The formation of a deposited layer was not observed. For potentials anodic to the peak shown in Fig. 2 of their paper, these authors observed a rise in the current on the anodic scan and a third reduction peak on the reverse scan, at a potential more positive than peak A. This peak was attributed to the reduction of PbO, identified as tetragonal PbO by photocurrent spectroscopy. We observed a slight rise in current for potentials greater than −600 mV, Fig. 2, but no corresponding reduction peak was observed.

The falling current transients observed at potentials around the foot of the main anodic peak (Fig. 1) show that the base layer is rapidly formed at all potentials ≥ −790 mV. There does not appear to be a potential region within which reversible dissolution of Pb^{2+} occurs from a film-free surface. The XRD results of Fig. 8, and the CSVs of Fig. 7, show that this base layer is plumbonacrite. The fact that the thickness of this layer, as determined from Q_B, is almost independent of scan rate (Fig. 3) and electrode rotation rate (Fig. 5B) indicates direct, solid-state growth on the electrode surface.

At potentials in the range $-790 < E < -740$ mV, the base layer thickens but remains plumbonacrite. The appearance of hydrocerussite at longer times (reduced at peak C, Fig. 7) indicates a slow conversion of this plumbonacrite base layer. This process appears to involve dissolution and reprecipitation, since the extent of hydrocerussite formation is very dependent on the electrode rotation rate. This is demonstrated for voltammetric conditions by the data of Fig. 5, which showed that there is competition for the dissolved Pb^{2+} between the deposition of hydrocerussite and transport to the bulk of solution.

The conversion of plumbonacrite to hydrocerussite has been shown to occur rapidly under the conditions of our experiment (8). The fact that the conversion to hydrocerussite, the thermodynamically stable phase under our conditions, is not accompanied by the disappearance of plumbonacrite, indicates that the plumbonacrite base layer is maintained by further anodic oxidation of the lead. The process can be represented by the following sequence of reactions:

[3] $10Pb + 8OH^- + 6CO_3^{2-} \xrightarrow{k_1(E)} Pb_{10}O(OH)_6(CO_3)_6 + H_2O + 20e$

[4] $Pb_{10}O(OH)_6(CO_3)_6 + H_2O + 7OH^- + 4CO_3^{2-} \xrightarrow{k_2(E)} 5\{Pb(OH)_3^-\}_{surf} + 5\{Pb(CO_3)_2^{2-}\}_{surf}$

[5] $2\{Pb(OH)_3^-\}_{surf} + \{Pb(CO_3)_2^{2-}\}_{surf} \xrightarrow{k} Pb_3(OH)_2(CO_3)_2 + 4OH^-$

[6] $\{Pb(OH)_3^-\}_{surf} + \{Pb(CO_3)_2^{2-}\}_{surf} \xrightarrow{\beta_T} \{Pb(OH)_3^-\}_{sol'n} + \{Pb(CO_3)_2^{2-}\}_{sol'n}$

In reactions [3]–[6], $k_1(E)$ and $k_2(E)$ represent potential-dependent rate constants for the solid-state growth of the base layer and its field-assisted dissolution, respectively; k is the potential-independent constant for the deposition process; β_T is a mass-transport constant and is given by D/δ under rotating disk conditions, where D is the diffusion coefficient for the dissolved Pb^{2+} species[4] and δ is the thickness of the diffusion layer ($\propto \omega^{-1/2}$); $\{\ \}_{surf}$ and $\{\ \}_{sol'n}$ designate surface and bulk concentrations, respectively. Since the electric field will be across the base layer on the electrode surface, the driving force for dissolution is the transport of Pb^{2+} species across this film.

Obviously, reactions [3]–[6] summarize a more detailed, but undetermined, series of reactions. The species $Pb(OH)_3^-$ and $Pb(CO_3)_2^{2-}$ are used because these are the predominant solution species present in 1.0 mol L^{-1} carbonate at pH = 12 (8). Reaction [4] is written as involving equal amounts of these species because they will be present in approximately equal concentrations in our solutions.

At higher potentials, around the maximum of the anodic peak in Fig. 1 (~ -700 mV), a second phase, hydrocerussite, is formed as part of the base layer. Since this layer is reduced at peak A, before the reduction of plumbonacrite at peak B, it is probably present as a layer on top of the initially formed plumbonacrite. The close crystallographic similarity between these two phases (8) may promote the epitaxial crystallization of hydrocerussite on plumbonacrite. Since this layer is, in effect, a continuation of the base-layer growth process, it can be considered a primary oxidation product of the lead, its growth being supported by the transport of Pb^{2+} species through the underlying plumbonacrite layer under the influence of the large electric field; i.e.,

[7] $3Pb + 2OH^- + 2CO_3^{2-} \rightarrow Pb_3(OH)_2(CO_3)_2 + 6e$

The presence of plumbonacrite directly on the electrode surface suggests this phase is stabilized by the high rate of supply of Pb^{2+} species.

[4] $D_{Pb(OH)_3^-}$ and $D_{Pb(CO_3)_2^{2-}}$ may have slightly different values.

Phase-sensitive tensammetry is shown to be a convenient and useful way to analyse polyacrylamides and associated derivatives (pams) in dilute aqueous solutions. Standard curves were obtained with ranges varying from 9 to 25 ppm and limits of detection varying from 0.7 to 2 ppm. Ways to change the range and sensitivity are discussed and demonstrated. Typical interferences and their effects are tabulated, and the analysis of pams in coal washings is discussed. The analysis of certain mixtures of polyacrylamides is shown to be possible.

TRUIS SMITH-PALMER, BYRON R. WENTZELL, JOHN C. DONINI et ROBERT J. JERRARD. Can. J. Chem. **66**, 2658 (1988).

On a démontré que la tensamétrie sensible à la phase est une méthode appropriée et utile d'analyser des solutions aqueuses diluées de polyacrylamides et des dérivés qui leur sont associés (pams). On a obtenu des courbes standards pour des concentrations allant de 9 à 25 ppm et des L.D.D allant de 0,7 à 2 ppm. On discute des méthodes qui permettraient de modifier la limite de détection ainsi que la sensibilité et on en fait la démonstration. On présente un tableau résumant les interférences typiques ainsi que leurs effets et on discute de l'analyse des pams dans les lavages de charbon. On démontre que l'analyse de certains mélanges de polyacrylamides est possible.

[Traduit par la revue]

Introduction

Polyacrylamides and polyacrylic-based polymers (pams) in ppm concentrations are widely used as flocculating agents in coal and other mineral washing operations. It would be of interest to be able to determine the residual levels of these polymers after flocculation has occurred. A fast analytical technique would also aid research into the mode of interaction of polyacrylamides with particles and salts, a poorly understood phenomenon.

We recently reported the determination of several polyacrylamide-based polymers by polarographic maximum suppression in mercury (II) solutions (1). The main disadvantage of this method is that it is non-specific; it cannot be used to analyse one pam in the presence of other pams, or in the presence of other types of surfactant. The clean-up step that is required prior to analysis is not a problem when determining anionic or neutral pams, but the loss of cationic pams during chromatography on cation exchange resins and Sephadex is significant.

Leung *et al.* (2) have reported a method of analysis of pams in coal washings involving ultrafiltration followed by HPLC. The method is rather involved and time-consuming, it produces a low percentage of recovery, and its applicability to cationic pams is not clear.

A second electrochemical method that has been used in the determination of surfactants is tensammetry. The general shape of the capacitive current–potential (tensammetric) curves is largely dependent on the anions present. In the absence of specific adsorption at the electrode surface U-shaped curves are observed with the minimum centred at the potential of zero charge (pzc). When there is specific adsorption of anions such as chloride, capacitance humps are observed. The sizes and shapes of these humps have been related to the structure and polarizability of the anion (3, 4). The capacitive current is lowered by the adsorption of surfactants such as sodium dodecyl sulphate (S.D.S.) onto the hanging mercury drop electrode (HMDE). On either side of this dip resulting from the lowering of the surface current, adsorption/desorption peaks are observed. Presumably the hydrocarbon tails of S.D.S. can "squeeze out" water molecules at the electrode surface, thus lowering the capacitance. Most analytical work using tensammetry has involved the analysis of similar detergent-type surfactants.

Dunsch *et al.* reported that polyacrylamide adsorption in aqueous solution had little effect on double layer capacitance (5). The absence of a marked depression of the capacitive current can be explained in terms of the structure of pams. On every second carbon of the polyacrylamide backbone there is a polar amide group which can interact with water molecules, thus preventing them from forming a condensed film and explaining the absence of a marked depression of the capacitive current.

However, contrary to Dunsch, Itoh found that polyacrylamide changed the size of the capacitance hump for perchlorate (6) and this suggested a way for us to analyse pam concentrations.

Tensammetric curves can be examined without interference from faradaic processes by means of a phase-selective detector (7–9). Most surface-active substances are adsorbed only over a small range of potentials, and this suggested a way of distinguishing different components of a mixture.

In this paper, we describe the use of phase-sensitive tensammetry to analyse pam concentrations in clean water and in coal washings, to study the adsorption of pams onto coal tailings and to investigate the analysis of pams in mixtures.

Experimental

Polarograms were obtained using a Princeton Applied Research Model 174A Polarographic Analyzer and a Model 303 static mercury drop electrode (SMDE) in conjunction with a PAR Model 174/50 AC

Polarographic Analyzer Interface and a PAR Model 122 Lock-In Amplifier. The analog output of the polarograph was digitized using an Apple IIe microcomputer with Interactive Microware software (Lab Data Manager, Scientific Plotter) and hardware (ADALAB Interface Card, ADA-AMP Instrumentation Amplifier). A modulation amplitude of 10 mV (p-p) at 200 Hz was used. The phase of the lock-in amplifier's phase-sensitive detector was adjusted to be 135 degrees away from the phase of the reference modulation to minimize faradaic currents. The HMDE and a scan rate of 5 mV/s were used.

Tensammetric curves were initially run scanning from 0 V. However, standard curves were normally obtained from scans starting at −600 mV, after a chosen hold time. Variations on this procedure are discussed in the next section. All potentials reported are relative to a silver – silver chloride reference electrode containing KCl (saturated).

Polyacrylic acid was purchased from Aldrich Chemical Company Inc., Milwaukee, WI. The polyacrylamides (1), polyalkylamine (10), and thickener feed were provided by the Coal Research Lab, Energy, Mines and Resources, Edmonton. Coal washings were prepared from four different raw coal samples as described previously (1).

Limits of detection (LOD) were calculated by taking three times the standard deviation of the blank. The range was considered to be the maximum concentration of pam that could be analysed.

Results and discussion

The tensammetric curve for chloride shows a hump centred at −300 mV because of specific adsorption of the chloride ions (Fig. 1*a*). A typical surfactant such as S.D.S. gives the curve shown in Fig. 1*b*. There is no chloride hump but rather a deep well indicating a decrease in capacitance as discussed in the Introduction. Although polyacrylamide cannot squeeze out the water molecules from the electrode surface and thus does not show a deep well in its tensammetric curve (Fig. 1*c*), it can displace adsorbed chloride ions and thus the chloride hump is absent from the curve. However, unlike the tensammetric curve for S.D.S., the curve for polyacrylamide has no adsorption/ desorption peaks; these are the usual way to measure concentration. Although for KCl and S.D.S. identical tensammetric curves were obtained using a dropping mercury electrode (DME) or a HMDE, this was not the case for polyacrylamide. The chloride hump was still present in the tensammetric curve for polyacrylamide obtained using a DME, even with high concentrations of polymer. Use of the HMDE is thus mandatory for the analysis of pams. A difference tensammetric curve (Fig. 2), obtained by subtracting the curve for KCl from the curve for polyacrylamide alone, shows up the effects of the polyacrylamide on the capacitance more clearly. The broad peak at −800 mV may be attributed to reorientation of the adsorbed molecules as the charge on the electrode changes. The curves in Fig. 2 were each obtained in two portions by scanning from −600 mV after a 2 min hold time. This potential is close to that used by Bednarkiewicz *et al.* and is in the potential region where maximum absorption occurs (8). These curves demonstrate the effect of concentration. Reading the change in the capacitive current at −350 mV, where the differences were large, enabled the standard curve shown in Fig. 3 to be constructed. The LOD was 0.8 ppm and the range was 16 ppm (0.8–16 ppm). The difference tensammetric curve obtained for a non-ionic polymer, Praestol 2810/73, was almost identical to that for polyacrylamide and a standard curve could be obtained in the same way (0.8–16 ppm). The difference tensammetric curve for an anionic pam with about 25% charge density, Praestol 2900/73, had the same general shape as that of the non-ionic polymers, but the troughs and humps were slightly shifted to less negative potentials. A standard curve could be constructed in the same way (0.7–9 ppm). Tensammetric curves were also obtained in acidic (0.1 *M* KCl, 0.01 *M* HCl) and basic (0.1 *M* KCl, 0.01 *M* KOH) solutions to determine the effect of ionization of the carboxyl groups. The peaks shifted somewhat and the difference tensammetric curve for the acidic solution showed a much larger trough at −400 mV, attributed to stronger adsorption of the unionized groups. In the difference tensammetric curve of the basic solution there was a pronounced hump at −700 mV. The tensammetric curves for polyacrylic acid, which could be classified as an anionic pam with a charge density of 100% (although with much smaller molecular weight than the other pams used), were even more affected by pH. At pH 6 the tensammetric curve for a 20 ppm polyacrylic acid solution resembled that of the supporting electrolyte alone, indicating that the polymer had little surface activity. This is no doubt due to its high solubility in the ionized state. At pH 3 the tensammetric curve for polyacrylic acid was that of a typical strongly adsorbed surfactant, with a marked depression in

capacitive current from −400 to −1200 mV and a sharp desorption peak at −1400 mV. Itoh has reported a similar pH dependence for polyacrylic acid in ClO_4^- (6).

Since cationic polymers are more strongly adsorbed at negatively, rather than positively, charged electrodes; they yield curves which are distinctly different to the above. Thus the chloride capacitance hump was largely unaffected by the cationic polymers, while the capacitive current was lowered at voltages negative with respect to the pzc. Typical tensammetric curves are shown in Fig. 4 for a cationic pam with close to 100% charge density, Praestol 444k. A standard curve was plotted using the difference current measured at −1600 mV after a 2 min hold time at −600 mV and is shown in Fig. 5 (0.7–11 ppm). Similar standard curves were able to be plotted for cationic pams of lesser charge densities, but the slope of the curves decreased with the charge density of the pam in question (compare Figs. 5 and 6), affecting the LOD's and the ranges. The slope of the curves also changed as the amount of preconcentration of pam onto the Hg drop was changed. The preconcentration was decreased (and thus the slope decreased) by decreasing the hold time and/or the length of the scan. For example, in Fig. 5 the range of the standard curve, and therefore of the analytical method, was increased from 11 to 23 ppm by not using a hold time and by starting the scan at −1200 mV rather than −600 mV. However, this is at the expense of the sensitivity and the LOD (increased to 1.3 ppm). The preconcentration was increased by using a hold time before a scan was started, and even more by stirring the solution during the hold time. This is shown in Fig. 6 for a cationic pam with around 70% charge density, Praestol 534k. The LOD went from 2 to 0.5 ppm as the range went from 20 to 7 ppm. For this polymer, the difference current was measured at −1450 mV rather than

−1600 mV because the differences were slightly larger at that voltage. The tensammetric curves for a polyalkylamine (10) were of the same basic shape but were generally shifted to more positive potentials. A standard curve was plotted using the current difference at −1100 mV (0.7 to 15 ppm); reading the difference at −1450 mV leads to a less useful curve (2 to 11 ppm) (Fig. 7). Thus it can be seen that the analytical parameters can be changed to alter the range and LOD of an analysis, depending on the levels of polymer being analyzed. The LOD and precision depend on the reproducibility of current measurements, and the capillary needs to be cleaned and siliconized regularly especially when using cationic pams. A typical precision of 0.3 ppm at the 95% confidence level was obtained for P534 (1 min stirring before analysis). Using a phase angle of 90° increases the sensitivity by increasing the size of the measured current by $\sqrt{2}$. However, at this angle there is also some contribution from faradaic current, thus leading to problems of interferences if reducible species are in solution with the polymer. Some species, particularly those that are surface-active, can interfere with the analysis even at the 135° phase angle. Tables 1–3 show the effect of a variety of salts and surfactants on the analysis of three pams (non-ionic, anionic, and neutral, respectively). These interferences were removed using chromatography on small precolumns before the tensammetric analysis. Recoveries are excellent for anionic and neutral

pams but lower for cationic pams (1). However, potential interferences generally had less effect on cationic analyses (compare Tables 1, 2, and 3), and in many cases of real samples of interest to us, no pretreatment was necessary before the analysis of cationic pams. For example, the tensammetric curves for four coal washings, a thickener feed supernatant and tap water containing humic acid were run, and only those for the Lingan coal washings showed interferences in the region used for analysis of cationic pams. (The Lingan coal washings were very acidic and contained high levels of iron.) The standard curves for cationic pams prepared in the other waters mentioned were identical to those prepared in pure water. Interferences were found in the region of these curves that are used for the analysis of anionic and neutral pams, but removal of these was quick and efficient. Thus for many coals, tensammetry provides a quick and facile method with which to analyse for pams in wash and waste waters. To demonstrate an application of this method, we include results obtained from a study of the absorption of cationic polymers onto thickener feed (mostly coal fines and clay). The solids in the slurry are generally negatively charged and thus the binding capacity of the slurry for cationic polymers is high. The binding increased linearly (slope = 0.8) with the amount of pam added, but the experiment was stopped before a binding maximum was reached (Fig. 8).

The tensammetric curves for mixtures of polyacrylamides were examined to see if it would be possible to distinguish the individual components. The difference tensammetric curves for a solution of 5 ppm Praestol 2810/73 and one containing

*Initial voltage = −600 mV; no hold time.

5 ppm Praestol 444k were added arithmetically and the resulting tensammetric curve was found to be almost identical to the experimentally determined difference tensammetric curve for a solution containing both (Fig. 9). Since the tensammetric curves of the individual components were quite different (Fig. 10), it should be possible to resolve the two components of the mixture mathematically. With higher concentrations of polymers (enough to completely cover the electrode) the tensammetric curves of mixtures were not additive and only the more strongly adsorbed component of a mixture was adsorbed. For a solution containing 40 ppm Praestol 2810/73 plus 40 ppm Praestol 444k the difference tensammetric curves resembled that of the non-ionic polymer where the electrode was positively charged (between 0 and approximately −500 mV), whereas at more negative voltages the tensammetric curves resembled that of the cationic polymer. Thus as the voltage was scanned past the potential of zero charge on the electrode the cationic polymer displaced the nonionic one at the electrode surface.

Similarly the effects of Praestol 2810/73 and Praestol 2900/73 were additive at low concentrations, and the difference tensammetric curves of the individual polymers showed distinctive differences at potentials between −1000 mV and −1900 mV. This suggested that mixtures of these should also be able to be resolved mathematically.

To demonstrate this, various prepared mixtures were run and experimental and actual concentrations were compared (Table 4). Measurements of the change in capacitive current at two potentials (−350 mV and −1340 mV for mixtures of P2810 and P2900, and −350 mV and −1600 mV for mixtures of P2810 and P444k) were used to prepare standard curves for each polymer, and then the concentration of each polymer was determined by solving the appropriate simultaneous equations. The potentials were chosen so that the difference current at at least one potential would be chiefly due to only one component. Standard curves obtained by tensammetric analysis are generally not linear, but for the concentration ranges over which mixtures of pams are additive, linear concentration curves were obtained (0–14 ppm for P2810, 0–12 ppm for P2900 and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/07/12
For personal use only.

P444k). Thus the solving of the simultaneous equations was trivial.

The difference tensammetric curve of a solution containing 5 ppm Praestol 2900/73 and 5 ppm Praestol 444k and the tensammetric curve calculated as the sum of the two individual curves were quite different. The actual measured capacitive current changes were much less than those calculated. This agreed with our maximum suppression experiments (1) which found that interaction between oppositely charged polymers reduced their surface activity.

Conclusions

Phase-sensitive tensammetry is a useful method of analysis for pams even in many dirty systems. The parameters used to run the tensammetric curves (hold time, stirring or lack thereof, initial potential, and the potential at which the difference current is read) can influence the slope and range of the standard curves, and thus these can be optimized for particular analytical requirements.

The shape of the tensammetric curve yields information on the nature of the charge of the pam being studied, and at low concentrations the curves of all except oppositely charged polymers are additive.

Equilibria between Bi_2O_3 and Bi_5O_7I in aqueous solutions at 10–60°C, and in oxygen atmospheres at 550–800°C[1]

PETER TAYLOR[2] AND VINCENT J. LOPATA

Received February 24, 1988

PETER TAYLOR and VINCENT J. LOPATA. Can. J. Chem. **66**, 2664 (1988).

Equilibria between Bi_5O_7I and Bi_2O_3 have been measured with the solids in contact with aqueous solutions at 10–60°C, and with low-pressure oxygen (0.2–100 kPa) at 550–800°C. In the aqueous systems, iodide activities were measured as functions of pH and temperature. In the dry system, iodine partial pressures were measured spectrophotometrically while varying the temperature and oxygen partial pressure. The standard enthalpy of formation and entropy of α-Bi_5O_7I were derived from these measurements, and values for BiOI were also estimated. The results combine to give a self-consistent account of phase relations between Bi_5O_7I and Bi_2O_3 up to 800°C. Some equilibria involving BiOI are discussed briefly.

PETER TAYLOR et VINCENT J. LOPATA. Can. J. Chem. **66**, 2664 (1988).

On a mesuré l'équilibre entre le Bi_5O_7I et le Bi_2O_3 alors que les solides étaient en contact avec des solutions aqueuses, à 10–60°C ou de l'oxygène à basse pression (0,2 à 100 kPa), à des températures allant de 550 à 800°C. Dans les systèmes aqueux, on a mesuré les activités de l'iode en fonction du pH et de la température. Dans le système sec, on a fait appel à des méthodes spectrophotométriques pour mesurer les pressions partielles de l'iode tout en faisant varier la température ainsi que la pression partielle de l'oxygène. A l'aide de ces mesures, on a calculé l'enthalpie standard de formation ainsi que l'entropie du α-Bi_5O_7I et on a évalué les valeurs correspondantes pour le BiOI. On peut combiner les résultats pour obtenir une évaluation auto-cohérente des relations de phase entre le Bi_5O_7I et le Bi_2O_3, jusqu'à 800°C. On discute brièvement de quelques équilibres impliquant le BiOI.

[Traduit par la revue]

I. Introduction

The phase assemblage α-Bi_2O_3 + α-Bi_5O_7I has been considered as a candidate material for immobilizing radioactive iodine-129 (1, 2). This combination of solids can buffer the dissolved iodide activity, $\{I^-\}$, at low levels in non-acidic aqueous solutions, in accordance with equilibrium [1].

[1] $$Bi_5O_7I(s) + OH^-(aq) \rightleftharpoons (5/2)Bi_2O_3(s) + I^-(aq) + (1/2)H_2O(l)$$

$$K_1 = \{I^-\}/\{OH^-\} = K_{10} \text{ of ref. 1}$$

$$\log_{10} K_1 = -3.39 \pm 0.20 \text{ at } 25°C \text{ (1)}.$$

whence

$$\log_{10} \{I^-\} = -17.39 + pH$$

This equilibrium can not be sustained at pH < 6, because of the high solubility of Bi_2O_3 in acidic solution (3). In addition, α-Bi_5O_7I has reasonably high thermal stability; it decomposes in air above about 550°C (1, 2, 4, 5) by reaction [2].

[2] $$2Bi_5O_7I(s) + \tfrac{1}{2}O_2(g) \rightarrow 5Bi_2O_3(s) + I_2(g)$$

The purpose of the present work was to examine the relationship between K_1 and temperature, and to obtain more quantitative information on reaction [2]. Specifically, we wished to see if reaction [2] is reversible and, if so, determine K_2.

[3] $$K_2 = p(I_2)/[p(O_2)]^{1/2}$$

The fact that equilibria [1] and [2] involve the same pair of solid phases permits us to compare and interrelate measurements of K_1 and K_2. Note that $p(I_2)$ and $p(O_2)$ represent partial pressures, whereas pI and pOH represent the negative logarithms of aqueous ion activities (cf. pH).

Hereafter, the formulae Bi_2O_3 and Bi_5O_7I refer to the α forms, unless otherwise specified. The name bismuth oxide refers to Bi_2O_3 in the generic sense.

II. Experimental

(a) Preparative work

We previously found (1) that partial conversion of Bi_2O_3 to Bi_5O_7I gave a product that equilibrated with aqueous solutions in subsequent experiments more rapidly than a simple mixture of the two solids, presumably because the oxyiodide crystals had grown in intimate contact with the oxide. We have also found that Bi_2O_3 powder is sometimes contaminated with basic bismuth carbonates, $(BiO)_2CO_3$ and $(BiO)_4(OH)_2CO_3$ (6), probably from reaction with atmospheric CO_2 and moisture.

For the present study, we used Bi_2O_3 that was 20% converted to Bi_5O_7I. The Bi_2O_3 (BDH, reagent grade) was first washed with concentrated NaOH (~10 mol dm^{-3}) for 16 h, to eliminate traces of carbonate, then washed repeatedly with freshly deionized, distilled water, and contacted with the appropriate amount of KI solution (~10^{-2} mol dm^{-3}) for 16 h. At much lower iodide concentrations, formation of Bi_5O_7I is sometimes delayed, while other solid products are formed at higher concentrations. These aspects are discussed in a separate publication (7).

(b) Aqueous equilibrium measurements

In the following discussion, all activities of aqueous ions refer to an ideal standard state of unit molality. We have used the approximation that pH = $-\log \{H^+\}$, where pH is measured according to the normal operational definition for measurements with a glass electrode. Solutions were sufficiently dilute that molarity and molality could be considered identical at ambient temperatures, within the limits of accuracy of our measurements. Standard solutions were therefore prepared volumetrically. Activity corrections for standard iodide solutions were made using the Davies equation.

(i) Isothermal experiments

Measurements of K_1 at different temperatures followed essentially the same procedure as described in ref. 1. The Bi_2O_3 + Bi_5O_7I was suspended with stirring in nitrogen-purged, distilled deionized water in a thermostatted vessel (±0.5°C). Successive aliquots of NaOH were added, and the pH and iodide activity were monitored using ion-selective electrodes. These values typically stabilized within

15–30 min at 25°C, and 5 min or less at 55°C. Equilibration "from above", i.e., after addition of iodide rather than hydroxide, was much slower. Therefore, only a few such additions were made, to assure that the experimental measurements did indeed represent close approach to equilibrium. Each titration was terminated when the hydroxide concentration reached about 10^{-2} mol kg^{-1}, then the solid was filtered and washed, and at least one further titration was run.

Since these experiments each lasted 1–3 days, there was some drift in electrode response during each run (typically 5–10 mV, corresponding to 0.1–0.2 units of pH or pI). Iodide activity and pH measurements were based on the average of calibrations at temperature before and after each run. Reliable calibration is difficult with iodide solutions more dilute than 10^{-5} mol kg^{-1}, so it was necessary to extrapolate the iodide calibration line. Similarly, pH measurements were based on standard buffers with pH of 6.86 and 9.18 at 25°C, using standard pH values at each experimental temperature. In our experience, such extrapolations give reliable measurements (±0.1) of pI and pH up to about 7 and 11.5, respectively (1).

(ii) Variable-temperature experiment at constant pOH

The Bi_2O_3 + Bi_5O_7I was first allowed to equilibrate with dilute NaOH (pH ≃ 11.3), then the pH and iodide electrodes were monitored as the temperature was changed in the following sequence: 25, 35, 45, 55, 25, 60, 50, 40, 30, 25, 10, 15, 20, 25°C. The four measurements at 25°C showed little drift of either electrode during this experiment. Since the hydroxide activity remained constant (see below), the pH electrode was calibrated only at 25°C; the iodide electrode was calibrated at six temperatures between 10 and 55°C.

(c) Gas–solid equilibrium measurements

To investigate reaction [2] in detail, we constructed a simple low-resolution, dual-beam, single-detector spectrophotometer, with the sample beam passing through a tube furnace. In this instrument, light from a tungsten lamp was first passed through a manual monochromator, then split into a sample and reference beam. The reference beam passed outside, and parallel to, the furnace tube through which the sample beam was directed. The reference beam was deflected back across the sample beam by a fixed mirror, and a movable mirror allowed either the sample or reference beam to be directed to the photomultiplier – tube detector. Filters could be introduced between this last mirror and the detector, as described below (III(*b*)(*i*)).

The spectrophotometric cells were constructed of fused silica tubing (2-cm O.D., 10-cm path length), with the solid samples held in a side-arm outside the optical path. Previous calibration had shown that the cells would be contained within the central plateau of the furnace tube's temperature profile. The cells were filled with a known partial pressure of oxygen (up to ~30 kPa) on a vacuum line at ambient temperature (23 ± 1°C), and flame-sealed. Iodine vapor densities, and hence partial pressures, were determined from optical density measurements, as described below (III(*b*)(*ii*)).

III. Results and discussion

(a) Aqueous equilibria

(i) Isothermal experiments

Measurements of K_1, as a function of pH, at 25, 35, 45, and 55°C, are shown in Fig. 1; the 25°C data are taken from ref. 1. In all cases there is a slight systematic decrease in apparent K_1 with increasing pH. This most likely arises from residual calibration errors, or perhaps interference from dissolved O_2 or CO_2; if real, it would imply a deviation from the stated solid stoichiometries. The 45°C data deviate more at pH < 9.5 as the iodide electrode approaches its detection limit. We therefore used only the data obtained within the pH range 9.5–11.5 to calculate K_1 at each temperature, as shown in Table 1. Some deterioration in the quality of data is evident at 55°C.

These results confirm that the system behaved in accordance with eq. [1] at each temperature and indicate that $\log_{10} K_1$ increases by about 0.6 between 25 and 55°C. This corresponds to an enthalpy of reaction, $\Delta_r H^0$, of about 40 kJ mol^{-1}.

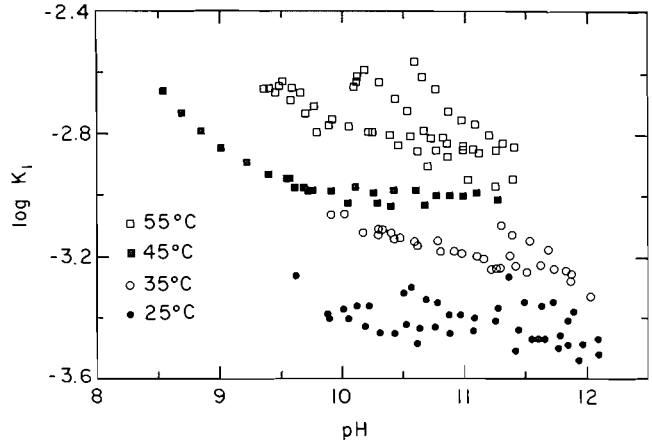

FIG. 1. Experimental measurements of $\log_{10} K_1$ (pK_w − pI − pH) in isothermal experiments at 25°C (from ref. 1), 35°C, 45°C, and 55°C vs. pH.

[a]Isothermal experiments; uncertainty limits are estimated accuracy.
[b]Variable temperature experiments; estimated precision ±0.07.
[c]From ref. 1.

(ii) Variable temperature experiment

The variable temperature experiment was designed to improve the precision of $\log_{10} K_1$ measurements, and hence the accuracy of the derived enthalpy of reaction, in three ways: (*a*) The experiment was shorter, reducing the opportunity for electrode drift, and allowing more accurate calibration; (*b*) Any variation arising from differences in sample history, or any other differences between isothermal runs at different temperatures, was eliminated; and (*c*) The hydroxide activity was sufficiently high to be effectively constant, eliminating the need for pH calibration at more than one temperature.

Four measurements at 25°C yielded an average pH value of 11.35 ± 0.05. The corresponding pOH of 2.65 ± 0.05 was used in the calculations at all temperatures, because the hydroxide concentration is much greater than the amount consumed or released by the adjustment of equilibrium [1] to temperature changes (<10^{-5} mol kg^{-1}). There is no other plausible cause for significant reversible variation of pOH with T (such as changes in speciation of bismuth (3)). The sequence of pH measurements at 25°C did not reveal any irreversible consumption of hydroxide by glass corrosion or absorption of CO_2.

Results of this experiment are presented in Table 1 and Fig. 2. The observation of a substantial, reversible variation of K_1 with temperature, without detectable hysteresis, indicates that equilibrium was achieved at each temperature. Linear regression

[c]Based on equilibrium data from ref. 1.

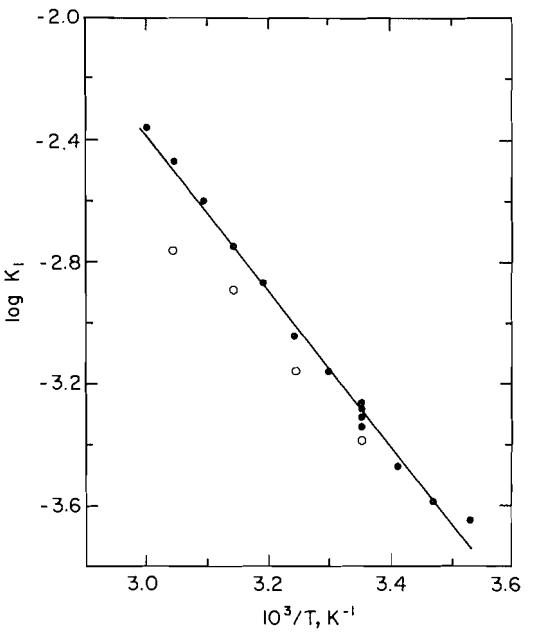

FIG. 2. Experimental measurements of $\log_{10} K_1$ (pOH − pI) from variable temperature experiment. Open circles represent mean values from isothermal experiments.

gave a relationship between $\log_{10} K_1$ and reciprocal absolute temperature.

[4] $$\log_{10} K_1 = (-3.082 \pm 0.010) - (2573 \pm 128)\left(\frac{1}{T} - 0.003275\right)$$

The slope, −2573 ± 128, corresponds to $\Delta_rH^0 = 49.3 \pm 2.5$ kJ mol^{-1} for reaction [1]. When combined with enthalpy data for Bi_2O_3, OH^-, I^-, and H_2O from ref. 8 (Table 3), this yields the enthalpy of formation of α-Bi_5O_7I.

[5] $$\Delta_fH^0(\alpha\text{-}Bi_5O_7I, s, 298\ K) = -1453.8 \pm 6.6\ kJ\ mol^{-1}$$

Using the previously reported Gibbs energy of formation, $\Delta_fG^0 = -1266.1 \pm 5.8$ kJ mol^{-1}, we then obtain the entropy of formation.

[6] $$\Delta_fS^0(\alpha\text{-}Bi_5O_7I, s, 298) = -630 \pm 42\ J\ mol^{-1}\ K^{-1}$$

whence

$$S^0_{298}(\alpha\text{-}Bi_5O_7I, s) = 430 \pm 45\ J\ mol^{-1}\ K^{-1}$$

These values are internally consistent with refs. 1 and 7. Alternative values, derived from the NBS thermodynamic database (9), are included in Table 2. The principal discrepancy between refs. 8 and 9 is in the enthalpy of formation of I^-(aq); the resulting difference in enthalpies for Bi_5O_7I (Table 2) is only a quarter of the experimental uncertainty.

The relationship between K_1 and T, expression [4], does not take into account any systematic bias in the variable temperature experiment. (This bias will include the slight discrepancy between pH and $-\log_{10}\{H^+\}$.) We have therefore combined the temperature dependence obtained here with the 25°C equilibrium data from ref. 1 ($\log K_1 = -3.39 \pm 0.20$). This combination is approximated by expression [7].

[7] $$\log_{10} K_1 = 5.24 - \frac{2573}{T} \pm 0.24 \quad (283 < T < 333\ K)$$

(b) Gas–solid equilibria

(i) Spectral measurements

The spectrophotometer was tested by measuring the spectrum of a fixed quantity of iodine vapour at various temperatures up to 780°C. The monochromator was manually scanned from 400 to 650 nm in increments of 5 or 10 nm. The resulting low-resolution peak profile was in broad agreement with published high-resolution spectra (10, 11), but, of course it lacked the fine structure displayed in the latter. The absorption feature extends from 420 to 650 nm, with a peak at about 510 nm and a shoulder near 545 nm.

The low-resolution spectrum of a fixed quantity of I_2 in an evacuated cell was insensitive to temperature changes up to 500°C, but it was difficult to measure at higher temperatures because of interference from furnace glow. We did not have sufficiently accurate control of $p(I_2)$ to measure the extinction coefficient, so partial pressure calculations were based on spectroscopic data in ref. 10, as detailed below.

The visible spectrum of I_2 vapor at ambient temperature has two distinct regions: a smooth continuum between 420 and 500 nm, and a region with vibrational fine structure between 500 and 650 nm (10, 11). Extinction coefficients vary considerably with total pressure within the latter region, but are insensitive to pressure in the former region (10, 11). Therefore, for the partial-pressure measurements, we removed the monochromator and introduced a narrow-band-pass filter at the receiving end (Andover Corporation filter: peak wavelength 481.8 nm; band width at half height, 9.4 nm). This had the added advantage of virtually eliminating interference from furnace glow.

The effective extinction coefficient, ϵ_{eff}, of iodine was calculated from the transmission profile of the filter and the corresponding portion of the I_2 spectrum. We obtained $\epsilon_{eff} = 335$ L mol^{-1} cm^{-1}, based on $\epsilon_{500} = 578$ L mol^{-1} cm^{-1} from

ref. 12, as recommended in ref. 10. Because ϵ varies by a factor of two across the filter band, the integrated absorbance shows a slight deviation from Beer's law; this amounts to less than 2% for absorbances below 1.0. The stated value of ϵ_{eff} refers to an overall absorbance of 0.3, which represents the mid-range of our data. This treatment is essentially in agreement with the spectra depicted in ref. 11.

(ii) Equilibrium measurements

Preliminary measurements showed that iodine was released reversibly from the mixture of bismuth oxide and oxyiodide in an oxygen atmosphere, between about 550 and 800°C. Typical equilibration times were of the order of tens of minutes. Therefore, we could readily measure $p(I_2)$ as a function of both T and $p(O_2)$.

For partial-pressure calculations, ϵ_{eff} was converted to units of equivalent ideal-gas partial pressure at 298 K.

$$[8] \quad \epsilon' = 1.35 \times 10^{-4}\ \text{Pa}^{-1}\ \text{cm}^{-1}$$

The value of $p(I_2)$ at given T is then determined from the absorbance, A, in a 10-cm path-length cell.

$$[9] \quad p(I_2) = \frac{A}{10\epsilon'} \times \frac{T}{298}$$

The corresponding oxygen partial pressure is given by eq. [10], which includes a minor correction for oxygen consumed by the reaction (eq. [2]).

$$[10] \quad p(O_2)_T = \left[p(O_2)_{296} \times \frac{T}{296} \right] - 0.5p(I_2)$$

Here, $p(O_2)_{296}$ is the partial pressure of oxygen originally loaded in the cell at 296 K. Substituting expressions [9] and [10] into eq. [3], we obtain K_2 at a given T. Iodine partial pressure measurements made at two values of $p(O_2)_{296}$ (26.7 and 3.3 kPa) are shown in Fig. 3. Experimental values of K_2, obtained in two runs at each of six starting partial pressures of oxygen, are presented in Fig. 4.

A break in the slope of the plots of $\log_{10} K_2$ vs. $1/T$, near 700°C, can be attributed to the α–δ phase transition of bismuth oxide (13–15). There is evidence of hysteresis on cooling below this transition, i.e., data obtained while running the temperature down lie on a metastable extension of the δ-Bi_2O_3/α-Bi_5O_7I equilibrium line. In several cases this persisted into the second heating stage of the run. There is also greater scatter in the data obtained at lower temperatures, reflecting the poorer accuracy of low absorbance measurements.

The apparent iodine partial pressures, and hence the values of K_2, obtained at the lowest oxygen partial pressure ($p(O_2)_{296}$ = 0.13 kPa (1 Torr)), and also some of the measurements at 1.3 kPa, were higher than expected, for several possible reasons. (*i*) Inaccurate oxygen metering at low pressures. (*ii*) Sublimation of bismuth oxide at low total pressures caused some fogging of the cell windows, and hence a positive bias in measured absorbances. (*iii*) Some other decomposition product (e.g. BiI_3) may have interfered with the spectrophotometric measurement. Bismuth oxyiodides have been reported to decompose by sequential loss of BiI_3 in a non-oxidizing atmosphere (4). Equilibrium measurements of BiI_3 vapor pressure over BiOI + $Bi_7O_9I_3$ have been reported by Klimakov *et al.* (16). (*iv*) One or both solids may deviate from ideal stoichiometry at low oxygen partial pressures. Substoichiometric bismuth oxides are known (13).

Excluding these measurements at $p(O_2)_{296}$ = 0.13 kPa, our data are consistent with equilibrium [2]. Figure 3 shows that measured iodine partial pressures varied with the square root of oxygen partial pressure at a given temperature, as required by eqs. [2] and [3].

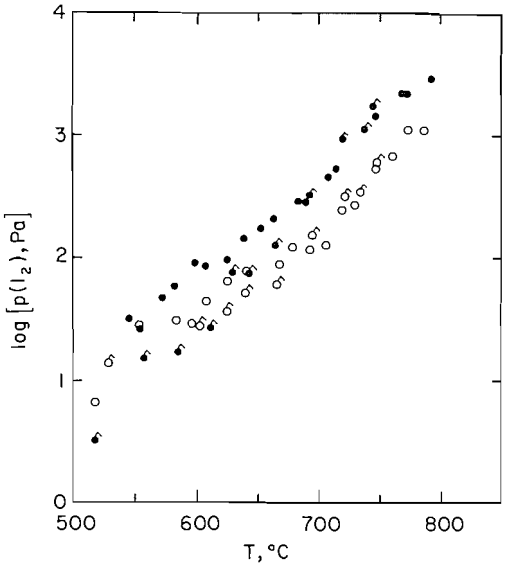

FIG. 3. Experimental measurements of iodine partial pressure vs. T, at initial oxygen pressures (296 K) of 26.7 kPa (●) and 3.3 kPa (○). Expected separation of the two data sets is 0.45 log units of $p(I_2)$. Flagged data points were obtained while running temperature down.

Enthalpies of reaction [2] above and below the phase transition were obtained by linear regression of data measured above and below 700°C, respectively. Below 700°C, we only included data from the heating half of the temperature cycle. We also omitted data that showed strong evidence of persistent hysteresis (i.e., persistence of δ-Bi_2O_3 into the second heating cycle). The resulting enthalpies are given in Table 3. From these, we estimate that $\Delta_r H^0$ for reaction [2] is 219 ± 29 kJ mol^{-1} above the phase transition temperature, and 97 ± 28 kJ mol^{-1} below. From the intersections of the five pairs of regression lines, we estimate a transition temperature of 698 ± 10°C, and a corresponding value of $\log_{10} K_2$ = 0.1 ± 0.3. Reported values for the transition temperature range from 701 to 730°C (14).

Our best estimate of the relationship between K_2 and T, based on the value at the transition temperature and the enthalpies of reaction above and below, is given by eqs. [11] and [12]:

$$[11] \quad \log_{10} K_2 = (0.1 \pm 0.3) + (11400 \pm 1500)\left[\frac{1}{971} - \frac{1}{T}\right] \qquad \text{(above 971 K)}$$

$$[12] \quad \log_{10} K_2 = (0.1 \pm 0.3) + (5100 \pm 1500)\left[\frac{1}{971} - \frac{1}{T}\right] \qquad \text{(below 971 K)}$$

The enthalpy change associated with the Bi_2O_3 phase transition, 122 ± 57 kJ mol^{-1}, lies at the high end of the range of reported values (30–117 kJ mol^{-1}) (14)). This suggests that some additional endothermic reaction may occur near the transition temperature. X-ray diffraction of quenched samples confirmed the presence of δ-Bi_2O_3 and also showed some diminution of Bi_5O_7I peaks above 700°C; a solid solution of Bi_5O_7I in δ-Bi_2O_3 may therefore have been formed. Differential thermal analysis showed a well-defined endotherm near 700°C,

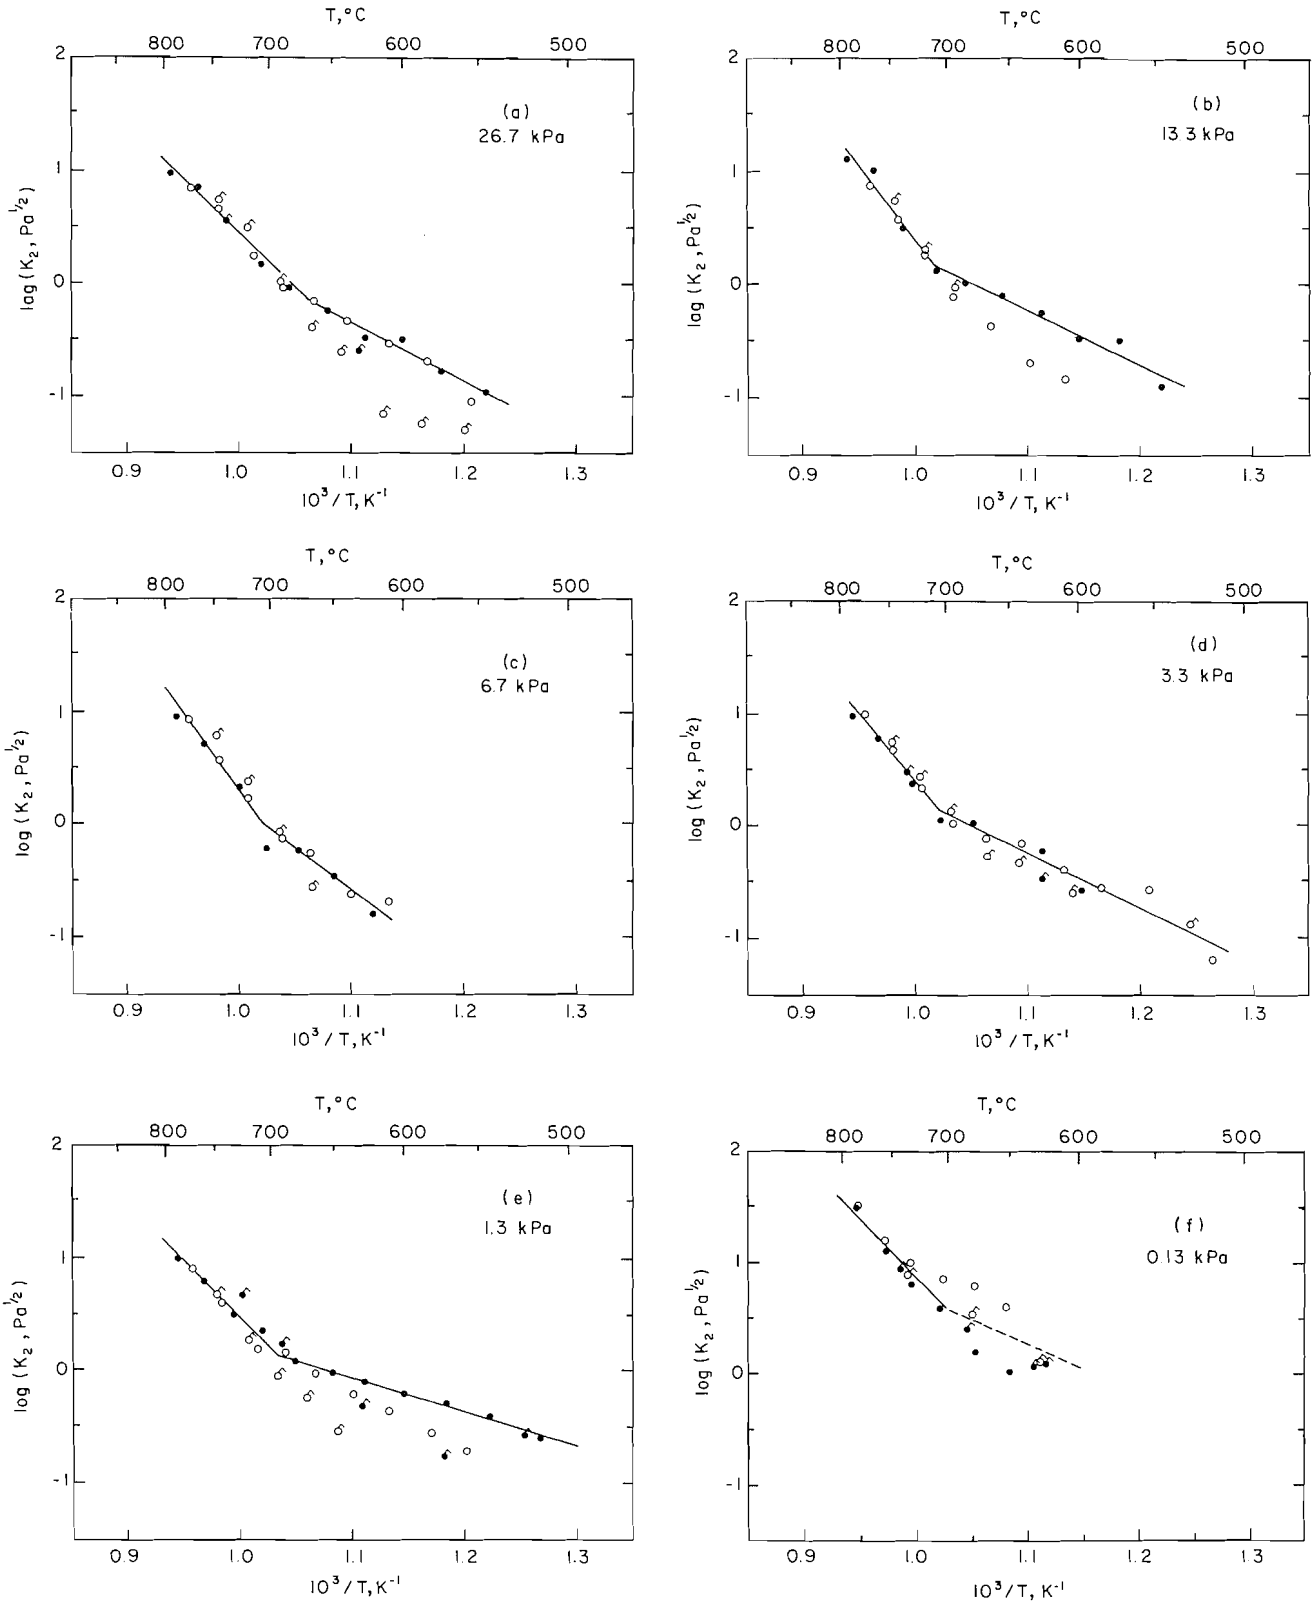

FIG. 4. Experimental measurements of $\log_{10} K_2$ at six different initial oxygen pressures (296 K): (*a*) 26.7 kPa; (*b*) 13.3 kPa; (*c*) 6.7 kPa; (*d*) 3.3 kPa; (*e*) 1.3 kPa; (*f*) 0.13 kPa. Closed and open circles represent successive runs with the same sample (different samples were used at each temperature). Flagged data points were obtained while running temperature down.

with evidence of a second feature at slightly higher temperature. Solid solubility between δ-Bi_2O_3 and Bi_5O_7I is reported in the phase-diagram study by Klimakov *et al.* (15). They report a eutectoidal decomposition of the δ-Bi_2O_3/Bi_5O_7I solid solution to α-Bi_2O_3 + Bi_5O_7I at 700 ± 5°C. This agrees well with our estimated transition temperature of 698 ± 10°C. A host of other oxides form compounds or solid solutions with bismuth oxide (13); this is partly responsible for the wide range of reported transition temperatures and enthalpies (14). Also, we can not rule out the possibility of some reaction with the silica sample

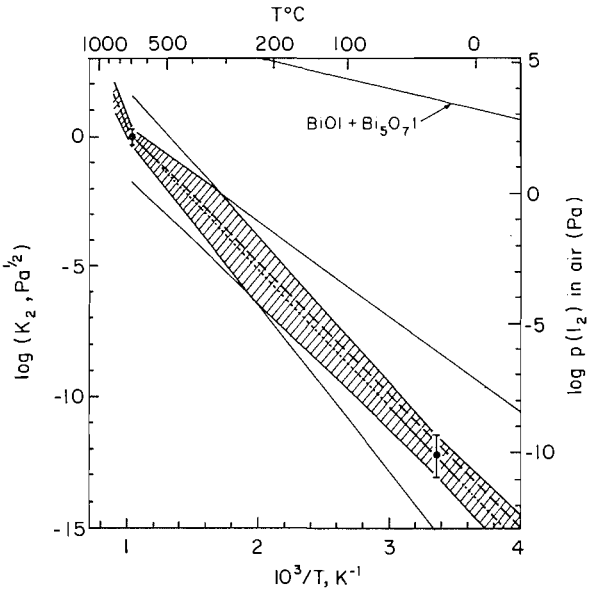

FIG. 5. Relationship between $\log_{10} K_2$ and T, based on measurements of the aqueous system at 10–60°C (eq. [13]), and the solid–gas system at 550–800°C (eqs. [11] and [12]). The hatched area represents estimated uncertainty limits on K_2 throughout the temperature range up to 800°C.

tubes in our own experiments. We have seen no evidence of β-Bi_5O_7I (17) in these experiments.

(c) Comparison of aqueous and anhydrous equilibria

It is desirable to integrate the equilibrium data obtained from the wet and dry experiments. We therefore derived a 25°C value of K_2 and its temperature dependence from the aqueous equilibrium data.

From the Gibbs energies of formation of Bi_2O_3 and Bi_5O_7I (Table 2), we obtain $\Delta_r G^0 = 84.3 \pm 4.3$ kJ mol^{-1} for reaction [2] at 25°C (standard state pressure = 10^5 Pa), whence $\log_{10} K_2 = -12.3 \pm 0.8$ (pressures in Pa). From the corresponding enthalpies of formation, we obtain $\Delta_r H^0 = 101 \pm 7$ kJ mol^{-1} at 25°C, in good agreement with the value of 97 ± 28 kJ mol^{-1}, determined directly at 700°C; the temperature dependence of this enthalpy is expected to be small. Many other reactions of the same general type, iodide + $(1/2)O_2 \rightleftharpoons$ oxide + I_2, have enthalpy changes of 100–120 kJ mol^{-1} (based on data in refs. 7 and 8).

From the experimental enthalpy of reaction, 101 ± 7 kJ mol^{-1}, we obtain the relationship between $\log_{10} K_2$ and T (K):

$$[13] \quad \log_{10} K_2 = (-12.3 \pm 0.8) + (5280 \pm 370)\left[\frac{1}{298} - \frac{1}{T}\right]$$

Figure 5 shows the relationship between K_2 and reciprocal temperature, derived from the anhydrous and aqueous experiments. Given the good mutual agreement of the two extrapolations, we can define K_2 over the range 0–800°C, with an uncertainty that varies between 0.3 and 1.3 orders of magnitude.

Reported thermogravimetric measurements on Bi_5O_7I (1, 4, 5), and those made by E. R. Vance (private communication) all show the onset of measurable decomposition in air near 550°C, which accelerates up to about 650°C and reaches completion around 750–800°C. These observations are qualitatively consistent with the magnitude of $p(I_2)$ values at these temperatures, as shown in Fig. 5.

(d) Further thermochemical estimates

Finally it is useful to compare the entropy of Bi_5O_7I, obtained from our aqueous equilibrium data, with values estimated from the principle of additivity (18). Using values recommended by Latimer (18) for Bi, O^{2-}, and I^- in inorganic solids, we obtain $S^0_{298} = 393.3$ J mol^{-1} K^{-1}, in agreement with our value of 430 ± 45 J mol^{-1} K^{-1}. Much closer agreement is obtained if we substitute the actual entropy of Bi_2O_3 (Table 2) into expression [14].

$$[14] \quad S^0(Bi_5O_7I) = 2.5S^0(Bi_2O_3) + S^0(I^-) - 0.5S^0(O^{2-})$$
$$= 429.9 \text{ J mol}^{-1} \text{ K}^{-1} \quad (!)$$

The same approach yields an estimate for the entropy of BiOI.

$$[15] \quad S^0(BiOI) = 0.5S^0(Bi_2O_3) + S^0(I^-) - 0.5S^0(O^{2-})$$
$$= 127.0 \text{ J mol}^{-1} \text{ K}^{-1}$$

whence $\Delta_f S^0(BiOI) = -90.4$ J mol^{-1} K^{-1}. Combining this with the Gibbs energy of formation of BiOI from ref. 1, and assuming an uncertainty of ±10 J mol^{-1} K^{-1} in the entropy, we then estimate the enthalpy of formation.

$$\Delta_f H^0(BiOI) = -275 \pm 6 \text{ kJ mol}^{-1}$$

We can now estimate the equilibrium constant for reaction [16] as a function of temperature:

$$[16] \quad (5/2)BiOI(s) + (1/2)O_2(g) \rightleftharpoons (1/2)Bi_5O_7I(s) + I_2(g)$$

$$K_{16} = p(I_2)/[p(O_2)]^{1/2}$$

$$\log_{10} K_{16} = 1.5 \pm 1.2 \text{ at } 25°C$$

(from Gibbs energies of formation; pressures in Pa)

$$\Delta_r H^0_{298} = 23 \pm 15 \text{ kJ mol}^{-1};$$

$$d(\log_{10} K_{16})/d(1/T) = -1200 \pm 800$$

These estimates are included in Fig. 5 and illustrate the much lower thermal stability of BiOI than Bi_5O_7I in air. Thermogravimetric analysis (1, 4, 5) has previously shown that reaction [16] proceeds quantitatively to the right near 300°C in air, in an open system. Using the spectrophotometric method described above, we have observed irreversible evolution of I_2 from BiOI above about 100°C.

We can also estimate the temperature dependence of equilibrium [17]:

$$[17] \quad (5/4)BiOI(s) + OH^-(aq) \rightleftharpoons (1/4)Bi_5O_7I(s) + I^-(aq) + (1/2)H_2O(l)$$

$$\Delta_r H^0_{298} \simeq 10 \text{ kJ mol}^{-1}$$

$$\log_{10} K_{17} = \{I^-\}/\{OH^-\} = 3.5 \pm 0.2 \text{ at } 25°C \text{ (from ref. 1)}$$

$$d(\log_{10} K_{17})/d(1/t) \simeq 550$$

Although this is a very rough estimate, it does indicate that

TABLE 3. Enthalpy data derived from anhydrous experiments

Solvent effects on a number of different processes have been surveyed, and results of the application of multiple linear regression analysis are discussed. The processes examined include examples of solubility of gases or vapours, distribution coefficients of solutes between water and a series of solvents, and solvent effects on conformational equilibria, on keto–enol tautomerism, and on reaction rates. It is shown that two particular equations, that due to Koppel and Palm and extended by Makitra and Pirig, and that due to Abraham, Kamlet, and Taft, can cope quite satisfactorily with solvent effects on these various processes. It is pointed out that interpretation of parameters obtained from equations that involve macroscopic quantities such as $\Delta G^{\ddagger}$ or ΔG^0 is not necessarily straightforward, and that some model is needed in order to interpret these macroscopic quantities in terms of microscopic quantities that can characterise, for example, solute–solvent interactions.

MICHAEL H. ABRAHAM, PRISCILLA L. GRELLIER, JOSE-LUIS M. ABBOUD, RUTH M. DOHERTY et ROBERT W. TAFT. Can. J. Chem. **66**, 2673 (1988).

On a évalué les effets de solvant sur un certain nombre de processus et on discute des résultats de l'application de l'analyse de regression linéaire multiple. Les processus étudiés comportent des exemples de solubilité des gaz ou des vapeurs, des coefficients de distribution des solutés entre l'eau et une série de solvants ainsi que des effets de solvant sur l'équilibre conformationnel, sur la tautomérie céto–énolique et sur les vitesses de réaction. On démontre que deux équations particulières, celle de Koppel et Palm qui a été étendue par Makitra et Pirig ainsi que celle d'Abraham, Kamlet et Taft, peuvent rendre compte d'une façon satisfaisante des effets de solvant sur ces divers processus. On note que l'interprétation des paramètres obtenus à l'aide de ces équations qui impliquent des quantités macroscopiques comme le $\Delta G^{\ddagger}$ ou le ΔG^0 ne sont pas simples; des modèles sont nécessaires pour interpréter ces quantités macroscopiques en fonction de quantités microscopiques qui peuvent caractériser, par exemple, les interactions soluté–solvant.

[Traduit par la revue]

Introduction

The first experimental observation to show that "inert" solvents could affect the rate of a chemical reaction was provided by Berthelot and Saint-Gilles (1). However, it was the classic paper of Menschutkin (2) in 1890 that initiated the widespread investigations on solvent effects that have characterised a large area of physical organic chemistry. Menschutkin (2) showed that rate constants for the reaction of triethylamine with ethyl iodide at 373 K were highly dependent on the solvent, there being factors of up to 700 between rate constants in hexane and acetophenone. Since the work of Menschutkin, there have been published a host of papers on solvent effects in organic chemistry, mainly dealing with reaction rates but also on equilibria.

At the outset, it is useful to consider the objectives of studies of solvent effects on reaction rates and other processes. In principle, there are two main objectives, (*a*) the prediction of rate constants in other solvents, and (*b*) to reach some understanding of the various influences that might affect reaction rates. The first objective is certainly important as regards testing theoretical models in the Popperian sense, but practically has been but little used. In the few recorded instances in which rate constants have been estimated for some particular purpose, rather simple procedures have been used. Thus log *k* values for the solvolysis of *t*-butyl bromide or *t*-butyl iodide in aqueous organic media can be estimated from corresponding values for *t*-butyl chloride, cf. the well-known Grunwald–Winstein *mY* equation. Again, rate constants for the Et_3N/EtI reaction can be estimated from corresponding values for the related Pr_3N/MeI reaction, and vice versa, if required. By far the greatest use of solvent effect studies has been in developing an understanding of the factors that influence reaction rates, that is to probe the reaction at a microscopic level in order to obtain information on the nature of any solute–solvent interactions, etc., that may be set up.

Unfortunately, there is no direct logical connection between

the macroscopic solvent parameters that are used in studies of solvent effects, and microscopic details of reaction processes. In order to establish such a connection, it is necessary to construct a "link", usually based on some theoretical model. As an example we can take the effect of solvent dielectric constant (ϵ) on reaction rate constants. It is quite well known that for a restricted range of solvents, usually aliphatic non-halogenated, non-hydroxylic solvents, there is often a quite good correlation between rate constants (as log k or $\Delta G^{\ddagger}$) and functions such as $1/\epsilon$ or $(\epsilon - 1)/(2\epsilon + 1)$. Steiner and Huisgen (3*a*) found for the addition of tetracyanoethylene (TCNE) to butylvinylether a correlation of the type,[2]

$$[1] \quad \Delta G^{\ddagger} = -16.1(\epsilon - 1)/(2\epsilon + 1) + \text{constant}$$

Such a correlation, by itself, leads to no information whatsoever of a microscopic nature. The "link" or model, in this case, was provided by Kirkwood (4) who showed that the electrostatic part of the Gibbs energy of a species was given by eq. [2], if the species could be regarded as a dipole of moment μ in a sphere of radius r. In eq. [2], ΔG_E is in kcal mol^{-1}, μ in Debyes, and r in Å.

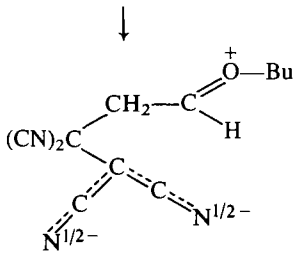
$$[2] \quad \Delta G_E = -14.4\frac{(\epsilon - 1)}{(2\epsilon + 1)}\frac{\mu^2}{r^3}$$

Laidler and Eyring (5, 6) then combined eq. [2] with the transition state theory, to yield eq. [3] for the effect of solvent dielectric constant on rate constants, as $\Delta G^{\ddagger}$.

$$[3] \quad \Delta G^{\ddagger} - \Delta G_0^{\ddagger} = 14.4\frac{(\epsilon - 1)}{(2\epsilon + 1)}\left(\frac{\mu_A^2}{r_A^3} + \frac{\mu_B^2}{r_B^3} - \frac{\mu_{\ddagger}^2}{r_{\ddagger}^3}\right) + \Delta\phi$$

The total nonelectrostatic effect is denoted as $\Delta\phi$, and A, B and the symbol $\ddagger$ stand for reactants A and B and the transition state. If $\Delta\phi$ is zero or constant, then a plot of $\Delta G^{\ddagger}$ against $(\epsilon - 1)/(2\epsilon + 1)$ will yield a line from whose slope the term in the square parentheses can be evaluated. Then knowing μ_A, r_A, μ_B, and r_B, the term $\mu_{\ddagger}^2/r_{\ddagger}^3$ can be deduced. If $r_{\ddagger}$ can be estimated, the microscopic quantity $\mu_{\ddagger}$ can be obtained. Steiner and Huisgen (3) carried out these calculations and found a reasonable value of 10.3 D for $\mu_{\ddagger}$. They also calculated a dipole moment of 17 D for the zwitterionic intermediate, so that the transition state seems reasonably close to the intermediate.

