Tandem Wessely oxidation and intramolecular Diels–Alder reactions. III. Synthesis of isotwistanes[1]

PETER YATES AND TADAS S. MACAS[2]

Lash Miller Chemical Laboratories, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received June 24, 1987

PETER YATES and TADAS S. MACAS. Can. J. Chem. **66**, 1 (1988).

Wessely oxidation of *o*-(3-alkenyl) phenols (**5**) with lead tetraacetate gives 6-acetoxy-6-(3-alkenyl)-2,4-cyclohexadien-1-ones (**6**), which undergo intramolecular Diels–Alder reactions to give isotwistene (hexahydro-1,5-methanoindene) derivatives (**7**). These, on hydrolysis followed by oxidation with periodic acid, give hexahydro-1-oxo-1*H*-indene-5-carboxylic acids (**41**, **46**). Compounds **5** were prepared either by Grignard coupling of *o*-methoxybenzyl chloride with allyl halides followed by de-*O*-methylation with sodium thioethoxide or via reduction of dihydrocoumarins (**18**–**20**) to 2-chromanols (**21**–**23**) with diisobutylaluminum hydride, followed by Wittig reaction of these with ethyl (triphenylphosphoranylidene)acetate.

PETER YATES et TADAS S. MACAS. Can. J. Chem. **66**, 1 (1988).

L'oxydation de Wessely des *o*-(alcène-3 yl) phénols (**5**) par le tétraacétate de plomb conduit aux acétoxy-6 (alcène-3 yl)-6 cyclohexadiène-2,4 ones-1 (**6**) qui subissent des réactions de Diels–Alder intramoléculaires conduisant à des dérivés de l'isotwistène (hexahydro méthano-1,5 indène) (**7**). Ceux-ci, soumis à une réaction d'hydrolyse suivie d'une oxydation par de l'acide periodique, conduisent aux acides hexahydro oxo-1 1*H*-indènecarboxyliques-5 (**41** et **46**). On a préparé les composés **5** soit par un couplage de Grignard du chlorure d'*o*-méthoxybenzyle avec des halogénures allyliques suivi d'une *O*-déméthylation par le thioéthylate de sodium soit par une réduction, par l'hydrure de diisobutylaluminium, des dihydrocoumarines (**18**–**20**) en chromanols (**21**–**23**) suivie d'une réaction de Wittig de ces derniers avec le (triphénylphosphoranylidène)acétate d'éthyle.

The oxidation of *ortho*-substituted phenols with lead tetraacetate LTA to give 6-acetoxy-2,4-cyclohexadien-1-ones (*o*-quinol acetates; **1**), which was first reported by Wessely and his co-workers in 1950 (4), is the simplest general method for the synthesis of the latter class of compounds. Wessely early recognized (5) the potential utility of *o*-quinol acetates in intermolecular Diels–Alder reactions leading to bicyclo[2.2.2]octenones and bicyclo[2.2.2]octadienones (e.g., **2** (R = CH_3)[3]) (Scheme 1).

Work in these laboratories (1, 2) has shown that an intramolecular version of the latter reaction can be effected by Wessely oxidation products that incorporate a dienophilic group in the ester moiety (e.g., **3**). This provides a route to tricyclic lactones of type **4**, as exemplified in Scheme 2.

It occurred to us that a related reaction sequence involving Wessely oxidation of an *o*-(3-alkenyl) phenol (**5**) to give a 2,4-cyclohexadienone of type **6**, followed by intramolecular Diels–Alder reaction, could provide a viable route to tricarbocyclic analogues of **4**, i.e., isotwistene (hexahydro-1,5-methanoindene) derivatives of type **7** (Scheme 3). Other workers (7) have already demonstrated the practicability of the synthesis of tricyclic systems via intramolecular reactions of alkenyl 1,3-cyclohexadiene derivatives, but none to our knowledge has coupled this reaction with the Wessely oxidation reaction.

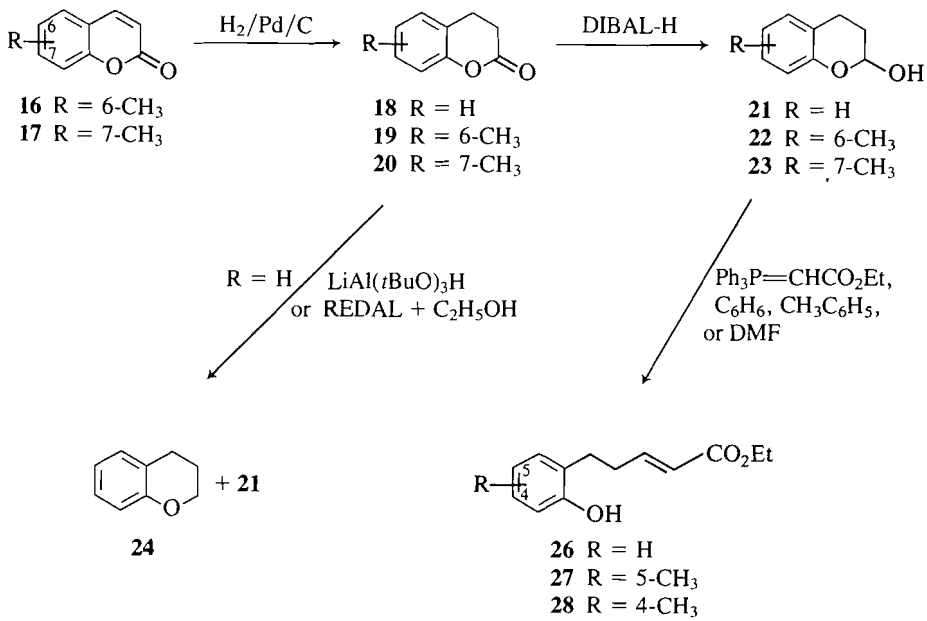

SCHEME 5

Synthesis of o*-(3-alkenyl) phenols*

Although in intermolecular Diels–Alder reactions of ethylenic dienophiles an activating, electron-withdrawing substituent is required for facile reaction, this is less true of intramolecular Diels–Alder reactions because of a favorable entropic factor. We therefore chose to develop two general routes for the synthesis of *o*-(3-alkenyl) phenols, one leading to 3-alkenyl side chains without electron-withdrawing substituents and the other to 3-alkenyl side chains with a 4-alkoxycarbonyl substituent.

The first route (Scheme 4) is based on earlier work by Oki and Iwamura (8). *o*-Methoxybenzyl chloride (**8**) was prepared by treatment of *o*-methoxybenzyl alcohol with thionyl chloride (9). The alcohol was obtained by reduction of anisaldehyde with sodium borohydride or methylation of *o*-hydroxybenzyl alcohol with dimethyl sulfate in dry dimethylformamide (10). In the latter case the product was contaminated with *o*-methoxybenzyl methyl ether; however, we found that this too was converted to **8** by thionyl chloride. Coupling of the Grignard reagent devised from **8** with allyl bromide and with methallyl chloride gave the *o*-(3-alkenyl) anisoles **9** and **10**, respectively. Not surprisingly, these reactions also gave rise to significant amounts of the symmetrical coupling products **11** and **12**, which were isolated and identified.

Attempted demethylation of **9** with trimethylsilyl chloride and sodium iodide in acetonitrile (11) gave the chromane **13**, indicating that although demethylation was occurring, adventitious acid was promoting ring closure. Resort was therefore had to demethylation of **9** and **10** under basic conditions with sodium thioethoxide in dimethylformamide (12) to give phenols **14** and **15**, respectively.

The second route (Scheme 5) entailed reduction of the dihydrocoumarins **18–20** to the 2-chromanols **21–23**. Compound **18** is commercially available and compounds **19** and **20** were prepared by hydrogenation of the coumarins **16** and **17**, respec-

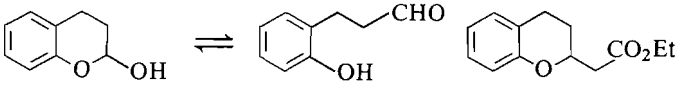
tively.[4] Reduction of **18** with lithium tri-(*tert*-butoxy)aluminum hydride (14) or sodium bis(2-methoxyethoxy)aluminum hydride (REDAL) plus one equivalent of ethanol (15) has previously been reported to give **21** in yields of 50%. We obtained similar yields but found that a persistent problem was the formation of chroman (**24**), an impurity that was found to be difficult to remove. However, compounds **18**–**20** were smoothly reduced by diisobutylaluminum hydride (DIBAL-H) in 84–93% yield.

It is known that 2-chromanol **21** is in mobile equilibrium with the corresponding phenolic aldehyde **25** (15), and it was



21 **25** **29**

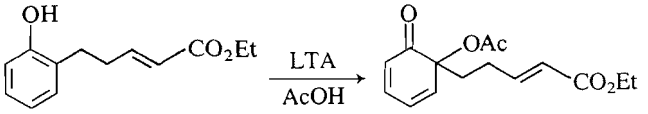
therefore expected that the 2-chromanols **21**–**23** would undergo the Wittig reaction via their aldehydic tautomers. An analogous reaction has already been carried out with tetrahydro-2-pyranol (16). Treatment of the 2-chromanols with ethyl (triphenylphosphoranylidene)acetate in benzene or dimethylformamide (16, 17) gave the 5-(*o*-hydroxyphenyl)-2-pentenoic esters **26**–**28**. In all cases the *E* isomer was the major product; this was obtained in admixture with a small amount of the *Z* isomer and the by-product, triphenylphosphine oxide. Separation of the phenol from the triphenylphosphine oxide proved to be difficult.[5] Molecular distillation or extraction of crude **27** with dilute aqueous base led to ring closure to give the chroman **29**. Molecular distillation of the acetylated mixture was only partially successful and subsequent hydrolysis under either basic or acidic conditions led to the formation of **29**. The mixture of **26**, its *Z* isomer, and triphenylphosphine oxide could be separated by chromatography, but not without some reduction in yield because of the formation of **29**. Ultimately it was found that the mixture could be subjected successfully to Wessely oxidation and that the optimum point for the removal of triphenylphosphine oxide was after the intramolecular Diels–Alder reaction. Recourse was also had to this *modus operandi* in the cases of the phenols **27** and **28**.

The second route could also be utilized for the preparation of *o*-(3-butenyl) phenol (**14**) via treatment of 2-chromanol (**21**) with methylenetriphenylphosphorane, but the first route was found to be preferable. It is not possible, of course, to use the first route for the synthesis of the phenols **26**–**28**.

The assignments of structure to the compounds discussed above are based on their provenance and spectra. The 2-chromanols **21**–**23** show in their ^{1}H nmr spectra two-proton multiplets at δ 1.7–2.2 and 2.5–3.1 for the C-3 methylene protons and C-4 benzylic protons, respectively. The C-2 protons of **21** and **22** give rise to doublets of triplets (J = 4, 3 Hz), at δ 5.46 and 5.56, which collapse to triplets (J = 3 Hz) after D_2O treatment; compound **23** gives rise to a triplet (J = 3 Hz) at δ 5.47. All show a one-proton signal for the hydroxyl proton in the δ 3–4 region that is absent after D_2O treatment. In the case of **23** this is a broad singlet and in the cases of **21** and **22** it is a doublet (J = 4 Hz). All 2-chromanols show multiplets for the aromatic protons, and compounds **22** and **23** show three-proton singlets for their aromatic methyl groups at δ 2.25. The phenols **26**–**28** show in their ^{1}H nmr spectra four-proton multiplets at δ 2.3–3.0 for their benzylic and allylic methylene groups, one-proton doublets of triplets (J = 15, 2 Hz) at δ 5.8 for their C-2 vinylic protons, singlets at δ 5.5–7 for their phenolic protons, and multiplets at δ 6.5–7.4 arising from the overlap of signals of their C-3 vinylic and their aromatic protons. The methyl protons of compounds **27** and **28** give rise to three-proton singlets at δ 2.1–2.2 and all three compounds show appropriate signals for the protons of their ethoxycarbonyl groups. The 15-Hz vicinal coupling constants of the C-2 vinylic protons establish that all compounds isolated have the *E* configuration about their ethylenic bonds. The ^{1}H nmr spectra of the phenols **14** and **15** resemble those of the phenols **26**–**28**, *mutatis mutandis*. The ^{13}C spectra of the dihydrocoumarins, 2-chromanols, and phenols (Tables 1 and 2) are in accord with the structural assignments.

Wessely oxidation and intramolecular Diels–Alder reactions

The Wessely oxidation of *o*-substituted phenols with lead tetraacetate has been carried out under a wide variety of conditions, especially with respect to the solvent used (19). The yields of *o*-quinol acetates and the distribution of oxidized products are often markedly sensitive to the conditions used. We therefore first oxidized the phenol **26** with lead tetraacetate in a number of solvents (and catalysts) that had been reported to give good yields of *o*-quinol acetates in other cases. This phenol was chosen for the purpose because we anticipated that of the two types of *o*-(3-alkenyl) phenol we had prepared, the one with a 4-ethoxycarbonyl substituent might be more susceptible to side reactions involving the side chain than those without such a substituent. The solvents (and catalysts) used were acetic acid (4*b*, 5*a*), dichloromethane (2*a*, 20), chloroform (21), chloroform and pyridine (22), dioxane, tetrahydrofuran (−60°C), and methanol/ethyl acetate/boron trifluoride (23). The efficiency of the reaction conditions was judged by the yield of the *o*-quinol acetate **30** as indicated by the ^{1}H nmr spectra of the crude reaction products. The use of acetic acid was judged to be the most effective; dioxane and methanol/ethyl acetate/boron trifluoride also gave satisfactory results.



26 **30**

The Wessely oxidation – Diels–Alder sequence was then investigated with the simplest *o*-(3-alkenyl) phenol, **14**. Treatment of **14** with lead tetraacetate in acetic acid gave a crude product whose ^{1}H nmr spectrum was dominated by a sharp methyl singlet at δ 2.01, assigned to the acetoxyl protons of the *o*-quinol acetate **31**; in addition, signals for the terminal alkene were evident at δ 4.8–5.8. Its ir spectrum showed strong peaks at 5.71 and 5.9 μm, consonant with the acetoxyl and 2,4-dienone functions of **31**.[6] This product was heated in boiling benzene and the progress of the intramolecular Diels–Alder reaction was followed by ^{1}H nmr spectroscopy. The formation of the tricyclic product **32** was evidenced by the appearance of a new acetoxyl proton signal at δ 1.97 and the diminution of the acetoxyl proton signal of **31** at δ 2.01. After 54

[4]Coumarin **16** is commercially available and coumarin **17** was prepared from *m*-cresol, malic acid, and sulfuric acid by a modification of the method of Bailey and Boethner (13).

[5]This difficulty may stem from the propensity for triphenylphosphine oxide to form very stable complexes with phenols (18).

[6]Each of these bands occurs at shorter wavelength than the wavelengths characteristic of the individual carbonyl functions; this is not uncommon for α-acyloxy ketones and results most probably from dipole–dipole interactions (24).

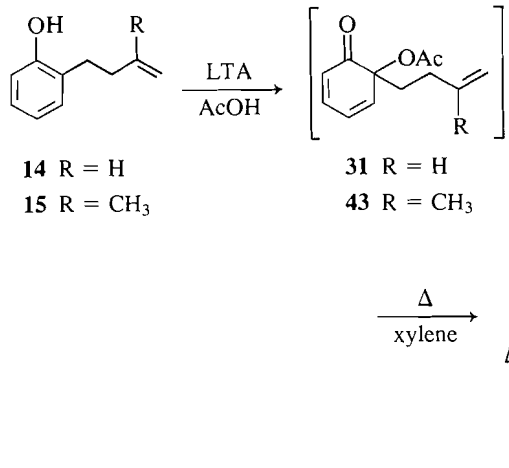
[a]See footnote *a*, Table 1.

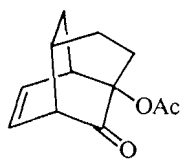
hours the ratio of these peaks remained constant. The lethargy of the Diels–Alder reaction was not unexpected since the dienophilic ethylenic bond was unactivated in this case. When the cyclization was carried out in boiling toluene or xylene, the rate of the reaction was increased but the yield and purity of **32** were not significantly improved. Since it is known that *o*-quinol acetates dimerize via an intermolecular Diels–Alder reaction at elevated temperatures (21), reaction conditions were then chosen so as to minimize the concentration of the Wessely product during the ring-closure reaction and thus favor the



SCHEME 6

monomolecular ring closure reaction over the intermolecular Diels–Alder reaction. Thus the slow addition of a solution of **31** in xylenes to the reaction flask containing boiling xylenes gave the highest, albeit still modest (*vide infra*), yield of **32**.

The structure of the Diels–Alder reaction product was provisionally assigned as **32** in analogy to structures of type **4** that had previously been assigned to the analogous tricyclic lactones (Scheme 2) (1, 2). This assumes that the addition is of the quasi "ortho" type (25). However, there is sufficient precedent to suggest that the product might possibly arise by the less usual quasi "pene" type of reaction (25), resulting in a twistane derivative **33** rather than the isotwistane derivative **32**.



33

Thus, for example, Greuter and Schmid (7*d*) have found that a mixture of both types of product, **35** and **36**, are formed from compound **34** (Scheme 7). Although it has been demonstrated that in the case of the lactones only the "ortho" products of type

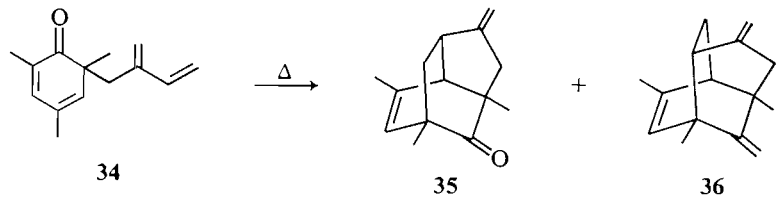
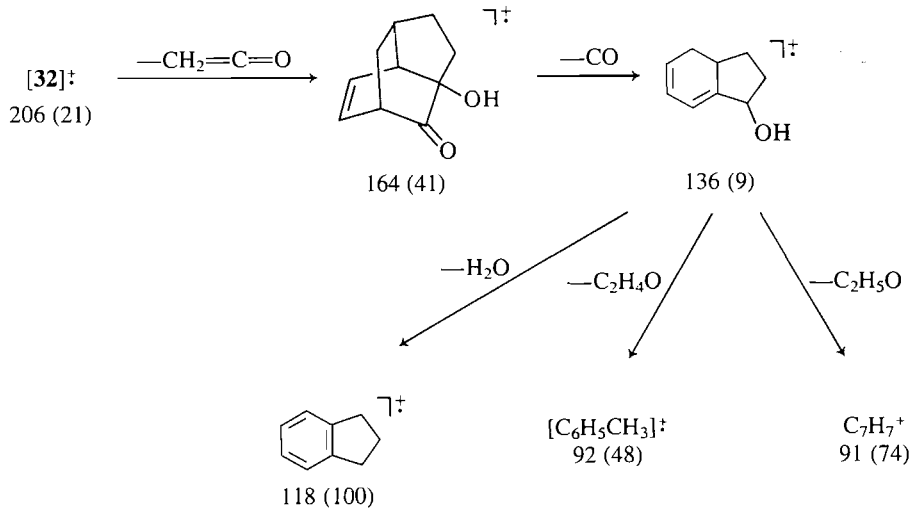


SCHEME 7



SCHEME 8

4 are formed (2), it could not be excluded *a priori* that the tricarbocyclic products in the present work were of type **33**. Their spectra and chemistry in fact establish that they are of type **32** rather than **33**. Nevertheless, several facets of their spectra can be interpreted in terms of either. We shall discuss the spectra in terms of structure **32**, emphasizing those aspects that distinguish it from **33**.

The ir spectrum shows carboxyl-stretching bands at 5.70 (sh) and 5.76 μm in accord with the α-acyloxy ketone function.[6] The mass spectrum shows several prominent peaks in addition to the molecular ion peak at *m/z* 206; the fragmentation is interpretable as shown in Scheme 8.

The 400-MHz ^{1}H nmr spectrum is given in Table 3 together with the assignments for structure **32**.[7] These are based on the chemical shifts and coupling constants and comparison of these with those in the spectra of **4** and its congeners (2). They are ambiguous in the cases of the C-9 and C-10 protons, but otherwise appear to be secure. In particular, decoupling experiments confirmed that the protons that give rise to signals at δ 3.47 and 6.12 are coupled, as are those giving rise to signals at δ 3.11 and 6.21. Thus irradiation at the frequencies corresponding to δ 3.47 and 3.11 led to collapse of the signals at δ 6.12 and 6.21 to doublets of doublets with J = 6 and 1.5 Hz, and J = 6.5 and 2 Hz, respectively.

It is important to note that this ^{1}H nmr spectrum does not of itself unambiguously distinguish structures **32** and **33**. However, from its relation to the spectrum of **31**, formed by mild hydrolysis of **32** (Scheme 9), such a distinction can be reached. The allylic bridgehead proton signals of **32** at δ 3.11 and 3.47 appear at δ 3.18 and 3.02, respectively, in the spectrum of **37**. The large upfield shift of Δδ −0.45 clearly

[7]The numbering system *A* used in Table 3 and in the ensuing discussion here is based on the numbering system for bicyclo[2.2.2]oct-5-en-2-one since we have used this previously for the lactones of type **4** (3). The *Chemical Abstracts* numbering of the 1,5-methanoindene system (*B*) is used in the experimental section. A further representation of this system is given in *C*.

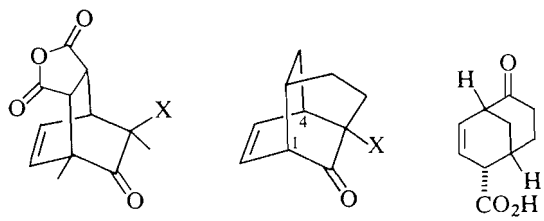
45 R = CH_3

41 R = H
46 R = CH_3

SCHEME 9

demonstrates that the protons giving rise to the δ 3.47 and 3.02 signals must be on carbon atoms adjacent to those bearing the acetoxyl and hydroxyl groups (cf., for example, the upfield shift of Δδ −0.51 previously observed for the corresponding proton signal in the alcohol **39** (δ 3.53) vs. the acetate **38** (δ 4.04) (6)). This excludes the possibility that the structure of the Diels–Alder product is **33** and that of its hydrolysis product is **40** and that the δ 3.11 and 3.47 signals are assignable to the C-1 and C-4 protons, respectively, in **33**.



38 X = OAc
39 X = OH

33 X = OAc
40 X = OH

42

Related evidence is provided by the ^{13}C nmr spectra of compounds **32** and **37** (experimental section). The signals for C-1 and C-4 in the former occur at δ 47.4 and 46.3, respectively, while they appear at δ 47.0 and 49.0, respectively, in the latter. The larger effect of conversion of the acetoxyl to a hydroxyl group (Δδ 3.7) is expected for the bridgehead carbons adjacent to the carbons bearing these groups, i.e., C-4 in **32** and **37**. The differential shift has the opposite sign to that observed in the proton spectra: this can readily be attributed to a γ-effect that is operative in the acetoxy but not in the hydroxy compound (26). A similar effect may be noted in the ^{13}C nmr spectra of compounds **38** and **39**, where Δδ = 1.6. The remainder of the ^{13}C nmr spectra of **32** and **37** are also in consonance with the structural assignments.[8]

A further piece of evidence that confirms the assignment of structure **32** rather than **33** to the Diels–Alder product comes from the ir spectrum of the product formed on treatment of the hydrolysis product **37** with periodic acid. This is a keto acid, as expected for either structure **32** or **33**. Its ir spectrum shows carbonyl peaks at 5.74 and 5.83 μm, demonstrating that the ketonic group is in a five-membered ring as in **41**, the product derived from **37**, and excluding the cyclohexanone derivative **42** that would be formed from **40**.

The spectra of the Diels–Alder product **44** derived from the Wessely oxidation product **43** of phenol **15** (Scheme 6) bear the expected relationship to those of **32**, as do the spectra of its hydrolysis product **45** and the periodic acid oxidation product, **46** (Scheme 9). In particular, the methyl group at C-8 shields the C-4 proton (Δδ −0.36) and deshields the C-4 carbon (Δδ 5.8) of **44**, and conversion of **44** and **45** results in a shielding of the C-4 proton (Δδ −0.52) and a deshielding of C-4 itself (Δδ 2.9). Analogy for the former effect is found in the effect of the C-8 methyl group in the tricyclic lactone **47** on the chemical shifts of the C-4 proton (Δδ −0.50) and of C-4 (Δδ 6.5) of the parent lactone **4** (2, 27). Again the ir spectrum of the periodic acid product **4***b* shows the presence of a cyclopentanone rather than a cyclohexanone moiety.

Wessely oxidation of the *o*-(3-alkenyl) phenols **26–28** bearing an ethoxycarbonyl group at the terminal carbon of the ethylenic double bond gave 6-acetoxy-2,4-cyclohexadienones that were not isolated but were directly subjected to Diels–Alder cyclization. As expected, the presence of the ethoxycarbonyl groups increased the dienophilicity of the side chain ethylenic double bonds, and the Diels–Alder reactions in boiling xylenes under the same conditions as previously described were complete in 12 h giving the tricarbocyclic acetoxy ketones **48–50**, which were converted to the corresponding alcohols **51–53** with potassium carbonate in boiling methanol. Comparison of their ir and ^1H and ^{13}C nmr spectra (see experimental section) with each other and with those of the acetoxy and hydroxy ketones discussed previously established that the Diels–Alder reactions had again given the "ortho" products **48–50**.

The feasibility of the synthesis of isotwistane derivatives of type **7** by tandem Wessely oxidation – Diels–Alder reaction sequences of *o*-(3-alkenyl) phenols has thus been established. Although the overall yields were modest (20–35%), we consider that this disadvantage is offset by the brevity of the synthetic sequence. Furthermore, this sequence, unlike some related sequences involving intramolecular reactions of 6-alkenyl-2,4-cyclohexadien-1-ones (7), results in isotwistane derivatives with both carbonyl and hydroxyl functions, a feature that is of potential importance in their further synthetic elaboration.

Experimental

Melting points were determined on a Fisher–Johns apparatus and are uncorrected. Infrared (ir) spectra were recorded in $CHCl_3$ solution; the appearance of bands, where noted, is designated as strong (s), medium (m), weak (w), and broad (br). Proton nuclear magnetic resonance (^1H nmr) spectra were recorded at 60 MHz in $CDCl_3$ solution unless otherwise specified. Carbon-13 nuclear magnetic resonance (^{13}C nmr) spectra were recorded in $CDCl_3$ solution; signal multiplicities were determined from single-frequency off-resonance decoupled spectra. Mass spectra were recorded at 70 eV with a Bell and Howell CEC 21-490 single-focussing mass spectrometer and molecular ion peak

[8]It is planned to discuss these spectra in detail elsewhere.

positions are reported in mass-to-charge (m/z) units followed by the relative abundance in parentheses. Exact mass measurements were determined from high resolution mass spectra obtained on an AEI-MS 902 double-focussing mass spectrometer.

Preparative thin-layer chromatography (tlc) was carried out on 200 × 200 × 2.0 mm silica gel "G" plates containing a fluorescent indicator. The bands were extracted with ether or methanol. Column chromatography was carried out with MN-Kieselgel 60 (70–270 mesh ASTM). Unless otherwise indicated, all organic solvents were evaporated by means of a Buchi "Rotovapor ⟨R⟩" rotary evaporator at water aspirator pressure. Solvents were distilled immediately before use. Where required, dry hydrocarbons and ethers were obtained by boiling the solvent under reflux over, and distilling from, sodium ribbon. Dry diethyl ether for the Grignard coupling reactions was distilled from $LiAlH_4$. Dry ethanol was obtained by boiling absolute ethanol over, and distilling from, magnesium. Anhydrous experiments were carried out under dry nitrogen that had been passed through concentrated H_2SO_4, followed by KOH. Brine refers to a saturated aqueous solution of NaCl.

*o-Methoxybenzyl chloride (**8**)*

An ice-cooled solution of *o*-anisaldehyde (31.9 g, 0.23 mol) in methanol (120 mL) was treated with a solution of $NaBH_4$ (7.68 g, 0.20 mol) in aqueous 5% NaOH (150 mL). The reaction mixture was stirred for 12 h and the methanol was evaporated under reduced pressure. The residue was taken up in ethyl acetate (150 mL), and the solution was washed with water (100 mL) and brine (100 mL) and dried over Na_2SO_4. Evaporation of the solvent left *o*-methoxybenzyl alcohol (25.9 g, 80%); ^{1}H nmr δ: 2.77 (bs, 1H), 3.79 (s, 3H), 4.63 (bs, 2H), 6.7–7.3 (m, 4H).

The crude alcohol (10.0 g, 72 mmol) in benzene (80 mL) and pyridine (0.2 mL) was treated dropwise with $SOCl_2$ (15 g, 126 mmol) over a period of 20 min. The solution was heated to reflux for 2.5 h, cooled, and evaporated under reduced pressure. The residue was taken up in ether (250 mL), and the organic solution was washed with water (100 mL) and brine (100 mL) and dried over Na_2SO_4. After evaporation of the solvent, **8** was distilled, bp 57°C/0.15 Torr (lit. (9) bp 64–65°C/0.3 Torr; 1 Torr = 133.3 Pa) as a colorless liquid (7.91 g, 51 mmol, 70%); ^{1}H nmr δ: 3.82 (s, 3H), 4.63 (s, 2H), 6.6–7.3 (m, 4H).

*4-(2-Methoxyphenyl)-1-butene (**9**)*

A solution of **8** (29.9 g, 0.190 mol) in dry ether (150 mL) was added to magnesium turnings (6.1 g, 0.25 mol) in 25 mL of ether at a rate that maintained reflux. The mixture was heated for a further 30 min, cooled to ambient temperature, and decanted under a nitrogen atmosphere through a glass wool plug into a three-necked flask equipped with an addition funnel and a reflux condenser. The filtrate containing the Grignard reagent was treated dropwise with allyl bromide (33.5 g, 0.280 mol) in ether (50 mL) at a rate that sustained reflux. The solution was heated for a further 2 h, cooled with an ice bath, and treated with aqueous NH_4Cl (25 mL). The mixture was diluted with water (100 mL) and the organic layer was separated. The aqueous layer was extracted with ether (3 × 100 mL) and the combined extracts were dried (K_2CO_3) and evaporated to give a pale yellow oil, which was distilled to give **9** as a colorless liquid (15.2 g, 0.094 mol, 49%), bp 89–90°C/14 Torr (lit. (8) bp 120–123°C/18 Torr); ^{1}H nmr δ: 2.3–3.0 (m, 4H), 3.82 (s, 3H), 4.9–5.3 (m, 2H), 5.7–6.3 (m, 1H), 6.8–7.3 (m, 4H).

*4-(2-Hydroxyphenyl)-1-butene (**14**)*

*(a) From **9***

Under a nitrogen atmosphere, a 50% dispersion of NaH (1.68 g, 350 mmol) in oil was washed with dry hexanes (10 mL) and dry ether (10 mL), and then the NaH was suspended in dry DMF (20 mL). A solution of ethanethiol (2.10 mL, 40 mmol) in DMF (40 mL) was added and when gas evolution had ceased, **9** (2.56 g, 15.2 mmol) in DMF (20 mL) was added. The mixture was heated at reflux for 2 h, cooled in an ice bath, and carefully neutralized with aqueous 10% HCl. The neutralized solution was extracted with ether (5 × 50 mL) and the ethereal extracts were washed with water (150 mL) and brine (3 × 50 mL). The resulting pale yellow solution was dried and evaporated to leave an orange oil. Consecutive molecular distillations (38°C/0.01 Torr; lit. (8) bp 78°C/2.5 Torr) gave **14** (1.63 g, 11.2 mmol, 74%) as a colorless liquid; ir λ_{max}: 2.88, 3.10, 3.51, 6.10, 6.29 μm; ^{1}H nmr δ: 2.3–2.9 (m, 4H), 4.8–5.3 (m, 3H), 5.18 (bs, 1H, absent after D_2O treatment), 5.5–6.2 (m, 1H), 6.5–7.2 (m, 4H); ms m/z: 148 (32).

*(b) From **21***

Under a nitrogen atmosphere, a 50% dispersion of NaH (2.16 g, 45 mmol) in oil was washed with dry pentanes and ether and then treated with DMSO (20 mL). The mixture was heated at 80°C until gas evolution ceased. To the deep gray solution was added methyl triphenylphosphonium bromide (15.72 g, 44 mmol) in DMSO (75 mL) at room temperature. After 15 min a solution of 2-chromanol (**21**) (3.23 g, 21 mmol) in DMSO (5 mL) was added. After a further 30 min the reaction mixture was quenched with water (50 mL), and the solution was neutralized (dilute aqueous HCl) and extracted with ether (4 × 50 mL). The organic extracts were washed with water (100 mL) and brine (100 mL) and dried over $MgSO_4$. The solution was evaporated and the residual yellow oil was purified by molecular distillation (110°C/0.10 Torr) to give **14** (1.06 g, 7.25 mmol, 35%) as a colorless oil. Its spectral data were identical to those of the product from route (*a*).

*4-(2-Methoxyphenyl)-2-methyl-1-butene (**10**)*

The Grignard reagent was prepared from **8** (7.82 g, 0.0482 mol) and magnesium (1.82 g, 0.078 mol) in ether (25 mL) as in the preparation of **9** above; in this case a crystal of iodine was added to initiate the reaction. The solution was cooled in a Dry Ice – acetone bath and treated with freshly distilled methallyl chloride (9.06 g, 0.100 mol) in ether (20 mL). The mixture was then warmed to reflux and maintained at reflux for 1 h. Work-up as in the case of **9** gave **10** as a colorless liquid (4.54 g, 0.0258 mol, 53.5%), bp 107–108°C/10 Tor; ^{1}H nmr δ: 1.77 (s, 3H), 2.1–2.4 (m, 2H), 2.6–2.9 (m, 2H), 3.77 (s, 3H), 4.68 (s, 2H), 6.6–7.2 (m, 4H).

*4-(2-Hydroxyphenyl)-2-methyl-1-butene (**15**)*

Compound **15** was prepared by treatment of **10** (2.95 g, 0.0167 mol) with sodium thioethoxide (from NaH (50% dispersion; 19.3 g, 0.0444 mol) and ethanol (293 g, 0.0471 mol)) in DMF was in the preparation of **14** from **10** above. Molecular distillation (80°C/0.005 Torr) of the crude product gave **15** as a colorless liquid (2.25 g, 0.0141 mol, 84.5%); ^{1}H nmr δ: 1.72 (s, 3H), 2.1–2.4 (m, 2H), 2.6–2.9 (m, 2H), 4.73 (s, 2H), 5.67 (bs, 1H, absent after D_2O treatment), 6.6–7.1 (m, 4H).

*2-Chromanol (**21**)*

Dihydrocoumarin (**18**) (14.6 g, 0.10 mol) in dry toluene (250 mL) was cooled to −78°C and treated over a period of 2 h with diisobutylaluminum hydride (25% in toluene; 74.6 mL, 0.110 mol). The reaction mixture was stirred for a further 2 h at −78°C, treated dropwise with water (50 mL), warmed to room temperature, treated with Celite, and suction filtered. The filtrate was extracted with ether (5 × 100 mL) and the combined organic solutions were washed with water (200 mL) and brine (200 mL) and dried over Na_2SO_4. The Celite and filtered salts were shaken with ether (200 mL) and the mixture was filtered. The filtrate was washed with water (100 mL) and brine (100 mL) and dried as above. Evaporation of the combined organic solutions left a pale yellow liquid, which was distilled (bp 95–96°C/0.10 Torr; lit. (14) bp 88–89°C/0.05 Torr) to give **21** as a colorless liquid (12.6 g, 0.84 mol, 84%); ir λ_{max}: 2.86, 3.02, 3.48, 6.33 μm; ^{1}H nmr δ: 1.8–2.2 (m, 2H), 2.5–3.1 (m, 2H), 3.44 (d, 1H, J = 4 Hz, absent after D_2O treatment), 5.56 (dt, 1H, J = 4, 3 Hz; t, J = 3 Hz after treatment with D_2O), 6.6–7.2 (m, 4H).

*Ethyl 5-(2-hydroxyphenyl)-2-pentenoate (**26**)*

2-Chromanol (**21**) (1.30 g, 8.65 mmol) in benzene (25 mL) was treated with carboethoxymethylenetriphenylphosphorane (3.05 g, 9.00 mmol) in benzene (25 mL). After 12 h the solvent was evaporated to leave a colorless, viscous oil that was a mixture of **26** and triphenylphosphine oxide. The crude mixture was used without

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.222.148.141 on 09/07/12
For personal use only.

purification in the subsequent Wessely oxidation. The phenol **26** could be isolated by preparative tlc (hexanes/ethyl acetate, 4:1) as a colorless oil; ir λ_{max}: 5.85 μm; ^{1}H nmr δ: 1.17 (t, J = 8 Hz, 3H), 2.3–3.0 (m, 4H), 4.18 (q, J = 8 Hz, 2HO), 5.84 (dt, J = 15, 2 Hz, 1H), 6.35 (s, 1H, absent after D_2O treatment), 6.6–7.4 (m, 5H); ms m/z: 220 (52). *Exact Mass* calcd. for $C_{13}H_{16}O_3$: 220.1100; found: 220.1101.

*3,4-Dihydro-6-methylcoumarin (**19**)*

6-Methylcoumarin (**16**) (10.54 g, 65.8 mmol) in ethyl acetate (250 mL) was added slowly to 10% Pd/C (1.20 g) in a Parr hydrogenation flask. The mixture was shaken under a hydrogen atmosphere (57 psi; 1 psi = 6.9 kPa) for 3 h, after which time no further uptake of hydrogen could be observed. The reaction mixture was filtered through a layer of Celite in a sintered glass funnel and, after evaporation of the solvent, a colorless oil was left, which crystallized on standing. Drying under vacuum (0.10 Torr) overnight left **19** as white crystals (10.51 g, 64.8 mmol, 98.5%), mp 80–81°C (lit. (28) mp 81°C); ir λ_{max}: 5.68 μm; ^{1}H nmr δ: 2.30 (s, 3H), 2.5–3.1 (m, 4H), 6.3–7.1 (m, 3H).

*6-Methyl-2-chromanol (**22**)*

3,4-Dihydro-6-methylcoumarin (**19**) (15.9 g, 98.0 mmol) in dry toluene (250 mL) under a nitrogen atmosphere was treated dropwise at −78°C (Dry Ice – acetone) with diisobutylaluminum hydride (70.0 mL, 104 mmol, 25% solution in toluene) over a period of 2 h. After a further 2 h at −78°C, water (50 mL) was added slowly to the stirred, cold solution. The mixture was allowed to warm to room temperature and more water (50 mL) was added, followed by ether (250 mL). The mixture was treated with Celite and filtered, and the precipitated salts were further extracted with ether (2 × 250 mL). The combined organic extracts were washed with brine (250 mL) and dried over Na_2SO_4. Removal of solvent left **22** as a colorless oil (14.6 g, 88.9 mmol, 90.7%); ir λ_{max}: 2.85 (w), 3.00 (w), 3.46 (w), 6.35 (m) μm; ^{1}H nmr δ: 1.7–2.1 (m, 2H), 2.23 (s, 3H), 2.5–3.0 (m, 2H), 3.75 (d, 1H, J = 4 Hz, absent after D_2O treatment), 5.46 (dt, 1H, J = 4, 3 Hz; t, J = 3 Hz, after D_2O treatment), 6.5–7.0 (m, 3H); ms m/z: 164 (29). *Exact Mass* calcd. for $C_{10}H_{12}O_2$: 164.0837; found: 164.0845.

*Ethyl 5-(2-hydroxy-5-methylphenyl)-2-pentenoate (**27**)*

6-Methyl-2-chromanol (**22**) (2.03 g, 12.3 mmol) in benzene (30 mL) was treated with carboethoxymethylenetriphenylphosphorane (4.40 g, 13.0 mmol) in benzene (30 mL) and the solution was stirred for 12 h. Evaporation of solvent left a pale yellow, viscous oil, which was used without purification in the Wessely oxidation. A sample of **27** was isolated by preparative tlc (hexanes/ethyl acetate, 4:1) as a colorless oil; ir λ_{max}: 5.85 μm; ^{1}H nmr δ: 1.25 (t, J = 7 Hz, 3H), 2.10 (s, 3H), 2.5–2.9 (m, 4H), 4.18 (q, J = 7 Hz, 2H), 5.77 (dt, J = 15.2 Hz, 1H), 6.5–7.2 (m, 4H), 6.80 (br s, 1H); ms m/z: 234 (43). *Exact Mass* calcd. for $C_{14}H_{18}O_3$: 234.1256; found: 234.1259.

*7-Methylcoumarin (**17**)*

A solution of *m*-cresol (54.1 g, 0.50 mol) in concentrated H_2SO_4 (125 mL) was heated to 110°C and treated over a 3-h period with malic acid (80.5 g, 0.60 mol). After being heated for a further 3 h, the reaction mixture was allowed to cool to room temperature and was then treated slowly with water (50 mL). After the reaction mixture had again cooled to room temperature, the dark solution was poured into ice (250 g) and the precipitate that formed was removed by filtering the mixture through a sintered glass funnel. The resulting tan solid was dissolved in boiling aqueous 50% ethanol (300 mL) and the solution was cooled slowly to −30°C. The cream-colored, shiny leaves that formed were recrystallized from aqueous 50% ethanol to give **17** (38.1 g, 0.24 mol, 48%) as white needles, mp 129–130°C (lit. (13) mp 128–130°C); ir λ_{max}: 5.78, 6.16 μm; ^{1}H nmr δ: 2.43 (s, 3H), 6.27 (d, J = 9.5 Hz, 1H), 6.9–7.5 (m, 3H), 7.60 (d, J = 9.5 Hz, 1H); ^{13}C nmr δ: 160.8 (s), 154.0 (s), 143.1 (s), 142.9 (d), 127.4 (d), 125.4 (d), 116.8 (d), 116.3 (d), 115.3 (d), 21.4 (q); ms m/z: 160 (11).

*3,4-Dihydro-7-methylcoumarin (**20**)*

7-Methylcoumarin (**17**) (10.0 g, 62.4 mmol) in ethyl acetate (250 mL) was added to 10% Pd/C (1.5 g) in a Parr hydrogenation vessel. The mixture was shaken under a hydrogen atmosphere (57 psi) for 6 h, at which time no further uptake of H_2 could be observed. The reaction mixture was filtered through Celite in a sintered glass funnel and evaporation of the solvent under reduced pressure left a colorless oil that crystallized upon standing. The crystalline mass was pulverized and dried *in vacuo* overnight to yield **20** (10.0 g, 61.7 mmol, 99%), mp 45–47°C (lit. (27) mp 44.5°C); ir λ_{max}: 5.67 μm; ^{1}H nmr δ: 2.31 (s, 3H), 2.5–3.1 (m, 4H), 6.7–7.2 (m, 3H).

*7-Methyl-2-chromanol (**23**)*

3,4-Dihydro-7-methylcoumarin (**20**) (1.62 g, 10.0 mmol) in dry toluene (40 mL) under a nitrogen atmosphere was treated at −78°C over a period of 90 min with diisobutylaluminum hydride (25% in toluene; 7.40 mL, 11.0 mmol). After a further 90 min the reaction mixture was quenched by the slow addition of water (50 mL). The solution was allowed to warm to room temperature. Celite was added to the mixture, which was then filtered and the filtrate was extracted with ether (4 × 100 mL). The extracts were washed with water (50 mL) and brine (50 mL) and dried over Na_2SO_4, and the solvent was evaporated to leave a pale yellow solid (1.42 g, 87%), which was recrystallized from hexanes – ethyl acetate to give **23** as white crystals, mp 103–103.5°C; ir λ_{max}: 2.86, 3.02, 3.47, 6.33 μm; ^{1}H nmr δ: 1.8–2.1 (m, 2H), 2.26 (s, 3H), 2.5–3.0 (m, 2H), 3.6 (br s, 1H), 5.47 (t, J = 3 Hz, 1H), 6.5–7.0 (m, 3H); ms m/z: 164 (65). *Exact Mass* calcd. for $C_{10}H_{12}O_2$: 164.0837; found: 164.0842. *Anal.* calcd. for $C_{10}H_{12}O_2$: C 73.14, H 7.37; found: C 73.08, H 7.43.

*Ethyl 5-(2-hydroxy-4-methylphenyl)-2-pentenoate (**28**)*

7-Methyl-2-chromanol (**23**) (2.75 g, 16.8 mmol) in benzene (30 mL) was mixed with carboethoxymethylenetriphenylphosphorane (6.09 g, 18.0 mmol) in benzene (30 mL). After 12 h the solvent was evaporated to leave a crude mixture of **28** and triphenylphosphine oxide as a colorless, viscous oil that was used without purification in the subsequent Wessely oxidation. Compound **28** could be purified by preparative tlc (hexanes/ethyl acetate, 5:2) to give a colorless oil that crystallized upon standing. Recrystallization from hexanes–$CHCl_3$ gave **28**, mp 63.5–64.5°C; ir λ_{max}: 5.79 μm; ^{1}H nmr δ: 1.26 (t, J = 7 Hz, 3H), 2.24 (s, 3H), 2.4–2.9 (m, 4H), 4.16 (q, J = Hz, 2H), 5.68 (br s, 1H), 5.78 (dt, J = 15, 2 Hz, 1H), 6.5–7.1 (m, 4H); ms m/z: 234 (48). *Anal.* calcd. for $C_{14}H_{18}O_3$: C 71.77, H 7.74; found: C 71.57, H 7.75.

*3a-Acetyloxy-1,2,3,3a,5,7a-hexahydro-1,5-methano-4*H*-inden-4-one (**32**)*

To a suspension of lead tetraacetate (14.5 g, 32.8 mmol) in acetic acid (100 mL) was added **14** (2.96 g, 20.0 mmol) in acetic acid (25 mL). The reaction mixture was stirred under nitrogen for 12 h and then treated with water (100 mL), stirred briefly, and evaporated to a viscous dark oil. The oil was extracted with ether (3 × 100 mL), the extracts were gravity filtered and washed with water (100 mL), saturated aqueous $NaHCO_3$ (100 mL), water (100 mL), and brine (100 mL). After being dried over Na_2SO_4, the solution was evaporated to a dark orange oil (2.52 g). The oil was taken up in freshly distilled xylenes (100 mL) and added over a 4-h period to boiling xylenes (200 mL). After 24 h at reflux, the bulk of the solvent was distilled at atmospheric pressure, and the residual solvent was distilled under vacuum (1.0 Torr), to leave a viscous yellow oil (1.40 g). This was molecularly distilled (45°C/0.01 Torr) to give **32** as a colorless solid (1.14 g, 5.51 mmol, 28%), mp 44–50°C, which was further purified by column chromatography (hexanes/ethyl acetate, 9:1), mp 51–53°C; ir λ_{max}: 5.70, 5.76 μm; ^{1}H nmr δ: 1.4–2.6 (m, 7H), 2.00 (s, 3H), 3.15 (m, 1H), 3.51 (m, 1H), 6.18 (m, 2H); ^{13}C nmr δ: 208.2 (s), 169.9 (s), 131.7 (d), 129.8 (d), 84.4 (s), 47.4 (d), 46.3 (d), 34.3 (d), 31.2 (t), 29.8 (t), 28.9 (t), 21.7 (q); ms m/z: 206 (21). *Exact Mass* calcd. for $C_{12}H_{14}O_3$: 206.0943; found: 206.0934.

*3a-Hydroxy-1,2,3,3a,5,7a-hexahydro-1,5-methano-4*H*-inden-4-one (**37**)*

Compound **32** (210 mg, 1.02 mmol) in ethanol (15 mL) was stirred with anhydrous K_2CO_3 (10 mg, 0.07 mmol) for 12 h. The mixture was filtered, the filtrate was evaporated, and the residue was extracted with

For personal use only.

ether (3 × 50 mL). The ether was evaporated to leave **37** as a colorless crystalline solid (0.12 g, 0.83 mmol, 82%), mp 101–104°C; ir λ_{max}: 2.79 (w), 5.77 (s) μm; ^{1}H nmr δ: 1.2–2.5 (m, 7H), 3.02 (m, 1H), 3.07 (br s, 1H, absent after D_2O treatment), 3.18 (m, 1H), 6.26 (m, 2H); ^{13}C nmr δ: 214.6 (s), 133 (d), 129.1 (d), 79.3 (s), 49.0 (d), 47.0 (d), 34.5 (d), 33.0 (t), 31.7 (t), 29.0 (t); ms *m/z*: 164 (5). *Exact Mass* calcd. for $C_{10}H_{12}O_2$: 164.0837; found: 164.0834.

*2,3,3a,4,5,7a-Hexahydro-1-oxo-1*H*-indene-5-carboxylic acid (**41**)*

Compound **37** (100 mg, 0.61 mmol) in THF (20 mL) was treated with $NaIO_4$ (150 mg, 0.70 mmol) in water (10 mL). The solution was acidified to pH 4 with dilute aqueous HCl and left to stand for 12 h. The solution was then diluted with water (20 mL) and the THF was evaporated. The aqueous solution was extracted with ether (2 × 50 mL), the ethereal extracts were dried over Na_2SO_4, filtered, and evaporated to give **41** as a pale yellow resin (71 mg, 39 mmol, 65%); ir λ_{max}: 5.74, 5.83 μm; ^{1}H nmr δ: 1.3–3.0 (m, 7H), 3.10 (m, 1H), 3.24 (m, 1H), 5.98 (s, 2H), 8.77 (br s, 1H, absent after D_2O treatment); ms *m/z*: 180 (8).

*3a-Acetyloxy-1,2,3,3a,5,7a-hexahydro-1-methyl-1,5-methano-4*H*-inden-4-one (**44**)*

Lead tetraacetate (32.8 g, 74.0 mmol) was mixed with acetic acid (200 mL), and **15** (6.00 g, 37.0 mmol) was added over a 2-h period. After a further 2 h, water (50 mL) was added and the mixture was evaporated to a dark oil. The oil was treated with water (200 mL) and extracted with ether (4 × 200 mL). The combined organic extracts were washed with water (100 mL), aqueous 5% $NaHCO_3$ (100 mL), water (100 mL), and brine (100 mL). After being dried over Na_2SO_4, the ethereal solution was evaporated to a dark, viscous oil. The oil was taken up in xylenes (50 mL) and added to boiling xylenes (250 mL) over a 4-h period. After 36 h at reflux, the solvent was evaporated to leave a dark oil, which was distilled (72–100°C/0.10 Torr) to give a yellow oil. This was purified by column chromatography (hexanes/ethyl acetate, 9:1) to give **44**, after recrystallization from pentane, as colorless crystals (1.79 g, 8.14 mmol, 22%), mp 87.5–90.5°C; ir λ_{max}: 5.71, 5.77 μm; ^{1}H nmr δ: 1.11 (s, 3H), 1.3–2.5 (m, 6H), 2.02 (s, 3H), 3.15 (m, 2H), 6.22 (m, 2H); ^{13}C nmr δ: 208.1 (s), 169.9 (s), 131.7 (d), 129.2 (d), 84.5 (s), 52.1 (d), 48.1 (d), 41.9 (s), 37.3 (t), 36.7 (t), 30.0 (t), 27.5 (q), 21.8 (q); ms *m/z*: 220 (60). *Exact Mass* calcd. for $C_{31}H_{16}O_3$: 220.1099; found: 220.1101.

*3a-Hydroxy-1,2,3,3a,5,7a-hexahydro-1-methyl-1,5-methano-4*H*-inden-4-one (**45**)*

Compound **44** (110 mg, 0.50 mmol) was stirred with anhydrous K_2CO_3 (10 mg, 0.07 mmol) in ethanol (15 mL) for 12 h. The mixture was filtered and the filtrate was evaporated to dryness. The residue was extracted with ether (3 × 50 mL) and the ether was evaporated to leave **45** as a colorless crystalline solid (86 mg, 0.48 mmol, 96%), mp 112–116°C; ir λ_{max}: 2.78 (w), 5.77 (s), μm; ^{1}H nmr δ: 1.10 (s, 3H), 1.1–2.0 (m, 6H), 2.63 (m, 1H), 3.12 (m, 1H), 3.41 (s, 1H, absent after D_2O treatment), 6.19 (m, 2H); ^{13}C nmr δ: 214.5 (s), 133.1 (d), 128.7 (d), 79.2 (s), 55.0 (d), 47.5 (d), 41.9 (s), 37.7 (t), 37.0 (t), 33.0 (t), 27.7 (q); ms *m/z*: 178 (4). *Exact Mass* calcd. for $C_{11}H_{14}O_2$: 178.0994; found: 178.0988.

*2,3,3a,4,5,7a-Hexahydro-3a-methyl-1-oxo-1*H*-indene-5-carboxylic acid (**46**)*

The hydroxy ketone **45** (145 mg, 81.3 mmol) was taken up in THF (20 mL) and treated with $NaIO_4$ (0.19 g, 0.87 mmol) in water (10 mL) and acidified with dilute HCl to pH 4. After 12 h the solution was reduced in volume to 10 mL and extracted with ether (4 × 25 mL). The ethereal extracts were dried over Na_2SO_4 and evaporated to give **46** as a light yellow oil (106 mg); ir λ_{max}: 5.76, 5.85 μm; ^{1}H nmr δ: 1.10 (s, 3H), 1.0–2.5 (m, 6H), 3.0–3.4 (m, 2H), 5.96 (s, 2H), 9.42 (br s, 1H, absent after D_2O treatment).

*Ethyl 1-acetyloxy-2,3,3a,4,5,7a-hexahydro-4-oxo-1,5-methano-1*H*-indene-8-carboxylate **48***

A mixture of **26** and triphenylphosphine oxide, prepared from **21** (1.30 g, 8.65 mmol), was taken up in acetic acid (50 mL) and added over a period of 2 h to lead tetraacetate (5.75 g, 13.0 mmol) in acetic acid (25 mL). After a further 2 h, water (100 mL) was added, and the mixture was evaporated to dryness. The residue was extracted with ether (5 × 50 mL), and the combined extracts were washed with water (2 × 100 mL), aqueous 5% $NaHCO_3$ (100 mL), and brine (100 mL). The organic solution was dried over Na_2SO_4 and evaporated to leave a deep orange resin. This was taken up in xylenes (100 mL) and the solution was slowly dripped into boiling xylenes (200 mL) over a period of 4 h. After a further 12 h, the solvent was evaporated and the residue was eluted with ether from a silica gel plug (10 g). The fractions containing **48** were combined and evaporated and the residue was purified by column chromatography (hexanes/ethyl acetate, 9:1) to give **48** (0.63 g, 2.25 mmol, 26%) as colorless crystals, mp 42–43°C; ir λ_{max}: 5.78 μm; ^{1}H nmr δ: 1.26 (t, J = 7 Hz, 3H), 1.5–2.6 (m, 5H), 2.05 (s, 3H), 2.83 (m, 1H), 3.64 (m, 2H), 4.16 (q, J = 7 Hz, 2H), 6.26 (m, 2H); ^{13}C nmr δ: 206.0 (s), 171.7 (s), 169.8 (s), 132.6 (d), 126.9 (d), 83.6 (s), 61.2 (t), 49.9 (d), 42.3 (d), 46.4 (d), 39.3 (d), 30.4 (t), 28.5 (t), 21.6 (q), 14.2 (q); ms *m/z*: 278 (4). *Anal.* calcd. for $C_{15}H_{18}O_5$: C 64.73, H 6.52; found: C 64.70, H 6.62.

*Ethyl 1-hydroxy-2,3,3a,4,5,7a-hexahydro-4-oxo-1,5-methano-1*H*-indene-8-carboxylate **51***

Compound **48** (73.2 mg, 0.26 mmol) in ethanol (10 mL) was stirred with anhydrous K_2CO_3 (10 mg, 0.07 mmol) for 12 h. The solvent was evaporated and the residue was extracted with ether (3 × 25 mL). The ethereal solution was filtered and evaporated to give **51** as a colorless oil (56.7 mg, 0.23 mmol, 88%); ir λ_{max}: 5.77 μm; ^{1}H nmr δ: 1.25 (t, J = 7 Hz, 3H), 1.5–2.3 (m, 4H), 2.5–3.0 (m, 2H), 3.15 (s, 1H), 3.63 (m, 2H), 4.17 (q, J = 7 Hz, 2H), 6.24 (m, 2H); ^{13}C nmr δ: 212.3 (s), 171.9 (s), 134.1 (d), 126.1 (d), 78.9 (s), 61.2 (t), 49.3 (d), 48.9 (d), 47.6 (d), 39.6 (t), 33.4 (t), 28.6 (t), 14.2 (q); ms *m/z*: 236 (10). *Exact Mass* calcd. for $C_{13}H_{16}O_4$: 236.1048; found: 236.1047.

*Ethyl 1-acetyloxy-2,3,3a,4,5,7a-hexahydro-7-methyl-4-oxo-1,5-methano-1*H*-indene-8-carboxylate **49***

The crude product **27** from the Wittig reaction of **22** (2.03 g, 12.3 mmol) in acetic acid (50 mL) was added to a suspension of lead tetraacetate (7.98 g, 18.0 mmol) in acetic acid (50 mL). After 12 h water (100 mL) was added, the reaction mixture was stirred for 15 min, and the solvents were evaporated. The residue was extracted with ether (5 × 50 mL) and the extracts were washed with water (2 × 100 mL), aqueous 5% $NaHCO_3$ (100 mL), and brine (100 mL). After being dried with Na_2SO_4, the ether was evaporated to leave a dark oil. The oil was taken up in xylenes (100 mL) and added slowly to boiling xylenes (200 mL). After 12 h, the solvent was evaporated and the residue was eluted with ether from a silica gel plug and then further purified by column chromatography (hexanes/ethyl acetate, 9:1) to give **49** as a colorless solid (1.19 g, 4.1 mmol, 33%), which was recrystallized from hexanes – ethyl acetate to give colorless crystals, mp 71.5–73°C; ir λ_{max}: 5.77 μm; ^{1}H nmr δ: 1.22 (t, J = Hz, 3H), 1.79 (d, J = 1.5 Hz, 3H), 1.5–2.6 (m, 5H), 2.02 (s, 3H), 2.80 (m, 1H), 3.42 (m, 2H), 4.14 (q, J = 7 Hz, 2H), 5.71 (m, 1H); ^{13}C nmr δ: 205.9 (s), 171.8 (s), 169.7 (s), 142.7 (s), 118.1 (d), 84.0 (s), 61.1 (t), 51.6 (d), 49.6 (d), 47.4 (d), 38.7 (d), 30.5 (t), 28.4 (t), 21.5 (q), 21.2 (q), 14.2 (q); ms *m/z*: 292 (15). *Exact Mass* calcd. for $C_{16}H_{20}O_5$: 292.1311; found: 292.1296. *Anal.* calcd. for $C_{16}H_{20}O_5$: C 65.74, H 6.90; found: C 65.38, H 7.01.

*Ethyl 1-hydroxy-2,3,3a,4,5,7a-hexahydro-7-methyl-4-oxo-1,5-methano-1*H*-indene-8-carboxylate **52***

The acetoxy ketone **49** (5.1 mg, 0.17 mmol) was treated with anhydrous K_2CO_3 (10.0 mg, 0.07 mmol) in ethanol (10 mL). After 12 h the solvent was evaporated and the residue extracted with ether (3 × 25 mL). The ethereal solution was filtered, dried with Na_2SO_4, and evaporated to leave a colorless solid (40.3 mg), which was recrystallized from hexanes – ethyl acetate to give **52** as a colorless crystalline solid (34.9 mg, 0.14 mmol, 83%), mp 105–106°C; ir λ_{max}: 5.77 μm; ^{1}H nmr δ: 1.22 (t, J = 7 Hz, 3H), 1.4–2.4 (m, 4H), 1.88 (s, 3H), 2.56 (m, 1H), 2.85 (m, 2H), 2.18 (s, 1H, absent after D_2O treatment), 3.52 (dd, J = 7, 3.5 Hz, 1H), 4.12 (q, J = Hz, 2H), 5.68 (m, 1H); ^{13}C nmr δ: 212.4 (s), 172.1 (s), 144.5 (s), 117.3 (d), 79.2 (s),

61.1 (s), 54.0 (d), 49.0 (d), 47.9 (d), 38.8 (d), 33.3 (t), 28.6 (t), 21.6 (q), 14.2 (q); ms *m/z*: 250 (8). *Exact Mass* calcd. for $C_{14}H_{18}O_4$: 250.1205; found: 250.1205. *Anal.* calcd. for $C_{14}H_{18}O_4$: C 67.18, H 7.25; found: C 67.06, H 7.25.

*Ethyl 1-acetyloxy-2,3,3a,4,5,7a-hexahydro-6-methyl-4-oxo-1,5-methano-1*H*-indene-8-carboxylate* ***50***

A mixture of phenol **78** and triphenylphosphine oxide, prepared from **23** (6.22 g, 37.9 mmol), in acetic acid (50 mL) was added to lead tetraacetate (33.7 g, 76.0 mmol) in acetic acid (50 mL). After 12 h the solvent was evaporated and the residue was extracted with ether (250 mL) and water (250 mL). The aqueous solution was extracted with ether (2 × 250 mL) and the combined organic extracts were washed with water (150 mL), aqueous 5% $NaHCO_3$ (3 × 150 mL), water (150 mL), and brine (150 mL). The deep orange solution was dried over Na_2SO_4 and evaporated. The red residue was taken up in xylenes (150 mL), added slowly to boiling xylenes (250 mL), and heated for 12 h. The solvent was evaporated and the residue was passed through a silica gel (10 g) plug with ether. The fractions containing **50** were combined and evaporated, and the dark, viscous resin that remained was purified by column chromatography (hexanes/ethyl acetate, 9:1) to give **50** as a colorless oil (3.88 g, 13.3 mmol, 35%). This was molecularly distilled to give a solid that was recrystallized from hexanes – ethyl acetate to give colorless crystals, mp 77–78°C; ir λ_{max}: 5.77, 5.79 μm; ^{1}H nmr δ: 1.26 (t, *J* = 8 Hz, 3H), 1.6–2.7 (m, 5H), 1.85 (d, *J* = 1.5 Hz, 3H), 2.02 (s, 3H), 2.82 (m, 1H), 3.47 (m, 2H), 4.16 (q, *J* = 8 Hz, 2H), 5.86 (m, 1H); ^{13}C nmr δ: 205.5 (s), 171.8 (s), 169.7 (s), 136.4 (s), 124.7 (d), 83.8 (s), 61.1 (t), 55.0 (d), 47.1 (d), 46.1 (d), 39.8 (t), 30.4 (t), 28.6 (t), 21.6 (q), 20.5 (q), 14.3 (q); ms *m/z*: 292 (15). *Exact Mass* calcd. for $C_{16}H_{20}O_5$: 292.1311; found: 292.1304. *Anal.* calcd. for $C_{16}H_{20}O_5$: C 65.74, H 6.90; found: C 65.77, H 6.94.

*Ethyl 1-hydroxy-2,3,3a,4,5,7a-hexahydro-6-methyl-4-oxo-1,5-methano-1*H*-indene-8-carboxylate* ***53***

Compound **50** (242.9 mg, 0.83 mmol) in ethanol (50 mL) was stirred with anhydrous K_2CO_3 for 12 h. The solvent was then evaporated and the residue was extracted with ether (3 × 50 mL). The ethereal solution was filtered and evaporated to a white crystalline solid. This was recrystallized from pentanes – ethyl acetate to give **53** (172 mg, 0.69 mmol, 83%), mp 110–112°C; ir λ_{max}: 5.77 μm; ^{1}H nmr δ: 1.26 (t, *J* = 7 Hz, 3H), 1.5–3.2 (m, 7H), 1.83 (d, *J* = 1.5 Hz, 3H), 3.11 (br s, 1H, absent after D_2O treatment), 3.39 (m, 1H), 4.19 (q, *J* = 7 Hz, 2H), 2.87 (m, 1H); ^{13}C nmr δ: 211.8 (s), 172.0 (s), 135.6 (s), 126.2 (d), 78.7 (s), 61.1 (t), 54.4 (d), 48.4 (d), 47.4 (d), 40.1 (d), 33.3 (t), 28.7 (t), 20.4 (q), 14.3 (q); ms *m/z*: 250 (7). *Exact Mass* calcd. for $C_{14}H_{18}O_4$: 250.1205; found: 250.1208.

Rate constants for abstraction of bromine from bromotrichloromethane by butyl, cyclopropylmethyl, and phenyl radicals in solution

LUKOSE MATHEW AND JOHN WARKENTIN[1]

Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received July 15, 1987

LUKOSE MATHEW and JOHN WARKENTIN. Can. J. Chem. **66**, 11 (1988).

The radical chain decomposition of cyclopropylmethyl (1-hydroxy-1-methylethyl)-diazene ($(CH_3)_2C(OH)N{=}NCH_2$—◁ **1**) at 253–341 K in hexafluorobenzene or in dichloromethane solution containing bromotrichloromethane affords cyclopropylmethyl bromide, 4-bromo-1-butene, 1-bromo-5,5,5-trichloro-2-pentene, and 3,5-dibromo-1,1,1-trichloropentane from the cyclopropylmethyl portion of **1**. Other major products are nitrogen, acetone, and chloroform. The rate constant for formation of cyclopropylmethyl bromide by attack of cyclopropylmethyl free radicals from **1** at bromine of $BrCCl_3$ (k_{Br}^{cpm}) was calculated from the product composition using the known rate constant for rearrangement of cyclopropylmethyl radicals to 3-buten-1-yl radicals. At 25°C, $k_{Br}^{cpm} = 6.5 \times 10^8\ M^{-1}\ s^{-1}$ and the temperature dependence is given by $\log (k_{Br}^{cpm}/M^{-1}\ s^{-1}) = (10.6 \pm 0.3) - (2.4 \pm 0.4)/\theta$, where $\theta = 2.3RT\ \text{kcal/mol}^{-1}$. Non-chain decomposition of $(CH_3)_2C(OH)N{=}N$—R (**2**, R = Bu, and **3**, R = Ph) in the presence of excess 1,1,3,3-tetramethylisoindolin-2-yloxyl (**4**) and bromotrichloromethane afforded BuBr and PhBr, respectively, in yields determined by the relative concentrations of **4** and $BrCCl_3$. Rate constants for coupling (k_c) of Bu· and Ph· with **4** were assumed to be proportional to rate constants for diffusion controlled reactions, k_d, which were estimated from measured viscosities. Values of k_{Br}^{Bu} and k_{Br}^{Ph}, calculated from k_c and product yields for reactions at 80°C, are 0.26×10^9 and $1.55 \times 10^9\ M^{-1}\ s^{-1}$, respectively. The relative radical reactivities toward $BrCCl_3$ at 80°C are Ph, 6; cpm, 5; Bu, 1.

LUKOSE MATHEW et JOHN WARKENTIN. Can. J. Chem. **66**, 11 (1988).

La décomposition radicalaire en chaîne du cyclopropylméthyl (hydroxy-1 méthyl-1 éthyl) diazène ($(CH_3)_2C(OH)N{=}NCH_2CH(CH_2)_2$, **1**), à des températures allant de 253 à 341 K, dans des solutions d'hexafluorobenzène ou de dichlorométhane contenant du bromotrichlorométhane, conduit au bromure de cyclopropylméthyle, au bromo-4 butène-1, au bromo-1 trichloro-5,5,5 pentène-2 et au dibromo-3,5 trichloro-1,1,1 pentane qui dérivent tous de la portion cyclopropylméthyle du composé **1**. Les autres produits importants sont l'azote, l'acétone et le chloroforme. On a calculé la constante de vitesse pour la formation du bromure de cyclopropylméthyle par attaque des radicaux libres cyclopropylméthyles, provenant du composé **1**, au niveau du brome du $BrCCl_3$ (k_{Br}^{cpm}); pour ce faire, on a fait appel à la composition des produits et on a utilisé la constante de vitesse connue pour la transposition des radicaux cyclopropylméthyles en radicaux butène-3 yles. À 25°C, $k_{Br}^{cpm} = 6{,}5 \times 10^8\ M^{-1}\ s^{-1}$ et la variation avec la température est donnée par l'équation suivante : $\log (k_{Br}^{cpm}/M^{-1}\ s^{-1}) = (10{,}6 \pm 0{,}3) - (2{,}4 \pm 0{,}4)/\theta$, dans laquelle $\theta = 2{,}3RT\ \text{kcal/mol}^{-1}$. Les décompositions des composés $(CH_3)_2C(OH)N{=}N$—R (**2**, R = Bu, et **3**, R = Ph) par un processus qui n'implique pas de chaînes, en présence d'un excès de tétraméthyl-1,1,3,3 isoindolinyl-2 oxyl (**4**) et de bromotrichlorométhane, fournissent respectivement du BuBr et du PhBr, avec des rendements qui ont été déterminés par les concentrations du composé **4** et du $BrCCl_3$. On a fait l'hypothèse que les constantes de vitesses pour les couplages (k_c) des radicaux Bu· et Ph· avec le composé **4** sont proportionnelles aux constantes de vitesse des réactions contrôlées par la diffusion, k_d, qui ont été évaluées à partir des viscosités mesurées. Pour les réactions à 80°C, les valeurs de k_{Br}^{Bu} et k_{Br}^{Ph}, calculées à partir des valeurs de k_c et des rendements en produits, sont respectivement égales à $0{,}26 \times 10^9$ et $1{,}55 \times 10^9\ M^{-1}\ s^{-1}$. À 80°C, les réactivités relatives des radicaux pour le $BrCCl_3$ sont Ph, 6; cpm, 5; Bu, 1.

[Traduit par la revue]

Introduction

Although it is well known that bromotrichloromethane reacts rapidly, by bromine atom transfer, with a large variety of free radicals, there are relatively few reports in the literature concerning rate constants for attack on $BrCCl_3$ by primary, secondary, and tertiary alkyl radicals in solution. A recent study (1) gave $k_{Br}^{25°C} = 3.4 \times 10^5\ M^{-1}\ s^{-1}$ for the reaction of the methyl radical with $BrCCl_3$ in the gas phase. Much larger values were reported recently for corresponding reactions of phenyl (2) and of cyclopropyl radicals (3) in solution, rate constants having values 1.7×10^9 (45°C) and $(2.8–3.7) \times 10^9$ (25°C) $M^{-1}\ s^{-1}$, respectively. In abstraction of Cl from CCl_4 at about 298 K, the phenyl radical (2, 4) reacts 6.5×10^2, 1.3×10^2, and 1.4×10^3 times faster than the neophyl radical (5), the butyl radical (6), and the 5-hexenyl radical (7) respectively.[2] Cyclopropyl radical is also more reactive toward CCl_4 (3*a*) than the above mentioned primary radicals; corresponding rate factors are 1.2×10^2, 26, and 2.8×10^2. It seemed likely, therefore, that the reported rate constants for abstraction of Br from $BrCCl_3$ by phenyl (2) and cyclopropyl radicals (3) are significantly higher than that for a primary alkyl radical, but not by a factor as large as the gas phase rate constant for the methyl radical (see above) would suggest. We now report the Arrhenius equation for abstraction of Br from $BrCCl_3$ by the cyclopropylmethyl radical, and rate constants at 80°C for the same reaction by butyl and by phenyl radicals.

Method

The method based on the determination of relative rates from product analysis (8) is simple, requiring only that the chosen radical must undergo a competitive "clocking" reaction (8) with a known rate constant of suitable magnitude and that the total chemistry be understood and clean enough for the reliable quantitative assay of products. The ring-opening reaction of the cyclopropylmethyl radical (eq. [1]) was chosen because it

$$[1] \quad c\text{-}C_3H_5CH_2\cdot \xrightarrow{k^{25°C} = 2.1 \times 10^8\ s^{-1}} H_2C{=}CH_2CH_2$$

occurs with a rate constant (9*a*, 10) large enough to clock a

[1]Author to whom correspondence may be addressed.

[2]The quoted reactivity ratios are for phenyl radical data from ref. 4. Somewhat smaller ratios result from use of the data of Lorand and co-workers (2).

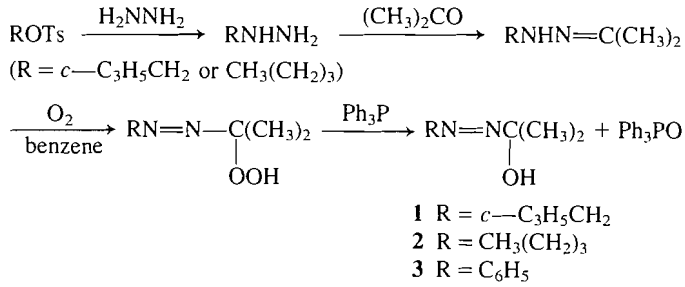
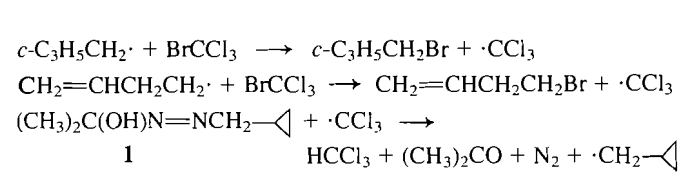


SCHEME 1



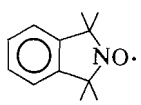
SCHEME 2

bimolecular competing reaction with a rate constant between about 10^7 and 10^{10} M^{-1} s^{-1}. Moreover, although the ring opening is known to be reversible, the rate constant for the reverse reaction is small (ca. 4.9×10^3 s^{-1} at 25°C) (9*b*) and reclosure should therefore be suppressed effectively in the presence of $BrCCl_3$.

α-Hydroxydiazene **1**, prepared by the sequence of reactions in Scheme 1, was chosen as the radical precursor for three reasons. First, α-hydroxydiazenes decompose thermally at temperatures near room temperature (11), offering the potential advantage of measured, rather than extrapolated, rate constants in that important temperature range. Second, their decomposition was known to be induced by a number of radicals (11) including the trichloromethyl radical. Therefore, for decomposition of **1** in $BrCCl_3$, a radical chain reaction with the following chain propagating steps seemed likely (Scheme 2). Even modest chain lengths would facilitate analysis by minimizing the importance of radical pair chemistry. Third, the by-products of induced decomposition ($HCCl_3$ and $(CH_3)_2CO$) should cause minimal problems during analysis by glpc or by ^1H nmr spectroscopy, and it seemed unlikely that they would undergo complicating chemical reactions to a detectable extent under the conditions of their formation.

Solutions of **1** in hexafluorobenzene or dichloromethane containing excess $BrCCl_3$ were degassed and sealed into nmr tubes. The tubes were irradiated (in low temperature experiments) or they were kept in a constant temperature bath until the *gem*-dimethyl signal of **1** could no longer be detected in the ^1H nmr spectrum. The contents of the tubes were then analyzed by glpc.

Butyl and phenyl radicals were generated by thermolysis of **2** and **3**, respectively. Coupling of the radicals with 1,1,3,3-tetramethylisoindolin-2-yloxyl (**4**) was used as the competing



4

reaction for clocking abstraction of Br from $BrCCl_3$. Coupling rate constants were estimated from those for diffusion control and the latter were calculated from measured viscosities (10). Coupling with **4** occurred under pseudo first-order conditions, with **4** in about 12-fold excess.

Results and discussion

Products

The nmr spectra of spent solutions of **1** indicated a simple mixture of $CHCl_3$, $(CH_3)_2CO$, *c*-$C_3H_5CH_2Br$ (**5**), CH_2=$CHCH_2CH_2Br$ (**6**), and $Cl_3CCH_2CH(Br)CH_2CH_2Br$ (**7**) and acetone azine (**8**), up to 8% from thermal runs and ca. 3% from photo-initiated reactions. The azine, giving ^1H nmr signals of equal intensities at δ 1.71 and 1.85 in the crude reaction mixture, was distinguished from the mixed azine ($(CH_3)_2C$=N—N=CH—◁) by comparison (^1H nmr and gc) with an authentic sample of the latter, synthesized independently from acetone hydrazone and cyclopropane carboxyaldehyde. Although the origin of acetone azine is not understood at this time, the possibility that it was a contaminant in the starting material (**1**) could be excluded. The ^1H nmr spectra of **1** from different batches did not show the azine singlets that are visible after thermolysis or photolysis. We assume that the mixed azine, formed by catalyzed dehydration of **1**, is an initial minor product that is subsequently equilibrated with acetone (a major product) to form mostly **8** at equilibrium.

Only trace amounts of additional uncharacterized products were registered by gc analysis[3] except for a material (**9**) with a long retention time that was eluted just before **7**. Examination of the reaction mixture by gc/ms gave (for **9**) m/z = 256, 254, 252, and 250, with intensity ratios appropriate for $C_5H_6BrCl_3$. Compound **9** is therefore the result of dehydrobromination (formally) of **7**. Partial dehydrobromination of **7**, to form **9**, was achieved by injection of **7** onto an old gc column. New columns, under the same conditions, gave only sharp symmetric peaks for **7**, indicating that **7** is thermally stable and that dehydrobromination was caused by residues present in the old column.[4]

The most likely structure for **9** is *trans*-1-bromo-5,5,5-trichloro-2-pentene, formed, in the $BrCCl_3$ medium, by disproportionation between 1-(2-bromoethyl)-3,3,3-trichloroprop-1-yl radicals (**10**) and trichloromethyl radicals. For the present purposes it is not critical that the mechanism of its formation, or its exact structure for that matter, be known. The important point is that **9** must be counted with **6** and **7**, as a product from 3-butene-1-yl radical, in calculating k_{Br}.

9

10

The source of 3–8% of **8** aside, the chemistry of **1** is adequately accounted for with the chain mechanism of Scheme 2 and with the subsequent reactions of Scheme 3. The large ratio (>70) of chain transfer product ($CHCl_3$) to chain termination product (C_2Cl_6) in the thermal runs was particularly satisfying, indicating an average kinetic chain length large enough to minimize complications from radical pair chemistry. Although photochemical initiation for the low temperature runs led to smaller ratios of $CHCl_3/C_2Cl_6$ (≃30), reaction products from the procedure were the same, but the yield of **8** was reduced.

Analysis of the relevant products from thermolysis of **2** in media containing both **4** and $BrCCl_3$ was achieved by straightforward gc analysis, after calibration of the detector response toward authentic 1-bromobutane and 2-(1-butoxy)-1,1,3,3-

[3]One of these, hexachloroethane, was identified by injection of a solution of authentic hexachloroethane in hexafluorobenzene.

[4]Repeated use of the new column for analyses of products from **1** did not result in deterioration of its performance. Pure **7** was not dehydrohalogenated and pure **5** was not isomerized to **6**.

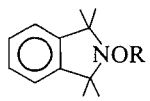
SCHEME 3

tetramethylisoindoline (**11**). The product of coupling between **4** and $\cdot CCl_3$ (**12**) was eluted late and its presence did not interfere. Analysis of the important products from thermolysis of **3** in similar media was not straightforward. While it was easy to analyze for bromobenzene, it was not possible to determine the relative yield of the expected 2-phenoxy-1,1,3,3-tetramethylisoindoline (**13**) from coupling of phenyl radicals with **4**. Presumably, **13** is unstable[5] and undergoes thermolysis, either



11 R = Bu
12 R = CCl_3
13 R = Ph

under the conditions of its formation (80°C) or in the gc column. The initial ratio of products was therefore determined as follows. The absolute yield of bromobenzene was determined by gc and that yield was corrected to take into account the fact that the yield of bromobenzene was 95%, instead of 100%, from thermolysis of **3** in $BrCCl_3$ without added **4**.[6] The phenyl moieties not accounted for with the corrected yield of bromobenzene were assumed to have gone, initially at least, to **13**. This determination of the product ratio by difference is not likely to be subject to serious error because it is very unlikely that phenyl radicals could be involved significantly in reactions that could compete with abstraction of Br from $BrCCl_3$ or with coupling to **4**. Moreover, it is not conceivable that **13**, in subsequent reactions, could lead to bromobenzene.

Rate constants

From the analytical results in Table 1, values of k_{Br}^{cpm}, for the reaction $c\text{-}C_3H_5CH_2\cdot + BrCCl_3 \rightarrow c\text{-}C_3H_5CH_2Br + \cdot CCl_3$, were calculated from eq. [2].

$$[2] \quad k_{Br}^{cpm} = \frac{k_i[\mathbf{5}]}{([\mathbf{6}] + [\mathbf{7}] + [\mathbf{9}])[BrCCl_3]}$$

In eq. [2], the symbols [**5**]–[**9**] represent the relative yields, $[BrCCl_3]$ is the initial concentration of that reagent, and k_i is the rate constant for ring opening of cyclopropylmethyl, calculated from the equation (10) $\log (k_i/s^{-1}) = 13.9\text{–}7.6/\theta$ where $\theta = 2.3RT$ kcal mol^{-1}. The rate constants so calculated for the 253–341 K temperature range gave $\log (k_{Br}^{cpm}/M^{-1}\,s^{-1}) = (10.6 \pm 0.3) - (2.4 \pm 0.4)/\theta$ where $\theta = 2.3RT$ kcal mol^{-1}, and $k_{Br}^{cpm} = 6.9 \times 10^8\,M^{-1}\,s^{-1}$ at 25°C.

Rate constants for the reactions of Bu· and Ph· with $BrCCl_3$ were calculated from eq. [3], where k_c is the rate constant for

$$[3] \quad k_{Br} = k_c\left(\frac{[\mathbf{4}]}{[BrCCl_3]} \times \frac{[RBr]}{[CP]}\right)$$

coupling between Bu· or Ph· and **4**, where [CP] is the relative yield of coupling product, and where [RBr] is the relative yield of 1-bromobutane or bromobenzene. The concentrations of **4** and of $BrCCl_3$ were calculated from their weights and from volumes of their solutions in C_6F_6 determined at room temperature. Corrections for thermal expansion at the reaction temperature (80°C) or for consumption of **4** and $BrCCl_3$ were not applied because the former cancel (eq. [3]). The latter cancel in part and are in any case very small because of the large stoichiometric excess of **4** and $BrCCl_3$ over the radical sources (**2** or **3**).

From the data in Tables 2 and 3, $k_{Br}^{Bu} = (2.61 \pm 0.38) \times 10^8\,M^{-1}\,s^{-1}$ and $k_{Br}^{Ph} = (1.55 \pm 0.64) \times 10^9\,M^{-1}\,s^{-1}$ at 80°C. The latter is in good agreement with the literature value (2), $k_{Br}^{Ph} = 1.7 \times 10^9\,M^{-1}\,s^{-1}$ at 45°C, considering that the effect of the temperature difference (35°C) corresponds to a rate factor[7] of only 1.5. At 80°C, $k_{Br}^{cpm} = 1.30 \times 10^9\,M^{-1}\,s^{-1}$ and the relative reactivities are therefore Ph, 5.9; cpm, 5.0; Bu, 1.0. Phenyl radical is expected to be more reactive than either of the primary alkyls and the higher reactivity of cpm over that of Bu probably reflects a polar transition state, depicted below.

$$\overset{\delta^+}{RCH_2}\text{----}\overset{}{Br}\text{----}\overset{\delta^-}{CCl_3}$$

The fact that rate constants in CH_2Cl_2 are ca. 10% larger than those for C_6F_6 solvent (Table 1) suggests a dipolar contributor. Moreover, a polar effect is known to be important in determining rate constants for Cl abstraction from CCl_4 and $CHCl_3$. For example, 1,1-dimethylethyl is about six times as reactive as methyl toward $CHCl_3$ (12) and 1-methylcyclopropyl is 10-fold more reactive than cyclopropyl toward CCl_4 (3*b*). Those factors presumably reflect minimum values of the polar enhancement factor because steric effects must operate in the opposite sense. Recent evidence indicates that a polar effect may operate also in the case of $BrCCl_3$, for 1-methylcyclopropyl is ca. 1.3 times as reactive as cyclopropyl, in Br abstraction (3*b*). A larger net enhancement for cyclopropylmethyl, compared to a simple 1° alkyl radical, is likely because of the effect of conjugative stabilization of the cyclopropylmethyl cation. However, the discrepancy between the gas- and solution-phase results (see Introduction) appears to be much too large to be explained away in terms of the effects of transition state solvation in solution.

It is interesting that the polar factor, which presumably is rate retarding[8] in the case of the phenyl analogue, can account for the fact that Ph and cpm are, within experimental error, equally reactive toward $BrCCl_3$. A similar argument can be used to accommodate the apparently higher reactivity ($k_{Br}^{cp} = 2.8 \times 10^9\,M^{-1}\,s^{-1}$) at 25°C of cyclopropyl radicals (cp) (3*b*) relative to that of phenyl radicals, toward $BrCCl_3$. That is, cp may be more polarizable than Ph, in the sense depicted above, by virtue of the four β hydrogens in cp. It must be emphasized, however, that the relative reactivities of cyclopropyl and phenyl radicals toward $BrCCl_3$ are based on different methodologies and that conclusions from the numbers available at this stage are necessarily tentative.

[5]The N—O bond strength of **13** probably falls between that of the N—N bond of phenylhydrazine and the O—O bond of an alkyl phenyl peroxide. Compounds of the latter class are not isolable.

[6]This small shortfall of the yield of PhBr is probably indicative of slightly impure **3**.

[7]The temperature dependence of k_{Br} for the change from 45 to 80°C is that of cpm. A similar factor has been assumed for Ph.

[8]The transition state for abstraction by phenyl is expected to be even less polar than that for abstraction by methyl, because of the higher electronegativity of sp^2-carbon compared to that of sp^3-carbon.

[a] Solutions of **4** in $BrCCl_3$. Initial concentration of **2** = 0.08–0.02 M.
[b] Corrected for detector response. The actual ratio of gc integrator counts from three or more injections has been divided by 0.32 to yield the numbers in this column. The material balance on butyl groups ranged from 91 to 96%.
[c] Calculated from eq. [3], with $k_c = 0.2k_d = 2.11 \times 10^9$ M^{-1} s^{-1}, where k_d, the diffusion controlled rate constant, was calculated from the viscosity of $BrCCl_3$ at 80°C (0.735 cP) as described earlier (10). The viscosity was not corrected for the presence of **4**, **2**, and the products of decomposition of **2**.
[d] CP signifies the coupling product, 2-(1-butoxy)-1,1,3,3-tetramethylisoindoline (**11**).

In summary, the reactivities of relatively unhindered carbon-centered radicals toward $BrCCl_3$ span a narrow range. The low sensitivity of k_{Br} toward radical structure suggests that abstraction of Br from $BrCCl_3$ might be used, without risk of serious error, as a clock to estimate rate constants for other fast reactions of a variety of carbon-centered free radicals.[9] For example, it is now possible to estimate a minimum rate constant for ring closure of radical **14**, an intermediate in the radical chain addition of $BrCCl_3$ to *cis,trans*-1,5-cyclodecadiene (13), eq. [4]. The reaction afforded the stereoisomers **15** (from initial

[b]The product ratio was determined from the absolute yield of PhBr; the yield of coupling product was determined by difference (see text).
[c]Viscosities were measured at 77°C, on solvents not containing **4**, **3**, or products from **3**. The viscometer was calibrated against CCl_4 and measured viscosities were extrapolated from 77 to 80°C.
[d]Calculated from eq. [3], where k_c is derived from k_d, which in turn is derived from the viscosity, see footnote *c*, Table 2.
[e]CP signifies the coupling product, 2-phenoxy-1,1,3,3-tetramethylisoindoline (**13**). See also footnote *b* of this table. Yields of PhBr: 77.9, 68.8, 74.1, 53.9, 48.2, 39.3, and 42.4%, in order from the top.
[f]Viscosity of neat C_6F_6 at 80°C.

was *isolated* from a 24:1 mixture), then the rate constant for cyclization of **14** must be at least 1.4×10^{11} s^{-1}.[10]

Experimental

The synthesis and spectra of **1** have been reported (10). Hydroxydiazenes **2** and **3** were prepared by analogous procedures, from 1-butylhydrazine and phenylhydrazine, respectively. Spectra of intermediates (Scheme 1) and of the final products are listed below.

Acetone (1-butyl)hydrazone: ^{1}H nmr ($CDCl_3$, 90 MHz) δ: 0.93 (t, 3H), 1.19–1.63 (m, 4H), 1.75 (s, 3H), 1.95 (s, 3H), 3.14 (t, 2H), 4.08 (s, br, 1H).

(1-Butyl)(1'-hydroperoxy-1'-methylethyl)diazene: ^{1}H nmr ($CDCl_3$, 90 MHz) δ: 0.97 (t, 3H), 1.12–1.71 (m) with 1.45 (s) superimposed, total 8H, 1.65–1.93 (m, 2H), 3.87 (t, 2H), 9.40 (s, br, 1H); ^{13}C nmr ($CDCl_3$, 62.90 MHz) δ: 13.95, 20.60, 21.80, 29.79, 68.82, 102.86. Iodometric titration, 96.9%, average of three.

(1-Butyl)(1'-hydroxy-1'-methylethyl)diazene (2): ^{1}H nmr ($CDCl_3$, 90 MHz) δ: 0.93 (t, 3H), 1.15–1.58 (m) with 1.42 (s) superimposed, total 8H, 1.70–1.88 (m, 2H), 3.92 (t, 2H), 4.80 (s, br, 1H); ^{13}C nmr ($CDCl_3$, 62.90 MHz) δ: 13.80, 20.38, 26.95, 29.66, 66.48, 93.55; tlc (0.2 mm, neutral alumina on plastic) R_f 0.53, 50% petroleum ether, 50% ether, one spot.

Acetone phenylhydrazone: ^{1}H nmr ($CDCl_3$, 90 MHz) δ: 1.83 (s, 3H), 2.03 (s, 3H), 6.7–7.6 (m, 5H).

(1-Hydroperoxy-1-methylethyl)phenyldiazene: ^{1}H nmr ($CDCl_3$, 90 MHz) δ: 1.47 (s, 6H), 7.32–7.88 (m, 5H), 8.5 (s, br, 1H); tlc (0.2 mm, neutral alumina) R_f 0.51, 50% petroleum ether, 50% ether, one spot.

(1-Hydroxy-1-methylethyl)phenyldiazene (3): ^{1}H nmr ($CDCl_3$, 90 MHz) δ: 1.53 (s, 6H), 4.97 (s, 1H), 7.3–7.9 (m, 5H), no extraneous signals.

2-(1-Butoxy)-1,1,3,3-tetramethylisoindoline (11)

This product of coupling between **4** and the butyl radical was prepared by thermolysis of **2** at 80°C in C_6F_6 containing **4**. It was isolated by preparative tlc on silica coated plates and the fraction thus obtained was purified by chromatography on a rotating, alumina-coated, plate (Chromatotron apparatus); ^{1}H nmr ($CDCl_3$, 90 MHz) δ: 0.89 (t, 3H), 1.20–2.67 (m, 16H), 3.88 (t, 2H), 6.96–7.32 (m, 4H); ^{13}C nmr ($CDCl_3$, 62.90 MHz) δ: 14.23, 19.92, 22–31 (broad signal for the four ring methyl groups), 31.67, 67.32, 77.38, 121.61, 127.25, 145.59; ms (ei) *m/z*: 247 (M^+), 232 ($M^+ - CH_3$, 100%), 176 (90%).

Cyclopropylmethyl bromide (5), 4-bromo-1-butene (6), 1-bromobutane, and bromobenzene

Authentic samples of these compounds, for identification of the reaction products and for calibration of the gc detector, were purchased from Aldrich.

3,5-Dibromo-1,1,1-trichloropentane (7)

4-Bromo-1-butene (2.7 g, 0.017 mol), benzoyl peroxide (0.2 g, 0.8 mmol), and bromotrichloromethane (5.0 g, 0.025 mol) were heated in a sealed, evacuated tube at 80°C for 4 days. The ^{1}H nmr spectrum of the resulting solution was nearly free from vinyl proton signals. A portion of the product was isolated by preparative tlc (silica gel-60, F_{254}, 1 mm thick, on glass) with petroleum ether (80 parts) and ether (20 parts) as the solvent system. The pure product had R_f = 0.46 on silica gel-60 (0.2 mm, on plastic), with the same solvent system; ^{1}H nmr ($CDCl_3$, 500 MHz) δ: 2.38 (m, 1H), 2.59 (m, 1H), 3.23 (dd, 1H), 3.52 (dd, 1H), 3.59 (m, 2H), 4.53 (m, 1H); ms (ei) *m/z*: 338, 336, 334, 332, 330 (M^+); 301, 299, 297, 295 ($M^+ - Cl$); 263, 261, 259 ($M^+ - 2Cl$); 255, 253, 251 ($M^+ - Br$); 221, 219, 217, 215 ($M^+ - Br - Cl$); 111, 109 ($C_2H_4Br^+$); 77, 75 ($C_3H_4Cl^+$); 40 (100%, $C_3H_4^+$).

Mixed azine of acetone and cyclopropanecarboxaldehyde

A solution of cyclopropanecarboxaldehyde and acetone hydrazone (1:1) in CCl_4 at room temperature was examined periodically by ^{1}H nmr spectroscopy. When the aldehyde signal was no longer visible, solid potassium carbonate was added and the supernatant solution was passed through a short column of magnesium sulfate. Evaporation of most of the solvent and chromatography on a rotating disk (Chromatotron apparatus) gave fractions containing the unsymmetric azine contaminated with symmetric aldazine. The latter was obtained in pure form by preparative tlc (Al_2O_3 on plastic), permitting assignment of the gc signals from the mixture of azines and the assignment of ^{1}H nmr signals of the mixture. For the mixed azine, ^{1}H nmr ($CDCl_3$) δ: 0.67–1.08 (m, CH_2), 1.53–1.92 (m, CH), 2.00 (s, CH_3), 2.03 (s, CH_3), 7.18 (d, J = 8 Hz, CH=N); gc retention time (conditions described below) 25.3 min. For the symmetric aldazine, ^{1}H nmr ($CDCl_3$) δ: 0.67–1.08 (m, 4H), 1.53–1.92 (m, 2H), 7.35 (d, J = 8 Hz, 2H); gc retention time 28.9 min.

[10]Additional assumptions are (*a*): temperature 35°C (Rayonet, 1 h (13)); (*b*) $k_{Br}^{14} \simeq 2 \times 10^8$ s^{-1} at 35°C, which is 4-fold lower than k_{Br}^{cpm} at 35°C; (*c*) $[BrCCl_3] = 7.5$ *M*, calculated from data in ref. 13 by using 0.90 and 1.96 g mL^{-1} for the densities of the diene and of $BrCCl_3$, respectively.

Thermolysis of 1 and product analysis

Stock solutions of $BrCCl_3$ and **1** in C_6F_6 or in CH_2Cl_2 were prepared. Solutions for thermolysis were prepared by measuring the appropriate volumes of the stock solutions with small pipettes or syringes into nmr tubes sealed to ground glass joints. The contents were freed from dissolved gases prior to sealing by means of several freeze–pump–thaw cycles, care being taken to warm the sample gently, and only until melting was complete. A sealed tube was then heated or photolysed (Table 1) until starting material could not be detected in the ^1H nmr spectrum. Thermal decompositions at 0°C and 30°C were complete in 10 days and 4 days, respectively. At higher temperatures, 2 days was sufficient. Photolyses with 300-nm light were carried out with a Rayonet apparatus. The sample tube was inside a quartz Dewar flask containing the thermostating fluid and a magnetic stirring bar. The photolyses were interrupted frequently to check and to adjust the temperature so as to maintain a $\pm 1°$ or better range (Table 1). Photolyses were complete (^1H nmr) in 2–3 h.

Analyses were carried out on the untreated reaction solution using a Varian Vista 6000 instrument fitted with a flame ionization detector and with a OV-17 column (8 ft × 1/8 in., 3% stationary phase) operating with a flow rate of 10 mL min^{-1} (N_2). The temperature was held at 35°C for 15 min before it was increased to 210°C at 10°C min^{-1}. The order of elution was acetone, $CHCl_3$ and C_6F_6 (together), **6** (8.5 min), $BrCCl_3$ (12.2 min), **5** (14 min), **8** (20.4 min), C_2Cl_6 (24.8 min), **9** (32.5 min), and 7 (33 min). The yield of **8** was estimated by integration of the ^1H nmr spectra because dibromodichloromethane, a minor (ca. 0.3%) contaminant in the $BrCCl_3$, eluted together with **8** from the gc column. Chloroform was fully separated from other volatile components on Carbowax (8 ft × 1/8 in., 5%) under similar conditions. The response factors of the flame ionization detector were determined by injection of standard solutions of **5**, **6**, 7, $CHCl_3$, and C_2Cl_6. Compounds **5**–7 and C_2Cl_6 gave the same response, to within ±5%, but signal intensities for $CHCl_3$ had to be multiplied by 3.6. The response factor for minor component **9** was assumed to be the same as that of **5**–7.

Thermolysis of 2 and 3

Solutions of these substrates and **4** in $BrCCl_3$, with or without C_6F_6, were prepared in volumetric flasks and portions were transferred into small Pyrex tubes for freeze–pump–thaw degassing prior to sealing. Tubes were immersed in an oil bath kept at 80 ± 0.2°C. Spent solutions were analyzed with the gc column and instrument described earlier (10).

For the 1-butyl system the temperature program was 35°C for 15 min, increased at 10°C min^{-1} to 300°C. Retention times, for a flow rate of 10 mL min^{-1} were (min) acetone (1.8), chloroform (2.9), 1-BuBr (5.8), $BrCCl_3$ (8.7), **4** (29.7), **4**-Bu (30.8), **4**-CCl_3 (35.7, broad), where **4**-Bu and **4**-CCl_3 are the coupling products.

In the case of the phenyl system the column temperature program was the same except for a shorter interval (10 min) at 35°C. Retention times were acetone (1.8), $CHCl_3$ (2.9), $BrCCl_3$ (8.7), PhBr (16.9), **4** (24.8), **4**-CCl_3 (32, broad). The expected product, **4**-Ph, was not eluted as such (see text) but a complex series of peaks was observed instead.

2-Hydroxy-1,1,3,3-tetramethylisoindoline was not separated from excess **4** by the gc column (10).

The rapid synthesis of organic compounds in microwave ovens

RICHARD N. GEDYE, FRANK E. SMITH, AND KENNETH CHARLES WESTAWAY
Chemistry Department, Laurentian University, Sudbury, Ont., Canada P3E 2C6

Received June 19, 1987

RICHARD N. GEDYE, FRANK E. SMITH, and KENNETH CHARLES WESTAWAY. Can. J. Chem. **66**, 17 (1988).

This work demonstrates that organic compounds can be synthesized up to 1240 times faster in sealed Teflon vessels in a microwave oven than by conventional (reflux) techniques. It is shown that all polar molecules absorb microwave energy rapidly and that the rate of energy absorption varies with the dielectric constant. The rates of reaction of polar molecules in nonpolar solvents are not increased appreciably by the microwave method. Also, the homogeneity of the reaction does not affect the rate enhancement. The rate enhancement arises predominantly because the oven superheats the solvent rapidly. Finally, pressure (temperature) measurements have shown that the maximum rate enhancement is achieved when the proper power level and volume of solvent are used. It appears that rate enhancements of approximately 200 are possible for many reactions if the reaction conditions are optimized.

RICHARD N. GEDYE, FRANK E. SMITH et KENNETH CHARLES WESTAWAY. Can. J. Chem. **66**, 17 (1988).

Dans ce travail, on démontre que les composés organiques peuvent être synthétisés 1240 fois plus rapidement dans des récipients de Téflon scellés, dans des fours à micro-ondes, que par les techniques conventionnelles de reflux. On démontre que toutes les molécules polaires absorbent rapidement l'énergie des micro-ondes et que les vitesses d'absorption de l'énergie varient avec la constante diélectrique. La méthode des micro-ondes ne provoque pas en une augmentation substantielle des vitesses des réactions impliquant des molécules polaires dans des solvants qui ne sont pas polaires. De plus, l'homogénéité du milieu réactionnel n'influence pas le taux d'augmentation des vitesses des réactions. L'augmentation des vitesses des réactions provient principalement du fait que le four provoque une surchauffe rapide du solvant. Enfin, des mesures de pression (température) ont permis de démontrer que le taux maximal d'augmentation des vitesses de réaction est atteint lorsqu'on utilise un niveau de puissance et un volume de solvant appropriés. Il semble que l'on puisse atteindre des taux d'augmentation des vitesses de réactions d'environ 200 si les conditions des réactions sont optimisées.

Introduction

Although several chemical applications of microwave heating have been reported (1–5), it is only recently that microwave ovens have been used in organic synthesis (6, 7). In a preliminary communication (6) we described the use of microwave ovens for synthesizing esters from carboxylic acids, carboxylic acids from alkyl benzenes and amides, and ethers from alkyl halides. In fact, these organic reactions occurred up to 1240 times more rapidly in sealed Teflon containers in the microwave oven than by classical reflux methods. Since then, Giguere *et al.* (7) reported dramatic reductions in reaction time in microwave syntheses using the Diels–Alder, Claisen, and ene reactions.

The present paper extends the scope of this new synthetic method and reports our investigations of several of the factors that affect the rate enhancements found in organic syntheses in microwave ovens.

Results and discussion

Several different types of organic reactions were carried out both in sealed Teflon vessels in a microwave oven and under traditional reflux conditions. In the reactions described previously (6), approximate rate enhancements of between 5 and 1240 times were observed. Some representative reactions are given in Table 1. Carrying out reactions in the microwave oven was also found to be very useful for the preparation of derivatives for the identification of organic compounds. This approach was particularly useful for preparing derivatives that require relatively long reflux periods. For example, derivatives that normally required up to 2.5 h to prepare can be synthesized effectively in 2–2.5 min in a microwave oven. This reduces the time required for the preparation of the derivatives by between 24 and 60 times. The results of some of these syntheses are shown in Table 2.

Heating rates

Once it had been demonstrated that this rapid new synthetic method could be used to synthesize a wide range of organic compounds, attention was turned to an examination of the factors that affected these syntheses. The first experiment involved heating 50 mL of several organic compounds in open vessels[1] in a microwave oven for 1 min at 560 watts to determine the types of molecules that absorb microwave energy. It was found, Table 3, that all polar compounds absorbed significant amounts of microwave energy. For example, all the polar compounds with boiling points of less than 100°C reached their boiling point within 1 min. While polar molecules such as acids, esters, alkyl halides, primary alcohols and amines, and carbonyl compounds absorb microwave energy readily, the less polar ether, tertiary amine, and higher molecular weight alcohols were poorer absorbers. As expected, little or no microwave energy was absorbed by the nonpolar carbon tetrachloride and hydrocarbon solvents.

The above results suggested that the rate at which a molecule absorbs microwave energy depends on the polarity of the molecule. This relationship was confirmed by an examination of the rate of energy absorption for a fairly wide range of polar organic liquids. The data in Table 4 and Fig. 1 suggest that the ability to absorb microwave energy is related to the dielectric constant (polarity) of the solvent. Although two out of the 13 compounds are not near the least-squares straight line, the correlation coefficient for the plot of the temperature increase found when 0.5 mol of each compound is heated for 15 s at 560 watts versus the dielectric constant is still 0.920. Since the correlation coefficient for the other 11 compounds is 0.985, it appears that one can use a solvent's dielectric constant to estimate a compound's ability to absorb microwave energy.

[1]See "Safety precautions", experimental section.

TABLE 1. A comparison of reaction times and yields in representative reactions using classical and microwave procedures

Compound synthesized	Procedure followed	Reaction time	Average[b] yield (%)	$\left[\frac{k_{microwave}}{k_{classical}}\right]$
Hydrolysis of benzamide to benzoic acid in water				
C_6H_5COOH	Classical	1 h	90	
C_6H_5COOH	Microwave	10 min	99	6
Oxidation of toluene to benzoic acid in water				
C_6H_5COOH	Classical	25 min	40	
C_6H_5COOH	Microwave[a]	5 min	40	5
Esterification of benzoic acid with methanol				
$C_6H_5COOCH_3$	Classical	8 h	74	
$C_6H_5COOCH_3$	Microwave	5 min	76	96
S_N2 reaction of 4-cyanophenoxide ion with benzyl chloride in methanol				
$NCC_6H_4OCH_2C_6H_5$	Classical	16 h	89	
$NCC_6H_4OCH_2C_6H_5$	Microwave	4 min[c]	93	240
$NCC_6H_4OCH_2C_6H_5$	Classical	12 h	65	
$NCC_6H_4OCH_2C_6H_5$	Microwave	35 sec[c,d]	65	1240

[a]Very high pressures developed and the study of this reaction was halted.
[b]The average yields are based on isolated yields and represent the average of at least two experiments. The S_N2 reaction was followed by titrating the chloride ion (8).
[c]Value for one run only.
[d]This reaction was done in a 50-mL Teflon bomb.

TABLE 2. A comparison of reaction times and yields for classical and microwave procedures in the preparation of derivatives

Substrate	Derivative	Reaction time		Yield (%)		Reduction in reaction time[a]
		Classical	M-wave	Classical	M-wave	
Cinnamic acid	4-Nitrobenzyl ester	1.5 h	2 min	26	39	×45
2-Naphthol	Aryloxyacetic acid	1.0 h	2 min	14	13	×30
Methyl benzoate	Carboxylic acid	1.0 h	2.5 min	95	84	×24
Benzophenone	Oxime	2.0 h	2 min	68	71	×60

[a]These values are not rate enhancements but should be similar to them. The reductions in reaction time are the time used for the classical syntheses/the time used for the microwave synthesis. The classical times were taken from the literature (10, 11).

Sample volume

The effect of the amount of material in the oven on the heating rate was determined by heating 0.51 and 1.2 mol of methanol and 1-propanol in an open vessel in the microwave oven at 560 watts. Since the smaller sample is always at a higher temperature after the same heating time, Fig. 2, both the methanol and the 1-propanol are heated more rapidly when less material is in the reaction vessel. This presumably occurs because the microwave energy entering the oven has to heat fewer molecules. This suggests that the fastest heating and greatest rate enhancements will be observed when small (less than one mole) amounts of material are in the Teflon reaction vessel.

Reactions in nonpolar solvents

An experiment was performed to determine if the rate of reaction of a polar substrate in a nonpolar solvent would be increased in the microwave oven. A comparison of the heating rate of a 1.6 M solution of 1-propanol in octane with that of 1-propanol in an open vessel in the microwave oven at 560 watts, Fig. 3, shows that dilute solutions of polar substrates in nonpolar solvents are heated very slowly in the microwave oven. This occurs because only the polar molecules in the solution absorb the microwave energy. Thermal energy is then transferred to the nonpolar solvent by molecular collisions. Because the heating rate is much slower and the reaction times for microwave syntheses are short, it appears that microwave heating will only cause significant rate enhancements in organic syntheses in polar solvents.

Heterogeneous and homogeneous reactions

Another interesting question, from a synthetic point of view, is whether the rate enhancements are similar in homogeneous and heterogeneous reactions. Almost identical rate enhancements of 5 and 6 were found in the heterogeneous aqueous oxidation of toluene to benzoic acid and in the homogeneous hydrolysis of benzamide, respectively, Table 1. This suggests that the microwave technique is equally effective in enhancing the rates of both homogeneous and heterogeneous reactions.

This hypothesis was confirmed by comparing the rate enhancement for the hydrolysis of isopropyl benzoate in aqueous KOH, a heterogeneous reaction, with that found under

Chloroform	49	61
Acetone	56	56
N,*N*-Dimethylformamide	131	153
Diethyl ether	32	35
1,4-Dioxane	53	101
1-Butylamine	70	77
Tripropylamine	56	157
Hexane	25	68
Heptane	26	98
Carbon tetrachloride	28	77

TABLE 4. The increase in temperature found when 0.5 mol of organic liquids is heated for 15 s at 560 watts in an open vessel in a microwave oven

Alcohol	Temperature increase after 15 s (°C)	Boiling point (°C)	Dielectric constant
1,4-Dioxane	11	101	2.2
Tripropylamine	10	156	2.4
Propanoic acid	19	141	3.3
Chloroform	24	62	4.8
n-Propyl acetate	28	102	5.6
Ethyl acetate	29	77	6.0
Acetic acid	38	118	6.2
1-Hexanol	45	158	13.3
1-Pentanol	51	137	13.9
2-Pentanone	49	102	15.4
1-Butanol	56	117	17.8
2-Butanone	41	80	18.5
1-Propanol	62	97	20.1

homogeneous conditions in alcoholic KOH. The results, Table 5, show that the rate enhancement is almost identical, i.e., 2.5 times and 3.0 times, in the heterogeneous and homogeneous reactions, respectively. Obviously the homogeneity of the reaction has little effect on the rate enhancement, and the microwave technique can be used to increase the rates of both types of reactions.

Safety

Although the observed rate enhancements of between 5 and 1240 are impressive, some problems were encountered in our early investigations. The chief obstacle in the use of microwaves for routine organic synthesis is that very high pressures can develop in the Teflon reaction vessels when the reactions are carried out in the microwave oven. The reactions described in this study were carried out in sealed 120-mL or 300-mL Berghof[2] or 150-mL Savillex[3] Teflon bottles. In some cases, the increase in pressure led to deformation of the Berghof vessels. In a few reactions, Berghof bottles exploded, destroying the Teflon bottle and in two cases damaging the microwave oven. The problem arises because the hot reaction mixture transfers heat to the Teflon container. This softens the Teflon and the pressure in the reaction vessel causes the walls of the vessel to deform and (or) explode. This problem is much less severe with the Savillex containers, which are made from a more temperature resistant type of Teflon, and should be absent when one uses a Savillex bottle with a pressure-release cap[3] that vents at approximately 100 psi (1 psi = 6.9 kPa). However,

[2]These bottles were purchased from Berghof/America Inc., Main St., Raymond, NH 03770, U.S.A.

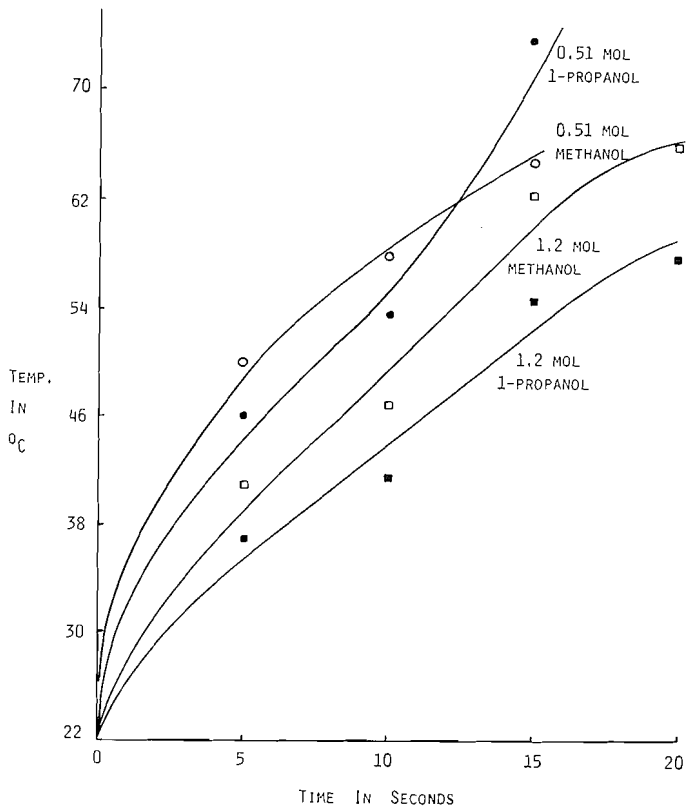

FIG. 2. The effect of the amount of solvent on the heating rate at 560 watts in open vessels.

long heating times and reactions using a large volume of reactants should be avoided because these conditions generate very high pressures in the Teflon vessels in some reactions. In practice, if the volume of the reaction mixture is kept to between 10 and 15% of the volume of the container, the pressure will not exceed safe limits.[1]

However, if this new synthetic method is to be useful, it is imperative that these syntheses be done safely. The following experiments were undertaken in an effort to understand why (*i*) the rates and (*ii*) the pressures are significantly greater when an organic reaction is carried out in a microwave oven.

Boiling point of the solvent

The results in Table 1 show that the most dramatic rate enhancements were obtained in methanol. Reactions in water and higher boiling alcohols, on the other hand, showed smaller rate increases. In the esterification of benzoic acid with a homologous series of alcohols, Table 6, the rate enhancement decreased with increasing boiling point of the alcohol, i.e., the rate enhancement decreased from 96 in the lowest boiling solvent, methanol, to a low of 1.3 in the highest boiling solvent, 1-pentanol.

The rate enhancement decreases with an increase in the boiling point of the solvent because the rates of the microwave and the classical reactions are affected differently by a change in solvent. The rate of the classical (reflux) reaction increases as the reaction temperature (the boiling point of the solvent) increases. Two pieces of evidence, on the other hand, suggest that the rate constants for the microwave reactions are almost identical in the different solvents. First, the esterifications in methanol, 1-propanol, 1-butanol, and 1-pentanol, Table 6, are all 78 ± 2% complete in approximately 6 min. Secondly, the final temperatures of the reaction mixtures in these four solvents

TABLE 5. The rate enhancements found for the heterogeneous and homogeneous saponification of isopropyl benzoate[a]

[b]The averages are for at least three separate experiments.

were virtually identical, i.e., they varied from 134°C in methanol to 137°C in 1-pentanol. The almost identical rate constants for the microwave reactions are probably found because all the solvents reach the same final temperature when the same amount of microwave energy (560 watts) is used. Finally, the rate enhancement decreases when a higher boiling solvent is used because the rate of the slower (reflux) reaction increases with the boiling point of the solvent while the rate of the microwave reaction does not change significantly.

While the major cause of the decreasing rate enhancements with higher boiling solvents appears to be the almost constant reaction rates in the microwave oven, the dielectric constant of the solvent may also affect the magnitude of the rate enhancement. Since the dielectric constants decrease from methanol to 1-pentanol, methanol will heat up more rapidly and reach the final temperature sooner than the higher alcohols. Thus, the microwave reaction in methanol should be faster than in the higher alcohols. Although the errors in the yield are too large to be certain, the reaction in methanol, which takes 5 min, seems to be slightly faster than that in 1-propanol, which takes 6 min, and those in 1-butanol and 1-pentanol, which take 7.5 min to reach 78 ± 2% of completion, Table 6.

The above results suggest that the microwave technique is only successful in increasing the rates of reactions that are carried out in low boiling solvents. This is not the case, however. The rate constant of a reaction in a high boiling solvent can, in fact, be increased in two ways: by adjusting the volume of the solvent in the container used in the microwave experiment (*vide infra*) and by increasing the amount of microwave energy used in the synthesis. For example, the rate enhancement for the esterification of benzoic acid with 1-pentanol is increased from 1.3 to 6.1 when the power level is increased from 560 to 630 watts, Table 6. It is worth noting that a small increase in the amount of microwave energy has a marked effect on the reaction temperature, i.e., the final temperature of the reaction mixture increased by approximately 20°C when the power level was increased by 10%. The important observation, however, is that the microwave technique can be used to increase the rates of reactions in both high and low boiling solvents.

Size of the reaction vessel

In another set of experiments, the rate enhancement in an S_N2 reaction between 4-cyanophenoxide ion and benzyl chloride in methanol was determined by reacting identical amounts of reagents to 65% completion in 50-mL, 120-mL, and 300-mL

[a]All reactions were done using 10 mL of the alcohol in a 300-mL Berghof bottle. With the exception of the 1-pentanol reaction at 630 watts, all the reactions were done at 560 watts.
[b]The yields are the averages from at least two separate experiments.

Teflon vessels. The results in Table 7 show that the rate of reaction increases markedly when the volume of the Teflon container is reduced. In fact, the linear relationship, Fig. 4, between 1/volume of the Teflon bottle and 1/the time it took for the reaction to go to 65% completion is excellent, with a correlation coefficient of 0.996. The reciprocal of the time to take the reaction to 65% completion is directly related to the rate of the reaction because the same amounts of reagents were used in each experiment. Thus, the rate of reaction varies inversely with the volume of the container. Since the pressure in the Teflon bottle is related to 1/volume of the container (*vide infra*), the rate of reaction increases when the pressure in the Teflon bottle increases. In fact, this relationship is reasonable because the boiling point of a liquid is greater when it is under pressure (9).

The above experiment suggested that the increased rates of reaction found in the microwave oven syntheses were the result of a pressure increase in the reaction vessel rather than the result

TABLE 8. Percent yield of *n*-propyl benzoate after heating equal amounts of reactants for 4 min in an oil bath at 160°C and in the microwave oven in an open vessel

Conditions	Percent ester	Percent acid	Percent total recovery
Oil bath, 4 min at 160°C	29	64	94
Microwave, 4 min (atmos. pressure)	25	69	94

of any special effect of the microwaves. An experiment was carried out to test this hypothesis. *n*-Propyl benzoate was synthesized by heating identical mixtures of benzoic acid, sulfuric acid, and 1-propanol in an open vessel in the microwave oven and in an oil bath at 160°C for 4 min. The yield of *n*-propyl benzoate in these two reactions was identical within experimental error, Table 8. This clearly illustrates that the microwaves only heat the molecules but do not activate them in any other way. Thus, the faster rate of reaction in the microwave oven is observed because the high pressure in the sealed Teflon vessels allows the microwaves to superheat the reaction mixture.

Pressure measurements, power levels

The above experiments demonstrated that the rate enhancements observed in the microwave oven were the result of the increased pressure that is generated in the Teflon bottles when they are heated in the microwave oven. Thus, it was important to determine the parameters that affected the pressure (temperature) of different solvents (reaction mixtures) in the Teflon containers. The first experiment was done to determine the effect of the power setting on the amount of microwave radiation that is absorbed by a fixed amount of liquid in the Teflon bottles. The results, Fig. 5, indicate that the pressure (temperature) of the liquid in the Teflon containers increases more rapidly when the power level is higher. Also, the final pressure (temperature) is higher when a higher power level is used with a particular solvent. These results were expected since more microwave energy will be absorbed by the solvent in the Teflon vessel when the power level is higher.

Volume of the reaction mixture

The next set of experiments involved examining the effect of the ratio of the volume of the reaction mixture/the volume of the Teflon container. In these experiments, different volumes of solvents were heated at 560 watts in the same Teflon vessel and the pressures (temperatures) of the solvents were determined at various times. The results are shown graphically in Figs. 6–8. When the volume of solvent is small, the pressure (temperature) increases as the volume of the solvent in the container increases. However, as the volume of solvent in the Teflon bottle increases, this trend is eventually reversed, i.e., a point is reached where the larger volume of solvent is not heated more quickly. In fact, this trend is found with every solvent that has been tested. It is worth noting, however, that the final pressure (temperature) reached with the larger volumes of solvent is at least as high as that found with smaller amounts of solvent, Fig. 7. This probably occurs because it takes longer to heat the larger volume of solvent to the same temperature at the same power level.

The point at which the maximum amount of microwave energy retained by the solvent (the maximum heating rate) is observed occurs at different volumes for different solvents. For example, the most rapid temperature increase is found with 15 mL of water, 20 mL of 1-propanol, and 30 mL of 1-butanol in a 150-mL Savillex bottle. Thus, the volume of a particular solvent that should be used to obtain the fastest increase in temperature (the maximum rate enhancement) is different for each solvent. This maximum increase in pressure (temperature) with a particular amount of solvent is found because the amount of microwave energy absorbed by the thicker layer of solvent in the Teflon container (the rate of increase in pressure) increases until the amount of solvent is too great to be heated by the available microwave energy.

The volume for which the maximum heating rate is observed seems to depend on the molecular weight and the heat capacity of the liquid. In water, the greatest increase in pressure occurs at 15 mL (0.83 mol) and a smaller rate of increase is found at 20 mL (1.11 mol), Fig. 6. Because 15 mL of 1-propanol and 1-butanol are only 0.20 and 0.16 mol, respectively, the greatest heating rate occurs with larger volumes of these solvents. In

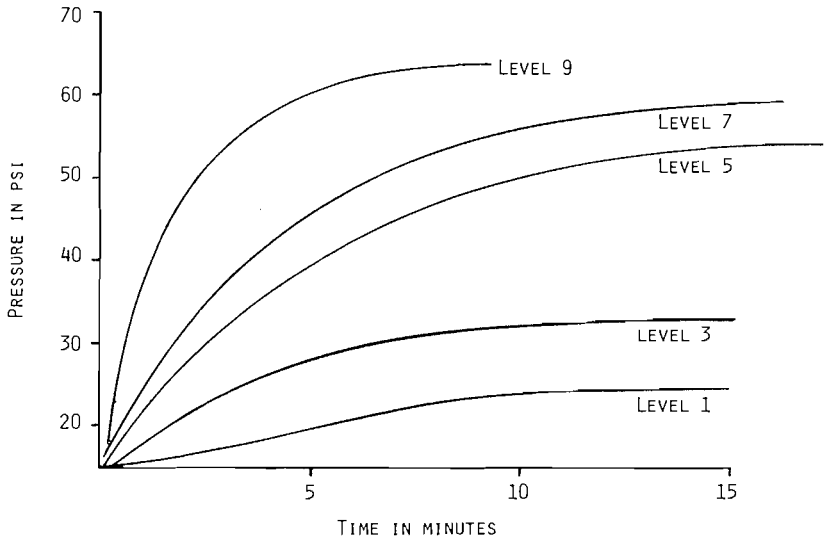

FIG. 5. The effect of the power setting on the microwave heating of 1-propanol.

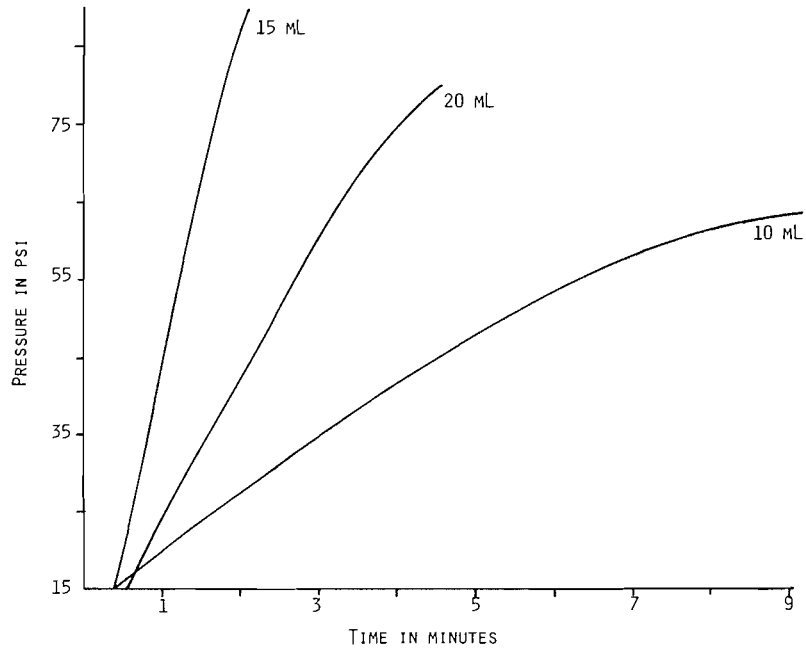

FIG. 6. The effect of the volume of water in a sealed 150-mL Savillex bottle on the heating rate.

fact, the most rapid increase in pressure for 1-propanol and 1-butanol occurs at 20 mL (0.27 mol) and 30 mL (0.32 mol), respectively. The maximum increase in pressure for 1-butanol presumably occurs at only 0.32 mol rather than the 0.83 mol found for water because the heat capacity of 1-butanol is approximately twice that of water. Thus, the amount of energy that is required to heat 15 mL of water and 30 mL of 1-butanol is almost identical and it is not surprising that these volumes have the maximum heating rate.

An experiment was carried out to learn if the volume of solvent/volume of the container or the amount of solvent in the container was important in determining the fastest heating rate and maximum rate enhancement. The volume (amount) of solvent in the bottle was important in determining the maximum heating effect. The maximum heating rate for water is at 15 mL in both a small (50-mL) and in a larger (150-mL) Savillex Teflon bottle, Fig. 9. This is not too surprising because the Teflon containers are made of the same material and should absorb and radiate similar amounts of energy.

However, the results in Fig. 9 also show that the pressure (temperature) increases faster in the smaller reaction vessel. Although we are unable to explain this phenomenon, the same trend is observed in our study of the S_N2 reaction between 4-cyanophenoxide ion and benzyl chloride in methanol (*vide supra*).

Optimization of conditions

Finally, the information that had been collected was used to try to increase the rate acceleration observed in the esterification of benzoic acid in 1-propanol, a reaction that had a fairly small rate enhancement in the microwave oven (6). The results in Table 9 show that the rate enhancement could indeed be

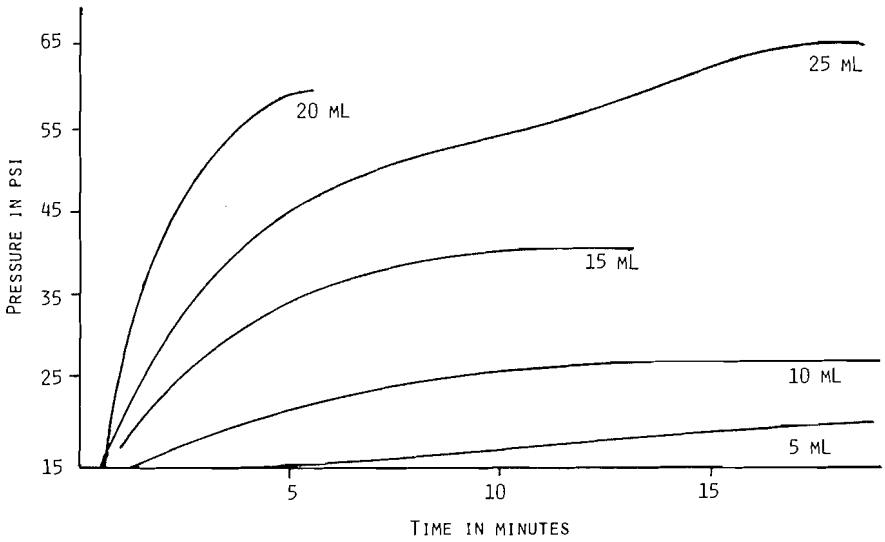

FIG. 7. The effect of the volume of 1-propanol in a sealed 150-mL Savillex bottle on the heating rate.

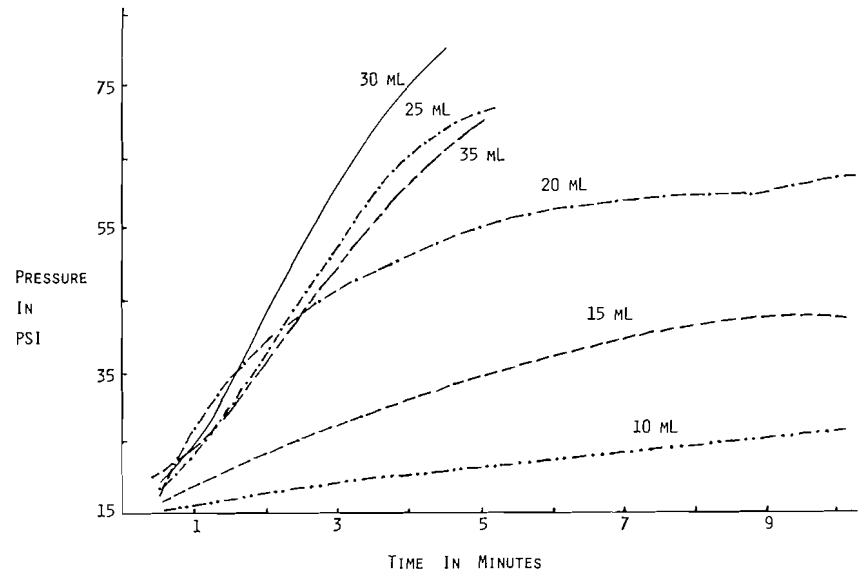

FIG. 8. The effect of the volume of 1-butanol in a sealed 150-mL Savillex bottle on the heating rate.

increased by varying the reaction conditions. For example, the rate enhancement for the esterification was increased from 18 to 60 when the volume of the reaction mixture was altered to maximize the heating rate. Increasing the power level from 560 watts to 630 watts increased the rate enhancement for the microwave reaction from 60 to 180 (*vide supra*). These results are important because they demonstrate that a rate enhancement of approximately 200 is possible if the conditions are optimized for the reaction in the microwave oven.

Conclusion

The nonoptimized rate enhancements of between 5 and 1240 found for several different classes of organic reactions, Table 10, show that organic reactions in polar solvents can be carried out quickly and conveniently in a microwave oven. However, rate enhancements of approximately 200 appear possible for many reactions when the reaction conditions are optimized. These syntheses can be carried out safely if the reaction volumes are limited to approximately 10% of the volume of the Teflon bottle used for the synthesis and if a pressure-release Savillex Teflon reaction vessel is used.[1] The rate enhancing properties of the microwave oven are predominantly due to its ability to superheat the solvent rapidly in the sealed Teflon vessels.

Experimental

Apparatus

The microwave oven used for this study was a domestic Toshiba model ER-8000 BTC with nine power settings, starting at 72 watts and increasing by 81-watt increments to 720 watts. Power setting 7 (a nominal 560 watts) was used unless otherwise stated. The Teflon vessels used for the reactions in the microwave oven were (*i*) 120- and 300-mL Teflon bottles manufactured by Berghof/America Inc.,[2] (*ii*) 50- and 150-mL PFA vessels manufactured by the Savillex Corporation,[3] and (*iii*) a Savillex 150-mL PFA vessel fitted with a pressure-releasing device designed to vent at approximately 100 psi.[3]

Product analysis

Reaction products were identified by their melting or boiling points (uncorrected) and by nmr and ir spectroscopy. The nmr spectra were recorded with a Varian T-60 nmr spectrometer and the ir spectra with a Beckman Acculab I double beam spectrophotometer.

General procedure

Each experiment was carried out by both the classical (reflux) method and in the microwave oven. In each case, the same quantities of reagents were used and the products were worked up and purified in the same way. Each reaction was carried out several times to find the reaction times that gave the same yields by the classical and microwave techniques. This allowed the relative rate constants for each experiment (the rate enhancement) to be calculated.

In all the microwave preparative experiments, the reagents were mixed in a Teflon vessel, the lid screwed on tightly, and the mixture heated in the oven for the specified time (Tables 1 and 2). After the heating was completed, the vessel was left to stand in the oven for 2 min to reduce the pressure in the bottle. Then the bottle, which was still hot, was removed from the oven and cooled in ice-water for 5 min before the top was unscrewed.

Safety precautions

Increasing the volume of solvent and (or) the power level or decreasing the size of the container can cause an increase in pressure and temperature that can lead to deformation of the reaction vessels or even to an explosion. To ensure a safe experiment, the solvent volumes should not exceed 10% of the volume of the container and heating times of more than 5 min at a power of 560 watts should be avoided. Higher power levels should be avoided regardless of the heating times or the volume of the container. It is possible, however, that these recommended volumes and power levels may be different for other microwave ovens. In any case, excess pressure is usually not a problem if small volumes of reagents are used and if the experiments are carried out in Savillex bottles with a pressure-releasing cap.

Flammable organic solvents have been heated in open vessels in microwave ovens in this study. Although one might be concerned that a spark from the oven might ignite the organic vapours, this has never occurred because a stream of air constantly blows any vapour out of the oven. In any case, these experiments were done in a fume hood to ensure that the vapours were carried away from the electronics. It is recommended that this procedure be followed when organic solvents are heated in microwave ovens.

Pressure and temperature measurements

Pressure measurements were carried out by connecting the cap of a pressure-release 150-mL Savillex bottle to a pressure gauge outside the microwave oven. The bottle was connected to the pressure gauge by a 1/4-in. to 1/8-in. Swagelok reducing adapter, a 1/8-in. Teflon tube that passed through a small hole drilled in the back of the oven, and a Swagelok fitting. The pressure was recorded every 30 s for the duration of the experiment. The final temperature in the sealed bottle was estimated by pointing a Williamson 600 infrared sensor at the mixture in the bottle immediately after the heating was completed. The temperature readings obtained on the infrared sensor were in good agreement with those predicted from the pressure in the Teflon bottles (9).

Synthetic procedures

Esterification of benzoic acid

In all of the esterifications, benzoic acid was reacted with 10 mL (approximately a tenfold excess) of the alcohol. A typical microwave procedure is described. A mixture of 1.6 g (13 mmol) of benzoic acid, 10 mL (0.13 mol) of 1-propanol, and 0.1 mL of concentrated H_2SO_4 was sealed in a 300-mL Teflon bottle and heated in the microwave oven for several minutes. After cooling (see General procedure), the mixture was made basic with 20% Na_2CO_3 and the ester extracted with ether. The aqueous layer was acidified with 10% H_2SO_4 and the unreacted benzoic acid extracted with ether. Both ether extracts were dried over anhydrous $MgSO_4$ and the ester and benzoic acid isolated by evaporation of the solvent under reduced pressure.

Hydrolysis of benzamide

A mixture of 1.0 g (8.4 mmol) of benzamide and 10 mL of a 20% sulfuric acid solution in the sealed 300-mL Teflon bottle was placed in the microwave oven and heated for several minutes. After cooling, the reaction mixture was made basic with 20% sodium carbonate and the unchanged amide isolated by extraction with chloroform, drying over anhydrous $CaCl_2$, and evaporation of the solvent. The aqueous layer was acidified with 20% H_2SO_4 and the benzoic acid extracted with ether. The ether extracts were dried with anhydrous $MgSO_4$ and the benzoic acid isolated by evaporation of the ether.

Oxidation of toluene

A mixture of 0.92 g (10 mmol) of toluene, 3.0 g (19 mmol) of $KMnO_4$ in 50 mL of water, and 13 mL of 6 M KOH were sealed in the 300-mL Teflon bottle and heated in the microwave oven for several minutes. After cooling, the reaction mixture was extracted with ether to remove the unchanged toluene. The aqueous layer was acidified with 20% H_2SO_4 and sufficient $NaHSO_3$ added to decolourize the solution. The solution was extracted with ether, the extracts dried with anhydrous $MgSO_4$, and the benzoic acid isolated by evaporation of the ether.

The reaction of sodium 4-cyanophenoxide with benzyl chloride

A mixture of 0.22 g (1.5 mmol) of sodium 4-cyanophenoxide, 0.19 g (1.4 mmol) of benzyl chloride, and 15 mL of methanol in the sealed 300-mL Teflon bottle was heated in the microwave oven for a few minutes. The reaction mixture, after cooling, was poured into 90 mL of water and extracted with ether. The yield of 4-cyanophenyl benzyl ether was determined by titrating the chloride ion in the aqueous phase with a standard silver nitrate solution (8).

Preparation of derivatives

The derivatives were synthesized both by the classical methods outlined in standard laboratory manuals (10, 11) and in sealed Teflon containers in the microwave oven. Typical examples of the preparation of each derivative using the microwave procedure are described. The reaction times and yields obtained in the preparation of the derivatives by microwave and by classical methods are listed in Table 2.

4-Nitrobenzyl esters from carboxylic acids

A mixture of 1.5 g (10 mmol) of cinnamic acid and 1 mL of water was neutralized with a 10% solution of NaOH. A solution of 1.5 g (9 mmol) of 4-nitrobenzyl chloride in 7 mL of ethanol was added and the mixture heated for 2 min in a sealed 150-mL Teflon bottle in the microwave oven. After cooling, 2 mL of water was added. The precipitated ester was collected by filtration and washed with a 5% Na_2CO_3 solution. Recrystallization from ethanol gave 0.67 g (26%) of 4-nitrobenzyl cinnamate, mp 115–116°C (lit. (11) mp 116°C).

Aryloxyacetic acids from phenols

A mixture of 0.2 g (1.4 mmol) of 2-naphthol in 3 mL of 6 M NaOH and 0.5 mL of 50% aqueous chloroacetic acid were sealed in the 150-mL Teflon bottle and heated in the microwave oven for 2 min. After cooling, 2 mL of water was added and the solution acidified with dilute HCl. The mixture was extracted with ether, and the ether extracts were washed with water and extracted with a 5% sodium carbonate solution. The sodium carbonate extract was acidified with dilute HCl and the precipitated acid collected by filtration. Recrystallization from water gave 0.04 g (14%) of the 2-naphthoxyacetic acid, mp 154–156°C (lit. (10) mp 154°C).

Oximes from aldehydes and ketones

A mixture of 1.0 g (5.5 mmol) benzophenone, 1.0 g (14.4 mmol) of hydroxylamine hydrochloride, 5 mL of pyridine, and 5 mL of absolute ethanol in a 150-mL sealed Teflon bottle was heated in the microwave oven for 2 min. After cooling, the solvents were removed under reduced pressure, the residue stirred with 5 mL of cold water, and the crude oxime collected by filtration. Recrystallization from ethanol gave 0.74 g (68%) of the benzophenone oxime, mp 139–140°C (lit. (11) mp 141°C).

Carboxylic acids from esters

A mixture of 1.0 g (7.4 mmol) of methyl benzoate and 10 mL of a 25% aqueous NaOH solution in a sealed 150-mL Teflon bottle was heated for 2.5 min in the microwave oven. Then the solution was cooled and acidified with dilute HCl. The acid was extracted with ether, and the extracts dried over anhydrous $MgSO_4$ and evaporated, giving 0.76 g (84%) of benzoic acid, mp 121–122°C (lit. (10) mp 122°C).

Studies of the synthesis of 8a-hydroxy-4a-methyloctahydronaphthalen-1(2*H*)-ones and their 2α-deutero derivatives

SHIRLEY STIVER, PETER D. CLARK, AND PETER YATES
Lash Miller Chemical Laboratories, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received June 19, 1987

SHIRLEY STIVER, PETER D. CLARK, and PETER YATES. Can. J. Chem. **66**, 27 (1988).

Two syntheses of the bicyclic α-ketols, 8a-hydroxy-4a-methyl-*trans*- and -*cis*-octahydronaphthalen-1(2*H*)-ones (**1** and **2**), have been effected. One involves epoxidation of 4a-methyl-1,2,3,4,4a,5,6,7-octahydronaphthalene (**4**), followed by hydrolysis and oxidation; direct "hydroxy ketonization" of **4** was found not to be practicable. The second involves treatment of 3,4,5,6,7,8-hexahydronaphthalen-1(2*H*)-one (**14**) with lithium dimethylcuprate, trimethylsilylation of the resulting enolate, oxidation of the enol ether, and hydrolysis. Syntheses of the 2α-deutero derivatives of **1** and **2** are also described.

SHIRLEY STIVER, PETER D. CLARK et PETER YATES. Can. J. Chem. **66**, 27 (1988).

On a effectué deux synthèses des α-cétols bicycliques, hydroxy-8a méthyl-4a octahydronaphtalène-1 (2*H*) ones-*trans* et -*cis* (**1** et **2**). Une de ces synthèses implique l'époxydation du méthyl-4a octahydro-1,2,3,4,4a,5,6,7 naphtalène (**4**), suivie d'une hydrolyse et d'une oxydation; on a trouvé que l'«hydroxy-cétonisation» directe du composé **4** n'est pas pratique. La deuxième synthèse implique une réaction de l'hexahydro-3,4,5,6,7,8 naphtalène-1 (2*H*) one (**14**) avec du diméthylcuprate de lithium, une triméthylsilylation de l'énolate qui en résulte, une oxydation de l'éther énolique et une hydrolyse. On décrit aussi les synthèses des dérivés deutéro-2α des composés **1** et **2**.

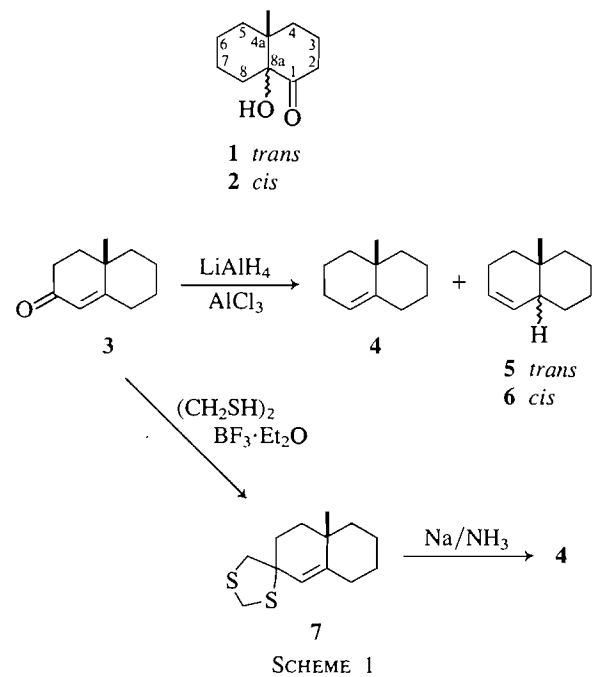
In a previous paper (1) we discussed the synthesis of 5-hydroxy 6-keto steroids and their 7α-deutero derivatives. We have also undertaken studies on the synthesis of the analogous bicyclic ketols **1** and **2** and their 2α-deutero derivatives, which, like the steroidal ketols, were required for our photochemical investigations (2). These studies have led to observations of intrinsic interest and are reported here; it is planned to report the full details of the photochemical work subsequently.

Syntheses of the bicyclic ketols

Application of different approaches furnished two syntheses of the *trans* and *cis* bicyclic ketols **1** and **2**. A "classical" synthesis analogous to that employed for the related steroidal ketols (1) provided a reliable, albeit not elegant, method for the preparation of **1**. An efficient synthesis of the olefin **4** was essential to the success of this route. Direct reduction of the bicyclic enone **3** with lithium aluminum hydride and aluminum chloride gave a mixture of three olefins, despite reports of the sole formation of unrearranged olefin from similar reaction of the analogous steroidal enone system (3). The target $\Delta^{8,8a}$ olefin **4** was the major product (~60%). The two additional products are considered to be *trans* and *cis* $\Delta^{7,8}$ olefins **5** and **6**, because of the presence of an additional vinyl signal at δ 5.50 and two additional methyl singlets at δ 0.80 and 0.93 in the ^{1}H nmr spectrum of the crude reaction product. Notorious difficulties associated with separations of double-bond isomers led us to investigate an alternative synthesis of **4**. Conversion of **3** to its thioketal **7** and reduction of this with sodium or lithium in liquid ammonia gave the olefin **4** without the formation of its isomers **5** and **6** (Scheme 1).

The lure of a one-stage transformation of olefin **4** to the *trans* and *cis* bicyclic ketols **1** and **2** led us to study its "hydroxy ketonization" with catalytic quantities of molybdenum hexacarbonyl and a large excess of anhydrous *tert*-butyl hydroperoxide in boiling benzene (4). This yielded a crude product in which the presence of the *trans* ketol **1** was evidenced as the major constituent by ^{1}H nmr spectroscopy. The spectrum also indicated the presence of *tert*-butyl-containing side products considered to arise from further reaction of *tert*-butoxy and *tert*-butylperoxy radicals, formed by a metal-catalyzed



SCHEME 1

decomposition of the *tert*-butyl hydroperoxide (5). Extensive chromatography led to the isolation of **1**, the *cis* ketol **2**, and the *trans* and *cis* 1-decalones **10** and **11** (Scheme 2), which were identified by direct comparison with authentic samples. The ketones **10** and **11** are thought to arise from isomerization of the A/B *trans* and *cis* epoxides **8** and **9**, which are considered to be intermediates in the hydroxy ketonization of **4** (6), via catalysis by a molybdenum species acting as a Lewis acid. The addition of disodium hydrogen phosphate or barium oxide to the reaction mixture retarded the metal-induced decomposition of the hydroperoxide, as reported in other cases (7, 8); however, even upon prolonged reaction, oxidation stopped at the stage of the epoxides **8** and **9**. Interestingly, the A/B-*cis* epoxide **9** proved to be the major isomer, in contrast to the preference for formation of the A/B-*trans* epoxide **8** from peracid epoxidation

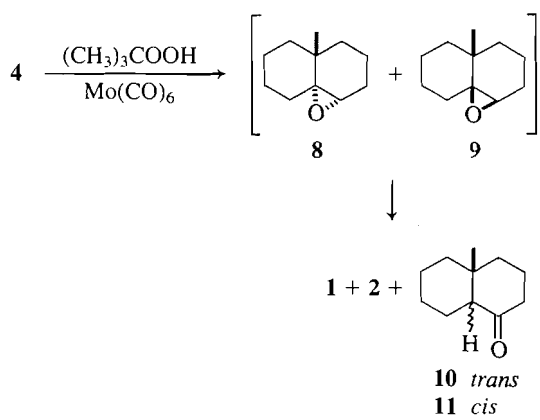
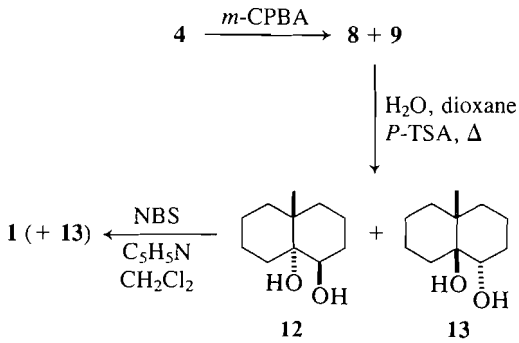


SCHEME 2

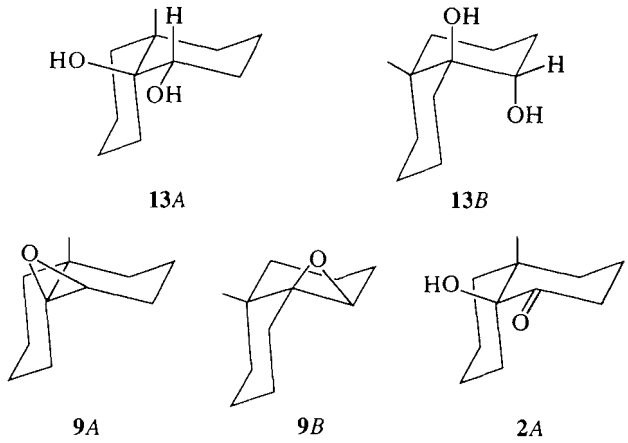


SCHEME 3

of **4** (*vide infra*).[1] The difficulties encountered during purification of the ketols and the resulting low yields render this one-stage hydroxy ketonization a procedure of limited synthetic utility.

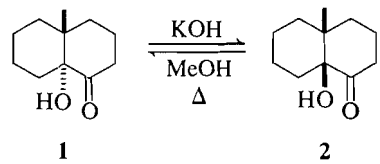
A practicable synthesis of **1** from olefin **4** was attained by the sequence of reactions in Scheme 3. Epoxidation of **4** with *m*-chloroperoxybenzoic acid by the procedure of Marshall and Hochstetler (10) gave in 91% yield a 3:2 mixture of the epoxides **8** and **9**, whose stereochemistry has been established by these workers (10). In our hands, reaction of this mixture with aqueous perchloric acid in tetrahydrofuran (11) gave a mixture of diols, olefins, and unconsumed **9**. We found that the mixture of epoxides underwent selective epoxide opening upon treatment with catalytic quantities of *p*-toluenesulfonic acid in boiling aqueous dioxane to give a 4:1 mixture of *trans* and *cis* fused diols **12** and **13** in 89% yield. In the ^{1}H nmr spectrum of this mixture the C*H*OH proton signal of **12** was observed as a narrow multiplet at δ 3.50, while a broad multiplet at δ 3.83 is ascribed to the corresponding proton of **13**, evidencing the preference of the *cis* fused diol for the steroid-like decalin conformation **13***A* rather than for **13***B*. Among other features **13***A* permits intramolecular hydrogen bonding, which is not possible in the nonsteroidal conformer **13***B*. By analogy with the acid-catalyzed reactions of steroidal oxirane systems (1), the A/B-*trans* and A/B-*cis* epoxides **8** and **9** are considered to open with *trans* diaxial selectivity. Thus, the *cis* fused diol **13** is postulated to arise from such opening of the nonsteroidal conformer **9***B*, rather than from the steroidal conformer **9***A*.

Oxidation of the mixture of diols **12** and **13** with *N*-bromo-



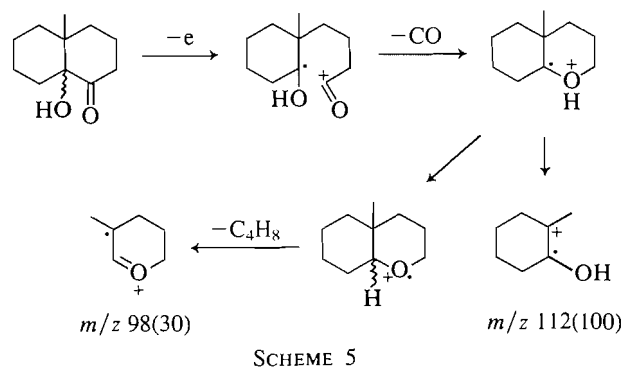
succinimide and pyridine in dichloromethane (12), a procedure that we found superior to the more frequently used *N*-bromosuccinimide in aqueous dioxane, gave a mixture of **1** and unconsumed diol **13** (Scheme 3), which were separated chromatographically. As observed in the ^{1}H nmr spectra of the steroidal 5α-ketols (1), the C-2 proton in **1** with a 1,3-diaxial relationship to the hydroxyl group is deshielded and gives rise to a multiplet at δ 3.04–3.13.

Equilibration of the *trans* ketol **1** with its *cis* epimer **2** was effected with methanolic potassium hydroxide (cf. ref. 13) (Scheme 4). The *cis* ketol **2** was isolated by flash chroma-



SCHEME 4

tography. The equilibrium ratio of **1** and **2** is 7:93, as shown by equilibration of either ketol under these conditions. In the ^{1}H nmr spectrum of *cis* ketol **2**, the sharp signal of the hydroxyl proton at δ 3.81 witnesses the presence of a strong intramolecular hydrogen bond (14) and thus the preference of **2** for the steroid-like conformation **2***A*. The mass spectra of **1** and **2** are essentially identical. Both exhibit base peaks at *m/z* 112 attributed to an ion arising from cleavage of the molecular ion followed by fragmentation (Scheme 5). Peaks at *m/z* 98 are



SCHEME 5

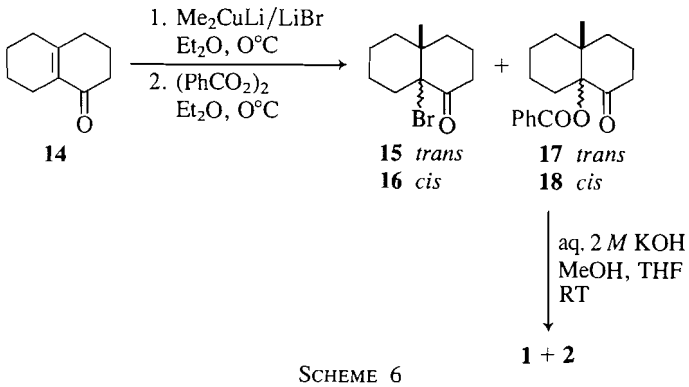
assigned to the bicyclic analogue of the ion considered to give rise to the base peak in the mass spectra of the corresponding steroidal 5β-ketols (1). While the steroidal 5α-ketols do not fragment in this manner, both the *trans* and *cis* bicyclic α-ketols exhibit *m/z* 98 peaks in their spectra. In the uv spectra of α-hydroxycycloalkanones, the position of the maximum depends on the spatial relationship between the carbonyl and hydroxyl

[1]Differences between metal catalyst and peroxy acid reagents in the stereoselectivity of olefin epoxidations have been observed previously (7, 9).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.222.148.141 on 09/07/12
For personal use only.

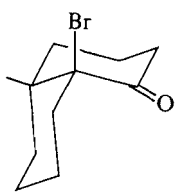
groups (15). Comparison of the uv and photoelectron spectra of 2-hydroxy- and 2-methoxycyclohexanone led Brown (16) to conclude that a marked blue shift of the $n \rightarrow \pi^*$ transition in the uv spectrum of the former is attributable to intramolecular hydrogen bonding. Consistent with this conclusion, the uv spectrum of the *cis* ketol **2** exhibits a maximum at 280 nm, hypsochromically shifted from that observed at 298 nm for the *trans* ketol **1**.

In a more contemporary approach, the *trans* and *cis* ketols **1** and **2** were also synthesized by the use of cuprate methodology. The pivotal intermediate, enone **14**, was prepared by a slight modification of the procedure of Rae and Umbrasas (17). The previous successful trapping of ketone enolates by benzoyl peroxide (18)[2] prompted us to treat enone **14** with lithium dimethylcuprate (19)[3] and to add the enolate thus formed to a suspension of benzoyl peroxide. However, the anticipated benzoyloxy ketones **17** and **18** constituted only a minor fraction of the crude reaction product, the major components being the *trans* and *cis* bromo ketones **15** and **16** (Scheme 6).



SCHEME 6

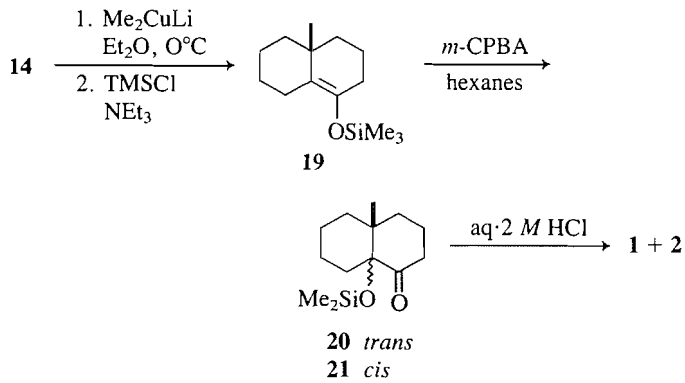
The epimeric bromo ketones **15** and **16** were separated chromatographically. The *trans* isomer **15** exhibits a carbonyl-stretching band at 5.84 μm in its ir spectrum and the position of this band, relative to that at 5.85 μm for the mixture of *trans* and *cis* 1-decalones **10** and **11**, establishes the axial orientation of the bromine substituent (20). The chemical shift of the methyl singlet (δ 1.03; $\Delta\nu$ 62 Hz) in the ^{1}H nmr spectrum of **15** correlates well with the predicted (21) 19-Hz deshielding of the methyl singlet of *trans* 1-decalone **10** (δ 0.77; $\Delta\nu$ 46 Hz). A multiplet at δ 3.30–3.90 (width ~ 36 Hz) is attributed to the C-2 proton that is 1,3-diaxial to the bromine substituent (22). The *cis* bromo ketone **16** exhibits a carbonyl-stretching band at 5.86 μm in its ir spectrum. As this is again indicative of an axial bromine substituent, it establishes the preference of the *cis* bromo ketone for the nonsteroidal decalin conformation **16***A*.



16*A*

[2]The synthetic utility of the trapping of enolate intermediates was first exploited by P. Deslongchamps (University of Toronto Chemistry Club Lecture, 1981).

[3]Cuprous bromide was used for the preparation of the cuprate reagent since the more commonly used cuprous iodide would have led to the reduction of the benzoyl peroxide.



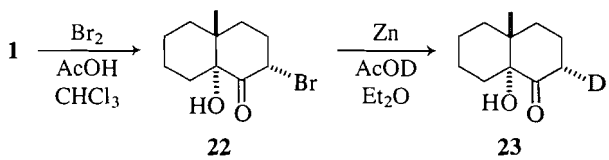
SCHEME 7

Low-halide lithium dimethylcuprate solutions (23) were employed in the above reaction in attempts to circumvent the formation of the bromo ketones. However, the yields of the benzoyloxy ketones **17** and **18** were not improved. These were not separated, but the methyl singlets at δ 0.98 and 1.27 in the ^{1}H nmr spectrum of the mixture of **17** and **18** can be assigned to the *trans* and *cis* isomers, respectively, since the methyl signal of the *trans* ketol **1** (δ 0.86) is expected to be less affected by benzoylation than that of the *cis* ketol **2** (δ 0.80). Hydrolysis of the mixture of **17** and **18** (Scheme 6) gave the *trans* and *cis* ketols **1** and **2** in 34 and 32% yield, respectively.

Since direct trapping of the enolate derived from cuprate addition to **14** had not proven efficient, the stepwise sequence shown in Scheme 7 was used for the preparation of **1** and **2**. The enolate formed by reaction of lithium dimethylcuprate with enone **14** was treated *in situ* with chlorotrimethylsilane and triethylamine to give the enol silyl ether **19** in quantitative yield. Treatment of this with *m*-chloroperoxybenzoic acid in anhydrous hexanes (cf. ref. 24)[4] yielded a crude mixture considered to consist largely of the *trans* and *cis* trimethylsiloxy ketones **20** and **21**, which were not fully characterized. Hydrolysis with aqueous acid gave the *trans* and *cis* ketols **1** and **2** in 53 and 16% yield, respectively (based on the enol silyl ether **19**).

Synthesis of 2α-deutero bicyclic ketols

Bromination of the *trans* ketol **1** and reductive cleavage of the resulting 2-bromo ketol **22** with zinc and *O*-deuteroacetic acid provided a highly stereoselective synthesis of the 2α-deutero *trans* ketol **23** (Scheme 8). Spectrometric analysis evidenced

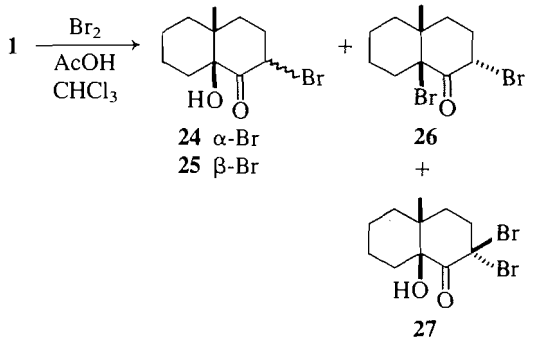


SCHEME 8

excellent incorporation of a single deuterium label into the ketol: d_0 6%, d_1 92%, d_2 2%.

The α stereochemistry of the deuterium atom in **23** was ascertained from its 400-MHz ^{1}H nmr spectrum. The intensity of the weak, broad multiplet at δ 3.00–3.18, which is assigned to the C-2α proton in **1**, relative to the methyl singlet indicated that the C-2α position was 84% deuterated in **23**. Given the

[4]Hexanes proved to be a better solvent than dichloromethane for this reaction; cf. the earlier report of a remarkable solvent effect of ether vs. dichloromethane (25).



SCHEME 9

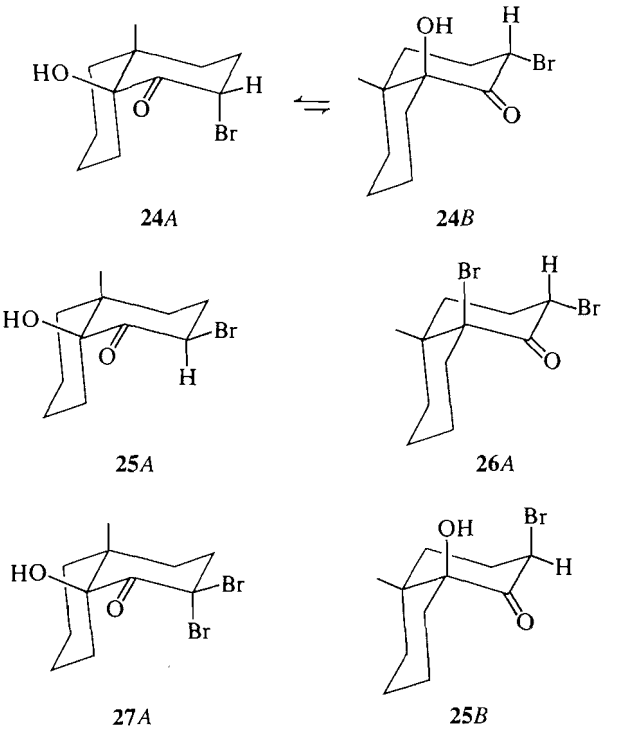
margin of error of the method, the 92% d_1 content calculated from the mass spectrum correlates well with that calculated from the ^{1}H nmr spectrum, and establishes that essentially all the deuterium label was incorporated into the C-2α site.

Bromination of the *cis* ketol **2** under the same reaction conditions led to a complex mixture comprised of the 2α- and 2β-bromo *cis* ketols **24** and **25**, the dibromo ketone **26**,[5] and the dibromo *cis* ketol **27** (Scheme 9).[6]

The structural assignments for the bromo compounds **24–27** rely heavily on the positions of the carbonyl-stretching bands in their ir spectra and known equatorial and axial bromine effects on such bands (20), the width and chemical shifts[7] of low-field C*H*Br multiplets (when present) in the ^{1}H nmr spectra, the chemical shifts of carbonyl carbon signals in the ^{13}C nmr spectra, and the characteristic relative intensities of isotopic clusters associated with the molecular ions in the mass spectra.

The 2α- and 2β-bromo *cis* ketols **24** and **25** exhibit carbonyl-stretching bands in their ir spectra at 5.87 and 5.79 μm, respectively, reflecting the effects of axial and equatorial bromine substituents, as present in the preferred steroidal conformers **24***A* and **25***A* on the position of the carbonyl band relative to that of the parent *cis* ketol **2** (5.85 μm). The α epimer **24** also exhibits a weaker band at 5.77 μm suggestive of the presence of the nonsteroidal conformer **24***B*, in which the bromine is equatorial. These assignments for the bromo ketols **24** and **25** were confirmed by the width of the C*H*Br multiplets in their ^{1}H nmr spectra. That of the 2α-bromo ketol **24** displays a triplet-like multiplet of width 12 Hz, which lies between the widths considered to be indicative of axial and equatorial bromine substitution (27, 28). This intermediate width for the C*H*Br multiplet is in accord with the postulated equilibrium between the two conformers **24***A* and **24***B*. A sharp singlet at δ 3.72 assigned to the hydroxyl proton (14) and a broad C*H*Br multiplet (width = 20 Hz) demonstrate the preference of the 2β-bromo ketol **25** for the hydrogen-bonded conformer **25***A*. In the ^{13}C spectra of **24** and **25**, both give rise to signals at δ 206, shielded relative to the carbonyl carbon signal of **2** (δ 215).

The presence of two bromine atoms in ketone **26** is indicated by the high-field carbonyl carbon signal at δ 196 in its ^{13}C nmr spectrum (29) and by the 1:2:1 ratio of the isotopic cluster



associated with the molecular ion in its mass spectrum. Comparison of the carbonyl-stretching band at 5.78 μm in its ir spectrum with that of the mixture of *trans* and *cis* 1-decalones **10** and **11** at 5.86 μm indicates that one bromine atom is equatorial, the other axial. In the ^{1}H nmr spectrum of **26**, the chemical shift of the methyl singlet (δ 1.33) compared to the chemical shifts of the methyl singlets of the *trans* and *cis* fused 8α-bromo ketones **15** and **16** (δ 1.03 and 1.32, respectively) indicates the *cis* fusion of the dibromo ketone **26**. Since the *cis* bromo ketone **16** exists in the nonsteroidal decalin conformation (*vide supra*), the excellent correlation between the chemical shifts of the pertinent methyl singlets noted above, together with the broad multiplet (width = 20 Hz) given by the C*H*Br proton, provides compelling evidence that **26** prefers to exist as the nonsteroidal decalin conformer **26***A*.

The gross structural assignment for the dibromo ketol **27** is based on the characteristic two-bromine 1:2:1 ratio of peaks related to the molecular ion in its mass spectrum and the absence of a low-field C*H*Br signal in its ^{1}H nmr spectrum. A sharp singlet at δ 3.27, in the latter signifying a hydrogen-bonded hydroxyl proton (14), indicates the *cis* ring fusion and the preference for the steroid-like decalin conformation **27***A*.

The ^{1}H nmr spectrum of the crude product obtained from bromination of the *cis* ketol **2** (Scheme 9) indicates that the predominant brominated product is the 2α-bromo *cis* ketol **24**. This was partially converted to its thermodynamically more stable epimer **25** during silica gel chromatography, and the close similarity of the R_f values of **24** and **25** rendered purification of the former difficult. Consequently, the ~4:1 mixture of 2α- and 2β-bromo ketols was stirred with a silica gel slurry to give a mixture rich in the β epimer **25**. Chromatographic purification of this proved much easier than that of **24**.

Reaction of **25** with zinc and *O*-deuteroacetic acid gave the 2α-deutero *cis* ketol **28**. As zinc and acetic acid mediated reductive cleavage of α-bromo ketones is known to occur with greater facility for axial than for equatorial orientations of the bromine (30), this reaction may be envisioned to proceed

[5]Replacement of the hydroxyl group by bromine with retention of configuration has been observed in the reactions of 5-hydroxy-5α-cholestan-4- and -6-ones with hydrobromic acid (26).

[6]In contrast, bromination of the related 5-hydroxy-5β-cholestan-6-one occurs stereoselectively to give the 7α-bromo derivative (1).

[7]An equatorial C*H*Br proton in an axial bromo ketone resonates in general at higher field than an axial C*H*Br proton in an equatorial bromo ketone (ref. 22, pp. 73–75).

28 X = H
29 X = D

via one or both the following pathways: (*i*) a less favorable reductive cleavage of the equatorial bromine substituent from the preferred steroidal conformer **25***A* and (*ii*) reaction of a small equilibrium concentration of the less favored conformer **25***B* in which the bromine is axial. The equilibrium of **25***A* with **25***B* may be catalyzed by the *O*-deuteroacetic acid in the medium. As evidenced by the mass spectrum of **28**, excellent incorporation of deuterium into the *cis* ketol was achieved by this method: d_0 7%, d_1 91%, d_2 1%.

The α stereochemistry of the deuterium label in **28** is indicated by its ^{1}H nmr spectrum, which differs from that of the undeuterated *cis* ketol **2** by the greatly reduced intensity of the multiplet at δ 2.56–2.74, whose width (35 Hz) suggests that it corresponds to the C-2α proton. Verification of the assignment of this signal to the C-2α proton was achieved from the ^{1}H nmr spectrum of the α,α-dideutero ketol **29**, prepared by two successive treatments of **2** with deuterium oxide in the presence of potassium carbonate. Relative to the spectrum of the undeuterated **2**, that of **29** lacks two multiplets, δ 2.34–2.45 (width = 23 Hz) and δ 2.56–2.74 (width = 35 Hz), assigned on the basis of their widths to the C-2β (equatorial) and C-2α (axial) protons, respectively, in **2**.

The intensity of the weak multiplet at δ 2.56–2.74 in the ^{1}H nmr spectrum of the monodeutero ketol **28**, indicates that 83% of the deuterium label has been incorporated into the α site. In comparison with the total deuterium content calculated from the mass spectrum (91%), the ^{1}H nmr spectrum indicates that essentially all of the label has the α stereochemistry. Furthermore, the multiplet at δ 2.28–2.44, comprising the C-2β proton signal and an overlapping signal that was not assigned, corresponds to two protons (relative to the methyl singlet), demonstrating that negligible deuteration has occurred at this site. Thus deuterium is incorporated with high stereoselectivity at the α site in **28**.

Experimental[8]

*Reduction of **3** with lithium aluminum hydride and aluminum chloride. Formation of 4a-methyl-1,2,3,4,4a,5,6,7-octahydronaphthalene (**4**) and 4a-methyl-*trans- *and* -cis-*3,4,4a,5,6,7,8,8a-octahydronaphthalene (**5** and **6**)*

Anhydrous aluminum chloride (2.69 g, 20.2 mmol) under argon was cooled to −97°C in a dichloromethane – Dry Ice bath and anhydrous ether (25 mL) was added with stirring over a period of 20 min. The grey, gummy mixture was allowed to warm slowly to room temperature to give a grey solution. Lithium aluminum hydride (0.387 g, 10.2 mmol) was added in portions over a period of 20 min. The resulting grey-white suspension was stirred and treated dropwise with a solution of **3** (31, 32) (0.946 g, 5.77 mmol) in ether (10 mL), and the mixture was boiled under reflux for 30 min. The colorless solution containing a brown-black precipitate was allowed to cool and was filtered. Ether – ethyl acetate (1:1 v/v; 30 mL) was added dropwise to the filtrate, and the resulting cloudy mixture was cooled in an ice bath and treated cautiously with water (10 mL). The organic layer was separated, washed with saturated aqueous $NaHCO_3$ (15 mL) and water (3 × 5 mL), and dried (Na_2SO_4). The solvent was removed by distillation at atmospheric pressure leaving a pale yellow liquid residue (0.87 g, 100%) shown by its ^{1}H nmr spectrum to be composed of **4** (~60%) and a 75:25 mixture of **5** and **6** (~40%); ^{1}H nmr δ: 0.80 (s, $\Delta^{7,8}$ Me—minor isomer), 0.93 (s, $\Delta^{7,8}$ Me—major isomer), 1.10 (s, **4** Me), 5.28 (m, **4** vinyl proton), 5.50 (m, $W_{1/2}$ = 4 Hz, $\Delta^{7,8}$ vinyl protons).

*4a-Methyl-1,2,3,4,4a,5,6,7-octahydronaphthalene (**4**)*

Sodium (20.7 g, 0.902 mol) was added over a period of 1.5 h to a stirred suspension of **7** (33) (10.1 g, 0.042 mol) in liquid ammonia (1.2 L) containing anhydrous ether (50 mL) and anhydrous *tert*-butyl alcohol (50 mL) at −33°C. The blue reaction mixture was maintained at reflux for 1 h and ethanol (200 mL) was added slowly; the ammonia was allowed to evaporate overnight. The residue was treated with ether (450 mL) and the mixture was filtered through Celite into water (200 mL). The Celite was washed with a further 100 mL of ether, and the aqueous phase was extracted with ether (4 × 25 mL). The combined organic phases were washed with saturated aqueous NaCl (30 × 25 mL) and dried ($MgSO_4$), and the ether was removed by distillation at atmospheric pressure. Hexanes (1 L) were added and the ethanol and *tert*-butyl alcohol were removed by azeotropic distillation at atmospheric pressure. Distillation of the residue using a Kugelrohr (92–94°C/14 Torr; 1 Torr = 133.3 Pa) gave **4** (4.74 g, 76%) as a colorless liquid; ir λ_{max}(neat): 5.98 (w) μm; ^{1}H nmr δ: 1.07 (s, 3H), 1.30–2.17 (m, 14H), 5.30 (m, $W_{1/2}$ = 7 Hz, 1H); ms *m/z*: 150 (70), 135 (100).

Preparation of anhydrous tert*-butyl hydroperoxide in benzene*

A 125-mL separatory funnel was charged with benzene (50 mL) and 70% *tert*-butyl hydroperoxide (13 mL). The mixture was swirled for 1 min, and the organic layer was transferred to a 250-mL round-bottomed flask. Boiling chips were added and the benzene–water azeotrope was distilled from a steam bath; the distillation was terminated when the boiling point of the distillate remained constant at 80°C. An estimate of the *tert*-butyl hydroperoxide concentration in benzene was obtained from the ^{1}H nmr spectrum by comparison of the areas of the *tert*-butyl and benzene proton signals; typical values were in the range of 1.4–1.8 *M*.

*Oxidation of **4** with molybdenum hexacarbonyl and* tert*-butyl hydroperoxide. Formation of 8a-hydroxy-4a-methyl-*trans- *and* -cis-*octahydronaphthalen-1-(2*H*)-one (**1** and **2**) and 4a-methyl-*trans- *and* -cis-*octahydronaphthalen-1(2*H*)-ones (**10** and **11**)*

A solution of freshly prepared anhydrous *tert*-butyl hydroperoxide in benzene (1.76 *M*; 35.0 mL, 61.6 mmol) was added dropwise over a period of 2 h to a stirred mixture of **4** (405 mg, 2.70 mmol) and molybdenum hexacarbonyl (54 mg, 0.20 mmol) in anhydrous benzene (35 mL) in an oil bath at 80°C under a nitrogen atmosphere. The mixture was heated for a further 4 h, and the resulting yellow solution was cooled and added to a stirred solution of aqueous 10% Na_2SO_3 (150 mL) cooled in ice. After starch–KI test paper acidified with aqueous 2 *M* HCl gave a negative test, the benzene – *tert*-butyl alcohol – water azeotrope was distilled at atmospheric pressure and the residue was extracted with ether (75 mL, 3 × 25 mL). The combined ethereal extracts were washed with saturated aqueous NaCl (4 × 20 mL), dried ($MgSO_4$), and concentrated. The residue (420 mg) was flash chromatographed on a 2.5 × 15 cm silica gel column with hexanes–ether (4:1 v/v) as eluent. A mixture of *cis* ketol **2** and ketones **10** and **11** (100 mg) was eluted first followed by *trans* ketol **1** (220 mg, 45%), contaminated with a small amount of *tert*-butyl-containing impurity. Sublimation (90–92°C/760 Torr) gave **1** (86 mg, 18%) as white needles, mp 105–114°C. The mixture of compounds **2**, **10**, and **11** was flash chromatographed again on a 1 × 14 cm silica gel column using dichloromethane–hexanes (1:1 v/v) as eluent to give first a mixture (~85:15)[9] of ketones **10** and **11** (25 mg, 5%) as a colorless liquid; ir λ_{max}: 5.86 μm; ^{1}H nmr δ: 0.80 (s, *trans* Me), 1.0 (s, *cis* Me); vpc retention time (3% OV-17; 140°C): 2.26 min, *cis* and *trans* isomers not separated. Further elution with dichloromethane gave the *cis* ketol **2**

[8]For a general description of the experimental procedures used, see refs. 1 and 2*b*.

[9]This ratio was estimated from the relative heights of the methyl singlets in the ^{1}H nmr spectrum.

(29 mg, 6%) as a colorless liquid; vpc retention time (3% OV-17; 140°C): 2.68 min.

*4a-Methyl-*trans- *and* -cis-*decahydronaphthalene-*trans-*1,8a-diols (12 and 13)*

A solution of the mixture of epoxides **8** and **9** (10) (1.19 g, 7.16 mmol) and *p*-toluenesulfonic acid monohydrate (76 mg, 0.40 mmol) in 9:1 (v/v) dioxane–water (50 mL) was boiled at reflux for 1.5 h, cooled, and poured into aqueous 10% Na_2CO_3 (50 mL). The dioxane was removed as a dioxane–water azeotrope using a rotary evaporator fitted with a cold trap condenser under water aspirator pressure. The residue was extracted with ether (80 mL, 3 × 20 mL), and the combined ether phases were washed with saturated aqueous NaCl (3 × 20 mL), dried (Na_2SO_4), and concentrated to give a 4:1[9] mixture of diols **12** and **13** (1.18 g, 89%) as a white solid; ir λ_{max}: 2.76 (sh, w), 2.86 (br, w) μm; ^{1}H nmr δ: 0.87–2.47 (m), 0.97 (s, *cis* Me), 1.23 (s, *trans* Me), 1.35 (m, OH, exchanges with D_2O), 3.50 (nar m, $W_{1/2}$ = 6 Hz, *trans* C*H*OH), 3.83 (br m, *cis* C*H*OH); ms *m/z*: 184 (20), 112 (100).

*8a-Hydroxy-4a-methyl-trans-octahydronaphthalen-1(2*H*)-one (1)*

A solution of a 4:1 mixture of diols **12** and **13** (329 mg, 1.79 mmol) in dichloromethane (20 mL) was treated with pyridine (175 μL, 2.16 mmol) and *N*-bromosuccinimide (341 mg, 1.92 mmol), and the mixture was allowed to stand with occasional swirling at room temperature for 3.5 h. The resultant orange solution was added to aqueous 10% $NaHSO_3$ (25 mL). The aqueous phase was extracted with ether (3 × 30 mL), and the combined organic phases were washed with aqueous 2 *M* HCl (2 × 20 mL), saturated aqueous $NaHCO_3$ (20 mL), and saturated aqueous NaCl (3 × 15 mL), dried (Na_2SO_4), and concentrated to give a mixture of *trans* ketol **1** and unconsumed *cis* fused diol **13** as a pale yellow solid (358 mg). Chromatography on neutral alumina with chloroform–ether (4:1 v/v) as eluent gave **1** (242 mg, 74%) as a white solid. Crystallization from hexanes gave white needles, mp 112–114°C. Sublimation (85°C/15 Torr) followed by crystallization from hexanes raised the melting point to 115–115.5°C; ir λ_{max}: 2.78 (sh, w), 2.90 (br, w), 5.83 μm; uv λ_{max}(EtOH): 298 nm (ε 31); ^{1}H nmr (400 MHz) δ: 0.86 (s, 3H), 1.05–1.20 (m, 2H), 1.41–1.64 (m, 5H), 1.76–1.91 (m) and 1.87 (br s, OH, exchanges with D_2O) (5H), 2.05–2.16 (m, 2H), 3.04–3.13 (m, width = 34 Hz, 1H); ms *m/z*: 182 (24), 112 (100). *Anal.* calcd. for $C_{11}H_{18}O_2$: C 72.49, H 9.96; found: C 72.47, H 9.88.

Further elution gave unconsumed **13** (44 mg, 13%) as a pale yellow oil; ^{1}H nmr δ: 0.80–2.13 (m), 0.97 (s), 1.87 (m, OH), 3.83 (br m, $W_{1/2}$ = 20 Hz, 1H).

Epimerization of 1. Formation of 2

A solution of **1** (2.96 g, 16.3 mmol) in methanol (25 mL) was added dropwise over a period of 10 min to a stirred solution of methanolic 10% KOH (250 mL), and the solution was heated at reflux under an argon atmosphere for 18 h. The resultant orange-red solution was shown by gas chromatography (3% OV-17; 140°C) to contain **2** and **1** in a ratio of 93:7. Ether (200 mL) was added, and the mixture was poured into water (200 mL). The aqueous phase was extracted with ether (2 × 100 mL, 4 × 50 mL). The combined ethereal phases were washed with saturated aqueous NaCl (6 × 10 mL), dried (Na_2SO_4), and concentrated. The residual orange liquid (2.82 g) was flash chromatographed on silica gel (4 × 19 cm) with dichloromethane–ether (98:2) to give **2** (2.20 g, 74%) as a yellow liquid. Molecular distillation (134°C/20 Torr) gave **2** (1.82 g, 61%) as a colorless liquid, which solidified on the cold finger of the molecular distillation apparatus (water temperature 20°C) and melted as the cold finger was allowed to warm to room temperature; ir λ_{max}(neat): 2.88 (sh, m), 5.83, 8.04 (m), 8.70 (m), 9.41 (m), 9.80 (m), 10.62 (m) μm; uv λ_{max}(EtOH): 280 nm (ε 33); ^{1}H nmr (200 MHz) δ: 0.80 (s, 3H), 1.14–2.16 (m, 11H), 2.28–2.45 (m, 2H), 2.56–2.74 (m, width = 35 Hz, 1H), 3.81 (m, OH, exchanges slowly with D_2O, 1H); ms *m/z*: 182 (19), 112 (100). *Accurate Mass* calcd. for $C_{11}H_{18}O_2$: 182.1307; found: 182.1294. *Anal.* calcd. for $C_{11}H_{18}O_2$: C 72.49, H 9.96; found: C 72.34, H 9.98.

Further elution with dichloromethane–ether (95:5 v/v) gave **1** (0.54 g, 18%) as a white solid.

*3,4,5,6,7,8-Hexahydronaphthalen-1(2*H*)-one (14)*

Compound **14** was prepared by a modification of the method of Rae and Umbrasas (17). Colorless polyphosphoric acid (Aldrich; 27.9 g), stirred and heated in an oil bath at 105°C, was treated dropwise with 4-cyclohexylidenebutyric acid (17) (2.73 g, 16.3 mmol). The mixture was heated at 110–115°C under argon for 4 h, and the cooled, brown syrup was poured with stirring onto ice-water (100 g). The mixture was stirred under argon at 0°C overnight and extracted with ether (150 mL, 4 × 50 mL, 3 × 20 mL). The combined ethereal phases were washed with saturated aqueous $NaHCO_3$ (50 mL, 20 mL) and saturated aqueous NaCl (3 × 20 mL), dried (Na_2SO_4), and concentrated to give **14** as an orange liquid (2.96 g). The ^{1}H nmr spectrum indicated that **14** was contaminated with 3% of tetralin. Distillation (oil bath 120°C/15 Torr) first removed the tetralin as a colorless liquid; ir λ_{max}(neat): 3.37 (w), 6.70 (m), 6.88 (m), 12.37 (w), 13.40 (v br) μm; ^{1}H nmr δ: 1.77 (m, 4H), 2.77 (m, 4H), 7.33 (s, 4H); ms *m/z*: 132 (70), 104 (100). Compound **14** (2.08 g, 85%) then distilled as a colorless liquid, bp 132°C/15 Torr (lit. (17) bp 120°C/14 Torr); ir λ_{max}(neat): 5.99, 6.11, 7.31, 7.77, 8.35 μm; ^{1}H nmr δ: 1.47–2.53 (m, maxima at δ 1.60 and 2.20); ms *m/z*: 150 (82), 122 (100).

*Reaction of lithium dimethylcuprate with 14 and trapping of the resulting enolate with benzoyl peroxide. Formation of 8a-bromo-4a-methyl-*trans- *and* -cis-*octahydronaphthalen-1(2*H*)-one (15 and 16) and 8a-benzoyloxy-4a-methyl-*trans- *and* -cis-*octahydronaphthalen-1(2*H*)-one (17 and 18)*

Cuprous bromide (0.97 g, 6.8 mmol), prepared by the reduction of cupric bromide with Na_2SO_3 according to the method of Theis and Townsend (34), was stirred in anhydrous ether (24 mL) under argon and cooled in an ice bath. A solution of methyllithium – lithium bromide complex in ether (1.82 *M*; 7.0 mL, 13 mmol) was added dropwise, followed by a solution of compound **14** (0.400 g, 2.67 mmol) in anhydrous ether (3 mL), also added dropwise. The resulting mixture was stirred at 0°C for 24 h and added via cannula to a stirred suspension of anhydrous benzoyl peroxide (Aldrich; 2.58 g, 10.7 mmol) in anhydrous ether (45 mL) cooled in an ice bath. After the mixture had been stirred at 0°C for 2.5 h, the reddish-brown color that initially formed faded, and the resulting brown suspension was added to aqueous 10% NH_3 (75 mL) cooled in an ice bath. The two-phase mixture was stirred and allowed to warm to room temperature overnight, when it was poured with stirring into cold (10°C) aqueous 10% Na_2SO_3 (300 mL). When starch–KI paper acidified with aqueous 2 *M* HCl gave a negative test, the layers were separated, and the blue aqueous phase was extracted with ether (3 × 25 mL). The ethereal phases were combined, washed with saturated aqueous NaCl (5 × 10 mL), dried (Na_2SO_4), and concentrated to a yellow oil (636 mg). Flash chromatography on silica gel (2 × 11 cm) with hexanes – ethyl acetate (9:1 v/v) as eluent gave a 3:2[9] mixture of bromo ketones **15** and **16** (416 mg, 64%) as a white solid. Further elution gave a yellow oil comprised of a 45:55[9] mixture of benzoyloxy ketones **17** and **18** (183 mg, 23%), which could not be separated; ir λ_{max}: 5.79 μm; ^{1}H nmr δ: 0.98 (s, *trans* Me), 1.27 (*cis* Me), 1.40–2.80 (m, 14H), 7.40–7.60 (m, 3H), 7.93–8.17 (m, 2H); ms *m/z*: 286 (3), 105 (100). *Accurate Mass* calcd. for $C_{18}H_{22}O_3$: 286.1569; found: 286.1569.

Partial separation of the bromo ketones **15** and **16** was achieved by flash silica gel chromatography with hexanes – ethyl acetate (97:3 v/v). Compound **16** was eluted first, and crystallization from pentane gave a white powder, mp 91–94°C; ir λ_{max}: 5.86 μm; ^{1}H nmr δ: 1.32 (s, 3H), 1.40–3.63 (m, 14H); ms *m/z*: 246 (4), 244 (4), 165 (100). *Accurate Mass* calcd. for $C_{11}H_{17}OBr$: 246.0444, 244.0463; found: 246.0465, 244.0464.

Following a mixed fraction, **15** was eluted. Crystallization from pentane gave white needles, mp 118–120°C; ir λ_{max}: 5.84 μm; ^{1}H nmr δ: 1.03 (s, 3H), 1.10–2.57 (m, 13H), 3.13–3.90 (m, 1H); ms *m/z*: 246 (15), 244 (15), 165 (100). *Accurate Mass* calcd. for $C_{11}H_{17}OBr$: 246.0444, 244.0463; found: 246.0456, 244.0459. *Anal.* calcd. for $C_{11}H_{17}OBr$: C 53.87, H 6.99, Br 32.61; found: C 53.93, H 7.04, Br 32.58.

Hydrolysis of the mixture of 17 and 18. Formation of 1 and 2

A 45:55[9] mixture of **17** and **18** (74 mg, 0.26 mmol) was dissolved in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.222.148.141 on 09/07/12
For personal use only.

tetrahydrofuran–methanol (2:1 v/v; 4 mL), and the solution was stirred with aqueous 2 *M* KOH (3 mL) at room temperature for 48 h. Water (10 mL) was added, and the mixture was extracted with ether (25 mL, 4 × 10 mL). The ethereal extracts were washed with saturated aqueous NaCl (3 × 10 mL), dried (Na_2SO_4), and concentrated to a colorless oil (40 mg), the ^1H nmr spectrum of which showed it to be a 45:55[9] mixture of **1** and **2**. Flash chromatography on silica gel (1.5 × 11 cm) with dichloromethane–ether (98:2 v/v) as eluent gave **2** (15 mg, 32%) as a colorless liquid. Further elution afforded **1** (16 mg, 34%), crystallized from hexanes as white needles, mp 113–114°C.

*4a-Methyl-8-(trimethylsiloxy)-1,2,3,4,4a,5,6,7-octahydronaphthalene (**19**)*

A solution of lithium dimethylcuprate in ether under argon was prepared by the dropwise addition of a solution of methyllithium – lithium bromide complex in ether (1.53 *M*; 13.0 mL, 19.9 mmol) to a cold (0°C), stirred suspension of cuprous iodide (1.90 g, 9.97 mmol) in anhydrous ether (35 mL). A solution of **14** (0.60 g, 4.0 mmol) in anhydrous ether (5 mL) was added dropwise over a period of 20 min, and the mixture was stirred at 0°C for 28 h. In a septum-capped centrifuge tube, anhydrous chlorotrimethylsilane (10.4 mL, 0.082 mmol) was added to anhydrous triethylamine (9.0 mL, 0.065 mmol); the white precipitate that formed was centrifuged, and the clear liquid was added via cannula to the yellow cuprate suspension. The mixture was stirred at 0°C under argon for 1 h, and cold (0°C) saturated aqueous $NaHCO_3$ (10 mL) was added dropwise over a period of 15 min. The gummy greyish-white precipitate that formed was filtered and washed with ether (3 × 20 mL). Water (50 mL) was added to the filtrate, the layers were separated, and the aqueous phase was extracted with ether (5 × 50 mL). The combined ethereal phases were washed with cold (0°C) aqueous 2% NH_3 (6 × 20 mL) and cold water (12 × 20 mL), dried (Na_2SO_4), and concentrated, with a drying tube containing self-indicating 6–20 mesh silica gel inserted between the aspirator and the rotary evaporator, to give the silyl enol ether **19** (0.97 g, quantitative) as a yellow liquid. Its ir and ^1H nmr spectra showed that this was essentially pure, and it was used without further purification in the following epoxidation procedure. Compound **19** could be obtained as a colorless liquid by molecular distillation (105°C/0.4 Torr); ir λ_{max}(neat): 5.97, 7.36, 8.81, 9.31, 9.71 μm; ^1H nmr δ: 0.17 (s, 9H), 1.07 (s, 3H), 1.23–2.27 (m, 13H), 2.68 (br d, J = 14 Hz, 1H).

*Epoxidation of **19** and hydrolysis of the resulting trimethylsiloxy ketones **20** and **21**. Formation of **1** and **2***

A solution of **19** (968 mg, 4.07 mmol) in anhydrous hexanes (5 mL) was added to a stirred suspension of *meta*-chloroperoxybenzoic acid (85%; 903 mg, 4.45 mmol) in anhydrous hexanes under argon and cooled to −13°C in an ice–methanol bath. The suspension became more flocculent during the addition. The cold bath was removed, and the suspension was stirred for 2 h following which a starch–KI test was negative. The suspension was filtered, and the solid was washed with hexanes (2 × 75 mL). The combined filtrate and washings were poured into aqueous 10% Na_2SO_3 (50 mL), and the organic layer was washed with saturated aqueous $NaHCO_3$ (2 × 10 mL) and saturated aqueous NaCl (4 × 10 mL), dried (Na_2SO_4), and concentrated to an off-white solid (1.4 g), considered to be a mixture of the trimethylsiloxy ketones **20** and **21**. The ir spectrum of the product exhibited a band at 5.84 μm, and the ^1H nmr spectrum displayed a distinctive singlet at δ 0.40. The solid was dissolved in ether (75 mL) and the solution was stirred with aqueous 2 *M* HCl (25 mL) at room temperature for 2 h. The aqueous phase was separated and extracted with ether (3 × 10 mL). The combined ethereal phases were washed with saturated aqueous $NaHCO_3$ (30 mL, 5 mL) and saturated aqueous NaCl (3 × 5 mL), dried (Na_2SO_4), and concentrated to give a yellow solid (742 mg). Flash chromatography on a silica gel column (3.5 × 15 cm) with the use of dichloromethane–pentane (95:5 v/v) as eluent gave **2** (116 mg, 16%) as a colorless liquid. Further elution with dichloromethane–ether (93:7 v/v) afforded **1** (393 mg, 53%) as a slightly off-white solid. Crystallization from hexanes gave **1** as white needles, mp 112–114°C.

*2α-Bromo-8a-hydroxy-4a-methyl-*trans*-octahydronaphthalen-1(2H)-one (**22**)*

A solution of **1** (136 mg, 0.75 mmol) in chloroform (5 mL) was treated with 2.28 mL of a solution of bromine (0.4 mL) in acetic acid (1 mL) and chloroform (20 mL). The red solution was allowed to stand at room temperature for 2 h, and the resulting gold colored reaction mixture was poured into aqueous 10% Na_2SO_3 (10 mL) and extracted with benzene (25 mL, 4 × 10 mL). The combined organic phases were washed with saturated aqueous $NaHCO_3$ (10 mL) and water (4 × 10 mL), dried (Na_2SO_4), and concentrated to a yellow solid (197 mg). Flash chromatography on silica gel (2 × 20 cm) with pentane–ether (4:1 v/v) as eluent gave **22** (145 mg, 75%) as a white solid. Crystallization from pentane afforded white needles, mp 79–80°C; ir λ_{max}: 2.93 (sh, w), 3.07 (br, w), 5.82 μm; ^1H nmr δ: 0.88 (s, 3H), 0.93–2.73 (m), 2.27 (s, OH), 4.28 (nar m, $W_{1/2}$ = 8 Hz, 1H); ms m/z: 262 (1), 260 (1), 112 (100). *Anal.* calcd. for $C_{11}H_{17}O_2Br$: C 50.57, H 6.56, Br 30.61; found: C 50.63, H 6.56, Br 30.66.

*2α-Deutero-8a-hydroxy-4a-methyl-*trans*-octahydronaphthalen-1(2H)-one (**23**)*

A solution of **22** (126 mg, 0.48 mmol) in ether (24 mL) was washed with D_2O (99.8%; 4 × 2 mL) and added via cannula to zinc dust (728 mg, 11.13 mmol) in a D_2O-pretreated flask under argon. The stirred suspension was treated dropwise with *O*-deuteroacetic acid (98%; 1.30 mL, 22.6 mmol), stirred at room temperature for 2.5 h, and neutralized by the addition of anhydrous Na_2CO_3 (12 g). The mixture was filtered, and the precipitate was washed with ether (3 × 15 mL). The filtrate was washed with 5% $NaHCO_3$ in D_2O (4 mL) and saturated aqueous NaCl (4 × 10 mL), dried over Na_2SO_4, and concentrated to give a pale yellow solid (85 mg). Sublimation (86°C/15 Torr) and crystallization from hexanes gave **23** (61 mg, 69%) as white needles, mp 113–114°C; ir λ_{max}: 2.94 (br, w), 5.83, 10.10 (w) μm; ^1H nmr (200 MHz) δ: 0.87 (s, 3H), 1.00–1.94 (m), 1.72 (s), 1.99–2.17 (m, 2H), 3.00–3.18 (m, 0.16H); ms m/z: 183 (24), 112 (100); d_0 6%, d_1 92%, d_2 2%.

*Bromination of **2**. Formation of 2α-bromo- and 2β-bromo-8a-hydroxy-4a-methyl-*cis*-octahydronaphthalen-1(2H)-one (**24** and **25**), 2α,8a-dibromo-4a-methyl-*cis*-octahydronaphthalen-1(2H)-one (**26**), and 2,2-dibromo-8a-hydroxy-4a-methyl-*cis*-octahydronaphthalen-1(2H)-one (**27**)*

A solution of **2** (217 mg, 1.19 mmol) in chloroform (8 mL) was treated with 3.64 mL of a solution of bromine (0.4 mL) in acetic acid (1 mL) and chloroform (20 mL). The red solution was allowed to stand at room temperature for 2 h, and the resulting colorless solution was poured into aqueous 10% Na_2SO_3 (10 mL). The mixture was extracted with benzene (40 mL), and the combined organic phases were washed with saturated aqueous $NaHCO_3$ (15 mL) and water (3 × 10 mL), dried over Na_2SO_4, and concentrated to give a pale yellow oil (359 mg), whose ^1H nmr spectrum showed the 2α-bromo *cis* ketol **24** to be the major product. Flash silica gel chromatography of the oil on a 2 × 19 cm column with pentane–ether (85:15 v/v) as eluent gave first the 2α,8a-dibromo ketone **26** (57 mg, 15%) as a white solid. Crystallization from pentane–methanol gave **26** as fine, white needles, mp 72–73.5°C; ir λ_{max}: 5.78, 8.79 (m) μm; ^1H nmr δ: 1.33 (s, 3H), 1.42–2.87 (m, 12H), 5.50–5.83 (m, width = 20 Hz, 1H); ms m/z: 326 (3), 324 (5), 322 (3), 245 (100). *Anal.* calcd. for $C_{11}H_{16}OBr_2$: C 40.75, H 4.98, Br 49.34; found: C 40.74, H 5.11, Br 49.34.

The 2,2-dibromo *cis* ketol **27** was eluted next and obtained as a colorless oil (37 mg, 9%). Molecular distillation (80°C/25 Torr) gave **27** as a colorless gummy solid that solidified on standing at 0°C; mp 60–62°C; ir λ_{max}: 2.96 (sh, m), 5.82, 8.87 (m), 9.78 (m), 10.19 (m), 11.47 (m) μm; ^1H nmr δ: 0.90 (s, 3H), 1.07–3.33 (m), 3.27 (s, OH); ms m/z: 342 (0.5), 340 (1), 338 (0.5), 112 (100). *Anal.* calcd. for $C_{11}H_{16}O_2Br_2$: C 38.83, H 4.74, Br 47.01; found: C 39.18, H 4.77, Br 46.73.

Further elution gave an 80:20[9] mixture of the bromo ketols **24** and **25** (224 mg, 72%). The β epimer **25** was eluted first and a fraction free of α epimer was isolated as a white solid (46 mg). Sublimation (70°C/25 Torr) gave fine white needles of **25**, mp 64–65.5°C; ir λ_{max}: 2.99 (sh, w), 5.79 μm; ^1H nmr δ: 0.86 (s, 3H), 1.13–2.80 (m, 12H), 3.72 (s, OH, 1H), 4.87–5.13 (m, width = 20 Hz, 1H); ms m/z: 262 (<1), 260 (<1), 135 (100). *Anal.* calcd. for $C_{11}H_{17}O_2Br$: C 50.57, H 6.56, Br 30.61; found: C 50.56, H 6.65, Br 30.89.

The mixture of **24** and **25** was repeatedly chromatographed as above with removal of the fractions containing **25**. In this manner, **24** (43 mg) contaminated by only a small amount of **25** could be isolated. Crystallization from pentane gave pure **24** as fine white needles, mp 74–76°C; ir λ_{max}: 3.00 (sh, m), 5.77, 5.87, 8.78 (m), 9.78 (m), 10.39 (m) μm; ^{1}H nmr δ: 0.92 (s, 3H), 1.33–2.67 (m, 12H), 2.93 (br s, OH, 1H), 4.73 (m, width = 12 Hz, 1H); ms *m/z*: 262 (2), 260 (2), 112 (100). *Anal.* calcd. for $C_{11}H_{17}O_2Br$: C 50.57, H 6.56, Br 30.61; found: C 50.62, H 6.63, Br 30.40.

*Epimerization of **24**. Formation of **25***

A solution of a ~75:25 mixture[9] of **24** and **25** (265 mg, 1.02 mmol) in pentane–ether (85:15 v/v; 10 mL) was added to a stirred suspension of 230–400 mesh silica gel (2.0 g) in pentane–ether (85:15 v/v; 10 mL). After 24 h the mixture was filtered through Celite and concentrated to give a mixture (~20:80)[9] of **24** and **25** (249 mg). Flash silica gel chromatography on silica gel (2 × 24 cm) with pentane–ether (85:15 v/v) as eluent gave **25** (187 mg, 71%) as a white solid followed by a colorless oil (43 mg, 16%), which was a mixture of **24** and **25**.

*2α-Deutero-8a-hydroxy-4a-methyl-*cis*-octahydronaphthalen-1(2*H*)-one (**28**)*

A solution of **25** (137 mg, 0.52 mmol) in ether (25 mL) was washed with D_2O (99.8%; 4 × 2 mL), and the organic phase was added via cannula to zinc dust (791 mg, 12.09 mmol) in a D_2O-pretreated flask under argon. The grey suspension was treated dropwise with *O*-deuteroacetic acid (98%; 1.45 mL, 25.1 mmol), stirred at room temperature for 2 h, and neutralized by the addition of anhydrous Na_2CO_3 (12 g). The mixture was filtered, and the grey-white solid was washed with ether (6 × 5 mL). The combined ethereal phases were washed with 5% $NaHCO_3$ in D_2O (4 mL) and saturated aqueous NaCl (4 × 20 mL), dried (Na_2SO_4), and concentrated. The residue on molecular distillation (92°C/15 Torr) gave **28** (79 mg, 82%) as a colorless liquid; ir λ_{max}: 3.00 (sh, m), 5.86, 8.74, 10.06 (w), 10.23 (w) μm; ^{1}H nmr (200 MHz) δ: 0.81 (s, 3H), 1.15–2.16 (m, 12H), 2.28–2.44 (m, 2H), 2.56–2.74 (m, 0.21H), 3.81 (s, 1H); ms *m/z*: 183 (29), 112 (100); d_0 7%, d_1 91%, d_2 1%.

*2,2-Dideutero-8a-hydroxy-4a-methyl-*cis*-octahydronaphthalen-1(2*H*)-one (**29**)*

A stirred solution mixture of **2** (70 mg, 0.38 mmol), anhydrous K_2CO_3 (202 mg, 1.46 mmol), and D_2O (99.8%; 2 mL) was heated under reflux in an argon atmosphere for 18 h. The reaction mixture was cooled and extracted with ether (30 mL), and the organic phase was washed with D_2O (5 × 1 mL), dried (Na_2SO_4), and concentrated. The concentrate was heated under reflux again with K_2CO_3 (213 mg, 1.54 mmol) and D_2O (2 mL) for 66 h, and the reaction mixture was subjected to the above work-up procedure. Molecular distillation (115°C/20 Torr) of the resulting residue (49 mg) gave **29** (28 mg, 40%) as a colorless liquid; ir λ_{max}: 3.01 (sh, w), 5.87, 8.73, 9.15 (w), 9.96 (w), 10.07 (w) μm; ^{1}H nmr (200 MHz) δ: 0.80 (s, 3H), 1.15–2.16 (m, 12H), 2.28–2.44 (dt, J = 13, 5 Hz, 1H), 3.81 (s, 1H); ms *m/z*: 184 (32), 112 (100); d_1 3%, d_2 95%, d_3 1%.

Received April 30, 1987

JEAN-YVES HUOT, DENIS SERVE, SYLVIE DESJARDINS, and JEAN LESSARD. Can. J. Chem. **66**, 35 (1988).

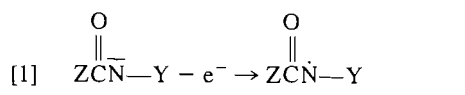
The electrochemical oxidation of [amide-Ag-amide]Ag, [amide-Ag-amide]Et_4N, and [amide]Et_4N salts of imides and formanilides, in acetonitrile containing tetraethylammonium tetrafluoroborate, at platinum and vitreous carbon electrodes, is a one-electron and irreversible ($\alpha n < 1$) process leading to an amidyl radicals that preferentially abstracts hydrogen from the medium to give the parent amide. *N,N*-Coupling (formation of hydrazine derivatives) was observed in the oxidation of the amide-Ag-amide anions of formanilide and *p*-methoxyformanilide. No coupling was observed in the oxidation of the amide-Ag-amide anion of *p*-cyanoformanilide and of imides, and in the oxidation of any of the tetraethylammonium salts (amidyl anions) studied. The formanilidyl radical was trapped by *N-tert*-butyl-α-phenylnitrone. Attempts to trap the succinimidyl radical by addition to olefins were unsuccessful.

JEAN-YVES HUOT, DENIS SERVE, SYLVIE DESJARDINS et JEAN LESSARD. Can. J. Chem. **66**, 35 (1988).

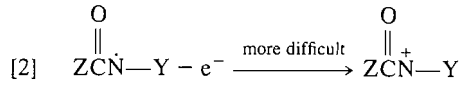
L'oxydation électrochimique des sels [amide-Ag-amide]Ag, [amide-Ag-amide]Et_4N, et [amide]Et_4N d'imides et formanilides, dans l'acétonitrile contenant du tétrafluoroborate de tétraéthylammonium sur des électrodes de platine et carbone vitreux est irréversible ($\alpha n < 1$) et fait intervenir un électron. Le radical amidyle formé réagit surtout avec le milieu par arrachement d'hydrogène pour donner l'amide parent. L'oxydation de l'anion amide-Ag-amide du formanilide et de son dérivé paraméthoxy a donné des dérivés hydrazines résultant du couplage azote–azote du radical amidyle. Aucun produit de couplage n'a été obtenu à partir d'un anion amide-Ag-amide dérivé du *p*-cyanoformanilide ou des imides, ou à partir du sel de tétraethylammonium (anion amidyle) d'aucun des amides étudiés. Le radical formanilidyle a été piégé par la *N-tert*-butyl α-phénylnitrone. Le radical succinimidyle n'a pu être piégé par addition à une oléfine.

Introduction

The oxidation of amidyl and imidyl anions should lead to the corresponding radicals (eq. [1]) and further oxidation of the radical to an acyl or diacyl nitrenium ion (eq. [2]) should be much more difficult.



[1] $ZC(=O)\overset{\cdot}{N}-Y - e^- \rightarrow ZC(=O)\overset{\cdot}{N}-Y$



[2] $ZC(=O)\overset{\cdot}{N}-Y - e^- \xrightarrow{\text{more difficult}} ZC(=O)\overset{+}{N}-Y$

Dimerization of imidyl or amidyl radicals has been observed in the anodic oxidation of the imido-disulfonate trisanion, $[N(SO_3)_2]^{3-}$, in water (~80% current yield) (1, 2), of the lithium and sodium salts of diaryl sulfimides, $[(ArSO_2)_2N]M$, in THF (2), and of the lithium salts of *N,N'*-disubstituted sulfamides, [RNHSO$_2$NR]Li, in methanol (intramolecular coupling with subsequent loss of SO_2 to give the azo compound) (3). In the latter case, the yield of *N–N* coupling derived products, diaryldisulfones, was low and the main reaction was hydrogen abstraction from THF regenerating the parent imide. The same authors (2) studied also the anodic oxidation of succinimide and phthalimide salts in THF and in methanol and no hydrazine derivative was formed. They obtained the parent imides only as a result of H-abstraction from the solvent.

N,N-Coupling has been reported to occur in high yields in the oxidation of *N*-alkoxycarboxamides, ZCONHOR (Z = alkyl or aryl), with lead tetraacetate and other oxidants (4, 5), and in the silver oxide (6) and anodic oxidation (7) of *N*-alkoxycarbamates (Z = O-alkyl). In the anodic oxidation of *N*-alkoxycarbamates (7), the dimerization was observed only in the presence of a base such as γ-collidine. The intermediate *N*-alkoxycarboxamidyl radical has been observed by esr in the chemical oxidation of *N*-alkoxy-acylcarboxamides (5).

No coupling was observed in the electrochemical oxidation of the sodium salt of acetanilide (8). The intermediate acetanilidyl radical was trapped with *N-tert*-butyl-α-phenylnitrone. Very recently, *N,N*-coupling (~60% of hydrazine derivative) was reported in the oxidation of the lithium salt of *N*-methylphenylacetamide in benzene with tetracyanoethylene (9). In THF solution, no hydrazine derivative was formed, the amidyl radical abstracting hydrogen from the solvent to afford the parent amide (9).

The electrochemical oxidation of enolate anions, which are closely related to amidyl anions, was shown to give the corresponding carbon radicals, which also undergo *C,C*-coupling and abstract hydrogen from the solvent (10–13). Addition to olefins has been observed in some cases (14). Correlations between the pK_a of the parent acid, the structure of the enolate anion, and the half-wave potential were discussed by Fern and Federlin (15).

This paper is concerned with the anodic oxidation of the silver (**1**), the mixed silver–tetraethylammonium (**2**), and the tetraethylammonium (**3**) salts of imides and carboxamides. The structure determination and the general electrochemical behavior of these salts have been reported (16). The electrochemical behavior is summarized here. The linear voltammogram of salts **1** on a platinum or a vitreous carbon electrode, in acetonitrile containing tetraethylammonium tetrafluoroborate (TEAFB) as supporting electrolyte, shows three diffusion controlled waves having nearly the same amplitude: two cathodic waves and one anodic wave. The first cathodic wave ($E_{1/2} \sim 0.2$ V vs. Ag^0/Ag^+ 0.01 M) corresponds to the reduction of the loosely bound silver ion of salts **1** (eq. [3]), and the second cathodic wave ($E_{1/2} \sim -1.4$ V), to the reduction

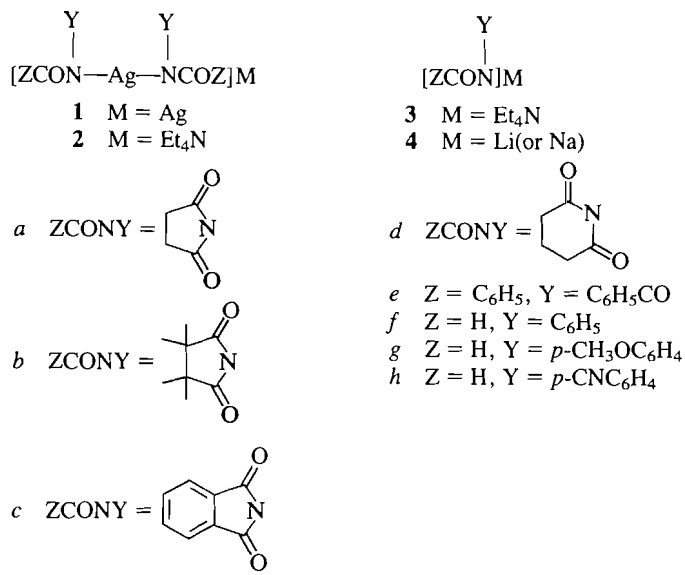
of the tightly bound silver ion of salts **2** (eq. [4]). The linear voltammogram of salts **2** shows the second cathodic wave only and the anodic wave as expected. The second cathodic wave and the anodic wave are irreversible (28).

We studied the oxidation of salts **1**, **2**, and **3** to compare the anodic behaviour of an amide-Ag-amide[4] anion (salts **1** and **2**) with that of an amidyl anion (salts **3**) and to see if amidyl radicals could be generated from amide-Ag-amide anions. As summarized above, amidyl radicals have been generated by oxidation of amidyl anions (1–8) and we were interested to see if the oxidation of an amide-Ag-amide anion would give a higher proportion of *N*,*N*-coupling (for instance by producing two amidyl radicals complexed to a silver ion) than the oxidation of an amidyl anion, and if an electrochemically generated



amidyl could be added to olefins. Amidyl radicals generated from *N*-haloamides have been shown to add efficiently to olefins in a chain reaction (17–27).

Results and discussion

As seen from Table 1, the half-wave potential of the anodic wave, on a platinum electrode in acetonitrile–TEABF, is about the same for salts **1** and **2** since the same species, the amide-Ag-amide anion, is oxidized. The amidyl anion (salt **3**) is either more easily oxidized (entries 2, 5, 6, 8) or more difficult to oxidize (entries 1, 3, 4) than the amide-Ag-amide anion (salts **1** and **2**); there is no general trend. The oxidation wave of the tetraethylammonium salts **3***a–d* shows a hysteresis effect (Fig. 1): the forward scan is more anodic than the backward scan for salts **3***a*, **3***c*, and **3***d* (entries 1, 3, 4) whereas the forward scan is less anodic in the case of salt **3***b* (entry 2).

Table 2 gives the oxidation potentials of the silver salts **1** measured at a vitreous carbon electrode in acetonitrile–TEABF. They are generally less anodic than those measured at a platinum electrode (Table 1). The same is true for the mixed silver–tetraethylammonium salt **2***e* ($E_{1/2}$ = 0.81 V at C vs. 1.01 V at Pt) and the tetraethylammonium salts **3***e* ($E_{1/2}$ = 0.71 V at C vs. 0.93 V at Pt) and **3***a* (see Fig. 1). The potential differences reflect differences in the strength of adsorption of the amide salts and (or) the parent amide on the two electrode materials. These adsorption differences can be seen also on the reduction potential of succinimide in acetonitrile–TEABF (0.1 M): $E_{1/2} = -1.85$ V vs. Ag^0/Ag^+ 0.01 M at platinum; no reduction wave before the reduction of the medium at vitreous carbon.

In methanol containing tetraethylammonium perchlorate (TEAP) (Table 3), the half-wave oxidation potential is now higher at carbon (entry 2) than at platinum (entry 1), contrary to the oxidation in acetonitrile–TEABF. The oxidation wave of **3***a* shows no hysteresis effect in methanol–TEAP either at platinum (entry 1) or at carbon (entry 2) and the half-wave potential is much lower than in acetonitrile–TEABF considering the fact that *E* vs. SCE ≅ E. vs. Ag^0/Ag^+ + 0.3 V (29) (compare entries 1 of Tables 1 and 3, entry 2 of Table 3, and footnote *f* of Table 2). In THF (Table 3), the anodic half-wave potentials of alkali metal salts of succinimide and phthalimide measured at carbon (entries 5 and 10) are the same as those measured at platinum (entries 6 and 11) and there is no mention of a hysteresis effect (2).

Table 3 also shows that the lithium (or sodium, see footnote *f*) salts of succinimide and phthalimide (entries 3 and 8 respectively) have more anodic half-wave potentials in methanol at carbon than the corresponding tetraethylammonium salts (entries 2 and 7). This could reflect a difference in ion-pairing strength between the amidyl anion and a lithium (or sodium) cation on the one hand, and a tetraethylammonium cation on the other hand, and (or) an effect of the cation adsorption on the double layer structure. However, the possibility of a surface effect being involved in the small potential differences observed cannot be excluded since the electrode material and (or) electrode conditioning are probably different in this work (entries 2 and 7) and in that reported by Wendt and co-workers (2) (entries 3 and 8).

The range of $E_{1/2}$ values obtained with different solutions of a given salt (see Tables 1, 2, and 3) is not due to concentration effects or to different preparations of the salt (e.g., **3***a* has been prepared by electrochemical reduction of **2***a* and of succinimide, and by a chemical route (16)) but to the difficulty of reproducing exactly the same electrode surface.

The structure of the imide moiety has little influence on the anodic potentials of the silver salts **1** and **2** of the four cyclic imides studied (*a*, *b*, *c*, and *d*) either at platinum (Table 1) or at carbon (Table 2) in acetonitrile–TEABF. The same is true for the lithium (sodium) salts **4** and tetraethylammonium salts **3** of succinimide (*a*) and phthalimide (*c*) in methanol–TEAP or in

[4]Amide = carboxamide or imide.

[a]When the voltammetric analyses were carried out on two or more different solutions, the range of values obtained for $E_{1/2}$ and αn values (the latter were generally quite reproducible) is given. In the case of salt **3***a* (entry 1), two sets of $E_{1/2}$ values were obtained, either 1.9 and 1.7 V or 2.2 and 1.9 V for forward and backward scan respectively.

[b]The salt concentration ranged from 1.2 mM (e.g., salts *f*) to 5.7 mM (e.g., salts *a*). In the case of salts *a*, the concentration had no effect on $E_{1/2}$ (up to 14.7 mM).

[c]Rotating disk electrode, ω = 660 rpm.

[d]*E* vs. Ag^0/Ag^+ 0.01 M.

[e]Obtained by plotting log $[(i_1 - i)/i]$ vs. potential according to the relationship given in ref. 28 for irreversible processes.

[f]Working potential (E_w) = $E_{1/2}$ + 0.1 to 0.2 V.

[g]Forward scan.

[h]Backward scan.

[i]In samples of the salt where formanilide was present, there was a peak with $E_{max} \simeq$ 1.4–1.5 V.

[j]The electrolysis stopped after the uptake of 0.5 F/mol. Acidification of the solid residue led to the recovery of 45% of formanilide, thus showing that 55% of **1***f* was oxidized.

[k]A solution of **3***f* prepared by electroreduction of formanilide in the cell at −2.26 V gave $E_{1/2}$ = 0.22 V.

[l]Additional wave at $E_{1/2}$ = 1.0 V due to the presence of *p*-methoxyformanilide.

[m]Not determined.

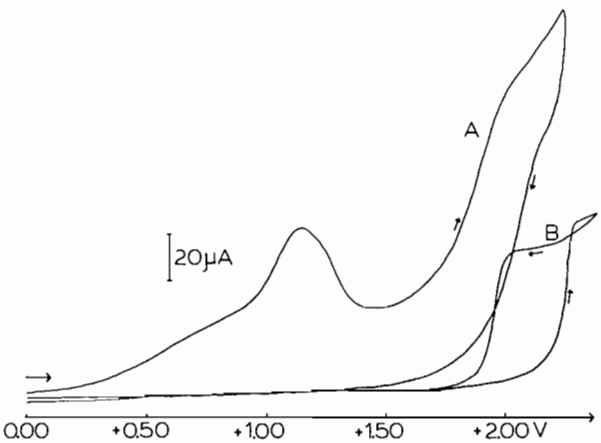

FIG. 1. Linear voltammetry of the tetraethylammonium salt of succinimide (**3***a*) (4.40 mM) in acetonitrile–TEABF (0.1 M) (ω = 660 rpm, sweep rate = 16 mV/s): A, on a vitreous carbon electrode; B, on a Pt electrode.

[c]*E* vs. Ag^0/Ag^+ 0.01 M.

[d]See footnote *e* of Table 1.

[e]$E_w = E_{1/2}$ + 0.1 to 0.7 V.

[f]Reduction at −1.5 V (1 F/mol of Ag^+) gave salt **3***a* with $E_{1/2}$ (ox.) at 1.60 V (forward scan) and 2.05 V (backward scan).

[g]Reduction of the solution at −0.3 V (0.5 F/mol of Ag^+) gave salt **2***e* ($E_{1/2}$ = 0.81 V, αn = 0.9), and further reduction at −0.9 V (another 0.5 F/mol of Ag^+) gave salt **3***e* ($E_{1/2}$ = 0.71 V, αn = 1.2). The voltammogram shows a non-diffusion-controlled wave at $E_{1/2}$ = 1.1 V for **1***e* and **2***e*, and at $E_{1/2}$ = 0.9 V for **3***e*.

[h]Peak at 1.50 V due to the oxidation of formanilide.

[i]It was not possible to carry out a coulometric determination due to a strong passivation of the electrode.

THF–TEAP (Table 3). However, for the tetraethylammonium salts **3***a–d* in acetonitrile–TEABF, the voltammogram of which shows a hysteresis effect as already pointed out, the anodic potential and the importance and direction of the hysteresis effect do vary with the structure of the imide moiety (Table 1). Surface effects seem therefore more important in acetonitrile–TEABF than in methanol–TEAP and more important for the tetraethylammonium salts **3** than for the silver salts **1** and **2**, and the lithium (sodium) salts **4**.

The silver salts **1***e* and **2***e* as well as the tetraethylammonium salt **3***e* of dibenzoylimide, an acyclic imide (Tables 1 and 2, entry 5), are more easily oxidized than those of cyclic imides (*a–d*). In the case of the imide-Ag-imide anions (salts **1** and **2**), this can be accounted for by the fact that an acyclic imidyl anion binds Ag^+ less tightly than a cyclic amidyl anion, as

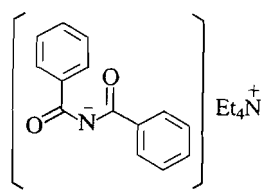
[f]The cation is not given in ref. 2 and there is no mention of the use of a supporting electrolyte. Presumably the authors have studied the lithium and (or) the sodium salts.
[g]Prepared *in situ* by reacting succinimide with 1 equiv. of *n*-BuLi.
[h]Solution (4.3 mM) of the potassium salt of phthalimide in a 0.1 M solution of TEAP in methanol.
[i]Solution (4.3 mM) of the potassium salt of phthalimide in a 0.3 M solution of $LiClO_4$ in THF.

shown by the reduction potential of the mixed silver–tetraethylammonium salts **2**, which is less negative for the dibenzoylimide salt **2***e* ($E_{1/2}$ = −0.5 V vs. Ag^0/Ag^+ 0.01 M) than for salts **2***a–d* ($E_{1/2}$ = −1.3 to −1.5 V) (16). The weaker N—Ag bonds of the acyclic imide salts **1***e* and **2***e*, when compared to the cyclic analogues **1***a–d* and **2***a–d*, must result mainly from a greater loss of entropy upon binding Ag^+ in the case of an acyclic imidyl anion. As for the tetraethylammonium salts **3**, the association between Et_4N^+ and the imidyl anion should involve mainly the oxygen atoms where the negative charge density should be the highest and such an association should be relatively weak. The lower oxidation potential of the dibenzoylimide salt **3***e*, when compared to that of salts **3***a–d*, probably reflects primarily a difference in charge delocalization between an acyclic imidyl anion having the *cis–trans* and (or) the *trans–trans* (or U) conformation and a cyclic imidyl anion having necessarily the *cis–cis* (or W) conformation (16).

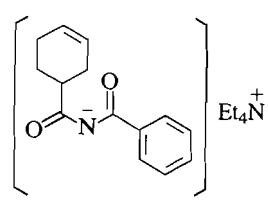
Interestingly, in the case of lithium enolates of β-dicarbonyl compounds, an acyclic enolate is now more difficult to oxidize than a cyclic enolate: E_{ox} of lithium acetylacetonate = 0.49 V vs. Ag^0/AgCl 0.1 M in DMSO; E_{ox} of the lithium salt of dimedone = 0.14 V (15). This is primarily due to the fact that the acyclic enolate anion in the U conformation is bonded more strongly to Li^+ (bonding involving the two oxygens) than the cyclic enolate ion in the W conformation (bonding to one oxygen only).

The oxidation potential of the tetraethylammonium salt of *N*-benzoyl-3-cyclohexenecarboxamide (**5**), both at platinum ($E_{1/2}$ = 0.72 V vs. Ag^0/Ag^+ 0.01 M) and at carbon ($E_{1/2}$ = 0.57 V), in acetonitrile–TEABF, is about 200 mV lower than that of the tetraethylammonium salt of dibenzoylimide (**3***e*) (see Table 1, entry 5, and Table 2, footnote *g*). This probably reflects the fact that a phenyl ring is more electron attracting than a cyclohexyl ring. As a result, the highest occupied molecular orbital (HOMO) from which the electron is removed (30) is lower in energy in the case of **3***e* than in the case of **5** (31). Similarly, and for the same reasons, the oxidation potential of enolates of aliphatic β-carbonyl nitriles (RCH(CN)COR′) is slightly lower (40–60 mV lower) than that of enolates of the aromatic analogues (ArCH(CN)COR′) (15).

The oxidation of the silver salts (**1***f* and **2***f*) and the tetraethylammonium salt (**3***f*) of formanilide, a carboxamide, is much easier than that of the same salts of imides (Tables 1 and 2), again because the energy of the HOMO of the amide-Ag-amide anion (salts **1** and **2**) and of the amidyl anion (salts **3**) should be lower when there are two electron-withdrawing carbonyl groups attached to the nitrogen (imide) than when there is only one (carboxamide) (31). For the same reason, the oxidation half-wave potentials of the silver (**1***h*) and tetraethylammonium (**3***h*) salts of paracyanoformanilide (Table 1, entry 8) are more anodic (CN is electron withdrawing) than those of formanilide salts (**1***f* and **3***j*, entry 6). Since CH_3O is electron donating and raises the energy of the HOMO (31), the oxidation potential of the silver salt of paramethoxyformanilide (**1***g*, entry 7) is less anodic than that of formanilide (**1***f*). Similarly, the oxidation potential of lithium enolates of the *p*-methoxy derivative of aromatic β-carbonyl nitriles is more anodic than that of the unsubstituted analogues (15).



3*e*



5

According to the αn values of Tables 1 and 2, the oxidation of the salts of formanilide (**1***f*, **2***f*, **3***f*) would be more reversible than that of the imide analogues, and the oxidation of the acyclic imide salts (**1***e*, **2***e*, **3***e*) slightly more reversible than that of the cyclic ones (*a–d*).

[a]The electrolyses were carried out on 14–20 mM solutions in a two-compartment cell using a platinum auxiliary electrode (see Experimental) until zero current. In most cases, some imide salt was still present according to voltammetric analyses. Acid hydrolysis of the solid residue after extraction of the products with ether followed by extraction with ether gave the parent imide.

[b]An excess of olefin was used: 10–15 mol per mol of salt.

[c]Working potential vs. Ag^0/Ag^+ 0.01 M.

[d]Determined by vapor phase chromatography (vpc) unless otherwise stated.

[e]The material balance includes the parent imide recovered after acid hydrolysis of the residue (see footnote *a*).

[f]Vitreous carbon. The current density was low.

[g]Beside succinimide, another product, presumably a dimer of sulfolene (see text), was formed in small amount.

[h]Yield of succinimide isolated by preparative layer chromatography (plc) on silica gel. Five other products present in very small amounts were detected and were not investigated further.

[i]Yield of parent imide isolated by plc on silica gel.

[j]The tetraethylammonium salt **5** was prepared in the cell by electrochemical reduction of a 4.2 mM solution of the parent amide in acetonitrile–TEABF (0.1 M) at −2.1 V vs. Ag^0/Ag^+ 0.01 M using 1.2 F/mol. The voltammogram of the resulting solution showed an anodic wave at ca. 0.5 V, both on Pt and C, and no cathodic wave.

[k]The current intensity dropped to zero a few seconds after applying the potential and it was not possible to carry out the electrolysis.

[l]There was still some salt left according to voltammetric analysis but it was not hydrolysed into the parent imide.

Both the αn values and the coulometric determinations of Tables 1, 2, and 3 show that the oxidation of salts **1**, **2**, **3**, and **4**, in acetonitrile–TEABF, in methanol–TEAP, and in tetrahydrofuran–TEAP, is a one-electron process. Removal of one electron from an amidyl (imidyl) anion should lead to an amidyl (imidyl) radical (eq. [1]), which could then abstract hydrogen from the medium to generate the parent amide or imide **6** (eq. [7]) and (or) undergo nitrogen–nitrogen coupling to give an hydrazine derivative **7** (eq. [8]).

[7] $ZCO\dot{N}Y + SH \longrightarrow \underset{\mathbf{6}}{ZCONHY} + S^{\cdot}$

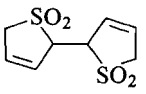
[8] $ZCO\dot{N}Y + ZCO\dot{N}Y \longrightarrow \underset{\mathbf{7}}{ZCON(Y)-(Y)NCOZ}$

The results of preparative electrooxidations of the silver salts of succinimide (**1***a*), phthalimide (**1***c*), and benzoylimide (**1***e*), and of the tetraethylammonium salt of succinimide (**3***a*), at platinum, in acetonitrile–TEABF, are reported in Table 4. The working potential is generally close to the half-wave potential except in entries 2 and 11 where it is more anodic by about 300–350 mV. At vitreous carbon, electrooxidation of **1***a* at a potential near the half-wave potential was very slow due to electrode passivation and stopped when about 30% of the silver salt was oxidized (entries 3 and 6). It was possible to obtain a higher conversion rate at a more anodic potential (entry 4). The sole product obtained from these oxidations was the parent imide. Thus an imidyl radical prefers to abstract hydrogen from the medium (eq. [7]) rather than to dimerize (eq. [8]). This was observed also by Wendt and co-workers (2) in the electrooxidation of the lithium (sodium) salts **4***a* (of succinimide) and **4***c* (of phthalimide) at platinum or carbon, in methanol or tetrahydrofuran: the parent imide was the sole product obtained. From the oxidation in methanol, small amounts of formaldehyde were detected and the authors (2) took this as evidence for hydrogen abstraction from methanol by the imidyl radical followed by oxidation of the resulting hydroxymethyl radical ($\cdot CH_2OH$). Hydrogen abstraction from acetonitrile would give a cyanomethyl radical ($\cdot CH_2CN$), which, among other things, could undergo carbon–carbon coupling to give succinonitrile.[5] We could not detect any succinonitrile in the oxidations of Table 4.

Imidyl radicals are known to be good hydrogen abstractors (34–38) but they are also known to add efficiently to a variety of olefins (17, 23, 24, 26, 27) and, among them, to 3,3-dimethyl-1-butene (23, 24, 26) and sulfolene (17). However, no product resulting from the addition of the succinimidyl radical to the olefin was detected in the electrooxidation of **1***a* and **3***a* in the presence of either 3,3-dimethyl-1-butene (Table 4, entries 5, 6, and 9) or 3-sulfolene (entry 4). From the oxidation in the presence of sulfolene, a compound was obtained in minute amounts to which structure **8** was tentatively assigned (see the Experimental). 3-Sulfolene, with its allylic hydrogens, should

[5]The formation of high yields of succinonitrile was reported by O'Donnell and Mann (32) in the electrochemical oxidation of carboxamides in dry acetonitrile. However, this work was repeated by Genies (33) and he was not able to detect any succinonitrile.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.222.148.141 on 09/07/12
For personal use only.



8

be a good hydrogen-atom donor, most probably better than acetonitrile, and dimer **8** would result from allylic hydrogen abstraction by the imidyl radical followed by coupling of two allylic radicals.[6]

Since the intramolecular addition of amidyl radicals to a double bond can be a very efficient process, as in the radical cyclization of *N*-chloro-*N*-methyl-3-cyclohexenecarboxamide (19, 20, 22), we investigated the electrooxidation of the tetraethylammonium salt of *N*-benzoyl-3-cyclohexenecarboxamide (**5**) (Table 4, entries 12 and 13). Salt **5** was prepared by electrochemical reduction of the parent amide in acetonitrile–TEABF. The voltammogram at platinum and at vitreous carbon showed no cathodic wave and an anodic wave at ca. 0.5 V vs. Ag^0/Ag^+ 0.01 M. It was not possible to carry out the oxidation of **5** on platinum because of electrode passivation (entry 12). On vitreous carbon, at a working potential of 1.0 V (entry 13), the electrolysis was successful but the current density was low. No product resulting from intramolecular trapping of the imidyl radical could be detected; again the sole product obtained was the parent amide.

Unequivocal evidence for the generation of an amidyl radical in the electrooxidation of an amide salt was obtained when the mixed silver–tetraethylammonium salt of formanilide (**2***f*) was oxidized in the presence of *N*-*tert*-butyl-α-phenylnitrone at 0.5 V on a platinum electrode, in acetonitrile–TEABF, in the cavity of an epr (electron paramagnetic resonance) spectrometer. The epr spectrum recorded is shown in Fig. 2. It corresponds to the nitroxide **9** resulting from the addition of the formanilidyl radical to the nitrone: $g = 2.0057$; $a^{N\alpha} = 13.9$ G, $a^{H} = 3.6$ G, $a^{N\gamma} = 1.7$ G (±0.1 G). This spectrum differs somewhat from that obtained by Bacon (8) upon oxidizing the sodium salt of acetanilide in the presence of the same nitrone: $a^{N\alpha} = 14.4$ G, $a^{H} = 1.5$ G, $a^{N\gamma} = 2.9$ G. In nitroxide **9**, a^{H} is larger than $a^{N\gamma}$, whereas in the nitroxide resulting from the trapping of the acetanilide radical (8), a^{H} is smaller than $a^{N\gamma}$. An acetyl group being larger than a formyl group, the preferred conformation around the C—N_α and C—N_γ bonds as well as the extent of delocalization of the N_γ electrons into the carbonyl group and the phenyl ring (hybridization of N_γ) are probably not the same in the two nitroxides, and these differences could account for the fact that the hyperfine coupling constants a^{H} and $a^{N\gamma}$ have different values in the two nitroxides.

The formation of *N*,*N*′-diformyl-*N*,*N*′-diphenylhydrazine (**7***f*; Z = H, Y = C_6H_5), in the preparative electrooxidation of the silver salts **1***f* and **2***f* of formanilide (see Table 5, entries 1 to 5), must result from the head-to-head coupling of two formanilidyl radicals and constitutes further evidence of the formation of amidyl radicals by electrooxidation of amide salts. No product resulting from head-to-tail or tail-to-tail coupling could be detected.

As mentioned in the introduction, high yields of *N*,*N*-coupling were reported for the oxidation of *N*-alkoxy derivatives of carboxamides and carbamates (4–7) where the intermediate

[6]Bicyclohexenyl, resulting from the coupling of two cyclohexenyl radicals, is formed when radicals are generated in the presence of cyclohexene (18).

[a]See footnote *a* of Table 4. The electrolyses were carried out on 10 mM solutions.

[b]Working potential vs. Ag^0/Ag^+ 0.01 M.

[c]Yield of products isolated by preparative layer chromatography.

[d]Water (4%) was added.

[e]In the presence of 1 mol of γ-collidine per mol of **1***f*.

[f]Salts **2***f* and **2***h* were prepared in the cell by electrochemical reduction of **1***f* and **1***h* respectively at −0.4 V.

[g]Salts **3***j* and **3***h* were prepared in the cell by electrochemical reduction of **1***j* and **1***h* respectively at −1.6 V.

[h]Salt **3***j* was prepared in the cell by electrochemical reduction of formanilide at −2.6 V.

[i]The residue after extraction with ether was not hydrolysed with acid (see footnote *a* of Table 4).

amidyl radical, having a π electronic configuration (4, 39),[7] is a capto-dative radical stabilized by the synergistic effect of resonance electron-donating methoxyl and electron-withdrawing acyl or acyloxyl groups (42).[8] We therefore studied the electrooxidation of the silver salts of *p*-methoxyformanilide (**1***g*) and of *p*-cyanoformanilide (**1***h* and **2***h*). No coupling was observed in the electrooxidation of **1***h* and **2***h* (Table 5, entries 10 and 11) where the *p*-cyanoformanilidyl radical is not a capto-dative radical since it is stabilized by two electron-withdrawing groups. However, contrary to expectation, no enhancement of *N*,*N*-coupling was observed in going from the formanilidyl radical (entries 1–5) to the *p*-methoxyformanilidyl radical (entry 9). The phenyl ring can be considered as electron donating and the formanilidyl radical becomes a capto-dative radical. But the capto-dative stabilization should be larger in the *p*-methoxy formanilidyl radical and this did not translate into a more effective *N*,*N*-coupling.

N,*N*-Coupling of the formanilidyl radical was observed only in the electrochemical oxidation of the silver salts **1***f* and **2***f* (Table 5, entries 1–5). There was no *N*,*N*-coupling in the electrooxidation of the tetraethylammonium salt **3***f* (entries 6–8). In the latter oxidation, an electron is removed from the

[7]*N*-Alkylcarboxamidyl radicals have been shown to have the π electronic configuration in their ground state (40, 41) and the π structure should be energetically even more favourable in *N*-alkoxyamidyl radicals (4).

[8]Such a resonance stabilization of a radical center has been described also as "push–pull" stabilization (43) and "merostabilization" (44).

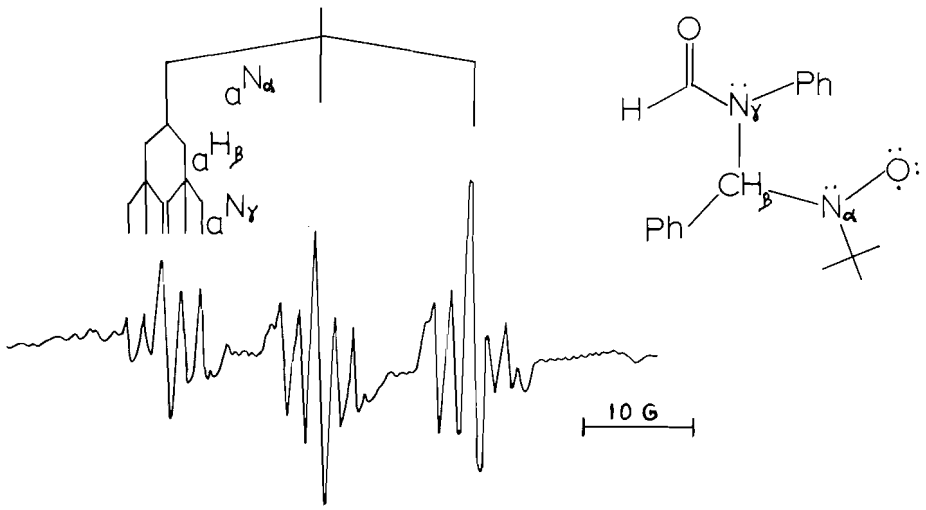

FIG. 2. The epr spectrum obtained in the electrochemical oxidation of the mixed silver–tetraethylammonium salt of formanilide (**2***f*), at a Pt electrode, in acetonitrile–TEABF(0.1 M), in the presence of *N*-*tert*-butyl-α-phenylnitrone: $a^{N\alpha} = 13.9$ G, $a^{H\beta} = 3.6$ G, $a^{N\gamma} = 1.7$ G; $g = 2.0057$.

amidyl anion to give an amidyl radical (eq. [1]), which abstracts hydrogen from the medium (eq. [7]). But, in the oxidation of the silver salts **1** and **2**, the electron is removed from an amide-Ag-amide anion (eq. [9]). The resulting radical could collapse to the silver salt and a free amidyl radical (eq. [10]), which would then abstract hydrogen from the medium (eq. [7]). However, the lifetime of the amide-Ag-amide radical could be long enough to allow further oxidation to occur to some extent to give a solvated radical pair and a silver ion and (or) a radical pair still complexed to the silver ion (eq. [11]). *N*,*N*-Coupling would then occur in the solvent cage and (or) the complex (eq. [12]) (45). Escape from the solvent cage and (or) the complex (eq. [13]) would give a free amidyl radical abstracting hydrogen

from the medium (eq. [7]). In the case of the electrooxidation of silver salts of *p*-cyanoformanilide (**1***h* and **2***h*) and of an imide (**1***a–e* and **2***a–e*), the lifetime of the amide-Ag-amide radical would be too short (electron-withdrawing groups only on nitrogen, N—Ag bond weaker) to allow further oxidation to occur before its breakdown to a free amidyl radical and the silver salt **1** (eq. [10]). Thus, the absence of *N*,*N*-coupling product in the electrooxidation of the silver salts of *p*-cyanoformanilide (**1***h* and **2***h*) and of imides (**1***a–e* and **2***a–e*), as well as in the electrooxidation of the tetraethylammonium salt of formanilide (**3***f*), is accounted for. Interestingly, the combination of the solvated and (or) complexed radical pair (eq. [12]) could be slightly slower in the case of the *p*-methoxyformanilidyl radical than in the case of the less stable formanilidyl radical, which would explain the smaller proportion of *N*,*N*-coupling obtained in the oxidation of the silver salt of *p*-methoxyformanilide (**1***g*) (15%) as compared to the oxidation of salts **1***f* and **2***f* of formanilide (21–26%).

Conclusion

The oxidation potential of an imidyl anion with two electron-attracting carbonyl groups attached to the nitrogen is higher than that of a carboxamidyl anion that has only one carbonyl group and therefore has a higher energy HOMO. The same is true for the oxidation of amide-Ag-amide anions (amide = imide or carboxamide).

The oxidation of these anions at platinum and at vitreous carbon is a one-electron process and gives rise to an irreversible wave ($\alpha n < 1$). It leads to an amidyl radical. *This electrochemically generated amidyl preferentially abstracts hydrogen from the medium to give the parent amide*. Attempts to trap the succinimidyl radical by intermolecular addition to an olefin were unsuccessful. The oxidation of the anion of *N*-benzoyl-3-cyclohexenecarboxamide (salt **5**) led to the parent amide only, and intramolecular addition of the imidyl radical to the

For personal use only.

double bond was not observed. Spin trapping of the formanilidyl radical was achieved by oxidizing the formanilide-Ag-formanilide anion (salt **2***f*) in the presence of *N-tert*-butyl-α-phenylnitrone.

In the oxidation of the amide-Ag-amide anion derived from formanilide (salts **1***f* and **2***f*) and *p*-methoxyformanilide (salt **2***g*), *N*,*N*-coupling does occur to some extent, the hydrazine derivative accounting for 15–26% of the oxidation products. However, no *N*,*N*-coupling product was detected in the oxidation of the corresponding formanilidyl anions (salts **3***f* and **3***g* respectively). This suggests that, in the oxidation of amide-Ag-amide anions, the presence of silver favors the formation of two amidyl radicals in a solvent cage and (or) complexed to a silver ion (see eqs. [9] and [11]). When the nitrogen radical bears two electron-attracting groups on the nitrogen such as in an imidyl radical or in the *p*-cyano-formanilidyl radical, no *N*,*N*-coupling was detected, suggesting that the amide-Ag-amide radical (eq. [9]) breaks down to an amidyl radical and silver salt **1** (eq. [10]) faster than it is oxidized (eq. [11]).

Experimental

The general information is the same as that given in ref. 16. Information concerning solvents, electrolytes, electrochemical instrumentation, and methods that is the same as that given in ref. 16 is not repeated here.

Solvents and electrolytes

Methanol was dried by refluxing over magnesium, then distilled, and THF was distilled over $LiAlH_4$. Tetraethylammonium perchlorate (TEAP), prepared from perchloric acid and Et_4NBr, was recrystallized from water until a negative silver ion test and was dried in vacuum for 2 days at 80°C. Commercially available $LiClO_4$ (Alfa Inorganic) was dried in vacuum for 24 h at 100°C.

Electrochemical instrumentation and methods

The voltammetric analysis and the electrodeposition of silver were carried out as described in ref. 16.

The preparative electrolyses were performed under a nitrogen atmosphere, at room temperature, in a two-compartment cell, either a cell of concentric construction with the cathode in a central compartment separated by a fritted glass disc (medium porosity) from the exterior anolyte (containing 50–70 mL), or a standard H-cell with a fritted glass disc as separator. A three-electrode system controlled by a Tacussel potentiostat, model ASA-100, having both an integrator, Tacussel type IG-5, and an ammeter connected in series with the auxiliary circuit, was used. The working electrode was either an 18-cm^2 platinum plate or a 19-cm^2 vitreous carbon plate. They were treated with concentrated nitric acid, thoroughly rinsed with water, and dried in an oven before each use. The auxiliary electrode was an 18-cm^2 platinum plate. The reference electrode was an Ag^0/Ag^+ (0.01 M) electrode (46).

For the spin-trapping experiments, the electrolyses were carried out at room temperature, in the cavity of a Varian E-9 epr spectrometer and in a Varian electrolytic cell, model E256, with a platinum anode, while flowing the solution through the cell. The epr spectrometer was equipped with an E-101 microwave module and a 9.6-GHz Klystron. A dispersion of manganese sulfide in zinc sulfide was used as external standard to determine the g value (g = 2.0054) and to check the magnetic field calibration (3rd and 4th peak, Δ = 67.5 G).

Amides

Succinimide, phthalimide, and glutarimide were obtained from commercial sources. The preparation of tetramethylsuccinimide, benzoylimide, and formanilide has been described in ref. 16.

p-*Methoxyformanilide*

It was prepared as described for formanilide (16) in 78% yield after recrystallization from chloroform–hexane, mp 78–79°C; ir ($CHCl_3$) ν_{max}: 3450, 3420, 1695, 1515, 1255 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 3.79 (s, OCH_3), 6.77, 6.99, 7.38, 7.53 (AA′BB′ quartet, 4H), 8.28, 8.31 (two s, CHO) ppm; ms (70 eV) *m/e*: 151 (M^+).

p-*Cyanoformanilide*

It was prepared as described for formanilide (16) in 70% yield after recrystallization from benzene, mp 189–190°C; ir (CH_2Cl_2) ν_{max}: 3400, 2230, 1710, 1610, 1515 cm^{-1}; ^{1}Hmr (CD_2Cl_2) δ: 7.53 (m, 4H), 8.29 (m, CHO), 8.7 (br m, NH) ppm; ms (70 eV) *m/e*: 146 (M^+). *Exact Mass* calcd. for $C_8H_6N_2O$: 146.0480; found (ms): 146.0482.

N-*Benzoyl-3-cyclohexene-carboxamide*

Benzamide (3.645 mg, 30 mmol) was added to a solution of 3-cyclohexene-carbonyl chloride (4.128 g, 30 mmol) in dry THF (50 mL) containing dry pyridine (2.4 mL, 30 mmol). The mixture was stirred at room temperature for seven days. Pyridinium chloride was removed by filtration and the solvent evaporated to dryness. The crystalline residue was washed with water and recrystallized from methylene chloride to afford the pure amide (4.00 g, 58% yield), mp 142–143°C; ir ($CHCl_3$) ν_{max}: 3400, 1700 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 2.27 (m, 6H), 3.59 (m, 1H), 5.74 (s, 2H), 7.69 (m, 5H), 8.69 (s, 1H) ppm; ms (70 eV) *m/e*: 229 (M^+). *Anal.* calcd. for $C_{14}H_{15}NO_2$: C 73.33, H 6.61, N 6.11; found: C 73.09, H 6.68, N 6.02.

Silver salts 1

The general procedure for preparing the silver salts of imides and formanilides has been given in ref. 16, as well as the characterization of the silver salts **1***a* (succinimide), **1***b* (tetramethylsuccinimide), **1***c* (phthalimide), **1***d* (glutarimide), **1***e* (benzoylimide), and **1***f* (formanilide).

*Salt 1*g (p-*methoxyformanilide)*

This salt was isolated as a brown solid, mp 160–163°C (87% yield), which was contaminated with Ag_2O, according to the elemental analysis. *Anal.* calcd. for $C_8H_8NO_2Ag \cdot 1/2H_2O$ + 0.1 Ag_2O: C 33.11, H 2.78, N 4.83, Ag 44.60; found: C 33.07, H 2.78, N 5.53, Ag 46.3.

*Salt 1*h *(*p-*cyanoformanilide)*

This salt was isolated as a beige solid, mp 225–227°C (85% yield), which was contaminated with Ag_2O, according to the elemental analysis. *Anal.* calcd. for $C_8H_5N_2OAg \cdot 1/2H_2O$ + 0.1 Ag_2O: C 33.69, H 1.77, N 9.82, Ag 45.39; found: C 33.31, H 1.72, N 10.15, Ag 45.8.

Silver salt of N-*benzoyl-3-cyclohexene carboxamide*

This salt was isolated as a brown solid (62% yield), which was contaminated with Ag_2O, according to the elemental analysis. *Anal.* calcd. for $C_{14}H_{14}NO_2 \cdot 1/2H_2O$ + 1/6 Ag_2O: C 43.70, H 3.93, N 3.64, Ag 37.38; found: C 43.47, H 3.86, N 3.46, Ag 37.0.

Mixed silver–tetraethylammonium salts 2

The chemical preparation of salt **2***a* (succinimide) has been described in ref. 16. Salts **2***a*, **2***b* (tetramethylsuccinimide), **2***c* (phthalimide), **2***d* (glutarimide), and **2***f* (formanilide) were prepared in the electrolysis cell by electrodeposition of Ag^0 at −0.5 vs. Ag^0/Ag^+ (0.01 M) from a solution of the silver salts **1**, in acetonitrile–TEABF, until the current dropped to 2% or less of its initial value. The yield of Ag^0 varied from 48 to 54%. For salt **2***e* (dibenzoylimide), the electrodeposition of Ag^0 was carried out at −0.25 V and the yield of Ag^0 was 54%.

Tetraethylammonium salts 3

The chemical preparation of salt **3***a* (succinimide) has been described in ref. 16. Salts **3***a*, **3***b* (tetramethylsuccinimide), **3***c* (phthalimide), **3***d* (glutarimide), **3***f* (formanilide), and **3***h* (*p*-cyano-formanilide) were prepared in the electrolysis cell by electrodeposition of Ag^0 at −1.5 to −1.6 V vs. Ag^0/Ag^+ (0.01 M), from a solution of the silver salts **1**, in acetonitrile–TEABF (0.1 M), until the current dropped to 2% or less of its initial value. The yield of electrodeposited Ag^0 varied from 97 to 105%. For salt **3***e* (dibenzoylimide), the electrodeposition of Ag^0 was carried out at −0.90 V and the yield of Ag^0 was 104%.

A solution of **3***c* in methanol was prepared by dissolving the commercially available potassium salt of phthalimide (0.6 mmol) in a 0.1 M solution of TEAP in methanol (100 mL).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.222.148.141 on 09/07/12
For personal use only.

Salts **3***a* and **3***f* were also prepared in the electrolysis cell by electrochemical reduction of the parent amide in acetonitrile–TEABF (0.1 M): at −2.00 V for **3***a*; at −2.26 V for **3***f*.

Tetraethylammonium salt **5** *(*N*-benzoyl-3-cyclohexene-carboxamide)*

This salt was prepared in the electrolysis cell by electrochemical reduction of the parent amide, 4.2 mM solution in acetonitrile–TEABF, at −2.10 V vs. Ag^0/Ag^+ (0.01 M), until the current dropped to 3% of its initial value (1.24 F/mol consumed). The voltammogram of the resulting solution showed an anodic wave at 0.5 V both at Pt and C, and no cathodic wave.

Lithium salts **4**

The lithium salt **4***a* (succinimide) was prepared by adding succinimide to a solution of LiOH in absolute methanol. Addition of ether caused the precipitation of **4***a*, which was filtered, washed with ether, and dried. The resulting precipitate contained 20% of succinimide, according to the ^{1}Hmr spectrum.

Lithium salt **4***a* was also prepared in the electrochemical cell by treating a solution of succinimide in dry THF with 1 equiv. of *n*-BuLi.

A solution of **4***c* (phthalimide) was prepared by dissolving the potassium salt of phthalimide (0.6 mmol) in a 0.3 M solution of $LiClO_4$ in THF (100 mL).

Authentic samples

N,N′-*Diformyl*-N,N′-*diphenylhydrazine (***7***, Z = H, Y = C_6H_5)*

A mixture of hydrazobenzene and azobenzene (2.40 g) in methylene-chloride (25 mL) was treated with the mixed acetic formic anhydride (47) in excess (54 mmol) at 25°C. After 3 days, more formic anhydride (54 mmol) was added. After 5 days, the reaction mixture was passed through a short column of silica gel and the solvent evaporated. The residue was recrystallized from CH_2Cl_2–ether, mp 95–96°C (0.56 g); ir ($CHCl_3$) ν_{max}: 1710, 1680, 1600 cm^{-1}; ^{1}Hmr (CD_3COCD_3) δ: 7.42 (m, 10H), 8.55 (s, 0.5 H), 8.91 (s, 1H), 9.14 (s, 0.5 H) (mixture of three rotational isomers) ppm; ms (70 eV) *m/e*: 240 (M^+), 212, 183. *Anal.* calcd. for $C_{14}H_{12}N_2O_2$: C 70.00, H 5.05, N 11.66; found: C 69.84, H 4.93, N 11.86.

N,N′-*Diformyl*-N,N′-*di*-p-*methoxyphenylhydrazine (***7***, Z = H, Y = p-CH_3O C_6H_4)*

N,*N*-Di-*p*-methoxyphenylhydrazine was prepared by the electrochemical reduction of *p*-methoxyazoxybenzene as described by Hazard and Tallec (48). It was reacted with the mixed acetic formic anhydride as described above to afford **7** (Z = H, Y = *p*-$CH_3OC_6H_4$) as a viscous oil; ir ($CHCl_3$) ν_{max}: 2825, 1715, 1680, 1605, 1510, 1250, 1035, 835 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 3.77, 3.80, and 3.81 (three s, OCH_3), 6.82, 6.93, 7.16, 7.26 (AA′BB′ quartet, aromatic protons), 8.46, 8.62, and 8.65 (three s, CHO) (mixture of three rotational isomers) ppm; ms (70 eV) *m/e*: 300 (M^+). *Exact Mass* calcd. for $C_{16}H_{16}N_2O_4$: 300.1140; found (ms): 300.1128.

Preparative electrolyses

Typical electrolyses are described below.

*Electrooxidation of the silver salt of succinimide (***1***a) in the presence of 3-sulfolene* (Table 4, entry 7)

Salt **1***a* (253 mg, 1.18 mmol), in acetonitrile–TEABF (0.1 M) (60 mL) containing sulfolene (2.35 g, 19.8 mmol), was electrolysed on a platinum electrode in the concentric cell, at an anodic potential of 1.5 V until zero current (0.67 F/mol) (45 min). The cathode compartment contained 10 mL of the 0.1 M electrolyte solution. The anolyte was evaporated to dryness *in vacuo* and the residue was extracted with refluxing ether (5 × 40 mL). The yield of succinimide determined by vpc was 65%. The chromatograms showed the presence of a small amount of another product, which was isolated by preparative vpc as a colorless liquid (15 mg); ir ($CHCl_3$) ν_{max}: 1610 (C=C), 1140, and 1300 (SO_2) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 3.14 (m) and 6.70 (m) ppm in a 3:2 ratio plus weak absorptions due to the presence of succinimide (detected by vpc also); ms (70 eV) *m/e*: 118 and ms (CI) *m/e*: 119. These spectral characteristics are consistent with structure **8**.

The solid residue after extraction with ether was treated with nitric acid (1.2 mmol) and extracted again with refluxing ether (3 × 40 mL) to yield an additional 25% of succinimide (by vpc) (total yield, 90%).

The catholyte solution was treated in the same way as the anolyte solution and it did not contain any organic product, according to vpc analysis.

*Electrooxidation of the silver salt of formanilide (***1***f)* (Table 5, entry 1)

Salt **1***f* (155 mg, 0.66 mmol), in acetonitrile–TEABF (0.1 M) (70 mL), was electrolysed on a platinum electrode, in the concentric cell, at an anodic potential of 0.50 V until zero current (0.66 F/mol) (6 h). The cathode compartment contained 10 mL of the 0.1 M electrolyte solution. Work-up of the anolyte was carried out as above and the crude product was separated by preparative layer chromatography (plc) on silica gel (ether–hexane 4:1) to yield two main fractions. The less polar fraction consisted of N,N′-*diformyl*-N,N′-*diphenylhydrazine* (**7**, Z = H, Y = C_6H_5), mp 93–95°C (11 mg, 14% yield), identical (ir, ^{1}Hmr, ms) to the authentic sample. The more polar fraction consisted of formanilide (31 mg, 39%).

The solid residue after ether extraction was treated with nitric acid (0.7 mmol) and extracted with refluxing ether to yield an additional 32% of formanilide (by vpc) (total yield, 71%).

Electrooxidation of the tetraethylammonium salt of N*-benzoyl-3-cyclohexenecarboxamide (***5***)* (Table 4, entry 13)

N-Benzoyl-3-cyclohexenecarboxamide (24 mg, 0.11 mmol), in acetonitrile–TEABF (0.1 M) (25 mL), was reduced on a platinum electrode in a concentric cell (central compartment: 5 mL of the 0.1 M electrolyte solution), at a cathodic potential of −2.10 V. The electrolysis was stopped after 1.24 F/mol. The auxiliary electrode was a magnesium rod. The voltammogram of the solution showed the absence of the cathodic wave of the parent imide and an anodic wave at $E_{1/2}$ = 0.5 V due to the oxidation of salt **5**.

The platinum and magnesium electrodes were removed and replaced by a vitreous carbon and a platinum electrode respectively. The solution of **5** was oxidized at an anodic potential of 1.00 V (0.8 F/mol) (90 min). The usual work-up followed by plc on silica gel (ether–hexane 2:1) gave the parent imide as the sole product, mp 138–140°C (19 mg, 80% yield).

Biologically active metabolites from *Agelas mauritiana*

R. FATHI-AFSHAR AND T. M. ALLEN
Department of Pharmacology, University of Alberta, Edmonton, Alta., Canada T6G 2H7

Received June 15, 1987

R. FATHI-AFSHAR and T. M. ALLEN. Can. J. Chem. **66**, 45 (1988).

Two novel bicyclic diterpenoides, agelasimine-A (**9**), and agelasimine-B (**10**), have been isolated from the orange sponge *Agelas mauritiana*. Also, a new bromine-containing alkaloid, 5-debromomidpacamide (**12**), along with midpacamide (**13**) and methyl *N*-methyl-4,5-dibromopyrrole-2-carboxylate (**11**), has been isolated. The structures were determined by interpretation of their spectral data. Agelasimine-A and -B exhibit a wide range of interesting biological activities such as cytotoxicity, inhibition of adenosine transfer into rabbit erythrocytes, Ca^{2+}-channel antagonistic action, and α_1 adrenergic blockade.

R. FATHI-AFSHAR et T. M. ALLEN. Can. J. Chem. **66**, 45 (1988).

On a isolé deux nouveaux diterpénoïdes bicycliques, les agélasimines-A (**9**) et -B (**10**), de l'éponge orange *Agelas mauritiana*. On a aussi isolé du *N*-méthyl dibromo-4,5 pyrrolecarboxylate de méthyle et un nouvel alcaloïde contenant du brome, le débromo-5 midpacamide (**12**), aux côtés du midpacamide (**13**). Les agélasimines-A et -B présentent un grand nombre de propriétés biologiques intéressantes comme de la cytotoxicité, une inhibition du transfert de l'adénosine dans les érythrocytes de lapin, une action antagoniste dans le canal du Ca^{2+} et un effet bloqueur adrénergique α_1.

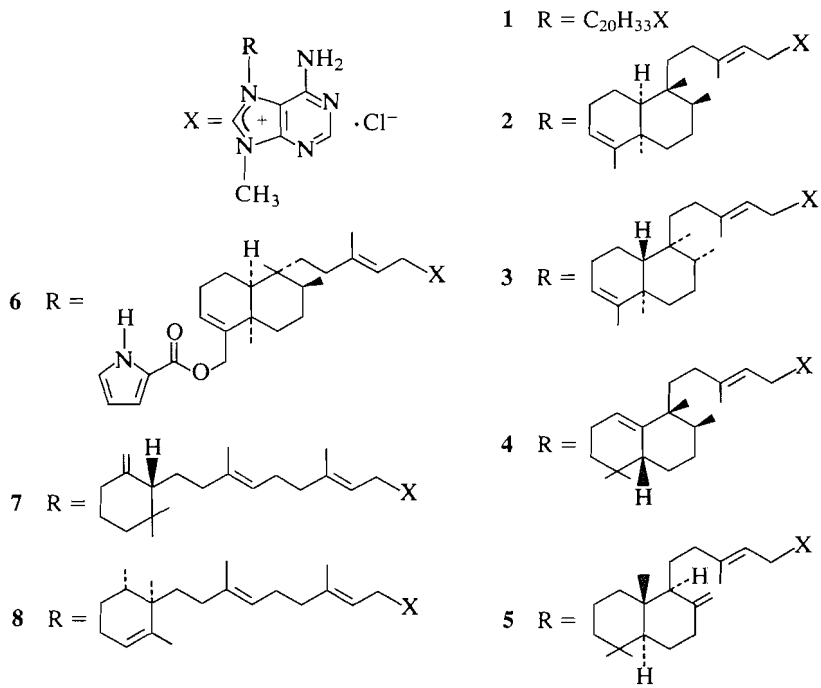
[Traduit par la revue]

Introduction

Some time ago Cullen and Devlin (1) reported the isolation and partial structure determination of agelasine (**1**), a mixture of diterpenes each bearing a novel 9-methyladenine group, from the sea sponge *Agelas dispar*. No attempts have been made on the complete structure determination of agelasine (**1**). However, recently the isolation of several quaternary 9-methyladenine derivatives of bicyclic diterpenes, agelasines A–D (**2–5**) (2), ageline B (**6**) (3), and also 9-methyladenine derivatives of the monocyclic diterpenes, agelasine E (**7**) (4) and ageline A (agelasine F)[1] (**8**) (3, 4), has been reported.

In our continuing search for new antineoplastic compounds from marine organisms, we have examined the cytotoxicity and antineoplastic properties of numerous species (5). In this paper we present the isolation and structure determination of two novel non-quaternary adenine derivatives of a bicyclic diterpene, agelasimine-A (**9**) and agelasimine-B (**10**), along with three bromine-containing alkaloids from the sponge *Agelas mauritiana*.

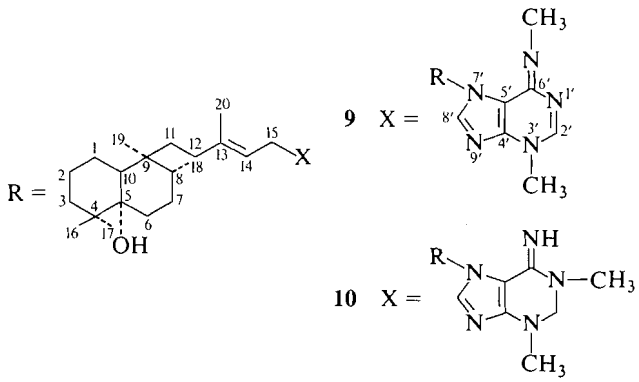
Specimens of the sponge were collected from Enewetak Atoll at 15-m depths, and maintained frozen (−20°C) until needed. The sponge was partially thawed, and homogenized in 95% ethanol. The chloroform-soluble portion of the crude extract was chromatographed on Sephadex LH-20. The resulting fractions were screened (in vitro) against the L1210 mouse leukemia cell line for cytotoxic activity. The major metabolites isolated from the most active fractions (after repeated chromatography over alumina[2]) are two non-quaternary adenine



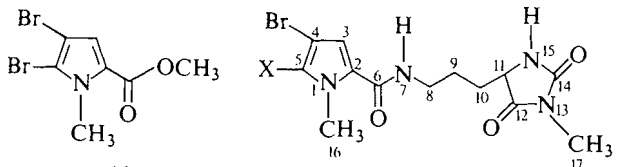
[1]Ageline A and agelasine F refer to the same compound.

[2]Chromatography using silica gel gave fractions with diminished cytotoxicity.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.222.148.141 on 09/07/12
For personal use only.

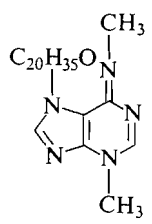


derivatives, agelasimine-A (**9**) ($C_{27}H_{43}N_5O$) and agelasimine-B (**10**) ($C_{27}H_{45}N_5O$), and methyl *N*-methyl-4,5-dibromopyrrole-2-carboxylate (**11**). The inactive fractions, after chromatography over alumina and silica gel, afforded 5-debromomidpacamide (**12**) and midpacamide (**13**) (6).



11 **12** X = H; **13** X = Br

The molecular formula $C_{27}H_{43}N_5O$ for agelasimine-A (**9**) was established by a combination of chemical ionization mass spectrometry (cims, molecular weight 453), and high resolution electron impact mass spectroscopy (hrms). Inspection of the fragmentation pattern of this compound in the hrms reveals that the compound fragments into two different portions: a nitrogen-containing heterocyclic nucleus ($C_7H_8N_5$), and an oxygen-containing hydrocarbon portion ($C_{20}H_{35}O$). The ultraviolet (uv) spectrum of the compound has absorptions at 227 nm (10 000) and 285 nm (10 277), similar to the values reported (7) for an adenine type molecule. The infrared (ir) spectrum of the compound shows strong absorption at 1642 cm^{-1} characteristic of the C=N group (8). The ^1H nmr spectrum (Table 1) exhibits two N-methyl singlets at δ 3.22 and 3.66, and two aromatic singlets at δ 7.5 and 7.65. These signals in the ^1H nmr spectrum account for the eight protons present in the $C_7H_8N_5$ nucleus. These observations suggest a dimethyladenine derivative for the heterocyclic portion of the agelasimine-A. Of the several ways of arranging the alkyl ($C_{20}H_{35}O$) and the two methyl groups on the adenine nucleus, we prefer the one shown in the partial structure **A**, on the following grounds. The possibility of



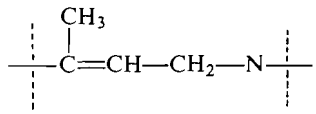
A

having a quaternary 9-methyladenine is rejected, since the characteristic proton signals (1–4) are absent in the ^1H nmr spectrum of the agelasimine-A. The presence of the two aromatic protons at unusually high field (δ 7.5, 7.65), compared to the reported values for *N*-methyl-7-alkyladenine derivatives (δ 7.85, 8.53) (3, 9), suggests the existence of an exocyclic double bond. The different chemical shifts observed (δ 3.22 and 3.66) for the two N-methyl singlets rule out the possibility that both methyl groups are located on the same or fairly similar nitrogen atom(s). Furthermore, irradiation of the C-2′ aromatic proton signal at δ 7.65 sharpens the methyl singlet at δ 3.22; on the other hand, no effect is observed when the other aromatic singlet at δ 7.5 is irradiated. This implies that the methyl group at δ 3.22 is attached to one of the nitrogens on the six-membered ring.

The suggested partial structure also accounts for the ^{13}C nmr signals at 113.8 (C), 137.8 (CH), 143.2 (C), 145.2 (CH), and 150.5 (C), as well as the two signals at δ 34.1 and 34.9 (2 NCH_3) (Table 1).[3]

The nitrogen-containing portion of the molecule is thus established, leaving a $C_{20}H_{35}O$ alkyl residue to be characterized.

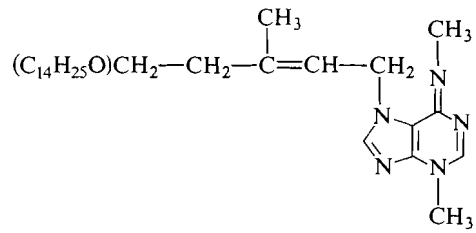
The ^1H nmr spectrum of the agelasimine-A contains the spin system depicted in the partial structure **B**; a broad singlet at



B

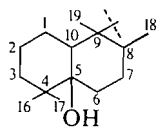
δ 1.8 (C=CCH_3), a doublet at 5.17 (NCH_2, J = 7.5 Hz), and a triplet at 5.44 (HC=C, J = 7.5 Hz). This partial structure is supported by corresponding carbon signals observed in the ^{13}C nmr at δ 17.4 (CH_3), 44.8 (CH_2), 118.1 (CH), and 143.3 (C).

Inspection of the mass spectrum of agelasimine-A and analysis of the major peaks at m/z 209 ($C_{14}H_{25}O$), 216 ($C_{11}H_{14}N_5$), 230 ($C_{12}H_{16}N_5$), and 244 ($C_{13}H_{18}N_5$) suggests that a C_6H_{10} chain links the heterocyclic nucleus (partial structure **A**) to a $C_{14}H_{25}O$ hydrocarbon portion. This gives rise to a partial structure **C**, as an expansion of the structures **A** and **B**. The facile loss of $C_{12}H_{27}O$ giving rise to the base peak at m/z 230 is explained by the cleavage of a bond allylic to the olefin bond.



C

The remaining portion of the molecule ($C_{14}H_{25}O$) is defined as the partial structure **D** by comparison of the nmr spectral



D

data with those reported for similar structures (2). The mass spectrum shows a fragment at m/z 191 ($C_{14}H_{23}$) arising from the loss of H_2O from the $C_{14}H_{25}O$ fragment. The ^1H nmr spectrum indicates the presence of an exchangeable proton (presumably an OH) at δ 1.2 ppm, and this is confirmed by the absorption shown at 3400 cm^{-1} in the ir spectrum and the ^{13}C nmr spectrum, which displays a singlet at δ 76.2 (C)

[3]Assignment of the diterpene substituent at N-7′ is not unambiguous. We prefer N-7′ to N-9′ since previously reported metabolites of sea sponge are substituted at N-7′.

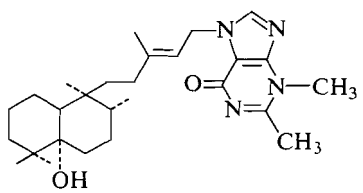
[a–c]Values with identical superscript within a column may be interchanged.

characteristic of a tertiary alcohol carbon (10). The ^{1}H nmr spectrum contains a methyl doublet (δ 0.8, J = 7 Hz), methyl singlet (δ 0.84), and a *gem*-dimethyl group at δ 0.87 and 0.98 (irradiation at 0.98 clearly enhances the signal at δ 0.87). The chemical shifts of the methyl signals imply that none of the four methyl groups are attached to the carbon bearing the hydroxyl group.

Thus we propose structure **9** for agelasimine-A. The main proof for this assignment comes from the comparison of the spectral data of **9** with that of the purino-diterpene (**14**), isolated by Nakatsu and Faulkner (11). This compound has been isolated



14

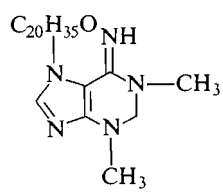
from the acetylated[4] mixture of the crude extract of the same sponge (*Agelas mauritiana*), and identified by X-ray analysis.

Another major metabolite isolated (compound **10**), which is biologically active, has a molecular formula of $C_{27}H_{45}N_5O$ as determined by cims and hrms. Analysis of the hrms shows that this compound also consists of two portions: a heterocyclic nucleus ($C_7H_{10}N_5$) and a hydrocarbon portion ($C_{20}H_{35}O$).

[4]Acetic anhydride in pyridine.

Inspection of the mass spectrum fragmentation and ^{1}H and ^{13}C nmr spectra (Table 1) reveals that the $C_{20}H_{35}O$ portion of this compound is very similar to the diterpene portion of the agelasimine-A (**9**).

The infrared spectrum displays absorption at 3400–3300 cm^{-1} (OH and (or) NH) and also exhibits the C=N— absorption at 1619 cm^{-1}. The presence of two exchangeable protons (OH at δ 1.2 and NH at δ 5.3) was detected in the ^{1}H nmr. Also, two methyl singlets are observed at δ 2.9 with 3.02, implying that they are attached to two nitrogens with very similar electronic environments. The presence of only one aromatic proton is observed at δ 7.26, as well as a singlet at δ 4.17 for two hydrogens. These data suggest the partial structure **E** for the heterocyclic portion of this molecule.



E

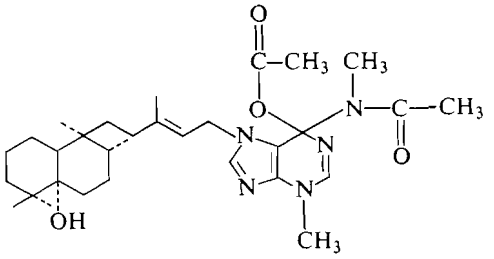
These changes in the structure of compound **10** compared with that of agelasimine-A are also reflected in the ^{13}C nmr spectrum (Table 1) of this compound. Most of the signals remain fairly unchanged; however, the C-2′ signal changes from δ 145.2 (CH) in agelasimine-A to δ 71.1 (CH_2) in this

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.222.148.141 on 09/07/12
For personal use only.

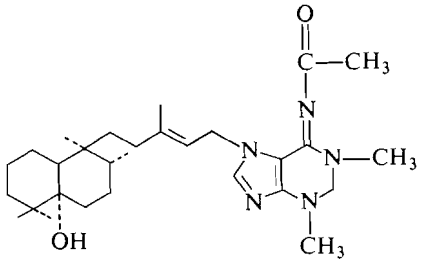
compound. At this stage we proposed the structure **10** for this metabolite, which was called agelasimine-B. Complete assignments for the ^1H and ^{13}C nmr spectra of compounds **9** and **10** are given in Table 1.

To study the relationship between the agelasimines and the purino-diterpene **14**, and to obtain more information regarding the stereochemistry of these two molecules, we investigated the reactions of the compounds **9** and **10** with acetic anhydride in pyridine.

Agelasimine-A, after purification, gave a product that, although its exact nature has not been firmly established (mixture of isomers), showed mass spectral fragmentation and ^1H nmr spectra in support of the formation of the diacetate (**15**). Acetylation reaction of agelasimine-B, on the other hand, produced one major product, which was characterized as *N*-acetylagelasimine-B (**16**) based on the following data. The



15



16

^1H nmr of this product exhibited all the signals observed for agelasimine-B plus a singlet at δ 2.15 representing the newly introduced acyl methyl group. This compound was also isolated by Dr. Faulkner and co-workers from their original acetylated mixture, along with the purino-diterpene **14**. The ^1H nmr spectrum for this compound provided us by Dr. Faulkner[5] is identical to the one recorded in our laboratory. Since this product has the same relative stereochemistry as compound **14**, one could also infer the same stereochemistry for the diterpene portion of the agelasimine-A and -B.

In addition to the agelasimines, a minor compound $C_7H_7Br_2NO_2$ was isolated as yellow crystals (mp 87–90°C) from the less polar fractions of the alumina column. This compound belonged to a different class of compounds and was identified as methyl *N*-methyl-4,5-dibromopyrrole-2-carboxylate (**11**) based on its ^1H and ^{13}C nmr spectra. This methyl ester is known as a synthetic product (12). It is possible that the ester is an artefact derived from the free acid, since similar observations have been made for 4,5-dibromopyrrole-2-carboxylic acid (13).

Several of the fractions (see Experimental) from the initial Sephadex chromatography were combined and evaporated. The orange solid was then chromatographed over alumina and silica gel[6] to yield two highly uv-active white solids, $C_{13}H_{16}Br_2N_4O_3$, and $C_{13}H_{17}BrN_4O_3$. The dibromo compound was identified as midpacamide (**13**), a known sponge alkaloid of the "oroidin group." The structure of this compound was confirmed by the comparison of its ^1H and ^{13}C data (Table 2) with the reported values (6).

TABLE 2. ^1H (400 MHz) and ^{13}C (100 MHz) data for compounds **12** and **13**

[a]Exchangeable protons.
[b]Values within a column may be interchanged.

The small coupling constant (1.7 Hz) observed between the two aromatic protons at δ 6.54 and 6.72 (W-coupling) supports the substitution pattern on the pyrrole ring (15, 16).

Identification of the monobrominated metabolite, 5-debromomidpacamide (**12**), was greatly facilitated by the structural resemblance of the compound to midpacamide. Structure **12** was assigned to this compound based on the ^1H and ^{13}C nmr (14) spectral data (Table 2).

The agelasimines have been tested for a variety of pharmacological activities. Both compounds show cell growth inhibition properties when tested against L1210 mouse leukemia cells in vitro (ED_{50} = 2–4 μg/mL). Their effect on the smooth muscle relaxation of rabbit gut and beef coronary artery was studied, and both compounds appear to be equipotent in causing relaxation in these tissues (ED_{50} = 3–10 μM). These compounds also showed ability to inhibit nucleoside transport into rabbit erythrocytes (IC_{50} = 6–14 μM). The most interesting biological activity was their ability to reverse the effects on rat aorta ring preparations of a variety of neurotransmitter and other substances. Both agelasimines (**9**, **10**) may act as Ca^{2+}-channel antagonists as well as α_1 adrenergic blockers. Pharmacological activities of agelasimines will be reported elsewhere in detail.

Experimental

General methods

All solvents were distilled prior to use. Camag aluminium oxide (neutral, activity III) was used for column chromatography. Analytical thin-layer chromatography (tlc) was carried out on aluminium oxide F254 (EM Reagents precoated tlc plates, 0.25 mm), and silica gel 60 F254 (Merck precoated tlc plates, 0.2 mm). Preparative thin-layer chromatography (ptlc) was carried out on silica gel 60 F254 (EM Reagents precoated ptlc plates 2 mm). Materials were detected

[5]Private communication.

[6]Several elutions (≈13) on preparative plate were required for this separation.

by visualization under an ultraviolet lamp or by using the phosphomolybdic acid (3%) – cerric sulfate (1%) in 5% aqueous sulfuric acid solution followed by heating.

Mass spectra (ms) were recorded on an A.E. ± MS-50 mass spectrometer, or an A.E.I. MS-90 mass spectrometer (chemical ionization), and are reported as m/z (relative intensity). Infrared spectra were recorded on a Nicolet 7199 FT interferometer, ultraviolet spectra on a Hewlett Packard 8450A ultraviolet spectrophotometer, and optical rotations on a Perkin–Elmer Model 241 polarimeter. The ^{1}H and ^{13}C nmr spectra were measured on a Bruker WH-200 spectrometer or a Bruker WH-400 spectrometer. All nuclear magnetic resonance measurements employed tetramethylsilane as an internal standard.

Most of the fractionation and purification stages were monitored by testing the fractions for their activities against L1210 (mouse leukemia) cell line in vitro.

Collection, extraction, and separation

Agelas mauritiana was collected by hand using SCUBA (−15 m) at Enewetak Atoll and frozen for transport to Edmonton.

The finely cut sponge (0.8 kg wet weight) was extracted with 95% ethanol (1 L × 3). The solvent was evaporated under reduced pressure to give a crude extract (23.47 g), which was then dissolved in methanol. The methanol-soluble portion (22 g) was triturated with chloroform, then evaporated to yield 10 g of dark red oil (the most active fraction). This fraction was dissolved in 20 mL of ethanol and chromatographed on Sephadex LH-20 (40 × 4 cm) with ethanol at a flow rate of 1.2 mL/min. Fractions (8 mL) were collected with the aid of an automatic fraction collector. The cytotoxic fractions (fractions 31–50) were combined to give 6.94 g of a mixture of compounds, which was further chromatographed over a larger (48 × 5 cm) Sephadex LH-20 column (ethanol, 0.5 mL/min, 7-mL fractions). The most active fractions (90–124) gave 3.72 g of a mixture of several compounds, which after further chromatography over alumina (300 g), using chloroform–methanol as solvent for elution (7-mL fractions), yielded agelasimine-A (**9**) and agelasimine-B (**10**). Also, methyl *N*-methyl-4,5-dibromopyrrole-2-carboxylate (**11**) was isolated from one of the less polar fractions after this chromatography.

Several inactive fractions (51–63) from the first Sephadex column were combined to give 2.39 g of an orange solid. This was further chromatographed over alumina, and the fractions eluted with chloroform gave 0.5 g of a mixture that, upon further purification employing preparative thin-layer chromatography (10–13 elutions, eluent:ethyl acetate), furnished the brominated pyrroles **12** and **13**.

*Isolation of agelasimine-A (**9**)*

Agelasimine-A was obtained as a yellowish oil (300 mg, 0.038% of the wet weight of the sponge) when the alumina column was being eluted with chloroform–methanol (97:3) in fractions 320–340. This was freed from the trace of colored impurities using another alumina column; $[\alpha]_D^{25}$ +2.3 (CH_3OH); uv (CH_3OH) $\lambda_{max}(\varepsilon)$: 209 (7911 sh), 227 (10 000 sh), 285 (10 277) nm; ir ($CHCl_3$): 3400, 2930, 2840, 2780, 1710, 1642, 1600, 1510, 1460, 1380, 760 cm^{-1}; ^{1}H and ^{13}C nmr ($CDCl_3$), see Table 1; hrms, m/z calcd. for $C_{27}H_{43}N_5O$ (M^+): 453.3467; found: 453.3462, 438, 420, 244, 230 (100), 217, 209, 189, 163, 135. Chemical ionization (NH_3) ms shows an $M + 1$ (m/z 454) peak.

*Isolation of agelasimine-B (**10**)*

When the preliminary alumina column of the active fraction was eluted with chloroform–methanol (99:1), agelasimine-B was obtained (tubes 141–240) as a viscous yellowish oil (160 mg, 0.02% of the wet sponge weight). Another purification over alumina eliminated the minor impurities; $[\alpha]_D^{25}$ +2.46 (CH_3OH); uv (CH_3OH) $\lambda_{max}(\varepsilon)$: 214 (10 965), 245 (5687 sh), 286 (3629) nm; ir ($CHCl_3$): 3350, 2940, 2860, 2800, 1720, 1619, 1570, 1520, 1460, 1380, 760 cm^{-1}; ^{1}H and ^{13}C nmr ($CDCl_3$), see Table 1; hrms, m/z calcd. for $C_{27}H_{45}N_5O$ (M^+): 455.3623; found: 455.3618, 440, 438, 291, 273, 246, 232, 209, 191, 165, 122 (100%). Chemical ionization (NH_3) ms shows a peak at m/e 456 ($M + 1$).

Reaction of agelasimine-A with acetic anhydride in pyridine

A mixture of agelasimine-A (**9**, 10 mg, 0.022 mmol), pyridine (0.2 mL), and acetic anhydride (0.1 mL) was stirred for 44 h at room temperature. Evaporation to dryness *in vacuo*, followed by column chromatography over silica gel (5 g, methanol–chloroform (1:99)) gave 7 mg of the diacetylagelasimine-A as an oil; ^{1}H nmr ($CDCl_3$) δ: 0.83 (3H, d, J = 7 Hz), 0.87 (3H, s), 0.89 (3H, s), 1.00 (3H, s), 1.76 (3H, bs), 2.2 (3H, s), 2.22 (3H, s), 3.2 (3H, s), 3.27 (3H, s), 4.61 (2H, d, J = 7.5 Hz), 5.36 (1H, t, J = 7.5 Hz), 7.48 (1H, s), 8.25 (1H, s); hrms, m/z calcd. for $C_{31}H_{49}N_5O_4$ (M^+): 555.3773; found: 555.3784, 541, 527, 513, 304, 290, 265, 248, 244, 222, 209, 195, 178, 165, 122.

Reaction of agelasimine-B with acetic anhydride in pyridine

N-*Acetylagelasimine-B (**16**)*

Agelasimine-B (20 mg, 0.044 mmol) was stirred with pyridine (0.4 mL), and acetic anhydride (0.2 mL) at room temperature for 50 h. The mixture was then evaporated to dryness and the residue was chromatographed over silica gel (flash, methanol–chloroform (1:99)) to give 10 mg of *N*-acetylagelasimine-B; ^{1}H nmr ($CDCl_3$) δ: 0.77 (3H, d, J = 7 Hz), 0.81 (3H, s), 0.84 (3H, s), 0.96 (3H, s), 1.16 (s, OH), 1.74 (3H, bs), 2.15 (3H, s), 2.94 (3H, s), 3.04 (3H, s), 4.4 (2H, s), 4.77 (2H, d, J = 7.5 Hz), 5.36 (1H, t, J = 7.5 Hz), 7.32 (1H, s); hrms m/z calcd. for $C_{29}H_{47}N_5O_2$ (M^+): 497.3719; found: 497.3722, 482, 480, 454, 289, 288, 274, 165.

*Isolation of methyl N-methyl-4,5-dibromopyrrole-2-carboxylate (**11**)*

The ester (**11**) was isolated as a yellow solid (80 mg, 0.01% of the wet weight) from the active fraction when the alumina column was eluted with chloroform. Traces of colored impurities were removed by preparative thin-layer chromatography, after which the ester (**11**) was crystallized from hexane to give white needles, mp 87–90°C (lit. (12) mp 87°C); ^{1}H nmr ($CDCl_3$) δ: 3.82 (3H, s), 3.98 (3H, s), 7.01 (1H, s); ^{13}C nmr ($CDCl_3$) δ: 160.2, 123.9, 119.3, 113.7, 98.8, 51.5, 35.8; hrms, m/z calcd. for $C_7H_7Br_2NO_2$ (M^+): 296.8821; found: 296.8837 (100), 265, 237.

*Isolation of 5-debromomidpacamide (**12**)*

This compound was obtained from the inactive fraction the same way as the midpacamide (**13**). This afforded white crystals, mp 116–119°C (0.02% wet weight); ir ($CHCl_3$): 3120, 1740, 1710, 1170 cm^{-1}; ^{1}H and ^{13}C nmr ($CDCl_3$), see Table 2; hrms m/z calcd. for $C_{13}H_{17}BrN_4O_3$ (M^+): 356.0476; found: 356.0479, 197 (100), 170, 153.

*Isolation of midpacamide (**13**)*

Midpacamide (**13**) was isolated from the inactive portion of the original Sephadex column, after chromatography over alumina followed by preparative plate, and recrystallized from acetonitrile as a white powder (0.05% of wet sponge), mp 93–95°C (lit. (6) mp 97°C); ir ($CHCl_3$): 3320, 1764, 1740, 1610 cm^{-1}; ^{1}H nmr ($CDCl_3$) and ^{13}C nmr ($CDCl_3$–MeOD), see Table 2; hrms, m/z calcd. for $C_{13}H_{16}Br_2N_4O_3$ (M^+): 435.9509; found: 435.9560, 436, 265, 197 (100), 153.

The chemical structure of a novel lactone isolated from the discolored heartwood of living western red cedar (WRC) (*Thuja plicata* Donn.) trees has been determined as 3,3,4,7,7,8-hexamethyl-2,6-dioxa-1,5-anthracene-dione, and given the trivial name thujin (**1**). The isolation, purification, and determination of the structure were carried out by a combination of chemical, chromatographic, and spectroscopic methods.

LEHONG JIN, JACK W. WILSON et ERIC P. SWAN. Can. J. Chem. **66**, 51 (1988).

On a déterminé que la structure chimique d'une nouvelle lactone, qui a été isolée du bois dur décoloré de cèdres rouges de l'ouest (cro) (*Thuja plicata* Donn.), est l'hexaméthyl-3,3,4,7,7,8 dioxa-2,6 anthracènedione-1,5 et que son nom trivial est thujine (**1**). On a isolé et purifié le produit et on a déterminé sa structure en faisant appel à une combinaison de méthodes chimiques, chromatographiques et spectroscopiques.

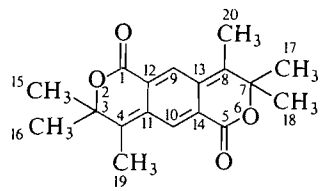
Introduction

During the past three decades, the large-scale chemical investigation of western red cedar (WRC) (*Thuja plicata* Donn.) heartwood extractives has led to identification of more than a dozen biologically active phenolic compounds (1). These heartwood extractives can be separated readily into volatile and nonvolatile fractions by steam distillation. The volatile fraction consists partly of compounds that are tropolone derivatives, the thujaplicins. The nonvolatile WRC heartwood extractives are mainly lignans (2–12). WRC is recognized as one of the world's most durable woods. It has long been understood from chemical and biological studies that the above two major groups of compounds in WRC heartwood extractives give the wood its durability. It is observed, however, that in certain areas of British Columbia (B.C.) there is a serious WRC heartwood decay problem, especially in living mature and over-mature trees. Questions arise on the biological roles of WRC heartwood extractives in response to microorganism attacks in living trees. In this study, a comparison of differences in extractive composition between healthy and discolored heartwood within the same growth zones in the tree was made. The discoloration of healthy wood was due to infection by microorganism attacks. We now report a novel lactone compound isolated from discolored heartwood extractives that was not present in healthy WRC heartwood extractives. Associated biological tests (13) in this study positively demonstrated that this lactone compound was a biodegradation product of the thujaplicins during infection by a fungus, *Sporothrix* sp., in the heartwood of a once living WRC tree.

Results and discussion

Isolation, purification, and elucidation of the chemical structure of this lactone compound were carried out by chemical, chromatographic, and spectroscopic methods. On the basis of the following results, the compound structure has been determined as 3,3,4,7,7,8-hexamethyl-2,6-dioxa-1,5-anthracene-dione, and given the trivial name thujin (**1**).

Thujin was preliminarily separated by extracting WRC discolored heartwood meal with a benzene–ethanol (2:1) solvent. After evaporation of this solvent, the crude material was liquid extracted by a series of solvents. The solvents used were ethyl ether, ethyl acetate, and ethanol. Thujin was found by thin-layer chromatography (tlc) to occur mainly in the ethyl acetate solubles. Removal of the ethyl acetate insoluble material from the extractives separated thujin from the more strongly polar components, such as plicatic acid, a most important lignin in WRC extractives. After the ethyl acetate solubles passed through a gradient elution chromatographic column, thujin was found to be present in the fraction eluted by a benzene–ethanol (85:15) solvent mixture. The final purified thujin was obtained by using a preparative tlc method with a benzene–ethanol (9:1) solvent system, and crystallization was achieved.



1

On the silica gel tlc plates, thujin had an R_f value of 0.79, which was considerably higher than R_f values for most known tropolone derivatives and lignans in WRC heartwood extractives (14). The blue fluorescence under shortwave ultraviolet (uv) light indicated that the chemical structure of thujin contained some chromophores or auxochromes, such as conjugated double bonds and carbonyl groups, or -OH and -OR groups.

Both low and high resolution mass spectra of thujin were recorded. The parent ion was observed at *m/e* as 300 (*m/z*). The isotopic peak of it was at *m/e* as 301. The intensity of the isotopic peak was 19.3% of the parent ion peak. From the natural isotopic abundance of carbon-13, this indicated approximately 18 carbons present in the structure. The high resolution mass spectrum gave a molecular weight of 300.1368 with an empirical formula of $C_{18}H_{20}O_4$. The elemental analysis for carbon and hydrogen further confirmed the molecular composition.

TABLE 1. Carbon-13 proton decoupled and APT nmr spectral data and assignments for thujin (**1**)

Chemical shift (ppm)	APT data	Assignment
167.95	Quaternary	C-1 or C-5
138.45	Methine	C-9 or C-10
135.63	Quaternary	{C-4, C-11, and C-12, or
123.57	Quaternary	C-8, C-13, and C-14}
122.93	Quaternary	
62.02	Quaternary	C-3 or C-7
35.14	Methyl	C-19 or C-20
26.22	Methyl	C-15 and C-16, or C-17 and C-18

The pattern of fragmentation in the mass spectra showed a very clear symmetry in the compound. The examples of such were those fragments with m/e at 300 (parent ion, M), $M/2$, $M - 15$, $M - (2 \times 15)$, $M - 44$, $M - (2 \times 44)$, and $M - (2 \times 14 - 2 \times 44)$. The peak with m/e at 149.0609 with an empirical formula of $C_9H_9O_2$ was half of the parent ion, with the additional loss of one hydrogen. The peak with mass of $M - (2 \times 15)$ may be assigned to the loss of two CH_3 groups while the peak with the mass of $M - (2 \times 44)$ can be assigned to the loss of two CO_2 groups in the molecule.

The proton nuclear magnetic resonance (nmr) spectrum of thujin was rather simple with only three singlet peaks. Their chemical shifts were 1.28, 2.3, and 7.3 ppm. Therefore there were only three types of protons with different environments present in the molecule. None of these protons had any neighbouring protons, since no coupling was observed. Integration of the peak areas showed that the relative numbers of the three types of protons present in the compound were 1:3:6 for the signals at 7.3, 2.3, and 1.28 ppm, respectively.

Carbon-13 Broad Band (BB) proton decoupled and Attached Proton Test (APT) nmr spectral data and assignments for thujin (**1**) are listed in Table 1.

An APT carbon-13 nmr spectrum determined the numbers of protons bonded to a carbon in the molecule (Table 1).

Evidence from mass spectral fragments showed that thujin had a symmetric dimer structure. According to proton and carbon-13 nmr information, it was assumed that the molecule had 2×9 carbons and 2×10 protons. The carbon at 167.95 ppm in the carbon-13 nmr spectrum was assigned to an acid, ester, or lactone carbonyl, which meant that this carbonyl carbon bonded directly to two oxygens in the molecule. Since thujin was a symmetric compound, it would have 2×2 oxygen atoms. Therefore, the empirical formula $C_{18}H_{20}O_4$ for thujin (**1**) was also strongly supported by the nmr spectral evidence.

Information provided by the infrared (ir) spectrum was quite conclusive. The lack of absorption peaks (3650–3200 cm^{-1}) in the ir spectrum of thujin indicated absence of an -OH group in the structure. One of the most distinctive bands in the ir spectrum of thujin was that arising from the carbonyl group at 1733 cm^{-1}, which was a characteristic peak for six-membered ring lactones.

Experimental

The WRC wood sample used for this study was obtained from a 420-year-old living tree that was infected by microorganisms (13). On the tree cross section, there was a discolored pocket that was surrounded by straw-colored healthy heartwood. Healthy and discolored WRC heartwood samples were collected within the same growth zones of the tree, air dried, and ground to pass a 50-mesh screen.

The wood meals were Soxhlet extracted with a benzene–ethanol (2:1) solvent. The evaporated benzene–ethanol extractives were fractionated with ether, ethyl acetate, and ethanol. The fractions were monitored by tlc with benzene–ethanol (9:1) as a developing solvent. The ethyl acetate solubles that contained thujin were chromatographed on a silica gel (Bio-sil A, 200–400 mesh) column (3 cm × 40 cm). The eluting solvents were chosen by trial experiments. The column was eluted with solvent mixtures of increasing polarity, starting with pure benzene and gradually increasing the percentage of ethanol to give an equal mixture of benzene–ethanol (50:50). The tlc result indicated that thujin was present mainly in the fraction eluted with a benzene–ethanol mixture at the ratio of 85:15. The final purification of thujin was achieved by using preparative tlc with Whatman PLK5F silica gel plates, 20 × 20 cm, 1000 μm thickness by benzene–ethanol (9:1) solvent. Thujin was found under shortwave uv light as a blue fluorescent band at an R_f value of 0.79. Shortwave uv light fluorescence was used to locate the thujin band, which was then scraped from the plate with care. The thujin–silica scraped from the plate was ground to very fine particles and then **1** was leached from the absorbent by ethanol. Crystallization of thujin was achieved by dissolving it in an ethyl acetate – heptane mixture (1:3) and keeping it in a freezer for about 5 weeks. The uncorrected melting range for thujin was 88–91°C.

Both proton and carbon-13 nmr spectra were taken on a Varian XL-300 machine. The samples were prepared in deuterochloroform solution with tetramethylsilane (TMS) as an internal standard. The ir spectrum was recorded on a Perkin–Elmer 137 spectrophotometer. The low resolution mass spectrum was determined on a MAT CH-4 spectrometer, while the high resolution mass spectrum was recorded on a Kratos MS-50 spectrometer. Elemental analysis was done by the Microanalytical Laboratory, Department of Chemistry, U.B.C. A Beckman model 24 spectrometer was used for uv and visible spectral measurements.

The important spectral data were: (*a*) ir: λ_{max} (cm^{-1}), no hydroxyl band, 2962 and 2878 (methyl C—H stretching), 1459 and 1381 (methyl C—H bending), 3016 (double bonding =C—H), 1733 (lactone), 1599, 1574, 1500, and 1459 (conjugated double bonds); (*b*) uv: λ_{max}, 285 nm (extended conjugation system including a carbonyl group); (*c*) proton nmr: 1.28 (6H, singlet, for CH_3 at C-15 and C-16, or at C-17 and C-18), 2.3 (3H, singlet, for CH_3 at C-19 or at C-20), 7.3 (1H, singlet, for CH at C-9 or at C-10); and (*d*) mass spectra: m/e, 300 (parent ion), 285, 270, 256, 212, 184 and 149. *Mol. Wt.* calcd. for $C_{18}H_{20}O_4$: 300.1362; found (hrms): 300.1368. *Anal.* calcd. for $C_{18}H_{20}O_4$: C 71.89, H 6.71%; found: C 72.14, H 6.78%.

Selenium-77 nuclear magnetic resonance studies of selenols, diselenides, and selenenyl sulfides

KHOON-SIN TAN, ALAN P. ARNOLD,[1] AND DALLAS L. RABENSTEIN[2]
Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received May 27, 1987

KHOON-SIN TAN, ALAN P. ARNOLD, and DALLAS L. RABENSTEIN. Can. J. Chem. **66**, 54 (1988).

^{77}Se and ^{1}H nuclear magnetic resonance spectra have been measured for selenols (RSeH), diselenides (RSeSeR), and selenenyl sulfides (RSeSR′), including selenenyl sulfides formed by reaction of glutathione and penicillamine with selenocystine and related diselenides. Exchange processes strongly affect the ^{77}Se and ^{1}H nuclear magnetic resonance spectra of all three classes of compounds. Sharp, exchange-averaged resonances are observed in the ^{1}H nuclear magnetic resonance spectra of selenols; however, selenol proton exchange causes the ^{77}Se resonances to be extremely broad over the pH range where the selenol group is titrated. Selenol/diselenide exchange ($\overset{*}{R}SeH + RSeSeR \rightleftarrows \overset{*}{R}SeSeR + RSeH$) also results in exchange-averaged ^{1}H resonances for solutions containing RSeH and RSeSeR; however, the ^{77}Se resonances were too broad to detect. Exchange reactions have similar effects on nuclear magnetic resonance spectra of solutions containing selenols and selenenyl sulfides. The results indicate selenol/diselenide exchange is much faster than thiol/disulfide exchange. The ^{77}Se chemical shift depends on the chemical state of the selenium, e.g., titration of the selenol group of selenocysteamine causes the ^{77}Se resonance to be shielded by 164 ppm, oxidation of the selenol to form the diselenide selenocystamine causes a deshielding of 333 ppm, and oxidation to form the selenenyl sulfide $\overset{+}{H_3}NCH_2CH_2SeSCH_2CH_2\overset{+}{N}H_3$ results in a deshielding of 404 ppm. ^{77}Se chemical shifts were found to be in the range -240 to -270 ppm (relative to $(CH_3)_2Se$) for selenolates, approximately -80 ppm for selenols, 230–360 ppm for diselenides, and 250–340 ppm for selenenyl sulfides. The ^{77}Se chemical shift is also affected by titration of neighboring carboxylic acid and ammonium groups, and their pK_A values can be calculated from ^{77}Se chemical shift data.

KHOON-SIN TAN, ALAN P. ARNOLD et DALLAS L. RABENSTEIN. Can. J. Chem. **66**, 54 (1988).

On a déterminé les spectres en résonance magnétique nucléaire du ^{77}Se et du ^{1}H de sélénols (RSeH), de disélénures (RSeSeR) et de disulfures de sélénényles (RSeSR′), y compris des sulfures de sélénényles qui se forment au cours de la réaction du glutathion et de la pénicillamine avec la sélénocystéine et des disélénures apparentés. Les processus d'échange affectent beaucoup les spectres en résonance magnétique nucléaire du ^{77}Se et du ^{1}H de ces trois classes de composés. Avec les sélénols, les spectres en résonance magnétique nucléaire du ^{1}H présentent des raies bien définies qui résultent de moyennes; toutefois, l'échange du proton du sélénol fait que les résonances du ^{77}Se sont extrêmement larges à tous les pH où le groupement sélénol peut être titré. Dans le cas des solutions qui contiennent du RSeH et du RSeSeR, l'échange sélénol/disélénure ($R^*SeH + RSeSeR \rightleftarrows R^*SeSeR + RSeH$) conduit aussi à des résonances du ^{1}H qui résultent de moyennes; toutefois, les résonances du ^{77}Se sont trop élargies pour être détectées. Les réactions d'échange ont des effets semblables sur les spectres en résonance magnétique nucléaire de solutions contenant des sélénols et des sulfures de sélénényles. Les résultats indiquent que l'échange sélénol/disélénure est beaucoup plus rapide que l'échange thiol/disulfure. Le déplacement chimique du ^{77}Se dépend de l'état chimique du sélénium; par exemple, le titrage du groupement sélénol de la sélénocystamine provoque un blindage de la résonance du ^{77}Se de 164 ppm, l'oxydation du sélénol conduisant au disélénure de sélénocystamine provoque un déblindage de 330 ppm et l'oxydation conduisant au sulfure de sélénényle $\overset{+}{H_3}NCH_2CH_2SeSCH_2CH_2\overset{+}{N}H_3$ provoque en déblindage de 404 ppm. On a trouvé que les déplacements chimiques sont de l'ordre de -240 à -270 ppm (par rapport au $(CH_3)_2Se$) pour les sélénolates, de -80 ppm pour les sélénols, de 230 à 360 ppm pour les disélénures et de 250 à 340 ppm pour les sulfures de sélénényles. Le déplacement chimique du ^{77}Se est aussi influencé par le titrage des groupements acide carboxylique et ammonium voisins et leurs pK_A peuvent être calculés à partir des déplacements chimiques du ^{77}Se.

[Traduit par la revue]

Introduction

Reactions of selenium-containing functional groups with thiols and disulfides are important in the biological chemistry of seleno compounds and the mechanism of action of seleno enzymes (1–4). For example, reaction of the diselenide RSeSeR with the thiol R′SH to form the selenol RSeH and the selenenyl sulfide RSeSR′, which in turn reacts with R′SH to form RSeH and the disulfide R′SSR′ (eqs. [1] and [2]), provides

[1] $R'SH + RSeSeR \rightleftarrows R'SSeR + RSeH$

[2] $R'SH + R'SSeR \rightleftarrows R'SSR' + RSeH$

a pathway for reduction of diselenide (5). The reaction of thiols with selenenyl sulfides (eq. [2]) is of particular interest because such a reaction (eq. [3]) is the third step in a proposed

[3] $GSH\text{-}Px\text{-}SeSG + GSH \rightleftarrows GSH\text{-}Px\text{-}SeH + GSSG$

mechanism for the glutathione peroxidase (GSH-Px-SeH) catalyzed reduction of hydroperoxides by glutathione (GSH) (2, 3). The selenium of a selenocysteine residue is the active site of glutathione peroxidase (2, 3).

Although the importance of reactions [1] and [2] in the biological chemistry of selenium is well established, little is known about their kinetics and equilibria, or about the chemistry of the intermediate selenenyl sulfides. As the first part of a study of the reduction of diselenides by thiols and of the oxidation of selenols by disulfides, we have investigated the feasibility of using ^{77}Se nmr to study the selenium-containing reactants and products in such reactions. The high sensitivity of ^{77}Se chemical shifts to electronic environment (6) suggests that ^{77}Se nmr is potentially a powerful technique for characterizing the solution chemistry of such compounds. We are particularly interested in characterizing selenenyl sulfides formed by reaction of glutathione with selenocystine and related diselenides as models for the selenenyl sulfide intermediate in the proposed

mechanism for glutathione peroxidase activity (2, 3). Luthra *et al.* have demonstrated that ^{77}Se nmr spectra can be obtained for selenenyl sulfides formed from phenyl- and nitrophenylselenenyl moieties and several thiol compounds (7, 8). However, phenylselenium may not be an appropriate model for the alkyl selenium in glutathione peroxidase and other biological selenium compounds. Also, the effect of the reactions in eqs. [1] and [2] on the measurement of ^{77}Se nmr spectra of selenols, diselenides, and selenenyl sulfides has not been established.

Experimental

D,L-Selenocystine and selenocystamine dihydrochloride were used as received from Sigma Chemical Company. They contained no impurities that could be detected by ^{1}H nmr. Bis(2-hydroxyethyl)diselenide was prepared by hydrolysis of 2-hydroxyethaneselenosulfate, which was prepared from 2-hydroxyethylbromide and potassium selenosulfate in water (9). The bis(2-hydroxyethane)diselenide was fractionally distilled under reduced pressure as an orange oil. The diselenodialkanoic acids $(HO_2C(CH_2)_nSe)_2$, $n = 1-3$, were prepared as described previously (10). Selenols were prepared from the diselenides by reduction over a Hg pool cathode (10), or by reduction with sodium borohydride.

L-Cysteine, D-penicillamine, and glutathione (Sigma Chemical Company) were used as received. Cysteamine hydrochloride (Aldrich Chemical Company) was sublimed *in vacuo* to purify it from the disulfide, cystamine, which was detected in the ^{1}H nmr spectrum of a 10 m*M* solution in D_2O.

pH measurements were made at 25°C with an Orion Model 701A pH meter equipped with a standard glass electrode (Philips GAT 130) and a double-junction saturated calomel reference electrode (Philips R44/2-SD/1); the outer junction solution was 0.3 *M* KNO_3 in D_2O. The pH meter was calibrated with pH 4.008 (0.05 *m* phthalate) and pH 6.865 (0.05 *m* phosphate) standard buffers prepared according to NBS specifications. Sample solutions were either in D_2O or 90%/10% H_2O/D_2O. pH measurements for D_2O solutions were corrected for deuterium isotope effects with the relation pD = pH meter reading + 0.40 (11). No correction was applied to the pH readings for the 90% H_2O solutions.

The ^{1}H nmr spectra were obtained at 360 MHz with a Bruker WM 360 nmr spectrometer operating in the pulse/Fourier transform mode. Measurements were made at a probe temperature of 25 ± 2°C. ^{1}H chemical shifts were measured relative to the methyl resonance of internal *tert*-butyl alcohol (TBA), but are reported relative to the methyl resonance of sodium-2,2-dimethyl-2-silapentane-5-sulfonate (DSS). The ^{77}Se nmr spectra were measured at 68.68 MHz with proton decoupling. The variable temperature unit was set to 25°C and spectra were measured with the decoupler on only during acquisition to minimize sample heating. ^{77}Se chemical shifts were measured relative to the resonance for an 8.4 *M* H_2SeO_3 solution; the chemical shift of this resonance is 1282 ppm relative to that for $(CH_3)_2Se$ (12). The 90° pulse width for ^{77}Se was 24 μs. Typically, spectra were measured with a repetition time of ~2 s, an acquisition time of ~0.2 s, and 60–90 min of signal averaging. Spin-lattice relaxation times were measured by the inversion–recovery pulse sequence, with relaxation delays of at least $5T_1$ between inversion–recovery pulse sequences and the decoupler gated on only during acquisition. Solutions used in the measurement of ^{77}Se nmr spectra had concentrations of 20 m*M* – 0.2 *M*. In most cases, solutions were made up in 90% v/v aqueous D_2O containing 0.3 *M* KNO_3. Solutions used for the measurement of relaxation times were degassed by bubbling with argon, and the nmr tubes were sealed under an argon atmosphere.

Results

The ^{77}Se and ^{1}H nmr spectra were measured for selenols, diselenides, and selenenyl sulfides with the objectives of establishing conditions under which spectra can be obtained for such compounds in aqueous solution and of identifying the chemical shift ranges for ^{77}Se in such compounds.

[a]Relative to $(CH_3)_2Se$.

Selenols

The ^{77}Se and ^{1}H nmr spectra were measured for selenocysteine, selenocysteamine, and selenoethanoic acid in aqueous solution as a function of pH. Selected ^{77}Se chemical shifts are listed in Table 1. Sharp, exchange-averaged resonances were observed in the ^{1}H nmr spectra, whereas the lineshape of the exchange-averaged ^{77}Se resonances is strongly dependent on pH. ^{77}Se resonances could be observed at low and high pH where the selenol is present as RSeH and RSe^-, respectively; however, the ^{77}Se resonance generally was too broad to observe in the pH region 4–7 where the selenol group is titrated (13). For example, the width at half-height of the ^{77}Se resonance for selenocysteine was 21, 28, 52, and >200 Hz at pH values of 11.68, 10.00, 7.60, and 6.36 respectively, and was too broad to observe at lower pH. The ^{77}Se resonance for selenocysteamine also broadened over the pH range 4–7; however, not so much that it could not be observed. At pH 3, selenocysteamine is present as **I** and its chemical shift was determined to be −81.6 ppm. As the pH is increased and the selenol group titrated to give **II**, the ^{77}Se resonance shifts to lower frequency,

[4] $H_3\overset{+}{N}CH_2CH_2SeH \rightleftarrows H_3\overset{+}{N}CH_2CH_2Se^- + H^+$
I **II**

reaching a limiting chemical shift of −245.6 ppm at pH 8. From the dependence of the chemical shift of the exchange-averaged ^{77}Se resonance on pH, the p*K* of the selenol group

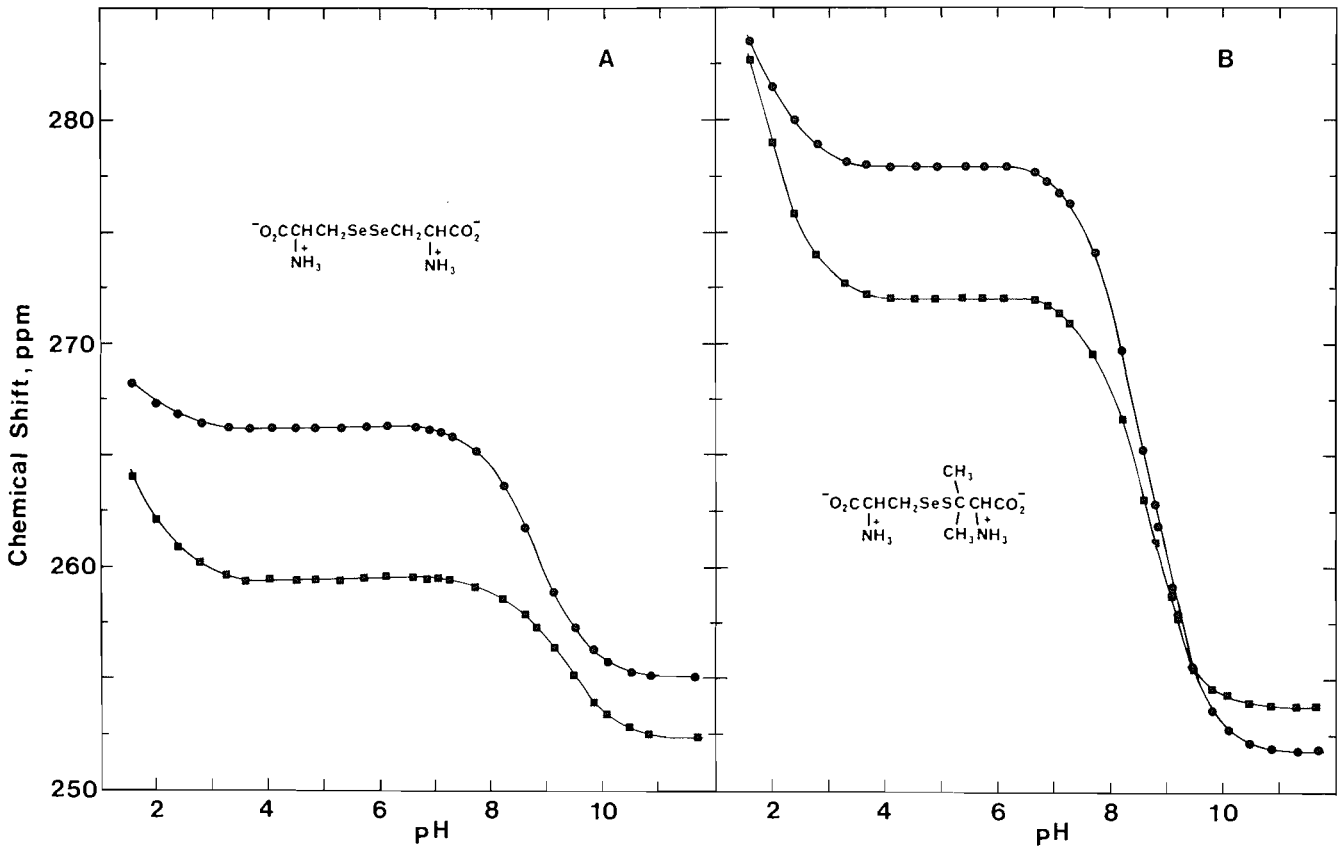

FIG. 1. pH dependence of the chemical shifts of the ^{77}Se resonances for D,L-selenocystine (A) and the selenenyl sulfide formed from D-penicillamine and D,L-selenocystine (B). The selenenyl sulfide was prepared by reacting 50 m*M* D-penicillamine with 50 m*M* D,L-selenocystine as described in the text. Ionic strength 0.3 *M* (KNO_3) and 25°C.

was estimated to be 5.31 ± 0.14. Because the change in the ^{77}Se chemical shift accompanying titration of the selenol group is so large (164 ppm for the ^{77}Se of selenocysteamine vs. 0.25 ppm for the methylene protons next to the selenol group of selenocysteamine), exchange broadening makes difficult or impossible the measurement of ^{77}Se spectra for selenol groups at pH values within ±2 pH units of the selenol pK_A at the spectrometer frequency used in this work.

Diselenides

The ^{77}Se and ^{1}H nmr spectra were measured as a function of pH for the diselenodialkanoic acids $(HO_2C(CH_2)_nSe)_2$, n = 1–3, selenocystamine $(H_3\overset{+}{N}CH_2CH_2Se)_2$, D,L-selenocystine $(^{-}O_2CCH(\overset{+}{N}H_3)CH_2Se)_2$, and bis(2-hydroxyethane)diselenide $(HOCH_2CH_2Se)_2$. The chemical shifts of the ^{77}Se and ^{1}H resonances for all but the last diselenide are pH dependent, changing over the pH region where carboxylic acid and (or) ammonium groups are titrated. ^{77}Se chemical shifts are reported in Table 1 for the diselenides at various stages of protonation.

Two resonances of equal intensity are observed for D,L-selenocystine, one for seleno-D,D-cystine and seleno-L,L-cystine, and one for seleno-D,L-cystine (14). The chemical shifts of the two resonances are plotted vs. pH in Fig. 1A. As the pH is increased from 6.5 to 11, the chemical shifts change due to titration of the ammonium group; however, the chemical shifts for the two diastereomers change by significantly different amounts (11.3 and 7.1 ppm), and by somewhat smaller amounts than the ^{77}Se resonance for selenocystamine (17.0 ppm). These results suggest that the chemical shift changes accompanying titration of the two ammonium groups of selenocystine are due to a combination of inductive and conformational effects. Acid dissociation constants for the ammonium groups of the two diastereomers, obtained by fitting the two sets of chemical shift data by nonlinear least-squares methods to a diprotic acid model (15), are different (pK_1 = 8.62 ± 0.04 and pK_2 = 9.81 ± 0.13 for the high frequency resonance and pK_1 = 8.32 ± 0.15 and pK_2 = 9.50 ± 0.06 for the low frequency resonance), which supports the conclusion that their conformations are different. pK values of 9.65 ± 0.03 and 10.77 ± 0.11 were obtained from the pH dependence of the ^{77}Se chemical shift data for selenocystamine.

Titration of the carboxylic acid groups of the diselenodialkanoic acids $(HO_2C(CH_2)_nSe)_2$ also causes the ^{77}Se chemical shift to change (Table 1). The magnitude of the change for diselenodiethanoic acid (n = 1) is somewhat larger than observed for titration of the ammonium groups of selenocystamine and selenocystine; however, the magnitude of the change decreases rapidly as n increases from 1 to 3, and in fact the direction of the change is reversed when n = 3. pK values of 3.47 ± 0.02 and 4.32 ± 0.03 were obtained by fitting the ^{77}Se chemical shift data for diselenodiethanoic acid to a diprotic acid model. For comparison, pK values of 3.49 ± 0.02 and 4.30 ± 0.01 were obtained from ^{1}H chemical shift data. The change in ^{77}Se chemical shifts accompanying titration of the carboxylic acid groups of diselenodipropanoic and diselenodibutanoic acids was too small for precise determination of their

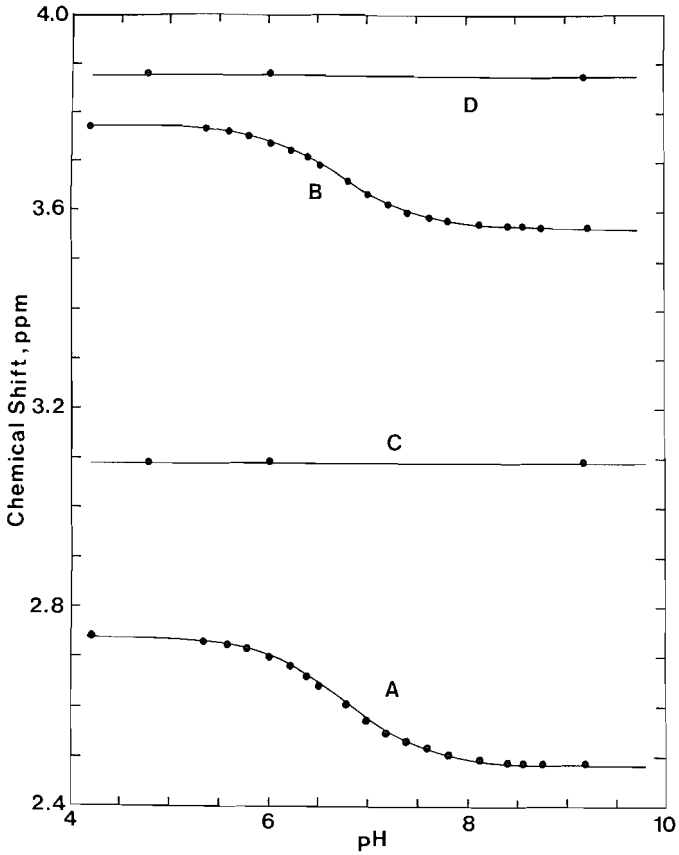

FIG. 2. pH dependence of the chemical shifts of the CH_2Se (A) and OCH_2 (B) protons of 0.020 *M* 2-hydroxyethaneselenol and of the CH_2Se (C) and OCH_2 (D) protons of bis(2-hydroxyethane)diselenide. Both solutions were in 90% H_2O/10% D_2O and contained 0.3 *M* KNO_3 for ionic strength control. The smooth curves through A and B are theoretical curves for a pK_A of 6.75.

p*K* values. The values obtained from ^1H chemical shift data are 3.88 ± 0.05 and 4.62 ± 0.04 for diselenodipropanoic acid and 4.29 ± 0.08 and 5.67 ± 0.03 for diselenodibutanoic acid.

^{77}Se spin-lattice relaxation times for several of the diselenides are reported in Table 2. Previous studies have shown that the spin rotation mechanism dominates ^{77}Se spin-lattice

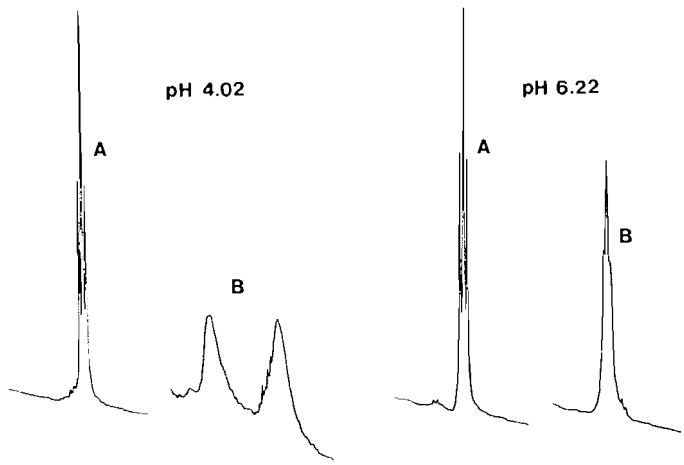

FIG. 3. The ^1H nmr spectra for the CH_2Se protons of a 20 m*M* solution of 2-hydroxyethaneselenol (A) and of the CH_2Se protons of a solution containing 20 m*M* 2-hydroxyethaneselenol and 12 mM bis(2-hydroxyethane)diselenide (B). At pH 4.02, selenol/diselenide exchange is slow, and separate resonances are observed for selenol and diselenide; at pH 6.22 a broad, exchange-averaged triplet is observed.

relaxation in small diselenides at low magnetic fields, with the chemical shift anisotropy mechanism becoming more important as the magnetic field strength and the size of the diselenide increase (13, 14, 16, 17). The decrease in ^{77}Se spin-lattice relaxation times for the diselenodialkanoic acids as their size increases is consistent with increased relaxation by the chemical shift anisotropy mechanism.

Selenol/diselenide exchange

Nuclear magnetic resonance measurements were also made on solutions containing both selenol and diselenide. By analogy with results from ^1H and ^{13}C nmr studies of thiol/disulfide exchange reactions (18–20), we expected to observe separate resonances for selenol and diselenide. However, ^1H resonances were either broadened or exchange-averaged, depending on pH and the relative concentrations of selenol and diselenide, and ^{77}Se resonances could not be detected for selenol/diselenide mixtures. To illustrate, ^1H nmr results for the 2-hydroxyethaneselenol (HES)/bis(2-hydroxyethane)diselenide (HEDS) system are presented in Figs. 2–4. The ^1H nmr spectrum of a solution containing HES alone consists of two triplets for the two methylene groups, the chemical shifts of which are pH dependent due to titration of the selenol group. The chemical shifts are plotted vs. pH in Fig. 2 (A is for CH_2Se and B for OCH_2). Sharp triplets were observed over the entire pH range, e.g., the resonances for the CH_2Se protons are shown in Fig. 3 at pH 4.02 (A) and 6.22 (A). The ^1H nmr spectrum of HEDS alone also consists of two sharp triplets whose chemical shifts are independent of pH as shown by C (for CH_2Se) and D (for OCH_2) in Fig. 2. However, in mixtures of HES and HEDS, resonances for the CH_2Se protons and for the OCH_2 protons of the two compounds are either exchange-broadened or exchange-averaged. For example, the spectra in Fig. 3 show that, at pH 4.02, separate, broadened resonances are observed at 2.740 and 3.090 ppm for the CH_2Se protons of HES and HEDS, respectively, in a mixture of the two. However, at pH 6.22, a single, broadened triplet (B) is observed at a chemical shift (2.857 ppm) intermediate between those of the CH_2Se protons of HES and HEDS. Exchange-averaged resonances were also observed at higher pH, and they were sharper the higher the

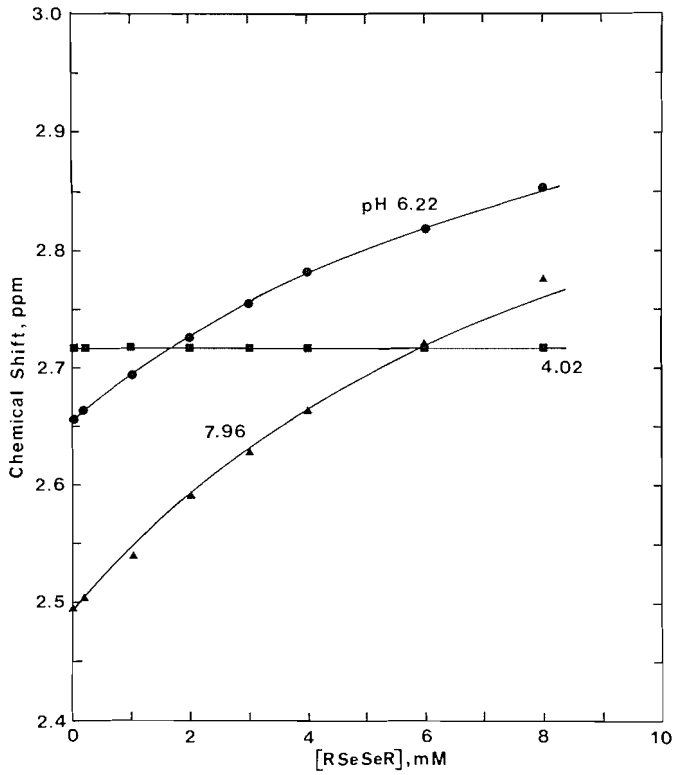

FIG. 4. Dependence of the chemical shift of the resonance for the CH_2Se protons of 2-hydroxyethaneselenol (20 m*M*) at pH 4.02 and the exchange-averaged resonance for the CH_2Se protons of 2-hydroxyethaneselenol and of bis(2-hydroxyethane)diselenide at pH 6.22 and 7.96 as a function of the diselenide concentration. The smooth curves through the experimental points at pH 6.22 and 7.96 are theoretical curves calculated assuming fast exchange.

pH. The chemical shifts of the exchange-averaged resonances depend on the concentrations of HES and HEDS and on the pH as shown in Fig. 4 for the results at pH 6.22 and 7.96. The chemical shifts are pH independent at pH 4.02 because exchange is slow, and separate, broadened resonances are observed for HES and HEDS.

Selenenyl sulfides

Solutions containing selenenyl sulfides were prepared by reaction of thiol with diselenide (eqs. [1] and [2]) or by chemical reduction of diselenide with $NaBH_4$ to give the selenol, and then addition of disulfide. Below pH 7, thiol groups are protonated and no reaction of thiol with diselenide was observed. Above pH 8, where the thiol group is partially or completely deprotonated, reaction proceeds rapidly. Selenols reacted more rapidly with disulfides, and at lower pH values as a result of the lower pK_A of the selenol group.

Resonances in ^1H nmr spectra for such reaction mixtures were broad while no resonances could be detected in the ^{77}Se spectra. As a result of exchange by eqs. [1] and [2], the solutions contained selenol, which, as discussed above, causes broadening of the ^1H resonances and loss of the ^{77}Se resonances for diselenide due to selenol/diselenide exchange. The observation of similar effects in nmr spectra for R′SSeR suggests that the reaction of selenol with R′SSeR also occurs on a similar time scale. ^{77}Se resonances could be observed for R′SSeR only after eliminating selenols from the solution. In the procedure generally followed, thiol and diselenide, or selenol and disulfide, were allowed to react for at least 4 h, and then the solution was bubbled with oxygen for 6–8 h to oxidize the selenol.

The ^{77}Se nmr spectra of several reaction mixtures prepared as described above are shown in Fig. 5. Resonances are observed for the selenenyl sulfide and the diselenide; diselenide resonances were assigned using chemical shift data from Table 1. ^{77}Se chemical shift data for selenenyl sulfides are presented in Table 3, and spin-lattice relaxation times for two selenenyl sulfides are reported in Table 2. Two resonances are observed in Fig. 5A for PSSeC due to formation of the diastereomers, D-PSSeC-D and D-PSSeC-L. Their chemical shifts are pH dependent (Fig. 1B) due to titration of the acidic functional groups.

Discussion

Exchange processes strongly affect nmr spectra of aqueous solutions of selenols, selenenyl sulfides, and diselenides. Sharp, exchange-averaged ^1H nmr spectra are observed for the carbon-bonded protons of selenols over the entire pH range; however, proton exchange between the selenol and selenolate forms causes the ^{77}Se resonance to be so broad over the pH range $pK_A \pm 2$ that it cannot be observed in most cases. No rate constants have been reported for selenol proton exchange; however, the results of this study indicate that it is fast relative to the chemical shift change in ^1H nmr spectra accompanying titration of the selenol proton but not compared to that in ^{77}Se spectra (~90 and ~11 000 Hz, respectively, at the spectrometer frequencies used in this work).

The exchange-averaged ^1H resonances observed for solutions containing selenol and diselenide are in sharp contrast with the separate resonances observed for thiol and for disulfide in both ^1H and ^{13}C spectra of solutions containing thiol and disulfide (18–20), indicating that selenol/diselenide exchange is much faster than thiol/disulfide exchange.

$$[5] \quad \overset{*}{R}SeH + RSeSeR \rightleftarrows \overset{*}{R}SeSeR + RSeH$$

The ^1H nmr results indicate that the rate of selenol/diselenide exchange increases as the pH is increased through the pH region where the selenol group is titrated, which suggests that the deprotonated selenolate, RSe^-, is the reactive form of the selenol. The ^{77}Se nmr spectra could be obtained for selenols only if the solution did not contain diselenides or selenenyl sulfides. Likewise, ^{77}Se spectra could be obtained for diselenides and selenenyl sulfides only in the absence of selenols. Exchange-averaged ^1H resonances are observable, whereas ^{77}Se resonances are not, because the chemical shift change on going from selenol to diselenide or selenenyl sulfide is much larger in the ^{77}Se spectra, and thus much faster exchange is necessary to observe exchange-averaged ^{77}Se resonances. For example, the chemical shift of protons on carbons bonded to selenium changes by ~0.4–0.6 ppm, depending on pH, when the selenium is converted from the selenol to the diselenide form. However, the results in Tables 1 and 3 indicate that the ^{77}Se resonance is deshielded by ~500 ppm and ~600 ppm on going from RSe^- to $(RSe)_2$ and from RSe^- to RSeSR′, respectively. It is of interest to note, however, that ^{77}Se resonances can be obtained for selenenyl sulfides formed by reaction of 6,6′-diselenobis(3-nitrobenzoic acid) with cysteine, acetylcysteine, and glutathione in the presence of the selenol (8). The exchange kinetics in this system are presumably slow due to steric effects.

The ^{77}Se chemical shift depends on the chemical state of the selenium. The most complete set of data in Tables 1 and 3 is for

[b]Relative to $(CH_3)_2Se$.

selenocysteamine ($H_3N^+CH_2CH_2SeH$, CySeH). Titration of the selenol proton causes the shielding to increase by 164 ppm; increased shielding is expected due to the increased electron density at the selenium. Oxidation of the selenol group to form CySeSeCy causes a deshielding of 332.9 ppm, while oxidation by reaction with cystamine to form CySeSCy causes an even larger deshielding of 404.3 ppm, consistent with the relative electronegativities of sulfur and selenium (7). The magnitude of the additional deshielding upon replacement of selenium in diselenides by sulfur in selenenyl sulfides depends on the nature of the sulfide and the protonation state of carboxylic acid and ammonium groups. For example, the ^{77}Se resonance of CySeSCy is deshielded 71.4 ppm relative to that of CySeSeCy and the two ^{77}Se resonances of D,L-CSeSC-L are deshielded by 70–80 ppm relative to those of D,L-CSeSeC. However, the ^{77}Se resonance of CySeSP-D is deshielded by only 31 ppm relative to that of CySeSeCy while the resonances of D,L-CSeSP-D are deshielded by 15–18 ppm, 11–13, and ~0 ppm relative to those of D,L-CSeSeC at pH values of 1.57, 6.64, and 11.71. It also is of interest to note that the selenium in phenylselenenyl sulfides experiences even greater deshielding than the selenium in alkylselenenyl sulfides. For example, ^{77}Se chemical shifts for phenylselenenyl sulfides are in the range of 420–740 ppm (7, 8) while those reported here for alkylselenenyl sulfides are in

the range 250–340 ppm. The additional deshielding of ^{77}Se in phenylselenenyl sulfides is consistent with the expected ring current effects from the phenyl ring.

The change in ^{77}Se chemical shift accompanying titration of a neighboring carboxylic acid or ammonium group also depends on the chemical state of the selenium, with the changes for selenium in selenide, diselenide, and selenenyl sulfide forms being somewhat larger than for selenium in the selenolate form. For example, the ^{77}Se resonance of the selenolate form of selenocysteine (CSe^-) is deshielded by 1.7 ppm when the ammonium group is titrated, whereas the ^{77}Se resonances of the diastereomers of selenocystine (CSeSeC) are shielded by 11.5 and 7.3 ppm, and those of the diastereomers of the selenenyl sulfide PSSeC are shielded by 25.9 and 18.6 ppm. For comparison, titration of the ammonium group of selenomethionine causes the ^{77}Se resonance to be shielded by 5.4 ppm.

Synthesis of cyclopentane analogs of 1-(2′,3′-dideoxy-β-*glycero*-pentofuranosyl)pyrimidine nucleosides

LUCJAN J. J. HRONOWSKI AND WALTER A. SZAREK
Department of Chemistry, Queen's University, Kingston, Ont., Canada K7L 3N6

Received November 10, 1986[1]

LUCJAN J. J. HRONOWSKI and WALTER A. SZAREK. Can. J. Chem. **66**, 61 (1988).

Synthesis of new carbocyclic analogs of 1-(2′,3′-dideoxy-*glycero*-pentofuranosyl)pyrimidine nucleosides having the uracil (**34**), 2-thiouracil (**33**), 2-thiothymine (**31**), cytosine (**44**), and 5-methylcytosine (**43**) bases is described. The nucleoside analogs having the uracil, 2-thiouracil, and 2-thiothymine bases were prepared by coupling *cis*-3-aminocyclopentanemethanol (**8**) with 3-ethoxypropenoyl isocyanate (**26**), 3-ethoxypropenoyl isothiocyanate (**25**), and 3-methoxy-2-methylpropenoyl isothiocyanate (**23**), respectively, to give the corresponding acyl urea (**30**) and acyl thioureas (**29** and **27**). The acyl urea was cyclized in 2 *N* H_2SO_4 and the acyl thioureas in 15 *N* aqueous ammonia to give the corresponding nucleoside analogs. The nucleoside analogs containing the cytosine (**44**) and 5-methylcytosine (**43**) bases were prepared from the uracil and thymine nucleoside analogs, respectively, by way of the 4-chloropyrimidinone intermediates (**42** and **41**). The synthesis of *cis*-3-aminocyclopentanemethanol (**8**) from norbornene by way of *cis*-1,3-cyclopentanedicarboxylic acid anhydride (**3**) is also described. In addition, the ease of nucleophilic opening of compound **3** is compared to the opening of camphoric anhydride (**9**), which contains a *cis*-vicinal substituent at position 2. The relative ease of opening of compound **3** is discussed with respect to the effect, observed in an earlier study, that a *cis*-vicinal acetoxy group has on the course of the nucleophilic opening of such anhydrides. The ^1H magnetic resonance spectra at 200 MHz of all of the synthetic intermediates and of the nucleoside analogs have been determined and discussed. The nucleoside analogs were screened for cell-growth inhibition using K-562 cells. Nucleoside analogs having the 2-thiouracil (**33**), 2-thiothymine (**31**), cytosine (**44**), and 5-methylcytosine (**43**) bases showed some growth inhibition with activity 150 to 300 times lower than that shown by 5-fluorouracil in this test system.

LUCJAN J. J. HRONOWSKI et WALTER A. SZAREK. Can. J. Chem. **66**, 61 (1988).

On décrit la synthèse de nouveaux analogues carbocycliques des nucléosides de la (didésoxy-2′,3′ *glycéro*-pentofuranno-syl)pyrimidine contenant de l'uracil (**34**), du thio-2 uracil (**33**), de la thio-2 thymine (**31**), de la cytosine (**44**) et de la méthyl-5 cytosine (**43**). On a préparé les analogues des nucléosides contenant les bases uracil, thio-2 uracil et thio-2 thymine en procédant au couplage de l'amino-3-*cis* cyclopentaneméthanol avec respectivement l'isocyanate d'éthoxy-3 propènoyle (**26**), l'isothiocyanate d'éthoxy-3 propènoyle (**25**) et l'isothiocyanate de méthoxy-3 méthyl-2 propènoyle (**23**); on obtient ainsi l'acyl urée **30** et les acyl thiourées **29** et **27** correspondantes. La cyclisation de l'acyl urée en présence de H_2SO_4 2 *N* et des acyl thiourées en présence d'ammoniac aqueux 15 *N* conduit aux analogues de nucléosides correspondants. On a préparé les analogues de nucléosides contenant de la cytosine (**44**) et de la méthyl-5 cytosine (**43**) à partir de leurs analogues de nucléosides correspondants contenant de l'uracil et de la thymine et en procédant par leurs intermédiaires chloropyrimidinones (**42** et **41**). On décrit aussi la synthèse de l'amino-3-*cis* cyclopentaneméthanol (**8**) à partir du norbornène, en passant par l'anhydride de l'acide cyclopentanedicarboxylique-1,3-*cis* (**3**). De plus, on compare la facilité d'ouverture du produit **3**, sous l'influence d'agents nucléophiles, avec celle observée pour l'anhydride de l'acide camphorique (**9**) qui contient un substituant vicinal-*cis* en position 2. On discute de la facilité relative d'ouverture du composé **3** en fonction de l'effet, observée dans une étude antérieure, qu'un groupement vicinal-*cis* peut avoir sur le cours de l'ouverture de tels anhydrides. On a déterminé les spectres en résonance magnétique du ^1H à 200 MHz de tous les intermédiaires de synthèse et de tous les analogues de nucléosides et on les discute. Utilisant des cellules K-562, on a évalué l'utilité des analogues de nucléosides comme inhibiteurs de la croissance des cellules. Comparées à l'activité du fluoro-5 uracil dans ce système, les analogues de nucléosides contenant les bases thio-2 uracil (**33**), thio-2 thymine (**31**), cytosine (**44**) et méthyl-5 cytosine (**43**) présentent des effets qui sont de 150 à 300 fois plus faibles.
[Traduit par la revue]

Introduction

The synthesis of 2′,3′-dideoxynucleosides was first described in 1955 by Michelson and Todd (1), who synthesized a variety of 3′-deoxythymidines. Nine years later Pfitzner and Moffatt (2) described the synthesis of various 2′,3′-dideoxyuridines. The importance of the 2′,3′-dideoxynucleosides as possible chain terminators of DNA synthesis was pointed out by Robins *et al.* (3), who synthesized 2′,3′-dideoxyadenosine. 2′,3′-Dideoxyadenosine was subsequently shown by Doering *et al.* (4) to be lethal to *Escherichia coli* cultures with activity at concentrations as low as 10^{-7} *M*; however, the 2′,3′-dideoxy derivatives of uridine and cytidine were found to be inactive in their test systems. 2′,3′-Dideoxyadenosine was shown to irreversibly inhibit DNA synthesis, possibly by adding to the end of a growing polydeoxynucleotide and thus blocking further chain elongation. Such a mechanism of action was shown for 3′-deoxythymidine in a cell-free system (5). 2′,3′-Dideoxy-5-fluorouridine was shown by Khwaja and Heidelberger (6) to be lethal to *E. coli* at a concentration of 2×10^{-4} *M* and it also inhibited the growth of HeLa cells at 10^{-4} *M*. An important recent use of the 2′,3′-dideoxynucleotides is in DNA sequencing, in which they are used as specific, chain-terminating inhibitors of DNA polymerase (7).

In contrast to the relatively large number of 2′,3′-dideoxynucleosides that have been synthesized (1–3, 6–8, and references therein), there have been described relatively few syntheses of the carbocyclic analogs of the 2′,3′-dideoxynucleosides and most of these were of analogs of purine nucleosides. Schaeffer *et al.* (9), in their studies on the structural requirements in inhibitors of the enzyme adenosine deaminase, have synthesized several *cis*-3-(6-substituted-9-purinyl)cyclopentylmethanols in which the substituent was the Cl, SH, OH, NH_2, $NHCH_3$, or $N(CH_3)_2$ group. Montgomery and Hewson (10) synthesized the carbocyclic analog of 2′,3′-dideoxytubercidin.

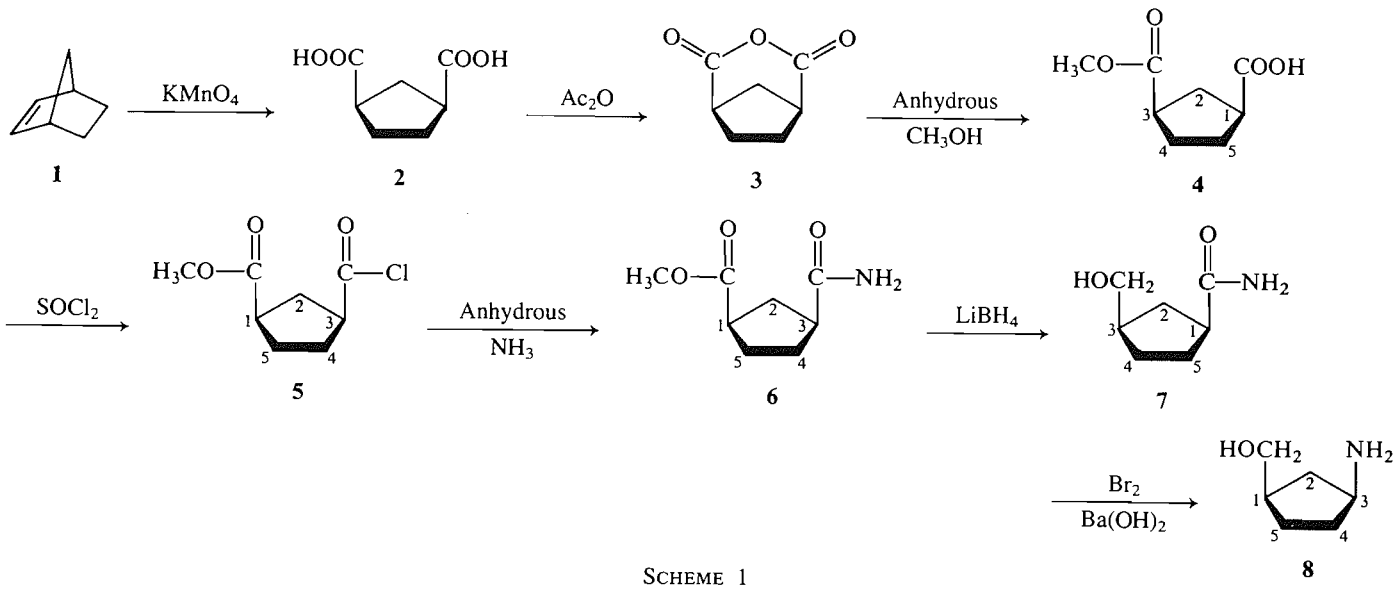

SCHEME 1

This compound, although somewhat cytotoxic, showed no activity against leukemia L1210. Shealy *et al.* (11) have synthesized the 2′,3′-dideoxy carbocyclic analogs of 8-aza-hypoxanthine and 8-azaadenine nucleosides; only the carbocyclic analog of 2′,3′-dideoxy-8-azaadenosine showed cytotoxicity to H. Ep./2 cells in culture (ED_{50} = 42 μg/mL), and both analogs showed no activity against leukemia L1210 in mice. The only carbocyclic analog synthesized of the 2′,3′-dideoxypyrimidine nucleosides is the analog of 3′-deoxythymidine (12). This compound was shown to be noncytotoxic to human epidermoid carcinoma cells and also showed no activity against L1210 leukemia in mice. The present paper describes the synthesis of the carbocyclic analogs of 2′,3′-dideoxypyrimidine nucleosides having the uracil, 2-thiouracil, 2-thiothymine, cytosine, and 5-methylcytosine bases. In addition, preliminary results are presented on their effects on the growth of K-562 cells in culture.

Results and discussion

cis-3-Aminocyclopentanemethanol (**8**), used in the synthesis of the carbocyclic analogs of 2′,3′-dideoxynucleosides, was prepared previously by Schaeffer *et al.* (9) from 3-oxocyclopentanecarboxylic acid (13). Shealy *et al.* (12) reported the synthesis of **8** from *cis*-1,3-cyclopentanedicarboxylic acid (**2**) without giving experimental details. In the present work **8** has been prepared from norbornene as shown in Scheme 1.

*Synthesis of (±)-*cis*-3-aminocyclopentanemethanol (8)*

The *cis* configuration of the two substituents in the cyclopentane derivatives shown in Scheme 1 is determined by the starting material, bicyclo[2.2.1]hept-2-ene (**1**), which, in the first step, is oxidized to *cis*-1,3-cyclopentanedicarboxylic acid (**2**) using potassium permanganate by the procedure described by Birch *et al.* (14). The *cis*-diacid (**2**) was then converted into (±)-*cis*-3-aminocyclopentanemethanol (**8**) by the same series of reactions that was used by O'Dell and Shealy (15) for the preparation of the cyclopentane analogs of 2′- and 3′-deoxy-*erythro*-pentofuranosylamine. The diacid was converted first into the anhydride (**3**) by heating at reflux temperature in acetic anhydride. The anhydride (**3**) was then opened with anhydrous methanol to give an intermediate (**4**)[2] having two different functional groups at positions 1 and 3 of the cyclopentane ring. The carboxylic acid and the ester functional groups were then converted selectively into the amino and the hydroxymethyl substituents, respectively, as shown in Scheme 1. In the final reaction shown in Scheme 1 the carbamoyl group was converted into the amino substituent by the Hofmann hypobromite reaction, in which the configuration of the original carbamoyl group is retained (16–18).

The ^{1}Hmr spectra of the compounds shown in Scheme 1 were determined on a 200-MHz spectrometer. However, even with this instrument, the signals of the methylene protons at positions 4 and 5 show complex second-order patterns, and thus only the ranges of their signals are given. The chemical shifts of the protons at positions 1, 2, and 3 could be more easily determined, although the signals of these protons often overlapped other signals to make the measurement of the exact chemical shifts difficult. The chemical-shift assignments were made with the aid of spin–spin decoupling experiments.

Nucleophilic opening of cis*-1,3-cyclopentanedicarboxylic acid anhydrides*

It was observed previously that nucleophilic opening of *cis*-1,3-cyclopentanedicarboxylic acid anhydrides, substituted at position 4 with an acetoxy group, gives a mixture of isomers when this group is in the *trans* configuration (16) and a single isomer when it is in the *cis* configuration (19). In the latter case only one isomer was isolated when ammonia or methanol was used as the nucleophile. With each of these nucleophiles the attack occurred at the carbonyl carbon farthest away from the acetoxy substituent. It was of interest, therefore, to study the effect of substituents at position 2. Scheme 2 shows a series of reactions using *dl*-camphoric anhydride (**9**) as the model compound. In contrast to compound **3**, which is converted

[2]The solvolysis of *cis*-1,3-cyclopentanedicarboxylic acid anhydride (**3**) generates a racemic mixture, since the attack by methanol is equally probable at both carbonyl carbons. Consequently, all of the subsequent cyclopentane derivatives are racemates, although only one enantiomer is shown in Schemes 1, 3, and 4.

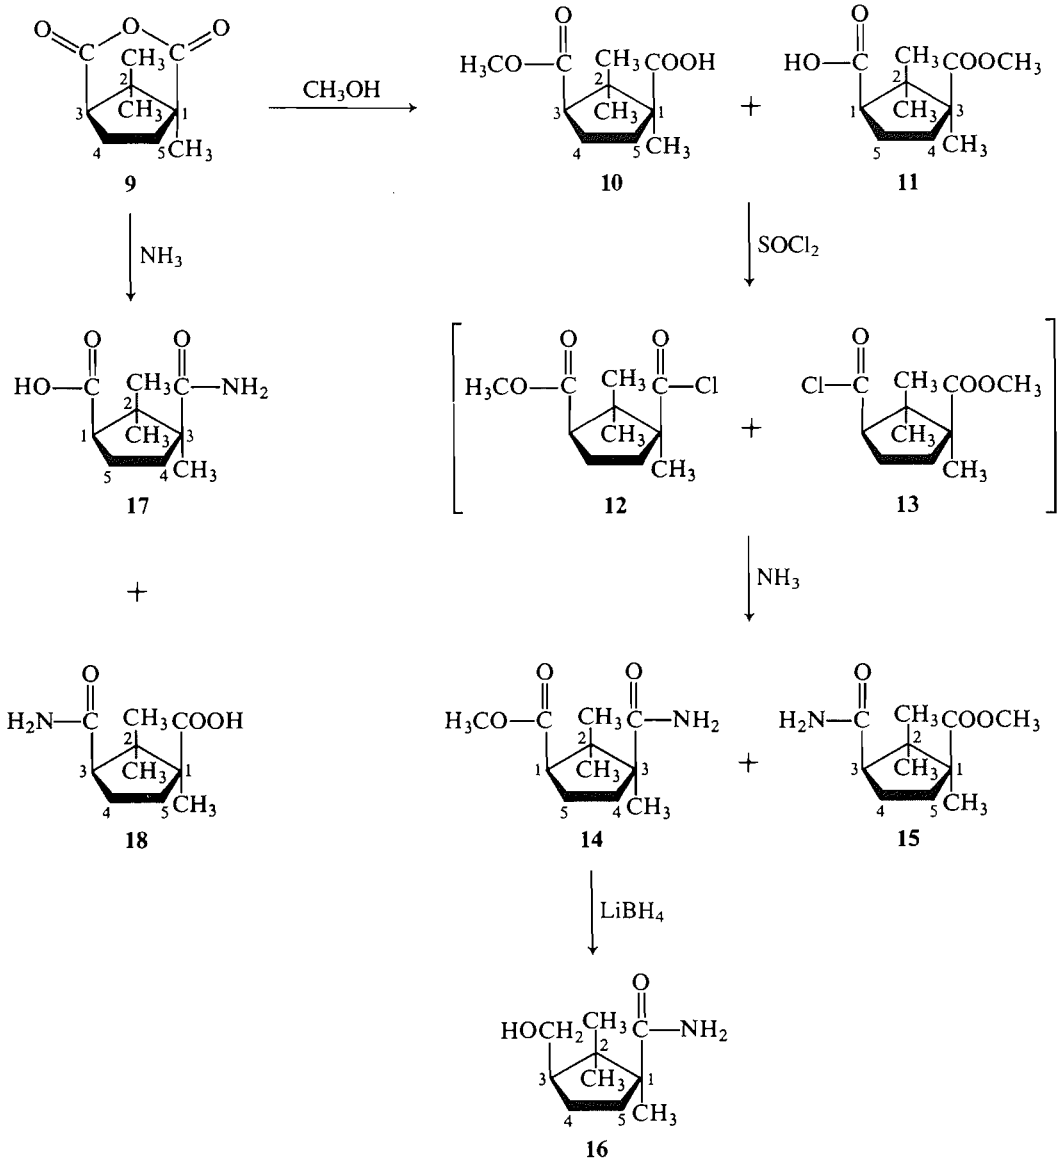

SCHEME 2

into compound **4** by stirring in anhydrous methanol at room temperature for 19 h, camphoric anhydride (**9**) is very resistant to methanolysis; no reaction was observed after 10 days of stirring in anhydrous methanol at room temperature. Moreover, even after being heated at reflux temperature for 2 days in methanol, over 81% of **9** was recovered and only a 12% yield of the solvolysis products, as a mixture of compounds **10** and **11**, was obtained. However, the opening of camphoric anhydride (**9**) was relatively rapid, when anhydrous ammonia in benzene was used, to give a mixture of compounds **17** and **18** in over 95% yield. The above observations and those with the acetoxy substituents (16, 19) indicate that steric interactions between *cis*-vicinal substituents in these compounds greatly reduce the rate of nucleophilic attack at the adjacent carbonyl carbon, thus accounting for the production of a single isomer in the nucleophilic opening of the anhydride containing the *cis*-acetoxy substituent at position 4 (19).

Assignment of the ^{1}Hmr signals in the spectra of the compounds shown in Scheme 2 was made after preparation of compound **16** from **14**. The signals of the protons in compound **16** were unambiguously assigned with the aid of spin–spin decoupling experiments. In general, the signals in the spectra of compounds **10**–**18** are much better resolved than those in the spectra of compounds **4**–**7**.

Synthesis of pyrimidine nucleoside analogs shown in Scheme 3

The base moiety of the 2-thiothymine nucleoside analog (**31**) was synthesized from 3-methoxy-2-methylpropenoyl isothiocyanate (**23**), which was prepared using the method of Shaw and Warrener (20). Compound **23** was coupled with (±)-*cis*-3-aminocyclopentanemethanol (**8**) to give compound **27**; this product was then cyclized in 15 *N* aqueous ammonia to give nucleoside analog **31**. The corresponding thymine nucleoside analog (**32**) was prepared as described previously (12).

The 2-thiouracil nucleoside analog (**33**) was prepared by coupling compound **8** with 3-ethoxypropenoyl isothiocyanate (**25**) (20) to give **29**, which was then cyclized in 15 *N* aqueous ammonia to give the nucleoside analog (**33**). The uracil

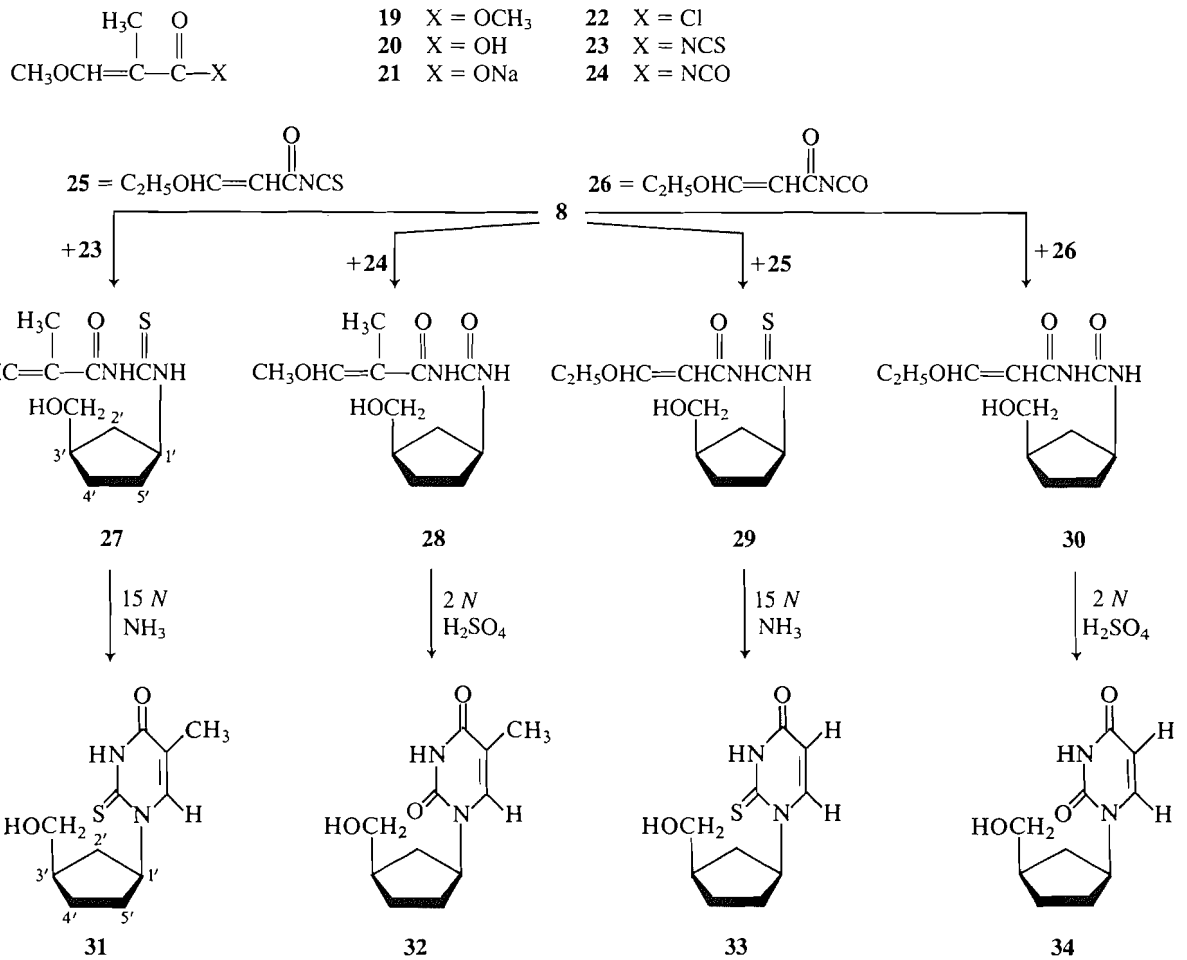


SCHEME 3

nucleoside analog (**34**) was prepared by coupling compound **8** with 3-ethoxypropenoyl isocyanate (**26**) (21) to give **30**, which was then cyclized in 2 *N* H_2SO_4 to give the nucleoside analog (**34**).

The signals of the protons on the cyclopentane rings in compounds **27**–**30** show complex patterns with many of the signals overlapping in a narrow region of the ^{1}Hmr spectrum. The signals of the other protons in each of these compounds are well resolved and allow relatively easy characterization of the different compounds (**27**–**30**). Also, as was observed previously (19, 22), the protons in the sulfur-containing compounds, in general, resonate further downfield than the corresponding protons in the oxygen-containing analogs. The only significant exception to this trend occurs for H-3 in compounds **29** and **30**; in the case of the oxygen-containing compound (**30**) this proton resonates at lower field than in the case of the sulfur-containing compound (**29**).

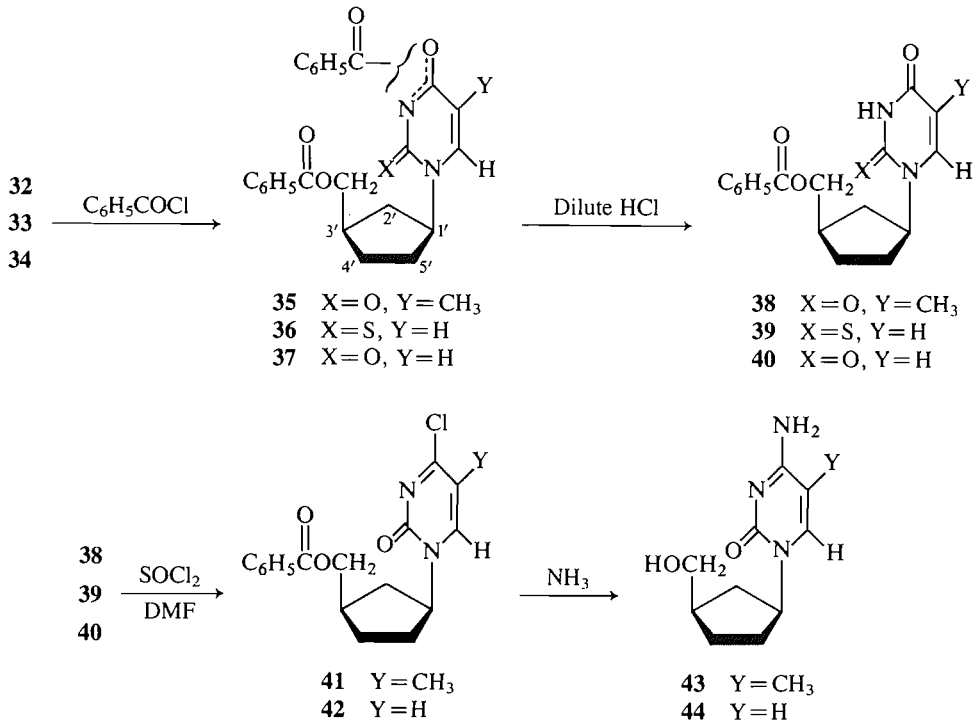
In the case of nucleoside analogs **31**–**34**, in a 200-MHz field all of the protons on the cyclopentane ring in each of these compounds, except for H-1′, have complex overlapping signals in the δ 1.2–2.2 region. The signals for the other protons in these nucleosides are easily resolved even at 60 MHz, and, as was seen above, protons in the sulfur-containing compounds resonate at lower fields than the corresponding protons in the oxygen-containing compounds. Also, as was seen previously (19, 22), this difference is largest for the protons nearest the sulfur atom. Thus, H-1′ and H-3 resonate 1.0 and 1.3 ppm, respectively, further downfield in the case of the sulfur-containing nucleosides (**31** and **33**) than in the case of the oxygen-containing nucleosides (**32** and **34**), whereas the methylene protons of the hydroxymethyl group have virtually the same chemical shifts in all four compounds. The chemical shifts of the protons in compound **32** were previously reported by Shealy *et al.* (12) using a 100-MHz spectrometer and agree with those observed in the present study to within ±0.02 ppm.

Synthesis of carbocyclic analogs of cytosine nucleosides

The cytosine nucleosides shown in Scheme 4 were synthesized using the method described by Žemlička and Šorm (23); however, the protection of the hydroxyl groups was performed as described by Shealy and O'Dell (24). Nucleosides **32**–**34** were treated first with an excess of benzoyl chloride in pyridine to give compounds **35**–**37**. The benzoyl group on the pyrimidine rings was then selectively removed using dilute hydrochloric acid solution to give the monobenzoyl derivatives (**38**–**40**). The protected nucleosides **38** and **40** were converted into the 4-chloropyrimidinone intermediates **41** and **42**, respectively, using a catalytic amount of *N*,*N*-dimethylformamide and an excess of thionyl chloride in chloroform; compounds **41** and **42** were then converted into the cytosine nucleosides **43** and **44**, respectively, using anhydrous ammonia in methanol. However, an attempt to prepare the 4-amino analog of the 2-thiouracil nucleoside (**33**) by the above method gave instead nucleoside **44**.

In the case of the nucleosides shown in Scheme 4, at 200 MHz the signals of the methylene protons occur as complex groups

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.222.148.141 on 09/07/12
For personal use only.



SCHEME 4

of overlapping multiplets, and thus only their chemical-shift ranges are given. The signals of the protons at C-1′, C-2′, and C-3′ are more resolved in the spectra of most of the nucleosides and, as was observed previously, the signals of the protons in the sulfur-containing nucleosides occur further downfield than those of the corresponding protons in the oxygen-containing nucleosides. The signals for the amino protons show different patterns in the two cytosine nucleosides (**43** and **44**). In the case of the nucleoside analog **44** these protons give rise to a single broad peak, whereas in the case of the 5-methylcytosine analog **43** they give rise to two broadened singlets at δ 6.66 and 7.04, suggesting that rotation of the amino group in the 5-methylcytosine analog **43** may be restricted.

Ultraviolet spectra of nucleoside analogs 31–34

The ultraviolet spectra of the uracil-nucleoside analog **34** closely resemble the spectra of 1-methyluracil (25) at the corresponding pH's. The absorption maxima in the spectra of the thymine analog **32** occur at slightly longer wavelengths (λ = 272–273 nm) than in the case of the uracil analog **34** (λ = 266–268 nm); otherwise, the spectra closely resemble those of **34** at the corresponding pH's. The absorption spectra of the 2-thiouracil- (**33**) and of 2-thiothymine- (**31**) -nucleoside analogs are more complex than those of **32** and **34**; however, they resemble closely the behavior of 1-methyl-2-thiouracil and 1-methyl-2-thiothymine, respectively, at the corresponding pH's (25). The absorption maximum at longer wavelength in the spectrum of **33** is relatively constant in both acidic and basic solvents; however, in the case of **31** the maximum shifts from 276 nm in acidic media to 266 nm in basic media. A similar behavior had been observed in the cases of 1-methyl-2-thiouracil and 1-methyl-2-thiothymine (25).

Biological evaluation

Compounds **31–34**, **43**, and **44** were tested for cell-growth inhibition using cultured K-562 cells by methods described previously (26). Nucleoside analogs having the 2-thiouracil (**33**), 2-thiothymine (**31**), cytosine (**44**), and 5-methylcytosine (**43**) bases showed some growth inhibition, with activity 150–300 times lower (higher values of ED_{50}) than that shown by 5-fluorouracil in this test system. Compounds **31–34** have also been tested for activity against the HSV-1 and the HSV-2 viruses. None of these compounds demonstrated antiviral activity in the 0.24–500 μg/mL concentration range.

Conclusion

The synthesis of (±)-*cis*-3-aminocyclopentanemethanol (**8**) from norbornene has been described. In addition, the effect of *cis*-vicinal substituents on the nucleophilic opening of *cis*-1,3-cyclopentanedicarboxylic acid anhydrides has been studied using *dl*-camphoric anhydride as a model. The results obtained with this anhydride, together with those obtained with the *cis*-1,3-cyclopentanedicarboxylic acid anhydrides having acetoxy substituents at position 4 (19, 22), show that *cis*-vicinal substituents greatly decrease the rate of nucleophilic attack at the adjacent carbonyl carbon. In the anhydride containing the 4-*cis*-acetoxy substituent, nucleophilic attack occurred only at the carbonyl carbon farthest away from the acetoxy group, thus allowing regiospecific opening of this anhydride (19).

(±)-*cis*-3-Aminocyclopentanemethanol was utilized for the synthesis of carbocyclic analogs of nucleosides having uracil, 2-thiouracil, 2-thiothymine, thymine, cytosine, and 5-methylcytosine bases. The 200-MHz ^{1}Hmr spectra of all of these nucleosides, as well as of the cyclopentane derivatives, have also been determined and discussed.

Experimental

Melting points were determined on a Fisher–Johns apparatus and are uncorrected. The ^{1}Hmr spectra were recorded on a Bruker CXP-200 spectrometer at 200 MHz. The proton chemical shifts (δ) are given relative to Me_4Si (δ = 0). Assignments of chemical shifts and coupling constants were made with the aid of spin-decoupling experiments. The following abbreviations are used in describing ^{1}Hmr signals: singlet (s), doublet (d), triplet (t), quartet (q), quintuplet (qu), sextuplet (se),

multiplet (m), and broadened (br). Ultraviolet spectra were recorded on a Perkin–Elmer 552 spectrophotometer. Thin-layer chromatography (tlc) was performed using silica gel 60 F-254 plates and column chromatography on silica gel 60. The plates and silica gel 60 were purchased from BDH Chemicals. The developed plates were dried and sprayed with a solution of ceric sulfate (1%) and molybdic acid (1.5%) in 10% aqueous sulfuric acid, and heated at ~150°C. Unless otherwise indicated, the same solvent was used for both tlc and column chromatography.

cis-1,3-Cyclopentanedicarboxylic acid (2)

Compound **2** was prepared from bicyclo[2.2.1]hept-2-ene (**1**) by the procedure of Birch *et al.* (14) using potassium permanganate instead of sodium permanganate. A solution of norbornene (**1**) (28.2 g, 0.30 mmol) in 2,2,4-trimethylpentane (200 mL) was added to water (1 L). To the stirred mixture, a solution of $KMnO_4$ (147 g, 0.93 mol) in water (2.5 L) was added over a period of 5 h (temperature 25–37°C), during which time CO_2 was vigorously bubbled through the reaction mixture. Immediately after the permanganate addition was complete, SO_2 was passed through the reaction mixture until it became colorless. The volume of the reaction solution was reduced to 825 mL. The solution was then cooled in an ice bath and acidified with concentrated HCl (90 mL). Extraction with diethyl ether (9 × 200 mL) gave a white solid (33.26 g, 70%), mp 104–114°C. After recrystallization of this material from diethyl ether – hexanes, the mp was 120°C (lit. (14) mp 119.9–120.6°C (corr.)); ^{1}Hmr (200 MHz, Me_2SO-d_6), δ: 1.67–1.94 (5H, m, H-2, H-4, H-4′, H-5, and H-5′), 2.11 (1H, d of t, J_{gem} = 13.2, ^3J = 8.0 Hz, H-2′), 2.64–2.80 (2H, m, H-1 and H-3), 12.1 (2H, br s, CO_2H). *Anal.* calcd. for $C_7H_{10}O_4$: C 53.16, H 6.37; found: C 53.19, H 6.45.

cis-1,3-Cyclopentanedicarboxylic acid anhydride (3)

Compound **2** (36.4 g, 230 mmol) was dissolved in acetic anhydride (100 mL) and 31 mL of solvent were removed by distillation. The reaction solution was heated at reflux temperature for a further 0.5 h and cooled. The solvent was removed under vacuum and the residue was recrystallized from tetrahydrofuran–hexanes to give a light-grey solid (25.56 g, 79%); in a melting point determination, this material turned from an opaque solid to a stiff, clear gel in the range 128–145°C and melted at 159–160°C (lit. (27) mp 161°C). Repeated recrystallizations from tetrahydrofuran–hexanes gave a white solid but did not alter the above melting behavior; ^{1}Hmr (200 MHz, $CDCl_3$), δ: 1.77 (1H, d of t, J_{gem} = 12.8, ^3J = 4.2 Hz, H-2), 1.98–2.33 (5H, m, H-2′, H-4, H-4′, H-5, and H-5′), 3.21–3.33 (2H, m, H-1 and H-3); ^{1}Hmr (200 MHz, Me_2SO-d_6), δ: 1.69 (1H, d of t, J_{gem} = 12.5, ^3J = 4.2 Hz, H-2), 1.82–2.21 (4H, m, H-4, H-4′, H-5, and H-5′), 2.36 (1H, br d, J_{gem} = 12.5 Hz, H-2′), 3.18 (2H, m, H-1 and H-3); spin–spin decoupling was performed at δ 1.69 and 2.36. *Anal.* calcd. for $C_7H_8O_3$: C 60.00, H 5.75; found: C 59.99, H 5.99.

(±)-Methyl hydrogen cis-1,3-cyclopentanedicarboxylate (4)

A solution of **3** (19.34 g, 138 mmol) in anhydrous methanol (400 mL) was stirred at room temperature for 19 h and left in the cold room (2°C) for 12 days. The solvent was removed on a rotary evaporator to give **4** as a light-brown oil (23.6 g); ^{1}Hmr (200 MHz, Me_2SO-d_6), δ: 1.68–2.05 (5H, m, H-2, H-4, H-4′, H-5, and H-5′), 2.13 (1H, d of t, J_{gem} = 12.7, ^3J = 8.0 Hz, H-2′), 2.66–2.97 (2H, m, H-1 and H-3), 3.60 (3H, s, OMe), 12.1 (1H, br s, CO_2H); ^{1}Hmr (200 MHz, $CDCl_3$), δ: 1.9–2.5 (6H, m, H-2, H-2′, H-4, H-4′, H-5, and H-5′), 2.8–3.0 (2H, m, H-1 and H-3), 3.71 (3H, s, OMe), 11.3 (1H, br s, CO_2H).

(±)-Methyl cis-3-(chloromethanoyl)cyclopentanecarboxylate (5)

Compound **4** (23.6 g) was dissolved in benzene (550 mL) and 50 mL were removed by distillation to remove traces of water. To the hot, benzene solution, thionyl chloride (50 mL, 0.68 mol) was added dropwise, and the solution was stirred for 5 min. Two drops of pyridine were then added and stirring was continued until the vigorous evolution of gases subsided; then 2 drops of *N*,*N*-dimethylformamide were added and the solution was heated at reflux temperature for 2 h. The mixture was kept at room temperature overnight, and the solvent was removed on a rotary evaporator to give **5** as a yellow oil (26.2 g); ^{1}Hmr (200 MHz, $CDCl_3$), δ: 1.95–2.48 (6H, m, H-2, H-2′, H-4, H-4′, H-5, and H-5′), 2.87 (1H, qu, ^3J = 8.1 Hz, H-1), 3.30 (1H, m, H-3), 3.70 (3H, s, OMe).

(±)-Methyl cis-3-carbamoylcyclopentanecarboxylate (6)

Compound **5** (26.2 g) was dissolved in dry benzene (450 mL) and anhydrous ammonia was bubbled through the reaction solution for 0.5 h. The resulting mixture was purged with nitrogen for 10 min. It was then diluted with ethyl acetate (400 mL), heated to boiling, and treated with charcoal. The hot mixture was filtered and the solid residue was washed with hot ethyl acetate. The combined filtrate and washings were cooled and the white crystalline solid was collected by filtration to give **6** (13.56 g), mp 122–123°C. The volume of the filtrate was reduced to 75 mL and additional **6** (2.21 g), mp 122–123°C, was collected by filtration. A final third crop of **6** (0.24 g) was obtained and had mp 117–121°C (total yield of 16.01 g, 67.8%, from **3**); ^{1}Hmr (200 MHz, Me_2SO-d_6), δ: 1.61–1.89 (5H, m, H-2, H-4, H-4′, H-5, and H-5′), 2.04 (1H, d of t, J_{gem} = 12.6, ^3J = 7.6 Hz, H-2′), 2.59 (1H, m, H-3), 2.78 (1H, m, H-1), 3.59 (3H, s, OMe), 6.78 (1H, br s, $CONH_2$), 7.29 (1H, br s, $CONH_2$). *Anal.* calcd. for $C_8H_{13}O_3N$: C 56.13, H 7.65, N 8.18; found: C 56.07, H 7.98, N 8.32.

(±)-cis-3-(Hydroxymethyl)cyclopentanecarboxamide (7)

A solution containing lithium borohydride (3.58 g, 164 mmol) in tetrahydrofuran (200 mL) was heated at reflux temperature for 1 h; heating was discontinued, compound **6** (14.09 g, 82 mmol) was added to the hot tetrahydrofuran solution, and heating at reflux temperature was then continued for 2 h. The reaction solution was cooled in an ice bath and diluted slowly with water (150 mL), then a slow addition of Amberlite CG-120 (H^+) cation-exchange resin (90 g) was made. The mixture was stirred overnight at room temperature. The resin was removed by filtration and washed with water (3 × 90 mL). The combined filtrate and washings were treated with Dowex 1-X8 (^-OH) anion-exchange resin to adjust the pH to 7. The resin was removed by filtration and washed with water (3 × 90 mL). The combined filtrate and washings were evaporated and the residue was evaporated with methanol (3 × 30 mL) to give a white solid (11.6 g), mp 112–117°C. This material was recrystallized from methanol–tetrahydrofuran to give **7** in two crops (9.14 g, mp 121–123°C, and 0.91 g, mp 119–122°C) for a total yield of 10.05 g (85.7%); R_f 0.49 (9:1 (v/v) acetonitrile–water), component visualized using iodine vapor; ^{1}Hmr (200 MHz, Me_2SO-d_6), δ: 1.15–1.76 (5H, m, H-2, H-4, H-4′, H-5, and H-5′), 1.78–2.09 (2H, m, H-2′ and H-3), 2.55 (1H, m, H-1), 3.29 (2H, d of d, $^3J_{to\ H\text{-}3}$ = 6.4, $^3J_{to\ CH_2OH}$ = 5.3 Hz, CH_2OH), 4.46 (1H, t, ^3J = 5.3 Hz, CH_2OH), 6.68 (1H, br s, $CONH_2$), 7.21 (1H, br s, $CONH_2$); the $CONH_2$ and OH protons exchanged with D_2O. *Anal.* calcd. for $C_7H_{13}O_2N$: C 58.72, H 9.15, N 9.78; found: C 59.16, H 9.17, N 10.28.

(±)-cis-3-Aminocyclopentanemethanol (8)

To a solution at 5°C containing $Ba(OH)_2 \cdot 8H_2O$ (95.4 g, 0.302 mol) in water (1.9 L), bromine (3.8 mL, 74 mmol) was added. Immediately after the bromine had dissolved, a solution of compound **7** (9.63 g, 67.2 mmol) in water (50 mL) was added in one portion, and the reaction solution was allowed to warm to room temperature over a period of 2 h. The solution was then heated at 50–65°C for 1.25 h, cooled to ice-bath temperature, and acidified with 3 *M* H_2SO_4 (85 mL). The mixture was stirred for 1 h and the precipitate was removed by centrifugation. The solution was stored in the cold room (2°C) overnight and then passed through Amberlite CG-120 (H^+) cation-exchange resin (150 g). The resin was washed with water (1.5 L) and then eluted with 2 *N* NH_3 in water; the elution was monitored by tlc (5:3:2 (v/v/v) *n*-butanol–water–acetic acid). No product was eluted in the first 2 L; an additional 2.5 L of 2 *N* NH_3 in water was required to elute the product from the column. The solvent was evaporated and the residual oil was dissolved in ethanol; the mixture was filtered to remove small amounts of insoluble matter. The solvent was evaporated to afford **8** as a yellow oil (5.70 g, 74%). The ^{1}Hmr spectrum showed no signals attributable to impurities; ^{1}Hmr (200 MHz, Me_2SO-d_6), δ: 0.95 (1H, d of t, J_{gem} = 12.4, ^3J = 7.0 Hz, H-2), 1.17–1.73 (4H, m, H-4, H-4′, H-5,

For personal use only.

and H-5'), 1.79–2.11 (2H, m, H-2' and H-1), 3.17 (1H, m, H-3), 3.28 (2H, d, J = 6.0 Hz, HOCH_2); spin–spin decoupling was performed at δ 0.95 and 3.17.

*(±)-3-Methyl hydrogen 1,2,2-trimethyl-*cis*-1,3-cyclopentanedicarboxylate (**10**) and (±)-3-methyl hydrogen 2,2,3-trimethyl-*cis*-1,3-cyclopentanedicarboxylate (**11**)*

A mixture of *dl*-camphoric anhydride (**9**, 50 g, 274 mmol) in anhydrous methanol (650 mL) was heated at reflux temperature for 2 days, cooled to room temperature, and a white solid (28.6 g) was collected by filtration, which was shown by ^{1}Hmr spectroscopy and a melting-point determination to be starting material (**9**). The volume of the filtrate was reduced to 150 mL, the solution was cooled to 4°C, and additional **9** (11.72 g) was collected by filtration. The solvent was evaporated and the resulting oil was fractionated by column chromatography on silica gel to give a component (6.96 g, 12%), R_f = 0.43 (9:1 (v/v) toluene–2-propanol), which was shown by ^{1}Hmr spectroscopy to be a mixture of compounds **10** and **11**, with compound **10** being the major isomer. Compound **10**, ^{1}Hmr (200 MHz, $CDCl_3$), δ: 0.84 (3H, s, Me), 1.25 (3H, s, Me), 1.27 (3H, s, Me), 1.52 (1H, m, J_{gem} = 13.5, $^3J_{5,4}$ = 9.6, $^3J_{5,4'}$ = 3.9 Hz, H-5), 1.72–1.94 (1H, m, H-4), 2.08–2.30 (1H, m, H-4'), 2.47–2.67 (1H, m, H-5'), 2.78–2.88 (1H, m, H-3), 3.70 (3H, s, OMe); compound **11**, ^{1}Hmr (200 MHz, $CDCl_3$), δ: 0.82 (3H, s, Me), 1.21 (3H, s, Me), 1.29 (3H, s, Me), 1.52 (1H, m, J_{gem} = 13.5, $^3J_{4,5}$ = 9.6, $^3J_{4,5'}$ = 3.9 Hz, H-4), 1.72–1.94 (1H, m, H-5), 2.08–2.30 (1H, m, H-5'), 2.47–2.67 (1H, m, H-4'), 2.78–2.88 (1H, m, H-1), 3.69 (3H, s, OMe); spin–spin decoupling was performed at δ 1.52 and 2.83.

*(±)-Methyl 2,2,3-trimethyl-*cis*-3-carbamoylcyclopentanecarboxylate (**14**) and (±)-methyl 1,2,2-trimethyl-*cis*-3-carbamoylcyclopentanecarboxylate (**15**)*

A solution of compounds **10** and **11** (6.64 g, 31.0 mmol) in benzene (100 mL) was treated with thionyl chloride (11 mL, 153 mmol), as described above for the preparation of **5**, to give an oily mixture of compounds **12** and **13**. The oil was dissolved in dry benzene (100 mL) and anhydrous ammonia was bubbled through the reaction solution for 0.5 h. The reaction mixture was then flushed with nitrogen for 10 min, heated to boiling, and filtered. The filtrate was evaporated to give a pale-yellow solid (5.68 g), which was fractionated by column chromatography on silica gel to give **14** (3.024 g) and a mixture of **14** and **15** (0.584 g), with **14** as the major component, for a total yield of 3.608 g (55% from **10** and **11**). An analytical sample of **14** was prepared by recrystallization from ethyl acetate – hexanes, mp 135°C, R_f 0.35 (tlc) (7:2:1 (v/v/v) toluene – ethyl acetate – 2-propanol); ^{1}Hmr (200 MHz, $CDCl_3$), δ: 0.83 (3H, s, Me), 1.22 (3H, s, Me), 1.30 (3H, s, Me), 1.55 (1H, m, H-4), 1.75–1.95 (1H, m, H-5), 2.16–2.48 (2H, m, H-4' and H-5'), 2.82 (1H, d of d, ^3J = 10.5, ^3J = 7.6 Hz, H-1), 3.69 (3H, s, OMe), 5.55 (2H, br s, $CONH_2$); ^{1}Hmr (200 MHz, Me_2SO-d_6), δ: 0.66 (3H, s, Me), 1.08 (3H, s, Me), 1.16 (3H, s, Me), 1.35 (1H, m, J_{gem} = 12.6, $^3J_{4,5}$ = 9.3, $^3J_{4,5'}$ = 3.2 Hz, H-4), 1.74 (1H, m, H-5), 1.99 (1H, m, H-5'), 2.33 (1H, t of d, J = 12.2, ^3J = 8.6 Hz, H-4'), 2.79 (1H, d of d, ^3J = 10.2, ^3J = 8.0 Hz, H-1), 3.60 (3H, s, OMe), 6.86 (1H, br s, $CONH_2$), 6.91 (1H, br s, $CONH_2$); spin–spin decoupling was performed at δ 2.79. *Anal.* calcd. for $C_{11}H_{19}O_3N$: C 61.95, H 8.98, N 6.57; found: C 61.86, H 9.00, N 7.04.

The mixture of **14** and **15** was fractionated again by column chromatography on silica gel to give a sample of **15**. An analytical sample of **15** was prepared by recrystallization from ethyl acetate – hexanes, mp 116–118°C, R_f 0.24 (tlc); ^{1}Hmr (200 MHz, $CDCl_3$), δ: 0.82 (3H, s, Me), 1.20 (3H, s, Me), 1.27 (3H, s, Me), 1.51 (1H, m, J_{gem} = 13.8, $^3J_{5,4}$ = 9.6, $^3J_{5,4'}$ = 4.3 Hz, H-5), 1.81 (1H, m, J_{gem} = 13.6, ^3J = 9.6, $^3J_{4,5'}$ = 6.9 Hz, H-4), 2.18 (1H, m, J_{gem} = 13.6, $^3J_{4',5'}$ = 11.6, $^3J_{4',3}$ = 9.1, $^3J_{4',5}$ = 4.3 Hz, H-4'), 2.61 (1H, m, H-5'), 2.63 (1H, t, ^3J = 9.3 Hz, H-3), 3.68 (3H, s, OMe), 5.35 (1H, br s, $CONH_2$), 5.54 (1H, br s, $CONH_2$); ^{1}Hmr (200 MHz, Me_2SO-d_6), δ: 0.63 (3H, s, Me), 1.11 (6H, s, Me), 1.38 (1H, m, J_{gem} = 13.3, $^3J_{5,4}$ = 9.4, $^3J_{5,4'}$ = 4.0 Hz, H-5), 1.62 (1H, m, J_{gem} = 12.9, $^3J_{4,5}$ = $^3J_{4,3}$ = 9.6, $^3J_{4,5'}$ = 6.8 Hz, H-4), 1.97 (1H, m, H-4'), 2.42 (1H, t of d, J = 12.8, $^3J_{5',4}$ = 6.8 Hz, H-5'), 2.62 (1H, t, ^3J = 9.6 Hz, H-3), 3.59 (3H, s, OMe), 6.88 (1H, br s, $CONH_2$), 7.13 (1H, br s, $CONH_2$). *Anal.* calcd. for $C_{11}H_{19}O_3N$: C 61.95, H 8.98, N 6.57; found: C 62.05, H 9.16, N 6.91.

*(±)-1,2,2-Trimethyl-*cis*-3-(hydroxymethyl)cyclopentanecarboxamide (**16**)*

Compound **14** (1.43 g, 6.70 mmol) was treated with lithium borohydride (0.5 g, 23 mmol) in tetrahydrofuran (100 mL) as described for the preparation of **7**. After treatment with cation- and anion-exchange resins, the solvent was evaporated and the residue was evaporated with methanol (10 × 2 mL). The residue was then stirred in tetrahydrofuran–hexanes, and the resulting white solid was collected by filtration to give 0.84 g of material. This material was fractionated by column chromatography on silica gel to give **16** (0.102 g, 8.2%), mp 159°C, R_f 0.26 (tlc) (4:1 (v/v) toluene–2-propanol). An analytical sample was prepared by recrystallization from ethyl acetate – methanol–hexanes, mp 162–163°C; ^{1}Hmr (200 MHz, Me_2SO-d_6), δ: 0.65 (3H, s, Me), 1.05 (6H, s, Me), 1.15–1.38 (2H, m, H-4 and H-5), 1.68–1.99 (2H, m, H-3 and H-4'), 2.27 (1H, t of d, J = 13.2, ^3J = 6.9 Hz, H-5'), 3.24 (1H, d of d of d, J_{gem} = 10.2, $^3J_{\text{to H-3}}$ = 7.6, $^3J_{\text{to HOCH}_2}$ = 5.0 Hz, HOCH_2), 3.47 (1H, m, J_{gem} = 10.2, ^3J = 5.1 Hz, HOCH_2), 4.27 (1H, t, ^3J = 5.0 Hz, HOCH$_2$), 6.76 (1H, br s, $CONH_2$), 6.79 (1H, br s, $CONH_2$); spin–spin decoupling was performed at δ 2.27, 3.47, and 4.27. *Anal.* calcd. for $C_{10}H_{19}O_2N$: C 64.83, H 10.34, N 7.56; found: C 64.92, H 10.12, N 7.81.

*(±)-2,2,3-Trimethyl-*cis*-3-carbamoylcyclopentanecarboxylic acid (**17**) and (±)-1,2,2-trimethyl-*cis*-3-carbamoylcyclopentanecarboxylic acid (**18**)*

Dry ammonia was bubbled through a solution of *dl*-camphoric anhydride (**9**, 40.0 g, 220 mmol) in tetrahydrofuran (500 mL) (which had been cooled initially to 5°C) for 40 min. The mixture was left at 0°C overnight and then flushed with nitrogen for 30 min. The ice-cold mixture was filtered and the solid was dissolved in water (250 mL). Insoluble material was removed by filtration, and the filtrate was cooled to ice-bath temperature and acidified to pH 2. The solution was kept in the cold room (2°C) for 2 days; the crystalline solid was collected by filtration and washed with ice-cold water to give a mixture of **17** and **18** (39.2 g) that, by integration of the ^{1}Hmr signals, was shown to contain **17** and **18** in a 1:3 ratio, respectively. Compound **18**, ^{1}Hmr (200 MHz, Me_2SO-d_6), δ: 0.72 (3H, s, Me), 1.11 (3H, s, Me), 1.13 (3H, s, Me), 1.28–2.46 (4H, m, H-4, H-4', H-5, and H-5'), 2.61 (1H, t, ^3J = 9.4 Hz, H-3), 6.83 (1H, br s, $CONH_2$), 7.06 (1H, br s, $CONH_2$), 12.1 (1H, br s, CO_2H). The volume of the filtrate was reduced to 50 mL, the solution was cooled for 8 h at 0°C, and an additional crop of a mixture of **17** and **18** (2.62 g) was obtained for a total yield of 41.82 g (95.4%); the second crop contained compounds **17** and **18** in a 4:1 ratio, respectively. Compound **17**, ^{1}Hmr (200 MHz, Me_2SO-d_6), δ: 0.72 (3H, s, Me), 1.08 (3H, s, Me), 1.18 (3H, s, Me), 1.28–2.46 (4H, H-4, H-4', H-5, and H-5'), 2.69 (1H, d of d, ^3J = 10.0, ^3J = 8.0 Hz, H-1), 6.85 (1H, br s, $CONH_2$), 6.89 (1H, br s, $CONH_2$), 12.1 (1H, br s, CO_2H).

*3-Methoxy-2-methylpropenoic acid (**20**)*

Compound **20** was prepared from methyl 2-methylpropenoate by way of the intermediacy of methyl 2,3-dibromo-2-methylpropanoate and methyl 3-methoxy-2-methylpropenoate (**19**) as described previously (12, 20). Compound **20**, ^{1}Hmr (200 MHz, $CDCl_3$), δ: 1.73 (3H, d, $^4J_{\text{to H-3}}$ = 1.2 Hz, Me), 3.86 (3H, s, OMe), 7.40 (1H, q, ^4J = 1.2 Hz, H-3); ^{1}Hmr (200 MHz, Me_2SO-d_6), δ: 1.59 (3H, d, $^4J_{\text{to H-3}}$ = 1.4 Hz, Me), 3.80 (3H, s, OMe), 7.31 (1H, q, ^4J = 1.4 Hz, H-3), 11.8 (1H, br s, CO_2H).

*3-Methoxy-2-methylpropenoyl chloride (**22**)*

Compound **20** was converted into its sodium salt (**21**) as described by Shaw and Warrener (20); ^{1}Hmr (200 MHz, Me_2SO-d_6), δ: 1.54 (3H, d, $^4J_{\text{to H-3}}$ = 1.3 Hz, Me), 3.60 (3H, s, OMe), 6.91 (1H, q, ^4J = 1.3 Hz, H-3). The sodium salt was then treated with $SOCl_2$ in ether as described previously (20); distillation gave **22**, ^{1}Hmr (200 MHz, $CDCl_3$), δ: 1.74 (3H, d, Me), 3.96 (3H, s, OMe), 7.66 (1H, q, ^4J = 1.2 Hz, H-3).

*(±)-*N*-{N′-[*cis*-3-(Hydroxymethyl)cyclopentyl]thiocarbamoyl}-3-methoxy-2-methylpropenamide (27)*

3-Methoxy-2-methylpropenoyl isothiocyanate (**23**) was prepared from equivalent amounts of compound **22** and potassium thiocyanate in acetonitrile as described previously (20). Compound **23** was purified by distillation under vacuum and used immediately for the preparation of **27**. Compound **23** (0.28 g, 1.8 mmol) was added to a solution of **8** (0.21 g, 1.8 mmol) in methanol (5 mL) and diethyl ether (5 mL) and the reaction solution was kept at room temperature overnight; the mixture was filtered and the solvent was evaporated. The residue was fractionated by column chromatography on silica gel to give **27** (0.337 g, 77%) as a colorless oil, R_f 0.50 (8:8:1 (v/v/v) toluene – ethyl acetate – 2-propanol). The ^{1}Hmr spectrum showed minor signals attributable to impurities; ^{1}Hmr (200 MHz, Me_2SO-d_6), δ: 1.14–2.23 (7H, m, H-2′, H-2″, H-3′, H-4′, H-4″, H-5′, and H-5″), 1.61 (3H, d, $^4J_{\text{to H-3}}$ = 1.1 Hz, Me), 3.29–3.36 (2H, m, HOCH_2), 3.85 (3H, s, OMe), 4.50 (1H, se, ^3J = 7.0 Hz, H-1′), 4.61 (1H, t, ^3J = 5.3 Hz, *H*OCH$_2$), 7.52 (1H, q, ^4J = 1.1 Hz, H-3), 10.40 (1H, br s, CON*H*CSNH), 10.97 (1H, br d, $^3J_{\text{to H-1′}}$ = 7.3 Hz, CONHCSN*H*); spin–spin decoupling was performed at δ 4.50.

*(±)-*N*-{N′-[*cis*-3-(Hydroxymethyl)cyclopentyl]carbamoyl}-3-methoxy-2-methylpropenamide (28)*

A solution of 3-methoxy-2-methylpropenoyl isocyanate (**24**) in benzene was prepared from **22** and silver cyanate as described by Shealy *et al.* (12) and was used immediately for the preparation of **28** without further purification. To a solution of **8** (0.67 g, 5.8 mmol) in dry *N*,*N*-dimethylformamide (12.2 mL), cooled to −15°C, a solution of **24** (1.22 equiv., theoretical) in benzene was added dropwise; the temperature of the reaction solution was maintained below −10°C with a cooling bath. After the addition of **24** was complete, the reaction solution was kept at room temperature overnight; the mixture was filtered and the solvent was evaporated. The residue was fractionated by column chromatography on silica gel to give **28** (1.05 g, 71%) as a white solid, R_f 0.44 (3:3:1 (v/v/v) toluene – ethyl acetate – 2-propanol). The ^{1}Hmr spectrum revealed only minute signals attributable to impurities; ^{1}Hmr (200 MHz, Me_2SO-d_6), δ: 1.02–1.18 (1H, m, H-2′), 1.29–2.11 (6H, m, H-2″, H-3′, H-4′, H-4″, H-5′, and H-5″), 1.61 (3H, d, $^4J_{\text{to H-3}}$ = 1.3 Hz, Me), 3.30 (2H, t, ^3J = 5.2 Hz, HOCH_2), 3.79 (3H, s, OMe), 3.99 (1H, se, ^3J = 6.9 Hz, H-1′), 4.55 (1H, t, ^3J = 5.2 Hz, *H*OCH$_2$), 7.45 (1H, q, ^4J = 1.3 Hz, H-3), 8.65 (1H, br d, $^3J_{\text{to H-1′}}$ = 7.3 Hz, CONHCON*H*), 9.67 (1H, br s, CON*H*CONH); spin–spin decoupling was performed at δ 1.10, 3.30, and 3.99.

*(±)-3-Ethoxy-*N*-{N′-[*cis*-3-(hydroxymethyl)cyclopentyl]thiocarbamoyl}propenamide (29)*

3-Ethoxypropenoyl isothiocyanate (**25**) was prepared as described previously (20) and used immediately after distillation for the preparation of **29**. Compound **25** (1.41 g, 8.97 mmol) was added to a solution of **8** (0.934 g, 8.11 mmol) in methanol (13 mL) and diethyl ether (20 mL), and the reaction solution was kept at room temperature overnight; the mixture was filtered and the solvent was evaporated. The resulting oil was fractionated by column chromatography on silica gel to give **29** (1.54 g, 70%) as a pale yellow-green oil; R_f 0.50 (8:8:1 (v/v/v) toluene – ethyl acetate – 2-propanol). The ^{1}Hmr spectrum showed minor signals attributable to impurities; ^{1}Hmr (200 MHz, Me_2SO-d_6), δ: 1.10–2.23 (6H, m, H-2′, H-2″, H-4′, H-4″, H-5′, and H-5″), 1.24 (3H, t, ^3J = 7.0 Hz, Me), 1.85–2.23 (1H, m, H-3′), 3.32 (2H, t, ^3J = 5.6 Hz, HOCH_2), 3.98 (2H, q, ^3J = 7.0 Hz, CH_3CH_2O), 4.48 (1H, se, ^3J = 6.9 Hz, H-1′), 4.56 (1H, t, ^3J = 5.0 Hz, *H*OCH$_2$), 5.70 (1H, d, $^3J_{2,3}$ = 12.2 Hz, H-2), 7.59 (1H, d, $^3J_{3,2}$ = 12.2 Hz, H-3), 10.84 (1H, br s, CON*H*CSNH), 10.96 (1H, br d, $^3J_{\text{to H-1′}}$ = 7.2 Hz, CONHCSN*H*); spin–spin decoupling was performed at δ 3.32, 4.48, and 10.96.

*(±)-3-Ethoxy-*N*-{N′-[*cis*-3-(hydroxymethyl)cyclopentyl]carbamoyl}propenamide (30)*

A solution of 3-ethoxypropenoyl isocyanate (**26**) in benzene was prepared as described previously (21, 28). A solution of compound **26** (26.6 mmol, theoretical) in benzene (60 mL) was added to a solution of **8** (2.73 g, 23.7 mmol) in *N*,*N*-dimethylformamide (60 mL) that had been cooled to −15°C; the temperature was maintained below −10°C during the addition. The reaction solution was kept at room temperature overnight. The mixture was filtered and the solvent was evaporated with ethanol (2 × 20 mL); fractionation of the residue by column chromatography on silica gel gave **30** (2.59 g, 43%) as a semisolid, R_f 0.57 (2:2:1 (v/v/v) toluene – ethyl acetate – 2-propanol). The ^{1}Hmr spectrum showed minor signals attributable to impurities; ^{1}Hmr (200 MHz, Me_2SO-d_6), δ: 1.05–2.15 (7H, m, H-2′, H-2″, H-3′, H-4′, H-4″, H-5′, and H-5″), 1.26 (3H, t, ^3J = 7.0 Hz, Me), 3.32 (2H, t, ^3J = 5.6 Hz, HOCH_2), 3.98 (1H, se, ^3J = 7.0 Hz, H-1′), 4.02 (2H, q, ^3J = 7.0 Hz, CH_3CH_2O), 4.53 (1H, t, ^3J = 5.3 Hz, *H*OCH$_2$), 5.59 (1H, d, $^3J_{2,3}$ = 12.7 Hz, H-2), 7.69 (1H, d, $^3J_{3,2}$ = 12.7 Hz, H-3), 7.98 (1H, br d, $^3J_{\text{to H-1′}}$ = 7.4 Hz, CONHCON*H*); spin–spin decoupling was performed at δ 3.32 and 4.00.

*(±)-2,3-Dihydro-1-{*cis*-3-(hydroxymethyl)cyclopentyl}-5-methyl-2-thioxo-4(1*H*)-pyrimidinone (31)*

A solution of compound **27** (0.359 g, 1.32 mmol) in 15 *N* aqueous ammonia (15 mL) was heated at 100°C in an oil bath for 30 min. After the reaction solution had cooled to room temperature, the solvent was evaporated and the residue was evaporated with ethanol (2 × 10 mL). The resulting material was fractionated by column chromatography on silica gel to give **31** (0.195 g, 62%). Recrystallization from ethanol–hexanes gave **31** (0.116 g) as a white crystalline solid, mp 138.5–139.5°C, R_f 0.39 (4:4:1 (v/v/v) toluene – ethyl acetate – 2-propanol); uv λ_{max} (C_2H_5OH): 221 (ε 15 300), 276 (15 400) nm; λ_{max} (0.01 *M* HCl in C_2H_5OH): 221 (ε 15 300), 276 (15 300) nm; λ_{max} (0.01 *M* NaOH in C_2H_5OH): 242 (ε 20 300), 255 (17 800), 266 (17 600) nm; ^{1}Hmr (200 MHz, Me_2SO-d_6), 1.26–2.21 (7H, m, H-2′, H-2″, H-3′, H-4′, H-4″, H-5′, and H-5″), 1.85 (3H, m, Me), 3.40 (2H, m, HOCH_2), 4.61 (1H, t, ^3J = 5.2 Hz, *H*OCH$_2$), 5.74 (1H, m, H-1′), 7.76 (1H, m, H-6), 12.51 (1H, br s, H-3). *Anal.* calcd. for $C_{11}H_{16}O_2N_2S$: C 54.98, H 6.71, N 11.66, S 13.34; found: C 55.19, H 6.96, N 11.73, S 13.52.

*(±)-1-{*cis*-3-(Hydroxymethyl)cyclopentyl}-5-methyl-2,4(1*H*,3*H*)-pyrimidinedione (32)*

A solution of **28** (1.106 g, 3.96 mmol) in aqueous ammonia (35 mL) was heated at 100°C in an oil bath for 65 min. After the solution had cooled to room temperature, the solvent was evaporated and the residue was then evaporated with ethanol (2 × 10 mL). The resulting material was fractionated by column chromatography on silica gel to give **32** (0.724 g, 82%) as a white solid. Recrystallization from ethanol–hexanes gave **32** (0.596 g) having mp 165–168°C (lit. (12) mp 173–174°C). Repeated recrystallization gave material having mp 166–168°C; R_f 0.34 (2:2:1 (v/v/v) toluene – ethyl acetate – 2-propanol); uv λ_{max} (C_2H_5OH): 210 (ε 9990), 272 (9980) nm; λ_{max} (0.01 *M* HCl in C_2H_5OH): 210 (ε 9960), 272 (9930) nm; λ_{max} (0.01 *M* NaOH in C_2H_5OH): 220 (ε 9590), 272 (7400) nm; ^{1}Hmr (200 MHz, Me_2SO-d_6), δ: 1.29–2.18 (7H, m, H-2′, H-2″, H-3′, H-4′, H-4″, H-5′, and H-5″), 1.79 (3H, d, $^4J_{\text{to H-6}}$ = 0.9 Hz, Me), 3.38 (2H, m, HOCH_2), 4.58 (1H, t, ^3J = 5.3 Hz, *H*OCH$_2$), 4.73 (1H, m, H-1′), 7.56 (1H, m, H-6), 11.19 (1H, br s, H-3). *Anal.* calcd. for $C_{11}H_{16}O_3N_2$: C 58.91, H 7.19, N 12.49; found: C 59.04, H 7.30, N 12.44.

*(±)-2,3-Dihydro-1-{*cis*-3-(hydroxymethyl)cyclopentyl}-2-thioxo-4(1*H*)-pyrimidinone (33)*

A solution of **29** (1.491 g, 5.47 mmol) in 15 *N* aqueous ammonia (50 mL) was heated at 100°C in an oil bath for 25 min. After the reaction solution had cooled to room temperature, the solvent was evaporated and the residue was then evaporated with ethanol (2 × 10 mL). The resulting material was fractionated by column chromatography on silica gel to give **33** (1.001 g, 81%) as a white solid, R_f 0.41 (3:3:1 (v/v/v) toluene – ethyl acetate – 2-propanol). An analytical sample was prepared by recrystallization from ethanol–hexanes, mp 145–147°C; uv λ_{max} (C_2H_5OH): 219 (ε 16 000), 272 (13 600) nm; λ_{max} (0.01 *M* HCl in C_2H_5OH): 219 (ε 16 700), 273 (13 700) nm;

For personal use only.

λ_{max} (0.01 *M* NaOH in C_2H_5OH): 240 (ε 18 500), 273 (16 000) nm; ^{1}Hmr (200 MHz, Me_2SO-d_6), δ: 1.23–2.19 (7H, m, H-2′, H-2″, H-3′, H-4′, H-4″, H-5′, and H-5″), 3.39 (2H, t, ^3J = 5.1 Hz, $HOCH_2$), 4.62 (1H, t, ^3J = 5.2 Hz, $HOCH_2$), 5.73 (1H, m, H-1′), 5.99 (1H, br d, $^3J_{5,6}$ = 7.8 Hz, H-5), 7.90 (1H, d, $^3J_{6,5}$ = 7.8 Hz, H-6), 12.63 (1H, br s, H-3). *Anal.* calcd. for $C_{10}H_{14}O_2N_2S$: C 53.08, H 6.24, N 12.38, S 14.17; found: C 53.13, H 6.40, N 12.20, S 13.95.

*(±)-1-{*cis*-3-(Hydroxymethyl)cyclopentyl}-2,4(1*H*,3*H*)-pyrimidinedione (**34**)*

A solution of **30** (2.47 g, 9.64 mmol) in 2 *N* H_2SO_4 (65 mL) was heated at reflux temperature for 30 min. After the solution had cooled to room temperature, it was treated with charcoal and the mixture was filtered. The filtrate was cooled to ice-bath temperature and neutralized with 2 *M* NaOH. The solvent was evaporated and the residue was extracted with ethanol (4 × 30 mL). The ethanol was then evaporated and the residue was fractionated by column chromatography on silica gel to give **34** (1.401 g, 69%) as a pale-yellow solid, mp 150–155°C, R_f 0.43 (1:1:1 (v/v/v) toluene – ethyl acetate – 2-propanol). An analytical sample was prepared by recrystallization from ethanol–hexanes, mp 158–159°C; uv λ_{max} (C_2H_5OH): 209 (ε 9490), 268 (10 400) nm; λ_{max} (0.01 *M* HCl in C_2H_5OH): 209 (ε 9460), 268 (10 300) nm; λ_{max} (0.01 *M* NaOH in C_2H_5OH): 220 (ε 8220), 266 (7490) nm; ^{1}Hmr (200 MHz, Me_2SO-d_6), δ: 1.27–2.18 (7H, m, H-2′, H-2″, H-3′, H-4′, H-4″, H-5′, and H-5″), 3.38 (2H, t, ^3J = 5.6 Hz, $HOCH_2$), 4.57 (1H, t, ^3J = 5.1 Hz, $HOCH_2$), 4.74 (1H, m, H-1′), 5.57 (1H, d of d, $^3J_{5,6}$ = 8.1, $^4J_{5,3}$ = 2.2 Hz, H-5), 7.69 (1H, d, $^3J_{6,5}$ = 8.1 Hz, H-6), 11.24 (1H, br s, H-3). *Anal.* calcd. for $C_{10}H_{14}O_3N_2$: C 57.13, H 6.71, N 13.32; found: C 57.18, H 6.83, N 13.35.

*(±)-1-{*cis*-3-(Hydroxymethyl)cyclopentyl}-5-methyl-2,4(1*H*,3*H*)-pyrimidinedione benzoate (**38**)*

A solution of benzoyl chloride (0.66 mL, 5.7 mmol) in pyridine (5 mL) was added to a solution of compound **32** (0.424 g, 1.89 mmol) in pyridine (20 mL). The reaction solution was kept at 55°C in a water bath for 48 h and then poured into a water–ice mixture (150 mL). An oil separated, which was extracted with chloroform (3 × 25 mL). The solvent was evaporated and the residue was evaporated with ethanol–water (1:1 (v/v), 2 × 20 mL). The resulting oil was fractionated by column chromatography on silica gel to give **35** (0.822 g) as a colorless solid foam, R_f 0.56 (3:2 (v/v) toluene – ethyl acetate). The ^{1}Hmr spectrum showed this sample to be contaminated by a small amount of benzoic acid; ^{1}Hmr (200 MHz, Me_2SO-d_6), δ: 1.58–2.12 (5H, m, H-2′, H-4′, H-4″, H-5′, and H-5″), 1.88 (3H, m, Me), 2.22 (1H, d of t, J_{gem} = 12.4, ^3J = 7.0 Hz, H-2″), 2.45 (1H, m, H-3′), 4.24–4.41 (2H, m, OCH_2C), 4.83 (1H, m, H-1′), 7.47–8.02 (10H, m, C_6H_5), 7.88 (1H, m, H-6); spin–spin decoupling was performed at δ 1.88. Compound **35** (0.758 g) was dissolved in hot ethanol (70 mL), and to this solution water (25 mL) and 1 *M* hydrochloric acid (6 mL) were added; the reaction solution was heated at reflux temperature for 24 h. The solution was cooled and the solvent was evaporated. The residue was fractionated by column chromatography on silica gel to give **38** (0.429 g, 75% from **32**) as a white crystalline solid, R_f 0.46 (8:8:1 (v/v/v) toluene – ethyl acetate – 2-propanol). An analytical sample was prepared by recrystallization from ethanol, mp 159–161°C; uv λ_{max} (C_2H_5OH): 202 (ε 17 300), 224 (16 600), 273 (10 800) nm; λ_{max} (0.01 *M* HCl in C_2H_5OH): 202 (ε 16 500), 224 (16 500), 273 (10 800) nm; λ_{max} (0.01 *M* NaOH in C_2H_5OH): 228 (ε 20 400), 272 (8170) nm; ^{1}Hmr (200 MHz, Me_2SO-d_6), δ: 1.47–2.00 (5H, m, H-2′, H-4′, H-4″, H-5′, and H-5″), 1.78 (3H, m, Me), 2.12 (1H, d of t, J_{gem} = 12.0, ^3J = 6.9 Hz, H-2″), 2.43 (1H, m, H-3′), 4.21–4.37 (2H, m, OCH_2), 4.82 (1H, m, H-1′), 7.50–8.02 (5H, m, C_6H_5), 7.63 (1H, m, H-6), 11.26 (1H, br s, H-3); spin–spin decoupling was performed at δ 1.78, 2.43, and 4.82. *Anal.* calcd. for $C_{18}H_{20}O_4N_2$: C 65.84, H 6.14, N 8.53; found: C 66.19, H 6.10, N 8.57.

*(±)-2,3-Dihydro-1-{*cis*-3-(hydroxymethyl)cyclopentyl}-2-thioxo-4(1*H*)-pyrimidinone benzoate (**39**)*

A solution of benzoyl chloride (0.60 mL, 5.2 mmol) in pyridine (5 mL) was added dropwise to a solution of compound **33** (0.338 g, 1.49 mmol) in pyridine (15 mL). The reaction solution was treated as for the preparation of **35**, and, after fractionation by column chromatography on silica gel, two major components were isolated, namely **36** (0.386 g) as a solid foam, R_f 0.54 (3:2 (v/v) toluene – ethyl acetate), and **39** (0.192 g) as a crystalline solid that, after recrystallization from ethanol–water, gave a sample of **39** (0.111 g) having mp 179–182°C, R_f 0.34. Compound **36**, ^{1}Hmr (200 MHz, Me_2SO-d_6), δ: 1.42–2.50 (7H, H-2′, H-2″, H-3′, H-4′, H-4″, H-5′, and H-5″), 4.22–4.42 (2H, m, OCH_2), 5.72 (1H, m, H-1′), 6.32 (1H, d, $^3J_{5,6}$ = 8.3 Hz, H-5), 7.46–8.02 (10H, m, C_6H_5), 8.22 (1H, d of d, $^3J_{6,5}$ = 8.3, J = 1.3 Hz, H-6); spin–spin decoupling was performed at δ 6.32 and 5.72. To a solution of compound **36** (0.362 g, 0.83 mmol) in hot ethanol (50 mL) were added water (25 mL) and 1 *M* hydrochloric acid (5 mL), and the reaction solution was heated at reflux temperature for 4 h. After the solution had cooled to room temperature, a white solid precipitated that, after reduction of the volume of the reaction mixture to 20 mL, was collected by filtration to give **39** (0.244 g), mp 179–182°C, for a total yield of 0.355 g (75% from **33**). An analytical sample was prepared by recrystallization from ethanol, mp 180–182°C; uv λ_{max} (C_2H_5OH): 203 (ε 17 200), 223 (26 700), 273 (15 600) nm; λ_{max} (0.01 *M* HCl in C_2H_5OH): 203 (ε 16 700), 223 (26 700), 273 (15 400) nm; λ_{max} (0.01 *M* NaOH in C_2H_5OH): 234 (ε 29 600), 273 (18 100) nm; ^{1}Hmr (200 MHz, Me_2SO-d_6), δ: 1.51 (1H, m, H-2′), 1.62–2.13 (4H, m, H-4′, H-4″, H-5′, and H-5″), 2.26 (1H, d of t, J_{gem} = 11.9, ^3J = 6.9 Hz, H-2″), 2.46 (1H, m, H-3′), 4.21–4.38 (2H, m, OCH_2), 5.82 (1H, m, H-1′), 6.01 (1H, d of d, $^3J_{5,6}$ = 8.1, $^4J_{5,3}$ = 1.3 Hz, H-5), 7.50–8.02 (5H, m, C_6H_5), 7.96 (1H, d, $^3J_{6,5}$ = 8.1 Hz, H-6), 12.62 (1H, br s, H-3); spin–spin decoupling was performed at δ 4.30 and 6.01. *Anal.* calcd. for $C_{17}H_{18}O_3N_2S$: C 61.80, H 5.49, N 8.48, S 9.70; found: C 62.17, H 4.97, N 8.46, S 10.17.

*(±)-1-{*cis*-3-(Hydroxymethyl)cyclopentyl}-2,4(1*H*,3*H*)-pyrimidinedione benzoate (**40**)*

Compound **34** (0.448 g, 2.13 mmol) was treated with benzoyl chloride (0.75 mL, 6.5 mmol) as described for the preparation of **35**, and, after fractionation by column chromatography on silica gel, **37** (0.85 g) was obtained as a colorless solid foam, R_f 0.44 (3:2 (v/v) toluene – ethyl acetate); ^{1}Hmr (200 MHz, Me_2SO-d_6), δ: 1.57–2.15 (5H, m, H-2′, H-4′, H-4″, H-5′, and H-5″), 2.24 (1H, d of t, J_{gem} = 12.2, ^3J = 7.0 Hz, H-2″), 2.43 (1H, m, H-3′), 4.22–4.38 (2H, m, OCH_2), 4.81 (1H, m, H-1′), 5.88 (1H, d, $^3J_{5,6}$ = 7.9 Hz, H-5), 7.50–8.01 (10H, m, C_6H_5), 8.03 (1H, d, $^3J_{6,5}$ = 7.9 Hz, H-6); spin–spin decoupling was performed at δ 2.43, 4.81, and 5.88. Compound **37** (0.81 g) was treated as described for the preparation of **38**, and, after fractionation by column chromatography on silica gel, **40** (0.449 g, 70% from **34**) was obtained as a white crystalline solid, mp 153–155°C, R_f 0.56 (4:4:1 (v/v/v) toluene – ethyl acetate – 2-propanol). An analytical sample was prepared by recrystallization from ethanol, mp 154–155°C; uv λ_{max} (C_2H_5OH): 202 (ε 17 700), 226 (14 700), 268 (11 000) nm; λ_{max} (0.01 *M* HCl in C_2H_5OH): 203 (ε 15 800), 227 (14 500), 268 (10 900) nm; λ_{max} (0.01 *M* NaOH in C_2H_5OH): 227 (ε 19 400), 266 (8040) nm; ^{1}Hmr (200 MHz, Me_2SO-d_6), δ: 1.47–2.02 (5H, m, H-2′, H-4′, H-4″, H-5′, and H-5″), 2.14 (1H, d of t, J_{gem} = 12.1, ^3J = 7.0 Hz, H-2″), 2.43 (1H, m, H-3′), 4.20–4.36 (2H, m, OCH_2), 4.79 (1H, m, H-1′), 5.59 (1H, d of d, $^3J_{5,6}$ = 8.0, $^4J_{5,3}$ = 2.0 Hz, H-5), 7.49–8.00 (5H, m, C_6H_5), 7.77 (1H, d, $^3J_{6,5}$ = 8.0 Hz, H-6), 11.28 (1H, br d, $^4J_{3,5}$ = 2.0 Hz, H-3); spin–spin decoupling was performed at δ 2.43, 4.79, and 5.59. *Anal.* calcd. for $C_{17}H_{18}O_4N_2$: C 64.96, H 5.77, N 8.91; found: C 64.93, H 6.02, N 8.87.

*(±)-4-Amino-1-{*cis*-3-(hydroxymethyl)cyclopentyl}-5-methyl-2(1*H*)-pyrimidinone (**43**)*

A solution of **38** (0.315 g, 0.96 mmol), thionyl chloride (1 mL, 13.8 mmol), *N*,*N*-dimethylformamide (55 mg, 0.75 mmol), and chloroform (16 mL) was heated at reflux temperature for 6 h. The solution was cooled and the solvent evaporated; the residue was dried overnight using a vacuum pump. The residue was transferred to a Teflon-lined steel bomb with dry methanol (11 mL). The steel bomb

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.222.148.141 on 09/07/12
For personal use only.

was cooled by immersion in crushed Dry Ice for a few min, and then anhydrous ammonia (11 mL) was added. The bomb was sealed and kept in an oil bath at 100°C for 21 h. The bomb was then cooled with Dry Ice, opened, and allowed to warm to room temperature. The contents were transferred with the aid of methanol and, after reduction of the volume using a rotary evaporator, the material was fractionated by column chromatography on silica gel to give **43** (0.158 g, 74%) as a light-yellow oil, R_f 0.33 (5:3:1 (v/v/v) acetonitrile – 1,2-dimethoxyethane – 15 *N* aqueous ammonia). An analytical sample was prepared by crystallization from ethanol–acetonitrile – diethyl ether, mp 217–220°C; ^{1}Hmr (200 MHz, Me_2SO-d_6), δ: 1.24–2.16 (7H, m, H-2′, H-2″, H-3′, H-4′, H-4″, H-5′, and H-5″), 1.84 (3H, s, Me), 3.39 (2H, t, ^3J = 5.8 Hz, HOCH_2), 4.54 (1H, t, ^3J = 5.4 Hz, HOCH$_2$), 4.79 (1H, m, H-1′), 6.66 (1H, br s, NH_2),[3] 7.04 (1H, br s, NH_2),[3] 7.46 (1H, s, H-6). *Anal.* calcd. for $C_{11}H_{17}O_2N_3$: C 59.16, H 7.67, N 18.82; found: C 58.89, H 7.55, N 18.73.

*(±)-4-Amino-1-{*cis*-3-(hydroxymethyl)cyclopentyl}-2(1*H*)-pyrimidinone (**44**)*

A solution of **40** (0.375 g, 1.19 mmol), thionyl chloride (1 mL, 13.8 mmol), *N*,*N*-dimethylformamide (51 mg, 0.70 mmol), and chloroform (17 mL) was treated as described for the preparation of **43**. After having been dried in a vacuum, compound **42** was dissolved in methanol – anhydrous ammonia (20 mL, 1:1 (v/v)) and the solution was heated in a Teflon-lined steel bomb at 100°C for 8.5 h. The bomb was opened as described for the preparation of **43**, and the material was fractionated by column chromatography on silica gel to give **44** (173 mg, 69%) as an oil, R_f 0.35 (5:3:1 (v/v/v) acetonitrile–1,2-dimethoxyethane – 15 *N* aqueous ammonia). An analytical sample was prepared by recrystallization from ethanol – diethyl ether, mp 200–202°C; ^{1}Hmr (200 MHz, Me_2SO-d_6), δ: 1.23–2.18 (7H, m, H-2′, H-2″, H-3′, H-4′, H-4″, H-5′, and H-5″), 3.3–3.45 (2H, m, HOCH_2), 4.58 (1H, br t, HOCH$_2$), 4.80 (1H, m, H-1′), 5.69 (1H, d, $^3J_{5,6}$ = 7.3 Hz, H-5), 7.05 (2H, br s, NH_2), 7.64 (1H, d, $^3J_{6,5}$ = 7.3 Hz, H-6). *Anal.* calcd. for $C_{10}H_{15}O_2N_3$: C 57.40, H 7.23, N 20.08; found: C 57.16, H 7.50, N 19.70.

Treatment of compound **39** as described for the preparation of **44** gave material having mp 195–199°C and an ^{1}Hmr spectrum identical to that obtained for compound **44**.

A semiempirical approach for predicting ^{13}C nuclear magnetic resonance chemical shifts of acyclic hydrocarbons has been adapted to a microcomputer program. A series of methyl and dimethyl substituted cholesterols has been studied using this program, and the predicted shifts are in agreement with literature reports. Preferred conformations of the steroidal side chains have been also predicted and agree with previous studies. A simple rule for analyzing the trends in the chemical shift of the carbon C-20, which is sensitive to changes in the configuration at C-22, is also given, not only for hydrocarbon side chains but also for hydroxy substituted compounds.

MANUEL GONZALEZ-SIERRA, DANIEL A. BUSTOS, EDMUNDO A. RUVEDA, ALEJANDRO C. OLIVIERI et MARIANO GRASSELLI. Can. J. Chem. **66**, 71 (1988).

Une approche semi-empirique permettant de prédire les déplacements chimiques en résonance magnétique nucléaire du ^{13}C d'hydrocarbures acycliques a été adaptée à une programme de micro-ordinateurs. Utilisant ce programme, on a étudié une série de cholestérols substitués par des méthyles ou diméthyles; les déplacements chimiques prévus sont en accord avec ceux rapportés dans la littérature. On a aussi prédit les conformations privilégiées des chaînes latérales des stéroïdes et ces conformations correspondent à celles prévues dans des études antérieures. On présente aussi une règle simple pour analyser les tendances dans le déplacement chimique du carbone C-20, qui est sensible aux changements de configuration en C-22; cette règle s'applique tant aux chaînes latérales hydrocarbonées qu'aux composés portant des groupements hydroxyles.

Introduction

^{13}C nuclear magnetic resonance spectroscopy is well established as a powerful tool in the structure elucidation of organic molecules. The range of ^{13}C chemical shifts is large (about 250 ppm in common organic compounds), and therefore this parameter is able to reflect subtle structural changes. However, the physical background of the factors influencing the position of ^{13}C resonances is not yet fully understood. A survey of the literature on substituent effects reveals that sp^2 carbons have been widely studied (1–7), and correlations have been found with known physicochemical properties. For aliphatic systems, on the other hand, there is no comprehensive treatment of the structural features involved in ^{13}C chemical shifts. Nevertheless, the number of empirical studies in this field is continually growing. Several rules for evaluating chemical shifts of sp^3 carbons have been proposed (8–12), but they cannot deal with molecular asymmetry or conformationally rigid molecules. The semiempirical method developed by Beierbeck *et al.* (13, 14) allows us to predict, with a satisfactory degree of accuracy, ^{13}C chemical shifts of saturated aliphatic hydrocarbons and rigid cyclohexanes having different substituents, and has been recently extended to epoxides (15).

Whereas in fixed substrates the calculations can be easily performed, the analysis of acyclic compounds requires considerable effort. In this report we use a microcomputer program to calculate conformer populations, ^{13}C chemical shifts of individual conformers, and conformationally averaged resonances according to the method of Beierbeck and Saunders (14). A comparison is presented between the observed shifts for a series of steroidal side chains and those calculated with the program. The implications of the results regarding the use of ^{13}C nmr spectroscopy in the structure elucidation of related steroids are discussed, and the predicted preferred conformations are compared with previous studies involving ^{1}H nmr spectroscopy.

Results and discussion

One of the earliest rules for predicting ^{13}C chemical shifts was that of Grant and Paul (8), later improved by Lindeman and Adams (9) to account for highly branched hydrocarbons. The latter rule has been extended to substituted alkanes by relating them to analogously constituted hydrocarbons in which the substituent heteroatoms are replaced by carbons (e.g., OH, Cl, Br, I by CH_3; -COO- by $-CH(CH_3)CH_2-$, etc.) (10–12). Since the parameters used in these analyses were based on conformational averages, they were not able to deal with molecular asymmetry or fixed structures.

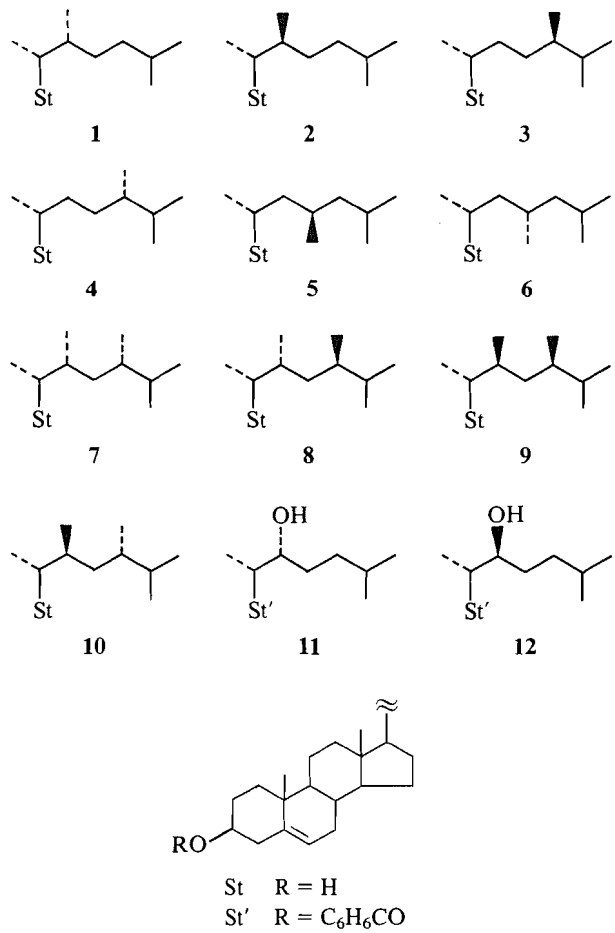
In the approach of Beierbeck and Saunders (14), conformer populations are estimated prior to the ^{13}C chemical shift study, using experimentally determined rotational energies and steric contributions. The conformer statistical weights Ω_j are taken as products of m contributions E_{ij} to the energy of the conformer j:

$$[1] \quad \Omega_j = \prod_{i=1}^{m} \exp(-E_{ij}/RT)$$

The conformer populations are then obtained according to

$$[2] \quad p_j = \Omega_j \Big/ \left(\sum_{j=1}^{n} \Omega_j \right)$$

where n is the total number of conformers. Details on the values of the contributions E_{ij} are given in ref. 14. Individual ^{13}C resonances are predicted using the substituent parameter set derived for rigid cyclic systems (13), and are conformationally averaged using the populations p_j.



Since the number of conformers grows exponentially with the number of rotated C—C bonds, the calculation of a medium size hydrocarbon requires considerable work. Therefore, we have devised a program written in ISOPASCAL for the microcomputer Sinclair QL, which calculates the conformer populations, their ^{13}C chemical shifts, and the final weighted values predicted for solution resonances. The user may select some bonds to remain fixed, allowing the others to rotate every 120°. This proves useful in the study of aliphatic side chains attached to rigid frameworks, as will be illustrated below. The output of the program consists of the averaged ^{13}C chemical shifts, a computer drawing of the most abundant conformer, and its relative population.

As an example of the potential application of this approach, the series of methyl and dimethyl substituted cholesterols **1–10** was studied. The ^{13}C nmr chemical shifts of these compounds are available from the literature, having attracted attention in recent years due to their biological significance (16–18). Compounds **3** and **4** exist in marine environments (19), and the rest are expected to be also naturally occurring.

To undertake the study of ^{13}C chemical shifts of the side chains of **1–10**, we choose as a convenient model the compound shown in Fig. 1, in which some bonds are maintained fixed by the computer program, while the others are allowed to rotate every 120° during the calculations. In Table 1 a comparison is shown between the experimental data and the values calculated with the program. The standard deviation is within the expected values (13, 14) although the errors may accumulate in some unfavourable cases. However, the power of the method rests in the prediction of relative shieldings or deshieldings, and is not intended to give reliable absolute values.

[a]Conformationally averaged chemical shifts according to the analysis of Beierbeck *et al.*

FIG. 2. Conformations of compound **3** obtained by rotating the 24,25 bond, and analysis of the chemical shifts of the C-25 methyls.

As shown in Table 1, the method is also able to deal with the nonequivalence of the methyls C-26 and C-27, induced by nearby chiral centers (20). Consider compound **3**, whose conformations around the 24,25 bond are depicted in Fig. 2. In the most favourable one (**3***a*), both methyls are predicted to have the same chemical shift, since they have the same number of HC interactions (associated with 1,3-diaxial-like H/H interactions, the dominant deshielding mode assumed by the method). In **3***b*, one of the methyls should be shielded relative to the other (one HC interaction has been removed), whereas the reverse situation is found in **3***c* (see Fig. 2). Since the population of **3***c* is larger than that of **3***b*, where two unfavourable R/Me interactions are seen, a small difference is expected in the averaged chemical shifts of C-26 and C-27. The nonequivalence is therefore accounted for by the chirality of C-24, which perturbs the energies of the rotamers **3***b* and **3***c*. In this way, molecular asymmetry is taken into account without postulating additional parameters than those required for rigid systems.

Another interesting feature to be found in Table 1 is the success of the method in predicting the chemical shift of C-20, since the values estimated with the aid of the Lindeman–Adams rule (9) are too low, although the latter has been especially devised to analyze highly branched alkanes. This can be explained on the basis of a restricted rotation about the 17,20 bond. In fact, the most abundant conformers predicted by the program are those that show an antiperiplanar relation between H-17 and H-20. Furthermore, in C-22 substituted compounds the 20,22 bond is predicted to adopt a conformation in which

[a]In ppm downfield from TMS.

[b]The data for compounds **1**, **2**, **3**, and **4** have been taken from ref. 16, those for **5** and **6** from ref. 17, and those for **7**, **8**, **9**, and **10** from ref. 18.

[c]Root mean square deviation between calculated and observed shifts is 1.51 ppm.

[d]In compounds **1**, **2**, **7**, **8**, **9**, and **10** the original assignments of carbons 20 and 22 have been interchanged.

interactions between the C-22 substituents and the methylene C-16 are avoided. These results, illustrated in Fig. 3 by computer drawings of the preferred conformations of **1** and **10**, are in agreement with previous studies performed by ^1H nmr spectroscopy (21). If the conformation around the 17,20 bond is somewhat fixed, then the failure of the Lindeman–Adams rule is not surprising, since its parameters are derived through conformational averages.

We now focus our attention on the determination of the configuration at C-22, a subject of great biological relevance (18). From the data presented in Table 1, it is clear that the chemical shift of C-23 is of diagnostic value: both predicted and observed values are upfield in the 22(*R*) substituted compounds. The resonance of C-20 seems also to be sensitive to changes in the configuration of C-22, being consistently shielded in the 22(*S*) series relative to the 22(*R*). The study of the chemical shift of C-20 is particularly interesting, since it can be analyzed in a simple way by assuming a fixed conformation

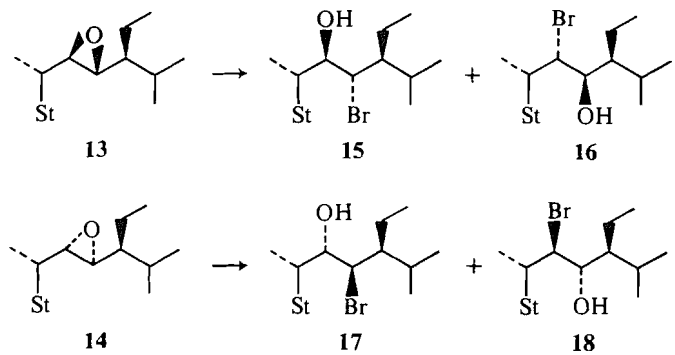

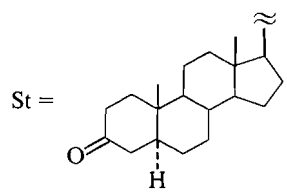

SCHEME 1

around the 17,20 bond, as stated above. Shown in Fig. 4 are the preferred conformations of **1** and **2**, which we assume to be fixed except for a rotation around the 22,23 bond. In both of them C-20 is predicted to have the same chemical shift. However, a rotation about the 22,23 bond in **2** will remove one parallel 1,3 interaction H-20/H-23, and this contribution will produce an average shielding on C-20. The possibility of a similar rotation exists in **1**, but in this case the number of HC interactions affecting C-20 is unchanged. An analogous situation is found in C-22 hydroxy substituted molecules, such as **11** and **12**. The set of parameters derived by Beierbeck *et al.* for rigid cyclohexane alcohols, applied to the preferred conformations shown in Fig. 4, gives nearly equal values for C-20 in both cases. Again, a rotation about the 22,23 bond is expected to lead to an average shielding in the 22(*S*) compound **12**, in agreement with the experimental data (22). Remarkably, this effect appears to be independent of the nature of the group attached to C-22, as has been observed in steroids substituted with halogens, amino, etc. (22).

An additional example is provided by the bromohydrins **15**–**18**. They have been obtained from the epoxides **13** and **14** (23), whose configurations are known from ^{13}C nmr studies (24) (Scheme 1). Table 2 shows ^{13}C chemical shifts of some selected carbons of these compounds, where the assignments have been confirmed by subsequent chemical transformation (25). The

diagnostic value of C-20 is apparent, being upfield in the 22(*R*) compounds.[1] This trend in the chemical shift of C-20 can be accounted for by analyzing the preferred conformations shown in Fig. 4 (22). The calculated values for C-20, assuming that Br induces β and γ effects similar to OH, are also included in Table 2, and are in good agreement with the observed ones. Similar values have been reported for C-20 in related chlorohydrins derived from naturally occurring epoxides (26). It should be noted that attempts to predict the values of C-22 and C-23 in this type of compound may fail due to nonadditive effects that are observed when two substituents are at vicinal positions (27, 28).

In conclusion, we have used a method for the derivation of ^{13}C chemical shifts in rigid systems, which is equally applicable to the calculation of chain conformer resonances. With the aid of a microcomputer program we have obtained an estimate of conformer populations and conformationally averaged chemical shifts for a series of steroidal side chains of biological interest. The results are in good agreement with the values reported in the literature. In addition, the configuration at C-22 has been shown to be monitored by the chemical shift of C-20, and rules have been given to analyze the effects produced by C-22 substitution on this resonance, on the basis of a preferred conformation around the 17,20 and 20,22 bonds.

An electron spin resonance spin trapping investigation of azide oxidation on TiO_2 powder suspensions

ANDREA MALDOTTI,[1] ROSSANO AMADELLI, AND VITTORIO CARASSITI

Centro di Studio sulla Fotochimica e Reattività degli Stati Eccitati dei Composti di Coordinazione del C.N.R. and Dipartimento di Chimica dell'Università degli Studi di Ferrara, 44100 Ferrara, Italy

Received March 24, 1987

ANDREA MALDOTTI, ROSSANO AMADELLI, and VITTORIO CARASSITI. Can. J. Chem. **66**, 76 (1988).

The oxidation of azide has been studied on TiO_2 powder suspensions in water, methanol, and mixtures of the two solvents. The esr spin trapping technique has been employed to provide evidence for the formation of azidyl radicals $N_3^{\bullet}$. The results show that an aqueous alkaline medium is necessary to obtain a high production of $N_3^{\bullet}$ radicals. A mechanism is proposed whereby the oxidation of N_3^- is mainly due to reaction with $OH^{\bullet}$ radicals which are in turn generated upon capture of holes by OH^- groups adsorbed on TiO_2. Azidyl anions adsorb weakly on TiO_2 and do not displace adsorbed OH^- from the surface.

ANDREA MALDOTTI, ROSSANO AMADELLI et VITTORIO CARASSITI. Can. J. Chem. **66**, 76 (1988).

On a étudié l'oxydation de l'azoture sur des poudres de TiO_2 en suspension dans l'eau, le méthanol et des mélanges des deux solvants. On a utilisé la technique du piégeage de spin par rpe pour obtenir des indications relatives à la formation des radicaux azidyles $N_3^{\bullet}$. Les résultats démontrent qu'il est nécessaire d'opérer dans un milieu aqueux alcalin pour obtenir une production élevée de radicaux $N_3^{\bullet}$. On propose un mécanisme selon lequel l'oxydation des ions N_3^--provient principalement d'une réaction avec des radicaux $OH^{\bullet}$ qui sont à leur tour générés par la capture de trous par les groupements OH^- adsorbés sur le TiO_2. Les anions azidyles ne s'adsorbent que faiblement sur le TiO_2 et ils ne déplacement pas les OH^- qui sont adsorbés sur la surface.

[Traduit par la revue]

Introduction

Considerable interest has recently been shown in the oxidation of azide, especially with a view to studying the addition of anodically generated radicals to olefins (1–3). The oxidation of N_3^- produces $N_3^{\bullet}$ radicals whose addition to an olefin competes with their dimerization. Interest has also been focused on the use of $N_3^{\bullet}$ as a selective oxidant of organic (4) and inorganic (5) compounds. It has been pointed out, in this respect, that $N_3^{\bullet}$ as opposed to, for example, $OH^{\bullet}$, reacts primarily by electron transfer.

We were interested in the possibility of using $N_3^{\bullet}$ radicals as oxidation mediators between a semiconductor surface at which they are photogenerated and species of interest, in particular organic compounds in the solution phase. In this work, we describe an esr spin trapping investigation on the formation of $N_3^{\bullet}$ radicals in a photoactivated TiO_2 suspension. The esr spin trapping technique is a powerful tool for detecting the formation of short-lived radicals and has been fruitfully employed in work with semiconductors (6–8). The spin trapping of electrochemically generated azidyl radicals has been previously described (9, 10).

Experimental

Titanium dioxide (99.99%) was obtained from Strem Chemicals. Sodium azide (Fluka), *N-tert*-butyl-α-phenylnitrone (PBN) (Janssen), 5,5-dimethyl-pyrrolinyl-1-oxy (DMPO), and Fe tetra-4-sulfonatophenyl porphine (Fluka) were used as received. Methanol and ethanol were Fluka spectroscopic grade reagents and were dried according to standard procedures (11). Sodium azide and PBN were added to the ultrasonically dispersed TiO_2 in water. Triply distilled water was used in all experiments.

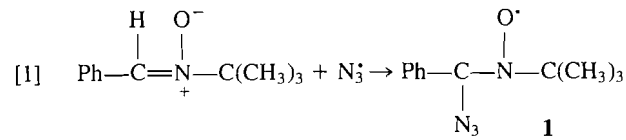
Electron spin resonance measurements were carried out with a Bruker ER 200 D spectrometer. Calibration was achieved as described in ref. 12. The suspension containing the required reagents was introduced into a Spectrosil flat cell and irradiated directly in the esr cavity using a medium pressure mercury lamp (Hanau Q 600). Light of wavelength lower than 360 nm was cut off using suitable glass filters.

Before each experiment with illumination, runs were performed in the dark to check for possible radicals formed thermally. The kinetic data were obtained by recording the esr signal intensity I at a fixed value of the magnetic field.

Results

Radical trapping under continuous irradiation

Irradiation ($\lambda > 360$) of a TiO_2 suspension in water containing sodium azide and PBN leads to the formation of a paramagnetic species whose esr spectrum, shown in Fig. 1*a*, is characteristic of the spin adduct (N_3PBN) (13). This implies that oxidation of azide produces azidyl radicals which are subsequently trapped according to reaction [1].



[1] $Ph{-}C(H)(O^-){=}N^+{-}C(CH_3)_3 + N_3^{\bullet} \rightarrow Ph{-}C(O^{\bullet})(N_3){-}N{-}C(CH_3)_3$ **1**

It is worthwhile mentioning the possible occurrence of the following reaction, in competition with the trapping process:

[2] $N_3^{\bullet} + N_3^- \rightarrow N_6^-$

There are controversial data in the literature concerning this reaction. According to Hayon and Simic (14) it does not occur at all, but Kremers and Singh (15) present evidence that it does take place at the higher N_3^- concentrations. The latter authors, however, state that there is no concentration effect on the esr signal intensity due to the adduct of the azidyl radicals with the spin trap; they conclude that $N_3^{\bullet}$ and N_6^- form adducts having the same esr spectral pattern. This is an important conclusion for the consistency of the experimental results reported in this work.

Figure 2 shows the different behavior of the kinetics curves in air and O_2-saturated TiO_2 aqueous suspensions. In the latter case, the signal intensity regains its initial value when light is switched on after a period in the dark. Harbour and Hair (7) observe a similar effect of O_2 in a study of the DMPO—OH adduct decay. We attribute the observed behavior to the fact that increasing the concentration of O_2 makes more efficient the

removal of conduction band electrons, which, in turn, gives longer life to the photogenerated holes.

Figure 3 shows a plot of the initial rate, r, of growth of the esr signal due to (N_3PBN) adduct vs. the concentration of N_3^-. The form of this curve is strongly reminiscent of a Langmuir isotherm, which means that the reaction leading to $N_3^{\cdot}$ occurs in the adsorbed phase. The rate[2] is then proportional to the surface coverage by adsorbed N_3^-. Indeed, a plot of $1/r$ vs. $1/C_{N_3^-}$ is linear (Fig. 4).

A prolonged irradiation leads to the appearance of another signal superimposed on the spectrum of the (N_3PBN) adduct. After light is switched off, the signal due to (N_3PBN) disappears and only the signal shown in Fig. 1*b* remains. The spectrum is characteristic of di-*t*-butyl nitroxide (DTN) (16).

Iron porphyrin induced oxidation of azide in homogeneous solution

In order to verify whether the decay of the esr signal is due to a reaction occurring in the homogeneous phase or on the photoactivated semiconductor, we have looked for a system in which it is possible to produce N_3^- radicals in the homogeneous solution.

The irradiation of deaerated solutions of Fe(III)$TPPS_4$ in ethanol/water solutions containing NaN_3 and PBN leads to the

[2]The true rate constant for $N_3^{\cdot}$ formation, R, is certainly higher than that we derived from the growth of the esr signal, r, which correspond to the formation of (N_3PBN). The reason for this is that not all $N_3^{\cdot}$ radicals are trapped by PBN. However, the purpose of this work is not to determine R; for our purposes it is sufficient that a linear proportionality exists between R and r. That this is the case is substantiated by the linearity of the plots in Fig. 4.

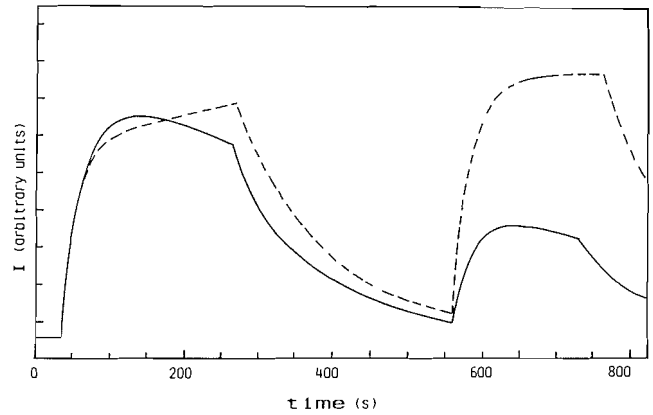

FIG. 2. Electron spin resonance signal intensity of the adduct (N_3PBN) as a function of illumination at a fixed field position. Solid line: air-saturated suspension; dashed line: O_2-saturated suspension.

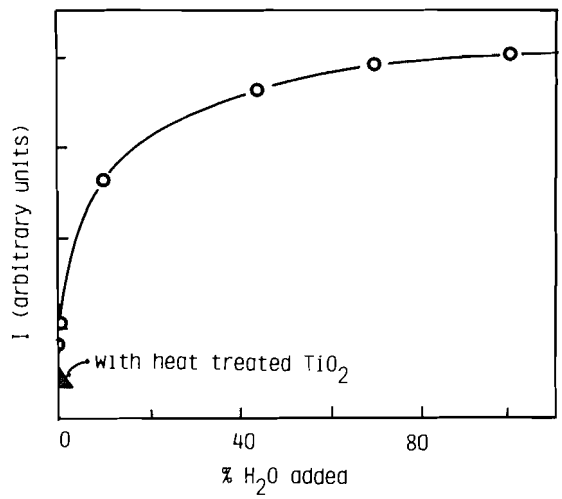

FIG. 3. Initial rate r of (N_3PBN) formation as a function of the N_3^- concentration at different pH values. The signal is measured within 5 min from switching on the light.

formation of both the (N_3PBN) adduct and DTN as seen from the esr spectra. The behavior is the same as that observed with the semiconductor suspension, and we can conclude that the decay of the spin adduct is not appreciably affected by the heterogeneous phase.

Irradiation in the presence of catalase

It is known that hydrogen peroxide is formed when TiO_2 is irradiated in aqueous solution (17). To examine the possibility that H_2O_2 might be involved in reactions with $N_3^{\cdot}$ according to

[3] $H_2O_2 + N_3^{\cdot} \rightarrow HN_3 + HO_2^{\cdot}$

We carried out experiments with catalase added to the suspensions. In these conditions, H_2O_2 should be decomposed by the enzyme to H_2O and O_2. Since we did not observe any effect on the rate of the esr signal intensity, we conclude that reaction [3] does not occur to an appreciable extent. The same conclusion is arrived at by Singh *et al.* (18) in their pulse radiolysis studies.

Solvent and pH effect

We observed a marked influence of solvent on the yield of (N_3PBN) formation. Figure 5 shows the change in the intensity of the esr signal due to (N_3PBN) on passing from methanol to water through mixtures of the two solvents. It is evident that a decrease in the water content leads to a marked decrease in the amount of $N_3^{\cdot}$ produced. Besides, if TiO_2 is evacuated at high temperature (300 to 400°C) to remove the surface OH groups and then suspended in dry methanol, a further decrease in the yield of $N_3^{\cdot}$ formation is observed with respect to unheated TiO_2.

A signal due to the formation of a PBN–CH_2OH adduct is observed immediately upon irradiation of a TiO_2 suspension in pure methanol in the absence of azide. With azide present, the formation of $\dot{C}H_2OH$ radicals is apparent only after prolonged irradiation. This suggests that the observed decrease in $N_3^{\cdot}$ formation on changing the solvent from water to methanol cannot be ascribed to the preferential oxidation of the organic solvent.

The influence of the solution pH on the yield of the N_3PBN spin adduct formation is displayed in Fig. 6. The esr signal increases as the solution is made more alkaline, the higher increase being found between pH = 6 and 9. Lower pH's were not tested to avoid protonation of N_3^-. The experiments were carried out with both buffered solutions or with solutions whose pH was adjusted to the desired value by addition of $HClO_4$ or NaOH.

Irradiation in the absence of azide

Irradiation of TiO_2 in water with PBN but without NaN_3 leads to the appearance of an esr spectrum consisting of a triplet of doublets with coupling constants $a_N = 16.2$ G and $a_H = 3.0$ G. This spectrum is ascribed to the formation of a PBN–OH adduct. The values of the coupling constants do not fit well into the equation given by Janzen *et al.* (19), i.e.,

[4] $a_H = 0.604a_N - 6.53$

On the other hand, a difference between the experimental values of a_H and those calculated from eq. [4] is also observed using the coupling constants for the PBN–OH reported in the literature (8). In experiments carried out with an aqueous semiconductor suspension and DMPO as a spin trap we unequivocally proved the formation of $OH^{\cdot}$ in the absence of azide (1:2:2:1 quartet $a_N = a_H = 15.2$ G) (20).

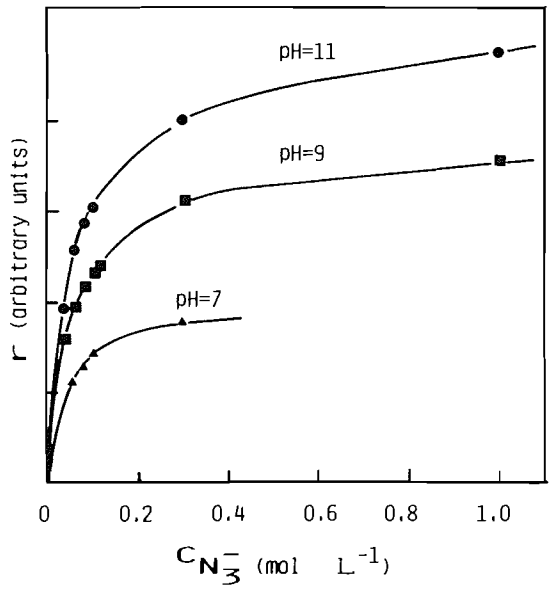

FIG. 5. Electron spin resonance signal intensity of the (N_3PBN) adduct formed by oxidation of N_3^- on TiO_2 suspended in a mixed solvent methanol/water. The dark triangle refers to dry methanol but with TiO_2 evacuated at 400°C.

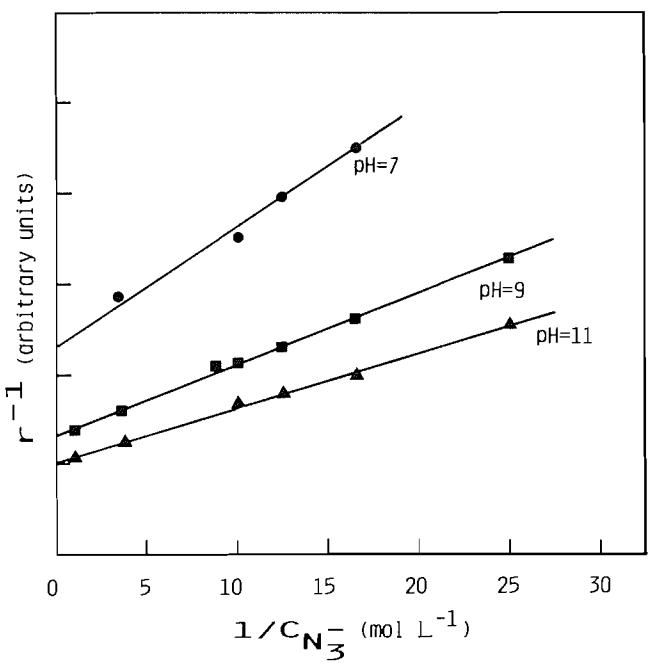

FIG. 6. Electron spin resonance signal intensity of the (N_3PBN) adduct as a function of pH.

Discussion

Surface interaction of N_3^- with TiO_2

The results reported in this work indicate that an aqueous alkaline medium is necessary to increase the amount of azidyl radicals formed upon N_3^- oxidation. It is also evident that the surface OH groups of TiO_2 play a fundamental part in the oxidation process.

As far as the pH dependence is concerned (Fig. 6), note that by virtue of the dissociation equilibrium

[5] $TiOH + OH^- \rightarrow TiO^- + H_2O$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.222.148.141 on 09/07/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.222.148.141 on 09/07/12
For personal use only.

The surface becomes negative as the pH increases. This would lead to the repulsion of N_3^- to the outer Helmholtz layer and one would thus expect a decrease in the formation of $N_3^{\cdot}$ as the pH increases. Indeed, this occurs in the oxidation of, e.g., I^- on TiO_2 (21) but contrasts with the data reported herein for N_3^-. A possible explanation for the data obtained with our system is that the azidyl ion may not compete significantly with OH^- for adsorption; the coverage by N_3^- would then be consistently low but the negatively charged surface would represent a less critical factor on the $N_3^{\cdot}$ formation as the pH increases.

Figure 4 shows that straight lines with different slopes and intercepts are obtained from the plot of $1/r$ vs. $1/C_{N_3^-}$ at different solution pH values. This means that the concentration of hydroxyl ions has an important role in the mechanism, in accordance with the reported pH dependence (Fig. 6).

The type of behavior illustrated in Fig. 4 is indicative of a Langmuir–Hinshelwood mechanism where OH^- and N_3^- are adsorbed on different sites (22). Under these conditions, the reaction rate for N_3^- oxidation is given by

$$[6] \quad R = \frac{kK_{OH^-}K_{N_3^-}[OH^-][N_3^-]}{(1 + K_{OH^-}[OH^-])(1 + K_{N_3^-}[N_3^-])}$$

and

$$[7] \quad 1/R = \frac{1}{kK_{OH^-}K_{N_3^-}}\left(K_{OH^-} + \frac{1}{[OH^-]}\right)\left(K_{N_3^-} + \frac{1}{[N_3^-]}\right)$$

The data in Fig. 4 allow us to calculate the equilibrium constant of adsorption $K_{N_3^-}$ at a constant pH from the ratio of the intercept to the slope. The calculation provides a value of $K_{N_3^-} = 16.5\ dm^3\ mol^{-1}$.

The surface coverage by N_3^- is given by

$$[8] \quad \theta_{N_3^-} = \frac{K_{N_3^-}[N_3^-]}{1 + K_{N_3^-}[N_3^-]}$$

From this one obtains a coverage $\theta_{N_3^-} = 14\%$ of the maximum coverage for $(N_3^-) = 0.01\ M$. The coverage by N_3^- is indeed low, as anticipated above, and should be compared with the coverage $\theta = 76\%$ for the adsorption of I^- (21) and $\theta = 98\%$ by oxalic acid (23) on TiO_2, for the same concentration of species in solution.

Mechanism of oxidation of azide

The relevant reactions at the TiO_2 interface in our system are as follows

$$[9] \quad TiO_2 \xrightarrow{h\nu} TiO_2(h^+/e_{cB}^-)$$

$$[10] \quad O_2 + e_{cB}^- \longrightarrow (O_2)^-$$

$$[11] \quad N_3^- + h^+ \longrightarrow N_3^{\cdot}$$

$$[12] \quad TiOH^- + h^+ \longrightarrow TiOH^0$$

$$[13] \quad TiOH^0 + N_3^- \longrightarrow TiOH^- + N_3^{\cdot}$$

Reaction [11] is the direct (isoenergetic) capture of photoproduced holes by N_3^-, while reaction [13] represents a mediated (inelastic) oxidation by surface states. The latter type of reaction appears in a number of cases to be operative with TiO_2, including the oxidation of halides (21, 24), the oxidation of methyl orange (25) and a number of organic compounds (26).

The data recorded in Fig. 5, showing that the removal of the surface OH groups leads to a dramatic decrease in trapped N_3^-, seem to indicate that the oxidation of N_3^- proceeds significantly via a reaction of type [13], although a contribution by the direct oxidation (reaction [11]) cannot be ruled out.

On the basis of the data reported herein we propose the following mechanism for the oxidation of N_3^- on TiO_2

$$[14] \quad TiOH^0 + (N_3^-)_{ads} \longrightarrow Ti{-}\square + (N_3OH)^{\cdot-}$$

$$[15] \quad Ti{-}\square + OH^- \longrightarrow Ti{-}OH^-$$

$$[16] \quad (N_3OH)^- \longrightarrow (N_3^{\cdot})_{aq} + (OH^-)_{aq}$$

The reaction sequence [14]–[16] is essentially a modification of reaction [13]. The formation of $(N_3OH)^-$ from $OH^{\cdot}$ and N_3^- and its dissociation (reaction [16]) is also proposed by Singh *et al.* (18) on the basis of pulse radiolysis measurements.

It has been reported that the OH^0 surface radicals are more loosely bound than OH^- (27). Their surface mobility makes the encounter with $(N_3^-)_{ads}$ (reaction [14]) easier despite a low coverage by N_3^-.

(N_3PBN) adduct reactivity

The decrease in the intensity of the signal due to (N_3PBN) after light is switched off (Fig. 2) allows some considerations to be made on the kinetics and mechanism by which this species decomposes thermally.

The decay of the (N_3PBN) adduct fits first order kinetics with $k = (8.13 \pm 0.9) \times 10^{-3}\ s^{-1}$ and $t_{1/2} = 83 \pm 8$ s. This latter figure is at variance with the $t_{1/2}$ reported by Rehorek *et al.* (13) of 20 s.

Reaction [18] represents a likely pathway for the (N_3PBN) adduct decay:

$$[18] \quad Ph{-}\underset{\displaystyle N_3}{\overset{\displaystyle H}{\overset{|}{C}}}{-}\overset{\displaystyle O^{\cdot}}{\overset{|}{N}}{-}C(CH_3)_3 \longrightarrow Ph{-}\underset{\displaystyle N_3}{\overset{\displaystyle H}{\overset{|}{C^{\cdot}}}} + (CH_3)_3{-}C{-}N{=}O$$

2

It is known that spin adducts with PBN tend to fragment thermally according to reactions of the type shown above (28). It is also known that methylnitrosopropane (**2**) (MNP) is photolyzed by visible light into nitric oxide and *t*-butyl radicals (16). These can be scavenged, in turn, by another MNP molecule

$$[19] \quad Bu^t{-}NO \xrightarrow{h\nu} NO + Bu^{t}\cdot \xrightarrow{MNP} Bu^t_2NO$$

In fact, we observed the growth of the signal due to Bu^tNO under prolonged illumination (Fig. 1). This behavior is the same as that observed with iron porphyrin in homogeneous solution, and we conclude that reaction [18] is not appreciably affected by the heterogeneous phase.

The possibility that reaction [18] is assisted by light cannot be ruled out *a priori* since the adduct (**1**) could be sensitive to visible light despite the fact that PBN is not. However, we did not observe any transient absorption above 360 nm, which seems to exclude the possibility that **1** absorbs an appreciable amount of visible light.

Reactions between Co(II) and bis(diphenylphosphino)methane (dppm) in the presence of $NaBH_4$ or $NaBH_3CN$ are described. The main products are the Co(I) complex, $CoCl(dppm)_3$, and Co(III) complexes of the type $[CoHX(dppm)_2]Y$ (where X = Cl, Y = Cl or BPh_4; X = Y = Br; X = Y = I; X = BH_3CN, Y = BH_3CN, ClO_4, or BPh_4). The former has been shown by X-ray crystallography to contain a Co atom tetrahedrally coordinated by a Cl and three P atoms from three monodentate dppm ligands. Possible mechanisms for the formation of Co(III) are discussed.

DAVID J. ELLIOT, DAVID G. HOLAH, ALAN N. HUGHES, STANISLAW MACIASZEK, VINCENT R. MAGNUSON et KENNETH O. PARKER. Can. J. Chem. **66**, 81 (1988).

On décrit les réactions entre le Co(II) et le bis(diphénylphosphino)méthane (dppm), en présence de $NaBH_4$ ou de $NaBH_3CN$. Les produits principaux sont le complexe du Co(I), $CoCl(dppm)_3$ et des complexes du Co(III) du type $[CoHX(dppm)_2]Y$ (dans lesquels X = Cl, Y = Cl ou BPh_4; X = Y = Br; X = Y = I; X = BH_3CN, Y = BH_3CN, ClO_4 ou BPh_4). Utilisant la diffraction des rayons-X, on a pu démontrer que le premier complexe comporte un atome de Co qui est tétracoordonné par un Cl et par trois atomes de P provenant de trois ligands dppm monodentates. On discute des mécanismes qui peuvent expliquer la formation du Co(III).

[Traduit par la revue]

Introduction

For a number of years we have been interested in reactions between metal ions and $NaBH_4$ (and some of its derivatives) in the presence of a variety of phosphines (1, 2). During the course of our studies (2) on Co(II)–$Ph_2P(CH_2)_nPPh_2$–$NaBH_4$ systems, it became clear that there is a fundamental difference between the type of product formed when n = 2–6 than when n = 1 (dppm). Isolated from the former reactions (2) were Co(I) hydrides and, with phosphines for which n = 4, 5, $[Co(BH_4)(phosphine)]_2$, containing a most unusual mode of attachment of the BH_4 group. A previous communication (3) on the latter (dppm) reactions reported the formation of not only Co(I) but also, unexpectedly, Co(III) compounds of which no trace was found in the n = 2–6 cases. An explanation of this may well rest with the more versatile coordination abilities of dppm (4) compared to the n = 2–6 phosphines. This paper reports more details of the Co(II)–dppm–$NaBH_4$ (or $NaBH_3CN$) reactions.

Results and discussion

Reactions between Co(II), dppm, and $NaBH_4$ are very complex, sensitive to reaction conditions, and difficult to control (as is the case with other phosphines). While the syntheses described in the Experimental section have been performed many times, the expected product is not always formed, even when the conditions have apparently been duplicated as closely as possible. Reactions involving $NaBH_3CN$ are slower and, generally, easier to handle. The routes to the various complexes to be described are summarized in Scheme 1.

A dark green precipitate **1**, was obtained as the first identifiable product from benzene–ethanol mixtures of $CoCl_2.6H_2O$, dppm, and $NaBH_4$. In order to stabilize this product and to prevent it from undergoing further reaction, it is important that, after its filtration, all traces of unreacted $NaBH_4$ be removed from the solid. The product has little solubility in all but the most polar of solvents and has only been recrystallized successfully from dmf–ether mixtures. In a previous communication (3), we tentatively identified **1** as $Co_2X_3(dppm)_2.xS$ (S = dmf, X = Cl) on the basis of total chemical analysis. The amount of solvent appears to increase from $x \sim 1$ after one recrystallization to $x \sim 2.5$ after two recrystallizations, with the Co:Cl:P ratio remaining constant. Blue crystals invariably formed along with the product during these recrystallizations but these were easily removed by washing the mixture with ethanol. Although the crystals of **1** (X = Cl) appeared to be well formed, all those examined by X-ray diffraction methods proved to be twinned and, therefore, unsuitable for data collection. For this reason the related compound **1**, X = Br, was made by an analogous reaction. However, recrystallizations of the initially formed product from dmf–ether produced only blue crystals of $CoBr_2.3dmf$ (presumably, $[Co(dmf)_6][CoBr_4]$ (5)) together with mixtures of **2** and **3**. Successful recrystallization was achieved from acetophenone–ether but again, no crystals suitable for X-ray work could be obtained. Without X-ray work it is clearly not possible to be definitive about the structure of **1**. Given, however, the apparent empirical formula, the propensity of dppm to bridge and the fact that all three chlorides of **1** appear to be coordinated (no ready reaction with $NaBPh_4$), it is tempting to suggest an A-frame type arrangement. On the other hand, the magnetic moment in the solid state measured as 6.1 BM (X = Cl, $x \sim 1.0$), i.e., a total of five unpaired electrons, would be surprising in such a structure. Another uncertainty is the role of the potentially strongly coordinating solvent dmf in the structure of **1**. The characteristic reflectance spectra of **1** (X = Cl, Br) are shown in Fig. 1, the peaks occurring at (for X = Cl) 7 800, 14 100, 16 900 (sh), and

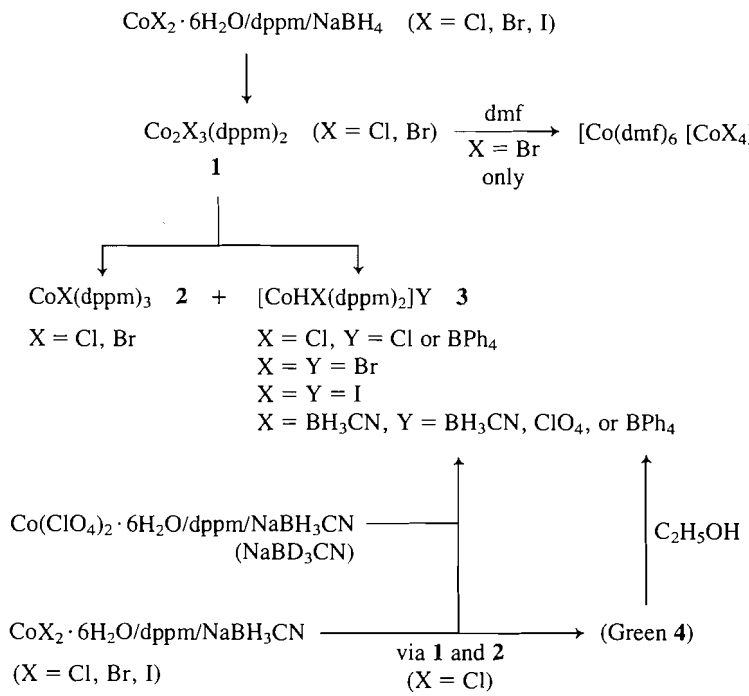

SCHEME 1

21 100 cm^{-1}. In dmf solution, the relative intensities change significantly; the lowest energy peak now occurs at 7 100 cm^{-1} ($\epsilon \sim 90$) while the 14 100 cm^{-1} signal shifts to 14 900 ($\epsilon \sim 560$). The solution spectrum is consistent with those of either tetrahedral d^8 or d^7 complexes (6). A related, neutral, mixed oxidation state Co(II)–Co(I) complex has recently been characterized (7), although in this case the molecule is low spin (one unpaired electron) and the Co atoms are square planar.[1]

Compound **2** (X = Cl, Br) forms a beautiful deep green cube-shaped crystals and, therefore, it is very easily recognizable in the various reaction product mixtures. It has been synthesized in two ways. Firstly, during attempts to obtain single crystals of **1** (X = Cl) from dmf–ethanol mixtures, large cubic crystals were obtained. Remarkably, this is a very convenient route to **2** in good yields. Secondly, **2** has been obtained as crystals from the filtrates of reactions between Co(II) chloride, dppm, and both $NaBH_4$ and $NaBH_3CN$. In these, **1** is recognizable as the first (insoluble) product which, if not removed by filtration, slowly dissolves as the reaction proceeds and **2** can be obtained from the resulting yellow–green solutions. It is easily separated from **1** because of its ready solubility in benzene, toluene, or dichloromethane.

The magnetic moment of 3.1 BM in the solid state is consistent with high spin Co(I). The reflectance spectrum shows (Fig. 1) peaks at 5 800, ~9 000 (sh), 10 400, 14 200, and 17 500 (weak sh) cm^{-1}, which very closely resemble those in the spectrum (8) of the high spin, tetrahedral $CoCl(PPh_3)_3$. Considering the stoichiometry of **2**, the implication is that the three dppm ligands are bound to the Co(I) atom in a monodentate fashion.