[4] $(CN)_2C{=}C(CN)_2 + H_2C{=}CH{-}OBu \rightarrow [Tr]^{\ddagger}$



We have dealt with this in some detail, because it is a very simple example of how a model or "link" can be set up in order to connect microscopic details of reaction mechanisms with bulk solvent properties. Other cycloaddition reactions were considered by Steiner and Huisgen (3),[3] and Abraham (7) has listed a number of transition-state dipole moments obtained via the Kirkwood equation [3]. More sophisticated reaction-field equations have been applied to the Et_3N/EtI reaction and to the heterolysis of *t*-butyl chloride (8, 9) leading also to transition-state dipole moments. Volumes of activation can also be correlated with the pressure derivative of the Kirkwood function to yield the microscopic quantities $\mu_{\ddagger}^2/r_{\ddagger}^3$ and hence $\mu_{\ddagger}$, as shown by McCabe and Eckert (10). Activation entropies can similarly be correlated with the temperature derivative of the Kirkwood function to give the same microscopic quantities (11).

Application of the Kirkwood function and its derivatives has mostly been to a series of pure organic solvents. Indeed, following Menschutkin, for many years studies on mixed solvents were rather uncommon. The advent of the Winstein–Grunwald equation (12, 13) specifically designed to apply to solvolyses in aqueous organic media brought about a radical change. Since that time, there have been a very large number of studies using such mixed solvents, usually in terms of the original mY equation [5] or some variant.

$$[5] \quad \log k/k_0 = mY = m \log (k/k_0)^{t\text{-BuCl}}$$

Here k and k_0 denote rate constants in a solvent and in the standard solvent of 80% aqueous ethanol, and m is defined as unity for the solvolysis of *t*-butyl chloride. The difficulty with the Winstein–Grunwald equation is that no link is provided between the macroscopic quantities in eq. [5] and microscopic parameters characteristic of the reaction or transition-state. Hence from eq. [5] it is impossible to deduce any such microscopic parameters.

Quite recently, however, there has been an interesting new approach to the study of medium effects in highly aqueous solutions. Blandamer, Engberts, and co-workers (14) have shown that by assuming a specific solvation model for the transition state, it is possible to apply pairwise group interaction parameters to reactant/solvent and transition-state/solvent interactions and hence to explain the effect of additives to aqueous media. They have carried out such an analysis for the hydrolysis of 4-methoxyphenyl dichloroacetate in aqueous solutions of urea and alkyl-ureas, and extension to other systems is eagerly awaited.

Multiple linear regression analysis

We now turn to processes in pure organic solvents. As far as rate constants are concerned, it is now quite clear that there is no single solvent parameter that will satisfactorily correlate log k values for a variety of widely differing reactions (15). Hence there has developed considerable interest into correlations by the method of multiple linear regression analysis (MLRA). The first general system of analysis by MLRA was devised by Koppel and Palm (16, 17), specifically for the correlation of rate constants. They argued that a number of solvent influences could be specified on general chemical grounds, and put forward their well-known equation [6]:

$$[6] \quad \log k = \log k_0 + g.f(\epsilon) + p.f(\eta) + c.E + b.B$$

Here $f(\epsilon)$ is a dielectric constant function, usually taken as $(\epsilon - 1)/(2\epsilon + 1)$, $f(\eta)$ is the refractive index function $(\eta^2 - 1)/(\eta^2 + 2)$, and E and B are measures of solvent electrophilic solvation ability and nucleophilic solvation ability,

[2]We shall deal in this paper not only with rate constants but with Gibbs energies. In order that the constants in various regression equations are all compatible, we shall transform any equations in log k into equation in $\Delta G^{\ddagger}$/kcal mol^{-1}, using the factor -1.36425 at 298 K.

[3]For a recent article, see ref. 3*b*.

respectively. Although Koppel and Palm did not explicitly set out a model to link the macroscopic quantities in eq. [6] with microscopic quantities, their approach is not too dissimilar to that of Abraham, Kamlet, and Taft and their co-workers (18–22) who have devised a more general equation based on a cavity theory of solution. In this approach, the solution of a solute in a solvent may be broken down conceptually into a number of stages, (*a*) the creation of a cavity of suitable size in the solvent, (*b*) reorganisation of solvent molecules around the cavity, and (*c*) introduction of the solute into the cavity, to set up various solvent–solute interactions. The endothermic or endoergic term (*a*) depends on the forces holding the solvent molecules together and on the size of the cavity. A measure of the solvent forces is the Hildebrand cohesive energy density, $(\delta_H^2)_1$, defined as the enthalpy of vaporisation of the solvent at 298 K per unit volume:

$$[7] \quad (\delta_H^2)_1 = (\Delta H_v^0 - RT)/\overline{V}_1$$

To a first approximation, the cavity size can be taken as proportional to the solute volume V_2; note that solvent properties are denoted by the subscript 1 and solute properties by the subscript 2. The reorganisation energy is probably not important, at least in terms of Gibbs energy, but the final term (*c*) will involve a number of exothermic or exoergic interactions, depending on the nature of the solvent and solute. Acid–base interactions will be set up if the solvent is a hydrogen-bond acid (α_1) and the solute a hydrogen-bond base (β_2), or if the solvent is the base (β_1) and the solute the acid (α_2). In addition there may be dipolar interactions of the dipole–dipole and dipole – induced dipole type, proportional to the dipolarity (π^x) of solvent and solute ($\pi_1^x \pi_2^x$).. A full equation for the solution of a solute in a solvent will therefore be given by eq. [8].

$$[8] \quad \Delta G^0 = \Delta G_0^0 + A\pi_1^x.\pi_2^x + B\alpha_1.\beta_2 + C\beta_1.\alpha_2 + D(\delta_H^2)_1.V_2$$

If we consider only the case of a single solute in a series of solvents, all the solute parameters are constant to leave an equation for the effect of solvents only:[4]

$$[9] \quad \Delta G^0 = \Delta G_0^0 + d.\delta + s.\pi_1^x + a.\alpha_1 + b.\beta_1 + h.(\delta_H^2)_1$$

Equation [9], the AKT equation, can be applied not only to the solubility of a single species, but to equilibrium constants, rate constants (as $\Delta G^{\neq}$), etc.[5] Values of the solvent parameters π_1^x, α_1, and β_1 have been listed for a wide range of solvents (23). Some of these, together with a number of cohesive energy densities, are given in Table 1. Whenever possible, the latter have been calculated from calorimetrically-determined ΔH_v^0 values at 298 K. Because the original Koppel–Palm equation [5] contains no parameter that can deal with a cavity term, it is restricted to processes in which cavity effects largely cancel out, i.e. to correlations of rate constants where initial-state and transition-state cavity contributions do, indeed, in general cancel. Makitra and Pirig (24, 25), however, have added the δ_H^2 cavity term to the Koppel–Palm equation giving a more general equation [10] that covers the same range of applicability as the AKT equation [9].[6]

$$[10] \quad \Delta G^0 = A_0 + A_1.f(\eta) + A_2.f(\epsilon) + A_3.\delta_H^2 + A_4.B + A_5.E$$

Equations [9] and [10] have both been applied to numerous solubility-related phenomena, generally with rather good results. The equations clearly closely resemble each other in the identification of the various solvent properties that will influence solvent–solute interactions, viz. solvent dipolarity as π_1^x or $f(\epsilon)$, solvent hydrogen-bond acidity or electrophilicity as α_1, or E, and solvent hydrogen-bond basicity or nucleophilicity as β_1 or B. Both equations have their disadvantages. The AKT equation [9] suffers in that there is no parameter directly related to solvent–solute dispersion interactions, and that for solvents with δ not equal to zero, it is not so easy to interpret the $d.\delta/s.\pi_1^x$ terms. On the other hand, the modified Koppel–Palm equation [10], includes a solvent basicity term B that is directly derived from the change in the OH infrared stretching frequency of phenol with the solvent, when both phenol and solvent are present in dilute solution in CCl_4 (26). Thus the B-scale is actually a *solute* scale and is not a solvent scale at all. Although a solute B-scale can probably be used as a solvent B-scale for nonassociated compounds, it is most unlikely that basicities of associated bulk solvents can be matched to those of monomeric solute species.[7]

There have been numerous applications of eqs. [6], [9], and [10], and we shall review these by taking examples from a variety of processes. It is as well, however, to point out a number of conditions that should be obeyed in such applications. Firstly, the solvent parameters in any given data set must not be colinear. If any two parameters are colinear over the given data set, incorporation of both of the parameters into eqs. [6], [9], or [10] may lead to meaningless coefficients. Secondly, parameters must be available for enough data points; usually five data points per each explanatory variable would be regarded as the minimum number. Thirdly, some statistical procedure, based on Student's *t*-test or the *F*-statistic, must be used to avoid the accumulation of extra unnecessary variables. In the equations that follow, we shall either exclude all parameters for which the confidence level (CL) is less than 95%, or else show these parameters specifically. Fourthly, and very importantly, results of application of equations based on some chemical model must make general chemical sense. Thus if *solvent* hydrogen-bond acidity (α_1) seems to be important in a process that does not involve any *solute* hydrogen-bond bases, the resulting equation cannot be taken seriously.

Similarly, for a process in which there is no, or little, volume change with respect to the species involved, the cavity contributions should cancel out, and the term in δ_H^2 should be redundant. This must certainly be the case for spectroscopic transitions that obey the Frank–Condon principle. However, we shall not discuss these here, since they have already been examined in detail (23, 27).

Application of MLRA to equilibria

There are a number of equilibria in which the cavity term (in δ_H^2) should cancel between reactants and products, especially

[4]The term $d.\delta$ in eq. [9] is a polarisability correction term, with δ taken as 0.5 for polyhalogenated solvents, 1.0 for aromatic solvents, and zero for all others.

[5]Note that in the first papers of AKT on this subject, the parameter δ_H was used (18, 19) rather than the better parameter δ_H^2.

[6]Makitra and Pirig (24, 25) use a log K term rather than ΔG^0 in eq. [10].

[7]The original Koppel–Palm equation [6] used ν(MeOD) in pure solvents as the basis of the B-parameter, but Koppel and Paju (26) suggested the alternative ν(PhOH) solute scale because of practical difficulties over the ν(MeOD) solvent scale. Koppel and Paju were well aware of the assumption involved in using a solute scale for a solvent scale, but concluded (26) that it was a satisfactory approximation.

[a]For an extensive list of π_1^x, α_1, and β_1 see ref. 23. Cohesive energy densities are in kcal dm^{-3} as calculated from ΔH_V^0 values at 298 K.

conformational equilibria where reactants and products will have almost exactly the same intrinsic volume. Although there have been numerous studies on solvent effects on conformational equilibria (28), only in very few cases have sufficient solvents of a wide variety been examined. In one study, Abraham (29) measured the nmr coupling constant, J, between the C_1 and C_2 protons in 1,1,2-trichloroethane in 22 aprotic solvents as 10% solutions. Solvent parameters are available for nineteen of these solvents, Table 2, and an analysis through eq. [9] leads to:

$$[11]\quad J = (6.27 \pm 0.05) + (0.25 \pm 0.10)\delta - (0.70 \pm 0.09)\pi_1^x - (0.45 \pm 0.12)\beta_1$$
$$n = 19, \quad \text{sd} = 0.10, \quad r = 0.967$$

Abraham and Bretschneider (28), and also Chen *et al.* (30), calculated ΔG^0 values for equilibrium [12] from the original (29) J-values. The two sets of ΔG^0 values are not the same, due to different assumptions over the absolute values for the conformers (I) and (II), and so we have correlated both sets of results, with ΔG^0 in kcal mol^{-1}, eqs. [13], [14].

[12] 
(I) (II)

$$[13]\quad \Delta G^0(28) = (1.22 \pm 0.05) + (0.29 \pm 0.11)\delta - (1.13 \pm 0.10)\pi_1^x - (0.30 \pm 0.13)\beta_1$$
$$n = 19, \quad \text{sd} = 0.10, \quad r = 0.978$$

$$[14]\quad \Delta G^0(30) = (0.60 \pm 0.03) + (0.18 \pm 0.07)\delta - (0.58 \pm 0.06)\pi_1^x - (0.34 \pm 0.08)\beta_1$$
$$n = 19, \quad \text{sd} = 0.07, \quad r = 0.974$$

As expected, the term in δ_H^2 is not significant, and the main factor influencing the equilibrium is solvent dipolarity. Since (**II**) will have a larger dipole moment than (**I**), any increase in π_1^x should decrease ΔG^0, exactly as observed in all three correlations. An unexpected observation is that solvent basicity also favours (**II**) over (**I**). Now in (**II**) the acidic C_1 proton is *trans* to the C_2 chlorine atom, and hence will be slightly more acidic than the C_1 proton in (**I**), so that an increase in basicity should favour (**II**), as observed. Although the absolute values

[b]Bulk pure solvent.

of the coefficients in eqs. [13] and [14] differ, the general interpretation remains the same. However, the calculated ΔG^0 value in the gas phase is not the same; if we take $\delta = 0$, $\beta_1 = 0$ and, from Abboud *et al.* (31), $\pi_1^x = -1.1$, then on eq. [13] ΔG^0 (gas phase) = 2.46 kcal mol^{-1} and on eq. [14] ΔG^0 (gas phase) = 1.24 kcal mol^{-1}. Abraham and Bretschneider (28) gave a range of possible values from 1.7 to 2.7 kcal mol^{-1} with a "best" value of 1.9 kcal mol^{-1}, whereas Chen *et al.* (30) using their own values of ΔG^0 extrapolated a value of 0.81 kcal mol^{-1}.

Interestingly, Abraham and co-workers (32) suggested a much lower value of −0.44 for the gas phase value of π_1^x, and this lower value yields ΔG^0 (gas phase) as 1.72 from eq. [13] and 0.86 from eq. [14], in much better agreement with the extrapolations given (28, 30).

Another equilibrium that involves conformers which differ in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/07/12
For personal use only.

dipole moment is that given as eq. [15]. Abraham and Griffiths (33) obtained ΔG^0 values in 13 non-hydroxylic solvents from which we have calculated equation [16]. The fit is not very good, but we have included all the solvents studied, including CCl_4 that the authors felt was anomalous. General chemical sense is maintained in that the δ_H^2 term is not significant, and that an increase in solvent dipolarity favours the more polar conformer (**IV**).

[15] 
(**III**) μ = 3.17 D (**IV**) μ = 4.32 D

[16] $\Delta G^0 = (0.88 \pm 0.07) + (0.53 \pm 0.14)\delta - (1.56 \pm 0.10)\pi_1^x$

$n = 13$, sd = 0.13, $r = 0.982$

A gas phase value of 1.5 kcal mol^{-1} was suggested (33), as compared to one of 1.57 kcal mol^{-1} calculated from eq. [16] if $\pi_1^x = -0.44$ for the gas phase (32), but no less than 2.60 if π_1^x is taken as -1.1 for the gas phase.[8]

Another, much studied, equilibrium that might also be uninfluenced by solvent cohesive energy density is the well-known keto $\rightleftharpoons$ enol equilibrium. A recent study by Emsley and Freeman (35) has yielded ΔG^0 values from results at zero concentration in 21 protic and aprotic solvents for pentane-2,4-dione, eq. [17].

[17] 
Of the 21 solvents, parameters were not available for formic acid or diglyme, but the remaining 19 solvents yielded eqs. [18] and [19]. The %CL for the α_1 term in eq. [18] is 96.7, so that this parameter is just about significant; ΔG^0 is in kcal mol^{-1}.

[18] $\Delta G^0 = (-2.24 \pm 0.14) + (2.39 \pm 0.21)\pi_1^x + (0.32 \pm 0.14)\alpha_1$

$n = 19$, sd = 0.26, $r = 0.953$

[19] $\Delta G^0 = (-2.22 \pm 0.16) + (2.54 \pm 0.23)\pi_1^x$

$n = 19$, sd = 0.29, $r = 0.936$

As suggested by Emsley and Freeman (35), polar solvents markedly favour the more polar keto form. Hydroxylic solvents are not anomalous and so the enol hydrogen-bond must remain intact, again as pointed out by Emsley and Freeman. There is a possibility, eq. [18], that solvents that are hydrogen-bond acids may stabilise the keto form preferentially. The keto form should be more basic than the enol form, certainly, but the effect is quite small. Emsley and Freeman (35) also gave results for 3-ethylpentane-2,4-dione in 6 solvents and for 3-methylpentane-2,5-dione in 12 solvents, but in neither case are there really enough solvents for MLRA to be carried out rigorously, although the dominant effect can still be seen to be that of solvent dipolarity.

One of the first processes to be investigated by either the extended Koppel–Palm equation [10] or the AKT equation was that of solubility. Various parameters can be used to express solubility, for example, the Ostwald solubility coefficient L, the Henry's law constant K^H, or ΔG^0, the standard Gibbs energy of solution based on some particular standard states. To avoid confusion over the sign of the coefficients in regression equations, we shall either set out equations in terms of ΔG^0, or when equations have been cast in terms of log K values, we shall recast these as equations in ΔG^0. Naturally, this does not affect any "goodness-of-fit" as denoted by the correlation coefficient.

On the cavity theory of solution, solubility of a solute in a series of solvents (or transfer of a solute from one solvent to another) should be inhibited by increase in cohesive energy density so that in any regression on ΔG^0, the δ_H^2 coefficient should be positive. Any solute-interaction that is set up will aid solution and hence the coefficients of terms in $f(\epsilon)$, $f(\eta)$, E, and B in eq. [10] or terms in π_1^x, α_1, and β_1 in eq. [9] should correspondingly all be negative. These considerations must be kept in mind when assessing any particular application, see the fourth condition, above.

Makitra and Pirig and their co-workers have applied eq. [10] to the solubility of a number of gases in a series of solvents (24, 25, 36–41). For example, the solubility of Freon-22 ($CHClF_2$) in 15 solvents is given by eq. [20] where N is the mole fraction solubility at 293 K (40):

[20] $\log N(CHClF_2) = 0.838 - 0.41\delta_H^2/100 + 0.00281B - 0.053E$

$n = 15$, sd = 0.161, $r = 0.966$

To be consistent with our other equations, we can simply transform eq. [20] into [21], where ΔG_S^0 is the standard Gibbs energy of solution in kcal mol^{-1} for the transfer from the gas phase to solution:

[21] $\Delta G_S^0(CHClF_2) = -1.13 + 0.56\delta_H^2/100 - 0.0038B + 0.072E$

$n = 15$, sd = 0.22, $r = 0.966$

Makitra and Pirig (40) point out that the two main factors influencing solution are solvent basicity which favours solution and solvent cohesive energy density which inhibits solution. The solvent electrophilicity, E, also seems to inhibit solution, but for the 15 solvents examined, the correlation coefficient between δ_H^2 and E is no less than 0.749, so that δ_H^2 and E are no longer independent parameters. With the exclusion of solvent THF, Makitra and Pirig (40) obtained the more sensible correlation,[9]

[22] $\Delta G_S^0(CHClF_2) = -1.05 + 0.84\delta_H^2/100 - 0.0042B$

$n = 14$, sd = 0.27, $r = 0.952$

The problem of parameter colinearity still exists if the AKT equation is applied to the solution of $CHClF_2$ since for the 14 solvents for which we have available values there is a marked

[8]The gas phase value of -1.1 has been obtained from gas phase spectrophotometric data (31) whereas that of -0.44 is an indirect value from the known gas phase ΔG^0 value for the 1,2-dibromo-4-*t*-butylcyclohexane conformational equilibrium (32). Suppan (34) has suggested that gas phase spectrophotometric shifts should not be compared with those in solution, and it is possible that for chemical processes the value of -0.44 is better.

[9]Note that Makitra and Pirig list δ_H^2 values as $\delta_H^2/1000$ when δ_H^2 is in kcal dm^{-3} (Table 1). In addition, many of the δ_H^2 values of Makitra and Pirig differ substantially from those that we consider to be the "best" values.

$Et_4\overset{+}{N} + I^-$	26.6	−39.3	−16.3	6.3	14	0.981	1.2
$Et_4\overset{+}{N} + \bar{Br}$	31.2	−41.9	−20.6	6.7	13	0.988	1.1
$Et_4\overset{+}{N} + \bar{Cl}$	34.7	−42.8	−23.7	6.8	13	0.992	1.0

[a]All solvents are aliphatic with $\delta = 0$, and in all cases the term in β_1 is statistically not significant, see ref. 44 and also Table 4.

correlation between δ_H^2 and α_1 ($r = 0.722$); we have had to exclude tributylphosphate for which we have no reliable δ_H^2 value. With the exclusion of any term in α_1, the best equation is,

$$[23]\quad \Delta G_S^0(CHClF_2) = 0.31 - 1.14\beta_1 + 0.78\delta_H^2/100$$
$$n = 14, \quad \text{sd} = 0.15, \quad r = 0.967$$

Both eqs. [22] and [23] lead to a chemically sensible interpretation, namely that the endoergic cohesive energy density term is counterbalanced by an exoergic solute–solvent interaction term that arises through hydrogen bonding between the somewhat acidic $CHClF_2$ molecule, and basic solvents.

The above discussion shows the difficulty of MLRA when explanatory variables are not independent. Other difficulties may arise if general chemical sense is not maintained. Abraham, Kamlet, and Taft (42) used a truncated version of eq. [9] to account for the solution of a number of solutes into a set of 22 solvents that were all non-acidic ($\alpha_1 = 0$), using just the π_1^x and (δ_H) terms. Makitra and Pirig (41) re-examined this work and showed that for two solutes, trimethylamine and 4-nitrobenzyl chloride, the truncated version of the AKT equation did not apply when the solvent set was extended to cover hydrogen-bond acidic solvents. They concluded, obviously erroneously, that the AKT equation was not satisfactory. Clearly, for solutes that are hydrogen-bond bases, a term in α_1 must be included in the regression equation. If this is done, then for all 15 solvents mentioned by Makitra and Pirig (41) the best equation for transfer Gibbs energies (43) from a standard solvent, in kcal mol^{-1} is given as:

$$[24]\quad \Delta G_t^0(Me_3N) = -0.34 - 0.55\delta - 2.40\alpha_1 + 1.03\delta_H^2/100$$
$$n = 15, \quad \text{sd} = 0.17, \quad r = 0.974$$

This compares very favourably with the corresponding correlation using the five parameter extended Koppel–Palm equation for which $r = 0.905$ for the same 15 solvents. Makitra and Pirig (41) do not give the resulting equation for these 15 solvents, but after the exclusion of chloroform find eq. [25]:

$$[25]\quad \Delta G_t^0(Me_3N) = 4.66 - 7.94f(\eta) + 7.24f(\epsilon) - 0.0042B - 0.112E$$
$$n = 14, \quad \text{sd} = —, \quad r = 0.958$$

The coefficients in eq. [24] make general chemical sense. Thus the (δ_H^2) term shows that increase in cohesive energy density inhibits solvation, exactly as expected on a cavity theory of solution, whilst increase in solvent hydrogen-bond acidity considerably aids solution, again exactly as expected for a solute that is a strong base. On the other hand, the reported (41) coefficients in eq. [25] make little general chemical sense — there is no apparent effect of solvent cohesive energy density, increase in solvent polarity as $f(\epsilon)$ *retards* solution, and an increase in solvent basicity B *aids* solution of the basic trimethylamine. This is an example of how application of the regression eqs. [9] and [10] must be carried out in accord with general chemical principles as well as with statistical ones.

The number of possible applications of eqs. [9] and [10] to the solubility of solutes is almost limitless, but we give possibly the most complicated example studied to date, that of the solubility (as transfer Gibbs energies) of tetra-alkylammonium halides and ion-pairs (44) using results for up to 18 aliphatic aprotic and hydroxylic solvents for which δ in eq. [8] is zero. For compounds of type $R_4\overset{+}{N}\bar{X}$ or ($R_4\overset{+}{N} + X^-$) it would be expected that solvent dipolarity and hydrogen-bond acidity would greatly reduce the value of ΔG_t^0, and that solvent cohesive energy density would considerably increase ΔG_t^0 through the endoergic cavity term. This is exactly as found, see ref. 44 and a summary of the regression equations in Table 3. What is somewhat unexpected is that solvents that are hydrogen-bond bases, all of which have lone pairs of electrons, seem to have no effect at all on ΔG_t^0. The coefficient in the $b.\beta_1$ term is always statistically insignificant, see also Table 4, and hence there can be no interaction between these basic solvents and the quaternary ammonium positive centre. The unit positive charge, even in the dissociated ions, must be almost completely shielded from the solvent. Inspection of Table 3 shows that the coefficients of π_1^x and α_1 very with solute in a chemically sensible way. Both the $s.\pi_1^x$ and the $a.\alpha_1$ term become more

negative (exoergic) along the series I^-, Br^-, and Cl^- both for the R_4NX and $(R_4N^+ + X^-)$ solutes, leading to increasing stabilisation of the chlorides by dipolar and by hydrogen-bond acid solvents. The $h.\delta_H^2$ term becomes more positive (endoergic) from Me_4N^+ to Et_4N^+ for the ion-pairs, but not so for the dissociated ions. Furthermore, the increase in $h.\delta_H^2$ is always in the order $I^- < Br^- < Cl^-$, the reverse of the order of ionic radius. It was suggested (44) that solvent electrostriction and possible solvent reorganisation around the ions or ion-pairs may play a significant role.

One difficulty over the reported (44) regression is that for the 18 solvents examined (Table 3) there is a non-negligible correlation between π_1^x and δ_H^2 ($r = 0.585$) and between α_1 and δ_H^2 ($r = 0.641$), so that extension to a wider set of solvents would be of interest. Results are available (45) for five other solvents (nitrobenzene, benzonitrile, chlorobenzene, benzene, and tetrachloromethane) with several of the ion-pairs, and for an extra eleven solvents for Et_4NI (the five given, plus ethyl benzoate, 1,1,2,2-tetrachloroethane, dichloromethane, 1,2-dichloroethane, anisole, and bromobenzene) and so we have applied eq. [9] to an extended solvent set. Unfortunately, this still does not resolve the problem of colinearity ($r = 0.435$ and 0.658) for the two above cases over the full 29 solvents, but if the equations in Table 3 are artificial, then incorporation of a different set of solvents should alter the magnitude of the coefficients considerably.[10] In Table 4 are details of regressions for ion-pairs, where now the $d.\delta$ term has had to be included. We give also the $b.\beta_1$ term, just to show how insignificant it is. Results in Tables 3 and 4 are very similar, as are the results in the two sections of Table 4. Hence we can conclude that the original equations (44) in Table 3 are, indeed "robust".

A process closely related to solubility is that of the distribution of a solute between solvent phases. Indeed, since the distribution, or partition, coefficient K_p is defined by eq. [26]

$$[26] \quad K_p = A_s/A_w$$

where A_s and A_w are the activities of the solute in solvent (s) and water (w), K_p is simply the ratio of the solubilities in the two phases, provided that the ratio of the secondary medium activity coefficients is unity. Thus for distribution of a given solute between water and a number of solvents, $\log K_p$ or ΔG_p^0 might

[10]This is quite a good test of the "robust" character of a regression — namely that the coefficients should remain the same for various subsets of data.

TABLE 5. Carbonyl compounds used in extraction experiments (46)

be expected to depend on $(\delta_H^2)_1$ and on parameters that reflect the various solute–solvent interactions in the solvent phases. Makitra and Pirig (46) have applied the extended Koppel–Palm equation [10] to the distribution of several carbonyl compounds between water and a number of solvents. Because the chosen solvents must be immiscible with water, the solvent variation is, perforce, limited. Furthermore, all the distributions refer to the water-saturated solvents and not the normal, dry, solvents, so that correlations using parameters for dry solvents would be expected to be not as good as usual. For a number of the carbonyl compounds, there are too few data points available, but for those shown in Table 5, we give the best regressions obtained using the AKT equation [9]; as usual we have transformed the given (46) K_p values into ΔG_p^0 values in kcal mol^{-1}. Results are in Table 6 for six carbonyl compounds. By and large, the regression coefficients make general chemical sense. Thus distribution is hindered by the endoergic $(\delta_H^2)_1$

term, and favoured by the various other terms that reflect exoergic solute–solvent interactions. The only exceptions are the small, but statistically significant endoergic β_1 terms for acetylacetone and benzoylacetone and the lack of any term in $(\delta_H^2)_1$ for salicylaldehyde. All distributions are favoured by increase in solvent π_1^x, as expected and are usually favoured by increase in solvent α_1 value, the latter arising no doubt through solute (base) – solvent (acid) interactions. The one marked exception, salicylaldehyde, is internally hydrogen-bonded and hence unable to interact with external hydrogen-bond acids. That is, the intramolecular hydrogen-bond competes effectively with any intermolecular hydrogen-bond.

It is rather difficult to compare results in Table 6 with those of Makitra and Pirig, since these workers give several "best" equations, all obtained after removing one or more solvents. We give in Table 7 the coefficients for some of these equations, after multiplication by −1.364 in order to transform them into coefficients related to ΔG^0. There is very little chemical sense to be made out of these coefficients — thus increase in dispersion hinders partition, whilst increase in solvent cohesive energy density actually aids partition into the solvent.

In truth, there are neither enough solvents nor a sufficiently varied collection of solvents to obtain "robust" MLRA equations for the distributions. We have considered these processes, however, because Makitra and Pirig (46) have used them as examples of the extended Koppel–Palm equation [10].

Application of MLRA to kinetics

The first comprehensive application of MLRA to kinetic phenomena was that of Koppel and Palm (17) who listed regression constants for the simple Koppel–Palm equation [6], for various processes. Shorter and co-workers (47) have applied correlation analysis to solvent effects on the reaction between diazodiphenylmethane and carboxylic acids, but one particular reaction that has been studied by several workers is the unimolecular decomposition of *t*-butyl chloride at 298 K. The "best" equation obtained by Koppel and Palm when a variety of solvents, including aprotic and hydroxylic, was considered is,[11]

$$[27]\quad \Delta G^{\ddagger}(\mathrm{Bu^tCl}) = (2.713 \pm 1.01) - (18.27 \pm 2.76)f(\epsilon) - (18.36 \pm 4.88)f(\eta) - (0.52 \pm 0.04)E$$
$$n = 23, \quad \mathrm{sd} = —, \quad r = 0.982$$

More recently, Dvorko and co-workers (48) applied the extended Koppel–Palm equation to 28 aprotic and hydroxylic solvents:

$$[28]\quad \Delta G^{\ddagger}(\mathrm{Bu^tCl}) = 24.83 - 9.63f(\epsilon) - 22.65f(\eta) - 0.400E - 0.651\delta_H^2/100$$
$$n = 28, \quad \mathrm{sd} = 0.91, \quad r = 0.960$$

As Dvorko and co-workers point out, both eq. [27] and eq. [28] lead to the conclusion that $\Delta G^{\ddagger}$ is reduced by solvent electrophilicity (E) and to a lesser extent by solvent polarity. Very significantly, solvent nucleophilicity (B) seems to play no part, in contrast to the conclusion of Fawcett and Krygowski (49). Abraham, Taft, and Kamlet (50) also examined the *t*-butyl chloride reaction using a truncated version of the AKT equation [9], without the $(\delta_H^2)_1$ variable. For a variety of aliphatic aprotic and hydroxylic solvents they obtained,

$$[29]\quad \Delta G^{\ddagger}(\mathrm{Bu^tCl}) = 20.54 - 9.47\pi_1^x - 7.30\alpha_1$$
$$n = 15, \quad \mathrm{sd} = —, \quad r = 0.995$$

Although the explanatory variables in eq. [29] are different to those in eqs. [27] and [28], the conclusions are very similar, namely that solvent polarity and hydrogen-bond acidity (or electrophilicity) reduce $\Delta G^{\ddagger}$ and hence increase log k.

The corresponding *t*-butyl bromide and *t*-butyl iodide reactions have also been examined by Dvorko and co-workers (48) and Abraham, Kamlet, and Taft (50), but the most recent set of

[11]Note that in eq. [27], $f(\epsilon) = (\epsilon - 1)/(2\epsilon + 1)$, and that the original equation was given in terms of log k.

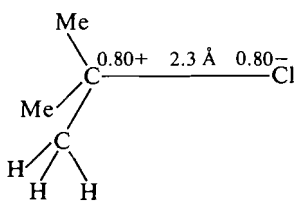
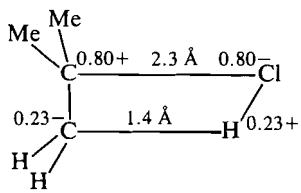
correlations is due to Abraham and co-workers (51). Details are given in Table 8. The solvents studied are a number of aliphatic aprotic and hydroxylic solvents, so that the $d.\delta$ term is zero, cf. eq. [29]. Although the regression coefficients in Table 8 are numerically smaller than those in eq. [29], for π_I^x and α_1, the general chemical sense is the same. As now seems clear from a number of different regressions, eqs. [27] to [29] and Table 8, the two main factors influencing the reaction are solvent dipolarity and solvent electrophilicity (or hydrogen-bond acidity). This is chemically quite reasonable because the transition-state seems to behave as a dipolar species of dipole moment around 8 D, with a substantial negative charge on the leaving chlorine atom. Transition states (**V**) and (**VI**) have previously been suggested (52), both of which would be stabilised by solvents with large π_I^x and α_1 values.



(**V**) μ = 8.80 D



(**VI**) μ = 7.29 D

Results in Table 8 show that there are minor accelerating effects of solvent cohesive energy density (suggested to be due to electrostriction of solvent by the dipolar transition state) and solvent hydrogen-bond basicity, β_1. Now since solvents that are hydrogen-bond bases are also nucleophiles, it follows that solvent nucleophilicity plays but a very minor rôle in stabilising (**V**) or (**VI**). Bentley (52) has quite correctly pointed out that the identification of solvent hydrogen-bond basicity, β_1, with solvent nucleophilicity is only an assumption. However, it can be shown (53) that there is a reasonable connection between the nucleophilic solvent parameter Y^+ of Kevill and Anderson (54) and solvent β_1 values,

$$[30] \quad Y^+ = 0.38 - (0.61 \pm 0.08)\beta_1$$
$$n = 8, \quad \text{sd} = 0.08, \quad r = 0.946$$

There seems little doubt, therefore, that solvent dipolarity and electrophilicity are the dominant factors that determine the magnitude of $\Delta G^{\ddagger}$ and hence log k for the unimolecular heterolysis of *t*-butyl chloride. Because solvent nucleophilicity and electrophilicity are colinear over many of the hydroxylic solvents used in solvolysis studies, it has been difficult to determine their individual contributions. The studies discussed here (51, 53) as well as other recent work (55, 56) has finally enabled the extent of nucleophilic and electrophilic assistance to be established.

It might be thought somewhat odd that the positive centre in transition state (**V**) and (**VI**), carrying some 0.8 units of charge, is not stabilised by nucleophilic solvents. However, we already know that R_4N^+ centres are completely unaffected by solvent nucleophilicity (as β_1), see Table 3 and especially Table 4. The very small nucleophilic assistance to the *t*-butyl chloride reaction is therefore quite consistent with effects on R_4NCl and $(R_4N^+ + Cl^-)$ solutes.

In Table 8 are given also regression coefficients for the *t*-butyl bromide and *t*-butyl iodide reactions (51). Nucleophilic assistance is not statistically significant in either case. The variation in the coefficients of π_I^x and β_1 is as expected on general chemical grounds. Along the series RCl, RBr, and RI the transition states will probably become slightly more dipolar, but much less susceptible to electrophilic assistance, hence the order of π_I^x coefficients in $\Delta G^{\ddagger}$ is numerically RCl < RBr < RI but for α_1 the order is RCl > RBr > RI. More recently, Abraham and co-workers (57) have extended results to cover aromatic and polyhalogenated solvents as well as the aliphatic solvents examined before (51). Although the fits are not as good as for the 21 aliphatic solvents, the various regression coefficients agree very well with those for the aliphatic solvent set, and the general conclusions based on the 21 solvent set remain unchanged.

One of the difficulties with MLRA is not only that quite a large number of solvents are needed, but also that there must be a wide variety of solvents. A number of Menschutkin reactions have been studied over a very wide range of solvents, and Koppel and Palm (17) have examined that between tri-*n*-propylamine and methyl iodide,

$$[31] \quad Pr_3N + MeI \rightarrow Pr_3NMe^+I^-$$

For 28 aprotic solvents, eq. [32] was found, but the correlation coefficient decreased markedly when the solvent set was extended to include hydroxylic solvents, eq. [33].

$$[32] \quad \Delta G^{\ddagger}(Pr_3N/MeI) = 12.27 - 12.52f(\epsilon) - 18.84f(\eta) - 0.47E$$
$$n = 28, \quad \text{sd} = —, \quad r = 0.945$$

$$[33] \quad \Delta G^{\ddagger}(Pr_3N/MeI) = 10.11 - 14.09f(\epsilon) - 13.22f(\eta) + 0.06E$$
$$n = 32, \quad \text{sd} = —, \quad r = 0.798$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/07/12
For personal use only.

Both equations indicate that solvent dipolarity and polarisability greatly reduce $\Delta G^{\neq}$ and hence increase $\log k$. However, on eq. [32] solvent electrophilicity is important but on eq. [33] it is statistically not significant (CL < 80%).

The related reaction between triethylamine and ethyl iodide has recently been examined by Abraham and co-workers (58) who find for 33 aprotic and hydroxylic solvents,[12]

$$[34]\quad \Delta G^{\neq}(Et_3N/EtI) = 5.41 + 1.29\delta - 7.31\pi_1^x + (0.111\alpha_1) + (0.222\beta_1) + 0.543(\delta_H^2)_1/100$$
$$n = 33, \quad sd = 0.35, \quad r = 0.980$$

According to eq. [34] the over-riding factor influencing the reaction rate is solvent dipolarity, with solvent hydrogen-bond acidity and basicity being statistically not significant. Presumably the stabilisation of the leaving iodide ion in the transition state by electrophilic assistance is exactly counterbalanced by stabilisation of triethylamine in the initial state.

If the leaving halide is altered, but the incoming amine is kept constant, then on the above suggestion, the effect of solvent electrophilicity will be to stabilise the transition state in the order RI < RBr < RCl and hence to lower $\Delta G^{\neq}$ in the same order, since a leaving chloride will be electrophilically solvated better than a leaving bromide or iodide. Auriel and Hoffmann (59) have studied the reaction of 1,4-diazabicyclo[2.2.2]octane, or Dabco, with 2-chloro-, 2-bromo-, and 2-iodoethylbenzene using a wide variety of aprotic and hydroxylic solvents. The best equations are given below:

$$[35]\quad \Delta G^{\neq}(Dabco/Cl) = 1.00 + 1.01\delta - 5.20\pi_1^x$$
$$n = 27, \quad sd = 0.40, \quad r = 0.927$$

$$[36]\quad \Delta G^{\neq}(Dabco/Br) = -2.12 + 1.00\delta - 4.90\pi_1^x + 0.74\alpha_1$$
$$n = 27, \quad sd = 0.35, \quad r = 0.946$$

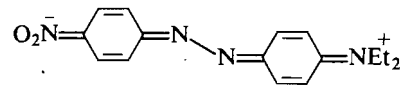
$$[37]\quad \Delta G^{\neq}(Dabco/I) = -3.05 + 1.04\delta - 4.85\pi_1^x + 1.54\alpha_1$$
$$n = 27, \quad sd = 0.32, \quad r = 0.964$$

In all eqs. [35]–[37] terms in β_1 and $(\delta_H^2)_1$ were not significant. Exactly as found for the Et_3N/EtI reaction, the main solvent influence is dipolarity, stabilising the transition state and increasing $\log k$. For all three reactions, the initial-state effect of solvent hydrogen-bond acidity will be the same, and hence the variation in the $a.\alpha_1$ term must be due to variation in transition-state property. As suggested above, the largest stabilising effect will be on the Dabco/Cl transition state, just counteracting the effect on the dibasic Dabco amine. But for the bromide and more so for the iodide, the stabilisation effect on the transition state is less, leading to more positive $a.\alpha_1$ coefficients and hence to a retarding effect on the rate.

The coefficients of π_1^x for the various Menschutkin reactions are all large and negative in eqs. [34]–[37], reflecting stabilisation of the dipolar transition states, a lowering of $\Delta G^{\neq}$, and an increase in $\log k$. Other studies (15) have yielded a dipole moment of 7.6 D for the Et_3N/EtI transition state and a charge separation of around 0.4 units, so that there is considerable independent evidence for transition-state structure. This is not necessarily so for other reactions that have been somewhat less studied, and we give as a final example the thermal *cis–trans* isomerisation of azobenzenes. Whitten and co-workers (60) determined rate constants for the isomerisation of *cis*-4-diethylamino-4′-nitroazobenzene (*cis*-DENAB) in a number of aprotic and hydroxylic solvents and correlated $\Delta G^{\neq}$ separately with π_1^x and α_1. We have applied the MLRA equation [9] to as many solvents as we had parameters for. The parameters β_1 and $(\delta_H^2)_1$ are not statistically significant, and the best regression equation is,

$$[38]\quad \Delta G^{\neq}(cis\text{-DENAB}) = 20.87 + 2.02\delta - 7.11\pi_1^x - 2.23\alpha_1$$
$$n = 22, \quad sd = 0.53, \quad r = 0.971$$

with all three parameters being significant at ≥99.99% CL. Such an equation suggests that the transition state is stabilised by dipole–dipole interactions and by hydrogen-bond interactions between acidic solvents and the nitro group in the rotational transition state, which may be close to the valence bond structure (**VII**). The lack of any stabilisation of the $=\overset{+}{N}R_2$



(**VII**)

centre (no β_1 effect) is not surprising in view of our previous discussion on R_4N^+ compounds. Whitten and co-workers (60) also examined the π, π^x transition of *trans*-DENAB for which we find,

$$[39]\quad E_{max}(trans\text{-DENAB}) = 62.97 - 6.36\pi_1^x - 0.77\alpha_1 - 0.92\beta_1$$
$$n = 22, \quad sd = 0.39, \quad r = 0.976$$

with %CL of >99.9999 (π_1^x), 95 (α_1), and 99 (β_1). Consideration of the Frank–Condon principle suggests that *trans*-DENAB itself is but marginally hydrogen-bonded. Presumably this is also the case for *cis*-DENAB, so that the transition state for isomerisation is preferentially stabilised by hydrogen-bonded acidic solvents. It follows from the coefficient of π_1^x in eqs. [38] and [39] that the dipolarity of the Frank–Condon excited state and the isomerisation transition state must be very similar, as pointed out by Whitten and co-workers (60). The latter suggest dipole moments of 8.0 D for *trans*-DENAB, 25 D for the excited state and 20.5 D for the transition state. From comparisons of the $s.\pi_1^x$ term in eqs. [38] and [39] with those in, for example, eqs. [34] to [37] and Table 8, it seems as though the dipolarity of the DENAB transition state is no more than that of the *t*-butyl chloride transition state (μ = 8.80 or 7.29 D). Possibly the degree of charge separation in the transition state is a determining factor, rather than the actual dipole moment.

Asano and Okada (61) studied the isomerism of the related compound *cis*-4-dimethylamino-4′-nitroazobenzene (*cis*-DMNAB) in a different set of aprotic plus hydroxylic solvents, leading to

$$[40]\quad \Delta G^{\neq}(cis\text{-DMNAB}) = 3.51 + 3.05\delta - 6.48\pi_1^x - 1.94\alpha_1$$
$$n = 18, \quad sd = 0.53, \quad r = 0.981$$

in good agreement with eq. [38]. Asano and Okada (61) showed also that for a number of other 4- or 4,4′-substituted azobenzenes there was very little solvent effect on the rate of isomerisation, e.g. for the ratio $k(MeOH)/k(hexane)$ they found 2.30 (4-nitro), 1.44 (4-*N*,*N*-diethylamino), 1.88 (4-*N*,*N*-dimethylamino-4′-chloro), and 1.08 (2,4-dinitro) as against a ratio of 25 500 for *cis*-DMNAB itself. Clearly, a push–pull mechanism leading to a rotational transition state close to (**VII**)

[12]Note in eq. [34], $\Delta G^{\neq}$ is calculated with respect to solvent DMF.

is favored only by the specific combination of a +R and −R substituent in the 4 and 4′ positions.

Although we have mostly dealt with solvent effects in terms of the AKT equation rather than the Koppel–Palm equation, both equations when properly used give results that are generally reasonable. Sometimes the AKT equation leads to statistically better fits, as we have seen in many of the examples discussed above, but sometimes a better fit is obtained using the Koppel–Palm equation. Zhong-yuan *et al.* (62) have applied several regression equations to the substitution of 2,4-dinitrofluorobenzene by the ethyl ester of tyrosine and find for the 11 solvents studied that the Koppel–Palm equation in B, E, and $f(\epsilon)$ leads to the best fit of the log k values. For a general discussion of solvent effects, especially on kinetic processes, the excellent book of Reichardt (63) is highly recommended.

The application of MLRA to chemical kinetics is clearly limited only by the number of reactions that have been studied in a wide variety of solvents and we have given but a selection of such processes. It must be kept in mind, however, that just as kinetic data relate only to differences between transition state and initial state, so do all the regressions based on log k or $\Delta G^{\ddagger}$ values. Although we have analysed regression equations in terms, especially, of transition-state effects, this can only be done through "chemical intuition", there being no logical connection whatsoever between any log k, $\Delta G^{\ddagger}$, or regression constant and a transition-state effect. In order to establish such a connection, solvent effects on log k or $\Delta G^{\ddagger}$ must first be broken down into initial-state and transition-state contributions; we deal briefly with this aspect of solvent effects in the next section.

Initial-state and transition-state effects and MLRA

The separation of solvent effects on rate constants (as log k or $\Delta G^{\ddagger}$ values) into initial-state and transition-state contributions is now a well-known technique in physical organic chemistry, see for example a number of reviews (7, 15, 64). Values of $\Delta G^{\ddagger}$ are rather more convenient to use than log k values, a general equation for the separation being (7),

$$[41] \quad \Delta G_t^0(\mathrm{Tr}) = \Delta G_t^0(\mathrm{Reactants}) + \Delta G_B^{\ddagger} - \Delta G_A^{\ddagger}$$

where ΔG_t^0 represents the Gibbs energy of transfer of a species from a standard reference solvent (A) to any other solvent (B). Values of ΔG_t^0(reactants) can be found by conventional thermodynamic methods (7) and are combined with kinetic measurements of $\Delta G_B^{\ddagger}$ and $\Delta G_A^{\ddagger}$ to give the resulting effect on the transition state, $\Delta G_t^0(\mathrm{Tr})$. It is not our intention to discuss the various applications of eq. [41], or equivalent equations that can be set up using any thermodynamic parameter such as H, S, V, etc., but only to deal with one specific recent advance, as follows.

Suppose that eq. [41] can be applied to a given reaction, using quite a large number of different solvents. It is then possible to apply the method of multiple linear regression analysis, not only to $\Delta G^{\ddagger}$ values but also to values of $\Delta G_t^0(\mathrm{Tr})$. In this way, the exact origin of all the terms in an equation such as the AKT equation [9] can be determined, without recourse to chemical intuition. Unfortunately, application of this method, known as the "unified method" (15), requires the availability of a very large quantity of experimental data, both kinetic and thermodynamic, and but few examples are known to date. We discuss now, the one complete published analysis on these lines — that of the *t*-butyl halide reactions carried out by Abraham and co-workers (57).

These workers first studied the 21 aliphatic solvents previously investigated (51). Values of $\Delta G_t^0(\mathrm{Bu^tX})$ were obtained and combined with $\Delta G^{\ddagger}$ values to yield the corresponding transition-state values via eq. [42]. The standard solvent was DMF.

$$[42] \quad \Delta G_t^0(\mathrm{Tr}) = \Delta G_t^0(\mathrm{Bu^tX}) + \Delta G_B^{\ddagger} - \Delta G_{\mathrm{DMF}}^{\ddagger}$$

It is then possible to apply the AKT equation [9] to $\Delta G_t^0(\mathrm{Tr})$, $\Delta G_t^0(\mathrm{Bu^tX})$ and $\delta\Delta G^{\ddagger} = \Delta G_B^{\ddagger} - \Delta G_{\mathrm{DMF}}^{\ddagger}$ and then to see exactly how each term in the equation originates. Details are in Table 9 for the case of Bu^{t}Cl and Bu^{t}Br. Inspection of the coefficients for the Bu^{t}Cl reaction shows very clearly that the π_I^x term in $\Delta G^{\ddagger}$ arises almost exclusively through a transition-state effect, as indeed does the α_1 term as well. The rather small β_1 term is again a transition-state effect, showing that a small amount of nucleophilic participation may take place. However, the negative δ_H^2 term in the $\Delta G^{\ddagger}$ equation can now be shown to arise through two positive endoergic effects on initial state and transition state that do not quite cancel out.

Effects on the Bu^{t}Br reaction for the same 21 solvents are very similar, but in this case the effect of nucleophilic participation is even smaller as judged by the β_1 term. Abraham and co-workers (57) also carried out an analysis using a further set of solvents that included aromatic and polyhalogenated ones as well as the original (53) 21 aliphatic solvents. Although a $d.\delta$ term is now required, the remaining coefficients are very close to those obtained for the 21 solvent set, compare Tables 9 and 10. However, the β_1 term in both $\delta\Delta G^{\ddagger}$ and $\Delta G_t^0(\mathrm{Tr})$ is rather less significant in the 30 solvent set, Table 10.

The only other reaction for which there are sufficient results to apply this "unified" method is the Menschutkin reaction of triethylamine and ethyl iodide. Abraham (15) has given a preliminary account of work on these lines, but since a more extensive and detailed account is in preparation (58) we refrain from an analysis until a later date.

Although it is unlikely ever to be applied to a great many reactions, we feel that it is important to use the unified method for the analysis of typical organic reactions. In the way, not only can solvent effects on $\Delta G^{\ddagger}$ be broken down into individual interactions, but it is then possible to assign exactly these interactions to initial-state and transition-state effects.

Summarising discussion

We have devoted much of this review to showing how the method of MLRA can be applied to various phenomena in organic chemistry and can lead to some understanding of solvent effects. As with all linear free energy relationships, equations such as [9] and [10] are based on the assumption that individual effects act independently and can be summed to yield an overall effect. Considering the complicated nature of solvents and solution, especially those involving solvents such as water and alcohols, it is remarkable that equations based on such an assumption hold over a wide range of processes and solvents. No doubt there will be situations in which this basic assumption breaks down, but it certainly seems to lead to chemically reasonable results for the processes we have considered.

There are, of course, other approaches to the study of solvent effects, notably factor analysis (FA) and principal component analysis (PCA). Factor analysis itself has been used in two quite different ways. Chastrette and Carretto (65) applied FA to several solvent properties and obtained four factors, or parameters, that were simply regarded as abstract factors, although it was shown, for example, that the first factor was strongly

correlated with solvent dipole moment and $f(\epsilon)$, etc. Svoboda *et al.* (66) also analysed solvent properties (35 properties for 85 solvents or a restricted set of 20 properties for 51 solvents) and showed that a minimum number of four abstract factors were required. They then rotated these factors to yield four orthogonal factors to which were ascribed a physical significance: *AP* (electrophilic solvation), *BP* (nucleophilic solvation), *EP* (polar solvation), and *PP* (dispersion solvation), and then set out a multiple linear regression equation,

[43] $A = A_0 + a.AP + b.BP + c.EP + d.PP$

where A is the dependent parameter (log k, $\Delta G^{\neq}$, etc.) and A_0, a, b, c, d are constants to be found by MLRA. Application of eq. [43] is no different in principle to the multiple linear regression equations we have already discussed. Whether eq. [43] is more general, or leads to better fits of the data, than the AKT equation [9] or the Koppel–Palm–Makitra–Pirig equation [10] could be decided by the simple, although lengthy procedure of comparing the three equations as applied to as many sets of data as possible. This is quite beyond the scope of this review, but since Svoboda *et al.* (66) list regressions for a large number of kinetic and spectroscopic processes, some idea of the relative success of the various MLRA equations can be obtained. Thus for some S_N1 reactions in hydroxylic and aprotic solvents, eq. [43] leads to good fits, with $r = 0.972$ and 0.990, compare the AKT eq. [9] where r ranges from 0.980 to 0.997, Table 8, and the simple Koppel–Palm equation [6] where values of r 0.982 and 0.985 are obtained (17). On the other hand, for S_N2 reactions of the Menschutkin type, the same "all-solvent" correlations by eq. [43] results in correlation coefficients between 0.764 and 0.846 as compared to values by the AKT equation [10] of 0.927 to 0.980, eqs. [34] and [37], and a value of 0.798 using the Koppel–Palm equation, see eq. [33]. At the moment, there does not seem to be any advantage of eq. [43] over the previous eqs. [9] and [10].

Wold and co-workers (67) take a rather different view. From a PC analysis of ^{13}C NMR shifts of indenyl-lithium, they derived two principal components, θ_1 and θ_2. Although θ_1 could be correlated with solvent parameters such as π_1^*, the second component θ_2 seemed to be system-specific. It can then be argued (68) that the appearance of system-specific parameters precludes the use of MLRA, because the latter is based on the assumption that *general* solvent parameters can be used in the correlation of solvent effects on various processes. In principle, Wold and co-workers (67, 68) are no doubt correct. The complicated nature of solvents and solvent–solute interactions must give rise ultimately to system-specific factors. However, in practice, it appears that MLRA can be applied to a reasonably wide range of processes, and, as we have seen, can yield coefficients in equations such as the AKT equation [9] that make general chemical sense.

Our conclusion is therefore that if MLRA is properly applied, with due consideration given to matters such as colinearity of explanatory variables, etc., it is possible to derive equations that can be interpreted in a chemically sensible way, and that can lead to further understanding of a rather large range of thermodynamic, kinetic, and spectroscopic processes.

MMPEP: Development and evaluation of peptide parameters for Allinger's MMP2(85) programme, including calculations on crambin and insulin

SAUL WOLFE,[1] DONALD FREDRIC WEAVER, AND KIYULL YANG
Department of Chemistry, Queen's University, Kingston, Ont., Canada K7L 3N6

Received September 22, 1987[2]

SAUL WOLFE, DONALD FREDRIC WEAVER, and KIYULL YANG. Can. J. Chem. **66**, 2687 (1988).

Allinger's MMP2(85) program has been converted to an IBM environment, and the dimensions expanded to a current maximum of 999 atoms. Substantial additional expansion will be possible. An all-atom set of parameters, which permit Allinger's comprehensive force field to be applied to the molecular mechanics treatment of peptides, has been determined. These parameters, termed MMPEP, contain 21 atom types: 5 for carbon, 6 for hydrogen, 5 for nitrogen, 4 for oxygen, and 1 for sulfur, and are based on crystallographic heavy atom bond lengths and bond angles, vibrational and microwave spectra, and *ab initio* calculations. To minimize the conformational energy of a peptide from an initial starting geometry, all internally stored parameters are released, and replaced by PEPCON, a 360-line external file containing the MMPEP parameters.

The ability of the MMPEP parameterization of MM85 to reproduce experimental crystal structures has been tested on several peptides and polypeptides, and the use of a dielectric constant $\varepsilon = 78.5$ D leads to the following results: Ala-Ala-Gly (rms = 0.261); Gly-Gly-Val (rms = 0.349); glutathione (rms = 0.417); crambin (327 heavy atoms; rms = 0.310 for all heavy atoms); insulin (389 heavy atoms; rms = 0.646 for all heavy atoms); the origins of deviations can be interpreted. No problems have been encountered in the application of the Newton–Raphson minimization procedure to such large molecules as crambin and insulin, even though all possible nonbonded interactions have been retained. On the IBM 3081 computer, real time minimization of tripeptides requires 1–2 min, crambin requires 250 min, and insulin 200 min. Since hydrogen bonding in Allinger's force field is a natural result of electrostatic and van der Waals interactions, in MMPEP hydrogen bonding is taken into account through the large number of hydrogen atom types and their different bond moments and van der Waals radii.

SAUL WOLFE, DONALD FREDRIC WEAVER et KIYULL YANG. Can. J. Chem. **66**, 2687 (1988).

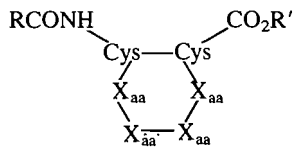
On a transformé le programme d'Allinger MMP2(85) pour un environnement IBM et on en a étendu les dimensions pour inclure actuellement un maximum de 999 atomes. Des expansions supplémentaires importantes sont possibles. On a déterminé un ensemble de paramètres couvrant tous les atomes; on pourra ainsi appliquer le champ de force global d'Allinger au traitement des peptides par la mécanique moléculaire. Ces paramètres, que l'on a appelé MMPEP, contiennent 21 types d'atomes : 5 pour le carbone, 6 pour l'hydrogène, 5 pour l'azote, 4 pour l'oxygène et 1 pour le soufre et ils sont basés sur des longueurs de liaisons et des angles de liaisons déterminées par des méthodes cristallographiques aux atomes lourds, sur des spectres de vibration et de micro-ondes et sur des calculs *ab initio*. Afin de minimiser l'énergie conformationnelle d'un peptide à partir d'une géométrie initiale, on remplace tous les paramètres conservés d'une façon interne par PEPCON, une filière externe de 360 lignes contenant les paramètres MMPEP.

Afin de vérifier les possibilités du programme MM85 incorporant les paramètres MMPEP de reproduire les structures cristallines expérimentales, on a utilisé plusieurs peptides et polypeptides; utilisant une constante diélectrique $\varepsilon = 78{,}5$ D, on obtient les résultats suivants : Ala-Ala-Gly (rms = 0,261); Gly-Gly-Val (rms = 0,349); glutathion (rms = 0,417); crambine (327 atomes lourds; rms = 0,310 pour tous les atomes lourds); insuline (389 atomes lourds; rms = 0,646 pour les atomes lourds); on peut interpréter les causes des déviations. On n'a pas rencontré de problèmes dans l'application de la méthode de minimisation de Newton–Raphson à des molécules de la taille de la crambine et l'insuline, même si toutes les interactions non-liées ont été conservées. Sur un ordinateur IBM 3081, le temps réel de minimisation des tripeptides est de 1 à 2 min; celui de la crambine est de 250 min et celui de l'insuline est de 200 min. Dans le champ de force d'Allinger, les liaisons hydrogènes sont un résultat naturel des interactions électrostatiques et de van der Waals; dans le MMPEP, on tient compte des liaisons hydrogènes par le biais de plusieurs types d'atomes d'hydrogène ainsi que par leurs moments de liaison et leurs rayons de van der Waals qui sont différents.

[Traduit par la revue]

Introduction

In the course of an investigation into the interaction of the anticonvulsant drug 5,5-diphenylhydantoin (DPH) with its receptor (1), it became necessary to study some properties of a hexapeptide containing two terminal cysteines (2). The four internal amino acids of this peptide had to be selected in such a manner that, in its oxidized cyclic form (**1**), the compound



1

would have a cavity with a diameter of 4.6 Å (3), five heteroatoms directed inwards, and the ability to complex sodium ions selectively. In addition, it was required that the complexation of sodium ions be inhibited by DPH, but not by biologically inactive analogs of this drug, e.g., 5,5-dibenzylhydantoin.

This kind of design problem has usually been solved (4) by trial and error, through the syntheses and experimental evaluation of many candidate structures. Since such a labour-intensive approach was not feasible for us, we decided to examine an alternative design strategy, based on molecular mechanics (5), that would allow three-dimensional structures to be viewed *prior* to synthesis. An essential requirement for this strategy was the development of the parameters of a force field for peptides that could be employed in conjunction with an accessible and well-documented computational procedure, e.g., MM2 (6).

The use of empirical potential energy functions to describe peptide conformations (7) began with the work of Sasisekharan and Ramachandran (8), Scheraga (9), Lifson and co-workers (10), Gelin and Karplus (11), Hagler (12), and Levitt (13). The early work initially employed a hard sphere model, which was gradually improved to include van der Waals and electrostatic interactions, and a cosine term for torsional interactions (14, 15). The computational procedure ECEPP (Empirical Conformation Energy Program for Peptides) (16) was then documented and distributed by Scheraga. In its use of fixed bond lengths and bond angles, the ECEPP force field exemplifies a "first-generation" molecular mechanics procedure. Other first-generation peptide force fields assume a united atom model, in which methyl, methylene, and methine groups are treated as spheres, or assume purely harmonic potential functions (17) for bond lengths and bond angles.

Programmes that implement these and other force fields exist (for a discussion, see ref. 18), but are not as accessible as ECEPP, and the FORTRAN source codes of these programmes are normally not made available. It is, therefore, difficult to accommodate modifications or extensions that may be needed to treat specific problems. For this reason, mainly, we chose the second-generation force field of MM2 (6) as the basis of our own work. The present article is concerned with the development of MMPEP, an all-atom parameterization of MM2 for peptides. The following article (19) describes modifications to ECEPP, which allow this latter programme to serve as a very convenient starting point for the application of MMPEP to the conformational analysis of peptides. Full details of these programming changes will be provided free of charge to all authorized users of MMP2 (85).

The MMPEP force field

The force field to be parameterized is given by eq. [1]:

$$[1] \quad E_{TOT} = \sum_{BL} E1 + \sum_{BA} E2 + \sum_{DA} E3 + \sum_{VDW} E4 + \sum_{EI} E5$$

where

$$[2] \quad E_1 = \frac{1}{2}K_1(l - l_0)^2 + K_1'(l - l_0)^3$$

$$[3] \quad E_2 = \frac{1}{2}K_2(\theta - \theta_0)^2 + K_2'(\theta - \theta_0)^4$$

$$[4] \quad E_3 = \frac{V_1}{2}(1 + \cos\omega) + \frac{V_2}{2}(1 - \cos 2\omega) + \frac{V_3}{2}(1 + \cos 3\omega)$$

$$[5] \quad E_4 = (2.90 \times 10^5)\varepsilon e^{-12.5(r_0/r)} - 2.25\varepsilon\left(\frac{r_0}{r}\right)^6$$

$$[6] \quad E_5 = \frac{\mu_i\mu_i}{Dr_{ij}^3}(\cos\chi - 3\cos\alpha_i\cos\alpha_j)$$

In eqs. [2]–[6], E_1 represents bond length energies, E_2 bond angle energies, E_3 dihedral angle energies, E_4 van der Waals interactions, and E_5, electrostatic interactions. All variables and constants are defined in subsequent discussions.

Atom types of MMPEP

The basis of a force field is the allocation of atom types, i.e., the selection of atoms that are sufficiently alike in a chemical sense to be treated identically in the molecular mechanics refinement. MMPEP employs 21 atom types for its description of amino acids and peptides (Table 1). Although the sp^3 atom types are straightforward, a variety of sp^2 types was necessary to improve geometrical precision. The number of atom types employed in MMPEP is considered to represent the minimum required for an accurate representation and concurrent avoidance of problems associated with excessive parameterization.

TABLE 1. Atom types used in MMPEP

Element	Atom type	Description of atom type
C	1	C_{sp^3}: CH_2, CH_3 (e.g., leucine side chain)
C	2	C_{sp^2}: 6-membered ring (e.g., phenylalanine)
C	3	C_{sp^2}: carbonyl, C=O (e.g., peptide backbone)
C	4	C_{sp^2}: 5-membered ring (e.g., histidine)
C	27	C_{sp^2}: junction between 5- and 6-membered rings
N	8	N_{sp^3}: amine nitrogen
N	9	N_{sp^2}: amide nitrogen
N	13	N_{sp^3}: ammonium nitrogen
N	19	Nitrogen in guanidino group (e.g., arginine)
N	26	Nitrogen in 5-membered ring (e.g., histidine)
H	5	Hydrogen attached to a carbon
H	14	Hydrogen attached to an amide nitrogen
H	23	Hydrogen attached to a non-amide nitrogen
H	21	Alcohol hydrogen (e.g., serine, tyrosine)
H	24	Carboxylic acid hydrogen, COOH
H	25	Hydrogen attached to sulfur
O	6	Alcohol oxygen, OH (e.g., serine)
O	7	Carbonyl oxygen, C=O
O	11	Oxygens in carboxylate, COO^-
O	12	Hydroxyl oxygen in carboxylic acid, COOH
S	15	Sulfur (e.g., methionine, cysteine)

Bond length parameters of MMPEP

While first-generation calculations treated bond lengths as constants, for many peptides bond energies vary significantly and require the introduction of a bond stretching potential function. Although it is possible to represent bond stretching with the harmonic potential of a Hooke's Law function (17), deviations from this harmonic potential for large bond length deformations dictate the introduction of an anharmonic correction. This correction may be approximated with the cubic term of a truncated Taylor series expansion (eq. [2]), in which l_0 is an ideal bond length, l is the bond length of interest, and K_1 and K_1' are stretching force constants.