This has been confirmed by X-ray crystallography, which shows the Co(I) atom on a three-fold axis of symmetry in a tetrahedral environment of one Cl atom and three P atoms from three crystallographically equivalent monodentate dppm ligands. Although the structure is incomplete, the results indicate that the Cl—Co—P bond angle is 112°, the distances of the Co, non coordinated P and methylene C atoms from the plane formed by the three bonded P atoms are +0.86, +0.79, and +1.71 Å, respectively, and the Co—Cl and Co—P distances are 2.14 and 2.28 Å, respectively. Attempts to resolve the apparently disordered phenyl ring on the coordinated P atom continue. However, the fact remains that, with $Z = 2$, in either space group $R32$ or $R\bar{3}$, the Co must be tetrahedral from which it follows that each ligand is monodentate.

Complexes which contain one (4) and two (refs. 4, 9*a*, 9*b*, and, more recently, $Ni(CO)_2(dppm)_2$ (9*c*)) monodentate dppm ligands are well known but this appears to be the first example of three such ligands on one metal ion. There is considerable interest in using complexes containing monodentate dppm as precursors to bimetallic systems (9*b*, 10) and we are currently examining the potential of **2** in this respect.

Another interesting feature of this work is the fact that the filtrates of CoX_2/dppm/$NaBH_4$ reactions which produce **2** also produce Co(III) compounds of the type $[CoHX(dppm)_2]^+Y^-$, i.e. **3**. Similar compounds are also produced from analogous reactions in which $NaBH_3CN$ is used instead of $NaBH_4$ and, as mentioned earlier, we have also positively identified **1** and **2** (X = Cl) from the $NaBH_3CN$ reactions. Thus, Co(III) compounds are being produced in significant amounts in reducing environments (more strongly so in the case of $NaBH_4$ than $NaBH_3CN$).

The well characterized Co(III) complexes, **3**, are all bright yellow crystalline solids. They all show a terminal ν_{Co-H} in their ir spectra at ~1 970 cm^{-1} which shifts to ~1 700 cm^{-1} on deuteration. The hydride signal appears in the ^1H nmr spectra as a quintet at $\delta -17$ ppm with $J_{PH} \sim 50$ Hz. In addition, the two P—CH_2—P protons appear as separate signals 0.5–0.8 ppm

[1]A referee has suggested that it may be more attractive to describe the structure of **1** in terms of a "cradle" structure as found in $Ni_2(CO)_3(dppm)_2$ and $Ni_2(CH_3NC)_3(dppm)_2$ (17). While this is possible, the magnetic properties of **1** require that there are no spin interactions between the Co atoms, and this would be unexpected in such an arrangement.

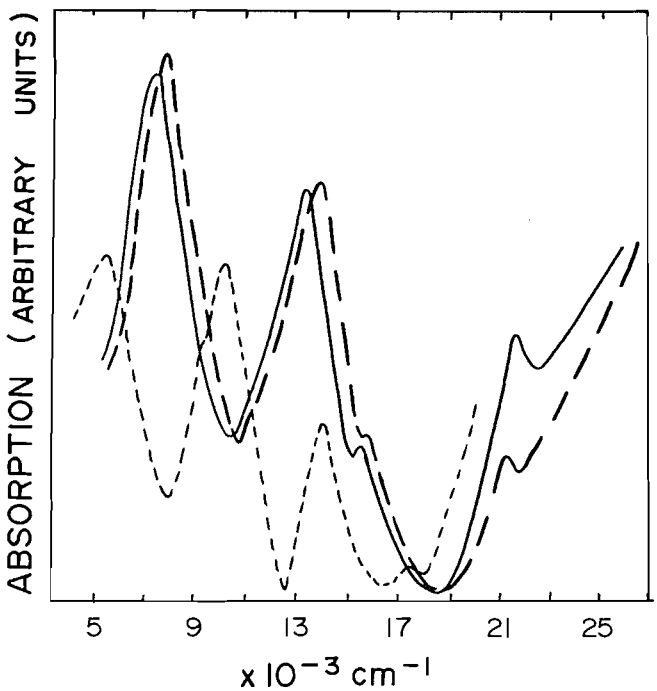

FIG. 1. Reflectance spectra: —, compound **1** (X = Cl); – – –, compound **1** (X = Br); ---, compound **2** (X = Cl).

apart in the δ 4.0–5.2 range depending upon the nature of X and Y and the solvent used for the nmr measurements. These signals are very well resolved in certain instances (e.g. with X = Cl or BH_3CN, Y = BPh_4 and with X = Y = I) and are typical (11) of the AA′A″A‴ MX pattern in which A, A′, A″, and A‴ are the P atoms of two chelating dppm ligands, while M and X are the magnetically non-equivalent protons of the P—CH_2—P unit. Such a pattern would be expected from a diamagnetic octahedral $[CoHX(dppm)_2]^+$ ion in which H and X are *trans*. Thus, each proton appears as a doublet of quintets and J_{HH} is essentially constant at ~15 Hz for all examples of **3**. The line separations (the apparent J_{PH}, i.e., the average of $^2J_{PH}$ and $^4J_{PH}$) are also remarkably constant for these signals with values of, for example, 5.2 Hz and 3.5 Hz for the lower and higher field CH_2 proton signals, respectively, in the spectrum of **3** (X = Cl, Y = BPh_4). In all cases, the line separation is larger in the lower field proton signal of the CH_2 group.

In the ^{31}P nmr spectra, the P singlet occurs close to δ = 0, consistent with chelating dppm (12). Electronic spectra of **3** show a strong, broad peak at 22 – 25 000 cm^{-1} (ε ~ 1 000 cm^{-1} M^{-1} L) similar to those of related Co(III) species (13). Thus, the Co(III) compounds appear to be analogous to $[RhHCl(dppm)_2](BPh_4)$ which has been shown by X-ray crystallography (14) to contain a Rh(III) atom surrounded by a slightly distorted octahedron. The hydrido and chloro ligands occupy *trans* positions with the phosphines in the equatorial positions. The space group and unit cell dimensions of **3** (X = Cl, Y = BPh_4) and the above Rh(III) complex are so close (see Experimental section) that the two complexes may be presumed to be isostructural.

Before discussing possible mechanisms for the formation of Co(III) in these reactions, it should be recalled that in our work (2) on Co(II)–$Ph_2P(CH_2)_nPPh_2$–$NaBH_4$ or $NaBH_3CN$, production of Co(III) has been observed only when n = 1. In all other cases, n = 2–6, either Co(II) or reduced cobalt compounds were the only ones isolated, with no evidence for Co(III) formation being observed at any time. Three possible mechanisms for Co(III) formation can be considered, namely, disproportionation, hydride abstraction, and oxidative addition. For example, the recent extensive study by Socol and Verkade (15) on the properties of phosphines which affect the disproportionation reaction

$$Co(II) + phosphine \rightarrow Co(I) + Co(III)$$

concluded that factors such as shape, bulk, and basicity all play a role. Unfortunately, bidentate phosphines of the type used in the work described here were not included. Secondly, it is possible that Co(III) is formed in a way similar to that proposed (14) for the formation of $[RhHCl(dppm)_2]^+$ from $[RhCl(CO)_2]_2$, namely by abstraction of hydride from the ethanol–water solvent. In related work (16) it has been observed that reactions between $Co(BF_4)_2.6H_2O$ and $HP(C_2H_5)Ph$ in 2-propanol lead immediately to $Co[HP(C_2H_5)Ph]_5^{2+}$, but when these are stirred for 4 days, they produce the Co(III) species $CoH[HP(C_2H_5)Ph]_5^{2+}$. Whether this too occurs by hydride abstraction from the alcohol or by disproportionation is not clear but it is difficult to see why either of these two mechanistic possibilities would be unique to dppm with the bidentate phosphines. Thirdly, we speculated (3) that, since **1** appears to be unique to the dppm reactions, Co(III) may be formed by oxidative addition of H_2 from $NaBH_4$ to the two Co centers of **1**. Accordingly, several attempts to react **1** with H_2 were made but all failed to yield any Co(III).

Some light has been thrown upon the reaction by experiments aimed at growing single crystals of **1**. In these, we obtained good yields of Co(III) by allowing ethanol to diffuse into concentrated solutions of **1**, in dmf in a freezer over 24 h. In this connection, it should also be remembered that, while **1** can be recrystallized unchanged from dmf–ether, when it is recrystallized from dmf–ethanol, crystals of **2** are also obtained. These points are consistent with our original observations that in reactions where **1** is not isolated, it slowly dissolves and reacts to produce mixtures of **2** and **3**. A further complication is that compounds of type **3** are readily produced from $Co(ClO_4)_2.6H_2O$–dppm–$NaBH_3CN$ reactions (Scheme 1) in which ethanol is present but in which **1** cannot occur as an intermediate (although a different dppm bridged binuclear Co intermediate may occur). It is therefore possible that it is indeed reactions between alcohol and the partially reduced cobalt species **1** which produce the Co(III) hydrides, as in the case with rhodium (14). It is unfortunate that solutions containing **1** and **2** are so strongly paramagnetic that nmr studies are impossible.

We have been unsuccessful in characterizing bright emerald green, highly crystalline compounds **4** (Scheme 1) obtained from CoX_2–dppm–$NaBH_3CN$ reactions (X = Cl, Br). In spite of repeated attempts and several recrystallizations, consistent chemical analyses were not obtained. The compounds contain halide (X-ray fluorescence) and coordinated BH_3CN and H (ir), exhibit a strong broad peak at ~25 500 cm^{-1}, (with additional peaks at ~7 000 and ~15 500 cm^{-1}), dissolve in dmf to give bright green unstable solutions which show a quintet δ −15 (J_{PH} ~ 47 Hz) and a singlet in the ^1H and ^{31}P nmr spectra, respectively, and turn yellow instantly in ethanol to produce **3**. It appears that each attempted recrystallization of **4** results in further decomposition.

Experimental

Materials

Dppm was obtained from Strem Chemicals Inc. and was used without further purification. The reducing agents $NaBH_4$, $NaBH_3CN$

(and their deuterated analogues), and $NaBPh_4$ were obtained from the Aldrich Chemical company and stored over $CaCl_2$ in a desiccator to protect them from hydrolysis. Even so, it was found that samples from freshly opened bottles can behave differently from samples which have been stored for periods of time, even under apparently dry conditions.

Analyses and measurements

The air-sensitive samples were protected from atmospheric oxidation or hydrolysis during weighing or data collection. Microanalytical data for C, H, and N, ir spectra and both ^{31}P and ^1H nmr spectra were measured as described previously (1). (For $^{31}P-\{^1H\}$ spectra, recorded at 32.3 MHz, chemical shifts of signals downfield of external 85% H_3PO_4 are positive.) Analyses for Co, Cl, and P were performed by Galbraith Laboratories Inc., Knoxville, TN. Magnetic momements were measured using the Gouy method, the tube being calibrated with $HgCo(SCN)_4$ and $Nien_3(S_2O_3)$.

Syntheses and X-ray crystallography

All synthetic work was carried out under pure nitrogen.

Crystals of $CoCl(dppm)_3$, **2**, and $[CoHCl(dppm)_2](BPh_4)$ were selected for X-ray data analysis on the basis of a polarizing microscope examination and precession photographs (the former compound was sealed under nitrogen in a quartz capillary). Data collection on **2**, using MoK_α radiation was on a CAD-4 Enraf-Nonius diffractometer using the θ–2θ scan. The compound was found to crystallize in the rhombohedral crystal class using the Enraf-Nonius CAD-4 SDP peak search centering and indexing programs. A tabulation of the crystal and intensity data is presented in Table 1. The Co, Cl, and the coordinated P atom were located using conventional heavy atom techniques. Successive full-matrix least-squares refinement and difference Fourier maps were used to find the non-coordinated P atom, the methylene C atom, and 18 of the C atoms in the phenyl rings. We have so far been unsuccessful in locating the C atoms of a phenyl ring on the P atom coordinated to Co. Attempts to refine the structure in the non-centrosymmetric space group $R32$ have also proven unsuccessful. In either case, the Co and Cl atoms are restricted to being on the three-fold axis of rotation. Accordingly, the Co(I) atom is tetrahedrally coordinated to one Cl and the three P atoms.

The hydrido complex was found to crystallize in the monoclinic space group $P2_{1/c}$. Unit cell dimensions are a = 19.464, b = 15.168, c = 22.165 Å, β = 107.08° with 4 formula units per unit cell. (Corresponding data (14) for $[RhHCl(dppm)_2](BPh_4)$, $P2_{1/c}$, a = 19.477, b = 15.266, c = 22.282 Å, β = 106.85, Z = 4.)

*$Co_2X_3(dppm)_2 \cdot xS$, **1***

(*a*) X = Cl. To a mixture of $CoCl_2.6H_2O$ (0.51 g, 2.1 mmol) dissolved in ethanol (20 mL) and dppm (1.81 g, 4.7 mmol) in benzene (10 mL) was added, over a ~7 min period, a suspension of $NaBH_4$ (0.025 g, 0.66 mmol) in ethanol (10 mL). The mixture was stirred for 1 h, when the green solid which formed was filtered off, washed with ethanol (20 mL), benzene (20 mL), ethanol (20 mL), water (10 mL), ethanol (20 mL), and finally ether (30 mL), and dried under reduced pressure. The extensive washings are necessary to remove any free phosphine and, particularly, residual $NaBH_4$ which may react during recrystallization. The product was recrystallized, at 0°C over ~48 h, from dmf–ether. Blue crystals, which may contaminate the product at this point, were removed by washing with ethanol until the washings were colorless. The remaining green crystals were washed with ether and dried under reduced pressure. Yield 30%.

The following results were obtained after one recrystallization. *Anal.* calcd. for $Co_2Cl_3(dppm)_2.dmf$: C 59.71, H 4.82, N 1.31, Co 11.06, P 11.62, Cl 9.98; found: C 59.49, H 4.78, N 1.68, Co 10.27, P 10.69, Cl 9.93. Infrared $\nu_{CO(dmf)}$ 1670(s) cm^{-1}. The following results were obtained after a second recrystallization. *Anal.* calcd. for $Co_2Cl_3(dppm)_2.2.5dmf$: C 58.74, H 5.27, N 2.98, Co 10.02, P 10.54, Cl 9.05; found: C 58.03, H 5.20, N 3.12, Co 9.90, P 10.38, Cl 9.06. Infrared $\nu_{CO(dmf)}$ 1670(vs) cm^{-1}.

The compound has slight solubility in CH_2Cl_2 but recrystallization from this results in a finely powdered form of the sample along with some decomposition. Recrystallization from dmf–ethanol is discussed below. The compound is insoluble in benzene, toluene, and ethanol.

(*b*) X = Br. A crude green product was filtered off from reactions which were carried out in analogous ways to those in (*a*) above. This product was washed with small amounts of benzene, ethanol, acetophenone, and finally ether, and recrystallized from acetophenone–ether (1:1) at 0°C overnight as green crystals. Yield 10%. *Anal.* calcd. for $Co_2Br_3(dppm)_2.0.5C_6H_5COCH_3$: C 54.67, H 4.08; found: C 54.33, H 4.09. Infrared ν_{CO} 1670 cm^{-1}. Attempts to recrystallize the compound from dmf–ether produced blue crystals. *Anal.* calcd. for $CoBr_2.3dmf$: C 24.68, H 4.83, N 9.60; found: C 25.25, H 4.91, N 9.76.

*Chlorotris[bis(diphenylphosphino)methane]cobalt(I), $CoCl(dppm)_3$, **2***

$CoCl_2.6H_2O$ (0.36 g, 1.5 mmol) was dissolved in ethanol (20 mL) and mixed with dppm (1.77 g, 4.6 mmol) in toluene (10 mL). To this stirred mixture was added slowly (10 min) a suspension of $NaBH_4$ (0.044 g, 1.2 mmol) in ethanol (10 mL). The stirring was continued for a further 10 min. Any green solid remaining at this point was removed by filtration. The dark green filtrate produced large green crystals after 3 days at 0°C. These were filtered off, washed with ethanol (20 mL) and hexane (20 mL), and dried under vacuum. Yield 30%. *Anal.* calcd. for $CoCl(dppm)_3$: C 72.20, H 5.33, Cl 2.84, Co 4.72; found: C 72.15, H 5.60, Cl 2.99, Co 4.25.

Alternatively, $Co_2Cl_3(dppm)_2$ was recrystallized from dmf–ethanol (1:2) overnight at 0°C to produce well-formed crystals of the product. *Anal.* calcd. for $CoCl(dppm)_3.dmf$: C 70.94, H 5.57, N 1.06; found: C 70.84, H 5.62, N 1.07. Infrared $\nu_{CO(dmf)}$ 1670 cm^{-1}.

This compound forms striking, perfectly formed crystals in the shape of cubes, and as such, is easily recognizable. It is readily soluble in benzene, toluene, CH_2Cl_2, and dmf to give green solutions. It is insoluble in ethanol.

*Hydridohalogenobis[(bis(diphenylphosphino)methane]cobalt(III) chloride, bromide, iodide, or tetraphenylborate $[CoHX(dppm)_2]^+Y^-$, **3***

(*a*) X = Cl, Y = Cl. $CoCl_2.6H_2O$ (0.52 g, 2.2 mmol) in ethanol (20 mL) and dppm (1.9 g, 4.9 mmol) in toluene (10 mL) were mixed and to the stirred solution was added $NaBH_4$ (0.037 g, 1.0 mmol) in ethanol (10 mL) over a period of ~2 h. A green solid was filtered off, washed with ethanol (20 mL) until the washings were colorless and the washings were added to the yellow–green filtrate. Hexane (15 mL) was added and the solution produced yellow crystals after ~12 h at 0°C. These were filtered off, washed with toluene and hexane, and dried under reduced pressure. Yield 25%. *Anal.* calcd. for $[CoHCl(dppm)_2]Cl.2C_2H_5OH$: Co 5.94, Cl 7.15, P 12.49, C 65.40, H 5.79; found: Co 6.00, Cl 7.11, P 12.10, C 64.29, H 5.95. Infrared ν_{Co-H} 1968, ν_{OH} (from C_2H_5OH) 1680, 3340 cm^{-1}; ^{31}P nmr ($CHCl_3$)

δ −1.8(s); ^{1}H nmr ($CDCl_3$) hydridic hydrogen at δ −17.5 (quintet), $^2J_{PCoH}$ 51 Hz; C_2H_5OH at δ 1.25(t), 3.75(q); integration C_2H_5OH: dppm = 1:1; —CH_2— at δ 4.38 and 4.98 (with each signal as a poorly resolved doublet of quintets), $^2J_{HH}$ ~ 14 Hz.

(*b*) X = Cl, Y = BPh_4. Compound (*a*) above reacts smoothly with $NaBPh_4$ in ethanol to produce the orange-colored $[CoHCl(dppm)_2](BPh_4)$ which was recrystallized from dmf–ethanol. Yield 80%. *Anal.* calcd. for $[CoHCl(dppm)_2](BPh_4)$: C 75.10, H 5.54; found: C 74.86, H 5.61. Infrared ν_{Co-H} 1968 cm^{-1}; ^{31}P nmr (dmf) δ −1.5(s); ^{1}H nmr (CD_2Cl_2) hydridic hydrogen at δ −16.95 (quintet), J_{PH} 52 Hz; —CH_2— at δ 4.18 (doublet of quintets, line separation i.e. the average of $^2J_{PH}$ and $^4J_{PH}$ 3.5 Hz) and 4.95 (doublet of quintets, line separation 5.3 Hz), $^2J_{HH}$ 14.8 Hz. Electronic spectrum (acetone) λ_{max} 22 700 cm^{-1}, ϵ ~ 1250.

(*c*) X = Br, Y = Br. This yellow compound was prepared from $CoBr_2.6H_2O$ in a way analogous to (*a*) above. Yield 40%. *Anal.* calcd. for $[CoHBr(dppm)_2]Br.2C_2H_5OH$: C 60.02, H 5.32; found: C 59.65, H 5.39. Infrared ν_{Co-H} 1965, ν_{OH} (from C_2H_5OH) at 1675 and 3330 cm^{-1}; ^{31}P nmr (CH_2Cl_2) δ −2.6(s); ^{1}H nmr (CD_2Cl_2) hydridic hydrogen at δ −14.7 (quintet) $^2J_{PCoH}$ 51 Hz; —CH_2— at δ 4.41 (doublet of quintets, line separation 3.5 Hz) and 5.05 (doublet of quintets, line separation 5.3 Hz), $^2J_{HH}$ 14.9 Hz.

(*d*) X = I, Y = I. This yellow compound was prepared from $CoI_2.6H_2O$ as in (*a*) above. Reactions were run for 1.4 and 12 h and, in each case, the yellow Co(III) was rapidly produced. No green intermediates were obtained. Yield 45%. *Anal.* calcd. for $[CoHI(dppm)_2]I.2C_2H_5OH$: C 55.21, H 4.89; found: C 55.28, H 4.72. Infrared ν_{Co-H} 1962, ν_{OH} (from C_2H_5OH) at 1670 and 3350 cm^{-1}; ^{31}P nmr (CH_2Cl_2) δ −2.8(s); ^{1}H nmr (CD_2Cl_2) hydridic hydrogen at δ −10.9 (quintet), $^2J_{PCoH}$ 51 Hz; —CH_2— at δ 4.58 (doublet of quintets, line separation ~3 Hz) and 5.14 (doublet of quintets, line separation 5.1 Hz) $^2J_{HH}$ 14.9 Hz.

*Hydrido(cyanotrihydroborato)bis[bis(diphenylphosphino)methane]-cobalt(III) perchlorate, tetraphenylborate, or cyanotrihydroborate [CoH(BH$_3$CN)(dppm)$_2$]Y (**3**), Y = ClO$_4$, BPh$_4$, or BH$_3$CN*

(*a*) Y = ClO_4. To the stirred pink solution obtained by mixing $Co(ClO_4)_2.6H_2O$ (0.45 g, 1.25 mmol) and dppm (1.44 g, 3.75 mmol) in toluene–ethanol (2.5:1, 15 mL) a solution of $NaBH_3CN$ (0.08 g, 1.25 mmol) in ethanol (10 mL) was added dropwise over a period of 10 min. The colour turned to dark green with the formation of some precipitate. The mixture was stirred for 24 h during which time a yellow solid was slowly precipitated from a brown solution. The solid was filtered off, washed with benzene (20 mL), ethanol (10 mL), and hexane (5 mL), dried, and finally, recrystallized from hot methanol as bright yellow crystals. Yield 45%. *Anal.* calcd. for $[CoH(BH_3CN)(dppm)_2]ClO_4$: C 63.28, H 5.00, N 1.45; found: C 63.96, H 5.26, N 1.49. Infrared ν_{BH} 2340(s), ν_{CN} 2200, ν_{Co-H} 1987, ν_{ClO_4} 1100(b) cm^{-1}; ^{31}P nmr (dmf) δ 1.8(s); ^{1}H nmr (dmf d_7) hydridic hydrogen at δ −15.5 (quintet), $^2J_{PCoH}$ 48 Hz; —CH_2— at δ 4.65 and 5.20 (with each signal as a poorly resolved doublet of quintets) $^2J_{HH}$ ~ 15 Hz.

This complex decomposes in CH_2Cl_2, $CHCl_3$, tetrahydrofuran, CH_3CN, and dimethylsulfoxide. It can be recrystallized from dmf–C_2H_5OH, although some dmf is retained in the lattice.

The analogous reaction was carried out with $NaBD_3CN$, and the resulting deuterated product was purified as described above. *Anal.* calcd. for $[CoD(BD_3CN)(dppm)_2]ClO_4$: C 63.02, H 5.39, N 1.44; found: C 64.36, H 5.24, N 1.36. Infrared ν_{CN} 2200, ν_{BD} 1752(m), 1678(w), 1638(w), ν_{CoD} was not observed.

(*b*) Y = BPh_4. The yellow hydride from (*a*) was dissolved in hot methanol and a solution containing a slight molar excess of $NaBPh_4$ in methanol added. The yellow crystals which slowly formed were filtered off and recrystallized from CH_2Cl_2/hexane. Yield 75%. *Anal.* calcd. for $[CoH(BH_3CN)(dppm)_2]BPh_4$: C 74.84, H 5.77, N 1.18; found: C 76.40, H 5.92, N 1.10. Infrared ν_{BH} 2380(s.b.), 2230(sh), ν_{CN} 2200, ν_{Co-H} 1987 cm^{-1}. ^{1}H nmr (CD_2Cl_2) hydridic hydrogen at δ −15.0 (quintet), $^2J_{PCoH}$ 51 Hz; —CH_2— at δ 4.08 (doublet of quintets, line separation, i.e., the average of $^2J_{PH}$ and $^4J_{PH}$ 4.3 Hz) and 4.66 (doublet of quintets, line separation 4.8 Hz).

(*c*) Y = BH_3CN. A mixture of $CoCl_2.6H_2O$ (0.3 g, 1.25 mmol) and dppm (1.5 g, 3.8 mmol) was dissolved in benzene–ethanol (15 mL, 2.5:1) to give a dark blue–green solution to which $NaBH_3CN$ (0.3 g, 5 mmol) in ethanol (10 mL) was added dropwise, with stirring, over a period of 10 min. During the addition, the color changed to dark green and finally to dark brown–green. The precipitate which formed started to redissolve after ~20 min. The mixture was stirred for ~24 h after which a brown solid was filtered off. The solid turns instantly to bright yellow when brought into contact with methanol, in which it dissolves and from which a yellow solid crystallized. Yield 30%. *Anal.* calcd. for $[CoH(BH_3CN)(dppm)_2](BH_3CN).CH_3OH$: C 67.79, H 5.90, N 2.98; found: C 67.81, H 5.90, N 3.02. Infrared ν_{BH} 2310, ν_{CN} (coordinated) 2190, ν_{CN} (ionic) 2162, ν_{CoH} 1980, ν_{OH} (from CH_3OH) 3360 cm^{-1}. ^{31}P nmr (dmf) δ 1.76(s); ^{1}H nmr (CD_3OD) hydridic hydrogen at δ −15.3 (quintet), $^2J_{PCoH}$ 49 Hz; —CH_2— at δ 4.64 and 5.18 (with each signal a poorly resolved doublet of quintets), $^2J_{HH}$ ~ 15 Hz.

Similar reactions using $CoBr_2.6H_2O$ lead to the production of a dark brown crude product. Recrystallization from dichloromethane/hexane produced (from the brown solution), green plates of variable composition (C 55–61, H 4.7–5.2, N 1.8–2.5). Infrared ν_{BH} 2330, ν_{CN} 2190, ν_{CoH} 1990; ^{31}P nmr (dmf) δ 0.71; ^{1}H nmr ($CDCl_3$) δ −15.3 (quintet), J_{PH} ~ 47 Hz. Repeated recrystallizations from either CH_2Cl_2 or CH_3CN failed to produce a pure compound. There is no immediate reaction between a solution of the green crystals and $NaBPh_4$, but addition of ethanol results in an immediate color change to yellow and the crystallization from solution of **3**, X = BH_3CN, Y = BPh_4.

The electrochemical behavior of flavin adenine dinucleotide in neutral solutions

V. I. BIRSS,[1] H. ELZANOWSKA, AND R. A. TURNER
Department of Chemistry, University of Calgary, Calgary, Alta., Canda T2N 1N4

Received February 20, 1987[2]

V. I. BIRSS, H. ELZANOWSKA, and R. A. TURNER. Can. J. Chem. **66**, 86 (1988).

A detailed investigation of the electrochemical behavior of flavin adenine dinucleotide (FAD) in neutral solutions has been carried out at Hg and glassy carbon electrodes. At FAD concentrations of about 10^{-4} *M*, cyclic voltammetry (CV) shows a pair of anodic and cathodic peaks having a peak separation at low sweep rates indicative of a two-electron transfer process and yielding a formal redox potential for FAD of -0.206 ± 0.003 V vs. NHE at pH 7. Evidence for FAD adsorption was obtained in experiments at high sweep rates, from the effect of time of exposure of the electrode surface to FAD in solution and from the effect of the potential limits on the cyclic voltammetric response. The process of FAD adsorption was studied in detail in dilute FAD solutions (ca 10^{-6} *M*) using a hanging mercury drop electrode and the techniques of CV and ac voltammetry. Three distinct stages of FAD adsorption were observed and a model of the orientation of FAD on the electrode surface as a function of time and potential is presented. In addition, the kinetics of oxidation and reduction of adsorbed FAD was studied for each of the stages of FAD deposition, and a surface standard rate constant of ca. 40 s^{-1} was obtained for Stages II and III of FAD adsorption.

V. I. BIRSS, H. ELZANOWSKA et R. A. TURNER. Can. J. Chem. **66**, 86 (1988).

Opérant en solutions neutres et à des électrodes de Hg ainsi que de verre, on a réalisé une étude détaillée du comportement électrochimique du dinucléotide de la flavine et de l'adénine (DFA). A des concentrations de DFA d'environ 10^{-4}, la voltamétrie cyclique (VC) présente une paire de pics anodique et cathodique qui possèdent, à des vitesses de balayage lentes, une séparation entre les pics qui suggère qu'il s'agit d'un processus de transfert de deux électrons et qui, à un pH de 7, fournit pour le DFA un potentiel redox formel de $-0{,}206 \pm 0{,}003$ V vs. NHE. On a obtenu des indications relatives à l'adsorption du DFA au cours d'expériences à des vitesses élevées de balayage; ces indications découlent de l'effet du temps d'exposition de la surface de l'électrode au DFA en solution ainsi que de l'effet des limites de potentiel sur la réponse voltamétrique cyclique. On a étudié en détail le processus d'adsorption du DFA en solutions diluées (environ 10^{-6} *M*) en utilisant un électrode à goutte tombante de mercure ainsi que les techniques de VC et de voltamétrie à c.a. On a observé trois stages distincts d'adsorption du DFA et on présente un modèle de l'orientation du DFA sur la surface de l'électrode en fonction du temps et du potentiel. De plus, on a étudié la cinétique de l'oxydation et de la réduction du DFA adsorbé pour chacun des stages de la déposition du DFA; on a obtenu une constante de vitesse standard d'environ 40 s^{-1} pour les stages II et III de l'adsorption du DFA.

[Traduit par la revue]

Introduction

The redox-active flavoproteins play a particularly important biological role in the electron transfer reactions of all living systems. These proteins utilize the cofactor flavin adenine dinucleotide (FAD) to dehydrogenate (oxidize) pyridine nucleotides and hydrogenate (reduce) the cytochromes (1, 2). This valuable cofactor, which is derived from riboflavin (RF) (Vitamin B_2), is unique in that, depending on the conditions, it can undergo either two separate one-electron transfer reactions or one essentially simultaneous two-electron transfer reaction. The flavin coenzymes occur in a variety of proteins and interface between organic oxidation and reduction reactions, which are usually two-electron processes, and electron transfer reactions to/from metal centers, often requiring only one electron. The two one-electron reactions are shown below involving a proton and producing neutral molecules (Fl = flavin).

[1] $\mathrm{Fl} + \mathrm{H}^+ + \mathrm{e}^- \rightleftharpoons \mathrm{FlH}$

[2] $\mathrm{FlH} + \mathrm{H}^+ + \mathrm{e}^- \rightleftharpoons \mathrm{FlH_2}$

All flavins share the isoalloxazine moiety, which is the electroactive part of the molecule (Fig. 1). Attached to this ring system is another group, depicted as R in Fig. 1, which aids in apoprotein–cofactor binding and specificity (1, 2). The isoalloxazine ring system can exist in an oxidized form (quinone), the radical semiquinone form, after the acceptance of the first electron, and the reduced hydroquinone form, after a second electron transfer. Therefore, all compounds derived from flavin, e.g., lumiflavin (LF), riboflavin, flavin mononucleotide (FMN), and FAD, which vary only in the nature of the R group (Fig. 1), are expected to have similar formal potentials to that of the isoalloxazine ring system. It should also be noted that depending on the solution pH, each of these species can exist in either neutral or ionic forms (1).

In biological systems, the factors which govern the mechanism of FAD reduction and oxidation, as well as its redox potential, are related to the microenvironment of the cofactor–apoprotein interaction site. For example, steric hindrance, solution pH, and ionic strength all give rise to unique microenvironments (2, 3), and therefore may affect the redox potential of the flavin.

It is also known that, in solution, the oxidized flavins are expected to have a planar structure, while the reduced flavin resembles a butterfly in conformation (2), with atoms 1 to 5 and 10, and 5 to 9 and 10 (Fig. 1) constituting two planes or wings intersecting the N(5)—N(10) axis, with a dihedral angle of 21° (4). Therefore, enforced flattening of the reduced flavin should increase its reducing power, and conversely, enhanced bending should increase the oxidizing power. Selectivity for a one- or two-electron reaction could conceivably be assisted in this manner (4). This may occur in the protein and could perhaps also occur at the surface of an electrode.

The electrochemical behavior of the flavins, particularly of RF, has been studied at Hg electrodes, primarily with the use of dc and ac polarographic and also chronopotentiometric methods (5–9). It has been reported that in acidic solutions, both the oxidized and the reduced forms of RF are strongly adsorbed on a Hg surface (5, 6, 10). One monolayer of oxidized RF oriented parallel to the electrode surface and two layers (a bilayer) of the reduced RF ($\mathrm{RFH_2}$) are thought to adsorb (8, 9). Despite the

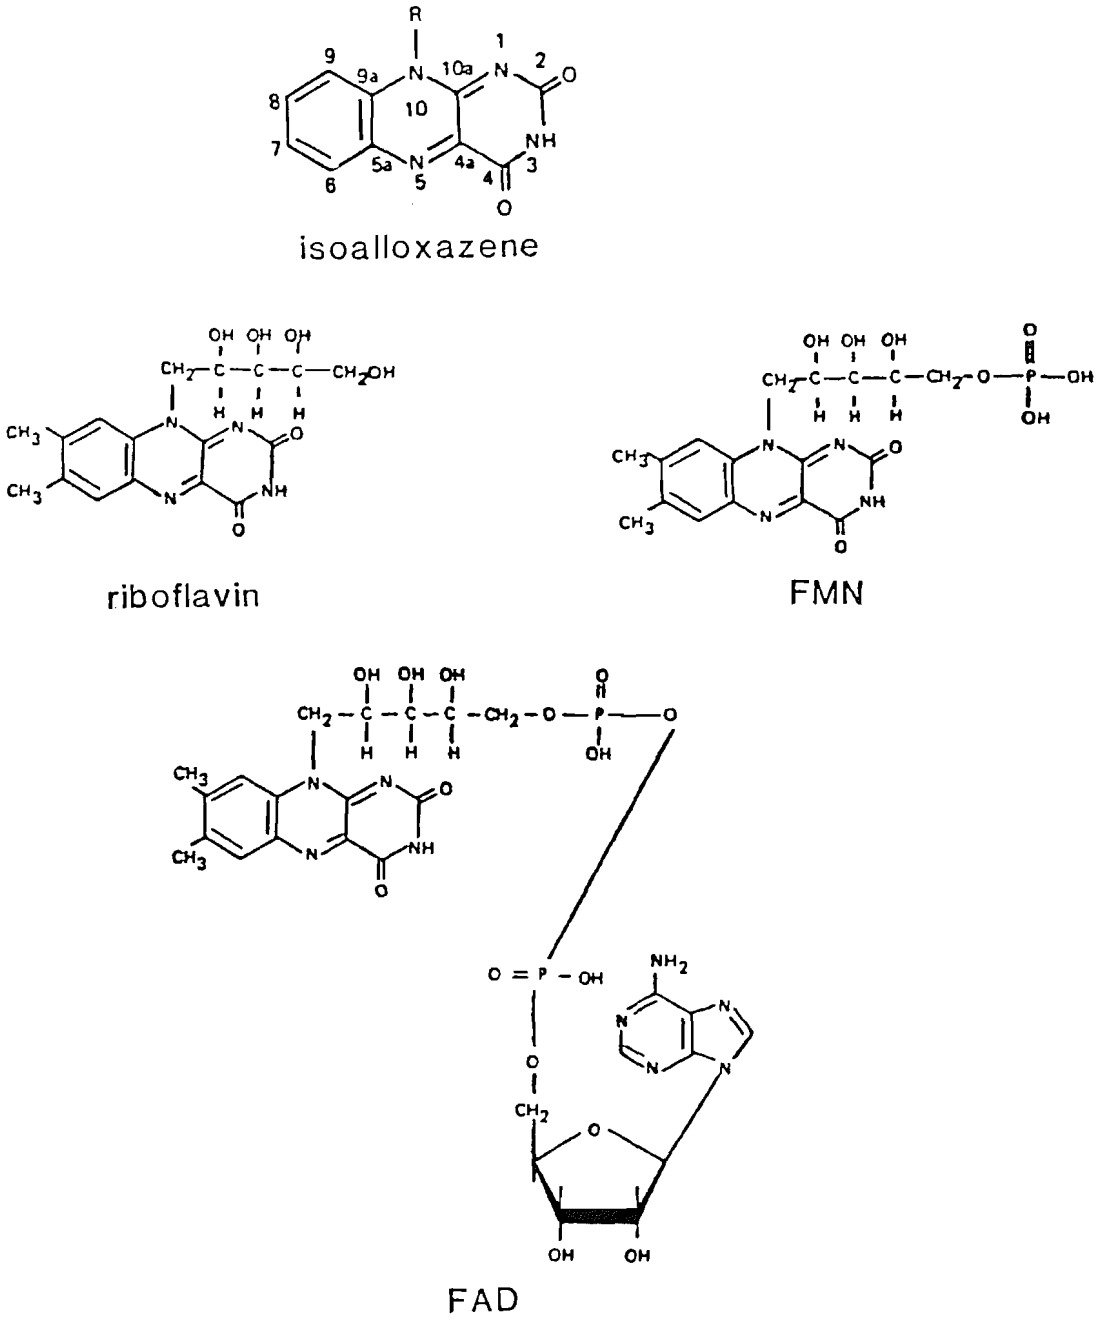

FIG. 1. Structure of isoalloxazine moiety and of the R groups for RF, FMN, and FAD.

presence of these adsorbed layers, the reduction of RF from solution was found to occur via a reversible two-electron transfer reaction (9).

A study of the adsorption behavior of FMN at Hg electrodes in acid solutions has also been reported (11). As in the case of RF, strong adsorption of both the oxidized and reduced forms of FMN are observed electrochemically. Also, a bilayer (1.2×10^{-10} mol/cm^2) of the reduced form is presumed to be present, while only a single layer (0.6×10^{-10} mol/cm^2) of the oxidized form of FMN is found to adsorb at the Hg electrode (11).

In a more recent work (12), it was shown that both the oxidized and the reduced forms of FMN are strongly adsorbed at a Hg drop electrode in buffered solutions of pH 4.9 and 6.9. The quantity of adsorbed FMN, as measured by cyclic voltammetry, was estimated to be in the range of 7 to 9×10^{-11} mol/cm^2, close to the predicted amount of FMN (7.5×10^{-11} mol/cm^2) having the isoalloxazine ring system parallel to the electrode surface (12).

The same authors also carried out a similar study using a Hg electrode in dilute FAD solutions buffered to a pH of 6.9 (13), and again, both the oxidized and reduced forms of the flavin were found to be strongly adsorbed. In concentrated FAD solutions, another investigation (14), carried out over the entire range of pH, has dealt in detail with the mechanism of reduction of FAD in solution, but did not discuss FAD adsorption.

An area of current interest which is of relevance to studies of flavin adsorption involves the attachment of various important redox materials to electrode surfaces, producing chemically modified electrodes. This has been carried out recently for FAD, which has been successfully attached to various graphite

and carbon electrode surfaces (15–20). At glassy carbon electrodes, a single layer of FAD can be attached, while at porous graphite electrodes, up to 50 to 100 monolayers of FAD have apparently been adsorbed (18, 20). However, it appears that the roughness factor of these porous graphite electrodes was not taken into account in estimating the number of FAD layers adsorbed, and therefore, it is likely that only ca. one layer is also deposited on these electrodes. In all of this work at carbon electrodes, it was found that glucose oxidase activity in solution could be restored with the use of the FAD-coated electrode. FAD has also been attached to an indium – tin oxide electrode via the adenine amino group (20).

While most of the papers described above have reported that the flavins do indeed adsorb at electrode surfaces, none of them has investigated the actual mechanism of build-up of adsorbed flavin layers or the kinetics of their oxidation and reduction. The present investigation has involved the use of cyclic voltammetry to study the oxidation and reduction of FAD at mercury electrodes in neutral solutions and to discover whether two separate one-electron transfer steps can be distinguished at rapid sweep rates. Also, a detailed examination of the process of FAD adsorption, the oxidation and reduction of adsorbed FAD and layer reorientation has been carried out using cyclic voltammetry (CV) and alternating current (ac) voltammetry.

Experimental

(a) Equipment

Standard three-electrode potentiostatic circuitry was employed, utilizing either a PAR 173 potentiostat and a PAR 175 universal programmer, or a PAR 273 digital potentiostat/function generator for the cyclic voltammetry experiments. I/E curves were usually plotted on a HP 7044A X/Y recorder at slow potential sweep rates (s), and on either a Nicolet 3091 digital oscilloscope or a HP 7090A digital recorder at s greater than about 200 mV/s.

The ac voltammetry experiments were carried out using a PAR 273 potentiostat in conjunction with a PAR 5206 Lock-in Amplifier. For most experiments, a voltage amplitude of 5 mV, a frequency of 329 Hz, and phase angles of either 0° or 90° were employed.

(b) Electrodes

The working electrodes (WE) utilized in this work were either a Hg pool electrode, a PAR 303A HMDE, or a glassy carbon electrode. The HMDE was utilized only on the medium drop size setting, producing a drop having a surface area of 1.3×10^{-2} cm^2. The Hg pool electrode, contacted with a Pt wire, had a surface area of 2 cm^2. The surface areas were determined by measuring the minimum capacity in a flavin-free buffer solution and comparison with the reported double layer capacity minimum of 15.4 μF/cm^2 for Hg in phosphate solutions (21). In this paper, all current and charge densities are given with respect to the electrode areas measured by this method.

The glassy carbon (GC) electrode (5 mm radius) consisted of a GC disc placed into the end of some shrinkable Teflon tubing, which was then heated, leaving only the end of the disc exposed to the solution. Electrical contact was made at the back of the GC disc by a Ni wire embedded into a drop of Hg. The GC electrode surface was prepared by polishing with γ alumina, followed by ultrasonic cleaning in acetone for about 1 min and then a thorough rinse with distilled water.

The counter electrode (CE) used in these experiments was either a Pt gauze or Pt wire electrode. The reference electrodes (RE) were either a Ag/AgCl electrode or an SCE. All potentials are given vs. the NHE in this paper.

(c) Cells and solutions

All experiments were carried out in either a two compartment cell or in the standard polarographic cell used with the PAR 303A HMDE. Both cells were constructed so that the cell solution could be thoroughly deoxygenated by bubbling argon or nitrogen either through the solution or passing it above the solution during the experimental runs.

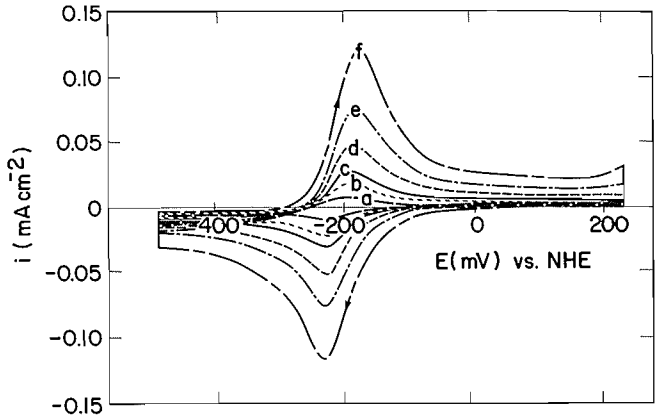

FIG. 2. Cyclic voltammograms obtained at a Hg pool electrode in 1.1×10^{-4} M FAD solution (pH = 7). s = 2 (a), 10 (b), 20 (c), 50 (d), 100 (e), and 200 (f) mV/s.

The experiments were carried out in buffered (sodium phosphate or potassium hydrogen phthalate) solutions. FAD was obtained as its sodium salt from Sigma Chemicals Co. The flavin solution concentrations ranged from about 2×10^{-6} to 1×10^{-4} M. All chemicals utilized were of reagent grade and all water was thrice distilled. All experiments were carried out at room temperature.

Results and discussion

(a) General electrochemical behavior of FAD at Hg electrodes

Initial experiments were carried out with the use of cyclic voltammetry (CV) to establish whether a single two-electron or two one-electron transfer steps would be observed for FAD reduction and oxidation over a wide range of s. A Hg pool electrode was used for these early experiments (at sweep rates less than or equal to ca. 500 mV/s), primarily as it was anticipated that in the subsequent adsorption studies, it would be desirable to transfer the Hg electrode from one solution to another and it was considered that a Hg pool electrode would facilitate this process.

Figure 2 shows a family of CVs for a range of s from 2 to 200 mV/s and a FAD concentration of 1.1×10^{-4} M (pH = 7). This rather high FAD concentration was selected so that the diffusion currents would be significantly larger than the current due to the reaction of adsorbed FAD. However, despite this, the peaks are somewhat non-ideal in shape, having a greater peak separation and being wider at half-height than theoretically predicted (22).

Figure 3a (□) shows that at low s, the difference in the anodic and cathodic peak potentials (ΔE_p) is constant at about 35 mV for the Hg pool electrode. This is somewhat larger than the expected value for a reversible two-electron transfer reaction, $57/z$ mV, where z is the number of electrons transferred in the process (2). At sweep rates greater than about 20 mV/s, the peak separation begins to increase, as is predicted for the onset of kinetic irreversibility.

When the peak current density (i_p) is plotted vs. $s^{1/2}$ (Fig. 3b), a linear relationship is observed up to a sweep rate of about 20 mV/s. However, rather than observing a decrease in the slope of this plot at high s, as might have been expected when a diffusion-controlled process becomes irreversible (22), the slope of the plot increases. This is indicative of the presence of adsorbed flavin, as the current due to the oxidation and reduction of adsorbed species is expected to vary linearly with s, rather than with $s^{1/2}$ (22). This result implies that the increased peak separation at higher sweep rates, shown in Fig. 3a, is

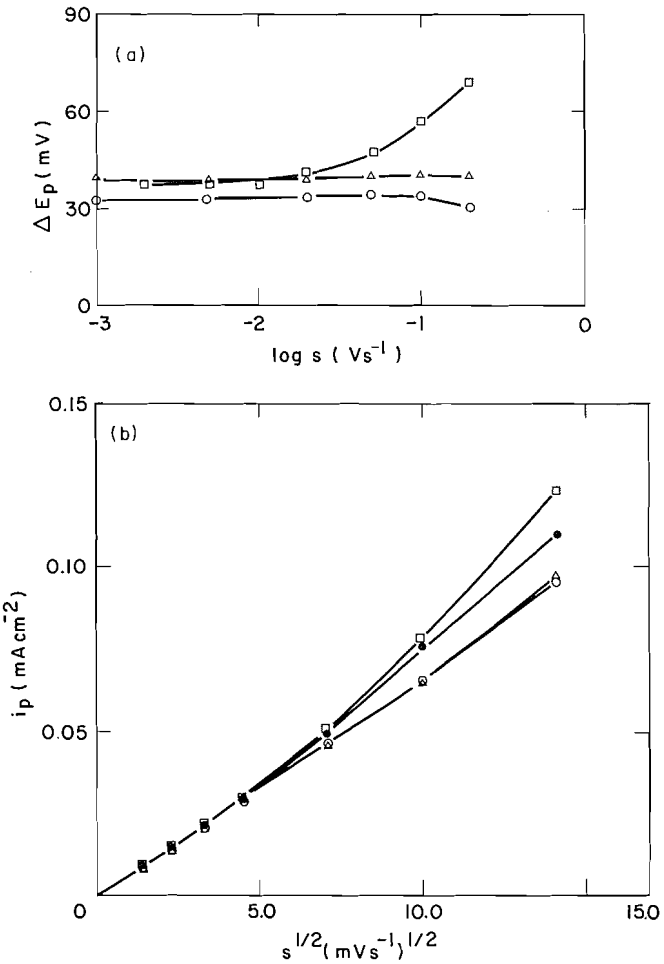

FIG. 3. (*a*) ΔE_p vs. log s; 1.1×10^{-4} *M* FAD solution (pH = 7), using a Hg pool electrode (□) or a HMDE, where (○) represents the "first scan" of potential and (△) scans nos. 2, 3, and 4. (*b*) The dependence of $i_{p,c}$ (●, ○) and $i_{p,a}$ (□, △) on $s^{1/2}$ for 1.1×10^{-4} *M* FAD solution (pH = 7) at a Hg pool electrode (●, □) and the HMDE (○, △).

related to contributions to the current peak from the reaction of both adsorbed flavin and flavin molecules diffusing to the surface from the solution. Therefore, a simple estimation of the rate constant for the reaction cannot be obtained from the results of Fig. 3. It can be seen in Fig. 3*b* that the anodic peak is influenced more by adsorption than is the cathodic peak. This is in agreement with the findings (reported below) that the adsorption peaks are centered at a somewhat more positive potential than the diffusion peaks (Table 1).

It should be noted that even at sweep rates greater than 500 mV/s, no evidence for the splitting of the main FAD reduction and oxidation peaks into those for the individual one-electron transfer steps was observed, notwithstanding the difficulty in avoiding the current response to adsorbed FAD at high sweep rates. This is consistent with the reported E^0 values for reactions [1] and [2], −240 and −130 mV, respectively (23), measured by the coulometric titration of flavin bound to a benzoate substrate. Anderson (24) utilized pulse radiolysis and obtained E^0 values of −314 and −124 mV for the two reactions. These values indicate that as soon as the first electron is transferred in the reduction process, the second should pass immediately thereafter. As stated earlier, in biological systems, it is possible that binding and local environment effects could

TABLE 1. Characteristics of FAD adsorption peaks (HMDE, 1.8×10^{-6} *M* FAD, pH = 7)

Stage	q (μC cm^{-2})	E_f' (mV vs. NHE)*	ΔE_p (mV)†

*Determined as the potential midway between the anodic and cathodic peak (cf. with E_f = ca. −206 mV).
†Measured at s = 100 mV/s.

cause the second step to become more difficult than the first, or the first to become more facile, so that the two one-electron steps could become more readily separated (23). The observation of a two-electron transfer process has been reported previously for FAD (14, 25–27), although two overlapping one-electron steps have sometimes been reported for RF (28), FMN (29, 30), and for FAD (14), particularly in acid solutions. It has also been reported that flavins coordinated to particular metal centers, e.g. $Ru^{2+/3+}$, undergo electron transfer in discreet one-electron steps, rather than in one two-electron step, in both aqueous and non-aqueous solutions, e.g. DMF (31–33).

Efforts were made to determine the formal potential, E_f, of the reaction from CVs such as those shown in Fig. 2. The potential midway between the anodic and cathodic peaks, −0.208 ± 0.002 V vs. NHE, was taken as E_f at pH = 7 at the Hg pool electrode. There are numerous values reported in the literature for this potential, e.g. −0.205 V (14), −0.210 V (26), −0.213 V (29), −0.219 V (34) etc. Our value is well within this range.

The strong adsorption of FAD at Hg electrodes has been demonstrated by replacing the FAD solution with buffer solution only and then monitoring the electrochemical response. A matching pair of peaks were observed in the same potential range as the diffusion peaks had been. These peaks were seen both when the Hg electrode was at open-circuit during the exchange of solutions as well as when potential control was maintained and the transfer of solutions was done in a flow-through cell. These peaks contain a charge equivalent to about one layer of adsorbed FAD (see below) and demonstrate conclusively the strong adsorption of both the oxidized and the reduced forms of FAD on the Hg surface.

It was also found that when the FAD solution was removed from the cell, the Hg was shaken/rinsed with water, and the pool electrode was replaced in the cell containing only the buffer solution, the small adsorption peaks were still present. The only absolute method for removing the adsorbed flavin was by washing the Hg electrode in HCl, after which only a small fraction of the adsorption peaks could still be seen. Very similar effects were seen with GC electrodes after exposure to FAD solutions. The only method by which the adsorbed FAD could be removed was by a mechanical polishing of the GC surface. These experiments indicate clearly why a simple kinetic analysis could not be carried out for the reduction and oxidation of FAD from solution at these Hg pool electrodes.

An interesting effect observed at the Hg pool electrode in phosphate buffered FAD solutions was that when the potential was extended to potentials more negative than about −0.800 V vs. NHE, a new pair of peaks was observed at ca. −0.85 V (Fig. 4). If the potential was held just negative of these peaks for several minutes, the next complete anodic run (Fig. 4) displayed a new peak on the positive side of the main FAD oxidation

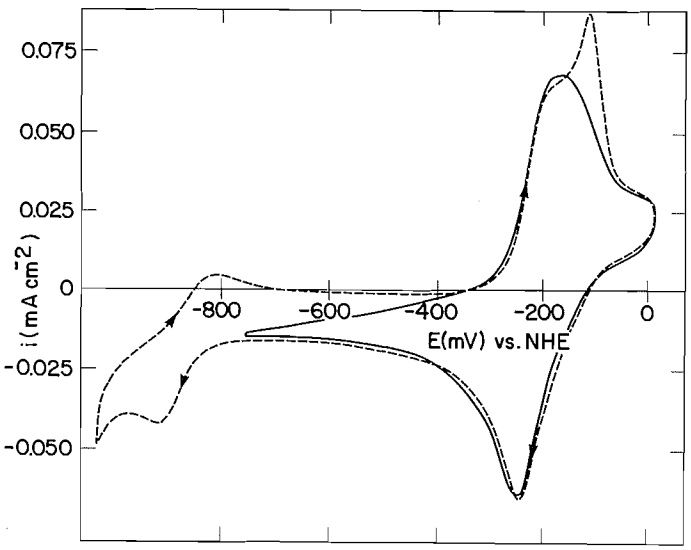

FIG. 4. Cyclic voltammogram at Hg pool electrode in 1×10^{-4} *M* FAD solution (pH = 7), s = 100 mV/s. The dashed line shows the influence of extended negative potential limit on anodic peak.

peak. This new peak was quite sharp and exceeded the anodic diffusion peak in magnitude. This was observed at both Hg and GC electrodes in this work. This is a similar effect to that reported for FMN at Hg electrodes in pH 1 solutions (11), in which an anodic "post-peak", considered to be due to $FMNH_2$ adsorption, splits to give a second, rather sharp post-peak at more positive potentials after time spent at potentials cathodic of the main reduction peak.

The behavior observed in Fig. 4 is therefore also likely to be indicative of FAD adsorption at the Hg pool electrodes. It will be shown below that it represents a reorientation within the underlying adsorbed FAD film. In the case of FMN (11), no small peaks such as those at negative potentials in Fig. 4 were reported.

It should be noted that at pH 4, neither the small peaks at ca. −0.85 V nor the new anodic spike are observed. It is probably significant that at pH 7, the anion form of both the semiquinone (FlH) and the hydroquinone (FlH_2) may be present in reasonable quantities, while at pH 4, all forms of FAD are neutral. Therefore, it is likely that the new anodic spike is related to reorientation of adsorbed negatively-charged FAD at negative potentials. It will be shown below that similar effects of holding the potential at the negative limit of the potential range are seen in the electrochemical response of adsorbed FAD. The small peaks at negative potentials in Fig. 4 will be shown below to be due to the capacitive change caused by the desorption and reorientation of FAD (see ac results below).

From the results presented above, it was concluded that the Hg pool electrode becomes covered with a strongly adsorbed FAD film which clearly influences the shape and position of the peaks observed by CV and which may influence the kinetics of the oxidation and reduction of FAD from solution. For these reasons, and also in order to produce a fresh, reproducible Hg electrode surface readily, all subsequent studies were carried out with the HMDE. The use of the HMDE also enabled a thorough study of the mechanism of the build-up of adsorbed FAD to be carried out.

(b) FAD electrochemistry at the HMDE

The CVs of FAD reduction and oxidation at the HMDE were generally similar to those in Fig. 2 for the Hg pool electrode. However, the extent of FAD adsorption could be more readily controlled by extruding a fresh Hg drop just before recording the CV, and comparing this result to those at later times. Figure 3*a* (○) shows ΔE_p as a function of the sweep rate for the first sweep at a fresh Hg drop as well as for later sweeps. A fresh Hg drop was extruded for the measurements at each sweep rate. For the first sweep at a fresh Hg drop, it can be seen that at sweep rates less than about 100 mV/s, ΔE_p is about 31 mV, close to the theoretically predicted peak separation of 28.5 mV (22). However, for the first sweep at sweep rates greater than 100 mV/s, a more ideal peak separation (29 mV) was observed, indicating that the electron transfer reaction is relatively rapid. It also indicates the probable influence of adsorption at low s (long times). This point is discussed further below.

These results indicate that FAD adsorption is a fast process at this high FAD concentration, causing an increased peak separation at low sweep rates. Only at high sweep rates, when little time is available for adsorption to occur, is the peak separation more ideal. The peak separation in the subsequent few sweeps at low s (Fig. 3*a*, △) is more similar to that at the Hg pool electrode, while at high s, the peak separation is smaller as less time has elapsed in the experiment and less FAD has adsorbed.

Figure 3*b* (○, △) also shows that less FAD is adsorbed at a Hg drop electrode in the first few sweeps of potential than at the Hg pool electrode, which remains exposed to the FAD solution for the duration of the experiment. This is seen by the fact that the $i_p/s^{1/2}$ relationship remains essentially linear, even at high s. In comparison, the results at the pool electrode in Fig. 3*b* (□, ●) show a significant deviation towards a linear i_p/s relationship at high s, indicative of a greater extent of current response from adsorbed FAD.

The formal potential of FAD reduction/oxidation, E_f, determined from these results at the HMDE, is −0.205 ± 0.002 V vs. NHE, again within the reported range of potentials for this reaction. It should be noted that by using the "first sweep" results at greater than ca. 100 mV/s at a freshly extruded Hg drop, it is likely that the potential is not influenced significantly by adsorption effects. Much of the older literature, e.g. ref. 29, shows non-ideal polarographic waves and has reported formal potentials from these waves. These potentials are likely to be more negative than those at a fresh Hg surface, when adsorption effects can be minimized.

(c) FAD adsorption at the HMDE in pH = 7 solutions

The study of the adsorption of FAD has been carried out in dilute FAD solutions (less than 5×10^{-6} *M*) and at relatively high s (greater than 100 mV/s). The purpose of this was to enhance the FAD adsorption currents relative to the diffusion controlled currents. The HMDE was used in all of this work because a fresh reproducible Hg surface could be produced at controlled intervals of time.

(i) General electrochemical behavior

The gradual build-up with time of adsorbed FAD at a fresh HMDE surface has been monitored using both CV and the out-of-phase (ϕ = 90°) "capacitive" current response to an ac signal. Figure 5*a* shows the ac response of the HMDE, first in the phosphate buffer supporting electrolyte solution only, with no FAD added, and then in a 1.8×10^{-6} *M* FAD solution in the buffer solution at s = 5 mV/s in the range of voltage between −0.650 and +0.250 V vs. NHE. The ac response is seen to reach a steady-state after the second scan. Figure 5*b* shows the analogous experiment, starting with a fresh Hg drop, using CV and s = 100 mV/s. The progression of time of cycling is

indicated by the number of each of the runs (each run is equivalent to 16 s), given in the figure caption. It should be noted that because of the different sweep rates used in the ac and CV experiments, the time which elapses in one complete ac cycle is about 20 times that in one CV cycle.

In Fig. 5*a*, the first scan with FAD present was commenced at a potential of 0.250 V vs. NHE. The ac response shows a fairly broad peak, due to the pseudocapacity of the adsorbed electroactive material, and the double layer capacity on either side of the peak. At the start of the first negative sweep, the ac current is already lower than that of the supporting electrolyte alone, indicative of the onset of an adsorption process (34). The capacitance peak appears at a potential very close to the formal potential for FAD reduction, i.e. about −0.205 V vs. NHE. It will be shown below that the appearance of a single broad ac peak in the first few scans is indicative of Stage I of the adsorption of FAD.

It can be seen in Fig. 5*a* that the ac current obtained in the FAD-containing solution is closer to that for the buffer alone at potentials negative of the capacitance peak than at positive potentials. At pH = 7, the reduced form is expected to be partly anionic (1) and therefore it is likely that the negatively charged electrode would "destabilize" the anionic reduced form of the FAD layer.

On the first positive-going sweep in Fig. 5*a*, the ac peak appears as two smaller, but sharper ac peaks. Only one peak is seen at lower frequencies or if the solution is made substantially more conductive. After crossing these peaks, the current reaches its lowest value, before rising sharply at about +0.050 V. On the second cathodic sweep, the current drops sharply at about −0.030 V. After crossing the two peaks in this direction, the current remains low, increasing suddenly at about −0.550 V. Therefore, a type of capacitance "pit" or "well", also seen in the adsorption of nucleosides (35, 36), is observed between ca. −0.550 and ca. 0 V. The presence of this "pit" and the two sharp peaks is characteristic of "Stage II" of FAD adsorption. It is interesting to note that the centre of the capacitance "pit" is close to the pzc of Hg in phosphate solutions, i.e. about −0.200 V vs. NHE (21).

"Stage III" of FAD adsorption is observed after several hours of potential cycling over the range of potential in Fig. 5*a*. The ac response of this stage is shown in Fig. 6*a*, and it can be seen that now, the two ac peaks have again partly merged into one and that the capacitance "pit" has disappeared.

The development of Stages I to Stages III of FAD adsorption can also be followed by CV, as seen in Figs. 5*b* and 6*b*. It should be recalled that as s (used in the CV experiments) is 100 mV/s, much less time elapses per cycle as compared to a single cycle in the ac experiment. In the first few cycles of potential in Fig. 5*b*, a pair of broad peaks having a width at half height of ca. 70 mV (Peaks A_I and C_I, respectively) are seen. Both of these increase in magnitude with each cycle, and are centered near the expected potential for FAD reduction and oxidation. The charging current which flows on either side of the peaks decreases with continued cycling of the potential, consistent with the ac results of Fig. 5*a*. These broad peaks, A_I and C_I, are considered to depict "Stage I" of FAD adsorption. When a critical charge density of about 8 to 9 $\mu C/cm^2$ has passed, Stage I is complete and Stage II commences.

As seen in Fig. 5*b*, a sudden change in the appearance of the CV occurs as Stage II of FAD adsorption ensues. This is seen by the fact that within one or two sweeps of potential, and as the charge continues to increase, the cathodic peak (C_{II}) becomes sharp and narrow (width at half height about 40 mV) and a small, sharp shoulder ($A_{II,sh}$) appears on the positive side (at about −0.150 V) of the anodic peak. In addition, several small peaks appear at about +0.050 V (peak A′), at about −0.080 V (peak C′) and at about −0.530 V (peak C″), precisely the same potentials as where the capacitance "pit" is entered and exited in Fig. 5*a*. These peaks will be referred to as "capacitance peaks" here, as they depict the sudden changes in the double layer capacitance with potential, as seen clearly in the ac results of Figs. 5*a* and 6*a*.

"Stage III" of FAD adsorption occurs after long times of potential cycling between the extended potential limits of Figs. 5 and 6, and the CV response for "Stage III" is shown in Fig. 6*b*. Now, only a single broad pair of anodic and cathodic peaks (Peaks A_{III} and C_{III}) are observed, having a width at half height of about 70 mV. It should also be noted that the capacitance peaks A′, C′, and C″ are all now absent, consistent with the disappearance of the "pit" in Stage III in Fig. 6*a*. The relative narrowness of the peaks for Stage II as compared to Stages I and

III is probably an indication of the presence of relatively strong lateral attractive forces within the adsorbed FAD layers in Stage II (37).

At higher FAD concentrations than 1.8×10^{-6} *M* (Figs. 5 and 6), the three stages of FAD deposition described above are also still seen, although in significantly fewer cycles, i.e. diffusion-controlled adsorption of FAD is observed. The i/E relationships for FAD adsorption are not in any way affected or controlled by the electrochemical technique utilized, e.g. CV, AC voltammetry or potential holding. However, the orientation of FAD on the electrode surface does depend strongly on time and on the potential.

(ii) Effect of potential limits

The effect of the potential limits on the mechanism of FAD adsorption can be seen most clearly from the results of the following two experiments. In Fig. 7, both the ac (Fig. 7*a*) and the CV (Fig. 7*b*) response is displayed for a fresh Hg drop when the negative voltage limit (E_-) is -0.350 V (rather than -0.650 V, as in Figs. 5 and 6), i.e. E_- is kept within the range of the capacitance "pit" during the adsorption of FAD. It is seen that when the transformation to Stage II commences, both the cathodic and anodic peaks become sharp and narrow (Fig. 7*b*), as opposed to the case when the potential is extended negatively outside of the "pit" in each scan (Fig. 5*b*) and the anodic peak remains broad. A further change observed in Fig. 7*b* vs. Fig. 5*b* is that the sharp shoulder ($A_{II,sh}$), seen previously at about -0.150 V at the positive side of A_I, now has only a transient existence. The effects shown in Fig. 7 are independent of whether or not the positive potential limit, E_+, is extended positively of the "pit".

The result of a second important experiment involving the effect of the potential limits is shown in Fig. 8. Here, Stage II of FAD adsorption has been reached after a number of cycles of potential (not shown in Fig. 8) in which E_- has been extended outside of the capacitance "pit" to -0.650 V, as in Figs. 5 and 6. The sharp cathodic peak (C_{II}), broad anodic peak (A_I), shoulder ($A_{II,sh}$), and the three capacitance peaks are all observed. By varying E_+ for each sweep as shown in Fig. 8, it is seen that when E_+ is kept negative of the potential of $A_{II,sh}$, the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.222.148.141 on 09/07/12
For personal use only.

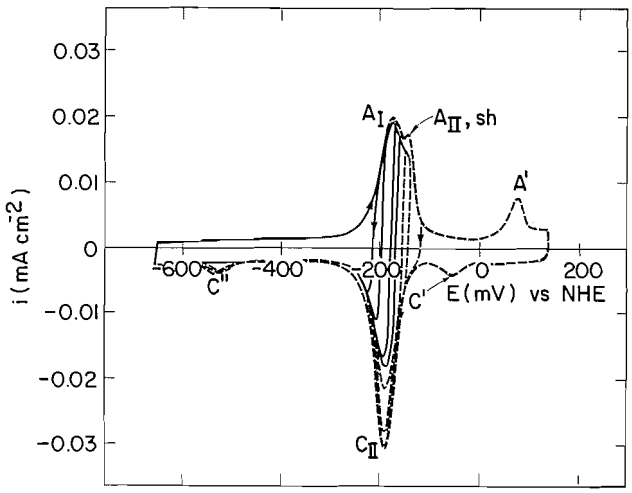

FIG. 8. Cyclic voltammograms of adsorbed FAD at HMDE after 24 cycles of potential at $s = 100$ mV/s; 1.8×10^{-6} M FAD solution (pH = 7). E_+ is increased with each potential cycle (nos. 1 to 8). Note that C'' appears only after cycle no. 5, when peak $A_{II,sh}$ has been reached.

principal cathodic peak is broad (C_I) and C'' is not observed. When E_+ reaches and crosses $A_{II,sh}$, the cathodic peak is narrower and C'' is clearly present, depicting Stage II of FAD adsorption.

These results show that if E_+ is not extended positively of the anodic shoulder, the "system" is not yet "within the capacitance pit". This confirms the ac results of Fig. 5*a*, which show that in Stage II, the capacitance drops as the two ac peaks are crossed when scanning positively. This experiment (Fig. 8) shows clearly that $A_{II,sh}$ is probably the indicator of this sudden change of the system capacitance as Stage I transforms to Stage II.

The results shown in Fig. 8 also give an indication of the kinetics of the oxidation and reduction of adsorbed FAD. When the potential is reversed within the range of peak A_{II}, the current immediately reverses in sign, indicative of a very fast process, particularly as the potential sweep rate is already reasonably high (100 mV/s). Also, the small peak separation indicates the rapid kinetics of adsorbed FAD oxidation and reduction. A more detailed kinetic discussion is presented later in this paper.

(iii) Surface formal potentials and charge densities – Stages I to III of FAD adsorption

Table 1 contains the surface formal potentials (E_f', the potential midway between the anodic and cathodic peaks) and the charge densities at the completion of each of the three stages of FAD adsorption described above. The table also lists the magnitude of the peak separation as well as the peak width at half height, all given at a potential sweep rate of 100 mV/s. It can be seen that Stages I and III, characterized by broad peaks having a width at half height of about 70 mV, have a E_f' about 20 mV more positive than does Stage II. Also, the formal potential of Stage II is closest to that obtained from the diffusion peaks (Fig. 2) at high FAD concentrations and low s. The peak separations given in Table 1 for the three stages of FAD adsorption also indicate that Stages I and III are similar, while Stage II is clearly different.

The variation of E_f' which occurs with time as the adsorption of FAD progresses through its stages points out clearly why it is difficult to reliably measure the formal potential (E_f) for FAD reduction and oxidation from the diffusion peaks (Fig. 2). At low s and high FAD concentrations, FAD adsorption would probably be complete by the time the reduction peak is reached in the first scan of potential. It is possible that Stage III would already be reached, which would lead to a positive shift of the measured E_f. At higher s, FAD adsorption would probably still be in Stage II, leading to a more negative measured E_f, while at very high s, Stage I could very well still be present in the first few sweeps. As the current response to adsorption would dominate at high s, a positive shift of the measured E_f might again be observed. This discussion stresses the difficulties associated with the measurement of a formal potential from a polarographic wave or a voltammetric peak when adsorption of the reactant and/or the product is occurring at the electrode surface as a function of time.

Significant disagreement exists in the literature regarding the quantity of RF and FMN which adsorbs at Hg electrodes and also how much charge constitutes a single layer of adsorbed flavin. For example, refs. 8 and 9 report that one molecule of adsorbed RF, with the isoalloxazine moiety parallel to the surface, would occupy an area of 150 Å^2, but observe 15 μC/cm^2 (212 Å^2) and 30 μC/cm^2 for one layer of oxidized RF and two layers of the reduced form of RF, respectively. Tedoradze *et al.* (10) have reported 22 μC/cm^2 (150 Å^2) as the charge for one monolayer of adsorbed oxidized RF and 30 μC/cm^2 for reduced RF on the electrode surface. The charge measured experimentally may depend on many variables such as solution pH, composition, and time of exposure of the electrode to the flavin solution. Some of these factors may account for the range in the reported values. Also, for bulkier molecules such as FAD, containing the phosphate and sugar groups of FMN, and also the rather large adenine group (Fig. 1), significantly more electrode surface area may be coupled per molecule, resulting in lower charge densities.

Overall, it appears that a value of 15 to 20 μC/cm^2 is a reasonable estimate of the charge equivalent to a single layer of flavin adsorbed with its isoalloxazine ring system flat on the electrode surface. Table 1 shows that Stage I of FAD adsorption is complete after 8 to 9 μC/cm^2 have passed, while Stages II and III involve a charge density of about 13 to 14 μC/cm^2. This latter charge density is consistent with the complete coverage of the Hg surface by FAD with its isoalloxazine system parallel to the electrode surface (the adenine ring can be assumed to lie above the surface, perhaps parallel to the isoalloxazine ring system, in a "stacked" configuration). The lower charge density observed for Stage I indicates a less tightly packed structure than for Stages II and III.

(iv) Kinetics of oxidation and reduction of adsorbed FAD

Figure 9*a* and *b* show plots of the peak current densities of Stages II and III as a function of potential sweep rate. In Fig. 9*a*, a linear relationship can be seen up to a sweep rate less than ca. 1 V/s, while Fig. 9*b* confirms that the deviation from linearity commences at a sweep rate greater than ca. 1 to 2 V/s. Although the charge density is the same for Stages II and III (Table 1), the currents are larger for Stage II (sharp, narrow peaks), as compared to Stage III (broad peaks), at any s.

The linear i_p/s relationship further confirms that Peaks II and III are due to the reduction/oxidation of adsorbed FAD. Because both the oxidized and the reduced form of FAD are strongly adsorbed on the Hg electrode surface, similar to the formation of a two-dimensional surface compound, it is probable that the reduction/oxidation reaction is activation controlled. Using CV, it is then anticipated that the i/E relationship should be exponential (38). However, the reaction

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.222.148.141 on 09/07/12
For personal use only.

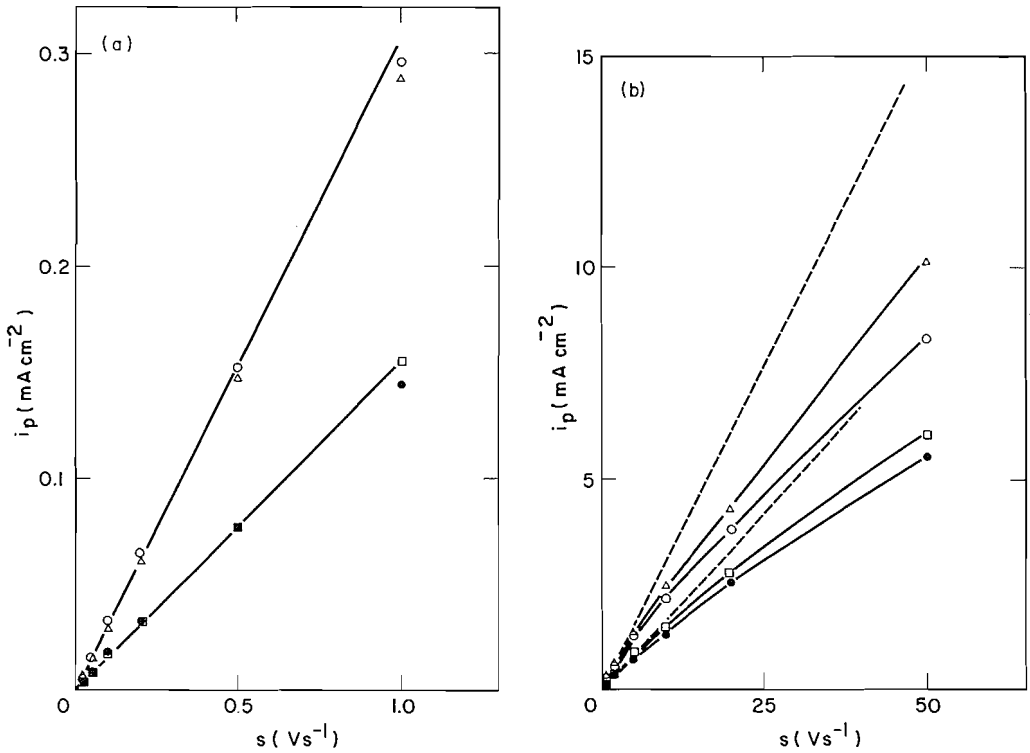

FIG. 9. Dependence of $i_{p,c}$ (○, ●) and $i_{p,a}$ (△, □) of adsorbed FAD on s; 1.8×10^{-6} M FAD solution (pH = 7); HMDE. Stage II (○, △); Stage III (●, □). (*a*) s less than 1 V/s. (*b*) s up to 50 V/s. The dashed lines represent the slope of the plots obtained at lower s (Fig. 9*a*).

rate will also depend on the number of available sites. Therefore, as the reaction progresses, e.g. cathodically, the tendency for the current to increase as the potential is made more negative will be offset by the decreasing number of reducible sites remaining. This then leads to a characteristic peak-shaped i/E response, such as seen in Figs. 5*b* and 6*b*. The same is true in the reverse (anodic) sweep.

As long as the ratio of i_p to s is constant (i.e. at a sweep rate less than 1 V/s in Fig. 9*a*), the reaction can be considered to be at equilibrium. Under these conditions, the peak potential should be constant and ΔE_p should be zero, as the concentration of oxidized and reduced species should adjust to the equilibrium values at each potential. As the sweep rate is increased, the reaction will become irreversible, as evidenced by the change of the slope of the i_p/s plot. By varying s over a reasonably wide range, the reversibility parameter, s_0, i.e. the point at which the reaction becomes irreversible, can be determined (39). s_0 is directly linked to the surface reaction standard rate constant, $k^{0'}$, according to eq. [3] (39):

$$[3] \quad k^{0'} = s_0 zF/2RT$$

where F, R, and T have their usual meaning, and z (= 2) is the number of electrons transferred per molecule of adsorbed species.

As is well known (39), the magnitude and shape of the current peaks should be independent of the concentration of reactants in solution when the surface reaction is activation controlled, and hence no bulk concentration terms appear in eq. [3]. Using an s_0 of 1 V/s, the surface standard rate constant is found to be 40 s^{-1}, which is indicative of a relatively fast surface reaction, similar to the rate of H^+ reduction at Pt electrodes in alkaline solutions (40).

Figure 10 shows a plot of ΔE_p vs. log s for Stages I to III. In this dilute FAD solution, there are no contributions from the reaction of FAD in solution, i.e. only adsorbed FAD is involved, as is seen by the constant charge for each Stage at all s. Contrary to the prediction above that ΔE_p should be equal to zero when the reaction is kinetically reversible (i.e. $s < 1$ V/s), the plot shows a peculiar rise in ΔE_p at $s < 0.5$ V/s, although it does show a sharp increase in ΔE_p at $s > 1$ V/s, at least for Stages II and III, which were examined in Fig. 9. Considering first the plot at high sweep rates, it is important to note that for Stage I, ΔE_p increases significantly only when $s > 10$ V/s, i.e. the reaction of FAD in Stage I is much faster than in the later stages. Stages II and III appear to behave similarly kinetically, apparently becoming kinetically irreversible at $s > 1$ V/s.

The unusual increase in ΔE_p at low sweep rates can only be understood by assuming that the oxidized and reduced forms of adsorbed FAD are thermodynamically different. This is consistent with a previous report regarding the lack of true reversibility seen in the diffusion waves for FAD in solutions of high FAD concentration (14). It is possible that this implies that at low sweep rates, there is adequate time for the conversion of FAD from its flat to its "butterfly" conformation as it is reduced, and vice versa, so that the oxidized and reduced forms are thermodynamically different (by 10 to 20 mV). At higher s, there may simply be too little time for this change to take place. It should be noted in Fig. 10 that this thermodynamic difference is more pronounced for Stage I than for Stages III and II.

It is also possible that the difference in peak potentials, and hence of E_f', at low s, depicts the fact that the reduced form of FAD is partly anionic, while the oxidized form is neutral, and that these two different chemical forms of FAD have somewhat different redox potentials. This would imply that at high sweep rates, both the oxidized and reduced forms of FAD would be anionic or both would be neutral.

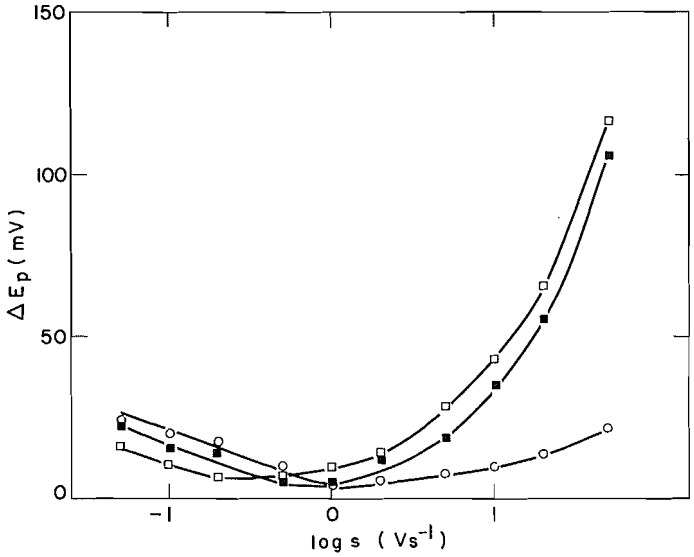

FIG. 10. ΔE_p vs. log s for adsorbed FAD; 1.8×10^{-6} M FAD solution (pH = 7). Stages of adsorption: (○) Stage I; (□) Stage II; (■) Stage III.

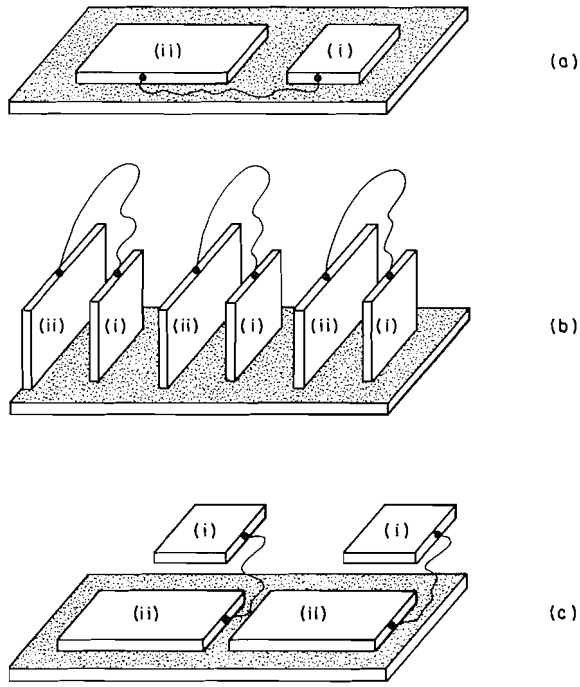

FIG. 11. Schematic of proposed orientation of adsorbed FAD at Hg electrodes, pH = 7; (*a*) Stage I; (*b*) Stage II; (*c*) Stage III. (*i*) Depicts the adenine group connected via the sugar–phosphato linkage to the isoalloxazine system (*ii*).

(v) Model of FAD adsorption at Hg electrodes

On the basis of all of the results presented above, the following model for the formation of an adsorbed FAD layer at Hg electrodes in pH 7 solutions is presented. When a fresh Hg drop is exposed to the FAD solution, FAD molecules adsorb as a function of time, as seen by the gradually increasing adsorption peaks with continuous potential sweeping (Fig. 5*b*). A time- and concentration-dependent loading of FAD on the surface of carbon electrodes has also been reported by Miyawaki and Wingard (19). It is proposed that the initial mode of adsorption (Peaks A_I/C_I) in the present work is such that the isoalloxazine moiety is approximately parallel to the electrode surface and the adenine groups are also on the Hg surface, as shown schematically in Fig. 11. This structure, having a large area per molecule (estimated to be about 400 Å^2), would be consistent with the relatively low charge densities of about 8 to 9 μC/cm^2 seen at this stage of deposition (Table 1). It should be noted that a "flat" orientation is actually more likely to be somewhat tilted, to enhance the overlap of the electron orbital on the N site on the isoalloxazine system with the Hg surface. A tilted structure has been suggested for the adsorption of pyridine on Pt electrode surfaces (41). The lack of significant lateral interactions between adjacent FAD molecules, due to the relatively loose structure of the layer and as the principal forces are probably between the Hg surface and the π electrons in the ring system would be consistent with the relatively broad nature of peaks A_I and C_I.

As the surface concentration of the loose FAD structure of Fig. 11*a* increases, a critical surface coverage is reached. Surface crowding then leads to a sudden change in orientation, represented by Stage II, for which it is suggested that the isoalloxazine ring system (and the adenine group) orients itself perpendicularly to the Hg surface, probably with the long end of the isoalloxazine moiety in contact with the electrode surface (Fig. 11*b*), similar to the vertical orientation assigned to adsorbed nucleosides when a "capacitance pit" is observed (35, 36). This suggestion is also supported by the larger surface coverage obtained in this orientation, as the π electrons of adjacent rings can overlap, leading to strong lateral interactions within the FAD layer. This leads to a more tightly packed layer, i.e. charge densities of about 13 to 14 μC/cm^2 and much sharper, narrower peaks (A_{II}, C_{II}) having a peak width of 35 to 40 mV (see Fig. 7). It should be pointed out that this perpendicular orientation is very stable when the potential is maintained within the region of the "capacitance pit", i.e. between $E = -0.550$ and 0.000 V. As long as the potential is kept within this range, the peaks will remain sharp and narrow and this orientation remains undisturbed.

When the potential is extended positively of the "pit", it is hypothesized that the now positively charged Hg surface provokes the isoalloxazine ring system to take on a parallel FAD orientation once again. This results in the observed increase in capacitance positive of the "pit". When the potential is scanned negatively, the FAD layer reorients itself again to the perpendicular orientation at $E = -0.050$ V (C′), resulting in a narrow cathodic peak (C_{II}) indicative of a perpendicular orientation with strong lateral interactions.

Figure 7 shows that when the potential is reversed during the cathodic sweep at a potential more positive than −0.550, i.e. inside the "pit", the FAD layer remains in the perpendicular orientation and a very sharp and narrow anodic peak, A_{II}, is observed. However, the extension of E_- to potentials negative of −0.550 V, i.e. out of the "pit", produces a broad anodic peak having a sharp shoulder in the next positive-going scan. On the basis of the above model, it appears that the reduced FAD layer, being at least partly anionic at pH 7, is not stable in the perpendicular orientation at negative electrode potentials and that the parallel orientation dominates at more negative potentials. This change to the parallel orientation at negative potentials is seen by the sudden increase of capacitance in Fig. 5*a* (i.e. C″ in Fig. 5*b*) at these potentials. The subsequent anodic sweep reveals a broad anodic peak, characteristic of a parallel orientation. However, as the FAD layer is oxidized,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.222.148.141 on 09/07/12
For personal use only.

it becomes neutral again, and therefore the perpendicular orientation is again favored. This transformation from parallel to perpendicular orientation occurs in the potential range of $A_{II,sh}$. This interpretation is consistent with the results of Fig. 5*a*, showing that the system is "inside the pit" after electro-oxidation, while it was "outside the pit" before the anodic reaction commenced.

After several hours of potential cycling over the full range of potential of Figs. 5 and 6, Stage III is reached. It is suggested that because of the broad nature of peaks A_{III} and C_{III} (Fig. 6*b*) and the similarity of these peaks to those seen in Stage I, the last stage of FAD adsorption again involves a parallel orientation of the isoalloxazine system to the Hg surface. This is supported by the absence of the capacitance peaks in CV experiments, i.e. the absence of the "pit". However, in order to make space for the equivalent of 13 $\mu C/cm^2$, the adenine group now positions itself directly above the isoalloxazene moiety in a "condensed structure" (Fig. 11*c*).

From Fig. 10, it is seen that the oxidation/reduction kinetics of adsorbed FAD are the most rapid for Stage I, when the principal interactions are thought to be between the isoalloxazine system and the Hg surface. For Stages II and III, when the strongest forces will be present between the isoalloxazine rings and the adenine system (Stage II and III) as well as between adjacent FAD molecules (Stage II), the redox reaction is somewhat slower.

Based on the above model (Fig. 11), it is also reasonable that Stage I, having no inter- or intra-molecular forces, other than to the electrode surface, would most readily take on the "butterfly" configuration in the reduced form at low s. This is consistent with the greatest thermodynamic difference being seen in Fig. 10 at low s for this stage, as compared to Stages II and III, which would be more constrained due to the presence of attractive forces between the isoalloxazine and adenine groups. Also, the observed negative shift of E_f' for Stage II vs. Stages I and III would be consistent with the predicted increase in the reducing power of the flavin, i.e. the negative shift of the redox potential, when the isoalloxazine ring system is held in the flat (vs. butterfly) orientation in the reduced state. This is more likely to be possible in Stage II than in the other Stages, as the strong lateral interactions between the FAD molecules (Fig. 11*c*) would tend to prevent any bending of the ring system during its oxidation and reduction.

Acknowledgements

Grateful acknowledgement is made to the Natural Sciences and Engineering Research Council of Canada for support of this work. Thanks are also extended to D. A. Armstrong for supplying the flavin salt and for numerous helpful discussions, and to Eileen Clarke for technical assistance.

Crystal and molecular structure of the di-μ-hydroxo-dimolybdenum compound, $[Mo(CO)_2(OH)(C_4H_7)(3,5\text{-diMepzH})]_2.C_6H_6$

STEVEN J. RETTIG, ALAN STORR,[1] AND JAMES TROTTER[1]

Department of Chemistry, University of British Columbia, Vancouver, B.C., Canada V6T 1Y6

Received April 3, 1987

STEVEN J. RETTIG, ALAN STORR, and JAMES TROTTER. Can. J. Chem. **66**, 97 (1988).

The synthesis and X-ray crystal analysis of a hydroxy-bridged molybdenum dimer are described. Crystals of di-μ-hydroxo-bis[dicarbonyl(3,5-dimethylpyrazole)(η^3-2-methylallyl)molybdenum(II)] benzene solvate are monoclinic, $P2_1/c$, $a = 7.508(1)$, $b = 20.747(1)$, $c = 20.717(3)$ Å, $\beta = 99.536(6)°$, $Z = 4$. The structure was determined by Patterson and Fourier methods and refined by full-matrix least-squares procedures to $R = 0.022$ for 3197 observed reflections. The dimeric molecule contains two distorted Mo coordination octahedra sharing an OH...OH edge to form a central folded four-membered $Mo(\mu\text{-}OH)_2Mo$ ring. The pyrazole ligands form bent N—H...O intramolecular hydrogen bonds to the bridging OH groups, and the other ligands occupy positions which result in approximate C_2 molecular symmetry. Two sets of Mo—OH bonds differ significantly in length, 2.237(2) and 2.140(2) Å; other molecular dimensions are within expected ranges. Molecules are linked into chains along *a* by O—H...OC hydrogen bonds, and benzene solvate molecules are well defined.

STEVEN J. RETTIG, ALAN STORR et JAMES TROTTER. Can. J. Chem. **66**, 97 (1988).

On décrit la synthèse et la cristallographie de rayons-X d'un dimère du molybdène pont d'hydroxyle. Les cristaux de di-μ-hydroxo-bis[dicarbonyl(diméthyl-3,5 pyrazolé)(η^3-méthyl-2 allyl)molybdène(II)] solvaté par la benzène sont monocliniques, $P2_1/c$, $a = 7{,}508(1)$, $b = 20{,}747(1)$, $c = 20{,}717(3)$ Å, $\beta = 99{,}536(6)°$, $Z = 4$. On a résolu la structure par les synthèses de Patterson et de Fourier et on l'a affinée par la méthode des moindres carrés (matrice entière) jusqu'à $R = 0{,}022$ pour 3197 réflexions observées. La molécule dimère comprend deux coordinations octaèdres déformés du molybdène qui partagent une arête OH...OH, en formant un cycle central plié à quatres membres, $Mo(\mu\text{-}OH)_2Mo$. Les ligands de pyrazol forment des liaisons hydrogène intramoléculaires et pliés, N—H...O, aux groupes pontés d'OH, et les autres ligands occupent les positions qui aboutent approximativement à la symétrie moléculaire C_2. Les longueurs des deux ensembles des liaisons Mo—OH sont significativement différentés, 2,237(2) et 2,140(2) Å; les autres dimensions moléculaires sont en dedans des domaines attendus. Les molécules s'articulent dans les chaînes le long de l'axe *a* par les liaisons d'hydrogène, et les molécules du solvant de benzène sont bien précises.

Introduction

In an earlier publication (1) we described the syntheses and properties of a number of manganese, molybdenum, and tungsten carbonyl derivatives incorporating the dimethylbis(1-pyrazolyl)gallate ligand, $[Me_2Gapz_2]^-$. These included the complex $[Me_2Gapz_2]Mo(CO)_2(\eta^3\text{-}C_3H_5)(pzH)$. Attempts to prepare the analogous $[Me_2Ga(3,5\text{-diMepz})_2]Mo(CO)_2(\eta^3\text{-}C_4H_7)(3,5\text{-diMepzH})$, however, were unsuccessful, but yielded instead a yellow crystalline complex since characterized as $[Mo(CO)_2(OH)(C_4H_7)(3,5\text{-diMepzH})]_2.C_6H_6$. The present account details the X-ray crystal analysis of this compound and describes the $Mo(\mu\text{-}OH)_2Mo$ bridging feature central to the dimeric molecule.

Experimental

Synthesis

The title complex resulted from the reaction of $Mo(MeCN)_2(\eta^3\text{-}C_4H_7)(CO)_2Cl$ (2) with the organogallate ligand $[Me_2Ga(3,5\text{-diMepz})_2]^-$ (3) in acetonitrile solvent, followed by recrystallization of the product mixture from benzene, and may have arisen via the attack of water on the coordinatively unsaturated species $[Me_2Ga(3,5\text{-diMepz})_2]Mo(CO)_2(\eta^3\text{-}C_4H_7)$ expected from the reaction. *Anal.* calcd. for $[Mo(CO)_2(OH)(C_4H_7)(3,5\text{-diMepzH})]_2.C_6H_6$: C 46.81, H 5.29, N 7.80; found: C 46.58, H 5.18, N 7.86%. Infrared (Nujol): ν_{OH} 3590, ν_{NH} 3200 br, ν_{CO} 1920, 1790 cm^{-1}. ^1H nmr (d_6-acetone $\delta = 2.11$) $\delta = 1.72$ (*Me*-allyl); 2.38, 2.50 (*Me*-pz); 5.81 (OH); 6.02 (pz-H[4]); 7.41 (C_6H_6).

Spectra

The infrared spectrum was recorded on a Perkin-Elmer 467 spectrometer, the ^1H nmr spectrum on a Varian 100 MHz spectrometer using FT technique, and the elemental analyses were performed by Mr. P. Borda of the UBC Microanalytical Laboratory.

X-ray crystal analysis of di-μ-hydroxo-bis[dicarbonyl(3,5-dimethylpyrazole)(η^3-2-methylallyl)molybdenum(II)] benzene solvate

A crystal of dimensions 0.39 × 0.17 × 0.06 mm, with {1 0 0}, {0 1 0}, {0 0 1} faces, was mounted in a general orientation. Unit cell parameters were determined from the settings of 25 reflexions measured on a diffractometer with Mo$K\alpha$ radiation ($\lambda\alpha_1 = 0.70930$ Å). Crystal data at 295 K are as follows:

$C_{22}H_{32}Mo_2N_4O_6.C_6H_6$ fw = 718.51

Monoclinic, $a = 7.508(1)$, $b = 20.747(1)$, $c = 20.717(3)$ Å, $\beta = 99.536(6)°$, $V = 3182.5(6)$ Å^3, $Z = 4$, $D_x = 1.499$ g cm^{-3}, $F(000) = 1464$, μ(Mo$K\alpha$) = 8.1 cm^{-1}. Absent reflections: $h0l$, $l \neq 2n$, $0k0$, $k \neq 2n$, space group $P2_1/c$ (C_{2h}^5, No. 14).

Intensities were measured with graphite-monochromatized Mo$K\alpha$ radiation on an Enraf-Nonius CAD4-F diffractometer. An ω–2θ scan was used, at 1.0–10.0° min^{-1} over a range of (0.65 + 0.35 tan θ) deg in ω (extended 25% on both sides for background measurement). Data were measured to $2\theta = 50°$. The intensities of three check reflections, measured every 3600 s throughout the data collection, showed small variations of ±3%. Lorentz and polarization factors were applied, and absorption corrections were made (4, 5), and transmission factors ranged from 0.873 to 0.956.[2] Of the 5565 independent reflections measured, 3197 (57.5%) had intensities $\geq 3\sigma(I)$, where $\sigma^2(I) = S + 2B + (0.04(S - B))^2$, where S = scan count and B = normalized background count.

The coordinates of the Mo atoms were determined from the Patterson function and those of the remaining non-hydrogen atoms from a subsequent difference map. Full-matrix least-squares refinement of the non-hydrogen atoms with anisotropic thermal parameters gave R = 0.034. A difference map at this point gave the coordinates of all 38 hydrogen atoms, which were included in all subsequent cycles of refinement with isotropic thermal parameters. The scattering factors used were those of ref. 6; the weighting scheme $w = 1/\sigma^2(F)$ gave uniform average values of $w\Delta F^2$, and was employed in the final stages of refinement of 513 variables. Convergence was reached at $R = 0.022$ and $R_w = 0.026$ for 3197 reflections with $I \geq 3\sigma(I)$; for all 5565 reflections $R = 0.080$. On the final cycle of refinement parameter shifts were 0.13σ (mean) and 2.8σ (maximum, for y of H(20b)); the mean error in an observation of unit weight was 0.81. A final difference map showed maximum fluctuations of ±0.3 e Å^{-3}. Final positional parameters are listed in Table 1, and a summary of the molecular dimensions is given in Table 2; thermal parameters, and full listings of bond lengths, bond angles, torsion angles, and structure factors have been placed in the Depository of Unpublished Data.[3] Analysis of the thermal parameters of all non-H atoms of the organometallic molecule, excluding the pyrazole carbon atoms, gave physically reasonable rigid body parameters, rms $\Delta U_{ij} = 0.0052$ Å^2; bond distance increases for libration are of the order of only 1σ, and have not been applied.

Results and discussion

The origin of the hydroxy species is not known with certainty, but the material must have resulted from the presence of water, most probably contained in the acetonitrile solvent, even though the solvent was carefully dried. Previous examples of water accidentally entering similar reactions have been documented. Thus the 3,5-dimethylpyrazolyl based ligand [MeGa(3,5-diMepz)$_3$]$^-$ is very prone to conversion to the hydroxy species [MeGa(3,5-diMepz)$_2$(OH)]$^-$ in sterically demanding situations, even when rigorous attempts to eliminate water are made (7). It is also reported that the reaction of $Mo_2(CH_3CO_2)_4$ with $Na^+Et_2Bpz_2^-$ results in the incorporation of [Et$_2$B(pz)(OH)]$^-$ ligands in the dimolybdenum product, an unexpected result attributed to the "adventitious" entry of water into the reaction mixture (8). A related reaction involving the gallate ligand [MeGapz$_3$]$^-$ gives an equally unexpected product (9).

The molecule (Fig. 1) is dimeric, with two distorted Mo

The syntheses of the novel anionic tridentate dimethyl(pyrazol-1-yl)(1-oxymethylpyrazolyl)gallate ligand and representative transition metal complexes thereof are reported. The direct reaction of Me_3Ga with 1-hydroxymethyl-3,5-dimethylpyrazole leads to the isolation of $Me_2Ga(\mu\text{-}OH)(\mu\text{-}Me_2pz)GaMe_2 \cdot HOCH_2Me_2pz$. Crystals of ($\mu$-hydroxy)($\mu$-3,5-dimethylpyrazolyl)bis(dimethylgallium) 1-hydroxymethyl-3,5-dimethylpyrazole solvate are monoclinic, a = 33.105(2), b = 7.3048(7), c = 8.8336(6) Å, β = 97.474(7)°, Z = 4, space group $P2_1/n$, and those of bis[dimethyl(pyrazol-1-yl)(1-oxymethylpyrazolyl)gallato-$N^2,N^{2\prime},O$]nickel(II) are monoclinic, a = 9.6345(3), b = 14.2731(6), c = 18.6356(7) Å, β = 99.660(3)°, Z = 4, space group $P2_1/c$. Both structures were solved by conventional heavy atom methods and were refined by full-matrix least-squares procedures to R = 0.044 and 0.037 for 2660 and 3904 reflections with $I \geq 3\sigma(I)$, respectively. Mean bond lengths in $Me_2Ga(\mu\text{-}OH)(\mu\text{-}Me_2pz)GaMe_2 \cdot HOCH_2Me_2pz$ are Ga—O = 1.918(11), Ga—N = 2.001(5), and Ga—C = 1.955(5) Å. *Fac*-$[Me_2Ga(pz)(OCH_2pz)]_2Ni$ crystallizes as an all-*cis* isomer with normal bond lengths and angles at Ga and Ni—O = 1.918(3) and 1.927(3), Ni—N = 2.030(4)–2.111(4) Å. The coordination geometry about Ni is irregular pseudo-octahedral with evidence of both steric and structural *trans* effects.

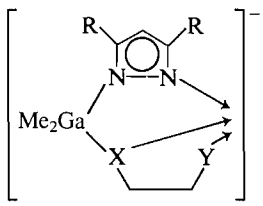
ARTHUR MAR, STEVEN J. RETTIG, ALAN STORR et JAMES TROTTER. Can. J. Chem. **66**, 101 (1988).

On rapporte les synthèses du nouveau ligand anionique tridentate diméthyl (pyrazolyl-1)(oxyméthyl-1 pyrazolyl) gallate et de complexes représentatifs de métaux de transition. La réaction directe du Me_3Ga avec l'hydroxyméthyl-1 diméthyl-3,5 pyrazole conduit au $Me_2Ga(\mu\text{-}OH)(\mu\text{-}Me_2pz)GaMe_2$. Les cristaux du ($\mu$-hydroxy)($\mu$-diméthyl-3,5 pyrazolyl)bis(diméthylgallium) solvaté par de l'hydroxyméthyl-1 diméthyl-3,5 pyrazole sont monocliniques avec a = 33,105(2), b = 7,3048(7) et c = 8,8336(6)], β = 97,474(7)°, Z = 4 et groupe d'espace $P2_1/n$ alors que ceux du bis [diméthyl(pyrazolyl-1)(oxyméthyl-1 pyrazolyl) gallato-$N^2,N^{2\prime},O$] nickel(II) sont monocliniques avec a = 9,6345(3), b = 14,2731(6) et c = 18,6356(7) Å, β = 99,660(3)°, Z = 4 et groupe d'espace $P2_1/c$. On a résolu les deux structures en faisant appel aux méthodes conventionnelles aux atomes lourds et on les a affinées par la méthodes des moindres carrés (matrice entière) jusqu'à des valeurs respectives de R de 0,044 et 0,037 pour 2660 et 3904 réflexions avec $I \geq 3\sigma(I)$. Les longueurs moyennes des liaisons dans le $Me_2Ga(\mu\text{-}OH)(\mu\text{-}Me_2pz)GaMe_2 \cdot HOCH_2Me_2pz$ sont Ga—O = 1,918(11), Ga—N = 2,001(5) et Ga—C = 1,955(5) Å. Le $[Me_2Ga(pz)(OCH_2pz)]_2Ni$-*Fac* cristallise sous la forme de l'isomère complètement *cis* et les longueurs et les angles sont normaux au niveau du Ga et Ni—O = 1,918(3) et 1,927(3), Ni—N = 2,030(4)–2,111(4) Å. La géométrie de coordination autour du Ni est du type pseudo-octaédrique irrégulier et l'on a relevé des données à l'effet qu'il existe des effets stériques ainsi que des effets structuraux *trans*.

[Traduit par la revue]

Introduction

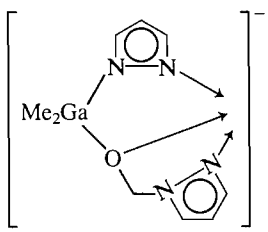
Recently Driessen reported a straightforward synthesis of 1-hydroxymethylpyrazole compounds (1). These compounds have been condensed with various primary and secondary amines and with ammonia to give a series of novel chelating ligands (2–6). The 1-oxymethyl-3,5-dimethylpyrazolate anion itself has shown interesting properties as a chelating ligand, having been incorporated into a number of transition metal cubane-type cluster compounds (7). More recently the reaction of 1-hydroxymethyl-3,5-dimethylpyrazole with a series of Ru complexes has resulted in the substitution of the 1-hydroxymethyl group by a hydrogen in the resulting coordination complex (8). Our continuing interest in unsymmetrical tridentate ligands of the type **1** (ref. 9 and references therein)



1 (R = H or Me, X and Y = donor atoms)

and the comparative dearth of information available on the coordination chemistry of the 1-oxymethylpyrazolyl moiety has prompted us to synthesize a novel organogallate ligand, L^-, which includes the 1-oxymethylpyrazolyl in addition to a gallium-substituted pyrazolyl ring system:

L^- =



The present paper describes the synthesis of representative transition metal complexes incorporating this ligand, and, through an X-ray crystallographic analysis of the L_2Ni complex, definitively establishes the expected tridenticity and chelating character of the organogallate ligand. Direct reaction of Me_3Ga and 1-hydroxymethylpyrazoles gave unexpected products; the structure of one of these has also been established by crystal analysis.

Experimental

Starting materials

Air-sensitive materials were handled in a nitrogen atmosphere.

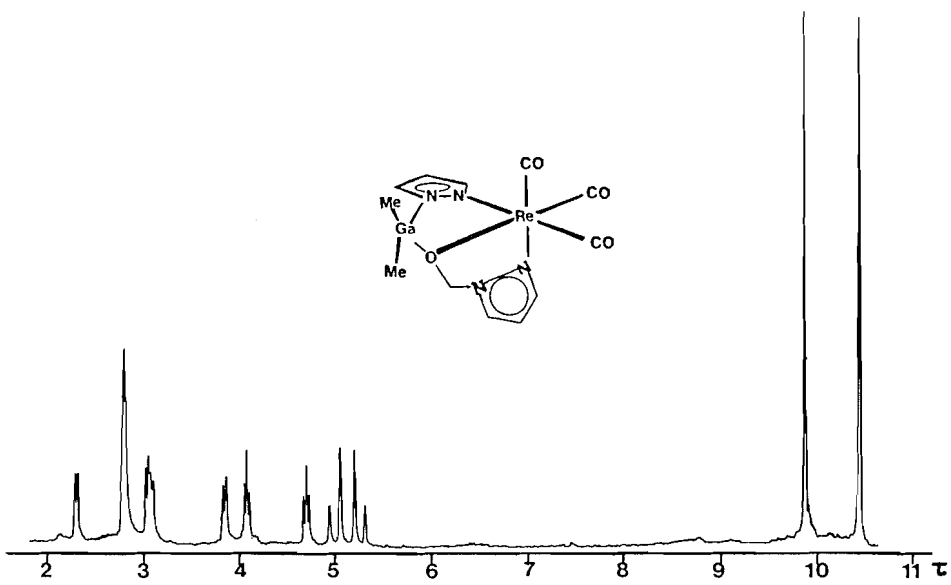

FIG. 1. Nuclear magnetic resonance spectrum of $[Me_2Ga(pz)(OCH_2pz)]Re(CO)_3$.

Tetrahydrofuran (THF), benzene, and CH_2Cl_2 were dried by refluxing over Na/benzophenone, potassium, and calcium hydride respectively, followed by distillation. $[Re(CO)_4Cl]_2$ (10), $Mn(CO)_5Br$ (11), Ni(NO)I (12), and Me_3Ga (13) were prepared as previously described. Sodium pyrazolides were prepared by reacting sodium hydride (Alfa) with the appropriate pyrazole (K and K Laboratories) in THF. The 1-hydroxymethylpyrazoles were prepared by the method described by Driessen (1).

Preparation of $Na^+[Me_2Ga(pz)(OCH_2pz)]^-$ (Na^+L^-)

$$Na^+pz^- + Me_3Ga \xrightarrow{THF} Na^+Me_3Gapz^-$$

$$Na^+Me_3Gapz^- + HOCH_2pz \xrightarrow[\Delta]{THF} Na^+L^- + CH_4$$

An equimolar amount of 1-hydroxymethylpyrazole (0.502 g, 5.12 mmol) in THF was added to a THF solution of $Na^+Me_3Gapz^-$ (14) and the mixture was refluxed overnight. The resultant clear solution was cooled and made up to standard volume with THF for use in subsequent reactions.

Preparation of $[Me_2Ga(pz)(OCH_2pz)]_2Ni$ (L_2Ni)

$$NiBr_2 + 2Na^+L^- \xrightarrow[rt]{THF} L_2Ni + 2NaBr$$

To a stirred slurry of $NiBr_2$ (0.112 g, 0.51 mmol) in THF was added a two molar equivalent of a THF solution of the ligand Na^+L^-. The reaction mixture was stirred for 2–3 days and the solvent was then removed *in vacuo*. The residue was extracted with benzene and the solvent allowed to evaporate from the filtered solution. Purple and blue crystals of the desired product, L_2Ni, were obtained in ~60% yield. *Anal.* calcd. for $[Me_2Ga(pz)(OCH_2pz)]_2Ni$: C 36.86, H 4.81, N 19.10; found: C 36.97, H 4.96, N 19.09. Analytical data for the blue and purple crystals are virtually identical. The X-ray structure of the purple crystals is described below.

In addition, a small quantity of orange crystals, identified as the previously characterized $[Me_2Gapz_2]_2Ni$ complex (15, 16), was obtained.

Preparation of $[Me_2Ga(pz)(OCH_2pz)]Re(CO)_3$ ($LRe(CO)_3$)

$$[Re(CO)_4Cl]_2 + 2Na^+L^- \xrightarrow[\Delta]{THF} 2LRe(CO)_3 + 2CO + 2NaCl$$

A two molar equivalent of the Na^+L^- ligand in THF solutuion was added to $[Re(CO)_4Cl]_2$ (0.082 g, 0.12 mmol) in the same solvent. The mixture was refluxed for ~3 h and the solvent then removed *in vacuo*. The residue was extracted with CH_2Cl_2 and the mixture filtered. On concentration, the filtrate yielded colorless crystals of the desired product. *Anal.* calcd. for $[Me_2Ga(pz)(OCH_2pz)]Re(CO)_3$: C 26.98, H 2.64, N 10.49; found: C 26.92, H 2.68, N 10.32. ^1H nmr (C_6D_6, 80 MHz, see Fig. 1) τ = 10.39 s, 9.84 s ($GaMe_2$), A = 5.26, B = 5.04, J = 8 Hz (—CH_2—), 4.71 t, 4.10 t (pz-H^4), 3.86 d, 3.13 d, 3.06 d, 2.32 d (pz-H^3, pz-H^5) ($\tau_{C_6H_6}$ = 2.84 ppm; $J \approx 2$ Hz for pz protons). Infrared (cyclohexane solution) ν_{CO} 2038, 1931, 1914 cm^{-1}. Mass spectrum: strong signals due to the monomer parent ion (P^+), P − Me^+, P − CO^+, P − $2CO^+$, P − CO − $2Me^+$, P − $3CO^+$, and P − Me − OCH_2^+ were observed with the signals arising from the latter ion being the most intense in the spectrum.

Preparation of $[Me_2Ga(pz)(OCH_2pz)]Mn(CO)_3$ ($LMn(CO)_3$)

$$Mn(CO)_5Br + Na^+L^- \xrightarrow[\Delta]{THF} LMn(CO)_3 + NaBr + 2CO$$

$Mn(CO)_5Br$ (0.423 g, 1.54 mmol) in THF was refluxed with a molar equivalent of the ligand Na^+L^- in the same solvent for ~4 h. The solvent was then removed and the residue extracted with benzene. An orange solid was obtained from the filtrate which was recrystallized from CH_2Cl_2. A yellow orange product was obtained. *Anal.* calcd. for $[Me_2Ga(pz)(OCH_2pz)]Mn(CO)_3$: C 35.76, H 3.48, N 13.91; found: C 35.58, H 3.41, N 13.83. ^1H nmr (C_6D_6, 80 MHz) τ = 10.39 s, 9.34 s ($GaMe_2$), A = 5.23, B = 5.15, J = 8 Hz (—CH_2—), 4.58 t, 3.96 t (pz-H^4), 3.79 d, 2.91 d, 2.91 d, 2.29 d (pz-H^3, pz-H^5). Infrared (cyclohexane solution) ν_{CO} 2045, 1951, 1930 cm^{-1}.

Preparation of $[Me_2Ga(pz)(OCH_2pz)]Ni(NO)$ ($LNiNO$)

$$Ni(NO)I + Na^+L^- \xrightarrow[rt]{THF} LNi(NO) + NaI$$

One molar equivalent of the ligand Na^+L^- in THF was added to a solution of Ni(NO)I (0.221 g, 1.02 mmol) in the same solvent. The resulting mixture was stirred at room temperature for ~3 h after which the solvent was removed to yield a dark blue oily residue. This was extracted with benzene and the solid recovered from the filtrate was recrystallized from CH_2Cl_2/hexane to yield a dark blue crystalline material. *Anal.* calcd. for $[Me_2Ga(pz)(OCH_2pz)]Ni(NO)$: C 30.65, H 3.97, N 19.86; found: C 30.90, H 4.00, N 19.88. ^1H nmr (C_6D_6, 80 MHz) τ = 10.14 s ($GaMe_2$), 5.74 s (—CH_2—), 4.31 t, 3.84 t

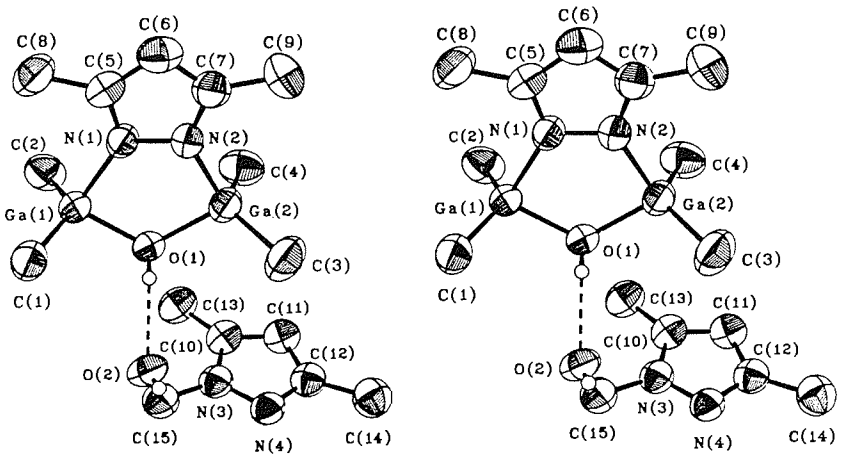

FIG. 2. Stereoscopic diagram of $Me_2Ga(\mu\text{-}OH)(\mu\text{-}Me_2pz)GaMe_2 \cdot HOCH_2Me_2pz$.

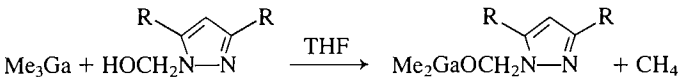
(pz-H^4), 3.29 d, 3.20 d, 2.90 d, 2.40 d (pz-H^3, pz-H^5). Infrared (Nujol) ν_{NO} 1793 cm^{-1}.

Reaction of Me_3Ga with 1-hydroxymethylpyrazoles

Anticipated reaction



R = H or Me

Equimolar amounts of Me_3Ga (0.225 g, 1.96 mmol) and 1-hydroxymethylpyrazole (0.192 g, 1.96 mmol) in THF solution were refluxed for ~5 h. The solvent was then removed to yield an intractable oily residue which we were unsuccessful in characterizing. In a second reaction, Me_3Ga (0.225 g, 1.96 mmol) and 1-hydroxymethyl-3,5-dimethylpyrazole (0.247 g, 1.96 mmol) dissolved in THF were refluxed for 5 h, and the solvent was then removed *in vacuo*. The residue was recrystallized from CH_2Cl_2 to yield a waxy crystalline material which has been characterized by X-ray crystallography (see Fig. 2), elemental analysis, and ^1H nmr spectroscopy. *Anal.* calcd. for $Me_2Ga(\mu\text{-}OH)(\mu\text{-}Me_2pz)GaMe_2 \cdot HOCH_2Me_2pz$: C 41.15, H 6.86, N 12.80; found: C 40.88, H 6.66, N 12.61. ^1H nmr (C_6D_6, 80 MHz) τ = 10.09 s (12H, $GaMe_2$), 8.14 s (3H), 8.04 s (6H), 7.84 s (3H) (pz-Me groups), 4.78 s (2H, —CH_2—), 4.44 s (1H), 4.39 s (1H) (pz-H^4 protons), 2.53 br (OH). Infrared (Nujol) ν_{OH} 3800 cm^{-1} br.

Spectra

^1H nmr spectra were recorded on a Bruker WP-80 instrument using FT techniques. Mass spectra were recorded on a Kratos AES MS-50 mass spectrometer, infrared spectra on a Perkin-Elmer 598 spectrometer. Elemental analyses were performed by Mr. P. Borda of the UBC microanalytical laboratory.

X-ray crystallographic analyses

Crystallographic data for $Me_2Ga(\mu\text{-}OH)(\mu\text{-}Me_2pz)GaMe_2 \cdot HOCH_2Me_2pz$ and $[Me_2Ga(pz)(OCH_2pz)]_2Ni$ appear in Table 1. Unit-cell parameters were refined by least-squares on 2 sin θ/λ values for 25 carefully centered reflections (2θ = 60–80° and 80–100°, respectively) measured with Cu-$K\alpha_1$ radiation. The intensities of three standard reflections, measured each hour of X-ray exposure time, showed only small random variations in each case. Data were reduced,[2] and corrected for absorption (analytical method (17)).

Both structures were solved by conventional heavy atom methods, the coordinates of the heavy atoms being determined from the Patterson functions and those of the remaining atoms from subsequent difference maps. Non-hydrogen atoms were refined with anisotropic thermal parameters. The OH hydrogen atoms of $Me_2Ga(\mu\text{-}OH)(\mu\text{-}Me_2pz)GaMe_2 \cdot HOCH_2Me_2pz$ and all hydrogen atoms of $[Me_2Ga(pz)(OCH_2pz)]_2Ni$ were refined with isotropic thermal parameters. The remaining hydrogen atoms in $Me_2Ga(\mu\text{-}OH)(\mu\text{-}Me_2pz)GaMe_2 \cdot HOCH_2Me_2pz$ were fixed in positions idealized from observed positions (C(sp^2)—H = 0.97 Å, C(sp^3)—H = 0.98 Å, $U_H \propto U_{\text{bonded atom}}$). Neutral atom scattering factors and anomalous scattering corrections (Ga and Ni) were taken from ref. 18. Isotropic type I extinction corrections were applied (19–21), the final values of g being 0.13(2) × 10^4 and 0.87(5) × 10^4, respectively.

Final positional and isotropic thermal parameters appear in Table 2. Bond lengths, bond angles, and intra-annular torsion angles are given in Tables 3–5, respectively. Calculated hydrogen atom parameters for $Me_2Ga(\mu\text{-}OH)(\mu\text{-}Me_2pz)GaMe_2 \cdot HOCH_2Me_2pz$, anisotropic thermal parameters, bond lengths and angles involving hydrogen, complete listings of torsion angles (Tables 6–10), and measured and calculated structure factor amplitudes have been placed in the Depository of Unpublished Data.[3]

Results and discussion

Alkane elimination from trimethylgallium and compounds containing active hydrogen has been well documented (9). The reaction of Me_3Ga with 1-hydroxymethylpyrazoles released the expected methane but did not yield the predicted products, "$pzCH_2OGaMe_2$". The reaction of Me_3Ga with 1-hydroxymethylpyrazole yielded an intractable oil. However, the reaction of Me_3Ga with 1-hydroxymethyl-3,5-dimethylpyrazole did yield a characterizable product. The crystal structure determination revealed an arrangement in which two "Me_2Ga" moieties are bridged by a 3,5-dimethylpyrazolyl fragment and an OH group (see Fig. 2). The structure is completed by a hydrogen-bonded 1-hydroxymethyl-3,5-dimethylpyrazole molecule. Evidently facile loss of the —CH_2OH group from a molecule of the starting pyrazole compound has occurred, a phenomenon well documented in a recent publication (8). The present structure can be compared with that of an earlier complex, $Me_2Ga(\mu\text{-}OH)(\mu\text{-}Me_2pz)GaMe_2 \cdot 2Me_2pzH$ (22), the primary difference between the two being the involvement of the μ-OH group of the previous complex in two hydrogen bonds, one to each of

[2]The computer programs used include locally written programs for data processing and locally modified versions of the following: AGNOST, absorption corrections, by J. A. Ibers; ORFLS, full-matrix least-squares, and ORFFE, function and errors, by W. R. Busing, K. O. Martin and H. A. Levy; FORDAP, Patterson and Fourier syntheses, by A. Zalkin; ORTEP II, illustrations, by C. K. Johnson.

[a]Temperature 295 K, Enraf-Nonius CAD4-F diffractometer, Cu-K_α radiation ($\lambda_{K\alpha_1}$ = 1.540562, $\lambda_{K\alpha_2}$ = 1.544390 Å), nickel filter, takeoff angle 2.7°, aperture (2.0 + tan θ) × 4.0 mm at a distance of 173 mm from the crystal, scan range extended by 25% on both sides for background measurement $\sigma^2(I) = C + 2B + [0.04(C - B)]^2$ (C = scan count, B = normalized background count), function minimized: $\Sigma w(|F_o| - |F_c|)^2$ where $w = 1/\sigma^2(F)$, $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$, $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$, $S = (\Sigma w(|F_o| - |F_c|)^2/(m - n))^{1/2}$. Values given for R, R_w, and S are based on those reflections with $I \geq 3\sigma(I)$.

the two Me_2pzH solvate molecules. In $Me_2Ga(\mu\text{-}OH)(\mu\text{-}Me_2pz)GaMe_2 \cdot HOCH_2Me_2pz$ the μ-OH group is hydrogen bonded only to the oxygen atom of the $HOCH_2Me_2pz$ molecule (O(1)—H(O1)···O(2), H···O = 2.03(6), O···O = 2.754(6) Å, O—H···O = 156(6)°). These 1:1 molecular complexes form well-separated dimeric units via O—H···N hydrogen-bonding of pairs of $HOCH_2Me_2pz$ molecules across centres of symmetry (O(2)—H(O2)···N(4)($-x$, $1 - y$, $1 - z$), H···N = 2.00(5), O···N = 2.721(7) Å, O—H···N = 165(6)°). The μ-OH group in the present structure acts only as a hydrogen bond donor while that in the earlier complex functions as both a donor and an acceptor. The Ga—O bonds are shorter and the Ga—N and Ga—C bonds longer in $Me_2Ga(\mu\text{-}OH)(\mu\text{-}Me_2pz)GaMe_2 \cdot HOCH_2Me_2pz$; respective mean[4] values of 1.918(11), 2.001(5), and 1.955(5) Å compared with corresponding values of 1.934(2), 1.989(6), and 1.948(8) Å for the bis(3,5-dimethylpyrazole) solvate. The five-membered Ga_2ON_2 ring has a flattened and twisted O-envelope conformation (see Table 5) similar to that noted previously (22). The Ga···Ga distance of 3.307(1) Å is slightly shorter than the earlier value of 3.316(1) Å. The pyrazolyl rings are both planar to within experimental error.

The successful synthesis of the ligand Na^+L^- is reflected in the subsequent incorporation of the ligand into a number of transition metal complexes. Thus reaction of Na^+L^- with $[Re(CO)_4Cl]_2$ resulted in a good yield of the rhenium tricarbonyl product, $[Me_2Ga(pz)(OCH_2pz)]Re(CO)_3$. The occurrence of three strong ν_{CO} bands in the ir spectrum and the ^{1}H nmr pattern (see Fig. 1) for this complex indicated that the tridentate organogallate ligand is *facially* coordinated. *Meridional* coordination would lead to a single peak for the $GaMe_2$ protons (2 signals are observed) and a singlet for the —CH_2— protons (an AB quartet is observed) in the ^{1}H nmr spectrum. In addition, for a *mer* coordination the ir spectrum should show two weak ν_{CO} bands and one strong ν_{CO} band. The analogous $LMn(CO)_3$ complex has been synthesized and the spectroscopic results again indicate quite clearly an octahedral arrangement of the ligating atoms about the transition metal with a *facial* coordination of the L^- ligand and concomitantly of the three CO groups.

The reaction of Ni(NO)I with Na^+L^- yielded a dark blue crystalline product characterized as LNi(NO). The room temperature solution ^{1}H nmr spectrum of the complex indicates a *mer* coordination of L^- in a square-planar arrangement about the Ni centre, the fourth coordination site being occupied by the NO group. Thus the ^{1}H nmr spectrum gives singlets for both the —$GaMe_2$ and —CH_2— protons, a pattern inconsistent with a *fac* coordination for the ligand. However, a square-planar Ni centre is unlikely in the light of previous studies which have shown that square-planar $\{MNO\}^{10}$ complexes should have an M—N—O bond angle of 120° (23, 24) which is contrary to the linear M—N—O group suggested by the ν_{NO} value of

[4]Here and elsewhere in this report mean values refer to weighted means with rms deviations from the mean in parentheses.

1793 cm^{-1} recorded for the LNi(NO) complex. In addition, previous studies on related complexes have established that even though room temperature ^1H nmr data indicate square-planar NiNO complexes, these are in fact tetrahedral Ni species undergoing fluxional processes at ambient temperatures (14, 25–27).

The reaction of the Na^+L^- ligand with anhydrous $NiBr_2$ in THF resulted in the isolation of purple and blue crystalline forms of the L_2Ni complex together with a small amount of the previously characterized $[Me_2Gapz_2]_2Ni$ complex (15, 16). The X-ray crystal structure of the purple crystals has been determined (Fig. 3) and confirms the arrangement of the tridentate ligands which are *facially* coordinated in the monomeric pseudo-octahedral complex. The crystal structure of *fac*-L_2Ni consists of discrete molecules separated by normal van der Waals distances. Unlike the symmetric all-*trans*

isomer observed for the related molecule *fac*-$[Me_2Ga(pz)(OCH_2CH_2NH_2)]_2Ni$ (28), *fac*-L_2Ni exists in the solid state as an all-*cis* isomer. High steric strain is noted for the NiOCNN chelate rings, evidenced by small angles at Ni and differences of 30° or more between the Ni—N—N and Ni—N—C angles. The Ni—N bonds in these highly strained chelate rings are significantly longer than those in the less-strained NiOGaNN chelate rings. There is one Ni—O bond *trans* to each type of pyrazolyl ligand, that opposite the more strained Ni—N bond being 0.009(4) Å shorter than the other. The mean Ni—O distance of 1.923(6) Å is significantly shorter than the corresponding values of 2.086(2) and 2.040(4) Å in *fac*- and *mer*-$[Me_2Ga(pz)OCH_2CH_2NH_2)]_2Ni$ (28) and 2.049(3) Å in *mer*-$[Me_2Ga(pz)(OC_6H_4NH_2)]_2Ni$ (29), which all have the oxygen donors *trans* to one another. A structural *trans* effect is noted for the Ni—N bonds: those *trans* to O are longer (by 0.019(6) and 0.011(6) Å for the less and more strained types, respectively) than those *trans* to N. The Ni—N distances of 2.030(4) and 2.049(4) Å in the NiOGaNN chelate rings of *fac*-L_2Ni may be compared with corresponding distances of 2.057(5)–2.098(4) Å (mean 2.08(2) Å) in the above-mentioned related molecules (28, 29). Other details of the molecular geometry (Tables 3–5) are normal.

We speculate that the blue crystals probably contain *meridionally* coordinated ligands as was shown in the crystal structure of the blue form of the analogous complex $[Me_2Ga(pz)(OCH_2CH_2NH_2)]_2Ni$. The purple form of this compound was shown to have *facially* coordinated tridentate ligands (28).

XI-ZHANG FENG, YING-TING XU, and PENG-NIAN SUN. Can. J. Chem. **66**, 109 (1988).

This paper presents the variation of coordination bond lengths in lanthanide complexes as a balance between van der Waals and coordination bond energies. Each coordination atom moves in a unified potential well that is a combination of the Morse potential of its coordination bond and the van der Waals potentials of its neighboring coordination atoms. This is termed the Unified Model of coordination bond length.

XI-ZHANG FENG, YING-TING XU et PENG-NIAN SUN. Can. J. Chem. **66**, 109 (1988).

Dans ce travail, on présente la variation des longueurs des liaisons de coordination dans des complexes de lanthanides qui est due à une balance entre les énergies de van der Waals et les énergies des liaisons de coordination. Chaque atome de coordination se déplace dans un puits de potentiel unifié qui est la combinaison du potentiel de Morse de sa liaison de coordination et les potentiels de van der Waals de ses atomes de coordination voisins. Ceci est le modèle unifié de la longueur des liaisons de coordination.

[Traduit par la revue]

I. Introduction

An analysis of the crystal structure of about 280 lanthanide and actinide complexes (1) shows that the coordination bond lengths vary appreciably. Even bond lengths from two identical coordination atoms of two identical ligands to the central metal ion are significantly different. For instance, in $Ln(C_2H_5SO_4)_3 \cdot 9H_2O$ (Ln represents the trivalent cations of 14 rare earth elements) (2), each metal ion is coordinated with the nine water molecules to form nine Ln—O coordination bonds. Six of them are identical and shorter, three of them are identical but longer, and the difference in bond lengths is far outside the experimental error. This phenomenon, resulting from the balance between van der Waals and coordination bond energies, merits extensive study. We propose the Unified Model of coordination bond length to explain this phenomenon.

II. Theory

The total potential appropriate to a given system may be considered as a sum of several potentials. In the present paper, for each coordination atom, a unified potential well that is a combination of the Morse potential of its coordination bond and the van der Waals (Lennard–Jones) potentials of its neighboring coordination atoms is sufficient to describe its motion.

If the bond length of a coordination atom k is $|\vec{R}| = R$ and that of its neighboring coordination atom i is $|\vec{R}_i| = R_i$ ($i = 1, 2, \ldots$), and the angle between $\vec{R}$ and $\vec{R}_i$ is θ_i, then the distance between k and i is

$$[1] \quad r_i = (R^2 + R_i^2 - 2RR_i \cos\theta_i)^{1/2}$$

the Morse potential at k is

$$[2] \quad V(R) = V_0\{\exp[-2(R - R_0)/a] - 2\exp[-(R - R_0)/a]\}$$

the sum of the van der Waals potentials at k is

$$[3] \quad \sum_i U_i(R) = \sum_i 4E_j\left[\left(\frac{r_{0j}}{r_i}\right)^{12} - \left(\frac{r_{0j}}{r_i}\right)^{6}\right]$$

and the unified potential at k is

$$[4] \quad V_T(R) = V(R) + \sum_i U_i(R)$$

where j represents the kind of coordination atom, V_0 and E_j are the energy parameters, r_{0j} and R_0 are the length parameters, and a is the width of the Morse potential. Because k is in its ground state, $V_T(R)$ is very near its minimum. Therefore, due to the effect of van der Waals potentials, the bond length of k is perturbed slightly from R_0 to R. This is the essence of the Unified Model of coordination bond length. By studying $V_T(R)$, we can also obtain the ratio between V_0 and E_j, and the value of a.

III. Analysis of experimental data

Using $Lu(C_2H_5SO_4)_3 \cdot 9H_2O$ as an example, we see that the central metal ion is coordinated with nine oxygen (j) atoms from nine water molecules. From the results of our Packing Model calculations (1), we choose the minimum van der Waals potential ($-E_j$) at a separating distance (r_{min}) of about twice the van der Waals radius of the oxygen atom, i.e., 2.800 Å, and r_{0j} = 2.4945 Å. We choose one oxygen atom k with a longer bond length whose R = 2.497 Å (long bond). The atom k has four neighboring oxygen coordination atoms with R_i = 2.318 Å (i = 1, 2, 3, 4; short bonds), $\theta_1 = \theta_2 = 66.1785°$ and $\theta_3 = \theta_4 = 72.5943°$. In order to minimize $V_T(R)$ with the condition of having both a unique a and a unique V_0, we use the following procedure. Choose $R_0 = R_i$ (the effect of van der Waals potentials on R_i is expected to be small) and θ_i to remain constant. Then, by using eqs. [1], [2], [3], and [4], we obtain $V_T(R)$, $V_T(R + 0.01$ Å), and $V_T(R - 0.01$ Å). If a = 0.10 Å is used, $V_0 = 1.068E_j$ is obtained from $V_T(R) = V_T(R + 0.01$ Å), and $V_0 = 1.070E_j$ is obtained from $V_T(R) = V_T(R - 0.01$ Å). If a = 0.09 Å is used, $V_0 = 1.139E_j$ is obtained from $V_T(R) =$

Tm	2.816	0.10	0.9	0.850
Er	2.824	0.10	0.9	0.849
Ho	2.832	0.10	0.9	0.847
Dy	2.840	0.10	0.9	0.846
Tb	2.850	0.10	0.8	0.844
Gd	2.864	0.09	0.8	0.840
Eu	2.878	0.09	0.7	0.840
Sm	2.892	0.09	0.7	0.839
Nd	2.920	0.09	0.7	0.838
Pr	2.928	0.09	0.7	0.839
Ce	2.952	0.09	0.7	0.834
La	2.980	0.09	0.7	0.833

$V_T(R + 0.01$ Å), and $V_0 = 1.126E_j$ is obtained from $V_T(R) = V_T(R - 0.01$ Å). Therefore, the results $a = 0.10$ Å and $V_0 = 1.1E_j$ are found.

To check the effect of van der Waals potentials on R_i, we have carried out the same analysis for the short bond. The bond angle between two neighboring short bonds is 75.3123°. Each short bond has two long bonds and two short bonds as its neighbors. The result is that when $R_0 = 2.315$ Å, V_T of the short bond reaches a minimum. The long bond is analyzed again with $R_0 = 2.315$ Å. The same results, $a = 0.10$ Å and $V_0 = 1.1E_j$, are obtained. In view of the symmetry of the molecule, three long bonds are identical and six short bonds are identical. Therefore, the whole analysis is self-consistent and complete.

The analysis of all fourteen $Ln(C_2H_5SO_4)_3 \cdot 9H_2O$ compounds shows that r_{min} increases slightly as the atomic number Z of the lanthanides decreases. The results are summarized in Table 1.

The lengths of both long and short bonds increase, their differences decrease, and thus the errors of the calculated results increase, all as the atomic number Z of Ln decreases. Generally, the errors are between ±5% and ±20%.

IV. Discussion

1. A plot of the short Ln—O bond lengths of the fourteen $Ln(C_2H_5SO_4)_3 \cdot 9H_2O$ compounds against the ionic radii of 14 lanthanide (3+) ions is a straight line. If the normal bond length is equal to the sum of the ionic radii of the lanthanides ion and oxygen (2−), then the ionic radius of oxygen (2−) is 1.29 Å, which is close to the literature value of 1.32 Å (see ref. 2). Therefore, the short bond lengths are normal bond lengths and the long bonds are elongated due to the balance between the van der Waals and the coordination bond energies.

2. Table 1 shows that V_0 decreases from $1.1E_j$ to $0.7E_j$, a decreases from 0.10 to 0.09 Å, and r_{min} increases from 2.800 to 2.980 Å as Z of Ln decreases from 71 to 57. This is in accordance with what we would have expected from the lanthanide contraction.

3. V_c is close to E_j. This is an important character of weak coordination bonds.

4. The solid angle factor sums (SAS) (1) in Table 1 are calculated by setting the van der Waals radius to be $\frac{1}{2}r_{min}$. They are between 0.855 and 0.833 and are all located within the packing saturation region. These results are closer to one another than those between 0.854 and 0.739, which would have been obtained had a constant $r_{min} = 2.800$ Å been used. The magnitudes of their solid angle factor vector sums ($|\Sigma\vec{S}\vec{A}\vec{F}|$) (1) are all equal to zero. Thus, all results are in agreement with the packing saturation rule and the uniform packing rule of the Packing Model (1).

5. The phenomena of packing saturation and uniform packing are the direct results of V_0 being close to E_j in complex compounds of the lanthanides and actinides. Therefore, the balance between van der Waals and coordination bond energies is the foundation of the Packing Model.

6. The Unified Model of the coordination bond length explains the difference between the bond lengths of the oxygen coordination bonds in each of the fourteen $Ln(C_2H_5SO_4)_3 \cdot 9H_2O$ compounds, which was not explained before.

Studies on density, viscosity, dielectric constant, and refractive index of binary mixtures of esters in benzene and carbon tetrachloride

SHANTILAL OSWAL
Department of Chemistry, South Gujarat University, Surat – 395 007, India

Received May 27, 1986[1]

SHANTILAL OSWAL. Can. J. Chem. **66**, 111 (1988).

Densities, viscosities, dielectric constants, and refractive indices have been determined for six binary mixtures of propyl acetate, butyl acetate, and ethyl butyrate in benzene and carbon tetrachloride at different mole fractions and temperatures. The excess volumes V^E, apparent excess values of viscosity $\delta\eta$, excess Gibbs energy of activation of flow ΔG^{*E}, excess molar polarizations P_m^E, excess molar refraction R_m^E, and excess dielectric constants ϵ^E have been calculated from the experimental data. The results for these binary mixtures are compared with those of ethyl acetate with benzene, carbon tetrachloride, and cyclohexane and of propyl acetate, butyl acetate, and ethyl butyrate with cyclohexane. The results for V^E, ΔG^{*E}, P_m^E, and ϵ^E indicate specific molecular interaction between unlike molecules in ester + benzene and ester + carbon tetrachloride. The specific molecular interaction for mixtures of esters with benzene may be due to n–π complex formation between the free electrons of carboxylic group and aromatic ring while with carbon tetrachloride it may be due to dipole – induced dipole interactions. The molar refractions for all six mixtures vary linearly with mole fraction of components. Comparison between experimental excess volume V^E and excess viscosity $\Delta \ln \eta$ and that calculated from Flory theory for ethyl acetate + benzene and ethyl acetate + carbon tetrachloride has also been made.

SHANTILAL OSWAL. Can. J. Chem. **66**, 111 (1988).

Opérant à diverses fractions molaires et à diverses températures, on a déterminé les densités, les viscosités, les constantes diélectriques et les indices de réfraction de six mélanges binaires d'acétate de propyle, d'acétate de butyle et de butyrate d'éthyle dans le benzène et le tétrachlorure de carbone. À partir de ces données expérimentales, on a calculé les volumes en excès, V^E, les valeurs apparentes d'excès de viscosité, $\delta\eta$, les énergies de Gibbs en excès pour l'activation de l'écoulement, ΔG^{*E}, les polarisations molaires en excès, P_m^E, les réfractions molaires en excès, R_m^E et les constantes diélectriques en excès, ϵ^E. On a comparé les résultats obtenus avec ces mélanges binaires avec ceux obtenus pour l'acétate d'éthyle dans le benzène, le tétrachlorure de carbone et le cyclohexane ainsi que pour l'acétate de propyle, l'acétate de butyle et le butyrate d'éthyle dans le cyclohexane. Les valeurs des V^E, ΔG^{*E}, P_m^E et ϵ^E suggèrent qu'il existe des interactions moléculaires specifiques entre les molécules qui ne sont pas semblables dans les mélanges ester + benzène et ester + tétrachlorure de carbone. Il est possible que les interactions moléculaires spécifiques observées dans les mélanges d'esters + benzène soient dues à des interactions dipôle – dipôle induit. Les réfractions molaires des six mélanges varient d'une façon linéaire avec les fractions molaires des composants. On a aussi fait une comparaison entre les valeurs expérimentales des volumes en excès, V^E, et des viscosités en excès, $\Delta \ln \eta$, et les valeurs calculées par la théorie de Flory pour l'acétate d'éthyle + benzène et pour l'acétate d'éthyle + tétrachlorure de carbone.

[Traduit par la revue]

Introduction

We are engaged in a systematic study of the thermodynamic, dielectric, and transport properties of binary mixtures of esters with various solvents. We have determined excess volumes, molar polarizations, molar refractions, viscosities, and excess Gibbs energy of activation of flow for ethyl acetate (EA) in cyclohexane, benzene, toluene, ethylbenzene, *p*-xylene, carbon tetrachloride, chloroform, and *p*-dioxane (1–5). It is found that specific interactions are present between ethyl acetate and aromatic hydrocarbons; and between ethyl acetate and carbon tetrachloride. These observations are in agreement with the findings of Loiseleur, Merlin, and Paris (6), Grolier, Ballet, and Viallard (7), and Dusart, Grolier, and Viallard (8) from the study of excess volumes and excess enthalpies of such mixtures. Studies on viscosities (9), excess volumes (9), and excess enthalpies (10, 11) have been reported for binary mixtures of propyl acetate (PA), butyl acetate (BA), and ethyl butyrate (EB) with cyclohexane, whereas no such work seems to exist for mixtures of these esters with benzene and carbon tetrachloride.

In this paper, I report the densities, viscosities, dielectric constants, and refractive indices for six binary mixtures of PA, BA, and EB with benzene and carbon tetrachloride at different mole fractions. From the experimental results the excess volumes V^E, apparent excess values of the viscosity $\delta\eta$, excess Gibbs energy of activation of flow ΔG^{*E}, excess molar polarizations P_m^E, excess molar refractions R_m^E, and excess dielectric constants ϵ^E have been calculated using appropriate relations. A comparison between experimental excess volume V^E and excess viscosity $\Delta \ln \eta$ and those evaluated from Flory theory (12) has also been made.

[1]Revision received August 18, 1987.

Experimental

Densities were determined with single stem pycnometer, having a bulb volume of about 11 cm^3 and capillary of internal diameter of 1 mm. Viscosities were determined with a modified Ubbelohde Viscometer calibrated with doubly distilled water and benzene. Dielectric constants were measured using modified Toshniwal Dipolemeter (Type RL09) which operates at 300 kHz. Refractive indices for the sodium D line of the pure components and of the mixtures were measured with Abbe's research refractometer. The details of the apparatus and procedures have been described in earlier papers (1–3). In these determinations both pycnometer and viscometer were suspended vertically for sufficient time in constant temperature bath maintained within ±0.02 K. The temperature for dielectric constant and refractive index measurements was maintained within ±0.05 K by a circulating water thermostat. The temperatures were read with certified thermometers. All the weighings were made on a monopan analytical balance (MERA-WAG-GDANSK, Poland) accurate to 0.1 mg. Densities, viscosities, dielectric constants, and refractive indices are accurate to ±0.0001, ±0.003, ±0.004, and ±0.0002 units, respectively.

Materials and solutions

Propyl acetate (Fluka AG), butyl acetate (Sarabhai GR), and ethyl butyrate (Fluka AG) were dried over potassium carbonate for 15 days

and were fractionally distilled (13). Benzene (BDH Analar) and carbon tetrachloride (BDH, spectroscopic) were of the same origin and purity as in ref. 3. Mixtures were prepared by weighing the liquids in ground stoppered weighing bottles, taking due precautions to minimise evaporation.

Results

The measured densities ρ and viscosities η at 303.15 and 313.15 K; dielectric constants ϵ and refractive indices n_D at 303.15 K for pure components and for binary mixtures: PA + C_6H_6, EB + C_6H_6, PA + CCl_4, BA + CCl_4, and EB + CCl_4 and densities, viscosities, dielectric constants, and refractive indices at 308.15 K for BA + C_6H_6, over entire range of mole fractions were measured.[2] The values of properties ρ, η, ϵ and n_D of pure liquids are in agreement with those available in the literature (13).

The values of the excess volume V^E, the apparent excess value of the viscosity $\delta\eta$, and the excess Gibbs energy of activation of flow ΔG^{*E} were calculated from the experimental data with the following equations (14)[2]

$$[1] \quad V = (x_1M_1 + x_2M_2)/\rho$$

$$[2] \quad V^E = V - (x_1V_1^0 + x_2V_2^0)$$

$$[3] \quad \delta\eta = \eta - (x_1\eta_1^0 + x_2\eta_2^0)$$

$$[4] \quad \Delta G^{*E} = RT[\ln \eta V - (x_1 \ln \eta_1^0 V_1^0 + x_2 \ln \eta_2^0 V_2^0)]$$

where ρ, η, and V are the density, viscosity, and molar volume of the mixture, M_1 and M_2 are the molar masses, η_1^0 and η_2^0 the viscosities, V_1^0 and V_2^0 the molar volumes, x_1 and x_2 the mole fractions of the first and second component, respectively. It is preferred to define $\eta - x_1\eta_1^0 - x_2\eta_2^0$ as the apparent excess value of viscosity $\delta\eta$ instead of excess viscosity η^E (15, 16) as it does not represent true excess function as per the definitions of excess functions (17).

The molar polarization P_m, the molar refraction R_m, the excess molar polarization P_m^E, and the excess dielectric constants ϵ^E were obtained from the following expressions from [5] to [8]:

$$[5] \quad P_m = V(\epsilon - 1)/(\epsilon + 2)$$

$$[6] \quad R_m = V(n_D^2 - 1)/(n_D^2 + 2)$$

$$[7] \quad P_m^E = P_m - (x_1P_{m,1}^0 + x_2P_{m,2}^0)$$

$$[8] \quad \epsilon^E = \epsilon - (\theta_1\epsilon_1^0 + \theta_2\epsilon_2^0)$$

where ϵ and n_D are the dielectric constant and refractive index of the mixture, $P_{m,1}^0$ and $P_{m,2}^0$ are the molar polarizations, ϵ_1^0 and ϵ_2^0 the dielectric constants, and θ_1 and θ_2 the dielectric fractions of the first and second component, respectively. The dielectric fraction $\theta_1 = 1 - \theta_2$ is given by eq. [9] as shown earlier (4)

$$[9] \quad \theta_1 = \frac{x_1V_1^0/(\epsilon_1^0 + 2)}{x_1V_1^0/(\epsilon_1^0 + 2) + x_2V_2^0/(\epsilon_2^0 + 2)}$$

The excess quantities Y^E (V^E, $\delta\eta$, ΔG^{*E}, P_m^E, and ϵ^E) over the entire range of composition have been fitted to empirical equation [10]

$$[10] \quad Y^E = x_1x_2 \sum_{i=0}^{3} A_i(x_1 - x_2)^i$$

The coefficients A_i of these fitting equations together with the standard deviations σ are summarized in Table 1.

It seems that there are no literature data on densities, viscosities, dielectric constants, refractive indices, and other derived excess properties of these binary mixtures with which the present data can be compared. Figures 1, 2, and 3 show the dependence of the values of V^E, ΔG^{*E}, and P_m^E on x_2 at 303.15 K for these mixtures.

Discussion

For the analysis of results the experimental values of V^E, ΔG^{*E}, P_m^E, and ϵ^E for binary mixtures of EA, PA, BA, and EB with C_6H_6 and CCl_4 at equimolar composition are summarised in Table 2. A close examination of Table 2 and Figs. 1 to 3 yields the following information.

Values of V^E for ester + C_6H_6 and ester + CCl_4 series are very small and decrease in the order: EA > PA > BA > EB. Values of V^E for ester + C_6H_6 mixtures are greater than those of corresponding ester + CCl_4 mixture. Thus by increasing —CH_2— group in the aliphatic chains of esters, V^E of their mixtures with C_6H_6 and CCl_4 regularly decreases. The results obtained indicated similarity to the behaviour of esters mixed with n-C_7H_{16} and c-C_6H_{12} (7, 9). The decrease in V^E from ethyl acetate through butyl acetate is apparently due to a weakening of the molecular interactions in the pure esters by the aliphatic chains of the esters. It is interesting to compare results of mixtures of alkyl alkanoates in C_6H_6, CCl_4, c-C_6H_{12}, and n-C_7H_{16} with those of ethyl acetate in n-alkanes and benzene in n-alkanes (n-hexane through n-dodecane). The values of V^E increase with the increase in chain length of n-alkanes (7, 18) but decrease with the increase in chain length of esters. Hence, —CH_2— group in the presence of —COO— group contributes differently to V^E than that in n-alkanes.

Values of $\delta\eta$ are small and negative for all the mixtures, the highest value of $\delta\eta$ is for EB + C_6H_6 ($\delta\eta = -0.012$ cP at 313.15 K) and lowest for EA + CCl_4 ($\delta\eta = -0.060$ cP at 303.15 K). The values of $\delta\eta$ increase with the increase in temperature for all these mixtures. It indicates that in these binary mixtures, the forces between pairs of unlike molecules are a little less than the forces between pairs of like molecules and that is why the mixture is less viscous.

Values of ΔG^{*E} are small and negative for all the mixtures of esters with C_6H_6 and CCl_4. It is observed that as the chain length increases, either in alkyl or alkanoates group in the esters the values of ΔG^{*E} increase for both the series of esters + C_6H_6 and esters + CCl_4, that is to say, the order for ΔG^{*E} values is ethyl < propyl < butyl in alkyl acetates mixtures and acetate < butyrate in ethyl alkanoates. Similar trends were observed by Dusart, Piekarski, and Piekarski (19) and Memmi and Piekarski (9) for esters + n-heptane and esters + cyclohexane, respectively. This effect arises from the varying size ratios of unlike components in the mixtures, as molar volume ratios of ester/C_6H_6 and ester/CCl_4 gradually increase by replacing ethyl acetate either with propyl acetate, butyl acetate, or ethyl butyrate. Similar results were also found for mixtures of trialkylamines + C_6H_6 and trialkylamines + c-C_6H_{12} (20). Present results are also consistent with the finding that the difference in the sizes of two unlike components in the binary mixture makes positive contribution to the values of ΔG^{*E}.

The values of V^E, $\delta\eta$, and ΔG^{*E} for esters with C_6H_6 and CCl_4 show relatively small deviations from ideal values, suggesting that either the different contributions arising from the mixing of the components are small or that opposite

contributions largely balance each other (21). It is interesting to compare present results of V^E, $\Delta\eta$, and ΔG^{*E} for mixtures of esters in C_6H_6 or CCl_4 with those of corresponding esters in c-C_6H_{12} (1, 3, 8, 9). The values of V^E for EA, PA, BA, and EB with c-C_6H_{12} are large and positive in the range 0.8 to 1.2 cm^3 mol^{-1} and the values of ΔG^{*E} are large and negative in the range −375 to −510 J mol^{-1} which are attributable to strong ester–ester interaction through dipole–dipole interaction and dispersion interaction between ester + c-C_6H_{12}. In the mixtures of esters with C_6H_6 and with CCl_4, these large contribution to V^E and ΔG^{*E} are reduced too much. This suggests that the specific molecular interactions between unlike molecules are

present. The specific interaction in mixtures of esters with C_6H_6 may be due to the formation of n–π complex between the free electrons of the carboxylic group and those of the aromatic ring. On the other hand, specific interaction with CCl_4 mixtures may be due to dipole – induced dipole interaction because of high polarizability of CCl_4 molecule. The similar conclusions were reached after analyzing available H^E results of these mixtures (6–8, 10, 11).

The values of P_m^E and ϵ^E are positive for all the mixtures investigated. From P_m of the mixtures the molar polarization P_1 of ester was determined in the manner described by Earp and Glasstone (22) using the relation $P_m = x_1P_1 + x_2P_2$. The polarization P_2 of the other component (C_6H_6 or CCl_4) is assumed to be equal to that in the pure liquid state and to remain constant throughout. When the molar polarization P_1 of ester in mixtures of C_6H_6 or CCl_4 was plotted against its mole fraction, a definite increase in P_1 at high dilution was observed and it was much greater than that of ester mixtures in c-C_6H_{12}. This exaltation of polarization further supports the specific interaction of esters with C_6H_6 and CCl_4. Earp and Glasstone (22) suggested that such results indicate formation of new coordinate link joining the two molecules. In this case the oxygen atom of esters acts as a donor while C_6H_6 and CCl_4 act as acceptors.

The molar refractions R_m calculated by eq. [6] are close to

those calculated from the mole fraction mixture rule, the slight differences may be attributed to the experimental error. This is to be expected as per Clausius–Mosotti theory, that the molar refraction represents the true volume of the matter in a mole (23).

Flory theory

A further comparison between experimental excess volume V^E and excess viscosity $\Delta \ln \eta$ and that calculated theoretically from Flory theory (12, 24–26) has been made for representative mixtures EA + C_6H_6 and EA + CCl_4. Excess viscosity $\Delta \ln \eta$ is obtained from the experimental viscosity of mixture and pure components through eq. [11]

$$[11]\quad \Delta \ln \eta = \ln \eta - (x_1 \ln \eta_1^0 + x_2 \ln \eta_2^0)$$

Following the Flory theory and original notations (12, 26), excess enthalpy H^E, excess entropy S^E, excess volume V^E, and excess viscosity $\Delta \ln \eta$ are given by

$$[12]\quad H^E = x_1P_1^*V_1^*(\tilde{v}_1^{-1} - \tilde{v}^{-1}) + x_2P_2^*V_2^*(\tilde{v}_2^{-1} - \tilde{v}^{-1}) + x_1\theta_2V_1^*X_{12}\tilde{v}^{-1}$$

$$[13]\quad S^E = -\frac{3x_1P_1^*V_1^*}{T_1^*}\ln\left(\frac{\tilde{v}_1^{1/3}-1}{\tilde{v}^{1/3}-1}\right) - \frac{3x_2P_2^*V_2^*}{T_2^*}\ln\left(\frac{\tilde{v}_2^{1/3}-1}{\tilde{v}^{1/3}-1}\right)$$

$$[14]\quad V^E = (\tilde{v} - \phi_1\tilde{v}_1 - \phi_2\tilde{v}_2)(x_1V_1^* + x_2V_2^*)$$

$$[15]\quad \Delta \ln \eta = -\frac{H^E}{RT} + \frac{S^E}{R} + \left\{\frac{1}{\tilde{v}-1} - \left(\frac{x_1}{\tilde{v}_1-1} + \frac{x_2}{\tilde{v}_2-1}\right)\right\}$$

or

$$[16]\quad \Delta \ln \eta = \ln \eta_H + \ln \eta_S + \ln \eta_{f.v.}$$

Equations [15] and [16] were developed by Bloomfield and Dewan (26). ln η_H, ln η_S, and ln $\eta_{f.v.}$ are the enthalpy, entropy, and free volume contributions, respectively, to the total excess viscosity $\Delta \ln \eta$. The equation of state parameters of pure liquids needed in the use of Flory theory are given in Table 3. Contact interaction parameter X_{12} is obtained from experimental H^E (12). The values of H^E, X_{12}, V^E_{cal}, δV^E ($= V^E_{exp} - V^E_{cal}$), ln η_H, ln η_S, ln $\eta_{f.v.}$, $\Delta \ln \eta_{cal}$, $\Delta \ln \eta_{exp}$, and δ ($= \Delta \ln \eta_{exp} - \Delta \ln \eta_{cal}$) are summarised in Table 4.

The differences 0.013 and 0.130 cm^3 mol^{-1} for EA + C_6H_6 and EA + CCl_4, respectively, between experimental V^E and that calculated from Flory theory are not very large. A perfect prediction of V^E for these mixtures would be somewhat surprising with such a simple van der Waals model for energy. A better agreement may be obtained by taking into account the order in pure ethyl acetate due to dipole–dipole interaction which is destroyed by the presence of C_6H_6 or CCl_4 molecules in the mixture.

A very good agreement between the experimental $\Delta \ln \eta$ and that calculated from Flory theory is obtained for EA + C_6H_6 and EA + CCl_4. The values of ln η_H and ln $\nu_{f.v.}$ contributions are small and negative while ln η_S is small and positive for EA + C_6H_6. The values of ln η_H and ln η_S contributions for EA + CCl_4 reflect that specific interactions are stronger in it than that in EA + C_6H_6.

Comparison of present results with those of EA + c-C_6H_{12} throws some more light on order, disorder, and specific molecular interactions which are operating in these mixtures. There is a large difference ($\delta = 0.333$) between the values of experimental excess viscosity and that predicted by Flory theory for EA + c-C_6H_{12}. This large positive difference for EA + c-C_6H_{12} is attributable to the effect of disorder (deorientation) which occurs due to the breaking of order in ester dipoles by the presence of c-C_6H_{12} molecules as suggested by Delmas, Purves, Saint Romain (27). Therefore, it can be safely said that in case of mixtures EA + C_6H_6 and EA + CCl_4, the effect of disorder of esters molecules is counter balanced by the formation of complex between unlike molecules due to specific interactions, thus leading to a very good agreement between the experiment and theory.

PETER K. L. CHAN, PAUL K. H. CHAN, DAVID C. FROST, BRIAN R. JAMES, and KIRSTEN A. SKOV. Can. J. Chem. **66**, 117 (1988).

A series of ruthenium(II) complexes of formulation $RuCl_2(dmso)_2L_n$, where dmso = S-bonded dimethylsulfoxide, L is a 4-nitroimidazole derivative, and n = 1 or 2, have been synthesized and characterized by spectroscopic methods, particularly ^1H nmr and X-ray photoelectron spectroscopy. With L = 4-nitroimidazole itself (4-NO_2Im), RSU-1170,[2] -3083 or -3100, n = 2 and the six-coordinate complexes are considered to be of *cis,cis,cis*-geometry. The *N*-methyl-4-nitroimidazole (NMe-4-NO_2Im) ligand (n = 1) chelates through the imidazole-*N* and the oxygen of NO_2. The RSU-3159 ligand (n = 1) binds through the sulfur and may be chelated. The complexes are of interest because of their radiosensitizer properties toward hypoxic tumour cells; the $RuCl_2(dmso)_2$(NMe-4-NO_2Im) complex has a higher sensitizing enhancement ratio than the free imidazole ligand, and shows no cytoxicity *in vitro*, and these data are compared to those reported previously for $RuCl_2(dmso)_2$(4-NO_2Im)$_2$. Some aspects of the aqueous solution chemistry of the complexes (aquation via loss of chloride, pK_a of coordinated water) are discussed in relation to their biological activities.

PETER K. L. CHAN, PAUL K. H. CHAN, DAVID C. FROST, BRIAN R. JAMES et KIRSTEN A. SKOV. Can. J. Chem. **66**, 117 (1988).

On a synthétisé une série de complexes du ruthénium(II), $RuCl_2(dmso)_2L_n$, dans lesquels dmso = diméthylsulfoxyde lié par le S, L = un dérivé nitro-4 imidazole et n = 1 ou 2; de plus, on les a caractérisés par des méthodes spectroscopiques, en particulier par rmn du ^1H et par spectroscopie photoélectronique des rayons-X. Lorsque L = nitro-4 imidazole (4-NO_2Im), RSU-1170,[2] -3083 ou -3100, n = 2 et on considère que les complexes hexacoordonnés possèdent la géométrie *cis,cis,cis*. Le ligand *N*-méthyl nitro-4 imidazole (NMe-4-NO_2Im) (n = 1) se chélate par le biais du N de l'imidazole et le O du NO_2. Le ligand RSU-3159 (n = 1) se lie par le soufre et il est possible qu'il soit chélaté. Les complexes sont intéressants à cause de leurs propriétés comme radiosensibilisateurs par rapport aux cellules tumorales hypoxiques. Le complexe de $RuCl_2(dmso)_2$(NMe-4-NO_2Im) possède un caractère sensibilisateur qui est plus élevé que celui du ligand imidazole libre et il ne présente aucune cytotoxicité *in vitro*; de plus, on compare ces données avec celles rapportées antérieurement pour le $RuCl_2(dmso)_2$(4-NO_2Im)$_2$. On discute de quelques aspects de la chimie en solution aqueuse de ces complexes (aquation par le biais d'une perte de chlorure et pK_a de l'eau qui est coordonnée) en relation avec leurs activités biologiques.

[Traduit par la revue]

Introduction

Many tumours contain cells which are low in dioxygen content (hypoxic) and consequently are relatively resistant to radiation treatment (1). This radioresistance may be significantly reduced through the identification of chemical radiosensitizers which enhance radiation-induced damage. Classic radiosensitizers are the so-called "electron-affinic" agents such as nitroimidazoles (2) and nitrofurans (3). The rationale is that the electron-affinic nitro group may mimic dioxygen (which is known to interact with damage on DNA induced by radiation) and lead to effective treatment (4). However, maximum sensitization cannot be achieved owing to the serious side-effects of the nitro-compound drugs (5).

Studies on DNA as a radiation target may well lead to the development of new species having radiosensitizing and DNA-binding properties. In this regard, attachment of a radiosensitizer to metals that bind to DNA may be of value. As a consequence of binding to DNA, the metal could act as a carrier, increase the local concentration of radiosensitizer at the target, and thus decrease the deleterious side-effects (6). In this respect, the strong binding of ruthenium to purine and pyrimidine bases (7) and their anti-neoplastic activity (8) suggested that ruthenium complexes containing known radiosensitizers could have interesting biological properties.

We have recently assessed the radiosensitizing ability of some ruthenium(II) complexes of nitroimidazoles (9, 10), and shown that $RuCl_2(dmso)_2$(4-nitroimidazole)$_2$, **1**, has a good sensitizing enhancement ratio (SER = 1.6) in hypoxic Chinese hamster ovary (CHO) cells (SER is defined as the ratio of X-ray doses between hypoxic control and drug at 1% cell survival), and also gives low genotoxicity (11).

In the present study, we report details on the synthesis, characterization, and solution chemistry of complex **1**, as well as related work on other Ru(II) complexes containing a range of 4-nitroimidazoles. Their biological properties are also reported on briefly. The general formula of the species can be represented as $RuCl_2(dmso)_2L_n$, where dmso = S-bonded dimethylsulfoxide, L is a 4-nitroimidazole (Fig. 1), and n = 1 or 2. In the absence of X-ray structural data, X-ray photoelectron spectroscopy (XPS) (12–15) has been particularly useful in elucidation of the structures of the complexes.

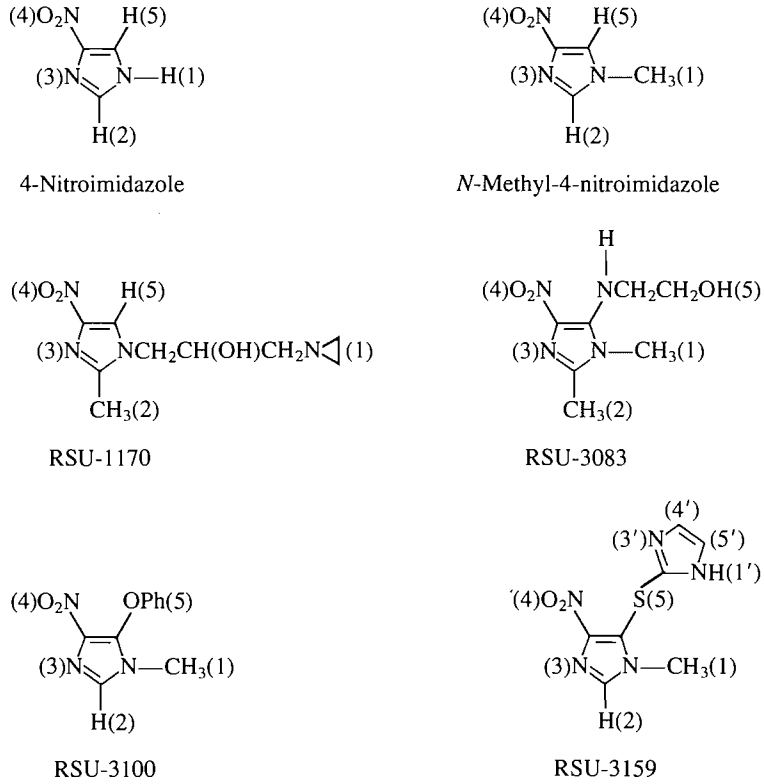

FIG. 1 Structure formulae and numbering scheme for the 4-nitroimidazole ligands.

Experimental section

Chemicals and complexes

$RuCl_3 \cdot 3H_2O$ was received on loan from Johnson Matthey Ltd. and 4-nitroimidazole (4-NO_2Im) was purchased from Sigma. Of the nitroimidazole ligands (Fig. 1), RSU-1170, RSU-3100, and RSU-3159 were kindly supplied by Dr. T. C. Jenkins,[2] and RSU-3083 by Dr. I. J. Stratford.[2] All these chemicals were used without further purification. All other common reagents were at least reagent grade. The precursor complex *cis*-$RuCl_2(dmso)_4$, which contains one O-bonded and three S-bonded sulfoxides (16), was prepared by a literature procedure (17), as was *N*-methyl-4-nitroimidazole, NMe-4-NO_2Im (18).

*$RuCl_2(dmso)_2$(4-NO_2Im)$_2$, **1***. Dry MeOH (15 mL) was added to $RuCl_2(dmso)_4$ (483 mg, 1 mmol) and 4-NO_2Im (382 mg, 2.5 mmol), and the mixture refluxed for 4 h under N_2. The resulting brown solution was cooled to room temperature and diethylether (40 mL) added slowly to precipitate out a brown product, which was filtered off, washed with acetone and diethylether, and dried *in vacuo* at room temperature (65% yield). *Anal.* calcd. for $C_{10}H_{18}O_6N_6S_2Cl_2Ru$: C 21.66, H 3.25, N 15.16; found: C 22.0, H 3.1, N 15.4. Ultraviolet/visible, see text. Infrared (Nujol): ν_{SO} 1127, 1090, ν_{NO_2} 1559, 1535 cm^{-1}.

*$RuCl_2(dmso)_2$(NMe-4-NO_2Im), **2***. The complex $RuCl_2(dmso)_4$ (483 mg, 1 mmol) was suspended in an isopropanol solution (20 mL) of NMe-4-NO_2Im (254 mg, 2 mmol), and the mixture refluxed for 4 h under N_2. The resulting blue solution was cooled to RT, when a blue precipitate formed. This was collected, dissolved in CH_2Cl_2 (10 mL), reprecipitated with diethylether (20 mL), and dried *in vacuo* at room temperature (80% yield). *Anal.* calcd. for $C_8H_{17}O_4N_3S_2Cl_2Ru$: C 21.06, H 3.73, N 9.22; found: C 21.0, H 3.9, N 9.25. λ_{max} nm (log ϵ), H_2O: 303(4.32), 427(3.06). Infrared (Nujol): ν_{SO} 1112, 1085, ν_{NO_2} 1543, 1523 cm^{-1}.

*$RuCl_2(dmso)_2$(RSU-1170)$_2$, **3***. The nitroimidazole (226 mg, 1 mmol) was mixed with $RuCl_2(dmso)_4$ (242 mg, 0.5 mmol) in dry MeOH (10 mL), and the mixture refluxed for 4 h under N_2. The resulting green solution was cooled to RT, and diethylether (30 mL) added slowly to precipitate out a green product, which was filtered off, washed with acetone, and dried *in vacuo* at room temperature (65% yield). *Anal.* calcd. for $C_{22}H_{40}O_8N_8S_2Cl_2Ru$: C 33.85, H 5.13, N 14.35; found: C 33.5, H 5.4, N 13.9. λ_{max} nm (log ϵ), H_2O: 310(4.39). Infrared (Nujol): ν_{SO} 1123, 1087, ν_{NO_2} 1560, 1522 cm^{-1}.

*$RuCl_2(dmso)_2$(RSU-3083)$_2$, **4***. The compound RSU-3083 (200 mg, 1 mmol) was added to $RuCl_2(dmso)_4$ (242 mg, 0.5 mmol) in dry EtOH (10 mL), and the mixture refluxed for 4 h under N_2. The resulting red solution was cooled to RT and filtered; slow addition of diethylether (30 mL) yielded a red solid, that was filtered off, washed with EtOH and acetone, and dried *in vacuo* at room temperature (70% yield). *Anal.* calcd. for $C_{16}H_{36}O_8N_8S_2Cl_2Ru$: C 29.67, H 4.98, N 15.37; found: C 29.3, H 4.6, N 15.7. λ_{max} nm (log ϵ), H_2O: 385(4.40), 450(4.12). Infrared (Nujol): ν_{SO} 1167, 1086, ν_{NO_2} 1627, 1599 cm^{-1}.

*$RuCl_2(dmso)_2$(RSU-3100)$_2$, **5***. The complex $RuCl_2(dmso)_4$ (242 mg, 0.5 mmol) was suspended in an isopropanol (10 mL) solution of RSU-3100 (219 mg, 1 mmol), and the mixture refluxed for 6 h under N_2. The resulting brown solution yielded a brown product as in the synthesis of **1** (65% yield). *Anal.* calcd. for $C_{22}H_{30}O_8N_6S_2Cl_2Ru$: C 37.58, H 3.92, N 10.96; found: C 37.7, H 4.3, N 10.7. λ_{max} nm (log ϵ), H_2O: 350(4.13), 396(4.09). Infrared (Nujol): ν_{SO} 1137, 1091, ν_{NO_2} 1614, 1583 cm^{-1}.

*$RuCl_2(dmso)_2$(RSU-3159), **6***. The complex $RuCl_2(dmso)_4$ (242 mg, 0.5 mmol) was added to RSU-3159 (225 mg, 1 mmol) in MeOH (15 mL), and the mixture refluxed for 3 h under N_2. The resulting dark green solution was filtered hot, and diethylether (30 mL) added slowly to the cooled filtrate to precipitate a green solid; this was filtered off, washed with acetone and diethylether, and dried *in vacuo* at room temperature (75% yield). *Anal.* calcd. for $C_{11}H_{19}O_4N_5S_3Cl_2Ru$: C 23.87, H 3.46, N 12.65; found: C 24.1, H 3.8, N 12.5. λ_{max} nm (log ϵ), H_2O: 325(4.22). Infrared (Nujol): ν_{SO} 1125, 1085, ν_{NO_2} 1684, 1653 cm^{-1}.

Microanalyses were performed by Mr. P. Borda of the Department of Chemistry, UBC.

Physical techniques and methods

Optical spectra were recorded on a Perkin Elmer 552A, and infrared (KI discs or Nujol nulls) on a Nicolet DX FTIR; ^1H and $^{13}C\{^1H\}$ nmr

For personal use only.

spectra (in $CDCl_3$ wrt TMS) were recorded on a Varian XL-300 operating in the Fourier transform mode. Conductivities were measured in water using a Beckman Serfass Conductance Bridge. pH-titrations were carried out in aqueous media under N_2 using a Corning 12 pH-meter using a combination glass-electrode: typically, 25 mL of aq. HCl (2 m*M*) in the absence and presence of added complex (2 m*M*), was titrated with standard 4 m*M* NaOH solution — differences between the two titration curves allow for a simple determination of pK_a values (19).

XPS spectra were taken on a Varian IEE-15 spectrometer, at a background pressure $< 10^{-7}$ Torr, using MgK_α radiation (1253.60 eV) at 280 W and an analyzer pass energy of 100 eV. Resolution was 1.6 eV at full width half maximum on Au($4f_{7/2}$). Each sample was lightly dusted onto single-sided 3M scotch tape and introduced into the spectrometer on a rapid insertion probe cooled by liquid N_2. All binding energies (BE) were calibrated with reference to the C_{1s} peak (284.0 eV) of graphite. There was no evidence for any sample deterioration during irradiation.

Results and discussions

Complexes of formulation $RuCl_2(dmso)_2L_2$ (L = 4-NO_2Im, RSU-1170, RSU-3083, and RSU-3100) and $RuCl_2(dmso)_2L$ (L = NMe-4-NO_2Im and RSU-3159) are readily synthesized from the precursor complex *cis*-$RuCl_2(dmso)_4$, of known structure (16), by substitution of two sulfoxide ligands. The XPS, ^{1}H nmr and ir data (see below) are consistent with the diamagnetic, hexacoordinate products (**1**, **3**–**5**) having a purely *cis* structure (i.e. *cis*,*cis*,*cis*), with both dmso ligands being S-bonded. The syntheses proceed via reaction [1]:

[1] 
(O or S implies oxygen- or sulfur-bonded dmso)

Complex **2** of formulation $RuCl_2(dmso)_2L$ is again hexacoordinate, L binding via an imidazole nitrogen, and oxygen of the NO_2 group; the S-bonded dmso ligands may be *trans*. Complex **6**, $RuCl_2(dmso)_2$(RSU-3159), has S-bonded dmso ligands and a coordinated thioether of RSU-3159, this ligand probably being chelated via the nitrogen of the NMe group.

X-ray photoelectron spectroscopy data

XPS can be used for determining bonding configurations because the technique detects changes in the electronic environment of an atom, as evidenced by shifts in the BE of core electrons. Data for N, O, Cl and S atoms within complexes **1**, **2**, **6**, and *cis*-$RuCl_2(dmso)_4$, and for some of the free ligands, are summarized in Table 1. Coordination of imidazole ligands via the tertiary nitrogen N(3) is well established for metal ions, including Ru(II) (20–22), and the XPS and ^{1}H nmr data (see below) are consistent with this. The shift to higher BE for all the N atoms present in **1** and **2**, compared to the energies within the free ligands, indicates delocalization of electrons within the systems; in the free ligands 4-NO_2Im and NMe-4-NO_2Im, N(3), adjacent to the electron-withdrawing NO_2 group, will have a

For personal use only.

binding energy higher than that of N(1), and in the complex the coordinated N(3) might be expected to have an even higher BE, although d^6, low-spin Ru(II) has a quite remarkable π-donor ability toward unsaturated N-atom donors (22). The perhaps greater shift to higher BE for N(3) of **2** (0.8 eV) as compared to **1** (0.5 eV) would be consistent with chelation (and therefore further loss of electron density) via an oxygen of NO_2. Stronger evidence for coordinated nitrito is provided by the doublet seen for the O 1*s* of the NO_2 group. This is not seen for **1** where the corresponding O 1*s* BE is the same as that of the free ligand. The 531.70 and 530.80 eV BE's for O in **2** are assigned to the coordinated and uncoordinated (23) oxygens, respectively. Chelating ligands utilizing a nitrito moiety are uncommon (24), and we are unaware of any other examples involving nitroimidazole ligands. On comparison of the N 1*s* and O 1*s* BE's of 4-NO_2Im and NMe-4NO_2Im, the lower values for the latter reflect the electron-donating properties of the methyl group which likely promote the chelation (25). The possibility of **2** being a chloride-bridged dimer with monodentate imidazole ligands is ruled out by the Cl $2p_{1/2,3/2}$ datum which is essentially identical to that for *cis*-$RuCl_2(dmso)_4$ (this is also true for complexes **1** and **6**).

Of interest, *cis*-$RuCl_2(dmso)_4$ shows two O 1*s* (and two S $2p_{1/2,3/2}$ peaks) in an intensity ratio of about 3:1, entirely consistent with structural data for the complex (16), see eq. [1]. The corresponding O 1*s* and S $2p_{1/2,3/2}$ data available for **1** and **2** (and **6**), on comparison with those for *cis*-$RuCl_2(dmso)_4$, reveal the presence of only sulfur-bonded dmso ligands in these complexes. Previous work using XPS to distinguish O- and S-bonded dmso ligands has generally been less definitive (26).

The BE for the S $2p_{1/2,3/2}$ level of the thioether sulfur atom of RSU-3159 (163.0 eV) is increased by 1.2 eV within **6**, strongly implying coordination via this sulfur; models suggest that chelation of RSU-3159 via the lone pair of N(1), the methylated nitrogen is plausible. However, the N 1*s* BE data for **6** (and for **4**) are insufficiently resolved to give information about binding to a nitrogen; ^{1}H nmr data (see below) provide some support for the chelation.

Nuclear magnetic resonance and infrared data

^{1}H nmr and ir spectroscopy have been widely used to distinguish between O- and S-bonded sulfoxide ligands, especially in Ru(II) complexes (17, 26–29). The Me protons of free dmso occur at δ 2.60, while those for O- and S-bonded dmso are found at δ ~2.7 and ~3.2–3.5, respectively; ν_{SO} for free dmso is seen at 1050 cm^{-1}, while coordination via O decreases this by about 100 cm^{-1} and coordination via S increases the value by about 40–100 cm^{-1}.

The ir data for all the complexes **1–6** (see Experimental) reveal ν_{SO} bands in both the 1085–1091 and 1112–1167 cm^{-1} regions, consistent with S-bonded dmso ligands. All the free nitroimidazole ligands reveal ir bands at about 1560–1565 and at 1545–1550 cm^{-1}, attributable to asymmetric and symmetric ν_{NO_2}, respectively (30). Values within complex **2**, 1543 and 1523 cm^{-1}, are both some 20 cm^{-1} lower than the free ligand values, presumably reflecting the coordinated nitrito group. Changes in ν_{NO_2} on coordination of the other nitroimidazoles are smaller. A 2815 cm^{-1} band of free NMe-4-NO_2Im (attributed to $\nu_{NCH_2—H}$) is found at 2800 cm^{-1} within **2**, while corresponding bands at 2724, 2730, and 2724 cm^{-1} for complexes **4–6**, respectively, are ~10 cm^{-1} lower than that found in the free ligands; the data provide no support for chelation of RSU-3159 via N(1) within **6**. Bands due to $\nu_{Ru—Cl}$ are not assigned because of uncertainty in the multi-band far-ir region. Even for *cis*-$RuCl_2(dmso)_4$, only one band at 344 cm^{-1} has been definitely assigned (31), and there are certainly bands in this region for complexes **1–6**.

Table 2 lists the relevant ^{1}H nmr data. Data for *cis*-$RuCl_2(dmso)_4$, discussed previously (17, 29, 31), are complex because of formation of isomers from dissolution of the complex that initially has three S- and one O-bonded dmso ligands (eq. [1]), but resonances at δ 2.60 and 2.73 are due to free and O-dmso, while the group of peaks at δ 3.3–3.5 results from S-dmso. Corresponding data for **1–6** show only S-bonded dmso: there is no dissociation of dmso in $CDCl_3$ solution, and even in D_2O **1** generates no free dmso. Oxygen-bonded dmso is known to be labile, relative to S-bonded dmso (26), and this has been demonstrated for *cis*-$RuCl_2(dmso)_4$ (17, 29, 31); thus, as seen in eq. [1], substitution of O-bonded dmso and a S-bonded dmso *cis* to it (necessarily so for the chelating ligand NMe-4-NO_2Im) would lead to the *cis,cis,cis*-geometry of the product. The presence of four major, equal intensity resonances, these occurring as partly resolved multiplets centred at the shifts listed in Table 2, for complexes **1**, and **3–5**, reveals inequivalent Me groups for each of the two inequivalent dmso ligands, and only the low symmetry all *cis*-structure of 6-coordinate complexes can give rise to such an nmr pattern (29). A model of **1** shows that free rotation about the Ru—S bonds for *cis*-dmso ligands is restricted because of steric interaction between methyl groups, but this is not a requirement for the magnetic inequivalence of the methyls (29). Proton decoupling experiments did simplify the observed multiplet patterns of the methyls, but this provided no further information on the structures. For the chelated complex **2**, the two Me resonances (again of equal intensity) are consistent with *trans* dmso ligands (and thus *cis*-chlorides) (29). The presence of four Me resonances within **6** is again consistent with a chelated 6-coordinate complex with *cis* arrangements for both chloride and dmso ligands.

On comparison with the free imidazole ligands, the H(2) and H(5) resonances in the complexes are generally shifted slightly to lower field, although the effects are more marked for **2**, presumably resulting from the chelation. Similar small shifts have been observed with other imidazole and *N*-methylimidazole complexes of, for example, Ru(II) (22) and Pt(II) (33). The somewhat larger downfield shift (0.13 ppm) for the NMe protons of RSU-3159 on coordination, and a surprising upfield shift of 0.28 ppm for H-2, provide evidence for interaction of the Ru(II) with the nitroimidazole ring, presumably via the nitrogen of the NMe. Thus, together with the ESCA data, the nmr data suggest formation of a five-membered chelate ring through the sulfur and nitrogen.

The $^{13}C\{^1H\}$ nmr spectrum of **1** shows four peaks for the inequivalent methyls (δ 35.40, 36.63, 44.77, 45.13) and imidazole carbons at 112.69 (C-2), 116.48 (C-5), and 120.49 (C-4). For **2**, consistent with the ^{1}H nmr, two ^{13}C shifts were seen at δ 38.13 and 45.02 for the methyls of the two equivalent dmso ligands; other assigned peaks were 112.41 (C-2), 116.18 (C-5), 119.94 (C-4), and 122.24 (N-Me).

Considerable efforts to grow suitable crystals of any of the complexes have thus far proved fruitless.

Aqueous solution chemistry

On dissolution in water under N_2, complex **1**, $RuCl_2(dmso)_2(4\text{-}NO_2Im)_2$, instantly gives a molar conductivity (100.8 ohm^{-1} mol^{-1} cm^2) corresponding to a 1:1 electrolyte (34), that results from loss of a single chloride ligand; no further chloride loss occurs over 2*d*. Further, the resulting solution

TABLE 2. Selected ^{1}H nmr chemical shifts for the Ru(II) compounds and free ligands[a]

Compound[b]	H-2[c]	H-5[c]	NMe[c]	Me(dmso)

[a] δ in ppm wrt TMS, in $CDCl_3$ at room temperature. In each case the integrations are consistent with the assignment.
[b] As for Table 1.
[c] Shift values given in parentheses are for the free nitroimidazole ligand.
[d] Values are in good agreement with literature data (17, 29).
[e] 4-NO_2Im was dissolved in $CDCl_3$ with 5% CF_3CO_2H; the NH protons are not seen because of proton exchange. Values agree well with literature data (32).
[f] Values agree well with literature data (32).
[g] Shift values for 4′ and 5′ protons are 7.05(7.02).

is weakly acidic, implying loss of a proton from coordinated water. Standard pH-titration experiments (19) yield data that analyze well for a pK_a value of 4.10 ± 0.10:

$$[2]\quad \mathbf{1} \xrightarrow[+H_2O]{-Cl^-} \underset{\mathbf{1}b}{[RuCl(H_2O)(dmso)_2(4\text{-}NO_2Im)_2]^+} \rightleftharpoons \underset{\mathbf{1}c}{RuCl(OH)(dmso)_2(4\text{-}NO_2Im)_2} + H^+$$

The pK_a value seems resonable for H_2O coordinated at a Ru(II) centre (35). A second proton loss measured at higher pH (pK_a = 8.90 ± 0.10) is attributed to loss of the pyrrolic-N hydrogen to form coordinated 4-nitroimidazolate; a corresponding value for imidazole itself within $Ru(NH_3)_5(imidazole)^{2+}$ is also 8.90 (22). A uv/vis spectrum recorded for **1** at pH 7.0 (λ_{max} 338 nm, log ε = 4.63) thus refers to species **1***c*; minor differences are noted at pH 3.0 (species **1***b*, λ_{max} 343 nm) and at similar acidity in the presence of added Cl^- (0.1 *M*) (species **1**, λ_{max} 345 nm)). Titration with base of the other complexes **2–6** shows no titratable protons are present at least up to pH ~ 11 and consistent with this, molar conductivity values measured within 10 min of dissolution are much lower (15.5–37.4), showing little replacement of Cl^- ligand by H_2O. Ultraviolet/visible spectra for **2–6** (see Experimental) are dominated by charge transfer bands in the 300–450 nm region, and offer little insight into the coordination geometry.

Clearly, the aqueous solution chemistry of the complexes is germane for an understanding of their biological properties. Of the complexes **1–6** synthesized thus far, only **1** demonstrates high lability according to eq. [2].

Biological activities

The techniques used for determination of SER values in hypoxic CHO cells, toxicity, and DNA binding capabilities, as well as reduction potentials for the complexes and ligands, are not given in the Experimental section, because they have been described in detail previously for complex **1** elsewhere (9, 10). Identical procedures were used to test **2–6**.

Both **1** and **2** have increased SER values and reduced toxicity properties compared to the free nitroimidazole ligands for CHO cells *in vitro*, the SER value for **1**, 1.6 at 2×10^{-4} *M* (9), being higher than that for **2** (1.35) at corresponding conditions. SER values for **3–6**, and the corresponding free nitroimidazole ligands are lower, 1.20 ± 0.1 (10), implying marginal effect. Further, of all the complexes, only **1** binds to DNA, as tested for by a DNA-binding enzyme inhibition assay (9, 10).

Binding of a nitroimidazole ligand to a metal centre results in an increase in reduction potential *of the ligand*, i.e., increases electron affinity, a property often correlated with effectiveness of radiosensitizer ability (2, 9, 10, 36). For **1**, this increase in potential (in H_2O vs. SCE) is ~70 mV (from −685 to −615 mV (9)), but for the other complexes the increase is ≤20 mV (10) and the corresponding potentials are significantly higher (−560 to −370 mV). Clearly then, all the properties of complex **1** (including lability) are "different" to those of **2–6**.

The better radiosensitizing ability of **1** may depend on some or all of the following factors: (*a*) increased reduction potential of the coordinated 4-NO_2Im ligand, (*b*) hydrolysis to a species capable of binding to DNA, as demonstrated for other Ru(II) species (37), and (*c*) the presence of the pyrrolic proton of imidazole, N—H(1), which could be involved in H-bonding that stabilizes a DNA–Ru interaction — as demonstrated for Pt(II) systems (33, 38, 39). As regards (*a*), a higher reduction potential will certainly favour thermodynamically abstraction of an electron from irradiation-damaged DNA; electron-donor substituents on the nitroimidazole (e.g. the N—CH_3, and the amino and thioether substituents of **4** and **6**, respectively) lower the reduction potentials. The effect of having the —NO_2 substituent coordinated, as in **2**, is less clear.

Physical and structural studies of *N*-substituted-3-hydroxy-2-methyl-4(1*H*)-pyridinones

WILLIAM O. NELSON, TIMOTHY B. KARPISHIN, STEVEN J. RETTIG, AND CHRIS ORVIG[1]

Department of Chemistry, University of British Columbia, 2036 Main Mall, Vancouver, B.C., Canada V6T 1Y6

Received May 15, 1987

WILLIAM O. NELSON, TIMOTHY B. KARPISHIN, STEVEN J. RETTIG, and CHRIS ORVIG. Can. J. Chem. **66**, 123 (1988).

A series of 3-hydroxy-2-methyl-4(1*H*)-pyridinones has been prepared with the substituents H, CH_3, n-C_6H_{11}, and $CH_2CH_2NH_2$ at the ring N. The dipyridinone 1,6-bis(3-hydroxy-2-methyl-4(1*H*)-pyridinon-1-yl)hexane has also been synthesized. The products with H and CH_3 substituents have been studied by single crystal X-ray diffraction. Crystals of 3-hydroxy-2-methyl-4-pyridinone are monoclinic, a = 6.8351(4), b = 10.2249(4), c = 8.6525(4) Å, β = 105.215(4)°, Z = 4, space group $P2_1/n$ and those of 3-hydroxy-1,2-dimethyl-4-pyridinone are orthorhombic, a = 7.3036(4), b = 13.0490(6), c = 13.7681(7) Å, Z = 8, space group *Pbca*. Both structures were solved by direct methods and were refined by full-matrix least-squares procedures to R = 0.037 and 0.044 for 914 and 857 reflections with $I \geq 3\sigma(I)$, respectively. Bond lengths and angles in the two compounds were normal. All the compounds have been studied by mass spectrometry, and by infrared and proton nmr spectroscopies. The importance of hydrogen bonding to both the solution and solid state properties of these compounds has been confirmed by these techniques.

WILLIAM O. NELSON, TIMOTHY B. KARPISHIN, STEVEN J. RETTIG et CHRIS ORVIG. Can. J. Chem. **66**, 123 (1988).

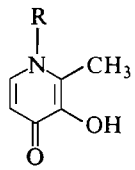
On a préparé une série d'hydroxy-3 méthyl-2 (1*H*)-pyridones-2 portant des substituants H, CH_3, n-C_6H_{11} et $CH_2CH_2NH_2$ sur l'azote du cycle. On a aussi synthétisé la dipyridone bis(hydroxy-3 méthyl-2 (1*H*)-pyridone-4 yl-1)-1,6 hexane. On a fait une étude par diffraction des rayons-X des produits portant des substituants soit H soit CH_3. Les cristaux de l'hydroxy-3 méthyl-2 pyridone-4 sont monocliniques avec a = 6,8351(4), b = 10,2249(4) et c = 8,6525(4) Å, β = 105,215(4)°, Z = 4, et groupe d'espace $P2_1/n$; par ailleurs, ceux de l'hydroxy-3 diméthyl-1,2 pyridone-4 sont orthorhombiques avec a = 7,3036(4), b = 13,0490(6) et c = 13,7681(7) Å, Z = 8 et groupe d'espace *Pbca*. On a résolu les deux structures par des méthodes directes et on les a affinées par la méthode des moindres carrés (matrice entière) jusqu'à des valeurs respectives de R de 0,037 et 0,044 pour 914 et 857 réflexions avec $I \geq 3\sigma(I)$. Les angles et les longueurs des liaisons sont normaux dans chacun des composés. On a étudié tous les composés par spectrométrie de masse ainsi que par infrarouge et par rmn. A l'aide de ces techniques, on a pu confirmer l'importance des liaisons hydrogènes pour les propriétés de ces composés tant en solution qu'à l'état solide.

[Traduit par la revue]

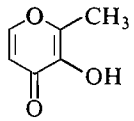
Introduction

There is considerable literature on 4-pyridinones (1) but a limited amount of information is available on the 3-hydroxy-4-pyridinones. Much of the preparative work on the latter is scattered and inaccessible, having been reported in the form of patents, and we discovered when we became interested in them, that a considerable effort was required before we had the requisite compounds for further study.

As part of a project to examine neutral water soluble complexes of aluminum, gallium, and other metals, we have prepared and characterized a series of *N*-substituted-3-hydroxy-2-methyl-4-pyridinones (**1**) to be used as ligands for these metals in aqueous solution. Recently, there has been significant interest in these compounds, and the related pyrones (e.g. maltol **2**), as binding groups for various metal ions. This



1



2

includes our work with Al and Ga (2–4), that of Kontoghiorghes and co-workers (5) with Fe and Pu, and that of Raymond and co-workers who have been extensively involved in the area studying the related 1-hydroxy-2-pyridinones (6–8) and 3-hydroxy-2-pyridinones (8) as sequestering agents for various metal ions including the actinides and iron. There has also been considerable attention focussed on mimosine (a 3-hydroxy-4-pyridinone amino acid derivative with depilatory properties) and its isomers as chelating agents for various divalent (9, 10) and trivalent metals (11).

The reaction of primary amines with 4-pyrones to form *N*-substituted-4-pyridinones has been known for more than eighty years (12). It has been utilized for the preparation of a variety of these pyridinones (1, 12–17), despite the fact that this reaction is somewhat limited in scope, being reliable only for small alkyl (15), and aryl (16, 17) amines. Attempts at *N*-alkylation to synthesize one pyridinone from another sometimes yields a mixture of *N*- and *O*-alkylated products (18). We were particularly interested in a variety of these compounds where there were alkyl or alkylamino substituents in order to prepare Al and Ga complexes with some lipophilicity, but also some water solubility. As a result of the rather unusual hydrogen-bonding observed in some of the Al and Ga complexes (4), we became interested in the preparation, complete characterization, and solid state structures of the 3-hydroxy-4-pyridinones themselves. Herein we report our studies of some of these pyridinones using various physical techniques including single crystal X-ray crystallography.

Experimental

Materials and methods

Melting points were recorded with a Mel-Temp apparatus and are uncorrected. Infrared spectra were determined as KBr pellets in the range 4000–200 cm^{-1} with a Perkin Elmer PE 783 and were referenced to polystyrene film. The proton nmr spectra were recorded in the indicated solvent with one of a Bruker WP-80, Varian XL-300, or Bruker WH-400 instrument. Elemental analyses (C, H, Cl, N) were performed by Mr. Peter Borda of the Microanalytical Laboratory of this Department. Electron impact mass spectra were recorded with a Kratos MS 50 spectrometer.

All chemicals were reagent grade (or better) and were used as received. The starting material 3-benzyloxy-2-methyl-4-pyrone (Bzma)

[a]Temperature 295 K, Enraf-Nonius CAD4-F diffractometer, Cu-K$_\alpha$ radiation ($\lambda_{K\alpha_1}$ = 1.540562, $\lambda_{K\alpha_2}$ = 1.544390 Å), nickel filter, takeoff angle 2.7°, aperture (2.0 + tan θ) × 4.00 mm at a distance of 173 mm from the crystal, scan range extended by 25% on both sides for background measurement, $\sigma^2(I) = C + 2B + [0.04(C - B)]^2$ (C = scan count, B = normalized background count), function minimized: $\Sigma w(|F_o| - |F_c|)^2$ where $w = 1/\sigma^2(F)$, $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$, $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$, $S = (\Sigma w(|F_o| - |F_c|)^2/(m - n))^{1/2}$. Values given for R, R_w, and S are based on those reflections with $I \geq 3\sigma(I)$.

[b]Measured by flotation in aqueous KI.

was made from commercially available (Aldrich) 3-hydroxy-2-methyl-4-pyrone (maltol – Hma) by the method of Harris (19). It is a viscous yellow liquid that is used without further purification (TLC pure). Yield >95%. Water was deionized (Barnstead D8902 and D8904 cartridges) and distilled (Corning MP-1 Megapure still). Thin layer chromatography (TLC) was performed on silica gel plates.

*3-Benzyloxy-2-methyl-4(1*H*)-pyridinone*, Bzmpp. This intermediate is made by the treatment of Bzma with a solution of ammonia in ethanol according to the method of Harris (19). Pale yellow crystals were obtained from ethanol in 60% yield. *Anal.* calcd. for $C_{13}H_{13}NO_2$: C 72.53, H 6.10, N 6.51; found: C 72.71, H 6.07, N 6.49. Melting point: 166–167°C.

*3-Hydroxy-2-methyl-4(1*H*)-pyridinone*, Hmpp. The final product is obtained by acid hydrolysis with HBr in acetic acid (19). The crude product was redissolved in water and brought to pH 7–8 by addition of aqueous ammonia. Chilling produced pale pink single crystals (suitable for X-ray diffraction) in 82% yield. Overall yield (from Hma) was 48%. *Anal.* calcd. for $C_6H_7NO_2$: C 57.57, H 5.65, N 11.24; found: C 57.58, H 5.70, N 11.23. Melting point 263°C dec.

*3-Hydroxy-1,2-dimethyl-4(1*H*)-pyridinone*, Hdpp. To a solution of Bzma (10.0 g, 46.0 mmol) in 50 mL ethanol was added 40% aqueous methylamine (100 mL, 130 mmol) and the mixture was stirred at 25°C for 72 h. The excess amine was removed under reduced pressure and the oily residue was taken up in 100 mL water. The organic phase was extracted into methylene chloride (2 × 100 mL). Removal of solvent in vacuum gave 8.64 g (82% yield) of a pure (TLC) oil (Bzdpp). The benzyl ether was dissolved in THF (50 mL) and subjected to hydrogenolysis under ambient conditions over 5% Pd/C catalyst (1 g) until hydrogen uptake ceased. The solution was filtered and the solid extracted with boiling water (3 × 100 mL). The aqueous solution was concentrated until crystallization commenced and then chilled (15°C) overnight. The product was recrystallized from hot methanol to yield 3.46 g, 65% based on Bzdpp. Single crystals suitable for X-ray diffraction were grown from methanol/ether by a liquid diffusion method (20). The overall yield based on Hma is 51%. *Anal.* calcd. for $C_7H_9NO_2$: C 60.41, H 6.53, N 10.07; found: C 60.45, H 6.49, N 10.00. Melting point 260°C dec.

*3-Hydroxy-2-methyl-1-(β-aminoethyl)-4(1*H*)-pyridinone*, Hmapp·2HCl. To a solution of Bzma (15.0 g, 69.4 mmol) in 100 mL ethanol was added ethylenediamine (21.5 g of a 98% aqueous solution, 351 mmol). After stirring at room temperature overnight, the solvent and excess ethylenediamine were removed under reduced pressure to give an amber coloured oil which was triturated with water to give a pale yellow solid and this was dried at room temperature. The solid was treated with charcoal in THF twice and triturated again to give a white solid. This solid was then treated with 100 mL 6 *M* HCl at room temperature overnight to remove the benzyl group. The acid was removed under reduced pressure and the resulting white solid was washed with methanol to give crude Hmapp·2HCl (3.00 g, 20% yield). Recrystallization was from 6 *M* HCl/ethanol. *Anal.* calcd. for

$C_8H_{14}Cl_2N_2O_2$: C 39.85, H 5.85, Cl 29.41, N 11.62; found: C 39.57, H 5.90, Cl 29.19, N 11.40. Melting point 250°C dec.

3-Hydroxy-2-methyl-1-hexyl-4(1H)-pyridinone, Hmhpp. Bzma (7.1 g, 32.8 mmol) and hexylamine (16.6 g, 164 mmol) were dissolved in 100 mL methanol and left stirring at 25°C for 72 h. The excess amine was removed under vacuum and 100 mL 12 *M* HCl added to the oily residue. After heating on a steambath for 1 h, the excess acid was removed under vacuum. To the residue was added 100 mL water and the pH adjusted to 8 with 2.0 *M* NaOH at which time a precipitate formed. Subsequent sublimation (*in vacuo* at 120°C) of this beige solid gave 3.40 g of a pale yellow powder in an overall yield (from Hma) of 48%. *Anal.* calcd. for $C_{12}H_{19}NO_2$: C 68.87, H 9.15, N 6.69; found: C 68.56, H 9.01, N 6.61. Melting point 123–125°C with slight discoloring.

1,6-Bis(3-hydroxy-2-methyl-4(1H)-pyridinon-1-yl)hexane, H_2exn. Bzma (3.0 g, 14.0 mmol) and 1,6-diaminohexane (8.0 g, 69.0 mmol) were stirred in 25 mL methanol for 2 days at room temperature and the solvents were removed at reduced pressure. The oily residue was treated with 50 mL concentrated HCl and heated for 30 min on a steambath. The acid was then removed by rotary evaporation, the residue dissolved in 50 mL water, and the pH was adjusted to 7–8 with 2 *N* KOH. Crude H_2exn precipitates and the filtrate may be extracted with $CHCl_3$ to increase the yield. The yield is 0.43 g (18% based on Hma). Sublimation (280–300°C at 3×10^{-2} Torr) gave an analytically pure sample. *Anal.* calcd. for $C_{18}H_{24}N_2O_4$: C 65.03, H 7.29, N 8.43; found: C 64.81, H 7.19, N 8.40. Melting point 270°C dec.

X-ray crystallographic analyses

Crystallographic data appear in Table 1. Unit-cell parameters were refined by least-squares on 2 sin θ/λ values for 25 reflections with $2\theta = 70–100°$ for Hmpp and $2\theta = 50–91°$ for Hdpp. The intensities of three standard reflections, measured each hour of X-ray exposure time, showed only small random fluctuations. The data were reduced[2] and corrected for absorption (numerical integration). Both structures were solved by direct methods, the positions of the non-hydrogen atoms being determined from *E*-maps and those of the hydrogen atoms from subsequent difference maps. The non-hydrogen atoms were refined with anisotropic thermal parameters and the hydrogen atoms with isotropic thermal parameters. Neutral atom scattering factors and anomalous dispersion corrections (O, N, and C) were taken from ref. 21. Isotropic type I extinction corrections were applied (22–24), the final values of g being $0.31(8) \times 10^4$ for Hmpp and $0.28(3) \times 10^4$ for Hdpp. Final positional and anisotropic thermal parameters appear in Tables 2 and 8,[2] respectively. Measured and calculated structure factors have been placed in the Depository of Unpublished Data.[3]

The thermal motion in both molecules has been analyzed in terms of rigid-body modes of translation, libration, and screw-motion (25). The rms errors in the temperature factors σU_{ij} (derived from the least-squares analyses) are 0.0008 and 0.0016 Å^2 for Hmpp and Hdpp respectively. Analysis of all non-hydrogen atoms gave physically reasonable results and rms ΔU_{ij} values of 0.0010 Å^2 for Hmpp and 0.0019 Å^2 for Hdpp. The appropriate bond distances have been corrected for libration (25, 26), using shape parameters q^2 of 0.08 for all atoms involved. Corrected bond lengths appear in Table 3 along with the uncorrected values; corrected bond angles do not differ by more than 1σ from the uncorrected values given in Table 4. Bond

lengths and angles involving hydrogen and a complete listing of torsion angles (Tables 9–11) are included as supplementary material.

Results and discussion

It is possible to prepare, in varying yields from benzylated maltol (Bzma), a series of 3-hydroxy-2-methyl-4(1*H*)-pyridinones with a number of different substituents on the ring nitrogen atom. The preparations of Bzma, and its ammoniated deprotected product Hmpp, are analogous to those published by Harris (19). The preparation of Hmpp from Bzma is simpler than that of Hodge and Nelson (27) which involves methyl-protection of the hydroxyl functionality. The synthesis of Hdpp has been reported by the reaction of methylammonium acetate with any of lactose, maltose, maltol, or isomaltol (28). The preparation of Hmapp·2HCl was analogous to that of mimosinamine dihydrochloride (19). The *N*-hexyl species Hmhpp has been reported previously from maltol protected with D-glucose (29). To our knowledge the doubly inserted amine product H_2exn has never been reported. Our interest in a compound of this type arose from a desire to prepare potentially four coordinating ligands based on the 3-hydroxy-4-pyridinone binding group.

The structures of Hmpp and Hdpp were established by single crystal X-ray diffraction. Stereoviews of the two molecules are shown in Fig. 1. Both structures contain centrosymmetric O—H···O=C hydrogen-bonded dimeric units (O(1)—H(O1)···O(2) ($1-x, 1-y, -z$ for Hmpp; $1-x, -y, 1-z$ for Hdpp), H···O = 1.90(3), 1.94(5) Å, O···O = 2.670(2), 2.692(3) Å, O—H···O = 144(3), 154(4)°). Stereodiagrams of the unit cell packing are shown for Hmpp in Fig. 2 and for Hdpp in Fig. 3. In the *N*-substituted compound Hdpp, interleaving dimeric units form stacks of pyridinone rings with interplanar spacings[4] of 3.435 and 3.462 Å along the *a* axis (see Fig. 3). All distances between the H-bonded dimers in Hdpp correspond to normal van der Waals contacts. In Hmpp each dimer is linked to four others by N—H···O=C hydrogen bonds (N—H(N)···O(2) ($x-\frac{1}{2}, \frac{1}{2}-y, \frac{1}{2}+z$), H···O = 1.90(2) Å, N···O = 2.796(2) Å, N—H···O = 166(2)°) to form a three-dimensional network (Fig. 2).

The six-membered rings in both Hmpp and Hdpp are significantly non-planar, maximum deviations from the mean

[4]Calculated as the displacement of the centroid of the neighboring ring from the mean plane of the reference ring.

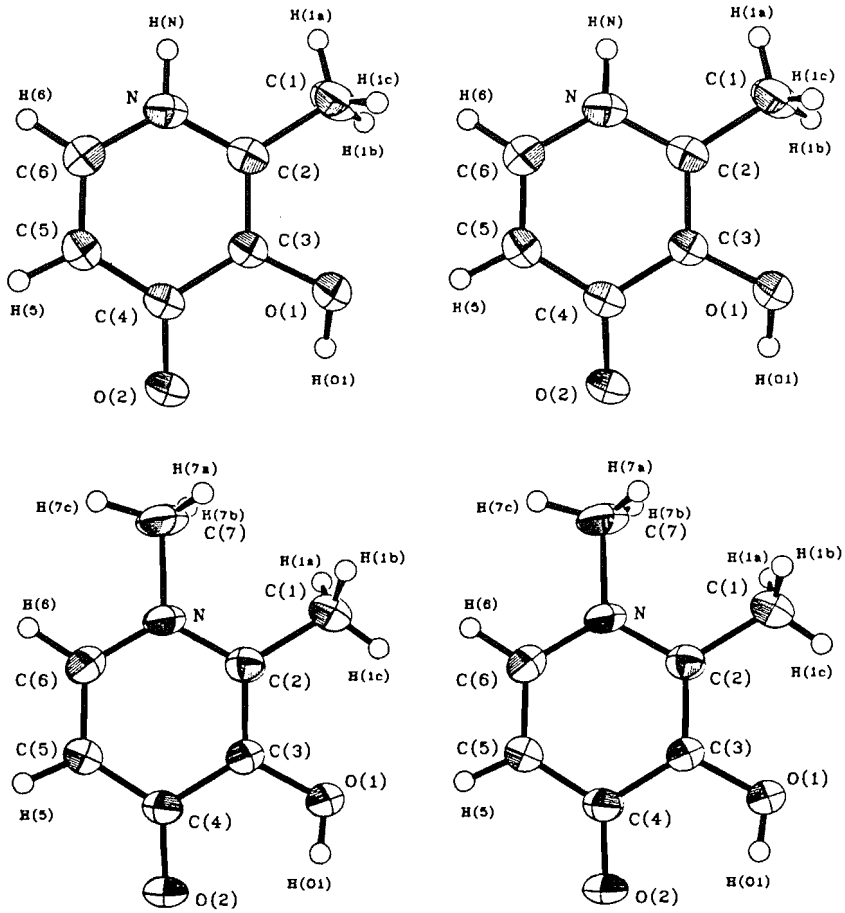

FIG. 1. Stereoscopic views of the Hmpp (top) and Hdpp (bottom) molecules; 50% probability thermal ellipsoids are shown. Hydrogen atoms have been assigned artificially small thermal parameters for the sake of clarity.

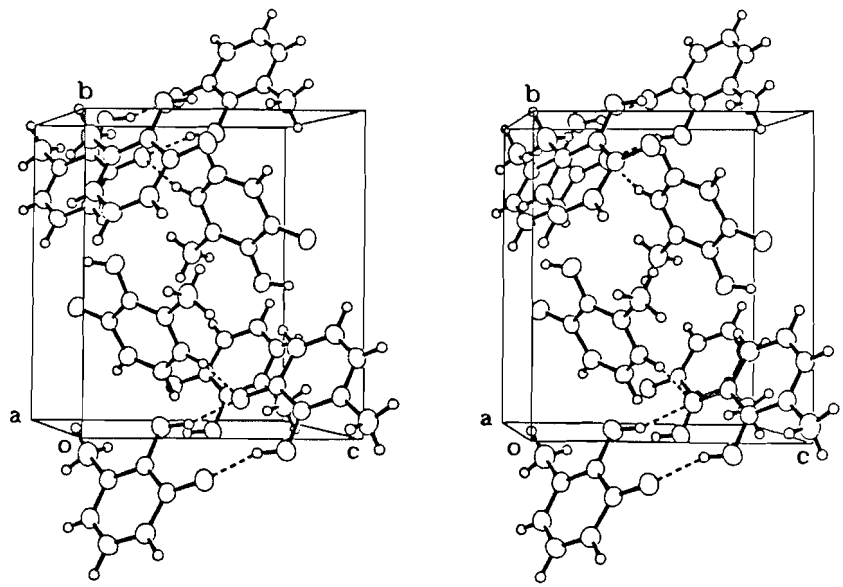

FIG. 2. Stereoscopic view of the packing arrangement in Hmpp.

planes being 0.019(2) Å in the former and 0.009(3) Å in the latter. The distortions from planarity are toward a C(4)-envelope in Hmpp and a C(2), C(5)-boat in Hdpp. Bond lengths and angles in the two compounds are very similar, *N*-methylation resulting in a significantly longer N—C(2) bond and a significantly smaller intra-annular bond angle at nitrogen. The only other significant difference between the two molecules is the O(1)—C(3)—C(4) angle, 1.23(25)° larger in Hmpp than in Hdpp. The nitrogen coordination is planar to within experimental error in both compounds and bond lengths indicate partial delocalization of the formal double bonds. The extent of the delocalization is greater than that observed in the

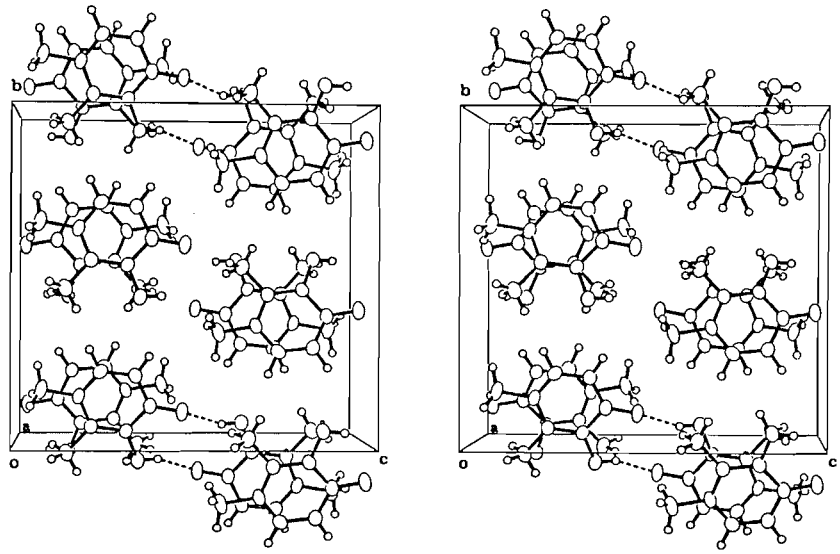

FIG. 3. Stereoscopic view of the packing arrangement in Hdpp.

isoelectronic molecule 4-pyrone (30). The structures of the diphenylboron chelates of the anions derived from Hmpp (mpp^-) and Hdpp (dpp^-) have been compared with that of Hmpp (31). Of note is the fact that in dpp^- complexed to $(Ph)_2B$ a marked bond length alternation is observed, unlike in the free ligands Hmpp and Hdpp or mpp-coordinated in $(Ph)_2B$mpp, all of which only show a slight alternation.

The mass spectra for all the compounds are reproduced in Fig. 4.[3] Some assignments have been made by comparison with the literature on 2-pyridinones because of the scant work available on the 4-pyridinones and their 3-hydroxy congeners (32). The spectrum of Hmpp shows the molecular radical cation $M^{+\cdot}$ as the base peak (m/z 125 (relative intensity = 100)) and peaks due to loss of CO (m/z 97(9)) and loss of HCO$^\cdot$ (m/z 96(47)). The stability of the m/z 125 radical cation is shown by the fact that it occurs in all five spectra and is the base peak in three. It is no doubt a result of the ability of the ring nitrogen to localize positive charge and the great stability of a (di)hydroxypyridinium moiety which should be favored in the gas phase (33). The basic ring fragments exclusively by loss of CO or HCO$^\cdot$ without any loss of HCN or CH_3CN. This is not surprising since there are two CO groups to lose. Loss of CO and HCO$^\cdot$ accounts for the m/z 111(25) and 110(100) peaks, respectively, in the spectrum of Hdpp ($M^{+\cdot}$ = m/z 139).

The H_2exn spectrum has a molecular ion at m/z 332(15) which fragments through loss of one ring (m/z 208(64)) followed by successive losses of methylene moieties (m/z 194(38), 180(8.2), 166(37), and 152(30)). The m/z 139 peak is the $Hdpp^{+\cdot}$ fragment and the subsequent peaks are exactly as previously observed for Hmpp and Hdpp. The spectrum of Hmhpp shows a parent at 209(38) plus the same methylene cascade as in H_2exn and the same 139, 125, 110, and 96 peaks as the other spectra. The Hmapp spectrum has been renormalized to make the m/z 153 peak the base peak since HCl serves that function in the salt. The molecular ion is observed at 168(29) and the new base peak is the loss of a methyl radical (60% relative to HCl). The m/z 126 peak in this spectrum and the others is most likely the 1-methyl-3,4-dihydroxypyridinium cation (from high resolution studies). In short, the ring fragments are dominated by CO loss and the longer chain substituents show the expected fragmentation patterns.

The infrared spectral bands of the five hydroxypyridinone compounds are listed in Table 5; infrared bands in Hmpp and selected analogues are listed in Table 6. These analogues, which were prepared to facilitate the ir assignments, are the dideuterated d_2-Hmpp, the benzyl-protected intermediate Bzmpp, and the aluminum complex $Al(mpp)_3$ (34).

The assignment of νOH in Hmpp is confirmed by Bzmpp where the 3270 cm^{-1} band disappears and by d_2-Hmpp, where it shifts to 2420 cm^{-1}. This gives a $\nu OH/\nu OD$ of 1.35, indicative of a relatively weak H-bond. The theoretical ratio is 1.375 (from the reduced masses) and for free OH it is 1.355 (35). This ratio falls systematically as the strength of the H-bond increases and can reach unity for very short H-bonds (36). A combination of a lower zero point energy for H than D, and a weaker O···D···O than O···H···O interaction explains this low ratio (36). The stretches are indicative of normal polymeric intermolecular hydrogen-bonding systems (37, 38). In Hdpp, the νOH drops further to 3170 cm^{-1}. The suggestion of stronger hydrogen bonding in this compound can be made on consideration of this and the lower νC=O.

The assignment of νNH is again confirmed by Bzmpp, deuteration, and Hdpp: the band is at 2800 cm^{-1} in Hmpp, shifts to 2650 cm^{-1} on benzylation, shifts to 2210–2150 cm^{-1} (split, mean = 2180 cm^{-1}) on deuteration, and finally disappears on methylation. The ratio ($\nu NH/\nu ND$) is 1.28 and splitting of the νND is not without precedent, as it is reported in deuterio-2-pyridinone (39). These authors list a 3100 cm^{-1} band (in KBr) for the protio compound which supports our assignment. They also state that the 2885 cm^{-1} νNH band seen for 2-thiapyridone is the strongest NH H-bonding yet recorded for other than zwitterionic structures. The deuteration ratio for the thiapyridone is 1.29, and the typical N···H···S stretch appears at 3160 cm^{-1}. The packing diagram in Fig. 3 shows that there is considerable N—H···O=C hydrogen-bonding which binds the dimeric units to each other in this compound but not in the N—CH_3 compound Hdpp.

It is impossible to separate the νC=O and the higher energy νring (C=C) stretches in any of the compounds, hence the assignments in Tables 5 and 6. Numerous authors have come to this same conclusion in their considerations of 4-pyridinone and related compounds (40, 41). The bands which do appear are

coupled and there is no mode which is localized in any one of these frequencies (42). There is a reproducible series of four ring stretching modes which appears in many pyridinones (43) and the fact that some of these bands are coupled to νC=O makes individual assignments impossible. Because Hmpp is the only one of the compounds capable of assuming a dihydroxypyridine-type tautomer, the separate modes contributing to each band in this region may be different in Hmpp than in the *N*-substituted compounds.

In the δCH region, weak to medium intensity bands are observed with additional bands for the compounds with *N*-substitution consistent with the presence of additional methyl and methylene groups. There is extensive mechanical coupling of the δOH and νCO modes in the region 1325 to 1235 cm^{-1} (36, 44, 45) and the presence of three bands in metal complexes of these species has been noted (34). Since the assignments in Table 6 for the other compounds are exactly analogous to those for Hmpp and Hdpp, they are given without further discussion. The deuteration and O-substitution studies corroborate the assignments of the infrared spectra of the compounds which we have given here.

The results of the proton nmr spectra are shown in Table 7. All the chemical shifts were recorded on the 400 MHz instrument except those of the NH and OH protons which were from the 80 MHz instrument. Generally, one observed two doublets for the ring protons with $J_{5,6}$ of 7 to 8 Hz, $J_{7,8}$ values of 7 to 8 Hz (when they could be resolved), a singlet for the ring methyl group, and a series of peaks for the R substituent with the OH proton detectable when the spectra were recorded in non-aqueous solution. Both Hmapp and Hmhpp were quite insoluble and these spectra were recorded in acidic solution, hence the absence of resonances for the hydroxyl protons. Samples (Hmpp and analogues, Hdpp, and Hmhpp) and solvents were rigorously dried to allow the observation of the NH/OH peaks. The NH resonance could be assigned based on a peak in Bzmpp at 11.30 ppm in d_6-DMSO and a peak in the spectra of M(mpp)$_3$ very near 12 ppm (M = Al, Ga) (34). Addition of a drop of water to solutions of the complexes resulted in a loss of the 12 ppm peak and the loss of the second order coupling to ^{6}H which appears as a less well resolved doublet in Hmpp and its complexes than in Hdpp or the other compounds. The presence of an NH chemical shift of 12.05 ppm in 2-pyridinone has been taken to suggest that the compound exists as hydrogen-bonded dimers in solution (46) just as it does in the solid state (47). The Hmpp crystal structure clearly shows the N—H···O=C bonds which hold the aggregates of dimers together so the 11.35 ppm shift may suggest that this same bond persists in solution.

The chemical shift of the OH proton is markedly dependent on the concentration of water in the system and also on the concentration of the nmr sample. The variation is considerable (from 6.90 ppm at 0.09 *M* to 5.64 ppm at 0.03 *M*) indicating

that in solution there is considerable intermolecular hydrogen-bonding in Hmpp.

The structural, infrared, and nmr studies show how important hydrogen-bonding is to the properties of the 3-hydroxy-4-pyridinones, a feature which we have observed in their complexes as well. Amine, hydroxl, and ketone functionalities contribute a number of hydrogen-bonding sites to each of the molecules discussed herein and the solution and solid state properties and structures reflect these interactions. Every one of these potential hydrogen-bonding sites is used in the solid state structures and the solution properties suggest that the same situation obtains therein as well.

Structural studies of organoboron compounds. XXVII.[1] (3-Hydroxy-2-methyl-4-pyridinonato)diphenylboron and (3-hydroxy-1,2-dimethyl-4-pyridinonato)diphenylboron

WILLIAM O. NELSON, CHRIS ORVIG, STEVEN J. RETTIG, AND JAMES TROTTER

Department of Chemistry, University of British Columbia, 2036 Main Mall, Vancouver, B.C., Canada V6T 1Y6

Received March 11, 1987

WILLIAM O. NELSON, CHRIS ORVIG, STEVEN J. RETTIG, and JAMES TROTTER. Can. J. Chem. **66**, 132 (1988).

Details of the preparation and crystal structures of the title compounds are given. Crystals of (3-hydroxy-2-methyl-4-pyridinonato)diphenylboron, **1**, are orthorhombic, $a = 13.4010(6)$, $b = 15.005(1)$, $c = 14.833(1)$ Å, $Z = 8$, space group *Pbca*, and those of (3-hydroxy-1,2-dimethyl-4-pyridinonato)diphenylboron, **2**, are monoclinic, $a = 8.2617(5)$, $b = 12.374(1)$, $c = 16.104(1)$ Å, $\beta = 92.741(5)°$, $Z = 4$, space group $P2_1/n$. Both structures were solved by direct methods and were refined by full-matrix least-squares procedures to $R = 0.047$ and 0.071 for 1654 and 1831 reflections with $I \geq 3\sigma(I)$, respectively. Both molecules contain five-membered C_2O_2B chelate rings, that in **2** being nearly planar. Structural data indicate weaker overall binding of the ligand oxygen atoms to boron in **1** than in **2**. Bond lengths (corrected for libration) are O—B = 1.497(5) and 1.650(5), C—B = 1.600(5) and 1.599(5) Å for **1**; O—B = 1.542(5) and 1.569(5), C—B = 1.607(6) and 1.609(6) Å for **2**.

WILLIAM O. NELSON, CHRIS ORVIG, STEVEN J. RETTIG et JAMES TROTTER. Can. J. Chem. **66**, 132 (1988).

On rapporte les détails relatifs à la préparation et à la détermination des structures cristallines des composés mentionnés dans le titre. Le (hydroxy-3 méthyl-2 pyridinonato-4) diphénylbore, **1**, est orthorhombique avec $a = 13,4010(6)$, $b = 15,005(1)$ et $c = 14,833(1)$ Å, $Z = 8$ et groupe d'espace *Pbca*; par ailleurs, ceux du (hydroxy-3 diméthyl-1,2 pyridinonato-4) diphénylbore, **2**, sont monocliniques avec $a = 8,2617(5)$, $b = 12,374(1)$ et $c = 16,104(1)$ Å, $\beta = 92,741(5)°$, $Z = 4$ et groupe d'espace $P2_1/n$. On a résolu les deux structures par des méthodes directes et on les a affinées par la méthode des moindres carrés (matrice entière) jusqu'à des valeurs respectives de R de 0,047 et 0,071 pour 1654 et 1831 réflexions avec $I \geq 3\sigma(I)$. Les deux molécules contiennent chacune des noyaux à cinq chaînons de chélate C_2O_2B; celui que l'on retrouve dans le composé **2** est pratiquement plan. Les données structurales indiquent que, dans l'ensemble, la liaison avec bore des atomes d'oxygène du ligand est plus faible dans le composé **1** que dans le composé **2**. Les longueurs des liaisons (corrigées pour la libration) sont les suivantes : O—B = 1,497(5) et 1,650(5), C—B = 1,600(5) et 1,599(5) Å pour le composé **1**; O—B = 1,542(5) et 1,569(5), C—B = 1,607(6) et 1,609(6) Å pour le composé **2**.

[Traduit par la revue]

Introduction

(Maltolato)diphenylboron ((3-hydroxy-2-methyl-4-pyronato)diphenylboron) was characterized in a previous report (1). It was established that the binding of the maltolate oxygen atoms to boron is weaker than that to aluminum in the neurotoxin tris(maltolato)aluminum (1, 2). In parallel with a study of neutral water-soluble Al and Ga compounds of neurological interest (2, 3) the diphenylboron complexes of the maltol analogs (by replacement of the ring oxygen by NR, R = H and Me) 3-hydroxy-2-methyl-4(1*H*)-pyridinone and 3-hydroxy-1,2-dimethyl-4(1*H*)-pyridinone have been synthesized and their crystal structures determined.

Experimental

(3-Hydroxy-2-methyl-4-pyridinonato)diphenylboron, 1

A solution of diphenylborinic acid was prepared by acid hydrolysis of (2-aminoethanolato)diphenylboron (1.30 g, 5.8 mmol, Aldrich Chemical) and was extracted with diethyl ether (4 × 50 mL). To the organic layer was added a solution of 3-hydroxy-2-methyl-4(1*H*)-pyridinone (0.73 g, 5.8 mmol, prepared according to the literature (4)) in 100 mL methanol. After stirring 1 h and reduction of volume to 100 mL, a white precipitate formed. Overnight cooling at 20°C, filtering and washing with water and ethanol produced 1.43 g (4.9 mmol, 85% yield). Analytically pure compound was obtained by recrystallization from acetone/water, mp (dec.) 225–228°C. *Anal.* calcd. for $C_{18}H_{16}BNO_2$: C 74.76, H 5.59, N 4.85; found: C 74.54, H 5.67, N 4.79. Infrared (KBr, all strong): 3320 cm^{-1} (NH); 1650 (CO); 1590, 1550, 1500 (pyridinone ring). ^1H nmr (d_6-acetone, 25°C, 80 MHz) δ (ppm): 2.50 (s, 3H, CH_3); 6.73 (d, 6.6 Hz, 1H, CHC(O)); 7.25 (m, 10H, 2 C_6H_5); 7.80 (d, 6.6 Hz, 1H, CHC*H*N). Crystals used for the X-ray analysis were obtained by liquid–liquid diffusion (5) from acetone/water.

(3-Hydroxy-1,2-dimethyl-4-pyridinonato)diphenylboron, 2

The procedure is essentially the same as that described above for **1**. A solution of (0.58 g, 4.2 mmol) 3-hydroxy-1,2-dimethyl-4(1*H*)-pyridinone (prepared according to the literature (6)) in 100 mL ethanol was added to Ph_2BOH (from acid hydrolysis of 5.2 mmol $Ph_2BOCH_2CH_2NH_2$) in 150 mL diethyl ether. Precipitate started to form within 10 min; the solution was heated (30°C) overnight to reduce volume and digest the precipitate. After cooling, the white solid mass was collected and recrystallized from acetone/water. This produced 0.78 g (2.6 mmol, 62% yield) of analytically pure compound, mp (dec.) 220–222°C. *Anal.* calcd. for $C_{19}H_{18}BNO_2$: C 75.26, H 6.00, N 4.62; found: C 75.40, H 6.01, N 4.54. Infrared (KBr, all strong): 1640 cm^{-1} (CO); 1580, 1530, 1500 (pyridinone ring). ^1H nmr (d_6-acetone, 25°C, 80 MHz) δ (ppm): 2.50 (s, 3H, NC(CH_3)); 3.94 (s, 3H, CN(CH_3)); 6.73 (d, 6.6 Hz, 1H, *CH*CHN); 7.25 (m, 10H, 2 C_6H_5); 7.80 (d, 6.6 Hz, 1H, CHC*H*N). Crystals used for the X-ray study were obtained by slow evaporation from acetone/ethanol.

Infrared spectra were recorded as KBr pellets on a Perkin-Elmer 783 from 4000–200 cm^{-1} and ^1H nmr spectra on a Bruker WP-80.

X-ray crystallographic analyses

Crystallographic data for **1** and **2** appear in Table 1. Unit-cell parameters were refined by least-squares on 25 reflections with $2\theta = 60–91°$ for **1** and $2\theta = 40–79°$ for **2**. The intensities of three check reflections, measured each hour of X-ray exposure time throughout the data collections, showed only small random variations in each case. The data were reduced[2] and, for **2**, corrected for absorption. No absorption correction was applied for **1** in view of the crystal dimensions (Table 1) and the low coefficient of absorption.

[1]Part XXVI: ref. 17.

[2]The computer programs used include locally written programs for data processing and locally modified versions of the following: AGNOST, absorption corrections, by J. A. Ibers; ORFLS, full-matrix least-squares, and ORFFE, function and errors, by W. R. Busing, K. O. Martin, and H. A. Levy; FORDAP, Patterson and Fourier syntheses, by A. Zalkin; ORTEP II, illustrations, by C. K. Johnson.

Maximum residual density (e/Å^3)	0.22	0.80

[a]Temperature 22°C, Enraf-Nonius CAD4-F diffractometer, Cu-K_α radiation ($\lambda_{K\alpha 1}$ = 1.540562, $\lambda_{K\alpha 2}$ = 1.544390 Å), nickel filter, takeoff angle 2.7°, aperture (2.0 + tan θ) × 4.00 mm at a distance of 173 mm from the crystal, scan range extended by 25% on both sides for background measurement, $\sigma^2(I) = S + 2B + [0.04(S - B)]^2$ (*S* = scan count, *B* = normalized background count), function minimized $\Sigma w(|F_o| - |F_c|)^2$ where $w = 1/\sigma^2(F)$, $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$, $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$, $S = (\Sigma w(|F_o| - |F_c|)^2/(m - n))^{1/2}$. Values given for *R*, R_w, and *S* are based on those reflections with $I \geq 3\sigma(I)$.

Both structures were solved by direct methods, the coordinates of the non-hydrogen atoms being determined from *E*-maps. Early in the refinement of the structure of **1** it was apparent that the pyridinone ligand was twofold disordered, the two orientations being related by a 180° rotation about the C(3)···B vector (see Fig. 1). Site occupancy factors were initially estimated as 0.75 and 0.25 from relative Fourier peak heights for the well-resolved atom pairs. Simultaneous refinement of both the thermal and site occupancy factors resulted in a poorly-conditioned matrix. The occupancy factors for the atom pairs O(1), O(2), C(2), C(4), and C(5) were refined with the thermal parameters fixed at equal values. The resulting normalized average occupancy factors were kept fixed in subsequent cycles of refinement. In the final stages of the refinement of **1**, all non-hydrogen atoms were refined with anisotropic thermal parameters except for the low-occupancy atoms N(b), C(1b), and C(6b) which were refined with isotropic thermal parameters due to their proximity to atoms of the high-occupancy ligand. Hydrogen atoms were included as fixed contributors to the structure of **1** in idealized positions (N—H = 0.90, C(sp^2)—H = 0.97, C(sp^3)—H = 0.98 Å, methyl group orientation based on observed hydrogen positions), with the exception of those associated with the low-occupancy methyl group. In the case of **2** all non-hydrogen atoms were refined with anisotropic thermal parameters and the hydrogen atoms with isotropic thermal parameters. Neutral atom scattering factors were taken from ref. 7. An isotropic type I extinction correction was applied for **1** (Thornley–Nelmes definition of mosaic anisotropy with a Lorentzian distribution) (8–10), the final value of *g* being 0.73(10) × 10^4. The F_o and F_c values for the intense reflections of **2** were in good agreement thus no extinction correction was necessary.

The relatively high final *R* value and the unusually large residual densities (located near O) for **2** are probably due to poor crystal quality. It was difficult to grow good crystals of **2**, most samples growing as multiple twins. The best crystal found was used for data collection but had ω peak widths of 0.4°, twice as large as those usually observed for compounds of this type.

Final positional and anisotropic thermal parameters appear in Tables 2, 6,[3] and 7,[3] respectively. Measured and calculated structure factors have been placed in the Depository of Unpublished Data.[3]

The thermal motion in both compounds has been analysed in terms of rigid-body modes of translation, libration, and screw motion (11). The rms errors in the temperature factors ΔU_{ij} (derived from the least-squares analyses) are 0.0025 Å^2 for **1** (excluding the low-occupancy atoms) and 0.0030 Å^2 for **2**. Three subunits were considered for each molecule (2 PhB, pyridinone-B), rms ΔU_{ij} = 0.0023–0.0048 Å^2 for **1** and 0.0027–0.0059 Å^2 for **2**. The appropriate bond distances have been corrected for libration (11, 12), using shape parameters q^2 of 0.08 for all atoms involved. Corrected bond lengths appear in Table 3 along with the uncorrected values; corrected bond angles do not differ by more than 1 σ from the uncorrected values given in Table 4. Intra-annular torsion angles defining the conformations of the five-membered chelate rings are listed in Table 5. Hydrogen atom parameters (Table 6) have been deposited. Bond lengths and

[3]The structure factor table, Table 7 (anisotropic thermal parameters) and other material mentioned in the text may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

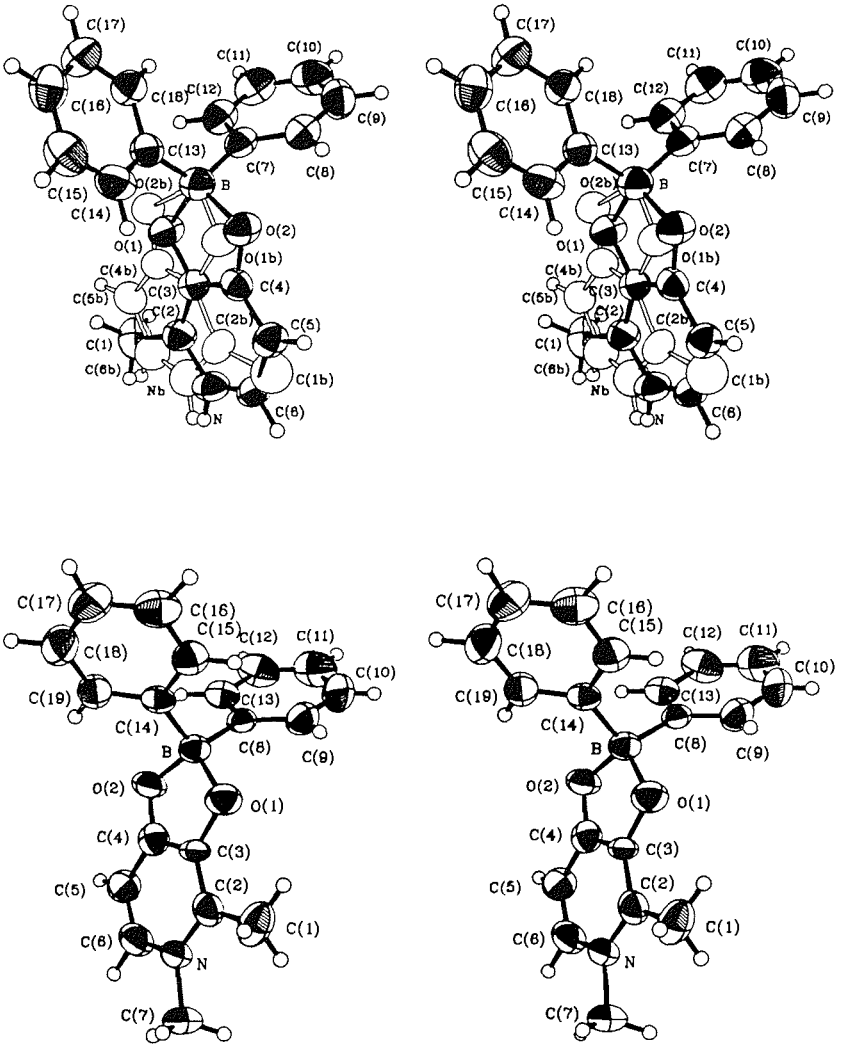

FIG. 1. Stereoscopic views of the (3-hydroxy-2-methyl-4-pyridinonato)diphenylboron (top) and (3-hydroxy-1,2-dimethyl-4-pyridinonato)diphenylboron (bottom) molecules; 50% probability thermal ellipsoids are shown for the non-hydrogen atoms. Hydrogen atoms have been assigned arbitrary thermal parameters for the sake of clarity.

angles involving hydrogen and a complete listing of torsion angles (Tables 8–10) are included as supplementary material.

Results and discussion

Both crystal structures consist of discrete molecules separated by normal van der Waals distances. In the case of the disordered structure of **1**, only the major component will be considered for the discussion of molecular geometry. Bond lengths and angles involving the minor component suggest that the Ph_2B moiety in **1** is also disordered although the disorder was not resolvable.

The molecular structures of **1** and **2** (Fig. 1) each feature central fused-ring systems and closely resemble that of the isoelectronic (maltolato)diphenylboron molecule, **3** (1). The pyridinone rings in **1** and **2** are both slightly, but significantly, non-planar (maximum deviations from the C_5N mean planes are 0.018(5) Å in **1** and 0.015(5) Å in **2**) as are those in the free ligands (6). The five-membered C_2O_2B ring is non-planar in **1** but nearly planar in **2** (maximum deviations from the mean planes are 0.067(4) Å in **1** and 0.011(5) Å in **2**). The C_2O_2B ring in **3** was found to have a non-planar conformation intermediate between those in **1** and **2**. The phenyl rings in both structures are planar within experimental error and have normal geometry (13).

Compound **1** contains both the shortest and longest O—B bonds yet observed for an *O,O*-chelate of Ph_2B containing a five-membered chelate ring, but the disorder in the structure may lead to some uncertainty in the O—B distances. The average O—B and C—B distances[4] (which should be less sensitive to the effects of the disorder) of 1.574 and 1.600 Å in **1** represent the weakest overall binding of ligand oxygen atoms to boron observed for this type of compound (see Table 5 of ref. 1). The isoelectronic compound **3** previously exhibited the weakest overall O—B binding with average O—B and C—B distances of 1.567 and 1.603 Å. The ligand binding is stronger in **2** with corresponding average values of 1.556 and 1.608 Å, respectively. The structures of five other molecules of this

[4]Libration corrected bond lengths (esd's assumed equal to those of the uncorrected values) are employed in the discussion and are compared with similarly treated (11) distances unless otherwise stated.

For personal use only.

type having unsaturated five-membered chelate rings have been determined (1, 14–16). The average O—B distances are shortest (1.550–1.555 Å) when the chelate rings are planar (15, 16) and longer (1.565–1.567 Å) when the chelate rings are non-planar (1, 14). Packing effects are probably responsible for deviations of the unsaturated chelate rings from planarity (14) and may influence the O—B distances in this type of compound. The ν_{CO} bands in the solid state ir spectra of **1–3** occur at 1650, 1640, and 1640 cm^{-1}, respectively, consistent with the weakest O(2)—B bond in **1**.

The geometry of the coordinated ligands in **1** and **2** differs from that of the free ligands (6) in the same way as discussed for the maltolate **3** (1). The ligand bite (O(2)···O(3)) is reduced from 2.761(2) and 2.740(3) Å in the free ligands to 2.400(5) Å in **1** and 2.394(5) Å in **2** (the corresponding distance in **3** is 2.384(2) Å) via angular distortions about the ring-junction atoms C(3) and C(4). Bond lengths do not change significantly upon coordination except in the O(1)—C(3)—C(4)—O(2) fragment which is part of the chelate ring. Both C—O distances increase (C(3)—O(1) and C(4)—O(2) by 0.007(5) and 0.031(6) Å in **1** and by 0.010(5) and 0.016(6) Å in **2**) and the C(3)—C(4) distance decreases significantly from 1.436(2) to 1.375(5) Å in **1** and from 1.435(4) to 1.374(5) Å in **2**. Comparison of the ligand geometries of **1** and **2** shows the effect of the *N*-methyl substitution. Except for the C(3)—C(4) distances which are the same in **1** and **2**, all pyridinone ring bonds in **2** are alternately shorter and longer than those in the unsubstituted molecule **1**. The largest differences occur for the N—C(6) and C(5)—C(6) bonds (see Table 3). This substituent effect may also account in part for the substantially different bonding to boron in **1** and **2** along with the steric effects discussed above and σ-hybridization effects.

Trace analysis for aluminum by furnace atomic absorption spectroscopy and differential pulse polarography

KEITH E. JOHNSON, A. KAREN BRICHTA, AND KATHY-LYNN HOLTER
Department of Chemistry, University of Regina, Regina, Sask., Canada S4S 0A2

Received March 2, 1987

KEITH E. JOHNSON, A. KAREN BRICHTA, and KATHY-LYNN HOLTER. Can. J. Chem. **66**, 139 (1988).

The determination of total aluminum in water by furnace atomic absorption spectrometry is best performed with a prior sample treatment with 1% HNO_3 + 2% H_2O_2 or Acid Alizarin Violet N: detection limits of a few $\mu g\ L^{-1}$ are reliably obtained. Ionic aluminum may be measured at levels down to 25 $\mu g\ L^{-1}$ by differential pulse polarography of the aluminum complex with Acid Alizarin Violet N; excesses of Fe^{3+}, Cl^-, and EDTA interfere.

KEITH E. JOHNSON, A. KAREN BRICHTA et KATHY-LYNN HOLTER. Can. J. Chem. **66**, 139 (1988).

Pour déterminer l'aluminium total dans l'eau en utilisant la spectrométrie d'absorption atomique, il y a lieu de soumettre l'échantillon à un traitement préalable avec du HNO_3 à 1% + du H_2O_2 à 2% ou de l'Alizarine Violet N Acide; on peut ainsi obtenir des limites de détection de quelques $\mu g\ L^{-1}$ qui sont faibles. On peut mesurer l'aluminium ionique à des niveaux allant jusqu'à 25 $\mu g\ L^{-1}$ en faisant appel à la polarographie pulsée différentielle du complexe de l'aluminium avec l'Alizarine Violet N Acide; des excès de Fe^{3+}, de Cl^- ou d'EDTA interfèrent dans cette réaction.

Acid rain (rain with a pH of less than 5.6) is able to leach several metals from sediments and soils; among the metals that pass into groundwater and, sometimes, surface water is aluminum which is believed to be toxic to fish, other aquatic organisms, and several plant species (1). The forms of aluminum in water included the hydrated ion, $Al(H_2O)_6^{3+}$, relatively weak inorganic complexes, and strong organic complexes and there is evidence that the toxicity *de*creases in this sequence. The aluminum levels of concern are $\mu g/L$ (ppb).

Any study of the aluminum toxicity of water would be aided if one could determine the ionic aluminum rather than simply the total aluminum. The approach of Campbell *et al.* (2) was to equilibrate with a chelating ion exchange resin and determine the non-exchanged aluminum remaining in solution: the exchanged or ionic aluminum amounted to the difference between the first value and the total. Most of their actual aluminum determinations were made by furnace atomic absorption spectroscopy (FAAS) although the Lumogallion spectrofluorometric method was also found to be satisfactory. They noted rapid exchange of inorganic aluminum species, slow exchange in the presence of fulvic and humic acids, and an intermediate rate of exchange for natural samples.

We have considered an alternative characterization of free ionic aluminum which might be susceptible to direct measurement, i.e., an electrochemical approach. Since most groups will probably continue to use FAAS or ICP spectrometry, if available, as a routine method for determining total aluminum, we have carried out a cursory statistical study of various FAAS preliminary sample treatments.

The obvious electrochemical technique to consider for an ion at trace levels in solution is some form of polarography but the aluminum reduction wave is obscured by that of hydrogen in the simple dc mode; although some resolution was obtainable by the differential pulse technique (3), the detection limit was in the mg/L range whilst many ions found in natural waters interfere in such an analysis. Willard and Dean (4), meanwhile, showed that aluminum could be determined at the 0.1 mg/L level by dc polarography of its complex(es) with an azo-dye such as Alizarin Violet N (Solochrome Violet RS). The next step was to apply the more sensitive variations of linear sweep polarography (5), derivative polarography (6, 7) and differential pulse polarography[1] to the aluminum–dye system: sensitivities of 20, 10, and 25 $\mu g/L$, respectively, were obtained. We elected to test differential pulse polarography of the aluminum–dye complex for sensitivity, for iron interference and for other chelon interactions. It should be noted that in utilizing the reduction (or oxidation!) of the aluminum–dye complex (6, 7), we are not changing the Al^{3+}/Al potential by complexing Al^{3+} with dye but, rather, the dye reduction potential by differential complexing of Al^{3+} with dye (—N=N—) and reduced dye (—NH—NH—) or the dye oxidation potential by differential complexing of Al^{3+} with dye (—N=N—) and oxidized dye (—N=N—). Any metal ion – dye wave should occur at

approximately RT/nF ln K_2K_1 from the dye wave where the K's are the corresponding stability constants of metal ion with dye in its different oxidation states.

Experimental

(a) Furnace atomic absorption spectroscopy

The primary standard aluminum solution (1 g/L) was obtained from Fisher Scientific Company: it had been made by dissolving high purity metal in dilute HCl. Acid Alizarin Violet N (sodium 4-hydroxy-3-[(2-hydroxy-1-naphthalenyl)azo]benzenesulfonate) (60%) was used as obtained from Aldrich Chemical Company.

All samples were prepared daily and stored in polypropylene flasks (8) (glass absorbs a significant proportion of aluminum ions when they are only present at the $\mu g/L$ level), Nalgene pipettes were used for transfers. Unused flasks and pipettes were kept in contact with HNO_3 and, when required, were repeatedly rinsed with acid and water.

Measurements were made on an Hitachi 180-80 Polarized Zeeman Atomic Absorption Spectrophotometer equipped with graphite furnace, high temperature sensor, and auto-sampler and Hitachi 180-0205 Data Processing Unit. The instrument parameters are given in Table 1. The graphite tubes only gave reproducible results if limited to 80 runs each and the plastic sample holders could not be adequately cleaned between runs and so were disposed of after each run. The sample volume was 10 μL, each sample was injected thrice and all measurements were made in the peak height mode.

(b) Differential pulse polarography

The aluminum stock solution was prepared from $AlK(SO_4)_2 \cdot 12H_2O$

	Clean	2800	3.0

(BDH). Acid Alizarin Violet N and Solochrome Violet RS are two names given to the same formulated dye. Acid Alizarin Violet N, ostensibly 60% from Aldrich, was either used as supplied (200 mg in 100 mL water to give 120 mg "pure" dye in 100 mL) or recrystallized to ~90% purity from absolute ethanol (130 mg of material in 100 mL water taken to yield 120 mg "pure" dye). Solochrome Violet RS from ICN Pharmaceuticals Inc. was taken, as supplied, to be 100% pure (an incorrect assumption as we shall see). Other chemicals were from BDH or Fisher. Flasks, pipettes, and vials were of polypropylene (Cole-Parmer) and were acid- and water-washed prior to use.

pH values were measured with a Corning Scientific pH Meter, Model 7. Polarograms were obtained with a Metrohm Polarecord 626 (with 60 Hz filter added) and a vintage (pre-1965) E354 Metrohm Polarography stand bearing a mercury electrode with electronically controlled drop knocker. The auxiliary electrode was platinum and the reference sce.

(c) Ultraviolet–visible spectroscopy

Dilute dye solutions were studied by means of a Beckman Model 26 UV/Visible spectrophotometer.

(d) Ion chromatography

Chloride determinations were performed on a Dionex 4002i ion chromatograph using an AS4A column in the HPIC mode with $NaHCO_3$ eluant.

(e) Natural water samples

Samples were collected from several sites in Southern Saskatchewan in 1983 and 1987.

Results and discussion

The average aluminum concentrations obtained by furnace AAS for several sample sets (a sample set is a set of samples derived from the standard and measured on a particular occasion) in the 4 matrices: distilled water, 1% HNO_3, 1% HNO_3 + 2% H_2O_2, and Acid Alizarin Violet N were compared. The statistical summary appears in Table 2. Although one might argue that distilled water and 1% HNO_3 give adequate sensitivity and lowest detection limits respectively, the decidedly better variance and coefficient of variation data obtained with the dye present or with 1% HNO_3 + 2% H_2O_2, particularly neglecting low concentrations in the latter case, suggest that *furnace AAS for aluminum be carried out either in the presence of a complexing agent or a mildly oxidizing acid solution of* $HNO_3 + H_2O_2$. This conclusion is consistent with the practices of some groups but no definitive study of the relative merits of different procedures has appeared.

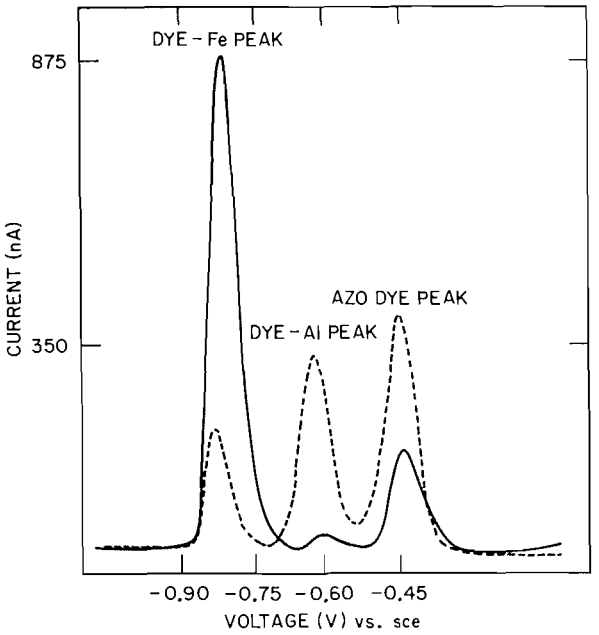

FIG. 1. Differential pulse polarograms of Acid Alizarin Violet N in the presence of different ratios of Fe^{3+} to Al^{3+}. Solid line represents 10-fold Fe^{3+} excess, broken line equal concentrations.

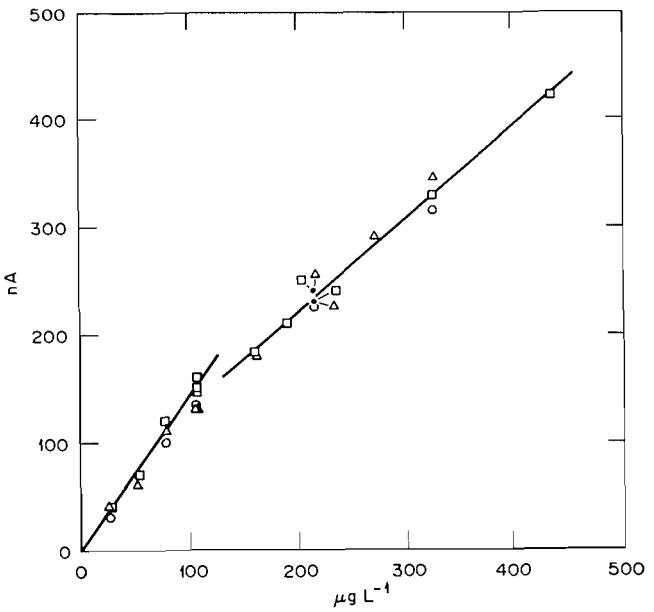

FIG. 2. Calibration graph for DPP of the aluminum–dye complex. AAVN concentration (unpurified) ~67 m*M*. SRVS concentration (actual) 45 m*M*. □, AAVN; △, AAVN recrystallized; ○, SRVS.

Acid Alizarin Violet N (AAVN) or Solochrome Violet RS (SVRS) in aqueous solution gave a differential pulse reduction peak at −0.44 V vs. sce (Fig. 1). Addition of aluminum ions reduced the size of the AAVN peak concurrent with the growth of a new peak at −0.60 V.

The peak current was least sensitive to pH in the range 4 to 4.5 so this condition was imposed. The peak current vs. concentration relation appears as Fig. 2. Two linear regions are apparent (25 to 120 μg L^{-1}, correlation coefficient 0.9971 and

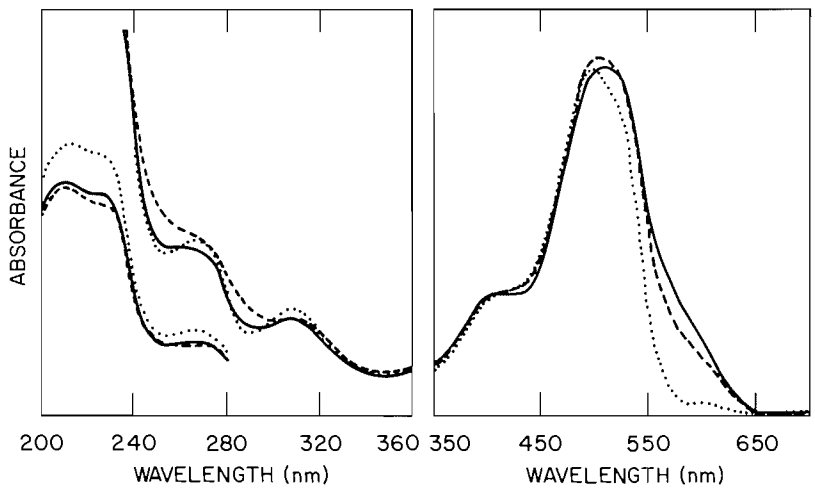

FIG. 3. Normalized (by 500 nm peak) spectra of AAVN (—), AAVN recrystallized (- - -) and SRVS (····) in water at 22°C dye concentrations 0.07 m*M* for visible and 0.035 m*M* for uv region.

TABLE 3. Al concentrations in natural waters

Site	Location	AA (1987)	AA (1983)	DPP (1987)
1	Estevan Gen. Stn., Souris	28.4± 3.9 ppb	64.5	
2	Boundary Dam CW Inlets	341.5±27.7	170	340
3	Poplar River Gen. Stn. CW Inlet	34.0± 3.3		
4	Sask River at Nipawin	6.2± 0.6	3.2	
5	Weyburn, Souris	3.7± 0.4		
6	Q.E. Gen. Stn., Saskatoon	24.2± 2.4	1.4	
7	Regina Beach-boat dock	97.9± 8.6	63	19.3
8	Buffalo Pound L-boat dock	12.5± 2.0	118	

140 to 400 μg L^{-1}, correlation coefficient 0.9988). The change-over concentration corresponded to a dye:aluminum molar ratio of 14. The formal stability constants of the [Al(AAVN)] and $[Al(AAVN)_2]^{3-}$ complexes were determined (9) as log K_1 = 18.4 and log K_2 = 13.2 so that complete conversion to the second complex would be anticipated. Recrystallization of AAVN did not substantially change the lines.

In the presence of Fe^{3+}, both the AAVN and Al—AAVN reduction peaks were reduced in size and a new Fe—AAVN peak appeared (Fig. 1). Provided the iron concentration did not exceed the aluminum concentration, the Al—AAVN peak still gave a satisfactory measure of the aluminum; a 10-fold Fe^{3+} excess virtually eliminated the Al—AAVN peak.

EDTA was examined as an organic ligand competitor of AAVN for the aluminum with the result that no Al—AAVN peak was obtained in the presence of a many-fold excess of EDTA.

Thus, electroactive or ionic aluminum can be determined by differential pulse polarography without interference from moderate iron concentration. However, calibration over a broad concentration range is essential for the obtaining of precise results.

The spectral study showed that the SVRS is also impure (~66% purity). The gross impurity in the manufactured products was identified by HPIC as sodium chloride from the "salting out" step. The finer structure of the spectra (Fig. 3) suggests that AAVN and SVRS are not exactly the same dyes (cf. especially the 600 nm region).

Table 3 gives the approximate locations of the 1987 sampling locations, together with the aluminum concentrations determined by FAAS with the AAVN matrix. The aluminum levels at or near some of these locations in 1983 are included for interest. When the AA standard solutions were examined by differential pulse polarography, aluminum levels <50 ppb were not measurable but solutions with ≥ 50 ppb Al gave the same pulse currents as those prepared from $AlK(SO_4)_2$ standards. This indicates that the Cl^- in the AA standards interferes with pulse polarography at low levels; the Cl^- inadvertently added with impure dye was insufficient in quantity to interfere. Only samples 2 and 7 contained sufficient aluminum to test the DPP method. As shown, all of the Al found by AA in sample 2 was electroactive but only some of that in sample 7 responded to DPP. No chloride was detected in sample 7. When the chloride content of sample 2 was increased to ~1300 times the Al content, ~90 ppb Al (of the 340 ppb) was found in sample 2 by DPP.

We conclude that the differential pulse polarographic determination of ionic aluminum holds promise provided the reagent chloride level is low. Further studies would be required to discern whether chloride would prevent aluminum uptake by live organisms and, if so, without killing them.

The He(I) photoelectron spectra of 2-butynal and related oxyalkynes

DIETER KLAPSTEIN[1] AND ROBERT T. O'BRIEN
Department of Chemistry, St. Francis Xavier University, Antigonish, N.S., Canada B2G 1C0

Received May 11, 1987

DIETER KLAPSTEIN and ROBERT T. O'BRIEN. Can. J. Chem. **66**, 143 (1988).

The He(I), λ = 58.4 nm, photoelectron spectra of 2-butynal and the related compounds 2-butynol, 2-butynoic acid, 2-butynoyl fluoride, and 2-butynoyl chloride were obtained. The lower ionization energy bands may be assigned to photoionization from specific orbitals by comparison within the series, with related species and with the use of semi-empirical MO calculations. The energy variation of the more localized orbitals with substituent variation may be rationalized in terms of the inductive and resonance effects of the substituents.

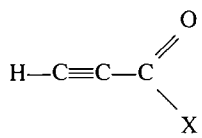
DIETER KLAPSTEIN et ROBERT T. O'BRIEN. Can. J. Chem. **66**, 143 (1988).

On a déterminé les spectres photoélectroniques He(I), à une longueur d'onde de 58,4 nm, du butyne-2 al et des composés suivants qui lui sont apparentés : le butyne-2 ol, l'acide butyne-2 oïque, les fluorure et chlorure de butyne-2 oyle. En se basant sur des comparaisons, à l'intérieur de séries, avec des espèces apparentées et en utilisant des calculs d'OM semi-empiriques, on peut attribuer les bandes d'énergies d'ionisation plus faibles à des orbitales spécifiques. Pour rationaliser la variation d'énergie des orbitales plus localisées en fonction de la nature des substituants, on fait appel aux effets inductifs et de résonance des substituants.

[Traduit par la revue]

Introduction

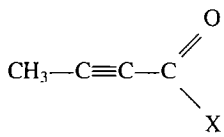
In a previous paper (1) the valence shell helium(I) photoelectron spectra of a series of α,β-unsaturated carbonyl compounds of the general structure (**I**):



I

with X = H, F, Cl, OH, and CH_3 were presented and interpreted. These species are of interest in the investigation of the electronic structure of molecules since their small size results in generally resolvable bands in the photoelectron spectra and also makes the species attractive for computational modelling of the electronic interactions.

This work extends the investigation to the methyl-substituted analogues of **I**:



II

where X = H, F, Cl, OH and the related alcohol, 2-butynol, the spectra of which have not previously been reported. The aim of the study was to determine (*i*) the relative energies and identities of the higher occupied molecular orbitals, and their variation with the carbonyl substituents, (*ii*) the degree of interaction of the out-of-plane orbitals in these planar species (C_s symmetry), and (*iii*) compare these results with those observed for the terminal alkynyl compounds (1) to deduce the influence of the methyl group.

Experimental

The spectra were obtained with a photoelectron spectrometer incorporating a helium high voltage d.c. discharge lamp (54.8 nm, 21.22 eV) and a 127° cylindrical sector electron analyzer operated in a constant resolution mode. Signals were acquired with a Nicolet 1170 Signal Averager and Apple IIe microcomputer data acquisition system. The ionization energies were calibrated with Ar, N_2, CH_3I, H_2O, and HCl. The full spectra were obtained with a resolution of 30 meV, while structured bands were recorded with a resolution of 20–25 meV. Sharp bands have an ionization energy uncertainty of ±0.02 eV, while for broad bands it is ±0.1 eV. Vibrational intervals are ±80 cm^{-1}.

Semi-empirical MO calculations were carried out using CNDO/2 (2) and HAM/3 (3) programs adapted for use on a VAX-11/780 computer. The HAM/3 program was not parameterized for chlorine. The CNDO/2 MO eigenvalues have been divided by a factor of 1.35 for comparison with the vertical ionization energies (for the low IE region this corresponds to the 4 eV correction factor (4) commonly used).

As no structural parameters have been determined experimentally for these species, the relevant parameters were transferred from propynal (5), propynoyl fluoride (6), propynoyl chloride (7), and propynoic acid (8). Vibrational assignments in the photoelectron spectra were made by comparison with the frequencies for the neutral molecules (9), when available, and considering the bonding characteristics of the source molecular orbitals.

Commercial samples of 2-butynol (Aldrich) and 2-butynoic acid (Farchan) were used. 2-Butynal was prepared by the oxidation of 2-butynol using aqueous CrO_3 (10). 2-Butynoyl fluoride was prepared by reacting 2-butynoic acid with benzoyl fluoride (11). 2-Butynoyl chloride was prepared by reacting 2-butynoic acid with thionyl chloride. Sample purities were checked by infrared spectroscopy (9).

Results and discussion

The photoelectron spectra are shown in Figs. 1 to 5. The measured vertical ionization energies and observed vibrational structure are given in Tables 1 to 5, along with the predicted ionization energies and orbital symmetries from the semi-empirical MO calculations, and the band assignments. The latter are only possible in the lower IE regions of the spectra where most of the bands are at least partially resolvable and for which comparisons with structurally related molecules may be made. The following discussions of the individual spectra are limited to the lower IE bands. The C_s symmetry of the molecular species results in MO classifications of *a'* (in-plane) or *a"* (out-of-plane). However, the higher occupied MOs are usually quite localized in specific areas of the molecules (e.g. n_O', π_{CC}''). The discussion uses this latter concept as it provides more chemically useful information.

2-Butynol

The full spectrum is shown in Fig. 1. The low IE bands are

expected to arise from ionization from orbitals which may be described as π'_{CC}, π''_{CC}, and n''_O. Considering related molecules, the (degenerate) π_{CC} band of 2-butyne appears at 9.56 eV (12), while the n''_O bands of CH_3OH (13) and $HC{\equiv}CCH_2OH$ (14) appear at 10.96 and 11.37 eV, respectively. The π_{CC} bands of 2-butynol are thus expected to be found at lower IEs than the n''_O band. The lowest IE band, at 9.74 eV, is assigned as $(\pi''_{CC})^{-1}$ and is overlapping with the second band at 10.01 eV, assigned as $(\pi'_{CC})^{-1}$. While both π_{CC} orbitals have been stabilized slightly relative to 2-butyne by the inductive effect of the alcohol group, the π''_{CC} orbital is also destabilized by conjugation with the energetically close n''_O orbital of the alcohol group. The energy difference of 0.27 eV between the $(\pi_{CC})^{-1}$ bands is twice that observed for 2-butynal (below), for which the other a'' orbitals (π''_{CH_3} and π''_{CO}) are much further away in energy. The first band shows some initial vibrational structure of 1200 cm^{-1} which is then lost due to overlap with the second band. The $(n''_O)^{-1}$ band is located at 11.06 eV; the weak cationic vibrational progression of 1200 cm^{-1} is probably excitation of the ν(C—O) stretching mode.

The broad band observed at 12.96 eV ionization energy is assigned to ionization from an in-plane orbital which the MO calculations predict to be centered mainly on the oxygen atom. Similar bands are assigned for methanol at 12.62 eV (13), ethanol at 12.18 eV (13), and prop-2-yn-1-ol at 13.22 (14).

2-Butynal

The structure of 2-butynal consists of the planar aldehyde functional group attached to a propynyl group. The low IE orbitals are predicted by the MO calculations to be n'_O and the acetylenic π''_{CC} and π'_{CC} orbitals. Figure 2 shows that the spectrum has only two distinct bands in the 9 to 13 eV region but the second has roughly twice the intensity of the first.

The location of the $(n'_O)^{-1}$ band can be predicted by considering the results for related molecules. The $(n'_O)^{-1}$ band of propynal has an IE of 10.70 eV (1). Substitution of the

terminal hydrogen with a methyl group should result in a shift to lower ionization energy, similar to the 0.41 eV shift observed for propionaldehyde (15) relative to acetaldehyde (16). Thus the first band of the 2-butynal spectrum at 10.15 eV, is assigned as $(n'_O)^{-1}$. Some vibrational structure is observed on this band (Fig. 2): the 1460 cm^{-1} main progression could be the cationic carbonyl stretching mode while the weaker 700 cm^{-1} progression could be the ν(C—C) stretching mode.

The second prominent band of the spectrum is assigned to ionization from the π''_{CC} and π'_{CC} orbitals. For propynal (1), these bands are observed at 11.52 and 11.57 eV, respectively, the out-of-plane orbital being slightly destabilized relative to the in-plane by interaction with the carbonyl π-orbital at higher binding energy. Close examination of the 2-butynal spectrum (Fig. 2) shows two distinct maxima on the second band, at 10.59 and 10.73 eV IE, which are assigned as the vertical IEs of the $(\pi''_{CC})^{-1}$ and $(\pi'_{CC})^{-1}$ bands. The substantial shift to lower IEs for these bands, compared to propynal, results from the electron-donating ability of the methyl group. The energy difference of the $(\pi_{CC})^{-1}$ bands reflects the relative degree of interaction of π''_{CC} with the other out-of-plane localized orbitals π''_{CH_3} and π''_{CO}, both of which are more stable. Since this difference is small, it is concluded that the interaction is also small (on the photoelectron energy scale).

The next band of the spectrum has a broad Franck–Condon profile, with an adiabatic IE of 13.30 eV, a vertical IE of

13.64 eV, and some resolved vibrational structure (Fig. 2). This band is assigned to the $(\pi''_{CO})^{-1}$ ionization on the basis of its energy and characteristic structure. The $(\pi''_{CO})^{-1}$ band of propynal is found at 14.22 eV (vertical), the shift to lower IE for 2-butynal resulting from both the positive inductive and resonance effects of the methyl group. While the vibrational structure is not completely resolved, the observed 1600 cm^{-1} progression could be the cationic $\nu(C{\equiv}C)$ mode while the 1200 cm^{-1} interval might be excitation of the $\nu(C{=}O)$ mode. As found for propynal and the propynoyl halides (1), the Franck–Condon profile of the $(\pi''_{CO})^{-1}$ band indicates a considerable change in geometry between the neutral ground state and the resulting doublet state of the cation.

2-Butynoic acid

For the interpretation of the photoelectron spectrum, 2-butynoic acid may be thought of as a hybrid of 2-butynol and 2-butynal, the alcohol and aldehyde groups combining to produce the acid group. The full spectrum is shown in Fig. 3. Four bands are expected with IEs less than 14 eV: ionization from the n'_O (carbonyl), π''_{CC}, π'_{CC}, and n''_O (hydroxyl) orbitals.

The $(n'_O)^{-1}$ band of 2-butynal is found at 10.15 eV. For the acid it should be shifted to higher IE by the inductive effect of the hydroxyl group. The first band of the spectrum, at 10.36 eV IE, is assigned as $(n'_O)^{-1}$. The next two bands, at 10.63 and 11.35 eV, are assigned as $(\pi''_{CC})^{-1}$ and $(\pi'_{CC})^{-1}$, respectively. The out-of-plane orbital energy is destabilized considerably relative to the in-plane by interaction with the n''_O orbital of the hydroxyl oxygen. The $(\pi''_{CC})^{-1}$ band is partially overlapping with the $(n'_O)^{-1}$ band but has a considerably broader profile than the $(\pi'_{CC})^{-1}$ band. This could be a result of delocalization of the out-of-plane system. The $(\pi'_{CC})^{-1}$ band has the characteristically sharp Franck–Condon profile of an acetylenic π-band (Fig. 3). The short vibrational progression of 1800 cm^{-1} results from excitation of the cationic $\nu(C{\equiv}C)$ stretching mode. A weaker progression of 1100 cm^{-1} could be a $\nu(C{-}C)$ stretching mode.

The fourth band, vertical IE 11.96 eV, arises from ionization from the n''_O orbital, centered on the hydroxyl oxygen atom. The corresponding band of 2-butynol appears at 11.06 eV while for methanol it is found at 10.96 eV (13). In this case, the n''_O orbital energy is lowered substantially (IE increased) by its interaction with the other out-of-plane orbitals, most importantly with π''_{CC}. The $(n''_O)^{-1}$ band has been shifted to higher IE while the $(\pi''_{CC})^{-1}$ band has been shifted to lower IE relative to the $(\pi'_{CC})^{-1}$ band as a result of this interaction. This delocalization is also evident from the extensive vibrational structure observed on the $(n''_O)^{-1}$ band, shown in Fig. 3, compared to the corresponding band of 2-butynol. The main progression of 1920 cm^{-1} is probably the $\nu(C{\equiv}C)$ stretching mode while the weaker 570 cm^{-1} progression could be a bending mode. An alternative band assignment scheme would be to assign the 11.35 eV band as (n''_O) and the 11.96 eV band as $(\pi'_{CC})^{-1}$. However, this gives a low IE for $(n''_O)^{-1}$ compared to other simple carboxylic acids: CH_3COOH, 12.05 eV (17); CH_3CH_2COOH, 12.04 eV (17); $HC{\equiv}CCOOH$, 12.46 eV (1); and $CH_2{=}CHCOOH$, 12.00 eV (18).

The $(\pi''_{CO})^{-1}$ band, clearly discernible for 2-butynal at 13.64 eV, has been shifted to higher IE by the inductive effect of the hydroxyl group and is probably one of at least two bands overlapping at 14.61 eV.

2-Butynoyl fluoride

Substitution of the aldehyde hydrogen of 2-butynal by fluorine results in two effects. The strong electron-withdrawing ability of fluorine should result in a general shift of ionization energies to higher values. Secondly the "lone-pair" orbitals of the halogen are of the correct symmetry and similar size to interact with other localized orbitals; this is especially true for the out-of-plane orbitals.

The spectrum of 2-butynoyl fluoride is shown in Fig. 4. The similarities in the electronic effects of the OH and F groups is demonstrated by the similarity of the shapes and relative positions of the first three bands of the acid and the acid fluoride. The $(n'_O)^{-1}$ band of the acid fluoride is the first band at 10.84 eV. No vibrational structure is observable as there is considerable overlap with the second band, vertical IE 11.06 eV, which is assigned to the $(\pi''_{CC})^{-1}$ ionization. The lack of vibrational structure on the second band might be the result of delocalization of the π''_{CC} orbital over the molecular out-of-plane π-system or simply due to the overlap of the first two bands.

The third band, at 12.03 eV, must be assigned to ionization from the π'_{CC} orbital. The well-resolved vibrational structure (Fig. 4) has a main progression of 1920 cm^{-1} which is the cationic $\nu(C{\equiv}C)$ stretching mode; a weaker excitation of 1180 cm^{-1} may be one of the combinations of C—C and C—F stretching modes. The relatively large energy difference of the π''_{CC} and π'_{CC} bands, 0.97 eV, implies a substantial degree of interaction of π''_{CC} with the other a'' orbitals with higher IEs. This was also found in the case of propynoyl fluoride (1).

The fourth band, maximum 13.62 eV, has complex vibrational structure (Fig. 4). The position of this band and the similarity of its structure with bands observed for 2-butynal (above) and the propynoyl halides (1) leads to its assignment as $(\pi''_{CO})^{-1}$. This band has essentially the same IE as in 2-butynal (13.64 eV); the strong inductive effect of fluorine is offset by the resonance interaction of π''_{CO} with the halogen out-of-plane lone pair orbital. The vibrational structure consists of intervals of 1780, 1240, and 460 cm^{-1}. The 1780 cm^{-1} value is too large to correspond to the $\nu(C{=}O)$ stretching mode since an electron has been removed from an orbital which is strongly π-bonding in the C=O internuclear region. A more likely assignment is to excitation of the $\nu(C{\equiv}C)$ stretching mode, as

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.222.148.141 on 09/07/12

For personal use only.

the out-of-plane delocalization extends to the acetylenic group. Excitation of the carbonyl stretching mode is assigned to the 1240 cm^{-1} interval. The 460 cm^{-1} interval could be excitation of a bending mode.

The intense band at 14.93 eV results from ionization of a fluorine in-plane "lone-pair" electron. Bands with this characteristic shape are observed for formyl fluoride at 15.45 eV (19) and propynoyl fluoride at 15.42 eV (1). In this case there is a shift to lower IE due to the positive inductive effect of the methyl group.

2-Butynoyl chloride

The spectrum of 2-butynoyl chloride, Fig. 5, is congested in the low IE region due to the bands arising from the $(n'_{Cl})^{-1}$ and $(n''_{Cl})^{-1}$ processes, in addition to the $(n'_O)^{-1}$ and $(\pi'_{CC})^{-1}$, $(\pi''_{CC})^{-1}$ bands. The relative ordering of the bands can be deduced from the spectra of similar species. The $(n_{Cl})^{-1}$ bands should be at higher IE values than the $(\pi_{CC})^{-1}$ bands since the former appear at 11.29 eV for CH_3Cl (20) and 11.69 eV for $HC{\equiv}CCH_2Cl$ (14), while the latter appear at 10.37 eV for propyne (21) and 10.76 and 10.98 eV for $HC{\equiv}CCH_2Cl$ (14). The relative placement of the $(n'_O)^{-1}$ band can be rationalized by considering the corresponding assignments for the aldehyde (10.15 eV) and the acid fluoride (10.84 eV). For both propynoyl chloride (1) and propenoyl chloride (22), the $(n'_O)^{-1}$ band is at an IE intermediate to that of the respective aldehydes and acid fluorides. This follows from a simple relative electronegativity argument. As there is only one band observed for 2-butynoyl chloride in this range, the first band at 10.59 eV, it must be assigned to the $(n'_O)^{-1}$ ionization.

The $(\pi''_{CC})^{-1}$ and $(\pi'_{CC})^{-1}$ ionizations are assigned to the bands at 10.92 and 11.26 eV, respectively. The $(\pi''_{CC})^{-1}$ band shows initial vibrational structure of 830 cm^{-1} before overlapping with the $(\pi'_{CC})^{-1}$ band. This value is too low to be excitation of the cationic $\nu(C{\equiv}C)$ stretching mode; a probable assignment is to the symmetric C—C stretching mode as there is some delocalization of the source orbital, as shown by the MO calculations and the energy difference of the π''_{CC} and π'_{CC} bands. This difference, 0.34 eV, is more than that of the aldehyde but less than that observed for the acid or the acid fluoride.

The broad bands with maxima at 11.87 and 12.13 eV are due to ionization from the chlorine 3*p* orbitals (lone pairs). It is not clear which should be the lower IE band, $(n''_{Cl})^{-1}$ or $(n'_{Cl})^{-1}$. This depends, in part, on the relative magnitudes of the interaction of the n''_{Cl} orbital with π''_{CC} (at lower binding energy) and π''_{CO} (at higher binding energy). It is felt that the interaction with π''_{CO} is more important, thus destabilizing n''_{Cl} relative to n'_{Cl}. The latter could also be stabilized somewhat by interaction with n'_O; the CNDO/2 MO calculation predicts a significant interaction. These arguments lead to the assignment of the lower IE band as $(n''_{Cl})^{-1}$ and the higher as $(n'_{Cl})^{-1}$.

Compared to the aldehyde and acid fluoride, the inductive and resonance effects of the chlorine in the acid chloride both shift the π''_{CO} orbital to a higher ionization energy. Unfortunately, the resultant band is lost in the multitude of overlapping bands beginning at about 14.5 eV. It could be the first maximum observed, 14.80 eV, as this is consistent with the expected shift based on the spectra of the propynoyl halides (1).

General trends

Only the lower IE bands are generally resolvable and assignable to ionizations from specific orbitals. The higher IE regions of the spectra contain a pseudo-continuum of bands owing to the number of accessible occupied σ-type orbitals. For the lower IE bands, Fig. 6 illustrates the general trends observed within the series. Within the approximation of Koopmans' Theorem (23), equating the measured ionization energies with the negative of the source orbital energies, Fig. 6 shows the variation of the orbital energies with substituent changes. Several comments are in order. For the carbonyl compounds the n'_O orbital energy changes as expected with the electronegativity of the carbonyl substituent, i.e. H > OH > Cl > F. The difference between the energies of the in- and out-of-plane π_{CC} orbitals indicates the degree of delocalization of the out-of-plane orbitals. For the carbonyl compounds the relative size of this splitting is H < Cl < OH < F. Both the OH and F substituents have out-of-plane orbitals of appropriate size to enable good π-type overlap with the adjacent carbonyl π-system. The size disparity between the chlorine 3*p* orbital and the 2*p* orbitals of the other atoms makes this less favourable. A large splitting is also observed for the alcohol; in this case the OH out-of-plane n''_O orbital is both physically and energetically close to the π''_{CC} localized orbital.

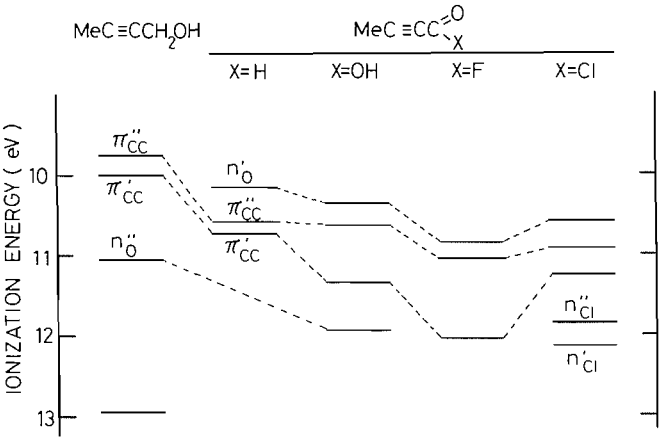

FIG. 6. Ionization energy correlation diagram for the higher occupied molecular orbitals.

The effect of the alkynyl methyl substituent, when compared to the corresponding results of the terminal alkynyl compounds (1), is mainly an inductive effect. There is a general shift to lower IEs for correlated bands between the two series. There is only a small effect on the interactions of the out-of-plane orbitals. The $(\pi''_{CH_3})^{-1}$ bands could not be identified as they are in the congested parts of the spectra.

The semi-empirical MO calculations were used to predict the ionization energies and bonding character of the occupied MOs giving rise to bands in the low ionization energy region of the spectra. The CNDO/2 method provided ionization energies from the MO eigenvalues by Koopmans' Theorem. In contrast, the HAM/3 method gave ionization energies directly by removing electron density diffusely. Comparison of the calculated results from the two methods with the experimental values shows that the HAM/3 method gives more satisfactory values. As noted previously, both sets of calculation were performed with structural parameters transferred from structurally similar molecules and without optimization. The experimental energies for these relatively simple molecular systems should be of use for more rigorous quantum chemical calculations, both for binding energies in the molecular species and for energy

differences between the molecules and the various electronic states of the cations.

Energy maxima in anionic nucleophilic additions to carbonyl groups: The location of a saddle point for the addition of hydride to formaldehyde

C. I. BAYLY AND F. GREIN[1]

Department of Chemistry, University of New Brunswick, Fredericton, N.B., Canada E3B 6E2

Received June 16, 1987

C. I. BAYLY and F. GREIN. Can. J. Chem. **66**, 149 (1988).

The reaction profile of the anionic nucleophilic addition of hydride to formaldehyde giving methanolate was re-investigated using theoretical *ab initio* methods. A variety of basis sets (including 4-31G and 6-31G with and without polarization and diffuse functions) were used, and electron correlation calculations were performed at the MP2, MP3, and MP4 levels with geometry optimizations at the MP2 level. Upon the addition of diffuse functions to the basis set, a local energy maximum was introduced into the SCF reaction profile, a major change in the character of the profile compared to the entirely attractive potential energy curve found in previous studies. On the reactants side of the barrier a local minimum 4.56 kcal/mol lower in energy was found, corresponding to an ion–dipole complex. With the inclusion of electron correlation, the local barrier almost disappeared, with the energy difference between the ion–dipole complex and the barrier maximum decreasing to less than 1 kcal/mol. Furthermore, the location of the energy maximum along the reaction coordinate changed by 0.4 Å. These results are used to critically re-evaluate some prevalent viewpoints on the nature of the reaction profiles of this type of anionic nucleophilic addition.

C. I. BAYLY et F. GREIN. Can. J. Chem. **66**, 149 (1988).

Faisant appel à des méthodes théoriques ab initio, on a réétudié le profil de la réaction d'addition nucléophile anionique de l'hydrure sur le formaldéhyde pour donner le méthanolate. On a utilisé divers ensembles de base (y compris 4-31G et 6-31G, avec et sans fonctions diffuse ou de polarisation) et on a réalisé des calculs de corrélations électroniques aux niveaux MP2, MP3 et MP4 avec des optimisations de géométries au niveau MP2. Par addition des fonctions diffuses aux ensembles de base, on a introduit une énergie locale maximale dans le profil de la réaction en champ auto-cohérent; ceci correspond à un changement majeur dans le caractère du profil par rapport à la courbe d'énergie potentielle entièrement attractive qui avait été trouvée dans les études antérieures. Du côté des réactifs, on a trouvé qu'il existe un minimum local dont l'énergie est 4,56 kcal/mol plus basse que la barrière et ce minimum correspond à un complexe ion-dipôle. Avec l'inclusion de la corrélation électronique, la barrière locale disparaît pratiquement complètement alors que la différence d'énergie entre le complexe ion-dipôle et la barrière maximale diminue à moins de 1 kcal/mol. De plus, la position du maximum d'énergie le long des coordonnées de la réaction est déplacée de 0,4 Å. On utilise ces résultats pour réévaluer d'une façon critique quelques points de vue qui prévalent actuellement sur la nature des profils réactionnels pour ce type d'addition nucléophile anionique.

Introduction

Anionic nucleophilic additions to carbonyl groups play a major role in key biochemical processes as well as being of great strategic importance in synthetic organic chemistry. The mechanism of this type of reaction has been studied intensively, with much interest focussing on the formation of the tetrahedral intermediate generally agreed to result from the initial (and normally rate-determining) step. In a "landmark" paper (1) published in 1974, SCF *ab initio* calculations were carried out on a prototype model reaction, the nucleophilic addition of hydride to formaldehyde to form methanolate. An important feature of the SCF potential energy (PE) profile in this study was the absence of energy maxima — the PE was always attractive as the hydride approached the carbonyl reaching a minimum only at the final equilibrium bonded distance. A number of subsequent theoretical studies (refs. 2 to 4, for example), simulating various anionic gas phase additions of similar types, verified this trend, leading to a general view that in the gas phase there are no PE local maxima as an anionic nucleophile attacks a carbonyl group (4). The above theoretical work was performed prior to the general use of diffuse functions (ref. 5 and references therein) by chemists, now widely accepted as being essential for the proper description of anions.

In contrast to the above results, in a recent *ab initio* study by Madura and Jorgensen (6) on the addition of hydroxide to formaldehyde, using a basis set containing diffuse functions, a small local maximum was found in the potential energy profile of the reaction. It is therefore of interest to establish whether or not reaction profiles in general for this class of reaction exhibit such an energy "hump". The effect of including electron correlation in the energy claculations would further indicate if the local maximum is a real feature of the potential energy profile of this reaction, or an artifact of the Hartree–Fock method.

In this paper we present the results of a theoretical reinvestigation of the original prototype reaction, the nucleophilic addition of hydride to formaldehyde to form methanolate. Diffuse functions were included in the basis set, and geometry optimizations were performed at both the Hartree–Fock and electron correlation levels. The strategy of the investigation was to determine the reaction profile of the hydride–formaldehyde system with basis sets of increasing sophistication, finding out at what basis set level the profile changed in character, and how further improvements of the basis set and the inclusion of electron correlation influenced the new profile.

Calculations

Calculations were carried out at the RHF (Restricted Hartree–Fock) and MP (Møller–Plesset) levels using the GAUSSIAN 80 (7*a*) and GAUSSIAN 82 (7*b*) computer programs. Several basis sets were tested, with polarization and diffuse functions added as described below. At each SCF level the geometry was fully optimized (using the GAUSSIAN 82 gradient-searching algorithms). MP2, MP3, and MP4 calculations with a very good basis set were performed with geometry optimization at the MP2 level. C_s symmetry was always enforced. The geometry was specified as follows: the formaldehyde H—C—H plane was chosen as the frame of reference, and a dummy atom X

[a]The energy at the global minimum is −114.41606 hartree.

placed bisecting this angle. The formaldehyde C—H bond lengths, and bond angles H—C—X were allowed to vary during optimization. Oxygen and hydride were allowed movement only in the plane perpendicular to the H—C—H plane and containing the line C—X. The hydride–carbon distance was used as the reaction coordinate.

Basis sets labeled with a *d* were augmented with *s* and *p* diffuse functions (8*a*) on oxygen (exponent 0.0845 with 6-31G, exponent 0.0680 with 4-31G) and hydride (exponent 0.0360). Basis sets labeled with a *p* were augmented with polarization *p* functions (8*b*) on hydride (exponent 0.110). Other basis set notation is according to standard practice: * for polarization functions and + for diffuse functions on all nuclei other than hydrogen; ** for polarization functions and ++ for diffuse functions on all nuclei including hydrogen. The notation *x*//*y* refers to a calculation with basis set *x* on geometries optimized with basis set *y* (e.g. 6-31G//4-31G means "the 6-31G energy calculated at the 4-31G optimized geometry"). For all SCF calculations involving a PE local maximum, the geometry for the structure at the maximum had a single negative eigenvalue in the Hessian matrix, showing it to be a true saddle point on the potential energy hypersurface.

Results

The minimal basis set STO-3G was used as a starting point, followed by split-valence basis sets. The effect of adding special functions was tested at the 4-31G level. First, polarization functions were added to carbon, oxygen, and hydride (4-31G*p), then diffuse functions only were added to oxygen and hydride (4-31Gd), and finally both polarization and diffuse functions were added (4-31G*pd). The relative energies at various carbon–hydride distances, including the local maximum and the secondary minimum, are given in Table 1. The effect of further basis set improvement was tested in calculations using the 6-31G**d basis set (Table 1, last column). These results are shown graphically in Fig. 1. The final basis set used was 6-31++G**, having both polarization and diffuse functions on all nuclei. In Table 2, the optimized geometry for each

carbon–hydride distance, including the local maximum and the secondary minimum, is given together with the corresponding energy relative to the global minimum (methanolate). The potential curve is shown in Fig. 2.

Møller–Plesset calculations were performed using the 6-31G**d basis set with geometry optimization at the MP2 level. The resulting geometries and the RHF, MP2, MP3, and MP4 energies are given in Table 3 and the energies are plotted in Fig. 3. Zero-point energy (ZPE) corrections were made at the geometry of methanolate and the intermediate minimum. Several structures from Table 2 are superimposed in Fig. 4 to indicate the changes in geometry taking place over the course of the reaction.

Discussion

The STO-3G and 4-31G results (Table 1) gave a reaction profile in agreement with the literature, indicating no PE maximum in the addition reaction. The minimal basis set drastically overestimated ΔE_{reac} (the energy difference between the separated reactants and the global minimum) to be 121 kcal/mol, while for the unaugmented 4-31G basis ΔE_{reac} was 65 kcal/mol, still much larger than the best RHF energy of 34 kcal/mol from the 6-31++G** basis set (Table 2).

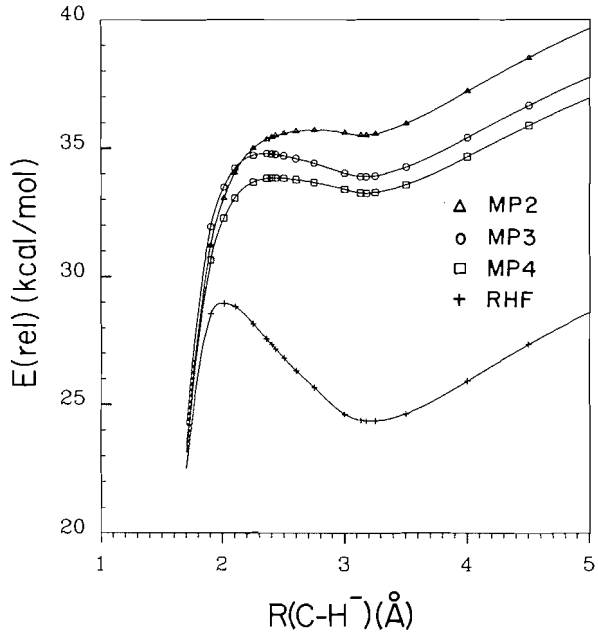

FIG. 3. Energy profiles of the MP2/6-31G**d optimized structures for the H^- + H_2CO addition.

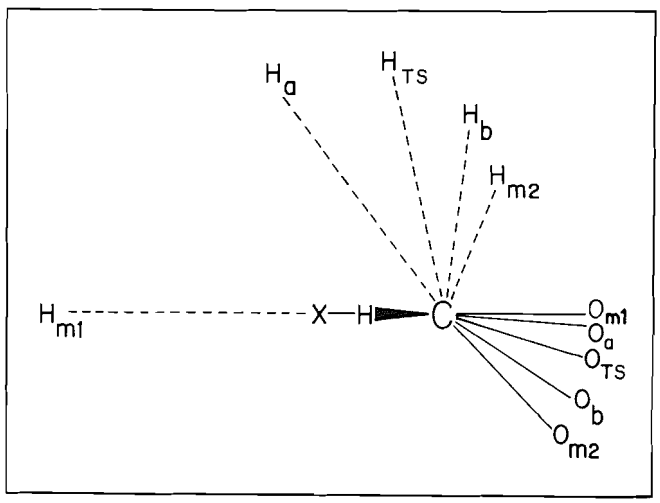

FIG. 4. Several structures of the H^- + H_2CO addition, superimposed to show geometry changes over the course of the reaction. Geometries (6-31++G**//6-31++G** calculations) are labelled as follows (with the C—H^- distance given): m1: charge dipole complex (C_{2v}), 3.2268 Å; *a*: 2.5 Å; TS: transition state, 2.0071 Å; *b*: 1.6 Å; m2: global minimum, methanolate (C_{3v}), 1.1226 Å.

It is interesting to compare the results for different kinds of extra functions added to the 4-31G basis set. The first step was to put polarization functions on those nuclei involved in polar bonding during the reaction process, viz. carbon, oxygen, and hydride (4-31G*p). While this did lower the total energies and improve the ΔE_{reac} by a few kcal/mol, the reaction profile was unchanged. The next basis set modification was the further addition of diffuse functions to hydride and to oxygen (the 4-31G*pd basis). These diffuse functions allow for a better description of extra electron density from the anionic electron, which is found on the hydride in the reactants and on the oxygen in the product.

It was upon the addition of diffuse functions that the reaction profile underwent its change of character. A potential energy hump appeared, giving a local energy minimum on the reactants side of the barrier (Fig. 1). Since the introduction of the diffuse functions into the 4-31G*p basis set caused such a radical change in the reaction profile, we decided to remove the polarization functions and recalculate the profile with only diffuse functions added (the 4-31Gd basis (Table 1)). While the resulting total energies were higher than those for the 4-31G*p basis set, the new reaction profile did contain the barrier. Furthermore, ΔE_{reac} for 4-31Gd was 42 kcal/mol, much closer to the 4-31G*pd value of 34 kcal/mol than the 4-31G*p value of 59 kcal/mol. This led us to conclude that the inclusion of polarization functions to accompany the diffuse functions was not necessary for an adequate SCF description of this reaction. In an *ab initio* study by Spitznagel *et al.* (8), using the standard 4-31G and 6-31G basis sets to investigate methyl anions, these authors also added diffuse functions with and without polarization functions, and found that diffuse functions alone were sufficient.

The qualitative difference in the reaction profile brought by diffuse functions is probably due to the large energy lowering given to hydride. Using differences between 4-31G and 4-31Gd energies, diffuse functions stabilize hydride by 40.6 kcal/mol, whereas they lower the energy of H_2CO by only 3.7 kcal/mol, and that of methanolate by 21.2 kcal/mol. Therefore, ΔE_{reac} decreases by 23.1 kcal/mol as a result of the introduction of diffuse functions, most of this decrease being due to hydride. It is likely that the energy maximum is hidden by the large value of ΔE_{reac} when diffuse functions are not used.

The SCF study was concluded with the increase of the basis set first to the 6-31G**d and finally to the 6-31++G** level. In the latter basis, all hydrogens received diffuse functions, not only the hydride, resulting in all C—H distances of methanolate (C_{3v}) to be identical. These two basis sets gave virtually identical profiles that were also very similar to those of the 4-31G*pd basis set (see Fig. 1), and it was felt that further basis set extension would not qualitatively change the reaction profile at the RHF level.

While the trajectory of the minimum energy pathway does not differ significantly from that found in previous studies, the RHF energy profile has major differences. The trajectory and profile can be summarised together (using data from Table 2) in the following way: the initial approach of the hydride (from the separated reactants having ΔE_{reac} = 34.1 kcal/mol) is along the C_{2v} symmetry axis of formaldehyde towards the carbon. A planar charge dipole complex is formed at a distance of 3.23 Å, representing a local energy minimum (the energy difference relative to the global minimum E(rel) = 23.2 kcal/mol). Further approach of the hydride, now rising out of the H—C—H plane of formaldehyde, requires the overcoming of a small (4.6 kcal/mol) energy barrier whose energy maximum (E(rel) = 27.8 kcal/mol) is lower than the energy of the separated reactants. At the barrier maximum the carbon–hydride distance is 2.007 Å, the hydride is 77° above the H—C—H plane, and the carbon is pyramidalizing, with the carbon–oxygen bond 15° below the H—C—H plane and lengthening. From here on the potential energy is highly attractive, with the nuclei completing their trajectories to take up their equilibrium positions in the product (E(rel) = 0 kcal/mol).

In the previously mentioned study by Madura and Jorgensen (6) on the addition of hydroxide to formaldehyde using the 6-31+G* basis set, a small local maximum in the potential

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.222.148.141 on 09/07/12
For personal use only.

energy was found in a similar area of the reaction coordinate. The hydroxide traces a similar trajectory to that outlined above in its approach to the carbonyl carbon, with the potential energy hump occurring at 2.39 Å for an O—C—O bond angle of 126.9°. This energy maximum is only 1.1 kcal/mol higher than the energy of the corresponding planar ion–dipole complex (formed at a C—OH distance of 2.47 Å), a quantity the authors claim could disappear upon the inclusion of electron correlation and zero-point energy, or basis set extension. In comparing the global minimum with the separated reactants, the authors also noted that the correlation and zero-point correction tended to cancel each other.

Møller–Plesset claculations were carried out on the hydride–formaldehyde system to check the effect of electron correlation on the SCF results. With geometry optimization done at the MP2/6-31G**d level, the resulting MP2, MP3, and MP4 energies (given in Table 3 and plotted in Fig. 3) showed a pronounced change in the reaction profile in that the potential energy barrier flattened greatly on the reactant side. Starting from the charge–dipole complex, the energy change in going to the top of the PE barrier decreased to less than 1 kcal/mol for all MP levels compared to 4.6 kcal/mol at the RHF level. In contrast, the MP results otherwise indicated a general increase in the relative energies, such as those between the product and the barrier maximum, and the barrier maximum and the separated reactants. The three levels of MP treatment gave very similar results.

These changes in the energy profile cannot be due to geometry differences between the RHF and MP2 optimized geometries because the RHF energies given in Table 3 calculated for MP2/6-31G**d optimized geometries show a 4.6 kcal/mol energy difference between the charge–dipole complex and the barrier maximum, in agreement with the RHF optimized 6-31G**d results. The differences between the RHF and MP2 reaction profile must therefore be attributed to the correlation energy changes during the course of the reaction.

Perhaps the most interesting feature of the changes caused by the introduction of electron correlation is the movement of the saddlepoint location on the reaction coordinate. The RHF results placed the saddlepoint at a carbon–hydride distance of 2.0 Å, whereas the saddlepoint was found at around 2.7 Å at the MP2 level, and around 2.4 Å at the MP3 and MP4 levels. This is presumably a consequence of having such a shallow maximum in this region, where small changes in the energy distribution result in large changes in internuclear distance.

In the study of closed-shell singlet state reactions such as the one investigated here, the inclusion of electron correlation is frequently considered to be unnecessary, since the RHF relative energies should be adequate to properly describe the reaction profile. From the above results, however, we see that not only is the character of the potential energy curve changed substantially, but the location of the saddlepoint changes by about 0.4 Å. At the RHF level the barrier, while not steep, would not lead one to expect such a large change.

The effect of the zero-point energy on the two minima found on the 6-31++G** profile was checked. The methanolate global minimum (ZPE/6-31++G**//6-31++G** total energy −114.37793 hartree) had a ZPE correction 4.93 kcal/mol higher than that for the charge dipole complex (ZPE/6-31++G**//6-31++G** total energy −114.34396 hartree). In agreement with the findings of Madura and Jorgensen (*vide infra*), this indicates a trend of the ZPE correction opposite to that of the correlation energy correction, so they would tend to cancel. In our case the ZPE correction reduces the MP4 relative energy difference between the global minimum and the charge dipole complex from 33.26 to 28.33 kcal/mol, still 3.98 kcal/mol above the RHF relative energy of 24.35 kcal/mol (Table 3).

Conclusions

For the gas-phase addition of hydride to formaldehyde, *ab initio* calculations indicate that at the RHF level the reaction profile does contain a potential energy local maximum, in contrast to previous studies. This maximum is sensitive to the choice of basis set. It is essential to include diffuse functions on centers having anionic character in reactants and product (to allow for proper distribution of the extra charge). Basis sets tried without diffuse functions, even those with polarization functions, showed no energy barrier.

Possibly the reason that local maxima are not commonly found for anionic nucleophilic reactions with carbonyl functionalities is that the basis sets used lack diffuse functions; this can be seen as forcing the anionic centers to be extraordinarily "hard". For calculations involving large anionic systems, the omission of diffuse functions might be considered necessary to avoid prohibitively large computations. This is understandable, since it is common practice to include polarization functions when adding diffuse functions (6), which together can correspond to a large increase in the total number of basis functions. While adding both kinds of extra functions is the better avenue, our results indicate that alternatively a basis set including only diffuse functions (even if they are on only the anionic centers – c.f. 6-31G**d vs. 6-31++G** results) might describe adequately the reaction profile; this could not be said of the results when no extra functions or only polarization functions were included.

Contrary to expectations, we found that the inclusion of electron correlation significantly changed the results for the closed-shell singlet-state addition reaction of hydride to formaldehyde. The local barrier found at the RHF level was flattened into a broad, shallow maximum, and the position of the saddlepoint changed by about 0.4 Å along the reaction coordinate.

It is unlikely that the differences between the new humped profile presented in this work and the barrier-less profile of previous studies would be experimentally measurable for the hydride–formaldehyde addition reaction. However, considering this reaction to be a prototype of anionic nucleophilic attack on carbonyl groups, a small increase in the barrier height on the order of a few kcal/mol could measurably influence the behaviour of larger systems at the experimental level. Our results suggest that such a barrier could pass entirely undetected at the RHF level without the inclusion of diffuse functions in the basis set. Furthermore, even for closed-shell singlet-state reactions the RHF energy profile might be significantly altered by the inclusion of electron correlation, with accompanying large changes in the geometries associated with the various intermediates along the reaction path.

Enaminic reactions of 4-*tert*-butyl-3,3-dimethyl-5-methylene-Δ^1-1,2,4-triazoline. Novel heterocycles by sequential [2 + 2] cycloaddition and ylide-forming [3 + 2] cycloreversion[1]

ADRIAN L. SCHWAN[2] AND JOHN WARKENTIN[3]

Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received May 21, 1987

ADRIAN L. SCHWAN and JOHN WARKENTIN. Can. J. Chem. **66**, 155 (1988).

Triazoline **1**, which is formally an α azoenamine, reacts with dimethyl acetylenedicarboxylate, acrylonitrile, methacrylonitrile, methyl methacrylate, phenylisocyanate, and sulfene to form products that appear to be derived from a common first step, the formation of a dipolar intermediate (e.g., **5**). That intermediate may close to form either a 4-membered ring (**6**, **8**) or ring-open to **7** with subsequent closure to a 5-membered ring (**4**). Alternatively it may lead to an enamine with extended conjugation (**10**, **11**) by a sequence of proton transfers. The spirotriazolines (e.g., **6**) are unstable and decompose by loss of N_2 to form spiro aziridines (e.g., **3**). Hydrogen cyanide, from acetone cyanohydrin, converts **1** to the cyanoaziridine **13** while methanol adds reversibly under acidic conditions to form **17**.

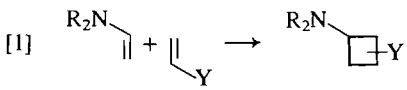
ADRIAN L. SCHWAN et JOHN WARKENTIN. Can. J. Chem. **66**, 155 (1988).

La triazoline **1**, qui est formellement une α-azoènamine, réagit avec l'acétylènedicarboxylate de diméthyle, l'acrylonitrile, le méthacrylonitrile, le méthacrylate de méthyle, l'isocyanate de phényle et le sulfène pour conduire à des produits qui semblent tous provenir d'une première étape commune, soit la formation d'un intermédiaire dipolaire (à savoir **5**). Cet intermédiaire peut soit se refermer pour former un cycle à 4 chaînons (**6**, **8**) soit s'ouvrir pour donner **7** qui subit une fermeture ultérieure conduisant à un composé cyclique à cinq chaînons (**4**). Par ailleurs, il peut aussi conduire à une ènamine comportant une conjugaison étendue (**10**, **11**) et provenant d'une séquence de transferts protoniques. Les spirotriazolines (comme **6**) sont instables et se décomposent, par perte de N_2, pour former des spiroaziridines (comme **3**). L'acide cyanhydrique, provenant de la cyanohydrine de l'acétone, transforme le composé **1** en cyanoaziridine **13**; par ailleurs, le méthanol s'additionne d'une façon réversible, dans des conditions acides, pour former le composé **17**.

[Traduit par la revue]

Introduction

The synthetic utility of enamines is well documented (1, 2). Stork's methodology (3) is still one of the most reliable procedures for overall monoalkylation of a ketone. Nucleophilic addition of an enamine to an electron-deficient unsaturated compound, on the other hand, often leads to formation of a [2+2] cycloadduct (eq. [1]), which in many cases is the final

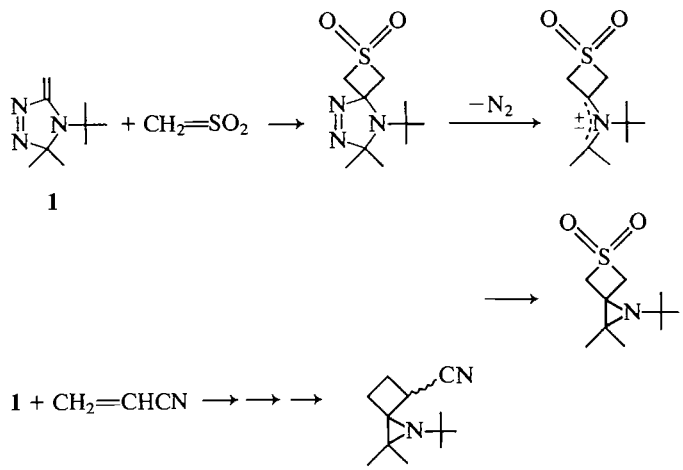


[1]

product (4). Electron-deficient unsaturated compounds that form [2+2] cycloadducts with enamines include sulfenes (5), ketenes (6), isocyanates (7), acetylenic compounds (8, 9), acrylic acid derivatives (10), tetracyanoethylene (11), and maleimide (12).

Recently, we reported (13) the synthesis of triazoline **1**, in which enamine and α,β-unsaturated azo functionalities are combined. Triazoline **1** showed enaminic reactivity toward sulfene and acrylonitrile (13) but the products (Scheme 1), although they had the expected 4-membered ring (eq. [1]), were also spiroaziridines. A likely mechanism for their formation, shown in the first line of Scheme 1, involves [2+2] cycloaddition followed by [3+2] cycloreversion to form an azomethine ylide, which undergoes electrocyclic ring closure to the final product.

Azomethine ylides are useful intermediates for the synthesis of alkaloids (14, 15) and the preparation and reactivity of such ylides are the topics of two recent reviews (16, 17). The



SCHEME 1

thermolysis (or photolysis) of Δ^1-1,2,4-triazolines (eq. [2]), as a route to azomethine ylides, has been considered (18) but the only examples of ylide generation by that general approach seem to be the two given in Scheme 1 (13).

We now report additional chemistry of **1** as well as details of the results that were presented earlier in the form of a preliminary communication (13).

Results and discussion

Heating of **1** in neat acrylonitrile (**2***a*) at temperatures between 50 and 80°C afforded the diastereomers of **3** in 1:1

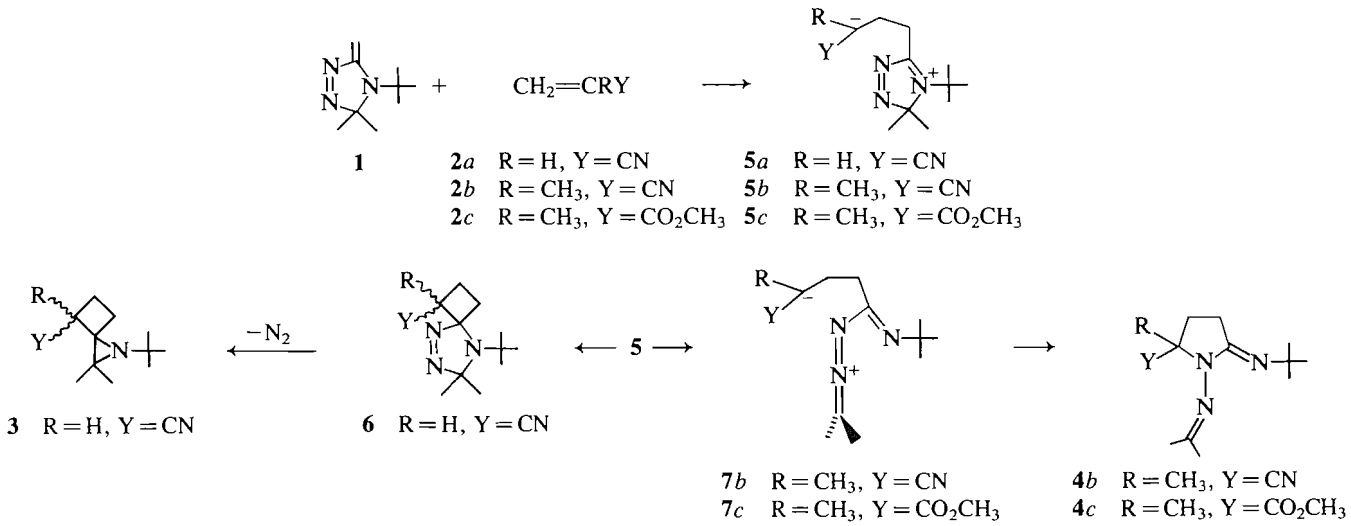
[f]In methanol.



SCHEME 2

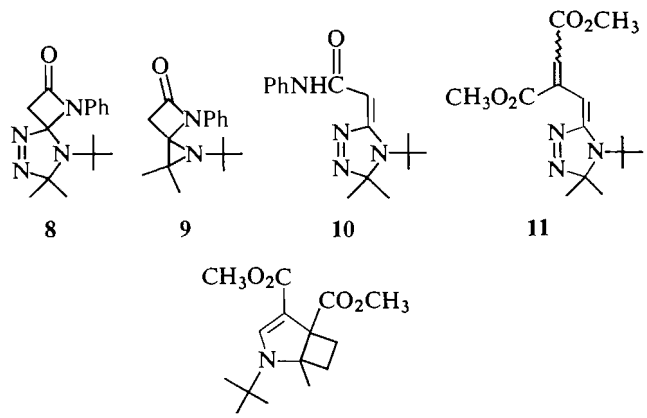
ratio and in 88% isolated yield. The diastereomers were barely separable by analytical glpc but separation on a preparative scale was unsuccessful. The ^{13}C nmr spectra (Table 1) indicate clearly that diastereomers **6** cannot be considered as alternatives to **3**. Triazolines **6** would give rise to a signal in the 100–110 ppm range for the *gem*-dimethyl bearing carbon, as in **1**, **11**, and **17**. Moreover, the ^{13}C nmr signals in the range 41–55 ppm suggest quaternary carbon atoms bonded to one nitrogen atom, while the ^1H nmr spectrum (500 MHz, Table 1), although not fully resolved, requires that the methylene and methine protons are attached to a rigid carbon framework.

Surprisingly, the reaction of **1** with methacrylonitrile (**2***b*) did not afford the analogues of **3** but gave, instead, compound **4***b* in 70% yield. Methyl methacrylate (**2***c*) behaved like **2***b*, affording **4***c* in about 70% yield. The hydrazone functional group of **4** follows from the methyl group singlets characteristic of the ^1H nmr spectra of hydrazones of acetone, and the five-membered ring is indicated by the fact that all four methylene protons are magnetically nonequivalent and coupled to one another. All of the additional spectroscopic evidence (Table 1) is fully consistent with the structures labelled **4**.

The above results can be rationalized as follows. Initial interaction of **1** with the acceptor involves formation of one C—C bond, to generate zwitterion **5** (Scheme 2). That species cyclizes, in the 4-*exo* sense, to form spiro compound **6**, or it undergoes ring opening to form intermediate **7**. The latter undergoes ring closure[4] to **4**. Steric effects on the rate constant for 4-*exo* cyclization are probably large because closure to **6** involves eclipsing interactions between neighbouring substituents of the developing cyclobutane ring. One of those substituents is the large N—$C(CH_3)_3$ group. Ring opening to **7**, on the other hand, is probably accompanied by a reduction of nonbonded interactions. Moreover, the stereoelectronic requirements for forming **7** are well provided for in **5** and there is precedent for such reactions in the [2,3]-sigmatropic rearrangement of allenic sulfonium ylides (19). Although we were not able to detect both **3** and **4** from a given **2**, the possibility that minor amounts of the appropriate coproduct were formed in each case has not been ruled out.

Geometric isomers of **4***b* and **4***c* were not observed. The *E* configuration at the C=NC$(CH_3)_3$ group is required by the proposed mechanism and it is also the least sterically congested of the possible configurations.

Reaction of **1** with phenyl isocyanate in chloroform at room temperature afforded neither **8** nor **9** but, instead, the β-amino-α,β-unsaturated amide (**10**) in 62% yield. Compound **10** is analogous to the *E* and *Z* isomers **11** formed, together with **12**, from reactions of **1** with dimethylacetylene dicarboxylate (8).



8 **9** **10** **11**

12

The mass spectrum of **10** deserves brief mention. Under ei conditions the molecular ion peak was not observed but there was, instead, a peak at *m/z* 258 corresponding to $M^+ - N_2$. Chemical ionization (ci) mass spectra (NH_3 or CH_4), on the other hand, led to a signal at *m/z* 289, corresponding to $M + 3)^+$. In the ci (NH_3) mass spectrum, the signal for *m/z* 289 was the most intense one, while in the case of ci (CH_4) the relative intensity for *m/z* 289 was 9% (base peak, *m/z* 110) and there were additional signals at *m/z* 288 (8%) and 287 (32%). Similar ci mass spectra of diethyl azodicarboxylate and of **11** (*E* isomer) revealed that they too had significant signals at *m/z* $(M + 3)^+$. Apparently reduction of such azo compounds is a significant process under the conditions for ci mass spectrometry. Although the low reduction potential of azocarbonyl compounds is well known (20), the apparent reduction of **10** and **11** by NH_3 or by CH_4 in the mass spectrometer was surprising.

Triazoline **10** is the type of product expected from the reaction of phenyl isocyanate with an enanime that has at least one hydrogen at the nucleophilic carbon. Enamines that are

[4]The intermediacy of **7** is postulated because the alignment of orbitals for concerted formation of **4** from **5** is poor.

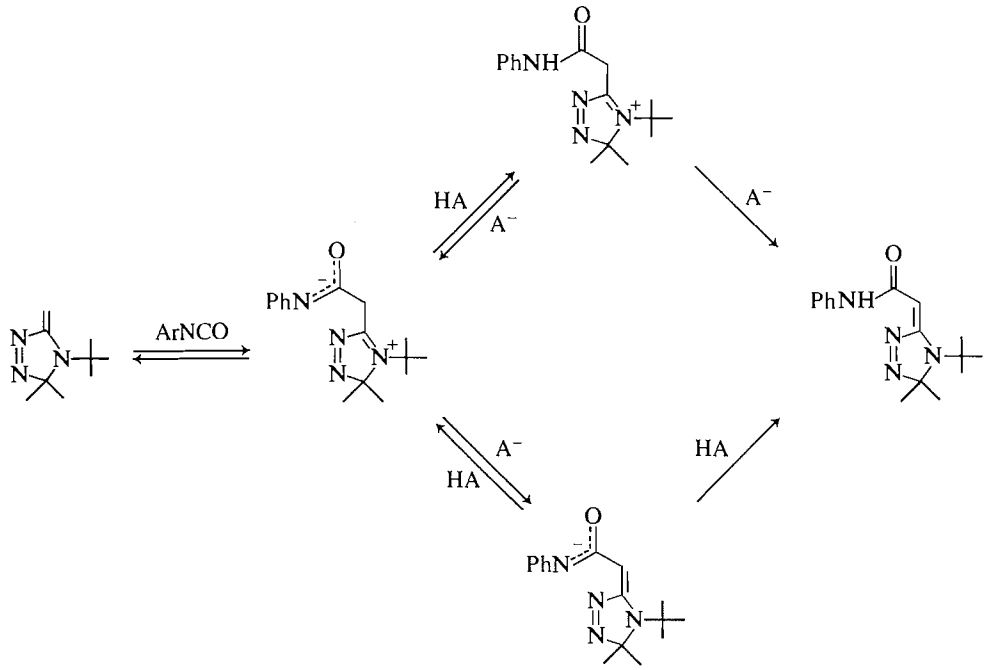
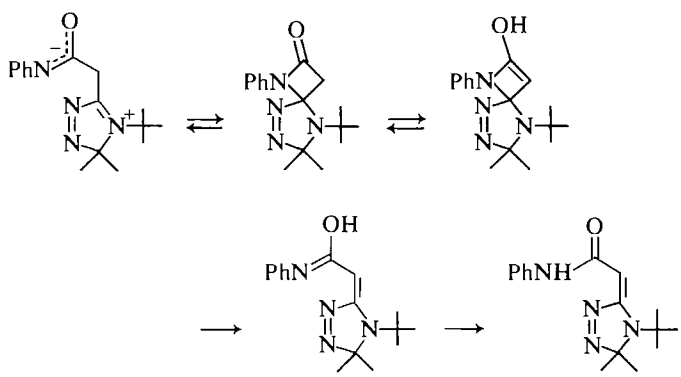


SCHEME 3

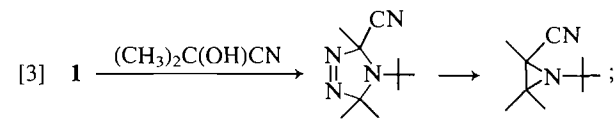
disubstituted at the β-carbon give isolable β-lactams when treated with phenyl isocyanate (7). The *E* configuration of **10** was assigned on the basis of signal intensity enhancements in the ^{1}H nmr spectrum of **10** (nuclear Overhauser effects) attributable to the proximity of the *tert*-butyl group and the vinyl proton of **10** (see Experimental).

There are at least two mechanisms by which **10** could be formed. First there is the sequential proton transfer mechanism (Scheme 3) by which compounds **11** appear to be formed from **1** and dimethyl acetylenedicarboxylate (8). Second is a mechanism usually postulated for reactions of enamines with isocyanates (7) but which, in fact, is not supported by any hard evidence, insofar as we are aware. That mechanism is the [2 + 2] cycloaddition, enolization, and [2 + 2] cycloreversion sequence of Scheme 4. At this time there is insufficient evidence to rule out either mechanism and we note only that the acid–base pair HA/A^- required for Scheme 3 is unidentified and that there is a problem with Scheme 4. It was not possible to detect any intermediates by ^{1}H nmr spectroscopy, implying that the β-lactam of Scheme 4 would have to be surprisingly reactive, either in the ring-opening sense or in the enolization sense. In Scheme 3, on the other hand, there are no intermediates that would be expected to accumulate to readily detectable concentrations.



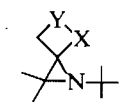
SCHEME 4

Acetone cyanohydrin in CH_3OH, CH_2Cl_2, or CH_2=CHCN reacted with **1** to afford **14** in 42–47% yield (eq. [3]). The



[3]

13 **14**



15*a* X = CH_2, Y = SO_2
15*b* X = SO_2, Y = CH_2

structure of **14** was inferred from its ^{1}H and ^{13}C nmr spectra (Table 1) and from its simple ci mass spectrum, with base peak at *m/z* 167 corresponding to $(M + 1)^+$. As in the case of **4** (above) the absence of ^{13}C nmr signals in the range 100–110 ppm, characteristic of 1,2,4-triazolines, excluded **13** from consideration.

Treatment of **1** with sulphene (CH_2=SO_2), generated *in situ* from methanesulfonyl chloride and triethylamine, gave **15***a* in 40% yield. In keeping with previous experience (5, 21) and with FMO analysis of the reacting double bonds (22), the regioisomer **15***b* was not observed. The structure of **15***a* followed from its ms and nmr data (Table 1). In the ^{13}C nmr spectrum the absence of signals near 105 ppm indicated that the azo function had been lost. Moreover, the signal at δ 70 is characteristic of the α-carbon of a thietane-1,1-dioxide (21). The ^{1}H nmr spectrum included a clean AB pattern centered at δ 4.22 (21). The clean AB pattern suggests that inversion of the aziridine nitrogen of **15***a* is fast enough, on the nmr time scale, to give the molecule an effective plane of symmetry passing through the aziridine ring atoms and through the S-atom of the thietane-1,1-dioxide ring. Facile inversion of a pentasubstituted

aziridine is not surprising because eclipsing between C and N substituents can be expected to drive the geometry at nitrogen towards planarity, thereby reducing the barrier to inversion (23).

A remarkable result that emerges from the present study is that the azomethine ylide intermediates that are necessary to account for the transformations of **1** into **3** (Scheme 2) and of **1** into **14**, by reaction with acetone cyanohydrin, are not readily intercepted. The yield of **3** in neat acrylonitrile was 88%, and the yield of **14** (42–47%) was essentially independent of the solvent (CH_2Cl_2 or CH_3OH or $CH_2{=}CHCN$). Although the failure of acrylonitrile to trap the ylide could be rationalized in terms of steric hindrance, methanol is known to capture ylides very rapidly (24), and therefore we are forced to conclude that the azomethine ylides in question cyclize to aziridines with very large rate constants.

The reason for very rapid ring closure may be complex, but an identifiable component has its roots in steric factors. In the ylides, the large *N-tert*-butyl substituent and the terminal *exo* substituents should be eclipsed to maximize π-bonding (25). In the transition structures for cyclization, those eclipsing interactions are relieved by twisting. The new steric interactions that develop should not be as large because all three C—N bonds must lengthen as N is rehybridized from a planar to a shallow pyramidal geometry. Moreover, the geminal and vicinal substituent separations are large because of the compressed internal angles of a small ring. An equivalent rationale begins with the assumption that the ylides cannot adopt the all-planar structure that is the ground state of less congested ylides (25) and that they are already substantially twisted in their most stable conformations. Whichever view is taken, the very fast ring closures of the ylides encountered here are attributed to a raised ground state energy level, as proposed by others (26, 27).

Triazoline **1** adds methanol reversibly in the presence of a protic acid (eq. [4]). Although the overall addition of methanol

[4] **1** $\overset{H^+}{\rightleftharpoons}$ **16** $\overset{CH_3OH}{\rightleftharpoons}$ **17**

to **1** is normal enamine chemistry, the survival of **17** is surprising in view of the apparent instability of analogous triazolines with quaternary ring carbons (**6**, **8**, **13**, for example). There was no evidence for appreciable decomposition of **17** even after weeks at room temperature in methanol. Although increased solvent polarity decreases rate constants for decomposition of *cis* azo compounds (28), the stability of **17** in methanol cannot be attributed to the solvent polarity because **13** does not accumulate during conversion of **1** to **14** in methanol at room temperature (eq. [3]). The ratio (**17**:**1**) at equilibrium at room temperature was 0.6 at a total concentration (**17** + **1**) near 0.2 *M*.

Experimental

Melting points were determined on a Thomas Hoover capillary melting point apparatus and are uncorrected. Proton nuclear magnetic resonance (^{1}H nmr) spectra were recorded on a Bruker AM-500 or a Varian EM-390 spectrometer using TMS or residual $CHCl_3$ in $CDCl_3$ as internal standard. Carbon nuclear magnetic resonance (^{13}C nmr) spectra were obtained on a Bruker WP 80/90 spectrometer. Infrared (ir) spectra, obtained with a Perkin–Elmer model 283 instrument, are reported in wavenumbers (cm^{-1}) calibrated against the 1601.4 cm^{-1} band of polystyrene. Ultraviolet (uv) spectra were obtained with a Hewlett–Packard model 8451A diode array spectrophotometer. Mass spectra (ms) were recorded on a VG 70-70F double focussing or a VG ZAB-E triple focussing mass spectrometer.

Centrifugal chromatography was carred out on silica (Merck, Kieselgel 60 PF_{254}) coated glass plates (coating 2 mm thick) spinning in a Chromatotron model 7924T apparatus. Plastic-backed, Merck Kieselgel 60 F_{254}, 0.2-mm silica plates or plastic-backed Polygram ALOX, N/UV_{254}, 0.2-mm neutral alumina plates were used for analytical thin-layer chromatography (tlc).

The following materials are commercially available and were distilled before use: CH_3SO_2Cl, Et_3N (from KOH), methacrylonitrile, and acrylonitrile. Also commercially available, but used as received, were methyl methacrylate, methanol (Baker Analyzed), anhydrous ether (Allied), phenyl isocyanate, acetone cyanohydrin, and methanol-OD (Aldrich). Methylene chloride (Caledon) and chloroform (Caledon) were distilled from P_2O_5 and stored over 4 Å molecular sieves.

The synthesis of triazoline **1** has been described (13).

Nuclear Overhauser enhancement (nOe) measurement

The substrate (10 mg) in 0.4 mL of $CDCl_3$ with a trace of added MeOH was sealed into a medium-walled nmr tube after three cycles of freeze–pump–thaw degassing at 0.3 Torr (1 Torr = 133.3 Pa). Eight scans on a Bruker WH250 nmr spectrometer with off-resonance irradiation were followed by eight scans taken with irradiation directed at the substrate's *t*-Bu signal. Each signal was integrated against the CH_3 signal of the internal MeOH. No correction was made for enhancement, if any, of the reference signal during double irradiation.

*Reactions of **1** with acrylonitrile, methacrylonitrile, and methyl methacrylate*

Triazoline **1** (0.120 g) in 10 mL of acrylonitrile was sealed into a tube that had been evacuated at 0.1 Torr. The tube and contents were heated with an oil bath at 80°C (8 h) or at 50°C (14.5 h). After cooling, the tube was opened and the excess acrylonitrile was removed under reduced pressure (aspirator). The residue, in ether, was applied to a neutral Al_2O_3(II) column from which it was eluted with 40% ether in light petroleum. The first fraction collected contained the diastereomeric 2-aza-2-(*tert*-butyl)-4-cyano-3,3-dimethyl-spiro[2.3]hexanes, **3** (R_f = 0.61, Al_2O_3, ether) isolated as an oil, 139 mg (88%).

Similar heating of **1** (0.127 g) in methacrylonitrile (9 mL) at 80°C for 26 h, and analogous work-up except for elution with ethyl acetate (10%) in light petroleum, afforded amidrazone **4***b* (0.128 g, 70%), R_f = 0.08 (Al_2O_3, ether). Recrystallization from light petroleum gave **4***b* as a colourless solid, mp 60–61.5°C.

Analogous treatment of **1** (0.260 g) with methyl methacrylate (10 mL) at 80°C for 26 h led to significant polymer formation. The contents of the tube were added to dry methanol (20 mL), the precipitate was filtered off, and the residue was concentrated to afford crude **4***c*, which is very easily hydrolyzed. The ^{13}C nmr spectrum was obtained directly with the crude sample. For other spectra (Table 1) pure samples were collected by preparative glpc (6 ft × 1/4 in. column packed with OV-17, 10% on Chromosorb W) at 172°C. With a helium flow rate of 18 mL min^{-1}, the retention time for **4***c* was 7 min.

*Reaction of **1** with acetone cyanohydrin*

A solution of triazoline **1** (210 mg) in 2.5 mL of a solvent (see below) and 0.25 mL of acetone cyanohydrin was stirred at room temperature until the triazoline was consumed (5 h for CH_2Cl_2 solvent, 3 h for methanol or acrylonitrile). Once the reaction was complete, CH_2Cl_2 (10 mL) and dilute aqueous base (20 mL) were added. After five minutes more of stirring, the layers were separated. The aqueous portion was extracted (3 × 10 mL) with CH_2Cl_2. The organic layers were combined and dried over $MgSO_4$.

After filtration and concentration (aspirator) the residue was applied to a column of 10 g of Al_2O_3(II) and eluted with 50% ether in light petroleum. The first fraction (R_f = 0.57, ether) was 1-(*tert*-butyl)-2-cyano-2,3,3-trimethylaziridine (**14**, 88–99 mg, 42–47%) obtained as an oil.

*Reaction of **1** with phenyl isocyanate*

A solution of triazoline **1** (0.158 g) in 6 mL of dry chloroform containing 0.25 mL of phenyl isocyanate was stirred at room tempera-

ture for 48 h. More isocyanate (0.25 mL) was added and stirring was continued for a further 48 h. Dry chloroform (20 mL) was added and the resulting solution was washed twice with aqueous NaOH (20 mL, 0.5 *M*). The organic layer was dried over $MgSO_4$. Concentration and chromatography of the residue on a silica column (ether) led to separation of an orange compound with R_f = 0.22 (SiO_2, ether). Fractions containing the orange material were concentrated and the residues were subjected to centrifugal chromatography (Chromatotron, SiO_2 plate) with ethyl acetate (25%) in light petroleum. The viscous orange product would not crystallize. The yield of triazoline **10** was 168 mg (62%). Irradiation at the frequency of the *tert*-butyl signal (^{1}H nmr) increased the intensity of the vinyl signal of **10** by 26%.

*Reaction of **1** with sulfene*

A 50-mL round-bottomed flask was charged with **1** (0.280 g, 1.7 mmol), triethylamine (0.350 g, 3.5 mmol), and 10 mL of anhydrous ether. The solution was stirred and cooled with ice while methanesulfonyl chloride (0.379 g, 3.3 mmol) was added dropwise in 20 min. The ice bath was removed and stirring was continued for 4 h. Dichloromethane (10 mL) was added, the precipitated amine salt was filtered off, and the filtrate was concentrated. The residue was applied to a column of Al_2O_3(II) from which the product was eluted with ether (50%) in light petroleum (R_f = 0.17, ether). Further chromatographic purification of the product from the first column gave 2-aza-2-(*tert*-butyl)-3,3-dimethyl-5-thiaspiro[2.3]hexane-5,5-dioxide (0.104 g, 40% based on 0.20 g of triazoline consumed), mp 78.5–80°C (from petroleum).

Methylenetriazoline–methoxytriazoline equilibrium

Triazoline **1** (0.20 g) in methanol (2 mL) containing a few crystals of toluenesulfonic acid hydrate was kept at room temperature for 5 h. Analysis of the solution by ^{1}H nmr and ^{13}C nmr spectroscopy showed the presence of unreacted **1** and 4-(*tert*-butyl)-3,5,5-trimethyl-3-methoxy-Δ^1-1,2,4-triazoline (**17**). The ratio **17**:**1** = 0.6, estimated by integration of the ^{1}H nmr spectrum, remained constant with time for several weeks. Spectra of **17** are in Table 1.

Methylation of polymethylbenzenesulfonic acids by hexamethylbenzene and pentamethylbenzenesulfonic acid in concentrated sulfuric acid[1]

HANS CERFONTAIN[2] AND ANKIE KOEBERG-TELDER

Laboratory for Organic Chemistry, University of Amsterdam, Nieuwe Achtergracht 129, 1018 WS Amsterdam, The Netherlands

Received May 25, 1987

HANS CERFONTAIN and ANKIE KOEBERG-TELDER. Can. J. Chem. **66**, 162 (1988).

The methylation of a series of polymethylbenzenes (PoMB's) or their sulfonic acids by added hexamethylbenzene (HMB) and pentamethylbenzene-1-sulfonic acid (PeMB-1-S) as reagents in 95.5 and 98.4% H_2SO_4 as solvent has been studied under homogeneous conditions. HMB effects methylation of 2,4,6-trimethylbenzene-1-sulfonic acid (2,4,6-TrMB-1-S), 2,3,4,6-tetramethylbenzene-1-sulfonic acid (2,3,4,6-TeMB-1-S), and 2,3,5,6-TeMB-1-S, but not of the sulfonic acids of 1,3-dimethylbenzene (1,3-DMB), 1,2,3-TrMB, 1,2,4-TrMB, and 1,2,3,4-TeMB. PeMB-1-S is less reactive as methylating reagent than HMB. The observed substrate reactivity towards methylation by HMB was observed to decrease in the order 2,3,4,6-TeMB-1-S $\approx$ 2,3,5,6-TeMB-1-S $>$ 2,4,6-TrMB-1-S $\gg$ 2,3,4,5-TeMB-1-S, and towards methylation by PeMB-1-S to decrease in the order PeMB-1-S $\gg$ 2,4,6-TrMB-1-S. On the basis of a comparison of these orders of substrate reactivities with those predicted for the series of the PoMB-1-sulfonates and the corresponding PoMB's, it is concluded that the substrate species undergoing methylation are the PoMB's and not the corresponding sulfonates.

HANS CERFONTAIN et ANKIE KOEBERG-TELDER. Can. J. Chem. **66**, 162 (1988).

Utilisant des conditions homogènes, dans du H_2SO_4 à 95,5 et 98,4%, on a étudié la méthylation d'une série de polyméthylbenzènes (PoMB) ou de leurs acides sulfoniques par de l'hexaméthylbenzène (HMB) et de l'acide pentaméthylsulfonique-1 (PeMBS-1) agissant comme réactifs. Le HMB provoque la méthylation des acides triméthyl-2,4,6 (TrM-2,4,6 BS-1), tétraméthyl-2,3,4,6 (TeM-2,3,4,6 BS-1) et tétraméthyl-2,3,5,6 (TeM-2,3,5,6 BS-1) benzènesulfoniques; toutefois, il ne provoque pas la méthylation des acides sulfoniques du diméthyl-1,3 (DM-1,3 B), des triméthyl-1,2,3 ou 1,2,4 (Tr-1,2,3 B ou Tr-1,2,4 B) et du tétraméthyl-1,2,3,4 (TeM-1,2,3,4 B) benzène. Comme agent de méthylation, l'acide PeMBS-1 est moins réactif que le HMB. On a observé que la réactivité des substrats, par rapport à la méthylation par le HMB, diminue dans l'ordre TeM-2,3,4,6 BS-1 $\approx$ TeM-2,3,5,6 BS-1 $>$ TrM-2,4,6 BS-1 $\gg$ TeM-2,3,4,5 BS-1; par ailleurs, par rapport à la méthylation par le PeMBS-1, la réactivité diminue dans l'ordre PeMBS-1 $\gg$ TrM-2,4,6 BS-1. En se basant sur une comparaison de ces ordres de réactivités des substrats avec ceux prédits pour des séries de PoMBsulfonates-1 ainsi que les PoMB correspondants, on en conclut que les espèces des substrats qui subissent la méthylation sont les PoMB et non pas les sulfonates correspondants.

[Traduit par la revue]

As a continuation of our studies on the behaviour of polyisopropyl- (1) and polyethylbenzenes (2) in sulfuric acid as solvent, we recently reported on the reactions of various polymethylbenzenes (PoMB's) and their sulfonic acids in that solvent system (3), reactions generally referred to as the Jacobsen reaction (for reviews see ref. 4). Whereas the 2,3,4,6- and 2,3,5,6-tetraethylbenzene-1 sulfonic acids isomerize to the (stable) 2,3,4,5-isomer *intra*-molecularly, as appears from the simple first-order kinetics (2), the corresponding tetramethyl homologues indeed yield the stable 2,3,4,5-tetramethylbenzene-1-sulfonic acid (2,3,4,5-TeMB-1-S), but not by first-order kinetics (3). The conversions of both the 2,3,4,6- and 2,3,5,6-TeMB-1-S are characterized by an induction period, illustrating autocatalysis. The induction period for 2,3,5,6-TeMB-1-S is in line with its observed initial slow disproportionation to the sulfonic acids of pentamethylbenzene (PeMB) and 1,2,4-trimethylbenzene (1,2,4-TrMB) and the subsequent partial methylation of PeMB (initially mainly by protonated 1,2,4,5-TeMB) to hexamethylbenzene (HMB). The isomerization of the 2,3,5,6- into the 2,3,4,6-TeMB-1-S then proceeds via *inter*-molecular *trans*-methylations involving PeMB-1-S and HMB as the methylating reagents. The isomerization of 2,3,4,6-TeMB-1-S into the stable 2,3,4,5 isomer was proposed to proceed in a similar mechanistic fashion by initial disproportionation of the substrate to the sulfonic acids of PeMB and 1,3,5-TrMB and subsequent *inter*-molecular *trans*-methylations involving PeMB and 1,3,5-TrMB as intermediates, although the presence of PeMB-1-S and 2,4,6-TrMB-1-S in the reaction mixtures could not be established beyond the limits of the ^{1}H nmr analysis, which in the presence of 2,3,4,6-TeMB-1-S was, however, 10% at the least.

To obtain more information on the various reactions of the intermediates possibly occurring in the Jacobsen reaction of the PoMB's, in particular on the proposed intermediacy of 1,3,5-TrMB and PeMB and their sulfonic acids in the conversion of 2,3,4,6- into 2,3,4,5-TeMB-1-S, we have studied the methylation of a series of polymethylbenzenes and their sulfonic acids in concentrated sulfuric acid by added HMB and PeMB-1-S.

Results

Varying amounts of a given PoMB or its monosulfonate have been treated in concentrated aqueous sulfuric acid with HMB and PeMB-1-S at 25°C under homogeneous conditions. The reaction mixtures have been analyzed as such by multicomponent ^{1}H nmr analysis. The pertinent data are compiled in Table 1. HMB effects methylation of 2,4,6-TrMB-1-S, 2,3,4,6-TeMB-1-S, and 2,3,5,6-TeMB-1-S, but not of (the sulfonic acids of) 1,2,3,4-TeMB (3), 1,2,3-TrMB, 1,2,4-TrMB, and 1,3-dimethylbenzene (1,3-DMB). The latter three hydrocarbons, upon addition to 98.4% H_2SO_4, are only sulfonated, and those of the resulting sulfonic acids, which contain a hydrogen atom *meta* to the sulfo group, are relatively slowly sulfonated in part further to the corresponding *meta*-disulfonic acids (6, 7). The sulfonic acids formed upon dissolving the TeMB's in 98.4% H_2SO_4 at 25°C are not further sulfonated.[3]

The methylation product of 2,4,6-TrMB-1-S is 2,3,4,6-

[1]Aromatic isomerizations and related reactions, part 7. Preceding paper, see ref. 3.

TeMB-1-S and that of both 2,3,4,6- and 2,3,5,6-TeMB-1-S is PeMB-1-S. The resulting three sulfonic acids are not stable in concentrated sulfuric acid and undergo Jacobsen type conversions. The equilibrium content of 1,3,5-TrMB present in a solution of 2,4,6-TrMB-1-sulfonic acid in 95.5 and 98.4% H_2SO_4 was determined at 25°C to be 0.03 and ≤0.006% respectively. These values compare with the value of 0.01% for 96.1% H_2SO_4 at 12°C, calculated from the extrapolated sulfonation and desulfonation rate coefficients (9).

Discussion

Relative reactivities of reagents and substrates

As appears from the initial rate of substrate conversion, the methylating reactivity is greater for HMB than PeMB-1-S (cf. entry 2 with 4 and entry 8 with 9). In aqueous sulfuric acid more concentrated than 95% H_2SO_4, HMB is for the greater part protonated (5) and the resulting hexamethylbenzenonium ion is in fact the active methyl transferring species (see later). In the study on the Jacobsen reaction of PeMB-1-, 2,3,4,6-TeMB-1-, and 2,3,5,6-TeMB-1-S we showed that the *trans*-methylating entity is the ring-protonated polymethylbenzene and not its ring-protonated sulfonate or sulfonic acid (3). Accordingly, on using the PeMB-1-S/PeMB methylating system the greater part of the reagent is present in the unreactive, mainly unionized (10), sulfonic acid form and this is the main reason for the observed lower methylating reactivity of PeMB as compared with HMB.

The rate of substrate conversion for the methylation by HMB in 98.4% H_2SO_4 is very similar on starting with 1,3,5-TrMB and 2,4,6-TrMB-1-S (cf. entries 1 and 3). Apparently for 98.4% H_2SO_4 the rate of methylation is slow relative to the time required to establish the 1,3,5-TrMB $\rightleftharpoons$ 2,4,6-TrMB-1-S equilibrium (9). However, for 95.5% H_2SO_4 the initial rates of conversion of both the substrate and the HMB reagent are significantly greater for 1,3,5-TrMB than 2,4,6-TrMB-1-S (entries 6 and 5), indicating that the rate of methylation of 1,3,5-TrMB in 95.5% H_2SO_4 is no longer negligibly small relative to its rate of sulfonation. In fact, the observed rate difference strongly suggests that the substrate species undergoing methylation is the polymethylbenzene and not the corresponding sulfonate or sulfonic acid (see also later).

Based on the foregoing discussion, the *trans*-methylation of an aromatic substrate $ArR^1R^2R^3$ by the PeMB-1-S/PeMB system and HMB is thought to proceed by steps [1]–[5] in which Ar stands for C_6Me_3 and R^1, R^2, and R^3 may be Me, H, SO_3^-, or SO_3H. In cases where R^3 = H, sulfonation of R^2R^3ArMe will take place (step [6]) to yield $R^2MeArSO_3H$ (step [6]).

[1] $PeMB\text{-}1\text{-}S + H_2SO_4 \rightleftharpoons PeMB + H_2S_2O_7$

[2] $ArR^1R^2Me + HB \rightleftharpoons R^1R^2Ar^+(Me)(H) + B^-$

[3] $R^1R^2Ar^+(Me)(H) + R^2R^3ArH \rightleftharpoons R^1R^2ArH + R^2R^3Ar^+(Me)(H)$

[4] $R^2R^3Ar^+(Me)(H) + B^- \rightleftharpoons R^2R^3ArMe + HB$

[5] $R^1R^2ArH + H_2S_2O_7 \rightleftharpoons R^1R^2ArSO_3H + H_2SO_4$

[6] $R^2MeArH + H_2S_2O_7 \rightleftharpoons R^2MeArSO_3H + H_2SO_4$

The substrate R^2R^3ArH being methylated by steps [3] and [4] may be the polymethylbenzenesulfonic acid, its sulfonate anion, or the corresponding polymethylbenzene. The methylation rate coefficient of the unionized sulfonic acid, which is the majority species in aqueous sulfuric acid more concentrated than 95% H_2SO_4 (10), will be very much smaller than that of the corresponding sulfonate anion (because of the difference in charge) and the rate coefficient of the latter will be a factor of at least 10^5 smaller than that of the corresponding hydrocarbon (11, 12). Presuming additivity of the methyl and sulfonate substituent effects,[4] the reactivity order of the polymethylbenzenes proper towards a given methylating reagent will increase in the order 1,3-DMB [0.1] < 1,2,4-TrMB [0.3] = 1,2,3-TrMB [0.3] < 1,2,4,5-TeMB [0.7] < 1,2,3,4-TeMB [1.3] < 1,3,5-TrMB [6] < 1,2,3,5-TeMB [15] < PeMB [30], and those of the corresponding polymethylbenzenesulfonates will increase in the order 2,3,5-TrMB-1-S [0.04] ≈ 2,3,4,5-TeMB-1-S [0.06] ≈ 2,3,5,6-TeMB-1-S [0.07] < 2,4-DMB-1-S [0.25] < 2,4,5-TrMB-1-S [0.35] < 2,3,4-TrMB-1-S [0.6] ≪ 2,4,6-TrMB-1-S [15] < 2,3,4,6-TeMB-1-S [30] in which the data in square brackets for a given series of compounds give a relative measure of the overall rate of methylation within that series. The actually observed reactivity order for methylation by HMB increases in the order 2,4-DMB-1-S, 2,3,4-TrMB-1-S, 2,4,5-TrMB-1-S, 2,3,4,5-TeMB-1-S (all nonreactive) ≪ 2,4,6-TrMB-1-S < 2,3,4,6-TeMB-1-S ≈ 2,3,5,6-TeMB-1-S (cf. Table 1, entries 2, 7, and 8). This order does not at all fit in with the order predicted for the polymethylbenzenesulfonate substrate species (compare, e.g., the position of 2,3,5,6-TeMB-1-S within the two series). The differences in the degree of ionization of the various polymethylbenzenesulfonic acids are only small[5] and cannot explain the apparent discrepancy.

Accordingly, the polymethylbenzenesulfonates can be ruled out as the substrate species being methylated. This then leaves the polymethylbenzenes as the species undergoing methylation. The observed order deviates to some degree from the one predicted for these type of species, but it should be realized that the relatively small amount of free hydrocarbon in equilibrium with its sulfonic acid and sulfonate in the sulfuric acid solvent system differs strongly for the various polymethylbenzenesulfonic acids; it increases in the order 1,2,4-TrMB ≈ 1,2,3,4-TeMB ≪ 1,3,5-TrMB < 1,2,3,5-TeMB < 1,2,4,5-TeMB < PeMB (cf. results and ref. 3).[6]

The absence of methylation of 2,3,4,5-TeMB-1-S is ascribed to the very low (equilibrium) content of 1,2,3,4-TeMB in the reaction mixture, if any (≪0.01% in 96.1% H_2SO_4 (3)).

Upon reaction of 2,4,6-TrMB-1-S with an equimolar amount of PeMB-1-S in 98.4% H_2SO_4 (entry 4), the initial decrease is

[4]The partial rate factors employed in the calculations of the relative rate coefficients were those reported for sulfonation by the $H_2S_2O_7$ mechanism in concentrated aqueous sulfuric acid (3, 11).

[5]The ionization of arenesulfonic acids in sulfuric acid is governed by the H^a acidity function (13). The $|ArSO_3^-|/|ArSO_3H|$ ratios for the various PoMB-1-S's in 98.4% H_2SO_4 (H^a = −8.24 (13)) were calculated taking pK_a ($C_6H_5SO_3H$) = −6.65 (14) and applying the principle of additivity of the methyl substituents with ΔpK_a for *o*-, *m*-, and *p*-Me = 0.10 (14), 0.04 (15), and 0.10 (15) respectively. The ionization ratios thus calculated, given in square brackets, increase (but in total only 30%) in the order 2,3,4,6-TeMB-1-S [0.012], 2,4,6-TrMB-1-S [0.013], 2,3,4,5-TeMB-1-S = 2,3,5,6-TeMB-1-S [0.014], 2,3,4-TrMB-1-S = 2,4,5-TrMB-1-S [0.015], 2,4-DMB-1-S [0.016].

[6]The equilibrium content of polymethylbenzene increases with increasing steric hindrance between the sulfo group and the adjacent methyls in the PoMB-1-S.

[a]Method A: The mixture of HMB and sulfuric acid was stirred for 30 min and then added to the substrate. Method B: The sulfuric acid was added to the mixture of the reactants.
[b]HMB is present predominantly as $C_6Me_6H^+$ (3, 5).
[c]The initial average number of methyl groups per benzene ring was set to be 100%.

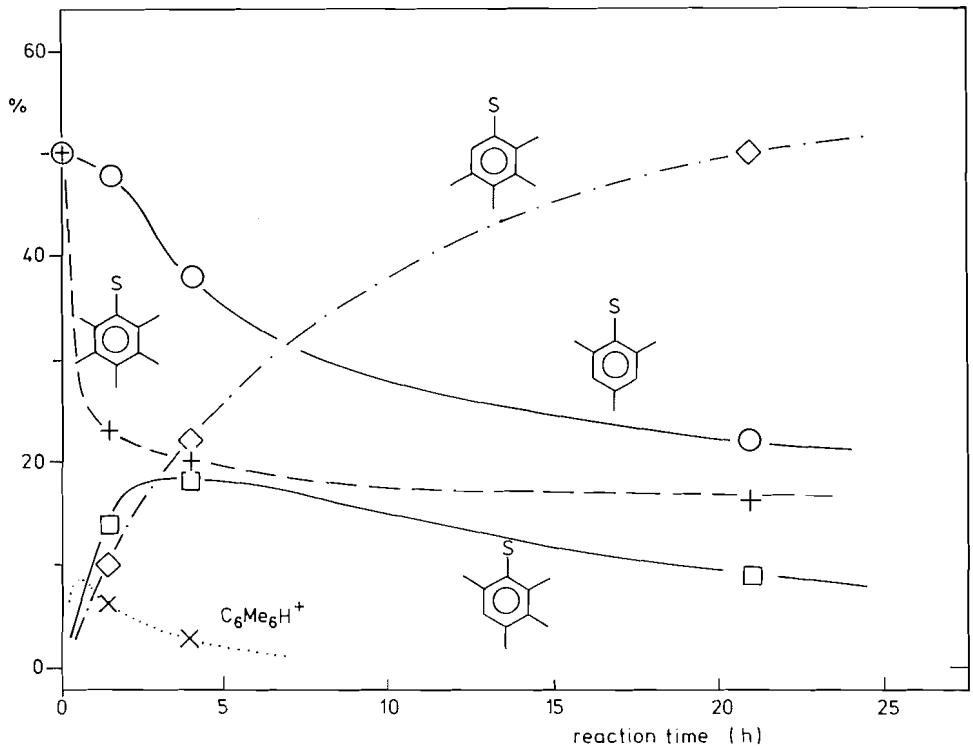

FIG. 1. Reaction of 2,4,6-TrMB-1-S (0.20 M) with PeMB-1-S (0.20 M) in 98.4% H_2SO_4 at 25°C.

far greater for PeMB-1-S than for 2,4,6-TrMB-1-S (Fig. 1). This is ascribed to methylation of PeMB in addition to that of 1,3,5-TrMB, of which the former is apparently very much faster (by a factor of 30–100) than the latter. The higher reactivity of PeMB is mainly due to the higher relative equilibrium content of this hydrocarbon in the system.

trans-*Methylation equilibrium*

Upon dissolving PeMB-1-S in 98.4% H_2SO_4, PeMB acts both as methylating agent and as substrate, the products of the rapid initial partial conversion being HMB and a (8:1) mixture of 2,3,4,6- and 2,3,4,5-TeMB-1-S formed in equal amounts (entry 10). The reverse reaction occurs on mixing equimolar amounts of HMB and 2,3,4,6-TeMB-1-S (entry 7). After 0.6 h of reaction, about the same compositions are obtained for the two experiments and the equilibrium constant for the apparent overall interconversion [7] is $K_7 = 12 \pm 2$. The initial

[7] HMB + 2,3,4,6-TeMB-1-S $\rightleftharpoons$ 2 PeMB-1-S

equilibrium is subsequently broken up as a result of the relatively slow, irreversible, conversion of the 2,3,4,6- into 2,3,4,5-TeMB-1-S.

Isomerization of tetramethylbenzenesulfonic acids

In the presence of HMB the substrates 2,3,4,6- and 2,3,5,6-TeMB-1-S, in addition to being methylated, are found to isomerize to the stable 2,3,4,5 isomer (entries 7 and 8). These isomerizations were shown to proceed *inter*-molecularly with PeMB-1-S and HMB as the *trans*-methylating agents involving the substrate hydrocarbons as the entities being methylated (see preceding discussion and ref. 3). In essence, the methyl transfers in these conversions proceed similarly to the isomerizations and disproportionations of the TrMB's and TeMB's induced by Brønsted acid catalysts other than sulfuric acid, such as $HF–BF_3$ (16) and methanesulfonic acid (17), in that they all involve polymethylbenzenonium ions as intermediates effecting the *trans*-methylations. As emphasized by Kilpatrick and Meyer (18), the outcome of the *inter*-molecular *trans*-methylation reactions of a given TeMB in sulfuric acid differs from the results obtained on using other acids, as a result of the partial or complete sulfonation of the hydrocarbon substrates, intermediates, and products. For that reason, upon starting with, e.g., 2,3,4,6- or 2,3,5,6-TeMB-1-S, the cycle of desulfonation, *inter*-molecular methyl transfer, and resulfonation leads eventually to the stable 2,3,4,5-TeMB-1-S as the only product, whereas on starting with any of the three TeMB's in, e.g., methanesulfonic acid the final thermodynamic equilibrium mixture contains all the PoMB's with the exception of toluene (17). Interestingly, sodium di- and trimethylbenzenesulfonates, containing at least one methyl *ortho* to the sulfonate group, upon fusion with an excess of aluminium chloride at elevated temperatures isomerize as such by migration of the *o*-methyl(s) (19). In the absence of a suitable proton donor in the system these isomerizations in all likelihood proceed *intra*-molecularly.

Experimental

The polymethylbenzenes were high-quality commercial compounds and were used without further purification. The preparations of the various potassium polymethylbenzenesulfonates have been described (6, 8, 20).

The ^1H nmr spectra of the various sulfuric acid solutions were recorded using a Varian HA-100 spectrometer. The quantitative analyses of the reaction mixtures in concentrated aqueous sulfuric acid were performed applying ^1H nmr multicomponent analysis based on the specific hydrogen absorptions of the various components (3). The equilibrium content of 1,3,5-TrMB present in a solution of 2,4,6-TrMB-1-S in sulfuric acid was determined as described previously (3).

Synthèses des alkyl-1 cyclanols fonctionnalisés aux positions α, β et γ de la chaîne hydrocarbonée

P. CANONNE, M. BELLEY, G. FYTAS ET J. PLAMONDON

Département de chimie, Faculté des sciences et de génie, Université Laval, Québec (Québec), Canada G1K 7P4

Reçu le 16 mars 1987

P. CANONNE, M. BELLEY, G. FYTAS et J. PLAMONDON. Can. J. Chem. **66**, 168 (1988).

Nous avons mis au point une synthèse générale, efficace et à hauts rendements des *N*,*N*-dialkylaminoalkyl-, chloroalkyl-, phénoxyalkyl-, thiophénoxyalkyl-, diéthoxyalkyl- et dithiolane-1,3 alkylcyclanols par action des α,ω-bis(bromomagnésio)alkanes sur les esters fonctionnalisés correspondants.

P. CANONNE, M. BELLEY, G. FYTAS, and J. PLAMONDON. Can. J. Chem. **66**, 168 (1988).

We have developed a general and versatile synthesis of *N*,*N*-dialkylaminoalkyl-, 1-chloroalkyl-, 1-phenoxyalkyl-, 1-thiophenoxyalkyl-, 1-diethyoxyalkyl-, and 1-(1,3-dithiolane)alkylcyclanols in good yields by the reaction of α,ω-bis(bromomagnesio)alkanes with the corresponding functionalized carboxylic acid esters.

Plusieurs méthodes de synthèses d'aminoalkyl-1 cyclanols ont été raportées dans la littérature (1, 2), mais ces méthodes mettent en jeu des transformations subséquentes des cyclanones correspondantes nécessitant parfois des réactifs coûteux.

Généralement, l'introduction du groupement amino s'effectue par trois voies différentes, selon la longueur de la chaîne aminoalkylée désirée. Par exemple, les α-aminoalkylcyclanols sont plus facilement accessibles par modification des cyanhydrines (3) ou des énamines (4) que les β-aminoalkylcyclanols, car ces derniers ne peuvent être formés que par des réactions plus élaborées effectuées sur la chaîne hydrocarbonée (5). Enfin, la synthèse des γ-aminoalkylcyclanols semble être encore plus difficile, car les résultats obtenus, lors des études précédemment réalisées, montrent que les rendements réactionnels sont faibles (6).

Nous avons alors pensé que notre méthode, basée sur l'utilisation des α,ω-bis(bromomagnesio)alcanes (7), conduirait aux composés désirés avec des bons rendements. L'examen de l'ensemble des résultats que nous avons obtenus par l'action de ces organodimagnésiens sur les lactones (8) et anhydrides des acides dicarboxyliques (9), nous suggère de ne pas vouloir tenir compte de ceux déjà rapportés dans la littérature (10) en utilisant quelques aminoesters avec ces mêmes réactifs. En effet, les rendements obtenus par ces auteurs sont anormalement trop faibles et il nous est difficile d'attribuer un rôle important à la présence de l'azote ou à la basicité de l'amine qui auraient influencé grandement le cours de cette réaction. Rappelons que dans une récente publication nous avons démontré que les isoxazolones-5 encombrées fournissent les β-hydroxyoximes α,α-bisubstituées (11) avec de très bons rendements par la réaction du bis(bromomagnésio)-1,4 butane.

La question se posa alors à savoir, si les dialkylaminoalkylesters utilisés dans les conditions des réactions d'annélation que nous avons mises au point, fourniraient d'aussi bons résultats ou s'ils présenteraient des particularités distinctes qui diminueraient l'efficacité de notre méthode.

Dans ce but, nous avons alors entrepris la présente étude en utilisant systématiquement divers types d'aminoesters (**1–10**) constituant ainsi une série homogène. Nous avons repris certains α- et β-*N*,*N*-dialkylaminoalkylesters que ces auteurs avaient utilisés mais aussi des γ-aminoalkylesters afin de démontrer l'influence éventuelle de la position de l'azote et de la basicité de l'amine sur les réactions de Grignard inter- et intramoléculaires (Schéma 1).

La synthèse des α- et β-aminoesters a été effectuée, d'une

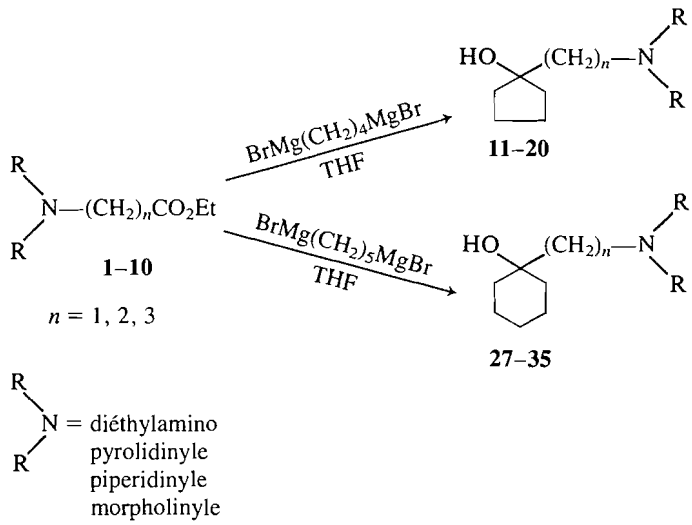

SCHÉMA 1

part, à partir des halogénoesters par substitution nucléophile (12) et, d'autre part, à partir du propénoate d'éthyle par addition conjuguée d'amines secondaires (13).

Le bis(bromomagnesio)-1,4 butane a été préparé dans le THF en présence d'un excès de tournures de magnésium et ses réactions avec les aminoesters ont fourni les aminoalkyl-1 cyclopentanols **11–20** avec des meilleurs rendements que celles rapportées précédemment (10). Nous constatons que les facteurs ci-haut mentionnés n'ont pas une influence considérable et ainsi nous démontrons que la différence de rendements trouvés ne peut être attribuée qu'aux conditions expérimentales que ces auteurs ont choisies, plutôt qu'à la structure des esters. Ces résultats suggèrent d'effectuer quelques réactions sur des aminoesters encombrés tels que (pyrrolidinyl-1)-2 propanoate d'éthyle (**21**), méthyl-2 (pyrrolidinyl-1)-2 propanoate d'éthyle (**22**) et (morpholinyl-4)-2 propanoate d'éthyle (**23**) afin de cerner les limites de notre méthode, à ce qui a trait l'influence de l'encombrement stérique sur la formation des cyclopentanols. Nous avons alors fait réagir le bis(bromomagnesio)-1,4 butane sur les esters **21**, **22** et **23** et avons constaté que les aminocyclopentanols **24**, **25**, **26** correspondants sont obtenus aussi avec des bons rendements. Nous rappelons que les rendements n'ont pas été optimisés et ont été calculés à partir des composés déjà purifiés (Schéma 2).

Il apparaît ainsi que l'encombrement stérique influence peu le

SCHÉMA 2

cours de la réaction au niveau de la cyclisation. Les réactions compétitives intermoléculaires ou intramoléculaires sont peu favorisées. En effet, nous n'avons pas trouvé en quantité appréciable ni les cétones intermédiaires, provenant de la réaction d'énolisation, ni les aminoalcools secondaires à chaîne ouverte provenant d'une réaction de réduction intramoléculaire. Nous pouvons en déduire que la réaction d'annélation à l'aide de bis(bromomagnesio)-1,4 butane est générale et applicable aux *N*,*N*-dialkylalkylaminoesters quelle que soit leur structure.

La question se posa encore une fois à savoir si notre méthode est aussi générale pour la formation des cyclohexanols correspondants en utilisant le bis(bromomagnesio)-1,5 pentane, sachant que le cycle à six membres est plus difficile à former par notre méthode (11).

Nous avons alors entrepris d'étudier les réactions de cet organodimagnésien avec les aminoesters **1**–**10** dans les mêmes conditions expérimentales et avons observé que les dialkylaminoalkyl-1 cyclohexanols **27**–**35** sont formés avec des rendements légèrement plus faibles que ceux trouvés lors de la préparation des dialkylaminoalkylcyclopentanols mais de loin supérieurs à ceux trouvés dans la littérature (10) pour l'ensemble des composés (tableau 1). Cette différence est principalement due à l'encombrement stérique au niveau du carbonyle qui se traduit par la formation d'une faible quantité d'alcools secondaires à chaîne ouverte (2–18%) formés par la réaction de réduction intramoléculaire (Schéma 3). De l'ensemble des résultats obtenus, il ressort que les réactions organodimagnésiennes effectuées dans le tétrahydrofuranne, en utilisant les conditions expérimentales précédemment décrites (3), sont applicables aux α-, β- et γ-aminoesters.

Ce travail démontre que notre méthodologie peut facilement être utilisée pour la synthèse de divers alkyl-1 cyclanols fonctionnalisés.

Il nous a semblé intéressant d'étendre les réactions de ces organodimagnésiens bis-primaires aux esters fonctionnalisés sur la chaîne hydrocarbonée par d'autres groupements importants pour leurs applications synthétiques (Schéma 4). Nous avons alors décidé d'utiliser comme substrats, d'une part, le phénoxyacétate d'éthyle (**36**), le phénylthioacétate d'éthyle (**37**), le chloro-2 propionate d'éthyle (**38**), le phénoxy-2 propanoate d'éthyle (**39**) et, d'autre part, le diéthoxyacétate d'éthyle (**40**) et le dithiolane-1,3 acétate d'éthyle (**41**). Les résultats obtenus consignés au tableau 2 montrent que les cyclanols correspondants **42**–**51** sont formés avec des rendements très satisfaisants. Les organomagnésiens attaquent sélectivement la fonction ester plutôt que les autres fonctions.

SCHÉMA 5

Les rendements ne sont pas optimisés; nous supposons qu'à une température plus basse ils peuvent être améliorés, surtout dans les expériences réalisées avec le bis(bromomagnésio)-1,5 pentane (Schéma 3).

Par la présente étude, nous pouvons obtenir plusieurs cyclanols substitués, à la position 1, par une chaîne fonctionnalisée (Schéma 5). De tels hydroxyaldéhydes, chlorocyclopentanols, sont plus difficilement accessibles par d'autres méthodes (14, 20). Nous concluons en nous basant sur les résultats des aminoalkylesters que cette méthode est très générale et applicable à la synthèse des divers α, β ou γ-hydroxycétones, hydroxyacides, chloroalkyl-1 cyclopentanols et hydroxyalkyl-1 cyclopentanols. En effet la déthioacétalisation de dithialanes-1,3 a été réalisée récemment (21).

Partie expérimentale

Les spectres ir ont été enregistrés à l'aide d'un appareil Beckman IR 4250 (sous forme de films ou en solution dans CCl_4 et CH_2Cl_2), les spectres rmn ^1H sur un appareil Bruker 90 MHz et sur un appareil Varian XL-200 (200 MHz). Les spectres rmn ^{13}C ont été effectués sur un appareil Bruker WP-80 (20 MHz). Les spectres de masse ont été effectués sur un appareil Hewlett–Packard 5992 (gs/mg). Les séparations chromatographiques sur colonne sous pression «flash» ont été effectuées sur gel de silice. Les esters **34**, **35**, **38** sont commercialement accessibles chez Aldrich. Les microanalyses ont été effectuées chez Galbraith Laboratories.

Matériel de départ

Le tétrahydrofuranne a été distillé sur sodium et gardé sous atmosphère d'azote. Les dialkylaminoacétates et dialkylamino-4 butanoates d'éthyle ont été préparés par les réactions précédemment décrites basées sur la transformation des halogénoalkylesters par les amines correspondantes (12*a*, 15). Les dialkylaminopropénoates d'éthyle ont été préparés à partir du propénoate d'éthyle (13).

N,N-*Dialkylaminoacétates,* N,N-*dialkylamino-4 butanoates d'éthyle et* N,N-*dialkylamino-2 propanoate d'éthyle*[1]

À une solution de 65 mmol de chloroacétate, bromo-2 propanoate, bromo-2 méthyl-2 propanoate ou bromo-4 butanoate d'éthyle dans 25 mL de benzène anhydre, on ajoute goutte à goutte 140 mmol d'amine dans 25 mL de benzène anhydre.

*(Pyrrolidinyl-1) acétate d'éthyle (**1**)* : Rdt = 79% (8,067 g); Eb = 95–96°C (20 Torr) (litt. (15) Eb 77°C (16 Torr)) (1 Torr = 133,3 Pa).

1. Tous les composés ont donné des spectres satisfaisants.

*(Pipérydinyl-1)-4 butanoate d'éthyle (**9**)* : Rdt = 88% (22,433 g); Eb = 110–111°C (15 Torr).

*(Morpholinyl-4)-4 butanoate (**10**)* : Rdt = 89% (11,625 g); Eb = 140–142°C (15 Torr).

*(Pyrrolidinyl-1)-2 propanoate d'éthyle (**21**)* : Rdt = 76% (8,478 g); Eb = 102–103°C (21 Torr) (litt. (13*a*) 84°C (12 Torr)).

*Méthyl-2 (pyrrolidinyl-1)-2 propanoate d'éthyle (**22**)* : Rdt = 70% (8,3 g); Eb = 108–110°C (22 Torr) (litt. (19) Eb 114°C (26 Torr)).

*(Morpholinyl-4)-2 propanoate d'éthyle (**23**)* : Rdt = 68% (8,232 g); Eb = 123–125°C (20 Torr) (litt. (18) Eb 110–113°C (15 Torr)).

Dialkylaminopropanoates d'éthyle

Dans un ballon de 50 mL, on introduit 10,012 g (100 mmol) de propénoate d'éthyle et 100 mmol d'amine et on chauffe à reflux sous agitation magnétique pendant 3 h. Le produit est purifié par distillation sous pression réduite.

*(Pyrrolidinyl-1)-3 propanoate d'éthyle (**5**)* : Rdt = 96% (16,386 g); Eb = 108–109°C (20 Torr) (litt. (15) Eb 82°C (8 Torr)).

*(Pipéridinyl-1)-3 propanoate d'éthyle (**6**)* : Rdt = 89% (16,577 g); Eb = 120–122°C (20 Torr) (litt. (13*b*) Eb 115–117°C (17 Torr)).

*(Morpholinyl-4)-3 propanoate d'éthyle (**7**)* : Rdt = 96% (18,065 g); Eb = 133–134°C (19 Torr) (litt. (13*c*) Eb 138–140°C (25 Torr)).

*Phénoxyacétate d'éthyle (**36**)*

En utilisant le mode opératoire décrit par Munch-Peterson (16*a*) on transforme 16,30 g (133 mmol) de chloroacétate d'éthyle en présence de 3,105 g (135 mmol) de sodium et de 12,545 g (133 mmol) de phénol en phénoxyacétate d'éthyle; Rdt = 69% (16,688 g); Eb = 84°C (0.05 Torr) (litt. (16) Eb 250–251°C).

*Phénylthioacétate d'éthyle (**37**)*

En utilisant le mode opératoire ci-dessus, nous avons opéré avec 11,011 g (100 mmol) de thiophénol, 2,415 g (0,105 mmol) de sodium et 12,255 g (100 mmol) de chloroacétate d'éthyle; Rdt = 90% (18,062 g); Eb = 90–93°C (0,05 Torr) (litt. (17) Eb 118°C (3 Torr)).

*Phénoxy-2 propanoate d'éthyle (**39**)*

En utilisant le mode opératoire général (16*a*), on ajoute 12,545 g (13,3 mmol) de phénol, 3,105 g de sodium et 27,2 g (15 mmol) de bromo-3 propionate d'éthyle et on recueille, par distillation, l'ester **39**; Rdt = 68%; Eb = 86°C (0.05 Torr).

Préparation des organodimagnésiens

Dans un tricol de 500 mL, sous atmosphère inerte, muni d'une agitation magnétique, d'une ampoule à additionner et d'un réfrigérant surmonté d'un tube de garde à $CaCl_2$, on introduit 1,07 g de Mg et on chauffe à l'aide d'un brûleur à gaz pour chasser l'humidité et activer le Mg. Après refroidissement de l'appareillage, on couvre le Mg d'une quantité de 3 mL de solution de dibromure dilué dans le THF. La réaction démarre rapidement et on poursuit l'addition de 0,0253 mol de dibromure dans 50 mL de THF. Après la fin de l'addition, on laisse agiter durant 4 h à la température ambiante, puis on y ajoute goutte à goutte, à la même température, une solution d'ester (0,02 mol). Après hydrolyse, à l'aide d'une solution saturée de chlorure d'ammonium,

(Morpholinyl-4)-1 éthyl-1 cyclopentanol (26)

En utilisant 2,706 g (14,0 mmol) d'ester **23** on obtient après purification 2,280 g de cyclopentanol **26**; Rdt = 80%; Eb = 81–83°C (0,03 Torr); ir ν_{max} (film) : 3955, 2955, 2845, 1118 cm^{-1}; rmn ^1H ($CDCl_3$) δ : 1,00 (3H, d, J = 7 Hz, CH_3CH), 1,33–1,90 (8H, m, CH_2 cycl.), 2,30–2,90 (5H, m, CH_2N, CH_2N), 3,73 (4H, t, J = 4,5 Hz, CH_2O), 4,63 (1H, s, OH) ppm; rmn ^{13}C ($CDCl_3$) δ : 82,3 (C-1), 67,5 (C-2″, C-6″), 66,4 (C-1′), 50,5 (C-3″, C-5″), 39,2 (C-5), 35,7 (C-2), 25,2 (C-4), 23,6 (C-3), 7,4 (C-2′) ppm; sm *m/e* : 199,25 (M^+, 1,0), 115,20 (7), 114,10 ($C_4H_8ONCH^+CH_3$, 100%), 70,15 (6). *Anal.* calc. pour $C_{11}H_{21}NO_2$: C 66,29, H 10,62, N 7,02; tr. : C 66,19, H 10,72, N 7,15.

Préparation des N,N-*dialkylaminoalkylcyclohéxanols*

En suivant le même mode opératoire que pour la préparation des *N,N*-dialkylcyclopentanols, on constate que le produit brut contient des quantités variant de 2 à 18% d'alcools secondaires insaturés. La séparation s'est avérée difficile dans certains cas. La spectroscopie de rmn ^1H montre des faibles quantités d'alcool insaturé même après purification des aminoalkylcyclopentanols liquides.

(Pyrrolidinyl-1)méthyl-1 cyclohexanol (10) (27)

En utilisant 1,852 (11,9 mmol) de l'ester **1** on obtient, après distillation, 1,356 g de cyclohexanol **27**; Rdt = 66%; Eb = 62–65°C (0,2 Torr); ir ν_{max} (CH_2Cl_2) : 3420, 2930, 2848, 2800 cm^{-1}; rmn ^1H ($CDCl_3$) δ : 1,10–1,93 (14H, m, CH_2), 2,45 (2H, s, NCH_2COH), 2,50–2,83 (4H, m, CH_2N), 3,47 (1H, s, OH) ppm; rmn ^{13}C ($CDCl_3$) δ : 70,0 (C-1), 66,6 (C-1′), 56,9 (C-2″, C-5″), 37,2 (C-2, C-6), 26,0 (C-4), 24,3 (C-3″, C-4″), 22,3 (C-3, C-5); ms *m/e* : 183,20 (M^+, 3,1), 85,15 (9), 84,15 ($C_4H_8NCH_2$, 100%), 55,15 (9).

(Pipéridinyl-1)méthyl-1 cyclohexanol (10) (28)

En utilisant 3,802 g (22,2 mmol) de l'ester **2** on obtient, après distillation, 1,601 g de cyclohexanol **28**; Rdt = 68%; Eb = 56–58°C (0,02 Torr); ir ν_{max} (film) : 3440, 2922, 2847, 2790, 1110 cm^{-1}; rmn ^1H ($CDCl_3$) δ : 1,46 (16H, m, CH_2 cycl.), 2,27 (2H, s, CH_2N), 2,43–2,70 (4H, m, CH_2N), 3,45 (1H, s, OH) ppm; rmn ^{13}C ($CDCl_3$) δ : 70,00 (C-1), 68,4 (C-1′), 57,5 (C-2″, C-6″), 37,2 (C-2, C-6), 26,6 (C-3″, C-5″), 26,1 (C-4), 24,1 (C-4″), 22,4 (C-3, C-5) ppm; sm *m/e* : 197,30 (M^+, 2), 99,15 (8), 98,15 ($C_5H_{10}NCH_2^+$, 100%), 55,05.

(Morpholinyl-4)méthyl-1 cyclohexanol (29)

En utilisant 1,732 g (10,0 mmol) de l'ester **4** on recueille 1,366 g de composé **29**; Rdt = 70%; Eb = 77–78°C (0,03 Torr); ir ν_{max} (film) : 3460, 2923, 2844, 2802, 1120, 1010 cm^{-1}; rmn ^1H ($CDCl_3$) δ : 1,33–1,70 (10H, m, CH_2 cycl.), 2,33 (2H, s, NCH_2), 2,50–2,73 (4H, m, CH_2N), 3,03 (1H, s, OH), 3,60–3,90 (4H, m, CH_2O) ppm; rmn ^{13}C ($CDCl_3$) δ : 70,6 (C-1), 68,5 (C-1′), 67,4 (C-2″, C-6″), 56,3 (C-3″, C-5″), 37,0 (C-2, C-6), 26,0 (C-4), 22,2 (C-3, C-5) ppm; sm *m/e* : 199,30 (M^+, 2,5), 101,15 (12), 100,15 ($C_4H_8ONCH_2^+$, 100%), 56,05 (14). *Anal.* calc. pour $C_{11}H_{21}NO_2$: C 66,29, H 10,62, N 7,02; tr. : C 66,20, H 10,49, N 6,98.

(Pyrrolidinyl-1)-2 éthyl-1 cyclohexanol (30)

En utilisant 2,002 g (11,7 mmol) de l'ester **5** on recueille, après distillation, 1,410 de l'aminocyclohexanol **30**; Rdt = 65%; Eb = 71–72°C (0,04 Torr); F = 46,5–47,5°C; ir ν_{max} (CH_2Cl_2) : 3200, 2936, 2860, 2809 cm^{-1}; rmn ^1H ($CDCl_3$) δ : 1,17–1,93 (16H, m, CH_2 cycl.), 2,42–2,90 (6H, m, CH_2N), 6,27 (1H, s, OH) ppm; rmn ^{13}C ($CDCl_3$) δ : 71,6 (C-1), 54,1 (C-2″, C-5″), 51,7 (C-2′), 38,3 (C-2, C-6), 37,6 (C-1′), 26,3 (C-4), 23,6 (C-3″, C-4″), 22,4 (C-3, C-5) ppm; ms *m/e* : 197,25 (M^+, 3,7), 85,05 (6), 84,15 ($C_4H_8NCH_2^+$, 100%), 71,70 (5), 70,10 (6), 55,15 (7). *Anal.* calc. pour $C_{12}H_{23}NO$: C 73,04, H 11,75, N 7,10; tr. : C 72,98, H 11,79, N 7,11.

(Pipéridinyl-1)-2 éthyl-1 cyclohexanol (31)

En utilisant 1,927 g (10,4 mmol) de l'ester **6** on obtient après purification 1,406 g de cristaux blancs; Rdt = 70%; Eb = 67–69°C (0,03 Torr) (litt. (Morpholinyl-4)-3 propyl-1 cyclohexanol (35)

En utilisant 2,088 g (10,4 mmol) de l'ester **10** on recueille, après distillation, 2,086 g de cyclohexanol **35**; Rdt = 75%; Eb = 106–107°C (0,03 Torr); ir ν_{max} (film) : 3440, 2929, 2850, 2804, 1120 cm^{-1}; rmn ^1H ($CDCl_3$) δ : 1,10–1,85 (14H, m, CH_2 cycl.), 2,30–2,67 (6H, m, CH_2N), 3,60–3,87 (4H, m, CH_2O), 5,00 (1H, s, OH); rmn ^{13}C ($CDCl_3$) δ : 69,8 (C-1), 66,7 (C-2″, C-6″), 59,8 (C-3′), 53,8 (C-3″, C-5″), 41,0 (C-1′), 38,1 (C-2, C-5), 26,1 (C-4), 22,5 (C-3, C-5), 20,0 (C-2′) ppm. *Anal.* calc. pour $C_{13}H_{25}NO_2$: C 68,68, H 11,08, N 6,16; tr. : C 68,45, H 11,16, N 6,11.

Phénoxyméthylcyclopentanol (42)

En utilisant 1,915 g (10,6 mmol) d'ester **36** on obtient 1,526 g de cyclopentanol **42**; Rdt = 80%; Eb = 80–81°C (0,05 Torr); F = 47–48°C; ir ν_{max} (film) : 3430, 2960, 2862, 1602, 1590, 1498, 1249, 1044, 757, 694 cm^{-1}; rmn ^1H ($CDCl_3$) δ : 1,87 (8H, m, CH_2 cycl.), 2,30 (1H, s, OH), 3,93 (2H, s, CH_2O), 6,83–7,53 (5H, m, 4 aromatiques) ppm; rmn ^{13}C ($CDCl_3$) δ : 159,3 (C-1″), 129,7 (C-3″, C-6″), 121,2 (C-4″), 115,0 (C-2″, C-6″), 81,4 (C-1), 75,0 (C-1′), 37,5 (C-2, C-5), 24,4 (C-3, C-4); ms *m/e* : 193,20 (M + 1, 7,8), 192,30 (M^+, 15,7), 108,10 ($C_6H_5OCH_3$, 100%), 94,20 ($C_6H_5OH^+$, 71), 85, 77,15, 67,15, 65,20, 51,20. *Anal.* calc. pour $C_{12}H_{16}O_2$: C 74,96, H 8,39; tr. : C 74,81, H 8,28.

Phénylthiométhyl-1 cyclopentanol (43)

En utilisant 2,085 g (10,6 mmol) d'ester **37** on recueille 1,856 g de cyclopentanol **43**; Rdt = 84%; Eb = 108–110°C (0,03 Torr); ir ν_{max} (film) : 3427, 2958, 2862, 1579, 1474, 1000, 737, 688 cm^{-1}; rmn ^1H ($CDCl_3$) δ : 1,70 (8H, m, CH_2 cycl.), 2,20 (1H, s, OH), 3,27 (2H, s, CH_2S), 7,20–7,63 (5H, m, aromatiques) ppm; rmn ^{13}C ($CDCl_3$) δ : 137,3 (C-1), 129,9 (C-3″, C-5), 129,1 (C-2″, C-6″), 126,4 (C-4′), 81,9

(C-1), 46,8 (C-1'), 39,5 (C-2, C-5), 24,1 (C-3, C-4) ppm; sm *m/e* : 209,15 (*M* + 1, 2), 208,15 (M^+, 14), 124,15 ($C_6H_5CH_3^+$, 21), 78,15 ($C_6H_5^+$, 11), 77,15 (C_6H_5, 13), 67,15 (21), 65,20 ($C_6H_5^+$, 15), 57,20 (11), 51,20 (14). *Anal.* calc. pour $C_{12}H_{16}OS$: C 69,18, H 7,74; tr. : C 69,27, H 7,70.

*Chlorométhyl-1 cyclopentanol (**44**)*

En utilisant 4,80 g (39,2 mmol) de chloroacétate d'éthyle (**38**) on obtient 3,203 g de cyclopentanol **44**; Rdt = 67%; Eb = 60–62°C (7 Torr) (litt. (14*b*) Eb 57–58°C (6 Torr)); ir ν_{max} (film) : 3400, 2955, 2869, 1437, 1322, 1285, 1249, 1217, 1188, 1066, 990, 727 cm^{-1}; rmn ^1H ($CDCl_3$) δ : 1,55–1,90 (8H, m, CH_2 cycl.), 2,23 (1H, s, OH), 3,62 (2H, s, CH_2Cl) ppm; rmn ^{13}C ($CDCl_3$) δ : 81,9 (C-1), 54,2 (C-1'), 38,3 (C-2, C-5), 24,4 (C-3, C-4) ppm; sm *m/e*: 136,5 (M^+ + 2, 0,4), 134,25 (M^+, 1,4), 107,10 ($C_4H_6O_{37}Cl$, 12), 105,10 ($C_4H_6O_{35}Cl$, 37), 92,10 (27), 85,25 ($C_3H_8OH^+$, 100%), 67,15 ($C_5H_7^+$, 44), 57,10, 55,10, 53,10. *Anal.* calc. pour $C_6H_{11}OCl$: C 53,53, H 8,23; tr. : C 53,43, H 8,15.

*(Phénoxy-1 éthyl)-1 cyclopentanol (**45**)*

En utilisant 5,00 g (26 mmol) de phénoxy-2 propanoate d'éthyle (**39**) on obtient, après distillation, 4,043 g de cyclopentanol **45**; Rdt = 87%; Eb = 125°C (0,03 Torr); ir ν_{max} (film) : 3450, 2960, 2885, 1595, 1488, 1447, 1288, 1240, 1170, 1050, 740 cm^{-1}; rmn ^1H ($CDCl_3$) δ : 1,32 (3H, d, CH_3), 1,74 (8H, m, CH_2 cycl.), 2,11 (1H, s, OH), 4,27 (1H, q, $CHCH_3$), 6,72–7,45 (5H, m, 4 aromatiques) ppm. *Anal.* calc. pour $C_{13}H_{18}O_2$: C 75,69, H 8,79; tr. : C 75,52, H 8,74.

*Diéthoxyméthyl-1 cyclopentanol (**46**)*

En utilisant 5,00 g (28 mmol) de diéthoxyacétate d'éthyle (**40**) on recueille, après distillation, 4,039 g de diéthoxyméthyl-1 cyclopentanol **46**; Rdt = 76%; Eb = 48°C (0,08 Torr); ir ν_{max} (film) : 3460, 2970, 2865, 1100, 1065 cm^{-1}; rmn ^1H δ : 1,25 (6H, t, CH_2-CH_3), 1,44–2,00 (8H, m, CH_2 cycl.), 2,18 (1H, s, OH), 1,47–4,10 (4H, m, CH_3CH_2), 4,38 (1H, s, OH) ppm. *Anal.* calc. pour $C_{10}H_{20}O_3$: C 63,79, H 10,71; tr. : C 63,71, H 10,76.

*(Dithiolane-1,3)-1 cyclopentanol (**49**)*

En utilisant 3 g (27 mmol) de dithiolane-1,3 acétate d'éthyle **41** on obtient, après distillation, 2,131 g de cyclopentanol **49**; Rdt = 67%; Eb = 92–94°C (0,05 Torr); ir ν_{max} (film) : 3440, 2950, 2865, 1355, 1278, 1000 cm^{-1}; rmn ^1H ($CDCl_3$) δ : 1,79 (8H, m, CH_2 cycl.), 2,28 (1H, s, OH), 3,27 (4H, s, CH_2-CH_2), 4,72 (1H, s, CH) ppm. *Anal.* calc. pour $C_8H_{14}OS_2$: C 50.49, H 7.41; tr. : C 50.42, H 7.46.

*Phénylthiométhyl-1 cyclohexanol (**50**)*

En utilisant 2,085 g (10,6 mmol) de l'ester **37** on recueille, après distillation, 1,080 g de cyclohexanol **50**; Rdt = 55%; Eb = 112°C (0,02 Torr); ir ν_{max} (film) : 3440, 2930, 2860, 1587, 1483, 1442, 1032, 987, 741, 695 cm^{-1}; rmn ^1H ($CDCl_3$) δ : 1,17–1,70 (10H, m, CH_2 cycl.), 2,23 (1H, s, OH), 3,10 (2H, s, CH_2S), 7,24 (5H, m, H aromatiques) ppm. *Anal.* calc. pour $C_{13}H_{18}OS$: C 70,22, H 8,16; tr. : C 70,21, H 8,14.

*(Phénoxy-1 éthyl-1)-1 cyclohexanol (**51**)*

En utilisant 4,00 g (21 mmol) de phénoxy-2 propanoate d'éthyle (**39**) on recueille, après distillation, 3,291 g de liquide incolore. D'après le spectre de rmn ^1H nous obtenons une quantité appréciable de phénoxy-2 heptène-6 ol-3. Le rendement approximatif en (phénoxy-1 éthyl-1)-1 cyclohexanol (**51**) est de 38%; Eb = 90–104°C (0,02 Torr); ir ν_{max} (film) : 3430, 2940, 2865, 1605, 1500, 1245, 918, 758, 700 cm^{-1}; rmn ^1H ($CDCl_3$) δ : 1,30 (3H, d, CH_3), 1,62 (10H, m, OH cycl.), 2,10 (1H, s, OH), 3,71 (1H, m, $CHCH_3$), 4,03–4,43 (1H, m, $CHCH_3$), 6,73–7,56 (5H, m, aromatiques) ppm. *Anal.* calc. pour $C_{14}H_{20}O_2$: C 76,32, H 9,15; tr. : C 76,28, H 9,03.

Remerciements

Nous remercions le Conseil de recherches en sciences naturelles et en génie du Canada et le Ministère de l'éducation du gouvernement du Québec pour l'aide financière apportée sous forme de subventions et bourses.

Dosage du Sr-90 dans l'eau des lacs et des rivières du Québec par précipitation avec l'oxine et comptage β

E. HADDAD ET L. ZIKOVSKY

École Polytechnique de Montréal, C.P. 6079, succursale A, Montréal (Québec), Canada H3C 3A7

Reçu le 17 juin 1987

E. HADDAD et L. ZIKOVSKY. Can. J. Chem. **66**, 174 (1988).

Une nouvelle méthode de dosage du Sr-90 dissout dans les eaux de surface a été mise au point. Elle est basée sur la précipitation du Sr avec l'hydroxy-8 quinoléine à pH de 11,3 et le comptage des particules β dont l'énergie dépasse 150 keV. La limite de détection qu'on peut obtenir est de 0,5 mBq/L et le rendement global de séparation est de 28%. Les facteurs de décontamination des principales interférences β sont supérieurs à 10 000. La méthode a été utilisée pour doser le Sr-90 dans 5 lacs et 5 rivières du Québec et les activités de 3 à 15 mBq/L ont été mesurées. La nouvelle méthode est moins onéreuse et aussi fiable et performante que la méthode conventionnelle.

E. HADDAD and L. ZIKOVSKY. Can. J. Chem. **66**, 174 (1988).

A new method for the determination of Sr-90 dissolved in surface waters has been developed. It is based on the precipitation of Sr with 8-hydroxyquinoline at pH 11.3 and counting of β particles with energy above 150 keV. The detection limit obtained is 0.5 mBq/L and the mean yield is 28%. The decontamination factors from other β emitters achieved are better than 10 000. This method has been used to measure the Sr-90 in 5 lakes and 5 rivers in Québec and activities ranging from 3 to 15 mBq/L were obtained. This new method is as efficient and reliable as conventional techniques while being less tedious.

Introduction

Le Sr-90 avec le Cs-137 constituent les deux radioéléments anthropogènes les plus importants. Ils ont été introduits dans l'environnement terrestre en grande quantité par les essais nucléaires dans les années 50 et 60. On a estimé (1) leur déposition globale en 1971 à 574 GBq (Sr-90) et à 920 GBq (Cs-137).

L'importance du Sr-90 provient de sa longue demi-vie (29 ans), de sa radiotoxicité élevée et de ses propriétés chimiques et biologiques similaires au calcium. Une fois introduit dans l'organisme, il se fixe dans les os où il présente un danger pour la santé.

Étant un émetteur β pur, le Sr-90 est difficile à doser. En 1984, Suchny (2) a présenté les résultats d'une étude comparative de dosage des radioéléments de 50 laboratoires de différents pays. Cette étude montre qu'il y avait un tiers des résultats à rejeter sans doute à cause des difficultés du dosage de cet isotope.

Sa concentration dans l'eau est très faible (0,16–10 mBq/L) et il est difficile à séparer d'autres émetteurs β qui sont présents dans l'eau.

Il existe (3, 4) plusieurs méthodes de dosage du Sr-90. Mais elles sont généralement très onéreuses et longues. Par conséquent, nous avons entrepris de mettre au point une nouvelle méthode de dosage du Sr-90 dans l'eau qui serait plus rapide que les méthodes existantes.

Partie théorique

Le Sr-90 est un émetteur β pur et, par conséquent, il ne peut pas être dosé directement par les méthodes instrumentales (spectrométrie).

Un dosage fiable du Sr-90 demande une séparation la plus complète possible de tous les émetteurs β du Sr-90. Les radioéléments qui risquent d'interférer avec le dosage du Sr-90 sont les radioéléments naturels primordiaux (U, Th et leurs descendants, K-40, etc.), les radioéléments produits par les rayons cosmiques (Na-22, Be-10, P-32, etc.) et les produits de fission ou d'activation (Fe-59, Co-60, Zn-65, etc.). Sur le plan chimique, il s'agit d'isoler sélectivement le Sr de tous les autres éléments. Grâce au fait que le Sr-90 forme rapidement un équilibre radioactif avec le Y-90, un émetteur β très énergétique (E_{max} = 2280 keV), on peut simplifier cette tâche difficile en coupant, au cours du comptage, les émetteurs β d'énergie faible. C'est cette approche que nous avons adoptée en choisissant un absorbeur en Al d'une épaisseur de 45 μm qui arrête tous les β dont l'énergie est plus faible que 100 keV.

La séparation se simplifie davantage en excluant les radioéléments dont la demi-vie est courte et nous avons choisi 1 mois comme la frontière entre les radioéléments qu'il faut étudier en détails et le reste.

À l'aide de ces deux critères, nous avons identifié les radioéléments (tableau 1) dont le comportement chimique doit être étudié et qui doivent être séparés du Sr-90. Nous avons inclus également quelques émetteurs α (Ra, U, Th) qui possèdent des émetteurs β parmi leurs descendants et les membres de la même famille chimique (Ba, Ca).

En sachant la concentration moyenne des éléments dans l'eau et l'activité spécifique des radioéléments primordiaux, on peut calculer facilement l'activité spécifique des émetteurs β dans l'eau. Egalement en connaissant les taux des effluents radioactifs provenant des installations nucléaires, on peut évaluer grossièrement la teneur des produits de fission dans l'eau. Suivant ce raisonnement, on conclut que le Ba-140, K-40, Ra-226, U-238, Zn-65 et Zr-95 sont les radioéléments qui sont les plus susceptibles de gêner le dosage du Sr-90. Pour augmenter la sélectivité de la séparation du Sr-90, nous avons ajouté une préconcentration sur une résine cationique. Ceci permet d'éliminer les anions qui pourraient interférer (I-129, Tc-99) et d'améliorer la limite de détection. Comme il est onéreux de transporter 100 litres d'eau au laboratoire, la préconcentration se fait sur le terrain.

Partie expérimentale

Notre méthode est basée sur la précipitation en milieu basique du Sr par hydroxy-8 quinoléine (oxine) et le comptage des particules β d'une énergie supérieure à 150 keV. Des études menées dans les années soixante (5, 6) ont montré qu'il est possible d'extraire le Sr avec l'oxine dans le chloroforme à pH plus élevé que 11,0. Cette approche malheureusement ne s'applique pas directement aux eaux de surface où la concentration du Ca est très supérieure à celle du Sr de manière que la capacité d'extraction est rapidement atteinte. Après nombreux essais, nous avons adopté la procédure suivante :

1. Préconcentration du Sr-90 : passer 100 L d'eau à travers une

TABLEAU 1. Propriétés nucléaires des émetteurs β qui peuvent interférer avec le Sr-90

RE	T (ans)	E_β (keV)	MF	CER (ng/g)	AS (Bq/g, mBq/L)	ASE	Réf.

MF = mode de formation (A = activation, C = rayons cosmiques, F = produit de fission, P = radioélément primordial).

CER = concentration moyenne d'élément correspondant dans les rivières.

AS = activité spécifique des radioéléments primordiaux.

ASE = activité spécifique des radioéléments dans l'eau évaluée à partir des concentrations moyennes, des activités spécifiques et des débits des effluents radioactifs.

* = activité dans la rivière Outaouais calculée à partir des effluents radioactifs (14) et du débit de la rivière (1260 m^3/s).

$ = activité évaluée à partir de la composition du combustible irradié (15) en utilisant l'activité du Zr-95 comme la base de comparaison.

colonne (rayon : 5 cm, hauteur : 1,3 cm, débit : 3 L/min) d'échange cationique (Dowex 50W-X8). Le Sr et autres cations sont absorbés sur la résine.

2. Elution du Sr avec 2 L de l'acide nitrique 2 M (3 élutions consécutifs).

Les deux étapes d'échange–élution se font sur place : l'eau à doser est prise à l'aide d'une pompe qui fonctionne avec une batterie d'auto. La quantité d'eau est mesurée après son passage à travers la colonne dans un tonneau gradué.

3. Neutraliser la solution avec le NaOH à pH 7.

4. Ajouter 0,5 g de $Sr(NO_3)_2$ comme entraîneur et précipiter les sulfates avec 250 mL de H_2SO_4 (96%).

Le but principal de cette étape est de séparer le Sr des métaux alcalins (Na, K, Rb et Cs), ces derniers pouvant coprécipiter avec l'oxine à pH 11,2.

5. Laisser reposer et séparer le précipité par filtration (papier Whatman 41).

6. Dissoudre le précipité dans 400 mL de HNO_3 (1 M), ajouter 45 mg de $FeCl_3$ et précipiter les hydroxydes à l'aide de l'ammoniac concentrée (0,4 M). On réduit ainsi la concentration du Co, Sn, V, Th, Zn et Zr.

7. Séparer le précipité et garder la solution.

8. Ajuster le pH à 9,5 avec le NaOH, ajouter 50 mL d'oxine 0,5 M dans le chloroforme et agiter 2 h.

L'oxine (C_9H_7ON) est un réactif organique très versatile, qui réagit facilement avec presque tous les métaux de la table périodique pour donner des chelates neutres : le cation métallique est pris entre deux ou plusieurs ions oxinates pour donner un complexe insoluble dans l'eau.

9. Laisser reposer, séparer et garder la phase aqueuse (à cette étape on enlève une partie du Ca).

Notons que la formation du complexe dépend fortement du pH du milieu. Nous profitions de cette propriété pour séparer le Sr, puisqu'il ne forme d'oxinate qu'à pH > 10,5.

10. Ajuster le pH à 11,3, ajouter 50 mL d'oxine 0,1 M, agiter 2 h et laisser reposer. Le Sr précipite tandis que le Ba et Ra restent en solution.

11. Sécher le précipité à l'aide d'une lampe infrarouge; carboniser le précipité sec avec un brûleur à gas pendant 2 min et compter tout de suite le Sr-90 et Sr-89.

12. Attendre 2 semaines et compter le Sr-90 et Y-90.

Pour compter nos échantillons, on utilise un compteur proportionnel Tennelec LB 1000 conçu pour le comptage des radiations α et β à un faible niveau. Il est formé de 2 chambres de gaz à circulation, l'une au-dessus de l'autre. Celle d'en haut détecte les radiations cosmiques, qui sont à haute énergie et les élimine grâce à un signal de coïncidence qu'elles déclenchent dans les 2 chambres. L'autre partie (plus basse) compte les radiations émises par l'échantillon à analyser, avec une fenêtre de 5,6 cm et de 50 $\mu g/cm^2$ d'épaisseur. Le détecteur est placé entre deux plaques de cuivre et le tout est entouré avec des briques de plomb formant un écran de 10 cm d'épaisseur. L'échantillon à compter est déposé sur une rondelle d'acier de 4,5 cm de diamètre qui a une position précise devant le détecteur, ce qui garde un facteur de géométrie constant et nous permet de comparer les échantillons aux étalons.

Comme efficacité de comptage (nombre de coups par désintégration d'un atome de Sr-90) nous avons trouvé 79 ± 1% pour Sr-90 et Y-90 une fois à l'équilibre et 39,5 ± 0,5% pour le Sr-90 seul.

Pour éliminer toute interférence possible des émetteurs α et des β des faible énergie (< 150 keV), on utilise un absorbeur (Al) qui assure l'arrêt des α < 8 MeV et des β < 100 keV, puis on met un seuil sur la fenêtre d'entrée de l'amplificateur pour arrêter les β de < 150 keV. De cette façon on réduit aussi le bruit de fond de 3 coups à 1,7 coups/min.

Après l'emploi de l'absorbeur (45 μm de Al) et du seuil de l'amplificateur, l'efficacité de comptage baisse à 21%.

Résultats et discussion

Les rendements de diverses opérations chimiques sont

déterminés à l'aide de traceurs radioactifs émetteurs γ. Les traceurs ont été préparés par irradiation dans le réacteur SLOWPOKE II de l'École Polytechnique de Montréal, avec un flux de 10^{12} n cm^{-2} s^{-1}.

Afin de vérifier le rendement du Sr et calibrer le compteur, un traceur (Sr-90, émetteur β pur) a été utilisé. Il a été fournit par la compagnie New England Nuclear Ltd.

Nous avons choisi la résine Dowex 50-X8 pour préconcentrer le Sr. Cette résine a fait ses preuves dans plusieurs études précédentes (7). La rétention du strontium sur la résine a été étudiée en fonction du débit de l'eau et de la quantité de résine dans la colonne. Pour réduire le temps de passage de l'eau dans la colonne, et maximiser le taux d'échange, nous avons choisi 100 g de résine et un débit de 2,5 L/m, la rétention étant de 56 ± 3%.

Malheureusement, cette approche ne permet pas de doser le Sr-90 qui se trouve dans l'eau sous forme des particules fines et insolubles. Par contre, ces particules devraient être peu absorbées par le système digestif et par conséquent, moins dangereuses pour la santé.

Pour l'élution du Sr, nous avons préféré l'acide nitrique aux acides sulfurique et chlorhydrique : les sulfates sont peu solubles et les chlorures risquent de former des complexes avec les réactifs organiques.

Pour améliorer le rendement d'élution avec un volume minimal d'acide, la solution éluante a été repassée plusieurs fois à travers la résine. Après 3 passages consécutifs de la même solution, le rendement atteint 90 ± 3%.

Toutes les étapes ont été vérifiées au moins 3 fois et les moyennes ont été prises.

Comme résultat on a réussi à diminuer le volume d'un facteur de 50 (100 L à 2 L) et la concentration de Sr a été augmentée d'un facteur de 25 (100 L × 90% × 56%/2 L).

La contamination possible des produits chimiques utilisés par Sr-90 a été vérifiée en utilisant l'eau distillée comme échantillon. La valeur ainsi obtenue est inférieure à 9 mBq à niveau de confiance de 90%.

Comme application de la procédure, le Sr-90 a été dosé dans 5 lacs et cinq rivières du Québec.

Les lacs choisis sont (1) Champlain et Memphrémagog, à côté de la frontière des Etats-Unis (état de New-York); (2) Manitou, Tremblant et Simon, qui sont loin des agglomérations et des usines.

Les cinq sites de prélèvements sur les rivières sont l'Outaouais, au nord-ouest de Montréal et qui reçoit des déversements des laboratoires de Chalk River; le fleuve Saint-Laurent à Beauharnois en amont de Montréal pour déterminer le Sr-90 qui provient de l'extérieur de la ville; à Montréal, près du centre-ville; à Varennes en aval de Montréal et à 20 km de la centrale Gentilly II, pour voir l'effet de ses déversements.

La valeur d'une méthode de séparation radiochimique dépend des facteurs de décontamination qui quantifient le degré auquel on réussit à purifier le mélange initial. Pour notre méthode, ces facteurs sont très élevés (tableau 2) et par conséquent, l'activité finale représente bien celle du Sr-90. Une purification supplémentaire s'effectue au cours de la préconcentration et au

TABLE 3. Concentration du Sr-90 dans les rivières et les lacs du Québec

Rivières du Saint-Laurent	Concentration (mBq/L)
Beauharnois	14 ± 0,7*
Montréal	5 ± 0,5
Varennes	11 ± 0,6
L'Outaouais, Montebello	12 ± 0,6
Gentilly, St-Pierre-Les-Besquets	15 ± 0,7
Lacs	
Memphremagog	7,4 ± 0,6
Champlain	5,4 ± 0,5
Manitou	5,9 ± 0,6
Tremblant	3,7 ± 0,5
Simon	3,2 ± 0,5

*Erreur statistique à un niveau de confiance de 90%. Les concentrations ont été calculées de la façon suivante :

$$\text{Concentration (Bq/L)} = \frac{\text{Taux de comptage (coups/s)}}{100 \times 0{,}28 \times 0{,}21}$$

cours du comptage quand on favorise aussi très fortement la détection du Sr-90 au dépens d'autres émetteurs β.

Il est intéressant de comparer les résultats obtenus (tableau 3) avec les mesures du Sr-90 faites par d'autres chercheurs. Les chercheurs canadiens du Ministère de la Santé et du Bien-être social (12) ont trouvé les concentrations du Sr-90 dans le fleuve St-Laurent allant de 3 à 21 mBq/L et dans le lac Ontario de 1 à 20 mBq/L. Dans la mer baltique en 1972, les chercheurs Vakulskij *et al.* (16) ont trouvés 27 mBq/L du Sr-90. Dans l'eau de mer du Golfe du Mexique on a trouvé (17) 3 mBq/L et dans l'eau potable dans les iles Faroe on a mesuré (18) 5.5 mBq/L.

On constate que les concentrations mesurées au Québec sont assez semblables aux valeurs déterminées ailleurs. Le rendement global de notre méthode est de 28% et la limite de détection est de 0,5 mBq/L avec un bruit de fond de 1,7 coups/min et le temps de comptage de 600 min. Cette limite se compare bien avec celle (1 mBq/L) obtenue par d'autres chercheurs (19).

Le rendement pourrait être déterminé pour chaque analyse en utilisant un traceur radioactif comme le Sr-85. Nous n'avons pas adopté l'emploi d'un traceur à cause des frais additionnels.

Notre méthode est plus courte (10 étapes) que la technique utilisée présentement par les autorités canadiennes (19) qui comporte 34 étapes et nous cryons qu'elle est aussi sélective que les méthodes compétitives.

La durée totale d'une analyse (sans prélèvement) est de 9 h, mais elle comporte des périodes d'attente qui totalisent 6 h et, par conséquent, on peut faire plusieurs analyses simultanément.

Conclusions

Nous avons mis au point une nouvelle méthode de dosage du Sr-90 dissout dans l'eau des lacs et des rivières. Cette méthode est moins onéreuse et aussi performante que la méthode conventionnelle et, nous croyons, aussi fiable. Cette méthode a été utilisée pour doser le Sr-90 dissout dans les lacs et les rivières du Québec et les activités variant de 3 à 15 mBq/L ont été mesurées.

Remerciements

Nous remercions sincèrement la Conseil de recherches en sciences naturelles et en génie du Canada pour une subvention qui a rendu la réalisation de ce travail possible. Nous exprimons notre gratitude au personnel du laboratoire SLOWPOKE de l'École Polytechnique pour la fabrication des traceurs radioactifs utilisés dans cette recherche.

Étude cinétique et thermodynamique de l'interaction d'un complexe de Pd(II) avec l'inosine et l'acide polyinosinique

ROBERT MÉNARD[1] ET MIKLOS ZADOR[2]

Département de chimie, Université de Montréal, C.P. 6128, succursale A, Montréal (Québec), Canada H3C 3J7

Reçu le 26 mai 1987

ROBERT MÉNARD et MIKLOS ZADOR. Can. J. Chem. **66**, 178 (1988).

Les réactions du complexe (dien)Pd(II) avec l'inosine et l'acide polyinosinique ont été étudiées à l'aide de méthodes spectroscopiques et de flux-stoppé. Dans les deux cas, le métal se lie initialement au site N7 de la base hypoxanthine. Les résultats des études cinétiques indiquent que le mécanisme implique deux voies réactionnelles : une substitution nucléophile directe ainsi qu'une réaction via un intermédiaire aquo. Les réactions sont plus rapides dans le cas du poly(I), due à la forte densité de charges négatives de ce polymère. La réaction initiale au site N7 est suivie d'une redistribution lente du métal vers le site N1 thermodynamiquement plus stable. La fixation du (dien)Pd(II) au poly(I) induit la formation d'une structure multi-hélicoïdale stable du polymère. Cette structure a été caractérisée par des mesures d'absorbance et de dichroïsme circulaire ainsi que par la détermination de la courbe de fusion du polymère. Il a aussi été observé qu'en présence du complexe de Pd(II), le poly(I) peut être hydrolysé à pH alcalin, dans des conditions relativement douces.

ROBERT MÉNARD and MIKLOS ZADOR. Can. J. Chem. **66**, 178 (1988).

Reactions of the (dien)Pd(II) complex with inosine and polyinosinic acid were studied by spectroscopic and stopped-flow methods. In both cases, the metal initially binds at the N7 site of the hypoxanthine base. The results of kinetic studies indicate the existence of a two-path mechanism: a direct nucleophilic substitution and a solvent path with formation of an aquo intermediate. The reactions are faster for poly(I), due to the high density of negative charges for this polymer. The initial reaction at N7 is followed by a slow redistribution of the metal towards the thermodynamically more stable N1 site. Binding of (dien)Pd(II) to poly(I) leads to formation of a stable, multistranded helicoidal structure of the polymer. This structure was characterized by absorption and circular dichroism measurements and by the melting curve of the polymer. It was also observed that in presence of the Pd(II) complex, poly(I) can be hydrolyzed at relatively mild conditions at high pH.

Introduction

À cause de la complexité des polynucléotides, les premiers travaux fondamentaux sur l'interaction des acides nucléiques avec les complexes de Pd(II) et de Pt(II) ont été orientés vers l'étude des unités constituantes plus simples, tels les bases nucléiques et les nucléosides (1–4). La plupart de ces travaux ont pour but la détermination des sites de liaison et de la stabilité des complexes formés. Parmi les divers nucléosides étudiés, l'inosine s'est avéré être un cas relativement complexe dû à la présence de deux sites potentiels de liaison pour le palladium et le platine : les azotes N1 et N7 (5–9). Le site N1 est protoné en solution neutre et la liaison à ce site dépend du pH. Divers types de complexes peuvent alors exister et, pour un composé tel (en)$PdCl_2$, des espèces polymériques sont connues (7). La formation d'un chélate entre les sites N7 et O6 a aussi été proposée à quelques reprises (10, 11) mais son existence est contestée (3).

Le complexe (dien)Pd(II), qui a l'avantage de ne posséder qu'un seul groupe labile, a fait l'objet d'études exhaustives (6, 8, 9, 12–14). Martin et coll. ont utilisé la rmn pour étudier l'importance des liaisons à chacun des sites en fonction du pH. Les résultats pour l'inosine indiquent que la liaison au site N7 est prédominante à pH < 4, tandis qu'à pH > 8, la liaison se fait presque exclusivement à N1. En solution neutre, les espèces Pd–N1, Pd–N7 ainsi que l'espèce binucléaire sont présentes. Avec l'inosine monophosphate, la distribution des espèces est similaire sauf que la présence du groupe phosphate tend à favoriser la liaison à N7. De plus, la présence du palladium en N7 cause une diminution du pK_a du site N1, ce qui conduit à une redistribution des ions métalliques et à la formation de liens avec le site N1 déprotoné (8).

Bien que l'importance des facteurs cinétiques ne soit pas mise en doute, très peu d'études quantitatives ont cependant été consacrées à cet aspect. Quelques études cinétiques ont été publiées impliquant la réaction de complexes de Pd(II) avec l'inosine, le poly(I)·poly(C) ainsi que la cytidine et ses dérivés (12, 15–18). Les résultats ont permis de démontrer l'existence de deux voies réactionnelles principales conduisant au produit final : une substitution nucléophile directe ainsi qu'une réaction via un ou des intermédiaires aquo. Il a aussi été observé, dans le cas des polynucléotides, que les facteurs de type électrostatique ont un effet prédominant sur la cinétique des réactions ainsi que sur la stabilité des complexes formés.[3]

Le but de ce travail est de définir avec précision le mécanisme de la réaction entre le (dien)Pd(II) et l'inosine, et de vérifier si ce mécanisme s'applique dans le cas du polynucléotide correspondant, le poly(I). Nous examinerons aussi comment la structure de ce polymère est affectée lors de la fixation de l'ion métallique.

Partie expérimentale

L'inosine (In) et l'inosine-5′-monophosphate (IMP, sel de sodium) ont été obtenus de Sigma Chemical Co. tandis que l'acide polyinosinique (poly(I), sel de potassium) provenait de Miles Laboratories Inc. La concentration du poly(I) est donnée en termes d'unité mononucléotide. Tous ces produits sont de haute pureté et furent utilisés sans purification supplémentaire. Les complexes [(dien)PdCl]Cl et [(dien)Pd(H_2O)](ClO_4)$_2$ (dien : diéthylènetriamine) ont été préparés tel que décrit précédemment (16). La force ionique est fixée par addition de $NaClO_4$, préparé à partir de $HClO_4$ (Biopharm) et de NaOH (Fisher Scientific Co.), étant donné que le $NaClO_4$ commercial contient souvent des impuretés pouvant interférer avec nos résultats. Le pH a été ajusté à l'aide de solutions concentrées de $HClO_4$ et de NaOH. Aucun tampon n'a été utilisé, de façon à éviter les interactions possibles avec les complexes de Pd(II).

Les mesures d'absorbance ont été effectuées à l'aide d'un spectro-

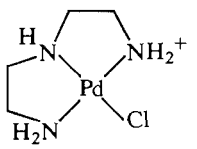
photomètre Perkin–Elmer modèle 552, équipé d'un système électronique de contrôle de la température permettant la détermination de la courbe de fusion d'un polynucléotide (vitesse d'accroissement de température utilisée : 1°C/min). Les réactions rapides ont été suivies par spectrophotométrie à flux-stoppé en utilisant un système décrit précédemment (16). Les spectres de dichroïsme circulaire ont été enregistrés au moyen d'un spectropolarimètre Cary modèle 61 à la température de la pièce (21–23°C), en utilisant des cellules circulaires de chemin optique l = 1 cm. Les conditions standards pour ce travail sont : pH 7,0, force ionique 0,20 M, température 25,0°C. Les conditions expérimentales différentes seront spécifiées.

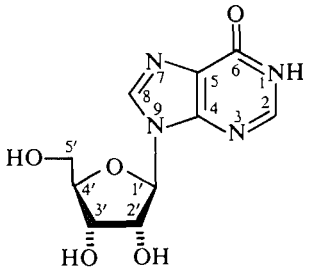
Résultats et discussion

Inosine

La cinétique de la réaction entre le (dien)PdCl$^+$ et l'inosine a d'abord été étudiée en mélangeant les réactifs à un pH initial de 7. On observe la présence de deux signaux distincts à 300 nm, le premier étant une augmentation relativement rapide ($t_{1/2}$ = 0,4 s) et importante de l'absorbance et attribuée à la fixation du (dien)Pd(II) au site N7 de l'inosine. Cette réaction est suivie



(dien)PdCl$^+$



Inosine

d'une autre, beaucoup plus lente ($t_{1/2}$ = 120 s), produisant une très faible augmentation d'absorbance et correspondant à la formation du complexe Pd–N1 à partir de Pd–N7 avec libération de protons. Ce transfert a lieu entre pH 4 et 8, tel qu'illustré à la figure 1(a). Le mécanisme de ce processus lent n'a pas été étudié, à cause du faible signal dans ces conditions. Par ailleurs, des travaux antérieurs (6, 8) ont démontré que ce processus résulte d'une série de réactions impliquant plusieurs espèces. À λ = 350 nm, où les espèces Pd–N1 et Pd–N7 possèdent pratiquement la même absorbance, un seul signal est observé, correspondant à la formation du complexe Pd–N7. La cinétique de la réaction au site N7 a donc été étudiée en suivant les variations d'absorbance à 350 nm. On considère que la variation du pH durant cette réaction n'affecte pas la cinétique de la fixation en N7. Cette variation est d'autant plus faible que la concentration d'inosine en excès est importante.

La figure 1(b) montre l'influence du pH sur la constante de vitesse de cette réaction. On note une augmentation de la constante de vitesse à pH > 7 suivie d'une importante diminution à pH > 9. À pH élevé, la déprotonation du site N1 de l'inosine (pK_a = 8,7 (3)) conduit à l'apparition de concentrations importantes d'inosine déprotonée [InH$_{-1}$]. Avec k_{i7} et k_{i1} comme constantes de vitesse pour la réaction du (dien)Pd(II) aux sites N7 et N1 déprotoné respectivement, on obtient l'équation [1] :

$$[1] \quad k_{exp} = k_{i7}[In] + k_{i1}[InH_{-1}]$$

À pH élevé, la contribution du deuxième terme devient importante et les résultats indiquent que la réaction au site N1 déprotoné est plus rapide que celle au site N7. À partir de pH ≈ 8, on a maintenant apparition du dérivé (dien)Pd(OH)$^+$. Cette espèce, moins réactive, conduit à un ralentissement de la

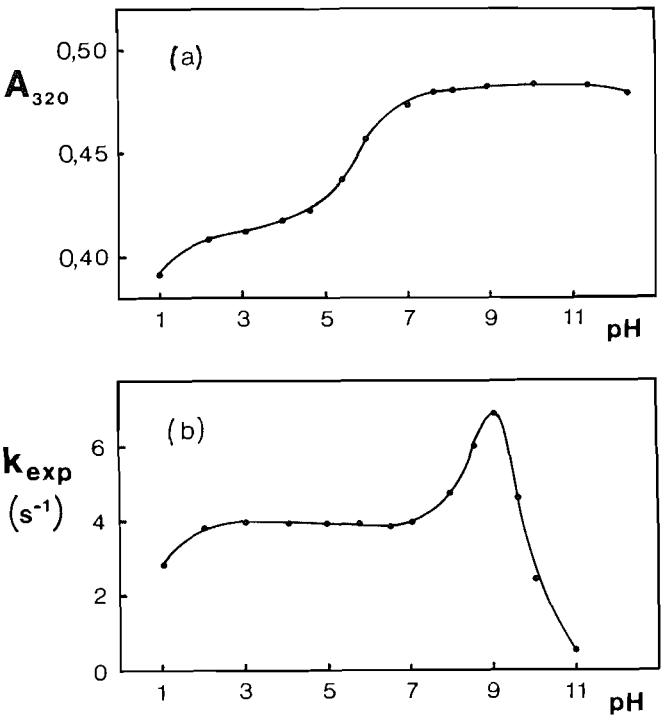


FIG. 1. Influence du pH sur l'absorbance (a) et sur la constante de vitesse de réaction (b) du système (dien)Pd(II)–inosine. Conditions : (a) inosine 1,0 × 10^{-2} M, [(dien)PdCl]Cl 1,0 × 10^{-3} M, NaCl 0,10 M, $NaClO_4$ 0,10 M; (b) inosine 5,0 × 10^{-3} M, [(dien)PdCl]Cl 5,0 × 10^{-4} M, NaCl 0,10 M, $NaClO_4$ 0,10 M.

réaction, tel qu'observé à pH > 9. La combinaison de ces deux effets permet d'expliquer l'allure de la courbe à pH > 7. La vitesse maximum se situe aux environs de pH 9, position qui est relativement sûre étant donné que la variation du pH durant la réaction devient négligeable à pH > 8. Entre pH 3 et 7, la valeur de k_{exp} est constante et reflète la réaction du (dien)Pd(II) au site N7 de l'inosine. La diminution de vitesse observée à pH < 2 peut être expliquée en considérant la protonation du site N7 à ce pH (pK_a ≈ 1,0 (3)).

La cinétique de la réaction à pH 7 a aussi été étudiée en fonction de la concentration en inosine et à diverses concentrations en ions chlorure ajoutés. Les résultats sont donnés à la figure 2. On remarque que la réaction est inhibée par l'addition d'ions chlorure et que l'ordre par rapport à l'inosine est inférieur à un à faible concentration en ion Cl$^-$. Les résultats sont semblables à ceux obtenus précédemment pour la réaction du (dien)Pd(II) avec la cytidine (16). On peut donc proposer un mécanisme similaire pour la formation du complexe Pd–N7 de l'inosine. Deux voies réactionnelles sont possibles : une substitution nucléophile directe ainsi qu'une réaction via un intermédiaire aquo.

$$[2] \quad In + (dien)PdCl^+ \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} (dien)Pd(In)^{2+} + Cl^- \quad \Big\} \text{ voie directe}$$

$$[3] \quad (dien)PdCl^+ + H_2O \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} (dien)Pd(H_2O)^{2+} + Cl^- \quad \Big\} \text{ voie du solvant}$$

$$[4] \quad In + (dien)Pd(H_2O)^{2+} \underset{k_{-3}}{\overset{k_3}{\rightleftharpoons}} (dien)Pd(In)^{2+} + H_2O \quad \Big\}$$

La constante d'équilibre pour la réaction du (dien)PdCl$^+$ au site N7 de l'inosine (équation [2] du mécanisme) a été évaluée par titrage spectrophotométrique en présence d'ions chlorure et

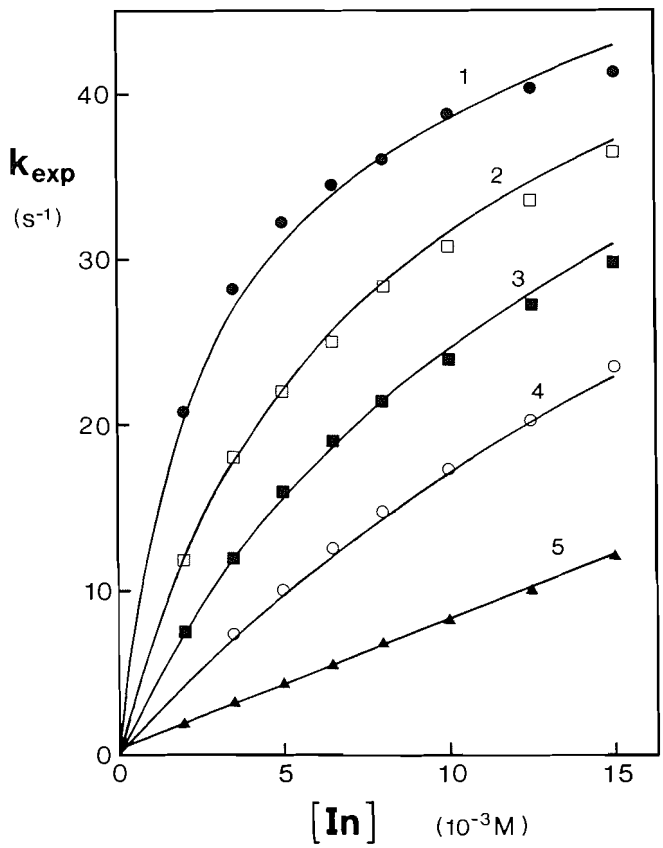

FIG. 2. Variation de la constante de vitesse expérimentale en fonction de la concentration en inosine, à diverses concentrations en ion Cl^- ajouté. Conditions : [(dien)PdCl]Cl 5,00 × 10^{-4} M, force ionique constante (0,20 M NaCl + $NaClO_4$), pH 7, NaCl ajouté : (1) 0, (2) 0,0030 M, (3) 0,0080 M, (4) 0,020 M, (5) 0,10 M. Les courbes sont calculées, d'après le mécanisme décrit par les équations [2]–[4].

TABLEAU 1. Paramètres cinétiques pour la réaction du (dien)$PdCl^+$ au site N7 de l'inosine à pH 7

k_1	450 M^{-1} s^{-1}
k_{-1}	1,88 M^{-1} s^{-1}
k_2	42 s^{-1}
k_{-2}	29 000 M^{-1} s^{-1}
k_3	27 000 M^{-1} s^{-1}
k_{-3}	0,16 s^{-1}

à pH 4 afin d'éliminer l'interférence du complexe Pd–N1. Une valeur de K_1 = 240 ± 40 a été obtenue. Les constantes de vitesse individuelles ont pu être évaluées en procédant tel que décrit précédemment pour la cytidine. Les résultats sont donnés au tableau 1.

La plus grande réactivité du dérivé aquo du (dien)Pd(II) permet d'expliquer l'inhibition par l'ion Cl^- observée. Les constantes de vitesse k_1 et k_3 sont comparables à celles obtenues pour le système analogue impliquant le (dien)$PdBr^+$ (12). Les différences sont dues à la force ionique plus élevée ainsi qu'à la contribution de l'espèce (dien)$Pd(OH)^+$ en l'absence d'ion Cl^- pour les expériences réalisées avec le (dien)$PdBr^+$. Les valeurs des constantes de vitesse individuelles diffèrent beaucoup cependant de celles obtenues pour la cytidine. En particulier, la valeur de k_1 pour l'inosine est six fois plus élevée que celle pour

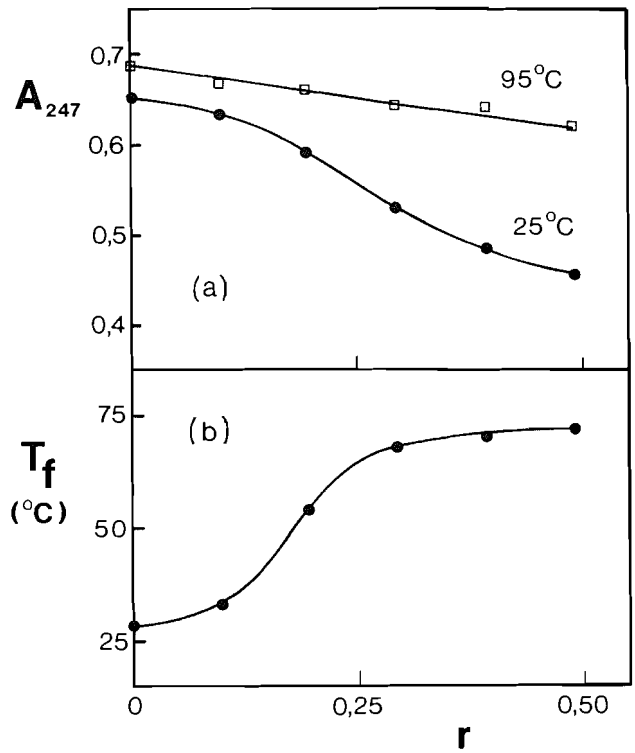

FIG. 3. Influence du (dien)Pd(II) sur l'absorbance (*a*) et sur la température de fusion (*b*) du poly(I). Conditions : poly(I) 6,14 × 10^{-5} M, $NaClO_4$, 0,20 M, pH 7. r = [(dien)PdCl]Cl/[poly(I)].

la cytidine (450 M^{-1} s^{-1} vs. 75 M^{-1} s^{-1}) tandis que pour k_3, le rapport est de neuf (27 000 M^{-1} s^{-1} vs. 2900 M^{-1} s^{-1}). L'inosine est donc un meilleur nucléophile pour les réactions de substitution des complexes du (dien)Pd(II) et, en présence de cytidine, la réaction au site N7 de l'inosine serait cinétiquement favorisée.

Induction d'une forme hélicoïdale du poly(I) par le (dien)Pd(II)

Le complexe formé entre le (dien)Pd(II) et le poly(I) a été caractérisé à l'aide de mesures d'absorbance, de dichroïsme circulaire et de température de fusion. Pour les mesures d'absorbance, la bande d'absorption du polynucléotide, dont le maximum se situe à 247 nm, a été utilisée. L'addition du complexe de palladium cause un léger déplacement du maximum vers 249 nm, accompagné d'une importante diminution de l'absorbance. L'importance de cette diminution est inhabituelle pour un système (dien)Pd(II)–polynucléotide et suggère la formation d'une structure hélicoïdale ordonnée avec recouvrement des bases hypoxanthine. La valeur de l'absorbance à 247 nm à 25°C en fonction du rapport r = [(dien)Pd(II)]/[poly(I)] est donnée à la figure 3(*a*). La diminution d'absorbance est de type coopératif, caractéristique des systèmes impliquant des polynucléotides hélicoïdaux. La complexation du Pd(II) à l'inosine produit une très légère diminution de l'absorbance à 247 nm (de 0,78 à 0,74) comparativement à celle observée pour le poly(I) (de 0,65 à 0,45).

Pour vérifier l'existence d'une telle structure, la variation de l'absorbance en fonction de la température a été étudiée. Les courbes obtenues à divers rapports r sont représentées à la figure 4. Pour r = 0, une très légère transition peu coopérative est observée à basse température, indiquant la présence de faibles proportions de poly(I) associé en l'absence de Pd(II). Lors de l'addition de concentrations croissantes de (dien)Pd(II), la transition est déplacée à des températures plus élevées

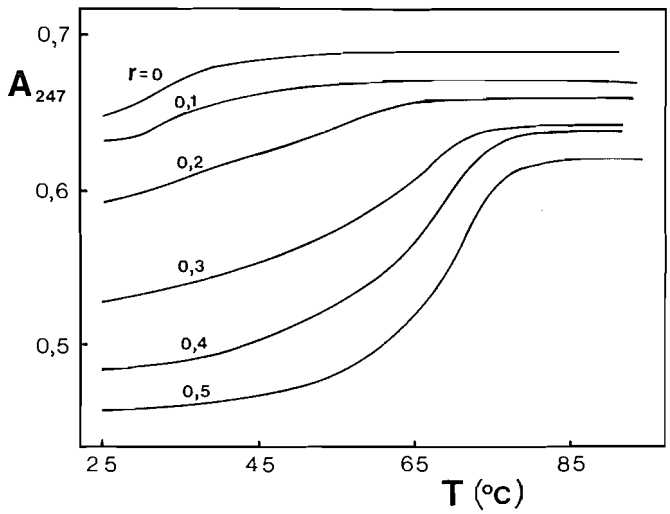

FIG. 4. Courbe de fusion du poly(I) en présence de diverses concentrations de (dien)Pd(II). Conditions : poly(I) 6,14 × 10^{-5} M, $NaClO_4$ 0,20 M, pH 7. r = [[(dien)PdCl]Cl]/[poly(I)].

et devient plus importante et coopérative. Ce comportement indique la formation d'une structure hélicoïdale de stabilité croissante avec l'addition du (dien)Pd(II). La température de fusion, correspondant au maximum de la courbe différentielle dA_{247}/dT en fonction de T, est représentée à la figure 3(b) en fonction du rapport r. La courbe obtenue démontre clairement l'effet coopératif de la fixation du (dien)Pd(II) sur la stabilité du produit formé. La température de fusion passe de 28°C en l'absence de Pd(II) à 72°C pour r = 0,49. À température élevée, où le polynucléotide est sous forme de pelote statistique, l'absorbance à 247 nm décroît aussi lorsque le rapport r augmente (figure 3(a)). Cette faible diminution est non-coopérative et reflète la fixation du Pd(II) à la base hypoxanthine du poly(I). D'ailleurs, le minimum de la bande d'absorption du poly(I) à 95°C se situe toujours à 249 nm en présence de (dien)Pd(II), comparativement à 247 nm pour le poly(I) libre, ce qui montre que le Pd(II) est complexé au poly(I) dans ces conditions. La diminution graduelle de la température conduit à une renaturation très lente du polymère, caractéristique du poly(I) (19). La vitesse de renaturation semble augmenter cependant avec la concentration en (dien)Pd(II). Le système est seulement partiellement réversible pour des temps courts (<1 h).

En l'absence du complexe de palladium, le poly(I) peut s'auto-associer en solution à force ionique élevée et à basse température (19–23). Les deux structures proposées pour ce polymère contiennent trois et quatre brins respectivement tenus ensemble par des ponts hydrogène N1—H···O6 (21, 23). Un modèle alternatif implique des ponts hydrogène N1—H···N7 (19). L'addition du complexe de Pd(II) peut faciliter la formation de la multiple hélice. Comme le site de fixation du (dien)Pd(II) se situe à N7 ou N1, la dernière structure proposée semble improbable. Pour les deux structures à ponts hydrogène N1—H···O6, le site N7 est suffisamment accessible pour permettre la complexation du (dien)Pd(II). Une fois fixé, le complexe de Pd(II), chargé positivement, neutralise les charges négatives des phosphates voisins, réduisant les répulsions interchaîne et favorisant ainsi l'association de plusieurs brins. Comme le (dien)Pd(II) est fixé plus fortement que des cations tels Na^+, l'effet structurant est plus important (T_f = 72°C à une force ionique de 0,20 M $NaClO_4$) et est rencontré à des

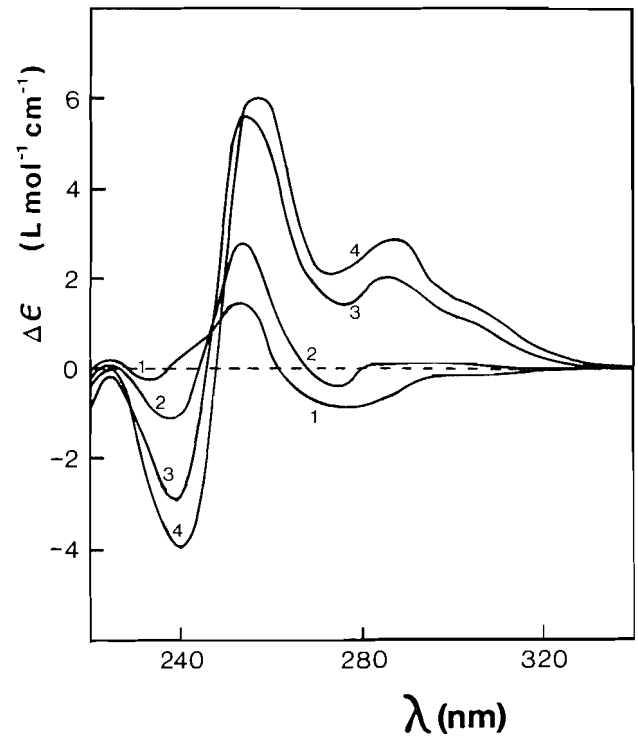

FIG. 5. Spectre de dichroïsme circulaire du poly(I) en présence de diverses concentrations de (dien)Pd(II). Conditions : poly(I) 8,02 × 10^{-5} M, NaCl 1,0 × 10^{-4} M, $NaClO_4$ 0,20 M, pH 7. r = [[(dien)PdCl]Cl]/[poly(I)] = (1) 0, (2) 0,1, (3) 0,3, (4) 0,5.

concentrations plus basses en métal (3,0 × 10^{-5} M). Ackermann et coll. ont déjà suggéré que la formation de la multiple hélice du poly(I) était due principalement à la diminution des répulsions électrostatiques entre les brins à force ionique élevée (22). De plus, comme la fixation du (dien)Pd(II) en N7 accroît l'acidité du proton en N1 pour l'inosine (6, 8), un effet similaire avec le poly(I) contribuerait à la stabilisation des ponts hydrogène N1—H···O6.

La stabilisation de la multiple hélice est possible avec des ions métalliques bivalents possédant une affinité reconnue pour le groupe phosphate, tels Mg^{2+} et Ca^{2+} (24). Il y a peu d'exemples similaires impliquant un métal qui se fixe préférentiellement aux bases nucléiques. L'ion Ag^+ peut conduire à la formation d'une multiple hélice avec le poly(I) (25). Cependant, cette structure est formée à l'aide de ponts interchaîne, avec l'ion Ag^+ lié simultanément aux sites N1 et O6 de deux hypoxanthines. Un tel complexe est impossible avec le (dien)Pd(II) possédant un seul groupe labile.

Lors de l'étude de l'interaction du poly(I)·poly(C) et du poly(I) avec le (dien)Pt(II), une autre hypothèse a été avancée qui implique des ponts hydrogène entre les groupes amino du dien et les sites N7 des bases hypoxanthines voisines du site de complexation du métal (26). Ces ponts hydrogène contribueraient à la stabilisation du poly(I)·poly(C) et existeraient aussi dans le cas du poly(I), bien que le degré de structuration ne soit pas quantifiable. Bien que de telles interactions puissent être présentes, nous croyons que les facteurs de type électrostatique jouent un rôle prédominant, tel que démontré précédemment lors de l'étude du système (dien)Pd(II)–poly(I)·poly(C) (17).

Les spectres de dichroïsme circulaire du poly(I) libre et en présence de (dien)Pd(II) sont représentés à la figure 5. Le spectre du poly(I) est relativement peu intense. L'addition du

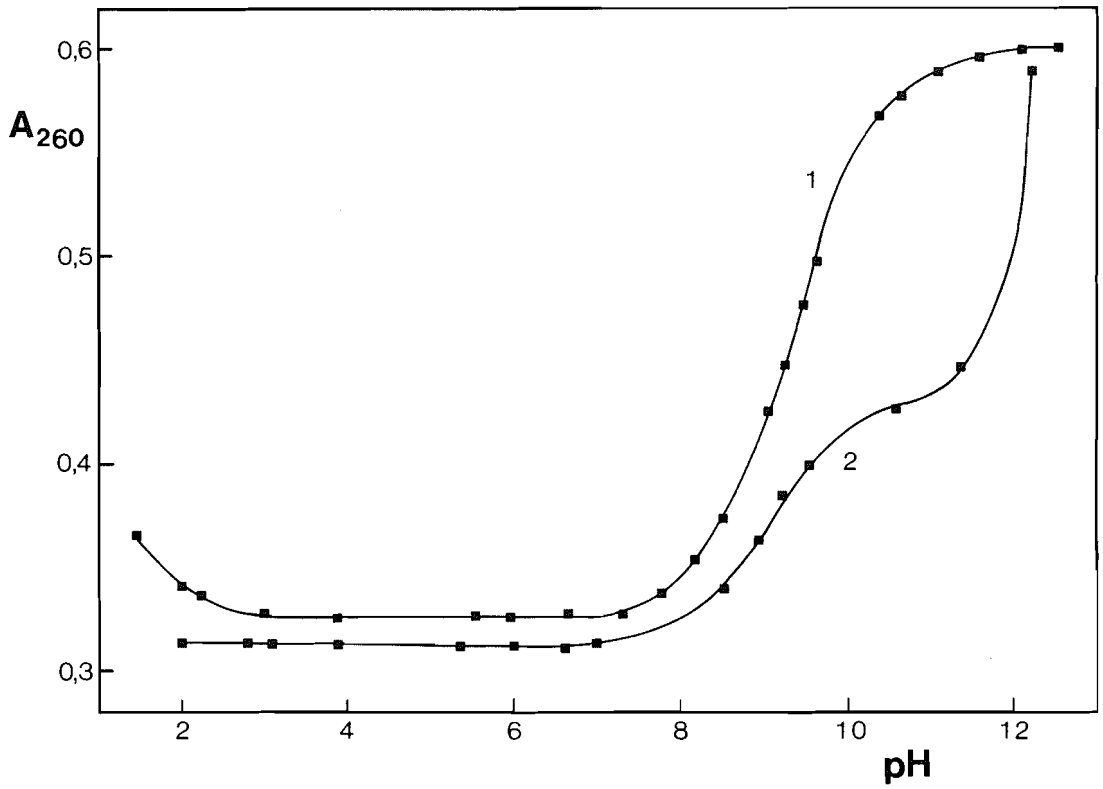

FIG. 6. Influence du pH sur l'absorbance du poly(I) libre (1) et du complexe (dien)Pd(II)–poly(I) (2). Conditions : (1) poly(I) $5{,}04 \times 10^{-5}$ M; (2) poly(I) $5{,}04 \times 10^{-5}$ M, [(dien)PdCl]Cl $2{,}50 \times 10^{-5}$ M. Dans les deux cas : $NaClO_4$ 0,20 M.

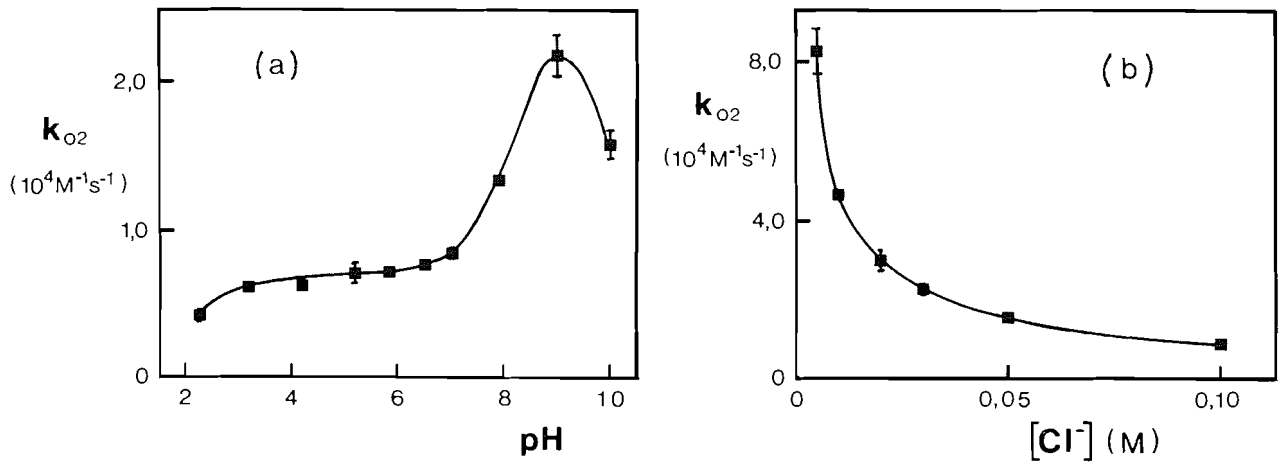

FIG. 7. Influence du pH (*a*) et de la concentration en ion chlorure (*b*) sur la constante de vitesse d'ordre 2 de la réaction du (dien)Pd(II) avec le poly(I). Conditions : (*a*) poly(I) $3{,}08 \times 10^{-5}$ M, [(dien)PdCl]Cl $1{,}00 \times 10^{-5}$ M, NaCl 0,10 M, $NaClO_4$ 0,10 M; (*b*) poly(I) $3{,}07 \times 10^{-5}$ M, [(dien)PdCl]Cl $1{,}00 \times 10^{-5}$ M, force ionique constante (0,20 M NaCl + $NaClO_4$), pH 7.

complexe de Pd(II) modifie profondément le spectre et accroît l'intensité des bandes. Un tel accroissement de l'intensité peut être attribué à la formation d'une structure hélicoïdale ordonnée. La forme de ce spectre est différente cependant de celles généralement attribuées à la multiple hélice du poly(I) à force ionique élevée ou à basse température (19, 20). En particulier, la bande négative vers 280 nm pour le poly(I) libre est remplacée par une bande positive en présence du (dien)Pd(II). Une bande négative, absente dans le cas de la multiple hélice du poly(I) libre, est aussi rencontrée vers 240 nm. Ces résultats suggèrent, pour le complexe poly(I)–Pd(dien), une géométrie différente de celle de la multiple hélice du poly(I). Une inversion de la bande positive, lors de l'addition de complexes de Pt(II), a déjà été remarquée (27). Cette inversion a été attribuée à une modification de l'empilement des bases et de la structure secondaire du polymère lors de la fixation du métal aux bases nucléiques.

La figure 6 illustre l'influence du pH sur l'absorbance à 260 nm du poly(I) et de son complexe avec le (dien)Pd(II). Pour le polynucléotide libre, la déprotonation du site N1 cause une importante augmentation de l'absorbance à pH $> 7{,}5$, correspondant à un pK_a de 9,3. Un début de transition à pH < 3 est aussi visible, attribué à la protonation du site N7 dont le pK_a est voisin de 1.

La valeur de l'absorbance à 260 nm est légèrement plus faible en présence du complexe de palladium. Deux transitions sont maintenant observées en milieu alcalin. La première, possédant un pK_a apparent de 9,2, correspond probablement à la déproto-

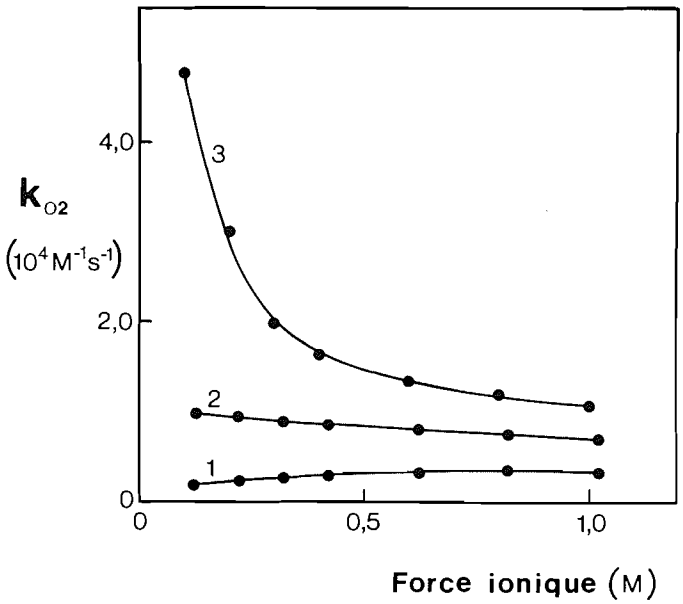

FIG. 8. Influence de la force ionique sur la constante de vitesse d'ordre 2 de la réaction du (dien)Pd(II) avec l'inosine (1), IMP (2) et poly(I) (3). Conditions : (1) inosine $2,5 \times 10^{-3}$ M, [(dien)PdCl]Cl $2,5 \times 10^{-4}$ M; (2) IMP $2,5 \times 10^{-3}$ M, [(dien)PdCl]Cl $2,5 \times 10^{-4}$ M; (3) poly(I) $3,10 \times 10^{-5}$ M, [(dien)PdCl]Cl $1,0 \times 10^{-5}$ M. Dans les trois cas : NaCl 0,020 M, pH 7. La force ionique a été ajustée par addition de $NaClO_4$.

nation des sites N1 des bases hypoxanthine non-complexées par le palladium. À pH > 11, une augmentation abrupte et importante de l'absorbance est aussi observée. Cette transformation est irréversible et très lente, nécessitant au minimum 3 h. Le spectre de la solution ramenée à pH 7 correspond à celui du complexe (dien)Pd–IMP, suggérant l'hydrolyse du poly(I). Le poly(I) libre peut être dégradé en milieu fortement basique (KOH, 0,2 M, 40°C, 4 h) et il a déjà été observé que certains ions métalliques pouvaient conduire à sa dégradation en milieu moins basique (28). Toutefois, contrairement aux ions interagissant fortement au phosphate (tels Mn(II), Zn(II), Cu(II), etc.), un pH relativement élevé est requis dans le cas du palladium.

Cinétique de l'interaction (dien)Pd(II)–poly(I)

La cinétique de la réaction du complexe de Pd(II) avec le poly(I) a été étudiée en fonction du pH, de la concentration en ion chlorure et de la force ionique. En plus de la réaction rapide habituelle au site N7, on observe subséquemment des variations d'absorbance lentes. Ces phénomènes lents, qui n'affectent pas la détermination des constantes de vitesse, peuvent être attribués à des réarrangements conformationnels du polymère après la fixation du (dien)Pd(II) ainsi qu'au transfert du complexe Pd–N7 au complexe Pd–N1. Le transfert ou fixation du Pd(II) au groupement phosphate ne devrait pas avoir une influence significative, dû à la faible stabilité par rapport au complexe Pd(II)–N (16).

L'influence du pH sur la constante de vitesse d'ordre deux de la réaction au site N7 du poly(I) (figure 7(*a*)) est très similaire au cas de l'inosine (voir figure 1(*b*)). Les effets observés peuvent donc être attribués aux mêmes facteurs : diminution de la vitesse à pH < 3, due à la protonation du site N7, et augmentation de la constante de vitesse à pH > 7, due à la contribution du site N1 déprotoné, suivie d'une diminution à pH > 9 attribuable à la présence du complexe $(dien)Pd(OH)^+$ peu réactif. Il est à noter que le maximum de réactivité se situe aux environs de pH 9, tout comme dans le cas de l'inosine. L'inhibition par l'ion chlorure à pH 7 est aussi observée avec le poly(I) (figure 7(*b*)). La constante de vitesse en l'absence d'ion Cl^- ajouté est très élevée, $k_{02} = 4,1 \times 10^5 M^{-1} s^{-1}$ (non-représenté sur la figure). Le comportement est identique à celui de l'inosine et des autres systèmes étudiés (16) et indique que le mécanisme général est le même dans tous les cas.

L'influence de la force ionique est représentée à la figure 8 pour les réactions du (dien)Pd(II) avec le poly(I), l'IMP est l'inosine. Le poly(I) réagit beaucoup plus rapidement avec les complexes de Pd(II) à faible force ionique, dû au champ électrostatique fort de ce polyélectrolyte. La vitesse de cette réaction est, de plus, fortement influencée par la force ionique de la solution, à cause de l'effet d'écran et de la condensation des ions autour du polymère, facteurs très importants pour un polyélectrolyte. La grande accélération, en passant de l'inosine à l'IMP, est attribuée à la proximité du site N7 et du groupe phosphate dans la conformation *anti* favorisée de l'IMP (3). Ceci conduit à un effet catalytique plus important du phosphate dans ce cas que dans le cas du CMP (16).

Remerciements

An unlikely coincidence in coupled ^{13}C nuclear magnetic resonance spectra. ^{2}J(C,H) in 2,6-dichlorotoluene and related molecules

TED SCHAEFER AND JAMES PEELING
Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received July 21, 1987

TED SCHAEFER and JAMES PEELING. Can. J. Chem. **66**, 184 (1988).

Although as many as 13 peaks are observable in each half of the ^{13}C nuclear magnetic resonance spectrum of C-4 in 2,6-dichlorotoluene at 22.6 MHz, the iterative analysis yields an incorrect value of ^{2}J(C,H). Theoretical spectra for two values of this coupling constant are essentially identical under normal linewidth conditions. At 75.5 MHz, the ^{13}C spectrum displays most of the 48 peaks expected for the X part of an AB_2XR_3 spectrum, yielding the correct choice for ^{2}J(C,H). The theoretical spectrum at 125 MHz is similar to that at 22.6 MHz but only for the correct ^{2}J(C,H). Correct values of ^{2}J(C-4,H) are given for the 2,6-dichloro derivatives of toluene, ethylbenzene, benzyl alcohol, benzyl bromide, and chloride; these were given incorrectly previously.

TED SCHAEFER et JAMES PEELING. Can. J. Chem. **66**, 184 (1988).

Même si on peut observer jusqu'à 13 bandes dans chacune des moitiés du spectre en résonance magnétique nucléaire ^{13}C du C-4 du dichloro-2,6 toluène mesuré à 22,6 MHz, l'analyse itérative conduit à une valeur incorrecte pour la constante ^{2}J(C,H). Les spectres théoriques pour deux valeurs de cette constante de couplage sont essentiellement identiques dans les conditions normales de largeur de raies. À 75,5 MHz, le spectre du ^{13}C comporte la plupart des 48 bandes que l'on peut attendre pour la partie X d'un spectre AB_2XR_3 et il conduit à un choix correct pour la valeur de la constante ^{2}J(C,H). Le spectre théorique à 125 MHz est semblable à celui à 22,6 MHz, mais uniquement pour la valeur correcte de ^{2}J(C,H). Les valeurs correctes pour ^{2}J(C-4,H) sont rapportées pour les dérivés dichloro-2,6 du toluène, de l'éthylbenzène, de l'alcool benzylique et des chlorure et bromure de benzyle; les valeurs rapportées antérieurement n'étaient pas correctes.

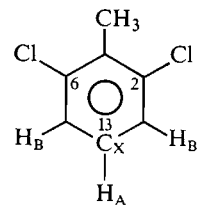
Introduction

The analysis of second order or tightly coupled high resolution nuclear magnetic resonance spectra is generally considered to be straightforward (1), although it is probable that analyses of high precision are not as common as sometimes assumed in the deduction of molecular properties from isotropic chemical shifts and spin–spin coupling constants. The complexity of ^{1}H nmr spectra at relatively low magnetic fields is often such that a precise, or even an approximate, analysis is impractical. In a proton-coupled ^{13}C nmr spectrum the so-called second-order effects arise because, while the ^{13}C nucleus is an X nucleus in the sense that its chemical shift is far removed from the chemical shifts of the protons, the protons are tightly coupled. These effects are often considered a nuisance both in one- and two-dimensional spectra. Recipes (2, 3) have been given for their amelioration, one being the use of high magnetic fields. In principle, of course, a first-order spectrum will be observed if the spectrometer frequency is sufficiently high. It does not follow, however, that the ^{13}C nmr spectrum of a particular ^{13}C nucleus in a molecule will be most informative at highest field.

If second-order effects in ^{13}C nmr are treated as informative phenomena, then, as shown by Jakobsen and co-workers (4, 5) and by Ernst *et al.* (6), for example, both the signs and magnitudes of relatively small proton–carbon coupling constants, J(C,H), are extractable. This conclusion is as expected, particularly for spectra of the type ABC...X, where ABC... represents the protons and X the ^{13}C nucleus.

A few years ago, a paper from this laboratory reported (7) on the conformational applications of the five-bond coupling constants between protons on the side chain and the C-4 or *para* ^{13}C nucleus in toluene derivatives. The symmetries of the molecules entailed the analysis of AB_2XR_n (n = 1–3) spectra. For example, for **1** the analyses of spectra, recorded at 22.63 MHz for ^{13}C and at 90.02 MHz for ^{1}H, also yield ^{2}J(C,H), and these were tabulated (7) but not used in the discussion. ^{2}J(C,H) varies between roughly −5 and +5 Hz in benzene derivatives (6, 8, 9). For monosubstituted benzenes, correlations of ^{2}J with substituent electronegativities or with Hammett σ constants exist (6, 10). In polysubstituted benzene derivatives, ^{2}J(C,H) is less easily predicted. Theoretical values (6) are unreliable.



1

In 2,6-dichlorobenzene, ^{2}J(C-4,H) is 0.67 Hz (11), while it is 1.07 Hz in toluene (4). ^{2}J(C,H) in benzene is reported as 1.15 Hz (4), so that a simple additivity scheme implies ^{2}J(C-4,H) as about 0.6 Hz in 2,6-dichlorotoluene, **1**. Indeed, the iterative analysis (7) gives ^{2}J(C-4,H) as 0.627 ± 0.006 Hz. This number is wildly incorrect, as illustrated below.

Results and discussion

Figure 1 displays half of the ^{13}C nmr spectrum of C-4 for **1** at 22.63 MHz. As discussed in the caption to this figure, the two halves have the same appearance at this frequency. The two theoretical spectra at 22.63 MHz in Fig. 1 assume different values for ^{2}J(C-4,H), 0.627 and 0.271 Hz. All other spectral parameters are identical for the two simulations, as are the appearances of the latter. The X region of an AB_2XR_3 spectrum can display 48 peaks, that is, 24 in each half of the spectrum. This result is easily ascertainable from the theoretical structure (12) of the simpler AB_2X arrangement. Only 13 discernible peaks appeared in the half-spectrum in Fig. 1, yet the analysis was deemed reliable. ^{5}J(C-4,H), the desired parameter (7), is 0.89 Hz, as expected from its value in toluene (4). Fortunately,

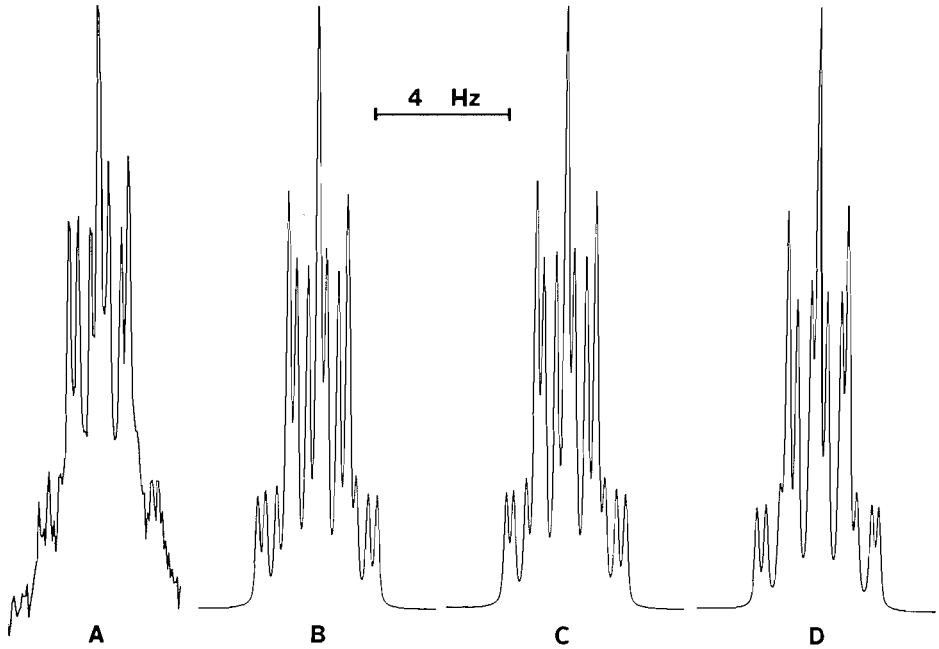


FIG. 1. The high-frequency half of the ^{13}C nmr spectrum of C-4 in 2,6-dichlorotoluene is shown in (A) for a relatively dilute solution described in Fig. 2. The spectrum was obtained with the INEPT sequence and is not of high quality. The low-frequency part of the spectrum has essentially the same appearance, also displaying evidence for 13 peaks. The computed spectra with ^2J(C,H) as 0.627 and 0.271 Hz are also shown in (B) and (C), respectively, and use the parameters indicated in Fig. 2, except for the internal proton chemical shifts, of course. The computed spectrum at 125 MHz (500-MHz spectrum) is displayed in (D) for the correct value of ^2J(C,H), 0.27 Hz. This spectrum alters markedly if ^2J(C,H) is set at 0.627 Hz.

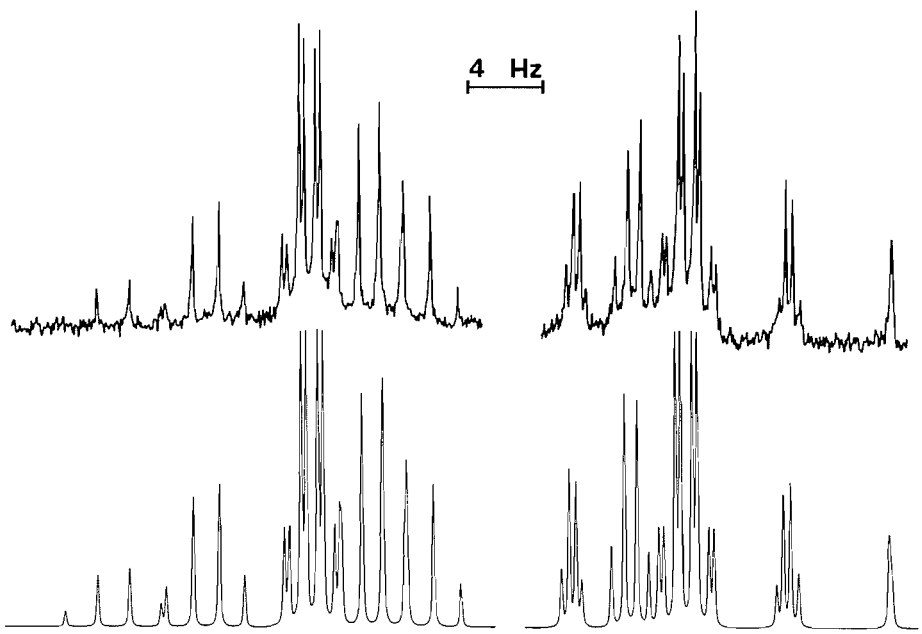

FIG. 2. The observed and computed ^{13}C nmr spectrum of C-4 at 75.477 MHz of 2,6-dichlorotoluene at 300 K. The solution consists of 20% v/v of the toluene in benzene-d_6, which itself contains 20% v/v of acetone-d_6. The difference between the chemical shifts of the protons in the AB_2XR_3 spectrum is 86.1 Hz, J_{AB} is 8.07 Hz, J_{AR} is -0.61 Hz, and J_{BR} is 0.43 Hz. ^1J(C,H), ^2J(C,H), and ^5J(C,H) are 164.92, 0.27, and 0.89 Hz, respectively. Each half of the spectrum consists, in principle, of 6 quartets. The half on the right at low frequency (high field) displays all six quartets because the outermost broad peak is a collapsed quartet. The spectrum was accumulated without polarization transfer procedures, the linewidth at half height is 0.15 Hz in the computed spectrum, and no resolution enhancement was done on the experimental spectrum.

this number does not change in the iterative analysis of the ^{13}C nmr spectrum of C-4 at 75.477 MHz in Fig. 2.

In this figure most of the 48 peaks are observable if it is noted that, in the part at low frequency, the broad band at the right is a collapsed quartet. The signs of ^2J(C,H) and ^3J(H,H) relative to ^1J(C,H) follow from the spectrum, as can be shown easily by simulation. In fact, the relative sign of ^5J(C-4,H) also follows. Note that ^2J(C,H) is unequivocally deduced as $+0.27$ Hz.

The ^{13}C nmr spectrum of C-3 in **1** is displayed in Fig. 3, corresponding to the X part of an $ABCXR_3$ pattern. The

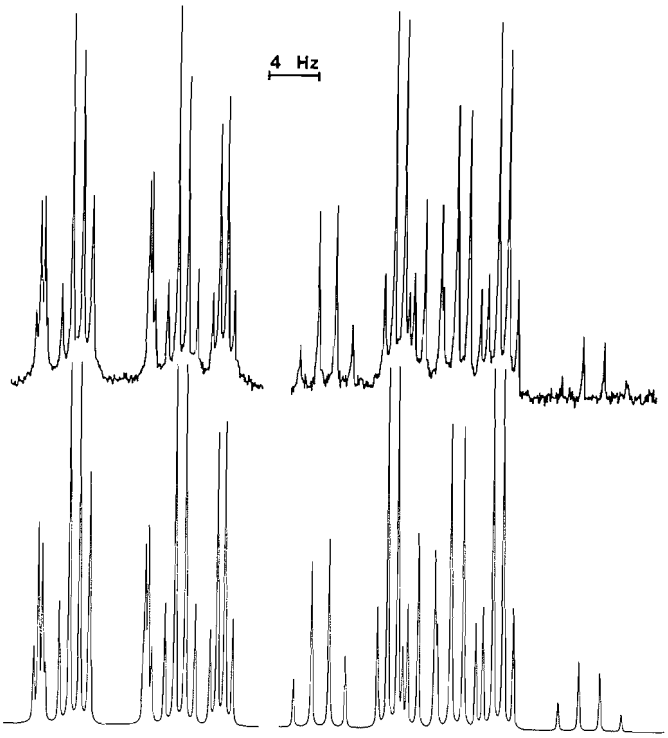

FIG. 3. The ^{13}C nmr spectrum of C-3 in 2,6-dichlorotoluene at 75.477 MHz is compared with the computed spectrum. Most of the peaks of the 12 quartets are apparent. $^1J(C,H)$, $^2J(C,H)$, $^3J(C,H)$, and $^4J(C,H)$ are 166.67, 1.27, 8.13, and −0.78 Hz, respectively. The computed peak widths are 0.15 Hz. The $^{13}C,^{12}C$ isotope shift on H-3, relative to H-5, is 0.37 Hz at 300.135 MHz (shift to low frequency, high field). The other ^1H nmr parameters are the same as for C-4 in Fig. 2, except that $^4J(H-3,H-5)$ is 1.30 Hz. The low-frequency half of the spectrum occurs on the right.

chemical shifts of H-3 and H-5 are not the same, of course, H-5 being more shielded by 0.37 Hz or 1.2 ppb. Again, the spectrum is sensitive to the relative signs of the coupling constants, $^4J(C-3,H)$ being −0.78 Hz, compared to −0.39 Hz in toluene (4). In the ^{13}C nmr spectrum at 22.63 MHz (not shown) this fact is not apparent.

Returning to Fig. 1, the computed ^{13}C nmr spectra of C-4 of **1** is also shown at a ^{13}C resonance frequency of 125 MHz. The number of peaks is reduced relative to those in the spectrum at 75.477 MHz, but the spectra at 125 MHz would allow a decision between the two values of $^2J(C,H)$. Whether the correct value would be obtained from an experimental spectrum is another matter.

Without going into great detail, the reason for the spectral complexity of the C-4 spectrum at 75.477 MHz in Fig. 2 is closely connected to the fact that, at this field intensity, twice the chemical shift difference between the *meta* and *para* protons of **1** is near $^1J(C-4,H)$. Such spectral coincidences have been described for the ABX spectrum (2).

In conclusion, the $^2J(C,H)$ values for C-4 in the 2,6-dichloro derivatives of toluene, ethylbenzene, benzyl bromide, benzyl chloride, and benzyl alcohol are 0.27, 0.31, 0.26, 0.31, and 0.31 Hz, respectively, as extracted from the ^{13}C nmr spectra at 75.477 MHz and, of course, from the ^1H nmr data at 300.135 MHz on the *same* nmr samples. Consequently, the reported $^2J(C-4,H)$, all near 0.6 Hz (7), are incorrect.

Experimental

The procedure for the accumulation of the ^{13}C nmr spectra at 22.63 MHz of the compound above has been described (7). The nmr samples described there (7) were later also used to accumulate ^{13}C and ^1H nmr spectra on an AM300 Bruker spectrometer at 300 K. The ^1H nmr spectra were recorded with the decoupler coil on the 10-mm ^{13}C probe. For 2,6-dichlorotoluene, the INEPT sequences (13) were not employed. Instead, 400 FIDs were stored in 32 K of memory, with acquisition times of 21.4 s and a spectral window of 766 Hz. No resolution enhancement was used for the spectra in Fig. 2, which had peak widths of about 0.15 Hz.

Iterative spectral analyses were performed with the computer program NUMARIT (14), as modified by R. Sebastian in this laboratory. Standard deviations of the spectral parameters were computed as 0.01 Hz or less and the rms errors in the analyses were 0.02 Hz or less.

Synthesis and biological activity of (*S*)-2′-fluorodaunorubicin

HANS H. BAER AND LISA SIEMSEN

Ottawa–Carleton Institute for Research and Graduate Studies in Chemistry, Department of Chemistry, University of Ottawa, Ottawa, Ont., Canada K1N 9B4

Received June 22, 1987

HANS H. BAER and LISA SIEMSEN. Can. J. Chem. **66**, 187 (1988).

Methyl 3-amino-2,3,6-trideoxy-2-fluoro-β-L-galactopyranoside was hydrolyzed to the free sugar, (*S*)-2-fluorodaunosamine hydrochloride, which was converted into the α,β-1,4-di-*O*-acetyl-*N*-trifluoroacetyl derivative and thence into the corresponding glycosyl bromide. The latter was condensed with daunomycinone, and the product was deprotected to give the title compound. The fluoroanthracycline displayed significant cytotoxicity against a number of tumor cell lines in vitro. Antitumor activity against L1210 murine leukemia in vivo was lower than that of the parent daunorubicin, but toxicity appeared to be reduced.

HANS H. BAER et LISA SIEMSEN. Can. J. Chem. **66**, 187 (1988).

On a hydrolysé l'amino-3 tridésoxy-2,3,6 fluoro-2 β-L-galactopyrannoside de méthyle en sucre libre, le chlorhydrate de la fluoro-2-(*S*) daunosamine, que l'on a transformé en dérivé di-*O*-acétyl-α,β-1,4 *N*-trifluoroacétyle et finalement en bromure de glycosyle correspondant. On a condensé ce dernier avec la daunomycinone et on a déprotégé le produit pour obtenir le composé mentionné dans le titre. La fluoroanthracycline présente une cytotoxicité in vitro importante contre un certain nombre de lignes de cellules tumorales. L'activité antitumorale in vivo contre les cellules de murine leucémique L1210 est plus faible que celle de la daunorubicine parente; toutefois, la toxicité semble être réduite.

[Traduit par la revue]

Introduction

In the course of a project aimed at procuring modified anthracycline antitumor agents that are substituted by fluorine in the amino sugar moiety we have described (1) a synthesis of methyl 3-amino-2,3,6-trideoxy-2-fluoro-β-L-galactopyranoside (**1**, methyl (*S*)-2-fluoro-β-L-daunosaminide). We now wish to record the coupling of that carbohydrate component with daunomycinone (**6**), which afforded (*S*)-2′-fluorodaunorubicin hydrochloride (**11**). While this work was in progress, various derivatives of **1** were also obtained elsewhere (2–5), and a coupling reaction with **6** was described (5), similar to ours in principle but different in detail.

Results and discussion

Although hydrolysis of the 2-fluoro glycoside **1** predictably was quite difficult, it succeeded by use of 4 M hydrochloric acid (6 h, reflux) and gave (*S*)-2-fluorodaunosamine hydrochloride (**2**) in 90% yield. Trifluoroacetylation of **2**, followed by methanolysis of the crude product to effect selective *O*-deacylation, furnished the trifluoroacetamido sugar **3** in yields of ~70–90%. Acetylation of **3** gave the 1,4-diacetate **4** as a crystalline mixture of anomers (93%) from which was obtained, by fractional crystallization, the pure α-anomer and sublimable, mixed crystals of the anomers (α:β = 2:1). Treatment of **4** in dichloromethane with hydrogen bromide in acetic acid generated the bromo sugar **5**, a reactive compound that was too unstable for storage and was therefore used without delay as a glycosyl donor for the subsequent operation. However, a sample of **5** was crystallized and characterized by its ^{1}H nmr spectrum; $J_{1,2}$ = 3.9 Hz indicated α-L stereochemistry. For chemical characterization, a sample was allowed to react with methanol in the presence of silver triflate, and the product was shown by its ^{1}H nmr spectrum to be an anomeric mixture of methyl glycosides, proving the bromide to act as a glycosyl donor (see Experimental).