In the parameterization of MMPEP, extensive use was made of experimental data. The X-ray and neutron diffraction bond lengths of all of the amino acids as well as a number of peptides were used to establish the strainless bond lengths for MMPEP (20–51). The ideal bond lengths used in MMPEP are listed in Table 2, and are the average of at least 10 experimental values in each case. All hydrogen atoms are considered explicitly. Since X-ray crystallography is limited in its ability to locate these atoms, the MMPEP values for X—H bond lengths were obtained from STO-3G calculations, using GAUSSIAN 80 (52). Schåfer has reported that the 4-21G C—H bond length is within 0.001 Å of spectroscopic values (53). Extensive peptide calculations by Peters and Peters (54–64) and by Kollman and co-workers (65*a*) suggest that an STO-3G basis set is also acceptable.

The N—H bond lengths of MMPEP were obtained from the optimized STO-3G structures of methylamine and formamide. Based on these calculations, the *8–23* and *9–14* type bond lengths of MMPEP have values of 1.015 and 0.991 Å respectively. Additional STO-3G calculations on 2-aminoethanol and acetic acid were used to obtain the O—H bond lengths of an alcohol and a carboxylic acid. Based on these calculations, the *6–21* and *12–24* type bond lengths are 0.968 and 0.972 Å, respectively. An STO-3G optimization of propane was used to obtain C—H (type *1–5*) bond lengths for the side chains of amino acids such as valine and leucine. Finally, a 3-21G* optimization of 2-mercaptoethanol provided the S—H (type *15–25*) bond length of cysteine.

The harmonic bond stretching force constants K_1 were assigned from a variety of data. Although desirable, the purely experimental determination of force constants tends to be a difficult task. Theoretical determinations by gradient calculations represent an alternative. Since the potential surface governing the nuclear movement is given, in the Born–Oppenheimer approximation, by the electronic energy of the molecule (as a function of the displacement coordinates), the theoretical calculation of force constants requires the calculation of the second derivatives of the molecular energy as obtained from the electronic Schrödinger equation. The development of analytical derivative techniques has made theoretical determination of force constants meaningful and accessible (66–70).

The force constants (K_1) used in MMPEP are listed in Table 3. The values for the peptide backbone have been adopted from model calculations with a 4-31G basis set (71). The force constants of the alkyl side chains of amino acids (e.g., leucine, isoleucine, valine) were based on examination of the molecular mechanics literature. For example, the C–C (type *1–1*) stretching constant is given as 4.40, 4.40, 4.40, and 4.48 mdyn/Å by Allinger, Schleyer, Lifson, and Boyd, respectively (72–75). The C–H (type *1–5*) constants are given as 4.60, 3.85, 4.60, 4.54, and 4.70 mdyn/Å by Allinger, Schleyer and co-workers,

[a]Where more than one angle is given for a particular angle type (e.g., 1–1–1, 3–1–9), the first value is for angles of the type X–CH_2–X, the second value is for angles of the type X–CHR–X, and the third is for angles of the type X–CR_2–X.

[b]Out-of-plane bending.

Ermer and Lifson, Boyd and co-workers, and Fitzwater and Bartell, respectively (72–76). MMPEP uses constants of 4.40 and 4.60 mdyn/Å for the *1–1* and *1–5* bond types.

Experimental force constants for carboxylic acids have been reported by Brooks and Haas and these have been used for residues bearing acidic side chains (e.g., glutamate, aspartate) (77). Experimental spectroscopic data also were used to obtain force constants for amino acids possessing alcohol groups (e.g., serine, tyrosine) (78). The stretching constants for amines, required for residues such as lysine, were taken from the experimental literature (79). The force constants necessary to calculate cysteine and cystine also were obtained from the experimental literature (80).

Lastly, the value of K_1' was assigned. The cubic term of eq. [2] represents an anharmonic modification of the Hooke's law function. As suggested by Allinger, the value of K_1' has been set at 2.0 mdyn/Å (5).

Bond angle parameters of MMPEP

It is known from X-ray crystallography (81) and vibrational spectroscopy (82) that bond angles exhibit a greater variability than bond lengths, and are thus of greater import for precise conformational analysis. The potential energy functions used to describe bond angle deformations are, in general, harmonic, but corrections for anharmonicity are again necessary (83–85). In MMPEP, the potential function for bond angle deformation is given by eq. [3].

As with bond lengths, both theoretical and experimental values may be employed for parameter selection. The strainless bond angles used in MMPEP are listed in Table 4. All heavy atom bond angles were taken from X-ray and neutron diffraction data (20–51), and are the average of at least 10 experimental values in each case. Angles containing hydrogen atoms were taken either from microwave data or from theoretical calculations. For angles of the type CNH, HNH, and NCH, microwave data on model molecules such as methylamine and dimethylamine were examined (86, 87). For hydroxyl groups, microwave data on methanol and dimethyl ether were employed (88). Microwave data on methanethiol and ethanethiol were used to describe the angles of the cysteine side chain (89). The amide hydrogen angles and the angles of carboxyl groups were obtained from STO-3G optimizations of formamide and acetic acid.

The harmonic bending force constants (K_2) are listed in Table 4, and, as with K_1, were derived from both experimental and theoretical data. The force constants for the peptide backbone were adopted from model peptide calculations with a 4-31G basis set (71). The force constants for alkyl side chains of amino acids (e.g., leucine, isoleucine, valine) were based on examination of the molecular mechanics literature. For example, the C–C–C (type *1–1–1*) bending constant is given as 0.450, 0.629, 0.570, 0.647, and 0.800 mdyn Å/rad^2 by Allinger, Schleyer, Lifson, Boyd, and Bartell respectively (72–76). Similarly, the C–C–H (type *1–1–5*) constants are 0.360, 0.322, 0.400, 0.521, and 0.608 mdyn Å/rad^2 and the H–C–H (type *5–1–5*) constants are 0.320, 0.350, 0.330, 0.549, and 0.508 mdyn Å/rad^2 (72–76). In MMPEP, values of 0.450, 0.360, and 0.320 mdyn Å/rad^2 are employed for the *1–1–1*, *1–1–5*, and *5–1–5* bond angle types.

Experimental spectroscopic data were used to provide force constants for carboxylate groups (e.g., glutamic acid, aspartic acid), alcohol groups (e.g., serine, tyrosine), and amines (e.g., lysine) (77–80).

Lastly, the value of K_2' was set at 7×10^{-8} mdyn Å/rad^2, as suggested by Allinger (5).

Table 5 compares a number of the bond lengths, bond angles, and force constants employed in the force fields of AMBER (65*a*), CHARMM (65*b*), MMP2(85), and MMPEP.

Torsional parameters of MMPEP

The explicit incorporation of torsional terms is necessary for the consideration of atom pairs that are separated by a chain of three bonds. An evaluation of the torsional energy about a single C_{sp^3}—C_{sp^3} bond can be made by study of one or more of the nine torsional angles defined for such a bond. Since symmetry problems arise with branched carbon skeletons when less than nine torsional angles are used, the MMPEP approach requires parameters for all possible dihedral angles.

In MMPEP the torsional potential function is represented as a Fourier series expansion, eq. [4]. Positive V_1 and V_3 terms destabilize eclipsed forms, while a positive V_2 term represents a minimum at 0° and 180°. The low periodicity (V_1 and V_2) terms tend to dominate in systems carrying heteroatoms; thus, the planarity of formamide is well described by a V_2 term. Hydrocarbons, on the other hand, have threefold symmetry requiring a V_3 term. Pople and co-workers have demonstrated the value of a Fourier expansion to interpret calculated torsional energy changes (90).

As described earlier, extensive use of STO-3G calculations has been made to determine bond length and bond angle parameters. Calculations of comparable quality were used to determine torsional parameters. This was done by computation of the torsional energy profile of the moiety of interest, followed by calculation of the Fourier expansion parameters by means of a least-squares fit.

The peptide backbone was evaluated first. The amide bond of a peptide is most stable in the planar *trans* form. This has been established by many X-ray and neutron diffraction studies, and more recently by gas-phase electron diffraction (91–93). In addition, the theoretical rotational barriers of amide bonds have been studied extensively. The available results include extended Hückel computations on model peptides (94, 95), and CNDO studies of N-substituted amides (96), formamide (97), various

methylated amides (98), and *N*-methylacetamide (99). *Ab initio* computations have been carried out on formamide (100–102), *N*-methylformamide, and acetamide (103). These *ab initio* studies suggest that the C—N rotational barrier in formamide is 20.3 kcal/mol. This compares to proton nmr results that yield a value of 19.7 kcal/mol for the Arrhenius activation energy (104). The calculated C—N rotational barrier in *N*-methylformamide is 21.1 kcal/mol, with the *trans* isomer more stable by 1.8 kcal/mol.

To reflect the torsional behaviour about the amide bond, MMPEP employs the values $V_1 = 1.8$, $V_2 = 6.49$, $V_3 = 0$ kcal/mol. This choice leads to a rotational barrier of 19.9 kcal/mol, and ensures the relative stability of the planar *trans* form.

Although the amide bond is the conformationally dominant feature of the peptide backbone, the ϕ (N—C_α) and ψ (C′—C_α) dihedral angles must also be considered. These angles exhibit a high degree of conformational variation, and are responsible for the overall flexibility of a peptide (105). In harmony with early work by Scott and Scheraga (106), Levitt (107) and Gelin and Karplus (108) have used rotational barriers of 0.6 and 0.2 kcal/mol for the ϕ and ψ dihedral angles, respectively. Kollman and co-workers initially set both of these torsional barriers at zero to maximize conformational freedom (17). Scheraga has argued that, provided the barriers lie between 0 and 1.0 kcal/mol, the results are essentially equivalent (109). Brant and Flory used values of 1.5 and 1.0 kcal/mol for ϕ and ψ, respectively, but noted that their results were not sensitive to these values (110); de Santis *et al.* neglected these barriers altogether (111). However, in a study of 22 globular proteins, Kolaskar and Prashanth concluded that non-zero torsional potential functions for ϕ and ψ are indeed necessary to account for the absence of the left-handed α-helix ($\psi = 60°$) and the high occurrence of dihedral angles in which $\psi = 0°$ (112).

Theoretical studies on small molecules provide further insight. *Ab initio* calculations on the barrier to rotation about the C_{sp^3}—C_{sp^2} bond in acetaldehyde gave a value of 0.38 kcal/mol (113). In CH_3—NH_3^+, which simulates the ϕ dihedral angle of a zwitterionic amino acid, the calculated barrier is 0.36 kcal/mol (114). A series of calculations on model dipeptides at the 4-21G level revealed that the ϕ and ψ torsional angles have relatively shallow minima as well as flat areas of potential energy (115). For example, a change of 3° in the optimized ψ dihedral angle causes an energy change of only 0.05 kcal/mol while a simultaneous 10° change in both ϕ and ψ is accompanied by an energy change of only 0.5 kcal/mol.

On the basis of these data MMPEP assumes a ψ rotational barrier of 0.30 kcal/mol. This is a threefold barrier, with minima at 0°, 120°, and 240° and maxima at 60°, 180°, and 300°. For the ϕ dihedral angle, a rotational barrier of 0.36 kcal/mol has been incorporated. Minima occur when the N—H bond is staggered with respect to the bonds C_α—H, C_α—R, and C_α—C′.

Just as the amide bond dominates the peptide backbone, the C_α—C_β (χ_1) torsional angle dominates the side chain. The χ_1 dihedral angle is C_{sp^3}–C_{sp^3} in form and is usually assigned a barrier of 2.7 kcal/mol. Calculations of the barrier to rotation in ethane support this choice (116).

Although χ_1 has been considered to be purely threefold in the work of Karplus, Kollman, Levitt, and Scheraga (11, 17, 107, 109), when polar atoms are attached to C_β a significantly asymmetrical environment is created and simple rotational behaviour, in which $V_1 = V_2 = 0$ and $V_3 = 2.7$, is no longer reasonable. Moreover, amino acids such as arginine, aspartic acid, glutamine, glutamic acid, histidine, leucine, lysine, methionine, phenylalanine, tryptophan, and tyrosine (Case 1), which have single branching distal to the β carbon must be differentiated from amino acids such as isoleucine, threonine, and valine (Case 2), which have double branching. Chuman and Momany have suggested the following equations to describe

these two cases (117):

[7] Case 1 $E = 0.5(1 + \cos 3x) + 0.2(1 + \cos x) + 0.75(1 + \cos (x - 120))$

[8] Case 2 $E = 0.5(1 + \cos 3x) + 0.3(1 + \cos x) + 0.4(1 + \cos (x - 120)) + 0.2(1 + \cos (x + 120))$

Accordingly, the Fourier expansion of MMPEP was modified to give eqs. [9] and [10].

[9] Case 1 $E = 0.13(1 + \cos \omega) + 0.49(1 - \cos 2\omega) + 0.77(1 + \cos 3\omega)$

[10] Case 2 $E = 0.28(1 + \cos \omega) + 0.29(1 - \cos 2\omega) + 0.67(1 + \cos 3\omega)$

Although V_3 remains numerically the most significant term, the contributions from V_1 and V_2 serve to destabilize the 0° and 90° conformations.

The remainder of the side-chain torsional angle parameters have been assigned by consideration of individual amino acids. For the alkyl-substituted amino acids (e.g., valine, leucine, isoleucine) and the alkyl chains of amino acids such as lysine, the usual approach has been to use a symmetrical threefold barrier with a height of about 2 kcal/mol to describe C_{sp^3}–C_{sp^3} dihedral angles (11, 17, 107, 109). This approach has been modified in MMPEP, because there seemed no *a priori* reason to eliminate one- and twofold torsional terms (118). Following Pople's Fourier treatment of torsional potentials (90), Bartell and Allinger found that better accuracy could be achieved by use of one-, two-, and threefold terms (118–120). MMPEP uses this procedure to treat alkyl side chains. In lysine, for example, the C_γ–C_δ torsional angle is represented by a Fourier series deconvolution in which $V_1 = 0.20$, $V_2 = 0.27$, and $V_3 = 2.13$ kcal/mol.

The rotational barriers of the hydroxyl groups in serine and threonine have been determined from a variety of sources. Kollman, Scheraga, and Allinger and Chung have represented this torsional angle with V_3 terms of 0.6, 0.81, and 1.0 kcal/mol, respectively (17, 109, 121). Molecular orbital calculations of the rotational barrier in methanol give variable results: extended Hückel, 0.4 kcal/mol (122); CNDO, 0.78 kcal/mol (123); *ab initio*, 0.95 kcal/mol (124). In MMPEP the rotational barrier of the hydroxyl group has been assigned the value $V_3 = 0.9$ kcal/mol.

The rotational barrier for the terminal ammonium group of lysine was determined analogously. For this χ_5 angle, Scheraga and Kollman have assigned V_3 terms of 1.8 and 2.8 kcal/mol, respectively (17, 109), while Profeta and Allinger's V_3 term is 1.8 kcal/mol for similar torsional angles (125). A variety of rotational barriers have been calculated for methylamine, ranging from 1.57 kcal/mol (CNDO) (126) to 2.02 kcal/mol (*ab initio*) (127). Spectroscopic measurements lead to a rotational barrier of 1.98 kcal/mol (128). A V_3 term of 1.8 kcal/mol has been selected for MMPEP.

Arginine has four torsional angles requiring different parameterizations. For the C_δ—N_ε bond, Kollman and Scheraga suggested $V_3 = 0$, thereby neglecting the intrinsic torsional term associated with this angle (17, 109). Low rotational barriers are expected for this angle, because the rotational barriers of methyl groups attached to planar conjugated groups are generally in the range 0–1.0 kcal/mol (129). A V_3 term of 0.5 kcal/mol has been included in MMPEP. The guanidino group of arginine is nearly planar, indicating high rotational barriers for χ_5, $\chi_{6.1}$, and $\chi_{6.2}$. Calculations (CNDO/2) give 18–20 kcal/mol barriers for each of these torsional angles (109). To achieve both planarity and a barrier of 18 kcal/mol, the value $V_2 = 18.0$ kcal/mol has been incorporated into MMPEP for these three torsional angles.

Torsional barriers are required for the carboxylic acid groups of aspartic acid and glutamic acid. Because of π-electron delocalization, the hydroxyl group tends to remain in the plane of the carbonyl group, and hydrogen bonding places the hydroxyl hydrogen *syn* to the carbonyl oxygen. Experimental results show that the *syn* conformation is more stable than the *anti* by 2–4 kcal/mol, and a value of 4.73 kcal/mol is calculated at the STO-3G level (130). In MMPEP, Allinger's MM2 values for carboxylic acids have been used directly (130). Experimental and theoretical estimates indicate that the rotational barrier about X—C—O—H (*X–3–12–24*) is 8.1, 10.9, and 13.4 kcal/mol (131–133). To reproduce these experimental and theoretical values for formic acid, Allinger determined that the HCOH dihedral angle should have $V_1 = 0.6$ and $V_3 = 6.3$ kcal/mol (130). These values have been incorporated in MMPEP. Microwave studies on acetic acid suggest a methyl rotational barrier of less than 0.5 kcal/mol (134, 135). Accordingly, a rotational barrier of 0.4 kcal/mol has been used for the *X–1–3–X* dihedral angle in MMPEP. For asparagine and glutamine, the side-chain amides have been treated as planar and have been given the same values as the peptide bond.

Aromatic amino acids are considered as a group. In accord with available experimental data, MMPEP uses a rotational barrier of 0.4 kcal/mol for χ_2 (136). In phenylalanine and tyrosine, the rotational barrier about the conjugated bonds of the aromatic ring has been set at 34 kcal/mol to agree with *ab initio* (137) and experimental studies (138). For histidine and tryptophan, the C—N conjugated double bonds have been assigned rotational barriers of 20 kcal/mol, as suggested by Kollman (17, 65). Since the experimental barrier to rotation of the hydroxyl group in phenol is 3.5 kcal/mol (136), an intrinsic torsional term $V_2 = 3.5$ kcal/mol has been adopted for MMPEP.

Finally, parameters were developed for the sulfur containing amino acids. The χ_3 and χ_4 dihedral angles of methionine are conformationally controlled by C–S torsion (type: *1–15*). Examination of applicable experimental data suggests that the C—S bond in dimethyl sulfide has a threefold rotational barrier of 2.1 kcal/mol while diethyl sulfide has a threefold barrier of 1.75 kcal/mol (136). The value $V_3 = 2.1$ kcal/mol provides MMPEP with the necessary threefold barrier of appropriate height. In the side chain of cysteine S—H replaces the —CH_2—S—CH_3 group of methionine. Experimental data for rotational barriers on relevant model compounds are 1.27 kcal/mol (methanethiol), 1.64 kcal/mol (ethanethiol), and 1.36 kcal/mol for 2-methyl-2-propanethiol (136). Calculations on methanethiol yield a C—S rotational barrier of 0.94 kcal/mol (CNDO), and 1.17 kcal/mol (*ab initio*) (139). MMPEP employs a threefold torsional barrier of 1.2 kcal/mol in its representation of this torsional angle. This value is 20% lower than the value $V_3 = 1.5$ kcal/mol used initially by Scheraga and later by Kollman.

MMPEP has also been parameterized for cystine, thereby permitting examination of disulfide linkages. Although it has been extensively discussed in the literature, the nature of the R—S—S—R torsional barrier remains uncertain. Experimental estimates vary, depending on the method used. A barrier height of 7.29 kcal/mol has been obtained from infrared data

(140) while Raman spectroscopy has produced values of 9.5 kcal/mol and 13.2 kcal/mol (141) for dimethyl disulfide and diethyl disulfide, respectively. Extended Hückel calculations on dimethyl disulfide suggest a *cis* barrier of 7.0 kcal/mol, (142, 143) and *ab initio* calculations on H_2S_2 give values of 7.7 and 7.4 kcal/mol (144, 145). At the 3-21G and 3-21G* levels, disulfides gave rotational barriers of 6–9 kcal/mol (146). This complicated torsional potential cannot be represented by a simple twofold term, but requires a minimum of two terms, both twofold and threefold. Allinger's disulfide torsional parameters give minima at ±90° and S—S rotational barriers of approximately 7.0 kcal/mol; consequently, they have been incorporated into MMPEP (147).

Table 6 lists the dihedral angle parameters of MMPEP.

van der Waals parameters of MMPEP

The Lennard–Jones equation is a general form of a nonbonded interaction potential for neutral, nonpolar molecules. The Buckingham potential, which has an exponential repulsive function, is also in common use (148). The Hill equation, (eq. [6]), used in MMPEP, is a specific example of the Buckingham potential (149). Hill showed that this equation provides a description for many simple molecules that reduces the problem of nonbonded interactions to the selection of two parameters, the van der Waals parameters, r_0 and ε. In this approach, atoms are regarded as distensible spheres of radius r_0 and hardness ε.

The selection of these van der Waals parameters is a difficult part of the parameterization process. Estimates of these parameters are available if one uses experimentally determined van der Waals potentials of rare gas atoms (150), and the fact that atomic radii increase across the periodic table. However, the final parameters must be derived empirically by a fitting of observed quantities. Allinger has employed such a procedure for a variety of amines, carboxylic acids, hydrocarbons, and sulfides, and the MMPEP values for r_0 and ε are based on MM2.

TABLE 7. van der Waals parameters of MMPEP

The van der Waals characteristics of a hydrogen attached to the oxygen of a carboxyl group have been made "small" and "soft" (151). The amide hydrogen, which is involved extensively in the hydrogen bonding process, has been treated analogously. The van der Waals parameters for sulfur require comment. For this atom, as for oxygen and nitrogen, the lone pairs are not considered explicitly (152, 153). Allinger and Hickey's molecular mechanics calculations on alkanethiols and thiaalkanes (154) suggest that this assumption may be acceptable.

The van der Waals parameters used in MMPEP are listed in Table 7.

Electrostatic parameters of MMPEP

Electrostatic interactions are of utmost importance in the consideration of nonbonded interactions (155, 156). In classical electrostatic theory the interaction energy between diffuse charge clouds is calculated by a series expansion. For interactions between point charges, the Coulomb potential is the leading term; for interactions between dipoles, the dipole/dipole interaction energy is the leading term, and can be calculated by Jeans' formula (157–160). Thus, there are two possible approaches for the treatment of electrostatic interactions: the point charge model, in which the charges are treated as geometric points placed at the atomic nuclei; and the dipole model, in which bond moments are assigned to every bond in the molecule. After evaluation of a number of different calculations, Allinger concluded that the two approaches are

3	6	0.000	27	27	0.000

equivalent (5). Although the point charge model is used by Kollman and Scheraga (17, 109), MMPEP employs the dipole model to exploit the computational versatility and flexibility of the MM2 force field.

To use the dipole model, bond moments were assigned to all possible peptide bond types. In accord with Smyth's definition, a bond moment is a vector quantity acting in the line of the bond (161). This vector has a charge at each end and a length equal to the bond length. Accordingly, the bond moment is equal to the product of charge difference and the bond length,

$$[11] \quad \mu = 2.385 l_0 (Q_1 - Q_2)$$

where $Q_1 > Q_2$ and 2.385 is a scalar multiplier which converts μ to debye units when l_0 is in Å and charge is expressed in units of electrons.

Bond lengths (l_0) have been discussed earlier. Charge densities were determined from STO-3G calculations after the method of Kollman (17, 65). For the atoms of the peptide backbone calculations were performed on the dipeptide glycylglycine. The charge densities for the side-chain atoms were determined from calculations on the *N*-acetyl amides (CH_3—CO—NH—CHR—CO—NH_2) of all 20 amino acids. The MMPEP values are listed in Table 8.

Modifications to MM2 to allow the use of MMPEP

Conversion of MMP2(85) from VAX to IBM environments

The MM2 and MMP2 programmes are dimensioned for a maximum of 100 atoms. These versions of the programme therefore allow the MMPEP parameters to be used for calculations on peptides containing up to six amino acid residues. Although this was adequate for our original design problem (1), for several reasons we wished to expand these dimensions. Since the 1985 version (MMP2(85)) had been expanded to 255 atoms, and the details of this expansion were documented (162), we began with MMP2(85), which was available in a VAX version.

The FORTRAN source code of MMP2(85) was, for the most part, ANSI standard Fortran-77. The programme was system independent, except for a few functions that interacted with the operating system; an acquiescent conversion to the VS operating system of the Queen's University IBM 3081 computer was, therefore, feasible.

The VAX version contained two routines, CPUTIM and IDATE, which provide information concerning timing and current date. These routines were modified with the aid of Queen's Subroutine Library (SUBLIB), specifically QTIME, to provide current date, current time, and virtual and total CPU time. In the IBM-VS version, timing was handled in two ways: one, which remained unchanged from the VAX version, related to total CPU time; the other made use of real time. The latter proved more important, especially for large molecules whose CPU time requirements were difficult to predict. Programme termination could then be initialized within the real time limitations imposed by the operating system (999 min).

A second problem related to the use of equivalence statements in the VAX version. The IBM-VS FORTRAN disallows equivalence of numeric integer and Hollerith type integer variables, as found in the VAX version. To overcome this restriction in the VS environment, routines were added to translate information stored in integer variables to character variables, and conversely.

Expansion of MMP2(85) to 999 atoms

The MMP2(85) programme makes extensive use of Include and Parameter FORTRAN statements to define and dimension most of the arrays. Redimensioning of these arrays was, therefore, relatively simple. However, an increase in the maximum number of atoms affected the dimensions of many interrelated arrays and, where applicable, their compile time initializations.

More serious problems were encountered in the integer packing function and unpacking subroutines, which were used to represent bond connectivity, especially the four atom numbers that describe a torsional angle. The packing routine of MMP2(85) used a 32-bit primary integer to store four secondary integers uniquely. This allowed 8 bits for each non-overlapping secondary integer, and thereby imposed a range of 0–255 ($2^8 - 1$) for each secondary integer. It became clear that more than 32 bits would be required to correct this problem. Accordingly, a 64-bit double precision real variable was used for the value of the packing functional. In such a configuration 8 bits are used to represent the exponent, leaving 56 bits to represent the mantissa. An artificial limit of 999 was imposed on the four secondary integers to be packed into the real, yielding the implementation of eq. [12],

$$[12] \quad \text{(Packed value) } P = \sum_{i=0}^{3} (I_i \times 10^{3i})$$

where I_i ($i = 0, \ldots 3$) are double precision floated representations of the secondary integers. The unpacking of such a packing scheme is straightforward.

Although packing and unpacking are normally accomplished by bit manipulating intrinsic functions, leading to faster schemes, these operate only on 32-bit integers, and were unwieldy for the present application.

Modification of MMP2(85) to accept the MMPEP parameters

The MMP2(85) programme contains partially filled arrays, to which additional parameters can be added. The atom types corresponding to such additional parameters must have been previously undefined. A failure to appreciate this point can lead

to erroneous results, which would not be detected by internal error-trapping procedures. For our purposes, the unfilled space proved to be insufficient to accommodate all of the atom types used in MMPEP. Accordingly, all internal parameters were released and replaced by information read in from an external file (PEPCON), which contained the MMPEP parameters. This approach has several advantages: it facilitates updating or expansion of the MMPEP parameters, and it can be applied readily to the treatment of other classes of compounds for which an external file can be created. PEPCON will be provided upon request.

Testing the MMPEP parameters

Any projected application of MMPEP to the theoretical conformational analysis of peptides has two prerequisites: the parameterization must be seen to provide geometries compatible with experiment; and procedures must be developed for the preliminary scanning of the conformational hyperspace of a general peptide, and the creation of an MMP2(85) input file. The question of strategy is examined in the following paper (19). Here we present tests of the parameters, performed on experimental crystal structures of several peptides and proteins.

The Newton–Raphson minimization is employed in MMP2(85); this is guaranteed to lead to the bottom of the energy well in which the initial structure is located, provided that the geometry of this structure is already close to the minimum (163). Although the conformation that crystallizes need not correspond to the global minimum, because of the effects of crystal packing and incorporation of solvent molecules, the coordinates of an X-ray structure are normally a reliable description of the geometry at a particular energy minimum. Thus, to the extent that intermolecular crystal packing forces are not severe, the use of crystal coordinates as input for a Newton–Raphson minimization should not alter the structure, if the force field and its parameterization are valid. Therefore, MMPEP was tested by comparison of minimized structures with crystal structures, starting with the X-ray coordinates, and a dielectric constant of 78.5. The consequences of this choice will be examined later.

Ala-Gly-Gly (44)

Figure 1 shows the numbering scheme employed for this peptide. Table 9 compares the calculated and experimental dihedral angles, and Fig. 2 is a superposition of the two structures, using SNOOPI.[3] The rms deviation, i.e., the root mean square fit in Å, compared to the coordinates of the starting crystal structure, is 0.261.

TABLE 11. Calculated[a,b] and crystallographic[c] dihedral angles of glutathione

Dihedral angle				Calculated (deg)	Found (deg)
2	3	4	5	−69	−70
2	3	15	16	171	170
2	3	15	23	−9	−11
4	5	6	7	103	102
6	7	8	9	−90	−88
6	7	8	17	145	147
7	8	17	18	65	69
7	8	9	10	−8	−4
8	9	10	11	180	−177
9	10	11	12	−77	−84
10	11	12	13	0	13
10	11	12	36	−180	−162

[a]Using the MMPEP parameters.
[b]See Fig. 3 for numbering scheme.
[c]Reference 164.

Crambin (165)

This polypeptide contains 46 residues, 327 heavy atoms, and 636 atoms including hydrogens. The published structure (165) includes diffraction data to 1.5 Å. A structure refined to 0.945 Å (166) has been used as the starting point for calculations with the united atom force field of AMBER (17). In these calculations (166), over 70 conjugate gradient minimizations were performed, with systematic variation of the electrostatic potential energy, the dielectric constant, the nonbonding cutoff, the van der Waals radii, the protein environment, and the presence or absence of α hydrogens. The best fit (rms = 0.245) was achieved with Jorgensen's van der Waals radii (167), a distance dependent dielectric constant of $4.0r$, and a 6.0-Å residue-based or a 9.0-Å atom-based nonbonding cutoff. Explicit inclusion of solvent or large portions of the crystal environment did not improve the fit sufficiently to justify the additional computational time.

In the present work, hydrogens were added to the heavy atoms of the 1.5 Å structure (162), and Newton–Raphson minimization was performed. The resulting rms deviation was 0.291 for the heavy atoms of the backbone, and 0.310 for all heavy atoms. Figure 7 shows a superposition of the calculated and experimental structures.[4]

Insulin (168)

The zinc complex of des-Phe B1 bovine insulin has been refined to 2.5 Å (168). The crystallographic asymmetric unit consists of two molecules, each containing two chains (A + B, and C + D). The two molecules are aggregated as a hexamer, with the dimers related by threefold rotational symmetry. In the hexamer, zinc atoms are coordinated to three symmetry-related imidazole rings of the 10 histidines. The monomer has 51 residues, 389 unique heavy atoms, and 756 atoms including hydrogens. The coordinates of A + B were used for the calculations, and led to a structure with rms = 0.511 for backbone atoms and 0.646 for all heavy atoms.[4] The superposition of the calculated and experimental structures is shown in Fig. 8.

[4]Copies of the calculated output will be provided upon request (BITNET: WOLFES@QUCDN).

Porcine insulin, resolved to 1.5 Å (404 heavy atoms) has been examined by Kollman, using both the united atom (17) and all-atom (65*a*) force fields of AMBER. With a distance dependent dielectric constant ($\varepsilon = R_{ij}$) and a 9.0-Å or 8.0-Å cutoff distance for evaluation of nonbonded interactions, rms = 0.43 (17) and 0.44 (65*a*).

Summary and conclusions

At the outset of our work we believed that Allinger's force field and the MMP2(85) programme constituted the most thoroughly tested and documented framework for the practical implementation of a molecular mechanics calculation. A reliable parameterization of the force field for peptides could, therefore, make the theoretical conformational analysis of such compounds generally accessible.

Some workers have argued that the Newton–Raphson minimization procedure that is implemented in MMP2(85) is too slow to be applied routinely to a force field that treats all nonbonded interactions of all atoms of a complex molecule. This has not been our experience. On the IBM 3081 computer, real time minimization of each of the tripeptides was achieved in 1–2 min, crambin in 250 min, and insulin in 200 min, starting with the geometries of the crystal structures. In the tripeptides, the deviations seen in Figs. 2, 4, and 6 occur at the charged ends of the molecules, and are considered to reflect the consequences of intermolecular interactions in the experimental structures. In crambin, deviations are found at residues 7 and 25, which exhibit conformational heterogeneity in the crystal structure, and at residue 22, which exhibits compositional heterogeneity. In view of these results, it is tempting to consider that the calculation of the insulin monomer provides a reasonable description of the structure that binds to the insulin receptor.

It is noteworthy that the use of a standard dielectric constant $\varepsilon = 78.5$ in MMPEP leads to acceptable agreement with experimental crystal structures in each case. Although more work is needed on this point, and on additional test examples, we believe that it will be possible to generate meaningful structures by one full Newton–Raphson minimization.

In contrast to the force fields of AMBER (17, 65*a*) and CHARMM (65*b*), the MMPEP parameterization of Allinger's force field contains no specific hydrogen bonding term. As noted by Allinger (5), hydrogen bonding in the MM2 force field occurs as a result of the electrostatic and van der Waals interactions. Similar views have been expressed by Lifson, Hagler, and co-workers for intermolecular interactions in amides (169) and carboxylic acids (170). The use of six different atom types for hydrogen in MMPEP, with different bond moments and different van der Waals radii, seems to be sufficient. For example, the van der Waals radii of H—NH— and H—N—CO are 1.320 and 0.930, respectively. The reduced radius of the amide N—H permits a short contact distance in a N—H...O=C interaction, and increases the electrostatic interaction between these groups.

The five nitrogen atom types of MMPEP permit a greater degree of geometric precision in the descriptions of the guanidine group of arginine and the five-membered rings of tryptophan and histidine. Finally, the use of low and high periodicity terms in the treatment of dihedral angles permits these to be shaped with a high degree of accuracy. It is thus possible to differentiate the χ_1 angles of amino acids such as valine and isoleucine, which have double branching distal to the β carbon atom, from other single branched residues.

Acknowledgements

The authors thank the Natural Sciences and Engineering Research Council of Canada for financial support, the Medical Research Council of Canada for the award of a Graduate Fellowship, and Queen's University for generous allocation of computer time. We are most grateful to Dr. George Birnbaum for encouragement and many helpful discussions, as well as the retrieval of many peptide crystal structures, including crambin and insulin, and the generation of the data shown in Figs. 7 and 8. We also acknowledge a helpful discussion with Michael Zucker on the subject of rms differences.

Scheraga's ECEPP program has been used to determine the relationship between one-point energies and the energies minimized by a quadratic procedure, for different sized (ϕ, ψ, χ_1) dihedral angle grid searches of simple peptides. Based on these trials, a new subroutine, INIT, has been written and incorporated into the program. This subroutine calculates the one-point ECEPP energies of up to 200,000 random permutations of (ϕ, ψ) = 0, ±90, 180 and (χ_1) = −60, 180 with all $\omega = \chi_{\neq 1} = 180$; after each 40,000 permutations, the structures having the 10 lowest energies are ordered and selected for minimization. The ECEPP program has been modified further to provide an MMP2(85) input file as part of its normal output. This allows structures located by INIT to be minimized automatically, and then refined by the Newton–Raphson minimization and MMPEP parameters of MMP2(85).

During the development of this protocol, it has been found that MMPEP correctly reproduces the C_7 conformational preference of the alanyl dipeptide in nonpolar media, and also the experimentally observed shift to α_R and P_{II} conformations in polar solvents, when the dielectric constant $\varepsilon = 78.5$ D. This dielectric constant has, therefore, been selected for a conformational analysis, using INIT/MMPEP, of the peptides Gly-Trp-Met-Asp-Phe-NH_2 (GLMAP), Gly-D-Trp-Met-Asp-Phe-NH_2 (GDMAP), and Gly-Gly-Met-Asp-Phe-NH_2 (GGMAP); GLMAP is CCK-5, a cholecystokinin fragment possessing anticonvulsant activity, which is found in the brain. The analogs GDMAP and GGMAP are not active, or much less so than GLMAP. One strongly preferred structure has been found, in each case, for GLMAP (GLMAP3) and GDMAP (GDMAP39). These structures are very similar, in the nature of the edge-to-face stacking of their Trp and Phe aromatic rings, but the C-terminal regions differ. The conformation of the C-terminal tetrapeptide of GLMAP3 is identical to a previously calculated structure of CCK-4. A comparison of the C-terminal regions of GLMAP3 and GDMAP39 with the structure of 5,5-diphenylhydantoin suggests that the mechanisms of anticonvulsant action of phenytoin and CCK-5 are not the same. In the absence of an aromatic–aromatic interaction, no clear-cut conformational preference is found for GGMAP. The structure of GGMAP whose C-terminal region is the same as that of GLMAP3 (GGMAP20) is 1.51 kcal/mol higher in energy than the lowest energy structure, and lacks the hydrophobic wall provided by the Trp residue of GLMAP3.

SAUL WOLFE, STEPHEN BRUDER, DONALD FREDRIC WEAVER et KIYULL YANG. Can. J. Chem. **66**, 2703 (1988).

On a utilisé le programme ECEPP de Scheraga pour déterminer la relation qui existe entre les énergies ponctuelles et les énergies minimisées par une méthode quadratique, pour diverses grilles de recherches d'angles dièdres (ϕ, ψ, χ_1) de peptides simples. Sur la base de ces essais, on a développé une nouvelle sous-routine, INIT, et on l'a incorporée dans le programme. Cette sous-routine calcule les énergies ponctuelles ECEPP de 200,000 permutations au hasard de (ϕ, ψ) = 0, ±90, 180 et (χ_1) = −60, 180 avec $\omega = \chi_{\neq 1} = 180$; après avoir examiné 40,000 permutations, les structures possédant les 10 énergies les plus basses sont ordonnées et choisies pour une minimisation. On a encore modifié le programme ECEPP de façon à obtenir un ensemble de données que le programme MMP2(85) peut utiliser normalement dans son cheminement. Cette possibilité permet de minimiser automatiquement des structures localisées par INIT et de les raffiner ensuite à l'aide de la méthode de minimisation de Newton–Raphson et des paramètres MMPEP du programme MMP2(85).

Au cours du développement de ce protocole, on a trouvé que MMPEP reproduit correctement la préférence conformationnelle du C_7 du dipeptide de l'alanyle dans des milieux non-polaires ainsi que le déplacement observé expérimentalement vers les conformations α_R et P_{II} dans des solvants polaires, lorsque $\varepsilon = 78{,}5$ D. On a donc choisi cette constante diélectrique pour une analyse conformationnelle, utilisant le programme INIT/MMPEP, des peptides Gly-Trp-Met-Asp-Phe-NH_2 (GLMAP), Gly-D-Trp-Met-Asp-Phe-NH_2 (GDMAP) et Gly-Gly-Met-Asp-Phe-NH_2 (GGMAP); le GLMAP est le CCK-5, un fragment cholécystokinine possédant une activité contre les convulsions et qui est retrouvé dans le cerveau. Les analogues GDMAP et GGMAP ne sont pas actifs ou beaucoup moins que le GLMAP. Dans chacun des ces du GLMAP (GLMAP3) et du GDMAP (GDMAP39), on a trouvé une structure qui est fortement privilégiée. Ces structures sont très voisines par la nature de l'empilement côté à face de leurs cycles Trp et Phe aromatique; toutefois, les régions C-terminales diffèrent. La conformation du tétrapeptide C-terminal du GLMAP3 est identique à celle calculée antérieurement pour la structure du CCK-4. Une comparaison des régions C-terminales du GLMAP3 et du GDMAP39 avec la structure de la diphényl-5,5 hydantoïne suggère que les mécanismes d'action contre les convulsions de la phénytoïne et du CCK-5 ne sont pas les mêmes. En l'absence d'une interaction aromatique–aromatique, on ne trouve pas de préférence conformationnelle marquée pour le GGMAP. L'énergie de la structure du GGMAP, dont la région C-terminale est identique à celle du GLMAP3 (GGMAP20), est 1,51 kcal/mol plus élevée que celle de la structure de plus basse énergie; de plus, elle ne possède pas le mur hydrophobe qui est fourni par le résidu Trp du GLMAP3.
[Traduit par la revue]

Introduction

The preceding article (1) has described the development of an all-atom peptide parameterization of Allinger's MMP2(85) programme (2). The MMPEP parameters provide calculated geometries of peptides in agreement with experimental crystal structures, when the Cartesian coordinates of these crystal structures are supplied as input for the block-diagonal Newton–Raphson minimization of MMP2(85).

This minimization procedure is most reliable for a function of many variables when the initial structure already lies near the bottom of its energy well (3), as is the case for the conformation that crystallizes. Therefore, any projected application of MMPEP to the search for other conformations of peptides,

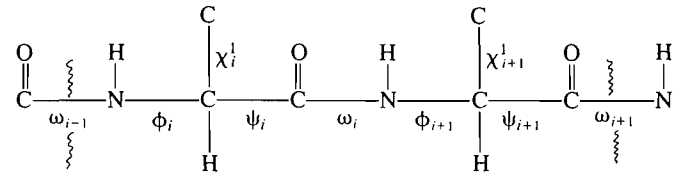

FIG. 1. Nomenclature used for the (i) and (i + 1) residues of a general peptide.

including conformations in solution, or conformations lower in energy than that of the crystal structure, would require initial geometries comparable in quality to those of X-ray structures. One possible approach is to proceed from the crystal structure to other minima by the use of successive dihedral drives. However, such a strategy does not seem practical, because of the large number of dihedral angles that would have to be examined for any peptide containing more than two or three residues.

The present work is concerned with the development and evaluation of a protocol for peptide conformational analysis based on the use of ECEPP (4) to obtain Cartesian coordinates suitable for the Newton–Raphson minimization of MMPEP. As described by Scheraga and co-workers (5), ECEPP (Empirical Conformational Energy Program for Peptides) is a molecular mechanics procedure whose force field assumes fixed bond lengths and bond angles. The input to ECEPP consists of a sequence of amino acids, together with two end groups and a set of backbone and side-chain dihedral angles. The output includes the Cartesian coordinates of all atoms, but in a format different from that required by MMP2(85). One of the features of the combined ECEPP/MMPEP analysis described herein is a routine that converts ECEPP output into a structure, analyzes this structure to obtain connected and attached atom lists, determines the atom types on the basis of connectivities, reformats the Cartesian coordinates, and creates an input file for MMPEP (see Appendix 1).

The application of this subroutine to the coordinates generated by a one-point ECEPP calculation with an arbitrary set of dihedral angles would be inappropriate, because these coordinates would normally describe a structure that is far from a minimum. Consequently, minimization of the initial ECEPP structure is necessary. Following Scheraga (5), we have incorporated into ECEPP a quadratic minimization procedure (6) that treats dihedral angles consecutively and iteratively.

Coordinates generated following the application of this procedure are suitable for MMPEP, but the structure thus obtained refers to the energy well reached in the quadratic minimization, and depends upon the choices of the initial dihedral angles and the step size. A central problem, therefore, is to preselect these initial angles according to criteria or search procedures that are sufficiently objective to be reproducible from one laboratory to another.

Figure 1 shows the (i) and (i + 1) residues of a general peptide in the standard convention (7). In the native conformation of a globular protein, peptide segments are folded so as to take advantage of intramolecular hydrogen bonding. These hydrogen bonds lead, *inter alia*, to α-helices, parallel or antiparallel β-pleated sheets, or β-bends (8). Each of these encompasses a specific number of residues, and a specific range of (ϕ,ψ) within a residue. In most cases, ω_i is ca. 180°, and the most common value of χ_1 observed in crystal structures is ca. −60° (9). Values of (ϕ,ψ) that reflect different folding patterns include (10): right-handed α-helix, (−57, −47); antiparallel β-pleated sheet ($\equiv C_5$ bend) (−139, +135); parallel β-pleated sheet (−119, +113); C_7 bend, (−80, +80); collagen (−75, +150).

The existence of trends in the crystal structures of peptides and proteins has led to the development of empirical rules to predict the probable secondary structure adopted by an amino acid that occupies a specific position within the molecule (11). These rules are undergoing continuous refinement (12), and it is presently considered that the statistical accuracy of a three-state definition of secondary structure (helix, sheet, loop/turn) is about 60%.

A proper appeal to such methods would constitute one possible criterion for the selection of the initial ECEPP structure(s). However, this strategy would be incomplete, for several reasons: (*i*) the single structure reached following minimization would retain any uncertainty in the secondary structure prediction; (*ii*) the search for other low energy structures would remain undefined; (*iii*) rules derived from crystal structures of globular proteins may not be applicable to shorter, conformationally flexible, peptides.

These considerations led us to examine the application of more generalized sampling methods to scan the conformational hyperspace of a peptide. Since, for any residue, the specification of the initial values of (ϕ, ψ, χ_1) is most important, an initial survey could reasonably be based on $\omega^i = \chi^i_{\neq 1} = 180°$, and the selection of a set of possible values of (ϕ^i, ψ^i, χ^i_1). An initial decision concerning these values was made on the basis of the following representative series of computations: (*i*) one-point ECEPP calculations were performed on the alanyl dipeptide (Ac-L-Ala-NHMe, **1**), and on Ac-D-Ala-D-Ala-OH (**2**), for all possible permutations of (ϕ,ψ) = 0, ±60, ±120, 180°, and all possible permutations of (ϕ,ψ) = 0, ±90, 180°; (*ii*) each of these structures was minimized, using a maximum step size of 0.5 radian; (*iii*) all of the structures found for **1**, and the 10 lowest energy structures found for **2**, were subjected to a Newton–Raphson minimization, using MMPEP.

The following observations were made: (*a*) the same set of low energy structures resulted, after minimization of ECEPP, whether the increment in (ϕ,ψ) was 60° or 90°; (*b*) the lowest energy ECEPP structure, after minimization, corresponded to one of the structures having the lowest one-point energy in the case of **1**, and also in the case of **2**, although some crossovers were seen with other structures; (*c*) energy differences, and some relative energies, were altered when the ECEPP structures were refined using MMPEP; (*d*) the lowest energy structure of **1**, after MMPEP minimization with the dielectric constant ε = 1.5, has the C_7^{eq} conformation (Fig. 2), and is 1.13 kcal/mol more stable than the crystal structure (ϕ,ψ) = (−88, 155) (13), whose P_{II} conformation is stabilized by *inter*molecular hydrogen bonding; (*e*) with a dielectric constant of 78.5, corresponding to water solvent, the C_7^{eq} conformation and the crystal structure of **1** have the same energy, but the global minimum is α_R (ϕ,ψ = −67, −47); (*f*) the lowest energy structure of **2**, after MMPEP minimization with a dielectric constant of 78.5, has a C_7 bend (Fig. 3) (ϕ,ψ = 79, −76; ϕ_2,ψ_2 = 76, 41), and is 11.0 kcal/mol more stable than the crystal structure (14) (ϕ_1,ψ_1 = 81, −152; ϕ_2,ψ_2 = 70, 40).

There have been many previous calculations on the alanyl dipeptide, the most commonly discussed minimum dipeptide unit (15). As summarized in Table 1, all calculations, including our own, find the C_7^{eq} conformation to be preferred under nonpolar conditions. This is also the experimental conclusion reached by Madison and Kopple (16), based on cd and nmr

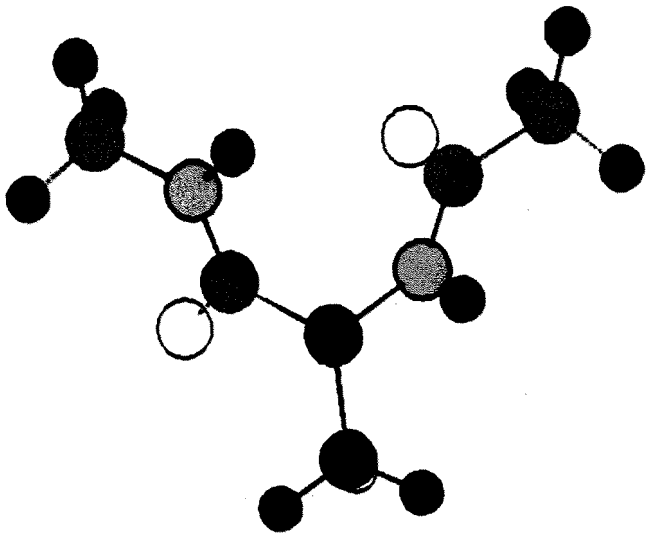

FIG. 2. Global minimum of the alanyl dipeptide (**1**), for a dielectric constant of 1.5.

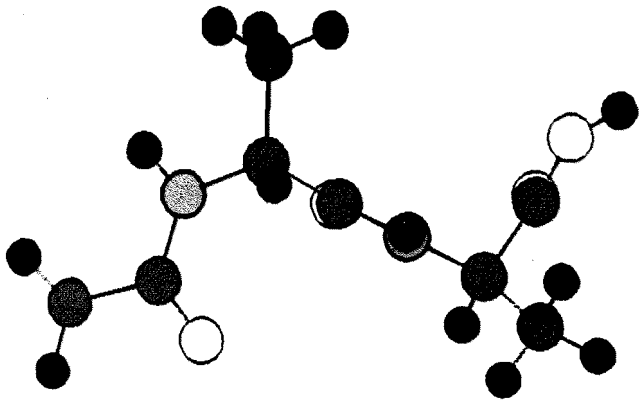

FIG. 3. Global minimum of Ac-NH-D-Ala-D-Ala-OH for a dielectric constant of 78.5.

measurements in chloroform solvent. These latter workers also find (16) that the conformation shifts from C_7-predominant to α_R and polyproline II (P_{II}) in water solvent; any C_5 conformation remains approximately constant in the two solvents. Inspection of Table 1 suggests that only the present calculations, using MMPEP and a dielectric constant of 78.5, reproduce these solvent-induced conformational changes. This is an encouraging result. It suggests that the MMPEP parameterization of MMP2(85) is valid not only for the calculation of geometries but also for the calculation of relative energy differences in water solvent. All subsequent MMPEP calculations were, therefore, performed using $\varepsilon = 78.5$.

The MMPEP results summarized in Table 1 are representative of many such calculations, starting with ECEPP, and it was concluded that a generalized search procedure could begin with one-point ECEPP calculations for permutations of $(\phi,\psi) = 0, \pm 90, 180°$, followed by ECEPP minimization of a sufficient number of the low energy structures thus identified.

This strategy would require 4^{2n} one-point calculations for a complete search of the (ϕ,ψ) space, where n is the number of residues in the peptide. Since the total number of such calculations rapidly becomes astronomical for $n > 5$, if χ_1 is not varied, and for $n > 4$ if χ_1 is allowed values of -60, 180°, some reduction of the problem was necessary. For this to be meaningful, it was essential that the selection be uniform, a condition that defines a problem in random number generation (see Appendix 2). This problem was approached in stages.

In the first stage, χ_1 was fixed at $+60$, -60, or 180°, and one-point energies were calculated for random permutations of (ϕ,ψ) generated using the integers 0, 1, 2 to code for the angles 90, 180, 270 ($\equiv -90°$) as a 60-digit base-three number. This allowed the treatment of peptides containing up to 28 amino acid residues, i.e., $2'(28 + 2'') = 60$, where $2''$ refers to end groups and $2'$ refers to the (ϕ,ψ) of each residue. In this first stage, a maximum of 6600 permutations was allowed for each seed value of the random number generator, and only the 60-digit number coding for the lowest energy structure was printed. This number was then decoded to create an ECEPP input file, and the structure was minimized.

The procedure just described was tested on peptides containing 4–28 amino acid residues, with χ_1 fixed successively at -60, $+60$, and 180°. In all cases, the one-point energies of the single structure found in a given search were $\chi_1^{60} >> \chi_1^{180} > \chi_1^{-60}$. After minimization, the energies were found to be $\chi_1^{60} >> \chi_1^{180} \sim \chi_1^{-60}$. These results strongly suggested that $\chi_1^i \neq 60°$.

In the second stage, a 90-digit base-four number was used to code a maximum of 28 amino acid residues as $3(28 + 2)$, where the 2 refers to end groups; the first two entries of the 3 refer to $(\phi,\psi) = 0, 90, 180, 270$, coded as 0, 1, 2, 3; the third entry of the 3 refers to $\chi_1 = -60$, 180, coded as 1, 2, with 0 used in the case of glycine, or when all χ_1 were fixed at $-60°$ or at 180°. In this second stage, the maximum number of permutations was expanded to 25,000, and only the lowest energy structure was again retained. The tests at this stage suggested that χ_1 be allowed to vary ($\chi_1 = -60$, 180).

In the next stage, the maximum number of permutations was increased to 40,000, and the *ten* lowest energy structures were retained and minimized. Table 2 summarizes the results thus obtained for the octapeptide H-Gly-Asn-Thr-Ile-Val-Ala-Val-Glu-OH (**3**). These results, which are typical, suggested that for complex peptides there is no obvious correlation between one-point energies and minimized energies, within the first few low energy structures, and that at least 10 such structures should be examined.

Accordingly, in the strategy that has been used to obtain the results discussed below, the maximum number of permutations was increased to 200,000, and, after each 40,000 permutations, the 10 lowest energy structures were retained. All of this is accomplished via a new subroutine, INIT, which has been incorporated into ECEPP. This strategy leads to the identification of 50 structures for examination by ECEPP/MMPEP.

The cholecystokinins: endogenous anticonvulsant peptides?

Cholecystokinin (CCK) was discovered as a gastrointestinal mediator of digestive function and feeding behaviour, and was subsequently found also to be present in high concentrations in several regions of the brain (for general reviews, see ref. 17). The peptide pro-CCK contains 95 residues, and is converted by human plasma enzymes into CCK-58, CCK-39, CCK-33, CCK-12, CCK-8, CCK-5, and CCK-4 (18). Of these fragments, CCK-33 and CCK-8 are the major forms present in gut and brain, respectively; CCK-5 is also present in large amounts in the brain (19), and is active in binding to brain receptors (20).

The C-terminal peptapeptide of CCK (CCK-5) has the

constitution H-Gly-Trp-Met-Asp-Phe-NH_2, and is identical to the C-terminus of gastrin, whose terminal tetrapeptide moiety H-Trp-Met-Asp-Phe-NH_2 (≡ CCK-4) constitutes the minimum requirement for physiological activity in the mammalian gut (21). However, the gastrin gene is not expressed in the cerebral cortex (19), and brain receptors for CCK fragments are distinctly different from the receptors for the same fragments in the pancreas and gallbladder (22).

Our interest in C-terminal CCK fragments was stimulated by reports (23) that these fragments possess potent anticonvulsant activity in several chemical convulsant models, including picrotoxin-induced seizures. Some workers speculate that CCK may function as an endogenous anticonvulsant, and that convulsive disorders can arise from an abnormal function of CCK-like peptides in the brain (23–26). The mechanism of the CCK anticonvulsant activity is uncertain, but is known to differ from that of diazepam (24). Structure–activity studies (25–31) suggest that a terminal Phe-NH_2, a side chain resembling Asp, and Trp (but not its D epimer) are necessary for anticonvulsant activity.

The requirement for a terminal aromatic amino acid amide is reminiscent of the conclusions of quantitative structure–activity relationships of hydantoin anticonvulsants (32), whose most important member is 5,5-diphenylhydantoin (DPH). In the case of DPH, the activity is associated with the presence of a conformationally constrained phenylacetamide (PhCHCONH) moiety. 5-Benzyl-substituted hydantoins, which contain a benzylacetamide ($PhCH_2CHCONH$) moiety, are inactive, because the aromatic ring lies over the hydantoin ring, and restricts access to the important amide bond (32). If it is assumed that a structural and mechanistic relationship exists between DPH and CCK, the presence of a benzylacetamide moiety (Phe-NH_2) in active CCK fragments would require that the role of L-Trp is to cause the phenyl group to be rotated away from the terminal amide bond in the biologically active conformation.

The nature of aromatic–aromatic interactions in peptides and proteins has received considerable recent attention (33). In contrast to expectations based on considerations of orbital interactions, edge-to-face stacking of aromatic rings is preferred energetically when the centroids are separated by 4.5–7 Å. The stabilization amounts to 1–2 kcal/mol, and is thought (34) to play an important role in the adoption of biologically active conformations. For example, constraint of somatostatin, which

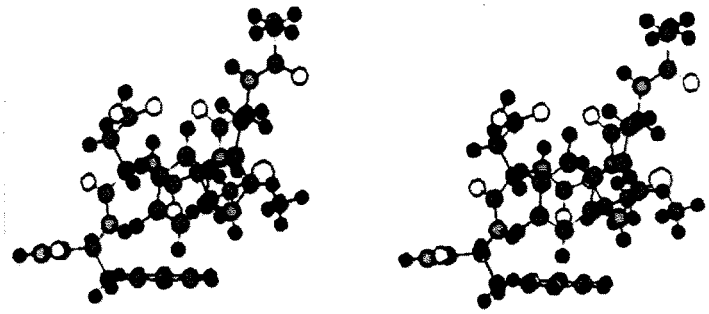

FIG. 4. Diastereoscopic view of GLMAP3.

For personal use only.

contains a perpendicular Phe...Phe interaction, by incorporation of a cystine moiety in place of the two phenylalanines, leads to a biologically active analog (35).

Other aromatic–X interactions have also been identified in the crystal structures and solution conformations of peptides (36). In particular, the sulfur atoms of *methionine* residues express an affinity for the *edges* of aromatic rings.

Roques and co-workers (37) have studied the ^{1}Hmr spectra and fluorescence transfer of various CCK fragments in DMSO-d_6 and D_2O, as a function of pH and temperature. They find that CCK-4, but not CCK-5, exhibits stacking of Trp and Phe, mainly on the basis of the pH dependence of chemical shifts. However, the pH-dependent conformational changes proposed by these workers are not associated with large variations of vicinal coupling constants. Roques and co-workers suggest that CCK-5 prefers a cyclic structure, in which there is close contact between the N-terminal amino group and the carboxyl group of aspartic acid. In DMSO-d_6, the CCK-4 analog H-Trp-Nle-Asp(O-*t*Bu)-Phe-NH_2 has a random structure, which transforms to a stacked conformation in 2,2,2-trifluoroethanol (38).

In view of these various findings, and as a test of our proposed strategy for peptide conformational analysis, we have carried out calculations on three variations of CCK-5: the parent structure H-Gly-Trp-Met-Asp-Phe-NH_2 (GLMAP), and the two analogs H-Gly-Gly-Met-Asp-Phe-NH_2 (GGMAP) and H-Gly-D-Trp-Met-Asp-Phe-NH_2 (GDMAP). In GGMAP, the biologically significant Trp residue is replaced by a conformationally flexible Gly; in GDMAP, the Trp residue is replaced by its less active D epimer. All calculations were performed on the uncharged molecules.

It was hoped that the calculations would provide information concerning (*i*) the relative energies of stacked and cyclic structures in GLMAP and GDMAP; (*ii*) the geometrical nature of Ar...Ar stacking; (*iii*) the role of Ar–sulfur interactions; (*iv*) the possible accessibility to a receptor of the Asp side chain and the terminal amide bond; (*v*) the relationship, if any, between CCK conformations and the active region of DPH.

Structures were examined, using the SNOOPI option of CHEMGRAF,[3] after the ECEPP minimizations, and again after the final MMPEP minimizations. It was quickly established that the use of the default dielectric constant ($\varepsilon = 2$) for the preliminary ECEPP search led to a pronounced energetic preference for cyclic structures, which did not remain cyclic following MMPEP refinement with $\varepsilon = 78.5$. Accordingly, all subsequent computations were performed using $\varepsilon = 78.5$ at all stages. With this dielectric constant, cyclic structures located in the ECEPP search remained cyclic after the final MMPEP refinement.

TABLE 3. Relative MMPEP energies[a] of 50 structures of GLMAP located following an initial search of 200,000 structures

Number	1–10	11–20	21–30	31–40	41–50

[a]In kcal/mol.

GLMAP

Table 3 lists the final MMPEP energies of 50 structures, located following a one-point initial search of 200,000 structures and ECEPP minimization of the 50 lowest energy structures thus identified. No structure lower in energy than GLMAP3 was found in a second search of 200,000 initial structures. The first search located only six structures within 3 kcal/mol of GLMAP3; the second search located an additional four structures within this energy range.

Figure 4 shows a diastereoscopic view of GLMAP3. The structure appears identical, in the region of the terminal tetrapeptide, to the structure calculated by Abillon *et al.* (39) for the gastrin tetrapeptide (CCK-4) (see also ref. 40), which is shown as Fig. 5 (41). Figure 6 is a space-filling view of GLMAP3, and the following observations are made: (*i*) the structure is not cyclic; (*ii*) there is a perpendicular stacking of the two aromatic rings; (*iii*) there is also an interaction between the sulfur atom of methionine and the edges of both aromatic rings; (*iv*) the aromatic–aromatic interaction creates a hydrophobic wall around two sides of the molecule; (*v*) the terminal amide bond and the side chain of Asp are jointly accessible to a potential receptor, on one side of the molecule.

[3]The authors thank Dr. Keith Davies for permission to use this option of CHEMGRAF, and Professor A. S. Cameron (Dalhousie University) and I. Kucirec (Perkin–Elmer Canada) for the Perkin–Elmer version of the programme.

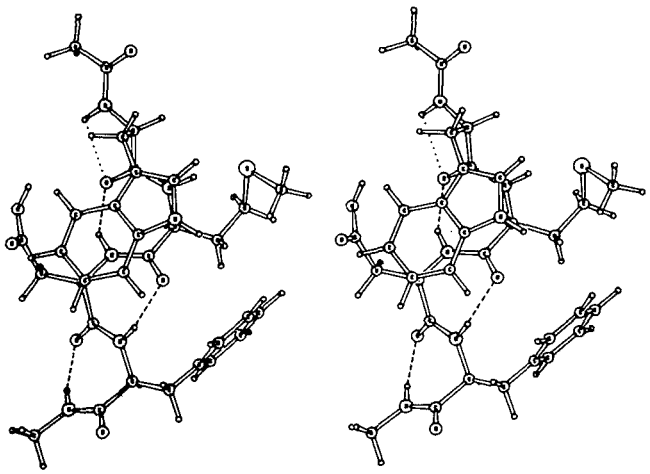

FIG. 5. Structure calculated for the gastrin tetrapeptide (CCK-4). Adapted from ref. 41.

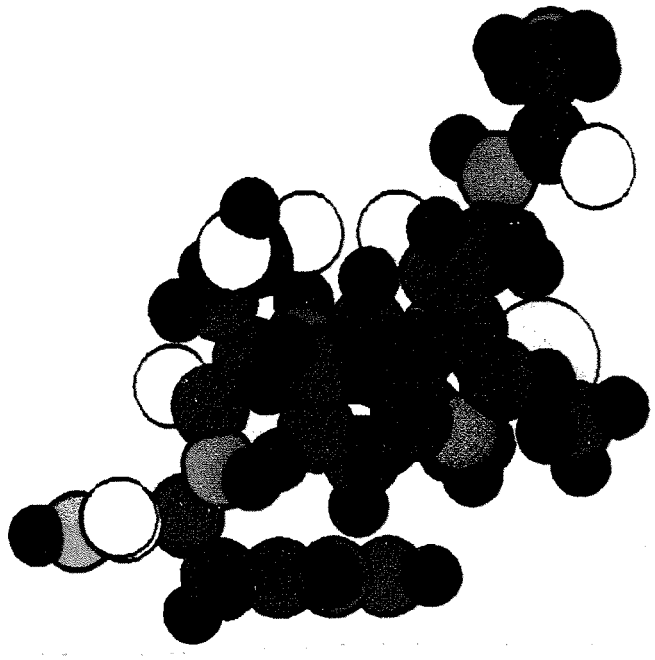

FIG. 6. Space-filling view of GLMAP3.

The finding that edge-to-face aromatic–aromatic and aromatic–sulfur interactions are present in GLMAP3 is of interest, because no specific parameterization of such effects is incorporated in ECEPP or MMPEP. We suggest that these interactions are dipole–dipole in nature and are, therefore, located by force fields in which the dipole–dipole term is properly taken into account.

Of the 10 other low energy GLMAP structures, only GLMAP41, which is 2.13 kcal/mol higher in energy than GLMAP3, is cyclic; in this structure, the terminal amide and the carboxyl group of Asp are on opposite sides of the molecule. In four of the structures, the terminal amide lies under one of the aromatic rings, or is buried within the molecule; in another three structures there is no aromatic–aromatic interaction. In GLMAP43 (Fig. 7), which is 2.8 kcal/mol higher in energy

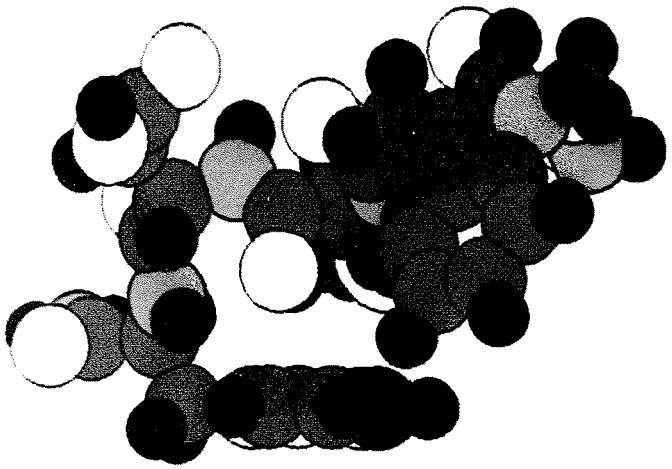

FIG. 7. Space-filling view of GLMAP43.