For the condensation of **5** with daunomycinone (**6**) we tried several of the procedures commonly employed in anthracycline synthesis (6), but were unable to achieve high α-selectivity. Best results were obtained when **6** and 1.2 mol equivalents of **5** were allowed to react in boiling toluene in the presence of mercuric cyanide and mercuric bromide; chromatographic isolation then gave the desired α-glycoside **7** in 41%, and its β-anomer **8** in 29% yield (based on **6**). Treatment of **5** with 1.75 mol equiv. of **6** in 1:1 dichloromethane–nitromethane solution in the presence of silver triflate proved less satisfactory; **7** and **8** could be isolated in yields (based on **5**) of 15 and 16.5% only.

Zemplén *O*-deacetylation of **7** gave crystalline (*S*)-2′-fluoro-*N*-trifluoroacetyldaunorubicin (**9**), which was then *N*-deacylated with aqueous barium hydroxide at room temperature to furnish the target compound as the free base **10**, obtained in the form of dark-red microscopic needles in 35% overall yield based on the amount of aglycon used. The hydrochloride **11** crystallized as a (nonhygroscopic) sesquihydrate showing strong dextrorotation, $[\alpha]_D$ +218° (in methanol). The product obtained by Castillon *et al.* (5), named 2′-*C*-fluoro-β-daunomycin, was isolated as a highly hygroscopic hydrochloride monohydrate that was accorded formula **11** but showed $[\alpha]_D$ −37° (in methanol).[1]

Biological activity

Tests to evaluate antitumor activity of **11** in comparison with parent daunorubicin were performed by Bristol–Myers

[1]The authors (5) prepared their compound by silver triflate-promoted condensation of aglycon **6** with the 4-*O*-benzoyl analog of **5** (compound **17** in ref. 5, erroneously depicted as the β-anomer), followed by sequential deacylation at positions 4′ and 3′. The reported (5) ^{1}H nmr data are in fair agreement with our values for **11**, but the reason for the discrepancy in optical rotation is unclear. The molecular rotation of our product **11**, $[M]_D$ +133 000°, is close to that of parent daunorubicin hydrochloride ($[M]_D$ +143 000°, from $[\alpha]_D$ +253° (7)) and to that of adriamycin hydrochloride ($[M]_D$ +144 000°, from $[\alpha]_D$ +248° (8)). In this series of aminoglycoside hydrochlorides, β-L anomers exhibit *higher* dextrorotation than their α-L counterparts. Although values for the β-anomers (9) of the daunorubicin and adriamycin hydrochlorides have apparently not been published, for the latter compound a value of $[\alpha]_D$ +472° (*c* 0.07, methanol) was communicated to us privately by Dr. S. Penco (Farmitalia Carlo Erba, Milan). Similarly, 4′-epi-daunorubicin hydrochloride and its β-anomer show $[\alpha]_D$ +314° and +357°, respectively (10), and their 6′-hydroxy analogs show $[\alpha]_D$ +388° and +412°, respectively (11).

Company, Wallingford, Connecticut. Although in vitro cytotoxicity tests with mouse melanoma B16-F10 and human colon tumor HCT-116, respectively, indicated a 5- to 8-fold lower potency for **11** than for daunorubicin (IC_{50} = 4.92 and 3.87 μg/mL versus 0.64 and 0.72 μg/mL), the two antibiotics showed comparable potency (IC_{50} = 17.30 vs. 21.40, 10.06 vs. 16.95, and 8.48 vs. 8.00 μg/mL) against the cell lines HCT/VP35, Moser, and SW900 (average values from four test series). Tests in vivo against L1210 murine leukemia in the dose range 0.8–16 mg/kg showed median survival time increases (T/C values) of 117–133% for **11**, whereas daunorubicin gave values of 133–167% in parallel tests with the dose range of 1–12 mg/kg. In subsequent tests compound **11** was dosed as high as 64 mg/kg; at that dose it achieved a maximum T/C of 129%. No toxicity was observed in **11** at the dose levels tested, which considerably exceeded the toxic limit for daunorubicin. Even though antitumor activity was but modest, this point encourages further study and we are currently engaged in the synthesis of similar fluoroanthracyclines for biological evaluation.

Experimental

General preparative and instrumental methods were the same as those previously employed (1). The following solvent combinations (v/v) were used for thin-layer chromatography (tlc) and column chromatography (medium pressure) on silica gel: methanol–chloroform, 1:3 (A) and 1:6 (B); methanol–acetone, 1:1 (C); acetone–dichloromethane, 1:4 (D); and ethyl acetate – hexanes in the proportions 3:1 (E), 3:2 (F), 1:1 (G), 1:2 (H), 1:3 (I), and 1:5 (J). Proton magnetic resonance spectra were taken at 300 MHz, with tetramethylsilane as internal standard. Infrared spectra were taken from Nujol mulls. Optical rotations were measured at ~25°C.

3-Amino-2,3,6-trideoxy-2-fluoro-L-galactose ((S)-2-fluoro-L-daunosamine) hydrochloride (2)

A solution of compound **1** (1) (1.08 g) in 4 M hydrochloric acid (108 mL) was boiled under reflux for 6 h. Complete conversion into the more slowly moving sugar **2** was indicated by tlc (solvent A). The acid was removed by coevaporation with added water, and the residual aqueous solution was decolorized with charcoal and brought to dryness at 35°C, to give **2** as a crystalline solid (1.10 g after drying *in vacuo* over KOH; 90%); mp ~190°C (dec.); $[\alpha]_D$ −70° (*c* 0.9, H_2O) (lit. (3) $[\alpha]_D$ −69.7°); ν_{max}: 3400 (br), 2700–2500 (several weak bands), 1600, 1580, 1530 (strong), 1300–990 (numerous sharp bands), 890, and 740 cm^{-1}. The ^1H nmr revealed the product to be the pure *β-anomer*; δ(DMSO-d_6): 8.45 (bs, 3H, exchangeable, H_3N^+), 7.18 and 5.74 (d, J = 6.7 and 5.9 Hz, exchangeable, 2 OH), 4.67 (td, collapsing to dd on D_2O exchange, $J_{1,F}$ = 3, $J_{1,2} \approx J_{1,OH} \approx$ 7.3 Hz, H-1), 4.40 and 4.23 (2 dd, 0.5H each, $J_{2,F}$ = 51.7, $J_{1,2}$ = 7.8, $J_{2,3}$ = 10.2 Hz, H-2), 3.75 (nm, H-4), 3.72 (q, $J_{5,Me}$ = 6.25, $J_{4,5}$ < 0.5 Hz, H-5), 3.52 (~td, $J_{3,4}$ = 2.4, $J_{2,3}$ = 10, $J_{3,F}$ = 12 Hz, H-3), and 1.12 (d, 3H, J = 6.25 Hz, *C*-Me).

When **2** was recovered from its aqueous solution by *freeze-drying*, it was obtained as a crystalline, 1:1 mixture of anomers; mp 182–185°C (dec.); $[\alpha]_D$ −85° (*c* 1.1, H_2O). The ir spectrum, similar to that of the pure β-anomer, was distinguished by additional, prominent peaks at 1495, 860, 807, and 755 cm^{-1}. The ^1H nmr spectrum, in addition to showing all the β-anomer signals listed above, contained the following set of signals, of equal strength, for the *α-anomer*; δ(DMSO-d_6): 7.00 and 5.69 (d, J = 3.5 and 6 Hz, exchangeable, 2 OH), 5.22 (~t, collapsing to ~d on D_2O exchange, $J_{1,2} \approx J_{1,OH} \approx$ 3.5, $J_{1,F} \approx$ 0.5 Hz, H-1), 4.76 and 4.59 (2 dd, 0.5H each, $J_{2,F}$ = 51, $J_{1,2}$ = 3.5, $J_{2,3}$ = 10.5 Hz, H-2), 4.05 (q, $J_{5,Me}$ = 6.5, $J_{4,5}$ < 0.5 Hz, H-5), 3.82 (nm, H-4), 3.58 (td, similar to, and partially overlapped by, the corresponding signal of the anomer, H-3), and 1.06 (d, 3H, J = 6.5 Hz, *C*-Me). *Anal.* calcd. for $C_6H_{13}ClFNO_3$ (201.5): C 35.76, H 6.50, Cl 17.59; found: C 35.66, H 6.50, Cl 17.71.

2,3,6-Trideoxy-2-fluoro-3-trifluoroacetamido-D-galactose (3)

A suspension of **2** (1.00 g) in dry ether (70 mL) containing triethylamine (0.7 mL) was stirred for 0.5 h, and for a further 2.5 h following the addition of trifluoroacetic anhydride (2.1 mL, 3 mol equiv.). The solution then showed a double spot, R_f ~ 0.8 (tlc, solvent D), for the α,β-ditrifluoroacetate of **3**; a small proportion of suspended

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.222.148.141 on 09/07/12
For personal use only.

solid gave a double spot at $R_f \sim 0.25$ and proved to be α,β-**3**. (Starting **2** had R_f 0). The mixture was evaporated, with added portions of ether, to give a yellow residue that was dissolved in dry methanol (50 mL). After 2 days at room temperature, all of the diester had been methanolized to α,β-**3** (tlc). The solvent was removed and a solution of the residue in EtOAc was washed once with a small amount of ice water, dried (Na_2SO_4), and evaporated. Trituration of the material with ether gave crystalline **3** (0.84 g), mp 162–165°C, and chromatographic processing of the mother liquor augmented the yield to 1.015 g (68%); $[\alpha]_D$ −129° (*c* 0.5, acetone). In one experiment (50-mg scale), direct crystallization gave a 93% yield of **3**, mp 153–156°C; ν_{max}: 3540, 3400, 1700, 1550 cm^{-1}. Different preparations showed variable anomeric composition, according to ^1H nmr, e.g., α:β ratio ~ 10:1 and 3:2. (The latter sample was a crystalline solvate containing ½ mol of diethyl ether, not removed by drying *in vacuo*; the former sample was solvent free.) The ^1H nmr data (DMSO-d_6; low-field OH and NH resonances removed by D_2O exchange) for the *α-anomer*, δ: 5.17 (~d, $J_{1,2} = 4$, $J_{1,F} \approx 0.5$ Hz, H-1), 4.81 and 4.64 (2 dd, 0.5H each, $J_{1,2} = 4$, $J_{2,3} = 10.6$, $J_{2,F} = 50$ Hz, H-2), 4.30 (m, H-3), 4.06 (qd, $J_{4,5} = 1$, $J_{5,Me} = 7$ Hz, H-5), 3.60 (~nt, H-4), and 1.04 (d, 3H, $J = 7$ Hz, *C*-Me); for the *β-anomer*, δ: 4.64 (m, H-1), 4.50 and 4.33 (2 dd, 0.5H each, $J_{1,2} = 8$, $J_{2,3} = 10$, $J_{2,F} = 51$ Hz, H-2), 4.3 (m, H-3), 3.74 (qd, $J_{4,5} = 1$, $J_{5,Me} = 6.5$ Hz, H-5), 3.56 (~nt, H-4), and 1.09 (d, $J = 6.5$ Hz, *C*-Me). The hemietherate showed a quartet (2H, $J = 6.5$ Hz) at δ 3.37 and a matching triplet that was superposed on the sugar *C*-Me signals for a total intensity of 6H. *Anal.* calcd. for $C_8H_{11}F_4NO_4 \cdot 0.5\ C_4H_{10}O$ (298.2): C 40.27, H 5.41; found: C 40.47, H 5.64.

1,2-Di-O-acetyl-2,3,6-trideoxy-2-fluoro-3-trifluoroacetamido-L-galactose (4)

Compound **3** (1.01 g) was acetylated with acetic anhydride and pyridine (23°C, 1 h), and the crude diacetate **4** (R_f 0.4, tlc with solvent H) was isolated by exhaustive evaporation of added toluene from the mixture. Crystallization from ethyl acetate – hexane gave two crops (670 and 90 mg, mp 165–168 and 161–164°C) of **4**, with the first one representing the pure *α-anomer*, $[\alpha]_D$ −178° (*c* 0.4, $CHCl_3$); ν_{max}: 3300, 1750 (doublet), 1700, 1540 cm^{-1}; δ ($CDCl_3$): 6.41 (d, $J_{1,2} = 3.4$ Hz, H-1), 5.36 (~td, $J_{4,5} = 1.5$, $J_{3,4} \approx J_{4,F} \approx 3.5$ Hz, H-4), 4.86 and 4.69 (2 dd, 0.5H each, $J_{1,2} = 3.4$, $J_{2,3} = 11$, $J_{2,F} = 52$ Hz, H-2), 4.76 (m, H-3), 4.23 (qd, $J_{4,5} = 1.4$, $J_{5,Me} = 6.5$ Hz, H-5), 2.19 and 2.17 (s, 3H each, 2 OAc), and 1.11 (d, 3H, $J = 7$ Hz, *C*-Me).

The mother liquor of crystallization was purified by passage over a column of silica gel with solvent I, to give another crop of **4** (480 mg), for a total yield of 1.24 g (93%). This crop gave a double spot in tlc ($R_f \sim 0.6$, solvent H) and was shown to be an anomer mixture (α:β = 2:1, by ^1H nmr). On heating at 110°C in an oil-pump vacuum for 16 h it sublimed almost without residue, and the sublimate showed unchanged spectral and tlc patterns; mp 130–134°C, $[\alpha]_D$ −138° (*c* 0.6, $CHCl_3$); ^1H nmr ($CDCl_3$) signals attributable to the *β-anomer*, δ: 5.79 (dd, $J_{1,F} = 3.5$, $J_{1,2} = 7.5$ Hz, H-1), 5.30 (td, $J_{4,5} = 1.7$, $J_{3,4} \approx J_{4,F} = 3.3$ Hz, H-4), 4.59 and 4.41 (2 dd, 0.5H each, $J_{1,2} = 7.5$, $J_{2,3} = 10.7$, $J_{2,F} = 54$ Hz, H-2), 4.48 (m, H-3), 3.99 (qd, $J_{4,5} = 1.7$, $J_{5,Me} = 6.5$ Hz, H-5), 2.18 and 2.17 (2 s, 3H each, 2 OAc), and 1.18 (d, 3H, $J = 6.5$ Hz, *C*-Me). *Anal.* calcd. for $C_{12}H_{15}F_4NO_6$ (345.3): C 41.74, H 4.38, N 4.06; found: C 41.33, H 4.54, N 3.98.

4-O-Acetyl-2,3,6-trideoxy-3-trifluoroacetamido-α-L-galactopyranosyl bromide (5)

To a solution of **4** (780 mg) in CH_2Cl_2 (20 mL, distilled from CaH_2) was added 30% hydrogen bromide in acetic acid (17 mL), at room temperature. After 30 min all of the **4** was consumed (tlc), and the mixture was processed by evaporation of the CH_2Cl_2, removal of the acid by coevaporation with added toluene, decolorization of the product with activated carbon, and brief drying *in vacuo* of the syrupy, almost colorless **5** so obtained. The crude **5** was homogeneous in tlc (R_f 0.5, solvent H) except for the presence of trace impurities, and, being rather unstable, it was used without delay for the intended condensation reaction.

For characterization, a sample of the syrup was crystallized from ether–hexane (0°C, overnight), whereby the trace impurities were removed and no change in the R_f value was observed. The crystals were immediately taken to ^1H nmr analysis; δ ($CDCl_3$): 6.59 (d, $J_{1,2} = 3.9$ Hz, H-1), 6.3 (br d, NH), 5.39 (td, $J_{4,5} = 1.25$, $J_{3,4} = J_{F,4} = 3.3$ Hz, H-4), 4.82 (symm. m, 10 lines, width 32 Hz, $J_{3,4} \approx J_{3,NH} \approx 4$, $J_{2,3} \approx 11$, $J_{3,F} \approx 13$ Hz, H-3), 4.73 and 4.57 (2 dd, 0.5H each, $J_{1,2} = 3.9$, $J_{2,3} = 10.8$, $J_{2,F} = 49.9$ Hz, H-2), 4.40 (qdd, $J_{5,Me} = 6.6$ and $J_{4,5} = 1.2$ Hz, with additional splitting due to long-range coupling, H-5), 2.17 (s, 3H, OAc), and 1.17 (d, 3H, $J = 6.6$ Hz, *C*-Me).

A 10-mg sample of **5** was allowed to react with methanol (0.5 mL) in the presence of a few milligrams of silver triflate. After 1 h at 25°C, **5** (R_f 0.5) had been converted into a new product, R_f 0.4 (tlc with solvent H). The mixture was filtered through Celite, which was washed with CH_2Cl_2, and the filtrate was washed once with aqueous $NaHCO_3$ and twice with water, dried (Na_2SO_4), and evaporated. The foamy residue of *methyl glycoside* was passed through a small column of silica gel with solvent J but still failed to crystallize. The eluate contained mainly the β-anomer; δ ($CDCl_3$): 6.3 (br m, NH), 5.29 (nm, H-4), 4.52–4.36 (m, 2.5H, H-1,3, and downfield part of H-2), 4.25 (dd, 0.5H, $J_{1,2} = 7.3$, $J_{2,3} = 10.5$ Hz, H-2, upfield part), 3.85 (qd, $J_{4,5} = 1$, $J_{5,Me} = 6.5$ Hz, H-5), 3.59 (s, 3H, OMe), 2.16 (s, 3H, OAc), and 1.19 (d, 3H, $J = 6.5$ Hz, C-Me). A small *C*-Me doublet at δ 1.11 indicated the presence of some α-anomer (< 10%).

7-O-(4-O-Acetyl-2,3,6-trideoxy-2-fluoro-3-trifluoroacetamido-β-L-galactopyranosyl)-daunomycinone (7) and its β-anomer 8

Procedure A

The syrupy glycosyl bromide (**5**) obtained from 100 mg (0.29 mmol) of diacetate **4** was dissolved in dry toluene (10 mL, distilled from Na), and $HgBr_2$ (200 mg, 2 mol equiv.), $Hg(CN)_2$ (145 mg, 2 mol equiv.), and daunomycinone (**6**; 100 mg, 0.25 mmol) were added. The mixture was boiled under reflux for 5 h, with exclusion of moisture and light. Thin-layer chromatography (solvent F) indicated complete consumption of **5** (R_f 0.9) but incomplete consumption of **6** (R_f 0.2); two ill-separated spots (R_f 0.4–0.5) representing **7** and **8** were seen. The filtered solution was evaporated and the resultant residue dissolved in $CHCl_3$. The solution was washed with water (3×), dried (Na_2SO_4), and evaporated to give a red solid that still contained some inorganic material and was, therefore, triturated with $CHCl_3$ (2 mL). The filtered solution gave 180 mg of product, which was subjected to preparative tlc (triple irrigation with solvent G), furnishing slower moving **7** (71 mg, 41.4%) and faster moving **8** (49 mg, 28.5%).

Compound **7** showed mp 194–196°C (with gradual darkening from 160°C); $[\alpha]_D$ +149°C (*c* 0.6, $CHCl_3$); ν_{max}: 3500, 3300, 1745, 1700, 1615, 1570 cm^{-1}; δ ($CDCl_3$): 8.03, 7.77, and 7.38 (d, t, and d, $J \approx 8$ Hz, H-1,2,3), 6.18 (d, $J_{3',NH} = 7.9$ Hz, NH), 5.70 (d, $J_{1',2'} = 3.9$ Hz, H-1'), 5.43 (sx, $J_{4',5'} = 1.5$, $J_{3',4'} \approx J_{4',F} \approx 3$ Hz, H-4'), 5.40 (nm, H-7), 4.73 and 4.565 (2 dd, 0.5H each, $J_{1',2'} = 4$, $J_{2',3'} = 11$, $J_{2',F} = 49.5$ Hz, H-2'), 4.50 (m, H-3'), 4.39 (qd, $J = 1.5$ and 6.2 Hz, H-5'), 4.07 (s, 3H, OMe), 4.01 (s, exchangeable, OH-9), 3.26 and 3.00 (2 d, $J_{gem} = 19$ Hz, H-10e,10a), 2.41 (s, 3H, Me-14), 2.33 and 2.22 (2 dd, $J_{gem} = 16$, $J_{vic} = 1.5$ and 4 Hz, H-8e,8a), 2.16 (s, 3H, OAc), and 1.16 (d, $J_{5',Me} = 6.2$ Hz, *C*-Me). *Anal.* calcd. for $C_{31}H_{29}F_4NO_{12}$ (683.5): C 54.47, H 4.28, F 11.12; found: C 54.38, H 4.51, F 10.91.

Compound **8** showed mp 105–110°C; $[\alpha]_D$ +116° (*c* 0.6, $CHCl_3$); ν_{max}: 3500, 3300 (strong), 3090, 1740–1700, 1615 (weak), 1560 cm^{-1}; δ ($CDCl_3$): 8.03, 7.78, and 7.39 (d, t, and d, $J \sim 8$ Hz, H-1,2,3), 6.25 (d, $J_{3',NH} = 8$ Hz, NH), 5.54 (nm, width 6 Hz, H-4'), 5.22 (nm, width 6 Hz, H-7), 5.10 (dd, $J_{1',F} = 3$, $J_{1',2'} = 7.5$ Hz, H-1'), 4.50 (m, H-3'), 4.42 and 4.25 (2 dd, 0.5H each, $J_{1',2'} = 7.8$, $J_{2',3'} = 10.5$, $J_{2',F} = 51$ Hz, H-2'), 4.08 (s, 3H, OMe), 3.83 (qd, $J_{4',5'} = 1.2$, $J_{5',Me} = 6.4$ Hz, H-5'), 3.26 and 3.06 (2 d, $J_{gem} = 19$ Hz, H-10e,10a), 2.40 (s, 3H, Me-14), 2.15–2.0 (m, 2H, H-8e,8a), 2.11 (s, 3H, OAc), and 0.99 (d, $J_{5',Me} = 6.3$ Hz, *C*-Me). *Anal.* calcd. for $C_{31}H_{29}F_4NO_{12} \cdot 3.5\ H_2O$ (746.6): C 49.87, H 4.86; found: C 49.87, 49.74; H 4.80, 4.79.

Procedure B

Daunomycinone **6** (278 mg, 0.7 mmol) in dry CH_2Cl_2 (20 mL) and nitromethane (20 mL) was stirred for 1 h with powdered molecular sieve (4 Å; 1 g). Silver triflate (180 mg, 0.8 mmol) was then added,

followed after 1 h by bromide **5** (obtained from 137 mg of diacetate **4** (0.4 mmol) and dissolved in a small volume of CH_2Cl_2). The bromide was completely consumed after 1 h (tlc with solvent F). The inorganic material was removed and washed exhaustively with CH_2Cl_2, and the filtrate was shaken with concentrated aqueous NaI solution followed by water, dried, and evaporated. The crude product mixture was chromatographed, first on a column (9 g of SiO_2) eluted with solvent I followed by solvent H, which separated **7** and **8** from most of the residual **6**, and then on preparative tlc plates (double irrigation with solvent G), which furnished pure **7** (41 mg, 15%) and **8** (45 mg, 16.5%).

*7-O-(2,3,6-Trideoxy-2-fluoro-3-trifluoroacetamido-α-L-galactopyranosyl)-daunomycinone (**9**)*

A sample of **7** (35 mg) in dry methanol (2 mL) was treated at room temperature under N_2 with methanolic 1 M sodium methoxide solution (0.5 mL). Clean conversion of **7** (R_f 0.6) into **9** (R_f 0.4) occurred within 20 min (tlc with solvent E). The dark blue to violet solution was deionized with a weak-acid ion exchange resin (Amberlite IRC-50, H^+). The orange-red solution was evaporated to give crystalline **9** (31 mg, 93%), decomposing at 160–165°C after recrystallization from ethyl acetate – hexane; $[\alpha]_D$ +177.5 ± 1.5° (*c* 0.3, $CHCl_3$); ν_{max}: 3500 (bd), 1710, 1610, 1570 cm^{-1}; δ($CDCl_3$): 8.02, 7.77, and 7.37 (d, t, and d, $J \approx 8$ Hz, H-1,2,3), 6.68 (d, $J_{3',NH} = 8.1$ Hz, NH), 5.66 (d, $J_{1',2'} = 3.8$ Hz, H-1′), 5.42 (dd, $J = 2.7$, 4.0 Hz, H-7), 4.69 and 4.53 (2 dd, 0.5H each, $J_{1',2'} = 4$, $J_{2',3'} = 10.5$, $J_{2',F} = 49$ Hz, H-2′), 4.45–4.3 (m, 2H, H-3′,5′), 4.09 (nm, H-4′), 4.06 (s, 3H, OMe), 3.92 (nm, exchangeable, OH), 3.27 and 2.99 (dd and d, $J_{gem} \approx 18$ Hz, H-10e,10a), 2.40 (s, 3H, Me-14), 2.34 and 2.21 (dt and dd, $J_{gem} = 15$, $J_{vic} = 4$ Hz, H-8e,8a; small long-range coupling present in H-8e), 2.03 (d, exchangeable, $J = 6$ Hz, OH), and 1.30 (d, 3H, $J_{5',Me} = 7$ Hz, *C*-Me). *Anal.* calcd. for $C_{29}H_{27}F_4NO_{11} \cdot 0.5\ H_2O$ (650.5): C 53.54, H 4.34, F 11.68; found: C 53.34, H 4.45, F 11.49.

*7-O-(3-Amino-2,3,6-trideoxy-2-fluoro-α-L-galactopyranosyl)-daunomycinone (**10**, (S)-2′-fluorodaunorubicin) and its hydrochloride **11***

Acetate **7** (310 mg) was *O*-deacetylated in methanol (5 mL) with $NaOCH_3$ as just described, and the crude **9** so obtained was dissolved under N_2 in a saturated, aqueous $Ba(OH)_2$ solution (10 mL) at 25°C. After 20 min, tlc (solvent C) indicated absence of **9** (R_f 1.0) and the presence of **10** (R_f 0.5), and after 30 min the blue solution was diluted with some water and neutralized by addition of solid CO_2. The red solution was filtered by suction through a layer of Celite from the precipitated $BaCO_3$, and the product was extracted from the filtrate into $CHCl_3$. The extract was washed once with water, and evaporated to give **10** as dark-red microscopic needles that were dried over KOH in a desiccator; yield, 221 mg (89.5%). The product charred at 209–210°C and melted indistinctly at 212–216°C; tlc (solvent C): R_f 0.5, with trace contaminant, R_f 0.9; ν_{max}: 3500, 3400, 3330 (3 weak bands), 1715 with shoulder at 1750, 1615, 1580, 1410, 1285, 1260–1030 (several sharp, medium intensity bands), 990, 820, 767, 745 cm^{-1}; δ($CDCl_3$): 8.02, 7.72, and 7.38 (d, t, and d, $J = 7$–8 Hz, H-1,2,3), 5.63 (d, $J_{1',2'} = 3.9$ Hz, H-1′), 5.43 (nm, H-7), 4.54 and 4.38 (2 dd, 0.5H each, $J_{1',2'} = 4$, $J_{2',3'} = 10$, $J_{2',F} = 49$ Hz, H-2′), 4.17 (~q, width 20 Hz, H-5′), 4.07 (s, 3H, OMe), 3.66 (nm, H-4′), 3.3–3.2 (m, 2H, H-3′,10e), 3.00 (d, $J_{gem} = 19$ Hz, H-10a), 2.39 (s, 3H, Me-14; partially obscuring downfield part of H-8e signal), 2.35 (dd, H-8e), 2.16 (dd, $J_{7,8a} = 4$, $J_{8a,8e} = 14$ Hz, H-8a), 1.34 (d, 3H, $J_{5',Me} = 6.2$ Hz, *C*-Me).

For preparing the *hydrochloride* **11**, a solution of **10** (210 mg) in 0.1 M HCl (15 mL) was first extracted with EtOAc for removal of the aforementioned impurity (R_f 0.9), and then evaporated to dryness with additions of ethanol and benzene. The solid **11** was crystallized from ethanol–ether and dried *in vacuo* over KOH; it was not noticeably hygroscopic, and gave a single spot (R_f 0.2) in tlc (solvent B). Yield after recrystallization, 193 mg (86%); mp 224°C (with prior darkening from 217°C); $[\alpha]_D$ +218° (*c* 0.32, CH_3OH); ν_{max}: 3600–3200 (br), 1705, 1615, 1575, 1410, 1285, 1230–1030 (several medium intensity bands), 990, and 960–720 cm^{-1} (several weak bands); δ(DMSO-d_6): 7.92 (m, 2H, H-1,3), 7.65 (t, H-2), 5.72 and 5.58 (d of 5.8 Hz, and s, exchangeable, 2 OH), 5.46 (d, $J_{1',2'} = 3.7$ Hz, H-1′), 5.08 (nm, H-7), 4.80 and 4.63 (2 dd, 0.5H each, $J_{1',2'} = 3.7$, $J_{2',3'} = 10.5$, $J_{2',F} = 49.5$ Hz, H-2′), 4.33 (~q, width 20 Hz, H-5′), 3.98 (s, 3H, OMe), 3.81 (m, narrowed after D_2O exchange, H-4′), 3.40 (m, H-3′), 2.97 (s, 2H, H-10a,e), 2.27 (s, 3H, Me-14), 2.22 (dd, H-8e), 2.11 (dd, $J_{7,8a} \approx 4$, $J_{8a,8e} = 14$ Hz, H-8a), and 1.14 (d, 3H, $J_{5',Me} = 6.6$ Hz, *C*-Me). *Anal.* calcd. for $C_{27}H_{29}ClFNO_{10} \cdot 1.5\ H_2O$ (609.0): C 53.25, H 5.13, Cl 5.82, F 3.12, N 2.30; found: C 53.00, H 5.17, Cl 5.67, F 3.45, N 2.29.

Acknowledgments

This work was financially supported by grant GM 35244 from the United States Public Health Service. The authors are grateful to Dr. T. W. Doyle, Director, Antitumor Chemistry, Bristol–Myers Company, for providing a generous sample of daunomycin from which the aglycon **6** used in this synthesis was prepared, and for kindly arranging the biological tests. Drs. W. Rose and S. Mamber are thanked for performing the in vivo tests, and Dr. Schurig and Ms. Farwell for determining in vitro cytotoxicity.

Oxidation with permanganate of caerulomycin A labeled biosynthetically from [U-^{14}C]lysine in cultures of *Streptomyces caeruleus* yielded picolinic acid with the same specific activity as the antibiotic. [^{3}H]Picolinic acid was incorporated into caerulomycin A with high efficiency and the label was also found exclusively in picolinic acid after oxidation, implicating free picolinic acid as an intermediate in the pathway from lysine. The substituted pyridyl ring of caerulomycin was labeled by [2-^{13}C, 1,3-^{14}C]glycerol. ^{13}C nuclear magnetic resonance analysis located the ^{13}C predominantly at C-6, suggesting that C-5, C-6, and C-7 were derived from glycerol as an intact three-carbon precursor. Since no incorporation of [1-^{13}C]glyceric acid was detected and [3-^{13}C, 3-^{14}C]methylglyoxal labeled the antibiotic only marginally, these compounds are probably not biosynthetic intermediates en route from glycerol. A new caerulomycin possessing an aldehyde in place of the aldoxime substituent at C-6 was isolated from culture broths and is postulated to be a late intermediate in the formation of caerulomycin A.

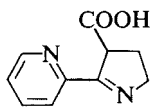
LEO C. VINING, A. GAVIN MCINNES, ARCHIBALD W. MCCULLOCH, DONALD G. SMITH et JOHN A. WALTER. Can. J. Chem. **66**, 191 (1988).

On a préparé de la caerulomycine A marquée par biosynthèse dans des cultures de *Streptomyces caeryleus*, à partir de [U-^{14}C]-lysine; l'oxydation de ce composé par du permanganate fournit de l'acide picolinique possédant la même activité spécifique que l'antibiotique. On a incorporé de l'acide [^{3}H]-picolinique dans de la caerulomycine A avec une haute spécificité et, lors de son oxydation, on n'a retrouvé le marqueur que dans l'acide picolinique; ce résultat suggère que l'acide picolinique libre est un intermédiaire dans la synthèse à partir de la lysine. On a procédé au marquage du cycle pyridyle substitué de la caerulomycine par du [^{13}C-2, ^{14}C-1,3]-glycérol. Une analyse par résonance magnétique nucléaire du ^{13}C a permis de déterminer que le ^{13}C se trouve principalement en position C-6; ce résultat suggère que les carbones C-5, C-6 et C-7 proviennent d'une molécule de glycérol agissant comme un précurseur à trois atomes de carbones qui est intact. Puisqu'on n'a pas détecté d'incorporation d'acide [^{13}C-1]-glycérique et que le [^{13}C-3, ^{14}C-3]-méthylglyoxal ne marque l'antibiotique que d'une façon marginale, on peut en déduire que ces composés ne sont probablement pas des intermédiaires dans la biosynthèse à partir du glycérol. Des bouillons de culture, on a isolé une nouvelle caerulomycine qui possède un aldéhyde à la place du substituant aldoxime en position C-6; on fait l'hypothèse qu'il s'agit d'un des derniers intermédiaires dans la formation de la caerulomycine A.

[Traduit par la revue]

Introduction

Caerulomycin A (**1**) is a member of the 2,2′-dipyridyl group of antibiotics produced by *Streptomyces caeruleus* (1–4), *Actinomyces* (*Streptomyces*) *coerulescens* (5), and *Nocardiopsis cirriefficiens* (6). An earlier study of its biosynthesis showed [U-^{14}C]lysine to be the most efficiently incorporated precursor tested and ^{13}C nmr analysis of the labelling patterns obtained with [^{13}C]acetate were consistent with formation of the unsubstituted pyridyl moiety (ring B) and bridging 2,2′-carbons from this amino acid (7). Although the results indicated that free picolinic acid could be an intermediate in the route from lysine to the antibiotic, as observed in the biosynthesis of proferrorosamine A (**2**) by *Pseudomonas fluorescens* (8), no direct evidence for this was obtained. The ^{13}C labelling experiments demonstrated that acetate also supplied C-3 and C-4 of the substituted pyridyl moiety (ring A) of caerulomycin but failed to identify a source of the remaining three carbons at C-5, C-6, and C-7. The possibility that these might be derived from serine could be discounted because [3-^{13}C]serine, although efficiently incorporated into the methoxyl substituent, did not enrich the ring or aldoxime carbons. Pyruvate could be excluded as a source of C-5, C-6, and C-7 because these carbon atoms were not labeled by ^{13}C-enriched precursors that labeled the carbon atoms of ring B derived from pyruvate via lysine.



2

In the present paper, we provide evidence that free picolinic acid is specifically incorporated into ring B of caerulomycin A and that glycerol serves as a precursor of C-5, C-6, and C-7. We also report the isolation of a new product, caerulomycin E, from culture broths and show that it has the structure **3**.

Experimental

Culture

The origin and maintenance of *Streptomyces caeruleus* strain 4/2, used throughout these studies, has been described (7). Cultures supplemented with isotopically labeled potential biosynthetic precursors or used for isolating caerulomycins were grown in 250-mL Erlenmeyer flasks containing 50 mL of medium 1 which contained (per liter): soluble starch (20 g), $NaNO_3$ (2.0 g), $CaCO_3$ (2.0 g), K_2HPO_4 (1.0 g),

For personal use only.

KCl (0.5 g), and $MgSO_4 \cdot 7H_2O$ (0.5 g). Where different nitrogen sources were tested they replaced $NaNO_3$ at equivalent nitrogen concentration. Growth conditions were as reported previously (7).

Labeled supplements

[U-^{14}C]Lysine, [1,3-^{14}C]glycerol, and [^{3}H]water were purchased from New England Nuclear Corporation, Boston, MA; [2-^{13}C]glycerol (90 at.% ^{13}C) was from Merck Sharp and Dohme Canada Ltd., Pointe Claire, P.Q. [^{3}H]Picolinic acid was prepared from unlabeled compound by catalytic exchange in [^{3}H]water.

[1-^{13}C]Glyceric acid was prepared by a modification of the method of Ashworth (9). Glycolaldehyde was converted to the dibenzoylated cyanohydrin by reaction with potassium [^{13}C]cyanide and benzoyl chloride. The product was washed well with petroleum ether. The acid hydrolysate was evaporated under high vacuum below 40°C and the residue was purified by trituration with diethyl ether (solubles discarded) and acetone (insolubles discarded). The labeled glyceric acid was obtained as a pale yellow syrup (46% overall yield) and was characterized by ^{1}H and ^{13}C nmr spectroscopy.

[3-^{13}C, 3-^{14}C]Methylglyoxal was prepared as required by acid hydrolysis of the diethyl acetal (10). The latter was synthesized by the method of Wohl and Lange (11). Thus ethyl diethoxyacetate was converted to the piperide (74%) and subjected to Grignard reaction using [1-^{13}C, 1-^{14}C]methyl iodide to give the desired acetal (46%).

All supplements were sterilized by filtration; times of addition and concentrations varied and are reported for each experiment.

Caerulomycin assay

Samples (2.0 mL) of culture broth were mixed with 10 m*M* ferrous ammonium sulfate (2.0 mL), basified with 1% sodium carbonate (1.0 mL), and extracted with *n*-butanol (5.0 mL). The absorbance of the clarified butanolic extract was measured at 532 nm and related to that of similarly treated reference solutions of caerulomycin A.

Isolation of caerulomycins

Cultures were harvested by filtration after reaching stationary phase (9–12 days from inoculation). Caerulomycins were extracted as described (7). In experiments with radioactive precursors, the products from 100 mL of broth were separated by thin-layer chromatography (tlc) on silica gel (Silicar T7G, Analabs, Inc., NJ) using successive development with chloroform and chloroform–acetone (19:1). Zones were located as quenched areas under ultraviolet (254 nm) irradiation, scraped from the plate, and extracted with ethanol. Where radioactivity was measured, the radiochemical purity of the product was confirmed by scanning after tlc of the eluted material in two additional systems (silica gel GHLF; chloroform–methanol – 6 *M* ammonium hydroxide, 20:3:10, lower phase; benzene – acetic acid – water, 42:24:1). In ^{13}C labelling experiments and for the isolation of caerulomycin E, the products from 1 L of broth were separated on a column of cross-linked dextran (Sephadex LH20, Pharmacia Limited, Uppsala) equilibrated with the solvent mixture benzene – ethyl acetate – acetic acid – water (1:6:2:6). Caerulomycins E and A were collected at elution volumes of 320–360 and 380–560 mL, respectively, during development with the organic phase. Caerulomycin A was purified for ^{13}C nmr examination as described previously (7).

Fractions containing caerulomycin E were evaporated and the residue was crystallized successively from hexane and aqueous methanol as colourless needles, mp 83°C. These were sublimed under high vacuum at 55°C to give clusters of prisms of the same mp (yield, 12.6 mg). The high resolution electron-impact mass spectrum showed two prominent peaks at m/z 213.0664 ± 0.0007 and 214.0738 ± 0.0007, corresponding to $C_{12}H_9N_2O_2$ (calculated m/z 213.0664) and $C_{12}H_{10}N_2O_2$ (calculated m/z 214.0742), respectively. The ^{1}H nmr spectrum in dimethyl sulfoxide-d_6 contained resonances at δ (ppm) 8.12 (H-3), 7.45 (H-5), 10.08 (H-7), 8.46 (H-3′), 7.99 (H-4′), 7.51 (H-5′), 8.71 (H-6′), and 3.98 (4-OCH_3); $J_{H,H}$ (±0.1 Hz): 2.5 (H-3,H-5), 7.8 (H-3′,H-4′), 1.2 (H-3′,H-5′), 0.9 (H-3′,H-6′), 7.5 (H-4′,H-5′), 1.8 (H-4′,H-6′), 4.7 (H-5′,H-6′). All values were obtained by simulation. The ^{13}C nmr spectrum of a sample in dimethyl sulfoxide-d_6 gave signals at δ (ppm) (J_{CH} (Hz)): 157.6 (m, C-2), 109.8 (dd, C-3, ^1J 166.3, $^3J_{3,5}$ 3.9), 167.3 (bm, C-4), 107.7 (ddd, C-5, ^1J 167.1, $^3J_{3,5}$ 4.2, $^3J_{5,7}$ 2.7), 153.8 (d, C-6, $^2J_{6,7}$ 23.3), 193.2 (d, C-7, ^1J 183.1), 153.9 (bm, C-2′), 120.8 (dddd, C-3′, ^1J 166.8, $^3J_{3',5'}$ 7.0, $^2J_{3',4'}$ 1.4, $^4J_{3',6'}$ 0.8), 137.4 (dd, C-4′, ^1J 165.7, $^3J_{4',6'}$ 6.1), 124.8 (ddd, C-5′, ^1J 165.5, $^2J_{5',6'}$ 8.6, $^3J_{3',5'}$ 6.5), 149.3 (ddd, C-6′, ^1J 179.2, $^2J_{5',6'}$ 3.8, $^3J_{4',6'}$ 7.0), 56.0 (q, 4-OCH_3, ^1J 146.2).

Oxidation of caerulomycin A

Caerulomycin A (20 mg) dissolved in 10% H_2SO_4 (5 mL) was heated on a steam bath with $KMnO_4$ (200 mg; 12.5 mol) until the permanganate color disappeared. The filtered reaction mixture was evaporated and the residue was extracted with ethanol. The extract, diluted with water, was applied to a column (1 × 5 cm) of cation exchange resin (Dowex 50W, H^+, 200–400 mesh size) and washed with water. Picolinic acid was recovered by further elution with water and sublimed under high vacuum at 65°C to give prisms, mp 142°C (2).

Instrumentation

Radioactivity on tlc plates was located with a gas-flow windowless detector linked to a recorder (model 7200 radiochromatogram scanner, Packard Instruments Limited). For quantitative measurements a liquid scintillation counter (model 1215, LKB Wallac, Helsinki) was used.

Carbon-13 nmr spectra at 25.2 MHz of caerulomycin A samples (approximately 40 mg in 0.5 mL of dimethyl sulfoxide-d_6) at natural abundance or labeled with ^{13}C were recorded at 25°C with a Varian XL-100 spectrometer. Conditions were as follows: spectral width 5120 Hz, acquisition time 0.8 s, flip angle approximately 40°C, relaxation reagent $Cr(acac)_3$ (10 mg mL^{-1}) added to solution, ^{1}H broadband decoupling switched off for 1.2 or 3.2 s between acquisition periods for further suppression of nuclear Overhauser enhancement (nOe), internal ^{2}H lock, 5-mm sample tubes. Carbon-13 enrichments were calculated by comparing integrated resonance intensities from the [^{13}C]-supplemented and natural abundance compounds as described previously (12).

The same conditions were used for ^{13}C nmr spectra of caerulomycin E (22 mg in 0.5 mL of dimethyl sulfoxide-d_6) except that $Cr(acac)_3$ was not added and the acquisition time was 1.6 s for broadband ^{1}H-decoupled spectra and 3.2 s for ^{1}H-coupled spectra with nOe maintained by ^{1}H irradiation between acquisition periods. Continuous-wave ^{1}H spectra of this compound were obtained with a Varian HA-100 spectrometer.

Electron-impact mass spectra were obtained with a Dupont/CEC model 21-110B mass spectrometer.

Results

Origin of ring B

Although the very high specific incorporation of 40.7% reported previously (7) was not reproduced under the culture conditions used in the present investigation, [U-^{14}C]lysine was an efficient precursor of caerulomycin A (Table 1). Oxidation of the labeled product with permanganate gave picolinic acid with virtually unchanged specific activity (Table 2). Cultures supplemented with [^{3}H]picolinic acid produced 32% more caerulomycin than unsupplemented control cultures and the specific incorporation of ^{3}H was 51.4%. All of the radioactivity in [^{3}H]caerulomycin A from this experiment was recovered in the picolinic acid obtained after permanganate oxidation.

Origin of ring A

Supplementation of cultures with [1,3-^{14}C]glycerol under a variety of regimens gave an optimum specific incorporation of 70.4% when aliquots of the precursor were fed at intervals in an overall concentration of 10 m*M*. An isotopic enrichment of 4–10%, adequate for ^{13}C nmr analysis of the labelling pattern, was obtained with successive supplementation to an aggregate of 1 m*M*. Under the latter conditions, a sample of [2-^{13}C, 1,3-^{14}C]glycerol exhibiting a specific radioisotopic incorporation of 4.4% preferentially labeled caerulomycin A with ^{13}C at C-6 (0.7% above natural abundance). The methoxyl carbon (0.2%), C-2′ (0.3%), C-4 (0.4%), C-4′ (0.5%), and

TABLE 1. Incorporation of radioactivity into caerulomycin A from ^{14}C-labeled compounds

Compound administered	Caerulomycin A		
	μCi/mmol	μCi/mmol	%
[^{3}H]Picolinic acid	0.167	0.086	51.4
[U-^{14}C]Lysine	65.7	6.72	10.2
[2-^{13}C, 1,3-^{14}C]Glycerol	17.4	0.767	4.41
[3-^{13}C, 3-^{14}C]Methylglyoxal	1.89	0.006	0.31

TABLE 2. Recovery of radioactivity in picolinic acid after oxidation of caerulomycin A

Caerulomycin A		Picolinic acid	
Labeled from	μCi/mmol	μCi/mmol	%
[U-^{14}C]Lysine	8.50	8.11	95
[^{3}H]Picolinic acid	0.086	0.085	99
[1,3-^{14}C]Glycerol	1.05	0.223	21

C-6′ (0.4%) were labeled to lesser extents (error, ±0.1%). In contrast, when cultures were supplemented under the same conditions with [1-^{13}C]glyceric acid, no ^{13}C enrichment of caerulomycin A carbons was detected. With [3-^{13}C, 3-^{14}C]-methylglyoxal, the incorporation of radioisotope was extremely low (Table 1) and ^{13}C enrichment was below detectable limits. Although unused supplement was identified in the broth at harvest, a 33% depletion of radioactivity during growth of the culture indicated that the labeled compound was taken up slowly by the mycelium. In support of this conclusion, an increase in the concentration of the supplement to 5 m*M* severely inhibited antibiotic production. Methylglyoxal has been shown to exert toxic effects in other organisms (13).

Isolation of caerulomycin E

Radiochromatogram scans after tlc of the basic ether-extractable product from cultures supplemented with [1,3-^{14}C]glycerol showed several minor radioactive, fluorescence-quenching components less polar than caerulomycin A. The most prominent of these (R_f 0.63; Silicar 7GF; chloroform–acetone, 19:1) gave an orange-brown color when the chromatogram was sprayed with $FeSO_4$ and could be identified by these properties in fractions obtained when culture extracts were chromatographed on partition columns on Sephadex LH20. With a solvent system modified from that used previously (7) to increase resolution of the less polar metabolites, the new product was separated from caerulomycin A and other components. It was then purified by crystallization and fractional sublimation for structural analysis by nmr.

Structure of caerulomycin E

The structure of caerulomycin E (**3**) was determined from its mass spectrum and comparison of its ^{13}C and ^{1}H nmr spectra with those of caerulomycin A (**1**) and the nitrile (**4**) for which ^{13}C and ^{1}H nmr resonances and spin–spin couplings have been assigned previously (3). The spectral data were in accord with a 2,2′-dipyridyl derivative in which the respective oxime and nitrile substituents of **1** and **4** were replaced by an aldehyde group. In particular, the chemical shifts for H-7 and C-7 as well as the $^{1}J_{CH}$ and $^{2}J_{CH}$ values for C-7 and C-6, respectively, were consistent with an aldehyde at the C-6 position. The ^{13}C substituent effects when a nitrile at C-6 is replaced by an aldehyde group are obtainable from the work of Retcofsky and Friedel (14). The predicted shifts (δ_C) based on known values for caerulomycin A nitrile (3) are C-2, 157.2; C-3, 109.7; C-4, 166.1; C-5, 108.7; and C-6, 152.5 ppm, all in close agreement with the measured values.

TABLE 3. Effect of nitrogen source on the production of caerulomycins by *S. caeruleus* 4/2*

Nitrogen source	Caerulomycins (mg L^{-1})
Sodium nitrate	226
Glutamate	68
Asparagine	68
Soytone	29
Ammonium sulfate	15
Serine	6

*Cultures were grown in medium 1 with the different nitrogen sources replacing nitrate at a concentration of 24 m*M* N L^{-1}. Broths were assayed for total caerulomycins after 10 days.

To ascertain whether generation of hydroxylamine as an intermediate in the assimilation of nitrate was a factor in the biosynthesis of caerulomycins containing the oxime substituent, cultures of *S. caeruleus* were grown in medium 1 with nitrate replaced by alternative nitrogen sources (Table 3). When the basic ether-extractable products from each culture were examined by tlc in system A, caerulomycin A was found to be the principal component. In addition, the relative amounts of minor components, including caerulomycin E, were not appreciably altered by changing the nitrogen source.

Discussion

The specificity with which [U-^{14}C]lysine is incorporated into the segment of caerulomycin A that is recovered as picolinic acid after oxidative degradation of the molecule is consistent with the pattern of ^{13}C labelling from [1-^{13}C]- and [1,2-^{13}C]-acetate found earlier (7), as well as with the high specific incorporation of the amino acid. That lysine is incorporated into the antibiotic after initial conversion to picolinic acid can be assumed from the significantly higher specific incorporation of [^{3}H]picolinic acid into the same structural segment. The results parallel those obtained in studies of proferrorosamine biosynthesis in *Pseudomonas roseus fluorescens* (8, 15). It is noteworthy that lysine is also known to be metabolized to 3-hydroxypicolinic acid before incorporation into etamycin by *Streptomyces griseoviridus* (16), and the structural relationships between caerulomycins, proferrorosamine, and the actinomycete-derived siderochelin (**5**, ref. 17) and siderochelin C (18) suggest that lysine may also be metabolized to 6-hydroxypicolinic acid in some species.

It is apparent from the 70% level of specific ^{14}C incorporation achieved with [1,3-^{14}C]glycerol at a supplement concentration much below that of the principal carbon source that glycerol is preferentially used to form the caerulomycins. The evidence from ^{13}C nmr analysis of the product obtained when [2-^{13}C]glycerol was combined with the radioactive precursor indicates that one glycerol molecule was incorporated as a unit into positions C-5, C-6, and C-7. The small ^{13}C enrichments at positions other than C-6 are explained by partial metabolic conversion of glycerol to products that are incorporated elsewhere in the antibiotic molecule. Thus the formation of [2-^{13}C]pyruvate and [2-^{13}C]aspartate semialdehyde would lead to [2,6-^{13}C]picolinic

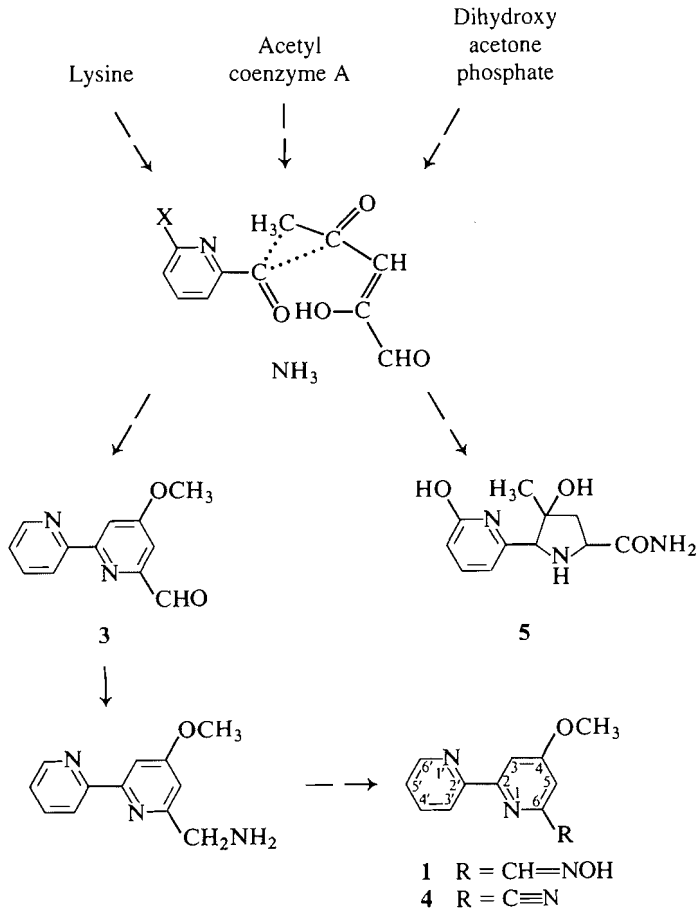

FIG. 1. Proposed biosynthesis of caerulomycins and siderochelin.

acid and generate caerulomycin A labeled at C-2′ and C-6′. Likewise, [1-^{13}C]acetyl coenzyme A formed from the labeled glycerol would introduce isotopic carbon into C-2, C-4, and C-4′. The earlier experiments with [1-^{13}C]acetate (7) showed much higher enrichments at C-4 and C-4′ than at C-2, accounting for the detection of small amounts of ^{13}C at the former two positions whereas incorporation at C-2 was below detectable limits. Labelling of the methoxyl carbon probably occurred through ^{13}C enrichment of the one-carbon pool via glycine.

Although glycerol itself is unlikely to be the immediate metabolic precursor, neither [1-^{13}C]glyceric acid nor [3-^{13}C, 3-^{14}C]-methylglyoxal, the two potential candidates tested, labeled the antibiotic to an appreciable extent. [1-^{13}C]Glyceric acid may not have been taken into the cells, but phosphoglycerates or phosphoenolpyruvate are not attractive intermediates since the carboxyl group they would introduce at C-7 would subsequently have to be reduced to an aldoxime or equivalent in caerulomycin A. The low incorporation of radioactivity from the methylglyoxal supplement cannot be attributed wholly to poor uptake since approximately one third of the radioactivity added to the culture was removed from the broth but less than 1% of this found its way into the antibiotic. If methylglyoxal is thus excluded as a precursor, it is likely that dihydroxyacetone phosphate, derived from glycerol when this supplement is fed, enters the secondary metabolic pathway directly. This could occur by condensation with acetyl or malonyl coenzyme A, either before or after the thioester had reacted with an activated form of picolinic acid. Alternative modes of condensation might lead to the caerulomycins or siderochelin. Proferrorosamine, which as neopurpuratin has recently been discovered as a product of *Streptomyces purpuratus* (19), might be similarly derived.

The isolation of caerulomycin E as a minor component of the caerulomycin complex produced by *S. caeruleus* raises the possibility that introduction of the oxime group is a terminal biosynthetic step. One route by which the oxime might be generated is by reaction of the aldehyde with hydroxylamine formed as an intermediate in the assimilation of nitrate. Nitrate supports the highest production of caerulomycins when supplied as the sole nitrogen source for growth of *S. caeruleus*; nevertheless, it is not an absolute requirement for biosynthesis of the secondary metabolite. Since generation of free hydroxylamine from organic nitrogen sources is questionable, a more likely origin for the oxime group of caerulomycin A and related products is through hydroxylation and dehydrogenation of an amino group. A mechanism of this kind probably accounts for formation of the oxime group in nocardicin from the amino group of *p*-hydroxyphenylglycine (20). With all of the above considerations in mind, we suggest the route shown in Fig. 1 for the biosynthesis of caerulomycins and related compounds.

Introduction

The design of polyfunctional molecular receptors, catalysts, and carriers involves the judicious combination of design elements of well-defined size, shape, and stereochemistry. Functionalized macrocycles with side chains of defined stereochemistries have found use as such design elements (1). The optically active 18-crown-6 **1**,[2] incorporating two *R*,*R*-tartaric acid residues (2), is a particularly attractive one because its carboxyl groups can be readily modified, via tetra-acid chloride **2** (2, 3), dianhydride (4), and *anti* diester-diacid chlorides **3***a* and **4***a* (5), or via the face-differentiated *syn* diester-diacid chlorides **3***b* and **4***b* (5), and may serve for introducing various side chains (3, 4). Furthermore, it and its derivatives form stable complexes with a variety of cations (3) through anchoring at the macrocycle and interaction with the side chains held in quasi-axial orientations (3, 4, 6).

To avoid problems of positional isomerism and diastereomerism in preparing complex macropolycyclic structures based on **1** using nonspecific linkage reactions, we chose to use C_2-symmetric linkage subunits. We describe herein the syntheses of two C_2-symmetric chiral 1,5-diamino-3-oxapentanes from D-glucosamine and the incorporation of one of them into chiral macrocyclic polyether ligands as a "bridge" in a macrobicycle and as a "spacer" unit in work toward the synthesis of a potential ion channel (*vide infra*). Many chiral macrocycles have been prepared that incorporate sugar or sugar-derived chiral ethylene glycol (for an earlier compilation, see ref. 7; see also ref. 8), diethylene glycol (9), or 1,4-butanediol (10) moieties or, although not of carbohydrate origin, 2*S*,5*S*-bis(hydroxymethyl)tetrahydrofuran (11) or another chiral 1,5-diamino-3-oxa-pentane, 2*S*,5*S*-bis(aminomethyl)tetrahydrofuran (12).

Chiral macrobicyclic polyethers

Recently, four novel macrobicyclic cryptands (exemplified by **5**) were prepared using 1,5-diamino-3-oxapentane to stereospecifically bridge over the face of **1** (5). The dianion of the diacid derived from **5** binds NH_4^+ and NH_3OH^+ as well as does the tetra-anion of **1**. This would imply a participation of the ether oxygen along the bridge in the stabilization of the complexes. The title diamines are conformationally more rigid than their achiral parent and, as bridges in structures analogous to **5**, would be expected to form more highly organized structures allowing better control of binding stabilities and selectivities.

Approaches to ion channels

Trans-membrane ion channels or "canals" have been implicated in the modes of action of the gramicidins (13), of alamethicin (14), and of amphotericin B and other polyene antifungals (15). Few synthetic channels have been reported. A polymer consisting of 4 helically-twisted "stacks" of closely-spaced 18-crown-6 moieties centred about the polymer backbone has been reported (16). The stacks are, on average, 40 Å long and composed of 10 monomer units each. The polymer extracts picrate salts from aqueous solutions more efficiently but less selectively than 18-crown-6. A 19–20 Å long half-canal has been based on a β-cyclodextrin unit bearing 4 hydrophobic chains and presenting 3 metal-ion binding sites (17). This model enables the passage of Cu^{2+} and Co^{2+} through vesicular membranes. The X-ray structure of the KBr complex of the tetra-*N*,*N*-dimethylamide of **1** (6*b*) shows a canal-like stack of disconnected macrocycles with half of the complexed K^+ ions bound in the plane of macrocycles and the other half frozen in mid-jump between two macrocycles. Such "jumps" between binding sites had been demonstrated in 1:1 Ca^{2+}, Ba^{2+}, and Sr^{2+} complexes of a cylindrical binuclear macrocycle (18).

We were interested in the possibility of using the title amines as C_2-symmetric spacers to link units of **1** into polynucleating stacks or canals such as **6** that may enable the transfer of a metal ion from one macrocyclic subunit to another and thus constitute operational models of an ion channel. The ether-type oxygens in **11** and **15** would facilitate that transfer, and the rigidity afforded by the backbone would help prevent the collapse of the internal cavities in **6**.

Results and discussion

Synthesis of the chiral linear diamines 11–15

The transformations of D-glucosamine to 2,5-anhydro-D-mannitol **7** (19), and thence to the tetraolditosylate **8** (20), are established procedures. We wished to methylate the secondary hydroxyl groups and to transform the tosyloxy functions to amino groups. However, electrophilic methylation of **8** (Ag_2O, CH_3I, THF) (19*b*) failed, as did nucleophilic conditions ($SO_2(OMe)_2$, aqueous NaOH). The problem could be avoided

by reversing the order of the reactions. Displacement of the tosyloxy groups of **8** with azide ion (2.2 equiv. NaN_3, DMSO, 24 h at 80°C) (21) provided **9** in 94% yield as a stable oil.[3] During the course of our work, Guthrie *et al.* (22) reported a slightly different, lower yielding preparation of **9**. The reported ^1H nmr data differ significantly from ours, however. Our spectrum and other data are both internally consistent and as expected for **9**. Hence, the previous report must clearly be in error. Methylation of **9** (2.5 equiv. NaH, 2.2 equiv. CH_3I, cat. n-$Bu_4N^+Br^-$ (23), THF, overnight at room temperature) proceeded smoothly to afford an 86% yield of **10**, as an initially slightly yellow oil that darkened over a period of weeks. Decomposition was only slight, however, and **10** could be chromatographed before use. Hydrogenation of **10** in acidic solution (3.0 equiv. H_2, cat. 10% Pd/C, EtOH containing 2.1 equiv. concentrated HCl, 24 h at RT) afforded crystalline **11**·2HCl in 72% yield. Neutralization gave a quantitative yield of oily free base **11**.

[3]Although no problems of explosive instability were encountered in our work, special care should be taken when preparing and handling organic polyazides. In particular, they should not be heated in large batches in the absence of solvents, and crystallization may release dangerous amounts of heat (21).

Our approach to the synthesis of "trimeric stack" **6** called for a high dilution coupling of two face-differentiated units (such as **3***a* (5)) with one bearing four spacers as a central unit. Alternatively, two face-differentiated units of **1**, each bearing two spacers, could be coupled to the central unit (e.g., **2**). In both cases, we wished to link diamine **11** to macrocycles via only one of the amine functions and therefore required a mono-protected form of **11**. As could be expected, mono-protection in homogeneous solution of diamine **11** by benzyloxycarbonyl (BzOC) groups proved to be nonselective. Treatment of **11**·2HCl with 1.0 equiv. benzyl chloroformate (BzOCCl) in 4:15 H_2O–EtOH (containing 1.0 equiv. Et_3N, 1 h at RT) produced a mixture of mono-BzOC **12**·HCl, di-BzOC **13**, and unreacted **9**·2HCl. Nevertheless, successive extractions in acidic and basic media resolved the statistical mixture of products (see Experimental) affording oily free base mono-BzOC **12** in 31% yield (ca. 49% based on converted **11**) and di-BzOC **13** in ca. 30% yield as an oil that slowly crystallized. Compound **13** could also be produced deliberately from free base **11** with 2 or more equiv. each of benzyl chloroformate and Et_3N. Substituting CH_3CN for EtOH, or NaOH for Et_3N, in the above procedure did not improve the yield of mono-BzOC **12**. When two phases were present in the reaction mixture, higher proportions of di-BzOC **13** were produced by virtue of the H_2O-insolubility of BzOCCl and the appreciable solubility of mono-BzOC **12**·HCl in organic media. Using free base **11** instead of the dihydrochloride salt gave only **13** for the same reason. The solvent mixture used in this preparation of **12** appeared to maintain homogeneity throughout the reaction.

Reduction of the protecting groups in **13** ($LiAlH_4$, THF, 2 days at reflux; basic work-up) produced a complex mixture from which a small amount of crystalline **15**·2HCl was isolated. Alternatively, methylation of **13**, in the same way as was done with **9**, produced oily **14** in quantitative yield. The room temperature nmr spectrum of **14** is complex, but a well-resolved spectrum could be obtained by heating to 60°C, where rotation about the carbonyl nitrogen bond of the tertiary amide groups becomes fast on the nmr timescale. Deprotection of **14** (excess HBr in HOAc, overnight at RT; ion exchange with Dowex 1X8 OH^- form) afforded oily free base **15**.

*Combination of diamine **11** with macrocycles*

syn-Dimethyl ester-diacid chloride **3***a* (5) and **11** were coupled under high dilution conditions, where equimolar CH_2Cl_2 solutions of **11** (containing 2 equiv. Et_3N) and of **3***a* were slowly pumped from syringes into rapidly stirred CH_2Cl_2 such that the initial reactant concentrations were ca. 10^{-6} M. Work-up afforded a crude mixture that consisted largely of **16** (according to nmr, ir, and tlc). However, this material did not well survive chromatography on Al_2O_3 or SiO_2, and pure **16** was isolated in only 5% yield as a thick oil.[4] The ^1H nmr spectrum (taken in $CDCl_3$) displays two singlets for the asymmetric crown (OCH-type) protons at 4.41 and 4.27 ppm, a single ester-type methoxyl peak at 3.77 ppm, and a single ether-type methoxyl peak at 3.37 ppm. Similarly, the ^1H nmr spectrum of the related macrobicycle **5** (taken in CD_3CN) also displays two singlets at 4.30 and 4.18 ppm for the corresponding asymmetric crown protons (5, 24). The ^{13}C nmr spectrum of **16** also showed single peaks for each of the structurally distinct carbons, analogous to those displayed by **5** (5, 24).

Tetra-acid chloride **2** (2, 3) and 4.0 equiv. of **12** were coupled in the presence of excess Et_3N (CH_2Cl_2, 0.5 h at RT) to provide, after chromatography on Al_2O_3, a 77% yield of oily tetra-"armed" crown **17**.[4] This could be deprotected in the same manner as was **14** to give a 92% yield of tetra-amine **18** as a slightly yellow foam.[4] Apart from characteristic signals assignable to asymmetric crown OCH, there was strong overlap in the region near 3.6 ppm of the ^1H nmr spectra of **17** and **18**. The ^{13}C spectra were more useful, but they also showed some accidental overlap and assignments were made by analogy. For instance, the signal at 86.6 ppm assigned to C2′ and C5′ of **17** was analogous to a signal also at 86.6 ppm for C2(C5) of **13**. Similarly, a signal at 87.1 ppm was assigned to C2′ and C5′ of **18** by analogy to peaks at 87.1 and 86.9 ppm for C2 and C5 of **12**. Further, the spectrum of **17** showed a taller peak at 81.6 ppm, with an upfield shoulder, which was attributed to C3′, C4′, and macro-ring O*C*H by analogy to the signal at 81.7 ppm for C3(C4) of **13** and to a signal at 81.8 ppm for O*C*H of the tetra(*N*-methyl)amide of **1** (2). This overlap was partially resolved in the spectrum of **18**, where two signals appeared for the corresponding nuclei at 83.8 and 81.4 ppm (in ca. 1:2 intensity ratio), analogous to signals at 84.3 and 81.1 ppm (in ca. 1:1 ratio) for C3 and C4 of **12**.

A high dilution coupling of **18** with two equivalents of *syn*-dimethyl ester-diacid chloride **3***a* (5) provided a complex mixture of products. Column chromatographic separation was unsuccessful, however. When *syn*-bis(naphth-1-yl)methyl ester-diacid chloride **4***a* (5) was used instead, a small amount

[4]The compounds **16**, **17**, and **18** were obtained as thick oils or foams. Although they appeared chromatographically homogeneous, the reader should be aware that, in the absence of crystalline materials, indications of their purity and proofs of their structure rely entirely on nmr and ir data.

of the chromatographically most mobile product (on tlc plates) could be isolated (ca. 6.5% yield) by column chromatography on basic Al_2O_3 (act. II/III). This material, largely homogeneous on tlc plates, unfortunately decomposed even at room temperature to liberate naphthalene-1-methanol. Exposure to basic alumina seemed to accelerate this process. Column chromatography on neutral Al_2O_3 (act. I), preparative tlc on Al_2O_3, or reverse-phase hplc, using 3–8:10 CH_3CN – 0.01 M $NH_4^+HCOO^-$ as eluent, failed to effect purification without decomposition. Coupling of **4***a* and **18** at 0°C or in the presence of CsOTf at −10°C failed to provide cleaner product mixtures. The ^1H nmr spectrum of the product displayed chemical shifts and integration ratios consistent with a "trimeric" macropentacyclic structure **6**. In particular, the spectrum, taken in $CDCl_3$, featured a single, well-resolved AB pattern at 5.69 ppm for the benzylic protons, 2 singlets of unequal intensity (ca. 1:2 integration ratio) at 4.37 and 4.30 ppm for the asymmetric crown protons, and a single peak for methoxyl protons at 3.34 ppm. Although there are three structurally distinct protons at the asymmetric centres of the macrocycles, viz. those α to the carboxamides on the central ring, those α to the carboxamides on the outer rings, and those α to ester groups, one may expect little difference in chemical environments between the first two types, and expect the signals from the latter type to occur at a lower field position than the first two. As well, one may expect overlap of the two structurally distinct methoxyl protons for the same reason. Recently, attempts at forming a macroheptacyclic entity **20** were made via high dilution condensation of 2 equiv. of *o*-phenylenediamine-bridged 18-crown-6 diacid chloride **19** (25) with one of tetra-amine **18** (24). The spectrum of this condensation product (taken in CD_3OD) displayed a signal at 4.50 ppm (assigned to four macro-ring OC*H*), a mass of signals near 4.3 ppm (assigned to the eight remaining macro-ring OC*H* and to eight H2′ and H5′), and two methoxyl peaks centred near 3.5 ppm. These and other similarities with the spectra of **16**, **17**, **18**, and **5** lend support to our assignment of the ^1H nmr peaks of our condensation product, but an unequivocal synthesis of **6** remains to be performed.

In conclusion, the 1,5-diamino-3-oxapentanes **11** and **15** are readily prepared from D-glucosamine, and are versatile structural units that, in addition to the couplings described here, may find use in other applications where rigidity, chirality, and C_2 symmetry are desired. From the results of our high dilution reactions, however, it would appear that, although the ester linkages of macrocycles **3***a* and **4***a* may be more amenable to conversion to other functionalities, amide-linked side chains such as in **19** are more stable and, hence, likely more preparatively useful in condensation reactions.

Experimental

General

The nmr spectra were run on 60 MHz Varian A-360 or 200 MHz Bruker Aspect 2000 instruments. Internal references were either TMS or the signal due to the protio-solvent in ^1H spectra, or the deuterio-solvent peak in ^{13}C spectra. A Beckman 197 instrument was used for ir spectra. Optical rotations were measured at room temperature on a Perkin–Elmer 110 polarimeter. Melting points are uncorrected. Column grade silica was type 60, and alumina was basic, with activity II/III, or neutral, with activity I. Flash chromatography used silica of 43–60 Å particle size. Thin-layer chromatography (tlc) was performed on Macherey–Nagel plastic-backed plates of Al_2O_3. Solvents were distilled over appropriate drying agents before use. 2,5-Anhydro-D-mannitol **7** was prepared from D-glucosamine hydrochloride (20), omitting the acetylation, chromatography, and deacetylation purification steps (19*b*). The product, a thick yellow syrup, was used directly in the preparation of 2,5-anhydro-1,6-di-*O*-tosyl-D-mannitol **8** (19*b*, 20). However, we replaced the chromatographic purification of **8** with a trituration with hot toluene, from which the product crystallizes upon cooling. The overall yield of **8** was ca. 37% from D-glucosamine hydrochloride.

*2,5-Anhydro-1,6-di-*C*-azido-1,6-dideoxy-*D*-mannitol* ***9***

A mixture of ditosyl ester **8** (21.39 g, 45.3 mmol) and NaN_3 (6.48 g, 2.2 equiv.) in 225 mL of dry DMSO was stirred at 80°C for 24 h. After cooling, the reaction mixture was diluted with H_2O (1 L) and extracted with EtOAc (6 × 500 mL). Each organic layer was separately washed with a series of five volumes of H_2O (100 mL), then evaporated to dryness and analysed by nmr. The first four were found to be free by DMSO, and were combined to give 9.07 g (94% yield) of slightly yellow oil. An analytical sample was obtained by flash chromatography of the combined fifth and sixth extracts, using 40% EtOAc in hexane as eluent; $[\alpha]_D$ +117.6° (0.037 M, $CHCl_3$); ir (thin film): 3400 (b), 2100 (s) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 4.14–3.94 (m, 4H), 3.67 (bs, 2H, OH), 3.51 (ddd, 4H, J = 3.7, 4.2, 13.2 Hz) ppm; ^{13}C nmr ($CDCl_3$) δ: 81.1 (C2, C5), 78.0 (C3, C4), 51.8 (C1, C6) ppm.

*2,5-Anhydro-1,6-di-*C*-azido-1,6-dideoxy-3,4-di-*O*-methyl-*D*-mannitol* ***10***

A two-necked flask, flushed with Ar, equipped with an outlet to a gas bubbler and an additional funnel, and cooled in a water bath, was charged with NaH (4.67 g of ca. 55% oil dispersion, ca. 107 mmol) and a trace of tetra-*N*-butylammonium bromide. This was suspended in dry THF (25 mL), and a solution of diazide **9** (9.17 g, 42.8 mmol) and CH_3I (5.86 mL, 2.2 equiv.) in dry THF (50 mL) was added over 5–10 min, avoiding internal reflux of the THF. After complete addition and flushing with Ar, the mixture was stirred overnight at RT. After quenching with a little H_2O, most of the THF was removed *in vacuo*, and the mixture was twice extracted with ether. The ether layers were separately washed with H_2O, then combined, dried ($MgSO_4$), and evaporated to dryness. Most of the oil was removed by partitioning the residue between CH_3CN and hexane. The CH_3CN layer was evaporated to give 9.0 g of crude product as a light yellow oil. This was chromatographed on a short column of SiO_2, using 20% EtOAc in hexane to elute 8.91 g (86%) of pure dimethoxy diazide **10** as a colourless, mobile liquid. The major impurity, eluted with 40% EtOAc in hexane, was the product of monomethylation; $[\alpha]_D$ +67.4° (0.089 M, $CHCl_3$); ir (thin film): 3430 (b), 2490 (s) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 4.18–4.10 (m, 2H, H2, H5), 3.72 (q, 2H, J = 1.1, 2.9 Hz, H3, H4), 3.40 (d, 4H, J = 5.6 Hz, H1, H6), 3.40 (s, 6H, OCH_3) ppm; ^{13}C nmr ($CDCl_3$) δ: 86.5 (C2, C5), 81.6 (C3, C4), 57.6 (CH_3), 52.2 (C1, C6) ppm.

*2,5-Anhydro-1,6-di-*C*-amino-1,6-dideoxy-3,4-di-*O*-methyl-*D*-mannitol* ***11***

A 500-mL stainless steel bomb was loaded with a solution of diazide **10** (8.93 g, 36.9 mmol) in EtOH (100 mL), to which was added 10% Pd on C (ca. 1.0 g) and 6.5 mL concentrated HCl (ca. 2.1 equiv.). After flushing with H_2, the bomb was charged with 6 atm H_2 (ca. 3.0 equiv.) and shaken overnight. After discharging the pressure, the solid mass deposited at the bottom was taken up in MeOH and the catalyst was filtered off. The filtrate was concentrated to give crude crystalline product. Recrystallization from MeOH–CH_3CN afforded 7.02 g of colourless crystals of the pure dihydrochloride salt of **11** (72% yield), mp 260°C; $[\alpha]_D$ +69.2° (0.019 M, H_2O); ^1H nmr (CD_3OD) δ: 4.39 (td, 2H, J = 1, 6.5 Hz, H2, H5), 3.84 (dd, 2H, J = 1.1 Hz, H3, H4), 3.43 (s, 6H, OCH_3), 3.15 (ddd, 4H, J = 1, 1, 6.5 Hz, H1, H6) ppm; ^{13}C nmr (D_2O) δ: 86.0 (C2, C5), 80.1 (C3, C4), 57.6 (OCH_3), 41.1 (C1, C6) ppm. *Anal.* calcd. for $C_8H_{20}N_2O_3Cl_2$: C 36.51, H 7.66, N 10.64%; found: C 36.52, H 7.61, N 10.67%. The free diamine was generated as needed by treating a MeOH solution of the salt with a slight excess of 1 M NaOH solution, evaporating to dryness, and triturating with dry CH_2Cl_2. Filtration of the triturate and evaporation of the filtrate afforded quantitative yields of the pure diamine as a slightly yellow oil that slowly carbonated in air; ^1H nmr ($CDCl_3$) δ:

3.84 (m, 2H, J = 1.6, 4.7 Hz, H2, H5), 3.54 (q, 2H, J = 1.0, 3.2 Hz, H3, H4), 3.34 (s, 6H, OCH_3), 2.80 (dd, 4H, J = 1.1, 3.2 Hz, H1, H6), 1.25 (s, 4H, NH_2) ppm; ^{13}C nmr ($CDCl_3$) δ: 87.2 (C2, C5), 83.4 (C3, C4), 57.1 (OCH_3), 43.8 (C1, C6) ppm.

2,5-Anhydro-1-C-(N-benzyloxycarbonyl)amino-6-C-amino-1,6-dideoxy-3,4-di-O-methyl-D-mannitol ***12*** *and 2,5-anhydro-1,6-di-C-(N-benzyloxycarbonyl)amino-1,6-dideoxy-3,4-di-O-methyl-D-mannitol* ***13***

A solution of **11**·2HCl (1.00 g, 3.80 mmol) in H_2O (4 mL) was diluted with EtOH (15 mL) and treated with Et_3N (0.53 mL, 1.0 equiv.). Then technical grade benzyl chloroformate (85% pure, 0.53 mL, ca. 1.0 equiv.) was added dropwise to the vigorously stirred solution. The mixture was allowed to stir at RT a further hour, then rid of solvents. Trituration with several volumes of CH_2Cl_2 left 0.75 g of insoluble residue, containing unreacted **11**·2HCl. The CH_2Cl_2-soluble portion was washed twice with dilute HCl (containing at least 4 mmol HCl per wash), and the aqueous phases were separately reextracted with CH_2Cl_2. The combined CH_2Cl_2 layers were evaporated to give impure bis-protected diamine **13**. The combined aqueous phases were concentrated and treated with NaOH pellets to bring the pH to about 12. The resulting turbid solution was extracted twice with CH_2Cl_2. The combined organic layers were evaporated to afford 0.378 g of mono-amine **12** (31% yield); $[\alpha]_D$ of the HCl salt +57.9° (0.047 M, H_2O); ir (thin film): 3410–3300 (b), 1695 (s) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 7.35 (bs, 5H, Ph), 5.31 (bt, 1H, NH), 5.11 (s, 2H, CH_2Ph), 4.03 (m, 1H, H2), 3.90 (m, 1H, H5), 3.59 (bs, 2H, H3, H4), 3.43 (m, 2H, H1), 3.37, 3.36 (2s, 6H, OCH_3), 2.81 (m, 4H, H6) ppm; ^{13}C nmr ($CDCl_3$) δ: 156.4 (C=O), 136.5, 128.3, 127.9 (Ph), 87.1 (C2), 86.9 (C5), 84.3 (C3), 81.1 (C4), 66.6 (CH_2Ph), 57.5 (C1), 57.2 (C6), 43.8, 42.9 (OCH_3) ppm. The crude by-product **13** was purified by column chromatography on SiO_2, using 40% EtOAc in hexane as eluent. This afforded a colourless oil that crystallized in the cold. Suspending the solid in 1:1 ether–hexane, followed by filtration and washing with cold toluene, afforded white crystals (ca. 30% yield) that could not be recrystallized, mp 69–71°C; $[\alpha]_D$ +37.8° (0.063 M, $CHCl_3$); ir ($CHCl_3$): 3580, 3565, 3445, 1705 cm^{-1}. ^1H nmr ($CDCl_3$) δ: 7.33 (s, 10H, Ph), 5.28 (bt, 2H, NH), 5.09 (s, 4H, CH_2Ph), 4.04 (bm, 2H, H2, H5), 3.58 (bs, 2H, H3, H4), 3.38 (m, 4H, H1, H6), 3.33 (s, 6H, OCH_3) ppm; ^{13}C nmr ($CDCl_3$) δ: 156.4 (C=O), 136.5, 128.4, 128.0 (Ph), 86.6 (C2, C5), 81.7 (C3, C4), 66.7 (CH_2Ph), 57.4 (C1, C6), 42.7 (OCH_3) ppm. *Anal.* calcd. for $C_{24}H_{30}N_2O_7$: C 62.87, H 6.59, N 6.11%; found: C 62.98, H 6.66, N 6.15%. The original CH_2Cl_2-insoluble residue was extensively triturated with CH_3CN to rid it of most of the Et_3N·HCl before recovery, as described above, of **11** as its free base.

2,5-Anhydro-1,6-di-C-(N-benzyloxycarbonyl-N-methyl)amino-1,6-dideoxy-3,4-di-O-methyl-D-mannitol ***14***

The di-*N*-benzyloxycarbonyl diamine **13** was methylated in the same manner as was diazide **9** to afford a quantitative yield of di-*N*-benzyloxycarbonyl di-*N*-methyl diamine **14** as a slightly yellow oil that could be purified by column chromatography on SiO_2 using 40% EtOAc in hexane as eluent; $[\alpha]_D$ +32.9° (0.139 M, $CHCl_3$); ir (thin film): 1690 cm^{-1}; ^1H nmr ($CDCl_3$, 60°C) δ: 7.30 (m, 10H, Ph), 5.10 (s, 4H, CH_2Ph), 4.11 (bq, 2H, H2, H5), 3.55–3.30 (m, 6H), 3.24 (bs, 6H, OCH_3), 2.95 (s, 6H, NCH_3) ppm; ^{13}C nmr ($CDCl_3$, RT) δ: 156.1, 155.6 (C=O), 136.3, 133.7, 133.4 (Ph), 86.8 (C2, C5), 84.1 (C3, C4), 66.8 (CH_2Ph), 56.9 (C1, C6), 50.9, 50.6 (OCH_3), 35.5 (NCH_3) ppm. *Anal.* calcd. for $C_{26}H_{34}N_2O_7 \cdot \frac{1}{2}H_2O$: C 63.02, H 7.12, N 5.65%; found: C 63.17, H 6.99, N 5.83%.

2,5-Anhydro-1,6-di-C-(N-methyl)amino-1,6-dideoxy-3,4-di-O-methyl-D-mannitol ***15***

A solution of **14** in HOAc was treated with 4 equiv. 37% HBr in HOAc and the solution was allowed to stand overnight. After evaporating to dryness, the crude product was dissolved in H_2O, then passed through a column of Dowex 1X8 resin (OH^- form). After evaporating to dryness, the residue was dissolved in EtOH and treated with a slight excess of 1 M HCl solution, then rid of solvents to afford **15**·2HCl, mp 220°C (dec.); $[\alpha]_D$ +61.0° (0.024 M, H_2O); ^1H nmr of free base ($CDCl_3$) δ: 3.85 (m, 2H, H2, H5), 3.60 (m, 2H, H3, H4), 3.45 (s, 6H, OCH_3), 2.85 (m, 4H, CH_2), 1.55 (s, 6H, NCH_3) ppm.

Macrobicycle ***16***

A flame-dried, three-necked, invaginated round-bottom flask, equipped with a mechanical stirrer and two stopcocks, was flushed with Ar and loaded with 5 mL of dry CH_2Cl_2. In an oven-dried gas-tight syringe was placed 24 mL of a CH_2Cl_2 solution of **3***a* (120 mg, 0.237 mmol). A second, identical syringe held an equal volume of CH_2Cl_2 containing free base diamine **11** (45 mg, 0.237 mmol) and Et_3N (67 μL, 2.02 equiv.). Identical 12 in. long needles (delivering ca. 5-μL drops of CH_2Cl_2) were fitted to the syringes, and these were mounted on a syringe pump. The needles were passed through the opened stopcocks and dipped just below the surface of liquid. Vigorous stirring was applied and the pumping rate of the syringe pump was adjusted to deliver ca. 1 drop/s. After complete addition, fresh solvent was drawn into the syringes and the rinses pumped into the reaction mixture. The resulting greenish solution was washed with H_2O (3×) and the aqueous layers extracted once with fresh CH_2Cl_2. The combined organic layers were concentrated and treated with toluene to precipitate an amorphous reddish solid that contained no desired product (as determined by tlc using 2.5–5% MeOH in CH_2Cl_2 as developer). The yellow supernatant was filtered and freed of solvents. The residue was chromatographed on a column of basic Al_2O_3, eluting with CH_2Cl_2 containing, firstly, 1% v/v MeOH, then 2% MeOH, and finally 3% MeOH. The yield of the combined fractions containing the desired product was ca. 8 mg. Similar preparations chromatographed on silica or neutral Al_2O_3 gave similar yields; $[\alpha]_D$ +66.3° (0.021 M, $CHCl_3$); ir (thin film): 3360 (b, shoulder at 3410), 1740 (s), 1642 (s), 1532 (m) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 8.45 (bm, 2H, NH), 4.41, 4.27 (2s, 4H, OCH), 4.04–3.52 (m, 28H), 3.77 (s, 6H, $COOCH_3$), 3.37 (s, 6H, $ROCH_3$) ppm; ^{13}C nmr ($CDCl_3$) δ: 169.8, 169.3 (C=O), 88.3 (C2′, C5′), 80.9 (C3′, C4′), 79.6, 79.0 (OCH), 70.5, 69.2, 68.3, 68.1 (OCH_2), 57.6 (C1′, C6′), 51.8 ($COOCH_3$), 41.6 ($ROCH_3$) ppm.

Tetra-N-benzyloxycarbonyl tetra-amine ***17***

Under an Ar atmosphere, a solution of tetra-acid chloride **2** (123 mg, 0.24 mmol) in dry CH_2Cl_2 (4 mL) was added over 0.5 h to a stirred solution of mono-*N*-benzyloxycarbonyl diamine **12** (310 mg, 4 equiv.) and Et_3N (133 μL, 4.4 equiv.) in dry CH_2Cl_2 (5 mL). The mixture was stirred a further 0.5 h, then evaporated to dryness. The crude product was purified on a column of Al_2O_3 by eluting first with 1% MeOH in CH_2Cl_2, then with 2% MeOH in CH_2Cl_2, to afford 305 mg (77%) of slightly yellow oily material; $[\alpha]_D$ +83.1° (0.018 M, $CHCl_3$); ir (thin film): 3305 (b), 1700 (s), 1660 (s), 1520 (s) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 7.30 (bs, 20H, Ph), 5.57 (bt, 4H, NH), 5.06 (s, 8H, CH_2Ph), 4.35 (bs, 4H, OCH), 4.05 (bq, 8H, H2′, H5′), 3.62, 3.56 (2bm, 24H), 3.34, 3.29 (2s+bm, 40H, OCH_3) ppm; ^{13}C nmr ($CDCl_3$) δ: 170.1 (RCONH), 156.3 (OCONH), 136.3, 128.2, 127.8 (Ph), 86.6 (C2′, C5′), 81.6 (C3′, C4′, OCH), 71.2, 69.2 (OCH_2), 66.4 (CH_2Ph), 57.3, 56.9 (C1′, C6′), 42.7, 40.7 (OCH_3) ppm.

Tetra-amine ***18***

A solution of tetra-*N*-benzyloxy tetra-amine **17** (354 mg, 0.213 mmol) in glacial HOAc (3.5 mL) was treated with a 33% solution of HBr in HOAc (0.30 mL, 8 equiv.) and allowed to stand overnight at RT. A reddish, oily second phase formed. The mixture was rid of solvent and the crude salt was partitioned between H_2O and CH_2Cl_2. The organic phase was washed once with H_2O and the aqueous layers were separately washed with fresh CH_2Cl_2. The combined aqueous phases were concentrated, then stirred with an excess of Dowex 1X8 resin (OH^- form) for 15 min. The resin was filtered off, washed with H_2O, and the combined filtrates were evaporated to dryness, leaving 220 mg of slightly yellow foam (92% yield); $[\alpha]_D$ of the tetra HCl salt +100.35° (0.029 M, MeOH); ^1H nmr (CD_3CN) δ: 7.54 (bm, 4H, amide NH), 4.22 (bs, 4H, OCH), 3.99, 3.84 (bm+q, 8H, J = 5.8, 9.7 Hz, H2′, H5′), 3.66, 3.61, 3.40 (3bm, 36H), 3.36, 3.34 (2s, 24H, OCH_3), 2.69 (d, 8H, J = 5.9 Hz, H6′) ppm; ^{13}C nmr ($CDCl_3$) δ: 170.0 (C=O), 87.1 (C2′, C5′), 83.8, 81.4 (1:2 ratio, C3′, C4′,

OCH), 71.2, 69.4 (OCH_2), 57.3, 57.1 (C1′, C6′), 43.8, 41.3 (OCH_3) ppm.

Attempted preparation of "trimer" 6

A procedure identical to that used in the preparation of **16** was employed in the condensation of 12 mL of CH_2Cl_2 solutions of **4***a* (92 mg, 0.121 mmol) with **18** (69 mg, 0.060 mmol) and Et_3N (28 μL, 4.55 equiv.) in 25 mL of CH_2Cl_2. After washing with H_2O and evaporation of solvent, the residue was chromatographed on a column of Al_2O_3 eluted firstly with $CHCl_3$, then with CH_2Cl_2 containing increasing amounts of MeOH (1–30%). As judged by tlc (using 2.5–5% MeOH in CH_2Cl_2 or 4% EtOH in $CHCl_3$ as developer), the fractions containing the chromatographically most mobile product were combined, freed of solvent, and loaded onto a second, similar column eluted with 2% MeOH in CH_2Cl_2. The fractions containing desired product were combined and evaporated to dryness to afford ca. 10 mg of an oil (ca. 6.5% yield); ^{1}H nmr ($CDCl_3$) δ: 8.06, 7.82, 7.57–7.28 (3m, 36H, Ar, NH), 5.69 (ABq, 8H, CH_2Ar), 4.37, 4.30 (2s, 12H, asymmetric crown H), 4.22–3.03 (m, 80H), 3.34 (s, 24H, OCH_3) ppm.

Anodic and cathodic reactions in acetonitrile/tetra-*n*-butylammonium tetrafluoroborate: an electrochemical and infrared spectroelectrochemical study

JOHN K. FOLEY,[1] CAROL KORZENIEWSKI, AND STANLEY PONS[2]
Department of Chemistry, University of Utah, Salt Lake City, UT 84112, U.S.A.

Received February 3, 1987

JOHN K. FOLEY, CAROL KORZENIEWSKI, and STANLEY PONS. Can. J. Chem. **66**, 000 (1988).

In situ infrared spectroelectrochemistry has been used to observe electrolyte/solvent breakdown processes in TBAF/acetonitrile at a platinum electrode. Anodic breakdown gives the adduct CH_3CNBF_3 as the major product. Cathodic breakdown gives the anion of 3-aminocrotonitrile as the major product in the absence of water, and the formation of this product is a consequence of reduction of hydrogen dissolved in the metal. In the presence of water the anion of acetamide is also formed, and breakdown commences at much less negative potentials.

JOHN K. FOLEY, CAROL KORZENIEWSKI et STANLEY PONS. Can. J. Chem. **66**, 000 (1988).

On a utilisé de la spectroélectrochimie infrarouge in situ pour observer les processus de décomposition électrolyte/solvant dans le TBAF/acétonitrile, à une électrode de platine. Le produit principal de la décomposition anodique fournit l'adduit CH_3CNBF_3. En absence d'eau, la décomposition cathodique fournit de l'amino-3 crotonitrile comme produit principal; la formation de ce produit une conséquence de la réduction de l'hydrogène dissous dans le métal. En présence d'eau, il y a aussi formation de l'anion acétamide et la décomposition commence à des potentiels beaucoup moins négatifs.

[Traduit par la revue]

Introduction

Acetonitrile is one of the most widely used aprotic solvents in electrochemistry. It has a high dielectric constant and a very wide useful potential window. Under ideal conditions the usable potential range of this solvent is determined by the potentials at which the supporting electrolyte breaks down. Half-wave potentials of up to +3.9 V have been measured for the oxidation of aliphatic hydrocarbons in acetonitrile (2), using a platinum ultramicroelectrode to eliminate the need for supporting electrolyte. Tetra-*n*-butylammonium tetrafluoroborate (TBAF) is a common supporting electrolyte which also has a wide usable potential range; the *n*-Bu_4N^+ cation is reduced at potentials more negative than is Li^+, for example, while the BF_4^- anion is oxidized at potentials more positive than is ClO_4^- (1). The acetonitrile/TBAF system is therefore in common use, and it is of interest to identify the solvent and electrode breakdown processes which limit its useful potential range under normal laboratory conditions.

The anodic breakdown of wet acetonitrile solutions at platinum electrodes has been studied with tetra-*n*-propylammonium tetrafluoroborate supporting electrolyte (3). No significant reaction was observed at potentials up to +2.4 V unless water was present (in about 0.1 *M* concentration), in which case the electrolysis products observed were mainly CO_2 and acetamide.

Pons and Khoo (4) have investigated the cathodic limiting reaction at platinum with TBAF as electrolyte. Short periods of electrolysis at −3.3 V gave 3-aminocrotonitrile (diacetonitrile) as the major product, and some 2,4,6-trimethyl-1,3,5-triazine (a trimer of acetonitrile) was formed at longer electrolysis times. With water present, acetamide was the major product of electrolysis at −2.2 V.

In this paper we report an *in situ* infrared spectroelectrochemical investigation of electrode reactions at high positive and negative potentials in nominally dry acetonitrile/TBAF. The reduction of pyrene, which takes place close to the negative potential limit, has been studied in the absence and in the presence of water, to examine the effect of cathodic solvent breakdown on this process.

Experimental

Infrared spectra were obtained by subtractively normalized interfacial FTIR spectroscopy (SNIFTIRS), which has been described in detail elsewhere (5). The FTIR spectrometer was an IBM 98 instrument equipped with a cooled 77 K HgCdTe solid-state detector. A specular reflectance attachment was used to control the angle of incidence of the beam on the cell window for maximum sensitivity. The cell itself was situated outside the spectrometer in a nitrogen purged box, so that the spectrometer could be evacuated to minimize the amount of water vapor and CO_2 in the optical path. The beam passed out of, and returned into, the spectrometer through a KBr window.

The spectroelectrochemical cell was constructed of Pyrex. The working electrode was a 7 mm diameter metal disk, mounted on the end of a brass shaft which was press fitted in a 9 mm diameter Kel-F tube. The tube, which could be moved in a direction perpendicular to the window, was held in place by expanding an O-ring located on the electrode barrel. The secondary electrode was a platinum wire loop. The reference electrode was a silver wire in contact with an acetonitrile solution of $AgNO_3$ (0.01 *M*) and TBAF (0.1 *M*), and all potentials reported herein are with respect to this electrode. A flat silicon infrared transparent window was used, which allowed the spectral region down to 800 cm^{-1} to be investigated. The angle of incidence of the beam on the window was 70°. The electrode potential was controlled with a potentiostat, and potential–time waveforms for cyclic voltammetry were supplied by a waveform generator (Hi Tek Instruments DT2101 and PPR1, respectively). Cyclic voltammograms were recorded on a Houston Instruments Omnigraphic 2000 X-Y recorder.

Before each experiment the electrode was polished to a mirror finish with alumina of successively smaller particle sizes, starting with 1 μm and ending with 0.05 μm. The solution was deaerated by bubbling purified nitrogen through the cell. After deaeration cyclic voltammograms were run with the electrode pulled back from the window. For spectroelectrochemical experiments, the electrode was pushed forward and the plane surface located about 1–2 μm from the window. Single beam spectra, each the average of 128 scans at 4 cm^{-1} resolution, were collected first at 0.0 V (E_1) and then at a series of increasing positive or negative potentials (E_2). Ratioing any pair of spectra gave a difference spectrum for the two potentials. Results are plotted as $\Delta R/R = (R_2 - R_1)/R_1$ vs. wavenumber, where R_1 and R_2 are the reflectivities at E_1 and E_2. Bands with positive $\Delta R/R$ values are

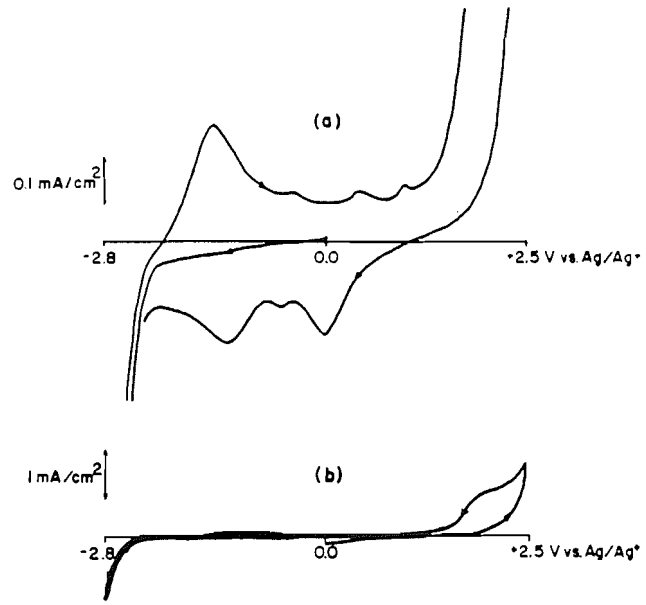

FIG. 1. Cyclic voltammograms for acetonitrile solution of TBAF (0.1 *M*) at a platinum electrode. The potential was swept negative from 0.0 to −2.8 V vs. Ag/Ag^+ (0.01 *M*), then positive to +2.5 V, and then negative again. The sweep rate was 100 mV s^{-1}. The current scale in (*a*) is 10 times more sensitive than in (*b*).

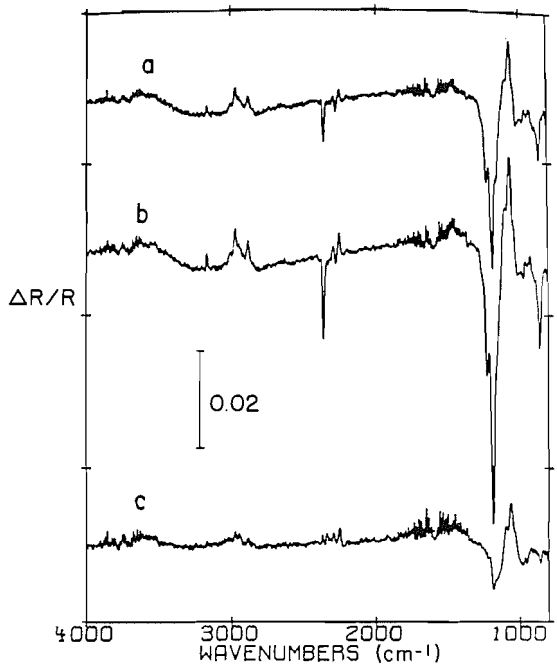

FIG. 2. SNIFTIRS spectra for TBAF (0.1 *M*) in acetonitrile at Pt. Reference spectrum taken at 0.0 V, sample spectra at (*a*) +2.0 V, then (*b*) 0.0 V, then (*c*) −2.0 V.

due to species in the solution at E_1 that are not present at E_2, while the converse is the case for bands with negative values of $\Delta R/R$.

Acetonitrile (Burdick and Jackson, nominal water content <0.005%) was used as received. TBAF (Chem-Biochem Research) was recrystallized from dichloromethane/diethyl ether. Anthracene (Aldrich) and pyrene (Eastman) were sublimed before use. Water was triply distilled.

Results and discussion

(i) Anodic reactions in dry TBAF/acetonitrile

Figure 1 shows cyclic voltammograms of the TBAF (0.1 *M*)/acetonitrile electrolyte system, including the potential region where anodic and cathodic breakdown commence. The potentials at which current densities of 1 mA cm^{-2} of anodic or cathodic current flows, E_f^c and E_f^a, are ca. −2.9 and +2.5 V. E_f^a is rather lower than the +2.91 V measured by Fleischmann and Pletcher (6) for oxidation of BF_4^-, and in fact two processes seem to be taking place at positive potentials. There is a broad plateau between ca. +1.5 and +2.3 V, and this is followed by a current which increases steadily with potential beyond +2.3 V.

A series of SNIFTIRS spectra were taken with base potential 0.0 V where, in a fresh solution, no electrochemical reaction occurs. A potential step to +1.0 V resulted in no new infrared bands, which indicates that there is no electrochemical reaction occurring at this potential. A potential step to +2.0 V, however, gave the difference spectrum shown in Fig. 2*a*. This spectrum includes vibrational bands from the Bu_4N^+, BF_4^-, and CH_3CN species, and the observed frequencies are compared with frequencies and assignments from the literature in Table 1. There are four bands in the C—H stretching region with positive $\Delta R/R$ values. Three of these (2966, 2943, and 2800 cm^{-1}) belong to the *n*-Bu_4N^+ species. The positive values of the absorbances indicate that there is less of this species at this potential (+2.0 V) relative to 0.0 V. The reason for this is well known: any anodic reaction will generate an excess of positive charge in the region close to the electrode surface. To maintain electroneutrality positive ions then must migrate out of the thin layer and negative ions into it. One might therefore expect to observe corresponding bands (negative $\Delta R/R$ values) from BF_4^-, but the bands for this species that are observed have positive values of $\Delta R/R$ indicating that the BF_4^- is being consumed in the electrode reaction at +2.0 V. (BF_4^- is tetrahedral, with only one fundamental ir-active stretching mode, but three or more bands are observed around 1000–1100 cm^{-1} because of the 20% and 80% natural abundances of ^{10}B and ^{11}B, and because of Fermi resonance with the overtone of the antisymmetric BF_2 deformation near 520 cm^{-1} (8, 9)). Positive absorption bands in the difference spectrum at 3163, 2999, 2287, 2249, and 918 cm^{-1} indicate that acetonitrile also reacts at +2.0 V. The frequencies of the 2287 and 2249 cm^{-1} bands are probably affected slightly by the negative band at 2272 cm^{-1}.

The products formed at +2.0 V absorb in the C≡N and B—F stretching regions. In particular, there is a sharp negative band at 2257 cm^{-1} and very strong negative bands at 1227, 1190, 1163, and 856 cm^{-1}. Although CO_2 has been detected as one of the major oxidation products of wet acetonitrile/BF_4^- (3), this cannot be the origin of the 2357 cm^{-1} band observed here, because bubbling CO into the solution and oxidizing it at potentials above +2.0 V gave the negative band for CO_2 formation at 2341 cm^{-1}, as expected. The high C≡N stretch frequency and loss of BF_4^- suggest that the 2357 cm^{-1} band arises instead from the adduct of CH_3CN and BF_3, and the negative bands from Fig. 2*a* indeed agree quite well with the literature infrared (10–12) and Raman (10) spectra of this adduct (Table 2).

The C≡N stretch frequency of the complex in acetonitrile is very close to that of the complex in benzene (11) and in methylene chloride (12). The large (100 cm^{-1}) increase in C≡N stretch frequency due to coordination has been attributed to an increase in the C—N force constant upon donation of the somewhat antibonding nitrogen lone pair to the empty BF_3 π orbital (12). The increase in intensity of this band upon coordination has been attributed to a contribution to the C≡N

stretch vibration from stretching of the highly polar B—N bond. The C≡N stretch frequency of the complex in solution is 20 cm^{-1} lower than that of the solid adduct at −196°C (10), because of the difference in temperature, and because of lattice interactions and symmetry changes in the solid state.

There are also some differences between the solution and solid state spectra in the B—F stretching region. In particular, the solid adduct has a strong Raman band at 856 cm^{-1}, assigned to the ν_5 symmetric BF_3 stretching mode, which could not be observed in the infrared (10). Instead there were strong infrared bands at 904 and 884 cm^{-1}, which were assigned to factor group splitting of the ν_5 mode. The adduct in solution has a strong infrared band at 856 cm^{-1}, but no strong bands around 900 cm^{-1}, which would seem to confirm that the solid state ir spectrum is affected by interactions between neighboring adducts, and that the assignment of the 856 cm^{-1} band to ν_5 in ref. 10 is correct. The variation in frequency of the ν_{11} antisymmetric BF_3 stretching mode (1208 cm^{-1} in the solid, 1227 cm^{-1} in solution) may have the same origin.

It is clear that CH_3CN and BF_4^- react at +2.0 V to form CH_3CNBF_3. Determining the nature of the other products, and the reason for breakdown of the solvent/electrolyte system at such a low potential, is more difficult. It is well known that BF_4^- acts as a fluorinating agent in acetonitrile at +2.0 V (13). The initial step in the reaction is believed to be the reaction of any previously formed cation radical which then reacts with BF_4^-, or with another fluorinating agent derived from it. The negative bands at 2272 cm^{-1} and at 959 cm^{-1} are shifted from the corresponding actonitrile modes in a direction that would be expected the cation of acetonitrile. Fluoroacetonitrile is most likely formed in the reaction; the ir spectrum of this species is so similar to acetonitrile (14, 15) that at the resolutions required in this technique we do not expect to see the difference spectrum for it. (The C≡N stretch frequencies are the same to within 0.5 cm^{-1}.) However, HF should be a product of this reaction, and the weak characteristic 3475 cm^{-1} absorption (16) for this species has been observed in experiments where several thousand spectra are signal averaged.

The evidence is strong that hydrogen sorbed in the platinum electrode plays the dominant role in the reaction mechanism of the solvent/electrolyte oxidation at positive potentials, just as it is known to do in the solvent/electrolyte reduction at negative potentials (*vide infra*). Hydrogen in platinum electrodes is oxidized at potentials greater than about +1.0 V to H^+ which diffuses into the reaction/diffusion layer near the surface of the electrode. The electrode then serves as Brønsted acid strong enough to protonate even the very weakly basic acetonitrile. The protonated acetonitrile then can extract F^- from BF_4^-, under the same mechanism as described above (13).

[1] $H(Pt) \rightarrow H^+ + e^-$

[2] $H^+ + CH_3CN \rightarrow CH_3CNH^+$

[3] $CH_3CNH^+ + BF_4^- \rightarrow CH_3CN + HF + BF_3$

[4] $BF_3 + CH_3CN \rightarrow CH_3CNBF_3$

Direct removal of F^- from BF_4^- by the strong acid H^+ at the electrode surface must also be considered. A product of this reaction is also HF, which as mentioned above, is observed.

Figure 2*b* shows the SNIFTIRS spectrum obtained by returning the potential to 0.0 V, the reference spectrum being that of Fig. 1*a*, also taken at 0.0 V. The bands from Bu_4N^+,

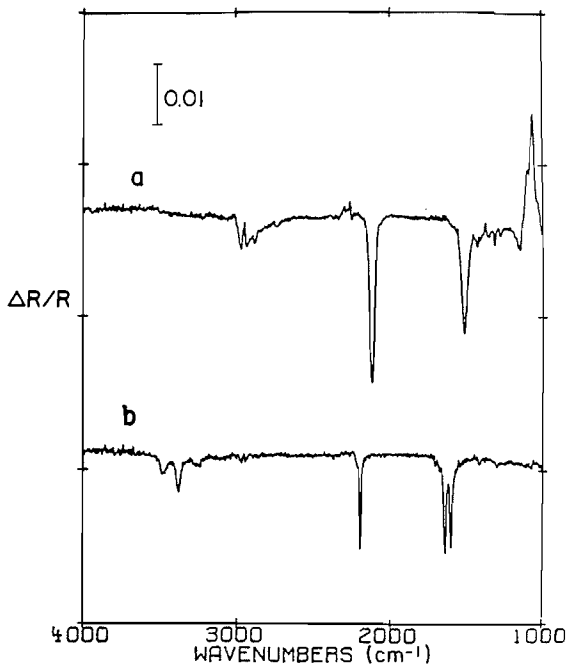

FIG. 3. SNIFTIRS spectra for TBAF (0.1 *M*) in acetonitrile at Pt. Reference spectrum taken at 0.0 V, sample spectra at (*a*) −3.0 V, then (*b*) 0.0 V.

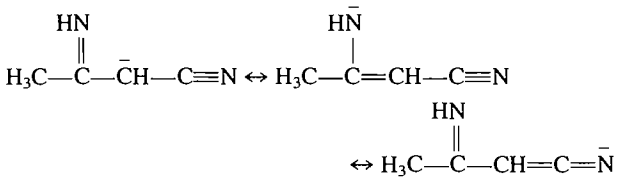
BF_4^-, CH_3CN, and CH_3CNBF_3 have increased in intensity, even though electron transfer is not taking place at this potential. This is a typical finding that results when an electron transfer reaction (such as that at +2.0 V) generates a species which reacts slowly with another species (cf. BF_4^-) in solution, and in which the reaction continues for some time after electron transfer has stopped. Making the electrode potential as negative as −2.0 V reverses the reaction to some extent (Fig. 2*c*).

(ii) Cathodic reactions in dry TBAF/acetonitrile

The single beam reference spectra shown in Fig. 3*a* and *b* were taken at 0.0 V in nominally dry acetonitrile/TBAF (0.1 *M*). The potential was changed to −3.0 V, where the sample spectrum in Fig. 3*a* was taken, and then changed back to 0.0 V, where the sample spectrum in Fig. 3*b* was taken. The spectrum in Fig. 3*b* shows only negative bands, at 3479(m), 3373(s), 3250(w), 2193(s), 1645(s), 1607(s), 1420(w), 1384(vw), and 1306(w) cm^{-1}, which correspond to the literature spectrum (17) of 3-aminocrotonitrile (3450, 3370, 3250, 2180, 1650, 1600, 1430, 1370, 1320, 1130, and 1030 cm^{-1}, KBr wafer). This agrees with the results of Pons and Khoo (4), who found mostly 3-aminocrotonitrile after isolating the products of bulk electrolysis at −3.3 V. In that work, it was proposed that the 3-aminocrotonitrile anion is formed at −3.3 V, and is protonated during workup. Figure 3*a* corroborates this result. The most prominent features of the spectrum are very strong negative bands at 2116 and 1516 cm^{-1}. There are weaker negative bands at 1427, 1315, 1275, and 1145 cm^{-1}. The 2116 cm^{-1} band can be assigned to the C≡N stretch of the 3-aminocrotonitrile anion,

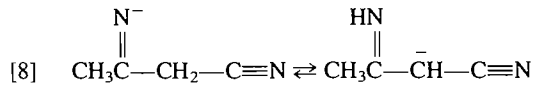


the frequency of which is lowered by delocalization of the negative charge. A Nujol mull of the sodium salt of 3-aminocrotonitrile gives a band at 2120 cm^{-1} (18), and in DMSO solution it absorbs at 2110 cm^{-1} (18).

The reaction mechanism was shown (4) to involve deprotonation of acetonitrile by hydride ion followed by nucleophilic attack of the resulting anion on another molecule of acetonitrile:

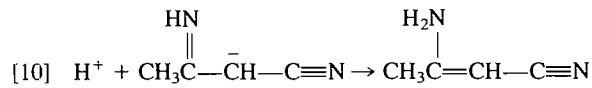
[5] $H(Pt) + e^- \rightarrow H^-$

[6] $H^- + CH_3CN \rightarrow H_2 + \bar{C}H_2CN$

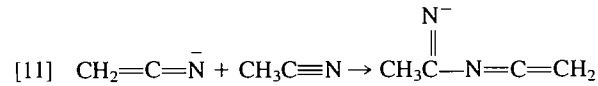


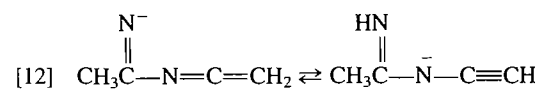
(It is well known that hydride ion is formed by reduction of hydrogen absorbed in the metal lattice; this is common in palladium, platinum, and nickel electrodes.) When the potential is returned to 0.0 V the 3-aminocrotonitrile anion is protonated, probably by oxidized hydrogen:

[9] $H_2 \rightarrow 2H^+ + 2e^-$



The intense band at 1516 cm^{-1} in Fig. 3*a* is probably due to the conjugated C=N stretch of the 3-aminocrotonitrile anion (there are no literature values for the spectrum of the anion below 1800 cm^{-1}). The band disappears upon addition of water to the system (see below), while the 2116 cm^{-1} band remains. The 1516 cm^{-1} band is most likely due to a product formed by a nucleophilic attack on the nitrogen of the acetonitrile anion (4):





This species decomposes to acetonitrile upon protonation since the only product at 0.0 V is 3-aminocrotonitrile.

At −3.0 V (Fig. 3*a*) there are also bands from both of the electrolyte ions and from the solvent (c.f. Table 1), which disappear when the potential is returned to 0.0 V (Fig. 3*b*). There are negative bands from Bu_4N^+ at 2964, 2928, and 2881 cm^{-1}, positive bands from BF_4^- at 1097, 1063, and 1036 cm^{-1}, and positive bands from CH_3CN at 2945, 2293, 2257, and 1377 cm^{-1}. The directions of all of these bands are consistent with the migration of BF_4^- out of, and of Bu_4N^- into, the thin optical reaction layer at the negative potential limit.

(iii) Cathodic reactions in a dry pyrene/TBAF/acetonitrile solution

The effect of adding pyrene (0.5 m*M*) to the TBAF (0.1 *M*) solution is shown in Fig. 4. The reference potential is again 0 V. At −2.0 V no difference spectrum is be observed (Fig. 4*a*), indicating no faradaic reaction occurring. At −2.5 V, which is 0.1 V negative of the half-wave potential of the pyrene/pyrene anion radical couple, negative bands appear at 1529, 1294, 1234, and 1159 cm^{-1}, which are due to absorption by the anion

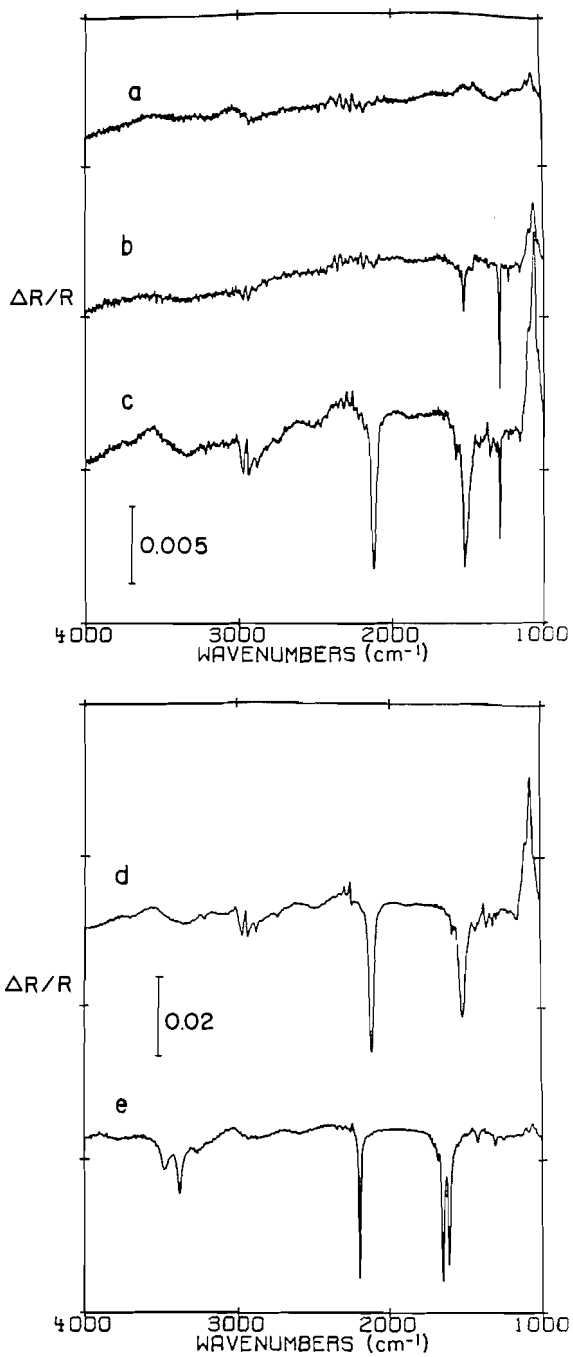

FIG. 4. SNIFTIRS spectra for pyrene (0.5 mM) and TBAF (0.1 M) in acetonitrile at Pt. Reference spectrum taken at 0.0 V, sample spectra at (a) −2.0 V, then (b) −2.5 V, then (c) −2.8 V, then (d) −3.0 V, then (e) 0.0 V.

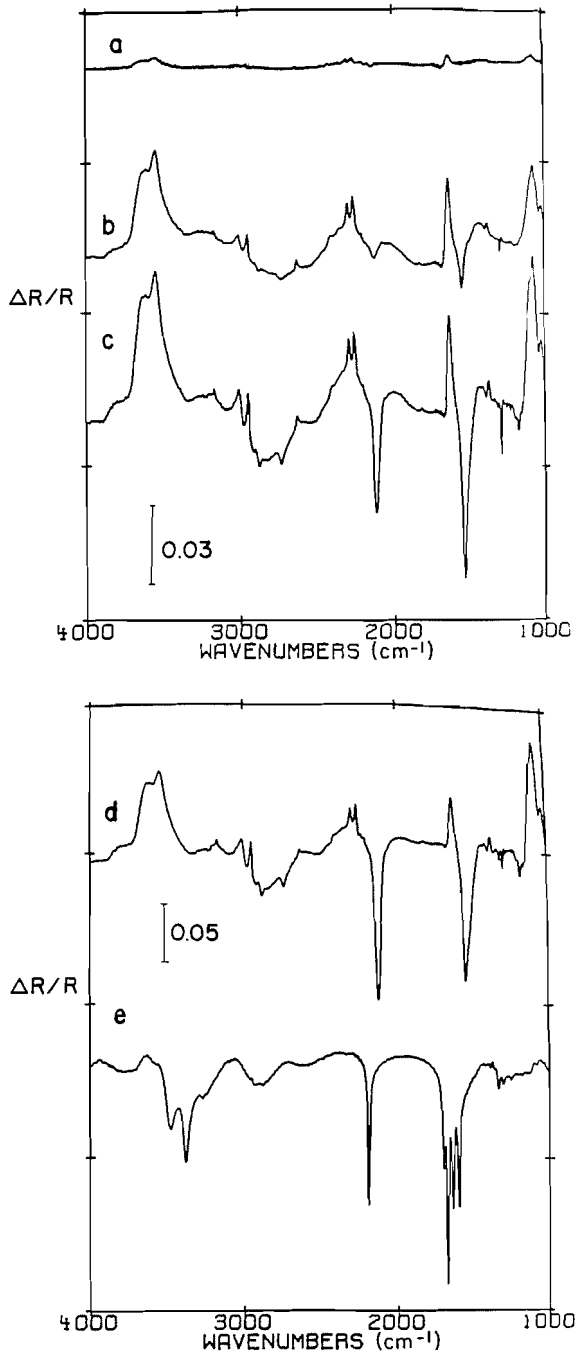

FIG. 5. SNIFTIRS spectra for acetonitrile solution of water (~0.1 M), pyrene (0.5 mM), and TBAF (0.1 M) at Pt. Reference spectrum taken at 0.0 V, sample spectra at (a) −2.0 V, then (b) −2.5 V, then (c) −2.8 V, then (d) −3.0 V, then (e) 0.0 V.

radical. Bands for acetonitrile, TBA^+, and BF_4^- also appear (Fig. 4b) due to differential migration as discussed above. At −2.8 V (Fig. 4c) solvent breakdown commences and strong negative bands at 2118 and 1528 cm^{-1} appear. There is a slight decrease in the intensities of the anion radical bands at 1294, 1234, and 1159 cm^{-1}. At −3.0 V the 2118 and 1528 cm^{-1} bands are very intense, and the bands from the pyrene anion radical have virtually disappeared. Returning the potential to 0.0 V results in the appearance of the spectrum for the acetonitrile reduction product 3-aminocrotonitrile, as in the system that did not contain pyrene. The disappearance of $pyrene^-$ at negative potentials is due to reduction of the anion to the dianion; the half-wave potential of the second reduction wave of pyrene is about 0.4 V more negative than the first (19).

(iv) Cathodic reactions in a wet pyrene/TBAF/acetonitrile solution

The spectra of a solution that is 0.1 M water, 0.5 mM pyrene, and 0.1 M TBAF in acetonitrile is shown in Fig. 5. The same reference spectrum, taken at 0.0 V, was used for all of the difference spectra. The spectra show that even at potentials as low as −2.0 V faradaic reaction is occurring, and the strong positive bands at 3610, 3540, and 1643 cm^{-1} indicate that water is one of the reactants. The main negative features are a

broad band around 2900 cm^{-1} and strong bands at 2120 and 1543 cm^{-1}. A negative band at 1294 cm^{-1} indicates that the pyrene anion radical is stable on the timescale of the experiment in the presence of water at −2.8 V. When the potential is returned to 0.0 V there are strong negative bands at 1709 and 1682 cm^{-1}, as well as the ubiquitous bands indicating 3-aminocrotonitrile formation.

The new bands at 1709 and 1682 cm^{-1} are assigned to acetamide, the literature values in acetonitrile solution having been reported at 1709 and 1684 cm^{-1} (20). The rest of the acetamide spectrum is very similar to that of 3-aminocrotonitrile, and will not be observed in these results. The strong negative band at 1543 cm^{-1} which appears at negative potentials is assigned to the anion of acetamide, the literature value of which is around 1500 cm^{-1} (20, 21). These spectra again confirm the results of Pons and Khoo (4), who found acetamide to be the major isolated product after bulk electrolysis in the presence of water, and suggested that the acetamide anion is formed at negative potentials by nucleophilic attack of OH^- on acetonitrile. The OH^- is formed in the reduction of water:

[13] $H_2O + e^- \rightarrow \frac{1}{2}H_2 + OH^-$

[14] $OH^- + CH_3C{\equiv}N \rightarrow CH_3C(N^-)—OH \rightleftarrows CH_3C(HN^-)=O$

When the potential is returned to 0.0 V, reoxidation of H_2 to H^+ and protonation of the anion form acetamide occurs (4). It can be seen by comparing Figs. 4 and 5 that the anion of 3-aminocrotonitrile is formed at less negative potentials in the presence of water. This suggests that OH^- acts as a base toward CH_3CN as well as a nucleophile, generating $[CH_3CN]^-$, which goes on to form $[CH_3C(NH)CHCN]^-$.

Chelation vs. non-chelation control in addition reactions of ethylmetallic reagents to acrolein dimer

SHANKAR M. SINGH AND ALLAN C. OEHLSCHLAGER
Department of Chemistry, Simon Fraser University, Burnaby, B.C., Canada V5A 1S6

Received August 13, 1987

SHANKAR M. SINGH and ALLAN C. OEHLSCHLAGER. Can. J. Chem. **66**, 209 (1988).

Reactions of 3,4-dihydro-2*H*-pyran-2-carboxaldehyde (acrolein dimer) with ethylmetallics based on lithium, titanium, and copper were examined for stereoselectivity. High selectivity (92:8) was found for non-chelation controlled addition yielding the *erythro* product when ethyllithium was employed in the presence of $BF_3 \cdot OEt_2$. High selectivity (89:11) for products of chelation controlled addition (*threo*) was observed for ethylcopper reagents in the presence of magnesium salts. Titanium reagents yielded mixtures rich in products of either chelation or non-chelation controlled addition depending on the titanium substituents. In no cases were stereoselectivities obtained with titanium reagents better than those obtained by use of the aforementioned lithium and copper reagents.

SHANKAR M. SINGH et ALLAN C. OEHLSCHLAGER. Can. J. Chem. **66**, 209 (1988).

Dans le but d'évaluer leurs stéréosélectivités, on a étudié les réactions du dihydro-3,4 2*H*-pyrannecarboxaldéhyde-2 (dimère de l'acroléine) avec des dérivés éthylmétalliques du lithium, du titane et du cuivre. Lorsqu'on utilise de l'éthyllithium en présence de $BF_3 \cdot OEt_2$, on observe une sélectivité élevée (92:8) pour cette addition qui n'est pas contrôlée par la chélation et qui conduit au dérivé *érythro*. Lorsqu'on utilise des réactifs d'éthyl-cuivre en présence de sels de magnésium, on observe aussi une sélectivité élevée (89:11) pour les produits de cette addition qui est contrôlée par la chélation (*thréo*). Les réactifs du titane fournissent des mélanges qui sont riches en produits provenant d'additions qui sont (ou qui ne sont pas) contrôlées par la chélation; les résultats dépendent de la nature des substituants portés par le titane. Les sélectivités observées avec les dérivés du titane ne sont jamais supérieures à celles obtenues avec les réactifs du lithium ou du cuivre qui ont été mentionnés antérieurement.

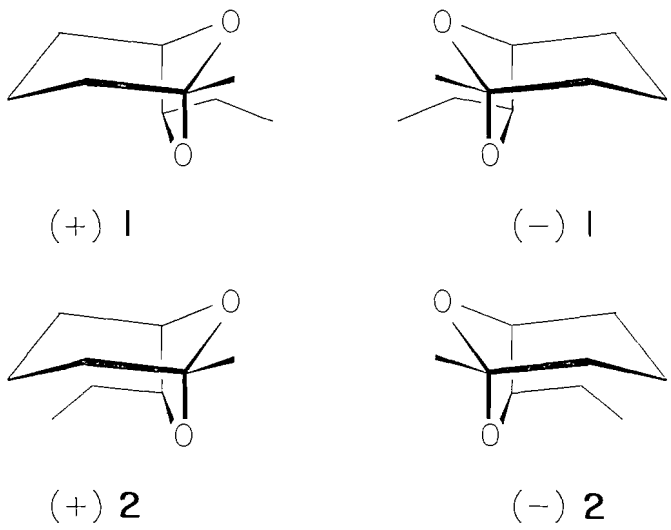
The *exo*- and *endo*-brevicomins, **1** and **2** respectively, are aggregation pheromones for several species of economically important bark beetles in the genus *Dendroctonus* (1) and *Dryocetes*.[1] For all species except *Dendroctonus frontalis*, the southern pine beetle, racemic formulations of the brevicomins are attractive in the field.[2]

Although there are many reported syntheses of racemic **1** (2) and **2** (2*b*,*h*,*i*,*v*, 3) as well as the chiral isomers of **1** (4, 5) and **2** (4*c*,*p*, 5), few rival the approach of Bhupathy and Cohen (2*aa*, 3*d*) in simplicity and versatility. In this approach acrolein dimer, **3**, is reacted with ethylmetallic reagents, **4**. Under the conditions of chelation, control mixtures of **5** and **6** are formed that are rich in **5**. When non-chelation conditions are utilized, **6** is the principal isomer. They were able to obtain mixtures rich in **5** with Et_2Zn (**5**:**6** = 85:15) and EtMgBr (**5**:**6** = 70:30) while reaction of **3** with EtLi in ether (**5**:**6** = 28:72), alone or with added HMPA (**5**:**6** = 12:88) or TMEDA (**5**:**6** = 20:80), gave mixtures rich in **6**. In the latter reaction subsequent deprotonation at C-6 and alkylation with methyl iodide to yield **7** could be conducted in the same flask. Isomeric alcohol **8** was similarly produced from **5** isolated by flash chromatography.



The purpose of the present investigation was to examine the effect of organometallic reagents and reaction conditions on the proportion of **5** and **6** obtained from reaction of **3**. The goal was to achieve conditions wherein **5** was the only diastereoisomer and wherein **6** was the only diastereoisomer.

Results and discussion

We carried out addition of ethylmetallic reagents **4** to acrolein dimer **3**, using various reaction conditions. Products **5** and **6** were isolated and the ratio of **5** to **6** was determined by capillary gas chromatographic analysis. The results are summarized in Table 1.

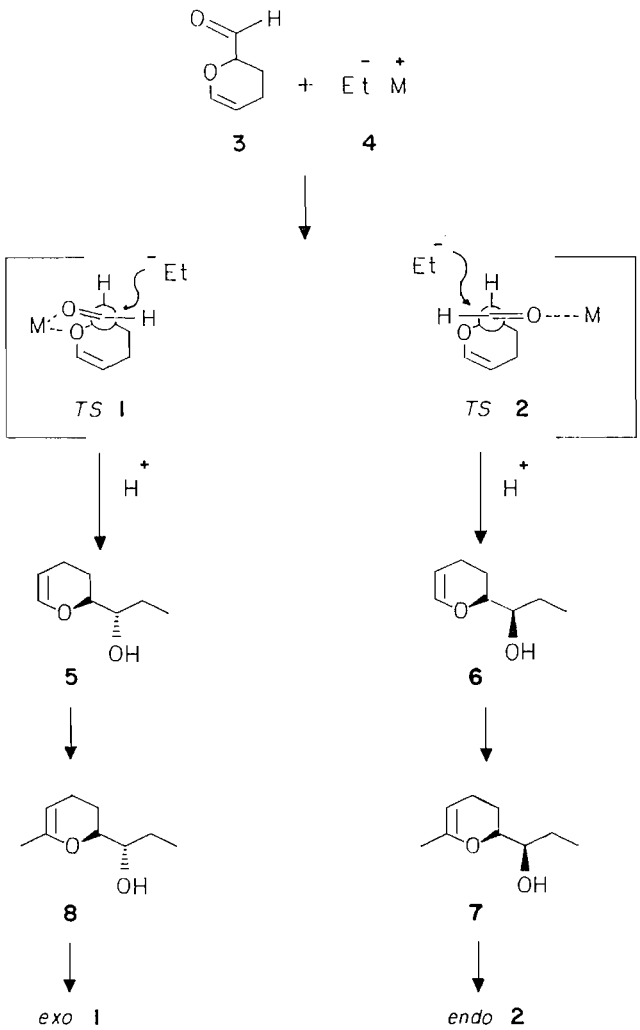
Addition of organometallic reagents to α-alkoxycarbonyls such as **3** is most easily induced to yield *threo* products **5** by conducting the reaction in the presence of Lewis-acidic reagents that are capable of forming a chelate between the substrate oxygens (*TS* **1**). Attack by the organometallic reagent from the least hindered side of the chelated carbonyl favors the formation of **5** (chelation control, ref. 6).

Attack of α-alkoxycarbonyl compounds from the least hindered side of the conformation in which the polar groups are *anti* (*TS* **2**) would yield **6** (non-chelation control, ref. 7).

Attainment of high stereoselectivity under non-chelation control requires conditions that induce a dramatic preference for the *anti* conformation of dipolar substrates (8). With few

[1] *exo*-Brevicomin is an aggregation pheromone from *Dryocetes confusus*, western balsam bark beetle, a pest of subalpine fir in the Pacific Northwest of America, ref. 12. *endo*-Brevicomin is an aggregation pheromone for *Dryocetes autographus*, a serious pest of Norway spruce, ref. 5*a* and references cited therein.

[2] *Dendroctonus frontalis* utilizes (+) **2** as an aggregation pheromone and (−) **2** as an antiaggregation pheromone, ref. 13.



SCHEME 1

exceptions alkyllithiums add to α-alkoxycarbonyl compounds to yield products of non-chelation control. We found that addition of ethyllithium to **3** in THF proceeded in a stereoselective fashion to yield **5** and **6** in a ratio of 11:89 (entry 1).

Addition of TMEDA to the reaction had little effect on the stereoselectivity (**5**:**6** = 19:81, entry 2). These results compare favorably with those of Bhupathy and Cohen (2*aa*). They achieved a **5**:**6** ratio of 28:72 in ether, and using HMPA (**5**:**6** = 12:88) or TMEDA (**5**:**6** = 20:80) as cosolvent did not improve selectivity.

Next we conducted the reaction of ethyllithium with **3** in the presence of $BF_3 \cdot OEt_2$ (entry 3). This reaction gave a significantly improved stereoselectivity (**5**:**6** = 8:92), presumably due to increased preference for the *anti* conformation of **3**.

Strong chelation control has been reported for alkyltitanium addition to α-alkoxycarbonyls wherein the titanium has significant Lewis acid character (8). Thus alkyltitanium trichlorides and dialkyltitanium dichlorides readily form octahedral complexes with donor atoms of solvent or substrate (8) and are very effective in delivering alkyl residues under conditions of chelation control.

In the present study we found that **3** reacted with ethyltitanium trichloride (**9**) in CH_2Cl_2 at −78°C to give only polymeric products (entry 4). Treatment of **3** with diethyltitanium dichloride (**10**) gave a good yield of product in which the isomer

$C_2H_5TiCl_3$ **9** $(C_2H_5)_2TiCl_2$ **10** $C_2H_5Ti(OiPr)_3$ **11**

of chelation control predominated (**5**:**6** = 76:24) but selectivity was not outstanding (entry 5).

Changing the ligands of alkyltitaniums from chloride to alkoxide produces reagents significantly reduced in Lewis acid properties. Such reagents deliver alkyl residues to α-alkoxycarbonyl compounds under conditions of non-chelation control (8, 9). Because of the steric bulk of alkylalkoxy reagents such as **11** we felt they would efficiently produce **6** from **3**. Reaction of **11** with **3** in both THF and ether (entries 6 and 7) gave only low (30–35%) yields of addition (**5**:**6** ≈ 20:80) because of competing reduction of **3** to 3,4-dihydro-2*H*-pyran-2-methanol. The two most attractive mechanisms for this latter reaction are a Merwein–Pondorff type reaction or elimination of ethylene followed by titanium hydride reduction. The yields and stereoselectivities of addition of **11** to **3** did not warrant further investigation.[3]

$(C_2H_5)_2Cu(I)Li$ **12** $(C_2H_5)_2Cu(I)MgBr$ **13** $C_2H_5Cu(I)Li$ **14**

$C_2H_5Cu(I)MgBr$ **15** $C_2H_5Cu(CN)MgBr$ **16**

Cuprate addition to α-alkoxycarbonyls gives products expected of chelation control (9, 10). Addition of the diethyl cuprates (**12** and **13**) as well as ethylcoppers (**14**, **15**, and **16**) to **3** gave products of chelation control (entries 8–22).

We prepared the diethylcuprates **12** and **13** and ethylcoppers **14–16** by treatment of ethyllithium or ethylmagnesium bromide with CuI or CuCN. Treatment of **3** with **12** in THF yielded **5** and **6** in a 1:1 ratio (entry 8). Addition of HMPA to this reaction (entry 9) gave, as expected, a higher proportion of non-chelation control product (**6**). Addition of $BF_3 \cdot OEt_2$ to the reaction of **12** with **3** (entry 10) surprisingly increased the proportion of chelation control product. A possible explanation for this effect is that the species in this solution is the boron "ate" complex **17** as suggested by Yamamoto (11). In this reaction, the copper cation would be the presumptive chelating ion.

Reaction of magnesium cuprate **13** with **3** gave higher proportions of products of chelation control than the corresponding lithium cuprate **12** (compare entry 8 with 11 and 12). Addition of magnesium bromide (9) to the reaction of **13** and **3** only

$$(C_2H_5)_2CuLi + BF_3 \rightleftharpoons (C_2H_5\bar{B}F_3)(LiCu^+C_2H_5)$$
12 **17**

slightly increased the proportion of product of chelation control (entry 13).

Finally we investigated the addition of ethylcopper reagents **14–16** to **3**. As with diethyl lithium cuprate (**12**), the ethylcopper lithium reagent (**14**) showed very low selectivity (**5**:**6** = 1:1, entry 14). Addition of $BF_3 \cdot OEt_2$ to this reaction increased the selectivity in favor of chelation controlled addition (**5**:**6** = 74:26, entry 15).

Changing the metal cation from lithium to magnesium dramatically increased the proportion of products of chelation control. Thus, reaction of **3** with **15** gave **5**:**6** = 88:12 (entry 16). Addition of $BF_3 \cdot OEt_2$ (entry 17) or magnesium bromide

[3]Bhupathy and Cohen reported that addition of titanium reagents to **3** gave low yields of addition products, but did not report formation of other products, ref. 2*aa*.

TABLE 1. Reaction of ethylmetallic reagents with 3,4-dihydro-2*H*-pyran-2-carboxaldehyde (**3**)

Entry	EtM	Solvent	Temperature (°C)	Yield[a] (%)	Product ratio[b] (**5**:**6**)
1	EtLi	THF	−78→0	(81)	11:89
2	EtLi, TMED	THF	−78→0	(85)	19:81
3	EtLi, $BF_3 \cdot OEt_2$	THF	−78→0	(66)	8:92
4	$EtTiCl_3$	CH_2Cl_2	−78→−20	—	—
5	Et_2TiCl_2	CH_2Cl_2	−78→−20	(56)	76:24
6	$EtTi(OiPr)_3$	THF	−50→RT	(35)[c]	21:79
7	$EtTi(OiPr)_3$	Ether	−50→RT	(30)[c]	19:81
8	$(Et)_2Cu(I)Li$	THF	−78→0	89	55:45
9	$(Et)_2Cu(I)Li$	THF, HMPA	−78→0	88	25:75
10	$(Et)_2Cu(I)Li$, $BF_3 \cdot OEt_2$	THF	−78→0	64	72:28
11	$(Et)_2Cu(I)Mg$	THF, Me_2S	−78→0	91	68:32
12	$(Et)_2Cu(I)Mg$	Ether, Me_2S	−78→0	88	71:29
13	$(Et)_2Cu(I)Mg$, $MgBr_2$	THF, Me_2S	−78→0	75	80:20
14	EtCu(I)Li	THF, Me_2S	−78→0	75	50:50
15	EtCu(I)Li, $BF_3 \cdot OEt_2$	THF, Me_2S	−78→0	50	74:26
16	EtCu(I)MgBr	THF, Me_2S	−78→0	(80)	88:12
17	$EtCu(I)MgBr \cdot BF_3$	THF, Me_2S	−78→0	81	86:14
18	EtCu(I)Mg, $MgBr_2$	THF, Me_2S	−78→0	81	89:11
19	EtCu(I)MgBr	Ether, Me_2S	−78→0	76	83:17
20	EtCu(I)MgBr	CH_2Cl_2	−78→0	82	76:24
21	EtCu(I)MgBrCN	THF, Me_2S	−78→0	78	76:25

[a]Capillary gc yield. Yield in the parentheses refers to isolated yield.
[b]The product ratios were determined by capillary gc.
[c]The reaction of ethyltitanium triisopropoxide with **3** also gave 3,4-dihydro-2*H*-pyran-2-methanol in 30 and 40% yields in THF and ether, respectively, along with the desired product.

(entry 18) to this reaction did not dramatically alter the preference for formation of products of chelation control, whereas changing the solvent from THF to ether or CH_2Cl_2 lowered preference for this mode of reaction (entries 19 and 20). Finally, comparison of entries 16 and 21 reveals that the presence of cyanide counterion **16** has a deleterious effect on chelation control. Overall, the simplest procedure for obtaining chelation control addition is that described in entries 16–18. These results are equivalent to those reported by Jefford *et al.* (10) for the addition of the *n*-decyl analog of **15** to **3** in which the chelation control to non-chelation control product ratio was 90:10. The present results are marginally better in favor of chelation control than those reported by Bhupathy and Cohen (2*aa*) for addition of diethylzinc to **3** (**5**:**6** = 85:15).

Experimental

Hewlett–Packard 5880A and 5890A gas chromatographs fitted with capillary inlet systems, flame-ionization detectors, and WCOT columns (15 or 30 m × 0.25 mm i.d.) of glass or fused silica were employed for analyses by gas–liquid chromatography (gc). Columns were coated with OV-101, SP-2100, or DB-1 liquid phases. Injection port and detector temperatures were 260 and 275°C, respectively. Helium was the carrier gas.

Low resolution mass spectra were obtained on a Hewlett–Packard 5985B coupled gas chromatograph – mass spectrometer using electron-impact ionization at 70 eV or chemical ionization (CI) with isobutane as the ionizing gas. The ^{1}H nmr spectra were recorded in $CDCl_3$ on a Bruker 400 WM spectrometer. The gc–ir spectra were recorded on a Bruker IFS-85 spectrophotometer. All reactions were run in flame-dried glassware under a positive pressure of nitrogen.

Rotary evaporation at water aspirator pressure was employed to concentrate or remove solvent from solutions obtained by extractive work-up of reactions. Column chromatography was performed by the flash chromatography method on silica gel (Kieselgel 60, 40–63 μm, E. Merck, Darmstadt). Solvents were distilled before use. Tetrahydrofuran (THF) was distilled from sodium benzophenone ketyl prior to use. Dichloromethane was distilled over P_2O_5 and stored over 4 Å molecular sieves. Hexamethylphosphoramide (HMPA), *N,N,N′,N′*-tetramethylethylenediamine (TMEDA), and $BF_3 \cdot OEt_2$ were distilled over calcium hydride. Diethylzinc and chlorotitanium triisopropoxide were purchased from Aldrich Chemical Co., and 3,4-dihydro-2*H*-pyran-2-carboxaldehyde (**3**) was purchased from Fluka, AG Chem.

*Reaction of ethyllithium with 3,4-dihydro-2*H*-pyran-2-carboxaldehyde (**3**)*

The following procedure is representative. To a mixture of **3** (0.7 g, 6.25 mmol) in THF (15 mL) was added $BF_3 \cdot OEt_2$ (1.15 mL, 9.37 mmol) at −78°C and the reaction mixture was stirred for 15 min. Ethyllithium (1.4 M in ether) (6.7 mL, 9.37 mmol) was added dropwise along the inner wall of the flask. After addition, the reaction mixture was stirred for 1 h at −78°C, then warmed to 0°C over 1 h. Ice-cold 1 M NaOH solution was added until the reaction mixture became basic. The organic layer was separated and the aqueous layer was extracted with ether (5 × 25 mL). The combined organic layers were washed twice with brine, dried (Na_2SO_4), and 0.5 mL of triethylamine added to prevent cyclization. Solvent was removed under partial vacuum (10–20 Torr; 1 Torr = 133.3 Pa). The crude product was flash chromatographed (ethyl acetate: *n*-hexane, 1:4) to provide pure **5** and **6** in 66% yield (0.57 g). The gc/ir of **6** gave (vapor): 3628, 3072, 2970, 2937, 1651, 1387, 1242, 1074, 970, and 729 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 1.0 (t, 3H, methyl, J = 7.5 Hz), 1.41–1.60 (m, 2H, methylene), 1.68–1.87 (m, 2H, C(3)), 1.95–2.13 (m, 3H, C(4), OH), 3.65 (dt, 1H, methine, J = 8.5, 4 Hz), 3.73 (ddd, 1H, C(2), J = 10.5, 4, 2.5 Hz), 4.68 (m, 1H, C(5)), 6.38 (dt, 1H, C(6), J = 6, 2 Hz); for product **5**, δ: 3.47 (1H, methine), 3.65 (1H, C(2); ms, *m/e* (%, rel. int.): 142(14.5%), 124(2%), 114(5%), 95(27%), 83(100%), 70(23%), 55(59%).

Reaction of diethyltitanium dichloride with 3

Diethylzinc (1.15 mL, 11.25 mmol) was added dropwise to a solution of titanium tetrachloride (1.2 mL, 11.25 mmol) in CH_2Cl_2 (75 mL). After addition, the reaction mixture was stirred for 15 min. Aldehyde **3** (0.56 g, 7.5 mmol) in CH_2Cl_2 (10 mL) was added dropwise and the reaction mixture was stirred for 7 h at −78°C to −20°C. The reaction mixture was poured into excess 1 M NaOH solution, filtered through Celite, and the aqueous layer was extracted with ether (5 × 30 mL). The combined ether extract was washed with brine and dried (Na_2SO_4). The crude product obtained from the removal of ether was flash chromatographed to yield **5** and **6** (0.41 g, 56%).

Reaction of ethyltitanium triisopropoxide with 3

To a solution of chlorotitanium triisopropoxide (4.8 mL, 20 mmol) in THF (40 mL) was added ethyllithium (1.4 M in ether) (14.28 mL, 20 mmol) at −50°C. The reaction was stirred for 0.5 h, then aldehyde **3** (1 g; 8.92 mmol) in THF (10 mL) was added at −50°C. The reaction mixture was warmed to room temperature over 12 h, then poured into excess ice-cold NaOH and filtered through Celite. The organic layer was separated and the aqueous layer was extracted with ether (5 × 30 mL). The combined organic layer was washed with brine and dried (Na_2SO_4). Solvent was removed to give crude product, which was flash chromatographed to provide **5** and **6** (0.45 g, 35%) as well 3,4-dihydro-2*H*-pyran-2-methanol (0.3 g, 30%). The identity of the products was confirmed by ir and nmr spectra, and gc coinjection with authentic samples.

Reaction of diethyl cuprates with 3

Diethyl cuprates were prepared by the addition of either ethyllithium or ethylmagnesium bromide to copper(I) iodide.

The following procedure is representative. To a mixture of copper(I) iodide (1.42 g, 7.5 mmol) in THF (16 mL) and Me_2S (4 mL) was added ethylmagnesium bromide (5 mL, 15 mmol) at −78°C. After addition, the reaction mixture was stirred for 10 min and then **3** (0.56 g, 5 mmol) in THF (6 mL) was added dropwise and the contents were stirred for 2 h at −78°C to 0°C. The reaction was poured into an excess of ice-cold 1 M NaOH. The aqueous layer was extracted with ether (5 × 30 mL). The combined organic layer was washed with brine, dried (Na_2SO_4), and analyzed by gas chromatography.

Reaction of ethylcoppers with 3

The following method is representative. Ethylmagnesium bromide (5 mL, 15 mmol) was added dropwise to a mixture of copper(I) iodide (3.22 g, 17 mmol) in THF (32 mL) and dimethylsulfide (8 mL) at −78°C. After addition, the reaction mixture was stirred for 15 min. Acrolein dimer (1.12 g, 10 mmol) in THF (10 mL) was added and the reaction mixture was stirred for 3 h at −78°C to 0°C. The mixture was poured into ice-cold 1 M NaOH. The aqueous layer was extracted with ether (5 × 30 mL). The combined extract was washed with brine, dried (Na_2SO_4), and the solvent removed to afford a crude product, which was purified by flash column chromatography to provide **5** and **6** in 80% yield (1.14 g). For product **5**, gc/ir (vapor): 3626, 3074, 2937, 1653, 1394, 1240, 1070, and 980 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.0 (t, 3H, methyl, J = 7.5 Hz), 1.42–1.68 (m, 2H, methylene), 1.68–1.89 (m, 2H, C(3)), 1.95–2.15 (m, 2H, C(4)), 2.23 (d, 1H, OH, J = 5 Hz), 3.47 (dt, 1H, methine, J = 8.5, 5.8 Hz), 3.65 (ddd, 1H, C(2), J = 10.5, 5.8, 2.5 Hz), 4.68 (m, 1H, C(5)), 6.37 (dt, 1H, C(6), J = 6, 2 Hz); product **6**, δ: 3.65 (1H, methine) and 3.74 (1H, C(2)); ms, m/e (%, rel. int.): 142(21%), 124(2%), 114(5%), 95(30%), 83(100%), 70(31%), and 55(38%).

Photochemistry of cyclic α-hydroxy ketones. I. The nature and genesis of the photoproducts from steroidal 5-hydroxy 6-keto steroids and related compounds[1]

SHIRLEY STIVER AND PETER YATES
Lash Miller Chemical Laboratories, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received September 9, 1987

SHIRLEY STIVER and PETER YATES. Can. J. Chem. **66**, 214 (1988).

Photolyses of 5-hydroxy-5α- and 5β-cholestan-6-one and their 3β-acetoxy- and 3β-benzyloxy derivatives in benzene or ethanol proceed stereospecifically with retention of configuration at C-5 to give the corresponding lactones, 6-oxa-B-homocholestan-7-ones. Photolyses of 3β-acetoxy-7α-deutero-5-hydroxy-5α- and 5β-cholestan-6-ones also proceed stereospecifically to give the corresponding 5-deutero lactones. 3β-Acetoxy-5-deuteroxy-5α- and 5β-cholestan-6-one give on irradiation 1:3 and 7:1 mixtures, respectively, of the corresponding 7aα- and 7aβ-deutero lactones. Irradiation of 3β-acetoxy-5-methoxy-5α-cholestan-6-one in ethanol leads to the stereoselective formation of ethyl 3β-acetoxy-5-methoxy-5,6-seco-5α-cholestan-6-oate, while that of 3β-acetoxy-5α-cholestan-6-one gives mainly photoreduction products. These observations are interpreted in terms of α-cleavage of the C-5—C-6 bond of the ketols to give alkyl acyl diradicals that undergo hydrogen transfer to give hydroxy ketenes, which then form the lactones. It is proposed that retention of configuration at C-5 results from two major factors—the nonplanar geometry of the hydroxyalkyl radical center, and fast hydrogen transfer in the diradical, the latter resulting from restricted rotation about the C-9—C-10 bond. The specific transfer of the 7α-deuterium atom in the 7α-deutero ketols is attributed to these factors and to the preferred direction of opening to the diradical on α-cleavage. The *O*-deuterium labelling results are interpreted in terms of product development control in the conversion of the hydroxy ketenes to the lactones and are in accord with restricted rotation about the C-9—C-10 bond. The photolysis of 3β-acetoxy-5-amino-5α-cholestan-6-one proceeds stereoselectively to give the 5β-lactam analogue of the 5β-lactone formed from the analogous 5α-ketol.

SHIRLEY STIVER et PETER YATES. Can. J. Chem. **66**, 214 (1988).

La photolyse des hydroxy-5 5α- et 5β-cholestanones-6 et de leurs dérivés acétoxy-3β et benzyloxy-3β, dans le benzène ou l'éthanol, se produit d'une façon stéréospécifique, avec rétention de configuration en C-5, pour conduire aux lactones correspondantes, oxa-6 B-homocholestanones-7. La photolyse des acétoxy-3β deutéro-7α hydroxy-5 5α- et 5β-cholestanones-6 se produit aussi d'une façon stéréospécifique pour conduire aux lactones correspondantes deutéro-5. Par irradiation, les acétoxy-3β deutéroxy-5 5α- et 5β-cholestanones-6 conduisent respectivement à des mélanges 1:3 et 7:1 des lactones correspondantes deutéro-7aα et -7aβ. L'irradiation de l'acétoxy-3β méthoxy-5 5α-cholestanone-6, dans l'éthanol, conduit à la formation stéréosélective de l'acétoxy-3β méthoxy-5 séco-5,6 5α-cholestanoate-6 d'éthyle alors que celles de l'acétoxy-3β 5α-cholestanone-6 donne principalement des produits de photoréduction. On interprète ces résultats en fonction d'un clivage-α de la liaison C-5/C-6 des cétols qui fournit des diradicaux alkyle acyle qui subissent des transferts d'hydrogène conduisant des hydroxy-cétènes qui forment alors des lactones. On suggère que la rétention de configuration en C-5 provient de deux facteurs principaux—la géométrie non-planaire du centre radicalaire hydroxyalkyle et le transfert rapide d'hydrogène dans le diradical; ce dernier facteur proviendrait d'une rotation empêchée autour de la liaison C-9/C-10. Le transfert spécifique de l'atome de deutérium 7α des cétols-7α est aussi attribué à ces facteurs ainsi qu'à la direction privilégiée de l'ouverture en diradical par clivage α. On interprète les résultats du marquage au deutérium de l'hydroxyle en fonction d'un contrôle au développement du produit lors de la conversion des hydroxy cétènes en lactones; cette interprétation est en accord avec une rotation empêchée autour de la liaison C-9/C-10. La photolyse de l'acétoxy-3β amino-5 5α-cholestanone-6 conduit d'une façon stéréospécifique à la lactame-5β analogue de la lactone-5β qui se forme à partir du cétol-5α analogue.

Introduction

Although the photochemistry of cyclic ketones has been investigated exhaustively (2), comparatively few studies have focused on the photochemistry of cyclic α-hydroxy ketones. Hamer (3) and Padwa and Au (4) have studied the photoreactions of several 2-hydroxy-1-indanones of type **1** and have observed that they can give epimerization products (**2**), keto aldehydes (**3**), and isochromenes (**4**), depending on the nature of the substituents and the solvent. The formation of all of these can be interpreted in very similar terms to those that have been used in the case of cyclic ketones lacking an α-hydroxyl substituent (2). Thus Norrish type I cleavage (α-cleavage) gives the alkyl acyl diradical **5**, which closes to give **1** and **2**, or undergoes 1,6 hydrogen transfer from the hydroxyl group to give **3** or 1,4 hydrogen transfer from the benzylic carbon to give **6**, which then cyclizes or reacts with solvent methanol to give **4**. Deuterium labeling results were in accord with the two postulated types of hydrogen transfer.

Our attention was first drawn to the photochemistry of cyclic α-hydroxy ketones by the report of Cookson *et al.* (5) that the steroidal α-hydroxy ketones **7** and **8** on photolysis in either benzene or ethanol give the lactones **9** and **10**, respectively. The general course of these reactions again appears to be closely analogous to the known photochemical reactions of cyclic ketones not bearing an α-hydroxyl group, viz., α-cleavage to give **11** followed by 1,5 hydrogen transfer to give a ketene **12** that can undergo intramolecular reaction with the hydroxyl group to give the lactones **9** and **10**. However, in detail two features appear to be extraordinary. First, the reactions of **7** and **8** are reported to be stereospecific, i.e., **7** gives only **9**, and **8** only **10**, whereas it would have been anticipated that C-5 in the diradical **11** would undergo configurational change and that stereospecificity would not be observed. Second, when the reaction is carried out in ethanol, intramolecular reaction of the ketene group of **12** with the hydroxyl group occurs to the

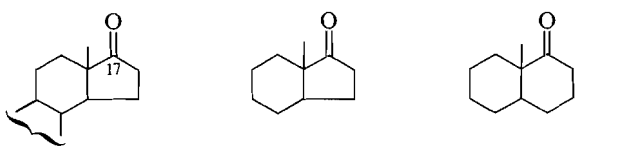
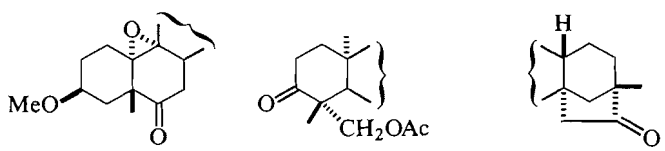
exclusion of intermolecular reaction with the solvent. With respect to the former feature it may be noted that photoepimerization at the α-carbon of a cyclic ketone that undergoes photocleavage is well known. In addition to the case of the compounds of type **1** referred to above, it has been well documented, for example, in the cases of 17-keto steroids (**13**) (6), octahydro-7a-methylinden-1-one (**14**), and octahydro-8a-methylnaphthalen-1(2*H*)-one (**15**) (7).



13 14 15



16 17 18

In rare cases retention of configuration has been reported (8–10). Photolysis of compounds with part-structures **16**–**18**, in alcohols, gives the corresponding ketene-derived esters via α-cleavage of the cycloalkanone moiety with retention of configuration at the α-carbon. However, in none of these cases was the photochemistry of the corresponding α-epimer examined. To the best of our knowledge compounds **7** and **8** represent the only case where the reaction has been shown to be *stereospecific*.

In the present work we have sought to define both the generality and the major controlling factors of this stereospecificity. Towards this end we have reexamined the photochemistry of **7** and **8** and have synthesized (11) and studied the photochemistry of a number of steroids related to them.

Results

Photolysis of 5α- and 5β-hydroxy 6-keto steroids

We first repeated the photolyses of **7** and **8** to determine whether the stereospecificity reported by Cookson *et al.* (5) would withstand the more searching scrutiny made possible by recent advances in instrumentation.

The total photolysates from irradiation of **7** and **8** in benzene or in ethanol were concentrated and analyzed by high performance liquid chromatography. In either solvent, ketone **7** gave only lactone **9** and ketone **8** only lactone **10**. The original stereochemical assignments (5) for the lactones were confirmed by ^1H nmr spectroscopy. In the 5β-lactone **9** equatorial–equatorial and axial–equatorial interactions of the C-5 methine proton with the C-4 α- and β-methylene protons, respectively, result in a narrow multiplet at δ 4.33 for the C-5 proton. In contrast the signal of the C-5 methine proton of **10** appears as a doublet of doublets (J = 11, 5 Hz) at δ 4.30; the 11-Hz splitting, indicative of an axial–axial type coupling, confirms the 5α-stereochemistry (Scheme 1).

Further confirmation of the stereospecificity of the reactions derives from the ^{13}C nmr spectra of the photolysates, which in each case showed the presence of only one of the epimeric lactones. These spectra again showed that the reactions proceeded with retention of configuration at the C-5 center.[2]

An attempt was made to promote epimerization at this center during photolysis by irradiation of **7** in *n*-butanol at 100°C. However, the effect of temperature was negligible and the only product obtained was lactone **9**.

To determine the effect, if any, of the 3-acetoxy group in **7** and **8** on the course of reaction we next investigated the photolysis of the 3-deoxy (**19** and **20**) and 3-benzyloxy analogues (**21** and **22**) of **7** and **8** in both benzene and ethanol. As shown by ^{13}C nmr spectroscopy, in all cases the stereospecificity of the reactions was maintained, with **19** and **21** giving only the lactones **23** and **25**, respectively, and **20** and **22** giving only the lactones **24** and **26**, respectively. The stereochemistry of the lactones was established by ^1H nmr spectroscopy as in the case of their 3-acetoxy analogues, and these stereospecific reactions were again found to proceed with retention of configuration at the C-5 center (Scheme 1).

Photolysis of deuterated 5α- and 5β-hydroxy 6-keto steroids

To obtain information concerning the hydrogen transfer reactions involved in the photoconversion of the hydroxy ketones to the lactones, we investigated the photolysis of the

[2]It is planned to discuss in detail elsewhere the ^{13}C nmr spectra of these lactones and of other compounds obtained in the present investigation.

7α-deutero-5α- and 5β-hydroxy 6-keto steroids **27** and **28** (11) in benzene and in ethanol. These reactions were found to proceed stereoselectively to give the 5-deutero lactones **29** and **30**, respectively (Scheme 2). The C-5 position of the deuterium label was made manifest by the ^{1}H nmr spectra of the product lactones by the greatly diminished intensities of the C-5 methine proton signals. The extent of deuterium incorporation at C-5, as determined from the relative areas of the C-5 and the C*H*OAc proton signals when compared with the deuterium content calculated from the mass spectra of the products, showed that the deuterium label was present essentially exclusively at the C-5 site and thus established the highly stereoselective nature of the deuterium transfer reactions.

The photolysis of the *O*-deuterated 5α- and 5β-hydroxy 6-keto steroids **31** and **32** was also investigated, to throw further light on the mechanism of lactone formation. Irradiation of **31** and **32** in benzene was carried out in the presence of deuterium oxide, the latter being added to improve the extent of deuterium incorporation. To exclude the possibility that, under these conditions, deuterium incorporation into the product lactones occurred *after* their formation, ε-caprolactone was similarly irradiated for a prolonged period. There was no evidence of any deuterium incorporation into this lactone.

Irradiation of **31** gave a ~1:3 mixture of the 7aα- and 7aβ-deutero 5β-lactones **33** and **34**, while **32** gave a ~7:1 mixture of the 7aα- and 7aβ-deutero 5α-lactones **35** and **36** (Scheme 3). The mass spectrum of the product mixture from **31** evidenced a d_1 content of 68%, an acceptable level of incorporation in the light of the well-known difficulties associated with the manipulation of compounds labelled at a heteroatom (12). In the case of **32** the mass spectrum of the product mixture showed excellent incorporation (d_1 88%) of the label.

FIG. 1

The conclusions concerning the location of the deuterium label in the product lactones are dependent on the assignments for the C-7a methylene protons in the ^{1}H nmr spectra of the undeuterated lactones **9** and **10**. The task of making these assignments proved not to be a simple one, because of the conformational flexibility of the seven-membered lactone rings. In order not to interrupt unduly our discussion of the photochemical results, we give only our conclusions regarding these assignments here and give a separate account of the basis for them in an Appendix. The assignments are shown in Fig. 1.

The 200-MHz ^{1}H nmr spectrum of the mixture of **33** and **34** exhibited a narrow multiplet ($W_{1/2}$ = 6 Hz) at δ 2.42 and a much weaker, broad doublet at δ 2.94 (J = 10 Hz). These must correspond to the C-7a methylene protons of the undeuterated lactone **9** shifted slightly upfield by the presence of deuterium at C-7a (13). The narrow multiplet at δ 2.42 is assigned to the C-7a α-proton of the 7aβ-deutero lactone **34**, and the broad doublet at δ 2.94 to the C-7a β-proton of the 7aα-deutero lactone **33**. The relative intensities of these peaks show that the **33**/**34** product ratio is ~1:3. In the case of the irradiation of **32** the spectrum of the mixture of **35** and **36** showed a broad singlet at δ 2.52, assigned to the C-7a β-proton of the 7aα-deutero lactone **35** and a very weak doublet at δ 2.38, assigned to the C-7a α-proton of the 7aβ-deutero lactone **36**. The relative intensities of these peaks showed that the reaction of **32** was somewhat more stereoselective than that of **31**, with a **35**/**36** product ratio of ~7:1.

Photolysis of other 6-keto steroids

The photolysis of 3β-acetoxy-5-methoxy-5α-cholestan-6-one (**37**) in methanol has been investigated previously by Morand and Samad (14). They assigned structure **38** to the single product isolated. Although the configuration at C-5 could not be assigned directly from the ^{1}H nmr spectrum of the product because of overlap of the methoxyl proton signal with that of the C-5 proton, they were able to assign the α configuration of the C-5 proton as shown in **38** (Scheme 4) after a series of chemical transformations.

To confirm the stereochemical assignment and to determine whether there is any evidence for the formation of other products, we have investigated the photolysis of **37** in ethanol. The ethyl ester **39** was found to be the sole photoproduct, as shown by both the ^{1}H and ^{13}C nmr spectra of the crude

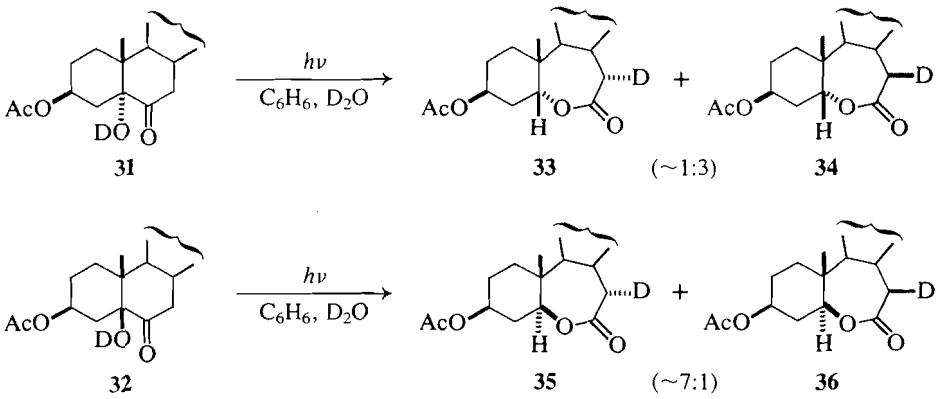
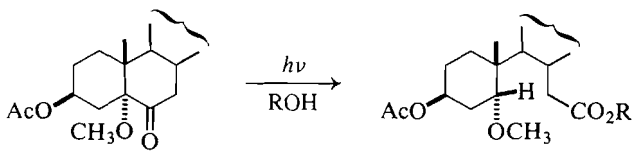


SCHEME 3

photolysate. In its ^{1}H nmr spectrum, the broad signal arising from the C*H*OAc proton evidenced the preference for the conformation **39***A*. The configuration at C-5 was established directly from the 200-MHz ^{1}H nmr spectrum in benzene-d_6, in which the coincidence of the C-5 methine and methoxyl proton signals observed in the spectrum in deuterochloroform was resolved. A narrow multiplet ($W_{1/2}$ = 8 Hz) at δ 3.36, assigned to the C-5 methine proton, established the 5α configuration of the methoxyl group, thus corroborating the earlier results (14).

Unfortunately, we were unable to examine the photochemistry of 3β-acetoxy-5-methoxy-5β-cholestan-6-one (**40**), the C-5 epimer of **37**, because of problems in its synthesis (11). However, it is likely that this would have undergone preferential Norrish type II cleavage (15, 16) to give 3β-acetoxy-5α- (**41**) and (or) 5β-cholestan-6-one (**42**) (Scheme 5), and its photolysis would not have shed light on the α-cleavage reactions under study.

An exploratory study was made of the photolysis in ethanol of a steroidal 6-ketone lacking any substituent at C-5, viz. 3β-acetoxy-5α-cholestan-6-one (**41**). Under the conditions

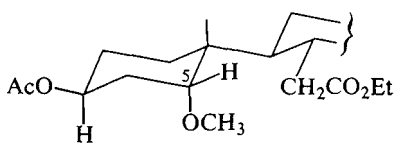


37

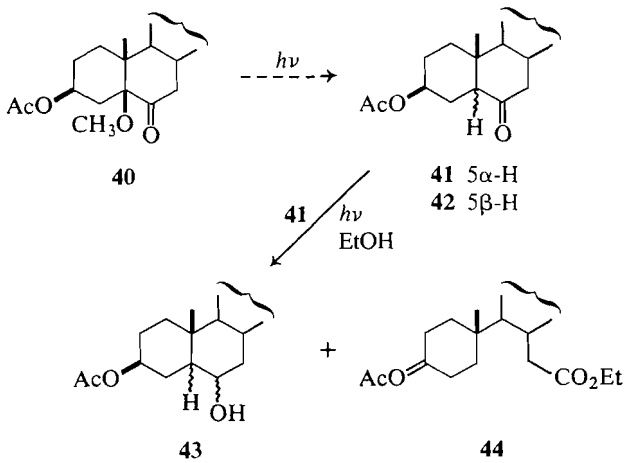
38 R = CH_3
39 R = C_2H_5

SCHEME 4

used previously (Pyrex tube; Rayonet apparatus; 300-nm lamps) photoreaction was slow, but irradiation in a quartz tube with this apparatus with 254-nm lamps or in Pyrex with a Hanovia 450-W medium pressure lamp proceeded much more rapidly, giving very similar product mixtures. The photolysis was much less clean than in the previous cases and thin-layer and vapor phase chromatography showed that the crude photolysate comprised a number of compounds. In the ^{1}H nmr spectrum of this photolysate a prominent broad multiplet at δ 3.5 and narrow multiplet at δ 3.8 indicated that the major constituents were hydroxyl



39*A*



SCHEME 5

compounds. These are considered to be alcohols of type **43** (Scheme 5), arising by photoreduction of **41**, and were not examined further. A second type of product isolated was the ester **44**. Although this was isolated in only 7% yield, the ^{1}H nmr spectrum of the crude photolysate suggested that this could account for ~30% of the photoproduct. Its structure was readily assigned on the basis of its spectra and analogy with the photochemistry of other simple cyclohexanones.

We have also examined the photochemistry of an amino analogue of the hydroxy steroids discussed above. 3β-Acetoxy-5-amino-5α-cholestan-6-one (**45**), prepared by hydrolysis of the corresponding (*E*)-oxime (17), on irradiation in benzene gave the 5β-lactam **46** in 69% yield (Scheme 6). The 60-MHz ^{1}H nmr spectrum of the crude photolysate gave no indication of the presence of another product; thus the epimeric 5α-lactam can be, at most, a very minor constituent of the reaction mixture. The lactam functionality of the product was readily apparent from its ir spectrum, which showed bands at 2.97 and 6.02 μm. The stereochemical assignment at C-5 derives from comparison of its ^{1}H nmr spectrum with that of its 5α-epimer **47**, which was prepared previously by Beckmann rearrangement of 3β-acetoxy-5α-cholestan-6-one (*E*)-oxime (**48**) (18) and as a minor product in the irradiation in methanol of **49**, the acetate of **48** (19) (Scheme 6). These spectra were similar, as expected, but exhibited well-defined differences. Thus the C-19 CH_3, C-5 CH, and C*H*OAc proton signals of **46** appeared at δ 1.03 (s), 3.23 (m, $W_{1/2}$ = 20 Hz), and 5.10 (m, $W_{1/2}$ = 16 Hz), respectively, while the corresponding signals of **47** appeared at δ 0.93 (s), 3.42 (ddd, J = 10, 5, 5 Hz), and 4.67 ($W_{1/2}$ = 24 Hz). It is of interest that the C*H*OAc signal of **46** ($W_{1/2}$ =

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.222.148.141 on 09/07/12

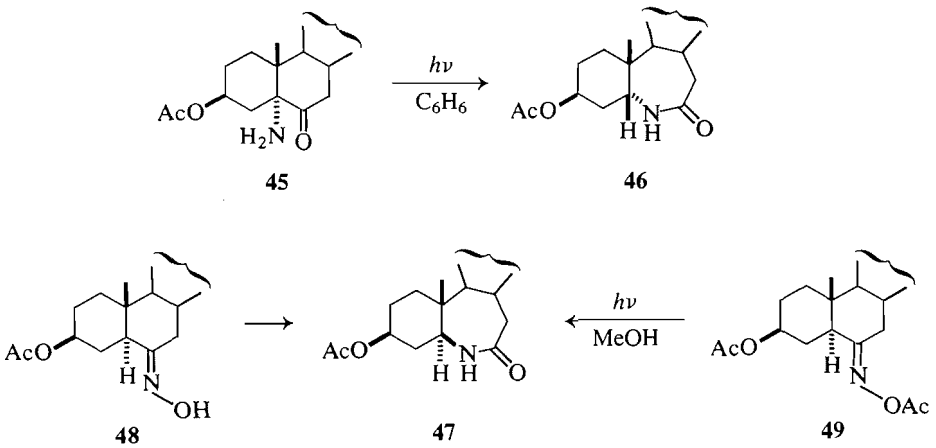


SCHEME 6

16 Hz) is narrower than usual for an axial proton at C-3 ($W_{1/2}$ = 20 Hz). This may reflect some distortion in ring A of this epimer resulting from planarity of the lactam function in ring B.

Discussion

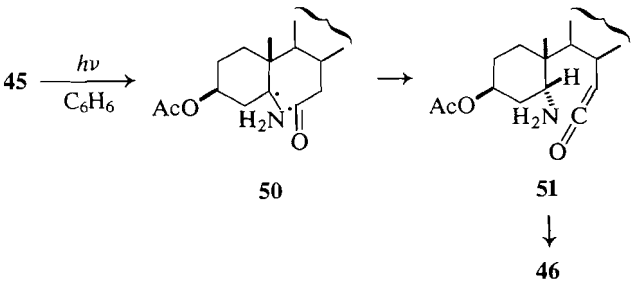
Modes of photoreaction of α-ketols and related compounds

Irradiation of the steroidal α-hydroxy ketones **7** and **8** in benzene or ethanol gave photoproducts **9** and **10**, whose structures are consistent with exclusive α-cleavage of the excited ketone to give acyl alkyl diradicals of type **11** that undergo intramolecular hydrogen transfer to give ketene intermediates of type **12**. The regiochemistry of the α-cleavage corresponds to that yielding the more stable, oxygen-substituted alkyl radical (or to that involving cleavage of the weaker α bond) in accord with expectation (20, 21). Photolyses in ethanol gave no indication of the formation of any products attributable to photoreduction.

Norrish II cleavage does not intervene as a competitive reaction pathway to α-cleavage in the irradiation of the 5α-methoxy ketone **37** in ethanol, which gives the ketene-derived ester **39** (Scheme 4). This is presumably because the hydrogens of the methoxyl group are held distant from the *n*-orbitals of the carbonyl group and thus do not satisfy the strict geometrical requirements for Norrish II cleavage (22).

Irradiation of the 5α-amino ketone **45** afforded the lactam **46** as the predominant photoproduct. As for the related oxygen-substituted ketones, a mechanism comprising α-cleavage and hydrogen abstraction in the resulting diradical **50** and intramolecular addition to the ketene intermediate **51** is considered to account best for the formation of **46** (Scheme 7). α-Dialkylamino cyclohexanone systems have been observed to undergo direct β-cleavage of the C—N bond (23), while hydrogen abstraction becomes a competitive process for α-dialkylamino ketones, where α-hydrogens that are geometrically favorably disposed (22) are available (24). To the best of our knowledge, the formation of amide **46** from irradiation of amino ketone **45** represents the first example of an α-cleavage reaction of an α-amino ketone.

In contrast to the selective α-cleavage photoreactivity exhibited by the α-hetero-substituted ketones studied, irradiation of the C-5 unsubstituted ketone **41** in ethanol induced photoreduction, via intermolecular hydrogen abstraction, as the predominant reaction (Scheme 5). The ketene-derived ester **44**, formed as a minor photoproduct, is considered to originate from α-cleavage of the C-5—C-6 bond, generating the more stable diradical intermediate, as in the cases of the major products from the α-hetero-substituted ketones.



SCHEME 7

The pronounced increase in the extent of α-cleavage upon introduction of a heteroatom α to the carbonyl group is considered to be primarily attributable to the increase in the rate of α-cleavage concomitant with the increased stability of the diradical intermediate (*vide supra*). In addition, the planar geometry of the cyclohexyl radical may not be as geometrically well disposed for hydrogen abstraction as the nonplanar radical centers of α-hetero-substituted cyclohexyl radicals (*vide infra*). Consequently, reclosure of the diradical to **41** may compete more effectively with hydrogen abstraction, resulting in a decrease in the apparent efficiency of α-cleavage for the unsubstituted ketone **41**.

Stereochemistry of α-ketol photolyses

We have shown that in steroidal systems the photolyses of 5α- and 5β-ketols proceed stereospecifically to give lactones wherein the stereochemistry of the C-5 carbon atom has been retained (Scheme 1). The stereospecificity observed for the irradiations of the C-3 deoxy steroidal ketols **19** and **20** excludes the possibility that the configuration of the radical center at C-5 is maintained during photolysis by interaction with the C-3 substituent.

Hydrogen bonding in the intermediate diradical (25) is discounted as a source of the stereospecific steroidal α-ketol photolyses on the basis of the stereoselectivity in the irradiation of the 5α-methoxy ketone **37** (Scheme 4).

We propose that two major factors, the shape of the hydroxyl-substituted carbon radical and fast hydrogen transfer in the diradical intermediate, are the source of the stereospecificity of the steroidal α-ketol photolyses.[3] We first discuss the radical site geometry. Simple alkyl radicals (26) (with the possible exception of the *tert*-butyl radical (27)) and cyclohexyl

[3]These factors are considered to account also for the stereoselective nature of the photolyses of the 5α-methoxy ketone **37** and the 5α-amino ketone **45**.

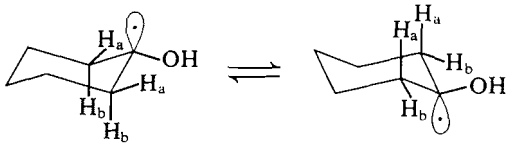


SCHEME 8

radicals (28) are generally considered to have a planar radical geometry.[4] Introduction of oxygen functionality at the carbon radical center induces deviation from planarity (30, 31). This deviation from planarity has been attributed primarily to delocalization involving a lone pair on the oxygen atom and the unpaired electron (30, 32).

A nonplanar geometry for the 1-hydroxycyclohexyl radical has been predicted by calculation (33) and supported by variable temperature esr spectroscopy (34). The activation barrier, E_a, for chair $\rightleftharpoons$ chair inversion of the 1-hydroxycyclohexyl radical was determined to be 6.6 kcal/mol. The higher value of this barrier relative to that measured for ring inversion of the cyclohexyl radical (4.9 kcal/mol) (28) has been interpreted as evidence for nonplanarity at the hydroxyl-substituted carbon radical (34).

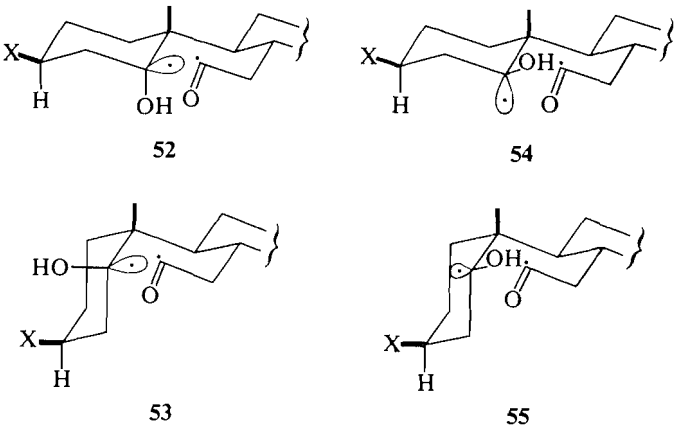
The low temperature esr spectrum of the 1-hydroxycyclohexyl radical is consistent only with a species in which the unpaired electron is in an axial orientation. At higher temperatures, the esr spectrum evidences the equivalence of all four β-protons. Lloyd *et al.* (33, 34) have concluded that a mechanism involving both chair $\rightleftharpoons$ chair inversion and simultaneous inversion of the nonplanar carbon radical center (Scheme 8) best accounts for the observed spectra. Consistent with this mechanism, the calculated activation barrier for inversion of the 1-hydroxyl-substituted radical center (3.5 kcal/mol) (33) is lower than that measured for ring inversion.

With regard to the ease of radical site inversion, Malatesta and Ingold (35) have observed that carbon radicals in cyclic systems with one or two oxygen substituents invert their nonplanar radical centers rapidly, and only in cases where the radical is flanked by three oxygen substituents was radical inversion observed to be "frozen" on the esr time scale.

Models demonstrate that an analogous nonplanar geometry of the hydroxycyclohexyl radical center in the diradicals formed from the steroidal α-ketols holds the unfilled orbital in a favorable orientation for hydrogen abstraction. In contrast, if the radical center at C-5 were planar, the unfilled orbital in the case of the 5α-ketols is not suitably disposed for hydrogen abstraction to give the observed stereochemistry of the lactone photoproducts. Moreover, a planar radical geometry would project the hydroxyl substituent into close proximity with the acyl radical; products derived from abstraction of the hydroxyl hydrogen atom that would then be anticipated were not observed in the cases of the steroidal α-ketols. Thus our results support a nonplanar geometry for the hydroxyl-substituted cyclohexyl radical and indicate that this geometry plays a significant role in the stereospecificity of the steroidal α-ketol irradiations.

However, we have found that photolyses of bicyclic α-ketol analogues of the steroidal α-ketols are not stereospecific (36). Thus the nonplanar geometry of the radical center is not of itself the controlling factor for the stereospecificity of the steroid ketol photolyses. As detailed in the following discussion, rapid hydrogen abstraction in the diradical is also considered to be critical for stereospecificity.

[4]A slight deviation from planarity has also been proposed for the cyclohexyl radical (29).



X = OAc, H, OBn

Hydrogen abstraction leading to ketene formation in the photolyses of the 5α- and 5β-steroidal ketols is postulated to occur from the diradicals **52** and **53**, respectively, first formed upon α-cleavage. Hydrogen transfer in these diradicals gives lactone photoproducts in which the configuration of the C-5 center is maintained.

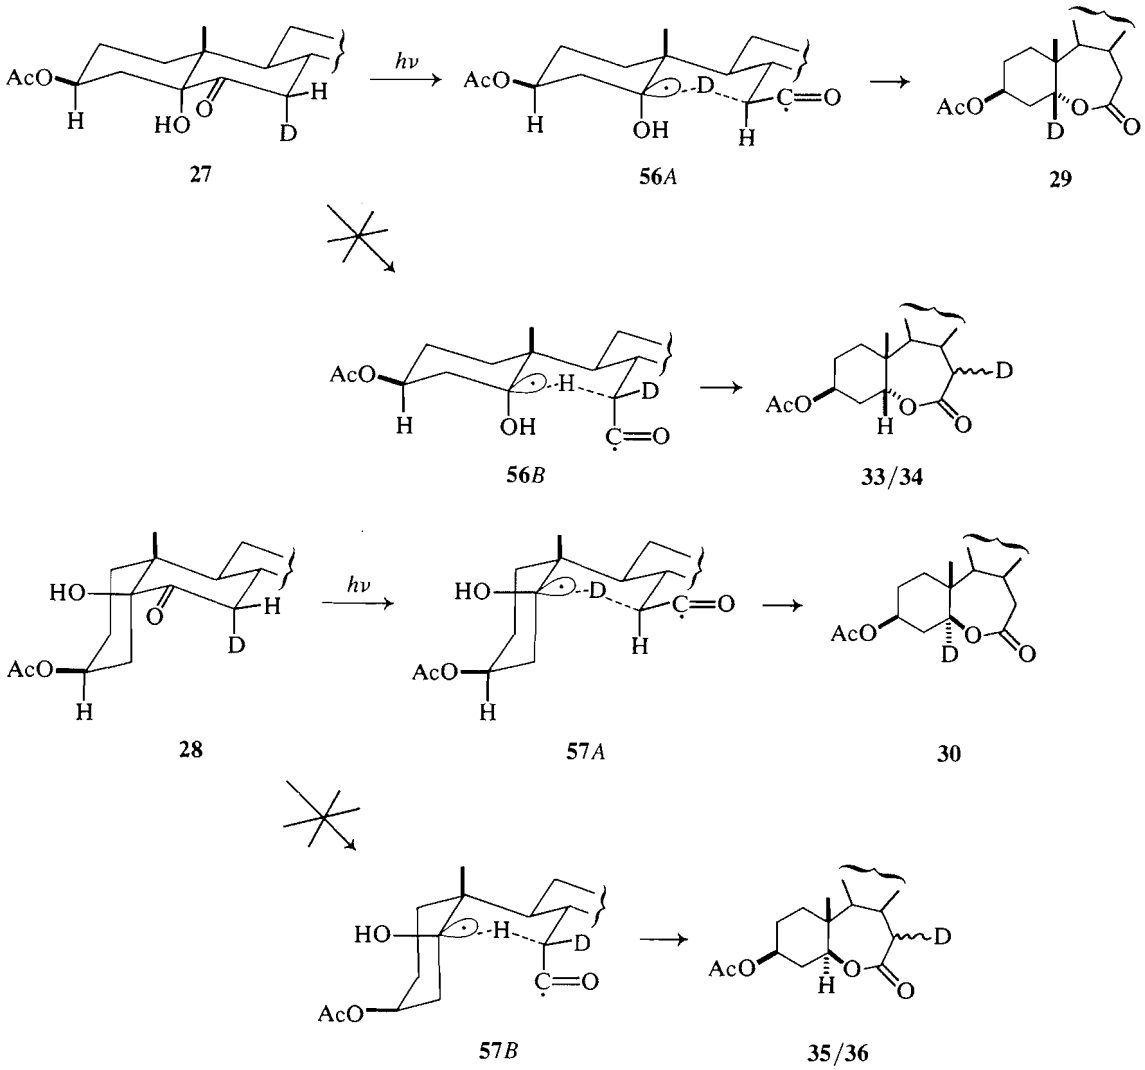
Consideration of the consequences of ring inversion and (or) inversion at the radical carbon center in diradicals **52** and **53** with respect to the configuration of the C-5 center in the resulting lactone photoproduct leads us to propose that hydrogen transfer occurs in diradicals **52** and **53** more rapidly than such ring inversion or radical center inversion. The persistence of the stereospecific character of the steroidal α-ketol photolyses with changes in the nature of the C-3 substituent indicates that conformational effects in the diradicals **52** and **53** are not important to the stereochemical course of the irradiations. This lends credence to the suggestion that ring inversion does not occur prior to hydrogen abstraction in these two diradicals.

Inversion of the radical center without concomitant chair inversion (i.e., **52** $\rightleftharpoons$ **54** and **53** $\rightleftharpoons$ **55**) is considered unlikely to be competitive with hydrogen abstraction, since it would require that hydrogen transfer occur selectively in the diradicals **52** and **53** and not in the inverted forms **54** and **55**. While this would be expected for the diradical **55**, where hydrogen transfer is geometrically not feasible, models indicate that hydrogen transfer should occur in both the diradicals **52** and **54**, leading to lactones with both the α and β stereochemistry at C-5. The fact that this is not observed precludes inversion of the radical center prior to hydrogen abstraction.

Further, we interpret the absence of the formation of keto aldehydes, products that would arise from abstraction of the hydrogen of the hydroxyl group, in the photolysis of the 5α- and 5β-steroidal ketols as evidence that inversion of the radical center is not competitive with hydrogen abstraction. In diradicals **52** and **53**, the hydroxyl groups are axial and, as models indicate, their hydrogen atoms are not readily accessible for abstraction by the acyl radicals. However, if the radical centers invert, the hydroxyl groups in the resultant diradicals **54** and **55** become equatorial and favorably disposed for abstraction of their hydrogen atoms by the acyl radicals. This argument is corroborated by the observation that photolyses of the corresponding bicyclic α-ketols proceed to some extent by abstraction of the hydroxyl hydrogen to afford the corresponding keto aldehyde (36).

Our conclusion that radical center inversion does not compete with hydrogen abstraction in the steroidal α-ketol photolyses, in spite of the very rapid rate of such inversion observed by Lloyd and Ingold and their co-workers (33–35), raises the possibility

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.222.148.141 on 09/07/12
For personal use only.



SCHEME 9

that the hydrogen abstraction process leading to ketene formation is concerted with α-cleavage. However, our C-7 deuterium labelling results contraindicate this. If the photolyses were concerted, the 7β-hydrogen in both the 5α- and 5β-steroidal ketols should, by affording better orbital overlap with the incipient acyl radical during α-cleavage, be transferred to the alkyl radical center. Contrary to this, the deuterium labeling studies showed that stereoselective transfer of the 7α-hydrogen occurs (1) (Scheme 2). Moreover, given a concerted reaction, the bicyclic α-ketol photolyses would also be expected to be stereospecific.

The fast hydrogen abstraction that we have invoked as the source of the stereospecificity of the steroidal α-ketol photolyses can be accounted for by the presence of the CD ring system in the steroid, which restricts the rotational motions of the acyl side chain in the diradicals **52** and **53**. This holds the alkyl radical center at C-5 and the hydrogen α to the acyl radical in close proximity, thus favoring fast hydrogen abstraction and preempting inversion of the radical center and (or) cyclohexyl ring inversion.

Evidence for this again comes from the deuterium labeling results involving irradiations of the 7α-deutero ketols **27** and **28**. As shown in Scheme 9, abstraction via the chair-like transition states **56***A* and **57***A* accounts for the completely stereoselective formation of the C-5 deutero lactones **29** and **30**, respectively. The preference of the diradicals **52** and **53** (R = OAc, 7α-D) for the ketene-forming transition states **56***A* and **57***A* is considered to result from the preferred direction of opening of the diradicals upon α-cleavage.[5]

Newman projections show that as the C-5—C-6 bond cleaves in the excited 5α- and 5β-ketols, clockwise rotation (as viewed along the C-7—C-8 bond) of the incipient acyl radical minimizes eclipsing interactions (Scheme 10). As the acyl group rotates clockwise, the 7α-deuterium atom approaches the electron-deficient orbital. This arrangement represents transition states **56***A* and **57***A* and results in favored abstraction of the deuterium atom.

As the rotation of the acyl group occurs about the C-7—C-8 bond, the C-8—C-9 framework is held by ring C and rotation about the C-9—C-10 bond is considered to be frozen relative to the time scale for hydrogen abstraction. The activation barrier to rotation about the C-9—C-10 bond is expected to be higher than that for rotation about the C-7—C-8 bond because of the greater eclipsing interactions involved in the former. Furthermore, the

[5]The direction of ring opening in α-cleavage reactions of cycloalkanones has been previously invoked to rationalize stereoselective hydrogen abstractions leading to ketene formation (37, 38).

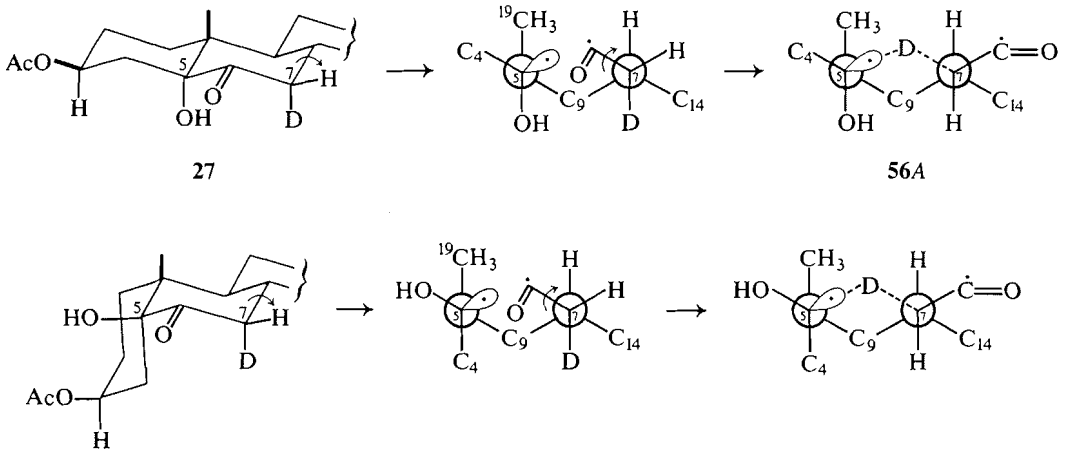

SCHEME 10

rotamer of the C-9—C-10 bond first formed upon α-cleavage is considered to be the preferred rotamer about this bond.

Thus, the presence of ring C is suggested to hold the C-8—C-9—C-10 framework in the diradicals **52** and **53** in an arrangement that mimics the one in their steroidal ketol precursors. This then maintains the alkyl and acyl radical centers in close proximity, facilitating rapid hydrogen abstraction.

We also note that the above clockwise opening upon α-cleavage affords the thermodynamically favored rotamers about the C-7—C-8 bond. In contrast, transition states **56*B*** and **57*B*** leading to hydrogen abstraction giving **33**/**34** and **35**/**36**, respectively (Scheme 9), incorporate unfavorable 1,3-diaxial interactions of the acyl radical with ring A and *gauche* interactions with C-9 and C-14.

In summary, in the photolyses of both the 5α and 5β steroidal ketols, a clockwise rotation of the acyl radical about the C-7—C-8 bond without concomitant rotation of the C-9—C-10 bond is postulated to give directly a favorable transition state for hydrogen abstraction leading to ketene formation. The fast hydrogen abstraction that results precludes competitive inversion of the ring conformation and (or) radical configuration in the intermediate diradicals and thereby gives rise to the stereospecificity of the steroidal α-ketol photolyses.

Reactions of the ketene intermediates

We conclude by discussing the addition reactions of the ketene intermediates. Although these are "dark" reactions, they are of importance in determining the nature of the products isolated from the photolytic reactions of the α-ketols. Intramolecular addition of the hydroxyl group to the ketene group in these intermediates formed in the steroidal photolyses gives rise to the lactone photoproducts. Deuterium labelling studies have provided us with information concerning the transition state for this addition.

Photolyses of the 5α- and 5β-deuteroxy 6-keto steroids **31** and **32** exhibited preferences for the formation of the C-7aβ-deutero 5β-lactone **34** and the C-7aα-deutero 5α-lactone **35**, respectively (Scheme 3). Concerted reactions involving four-membered ring transition states are considered to be involved in the addition of the deuteroxyl group to the ketene intermediate (39). In the case of **31**, transition state **58** leads to the formation of the C-7aβ-deutero lactone **34**. Models show that **34** is first formed in its preferred conformation, whereas addition to the other face of the ethylenic bond would give rise to the C-7aα-deutero lactone initially in a nonpreferred conformation. For the 5β-ketol **32**, transition state **59** leads to initial formation of the C-7aα-deutero lactone **35** in its preferred conformation, whereas addition to the other face of the ethylenic bond would give rise to a nonpreferred conformation of the C-7aβ-deutero lactone **36**.

In the photolyses of **31** and **32** selective formation of the lactones **34** and **35**, respectively, is observed (Scheme 11). Since these products correspond to the transition states that lead directly to the preferred conformations of these lactones (*vide* Appendix), the addition of the C-5 hydroxyl groups to the ketene groups is considered to be under product development control, with the transition states for the additions being formed relatively late on the reaction coordinate. The importance of product development control in these additions is considered to be fostered by the maintenance of the C-8—C-9—C-10 framework in the ketene in an arrangement that approximates the backbone of the preferred conformation of the lactone ring.

Finally we note that the maintenance of this framework in the ketenes accounts for the exclusive formation of intramolecular addition products when the photolyses of the steroidal α-ketols are carried out in ethanol. The presence of ring C is considered to hold the C-5 hydroxyl group and the ketene system in close proximity, thus leading to lactone photoproducts rather than the esters that would arise if the ketenes reacted with the solvent ethanol.

Conclusions

Our studies of the photochemistry of a variety of α-ketols and related ketones have shown that introduction of an oxygen, and in one case a nitrogen, function α to the carbonyl group induces a highly efficient and highly regioselective α-cleavage reaction of the excited state of cycloalkanones. The efficiency and regioselective nature of these photolyses is attributed primarily to the increase in the stability of the diradicals, formed on α-cleavage, as a result of heteroatom substitution.

We have established that stereospecificity is a general feature of the photolyses of the steroidal 5α- and 5β-ketols (Scheme 1). The stereospecific nature of these photolyses is attributed to a relatively rapid hydrogen transfer in the diradicals first formed from α-cleavage (Scheme 9). Efficient hydrogen abstraction in these diradicals is fostered by the preferential clockwise rotation (viewed along the C-7—C-8 bond) of the acyl radical following α-cleavage. This rotation directs the C-7a hydrogen towards the electron-deficient alkyl radical center. This, together with the nonplanar geometry of this center, generates directly favorable

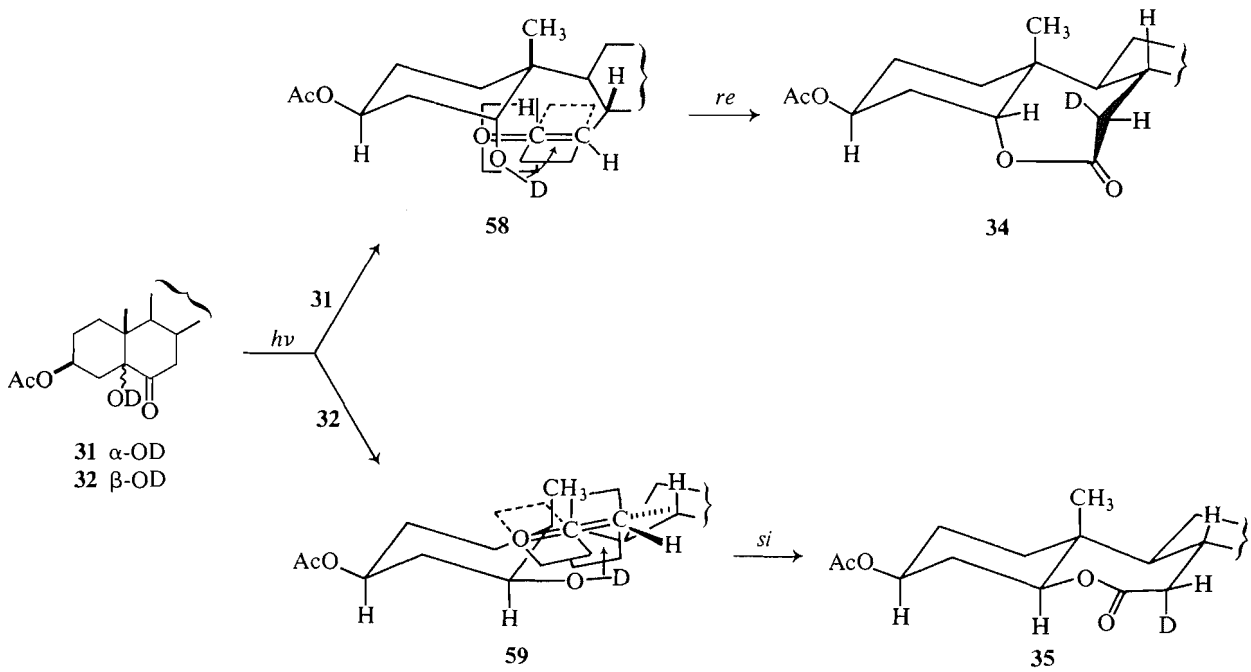

SCHEME 11

chair-like transition states for hydrogen abstraction leading to ketene formation in these photolyses. As the acyl radical rotates, the presence of the CD ring system in the steroid is considered to hinder rotational movement in the C-8—C-9—C-10 framework of the diradical, thereby maintaining the alkyl and acyl portions of the diradical in close proximity. This facilitates rapid hydrogen abstraction from the diradicals first formed from α-cleavage, precluding inversion of the ring conformation or of the configuration of the radical center prior to hydrogen transfer, and thereby giving rise to the stereospecificity of the steroidal α-ketol photolyses.

Thus, the stereospecificity of the photolyses of 5-hydroxy 6-keto steroids is not a general attribute of all α-ketol irradiations, but neither is it necessarily limited to these steroidal cycloalkanones. It is considered to arise from an unusual confluence of special circumstances. In principle, other cycloalkanones giving rise to diradicals wherein hydrogen transfer is a fast process compared to competitive processes may also be expected to be highly stereoselective or possibly stereospecific. However, in general, ring and radical inversion motions in the diradical are expected to be strongly competitive with hydrogen abstraction, and the relative stabilities of the diradicals that result from these inversions are then expected to determine the stereochemistry of the photoproducts. Thus, studies of the stereochemical fate of the alkyl radical center can provide interesting insights into the intricacies of α-cleavage reactivity in the photochemistry of cycloalkanones.

Experimental

Melting points were recorded on a Fisher–Johns melting point apparatus and are uncorrected. The ir spectra were recorded in chloroform and the ^{1}H nmr spectra at 60 MHz in deuterochloroform unless otherwise specified. For symmetrical multiplets in the latter, the width at half height ($W_{1/2}$) is recorded while for unsymmetrical multiplets the total width is given. Low resolution mass spectra were recorded with a Bell and Howell CEC 21-490 mass spectrometer. For the deuterium content calculations, 10–20 scans of the region of the spectrum containing the isotopic cluster associated with the molecular ion or, where appropriate, of the (M − AcOH) fragment were obtained at a high signal-to-noise ratio and averaged. Exact mass measurements were made with an AEI MS-3074 spectrometer with a DS-50 data system.

Organic solutions were dried over $MgSO_4$ or Na_2SO_4 and concentrated on a rotary evaporator under water aspirator pressure. Column chromatography was carried out on silica gel (Grace Davison, grade 923, 100–200 mesh), neutral alumina (Merck, activity 1, 70–230 mesh, 90 Å mean pore diameter), or Florisil (Aldrich, 100–200 mesh). Flash chromatography was performed on 40- to 60-μm silica gel (Merck, grade 60, 230–400 mesh, 60 Å mean pore diameter) under air, nitrogen, or argon pressure so that the drop in solvent height was ~5 cm/min. Analytical high performance chromatography was carried out on a Waters Associates Model ALC 100 liquid chromatograph equipped with a μ-Porasil column (4.2 mm × 30 cm). The eluates were monitored with a differential ultraviolet absorption detector.

Deuterium-labeling experiments were carried out in glassware that had been washed three times in D_2O and flame dried while subjected to an argon flow.

General procedure for irradiation of the steroidal 5α- and 5β-hydroxy ketones ***7***, ***8***, ***19***, ***20***, ***21***, *and* ***22***

A solution (diameter × height dimensions of the solution enclosed in parentheses) of the hydroxy ketone in anhydrous ethanol or anhydrous benzene in a Pyrex tube was degassed with argon or nitrogen for 1 h and irradiated at 300 nm in a Rayonet photochemical reactor. The progress of the photolysis was monitored by thin-layer chromatography, and the irradiation was carried out typically for 6–24 h depending on the age of the lamps. The temperature inside the reactor rose to 50–53°C during the photolysis. The photolysate was concentrated on a rotary evaporator under water aspirator pressure, and the crude product was analyzed by ^{13}C nmr spectroscopy for stereochemical purity. In all cases, the ^{13}C spectra of lactone pairs epimeric at C-5 were distinct, and the concentrated photolysate was shown, within the limits of detection of the ^{13}C nmr spectrum, to contain only one epimer. Although the epimeric acetoxy lactones **9** and **10** could not be separated by thin-layer chromatography, analytical high performance liquid chromatography of the crude photolysates on a μ-Porasil column (4.2 mm × 30 cm) with hexanes – ethyl acetate (9:1 v/v) as eluent further evidenced the stereospecificity of the photolyses in the acetoxy series. For the deoxy ketols **19** and **20**, thin-layer chromatography with chloroform–acetone (95:5 v/v) indicated, in addition to the ^{13}C nmr spectra, that each photolysis gave only one lactone epimer. Thin-layer chromatography

with hexanes – ethyl acetate (4:1 v/v) gave further evidence of stereospecificity in the photolyses of the benzyloxy ketols **21** and **22**. The ir, ^{1}H nmr, and ^{13}C nmr spectra of the lactones obtained from photolyses in benzene were identical to those obtained by irradiation in ethanol.

Irradiation of 3β-acetoxy-5-hydroxy-5α-cholestan-6-one (7). Formation of 3β-acetoxy-6-oxa-B-homo-5β-cholestan-7-one (9)

(i) In ethanol

A solution (2 × 5 cm) of **7** (56 mg, 0.12 mmol) in ethanol (8 mL) was irradiated under argon for 6 h. Thin-layer chromatography (chloroform–acetone (9:1 v/v)) showed that the starting ketol had completely reacted. The photolysate was concentrated to give **9** (58 mg) as a white solid in quantitative yield. Crystallization from methanol gave **9** as white needles, mp 230–231°C (lit. (5) mp 228–229°C); ir λ_{max}: 5.78 μm; ir λ_{max} (KBr): 5.80, 8.10, 9.66 μm; ^{1}H nmr (200 MHz) δ: 0.66 (s, C-18 Me), 0.86 (d, J = 6 Hz, C-26,27 Me), 0.90 (d, J = 7 Hz, C-21 Me), 1.00 (s, C-19 Me), 2.02 (s), 2.44 (br d, J = 14 Hz, 1H), 2.96 (dd, J = 14, 10 Hz, 1H), 4.33 (nar m, $W_{1/2}$ = 8 Hz, 1H), 5.02 (br m, $W_{1/2}$ = 23 Hz, 1H); ^{1}H nmr (benzene-d_6, 200 MHz) δ: 0.46 (s), 0.49 (s), 0.95 (d, J = 7 Hz, C-21,26,27 Me), 1.75 (s), 2.12 (br d, J = 14 Hz, 1H), 2.32 (nar m, $W_{1/2}$ = 11 Hz, 2H), 3.68 (nar m, $W_{1/2}$ = 10 Hz, 1H), 4.30 (br m, $W_{1/2}$ = 24 Hz, 1H); ms m/z: 460 (1), 318 (100).

(ii) In benzene

A solution (1.5 × 7 cm) of **7** (42 mg, 0.09 mmol) in benzene (8 mL) was irradiated under argon for 8 h, and the photolysate was concentrated to give **9** (40.5 mg, 96%) as a pale yellow solid.

(iii) In butanol at 100°C

A solution (4 × 9 cm) of **7** (84 mg, 0.18 mmol) in freshly distilled *n*-butanol (100 mL) in a Pyrex tube was degassed with nitrogen for 1 h. The photolysis tube was fitted with a condenser, and the solution was stirred, heated to 100°C with a heating mantle, and irradiated at 300 nm under a nitrogen atmosphere for 14 h. Thin-layer chromatography (chloroform–acetone (9:1 (v/v)) evidenced complete reaction of the starting material, and the cooled photolysate was concentrated to give **9** (80 mg, 95%) as a white solid. The ir, ^{1}H nmr, and ^{13}C nmr spectra were superimposable with those of the lactone **9** obtained by photolysis of ketol **7** in ethanol.

Irradiation of 3β-acetoxy-5-hydroxy-5β-cholestan-6-one (8). Formation of 3β-acetoxy-6-oxa-B-homo-5α-cholestan-7-one (10)

(i) In ethanol

A solution (1.5 × 9 cm) of **8** (62 mg, 0.13 mmol) in ethanol (12 mL) was irradiated under argon, and the photolysis was followed by thin-layer chromatography (chloroform – ethyl acetate (9:1 v/v)). After 24 h, when the starting material had completely reacted, the photolysate was concentrated to give **10** (62 mg) as a white solid in quantitative yield. Crystallization from hexanes gave lactone **10** as fine white needles, mp 175–177°C (lit. (5) mp 178°C); ir λ_{max}: 5.80 μm; ir λ_{max} (KBr): 5.76, 8.05, 9.68 (m) μm; ^{1}H nmr (200 MHz) δ: 0.69 (s, C-18 Me), 0.86 (d, J = 6 Hz, C-26,27 Me), 0.89 (d, J = 7 Hz, C-21 Me), 0.93 (s, C-19 Me), 2.05 (s), 2.39 (dd, J = 14, 11 Hz, 1H), 2.54 (dd, J = 14, 2 Hz, 1H), 4.30 (dd, J = 11, 5 Hz, 1H), 4.63 (tt, J = 12, 4 Hz, 1H); ms m/z: 460 (2), 318 (100).

(ii) In benzene

Lactone **10** (49 mg) was obtained as a white solid in quantitative yield by irradiation of a solution (1.5 × 8 cm) of **8** (49 mg, 0.11 mmol) in benzene (12 mL) under argon for 24 h.

Irradiation of 5-hydroxy-5α-cholestan-6-one (19). Formation of 6-oxa-B-homo-5β-cholestan-7-one (23)

(i) In ethanol

A solution (1.5 × 4 cm) of **19** (26.5 mg, 0.07 mmol) in anhydrous ethanol (5 mL) was irradiated under argon. After 6 h, thin-layer chromatographic analysis (hexanes – ethyl acetate (4:1 v/v)) indicated complete reaction of the starting ketol, and the photolysate was concentrated to give **23** (25 mg, 94%) as a white solid. Flash chromatography on a silica gel column (0.5 × 14 cm) with dichloromethane as eluent gave **23** (18 mg, 69%) as a white solid. Crystallization from methanol afforded **23** as long, colorless needles, mp 122–123.5°C; ir λ_{max}: 5.79 μm; ^{1}H nmr δ: 0.67 (s, C-18 Me), 0.97 (s, C-19 Me), 2.42 (br d, J = 14 Hz, 1H), 3.00 (dd, J = 14, 9 Hz, 1H), 4.20 (nar m, $W_{1/2}$ = 8 Hz, 1H); ms m/z: 402 (7), 318 (100). *Exact Mass* calcd. for $C_{27}H_{46}O_2$: 402.3498; found: 402.3480. *Anal.* calcd. for $C_{27}H_{46}O_2$: C 80.54, H 11.52; found: C 80.72, H 11.55.

(ii) In benzene

A solution (1.5 × 6 cm) of **19** (43 mg, 0.11 mmol) in anhydrous benzene (7 mL) was degassed with nitrogen and irradiated for 19 h. The progress of the reaction was monitored by thin-layer chromatography (chloroform–acetone (9:1 v/v)) and, following completion of the reaction, the photolysate was concentrated to give **23** (42 mg, 98%) as a pale yellow solid.

Irradiation of 5-hydroxy-5β-cholestan-6-one (20). Formation of 6-oxa-B-homo-5α-cholestan-7-one (24)

(i) In ethanol

A solution (1.5 × 7 cm) of **20** (51.5 mg, 0.13 mmol) in anhydrous ethanol (9 mL) was irradiated under argon, and the photolysis was monitored by thin-layer chromatography (hexanes – ethyl acetate (4:1 v/v)). After 6 h, thin-layer chromatography showed that the starting ketol had completely reacted, and the photolysate was concentrated to give **24** (50 mg, 97%) as a white solid. Crystallization from methanol afforded lactone **24** as colorless plates, mp 159.5–160.5°C (lit. (40) mp 143–144°C; lit. (41) mp 155°C (light petroleum)); ir λ_{max}: 5.81 μm; ^{1}H nmr δ: 0.67 (s, C-18 Me), 0.90 (s, C-19 Me), 2.40–2.53 (m, 2H), 4.17 (dd, J = 10, 5 Hz, 1H); ms m/z: 402 (7), 318 (100). *Exact Mass* calcd. for $C_{27}H_{46}O_2$: 402.3498; found: 402.3507. *Anal.* calcd. for $C_{27}H_{46}O_2$: C 80.54, H 11.52; found: C 80.54, H 11.52.

(ii) In benzene

A solution (1.5 × 5 cm) of **20** (30 mg, 0.08 mmol) in benzene (5 mL) was irradiated under nitrogen for 11 h. Concentration of the photolysate gave **24** (28 mg, 94%) as a white solid.

Irradiation of 3β-benzyloxy-5-hydroxy-5α-cholestan-6-one (21). Formation of 3β-benzyloxy-6-oxa-B-homo-5β-cholestan-7-one (25)

(i) In ethanol

A solution of **21** (121 mg, 0.24 mmol) in ethanol (20 mL) was irradiated under argon, and the photolysis was monitored by thin-layer chromatography (hexanes – ethyl acetate (9:1 v/v)). After 17 h of irradiation, when the starting material was shown to have completely reacted, the photolysate was concentrated to give **25** (132 mg) as a white solid in quantitative yield. Flash chromatography of the solid on a silica gel column (1.5 × 15 cm) with chloroform – ethyl acetate (97:3 v/v) as eluent gave **25** (111 mg, 92%). Crystallization from methanol gave **25** as fine white needles, mp 154–155°C; ir λ_{max}: 5.79 μm; ^{1}H nmr δ: 0.67 (s, C-18 Me), 0.98 (s, C-19 Me), 2.98 (dd, J = 14, 9 Hz, 1H), 3.75 (br m, $W_{1/2}$ = 24 Hz, 1H), 4.32 (nar m, $W_{1/2}$ = 8 Hz, 1H), 4.53 (s, 2H), 7.32 (s, 5H); ms m/z: 91 (100). *Anal.* calcd. for $C_{34}H_{52}O_3$: C 80.26, H 10.30; found: C 80.46, H 10.33.

(ii) In benzene

A solution (1.5 × 14 cm) of **21** (93 mg, 0.18 mmol) in benzene (20 mL) was irradiated under argon for 17 h, and the photolysate was concentrated to give **25** (93 mg) as a white solid in quantitative yield.

Irradiation of 3β-benzyloxy-5-hydroxy-5β-cholestan-6-one (22). Formation of 3β-benzyloxy-6-oxa-B-homo-5α-cholestan-7-one (26)

(i) In ethanol

A solution (1.5 × 14 cm) of **22** (155 mg, 0.30 mmol) in anhydrous ethanol (20 mL) was irradiated under argon for 6 h. A thin-layer chromatography plate spotted with the photolysate was eluted twice with hexanes – ethyl acetate (85:15 v/v) and evidenced complete reaction of the starting ketol. The photolysate was concentrated to give **26** (153 mg, 99%) as a white solid. Crystallization from methanol gave **26** as very fine white needles, mp 171–173°C; recrystallization from

methanol gave an analytical sample, mp 174.5–175.5°C. Lactone **26**, ir λ_{max}: 5.81 μm; ^{1}H nmr δ: 0.68 (s, C-18 Me), 0.93 (s, C-19 Me), 3.32 (br m, $W_{1/2}$ = 24 Hz, 1H), 4.20 (dd, J = 11, 5 Hz, 1H), 4.56 (s, 2H), 7.33 (s, 5H); ms m/z: 508 (1), 91 (100). *Anal.* calcd. for $C_{34}H_{52}O_3$: C 80.26, H 10.30; found: C 80.25, H 10.32.

(ii) In benzene

A solution (1.5 × 12 cm) of **22** (79.5 mg, 0.16 mmol) in benzene (15 mL) was irradiated under argon for 6 h. Concentration of the photolysate gave **26** (76 mg, 96%) as a pale yellow solid.

Irradiation of the 7α-deutero 5α-ketol 27. Formation of 3β-acetoxy-5-deutero-6-oxa-B-homo-5β-cholestan-7-one (29)

(i) In benzene

A solution (1.5 × 6 cm) of **27** (38.1 mg, 0.083 mmol) in anhydrous benzene (6 mL) was irradiated in Pyrex at 300 nm under an argon atmosphere for 22 h. Concentration of the photolysate gave **29** (37 mg, 97%) as an off-white solid; ir λ_{max}: 5.79 μm; ^{1}H nmr (200 MHz) δ: 0.66 (s, C-18 Me), 0.86 (d, J = 7 Hz, C-26,27 Me), 0.90 (d, J = 7 Hz, C-21 Me), 1.00 (s, C-19 Me), 2.02 (s), 2.44 (br d, J = 14 Hz, 1H), 2.96 (dd, J = 14, 10 Hz, 1H), 4.33 (nar m, 0.21H), 5.02 (br m, $W_{1/2}$ = 23 Hz, 1H); ms m/z: 461 (2), 319 (97), 318 (100); d_0 21%, d_1 76%, d_2 3% (based on M − AcOH).

(ii) In ethanol

The 7α-deutero 5α-ketol **27** (ms: d_0 36%, d_1 62%, d_2 2%; 18.0 mg, 0.039 mmol) was irradiated in anhydrous ethanol (5 mL) in a Pyrex tube under a nitrogen atmosphere at 300 nm for 23 h. The photolysate was concentrated to give the 5β-deutero lactone **29** (16 mg, 89%) as a white solid; ^{1}H nmr (200 MHz) δ: 4.33 (nar m, 0.38H; C-5 methine); ms: d_0 42%, d_1 55%, d_2 3%.

Irradiation of the 7α-deutero 5β-ketol 28. Formation of 3β-acetoxy-5-deutero-6-oxa-B-homo-5α-cholestan-7-one (30)

(i) In benzene

A solution (1.5 × 3 cm) of **28** (18.0 mg, 0.039 mmol) in anhydrous benzene (4.5 mL) was irradiated in Pyrex under argon at 300 nm for 24 h. The photolysate was concentrated to give **30** (17 mg, 95%) as a white solid; ir λ_{max} (KBr): 5.76, 7.68 (w), 9.29 (m) μm; ^{1}H nmr (200 MHz) δ: 0.69 (s, C-18 Me), 0.86 (d, J = 6 Hz, C-26,27 Me), 0.89 (d, J = 7 Hz, C-21 Me), 0.93 (s, C-19 Me), 2.05 (s), 2.39 (dd, J = 13, 11 Hz, 1H), 2.54 (dd, J = 14, 2 Hz, 1H), 4.30 (dd, J = 11, 5 Hz, 0.13H), 4.63 (tt, J = 12, 4 Hz, 1H); ms m/z: 461 (3), 319 (89), 318 (100); d_0 11%, d_1 86%, d_2 3% (based on M − AcOH).

(ii) In ethanol

A solution of **28** (16.5 mg, 0.036 mmol) in anhydrous ethanol (3 mL) was irradiated in Pyrex under argon at 300 nm for 27 h. Concentration of the photolysate gave the 5α-deutero lactone **30** (14 mg, 86%) as a white solid; ^{1}H nmr (200 MHz) δ: 4.30 (dd, J = 11, 5 Hz, 0.14H, C-5 methine); ms: d_0 11%, d_1 87%, d_2 2% (based on M − AcOH); d_0 9%, d_1 87%, d_2 4% (based on M).

Irradiation of 3β-acetoxy-5-deuteroxy-5α-cholestan-6-one (31). Formation of 3β-acetoxy-7aα- and 7aβ-deutero-6-oxa-B-homo-5β-cholestan-7-one (33 and 34)

In a separatory funnel, a solution of 3β-acetoxy-5-hydroxy-5α-cholestan-6-one (**7**) (20.4 mg, 0.044 mmol) in benzene (15 mL) was washed with deuterium oxide (99.8%, Aldrich; 5 × 1 mL), and deuterium oxide (1 mL) was added to the organic layer. The two-phase mixture was added via cannula under argon to a Pyrex photolysis tube pretreated with deuterium oxide. The mixture (1.5 × 13 cm) was degassed with argon for 1 h, and stirred and irradiated at 300 nm for 22 h. The deuterium oxide layer of the photolysate was extracted with benzene (2 × 5 mL), and the combined benzene phases were concentrated to give a 26:74 mixture of **33** and **34** (19.8 mg, 97%) as a white solid; ir λ_{max}: 5.77 μm; ^{1}H nmr (200 MHz) δ: 0.66 (s, C-18 Me), 0.86 (d, J = 7 Hz, C-26,27 Me), 0.89 (d, J = 7 Hz, C-21 Me), 1.00 (s, C-19 Me), 2.02 (s), 2.42 (nar m, $W_{1/2}$ = 6 Hz, 0.58H), 2.94 (br d, J = 10 Hz, 0.20H), 4.33 (nar m, $W_{1/2}$ = 8 Hz, 1H), 5.03 (br m, $W_{1/2}$ = 24 Hz, 1H); ms m/z: 461 (1), 319 (100); d_0 28%, d_1 68%, d_2 3% (based on M − AcOH).

Irradiation of 3β-acetoxy-5-deuteroxy-5β-cholestan-6-one (32). Formation of 3β-acetoxy-7aα- and 7aβ-deutero-6-oxa-B-homo-5α-cholestan-7-one (35 and 36)

A solution (1.5 × 16 cm) of **32** (25.3 mg, 0.055 mmol) in benzene (20 mL) was prepared by the procedure used for the analogous 5α-deuteroxy ketol **31** (*vide supra*). Deuterium oxide (1 mL) was added, and the stirred two-phase mixture was irradiated at 300 nm for 24 h. The organic phase of the photolysate was washed with saturated aqueous sodium bicarbonate (1 × 2 mL) and water (5 × 2 mL), dried over anhydrous sodium sulfate, and concentrated to give an 88:12 mixture of **35** and **36** (24 mg, 94%) as a white solid; ir λ_{max} (KBr): 5.77, 5.81 (sh), 5.84 (sh), 7.66 (m), 8.52 (w) μm; ^{1}H nmr (200 MHz) δ: 0.69 (s, C-18 Me), 0.86 (d, J = 6 Hz, C-26,27 Me), 0.89 (d, J = 7 Hz, C-21 Me), 0.93 (s, C-19 Me), 2.05 (s), 2.38 (br d, J = 12 Hz, 0.12H), 2.52 (br s, $W_{1/2}$ = 3 Hz, 0.91H), 4.30 (dd, J = 11, 5 Hz, 1H), 4.63 (tt, J = 12, 4 Hz, 1H); ms m/z: 461 (2), 319 (100); d_0 9%, d_1 88%, d_2 3% (based on M − AcOH); d_0 8%, d_1 88%, d_2 4% (based on M).

Irradiation of the 5α-methoxy ketone 37 in ethanol. Formation of 3β-acetoxy-5-methoxy-5,6-seco-5α-cholestan-6-oic acid ethyl ester (39)

A solution of **37** (153 mg, 0.32 mmol) in anhydrous ethanol (100 mL) in a Pyrex tube was degassed with nitrogen for 1.5 h. The Pyrex tube was fitted with a cold finger insert, and the solution was irradiated at 300 nm in a Rayonet photochemical reactor at 22°C for 4.5 h. The photolysate was concentrated to give **39** (169 mg) as a yellow oil in quantitative yield. A ^{13}C nmr spectrum of the crude photolysate evidenced only one component. Flash chromatography of the oil on a silica gel column (2 × 13 cm) with hexanes – ethyl acetate (85:15 v/v) as eluent gave the seco ester **39** as a colorless oil that resisted crystallization; ir λ_{max}: 5.78 μm; ^{1}H nmr δ: 0.67 (s, C-18 Me), 1.02 (s, C-19 Me), 1.25 (t, J = 7 Hz), 2.03 (s), 3.32 (overlapping s and m, 4H), 4.13 (q, J = 7 Hz, 2H), 4.80 (br m, $W_{1/2}$ = 24 Hz, 1H); ^{1}H nmr (benzene-d_6, 200 MHz) δ: 0.69 (s, C-18 Me), 0.92 (d, J = 6 Hz, C-26,27 Me), 0.95 (s, C-19 Me), 0.98 (d, J = 7 Hz, C-21 Me), 0.98 (t, J = 7 Hz), 1.73 (s), 3.26 (s, 3H), 3.36 (nar m, $W_{1/2}$ = 8 Hz, 1H), 3.89–4.09 (m, width = 39 Hz, 2H), 5.10 (br m, $W_{1/2}$ = 24 Hz, 1H); ms m/z: 520 (4), 460 (55), 84 (100). *Exact Mass* calcd. for $C_{30}H_{52}O_3$ (M − AcOH): 460.3916; found: 460.3922. *Anal.* calcd. for $C_{32}H_{56}O_5$: C 73.80, H 10.84; found: C 73.81, H 10.83.

Irradiation of 3β-acetoxy-5α-cholestan-6-one (41) in ethanol. Formation of 3β-acetoxy-5,6-seco-cholestan-6-oic acid ethyl ester (44)

A solution of **41** (308 mg, 0.69 mmol) in anhydrous ethanol (30 mL) was degassed with nitrogen for 1 h in a quartz photolysis tube. The solution was irradiated at 254 nm in a Rayonet photochemical reactor for 3.5 h, and the photolysate was concentrated to give a pale yellow oil (290 mg). The ^{1}H nmr spectrum of the oil evidences complete reaction of the starting material. Flash chromatography of the oil on a silica gel column (2.5 × 15 cm) with hexanes – ethyl acetate (95:5 v/v) gave 3β-acetoxy-5,6-seco-cholestan-6-oic acid ethyl ester **44** (23 mg, 7%) as a colorless oil that resisted crystallization; ir λ_{max}: 5.76, 5.79 μm; ^{1}H nmr δ: 0.65 (s, C-18 Me), 0.97 (s, C-19 Me), 1.22 (t, J = 7 Hz), 2.00 (s), 2.48 (m, $W_{1/2}$ = 6 Hz, 2H), 4.10 (q, J = 7 Hz, 2H), 4.70 (br m, $W_{1/2}$ = 22 Hz, 1H); ms m/z: 490 (<1), 95 (100).

Irradiation of 3β-acetoxy-5-amino-5α-cholestan-6-one (45) in benzene. Formation of 3β-acetoxy-6-aza-B-homo-5β-cholestan-7-one (46)

A solution of **45** (20 mg, 0.43 mmol) in anhydrous benzene (5 mL) was irradiated in Pyrex under a nitrogen atmosphere at 300 nm in a Rayonet photochemical reactor for 14 h. The photolysate was concentrated to give **46** (22 mg) as a pale yellow oil in quantitative yield. Flash chromatography of the oil on a silica gel column (0.5 × 14 cm) with dichloromethane removed a small amount (2 mg) of high R_f materials. Further elution with dichloromethane–methanol (95:5 v/v) gave the lactam **46** (14 mg, 69%) as a colorless oil, which crystallized on standing, mp 84–91°C; ir λ_{max}: 2.97 (sh, w), 5.75, 6.02 μm; ^{1}H nmr δ:

0.67 (s, C-18 Me), 1.03 (s, C-19 Me), 2.03 (s), 3.23 (br m, $W_{1/2}$ = 20 Hz, 1H), 5.10 (br m, $W_{1/2}$ = 16 Hz, 1H), 6.27 (br d, J = 8 Hz, 1H); ms m/z: 459 (20), 399 (100). *Exact Mass* calcd. for $C_{29}H_{49}O_3N$: 459.3712; found: 459.3714.

Appendix

For the interpretation of the photochemistry of the *O*-deuteroxy ketols, the resonances for the C-7a methylene protons in the ^{1}H nmr spectra of the undeuterated lactones **9** and **10** had to be assigned. This proved not to be a simple task since the seven-membered lactone rings were conformationally flexible.

In the case of the acetoxy 5β-lactone **9**, two lactone conformers, **9***A* and **9***B*, are consistent with the 200-MHz ^{1}H nmr spectrum, but predicted coupling constants for the dihedral angles measured from Dreiding models led to opposite assignments for the C-7a methylene protons. The preference of

9 to exist as conformer **9***A* was established as follows. In the ir spectrum of **9**, a carbonyl stretching band at 5.79 μm, viewed relative to the band at 5.79 μm recorded in carbon tetrachloride for ε-caprolactone (42), is consistent with conformer **9***A*, wherein a lone pair on the ring oxygen is aligned with the carbonyl π-bond so as to allow favorable overlap. However, in conformer **9***B* the disposition of the oxygen lone pairs and carbonyl π-orbitals of the lactone group prohibits good overlap, and the carbonyl stretching band for **9***B* would be expected to occur at shorter wavelength than the band position observed for **9**.

Direct evidence for the preference of **9** to exist as conformer **9***A* was procured by a nuclear Overhauser enhancement (nOe) study. Dreiding models show that the C-5 methine and C-7a β protons in conformer **9***A* are approximately 1.3 Å apart, ideally disposed to exhibit an nOe effect. The C-7a methylene protons in conformer **9***B* were each estimated to be ~3.5 Å distant from the C-5 methine proton, a distance considered too remote for any nOe enhancement between these protons (43). Irradiation of the doublet of doublets at δ 2.96 induced a 12% enhancement of the area of the C-5 methine proton signal in the ^{1}H nmr spectrum of **9**, thereby confirming that **9***A* is the preferred conformation. Thus, the doublet of doublets at δ 2.96 and the broad doublet at δ 2.44 could be assigned unequivocally to the C-7a β- and C-7a α-protons, respectively.

There are also two conformations, **10***A* and **10***B*, available to the 5α-lactone **10**, both of which are consistent with the coupling pattern observed for the C-7a methylene protons in the 200-MHz ^{1}H nmr spectrum. Measurement of the dihedral angles in Dreiding models in conjunction with estimated coupling constants led to opposite assignments of the C-7a methylene protons for the two conformers.

The ir spectrum of **10** exhibits a carbonyl stretching band at 5.80 μm ($CHCl_3$), indicative of effective orbital overlap in the lactone group, thus favouring conformation **10***A*. Again, the preference of **10** to exist in conformation **10***A* was verified by an nOe experiment. Irradiation of the doublet of doublets at δ 2.39 gave rise to a 13% increase in the area of the C-5 methine proton signal of **10**. The observation of an nOe effect is in accord only with conformer **10***A*, for which a Dreiding model indicates that the C-7a α-proton is situated ~1.5 Å from the C-5 methine proton. Thus the doublet of doublets at δ 2.39 can be assigned unambiguously to the C-7a α-proton and that at δ 2.54 to the C-7a β-proton.

Synthesis of maytenoquinone

ROBERT H. BURNELL,[1] MICHEL JEAN, AND SONIA MARCEAU
Département de chimie, Université Laval, Québec (Québec), Canada G1K 7P4

Received July 29, 1987

ROBERT H. BURNELL, MICHEL JEAN, and SONIA MARCEAU. Can. J. Chem. **66**, 227 (1988).
A synthesis of maytenoquinone (**11**) from natural podocarpic acid (**1**) is described.

ROBERT H. BURNELL, MICHEL JEAN et SONIA MARCEAU. Can. J. Chem. **66**, 227 (1988).
Nous avons transformé l'acide podocarpique naturel (**1**) en maytenoquinone (**11**).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.222.148.141 on 09/07/12
For personal use only.

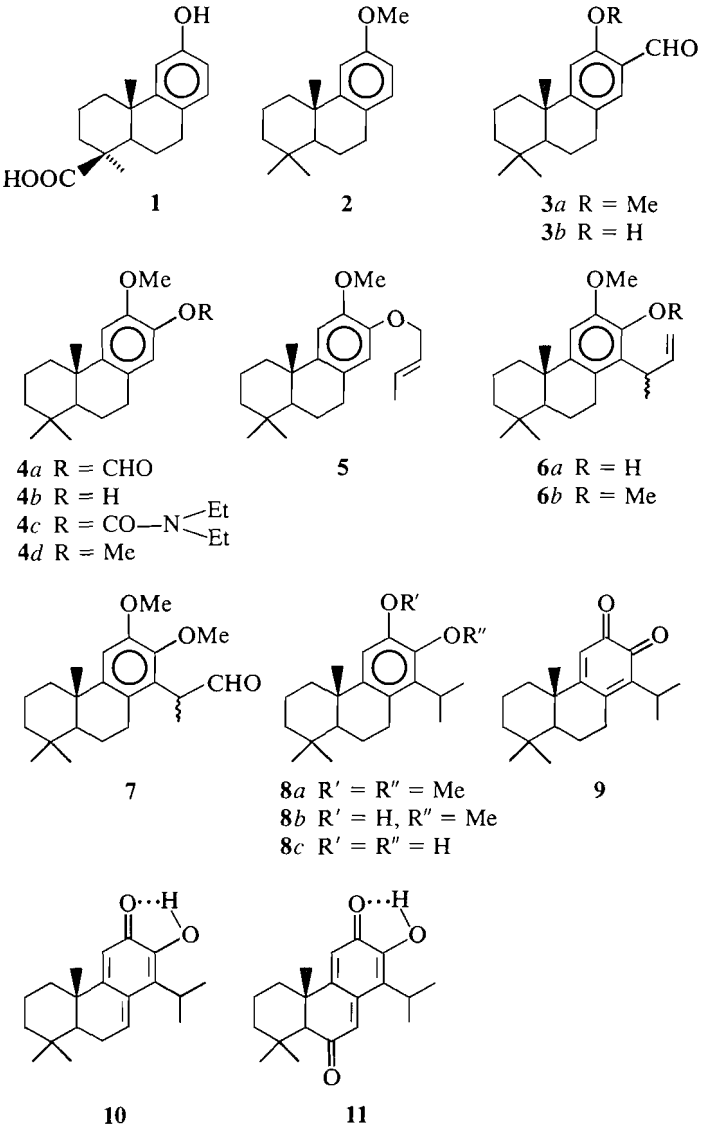
Following our synthesis of taxodione (1) we turned our attention to the positional isomer maytenoquinone **11** (2). The straightforward sequence described below enabled us to obtain several hundred milligrams of this interesting extended quinone, and while the unoptimized yields of some of the steps are low, this is normal in this area of synthesis (3).