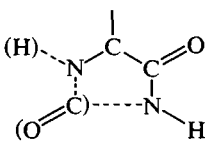
than GLMAP3, there is a phenyl–S interaction, but the hydrophobic wall is absent, and the terminal amide is rotated from its orientation in the lowest energy structure.

GDMAP

Table 4 lists the MMPEP energies of 50 structures located following a single search of 200,000 initial structures, in the usual manner. One of these structures, GDMAP39, is strongly preferred, and is shown in Fig. 8. Seven other structures are about 3 kcal/mol higher in energy and, in each of these seven structures, the terminal amide is buried within the interior of the molecule.

A comparison of Fig. 8 with Fig. 6 reveals numerous similarities in the structures of GDMAP39 and GLMAP3. Thus, in GDMAP39: (*i*) the structure is not cyclic; (*ii*) there is a perpendicular stacking of the two aromatic rings; (*iii*) the aromatic–aromatic interaction creates a hydrophobic wall around two sides of the molecule, but the sulfur atom is more exposed on one of these sides than in GLMAP3; (*iv*) the terminal amide bond and the side chain of Asp are jointly accessible to a potential receptor, on one side of the molecule.

The most significant difference between the two structures is observed in the relative orientations of the terminal amide moieties, which differ by ca. 180°. The difference is seen more clearly in Figs. 9 and 10, which show, respectively, the C-termini of GDMAP39 and GLMAP3 and their relationship to **4**, the active region of 5,5-diphenylhydantoin (32). If



4

GDMAP39 and GLMAP3 were biologically significant conformations of the epimeric CCKs it is evident that only the *less active* epimer resembles DPH. This would imply that the mechanisms of the anticonvulsant activities of CCK-5 and DPH are not the same. We plan to check this point experimentally in our biomimetic model of DPH activity (42).

GGMAP

For GLMAP, the random number search covered 2%, and

for GDMAP, 1% of the total (ϕ, ψ, χ_1) space. An analogous structure is found in each case, and there is a significant energetic preference for this structure. Much more work would be needed to support a claim that the magnitudes of such energetic preferences signal the presence of *global* minima. In any event, we have no information concerning the nature of the anticonvulsant receptor for CCK, and it is, therefore, not established that GLMAP3 and GDMAP39 are biologically relevant.

Table 5 lists the MMPEP energies of 50 GGMAP structures located following a search of 200,000 initial structures. This represents 2% of the total space. In contrast to GLMAP and GGMAP, 12 structures are within 1.5 kcal/mol of the lowest energy structure, GGMAP1. This may reflect a failure to locate a global minimum or, more significantly, the consequences of the removal of the stabilizing Ar...Ar interaction, and the conformational flexibility introduced with the Gly-Gly unit.

The structure that corresponds most closely to GLMAP3, in the relationships of the terminal amide and the side chain of Asp to the single aromatic ring, is GGMAP20, shown in Fig. 11.

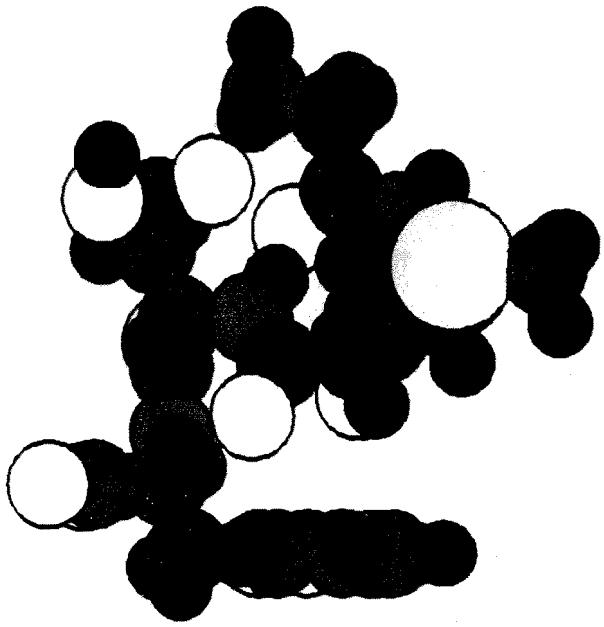

FIG. 14. Space-filling view of GGMAP49.

This is 1.51 kcal/mol higher in energy than GGMAP1, shown in Fig. 12. In GGMAP20, the N-terminus is superimposable on that of GLMAP3, but one of the hydrophobic walls has been replaced by a series of heteroatoms. In GGMAP1, the terminal amide and the side chain of Asp are on opposite sides of the molecule. Other structures of interest are GGMAP10 (Fig. 13) and GGMAP49 (Fig. 14), which resemble GGMAP20 in the N-terminal region, but are cyclic.

Table 6 summarizes the dihedral angles of GLMAP3, GDMAP39, and GGMAP20.

Concluding remarks

The principal objective of this work was the development of a protocol that could be applied generally to the theoretical conformational analysis of peptides, and be accessible through the use of the well-documented programmes ECEPP and MMP2(85). A first requirement, the parameterization of MMP2(85) for peptides (MMPEP), has been published, along with a description of the expansion of the dimensions of the programme (1). A new, energy-based, subroutine, INIT, which searches 200,000 initial structures, has been written and incorporated into ECEPP. Programmes to decode the results of INIT and to create an input file for MMP2(85) have also been written for the IBM-VS operating system. These are described in the appendices; their FORTRAN source codes will be made available upon request.

In the course of the establishment of the INIT variables, we have found that the MMPEP parameterization of MMP2(85) is valid not only to reproduce the geometries of crystal structures, but also to achieve proper ordering of energy differences. The use of the dielectric constant ε = 78.5 D appears to be appropriate. With this choice, the entire strategy becomes fixed, except for the selection of a seed value for the random number generator of INIT.

It is not yet clear how many searches of 200,000 structures should be performed in any given case, although there is a suggestion, in the results obtained with GLMAP and GDMAP, that a strong energetic preference for one structure is meaningful. For each of the examples presented here, the entire protocol, leading to 50 MMPEP structures, can be carried out in less than 1 day. In the case of the 28-residue atrial natriuretic factor, cardionatrin (43), an INIT search of 40,000 structures required 6 h, and the subsequent ECEPP + MMPEP minimization of the 10 structures identified in this search required 2–3 h in each case.[4]

As noted during the presentation of the CCK results, the conclusions that can be reached from theoretical calculations are permissive, if not compelling. Ideally, calculations should be performed not only on a biologically active peptide, and its receptor (if known), but on the complex formed between them. Our first attempt in this direction is described elsewhere (45).

Since the subject of active site conformational analysis of receptors is still in a primitive state (46), it seems that the proper place for the type of work presented here will continue to be in biomimetic design (42), or as part of a multidisciplinary approach, which includes the synthesis and biological evaluation of conformationally constrained analogs and simpler structures suggested by theory.

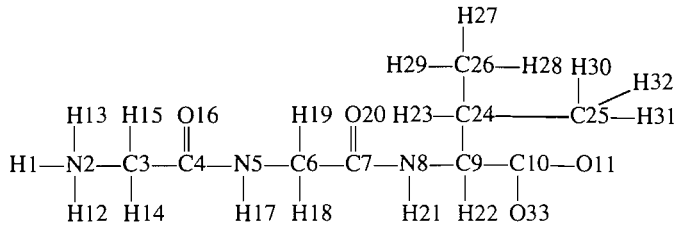
Appendix 1

Conversion of ECEPP output into an MMP2(85) input file

The conversion by hand of the Cartesian coordinates generated in an ECEPP calculation to an acceptable input file for MMP2(85) is a tedious, error-prone task. The method introduced here creates the file from an ECEPP calculation as part of its output.

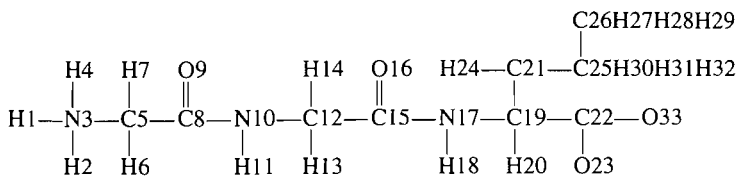
An MMP2(85) input file requires the specification of lists of connected and attached atoms, and the Cartesian coordinates of all of the atoms. Structure **5** illustrates a numbering scheme that might be employed for the zwitterionic tripeptide Gly-Gly-Val by following the instructions in the MMP2(85) manual. However, the ECEPP Cartesian coordinates are listed in a standard peptide format, with each residue presented consecutively.



5

Accordingly, a standard reference set of amino acid residues was constructed, which contained connected and attached atom lists for each amino acid and the various end groups normally encountered in ECEPP. This reference set contained relative numbering schemes for each group or residue, based on the ECEPP numbering scheme.

The sequence of amino acids, together with the two end groups, is processed by a table look-up method. This entails the concatenation of the relative connected and attached atom lists, from a knowledge of the total number of atoms in any group. The numbers of the next group are then offset accordingly. Structure **6** shows the numbering scheme that results for Gly-Gly-Val.



6

Appendix 2

Random number generation of initial structures (47, 48)

It is required to generate a set of "l" matrices

$$\mathbf{A}_p \in \mathbf{S}^{j\times 3} = \begin{vmatrix} a^p_{11} & a^p_{12} & a^p_{13} \\ a^p_{21} & a^p_{22} & a^p_{23} \\ \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot \\ a^p_{j1} & a^p_{j2} & a^p_{j3} \end{vmatrix}$$

where

$$p \in [1, \ldots, l], \quad j \in [1, \ldots, 30], \quad a_{ji} \in I^1$$

(the set of integers)

such that the distribution function $f_{\mathbf{A}_p}(a^p_{11}, a^p_{12}, \ldots, a^p_{j3})$ is jointly uniform, and

$$E\{\mathbf{A}_p\mathbf{A}_q^{\mathrm{T}}\} = \mathbf{B} \text{ (a matrix of constants)}, \quad \text{for all } p = q$$
$$= \mathbf{0} \text{ (null matrix)}, \quad \text{otherwise}$$

An intuitive rationalization of the above is to consider the $a^p_{11}, a^p_{12}, \ldots, a^p_{j3}$ ($3j$ elements) as the coordinates of the pth point in the $3j$ dimensional space $\mathbf{S}^{j\times 3}$. The "l" points should then be distributed uniformly over the space, in a random manner.

In practice, realization of the above protocol becomes, at best, forbiddingly abstruse. A less computationally demanding approach involves use of three sequential generators to obtain the values of the corresponding three columns of the $\mathbf{A}_p$ matrix, and thereby allow the desired joint distribution and sequential correlation characteristics.

For the practical implementation under consideration here, the maximum value of "l" was set at 200,000, and required the generation of up to 1.8×10^7 random variates in total.

Mixed congruential recursive generation techniques allow a pseudorandom variate to be produced from a preceding variate, with as little as one (floating point) multiplication and addition. The statistical characteristics of such generators are well documented (49–51), and are normally represented as

$$z_{i+1} = [az_i + c] \bmod m$$

where $z_1 \in [0, \ldots, m]$, and m, a, and c are integer constants. Extensive empirical studies (49) have led to the determination of strategies for the selection of a, c, and m to obtain desirable statistical properties, such as minimum serial correlation, and uniformity of distribution. The mod m arithmetic is performed automatically by most finite length computers. In the case of a 32-bit word computer (IBM), m becomes $2^{31} - 1$.

The main drawback to the application of a mixed congruential generation method to the required application is the phenomenon of clustering of successive sets of k points in the sequence on planes in k-dimensional space.

Once each $\mathbf{A}_p$ matrix has been generated, it is used to represent part of the geometry of the molecule. This information is optimally encoded, and stored in five 32-bit integers; the energy of this structure is stored via a 32-bit real variable.

For personal use only.

Up to 40,000 randomly generated geometries and their energies are stored in this manner, with a requirement of less than 1 megabyte, and are then sorted to find the geometries that correspond to the 10 lowest energies. To obtain a relatively short ordered list, it is known (44, 52) that the average number of comparisons for an Insertion type sort is the smallest of the generally available methods (including a Quick sort). Therefore, to locate the 10 lowest energies from a list of 40,000, an Insertion type sorting technique, which uses a binary search rather than a linear search, was implemented. Once these 10 lowest energies are obtained, the 50 corresponding integers are decoded to generate 10 starting geometries for minimization.

MMPEN: Development and evaluation of penicillin parameters for Allinger's MMP2(85) programme

SAUL WOLFE,[1] MAGED KHALIL, AND DONALD FREDRIC WEAVER
Department of Chemistry, Queen's University, Kingston, Ont., Canada K7L 3N6
Received September 22, 1987[2]

SAUL WOLFE, MAGED KHALIL, and DONALD FREDRIC WEAVER. Can. J. Chem. **66**, 2715 (1988).

A set of parameters, termed MMPEN, has been determined for the bicyclic nucleus of penicillin, which, in conjunction with the appropriate parameters from MMPEP and the internally stored parameters of the program, allow Allinger's force field and MMP2(85) program to be applied to the molecular mechanics treatment of penicillins. The MMPEN parameters are based on crystallographic heavy atom bond lengths and bond angles, vibrational spectra, and molecular orbital calculations. The parameters reproduce the experimental crystal structures of several penicillins, including penicillin G and penicillin V, with an average deviation of 0.005 Å in bond lengths, 0.5° in bond angles, and 3° in dihedral angles. Conformational analyses of penicillin G and penicillin V, for a dielectric constant $\epsilon = 78.5$ D, suggest that neither penicillin retains the crystal structure in solution. In both cases, the global minima have the C3-carboxyl group antiperiplanar to the 2β-methyl group in the thiazolidine ring, and the side chains are oriented so that the amide N-H occupies the convex face of the molecule. The predicted conformations of the methyl esters of penicillin G and bisnorpenicillin G, for a dielectric constant of 4.8 D, are consistent with the nuclear magnetic resonance spectra obtained for these compounds in chloroform solvent.

SAUL WOLFE, MAGED KHALIL et DONALD FREDRIC WEAVER. Can. J. Chem. **66**, 2715 (1988).

On a déterminé un ensemble de paramètres, apelés MMPEN, pour le noyau bicyclique de la pénicilline qui, utilisés de concert avec les paramètres appropriés de MMPEP ainsi que les paramètres emmagasinés d'une façon interne, permettent d'appliquer le champ de force d'Allinger et le programme MMP2(85) à l'étude des pénicillines par mécanique moléculaire. Les paramètres MMPEN sont basés sur des longueurs et des angles de liaisons d'atomes lourds, sur des spectres de vibration ainsi que sur des calculs d'orbitales molèculaires. Les paramètres reproduisent les structures cristallines expérimentales de plusieurs pénicillines, y compris les pénicillines G et V, avec une déviation moyenne de 0,005 Å pour les longueurs des liaisons, de 0,5° pour les angles de liaison et de 3° pour les angles dièdres. Des analyses conformationnelles sur les pénicillines G et V, pour une constante diélectrique $\epsilon = 78,5$ D, suggèrent que ni l'une ni l'autre des pénicillines ne retient sa structure cristalline en solution. Dans chacun des cas, les valeurs minimales d'une façon globale correspondent à des structures comportant un groupement carboxyle en C3 qui est antipériplanaire par rapport au groupement méthyle en 2β du noyau thiazolidine et des chaînes latérales qui sont orientées d'une façon telle que le N-H de l'amide occupe la face convexe de la molécule. Les conformations prévues pour les esters méthyles de la pénicilline G et de la bisnorpénicilline G, pour une constant diélectrique $\epsilon = 4,8$ D, sont en accord avec les spectres en résonance magnétique nucléaire obtenus pour des solutions chloroformiques de ces composés.

Introduction

We have recently described MMPEP, a set of all-atom peptide parameters for use with Allinger's versatile and well-documented MMP2(85) programme (1, 2). Using MMPEP, the structures obtained following minimization are in excellent agreement with experimental crystal structures of peptides, when the Cartesian coordinates of these X-ray structures are supplied as input. More importantly, in conjunction with protocols for secondary structure prediction (3), and (or) the use of Scheraga's ECEPP (Empirical Conformation Energy Program for Peptides) (4) for a preliminary mapping of large portions of the conformational hypersurface, MMPEP leads to "global minima" compatible with experiment in a number of cases (5), as well as other low energy structures. Conformations lower in energy than the crystal structures can also be found, and reasons for their computational existence identified.

Penicillins and cephalosporins are formed biosynthetically by oxidative transformations of a peptide precursor (6). The peptide origin of these antibiotics suggested that parameters to describe the fused thiazolidine– and dihydrothiazine–azetidinone ring systems, together with the appropriate parameters from MMPEP, would allow MMP2(85) to be applied to the conformational analysis of these antibiotics. The present work is concerned with the development and evaluation of MMPEN, an all-atom parameterization of MMP2(85) for penicillins.

TABLE 1. Atom types used in MMPEN[a]

Element	Atom	Type	Number
C	C_{sp^3}	C2, C3 of penam nucleus	16
C	C_{sp^3}	C6 of penam nucleus	20
C	C_{sp^3}	C5 of penam nucleus	22
C	C_{sp^2}	C7 of penam nucleus	31
N		β-lactam nitrogen	32
O		β-lactam oxygen	28
O[b]		OH of CO_2H	29
O[c]		Oxygen of CO_2^-	30
S		Sulfur	15

[a]This list supplements those used in MMP2(85) and MMPEP.
[b]Same as atom type 12 of MMPEP.
[c]Same as atom type 11 of MMPEP.

Penicillins (**1**) contain a fused β-lactam–thiazolidine nucleus, and an acylamino side chain. The nucleus, 6-aminopenicillanic acid (6-APA, **2**), originates from the amino acids L-cysteine and D-valine. The thiazolidine ring of 6-APA, and of penicillins generally, is flexible. It can exist in two principal conformations, **3***a* and **3***b*, that are interconvertible via the pseudorotation associated with S1—C2—C3—N4 torsion, which causes the C2-methyl substituents and the C3-carboxyl

group to move synchronously. In **3***a*, the 2β and 3α substituents are pseudoaxial (7) in the five-membered ring, and C3 is out of the plane of an envelope conformation (8); in **3***b*, these substituents are pseudoequatorial (7), and sulfur is out of the plane of the envelope conformation (8). Both types of conformation have been encountered crystallographically (for reviews, see refs. 9 and 10), but only the pseudoequatorial conformation is observed in aqueous solution at pH 4.0–4.6, in the presence of the lanthanides La^{III}, Pr^{III}, Eu^{III}, and Gd^{III} (11). Since these lanthanides are thought to bind to the C3-carboxyl group (12), it is not clear whether the conclusions of ref. 11 also apply to the uncomplexed antibiotics (13). Further, although the different conformations observed in the solid state have been implicated in structure–activity studies (9, 10), it is noteworthy that the potassium salt of penicillin G crystallizes in the pseudoaxial conformation **3***a*, but the procaine salt of this penicillin crystallizes in the pseudoequatorial conformation **3***b* (14).

The force field (15, 16)

Atom types

Taking the view that penicillins are modified peptides, MMPEN incorporates several of the atom types of MMPEP. However, the description of the bicyclic nucleus is based on a unique set. These are indicated in **4**, and are summarized in Table 1.

Bond lengths

The required standard bond lengths were obtained from crystallographic data (7, 8, 17–24), as the average of four representative pseudoaxial (17–19, 22) and four representative pseudoequatorial (8, 20, 21, 23) structures (Table 2). The X—H bond lengths were taken from MMPEP.

Stretching force constants for the thiazolidine ring and 2-azetidinone were taken from experimental infrared (25) and Raman data (26). The complete list of bond length parameters is collected in Table 3.

Bond angles

Crystallographic data for eight representative penicillins were again used to obtain heavy atom bond angles (Table 4) (8, 17–23). An angle of particular interest is C5—S1—C2, which correlates with the conformation of the thiazolidine ring. In a pseudoequatorial penicillin this angle is ca. 90°; in a pseudoax-

TABLE 3. Stretching parameters of MMPEN

Bond types		Force constant (mdyn/Å)	Bond length (Å)

28	31	8.65	1.210
31	32	4.79	1.380

ial penicillin, this angle is ca. 96°. MMPEN employs a value of 93°. As will be seen, this value allows the trends in the C5—S1—C2 angles to be reproduced.

The angles associated with the hydrogen atoms at C3, C5, and C6 were determined with the MMP2(85) programme (1), which has the ability to place a hydrogen on any atom, and to minimize the resulting structure.

Bending force constants were taken from refs. 25 and 26. Table 5 contains the complete list of bond angle parameters.

van der Waals parameters

The values of ϵ and r_e for the atom types of MMPEN have been taken from MMP2(85), and are collected in Table 6.

Electrostatic parameters

The MMP2(85) force field incorporates the electrostatic potential as a dipole–dipole term, expressed by Jeans' equation (eq. [1]).

$$[1] \quad E_{ES} = (\mu_i\mu_j/Dr_{ij}^3)\,(\cos\chi - 3\cos\alpha_i\cos\alpha_j)$$

In eq. [1], D is the effective dielectric constant, χ is the angle between the dipoles μ_i and μ_j, and α_i and α_j are the angles formed by the dipoles with the vector connecting them.

The bond moments required for the dipole–dipole term were obtained from the net atomic charges (Q_i) of STO-3G calculations (27) on thiazolidine and 2-azetidinone, using eq. [2]. In eq. [2], the units of Q_i and Q_j are electrons, l_0 is the length of the bond, and 2.385 is a scalar multiplier that converts the bond moment to debye units. The calculated atomic charges are collected in Table 7, and the bond moments of MMPEN are provided in Table 8.

$$[2] \quad \text{Bond moment} = 2.385 l_0\,(Q_i - Q_j)$$

Torsional parameters

These refer to the V_1, V_2, and V_3 terms of the Fourier expansion, eq. [3], in which ϕ is the A/D dihedral angle in a moiety A-B-C-D. When energy is calculated as a function of ϕ by both molecular orbital (MO) and molecular mechanics (MM) methods, E_ϕ can be estimated using eq. [4], where P_{MO} (ϕ) is

TABLE 9 (*concluded*)

[a]This torsional angle is part of a four-membered ring.

V_3 were identified by a least-squares fit, using the programme provided in the appendix of ref. 28.

For example, to obtain the parameters for torsion about S1—C5, calculations were performed on CH_3S–CH_2NH_2. Other appropriate model structures, corresponding to fragments of the penicillin nucleus, were treated analogously, and the resulting parameters were introduced into the force field.

An initial force field, which contained torsional parameters arrived at in this manner, did not give acceptable results when applied to penicillin G. Thus, for the C5—C6—C7—O8 dihedral angle, MMPEN yielded 154°, compared to 169° in the crystal structure. The discrepancy was traced to the highly constrained torsion that exists in a fused ring system, which causes the use of normal, unconstrained, torsional parameters to be inappropriate for the problem.

Since inspection of molecular models suggested that the maximum torsion about S1—C2—C3—N4 is ±60°, a second set of calculations for the fragments of the thiazolidine ring was performed, and was restricted to this range of dihedral angles. The resulting parameters, with additional minor modifications by trial and error (29), proved acceptable. Table 9 lists the torsional parameters of MMPEN.

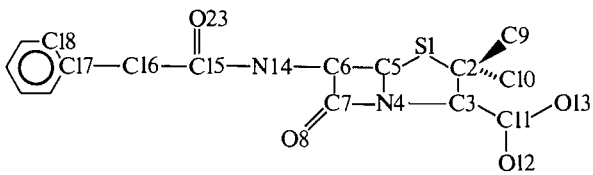
[a]See **5** for numbering.

Minimization

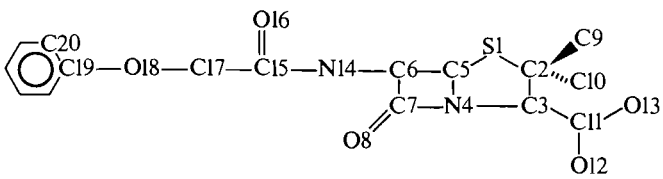
The block-diagonal Newton–Raphson procedure, which is standard in MMP2(85), leads reliably to the minimum of the potential well that contains the initial structure. However, when this geometry is far from the minimum of the well, convergence of the Newton–Raphson procedure can be slow and unreliable (30).

Testing the MMPEN parameters

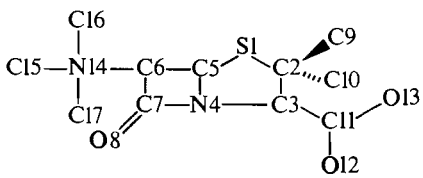
Calculations were performed on the anions of penicillin G (**5**) and penicillin V (**6**), on the zwitterion **7**, and on the ester **8**. The heavy atom Cartesian coordinates of the crystal structures of potassium penicillin G (18), penicillin V (17), **7** (31), and **8** (32) were supplied as input, hydrogen atoms were added as necessary (1), and one-point energies were computed, followed by minimization, using a dielectric constant of 78.5. In each case, minimization proceeded rapidly, and was achieved within 25 iterations. Since each of **5** – **8** crystallizes in the pseudoaxial conformation, and minimization with MMPEN did not change the initial conformation of the thiazolidine ring, C5—S1—C2 bond angles of 96° resulted in each case. Tables 10–13 contain comparisons of the crystallographic and calculated dihedral angles, after minimization.



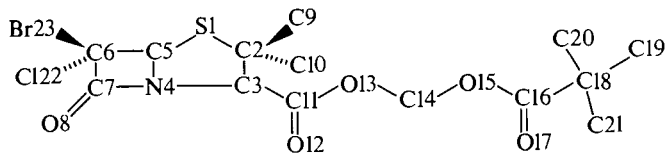
5



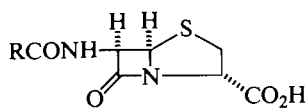
6



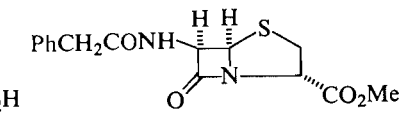
7



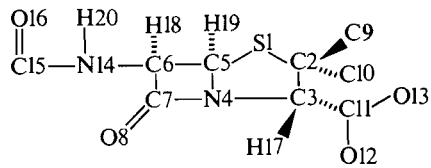
8



9



10



11

For the more than 300 dihedral angles compared in Tables 10–13, the average deviation between the calculated and experimental values is less than 3°. Only the angles associated with the carboxyl group of penicillin V and the β-lactam carbonyl oxygen atom of **7** show significant deviation. In the latter case, this deviation can be traced to an unusually short C=O bond length of 1.15 Å in the crystal structure, compared to the calculated value of 1.21 Å. This longer C=O bond length is observed experimentally in penicillin G, penicillin V, and **8**.

It can be concluded that the MMPEN parameterization is

appropriate for the molecular mechanics treatment of penam compounds.[3]

Conformational analysis of penicillin G

Figure 1 shows a stereoscopic view (along the N4—C5 bond) of penicillin G in the calculated conformation of the crystal structure. Three aspects of this structure are of particular interest: (*i*) the carboxylate anion and the 2β-methyl group are antiperiplanar in the thiazolidine ring, illustrative of the pseudoaxial conformation; (*ii*) the carbonyl oxygen of the side chain is directed towards the convex face of the molecule; (*iii*) the aromatic ring is directed towards the concave face of the bicyclic ring system, leading to a compact structure.

Figure 2 shows, in more detail, the relationship between the aromatic ring and the sulfur atom. In this figure, the view is from the C5—S1—C2 plane to the benzene ring, and it can be seen that the *p*-type nonbonding orbital of sulfur is directed approximately perpendicular to C17, the ipso carbon atom. This kind of orientation is characteristic of the aromatic–S interaction found in the crystal structures of globular proteins (33), in which the sulfur atoms of cyst(e)ine and methionine residues express an affinity for the edges of aromatic rings.

The conformational analysis of penicillin G proceeded in three stages. In the first, the acylamino side chain was optimized by successive dihedral drives along C6—N14, C15—C16, and C16—C17; these were performed in 20° increments from +180° to −180°, and in each case the lowest energy structure was minimized fully before proceeding to the next dihedral angle. Although two complete cycles were performed, the second did not lead to a lower energy structure. In the second stage of the conformational analysis, the thiazolidine ring was inverted from the pseudoaxial to the pseudoequatorial conformation; this was done by driving the S1—C2—C3—N4 dihedral angle in increments from its optimized value (ca. −36°) to −0.1°, manually changing the Cartesian coordinates of these four atoms to obtain a positive dihedral angle, and then proceeding with the dihedral drive. The lowest energy pseudoequatorial structure was then minimized fully. In the final stage of the conformational analysis the acylamino side chain of the pseudoequatorial structure was reoptimized, by successive dihedral drives, as before.

The optimization of the acylamino side chain led to a structure, displayed in Fig. 3, which is calculated to be

[3]Referees have questioned the need to create a unique set of parameters for the bicyclic nucleus of penicillin, and argue that this detracts from the utility of the molecular mechanics approach. Our view is that, for the method to be credible, *every* class of compound examined with MMP2(85) must be described in a manner compatible with all available experimental and (or) theoretical data for that compound. In the present case, it seemed obvious that the β-lactam ring is a unique entity; it was also clear, from our examination of the crystal structures of penicillins, that the bond lengths and bond angles associated with the sulfur atom are conformation-dependent, and require special treatment. The need for caution in the uncritical use of asterisked (i.e., not fully determined) parameters of MMP2(85) and its predecessors has been emphasized repeatedly by Allinger; these programmes will also run with unknown torsional parameters set at $V_1 = V_2 = V_3 = 0$. It is not clear to us how such restrictions can be compatible with claims that quantitative conformational analyses are being performed. To illustrate these points, we attempted to perform calculations on penicillin G, using the parameters of MMPEP, and also the parameters of MMP2(85). The MMPEP parameters led to 27 error messages; the MMP2(85) parameters led to 31 error messages, corresponding to structural features of this compound that are unknown in these force fields. One of the aspects of the modified and expanded version of MMP2(85) described in ref. 2 is an ability to release all internal parameters, and replace these by an external file for the molecule of interest. We will provide the required source code to all authorized users of MMP2(85). There is no doubt that reliable, fully documented parameters are central to the application of molecular mechanics to quantitative conformational analysis. Accordingly, in subsequent papers we plan to describe novel strategies for the relatively rapid establishment of parameters.

3.10 kcal/mol *lower* in energy than the crystal structure. This is the global minimum of penicillin G for a dielectric constant of 78.5. The fully optimized pseudoequatorial structure, shown in Fig. 4, is 1.93 kcal/mol *higher* in energy than the global minimum.

In the pseudoequatorial structure (Fig. 4) the C5—S1—C2 angle is calculated to be 93°, significantly smaller than the corresponding angle in the pseudoaxial structure (96°). This trend is consistent with experiment, and offers additional support for the validity of the MMPEN parameters.

The orientation of the side chain of the global minimum differs significantly from that in the crystal structure. Although the aromatic ring is still folded under the bicyclic ring system, retaining the compact shape of the molecule, and an aromatic–S interaction is still present (Fig. 5), the *amide hydrogen* of the acylamino side chain now resides on the convex face of the molecule. We note that, in the crystal structure, the H6—O23 distance is 2.40 Å, significantly less than the sum of the van der Waals radii of these two atoms (3.4 Å).

The conformational analysis of penicillin G, if correct, is of some importance in relation to the significance of structure –activity studies based on crystallographic data (9, 10, 34). It

was, therefore, desirable to compare results obtained theoretically using MMPEN to the results of experimental measurements in solution.

Experimental tests of the MMPEN strategy for conformational analysis. The methyl esters of penicillin G and bisnorpenicillin G

Osborne has described an efficient sequence for the conversion of a penicillin into its bisnor derivative **9** (35). In such compounds the conformation of the thiazolidine ring can be determined from measurements of the vicinal H2–H3 coupling constants. In addition, in chloroform solvent, the orientation of the side chain can be probed by determination of the H-N-C6-H coupling constant, and by nOe measurements. Accordingly, **10**, the methyl ester of bisnorpenicillin G was synthesized,[4]

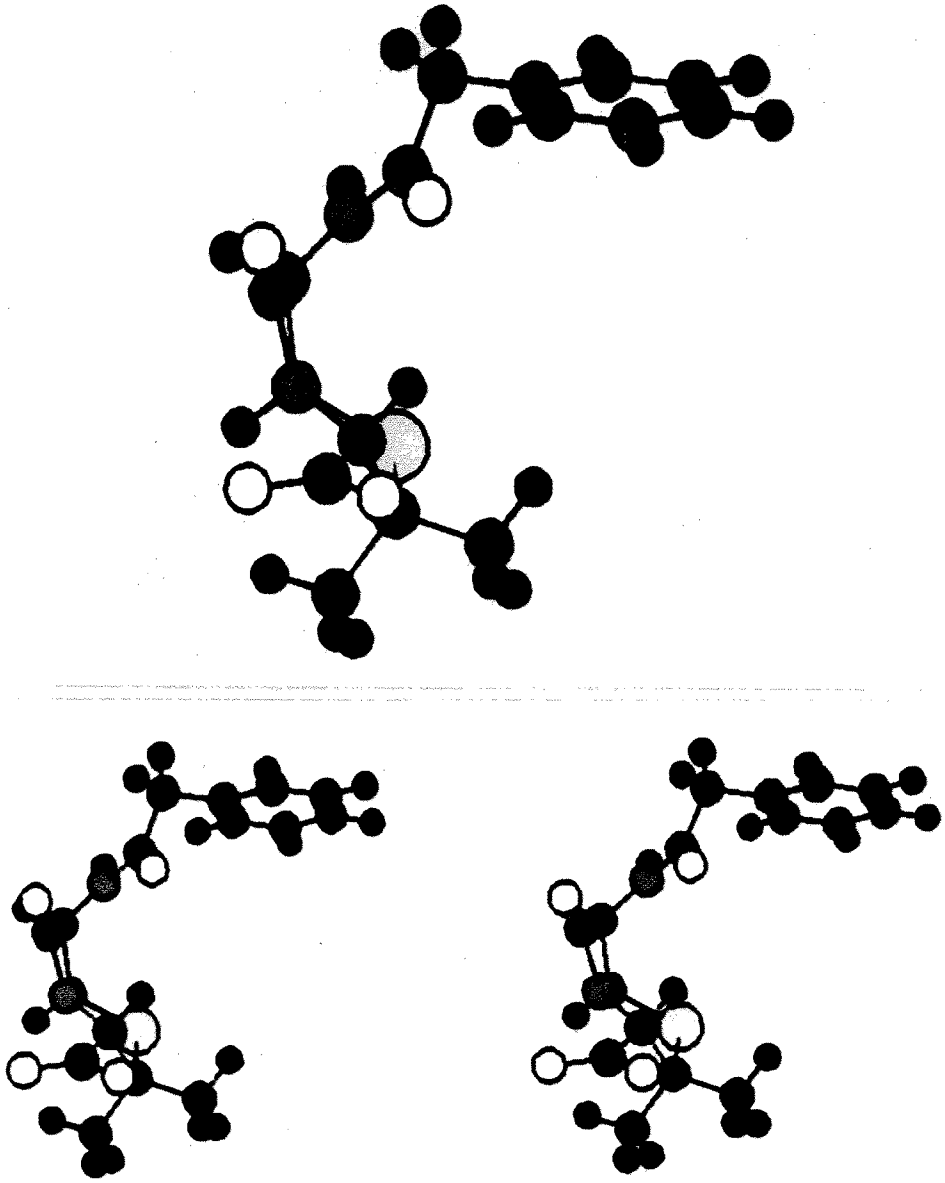

FIG. 4. Calculated pseudoequatorial conformation of penicillin G.

and its 400 MHz ^{1}Hmr spectrum was measured in chloroform. Concurrently, a conformational analysis of methyl bisnorbenzylpenicillanate was undertaken, using MMPEN, with a dielectric constant of 4.8, corresponding to chloroform solvent.

The theoretical conformational analysis began with the coordinates of the global minimum of penicillin G, with deletion of the C2-methyl groups and their replacement by hydrogens, and the attachment of a methyl group to the carboxyl. The pseudoaxial and pseudoequatorial conformations were then optimized, as already described. Figure 6 shows the optimized pseudoaxial structure; the optimized pseudoequatorial structure is shown in Fig. 7. The two structures have the same energy.

Table 14 compares the calculated H2β—C2—C3—H3, H2α—C2—C3—H3, and H—N—C6—H6 dihedral angles of the pseudoaxial and pseudoequatorial conformations to the experimentally determined vicinal coupling constants. The observed H2–H3 coupling constants are consistent only with a pseudoequatorial conformation of the thiazolidine ring. This is compatible with the calculations. The H-N-C-H coupling

TABLE 14. Calculated dihedral angles and observed vicinal coupling constants[a] in methyl bisnorbenzylpenicillanate

Dihedral angle	Value (deg)		Coupling constant (Hz)

constant is consistent either with an *endo* N-H, as in the crystal structure of penicillin G, or with an *exo* N-H, as in Fig. 7. As can be seen from Fig. 7, an *endo* N-H should exhibit a nuclear Overhauser effect with H3, if the thiazolidine ring has the pseudoequatorial conformation. This nOe was not observed.

In a second test of the computational strategy, the methyl ester of penicillin G was calculated for a dielectric constant of 4.8, and the pseudoaxial conformation, shown in Fig. 8, was found to be 2.2 kcal/mol lower in energy than the pseudoequatorial conformation (not shown). The observed H-N–C-H coupling constant, in chloroform-*d* solvent, is 7.5 Hz, and is again consistent with either an N-H *endo* or an N-H *exo* conformation. No nOe is observed[5] between H5 and the methyl hydrogens, or between N-H and the methyl hydrogens. The absence of an nOe between H5 and methyl hydrogens has been taken as evidence for a pseudoaxial conformation in CCl_4 solvent in the case of the methyl ester of penicillin V (36). The absence of an nOe between N-H and methyl hydrogens is consistent with the structure shown in Fig. 8.

Conformational analysis of penicillin V

Figure 9 shows the crystal structure of penicillin V, and Fig. 10 displays the relationship between the aromatic ring and the sulfur atom in this crystal structure. Several points may be noted: (*i*) the thiazolidine ring has a pseudoaxial conformation; (*ii*) the amide bond of the side chain is orientated as in the crystal structure of penicillin G, with the carbonyl oxygen directed towards the convex face of the molecule; (*iii*) the aromatic–S interaction is absent. In the case of (*iii*), it is observed in Figs. 7

[5]The authors thank Professors B.K. Hunter and B.M. Pinto for these nOe measurements, details of which will be published elsewhere.

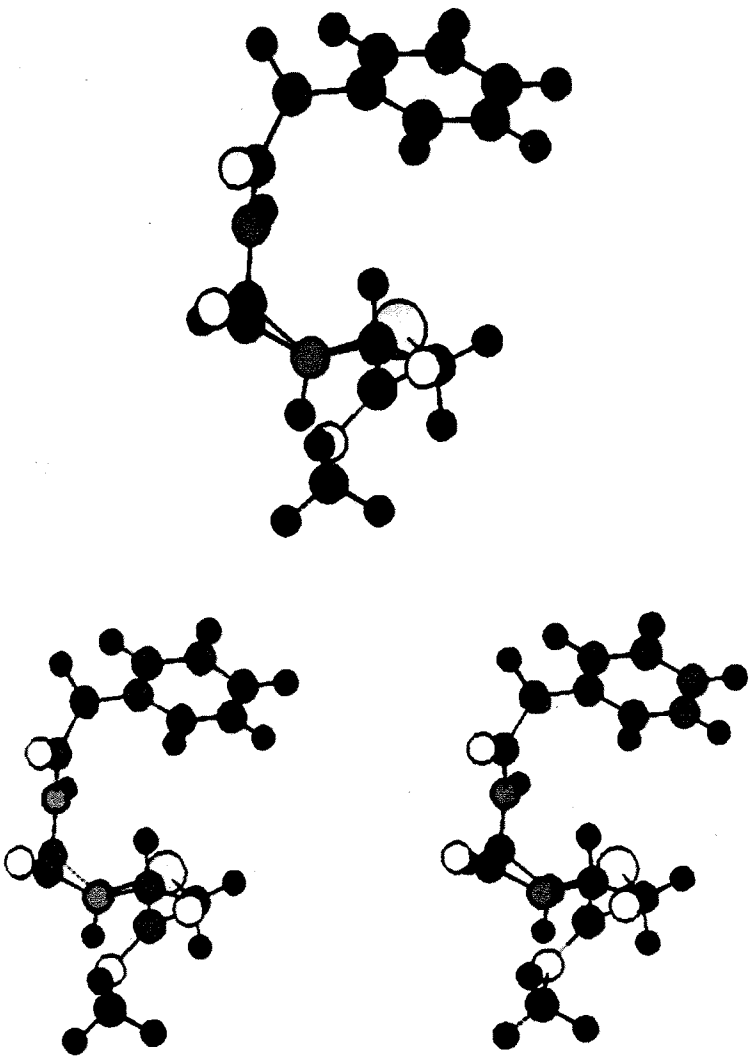

FIG. 7. Pseudoequatorial conformation of **10**.

and 8 of ref. 17 that crystal packing of penicillin V emphasizes *inter*molecular aromatic–aromatic interactions, rather than an intramolecular aromatic–*S* interaction.

The conformational analysis of penicillin V was performed as described for penicillin G, and led to a pseudoequatorial structure 2.52 kcal/mol lower in energy than the crystal structure, with a C5—S1—C2 angle of 93°, and a pseudoaxial structure 4.22 kcal/mol lower in energy than the crystal structure. This latter structure is shown as Fig. 11, and its aromatic–S interaction is seen in Fig. 12.

The calculated global minimum of penicillin V, like that of penicillin G, is compact, because of the enforcement of the aromatic–S interaction in solution, and the orientation of the side-chain amide bond is again opposite to that observed in the crystal structure. The amide oxygen is found on the concave face of the molecule, and the amide nitrogen is on the convex face.

The implications of these findings concerning the side chains of penicillins are extended and examined in more detail in the accompanying paper (37).

Conformational analysis of the penam derivatives 7 and 8

Figure 13 shows the pseudoaxial (crystal) structure of the zwitterion **7** and Fig. 14 displays the calculated pseudoequatorial structure of this compound. The pseudoaxial structure is 1.80 kcal/mol more stable.

Figures 15 and 16 refer to the pseudoaxial and pseudoequatorial structures of the ester **8**, respectively. In this case, the pseudoequatorial conformation is lower in energy, by 1.53 kcal/mol.

Summary and concluding remarks

A major incentive for this work has been the desire to have a convenient, accessible, and reproducible procedure for the theoretical conformational analysis of penicillins. Allinger's force field is well established, and versions of the MM2 programme are available for many types of computers. Thus, it seemed reasonable to believe that a standardized molecular mechanics approach to penicillins, based on MM2, could be devised, whose results would be as reproducible as the description of a synthesis or the report of an *ab initio* calculation

with a standard basis set. The MMPEN parameterization reported herein is a first step towards this objective. To facilitate the use of MMPEN, Tables 15 and 16 contain Cartesian coordinates of the pseudoaxial and pseudoequatorial conformations of **11**.

There have been many previous theoretical studies on β-lactam compounds, including penicillins (38). Since the antibacterial activities of β-lactam compounds are known to be the result of acylation of the active site serines of a group of serine proteases (39), the majority of the molecular orbital

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/07/12
For personal use only.

calculations have focused on properties of azetidinone rings, including the charge distribution in the N—CO region, and the pyramidality of the nitrogen atom.

It is not surprising that β-lactam antibiotics do not exhibit unusual reactivities or hydrolysis mechanisms (40). The antibacterial activity of a penicillin must depend not only on the intrinsic chemical reactivity of its β-lactam ring, but on the ability of the compound to reach its site of action and bind to it. This binding involves the action of the entire molecule, and not just that portion that undergoes the chemical change. With this view, an ability to treat the conformation of the entire molecule may be useful.

Studies towards this goal have been initiated by Rao (38), and by Cohen (10). Rao's approach is based on a first generation molecular mechanics strategy. A hard sphere model is employed, methyl groups are treated as united atoms, and a single threefold torsional term is used. Side chains are minimized, but with the amide bond oriented as in the crystal structure of penicillin G. Cohen focuses on the pseudoaxial–pseudoequatorial relationship, using a combination of crystal structures and the molecular modelling system SCRIPT (41). Side chains are not considered.

Although the conclusions reached by Rao and by Cohen may be valid, we do not know how to reproduce their results, because of the limited documentation of the procedures used. This lack of documentation obviously inhibits the ability of other groups to contribute to these problems. We hope that this apparent absence of (published) activity can be overcome by the development and publication of MMPEN. Extensions of the MMPEN approach to other classes of β-lactam antibiotics are currently in progress.

Conformation–activity relationships and the mechanism of action of penicillin

SAUL WOLFE,[1] KIYULL YANG, AND MAGED KHALIL
Department of Chemistry, Queen's University, Kingston, Ont., Canada K7L 3N6
Received September 22, 1987[2]

SAUL WOLFE, KIYULL YANG, and MAGED KHALIL. Can. J. Chem. **66**, 2733 (1988).

Using the MMPEN parameters of Allinger's MMP2(85) force field, a conformational analysis has been performed on four biologically active penicillins: D-ampicillin, L-α-phenoxyethylpenicillin, penicillin G, and penicillin V, and on five biologically inactive or much less active penicillins: L-ampicillin, D-α-phenoxyethylpenicillin, *N*-methylpenicillin G, 6α-methylpenicillin G, and bisnorpenicillin G. Antibacterial activity is found to be associated with the existence of a global minimum having a compact structure, whose convex face is accessible to a penicillin binding protein (PBP), with the C3-carboxyl group and the side-chain N-H exposed on this face. Using the MMPEP parameters of MMP2(85), a conformational analysis has been performed on phenylacetyl-D-Ala-D-Ala-O^-, a peptide model of the normal substrate of a PBP. Labischinski's global minimum has been reproduced, along with structures that correspond to Tipper and Strominger's proposal that the N4—C7 bond of a penicillin corresponds to the Ala–Ala peptide bond, and to Hasan's proposal that the N4—C5 bond of penicillin corresponds to the peptide bond. For both models, conformations of the peptide related to the pseudoaxial and pseudoequatorial conformations of the thiazolidine ring of penicillin G have been examined. It is concluded that penicillin is not a structural analog of the global minimum of the peptide; however, comparisons based on unbound conformations of PBP substrates are unable to determine which model is more appropriate, or which conformation of penicillin G is the biologically significant one. Using the ECEPP/MMPEP strategy, a model of the active site of a PBP has been obtained, following a search of 200,000 structures of the peptide Ac-NH-Val-Gly-Ser-Val-Thr-Lys-NH-Me. This peptide contains the sequence at the active site of a PBP of *Streptomyces* R61, for which it is also known that the C3-carboxyl group of penicillin binds to the ε-amino group of lysine, and the β-lactam reacts chemically with the serine OH. The lysine and serine side chains and the C-terminal carbonyl group are found to occupy the concave face of the active site model.

A strategy for the docking of penicillins or peptides to this model, with full minimization of the conformational energies of the complexes, has been devised. All active penicillins bind through strong hydrogen bonds to the C3-carboxyl group and the side-chain N-H, and with a four-centered relationship between the O-H of serine and the (O)C-N of the β-lactam ring. The geometrical parameters of this relationship are reminiscent of those found in the *gas phase* transition state of *neutral* hydration of a carbonyl group. When the energies of formation and geometries of the pseudoaxial and pseudoequatorial penicillin G complexes are examined, there is now a clear preference for the binding of the *pseudoaxial* conformation, which is the global minimum of the uncomplexed penicillin in this case. A similar examination of the peptide complexes reveals that only the conformation of the peptide that corresponds to Tipper and Strominger's model, and is based on the pseudoaxial conformation of penicillin G, can form a complex with a geometry and energy comparable to those of a biologically active penicillin.

SAUL WOLFE, KIYULL YANG et MAGED KHALIL. Can. J. Chem. **66**, 2733 (1988).

Utilisant les paramètres MMPEN du champ de force MMP2(85) d'Allinger, on a effectué une analyse conformationnelle sur quatre pénicillines biologiquement actives (D-ampicilline, L-α-phénoxyéthylpénicilline, pénicilline G et pénicilline V) et sur cinq pénicillines inactives ou beaucoup moins actives (L-ampicilline, D-α-phénoxyéthylpénicilline, *N*-méthylpénicilline, méthyl-6α pénicilline G et bisnorpénicilline G). On a trouvé que l'activité antibactérienne est associée à l'existence d'un minimum global possédant une structure compacte, dont la face convexe est accessible à une protéine pouvant lier une pénicilline (PLP) et qui porte sur cette face un groupement carboxyle en C3 ainsi qu'une chaîne latérale du N-H qui est exposée. Utilisant les paramètres MMPEP du MMP2(85), on a effectué une analyse conformationnelle sur le phénacetyl-D-Ala-D-Ala-O^-, un peptide modèle du substrat normal d'une PLP. On a pu reproduire le minimum global de Labischinski ainsi que les structures qui correspondent à la proposition de Tipper et Strominger concernant le fait que la liaison N4—C7 d'une pénicilline correspond à la liaison Ala–Ala du peptide et à la proposition de Hasan à l'effet que la liaison N4—C5 de la pénicilline correspond à la liaison peptidique. Pour chaçun des modèles, on a examiné les conformations du peptide qui sont reliées aux conformations pseudo-axiale et pseudo-équatoriale du cycle thiazolidine de la pénicilline G. On en conclut que la pénicilline n'est pas un analogue de structure du minimum global du peptide; toutefois, des comparaisons basées sur les conformations qui ne sont pas liées de substrats de PLP ne permettent pas de déterminer quel modèle est le plus approprié ou quelle conformation de la pénicilline G est la plus importante d'un point de vue biologique. Utilisant la stratégie ECEPP/MMPEP et après avoir fait une recherche parmi 200,000 structures du peptide Ac-NH-Val-Gly-Ser-Val-Thr-Lys-NH-Me, on a obtenu un modèle du site actif d'une PLP. Ce peptide contient la séquence du site actif d'une PLP du *Streptomyces* R61 pour lequel on sait aussi que le groupement carboxyle en C3 de la pénicilline se lie au groupement ε-amino de la lysine et que le β-lactame réagit d'une façon chimique avec le OH de la sérine. On a trouvé que les chaînes latérales lysine et sérine ainsi que le groupement carbonyle du terminus-C occupent la face concave du modèle du site actif.

On a mis au point une stratégie d'arrimage des pénicillines ou des peptides à ce modèle; elle comporte une minimisation complète des énergies conformationnelles des complexes. Toutes les pénicillines actives forment des liaisons hydrogènes importantes avec le groupement carboxyle en C3 et avec la chaîne latérale du N-H et aussi, par une relation à quatre centres, entre le O-H de la sérine et le (O)C-N du cycle du β-lactame. Les paramètres géométriques de cette relation ressemblent à ceux qu'on retrouve dans l'état de transition en *phase qazeuse* de l'hydration *neutre* d'un groupement carbonyle. Lorsqu'on examine les énergies de formation et les géométries des complexes pseudo-axial et pseudo-équatorial de la pénicilline G, on observe

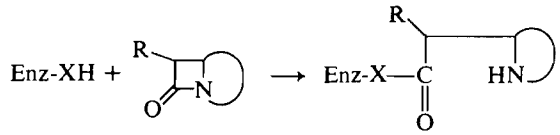
qu'il existe une préférence marquée pour une liaison de la conformation *pseudo-axiale* qui, dans ce cas, correspond au minimum global de la pénicilline qui n'est pas complexée. Un examen semblable des complexes du peptide révèle que seule la conformation du peptide qui correspond au modèle de Tipper et Strominger et qui est basée sur la conformation pseudo-axiale de la pénicilline G peut former un complexe avec une géométrie et une énergie qui se comparent à celles d'une pénicilline qui est active d'un point de vue biologique.

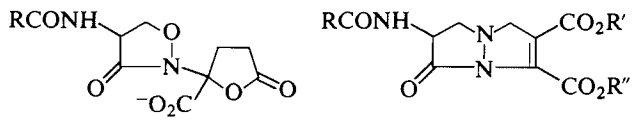
[Traduit par la revue]

Introduction

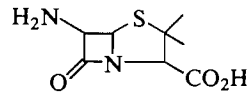
β-Lactam compounds manifest their antibacterial activity through an ability to interfere with the biosyntheses of bacterial cell walls (1). This is accomplished, at the molecular level, by covalent binding (2) (see **1**) to the active sites of one or more of a



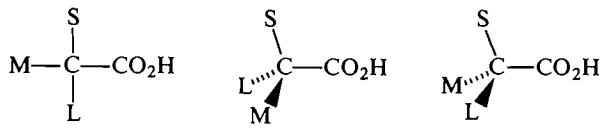
1



4 **5**



7

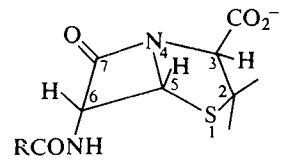


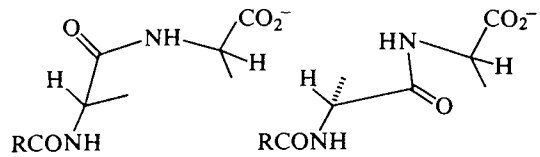
8 **9a** **9b**

group of enzymes termed penicillin binding proteins (PBPs) (3). The PBPs are transpeptidases and (or) carboxypeptidases, whose function in the cytoplasmic membrane (4) is to complete cell wall synthesis by a cross-linking of peptidoglycan chains. The peptide segments of these chains terminate in the sequence R-X-D-Ala-D-Ala (most commonly X = L-Lys or *meso*-diaminopimelate), and the simplest model substrate for PBPs is Ac_2-L-Lys-D-Ala^1-D-Ala^2 (5).

The cross-linking reaction mediated by PBPs, and inhibited by β-lactam antibiotics, is R-X-D-Ala-D-Ala + $H_2NR' \rightarrow$ R-X-D-Ala-NHR′ + D-Ala, where R and R′ belong to different chains. This was discovered, initially for the case of penicillins, in 1965 (6), and Tipper and Strominger proposed that penicillin is a structural analog of *N*-acyl-D-Ala^1-D-Ala^2 (**2**). In their view (Model A), the N4—C7 bond of penicillin corresponds to the D-Ala^1-D-Ala^2 peptide bond, as depicted in **3***a*.

Although Model A has survived for more than 20 years (7), the stereochemical problems that it raises (8) remain unresolved. Thus, C6 of penicillin, which has the L configuration, must correspond to the asymmetric centre of Ala^1, which has the D configuration. However, 6-epipenicillins (8) are inactive (9), and Ac_2-L-Lys-L-Ala-D-Ala is not a substrate for PBPs (10). Since the orientation and nature of the acylamino side chain are critical to the activity of penicillin, a structural analogy between penicillin and **2** based on Model A therefore requires that the Ala^1 methyl group correspond to H6 of penicillin in the





3*a* **3***b*

conformations that bind to the active site of PBP. This point was recognized by Strominger and Tipper (11), who suggested that 6α-methylation of penicillin (see Fig. 5) would improve the structural analogy. The required compounds were synthesized in 1971 (12), and found to be inactive.

The caveats expressed in ref. 8 led (13) to an alternative proposal (Model B) (see **3***b*), in which the N4—*C5* bond of penicillin corresponds to the D-Ala–D-Ala peptide bond, and C6—C7 corresponds to C_α-CH_3 of Ala^1. The effect of Model B is to interchange the oxidation levels of the atoms of **2** that correspond to C5 and C7 of penicillin in the comparison of the two structures. This overcomes the stereochemical problem and, at the same time, maintains similar spatial arrangements of the two side chains.

Two features of Model B were of particular interest (13): (*i*) the *sulfur* atom of penicillin corresponds spatially to the *oxygen* atom of the D-Ala^1–D-Ala^2 peptide bond. This observation suggested that replacement of the sulfur atom by oxygen would improve the analogy, and it stimulated work on synthetic approaches to oxapenicillins and oxacephalosporins (14), which led ultimately to the discovery of Latamoxef, a clinically important antibiotic (15); (*ii*) *the presence of the β-lactam ring is not essential for the structural analogy*; the covalent bonding depicted in **1** only becomes possible after the β-lactam ring has been positioned over X in the primary complex.

Very recently, two non β-lactam structures consistent with (*ii*) have been discovered; lactivicin (**4**, R = CH_3), a natural product (16); and pyrazolidinone **5** (R = *t*-BOC), a synthetic compound (17). Both **4** and **5** inhibit the action of PBPs, and are potent antibacterial agents when R is a side chain known to confer high activity upon penicillins (18).

Although Model B continues to be permissive, we felt that it could not be tested properly until it became possible to carry out detailed analyses of the conformations of penicillins, **2**, and the putative binding site of a PBP in water solvent.

The problems associated with these requirements have now been largely overcome. Thus, the nature of the binding sites of several PBPs has become known in some detail (19); in addition, in several accompanying papers (20), we have described and evaluated procedures for the conformational analysis of peptides and penicillins in water solvent. The theoretical procedures are based on successful parameteriza-

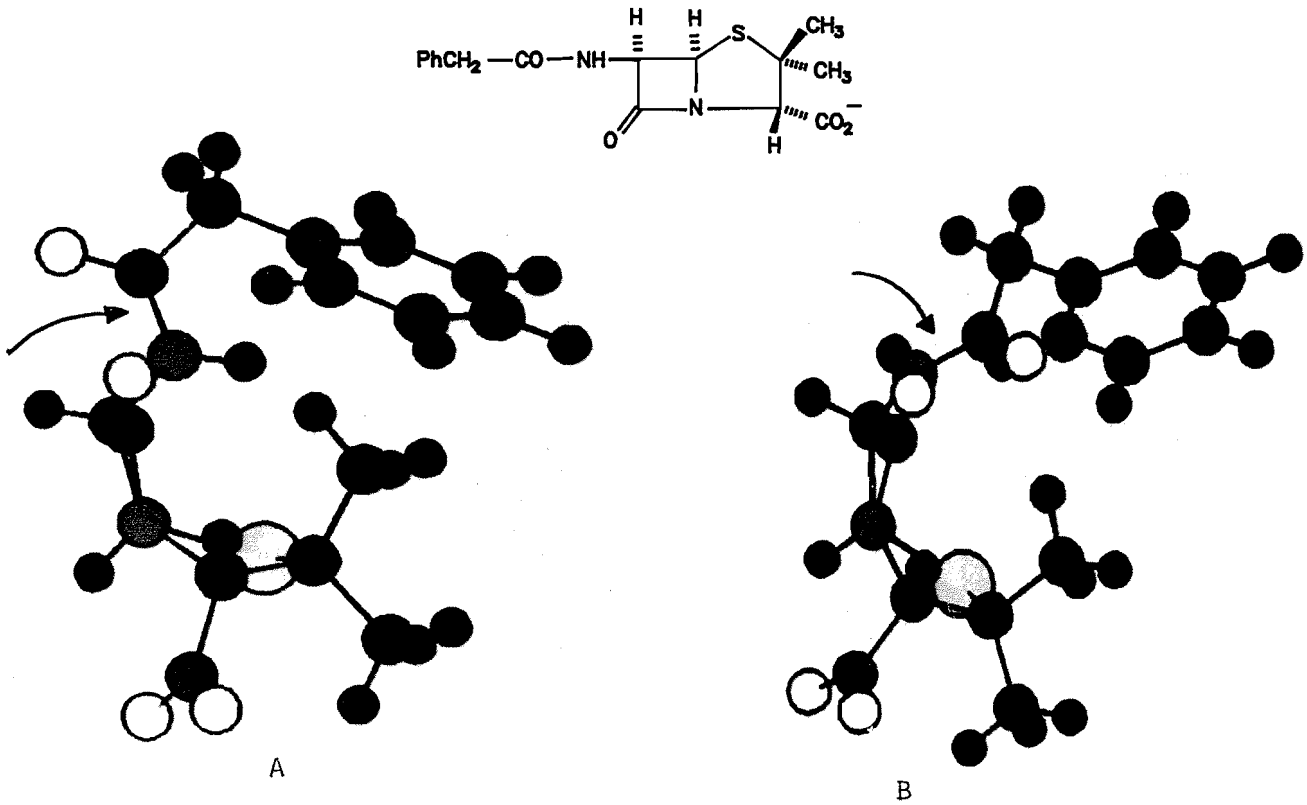

FIG. 1. (A) Crystal structure of penicillin G; (B) Calculated global minimum of penicillin G.

tions of Allinger's well-tested molecular mechanics force field (21, 22) for peptides and penicillins, and the use of MMP2(85) (23) in the computations. The objectives of the present work are, therefore, as follows: (*a*) to examine the conformations of active and inactive penicillin derivatives, in order to map out intramolecular relationships associated with activity; (*b*) to generate, from the coordinates of the global minimum of penicillin G, conformations of $PhCH_2CONH$-D-Ala-D-Ala (**6**) that correspond to Models A and B, to examine the "fit" of the resulting structures to the parent penicillin, and to compare the energies of these conformations of **6** to those obtained in a more general search; (*c*) to carry out a conformational analysis of a hexapeptide that contains the active site of the PBP of *Streptomyces* R61 (24); (*d*) to examine the intermolecular complexes formed between different conformations of penicillin G and the calculated active site, taking into account known experimental features of these complexes (25); (*e*) to determine which calculated conformation of **6** exhibits the best fit to the calculated active site of the PBP.

All calculations were performed with a dielectric constant $\epsilon = 78.5$ (20).

Conformational analysis of active and inactive penicillin derivatives

Figures 1A and 1B recall, respectively, the crystal structure and the calculated global minimum of penicillin G (20*c*). The most important difference is in the orientation of the amide moiety of the side chain (see arrows). In the crystal structure, oxygen is on the convex face and hydrogen on the concave face of the molecule (< H6—C6—N—H = −156°.) The locations of these two atoms are reversed in the calculated structure (< H6—C6—N—H = −36°). The calculated higher energy pseudoequatorial conformation of penicillin G (20*c*) resembles the global minimum in the orientation of its —CO—NH— moiety.

The crystal structure and the calculated structures of penicillin V differ in the same way (20*c*). As will be seen, most of the calculated structures of acylaminopenicillins examined in the present work resemble penicillin G and penicillin V in this respect. On the other hand, the *oxygen–exo* orientations seen in the crystal structures of penicillin G and penicillin V also appear to be general (26). Since the —CO—NH— orientation found in X-ray structures has been assumed in all previous structure–activity studies and comparisons of penicillin with *N*-acyl-D-Ala-D-Ala (26, 27), it is not surprising that the orientation of the amide N-H or, indeed, of the side chain itself, have received only limited attention (28).

However, it has long been known (29) that not only C6-alkylation, but also N-alkylation of penicillin (see Fig. 2) abolishes its antibacterial activity. It is also found (30) that the diastereomeric penicillins formed by acylation of 6-aminopenicillanic acid (**7**) with a carboxylic acid of type **8**, in which S, M, and L refer to small, medium, and large substituents, differ greatly in antibacterial activity; the penicillin formed from **9***a* is significantly more active. Thus, in the case of ampicillin and related penicillins (see Fig. 3), only the D epimers (**9***a*: S = H, M = NH_2, L = Ar) are clinically useful, whereas in the case of α-substituted penicillin V analogs, e.g., α-phenoxyethylpenicillin (see Fig. 4), only the L epimers (**9***a*: S = H, M = alk, L = OAr) are of clinical value. It was clear in

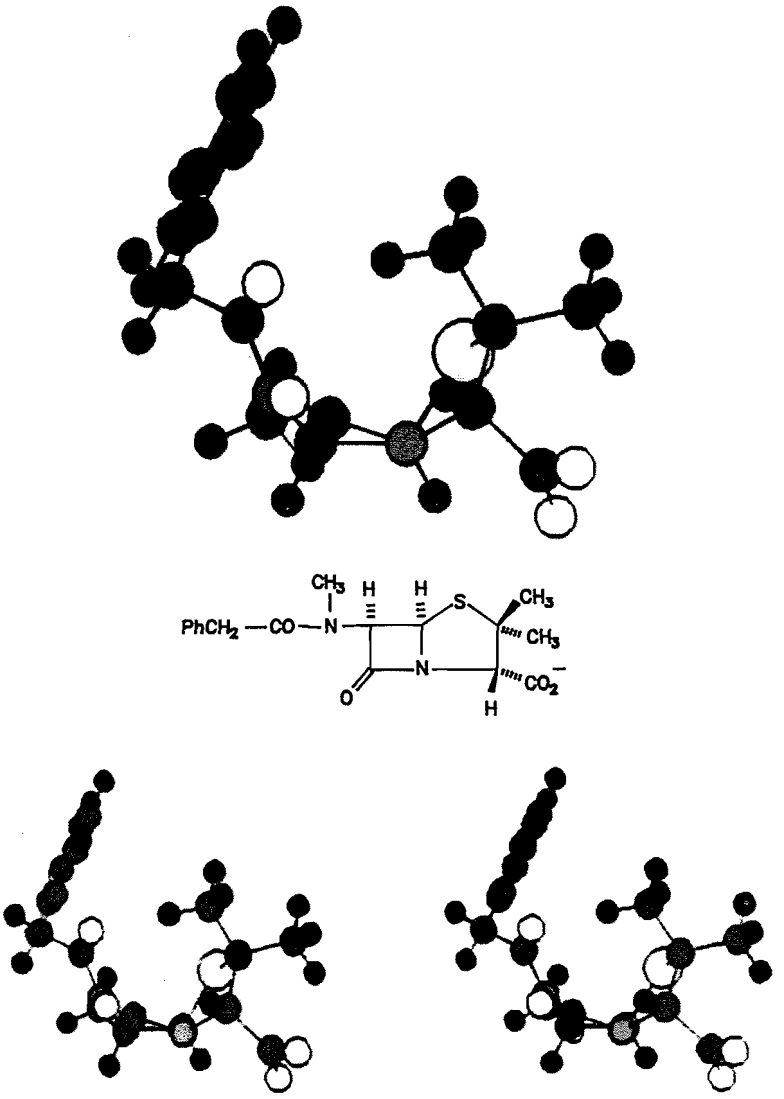

FIG. 2. Calculated structure of *N*-methylpenicillin G.

1961 (30) that such differences in properties must reflect subtle three-dimensional differences in the abilities of side-chain epimers to interact with the penicillin receptor; however, the information and techniques needed to pursue this point did not exist at that time.

Figure 2 shows the calculated structure of *N*-methylpenicillin G. The structure is virtually identical to that found for penicillin G itself: the thiazolidine ring has a pseudoaxial conformation, and the benzyl moiety is folded towards the concave face, leading to a compact molecule. But, whereas in the active compound, penicillin G, N-H points towards a putative receptor, in the inactive *N*-methyl derivative, N-CH_3 occupies the same relative position.

Figures 3A and 3B show, respectively, the calculated structures of D- and L-ampicillin. The D isomer is compact; the L isomer is not (31). In both cases, the amide N-H is on the convex face of the molecule (see arrows in Figs. 3A,B). Interestingly, both epimers have a pseudoequatorial conformation of the thiazolidine ring, as is observed in the crystal structure of D-ampicillin (32).

Figures 4A and 4B show, respectively, the calculated structures of L- and D-α-phenoxyethylpenicillin. In this case, the L isomer is compact and the D isomer is not. Both epimers have a pseudoaxial conformation of the thiazolidine ring and, in both cases, the amide N-H is on the convex face of the molecule (see arrows in Figs. 4A,B)

Significantly, the conformational differences found for these active and inactive penicillin epimers are expressed within the side chains and not within the nuclei. It is difficult to avoid the conclusion that whether the thiazolidine ring is pseudoaxial or pseudoequatorial is less important than has been suggested previously (26).

In both D- and L-ampicillin, the C_α—N and amide N—H bonds are *syn*-periplanar (**10***a,b*). This is the dominant conformational effect, and it causes Ar to reside on the concave face of the molecule in the D isomer, and on the convex face in the L isomer. On the other hand, in both L- and D-α-phenoxyethylpenicillin, the C_α—H and amide C=O bonds are eclipsed (**11***a,b*). This causes Ar to reside on the concave face in the L isomer, and on the convex face in the D isomer.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/07/12
For personal use only.

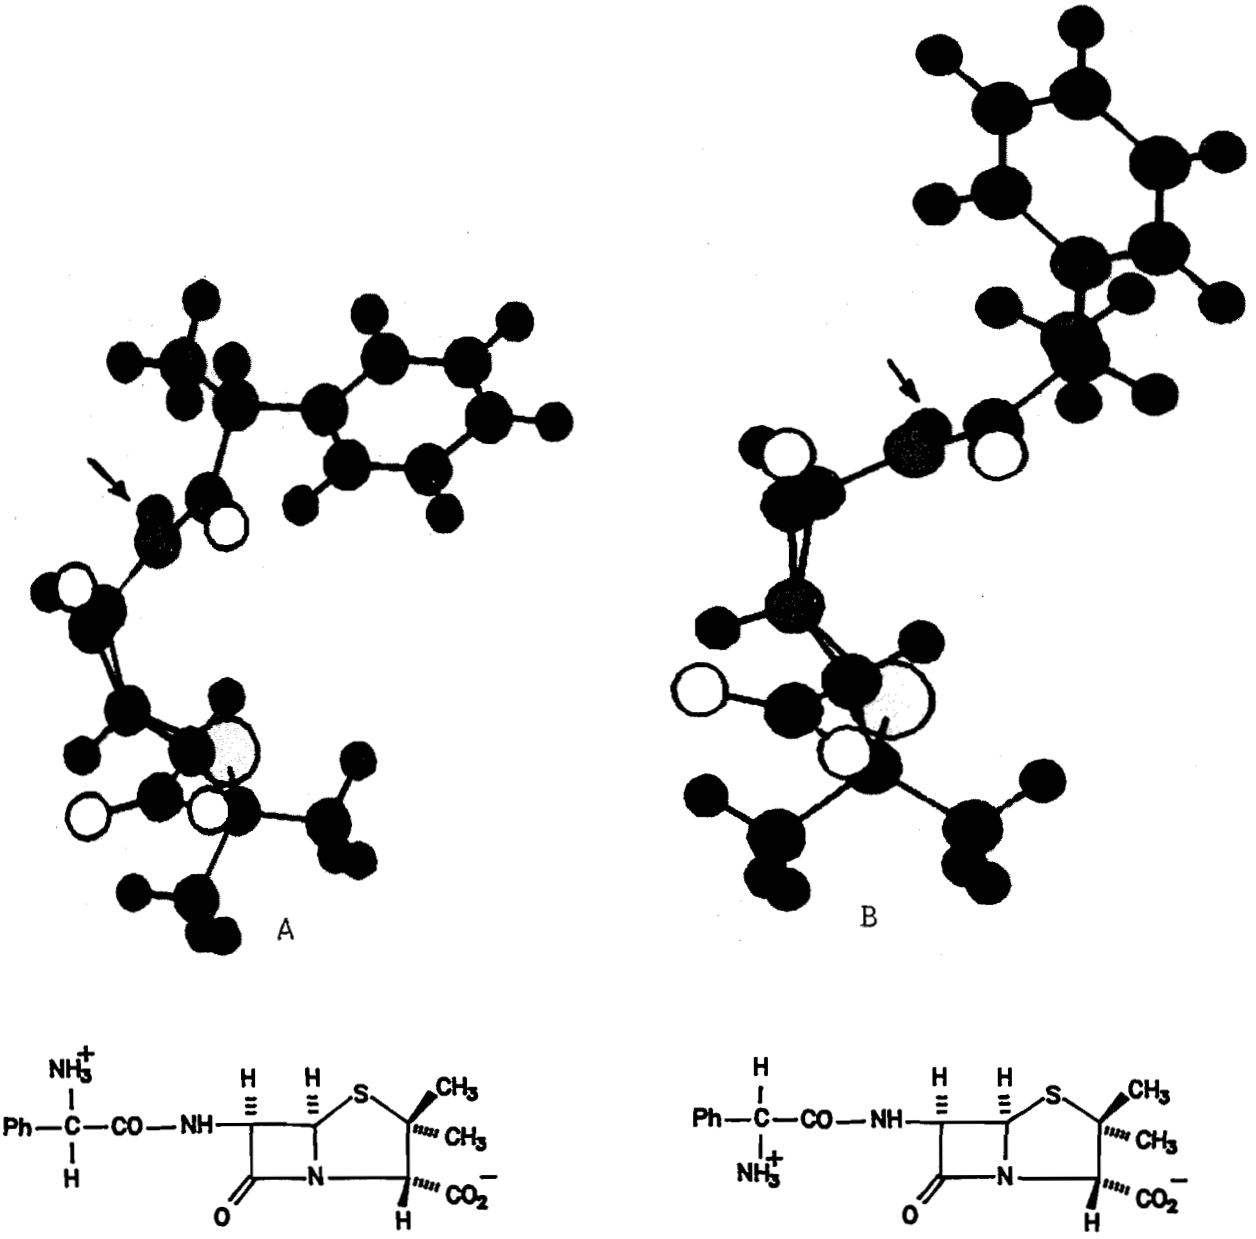

FIG. 3. (A) Calculated structure of D-ampicillin; the amide N-H is indicated by the arrow. (B) Calculated structure of L-ampicillin; the amide N-H is indicated by the arrow.

All of these results are consistent with the hypotheses that the convex face of penicillin is presented to its receptor, and that the carboxyl group and the *amide N-H* are involved in the bonding to this receptor. Since 6-aminopenicillanic acid (**7**), whose amino group is a hydrogen bonding donor at pH 7, is not active, acylation must be necessary to create a hydrogen bonding *acceptor* at this position (33). It is noteworthy that sulfonamide (34), sulfinamide (35), and phosphonamide (36) isosteres of penicillins are active, but the carbon, sulfur, and oxygen isosteres of the NH moiety are not (37).

Figure 5 shows the structure calculated for the biologically inactive 6α-methylpenicillin G. The introduction of the methyl group on the convex face of the molecule causes a significant increase in the dihedral angle with the amide N-H, from −36° in the parent compound to −69° in the derivative. This amide hydrogen has moved towards the concave face of the molecule.

The bisnorpenicillins (**12**; see Fig. 6) comprise a family of penicillin derivatives whose low activity (38) is not understood. Figure 6 is the structure calculated for bisnorpenicillin G. The structure resembles that of penicillin G in several respects: (*i*) the thiazolidine ring has a pseudoaxial conformation; (*ii*) the benzene ring is folded on the concave face of the molecule; (*iii*) the β-lactam nitrogen is significantly nonplanar. The sum of the angles at this nitrogen atom is 334.4°, compared to 335.8° in penicillin G. *However, the orientation of the amide N-H is significantly different.* In bisnorpenicillin G, the

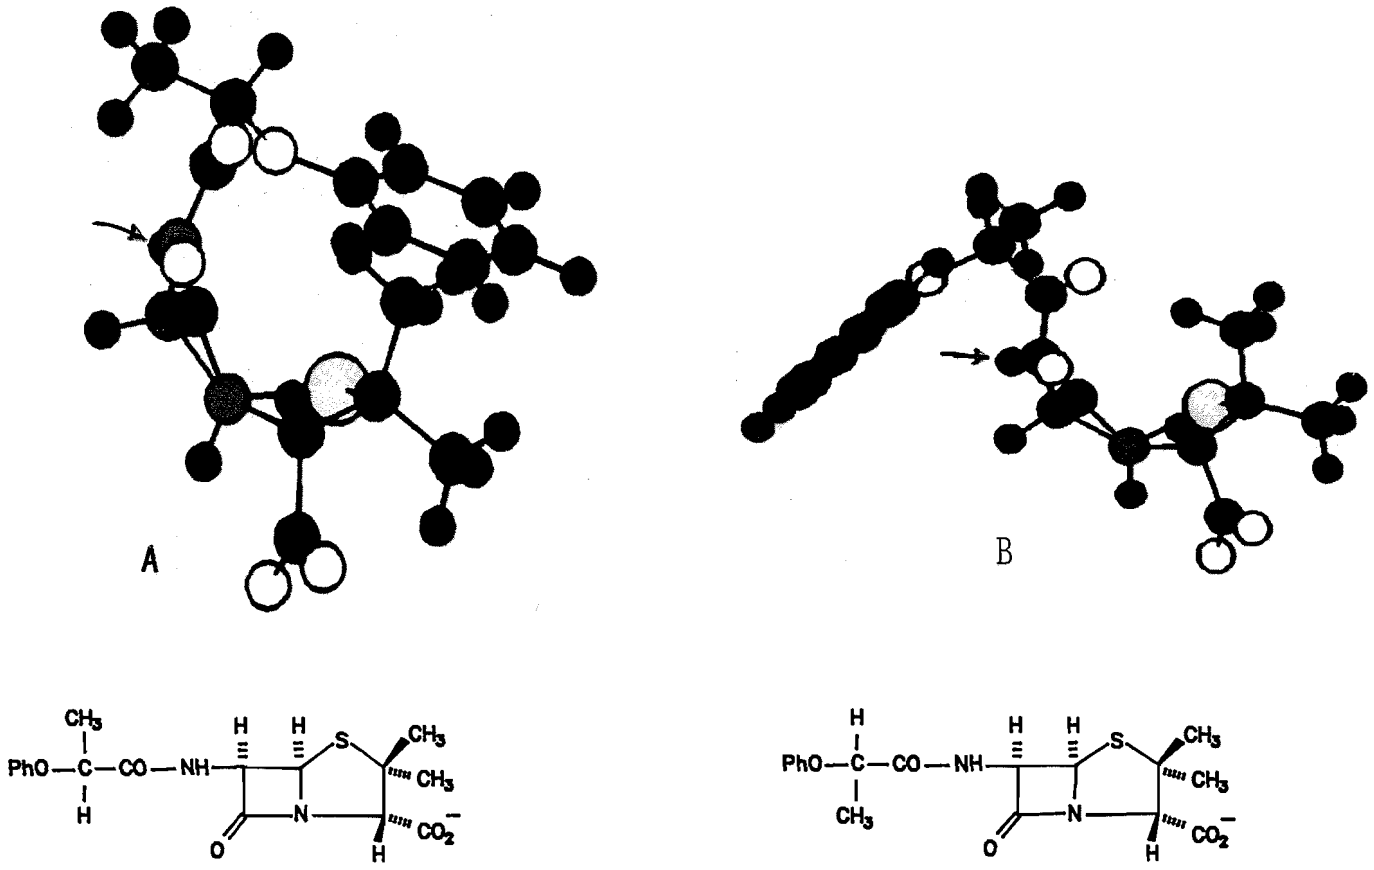

FIG. 4. (A) Calculated structure of L-α-phenoxyethylpenicillin; the amide N-H is indicated by the arrow. (B) Calculated structure of D-α-phenoxyethylpenicillin; the amide N-H is indicated by the arrow.

H—N—C6—H6 dihedral angle has increased from −36° to −60°. As in 6α-methylpenicillin G, the amide hydrogen has moved towards the concave face of the molecule.

All of these results continue to be consistent with the view that the amide N-H of the penicillin side chain participates in binding to the penicillin receptor.

Conformational analysis of phenylacetyl-D-alanyl-D-alanine

Labischinski *et al.* (27) have carried out a conformational analysis on the non-ionized form of **6**, using ECEPP (39). Their calculations, presumably with a dielectric constant $\epsilon = 2.0$ D, identified 55 low energy conformations within 3 kcal/mol of their lowest energy structure, here termed **6*L***, and shown in Fig. 7. This structure was reproduced, within the MMPEP parameterization of MM85 (20*a*), in the following manner: (*i*) a one-point ECEPP calculation was performed on Ac-NH-D-Ala-D-Ala-O$^-$ with a dielectric constant $\epsilon = 78.5$ D (20*b*), using the (ϕ,ψ) dihedral angles of **6*L*** (ϕ_1,$\psi_1 = 75,42$; ϕ_2,$\psi_2 = 154,-164$); (*ii*) from the resulting MM85 input file (20*b*), six starting geometries of **6** were generated by replacement of acetyl methyl hydrogens by a phenyl group in two possible orientations (23); (*iii*) each of these six was minimized, using MMPEP and a dielectric constant $\epsilon = 78.5$ D (20*b*). One of the six minimized structures, **6*LA***, was significantly lower in energy than the others. This structure has (ϕ_1,ψ_1) = (56,42) and (ϕ_2,ψ_2) = (159,−120) (see Fig. 7). As shown in Fig. 8, **6*LA*** corresponds to **6*L*** (Fig. 7), except for the orientation of the terminal carboxylate group. The carboxyl orientation of **6*L*** is not a minimum in **6*LA***.

The skeleton of **6*LA*** does not have the conformation that seems to be associated with antibacterial activity in a penicillin.

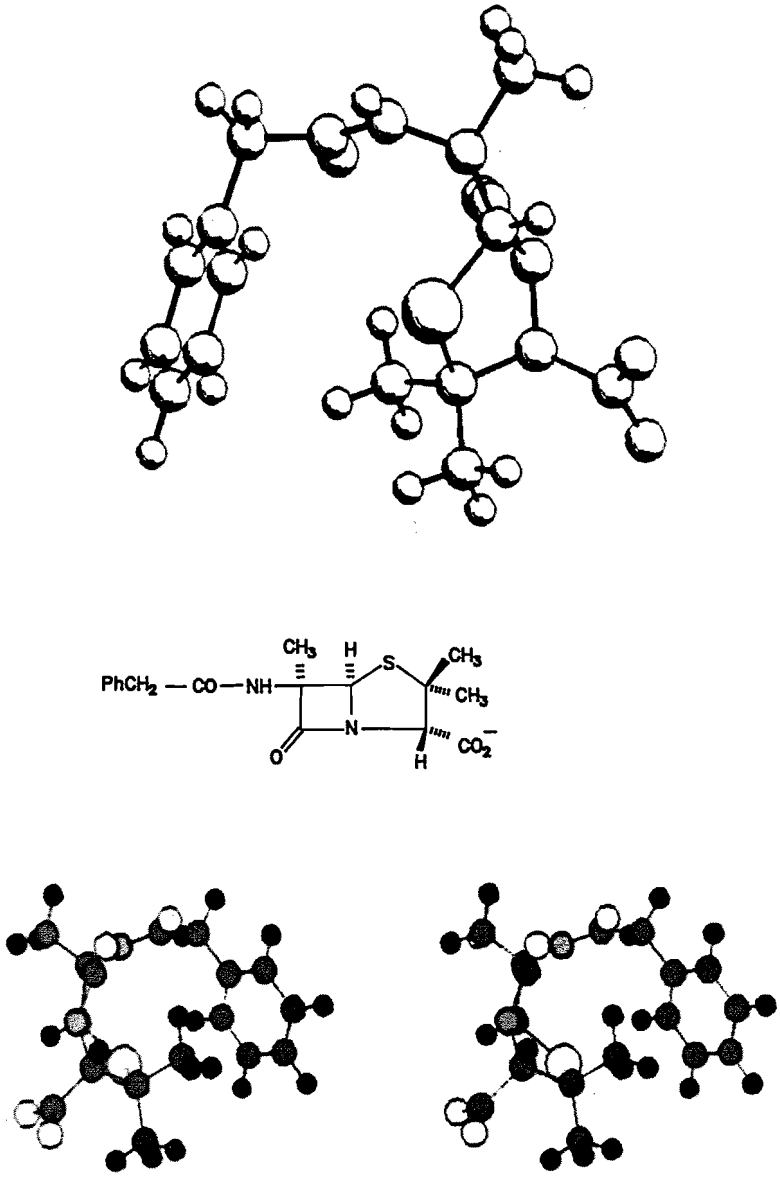

FIG. 5. Calculated structure of 6α-methylpenicillin G.

In particular, the H—N—C—H dihedral angle of **6***LA* that mimics H—N—C6—H6 of penicillin is +121° compared to −36°.

To obtain conformations of **6** that correspond more closely to the essential portions of the penicillin skeleton, we began with the Cartesian coordinates of the pseudoaxial and pseudoequatorial conformations of penicillin G. These were truncated, to obtain initial geometries appropriate for Model A and for Model B. As shown in Scheme 1, to simulate Model A, the two conformations of penicillin G were truncated to **13**. The atom type of H_A was then changed from *5* to *1* (to correspond to the sp^3 carbon), and hydrogens were added to this carbon, and at B, C, and D, to give $\mathbf{6}A_{ax}$ and $\mathbf{6}A_{eq}$. To simulate Model B, the two conformations of penicillin G were truncated to **14**, C_A was changed to atom type *1*, and C_B to atom type *3*; a carbonyl oxygen was then added at B, and hydrogens at A, C, and D, to give $\mathbf{6}B_{ax}$ and $\mathbf{6}B_{eq}$. Each of $\mathbf{6}A_{ax}$, $\mathbf{6}A_{eq}$, $\mathbf{6}B_{ax}$, and $\mathbf{6}B_{eq}$ was then minimized, using MMPEP and $\epsilon = 78.5$ D.

Table 1 summarizes the relative energies and dihedral angles of the five conformations of **6** examined in this work. Figures 9 and 10 show, respectively, superpositions of $\mathbf{6}A_{ax}$ and $\mathbf{6}B_{ax}$ on the pseudoaxial conformation of penicillin G. Close inspection of these diastereoscopic views reveals that the methyl group of Ala^1 projects onto the convex face of penicillin in the case of $\mathbf{6}A_{ax}$, but is perpendicular to this face in $\mathbf{6}B_{ax}$. For a more quantitative evaluation of the fits, the coordinates of **15** and **16** were generated from the pseudoaxial, and also from the pseudoequatorial conformations of penicillin G, and the rms deviations between **15** and the corresponding atoms of $\mathbf{6}A_{ax}$ and $\mathbf{6}A_{eq}$, and between **16** and the corresponding atoms of $\mathbf{6}B_{ax}$ and $\mathbf{6}B_{eq}$, were calculated. These are included in Table 1.

The data of Table 1 allow several tentative conclusions at this

stage: (*i*) the conformation of **6** of which penicillin is a structural analog is not the global minimum of this peptide; (*ii*) based on their structural analogy to the appropriate atoms of penicillin G, Models A and B are equally valid; (*iii*) it is not yet possible to state which conformation of the thiazolidine ring is bound to the penicillin receptor. Additional insights require information concerning the active site of a penicillin binding protein.

Modeling the active site of a penicillin-binding protein

The PBPs have been defined (3) as those bacterial proteins that bind penicillins and other β-lactam antibiotics covalently. For any organism, these are numbered 1,2,..., in order of decreasing molecular weight. The higher molecular weight PBPs of *E. coli* (PBPs 1a, 1b, 2, 3) are essential to the cell, and are the killing sites of the antibiotics (40). The lower molecular weight PBPs (PBPs 4, 5, 6) are D-alanine carboxypeptidases.

Regardless of their origin or molecular weight, each of the PBPs whose sequence and (or) active site region have so far been determined has been found to contain a unique serine residue that reacts with penicillin G (see **1**), and is followed in the sequence by X-X-Lys (41, 42).

The active site serine D-alanyl carboxypeptidase-transpeptidase of *Streptomyces* R61 (M_r 38,000) has been crystallized with incorporation of β-lactam compounds (19, 24), and the crystal structure has been partially solved. The pH dependence of the same enzyme has also been examined (25). Both kinds of studies strongly suggest that the carboxyl group of a penicillin is closely associated with the protonated ε-amino group of the lysine residue of X-X-Lys. The X-ray structure confirms that, in the complex, the β-lactam ring of penicillin is in close proximity to the active site serine; the pH-dependence study rules out involvement of a histidine residue in the chemical process, in

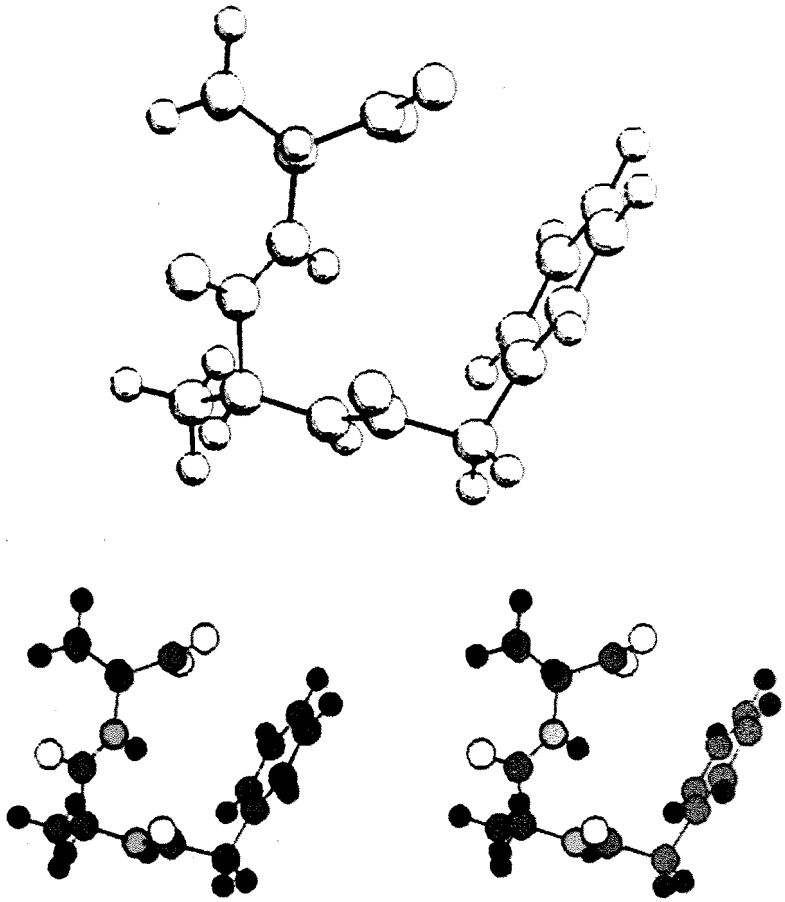

FIG. 8. Structure of **6***LA* corresponding to the structure of ref. 27.

contrast to the behaviour of chymotrypsin and related serine peptidases.

These observations suggest that, even in the absence of published atomic coordinates for this enzyme, it might be possible to obtain a valid model of the active site solely in terms of the amino acids that surround the unique serine residue, viz., Val-Gly-Ser-Val-Thr-Lys. Accordingly, the peptide Ac-HN-Val-Gly-Ser-Val-Thr-Lys-NH-Me was subjected to a theoretical conformational analysis at $\epsilon = 78.5$ D, using an initial ECEPP search of 200,000 structures (20*b*), followed by MMPEP refinement (20*a*,*b*) of 50 low energy structures identified in this search. Attention was focused, especially, on conformations that placed the serine and lysine side chains in proximity. One such structure, ca. 1.0 kcal/mol higher in energy than the lowest energy structure, was found. This structure (**17**), after further dihedral drive refinement of the serine and lysine side chains and the N-terminus, is shown in Fig. 11. The dihedral angles of **17** are summarized in Table 2.

Structure **17** has several features of interest. The convex face is mainly hydrophobic, and the concave face, which includes the serine and lysine side chains, is mainly hydrophilic. The concave face also contains the amide oxygen of the N-terminal acetyl group. The existence of a lock-and-key relationship (43) between the concave face of **17** and the convex face of a penicillin seems inherently appealing and, in terms of such a relationship, the role of the amide N-H of the penicillin side chain becomes clear: there is an N—H...O=C hydrogen bond between this hydrogen of penicillin and the N-terminal carbonyl oxygen of **17**.

We therefore wish to examine a supermolecule in which **17** is docked (44) to a penicillin or peptide through $-NH_3^+ \ldots {}^-O_2C-$ and N—H...O=C interactions. The MMPEP (20*a*) and MMPEN (20*c*) parameterizations of MMP2(85) allow Allinger's complete force field to be applied to the minimization of the energy of such a supermolecule, provided that a set of initial Cartesian coordinates can be specified.

A solution to such problems has been devised that obviates a requirement for sophisticated real-time computer graphics. The method, a full account of which will be given separately,[3] may be summarized as follows. Let A refer to a receptor molecule containing N_1 atoms and B a substrate molecule containing N_2 atoms, which is to be docked to A. We assume that the geometries of A and B are known in Cartesian coordinates or in internal coordinates, and that transformation between the two types of coordinate systems is possible. In this case, we begin with $(3N_1-6)$ and $(3N_2-6)$ predetermined internal coordi-

[3]K. Yang and S. Wolfe. To be published.

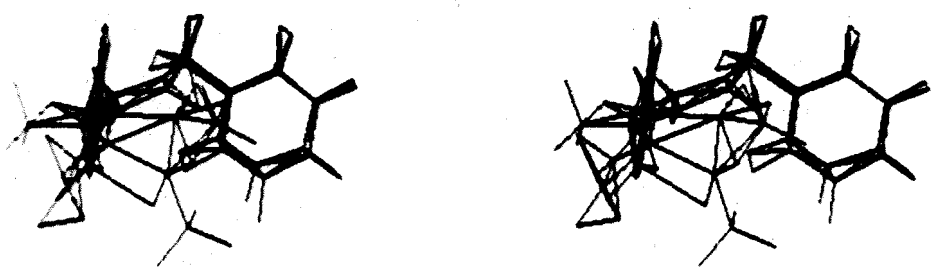

FIG. 9. Superposition of $\mathbf{6}A_{ax}$ on the pseudoaxial conformation of penicillin G.

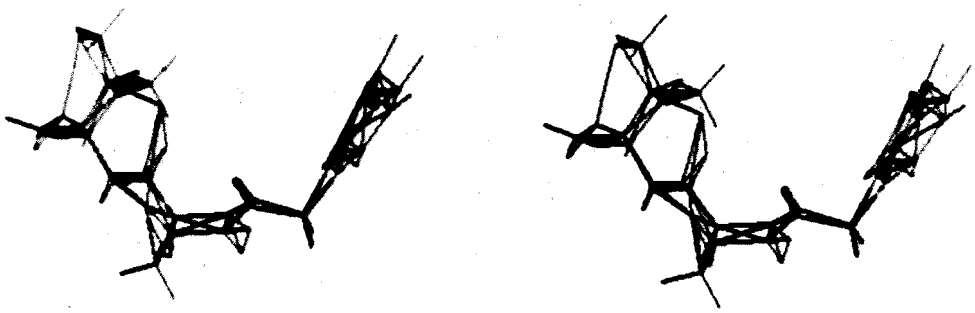

FIG. 10. Superposition of $\mathbf{6}B_{ax}$ on the pseudoaxial conformation of penicillin G.

nates. To describe the geometry of the supermolecule containing $(N_1 + N_2)$ atoms requires 3 $(N_1 + N_2) - 6$ internal coordinates, i.e., six additional internal coordinates must be determined. These comprise, typically, one bond length, two bond angles, and three dihedral angles, and they may be termed "intermolecular" internal coordinates.

A variety of procedures can be employed (46) to minimize an unconstrained, multivariable nonlinear function $F(r, \theta_1, \theta_2, \phi_1, \phi_2, \phi_3)$, but are unnecessary in the present case, in which contact between $-NH_3^+$ and $^-O_2C-$, and between N—H and C=O is desired. Accordingly, we select one of these interactions, e.g., (N—H...O=C), and set $r_{H...O}$ = 1.7–2.5 Å, a typical intermolecular hydrogen bonding distance. Initial values are then given to the five remaining variables, and the energy is minimized, using eq. [1], with $r_{NH_2—H^+...^-O—CO}$ as a probe. The geometry of the resulting supermolecule, now expressed in Cartesian coordinates, is considered appropriate for MMPEP/MMPEN refinement when the minimization leads to $r_{NH_3^+...^-O_2C}$ = 1.7–2.5 Å.

$$[1] \quad E_{INT} = \Sigma(2.9 \times 10^5 \epsilon e^{-12.5}(r_0/r) - 2.25\epsilon(r_0/r)^6) + \Sigma 332.0 q_i q_j / r_{ij}$$

Equation [1] consists of the electrostatic and van der Waals terms of Allinger's force field (21, 23).

Binding of penicillins to the PBP model *17*

Figure 12 shows the structure obtained when the pseudoaxial conformation of penicillin G is docked to **17** by the procedure just described. Although this is not a fully optimized structure, some remarkable features are already evident. The assumption that the carboxyl group and the amide N-H of the penicillin side chain engage in primary interactions with the receptor leads to a fit in which the hydroxyl group of the unique serine is almost perfectly positioned for attack upon the β-lactam carbonyl group. In this structure the Ser-O...C=O distance is 3.59 Å, and the O...C=O angle is 108.8.° (47).

TABLE 2. Dihedral angles of **17**, the model of the active site of the PBP of *Streptomyces* R61

	Dihedral angle (deg)							
Residue	ϕ	ψ	ω	χ1	χ2	χ3	χ4	χ5
Ac			180					
Val	−72	121	180	−60	178	180		
Gly	160	−179	178					
Ser	79	−62	−177	−55	62			
Val	72	−86	177	−52	180	180		
Thr	−71	152	176	−172	176	−179		
Lys	−69	−47	179	−179	62	176	180	180

Minimization of the structure of Fig. 12 leads to **18**, shown in Fig. 13. In **18** the O...C=O distance is 3.93 Å, the O...C=O angle is 113.0°, and the geometrical parameters of the N—H...O=C hydrogen bond are $r_{H...O}$ = 2.25 Å; < N—H...O = 149.3° (48).

Figure 14 shows a closer view of the relationship in **18** between the C—O—H of serine and the N—C=O of the β-lactam ring. This geometry is reminiscent of the cyclic transition structures found by Schowen and co-workers for the addition of water and methanol to formaldehyde in the gas phase

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/07/12

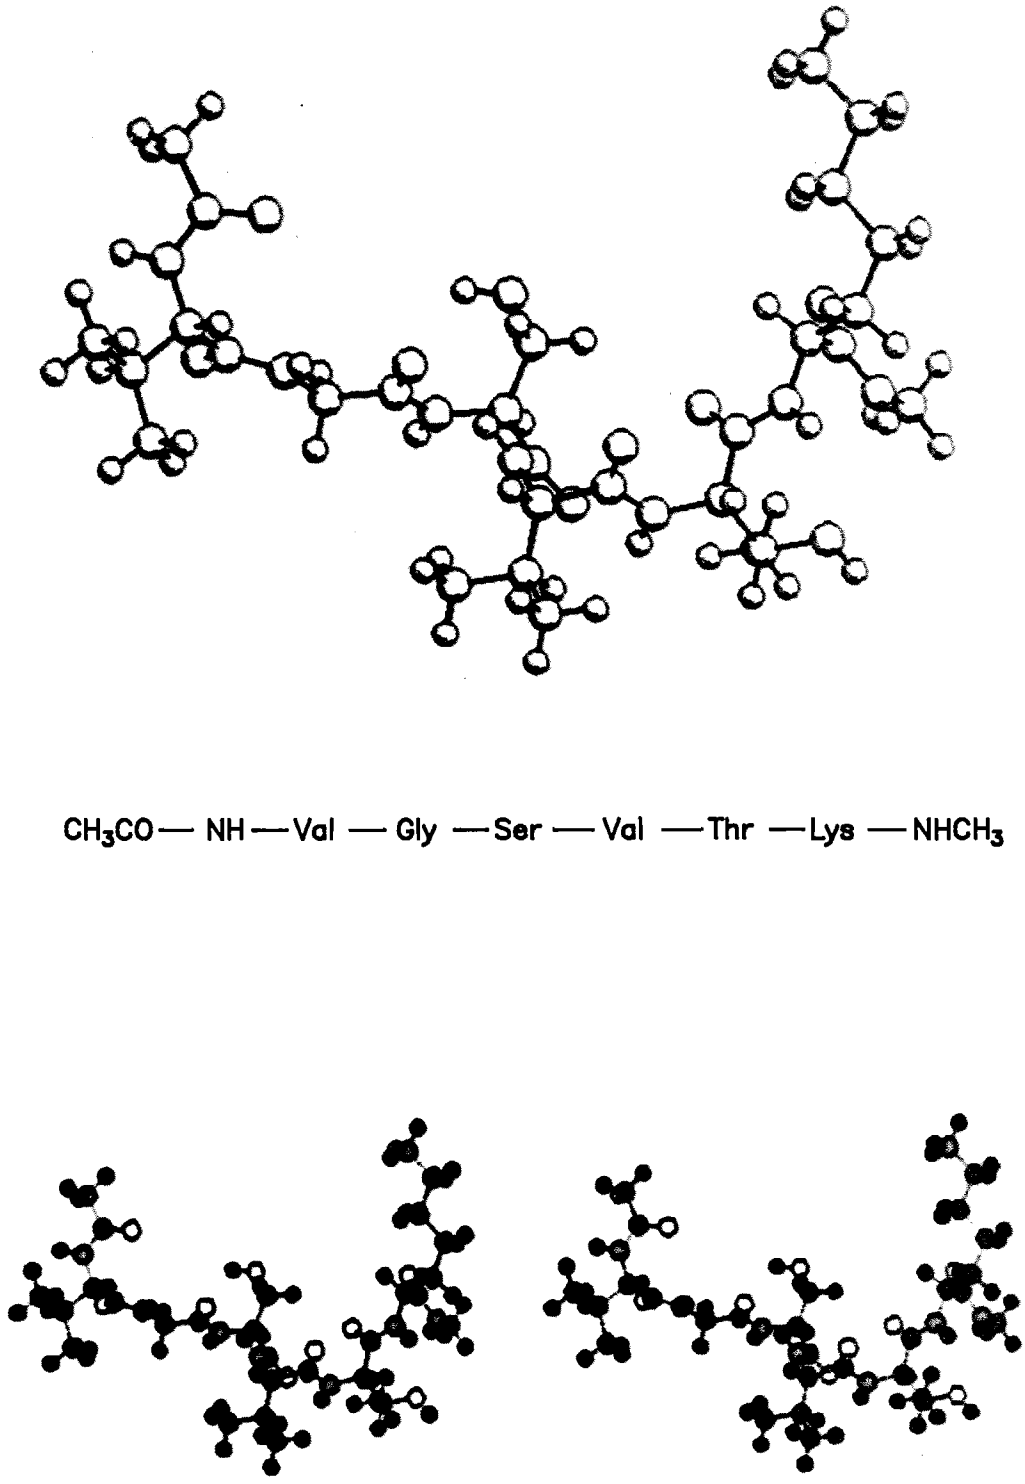

FIG. 11. Calculated structure (**17**) of the binding site of penicillin.

(49). Significantly, such structures do not persist in water solvent (50), and are not found in anionic addition to formaldehyde or formamide, either in the gas phase or in water solvent (51).

Structure **18** is, therefore, compatible not only with the observation (25) that a histidine residue does not participate in the chemical reaction between the serine residue of a PBP and penicillin G, but also with the notion (52) that the environment in which this reaction occurs must be essentially water-free. In terms of this model, the convex face of penicillin is the site of the chemical reaction, in part because there is proton transfer to the pyramidal β-lactam nitrogen in the transition structure (53).

These views appear to be consistent with those of Pauling (54) and Wolfenden (55), i.e., that the function of an enzyme is

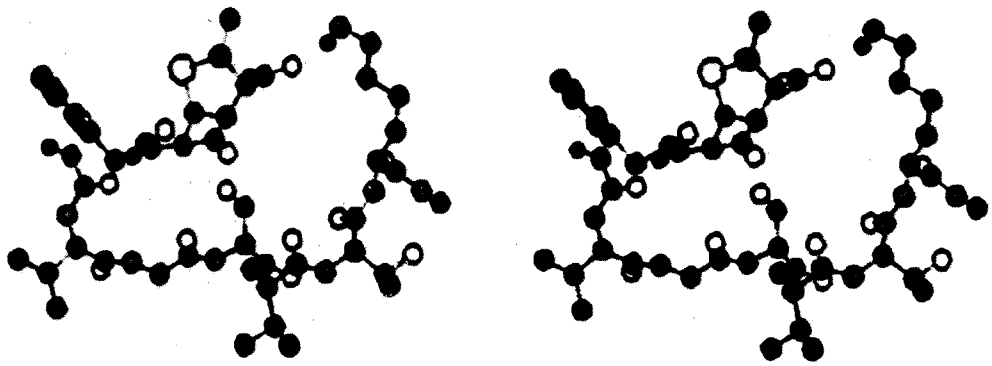

FIG. 12. Structure obtained following docking of pseudoaxial penicillin G to **17** (before final minimization).

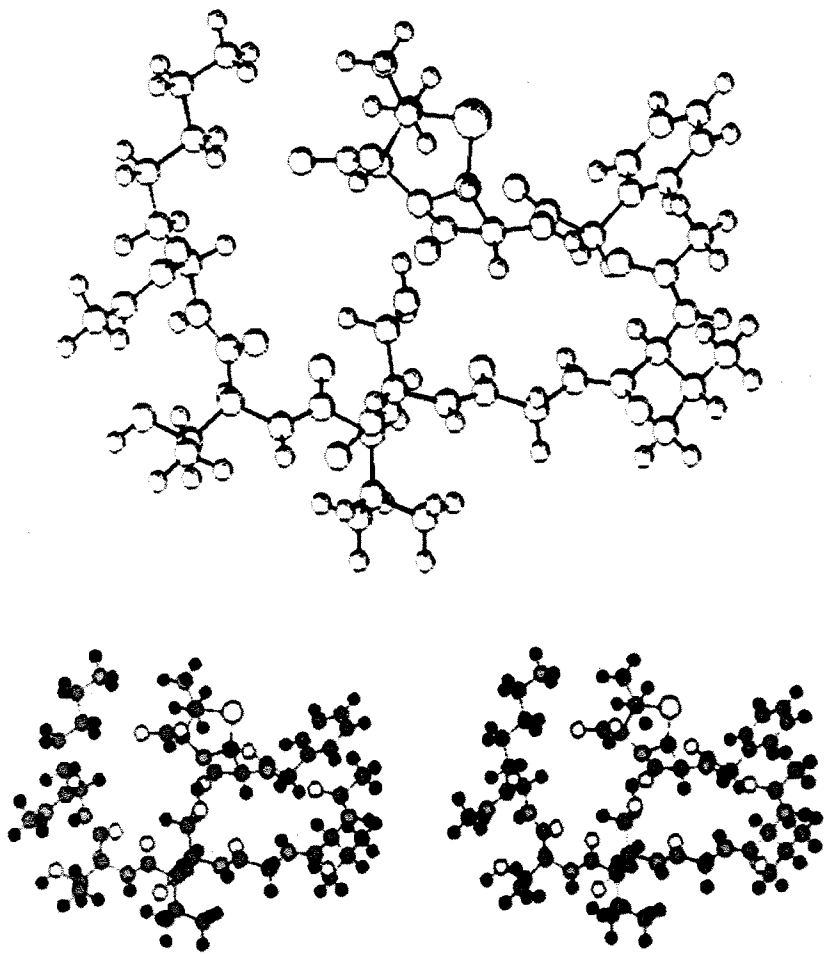

FIG. 13. Structure (**18**) obtained following full minimization of the structure of Fig. 12.

to encourage the formation of a transition state; this is evident in **18**. As will be seen in the following section, the complexes formed between the PBP model **17** and phenylacetyl-D-Ala-D-Ala are closely analogous to **18** in this respect, so that it does not seem necessary to postulate (56) that penicillin itself is a conformational analog of the tetrahedral transition state of peptide hydrolysis.

It should be possible eventually to relate the energetics of formation and the geometry of **18** and its analogs quantitatively to experimental kinetic data, and to antibacterial activity. This

will require: (*i*) that the conformational energies now calculated with MMPEP/MMPEN be expressed as heats of formation and, preferably, as free energies of formation; (*ii*) knowledge of the precise geometry of the transition state for neutral alcoholysis of a β-lactam. Although (*i*) and (*ii*) are not yet available, the properties of **18**, relative to those of other penicillin and peptide complexes with the PBP model **17**, can be compared at this stage.

Table 3 summarizes the results obtained following full minimization of the complexes of **17** with pseudoequatorial penicillin G, 6α-methylpenicillin G, and bisnorpenicillin G, in the manner already described for **18**. In each case, the H...N distance between the hydroxyl hydrogen of serine and the β-lactam nitrogen is less than the O...C distance between the serine oxygen and the carbonyl carbon of the β-lactam. The pseudoaxial and pseudoequatorial conformations of penicillin G bind with very similar geometries, but the energies of the two complexes differ by 2.73 kcal/mol. Since these are conformational isomers, the Curtin–Hammett principle applies (57), and only this energy difference is needed. It follows that *the pseudoaxial conformation of penicillin G is bound preferentially to* ***17***.

Bisnorpenicillin G binds to **17** with a geometry similar to that of penicillin G in the region of the β-lactam, but the N—H...O=C hydrogen bond is poorly formed, and the energy of complexation is less than that of penicillin G by 2.90 kcal/mol. In the case of 6α-methylpenicillin G, the energy of complexation is lower than that of penicillin G, the geometry of the serine–β-lactam interaction is poor, and the N—H...O=C hydrogen bond is poorly formed.

There is thus a one-to-one correspondence between the properties of these complexes and the relative antibacterial activities of the penicillins concerned. We hope that the quantitative nature of the correspondence will become clearer when (*i*) and (*ii*) above have been clarified.

Binding of the peptide 6 to the PBP model 17

Table 4 summarizes the results obtained following minimization of the complexes of **17** with the five conformations of **6** determined earlier. Figure 15 is the complex with $\mathbf{6}A_{ax}$. This figure shows that, in the complex, the serine hydroxyl group has the same relationship to the carbonyl group of the Ala–Ala peptide bond as to the β-lactam group of a penicillin, and the face of the carbonyl group that is attacked by serine corresponds to the convex face of penicillin G (cf Figs. 13 and 15). The steric effect of the Ala[1] methyl group (8) can be seen in Fig. 15 in the contact between this carbon and the oxygen atom of serine; this may be responsible for the decrease in the O...C=O angle, from 109.4° in the penicillin G complex to 99.5° in the peptide complex.

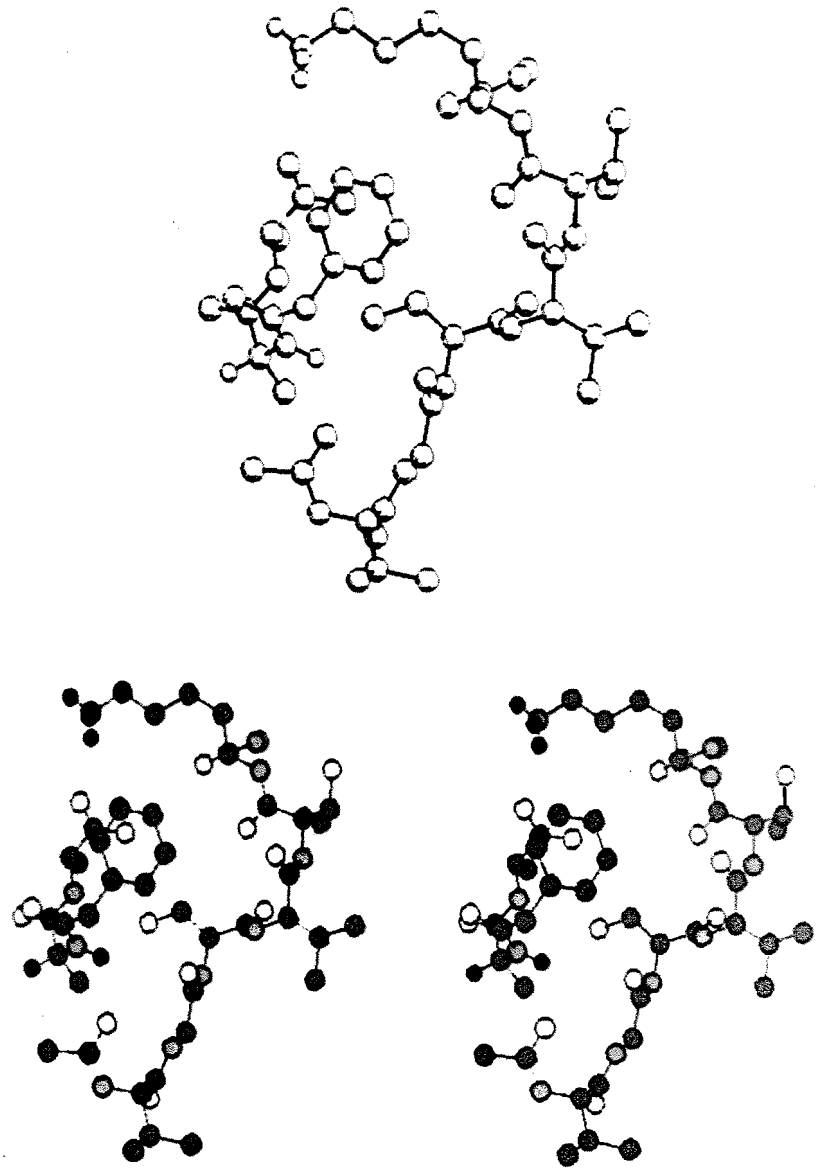

FIG. 16. Structure obtained following full minimization of the complex formed between **6***LA* and **17**.

Figure 16 is the complex of **17** with **6***LA*, the lowest energy conformation found for the peptide. The energy of this complex is higher than that of the $\mathbf{6}A_{ax}$ complex and the geometrical parameters are not as good. Most importantly, comparison of Fig. 13 and 16 reveals *that the face of the Ala^1 carbonyl group of* **6***LA that is attacked by the serine hydroxyl group corresponds to the concave face of penicillin.*

With these specific comments, it is clear that the data of Table 4 permit the following conclusions: (*i*) Strominger's 1965 model is most appropriate representation of the relationship between the skeleton of a penicillin and that of a peptide which serves as a substrate for a PBP; (*ii*) conclusion (*i*) is valid only when the peptide is compared to the pseudoaxial conformation of penicillin. The study of the complexes of **17** with penicillins and with **6** therefore leads to the consistent conclusion that the pseudoaxial conformation of penicillin G, which is the global minimum in this case, is the biologically active conformation.

Summary and concluding remarks

In this work we have employed the MMPEP (20*a*) and MMPEN (20*c*) parameterizations of Allinger's molecular mechanics force field (21, 23) to analyze the conformational factors that are associated with antibacterial activity of penicillins, and to determine the conformations of phenylacetyl-D-Ala-D-Ala that can be compared to appropriate regions of the conformationally constrained penicillin skeleton. In conjunction with a strategy for peptide conformational analysis (20*b*), the work has allowed a model for the active region of a penicillin binding protein to be proposed. A method has been developed to determine the minimized structures and conformational

[b]Relative energy of the complex, in kcal/mol.

energies of the complexes formed between penicillins or peptide substrates and the putative active site. The origin of antibacterial activity can thus be traced to the formation of a complex in which the hydroxyl group of a unique serine residue is positioned over the convex face of the β-lactam ring in a geometry close to that of the gas-phase transition state of the chemical process of alcoholysis of this ring (45).

The model of the active site has been deduced without access to the coordinates of the crystal structure of a penicillin binding protein, and may require revision when these coordinates become available. Nevertheless, it seems clear at this stage that the nature of the lock-and-key relationships between β-lactam compounds and PBPs can be treated in some detail by the methods of molecular mechanics. We plan to extend the approach described here and in ref. 20*c* to other classes of β-lactam antibiotics, and to non-β-lactam compounds, including lactivicin (**4**) and pyrazolidinones (**5**).

5,5-Diphenylhydanytoin (phenytoin) is the most widely used anticonvulsant drug, but has many side effects. Although its chemical mode of action is unknown, phenytoin is believed to function primarily by interference with the transport of sodium ions across the neuronal membrane. Structure–activity and lipophilicity–activity studies suggest that the drug interacts with its receptor through hydrogen bonding to the N3—C4 amide bond, and an aromatic–aromatic interaction with the C5 substituent. Since sodium channels are cysteine-rich peptides, whose function depends upon the cysteine⇄cystine redox process, it has been hypothesized that the action of the phenytoin receptor may be mimicked by a properly designed cyclodepsipeptide containing a cystinyl moiety, a cavity lined with five oxygen atoms oriented in the trigonal-bipyramidal manner appropriate for selective transport of sodium ions, and a site for the binding of phenytoin. A computer programme and strategy were developed to permit the three-dimensional structures of potential target molecules to be viewed, prior to synthesis. Use of this programme led to the discovery of Boc-L-cystinyl-glycyl-L-prolyl-glycyl-L-prolyl-L-cystine-$OCHPh_2$. This compound, termed phenceptin, was synthesized from a linear precursor containing *tert*-butoxycarbonyl protection at the N-terminus, benzhydryl ester protection at the C-terminus, and trityl protection at sulfur. Detritylation and cyclization to phenceptin were accomplished with iodine in methanol–pyridine. Using an *n*-octanol membrane to study the kinetics of ion transport, phenceptin was found to transport sodium ions selectively, but only in its oxidized, cyclic form. This transport was inhibited significantly by one mol-equiv. of phenytoin, and not at all by biologically inactive analogs of the drug. The nature of the binding of phenytoin to phenceptin was examined by nuclear magnetic resonance, in *n*-C_8D_{17}-OH solvent, and found to involve hydrogen bonding of the drug to a glycine residue whose oxygen atom is involved in complexation to sodium ions.

SAUL WOLFE, RAYMOND JOHN BOWERS, HEE-SOOK SHIN, CHANG-KOOK SOHN, DONALD FREDRIC WEAVER ET KIYULL YANG. Can. J. Chem. **66**, 2751 (1988).

La diphényl-5,5 hydantoïne (phénytoïne) est le médicament le plus utilisé comme anticonvulsivant; toutefois, il provoque de nombreuses réactions secondaires. Même si son mode d'action chimique est inconnu, on croit que la phénytoïne agit principalement par interférence avec le transport des ions sodium à travers les membranes neuronales. Des études de structure/activité et caractère liphophilique/activité suggèrent que la drogue interagit avec son récepteur par le biais de liaisons hydrogènes avec la liaison amide N3—C4 et par une interaction aromatique/aromatique avec le substituant en C5. Puisque les canaux du sodium sont des peptides riches en cystéine dont la fonction dépend du processus redox cystéine/cystine, il a été suggéré que l'on pourrait répliquer l'action du récepteur de la phénytoïne à l'aide d'un cyclodepsipeptide approprié contenant une portion cystinyle, une cavité contenant cinq atomes d'oxygène orientés d'une façon trigonale/bipyramidale appropriée au transport sélectif d'ions sodium et d'un site pour la liaison de la phénytoïne. On a mis au point un programme d'ordinateur et une stratégie qui permettent de voir les structures tri-dimensionnelles des molécules cibles potentielles avant d'en réaliser la synthèse. L'utilisation de ce programme a conduit a la découverte du Boc-L-cystinyl-glycyl-L-prolyl-L-cystine-$OCHP_2$. On a synthétisé ce composé, appelé phenceptine, à partir d'un précurseur linéaire contenant le groupement protecteur *tert*-butoxycaronyle sur l'acide portant le N-terminal, un groupement protecteur ester benzhydryle sur l'acide du C-terminal et une protection trityle sur le soufre. On a réalise la détritylation et la cyclisation de la phenceptine à l'aide d'iode dans un mélange de méthanol et de pyridine. Utilisant un membrane de *n*-octanol pour étudier la cinétique du transport ionique, on a trouvé que la phenceptine transporte sélectivement les ions sodium uniquement dans sa forme oxydée, cyclique. Ce transport subit une inhibition importante par un équivalent molaire de phénytoïne; les analogues biologiquement inactifs de la drogue ne causent toutefois pas d'inhibition. Opérant dans le *n*-C_8H_{17}-OH comme solvant et faisant appel à la résonance magnétique nucléaire, on a examiné la nature de la liaison de la phénytoïne à la phenceptine; on a trouvé que celle-ci implique une liaison hydrogène de la drogue avec un résidu glycine dont l'atome d'oxygène est impliqué dans la complexation avec les ions sodium.

[Traduit par la revue]

Introduction

The epilepsies are a group of diverse disorders with a common central nervous system manifestation, the occurrence of seizures (convulsions). An accurate epidemiology of the illness is difficult, but various studies suggest an overall incidence of 1% in the general population (1). Ten times this number of persons require medical attention at some time during their lives as the result of a seizure.

A seizure is primarily an electrical event: a high voltage discharge of an assemblage of brain cells (neurons), and aberrant neuronal excitability is associated mainly with the ion transport behaviour of sodium channels (2). As these open and close sequentially throughout the cerebral cortex, an electrical discharge spreads from an initial focus, and the symptoms of the epileptic state become manifest.

Treatment of epilepsy is imperative, because brain damage and (or) death are not infrequent sequelae of untreated abnormal electrical activity. Any successful drug therapy for the control of seizures must function by interference with the development and propagation of this activity.

The most important drug for the control of seizures is 5,5-diphenylhydantoin (**1**), known in medicine as Dilantin or phenytoin (3). However, phenytoin and all other anticonvulsant drugs have deficiencies associated with their use: only 60% of epileptic patients can be controlled adequately (5) and each of the drugs exhibits many side effects.

Consequently, there is a need to develop new drugs for the

treatment of epilepsy, a point emphasized repeatedly in the medical literature (4, 5). The present work is concerned with the development and experimental evaluation of a biomimetic model of the activity of phenytoin. This is the first stage of a programme that, it is hoped, will eventually allow the design of novel anticonvulsants, whose activity is based on the mechanism of action of phenytoin.

Structure–activity and lipophilicity–activity relationships of phenytoin analogs

A search of the literature yielded data for over 800 analogs of phenytoin, about one quarter of which had been evaluated comparably using maximal electroshock techniques. Structure–activity studies have led to the view (6) that the phenytoin receptor interacts with the drug primarily through the formation of intermolecular hydrogen bonds, but also possesses a hydrophobic pocket that interacts with the C5 substituent. In addition, within the hydantoin ring, an unsubstituted N3—C4 amide bond is the most important, one phenyl group or a bulky aliphatic group is necessary at C5, and the introduction of one or more benzyl substituents at C5 causes loss of activity.

Conformational studies on 5-phenyl and 5-benzyl substituted hydantoins provide insight into the origin of the benzyl effect. In phenytoin, the phenyl groups are approximately perpendicular to the hydantoin ring (7); in 5-benzylhydantoin the phenyl group is approximately parallel to the hydantoin ring (8), in harmony with an early suggestion (9) concerning the existence of aromatic–amide interactions in phenylalanyl-containing peptides. To probe this point further, 3-ethyl-5-phenyl- (**2**) and 3-ethyl-5-benzyl-hydantoin (**3**) were synthesized (see Experimental), and their ^{1}Hmr spectra examined. In the 5-benzyl compound, both the methylene and the methyl hydrogens of the 3-ethyl group are shifted upfield by 0.3 ppm, as expected for a structure in which the aromatic ring lies over the ethyl group.

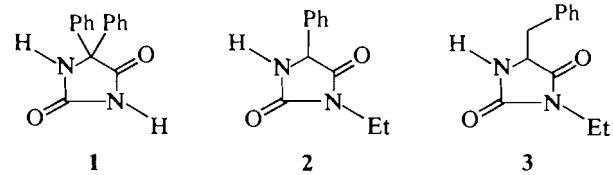
The existence of an aromatic–N3C4 amide interaction in a 5-benzylhydantoin would have two consequences: access by a receptor to the N3—C4 amide bond would be impaired; and the aromatic ring would no longer possess the proper orientation for interaction with the hydrophobic pocket of the receptor (cf. Fig. 12 of ref. 7).

It is also necessary that the drug reach this receptor, and this capability will depend upon the lipophilicity of the hydantoin (10, 11). Our examination of the literature (12) suggests that, although the contribution of lipophilicity cannot be ignored (13), the anticonvulsant activity of a hydantoin depends primarily upon its ability to bind to the phenytoin receptor. Any attempt to model this process requires information concerning the nature of this receptor and its chemical constitution.

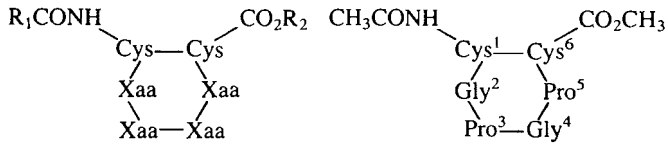
Phenytoin and the sodium channel

The anticonvulsant activity of phenytoin can be ascribed to a single demonstrable primary event: the specific inactivation of sodium channels (14, 15).

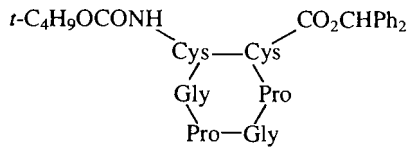
Recent studies (see ref. 16 for a review) have demonstrated that sodium channels are glycoproteins, containing up to 36% by weight of carbohydrate, principally sialic acid (7). Studies of the function of these channels suggest that the carbohydrate portion is directed extracellularly, and the peptide portion is directed intracellularly; the movement of ions occurs through a fixed pore or channel, rather than as part of a larger membrane macromolecule, and is selective for sodium. A model of the ion-selectivity filter, i.e., the narrowest region of the ion-conducting pore of the sodium channel, has been proposed (18).



1 **2** **3**



4 **5**



6

This consists of a 3 × 5 Å orifice *lined by oxygen atoms* (italics added).

All sodium channels contain a ca. 260 kD unit, and the primary structure of the peptide portion of this unit (M_r 208,321) in the electric eel, *Electrophorus electricus*, has been determined by Noda *et al.* (19). The peptide contains 36 cysteine residues, and shows sequence homology to the corresponding peptide of rat brain (20).

Hypothesis

Noda *et al.* (19) and Kosower (21) have developed models for the sodium channel of *Electrophorus electricus*, based on slightly different analyses of the structure of the 180-residue protein. In both models, the sodium binding site consists of a series of negatively charged (−) residues (Asp^-, Glu^-), and is surrounded by a series of positively charged (+) residues (Arg^+, Lys^+). Opening (activation) and closing (inactivation) of the channel is determined by conformational motion of side chains, e.g., (−, −, −, −) (open) ⇄ (−, −, −, +) (closed). In Kosower's model, possible (−) residues are Asp-908, Asp-910, Glu-943, and Glu-944; possible (+) residues are Arg-210, Arg-657, and Arg-1417.

If we accept such models as plausible representations of the chemical events associated with normal electrical behaviour, is it possible that aberrant behaviour is the result of the creation of additional sodium binding sites?

A number of reagents have been found to slow or prevent sodium channel inactivation, including *N*-bromoacetamide, *N*-chlorosuccinimide, *N*-bromosuccinimide, and *N*-chloro-*p*-toluenesulfonamide (chloramine-T) (22). All of these are mild oxidants; in a molecule containing an abundance of cysteine residues, the primary effect of such reagents must be to maintain the cysteine–cystine couple in its oxidized form. Significantly, sulfhydryl-specific reagents, such as *N*-ethylmaleimide and 5,5′-dithiobis-2-nitrobenzoic acid, neither slow nor prevent inactivation of sodium channels (22).

The simplest reagent for the oxidation of a mercaptan to a disulfide is O_2 (23), and it is known that hyperventilation (24) or hyperbaric oxygen (25) precipitate seizures, which can be suppressed with phenytoin.

We are, therefore, led to the hypothesis that the opening of

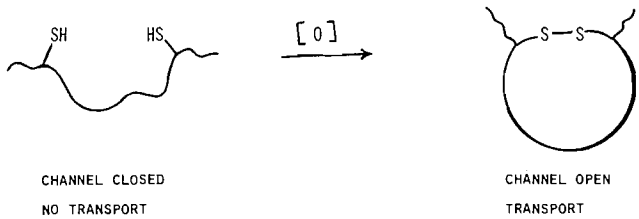


FIG. 1. Hypothesis of the present work: the opening and closing of sodium channels associated with abnormal electrical behaviour is a redox process.

sodium channels that initiates a seizure corresponds chemically to the creation of a sodium-selective *cyclodepsipeptide ionophore* (26), by an oxidative process, as depicted schematically in Fig. 1.[3]

The concept of "redox-switched" ionophores is not new. Shinkai and co-workers (28) and Raban *et al.* (29) have reported the syntheses of α,ω-dimercapto polyoxy compounds, which behave as pro-ionophores. In their reduced forms these compounds are poor ionophores; oxidation generates effective crown ether ionophores, whose cation selectivity depends on ring size. The oxidation reaction exhibits a marked template effect (28), and it has been argued (29) that "chemically switchable pro-ionophore–ionophore couples can serve as models for biological "ion gates", structures in which ion transport is initiated by an external stimulus."[3]

Phenceptin: design[4]

To convert the concept of Fig. 1 into a biomimetic model of the phenytoin receptor required a peptide containing two terminal cysteines. The number, nature, and sequence of the internal amino acids of this peptide had to be selected so that, in its reduced form, the compound would not behave as an ionophore. In its oxidized, cyclic form it was necessary that (*i*) the substance be sodium-selective; (*ii*) the transport of sodium ions be blocked by phenytoin; (*iii*) biologically inactive phenytoin analogs, e.g., 5,5-dibenzylhydantoin, have no effect on sodium transport.

Many cyclopeptides behave as ionophores (30), but none exhibits selectivity for sodium ions. The structures of cyclodepsipeptide ionophores and their complexes are also well established (26, 31), but none of these ionophores possesses the desired redox-switching feature, or selectivity for sodium. Although both natural (32) and synthetic (33) peptides containing the cysteine–cystine couple are known, their transport properties have not been studied.