We chose, as has become a tradition, to use podocarpic acid **1** as our naturally available chiral starting material, which led to the natural maytenoquinone **11**. After modifying the carboxyl group at C.4 to establish the *gem*-dimethyl moiety by well-documented methods (4), a Duff reaction was used to introduce a formyl residue at C.13 and this product **3** was oxidized to the *O*-formyl derivative **4***a*. Hydrolysis of the latter afforded the catechol monoether **4***b*.

Of several attempts to introduce useful substituents at C.14, none was successful, presumably for steric reasons. A small amount of the 14-formyl derivative was obtained when the dimethoxy compound **4***d* was subjected to the conditions used to prepare **3***a* but the best yield was only 3%. By directed lithiation of the carbamate **4***c* by the Snieckus procedure (5) we were unable to introduce even deuterium at C.14, so an intramolecular route was employed. Williamson type alkylation of **4***b* with crotyl bromide gave the allylic ether **5**, which rearranged smoothly but not too efficiently to the 14-substituted compound **6**. At this stage a superfluous chiral centre had been formed (wavy line in **6** and **7**) but no attempt was made to separate the epimers since this asymmetry would disappear in subsequent steps. The nmr spectra of **6** and **7** show the presence of two diastereomers in each case.

After methylating the phenolic hydroxyl in **6***a*, the double bond in the product **6***b* was cleaved by the osmium tetroxide/periodate procedure to afford the aldehyde **7** and the latter was reduced under Huang–Minlon conditions to afford the 14-isopropyl derivative **8***a*. The dimethoxy aldehyde **7** suffered some partial demethylation during the reduction, as evidenced by the isolation of a small quantity of dispermol (the 13-methoxy-12-hydroxy compound **8***b*, 7% yield). These compounds were described by Matsumoto, Ohmura, and Usui (6) in their earlier synthesis of maytenoquinone **11**.

The diether **8***a* was demethylated with boron tribromide and the resulting catechol **8***c* promptly oxidized with silver oxide, which should have given the *o*-quinone **9** according to published precedent. The latter was not the product isolated. As in our previous taxodione synthesis, the *o*-quinone enolized to the methylene-quinone **10**, as seen from the spectral characteristics of the material obtained. Slow column chromatography of the latter gave maytenoquinone **11** showing identical uv, ir, and nmr spectra with those described by Matsumoto (6). We were unable to isolate the intermediate with a hydroxyl or a hydroperoxyl group at C.6, which is probably on the reaction path from **10** to **11**. Presumably its ready oxidation precludes its isolation.



1 **2** **3***a* R = Me; **3***b* R = H

4*a* R = CHO; **4***b* R = H; **4***c* R = CO—N(Et)(Et); **4***d* R = Me

5 **6***a* R = H; **6***b* R = Me

For personal use only.

ments in parentheses), Varian XL-200; mass spectra, Hewlett Packard 5992. Elemental analyses were by Galbraith Laboratories, Knoxville. The high resolution mass spectra were recorded at the Centre Régional de Spectrométrie de masse, Université de Montréal. Unless otherwise stated, dry column chromatography implies the use of Merck Kieselgel 60F (70–230 mesh) and elution with hexane – ethyl acetate (proportions determined by prior thin-layer chromatography using Baker-flex Silica gel 1B2-F precoated plastic sheets).

Formylation of 12-methoxypodocarpa-8,11,13-triene

Following the method described by Smith (7), the methoxy derivative **2** (13.5 g) was dissolved in trifluoroacetic acid (150 mL) and hexamethylenetetramine (16 g) was added. The mixture was well stirred and heated under reflux for 10 h and then, after cooling, the acid was neutralized with sodium bicarbonate and the product obtained by ether extraction. The crude material was chromatographed over silica gel, affording first the aldehyde **3***a*: *12-methoxy-13-formylpodocarpa-8,11,13-triene* (8) (9.3 g; 62%), as a colorless oil; uv (MeOH): 264 (13 800) and 334 (4800) nm; ir: 3060, 1685, 1610, and 1490 cm^{-1}; ^1H nmr δ: 0.93, 0.95, and 1.20 (3s, Me-C at C.4 and C.10), 3.88 (s, Me-O-Ar), 6.85 and 7.49 (2s, arom. H at C.11 and C.14 respectively), and 10.36 (s, Ar-CHO); ^{13}C nmr, see Table 1; ms *m/z*: 286 (86, M^+), 271 (28), 215 (23), 203 (58), 201 (47), and 189 (100). *Exact Mass* calcd. for $C_{19}H_{26}O_2$: 286.1934; found (hrms): 286.1925. *Anal.* calcd. for $C_{19}H_{24}O_2$: C 79.68, H 9.15; found: C 79.67, H 9.48. Further elution of the column gave the phenolic aldehyde **3***b*: *12-hydroxy-13-formylpodocarpa-8,11,13-triene* (3.50 g; 25%), mp 133–134°C (from ether–hexane); ir: 3140, 3060, 1650, 1570, and 1475 cm^{-1}; ^1H nmr δ: 0.93, 0.95, and 1.18 (3s, Me-C), 6.87 (s, H-C.11), 7.19 (s, H-C.14), 9.77 (s, CHO), and 10.64 (s, Ar-OH, diss. D_2O); ^{13}C nmr, see table. *Exact Mass* calcd. for $C_{18}H_{24}O_2$: 272.1777; found (hrms): 272.1754. *Anal.* calcd. for $C_{18}H_{24}O_2$: C 79.37, H 8.88; found: C 79.70, H 8.93.

The phenol **3***b* (5.2 g) was dissolved in acetone (200 mL), and potassium bicarbonate (1.5 g) and methyl iodide (2.3 mL) were added. The mixture was refluxed for 48 h. After cooling, the bicarbonate was filtered off and the residue remaining after evaporating the solvent was chromatographed as above, affording the methoxy compound **3***a* (5.4 g; 99%).

*Baeyer–Villiger oxidation of the aldehyde 3*a

m-Chloroperbenzoic acid (4 g; 85%) was added to a solution of the aldehyde **3***a* (4.6 g) in dichloromethane (70 mL) and the mixture was refluxed for 18 h. The cooled solution was well washed with sodium bicarbonate solution, saturated sodium chloride, dried, and the crude formate **4***a* (4.8 g; 98%) obtained by evaporation. In the ir spectrum it showed bands at 1745 (formate), 1620, and 1500 cm^{-1}, and the following ^1H nmr singlets were measured at 60 MHz: 0.95 (6H), 1.20 (Me-C), 3.80 (Me-O-Ar), 6.75 and 6.90 (H-Ar), and 8.25 (formate). The product was not purified further but was hydrolysed by dissolving in methanol (70 mL) to which was added aqueous potassium hydroxide (15 mL of 10%) and the solution was refluxed for 4 h. The cooled mixture was evaporated to remove most of the solvent, diluted with water, and the product obtained by ether extraction. Chromatography afforded the phenol **4***b*: *12-methoxy-13-hydroxypodocarpa-8,11,13-triene* (9) (3.5 g; 79%), mp 109–110°C (from ether–hexane); uv: 286 (3700) nm; ir: 3510, 3420, 1620, 1590, and 1500 cm^{-1}; ^1H nmr δ: 0.91, 0.94, 1.17 (Me-C at C.4 and C.10), 3.83 (s, Me-O-Ar), 5.43 (s, OH, diss. D_2O), 6.57 and 6.73 (2s, arom. H); ^{13}C nmr, see table; ms *m/z*: 274 (M^+, 45), 259 (100), 203 (18), 189 (54), 177 (44), and 163 (74). *Exact Mass* calcd. for $C_{18}H_{26}O_2$: 274.1934; found (hrms): 274.1924. *Anal.* calcd. for $C_{18}H_{26}O_2$: C 78.79, H 9.55; found: C 78.82, H 9.62.

N,N-*Diethylcarbamate of phenol 4*b

The literature method (10) was modified. The phenol **4***b* (83 mg) was dissolved in acetone (20 mL), and potassium carbonate (120 mg) and *N*,*N*-diethylcarbamoyl chloride (0.2 mL) were added and the mixture

heated under reflux for 24 h. The solution was filtered and evaporated and the crude material chromatographed to afford the derivative **4***c* (103 mg; 91%), mp 76–78°C (from ethanol); uv (MeOH): 221 (9500), 267 (1700), and 279 (3800) nm; ir ($CHCl_3$): 1700, 1610, 1500, 1260, and 1150 cm^{-1}; ^1H nmr δ: 0.91, 0.94, and 1.17 (3s, Me-C), 1.25 (m, 6H, CH_3CH_2-N), 3.40 (m, 4H, CH_3CH_2-N), 3.77 (s, Me-O-Ar), 6.73 and 6.81 (2s, arom. H); ms *m/z*: 373 (M^+, 16), 301 (29), 300 (100), and 285 (34). *Exact Mass* calcd. for $C_{23}H_{35}NO_3$: 373.2619; found (hrms): 373.2634. *Anal.* calcd. for $C_{23}H_{35}NO_3$: C 73.96, H 9.45, N 3.75; found: C 74.09, H 9.81, N 3.64. *Note*: Under the conditions described by Snieckus *et al.* (5) we were unable to introduce substituents at the C.14 position via the lithiated species. Neither acetone, 2-bromopropane, nor carbon dioxide gave even traces of substituted products.

Methylation of phenol **4**b *to dimethoxy compound* **4**d

Potassium carbonate (2 g) and methyl iodide (1.05 mL) were added to a solution of phenol **4***b* (2.3 g) in acetone (75 mL). After 24 h at reflux, the cooled solution was filtered and evaporated, and the product obtained by chromatography: *12,13-dimethoxypodocarpa-8,11,13-triene* (9) (**4***d*) (2.25 g; 93%), colourless oil; ir: 1605 and 1505 cm^{-1}; ^1H nmr δ: 0.92, 0.95, and 1.18 (3s, Me-C), 3.82 and 3.84 (2s, Me-O-Ar), 6.52 and 6.77 (2s, arom. H); ms *m/z*: 288 (56), 273 (100), 203 (56), and 191 (69). *Exact Mass* calcd. for $C_{19}H_{28}O_2$: 288.2090; found (hrms): 288.2062.

Formylation of the dimethoxy compound **4**d

The dimethoxy product **4***d* (1.35 g) was formylated in exactly the same manner as used to prepare **3***a*. Chromatography of the mixture obtained gave the starting material (1.28 g) and then the formyl derivative: *12,13-dimethoxy-14-formylpodocarpa-8,11,13-triene* (40 mg; 3%) ir: 2845, 1690, 1610, and 1480 cm^{-1}; ^1H nmr δ: 0.92, 0.95, and 1.20 (3s, Me-C), 3.88 and 3.90 (2s, Me-O-Ar), 7.10 (s, arom. H at C.11), and 10.56 (s, CHO); ms *m/z*: 316 (97), 301 (30), 245 (28), 231 (74), 219 (63), and 305 (100). *Exact Mass* calcd. for $C_{20}H_{28}O_3$: 316.2039; found (hrms): 316.2101.

Note of this compound was obtained in several versions of the Vilsmeier–Haack procedure.

Allylic ether **5**

To a solution of phenol **4***b* (3.02 g) in acetone (75 mL) was added potassium bicarbonate (3 g), and then, with efficient stirring, crotyl bromide (3.4 mL). After refluxing for 24 h, the cooled mixture was poured into aqueous hydrochloric acid (100 mL) and most of the acetone was removed at the pump. Ether extraction and chromatography afforded the ether **5**: *12-methoxy-13-but-2-enyloxypodocarpa-8,11,13-triene* (3.12 g; 86%); uv: 222 (10 500) and 281 (4100) nm; ^1H nmr δ: 0.92, 0.94, and 1.18 (3s, Me-C), 1.74 (d, CH_3-CH), 3.82 (s, Me-O-Ar), 4.44 (dd, J = 3.8 and 1.3 Hz, CH_2-O), 5.78 (m, vinyl H in side chain), 6.52 and 6.76 (2s, arom. H); ^{13}C nmr, see table; ms *m/z*: 328 (M^+, 10), 274 (14), 259 (34), 203 (12), 189 (17), and 177 (22). *Exact Mass* calcd. for $C_{22}H_{32}O_2$: 328.2404; found (hrms): 328.2448. *Anal.* calcd. for $C_{22}H_{32}O_2$: C 80.44, H 9.83; found; C 79.92, H 10.09.

Claisen rearrangement of ether **5**

The ether **5** (2.0 g) was refluxed in dimethylaniline (100 mL) during 48 h with efficient stirring. After cooling, the solution was diluted with ether and washed exhaustively with 10% hydrochloric acid, and the product was then obtained in the normal manner. Chromatography using CCl_4 gave the product **6***a*: *12-methoxy-13-hydroxy-14-(1-methylallyl)-podocarpa-8,11,13-triene* (1.60 g; 80%); uv: 285 (3300) nm; ir: 3540, 3060, 1630, 1610, and 1485 cm^{-1}; ^1H nmr δ: 0.91 and 0.95 (2s, Me-C and C.4), 1.17 and 1.19 (2s, Me-C.10, two epimers), 1.44 and 1.46 (2d, J = 7.0 Hz, Me in side chain, two epimers), 2.81 (m, H-C.15), 3.83 (s, Me-O-Ar), 5.01 (dd, J = 10.3 and 1.9 Hz, *cis* coupled terminal vinyl), 5.09 (dd, J = 17.1 and 1.9 Hz, *trans* coupled terminal vinyl), 5.62 (s, OH, diss. D_2O), 6.34 (ddd, J = 6.7, 10.2, and 16.8 Hz, vinyl), and 6.69 (s, arom. H); ^{13}C nmr, see table; ms *m/z*: 328 (M^+, 56), 314 (21), 313 (100), 257 (17), 243 (44), and 231 (25). *Exact Mass* calcd. for $C_{22}H_{32}O_2$: 328.2404; found (hrms): 328.2395.

12,13-Dimethoxy-14-(1-methylallyl)podocarpa-8,11,13-triene **6**b

The phenol **6***a* (2.77 g) was dissolved in ethanol (100 mL), and aqueous sodium hydroxide (20 mL of 50%) was added. After 10 min stirring, dimethyl sulfate was introduced (15 mL) and the mixture was refluxed for 48 h. The cooled solution was acidified with dilute hydrochloric acid and the product obtained by either extraction was chromatographed to afford the methylated compound **6***b* (2.55 g; 88%) as a colorless oil; ir: 3070, 1630, and 1590 cm^{-1}; ^1H nmr δ: 0.92, 0.94, and 1.20 (3s, Me-C), 1.39 and 1.41 (2d, J = 7.0 Hz, Me in side chain, two epimers), 2.84 (m, H-C.15), 3.77 and 3.80 (2s, Me-O-Ar), 4.94 (dd, J = 10.3 and 1.9 Hz, *cis* coupled terminal vinyl), 5.04 (dd, J = 16.3 and 1.9 Hz, *trans* coupled terminal vinyl), 6.20 (ddd, J = 16.2, 10.5, and 1.9 Hz, vinyl), and 6.74 (s, arom. H); ^{13}C nmr, see table; ms *m/z*: 342 (M^+, 46), 327 (60), 313 (11), 271 (16), 257 (43), 245 (29), 231 (62), and 218 (24). *Exact Mass* calcd. for $C_{23}H_{34}O_2$: 342.2560; found (hrms): 342.2560.

Double bond cleavage to give the aldehyde **7**

Following essentially the method of Graham and Williams (11), the olefin **6***b* (1.42 g) was dissolved in dioxane (100 mL) and water (30 mL). Osmium tetroxide (200 mg) was added, and then small portions of sodium metaperiodate (total 2.5 g). Stirring was continued at room temperature for 3 h and, after dilution with water, the product was obtained by ether extraction. Chromatography afforded the aldehyde **7**: *12,13-dimethoxy-14-(1-formylethyl)-podocarpa-8,11,13-triene* (774 mg; 54%) as a colorless oil; ir: 2700, 1720, 1595, and 1485 cm^{-1}; uv: 284 (2300) nm; ^1H nmr δ: 0.93 and 0.96 (2s, Me-C), 1.21 and 1.22 (2s, Me-C.10, two epimers), 1.31 and 1.35 (2d, J = 7.0 Hz, Me in side chain, two epimers), 3.49 (m, H-C.15), 3.76 and 3.81 (2s, Me-O-Ar), 6.82 (s, arom. H), and 9.65 (CHO, two epimers); ^{13}C nmr, see table; ms *m/z*: 344 (M^+, 34), 329 (23), 315 (7), 287 (13), 273 (13), 259 (18), 247 (20), 233 (42), and 203 (43). *Exact Mass* calcd. for $C_{22}H_{32}O_3$: 344.2353; found (hrms): 344.2345.

Reduction of the aldehyde **7**

Hydrazine hydrate (1.8 mL of 85%) was added to a solution of the aldehyde **7** (1.25 g) in diethylene glycol (50 mL) and the mixture was heated at 100°C for 2.5 h. After cooling to room temperature, potassium hydroxide (1.3 g) was added, the solution was distilled until the flask contents boiled at 210°C, and then refluxing was continued for 1 h. The cooled reaction mixture was acidified to pH 2 with 6 M hydrochloric acid and the product was recovered by ether extraction. Chromatography gave first the dimethoxy compound **8***a*: *12,13-dimethoxy-14-isopropylpodocarpa-8,11,13-triene* (0.833 g; 74%), mp 75–76°C (from ether–hexane); uv: 284 (2000) nm; ir: 1590 and 1480 cm^{-1}; ^1H nmr δ: 0.91, 0.94, and 1.21 (3s, Me-C), 1.32 and 1.33 (2d, J = 7.0 Hz, iso-Pr Me), 2.78 (m, 2H, H-C.7), 3.23 (m, H-C.15), 3.81 and 3.82 (2s, Me-O-Ar), and 6.72 (s, arom. H); ^{13}C nmr, see table; ms *m/z*: 300 (M^+, 29), 315 (29), 259 (10), 245 (36), 233 (24), 231 (28), and 219 (91). *Exact Mass* calcd. for $C_{22}H_{34}O_2$: 330.2560; found (hrms): 330.2565. *Anal.* calcd. for $C_{22}H_{34}O_2$: C 79.95, H 10.37; found: C 79.84, H 10.46.

Further elution of the column afforded the monomethoxy derivative **8***b*: *13-methoxy-12-hydroxy-14-isopropylpodocarpa-8,11,13-triene or dispermol* (75 mg; 7%), colorless oil; ir: 3540, 3390, 1590, and 1480 cm^{-1}; ^1H nmr δ: 0.91, 0.94, and 1.17 (3s, Me-C), 1.32 and 1.35 (2d, J = 7.0 Hz, iso-Pr Me), 2.80 (m, 2H, H-C.7), 3.34 (m, H-C.15), 5.32 (s, OH, diss. D_2O), and 6.72 (s, arom. H); ^{13}C nmr, see table; ms *m/z*: 316 (21), 301 (9), 259 (11), 245 (43), 231 (27), and 219 (83). *Exact Mass* calcd. for $C_{21}H_{32}O_2$: 316.2404; found (hrms): 316.2399.

Demethylation to the catechol **8**c

A solution of the dimethoxy compound **8***a* (875 mg) in dichloromethane (50 mL) was cooled in an ice bath. The reaction was conducted under rigorously dry nitrogen. After pouring the mixture into water, the product was extracted into ether, affording a crude yield of 98% (788 mg) of **8***c*: *12,13-dihydroxy-14-isopropyl-podocarpa-8,11,13-triene*; uv: 285 (3650) nm; ir: 3420, 1610, and 1490 cm^{-1};

For personal use only.

^{1}H nmr δ: 0.89, 0.93, and 1.13 (3s, Me-C), 1.35 and 1.36 (2d, J = 7.0 Hz, iso-Pr Me), 2.78 (m, 2H, H-C.7), 3.24 (sept, J = 7.0 Hz, iso-Pr CH), 5.35 (br s, 2H, OH, diss. D_2O), and 6.64 (s, arom. H); ^{13}C nmr, see table; ms m/z: 302 (M^+, 37), 299 (18), 287 (43), 245 (12), 231 (12), 217 (60), 205 (39), 203 (31), 201 (12), and 191 (100). *Exact Mass* calcd. for $C_{20}H_{30}O_2$: 302.2247; found (hrms): 302.2245. *Note*: This catechol was understandably unstable and attempts to purify the material were counterproductive. The same mass spectroscopy sample described above showed that the catechol (37% relative intensity) was accompanied by the oxidation product **10** (300.2057, 6%) and maytenoquinone **11** (314.2248, 7%) after vacuum sublimation!

Oxidation of catechol ***8****c* *to intermediate* ***10*** *and maytenoquinone* ***11***

To a solution of catechol ***8****c* (465 mg) in chloroform (50 mL) was added silver oxide (700 mg) and the mixture was refluxed for 4 h. After filtering, the solvent was evaporated and the residue quickly chromatographed to afford the product **10** (402 mg; 87%): *12-oxo-13-hydroxy-14-isopropylpodocarpa-7,9(11),13-triene*, as a reddish oil; uv: 289 (5600) and 312 (5700) nm; ir: 3520, 3440, 1720, 1670, 1620, and 1550 cm^{-1}; ^{1}H nmr δ: 0.92, 0.99, and 1.08 (3s, Me-C), 1.34 and 1.37 (2d, J = 7.3 Hz, Me-C.15), 3.13 (sept, J = 7.3 Hz, iso-Pr CH), 6.32 (s, H-C.11), 6.98 (s, OH, diss. D_2O), and 7.21 (dd, J = 3.8 and 2.0 Hz, H-C.7; ^{13}C nmr, see table; ms m/z: 300 (M^+, 19), 258 (19), 257 (21), 232 (76), 228 (49), 215 (43), and 204 (44). *Exact Mass* calcd. for $C_{20}H_{28}O_2$: 300.2090; found (hrms): 300.2056.

The intermediate **10** (69 mg) was adsorbed on a small quantity of silica gel by evaporation of the solvent and the resulting powder was introduced at the top of a chromatographic column. Slow elution of the column with benzene afforded some of the starting intermediate **10** (45 mg) followed by maytenoquinone (18.8 mg; 26% rising to 75% if the recovery of the starting material is taken into account), orange glass; uv: 318 (11 650), 326 (11 000), and 410 (1700) nm; ir: 3370, 1670, and 1625 cm^{-1}; ^{1}H nmr δ: 1.17 (3H) and 1.26 (6H, 2s, Me-C), 1.31 and 1.37 (2d, J = 7.0 Hz, iso-Pr Me), 2.49 (s, H-C.5), 3.07 (sept, J = 7.0 Hz, iso-Pr CH), 6.40 (d, J = 1.3 Hz, H-C.7), 6.61 (d, J = 1.3 Hz, H-C.11), and 7.14 (s, OH); ^{13}C nmr, see table; ms m/z: 314 (M^+, 41), 299 (13), 271 (20), 257 (12), 243 (11), 229 (20), 217 (19), and 215 (19). *Exact Mass* calcd. for $C_{20}H_{26}O_3$: 314.1883; found (hrms): 314.1911. *Anal.* calcd. for $C_{20}H_{26}O_3$: C 76.40, H 8.33; found: C 76.63, H 9.06.

Cinétique et mécanisme des réactions bromate–chlorite et bromate – dioxyde de chlore[1]

GUY SCHMITZ ET HENRI ROOZE

Faculté des sciences appliquées, Université libre de Bruxelles, 50 Avenue F. Roosevelt, 1050 Bruxelles, Belgique

Reçu le 3 juillet 1987

GUY SCHMITZ et HENRI ROOZE. Can. J. Chem. **66**, 231 (1988).

Dans une solution acide contenant initialement de l'acide chloreux et un excès de bromate on observe deux réactions consécutives, l'oxydation de l'acide chloreux en dioxyde de chlore suivie de l'oxydation du dioxyde de chlore : $BrO_3^- + 4ClO_2 + 2H_2O = 4ClO_3^- + 3H^+ + HOBr$. Nous avons étudié la cinétique de cette réaction et proposé un mécanisme en accord avec celui accepté pour la réaction apparentée entre le bromate et le Ce(III). Ce mécanisme, complété par des réactions de l'acide chloreux, permet de reproduire les courbes expérimentales d'évolution du dioxyde de chlore dans les solutions d'acide chloreux et de bromate. Les valeurs des constantes d'équilibres et des constantes cinétiques sont discutées.

GUY SCHMITZ and HENRI ROOZE. Can. J. Chem. **66**, 231 (1988).

In an acidic solution, containing initially chlorous acid and bromate in excess, two consecutive reactions are observed, the oxidation of chlorous acid to chlorine dioxide followed by the oxidation of chlorine dioxide: $BrO_3^- + 4ClO_2 + 2H_2O = 4ClO_3^- + 3H^+ + HOBr$. The kinetics of this reaction has been studied and a mechanism proposed. It agrees with the one accepted for the related reaction between bromate and Ce(III). Extended by reactions of chlorous acid, the mechanism reproduces the experimental curves of chlorine dioxide evolution in chlorous acid – bromate solutions. The values of the equilibrium and kinetic constantes are discussed.

Introduction

L'intérêt pour les réactions périodiques en phase homogène a suscité de nombreuses études de sous-systèmes et de réactions apparentées, en particulier celles du bromate et du chlorite. La compréhension de leurs mécanismes a fortement progressé ces 15 dernières années. Cependant celui de la réaction entre le bromate et le chlorite n'a jamais été entièrement élucidé. La figure 1 donne un exemple de nos résultats confirmant l'allure générale observée par Thompson (1) dans l'acide perchlorique 0,2–2 M. On utilise l'alcool allylique pour capter l'acide hypobromeux produit avant qu'il ne réagisse avec le chlorite. Ceci évite une série de réactions secondaires compliquant fortement la stoechiométrie et la cinétique du système. Avec un excès de bromate on observe deux périodes : l'oxydation du chlorite en dioxyde de chlore suivie d'une réaction entre le dioxyde de chlore et le bromate. Thompson a établi les caractéristiques stoechiométriques et cinétiques de la première période et a proposé un mécanisme qui en rend compte. Par contre il n'a pas trouvé d'interprétation de la cinétique de la réaction entre le dioxyde de chlore et le bromate. Effectivement, dans ses conditions expérimentales, la cinétique de cette réaction ne se laisse pas représenter par une loi simple. En élargissant le domaine de concentrations étudié nous avons pu établir son mécanisme et montrer qu'il est en accord avec celui admis pour la réaction apparentée bromate–Ce(III).

Partie expérimentale

Le dioxyde de chlore est préparé par la méthode de Bray (2), lavé dans une solution acide de chlorite (pour éliminer des traces éventuelles de chlore), dans une solution de nitrate d'argent (pour éliminer des traces éventuelles d'acide chlorhydrique) et dissout dans l'eau distillée. Les autres réactifs sont de la qualité «pour analyse».

Lors de l'étude cinétique de la réaction entre le dioxyde de chlore et un excès de bromate on mélange les réactifs dans la cuvette thermostatisée à 25°C d'un spectrophotomètre Spectronic 2000 et on suit la diminution de l'absorbance à 355 nm, maximum du spectre du dioxyde de chlore. Son coefficient d'absorption molaire a été remesuré et vaut 1265 M^{-1} cm^{-1}. Nous avons constaté que l'alcool allylique n'a pas d'effet sur les vitesses de cette réaction, ce qui indique que le HOBr n'induit pas de réaction secondaire en absence de chlorite. Les résultats présentés ont donc été obtenus sans addition d'alcool.

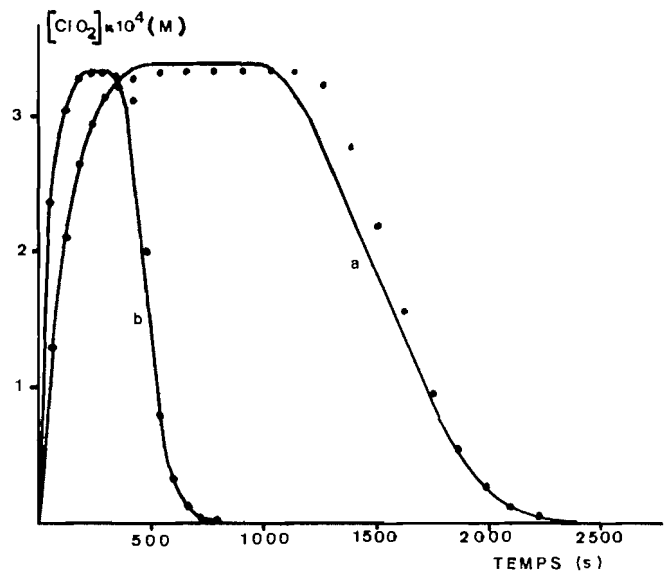

FIG. 1. Réaction bromate–chlorite. $[HClO_4] = 1$ M; $[NaClO_2] = 6{,}3 \times 10^{-4}$ M; $[C_3H_5OH] = 5 \times 10^{-3}$ M; $[KBrO_3] = 2 \times 10^{-3}$ (a) et 5×10^{-3} M (b). Résultats expérimentaux (—) et calculés (●).

Lorsque tout le dioxyde de chlore a été consommé, le spectre de la solution correspond à celui d'un mélange d'halogénates et de HOBr. En utilisant les coefficients d'absorption molaire mesurés par Betts et MacKenzie (3), on obtient $[HOBr]/[ClO_2]_0 = 0{,}245 \pm 0{,}005$. On vérifie donc la stoechiométrie [1].

$$[1] \qquad BrO_3^- + 4ClO_2 + 2H_2O = 4ClO_3^- + 3H^+ + HOBr$$

La figure 2 montre qu'après une période d'induction, les courbes expérimentales présentent une partie linéaire dont les pentes donnent les vitesses reprises dans le tableau 1. Si la concentration en ClO_2 est suffisamment grande, les vitesses n'en dépendent pas et on obtient la loi cinétique [2]. Par contre lorsque la concentration en ClO_2 est faible il n'existe pas de loi cinétique simple.

$$[2] \qquad -\frac{d[ClO_2]}{dt} = k_{exp}[KBrO_3]^2[HClO_4]^2$$

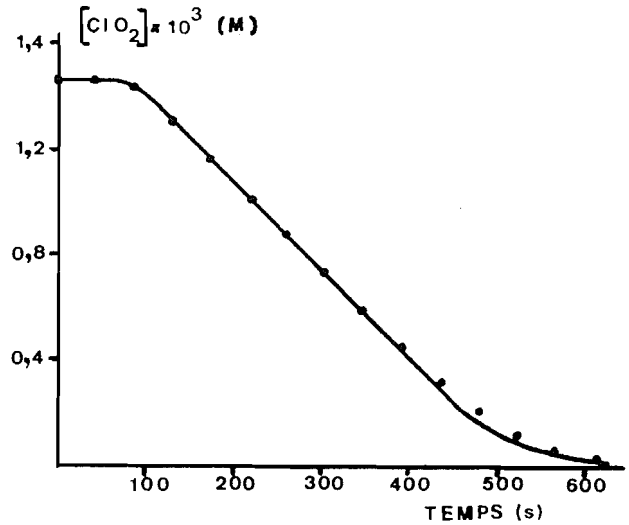

FIG. 2. Réaction bromate – dioxyde de chlore. $[HClO_4] = 1$ M; $[KBrO_3] = 5 \times 10^{-3}$ M; $[ClO_2]_0 = 1{,}46 \times 10^{-3}$ M. Résultats expérimentaux (—) et calculés (●).

TABLEAU 1. Effet des concentrations du bromate et du dioxyde de chlore

$[ClO_2]_0$ (10^{-3} M)	$[KBrO_3]$ (10^{-3} M)	Vitesse (10^{-6} M s)	k_{exp} (M^{-3} s^{-1})
1,6	1,0	0,147	0,139
1,6	2,0	0,592	0,140
0,4	2,5	0,850	0,128
1,6	2,5	0,840	0,127
3,2	2,5	0,877	0,132
1,6	5,0	3,64	0,137
1,6	10,0	13,86	0,131

$[HClO_4] = 1{,}03$ M.

TABLEAU 2. Effet de l'acidité et de la force ionique

$[HClO_4]$ (M)	k_{exp} (M^{-3} s^{-1})	k_{cor} (M^{-3} s^{-1})
0,103	0,460	0,493
0,103[a]	0,315	0,338
0,206	0,320	0,368
0,206[a]	0,245	0,281
0,515[a]	0,178	0,247
1,03	0,133	0,244
2,06	0,113	0,330

$[ClO_2]_0 = (0{,}4\text{–}3{,}2) \times 10^{-3}$ M; $[KBrO_3] = 10^{-3}$–10^{-2} M.

[a]Force ionique ajustée à 1 M avec du $NaClO_4$.

La variation de k_{exp} en fonction de l'acidité résulte, au moins en partie, de la différence entre la concentration en bromate $[KBrO_3]$ correspondant à la quantité de réactif utilisée et les concentrations réelles en solution $[BrO_3^-]$ et $[BrO_3H]$ calculées en tenant compte de l'équilibre [3].

[3] $\quad BrO_3^- + H^+ = BrO_3H$

Avec la valeur $K_3 = 2{,}9$ admise antérieurement (4) on obtient les valeurs de k_{cor} reprises dans le tableau 2.

$$k_{cor} = \left[1 + \frac{[H^+]}{K_3}\right]^2 k_{exp}$$

On déduit des séries de mesures faites sans ajuster la force ionique que la constante cinétique passe par un minimum aux environs de $I = 1$ M. Il est classique d'observer ce type de variation des coefficients d'activités.

Mécanisme de la réaction bromate – dioxyde de chlore

Les observations précédentes peuvent être expliquées par les réactions [R1]–[R3]. On obtient la stoechiométrie [1] en faisant la somme 2[R1] + 4[R2] + [R3].

[R1] $\quad BrO_3^- + H^+ + HBrO_2 \rightleftharpoons 2BrO_2 + H_2O$

[R2] $\quad BrO_2 + ClO_2 + H_2O \rightarrow ClO_3^- + H^+ + HBrO_2$

[R3] $\quad 2HBrO_2 \rightarrow BrO_3^- + H^+ + HOBr$

Tant que la concentration $[ClO_2]$ est suffisamment grande pour avoir $r_{+2} \gg r_{-1}$, la quasi-stationnarité des concentrations des intermédiaires BrO_2 et $HBrO_2$ donne

$$[HBrO_2] = \frac{k_1}{2k_3}[BrO_3^-][H^+]$$

$$[4] \qquad -\frac{d[ClO_2]}{dt} = \frac{k_1^2}{k_3}[BrO_3^-]^2[H^+]^2$$

On retrouve la loi expérimentale avec $k_{cor} = k_1^2/k_3$. Lorsque la concentration $[ClO_2]$ diminue, la réversibilité de [R1] cesse d'être négligeable. La concentration quasi stationnaire de $HBrO_2$ est alors donnée par une équation du troisième degré et la loi cinétique ne peut plus être mise sous une forme analytique simple.

Période d'induction de la réaction bromate – dioxyde de chlore

La durée t_i de cette période, en secondes, ne dépend pas de la concentration initiale en ClO_2 et varie comme l'inverse des concentrations en acide et en bromate. L'addition initialement de 2×10^{-5} mol L^{-1} de Br^- allonge notablement la période d'induction mais n'a pas d'effet sur la vitesse de disparition du ClO_2. L'addition de 2×10^{-5} mol L^{-1} de Cl^- n'a aucun effet.

$$t_i = \frac{0{,}4 \pm 0{,}05}{[BrO_3^-][H^+]}$$

Montrons que l'on peut justifier cette relation en admettant que la période d'induction correspond au temps nécéssaire pour que la concentration $[HBrO_2]$ atteigne sa valeur quasi stationnaire. Si on peut faire l'approximation $2r_{+1} = r_{+2} \gg r_{-1}$ on obtient :

$$\frac{d[HBrO_2]}{dt} = k_1[BrO_3^-][H^+][HBrO_2] - 2k_3[HBrO_2]^2$$

On pose $X = [HBrO_2]/[HBrO_2]_s$, où l'indice s désigne la valeur quasi stationnaire de la concentration, et on intègre.

$$k_1[BrO_3^-][H^+]t = \ln\frac{(1 - X_0)X}{X_0(1 - X)}$$

Le temps nécessaire pour atteindre une valeur donnée de X, pour X_0 donné, varie comme l'inverse de $[BrO_3^-][H^+]$. Ceci peut expliquer la variation observée de t_i. L'intégration des équations générales associées aux réactions [R1]–[R3] (cf. *infra*) a confirmé cette interprétation de la période d'induction.

La réaction bromate–chlorite

Ses caractéristiques ont été établies par Thompson (1) dans l'acide perchlorique 0,2–2 M en présence d'alcool allylique. Elles peuvent se résumer comme suit.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.222.148.141 on 09/07/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.222.148.141 on 09/07/12
For personal use only.

En présence d'un large excès de chlorite la réaction principale est [5]. Elle est accompagnée de la dismutation du chlorite (14).

[5] $BrO_3^- + 3HClO_2 = 2ClO_2 + ClO_3^- + HOBr + H_2O$

En présence d'un excès de bromate on obtient des courbes du type de celles de la figure 1. Lorsque la concentration $[ClO_2]$ est maximale le chlorite a été entièrement consommé. Les réactions bromate–chlorite et bromate – dioxyde de chlore sont donc consécutives et bien séparées dans le temps. Le palier de la concentration du ClO_2 correspond à la période d'induction de la réaction bromate – dioxyde de chlore. Le rapport $\Delta[ClO_2]/\Delta[HClO_2]$ dépend des conditions expérimentales. Pour $[BrO_3^-]_0 = (1{,}7–7{,}9) \times 10^{-3}$ M et $[HClO_2]_0 = (0{,}7–8{,}6) \times 10^{-4}$ M, il vaut 0,48 dans l'acide perchlorique 1,9 M et augmente si la concentration de l'acide diminue. Il diminue si la concentration en ClO_2 augmente. La vitesse de formation du ClO_2 est proportionnelle à la concentration du bromate et à celle du chlorite. Elle augmente plus que proportionnellement à la concentration de l'acide.

Thompson a interprété ces observations en considérant les réactions [R2] et [R4]–[R6].

[R4] $BrO_3^- + H^+ + HClO_2 \rightarrow BrO_2 + ClO_2 + H_2O$

[R5] $BrO_2 + HClO_2 \rightarrow HBrO_2 + ClO_2$

[R6] $HBrO_2 + HClO_2 \rightarrow ClO_3^- + H^+ + HOBr$

Lorsque la concentration en chlorite est grande le BrO_2 réagit principalement suivant [R5] et la somme [R4] + [R5] + [R6] donne la stoechiométrie expérimentale [5]. Si par contre le BrO_2 réagit également suivant [R2] on obtient également [6] = [R4] + [R2] + [R6] et un rapport $\Delta[ClO_2]/\Delta[HClO_2]$ inférieur à 2/3.

[6] $BrO_3^- + 2HClO_2 = 2ClO_3^- + H^+ + HOBr$

La compétition entre [R2] et [R5] explique que ce rapport diminue si la concentration $[ClO_2]$ augmente. Elle explique qu'il augmente si la concentration en acide diminue à condition d'écrire [R5] sous la forme [R5′].

[R5′] $BrO_2 + ClO_2^- \rightarrow BrO_2^- + ClO_2$

Les réactions [R1] et [R3] sont négligeables pendant la réaction bromate–chlorite car la concentration $[HBrO_2]$ est beaucoup plus faible que pendant la réaction bromate – dioxyde de chlore. La simulation numérique ci-après précisera ce point.

Constantes d'équilibre des réactions [R1]–[R6] à 25°C

Les enthalpies libres de formation, en kJ/mol, des différents composés intervenant dans ces réactions peuvent être estimées comme suit.

$$\Delta G_f^0(ClO_2\ aq.) = 119 \pm 3$$

Cette valeur a été déduite (5) de celle mesurée en phase gazeuse (6). Le potentiel standard du couple ClO_2/ClO_2^- vaut 0,935 ± 0,005 V et sa valeur apparente en milieu perchlorique de force ionique 1 M est 0,950 V (7–13). Cette différence est compatible (14) avec l'effet de la force ionique sur la constante d'acidité du $HClO_2$ (15). Avec $K_a^0\ (HClO_2) = 1{,}1 \times 10^{-2}$ on obtient :

$$\Delta G_f^0(HClO_2) = \Delta G^0(ClO_2\ aq.) - 101{,}4 \pm 0{,}5$$

Pour le chlorate et le bromate, nous adoptons les valeurs, et les estimations d'erreurs, de Johnson *et al.* (16). Latimer (17) avait admis respectivement −2,6 et 21 kJ/mol. La valeur 1,7 kJ/mol pour le bromate proposée récemment (18) est peu vraisemblable.

TABLEAU 3. Constantes d'équilibres et constantes cinétiques dans $HClO_4$ 1 M

Réactions	K_q	k_+	k_-
[R1]	10^{-6}	21	$2{,}1 \times 10^7$
[R2]	$1{,}2 \times 10^6$	$1{,}2 \times 10^5$	[a]
[R3]	5×10^{10}	$3{,}3 \times 10^3$	[a]
[R4]	80	1,15	[a]
[R5]	K_4/K_1	$3{,}8 \times 10^5$	[a]
[R6]	$K_2K_3K_4$	5×10^4	[a]

Unités : mol L^{-1} s.

[a]Les vitesses correspondantes sont négligeables dans les conditions étudiées.

$$\Delta G_f^0(ClO_3^-) = -7{,}95 \pm 0{,}75$$

$$\Delta G_f^0(BrO_3^-) = 19{,}0 \pm 0{,}6$$

L'enthalpie libre de formation du HOBr semble bien établie (17, 18).

$$\Delta G_f^0(HOBr) = -83 \pm 0{,}5$$

La constante d'équilibre de [R1] a été mesurée par Field et Försterling (19) :

$$K_1 = 10^{-6} \text{ à } 20°C \text{ dans } H_2SO_4\ 1\ M$$

Pour en déduire une relation entre les enthalpies libres de formation de BrO_2 et de $HBrO_2$ il faut tenir compte de la formation de $HBrO_3$, en multipliant K_1 par $(1 + [H^+]/K_3)$, et de la force ionique. Il faudrait également tenir compte de l'effet de la température mais on n'a aucune indication concernant celui-ci. Avec $K_3 = 2{,}9$ et $\gamma_\pm = 0{,}7$ on obtient :

$$2\Delta G_f^0(BrO_2) - \Delta G_f^0(HBrO_2) = 239{,}17 + 19 - RT \ln (2.7 \times 10^{-6}) = 290$$

Une estimation $\Delta G_f^0(BrO_2)$ a été déduite (20) des mesures de vitesses d'échange isotopique de Betts et MacKenzie (21). Cependant les calculs impliquent que lors de ces mesures le système était à l'équilibre chimique. Betts et MacKenzie ayant souligné (réf. 21, p. 664) que ce n'était pas le cas, nous préférons nous baser sur des données récentes permettant d'estimer la constante d'équilibre de la réaction [7].

[7] $Ce(III) + BrO_2 + H^+ = Ce(IV) + HBrO_2$

Field et Försterling (réf. 19, note 33) ont obtenu $k_7 = 8 \times 10^4\ M^{-2}\ s^{-1}$ à 20°C dans H_2SO_4 1 M. Une courte extrapolation des mesures de Sullivan et Thompson (22) donne $k_{-7} = 9 \times 10^3$ à 25°C dans H_2SO_4 1 M. Le rapport des deux constantes vaut 12. D'autre part Försterling *et al.* (23) ont observé que dans une solution 1 M en H_2SO_4 et 1 M en BrO_3^-, l'équilibre de [7] correspond à 80% du cerium sous la forme Ce(IV) lorsque $[BrO_2] = 4{,}7 \times 10^{-6}$. On en déduit $K_7 = (1{,}9 \times 10^{-5})/K_1$ en parfait accord avec l'estimation précédente. Sachant que dans l'acide sulfurique 1 M le potentiel du couple Ce(IV)/Ce(III) vaut 1,44 V (18), on obtient 1,51 V pour le potentiel du couple $BrO_2/HBrO_2$ et

$$\Delta G_f^0(BrO_2) - \Delta G_f^0(HBrO_2) = 146$$

On dispose ainsi de toutes les données nécessaires pour calculer les constantes d'équilibre des réactions [R1]–[R6]. À 25°C dans l'acide perchlorique 1 M, en incluant l'effet de l'équilibre [3] dans les constantes apparentes, on obtient les valeurs du tableau 3. Il faut cependant souligner qu'une erreur de 2 kJ sur les ΔG_f^0 entraine une erreur d'un facteur 2 sur

735,4	0,03	—	2,310	0,103	0,916

ces constantes. Ceci constitue certainement une estimation optimiste de l'incertitude relative aux valeurs adoptées. Elles permettent cependant d'établir que lors de nos expériences les réversibilités des réactions [R2]–[R6] étaient négligeables. L'interprétation des résultats est donc insensible à la valeur exacte des constantes d'équilibre correspondantes.

Constantes cinétiques à 25°C dans $HClO_4$ 1 M

La réaction [R1] n'est pas élémentaire et résulte de $BrO_3^- + H^+ + HBrO_2 = Br_2O_4 + H_2O$ et $Br_2O_4 = 2BrO_2$. La cinétique de la réaction inverse, l'hydrolyse du BrO_2, a été étudiée par Buxton et Dainton (24). Si on admet qu'au cours de leurs expériences de radiolyse la réaction $BrO_2 + OH \rightarrow BrO_3^- + H^+$ (25) était négligeable et si les valeurs obtenues en milieu neutre sont valables en milieu acide, on peut montrer qu'au cours des expériences considérées içi, Br_2O_4 est en équilibre avec BrO_2 et qu'on a $r_{-1} = 2{,}1 \times 10^7[BrO_2]^2$. Avec $K_1 = 10^{-6}$ on en déduit $k_1 = 21$.

Nous avons mesuré $k_1^2/k_3 = 0{,}133$ dans l'acide perchlorique 1 M. Cette valeur apparente comprend, comme celle de k_1 ci-dessus, l'effet de la formation de $HBrO_3$. On en déduit $k_3 = 3{,}3 \times 10^3$. L'accord avec les autres déterminations de k_3 (19, 23, 26, 27) est excellent : $1{,}4 \times 10^3$ (24°C, H_2SO_4 0,15 M), $2{,}2 \times 10^3$ (24°C, H_2SO_4 0,5 M), $3{,}8 \times 10^3$ (24°C, H_2SO_4 1 M) et $3{,}5 \times 10^9$ K_1 (20°C, H_2SO_4 1 M). Cet accord confirme indirectement la valeur de k_1 ci-dessus, deux fois plus faible[2] que celle adoptée par Field et Försterling (19).

La valeur de k_2 peut être déduite de notre étude de la cinétique de la réaction bromate – dioxyde de chlore. Tant que $[ClO_2]$ est assez grand pour que la réaction [R1] soit irréversible, la vitesse est donné par [4]. Soit r_0 cette vitesse et $[ClO_2]_{1/2}$ la concentration telle que suite à la réversibilité de [R1] la vitesse soit tombée à la moitié de cette valeur.

$$0{,}5r_0 = 2k_1[BrO_3^-][H^+][HBrO_2] - 2k_{-1}[BrO_2]^2$$
$$= k_2[BrO_2][ClO_2]_{1/2}$$
$$= 4k_3[HBrO_2]$$

En éliminant $[HBrO_2]$ et $[BrO_2]$ on obtient

$$k_2^2 = 2{,}41k_{-1}\frac{r_0}{[ClO_2]_{1/2}^2}$$

Avec $k_{-1} = 2{,}1 \times 10^7$, nos mesures dans l'acide perchlorique 0,5–2 M donnent $k_2 = (1{,}2 \pm 0{,}2) \times 10^5$.

Nous avons mesuré antérieurement (4) la valeur de k_4. Celle de k_5 est déduite des mesures par Thompson (1) du rapport k_2/k_5. Il dépend de l'acidité et vaut 0,32 dans l'acide perchlorique 1 M. La constante k_6 n'a d'effet que sur le temps écoulé entre les périodes de production et de consommation du ClO_2 lors de la réaction bromate–chlorite. C'est le seul paramètre ajustable du modèle. La valeur adoptée doit être considérée comme une limite supérieure car elle inclut l'effet éventuel de réactions de disparition du $HClO_2$ que nous avons négligées.

Les équations différentielles associées aux réactions [R1]–[R6] ont été intégrées par une méthode de Gear en utilisant les valeurs des constantes cinétiques reprises dans le tableau 3. Les figures 1 et 2 montrent que l'accord avec les résultats expérimentaux est excellent. Le tableau 4 donne les valeurs des concentrations à quelques moments caractéristiques de l'évolution du système. Au palier de la concentration $[ClO_2]$ on a bien consommé tout le $HClO_2$ et on voit augmenter la concentration $[HBrO_2]$ vers sa valeur quasi stationnaire correspondant à la réaction bromate – dioxyde de chlore. Avec les constantes d'équilibre données dans le tableau 3 on peut vérifier que les réversibilités des réactions [R2]–[R6] sont négligeables. On voit par contre que lorsque la concentration $[ClO_2]$ diminue, la réversibilité de la réaction [R1] devient importante.

Conclusions

Les réactions [R1]–[R3] suffisent pour expliquer la cinétique de la réaction bromate – dioxyde de chlore. Ce ne sont pas des réactions élémentaires mais, mis à part l'effet de l'acidité, les ordres correspondent aux coefficients stoechiométriques. Lorsque la concentration en dioxyde de chlore est assez grande pour que la réaction [R1] soit irréversible on obtient la loi cinétique [4]. Sinon il n'existe pas de loi cinétique simple. En y ajoutant les réactions [R4]–[R6] on peut reproduire les courbes de production et de consommation du ClO_2 lors de la réaction bromate–chlorite. Les constantes cinétiques utilisées provenant de diverses séries de mesures indépendantes, l'accord entre les courbes expérimentales et calculées place ce travail dans le cadre d'un ensemble cohérent ayant permis ces dernières années de mieux comprendre le mécanisme des réactions des dérivés oxygènés des halogènes.

2. Un rapporteur nous a demandé de préciser l'origine de cette différence. Les calculs de Field et Försterling s'enchaînent comme suit. Ils adoptent $k_1^2/k_3 = 0{,}60$ et $k_3 = 3000$ et en déduisent $k_1 = 42$, ensuite $K_1 = 10^{-6}$ donne $k_{-1} = 4{,}2 \times 10^7$. Par contre nous partons de $k_{-1} = 2{,}1 \times 10^7$ (24) et $K_1 = 10^{-6}$ ce qui donne $k_1 = 21$. Ensuite la valeur $k_1^2/k_3 = 0{,}133$, déduite de notre étude cinétique de la réaction $BrO_3^- + ClO_2$, donne $k_3 = 3300$. Aucune des valeurs que nous avons adoptées n'est basée sur les mesures de vitesses d'échanges isotopiques de Betts et MacKenzie (21), ces auteurs ayant clairement précisé que toute corrélation entre ces mesures et la loi d'action des masses serait injustifiable.

Étude des complexes fluorés et chlorés du cadmium dans les mélanges eau–HF

RÉJEAN BEAUDOIN ET HUGUES MÉNARD

Département de chimie, Faculté des sciences, Université de Sherbrooke, Sherbrooke (Québec), Canada J1K 2R1

Reçu le 7 avril 1987

RÉJEAN BEAUDOIN et HUGUES MÉNARD. Can. J. Chem. **66**, 236 (1988).

L'étude des complexes fluorés et des complexes chlorés du cadmium dans les mélanges eau–HF a été effectuée par polarographie. La diminution de l'ordre des complexes fluorés de CdF_3^- à CdF^+ est en accord avec la diminution de l'activité en ions fluorure, $R_0(F)$, mesurée en augmentant la concentration en HF. À plus de 60% en HF, le déplacement du potentiel de demi-vague ne peut plus être expliqué par les complexes de l'ion fluorure libre. La formation de complexes chlorés de degré trois et quatre a été observée en augmentant la concentration de HF jusqu'à 60% en poids.

RÉJEAN BEAUDOIN and HUGUES MÉNARD. Can. J. Chem. **66**, 236 (1988).

The formation of fluoride and chloride complexes in water – hydrogen fluoride mixtures has been studied using polarography. The reduction of the complexation by the fluoride ions from CdF_3^- down to CdF^+ is in good agreement with the reduction of the fluoride ion activity, $R_0(F)$ with increasing HF concentration. At higher HF concentration than 60%, the half-wave potential for the reduction of cadmium is shifted in a pattern that cannot be explained by fluoride in complexation. The formation of $CdCl_3^-$ and $CdCl_4^{2-}$ has been observed in H_2O–HF–KCl mixtures when the HF concentration was increased to 60%.

Introduction

L'étude des complexes métalliques du cadmium dans les mélanges eau–HF a été réalisée à l'aide de la polarographie classique. Une bonne connaissance des différentes espèces ioniques et moléculaires présentes dans les mélanges eau–HF (1–5) permet de calculer les constantes de formation des divers complexes du fluor en solution. L'utilisation d'un système de référence indépendant du solvant est une condition nécessaire (6) à cause de la variation de la force ionique et de l'acidité très élevée de ces mélanges.

Dans les solutions aqueuses, Bond et O'Donnell (7, 8) ont observé le complexe CdF^+ et le complexe CdF_2 à haute concentration en ions fluorure. Eliezer et Moreno (9) ont étudié le comportement du cadmium face aux autres halogènes. On a la possibilité de trois complexes chlorés alors que le brome et l'iode forment quatre complexes avec le cadmium. Bond et O'Donnell (10, 11) ont obtenu une vague réversible pour la réduction du cadmium dans les solutions aqueuses de HF.

Cette étude a permi de déterminer les complexes fluorés du cadmium dans les mélanges eau–HF et d'examiner la formation des complexes chlorés dans ces mélanges jusqu'à 60% en poids de HF. Les constantes de formation permettent de calculer la distribution des différents complexes en fonction de la proportion de HF dans le mélange.

Partie expérimentale

Les solutions ont été préparées à partir de HF 48% en poids (J. T. Baker) et à partir de HF 100% (Matheson) dilué à la concentration voulue avec de l'eau distillée. Les autres produits sont de grade ACS. Un potentiostat modèle PAR 174 A (Princeton Applied Research) a été utilisé avec un système à trois électrodes. L'électrode de référence au calomel saturé est séparée de la solution par une jonction en Teflon poreux jusqu'à environ 60% en poids de HF. À partir de 50% en poids de HF, l'électrode Cu/CuF_2 séparée de la solution par une jonction en Teflon poreux a été utilisée (12). Le capillaire polarographique est recouvert de polyéthylène (13) et l'électrode auxiliaire est faite d'un fil de platine. La cellule a été fabriquée dans nos ateliers à partir de $KelF^-$ et de Teflon. La diffraction des rayons-X a été effectuée avec un appareil Philips PW 1140/1139.

La méthode expérimentale consiste à mesurer le potentiel de demi-vague du cadmium par rapport à l'électrode de référence ECS ou Cu/CuF_2. Le potentiel de demi-vague du système de référence indépendant du solvant, le système ferricinium/ferrocène, est ensuite mesuré dans la même solution, lorsque c'est possible. Si les vagues polarographiques sont trop près l'une de l'autre, on prend les mesures séparément mais l'une après l'autre.

L'étude du cadmium en présence d'ions chlorure se fait en ajoutant du KCl à une solution de 10^{-3} M en cadmium. L'activité en ions chlorure est mesurée à l'aide d'une électrode sélective Ag/AgCl, de façon à s'assurer que l'activité est près de la concentration. Jusqu'à 55% en HF, la correspondance est suffisamment bonne pour assumer l'activité égale à la concentration.

Résultats et discussion

Les résultats pour les complexes fluorés sont présentés en rapport avec la fonction $R_0(F)$ et les constantes de formation des complexes chlorés ont été calculées selon la théorie de DeFord et Hume (5, 14, 15).

Les complexes fluorés du cadmium

Les potentiels de réduction du cadmium en fonction de la concentration en HF sont présentés au tableau 1. Le tableau montre les mesures par rapport au système ferricinium/ferrocène et les résultats calculés par rapport au potentiel de l'électrode réversible aux ions fluorure. Les valeurs de $R_0(F)$ et de E_{F^-} sont les mêmes que celles publiées par Vaillant *et al.* (2) et Ménard *et al.* (3).

La figure 1 présente le graphique du potentiel de demi-vague réversible aux ions fluorure en fonction de $R_0(F)$. On peut calculer la pente $E_{1/2}$ versus $R_0(F)$ et déterminer les complexes fluorés en solution. La fonction $R_0(F)$ est définie selon l'équation [1].

$$[1] \quad R_0(F) = -\log a_{F^-}$$

Pour confirmer les résultats obtenus par polarographie, nous avons mesuré le potentiel d'oxydation d'une électrode de cadmium dans les mélanges eau–HF. Les résultats sont présentés au tableau 2 et à la figure 2. Le potentiel d'oxydation du cadmium est donné par rapport au système de référence ferricinium/ferrocène et calculé par rapport au potentiel de l'électrode réversible aux ions fluorure. On peut calculer la pente du potentiel réversible aux ions fluorure et déterminer les complexes fluorés en solution. La pente est donnée en fonction de $\log a_{F^-}$.

L'interprétation des résultats se fait à partir de la pente du graphique de $E_{1/2}$ versus $R_0(F)$ pour la polarographie et de

la même façon pour l'oxydation de l'électrode de cadmium. Les tableaux 3 et 4 donnent les pentes et les complexes correspondants.

Nous allons diviser les mélanges eau–HF en trois sections. Les solutions de KF dans l'eau représentent la première partie, les solutions aqueuses de HF jusqu'à 60% représenteront la deuxième partie et les mélanges contenant plus de 60% en HF représenteront la troisième partie.

Les solutions aqueuses contenant Cd^{2+} et l'ion fluorure ont été étudiées par plusieurs auteurs. Mesaric et Hume (16) ont mesuré la constante de formation du complexe CdF^+. Ils ont donné une valeur de $\beta_1 = 6{,}4$. Le cadmium forme un complexe faible avec l'ion fluorure. Bond et O'Donnell (7, 8) ont mesuré les constantes de formation de deux complexes; $\beta_1 = 5{,}8$ pour le complexe CdF^+ et $\beta_2 = 4$ pour le complexe CdF_2 qui apparaît

80– 90	−0,027		
90–100	Négative		

à plus grande concentration en ions fluorure. Les mesures que nous avons effectuées dans les solutions contenant du KF nous permettent de conclure à l'existence du complexe CdF^+. La pente de $E_{1/2}$ versus le logarithme de l'activité en ions fluorure est de +0,031 volt. Lorsque nous passons aux solutions contenant du HF, la pente passe par zéro puis devient négative. On peut donc dire qu'à faible concentration en ions fluorure on

TABLEAU 4. Pentes tirées du graphique de l'oxydation d'une électrode de cadmium

Domaine de % en HF (poids)	Pente (volt)	Complexe	Pente calculée (volt)
2– 20	−0,031	CdF_3^-	−0,029

70– 90	−0,052		
90–100	Négative		

a le complexe CdF^+, ensuite CdF_2 lorsque la concentration de ligand augmente.

Eliezer et Moreno (9) ont étudié le comportement du cadmium face aux autres halogènes. On a la possibilité de trois complexes chlorés alors que le brome et l'iode forment quatre complexes avec le cadmium. Même si le fluor est moins complexant que les autres halogènes, il est raisonnable que le cadmium forme des complexes de degrés supérieurs à un avec l'ion fluorure.

Bond et O'Donnell (10, 11) ont étudié le cadmium dans des solutions aqueuses de HF. La vague polarographique est réversible. Ils concluent à partir du déplacement du potentiel de demi-vague que la solvatation ou la coordination n'est pas la même qu'en solution aqueuse. Nos résultats montrent que la réduction du cadmium est réversible sur tout le domaine de concentration en HF.

Dans le domaine de 2 à 60% en HF, il y a formation de trois complexes fluorés différents. Les pentes mesurées sur la figure 1 et données au tableau 3 permettent de dire qu'on a le complexe CdF_3^- entre 2 et 20% en HF. De 20 à 45% en HF on a le complexe CdF_2. De 45 à 60% en HF, il est difficile de mesurer de façon précise la pente. Cependant on voit qu'elle est positive et on conclut au complexe CdF^+.

Les écarts entre les valeurs de potentiels de demi-vague étant petits, nous avons mesuré le potentiel d'oxydation d'une électrode de cadmium pour appuyer les résultats obtenus par polarographie. Les résultats obtenus confirment et même précisent ceux mesurés par polarographie. On a le complexe CdF_3^- de 2 à 20% en HF, CdF_2 de 20 à 45% en HF et CdF^+ de 45 à 60% en HF. Dans la dernière région, la pente est de +0,027 volt. Le tableau 4 montre les pentes obtenues pour l'oxydation du cadmium métallique.

On peut écrire les équilibres suivants pour la réduction du cadmium dans les mélanges eau–HF de 2 à 60 :

[2] $CdF_3^- + 2\acute{e} \rightleftarrows Cd_{Hg} + 3F^-$

[3] $CdF_2 + 2\acute{e} \rightleftarrows Cd_{Hg} + 2F^-$

[4] $CdF^+ + 2\acute{e} \rightleftarrows Cd_{Hg} + F^-$

Dans le domaine de 60 à 100% en HF, il n'est pas possible de traiter les résultats à partir des mêmes hypothèses de départ. L'évolution du potentiel de demi-vague ressemble à une courbe de titrate. La formation de l'ion HF_2^- serait responsable du déplacement rapide du potentiel de demi-vague. On peut postuler un équilibre du type suivant :

[5] $CdF^+ + xHF_2^- \rightleftarrows CdF(HF_2^-)_x^{(1-x)}$

L'activité de l'ion HF_2^- n'étant pas connue, il n'est pas possible d'évaluer l'ordre des complexes formés avec cet ion.

TABLEAU 5. Constantes d'équilibre et de formation successive des complexes fluorés du cadmium

Complexe	log K	log β
CdF^+	9,3	9,3
CdF_2	7,8	17,1
CdF_3^-	3,6	20,7

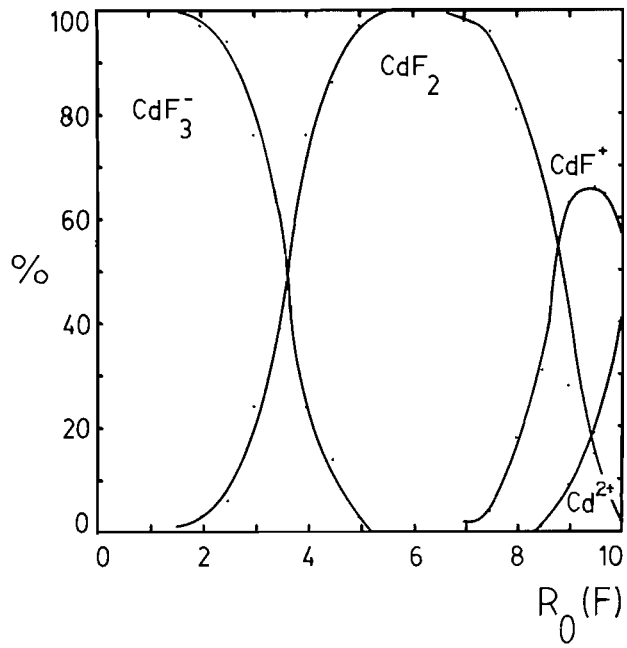

FIG. 3. Distribution des complexes fluorés dans les mélanges eau–HF jusqu'à 60% en poids.

Il est possible d'évaluer les constantes de formation des complexes fluorés à partir du changement de pente du potentiel de demi-vague réversible aux ions fluorure en fonction de l'activité en ions fluorure, R_0(F) (17). Si on établit l'équilibre suivant :

[6] $CdF_2 \overset{K_2}{\rightleftharpoons} CdF^+ + F^-$

La constante d'équilibre s'établit comme suit :

[7] $$K_2 = \frac{[a_{F^-}][a_{CdF^+}]}{[a_{CdF_2}]}$$

Au point d'inflection, à la figure 1, on peut faire l'approximation que la concentration des deux complexes fluorés est équivalente. L'équilibre est alors contrôlé par l'activité en ions fluorure du milieu. La constante d'équilibre du complexe peut alors être exprimée de la façon suivante :

[8] $K_2 = 1/a_{F^-}$

[9] $\log K_2 = -\log a_{F^-} = R_0(F)$

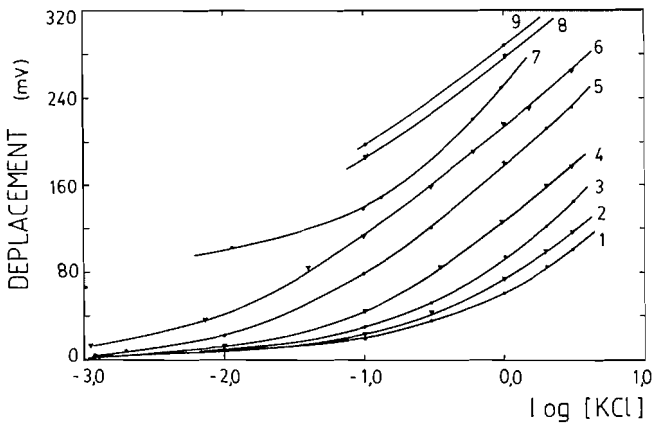

FIG. 4. Déplacement du potentiel de demi-vague du cadmium en fonction de la concentration en HF. 1, 5%; 2, 10%; 3, 20%; 4, 30%; 5, 40%; 6, 46%; 7, 52%; 8, 55%; 9, 61%.

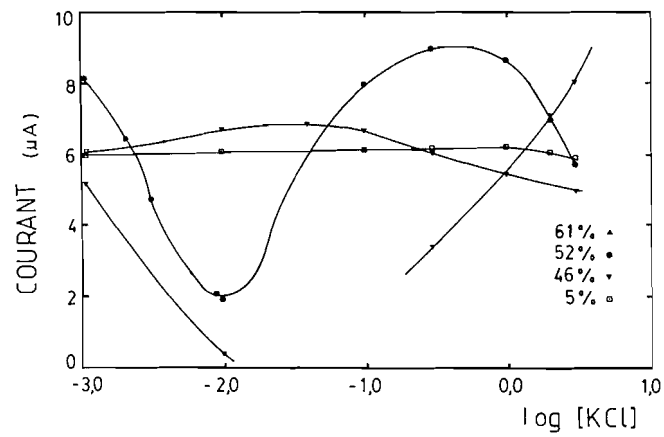

FIG. 5. Évolution du courant de diffusion du cadmium en fonction de la concentration en HF.

Les complexes chlorés du cadmium

L'addition de KCl à une solution de cadmium cause un déplacement du potentiel de demi-vague et dans certains cas des changements importants du courant de diffusion. La figure 4 montre le déplacement du potentiel de réduction du cadmium à plusieurs concentrations en HF et la figure 5 montre le courant de réduction du cadmium en fonction de la concentration en KCl pour différentes solutions de HF. La diminution très importante du courant de diffusion pour les solutions de 52 et 61% en HF

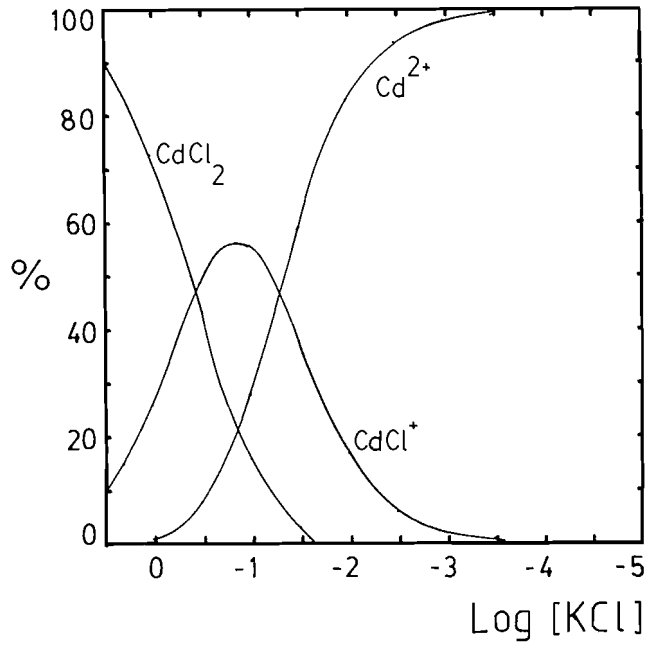

FIG. 6. Distribution des complexes chlorés dans HF 5%.

est due à la précipitation de chlorure de cadmium sous forme hydratée $CdCl_2 \cdot H_2O$. Le précipité a été identifié par diffraction des rayons-X et comparé avec les valeurs ASTM.

Les constantes de formation des complexes chlorés ont été calculées à partir de la théorie de DeFord et Hume (15). Le tableau 6 présente les constantes de formation jusqu'à 61% en HF. À plus grande concentration en HF, le KCl se transforme en HCl et l'activité en ions chlorure ne suit donc plus la concentration en KCl ajouté. À partir des constantes de formation données au tableau 6, on peut calculer la proportion de chaque complexe chloré dans les mélanges eau–HF. Les figures 6–10 montrent la distribution des complexes en fonction de la concentration en KCl dans la solution. La figure 11 montre la distribution des complexes chlorés en solution aqueuse calculée à partir des constantes de formation de Eliezer et Moreno (9).

En solution aqueuse, le cadmium donne deux complexes chlorés. Il donne cependant dans les mêmes conditions quatre complexes avec le brome et l'iode (9). On peut soupçonner qu'à plus grande concentration en ions chlorure et à force ionique plus élevée, on aurait un quatrième complexe chloré. Dans le

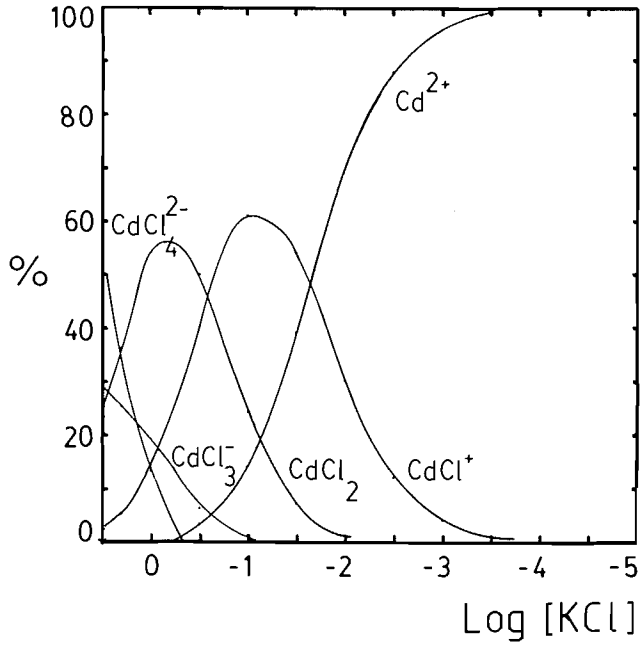

FIG. 7. Distribution des complexes chlorés dans HF 10%.

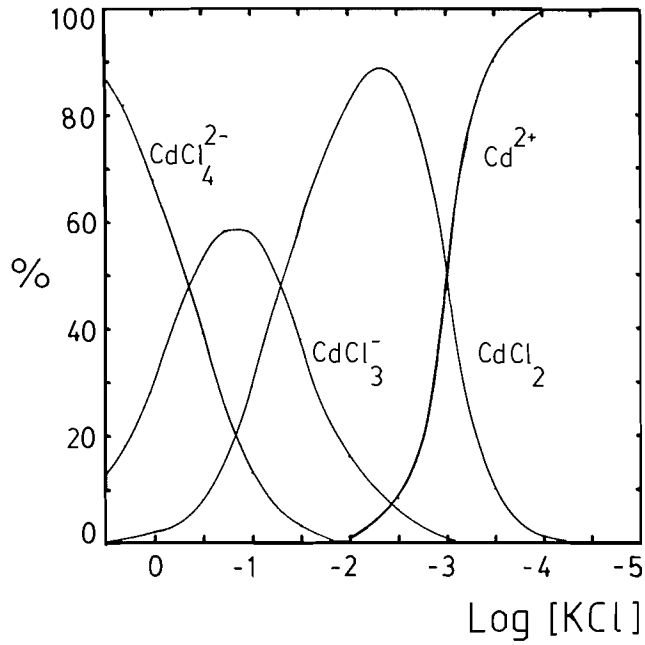

FIG. 9. Distribution des complexes chlorés dans HF 52%.

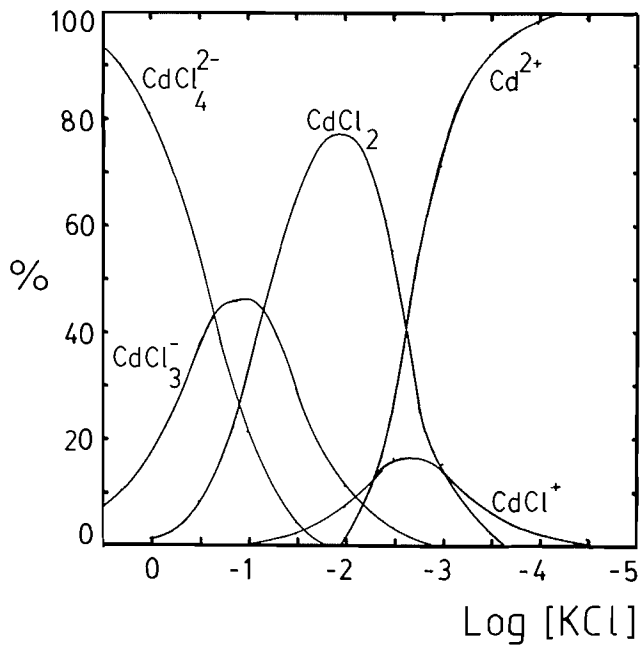

FIG. 8. Distribution des complexes chlorés dans HF 46%.

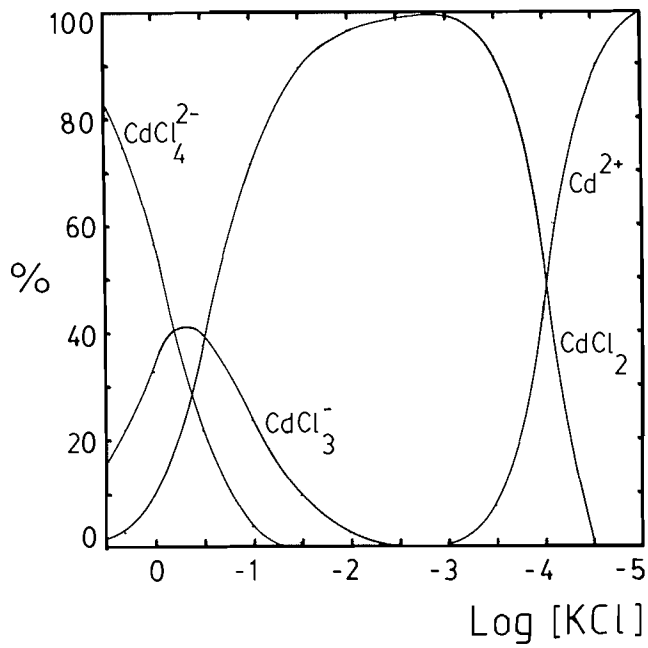

FIG. 10. Distribution des complexes chlorés dans HF 61%.

mélange eau–HF à 5%, on observe seulement trois complexes chlorés. À cette concentration en HF, on a en solution CdF_3^-. La compétition entre les complexes fluorés et les complexes chlorés empêche probablement l'obtention de complexes de degrés supérieurs dans ce domaine de concentration en KCl. En solution aqueuse (9), on observe le complexe $CdCl_3^-$ à des concentrations en KCl supérieures à 0,1 M ce qui indique que le complexe n'est pas très fort. La compétition due aux ions fluorure est suffisante dans notre cas pour empêcher la formation de $CdCl_3^-$ en quantité appréciable. Dans les mélanges eau–HF à 10%, on peut observer quatre complexes chlorés. La force ionique est beaucoup plus grande qu'en solution aqueuse. Il suffit de mentionner que l'activité en ions hydrogène est supérieure à un molaire. Les deux complexes de degré supérieur apparaissent à des concentrations en KCl de un molaire et plus. On a cependant une incertitude très grande sur les constantes de formation. Dans les mélanges eau–HF de 20 à 40%, les quatre complexes chlorés évoluent de façon à peu près régulière. Le complexe fluoré dans le solvant pur est CdF_2 sur tout le domaine; les complexes chlorés de degré supérieur apparaissent à plus faible concentration en KCl que dans HF à 5%. Dans les mélanges eau–HF à 46%, la distribution des complexes commence à changer de façon importante. La proportion du premier complexe $CdCl^+$ diminue de façon importante. La constante de formation β_1 est beaucoup plus faible que dans HF 40%. Le second complexe $CdCl_2$ prend une très grande

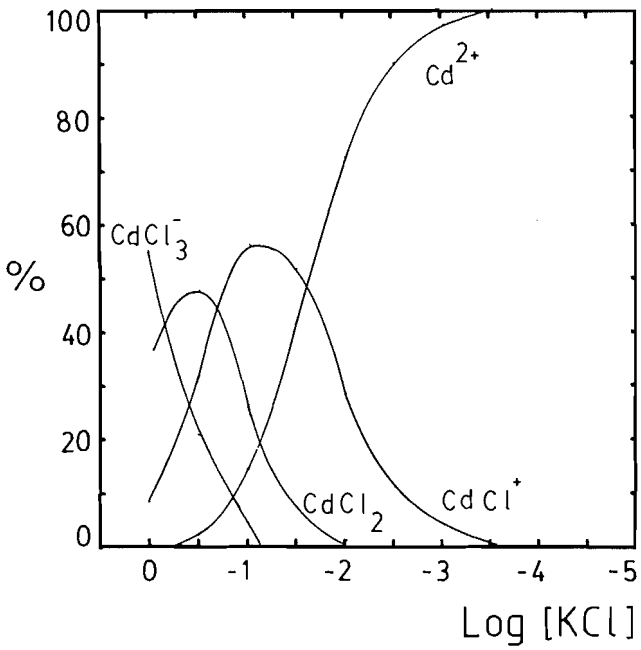

FIG. 11. Distribution des complexes chlorés en solution aqueuse.

importance. Dans les mélanges contenant 52–61% en HF, on voit que le domaine de concentration en KCl où $CdCl_2$ prédomine est de plus en plus important. La constante de formation du premier complexe chloré β_1 est à zéro. Si on considère la distribution des complexes fluorés dans les mélanges eau–HF telle que définie précédemment, on voit qu'à HF 50% le complexe CdF^+ prédomine. En ajoutant des ions chlorure, on peut avoir formation de CdClF dans la solution. La formation de $CdCl_2$ semble cependant beaucoup plus rapide et on a précipitation du complexe hydraté, selon l'équilibre [10].

[10] $Cd^{2+} + 2Cl^- + H_2O \rightleftarrows CdCl_2 \cdot H_2O$

Conclusion

L'étude des vagues polarographiques du cadmium dans les mélanges eau–HF a conduit à la détermination de trois complexes fluorés, le CdF_3^- à faible concentration en HF, le CdF_2 entre 20 et 45% en poids de HF et le CdF^+ jusqu'à 60% en HF. À plus grande concentration en HF, la connaissance précise des espèces présentes en solution n'est pas suffisante pour établir le type de complexe présent.

La précipitation de $CdCl_2 \cdot H_2O$ et la formation de complexes de degré trois et quatre, lorsque la proportion du HF augmente, indique que le mélange eau–HF est un milieu où la solvatation est faible et que les complexes du fluor avec le cadmium sont aussi très faibles par rapport aux complexes chlorés.

Mixed alkali effect in sodium thiosulfate pentahydrate melt

SHAKIRA S. ISLAM AND KOCHI ISMAIL[1]

Department of Chemistry, North-Eastern Hill University, Bijni Campus, Laitumkhrah, Shillong – 793003, India

Received January 5, 1987[2]

SHAKIRA S. ISLAM and KOCHI ISMAIL. Can. J. Chem. **66**, 242 (1988).

Density and electrical conductance measurements of $0.35[X\text{NaNO}_3 + (1 - X)\text{KNO}_3] + 0.65\text{Na}_2\text{S}_2\text{O}_3.5\text{H}_2\text{O}$ melt were made as functions of temperature and X. Molar volume, V, is found to be additive. The percent deviation of V_{ext} (extrapolated V of the pure solute from the plot of V vs. total added alkali ion fraction) from V_{cal} (calculated V of the pure solute from its high temperature density data) increases monotonically as the amount of NaNO_3 in the hydrate melt increases, thereby manifesting a "structure-forming" tendency of NaNO_3. The non-Arrhenius temperature dependence of molar conductance, Λ is analyzed in terms of the Vogel–Tammann–Fulcher (VTF) equation. Mixed alkali effect (MAE) has been observed on Λ and T_0 (ideal glass transition temperature). A competitive polarization model has been used to explain the MAE on Λ.

SHAKIRA S. ISLAM et KOCHI ISMAIL. Can. J. Chem. **66**, 242 (1988).

On a effectué des mesures de densité et de conductivité électrique sur des mélanges fondus de $0{,}35[X\text{NaNO}_3 + (1 - X)\text{KNO}_3] + 0{,}65\text{Na}_2\text{S}_2\text{O}_3.5\text{H}_2\text{O}$, en fonction de la température et de la valeur de X. On a trouvé que le volume molaire, V, est une propriété additive. Le pourcentage de déviation de la valeur V_{ext} (la valeur de V du soluté pur extrapolée à l'aide du courbe de V en fonction de la fraction totale des ions alcalins ajoutés) par rapport à la valeur V_{cal} (la valeur V calculée du soluté pur obtenue à partir de ses données de densité à haute température) augmente d'une façon monotone avec l'augmentation de la quantité de NaNO_3 dans la phase hydratée fondue; ces résultats suggèrent que le NaNO_3 a tendance à former des structures. La relation entre conductivité molaire, Λ, et la température ne suit pas la loi d'Arrhénius; on analyse ce fait en fonction de l'équation de Vogel–Tamman–Fulcher (VTF). On a observé l'effet des sels alcalins mixtes (EAM) sur Λ et sur T_0 (température de transition vitreuse idéale). On a utilisé un modèle de polarisation compétitive pour expliquer l'EAM sur Λ.

[Traduit par la revue]

Introduction

The mixed alkali effect (MAE) is an established phenomenon which has long been known to occur in a glassy or molten medium (1–6). It refers to deviations from additivity in isotherms of various physical properties as a function of composition which is being varied by progressively replacing one alkali ion by another in a glass or melt. In a more general term this effect is known as a mixed monovalent cation effect. Normally the MAE is most pronounced for properties related to ionic transport. In contrast to transport properties, equilibrium properties such as molar volume are additive or sometimes nearly additive functions of composition even when transport properties show a large MAE.

Continuing interests are being shown on MAE mainly because of the following reasons. Firstly, it has a direct relevance to glass industry (5, 7). A knowledge about the MAE helps a glass technologist in deciding about the glass compositions for achieving glasses with specific properties. Secondly, the problem of providing a completely satisfactory explanation for the existence of MAE is not yet settled (2–4, 8–11). Thirdly, curiosity has recently arisen among workers to look for MAE in media other than glass or melt of rigid network structure. One such convenient medium for testing the existence of MAE is hydrate melt. A few reports (11–14) have been made on the study of MAE in hydrate melts. In all these studies made up till now only calcium nitrate tetrahydrate has been used as the medium.

Recently we have reported (15) the feasibility of using $\text{Na}_2\text{S}_2\text{O}_3.5\text{H}_2\text{O}$ melt as a molten solvent for physicochemical studies. This melt has been found to dissolve about 60 mol% of KNO_3. Therefore in the present study we have made an attempt to look for MAE in molten sodium thiosulfate pentahydrate medium by measuring the density and electrical conductance of $0.35[X\text{NaNO}_3 + (1 - X)\text{KNO}_3] + 0.65\text{Na}_2\text{S}_2\text{O}_3.5\text{H}_2\text{O}$ system.

Experimental section

The solutes, NaNO_3 and KNO_3 (BDH, LR grade), were recrystallized twice from distilled water and dried over P_2O_5 in a vacuum desiccator for several days before use. Sodium thiosulfate pentahydrate (SMerck, GR grade) was used as molten solvent without further purification. The actual H_2O/Na^+ mole ratio in the sodium thiosulfate pentahydrate sample used was determined to be 5 ± 0.01 (0.2% error on the molality scale) from iodometric titration.

Although sodium thiosulfate pentahydrate melt dissolves ~60% mol% of KNO_3, it dissolves only ~35 mol% of NaNO_3. Therefore the total solute alkali ion concentration in the samples was kept constant at 0.35 mole fraction. The crystallization temperature of the melt increased with increase in the amount of NaNO_3.

Methods of density and conductance (at 1 kHz) measurements are the same as described earlier (14, 16). For the conductivity measurement the samples were taken in a closed Corning glass container attached with the conductivity cell to prevent water loss. The temperature control of the thermostat was improved ($< \pm 0.02$°C) by connecting an additional voltage divider to the heating element of the NBE Type Ultra Thermostat.

Results and discussion

Volumetric property

Measured density of the system under study is a linear function of temperature and is presented in Table 1. Composition dependence of molar volumes of systems containing hydrate melts is rather more interesting. Previous studies (15–18) on the composition dependence of molar volumes of binary systems containing anhydrous solute and hydrate melt have led to treat these systems as a mixture of hydrate melt and hypothetical supercooled solute. This general feature of such binary melts is, however, expected only in systems containing anhydrous solutes whose cations do not get hydrated by the water molecules of the hydrate melt. The water–anion interaction is normally not taken into consideration.

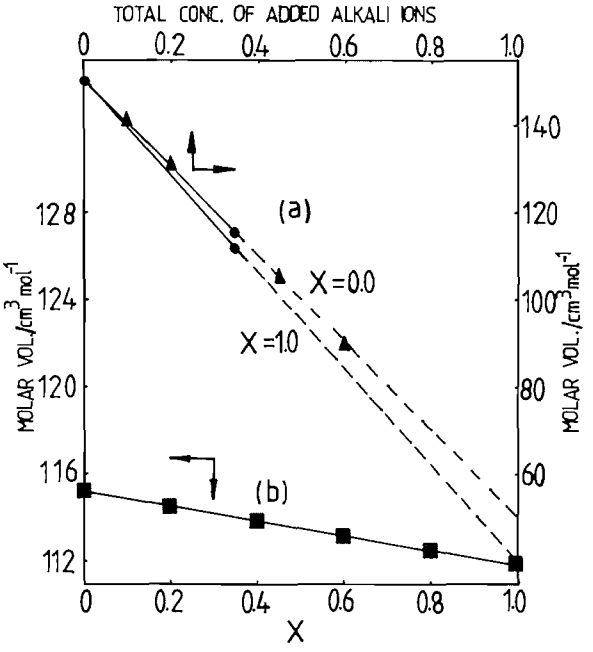

FIG. 1. Plots of molar volume of $0.35[X NaNO_3 + (1 - X)KNO_3] + 0.65Na_2S_2O_3.5H_2O$ melt as functions of (a) total concentration of added alkali ion and (b) X. (▲: data from ref. 15).

In the present system of interest there is an opportunity to examine the above aspect for the two types of solutes, viz., one having cation which competes and the other having cation which does not compete for the water of hydration of the solvent molecule. Although we have here only two concentration points (0 and 0.35 mole fraction of solute) to draw the molar volume vs. mole fraction isotherms, an attempt to draw such isotherms and then to extrapolate them to the pure solute concentration is justifiable in view of the fact that the linearity of this type of isotherms is already established for $Na_2S_2O_3.5H_2O + KNO_3$ system (15). Two such exemplary plots at 60°C are illustrated in Fig. 1. It may be noted that in those systems containing both $NaNO_3$ and KNO_3 the mixture of these two with the respective proportion is considered to be the solute of 0.35 mole fraction. The molar volumes, V_{ext}, of the pure solutes at 60°C obtained by extrapolating the plots of the type shown in Fig. 1 are listed in Table 2 along with the corresponding values of the molar volume, V_{cal}, evaluated from the high temperature density data (19) of these molten solutes. The interesting point to note from Table 2 is the % deviation of V_{ext} from V_{cal}. This deviation is minimum (0.87%) for the case of pure KNO_3 which is in accordance with our earlier result (15). The % deviation monotonically increases as the solute contains more and more amounts of $NaNO_3$ and is maximum (4.45%) for the case of pure $NaNO_3$. Similar trend in the % deviation was observed at other ambient temperature also. Since the experimental uncertainties involved are the same at all compositions, such a monotonic increase in the % deviation of V_{ext} from V_{cal} with increase in the amount of $NaNO_3$ is not attributable to experimental errors. Another possible source of error is the uncertainty in the high temperature density data from which V_{cal} is evaluated. We found that the monotonic increase in the % deviation exists even after accounting for the uncertainty (0.5%) in the high temperature density data (19).

Since the K^+ ion has a smaller ionic potential than the Na^+ ion, it does not compete with the Na^+ ion of the solvent for the water of hydration. Therefore KNO_3 appears to behave like an inert solute in molten sodium thiosulfate pentahydrate. On the other hand, as K^+ ions are replaced by Na^+ ions, these added Na^+ ions also compete with the solvent Na^+ ion for the water of hydration. This "structure-forming" tendency of the Na^+ ion added to molten sodium thiosulfate pentahydrate appears to cause a decrease in the volume of the system and may thereby account for the increase in the % deviation of V_{ext} from V_{cal} with increase in the amount of $NaNO_3$. In Fig. 1 we have also plotted the molar volume (at 60°C) of the system of interest against X. This plot is linear as is the case with other similar systems (13, 14). The linearity of this particular plot reveals that the above referred "structure-forming" tendency of the added Na^+ ion does not seem to cause an observable amount of non-ideality in the molar volume of the system.

Conductance property

The measured values of Λ in the temperature range 20–90°C are represented in Fig. 2 in the form of Arrhenius plots. From Fig. 2 it is apparent that the temperature dependence of Λ is non-Arrhenius which is normally the case with systems containing hydrate melts. The molar conductances are therefore least-squares fitted using an iterative least-squares method to the VTF equation of the form

$$[1] \quad \ln \Lambda = A - B/(T - T_0)$$

A, B, and T_0 are temperature independent parameters. The best-fit values of A, B, and T_0 obtained thus are listed in Table 3. It is interesting to note the variation in T_0 with the concentration of one of the added alkali ions. The plot (Fig. 3) of T_0 vs. X passes through a minimum around $X = 0.5$. Such a behaviour of T_0 with X may be attributed to the MAE. Although similar trends in the variation of experimental glass transition temperature, T_g with the ion fraction of either of the alkali ions were reported for mixed alkali systems in hydrate (12, 13) as well as anhydrous melts (2, 20), to date no report of T_0 of mixed alkali system varying in this fashion with composition has been made. However, it may be pointed out that since in the temperature ranges of this study the conductance varies by only factors of 3 to 6 the computed values of the T_0 parameter may not be very precise. As a consequence the minimum in the T_0 vs. X plot in Fig. 3 could be illusory. Therefore, in order to assess the uncertainties in T_0 we also analyzed the conductance data using the procedure adopted by Moynihan (21). The best-fit values (corresponding to minimum average |% dev.| in Λ) of A, B, and T_0 thus obtained are found to be in agreement with the values given in Table 3. In the light of the percent deviations of

TABLE 2. Molar volumes of $0.35[X NaNO_3 + (1 - X)KNO_3] + 0.65Na_2S_2O_3.5H_2O$ melts (V) and of pure solutes (V_{ext} and V_{cal}) at 60°C

X	Solute	$V/(cm^3\ mol^{-1})$	$V_{ext}/(cm^3\ mol^{-1})$	$V_{cal}/(cm^3\ mol^{-1})$	% dev. between V_{ext} and V_{cal}

0.8	$0.2KNO_3 + 0.8NaNO_3$	112.54	42.13	43.88	3.99
1.0	$NaNO_3$	111.94	40.38	42.26	4.45

$V(Na_2S_2O_3.5H_2O) = 150.47$

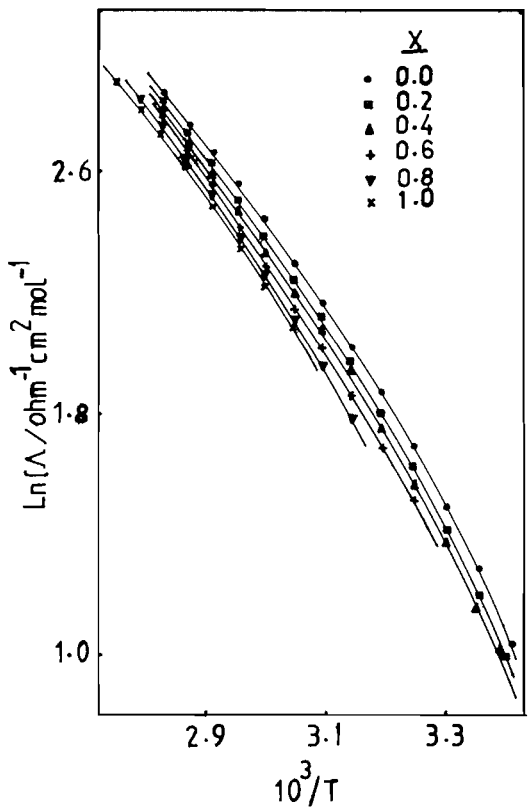

FIG. 2. Plots of ln Λ of $0.35[X NaNO_3 + (1 - X)KNO_3] + 0.65Na_2S_2O_3.5H_2O$ melt against $1/T$ for different X.

experimental values of the conductance from the least-squares curve for various values of T_0, the uncertainties involved in T_0 are estimated and are included in Table 3. For the T_0 values lying within the uncertainty range the least-squares fit of the conductance data is found to be very close to the best-fit. Since the uncertainties involved in the T_0 values are almost the same (6–8 K) for all the compositions, the nature of the T_0 vs. X plot (Fig. 3) does not seem to be very much affected.

The composition dependence of Λ is illustrated in Fig. 3. There is a negative deviation of Λ from additivity at temperatures below ~338 K. At temperatures higher than this Λ appears to approach additive behaviour. Increase in the amount of non-ideality of conductance with decreasing temperature is a general phenomenon observed in mixed alkali systems. The negative deviation of Λ from ideal behaviour therefore reveals the presence of MAE in the present system of study. The above

referred "structure-forming" tendency of the Na^+ ion added to molten $Na_2S_2O_3.5H_2O$ may also be causing, superimposed on MAE, non-ideality of Λ of the present system.

However, since the solvent used in this study contains also alkali ion, it is worthwhile to make a comment on the presence of MAE. It may be noted that in $0.35[X NaNO_3 + (1 - X)KNO_3] + 0.65Na_2S_2O_3.5H_2O$ system although X varies from 0 to 1, the mole fraction, $K^+/(Na^+ + K^+)$ varies from 0 to 0.21 only unlike the case with other similar systems studied (11–14) containing solvent free from alkali ion. Consequently, for systems of the present type a complete estimation of MAE may not be possible. On the other hand, it is interesting to note that the maximum negative deviation of conductance from additivity observed in this study and that reported (14) in $0.3[X KSCN + (1 - X)NaSCN] + 0.7Ca(NO_3)_2.4.06H_2O$ are of the same order (~4% at 328 K). Therefore, in this work the presence of alkali ion in the solvent does not seem to affect the MAE significantly. A probable explanation to this may be that the hydration sheath around the Na^+ ions of the solvent makes the interaction with the K^+ ion very weak, thereby causing negligible MAE. This view is further supported by the above mentioned fact that the added K^+ ion does not compete for the water of hydration of the solvent. About 11% negative deviation from ideality is however reported (13) in $0.45[X LiNO_3 + (1 - X)KNO_3] + 0.55Ca(NO_3)_2.4.09H_2O$ at 298 K which is attributable to the higher alkali ion concentration, the lower temperature, and to the larger difference in the radii of the two alkali ions. The small amount of MAE generally observed in hydrate melts is attributed to the absence of rigid type structure in these melts.

Numerous explanations have been proposed for the MAE on electrical conductivity. The structural/mechanistic theories appear to be more successful in systems of rigid network structure which exhibit normally large MAE. On the other hand,

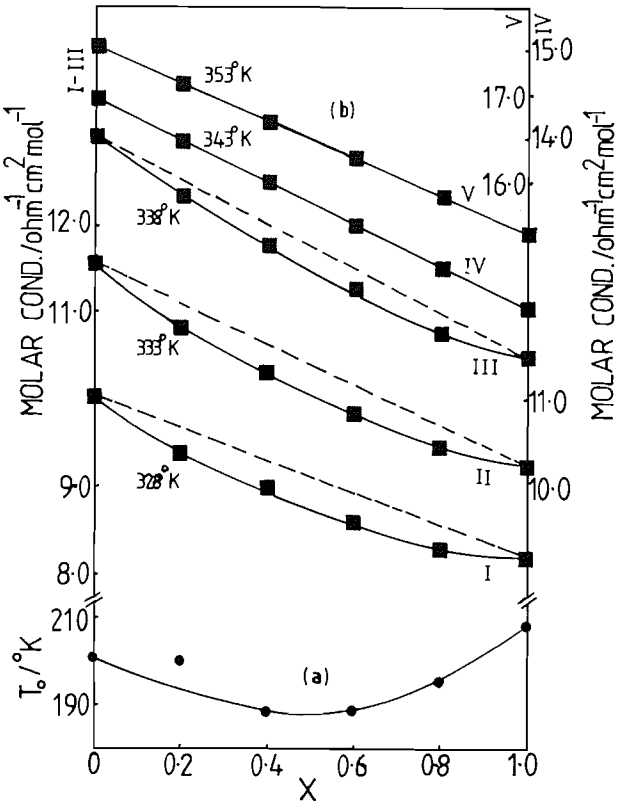

FIG. 3. Variation of (*a*) T_0 and (*b*) Λ of $0.35[X\text{NaNO}_3 + (1 - X)\text{KNO}_3] + 0.65\text{Na}_2\text{S}_2\text{O}_3.5\text{H}_2\text{O}$ melt with X.

in mixed alkali systems containing hydrate melts which do not show large MAE as seen above, the cationic interaction theories seem to be more appropriate.

Moynihan and Laity (22, 23) explained the negative deviations of conductance from additivity observed in molten binary systems like LiCl + KCl, LiNO_3 + KNO_3, etc. in terms of an anion polarization model. Such a polarization model applicable to binary melts may also be employed to explain the MAE observed in the present system of interest. The following two factors seem to provide support to this view. (1) The NaNO_3 + KNO_3 mixture behaves nearly like a hypothetical supercooled mixture in molten $\text{Na}_2\text{S}_2\text{O}_3.5\text{H}_2\text{O}$ as mentioned above which is, of course, more true when the interactions between the added alkali ions and the water molecule of the hydrate melt are negligible. (2) Negative deviations of Λ from additivity are observed in the cases of both binary NaNO_3 + KNO_3 melt (19) and the present system. Easteal (13) also made a similar attempt to compare the electrical conductance behaviour of $0.45[X\text{LiNO}_3 + (1 - X)\text{KNO}_3] + 0.55\text{Ca}(\text{NO}_3)_2.4.09\text{H}_2\text{O}$ with that of molten (Na + Tl)NO_3 system and then to use the anion polarization model to explain the MAE observed in the former molten system.

According to the anion polarization model the NO_3^- ion is considered to experience an average symmetrical field when the hydrate melt medium contains either NaNO_3 or KNO_3. When Na^+ ions are partially replaced by K^+ ions, some of the NO_3^- ions find themselves between electric fields of differing intensities. Due to this a competitive polarization of the anion occurs and the NO_3^- ion gets more polarized towards the smaller ion, i.e., Na^+. Consequently, in a hydrate melt medium addition of KNO_3 to NaNO_3 results in a decrease of the internal mobility of the Na^+ ion whereas addition of NaNO_3 to KNO_3 increases the internal mobility of K^+ ion. Presuming that the degrees of ionization of NaNO_3 and KNO_3 in the hydrate melt are equal and do not change with X we may write, $\Lambda = F[X|u_{\text{Na}^+}| + (1 - X)|u_{\text{K}^+}|]$, where F is the Faraday constant and the u terms refer to the internal mobilities of cations with respect to the NO_3^- ion. Therefore, the observed negative deviation of Λ from additivity implies that in the hydrate melt when both NaNO_3 and KNO_3 are present the decrease caused in $|u_{\text{Na}^+}|$ is always greater than the increase in $|u_{\text{K}^+}|$. Considering linear composition dependences of cationic internal mobilities it is possible to write the excess molar conductance as $\Delta\Lambda = KX(1 - X)$, where $\Delta\Lambda = \Lambda - \Lambda_{\text{id}}$ and K is a constant. A similar equation for $\Delta\Lambda$ was reported by Timmermann (24). In the present case it has, however, been found that the plot of $\Delta\Lambda$ vs. X is not exactly a symmetric parabola in X thereby indicating that in the system under study the cationic mobilities vary non-linearly with composition as is the case with binary mixtures of molten nitrates (22).

The crystal structure and stereochemistry of 2-acetyl-3,5,6-trihydroxy-5,6-dimethyl-2-cyclohexenones

GIORGIO ADEMBRI, MIRELLA SCOTTON, AND ALESSANDRO SEGA
Istituto di Chimica Organica, Piano dei Mantellini, 44 – 53100 Siena, Italy

Received June 3, 1987

GIORGIO ADEMBRI, MIRELLA SCOTTON, and ALESSANDRO SEGA. Can. J. Chem. **66**, 246 (1988).

The stereochemistry of **3***a*, one of the 2-acetyl-3,5,6-trihydroxy-5,6-dimethylcyclohexenones, obtained by rearrangement of 2,3-diacetyl-4-hydroxy-4-methylcyclopentenone, **2***a*, under basic conditions, was determined by an X-ray crystal structure analysis. An ORTEP plot shows the configuration of (5*RS*,6*RS*)-2-acetyl-3,5,6-trihydroxy-5,6-dimethylcyclohexenone and the presence of a conjugated chelated system involving the H-bonding between O(3)...H(31) and H(31)...O(2).

Crystals of **3***a* are triclinic, $a = 10.979(4)$, $b = 7.766(3)$, $c = 6.382(3)$ Å, $\alpha = 86.23(2)$, $\beta = 72.86(1)$, $\gamma = 88.23(2)°$, $Z = 2$, space group $P\bar{1}$. The structure was solved by direct methods and was refined by full-matrix least-squares procedures to $R = 0.036$ and $R_w = 0.039$ for 1324 reflections with $I > 3\sigma(I)$.

The structure of **3***a* consists of centrosymmetric dimers which contain a nearly planar bicyclic system of a cyclohexenone moiety and a chelated system (Scheme 2).

The pathway of the reaction allows one to put forward some hypothesis on the stereochemistry of some analogues of the cyclohexenones **3***a* and **3***b*.

GIORGIO ADEMBRI, MIRELLA SCOTTON et ALESSANDRO SEGA. Can. J. Chem. **66**, 246 (1988).

Faisant appel à la diffraction des rayons-X, on a déterminé la stéréochimie du composé **3***a*, une des acétyl-2 trihydroxy-3,5,6 diméthyl-5,6 cyclohexénones obtenues par une transposition de la diacétyl-2,3 hydroxy-4 méthyl-4 cyclopenténone, **2***a*, en milieu alcalin. Une courbe ORTEP démontre que la configuration est (5*RS*,6*RS*) pour l'acétyl-2 trihydroxy-3,5,6 diméthyl-5,6 cyclohexénone et qu'il existe un système de chélation conjugué impliquant des liaisons hydrogènes entre O(3)...H(31) et H(31)...O(2).

Les cristaux du composé **3***a* sont tricliniques avec $a = 10{,}979(4)$, $b = 7{,}766(3)$ et $c = 6{,}382(3)$ Å, $\alpha = 86{,}23(2)$, $\beta = 72{,}86(1)$ et $\gamma = 88{,}23(2)°$, $Z = 2$ et groupe d'espace $P\bar{1}$. On a résolu la structure par des méthodes directes et on l'a affinée par la méthode des moindres carrés (matrice entière) jusqu'à des valeurs de $R = 0{,}036$ et $R_w = 0{,}039$ pour 1324 réflexions avec $I \geq 3\sigma(I)$.

La structure du composé **3***a* comporte des dimères centrosymétriques qui contiennent un système bicyclique pratiquement plan d'une portion cyclohexénone et un système chélaté (Schéma 2).

Le chemin réactionnel permet de suggérer quelques hypothèses concernant la stéréochimie de quelques analogues des cyclohexénones **3***a* et **3***b*.

[Traduit par la revue]

Introduction

Our previous research has shown that with bases in non-hydroxylic solvents compounds **1***a–c* gave functionalized cyclopentenones **2** (1), whereas in hydroxylic solvents **1***a* led to the isomers **3***a* and **3***b* in a 4:1 ratio (2).

That **3***a* and **3***b* had cyclohexenone structures followed from their ir, ^{1}H, and ^{13}C nmr spectra. With these data we could establish neither the relative configuration of C(5) and C(6) of the two isomers nor the site of the enol bond. The most relevant signals in the nmr experiments are overlapped or too near to each other to allow a selective irradiation of significant resonances even with a 200 MHz instrument. Moreover, the nmr analysis shows, besides a very strong intramolecular hydrogen bond, strong intermolecular hydrogen bonds even in dilute solutions. Thus we undertook a X-ray crystal structure analysis on the more abundant isomer (mp 108–110°C).

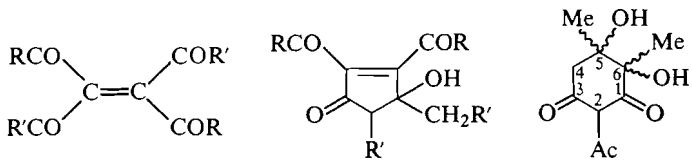
Experimental

Crystal data of compound **3***a* are as follows:

$C_{10}H_{14}O_5$ mw = 214.22

Triclinic, $a = 10.979(4)$, $b = 7.766(3)$, $c = 6.382(3)$ Å, $\alpha = 86.23(2)$, $\beta = 72.86(1)$, $\gamma = 88.23(2)°$,[1] $V = 518.82$ Å^3, $\rho_c = 1.37$ g cm^{-3}, $Z = 2$, $F(000) = 228$ (20°C, graphite monochromated Mo-Kα, $\lambda = 0.71069$ Å), μ(Mo-Kα) = 0.69 cm^{-1}. Space group $P\bar{1}$.

Single crystals of **3***a* were obtained from a cyclohexane solution at room temperature. An irregular prism shaped fragment (0.6 × 0.4 × 0.3 mm) was mounted on a Philips PW 1100 four circle automated diffractometer. Cell constants were determined by least squares treatment of angles of 25 reflections in the range $8.2 < 2\theta < 16.6°$: the reflections were collected within $2\theta < 50°$ by ω–2θ step-scan technique at a scan speed of 0.07° s^{-1} and a scan width of $(0.90 + 0.3 \tan\omega)°$ in ω. The intensities of three standard reflections monitored periodically showed no significant variation. After correction for Lorentz and polarization effects, 1324 reflections with $I > 3\sigma(I)$ were considered significant and used in the structure solution and refinement. The total number of unique reflections measured were 1764. No absorption correction was applied. The structure was solved by using the phasing program SHELX 76 (3) and the *E* map showed all non-hydrogen atoms. The refinement was pursued using the SHELX 76 program system. Two cycles of full-matrix least-squares refinement with isotropic temperature factors reduced the *R* value to 0.20. Subsequently, three full-matrix least-squares cycles with anisotropic temperature factors converged at $R = 0.10$. All the hydrogen atoms were located on the difference Fourier map and all were isotropically refined. The final disagreement indexes obtained were $R = 0.036$ and



1*a* R = R′ = Me
1*b* R = Me, R′ = OEt
1*c* R = Et, R′ = OEt

2*a* R = Me, R′ = H
2*b* R = OEt, R′ = H
2*c* R = OEt, R′ = Me

3*a*, **3***b*

SCHEME 1

[1]The reduced cell has the following parameters: $a = 6.382$, $b = 7.766$, $c = 10.953$ Å, $\alpha = 89.58$, $\beta = 73.31$, $\gamma = 86.23°$, and the transformation matrix is (001, 010, −101) (see International Tables Vol. A, p. 737).

O(5)	3625(1)	4669(2)	−1248(2)	56

[a]Coordinates × 10^4, estimated standard deviations are given in parentheses; U_{eq} is the equivalent isotropic temperature parameter; temperature parameters × 10^3; $U_{eq} = (1/3)\sum_i\sum_j U_{ij}a_i^*a_j^*(a_i\cdot a_j)$.

$R_w = 0.039$. The maximum fluctuation of the residual electron density was 0.16 e Å^{-3}. The weighting scheme used was $w = [\sigma^2(F_o)]^{-1}$, where $\sigma(F_o)$ is the individual standard deviation for each reflection from the diffractometer counting statistics.

The final atomic positional parameters and the equivalent isotropic temperature factors are listed in Table 1, bond distances and angles are listed in Tables 2 and 3, respectively.

Anisotropic temperature parameters, C—H and O—H distances and a list of observed and calculated structure factors are available from the Depository of Unpublished Data.[2]

Discussion

An ORTEP plot (4), shown in Fig. 1, clearly shows the configuration of (5*RS*,6*RS*)-2-acetyl-3,5,6-trihydroxy-5,6-dimethyl-2-cyclohexenone and the presence of an enolic group at C(3). The cyclohexenone system shows an envelope-like conformation with the methyl groups at 5 and 6 positions in a pseudo-axial and pseudo-equatorial position respectively. The

TABLE 2. Bond lengths (Å)

Bond	Length	Bond	Length
C(1)—C(2)	1.468(2)	C(6)—C(9)	1.529(3)
C(1)—C(6)	1.532(2)	C(7)—C(10)	1.482(3)
C(2)—C(3)	1.394(2)	C(1)—O(1)	1.217(2)
C(2)—C(7)	1.430(3)	C(3)—O(3)	1.297(2)
C(3)—C(4)	1.485(3)	C(5)—O(4)	1.433(2)
C(4)—C(5)	1.521(2)	C(6)—O(5)	1.426(2)
C(5)—C(6)	1.538(2)	C(7)—O(2)	1.274(2)
C(5)—C(8)	1.521(3)		

sequence of torsion angles of the ring is C(1)—C(2)—C(3)—C(4) = 1.4(2), C(2)—C(3)—C(4)—C(5) = −19.6(2), C(3)—C(4)—C(5)—C(6) = 49.2(2), C(4)—C(5)—C(6)—C(1) = −61.0(2), C(5)—C(6)—C(1)—C(2) = 45.5(2), and C(6)—C(1)—C(2)—C(3) = −15.3(2)°.

The C(2)—C(3), C(3)—O(3), C(2)—C(7), and C(7)—O(2) distances are intermediate between the respective single and double bonds. These atoms (and H(31)) lie on a plane with maximum and minimum deviations of 0.037(3) and −0.03(3) Å, respectively. These data show the presence of a conjugated chelated system as already inferred from nmr analysis (2, 5). The O(2)...O(3) distance is 2.432(3) Å and the O(2)...H(31)...O(3) angle is 157(3)°. The O(3)...H(31) = 1.22(3) and O(2)...H(31) = 1.26(3) Å distances are also in agreement with this system shown by **3***a* in Scheme 2.

In the solid state **3***a* is present as a dimer with two molecules centrosymmetrical correlated, connected by two hydrogen bonds between H(4) and O(5)* (H(4)—O(4) = 0.90(3) Å, O(4)...O(5)* = 2.81(4) Å, and O(4)—H(4)...O(5)* = 161(1)°) as shown in Fig. 1.

The isomeric cyclohexanone **3***b* has been assigned the structure of (5*RS*,6*SR*)-2-acetyl-3,5,6-trihydroxy-5,6-dimethyl-2-cyclohexenone. The alternative structure having the enolic group at position 1 was discarded by the strict analogy of the spectral data (ir, uv, ^{1}H and ^{13}C nmr spectra) with those of **3***a*. Since isomers **3***a* and **3***b* can be obtained from cyclopentenone **2***a* under the same conditions as from **1***a* and the presence of a carbonyl group at 3 position seems essential, whereas **2***b* and **2***c* behave in a different way, the most reasonable mechanism is outlined below. It cannot explain the stereoselectivity of the reaction. A Dreiding model of **3***a* shows some interaction

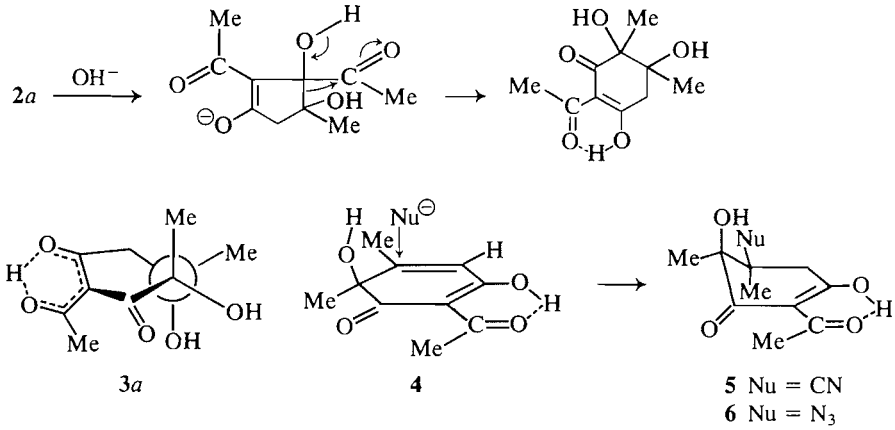

SCHEME 2

between the pseudo-axial methyl group at position 6 and the pseudo-axial hydrogen atom at 4. Since the isomer **3***b* has the methyl groups *trans*, it could assume an ee or an aa conformation. The corresponding Dreiding models show that the aa conformation offers a less steric hindrance, even if there is interaction between the methyl group at 6 and the pseudo-axial hydrogen atom of the methylene group. We have to bear in mind that a methyl group of cyclohexene, as in our case, is opposed by one less 1,3-diaxial interaction than in cyclohexane.

As we observed earlier (6), the presence of an allyl carbon atom substituted with a methyl and a hydroxyl group affects addition reactions in a highly stereoselective manner. Thus the cyclohexene **4**, obtained by facile dehydration of **3***a* or **3***b*, adds nucleophiles giving rise to only one of the expected stereoisomers. So the ions CN^- or N_3^- led, respectively, to compounds **5** or **6**, whose stereochemistry were assigned on the basis of the following considerations: (*i*) the Dreiding model of the cyclohexadienone **4** shows that the less hindered face is the si face; (*ii*) the selectivity of the attack is enhanced by the anchimeric assistance on the behalf of the OH group; (*iii*) this kind of attack leads to the less hindered isomer. On the basis of these observations we suggest that compounds **5** and **6** have the stereochemistry *5RS,6RS*.

Interaction of Pd(II), Pt(II), Ag(I), and Au(III) with 4,6-diamino-2-thiopyrimidine (DATP) and 4,6-diamino-2-methylthiopyrimidine (DAMTP) in aqueous medium resulted in the formation of new complexes which have been characterized by elemental analysis, ir, ^{1}H-nmr spectroscopic techniques, magnetic susceptibility measurements in the solid state, and conductivity measurements in DMF solution. The ir and ^{1}H-nmr spectra were consistent with coordination involving the non-protonated ring nitrogen atom, the exocyclic sulphur atom, or *N*,*S*-chelation.

La réaction, en milieu aqueux, de sels de Pd(II), Pt(II), Ag(I) et Au(III) avec de la diamino-4,6 thio-2 pyrimidine (DATP) et de la diamino-4,6 méthylthio-2 pyrimidine (DAMTP) conduit à la formation de nouveaux complexes qu'on a caractérisés par analyse élémentaire, par spectroscopies ir et rmn du ^{1}H, par des mesures de susceptibilité magnétique à l'état solide et par des mesures de conductivité en solution dans le DMF. Les spectres ir et rmn du ^{1}H suggèrent la présence d'une coordination impliquant l'atome d'azote du cycle qui n'est pas protoné, l'atome de soufre exocyclique ou un chélation-*N*,*S*.

[Traduit par la revue]

Introduction

Pyrimidine derivatives with sulphur in their structures are known to act as potent inhibitors (1, 2) and as antimetabolites (3, 4). Some authors (5) have explained the cytotoxicity of 2-thiocytosine and 2-thiouracil on the basis of the interference of these compounds in ARN synthesis. Furthermore, the effect of 2-thiocytosine on the mytosis of human lymphocytes has been described as well (6). The compound 2-thiopyrimidine shows a pronounced "*in vitro*" bacteriostatic activity (7), whereas 6-amino-2-thiouracil exhibits antiviral activity (8) besides acting chemotherapeutically (8–10). For these reasons, the interactions between metal ions and this type of ligand have been widely investigated (11).

Some of our earlier papers discussed the interactions of some thiopyrimidine and thiopurine derivatives with metal ions both in solution and in the solid phase (12–21). In this paper we report the characterization of two thiopyrimidine derivatives: 4,6-diamino-1,2-dihydro-2-thiopyrimidine (DATP) and 4,6-diamino-2-methyl-thiopyrimidine (DAMTP) and the synthesis and characterization of their Pd(II), Pt(II), Ag(I), and Au(III) complexes.

Experimental

Preparations

DATP and DAMTP. Thiopyrimidine derivatives were synthesized using methods previously described (22, 23).

Palladium(II) and platinum(II) complexes. The corresponding thiopyrimidine derivative (2 mmol) was added to a hot solution of $PdCl_2$ or $PtCl_2$ (1 mmol) dissolved in the minimum amount of saturated aqueous NaCl or NaBr. The resulting solutions were kept in a thermostatic bath at 40°C until the initial volume was reduced to 1/4. By cooling these solutions a precipitate was obtained in all cases. The complexes were washed with cold water, ethanol, and ether, and dried over P_4O_{10}.

Silver(I) complexes. A thiopyrimidine derivative (2 mmol) was dissolved in the minimum amount of water at 60–70°C, and an $AgNO_3$ aqueous solution was added until a 1:1 ligand–metal ratio was achieved. The complexes precipitated immediately and were then washed with water, ethanol, and ether, and dried over P_4O_{10}.

Gold(III) complexes. The corresponding pyrimidine derivative (2 mmol) was dissolved in 150 mL hot water (60°C). An aqueous solution of 2 mmol of $H[AuCl_4].3H_2O$ was neutralized with 0.1 *M* NaOH and added, with stirring, to the former solution. After a few minutes, the precipitation was complete and the solids were washed and dried as before.

Methods

Infrared spectra were obtained with Beckman 4250 and Perkin-Elmer 983 G spectrophotometers, using KBr and polyethylene discs in all cases. ^{1}H-nmr spectra were recorded on a Hitachi Perkin-Elmer R-600 FT NMR spectrometer using DMSO-d_6 and D_2O as solvents, and TMS as internal standard.

Magnetic measurements at room temperature were realized on a Faraday Bruker Magnet B-E15 using $HgCo(NCS)_4$ as standard. Microanalyses of C, H, and N, were performed in the Instituto de Química Bio-orgánica, C.S.I.C. (Barcelona), and Technical Services of University of Granada.

Thermal studies have been carried out on a Mettler TA-3000 system consisting of a thermobalance (Mettler TG-50) and a differential scanning calorimeter (model DSC-20); TG studies were realized in a dynamic atmosphere of pure air (100 mL min^{-1}). The determination of the acidity constants of both thiopyrimidine derivatives was carried out by potentiometric titration using a Radiometer TTT-60. The measurements were performed at 20, 25, 30, 40, and 50°C. The ionic strength was adjusted to 0.1 mol L^{-1} with potassium nitrate. To obtain the distribution diagrams we used the data treatment generally recommended (24).

Results and discussion

Ligands

Infrared, uv-visible, and ^{1}H-nmr data of the ligands are given in Table 1. These assignments are based on a comparison of the ligand spectra with those of several 2-thiopyrimidine derivatives (25–29), their complexes (30–34), and those with the —NH—CS—NH— grouping (11, 35, 36).

The infrared spectrum of DATP supports the preponderance of the thione form in the solid phase with the presence of ν(NH) bands (ca. 3100 cm^{-1}), the absence of ν(SH) (ca. 2500 cm^{-1}), and the production of the characteristic "thioamide" bands (see Table 1) due to extensive coupling of (CH), (NH), (CN), and

(CS) vibrational activity (11). On the other hand, the uv and ^{1}H-nmr spectra of both pyrimidine derivatives show the normal bands and signals, respectively, for these type of compounds (37–43). Proton nmr measurements for DATP support the presence of a tautomeric equilibrium between the thione and mercapto forms in DMSO solution, and therefore, C_s symmetry has been proposed for both molecules.

In aqueous solution, DATP can be considered a weak acid. The pK_A values at various temperatures were obtained by applying Bjerrum's (44) and Chaberek-Martell's (45) methods, and are given in Table 2. These values are in good agreement with those previously reported for 4-amino-2,6-dioxo-3-methyl-5-nitroso-1,2,3,6-tetrahydro-pyrimidine (46), and several nucleic bases (47). The values of ΔH and ΔS accompanying the dissociation process of DATP were calculated by plotting log K_A vs. $1/T$ (ΔH = 46.8 kJ mol^{-1} and ΔS = 31.5 J K^{-1} mol^{-1}).

The protonation constants (K_B) of DATP and DAMTP have been determined in aqueous medium at 25°C (I = 0.1 *M* KNO_3) by the Pease-Williams spectrophotometric method (pK_B = 5.3 and 4.9, respectively). From pK_A and pK_B values, the distribution diagrams of the different forms as a function of pH were obtained (Fig. 1).

preparative methods described in the experimental part of this paper. Analytical and colour data for these complexes are shown in Table 3. They all are soluble in water, DMSO, ethanol, and DMF, and exhibit a 2:1 ligand-to-metal ratio.

The molar conductivities in DMF solutions (10^{-3} *M*) of the Pd(II) complexes are in the 12.2–26.0 Ω^{-1} cm^2 mol^{-1} range, which suggest that these are non-electrolytes in solution (48).

In $Pd(DATP)(DATP^-)Cl.H_2O$ molecular and anionic forms of DATP are present as observed from the uv spectrum, which shows characteristic bands at 291, 262, 242, and 270 nm (see Table 1).

Although the ligand and the complexes show many ir absorption bands (Table 4) only the significant ones will be discussed here. The band assigned to δ(NH) is unusually broad in the complexes compared to the free ligand and we have tentatively assigned it as the hydrogen-bonded form NH—X (49). All Pd(II) complexes show one strong ν(Pd—X) band (X = Cl or Br), in the 250–355 cm^{-1} range, which corresponds to a *trans*-coordinated halogen atom. The frequency ratios ν(Pd—Br): ν(Pd—Cl) (0.87 for DATP and 0.82 for DAMTP complexes) are close to the values accepted for analogous structures (50). On the other hand, in the Pd(II)–DATP complexes the ν(C=S) band is slightly modified. From its position in the ir spectrum of free DATP. This is indicative of the involvement of sulphur atom in the coordination to the Pd(II) ion; analogous displacement has been observed in an other complex of DATP (solved by X-Ray) where the sulphur atom is involved in the coordination (21).

The most significant ^{1}H-nmr data for Pd(II) complexes have been collected in Table 5. The ^{1}H-nmr spectrum of $Pd(DATP)(DATP^-)Cl.H_2O$ shows two signals, at 5.00 and 5.25 ppm assigned to C5-H resonances in $DATP^-$ and DATP, respectively. Likewise in this complex, NH_2 signals of both DATP and $DATP^-$ ligands appear split between 6.50–7.60 ppm, although the low resolution of the spectrum suggests the hiding of some other signals. The non-equivalence of the H atoms of such groups could be attributed to hydrogen bonding interactions between the chlorine atom and NH_2 groups. The same behaviour has been found in the remaining Pd(II) complexes. Finally, the N1—H signal in Pd(II) complexes of DATP overlaps with that of water hydration, which can be explained by the increasing of acidic character due to the coordination of the aromatic ring to the Pd(II) ion. In spite of the above, another possible interpretation of the splitting of NH_2 signals supposes that the coordination takes place though the nitrogen atom of one of the two NH_2 groups which would give rise to a lowering of the electronic density of the two corresponding hydrogen atoms. In the complexes $Pd(DAMTP)_2Cl_2$ and $Pd(DAMTP)_2Br_2$, the S—CH_3 resonances are shifted downfield by 0.2 ppm, implying a possible coordination of Pd(II) via the sulphur atom.

From the above data and the consideration that the four Pd(II) complexes are diamagnetic, we propose for all of them a monomeric square-planar structure, where the halogen atoms are linked to Pd(II) ions in *trans* positions and DATP and DAMTP act as monodentate ligands through the S atom of the thione group; nevertheless, in $Pd(DATP)(DATP^-)Cl.2H_2O$, $DATP^-$ acts probably as (*N*,*S*) chelating ligand.

The most significant thermal data for the Pd(II) complexes, obtained from TG and DSC curves, have been collected in Table 6 showing the hydrated character of the $Pd(DATP)(DATP^-)Cl.2H_2O$ and $Pd(DATP)Br_2.H_2O$ complexes. The dehalogenation processes, in all cases, overlap with the pyrolytic decomposition of the pyrimidine ring, and suggest very strong palladium—halide bonds. For all the complexes the pyrolitic residue is PdO, identified by infrared spectroscopy. Experimental values are in good agreement with those expected theoretically.

Platinum(II) complexes. Analytical data of Table 3 show a great variation in the stoichiometries of the isolated Pt(II) complexes, varying between 4/1 and 1/1 (ligand-to-metal ratio).

DATP complexes show different ir spectra. For the $Pt(DATP)_4Cl_2.2H_2O$ complex a positive shift in the thioamide(I) band (20 cm^{-1}) is observed while the band at 1195 cm^{-1} (predominantly the ν(C=S) mode) remains unchanged. This is associated with cyclic nitrogen donation (11). However the ir spectrum of $Pt(DATP)Br_2.H_2O$ suggests the involvement of exocyclic sulphur in metal coordination due to the shift observed in the ν(C=S) band. In the 500–400 cm^{-1} range, the Pt(II)–DATP complexes show, besides some ligand bands, a new band assignable to the (Pt—N) mode. The bands at 320 cm^{-1} ($Pt(DAMTP)_2Cl_2.\frac{1}{2}H_2O$) and 235 cm^{-1} ($Pt(DAMTP)_2Br_2.\frac{1}{2}H_2O$) may be assigned to ν(Pt—Cl) and ν(Pt—Br), respectively. Pt–halogen bands have not been detected in Pt(II)—DATP complexes, which suggests that for $Pt(DATP)_4Cl_2.2H_2O$ (which is very water soluble) the halogen atoms are not coordinated; however, for $Pt(DATP)Br_2.H_2O$, whose stoichiometry implies

the presence of coordinated Br atoms, it can be supposed that ν(Pt—Br) bands, in this complex, may appear at lower values than 180 cm^{-1}.

^1H-nmr spectra of Pt(II) complexes show (*i*) a slight downfield shift of the C5-H signals which is probably due to the lowering in electronic density of the aromatic ring caused by the coordination to the metal ion; (*ii*) the splitting in four of the single signals of NH_2 groups could be explained by the hydrogen bond interactions between these groups and halogen or water molecules.

In agreement with the diamagnetic behaviour of these complexes, and from the above data, we propose for the $Pt(DAMTP)_2X_2.\frac{1}{2}H_2O$ (X = Cl, Br) complexes a monomeric structure with a *trans* square planar arrangement where the thiopyrimidine ligand is ring N cyclic coordinated. The same coordination is proposed for $PT(DATP)_4Cl_2.2H_2O$. In $Pt(DATP)Br_2.H_2O$ the ligand coordination takes place through the S atom of the thione group and the ring N atom.

From the TG and DSC curves three different steps can be clearly established for these complexes: (*a*) dehydration processes, where corresponding enthalpy values confirm the loss of coordinated water (see Table 6); (*b*) dehalogenation processes, with endothermic effects peaking at temperatures between 216–258°C; and (*c*) pyrolitic decomposition, ending at temperatures varying from 500–650°C.

Silver(I) complexes. The ir spectrum of $Ag(DATP)NO_3.H_2O$ is very similar to that of free DATP (Table 4) and to that of the $Cd(DATP)Cl_2.H_2O$ complex (21) with the exception of a new strong band at 1380 cm^{-1} (assigned to $\nu(NO_3^-)$) which proves

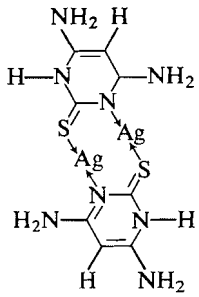
the presence of NO_3^- as a free ion in this complex. Likewise, in the 600–180 cm^{-1} range, a new strong band at 362 cm^{-1} was detected and assigned as ν(Ag—N) (50).

All these data suggest that DATP has a coordination pattern similar to that in the above cited $Cd(DATP)Cl_2.H_2O$ complex, acting as a bidentate ligand through the ring N and the S of the 2-thione group. We propose the structure showed in Scheme 1, similar to that found by other authors for a Ag(I)—1-methylthymine complex (51).

The signals corresponding to C5—H and NH_2 groups in the ^{1}H-nmr spectrum of this complex are slightly shifted to downfield values, arising from the lowering in electronic density of the aromatic ring. This also explains the acidic character of N1—H group whose signal is probably under that of water (3.4 ppm).

Finally, from TG and DSC data together with the ir spectrum, the following thermal decomposition mechanism has been proposed:

$$Ag(DATP)NO_3.H_2O \xrightarrow[endo]{97°C} Ag(DATP)NO_3 \xrightarrow[exo]{300°C} Ag(DATP) \xrightarrow[exo]{320\text{–}700°C} Ag$$



SCHEME 1. Possible structure for $Ag(DATP)NO_3 \cdot H_2O$.

$Ag(DAMTP)_2NO_3.3H_2O$. The ir spectrum of this complex shows the same bands as those of DAMTP at similar wavenumbers, plus two new bands at 1380 and 340 cm^{-1} which have been assigned to ν(NO_3^-) and ν(Ag—N), respectively.

The ^{1}H-nmr spectrum shows the same signals as those of DAMTP; those corresponding to NH_2 and C5-H groups being slightly shifted to downfield values while the remainder are unmodified value.

According to these data, we propose a monomeric linear structure for the complex in which the linking of DAMTP occurs via ring N atoms, as shown in Scheme 2.

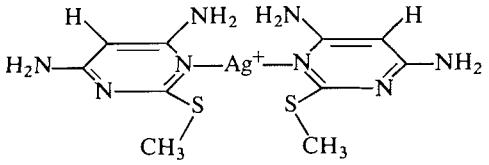
For personal use only.



SCHEME 2. Possible structure for $Ag(DAMTP)_2NO_3 \cdot 3H_2O$.

The thermal decomposition of this complex takes place as follows:

$$Ag(DAMTP)_2NO_3.3H_2O \xrightarrow[endo]{72°C} Ag(DAMTP)_2NO_3$$

$$\xrightarrow[endo]{161°C} Ag(DAMTP)_2NO_3 \text{ (melting point)} \xrightarrow[exo]{260°C} Ag(DAMTP)_2$$

$$\xrightarrow[exo]{270-700°C} Ag$$

All the steps of this process were proven by ir spectroscopy.

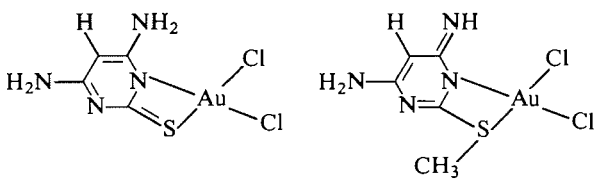
Gold(III) complexes. The two Au(III) complexes are slightly soluble in water and the common organic solvents, and their anhydrous character was proved by TG and DSC data (see Table 6). The dehalogenation processes of both complexes have not been observed in the DSC curves due to the overlap with pyrolitic decomposition of the ligands, which finished at about 700°C giving Au.

The most significant ir data for both Au(III) complexes are the shifts to higher wavenumber observed for ν(C=C) and ν(C=N) vibration modes, indicating an increase in the double bond character of C=C and C=N linkages.

The ir of the $Au(DAMTP^-)Cl_2$ complex shows a new band at 350 cm^{-1} which is assigned to ν(Au—Cl); whereas the $Au(DATP)Cl_2$ ir spectrum exhibits two broad bands. The first one, between 300–400 cm^{-1} would be ν(Au—Cl), and the second between 470–550 cm^{-1} is assigned to ν(Au—N).

The ^{1}H-nmr spectrum of $Au(DAMTP^-)Cl_2$ shows the following features; (*a*) amino and imino group signals appear at 0.9 ppm, which are shifted downfield probably due to the presence of the imino group; (*b*) the signal of the C5-H group appears downfield shifted 0.2 ppm; (*c*) the SCH_3 signal is a doublet (J = 6 Hz) which could be explained by coupling to ^{197}Au, suggesting that the coordination occurs through the S atom. The ^{1}H-nmr spectrum of the $Au(DATP^-)Cl_2$ complex could not be obtained because of its insolubility in DMSO-d_6.

The two Au(III) complexes are diamagnetic, which indicates that the ligands define a square-planar arrangement around the Au(III) ions. Thus, in accord with the above data it could be assumed that in the $Au(DAMTP^-)Cl_2$ complex the thiopyrimidine derivatives are in the 4-iminic form acting as monoanionic bidentate ligands. The coordination positions are the S atom of the SCH_3 group and the negatively charged ring N atom. This implies that the two Cl atoms of each complex are cis, as shown in Scheme 3.



SCHEME 3. Possible structures for $Au(DATP^-)Cl_2$ and $Au(DAMTP^-)Cl_2$.

Received April 16, 1987

M. M. SELIM, TH. A. EL-NABARAWY, and N. A. YOUSSEF. Can. J. Chem. **66**, 256 (1988).

The catalytic conversion of cyclohexene was studied on steam-activated carbon using microcatalytic technique. Three sets of experiments were carried out to investigate the conversion of cyclohexene, depending on reaction temperature. The first set was conducted at a constant temperature while the other two sets were performed either by increasing the temperature from 300 to 400°C or by decreasing it from 400 to 300°C. In all cases, the activity of carbon in cyclohexene conversion was influenced by the nature of condensation products formed on the surface during conversion.

M. M. SELIM, TH. A. EL-NABARAWY et N. A. YOUSSEF. Can. J. Chem. **66**, 256 (1988).

Utilisant une technique microcatalytique, on a étudié la conversion catalytique du cyclohexène sur un charbon activé par de la vapeur d'eau. Dans le but d'étudier la conversion du cyclohexène et dépendant de la température de la réaction, on a réalisé trois séries d'expériences. La première série a été réalisée à température constante alors que les deux autres ont été réalisées soit en augmentant la température de 300 à 400°C ou en la diminuant de 400 à 300°C. Dans tous les cas impliquant la conversion du cyclohexène, l'activité du charbon est influencée par la nature des produits de condensation formés sur la surface au cours de la conversion.

[Traduit par la revue]

1. Introduction

Activated carbon possesses not only adsorption but also important catalytic properties which are the basis of many industrial applications. The catalytic activity may be attributed to the carbon surface and complexes formed on it. Active carbon catalysts comprise a number of oxidation, decomposition, and pyrolysis reactions. Little is known about the mechanism of their effects; however, probably the surface complexes of carbon and oxygen are mainly responsible for these effects. It is interesting to mention that in many cases (1–5) the activity and selectivity of some catalysts may depend on the cokes or condensation polymers formed on the surface. One of these catalysts has been active for conversion of cyclohexene with selective poisoning for cyclohexane conversion (6). The suggested mechanism through which the reaction proceeded in this case was a polymolecular one.

The objectives of this investigation have been to study the conversion of cyclohexene on activated carbon and to explain the effect of condensation products on the activity of the surface.

2. Experimental

2.1. Materials

A steam-activated carbon, OL (20 × 50), was kindly provided by the Pittsburgh Activated Carbon Division; Calgon Corporation, USA. The textural characteristics of the OL-activated carbon are given in the following table:

Textural characteristics of OL-activated carbon

S_{BET} m^2/g	S_t m^2/g	S_{cum} m^2/g	V_{cum} mL/g	V_p mL/g
808	793	850	1.1483	1.625

where S_{BET} = surface area obtained from BET method, S_t = surface area obtained from the V_{1-t} plots, S_{cum} = cumulative surface area, V_{cum} = cumulative pore volume are calculated from pore volume distribution curves, V_p = total pore volume is the volume adsorbed at saturated vapour pressure $P/p_0 = 1$ as taken from the adsorption isotherm.

The carbon material used in this investigation possesses high surface area, low ash content, and microporosity. The impurity, qualitatively estimated by emission spectroscopy, were mainly Ca, Mg, and Al.

2.2 Apparatus

The catalytic measurements were carried out using a microreactor followed closely the design of Emmett (7, 8). The reactor was a silica tube of 5 mm-inner diameter and about 30 cm long. A known weight of the carbon sample, (50–250 mg), was supported by a Pyrex wool plug midway through the reactor. The reactor was heated by means of a tube furnace. A control chromel–alumel thermocouple was placed between the furnace and the reactor tube. The hydrocarbons were introduced ($1–5 \times 10^{-3}$ mL) to the catalyst through an injection septum just upstream from the reactor. The reaction products were transferred directly by the carrier gas at a flow of 50 mL min^{-1} to a gas liquid chromatograph (Perkin Elmer Sigma 3B) equipped with hot wire detector. A column of 4 m was used, packed with chromosorb W-NAW 80/100 Mesh with 15% Apiezon L, which was suitable for the separation of hydrocarbons. The temperature of both column and detector was kept constant at 100°C. A valuable advantage of this method is that it can trace the first steps of the catalytic reactions, which cannot be obtained by the usual flow system.

3. Results

3.1. Preliminary investigations

A preliminary experiment was carried out using the silica reactor without carbon. It was found that even at 500°C, the conversion on the reactor wall was not significant.

Other preliminary experiments with cyclohexane and benzene were performed at different temperatures. These experiments revealed that carbon surface showed no conversion of any of

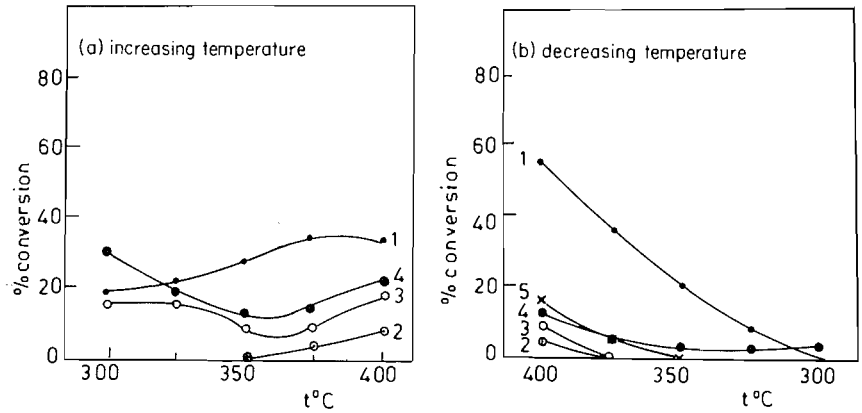

FIG. 1. Dependence of cyclohexene conversion on reaction temperature: (*a*) increasing reaction temperature; (*b*) decreasing reaction temperature. *1*, benzene; *2*, cyclohexane; *3*, methane; *4*, condensation products; *5*, toluene.

these substances. This reveals that the different kinds of active centers are not so active to convert cyclohexane or benzene.

3.2. Effect of reaction temperature on cyclohexene conversion

The results of cyclohexene conversion on activated carbon are represented in Fig. 1. These measurements were carried out by injection of 1 μL of cyclohexene into the micro-reactor charged with 50 mg of the carbon preheated at 450°C in a stream of helium for 2 h. Figure 1*a* shows the change in conversion when the starting reaction temperature increased from 300 to 400°C. Figure 1*b* shows a different trend when reaction temperature decreased from 400 to 300°C.

In the first case, at 300°C on a fresh catalyst, cyclohexene was converted into benzene (20%), methane (16%), and condensation products (34%); the remaining balance (30%) condensed on the carbon surface. Increasing reaction temperature was accompanied by an increase of percentage of benzene, a gradual increase in methane and condensation products.[1] The conversion percentages of the last two products passed through a minimum at 350–375°C and was followed by an increase in concentration up to 400°C. At 350°C, the conversion of cyclohexene to yield cyclohexane commenced and continued at higher temperatures.

On the other hand (Fig. 1*b*) starting at 400°C on a fresh sample catalyst, cyclohexene was converted into benzene (55%), cyclohexane (7%), methane (10%), toluene (17%), and condensation products (13%). Decreasing the temperature to 300°C was accompanied by a gradual decrease in all products. At 300°C, carbon showed almost no activity for cyclohexene conversion.

Figure 2 shows the effect of successive cyclohexene injections on its conversion at 400°C. For the first injection dose, cyclohexene was converted into benzene (55%), toluene (17%), methane (10%), cyclohexane (5%), and a very small quantity of condensation products. Successive injections of cyclohexene showed a gradual decrease in the percentages of all products except for cyclohexane; its percentage increased gradually reaching about 10% after the fifth injection.

4. Discussion

The first set of experiments (Fig. 1*a*) reveals that at 300°C carbon has moderate selectivity to form benzene (20%) and

[1]The condensation products were calculated by the difference between the quantity of injected cyclohexene and the sum of detected products.

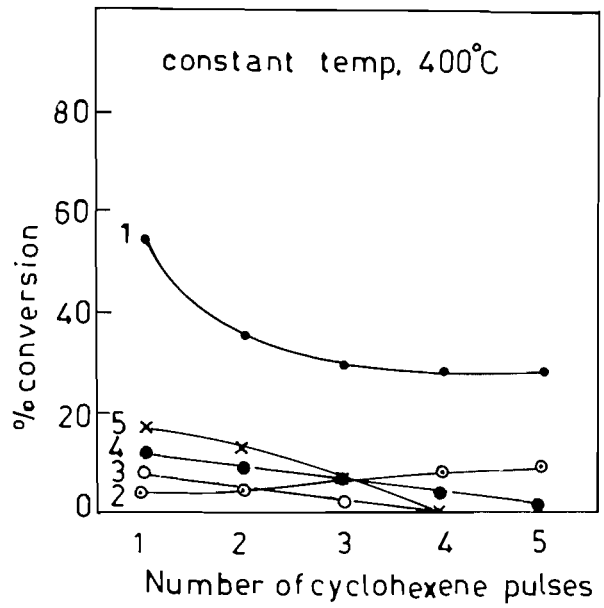

FIG. 2. Dependence of conversion on successive injections of cyclohexene at constant reaction temperature of 400°C. *1*, benzene; *2*, cyclohexane; *3*, methane; *4*, condensation products; *5*, toluene.

methane (16%). The condensation products remaining on the surface were 30% of the total injected cyclohexene. However, the second set of experiments (Fig. 1*b*) shows that at 300°C the catalyst is not active at all, and that only about 4% of cyclohexene was adsorbed at the surface. On the other hand, at 400°C (Fig. 1*a*) the percentages of benzene, methane, cyclohexane, and condensation products were 35, 17, 7, and 22, respectively. Starting from 400°C (Fig. 1*b*) the catalyst showed another behaviour; the percentages of benzene, methane, cyclohexane, and condensation products were 55, 10, 5, and 13, respectively. At this temperature a new product, toluene, was detected while it had not been observed when the reaction started at 300°C. This means that the nature of the condensation products, or the intermediate complexes formed on the surface at low temperatures, is different than those formed at high temperatures. In other words, at one and the same temperature, the conversion on a fresh carbon surface is not the same as on another surface on which the reaction has previously proceeded.

The formation of toluene at 400°C on a fresh carbon surface may be attributed to (*i*) the combination of benzene with

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/07/12
For personal use only.

methane (alkylation) (1), (*ii*) the particular activity of the condensation products accumulated on the surface at high temperature, and (*iii*) the condensation of benzene on the fresh carbon surface with splitting of other products as toluene.

It remains now to confirm the mode of formation of toluene. An additional experiment was carried out to detect the mode of toluene formation when benzene was injected on a fresh carbon catalyst at 400°C, no products were observed, thus indicating that toluene is not formed from benzene. Another experiment was done by injecting benzene into a carbon bed previously exposed to cyclohexene at 400°C. The products had 10% toluene and the balance was unreacted benzene. These experiments indicate that the condensation products formed on the surface can participate with the reactant to produce a particular product. These results are confirmed with the results obtained by Hoffman *et al.* (9). They reported that, in propylene pyrolysis on graphitized carbon black, the carbon species were found to deposit on the active sites and become new active sites. The injection of cyclohexene at 300°C followed by benzene did not produce toluene. Again indicating that the condensation products formed at low temperature are not the same as those formed at high temperature. These results confirmed to those previously obtained on Ni catalyst (2). The successive injections of cyclohexene into the carbon bed at 400°C (Fig. 2) reveals that there is a gradual decrease in benzene formation. The formation of toluene and methane also decreased but that of cyclohexane increased. This means that the accumulated condensation products on the surface were subjected to a particular change in their nature due to the continuous splitting of products such as toluene and methane. The remaining condensation products on the surface are thus capable of converting cyclohexene into cyclohexane.

According to the mechanism mentioned above, the formation of toluene may also be a result of the dissociation of a certain type of the polymer–catalyst complexes formed at high temperature in the presence of benzene molecules.

Anodic oxidation of UO_2. V. Electrochemical and X-ray photoelectron spectroscopic studies of film-growth and dissolution in phosphate-containing solutions

D. W. SHOESMITH, S. SUNDER, M. G. BAILEY, AND G. J. WALLACE

Atomic Energy of Canada Limited, Whiteshell Nuclear Research Establishment, Pinawa, Man., Canada R0E 1L0

Received March 27, 1987

D. W. SHOESMITH, S. SUNDER, M. G. BAILEY, and G. J. WALLACE. Can. J. Chem. **66**, 259 (1988).

The anodic oxidation of UO_2 has been studied in aqueous phosphate solutions over the pH range 4 to 11, using a combination of electrochemical and X-ray photoelectron spectroscopic techniques. The early stages of oxidation, leading to the formation of a film of composition $UO_{2.33}$, are unaffected by the presence of phosphate in the solutions. Phosphate concentrations $\gtrsim 10^{-1}$ mol L^{-1} prevent the formation of higher-oxide films that are present in phosphate-free solutions at higher oxidation potentials. Dissolution under steady-state conditions proceeds via a surface film of uranyl phosphate. For potentials $\gtrsim 200$ mV (vs. SCE), the rate of dissolution to yield $UO_2(HPO_4)_2^{2-}$ is controlled by charge-transfer kinetics. For potentials $\gtrsim 300$ mV, the rate-determining step is the chemical dissolution of the uranyl phosphate layer.

D. W. SHOESMITH, S. SUNDER, M. G. BAILEY et G. J. WALLACE. Can. J. Chem. **66**, 259 (1988).

Faisant appel à une combinaison de techniques électrochimiques et de spectroscopie photoélectronique des rayons-X, on a étudié l'oxydation anodique du UO_2, dans des solutions aqueuses de phosphate, à des pH allant de 4 à 11. Les étapes initiales de l'oxydation conduisent à la formation d'un film de composition $UO_{2.33}$ et elles ne sont pas affectées par la présence du phosphate dans les solutions. Des concentrations de phosphate $\gtrsim 10^{-1}$ mol L^{-1} empêchent la formation de films plus oxygénés qui sont formés, à des potentiels d'oxydation plus élevés, dans des solutions sans phosphate. La dissolution, dans des conditions d'état stationnaire, se produit par le biais d'un film à la surface du phosphate d'uranyle. A des potentiels $\gtrsim 200$ mV (vs. SCE), la vitesse de dissolution conduisant au $UO_2(HPO_4)_2^{2-}$ est contrôlée par la cinétique du transfert de charge. A des potentiels $\gtrsim 300$ mV, l'étape déterminant la vitesse de la réaction est la dissolution chimique de la couche de phosphate d'uranyle.

Introduction

A knowledge of the mechanism and kinetics of the oxidative dissolution of UO_2 fuel from CANDU nuclear reactors is essential to the determination of the rate of release of radionuclides under waste-disposal conditions. The stability of UO_2 is controlled primarily by the redox conditions at the UO_2 surface and the chemical species present in the groundwaters to which it may be exposed. Previously, we have reported the mechanism of oxidative dissolution in neutral (1) and alkaline (2) solutions, determined by a combination of electrochemical techniques and X-ray photoelectron spectroscopy (XPS). We have also investigated the effect of carbonate, an anion known to complex the uranyl ion (UO_2^{2+}), which is the product of the dissolution process (3, 4). The dissolution of UO_2 in the presence of various oxidants has also been reported (5, 6).

In this paper, we report our results on the anodic dissolution of UO_2 in solutions containing phosphate, an anion known to complex both U(IV) and UO_2^{2+} (7). As in our previous studies, electrochemical techniques, complemented by XPS, have been used.

Experimental

The UO_2 electrodes used in our experiments were prepared from pellets of UO_2 taken from unused, CANDU fuel bundles. The design and preparation of the electrodes used in rotating-disk studies and those used for surface-analytical experiments have been described previously (8). A standard, three electrode, three compartment, electrochemical cell was used. All potentials were measured, and are quoted, against a saturated calomel reference electrode (SCE). The supporting electrolyte was either 0.5 mol L^{-1} Na_2SO_4 or 0.1 mol L^{-1} $NaClO_4$. No significant difference in UO_2 behaviour was observed between the two solutions.

For XPS studies, the electrochemical experiments were performed in the inert, oxygen-free (nitrogen) atmosphere of a glove box attached to the sample compartment of the McPherson ESCA-36 X-ray photoelectron spectrometer. Transfer of the electrode from the cell to the spectrometer was performed without exposing the electrode to atmospheric oxygen, using a fast-transfer probe, as described earlier (1, 9). All photoelectron spectra were excited using Al-Kα radiation.

Results

Preliminary information on the anodic oxidation process was obtained by cyclic voltammetry. Figure 1 shows sections of a series of voltammograms (from -2.0 V to $+0.8$ V and back) recorded in 0.1 mol L^{-1} $NaClO_4$ plus 0.1 mol L^{-1} Na_2HPO_4 over the range $4 \leq pH \leq 10$. To avoid confusion, only the potential range where anodic currents were obtained is shown. Although the voltammograms shown were recorded under stationary conditions, the effect of electrode-rotation rate was negligible, indicating that the anodic process is not transport-controlled. The corresponding reverse sweeps (limited to the cathodic-current regions) are shown in Fig. 2.

The position and size of the small oxidation peak occurring at negative potentials (~ -100 mV at pH = 4) are independent of phosphate concentration ($[PO_4]_T$). With increasing pH, this peak increases slightly in size and shifts to more cathodic potentials, as previously observed over a much narrower pH range, 10 to 12 (2). As discussed in our previous publications, this peak can be attributed to the formation of a thin layer of UO_{2+x} (Fig. 1).

The second oxidation peak, seen at positive potentials ($\sim +600$ mV at pH = 6.0), was not observed in the absence of phosphate. The position and size of this peak are independent of pH over the range $5 < pH \leq 10$ (Fig. 1). The majority of the charge consumed in this oxidation goes to the formation of a surface layer that is reduced at the more negative of the two reduction peaks (e.g., ~ -700 mV at pH = 7.1) observed in the subsequent reverse cathodic sweep (Fig. 2). As indicated in Fig. 2, this peak is attributed to the reduction of a layer of $UO_{2.33}$, by analogy to the reduction processes observed in sulphate, and sulphate plus carbonate solutions (1, 4). The XPS results discussed later confirm this assignment.

The first reduction process in the cathodic sweep (Fig. 2) is

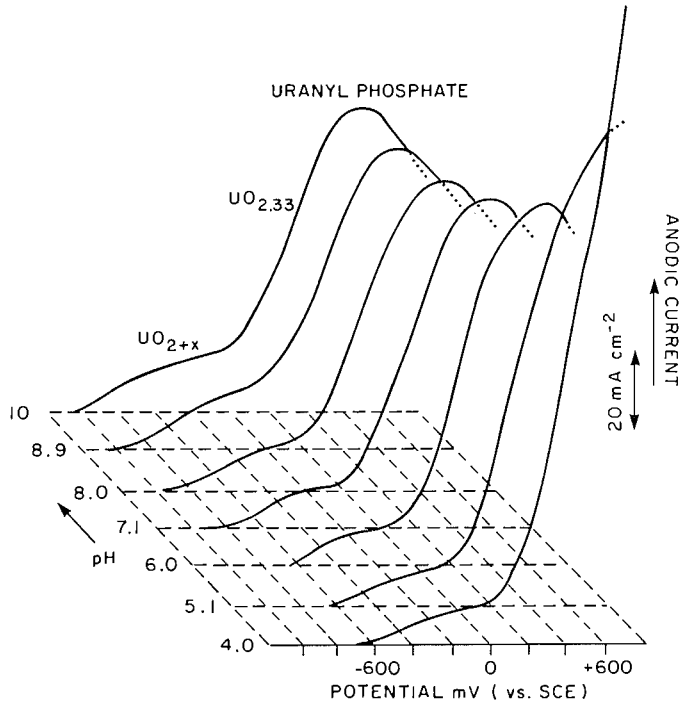

FIG. 1. Sections of a series of anodic sweeps at 20 mV s^{-1} from −2.0 V to +0.8 V recorded in a solution containing 0.1 mol L^{-1} $NaClO_4$ plus 0.1 mol L^{-1} Na_2HPO_4 for various pH values in the range $4.0 \leq pH \leq 10$.

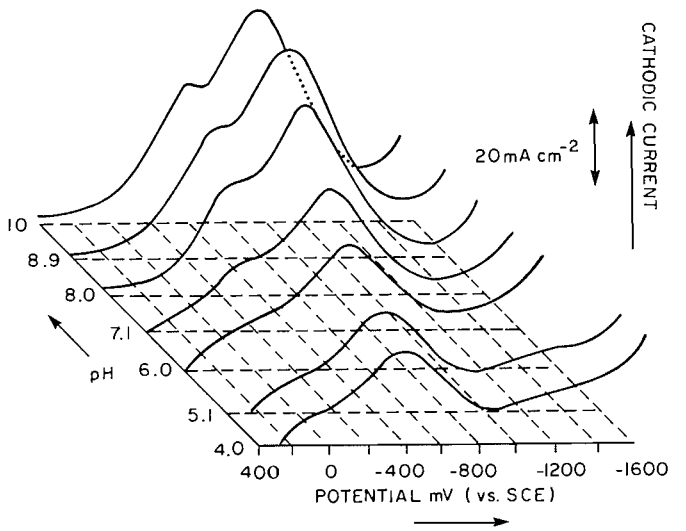

FIG. 2. Sections of the cathodic sweeps (20 mV s^{-1}) recorded after the corresponding anodic sweeps of Fig. 1.

only seen when the major anodic peak is observed in Fig. 1, and can be attributed to the reduction of a partially passivating layer formed at very positive potentials during the anodic sweep. This cathodic peak is absent at $pH \lesssim 5$ when no anodic peak is observed in Fig. 1. However, its size increases with increasing pH, indicating that this layer thickens at higher pH values despite the fact that the anodic peak in Fig. 1 does not vary in size or position with pH. As indicated, this partial-passivation process is tentatively attributed to the formation (Fig. 1) and reduction (Fig. 2) of a uranyl phosphate layer.

The surfaces of UO_2 electrodes subjected to potentiostatic oxidation in phosphate-containing solutions were analyzed using XPS. In addition to survey spectra recorded to determine

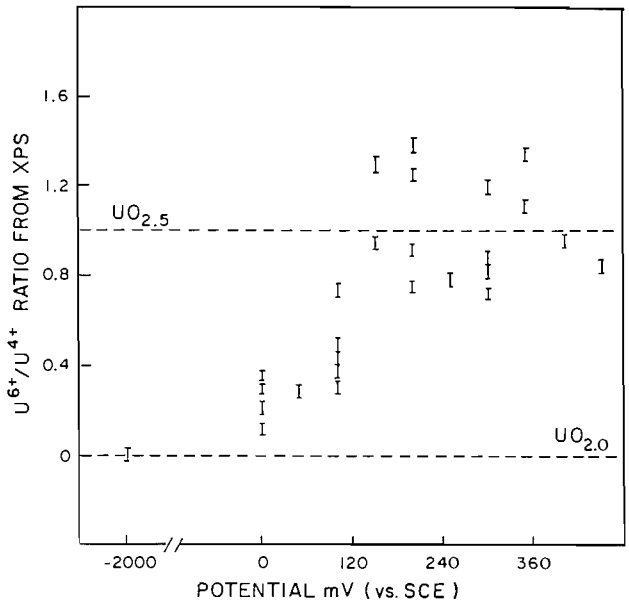

FIG. 3. Stoichiometry of the UO_2 electrode surface, expressed as the U^{6+} to U^{4+} ratio from XPS, after anodic oxidation for 20 min in 0.5 mol L^{-1} Na_2SO_4 + 0.1 mol L^{-1} Na_2HPO_4 solution, pH = 9.2, at various potentials.

the elemental composition of the surface layer, high-resolution spectra were recorded for U-4*f*, C-1*s*, O-1*s* and the valence region bands (0–20 eV) to determine the extent of oxidation of the UO_2 surface. The U-$4f_{7/2}$ band was resolved into U^{6+} and U^{4+} components according to procedures described earlier (1, 9). The results of this analysis were verified by the relative intensity of the bands in the valence region. The C-1*s* spectra were recorded to monitor any charging of the electrode surface.

Figure 3 shows the U^{6+} to U^{4+} ratio on the surface of the electrode after potentiostatic oxidation at various potentials for 20 min (1200 s) in a solution containing 0.1 mol L^{-1} Na_2HPO_4 plus 0.5 mol L^{-1} Na_2SO_4 (pH = 9.2). At −2.0 V, the U^{6+} to U^{4+} ratio is zero, consistent with a completely reduced electrode surface of composition UO_2. The ratio increases as the applied potential (E) increases, achieving a value of 1.0 ± 0.2 for $E \geq +200$ mV. A similar value of this ratio is obtained at these potentials in the absence of phosphate. This value is close to that expected for $UO_{2.5}$ (U_2O_5), as indicated in Fig. 3.

Figure 4 shows the U^{6+} to U^{4+} ratio achieved after potentiostatic oxidation at +300 mV for 20 min in 0.5 mol L^{-1} Na_2SO_4 containing various amounts of Na_2HPO_4 (pH = 9.2). For $[PO_4]_T \leq 10^{-2}$ mol L^{-1}, the ratio is ~1.0 and unaffected by the presence of phosphate. For $10^{-2} < [PO_4]_T < 10^{-1}$ mol L^{-1}, the ratio ranges from ~0.6 to ~1.5 with an average value close to 1, as observed at lower concentrations. For $[PO_4]_T > 10^{-1}$ mol L^{-1}, the ratio falls to a value of ~0.6, close to that expected for $UO_{2.33}$ (U_3O_7).

The voltammetric data of Figs. 1 and 2 indicate that a thin surface layer, possibly of uranyl phosphate, is formed at anodic potentials, and this could account for the high values of the U^{6+} to U^{4+} ratio (i.e., >1.0, the value expected) observed in the concentration range $10^{-2} < [PO_4]_T < 10^{-1}$ mol L^{-1}. Consequently, the survey spectra were analyzed in an attempt to determine whether phosphate anions were incorporated into the surface film during anodic oxidation. Unfortunately, it was not possible to directly distinguish between the phosphorus signal arising from phosphate incorporated in the oxidized surface

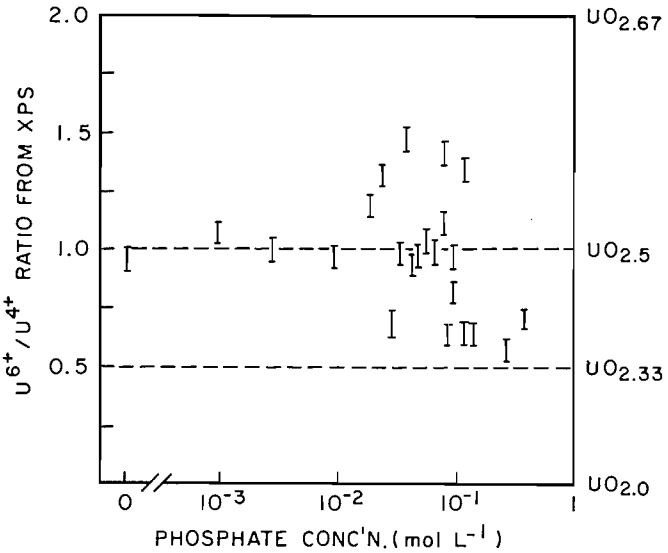

FIG. 4. Stoichiometry of the UO_2 electrode surface, expressed as the U^{6+} to U^{4+} ratio from XPS, after anodic oxidation at 300 mV for 20 min, in a solution of 0.5 mol L^{-1} Na_2SO_4 (pH = 9.2) containing various concentrations of Na_2HPO_4.

layer and that due to phosphate deposited from the solution, as a result of incomplete washing of the electrolyte from the electrode surface prior to transfer to the spectrometer vacuum chamber.

In an attempt to determine whether phosphate was incorporated into the oxidized surface layer, we measured the observed signal for phosphorus against that of sulphur, present as sulphate in the electrolyte. The intensities of the P-2*p* band (~133 eV) and the S-2*p* band (~168 eV) were normalized with respect to the intensity of the strongest uranium band (U-4$f_{7/2}$). An analysis of the relative intensity data of the P, S, and U indicated that a very thin, or incomplete, layer of "uranyl phosphate" is present (10). By lengthening the washing procedure and observing the corresponding disappearance of the P-2*p* band, we confirmed that redissolution of this layer did occur.

Consequently, we can attribute the high U^{6+} to U^{4+} ratios (>1.0), observed in Fig. 4 for $10^{-2} < [PO_4]_T < 10^{-1}$ mol L^{-1}, to the presence of a thin "uranyl phosphate" layer. The scatter in this concentration range suggests that, in some cases, we succeed in transfering the uranyl phosphate layer to the spectrometer ($U^{6+}/U^{4+} > 1.0$). In other cases, its redissolution in the electrolyte after the applied potential is switched off, or during the subsequent washing procedure, means that this layer is not observed by XPS analysis ($U^{6+}/U^{4+} < 1.0$, Fig. 4).

Figure 5 shows a series of logarithmic current–time plots recorded in 0.1 mol L^{-1} $NaClO_4$ plus 0.1 mol L^{-1} Na_2HPO_4 (pH = 9.5) for various potentials. For $E < 200$ mV, the plot is linear with a slope close to −1.0. This behaviour is consistent with a field-assisted, film growth process (4). For $E < 200$ mV, similar behaviour is observed at short times, indicating that the film-growth process is initially the same for all potentials. For longer times, the current deviates from this linear relationship. The potential range within which this deviation occurs ($E \geq 200$ mV, Fig. 5) coincides with the range over which the U^{6+} to U^{4+} ratio stabilizes around 1.0 ± 0.25, Fig. 3.

Figure 6 shows plots of Q_D (= $Q_A - Q_C$) and Q_C recorded at a potential of 300 mV for various phosphate concentrations as a function of the duration of oxidation, t_A. The anodic charge values, Q_A, were obtained by integration of potentiostatic

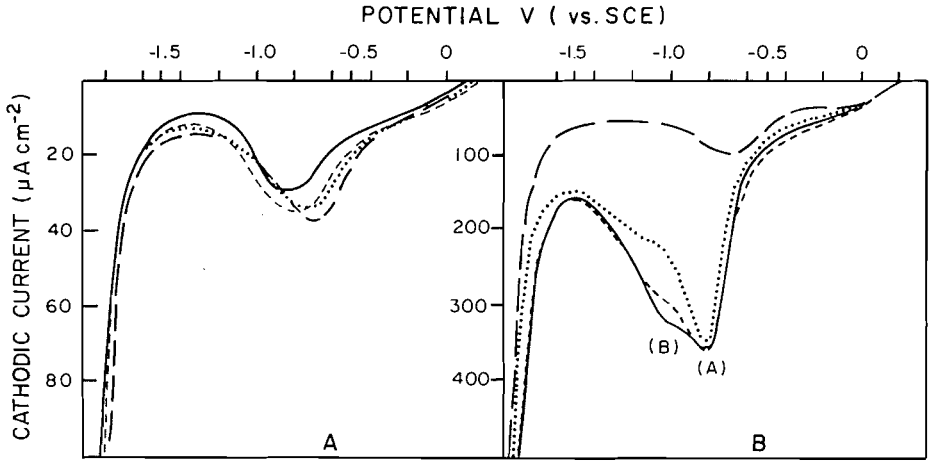

FIG. 7. Cathodic stripping voltammograms (20 mV s^{-1}) recorded after 10 s (A) and 17 h (B) of potentiostatic oxidation at 300 mV in a 0.5 mol L^{-1} Na_2SO_4 solution (pH = 9.0) containing various amounts of phosphate, $[PO_4]_T$; — 10^{-3} mol L^{-1}; ---- 10^{-2}; ··· 10^{-1}; --- 5×10^{-1}.

current–time curves, and Q_C values were obtained by integration of the subsequent cathodic stripping voltammograms (CSV). Q_D is a measure of the extent of dissolution up to the time t_A, and Q_C is a measure of the charge required to electroreduce the surface films formed during oxidation, and hence is a measure of film thickness.

For short times, $Q_C > Q_D$ since most of the anodic charge is consumed in film growth. This is consistent with the linear log i vs. log t plots of Fig. 5. For $[PO_4]_T = 10^{-1}$ mol L^{-1}, Q_D becomes substantial for $t_A > 10^2$ s. This is the time at which the log i vs. log t curve (for 300 mV) deviates from the initial linear relationship (indicated by the arrow in Fig. 5), showing that this deviation can be attributed to the predominance of dissolution over film growth. Similar cathodic stripping experiments at the other potentials used to construct Fig. 5 confirm that all the deviations from the linear log i vs. log t plots can be attributed to the onset of dissolution.

From Fig. 6, we can see that at +300 mV, for $[PO_4]_T < 10^{-1}$ mol L^{-1}, dissolution does not become extensive until $t > 10^3$ s. For these concentrations, the fast initial film formation is followed by a slower, second stage of film growth. Both the extent of dissolution, Q_D, and the film thickness, Q_C, are independent of $[PO_4]_T$. The arrow in Fig. 6 indicates the time for which the U^{6+} to U^{4+} ratios of Fig. 4 were measured. At $[PO_4]_T = 10^{-2}$ and 10^{-3} mol L^{-1}, a composition of $UO_{2.5}$ was achieved after 20 min.

For $[PO_4]_T = 0.5$ mol L^{-1}, dissolution is substantial even at short times ($t > 20$ s, Fig. 6), and the second stage of film growth is not observed. On the contrary, the initially formed film thins with time. The XPS data of Fig. 4 show that a composition close to $UO_{2.33}$ is achieved after 20 min. For $[PO_4]_T = 10^{-1}$ mol L^{-1}, the second stage of film growth is observed but only after $t > 10^4$ s, indicating that the switch from film thickening to film thinning occurs around this concentration. The U^{6+} to U^{4+} ratio (Fig. 4) is erratic in this region, consistent with a system balanced between film growth and dissolution. The XPS data indicate that for $[PO_4]_T > 10^{-1}$ mol L^{-1}, dissolution is occurring from a $UO_{2.33}$ surface covered with a thin uranyl phosphate layer. This conclusion is consistent with the voltammetric data of Figs. 1 and 2.

The forms of the CSVs for the shortest (10 s) and longest times (17 h) used to obtain the data of Fig. 6 are shown in Figs. 7*A* and 7*B* as a function of $[PO_4]_T$. The similar shape and size of the CSVs after 10 s of oxidation confirm that the first stage of oxidation is the same for all phosphate concentrations. This is consistent with the fast formation of a layer of $UO_{2.33}$ previously observed for sulphate and carbonate solutions (1, 4). After 17 h of oxidation, the size of this reduction peak (*A* in Fig. 7*B*) is increased, indicating a thickening of the $UO_{2.33}$ layer with time. For $[PO_4]_T \leq 0.5$ mol L^{-1}, this reduction peak observed after 17 h is much smaller than after 10 s since dissolution is much faster at this concentration, leading to a thinning of the $UO_{2.33}$ layer, Fig. 6.

The most marked difference between the CSV obtained after 10 s and that observed after 17 h of potentiostatic oxidation is the appearance of a second reduction peak (*B* in Fig. 7*B*) that increases in size as the phosphate concentration decreases. Similar CSVs for intermediate times, between 10 s and 17 h, show that this peak is due to the reduction of the oxide formed during the second stage of film growth observed for $t > 10^3$ s, Fig. 6. The U^{6+} to U^{4+} ratios recorded after 1.2×10^3 s (arrow in Fig. 6) show that the initially formed $UO_{2.33}$ layer is further oxidized to $UO_{2.5}$ at the beginning of this second stage of oxidation. This second oxidation process probably proceeds to the $UO_{2.67}$ stage after 17 h, as observed in solutions containing only sulphate (1).

The potentiostatic transients of Fig. 5 show that for long times at sufficiently anodic potentials, the current achieves a steady-state value. As discussed above, this current can be attributed to dissolution. Figure 8 shows steady-state currents recorded in a 0.1 mol L^{-1} Na_2SO_4 (pH = 9.4) solution and in the same solution containing either 0.1 mol L^{-1} $NaHCO_3$ or 0.1 mol L^{-1} Na_2HPO_4. The addition of phosphate to sulphate solutions accelerates dissolution for low anodic potentials, but inhibits the process at higher potentials. However, dissolution currents in phosphate solutions are always much lower than those in carbonate solutions.

Figure 9 shows steady-state currents as a function of potential for various phosphate concentrations at pH = 9.5. Two distinct regions of behaviour are observed. For potentials <300 mV, the current exhibits a Tafel region with a slope close to 60 mV^{-1}. For low potentials (<100 mV), steady-state is difficult to achieve. At higher potentials, the current becomes independent of potential, indicating a chemically, as opposed to electrochemically, controlled dissolution process. On the basis of the voltammetric data of Figs. 1 and 2 and the XPS data of Figs. 3

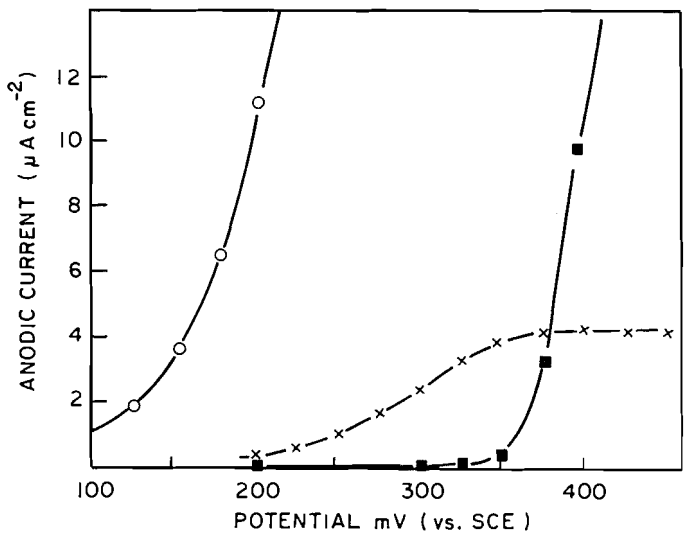

FIG. 8. Steady-state current voltage curves recorded in 0.1 mol L^{-1} Na_2SO_4 (pH = 9.4) (■) and in the same solution containing 0.1 mol L^{-1} $NaHCO_3$ (○) or 0.1 mol L^{-1} Na_2HPO_4 (×).

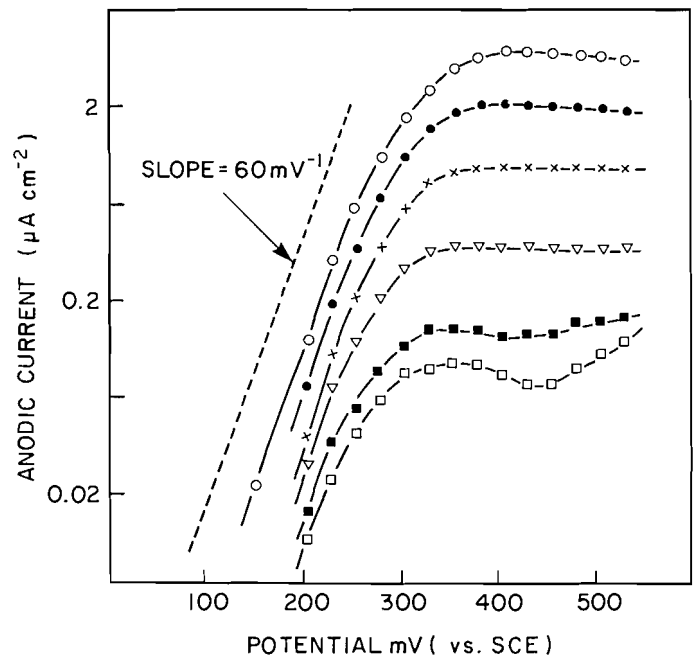

FIG. 9. Steady-state current–voltage curves recorded on a rotating-disk electrode (ω = 16.7 Hz) in 0.1 mol L^{-1} $NaClO_4$ (pH = 9.5) containing various amounts of Na_2HPO_4; □, $[PO_4]_T = 10^{-2}$ mol L^{-1}; ■, 2×10^{-2}; ▽, 5×10^{-2}; ×, 10^{-1}; ●, 2×10^{-1}; ○, 5×10^{-1}.

and 4, we can attribute chemical control to the potential-independent dissolution of a "uranyl phosphate" layer.

Chemical control of the dissolution process in the plateau region is confirmed by pulsing between potentials in this region. The current decay to a steady-state value after an anodic pulse is quite rapid (20–50 s) indicating that the formation of the uranyl phosphate layer is rapid. On pulsing back to the original, less positive potential, the current is depressed below the original value at this potential and only slowly recovers (200–500 s) to the steady-state value. This slow recovery confirms that the thick uranyl phosphate layer formed at the higher potential is only slowly dissolved.

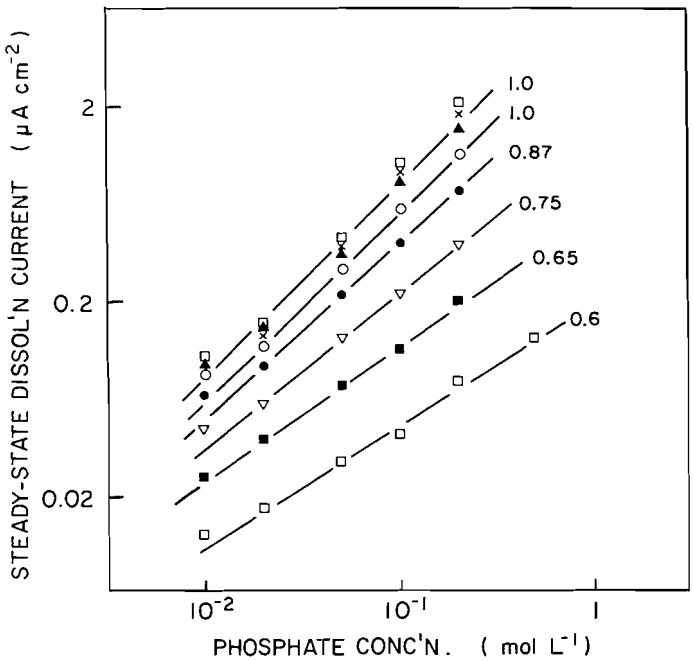

FIG. 10. Steady-state currents of Fig. 9 plotted as a function of phosphate concentration for various potentials; □, 200 mV; ■, 225 mV; ▽, 250 mV; ●, 275 mV; ○, 300 mV; ▲, 350 mV; ×, 375 mV; □, 400 mV. The numbers on the figure are the slopes of the various lines.

Figure 10 shows the steady-state currents plotted as a function of $[PO_4]_T$ for various potentials. These data show that the dissolution current is first order in phosphate concentration in the plateau region (i.e., for $E > 300$ mV), but the reaction order decreases with decreasing potential in the Tafel region. Also for $E \geq 400$ mV the dissolution current is independent of pH over the range $4 \leq$ pH ≤ 11.

Discussion

Figure 11 is an attempt to represent the different stages of oxidation and dissolution of UO_2 in phosphate-containing solutions. As previously determined in sulphate (1), and sulphate plus carbonate (4) solutions, the anodic oxidation of UO_2 proceeds in two stages.

The initial, fast stage of film formation, reaction [1] of Fig. 11, produces a layer of $UO_{2.33}$, approximately 4 nm thick,[1] in 10 s (Fig. 6).

[1] $UO_2 + 0.33H_2O \rightarrow UO_{2.33} + 0.66H^+ + 0.66e$

Under voltammetric conditions (Fig. 1) this process is preceded, in the potential range -600 mV $< E < 0$, by the formation of a very thin layer of undetermined composition, UO_{2+x}. It is likely that, under potentiostatic conditions, a layer of UO_{2+x} is also formed prior to further oxidation to $UO_{2.33}$. However, at the potential of 300 mV at which most of our studies were performed, the experimental techniques employed cannot resolve UO_{2+x} formation.

During the second, slower stage of film growth, the $UO_{2.33}$ layer thickens, and is partially oxidized to $UO_{2.5}$. Although not

[1]Film thicknesses are calculated assuming an initial composition of $UO_{2.33}$ and a final composition of $UO_{2.67}$. The volume per uranium atom is 0.0398 nm^3 for $UO_{2.33}$ and 0.0555 nm^3 for $UO_{2.67}$. These volumes are calculated by dividing the unit-cell volume with the number of uranium atoms per unit cell (4).

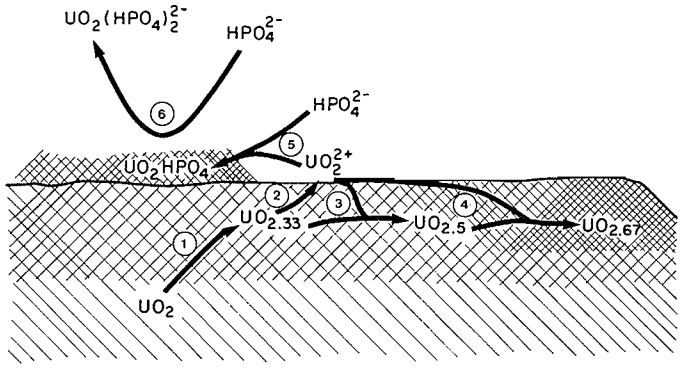

FIG. 11. Schematic of the mechanism of anodic film growth and dissolution of UO_2 in phosphate-containing solutions.

demonstrated in this paper, it is likely that $UO_{2.5}$ is simply a precursor (after a sufficient duration of oxidation) to the eventual formation of $UO_{2.67}$ as shown to occur in sulphate solutions (1). This second stage of film growth appears to be a recrystallization, because a significant structural rearrangement is required to convert the densely packed fluorite structure of $UO_{2.33}$ to the more open orthorhombic structure of $UO_{2.67}$. Since this second stage of oxidation is not observed when dissolution becomes extensive (Fig. 6) we have suggested previously (1) that dissolution and recrystallization proceed via a common intermediate and hence are in competition. In terms of Fig. 11, this represents a competition between reactions [2] and [5] (dissolution) and [2] and [3] (recrystallization). The nature of this intermediate has not been determined. It is assumed to be a UO_2^{2+} species, produced from the $UO_{2.33}$ layer and still partially coordinated to the electrode surface. This intermediate is then incorporated into the recrystallized oxide film;

$$[2] \quad UO_{2.33} + 0.33H^+ \rightarrow (UO_2^{2+})_{ads} + 0.33OH^- + 1.33e$$

$$[3] \quad (UO_2^{2+})_{ads} + 3UO_{2.33} + H_2O \rightarrow 4UO_{2.5} + 2H^+$$

Variations in phosphate concentration have no effect on the fast, initial film growth process, as previously demonstrated for carbonate (4). This is so even at the highest phosphate concentration employed, 0.5 mol L^{-1}. The formation of the $UO_{2.33}$ layer proceeds by the inclusion of oxide ions (O^{2-}) at interstitial sites in the UO_2 lattice, and hence is unaffected by the presence of complexing anions, such as phosphate and carbonate.

Since the second stage of film growth is in competition with dissolution, we would expect the addition of complexing anions, such as phosphate, to have an impact on the rate and extent of $UO_{2.5}/UO_{2.67}$ formation. The data of Fig. 6 show that the second stage of film growth can be prevented for $[PO_4]_T > 0.1$ mol L^{-1} and significantly retarded at a concentration of 0.1 mol L^{-1}. This is confirmed by the XPS data of Fig. 4. By comparison, in carbonate solutions the second stage of film growth is prevented for carbonate concentrations greater than $\sim 10^{-3}$ mol L^{-1}. This difference is consistent with the dissolution currents of Fig. 8, which show a much larger impact of carbonate than phosphate.

Compared to the behaviour in sulphate solutions, Fig. 8, phosphate is observed to accelerate dissolution over the potential range $200 < E < 380$ mV, but to inhibit the process for $E > 380$ mV. The equilibrium potential for the overall dissolution reaction

$$[4] \quad UO_2 \rightleftarrows UO_2^{2+} + 2e$$

will be decreased by complexation of the dissolution product

$$[5] \quad UO_2^{2+} + nA^- \overset{K}{\rightleftharpoons} UO_2A_n^{(n-2)-}$$

where K is the equilibrium constant. Thus, the extent by which the equilibrium potential for reaction [4] is shifted to more negative values, and hence the potentials at which dissolution is first observed will be determined by the value of K. On this basis, the observation of dissolution currents at lower potentials in phosphate than in sulphate is understandable, given the relative values of K for the specific equilibria involved

$$[6] \quad UO_2^{2+} + SO_4^{2-} \rightleftarrows UO_2SO_4(aq) \qquad (\log K = 2.9 \pm 0.5)$$

$$[7] \quad UO_2^{2+} + HPO_4^{2-} \rightleftarrows UO_2HPO_4(aq) \qquad (\log K < 8)$$

$$[8] \quad UO_2^{2+} + 2HPO_4^{2-} \rightleftarrows UO_2(HPO_4)_2^{2-} \qquad (\log K < 19)$$

The values of K are taken from the critical evaluation of Lemire and Tremaine (7). Complexation of UO_2^{2+} by carbonate is stronger than by phosphate and, hence, carbonate would cause dissolution of UO_2^{2+} even at lower potentials, as observed in Fig. 8.

The eventual inhibition of dissolution at higher potentials in phosphate solutions, Figs. 8 and 9, can be attributed to the stability of solid uranyl phosphates

$$[9] \quad (UO_2)_3(PO_4)_2 + 2H^+ \rightleftarrows 3UO_2^{2+} + 2HPO_4^{2-} \qquad (\log K = -24 \pm 3)$$

$$[10] \quad (UO_2)_2(HPO_4)_2 \rightleftarrows 2UO_2^{2+} + 2HPO_4^{2-} \qquad (\log K = -23 \pm 2)$$

$$[11] \quad UO_2HPO_4 \rightleftarrows UO_2^{2+} + HPO_4^{2-} \qquad (\log K = -12.33 \pm 0.06)$$

Here values of K for equilibria [9] and [10] are from ref. 7 and that for equilibrium [11] is from ref. 12. Our attempts to identify the "uranyl phosphate" layer formed in our experiments by XPS were only partially successful, due to redissolution of the layer during transfer of our electrode from cell to spectrometer vacuum chamber. However, the electrochemical evidence for the presence of a partially passivating surface layer (Figs. 1, 2, and 9) is overwhelming, and the dissolution of this layer eventually controls the overall process for $E > 300$ mV, Fig. 9.

The steady-state dissolution currents of Fig. 9 show two distinct regions: a Tafel region with a slope close to 60 mV^{-1}; and a region, at higher potentials, where the dissolution current is independent of potential and first order with respect to $[PO_4]_T$, Fig. 10. At these high potentials, if we assume the surface phase present is UO_2HPO_4, we can write the dissolution reaction as

$$[12] \quad UO_2HPO_4 + HPO_4^{2+} \rightarrow UO_2(HPO_4)_2^{2-}$$

corresponding to reactions [5] and [6] in Fig. 11. The data of Fig. 10 show that the thickness of the uranyl phosphate layer increases with potential in the plateau region of Fig. 9. This increase in thickness leads to an electric field in the surface film which does not vary with potential, thereby making the film dissolution/film replacement process potential-independent.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.222.148.141 on 09/07/12
For personal use only.

As written, this reaction is independent of pH, in agreement with our observations, which show that the dissolution current is independent of pH over the range $4 \leq pH \leq 11$. This suggests that the nature of the film present on the electrode surface does not vary with pH. This is not surprising since $UO_2(HPO_4)_2^{2-}$ is the predominant solution species over this whole pH range (11).

The 60 mV^{-1} slope obtained in the Tafel region of Fig. 9 indicates a direct, two-electron transfer process. Such processes are statistically unlikely. In the present case, it is probable that the two-electron process arises as a consequence of the stability of the "uranyl phosphate" surface layer. Any intermediate U^{5+} species formed must be rapidly, and irreversibly, converted into the U^{6+} species incorporated in the uranyl phosphate layer. Hence, in the Tafel region, dissolution proceeds via the reaction

$$[13] \quad UO_2 + HPO_4^{2-} \rightarrow UO_2HPO_4 + 2e$$

followed by reaction [11]. The intervening $UO_{2.33}$ layer exerts no kinetic influence on the dissolution process under steady-state conditions. Its rate of conversion to UO_2^{2+} (reaction [2]) is balanced by its rate of replacement (reaction [1]). Consequently, the overall charge transfer process can be taken as reaction [13].

The decrease in reaction order as the potential decreases, Fig. 10, is consistent with a switch at lower potentials from rate-control by chemical reaction [12] to rate-control by electrochemical reaction [2]. Since steady-state measurements were difficult to make below $E = 200$ mV, we did not measure the reaction order in the true Tafel region, where it would be expected to approach zero as the charge-transfer reaction, [2], assumed total rate control.

Summary

The anodic dissolution of UO_2 in phosphate solutions proceeds by the same basic mechanism as that observed previously in sulphate and carbonate solutions, except that the dissolution rate is limited at more anodic potentials (>300 mV) by the presence of a uranyl phosphate layer. This layer is formed by an irreversible, two-electron, charge-transfer process that controls the dissolution at potentials <200 mV. At potentials >300 mV, the dissolution process is controlled by chemical dissolution of the uranyl phosphate layer and is first order in total phosphate concentration.

Received October 17, 1986[2]

JESSICA R. HALLETT, MICHAEL THOMPSON, EDWARD J. KEALL, and ROBERT B. MASON. Can. J. Chem. **66**, 266 (1988).

Microscopic examination and electron microprobe analysis were employed to determine the materials and techniques used to decorate ten glazed types of medieval Islamic ceramics from North Yemen. Eight types were underglaze-painted, one was slip-painted, and one was monochrome glazed. The glazes were of two compositions, soda–silica and lead oxide – silica with annealing temperatures of approximately 835 and 640°C, respectively. The colourants used in the glazes and paints were cobalt (blue), iron (green), copper (green and blue), and antimony (yellow). Where clay slips or slip-paints were present, alumina enrichment of the glaze had occurred during application or firing, and pigment-paints on top of slip grounds masked enrichment. The Mellor ratio for the lead glazes ranges from 0.68 to 0.74 and is well above the acceptable safety limit of 0.5.

JESSICA R. HALLETT, MICHAEL THOMPSON, EDWARD J. KEALL et ROBERT B. MASON. Can. J. Chem. **66**, 266 (1988).

On a utilisé des examens microscopiques et des analyses à l'aide d'une micro-sonde électronique pour déterminer la nature des matériaux et des techniques qui ont été utilisés pour décorer dix types de céramiques islamiques médiévales émaillées provenant du Yémen du Nord. Huit types avaient été peints sous la glaçure, un avait été engobé et un portait une glaçure monochrome. Les glaçures sont de deux compositions, soude/silice et oxyde de plomb/silice, et les températures de recuisson étaient respectivement de 835 et de 640°C. Les colorants utilisés dans les glaçures et les peintures sont le cobalt (bleu), le fer (vert), le cuivre (vert et bleu) et l'antimoine (jaune). Dans les cas où des engobes d'argile ou des peintures par engobage sont présents, un enrichissement de l'aluminium de la glaçure s'est produit soit durant l'application ou durant la cuisson et les pigments de peinture présents sur les masses d'engobage masquent l'enrichissement. Dans les glaçures de plomb, le rapport de Mellor varie de 0,68 à 0,74 et se trouve bien au-dessus de la limite de 0,5 qui est considérée comme sécuritaire.

Introduction

The Yemen Archaeological Project is concerned with the history and culture of a medieval Islamic university town, Zabid, and its interaction with neighboring settlements and the outside world, from A.D. 700 to 1750 (1). Zabid is 25 km inland, half-way between the Red Sea and the Yemeni highlands, on the Tihamah coastal plain. In the absence of any previous systematic archaeological work in the region, the initial surface reconaissance involved collection of pot sherds from abandoned sites in order to establish a ceramic typology, as a way of determining the nature, location, and period of settlements in the region. Sherds (2400) were collected and classified from a total of 73 sites within the 100 by 70 km study area. Almost all of the pottery is considered to be of local manufacture, and can be divided into separate *types* according to the colour of the fired clay, shape, and surface decoration treatment. The pottery can be tentatively dated by association with import pieces from other countries, such as 15th century "Ming" blue-and-white porcelain or 13th century Yuan celadons.

Neutron activation analysis of the clay bodies of 20 ceramic types supported the hypothesis that the ceramics were manufactured in the Tihamah coastal plain of Yemen (2). Petrographic analysis has indicated the presence of at least two production centres for the material, Hays and Zabid (3). Similar types appear to have been manufactured at both places in the heyday of the region between 12th–15th centuries, with Hays emerging as the dominant pottery producer once Zabid ceased to be a major administrative centre of the ruling dynasties.

Stylistically, there are no precise parallels for the Yemeni ceramics in the previously documented collections of Islamic pottery. In order to improve the initial visual classification of the material, it was considered essential to determine the physical components of decoration (glaze, slip, paint, etc.), their composition and order of application, and the firing temperature and kiln atmosphere used. Hence, consistency of composition among different types could indicate contemporaneity, and whether the glazing traditions remained constant throughout this 600 year period.

In the present paper, the application of electron microprobe analysis (EMPA) to selected Yemeni glaze samples is described. The advantages of this technique include the ability to obtain quantitative cross-sectional information, avoiding possible problems associated with glaze surface alteration caused by weathering, or by volatilization of components during manufacturing (4).

Experimental

(a) Microscopic analysis

Whole sherds were examined under a binocular microscope to observe the surface structure of the glaze, the state of preservation, degree of crazing[3] or peeling,[4] colour of the glazed areas, and presence of inclusions and of gases trapped in the glaze. Polished thin sections of two sherds per type were examined in reflected and transmitted light under a polarizing microscope to determine the components of decoration, size of slip and pigment particles, degree of vitrification[5] and of bonding between the glaze, slip, and body.

(b) Sample preparation

Resin impregnated polished thin sections of sherds from each of ten

TABLE 1. Geological standards

Soda–silica glaze		Lead oxide – silica glaze	
Standard	Element	Standard	Element
Scapolite	Si, Ca, Na, Cl	Crocoite	Pb
Orthoclase	K	Amphibole	Si, Al, Ti, Fe, Mg, Ca, Na, K
Pyroxene	Al, Mg, Fe, Ti		
Doped troilite	Co, Cu	Chalcopyrite	Cu

ceramic types were prepared as follows. Small slivers of the glaze and body were removed from the sherds using a diamond impregnated steel saw perpendicular to the glaze surface. The samples were impregnated with epoxy resin, and mounted on glass slides. This section was cut and ground to 30 μm using a thin section grinder, followed by treatment with 1000 mesh silicon carbide grains, and finally polished with 1 μm diamond compound on a nylon cloth.

(c) Electron microprobe analysis

Electron microprobe analyses were performed using an ETEC Autoprobe (ETEC Corp., USA) with an energy dispersive method of X-ray detection. A thin layer of carbon was vacuum deposited on the sample to prevent charging of local areas of the surface and subsequent distortion and deflection of the electron beam. The accelerating voltage was 20 kV; the probe current, approximately 200 picoamperes; take-off angle, 38°; beam size, 2 μm; and counting time, 100 s. Twelve elements were determined and the data were reduced with full ZAF correction. For Pb, the M α line was used; for Sn and Sb, the L α line; and for all other elements, the K α lines. Areas that appeared to be optically homogeneous glass, free from inclusions and devitrification products, were selected for analysis. The counts were checked throughout the analysis to detect wide variations which could indicate inhomogeneity. In addition to using a low probe current, the sample was slightly moved every 25 s to avoid problems associated with diffusion of the more mobile ions, like Na, under the effect of the beam. At least three analyses were made of the glaze, pigment-paint in solution with the glaze, or pigment particle. Elemental concentrations are reported here as equivalent oxide weight percent concentrations.

Peak overlaps occur with the EDS method which the software at our disposal could not resolve, in particular, the overlap of Pb and S. Hence, these two elements could not be analysed simultaneously. For Type J with a soda–silica glaze coloured with copper, the concentration of S was sought owing to the probability the pigment was CuS. In the case of the lead oxide – silica glaze of Type A, also coloured with a Cu pigment, Pb was determined as it was important to our understanding of the basic glaze composition. However, sulphur is usually present only in small concentrations in glazes owing to vaporization during firing (5).

Finally, the concentrations of the glass-forming oxides and colourants were not consistently similar to any one glass or mineral standard available. The standards used are listed in Table 1.

Results and discussion

Microscopic examination was used to refine the descriptions of the potting process for the ten types (Table 2). The process consists of the manufacture of a clay body, and the application of a slip, paint, and glaze. A slip is a mixture of clay in water and can be applied all over the surface as a ground for painting. Paint is either a slip-paint, where a slip is brushed on as a design, or a pigment-paint where either common ores, earthy materials, or ground coloured glass, with water as a vehicle, are used. The painted design can be applied beneath a transparent glaze (underglaze-painted) with or without colouring, or can be painted onto the wet glaze. A third method involving application of the paint on top of a vitrified glaze which is fixed in a second firing was not observed.

Microscopic examination identified four methods of glazed decoration (Fig. 1). Type A was "monochrome glazed"; types B, C, D, E, F, and I were "underglaze-painted" on a white slip ground over a red body; types G and H were underglaze-painted directly on a white clay body; and type J was underglaze "slip-painted".

For all ceramic types with pigment-painted decoration, the colourant transferred into solution with the glaze during firing, and only in green and brown paints were pigment particles identified. Where a slip ground was observed in types defined as underglaze-painted, the glaze is well fused with the slip. But, the slip poorly adheres to the body and is the weakest interface in the structure. Thus, the only function of an overall slip is to provide a white ground for painting.

The analyses for the glazes and paints are reported in Table 3. The sets of analyses are referred to by type, name, and number. In ancient times borax was not used in glazes. Boron could not be detected with the facilities available, but the fact that the analytical totals are reasonably close to 100% suggests that boron cannot be present in substantial amounts in these medieval glazes.

The general composition of all glaze samples with silica and soda as their major constituents (types D–J) are approximately 12 parts SiO_2, 2 parts Na_2O, and 1 part each of Al_2O_3, FeO, MgO, CaO, K_2O. Potash and soda are useful fluxes for a wide range of temperatures, however the alkaline earths, calcia, and magnesia are active fluxes only at high temperatures (6). The melting point of a soda–silica eutectic mixture (Na_2O–$4.579SiO_2$) with 18.4% soda and 81.6% silica, comparable to this general composition, is 860°C (7). The average of the calculated fusion temperature for these glazes, using West and Gerow's (5) coefficients, was 835 ± 24°C. Thus, these glazes should have been fired at a temperature of approximately 813°C for fusion of the glaze.

Silica was probably added to the glaze batch in the form of quartz sand, but no consistent stoichiometric relationships between Na_2O, K_2O, CaO, or MgO were observed that could conclusively identify plant ash ($Na_2CO_3.10H_2O + K_2CO_3.2H_2O$), dolomite ($CaCO_3.MgCO_3$), or carnallite ($MgCl_2.KCl.6H_2O$) as raw materials. The small concentrations of chlorine and sulphur detected suggest that part of the alkalis were added to the frit as chlorides and sulphides.

Calculations were performed to determine the coefficient of linear expansion for each of the glaze samples, using the empirical values established by English and Turner (6). The relationship between the thermal expansion coefficient of glass and composition is expressed by the Winkelmann and Shott equation (16):

$$P = p_1x_1 + p_2x_2 + p_3x_3$$

where P is the volume coefficient of expansion, p_1 ... are the percentages of the constituent oxides of the glass, and x_1 ... are values for the volume coefficients of expansion of the oxides (from English and Turner). The linear coefficient of expansion is one-third of P.

Dayton (6) calculates the linear expansion of a typical ancient alkaline glaze to be $10.54 \times 10^{-6}\,cm\,°C^{-1}$. For the soda–silica glazes the linear coefficient of expansion varies from 7.1 to 9.1 $\times 10^{-6}\,cm\,°C^{-1}$. A typical earthenware body has a value of 7.8 $\times 10^{-6}\,cm\,°C^{-1}$ (6). In cases where the glaze has a smaller factor than the body, the glaze would be compressed and thus

TABLE 2. Descriptions of ten types of Yemeni ceramics from microscopic examination of whole sherds, and of thin sections through glaze, paint, slip, and clay body

Type name	Clay*	Slip	Paint	Glaze
Monochrome glazed				
A. Monochrome Green	Red	No slip	No paint	Lead oxide – silica glaze, opaque green (CuO), abraded and pin-holed, partially devitrified, 0.07–0.12 mm thick
Underglaze-painted on white slip ground				
B. Green-on-White	Red	Continuous white clay slip, 0.04 mm thick	Green paint (CuO), pigment particles 0.02 mm in diameter	Lead oxide – silica glaze, colourless, abraded and pin-holed, partially devitrified, up to 0.07 mm thick
C. Green-on-Yellow	Red	Continuous white clay slip, 0.02 mm thick	Green paint (CuO), pigment particles 0.02 mm in diameter	Lead oxide – silica glaze, yellow (Sb_2O_3), slightly opaque, abraded and pin-holed, partially devitrified, 0.05–0.15 mm thick
D. Bleeding Green	Red	Continuous white clay slip, rich in quartz, 0.4–0.1 mm thick	Green paint (CuO), pigment particles 0.05 mm in diameter	Soda–silica glaze, transparent with yellow tinge, numerous bubbles, crazed and abraded, 0.11–0.20 mm thick
E. Brown-on-White	Red	Continuous white clay slip, rich in quartz, 0.08 mm thick	Brown pigment-paint, quartz grains in opaque ground mass, 0.05 mm thick	Soda–silica glaze, transparent with yellow tinge, numerous bubbles, crazed and abraded, pin-holing only above painted areas, 0.17 mm thick
F. Blue-on-White (red)	Red	Continuous white clay slip, rich in quartz, 0.08 mm thick	Blue paint (CoO), in solution with glaze	Soda–silica glaze, transparent (slight green tinge from FeO), numerous bubbles, crazed and abraded, 0.2 mm thick
I. Black-on-Blue	Red	Continuous white clay slip, quartz and mica inclusions, 0.04–0.08 mm thick	Black paint, opaque grains, non-vitreous, 0.05–0.08 mm thick	Soda–silica glaze, transparent turquoise (CuO) with green tinge from FeO, numerous bubbles, crazed and abraded, pin-holing above black paint only, 0.2 mm thick
Underglaze-painted on white clay body				
G. Blue and Green on White	White	No slip	Blue paint (CoO) and green stain (CuO?), in solution with glaze	Soda–silica glaze, transparent (slight green tinge from FeO), numerous bubbles, crazed and abraded, 0.1–0.16 mm thick
H. Blue-on-White	White	No slip	Blue paint (CoO), in solution with glaze	Soda–silica glaze, transparent (slight green tinge from FeO), numerous bubbles, crazed and abraded, 0.15 mm thick
Underglaze slip-painted				
J. Blue Tihamah	Red	No slip ground	White clay slip-paint, quartz and mica inclusions, 0.1 mm thick	Soda–silica glaze, transparent turquoise (CuO), numerous bubbles, crazed and abraded, 0.1–0.2 mm thick

*As designed by INAA (2).

grip the clay body (providing the tensile strength of the glaze is not exceeded). Hence, medieval Yemeni glaze technology is a definite advancement over the ancient composition.

Although soda in glazes acts as a strong flux, it has a very high coefficient of thermal expansion. In the case of the Yemeni glazes the coefficient is directly related to the concentration of soda. Glazes high in soda tend to craze, and are often soft and easily abraded (8). Re-examination of the glazes on the sherds themselves revealed that the degree of crazing discernable to the unaided eye reflects the extremes calculated (as noted by Lawrence (7)). The brilliance of the coloured soda–silica glazes and pigment-painted decoration can also be attributed to the high concentration of soda (9).

The blue pigment used in the blue painted designs is cobalt. The turquoise–green glaze of type I (Black-on-Blue) and the turquoise–blue glaze of type J (Blue Tihamah) are coloured with copper. The concentration of sulphur detected is too small to establish, on the basis of stoichiometry, that it is Copper Blue (CuS). However, one cannot rule out the possibility considering that sulphur could easily have vaporized during firing (5). Although both of these glazes are coloured with copper, they have slightly different colours. The iron oxide concentration in the type I glaze is higher (2.3%) than observed for type J (1.6%). This increased concentration of iron in the presence of an alkali glaze (9) is the reason for the green tinge in type I. The colourless glazes of types F, H (Blue-on-White) have a marked green tinge, unlike the glazes on types D, E (Bleeding Green; Brown-on-White), and have a higher FeO concentration than the latter. The green paint used in type D is also copper.

Rye and Evans (10) state that in order to characterize the compositional changes occurring in a glaze during firing, it would be necessary to have complete analytical data for glaze, slip, pigment, and body materials before firing. However, the nature of the decoration of the Yemeni ceramics provides a

*Values are reported as percent equivalent oxide concentrations (where no value is given component was not detected above two standard deviations). Also shown are linear coefficients of expansion and temperature of fusion values.

means of establishing certain changes without prior knowledge of the original materials. For example, type J (Blue Tihamah) has a slip-painted decoration and samples of this type provide a direct means of determining how glaze and slip react, since the slip is discontinuous in this case. Alumina concentration is higher in the glaze area with slip (3.9%) than where the glaze was in contact with the body (3.2%).

All of the underglaze-painted ceramics with red bodies have an overall white slip to mask the clay colour, and enhance the pigment-painted decoration. The glazes of these types are consistently higher in alumina than types with white bodies which do not require an overall slip. The alumina concentration is higher in glaze directly above a slip than in areas where pigment-paint had been applied on top of the slip prior to the glaze. For example, in type D (Bleeding Green) the alumina concentration for the colourless glaze is 5.4% and for the green paint, 2.5%. Similarly, for type F (Blue-on-White) the alumina concentration for the clear glaze is 4.8% and for the blue paint, 3.7%. Thus, the level of alumina enrichment appears to be highest where an overall slip is present, masked by a pigment-paint on top of a slip, and lowest where no clay slip is present. It is not possible to extrapolate from this observation whether alumina migration occurred during application of the aqueous glaze mixture, or during firing.

Alumina enrichment is also observed for glazes applied over white firing pottery (types G, H). Neutron activation analysis determined the Al content in white pottery to be as high as 30%, in contrast to 8% for red pottery (2). Unfortunately, it is too difficult to cleanly separate slip from glaze in sufficient quantity to determine its trace element concentration for comparison with the data available for white pottery.

In general all glaze samples with lead oxide and silica as their major constituents (types A, C) have from approximately 1 part silica to 2 parts lead oxide. The calculated average temperature of fusion for these glazes is 640°C; this is 200°C lower than for the soda–silica glazes. The linear coefficient of thermal expansion is approximately 7.8×10^{-6} cm °C^{-1} for these glazes. Here too, the coefficient is directly related to the concentration of soda.

The lead oxide – silica glazes are mostly devitrified. This suggests that the glazes were cooled too slowly, or not fired at a sufficiently high temperature for annealing (just below the liquidus temperature the rate of crystal growth in glasses reaches a maximum). Since these ceramics were probably made at the same workshop as those with soda–silica glazes, it seems likely that a higher kiln temperature than necessary was used, along with too long a cooling period. Owing to devitrification, the glazes are more heterogeneous and the three analyses of each sample are not as consistent as observed for the soda–silica glazes.

The green colourant in the paints of types B, C (Green-on-Yellow; Green-on-White), and in the glaze of type A (Monochrome Green) is copper. The source of the yellow colouring of the glaze in Type C is antimony (lead antimonate). Tin was detected in these glazes but not in the soda–silica glazes. The intense colouring of the glazes and pigment-paints indicates that an oxidizing kiln atmosphere was used since lead glazes, if reduced, will turn grey or black (11).

The lead content in these glazes is sufficiently high that consistent use of these vessels for food storage and consumption could result in lead poisoning. Calculation of the Mellor ratio for the Yemeni glazes gives values from 0.68 to 0.74, above the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.222.148.141 on 09/07/12
For personal use only.

acceptable limit of 0.5 (8).[6] The solubility of lead into food or beverages stored in pottery is dependent on the type of lead compound used, its particle size, and the nature, pH and temperature of the chemical compounds present in the food or beverage. An increase in surface area and a decrease in lead compound particle size will increase lead solubility (12). The crazing due to the high soda content, and pitting due to escaping gases in the Yemeni glazes, would enhance the possibility of lead dissolving into the vessel contents. The presence of copper oxide in the paints and glazes of all of these types is also cause for concern, as a 2% addition of CuO to a low temperature lead glaze results in PbO release ten times that of the base glaze (8).

Conclusions

The results of this exploratory investigation have significantly extended understanding of glaze technology in medieval Yemen. What is apparent from the analysis of the pottery from this and other studies is that there was a viable ceramic industry, with a relatively wide variety of different decorative types being produced using four basic production techniques. Questions that are raised by the study involve comparison of the results with known data on ceramics from the high cultural centres of the Islamic world, notably from Egypt, Syria, Iraq, and Iran. Comparative data on Iranian ceramics is particularly significant. The "Monochrome Green", "Green-on-Yellow" and "Green-on-White" lead glazed ceramics are associated with Rasulid occupation of the region from the 13th–15th centuries. Contemporaneous Iranian lead glazes (13) contain much higher concentrations of tin oxide (13–20%) and lower concentrations of lead oxide (13–21%) than the Yemeni ceramics (less than 1% SnO_2, 52–62% PbO). However, Iranian glazes from the 9th–10th centuries (14) are similar to the Yemeni composition (less than 1% SnO_2, 28–36% PbO). Thus, the 13th–15th century Yemeni tradition of lead glazing may be perceived as similar to that of 9th–10th century Persia.

Lane (15) mentions that in the ninth century A.D., the potters of Samarkand (north of modern day Afghanistan) made the important discovery that "painted decoration, normally apt to "run" if the fluid lead glaze were applied over it, would stay if the metallic colouring agents were mixed with a paste of fine clay slip." The painted decoration in "Green-on-Yellow" and "Green-on-White" does not bleed in the lead glaze, and microscopic examination of thin sections of these types did not reveal the presence of clay in the paint. It has also been assumed that the tin present in Iranian glazes came into the region from the north, presumably by way of the Caucasus, as well as from the west (from Europe) and the east (from China) (11). Tin was detected in three Yemeni types. It is clear that, in the future, the composition of the glass-forming constituents and pigments identified must be compared with geological surveys of the area to determine whether these raw materials were locally available or imported. This investigation of the geology of the region, together with analysis of historic texts, may enhance our understanding of cultural diffusion, and how innovations in glaze technology migrated through the Middle East.

[6]Mellor ratio: $(RO + Al_2O_3)/RO_2 = 0.5$ maximum.

Complexation of water by chlorophyll molecules in natural photosynthetic processes is a matter of great interest. In the present work the influence of water on a model porphyrin, magnesium 2,7,12,17-tetrahexyl-3,8,13,18-tetramethyl porphin (MgTHTMP) has been studied by infrared spectroscopy. A CCl_4 (spectroscopic grade) solution of MgTHTMP showed two small bands in the 3600 cm^{-1} infrared region. These bands are assigned to ν_3 and ν_1 vibrations of water coordinated to the Mg atom. For MgTHTMP in the solid state, either deposited on an infrared plate or suspended in a Nujol film, none of the OH bands is observed. An elemental analysis confirmed that the solid porphyrin was anhydrous. This evidence indicates that while no water is complexed with MgTHTMP in the solid state, this porphyrin is highly hygroscopic in a CCl_4 solution and will easily complex with the few water molecules (less than 0.01%) present in the spectro grade solvent by forming a coordinate bond between the central magnesium atom and the oxygen of water. Several other metallic porphyrins in CCl_4 solutions have been studied for comparison with the Mg porphyrin. The spectra of these substances did not show any complexed water. A model of the H_2O–MgTHTMP interaction is given and the implication of this model on the aggregation states of chlorophyll will be discussed.

CAMILLE CHAPADOS, DENIS GIRARD et MICHEL RINGUET. Can. J. Chem. **66**, 273 (1988).

Le complexation de l'eau par des molécules de chlorophylle, dans des processus naturels, est une question fondamentale. Dans le présent travail, on a étudié l'influence de l'eau sur une porphyrine modèle, la tétrahexyl-2,7,12,17 tétraméthyl-3,8,13,18 porphine – magnésium (THTMPMg), en faisant appel à la spectroscopie infrarouge. Une solution de THTMPMg dans du CCl_4 (qualité spectroscopique) présente deux petites bandes dans la région de 3600 cm^{-1} de l'infrarouge. On a attribué ces bandes aux vibrations ν_3 et ν_1 de l'eau coordonnée à l'atome de Mg. Dans le cas du THTMPMg à l'état solide, soit déposé sur une plaque infrarouge soit suspendu dans le Nujol, on n'observe aucune de ces bandes. Une analyse élémentaire a permis de confirmer que la porphyrine solide est anhydre. Ces données indiquent que, même s'il n'y a pas d'eau complexée avec la THTMPMg à l'état solide, cette porphyrine en solution dans le CCl_4 est tellement hygroscopique qu'elle se complexe facilement avec les quelques molécules d'eau présentes (moins que 0,01%) dans le solvant de qualité spectroscopique en formant une liaison de coordinence entre l'atome de magnésium central et l'oxygène de l'eau. Pour fins de comparaison avec la porphyrine de Mg, on a aussi étudié plusieurs autres porphyrines métalliques en solution dans le CCl_4. Les spectres de ces substances ne présentent pas de bandes correspondant à de l'eau complexée. On présente un modèle de l'interaction H_2O–THTMPMg et on discute des implications de ce modèle sur les états d'agrégation de la chlorophylle.

[Traduit par la revue]

1. Introduction

In algae and higher plants, water is being oxidized by photosynthetic process to produce oxygen at the reaction center of photosystem 2. Some chlorophyll *a* (Chl *a*) molecules are present in this reaction center as well as in the reaction center of photosystem 1 and in the antenna chlorophyll. These Chl *a* molecules are situated in the chloroplast where water is abundant. The aggregation state of chlorophyll within these systems is known to vary. The influence of water on these aggregation states is not fully understood because water can make several types of bonding with the chlorophyll at different sites: i.e. with the Mg atom, and with the carbonyl groups. No experimental technique has given a definitive answer for the structures of these organizations.

Infrared spectroscopy has been used in several occasions to study the influence of water on the chlorophyll molecules (1–8). Typical ir spectra of some chlorophylls and some Chl derivatives have been obtained by Katz *et al.* (1). Most of the spectra taken in CCl_4 solutions showed a broad featureless band in the 3400 cm^{-1} ir region. This band has been assigned to the OH stretch band of bonded water. Efforts to remove the water from the chlorophyll samples were mostly unsuccessful.

An infrared study of chlorophyll–chlorophyll and chlorophyll–water interactions in organic solutions (2) has shown in the OH stretch region a complex set of bands comprising some sharp bands in the 3700 cm^{-1} region and a broad band with unresolved features in the 3300 cm^{-1} region. An effort to dry the solutions did not remove those bands entirely. Pheophytin *a* in CCl_4 showed some sharp bands at 3397, 3538, 3622, and 3690 cm^{-1}. On exchange with D_2O, the first two bands were displaced to lower frequencies and the last two were replaced by one at 3665 cm^{-1}. The 3538 cm^{-1} band was assigned to enolic chlorophyll *a*.

Solutions of chlorophyll made up in undried solvents showed a broad, medium intensity band centered at ~3400 cm^{-1} (3). This absorption maximum appears to include the bands of free water dissolved in the solvent (ν_1 at 3620 cm^{-1} and ν_3 at 3710 cm^{-1}), of water coordinated to Mg at 3380 and 3665 cm^{-1}, and of water hydrogen bonded to the coordinated water molecule. Codistillation with dry solvents removes water to the point that no appreciable absorption can be detected in the OH stretch region although the spectrum is not coincident with the base line.

When a solution of Chl *a* hydrate in dry CCl_4 was studied by ir spectroscopy (4), the spectrum contained several peaks assigned to the symmetric (3620 cm^{-1}) and anti-symmetric

(3715 cm^{-1}) stretch of free water, to OH stretch of water coordinated to the Mg atom of Chl (3665 cm^{-1}), and to hydrogen bonded water (3380 cm^{-1}). Two shoulders at 3300 and 3440 cm^{-1} are assigned to carbonyl overtones. Dry Chl *a* in dry CCl_4 showed three small bands (3280, 3365, and 3450 cm^{-1}) which are assigned to either carbonyl overtones following Ballschmiter and Katz (2) or to residual hydrogen bonded water (less than 3% mol relative to Chl).

Solid samples of anhydrous and hydrated chlorophyll species showed a broad, mostly featureless band in the 3350 cm^{-1} region (5). Depending on the hydration conditions, the band is more or less intense and the position of the maxima is slightly different for each aggregation species.

Microcrystalline Chl *a* hydrate deposited on a germanium ATR plate showed in the infrared a large structureless band centered ~3150 cm^{-1} indicative of bonded water molecules (unpublished results). To remove water, the sample is placed in a high vacuum of 10^{-7} Torr for more than 72 h. This treatment gave an amorphous dried species that showed no bands in the OH region (6). The dryness of the sample was further substantiated by a test with SO_2 vapor that showed no reaction (unpublished results), whereas, in the presence of water, Chl *a* reacts with SO_2 to give pheophytin *a* (7).

The influence of water on mono- and multilayers of Chl *a* obtained by the Langmuir–Blodgett technique have been reported previously (7, 8). A fresh multilayer kept in a moist atmosphere showed in the infrared a broad band centered at 3400 cm^{-1} which disappears rapidly under a vacuum of 10^{-3} Torr (7). A fresh monolayer deposited on a germanium ATR plate and placed in the dry sample compartment of the spectrometer showed no band in the OH stretch region (8).

The only study of the interaction of water with another metallic porphyrin is an X-ray diffraction study on a magnesium tetraphenylporphyrin (MgTPP) made by Timkovich and Tulinsky (9). The presence of water was confirmed by density measurements carried out by flotation in aqueous silver nitrate solution. The lack of other studies is probably due to the insolubility of most porphyrin molecules in ir organic solvents.

In order to understand the interaction of water with the Mg atom in a porphyrin environment, we studied by ir spectroscopy a model molecule, a synthetic liposoluble magnesium porphyrin, MgTHTMP (Fig. 1), in which the absence of other polar functional groups would limit the interactions of water to the Mg atom site and to the π electron system of the chromophore. This work was intended to verify the assignments reviewed above and to complement our knowledge of H_2O–Mg interactions in chlorophyll.

Several samples were made of MgTHTMP (Fig. 1): a suspension in Nujol, several solutions in CCl_4 of different dryness conditions, a solution in a mixture of pyridine and CCl_4, and a solid sample exposed to different moisture conditions. For comparison, we have obtained the ir spectra of several other metallic porphyrin compounds. The results of these experiments will be given and a model of the interaction between water and MgTHTMP will be presented.

2. Experimental

2.1. Synthesis

The synthesis of THTMP was made following the method used by Smith and Bisset for the synthesis of tetrapentyltetramethylporphin (10). The synthesis of ZnTHTMP was made by incorporating zinc in THTMP by the acetate method (11). The MgTHTMP compound was obtained by the reaction of propioxymagnesium bromide on THTMP at low heating temperature (70–75°C) (12). All manipulations of this compound have been done under red light because solutions of MgTHTMP are sensitive to white light. The samples were dried in a vacuum desiccator over $CaCl_2$ before recording the spectra.

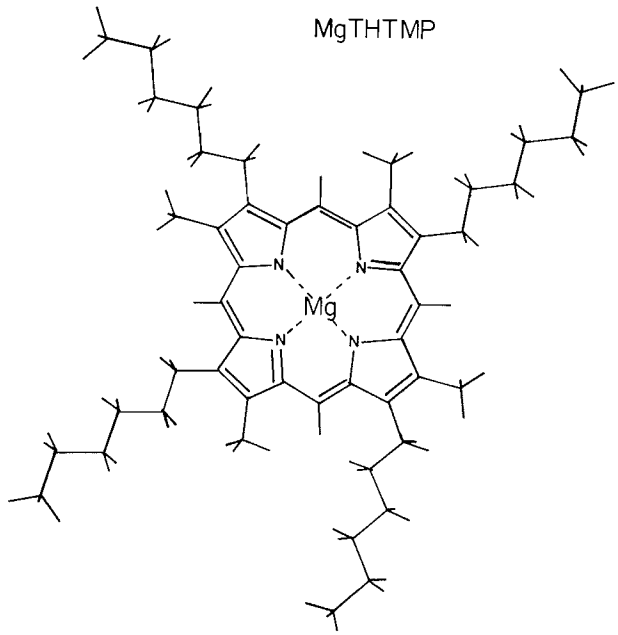

FIG. 1. Molecular model of MgTHTMP.

Elemental analyses were made by Guelph Chemical Lab., Guelph, Ont. and showed that these substances were pure and contained no water. *Anal.* calcd. for $C_{48}H_{68}N_4Zn$ (ZnTHTMP): C 75.54, H 9.05, N 7.03; found: C 75.22, H 8.94, N 7.31. *Anal.* calcd. for $C_{48}H_{68}N_4Mg$ (MgTHTMP): C 79.75, H 9.60, N 7.68; found: C 79.48, H 9.45, N 7.72.

2.2 Spectrum recording

The CCl_4 solutions of the porphyrin compounds were made using spectro grade solvent (Anachemia Chemicals Ltd.; water <0.01%) at a concentration of ~1×10^{-2} mol/L. The solutions were enclosed in a standard KBr cell with a pathlength of 1 mm. The Nujol suspension was made by the standard procedure. The solid sample was obtained from the CCl_4 solution in the following way: drops of the solution were put on a BaF_2 plate, when the solvent was evaporated, the plate was immediately transfered to an enclosed cell equipped with BaF_2 windows. Several spectra were taken successively. When no spectral modification was observed, the sample was put under vacuum of 10^{-3} Torr and several other spectra were recorded. The BaF_2 plate coated with MgTHTMP was then placed in a closed chamber and exposed to water vapor for 4 h. Thereafter, the plate was immediately transfered to the enclosed cell and successive spectra were taken. The sample was then put under vacuum and several other spectra were taken. Thereafter, the sample was dissolved in CCl_4, and more spectra were taken.

The spectra were recorded on a model 180 Perkin-Elmer spectrophotometer with a resolution of ~2 cm^{-1}. The calibration of the spectrophotometer was made with the water vapor bands; the precision of the bands was better than 1 cm^{-1} except for the broad bands. Three spectra were recorded for each sample except when successive spectra were needed to record the behavior of the OH stretch band with time. The spectral data were transfered to a computer where dedicated programs were used to obtain the figures given in this paper. For each spectra, the average of the original spectra were made, calibrated, and subtracted from the background.

3. Results and discussion

The spectra of ZnTHTMP and of MgTHTMP in CCl_4 solutions are given in Fig. 2*A* and *B*, respectively. On this

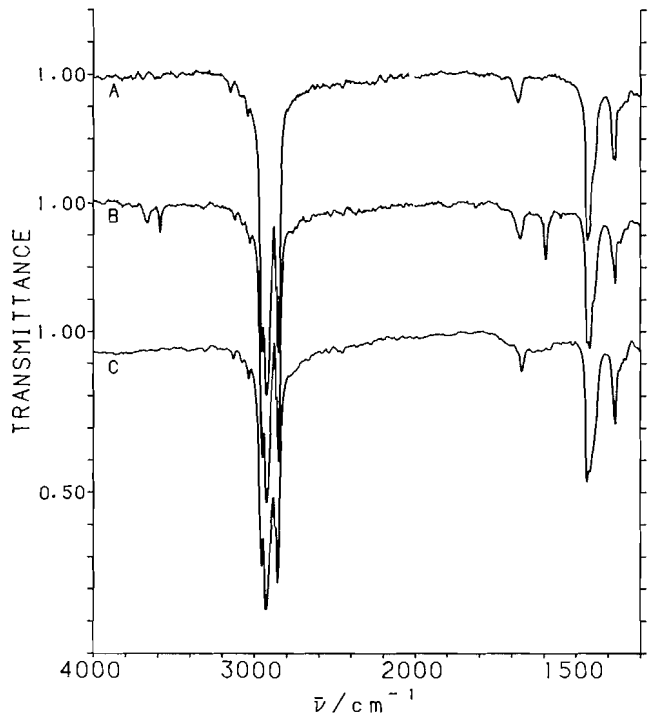

FIG. 2. Infrared spectra of *A*, ZnTHTMP in CCl_4 ($\sim 1 \times 10^{-2}$ mol/L); *B*, MgTHTMP in CCl_4 ($\sim 1 \times 10^{-2}$ mol/L); *C*, MgTHTMP solid.

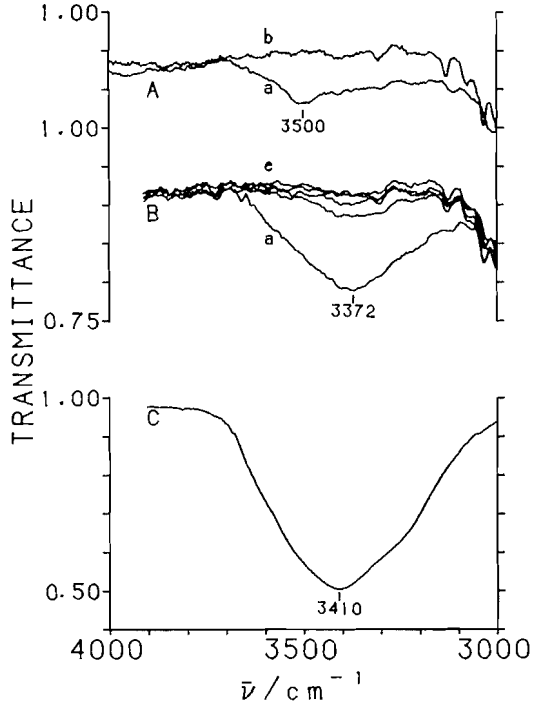

FIG. 3. Infrared spectra of MgTHTMP solid: *A*, obtained from CCl_4 solution: (*a*) immediately after evaporation of the solvent, (*b*) 2 min after; *B*, obtained after the solid was put in water vapors for 4 h: (*a*) immediately after transfering the ir plate in the closed cell, (*b*) 2 min after, (*c*) 5 min after, (*d*) 8 min after, (*e*) 11 min after; *C*, liquid water.

figure we present the OH stretch (3700 to 3200 cm^{-1}) and OH deformation (1650 to 1550 cm^{-1}) regions. In these regions, the zinc compound shows no bands whereas the magnesium compound shows two bands in the first region and one in the second one. The observation of these bands, which are typical of water bands, was surprising since other analyses of the magnesium compound (ir of the solid compound and elemental analysis) showed no evidence of water. The other metallic compounds (Co, Ni, Cu, Cd, Hg, MnCl, FeCl), and the free base of the same porphyrin substrate, in CCl_4 solutions did not show these bands (13). Solid MgTHTMP in a Nujol suspension did not show any bands in these regions, nor did the pure solid deposited directly on a BaF_2 plate (Fig. 2*C*). For reasons of clarity, only spectra of the pure solid sample are presented since those of the suspension in Nujol are identical. These last two results indicate that the original solid MgTHTMP is not hydrated.

Solid samples

To further access the hygroscopic nature of solid MgTHTMP, we have put the sample, obtained from a CCl_4 solution, in a closed cell and an ir spectrum was taken immediately after preparation. This spectrum is given in Fig. 3*Aa*. This figure shows a broad featureless band centered at 3500 cm^{-1}. A spectrum taken 5 min later (Fig. 3*Ab*) shows that the band has disappeared. Under vacuum, the sample showed no further modification. The same sample was then exposed to water vapor for 4 h and returned to the closed cell where five spectra were immediately taken in succession over a period of less than 15 min. The first spectrum of this series (Fig. 3*Ba*) shows a broad band centered at 3372 cm^{-1} which quickly disappears. After 5 min (Fig. 3*Bc*), the band is barely seen, and after 8 min (Fig. 3*Bd*) the band is gone. Another spectrum taken after 11 min (Fig. 3*Be*) and another one taken after pumping the sample to 10^{-3} Torr did not show any further modification. When the sample was dissolved again in CCl_4, the OH bands reappeared with the same intensity as observed previously.

The position of 3372 cm^{-1} for the OH band in solid hydrated MgTHTMP (Fig. 3*Ba*) indicates the presence of hydrogen bonded water, such a bond being possible with another water molecule. Therefore water is essentially aggregated to itself in liquid like form and is not bonded strongly to the Mg, that is the reason for its rapid evaporation. The position of this band is higher than that observed for hydrates of solid Chl *a* and for hydrated solid films of Chl *a* where the bands are observed at $\sim$3300 cm^{-1} (5). In these Chl *a* solid samples, the OH bands of water are difficult to remove requiring pumping and heating; beside the coordinate bond with the Mg, hydrogen bonds between the carbonyl groups of Chl *a* and water have been postulated. These two types of bands are necessary to hold strongly the water molecules in the chlorophyll environment.

In fresh multilayers, Chl *a* and water may aggregate in another way showing a band at 3400 cm^{-1} which disappears rapidly under vacuum (7). The special arrangement of the multilayer, where the ketone carbonyl of one molecule forms a coordinated bond with the Mg atom of another molecule, keeps the Mg from making a coordinate bond with water. Hence, the water molecules incorporated into the multilayers are essentially bonded to themselves and evaporate rapidly. Our results show that water in solid MgTHTMP behaves in the same fashion, and the position of the OH stretch band is indeed similar (3372 cm^{-1} for MgTHTMP and 3400 cm^{-1} for a fresh multilayer of Chl *a*). Therefore, in the solid state, MgTHTMP is not hygroscopic and does not retain water.

Solutions

The behavior of MgTHTMP in a CCl_4 solution is different from that in the solid state; the porphyrin molecule complexes

quickly the few water molecules present in the solution. To understand the nature of the interaction of water with MgTHTMP in a CCl_4 solution, we compare in Fig. 4 the OH stretch bands of a saturated solution of water in CCl_4 (Fig. 4*C*) with that of MgTHTMP in CCl_4 (water content less than 0.01%) (Fig. 4*A*).

The spectrum of water in a CCl_4 solution shows two bands situated at 3707 and 3615 cm^{-1} (Fig. 4*C*) and assigned to ν_3 and ν_1, respectively. These bands have been reported previously (2, 14–16). In Table 1, we have tabulated these values along with those of oligometric species of water (15, 16). The positions of the OH bands of water in a liquid crystal and those of a complex of water in benzonitrile (17) are listed in the same table. Also included are the positions of OH stretch bands of water interacting with Chl *a* in different aggregation states (2) and with MgTHTMP in CCl_4 solution and in the solid state.

MgTHTMP in CCl_4 gives two bands in the OH stretch region (Fig. 4*A*): one broad band centered at 3667 cm^{-1} and a sharper one situated at 3587 cm^{-1}. The positions of these bands is lower than those of water in CCl_4 and are an indication of the formation of a complex. The first band is assigned to ν_3 and the second one to ν_1 of water coordinated to the Mg atom. The shape of the ν_3 band of H_2O–MgTHTMP in CCl_4 is comparable to that of H_2O in CCl_4 (Fig. 4*A* and *C*). The ν_1 bands are different: in uncoordinated water the band is much weaker and broader than ν_3 but for the complex in solution, the ν_1 band is stronger and sharper than ν_3.