Nevertheless, the dimensions of the cavity (3 × 5 Å) of the cyclic target were clear from the properties, already discussed, of the ion-selectivity filter of the sodium channel (18). These correspond closely to the hole size observed in the crystal structures of sodium-selective *crown ether* ionophores (26, 34), whose cavities have a ca. 4.6 Å diameter. The complexation of sodium ions is accomplished, in such cases, by a trigonal-bipyramidal arrangement of five oxygens.

[3]For an alternative model of a receptor channel, see ref. 27.

[4]The authors thank Professor Morton Raban and his co-workers for helpful discussions during the formative stages of this design project, including prepublication information concerning ref. 29, and its potential implications for our own work.

[c]$N-C'$ dihedral angle.
[d]$C_\alpha-C_\beta$ dihedral angle.

Examination of molecular models suggested that a cyclohexadepsipeptide would be the simplest system potentially containing these features (cf. ref. 35). This redefined the design problem to a structure of type **4**.

For the case of valinomycin, the best-known cyclodepsipeptide ion carrier (26, 31, 36), selection and syntheses of analogs (31, 37) have been conducted mainly by trial and error. This labour-intensive process was not feasible for us, and it was necessary to devise a theoretical strategy to screen candidate structures *prior* to synthesis. This strategy is based on molecular mechanics (38), and it has been documented fully (39).

Attention was focused, especially, on the use of proline and glycine residues. Proline residues were expected to reside on the exterior of the molecule, and enhance the lipophilicity required to maintain the ionophore in a membrane environment. In addition, the presence of this amino acid should inhibit transannular hydrogen bonding and excessive conformational lability (40). Glycine was expected to fit into a tightly turned cyclic peptide structure, promote cyclization (41), and reduce the possibility of steric interactions between amino acid side chains and a putative phenytoin binding site.

Figure 2 is the lowest energy structure calculated for the cyclohexadepsipeptide **5**, which contains a Gly-Pro-Gly-Pro sequence (42). The strategy consisted of a preliminary ECEPP search (39*b*, 43) of 200,000 structures, followed by final refinement of the 50 low energy structures identified in this search, using the peptide parameters (39*a*) of Allinger's MMP2(85) programme (44). Table 1 summarizes the dihedral angles of **5**.[5]

Inspection of Fig. 2 reveals that six carbonyl oxygens are directed towards the interior of the molecule, and that a trigonal-bipyramidal arrangement can be achieved from apical carbonyl oxygens of Cys^1 and Gly^4, whose separation is 5.56 Å, and equatorial carbonyl oxygens from three of CH_3CO, Gly^2, Pro^3, Cys^6. Three of the latter are amide carbonyls, and the fourth (Cys^6) is an ester carbonyl. The carbonyl oxygens of Gly^2, Pro^3, and Cys^6 form an equilateral triangle, and the diameter of the circumscribed circle is 3.63 Å.

In the potassium complex of valinomycin, the cation is bound

[5]Other peptides examined analogously led to low energy structures whose cavities did not contain the number and orientation of oxygen atoms considered necessary for complexation of sodium ions. For example, with Gly-Gly-Gly-Gly, Ala-Pro-Ala-Pro, and Pro-Pro-Pro-Pro as the four internal amino acids, substantial conformational changes appeared to be necessary to achieve a backbone structure analogous to **5**.

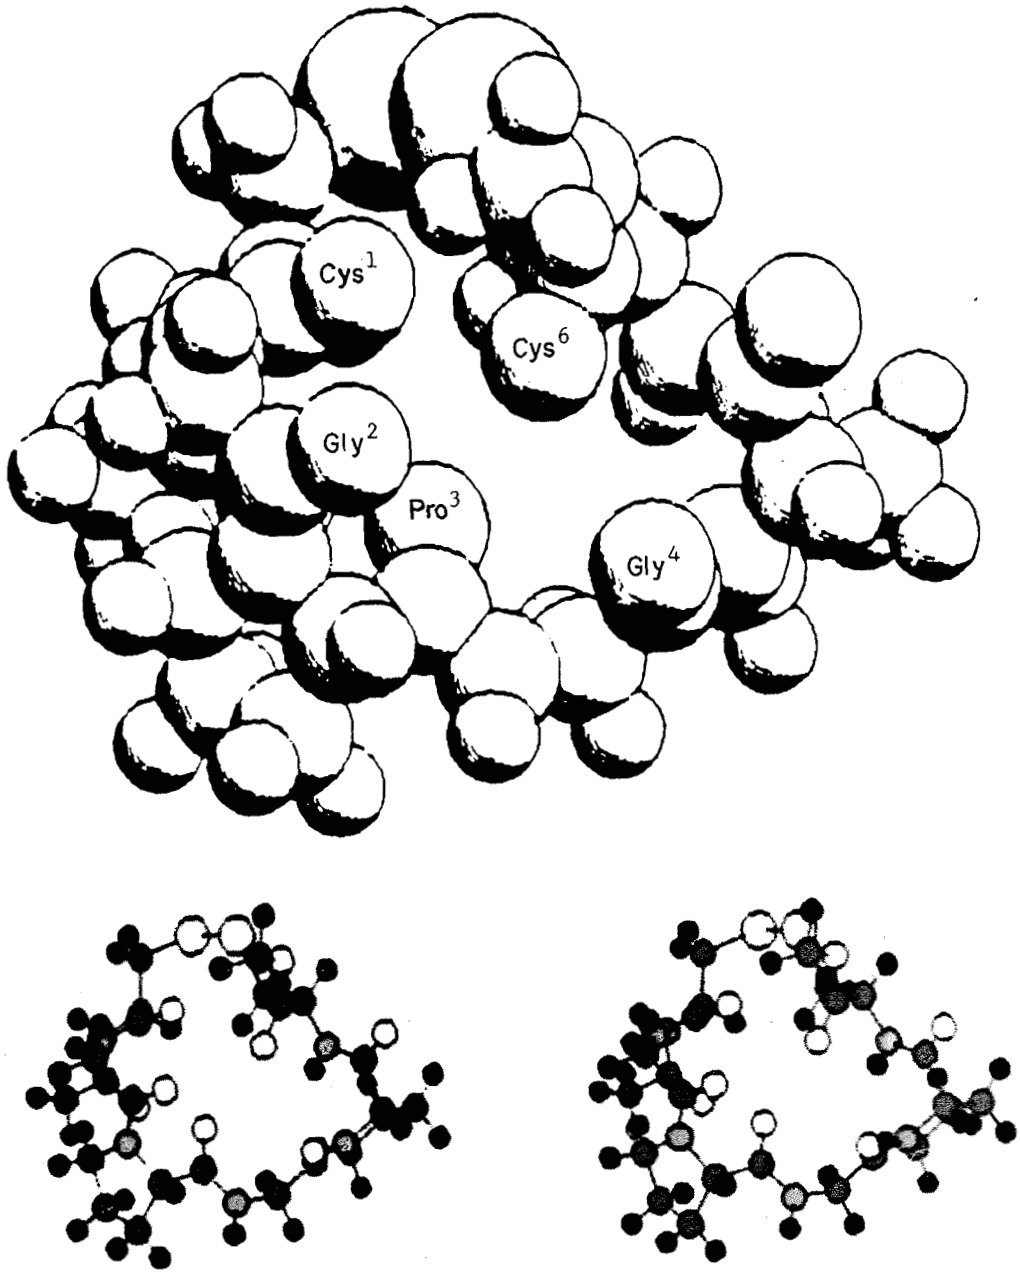

FIG. 2. The lowest energy structure calculated for the cyclohexadepsipeptide **5**. The atoms labelled Cys^1, Gly^2, ... are the carbonyl oxygens of these residues. The lower view of **5** requires a diastereoscopic viewer.

octahedrally to six ester carbonyl oxygens (26). In the potassium complex of enniatin B, three amide carbonyl and three ester carbonyl oxygens bind to the cation (26). Thus, binding to both ester and amide carbonyl oxygens is known.

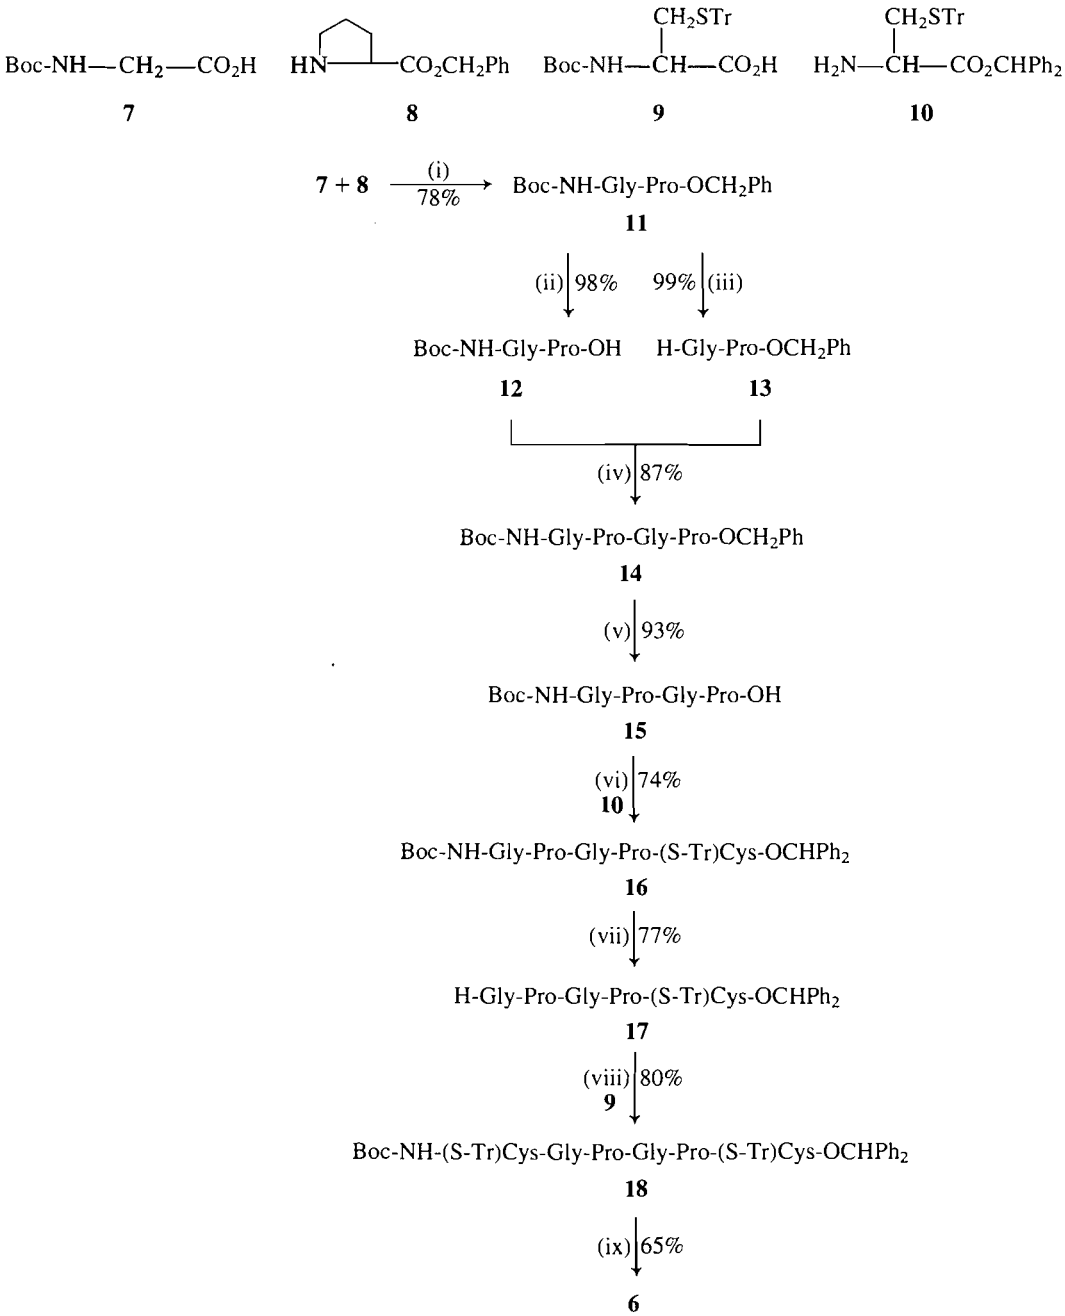
Compound **6** was selected for synthesis and experimental evaluation as a biomimetic model of the phenytoin receptor. In **6**, the replacement of CH_3CO by *t*-BuOCO was expected to reduce the basicity of this carbonyl oxygen, and promote the formation of a trigonal-bipyramidal cation complex. According to Fig. 2, the C-terminal ester methyl group lies over the carbonyl oxygens of Gly^2 and Gly^4; if one of these oxygens were to serve as a phenytoin binding site, aromatic–aromatic interactions would be promoted by the attachment of one or more phenyl substituents to the methyl carbon. The choice of benzyhydryl at this position meets this requirement, and simplifies the synthesis.

The cyclohexadepsipeptide **6** has been named "phenceptin" (*phen*ytoin re*cept*or).

Phenceptin: synthesis

The synthesis of phenceptin was carried out from Boc-glycine (**7**), the benzyl ester of L-proline (**8**), Boc-*S*-trityl-L-cysteine (**9**), and the benzhydryl ester of *S*-trityl-L-cysteine (**10**).

As summarized in Scheme 1, coupling of **7** with **8** afforded **11**, fully protected Gly-Pro. This was O-deprotected by hydro-



Reagents: (i) EEDQ; (ii) 10% Pd/C; (iii) HCl; (iv) EEDQ; (v) 10% Pd/C; (vi) EEDQ; (vii) HCO_2H; (viii) EEDQ; (ix) I_2-MeOH–pyridine

SCHEME 1

genolysis to **12**, and N-deprotected with HCl to **13**. Coupling of **12** with **13** gave **14**, fully protected Gly-Pro-Gly-Pro. Hydrogenolysis of **14** exposed the terminal carboxyl group (**15**), and coupling with **10** yielded the fully protected pentapeptide **16**, Gly-Pro-Gly-Pro-Cys. This was deprotected selectively at the N-terminus, using anhydrous formic acid (45), and the product (**17**) was coupled with **9** to form the acyclic, fully protected hexapeptide Cys-Gly-Pro-Gly-Pro-Cys (**18**). Removal of the *S*-trityl protecting groups, and cyclization to phenceptin were accomplished by treatment of **18** with iodine, in a mixture of methanol and pyridine (46).

Phenceptin was obtained in analytically pure form as an amorphous solid, which has not yet been crystallized. Although the compound is homogeneous on thin-layer chromatography in several systems, its 400 MHz ^{1}Hmr spectrum (in $CDCl_3$) is temperature dependent and suggests a 4:1 mixture of two conformations.[6] Comparison of the spectrum of phenceptin with those of the intermediates of the synthesis allowed assignment of proton resonances associated with the different residues (see Experimental).

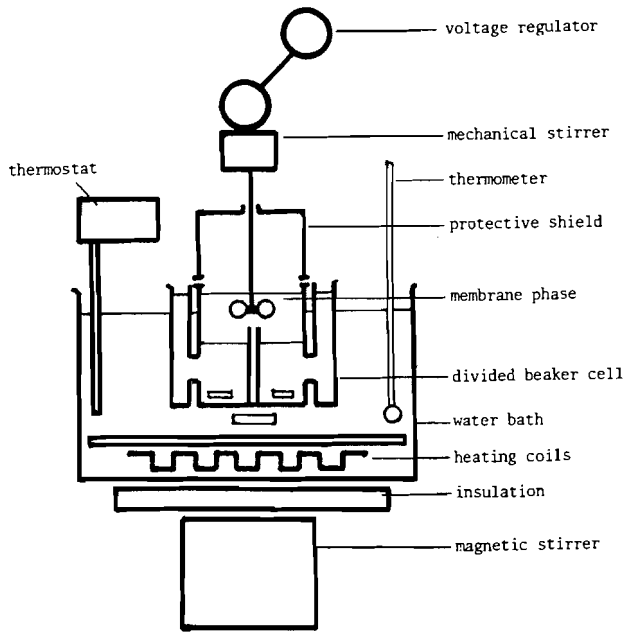

FIG. 3. Divided beaker cell for kinetic studies of cation transport through a 1-octanol membrane.

Cation transport through an *n*-octanol membrane

Most workers employ a U-tube to model the process of ion transport across a liquid membrane. In such an apparatus, water occupies each of the arms, and an organic solvent denser than water, e.g., chloroform, is placed in the base. If a salt is added to one of the arms and the organic solvent is stirred, no transport to the second arm is observed until a water-insoluble ionophore is added to the system. When an ionophore is present, the movement of salt from one arm to the other represents a biomimetic model of transport from an extracellular phase, through a membrane, to an intracellular phase.

This system did not seem biologically appropriate for an examination of the properties of phenceptin, for several reasons: (*i*) chloroform is not a proper model of a cell membrane; (*ii*) the membrane employed in a typical U-cell is too thick, averaging 8–10 cm between the two aqueous phases; (*iii*) the area of surface contact between each aqueous phase and the membrane is typically of the order of 1.15 cm^2.

The selection of 1-octanol as the membrane phase seemed more meaningful. It has been known for many years (48) that pharmacological activity can be related to octanol–water partition coefficients.

This choice necessitated a modification of the usual apparatus, because 1-octanol is less dense than water. Figure 3 shows the "divided beaker" transport cell devised for this purpose. This apparatus minimizes the separation of the intracellular and extracellular aqueous phases, and increases the area of surface contact between the membrane phase and each aqueous phase to 39.3 cm^2. All phases are stirred continuously to minimize effects of concentration gradients upon solute distribution; a series of voltage regulators control the stirring devices, and promote experimental reproducibility. All kinetic measurements were performed at 37.0 ± 0.1°C.

To evaluate the capabilities of the apparatus, an initial set of experiments was performed, using as ionophores the crown ethers 12-crown-4, 15-crown-5, and 18-crown-6. In a typical run the ionophore was dissolved in the octanol layer at a concentration of 150 μM. The extracellular aqueous phase contained an inorganic salt at a concentration of 20 mM, and the intracellular aqueous phase consisted of redistilled water.

The transport rate was determined through periodic sampling of the intracellular phase, and measurement of the concentration of the anion that migrates concomitantly with the cation to preserve electrical neutrality. With thiocyanate as the counter-anion, 12-crown-4 prefers Li^+ over Na^+, 18-crown-6 prefers K^+ over Na^+, and 15-crown-5 is selective for Na^+ (cf. refs. 26 and 31).

The behaviour of 15-crown-5 was studied more fully. The role of the counter-anion was examined using sodium chloride, sodium thiocyanate, and sodium picrate. This was found to be picrate ≈ thiocyanate ≫ chloride. Evidently the weakly hydrated picrate and thiocyanate anions are transported more rapidly than the small, spherical, strongly hydrated chloride anion. This trend is well established for chloroform membranes (49).

Chloride is obviously more appropriate than picrate for use in a biomimetic process, but this choice would have led to inconveniently slow transport rates. The problem might, in principle, be overcome by measurement of junction potentials (50) in place of transport rates, but it was considered that this was not essential at this stage. Thiocyanate was selected as a compromise, and all subsequent work was performed with this anion.

Further studies demonstrated that the transport of sodium thiocyanate is first order in the concentration of ionophore, as is observed in a U-cell with a chloroform membrane (51), and second order in the concentration of sodium thiocyanate (data not shown); this has also been observed with a chloroform membrane (25). Thus, replacement of the standard chloroform membrane with a biologically more appropriate 1-octanol membrane does not appear to alter the mechanism of the transport process when 15-crown-5 is employed as the membrane carrier. It can be concluded that the divided beaker cell is suitable for experimental studies with phenceptin.

Phenceptin is a redox-switched sodium selective ionophore with specific phenytoin binding capability

Figure 4 compares the transport behaviour of phenceptin and 15-crown-5. Under the conditions [NaSCN] = 20 mM, [Ionophore] = 150 μM, the transport rates are 0.347 μM/h with phenceptin, and 0.435 μM/h with 15-crown-5.

Reduction of phenceptin with dithiothreitol gave the acyclic compound **19**. Neither this peptide nor the phenceptin precursor **18** transported sodium ions at a measurable rate.

Replacement of NaSCN by KSCN led to the transport of potassium ions at a rate of 0.204 μM/h (Fig. 4). The selectivity for sodium ions is, therefore, 1.7. This compares to the Na^+/K^+ selectivity of 5.9 found with 15-crown-5, and the Na^+/K^+ selectivity of 12.5 observed in a functioning sodium channel (16).

These experiments demonstrate phenceptin to be a redox-switched sodium selective ionophore, as required for our biomimetic model of the sodium channel.

The effect of phenytoin on the behaviour of various membrane carriers could now be examined. Preliminary experiments were performed with the 15-crown-5/NaSCN and 18-crown-6/NaSCN systems. For these studies, the cell was operated initially for 4 h, to ensure that sodium transport was occurring. Then 1.0 mol-equiv. of phenytoin was injected into the extracellular phase. There was no change in the transport rate. The same result was obtained in subsequent experiments in which 0.5,

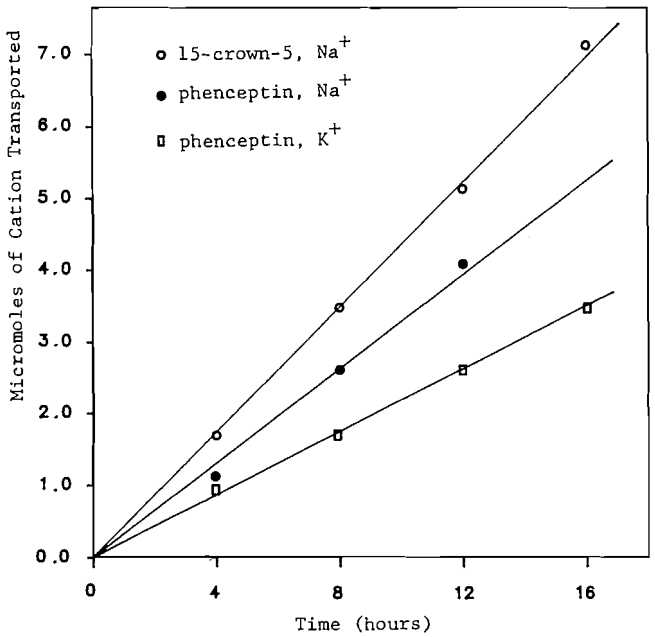

FIG. 4. Transport of sodium thiocyanate by 15-crown-5 (open circles) and by phenceptin (closed circles), and transport of potassium thiocyanate by phenceptin (squares). All data refer to experiments at 37.0°C, with cation and ionophore concentrations of 20 mM and 150 μM, respectively.

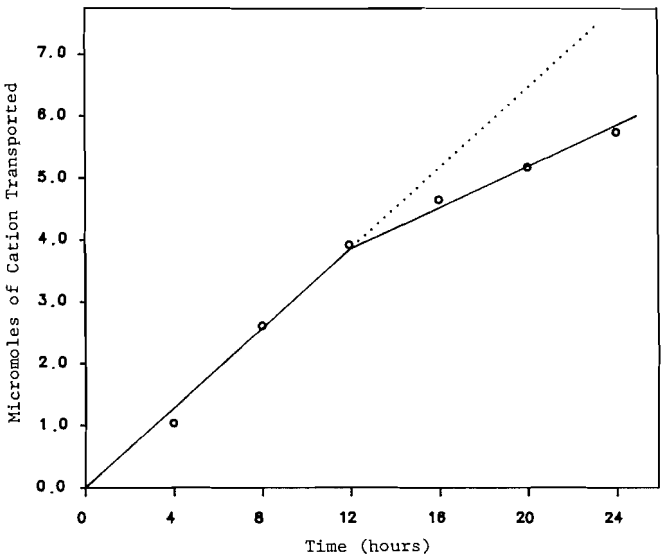

FIG. 5. Effect of addition of 5,5-diphenylhydantoin (one molar-equivalent) upon sodium ion transport by phenceptin. The hydantoin was added after 12 h, using the conditions of Fig. 4.

2.0, and 1000 mol-equiv. of phenytoin were injected after 4 h. It is clear that phenytoin has no effect on sodium ion transport by crown ether ionophores.

An entirely different result is obtained when these experiments are repeated with the phenceptin/NaSCN system. Figure 5 shows the effect of an injection of *1 mol-equiv.* of phenytoin after 12 h of sodium transport under the usual conditions. There is an immediate reduction in the rate of transport, which then continues at 40% of the original rate (60% inhibition).

However, when the *biologically inactive* 5,5-dibenzylhydantoin is substituted for phenytoin in such an experiment (Fig. 6), there is a very slight *increase* in the transport rate.

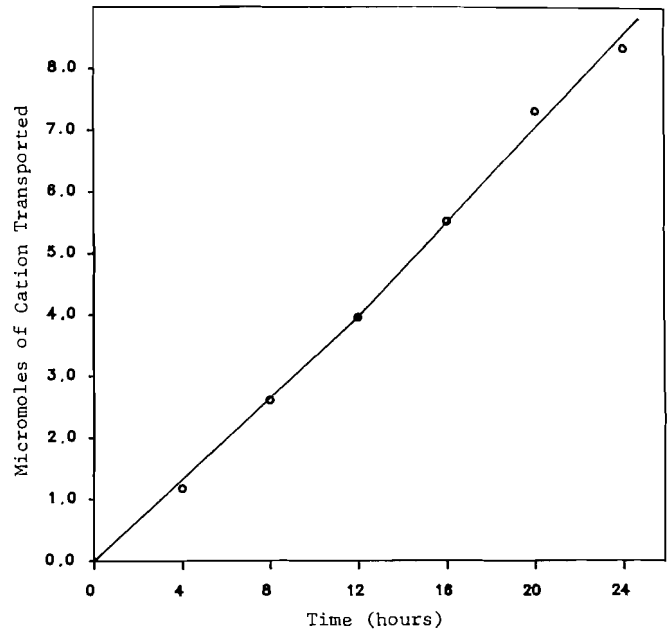

FIG. 6. Effect of addition of 5,5-dibenzylhydantoin (one molar-equivalent) upon sodium ion transport by phenceptin. The hydantoin was added after 12 h, using the conditions of Fig. 4.

Phenceptin is, therefore, a valid biomimetic model of a sodium channel phenytoin receptor.

Nature of the interaction between phenytoin and phenceptin

The inhibition of sodium ion transport by phenceptin was found to be linear in the concentration of added phenytoin, up to a 1:1 [phenytoin]/[phenceptin] ratio. Further increases in the phenytoin concentration did not increase the inhibition beyond the 60% observed with the 1:1 mixture. These observations suggested that the inhibition of sodium ion transport is achieved through the formation of a 1:1 complex.

The structure of this complex was studied by 400 MHz ^{1}Hmr at 37°C, using *n*-C_8D_{17}-OH as the solvent. Figure 7A shows the aromatic region of phenceptin in this solvent; addition of one mol-equiv. of phenytoin (Fig. 7B) leads to a significant change in the chemical shift differences of the aromatic protons of phenceptin. An aromatic–aromatic interaction (53) is suggested by these changes, but the data do not allow the nature of this interaction to be specified with certainty.

The effect of phenytoin upon the methylene protons of Gly^4 of phenceptin is more interesting, and can be interpreted. Figure 8A shows this region of the spectrum for a solution of phenceptin in *n*-C_8D_{17}-OH; Fig. 8B is the spectrum obtained immediately after addition of 1 mol-equiv. of phenytoin; Fig. 8C is the spectrum that results when the solution of 8B is shaken overnight with D_2O.

The glycine methylene protons are anisochronous because of the asymmetric environment, but coupling to the adjacent N—H is not observed in the hydroxylic solvent as a result of rapid exchange with the O—H protons. Addition of phenytoin must lead to the formation of a fairly strong complex with the glycyl amide hydrogen, because coupling of N—H to adjacent methylene protons is now observed. That this is the correct explanation of Fig. 8B is seen by the restoration of the original spectrum (Fig. 8C) following exchange of N—H with D_2O.

These observations can be understood by reference to the calculated phenceptin structure of Fig. 2. Only the N—H and

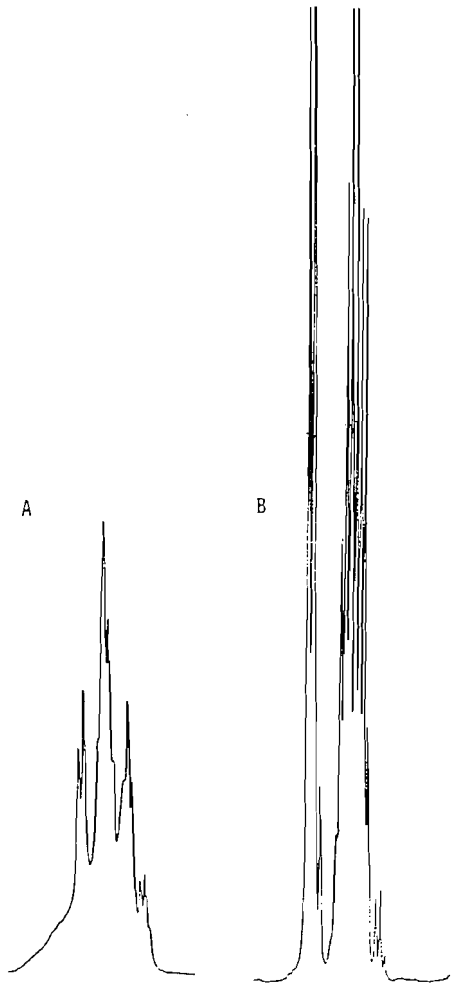

FIG. 7. (A) Aromatic region of the ^{1}Hmr spectrum of phenceptin in n-C_8D_{17}-OH solvent; (B) after addition of phenytoin (1 mol-equiv.).

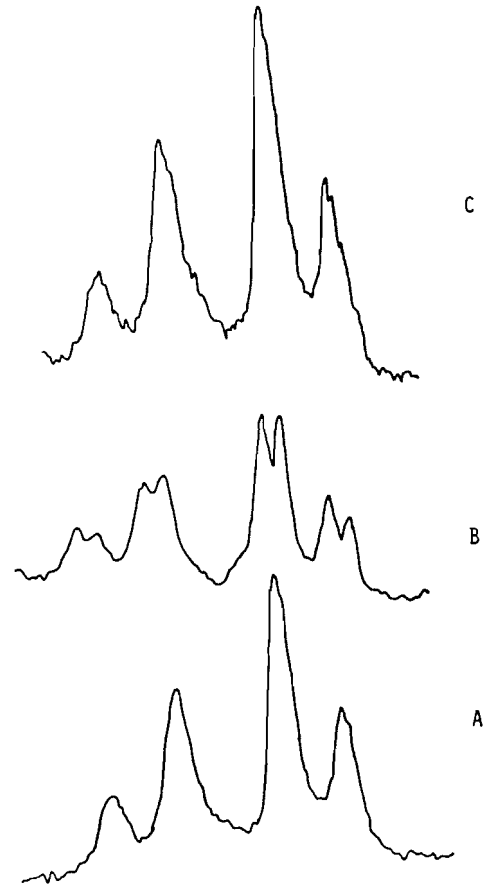

FIG. 8. (A) Glycine region of the ^{1}Hmr spectrum of phenceptin in n-C_8D_{17}-OH solvent; (B) after addition of phenytoin (1 mol-equiv.); (C) after shaking the solution of B overnight with D_2O.

C=O of Gly^4 possess orientations capable of complexation to an amide bond of phenytoin. This is shown schematically in Fig. 9, which provides an explanation for the inhibition of sodium ion transport by phenytoin, if the carbonyl oxygen of Gly^4 is also a cation binding site. The experimental and theoretical studies suggested by Fig. 9 have been completed, and will be published separately (47).

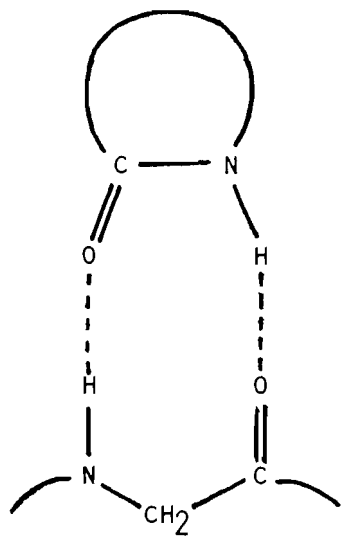

FIG. 9. Proposed interaction between Gly^4 of phenceptin and phenytoin.

Experimental

A. Syntheses

General

All solvents (Fisher or Anachemia, reagent grade) were purified before use, by standard methods (55–57). Several reagents were also purified before use. 2-*tert*-Butoxycarbonyloxyimino-2-phenylacetonitrile (BOC-ON) (Aldrich) was recrystallized from warm methanol. 1-Ethoxycarbonyl-2-ethoxy-1,2-dihydroquinoline (EEDQ) (Aldrich, 97% pure) was recrystallized from methylene chloride – ethyl ether. Diphenylhydantoin (Aldrich, Gold Label) was recrystallized twice from ethanol. Boc-glycine (Sigma) and L-proline benzyl ester hydrochloride (Sigma) were used as received.

Proton nmr spectra of hydantoins were obtained at 60 MHz on Varian T60 or EM360 spectrometers. Proton nmr spectra of peptides were recorded at 400 MHz on a Bruker AM400 spectrometer. Chemical shifts are reported in δ values relative to tetramethylsilane or 2,2-dimethyl-2-sila-pentane-5-sulfonate as internal standards. Infrared (ir) spectra were taken on a Perkin–Elmer 180 spectrometer. Absorption spectroscopy readings were made on a Bausch and Lomb Spectronic 20 spectrophotometer. Melting points were determined on a Meltemp apparatus and are uncorrected. Thin-layer chromatography (tlc) was performed on precoated Brinkmann silica gel 60F-254 plates with aluminium backing; spots were visualized with ninhydrin, palladium chloride, iodine vapour, or ultraviolet light.

Hydantoins

3-Ethyl-5-phenylhydantoin (2): L-Phenylglycine (Aldrich, 1.97 g, 0.013 mol) was dissolved in water (6.0 mL) containing potassium hydroxide (Fisher, 0.91 g, 0.016 mol), and ethyl isocyanate (Aldrich, 1.07 g, 0.015 mol) was added dropwise with stirring, during 3 h. The mixture was stirred overnight, filtered, and the filtrate acidified to pH 1.0. The *N*-ethylhydantoic acid was collected, dried, and cyclized by refluxing for 3 h with 6 N HCl (10.0 mL). The product crystallized upon cooling and was recrystallized from ethanol, 1.98 g (74%); mp 138°C; ir (Nujol): 1710, 1760 cm^{-1}; ^{1}Hmr ($CDCl_3$): 1.22 (3H, t), 3.60 (2H, q), 5.03 (1H, s), 6.80 (1H, s), 7.37 (5H, m); tlc: R_f 0.56 (methylene chloride: acetone: acetic acid 100.0: 100.0: 0.5), R_f 0.61 (ethanol: acetic acid 20:1), R_f 0.84 (methylene chloride: methanol 5:2).

3-Ethyl-5-benzylhydantoin (3): The synthesis was carried out as for **2**, except that L-phenylalanine (Sigma, 2.15 g, 0.013 mol) was used in place of phenylglycine. The product was recrystallized twice from ethanol to give 2.13 g (75%), mp 145°C; ir (Nujol): 1708, 1758 cm^{-1}; ^{1}Hmr ($CDCl_3$): 0.90 (3H, t), 3.02 (2H, q), 3.30 (2H, q), 4.19 (1H, t), 5.90 (1H, s), 7.37 (5H, m); tlc: R_f 0.57 (methylene chloride: acetone: acetic acid 100.0: 100.0: 0.5), R_f 0.63 (ethanol: acetic acid 20:1), R_f 0.85 (methylene chloride: methanol 5:2).

5,5-Dibenzylhydantoin: 1,3-Diphenyl-2-propanone (Aldrich, 4.10 g, 0.02 mol), potassium cyanide (Fisher, 2.5 g, 0.039 mol), and ammonium carbonate (Fisher, 7.4 g, 0.077 mol) were mixed with 50% aqueous ethanol (80.0 mL) and heated at 60°C for 15 h, to give a clear yellow solution. A slush of crystals formed rapidly when this solution was cooled. This crude product was dissolved in 5% sodium hydroxide (50.0 mL), filtered, treated with decolourizing carbon, and reprecipitated by the addition of an excess of concentrated hydrochloric acid. The product was recrystallized twice from 60% aqueous ethanol to give 3.92 g (70%) of material, mp 304–306°C, (lit. (58) mp 305°C); ir (Nujol): 1705, 1720, 1754 cm^{-1}; ^{1}Hmr (CD_3OD): 2.94 (2H, d, 15 Hz), 3.23 (2H, d, 15 Hz), 7.24 (10H, m); tlc: R_f 0.66 (methylene chloride: acetone: acetic acid 100.0: 100.0: 0.5), R_f 0.69 (ethanol: acetic acid 20:1), R_f 0.83 (methylene chloride: methanol 5:2).

Synthesis of phenceptin

N-Boc-S-trityl-L-cysteine dicyclohexylamine salt (9): *S*-Trityl-L-cysteine (8.74 g, 24.1 mmol) was suspended in dichloromethane (50.0 mL) and dicyclohexylamine (Aldrich, 5.3 mL, 26.5 mmol) was added, followed by BOC-ON (6.48 g, 26.4 mmol). The solution was stirred at room temperature for 24 h. Removal of the solvent under reduced pressure yielded a yellow foam, to which was added anhydrous ether (200 mL). The product crystallized after storage at −20°C for 15 h, and it was collected, dried, and recrystallized from absolute methanol. 13.0 g, mp 215–216°C, (lit. (46) mp 211–212°C).

S-Trityl-L-cysteine benzhydryl ester (10): A mixture of benzophenone (Aldrich, 25.2 g, 0.138 mol), hydrazine hydrate (BDH, 10.0 g, 0.2 mol), and absolute ethanol (15 mL) was refluxed for 10 h. Benzophenone hydrazone was recrystallized from 95% ethanol to give long pale brown needles: 22 g (80%), mp 96–98°C (lit. (59) mp 98°C). A solution of benzophenone hydrazone (5.8 g, 30 mmol), anhydrous magnesium sulfate (Anachemia, 3.0 g), and methylene chloride (60.0 mL) was stirred rapidly in an ice-bath. To this was added activated manganese dioxide (Aldrich, 9.2 g) in one portion. Stirring was continued for 2 h at 0°C and for 1 h at room temperature. Removal of the solvent gave a dark purple oil, which, upon storage at −16°C, afforded red needles of diphenyldiazomethane: 5.2 g (88%), mp 33–34°C (lit. (60) mp 35°C).

S-Trityl-L-cysteine (11.0 g, 30.3 mmol), diphenyldiazomethane 11.74 g, 60.6 mmol), methanol (100 mL), and methylene chloride (150 mL) were mixed, yielding a suspension, which was stirred at room temperature. After 12 h a pink solution had formed. Evaporation of the solvent gave an oil, which was dissolved in a minimum of acetone and treated with *p*-toluenesulfonic acid (Eastman, 5.76 g, 30.3 mmol); The acetone was evaporated, and subsequent trituration with hexane produced an amorphous solid, 21.33 g (98%); $[\alpha_D]$ 70.7 (*c* 1.35, methanol); tlc (free base); R_f 0.78 (methylene chloride: ethyl acetate 9:1). The compound gave a single spot, which was visualized with ninhydrin and with palladium chloride spray.

N-Boc-glycyl-L-proline benzyl ester (11): A solution of *N*-Boc-glycine (8.76 g, 50 mmol) and EEDQ (Aldrich, 13.6 g, 55 mmol) in methylene chloride (120 mL) was stirred for 5 min. Then L-proline benzyl ester hydrochloride (12.08 g, 50 mmol), triethylamine (Anachemia, 5.16 g, 51 mmol), and additional methylene chloride (40 mL) were added. Stirring was continued at room temperature for 20 h. The reaction mixture was washed successively with 10% aqueous potassium bisulfate (5 × 160 mL), saturated brine (1 × 160 mL), saturated sodium bicarbonate (3 × 160 mL), and brine (1 × 160 mL), dried over anhydrous magnesium sulfate, and evaporated to give a viscous oil. This was dissolved in warm ethyl acetate (15 mL), and hexane was added to the cloud-point (100 mL). After overnight storage at 4°C, the product crystallized, and was recrystallized twice from ethyl acetate – hexane to give colourless needles, 14.24 g (78%), mp 77–78°C (lit. (61) mp 76–77°C); ^{1}Hmr ($CDCl_3$): 1.47 (9H, s, *t*-Bu), 2.02 (3H, m, Pro β- + γ-CH_2), 2.20 (1H, m, Pro β- + γ-CH_2), 3.47 (1H, m, Pro δ-CH_2), 3.60 (1H, m, Pro δ-CH_2), 3.92 (1H, dd, 7, 18 Hz, Gly CH_2), 4.02 (1H, dd, 7, 18 Hz, Gly CH_2), 4.59 (1H, q, 5.0, 7.5 Hz, Pro α-H), 5.44 (1H, br s, urethane N-H), 7.37 (5H, d, aromatic), tlc: R_f 0.43 (methylene chloride: ethyl acetate, 9:1), R_f 0.86 (methylene chloride: methanol 5:2), one spot, ninhydrin negative.

N-Boc-glycyl-L-proline (12): *N*-Boc-glycyl-L-proline benzyl ester (14.0 g, 38.7 mmol) was dissolved in methanol (300 mL), and 10% palladium on carbon (Aldrich, 1.01 g) was added under nitrogen. The reaction vessel was purged three times with nitrogen and three times with hydrogen, and the mixture was then stirred for 4 h under hydrogen at atmospheric pressure. The catalyst was removed by filtration through diatomaceous earth (Fisher, Celite), and the filtrate was evaporated to a viscous oil. After trituration with ethyl acetate – ethyl ether (50 mL ethyl acetate, 50 mL ethyl ether), a white crystalline solid formed, 9.75 g (98%), mp 145–146°C; ^{1}Hmr ($CDCl_3$): 1.45 (9H, s, Boc), 2.08 (3H, m, Pro β- + γ-CH_2), 2.26 (1H, m, Pro β- + γ-CH_2), 3.48 (1H, m, Pro δ-CH_2), 3.58 (1H, m, Pro δ-CH_2), 3.94 (1H, q, 5, 20 Hz, Gly CH_2), 4.08 (1H, q, 6, 20 Hz, Gly CH_2), 4.60 (1H, q, 6, 8 Hz, Pro α-H), 5.51 (1H, br, urethane N-H), 9.13 (1H, br s, CO_2H); tlc: R_f 0.41 (methylene chloride: methanol 5:2), one spot, ninhydrin negative. The compound became ninydrin positive after pretreatment with formic acid.

Glycyl-L-proline benzyl ester hydrochloride (13): *N*-Boc-glycyl-L-proline benzyl ester (13.91 g, 38.4 mmol) was dissolved in dry ethyl acetate (360 mL). The solution was cooled to 0°C in an ice-bath, and anhydrous hydrogen chloride gas (Matheson Gas Products) was bubbled into the solution for 25 min. Stirring was continued at 0°C for 1 h, and then at room temperature for an additional 30 min. The solvent was then removed at 26°C to yield a white foam, which was crystallized from ethanol (20 mL) and ether (200 mL), 11.21 g (100%), mp 108–113°C; ^{1}Hmr ($CDCl_3$): 1.90 (3H, br, Pro β- + γ-CH_2), 2.12 (1H, br, Pro β- + γ-CH_2), 3.54 (2H, br, Pro δ-CH_2), 4.03 (1H, d, 17.5 Hz, gly CH_2), 4.17 (1H, d, 17.5 Hz, Gly CH_2), 4.60 (1H, d, 7 Hz, Pro α-H), 5.11 (1H, d, 14 Hz, CH_2Ph), 5.18 (1H, d, 14 Hz, CH_2Ph), 7.35 (5H, d, Ph), 8.36 (3H, br, NH_3^+); tlc: R_f 0.46 (methylene chloride: methanol 5:2). The compound gave one spot which was ninhydrin positive.

N-Boc-glycyl-L-prolyl-glycyl-L-proline benzyl ester (14): A solution of *N*-Boc-glycyl-L-proline (9.71 g, 38 mmol) and EEDQ (Aldrich, 10.32 g, 42 mmol) in methylene chloride (250 mL) was stirred at room temperature for 5 min, and glycyl-L-proline benzyl ester hydrochloride (11.10 g, 38 mmol) and triethylamine (BDH, 3.84 g, 38 mmol) were then added. The resulting solution was stirred at room temperature for 20 h and then washed successively with 10% aqueous potassium bisulfate (3 × 250 mL), saturated brine (2 × 250 mL), saturated sodium bicarbonate (3 × 250 mL), saturated brine (1 × 250 mL), dried over anhydrous sodium sulfate, and evaporated to a white amorphous solid. This was crystallized from ethyl acetate – hexane, and then recrystallized from acetone (25 mL) and hexane (50 mL), 16.23 g (87%), mp 162–164°C (lit. (42) mp 162–163°C); ^{1}Hmr ($CDCl_3$): 1.47 (9H, s, Boc), 2.04 (4H, m, Pro CH_2), 2.20 (4H, m, Pro CH_2), 3.46 (2H, m, Pro δ-CH_2), 3.60 (2H, m, Pro δ-CH_2), 3.90–4.16 (4H, m, glycine CH_2), 4.60 (2H, m, Pro α-H), 5.16 (1H, d, 12 Hz, benzyl), 5.22 (1H, d, 12 Hz, benzyl), 5.49 (1H, br, urethane N-H), 7.21 (1H,

For personal use only.

br, NH), 7.38 (5H, br d, aromatic), tlc: R_f 0.38 (methylene chloride: acetone: acetic acid 100.0: 100.0: 0.5), R_f 0.81 (methylene chloride: methanol 5:2), one spot, ninhydrin negative.

N-Boc-glycyl-L-prolyl-glycyl-L-proline (15): *N*-Boc-glycyl-L-prolyl-glycyl-L-proline benzyl ester (5.0 g, 9.6 mmol) was dissolved in methanol (350 mL), and 10% palladium on carbon (Alfa, 800 mg) was added under nitrogen. The reaction vessel was purged three times with nitrogen and three times with hydrogen, and the mixture was then stirred vigorously for 5 h under hydrogen at atmospheric pressure. The catalyst was removed by filtration through diatomaceous earth (Fisher, Celite) and the filtrate was evaporated to dryness under reduced pressure to give a white foam, which crystallized from ethyl acetate. Three recrystallizations from ethyl acetate gave 3.83 g (93%), mp 191–193°C; $[\alpha_D]$ −135° (*c* 1.5, methanol); ^{1}Hmr ($CDCl_3$): 1.46 (9H, s, *tert*-butyl), 1.94–2.32 (8H, m, Pro β- + γ-CH_2), 3.45–3.62 (4H, m, Pro δ-CH_2), 3.69–4.26 (4H, m, overlapping Gly CH_2), 4.52 (1H, m, Pro α-H), 4.60 (1H, m, Pro α-H), 5.60 (1H, br, urethane NH), 7.51 (1H, br, NH). *Anal.* calcd. for $C_{19}H_{30}N_4O_7$: C 53.46, H 7.03, N 13.13; found: C 53.54, H 7.31, N 12.95.

N-Boc-glycyl-L-prolyl-glycyl-L-prolyl-S-trityl-L-cysteine benzhydryl ester (16): A solution of *N*-Boc-glycyl-L-prolyl-glycyl-L-proline (7.0 g, 16.63 mmol) and EEDQ (Aldrich, 4.52 g, 18.3 mmol) in methanol (200 mL) was stirred for 5 min, and *S*-trityl-L-cysteine benzhydryl ester *p*-toluenesulfonate (11.67 g, 16.63 mmol) and triethylamine (1.68 g, 16.63 mmol) were then added. The solution was stirred for 44 h, and then evaporated to an oily residue. This was dissolved in ethyl acetate (170 mL) and washed successively with 10% potassium bisulfate (5 × 170 mL), saturated brine (1 × 170 mL), saturated sodium bicarbonate (3 × 170 mL), and brine (1 × 170 mL), dried over anhydrous sodium sulfate, and evaporated under reduced pressure. The residue was converted to a foam by addition of methylene chloride (50 mL) and removal of the solvent, followed by repetition of this process twice more. This foam crystallized from ethyl acetate (26 mL) and hexane (130 mL), (11.75 g (75%), mp 110–120°C; $[\alpha_D]$ −55.8° (*c* 1.25, methanol); ^{1}Hmr ($CDCl_3$): 1.44 (9H, s, *tert*-butyl), 1.92 (6H, m, Pro β- and γ-CH_2), 2.21 (2H, m, Pro β- and γ-CH_2), 2.66 (2H, m, Cys CH_2), 3.30–3.52 (4H, m, Pro δ-CH_2), 3.83–4.16 (4H, m, Gly CH_2), 4.47 (1H, m, Cys α-H), 4.54 (2H, m, Pro α-H), 5.45 (1H, br, urethane NH), 6.80 (1H, s, benzhydryl), 7.12 (1H, d, 12 Hz, NH), 7.28 (25H, m, aromatic); tlc: R_f 0.51 (methylene chloride: acetone: acetic acid 100.0: 100.0: 0.5), R_f 0.81 (methylene chloride: methanol 5:2). The compound gave a single spot, which was ninhydrin negative but readily visualized with palladium chloride spray.

Glycyl-L-prolyl-glycyl-L-prolyl-S-trityl-L-cysteine benzhydryl ester (17): *N*-Boc-glycyl-L-prolyl-glycyl-L-prolyl-*S*-trityl-L-cysteine benzhydryl ester (2.0 g, 2.13 mmol) was dissolved in formic acid (BDH, 100%, AnalR grade, 200 mL) that had been precooled to 10°C. The resulting solution was stirred at 10.0 ± 0.1°C for 25 min and then frozen using liquid nitrogen. The formic acid was quickly removed by freeze-drying to leave an amorphous white solid. This was dissolved in ethyl acetate, and the solution was washed with saturated sodium bicarbonate (3 × 100 mL), dried over anhydrous sodium sulfate, and evaporated. Two treatments with methylene chloride, followed by reevaporation, yielded a white foam, 1.36 g (77%); $[\alpha_D]$ −61.9° (*c* 1.1, methanol); ^{1}Hmr ($CDCl_3$): 1.63 (2H, br, NH_2), 1.91 (6H, m, Pro β- + γ-CH_2), 2.22 (2H, m, Pro β- + γ-CH_2), 2.60 (1H, q, 5, 12 Hz, Cys CH_2), 2.69 (1H, q, 8, 12 Hz, Cys CH_2), 3.28 (2H, m, Pro δ-CH_2), 3.38 (1H, d, 15 Hz, Gly CH_2), 3.40 (1H, d, 15 Hz, Gly CH_2), 3.50 (2H, m, Pro δ-CH_2), 3.92 (1H, q, 5, 15 Hz, Gly CH_2), 4.08 (1H, q, 5, 15 Hz, Gly CH_2), 4.44 (1H, m, Cys α-H), 4.54 (2H, d, 7 Hz, Pro α-H), 6.78 (1H, s, benzhydryl), 7.21 (1H, d, 7 Hz, N-H), 7.35–7.50 (26H, aromatic + N-H); tlc: R_f 0.77 (methyl ethyl ketone: acetic acid: water 4:1:1). The compound gave a single spot and was ninhydrin positive.

N-Boc-S-trityl-L-cysteinyl-glycyl-L-prolyl-glycyl-L-prolyl-S-trityl-L-cysteine benzhydryl ester (18): *N*-Boc-*S*-trityl-L-cysteine dicyclohexylammonium salt (1.05 g, 1.63 mmol) was partitioned between ethyl acetate (50 mL) and 10% citric acid (50 mL). The organic phase was separated, washed with 10% citric acid (2 × 30 mL) and brine (1 × 30 mL), dried over anhydrous sodium sulfate, and evaporated to yield 780 mg of material. This was dissolved in ethyl acetate (15 mL), and EEDQ (Aldrich, 0.443 g, 1.77 mmol) was added. The solution was stirred for 10 min, and a solution of glycyl-L-prolyl-glycyl-L-prolyl-*S*-trityl-L-cysteine benzhydryl ester (1.36 g, 1.63 mmol), in ethyl acetate (25 mL), was added. Stirring was continued for 20 h, and the cloudy reaction mixture was then filtered. The filtrate was washed successively with 10% potassium bisulfate (4 × 100 mL), brine (1 × 100 mL), saturated sodium bicarbonate (3 × 100 mL), brine (1 × 100 mL), dried over anhydrous sodium sulfate, and evaporated. Two treatments with methylene chloride yielded a white foam, 895 mg (80%); ^{1}Hmr ($CDCl_3$): 1.40 (9H, s, *tert*-butyl), 1.84 (3H, m, Pro β- and γ-CH_2), 1.95 (3H, m, Pro β- and γ-CH_2), 2.13 (1H, m, Pro β- and γ-CH_2), 2.22 (1H, m, Pro β- and γ-CH_2) 2.50–2.71 (4H, overlapping AB of ABX, Cys CH_2), 3.34 (2H, m, Pro δ-CH_2), 3.50 (2H, m, Pro δ-CH_2), 3.82–4.10 (4H, overlapping Gly CH_2), 4.43 (1H, d, Cys α-H), 4.48 (1H, d, Pro α-H), 4.53 (1H, d, Pro α-H), 4.87 (1H, d, Cys α-H), 4.98 (1H, br, urethane NH), 6.77 (1H, s, benzhydryl), 6.94 (2H, br, NH), 7.08 (1H, d, 6 Hz, NH), 7.17–7.35 (30 H, m, aromatic), 7.40 (10 H, d, aromatic); tlc: R_f 0.89 (dichloromethane: methanol 5:2). The compound gave one spot, which was ninhydrin negative.

Phenceptin (N-Boc-L-cystinyl-glycyl-L-prolyl-glycyl-L-prolyl-L-cysteine benzhydryl ester): *N*-Boc-*S*-trityl-L-cysteinyl-glycyl-L-prolyl-glycyl-L-prolyl-*S*-trityl-L-cysteine benzhydryl ester (2.5 g, 2.27 mmol) was dissolved in a mixture of methanol (500 mL) and methylene chloride (500 mL), and the solution was added dropwise, with stirring, to an ice-cold solution prepared from iodine (1.15 g, 2 equiv.) and pyridine (2 mL, 10 equiv.), in methanol (1 L). When the addition was complete (4.5 h), the ice-bath was removed and stirring was continued for 2 h, by which time tlc (methylene chloride – acetone, 1:1) showed that the starting material had been consumed. The methanol solvent was removed under reduced pressure to give a dark brown oil. This was dissolved in methylene chloride (500 mL), and the solution was washed successively with 10% potassium bisulfate (1 × 400 mL), 10% sodium bisulfate (2 × 300 mL), and water (3 × 300 mL), dried over anhydrous sodium sulfate, and evaporated. The white foam was triturated with hexane (3 × 50 ML) and filtered to give 1.811 g of material, which was chromatographed on silica gel (35 g) using acetone as eluant and a flow rate of 5 mL/min, yielding 1.18 g (65%) of phenceptin. The analytical sample was prepared by repetition of the column chromatography. $[\alpha_D]$ −1.29 (*c* 1.15, methanol); ^{1}Hmr ($CDCl_3$, 273 K, major conformation): 2.01 (6H, m, Pro β- + γ-CH_2), 2.16 (2H, m, Pro β- + γ-CH_2), 2.72 (2H, q, 4, 16 Hz, Cys CH_2), 3.08 (2H, q, 7, 16 Hz, Cys CH_2), 3.19 (2H, br, CH_2 of Gly^2), 3.47 (2H, m, Pro δ-CH_2), 3.59 (2H, m, Pro δ-CH_2) 3.92 (1H, q, 4, 18 Hz, CH of Gly^4), 4.09 (1H, q, 4, 18 Hz, CH of Gly^4), 4.42 (1H, m, Cys α-H), 4.53 (1H, m, Cys α-H), 4.66 (1H, m, Pro α-H), 4.94 (1H, m, Pro α-H), 6.20 (1H, d, 9 Hz, urethane N-H), 6.93 (1H, s, benzhydryl), 7.14 (2H, d, 7 Hz, N-H), 7.35 (11H, m, Ar + N-H); tlc: R_f 0.65 (methylene chloride: methanol 5:2), R_f 0.87 (methyl ethyl ketone: acetic acid: water 4:1:1). The peptide gave a single spot on tlc, which was not visualized with ninhydrin but became ninhydrin positive after pretreatment with formic acid. *Anal.* calcd. for $C_{38}H_{48}N_6O_9S_2 \cdot H_2O$: C 56.01, H 6.18, N 10.31, S 7.85; found: C 56.18, H 6.07, N 10.13, S 8.61.

B. Transport studies

General

The divided beaker cell was sealed with a protective shield, to minimize loss of solvent, and immersed in a water bath maintained at 37.0 ± 0.1°C, using a Haake temperature controller. The extracellular phase contained a salt (20 mM) in water (80.0 mL). The membrane phase contained the ionophore (150 μmol/L) in 1-octanol (50.0 mL). The intracellular phase was water (80.0 mL). All phases were stirred simultaneously at constant, reproducible rates. Periodic sampling of the intracellular phase allowed determination of transport rates. Experiments were repeated several times to ensure reproducibility. Blank runs were always used as controls. At no time did the divided beaker cell "leak" ions into the intracellular phase in the absence of an ionophore.

Analytical methods

Transport rates were quantified by determination of the concentration of the counter-anion in the intracellular phase. For studies involving thiocyanate as the counter-anion, the anion concentration was determined spectrophotometrically at 480 nm. Aliquots (0.50 mL) of the intracellular phase were mixed with 0.005 M ferric chloride (5.00 mL), which was made 0.18 M in perchloric acid and the thiocyanate concentration was determined from a Beer's Law plot. A new calibration curve was determined prior to each kinetic run.

When picrate was the counter-anion, the extracellular phase contained picric acid (50 mM) and HEPES buffer (10 mM) at pH 7.0. The appearance of the yellow picrate anion in the intracellular phase was determined spectrophotometrically at 355 nm.

When chloride was the counter-anion, the concentration was determined indirectly by the Volhard method (54).

Pressure effects on the rate of electron transfer between tris(1,10-phenanthroline)iron(II) and -(III) in aqueous solution and in acetonitrile

HIDEO DOINE AND THOMAS WILSON SWADDLE[1]

Department of Chemistry, The University of Calgary, Calgary, Alta., Canada T2N 1N4

Received May 25, 1988

HIDEO DOINE and THOMAS WILSON SWADDLE. Can. J. Chem. **66**, 2763 (1988).

Proton nmr line-broadening experiments at ambient and elevated (to 215 MPa) pressures show that the rate of electron transfer between $Fe(phen)_3^{2+}$ and $Fe(phen)_3^{3+}$ as bisulfates in D_2O/D_2SO_4 is represented by the activation parameters (at ionic strength $I \sim 0.4$ mol kg^{-1}) $\Delta H^{\ddagger} = 1.6 \pm 0.5$ kJ mol^{-1}, $\Delta S^{\ddagger} = -102.2 \pm 1.6$ J K^{-1} mol^{-1}, $k(276\text{ K}) = 1.31 \times 10^7$ kg mol^{-1} s^{-1}, and (at $I \sim 0.3$ mol kg^{-1} and a mean pressure of 100 MPa) $\Delta V^{\ddagger} = -2.2 \pm 0.1$ cm^3 mol^{-1}. For the same reaction of the perchlorate salts (total [Fe] 0.046–0.065 mol kg^{-1}) in CD_3CN, $\Delta H^{\ddagger} = 11.0 \pm 1.0$ kJ mol^{-1}, $\Delta S^{\ddagger} = -72.5 \pm 3.6$ J K^{-1} mol^{-1}, $k(277\text{ K}) = 8.0 \times 10^6$ kg mol^{-1} s^{-1}, and $\Delta V^{\ddagger} = -5.9 \pm 0.5$ cm^3 mol^{-1}. For water as solvent, $\Delta V^{\ddagger}$ is satisfactorily accounted for by a classical theory of the Stranks–Hush–Marcus type. Volumes of activation for electron self-exchange are shown to provide criteria for non-adiabaticity and for dominance of (non-aqueous) solvent reorganization dynamics; on this basis, it is seen that neither of these factors is important in the title reactions.

HIDEO DOINE et THOMAS WILSON SWADDLE. Can. J. Chem. **66**, 2763 (1988).

Des expériences d'élargissement de raies dans les spectres rmn du proton, effectuées à la pression ambiante et à des pressions allant jusqu'à 215 MPa, permettent de démontrer que la vitesse de transfert d'électron, entre les ions $Fe(phen)_3^{2+}$ et le $Fe(phen)_3^{3+}$ qui existent sous la forme de bisulfates dans une solution de D_2O/D_2SO_4, peut être représentée par les paramètres d'activation suivants : (à une force ionique de $I \sim 0{,}4$ mol kg^{-1}), $\Delta H^{\ddagger} = 1{,}6 \pm 0{,}5$ kJ mol^{-1}, $\Delta S^{\ddagger} = -102{,}2 \pm 1{,}6$ J K^{-1} mol^{-1}, $k(276\text{ K}) = 1{,}31 \times 10^7$ kg mol^{-1} s^{-1} et (à $I = 0{,}3$ mol kg^{-1} et une pression moyenne de 100 MPa) $\Delta V^{\ddagger} = -2{,}2 \pm 0{,}1$ cm^3 mol^{-1}. Pour la même réaction des perchlorate ([Fe] totale de 0,046 à 0,065 mol kg^{-1}) dans le CD_3CN $\Delta H^{\ddagger} = 11{,}0 \pm 1{,}0$ kJ mol^{-1}, $\Delta S^{\ddagger} = -72{,}5 \pm 3{,}6$ J K^{-1} mol^{-1}, $k(277\text{ K}) = 8{,}0 \times 10^6$ kg mol^{-1} s^{-1} et $\Delta V^{\ddagger} = -5{,}9 \pm 0{,}1$ cm^3 mol^{-1}. Lorsque l'eau est le solvant, on peut facilement expliquer la valeur du $\Delta V^{\ddagger}$ par une théorie classique du type Stranks–Hush–Marcus. On démontre que les volumes d'activation pour l'auto-échange des électrons fournissent des critères pour expliquer les propriétés non-adiabatiques ainsi la dominance de la dynamique de réorganisation des solvants non-aqueux; sur cette base, on peut comprendre pourquoi aucun de ces facteurs n'est important dans les réactions mentionnées dans le titre.

[Traduit par la revue]

Introduction

A continuing theme in the work of our laboratory has been the quantitative prediction, tested by experimental measurement, of the effects of pressure on the rates of inorganic reactions in solution (1–5). Outer-sphere electron transfer reactions are particularly attractive subjects in this respect, since the Stranks–Hush–Marcus ("SHM") theory (6) allows one, in principle, to calculate the effect of pressure on the rate constant k (expressed as the volume of activation $\Delta V^{\ddagger} = -RT(\partial \ln k/\partial P)_T$) from basic physical properties of the reactants and the solvent. The initial apparent success (6) of simple SHM theory for self-exchange reactions of metal complexes in aqueous solution, however, has been shown to have been fortuitous (7, 8), and we have therefore undertaken a re-evaluation of this approach.

Our early considerations (4) suggested that, subject to some minor modifications (notably the treatment of the separation σ between the reacting metal–ion centres as a pressure-sensitive variable), the SHM theory might prove adequate for self-exchange reactions of transition metal complexes containing large ligands with extended π-electron systems. In such cases, fully adiabatic electron transfer (*i.e.*, electronic transmission coefficient $\varkappa_{el} \sim 1$) might be expected, and the solvent should be adequately represented as a continuous dielectric with relative permittivity equal to the bulk value D throughout. Indeed, Braun and van Eldik (9) reported that $\Delta V^{\ddagger}$ for electron transfer between $Co(terpy)_2^{2+}$ and $Co(bipy)_3^{3+}$ in water comes close to the predictions of simple SHM theory (this is, however, a *net reaction* rather than self-exchange).

An appropriate test case is the self-exchange reaction of tris(1,10-phenanthroline)iron(II) and -(III)

[1] $$Fe(phen)_3^{2+} + Fe(phen)_3^{3+} \rightleftharpoons Fe(phen)_3^{3+} + Fe(phen)_3^{2+}$$

the ambient-pressure kinetics of which were mapped out for various solvents by Wahl and co-workers with ^{1}H nmr line-broadening (10, 11). We report here a high-pressure study of this system in water and acetonitrile, in addition to refinements of some of the measurements of Larsen and Wahl (10, 11). An attractive feature of this widely-used couple is that the Fe—N bond lengths are identical in the oxidized and reduced species (12), so that the contributions of internal reorganization $\Delta V_{IR}^{\ddagger}$ and $\Delta G_{IR}^{\ddagger}$ to $\Delta V^{\ddagger}$ and the free energy of activation $\Delta G^{\ddagger}$, respectively, should be negligible, thereby permitting simplification of the theoretical calculations.

Experimental

Preparation of materials

$[Fe(phen)_3](ClO_4)_2$ and $[Fe(phen)_3](ClO_4)_3$ were made by the methods of Chan and Wahl (11). $[Fe(phen)_3]SO_4 \cdot 9H_2O$ was prepared by dissolving $FeSO_4 \cdot 7H_2O$ (0.9 g) in 15 mL water to which phen$\cdot H_2O$ (3 g) was added. The mixture was stirred for 1 h in the dark and then filtered; to the filtrate, 200 mL acetone was added. The combined precipitates were recrystallized twice from ethanol–acetone. All complex salts were shown spectrophotometrically to be >99% pure, and were stored *in vacuo* over P_2O_5.

For the kinetic studies in aqueous media, $Fe(phen)_3^{3+}$ could not be introduced as a solid salt (the sulfate could not be obtained pure, and the perchlorate caused precipitation of $[Fe(phen)_3](ClO_4)_2$) and was therefore generated in solution by oxidation of $[Fe(phen)_3]SO_4$ in aqueous sulfuric acid with the stoichiometric amount of ammonium hexanitratocerate(IV) (G. Frederick Smith Chemical Co., 99.98%). It was shown by spectrophotometric titration that the oxidation was quantitative in the time required for solution preparation, and further-

more that $Fe(phen)_3^{3+}$ was stable enough in solution in aqueous sulfuric acid (0.1 mol L^{-1}) below 5°C for completion of a cycle of pressurized nmr experiments (ca. 8 h); significant decomposition of the iron(III) complex in solution, however, precluded reliable kinetic measurements under pressure at higher temperatures (cf. refs. 11 and 13). In acetonitrile, on the other hand, $[Fe(phen)_3](ClO_4)_3$ proved to be very stable even at room temperature.

Nuclear magnetic resonance measurements

All nmr spectra were taken on a Bruker WH-90 spectrometer with quadrature detection. The spectra of the separate $Fe(phen)_3^{2+}$ and $Fe(phen)_3^{3+}$ complexes in solution were in good agreement with those in the literature (11, 13). The required quantities were the full widths W at half height and chemical shifts δ of the protons in the 2 and 9 positions on the phenanthroline ligands. Temperature dependence studies were made with a standard Bruker ^1H probehead, and spectra at elevated pressures (to 215 MPa) were obtained with the pressurizable assembly described previously (5). For measurements on aqueous systems, the solutions were prepared from $[Fe(phen)_3]SO_4 \cdot 9H_2O$ and D_2SO_4 (Sigma, 98 atom%) in D_2O (Aldrich, 99.8 atom%). Ammonium hexanitratocerate(IV) in D_2O/D_2SO_4 was used to produce $Fe(phen)_3^{3+}$, and DSS (sodium 3-(trimethylsilyl)propanesulfonate; MSD) was introduced as an internal standard. For measurements in acetonitrile, the requisite amounts of $[Fe(phen)_3](ClO_4)_2$ and $[Fe(phen)_3](ClO_4)_3$ were dissolved in CD_3CN (Aldrich, 99 atom%) which had been dried over a 4A molecular sieve.

Results

Aqueous solutions at variable temperature

The rate constant k for reaction [1] was obtained from the "fast exchange" expression (5, 11)

$$[2] \quad k = 4\pi f_P(1 - f_P)(\Delta\nu)^2/\{W_{DP} - (1 - f_P)W_D - f_P W_P\}[Fe]_T$$

where f_P is the fraction of the total iron concentration $[Fe]_T$ corresponding to the paramagnetic Fe^{III} species (calculated as in ref. 5), $\Delta\nu$ is the difference in chemical shift between the 2,9-proton resonances of the Fe^{II} and Fe^{III} complexes in separate solutions, and W_{DP}, W_D, and W_P are respectively the linewidths of these resonances in the reaction mixture, in a corresponding solution containing the Fe^{II} complex without Fe^{III}, and in a solution containing the Fe^{III} complex without Fe^{II}. Equation [2] is applicable only in the "fast exchange limit" and is appropriate here because the criterion $k[Fe]_T/2\pi\Delta\nu \gg 1$ was satisfied in all the experiments reported in this paper. At 11.2°C, $\Delta\nu$ = 5055 and W_P = 298.5 Hz; at 1.0°C, the corresponding values were 5244 and 309.6 Hz. Thus, W_P follows Curie's law. Values of $\Delta\nu$ and W_P for other temperatures were obtained by interpolation. The assumption implicit in eq. [2], that the effects on W of coupling of the 2,9 with the 3,8 and 4,7 protons can be neglected, was shown to be valid; like Chan and Wahl (11), we calculated that this contribution to W would in no case exceed 10%.

Measurements were made with $[Fe]_T$ ranging from 0.0608 to 0.1485, $[D_2SO_4]$ from 0.100 to 0.201, and ionic strength I from 0.22 to 0.48 mol kg^{-1}. Surprisingly, the twenty values of k so obtained, calculated from eq. [2] and subject to an estimated error of less than ±5%, ranged only from 1.26×10^7 to 1.37×10^7 mol kg^{-1} s^{-1} over the accessible temperature range −2.4 to +11.2°C and showed no discernable dependence on I. Full details are given in the Supplementary Tables,[2] but values of k are well represented by the Eyring equation

$$[3] \quad k = (\varkappa k_B T/h) \exp((\Delta S^{\ddagger}/R) - (\Delta H^{\ddagger}/RT))$$

where $\Delta H^{\ddagger}$ = 1.6 ± 0.5 kJ mol^{-1}, $\Delta S^{\ddagger}$ = −102.2 ± 1.6 J K^{-1} mol^{-1}, transmission coefficient $\varkappa$ = 1 (assumed), and the other symbols have their unusual meanings.[3] At 25°C, the extrapolated value of k is 1.49×10^7 kg mol^{-1} s^{-1}. Chan and Wahl reported $k = (3.6 \pm 1.0) \times 10^7$ and $(4.9 \pm 1.5) \times 10^7$ L mol^{-1} s^{-1} for reaction [1] at 5 and 17°C, respectively, but the counterion in their experiments was chloride rather than HSO_4^-, and the rate data may have been affected by decomposition of the Fe^{III} complex (11).

Acetonitrile solutions at variable temperature

In acetonitrile, the perchlorate salts of $Fe(phen)_3^{2+}$ and $Fe(phen)_3^{3+}$ were used, as they are both sufficiently soluble and stable at room temperature. The quantities $\Delta\nu$ and W_P in eq. [2] had the values 5105 and 239 Hz at 19°C, and 5564 and 261 Hz at −5.1°C, respectively, in good agreement with previous reports (11, 12). Thus, they conformed to Curie's law, and values for other temperatures were obtained by interpolation. Determinations of the rate constant k were made from eq. [3] for five temperatures ranging from −8.9 to +15.9°C for three different solutions ($[Fe]_T$ = 0.0646, 0.0651, 0.0463 mol kg^{-1}; I = 0.19, 0.20, 0.14 mol kg^{-1}) but the results were independent of concentration within the experimental error. The data (Supplementary Tables[2]) are represented by $\Delta H^{\ddagger}$ = 11.0 ± 1.0 kJ mol^{-1} and $\Delta S^{\ddagger}$ = −72.5 ± 3.6 J K^{-1} mol^{-1} if $\varkappa$ = 1, so that $k = 1.20 \times 10^7$ kg mol^{-1} s^{-1} at 25°C. These agree satisfactorily with the results of Chan and Wahl (11) for reaction [1] in CD_3CN with perchlorate as counterion (note different concentration units and $[Fe]_T$).

Aqueous solutions at variable pressure

Here, the anions were again HSO_4^- and SO_4^{2-}. It was not possible to determine accurately the effect of pressure on the contact shifts and line widths of the pure paramagnetic Fe^{III} species, since the high pressure probehead is relatively insensitive and because small amounts of the Fe^{II} complex tended to form, with consequent exchange broadening, on the longer timescale of the high pressure experiments. The Debye equation, however, suggests that W_P should be proportional to the viscosity η of the solvent at a given temperature (14). Water is an anomalous fluid in that η is only slightly affected (it is actually *decreased* and then increased (15, 16)) by rising pressure under the conditions of our experiments (3.0°C, 0.1–215 MPa), so that the pressure dependences of $\Delta\nu$ and W_P in aqueous solutions can be safely neglected.

Values of the rate constant k obtained for reaction [1] at various pressures P at 3.0 ± 0.3°C are given in the Supplementary Material and are summarized in Fig. 1. There is no evidence of any dependence of k on concentrations or ionic strength ($I \sim 0.17$–0.32 mol kg^{-1}), and the ln k vs. P plot can be regarded as linear within the experimental error, giving $\Delta V^{\ddagger} = -2.2 \pm 0.1$ cm^3 mol^{-1} for the mean conditions P = 100 MPa, I = 0.3 mol kg^{-1}, and T = 3.0°C; $k_{P=0} = 1.29 \times 10^7$ kg mol^{-1} s^{-1}, in excellent agreement with the variable-temperature result. Data obtained at the lower $[Fe]_T$ are less precise and hence more scattered in Fig. 1.

Acetonitrile solutions at variable pressure

The perchlorate salts of the complexes were used. In

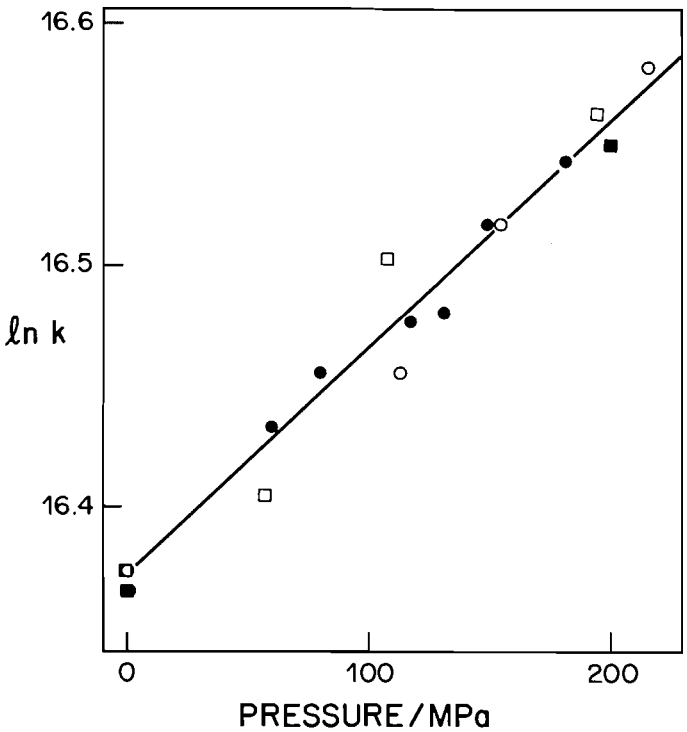

FIG. 1. Pressure dependence of the rate of reaction [1] in aqueous acidic (D_2O/D_2SO_4) solution at 3.0°. Filled circles: $[Fe]_T = 0.0352$, $[D_2SO_4] = 0.1001$, $I = 0.17$ mol kg^{-1}. Filled squares: $[Fe]_T = 0.0621$, $[D_2SO_4] = 0.1351$, $I = 0.26$ mol kg^{-1}. Open circles: $[Fe]_T = 0.0706$, $[D_2SO_4] = 0.1351$, $I = 0.28$ mol kg^{-1}. Open squares: $[Fe]_T = 0.1050$, $[D_2SO_4] = 0.1001$, $I = 0.32$ mol kg^{-1}.

acetonitrile, $Fe(phen)_3^{3+}$ is sufficiently stable that the pressure dependence of the linewidth W_P could be measured, and the results over the range 0.1–205 MPz at 3.8°C and [Fe] = 0.042 mol kg^{-1} are represented adequately by

$$[4] \quad \ln W_P = 5.548 + 0.00168P$$

where P is in MPa. This type of relationship reflects the behavior of acetonitrile as a normal fluid (5). There was no detectable variation of $\Delta\nu$ with pressure (5380 ± 60 Hz).

The data (Supplementary Tables[2]) are summarized in Fig. 2. The scatter is worse than for the acidic aqueous systems, but again there is no discernable concentration effect over the admittedly limited range $[Fe]_T = 0.0468$ to 0.0677 mol kg^{-1}. The ln k vs. P plot may be taken to be linear within the experimental uncertainty, giving $\Delta V^{\ddagger} = -5.9 \pm 0.5$ cm^3 mol^{-1} and $k_{P=0} = 8.1 \times 10^6$ kg mol^{-1} s^{-1} (*cf.* 7.9×10^6 kg mol^{-1} s^{-1} from the temperature dependence study) at 3.8°C and $I \sim 0.18$ mol kg^{-1}.

Discussion

Three models were considered in interpreting the above kinetic data for reaction [1]: (*a*) a two-sphere, weakly adiabatic, continuous-dielectric model of the SHM type, developed elsewhere (3–5) from principles laid down by Sutin (17); (*b*) an adaptation of model (*a*) with allowance for possible non-adiabaticity (3); and (*c*) following recent developments (18–22), a model in which solvent reorganization dynamics are important.

(a) Adiabatic continuous-dielectric model

In this case, the rate coefficient k is given by

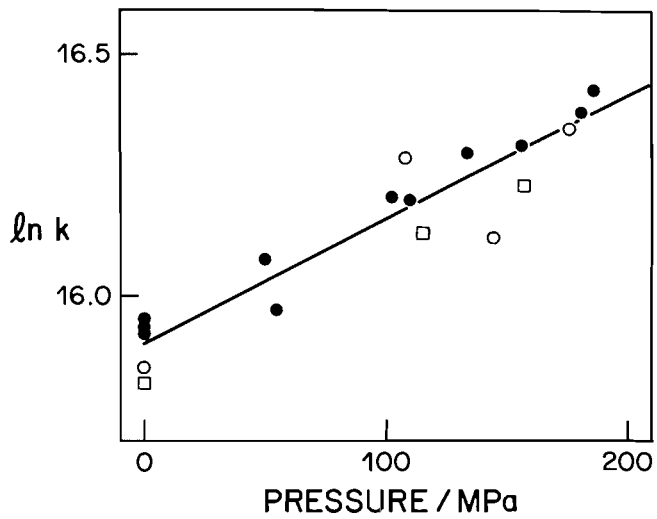

FIG. 2. Pressure dependence of the rate of reaction [1] in acetonitrile (counterion: perchlorate) at 3.8°C. Open circles: $[Fe]_T = 0.0468$ mol kg^{-1}. Open squares: $[Fe]_T = 0.0668$ mol kg^{-1}. Filled circles: $[Fe]_T = 0.0677$ mol kg^{-1}.

$$[5] \quad k = (K_A \varkappa_{el} \nu_n) \exp[-(\Delta G_{IR}^{\ddagger} + \Delta G_{OS}^{\ddagger})/RT]$$

where K_A is the formation constant for the precursor assembly $\{Fe(phen)_3^{2+}, Fe(phen)_3^{3+}\}$, ν_n is the nuclear frequency factor, and $\Delta G_{IR}^{\ddagger}$ and $\Delta G_{OS}^{\ddagger}$ are the contributions to the free energy $\Delta G^{\ddagger}$ of activation from reorganization within the reactants and from the surrounding solvent, respectively, in the activation process. For reaction [1], $\Delta G_{IR}^{\ddagger}$ will be negligible because neither the Fe—N bond lengths (12) nor the stretching frequencies (23) change significantly on going from Fe^{II} to Fe^{III}. The formation of the precursor assembly involves exponential factors $\Delta G_{COUL}^{\ddagger}$ and $\Delta G_{DH}^{\ddagger}$ representing the Coulombic work and Debye–Hückel effects, respectively, which can be combined with the solvent reorganization term $\Delta G_{SR}^{\ddagger}$ to give $\Delta G^{\ddagger}$ while K_A is replaced by $4000\pi N\sigma^3/3$ (in L mol^{-1} s^{-1}, for σ in metres) where σ is the Fe—Fe separation and N is Avogadro's number (17). For consistency with transition state theory (eq. [3]), ν_n may be set equal to $k_B T/h$. We have, in SI units and symbols,

$$[6] \quad \Delta G_{SR}^{\ddagger} = (Ne^2/16\pi\varepsilon_0)(r^{-1} - \sigma^{-1})(n^{-2} - D^{-1})$$

where r is the effective radius of the reactant ions approximated to spheres (here, r is the same for each), n is the refractive index of the solvent (for convenience, taken to be the Na-D-line value commonly tabulated), and D is the relative permittivity (dielectric constant) of the solvent. If a is the distance of closest approach of the reactant cations (charges z_1 and z_2) to the counter-ions, we have

$$[7] \quad \Delta G_{COUL}^{\ddagger} = (Nz_1z_2e^2/4\pi\varepsilon_0)/D\sigma$$

$$[8] \quad \Delta G_{DH}^{\ddagger} = -2RTz_1z_2CI^{1/2}/(1 + BaI^{1/2})$$

where B and C are the usual Debye–Hückel parameters.

The approximation of $Fe(phen)_3^{x+}$ to a sphere is obviously crude, but values of $r \sim 700$ pm and $a \sim 900$ pm seem reasonable (11, 12), and in any event it turns out that the calculated values of k are not very sensitive to these choices. Similarly, although σ is to be regarded as variable (4, 17), it transpires that k changes very little as σ is allowed to vary from 1.0 to 1.8 nm; for $\sigma = 2r = 1.4$ nm, $k = 8.2 \times 10^{10}$ kg mol^{-1} s^{-1}, $\Delta G_{SR}^{\ddagger} = 13.7$, $\Delta G_{COUL}^{\ddagger} = 6.9$, and

$\Delta G_{DH}^{\ddagger} = -6.6$ kJ mol^{-1} in water at 3°C, 0.1 MPa and $I = 0.3$ kg mol^{-1}. In view of the simplicity of the model, the discrepancy between the calculated and the observed value of k (1.3×10^7 kg mol^{-1} s^{-1}) is not excessive. It may be noted that the coulombic and Debye–Hückel terms tend to cancel at the ionic strengths used in this study.

For acetonitrile as the solvent with the same choices of r, σ, and a, but with $I = 0.2$ mol kg^{-1} and $T = 25.0$°C, eqs. [5]–[8] predict $k = 2 \times 10^{11}$ kg mol^{-1} s^{-1}, with $\Delta G_{SR}^{\ddagger} = 13.1$, $\Delta G_{COUL}^{\ddagger} = 16.4$, and $\Delta G_{DH}^{\ddagger} = -16.2$ kJ mol^{-1}. Although the latter two terms are much larger than for aqueous solution, once again they cancel at the relevant ionic strength, and indeed the measured k, though 10^4-fold smaller than predicted, is almost the same in the two solvents because $\Delta G_{SR}^{\ddagger}$ is little affected. Our failure to detect the acceleration of reaction [1] in acetonitrile by the perchlorate counter-ion as reported by Chan and Wahl (11) may mean that $Fe(phen)_3^{3+}$–ClO_4^- pairing was approaching saturation in our concentration range (which, however, was narrow). Indeed, recent measurements by Schmid *et al.* (24) indicate that $Fe(phen)_3^{3+}$–ClO_4^- pairing would be about 90% complete in our acetonitrile solutions at 25°C.

The prediction of k from eqs. [5]–[8] is clearly subject to errors from the numerous assumptions and simplifications, but at least some of these should cancel out in taking the pressure derivative of $\ln k$ to obtain $\Delta V^{\ddagger}$. Thus, a model which gives only rough predictions of k may estimate $\Delta V^{\ddagger}$ quite accurately. Differentiation of eqs. [5]–[8] with respect to pressure gives the following expressions for the volume of activation in the adiabatic two-sphere continuous-dielectric model (3); β is the isothermal compressibility of the solvent, and, for reaction [1], $\Delta V_{IR}^{\ddagger}$ is zero.

$$[9]\quad \Delta V^{\ddagger} = \Delta V_{IR}^{\ddagger} + \Delta V_{OS}^{\ddagger} + \beta RT = \Delta V_{IR}^{\ddagger} + (\Delta V_{SR}^{\ddagger} + \Delta V_{COUL}^{\ddagger} + \Delta V_{DH}^{\ddagger}) + \beta RT$$

$$[10]\quad \Delta V_{SR}^{\ddagger} = (Ne^2/16\pi\varepsilon_0)[(r^{-1} - \sigma^{-1}) \times (\partial(n^{-2} - D^{-1})/\partial P)_T - (n^{-2} - D^{-1})\beta/3\sigma]$$

$$[11]\quad \Delta V_{COUL}^{\ddagger} = (Nz_1z_1e^2/4\pi\varepsilon_0\sigma)[(\partial D^{-1}/\partial P)_T + \beta/3D]$$

$$[12]\quad \Delta V_{DH}^{\ddagger} = [RTz_1z_2CI^{1/2}/(1 + BaI^{1/2})^2] \times [(\partial \ln D/\partial P)_T(3 + 2BaI^{1/2}) - \beta]$$

Parameters such as $(\partial n/\partial P)_T$, $(\partial D/\partial P)_T$, and β are themselves pressure dependent, with the result that $|\Delta V^{\ddagger}|$ must decrease with rising pressure (i.e., a plot of $\ln k$ vs. P will be a curve tending towards the horizontal) (3–5). This anticipated curvature, however, is often lost within the experimental uncertainty of k, as is the case here (Figs. 1 and 2), and it is then expedient to treat the $\ln k$ vs. P plot as linear, giving a mean $\Delta V^{\ddagger}$ that would be representative of the mid-point of the pressure range — here, 100 MPa. We have therefore evaluated eqs. [9]–[12] for water at 100 MPa, 3.0°C, $I = 0.3$ mol kg^{-1}, $r = 700$ pm, $a = 900$ pm, and $\sigma = 1.4$ nm: $\Delta V_{SR}^{\ddagger} = -4.18$, $\Delta V_{COUL}^{\ddagger} = -1.81$, $\Delta V_{DH}^{\ddagger} = +2.56$, $\beta RT = +0.88$, and $\Delta V^{\ddagger} = -2.5$ cm^3 mol^{-1}. This last is in close agreement with the observed value of -2.2 cm^3 mol^{-1}. The calculations are not significantly affected by the choice of r, and, if σ is varied from 1.0 to 1.8 nm with $r = 700$ pm, opposing trends in $\Delta V_{SR}^{\ddagger}$ and $\Delta V_{COUL}^{\ddagger}$ result in a very small change in $\Delta V^{\ddagger}$ (from -3.0 to -2.3 cm^3 mol^{-1}). For $I = 0.4$ mol kg^{-1}, the calculated $\Delta V^{\ddagger}$ is -2.2 cm^3 mol^{-1}.

It is not possible at present to evaluate eqs. [9]–[12] for acetonitrile, since the pressure dependence of its refractive index is not known, and furthermore there are indications (11) that anion–cation association influences the reaction rate.

(b) Possibility of non-adiabaticity

Since eqs. [5]–[8] overestimate k, the possibility should be considered that reaction [1] is non-adiabatic with $\varkappa_{el} \sim 10^{-4}$. If non-adiabaticity applies at Fe–Fe separations σ greater than a certain value σ_{ad}, a semi-classical approach (17) can be adopted, noting that $\Delta G_{IR}^{\ddagger}$ is negligible for reaction [1]. The electronic coupling factor H_{AB} is given approximately by

$$[13]\quad H_{AB} = H_{AB}^0 \exp[-\alpha(\sigma - \sigma_{ad})]$$

whence, if the distance scaling factor α is known, $\varkappa_{el}$ is calculable from

$$[14]\quad \varkappa_{el} = 2[1 - \exp(-\nu_{el}/2\nu_n)]/[2 - \exp(\nu_{el}/2\nu_n)]$$

where the electronic frequency ν_{el} is given by

$$[15]\quad \nu_{el} = (H_{AB}^2/h)(\pi^3/RT\Delta G_{OS}^{\ddagger})^{1/2}$$

Thus, from eq. [5], we have

$$[16]\quad \ln k = \ln(4000\pi N\sigma^3/3h) + 2\ln H_{AB} + [\ln(\pi^3/RT)]/2 - (\ln \Delta G_{OS}^{\ddagger})/2 - \Delta G_{OS}^{\ddagger}/RT$$

and hence, proceeding as above and in ref. 3, with the assumptions that H_{AB}^0, σ_{ad}, and α are independent of P, the non-adiabatic volume of activation $\Delta V_{NON}^{\ddagger}$ is given by

$$[17]\quad \Delta V_{NON}^{\ddagger} = -RT(\partial \ln k/\partial P)_T = \beta RT - (2\alpha\beta\sigma RT/3) + (RT\Delta V_{OS}^{\ddagger}/2\Delta G_{OS}^{\ddagger}) + \Delta V_{OS}^{\ddagger}$$

For reaction [1] in water, α is not known, but is probably in the usual range 6 to 25 nm^{-1} (17), in which case $\Delta V_{NON}^{\ddagger}$ lies between -8 and -23 cm^3 mol^{-1} for $T = 3.0$°C, $P = 100$ MPa, $I = 0.3$ mol kg^{-1}, $a = 900$ pm, and $\sigma = 2r = 1.4$ nm. Clearly, this range is quite inconsistent with the observed value of -2.2 cm^3 mol^{-1}, and it may be confidently concluded that reaction [1] in water is fully adiabatic, as Taube (25) and Chan and Wahl (11) have suggested.

Thus, in favorable cases (such as when the components of eq. [9] are all quite small), the pressure effect on the rate of a self-exchange redox reaction can be diagnostic of its adiabaticity. It will be noted that σ_{ad} and H_{AB}^0 need not be known for this purpose; either the reaction is fully adiabatic because $\sigma < \sigma_{ad}$, in which case eq. [9] should account for the observed $\Delta V^{\ddagger}$, or it is non-adiabatic and eq. [17] applies.

(c) Solvent-dynamical models

Grampp *et al.* (19) have analyzed adiabatic electron exchange processes in which solvent reorganization dynamics are dominant. Consider a solvent of viscosity η, molar volume V_M, high frequency dielectric constant D_∞ ($\sim n^2$) and longitudinal relaxation time τ_L. If the Ovchinnikova condition (19, 26)

$$[18]\quad [\Delta G_{IR}^{\ddagger}/(\Delta G_{IR}^{\ddagger} + \Delta G_{SR}^{\ddagger})]^{1/2}\nu_{IR}\exp(-\Delta G_{IR}^{\ddagger}/RT) > \tau_L^{-1}$$

is satisfied, the pre-exponential part of eq. [5] becomes solvent dependent; for reaction [1] in water at 3°C and acetonitrile at 25°C, this requires $\Delta G_{IR}^{\ddagger} \leq 200$ and 100 J mol^{-1} respectively, and these conditions could be met, in view of the insensitivity of the Fe—N bond lengths and stretching frequencies to the oxidation state of the iron (12, 23). If $\Delta G_{IR}^{\ddagger}$ is negligible, the solvent frequency ν_S

[19] $\nu_S = DRT(\Delta G_{SR}^{\ddagger}/4\pi RT)^{1/2}/3V_M\eta D_\infty$

can be used directly to predict values of k for reaction [1]

[20] $k = (4000\pi N\sigma^3/3)\nu_S \exp(-\Delta G_{OS}^{\ddagger}/RT)$

of 1.2×10^{10} and 1.8×10^{10} kg mol^{-1} s^{-1} for water (3°C) and acetonitrile (25°C), respectively. Thus, regardless of whether condition [18] is met, this approach gives essentially the same result as model (*a*).

A solvent-dynamical treatment of pressure effects on k (in the case where $\Delta G_{IR}^{\ddagger}$ is negligible) involves the replacement of eq. [9] by

[21] $\Delta V^{\ddagger} = \Delta V_{IR}^{\ddagger} + \Delta V_{OS}^{\ddagger} + \beta RT - RT(\partial \ln \nu_S/\partial P)_T$
$= \Delta V_{OS}^{\ddagger} + \Delta V_{SD}^{\ddagger}$

where

[22] $\Delta V_{SD}^{\ddagger} = RT[(2/n)(\partial n/\partial P)_T + (\partial \ln \eta/\partial P)_T - (\partial \ln D/\partial P)_T - (\Delta V_{SR}^{\ddagger}/2\Delta G_{SR}^{\ddagger})]$

For water at 3°C, it can be estimated (16) that $RT(\partial \ln \eta/\partial P)_T$ ranges from -2.9 to $+1.2$ cm^3 mol^{-1} on going from 0.1 to 200 MPa, and is zero near 120 MPa. Thus, the mean calculated $\Delta V^{\ddagger}$ on the basis of eqs. [10], [11], [12], [21], and [22] for water at 3°C and $I = 0.3$ mol kg^{-1} is about -4.7 cm^3 mol^{-1}, which is 2.5 cm^3 mol^{-1} too negative. The discrepancy is not large, but model (*a*) gives a closer prediction.

For "normal" liquids, η rises monotonically and roughly exponentially with pressure, often doubling between 0.1 and 100 MPa (15, 27). Consequently, for non-aqueous solutions, the term $RT(\partial \ln \eta/\partial P)_T$ will typically make a large (20 cm^3 mol^{-1} or more) *positive* contribution to $\Delta V^{\ddagger}$ where solvent reorganization dynamics are dominant. Since the volumes of activation generated by models (*a*) and (*b*), and by refinements of these (3), are generally in the range 0 to -20 cm^3 mol^{-1}, the observation of a markedly positive $\Delta V^{\ddagger}$ for outer-sphere electron transfer in a non-aqueous system may be taken as evidence for dominance of solvent dynamics. Clearly, reaction [1] in acetonitrile is not such a case.

On chemical relaxation modes in homogeneous chemical systems

F. PALOMARES, J. VEGUILLAS, AND M. A. DIAZ

Universidad del Pais Vasco, Facultad de Ciencias, Departamento de Química-Física, apartado 644, Bilbao, Spain

Received November 12, 1987[1]

F. PALOMARES, J. VEGUILLAS, and M. A. DIAZ. Can. J. Chem. **66**, 2768 (1988).

We study the compatibility between the linearized phenomenological equations of an homogeneous chemical gaseous system, and the theoretical ones obtained with the aid of the kinetic theory of gases. Our discussion is based on the concept of chemical relaxation mode. The theoretical description is provided by a reactive Boltzmann equation for each component of the system. Then, we show the conditions under which the linearized phenomenological equations can be reproduced.

F. PALOMARES, J. VEGUILLAS et M. A. DIAZ. Can. J. Chem. **66**, 2768 (1988).

On a effectué une comparaison entre l'étude de compatibilité des équations phénoménologiques linéarisées d'un système chimique gazeux homogène et les équations théoriques obtenues à l'aide de la théorie cinétique des gaz. Notre discussion est basée sur le concept du mode de relaxation chimique. On fait l'hypothèse que l'on peut obtenir une description théorique à l'aide d'une équation de Boltzmann réactive pour chacune des composantes du système. On présente alors les conditions permettant de reproduire les équations phénoménologiques linéarisées.

[Traduit par la revue]

1. Introduction

In dilute gases, the microscopic foundations of chemical reactions are mostly based on the use of Boltzmann equations, generalized to include reactive collisions. Such generalizations have been postulated "ad hoc" (1–21), although can be derived using different formalisms (see, for instance, refs. 22–29).

The homogeneous reacting systems have been studied for the first time by Prigogine and co-workers (1, 2) and independently by Curtiss (3), in the case of bimolecular reactions in which the reaction products were ignored. They have obtained the expression of the reaction rate using a modification of the Chapman–Enskog perturbation method for transport processes, by considering the reactive cross sections smaller than the elastic ones. Subsequently, many other authors (4–21) have given a more definitive form to the theory of these systems, analysing the deviation produced by the chemical reaction on the Maxwellian distribution function and calculating the reaction rates and rate coefficients by a Chapman–Enskog or a moment method. For this, they have considered the momentum relaxation time of all gaseous species very short compared with the chemical relaxation time.

One of the most interesting questions in connection with the preceding systems is to know the conditions under which a microscopic description is compatible with the macroscopic description furnished by linear thermodynamics (30). In this way, Snider and Ross (15) have discussed in detail, for the exchange reaction

$$[1.1] \qquad A + B \rightleftharpoons C + D$$

the compatibility between the microscopic description and the phenomenological equation

$$[1.2] \qquad -\frac{dn_A}{dt} = K_f n_A n_B - K_r n_C n_D$$

where the rate constants are independent of composition and time, and verify the mass action law

$$[1.3] \qquad K = \frac{K_f}{K_r}$$

K being the equilibrium constant. They have shown that this compatibility holds in linear cases when one of the components is present in a large excess or when the chemical reaction is a slow process. In their paper, Snider and Ross have only considered an isothermal system in which all molecules maintain translational equilibrium.

On the other hand, in refs. 1–21, the problem of the deduction of the phenomenological equations from the kinetic theory in the most general situation (nonisothermal case) has not been studied.

The purpose of this paper is to study, using the kinetic theory, the chemical relaxation of a nonisothermal homogeneous reacting system from a perturbed initial equilibrium state to final equilibrium state. This study permits us to obtain the microscopic expression of the phenomenological equations which govern such an evolution and to establish their range of validity. Indeed, the chemical relaxation provides a method (31) to measure reaction rates. In this method, one starts from a system which is already at chemical equilibrium and a small perturbation, either transient or stationary, is applied to it. The system will then relax to a new equilibrium, and from the knowledge of the relaxation time and the equilibrium constant, one finds the value of the rate constants. In the transient case, the perturbation is usually a sudden change of some parameter, such as the temperature, the pressure or, in special cases, the electric or magnetic field. For the stationary measurements, the sound absorption and dispersion method is the most widely used (32).

We will consider that the system is a dilute gas consisting of four components that participate in a reaction of the type [1.1], and whose statistical evolution is described by a reactive Boltzmann equation. We will see that, for a system in which the reactive collisions are much less probable than the elastic ones, there exists a microscopic expression for the phenomenological equation from which we obtain rate coefficients that satisfy the mass action law. This analysis will be based on the extension, for reacting systems, of the concept of hydrodynamical modes introduced by Résibois (33–35) and on a generalization of the method introduced by Theodosopulu, Grecos, and Prigogine (36, 37) in the microscopic derivation of the linearized transport equations for a simple fluid.

The present paper is organized as follows. In the next section, we establish the phenomenological equations and we introduce the concept of the chemical relaxation mode. The

derivation of the microscopic expressions of the phenomenological equations is given in third section. Finally, in the fourth section the main results of this paper are discussed.

2. Phenomenological equations

In this section, we establish the phenomenological equations for an uniform and isolated multi-component reacting system characterized by the reaction

[2.1] $A + B \rightleftharpoons C + D$

and we introduce the concept of chemical relaxation mode.

The basic variables to describe a multi-component system are the total density ρ, the concentration γ_i of each component defined as the mass fraction ρ_i/ρ, the momentum density $\boldsymbol{g}$ and the energy density U (30). As this system is uniform, it is not necessary to consider the evolution equations of the total density and momentum density. Therefore, in the absence of external forces, the conservation equations may be written in the form

[2.2] $$\rho \frac{\partial \gamma_i}{\partial t} = \bar{\nu}_i m_i J \qquad (i = 1, 2, 3 \equiv \text{A, B, C})$$

[2.3] $$\rho \frac{\partial U}{\partial t} = 0 \qquad \text{(uniform and isolated system)}$$

where $\bar{\nu}_i$, m_i, and J are the stoichiometric coefficients, the molecular mass of the i-component, and the chemical reaction rate, respectively.

The system of equations [2.2], [2.3] can be reduced to a system of two equations if we introduced the parameter, ξ, called degree of advancement of the reaction, defined by (30),

[2.4] $$\xi(t) = \frac{\gamma_i(t) - \gamma_i(0)}{\bar{\nu}_i m_i}$$

Thus, from [2.2]–[2.4] we get

[2.5] $$\rho \frac{\partial \xi}{\partial t} = J$$

[2.6] $$\rho \frac{\partial U}{\partial t} = 0$$

Assuming the system is very close to equilibrium, it is possible to consider a linear relation among the fluxes and thermodynamic forces (30). Thus, we may write the chemical reaction rate as

[2.7] $$J = -\frac{l_{rr}}{T} A = -\epsilon A$$

A being the chemical affinity of the reaction [2.1], defined by means of the chemical potentials μ_k (k = A, B, C, and D) (30)

[2.8] $$A = m_C\mu_C + m_D\mu_D - m_A\mu_A - m_B\mu_B$$

ϵ is a scalar phenomenological coefficient related with the rate coefficients, K_f and K_r, of the forward and reversal reactions, by the expression

[2.9] $$\epsilon = K_r\left(\frac{\gamma_C\gamma_D}{k_B T}\right) = K_f\left(\frac{\gamma_A\gamma_B}{k_B T}\right)$$

or, in function of the degree of advancement of the reaction

[2.10] $$\epsilon = K_r\left(\frac{\xi^2\bar{\nu}_C\nu_D m_C m_D}{k_B T}\right) = K_f\left(\frac{\xi^2\bar{\nu}_A\bar{\nu}_B m_A m_B}{k_B T}\right)$$

When the state of the system is very close to equilibrium, we can write all the variables in the following way

[2.11] $$\varphi(t) = \varphi^e + \delta\varphi(t): \frac{|\delta\varphi(t)|}{\varphi^e} \ll 1$$

φ^e being the equilibrium value of $\xi(t)$, $U(t)$, and $A(t)$ (in this particular case $A^e = 0$).

Now, we will assume that the Gibbs thermodynamic relation remains valid for our system

[2.12] $$\delta U = C_v\delta T + \left[\frac{P}{\rho^2} - \frac{T}{\rho^2}\left(\frac{\partial P}{\partial T}\right)_{\rho\xi}\right]\delta\rho + \left\{\sum_{i=1}^{3}\left[\mu_i - T\left(\frac{\partial\mu_i}{\partial T}\right)_{\rho\xi}\right]\bar{\nu}_i m_i\right\}\delta\xi$$

where C_v is the specific heat at constant volume and μ_i (i = 1, 2, and 3) denotes the differences among the chemical potentials; $\mu_1 = \mu_A - \mu_D$, $\mu_2 = \mu_B - \mu_D$, and $\mu_3 = \mu_C - \mu_D$. Thus by expressing δA in function of $\delta\xi$ and δT,

[2.13] $$\delta A = \left(\frac{\partial A}{\partial T}\right)_{\rho\xi}\delta T + \left(\frac{\partial A}{\partial \xi}\right)_{\rho T}\delta\xi$$

from eqs. [2.5]–[2.7] and [2.11]–[2.13], we arrive at the following linear phenomenological equations

[2.14] $$\frac{\partial\delta\xi}{\partial t} = -\frac{\epsilon}{\rho}\left(\frac{\partial A}{\partial T}\right)_{\rho\xi}\delta T - \frac{\epsilon}{\rho}\left(\frac{\partial A}{\partial\xi}\right)_{\rho T}\delta\xi$$

[2.15] $$\frac{\partial\delta T}{\partial t} = -\frac{T\epsilon}{\rho C_v}\left(\frac{\partial A}{\partial T}\right)^2_{\rho\xi}\delta T - \frac{T\epsilon}{\rho C_v}\left(\frac{\partial A}{\partial\xi}\right)_{\rho T}\left(\frac{\partial A}{\partial T}\right)_{\rho\xi}\delta\xi$$

Equations [2.14]–[2.15] constitute a system of ordinary differential equations, which may be written in the compact form

[2.16] $$\frac{\partial\Psi(t)}{\partial t} = \hat{\mathbf{M}}\cdot\Psi(t)$$

where we have used a two-dimensional space, $\Psi(t)$ being the vector

[2.17] $$\Psi(t) = \begin{bmatrix}\delta\xi\\ \delta T\end{bmatrix}$$

The matrix elements of $\hat{\mathbf{M}}$ are the thermodynamic coefficients which appear in eqs. [2.14]–[2.15]. $\hat{\mathbf{M}}$ is an hermitian matrix and its eigenvalue problem

[2.18] $$\hat{\mathbf{M}}\cdot\chi_i = \omega_i\cdot\chi_i$$

has two linearly independent solutions. Thus, any vector Ψ can be written as

[2.19] $$\Psi = \sum_{i=1}^{2} C_i(0)\exp(\omega_i t)\chi_i$$

with

[2.20] $$C_i(0) = \langle\chi_i|\Psi(0)\rangle$$

The eigenvalues ω_i are the solutions of the secular determinant

[2.21] $$\|\hat{\mathbf{M}} - \omega_i\mathbf{U}\| = 0$$

(here $\mathbf{U}$ represents the unit matrix in a two-dimensional space), from which we get

[2.22] $$\omega_1 = -\frac{\epsilon}{\rho}\left(\frac{\partial A}{\partial\xi}\right)_{\rho T} - \frac{T\epsilon}{\rho C_v}\left(\frac{\partial A}{\partial T}\right)^2_{\rho\xi}$$

[2.23] $\omega_2 = 0$

Hence, from these results the Ψ vector becomes

[2.24] $\Psi(t) = C_1(0) \exp(\omega_1 t)\chi_1 + C_2(0)\chi_2$

The time-dependent term of the right hand side is called chemical relaxation mode; it determines the evolution of the system to equilibrium state, with a relaxation time equal to $(-\omega_1^{-1})$, and describes the dissipation due to the chemical reaction.

The thermodynamic stability of the system requires ω_1 to be negative. In order to show this fact, we take into account that ϵ is positive as a consequence of the positive character of the entropy production (30), and that

[2.25] $$\left(\frac{\partial A}{\partial \xi}\right)_{\rho T} = \left(\frac{\partial^2 F}{\partial \xi^2}\right)_{\rho T} > 0$$

is a positive derivative because the Helmholtz free energy, F, has a minimum in the equilibrium at constant density and temperature. Therefore, under these considerations, we conclude that ω_1 must be negative. This result insures the stability of the system.

3. Microscopic derivation of the phenomenological equations

As our system is a dilute gas, it is reasonable to assume that its statistical time evolution is given by the Boltzmann equation, which in absence of external forces takes the form

[3.1] $$\frac{\partial f_A}{\partial t} = \sum_S \int d\upsilon_s\, d\Omega' \sigma_{AS}^{(e)} g_{AS}[f_A' f_S' - f_A f_S] + \int d\upsilon_B\, d\Omega' \sigma_{AB}^{(r)} g_{AB}[f_C f_D - f_A f_B]$$

where S = A, B, C, and D; υ_s is the velocity of S-particle; Ω' the solid angle into which the particles are scattered in a particular collision event; $\sigma_{AS}^{(e)}$ and $\sigma_{AB}^{(r)}$ are the differential elastic and reactive cross sections, respectively; g_{AS} is the relative velocity and f_S is the singlet distribution function. Similar equations hold for B, C, and D. Now, we assume the separation between the fundamental internal level and the first excited one to be sufficiently large, to avoid the inelastic collisions; later, this situation will be analysed.

As we consider that the gas is only slightly perturbed away from absolute equilibrium, we can write the distribution function in the form

[3.2] $$f_S(t) = f_S^e(\upsilon_s) + \delta f_S^e(\upsilon_s; t); \frac{|\delta f_S|}{f_S^e} \ll 1$$

$f_S^{(e)}$ being the Maxwell–Boltzmann distribution function and δf_S the deviation of f_S from its equilibrium value. Introducing this expression into [3.1] yields a linearized Boltzmann equation

[3.3] $$\frac{\partial \delta f_A}{\partial t} = \sum_S \int d\upsilon_s\, d\Omega' \sigma_{AS}^{(e)} g_{AS} f_A^e f_S^e \times \left[\left(\frac{\delta f_A}{f_A^e}\right)' + \left(\frac{\delta f_S}{f_S^e}\right)' - \left(\frac{\delta f_A}{f_A^e}\right) - \left(\frac{\delta f_S}{f_S^e}\right)\right] + \int d\upsilon_B\, d\Omega' \sigma_{AB}^{(r)} g_{AB} f_A^e f_B^e \times \left[\left(\frac{\delta f_C}{f_C^e}\right)' + \left(\frac{\delta f_D}{f_D^e}\right)' - \left(\frac{\delta f_A}{f_A^e}\right) - \left(\frac{\delta f_B}{f_B^e}\right)\right]$$

This equation may also be written as

[3.4] $$\frac{\partial \delta f_A}{\partial t} = \sum_S \hat{C}_{AS}^{(e)} \delta f_S + \sum_S \hat{C}_{AS}^{(r)} \delta f_S$$

where $\hat{C}_{AS}^{(e)}$ = operators come from the linearized elastic collision terms and $\hat{C}_{AS}^{(r)}$ = operators from the linearized reactive ones.

Similar equations hold for the other components of the system. This allows us to express the statistical evolution of our system by means of a matrix equation

[3.5] $$\frac{\partial}{\partial t}\begin{bmatrix}\delta f_A\\ \delta f_B\\ \delta f_C\\ \delta f_D\end{bmatrix} = \hat{C}^{(e)}\cdot\begin{bmatrix}\delta f_A\\ \delta f_B\\ \delta f_C\\ \delta f_D\end{bmatrix} + \hat{C}^{(r)}\cdot\begin{bmatrix}\delta f_A\\ \delta f_B\\ \delta f_C\\ \delta f_D\end{bmatrix}$$

If δf means

[3.6] $$\delta f \equiv \begin{bmatrix}\delta f_A\\ \delta f_B\\ \delta f_C\\ \delta f_D\end{bmatrix}$$

then expression [3.5] becomes

[3.7] $$\frac{\partial \delta f}{\partial t} = (\hat{C}^{(e)} + \hat{C}^{(r)})\cdot\delta f$$

$\hat{C}^{(e)}$ and $\hat{C}^{(r)}$ being matrix operators which will be called "elastic and reactive collision operators", respectively. These linear operators are characterized by a set of useful mathematical properties. Thus with the aid of the following scalar product

[3.8] $$\langle F|G\rangle = \sum_S \int d\upsilon_s [f_s^e(\upsilon_s)]^{-1} F_s^*(\upsilon_s) G_s(\upsilon_s)$$

where

[3.9] $$F \equiv \begin{bmatrix}F_A(\upsilon_A)\\ F_B(\upsilon_B)\\ F_C(\upsilon_C)\\ F_D(\upsilon_D)\end{bmatrix};\quad G \equiv \begin{bmatrix}G_A(\upsilon_A)\\ G_B(\upsilon_B)\\ G_C(\upsilon_C)\\ G_D(\upsilon_D)\end{bmatrix}$$

the operators $\hat{C}^{(e)}$ and $\hat{C}^{(r)}$ are hermitian. Hence, their corresponding eigenvalues $\lambda_j^{(e)}$ and $\lambda_j^{(r)}$ are real. Moreover, it can be easily shown that these eigenvalues are non-positive.

Assuming that the set of eigenfunctions $\{|\phi_j\rangle\}$ of the operator $(\hat{C}^{(e)} + \hat{C}^{(r)})$ is a complete set, the solution of [3.7] will be given by

[3.10] $$\delta f(t) = \sum_j a_j(0) \exp(\lambda_j t)\phi_j$$

with

[3.11] $$a_j(0) = \langle \phi_j|\delta f(0)\rangle$$

On the other hand, we shall assume as it is habitual that reactive collisions are less frequent than elastic ones. Therefore, we shall treat $\hat{C}^{(r)}$ as a perturbation with respect to $\hat{C}^{(e)}$. This assumption allows us to simplify the complex equation [3.10]. In fact, for non-reacting systems (where $\hat{C}^{(r)} \equiv \mathbf{0}$) there exist eight eigenfunctions corresponding to the eigenvalue zero ($\lambda_\alpha^{(e)} = 0$, $\alpha = 1, \ldots, 8$) (see Appendix 1). This is a consequence of the eight collisional invariants associated to the non-

For personal use only.

reactive collisions. The eigenvalues $\lambda_j^{(e)}$ ($j \geq 9$) measure the rate of approach to equilibrium by means of elastic collisions. We introduce the elastic relaxation times, $\tau_{rel,j}^{(e)}$, through (39),

$$[3.12] \quad \tau_{rel,j}^{(e)} = -(\lambda_j^{(e)})^{-1} > 0; \qquad j = 9, 10, \ldots$$

We shall assume that the spectrum of $\hat{C}^{(e)}$ is discrete and has no accumulation point. In particular, this implies that there exists a finite positive number μ such that

$$[3.13] \quad \lambda_j^{(e)} < -\mu; \qquad j = 9, 10, \ldots$$

This has been shown (40) for repulsive r^{-n} ($n > 2$) potentials and we shall assume that it remains valid even when we deal with forces that are not strictly repulsive (35). Consequently, the eigenvalue $\lambda_9^{(e)}$, closest to zero will be separated from the origin by a finite maximum elastic relaxation time, $\tau_{rel,9}^{(e)}$, that fixes the duration of the elastic relaxation towards equilibrium. This time is the so-called elastic relaxation time and will be denoted by $\tau_{rel}^{(e)}$.

For times, $t \gg \tau_{rel}^{(e)}$, and for a non-reacting system, we have

$$[3.14] \quad \delta f \simeq \sum_{\alpha=1}^{8} a_\alpha^{(e)}(0)\phi_\alpha^{(e)}$$

Therefore, for the reacting system considered in the present section, a similar equation to [3.14] holds

$$[3.15] \quad \delta f(t) = \sum_{\alpha=1}^{8} a_\alpha(0) \exp(\lambda_\alpha t)\phi_\alpha$$

Precisely, if we assume the eigenvalues λ_α to be evaluated by a perturbation theory, there will be eight eigenvalues vanishing when the reactive cross section tends to zero, the other remaining finite. Hence, only the corresponding eight terms survive in eq. [3.10] for times longer than the elastic relaxation time. In fact, for reacting systems (where $\hat{C}^{(r)} \neq \mathbf{0}$) the chemical species are not independent of each other since reaction [1.1] imposes the constraint that every time a molecule A (or B) disappears a molecule C (or D) must appear. For that, there exist only seven eigenfunctions of the $\hat{C}$ operator for the zero eigenvalue ($\lambda_\alpha = 0$, $\alpha = 1, \ldots, 7$) (see Appendix I). Of course, this is a consequence of the seven collisional invariants associated to the reactive collisions (the eighth invariant is destroyed by the constraint imposed by the chemical reaction). Consequently, the goal must be to find the remaining non-zero eigenvalue and its associated eigenfunction.

Thus, in order to solve the eigenvalue problem associated to the operator $(\hat{C}^{(e)} + \hat{C}^{(r)})$, we can utilise a perturbation calculus expanding λ_α and ϕ_α according to

$$[3.16] \quad \lambda_\alpha = \lambda_\alpha^{(1)} + \lambda_\alpha^{(2)} + \lambda_\alpha^{(3)} + \ldots$$

$$[3.17] \quad \phi_\alpha = \varphi_\alpha + \phi_\alpha^{(1)} + \phi_\alpha^{(2)} + \ldots$$

Introducing these expansions in the eigenvalue problem

$$[3.18] \quad (\hat{C}^{(e)} + \hat{C}^{(r)})|\phi_\alpha\rangle = \lambda_\alpha|\phi_\alpha\rangle$$

and using the projection operators P and Q, defined as

$$[3.19] \quad P = \sum_{\alpha=1}^{8} |\varphi_\alpha\rangle\langle\varphi_\alpha|; \qquad Q = \sum_{k\neq\{\alpha\}} |\phi_k^{(e)}\rangle\langle\phi_k^{(e)}|, \{\alpha\} = \{1, \ldots, 8\}$$

that satisfy the properties

$$[3.20] \quad P + Q = \mathbf{1}, \qquad P\hat{C}^{(e)} = \hat{C}^{(e)}P = \mathbf{0}$$

we get (Appendix I)

$$[3.21] \quad \lambda_\alpha^{(1)} = 0, \lambda_\alpha^{(2)} = 0, \lambda_\alpha^{(3)} = 0 \qquad (\alpha = 1, \ldots, 7)$$

$$[3.22] \quad \lambda_8^{(1)} = \left[\frac{2}{3n}\left(\frac{\Delta E}{k_B T}\right)^2 + \sum_{i=A,B,C,D} n_i^{-1}\right]\Lambda$$

$$[3.23] \quad \lambda_8^{(2)} = \left[\frac{2}{3n}\left(\frac{\Delta E}{k_B T}\right)^2 + \sum_{i=A,B,C,D} n_i^{-1}\right] \times \langle\Psi|Q\hat{C}^{(e)-1}Q|\Psi\rangle$$

$$[3.24] \quad \lambda_8^{(3)} = \left[\frac{2}{3n}\left(\frac{\Delta E}{k_B T}\right)^2 + \sum_{i=A,B,C,D} n_i^{-1}\right] \times \{-\lambda_8^{(1)}\langle\Psi|Q\hat{C}^{(e)-1}Q\hat{C}^{(e)-1}Q|\Psi\rangle + \langle\Psi|Q\hat{C}^{(e)-1}Q\hat{C}^{(r)}Q\hat{C}^{(e)-1}Q|\Psi\rangle\}$$

The results [3.21]–[3.24] show, according to [3.15] that the δf function may be expressed as

$$[3.25] \quad \delta f(t) = \sum_{\alpha=1}^{7} a_\alpha(0)\phi_\alpha + a_8(0) \exp(\lambda_8 t)\phi_8$$

Defining the chemical relaxation time, $\tau_{rel}^{(r)}$ as

$$[3.26] \quad \tau_{rel}^{(r)} = (-\lambda_8)^{-1}$$

the solution [3.25] holds for times, $t \gg \tau_{rel}^{(r)}$, but for times $t \gg \tau_{rel}^{(r)}$, the second term of this solution (associated with the so-called reactive mode) will decay, driving the system towards a new equilibrium state characterized by the distribution function (35)

$$[3.27] \quad f^e = f_{in}^e + \delta f^e$$

f_{in}^e being the distribution of the initial equilibrium state.

From eq. [3.25] we can obtain all the variables which describe the system. For instance (41),

$$[3.28] \quad \delta T = T\sqrt{\frac{2}{3n}}\langle\phi_8^{(e)}|\delta f\rangle = T\sqrt{\frac{2}{3n}}\left[\sum_{\alpha=1}^{7} a_\alpha(0)\langle\phi_8^{(e)}|\phi_\alpha\rangle + a_8(0) \exp(\lambda_8 t)\langle\phi_8^{(e)}|\phi_8\rangle\right]$$

$\phi_8^{(e)}$ being the eighth eigenfunction of $\hat{C}^{(e)}$ for $\lambda_j^{(e)} = 0$.

If we compare [3.28] with its macroscopic expression obtained of the fourth component of Ψ in eq. [2.24], we find

$$[3.29] \quad \lambda_8 = \omega_1$$

Taking into account the standard formula for the affinity of a dilute reacting gas (30)

$$[3.30] \quad A = -\frac{3}{2}k_B T \ln\left(\frac{m_C m_D}{m_A m_B}\right) + \Delta E + k_B T \ln\left(\frac{n_C n_D}{n_A n_B}\right)$$

eq. [2.22] becomes

$$[3.31] \quad \omega_1 = -\epsilon k_B T\left\{\frac{2}{3n}\left(\frac{\Delta E}{k_B T}\right)^2 + \sum_{S=A,B,C,D} n_S^{-1}\right\}$$

Hence, the coefficient ϵ is given by

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/07/12
For personal use only.

[3.32] $$\epsilon = -\frac{1}{k_B T\left\{\frac{2}{3n}\left(\frac{\Delta E}{k_B T}\right)^2 + \sum_{S=A,B,C,D} n_S^{-1}\right\}} \times \{\lambda_8^{(1)} + \lambda_8^{(2)} + \lambda_8^{(3)}\}$$

From here, one can obtain immediately K_f and K_r by using [2.9]

[3.33] $$K_r = \frac{1}{\gamma_C \gamma_D}\left\{\int dv_C\, dv_D\, d\Omega'\, \sigma_{CD}^{(r)} g_{CD} f_C^e f_D^e + \langle\Psi|Q\hat{C}^{(e)-1}Q|\Psi\rangle + \lambda_8^{(1)}\langle\Psi|Q\hat{C}^{(e)-1}Q\hat{C}^{(e)-1}Q|\Psi\rangle - \langle\Psi|Q\hat{C}^{(e)-1}Q\hat{C}^{(r)}Q\hat{C}^{(e)-1}Q|\Psi\rangle\right\}$$

[3.34] $$K_f = \frac{1}{\gamma_A \gamma_B}\left\{\int dv_A\, dv_B\, d\Omega'\, \sigma_{AB}^{(r)} g_{AB} f_A^e f_B^e + \langle\Psi|Q\hat{C}^{(e)-1}Q|\Psi\rangle + \lambda_8^{(1)}\langle\Psi|Q\hat{C}^{(e)-1}Q\hat{C}^{(e)-1}Q|\Psi\rangle - \langle\Psi|Q\hat{C}^{(e)-1}Q\hat{C}^{(r)}Q\hat{C}^{(e)-1}Q|\Psi\rangle\right\}$$

In expressions [3.32]–[3.34], all the terms are expressed in function of equilibrium properties. This is a consequence of the fact that the considered reference state is the absolute equilibrium. Thus, the two rate coefficients are constants and satisfy the mass action law.

The first term of the rate coefficients, coming from the first correction $\lambda_8^{(1)}$ to the eigenvalue λ_8, represents the equilibrium contribution of the coefficients, whereas the other terms represent the non-equilibrium contributions.

Now, we will deduce the microscopic expressions of the phenomenological equations from the distribution function.

Using the linearized expressions of density, the degree of advancement of the reaction and temperature (41), i.e.,

[3.35] $$\delta\rho = \langle I|\delta f\rangle$$
$$|I\rangle = m_A n_A^{1/2}|\phi_1^{(e)}\rangle + m_B n_B^{1/2}|\phi_2^{(e)}\rangle + m_C n_C^{1/2}|\phi_3^{(e)}\rangle + m_D n_D^{1/2}|\phi_4^{(e)}\rangle$$

[3.36] $$\delta\xi = \langle II|\delta f\rangle$$
$$|II\rangle = \frac{m_B n_A^{1/2} n_B^{1/2}}{\rho^2}[n_A^{1/2}|\phi_2^{(e)}\rangle - n_B^{1/2}|\phi_1^{(e)}\rangle] + \frac{m_C n_A^{1/2} n_C^{1/2}}{\rho^2}[n_A^{1/2}|\phi_3^{(e)}\rangle - n_C^{1/2}|\phi_1^{(e)}\rangle] + \frac{m_D n_A^{1/2} n_D^{1/2}}{\rho^2}[n_A^{1/2}|\phi_4^{(e)}\rangle - n_D^{1/2}|\phi_1^{(e)}\rangle]$$

[3.37] $$\delta T = \langle III|\delta f\rangle$$
$$|III\rangle = T\sqrt{2/3n}\,|\phi_8^{(e)}\rangle$$

one can deduce the following general evolution equation

$$\frac{\partial\delta\omega}{\partial t} = \sum_{\alpha=1}^{8}\langle\beta|Z|\phi_\alpha^{(e)}\rangle\langle\phi_\alpha^{(e)}|\delta f\rangle$$

[3.38] $$\beta = I, II, III$$
$$\delta\omega = \delta\rho, \delta\xi, \delta T$$

where

[3.39] $$Z = \lambda_8|\phi_8\rangle\langle\phi_8|$$

If we consider the property,

[3.40] $$\hat{C}^{(r)}|\varphi_\alpha\rangle = 0 \qquad (\alpha = 1, \ldots, 7)$$

then

[3.41] $$\langle\varphi_\alpha|\phi_\beta^{(1)}\rangle = (\lambda_\alpha^{(1)} - \lambda_\beta^{(1)})^{-1}\langle\varphi_\alpha|\hat{C}^{(r)}Q\hat{G}^{-1}Q\hat{C}^{(r)}|\varphi_\beta\rangle = 0$$

and similar results are found for $\phi_\beta^{(n)}$ $(n > 1)$. In this case Z becomes

[3.42] $$Z = \lambda_8|\varphi_8\rangle\langle\varphi_8|$$

Calculating the matrix elements $\langle\beta|Z|\phi_\alpha^{(e)}\rangle$ and taking into account,

[3.43] $$\langle\phi_1^{(e)}|\delta f\rangle = \frac{n_A^{1/2}}{\rho}\delta\rho - \frac{\rho}{n_A^{1/2}}\delta\xi$$

[3.43] $$\langle\phi_2^{(e)}|\delta f\rangle = \frac{n_B^{1/2}}{\rho}\delta\rho - \frac{\rho}{n_B^{1/2}}\delta\xi$$

[3.45] $$\langle\phi_3^{(e)}|\delta f\rangle = \frac{n_C^{1/2}}{\rho}\delta\rho + \frac{\rho}{n_C^{1/2}}\delta\xi$$

[3.46] $$\langle\phi_4^{(e)}|\delta f\rangle = \frac{n_D^{1/2}}{\rho}\delta\rho + \frac{\rho}{n_D^{1/2}}\delta\xi$$

we arrive at the microscopic expressions of the phenomenological equations

[3.47] $$\frac{\partial\delta\rho}{\partial t} = 0$$

[3.48] $$\frac{\partial\delta\xi}{\partial t} = \frac{\lambda_8\sum_{S=A,B,C,D} n_S^{-1}}{\left\{\frac{2}{3n}\left(\frac{\Delta E}{k_B T}\right)^2 + \sum_{S=A,B,C,D} n_S^{-1}\right\}}\delta\xi - \frac{\lambda_8\left(\frac{\Delta E}{k_B T}\right)}{\rho T\left\{\frac{2}{3n}\left(\frac{\Delta E}{k_B T}\right)^2 + \sum_{S=A,B,C,D} n_S^{-1}\right\}}\delta T$$

[3.49] $$\frac{\partial\delta T}{\partial t} = -\frac{\lambda_8\left(\frac{2\rho T}{3n}\right)\left(\frac{\Delta E}{k_B T}\right)\sum_{S=A,B,C,D} n_S^{-1}}{\left\{\frac{2}{3n}\left(\frac{\Delta E}{k_B T}\right)^2 + \sum_{S=A,B,C,D} n_S^{-1}\right\}}\delta\xi + \frac{\lambda_8\left(\frac{2}{3n}\right)\left(\frac{\Delta E^2}{k_B T}\right)}{\left\{\frac{2}{3n}\left(\frac{\Delta E}{k_B T}\right)^2 + \sum_{S=A,B,C,D} n_S^{-1}\right\}}\delta T$$

Since for a dilute gas the following relations are verified

$$\left(\frac{\partial A}{\partial\xi}\right)_{\rho T} = -\rho k_B T\sum_{S=A,B,C,D} n_S^{-1}$$

[3.50] $$\left(\frac{\partial A}{\partial T}\right)_{\rho\xi} = -\frac{\Delta E}{T}$$

$$C_v = \frac{3k_B n}{2\rho}$$

eqs. [3.48], [3.49] can be compared with the phenomenological

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/07/12
For personal use only.

eqs. [2.14], [2.15]. This comparison permits us to identify the phenomenological coefficient ϵ, recovering eq. [3.32].

Until this point, we have considered, for simplicity, a system in which there exist no inelastic collisions. Even if there are inelastic collisions, we can make the same analysis by considering each internal state as a new component of the system. For instance, whenever the component A appears in the states A_1 and A_2 (characterized by the energies E_{A_1} and E_{A_2}, respectively) the following reactive collisions

[3.51] $A_1 + B \rightleftharpoons C + D$

[3.52] $A_2 + B \rightleftharpoons C + D$

could be possible.