The increase in intensity of ν_1 of H_2O complexed to MgTHTMP in CCl_4 (3587 cm^{-1}) compared to that of H_2O in CCl_4 (3615 cm^{-1}) can be explained by looking at the different vibrations (Fig. 5). When the oxygen of water makes a coordinate bond with Mg of the porphyrin, the displacement of oxygen for ν_1 is inhibited and the whole movement of this mode is transfered to the hydrogens. Therefore the amplitude of this vibration will be greater in the complex than on pure water; since the intensity of a band is directly proportional to the square of variation of the dipole moment, if the amplitude of vibration is greater, then the variation of the dipole moment will be greater and so will be the intensity of the band. The same thing happens for the ν_2 band at 1593 which is stronger than ν_3 (Fig. 2). In uncomplexed water, ν_3 is stronger than ν_2. For ν_3, the situation is different because the movement of the oxygen is perpendicular to the axis of symmetry and so the displacement of the oxygen will not be much affected by the coordinate bond; therefore the intensity of the band will not vary as much as for ν_1 or ν_2. One must also remember that the Mg is bonded to the rest of porphyrin by the nitrogens, therefore not only the Mg inhibits the movement of the oxygen in ν_1 and ν_2 but that of the whole porphyrin molecule.

Another mechanism that could influence the intensity of the bands is the π electron cloud of the porphyrin molecule that could orient water molecules with its electric field. The effect of orientation on the ir bands of water has been observed with water in a liquid crystal under the influence of a magnetic field (17). When the electric vector is parallel to the magnetic field the ν_1 band is stronger than ν_3 and when the electric vector is perpendicular to the magnetic field the ν_1 band is less intense than ν_3. In the case of water bonded to MgTHTMP, the electric vector is perpendicular to the electric field of the π electron cloud. Since the influence of an electric field and a magnetic field are orthogonal, water bonded to MgTHTMP could be affected by the electric field very much like water in the liquid crystal.

A more intense ν_1 band compared to ν_3 band has also been observed in a crystal of cyclotriveratrylene with water included to form a clathrate (18). In this case the crystal field and the inclusion cavities orient the water molecules.

Although MgTHTMP is highly hygroscopic in CCl_4, the water molecules are not strongly coordinated to the magnesium atoms because the displacement of the bands is not great compared to that of H_2O in CCl_4. Also, as we have seen previously, once CCl_4 is evaporated from an MgTHTMP solution to obtain a solid, the water molecules rapidly evaporate. An additional proof of the coordination of water to MgTHTMP in CCl_4 solution has been obtained by a displacement experiment made by adding a small amount of pyridine to a CCl_4 solution of MgTHTMP. Pyridine is a stronger ligand than water and should replace it to form a new complex. The result of this experiment is given in Fig. 4*B*. Indeed the original spectrum (Fig. 4*A*) is modified and the bands that we observe are comparable to that of water in CCl_4 (Fig. 4*C*) although slightly displaced because of the presence of pyridine.

The coordination number of magnesium in a porphyrin environment is mostly 5 because the energy of extra coordination of additional ligands is so small as to be almost negligible (19). Therefore only one molecule of water should be attached to MgTHTMP in CCl_4. In the solid state the coordination number should be 4 because water is not bonded to the porphyrin and no other ligand is available.

This result differs from that obtained for MgTPP by X-ray measurements (9) which showed that the crystal was hydrated. The presence of water in this crystal was determined by density measurements using flotation in aqueous silver nitrate solution. Our results show that for solid MgTHTMP maintained in a moist atmosphere, water is incorporated in the substance but is not bonded to the magnesium atom. Water disappears rapidly when the substance is removed from the moist atmosphere. It may possibly be due to the phenyl rings that MgTPP could be more hygroscopic than MgTHTMP.

Comparison with chlorophyll

The environment of the magnesium of chlorophyll molecule is similar to that of MgTHTMP. Therefore the interaction of water with Mg should be the same for both molecules. To have water strongly bonded to chlorophyll it is necessary to have the oxygen and at least one of the hydrogens of water attached to the Mg and the carbonyl of the chlorophyll molecules respectively, in a chain-like organization. When the ketone carbonyl of Chl *a* is unavailable for making a hydrogen bond with water the latter is not strongly attached to the chlorophyll molecule. Such is the case in fresh mono- and multilayer of Chl *a* where the special arrangement of the molecules have the ketone carbonyl either coordinate bonded to the magnesium of another molecule as in the case of the multilayer or free or bonded to the surface as in the case of the monolayer. With such arrangements, water is not retained in the layers of Chl *a* (7, 8).

Microcrystalline Chl *a* is a hydrate from which water is very difficult to remove. There is no free OH band, and the bonded OH band is situated at $\sim 3100\ cm^{-1}$; there is no free ketone carbonyl, and the bonded carbonyl band is situated at $1635\ cm^{-1}$ (unpublished results). The position of these bands which are displaced from the position of the free groups is indicative of strong intermolecular bonds which can be obtained from a coordinate bond between oxygen and magnesium on the one side, and between hydrogen and ketone carbonyl on the other side.

Microcrystalline Chl *a* dissolved in CCl_4 or Chl *a* dissolved in CCl_4 containing water give the same bands (Table 1) (2, 4). Beside the two free water bands seen in these solutions, two bands are observed: one at $3665\ cm^{-1}$ and a large band at $3380\ cm^{-1}$. No band is observed at the position of ν_1 of MgTHTMP in solution. We conclude from this observation that no water is bonded to Chl *a* in a fashion similar to that observed on MgTHTMP in solution, that is only bonded to the Mg site by oxygen. The band situated at $3665\ cm^{-1}$ is assigned to free OH and the one at $3380\ cm^{-1}$, to hydrogen-bonded OH. Such bands can be obtained if water is linked to Chl *a* by forming a coordinate bond between oxygen and magnesium on one side and by forming a hydrogen bond between hydrogen and carbonyl on the other side.

The visible spectrum of these species gives a strong band at 665 nm and minor absorptions at 680 and 700 nm (4). The position of 665 nm indicates that there is not much overlap of the π electron network of the two molecules; therefore there are probably not one but two molecules of water linked together by a hydrogen bond and sandwiched between two Chl *a* molecules. With one molecule of water between two molecules of Chl *a*, the distance between the porphyrin plane of the chlorophyll molecules would be too short to give the strong absorption at 665 nm.

Conclusion

We have showed that the presence of Mg is necessary for developing hygroscopicity of the porphyrin ring. This hygroscopicity is observed only in solution and water is lost rapidly with solid samples. If a carbonyl is present in the molecule and can lead to hydrogen bonds with the complexed water as in microcrystalline Chl *a*, the molecule is much more hygroscopic and can retain water even in the solid form.

This paper is dedicated to Professor C. A. McDowell

ARON SZÖLLÖSY, GEORGE KOTOVYCH, GÁBOR TÓTH, and ALBERT LÉVAI. Can. J. Chem. **66**, 279 (1988).

The synthesis and stereochemistry of seven β-lactam derivatives of 1,5-benzothiazepines are presented. The configurational and conformational analysis is based on nuclear Overhauser effect experiments, together with analysis of the vicinal proton–proton coupling constants. In the preferred conformation, the seven-membered ring is in a half-chair. Only for one compound, 2-aza-4-bromo-4-methyl-5,7-diphenyl-8-thiatricyclo[7.4.0.0^{2,5}]trideca-$\Delta^{1,9}$,10,12-trien-3-one, were two diastereomers isolated (compounds **6***a* and **6***b*). Six of the compounds have the 4*S**, 5*R**, 7*R** configuration while compound **6***b* has the 4*R**, 5*R**, 7*R** configuration.

ARON SZÖLLÖSY, GEORGE KOTOVYCH, GÁBOR TÓTH et ALBERT LÉVAI. Can. J. Chem. **66**, 279 (1988).

On rapporte la synthèse et la stéréochimie de sept dérivés β-lactames des benzothiazépines-1,5. Les analyses de configuration et de conformation sont basées sur des expériences d'effets Overhauser nucléaires ainsi que sur une analyse des constantes de couplage proton–proton vicinaux. Dans sa conformation privilégiée, le cycle à sept chaînons est dans un forme demi-chaise. On n'a isolé deux diastéréoisomères (les composés **6***a* et **6***b*) que dans le cas d'un seul composé, l'aza-2 bromo-4 méthyl-4 diphényl-5,7 thia-8 tricyclo[7.4.0.0^{2,5}]tridécatriène-1(9),10,12 one-3. Six des composés possèdent la configuration 4*S**, 5*R**, 7*R** alors que la configuration du composé **6***b* est 4*R**, 5*R**, 7*R**.

[Traduit par la revue]

Owing to their biological importance, numerous β-lactam compounds are discussed in the literature. A few examples of the β-lactam derivatives of benzoxazepines, benzothiazepines, and benzodiazapines have also been published (2, 3). The β-lactam moiety may modify the biological activity of the benzazepines or may result in new effects and, therefore, synthesis of new substances can be beneficial for pharmaceutical research. During the past decade we performed detailed investigations on the synthesis and stereochemistry of 2,3-dihydro-1,5-benzothiazepines (4–10). As a result, numerous compounds were obtained that are potential starting materials for the preparation of condensed β-lactams. In these compounds the C=N double bond can be attacked by suitable reactants to form β-lactam derivatives.

The synthesis of seven β-lactam derivatives is presented and their configurations and conformations are deduced based on proton and ^{13}C nuclear magnetic resonance experiments. In view of the fact that conformations of the conformationally flexible seven-membered ring (11), attached to the strained four-membered ring, have not been extensively studied, especially with different bulky substituents on the four-membered ring, we have proceeded with the configurational and conformational analysis of these systems. The spectra of 2,4-diphenyl-2,3-dihydro-2,3-dihydro-1,5-benzothiazepine have been previously analyzed (12).

Results and discussion

We report in this paper the reaction of 2,3-dihydro-2,4-diphenyl-1,5-benzothiazepine **1** with various acid halides, and the nmr investigation of the stereochemistry of the prepared compounds. According to the literature data (13–16), β-lactam formation may take place either by the addition of the acid halide to the imine to produce a reactive intermediate that cyclizes to β-lactam under the influence of a tertiary amine, or by the formation of a ketene from the acid halide and tertiary amine followed by a two-step formation of the β-lactam moiety. Since in our cases triethylamine was added first to the solution of compound **1**, the mechanism involving ketene formation seems most probable (16) (Fig. 1).

We have carried out the cycloaddition of compound **1** with several acid halides, namely with phenoxyacetyl chloride, thiophene-2-acetyl chloride, chloroacetyl chloride, dichloroacetyl chloride, α-bromopropionyl bromide, and α-bromobutyryl bromide. The reaction was monitored by thin-layer chromatography and the mixture was refluxed and stirred until the starting material disappeared. As a result of the incident side reactions and (or) decompositions, crude products were usually mixtures from which β-lactams (**2**–**7**) were isolated by column chromatography. All the β-lactams isolated (except **6**) were found to be stereochemically homogeneous according to spectroscopic evidence. Only in the case of the α-bromopropionyl bromide reagent were two β-lactams detected. One compound (**6***a*) was obtained by a further chromatographic procedure. The other product (**6***b*, minor product) was studied in a mixture with **6***a* where **6***a* was in excess (ca. 65%), and **6***b* was not isolated as a pure compound.

The configuration of the compounds was established by the application of several nmr methods. Since the racemic starting compound **1** has only one chiral centre, and the products contain three (ignoring the β-lactam nitrogen), four diastereomeric pairs of enantiomers should be considered (except for **5**, where

$R_x = R_y$ and consequently the number of possible diastereomeric pairs is two). By inspection of Dreiding models the possible relative stereochemistry and more stable conformations were established as depicted in Fig. 2. With three chiral centres, four products in racemic form are possible. In addition, a conformational equilibrium also should be considered. In structures of type I and II, boat ⇄ half-chair, and in structures of type III and IV, boat ⇄ boat conformational equilibria are represented. The twist-boat conformation was previously shown to be unimportant (12).

The conformational arguments will be presented first of all. The ^{1}H nmr chemical shift and coupling constants observed for compounds **2–7** in $CDCl_3$ solution are presented in Table 1. Concerning the tetrahydro-1,5-benzothiazepine ring conformation, the most valuable data are the ^3J coupling constants between the 6-H and 7-H protons. These form an ABX spin system, which was analysed to first-order as well as using the Bruker PANIC software for several cases. The coupling constants obtained were compared with those calculated using a modified Karplus curve taking into consideration the substituent effect (17). This analysis shows that the conformational equilibrium is shifted and structures Ia, IIb, IIIb, and IVa could be excluded. Conformations Ib and IIIa are more likely than the remaining two, IIa and IVb, on the basis of the $^3J_{6H,7H}$ coupling constants. The observed $^3J_{6,7}$ coupling constants (~11 Hz) also show that the 7-phenyl group occupies a quasi-equatorial position in the predominant conformation. This is in accordance with our previous results for several dihydro-1,5-benzothiazepine derivatives (10, 12). The data in Table 1 also show that compounds **2**, **3**, and **4** should have the same structure.

Configurational information can be found by comparison of the proton data (Table 1). There are two significant differences in the data for ***6a*** and ***6b***. First, the chemical shift of the 4-CH_3 methyl group signals differs considerably and in ***6b*** it is shielded by 0.66 ppm. This shielding arises from the aromatic ring current effect of the 5-phenyl group. It means that compounds ***6a*** and ***6b*** differ from each other in that the 5-phenyl and 4-methyl groups are *cis* in ***6b*** and *trans* in ***6a***. The second significant difference also confirms this conclusion. In compound ***6b*** the signal of the 6-H_{ax} proton is shifted downfield and $\delta H_{ax} > \delta H_{eq}$, which is opposite to the assignment for ***6a***, **2**, **3**, **4**, and **7**. Similar effects can be noticed by comparing the ^{1}H nmr data for **4** and **5**. Compounds **4** and **5** differ from each other in that **5** has an additional C—X bond (X = halogen) and this results in a downfield shift of the 6-H_{ax} signal. This very likely arises from the anisotropy of the C—X bond, and this effect is responsible for the downfield shifts (0.4 ppm) of 6-H_{ax} in ***6b*** and **5**.

Further evidence could be achieved from the one-dimensional proton–proton difference nOe (nuclear Overhauser enhancement) measurements. The magnitude of the nOe depends to a large extent on the intramolecular proton–proton distances (18, 19). Characteristic nOe data for compounds **4**, ***6a***, and **7** are summarized in Table 2. A characteristic feature of compound **4** is that the 6-H_{ax} and 6-H_{eq} protons differ from each other in steric proximity with respect to the other protons, which is clearly seen from the nOe data. Irradiation of 4-H resulted in a considerable nOe for the 6-H_{ax} signal while an nOe was not detectable at 6-H_{eq}. The irradiation of 6-H_{ax} and 6-H_{eq} also corroborates this different behaviour. Saturating the 7-H signal, an enhancement was only observed at 6-H_{eq} and in the aromatic region (H-2′,6′). Very similar effects can be observed for ***6a*** and **7**, which shows that the 4-H, 4-CH_3, and 4-Et groups occupy the same position in these compounds. The results of the nOe difference experiments are in accordance only with a Ib structure, where the 5-phenyl group and the halogen atom are *cis*.

These conclusions prove that compounds **2–*6a*** and **7** can be characterized as having conformation Ib_{cis} (4*S**, 5*R**, 7*R** configuration), while ***6b*** has the Ib_{trans} (4*R**, 5*R**, 7*R** configuration) conformation.

^{13}C chemical shifts and assignments for compounds **2–7** are summarized in Table 3. ^{13}C analysis of dihydro-1,5-benzothiazepines (9) together with the substituent effects were utilized for the assignments. For the β-lactam moiety, ^{13}C data for similar condensed derivatives of benzothiazines (16, 20) also were used. On the basis of the ^{1}H nmr conclusions, the chemical shift of the C-6 atom should be the best indicator of

structure. In compounds **2**–**4** the C-4 substituents cause a γ_{anti} effect on C-6, while for **5**, C-6 is affected by the superposition of the γ_{anti} and γ_{gauche} chlorine atoms. In compound **3**, this signal is quite distinct, possibly due to the thiaphenyl group. In compounds **6***a* and **6***b* a superposition of the methyl and bromine effect is observed. In **6***a* the bromine is *anti* and the methyl group is in a *gauche* position, and these are opposite in **6***b* so that the C-6 signal is shifted by ~4 ppm downfield. These

data have less utility for the independent verification of the structures because data for more derivatives should be analyzed. Furthermore, the tetrahydro-benzothiazepine ring may not be rigid for the γ steric shifts to be applied for the stereochemical study.

Our studies have shown that most compounds obtained by the addition of acid halides to dihydro-1,5-benzothiazepines have the Ib_{cis} conformation. The structure of the intermediate is not known; the structure of the products, however, shows that its dominant conformation favours an arrangement where the 5-phenyl group and the halogen atom (or other bulky group) are on the same side. This arrangement should be governed by steric factors and, when the steric requirement for the R_x and R_y groups is nearly comparable (e.g., methyl and bromo groups), both *cis* and *trans* compounds appear. The conformation of the seven-membered ring is independent of the substituents present on the four-membered ring.

Experimental

uncorrected. Thin-layer chromatography was performed on Merck Kieselgel foils using a petroleum ether:acetone (3:1 v/v) developing mixture. The spots were observed by uv light. Kieselgel 40 columns and petroleum ether:acetone (3:1 v/v) eluent were utilized for column chromatography.

(b) Synthesis

The general procedure for the preparation of compounds **2–7** is presented. A mixture of 2,3-dihydro-2,4-diphenyl-1,5-benzothiazepine (5 mmol), triethylamine (10.0 mmol), and anhydrous benzene (20.0 mL) was stirred and refluxed, and the appropriate acid halide (10.0 mmol) dissolved in anhydrous benzene (20.0 mL) was added dropwise for 15 min. Refluxing and stirring were continued for another 60 min, then the triethylamine salt was filtered off and the solvent evaporated. The residue was purified by column chromatography to produce compounds **2–7**. These are as follows: 2-Aza-4-phenoxy-5,7-diphenyl-8-thiatricyclo[7.4.0.0^{2,5}]trideca-$\Delta^{1,9}$,10,12-trien-3-one **2**. Yield 86.3%; mp 194–195°C. *Anal.* calcd. for $C_{29}H_{23}NO_2S$: N 3.11, S 7.12; found: N 3.05, S 7.78. 2-Aza-5,7-diphenyl-8-thia-4-thiaphenyltricyclo[7.4.0.0^{2,5}]trideca-$\Delta^{1,9}$,10,12-trien-3-one **3**. Yield 22.7%; mp 173–174°C. *Anal.* calcd. for $C_{27}H_{21}NOS_2$: N 3.18, S 14.57; found: N 3.08, S 14.72. 2-Aza-4-chloro-5,7-diphenyl-8-thiatricyclo[7.4.0.0^{2,5}]trideca-$\Delta^{1,9}$,10,12-trien-3-one **4**. Yield 27.8%; mp 214–215°C. *Anal.* calcd. for $C_{23}H_{18}NOSCl$: N 3.57, S 8.16; found: N 3.54, S 8.13. 2-Aza-4-dichloro-5,7-diphenyl-8-thiatricyclo-[7.4.0.0^{2,5}]trideca-$\Delta^{1,9}$,10,12-trien-3-one **5**. Yield 19.1%; mp 239–240°C. *Anal.* calcd. for $C_{24}H_{20}NOSBr$: N 3.11, S 7.11; found: N 3.09, S 7.17. 2-Aza-4-bromo-4-ethyl-5,7-diphenyl-8-thiatricyclo-[7.4.0.0^{2,5}]trideca-$\Delta^{1,9}$,10,12-trien-3-one **7**. Yield 34.7%; mp 224–225°C. *Anal.* calcd. for $C_{25}H_{22}NOSBr$: N 3.01, S 6.89; found: N 3.03, S 6.94.

(c) Spectroscopy

The ^1H nmr spectra were obtained on a Bruker WM 360 nmr spectrometer equipped with an Aspect 2000 computer. Samples were prepared in chloroform solution using TMS as internal standard. For the 1-D and 2-D nOe measurements the solutions were degassed using the freeze–pump–thaw cycle several times.

Typical spectral conditions were as follows: The number of data points, 32K; flip angle, 30°; sweep width, 3200 Hz. For the nOe difference experiments, a preirradiation delay of 2–2.4 s, a relaxation delay of 6–7 s, and a 90° flip angle were applied. The lines of the multiplets were irradiated separately and several times during the preirradiation (21).

The ^{13}C nmr spectra were measured on a JEOL FX-100 spectrometer at 25.00 MHz. Typical spectral parameters were as follows: sweep width, 6000 MHz; data points, 16 K; repetition time, 2 s; flip angle, 30°. Broadband proton decoupled and the attached proton test (APT) (or DEPT) spectra were recorded for the determination of multiplicity.

JEAN ZYLBER, NICOLE ZYLBER, DANIEL LEFORT, CHRISTIANE FERRADINI et BERNARD HICKEL. Can. J. Chem. **66**, 283 (1988).

La réactivité des radicaux ȮH et $(CH_3)_2\dot{C}OH$ avec l'hypoxanthine a été étudiée dans des conditions d'irradiation γ comparables. Une différence de régiosélectivité de l'attaque du radical ȮH, électrophile, et du radical $(CH_3)_2\dot{C}OH$, nucléophile, est mise en évidence. Ce dernier conduit au produit substitué en C-8 avec un rendement de 70%; la constante de vitesse d'addition du radical à l'hypoxanthine déterminée, en milieu acide, par radiolyse pulsée est $k = 1{,}4 \times 10^8\ M^{-1}\ s^{-1}$, et $k = 7 \times 10^5\ M^{-1}\ s^{-1}$ en milieu neutre. Le radical OH, beaucoup plus réactif, conduit essentiellement à des produits de dégradation dont le point de départ serait, entre autres, l'attaque en C-2 (donc formation de xanthine qui disparait rapidement); l'attaque en C-8, environ trois fois moins rapide, conduit à la dicéto-6,8 purine qui résiste aux réactions ultérieures et s'accumule dans le milieu.

JEAN ZYLBER, NICOLE ZYLBER, DANIEL LEFORT, CHRISTIANE FERRADINI, and BERNARD HICKEL. Can. J. Chem. **66**, 283 (1988).

The reactivity of ȮH and $(CH_3)_2\dot{C}OH$ radicals with hypoxanthine was studied under comparable γ-irradiation conditions. A difference in regioselectivity of attack by the electrophilic ȮH radical and the nucleophilic $(CH_3)_2\dot{C}OH$ radical is observed, the latter leading in 70% yield to a C-8 substituted product. The rate constants of the addition of the radical to hypoxanthine were determined by pulse radiolysis to be $k = 1.4 \times 10^8\ M^{-1}\ s^{-1}$ in acid medium, and in neutral medium $k = 7 \times 10^5\ M^{-1}\ s^{-1}$. The much more reactive ȮH radical leads essentially to degradation products arising, *inter alia*, from attack on C-2 (resulting in the formation of xanthine, which disappears rapidly), while attack at C-8, approximately three times less rapid, leads to the 6,8-diketo purine, which does not undergo further reactions and thus accumulates in the medium. [Journal translation]

L'action des radicaux hydroxyle produits par radiolyse de l'eau sur les bases puriques a fait l'objet de nombreux travaux dans le but de déterminer le mécanisme de dégradation des acides nucléiques soumis à l'irradiation γ (1).

La position 6 du noyau purique est le site privilégié d'attaque aussi bien des radicaux ·OH (2) que des radicaux carbonés (3). De nombreuses études ont montré que lorsque cette position 6 est substituée, la substitution par des radicaux carbonés se fait préférentiellement en 8 (4). La comparaison des résultats obtenus pour différents modèles a permis à certains auteurs (2, 5) de proposer la séquence de réactivité C6 > C8 > C2 en accord avec les conclusions d'une étude théorique (6).

La régiosélectivité de substitution des radicaux ·OH sur les bases puriques et en particulier sur l'hypoxanthine, premier maillon de la dégradation oxydative biochimique, n'est pas aussi évidente. En effet, selon certains auteurs, les radicaux ·OH produits lors de la radiolyse γ de l'eau, en solution oxygénée, réagissent quantitativement avec la double liaison centrale 4,5 pour conduire à des produits carbonylés de dégradation (7); d'autres auteurs ont montré que ·OH, obtenu à partir du réactif de Fenton, attaque l'hypoxanthine sur le cycle imidazole en position 8 pour donner la dicéto-6,8 purine (2).

Cette substitution en 8 a été établie également dans le cas de la radiolyse γ de l'adénine (8). Par ailleurs, l'un d'entre nous (9) a montré par une étude de radiolyse pulsée, que la réaction de ·OH sur l'hypoxanthine conduit principalement à la xanthine. Ni les études théoriques (10, 11), ni les analyses de spectres (résonance paramagnétique électronique) (12) ne permettent de prévoir ou d'expliquer sans ambiguïté les résultats expérimentaux; dans le premier cas l'ordre de réactivité d'un radical sur les différents atomes de carbone du noyau purique varie selon la méthode de calcul; dans le second, si le spectre du radical résultant de l'addition de ·OH en 8 est parfaitement défini pour le cas de la caféine, il n'en est pas de même pour ceux obtenus avec les purines non substituées en 2 ou 6.

Pour lever cette ambiguïté d'attaque par ·OH en 2 ou en 8 nous avons donc étudié les produits obtenus lors de la radiolyse γ d'une solution aqueuse d'hypoxanthine désaérée et saturée en N_2O. Les radicaux ·OH sont produits par les processus bien connus :

$$H_2O \rightsquigarrow \cdot OH,\ H\cdot,\ e^-_{aq.},\ H_2,\ H_2O_2$$

$$e^-_{aq} + N_2O \rightarrow N_2 + \cdot OH + {}^-OH$$

Puisque la réactivité et la régiosélectivité d'un radical dépendent, pour un substrat donné, de son caractère nucléophile ou électrophile (13, 14), il était intéressant de comparer les résultats obtenus, dans les mêmes conditions expérimentales, avec le radical ·OH électrophile et avec un radical nucléophile comme le radical **1** (hydroxy-2 propyle-2).

Celui-ci est formé lors de la radiolyse d'une solution aqueuse d'isopropanol; conformément aux travaux précédents (4), la

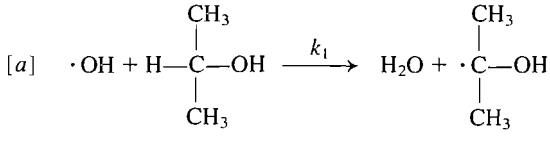
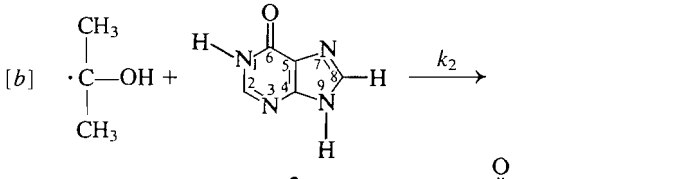
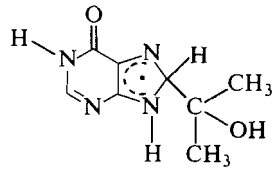
réaction avec l'hypoxanthine se déroule selon le schéma classique de substitution aromatique homolytique (14, 15) :



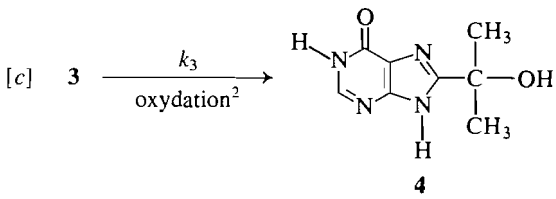
1



2



3



4

Le produit **4** a déjà été obtenu par d'autres méthodes photochimiques uv avec ou sans sensibilisateur (5, 16). De plus, par radiolyse pulsée, nous avons pu déterminer la constante de vitesse d'addition du radical **1** sur l'hypoxanthine et la comparer à celle obtenue précédemment pour ·OH (9).

Partie expérimentale

Le déroulement de la réaction est suivi par ccm (chromatographie sur couche mince) sur gel de silice (Kieselgel 60F254, Merck). Les points de fusion sont pris sous microscope. Les chromatographies hplc sont effectuées avec un appareil Varian 5000 muni d'un détecteur uv Shimadzu SPD/6A. Les spectres de masse sont obtenus avec un appareil de Ribermag 10-10. Les spectres de rmn sont enregistrés à 90 ou 200 MHz sur des appareils Bruker. Les déplacements chimiques sont exprimés en ppm avec le tétraméthylsilane comme référence interne. Les analyses sont exécutées par le Service central d'analyse du C.N.R.S. Toutes les expériences ont été effectuées sur des solutions aqueuses préalablement saturées en N_2O et irradiées à l'aide d'une source de ^{60}Co à une dose de 1055 rad/min.[3]

Matières premières

Les matières premières sont des produits commerciaux : hypoxanthine (Ega), acide urique (Aldrich), xanthine (Fluka), thymidine (Sigma).

Les solvants pour hplc sont des produits Carlo Erba.

*(Hydroxy-2' méthyl-2' éthyl)-8 hypoxanthine **4***

Une solution de 0,340 g (2,5 mmol) d'hypoxanthine et 30 g (0,5 mol) de propanol-2 dans 500 mL d'eau, saturée en N_2O, est irradiée pendant 16 h. La solution est ensuite lyophilisée; le résidu obtenu est chromatographié sur SiO_2 (70–230 mesh); par élution avec $CHCl_3$ à 10% MeOH on obtient une fraction brute de 219 mg dont le dosage par rmn ^1H permet de déterminer la présence de 100 mg de produit **4** (73% par rapport à l'hypoxanthine ayant réagi). La cristallisation dans l'acétate d'éthyle fournit 20 mg d'un échantillon pur d'(hydroxy-2' méthyl-2' éthyl)-8 hypoxanthine; F = décomposition au dessus de 350°C; uv (EtOH) : λ_{max} = 250 nm (log ε = 4,05); rmn 90 MHz (DMSO-d_6) δ : 1,53 (S, 6H, $2CH_3$, C-8 diméthylcarbinol), 7,93 (S, 1H, H en 2). Ce signal persiste après chauffage à reflux dans D_2O. Masse, m/e : 194. *Anal.* calc. pour $C_8H_{10}N_4O_2 + 1/2H_2O$: C 47,28, H 5,41, N 27,41; trouvé : C 48,08, H 5,25, N 27,58.

*(Hydroxy-2' méthyl-2' éthyl)-8 caféine **5***

Une solution de 0,970 g (5 mmol) de caféine et 30 g (0,5 mol) de propanol-2 dans 500 mL d'eau, saturée en N_2O, est irradiée pendant 16 h. L'extraction avec $CHCl_3$ donne 1 g de produit. Par chromatographie sur silice (70–230 mesh) et élution par l'acétate d'éthyle on obtient 0,240 g de produit **5** chromatographiquement pur (95% par rapport à la caféine ayant réagi). La cristallisation dans un mélange acétate d'éthyle – méthanol fournit 170 mg de cristaux, pf 200–202°C (sublim. à 180°C) (lit. (5) pf 199–200°C); rmn 90 MHz (DMSO-d_6) δ : 1,8 (S, 6H, $2CH_3$, C-8 diméthylcarbinol), 3,4 (S, 3H), 3,6 (S, 3H), 4,25 (S, 3H) ($3CH_3$ en N-1, N-3 et N-7); masse, m/e : 252. *Anal.* calc. pour $C_{11}H_{16}N_4O_3$: C 52,37, H 6,39, N 22,21; trouvé : C 52,32, H 6,33, N 22,6. Par élution avec un mélange d'acétate d'éthyle – méthanol (99 : 1) on récupère 0,776 g (80%) de la caféine de départ.

*Irradiation de l'hypoxanthine dans H_2O. Dicéto-6,8 purine **7***

Une solution de 0,3 g (2,2 mmol) d'hypoxanthine dans 500 mL d'eau bidistillée, saturée en N_2O, est irradiée pendant 8, 16, 24 et 48 h. Pour chaque période la solution est lyophilisée; le produit obtenu est analysé par hplc; colonne Lichrosorb SRP 18, 150 × 46 mm; éluant eau/CH_3CO_2H/MeOH = 79,5 : 0,5 : 20. Détection à 270 nm. Dosage de l'hypoxanthine par rapport à la thymidine comme étalon interne. Résultats tableau 1. Temps de rétention (min) : acide urique, 3,3; dicéto-6,8 purine **7**, 3,5; xanthine, 3,9; hypoxanthine, 4,2. Débit 0,7 mL/min.

*Isolement et identification du produit **7***

Le mélange de produits obtenu après 48 h d'irradiation est chromatographié sur SiO_2 (200–400 mesh) sous pression (technique chromatographie «flash» et élué par $CHCl_3$/MeOH/NH_4OH 16 *M* : 40 : 10 : 1. On obtient 0,024 g de produit chromatographiquement pur (7% par rapport à l'hypoxanthine de départ). La cristallisation dans un mélange eau/MeOH fournit 8 mg de cristaux, pf : décomp. au délà de 350°C; les spectres uv sont différents de ceux de l'hypoxanthine et de la xanthine; aux pH 1 et 5, λ_{max} = 257 nm (log ε = 4,05) avec un épaulement caractéristique à 280 nm (log ε = 3,77); à pH 10, λ_{max} = 265 nm (log ε = 4,04), à pH 12, λ_{max} = 271 nm (log ε = 4,1) (17); rmn 90 MHz (DMSO-d_6) δ : 7,88 (S, 1H, H en 2), 11,07 (S, 1H, échangeable), 11,95 (S, 2H, échangeable); masse, m/e : 152, 124 (perte CO), 101 (pic métastable).

2. L'étape d'oxydation [c] peut se faire par différents processus selon la nature du milieu : dismutation avec un autre radical, oxygène de l'air, etc ...

3. Nous remercions M. Chapiro, C.N.R.S. à Thiais, d'avoir mis à notre disposition l'installation d'irradiation γ.

Réaction de l'hypoxanthine avec le propanol-2 en radiolyse pulsée

Une solution aqueuse à pH 0,95 d'hypoxanthine ($1,9 \times 10^{-3}$ *M*), de propanol-2 (0,75 *M*) et de $HClO_4$ (0,117 *M*) est soumise à la radiolyse pulsée.

La source d'électrons est un accélérateur type Febetron 707 situé au CEN de Saclay (DPC) (18). Dans cet appareil la décharge d'une série de modules comportant chacun deux résistances, deux condensateurs et un éclateur, est appliquée à une cathode à émission de champ contenue dans un tube sous vide. Une sélection magnétique des électrons de 1,8 MeV est alors utilisée pour réduire la durée de l'impulsion à environ 20 nanosecondes. Ces solutions sont contenues dans une cellule en Spectrosil (2,5 × 2,5 × 0,25 cm). À chaque impulsion l'énergie absorbée par la solution varie entre 70 et 700 Gray de sorte que la concentration initiale en radicaux libres ·OH est comprise entre 4×10^{-5} et 4×10^{-4} *M*.

L'analyse spectrophotométrique est effectuée par un montage optoélectronique classique incluant une lampe au xénon, un monochromateur et un photomultiplicateur. Le trajet optique est de 2,5 cm. Pour chaque longueur d'onde étudiée, le changement d'absorption est analysé en fonction du temps, le début de l'impulsion étant pris comme origine de l'échelle des temps.

Résultats et discussion

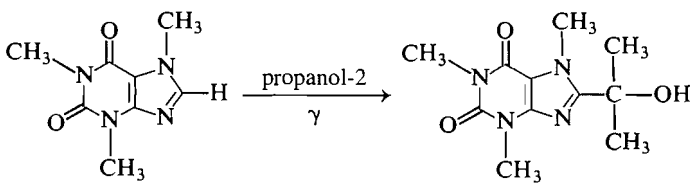
A. Réaction avec le propanol-2

1. Produit de réaction

Une solution aqueuse d'hypoxanthine (5×10^{-3} *M*) contenant de l'isopropanol (1 *M*) est irradiée sous N_2O à température ambiante pendant 16 h. Le taux de conversion est de 28%; le produit **4**, identifié par rmn et sm, est obtenu avec des rendements respectifs de 20 et 71% par rapport à l'hypoxanthine mise en oeuvre ou ayant réagi. Les 29% de produits secondaires formés n'ont pas été identifiés; toutefois aucun d'eux ne correspond au composé substitué en 2. Le produit disubstitué en 2 et 8 a été isolé en très petite quantité. Ce résultat montre que l'ordre de réactivité est bien C8 ≫ C2.

Dans ce système, le fait que les radicaux ·OH réagissent exclusivement avec l'isopropanol selon [*a*] pour conduire finalement au produit **4** plutôt qu'avec l'hypoxanthine (*vide infra*) n'est pas surprenant. En effet, les constantes de vitesse de ·OH avec l'hypoxanthine et avec l'isopropanol sont respectivement de $6,5 \times 10^9\ M^{-1}\ s^{-1}$ (9) et environ de $2 \times 10^9\ M^{-1}\ s^{-1}$ (19). Mais comme la concentration en isopropanol est 200 fois supérieure à celle de l'hypoxanthine, la réaction [*a*] de ȮH avec l'alcool est environ 60 fois plus rapide.

Dans les mêmes conditions réactionnelles nous avons obtenu avec la caféine le produit **5** substitué en 8, avec un rendement de



5

95% par rapport à la caféine ayant réagi et un taux de conversion analogue à celui obtenu avec l'hypoxanthine.

Un tel produit a déjà été obtenu par d'autres auteurs (5, 20) par irradiation uv ou γ. Nos résultats confirment la grande sélectivité du radical nucléophile hydroxypropyle **1** pour le sommet 8, en particulier dans le cas de la caféine où la transformation est pratiquement quantitative.

*2. Cinétique d'addition du radical **1** sur l'hypoxanthine*

L'étude a été faite en radiolyse pulsée; le spectre uv du radical intermédiaire **3** déterminé 10 μs après une impulsion délivrant une dose de 700 Gray environ, présente un maximum à 285 nm (fig. 1). Celui de l'hypoxanthine substituée **4** donne, en milieu neutre, deux maxima à 202 et 250 nm. Le déplacement bathochrome est donc conforme à ce que l'on sait des spectres uv des radicaux libres (15).

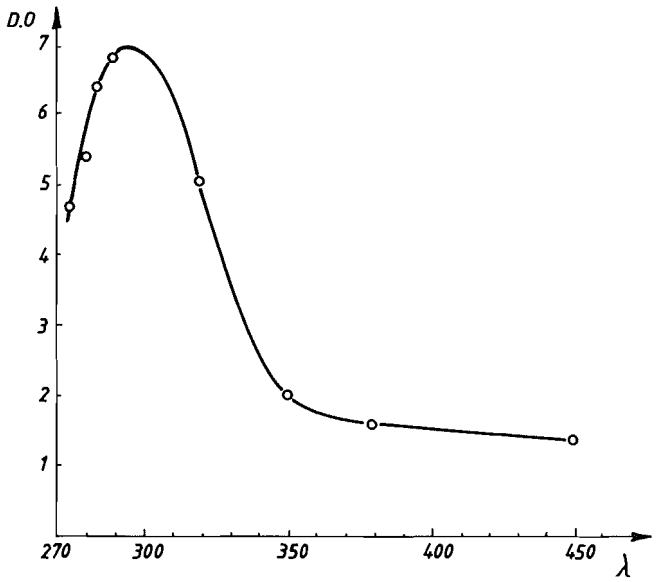


FIG. 1. Spectre différentiel d'absorption uv d'une solution aqueuse d'hypoxanthine ($1,9 \times 10^{-3}$ *M*) et de propanol-2 (0,75 *M*); 10 μs après l'impulsion; pH 0,95 ($HClO_4$ 0,117 *M*).

En milieu acide la réaction d'addition du radical hydroxypropyle **1** sur l'hypoxanthine est rapide. On peut suivre en fonction du temps l'apparition du radical **3** à 300 nm qui suit une cinétique de pseudo premier ordre avec un coefficient de corrélation de 0,999. En effet, la concentration initiale de l'hypoxanthine ($1,9 \times 10^{-3}$) est 40 fois supérieure à celle du radical hydroxypropyle **1**. La valeur de la constante de vitesse de la réaction [*b*] est alors $k_2^{(acide)} = 1,4 \times 10^8\ M^{-1}\ s^{-1}$.

Il est intéressant de comparer cette valeur à celles déjà connues pour des réactions de substitution homolytique de bases hétéroatomiques[4] dont la réactivité vis-à-vis de radicaux nucléophiles est plus élevée sous leur forme protonée que sous leur forme neutre (21) (dans le cas de la pyridine le facteur est de 70 environ).

En milieu neutre, une détermination directe de k_2 n'est pas possible car seulement une faible fraction de radicaux hydroxypropyle **1** réagissent sur l'hypoxanthine. Les autres disparaissent par dimérisation et dismutation selon la réaction [*d*], dont la valeur de la constante de vitesse est $k_4 = 7 \times 10^8\ M^{-1}\ s^{-1}$ (22). Néanmoins, en faisant l'hypothèse que l'absorption à 300 nm est due au radical **3** et que ε est du même ordre de grandeur en milieu acide et en milieu neutre (23), on peut calculer la fraction des radicaux hydroxypropyle **1** ayant réagi sur l'hypoxanthine et avoir ainsi une estimation de la valeur de k_2 en résolvant numériquement le système d'équations différentielles simultanées correspondant aux réactions [*b*] et [*d*]. On trouve alors k_2 (neutre) $\cong 7 \times 10^5\ M^{-1}\ s^{-1}$. Celle-ci, comparée à celle de ȮH, et déterminée également en milieu neutre (9) (*vide supra*), montre que le radical électrophile ȮH est

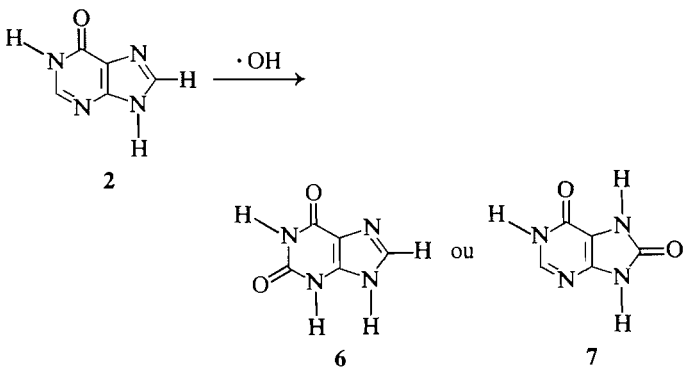
4. Les constantes de vitesse d'addition d'un radical primaire sur la quinoxaline et la pyridine protonées sont respectivement de $2,7 \times 10^7$ et $1,1 \times 10^5\ M^{-1}\ s^{-1}$ (21).

beaucoup plus réactif (environ 10 000 fois) que le radical hydroxypropyle **1** sur l'hypoxanthine.

On peut noter qu'en radiolyse γ la concentration stationnaire des radicaux hydroxypropyle **1** est de plusieurs ordres de grandeur plus faible qu'en radiolyse pulsée; par conséquent, dans le premier cas, la réaction [*d*] est négligeable par rapport à la réaction [*b*], même en milieu neutre.

B. Réaction avec les radicaux ·OH

L'action des radicaux ·OH sur l'hypoxanthine peut conduire soit à la xanthine **6** (attaque en 2), soit à la dioxo-6,8 purine **7** (attaque en 8):



2 **6** **7**

Par ailleurs l'attaque sur la double liaison centrale selon Hollian et Garrison (7) conduirait à des produits de dégradation carbonylés. En régime permanent de production de ·OH, comme c'est le cas dans le présent travail, les produits **6** et **7** peuvent être oxydés en acide urique qui lui-même est dégradé.

L'irradiation pendant 48 h d'une solution 5×10^{-3} *M* d'hypoxanthine, saturée en N_2O, conduit à un mélange de 38% de produit de départ, 6% de dioxo-6,8 purine **7** (caractérisé par les spectres uv et de masse et par hplc) et 56% de produits non identifiés mais parmi lesquels nous n'avons pu mettre en évidence ni xanthine, ni acide urique.

Nous avons suivi au cours du temps la disparition de l'hypoxanthine par hplc en utilisant la thymine comme étalon interne. Par un traitement de lissage de courbe on trouve que la vitesse de disparition obéit à une loi d'ordre 0,80, ce qui traduit bien la complexité de la réaction. En l'absence d'un échantillon authentique de dioxo-6,8 purine nous n'avons pu faire de dosage exact de ce composé mais nous avons pu évaluer la quantité formée par rapport à celle de l'hypoxanthine restante. Les résultats donnés dans le tableau 1 permettent de faire deux constatations:

(*i*) La quantité de dioxopurine **7** croît au fur et à mesure de la disparition de l'hypoxanthine.

(*ii*) Le rapport de la quantité de dioxopurine **7** à celle de l'hypoxanthine consommée reste constant au cours de l'expérience.

Nous pouvons donc conclure que la dioxopurine **7** formée à partir de l'hypoxanthine ne subit pas ou peu de dégradation ultérieure par irradiation. À partir de cette déduction un raisonnement cinétique montre que ȮH est environ 3 fois plus réactif en position **2**, on peut-être sur d'autres sites, qu'en position 8.[5]

Les constantes de vitesse de réaction de ȮH sur la xanthine et sur l'hypoxanthine sont à peu près équivalentes (9). Néanmoins, nous avons voulu vérifier la vitesse de disparition de la xanthine dans nos conditions expérimentales.

Dans ce but nous avons irradié à la même dose que précédemment une solution aqueuse $0,87 \times 10^{-4}$ *M* de xanthine. Après 4 h, l'analyse par hplc montre qu'il reste seulement 5% de produit de départ; aucune trace d'acide urique n'a pu être détectée.

Conclusion

Les résultats de ce travail permettent de comparer la réactivité et la régiosélectivité des radicaux ȮH et hydroxy-2 propyle-2 **1** sur l'hypoxanthine dans des conditions expérimentales comparables.

Le radical hydroxy-2 propyle-2 **1**, nucléophile, conduit principalement au produit substitué en C-8 avec un rendement de 70%. Sa constante de vitesse d'addition sur l'hypoxanthine déterminée par radiolyse pulsée est $k = 1,4 \times 10^8 M^{-1} s^{-1}$ en milieu acide et environ $7 \times 10^5 M^{-1} s^{-1}$ en milieu neutre. Aucun produit de substitution en C-2 n'est décelable. Ceci confirme donc la plus grande réactivité d'un radical nucléophile en C-8 qu'en C-2 (cf. réf. 4 et réf. 5).

Le radical ·OH, électrophile, très réactif (environ 10 000 fois plus que **1**) conduit surtout à des produits de dégradation. Il y a tout lieu de penser (cf. réf. 9) que le premier intermédiaire est la xanthine, résultant de l'attaque en C-2, qui disparait rapidement par réaction avec ·OH. Néanmoins il se forme une certaine quantité de dicéto-6,8 purine qui résiste aux réactions ultérieures. Ce résultat suggère que la présence du carbonyle en C-8 diminue considérablement la réactivité du carbone C-2 ou d'autres sites vis-à-vis de ȮH.

Remerciements

Nous remercions vivement de Dr Jacques Fossey pour les discussions fructueuses que nous avons eues au cours de ce travail, Mme Andrée Druilhe pour les analyses qualitatives et quantitatives par hplc et J. Potier pour les expériences de radiolyse pulsée.

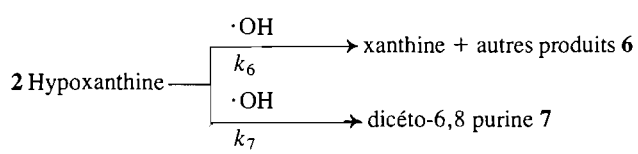
3. (*a*) H. Linschitz et J. Connolly. J. Am. Chem. Soc. **90**, 2979

5. À partir du schéma:



Supposons que le produit **7** ne disparait pas au cours de la réaction; en faisant le rapport des vitesses d'apparition de **7** et de disparition de **2** on obtient:

$$\frac{d|7|}{d|2|} = -\frac{1}{1 + k_6/k_7}$$

En intégrant entre le temps initial (0) et final (f)

$$\frac{|7|_f - |7|_0}{|2|_f - |2|_0} = -\frac{1}{1 + k_6/k_7}$$

au temps initial $|7|_0 = 0$, donc:

$$\frac{|7|_f}{|2|_0 - |2|_f} = -\frac{1}{1 + k_6/k_7} = a$$

En prenant $a = 0,26$ (tableau 1), on obtient $k_6/k_7 = 2,85$, c'est-à-dire que ȮH réagit environ 3 fois plus rapidement sur la position 2 (ou peut-être sur d'autres sites) qu'en position **8**.

Comment: Limitations of the mixing rule proposed by Humffray for estimating the densities of aqueous mixed electrolyte solutions

ANIL KUMAR

Department of Sugar Chemistry, Deccan Sugar Institute, Manjari (Bk) Poona 412 307, India

Received July 21, 1987

ANIL KUMAR. Can. J. Chem. **66**, 288 (1988).

The recently proposed mixing rule by Humffray (Can. J. Chem. **65**, 833 (1987)) is examined using very precise experimental density data on aqueous mixed electrolytes. It is observed that the computed results deviate systematically from the experimental data, where the mixture densities are not linear with the component electrolyte densities.

ANIL KUMAR. Can. J. Chem. **66**, 288 (1988).

Utilisant des données très précises pour les densités expérimentales d'électrolytes mixtes en solutions aqueuses, on réexamine la règle des mélanges qui a été proposée récemment par Humffray (Can. J. Chem. **65**, 833 (1987)). On observe que les résultats calculés dévient systématiquement des données expérimentales lorsque les densités des mélanges ne sont pas linéaires avec les densités des composantes de l'électrolyte.

In a recent article, Humffray (1) has derived a simple mixing rule for predicting the densities of aqueous mixed electrolyte solutions. He claimed excellent fits for the densities of aqueous NaCl–KBr (2), KCl–$CaCl_2$ (3), and satisfactory fits for NaCl–$CaCl_2$ (4, 5) systems using the mixing rule.

His equation for estimating the increments in density, Δd, is

$$[1] \quad \Delta d = \sum_j y_j \Delta d_j$$

where $\Delta d = d - d_0$; d and d_0 are densities of solution and water, respectively; y_j is ionic strength fraction of component j in mixture; and Δd_j is increment in density of a pure electrolyte solution.

In this note, I examine his mixing rule using very reliable density data for various systems and bring out the limitations, which restrict its application in estimating the densities of these mixtures.

The density data examined are listed in Table 1 along with their source and conditions. Equation [1], when applied to the systems with common and uncommon ions, yields results deviating systematically from the experimental densities. In Fig. 1 are plotted the deviations, δd, the differences obtained from the experimental and calculated densities ($d_{exp} - d_{calcd}$ by eq. [1]), as a function of y_2 the ionic strength fraction of second electrolyte in mixtures. One clearly observes large positive or negative systematic deviations. For example, for three ion systems like aq. $MgCl_2$–NaCl (6) at $I = 3$, δd reaches up to approximately +570 ppm and −671 ppm in the case of aq. NaCl–Na_2SO_4 (6) at $I = 3$. The similar situation can be observed for aq. NaCl–$CaCl_2$ (4) system, where Humffray quoted satisfactory standard deviations. However, one finds in Fig. 1 that for $I = 5$, the δd values pass a maximum of +273 ppm starting and ending at approximately −400 ppm. In general the deviation plots exhibit a symmetric parabola. The situations for four-ion systems are equally inferior extending δd to −603 ppm. The equation was also examined for aq. Li_2SO_4–LiCl, Na_2SO_4–NaCl, and Li_2SO_4–Na_2SO_4 reported by Wirth and Losurdo (7), yielding results with systematic deviations. In Table 1, the values of δd at $y_2 = 0.5$ are also listed. The equation also fails (maximum $\delta d = -169$ ppm) to predict the densities (8) of aq. KCl–K_2SO_4 at $I = 1.5$ where Δd for constituent electrolyte solutions differ only by 294 ppm. It is interesting that the equation overestimates the densities for the mixing of uncommon cations in the presence of common anion. In the case of uncommon anion mixing with common cation, the estimations are generally lower than the experimental data.

TABLE 1. Summary of experimental data used in testing the Hummfray mixing rule

Systems	Range of ionic strength (mol kg^{-1})	Maximum δd at $y_2 = 0.5$	No. of data points	Reference
NaCl–$CaCl_2$	0.3–5	+273	93	4, 5
NaCl–Na_2SO_4	1–3	−671	24	6, 8
Na_2SO_4–$MgSO_4$	1,3	+267	15	6
$MgSO_4$–$MgCl_2$	1,3	−333	18	6
$MgCl_2$–NaCl	1,3	+570	18	6
NaCl–$MgSO_4$	1,3	+363	18	6
$MgCl_2$–Na_2SO_4	1,3	−603	18	6
NaCl–KCl	1.5	+30	8	8
KCl–K_2SO_4	1.5	−169	8	8
K_2SO_4–Na_2SO_4	1.5	−20	8	8
NaCl–K_2SO_4	1.5	−214	8	8
KCl–Na_2SO_4	1.5	−186	8	8

Humffray reported the use of this equation with excellent accuracy in the cases of aq. NaCl–KBr and KCl–$CaCl_2$ systems. It is natural that the equation will fit experimental density data for the mixtures, where the variation of densities in mixture is linear with the component densities. This is the situation with the above two systems. But, as one can see that the densities do not always vary linearly, and thus this equation proposed by Humffray does not find extensive use in estimating the densities of mixtures. In general, the equations that predict the densities of the four-ion system, also do predict for the three-ion system with good accuracy, but this equation fails to do so.

Moreover, if the densities of mixture vary linearly with the component densities, it does not imply that the systems will obey the Young rule (9). A correction term, ΔV_m (excess volumes) is needed in order to fit the mixture data. This has been accomplished by several authors (6–12). It must be noted that whatever the δd values one obtains using eq. [1], these values will not indicate the magnitude of the correction term, ΔV_m.

Thermodynamic investigation of molecular complexation in binary acetone + bromoform mixture

HARI P. DAHIYA, PREM P. SINGH, AND SHASHI DAGAR

Department of Chemistry, Maharshi Dayanand University, Rohtak-124001, India

Received July 7, 1987

HARI P. DAHIYA, PREM P. SINGH, and SHASHI DAGAR. Can. J. Chem. **66**, 290 (1988).

Molar excess volumes, V^E, and molar excess enthalpies, H^E, have been measured for acetone (A) + bromoform (B) mixtures at 298.15 and 308.15 K. Results of these measurements suggest the formation of a 1:1 acetone–bromoform molecular complex. The equilibrium constant, K, the enthalpy of formation, ΔH, of the AB complex as also the molar volume change, ΔV, accompanying the complexation reaction A + B $\rightleftarrows$ AB have been evaluated from the measured H^E and V^E data. The K value so obtained has further been substantiated by the K value determined for the AB molecular entity from nmr studies on this mixture. Partial molar enthalpy of B (at infinite dilution) in A and vice versa have also been evaluated from the measured H^E data at 298.15 K and used to calculate a consistent molar enthalpy of AB complex formation.

HARI P. DAHIYA, PREM P. SINGH et SHASHI DAGAR. Can. J. Chem. **66**, 290 (1988).

Opérant à 298,15 et 308,15 K, on a mesure les volumes molaires en excès, V^E, et les enthalpies molaires en excès, H^E, de mélanges d'acétone (A) et de bromoforme (B). Les résultats de ces mesures suggèrent qu'il y a formation d'un complexe moléculaire 1:1 acétone:bromoforme. En se basant sur les données de H^E et de V^E, on a calculé la constante d'équilibre, K, l'enthalpie de formation, ΔH, du complexe AB ainsi que le changement de volume molaire, ΔV, qui accompagne la réaction de complexation A + B $\rightleftarrows$ AB. La valeur de K ainsi déterminée a aussi été confirmée par la valeur de K déterminée pour l'entité moléculaire AB en se basant sur des études rmn sur le mélange. Sur la base des valeurs de H^E mesurées à 298,15 K, on a évalué l'enthalpie molaire partielle de B (à dilution infinie) dans A (et vice versa) et on a aussi calculé une enthalpie molaire consistante pour la formation du complexe AB.

[Traduit par la revue]

Introduction

Very few spectroscopic studies are available that yield precise equilibrium constant and molar enthalpy of formation data for weak molecular complexes in binary non-electrolyte mixtures. A number of workers (1–5) have, however, suggested that it is possible to determine both the equilibrium constant and the enthalpy of formation of such weak molecular complexes if molar excess enthalpy (H^E) data for these binary mixtures are available. Since acetone (A) is expected to undergo specific interactions with bromoform (B), the present studies were undertaken to first investigate the nature of the molecular complex and second evaluate equilibrium constant, K, the molar enthalpy of formation, ΔH, and the change in molar volume (ΔV) associated with the formation of the molecular moiety in this (A + B) mixture.

Experimental

Acetone and bromoform (Merck, Analar grade) were purified as suggested by Vogel (6). The purities of the final samples were checked by measuring their densities at 298.15 ± 0.01 K and these agreed to within ±0.00005 g cm^{-3} with their corresponding literature values (7, 8); the density of bromoform at 298.15 K was, however, evaluated from the density vs. temperature plot utilizing the relevant data reported in the literature (8).

Molar excess volume (V^E) data at 298.15 and 308.15 K were measured dilatometrically in the manner described earlier (9). In essence the two accurately weighed components were kept separated in a U shaped dilatometer by a thread of mercury. The dilatometer was then placed in a water bath maintained at 298.15 K or 308.15 ± 0.01 K and the position of the liquid in the calibrated dilatometer capillary and of the reference mark on the dilatometer capillary were noted with a cathetometer that could read to ±0.001 cm after thermal equilibrium. The contents of the dilatometer were then mixed thoroughly by tilting the dilatometer. To ensure that the liquid in the dilatometer capillary had the same composition as that of the bulk, the dilatometer was taken out of the water bath and cooled slightly so as to have a minimum amount of liquid in the capillary. The dilatometer was again placed in the water bath and this process was repeated three times before the dilatometer was finally clamped in the water bath for thermal equilibrium. The position of the liquid in the dilatometer capillary and that of the reference mark were again noted. From the change in position of the liquid level in the dilatometer capillary and the volume per cm length, V^E values were calculated (9). The capillary was calibrated by weighing a column of mercury thread (9). Uncertainties in the measured V^E values were about 0.5%.

Molar excess enthalpies, H^E, at 298.15 and 308.15 K were determined by an LKB flow microcalorimeter LKB-2107 (M/s LKB, Broma, Sweden) in the manner described by Monk and Wadso (10). The precision and stability of the instrument in terms of temperature is 0.1 K and ±0.01 K/24 h, respectively. Two identical Braun perfusor pumps (B. Braun Melsungen AG, W. Germany) and gas-tight Hamilton syringes were employed to pump liquids through the calorimeter. Using 10, 20, and 50 cm^3 syringes and 10 speed gear boxes of the perfusor pumps, different mixing ratios were achieved. The flow rates were determined by pumping distilled water through the calorimeter and weighing the amounts collected in a specific time interval. For each typical H^E measurement, different calibration constants were determined according to the flow rate, the amplification needed, and the composition of the mixture. The uncertainties in our measured H^E values are of the order of 1% or better. The performance of the calorimeter was checked (11) by measuring H^E data for benzene + carbon tetrachloride mixture at 298.15 K. Our measured H^E values (11) for this mixture agreed within the reported uncertainties with reliable literature values (12).

Samples for nmr studies were prepared by mixing bromoform with acetone (by weight) in nmr tubes followed by dilution with a fixed quantity of cyclohexane. Immediately after preparation, a fixed quantity of tetramethylsilane (TMS) was added to each tube and the spectra was recorded on a Varian 90 MHz spectrometer. The chemical shift of bromoform relative to TMS was then obtained using the side band method (13) and shifts for all the mixtures were averaged over three determinations and were reproducible to ±0.5 Hz.

Results

Molar excess volume, V^E, and molar excess enthalpy, H^E, data for this mixture as a function of composition at 298.15

and 308.15 K (recorded in Tables 1 and 2) were fitted to the equation.

$$[1] \quad X^E\,(X = V \text{ or } H) = x_A x_B \Sigma X_0^{(n)}(2x_A - 1)^n$$

where x_A is the mole fraction of acetone. Binary coefficients, $X_0^{(n)}$ ($X = V$ or H), were calculated by fitting X^E ($X = V$ or $H)/x_A x_B$ to eq. [1] by the method of least squares and are reported in Tables 1 and 2 along with the standard deviations, $\sigma(X^E)$.

The proton chemical shifts of bromoform in its mixture with acetone relative to pure bromoform are reported in Table 3.

Discussion

We are unaware of any recent V^E data at 298.15 and 308.15 K with which to compare our results. Trew (14) determined densities of this mixture at 298.15 K but the resulting V^E data are of poor quality and are predominantly negative in contrast to the present results. For the two sets of older H^E results reported (15) for this mixture at 298.15 K, the data agree fairly well over the range $0.5 < x_A < 1.0$ and are considerably less negative than the present results.

Interestingly while the present V^E data are 298.15 K for this mixture are positive, they are negative at 308.15 K over the entire range of x_A. On the other hand, H^E data are negative at 298.15 and 308.15 K and $\partial H^E/\partial T$ is positive.

V^E and H^E values of acetone + bromoform may be explained if it is assumed that this mixture is characterized by (*i*) specific O---H interaction between the oxygen atom of A and the proton of B and (*ii*) steric repulsion between the bulky —CH_3 substituents and the bromine atoms. Consequently, the transition from negative V^E value at 308.15 to positive V^E values at 298.15 K should mean that although the lowering of temperature should cause A to interact strongly with B, the steric repulsion between the bulky —CH_3 substituents and the bromine atoms should also increase appreciably. Since V^E is a packing effect and its values are positive at 298.15 K and negative at 308.15 K, one may infer that steric repulsions (between the bulky —CH_3 subsituents and the bromine atoms) at 298.15 K outweigh specific interactions between A and B. To prove this one has to compare H^E data at 298.15 K with those at 308.15 K. The latter should be less negative. Experimental H^E data of this mixture tends to support this conjecture.

Since H^E data at 298.15 and 308.15 K are almost symmetrical about x_A, they suggest the following reaction for the formation of a single molecular complex.

$$[2] \quad A + B \rightleftharpoons AB$$

Matsui *et al.* (17), Singh and Sharma (3), and Fenby and Helper (2, 4) have shown that the equilibrium constant K, and the molar enthalpy of complex formation, ΔH, are related to the H^E data by

$$[3] \quad \frac{x_A x_B}{H^E} = -\left[\frac{(K+1)}{K(\Delta H)^2}\right]H^E + \frac{(K+1)}{K(\Delta H)}$$

provided the "physical" interactions between A and B are negligibly small compared to the "chemical" interactions. Matsui *et al.* (17) have further suggested that this requirement is met if the measured H^E value is greater than about 1.5 kJ/mol at

$x_A = 0.5$. The measured H^E for acetone + bromoform mixture fulfills this requirement, at 298.15 K and a linear plot of $x_A x_B/H^E$ versus H^E was observed.

The intercept (-2.18×10^{-4} J^{-1} mol) and the slope (-3.333×10^{-8} J^{-1} mol^2) then yielded $K = 2.35$ and $\Delta H = -6.54$ kJ mol^{-1}. Equation [3], however, could not be applied to H^E data at 308.15 K of this (A + B) mixtures since the measured $-H^E$ value at $x_A = 0.5$ is much less than 1.5 kJ.

To further supplement the numerical value for the equilibrium constant, we studied the proton chemical shift, δ, of bromoform relative to that of pure bromoform in its binary mixtures with acetone. The relevant δ data are recorded in Table 3 and it is clearly evident that there is a net shift of the bromoform proton towards low magnetic fields. Thus the protons of bromoform are deshielding in its interactions with acetone. The nmr data of binary acetone + bromoform mixture were then used to calculate the equilibrium constant.

If $\mathscr{C}_A$, $\mathscr{C}_B$, and $\mathscr{C}_{AB}$ denote the actual mole fractions of acetone, bromoform, and the complex AB, respectively, then

$$[4] \quad K = \mathscr{C}_{AB}/\mathscr{C}_A\mathscr{C}_B$$

Further $\mathscr{C}_A$, $\mathscr{C}_B$, and $\mathscr{C}_{AB}$ are related (18) to the stoichiometric mole fractions of A and B by

$$[5] \quad x_B = (\mathscr{C}_B + \mathscr{C}_{AB})/(\mathscr{C}_A + \mathscr{C}_B + 2\mathscr{C}_{AB})$$

and

$$[6] \quad x_A = (\mathscr{C}_A + \mathscr{C}_{AB})/(\mathscr{C}_A + \mathscr{C}_B + 2\mathscr{C}_{AB}) = (1 + K)\mathscr{C}_A/[1 + K\mathscr{C}_A(2 - \mathscr{C}_A)]$$

In deriving eq. [6] it has been assumed that $\gamma_A\gamma_B/\gamma_{AB} \approx 1$ and this assumption (19) does not seem to lead to serious errors in K. Now if the observed chemical shift δ_{obs}, of the bromoform proton in its mixture with acetone relative to that of the pure bromoform is assumed to be the weighted average of the shifts in the complexed state, δ_{AB}, and the uncomplexed state, δ_B, then

$$[7] \quad \delta_{obs} = \delta_B[\mathscr{C}_B/(\mathscr{C}_B + \mathscr{C}_{AB})] + \delta_{AB}[\mathscr{C}_{AB}/(\mathscr{C}_B + \mathscr{C}_{AB})] = \delta_B + C(\delta_{AB} - \delta_B)$$

where

$$[8] \quad C = \mathscr{C}_{AB}/(\mathscr{C}_B + \mathscr{C}_{AB}) = K\mathscr{C}_A/(1 + K\mathscr{C}_A)$$

To evaluate K from eqs. [4]–[8], a series of values were assumed for K and for each K value, $\mathscr{C}_A$ was evaluated from eq. [6] using the corresponding experimental x_A value. These $\mathscr{C}_A$ values were further utilized to obtain the values of C from eq. [8]. Only that particular value of K was retained that gave the best straight line of δ_{obs} against C. The criterion for the best value of K was that for which $\sigma = \Sigma(\delta_{obs} - \delta_{calc})^2$ is minimum. This analysis of our δ_{obs} data yielded $K = 2.38$. The uncertainty in our K value is of the order of ±0.05. This value of $K = 2.38 \pm 0.05$ obtained from nmr data is thus very close to the value of $K = 2.35$ evaluated from the measured enthalpy data at 298.15 K.

We next attempted a slightly different computational method for evaluating the molar volume change and molar enthalpy of complexation. If n_A, n_B, and n_{AB} are the stoichiometric number of moles of A, B, and AB entities then the equilibrium mixture contains $(n_A - n_{AB})$ mol of A, $(n_B - n_{AB})$ mol of B, and n_{AB} mol of AB. Again, if $\mathscr{C}_A$, $\mathscr{C}_B$, and $\mathscr{C}_{AB}$ are the equilibrium mole fractions of A, B, and AB then it has been shown (20) that these are related to the stoichiometric mol fractions of A and B by the following equations.

$$[9] \quad \mathscr{C}_A = (x_A - r)/(1 - r)$$

$$[10] \quad \mathscr{C}_B = (x_B - r)/(1 - r)$$

$$[11] \quad \mathscr{C}_{AB} = r/(1 - r)$$

where

$$[12] \quad r = n_{AB}/(n_A + n_B)$$

The mole fraction equilibrium constant K (for ideal associated solutions) therefore, can then be expressed as

$$[13] \quad K = r(1 - r)/(x_A x_B - r + r^2) = \frac{\mathscr{C}_{AB}}{\mathscr{C}_A\mathscr{C}_B}$$

thus by using $K = 2.38$ (obtained from nmr data), r can be evaluated for each x_A. This value of r was then used to calculate ΔX^0 from the relations (21) $X^E = r(\Delta X^0)$, where $X = H$ or V and ΔX^0 is the change in molar property X due to the complexation reaction [2].

The ΔH^0 and ΔV^0 values were then found to vary with x_A as

$$[14] \quad \Delta H^0(\text{kJ mol}^{-1}) = 0.857x_A - 7.00$$

$$[15] \quad \Delta V^0(\text{cm}^3\ \text{mol}^{-1}) = 0.3 + 0.21x_A + 2.076x_A^2$$

yielding $\Delta H^0 = -7.00$ kJ mol^{-1}. $\Delta V^0 = 0.3$ cm^3 mol^{-1} at $x_A = 0$; $\Delta H^0 = -6.57$ kJ mol^{-1}; $\Delta V^0 = 0.924$ cm^3 mol^{-1} at $x_A = 0.5$ and $\Delta H^0 = -6.14$ kJ mol^{-1}; $\Delta V^0 = 2.586$ cm^3 mol^{-1} at $x_A = 1.0$.

Again, Matsui *et al.* (17) have shown (for an ideal associated solution) that the molar enthalpy, ΔH, of AB complex formation is given by

$$[16] \quad \Delta H = \overline{\mathscr{L}}_B^0(1 + K)/K = \overline{\mathscr{L}}_A^0(1 + K)/K$$

where $\overline{\mathscr{L}}_B^0$ and $\overline{\mathscr{L}}_A^0$ represent the partial molar enthalpies of solution of B (at infinite dilution) in A and of solution of A (at infinite dilution) in B. To calculate ΔH from eq. [16] $\overline{\mathscr{L}}_B^0$ and $\overline{\mathscr{L}}_A^0$ values were first evaluated as suggested by Van Ness and Mrazek (22), i.e., by plotting $H^E/x_A x_B$ against x_A and extrapolating the intercepts to $x_A = 0$ and $x_A = 1$. This yielded $\overline{\mathscr{L}}_B^0 = -4.25$ kJ mol^{-1} and $\overline{\mathscr{L}}_A^0 = -4.95$ kJ mol^{-1} and the ΔH values obtained from eq. [16] with $K = 2.35$ range between -6.06 and -7.06 kJ mol^{-1}. On the other hand, an average value of $\overline{\mathscr{L}}_A^0$ and $\overline{\mathscr{L}}_B^0$ yielded $\Delta H = -6.56$ kJ mol^{-1} from eq. [16]. The ΔH values obtained from eqs. [16] and [3] are thus in reasonably good agreement with each other.

High pressure–temperature aqueous oxidations. III. A kinetic study of the enolization and oxidation of cyclohexanone

JOHN W. THOMAS[1] AND JAY E. TAYLOR[2]

Department of Chemistry, Kent State University, Kent, OH 44242, U.S.A.

Received July 22, 1987

JOHN W. THOMAS and JAY E. TAYLOR. Can. J. Chem. **66**, 294 (1988).

The rates of enolization of cyclohexanone have been determined at 145 and 172°C in D_2O and with buffers. The rates of oxidation were evaluated at temperatures of 145, 172, and 193.5°C with oxygen partial pressures of 20.4 to 131 atm. The rate of enolization was 10–160 times faster than the rate of oxidation thereby supporting the previously proposed concept of enol intermediacy for the oxidation of ketones. The oxidation was first order in cyclohexanone and 1/2 order in oxygen. The rate of oxidation was *increased* by the addition of traditional phenolic inhibitors. The products isolated were formic, acetic, butanedioic, pentanedioic, hexanedioic, and 5-oxohexanoic acids. The activation parameters were calculated to be $\Delta H^{\neq}$, 22 kcal/mol; $\Delta S^{\neq}$, −27 eu, log A, 7.6 for the oxidation and $\Delta H^{\neq}$, 12 kcal/mol; $\Delta S^{\neq}$, −42.3 eu, log A, 4.13 for the enolization. Based on these observations a mechanism has been postulated whereby an oxygen molecule forms a transitory adduct with two enolates of cyclohexanone. The latter may then split by a reversible reaction to form an intermediate which may then isomerize or oxidize to either 2-hydroxycyclohexanone or 1,3-cyclohexanedione. Upon further oxidation the former yields hexanedioic acid. The latter then undergoes a reverse condensation in the aqueous media to 5-oxohexanoic acid which upon further oxidation yields formic plus pentanedioic acid and acetic plus butanedioic acid.

JOHN W. THOMAS et JAY E. TAYLOR. Can. J. Chem. **66**, 294 (1988).

Opérant à 145 et à 172°C, dans le D_2O et des tampons, on a déterminé les vitesses d'énolisation de la cyclohexanone. Opérant à des températures de 145, 172 et 193,5°C et à des pressions partielles d'oxygène de 20,4 et 131 atm, on en a aussi évalué les vitesses d'oxydation. Les vitesses d'énolisation sont de 10 à 160 fois plus rapides que les vitesses d'oxydation; ces résultats supportent le concept proposé antérieurement selon lequel les énols sont des intermédiaires dans l'oxydation des cétones. L'oxydation est du premier ordre en cyclohexanone et d'ordre 1/2 en oxygène. Les vitesses d'oxydation sont *augmentées* par l'addition des inhibiteurs phénoliques traditionnels. Les produits isolés sont les acides formique, acétique, butanedioïque, pentanedioïque, hexanedioïque et oxo-5 hexanoïque. On a calculé que les paramètres d'activation sont $\Delta H^{\neq}$, 22 kcal/mol; $\Delta S^{\neq}$, −27 ue et log A, 7,6 pour l'oxydation et $\Delta H^{\neq}$, 12 kcal/mol; $\Delta S^{\neq}$, −42,3 ue et log A, 4,13 pour l'énolisation. Sur la base de ces observations, on propose un mécanisme par lequel une molécule d'oxygène forme un adduit transitoire avec deux énolates de cyclohexanone. Ce dernier adduit peut alors se décomposer, par une réaction réversible, pour former un intermédiaire qui peut alors s'isomériser ou s'oxyder soit en hydroxy-2 cyclohexanone ou en cyclohexanedione-1,3. Par oxydation subséquente, le premier conduit à de l'acide hexanedioïque. En milieu aqueux, le deuxième subit alors une condensation inverse qui transforme en acide oxo-5 hexanoïque dont l'oxydation subséquente conduit à la formation d'acide formique plus de l'acide pentanedioïque et d'acide acétique plus de l'acide butanedioïque.

[Traduit par la revue]

Introduction

That the enol is an intermediate in the aqueous oxidation of ketones at elevated temperatures and pressures was first postulated in an earlier study (1). This conclusion was based on the correlation of the rates of oxidation with the relative extents of enolization for several ketones. More recently the rates of enolization and oxidation of acetone were compared at 193.5°C in an aqueous media (2). Since the rate of enolization exceeded the rate of oxidation by a factor of ~75, the concept of the intermediacy of the enol was further supported.

Acetone oxidized very slowly at 193.5°C. Since this temperature was the practical upper limit for the constant temperature bath as previously described (2), the studies with acetone were necessarily limited. Cyclohexanone exhibited rates of oxidation and enolization which were appreciably faster than those of acetone; thus, a much broader and more complete survey of cyclohexanone has been possible and is herein described.

Experimental

The vapor pressure controlled constant temperature bath used for these experiments and the procedure for the determination of the rates of oxidation have been previously described (2).

Approximately 0.3 g of ketone was mixed with 10 mL water for both the enolization and oxidation experiments. Since in each case the ketone was sealed into a glass bulb as previously described (2) and the bulb was broken to initiate the reaction, the amount of ketone varied slightly with each experiment. The initial concentration for each experiment may be determined by extrapolation of the rate curve to zero time. For the enolization experiments a nitrogen pressure equal to the highest oxygen pressures was employed. Cyclohexane concentrations were determined by gas chromatographic analysis.

The cyclohexanone was from Eastman Kodak Company and was purified first by elution from an alumina column followed by double distillation through a 120 cm glass helix packed column. The fraction boiling at 153.5°C (735 Torr) was then used for these experiments.

In place of the mass spectrometric technique used with acetone (2), the rates of enolization of cyclohexanone were determined by following the substitution of deuterium on carbons 2 and 6 (H_α) using proton magnetic resonance, pmr, spectroscopy. Since only the α protons exchange, the remaining β and γ protons, whose signals were distinguishable from the α protons, provided a convenient internal standard for quantification of the rate of signal decay. At any time t the pmr signal was the resultant of the product of the instrument scale factor times the sum of the concentrations of the products multiplied by the number of remaining protons per cyclohexanone molecule.

Thus, the plots of ln $(H_\alpha/H_{\beta+\gamma})$ versus time were found to be linear, and slopes of these plots were equal to k, the rate constant. However, there were four α protons, and the replacement of one hydrogen by a deuterium introduced the possibility of a secondary isotope effect upon replacement of the second hydrogen on this same carbon. Since the reaction was not carried to completion, the probability of replacement of a second hydrogen on either side was small. Accordingly, the contribution of a secondary isotope effect was deemed negligible and was disregarded.

The rate of enolization of cyclohexanone was determined by

substituting D_2O for water. Since enolization is a prototopic reaction, the rate was significantly altered by the presence of added base or acid. Buffers were employed in many of the reactions and consisted of acetic acid-D_4 with sodium acetate-D_3 or acetic acid with sodium acetate both in D_2O. Under the latter conditions there was difficulty in following the H_α decay signal due to the interference of the large proton signal from the CH_3 of the buffer acetate. The kinetic analysis was based on the growth of the DOH peak, thereby avoiding this difficulty.

Deuterium substituted for the protons in the methyl group of acetic acid at ordinary temperatures produces roughly a 3% change in acid strength (3). This effect was disregarded since it would be even smaller at elevated temperatures. However, isotope effects due to the solvent, D_2O, and to the substitution of D for H on the carboxyl group of acetic acid are more significant. Due to a lack of information about either of these effects with cyclohexanone, particularly at elevated temperatures, no explicit corrections have been made. A rough estimation suggests that the rate may be 10–30% greater in H_2O as compared to D_2O.

With acetone the only detectable products of oxidation were acetic acid and carbon dioxide. In contrast, cyclohexanone led to a variety of products including formic, acetic, butanedioic, pentanedioic, hexanedioic, and 5-oxohexanoic acids. Formic and acetic acids were identified by matching their gas chromatograph retention times with known samples of these acids.

The nonvolatile acids were identified by a combination of methods. Thin layer chromatography on silica gel-G and visualization with bromocresol blue revealed the presence of four nonvolatile carboxylic acids. The R_f values of three of these matched the R_f values of the three dibasic acids, hexanedioic, pentanedioic, and butanedioic acid. These acids were also identified by comparing gas chromatograph retention times of their methyl and trimethylsilyl esters against the corresponding esters of the known acids. The mass spectra of the methyl esters of these three acids also matched the corresponding methyl esters of the known acids.

The remaining acid was less easily characterized. Its methyl and trimethylsilyl esters showed gas chromatograph retention times close to those of pentanedioic acid. The mass was determined to be 144 from mass spectral data, and a prominent low energy fragment of mass 43, corresponding to the CH_3CO^+ ion, was observed thus strongly suggesting the 5-oxo isomer.

Since 6-oxohexanoic acid (adipic aldehyde or 5-formylvaleric acid) has been variously reported as a product of the oxidation of cyclohexanone (4, 5), both the 5- and 6-oxohexanoic acids were considered as possible identities of this acid. 6-Oxohexanoic was synthesized by the method of Baer (6) and 5-oxohexanoic acid was obtained from Aldrich Chemical Company. Thin layer chromatography was of little value since the R_f values were approximately the same. From gas chromatography methyl 5-oxohexanoate showed a retention time relative to dimethyl pentanedioate of 0.8 as did the unknown ester; whereas, methyl 6-oxohexanoate showed a relative retention time of 0.91. These various data served to identify the unknown acid as 5-oxohexanoic acid (4-acetylbutyric acid).

EDTA was added to many oxidations to minimize the effects of possible contamination by metal ion impurities from the reactor.

Data and discussion

Kinetics of enolization

The rates of enolization as determined from the rates of isotopic exchange were found to be sensitive to both pH and anions of weak bases. Some specific data are listed in Table 1. As may be seen there were marked changes in the rates of enolization as the conditions were altered. Typical first order rate curves using acetic acid-D_4 and sodium acetate-D_3 determined at 145°C and acetic acid – sodium acetate at 172°C are seen in Fig. 1.

Kinetics of oxidation

The first order rate constants for the oxidation of cyclohexanone were observed at three temperatures in a variety of oxygen pressures and with several buffer systems. The data are listed in Table 2. Typical rate curves demonstrating the first order character of the oxidation of cyclohexanone with constant oxygen partial pressures are seen in Fig. 2.

TABLE 1. First order rate constants for the substitution of the α-hydrogens of cyclohexanone by deuterium atoms from the deuterium oxide solvent

Temperature (°C)	Buffer HOAc (*M*)	Buffer NaOAc (*M*)	$OAc^-/HOAc$	$k \times 10^4$ (s^{-1})
172	—	—	—	3.7
172	0.284	0.50	1.76	20.
172	0.059	0.186	3.15	13.
145	0.228[a]	0.495[a]	8.4	2.2
145	0.234[a]	0.486[a]	7.7	2.1

[a]All hydrogens were replaced by deuterium. The product concentrations and overall pressures (nitrogen) were maintained as close as possible to the oxidation runs.

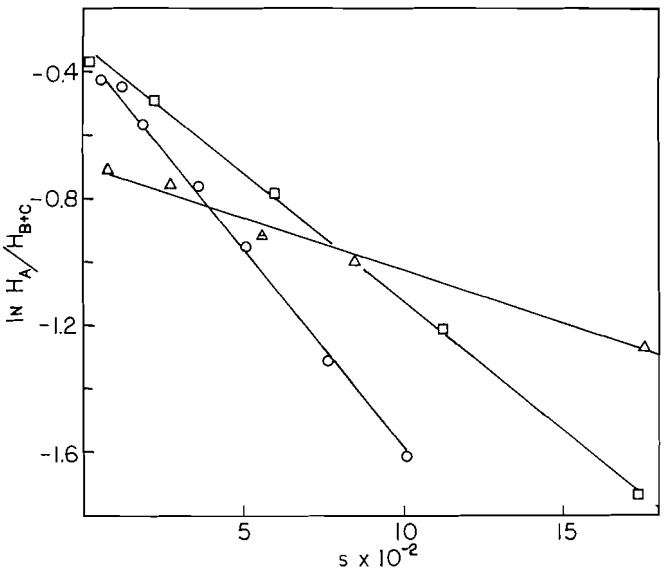

FIG. 1. Typical graphs of the rate of exchange of deuterium atoms with the hydrogen of cyclohexanone in deuterium oxide: △, no buffer, 172°C; ○, 0.059 *M* acetic acid, 0.186 *M* sodium acetate, 172°C; □, 0.234 *M* acetic acid-D_4, 0.486 *M* sodium acetate-D_3, 145°C. A, B, C are α, β, γ.

The relative rates of enolization and oxidation

The comparative rates of enolization and oxidation are listed in Table 3 at 145 and 172°C. As may be seen enolization was 10–160 times greater than oxidation, and the concept of the enol intermediate is thereby further supported. Thus, the rate of enol formation was more than adequate to maintain a constant source of the enol as an intermediate for the oxidation. However, the rate of enolization was dependent on pH and buffer concentrations; whereas the rate of oxidation was not. The simple oxidation is not a protonic reaction and should not be pH dependent. Since the rate of enolization is so much faster and is obviously a reversible reaction, an equilibrium concentration of the enol should be rapidly attained. The pH dependence of an enolization reaction lies in the rate of attainment of the equilibrium concentration, but there is no significant effect of pH on the concentrations of keto and enol forms once an equilibrium is attained. Thus the oxidation should show no pH dependency even if the enol is a precursor.

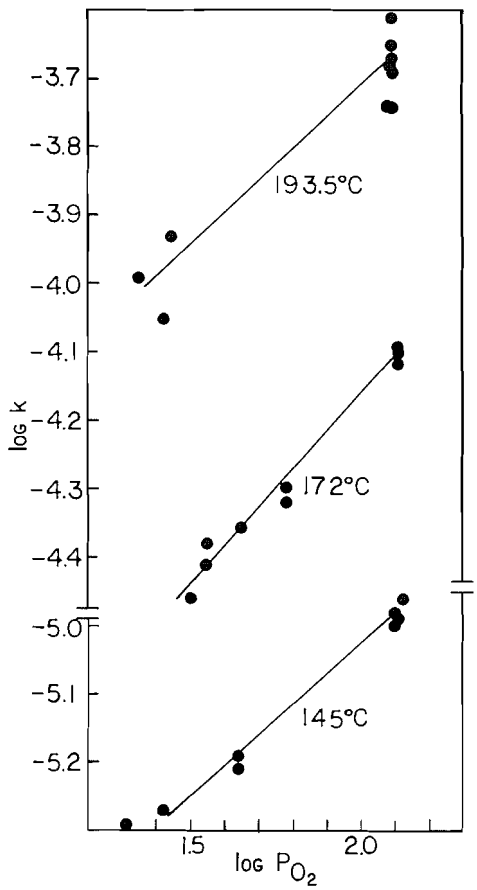

FIG. 3. Plots of log partial pressures of oxygen versus log rate constants demonstrating the one-half kinetic order with respect to oxygen concentration. The indicated slopes at the three temperatures are 0.46, 193.5°C; 0.53, 172°C; 0.44, 145°C.

Reaction order

The oxidation reaction is first order with respect to cyclohexanone since, as seen in Fig. 2, the rate of consumption of ketone clearly follows a first order relationship.

An earlier determination (1) of reaction order for several alcohols and ketones indicated that the reaction was first order in oxygen. However, only two pressures were compared, and these data were of a lower order of accuracy than the present work.

In Table 2 the pseudo first order rate constants are listed at varying oxygen partial pressures. These have been determined by correcting the gauge pressures for the partial pressures of water vapor and for temperatures. The applicability of Henry's law is assumed for the determination of the relative concentrations of oxygen in solution.

Data for the determination of the kinetic order of oxygen are listed in Table 2. The values of log *k* (first order rate constants) are plotted against the log partial pressures of oxygen at each of three temperatures in Fig. 3. As may be seen the slope is 0.5 in each case within experimental error. This relationship is further demonstrated in Fig. 4. For this experiment the oxygen partial pressure was changed from 26.5 to 123 atm during the course of a run by introducing additional oxygen. Upon calculation of the apparent order with respect to oxygen the value is 0.6 which is in good agreement with the above data in view of the magnitude of the experimental error.

Effects of added inhibitors

Since this is a reaction with elemental oxygen, a radical chain

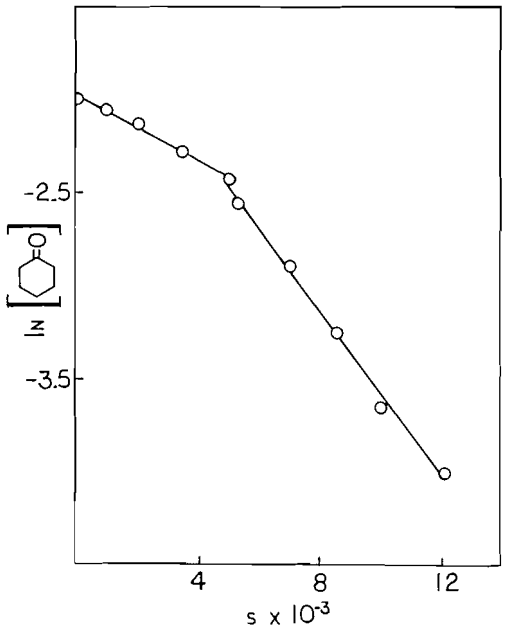

FIG. 4. A graph of the change in rate corresponding to a change in pressure from 26.5 to 123 atm during the course of an oxidation of cyclohexanone at 193.5°C. The observed first order rates are 8.8×10^{-5} and $22.0 \times 10^{-5}\ s^{-1}$. The determined oxygen order is 0.6.

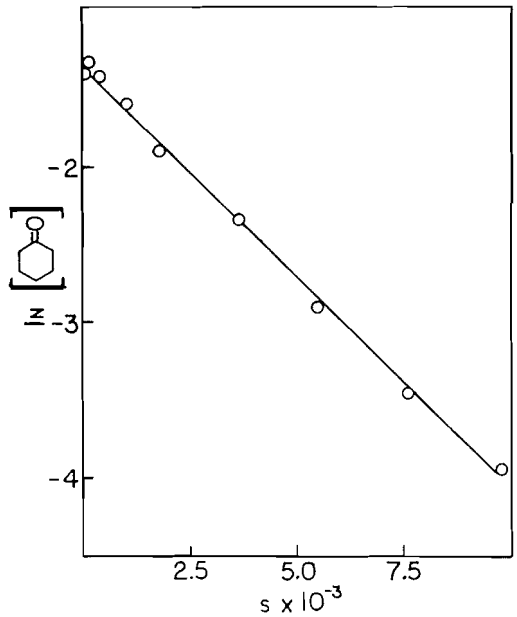

FIG. 5. Demonstration of the first order character of the oxidation of cyclohexanone in the presence of 10% 1-naphthol at 193.5°C. The rate constant is $2.8 \times 10^{-4}\ s^{-1}$.

mechanism must be considered. This possibility has been tested by the addition of typical inhibitors, 1-naphthol and 4-hydroxybenzoic acid. These were chosen because of their partial solubility in water. Other more efficient inhibitors such as *t*-butyl substituted phenols or anilines are less soluble in water and presumably would be very rapidly oxidized.

None of the 1-naphthol runs showed an induction period during the oxidation of cyclohexanone nor were there any reductions in the observed first order rate constants. There were minimal disturbances of the rates of oxidation since smooth first order plots were obtained as seen in Fig. 5. At 193.5°C the naphthol was 90% oxidized in 4000 s or about midway through the cyclohexanone run. In general there was a mild rate enhancement, 20–50%, for the seven experiments at 193.5°C and about 100% for the two runs at 172°C.

Two oxidations with added 0.04 *M* 4-hydroxybenzoic acid were made at 193.5°C. This compound has a solubility of about 1% at 25°C in water and has the position *para* to the hydroxyl group blocked. Again there was no evidence of an induction period, but there was an enhancement of the rate of oxidation of about twofold.

Thus, these experiments provide no evidence to indicate a radical chain mechanism.

TABLE 4. Activation parameters for cyclohexanone

Reaction	E_a (kcal/mol)	$\Delta H^{\ddagger}$ (kcal/mol)	$\Delta S^{\ddagger}$ (eu)	log *A*
Oxidation	23	22	−27	7.6
Enolization	12.7	11.9	−42.3	4.13

Activation parameters

The various constants of activation are listed in Table 4. These have been calculated using three-halves order rate constants for the oxidation and first order rate constants for the enolizations.

A proposed mechanism

The reaction of elemental oxygen with organic compounds is generally assumed to be a radical chain mechanism as typified by a general mechanism given for the oxidation of hydrocarbons (7). Ketones, exemplified by cyclohexanone, are deemed to react in a similar manner (8).

The data of this paper tend to distinguish aqueous oxidations (at least in part) from other typical neat or nonpolar solvent oxidations or autoxidations. No evidence for a radical-chain mechanism appeared since the phenols did not inhibit the

reaction. The multiplicity of products indicated a mechanism of appreciable complexity with a combination of successive and/or parallel reactions. Because the reaction was followed by the disappearance of cyclohexanone in a constant supply of oxygen, the only information presently available concerning the successive reactions is the identity of the products.

The reaction order suggests that a cyclohexanone molecule reacted with an O atom ($(1/2)O_2$). However, the activation energy is quite insufficient to accommodate a direct fission of an oxygen molecule whose bond strength is 118 kcal/mol (9).

Based on these considerations, it is suggested that the oxygen molecule can be split in a reversible reaction with two enolates of cyclohexanone. The resulting fragments, each containing only one oxygen atom from the original oxygen molecule, then react irreversibly to form intermediates which lead to the final products. Since the fracture of one oxygen molecule forms two reacting units, the bond dissociation energy of the oxygen fissure is divided by two for its contribution to the observed activation energy. Accordingly, a reduction in the O—O bond energy, resulting from its interaction with the enol, is needed to maintain the integrity of the observed activation energy with respect to this mechanism.

Although the data are insufficient to define this mechanism rigorously, a proposal will be advanced concerning how such a process may occur.

First the enol is formed.

[1] 
Two enol molecules then react reversibly with an oxygen molecule to form a transitory intermediate by interaction with the double bonds of the enol. This intermediate may take any of several forms, which due to insufficient evidence, are as yet not clearly defined. A possible mechanism is proposed below.

[2] 
The resulting oxide intermediate then undergoes an irreversible change to a more stable configuration.

It should be emphasized that the interaction between an oxygen molecule and the enol as previously suggested can form only under extreme conditions of high pressure and temperature due to both the endothermic nature of the reaction and compression of the oxygen molecule onto the double bonds of the enols. Thus, under neat conditions with high pressure oxygen, the reaction may proceed with explosive violence since water[3] is not present to disperse the heat of reaction generated by the reactions which follow [2].

[3]We encountered two examples of the violence of this type of reaction in our earlier studies. For the first case the grease in a gauge reacted with tank pressure oxygen at room temperature. The resulting internal explosion made the gauge unusable. For the second case an attempt was made to use perfluorotoluene as a solvent for a ketone. After the reaction was heated the mixture ignited and emerged as a tongue of flame through the safety rupture disk. Because of the extra large safety factor allowed in design, the apparatus was reusable after minor internal replacements.

The mathematical relationships derived from the above proposal concur with the observed kinetic relationships. Treating step [1] and [2] as a single equilibrium where Cy is the original cyclohexanone molecule and RO· is the end product of step [2].

$$[3]\quad K = \frac{[RO\cdot]^2}{[Cy]^2[O_2]} \text{ and } [RO\cdot] = (K_1K_2)^{1/2}[Cy][O_2]^{1/2}$$

then assuming that the irreversible isomerization of RO· is the rate-determining step,

$$[4]\quad \frac{dx}{dt} = k[RO\cdot] = k(K_1K_2)^{1/2}[Cy][O_2]^{1/2}$$

In order that this mechanism apply, it is essential that the equilibria represented by [3] be rapidly formed, i.e., the forward reactions in steps [1] and [2] must be faster than the decomposition of RO· (step [4]) to maintain the equilibrium concentrations of the intermediates. The actual concentrations of these radical intermediates can only be very small.

As previously noted the sluggish reaction of acetone (2) as compared to cyclohexanone correlates with the relative ease of enol formation.

The enhancement of the rate of oxidation with added phenolics becomes explainable with this mechanism. Although the phenols were independently oxidized, they should also react with the oxide radical of step [2]. Such an interaction should shift the point of equilibrium of steps [1] and [2] to the right, thereby increasing the rate of consumption of cyclohexanone.

The variety of products: formic, acetic, butanedioic, pentanedioic, hexanedioic, and 5-oxohexanoic acids, indicate the complexity of the mechanism of the reaction. That the $—CH_3$ group of the latter acid was formed under oxidizing conditions from a molecule with only $—CH_2—$ bonding and that formic and acetic acid were also products require special consideration.

5-Oxohexanoic acid was a major component among the isolated products. Some specific analyses are shown in Table 5.

Proceeding from step [2] more stable intermediates may be formed by rearrangement of the oxygen radical.

[5] 
[5a] 
Both 2-hydroxycyclohexanone and its corresponding hydroperoxide have been isolated as products of oxidations of cyclohexanone at lower temperatures (10, 11). The peroxide has been reported to decompose at 120°C (12). Hexanedioic acid may then be rapidly formed by further oxidation of the 2-hydroxyketone.

[6] 
TABLE 5. Analysis of C_4–C_6 acid residues from selected oxidations at 193.5°C at the indicated reaction times

Reactant	Concentration when reaction time = 2850 s	3500 s	10000 s
Butanedioic acid	50	42	63
Pentanedioic acid	18	18	14
Hexanedioic acid	5	22	13
5-Oxohexanoic acid	27	18	10

5-Oxohexanoic acid is presumably formed from the 1,3-diketone by a reverse condensation. β-Diketones react with bases to form the corresponding acid and methyl ketone (13). That such a reaction could occur with water alone or with a near neutral buffer seems quite probable in view of the extreme conditions of elevated temperatures and pressures to which the oxidation of cyclohexanone was subjected. Also with the small concentrations of ions present the ionic or protonic character of the reaction would be greatly enhanced by the high temperature of the aqueous media.

[7] 
Upon further oxidation of 5-oxohexanoic acid, the shorter chain diacids should form along with formic and acetic acids.

[8] $$(3/2)O_2 + CH_3CO(CH_2)_3CO_2H \rightarrow HCO_2H + HO_2C(CH_2)_3CO_2H \rightarrow CH_3CO_2H + HO_2C(CH_2)_2CO_2H$$

Shorter chain diacids may also have been formed by direct oxidation of 1,3-cyclohexanedione. If propanedioic (malonic) acid were formed it would have decomposed to acetic acid and carbon dioxide, and could have served as another route to acetic acid.

As previously noted 6-oxohexanoic acid has been reported by several investigators, but only the 5-oxo isomer was observed in this study. The difference appears to be in the media. The 6-oxo isomer was obtained under neat or low polarity solvent conditions and the 5-oxo isomer from an aqueous media. Thus, upon formation of the 1,3-diketone this intermediate could rearrange to the 5-oxo isomer only in an aqueous environment since water is a reactant. Under less polar conditions the diketone would merely by oxidized to any of several diacids. The 6-oxo isomer, if formed in the aqueous media, must have been largely oxidized to hexanedioic acid. The 6-oxo isomer has been reported to be formed in the presence of 5% water with a copper ion catalyst (14).

Further work is needed in order to verify the proposed mechanism.

Structure dependent regularities of zero-point plus heat content energies in organic molecules

S. FLISZÁR, F. POLIQUIN, I. BĂDILESCU, AND E. VAUTHIER[1]

Département de Chimie, Université de Montréal, C.P. 6128, Succ. A, Montréal (Qué.), Canada H3C 3J7

Received July 23, 1987

S. FLISZÁR, F. POLIQUIN, I. BĂDILESCU, and E. VAUTHIER. Can. J. Chem. **66**, 300 (1988).

A representative collection of heat content plus zero-point energies deduced in the harmonic oscillator approximation suggests a number of simple additivity rules which allow ZPE + $(H_T - H_0)$ to be related to structural features. Accurate evaluations are obtained for alkanes, alkenes, alkynes, cycloalkanes, chloroalkanes, and amines, as well as for large and small cycloalkanes in which CH_2 is replaced by O.

S. FLISZÁR, F. POLIQUIN, I. BĂDILESCU et E. VAUTHIER. Can. J. Chem. **66**, 300 (1988).

Une collection représentative d'enthalpies et d'énergies au point zéro qui ont été déduites en faisant appel à l'approximation de l'oscillateur harmonique suggère un certain nombre de règles simples d'additivité qui permettent d'établir une relation entre la valeur de ZPE + $(H_T - H_0)$ et des caractéristiques structurales. On a obtenu des évaluations précises pour les alcanes, les alcènes, les alcynes, les cycloalcanes, les chloroalcanes et les amines ainsi que pour les cycloalcanes à petits et à grands cycles dans lesquels le CH_2 a été remplacé par un O.

[Traduit par la revue]

Introduction

In our endeavour to understand the physics governing the energy of a molecule, traditional quantum mechanical energy minimization ends up describing a molecule at equilibrium, at its potential minimum. Thermochemistry, on the other hand, offers energy data (e.g., standard enthalpies of formation) for molecules possessing vibrational, rotational, and translational energies. This is where the problem lies. Vibrational energies are usually not as readily available as desired, thus rendering bona-fide comparisons between theory and experiment difficult, in spite of a wealth of thermochemical information. Indeed, the spectroscopic determination of the required complete sets of fundamental vibrational frequencies is usually far from being trivial, hence our interest in alternate rules which would allow the construction of reliable vibrational energies in a simple manner.

The sum of zero-point (ZPE) plus heat content $(H_T - H_0)$ energies is our target. It is fortunate that ZPE + $(H_T - H_0)$ energies can often be constructed to a good approximation by means of additivity rules (1). Theoretical foundation for this additivity, which has a long history (2), has been established (3). In the following, we calculate ZPE + $(H_T - H_0)$ energies from spectroscopic data and examine how these results can be related to structural features. In essence, this is a presentation of facts — a point worth remembering because, at times, the observed regularities exceed present theoretical expectations.

Calculations

The results were derived in the harmonic oscillator approximation using, whenever possible, observed infrared and Raman fundamental frequencies, ν_i. The inactive frequencies were taken from appropriate force field calculations. In this approximation we have

$$\text{ZPE} = \tfrac{1}{2}\sum_i h\nu_i$$

$$E_{\text{vibr}}(\text{therm}) = \sum_i h\nu_i \exp(-h\nu_i/kT)/[1 - \exp(-h\nu_i/kT)]$$

and

$$H_T - H_0 = E_{\text{vibr}}(\text{therm}) + 4RT$$

for nonlinear molecules. All the calculations were made for $T = 298.15$ K.[2]

Results

(a) Open chain alkanes, alkenes, and alkynes

A detailed study of the alkanes has revealed (1) that their ZPE + $(H_T - H_0)$ energies are satisfactorily described as follows, in kcal mol^{-1},

$$[1]\quad \text{ZPE} + (H_T - H_0) = 11.479 + 18.213n_C - 0.343n_{br}$$

where n_C is the number of carbon atoms and n_{br} is the number of branchings. The average deviation between the results deduced in this manner and their spectroscopic counterparts is 0.125 kcal mol^{-1}.

For the simple ethylenic compounds, C_nH_{2n}, it was shown (1) that eq. [2], in kcal mol^{-1},

$$[2]\quad \text{ZPE} + H_T - H_0 = 33.35 + 18.213(n_C - 2) - 0.343n_{br}$$

represents a valid approximation. Back calculations of enthalpies of formation using eqs. [1] and [2] and the appropriate atomization energies of molecules in their hypothetical vibrationless state at 0 K yields results which are well within experimental uncertainties (1).

Now we proceed with the conjugated and nonconjugated polyenic hydrocarbons indicated in Table 1. The ZPE + $H_T - H_0$ results can be estimated from those of their olefinic fragments, eq. [2], simply by subtracting 11.56 kcal mol^{-1} for each pair of hydrogen atoms eliminated in the condensation of the fragments. For example, the result predicted for 1,3-pentadiene follows from the values for ethene and propene less 11.56 kcal mol^{-1}. Similarly, the result for 1,3,5-hexa-

[1]Visiting scientist on temporary leave from the Université P. et M. Curie, Département de Recherches Physiques, 4, Place Jussieu, Paris, France.

[2]Planck's constant was taken as $h = 6.6256 \times 10^{-27}$ and Boltzmann's constant at $k = 1.38054 \times 10^{-16}$ erg K^{-1}. For the speed for light we have used 2.997925×10^{10} cm s^{-1}. Thus we obtain, for use with the usual wave number ω, in cm^{-1},

$$\tfrac{1}{2}h\nu_i = 1.42956 \times 10^{-3}\,\omega_i \quad \text{kcal mol}^{-1}$$

$$h\nu_i/kT = 4.82572 \times 10^{-3}\,\omega_i \quad \text{at 298.15 K}$$

Dimethyl-1,3-butadiene	91.08 (6, 7)	90.88
trans-1,3,5-Hexatriene	76.70 (8)	76.93
cis-1,3,5-Hexatriene	76.99 (8)	76.93
1,3,5,7-*trans*,*trans*-Octatetraene	99.97 (9, 10)	98.72

[a]Numbers in parentheses indicate references reporting the vibrational frequencies used in this work.

[b]NOTE ADDED IN PROOF: This result follows from the spectral analyses given by Compton *et al.* (39*a*) (ir) and Kuznetsov *et al.* (39*b*) (Raman), reported by Bock *et al.* (39*c*).

TABLE 2. Experimental and predicted ZPE + $(H_T - H_0)$ results of selected alkynes

Molecule	ZPE + $(H_T - H_0)$, kcal mol^{-1} Exptl.[a]	Predicted
Ethyne	18.57 (11)	18.74
Propyne	37.05 (11)	36.87
1-Butyne	54.98 (12)	55.00
2-Butyne	55.17 (11)	55.00
1-Pentyne	72.98 (12)	73.13

[a]Numbers in parentheses indicate references reporting the vibrational frequencies.

triene corresponds to three times that of ethene less twice 11.56 kcal mol^{-1} or, alternatively, to the sum obtained from ethene and butadiene less 11.56 kcal mol^{-1}.

The alkynes (Table 2) are described by an equation similar to that given for the alkenes, i.e., in kcal mol^{-1},

$$[3]\quad \text{ZPE} + (H_T - H_0) = 18.74 + 18.13(n_C - 2) - 0.343n_{br}$$

Inspection of eqs. [1]–[3] indicates that the addition of one CH_2 group increases ZPE + $(H_T - H_0)$ by ~18.2 kcal mol^{-1}. In addition, the values of ethane (47.91), ethene (33.35), and ethyne (18.74 kcal mol^{-1}), from eqs. [1], [2], and [3], respectively, indicate that ZPE + $(H_T - H_0)$ decreases regularly by ~14.6 kcal mol^{-1} for each added multiple bond. Thus we can describe the alkanes, alkenes, and alkynes by a single equation, namely, in kcal mol^{-1},

$$[4]\quad \text{ZPE} + (H_T - H_0) = 47.77 + 18.30(n_C - 2) - 0.474n_{br} - 14.605n_{mb}$$

where n_{mb} is the number of multiple bonds (e.g., 1 in C_2H_4, 2 in C_2H_2). The validity of this approximation is illustrated in Table 3. The average deviation, 0.20 kcal mol^{-1}, is only slightly larger than what is obtained from separate correlations, confined to series of homologous compounds. Here, the striking feature lies in the remarkably regular decreases of vibrational energy in going from a single to a double and to a triple carbon—carbon bond.

The chloroalkanes follow the same general pattern as their

parent hydrocarbons (eq. [1]), i.e., in kcal mol^{-1},

$$[5]\quad \text{ZPE} + (H_T - H_0) = 25.27 + 18.213(n_C - 1) - 4.98(n_{Cl} - 1)$$

where n_{Cl} is the number of chlorine atoms. Although the possible verifications are presently limited in number, in essence because the vibrational analyses of haloalkanes are unfortunately often incomplete, it appears that our approximation, eq. [5], is reasonable (Table 4).

The ZPE + $(H_T - H_0)$ energies of amines and hydrazines also appear to follow simple additivity rules. For the amines, we predict ZPE + $(H_T - H_0)$ from NH_3 (22.94 kcal mol^{-1}) and the appropriate alkanes (eq. [1]), by subtracting 11.55 kcal mol^{-1} for each pair of H atoms lost during the condensation giving the amine. Dimethylamine, for example, is estimated by taking twice the value of CH_4 plus that of NH_3, less twice 11.55 kcal mol^{-1}. We proceed similarly with the alkyl-substituted hydrazines (Table 5). Our approximation is generally satisfactory. As regards diethylamine, we have to take into account that no provision was made in our estimate for the (at least partial) hindrance of internal rotations in the ethyl groups as a result of steric crowding. Earlier studies (1, 24) have revealed a systematic lowering of ZPE + $(H_T - H_0)$ by ~0.3 kcal mol^{-1} for one hindered internal rotation, suggesting

[a]The references, in parentheses, report the vibrational analyses used in this work.

that our estimate for diethylamine is possibly too high by $\sim$0.6 kcal mol^{-1}.

(b) Cyclic molecules

Cycloalkanes constructed from six-membered rings behave in essence like their noncyclic counterparts (eq. [1]) as regards their vibrational energies, provided that the suppression of internal rotations is adequately taken into account (1, 24). Their ZPE + $(H_T - H_0)$ energies can be evaluated by counting 18.213 kcal mol^{-1} for each C atom of the molecule (rule 1) and subtracting 0.343 kcal mol^{-1} for each tertiary C atom that is formed (rule 2). A number of H atoms are eliminated in the formation of polycyclic compounds, e.g., 2 H atoms in *trans*-decalin. The 11.479 kcal mol^{-1} term of eq. [1] represents roughly the contribution of two H atoms. Accordingly, we approximate the decrease in ZPE + $(H_T - H_0)$ due to the loss of one H atom by subtracting 5.74 kcal mol^{-1} per H atom that is removed (rule 3). Considering now that eq. [1] describes noncyclic molecules in which internal rotations are as free as possible and, moreover, that internal rotations are hindered in cyclic compounds, we tentatively subtract $RT/2$ = 0.296 kcal mol^{-1} (at 298.15 K) for each CC bond in the cycle (rule 4). These simple rules, modelled on eq. [1], as discussed elsewhere in detail (1, 24), lead to satisfactory estimates of

TABLE 6. ZPE + $(H_T - H_0)$ values of cycloalkanes[a]

Molecule	ZPE + $(H_T - H_0)$, kcal mol^{-1} Exptl.	Predicted
Cycloheptane	124.15	126.09

1,3-Dioxetane		41.45
1,3,5,7-Tetroxocane	86.2 (30)	86.63

[a]The result for tetrahydropyran is reported in ref. 1. The references, indicated in parentheses, report the vibrational analyses used in our calculations.

ZPE + $(H_T - H_0)$ energies for six-membered cycloalkanes. Here we examine the effect of ring size (Table 6).

The results indicate that any shrinking of a cycle accompanying the removal of one CH_2 group translates into a regular decrease of ZPE + $(H_T - H_0)$ by 18.545 kcal mol^{-1}. It is remarkable that this regularity includes the shrinking from cyclopropane to give the "two-membered cycle" ethylene.

Similar regularities are also observed for cycles containing one or more oxygen atoms (Table 7). It suffices to calculate the ZPE + $(H_T - H_0)$ value of the corresponding cycloalkane and to subtract 14.50 kcal mol^{-1} for each CH_2 which is replaced by an oxygen atom. The agreement with spectroscopic results is remarkable considering that this verification includes an eight-membered cycle with four oxygen atoms as well as small cycles such as ethylene oxide and the "two-membered cycle" formaldehyde.

The replacement of CH_2 by NH also translates into a lowering of ZPE + $(H_T - H_0)$. The few spectroscopic analyses which are presently available suggest a lowering of $\sim$7.1 kcal mol^{-1}. The values thus estimated for piperidine, pyrolidine, and ethyleneimine are 100.4, 81.9, and 44.8 kcal mol^{-1}, respectively, in moderate agreement with their experimental counterparts, namely, 100.53 (axial) and 100.25 (equatorial piperidine) (31), $\sim$81 (estimated for pyrolidine from an incomplete spectral analysis) (32), and 45.95 kcal mol^{-1} for ethyleneimine (33).

A tentative estimate for the loss in vibrational energy

TABLE 8. ZPE + $(H_T - H_0)$ results of selected azines

Molecule	ZPE + $(H_T - H_0)$, kcal mol^{-1} Exptl.	Predicted
Benzene	66.22 (11)	66.06
Pyridine	57.29 (34)	57.61
1,3-Diazine	49.40 (35)	49.16
1,4-Diazine	49.07 (35)	49.16
1,2-Diazine	49.16 (35)	49.16
1,3,5-Triazine	42.9 (36)	40.71

accompanying the replacement of an aromatic CH group by N follows from an unfortunately limited set of spectral data. ZPE + $(H_T - H_0)$ is approximately given by $66.06–8.45n_N$ kcal mol^{-1} with respect to benzene (with n_N = number of N atoms), but this approximation seems to be of limited validity (Table 8).

Conclusions

Simple additivity rules relating ZPE + $(H_T - H_0)$ energies to structural features have proven their usefulness in the past, namely for alkanes, six-membered cycloalkanes, alkenes (1), ethers (37), carbonyl compounds (37), and aromatic hydrocarbons (38) and were essentially examined because of the need to link thermochemical data to theoretical calculations made for molecules in their hypothetical vibrationless state. In this vein, it now appears that our arsenal of rules can be extended, giving access to additional classes of compounds amenable to simple evaluations. While certainly pleasing in problems requiring their application, the quality of the correlations obtained from bona fide spectral analyses at times exceeds what we might normally expect. This is, namely, the case with the remarkable regularities observed for the replacement of a single by a double or triple CC bond, the fundamental similarity between open chain and cyclic alkanes, the progressive shrinking of cycloalkanes and the replacement of CH_2 by O in a cycle. Thus, beyond any consideration of their practical merits, it is comforting to witness the surprising simplicity and the unifying trends governing ZPE + $(H_T - H_0)$ energies in relation to structural features although, admittedly, all of it is presently recognized only on an empirical basis.

Oxidation of 3-alkylidene-β-lactams. A preparation of 3-alkenyl-3-hydroxy-β-lactams

WILLIAM W. OGILVIE AND TONY DURST

Ottawa–Carleton Chemistry Institute, Department of Chemistry, University of Ottawa, Ottawa, Ont., Canada K1N 9B4

Received August 4, 1987

WILLIAM W. OGILVIE and TONY DURST. Can. J. Chem. **66**, 304 (1988).

Hydroxylation of the enolates of several 3-alkylideneazetidin-2-ones with MoOPH leads to the formation of 3-hydroxy-3-alkenylazetidin-2-ones in fair to good yields. The products were formed with *trans* stereochemistry in the alkenyl moiety and a presumed *trans* relationship between the hydroxyl substituent and a 4-substituent. Hydrogenation leads to 3-alkyl-3-hydroxyazetidin-2-ones. The prerequisite 3-alkylideneazetidin-2-ones were formed from 3-trimethylsilylazetidin-2-ones and aldehydes via a Peterson olefin synthesis.

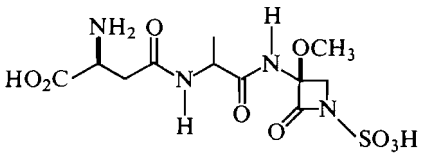
WILLIAM W. OGILVIE et TONY DURST. Can. J. Chem. **66**, 304 (1988).

L'hydroxylation des énolates de plusieurs alkylidène-3 azétidinones-2 par le MoOPH conduit à la formation d'hydroxy-3 alcènyl-3 azétidinones-2, avec des rendements qui vont de moyens à bons. Les produits qui se forment présentent une stéréochimie *trans* dans la portion alcènyle et une relation que l'on croit *trans* entre le substituant hydroxyle et un substituant en position 4. Une hydrogénation conduit à la formation d'alkyl-3 hydroxy-3 azétidinones-2. On a obtenu les alkylidène-3 azétidinones-2 de départ à partir des triméthylsilyl-3 azétidinones-2 et des aldéhydes par le biais d'une synthèse d'oléfine suivant Peterson.

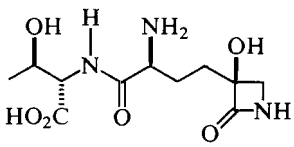
[Traduit par la revue]

Introduction

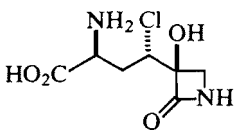
Several monobactams have been described that contain a 3-hydroxy or 3-alkoxy-β-lactam moiety, such as Sulfazecin **1** (1), Tabtoxin **2** (2), and the related microbial product **3** (2*a*). As part of a study directed towards the synthesis of monobactams of this type, we required an entry into 3-hydroxy-3-alkyl-β-lactams, which we envisaged could be readily obtained from 3-hydroxy-3-alkenyl-β-lactams. Compounds of type **4** (R^1 = Me, Ph) had previously been produced by photolysis of α-oxo amides (3), photolytic reaction of benzoylformate in the presence of imines (4), and by the [2 + 2] cycloaddition of imines with ketenes derived with hydroxyacetic acid derivatives (5, 6) to give products of type **4** (R^1 = H, Ph). However, no general route to **4** (R^1 = alkenyl) was apparent in the literature.



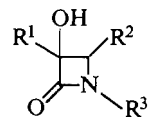
1



2



3



4

We would like to report a straightforward method for the preparation of 3-alkenyl-3-hydroxy-β-lactams via oxygenation of the anion derived from 3-alkenyl-β-lactams. Hydrogenation of these compounds should readily give the above mentioned 3-alkyl-3-hydroxy-β-lactams.

We briefly investigated the addition of organolithiums to 3-oxo-β-lactams as a route to 3-hydroxy-3-alkyl-β-lactam derivatives. Previous literature work indicated that such 3-oxo-β-lactam derivatives react with nucleophilic species such as hydride (7*a*), cyanide (7*a*), and Wittig reagents (7*b*,*c*) to give the expected products. In our hands the reaction of 3-oxo-4-phenyl-1-*p*-methoxyphenylazetidin-2-one, prepared from 3-ethylidene-4-phenyl-1-*p*-methoxyphenylazetidin-2-one, with several organolithiums gave complex mixtures of products, which were not further investigated.

Results and discussion

The formation of β-lactam enolates is a well-known and convenient method of introducing a variety of substituents onto position 3 of the azetidin-2-one ring. We therefore envisaged the formation of **4** by enolate hydroxylation of 3-alkylazetidin-2-ones (eq. [1]), since methods for hydroxylations

[1] 
4

of carbanions have previously been described (8, 9). Initial attempts to hydroxylate 3-alkylazetidin-2-ones directly were unsuccessful, mainly due to difficulties in generating the required carbanions. Thus treatment of 3-methyl-4-phenylazetidin-2-one **5**, prepared in 70% yield from 4-phenyl-*N*-pyrrolidinomethyl-azetidin-2-one (10), with LDA at −78°C followed by quenching with methyl iodide resulted in recovery of the starting lactam. A similar result was observed using trimethylsilyl chloride as the electrophile, thus indicating that no enolate formation had taken place under these conditions.

Anion formation from **5** did occur upon treatment with LDA in the presence of one equivalent of tetramethylethylenediamine (TMEDA), based upon isolation of the *cis* 3,4-disubstituted lactam **6** and the formation of the 3,3-dimethylazetidin-2-one **7**.

Quenching of this enolate with CH_3I gave a mixture of 3,3-dimethyl product **7** (36%) as well as smaller amounts of **5** and **6**. The product **7** was characterized by the appearance of two methyl signals at δ 1.49 and 0.77 in the proton nmr. The signal

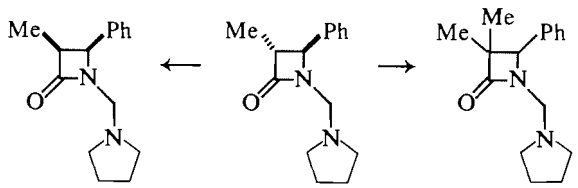
for the 3-methyl group in the *cis* isomer **6** was located 0.63 ppm upfield of the 3-methyl signal in **5**. Correspondingly, the signal for the α-hydrogen in **6** was 0.52 ppm downfield from the 3-hydrogen in **5**. These differences are explained by the anisotropic effect of the phenyl ring on the *cis* methyl group of **6** and on the *cis* H of **5**. In addition, the coupling constant for H-3 and H-4 of **6** was much larger (5.0 Hz) than the respective coupling in **5** (2.2 Hz), verifying that **6** had the *cis* 3,4 stereochemistry. This geometry was expected since **6** would arise by protonation of the enolate of **5**, which should preferentially occur *trans* to the 4-phenyl group.

Reaction of the enolate of **5**, generated as above, with TMS chloride gave no incorporation of a trimethylsilyl group, and resulted only in the recovery of starting material **5** and isomerization product **6**. Attempted oxidation of the **5** enolate with 2-sulfonyloxaziridine (11) or with molecular oxygen failed to give oxidation products and resulted only in the recovery of **5** and **6**.



6 **5** **7**

To enhance anion formation at C-3 we decided to employ a vinylogous carbanion of type **8**. Since allyl anions are known to preferentially add hard electrophiles in the α position rather than at the γ-carbon (see ref. 12 for leading references), we felt that the control of regiochemistry in the hydroxylation reaction would not be a problem.

As an initial test of our hypothesis, we treated the lithium enolate of **9** (13) with oxodiperoxymolybdenum(pyridine)hexamethylphosphoramide (MoOPH) (8, 14, 15). After flash chromatography, 3-hydroxy-β-lactam **10** was isolated in 67% yield. The product **10** was also obtained in 30% yield upon treatment of the enolate of **9** with O_2. Compound **10** exhibited an infrared absorption at 1750 cm^{-1} indicating the presence of a β-lactam. The nmr spectrum showed a clear ABX pattern at δ 5.59 (H_A), δ 5.47 (H_B), and at δ 5.18 (H_X). Presumably the hydroxyl group and phenyl group are *trans*, since alkylations of β-lactam enolates at position 3 are known to proceed *anti* to any large group at position 4. Unfortunately, this conclusion could not be corroborated spectroscopically. This compound was smoothly hydrogenated over PtO_2 to give a highly crystalline solid, mp 129–130°C, which was identified as **11**.

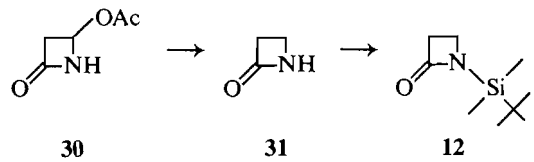
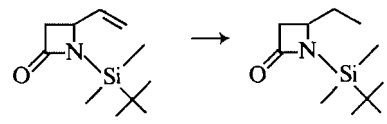
SCHEME 1

Compounds such as **11** are thus easily accessible via the route described above. The prerequisite 3-alkenylazetidin-2-ones are readily available via Peterson olefination starting with 3-trimethylsilylazetidin-2-ones and ketones (16), and presumably also aldehydes.

The preparation of the required alkenyl-β-lactams is shown in Scheme 1. The 4-unsubstituted β-lactam **12**, was obtained from the readily available 4-acetoxyazetidin-2-one **30** (17). Pfaendler and Hoppe (18) had reported that treatment of **30** with KBH_4 in H_2O gave **31** in 69% yield. We found that $NaBH_4$ in ethanol gave **31** in 84% yield from a nonaqueous work-up. This compound was readily protected as **12** with *tert*-butyldimethylsilyl chloride in DMF in 61% yield. 4-Ethylazetidin-2-one **13** was obtained by hydrogenation of 4-vinyl-1-*tert*-butyldimethylsilylazetidin-2-one **32** (19).



30 **31** **12**



32 **13**

Both derivatives were smoothly converted to the 3-trimethylsilyl products **15** and **16** by treatment with LDA followed by addition of trimethylsilyl chloride. The thiophenyl derivative **17** was prepared in a similar manner from 4-thiophenylazetidin-2-one (20). Compounds **16** and **17** were obtained in pure form by flash chromatography while **15** was used without further purification.

The lithium enolate of **15**, prepared by treatment with LDA at −78°C, was reacted with propionaldehyde to give a mixture of **18** and **24** in 66% overall yield. These isomers could be easily separated by flash chromatography and were readily distinguished by ^1H nmr. The vinyl hydrogen of **18** appeared at δ 5.52, upfield of the vinyl hydrogen of **24** at δ 6.11.

For personal use only.

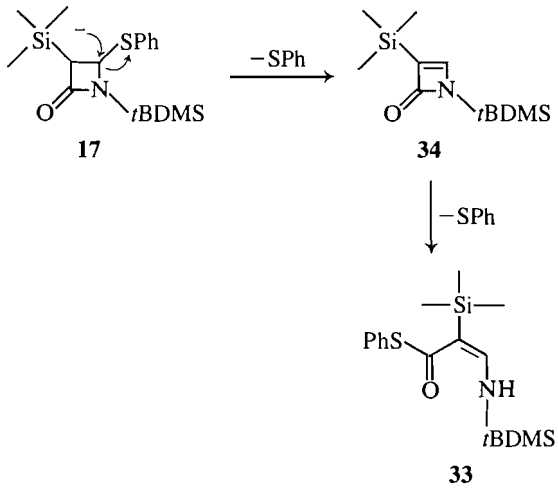
Additionally, the vinylic methylene group of **18** was downfield of the analogous CH_2 group in **24**. The assignment of stereochemistry was based on observations noted previously (21). Reaction of **15** with hydrocinnamaldehyde gave **19** and **25** in 58% overall yield. As with **18** and **24**, the *Z*-isomer **19** was easily distinguished from the *E*-isomer **25** by the chemical shift differences in the olefinic hydrogens of each isomer.

In a similar manner, **16** and propionaldehyde gave **20** and **26** in yields similar to those obtained by the reaction of **15** with propionaldehyde. Reaction of the anion of **16** with hydrocinnamaldehyde gave a good yield of **21** and **27**. In all reactions, the *Z*-ene-lactams **18–21** were eluted before the corresponding *E*-isomers upon flash chromatography, and were obtained in higher proportions.

The reaction of the enolate of **17** with propionaldehyde at −78°C gave a disappointing yield of **22** and **28**. The reaction mixture smelled strongly of thiophenol and we isolated as the major product, in 30% yield, a crystalline material assigned structure **33** on the basis of spectroscopic data. An infrared spectrum showed signals at 1605 and 1551 cm^{-1} only, indicating that the β-lactam was no longer intact. Aside from signals for thiophenoxy, trimethylsilyl, and *tert*-butyldimethylsilyl groups, compound **33** showed only a doublet at δ 6.67 (J = 15.25) and a broad singlet at δ 9.0. A HOMCOR spectrum of this material indicated that the signals at δ 6.67 and δ 9.0 were coupled, as expected for a structure such as **33**.

This compound could arise by elimination of thiophenoxide to give the unsaturated β-lactam **34** followed by attack at the carbonyl group by thiophenoxide to afford thioester **33** (eq. [2]). The yield of desired products **22** and **28** could be

[2]



17 **34** **33**

increased to 37 and 28% respectively by allowing only 1 min for the formation of the enolate of **17**. The reaction of the enolate of **17** with hydrocinnamaldehyde using the normal reaction time gave **33** as the major product, with **23** and **29** being formed in smaller amounts. Using the short enolate formation time, **23** and **29** were obtained in 35 and 26% yield respectively.

Generation of the allylic enolates of **18–21** with LDA followed by addition of solid MoOPH at −78°C and subsequent warming until the solution had cleared gave crude products that were purified by flash chromatography to give the desired 3-hydroxy-3-alkenyl-β-lactams **35–38** in yields of 31–53%. Attempted oxidation of the 3-alkenyl-4-thiophenoxyazetidin-2-ones **22** and **23** was unsuccessful, possibly due to the instability of the anion. The crude reaction mixture smelled strongly of thiophenol.

In all cases the regenerated alkene moiety was shown to have an *E*-configuration as indicated by the large (approximately 15 Hz) coupling of the olefin protons. As mentioned above, the relative 3,4 stereochemistry could not be assigned on the basis of spectroscopic evidence. However, as with **10**, it is presumed that the hydroxyl group enters *trans* to the substituent at position 4.

Experimental

Melting and boiling points are uncorrected. Nuclear magnetic resonance spectra were measured with a Varian XL-300 spectrometer in $CDCl_3$ solution. Values are given as δ values in ppm downfield from TMS. Infrared spectra were recorded with a Perkin–Elmer 783 spectrometer; values are given in cm^{-1}. Mass spectra were obtained on a VG 7070E. Column chromatography was performed using 60–200 mesh silica gel (Baker) and flash chromatography was done with Merck type 9385 silica gel (Terochem). In both cases ethyl acetate – hexane mixtures were used for elution.

CH_2Cl_2 was distilled from P_2O_5. THF was dried over benzophenone ketyl. DMF and diisopropylamine were distilled from CaH_2. Butyllithium was used as received from Aldrich after titration with diphenylacetic acid.

4-Phenyl-2-pyrrolidinomethylazetidin-2-one

4-Phenylazetidin-2-one (8.16 g) was refluxed in 45 mL of ethanol containing 6.4 mL of formalin and 5.5 mL of pyrrolidine for 7 h. The solvent was then removed under reduced pressure and the residue distilled (155°C/0.8 Torr; 1 Torr = 133.3 Pa) to give 9.6 g (75%) of 4-phenyl-2-pyrrolidinomethylazetidin-2-one as a pale yellow liquid; ir ($CHCl_3$): 1748; ^{1}H nmr δ: 7.40–7.36 (m, 5H), 4.72–4.69 (bs, 1H), 4.25 (d, J_{AB} = 13.12, 1H), 3.59 (d, J_{AB} = 13.12, 1H), 3.41 (dd, J = 5.25, 14.85, 1H), 2.85 (dd, J = 2.40, 15.00, 1H), 2.62–2.55 (m, 4H), 1.76–1.72 (m, 4H); ms: 230 (M^+), 70 (base peak) (M^+ − 160).

trans-*3-Methyl-4-phenyl-2-pyrrolidinomethylazetidin-2-one* ***5***

To a solution of 1.2 equivalents of LDA in THF at −78°C was added 3.0 g of 4-phenyl-2-pyrrolidinomethylazetidin-2-one in THF. The resulting deep orange solution was stirred at −78°C for 10 min and then 2 mL of MeI was added all at once. This solution was stirred at −78°C for an additional 10 min and then quenched with saturated NH_4Cl solution. The mixture was extracted with CH_2Cl_2, washed with water, and dried over $MgSO_4$. Removal of solvent followed by flash chromatography gave 2.2 g of **5** as a pale yellow oil (69%); ir (thin film): 1750; ^{1}H nmr δ: 7.25 (s, 5H), 4.21 (d, J_{AB} = 12.90, 1H), 3.55 (d, J_{AB} = 12.90, 1H), 4.22 (d, J = 2.2, 1H), 2.98 (dq, J_q = 7.4, J_d = 2.2, 1H), 2.70–2.41 (m, 4H), 1.90–1.52 (m, 4H), 1.41 (d, J = 7.4, 3H); ms: 244 (M^+).

cis-*3-Methyl-4-phenyl-2-pyrrolidinomethylazetidin-2-one* ***6***

To a solution of 1 equivalent of LDA and 1 equivalent of TMEDA in THF at −78°C was added 117 mg of **5** in THF. The solution was stirred for 10 min and 0.2 mL of freshly distilled trimethylsilyl chloride was added. Stirring was continued at −78°C for a further 20 min. Then the reaction mixture was quenched with saturated NH_4Cl, extracted with ether, washed with water, and dried over $MgSO_4$. Flash chromatography gave 38 mg of **6** as a pale yellow oil (33%); ir (thin film): 1745; ^{1}H nmr δ: 7.18 (m, 5H), 4.84 (d, J = 5.0, 1H), 4.28 (d, J_{AB} = 13.30, 1H), 3.50 (dq, J_q = 7.8, J_d = 5.0, 1H), 3.65 (d, J_{AB} = 13.30, 1H), 2.7–2.4 (m, 4H), 1.9–1.6 (m, 4H), 0.78 (d, J = 8.0, 3H); ms: 244 (M^+).

3,3-Dimethyl-4-phenyl-1-pyrrolidinomethylazetidin-2-one 7

Azetidin-2-one **5** (106 mg) in 2 mL of THF was added to a solution of 1 equivalent of LDA in 5 mL THF containing 1 equivalent of TMEDA at −78°C. The reaction mixture was stirred for 20 min, 0.2 mL of MeI was added, and the resulting solution stirred for a further 20 min at −78°C. The reaction mixture was then quenched with saturated NH_4Cl, extracted with ether, washed with water, and dried over $MgSO_4$. Removal of solvent and flash chromatography gave 40 mg of 7 as a pale yellow oil (36%); ir (thin film): 1750; ^{1}H nmr δ: 7.4–7.1 (m, 5H), 4.5 (s, 1H), 4.32 (d, J_{AB} = 12.25, 1H), 3.70 (d, J_{AB} = 12.25, 1H), 2.7–2.4 (m, 4H), 1.9–1.6 (m, 4H), 1.49 (s, 3H), 0.77 (s, 3H); ms: 258 (M^+).

Azetidin-2-one 31

To an ethanolic solution of 3.44 g of **30** at 0°C was added 1.01 g of $NaBH_4$ and the resulting solution stirred for 1 h at 0°C until the evolution of hydrogen had ceased. An excess of acidic Amberlite resin was then added at once and this suspension stirred for 1/2 h at 0°C. The resin was then filtered off and the ethanol removed under reduced pressure. The resulting white solid was washed with ethyl acetate to remove boron compounds, filtered, and the ethyl acetate removed under reduced pressure. This process was repeated with CH_2Cl_2 to give 1.60 g (84%) of **31** as white crystals, mp 72°C (lit. (22) mp 73–74°C).

*1-*tert*-Butyldimethylsilylazetidin-2-one 12*

A solution of 1.60 g of **31**, 3.72 g of *tert*-butyldimethylsilyl chloride and 3.76 mL of triethylamine in 20 mL DMF was stirred at 0°C for 1/2 h. The amine hydrochloride was filtered off and 40 mL of water added to the filtrate. This solution was extracted with ether (4 × 50 mL) and the combined ether fractions washed with water. Drying over $MgSO_4$ followed by removal of solvent under reduced pressure gave a pale yellow oil, which was distilled (75–77°C/1 Torr) to give 2.54 g (61%) of **12** as a colorless liquid; ir (thin film): 1745; ^{1}H nmr δ: 3.22 (t, J = 4.90, 2H), 3.00 (t, J = 4.90, 2H), 0.93 (s, 9H), 0.21 (s, 6H); ms: 185 (M^+), 128 (base peak) (M^+ − 57). *Anal.* calcd. for $C_9H_{19}NOSi$: C 58.38, H 10.27, N 7.57; found: C 58.02, H 10.24, N 7.33.

*4-Ethyl-1-*tert*-butyldimethylsilylazetidin-2-one 13*

4-Vinylazetidin-2-one **32** (2.87 g) was stirred in methanol with 100 mg of 10% Pd/C under H_2 at atmospheric pressure until 333 mL of H_2 had been consumed (2 h). The solution was then filtered and the methanol removed under reduced pressure. The pale yellow oil containing residual catalyst was purified by column chromatography to give 91% of **13** as a clear, colorless liquid; ir (thin film): 1750; ms: 213 (M^+), 156 (base peak) (M^+ − 57). *Anal.* calcd. for $C_{11}H_{23}NOSi$: C 61.97, H 10.80, N 6.57; found: C 62.07, H 10.66, N 6.44.

*General procedure for the preparation of 3-trimethylsilyl-1-*tert*-butyldimethylsilylazetidin-2-ones: 15, 16, 17*

A solution of *tert*-butyldimethylsilylazetidin-2-one (**12**, **13**, **11**) in THF was added to 1.2 equivalents of LDA generated *in situ* from diisopropylamine and *n*-butyllithium (ca. 2.5 M in hexane) in THF at −78°C. After 10 min, 1.2 equivalents of freshly distilled trimethylsilyl chloride was introduced and the mixture stirred at −78°C for an additional 10–20 min. The solution was then quenched with saturated NH_4Cl and extracted twice with ether. The combined extracts were washed with H_2O and dried over $MgSO_4$ before the solvent was removed under reduced pressure.

*3-Trimethyl-1-*tert*-butyldimethylsilylazetidin-2-one 15*

A portion of **12** (1.07 g) was treated as described above to give 1.49 g (96%) of **15** as a clear colorless oil. This material was used without further purification; ir (thin film): 1730; ^{1}H nmr δ: 3.26 (t, J = 5.93, 1H), 2.94–2.86 (m, 2H), 0.92 (s, 9H), 0.19 (s, 3H), 0.18 (s, 3H), 0.09 (s, 9H); ms: 257 (M^+), 242 (M^+ − 15), 200 (M^+ − 57).

*3-Trimethylsilyl-4-ethyl-1-*tert*-butyldimethylsilylazetidin-2-one 16*

Compound **13** (525 mg) gave 585 mg (83%) of **16** after flash chromatography; ir (thin film): 1730; ^{1}H nmr δ: 3.21–3.18 (m, 1H), 2.42 (d, J = 2.63, 1H), 1.90–1.80 (m, 1H), 1.40–1.30 (m, 1H), 0.93 (s, 9H), 0.85 (t, J = 7.44, 3H), 0.18 (s, 3H), 0.17 (s, 3H), 0.09 (s, 9H); ms (chemical ionization (CI)): 286 (base peak) (M^+ + 1). *Anal.* calcd. for $C_{14}H_{31}NOSi$: C 58.95, H 10.88, N 4.91; found: C 59.23, H 10.69, N 4.63.

*3-Trimethylsilyl-4-thiophenyl-1-*tert*-butyldimethylsilylazetidin-2-one 17*

Azetidin-2-one **11** (1.04 g) gave 980 mg (75%) of **17** after flash chromatography (75%); ir (thin film): 1740, 1580; ^{1}H nmr δ: 7.46–7.43 (m, 2H), 7.34–7.30 (m, 3H), 4.64 (d, J = 2.38, 1H), 2.89 (d, J = 2.39, 1H), 0.98 (s, 9H), 0.25 (s, 3H), 0.23 (s, 3H), −0.03 (s, 9H). *Exact Mass* (hrms) calcd. for $C_{12}H_{26}NOSi$: 256.1552; found: 256.1532 (M^+ − 109).

General procedure for the preparation of 3-alkylideneazetidine-2-ones 18–29

To a solution of 1.2 equivalents of LDA in THF (prepared as above) was added a solution of 3-trimethylsilyl-1-*tert*-butyldimethylsilyl-azetidin-2-one (**15**, **16**, **17**) in THF at −78°C. After stirring for 10 min, 1.5 equivalents of aldehyde was added to the golden yellow solution via syringe. The resulting mixture was stirred for 10–20 min and then quenched with saturated NH_4Cl, extracted twice with ether, washed with water, and dried over $MgSO_4$. Removal of solvent under reduced pressure gave a syrup, which was purified by flash chromatography. In all cases, the *Z*-isomers **18–23** were eluted before the *E*-isomers **24–29**.

From 664 mg of **15** and 50% excess propionaldehyde was obtained 203 mg (33%) of **18** and 181 mg (31%) of **24** as clear colorless oils. For **18**: ir (thin film): 1730; ^{1}H nmr δ: 5.52 (t, J = 8.4, 1H), 3.60 (s, 2H), 2.48 (quint, J = 8.5, 2H), 1.02 (t, J = 8.4, 3H), 0.92 (s, 9H), 0.20 (s, 6H); ms: 225.1 (M^+), 168 (base peak) (M^+ − 57). *Anal.* calcd. for $C_{12}H_{25}NOSi$: C 64.00, H 10.22, N 6.22; found: C 64.12, H 10.08, N 6.19. For **24**: ir (thin film): 1740; ^{1}H nmr δ: 6.11 (t, J = 7.5, 1H), 3.75 (s, 2H), 2.10 (quint, J = 7.5, 2H), 1.05 (t, J = 7.5, 3H), 0.95 (s, 9H), 0.24 (s, 6H); ms: 225.1 (M^+), 168 (base peak) (M^+ − 57). *Anal.* calcd. for $C_{12}H_{23}NOSi$: C 64.00, H 10.22, N 6.22; found: C 64.09, H 10.29, N 6.07.

From 164 mg of **15** and 50% excess hydrocinnamaldehyde was obtained 57.2 mg (35%) of **19** and 38.6 mg (23%) of **25**, both as clear colorless oils. For **19**: ir (CH_2Cl_2): 1720; ^{1}H nmr δ: 7.29–7.16 (m, 5H), 5.54 (t, J = 8.5, 1H), 3.59 (s, 2H), 2.84–2.75 (m, 4H), 0.93 (s, 9H), 0.22 (s, 6H); ms: 301 (M^+), 244 (89.2) (M^+ − 57). *Exact Mass* (hrms) calcd. for $C_{18}H_{27}NOSi$: 301.1860; found: 301.1870. For **33**: ir ($CHCl_3$): 3600, 1605, 1551; ^{1}H nmr δ: 9.0 (b, 1H), 7.45–7.36 (m, 5H), 6.77 (d, J = 15.25, 1H), 0.86 (s, 9H), 0.30 (s, 9H), 0.14 (s, 3H); ms (CI): 366 ($M^+ + 1$). *Exact Mass* (hrms) calcd. for $C_{12}H_{26}NOSi_2$: 356.1552; found: 256.1532 ($M^+ - 109$).

From 468 mg of **17** and 50% excess hydrocinnamaldehyde was obtained 81 mg (15%) of **23** and 61 mg (12%) of **27**, both as clear colorless oils; 127 mg of **33** (27%) was also obtained in the fastest fractions. For **23**: ir (thin film): 1740; ^{1}H nmr δ: 7.42–7.36 (m, 5H), 7.28–7.20 (m, 5H), 5.54 (t, J = 7.8, 1H), 5.24 (s, 1H), 2.83–2.73 (m, 4H), 0.96 (s, 9H), 0.29 (s, 3H), 0.245 (s, 3H); ms (CI): 410 ($M^+ + 1$), 300 (base peak) ($M^+ - 109$). *Exact Mass* (hrms) calcd. for $C_{18}H_{26}NOSi$: 300.1782; found: 300.1760 ($M^+ - 109$). For **27**: ir (thin film): 1750; ^{1}H nmr δ: 7.42–7.36 (m, 10H), 6.00 (t, J = 8.1, 1H), 4.98 (s, 1H), 2.80–2.45 (m, 4H), 0.93 (s, 9H), 0.26 (s, 3H), 0.22 (s, 3H); ms (CI): 410 ($M^+ + 1$), 300 (base peak) ($M^+ - 109$). *Exact Mass* (hrms) calcd. for $C_{18}H_{26}NOSi$: 300.1782; found: 300.1775 ($M^+ - 109$).

General procedure for MoOPH hydroxylations

To a solution of LDA (1.2 equivalents) in THF at −78°C was added a solution of 3-alkylidene-1-*tert*-butyldimethylsilylazetidin-2-one **10**, **18**, **19**, **20**, **21** in THF. After stirring for 10 min, 1.5 equivalents of MoOPH was added at once. The solutions immediately turned orange or blue. Following MoOPH addition, the acetone bath was removed and the solution stirred until clear (10–15 min). Once MoOPH dissolution was complete, the solution was quenched with 10% Na_2SO_3, extracted twice with ether, washed with 10% HCl, dried over $MgSO_4$, and the solvent removed under reduced pressure. Products were purified by flash chromatography.

10: From 100 mg of **9** was obtained 71 mg (67%) of **10** as a white solid, which was recrystallized from ethyl acetate, mp 145°C; ir (thin film): 3600, 1750; ^{1}H nmr δ: 7.33–7.17 (m, 5H), 7.24 (d, J_{AB} = 9.07, 2H), 6.78 (d, J_{AB} = 9.07, 2H), 5.59 (dd, J_{AB} = 17.34, J_{AX} = 11.10, 1H), 5.47 (dd, J_{AB} = 17.34, J_{BX} = 0.92, 1H), 5.18 (dd, J_{AX} = 11.10, J_{BX} = 0.92, 1H), 5.10 (s, 1H), 3.74 (s, 3H); ms: 295 (M^+). *Exact Mass* (hrms) calcd. for $C_{18}H_{17}NO_3$: 295.1207; found: 295.1244.

35: From 95 mg of **18** was obtained 41.2 mg (41%) of **35** as a clear colorless oil; ir (CH_2Cl_2): 3550, 1642; ^{1}H nmr δ: 5.96 (dq, J_q = 6.47, J_d = 15.50, 1H), 5.67 (dd, J = 1.74, 15.50, 1H), 3.33 (d, J_{AB} = 6.05, 1H), 3.28 (d, J_{AB} = 6.05, 1H), 1.73 (dd, J = 1.59, 6.47, 3H), 0.93 (s, 9H), 0.24 (s, 3H), 0.21 (s, 3H); ms (CI): 242 (base peak) ($M^+ + 1$). *Anal.* calcd. for $C_{12}H_{23}NO_2Si$: C 59.75, H 9.54, N 5.81; found: C 59.86, H 9.56, N 6.00.

36: From 161.5 mg of **19** was obtained 52 mg (31%) of **36** as a clear colorless oil; ir ($CHCl_3$): 3500, 1740; ^{1}H nmr δ: 7.29–7.14 (m, 5H), 6.12 (dt, J_d = 15.57, J_t = 6.75, 1H), 5.72 (dt, J_d = 15.54, J_t = 1.54, 1H), 3.41 (dd, J = 6.05, 2H), 3.34 (d, J_{AB} = 6.11, 1H), 3.30 (d, J_{AB} = 6.11, 1H), 2.78 (s, 1H), 0.91 (s, 9H), 0.24 (s, 3H), 0.21 (s, 3H); ms (CI): 318 ($M^+ + 1$). *Anal.* calcd. for $C_{18}H_{27}NO_2Si$: C 68.14, H 8.52, N 4.42; found: C 67.99, H 8.93, N 4.38.

37: From 159 mg of **20** was obtained 90 mg (53%) of **37** as a white solid, mp 99°C. Recrystallization from hexanes did not change the melting point; ir ($CHCl_3$): 3500, 1740; ^{1}H nmr δ: 5.95 (dq, J_d = 15.62, J_q = 6.53, 1H), 5.59 (dd, J = 1.65, 15.62, 1H), 3.45 (dd, J = 3.17, 11.45, 1H), 2.64 (s, 1H), 1.77 (dd, J = 1.60, 6.51, 3H), 1.7–1.6 (m, 1H), 1.5–1.4 (m, 1H), 0.94 (s, 9H), 0.88 (t, J = 7.35, 3H), 0.25 (s, 3H), 0.22 (s, 3H); ms: 269 (M^+), 212 (9.3) ($M^+ - 57$). *Anal.* calcd. for $C_{14}H_{27}NO_2Si$: C 62.45, H 10.04, N 5.20; found: C 62.65, H 10.22, N 5.20.

38: From 290 mg of **21** was obtained 100 mg (33%) of **38** as a white solid, which was recrystallized from hexane, mp 101°C; ir ($CHCl_3$): 3300, 1730; ^{1}H nmr δ: 7.30–7.21 (m, 5H), 6.11 (dt, J_d = 15.56, J_t = 6.62, 1H), 5.61 (dt, J_d = 15.61, J_t = 1.55, 1H), 3.48–3.42 (m, 3H), 2.60 (s, 1H), 1.7–1.6 (m, 1H), 1.4–1.3 (m, 1H), 0.92 (s, 9H), 0.86 (t, J = 7.41, 3H), 0.24 (s, 3H), 0.21 (s, 3H); ms: 345 (M^+), 288 (10) ($M^+ - 57$). *Anal.* calcd. for $C_{20}H_{31}NO_2Si$: C 69.56, H 8.98, N 4.06; found: C 69.30, H 8.98, N 3.92.

3-Ethyl-3-hydroxy-4-phenyl-1-(4-methoxyphenyl)-azetidin-2-one ***11***

Compound **10** (71 mg) in THF was stirred with 21 mg of 10% PtO_2 under an atmosphere of H_2 at atmospheric pressure for 1 h. The solution was then filtered through a pad of Celite and the solvent removed under reduced pressure to give 73 mg (100%) of **11** as a white solid melting at 130°C. Recrystallization from ethyl acetate did not change the melting point; ir (KBr): 3400, 1720; ^{1}H nmr δ: 7.33–7.23 (m, 5H), 7.21 (d, J_{AB} = 9.04, 2H), 6.77 (d, J_{AB} = 9.04, 2H), 4.99 (s, 1H), 3.73 (s, 3H), 1.57 (sextet, J = 7.45, 1H), 1.37 (sextet, J = 7.27, 1H), 0.84 (t, J = 7.45, 3H); ^{13}C nmr δ: 168.68 (s), 156.20 (s), 134.27 (s), 130.45 (s), 128.67 (d), 128.25 (d), 126.98 (d), 119.15 (d), 114.19 (d), 87.93 (s), 69.50 (d), 55.33 (q), 25.08 (t), 6.84 (q). *Exact Mass* (hrms) calcd. for $C_{18}H_{19}NO_3$: 297.1363; found: 297.1367.

Reçu le 14 juin 1987

ANDRÉ DEHNEL, JOLANTA M. KANABUS-KAMINSKA et GILBERT LAVIELLE. Can. J. Chem. **66**, 310 (1988).

Les anions des aza-2 allylphosphonates **1** se combinent avec les esters α,β-insaturés **2** en donnant les intermédiaires chargés **4'**. Ces intermédiaires conduisent à la suite de protonation aux diéthoxyphosphonyl-2 éthoxycarbonyl-4 pyrrolidines **4**, ou bien à la suite de l'élimination de l'anion du diéthylphosphonate aux éthoxycarbonyl-4 Δ^1-pyrrolines **5**. Les proportions de ces deux produits dépendent des conditions de la réaction et de l'encombrement de substrats. La formation de produits cycliques a été étudiée pour de nombreux substrats et en présence de diverses bases. La réaction est régiosélective et stéréospécifique et l'obtention d'un diastéréoisomère cinétique plus encombré permet de déterminer que c'est une cycloaddition concertée. Les diastéréoisomères thermodynamiques moins encombrés **6** et **7** sont obtenus à partir de **4** et **5** respectivement par l'action d'une base dans un milieu protique. Les autres épimères de **4**, composés **8** et **9**, ont été obtenus par l'addition de diéthylphosphite sur les pyrrolines **5** et **7**. Les pyrrolines **5** ont été réduites pour donner les éthoxycarbonyl-3 pyrrolidines **12**. L'isomérisation de pyrrolines **5** possédant un substituant phényle dans la position 5 mène vers les éthoxycarbonyl-3 phényl-2 Δ^1-pyrrolines **10**. Ces dernières s'oxydent spontanément avec l'oxygène de l'air jusqu'au éthoxycarbonyl-3 hydroxy-3 phényl-2 Δ^1-pyrrolines **11**.

ANDRÉ DEHNEL, JOLANTA M. KANABUS-KAMINSKA, and GILBERT LAVIELLE. Can. J. Chem. **66**, 310 (1988).

The anions of the 2-azaallylphosphonates **1** react with the α,β-unsaturated esters **2** to yield the intermediates **4'**. These intermediates form the 2-diethoxyphosphonyl-4-ethoxycarbonylpyrrolidines **4** following a protonation while an elimination of the anion of the diethylphosphonate leads to the 4-ethoxycarbonyl-Δ^1-pyrrolines **5**. The proportions of these two products vary with the experimental conditions and the bulkiness of the substrates. The formation of the cyclic products has been studied for numerous substrates and in the presence of a number of bases. The reaction is regioselective and stereospecific and on the basis of the formation of the kinetically more strained diastereoisomer it is possible to conclude that the cycloaddition is a concerted one. The thermodynamically less strained diastereoisomers **6** and **7** are obtained from the compounds **4** and **5** respectively when they are subjected to the action of a base in a protic media. The other epimers of **4**, the compounds **8** and **9**, have been obtained by the addition of diethylphosphite to the pyrrolines **5** and **7**. The pyrrolines **5** have been reduced to the 3-ethoxycarbonylpyrrolidines **12**. The isomerization of the pyrrolines **5** with a phenyl substituent in position 5 leads to the formation of the 3-ethoxycarbonyl-2-phenyl-Δ^1-pyrrolines **10**. The latter spontaneously oxidize with atmospheric oxygen to yield the 3-ethoxycarbonyl-3-hydroxy-2-phenyl-Δ^1-pyrrolines **11**.

[Journal translation]

Introduction

Les aza-2 allylphosphonates **1** se sont avérés de précieux intermédiaires de synthèse. Grâce à la présence de deux groupes activants leurs anions se forment aisément sous l'action de diverses bases. Ces carbanions ont trouvé une première application dans une séquence, comprenant leur acylation, menant vers la synthèse de céphalosporines (1). Par la suite nous avons étudié leur alkylation (2, 3), leurs réactions de type Wittig–Horner avec les dérivés carbonylés (3, 4) et enfin les réactions avec les esters α,β-insaturés menant vers des composés cycliques (3, 5). Le présent travail est consacré à l'étude détaillée de cette dernière réaction. Elle donne, d'une manière régiosélective et stéréospécifique, accès aux diéthoxyphosphonyl-2 éthoxycarbonyl-4 pyrrolidines **4** ainsi qu'aux éthoxycarbonyl-4 Δ^1-pyrrolines **5** (cf. schéma 1) (3, 5). Les Δ^1-pyrrolines, intermédiaires de synthèse très intéressants, sont difficilement accessibles par une autre voie (5*a*, 6).

Dans ce travail, nous analyserons l'influence des conditions opératoires sur le déroulement de la réaction et, par ce moyen, le mécanisme réactionnel. D'autre part nous étudierons certaines transformations des Δ^1-pyrrolines.

Résultats

A. Cycloadditions

La réaction entre les carbanions formés à partir des imines **1** et les esters α,β-insaturés **2** (schéma 1) a été étudiée sur de nombreux exemples (tableau 1). Comme il est indiqué dans le schéma 1 elle peut mener vers trois produits : le composé linéaire **3** provenant de l'addition de Michael, la pyrrolidine **4** et la pyrroline **5**, obtenues à partir de l'intermédiaire **4'**, respectivement par sa protonation et par l'élimination de l'anion du diéthylphosphonate. L'obtention du composé **3** étant accessoire, nous nous concentrerons sur les conditions de synthèse des deux produits principaux.

À l'issue de la cycloaddition nous obtenons la pyrrolidine et tant que diastéréoisomère unique **4** possèdant les groupes éthoxycarbonyle et phosphonyle orientés mutuellement *cis* et également *cis* par rapport au substituant R^2 (s'il est plus encombrant que R^3). De même nous obtenons une seule Δ^1-pyrroline **5**. Or, si on tient compte de l'asymétrie uniquement dans les positions 2, 4 et 5, les pyrrolidines résultant

*Obtenu sur une autre voie. Les autres : rendements de produits purifiés.

cinétiques plus encombrés que les produits thermodynamiques obtenus par l'équilibration. C'est une information importante pour déterminer le mécanisme de la cycloaddition.

La structure de pyrrolidines obtenues dans ces réactions a été établie à l'aide de la spectroscopie de la rmn (*5b*).

1. Conditions de préparation de produits cycliques

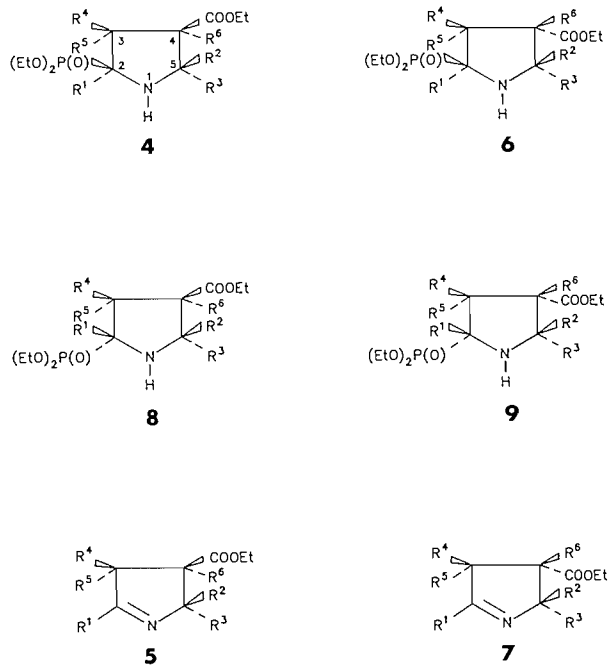
La cycloaddition a été réalisée selon deux procédés différents présentés ci-dessous.

(*a*) La réaction entre les composés du type **1** et les composés du type **2** en présence de quantités catalytiques de l'hydrure de sodium à température ambiante et arrêtée par l'addition de l'eau donne les pyrrolidines **4** avec d'excellents rendements (cf. tableau 2). Elle reste cependant limitée aux substrats possèdant en tant que R^2 un substituant aromatique. Dans ces conditions on n'observe pas la formation de pyrrolines **5**.

(*b*) Les carbanions des imines **1** sont formés par l'action du butyllithium ou du diisopropylamidure de lithium, habituellement à −70°C. L'ester α,β-insaturé est ajouté à la même température. La réaction est arrêtée par l'addition de l'eau à la température indiquée. La composition du mélange résultant dépend de la nature des substrats et de cette température. Les conditions et les rendements de produits **4** et **5** dans ces réactions sont présentés dans le tableau 1.

De l'examen de ces résultats on peut tirer les conclusions suivantes :

(*i*) Le taux d'élimination du diéthylphosphite, menant vers la formation du produit **5**, est généralement plus élevé dans les



Dans les cas ou $R^2 = R^3$ et $R^4 = R^5$, l'isomérie *cis–trans* n'existant pas, les produits sont arbitrairement joints à la classe *cis*.

SCHÉMA 2

For personal use only.

réactions où le carbanion est obtenu avec du butyllithium en comparaison au LDA (*h*, *l*, *m*).

(*ii*) Pour la même base, la proportion de produit d'élimination **5** croît avec la température d'hydrolyse (*c*, *i*).

(*iii*) D'une manière générale, les esters éthyléniques **2**, très encombrés en position β (par exemple, cyclohexénylacétate d'éthyle, cf. *m* et *t*), ne réagissent pas à la température de −70°C. La réaction a lieu dans ce cas entre −70°C et 0°C et la proportion de la pyrroline **5**, par rapport à la pyrrolidine **4**, est élevée.

(*iv*) L'encombrement de l'imine **1** semble être le facteur limitatif de la cycloaddition. Ainsi le produit **5***q* est obtenu avec le rendement de 77% accompagné de 18% du produit linéaire **3***q*, tandis que l'imine **1** avec R^2 = *tert*-butyle et R^3 = méthyle dans les mêmes conditions uniquement l'adduit de Michael **3**.

Dans certains cas nous avons réalisé des cycloadditions dans des conditions différentes :

(*i*) Les produits **4***a* et **4***c* sont obtenus, avec des bons rendements, en présence de défaut de base (environ 20% mol de BuLi ou LDA) par rapport à l'imine **1**. Les réactions, avec les mêmes substrats réalisées dans des conditions standard, donnent dans le cas *a* le mélange contenant des produits de polycondensation de l'acrylate d'éthyle, dans le cas *c* un mélange de produits dont nous parlerons dans le paragraphe suivant.

(*ii*) Si nous essayons de synthétiser le produit **4***l* en menant la réaction entièrement à −90°C, l'anion étant formé au butyllithium, nous obtenons essentiellement le produit linéaire **3***l*. Les produits cycliques sont cependant obtenus dans la réaction réalisée à température plus élevée.

(*iii*) Dans certains cas (*c* et *e*) de réactions réalisées à température comprise entre −70°C et −100°C (le carbanion étant préparé au butyllithium) nous obtenons à part les produits habituels **4** et **5** également leurs diastéréoisomères **6** et **7** ainsi que les produits linéaires **3**.

Le tableau 3 donne les résultats de synthèse de produits *c* dans des conditions variables.

Pour pouvoir expliquer ces anomalies nous avons réalisé quelques expériences qui ne sont pas des cycloadditions à proprement parler : (*i*) Le produit **4***c*, obtenu préalablement, en présence d'un équivalent de butyllithium à −100°C se transforme en produit linéaire **3***c* avec le rendement de 30%. On n'observe pas cette ouverture du cycle en présence de LDA. (*ii*) L'adduit de Michael **3***e*, obtenu sur une autre voie, soumis à l'action d'un équivalent de LDA à −70°C donne le produit *trans* **7***e* avec le rendement de 70%.

2. *Mécanisme de formation de produits cycliques*

Deux mécanismes peuvent expliquer la formation de produits cycliques : cycloaddition concertée ou bien la formation d'un intermédiaire linéaire **3** et sa cyclisation. La formation, dans la majeure partie des cas pour les trois bases utilisées, d'un produit unique cinétique semble indiquer un mécanisme concerté. Pour étayer cette hypothèse, en ce qui concerne les réactions en présence de l'hydrure de sodium, hous avons vérifié que les produits linéaires **3**, obtenus sur une autre voie, ne se cyclisent pas sous l'action de cette base.

La formation, dans certains cas particuliers, du mélange de produits comprenant les composés *trans* doit s'expliquer par la cyclisation d'un intermédiaire linéaire. L'exemple présenté dans le tableau 3 nous montre l'influence de la température sur la composition du mélange réactionnel. La pyrroline *trans* **7***c* obtenue à température élevée ne peut pas provenir directement

TABLEAU 3. Rendements de pyrrolidines et pyrrolines ayant les substituants *c* obtenues dans des conditions variables

Température (°C)		Rendement (%)				
		cis		*trans*		Linéaire
add.	hyd.	**4**	**5**	**6**	**7**	**3**
−100	−100	70	10*			10*
−100	+35		40		25	
−70	0	20	25	15	10	

*Les rendements estimés par la rmn. Les autres : rendements de produits purifiés.

de cyclisation car à basse température nous observons uniquement les produits *cis*. Elle ne peut non plus être le résultat d'une épimérisation, le substituant R^6 étant un méthyle. La seule explication de sa formation est donc l'ouverture de l'intermédiaire **4***c*′ et sa cyclisation en produit *trans*.

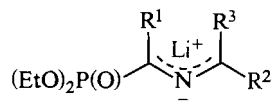
Pour certains substrats, à une température de l'ordre de −100°C, la formation de l'adduit de Michael est énergétiquement plus favorable que la cycloaddition. Dans ces cas les produits *trans* peuvent provenir de la cyclisation secondaire de ces intermédiaires.

Il nous faut donc conclure que les produits cycliques sont obtenus par deux voies différentes dont la première est unique dans le cas de l'hydrure de sodium et généralement prédominante :

(1) Cycloaddition concertée conduisant d'une façon stéréospécifique (7), avec un bon rendement, au produit unique cinétique, peu stable.

(2) Cyclisation d'un produit linéaire menant vers un mélange de produits. Le rendement est généralement faible car c'est une cyclisation du type 5-*endo*–*trig* qui est géométriquement défavorisée (8).

Quel que soit le mécanisme de la fermeture du cycle le produit formé possède toujours le groupe phosphonyle en position *cis* par rapport à R^2 plus volumineux que R^3. Ce fait explique par la stabilité de la conformation *trans*–*trans* du carbanion **1**′ (7) :



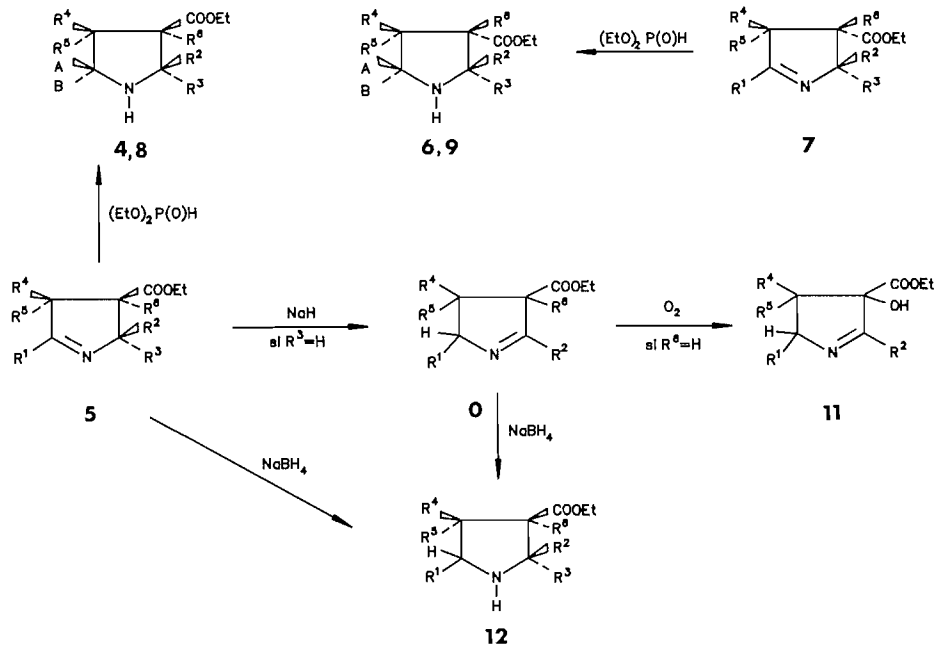
3. *Les transformations des amidures* **4**′

Dans les cas où le substituant R^2 est un phényle la cycloaddition peut avoir lieu en présence de quantités catalytiques de base. Ceci signifie que l'amidure cyclique **4**′, formé en petite quantité, est suffisamment basique pour déprotoner les molécules suivantes du substrat **1** et ainsi perpétuer la réaction (9).

Nous observons dans ce cas une réaction univoque car l'amidure **4**′ protoné par le substrat **1** ne peut plus évoluer dans le sens de l'élimination de l'anion phosphonate ou de l'ouverture du cycle.

D'une façon analogue, une plus faible tendance à l'élimination du diéthylphosphite et l'absence de produits *trans* dans le cas de réactions réalisées en présence de LDA indiquent que l'intermédiaire **4**′ est protoné par la diisopropylamine.

La β élimination des anions phosphoniques, que nous observons, est beaucoup mieux connue pour les esters des acides α-hydroxyalkylphosphoniques (10) que pour les composés azotés (11).



4 et **6** : A = $(EtO)_2P(O)$, B = R^1
8 et **9** : A = R^1, B = $(EtO)_2P(O)$

B. Transformations de Δ^1-pyrrolines 5 et 7

Les pyrrolines **5** et **7** peuvent subir certaines transformations qui soit présentent un intérêt théorique (éclaircissement de la structure de produits synthétisés), soit peuvent avoir une application pratique dans la synthèse. Les trois transformations que nous avons étudiées sont visualisées dans le schéma 3.

1. Addition du diéthylphosphite

Parmi quatres diastéréoisomères possibles de pyrrolidines étudiées deux seulement sont obtenus par la cycloaddition (ou cycloaddition suivie d'épimérisation). Afin de pouvoir déterminer indubitablement la structure des pyrrolidines, nous avons synthétisé les diastéréoisomères manquants en faisant réagir les pyrrolines **5** et **7** avec le diéthylphosphite. À l'issue de cette réaction nous avons obtenus les mélanges de pyrrolidines **4** et **8** (en partant de **5**) ou **6** et **9** (en partant de **7**) dont la composition est indiquée dans le tableau 4.

Le groupe phosphonyle a tendance à s'additionner sur la face opposée au carboxyle. Ainsi nous obtenons les pyrrolidines **6***c*, **6***l*, **8***h* et **8***m* en tant que produits uniques. Cette tendance peut être contrebalancée par la présence des autres substituants encombrants et nous constatons alors la formation de mélanges (cf. tableau 4).

2. Préparation de pyrrolines isomérisées 10 et leur oxydation

Sous l'action de l'excès de l'hydrure de sodium les pyrrolines **5** et **7**, si elles possèdent un atome d'hydrogène en tant que substituant R^3, sont transformées en pyrrolines **10**. Pratiquement nous réalisons plutôt une séquence ininterrompue de réactions qui en partant de **1** et **2**, en présence de l'hydrure de sodium, abouti à la formation de **10**. Le produit de cycloaddition **4** formé initialement s'épimérise jusqu'au **6**, celui-ci subit l'élimination du diéthylphosphonate de sodium pour donner la pyrroline **7**, qui à la suite de la migration de la double liaison donne la pyrroline **10**.

Dans des cas où le substituant R^1 est un phényle, cette séquence s'arrête au stade de l'élimination, la migration de la double liaison n'ayant pas lieu. Ainsi nous obtenons dans des conditions identiques le produit **7***g* avec le rendement de 60% et, dans une autre expérience, le mélange de 25% de produit **5***k* avec 42% de **7***k*.

Ces résultats signifient que la migration de la double liaison a lieu s'il en résulte un système plus stable où la double liaison C=N est conjuguée avec le noyau aromatique. Dans le cas où un tel système existe à l'origine, l'isomérisation ne se fait pas.

Les produits **10** obtenus ainsi sont des huiles. Exposés à l'air ils s'oxydent spontanément, si le substituant R^6 est un atome d'hydrogène, pour donner les dérivés hydroxylés cristallins **11**. Nous avons obtenu de cette manière les produits **11***a*, **11***b*, **11***d* et **11***m*.

L'oxydation spontanée de composés semblables est connue (12).

3. Réductions menant vers les pyrrolidines 12

La réduction de pyrrolines **5** et **10** au borohydrure de sodium donne, avec un excellent rendement, les pyrrolidines **12**. Ont été obtenus : les produits **12***p–u* par la réduction de pyrrolines **5** correspondantes, ainsi que **12***a* par la réduction du composé **10***a*. Dans tous ces cas on obtient le produit ayant le substituant

R^2 en position *cis* par rapport au carboxyle. Dans le cas de la réduction de produits du type **5**, la stéréochimie est sauvegardée et la réduction de composés du type **10***a* conduit à des produits avec la même stéréochimie, l'approche du borohydrure se faisant du coté moins encombré, c'est-à-dire opposé au groupe carboxyle.

Conclusion

La nouvelle méthode de synthèse, présentée dans ce travail, permet d'obtenir un grand nombre de produits difficilement accessibles entre autres d'intéressants composés spiranniques ou polycycliques.

Le choix judicieux de conditions permet d'orienter la réaction vers des pyrrolidines ou des pyrrolines.

Les transformations de produits initialement obtenus offrent d'intéressants débouchés synthétiques.[4]

L'analyse détaillée de produits obtenus a permis de proposer un mécanisme réactionnel pour la cycloaddition.

Partie expérimentale

Les points de fusion ont été déterminés sur le banc de Kofler. Les analyses élémentaires ont été effectuées au Laboratoire central de microanalyse du Centre national de la recherches à Thiais ou par le Laboratoire de sciences biologiques du Conseil national de recherches du Canada à Ottawa. Les spectres rmn du proton ont été enregistrés sur le spectromètre Hitachi Perkin–Elmer R-24B, 60 MHz, et sur le spectromètre Bruker WP-80 FT, 80 MHz. Ce dernier appareil a servi également pour enregistrer les spectres du ^{13}C à 20.15 MHz. Les chromatographies sur couche mince (ccm) ont été réalisées sur gel de silice G type Merck 60 F-254 en plaques prêtes à l'emploi. L'éluant utilisé est un mélange chlorure de méthylène – méthanol 90 : 10 et le révélateur utilisé est le réactif de Dragendorff. Les chromatographies sur colonne ont été effectuées sur gel de silice 60 0,2–0,5 mm, Merck; l'éluant est habituellement le chlorure de méthylène pur ou mélangé avec 1–5% de méthanol.

Les α-aminoalkylphosphonates de diéthyle ont été préparés par des méthodes connues : aminométhylphosphonate de diéthyle (1), α-aminoéthylphosphonate de diéthyle (13) et phénylaminométhylphosphonate de diéthyle (14).

Les imines **1** ont été préparées par la réaction entre les α-aminoalkylphosphonates et dérivés carbonylés appropriés. Le composé **1** R^1 = H, R^2 = R^3 = Me est préparé par la réaction entre 1 mol de aminométhylphosphonate de diéthyle et 10 mol d'acétone à température ambiante pendant 48 h en présence de 30 g de tamis moléculaires du type 5Å. Les tamis sont filtrés, la solution évaporée et l'imine **1**, obtenue sous forme d'huile, est utilisée brute dans l'étape suivante. Dans tous les autres cas une mole de α-aminoalkylphosphonate est mise en présence d'une mole de dérivé carbonylé dans 500 mL de benzène. Dans le cas de l'acétophénone on ajoute 0,5 g de l'acide *p*-toluènesulfonique. La solution est chauffée à l'ébullition et l'eau formée séparée dans le séparateur de phases (Dean–Stark). Le temps de réaction varie de 0,5 jusqu'à 4 h. Le solvant est évaporé (si l'acide *p*-toluènesulfonique est employé la solution est lavée préalablement avec la solution saturée du bicarbonate de sodium, de l'eau et séchée). Les imines **1** obtenues, sous forme d'huile, avec un rendement de 92–98% sont utilisée brutes.

Cycloadditions en présence de l'hydrure de sodium

Une solution de 20 mmol de l'aza-2 allylphosphonate **1** et de 20 mmol de l'ester éthylénique **2** dans 30 mL de THF est ajoutée, sous agitation (cf. tableau 1 pour la température), en une seule fois, à une suspension de 0,2 g (4 mmol) d'hydrure de sodium dans 50 mL de THF. Une augmentation de température de l'ordre de 10°C est observée. Quand la température commence à diminuer, le mélange est refroidi à la glace et traité avec 50 mL d'une solution aqueuse de chlorure d'ammonium à 10%. La couche organique est séparée et la couche aqueuse extraite avec de l'éther. Les extraits réunis sont séchés sur sulfate de sodium et évaporés sous pression réduite. La pyrrolidine **4** est purifiée par recristallisation dans l'éther isopropylique ou transformée en picrate.

Les conditions de réaction, les rendements de pyrrolidines **4** et les données analytiques sont indiqués dans le tableau 2. Les données rmn des produits qui n'ont pas été publiées auparavant (5*b*) sont rapportées dans le tableau 5.

Cycloaddition des sels lithiens des carbanions de 1

Une solution de 20 mmol de l'aza-2 allylphosphonate **1** dans 30 mL de THF est ajoutée, goutte à goutte, à une solution dans le THF de 20 mmol (ou 4 mmol dans certains cas indiqués dans le tableau 1) de butyllithium, ou bien de LDA préparée préalablement. Cette addition est effectuée en atmosphère inerte, sous agitation, à la température indiquée dans le tableau 1. La solution devient rouge carmin. Ensuite, à la même température, est additionnée une solution de 20 mmol d'ester **2** dans 20 mL de THF. La réaction est suivie en rmn et terminée par l'addition de l'eau à la température indiquée dans le tableau 1. La couche organique est séparée et la couche aqueuse extraite avec de l'éther. Les extraits réunis sont séchés sur sulfate de sodium et évaporés sous pression réduite. Dans le cas où un des produits est nettement majoritaire il est séparé par la cristallisation dans l'éther isopropylique ou par la formation du picrate. Dans le cas contraire les produits sont séparés par la chromatographie sur silice. Les rendements sont indiqués dans le tableau 1, les donnés analytiques de pyrrolidines **4** dans le tableau 2, leurs données rmn dans le tableau 5, les données analytiques et rmn de pyrrolines **5** dans le tableau 6.

4. Les auteurs présenteront bientôt un travail concernant l'obtention des nitrones par l'oxydation des pyrrolidines **12**.

Épimérisation de dérivés cis ***4*** *et* ***5***

La pyrrolidine **4** ou la pyrroline **5** est soumise à l'action d'une quantité équimolaire de la solution 1 M d'éthylate de sodium dans l'éthanol à température ambiante. La réaction est suivie en ccm. Le mélange réactionnel est concentré sous vide jusqu'à un tiers du volume initial et dilué avec l'éther. La solution résultante est lavée avec de l'eau, séchée sur du sulfate de sodium et le solvant évaporé sous pression réduite. Le résidu, pyrrolidine **6** ou pyrroline **7**, est purifié par recristallisation de l'éther isopropylique ou par formation du picrate. Les rendements sont de 80–90%. Le taux de transformation *cis–trans* est habituellement de 75 à 100%. Les données analytiques pour les pyrrolidines **6** sont rapportées dans le tableau 7, leur données rmn dans le tableau 5. Les données analytiques et rmn de pyrrolines **7** se trouvent dans le tableau 6.[5]

Préparation de l'adduit de Michael ***3***e

Une quantité (0,9 mL) de solution éthanolique de Triton B (2 mmol) est diluée avec 30 mL de benzène anhydre et on lui ajoute 20 mmol de l'imine **1** (R^1 = Me, R^2 = Ph, R^3 = H). Ensuite, une solution de 20 mmol d'acrylate d'éthyle dans 10 mL de benzène est ajoutée goutte à goutte, à la température de 15°C. Après 1 h le mélange réactionnel est traité par 15 mL de la solution saturée de chlorure d'ammonium et lavé à l'eau. La phase organique est séchée et le solvent est évaporé sous pression réduite. Le rendement est de 90%. Le produit ***3****e* obtenu

5. Les pyrrolines **7** se distinguent facilement des pyrrolines **5** grâce à la différence de déplacements chimiques de groupes éthyles d'ester respectivement *cis* et *trans* par rapport à R^2 si celui-ci est un phényle (*5b*); cf. tableau 6*a*.

contenant environ 5% de produit cyclique **6***e* est utilisé brut. δ H, ppm (CCl_4/TMS) : 1,0–1,4 (9H, m, 3 Me), 1,43 (3H, d $^3J_{HP}$ = 16 Hz, Me), 2,0–2,5 (4H, m, $(CH_2)_2$), 3,6–4,3 (6H, m, 3 OCH_2), 7,0–7,3 et 7,6–7,8 (2H et 3H, m, Ph), 8,20 (1H, d $^4J_{HP}$ = 5 Hz, HC=N).

Cyclisation de l'adduit de Michael **3**e

L'adduit de Michael **3***e* est additionné à une solution d'une quantité équimolaire de LDA dans le THF à −70°C. La température est remontée jusqu'à −10°C et l'eau est additionnée. La couche organique est séparée et la couche aqueuse extraite trois fois à l'éther. Les extraits réunis sont séchés et le solvant évaporé sous pression réduite. Le mélange obtenu, comprenant la pyrrolidine **6***e* et les pyrrolines **5***e* et **7***e*, est séparé par chromatographie. Le rendement en pyrroline **7***e* est de 70%.

Ouverture du cycle de la pyrrolidine **4**c

Une solution de 10 mmol de pyrrolidine **4***c* dans 30 mL de THF est ajoutée à une solution de 13 mmol de butyllithium dans 50 mL de THF à −100°C. Le spectre rmn d'un échantillon prélevé indique la présence du produit linéaire **3***c* (bande imine à 8,2 ppm). Le mélange est réchauffé progressivement (1,5 h) jusqu'à +35°C. La composition du mélange en fonction de la température, déterminée d'après les spectres rmn, est la suivante : température (°C), part de **4***c*, **5***c*, **6***c*, **7***c*, **3***c* (%) : −100, 70, 0, 0, 0, 30; −55, 60, 15, 5, 5, 15; −10, 45, 30, 10, 15, 0; +35, 20, 40, 20, 20, 0. Le traitement habituel donne 2,3 g de mélange qui est séparé par chromatographie.

Addition du diéthylphosphite sur les pyrrolines **5** *et* **7**

La pyrroline **5** ou **7** est chauffée avec cinq équivalents du diéthylphosphite à 130°C pendant 3 h. La réaction est suivie en ccm. Après être refroidi le mélange réactionnel est traité avec l'acide chlorhydrique à 5% et la solution ainsi obtenue est extraite avec deux portions d'éther. Ensuite elle est rendue basique par addition de carbonate de potassium et extraite trois fois à l'éther. L'extrait éthéré est séché sur sulfate de sodium et le solvant est évaporé sous pression réduite. Le résidu (comprenant les pyrrolidines, cf. tableau 4) est purifié par recristallisation de la base ou du picrate, ou bien par chromatographie. Les rendements de diastéréoisomères obtenus sont indiqués dans le tableau 4, les données analytiques dans le tableau 7 en rmn dans le tableau 5.

Préparation de pyrrolines ***10***

Une solution de 20 mmol de **1** et de 20 mmol d'ester éthylénique **2** dans 40 mL de THF est ajoutée à une suspension de 22 mmol

d'hydrure de sodium dans 50 mL de THF. Après la fin de la réaction exothermique, le mélange est porté à l'ébullition (cf. tableau 8). Ensuite, il est refroidi et traité avec 50 mL d'une solution de chlorure d'ammonium à 10%. La couche organique est séparée et la couche aqueuse extraite avec de l'éther. Les extraits réunis sont séchés et le solvant évaporé sous pression réduite. Le résidu, pyrrolidine **10**, est transformé en picrate et celui-ci recristallisé. Les conditions de réaction ainsi que les résultats analytiques et rmn sont présentés dans le tableau 8.[6]

Les hydroxy pyrrolines **11** sont obtenues par oxydation spontanée de pyrrolines **10**. À la suite de l'exposition de ces dernières à l'action de l'air pendant plusieurs jours est observée la transformation de l'huile en masse semi-cristalline. Celle-ci est cristallisée dans l'éther isopropylique et recristallisée dans ce solvant ou l'acétate d'éthyle. Les rendements sont d'environ 85%. Les données analytiques et rmn sont rassemblées dans le tableau 8.[6]

Les pyrrolidines **12** sont préparées par réduction des pyrrolines **5** au borohydrure de sodium dans l'éthanol (pour éviter la transestérification).

12*l* : rendement 90%; δ H, ppm (CCl_4/TMS) : 0,88 (3H, t, Me), 1,05 (3H, d, R^5 = Me), 1,60 (3H, s, R^3 = Me), 2,3–3,3 (4H, m), 3,70 (2H, q, OCH_2), 7,25 (5H, m, Ph). Picrate, *F* (éthanol) 167°C. $C_{21}H_{24}N_4O_9$ (476,41) calculé/trouvé : C 52,94/52,77; H 5,08/5,04; N 11,76/11,74.

R. J. DeVoe, M. R. V. Sahyun, Einhard Schmidt, N. Serpone, and D. K. Sharma. Can. J. Chem. **66**, 319 (1988).

We have studied the anthracene-sensitized photolyses of both diphenyliodonium and triphenylsulphonium salts in solution using both steady-state and laser flash photolysis techniques. Photoproducts, namely, phenylated anthracenes along with iodobenzene or diphenylsulphide, respectively, are obtained from both salts with quantum efficiencies of ca. 0.1 at 375 nm. We infer the intermediacy of diphenyliodo and triphenylsulphur radicals formed by single electron transfer from the singlet-excited anthracene. We have developed a quantitative model of this chemistry, and identify the principal sources of inefficiency as back electron transfer, which occurs at nearly the theoretically limiting rate, intersystem crossing from the initially formed sensitizer–'onium salt encounter complex, and in-cage radical recombination.

R. J. DeVoe, M. R. V. Sahyun, Einhard Schmidt, N. Serpone et D. K. Sharma. Can. J. Chem. **66**, 319 (1988).

Faisant appel aux techniques de l'état stationnaire et de la photolyse laser éclair, on a étudié la photolyse sensibilisée par l'anthracène des sels de diphényliodonium et de triphénylsulfonium en solution. Pour chacun des sels, à 375 nm, les efficacités quantiques en photoproduits, soit des anthracènes phénylés ainsi que respectivement de l'iodobenzène et du sulfure de diphényle, sont d'environ 0,1. On en déduit que les radicaux diphényliodo- et triphénylsoufre se forment comme intermédiaires par le transfert d'un électron de l'anthracène excité singulet. On a développé un modèle quantitatif de cette chimie et on a identifié que les principales causes de l'inefficacité sont un transfert en retour d'électron qui se produit à une vitesse proche de la limite théorique, un passage intersystème se produisant à partir du complexe de rencontre sensibilisateur–sel onium qui se forme initialement et une recombinaison radicalaire se produisant dans la cage.

[Traduit par la revue]

Introduction

'Onium cations, especially diaryliodonium and triarylsulphonium, are used in the photoinitiation of both radical and cationic polymerizations (1–3). Technologically useful spectral response requires that the photolyses of the 'onium salts are spectrally sensitized, as the 'onium salts themselves absorb light significantly only below ca. 280 nm. A photoinduced electron transfer mechanism is usually proposed for this sensitization (1–3), although recent results (4) indicate that a triplet energy transfer pathway is also feasible. In this study we concentrate on the electron transfer pathway, in which decomposition of the 'onium salts proceeds from the corresponding heteroatom-centered free radicals (1), vis-a-vis direct photolysis, in which reaction occurs from an excited state of the cation, thought to be the lowest triplet, at least in the case of diphenyliodonium cation (4).

We are specifically seeking to provide a mechanism for the initial steps of the photoreaction, which accommodates the observed discrepancies between reported (1) high quantum yields for solution photolyses and low quantum yields for photoinitiation of radical polymerization (5), and which identifies the photon energy-loss pathways, so they can be engineered out of applied photoinitiation systems. We employ both quantum yield and product studies on steady state photolyses, as well as photo-CIDNP (Chemically Induced Dynamic Nuclear Polarization) and picosecond laser flash spectroscopy, and concentrate our efforts on the diphenyliodonium and triphenylsulphonium hexafluorophosphate salts in acetonitrile (AN) with anthracene sensitization.

The fate(s) of the radicals formed subsequent to 'onium cation decomposition in the sensitized photolyses is beyond the scope of the present investigation.

Results and discussion

Photo-CIDNP studies

Photoinduced electron transfer yields singlet or triplet radical pairs. In studies on the model systems in acetonitrile-d_3, strong photo-CIDNP signals were observed,[3] similar to the photo-CIDNP spectra shown in Fig. 1. Iodonium salt, present at the 0.1 *M* level, appears as a strong emission (ca. 8.1 ppm), as does benzene (7.38 ppm). No signals are observed corresponding to iodobenzene, anthracene, or anthracene-derived photoproducts, owing in the latter two cases to exchange broadening by interaction of arene radical cations with the neutral hydrocarbons (6). Only benzene emission was observed when the sulphonium salt replaced iodonium under our conditions.

Photo-CIDNP results may be interpreted in accordance with Kaptein's Rules (7), whereby

$$\text{Net polarization} = \mu\epsilon\Delta g a_{\text{H}}$$

where μ is positive for a triplet radical pair precursor of the product in which the polarization is observed and negative for a singlet precursor, and ϵ is defined as positive for (in-cage) recombination products and negative for cage escape products. The other two factors in the vector model correspond to the difference between the so-called *g*-factors of the precursor radicals and the hyperfine coupling constant for the protons for

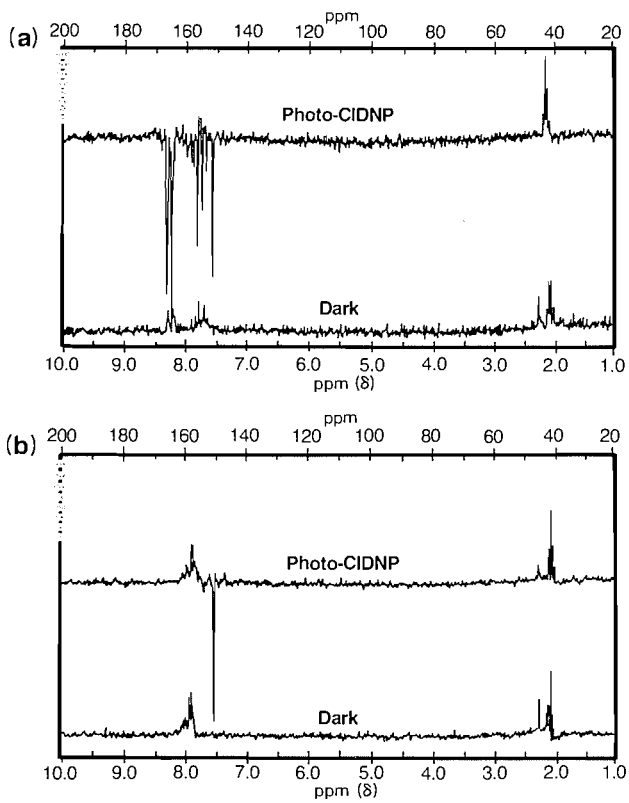

FIG. 1. Photo-CIDNP and dark spectra of electron transfer sensitized photodecompositions of (*a*) diphenyliodonium hexafluorophosphate and (*b*) triphenylsulphonium hexafluorophosphate in AN. For purpose of clarity, spectra shown here were obtained with 0.05 *M* perylene as sensitizer. (See Experimental section of text.)

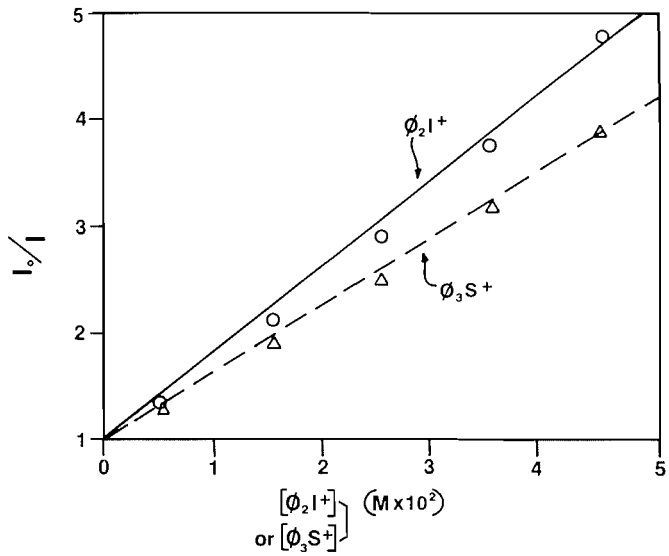

FIG. 2. Stern–Volmer plot for quenching of anthracene fluorescence by diphenyliodonium (○) and triphenylsulphonium (△) hexafluorophosphates in AN.

which the CIDNP signal is observed. As emission is observed for *both* the recombination product, iodonium salt, and the cage-escaped benzene, we infer from the opposite signs of ϵ in the two cases that these two products must result, at least in part, from radical pairs of opposite multiplicity. (Alternatively, the same signs for the two observed polarizations may reflect opposite signs for the product of Δg in the two precursor radical pairs and a_H in the corresponding emitters. This possibility was rendered unlikely by carrying out the photo-CIDNP experiment with Michler's Ketone, 4,4′-bis(*N*,*N*-dimethylamino)benzophenone, as sensitizer, which sensitizes exclusively from its triplet state (8), i.e. yields only triplet radical pairs. In this case net emission was again observed for the iodonium cation, but net absorption was observed for benzene, opposite to the result obtained with anthracene.

We accordingly hypothesize that the benzene is a cage-escaped product from a singlet radical pair ^{1}(anthracene$^{+\bullet}$/$C_6H_5^\bullet$). On the basis of the observed emission from *all* protons, we tentatively assign the iodonium salt polarization to back electron transfer by magnetic-field induced T_-–S_0 mixing (7) in the triplet radical pair, ^{3}(anthracene$^{+\bullet}$/$Ph_2I^\bullet$). To the extent that it competes with formation of ^{1}(anthracene$^{+\bullet}$/$C_6H_5^\bullet$) from ^{1}(anthracene$^{+\bullet}$/$Ph_2I^\bullet$), back electron transfer entirely within the singlet manifold would be expected to be transparent to CIDNP, insofar as it derives from hyperfine interactions. In this case we expect the in-cage decomposition of diphenyliodo (or triphenylsulphur) radical to be rapid compared to cage escape (see below), and no spin-sorting pathway is thus available (7*c*).

As the extent of the magnetic-field induced T_-–S_0 mixing is dependent on the magnitude of the spin–orbit coupling at the transition center (sulphur or iodine), the accessibility of the triplet pathway for recombination under photo-CIDNP conditions is greatly reduced in the sulphonium salt system compared to the iodonium (7*b*, 9). Apparently only the CIDNP-transparent recombination pathway is available to the (anthracene$^{+\bullet}$/$Ph_3S^\bullet$) pair.

Fluorescence quenching

Anthracene is an efficient fluorophore and the quenching of its fluorescence provides one probe of the sensitizing interactions with the 'onium salts. The quenching may occur by either or both of two pathways: (*a*) electron transfer to the 'onium salt (1), which on the basis of the relationship established by Rehm and Weller (10), we expect to occur at a diffusion limited rate; and (*b*) external heavy atom induced intersystem crossing, which is also thought to require contact between the excited molecule and the heavy atom containing species (9).

Quenching of anthracene fluorescence in acetonitrile (AN) solution in the presence of up to 0.05 *M* of either the iodonium or the sulphonium salt obeyed the Stern–Volmer relationship (11), as shown in Fig. 2. The slopes were 84 M^{-1} and 64 M^{-1}, respectively, compared with a theoretical value for diffusion control of 90 M^{-1}, calculated as the product of the bimolecular diffusion constant in AN, 2×10^{10} L s^{-1}, and the lifetime of the singlet excited state of anthracene, 4.5 ± 0.2 ns, as measured in our laboratory by time-correlated single photon counting.

On the other hand, with 1-iodopropane, which could quench *only* by the external heavy atom effect, a Stern–Volmer slope of 22 M^{-1} was found. Less than diffusion-controlled quenching implies a competition between intersystem crossing and escape of the reagents from the encounter complex of the excited sensitizer with the quencher, occurring at the characteristic solvent reorganization rate for AN, namely 5×10^8 s^{-1} (12). The intersystem crossing frequency in the encounter complex is accordingly ca. 1×10^8 s^{-1}. *If* a comparable intersystem crossing frequency also applies to the interaction of photoexcited anthracene with iodonium cation, the intersystem process is slow compared with exergonic electron transfer (10, 13).

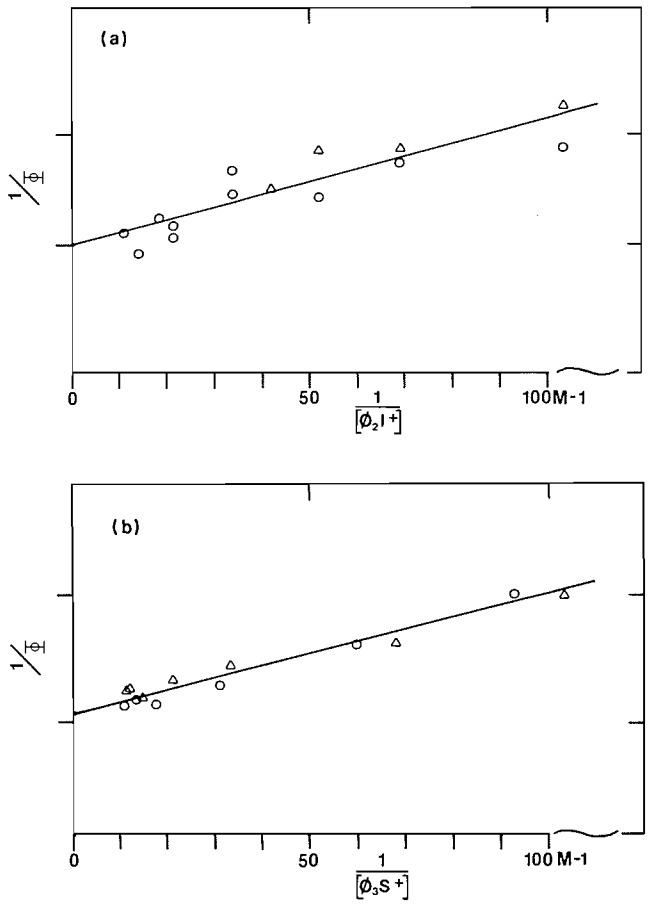

FIG. 3. Double reciprocal plots for anthracene sensitized photolyses of (*a*) diphenyliodonium and (*b*) triphenylsulphonium hexafluorophosphates in AN; (△) designates appearance of (*a*) iodobenzene or (*b*) diphenyl sulphide, and (○) designates disappearance of anthracene.

Accordingly we infer that sensitizer intersystem crossing, mediated by the heavy atom in the iodonium cation is a potential, though minor, source of inefficiency in the sensitized iodonium salt photolyses.

Quantum yields

Two probes proved useful in following the anthracene-sensitized photolyses at 375 ± 10 nm of either 'onium salt in AN: (*a*) iodobenzene or diphenyl sulphide could be quantitated by glc with reference to a dodecane internal standard: (*b*) alternatively, anthracene disappearance could be monitored spectrophotometrically, e.g. at 374 nm. Quantum yields obtained by the two methods were in agreement within experimental error for both salts; thus anthracene disappearance is stoichiometric with 'onium salt decomposition. Additionally, the photolyses were not oxygen sensitive; there was no difference in the quantum yields whether or not the solutions were deoxygenated by prolonged passage of dry argon prior to photolysis.

Double reciprocal plots of quantum yield data are shown in Figs. 3(*a*) and (*b*) for the iodonium and sulphonium salts, respectively. When sensitization (electron or energy transfer) occurs by diffusion controlled, collisional interaction of sensitizer and acceptor, the intercepts of such plots are the reciprocals of the limiting quantum yields, Φ_0, at infinite concentration of the acceptor (14), i.e., 'onium salt. These parameters are 0.10 ± 0.02 for the iodonium salt and 0.09 ± 0.01 for the sulphonium, and are substantially lower than reported by Pappas *et al.* (1) but in agreement with recent results of Timpe and Bah (28).[4]

The reciprocal of the product of the slope of the plot and Φ_0 should be equal to the slope of the Stern–Volmer plot from the quenching experiment under the same conditions, providing the photochemistry follows from collisional interaction of excited sensitizer with the 'onium acceptor. Accordingly the Stern–Volmer slopes estimated from the plots of Figs. 3(*a*) and (*b*) are 92 ± 24 M^{-1} and 109 ± 35 M^{-1}, in order-of-magnitude agreement with the values obtained by fluorescence quenching (Fig. 2).

Analysis of the reaction products (ca. 20% conversion) by capillary glc coupled with mass spectrometry[5] indicated that phenylanthracenes were the only *identifiable* anthracene products--one major isomer and small quantities of two others. The alteration of the absorption spectrum of the reaction mixture between 340 and 400 nm on irradiation with either salt could be accounted for by consumption of anthracene and generation of a product with a similar absorption spectrum but red-shifted by ca. 12 nm, consistent with 9-phenylanthracene (15). From the extinction coefficients, ca. 40% of the consumed anthracene appeared to become 9-substituted. On the other hand, quantitative glc (which did not separate the phenylanthracene isomers) indicated 55 ± 9% of the lost anthracene was present as the mixture of isomeric phenylanthracenes; the discrepancy between these two estimates represents the minor products, which must be the 1- and 2-phenylanthracenes. The fate of the rest of the anthracene consumed in the photoreaction was undetermined.

When anthracene-sensitized photolysis of the diphenyliodonium salt (0.05 M) was carried out in the presence of 1-iodopropane (1 M), Φ for iodobenzene formation was 0.0045 ± 0.0005. This concentration of 1-iodopropane reduced the anthracene fluorescence intensity to 4.3% by intersystem crossing, i.e., by the same factor as the photolysis quantum yield was reduced. We infer that sensitization occurs only from singlet photoexcited anthracene, even though electron-transfer sensitization of the iodonium cation by triplet anthracene may be energetically feasible (1). This interpretation is consistent with the absence of oxygen inhibition of the photochemistry.

Picosecond studies

Formation of the anthracene radical cation in the quenching of photoexcited anthracene by diphenyliodonium cation was followed on the ps time scale; a deoxygenated solution 4 × 10^{-4} M in anthracene and 0.10 M in the iodonium salt in AN was photolyzed with a ca. 30 ps pulse of 355 nm radiation from a mode-locked, frequency tripled Nd-YAG laser. Typical time-resolved absorption spectra of the quenching reaction over the continuum 425–675 nm are shown in Figs. 4(*a*) and (*b*).

The transient species absorbing at 565 and 610 nm is singlet-excited anthracene (16). It disappears with a pseudo-first order rate constant of ca. 3 (±1) × 10^9 s^{-1}, consistent with the diffusion-limited quenching of the anthracene fluorescence. An additional peak at close to 675 nm is consistent with the absorption of solvated electron, often observed in laser flash photolyses under these conditions (17); this species is also responsible for broad absorption across the visible region.

The absorption seen at ca. 430 nm is assigned to triplet

[4]We thank Professor S. P. Pappas for bringing this reference to our attention.

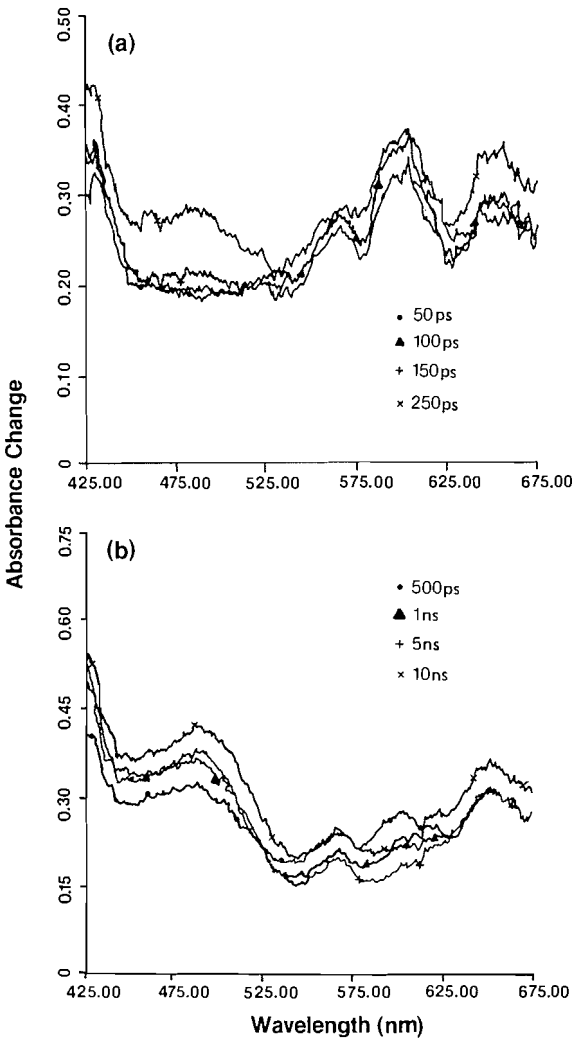

FIG. 4. Transient visible absorption spectra observed following anthracene sensitized laser flash photolysis of diphenyliodonium hexafluorophosphate in AN; (*a*) time scale 50–250 ps; (*b*) time scale 0.5–10 ns.

anthracene (18). A significant portion of this absorption apparently arises during the laser irradiation (<50 ps); the band does not grow in appreciably above the baseline of other overlapping absorptions after 500 ps, i.e. the apparent subsequent increase in absorbance at 430 nm appears to be more related to the increase in the broad-based absorbance underlying the sharp triplet band. This observation is consistent with the inference, above, that anthracene intersystem crossing is not a significant consequence of collisional interactions between photoexcited anthracene molecules and the iodonium cation. More to the point, the triplet does not appear to be consumed over the time scale of the observations. This observation supports the inference that triplet excited anthracene does not sensitize the 'onium salt photolysis, nor does a triplet exciplex (which would provide a deactivation pathway) form on diffusional encounter between triplet anthracene and iodonium cation.

Anthracene radical cation, generated by intense X-ray exposure of anthracene in a boric acid glass, absorbs primarily at 475 and 714 nm (19). In methylene chloride solution the anodically generated cation radical absorbs at 440 and 725 nm (20). The longer wavelength in both cases is outside the continuum probed in our experiment; however, we can assign the ca. 480 nm absorption to the radical ion. This transient grows in over the first 2 ns following the laser pulse, as shown in Fig. 5, with a

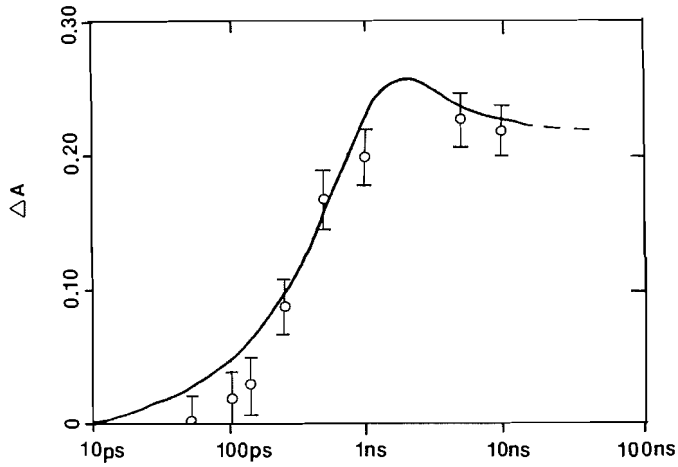

FIG. 5. Time evolution of 480 nm absorbing transient in anthracene-sensitized laser flash photolysis of diphenyliodonium hexafluorophosphate in AN; solid line is computer fit of the experimental data using parameters in Table 1 (see text).

pseudo-first order rate constant (evaluated from a plot of $\ln \Delta A$ vs. t, where ΔA is the absorbance at 480 nm above the absorbance minimum at 540 nm, read from the digital output of the vidicon (21)) of $1.9 \pm 0.3 \times 10^9\ s^{-1}$; conversion of photoexcited anthracene to its radical cation is thus diffusion controlled for a solution 0.10 *M* in the 'onium electron acceptor.

Preliminary experiments involving the laser flash photolysis of anthracene in the presence of the triphenylsulphonium cation indicate analogous results in this system.

Computer modelling

We propose the mechanistic scheme of Fig. 6 as containing all the elements necessary to rationalize the experimental results. The singlet-excited anthracene forms an encounter complex with the iodonium cation, from which the electron transfer photochemistry occurs.

Quantitative description of the system apparently requires specification of twelve rate constants: as the value for k_2 we take the estimate for the frequency of external heavy atom induced intersystem crossing inferred from the iodopropane quenching experiment, $1 \times 10^8\ s^{-1}$; k_{10} may be evaluated as "fast", i.e. $\geq 10^{10}\ s^{-1}$, on the basis of the Rehm–Weller treatment (10). (The triplet radical pair must, however, live for at least tens of ps for its reaction products to yield a CIDNP signal (22).) The processes described by k_7 and k_8 do not appear to contribute significantly to the observed chemistry, and they may be ignored; numerical evaluation (below) demonstrates that no more than 0.5% of the total excitation is dissipated by the pathway involving k_8. The constant k_1 is the rate constant for diffusional encounter and k_5, k_7, and k_{11} are the solvent cage relaxation rate constant, $5 \times 10^8\ s^{-1}$ for AN (12).

The problem then reduces to evaluation of four rate constants, k_3, k_4, k_6, and k_9, along with the product of the extinction coefficient for anthracene radical cation at 480 nm and the initial concentration of singlet photoexcited anthracene, $\epsilon[A^*]$ (cm^{-1}), in order to fit the time evolution of the six usable ΔA values of Fig. 5, as well as the quantum yields for iodobenzene and phenylanthracene formation. In the iodonium case, k_6 is a composite of the rate constants for the rate-determining steps of both direct and indirect (magnetic field-induced spin inversion) pathways leading to back electron transfer. In the absence of a heavy atom, the pathway involving a ground state spin flip in the radical pair should not contribute significantly, i.e. k_6 will be

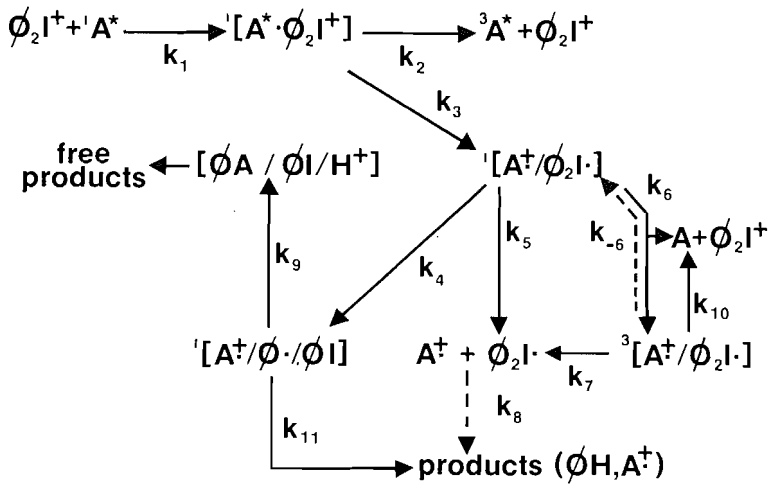

FIG. 6. Reaction scheme to account for the observations on anthracene-sensitized photolysis of diphenyliodonium cation. We propose that a similar scheme, without intervention of a triplet radical pair, applies to photolysis of triphenylsulphonium cation.

TABLE 1. Parameters of the mechanistic scheme of Fig. 6

Variable	Model value	Experimental value
Parameters		
k_1	2×10^{10} [Ph_2I^+] s^{-1}	
k_2	1×10^8	
k_3	1×10^9	
k_4	5×10^9	
k_5	5×10^8	
k_6	5×10^{10}	
k_9	1×10^9	
k_{11}	5×10^8	
ϵ[A*]	60 cm^{-1}	
Responses		
Φ_0 (PhI)	0.090	0.10 ± 0.02
Φ_0 (PhA)	0.054	0.055 ± 0.010
d ln [A^+]/dt	2.1×10^9 s^{-1}	$1.9 \pm 0.3 \times 10^9$ s^{-1}

dominated by the direct back electron transfer process. This inference is consistent with the CIDNP results, above, which indicate that no spin sorting is involved in back electron transfer from the sulphonium cation.

Differential equations describing the time dependence of the concentrations of the various intermediates in the scheme of Fig. 6 were numerically integrated for various values of the four adjustable rate constants in order to obtain "best fit" values. We assumed that both singlet radical pairs as well as the triplet pair, along with cage-escaped anthracene radical cation, contributed to the observed transient absorption, and that the lifetime of the cage-escaped species was long relative to the time scale of interest (≤ 10 ns). These "best fit" values and comparisons with experimental probes are reported in Table 1, and the evolution of the anthracene radical cation absorbance, with ϵ[A*] = 60 cm^{-1}, predicted by the model is shown in Fig. 5. The calculations proved quite sensitive to the *relative* values of the adjustable parameters, but less so to their *absolute* values; the numbers thus ought to be taken as order of magnitude estimates of the rate constants.

From the reciprocal of k_4, the upper-limiting lifetime under these conditions of the hypothetical (1) diphenyliodo radical intermediate, with respect to decomposition, is at most a few hundred picoseconds. In the photolysis of diphenyliodonium iodide (4), we observed a transient with broad absorption centering on 550 nm which lasted for ca. 250 ps after the laser pulse. On the basis of the present estimate for the lifetime of the diphenyliodo radical, we now suspect that a minor fraction of the *CT excited iodode salt dissociated to this radical and iodine atom, analogous to the known (23) photochemistry of triphenylsulphonium iodide, giving rise to the 550 nm transient. We estimate the energy of the lowest energy allowed transition in diphenyliodo radical to be approximately 2.25 eV (by analogy to the S_3–S_1 separation in the cation), consistent therewith.

Formation of iodobenzene in-cage at a rate much greater than cage escape is consistent with the lack of a photo-CIDNP signal from it (7, 22). The value of k_6 is in the range expected for exergonic, adiabatic electron transfers (13, 24) and observed in the radical pair formed from photolysis of the anthracene–TCNE complex (20). The value for k_9 likewise compares with the rate constant observed for in-cage combination in the anthracene–tetranitromethane system (20).

Conclusions

The anthracene-sensitized photolysis of either diphenyliodonium or triphenylsulphonium cation depends on collisional interaction between photoexcited anthracene and the 'onium cation; long range interactions, even though theoretically feasible (25), do not appear to contribute to the observed chemistry.

From the point of view of photogeneration of technologically useful free radicals, there are one major and two minor loss pathways: back electron transfer (k_6), which proceeds at close to the theoretically limiting rate with both salts; external heavy atom induced anthracene intersystem crossing (k_2); and in-cage combination of the phenyl radical and anthracene radical cation photoproducts (k_9).

Experimental

Materials and methods

Diphenyliodonium hexafluorophosphate (3), mp 136°C, and triphenylsulphonium hexafluorophosphate (3), mp 200–203°C, were purified by recrystallization from *iso*-propanol. The latter salt was shown to be free from thioether sulphonium salts.

Spectral quality, glass-distilled acetonitrile (EM Omni-Solv^R) was used for solution preparation. Scintillation grade anthracene, mp 214–217°C, exhibited a fluorescence lifetime of 4.5 ± 0.2 ns, as measured by time-correlated single photon counting (PRA System

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.222.148.141 on 09/07/12
For personal use only.

3000), compared to the literature value of 4.9 ns (26). High resolution glc coupled with mass spectrometry (15) indicated low level (<1%) contamination with various alkylanthracenes, before and after irradiation experiments. The 1-iodopropane, bp 100–102°C, was used as received from MC&B, Ltd., as was the acetonitrile-d_3 (Cambridge Isotopes).

Fluorescence intensities were recorded on a Perkin Elmer MPF-44B fluorescence spectrophotometer. The data for the Stern–Volmer plots, Fig. 2, are based on emission intensities of 0.1 m*M* anthracene solutions at 403 nm, excited by 375 nm radiation; the photomultiplier was protected with a 390 nm cutoff filter.

Photo-CIDNP

The photo-CIDNP spectra were obtained using the proton probe on a Varian XL-100 magnetic resonance spectrometer, with the probe modified to allow direct irradiation of the sample at the receiver coil.[3] Typical sample composition was 0.01 *M* 'onium salt and ca. 0.05 *M* (saturated) anthracene or perylene in acetonitrile-d_3. The signals observed with these two sensitizers were qualitatively identical with respect to all features; stronger signals, hence better signal-to-noise characteristics in the spectra as recorded, were obtained using perylene, owing to the higher light absorptivity of its solutions. The light source was a 300 W Xe arc operating at full power, focused on the receiver coil using quartz optics on an optical rail. Heating of the sample was a problem, as infrared filtration decreased the light intensity too much to observe CIDNP. Consequently, photo-CIDNP spectra were recorded in the Fourier transform mode of the XL-100, collecting two transients over ca. 5 s exposure time, during which heating was minimal. Samples (2 mL volume) were deoxygenated by nitrogen purge, and dark spectra were taken before and after irradiation.

Quantum yields

Quantum yields were measured with no more than 10% conversion of anthracene on solutions 3×10^{-4} *M* in anthracene and 0.01–0.10 *M* in the 'onium salt. The solutions were deoxygenated by dry argon purge, as required. Aliquots (3 mL) in a 1 cm quartz spectrophotometer cell were irradiated at 375 ± 10 nm on an optical bench with light from the Xe arc lamp, passed through a monochromator with the slits adjusted to allow a 20 nm bandpass. The output of the source was calibrated by means of potassium ferrioxalate actinometry (27) and continuously monitored with a radiometer. Typical fluxes of 6×10^{17} photons s^{-1} required 2 min irradiation in order to yield ca. 10% conversion. Ultraviolet absorption spectra were recorded on the samples in the reaction vessel before and after irradiation.

The spectrophotometric quantum yields for anthracene disappearance were based on observed changes in optical density at 340, 356, and 374 nm, corrected for absorption at these wavelengths by the product 9-phenylanthracene (16), measured at ca. 10% conversion. For glc analyses, the photolysis mixtures obtained after up to 10% conversion were diluted with 5 mL of 1 *M* aq. sodium chloride and extracted with 1 mL cyclohexane containing 1×10^{-4} *M* dodecane as internal standard.

Laser flash photolyses

The instrumentation used for these experiments has already been described in detail (21). The double beam, mode-locked Nd-YAG laser system employed a silicon intensified target vidicon detector. Light pulses at 355 nm were obtained by frequency-tripling; typical irradiances were ca. 2 mJ per pulse focused to a 2 mm diameter spot on the face of a 2 mm quartz sample cuvette. The pulse width was 30 ps (FWHM). Individual experiments utilized 0.6 mL aliquots of solutions 4×10^{-4} *M* in anthracene and 0.10 *M* in the 'onium salt; the solutions were deoxygenated by dry argon purge prior to irradiation.

Conductance measurements were used to identify and to obtain association constants for the complexes formed between cyclodextrins (CD) with emphasis on β-cyclodextrin (βCD), and surfactants such as sodium dodecylsulfate (SDS) and tetradecyltrimethyl ammonium bromide. With both anionic and cationic surfactants, αCD forms predominantly a 2:1 CD/surfactant complex while with both βCD and γCD the main species is 1:1. γCD binds much less strongly with surfactants than both αCD and βCD. Cyclodextrins destroy micelles by complexing the surfactant monomers more strongly than they are bound in self-association.

RAMAMURTHY PALEPU et VINCENT C. REINSBOROUGH. Can. J. Chem. **66**, 325 (1988).

On a utilisé des mesures de conductance pour identifier et pour obtenir les constantes d'association des complexes qui se forment entre des cyclodextrines (CD) et des agents de surface, principalement entre la β-CD et le dodécylsulfate de sodium (DSS), tant au-dessous qu'au-dessus de la concentration micellaire critique. Tant avec les agents de surface anioniques que cationiques, la α-CD forme principalement un complexe 2:1 de CD:agent de surface; par ailleurs, les β- et γ-CD forment principalement des complexes 1:1. La γ-CD se lie moins fortement que les α- et β-CD avec les agents de surface. Par comparaison avec leurs propres auto-associations, les cyclodextrines complexent avec les agents de surface monomères plus fortement que les monomères se complexent avec lui-mêmes et elles détruisent ainsi les micelles.

Introduction

Cyclodextrins form inclusion complexes with a variety of solutes usually with a 1:1 stoichiometry (1). More recently, a number of 2:1 cyclodextrin-substrate complexes have been characterized (2). With surfactants, a 1:1 stoichiometry is usually presumed (3–5) but Hersey and co-workers (6) have demonstrated that α-cyclodextrin binds with alkylsulphate anions in a 2:1 ratio. The object of this study was to determine the binding ratio of β-cyclodextrin to various surfactants and to ascertain the effect this inclusion process had upon micellization. Conductance measurements were undertaken to determine the stoichiometry and association constants of cyclodextrin-surfactant inclusion complexes in the pre-cmc and post-cmc regions (cmc = critical micelle concentration). Most of the work was done with β-cyclodextrin (βCD) with some comparison results being also obtained with α-cyclodextrin (αCD) and γ-cyclodextrin (γCD). The chief surfactant studied was sodium dodecylsulphate (SDS) with sodium decylsulphate (SDeS), sodium octylsulphate (SOS), tetradecyltrimethylammonium bromide (TTAB) and dodecylammonium chloride (DAC) also receiving attention.

Experimental

Conductometric measurements were obtained with a Radiometer CDM83 Bridge together with a CDM 304 Immersion Cell thermostatted at 25.0°C. Cyclodextrins were obtained from Sigma Chemical and the surfactants were the best available commercially.

Results and discussion

Figure 1 shows the effect upon the molar conductances of pre-micellar sodium dodecylsulphate (SDS) solutions of adding β-cyclodextrin (βCD). Four SDS systems were studied in the pre-micellar region (cmc = 8×10^{-3} mol dm^{-3}) with one, 2.00×10^{-3} mol dm^{-3} SDS, being omitted from the diagram for the sake of clarity. The molar conductance decreased sharply as βCD was added presumably because the dodecyl sulfate ion having been complexed by βCD was less effective as a charge carrier. Na^+ ion is not thought to be complexed by βCD to any extent (7). At a certain concentration in βCD, this linear decrease of molar conductance with βCD concentration halted rather abruptly to show no or little further decrease with further βCD additions. The stoichiometry at which this halt occurred was 1.2:1 βCD:SDS for 1.00×10^{-3} mol dm^{-3} SDS; 1.1:1 for 2.00×10^{-3} mol dm^{-3} SDS; 1.1:1 for 3.0×10^{-3} mol dm^{-3}; and 1.1:1 for 5.00×10^{-3} mol dm^{-3}. This indicates that the chief inclusion complex of βCD with SDS in this range is 1:1 with possibly a little 2:1 complex also present. The plateau in the molar conductance beyond the 1:1 stoichiometry indicates that the SDS has been almost totally complexed. The molar conductance at this stage is due only to the charged inclusion complex and Na^+ ions originating from the surfactant.

Above the cmc, the molar conductance pattern for SDS solutions containing βCD is less simple, but consistent as a function of SDS concentration. Figure 2 demonstrates this for three post-cmc SDS systems. Again, one system, 1.50×10^{-3} mol dm^{-3} SDS, was omitted from the diagram. The consistent trend in all four systems was a sharply rising conductance with βCD addition to a maximum, which was more swiftly reached in more dilute micellar systems, followed afterwards by a drop in conductance in which two linear portions could be discerned as with the pre-cmc SDS systems. The addition of βCD to the micellar SDS thus appears to break up the micelles releasing monomeric SDS and gegen Na^+ ions. The former subsequently complex with βCD in the 1:1 stoichiometry observed in the pre-cmc range and the latter largely give rise to a marked increase in conductance. At the maximum of the curve, the micelles have disappeared and subsequent addition of βCD simply removes free SDS anions largely in a 1:1 complex (intersection of the two linear portions of the curve occurs at a CD to SDS ratio of 1.2 for all four

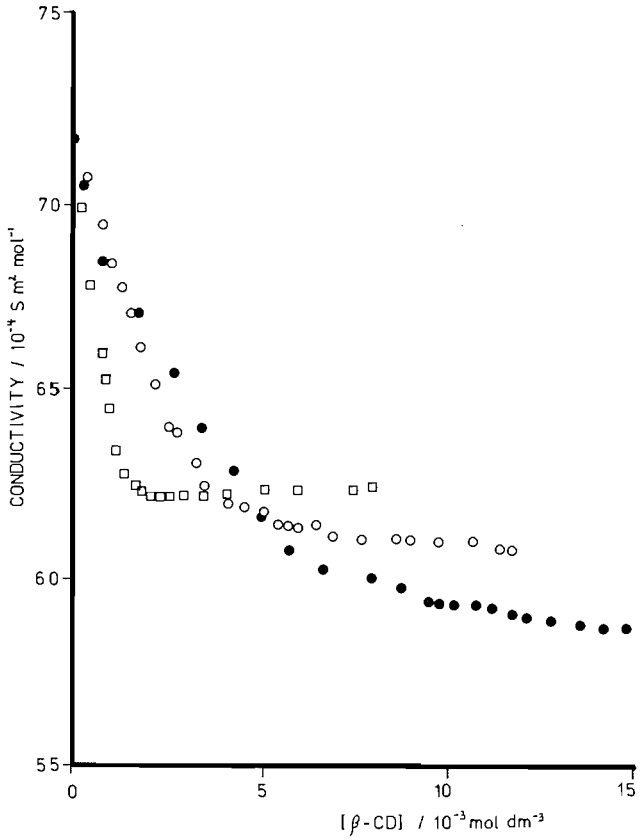

FIG. 1. Molar conductivity of SDS in βCD solutions below the cmc: open squares, 1.00×10^{-3} mol dm^{-3} SDS; closed circles, 5.00×10^{-3} mol dm^{-3} SDS.

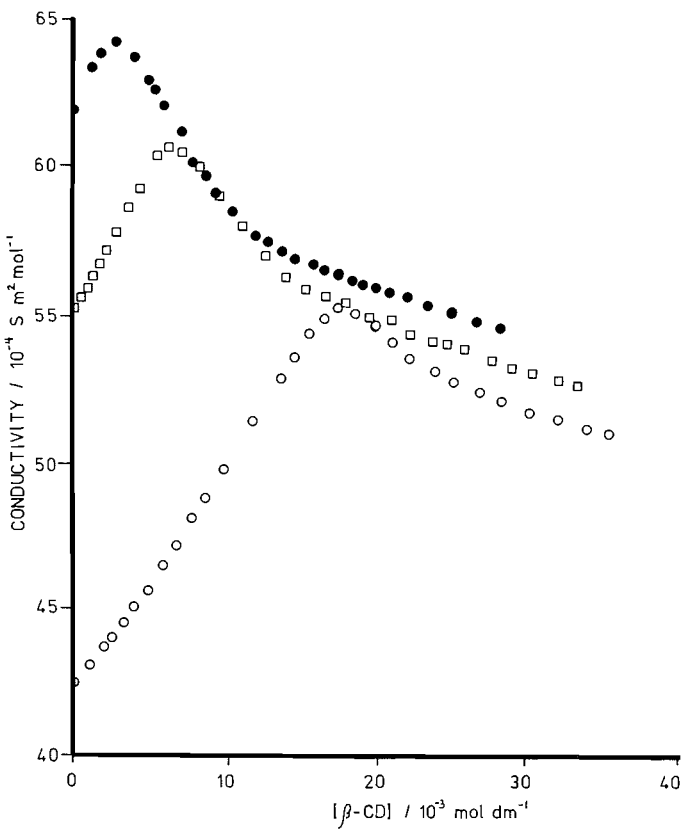

FIG. 2. Molar conductivity of SDS in βCD solutions above the cmc: closed circles, 0.95×10^{-2} mol dm^{-3} SDS; open squares, 1.20×10^{-2} mol dm^{-3} SDS; open circles, 2.00×10^{-2} mol dm^{-3} SDS.

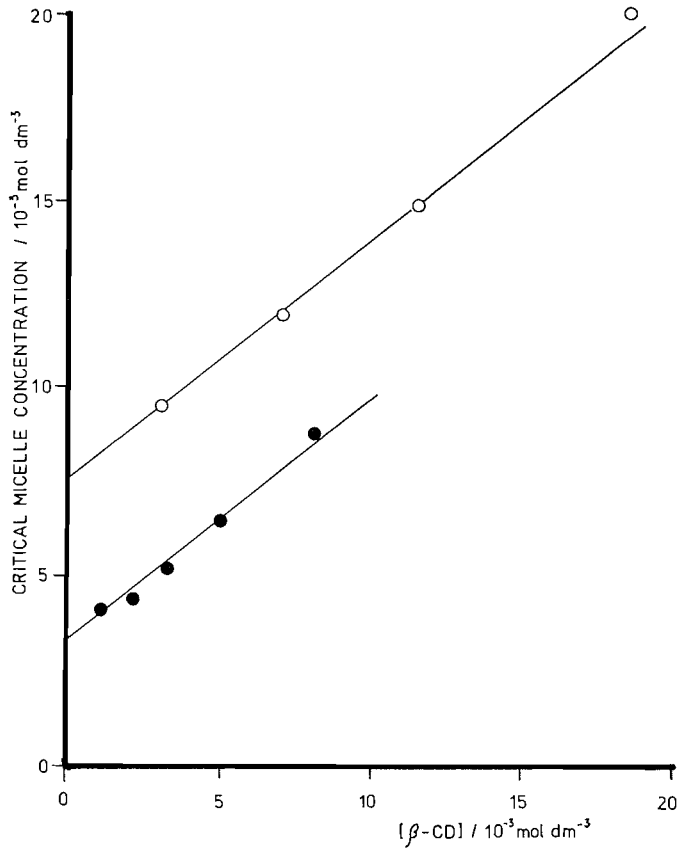

FIG. 3. Effect of βCD on the cmc values of SDS and TTAB.

post-cmc systems studied). The maximum of the curve may thus be interpreted as the cmc of the mixed surfactant system. These values are plotted in Fig. 3 and agree with the findings of Okubo *et al.* (3) that addition of cyclodextrins to SDS systems generally leads to an increase in the cmc. Extrapolation to zero βCD concentration yields the cmc of pure SDS as 7.5×10^{-3} mol dm^{-3}, in agreement with literature values.

An alternate explanation is that the initial βCD additions are incorporated into the SDS micelles as solubilizates and that the increase in conductance originates with the release of Na^+ ions with micelle swelling or increase in hydrophobicity. However, it is well known from solubilization studies that remarkably large quantities of hydrophobic solubilizates can oftentimes be incorporated within micelles with relatively little change in micellar size, structure, and effetive charge (8, 9). Thus, this explanation appears less likely.

When the chain length of the surfactant is shortened to 10 and 8 carbon atoms as in SDeS and SOS, the βCD concentration dependence of the conductance in the pre-cmc region differs little from SDS with the stoichiometry of the βCD–surfactant complex being 1.1:1 for SDeS and 1.2:1 for SOS (Fig. 4).

Even when the surfactant is cationic, the same behaviour and stoichiometry are found: 1.2:1 for both TTAB and DDAC. This suggests that it is the alkyl chain of the surfactant and not its polar head that is being fitted into the βCD torus. Fluorescence probes incorporated into cyclodextrins experience a more hydrophobic environment when surfactants are introduced (10, 11). This is consistent with the hydrocarbon tail of the surfactant being within the torus. Also, the maxima in the conductance curves appear again for cationic surfactants in the post-cmc range and, assuming these are in effect cmc values of the mixed cyclodextrin–surfactant systems, can be extrapolated to zero βCD concentration to yield the cmc of the pure surfactant. In

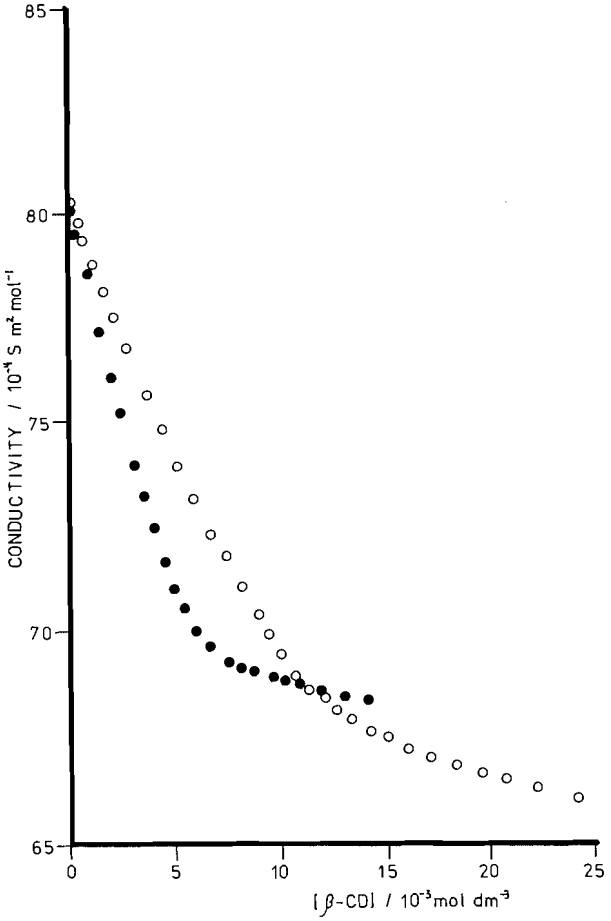

FIG. 4. Molar conductivity of 1.00×10^{-2} mol dm^{-3} sodium octylsulfate (open circles) and of 5.00×10^{-3} mol dm^{-3} sodium decylsulfate (closed circles) in βCD solutions.