If we assume that the elastic and inelastic collisions are more probable than the reactive ones, the matrix kinetic equation may be written as follows

$$[3.53] \quad \frac{\partial \delta f}{\partial t} = (\hat{C}' + \hat{C}^{(r)})\delta f$$

where $\hat{C}'$ is the collision operator associated with the elastic and inelastic collisions, $\hat{C}^{(r)}$ the collision operator associated with the reactive ones [3.51], [3.52], and now δf means

$$[3.54] \quad \delta f \equiv \begin{bmatrix} \delta f_{A_1} \\ \delta f_{A_2} \\ \delta f_B \\ \delta f_C \\ \delta f_D \end{bmatrix}$$

Therefore, eq. [3.53] can be resolved by a perturbation method assuming $\hat{C}^{(r)}$ as a small perturbation of $\hat{C}'$. Proceeding in this way, it is possible to arrive at the microscopic expressions of the phenomenological eqs. [2.14], [2.15], where now

$$[3.55] \quad \epsilon = \frac{1}{k_B T}\left\{\sum_{j=1,2}\int dv_{A_j}\, dv_B\, d\Omega' \sigma^{(r)}_{A_jB} g_{A_jB} f^e_{A_j} f^e_B + \langle \Psi | Q\hat{C}^{-1}Q|\Psi\rangle + \ldots\right\}$$

and

$$[3.56] \quad \Psi \equiv \begin{bmatrix} \sum_{j=1,2}\int dv_B\, d\Omega' \sigma^{(r)}_{A_jB} g_{A_jB} f^e_{A_j} f^e_B \\ \int dv_{A_1}\, d\Omega' \sigma^{(r)}_{A_1B} g_{A_1B} f^e_{A_1} f^e_B \\ \int dv_{A_2}\, d\Omega' \sigma^{(r)}_{A_2B} g_{A_2B} f^e_{A_2} f^e_B \\ -\int dv_D\, d\Omega' \sigma^{(r)}_{CD} g_{CD} f^e_C f^e_D \\ -\int dv_C\, d\Omega' \sigma^{(r)}_{CD} g_{CD} f^e_C f^e_D \end{bmatrix}$$

4. Discussion

In the present paper, we have discussed, using the kinetic theory of fluids, the derivation of macroscopic evolution equations for a non-isothermal homogeneous reacting system. This study has been achieved for a system characterized by a bimolecular reaction like [2.1]. Such an analysis has also permitted the identification of true non-equilibrium rate constants in terms of equilibrium quantities and microscopic properties of the particles and verification of the mass action law. We have assumed that reactive collisions are less probable than elastic ones and the study has been achieved in the framework of the method introduced by Résibois (33–35), Theodosopulu, Grecos, and Prigogine (36, 37). We must point out that this method, based on a standard perturbation calculus, consists of assuming the system only slightly perturbed away from absolute equilibrium, according to [3.2]. Indeed, when the system is deviated from equilibrium state, it experiments a relaxation process and reaches a new equilibrium state described by

$$[4.1] \quad f^e = f^e_{in} + \delta f^e$$

This state is perfectly defined by the collision invariants which characterize the reacting system. Precisely, this feature of the method enables us to write non-equilibrium properties, like the rate coefficients, as functions of equilibrium quantities.

Nevertheless, the deviation from equilibrium state is defined by the collision invariants and by the relaxation modes. The relaxation modes decay exponentially and as $t \to \infty$, such modes vanish. In this way, $\delta f(t)$ becomes exclusively defined by the collision invariants. The relaxation modes are dependent on the type of system under consideration. Therefore, for systems as the ones considered in section 3, all the relaxation modes except one are fundamentally elastic, i.e., the more important contribution associated with such modes comes from elastic collisions; the other mode being characterized by a reactive collision frequency, λ_8 (to which we have associated the chemical relaxation time, $\tau^{(r)}_{rel}$) has been called "chemical relaxation mode".

We have seen that for times satisfying the condition, $t \geqslant \tau^{(r)}_{rel}$, the equilibrium established by elastic collisions is perturbed by the presence of the reactive ones; this occurs because, the reaction introduces a constraint which reduces the number of collision invariants. This fact removes partially the initial degeneration of the $\hat{C}^{(e)}$ operator (from eight eigenfunctions to seven for the zero eigenvalue). Calculating λ_8, by considering the $\hat{C}^{(r)}$ operator as a small perturbation of $\hat{C}^{(e)}$ operator, we have derived the microscopic expressions of the phenomenological equations.

We must point out that the procedure used for solving the eigenvalue equation [3.18], i.e., to consider $\hat{C}^{(r)}$ as a perturbation with regards to $\hat{C}^{(e)}$ permits to establish the time scale

$$[4.2] \quad \tau^{(e)}_{rel} \ll \tau^{(r)}_{rel}$$

Obviously, eq. [3.7] has a different solution for each of the following conditions: $\tau^{(r)}_{rel} > t \geqslant \tau^{(e)}_{rel}$, $t \geqslant \tau^{(r)}_{rel}$, or $t \gg \tau^{(r)}_{rel}$. In the first case, the evolution of the system is described by a set of infinite relaxation modes. In the last case, the system does not experiment an evolution because it has already reached the absolute equilibrium. Nevertheless, in the second case (the most important here) the evolution of the system is described by a single mode, the chemical relaxation mode. Of course, we are interested in this case because we must analyse the system at times in which the chemical reaction occurs ($t \geqslant \tau^{(r)}_{rel}$). Hence, for times of the order of the chemical relaxation time, $\tau^{(r)}_{rel}$, the chemical relaxation mode, associated with λ_8, is sufficient for describing the macroscopic behaviour of the system.

The comparison of both sets of equations has permitted us to identify the rate coefficients as true constants, which verify the mass action law. At this point, we want to detach that their first

For personal use only.

correction represents the equilibrium contribution, while the other corrections represent non-equilibrium contributions, but expressed by means of the equilibrium values of the variables.

Finally, we point out that the present study can be extended for non-uniform systems, by incorporating to the Boltzmann equations the flux term and assuming a slow local dependance of the distribution function. We are working on the subject.

Appendix I

In this appendix we show the eigenfunctions of the zero eigenvalue for $\hat{C}^{(e)}$. We provide too, a detailed perturbation calculus of the eigenvalue λ_8 of the operator $\hat{C} = (\hat{C}^{(e)} + \hat{C}^{(r)})$.

We can obtain the eigenfunctions $\{\phi_\alpha^{(e)}\}$ of $\hat{C}^{(e)}$ taking into account that in a system composed of four components there exist eight collision invariants associated with the elastic collisions (35). Thus, using the orthogonality condition

$$[I.1] \qquad \langle \phi_\alpha^{(e)} | \phi_\beta^{(e)} \rangle = \delta_{\alpha\beta}^{kr}$$

we easily get, for instance

$$|\phi_1^{(e)}\rangle = \begin{bmatrix} n_A^{-1/2} f_A^e \\ 0 \\ 0 \\ 0 \end{bmatrix}; \quad |\phi_2^{(e)}\rangle = \begin{bmatrix} 0 \\ n_B^{-1/2} f_B^e \\ 0 \\ 0 \end{bmatrix};$$

$$|\phi_3^{(e)}\rangle = \begin{bmatrix} 0 \\ 0 \\ n_C^{-1/2} f_C^e \\ 0 \end{bmatrix}; \quad |\phi_4^{(e)}\rangle = \begin{bmatrix} 0 \\ 0 \\ 0 \\ n_D^{-1/2} f_D^e \end{bmatrix} \qquad [I.2]$$

$$|\phi_i^{(e)}\rangle = (\rho k_B T)^{-1/2} \begin{bmatrix} m_A v_{A,i} f_A^e \\ m_B v_{B,i} f_B^e \\ m_C v_{C,i} f_C^e \\ m_D v_{D,i} f_D^e \end{bmatrix};$$

$$(i = 5, 6, 7 \equiv X, Y, Z)$$

$$|\phi_8^{(e)}\rangle = \sqrt{\frac{2}{3n}} \begin{bmatrix} \left(\frac{m_A v_A^2}{2k_B T} - \frac{3}{2}\right) f_A^e \\ \left(\frac{m_B v_B^2}{2k_B T} - \frac{3}{2}\right) f_B^e \\ \left(\frac{m_C v_C^2}{2k_B T} - \frac{3}{2}\right) f_C^e \\ \left(\frac{m_D v_D^2}{2k_B T} - \frac{3}{2}\right) f_D^e \end{bmatrix}$$

In a similar way, it is possible to find the eigenfunctions $\{\phi_\alpha^{(r)}\}$ of $C^{(r)}$, but considering that in a reactive collision there are only seven collision invariants (one invariant disappears because of the constraint imposed by the chemical process).

Whenever $\hat{C}^{(r)}$ may be considered as a small pertubation of $\hat{C}^{(e)}$, the following relations can be derived from [3.16]–[3.18]

$$[I.3] \qquad \hat{C}^{(e)} |\varphi_\alpha\rangle = 0$$

$$[I.4] \qquad \hat{C}^{(r)} |\varphi_\alpha\rangle + \hat{C}^{(e)} |\phi_\alpha^{(1)}\rangle = \lambda_\alpha^{(1)} |\varphi_\alpha\rangle$$

$$[I.5] \qquad \hat{C}^{(r)} |\phi_\alpha^{(1)}\rangle + \hat{C}^{(e)} |\phi_\alpha^{(2)}\rangle = \lambda_\alpha^{(1)} |\phi_\alpha^{(1)}\rangle + \lambda_\alpha^{(2)} |\varphi_\alpha\rangle$$

$$[I.6] \qquad \hat{C}^{(r)} |\phi_\alpha^{(2)}\rangle + \hat{C}^{(e)} |\phi_\alpha^{(3)}\rangle = \lambda_\alpha^{(1)} |\phi_\alpha^{(2)}\rangle + \lambda_\alpha^{(2)} |\phi_\alpha^{(1)}\rangle + \lambda_\alpha^{(3)} |\varphi_\alpha\rangle$$

Equation [I.3] allows us to express

$$[I.7] \qquad |\varphi_\alpha\rangle = \sum_{\alpha'=1}^{8} C_{\alpha\alpha'}^0 |\phi_{\alpha'}^{(e)}\rangle$$

By using the projection operators P and Q defined in [3.19], we find

[I.8] $P\hat{C}^{(r)}P|\varphi_\alpha\rangle = \lambda_\alpha^{(1)}|\varphi_\alpha\rangle$

showing that $|\varphi_\alpha\rangle$ and $\lambda_\alpha^{(1)}$ are the eigenfunctions and eigenvalues of the $P\hat{C}^{(r)}P$ operator. Multiplying by the bra $\langle\phi_\beta^{(e)}|$, we get the set of equations

[I.9] $$\sum_{\alpha'=1}^{8} C^0_{\alpha,\alpha'}[\langle\phi_\beta^{(e)}|\hat{C}^{(r)}|\phi_{\alpha'}^{(e)}\rangle - \lambda_\alpha^{(1)}\delta^{K_r}_{\beta\alpha'}] = 0$$

having solution whenever the following determinant vanishes

[I.10] $$\|\langle\phi_\beta^{(e)}|\hat{C}^{(r)}|\phi_\alpha^{(e)}\rangle - \lambda_\alpha^{(1)}\delta^{K_r}_{\beta\alpha'}\| = 0$$

from which, the corrections of first order $\lambda_\alpha^{(1)}$ can be obtained. Taking into account that the matrix elements,

[I.11] $$C^{(r)}_{i,j} \equiv \langle\phi_i^{(e)}|\hat{C}^{(r)}|\phi_j^{(e)}\rangle \qquad (i, j = 1, \ldots, 8)$$

vanish except for

$$C^{(r)}_{1,1} = n_A^{-1}\Lambda, \quad C^{(r)}_{2,2} = n_B^{-1}\Lambda, \quad C^{(r)}_{3,3} = n_C^{-1}\Lambda, \quad C^{(r)}_{4,4} = n_D^{-1}\Lambda$$
$$C^{(r)}_{1,2} = C^{(r)}_{2,1} = n_A^{-1/2}n_B^{-1/2}\Lambda, \quad C^{(r)}_{1,3} = C^{(r)}_{3,1} = -n_A^{-1/2}n_C^{-1/2}\Lambda, \quad C^{(r)}_{1,4} = C^{(r)}_{4,1} = -n_A^{-1/2}n_D^{-1/2}\Lambda$$
[I.12] $$C^{(r)}_{2,3} = C^{(r)}_{3,2} = -n_B^{-1/2}n_C^{-1/2}\Lambda, \quad C^{(r)}_{2,4} = C^{(r)}_{4,2} = -n_B^{-1/2}n_D^{-1/2}\Lambda, \quad C^{(r)}_{3,4} = C^{(r)}_{4,3} = n_C^{-1/2}n_D^{-1/2}\Lambda$$
$$C^{(r)}_{1,8} = C^{(r)}_{8,1} = \sqrt{\frac{2}{3nn_A}}\left(\frac{\Delta E}{k_BT}\right)\Lambda, \quad C^{(r)}_{2,8} = C^{(r)}_{8,2} = \sqrt{\frac{2}{3nn_B}}\left(\frac{\Delta E}{k_BT}\right)\Lambda, \quad C^{(r)}_{3,8} = C^{(r)}_{8,3} = -\sqrt{\frac{2}{3nn_C}}\left(\frac{\Delta E}{k_BT}\right)\Lambda$$
$$C^{(r)}_{4,8} = C^{(r)}_{8,4} = -\sqrt{\frac{2}{3nn_D}}\left(\frac{\Delta E}{k_BT}\right)\Lambda, \quad C^{(r)}_{8,8} = \frac{2}{3n}\left(\frac{\Delta E}{k_BT}\right)^2\Lambda$$

where

[I.13] $$\Lambda = -\int dv_A\, dv_B\, d\Omega' \sigma^{(r)}_{AB} g_{AB} f^e_A f^e_B, \qquad \Delta E = E_C + E_D - E_A - E_B$$

takes the form

[I.14] $$\lambda_\alpha^{(1)} = 0, \qquad \alpha = 1, \ldots, 7$$
$$\lambda_8^{(1)} = \left[\frac{2}{3n}\left(\frac{\Delta E}{k_BT}\right)^2 + \sum_{i=A,B,C,D} n_i^{-1}\right]\Lambda$$

Now we can calculate the φ_α functions by solving [I.9]. So, it results

[I.15] $$|\varphi_1\rangle = |\phi_5^{(e)}\rangle$$

[I.16] $$|\varphi_2\rangle = |\phi_6^{(e)}\rangle$$

[I.17] $$|\varphi_3\rangle = |\phi_7^{(e)}\rangle$$

[I.18] $$|\varphi_4\rangle = \frac{1}{\sqrt{1 + \frac{3n}{2}\left(\frac{k_BT}{\Delta E}\right)^2 n_A^{-1}}}\left[|\phi_1^{(e)}\rangle - \sqrt{\frac{3n}{2n_A}}\left(\frac{k_BT}{\Delta E}\right)|\phi_8^{(e)}\rangle\right]$$

[I.19] $$|\varphi_5\rangle = \frac{1}{\sqrt{\left[1 + \frac{3n}{2}\left(\frac{k_BT}{\Delta E}\right)^2 n_A^{-1}\right]\cdot\left[1 + \frac{3n}{2}\left(\frac{k_BT}{\Delta E}\right)^2 \sum_{S=A,B} n_S^{-1}\right]}}\left\{-\frac{3n}{2\sqrt{n_An_B}}\left(\frac{k_BT}{\Delta E}\right)^2|\phi_1^{(e)}\rangle\right.$$
$$\left. + \left[1 + \frac{3n}{2}\left(\frac{k_BT}{\Delta E}\right)^2 n_A^{-1}\right]|\phi_2^{(e)}\rangle - \sqrt{\frac{3n}{2n_B}}\left(\frac{k_BT}{\Delta E}\right)|\phi_8^{(e)}\rangle\right\}$$

[I.20] $$|\varphi_6\rangle = \frac{1}{\sqrt{\left[1 + \frac{3n}{2}\left(\frac{k_BT}{\Delta E}\right)^2 \sum_{S=A,B} n_S^{-1}\right]\cdot\left[1 + \frac{3n}{2}\left(\frac{k_BT}{\Delta E}\right)^2 \sum_{S=A,B,C} n_S^{-1}\right]}}\left\{\frac{3n}{2\sqrt{n_An_C}}\left(\frac{k_BT}{\Delta E}\right)^2|\phi_1^{(e)}\rangle\right.$$
$$\left. + \frac{3n}{2\sqrt{n_Bn_C}}\left(\frac{k_BT}{\Delta E}\right)^2|\phi_2^{(e)}\rangle + \left[1 + \frac{3n}{2}\left(\frac{k_BT}{\Delta E}\right)^2 \sum_{S=A,B} n_S^{-1}\right]|\phi_3^{(e)}\rangle + \sqrt{\frac{3n}{2n_C}}\left(\frac{k_BT}{\Delta E}\right)|\phi_8^{(e)}\rangle\right\}$$

[I.21] $$|\varphi_7\rangle = \frac{1}{\sqrt{\left[1 + \frac{3n}{2}\left(\frac{k_BT}{\Delta E}\right)^2 \sum_{S=A,B,C} n_S^{-1}\right]\cdot\left[1 + \frac{3n}{2}\left(\frac{k_BT}{\Delta E}\right)^2 \sum_{S=A,B,C,D} n_S^{-1}\right]}}\left\{\frac{3n}{2\sqrt{n_An_D}}\left(\frac{k_BT}{\Delta E}\right)^2|\phi_1^{(e)}\rangle\right.$$
$$+ \frac{3n}{2\sqrt{n_Bn_D}}\left(\frac{k_BT}{\Delta E}\right)^2|\phi_2^{(e)}\rangle - \frac{3n}{2\sqrt{n_Cn_D}}\left(\frac{k_BT}{\Delta E}\right)^2|\phi_3^{(e)}\rangle + \left[1 + \frac{3n}{2}\left(\frac{k_BT}{\Delta E}\right)^2 \sum_{S=A,B,C,D} n_S^{-1}\right]|\phi_4^{(e)}\rangle$$
$$\left. + \sqrt{\frac{3n}{2n_D}}\left(\frac{k_BT}{\Delta E}\right)|\phi_8^{(e)}\rangle\right\}$$

$$[I.22]\quad |\varphi_8\rangle = \frac{1}{\sqrt{\frac{2}{3n}\left(\frac{\Delta E}{k_B T}\right)^2 + \sum_{S=A,B,C,D} n_S^{-1}}} \left\{ n_C^{-1/2}|\phi_3^{(e)}\rangle + n_D^{-1/2}|\phi_4^{(e)}\rangle - n_A^{-1/2}|\phi_1^{(e)}\rangle - n_B^{-1/2}|\phi_2^{(e)}\rangle - \sqrt{\frac{2}{3n}}\left(\frac{\Delta E}{k_B T}\right)|\phi_8^{(e)}\rangle \right\}$$

The functions φ_i ($i = 1, \ldots, 8$) are a linear combination of the set $\phi_i^{(e)}$ ($i = 1, \ldots, 8$) and hence, are eigenfunctions with zero eigenvalue of $\hat{C}^{(e)}$. However, it is the eigenfunction φ_8 that must be singled out, since this is the only linear combination of the elastic collisional invariants that gets a non-zero eigenvalue in a reacting system. Indeed, in the presence of reactive collisions, we could have started the study of the reacting system from the set φ_i ($i = 1, \ldots, 8$). From this point of view, our goal should be to evaluate the eigenvalue associated with φ_8 becoming non-zero for existing reactive collisions.

Introducing P and Q in formula [I.4], we have

$$[I.23]\quad \hat{C}^{(r)}|\varphi_\alpha\rangle + \hat{C}^{(e)}Q|\phi_\alpha^{(1)}\rangle = \lambda_\alpha^{(1)}|\varphi_\alpha\rangle$$

and by applying the Q operator we express $Q|\phi_\alpha^{(1)}\rangle$ as a function of $|\varphi_\alpha\rangle$,

$$[I.24]\quad Q|\phi_\alpha^{(1)}\rangle = -\hat{G}^{-1}Q\hat{C}^{(r)}|\varphi_\alpha\rangle$$

$\hat{G}$ being the $Q\hat{C}^{(e)}Q$ operator.

Multiplying eq. [I.5] by the bra $\langle\varphi_\alpha|$, we have

$$[I.25]\quad \langle\varphi_\alpha|\hat{C}^{(r)}|\phi_\beta^{(1)}\rangle = \lambda_\beta^{(1)}\langle\varphi_\alpha|\phi_\beta^{(1)}\rangle + \lambda_\beta^{(2)}\delta_{\alpha\beta}^{K_r}$$

and inserting the identity resolution, $\mathbf{1} = P + Q$, in the left hand side of the [I.25], we get

$$[I.26]\quad \langle\varphi_\alpha|P\hat{C}^{(r)}P|\phi_\beta^{(1)}\rangle + \langle\varphi_\alpha|\hat{C}^{(r)}Q|\phi_\beta^{(1)}\rangle = \lambda_\beta^{(1)}\langle\varphi_\alpha|\phi_\beta^{(1)}\rangle + \lambda_\beta^{(2)}\delta_{\alpha\beta}^{K_r}$$

As

$$[I.27]\quad \langle\varphi_\alpha|P\hat{C}^{(r)}P|\phi_\beta^{(1)}\rangle = \lambda_\alpha^{(1)}\langle\varphi_\alpha|\phi_\beta^{(1)}\rangle$$

with the help of [I.24], formula [I.26] becomes

$$[I.28]\quad \lambda_\alpha^{(1)}\langle\varphi_\alpha|\phi_\beta^{(1)}\rangle - \langle\varphi_\alpha|\hat{C}^{(r)}Q\hat{G}^{-1}Q\hat{C}^{(r)}|\varphi_\beta\rangle = \lambda_\beta^{(1)}\langle\varphi_\alpha|\phi_\beta^{(1)}\rangle + \lambda_\beta^{(2)}\delta_{\alpha\beta}^{K_r}$$

This relation is verified for all the functions $|\varphi_\alpha\rangle$, since the functions $\{|\varphi_\alpha\rangle\}_{\alpha=1}^{7}$ are the eigenfunctions of $\hat{C}^{(r)}$ for the zero eigenvalue

$$[I.29]\quad \hat{C}^{(r)}|\varphi_\alpha\rangle = 0 \qquad (\alpha = 1, \ldots, 7)$$

Thus the residual degeneration corresponding to the first correction does not cause any problematical situation. This permits us to calculate the second correction with the aid of the following formula

$$[I.30]\quad \lambda_\alpha^{(2)} = -\langle\varphi_\alpha|\hat{C}^{(r)}Q\hat{G}^{-1}Q\hat{C}^{(r)}|\varphi_\alpha\rangle$$

It can be easily shown from [I.30] that

$$[I.31]\quad \lambda_\alpha^{(2)} = 0 \qquad (\alpha = 1, \ldots, 7)$$

$$\lambda_8^{(2)} = -\left[\frac{2}{3n}\left(\frac{\Delta E}{k_B T}\right)^2 + \sum_{S=A,B,C,D} n_S^{-1}\right] \times \langle\Psi|Q\hat{C}^{(e)-1}Q|\Psi\rangle$$

where Ψ means

$$[I.32]\quad \begin{bmatrix} \int dv_B\, d\Omega'\, \sigma_{AB}^{(r)} g_{AB}\, f_A^e f_B^e \\ \int dv_A\, d\Omega'\, \sigma_{AB}^{(r)} g_{AB}\, f_A^e f_B^e \\ -\int dv_D\, d\Omega'\, \sigma_{CD}^{(r)} g_{CD}\, f_C^e f_D^e \\ -\int dv_C\, d\Omega'\, \sigma_{CD}^{(r)} g_{CD}\, f_C^e f_D^e \end{bmatrix}$$

Analogously, higher corrections can be found. For instance

$$[I.33]\quad \lambda_\alpha^{(3)} = 0 \qquad (\alpha = 1, \ldots, 7)$$

$$\lambda_8^{(3)} = \left[\frac{2}{3n}\left(\frac{\Delta E}{k_B T}\right)^2 + \sum_{S=A,B,C,D} n_S^{-1}\right] \times \{-\lambda_8^{(1)}\langle\Psi|Q\hat{C}^{(e)-1}Q\hat{C}^{(e)-1}Q|\Psi\rangle + \langle\Psi|Q\hat{C}^{(e)-1}Q\hat{C}^{(r)}Q\hat{C}^{(e)-1}Q|\Psi\rangle\}$$

From the results [I.14]–[I.22], [I.31], and [I.33] we must point out that the initial degeneration has been very partially eliminated. Initially, there were eight eigenfunctions $\phi_\alpha^{(e)}$ of $\hat{C}^{(e)}$ for the zero eigenvalue and when the perturbation $\hat{C}^{(r)}$ is applied only one function arises with an eigenvalue different from zero. This is a logical result because there are seven collision invariants associated with reactive collisions (the chemical reaction is a restriction that eliminates one invariant), and for that the operator $\hat{C} = (\hat{C}^{(e)} + \hat{C}^{(r)})$ owns seven eigenfunctions for the zero eigenvalue. Indeed, the introduction of the perturbation $\hat{C}^{(r)}$ has allowed us to get the first non-zero eigenvalue λ_8 of $\hat{C}$ and its eigenfunction (at least in the zero order approximation φ_8).

Structural investigation of water-hyacinth (*Eichhornia crassipes*) polysaccharides. Part I. Water-soluble polysaccharides

MOHAMADY A. ISSA
Agricultural Chemistry Department, Faculty of Agriculture, El Minia University, El-Minia, Egypt

Received May 4, 1988

MOHAMADY A. ISSA. Can. J. Chem. **66**, 2777 (1988).

A galactomannan and a branched (1→3)-β-D-glucan were isolated from the water hyacinth plant. The galactomannan, purified from the cold water extract, is composed of D-galactose and D-mannose in a ratio of 1.0:2.8. It has a (1→4)-linked D-mannose backbone, one out of three D-mannose residues being substituted with a single α-D-galactosyl unit. The branched (1→3)-β-D-glucan isolated from the hot water extract has a main chain composed of β-(1→3)-linked D-glucopyranosyl residues, and two single β(1→6)-D-glucopyranosyl groups attached as side chains to, on average, every 5 sugar units of the main chain. In addition, the branching of the β-glucan occurs regularly at O-6 of the β-(1→3)-linked backbone.

MOHAMADY A. ISSA. Can. J. Chem. **66**, 2777 (1988).

On a isolé un galactomannane ainsi qu'un β-D-glucane portant une chaîne (1→3) à partir de plants de jacinthes d'eau (*Eichornia*). Le galactomannane, purifié à partir des produits extraits à l'eau froide, se compose de D-galactose et de D-mannose dans un rapport de 1,0 à 2,8. Il possède un squelette de D-mannoses liés en (1→4) et un résidu D-mannose sur trois est substitué par une seule unité α-D-galactosyle. Le β-D-glucane portant une chaîne (1→3) a été isolé par de l'eau chaude et il possède une chaîne principale formée de résidus D-glucopyrannosyles liés en β-(1→3) ainsi que deux groupements β-(1→6) D-glucopyrannosyles attachés individuellement comme chaînes latérales à, en moyenne, cinq unités de sucre de la chaîne principale. De plus, il se produit régulièrement une ramification du β-glucane au niveau du O-6 du squelette lié en β-(1→3).
[Traduit par la revue]

Introduction

The water hyacinth (*Eichhornia crassipes*) is known as the most noxious weed in the River Nile streams. The rapid growth of this plant causes a great deal of water loss as well as danger of blocking the streams. Many attempts have been made to use this plant as animal feed, e.g., forage for cattle (1–3). A considerable number of reports (4–6) reveal that it could be used as a source of fermentable sugars and in the manufacture of paper and pressed boards. As well, reports on the effect of different extracts as growth regulators have been published (7–10).

The chemical composition of the water hyacinth has been studied by many investigators (1, 11–13); however, no reports on its polysaccharides have been published.

This work was conducted to study the possible structural features of water-soluble polysaccharides isolated from the water hyacinth, as revealed by methylation fragmentation analysis and enzymatic degradation as well as by ^{13}C nmr spectra.

Discussion

Fractionation and chemical constitution of water-soluble polysaccharides of the water hyacinth

The dried water hyacinth (*Eichhornia crassipes*) flour was first defatted and the polysaccharides in this study were extracted successively with phosphate-buffered saline (PBS) at 2–4°C, hot water at 85°C, and again at 100°C. This fractionation afforded the following polysaccharide fractions: the cold water extractable fraction (Fr. CW) and the hot water extractable fraction (Fr. HW). The polysaccharide in each fraction was purified and lyophilized.

The water-soluble polysaccharides so obtained were hydrolyzed with acid and their sugar constituents were examined. Table 1 lists their yields and compositions.

Structural characterization of the polysaccharides

Galactomannan

As shown in Table 1, the water-soluble neutral polysaccharide isolated from the PBS extract was a galactomannan, composed of D-galactose and D-mannose in a molar ratio of 1.0:2.8 as analyzed by glc. It had a molecular weight of 5.0×10^5, as determined by hplc. Its negative specific optical rotation $[\alpha]_D^T -10.2°$ (*c* 1.0, 0.5 M NaOH) and an absorption band at 875 cm^{-1} in the infrared spectrum suggest that most sugar residues are of the β configuration (14).

TABLE 1. Water-soluble polysaccharide fractions of water-hyacinth and their chemical composition

Polysaccharide fraction	Yield (%)[a]	Carbohydrate component (%) Glc	Man	Gal
PBS extract (CW) (galactomannan)	3.0	—	73	27
Hot water extract (HW) (branched β-glucan)	2.1	100	—	—

[a]Values were on dry defatted basis.

To obtain information on the mode of glycosidic linkages of the sugar constituents of galactomannan and their sequential arrangements, the galactomannan was subjected to methylation followed by acid hydrolysis and to partial acid hydrolysis. Acid hydrolysis of methylated galactomannan gave 2,3,4,6-tetra-*O*-methyl-D-galactose, in a quantity equivalent to all the galactose present, and 2,3,6-tri-*O*-methyl- and 2,3-di-*O*-methyl-D-mannose in a molar ratio of 1.0:1.9:1:1 (Table 2) as analyzed by glc–ms. This result indicates that the galactomannan contains a backbone of (1→4)-linked D-mannose residues and one out of three D-mannose residues is substituted at the O-6 atom (branching point) with a single D-galactose residue as a side chain. This was confirmed by partial acid hydrolysis of the polysaccharide (see experimental section). The hydrolyzate contained a mixture of two di- and trisaccharides as well as two tetrasaccharides (Fig. 1), separable first by chromatography on an activated charcoal column and then on a

TABLE 2. Molar ratios of methyl sugar components of the methylated galactomannan and β-glucan

O-Methyl sugar (alditol acetate)	Mode of linkage	Molar ratio	
		Galactomannan	β-glucan
O-Methyl-D-galactose			
2,3,4,6-tetra	(Gal)1→	1.0	
O-Methyl-D-mannose			
2,3,6-tri-	→4(Man)1→	1.9	
2,3-di-	→4(Man)1→ ↑ 6	1.1	
O-Methyl-D-glucose			
2,3,4,6-tetra-	(Glc)1→		1.00
2,4,6-tri-	→3(Glc)1→		1.48
2,4-di-	→6(Glc)1→ ↑ 3		0.99

Bio-gel P-2 column. Each oligosaccharide was further purified by tlc and its structure was examined by methylation analysis. As shown in Table 3, the two disaccharides were characterized as 4-*O*-β-D-mannopyranosyl-D-mannose (**1**) and 6-*O*-α-D-galactopyranosyl-D-mannose (**2**) respectively.

The trisaccharide (**3**) was shown to contain three D-mannose units linked β-(1→4) whereas the trisaccharide (**4**) was shown to contain two nonreducing terminal D-mannose and D-galactose residues, and the doubly substituted D-mannose (third unit) at the O-4 and O-6 positions. In addition, two tetrasaccharides (**5** and **6**) were isolated and their possible structural features were elucidated on the basis of results of methylation analysis (Table 3).

Characteristic ^{13}C chemical shifts for sugar residues of the polysaccharides are given in Table 4. The chemical shift of C-1 at 93.80 ppm should be attributed to α-D-galactopyranose residues at the nonreducing ends, and that at 102.3 ppm to (1→4)-linked β-D-mannopyranose residues, by comparison with previous data (15, 16). The chemical shift at 69.81 should be due to the O-substituted C-6 of β-(1→4) D-mannose residues, and the peak at 75.52 ppm could be assigned as the C-4 of β-(1→4) D-mannopyranose residues, as deduced from the data for β-(1→4)-linked D-glucan (17).

Periodate oxidation revealed galactomannan consumed ca. 1 mol of oxidant per mol of hexose residue without liberation of formic acid. This and the absence of D-galactose or D-mannose in the hydrolyzate of the periodate-oxidized polysaccharide indicated that the galactomannan contained substituted sugar units at neither the O-2 nor O-3 positions.

Thus, the most probable structure of the galactomannan is as shown in Fig. 2.

Galactomannan occurs in most leguminous seeds (18) having a chain of D-mannose units linked β(1→4) with single side chains of α-D-galactopyranosyl linked α-(1→6) to one or more D-mannose units, but differing from each other in yield, optical rotatory power, mannose/galactose ratio, and degree of polymerization. Sometimes the galactosyl stubs are more than one unit long (18, 19) and occasionally there are linkages other than (1→4) between D-Manp residues (20–22). In general, the galactomannan found in this study was structurally quite similar to leguminous seed galactomannans.

Branched (1→3) glucan

The water-soluble glucan, isolated from the hot water extract (HW) in 2.1% yield, was composed solely of D-glucose residues (Table 1), as shown by pc (paper chromatography) of the hydrolyzate, by glc of the alditol acetate prepared from the hydrolyzate. It had a negative specific rotation $[\alpha]_D^{25}$ −13.5° (*c* 1.5, 1 M NaOH) and showed a characteristic ir absorption at 892 cm^{-1}, indicating the presence of β-D-glycosidic linkages (23). It had a molecular weight of 6.5×10^5 as measured by hplc (water system). The glucan was methylated, followed by acid hydrolysis. The partially methylated sugars were analyzed as the alditol acetate derivatives by glc and glc–ms, and identified by comparing their retention times in glc and their mass spectra with those of authentic samples, or with the values reported in the literature (24). As shown in Table 2, the methylation analysis indicated the presence of 2,3,4,6-tetra-, 2,4,6-tri-, and 2,4-di-*O*-methyl-D-glucose in a molar ratio of 1.00:1.48:0.99.

Periodate oxidation showed that the β-glucan consumed 0.58 mol of IO_4^- with liberation of 0.28 mol of formic acid per anhydrous glucose residue. The values were in good agreement with those computed from the results of the methylation analysis, namely, 0.58 and 0.29 mol (Table 2). The oxidized polysaccharide was reduced with $NaBH_4$ and the resultant polyalcohol was hydrolyzed. The hydrolyzate (containing the Smith degradation product) was analyzed by glc as the alditol acetate derivatives, and glycerol and glucose were detected in a

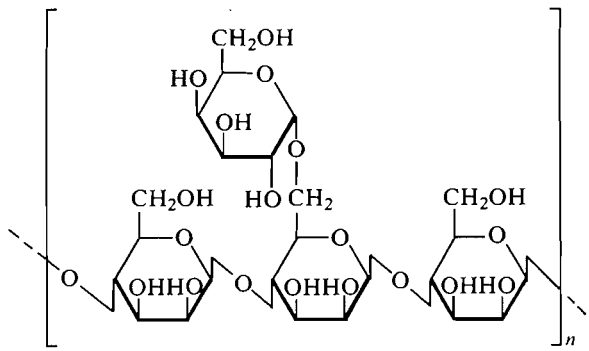

FIG. 2. Possible structure of the repeating unit of galactomannan.

molar ratio of 1.00:2.57. The glycerol must have arisen from the terminal D-glucose residues, and the occurrence of glucose must be due to the presence of oxidation-resistant D-glucose such as (1→3)-linked residues. These results were in good agreement with those from the methylation analysis.

The β-glucan was incubated with *exo*-(1→3)-β-D-glucanase (Lysing Enzymes) from Basidiomycetes, in 0.1 M acetate buffer (see experimental section). Each enzymic degradation product was subjected to gel filtration on Bio-Gel P-2; only two peaks, corresponding to the mono- and di-saccharide, were observed. The products recovered from the eluates at 5 and 48 h were analyzed by pc, or by glc as the trifluoroacetyl derivative of the disaccharide-alditol (25). Consequently, in each case, glucose and gentiobiose were detected. The molar ratio of gentiobiose to glucose was almost constant, that is, 0.68 at 5 h and 0.63 at 48 h, vs. 0.67 expected from the methylation analysis (Table 2).

The foregoing data indicate that glucan, isolated from the hot water extract of the water hyacinth, has a main chain composed of (1→3)-β-D-glucopyranosyl residues, and has as side chains two single β-(1→6)-linked D-glucopyranosyl groups attached, on average, to every five sugar residues of the main chain as shown in Fig. 3. Furthermore, from the results of the enzymic hydrolysis it was indicated that the branching of β-glucan occurs regularly at O-6 of the β(1→3)-linked backbone.

Such a branched structure of (1→6)-branched (1→3)-β-D-glucan was supported by its ^{13}C nmr, as shown in Table 4, including characteristic peaks of chemical shifts of C-1 (103.56 ppm), O-substituted C-3 (86.79 ppm), and O-substituted C-6 (70.65 ppm).

β-D-Glucans made up of (1→3) and (1→4)-linked pyranosyl residues are found usually in small amounts, but widely spread throughout, in the seed of Gramineae. These β-D-glucans are linear polymers in which (1→3) and (1→4) linkages are interspersed (26–29). It is interesting that the β-D-glucan obtained in this study has a quite different structure from cereal β-D-glucans.

Experimental

Materials

Water hyacinth plants were collected from the River Nile at the front of El-Minia city, Egypt. In this study the air-dried whole plant of the water hyacinth was used. Carbohydrates and Lysing Enzymes were purchased from Sigma, and Tsk G-500 PW for hplc, ECNSS-M, and Gas Chromosorb W (80–100 mesh) from Applied Science Laboratories. OV-225 coated on Gas Chrom Q (100–120 mesh) was obtained from Supelco Inc. Standard pullulan fractions having definite molecular weights, P-800, P-400, and P-200, for hplc were from Worthington Biochemicals, Bio-Gel P-2 was purchased from Bio-Rad Laboratories, and Sephadex LH-20 from Pharmacia Fine Chemicals. Other chemicals were commercially available.

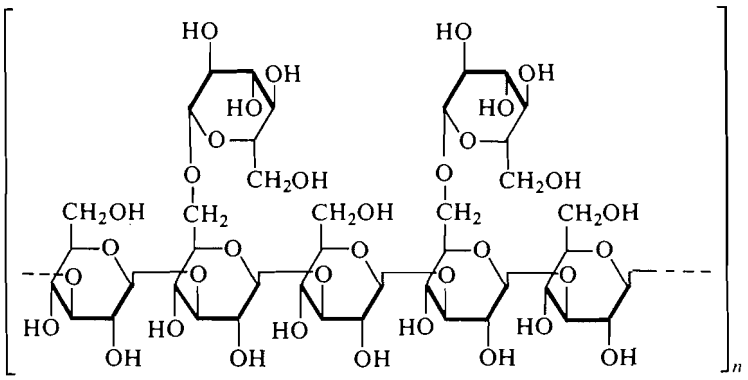

FIG. 3. Possible structure of repeating unit of β-glucan.

General analytical method

All evaporations and concentrations of solutions were conducted under diminished pressure at temperatures not exceeding 35–40°C. Specific optical rotations were measured at room temperature with a Perkin–Elmer automatic digital polarimeter, model 141. Paper chromatography (pc) was performed by the double-descending technique on Whatman No. 1 filter paper using the following solvent systems (v/v): (a) *n*-butanol–pyridine–water (6:4:3) for unsubstituted sugars; (b) benzene–ethanol–water (38:10:1) for methylated sugars, and (c) ethyl acetate – pyridine–water (8:2:1) for oligosaccharides. Sugars were located on the paper by alkaline silver nitrate and *p*-anisidine–HCl. Thin-layer chromatography (tlc) was carried out on precoated glass plates (0.25 mm) of silica gel 60F-254 (E. Merck, Darmstadt, FRG) using the solvent (d): benzene–ethanol – acetic acid – water (200:47:15:1, v/v) for further purification of oligosaccharides. Their spots were detected by spraying the plates with 20% H_2SO_4 in ethanol, with heating. Quantitative determination of the total carbohydrate content was generally done by the phenol – sulfuric acid colorimetric method (30) using D-glucose or D-mannose as a standard. Gas–liquid chromatography (glc) of neutral sugars and their methyl derivatives was usually performed after conversion into their corresponding alditol acetates, using a Hewlett Packard 5720 A chromatograph equipped with a flame-ionization detector at a gas flow rate of 35–40 mL of N_2/min and a glass column (0.3 × 175 cm) packed with 3% ECNSS-M on Gas Chrom Q at 200°C and 190°C for free sugars and methyl sugars respectively. The ir spectra were recorded with a Perkin–Elmer 457 grating spectrophotometer. Gas–liquid chromatography – mass spectrometry (gs–ms) of the alditol acetates of methylated sugars was carried out on a Shimadzu LKB-9000BGC mass spectrometer with a column packed with 3% ECNSS on Gas Chromosorb W or 3% OV-225 on Gas Chrom Q, at temperatures programmed from 120°C to 180°C at 1°C/min. For identification of sugar constituents, a sample of polysaccharide (ca. 10 mg) was heated, first with 90% formic acid (1 mL) at 100°C for 10 h in screw-capped tubes, and after evaporation the residue was heated further with 2 M trifluoroacetic acid (TFA, 0.5 mL) for 8 h. After removing TFA by repeated evaporation with H_2O, the sugars in the hydrolyzate were analyzed by glc or pc. The molecular weights of the polysaccharides were estimated by hplc using a Hitachi liquid chromatograph model 635 with a TSK G-5000 PW column and water as the carrier system (31).

Isolation of polysaccharides

Generally, pure polysaccharide fractions were obtained by repeated ethanol precipitations followed by lyophilization. The insoluble residue after each step was washed thoroughly with distilled H_2O.

Lipids and pigments were first extracted from dried water hyacinth flour (100 g) in a Soxhlet apparatus, by successive treatments with $CHCl_3$–MeOH (2:1, v/v) and MeOH–H_2O (4:1, v/v). After air-drying, the defatted flour (75.5 g) was homogenized in phosphate-buffered saline (3 litres, PBS, 0.01 M, pH 7.1) with a Waring blender, and stirred at 2–4°C overnight. The insoluble material was collected by centrifugation. The supernatant was concentrated to small volume, which gave a negative starch/iodine reaction, and then added to 3 volumes of ethanol to give precipitation of PBS-extractable polysaccharide (Fr. CW yield 2.3 g, ca. 3.0% on dry defatted basis). After extraction with PBS, the residue was suspended in 3.5 L of distilled H_2O and heated to 85°C for 5 h with constant stirring. The insoluble residue was collected by centrifugation and heated again at 100°C for 1 h. After centrifugation the insoluble residue was kept for further study elsewhere. The hot water extracts were combined and concentrated; they gave a weak positive starch/iodine reaction, and were treated, first, with a mixture of α- and β-amylases (Sigma) overnight at 37°C in phosphate buffer (pH 5.8) to remove contaminating starch and then with cetylpyridinium chloride to remove any uronic-acid polysaccharide according to ref. 32. After such treatments, the extract was dialyzed, giving no colouration with I_2/KI solution, and then the H_2O-soluble protein was removed by the method of Sevag (33). The hot water-soluble neutral-polysaccharide protein-free extract was concentrated and poured into 3 volumes of ethanol to give hot water extractable neutral polysaccharide (Fr. HW yield 1.6 g, 2.1% on dry defatted basis).

Methylation analysis

The polysaccharide (10 mg, dissolved in dry DMSO under nitrogen atmosphere) was methylated by the method of Hakomori (34) with fresh methylsulfinyl carbanion and methyl iodide. The methylation was repeated until the product showed no absorption attributable to hydroxyl in its ir spectrum. The fully methylated product was hydrolyzed with 90% formic acid (1 mL) for 13 h at 105°C and then with 2 M TFA (1 mL) for 4 h. After removal of the acids as before, the methylated sugars in the hydrolyzate were converted into their corresponding alditol acetates (35) and analyzed by glc (36) and glc–ms (37).

Isolation of oligosaccharides obtained by partial acid hydrolysis of galactomannan

The native polysaccharide (1.2 g) was partially hydrolyzed by heating with 0.5 M TFA (125 mL) for 3 h at 100°C. After evaporation of the acid, the residue was put on an active charcoal column (2 × 30 cm), the column being washed first with water until monosaccharides are removed (650 mL) and then with 75% ethanol (650 mL) to give a mixture of oligosaccharides (340 mg). The oligosaccharide fraction was fractionated using a Bio-gel P-2 column (2 × 175 cm), by elution with water. Each of the five fractions obtained by the above procedure (elution volume ~350 mL) was further purified by tlc to isolate each oligosaccharide.

Structural analysis of oligosaccharides

The oligosaccharides (3–5 mg, each) were hydrolyzed with 2 M TFA for 5 h at 100°C. After evaporation of the acid, the monosaccharides in the hydrolyzate were converted into the alditol acetates and analyzed by glc. Methylation of the oligosaccharide was done by

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/07/12
For personal use only.

the method of Hakomori. The methylated oligosaccharide was purified on a Sephadex LH-20 column (1 × 25 cm) by elution with dichloromethane. The pure methylated oligosaccharide was hydrolyzed successively with 90% formic acid and 2 M TFA as described previously and then converted into the alditol acetate for analysis by glc.

Periodate oxidation

A 10-mg sample of the polysaccharide was dissolved in 15 mL of 0.3 M $NaIO_4$ and periodate uptake at room temperature in the dark was estimated, as described in ref. 38, at intervals until constant (40 and 96 h for galactomannan and β-glucan respectively). The formic acid liberated was determined by titration with 5 mM NaOH (39). In a separate experiment the polysaccharide (100 mg) was oxidized with periodate (40) for 50 h at room temperature. The excess periodate was destroyed by addition of ethylene glycol and the solution was dialyzed against tap water for 72 h. The non-dialyzed material was recovered by concentration and hydrolyzed with 1 N H_2SO_4. The hydrolyzate was neutralized with $BaCO_3$, filtered, and concentrated for examination by pc.

Smith degradation

A sample of β-glucan (100 mg) was treated with 0.3 M $NaIO_4$ (100 mL) at room temperature. After 7 days, a few drops of ethylene glycol were added to the reaction mixture and it was dialyzed against tap water to remove $NaIO_3$. The polyaldehyde was reduced with a 10-fold molar excess of $NaBH_4$ at room temperature overnight. Addition of ice-cold 4 N acetic acid to chilled polyalcohol (final pH, 5.5) was used to terminate the reaction, and the solution was again dialyzed and lyophilized (yield, 50.2 mg glucan polyol). For complete Smith degradation, 1% solutions of polyalcohol were successively treated with 90% formic acid for 3 h at 100°C as before and then with 0.5 N H_2SO_4 for 8 h at 100°C. The hydrolyzate was made neutral with $BaCO_3$ in the usual way and the hydrolysis product was analyzed by glc, after $NaBH_4$ reduction followed by acetylation.

Enzymic hydrolysis

β-Glucan (6 mg) was treated with *exo*-(1→3)-β-D-glucanase (Lysing Enzymes, 2.5 mg) in 0.1 M acetate buffer, pH 5.0 (15 mL), and incubated at 37°C; half of the reaction mixture was taken at 5 h and the residual portion was allowed to react for 48 h. Each enzymic degradation product, prepared according to ref. 41, was subjected to gel filtration on a column of Bio-Gel P-2, and two peaks were revealed. The products recovered were analyzed by pc (solvent c) and two spots, corresponding to glucose and gentiobiose (R_{glc} 0.63), were detected. The gentiobiose was further identified by glc as the trifluoroacetate of the disaccharide-alditol as previously reported (41). The molar ratio of the sugars was calculated from the peak in gel filtration on Bio-Gel P-2.

^{13}C nuclear magnetic resonance spectroscopy

The ^{13}C nmr spectra of the polysaccharides were determined at 25 MHz with a Bruker WP-200 spectrometer. All spectra were recorded for solutions in dimethyl sulfoxide-d_6 at a concentration of 6% at 60°C using 8K data points and a spectral width of 5K/3 Hz.

Acknowledgment

Most of the analyses were conducted in the laboratory of Professor Dr. D. Horton, Ohio State University. I wish to express my appreciation to him for the use of his facilities during the peace fellowship program.

M. FELIZ, D. MAULEÓN, and C. MINGUILLÓN. Can. J. Chem. **66**, 2782 (1988).

The stereochemical assignment as *erythro* and *threo* for two pairs of 2-(aryloxy)-1-(2-piperidyl)ethanols **1** and **2** is described. Their CHO–CHN coupling constants were measured on the phase sensitive $^1H-^1H$ homocorrelation spectra (DQF–COSY), optimized by means of the LAOCOON-3 program, and compared with the calculated values from an MM2 conformational analysis. The experimental constants were $J_{erythro}$ = 3.3/3.8 Hz and J_{threo} = 6.4/6.8 Hz, whereas the calculated values were 2.5 and 5.4 Hz, respectively. ^{13}C nuclear magnetic resonance steric shielding of the C(3) carbon atom in the *erythro* diastereomers confirms the results of the conformational analysis.

M. FELIZ, D. MAULEÓN et C. MINGUILLÓN. Can. J. Chem. **66**, 2782 (1988).

On décrit l'attribution des stéréoisoméries *érythro* et *thréo* aux deux paires d'(aryloxy)-2 (pipéridyl-2)-1 éthanols **1** et **2**. On a mesuré leurs constantes de couplage CHO–CHN dans la portion sensible à la phase du spectre d'homocorrélation $^1H-^1H$ (DQF–COSY), on les a optimisées à l'aide d'une programme LAOCOON-3, et on les a comparées aux valeurs calculées à l'aide d'une analyse conformationnelle MM2. Les valeurs expérimentales sont $J_{érythro}$ = 3,3/3,8 Hz et $J_{thréo}$ = 6,4/6,8 Hz alors que les valeurs calculées sont respectivement 2,5 et 5,4 Hz. Le blindage stérique de l'atome de carbone C(3) dans le spectre en résonance magnétique nucléaire du ^{13}C des diastéréomères *érythro* confirme les résultats de l'analyse conformationnelle.

[Traduit par la revue]

Introduction

As a part of our work directed to the synthesis of β-adrenergic agents, we became interested in the new 2-aryloxy-1-(2-piperidyl)ethanol structure, which can be considered as a cyclic analogue of the classic aryloxypropanolamine drugs. Thus, we separately obtained (1) the *erythro* and *threo* isomers of compounds **1** and **2**, which were *O*-debenzylated to the corresponding phenols **3** and **4**. These are cyclic analogues of the β-adrenergic agonist prenalterol (2) and of its *meta* isomer.

Since it has been established (3) that a difference in the stereochemistry of α-substituted aryloxypropanolamines markedly affects their β-adrenergic properties, the unequivocal assignment of the *erythro* and *threo* **1–4** diastereomers was imperative. This paper deals with this stereochemical assignment, carried out mainly through the measurement of ^1H nmr coupling constants by a two-dimensional technique.

Results and discussion

The assignment of *erythro* and *threo* stereoisomers in the structurally related aryl 2-piperidyl methanols has usually been carried out from the C*H*OH–C*H*N coupling constant values, which are 3–6 Hz greater in the *threo* compounds than in the *erythro* isomers. However, the ^1H nmr spectra of aryloxy derivatives **1–4** are very complex and the C*H*OH proton appears as a multiplet, overlapped with the -OCH_2- signals. This complexity precluded the direct measurement of the CHO–CHN coupling, as well as the complete assignment of signals in the spectra. Although the use of $^1H-^1H$ homocorrelation spectra (COSY), in absolute value, allows the determination of chemical shifts, these experiments also have some drawbacks. Among them, a lack of sensitivity (4), low resolution, and a loss of information about coupling constant values can be noted. These problems have been recently overcome through the development of two-dimensional experiments directed to obtain phase sensitive homocorrelation spectra (5).

Figure 1 shows the correlation map (positive signals) of the phase sensitive double quantum filter spectrum (DQF–COSY,

SCHEME 1

ref. 6) for *threo*-**1**. Coupling patterns of the non-aromatic protons are indicated by means of connectivity lines between diagonal peaks and cross peaks. The correlation blocks used to perform a first measurement of coupling constants are enclosed in squares. Measurements were performed on expanded plots, along the f_2 dimension that has the higher digital resolution (0.4 Hz) and using the cross peaks from both sides of the diagonal.

Figure 2 is an expansion of the zone 1 (Fig. 1) in which couplings have been indicated. We could measure the H_C/H_D coupling constant, as the active constant (i.e., the coupling that generates the cross peak). Furthermore, two passive constants between H_D and each of the two C(3)H_2 (H_E and H_F) protons are also observed. The corresponding signals on the other side of the diagonal (zone 2, Fig. 1) allowed us to measure the same H_C/H_D coupling, as well as two passive constants between H_C and the -OCH_2- protons H_A and H_B. Finally, in zone 3 (Fig. 1) we could verify the H_B/H_C and H_A/H_B coupling constants previously measured.

The above measurement procedure was also applied to the phase sensitive DQF–COSY spectra of *erythro*-**1**, *erythro*-**2**,

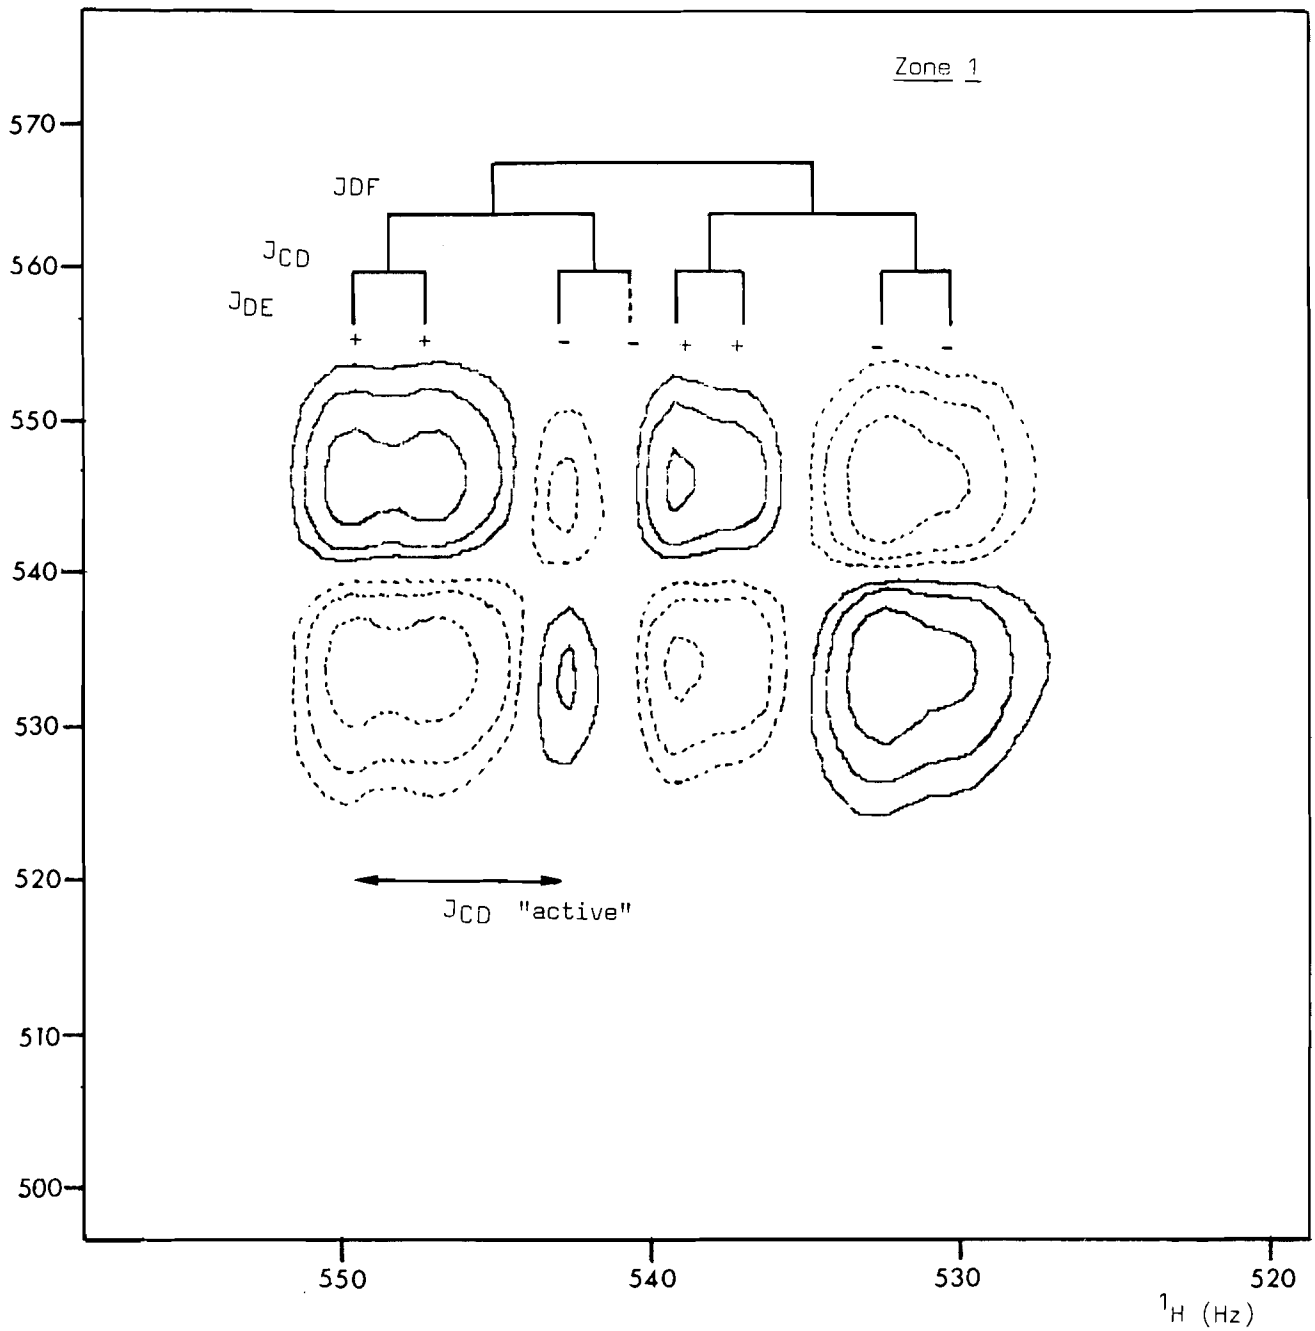

FIG. 2. Expansion of correlation signal between H_C and H_D (zone 1, see Fig. 1).

and *threo*-**2**. The resulting sets of chemical shifts and coupling constants were optimized by means of the LAOCOON-3 program, until a good superposition between real and theoretical monodimensional spectra was achieved. The final values are collected in Table 1.

As expected, the most important difference between the spectral parameters of *erythro* and *threo* diastereomers was the magnitude of the CHO–CHN coupling (J_{CD}). The observed increment of $J_{threo} - J_{erythro} = 3$ Hz can be explained in conformational terms. The reported interpretations in the aryl(2-piperidyl)methanol series (7) only take into account the OH...N hydrogen bond, which stabilizes the O/N *gauche* conformers. However, in the 2-aryloxy-1-(2-piperidyl)ethanols **1** and **2**, three different intramolecular hydrogen bonding interactions can occur (OH...N, NH...OH, and OH...OAr) and thus the conformational preferences could be different from those found in the piperidylmethanols. Therefore, we decided to perform a theoretical conformational analysis of two model structures, *erythro*-**5** and *threo*-**5**, by means of the MM2 force field program (8). A set of 72 conformers for each diastereomer was considered;[2] the resulting most stable conformations *erythro*-**5***a–e* and *threo*-**5***a–d* are depicted in Scheme 2. All the

[2]These correspond to three values (60°C, 180°, and 300°) for each of the O—CH_2—CHOH—C(2) and CH_2—CHOH—C(2)—N dihedral angles, two piperidine chair forms, the equatorial and axial disposition of the NH group, and the O—H...N and N—H...O directed hydrogen bonds ($3 \times 3 \times 2 \times 2 \times 2 = 72$ conformers). After location of the minima, these were optimized by rotation of the aromatic ring plane.

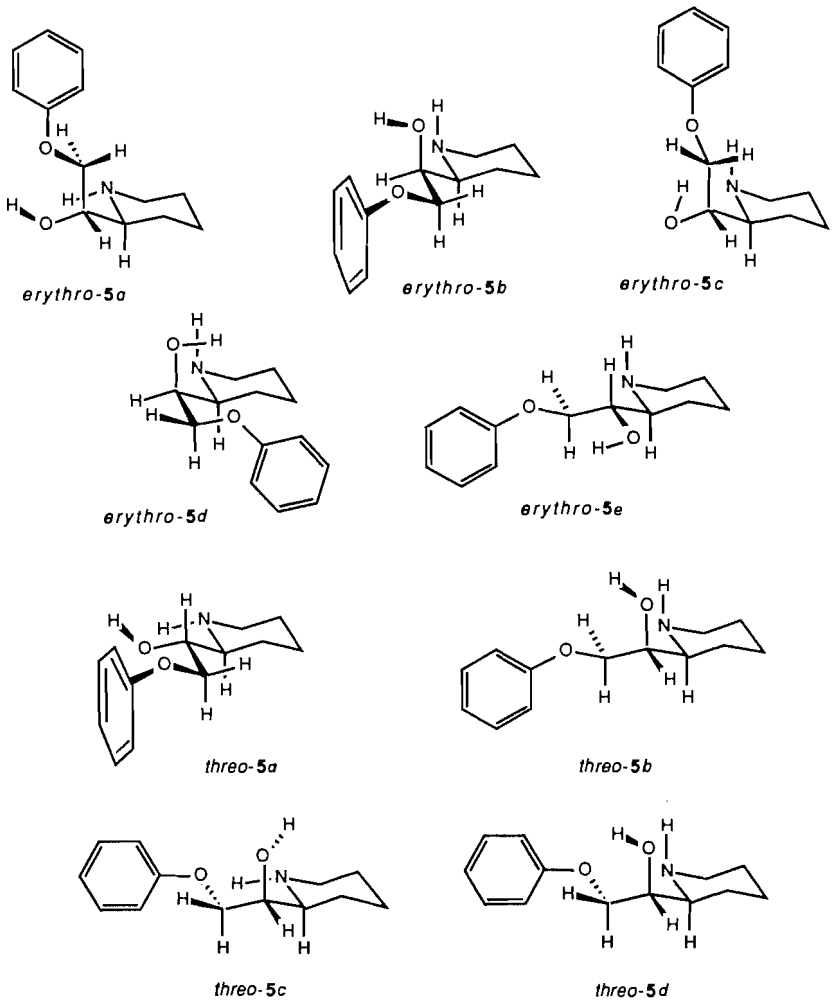

SCHEME 2

remaining conformers have energies >2 kcal/mol above the absolute minima **5***a* and their population contributions are negligible.

Relevant geometric parameters, relative energies, and relative populations for the above conformers are collected in Table 2, together with the individual CHO–CHN coupling constants, calculated from the corresponding dihedral angles by means of the Karplus–Altona equation (9). From these J_i values and the percent populations P_i, two average $J_{erythro}$ and J_{threo} constants were calculated, through the equation:

$$J_{avg} = \Sigma_i(J_i, P_i)/100$$

The resulting mean values ($J_{erythro}$ = 2.5 Hz and J_{threo} = 5.4 Hz) are in good agreement with the experimental coupling constants.

The above stereochemical assignment is also in accordance

TABLE 3. The ^{13}C nmr chemical shifts (ppm) for compounds **1** and **2**

Carbon atom	*erythro*-**1**	*threo*-**1**	*erythro*-**2**	*threo*-**2**
C(2)	58.65	58.40	58.78	58.21
C(3)	25.44	28.40	26.59	28.95
C(4)	23.28	24.02	24.55	24.30
C(5)	25.44	25.67	27.25	26.24
C(6)	46.41	46.22	47.05	46.39
C-OH	71.15	72.55	72.57	72.81
ArO-C	69.63	70.70	69.36	70.02
Ph-C-O	70.85	70.52	70.03	70.02
C(1′)	153.00*	153.06*	159.89*	159.93*
C(2′)	115.58#	115.59#	102.01	102.03
C(3′)	116.02#	115.89#	160.04*	160.02*
C(4′)	153.30*	153.29*	107.18#	107.14#
C(5′)	116.02#	115.89#	129.93	129.91
C(6′)	115.58#	115.59#	107.48#	107.46#
C(1″)	137.25	137.26	136.93	136.92
C(2″) + C(6″)	127.57§	127.44§	127.46§	127.45§
C(3″) + C(5″)	128.60§	128.53§	128.56§	128.55§
C(4″)	128.00	127.88	127.94	127.93

The signals marked with *, #, and § symbols are interchangeable.

with ^{13}C nmr spectral data (Table 3). The *erythro* and *threo* isomers of **1** and **2** gave very similar spectra, except for the signals of the piperidine C(3) carbon atoms, which are shielded in the *erythro* diastereomers. The $\Delta\delta$ = 2.5–3 ppm can be explained by considering that conformations *erythro*-**5***b* and *erythro*-**5***d* have greater steric interactions between the lateral chain and the C(3) hydrogen atoms than the remaining stable conformers (Scheme 2). Thus, from the MM2 conformational analysis we could expect a greater steric shielding for C(3) in the *erythro* diastereomers than in the *threo* ones, as was experimentally observed.

Experimental

The nmr spectra were recorded on a Varian XL-200 spectrometer operating at 200 MHz (^1H) or 50.3 MHz (^{13}C). For ^1H nmr spectra, 15 mg of sample were dissolved in 0.7 mL of $CDCl_3$ and introduced in 5-mm tubes. The ^{13}C nmr spectra were obtained from 150–200 mg of sample, dissolved in $CDCl_3$, in 10-mm tubes. Chemical shifts were directly measured from TMS.