Fig. 3 these maxima are plotted against βCD concentration of TTAB to yield a cmc of 3.5×10^{-3} mol dm^{-3} which is consistent with literature values.

When αCD or γCD rather than βCD is the additive, the conductance behaviour in the SDS and TTAB systems is similar with these important differences: αCD apparently forms a 2:1 complex with SDS and TTAB as well as 1:1 complex and γCD, although still forming a 1:1 inclusion complex with surfactants, binds much less strongly than the other cyclodextrins (Figs. 5, 6). With αCD, the conductance curves consist of three linear sections, the intersections of which indicate 2:1 and 1:1 stoichiometric species. The former is more distinct and is the ratio reported by Hersey, Robinson, and Kelly (6). If the first αCD encapsulates the hydrocarbon chain of the surfactant, then the second αCD probably envelopes the polar end in a CD/S/CD complex where S represents the surfactant monomer. Because of its wider annulus, βCD must fit too loosely over the polar heads of the surfactants to form a 2:1 complex, so that the 1:1 complex is the predominant inclusion form. When the annulus becomes even larger as with γCD, the hydrocarbon tail also is accommodated only loosely within the cyclodextrin torus. Above the cmc, αCD showed no major differences in conductance behaviour from βCD. For the 9.50×10^{-3} mol dm^{-3} SDS system which is just above the cmc for pure SDS, the same apparent destruction of micelles was observed as αCD was added. The maximum in the conductance curve occurred at 3.0×10^{-3} mol dm^{-3} αCD which indicates that 9.5×10^{-3} mol dm^{-3} is the cmc in the presence of 3.0×10^{-3} mol dm^{-3} αCD, exactly the same value as for βCD (Fig. 3).

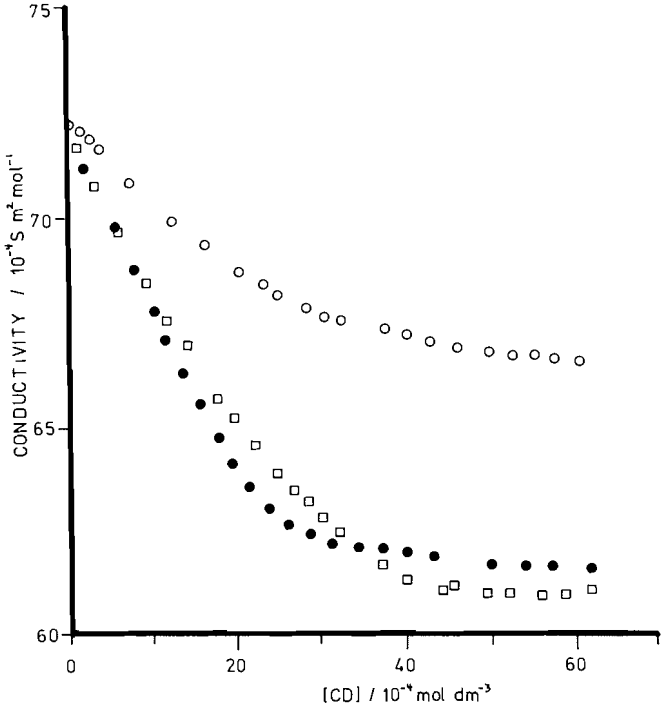

FIG. 5. Molar conductivity of 2.00×10^{-3} mol dm^{-3} SDS with added cyclodextrins: open squares, αCD; closed circles, βCD; open circles, γCD.

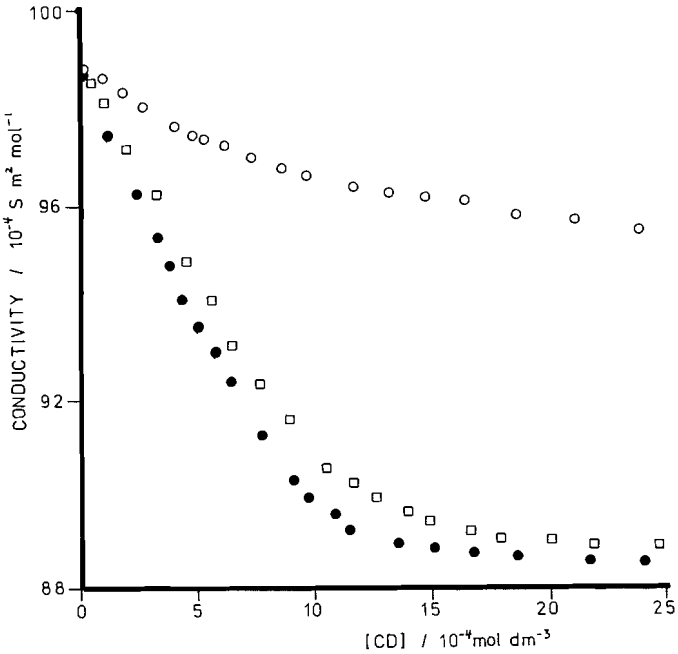

FIG. 6. Molar conductivity of 7.50×10^{-4} mol dm^{-3} TTAB with added cyclodextrins: open squares, αCD; closed circles, βCD; open circles, γCD.

The association constants for the formation of a 1:1 complex can be calculated with the equation given by Satake *et al.* (4, 5):

$$\Delta\Lambda = \frac{\Delta\lambda}{2KC_s}\left\{K(C_s + C_c) + 1 - ([K(C_s + C_c) + 1]^2 - 4K^2C_sC_c)^{1/2}\right\}$$

TABLE 1. Equilibrium constants for surfactant/cyclodextrin complexation

Complex	Surfactant concentration C_s (mmol dm^{-3})	Conductance difference $\Delta\lambda$ (10^{-4} S m^2 mol^{-1})	Equilibrium constant K (dm^3 mol^{-1})
βCD/SDS	1.00	10.5	7230
	2.00	11.6	4690
	3.00	11.3	3340
	5.00	12.5	1380
βCD/SDeS	5.00	12.7	2310
βCD/SOS	10.0	15.9	565
βCD/DDAC	5.00	14.5	1290
βCD/TTAB	0.800	11.1	11700
	5.00	10.3	9610
γCD/SDS	2.00	7.1	830
γCD/TTAB	0.800	4.3	2300
αCD/SDS	2.00	16.0	754
αCD/TTAB	0.800	11.8	4500

where $\Delta\Lambda$ is the decrease in molar conductivity brought about by the addition of CD; $\Delta\lambda$, the difference in the ionic conductivities of the unassociated and associated surfactant ions; C_s, the surfactant concentration and C_c, the CD concentration. The values of the association constant K were obtained by non-linear least-squares regression and are given in Table 1.

A point of comparison from the literature is 3630 for K for 2.60 mmol dm^{-3} SDS in βCD solutions (5) in excellent agreement with the present results. In the CD/SDS system, K is roughly inversely proportional to the total surfactant concentration. If the concentration of free surfactant is assumed to be proportional to the total surfactant concentration, then the ratio of bound βCD to free βCD will be constant over the entire pre-cmc range which is a reasonable expectation. As expected from the conductance curves, γCD forms much weaker complexes with SDS and TTAB than βCD. With αCD, the 1:1 complex is seen to be weakly formed compared to the corresponding βCD complexes with both SDS and TTAB.

In summary, below the cmc αCD appears to form predominantly a 2:1 complex while βCD and γCD form a 1:1 complex with both anionic and cationic surfactants. This is the situation even above the cmc where CDs act as micelle destroyers eventually complexing all of the surfactant if sufficient CD is available.

Spectroscopic properties of SO_4 (and OH) in different molecular and crystalline environments. I. Infrared spectra of $Cu_4(OH)_6SO_4$, $Cu_4(OH)_4OSO_4$, and $Cu_3(OH)_4SO_4$[1,2]

ETALO A. SECCO
Chemistry Department, St. Francis Xavier University, Antigonish, N.S., Canada B2G 1C0

Received June 25, 1987

ETALO A. SECCO. Can. J. Chem. **66**, 329 (1988).

The infrared spectra over the range 4000–50 cm^{-1} of three copper basic sulfates, viz. $Cu_4(OH)_6SO_4$, $Cu_4(OH)_4OSO_4$, $Cu_3(OH)_4SO_4$ along with site group and factor group analysis for $Cu_4(OH)_6SO_4$ are reported for the first time. The observed absorption frequencies associated with OH and SO_4 activities show distinct individual structural features.

Three distinct types of OH groups are present in $Cu_4(OH)_6SO_4$ and $Cu_4(OH)_4OSO_4$ but only two types are evident in $Cu_3(OH)_4SO_4$. The two OH groups involved in the dehydroxylation reaction to give the oxycompound $Cu_4(OH)_4OSO_4$ are tentatively identified. The multiple frequencies involving Cu—O—H bending modes further reflect the varying degrees of H-bonding and OH coupling in $Cu(OH)_4O_2$ and $Cu(OH)_5O$ entities.

The SO_4 internal optic modes' multiplet structure and frequencies in the basic sulfates illustrate the different extent of dipolar coupling effects (OH and Cu) with respect to specific modes relative to Li_2SO_4 with same site symmetry. The SO_4 external optic modes relative to Li_2SO_4 are barely affected by neighboring OH groups.

The Cu—O mode frequencies show parallel behavior with minor interaction effects in all compounds.

ETALO A. SECCO. Can. J. Chem. **66**, 329 (1988).

On a déterminé les spectres infrarouges (de 4000 à 50 cm^{-1}) de trois sulfates basiques de cuivre, à savoir le $Cu_4(OH)_6SO_4$, le $Cu_4(OH)_4OSO_4$ et le $Cu_3(OH)_4SO_4$, et on a effectué une analyse de groupe des sites et des facteurs pour le $Cu_4(OH)_6SO_4$. Les fréquences d'absorption observées pour les activités du OH et du SO_4 présentent des caractéristiques structurales individuelles distinctes.

Il existe trois types distincts de groupements OH dans le $Cu_4(OH)_6SO_4$ et le $Cu_4(OH)_4OSO_4$; toutefois, seulement deux types sont évidents dans le $Cu_3(OH)_4SO_4$. On a identifié avec une certaine hésitation les deux groupements OH qui sont impliqués dans la réaction de déshydroxylation conduisant au composé oxy $Cu_4(OH)_4OSO_4$. Par ailleurs, les fréquences multiples impliquant les modes de déformation Cu—O—H indiquent aussi les degrés des liaisons hydrogènes et des couplages OH que l'on retrouve dans les entités $Cu(OH)_4O_2$ et $Cu(OH)_5O$.

La structure multiplet des modes optiques internes du SO_4 et les fréquences observées dans les sulfates basiques illustrent les degrés divers des effets de couplage dipolaire (OH et Cu) par rapport aux modes spécifiques relatifs au Li_2SO_4 possédant la même symétrie de site. Les modes optiques externes du SO_4 par rapport au Li_2SO_4 sont à peine affectés par les groupements OH voisins.

Pour tous les composés, les fréquences du mode Cu—O présentent un comportement parallèle qui n'est que faiblement influencé par les effets d'interaction.

[Traduit par la revue]

Introduction

Recent spectroscopic studies have investigated the nature and internal properties of the SO_4 ion in various crystalline environments (1–4). Interest in the SO_4 ion is based on (*i*) its simple tetrahedral symmetry which can undergo various steps of symmetry reduction and (*ii*) its proposed "rotational" coupling in promoting cation mobility in fast ion conductors of sulfates such as Li_2SO_4 (5, 6).

A polyatomic species such as the SO_4 ion in a crystal may be sited in different potential energy environments and therefore subjected to various interacting molecular forces. These intermolecular forces can yield a vibrational multiplet structure where a single vibrational frequency or no frequency is observed in the isolated molecular state. The observed multiplet structure can be attributed to three main effects: (*i*) *factor group* or *correlation field splitting*, (*ii*) *site group splitting*, and (*iii*) *multiple site splittings*. The observed spectrum may incorporate one or all of these multiplet contributions.

Frech and his group along with others (7–10) have analyzed the vibrational dynamics of internal optic modes in molecular crystals using the molecular dipole model. The dominant interaction of a normal internal optic mode in this model is the vibrationally induced dipole moment derivative $\partial\mu_\alpha/\partial q_j$ corresponding to the jth vibrational molecular normal coordinate q_j. The relation between the phonon frequency ν_j, the static crystal frequency ν_{0j}, and the dipolar coupling factor resulting from the interactions between vibrationally induced dipoles is given by

$$[1]\quad \nu_j^2(\kappa_\gamma) = \nu_{0j}^2 + \sum_\alpha S_{\alpha\alpha}(\kappa_\gamma)[I + \alpha_{0,\alpha\alpha}S_{\alpha\alpha}(\kappa_\gamma)]^{-1}\left(\frac{\partial\mu_\alpha}{\partial q_j}\right)^2$$

In this equation α is a Cartesian coordinate describing the polarization of the phonon, α_0 refers to the electronic polarizability, γ is the irreducible representation of the unit cell group, κ is the wave vector of the phonon, and $S_{\alpha\alpha}(\kappa_\gamma)$ is the unit cell symmetrized (γ) linear combination of dipole sums $S_{\alpha\alpha}$. The quantity $[I + \alpha_{0,\alpha\alpha}S_{\alpha\alpha}(\kappa_\gamma)]^{-1}$ is, therefore, a linear combination of functions of the various dipole sums and electronic polarizability components.

In an effort to extend our knowledge on the internal properties of the SO_4 ion in slightly modified crystalline environments an infrared study was carried out on two copper basic sulfates, $Cu_4(OH)_6SO_4$, also known as the mineral brochantite, and

[1]Preliminary results of this study, Paper No. 07L08, were presented at Symposium on Spectroscopy in Inorganic Chemistry, The 1984 International Congress of Pacific Basin Societies, Honolulu, Hawaii, December 16–21, 1984.

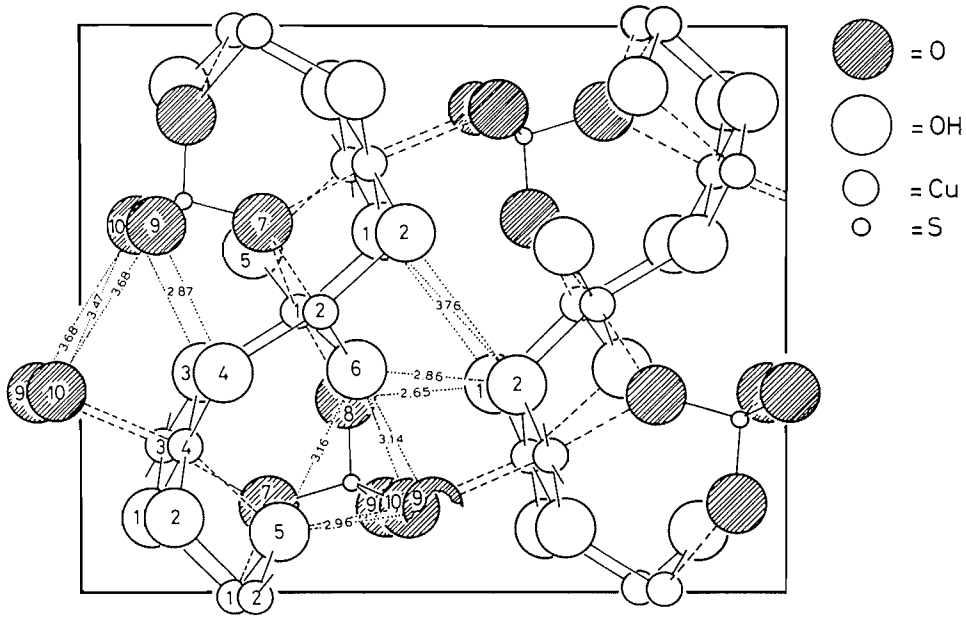

FIG. 1. Unit cell structure of brochantite $Cu_4(OH)_6SO_4$ taken from ref. 12.

$Cu_3(OH)_4SO_4$. These compounds were chosen because (*i*) a high potential for comparison and correlation in their spectral properties is expected and (*ii*) the existence of a stable decomposition intermediate $Cu_4(OH)_4OSO_4$ obtained from $Cu_4(OH)_6SO_4$ (11) should provide related but significant variations in the critical factors of dipole moment and electronic polarizability interactions as contained in eq. [1] which affect the SO_4 vibrational frequencies. The known crystal structure of brochantite should permit vibrational assignments on the basis of group and site effects. Furthermore, since the crystal structure of $Cu_4(OH)_6SO_4$ and Li_2SO_4 fit the same space group $P2_1/a$ (C_{2h}^5) with $Z = 4$ and SO_4 has the same site symmetry, the infrared spectra would provide a critical basis for comparison of SO_4 and OH interaction effects in $Cu_4(OH)_6SO_4$ with the known vibrational assignments for SO_4 external and internal optic modes in Li_2SO_4 obtained from Raman spectra (5). The crystal structures of the other compounds are unknown to us but can be assumed to be related to the brochantite structure.

While the main object of this study is intended to focus on the SO_4 ion (see following paper, Part II) these hydroxy-sulfates are expected to furnish fundamental structural knowledge on the nature of the OH species in related crystalline environments and their involvement in varying degrees of H-bridgings as discussed below.

Structure of $Cu_4(OH)_6SO_4$

The most recent structural assignment for brochantite, $Cu_4(OH)_6SO_4$ is monoclinic (12) with space group $P2_1/a = C_{2h}^5$ superseding earlier monoclinic assignments (13, 14). Using the notation given for the first setting of the C_{2h}^5 space group in the International tables for X-ray crystallography (15), we find that only the 4e sites (Wyckoff notation) with C_1 symmetry are occupied. The unit cell containing four molecular units, with dimensions $a_0 = 13.00$ Å, $b_0 = 9.85$ Å, $c_0 = 6.02$ Å, $\beta = 103° 22'$, shown in Fig. 1 is taken from Cocco and Mazzi (12) with the projection slightly tilted on the [001] plane to avoid masking superposed atoms along the [001]. The interatomic separation values noted on the figure are in Å units. The H atom of OH, not shown, forms Cu—O—H bond angles of 112 and 118°.

The disposition of the OH groups, their orientations, and their intermolecular distances as depicted in Fig. 1, suggest three classes of OH bridges. The first class is OH with no effective H-bonding, represented by O_6H and O_5H. The second class is strong H-bonded OH represented by $O_1H...O_8$. The third class is classified as medium strength H-bonded OH with slight variation in the degree of H-bonding, viz. $O_2H...O_6$, $O_3H...O_{10}$, $O_4H...O_9$.

It appears from Fig. 1 that Cu has a slightly distorted octahedral coordination with four equal coplanar Cu—OH bonds with interatomic separations 2.00 ± 0.02 Å and two Cu—O bonds. Both oxygens in one pair of Cu—O bonds are from the SO_4 ion forming the entity $Cu(OH)_4O_2$ while the second pair involves one oxygen from SO_4 and the other oxygen from OH to form the entity $Cu(OH)_5O$. There are three $Cu(OH)_4O_2$ and one $Cu(OH)_5O$ associated with each SO_4 in the unit cell. On the basis of Cu—O separations (12) two types of $Cu(OH)_4O_2$ are identified, (*i*) two equal Cu—O distances of 2.36 Å and (*ii*) one Cu—O separation of 2.32 Å and the other of 2.52 Å. $Cu(OH)_5O$ has one Cu—OH separation of 2.31 Å and one Cu—O separation of 2.52 Å. The octahedra are linked to form "layers" parallel to the cleavage plane [100] and these are held together by hydrogen bonds and Cu—O bonds.

Factor group analysis of $Cu_4(OH)_6SO_4$

A unit cell of $Cu_4(OH)_6SO_4$ containing 84 atoms gives rise to 252 degrees of freedom involving copper ion motion, OH group external and intramolecular motions, and sulfate external and intramolecular motions. A free sulphate ion belongs to the molecular point group T_d with irreducible representations for internal modes $\Gamma_{int} = A_1 + E + 2T_2$ which correspond to the intramolecular normal modes ν_1, ν_2, ν_3, ν_4, respectively. The low site symmetry C_1 of the SO_4 in the cell removes all the degeneracies of the T_d representations to yield the non-degenerate A representations. From correlation procedures (5, 16) each site group A representation is found to transfer to $A_g + B_g + A_u + B_u$ in the factor group C_{2h}. The number of irreducible representations of the modes for SO_4 is determined to be $9A_g + 9B_g + 9A_u + 9B_u$ for internal vibrational modes and 24 similar representations for translational and rotational

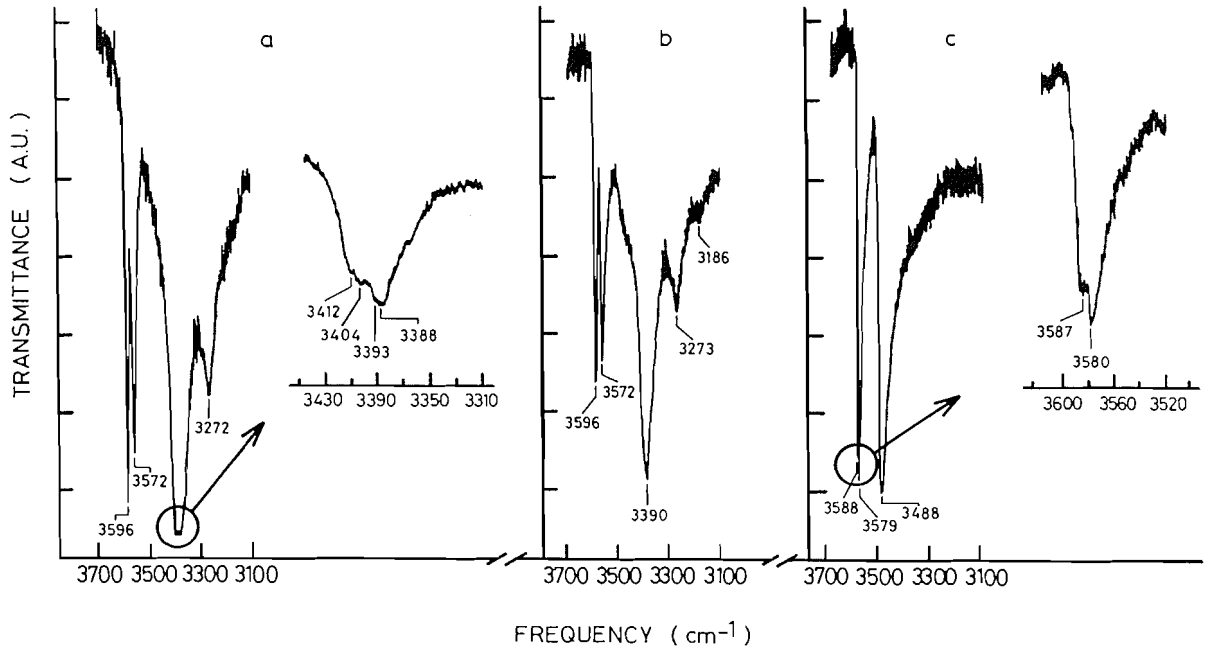

FIG. 2. Infrared spectra for region 3700–3100 cm^{-1}: (*a*) $Cu_4(OH)_6SO_4$, (*b*) $Cu_4(OH)_4OSO_4$, (*c*) $Cu_3(OH)_4SO_4$.

modes or external modes. The remaining representations are identified with 24 internal modes for OH, 48 Cu—O—H bending modes, 24 Cu—O stretching modes, 48 O—Cu—O angle deformation modes and 48 modes involving Cu ion motion.

Experimental

$Cu_4(OH)_6SO_4$ and $Cu_3(OH)_4SO_4$ were prepared according to accepted procedures and analyzed as described (11). The intermediate $Cu_4(OH)_4OSO_4$ was obtained from the parent $Cu_4(OH)_6SO_4$ according to the reaction, $Cu_4(OH)_6SO_{4(s)} \rightarrow Cu_4(OH)_4OSO_{4(s)} + H_2O_{(g)}$, by annealing in a Pt crucible placed in a well-type furnace maintained at 310 ± 5°C for 3–5 h. The sample color change was blue to olive green (11).

The infrared transmission spectra were recorded with a Perkin-Elmer 180 spectrophotometer using both the standard compressed KBr disc technique and Nujol mull samples between polyethylene windows. The observed absorption frequencies were reproducible within 2 cm^{-1} for most of the overlapping spectral regions using both sample techniques. Each compound was maintained in an oven at 150–160°C for 5–15 h before using.

Results and discussion

The infrared transmittance spectra recorded in this study are presented and interpreted with respect to OH and SO_4 optic modes in the compounds $Cu_4(OH)_6SO_4$, $Cu_4(OH)_4OSO_4$, and $Cu_3(OH)_4SO_4$. The spectral intensities are given in arbitrary units (A.U.). No HOH bending absorption was observed, in contrast to the assignment in other hydroxysulfates (17).

OH absorption

The fundamental vibrational frequency for OH was found to occur over the range 3600–3200 cm^{-1} depending on the degree of H-bonding, Fig. 2. Tarte (18) reported the range to be 3586–3270 cm^{-1} for $Cu_4(OH)_6SO_4$ and $Cu_3(OH)_4SO_4$.

Figure 2*a* shows a clearly resolved multiplet structure in the spectrum of $Cu_4(OH)_6SO_4$ indicating the three distinct classes of hydroxy groups known to exist in the crystal. The sharp peaks at 3596 and 3572 cm^{-1}, with fine splitting of 4 cm^{-1} in the 3572 cm^{-1} peak evident at higher resolution, are assigned to "free" non-hydrogen bonded OH identified as O_6H and O_5H, respectively. That is, three of the expected four components are observed. The 3596 cm^{-1} frequency is within range of 3600–3640 cm^{-1} and 3550–3570 cm^{-1} reported for "free" OH groups in weak alcohol solutions (19) and lanthanide (Gd, Nd) basic nitrates (20), respectively. The sharp band at 3272 cm^{-1} is assigned to strongly H-bonded $O_1H\ldots O_8$ with a separation of 2.65 Å. The slightly broader band centred at 3396 cm^{-1}, with fine structure 3412, 3404, 3393, 3388 cm^{-1} evident at higher resolution, is consistent with the different degrees of hydrogen bridging found for $O_2H\ldots O_6$, $O_3H\ldots O_{10}$, $O_4H\ldots O_9$ with separations of 2.86 and 2.87 Å.

Figure 2*b* is the spectrum of $Cu_4(OH)_4OSO_4$ obtained as a product from $Cu_4(OH)_6SO_4$ described above. The loss of two OH groups leaves the spectrum virtually unchanged relative to the parent spectrum Fig. 2*a*. The only discernible differences are the profile of the 3390 cm^{-1} which appears less broad and the appearance of a weak band at 3186 cm^{-1}. These features suggest dehydroxylation to involve group O_4H with either O_3H or O_2H from the $Cu(OH)_5O$ entity. This OH frequency parallels the dimer reported for alcohol solutions (19).

The spectrum of $Cu_3(OH)_4SO_4$ is given in Fig. 2*c*. The crystal structure of $Cu_3(OH)_4SO_4$ has yet to be determined, hence the disposition of the OH groups in the unit cell is unknown. The spectrum indicates two types of OH groups — a "free" (no H-bond) type and a medium strength H-bonded type as found in a dimer, viz. $OH_a\ldots OH_b$ where H_a is bridged but H_b is a terminal "free" entity. The $O—H_a\ldots O$ frequency of 3490 cm^{-1} agrees very well with the OH stretching frequency of 3485 cm^{-1} for the dimer observed in alcohol solutions (19). The splitting (site or LO-TO?) of 8 cm^{-1} for "free" OH, viz. 3588 and 3580 cm^{-1}, is evident.

The spectra of the three compounds in the 1300–50 cm^{-1} region are presented in Figs. 3, 4, and 5 with the absorption frequencies noted. The OH frequencies along with their assignments are tabulated in Table 1. The Cu—OH deformation

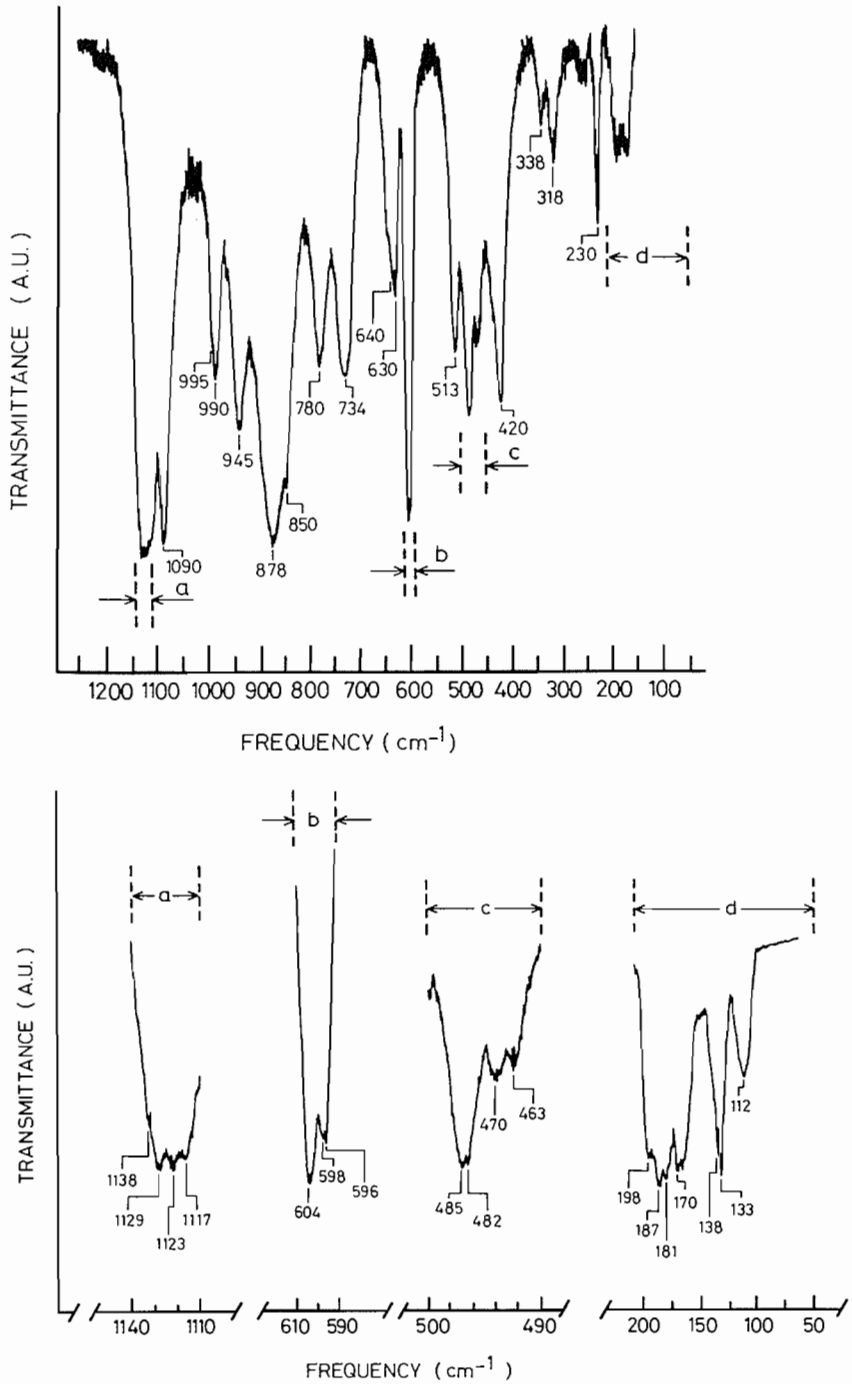

FIG. 3. Infrared spectrum of $Cu_4(OH)_6SO_4$ with expanded portions *a*, *b*, *c*, *d*.

assignments are based on the deuterium shift and these frequencies are within $\pm 2\,cm^{-1}$ of the values reported by Tarte (18). Again the frequencies involving the Cu—O—H bending modes reflect the disposition of the OH groups and the varying degrees of H-bonding. The larger shift of the bending mode frequencies, $\Delta\nu_b/\nu_b$, relative to the O—H stretching mode frequencies, $\Delta\nu_s/\nu_s$, by a factor ~4, usually $\Delta\nu_b/\nu_b < \Delta\nu_s/\nu_s$, implies that the bending modes involve coupling in the $Cu(OH)_4O_2$ and $Cu(OH)_5O$ entities discussed above. The additional frequencies in $Cu_4(OH)_6SO_4$ and $Cu_4(OH)_4OSO_4$ relative to $Cu_3(OH)_4SO_4$ correlate with the two extra CuOH units and the variation in CuO distances, 2.00–2.52 Å (21, 22). The assignment of the OH torsional and translational modes given in Table 2 is made on the basis of their absence in $CuSO_4$ and $Cu_3O_2SO_4$ spectra, as reported in Part II (23).

SO_4 absorption

The fundamental vibration frequencies for SO_4 of T_d symmetry observed in the infrared are $\nu_3(T_2)$ 1104 cm^{-1} and $\nu_4(T_2)$ 613 cm^{-1}. The fundamental vibration frequencies for SO_4 of reduced symmetry have been reported for infrared transmittance (2–5) to occur over a range of values, viz. $\nu_1(A_1)$ 971–993, $\nu_2(E)$ 445–490, $\nu_3(T_2)$ 1070–1190, and $\nu_4(T_2)$ 613–648 cm^{-1}.

The recorded spectra given in Figs. 3, 4, and 5 show the multiplet vibrational structure expected from factor group analysis for SO_4 in $Cu_4(OH)_6SO_4$ and assumed parallel consi-

derations for SO_4 in $Cu_4(OH)_4OSO_4$ and $Cu_3(OH)_4SO_4$. The pattern of infrared activity parallels the Raman activity of SO_4 for C_1 symmetry as expected. The internal optic mode frequencies of SO_4 noted on these spectra and their tentative correlated assignments are tabulated in Table 3 along with the Raman spectra frequencies and symmetry assignments for Li_2SO_4 (5) for comparison purposes. The frequencies noted on the main spectrum were taken from spectra with the abscissa expanded 2.5 or 5 times. The various absorption frequencies and splittings are discussed.

The weak $\nu_1(A_1)$ peak adjacent to the stronger OH deformation peak in $Cu_4(OH)_6SO_4$ and $Cu_3(OH)_4OSO_4$ is in contrast to the single sharp $\nu_1(A_1)$ absorption in $Cu_3(OH)_4SO_4$.

The multiplet and fine structure evident for $\nu_2(E)$ over a range of 100 cm^{-1} for the three compounds with splittings 20–65 cm^{-1} and 8 cm^{-1} indicates stronger site group or dipolar coupling effects relative to Li_2SO_4. Powers *et al.* assigned infrared frequencies of iron basic sulfates in the 412–550 cm^{-1} region to vibrations of FeO_6 octahedra (17). These frequencies are consistent with site group splitting of $\nu_2(E)$ in SO_4 rather than FeO_6 vibrations.

The $\nu_3(T_2)$ mode displays contrasting features in its multiplet structure for the three compounds. $Cu_4(OH)_6SO_4$ and $Cu_4(OH)_4OSO_4$ show similar absorption frequencies with the additional peak at 1040 cm^{-1}. Assuming the same site symmetry for SO_4 in both compounds, one might correlate the 1040 cm^{-1} absorption in $Cu_4(OH)_4OSO_4$ with different interactions of selective SO_4 units to permit extra splitting. The weak splitting observed for $Cu_3(OH)_4SO_4$ in the 1083–1112 cm^{-1} interval and the strong sharp peak at 1155 cm^{-1} are in distinct contrast to the profiles of the other two basic sulfates, suggesting effects originating with different site symmetry and/or dipolar coupling contributions as contained in eq. [1].

Most features in the multiplet structure of the $\nu_4(T_2)$ mode are common to the three compounds. The contrasting features of $Cu_3(OH)_4SO_4$ are (*i*) the lack of fine structure in the 600 cm^{-1} peak, (*ii*) the absence of the 628–630 cm^{-1} absorption, and (*iii*) the prominent and clearly resolved 666, 640, and 616 cm^{-1} peaks. $Cu_4(OH)_6SO_4$ does not show the 666–670 cm^{-1} absorption. The ν_2 of CO_2 appears sporadically as a distinct spike at 667 cm^{-1}.

The multiplets observed in the specific deformation modes ν_2 and ν_4, viz. 470–462, 604–597, 616–611, indicate either varied SO_4—OH interactions or selective site splittings.

The frequencies of the Cu—O stretching and O—Cu—O bending mode frequencies are presented in Table 5 along with those observed for $Cu_3O_2SO_4$ (23) and $Cu_4(OH)_6(NO_3)_2$ (24) for comparison purposes. The values 170–176 cm^{-1} also cited in Table 4 are also assigned to SO_4 external modes on the basis of possible coincident frequencies.

The frequencies of sulfate external optic modes of the basic sulfates are given in Table 4, along with those reported for Li_2SO_4 from Raman studies (5) for comparison purposes. The mode symmetries parallel assignments for Li_2SO_4. The high degree of agreement in their frequencies imply the sulfate external mode to be virtually unaffected by the surrounding OH groups.

Conclusions

The infrared spectra of three related basic sulfates, viz. $Cu_4(OH)_6SO_4$, $Cu_4(OH)_4OSO_4$, $Cu_3(OH)_4SO_4$, show the individual structural features and the binary interactions of the OH and SO_4 species. Three major types of OH groups are identified in $Cu_4(OH)_6SO_4$ whose structure is known. These are (*i*) "free" non H-bonded OH, (*ii*) medium strength H-bonded OH, and (*iii*) strong H-bonded OH. A separation of 4 cm^{-1} near the 3572 cm^{-1} peak is observed for the bifurcated OH hydrogen between two equidistant SO_4 oxygens. The two OH groups reacting in the dehydroxylation step to yield the oxycompound, via $Cu_4(OH)_6SO_{4(s)} \rightarrow Cu_4(OH)_4OSO_{4(s)} + H_2O_{(g)}$, are tentatively identified. Two types of OH groups are evident in $Cu_3(OH)_4SO_4$, structure unknown, namely (*i*) "free" OH and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 213.222.148.141 on 09/07/12
For personal use only.

(*ii*) medium strength H-bridged OH. Splittings are observed in the "free" OH stretching mode, 8 cm^{-1}, and the Cu—OH bending mode, 10 cm^{-1}.

The SO_4 internal optic modes show a general trend to lower frequencies in all modes accompanied by stronger splittings in ν_2 and ν_4 and weaker splittings in ν_3. The magnitude of these splittings emphasize the interplay of the dipole coupling, the correlation field, and the site group effects. The SO_4 external optic modes in the basic sulfates are barely affected by neighboring OH groups as indicated by the high degree of agreement between their frequencies and the analogous mode frequencies for SO_4 of the same site symmetry in Li_2SO_4.

Acknowledgments

I thank the National Research Council of Canada for an equipment grant to purchase the infrared spectrometer and Professor Roger Frech, University of Oklahoma, and Dr. Anthony Secco, University of Manitoba, for their generous assistance regarding interpretations.

Spectroscopic properties of SO_4 in different molecular and crystalline environments. II. Identification and infrared spectra of $Cu_3O_2SO_4$ and its hydroxylated derivative[1,2]

ETALO A. SECCO
Chemistry Department, St. Francis Xavier University, Antigonish, N.S., Canada B2G 1C0

Received June 25, 1987

ETALO A. SECCO. Can. J. Chem. **66**, 337 (1988).

The infrared spectra of $Cu_3O_2SO_4$, identified for the first time and obtained from three different preparations are reported. The proposed structure of $Cu_3O_2SO_4$ contains the copper oxysulfate anion $[(CuO)_2SO_4]^{2-}$ of C_s symmetry with each CuO attached by the Cu to two oxygens of the SO_4 group. Of the 21 infrared-active modes predicted for this anion 17 modes are discernible. Its hydroxylated derivative $Cu_3(OH)_4SO_4$ shows clearly resolved and evenly split peaks of the ν_3 mode of SO_4 in strong contrast to the strong overlap of this mode in its crystalline analog; the frequencies of the remaining SO_4 modes stay effectively unchanged.

ETALO A. SECCO. Can. J. Chem. **66**, 337 (1988).

On rapporte le spectre infrarouge du $Cu_3O_2SO_4$ qui a été identifié pour la première fois et qui a été préparé par trois méthodes différentes. La structure qui est proposée pour le $Cu_3O_2SO_4$ contient l'anion oxysulfate cuivre $[(CuO)_2SO_4]^{2-}$ qui possède la symétrie C_s et dans lequel chacun des CuO est attaché par le Cu à deux oxygènes du groupement SO_4. Des 21 modes qui d'après les prédictions devraient être actifs en infrarouge, on en discerne 17. Le dérivé hydroxylé $Cu_3(OH)_4SO_4$ présente les bandes bien résolues et bien séparées du mode ν_3 de SO_4 et ce résultat est en opposition avec l'important recouvrement de ce mode dans l'analogue cristallin; les fréquences des autres modes du SO_4 demeurent effectivement inchangées.

[Traduit par la revue]

Introduction

The SO_4 ion can undergo various steps of descent in symmetry from its simple isolated tetrahedral T_d symmetry to the low site symmetry C_1 in a crystalline lattice (1–4) and also by substitution to yield the monodentate sulfate group of C_{3v} symmetry or the bidentate sulfate group with C_{2v} symmetry (5–7). The infrared spectra of three copper basic sulfates have been reported in the preceding paper (4). In an effort to gain more insight into the intramolecular effects on the optic modes of SO_4 by the surrounding molecular units this paper extends the preceding study by reporting the infrared spectra of the compound $Cu_3O_2SO_4$, identified for the first time and obtained from three different preparations, along with its hydroxylated derivative $Cu_3(OH)_4SO_4$. This derivative shows physicochemical and spectral properties distinct from the crystalline compound $Cu_3(OH)_4SO_4$ presented in the preceding paper (4).

Experimental

$Cu_3O_2SO_4$ was obtained from three preparations: (*i*) solid state synthesis from $CuSO_4$ and CuO, (*ii*) dehydroxylation of $Cu_3(OH)_4SO_4$, and (*iii*) dehydroxylation of $Cu_4(OH)_6SO_4$.

The solid state synthesis of $Cu_3O_2SO_4$ was carried out by annealing the requisite composition of $CuSO_4$ and CuO, previously well ground manually, in a Pt crucible at <700°C for ca. 20 h. CuO was Fisher Certified ACS grade and $CuSO_4$ was from dehydrated $CuSO_4 \cdot 5H_2O$ Baker Analyzed Reagent grade.

The $Cu_3(OH)_4SO_4$ and $Cu_4(OH)_6SO_4$ used to obtain $Cu_3O_2SO_4$ were from the same origins as in the preceding paper (4). The dehydroxylation of $Cu_4(OH)_6SO_4$ as reported earlier (8) can occur via a single step,

$$[1] \quad Cu_4(OH)_6SO_{4(s)} \xrightarrow{>450°C} Cu_3O_2SO_{4(s)} + CuO_{(s)} + 3H_2O_{(g)}$$

or two separate steps [2*a*] and [2*b*],

$$[2a] \quad Cu_4(OH)_6SO_{4(s)} \xrightarrow{300°C} Cu_4(OH)_4OSO_{4(s)} + H_2O_{(g)}$$

and

$$[2b] \quad Cu_4(OH)_4OSO_{4(s)} \xrightarrow{>450°C} Cu_3O_2SO_{4(s)} + CuO_{(s)} + 2H_2O_{(g)}$$

The dehydroxylation of $Cu_3(OH)_4SO_4$ occurs in a single step [3],

$$[3] \quad Cu_3(OH)_4SO_4 \xrightarrow{510°C} Cu_3O_2SO_{4(s)} + 2H_2O_{(g)}$$

In the earlier report (8) the oxysulfate was assigned the formula Cu_2OSO_4 but this present study shows a more appropriate representation of the oxysulfate to be $Cu_3O_2SO_4$.

The infrared transmission spectra were recorded with a Perkin-Elmer 180 spectrometer using techniques described in the preceding paper (4).

Results and discussion

$Cu_3O_2SO_4$ from dehydroxylation

The infrared transmittance spectra of the dehydroxylated residue from reaction [1] and reaction [2*b*] are identical and presented as the full line in Fig. 1; the infrared spectrum of the dehydroxylated residue from reaction [3] is presented in Fig. 1 as the broken line. The vibrational frequencies from these spectra and the frequencies of SO_4 in the binuclear sulfate complex $[Co_2(NH_3)_8NH_2SO_4]^{3+}$ with C_{2v} molecular point group symmetry (6) are tabulated in Table 1 for comparison purposes. The $Cu_3O_2SO_4$ frequencies can also be compared with SO_4 frequencies tabulated in Tables 3 and 4 of the preceding paper (4).

The spectrum of the hydroxylated derivative of $Cu_3O_2SO_4$ from reaction [3], obtained by exposing it to H_2O vapor at room temperature, is given in Fig. 2. The hydroxylated derivative decomposes in a single step at 425°C as recorded by DSC. The ΔH of dehydroxylation is within 10% of the reported ΔH value determined for the dehydroxylation of the compound $Cu_3(OH)_4SO_4$, shown by TGA to correspond to the loss of two molecules of H_2O (8). This result confirms the derivative's composition to be $Cu_3(OH)_4SO_4$. The residue of the dehydroxylated derivative, i.e., $Cu_3O_2SO_4$, gives a spectrum identical to the broken line spectrum of Fig. 1. The dark brown color of $Cu_3O_2SO_4$ remained unchanged on hydroxylation, which is in

[1]Preliminary results of this study, Paper No. 07L08, were presented at Symposium on Spectroscopy in Inorganic Chemistry, The 1984 International Congress of Pacific Basin Societies, Honolulu, Hawaii, December 16–21, 1984.

strong contrast with the blue color of crystalline $Cu_3(OH)_4SO_4$, the parent compound from which $Cu_3O_2SO_4$ was obtained.

The hydroxylated solid residue from reaction [2*b*] gives virtually the same spectrum (not shown) as Fig. 2 displaying the same frequencies with minor variations in peak intensities. Spectra of the hydroxylated solid residue from reactions [2*b*] and [3] reveal the same essential features exhibited by $Cu_3(OH)_4SO_4$ of the preceding paper (4) except for the clearly resolved peaks in the 1070–1155 cm^{-1} region. The same spectrum for the hydroxylated derivative of reaction [2*b*] and [3] residues indicates a common oxysulfate reactant of composition $Cu_3O_2SO_4$ whose reaction with H_2O is described by

[4] $Cu_3O_2SO_{4(s)} + 2H_2O_{(g)} \rightarrow Cu_3(OH)_4SO_{4(s)}$

where the excess CuO from [2*b*] does not present any distinctive absorption peak.

The spectra in Fig. 1, displaying minor variations in absorption frequencies and in relative peak intensities in the 610–650 cm^{-1} and 1000–1250 cm^{-1} regions, show a high degree of internal consistency. These minor variations are not due to sample preparations but are reproducible and therefore genuine. The difference in the chemical composition of the full line spectrum, i.e. $Cu_3O_2SO_4$ + CuO relative to $Cu_3O_2SO_4$, may be responsible for the minor variations in these fundamental mode absorption regions. This fact suggests that molecularly dispersed non-chemically bonded CuO can affect the internal mode vibrations of $Cu_3O_2SO_4$. Since vibrational coupling is not confined to structural units contained within the unit cell one might expect weaker coupling effects with more distant vibrating neighbors (9).

The compound $Cu_3O_2SO_4$ is thought to incorporate the copper oxysulfate anion $[(CuO)_2SO_4]^{2-}$ of C_s point symmetry where the Cu of each CuO is attached to two oxygens of the SO_4 group with the O of the CuO extending out from the SO_4 tetrahedron, Fig. 4*a*. The anion $[(CuO)_2SO_4]^{2-}$ reacts with H_2O vapor to form the hydroxylated derivative by incorporating one OH group from the Cu extending to an opposite oxygen of SO_4 to form a weak H-bridge, i.e. Cu—O—H...OSO_3 while the other non-hydrogen bonded OH group projecting away from the SO_4 unit is effectively free as shown in Fig. 4*b*. The clearly resolved ν_3 peaks of SO_4 for the non-crystalline $Cu_3(OH)_4SO_4$, viz. 1150, 1112, 1078 cm^{-1}, are in strong contrast to the overlap between 1083–1112 cm^{-1} in the crystalline $Cu_3(OH)_4SO_4$. The clearly resolved peaks suggest the absence of any overlapping or crowding factor, and the specific modes of the molecule appear essentially unaffected by any near neighbors.

The space group of neither $Cu_3O_2SO_4$ nor of crystalline $Cu_3(OH)_4SO_4$ is known to us. Theoretically, the crystal structure could be derived from a unit cell group analysis of a complete infrared and Raman study of all the active normal modes but such an analysis would be far from unambiguous in view of a multiplicity of complications. Such a lack of site symmetry of SO_4 in $Cu_3O_2SO_4$ militates against the assignment of the infrared-active modes and the interpretation of the

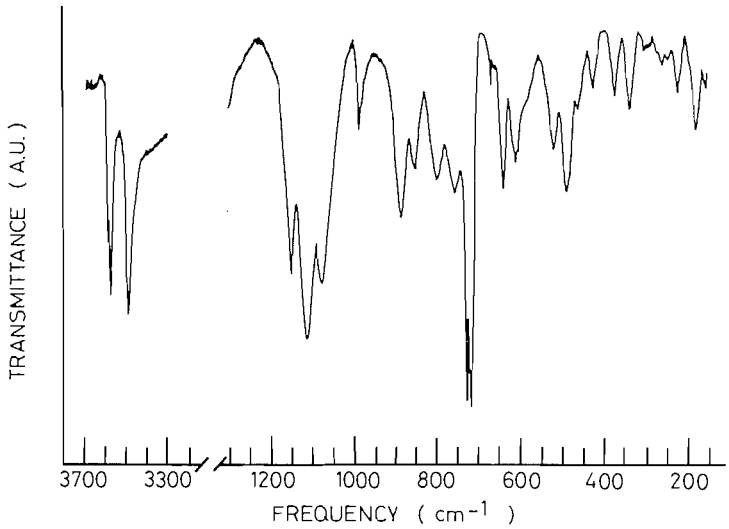

FIG. 2. Infrared spectrum of hydroxylated derivative of $Cu_3O_2SO_4$, i.e. $Cu_3(OH)_4SO_4$.

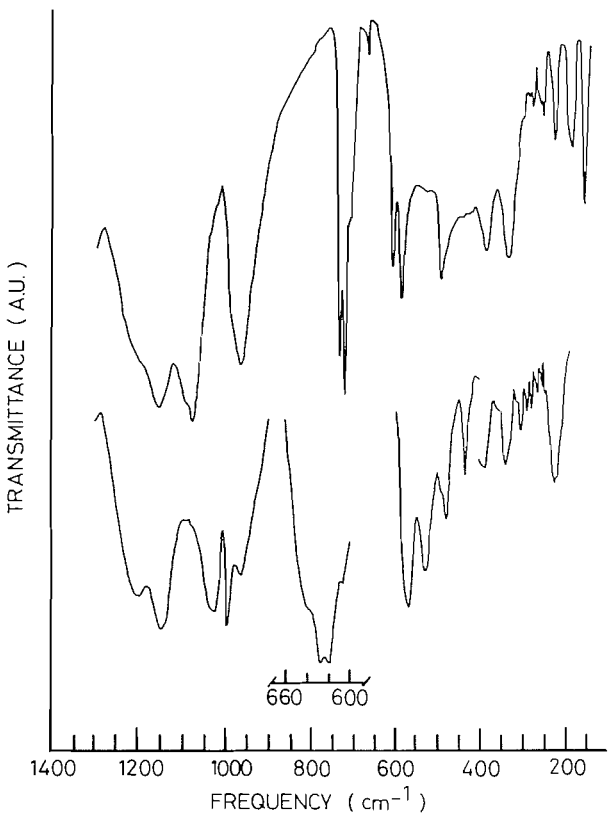

FIG. 3. Infrared spectra of 1:2 mole mixture $CuSO_4$:CuO; (*a*) upper line, unannealed, (*b*) lower line, annealed.

various splitting effects. The large number of absorption peaks, however, points to a low site symmetry consistent with the molecular point group symmetry C_s. The strong resemblance of $Cu_3O_2SO_4$ vibrational frequencies with those of the bidentate sulfate complex, Table 1, indicates the relative strength of the intra-molecular bonding in both species. Considering the $[(CuO)_2SO_4]^{2-}$ anion as an isolated unit of C_s point group the spectra show 15–17 of the possible 21 infrared-active internal modes.

The equally spaced weaker splitting, i.e. 36 ± 1 cm^{-1} in the asymmetric stretch of the $\nu_3(SO_4)$ in the hydroxylated derivative of $Cu_3O_2SO_4$, viz. $Cu_3(OH)_4SO_4$ relative to the uneven stronger splitting, i.e. 65 cm^{-1} and 110 cm^{-1}, in the original $Cu_3O_2SO_4$ indicates the moderating effect of OH presence and its H-bridging on the $\nu_3(SO_4)$ modes. However, the opposite trend in frequency shift with equal splitting occurs for the CuO modes involved in bending, viz. 340 and 300 versus 366 and 328 cm^{-1}. The effect of OH on the symmetric stretch of $\nu_1(SO_4)$ is minimal, a decrease of 12 cm^{-1}; a similar shift of 10 cm^{-1} is evident for the 227 cm^{-1} assigned to O—Cu—O bending mode.

The doublet at 730 and 720 cm^{-1} in Figs. 2 and 3*a* originating with polyethylene are presented as reference frequencies.

$Cu_3O_2SO_4$ from synthesis

The infrared spectrum of the CuO:$CuSO_4$ (2:1) unannealed mixture is given in Fig. 3*a*, upper line, along with the spectrum of the annealed product of CuO:$CuSO_4$ (2:1), Fig. 3*b* lower line. The infrared spectra of the annealed products of 1:1 and 3:1 mixtures of CuO:$CuSO_4$, not shown, were also recorded. The 1:1 product spectrum always contained intense peaks characteristic of SO_4 of unreacted $CuSO_4$ after twice the anneal time for the 2:1 mixture. The only distinct $CuSO_4$ internal fundamental in the annealed 2:1 product is the weak absorption at 965 cm^{-1}. There must be unreacted CuO present with unreacted $CuSO_4$. There is a striking similarity in the profiles of the spectrum of $Cu_3O_2SO_4$ + CuO, broken line Fig. 1, and of the spectrum of $Cu_3O_2SO_4$ from synthesis 2CuO:$CuSO_4$, lower Fig. 3, in the ν_3 region, excluding the $CuSO_4$ 965 cm^{-1} peak. This similarity lends further support to our interpretation that the brown residue is $Cu_3O_2SO_4$ from reaction [3] and $Cu_3O_2SO_4$ + CuO from reactions [1] and [2*b*]. The synthesized product's color is slightly dark olive-green which after exposure to H_2O vapor at room temperature hydroxylates and turns to light blue. The hydroxylated derivative of this synthesis product gives a complex spectrum which resembles a composite of spectral features found in $Cu_4(OH)_4OSO_4$, $Cu_3(OH)_4SO_4$, and $Cu_3O_2SO_4$. These multiple features suggest the sample contains partially hydroxylated products mixed with unreacted $Cu_3O_2SO_4$. The rate of hydroxylation of brown $Cu_3O_2SO_4$ is extremely fast relative to the olive–green 2:1 oxide–sulfate synthesized product $Cu_3O_2SO_4$. X-ray diffraction shows a complex pattern for the synthesized $Cu_3O_2SO_4$ whereas the dehydroxylated

For personal use only.

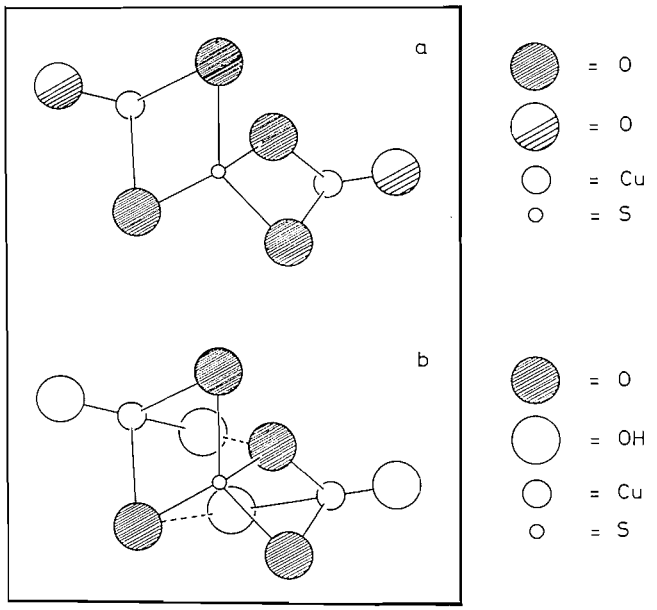

FIG. 4. Postulated configurations of (*a*) $Cu_3O_2SO_4$ and (*b*) $Cu_3(OH)_4SO_4$.

brown analog showed no discernible diffraction peaks. The brown $Cu_3O_2SO_4$ and its hydroxylated derivative $Cu_3(OH)_4SO_4$ required no grinding in making the Nujol mull whereas the synthesized analogous product required considerable grinding to obtain a consistently reproducible mull. All these distinctive features clearly indicate the brown $Cu_3O_2SO_4$ from dehydroxylation to be of high surface area and particle size of colloidal dimensions, possibly a non-crystalline state. It is worthwhile to contrast the infrared spectra of brown $Cu_3O_2SO_4$, Fig. 1, and its brown hydroxylated derivative $Cu_3(OH)_4SO_4$, Fig. 2, with the infrared spectrum of the crystalline compound $Cu_3(OH)_4SO_4$ in the far-infrared region, Fig. 5, Part I. No absorption is detected below 200 cm^{-1} for $Cu_3O_2SO_4$ and 176 cm^{-1} is the lowest absorption observed for its hydroxylated derivative $Cu_3(OH)_4SO_4$. However, crystalline $Cu_3(OH)_4SO_4$ exhibits high activity between 200 cm^{-1} and 60 cm^{-1}, see Part I. The absence of any SO_4 external optic mode activity in $Cu_3O_2SO_4$ and its hydroxylated derivative suggests a non-crystalline state or the $[(CuO)_2SO_4]^{2-}$ entity.

Conclusions

The infrared spectra of the compound $Cu_3O_2SO_4$, identified for the first time and observed from three different preparations, along with its hydroxylated derivative $Cu_3(OH)_4SO_4$ reveal contrasting spectral features and interactions of the SO_4 species. $Cu_3O_2SO_4$ obtained from the parent compounds $Cu_4(OH)_6SO_4$ or $Cu_3(OH)_4SO_4$ exhibits physicochemical properties distinctly different from the direct synthesis product from $2CuO:CuSO_4$. The proposed structure of $Cu_3O_2SO_4$ consists of the copper oxysulfate anion $[(CuO)_2SO_4]^{2-}$ of C_s symmetry with each CuO attached by the Cu to two oxygens of the SO_4 group. Of the 21 infrared-active modes predicted for this anion 17 modes are discernible.

The hydroxylated derivative $Cu_3(OH)_4SO_4$ shows physicochemical and spectral properties distinct from its crystalline analog $Cu_3(OH)_4SO_4$. The clearly resolved and evenly split peaks of the ν_3 mode of SO_4 for the derivative are in obvious contrast to the strong overlap of this mode in crystalline $Cu_3(OH)_4SO_4$ while the frequencies of the other SO_4 modes remain effectively unchanged. The OH frequencies and peak profiles remain unchanged except for the absence of the 750 cm^{-1} absorption peak in the derivative.

Received August 6, 1987

SUZANNE DEGUIRE and FRANÇOIS BRISSE. Can. J. Chem. **66**, 341 (1988).

The crystal structures of 1,4-dibenzoylbutane, 2DBC, and ethyleneglycol dithiobenzoate, 2DBS, have been solved by direct methods in order to follow the evolution of the geometry and the conformation of the Y—CH_2—CH_2—Y sequence in the isoelectronic series of C_6H_5—CO—Y—CH_2—CH_2—Y—CO—C_6H_5 where Y = CH_2, NH, O, and S. 2DBC is monoclinic, a = 7.750(4), b = 21.287(6), c = 8.905(2) Å, β = 100.55(3)°, Z = 4. 2DBS is also monoclinic, with a = 5.702(3), b = 16.171(15), c = 8.001(4) Å, β = 98.79(4)°, and Z = 2. Both compounds belong to the $P2_1/n$ space group. The weighted least-squares refinements converged to R_w = 0.049 (2DBC) and 0.043 (2DBS). The conformation of the methylenic sequence is all-*trans* (2DBC) and g^+tg^- for 2DBS (t = *trans*, g = *gauche*). The ir spectra have absorptions at 1467, 1308, and 931 cm^{-1} (2DBC) and at 1408, 1239, and 727 cm^{-1} (2DBS), respectively, characteristic of the *trans* conformation of the Y—CH_2—CH_2—Y sequence. The ^{13}C CP/MAS solid-state nmr spectra of these and other related compounds have been recorded. It is, in turn, possible to propose that the τ torsion angle between the amide group and the methylenic sequence, has a value of 85° in the aromatic polyamide, Nylon 2T.

SUZANNE DEGUIRE et FRANÇOIS BRISSE. Can. J. Chem. **66**, 341 (1988).

Dans le but de suivre l'évolution de la géométrie et de la conformation de la séquence Y—CH_2—CH_2—Y dans la série isoélectronique des composés C_6H_5—CO—Y—CH_2—CH_2—Y—CO—C_6H_5 (dans lesquels Y = CH_2, NH, O et S), on a résolu les structures cristallines du dibenzoyl-1,4 butane (2DBC) et du dithiobenzoate de l'éthylèneglycol (2DBS) par des méthodes directes. Le 2DBC est monoclinique avec a = 7,750(4), b = 21,287(6) et c = 8,905(2) Å, β = 100,55(3)° et Z = 4. Le 2DBS est aussi monoclinique avec a = 5,702(3), b = 16,171(15) et c = 8,001(4) Å, β = 98,79(4)° et Z = 2. Chacun des composés appartient au groupe d'espace $P2_1/n$. Les affinements par la méthode des moindres carrés (matrice entière) convergent vers des valeurs de R_w = 0,049 (2DBC) et 0,043 (2DBS). La conformation de la séquence des groupements méthylènes est complètement-*trans* pour le 2DBC et g^+tg^- pour le 2DBS. Les spectres ir présentent des absorptions à 1467, 1308 et 931 cm^{-1} pour le 2DBC et à 1408, 1239 et 727 cm^{-1} pour le 2DBS; ces absorptions sont caractéristiques de la conformation *trans* pour la séquence Y—CH_2—CH_2—Y. On a aussi enregistré les spectres rmn du ^{13}C CP/MAS à l'état solide de ces composés ainsi que d'autres composés apparentés. Ainsi, on peut proposer que, dans le polyamide aromatique Nylon 2T, l'angle de torsion τ entre le groupement amide et la séquence des groupements méthylènes est de 85°.

[Traduit par la revue]

Introduction

Brisse and co-workers (1–5) first studied the poly(oligomethylene terephthalates) and their model compounds, nDBO. They established that there are structural correlations between the conformation of the polyester and its model compounds. One of these, the polyethylene terephthalate, 2GT, studied by Astbury and Brown (6), Daubeny, Bunn, and Brown (7), Tomashpol'skii and Markova (8), and Arnott and Wonacott (9) has a fiber repeat shorter by 0.15 Å than expected for the all-*trans* zigzag conformation. To remedy this, a short CH_2—CH_2 distance was suggested by Daubeny and co-workers (7) but no clear justification was offered. On the other hand, the crystal structure of ethylene glycol dibenzoate, 2DBO, [C_6H_5—CO—O—$(CH_2)_2$—O—CO—C_6H_5] revealed some unusual geometrical features (1). First of all, the bond distance between methylene groups is significantly shorter than the expected distance for this type of bond and secondly, the two angles involving the CH_2—CH_2 bond are not as open as expected. As a result, the distance between the centers of the aromatic rings of ethylene glycol dibenzoate turns out to be identical to the fiber repeat, c, found by Daubeny *et al.* for poly(ethylene terephthalate). In these compounds, the only molecular interactions are of the van der Waals type.

In order to establish whether the same type of structural correlation exists between a polymer and its related model compounds when held by hydrogen bonds, Palmer and Brisse (10) determined the crystal structure of *N,N'*-ethylene bisbenzamide, 2DBN, [C_6H_5—CO—NH—$(CH_2)_2$—NH—CO—C_6H_5]. This molecule is isoelectronic with ethylene glycol dibenzoate and is a model compound for poly(ethylene terephthalamide) or Nylon 2T. To complete the series, we then decided to investigate two other isoelectronic molecules of ethylene glycol dibenzoate; 1,4-dibenzoylbutane, 2DBC, [C_6H_5—CO—CH_2—$(CH_2)_2$—CH_2—CO—C_6H_5] and ethylene glycol dithiobenzoate, 2DBS, [C_6H_5—CO—S—$(CH_2)_2$—S—CO—C_6H_5] where the oxygen atom is replaced by a CH_2 group and a sulfur atom, respectively. A comparative study of these four isoelectronic compounds will serve to show the influence of the adjacent atoms of the CH_2—CH_2 group upon the geometry and the conformation of the glycol segment.

Combining ^{13}C CP/MAS solid state nmr spectra of these and other related model compounds will yield some useful structural information on the parent polymers. In this manner 2DBO and poly(ethylene terephthalate) are related and so are 2DBN and the aromatic polyamide, Nylon 2T.

Experimental

1,4-Dibenzoylbutane was purchased from Aldrich Co. Ltd. Crystals were obtained by slow evaporation of a chloroform–ether 50:50 mixture.

Ethylene glycol dithiobenzoate was prepared by dissolving thiobenzoic acid and KOH in methanol (100 mL). The solution was cooled to 0°C. 1,2-Dibromoethane was then added. The solution was stirred under reflux for 8 h at 65°C. These steps are summarized by the equation:

$$2C_6H_5\text{-CO-SH} + 2KOH + \text{Br-}CH_2\text{-}CH_2\text{-Br} \rightarrow C_6H_5\text{-CO-S-}CH_2\text{-}CH_2\text{-S-CO-}C_6H_5 + 2H_2O + 2KBr$$

KBr was then filtered out and ethylene glycol dithiobenzoate was

obtained by concentration of the filtrate. Good crystals of ethylene glycol dithiobenzoate were obtained by slow evaporation of an ethanol solution.

X-ray diffraction

A well-developed single crystal of each compound was mounted on a Nonius-CAD4 diffractometer. The unit cell dimensions and the orientation matrix have been obtained by a least-squares refinement of the angular settings of 25 well-centered reflections. Crystal data of interest are given in Table 1. The densities were measured by the flotation method using an aqueous $ZnCl_2$ solution. The intensities were collected by the $\omega/2\theta$ scan technique (Table 2). The intensities of seven reference reflections for 2DBC and of six reference reflections for 2DBS measured every hour showed a maximum random variation of 3.0% for 2DBC and 4.3% for 2DBS over the duration of the data collection. The orientation of the crystals was verified after every 100 measurements. The diffracted intensities were corrected for Lorentz and polarization effects, but since the absorption coefficient for the Mo radiation (λ = 0.71069 Å) was small, no absorption correction was applied to either set of data.[1]

The structures were solved using the multisolution program MULTAN. All non-hydrogen atoms were found on the first E-map. The hydrogen atoms were located on subsequent difference Fourier syntheses. The weighted least-squares refinement, minimizing $\Sigma w(|F_o| - |F_c|)^2$, was carried out with anisotropic temperature factors for S, O, and C atoms and isotropic temperature factors for H atoms. The details of the least-squares refinement are given in Table 2 for the two compounds.

The general position of the $P2_1/n$ space group requires that eight 2DBS molecules be present within a unit cell. However, since the observed density of 2DBS allows for only 4 molecules, these must sit on crystallographic centers of symmetry of the unit cell.

The scattering curves for non-hydrogen atoms were taken from ref. 15 and those for H-atoms from ref. 16. The anomalous dispersion correction for S was taken from ref. 17.

[1]The programs used here are modified versions of NRC-2, data reduction; NRC-10, bond distances and angles; and NRC-22, mean planes; FORDAP, Fourier and Patterson maps (A. Zalkin); MULTAN, multisolution program; NUCLS, least-squares refinement; and ORTEP, stereodrawings (11–14).

Infrared spectroscopy

The ir spectra were recorded from KBr pellets on an FTIR Nicolet 7199 equipped with a He–Ne class II laser with a resolution of 2 cm^{-1} and 200 scans per spectra, while the background noise spectra were signal-averaged with 100 scans.

^{13}C CP/MAS nmr study

The ^{13}C CP/MAS solid-state nmr spectra were recorded with a Varian CXP 300 MHz spectrometer at a frequency of 75.431 MHz. A contact time of 2.0 to 2.5 μs was used with a delay of about 4 s between sequences (specific details are available as supplementary materials).[2] The number of contacts varied between 773 and 1500. The chemical shifts are given with respect to that of powdered hexamethylbenzene whose aromatic signal is at 132.1 ppm.

Results and discussion

Structural considerations

The final positional parameters and their standard deviations are presented in Table 3. The atomic numbering is shown in Fig. 1 and the molecular structures are presented as stereopairs in Fig. 2. The packing of the molecules is shown in Fig. 3. The bond distances and angles of the 2DBC and 2DBS are given in Table 4 and are compared to the corresponding quantities for 2DBO and 2DBN.

The benzoate groups

The C(sp^2)—C(sp^2) bond distances in the benzene rings average 1.374 and 1.380 Å for 2DBC, 1.378 Å for 2DBN, 1.379 and 1.384 Å for 2DBO, and 1.384 Å for 2DBS. They are very close to the mean bond length of 1.379 Å computed from 78 C(sp^2)—C(sp^2) distances by Brisse and Sygusch (18). The average angle in each of the six-membered rings is 120°. In the case of 2DBC, 2DBN, and 2DBS, it is observed that the angle C(6)—C(1)—C(2) deviates the most from the mean value. This feature may be explained by the geometry of the O=C—Y group. If we look at the value of the angle C(1)—C(7)—O(1), we see that it varies from 119.3 to 124.6° from one compound to another. The smaller this angle is, the closer the carbonyl oxygen and a phenyl hydrogen are. In order to minimize the interactions between the carbonyl group and the hydrogen atom on the C(6) atom, the C(6)—C(1)—C(2) angle tends to decrease. At the same time, the bond distances in the phenyl rings also reflect these repulsions between the H atom on C(6) and O(1). We observe that the bond distances C(1)—C(2) and C(6)—C(1) are the longest of all the aromatic ring bond distances. This is so in order to minimize the interactions between the hydrogen atom and the carbonyl group. In a

molecule of 2DBC, the two aromatic ring planes form an angle of 10° with each other while they are exactly parallel to one another in 2DBS since this molecule sits on a crystallographic center of symmetry.

The methylenic sequence

The observed CH_2—CH_2 bond lengths are significantly shorter than the expected C(sp^3)—C(sp^3) distance of 1.541(3) Å (19). A study undertaken by Brisse, Molhant, and Pérez (20) has shown the influence of the X and Y atoms on the CH_2—CH_2 distance in a sequence X—CH_2—CH_2—Y. When X = Y = O, X = O and Y = NH^+ or CH_3, X = S and Y = Cl, the CH_2—CH_2 bond length varies from 1.460 to 1.506 Å. In the case where X = NH_2 and Y = CH_3, no significant difference from the expected value of 1.541(3) Å was observed. The case of 2DBS, where X = Y = S, completes these results with a CH_2—CH_2 bond distance of 1.506(5) Å. For 2DBC, for which X = Y = CH_2, the observed CH_2—CH_2 bond length of 1.512(5) Å is also shorter than the expected one. For 2DBN, for which X = Y = NH, the CH_2—CH_2 bond distance of 1.522(6) Å is shorter than expected but it is the largest of all. The Y—CH_2—CH_2 bond angles is 2DBC, 2DBN, and 2DBS which average 112.2° are normal but differ significantly from the angle value of 2DBO whose average is 105.0°. These different effects seem to be independent of the value of the Y—C—C—Y torsion angle.

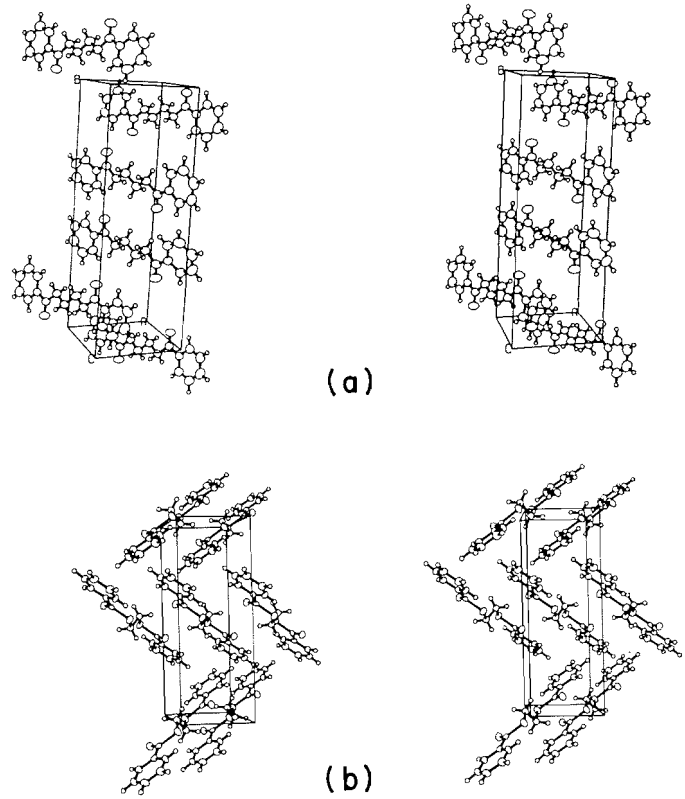

FIG. 3. Stereopairs showing the packing of the molecules (*a*) 2DBC and (*b*) 2DBS.

The conformational angles for the isoelectronic compounds correspond to the calculated conformations which are considered energetically stable. The torsional angles which characterize the methylenic sequence are defined by ϕ_1 = C(7)—Y—C(8)—C(8′), ϕ_2 = Y—C(8)—C(8′)—Y′, and ϕ_1' = C(8)—C(8′)—Y′—C(7′). The values of these torsional angles are given in Table 5. We observe two types of conformations: all-*trans* and *gauche*$^+$ *trans gauche*$^-$. Poulin-Dandurand (21) has calculated the conformational energy of an isolated molecule of ethylene glycol dibenzoate, 2DBO. The two conformations observed in the isoelectronic compounds correspond to some of the calculated energy minima. Indeed, the second energy minimum (21) is associated with the conformation observed for 2DBC (and 2DBO), while 2DBS (and 2DBN) have conformations near that calculated for the fifth energy minimum. At this point, it is worth noting that although the

two halves of each molecule are chemically identical, they are crystallographically equivalent only for the two molecules with the *gauche*$^+$ *trans gauche*$^-$ conformation, i.e., 2DBN and 2DBS. The two moieties of the two other molecules, 2DBO and 2DBC, with the nearly all-*trans* conformation are only approximately equivalent.

We have undertaken a bibliographic search of the Cambridge Data File to locate molecules with the C—S—CH_2—CH_2—S—C segment. Only two of them were not macrocyclic polyethers or cyclic molecules: ethylene dithiodiacetic acid (22) and ethylene dithiocyanate (23). In both cases the conformations were *gauche*$^+$ *trans gauche*$^-$ similar to that of 2DBS.

Packing of the molecules

For 2DBC, 2DBO, and 2DBS, none of the intermolecular contacts are less than 3.30 Å, therefore these molecules are held in the crystal by van der Waals forces only. In 2DBN, each molecule is held to four other ones by hydrogen bonds.

In 2DBN, 2DBO, and 2DBS, the molecules are packed in a herring-bone manner while the molecules of 2DBC place themselves parallel to one another.

Infrared spectra

Since our interest was in the conformation of the methylenic sequence, the relevant absorption bands are those of methylene bending, wagging, and rocking. The FTIR bands observed for these vibrational modes for the isoelectronic compounds are compared in Table 6.

For the 2DBC, the band assignment follows the work of Snyder *et al.* (24, 25) for a *trans* conformation for the CH_2—CH_2—CH_2—CH_2 angle.

For the molecule 1,2-ethanediamine, NH_2—CH_2—CH_2—NH_2, Theophanides and Kong (26) observed absorption bands at 1464, 1367, and 877 cm^{-1} for a *trans* conformation of the molecule. They assigned them to the methylene bending, wagging, and rocking, respectively. The corresponding absorption bands for a *gauche* conformation have been identified by Borring and Rasmussen (35). For the 2DBN, the bond assignment and corresponds to the observed *trans* conformation.

For the 2DBO, the three bands observed were associated to the *trans* conformation as proposed by Boitsov and Gotlib (27), Schneider *et al.* (28), and Ward and Wilding (29). All of them assigned the absorption bands at 1470, 1340, and 845 cm^{-1} to the methylene bending, wagging, and rocking of a segment O—CH_2—CH_2—O with the *trans* conformation.

In the case of 2DBS, we compared the infrared spectrum with that of 1,2-ethanedithiol (30–32). All the authors assigned the absorption bands at 1421, 1219, and 737 cm^{-1} to the methylene bending, wagging, and rocking of the isomer with a *trans* conformation. Since the spectrum of 2DBS has absorption bands at 1408, 1239, and 727 cm^{-1}, it supports a *trans* conformation for the S—CH_2—CH_2—S segment.

Therefore, in the four cases, the absorptions for the vibration modes of the methylene groups support a *trans* conformation for the sequence Y—CH_2—CH_2—Y.

^{13}C CP/MAS nmr

The ^{13}C CP/MAS solid-state nmr spectra of 2DBC, 2DBO, 2DBN, and 2DBS are shown in Fig. 4 while the chemical shifts are listed in Table 7. Depending on the compound, the aromatic carbons appear with one to four peaks in the range 128.4–136.8 ppm. The signals for C(7) are either single (2DBS) or doubled peaks (2DBC, 2DBN, 2DBO). Since the 2DBS molecule lies on a crystallographic center of symmetry, there will be only one signal for each pair of centrosymmetrically related atoms. The nmr signals of C(7) and C(8) of the 2DBN molecule, which is also centrosymmetric, are doubled because of the quadrupolar moment of the adjacent nitrogen atom which is not averaged out entirely by the rotation of the sample. The other two molecules, 2DBC and 2DBO, do not have any symmetry element. Thus, the nmr signals for C(7) and C(8) will be doubled.

The chemical shift of a given atom may be affected by the γ-*gauche* effect and/or molecular packing interactions. In this series of compounds, the chemical shift of C(8) varies from 22.9 for 2DBC to 62.5 ppm for 2DBO but this is mostly due to the nature of the Y atom. Indeed, these values are linearly related to the electronegativity (33) of Y (see Fig. 5). The higher the electronegativity of Y the more deshielded C(8) will be. A similar relationship has already been reported (34) for

	22.9	41.0	62.5	
C(Y)	38.2			

the uracil molecule where the 5-position has been variously substituted.

However, we may compare the chemical shifts of C(8) in 2DBO with the values reported for a series of *para*-substituted 2DBO molecules whose structures have been established by single crystal X-ray diffractometry. The torsion angles that may affect the chemical shift of C(8) (γ-*gauche* effect) are all nearly *trans* no matter what the *para* substituent (X) may be. The chemical shifts vary between 60.2 (X = Ph) and 65.0 ppm (X = Cl). These values compare well with those recorded here for the unsubstituted molecule (61.9 and 62.5 ppm).

In the case of 2DBN, another related molecule, *N,N'*-ethylene bis(*para*-chlorobenzamide), and the parent polymer, Nylon 2T or poly(ethylene terephthalamide) have also been examined by solid state nmr. The crystal structure of the *para*-chloro derivative reveals that its molecular conformation is similar to that of 2DBN. The torsion angle of interest, τ, is 88.8(4)° for 2DBN and 82.0(5)° for the *para*-chloro derivative. Since these two compounds also have the same molecular packing, one may assign the chemical shift of 40.5 ppm (average) for C(8) to a τ torsion angle of about 85°.

By extrapolation to Nylon 2T, whose structure has not yet been established, we propose that in this aromatic polyamide, τ has a value near 85°. This is supported by the comparable value of the chemical shift of C(7). They are 168.3 and 167.7 ppm (average) in 2DBN and the *para*-chloro derivative, respectively, and 168.4 ppm for Nylon 2T. Furthermore, it is quite likely that the packing modes in the model compounds and the parent polyamide are similar.

Conclusion

The study of these four isoelectronic compounds had served to establish the following. (*1*) The CH_2—CH_2 bond length is always shorter than the expected C(sp^3)—C(sp^3) distance. Its value ranges from 1.499(3) to 1.522(6) Å. (*2*) The Y—CH_2—CH_2 bond angles average 112.2° for 2DBC, 2DBN,

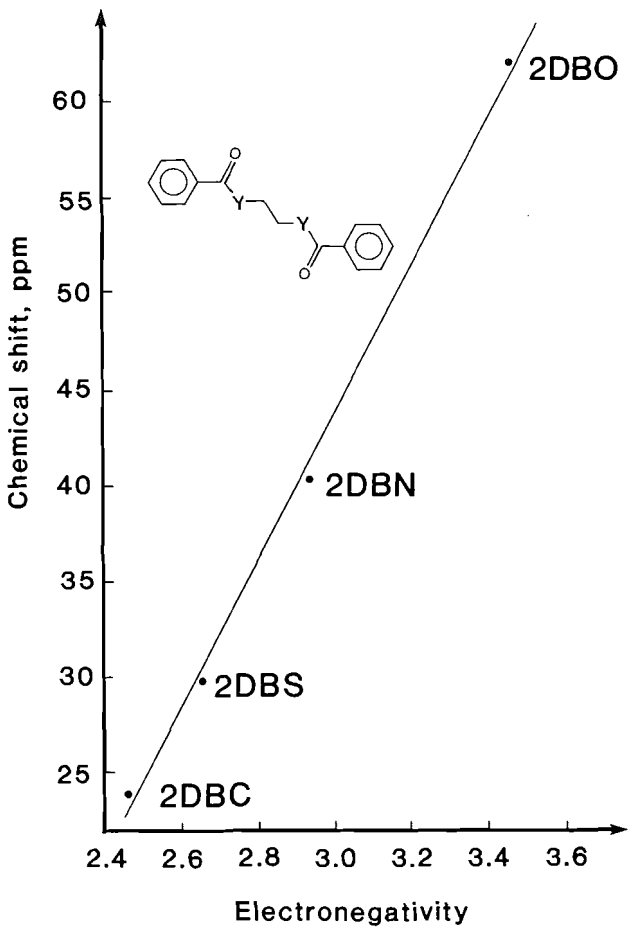

FIG. 5. Plot of the ^{13}C chemical shift of C(8) atom vs. the electronegativity of Y in —Y—CH_2—CH_2—Y—.

and 2DBS. In 2DBO, these angles average 105.0°. (*3*) We observe two types of conformation for the sequence C(7)—Y—C(8)—C(8′)—Y′—C(7′): all-*trans* and *gauche*$^+$ *trans gauche*$^-$.

Received June 24, 1987

LAURENCE K. THOMPSON, SANAT K. MANDAL, JEAN-PIERRE CHARLAND, and ERIC J. GABE. Can. J. Chem. **66**, 348 (1988).

The ligand PTP (3,6-bis(2-pyridylthio)pyridazine) generates both hydroxo- and halogeno-bridged, square-pyramidal, binuclear copper(II) complexes ($[Cu_2(PTP)X_4]$ (X = Cl (**I**), Br (**II**)); $[Cu_2(PTP)(OH)X_3]$ (X = Cl (**IV**), Br (**V**)), which are antiferromagnetically coupled. The hydroxo-bridged derivatives are more strongly coupled than those with just halogen bridges and within each pair of complexes substantially increased spin exchange is observed for the bromo-derivatives ($-2J$ = 130.5 ± 0.4 (**I**), 243.5 ± 0.3 (**II**), 294 ± 3 (**IV**), 326 ± 6 (**V**) cm^{-1}). A related halogen-bridged derivative $[Cu_2(PAP46Me)Cl_4]$ (**III**) (PAP46Me = 1,4-di(4,6-dimethyl-2-pyridylamino)phthalazine) exhibits much weaker spin exchange associated with the diminished superexchange capacity of the phthalazine bridge compared with pyridazine ($-2J$ = 55 ± 0.1 cm^{-1}). An X-ray study on $[Cu_2(PTP)Br_4]$ reveals an asymmetric tribridged structure involving a pyridazine and two bromo-bridges with a copper–copper separation of 3.318(3) Å, one relatively short terminal copper–bromine bond (2.375(3), 2.398(3) Å), and a short and long copper–bromine bridging contact (2.380(3), 2.801(3); 2.414(3), 2.766(3) Å) per copper. The complex formed green crystals with a = 11.1042(18), b = 15.6554(10), c = 12.6058(14) Å, β = 113.485(11)°, $P2_1/c$, Z = 4, R_f = 0.045.

LAURENCE K. THOMPSON, SANAT K. MANDAL, JEAN-PIERRE CHARLAND et ERIC J. GABE. Can. J. Chem. **66**, 348 (1988).

Le ligand PTP (bis(pyridylthio-2)-3,6 pyridazine) fournit des complexes binucléaires du cuivre(II) ($[Cu_2(PTP)X_4]$ dans lesquels X = Cl (**I**) ou Br (**II**); $[Cu_2(PTP)(OH)X_3]$ dans lesquels X = Cl (**IV**) ou Br (**V**)) qui sont pyramidaux à base carrée, qui sont pontés par des groupements hydroxo ou halogéno et qui sont couplés d'une façon antiferromagnétique. Le couplage des dérivés qui sont pontés par le groupement hydroxy est plus fort que celui qu'on retrouve dans les dérivés qui ne sont pontés que par un halogène; de plus, dans chacune des paires de complexes, on observe une augmentation sensible de l'échange de spin pour les dérivés bromés ($-2J$ = 130,5 ± 0,4 (**I**), 243,5 ± 0,3 (**II**), 294 ± 3 (**IV**) et 326 ± 6 (**V**) cm^{-1}). Un dérivé apparenté ponté par un halogène, le $Cu_2(PAPMe\text{-}4,6)Cl_4$ (**III**) dans lequel le PAPMe-4,6 représente le di(diméthyl-4,6 pyridylamino-2)-1,4 phtalazine, présente un échange de spin qui est beaucoup plus faible et cette caractéristique est associée avec une capacité de superéchange qui est diminuée dans le cas de la phtalazine par rapport à la pyridazine ($-2J$ = 55 ± 0,1 cm^{-1}). Une étude par diffraction des rayons-X effectuée sur le $[Cu_2(PTP)Br_4]$ révèle la présence d'une structure asymétrique tripontée impliquant une pyridazine et deux bromes agissant comme ponts; la séparation cuivre–cuivre est de 3,318(3) Å et on observe une liaison cuivre–brome terminale relativement courte (2,375(3) et 2,398(3) Å) ainsi qu'un contact de pontage cuivre–brome court et un long (2,380(3), 3,801(3); 2,414(3), 2,766(2) Å) par cuivre. Le complexe forme des cristaux verts avec a = 11,1042(18), b = 15,6554(10) et c = 12,6058(14) Å, β = 113,485(11)°, $P2_1/c$, Z = 4 et R_f = 0,045.

[Traduit par la revue]

Introduction

Binucleating, tetradentate (N_4) phthalazine and pyridazine ligands in general preferentially form binuclear copper(II) complexes involving a hydroxide bridge, in addition to the diazine bridge, and in those cases where the ligand forms six-membered chelate rings a third ligand (e.g. halogen, NO_3, SO_4, IO_3) can act as a bridge between the two metal centres (1–16). Two such ligands, PTP and PAP46Me (Fig. 1), form not only hydroxo-bridged derivatives, $[Cu_2(PTP)(OH)X_3]$ (X = Cl, Br), $[Cu_2(PAP46Me)(OH)Cl_3]$ but also dihalogeno-bridged compounds $[Cu_2(PTP)X_4]$ (X = Cl, Br), $[Cu_2(PAP46Me)\text{-}Cl_4]$. The hydroxo-bridged complexes exhibit antiferromagnetic exchange between the two copper(II) centres, which is propagated by a superexchange mechanism via the ligand groups that bridge the copper magnetic orbitals (3–7, 9, 10). The hydroxide group acts as an important superexchange bridge, while the diazine bridges also contribute significantly to the total exchange with pyridazine being more efficient than phthalazine (16, 17).

The choice of metal magnetic orbital depends upon the ground state of the copper ion and the extent of magnetic exchange is influenced by such factors as metal–ligand bond lengths and bond angles, the identity of the bridge group(s) and also terminal ligand groups (16, 18), and by distortions at the metal centre from idealized geometries. Of these factors the ones that influence exchange for copper(II) systems to the largest extent are the identity of the bridge and the angle subtended at the bridge by the two metal centres. In a related series of dihydroxo-bridged, square planar or square pyramidal copper(II) complexes $[LCu(OH)_2CuL]^{2+}$ (L = aliphatic or heterocyclic N_2 donor) a linear relationship was observed between hydroxide bridge angle and exchange integral, with a critical changeover from antiferromagnetic to ferromagnetic behaviour occurring at a Cu—O—Cu angle of approximately 97.5° (19).

In the present study we compare a series of related binuclear copper(II) complexes involving both terminal and bridging halogens and examine the role of the halogen, in terms of how it influences exchange, both as a bridging and terminal ligand. The crystal structure of the complex $[Cu_2PTPBr_4]$ is reported and consists of a binuclear arrangement of two copper square pyramids bound to the tetradentate ligand and bridged by three

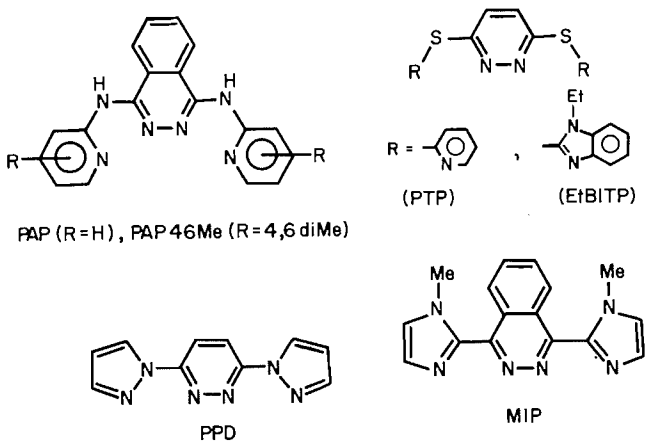

FIG. 1. Phthalazine and pyridazine ligands.

groups, the diazine (N_2) and two bromine atoms, which act as both equatorial and axial bridge groups to each copper centre. A similar structural arrangement has been observed for the analogous chloro-complex $[Cu_2(PTP)Cl_4].CH_3CH_2OH$. Variable temperature magnetic data indicate much stronger antiferromagnetic coupling in the case of the tetrabromo-derivative ($-2J$ = 243.5 (Br), 130.5 (Cl) cm^{-1}). Variable temperature magnetic data are also reported for $[Cu_2(PTP)(OH)X_3]$ (X = Cl, Br), which have stronger exchange than the tetrahalide derivatives, due to the presence of the hydroxide bridge.

Experimental

Synthesis of the ligands and complexes

PTP (11) and PAP46Me (21) were synthesized according to published procedures. Microanalyses were carried out by Canadian Microanalytical Service, Vancouver.

Cu_2PTPBr_4 (II)

$CuBr_2$ (1.8 g, 8.0 mmol) was dissolved in methanol (2 mL) and added to a solution of PTP (1.2 g, 4.0 mmol) in hot methanol (100 mL). A brown precipitate formed was filtered off, washed with methanol and chloroform, and air dried. The brown product was extracted with cold acetonitrile (300 mL) and the filtrate allowed to stand at room temperature for several weeks. Green crystals formed, which were filtered off, washed with acetonitrile, and air dried (yield 0.52 g). *Anal.* calcd. for $Cu_2(C_{14}H_{10}N_4S_2)Br_4$: C 22.55, H 1.34, N 7.52, Br 42.89; found: C 22.76, H 1.47, N 7.66, Br 39.49.

$[Cu_2PTP(OH)Cl_3]$ (IV)

PTP (1.2 g, 4.0 mmol) was dissolved in boiling methanol (80 mL). To this boiling solution an aqueous solution (40 mL) of $CuCl_2.2H_2O$ (1.4 g, 8.0 mmol) was added, with stirring, followed by a methanolic solution (10 mL) of triethylamine (0.41 g, 4.0 mmol) and the mixture refluxed for 20 min. The resulting green solution was filtered and the filtrate evaporated to a volume of approximately 40 mL on a steambath. On cooling green crystals formed and were filtered off, washed with methanol, and recrystallized from a DMF/ethanol/water mixture (yield 0.85 g). *Anal.* calcd. for $Cu_2(C_{14}H_{10}N_4S_2)(OH)Cl_3$: C 30.60, H 2.00, N 10.20, Cl 19.40; found: C 30.63, H 2.04, N 10.19, Cl 19.32.

$[Cu_2(PTP)Cl_4].CH_3CH_2OH$ (I) (20), $[Cu_2(PTP)(OH)Br_3]$ (V) (11) and $[Cu_2(PAP46Me)Cl_4]$ (III) (7) were prepared according to published procedures. $[Cu_2(PTP)(OH)Br_3]$ was also prepared by the same procedure used for IV. *Anal.* calcd. for $Cu_2(C_{14}H_{10}N_4S_2)(OH)Br_3$: C 24.65, H 1.61, N 8.21, Br 35.04; found: C 24.55, H 1.67, N 8.11, Br 35.61.

Magnetic measurements, infrared and electronic spectra

Variable temperature magnetic susceptibility data were obtained in the range 5–300 K (compounds II–IV) using an Oxford Instruments superconducting Faraday magnetic susceptibility system with a Sartorius 4432 microbalance. Main solenoid fields of 1.5 and 2.0 Telsa and a gradient field of 10 Tm^{-1} were employed. Susceptibility data are corrected for diamagnetism (Pascal corrections), temperature-independent paramagnetism, and for the presence of monomer impurity. $HgCo(NCS)_4$ was used as calibrant. Infrared spectra were obtained as Nujol mulls using a Perkin-Elmer 283 and electronic spectra (mull transmittance) using a Cary 17.

X-ray crystallographic analysis for $[Cu_2(PTP)Br_4]$ (II)

$C_{14}H_{10}N_4S_2Br_4Cu_2$ fw = 745.09

Monoclinic, $P2_1/c$, a = 11.1042(18), b = 15.6554(10), c = 12.6058(14) Å, β = 113.485(11)°, V = 2009.88 Å^3, Z = 4 (MoKα, λ = 0.70930 Å); μ = 10.21 mm^{-1}, D_{calcd} = 2.462 g cm^{-3}.

Crystals of II are green in colour. The diffraction intensities of an approximately 0.11 × 0.13 × 0.30 mm crystal were collected with graphite monochromatized MoKα radiation using the ω scan mode to $2\theta_{max}$ = 45° using a Nonius diffractometer. A total of 2869 reflections were measured, of which 2631 were considered unique, and 1580 reflections were considered significant with $I_{net} > 2.5\sigma(I_{net})$. Lorentz and polarization factors were applied but no correction was made for absorption. The cell parameters were obtained by the least-squares refinement of the setting angles of 44 reflections with 2θ in the range 38.0–43.1° (λMoKα = 0.70930 Å). The structure was solved by direct methods using MULTAN (22) and refined by full-matrix least-squares methods to final residuals of R_f = 0.045 and R_w = 0.033 for significant data (0.105 and 0.034 for all data) with weights based on counting statistics. The hydrogen atoms were fixed at calculated positions after the refinement of all the other atoms with anisotropic thermal motion. The refinement was then resumed including the hydrogen atoms. All calculations were performed with NRCVAX system of programs (23). Scattering factors were taken from ref. 24. The final atomic positional parameters and equivalent isotropic temperature factors are listed in Table 1, thermal parameters in Table 2,[3] and observed and calculated structure factors in Table 3.[3] Table 6[3] lists calculated atomic positional parameters for the hydrogen atoms and Table 7[3] lists detailed bond distances and angles for $[Cu_2(PTP)Br_4]$ (II). On the final difference map the deepest hole was $-0.840\bar{e}/Å^3$ and the highest peak $0.830\bar{e}/Å^3$. The maximum value of $|\Delta/\sigma|$ was 0.033.

Results and discussion

Description of the structure of $[Cu_2(PTP)Br_4]$ (II)

The molecular structure of II in the crystal is shown in Fig. 2 and consists of two somewhat distorted square-pyramidal copper centres bound to the tetradentate ligand, PTP, and bridged by the diazine nitrogen atoms (N2, N3) and two bromine atoms. Interatomic distances and angles relevant to the copper coordination spheres are listed in Table 4. The copper–nitrogen distances fall in the range 2.009–2.081 Å and are, on average, slightly longer than those found for the analogous complex, $[Cu_2(PTP)Cl_4].CH_3CH_2OH$ (I) (20). Terminal copper–halogen separations are longer than those observed for I, as would be expected, and, as in the case of I, the two bromine bridges are bound asymmetrically with respect to the two square-pyramidal copper centres, with each one occupying an axial and an equatorial ligand position. The axial interaction is weak with long copper–bromine bonds (2.766, 2.801 Å), while the equatorial ligands are much more strongly bound (2.380, 2.414 Å). The copper–copper separation (3.318 Å) is significantly longer than that observed for (I) (3.198 Å) and can be attributed to the presence of the more bulky bromine bridges in II. Another effect of replacing the chlorine bridges by bromine is to lengthen the diazine separation (N2—N3) which

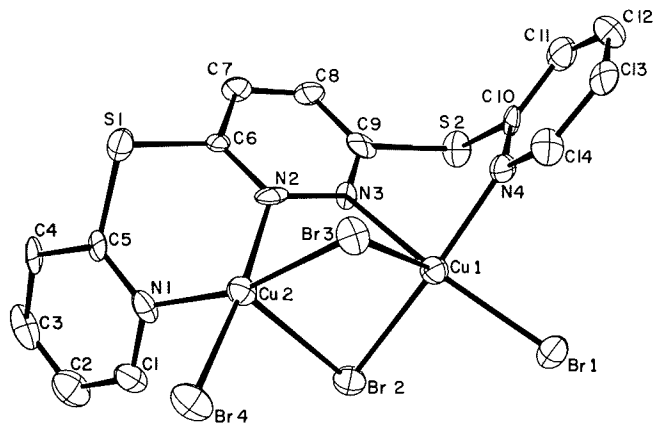

FIG. 2. Structural representation of $[Cu_2(PTP)Br_4]$ (**II**) with hydrogen atoms omitted (40% probability thermal ellipsoids). Bond distances (Å) and angles (deg): Cu(1)—Cu(2) 3.318(3), Cu(1)—Br(1) 2.375(3), Cu(1)—Br(2) 2.380(3), Cu(1)—Br(3) 2.801(3), Cu(1)—N(3) 2.081(12); Cu(2)—Br(4) 2.398(3), Cu(2)—Br(2) 2.766(3), Cu(2)—Br(3) 2.414(3), Cu(2)—N(2) 2.070(13); Br(2)—Br(3) 3.756(2); Cu(1)—Br(3)—Cu(2) 78.64(8), Cu(1)—Br(2)—Cu(2) 79.91(8); Cu(1)—Br(2)—Br(3) 48.16(8), Cu(1)—Br(3)—Br(2) 39.28(5), Cu(2)—Br(2)—Br(3) 39.94(5), Cu(2)—Br(3)—Br(2) 47.36(6).

increases from 1.316 Å in **I** to 1.366 Å in **II**. Very slight increases in the copper–nitrogen (diazine) bond lengths and bond angles (Cu—N—N) also occur.

The ligand in **II** is severely twisted with angles of 106.2° and 71.0°, respectively, between the pyridine mean planes 2 and 3 and the pyridazine mean plane (1) and an angle of 122.1° between the two pyridine mean planes (Fig. 2). Cu(1) is displaced by 0.202 Å above the mean plane of the four in plane donors N3, N4, Br1, Br2 (towards Br3) and Cu2 is displaced by 0.168 Å above the mean plane of the donors N1, N2, Br3, Br4 (towards Br2). The two N_2CuBr_2 mean planes are mutually inclined by 58.4°.

Magnetism, spectra, and structure

Variable temperature magnetic studies were carried out on **II**, **IV**, and **V** in the temperature range 5–300 K. The results are summarized in Table 5 along with data obtained previously for compounds **I** (25), **III** (16), $[Cu_2(EtBITP)(OH)Cl_3].DMF$ (**VI**) (26), and $[Cu_2(PAP)(OH)Cl_3].1.5H_2O$ (**VII**) (1). The best fit of the experimental data was calculated from the Van Vleck equation (27) for exchange coupled pairs of copper(II) ions (eq. [1]):

$$[1]\quad \chi_m = \frac{N\beta^2 g^2}{3kT}\left[1 + \frac{1}{3}\exp(-2J/kT)\right]^{-1}(1-\rho) + \left[\frac{N\beta^2 g^2}{4kT}\right]\rho + N\alpha$$

In this expression $2J$ (in the spin Hamiltonian $H = 2J\hat{s}_1.\hat{s}_2$) is the singlet–triplet splitting or exchange integral and other symbols have their usual meaning (ρ represents the fraction of a possible magnetically dilute copper(II) impurity). The temperature independent paramagnetism for a binuclear copper(II) complex, $N\alpha$, was taken as 120×10^{-6} cgs units/mol and the parameters giving the best fit were obtained by using a non-linear regression analysis (28) with ρ as a floating parameter. The experimental data and best fit lines for **II**, **IV**, and **V** are given in Fig. 3*a*, *b*, *c*, respectively. The complex $[Cu_2(PTP)(OH)Br_3]$ (**V**) contained significant amounts of paramagnetic impurity in different preparations and the sample chosen for magnetic study was analysed by non-linear, regression of the susceptibility–temperature data to a good fit with 7.5% monomeric, paramagnetic impurity (Fig. 3*c*).

A comparison of the magnetic data for **I** and **II** (Table 5) indicates greatly enhanced exchange in the case of the bromo-derivative. The structures of these two molecules are very similar with the dimensions of the binuclear centres differing slightly. The increased copper–copper separation in **II** is accompanied by increased copper–halogen distances and by a slight increase in the diazine N—N separation, which might be expected to weaken the exchange very slightly via the diazine bridge. The copper–nitrogen (diazine) separation and average Cu—N—N (diazine) angles are, however, essentially the same. The asymmetric halogen bridging arrangement in these two molecules effectively creates a situation where "no" magnetic exchange should occur via these bridge groups. This results because, on the assumption that the copper ion ground state is $d_{x^2-y^2}$, only one magnetic orbital lobe per copper is directed towards a bromine bridge. The other bridging interaction to each copper centre involves an axial orbital. This effectively orthogonal situation would, therefore, dictate that any spin-coupling should occur via the pyridazine bridge.[4] While

[4]A reviewer has suggested that, because the Br2—Br3 separation (3.756(2) Å) is slightly less than the sum of their van der Waals radii, a viable superexchange pathway could occur via this Br----Br bridge, which would contribute an antiferromagnetic term to the total exchange. Such interactions have been shown to occur between quite widely separated layers involving $CuCl_4^{2-}$ units (see, for example, ref. 30) but that deviations from linearity of the Cu—X----X—Cu bridge rapidly diminish this effect. The severely twisted bridging arrangement in **II** would, therefore, be unlikely to contribute such an exchange component.

it is known that symmetrically dibromo-bridged dicopper(II) compounds involving the anion $[Cu_2Br_6]^{2-}$ have significantly larger antiferromagnetic contributions to exchange than corresponding chloro-analogues (29) the bromine bridges in such compounds are poised appropriately to take part in magnetic exchange via the magnetic copper orbitals. For **I**, **II** this cannot be the case and so the difference in spin-exchange must be associated with other factors. A comparison of the magnetism for the isostructural pairs of compounds $[Cu_2(MIP)(OH)X_3(H_2O)].H_2O$ (MIP = 1,4-bis(1-methyl-2-imidazolyl)phthalazine (Fig. 1); X = Cl, Br) (4, 10) and $[Cu_2(PPD)(OH)X_3(H_2O)].nH_2O$ (PPD = 3,6-bis(1-pyrazolyl)pyridazine (Fig. 1); X = Cl, Br) (10) reveals in both cases that the bromo-complexes have considerably enhanced antiferromagnetic exchange. The difference in exchange is considered to be associated with the degree to which these terminal halogen ligands would polarize electron density in the copper magnetic orbital. The less electronegative bromine ligand would thus allow more unpaired spin to take part in the exchange process (16). The same criterion would explain the enhanced spin exchange in **II**, although in these two cases both terminal and bridging halogen ligands would be involved.

The pyridazine bridge is considerd to be the superexchange

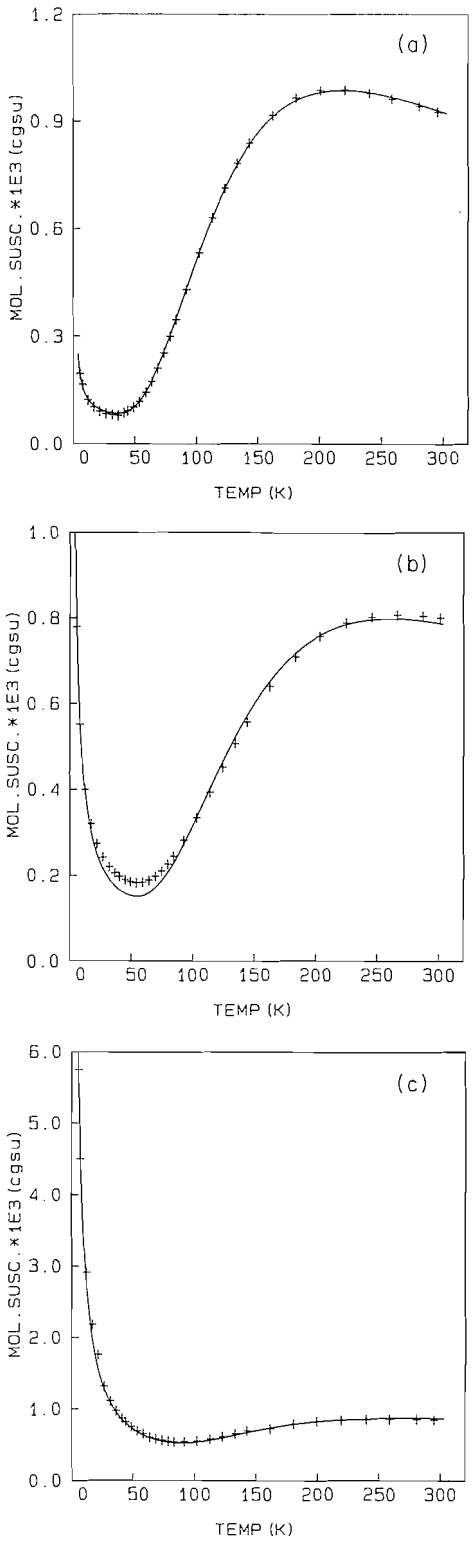

FIG. 3. (*a*) Magnetic susceptibility data for $[Cu_2(PTP)Br_4]$ (**II**). The solid line was calculated from eq. [1] with $g = 2.072 \pm 0.002$, $-2J = 243.5 \pm 0.3\ cm^{-1}$, and $N\alpha = 60 \times 10^{-6}$ cgs units ($cm^3\ mol^{-1}$)/Cu and assuming 0.19% paramagnetic impurity ($\rho = 0.0019$). (*b*) Magnetic susceptibility data for $[Cu_2(PAP)(OH)Cl_3]$ (**IV**). The solid line was calculated from eq. [1] with $g = 2.02 \pm 0.02$, $-2J = 294 \pm 3\ cm^{-1}$, and $N\alpha = 60 \times 10^{-6}$ cgs units ($cm^3\ mol^{-1}$)/Cu and assuming 1.1% paramagnetic impurity ($\rho = 0.011$). (*c*) Magnetic susceptibility data for $[Cu_2(PTP)(OH)Br_3]$ (**V**). The solid line was calculated from eq. [1] with $g = 2.162 \pm 0.008$, $-2J = 326 \pm 6\ cm^{-1}$, and $N\alpha = 60 \times 10^{-6}$ cgs units ($cm^3\ mol^{-1}$)/Cu and assuming 7.5% paramagnetic impurity ($\rho = 0.075$).

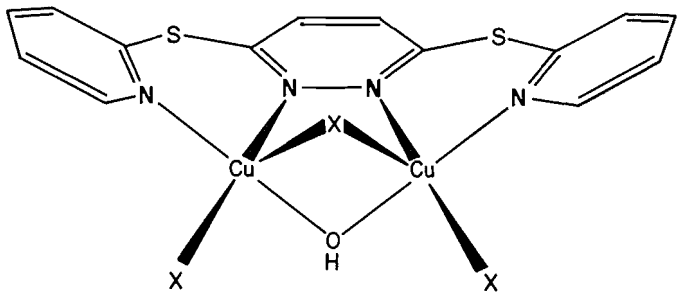

FIG. 4. Proposed structure for $[Cu_2(PTP)(OH)X_3]$ (X = Cl, Br).

pathway responsible for antiferromagnetic coupling in **I** and **II**, but it is not clear whether in the case of the bromo-derivative the bromine atoms have reduced the exchange capacity of the diazine bridge to a significant extent. No spin-coupled binuclear copper(II) complexes involving just pyridazine bridges have been characterized, to our knowledge, but the symmetrically chloro-bridged compound $[Cu_2(PTP)_2Cl](ClO_4)_3.CH_3CN$ exhibits strong antiferromagnetic coupling ($-2J = 480\ cm^{-1}$) (17). In this complex the two square pyramidal copper(II) centres are bridged equatorially by the pyridazines and axially by the chlorine, thus creating an effectively orthogonal situation in which no coupling should occur via the chlorine bridge. Each of the pyridazine rings, which bridge the two copper atoms via the magnetic $d_{x^2-y^2}$ orbital, can be considered to be responsible for half the total exchange observed for this complex. The close similarity between this value ($-2J = 240\ cm^{-1}$) and the value associated with **II** may be fortuitous but suggests that bromine may in fact have little influence on the exchange process and that the presence of more electronegative chlorine atoms bound to the copper magnetic orbitals leads to reduced exchange via the diazine bridge. A similar structural situation is found for $[Cu_2(PAP46Me)Cl_4]$ (**III**) (7) where exchange is effectively restricted to the phthalazine diazine bridge. However, the clear distinction between the exchange integrals of **I** and **III** indicates phthalazine to be a weaker exchange bridge, which may be associated with the extended delocalisation pathway present in the phthalazine group.

In a previous report the complex $[Cu_2(PTP)(OH)Cl_3].CH_3CH_2OH$ was described (11) with a room temperature magnetic moment (μ_{eff}) of 1.62 BM. Reexamination of this system suggests that this compound was in fact $[Cu_2(PTP)Cl_4].CH_3CH_2OH$ ($\mu_{eff}(RT) = 1.61$ BM; refs. 20, 25) and so compound **IV** is effectively reported here for the first time. The choice of an aqueous solvent medium for the synthesis of hydroxo-bridged copper(II) derivatives of this sort was based on the almost exclusive synthesis of such compounds from the pyridylphthalazine ligands in aqueous media (1, 3, 5, 7, 9). $[Cu_2(PTP)(OH)Br_3]$ (**V**) was, in fact, synthesized in this way (11). However, the use of triethylamine in this study ensures the formation of hydroxo-bridged species.

The hydroxo-bridged complexes $[Cu_2(PTP)(OH)X_3]$ (X = Cl, Br) (**IV**, **V**) are more strongly coupled than their tetrahalide counterparts and this clearly is a result of the presence of a hydroxide bridge disposed favorably with respect to the copper magnetic orbitals. Infrared spectra of these two complexes are virtually identical above 300 cm^{-1} with absorptions at 3460 cm^{-1} associated with OH stretch. Far infrared absorptions for **IV** at 290, 260 cm^{-1}, which are absent in **V**, are associated with terminal and bridging chloride groups, respectively. Electronic spectra (mull transmittance) have one major absorption with a low energy shoulder (15400, 11800 cm^{-1} (**IV**); 14900, 11600 cm^{-1} (**V**)) typical of square-pyramidal copper.

Structurally these complexes are assumed to resemble $[Cu_2(PAP)(OH)Cl_3].1.5H_2O$ (**VII**) (Table 5) (2) (PAP, Fig. 1) which involves two square-pyramidal copper(II) centres bound to the tetradentate pyridylphthalazine ligand and bridged equatorially by hydroxide and axially by chlorine. A proposed structural representation for these compounds is given in Fig. 4. The antiferromagnetic coupling would be the sum of the effects of both the pyridazine and hydroxide bridges, which are both bound to the magnetic orbital associated with the $d_{x^2-y^2}$ copper centres. Exchange integrals for $[Cu_2(PAP)(OH)X_3].1.5H_2O$ ($-2J$ = 201 (Cl), 191 (Br) cm^{-1}) (3) are much smaller than those observed for **IV** and **V** and again reflect the difference between pyridazine and phthalazine as a superexchange bridge. In the absence of structural data on these systems and, in particular hydroxide bridge angles, little can be said about the direct influence of the hydroxide bridge itself on exchange. However, the similarity between PTP and the pyridylphthalazine ligand PAP suggests that the binuclear centre dimensions for hydroxo-bridged derivatives of the two ligands would be comparable and in particular the hydroxide bridge angles. These angles are in the range 100–103° for $[Cu_2(PAP)(OH)X_3].1.5H_2O$ (X = Cl, Br) and comparable angles would seem reasonable for the PTP derivatives.

The copper ion ground state for **I**–**V** is $d_{x^2-y^2}$, associated with the square-pyramidal copper centres. Limited distortions from an idealized square-pyramidal situation do not seem to disrupt the effective ground state situation. However, major distortions do. The complex $[Cu_2(EtBITP)(OH)Cl_3].DMF$ (**VI**) (EtBITP, Fig. 1) has been shown to have a triple bridged structure involving pyridazine, hydroxide, and chloride bridges, but with trigonal bipyramidal copper centres (26). The hydroxide occupies an axial bridge position while the chlorine and pyridazine bridge equatorially. For a d_{z^2} ground state system exchange would involve both axial and equatorial interactions and so all three bridges would be involved in exchange, but the axial interaction would dominate since the major magnetic orbital lobe would coincide with this axis. The reduced exchange observed for this compound is consistent with a situation where the pyridazine bridge is involved in a magnetic interaction with the minor magnetic orbital lobe of the d_{z^2} ground state copper centre.

Crystal and molecular structure of [dimethyl(1-pyrazolyl)(2-pyridylmethoxy)gallato-N^2,O,N^3](η^3-allyl)dicarbonylmolybdenum(II)

STEVEN J. RETTIG, ALAN STORR,[1] AND JAMES TROTTER[1]

Department of Chemistry, University of British Columbia, 2036 Main Mall, Vancouver, B.C., Canada V6T 1Y6

Received April 7, 1987

STEVEN J. RETTIG, ALAN STORR, and JAMES TROTTER. Can. J. Chem. **66**, 355 (1988).

Crystals of [dimethyl(1-pyrazolyl)(2-pyridylmethoxy)gallato-N^2,O,N^3](η^3-allyl)dicarbonylmolybdenum(II) are triclinic, a = 9.632(2), b = 9.798(2), c = 10.255(2) Å, α = 80.16(1), β = 87.38(1), γ = 81.75(1)°, Z = 2, space group $P\bar{1}$. The structure was solved by conventional heavy-atom methods and was refined by full-matrix least-squares procedures to R = 0.033 and R_w = 0.037 for 3000 reflections with $I \geq 3\sigma(I)$. The molecule has pseudo-octahedral coordination geometry with the tridentate [$Me_2Ga(N_2C_3H_3)(OCH_2(C_5H_4N))$]$^-$ ligand *facially* coordinated and the η^3-allyl ligand occupying one coordination site *trans* to the pyridyl nitrogen atom. Important bond lengths are Mo—O = 2.219(2), Mo—N(py) = 2.212(3), Mo—N(pz) = 2.232(2), Mo—C(allyl) = 2.290(4), 2.189(4), 2.341(4), Mo—CO (*trans* to O) = 1.928(4), and Mo—CO (*trans* to N) = 1.952(4) Å.

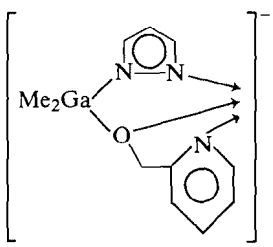
STEVEN J. RETTIG, ALAN STORR et JAMES TROTTER. Can. J. Chem. **66**, 355 (1988).

Les cristaux du [diméthyl(pyrazolyl-1)(pyridyl-2 méthoxy)-gallato-N^2,O,N^3](η^3-allyl) dicarbonylmolybdène (II) sont tricliniques avec a = 9,632(2), b = 9,798(2) et c = 10,255(2) Å, α = 80,16(1), β = 87,38(1) et γ = 81,75(1)°, Z = 2 et groupe d'espace $P\bar{1}$. On a résolu la structure par les méthodes conventionnelles aux atomes lourds et on l'a affinée par la méthode des moindres carrés jusqu'à des valeurs de R et R_w de 0,033 et 0,037 pour 3000 réflexions avec $I \geq 3\sigma(I)$. La molécule possède une géométrie de coordination pseudo-octaédrique dans laquelle le ligand tridentate [$Me_2Ga(N_2C_3H_3)(OCH_2(C_5H_4N))$]$^-$ est coordonné d'une façon faciale alors que le ligand η^3-allyle occupe une site de coordination qui est *trans* par rapport à l'atome d'azote du pyridyle. Le longueurs importantes sont : Mo—O = 2,219(2), Mo—N(py) = 2,212(3), Mo—N(pz) = 2,232(2), Mo—C(allyle) = 2,290(4), 2,189(4), 2,341(4), Mo—CO (*trans* par rapport au O) = 1,928(4) et Mo—Co (*trans* par rapport au N) = 1,952(4) Å.

[Traduit par la revue]

Introduction

Earlier publications have reported the synthesis and complexation of the novel tridentate unsymmetric anionic organogallate ligand **1**, [$Me_2Ga(N_2C_3H_3)(OCH_2(C_5H_4N))$]$^-$ (1, 2).



1

The flexibility of the tridentate ligand system has been demonstrated through the crystal structure determinations of the complexes [$Me_2Ga(N_2C_3H_3)(OCH_2(C_5H_4N))$]$Re(CO)_3$ and [$Me_2Ga(N_2C_3H_3)(OCH_2(C_5H_4N))$]$Rh(CO)$. In the former octahedral Re complex the ligand is *facially* coordinated whereas in the latter square planar Rh complex the ligand is in a *meridional* coordination mode. The present paper describes the crystal structure of the Mo complex, [$Me_2Ga(N_2C_3H_3)$-$(OCH_2(C_5H_4N))$]$Mo(CO)_2(\eta^3$-$C_3H_5)$. This complex was described in an earlier account at which time predictions were made about its most likely molecular stereochemistry (1). A *fac* coordination of the organogallate ligand was proposed with the allyl group positioned opposite the pyrazolyl moiety of the ligand. The X-ray structure described herein confirms the *facial* coordination of the organogallate ligand and also establishes the location of the allyl group in the pseudo-octahedral complex. The structural parameters obtained are discussed in conjunction with data available for similar Mo allyl complexes.

Experimental

The title compound was prepared and characterized as described previously (1). Crystals suitable for X-ray study were obtained by recrystallization from benzene. A crystal bounded by the eight faces (followed by their distances in mm from a common origin): {0 1 1}, 0.16, {1 1 −1}, 0.28, (−1 −1 3), 0.27, (1 5 0), 0.21, {1 0 0}, 0.04, was mounted in a general orientation. Unit-cell parameters were refined by least squares on 2 sin θ/λ values for 25 reflections (2θ = 35–40°) measured on a diffractometer with Mo-$K\alpha$ radiation ($\lambda(K\alpha_1)$ = 0.70930, $\lambda(K\alpha_2)$ = 0.71359 Å). Crystal data at 22°C are as follows:

$C_{16}H_{20}GaMoN_3O_3$ fw = 468.0

Triclinic, a = 9.632(2), b = 9.798(2), c = 10.255(2) Å, α = 80.16(1), β = 87.38(1), γ = 81.75(1)°, V = 943.6(3) Å^3, Z = 2, ρ_c = 1.647 Mg m^{-3}, $F(000)$ = 468, μ(Mo-$K\alpha$) = 20.9 cm^{-1}. Absent reflections: none, space group $P\bar{1}$ (Buerger reduced cell) from structure analysis.

Intensities were measured with graphite-monochromatized Mo-$K\alpha$ radiation on an Enraf-Nonius CAD4-F diffractometer. An ω-2θ scan at 0.87–10° min^{-1} over a range of (0.85 + 0.35 tan θ) degrees in ω (extended by 25% on both sides for background measurement) was employed. Data were measured to 2θ = 55°. The intensities of three check reflections, measured every hour throughout the data collection, decreased uniformly to final values of 0.96 times the initial values. The data were scaled accordingly. After data reduction,[2] an absorption correction was applied using the Gaussian integration method (3, 4). Transmission factors ranged from 0.482 to 0.759 for 128 integration points. Of the 4318 independent reflections measured, 3000 (69.5%) had intensities greater than or equal to $3\sigma(I)$ above background where $\sigma^2(I) = S + 2B + (0.04(S - B))^2$ with S = scan count and B = normalized background count.

The structure was solved by conventional heavy-atom methods in the

centrosymmetric space group $P\bar{1}$ which was confirmed by the success of the refinement. The heavy atoms were positioned from the Patterson function and all other atoms, including hydrogen, were positioned from subsequent difference Fourier syntheses. In the final stages of refinement the non-hydrogen atoms were refined with anisotropic thermal parameters and the hydrogen atoms with isotropic thermal parameters. Scattering factors for all atoms and anomalous dispersion corrections for Mo and Ga were taken from ref. 5. The weighting scheme $w = 1/\sigma^2(F)$, where $\sigma^2(F)$ is derived from the previously defined $\sigma^2(I)$, gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of both $|F_o|$ and $\sin\theta/\lambda$ and was employed in the final stages of full-matrix refinement of 297 variables. Reflections with $I < 3\sigma(I)$ were not included in the refinement. Convergence was reached at $R = 0.033$ and $R_w = 0.037$ for 3000 reflections with $I \geq 3\sigma(I)$. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$, $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$ and $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$.

On the final cycle of refinement the mean and maximum parameter shifts corresponded to 0.03 and 0.32σ, respectively. The mean error in an observation of unit weight, $(\Sigma w(|F_o| - |F_c|)^2/(m - n))^{1/2}$, was 1.568. A final difference Fourier synthesis showed maximum fluctuations of −1.2 to +0.8 e Å^{-3}, both near Mo, and was featureless away from the heavy atoms. The final positional parameters for the non-hydrogen atoms appear in Table 1. Bond lengths, bond angles, and intra-annular torsion angles are given in Tables 2–4, respectively. Hydrogen atom parameters, bond lengths and angles involving hydrogen, a complete listing of torsion angles, and structure factors have been deposited.[3]

Results and discussion

The crystal structure of [dimethyl(1-pyrazolyl)(2-pyridylmethoxy)gallato-N^2,O,N^3](η^3-allyl)dicarbonylmolybdenum(II) consists of discrete molecules separated by normal van der Waals distances, the shortest intermolecular contacts being O(2)···H(5a) = 2.59(5), O(1)···C(8) = 3.340(6), and O(1)···O(2) = 3.333(5) Å. The molecule (Fig. 1) contains a *facially* coordinated $[Me_2Ga(N_2C_3H_3)(OCH_2(C_5H_4N))]^-$ ligand, as expected (1). The η^3-allyl ligand occupies one coordination site of the pseudo-octahedral complex, *trans* to the pyridyl nitrogen atom rather than *trans* to the pyrazolyl nitrogen atom as predicted earlier (1) on the basis of the crystal structure of

the related molecule $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2NH_2)]Mo(CO)_2(\eta^3\text{-}C_4H_7)$, **2** (6). Inspection of Fig. 1 shows that a steric interaction with one of the hydrogen atoms bound to C(11) would result if the allyl ligand were located *trans* to the pyrazolyl nitrogen atom. The location of the allyl ligand in the present structure is analogous to that observed for the $\eta^3\text{-}C_7H_7$ ligands in the complexes $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2NH_2)]Mo(CO)_2(\eta^3\text{-}C_7H_7)$ (7) and $[Me_2Ga(N_2C_5H_7)(OCH_2CH_2SEt)]Mo(CO)_2(\eta^3\text{-}C_7H_7)$ (8), *trans* to the amino nitrogen and alkyl sulphur atoms, respectively. The overall ligand shape and chelate ring conformations are very similar to those reported for $[Me_2Ga(N_2C_3H_3)(OCH_2(C_5H_4N))]Re(CO)_3$ (1).

The η^3-allyl ligand is oriented such that the central carbon atom is directed away from the carbonyl ligands. The central Mo—C(allyl) bond (2.189(4) Å) is significantly shorter than the two others (2.290(4) and 2.341(4) Å). These features are similar to those observed in related structures (refs. 9–13 and references therein). The Mo—N(pyrazolyl) bond length of 2.232(2) Å, *trans* to CO, is significantly shorter than corresponding distances ranging 2.276(4)–2.322(3) Å in related compounds (9–11). The Mo—N(pyridyl) bond at 2.212(3) Å and *trans* to the allyl group is, as expected, shorter than the Mo—N(pz) bond. The Mo—O distance of 2.219(2) Å is shorter than the corresponding distance of 2.269(2) Å in **2** (6) but is consistent with the relatively short metal—O distances observed for the rhenium analog $[Me_2Ga(N_2C_3H_3)(OCH_2(C_5H_4N))]Re(CO)_3$ (1). The Mo—C(O) distances reflect a structural *trans* effect, the bond *trans* to O (1.928(4) Å) being significantly shorter than that *trans* to N (1.952(4) Å). The corresponding C—O distances differ by 0.020(7) Å (in the opposite sense).

TABLE 4. Intra-annular torsion angles (deg) standard deviations in parentheses

Atoms	Value (deg)
N(1)—Mo—O(3)—Ga	−20.8(1)
N(2)—Ga—O(3)—Mo	24.9(1)
O(3)—Ga—N(2)—N(1)	−19.8(3)
Mo—N(1)—N(2)—Ga	7.7(4)
O(3)—Mo—N(1)—N(2)	7.4(3)
N(3)—Mo—O(3)—C(11)	33.9(2)
Mo—O(3)—C(11)—C(12)	−44.2(4)
O(3)—C(11)—C(12)—N(3)	29.3(5)
Mo—N(3)—C(12)—C(11)	0.8(4)
O(3)—Mo—N(3)—C(12)	−18.9(2)

The pyrazolyl and pyridyl rings are both planar to within experimental error. The Mo···Ga distance is 3.5552(5) Å. Other features of the molecular geometry (Tables 2–4) are as expected.

Received July 16, 1987

B. SIMARD, R. P. STEER, R. H. JUDGE, and D. C. MOULE. Can. J. Chem. **66**, 359 (1988).

The $\tilde{a} \leftarrow \tilde{X}$ absorption spectra of BrClCS and Br_2CS have been photographed under low resolution at room temperature. The electronic origins of BrClCS and Br_2CS have been placed at 17116 and 16859 cm^{-1}, respectively. Vibronic analyses show that the molecules are non-planar in their $\tilde{a}$ states. By fitting quadratic–Gaussian and quadratic–quartic double-minimum potentials to the observed vibrational levels of the out-of-plane manifolds, the equilibrium out-of-plane angles and the barrier heights to molecular inversion have been estimated to be 25 ± 1 deg and 541 ± 10 cm^{-1} for BrClCS, and 17.5 ± 1 deg and 524 ± 10 cm^{-1} for Br_2CS. In the case of BrClCS, all six $\tilde{a}$ state vibrational frequencies have been obtained. In the case of Br_2CS, only modes 1 (C—S stretch), 2 (symmetric C—Br stretch), 3 (in-plane Br—C—Br scissor), and 4 (out-of-plane bend) are active in the spectrum. Comparisons with other tetraatomic thiocarbonyls support the given assignments.

B. SIMARD, R. P. STEER, R. H. JUDGE et D. C. MOULE. Can. J. Chem. **66**, 359 (1988).

Les spectres d'absorption des transitions ($\tilde{a} \leftarrow \tilde{X}$ d'BrClCS et d'Br_2CS ont été photographiés dans des conditions de basse résolution à la température de la pièce. Les origines des transitions électroniques pures dans le BrClCS et le Br_2CS ont été respectivement placées à 17116 et 16859 cm^{-1}. Des analyses vibrationelles indiquent que les molécules sont non-planaires dans leurs états $\tilde{a}$. En modelant des potentiels à double minimum de types quadratique–Gaussien et quadratique–quartique aux niveaux vibrationel observés du mouvement hors du plan, les angles d'équilibre hors du plan et les hauteurs des barrières opposant l'inversion moléculaire ont été estimés à 25 ± 1° et 541 ± 10 cm^{-1} pour BrClCS, et 17.5 ± 1° et 524 ± 10 cm^{-1} pour Br_2CS. Dans le cas d'BrClCS, les fréquences vibrationelles des six modes de vibration ont pu être determinées. Dans le cas de Br_2CS, seulement les modes 1 (élongation C—S), 2 (élongation symmétrique C—Br), 3 (cisaillement dans le plan Br—C—Br), et 4 (repliement hors du plan) sont actifs dans le spectre. Des comparaisons avec d'autre thiocarbonyles tétra-atomiques appuient les attributions vibrationelles apportées.

Introduction

Interest in the spectroscopy, photophysics, and photochemistry of small thiocarbonyl molecules has grown rapidly in recent years. The initial interest in these compounds resulted partly from similarities with their carbonyl analogues whose spectroscopy and photochemistry have been relatively well-understood for many decades. However, it was soon realized that the thiocarbonyls are in many respects different from and more interesting than their carbonyl counterparts. One important reason for this lies in the fact that substitution of sulfur for oxygen shifts the excited electronic states of a molecule to lower energies. As a result, the low-lying excited states of the thiocarbonyls are bound, enabling one, in principle, to determine their excited state structures from their vibrationally and rotationally discrete absorption spectra.

The $\tilde{a}$–$\tilde{X}$ and $\tilde{A}$–$\tilde{X}$ band systems of most thiocarbonyls are found in the visible region of the spectrum. Both are associated with nominal $n \rightarrow \pi^*$ one electron promotions on the C=S moiety and are relatively weak (1). Their origins are separated by no more than ca. 1900 cm^{-1} and their oscillator strengths often differ by a factor of 10 or less, leading to extensive overlap of the two systems. The $\tilde{a}$–$\tilde{X}$ and $\tilde{A}$–$\tilde{X}$ spectra of H_2CS (2), HClCS (3), F_2CS (4, 5), FClCS (6, 7), and Cl_2CS (8, 9) have been analyzed to date.

Until recently, little has been known about the corresponding transitions in the heavier BrClCS and Br_2CS molecules. The $\tilde{A}$–$\tilde{X}$ band systems of these two thiocarbonyls were recently analyzed (10) using both conventional room temperature and jet-cooled excitation spectroscopy. These techniques failed to reveal observable emission from their lowest triplet states. In order to complete the characterization of the low-lying excited states of these molecules we therefore undertook to investigate their $\tilde{a}$–$\tilde{X}$ and systems using conventional room temperature photographic absorption spectroscopy. This method has been very successful in the past for studying such systems in spite of their relatively small oscillator strengths. We report here vibrational analyses of the low resolution $\tilde{a}$–$\tilde{X}$ absorption spectra of BrClCS and Br_2CS.

Experimental

BrClCS and Br_2CS were prepared by the method of Diderrich and Hass (11) by the direct reaction of boron tribromide with thiophosgene (Cl_2CS). Both reactants (Aldrich) were used as received. Purification of both BrClCS and Br_2CS was achieved by trap-to-trap vacuum distillation on a grease- and mercury-free vacuum line. Immediately following purification, the sample of BrClCS was analyzed by mass spectrometry which showed that the main contaminants were Br_2CS and Cl_2CS. In the case of Br_2CS, BBr_3, and BCl_3 (both non-emissive) were found to be the main contaminants; there was no evidence of residual Cl_2CS or BrClCS. No other spectral analyses were carried out before photographing the spectrum. When not in use the samples were kept in the dark at about −10°C to prevent dimerization and thermal decomposition.

A 2 m White-type multiple reflection cell was filled with either BrClCS or Br_2CS at its room temperature vapor pressure (ca. 17 and 6 Torr, respectively) and was illuminated with a 450 W high pressure Xe arc. The exit beam was then directed into a 1.5 m Bausch and Lomb grating spectrograph with a reciprocal dispersion of 15 nm/cm. The resulting spectrum was photographed with Kodak high speed infrared film. The absolute positions of the bands were determined by

comparison with the simultaneously photographed emission lines of an Fe–Ne hollow cathode lamp.

Results and discussion

The $\tilde{a}$–$\tilde{X}$ and $\tilde{A}$–$\tilde{X}$ absorption systems of both BrClCS and Br_2CS are of comparable intensity and overlap substantially. Fortunately neither molecule phosphoresces strongly whereas both fluoresce with high quantum yield when excited at wavelengths below their dissociation thresholds (10). Thus, absorption bands due to the singlet systems may be identified from the laser-induced fluorescence excitation spectra. The remaining bands are assigned to the triplet systems.

Considerable photodecomposition of the samples occurred during the recording of the spectra. Fortunately, the most probable decomposition products either do not absorb in the same spectral region (e.g. dimer) or were not observed (e.g. Cl_2CS (9), Cl_2 (12), BrCl (13), Br_2 (14)).

The mechanism whereby the spin forbidden $\tilde{a}$–$\tilde{X}$ absorption systems gain intensity is well known (15–17). Assuming that the $\tilde{a}$–$\tilde{X}$ transitions in these molecules "borrow" intensity from the strong electric dipole allowed $\tilde{B}$–$\tilde{X}$ transitions, the origin bands should be observed, no restrictions should apply to Δv for transitions among totally symmetric vibrations, and Δv even is expected for transitions among non-totally symmetric vibrations (1, 15). Successful vibrational analysis (*vide infra*) of the $\tilde{a}$–$\tilde{X}$ systems in Br_2CS and BrClCS based upon these selection rules attest to the validity of the assumptions on which they are based.

1. The $\tilde{a}$–$\tilde{X}$ *absorption spectrum of BrClCS*

The low resolution $\tilde{a}(^3A'')$–$\tilde{X}(^1A')$ absorption spectrum of BrClCS was photographed in the 490–595 nm region. The 510–585 nm segment is shown in Fig. 1. Strong absorption begins at about 584 nm, and bands belonging to the $\tilde{A}(^1A'')$–$\tilde{X}(^1A')$ system can be observed in the blue part of the spectrum. The separations between the origins of the $\tilde{A}$ and $\tilde{a}$ states of thiocarbonyls for which data are already available is of immediate help in the analysis. The relevant data are given in Table 1, and from them an $\tilde{A}$–$\tilde{a}$ separation of the order of 1200 cm^{-1} is anticipated for BrClCS. Since the origin of the $\tilde{A}$ state is located at 18363 cm^{-1} (10), the origin of the $\tilde{a}$ state of BrClCS should therefore lie near 17160 cm^{-1}. The lowest energy strong absorption band lies at 17115.8 cm^{-1} and because progressions can be built on this band, this feature is assigned as the origin. The actual $\tilde{A}$–$\tilde{a}$ separation is therefore 1247 cm^{-1}.

The following band assignments were achieved on the basis that the $\tilde{a}$ state frequencies should be similar to those of the $\tilde{A}$ state, as is the case with other tetraatomic thiocarbonyls (see references in Table 1).

Modes 4 (Br—C—Cl rock) and 5 (Br—C—Cl scissor)

Excluding the anharmonic ν_6' stack, the lowest frequency mode is expected, by comparison with the $\tilde{A}$ state, to be ν_4'. The first strong band to the blue of the origin (17115.8 cm^{-1}) is located at 17259.0 cm^{-1}. The difference, 143.2 cm^{-1}, is attached to many hot and cold combination bands, and a progression extends to 4^3 in combination with 5_0^2. The band at 17259.0 cm^{-1} is therefore unambiguously assigned as 4_0^1. The frequency of $\nu_4' = 143.2\ cm^{-1}$ is only slightly smaller than the $\tilde{A}$ state value of 159 cm^{-1} (10).

The band located +237.0 cm^{-1} from the origin at 17352.9 cm^{-1} is assigned as the 5_0^1 band for two reasons. First, it is the first strong band to be detected to the blue of the 4_0^1 band and second, the combination bands $4_0^1 5_0^1$, and $4_0^1 5_0^2$ can be observed and are among the strongest bands of the spectrum.

A value of 237.0 cm^{-1} for ν_5' is nearly the same as the ground state frequency (235 ± 3 cm^{-1} from ref. 10). It was originally thought that the band at 17352.9 cm^{-1} was hot, but it was not possible to suitably assign the spectrum on this basis. Mode 5 is approximately described as the Br—C—Cl scissoring motion. As shown in Table 2, the ratio of ν_5':ν_5'' in the $\tilde{a}$:$\tilde{X}$ states for this vibration increases in the order F_2CS ($\tilde{a}$:$\tilde{X}$ = 0.74) > ClFCS ($\tilde{a}$:$\tilde{X}$ = 0.81) > Cl_2CS ($\tilde{a}$:$\tilde{X}$ = 0.84). The present value of

nearly unity for BrClCS appears to be a continuation of this trend.

Mode 3 (Br—C—Cl symmetric stretch)

In the case of F_2CS (4, 5) and Cl_2CS (8, 9) the frequency of the X—C—Y symmetric stretch is observed to be somewhat higher in the $\tilde{a}$ state than in the $\tilde{A}$ state. The frequency of this mode in BrClCS is therefore expected to be higher than the $\tilde{A}$ state value of 423 cm^{-1} (10). The feature located +442.5 cm^{-1} from the origin is therefore assigned as the 3_0^1 band. This choice was motivated by the ability to assign several additional features in terms of combination bands involving this mode.

Again the ratio of $\nu_3':\nu_3''$ in the $\tilde{a}:\tilde{X}$ states is calculated to be very close to unity (1.01). This ratio is somewhat larger than the nearly constant ratio of 0.94 observed for F_2CS, ClFCS, and Cl_2CS (see Table 2).

Mode 1 (C—S stretch)

In the case of F_2CS (4, 5) and Cl_2CS (8, 9), the frequency of this mode is observed to be somewhat higher in the $\tilde{a}$ state than in the $\tilde{A}$ state. The same should apply for BrClCS. Thus, the $\tilde{a}$ state C—S stretching frequency is anticipated to be higher than the $\tilde{A}$ state value of 890 cm^{-1} (10). The feature located +934.7 cm^{-1} from the origin is assigned as the 1_0^1 band. Several combination bands involving this frequency can be found. The $\tilde{a}:\tilde{X}$ ratio of 0.83 compares well with those of other similar molecules listed in Table 2.

Mode 2 (Br—C—Cl asymmetric stretch)

There is a feature +570.3 cm^{-1} from the origin which could not be assigned in terms of bands involving modes 1, 3, 4, 5, or 6. This band is tentatively assigned as 2_0^1. On the grounds that most of the $\tilde{a}$ state frequencies of other tetraatomic thiocarbonyl halides are higher than the corresponding $\tilde{A}$ state values, the observed $\nu_2':\nu_2''$ ratio of 0.75 compares very well with the recently reported value of 0.71 in the $\tilde{A}:\tilde{X}$ states (10).

Mode 6 (out-of-plane bend)

By analogy with other similar systems (1), this mode is expected to be very active. In the $\tilde{A}$–$\tilde{X}$ system 6_0^2 is the strongest band. Because both the $\tilde{a}$–$\tilde{X}$ and the $\tilde{A}$–$\tilde{X}$ systems involve the same one electron, $n \rightarrow \pi^*$, promotion, the $\tilde{a}$ state structure is expected to be not too different from that of the $\tilde{A}$ state. Thus, the 6_0^2 band should also be very strong in the $\tilde{a}$–$\tilde{X}$ absorption spectrum. The strong feature +257.8 cm^{-1} from the origin is therefore assigned as the 6_0^2 band. This assignment is straightforward since this feature is the only strong band which could bear this assignment. The $\tilde{a}:\tilde{X}$ frequency ratio for this mode (see Table 2) decreases in the order F_2CS (0.91) > ClFCS (0.79) > Cl_2CS (0.63). The observed $\tilde{a}:\tilde{X}$ ratio of 0.58 for BrClCS fits very nicely into this pattern.

The complete analysis is given in Table 3; almost all the bands lying in the 528–595 nm region have been assigned. The frequencies of all six modes in each of the $\tilde{X}$, $\tilde{a}$, and $\tilde{A}$ states of BrClCS are summarized in Table 4.

2. The $\tilde{a}$–$\tilde{X}$ *absorption spectrum of* Br_2CS

The absorption spectrum of Br_2CS photographed at a pressure–path of 70 atm cm is shown in Fig. 2. The banded absorption system commences near 613 nm. Two types of features can be distinguished: (1) line-like features which lie in the blue part of the spectrum, and (2) broader bands which lie in the red part of the spectrum. Comparison with the recently reported fluorescence excitation spectrum of Br_2CS (10) shows that the line-like features belong to the $\tilde{A}(^1A_2)$–$\tilde{X}(^1A_1)$ singlet band system. As the broad features could not be associated with this system, these bands have been ascribed to the $\tilde{a}(^3A_2)$–$\tilde{X}(^1A_1)$ absorption.

Using the data of Table 1, together with the $\tilde{A}$–$\tilde{a}$ separation of 1247 cm^{-1} for BrClCS, and the origin of the $\tilde{A}$–$\tilde{X}$ system at 17992 cm^{-1} (10), the origin of the $\tilde{a}$–$\tilde{X}$ system of Br_2CS should be located in the 592–595 nm region. This appears to be reasonable at first sight since bands lying at $\lambda > 595$ nm are weak while those lying at $\lambda < 595$ nm are much stronger. The assignment was facilitated by the identification of progressions of 154 and 258 cm^{-1}. Both progressions converge to the weak band at 16859 cm^{-1}, which has been assigned to the electronic origin. The resulting $\tilde{A}$–$\tilde{a}$ separation of 1133 cm^{-1} compares very well with the data of Table 1.

17636	s	$2_0^3, 3_0^5$
17687	s	$2_0^2 3_0^2$
17754	m	1_0^1
17794	m	$2_0^3 3_0^1, 3_0^6$
17845	w	$2_0^2 3_0^3$

By comparison with the $\tilde{A}$–$\tilde{X}$ band system (10), the progressions of 154 and 258 cm^{-1} are attributed to activities in modes 3 (Br—C—Br scissor) and 2 (Br—C—Br symmetric stretch), respectively.

Only a few bands could not be assigned in terms of modes 2, 3, and their combinations. On the basis of the absorption spectra of other small thiocarbonyls (1), mode 1 (C—S stretch) should be active, and the band located +895 cm^{-1} from the origin could thus be 1_0^1. This assignment must be considered tentative because (1) the $\tilde{a}$:$\tilde{X}$ ratio (0.80) is somewhat smaller than the constant value of 0.87 observed for F_2CS and Cl_2CS (see Table 2), and (2) contrary to expectation no combination bands involving mode 1 could be positively identified.

Because the excited molecule exhibits a non-planar structure (*vide infra*), the out-of-plane bending mode is expected to be active. The band located +336 cm^{-1} from the origin is the strongest band in the spectrum and, by analogy with the previous analysis of the $\tilde{A}$–$\tilde{X}$ band system of BrClCS (10), this band is assigned as 4_0^2. The 4_1^3, 4_0^4, and 4_1^5 bands could also be observed and their positions have been listed in Table 5 together with the whole spectral assignment. Table 6 summarizes the vibrational frequencies of Br_2CS in its $\tilde{X}$, $\tilde{a}$, and $\tilde{A}$ states.

3. $\tilde{a}$ *state geometries*

The assignments of Tables 3 and 5 indicate that both BrClCS and Br_2CS are non-planar in their $\tilde{a}$ states. Whereas mildly anharmonic progressions are observed for most excited and ground state modes, one set of excited state frequencies in each

molecule does not fit this pattern. These are assigned to the excited state out-of-plane bending mode, and their extreme anharmonicity is therefore associated with the existence of an equilibrium non-planar nuclear conformation. This is in complete agreement with the observed behavior of the $\tilde{a}$ and $\tilde{A}$ states of all other thiocarbonyl halides investigated to date (1–9).

As shown previously for the $\tilde{A}$ states of these molecules (10, 18), either the quadratic–Gaussian or quartic–quadratic double-minimum potential models can be used to determine the out-of-plane angle and the barrier height opposing molecular inversion. The eigenvalues for the excited state out-of-plane bending levels in the quadratic–Gaussian model have been calculated and tabulated by Coon *et al.* (30) for various values of ρ, a shape factor, and B, a parameter directly proportional to the barrier height. The eigenvalues of the quartic–quadratic potential have been reported by Laane (31) but this model was found to provide a significantly poorer fit to the observed data. We take this as an indication that the shape of the inversion barrier is approximated better by a Gaussian function than a quadratic, a result which has often been observed in thiocarbonyl systems (1).

The results of the calculations for the quadratic-Gaussian model are summarized in Table 7 for BrClCS, and in Table 8 for Br_2CS. Following the technique of Coon *et al.* (30), these data were obtained by arbitrarily selecting a range of values of ρ (in increments of $\Delta\rho = 0.3$) and then determining the values of B (in increments of $\Delta B = 0.05$ or 0.10) which yielded reasonable agreement between the resulting calculated inversion vibrational energies and those oberved in the spectra. The "best" values of ρ and B were then selected from among several sets of such values. Because both the barrier height and the equilibrium out-of-plane angle exhibit only small differences for the set of nearly acceptable combinations of ρ and B (cf. Tables 7 and 8), we estimate the uncertainties to

be ca. $\pm 10\,cm^{-1}$ in the barrier heights and ca. $\pm 1°$ in the out-of-plane angles, within the limits imposed by the applicability of the model.

In the case of BrClCS, the best fit with the quadratic–Gaussian model is obtained using a shape factor of 1.5 and a B value of 3.1. This gives a barrier of 541 cm^{-1} and an equilibrium out-of-plane angle of 25°. A comparison of the above parameters with those of the $\tilde{A}$ state (10) indicates that both the $\tilde{A}$ and the $\tilde{a}$ states have nearly the same geometry. This result does not follow the trend established with other thiocarbonyls in which the barrier is somewhat higher in the $\tilde{a}$ state than in the $\tilde{A}$ state. A higher barrier would require a smaller separation between $\nu_6' = 2$ and $\nu_6' = 3$. The strong 6_0^2 band is undoubtedly correctly assigned. In order to obtain a smaller 2–3 splitting, the 6_1^3 band would have to lie to the red of its present position. Assuming that the 6_1^3 band can be observed in the present spectrum, careful examination of Fig. 1 reveals that there is no band which could be thus assigned.

The $\tilde{a}$–$\tilde{X}$ spectrum of Br_2CS consists of bands which are considerably broader than those of BrClCS, making the identification of closely spaced features difficult. The best fit to the ν_4' stack with the quadratic–Gaussian model is obtained using a shape factor of 0.9 and a B value of 1.475. This gives an out-of-plane angle and an inversion barrier height of 17.5° and 524 cm^{-1}, respectively. Unfortunately a definite assignment of a hot band transition terminating in $\nu_4' = 1$ could not be made, so a key datum on which to judge the quality of the calculated ν_4' levels is missing. Nevertheless, the calculated barrier and equilibrium out-of-plane angles are reasonable. The $\tilde{a}$ state inversion barrier is calculated to be about 60 cm^{-1} higher than that of the $\tilde{A}$ state, as expected on the basis of the structures of similar molecules.

The $\tilde{a}$–$\tilde{X}$ band systems of both BrClCS are associated with $n_S \rightarrow \pi^*_{CS}$ one electron promotions. Thus, the C—S bond order drops from 2 to 1.5 upon excitation and a substantial drop in the C—S stretching frequency must result. Our analyses assign ν_1' (BrClCS) = 934 cm^{-1} and ν_1' (Br_2CS) = 895 cm^{-1} which represent decreases of about 20% compared with the ground state values. Using Badger's empirical relationship (32), $r^2\omega$ = constant, Δr(C—S) = 0.10 and 0.12 Å are calculated for BrClCS and Br_2CS, respectively.

The decrease in frequency of the symmetric stretching mode, ν_2, in Br_2CS is similar to that observed upon excitation to the $\tilde{A}$ state (10), but is much larger than expected on the basis of a comparison with other tetraatomic thiocarbonyls. In the $\tilde{A}$ state (10, 18) the potential energy hypersurface along the C—Br symmetric stretching coordinate is highly perturbed by a dissociative process, most likely molecular fragmentation to form products in their ground electronic states (33). Such a process is also probably responsible for the lower than expected frequency of ν_2 in the $\tilde{a}$ state of Br_2CS.

Excess molar volumes and excess viscosities of 2-propanol + methylacetate + dichloromethane system at 298.15 K[1]

INÉS L. ACEVEDO, MIGUEL A. POSTIGO, AND MIGUEL KATZ[2]

Cátedra de Fisicoquímica, Instituto de Ingeniería Química e Instituto de Física, Facultad de Ciencias Exactas y Tecnología, Universidad N. de Tucumán, Avda. Independencia 1800, S.M. de Tucumán (4000), Argentina

Received July 17, 1987

INÉS L. ACEVEDO, MIGUEL A. POSTIGO, and MIGUEL KATZ. Can. J. Chem. **66**, 367 (1988).

Densities and viscosities were determined for the 2-propanol + methylacetate + dichloromethane system at 298.15 K. From the experimental results, molar excess volumes and excess viscosities were calculated. Different expressions exist in the literature to predict these excess properties from the binary mixtures. The empirical correlation of Tsao–Smith and Toop is the best for this system.

INÉS L. ACEVEDO, MIGUEL A. POSTIGO et MIGUEL KATZ. Can. J. Chem. **66**, 367 (1988).

Opérant à 298,15 K, on a déterminé les densités et les viscosités du système propanol-2 + acétate de méthyle + dichlorométhane. Utilisant les données expérimentales, on a calculé les volumes et les viscosités molaires en excès. Dans la littérature, on retrouve diverses expressions pour prédire ces propriétés en excès à partir de celles de mélanges binaires. La corrélation empirique de Tsao–Smith et Toop est la plus appropriée pour ce système.

Introduction

In the chemical literature, properties of binary systems are relatively abundant, properties of ternary systems are scarce, and properties for high order multicomponent systems are very rare. For ternary systems we can find in the literature the works of Heric and Brewer (1), Rastogi *et al.* (2), Radojkovic *et al.* (3), Cibulka (4), Singh *et al.* (5), and Tsao and Smith (6).

It is the intention of this work to present molar excess volume (v^E) and excess viscosity (η^E) for the 2-propanol (*1*) + methylacetate (*2*) + dichloromethane (*3*) system at 298.15 K, and for the three corresponding binary systems as well as to consider some methods for empirical correlations if interactions in a ternary mixture are assumed to be closely dependent on the interactions of the constituent in binary mixtures.

Experimental

The methods used in our laboratory have been described previously (7, 8). Densities were determined with a digital densimeter A.P., model DMA 45. All weighings were made on a H315 Mettler balance. A thermostatically controlled bath (constant to 0.01°C) was used. Temperatures were read from calibrated thermometers. Calibration was done with doubly distilled water with an error of ± 0.1 kg m^{-3}.

Viscosities of the pure liquids and of the mixtures were determined with a Cannon–Fenske viscosimeter calibrated with doubly distilled water and benzene. Kinetic energy corrections were applied to viscosity data. The estimated error was ± 0.005 mPa s.

Materials and solutions

2-Propanol and dichloromethane Merck (puriss.) was fractionally distilled over calcium chloride and the middle colorless fractions collected. Methylacetate Mallinckrodt (puriss.) was heated by reflux with acetic anhydride and then distilled over potassium carbonate. Mixtures were prepared by mixing weighed amounts of the pure liquids. Caution was taken to prevent evaporation.

Results and discussion

The experimental results for the pure liquids are reported in Table 1, together with the values from the literature for comparison. Densities and viscosities of the binary mixtures can be calculated from the experimental data, knowing the mole fraction with the following equation:

TABLE 1. Properties characterizing the pure components at 298.15 K

	$\rho \times 10^{-3}$ (kg m^{-3})		η (mPa s)	
Substance	Exp.	Lit.	Exp.	Lit.
2-Propanol	0.7800	0.7804(9)	2.053	2.036(9)
Methylacetate	0.9274	0.9273(10)	0.361	0.360(9)
Dichloromethane	1.3163	1.3168(10)	0.420	0.412(10)

$$[1] \quad P = x_iP_i + x_jP_j + x_ix_j \sum_{\substack{k=0 \\ i<j}}^{n} a_k(x_i - x_j)^k$$

where P_i and P_j are the properties of the pure components. Table 2 shows the values of the coefficients a_k as well as their standard deviation, calculated by the method of least squares with a VAX 11/780 computer.

The excess function of the binary systems could be represented by a Redlich–Kister form of the type:

$$[2] \quad X^E = x_ix_j \sum_{k=0}^{n} a_k(x_i - x_k)^k$$

where X^E represents v^E or η^E, x_i and x_j the mole fractions of the components i and j, and a_k the polynomial coefficients. The method of least squares was used to determine the values of the coefficients. In each case, the optimum number of coefficients was ascertained from an examination of the variation of the standard error of estimate with n:

$$[3] \quad \epsilon = [\Sigma(X^E_{obs} - X^E_{cal})^2/(n_{obs} - n)]^{1/2}$$

The values adopted for the coefficients and the standard error of estimate associated with the use of eq. [3] are summarized in Table 3 for the three binary systems.

Figure 1 shows the experimental values of v^E and η^E for the three systems. The continuous curves were calculated from eq. [2] using these values for the coefficients.

The experimental values of densities and viscosities of the ternary system are obtained, adding the third component to

TABLE 3. Coefficients a_k from eq. [2] and standard deviations for the binary systems at 298.15 K

Systems	a_0	a_1	a_2	a_3	a_4	a_5	ϵ
(*1*) + (*2*)							
$v^E \times 10^6$ (m^3 mol^{-1})	1.829	−0.329	2.04	2.8	−6.7	−9.2	0.02
η^E (mPa s)	−1.33	−1.9	−1.4	−0.4	—	—	6×10^{-3}
(*1*) + (*3*)							
$v^E \times 10^6$ (m^3 mol^{-1})	1.972	−1.202	−3.29	−1.9	2.2	—	0.02
η^E (mPa s)	−1.12	−1.08	−0.2	—	—	—	4×10^{-3}
(*2*) + (*3*)							
$v^E \times 10^6$ (m^3 mol^{-1})	1.315	−0.29	—	—	—	—	4×10^{-3}
η^E (mPa s)	0.061	0.007	—	—	—	—	8×10^{-4}

a constant relation of the other two. Molar excess volume is calculated with the following equation:

$$[4] \quad v^E = \frac{x_1M_1 + x_2M_2 + x_3M_3}{\rho} - (x_1v_1 + x_2v_2 + x_3v_3)$$

where M_1, M_2, and M_3 are the molecular weights of the components; v_1, v_2, and v_3 are the molar volumes; and ρ the density of the solution. The excess viscosity is defined by the following equation:

$$[5] \quad \eta^E = \eta - \exp(x_1 \ln \eta_1 + x_2 \ln \eta_2 + x_3 \ln \eta_3)$$

where η, η_1, η_2, and η_3 are the viscosities of the mixture and of the pure components.

Table 4 shows the experimental values of densities and viscosities at different mole fractions.

Figures 2 and 3 show the experimental equal values of v^E_{123} and η^E_{123}.

If interaction in a ternary system $i + j + k$ is assumed to be closely dependent on the interactions of the constituent $i + j$, $j + k$, and $i + k$ mixtures, it should be possible to evaluate thermodynamic excess functions for ternary mixtures of non-electrolytes, when the corresponding functions for the binary $i + j$, $j + k$, and $i + k$ mixtures are known.

Rastogi *et al.* (2) suggested a form for predicting the excess volumes of a ternary solution:

$$[6] \quad v^E_{123} = \tfrac{1}{2}[(x_1 + x_2)v^E_{12} + (x_1 + x_3)v^E_{13} + (x_2 + x_3)v^E_{23}]$$

in which v_{ij}^{E} represents the excess molar volume of the binary mixtures at composition x_i^0, x_j^0, such that:

$$[7] \quad x_i^0 = 1 - x_j^0 = \frac{x_i}{x_i + x_j}$$

This expression is inappropriate for describing the system near infinite dilution.

Radojkovič *et al.* (3) takes an expression proposed by Redlich and Kister (11) for the excess free energy:

$$[8] \quad v_{123}^{E} = v_{12*}^{E} + v_{23*}^{E} + v_{13*}^{E}$$

where v_{12*}^{E}, v_{23*}^{E}, and v_{12*}^{E} represent the excess molar volumes with x_1, x_2, and x_3 mole fractions of the ternary system calculated with eq. [2] using coefficients of Table 3.

Kohler (12) proposed an equation for a ternary solution of the following form:

$$[9] \quad v_{123}^{E} = (x_1 + x_2)^2 v_{12}^{E} + (x_1 + x_3)^2 v_{13}^{E} + (x_2 + x_3)^2 v_{23}^{E}$$

Kohler's equation is symmetrical in that all three binary systems are treated identically. In this equation v_{ij}^{E} refers to the excess volumes of x_i^0, x_j^0 in the binary mixtures using eq. [7].

Jacob and Fitzner (13) suggested an equation for estimating the properties of a ternary solution based on the binary data at composition nearest the ternary composition taking the form for excess molar volume:

$$[10] \quad v_{123}^{E} = \frac{x_1 x_2 v_{12}^{E}}{\left(x_1 + \frac{x_3}{2}\right)\left(x_2 + \frac{x_3}{2}\right)} + \frac{x_1 x_3 v_{13}^{E}}{\left(x_1 + \frac{x_2}{2}\right)\left(x_3 + \frac{x_2}{2}\right)} + \frac{x_2 x_3 v_{23}^{E}}{\left(x_2 + \frac{x_1}{2}\right)\left(x_3 + \frac{x_1}{2}\right)}$$

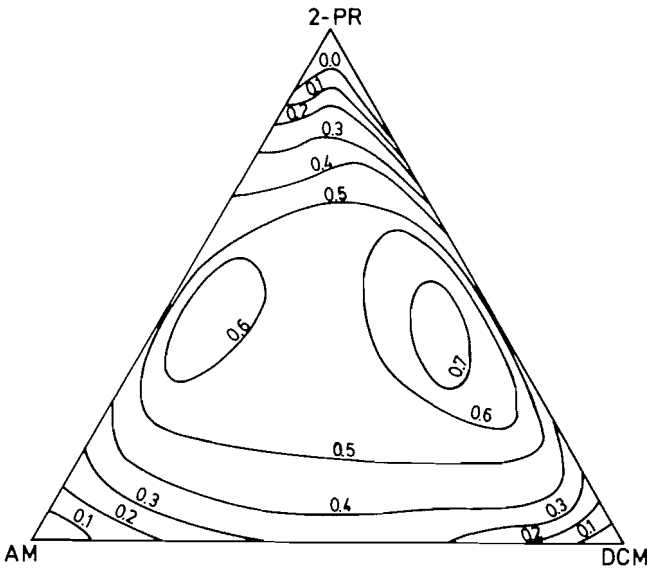

FIG. 2. Lines of constant excess molar volumes ($\times 10^6$ m^3 mol^{-1}) for 2-propanol (*1*) + methylacetate (*2*) + dichloromethane (*3*) system at 298.15 K.

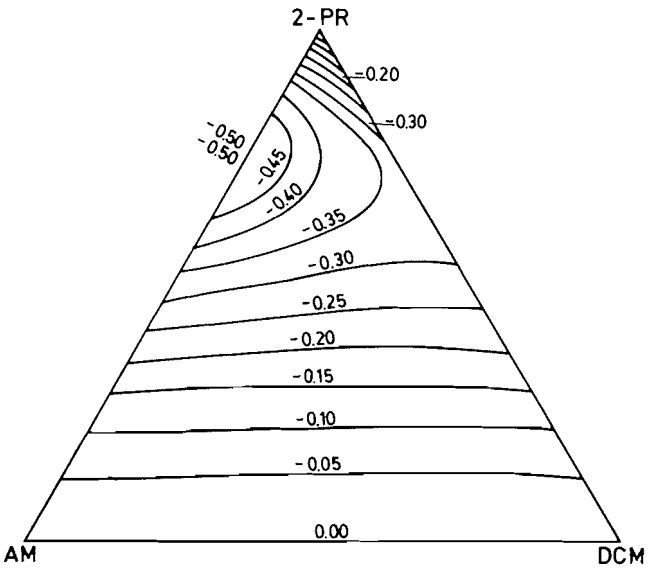

FIG. 3. Lines of constant excess viscosities (mPa s) for 2-propanol (*1*) + methylacetate (*2*) + dichloromethane (*3*) system at 298.15 K.

such that for the binary system at composition x_i^0, x_j^0:

[11] $$x_i - x_j = x_i^0 - x_j^0$$

Tsao and Smith (6) proposed an equation for predicting the excess enthalpy of a ternary system. For excess molar volume, it is

[12] $$v_{123}^E = \left(\frac{x_2}{1 - x_1}\right) v_{12}^E + \left(\frac{x_3}{1 - x_1}\right) v_{13}^E + (1 - x_1) v_{23}^E$$

in which the v_{ij}^E refer the excess volume for the binary mixtures at compositions x_i^0, x_j^0 such that $x_i^0 = x_i$ for the *1,2*, and *1,3* binary systems and $x_2^0 = x_2/(x_2 + x_3)$ for the *2,3* binary system.

TABLE 5. Standard deviations for 2-propanol (*1*) + methylacetate (*2*) + dichloromethane (*3*) system at 298.15 K

Equation	$\epsilon(v^E) \times 10^6$ (m^3 mol^{-1})	$\epsilon(\eta^E)$ (mPa s)
[8]	0.13	0.07
[9]	0.18	0.09
[10]	0.13	0.07
[12]	0.08	0.01
[13]	0.15	0.03

Toop (14) developed an equation for excess Gibbs free energy of mixture similar to that suggested previously by Tsao and Smith.

Singh *et al.* (5) proposed an equation of the following form:

[13] $$v_{123}^E = v_{12*}^E + v_{13*}^E + v_{23*}^E + Ax_1x_2x_3 + Bx_1(x_2 - x_3) + Cx_1^2(x_2 - x_3)^2$$

where A, B, and C are parameters characteristic of the mixtures evaluated by fitting this equation by the method of least squares, with a standard deviation defined as eq. [3].

The parameters obtained for this system are for v_{123}: $A = 1.6709$, $B = -13.032$, $C = 121.239$; for η_{123}: $A = 2.6439$, $B = -2.7820$, $C = 38.9507$.

Table 5 shows the standard deviations calculated from applications of eq. [8] of Radojkovič; eq. [9] of Kohler; eq. [10] of Jacob and Fitzner; eq. [12] of Tsao and Smith, and eq. [13] of Singh *et al.* for molar excess volumes and excess viscosities for the ternary system.

Equation [12] shows the best agreement with the experimental data.

Temperature dependance of adiabatic compressibility, sound velocity, and specific acoustic impedance of water–cyclohexanone mixture

T. RAMANJAPPA AND E. RAJAGOPAL

Department of Physics, Sri Krishnadeveraya University, Anantapur – 515 003, India

Received July 6, 1987

T. RAMANJAPPA and E. RAJAGOPAL. Can. J. Chem. **66**, 371 (1988).

The temperature dependance of adiabatic compressibility minimum (TACM), sound velocity maximum (TSVM), and specific acoustic impedance (TSAIM) of water–cyclohexanone mixture has been studied by experimentally determining the sound velocity in and density of aqueous solution at different concentrations over a temperature range 36–77°C. The structural contribution to the shift in TACM, TSVM, and TSAIM has been evaluated. The shifts are negative and increase with concentration. The results indicate that cyclohexanone behaves as a structure breaker at higher temperature.

T. RAMANJAPPA et E. RAJAGOPAL. Can. J. Chem. **66**, 371 (1988).

Opérant à des températures allant de 36 à 77°C, on a mesuré les densités et les vitesses du son dans des solutions aqueuses, à diverses concentrations de cyclohexanone; on en a déduit la relation qui existe entre la température et la compressibilité adiabatique minimale (TCAM), la vélocité maximale du son (TCMS) et l'impédance acoustique spécifique (TIMAS). On a évalué le contribution de la structure au déplacement dans la TCAM, la TCMS et la TIMAS. Les déplacements sont négatifs et ils augmentent avec la concentration. Les résultats indiquent que, à des températures élevées, la cyclohexanone se comporte comme une substance qui brise les structures.

Literature survey indicates that the thermodynamic behaviour of the system water–cyclohexanone has not been extensively studied but for a few measurements on excess heats of mixing and excess volumes of mixing (1, 2). Both the excess heats of mixing and excess volumes of mixing for this system have been found to be negative ($\Delta H = -5365$ cal mol^{-1} and $\Delta V = -4.5$ mL mol^{-1}). The magnitude and sign of ΔH and ΔV for this system fall in line with alcohols and amines (2). In general the contraction has been explained by the strong cohesive nature of water molecules. The behaviour of excess heats of mixing of this solute with water may be attributed to the formation of icebergs like alcohols and amines. However, no authentic evidence exists regarding the structural interaction of this solute with water. Since the studies on the effect of different solutes on temperature corresponding to velocity maximum (TSVM) and temperature corresponding to adiabatic compressibility minimum (TACM) of water have been found to characterize the structural propensity of any solute (3–7), the authors made an attempt to see how this solute modifies the hydrogen bonded structure of water by determining the structural contributions to the shift in TSVM and TACM. In addition to these studies, temperature corresponding to specific acoustic impedance maximum (TSAIM) studies of water have been also carried out and the results are reported in this paper.

Experimental

Triple distilled water was used to prepare stock solutions of aqueous cyclohexanone. Cyclohexanone was purified using standard procedures (8). The density of the purified liquid, determined using a bicapillary type pycnometer with an accuracy of 2 parts in 10^5, was found to be 942.77 kg m^{-3} at 25°C and is in good agreement with the literature data (9). Ultrasonic velocities in pure components and aqueous cyclohexanone solutions were determined using a single crystal variable path interferometer working at 3 MHz with an accuracy of ±0.003%. The details of the experimental technique were reported earlier (10) from our laboratory. Densities and ultrasonic velocities in the solutions were determined at ≃2°C intervals over a range of 5°C on either side of T_u, T_β, and T_z where T_β, T_u, and T_z are the temperatures corresponding to the adiabatic compressibility minimum, sound velocity maximum, and specific acoustic impedance maximum, respectively.

Results

The results of adiabatic compressibility, ultrasonic velocity, and specific acoustic impedance as a function of temperature at different concentrations of aqueous cyclohexanone are shown in Figs. 1, 2, and 3, respectively.

Discussion

The adiabatic compressibility minimum (T_β) of the solution is given (3) by

$$[1]\quad T_\beta = \left[64 - \frac{\phi_2}{\phi_1}\frac{\alpha_\beta}{0.0032}\right]\left[1 + \frac{\phi_2}{\phi_1}\frac{\alpha_\beta^1}{0.0016}\right]^{-1} - \left[\frac{d\beta^E}{dt}\right]\left[1 + \frac{\phi_2}{\phi_1}\frac{\alpha_\beta^1}{0.0016}\right]^{-1}[\phi_1 \times 0.0032]^{-1}$$

where ϕ_1 and ϕ_2 represent the volume fractions of pure water and organic solution, respectively, in the solutions. α_β and α_β^1 are the constants of organic solute involved in adiabatic compressibility versus temperature relation given by

$$[2]\quad \beta_2 = \beta_2^0 + \alpha_\beta t + \alpha_\beta^1 t^2$$

The sound velocity maximum (T_u) of the solution is given (3) by

$$[3]\quad T_u = 74 - \left[\frac{\phi_2}{\phi_1}\right]^2 \frac{w_1}{w_2}\frac{\alpha_u}{0.049}\left[\frac{u_1}{u_2}\right]^3 - \frac{w_1}{\phi_1^2}\frac{u_1^3}{0.098}\left[\rho\frac{d\beta^E}{dt} + \beta^E\frac{d\rho}{dt}\right]$$

where w_1 and w_2 represent weight fractions of pure water and organic solute, respectively, in the solution. α_u is the temperature coefficient of sound velocity in the relation

$$[4]\quad u_2 = u_2^0 - \alpha_u t$$

The specific acoustic impedance maximum (T_z) of the

mentally from the relation

$$[7]\quad (\Delta T_{\beta\,or\,u\,or\,z\,str})_{exp} = T_{\beta\,or\,u\,or\,z\,exp} - T_{\beta\,or\,u\,or\,z\,id}$$

The results of $[\Delta T_{\beta\,str}]_{exp}$, $[\Delta T_{u\,str}]_{exp}$, and $[\Delta T_{z\,str}]_{exp}$ are presented in Table 2 and are represented graphically against the mole fraction X_2 of cyclohexanone in Figs. 4*a*, *b*, and *c*, respectively. $[\Delta T_{\beta\,str}]_{exp}$, $[\Delta T_{u\,str}]_{exp}$ and $[\Delta T_{z\,str}]_{exp}$ for cyclohexanone are negative throughout the concentration range in the present study and increase with concentration. The negative values of structural shifts clearly demonstrate the structure disrupting nature of cyclohexanone. But carbonyl oxygen of ketone (1, 2, 11) is known to form hydrogen bond to water indicating this solute to behave as hydrophobic.

Excess heats of mixing and volumes of mixing (1, 2) indicate structure stabilization leading to iceberg formation around the solute molecule. It is worthwhile to note here that while excess heats and volumes of mixing data confined to 26.5°C, whereas the present studies are confined to high temperature range (36–77°C). Therefore it may be concluded that the structural propensity of a solute as revealed by physical property is dependent on temperature and literature survey (12, 13) indicates that structural interactions are sensitive to temperature and structure promoting interactions decrease with rise in temperature (14). The results of present study on water + cyclohexanone indicate that cyclohexanone loses its structure stabilizing character as temperature is increased and behaves as a structure breaker at higher temperature.

Remote steric effects on the disproportionation/recombination ratio of cumyl radicals[1]

KARL R. KOPECKY AND MEI-YUK YEUNG[2]
Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received August 14, 1987

KARL R. KOPECKY and MEI-YUK YEUNG. Can. J. Chem. **66**, 374 (1988).

The disproportionation/combination ratio in the reaction between two 3,5-di-*tert*-butylcumyl radicals, generated by thermolysis of the corresponding diazene, is 0.21 ± 0.03 at 60°C in benzene. This is much larger than the value of 0.06 found for the unsubstituted cumyl radicals. It is suggested that the *tert*-butyl groups hinder the formation of a parallel association complex, which has been proposed to account for the much smaller amount of disproportionation in the reaction between benzylic radicals as compared with alkyl radicals.

KARL R. KOPECKY et MEI-YUK YEUNG. Can. J. Chem. **66**, 374 (1988).

À 60°C, dans le benzène, on a évalué à 0,21 ± 0,03 le rapport dismutation/recombinaison pour la réaction de deux radicaux di-*tert*-butyl-3,5 cumyles provenant de la thermolyse du diazène correspondant. Cette valeur est beaucoup plus élevée que la valeur de 0,06 observée pour les radicaux cumyles qui ne sont pas substitués. On croit que les groupements *tert*-butyles empêchent la formation du complexe d'association parallèle dont la formation a été suggérée pour expliquer la faible quantité de produit de dismutation qui se forme au cours de la réaction entre radicaux benzyliques par opposition à ce qui est observé avec les radicaux alkyles.

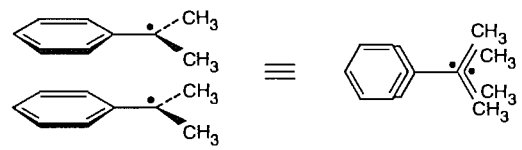
Introduction

The amount of coupling product formed upon reaction between two benzylic radicals with β-hydrogen atoms (1) is much larger than that between two alkyl radicals (2). For example, at 60°C the disproportionation/combination ratio for cumyl radicals is 0.06 while that for *tert*-butyl radicals is 5.4 (1*a*). It has been suggested that the reason for the difference is that benzylic radicals can form dimeric association complexes, such as **A** for cumyl radicals, which could easily collapse to coupling product but whose geometry would be unfavorable for disproportionation (3). If such a parallel association complex were an important entity, large substituents on the benzene ring should result in decreased stability and distortion of the complex. There is a bit more disproportionation between *p-tert*-butylcumyl radicals, but the effect of the *tert*-butyl group, if real, is small (1*b*). Inspection of molecular models suggests that there can be close association between two *p-tert*-butylcumyl radicals. The orientation can be nearly parallel and the benzylic carbon atoms could still be very close to bonding distance of one another.

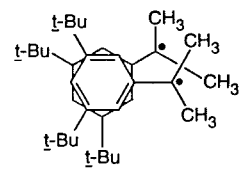
In the present study, the disproportion/combination ratio of 3,5-di-*tert*-butylcumyl radicals was measured to explore further the effect of bulky ring substituents on this ratio. Inspection of molecular models suggests that there can still be a close association between two 3,5-di-*tert*-butylcumyl radicals but the orientation would be skewed toward that shown in **B** for closest approach. The benzylic radical centers would not be as close to each other as in **A** but would be closer to the benzylic methyl group of the partner in the complex. This should result in a higher disproportionation/combination ratio.

Results and discussion

The 3,5-di-*tert*-butylcumyl radicals were generated by thermolysis of the corresponding diazene **1**, Scheme 1. Degassed C_6D_6 solutions containing accurately known amounts of **1** (~0.05 *M*) and methyl triphenylmethyl ether as internal standard were kept at 60°C for 10 half-lives of decomposition. The rate of thermolysis of **1** was assumed to be equal to that of the corresponding diazene lacking *tert*-butyl groups (1*a*) since there is only a small effect of ring alkyl substituents on the rate of thermolysis (1*b*,*c*). The concentrations of the disproportionation products **2** and **3** were then determined by ^{1}H nmr, by comparing the areas of the benzylic proton of **2** and the allylic methyl group of **3** with the area of the methoxy group of the internal standard. As has been observed before (1*a*,*b*) there is more cumyl than α-methylstyryl disproportionation product, Table 1. This has been attributed to a possible polymerization of the latter product (1*a*) but its conversion to trimer, Scheme 2, seems more plausible. No attempt was made to isolate the trimer, which should be present in ~5% yield. The coupling reaction to give trimer will, of course, be accompanied by some disproportionation but the amount will be insignificant.



A



B

The nmr spectra of the reaction mixtures from thermolysis of **1** are very clean. Between the signals of the aromatic protons and the homobenzylic methyl groups there is only one unidentified signal. It is a singlet 25 Hz downfield from the signal of the allylic methyl group of **3** with an area about 5% of that of the methyl group.

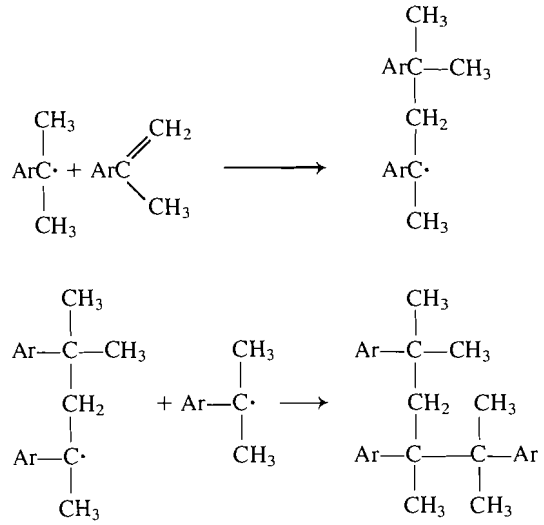
[a]Methyl triphenylmethyl ether was the internal standard.
[b]Area of the OCH_3 group.
[c]Area of the methine proton.
[d]Area of the allylic methyl group.
[e]Calculated according to eq. [1].

The reactions of Scheme 2 will have a negligible effect on the k_{disp}/k_{comb} ratio, calculated by eq. [1]. This ratio,

$$[1] \quad k_{disp}/k_{comb} = \frac{\%2}{100 - \%2}$$

0.21 ± 0.03, is much larger than that, 0.06, found for the reaction of unsubstituted cumyl radicals (1*a*) and cumyl radicals containing alkyl groups in the 4-position (1*b*,*c*). This lends support to the notion that the large amount of coupling found with benzylic radicals is the result of an association complex like **A**. However, it appears that the two *tert*-butyl groups in the 3 and 5 positions are not large enough to disrupt completely the formation of such a complex, since there is still much more coupling than with alkyl radicals.

Semibenzene dimers (4), formed by coupling of benzyl radicals at the α and *ortho* or *para* positions, probably play no role here. The α-*para* dimer, which is formed in ~20% yield by coupling of unsubstituted cumyl radicals, should be prevented from forming when two bulky *tert*-butyl groups flank the *para* position. Similarly, steric hindrance should greatly retard the formation of the α-*ortho* dimer, which is formed in lower yield than the α-*para* dimer from the unsubstituted cumyl radicals.



SCHEME 2

Experimental

Melting and boiling points are uncorrected. The nmr spectra were measured on Varian A50/60 and Bruker WP80 and WH200 spectrometers. Elemental analyses were performed in the Microanalytical Laboratories of the Chemistry Department under the supervision of Mrs. Darlene Mahlow.

*1-(Bromomethyl)-3,5-di-*tert*-butylbenzene*

A mixture of 146.8 g (0.718 mol) of 1,3-di-*tert*-butyl-5-methylbenzene (5), 127.8 g (0.718 mol) of *N*-bromosuccinimide, and 200 mL carbon tetrachloride was heated under reflux for 18 h, cooled, filtered, and the filtrate concentrated. The residual oil was distilled through a short Vigreux column to give 101 g (50%) of an oil, bp 122–126°C/5 Torr (1 Torr = 133.3 Pa), which crystallized on standing. The solid was recrystallized from ethyl acetate to give colorless crystals, mp 34–35°C; ^{1}H nmr ($CDCl_3$) δ: 7.30 (m, 3H), 4.38 (s, 2H), and 1.29 (s, 18H). *Anal.* calcd. for $C_{15}H_{23}Br$: C 68.61, H 8.18, Br 28.21; found: C 68.34, H 8.14, Br 28.02.

*1,3-Di-*tert*-butyl-5-(cyanomethyl)benzene*

The procedure for the preparation of phenylethanenitrile (6) was used starting with 100 g of the above bromide. The crude product, 75.5 g, was recrystallized four times from hexane to give 42.3 g colorless crystals. The mother liquors were combined, concentrated, and the residue was distilled through a 15-cm Vigreux column, collecting the fraction boiling at 94–101°C/0.3 Torr. This was crystallized from hexane. A total of 59.2 g (72.5%) of product was obtained, mp 49–50°C; ^{1}H nmr ($CDCl_3$) δ: 7.28 (m, 3H), 3.68 (s, 2H), and 1.30 (s, 18H). *Anal.* calcd. for $C_{16}H_{23}N$: C 83.78, H 10.11, N 6.11; found: C 83.71, H 10.11, N 6.01.

*2-(3,5-Di-*tert*-butylphenyl)-2-methylpropanenitrile*

A mixture of 59.2 g (0.26 mol) of the above cyanide and 119.5 g (0.84 mol) of iodomethane in 150 mL dimethylsulfoxide was added over 2 h to a stirred mixture of 64.0 g (1.14 mol) potassium hydroxide, 25 mL water, and 100 mL dimethylsulfoxide, which was cooled in an ice bath. Product precipitated during the addition. The resulting mixture was stirred at 22°C overnight and a large amount of ether and water were added. The organic layer was shaken three times with water, dried, and concentrated. The residue was recrystallized from hexane to give 44.2 g (66.5%) of colorless crystals, mp 70–71°C; ^{1}H nmr ($CDCl_3$) δ: 7.28 (m, 3H), 1.73 (s, 6H), and 1.35 (s, 18H). *Anal.* calcd. for $C_{18}H_{27}N$: C 83.99, H 10.57, N 5.44; found: C 84.05, H 10.71, N 5.54.

*2-(3,5-Di-*tert*-butylphenyl)-2-methylpropanamide*

A mixture of 44.2 g of the above cyanide and 763 g of 85% sulfuric acid was stirred at 50°C for 7 h (6) and poured onto crushed ice. The solid product was taken up in ether. The organic layer was dried, concentrated, and the residue recrystallized from ethyl acetate–hexane to give 27.6 g colorless crystals, mp 125–126°C; ^{1}H nmr ($CDCl_3$) δ: 7.28 (m, 3H), 5.52 (br, 2H), 1.55 (s, 6H), and 1.30 (s, 18H). *Anal.* calcd. for $C_{18}H_{29}NO$: C 78.49, H 10.61, N 5.08, O 5.81; found: C 78.56, H 10.76, N 5.04, O 5.87.

*Methyl 1-(3,5-di-*tert*-butylphenyl)-1-methylethylcarbamate*

Bromine, 17.1 g (0.11 mol), was added dropwise to a solution of 27.6 g (0.11 mol) of the above amide in 140 mL of methanol containing 0.28 mol of sodium methoxide at 0°C. The reaction mixture then was heated under reflux for 45 min and methanol removed. Water and ether were added to the residue, the organic layer was dried and concentrated, and the residual solid recrystallized from hexane to give 25.3 g (83%) of colorless crystals, mp 80–81°C; ^{1}H nmr ($CDCl_3$) δ: 7.30 (m, 3H), 5.07 (br, 1H), 3.58 (s, 3H), 1.68 (s, 6H), and 1.30 (s, 18H). *Anal.* calcd. for $C_{19}H_{31}NO_2$: C 74.71, H 10.23, N 4.58, O 10.48; found: C 74.89, H 10.24, N 4.57, O 10.30.

*2-Amino-2-(3,5-di-*tert*-butylphenyl)propane*

A solution of 4 g (0.013 mol) of the above carbamate and 2.1 g (0.052 mol) of sodium hydroxide in 40 mL methanol was heated at 155°C for 4 h, cooled, and then treated with excess hydrochloric acid at 0°C. A white precipitate formed, which was filtered and dissolved in methanol. The resulting solution was treated with excess 40% aqueous sodium hydroxide, and the resulting mixture was shaken with 100 mL and then with 3 × 20 mL ether. The combined extract was washed with water, dried, and concentrated to give 3.08 g (95%) of a colorless solid. Recrystallization from a variety of solvents did not produce analytically pure material. The product could be sublimed quantitatively to give material that analyzed correctly if the analysis was done immediately, mp 68–69°C; ^{1}H nmr ($CDCl_3$) δ: 7.33 (m, 3H), 1.58 (s, 2H), 1.48 (s, 6H), and 1.32 (s, 18H). *Anal.* calcd. for $C_{17}H_{29}N$: C 82.52, H 11.81, N 5.66; found: C 82.68, H 11.87, N 5.50.

*Bis[1-(3,5-di-*tert*-butylphenyl)-1-methylethyl]diazene* ***1***

A solution of 2.0 g (8.1 mmol) of the above amine in 10 mL dichloromethane was added dropwise to a stirred mixture of 4 mL pyridine and 0.60 mL (8.1 mol) of iodine pentafluoride in 16 mL dichloromethane at −78°C (7). The resulting mixture was stirred at 78°C for 1 h, allowed to warm to 22°C, and treated with 10 mL water. The organic layer was washed with 5% hydrochloric acid, 5% aqueous sodium bicarbonate, and brine. Removal of solvent left 1.66 g (83.7%) of a yellow oil, which soon solidified. The product was purified by chromatography on neutral alumina, followed by recrystallization from pentane to give light yellow crystals, mp 84–85°C (preheated melting point block); ^{1}H nmr ($CDCl_3$) δ: 7.27 (m, 3H), 1.58 (s, 6H), and 1.30 (s, 18H). *Anal.* calcd. for $C_{34}H_{53}N_2$: C 83.20, H 11.09, N 5.71; found: C 83.50, H 11.22, N 5.74.

*2,3-Di-(3,5-di-*tert*-butylphenyl)-2,3-dimethylbutane*

A solution of 0.2 g of the above diazene in 5 mL benzene was deoxygenated by bubbling a slow stream of argon through it for 15 min and was then heated under reflux for 18 h. Benzene was removed and the residual solid was recrystallized from petroleum ether to give colorless crystals, mp 211–212°C; ^{1}H nmr ($CDCl_3$) δ: 7.04 (m, 6H), 1.35 (s, 12H), and 1.23 (s, 36H). *Anal.* calcd. for $C_{34}H_{54}$: C 88.24, H 11.76; found: C 88.51, H 11.57.

*2-(3,5-Di-*tert*-butylphenyl)-2-(dimethylamino)propane*

A mixture of 2.25 g (9.1 mmol) of 1-(3,5-di-*tert*-butylphenyl)-1-methylethylamine, 2.32 g (45 mmol), and 1.72 g (20 mmol) of 35% formaldehyde was heated under reflux for 12 h, cooled, treated with 1 mL concentrated hydrochloric acid, and then evaporated to dryness. The residue was treated with aqueous sodium hydroxide, enough water was added to dissolve the precipitate, and the resulting mixture was extracted three times with ether. The oil (2.23 g; 89%) that was obtained from concentration of the combined extracts did not give a satisfactory analysis in spite of a variety of attempts at purification; ^{1}H nmr ($CDCl_3$) δ: 7.23 (m, 3H), 2.13 (s, 6H), 1.35 (s, 6H), and 1.32 (s, 18H). A portion of the amine was converted (8) to the picrate, mp 190–191°C; ^{1}H nmr ($CDCl_3$) δ: 8.82 (s, 2H), 7.40 (m, 3H), 2.75 (s, 6H), 1.93 (s, 6H), and 1.26 (s, 18H). *Anal.* calcd. for $C_{27}H_{36}N_3O_7$: C 59.51, H 7.19, N 11.10; found: C 59.49, H 7.25, N 11.14.

*2-(3,5-Di-*tert*-butylphenyl)propene*

A cold solution of 0.78 g (3.6 mmol) of *m*-chloroperbenzoic acid in 10 mL of chloroform was added gradually to 1.0 g (3.6 mmol) of the above amine in 6 mL of chloroform at 0°C. The reaction mixture was stirred for 3 h more, allowing it to come to room temperature, and then concentrated to ~5 mL. The residue was chromatographed on 35 g basic alumina using 1:3 methanol:chloroform as eluent. Concentration of the eluent gave 0.78 g (93%) of a colorless oil that contained no amine oxide and is extremely readily oxidized by air, bp 65–66°C/0.1 Torr; ^{1}H nmr ($CDCl_3$) δ: 7.23 (m, 3H), 5.27 (m, 1H), 5.00 (m, 1H), 2.16 (m, 3H), and 1.31 (s, 18H). *Anal.* calcd. for $C_{17}H_{26}$: C 88.62, H 11.38; found: C 88.13, H 11.36.

*2-(3,5-Di-*tert*-butylphenyl)propane*

The above alkene, 0.38 g, was hydrogenated over palladium on carbon in ethanol to give 0.33 g (86%) of colorless oil, bp 74–75°C/0.4 Torr; ^{1}H nmr ($CDCl_3$) δ: 7.20 (m, 3H), 2.85 (heptet, J = 6.5 Hz, 1H), 1.30 (s, 18H), and 1.24 (d, J = 6.5 Hz, 6H). *Anal.* calcd. for $C_{17}H_{28}$: C 87.86, H 12.14; found: C 87.89, H 12.05.

Yields of disproportionation products

C_6D_6 solutions of **1** and methyl triphenylmethyl ether, both of which had been accurately weighed out on a microbalance, in nmr tubes were degassed with three freeze–thaw cycles under 0.1 Torr, and the tubes sealed and placed in a 60°C bath for 12 h. The yields of **2** and **3** were determined by integration of the ^{1}H nmr spectra taken at 200 MHz as described in Results and discussion. The results are given in Table 1.

Received June 2, 1987

WOLFGANG KLIEGEL, STEVEN J. RETTIG, and JAMES TROTTER. Can. J. Chem. **66**, 377 (1988).

The preparation of the title compounds demonstrates the bis-*N*-alkylation of secondary amines by formaldehyde, these labile ammonium inner salts being captured as diphenylboron chelates. Crystals of 5,5-trimethylene-2,2-diphenyl-1,3-dioxa-5-azonia-2-boratacyclohexane are orthorhombic, $a = 8.8461(3)$, $b = 10.7290(4)$, $c = 15.8773(5)$ Å, $Z = 4$, space group $P2_12_12_1$, and those of 5,5-dimethyl-2,2-diphenyl-1,3-dioxa-5-azonia-2-boratacyclohexane monohydrate are monoclinic, $a = 6.2432(3)$, $b = 17.1469(8)$, $c = 14.3701(5)$ Å, $\beta = 90.647(3)°$, $Z = 4$, space group $P2_1/n$. Both structures were solved by direct methods and were refined by full-matrix least-squares procedures to $R = 0.030$ and 0.047 for 1400 and 2258 reflections with $I \geq 3\sigma(I)$, respectively. Both compounds have a *B,N*-betaine structure, the six-membered chelate rings adopting chair conformations. Libration-corrected bond lengths, O—B = 1.508(3)–1.522(3) and C—B = 1.612(4)–1.637(4) Å, indicate relatively strong binding of the diphenylboron moiety to the oxygen atoms of the *O,O*-chelating ligands.

WOLFGANG KLIEGEL, STEVEN J. RETTIG et JAMES TROTTER. Can. J. Chem. **66**, 377 (1988).

La préparation des composés mentionnés dans le titre démontre que le formaldéhyde provoque une bis-*N*-alkylation des amines secondaires, alors que les sels d'ammonium internes qui sont labiles sont captés sous la forme de chélates de diphénylbore. Les cristaux du triméthylene-5,5 diphényl-2,2 dioxa-1,3 azonia-5 borata-2 cyclohexane sont orthorhombiques avec $a = 8{,}8461(3)$, $b = 10{,}7290(4)$ et $c = 15{,}8773(5)$ Å, $Z = 4$ et groupe d'espace $P2_12_12_1$ alors que ceux du monohydrate du diméthyl-5,5 diphényl-2,2 dioxa-1,3 azonia-5 borata-2 cyclohexane sont monocliniques avec $a = 6{,}2432(3)$, $b = 17{,}1469(8)$ et $c = 14{,}3701(5)$ Å, $\beta = 90{,}647(3)°$, $Z = 4$ et groupe d'espace $P2_1/n$. On a résolu les deux structures par des méthodes directes et on les a affinées par la méthode des moindres carrés jusqu'à des valeurs de R de 0,030 et 0,047 pour respectivement 1400 et 2258 réflexions avec $I \geq 3\sigma(I)$. Les deux composés présentent une structure *B,N*-bétaïne dans laquelle les cycles des chélates à six chaînons adoptent des conformations chaises. Les longueurs des liaisons corrigées pour la libration, O—B = 1,508(3)–1,522(3) et C—B = 1,612(4)–1,637(4) Å, indiquent que la portion diphénylbore est assez fortement liée aux atomes d'oxygène des ligands *O,O*-chélatants.

Introduction

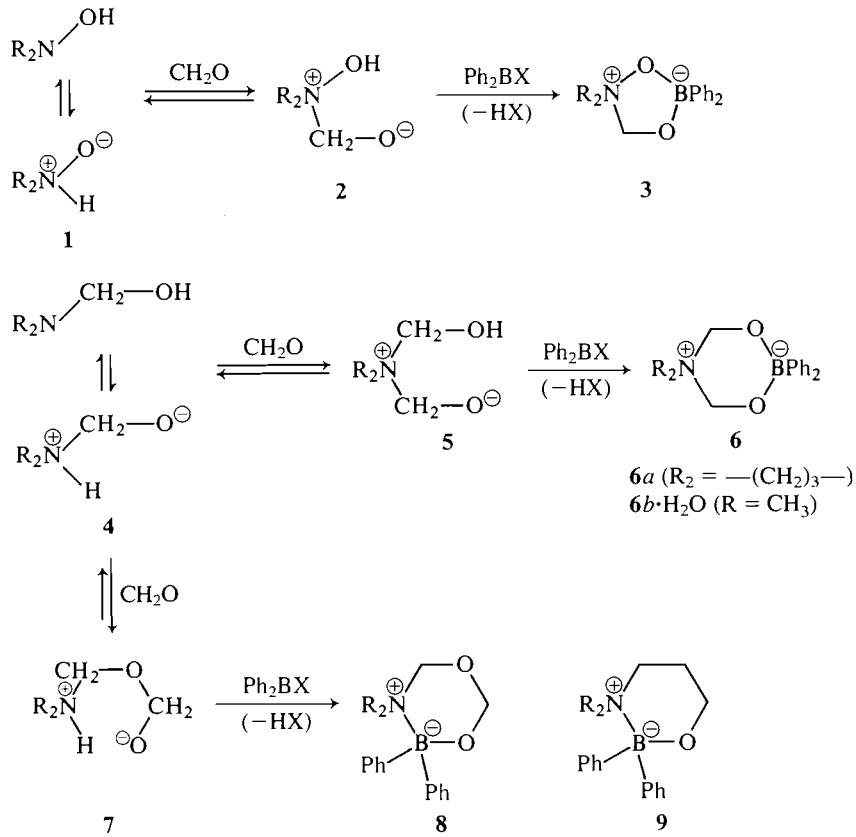
The alkylation of *N,N*-dialkylhydroxylamines **1** by formaldehyde leads to labile adducts **2** which can be trapped as diphenylboron chelates **3**, as shown for *N,N*-dimethylhydroxylamine (**1**, R = CH_3) by an X-ray crystallographic analysis (1). The formal insertion of methylene into **1** results in *N*-hydroxymethylamines **4** which are also described as zwitterionic primary adducts of formaldehyde and an amine (2). Formaldehyde adducts of dialkylamine (3) are known as very labile compounds[2] and exist generally as short-lived intermediates during the formation of enamines, aminals, iminium salts, Mannich bases, or similar compounds. Compared to the hydroxylamines **1**, the hydroxymethylamines **4** should be nucleophilic enough to add a second molecule of formaldehyde in a reversible reaction to give the labile intermediate **5** by *N*-alkylation of the tertiary amine, or an intermediate **7** by *O*-alkylation of the zwitterionic form. As reported in a preliminary communication (3), the dialkylamine–bisformaldehyde adducts can also be captured as diphenylboron chelates which are stable crystalline materials. A cyclic *B,N*-betaine structure **6**, derived from the *N,N*-bisalkylation product **5**, has been postulated for these compounds. The symmetric structure **6** is supported by evidence of two magnetically equivalent methylene groups in the ^{1}H nmr spectra. Compound **6** is also a ring-enlarged analog (by methylene insertion into the N—O bond) of **3**, the structure of which has been established (1). On the other hand, an intermediate like **7** could exist within the equilibrium reactions between the different formaldehyde–amine adducts[3] and could have been captured as the diphenylborinic acid derivative **8**. Compounds of structure **8** could be considered as "oxa-analogs" of the well-known diphenylborinates of 3-hydroxypropylamines (6) which possess a six-membered ring system **9** as a result of intramolecular N → B coordination (7).

In order to make an unambiguous decision between the alternate structures **6** and **8**, an X-ray crystallographic analysis of well-formed crystals of the azetidine derivative **6***a* (R_2 = —$(CH_2)_3$—) was undertaken. The dimethylamine derivative **6***b* was isolated as a monohydrate in every batch of crystals obtained during various preparations. This is indicated by elemental analysis and ^{1}H nmr data. Neither from nmr signals nor from ir data (which show bands for both associated and free O—H bonds) could a definite mode of binding be established

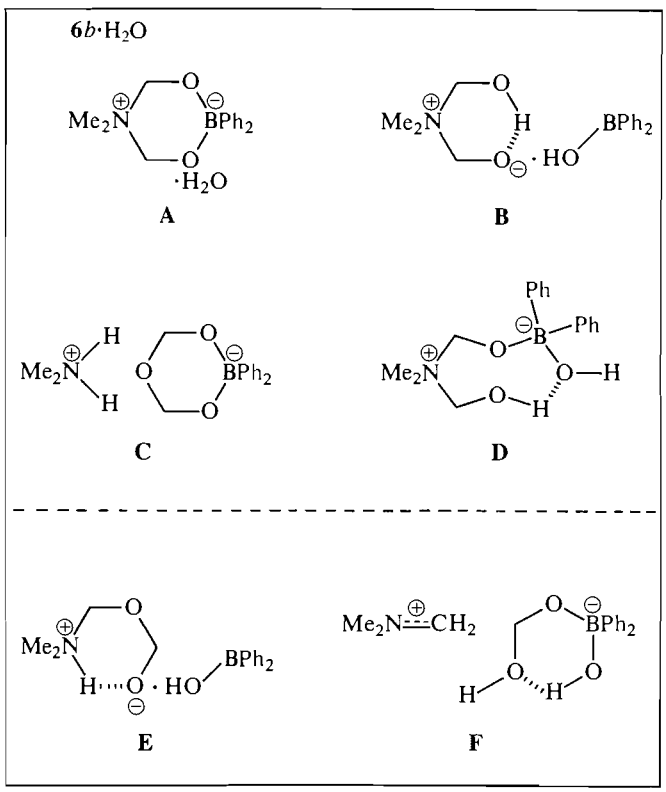
[1]Part XXVII: ref. 42.

[2]Only the formaldehyde adducts of weakly basic amines are known to be thermally stable, cf. ref. 4.

[3]"Macrozwitterions" such as **7** are supposed to be intermediates in amine-catalyzed formaldehyde polymerization reactions (5).



for the water molecule. Four-proton singlets in the ^1H nmr spectra of both the azetidine derivative **6***a* and **6***b*·H_2O indicate two (at least nearly) identical methylene groups, as realized in structures **A**–**D**. Less symmetrical structures that could derive from **8**·H_2O or structures like E or F should be ruled out. The most probable formulation of compound **6***b* appeared to be structure **A** with hydrogen-bonded water in the solid state. An alternative structure **B** represents a simple addition compound of **5** and diphenylborinic acid, which tends to form hydrogen bonds to nucleophilic centres such as an oxygen atom in a chelate ring system (7). Compound **C** with a cyclic diphenylborinate anion could result from condensation of two formaldehyde equivalents and diphenylborinic acid, and crystallization as a dimethylammonium salt, analogous to the formation of a tetramethylammonium salt of tetraphenylboroxinate (8). An open-chain betainic form **D** could derive from a ring-opening of **6** by water insertion. An X-ray crystallographic analysis of **6***b*·H_2O was also undertaken to provide a definitive structural assignment.



Experimental

5,5-Trimethylene-2,2-diphenyl-1,3-dioxa-5-azonia-2-boratacyclohexane, **6***a*

Azetidine (10 mmol) is dissolved in 5–10 mL ethanol and mixed with formaldehyde (20–25 mmol, 40% aqueous solution). After addition of (*a*) oxybisdiphenylborane (1.73 g, 5 mmol), or (*b*) (2-aminoethyloxy)diphenylborane (2.25 g, 10 mmol), or (*c*) triphenylborane (2.42 g, 10 mmol) the mixture is heated until the solution becomes clear. Crystallization begins to occur during the heating or after cooling down to room temperature. Yields: (*a*) 88%, (*b*) 85%, (*c*) 76%. Melting point (decomp) 157–159°C, literature (3) 157°C. *Anal.* calcd. for $C_{17}H_{20}BNO_2$: C 72.62, H 7.17, B 3.85, N 4.98; found: C 72.51, H 6.94, B 3.88, N 5.06. The substance gives a blue solution upon reaction with diphenylcarbazone in methanolic solution, indicating the presence of a diphenylboron moiety in the molecule (9). During the melting process the substance decomposes and the solution of the pyrolytic gases in water contains formaldehyde detectable by reaction with chromotropic acid (10) or dimedone (11). ^1H nmr (90 MHz, d_6-acetone/TMS): δ(ppm) = 2.34 (quint, J = 9 Hz, C—CH_2—C), 3.78 (t, J = 9 Hz, CH_2—C—CH_2), 4.68 (s, O—CH_2—N—CH_2—O), 6.8–7.4 (m, BPh_2); (60 MHz, CF_3COOH/

[a]Temperature 295 K, Enraf-Nonius CAD4-F diffractometer, Cu-K$_\alpha$ radiation ($\lambda_{K\alpha_1}$ = 1.540562, $\lambda_{K\alpha_2}$ = 1.544390 Å), nickel filter, takeoff angle 2.7°, aperture (2.0 + tan θ) × 4.0 mm at a distance of 173 mm from the crystal, scan range extended by 25% on both sides for background measurement, $\sigma^2(I) = C + 2B + [0.04(C - B)]^2$ (C = scan count, B = normalized background count), function minimized: $\Sigma w(|F_o| - |F_c|)^2$ where $w = 1/\sigma^2(F)$, $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$, $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$, $S = (\Sigma w(|F_o| - |F_c|)^2/(m - n))^{1/2}$. Values given for *R*, R_w, and *S* are based on those reflections with $I \geq 3\sigma(I)$.

$CDCl_3$/TMS): δ(ppm) = 2.73 (quint, J = 8 Hz, C—CH_2—C), 4.30 (t, J = 8 Hz, CH_2—C—CH_2), 5.14 (s, O—CH_2—N—CH_2—O), 7.3–7.9 (m, BPh_2). ^{11}B nmr (32.1 MHz, DMSO/Et_2OBF_3): δ(ppm) = 2.4. Crystals suitable for X-ray analysis were obtained by recrystallization from ethanol.

5,5-Dimethyl-2,2-diphenyl-1,3-dioxa-5-azonia-2-boratacyclohexane monohydrate, **6**b·H_2O

Dimethylamine (10 mmol, aqueous solution) is reacted with formaldehyde (20–25 mmol) and (*a*) oxybisdiphenylborane (5 mmol), or (*b*) (2-aminoethyloxy)diphenylborane (10 mmol), or (*c*) triphenylborane (10 mmol), as described above for compound **6***a*. Yields: (*a*) 80%, (*b*) 75%, (*c*) 72%. Melting point (decomp) 121–125°C (slow heating) and 130–132°C (rapid heating). *Anal.* calcd. for $C_{16}H_{22}BNO_3$: C 66.93, H 7.72, B 3.77, N 4.88; found: C 67.37, H 7.61, B 3.67, N 4.86. As described above for **6***a*, the substance gives a blue color reaction with diphenylcarbazone and develops formaldehyde on pyrolysis. Infrared (KBr): 3630 cm^{-1} (sharp, O—H), 3400 (broad, O—H), 1630 (H_2O). ^{1}H nmr (90 MHz, d_6-DMSO/TMS): δ(ppm) = 2.72 (s, $N(CH_3)_2$), 3.30 (s, H—O—H, exchangeable), 4.53 (s, O—CH_2—N—CH_2—O), 6.8–7.4 (m, BPh_2). ^{11}B nmr (32.1 MHz, DMSO/Et_2OBF_3): δ(ppm) = 2.7. Crystals suitable for X-ray analysis were obtained by recrystallization from ethanol.

X-ray crystallographic analyses of **6**a *and* **6**b·H_2O

Crystallographic data for the two compounds appear in Table 1. Unit-cell parameters were refined by least-squares on 2 sin θ/λ values for 25 carefully centered reflections with 2θ = 60–87° for **6***a* and 2θ = 80–100° for **6***b*·H_2O. The intensities of three standard reflections, measured each hour of X-ray exposure time, showed only small random variations in each case. The data were reduced[4] and corrected for absorption (numerical integration). Both structures were solved by direct methods, the positions of all non-hydrogen atoms being determined from *E*-maps and those of the hydrogen atoms from subsequent difference maps. The non-hydrogen atoms were refined with anisotropic thermal parameters and the hydrogen atoms with isotropic thermal parameters. One hydrogen atom H(O3b), associated with the water molecule in **6***b* monohydrate, refined to an unreasonable position and was therefore kept fixed in its observed position and assigned a thermal parameter of 0.304 Å^2 in the final stages of refinement. Neutral atom scattering factors and anomalous scattering corrections (O, N, and C) were taken from ref. 12. Isotropic Type I extinction corrections (13–15) were applied, the final values of *g* being 0.49(5) × 10^4 for **6***a* and 1.48(10) × 10^4 for **6***b*. Parallel refinement of the mirror-image of the structure of **6***a* resulted in marginally higher residuals, the *R* and R_w value ratios of 1.0010 and 1.0006 being

[4]The computer programs used include locally written programs for data processing and locally modified versions of the following: MULTAN 80, multisolution program by P. Main, S. J. Fiske, S. E. Hull, L. Lessinger, G. Germain, J. P. Declercq, and M. M. Woolfson; AGNOST, absorption corrections, by J. A. Ibers; ORFLS, full-matrix least-squares, and ORFFE, function and errors, by W. R. Busing, K. O. Martin, and H. A. Levy; FORDAP, Patterson and Fourier syntheses, by A. Zalkin; ORTEP II, illustrations, by C. K. Johnson.

significant at approximately the 90 and 75% levels, respectively (ref. 12, pp. 288–292). Final positional parameters and equivalent isotropic thermal parameters for the non-hydrogen atoms are given in Table 2. Hydrogen coordinates and thermal parameters (Table 6), anisotropic thermal parameters (Table 7), and measured and calculated structure factors have been placed in the Depository of Unpublished Data.[5]

The thermal motion in both molecules has been analysed in terms of the rigid-body modes of translation, libration, and screw-motion (16). The rms errors in the thermal parameters σU_{ij} (derived from the least-squares analyses) are 0.0016 and 0.0014 Å^2 for **6***a* and **6***b*, respectively. The structural subunits PhB and the spiro-fused ring system for **6***a* and PhB and the six-membered heterocyclic ring along with the two *N*-methyl carbon atoms for **6***b* were separately analysed (rms ΔU_{ij} = 0.0014–0.0018 Å^2 for **6***a* and 0.0014–0.0024 Å^2 for **6***b*). The appropriate bond distances have been corrected for libration (16, 17), using shape parameters q^2 of 0.08 for all atoms involved. Corrected bond lengths appear in Table 3 along with the uncorrected values; corrected bond angles do not differ by more than 1σ from the uncorrected values given in Table 4. Intra-annular torsion angles defining the conformations of heterocyclic rings are listed in Table 5. Bond lengths and angles involving hydrogen and a complete listing of torsion angles (Tables 8–10) are included as supplementary material.

[5]The structure factor table and Tables 6–10 may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

Results and discussion

5,5-Trimethylene-2,2-diphenyl-1,3-dioxa-5-azonia-2-boratacyclohexane and 5,5-dimethyl-2,2-diphenyl-1,3-dioxa-5-azonia-2-boratacyclohexane monohydrate both possess the general structure **6** (Fig. 1). The crystal structure of **6***a* consists of discrete molecules separated by normal van der Waals distances. Even though individual molecules of **6***a* are non-chiral, the crystal structure itself is chiral, probably with equal numbers of right- and left-handed crystals being formed. In **6***b*·H_2O each molecule of **6***b* is hydrogen-bonded to one water molecule (O(3)—H(O3a)···O(2), H···O = 1.51(8) Å, O···O = 2.891(3) Å, O—H···O = 164(5)°), these 1:1 molecular complexes forming centrosymmetric dimeric units via weak C—H···O interactions involving the water molecule (C(3)—H(3a)···O(3) (−*x*, −*y*, 1 − *z*), H···O = 2.39(4) Å, C···O = 3.324(5) Å, C—H···O = 157(3)°). The second hydrogen atom

associated with the water molecule, H(O3b), is not involved in H-bonding. This is the first unequivocal proof of a cyclic *B*,*N*-betaine of this type, demonstrating the bis-*N*-alkylation of a secondary amine by formaldehyde via *N*-alkylation of the *N*-hydroxymethyl intermediate **4**. The addition of a second formaldehyde molecule to *N*-hydroxymethyl-*N*,*N*-dialkylamines had already been assumed by Künzel *et al.* (5*a*), but the product could not be isolated. The trapping of **5** by diphenylborinic acid (3) allowed the fixation of this labile ammonium inner salt within the *B*,*N*-betaine ring system **6**, the structure of which has now been established. A diphenylborinic ester of a tris-hydroxymethylated phenylphosphine, **10**, has been shown to contain an analogous *B*,*P*-betaine ring (18).

The six-membered heterocyclic rings in **6***a* and **6***b* adopt the sterically favorable chair conformation, as does that in compound **10** (18). In **6***b* the hydrogen bond to the water molecule occupies an axial position. The *B*-phenyl substituents in axial positions show significantly longer B—C bonds[6] than those in equatorial positions (see Table 3), the differences being 0.025(6) Å for **6***a* and 0.015(4) Å for **6***b*. Corresponding differences in the same range have been noted for **10** (18) and **11** (19), the substituents occupying pseudo-axial and pseudo-equatorial positions in the latter. Less pronounced differences are reported for six-membered diphenylboron chelates of salicylaldehyde (20) and acetylacetone (21), in which pseudo-axial and pseudo-equatorial B—C distances differ by 0.007 Å.

The N—C—O—B system in **6** is chemically the same as that in **3** (R = Me) (1) and similar to that in the corresponding *C*,*C*-dimethyl derivative (acetone analog) of **3** (22). The N—C(1) and N—C(2) distances of 1.521(4) and 1.519(4) Å in **6***a* and 1.540(3) and 1.539(3) Å in **6***b* lie between the corresponding distance of 1.505(10) Å (uncorrected) in **3** and the sterically lengthened N—C(1) distance of 1.591(3) Å in the *C*,*C*-dimethyl derivative of **3**. Bond lengths and angles in the non-planar (torsion angles of 8.0(3)°) azetidinium system in **6***a* show considerable steric strain. The higher nucleophilicity (basicity) of the azetidine component in **6***a* relative to that of the dimethylamine component in **6***b* may also be a cause of the difference between the N—C(1) and N—C(2) bond lengths in **6***a* and **6***b*, averaging 0.02 Å longer in the latter. The pK_a values of azetidine and dimethylamine are reported as 11.29 and 10.73, respectively, in aqueous solution at 25°C (23).

The average O—B and C—B distances in compounds **6** and **10** (1.510 and 1.625 Å in **6***a*, 1.518 and 1.623 Å in **6***b*, 1.514 and 1.621 Å (uncorr.) in **10**), which contain saturated six-membered chelate rings, are shorter and longer, respectively, than the corresponding averages of 1.528–1.538 and 1.606–1.607 Å reported for *O*,*O*-chelates of diphenylboron containing unsaturated six-membered chelate rings (19–21, 24). This is indicative of relatively strong binding of the ligand oxygen atoms to boron and is consistent with trends reported for analogous compounds containing five-membered chelate rings (24). The O(2)—B bond in **6***b* (1.522(3) Å) is longer than the O(1)—B bond in **6***b* and both O—B bonds in **6***a* (1.508(3)–1.513(3) Å), most likely as a result of the involvement of O(2) in the hydrogen bond to water in **6***b*·H_2O. The O—B bonds in compounds **6** (mean 1.514(6) Å), **3** (1.506(7) (uncorr.) and 1.507(3) Å), and **10** (1.514 Å (uncorr.)) are longer than those observed for diphenylboron chelates of aminoalcohols with five- and six-membered chelate rings (1.471–1.484 Å) (7,

[6]Libration corrected bond lengths (esd's assumed equal to those of the uncorrected values) are employed in the discussion and are compared with similarly treated (16) distances unless otherwise stated.

25–27). This indicates a weaker oxygen atom nucleophilicity of the *N*-hydroxymethyl group relative to those of *N*-(2-hydroxymethyl) and *N*-(3-hydroxypropyl) groups.

Electronic differences are also reflected by the short C—O bonds in **6** and **3** (average 1.373 Å in **6**, 1.378(9) Å (uncorr.) and 1.387(3) Å in **3** (1, 22)) compared with an average of 1.428 Å in the 2- and 3-hydroxyalkylamine derivatives (7, 25–27). The C—O distances in **6** and **3** lie between the uncorrected distances of 1.209 Å in formaldehyde (28) and 1.430 Å in the formaldehyde trimer (trioxane) (29), and show a double bond character of approximately 20% (30) resulting from back-donation from oxygen to carbon in the formaldehyde moiety within the molecule **6**. The transition state of the thermally induced dissociation of **6**, which results in the formation of formaldehyde, may be represented by the structure **12**. The short C—O distances can also be described by the concept of "double bond – no bond" resonance (31), compound **6** being represented by a hybrid of the resonance structures **13**.

C=O bond lengthening during *nucleophilic* addition of amines to carbonyl groups has been observed in the course of a survey of crystal structures of compounds containing both functions (32). C—O bond lengths ranging from 1.209 to 1.38 Å demonstrate the approach of the nucleophilic nitrogen

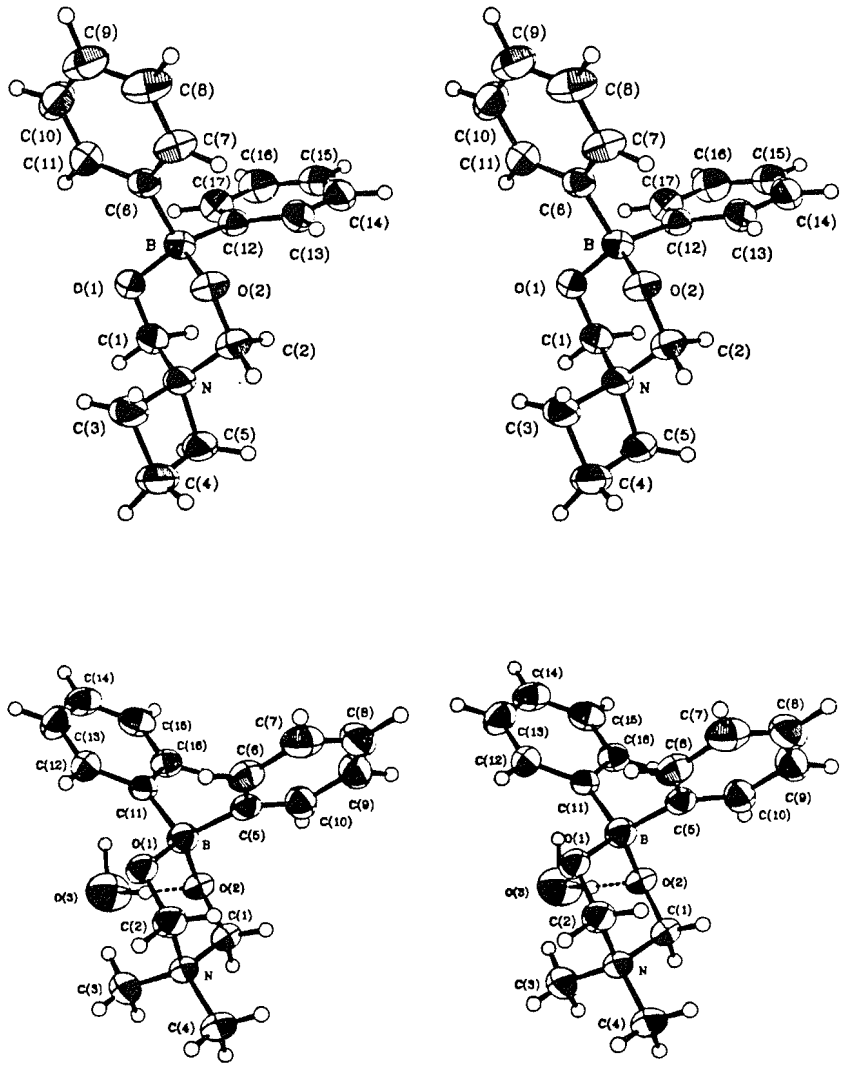

FIG. 1. Stereoscopic views of 5,5-trimethylene-2,2-diphenyl-1,3-dioxa-5-azonia-2-boratacyclohexane (top) and 5,5-dimethyl-2,2-diphenyl-1,3-dioxa-5-azonia-2-boratacyclohexane monohydrate (bottom); 50% probability thermal ellipsoids are shown for the non-hydrogen atoms. Hydrogen atoms have been assigned arbitrary thermal parameters for the sake of clarity.

centre to the electrophilic carbon centre at different stages of N···C=O interaction. C=O bond lengthening during *electrophilic* addition of Lewis acids to carbonyl groups is also documented by calculation and experiment, with C—O distances for C=O···A (A = Lewis acid) systems ranging from 1.244 to 1.33 Å (20, 21, 33–37). Nucleophilic and electrophilic forces both play a fundamental role in the formation and stability of **6** and **3**, adducts in which formaldehyde is trapped in a push–pull mechanism. Similar C—O distances are also found in the borate complex antibiotics boromycin (38) and aplasmomycin (39). These C—O bonds (uncorrected distances of 1.34 and 1.37 Å, respectively) are chemically similar to those in **3** and **6**: a carbonyl function participates as a nucleophilic ligand to the boron centre and as an electrophilic component in an acetal group, **14**. Comparable C—O distances of 1.37–1.38 Å are also found in acetal systems with halogen "leaving" groups, **15** (40).

The phenyl groups in both **6***a* and **6***b* are planar to within experimental error. Bond lengths and angles in the *B*-substituted phenyl rings show normal substituent-induced deviations from "ideal" values (41).

Thermal intramolecular reactions of Δ^1-1,2,4-triazolines with extended exocyclic unsaturation

ADRIAN L. SCHWAN[1] AND JOHN WARKENTIN[2]

Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received June 16, 1987

ADRIAN L. SCHWAN and JOHN WARKENTIN. Can. J. Chem. **66**, 385 (1988).

Fumaratotriazoline (**1**) and amidotriazoline (**3**) undergo thermal first-order transformations in solution at 65°C. The former affords the isomeric pyrrole **5** and its hydrolysis product **6**. A mechanism involving opening of the initial five-membered ring to form **8**, followed by closure to a new five-membered ring (**9**), is proposed. Amidotriazoline (**3**) loses N_2 on heating to form **19**. The experimental results are best accommodated in terms of a novel mechanism involving an electrocyclic ring closure, a [3 + 2] cycloreversion to form an ylide, a sigmatropic rearrangement of the ylide, and, finally, an electrocyclic ring-opening reaction.

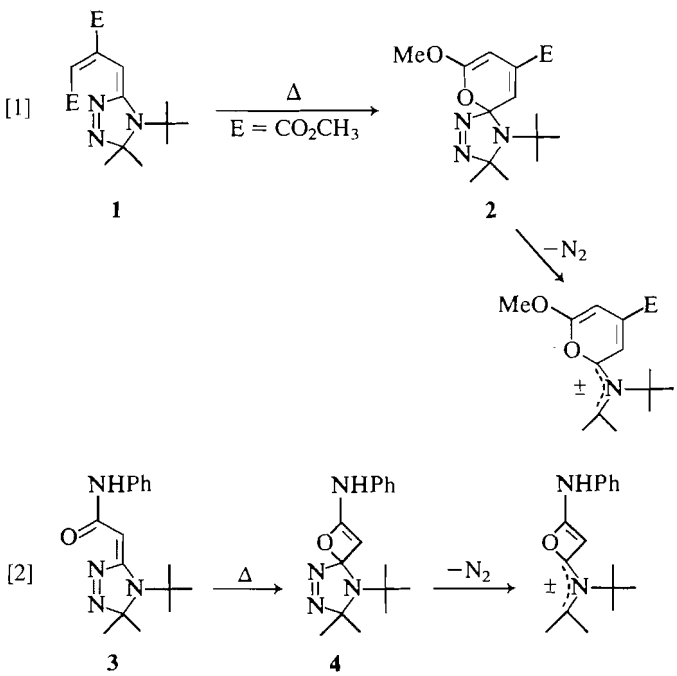
ADRIAN L. SCHWAN et JOHN WARKENTIN. Can. J. Chem. **66**, 385 (1988).

En solution, à 65°C, la fumaratotriazoline (**1**) et l'amidotriazoline (**3**) subissent des transformations thermiques du premier ordre. Le premier composé fournit le pyrrole isomère **5** ainsi que son produit d'hydrolyse **6**. On propose un mécanisme impliquant dans une première étape l'ouverture du cycle à cinq chaînons qui se forme initialement; il s'en suit la formation du composé **8** qui est suivie d'une fermeture conduisant à un nouveau cycle à cinq chaînons (**9**). Par chauffage, l'amidotriazoline (**3**) perd du N_2 et forme le composé **19**. Pour expliquer les résultats expérimentaux, on doit faire appel à un nouveau mécanisme impliquant une cyclisation électrocyclique, une cycloréversion [3 + 2] conduisant à un ylure, une transposition sigmatropique de l'ylure et, finalement, une réaction électrocyclique d'ouverture de cycle.

[Traduit par la revue]

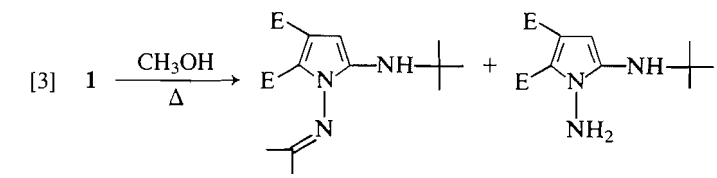
Introduction

The syntheses of fumaratotriazoline (**1**) (1) and of amidotriazoline (**3**) (2) from 4-(*tert*-butyl)-3,3-dimethyl-5-methylene-Δ^1-1,2,4-triazoline have been described. As cross-conjugated azoenamines with extended conjugation, **1** and **3** held promise for the generation of azomethine ylides (3, 4). Thus, **1** and **3** could conceivably lead to the spirotriazolines, **2** and **4**, respectively, by unimolecular cyclization, eqs. [1], [2]. With quaternary carbons at C3 and C5 of the Δ^1-1,2,4-triazoline ring, **2** and **4** might be susceptible to ylide-forming [3 + 2] cycloreversion, eqs. [1], [2]. We now report the results of thermal decomposition of **1** and **3**.



Results and discussion

Refluxing of a solution of fumaratotriazoline **1** in methanol for 48 h resulted in the consumption of **1**. Careful separation of the products by means of centrifugal chromatography under N_2 (Chromatotron) afforded pyrroles **5** and **6** in 91% combined yield, eq. [3]. Neat **5**, on exposure to the atmosphere, was



5 **6**

(E = CO_2CH_3)

converted to **6** at a remarkably high rate; the reaction was largely completed in 15 min. It is very likely, therefore, that **1** is converted to **5** in nearly quantitative yield and that **6** is a product of the hydrolysis of **5**, by traces of water in the solvent and (or) by contact with moisture during work-up.

The structures of **5** and **6** are based on spectroscopic data. Their infrared spectra are similar to the spectra of pyrroles bearing conjugating substituents (5) and both the ^1H (6) and ^{13}C nmr spectra support the assignments (Table 1).

A mechanism that can account for the results is shown in Scheme 1. According to this mechanism, **1** undergoes ring opening, probably reversibly, to the dipolar species **8**, which then cyclizes to **9**. Intermediate **9** may isomerize to **10** by prototropic shifts and either **9** or **10** isomerizes to the aromatic product **5**. In a slightly different version (Scheme 2), ring closure of **1** to **11** is the first step. Ylide **11**, which has a cyclopentadiene-like upper ring, rearranges to **12** by means of sequential 1,5-sigmatropic hydrogen shifts and **12** undergoes an electrocyclic ring-opening reaction to form **10**. The latter mechanism is considered less likely than that of Scheme 1 because the geometric requirements for 5-*exo* closure to **11** are not well met in **1**. An alternative and essentially equivalent rationale for preferring Scheme 1 is that the first step is an

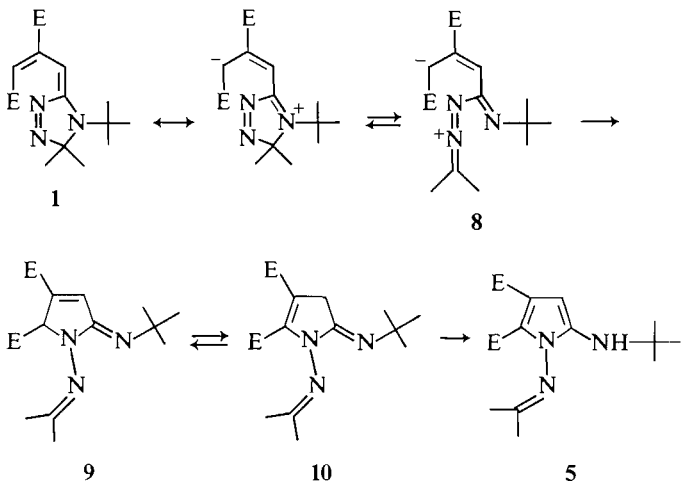
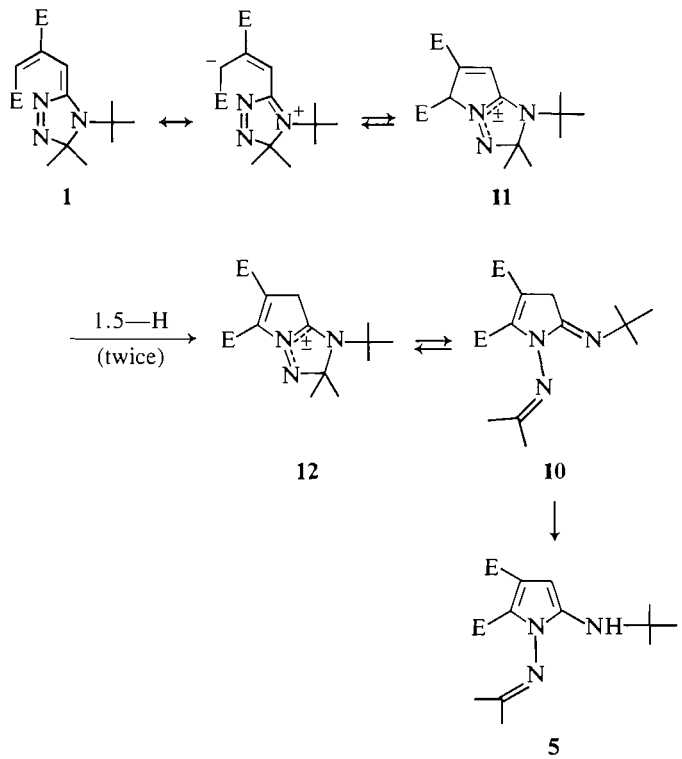


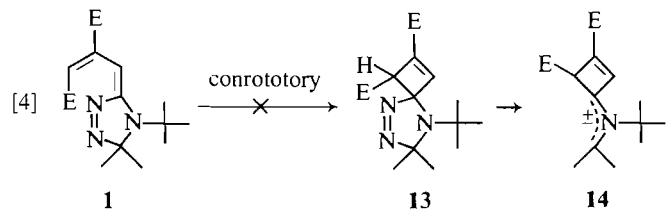
SCHEME 1



SCHEME 2

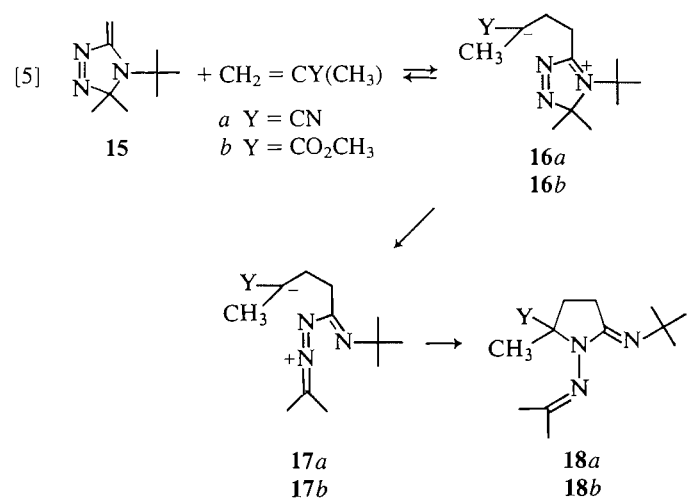
entropically favoured ring scission rather than a ring closure with accompanying increase of rigidity.

Although slightly different versions of the proposed mechanism can be put forward, it is clear from the high yield that the rearrangement of **1** to **5** is a clean process. Excluded specifically are the sequential reactions [1] and the electrocyclic rearrangement of **1** to **13**, reaction [4], as significant competitors. An



intermediate such as **13** is expected to lose N_2 rapidly, to form an azomethine ylide **14**, as demonstrated for a close analogue (1). Even the material not accounted for (compound X, 9%) has three nitrogen atoms per molecule, as indicated by the combined ms and ^1H nmr data (Experimental). The former, with highest m/z = 269, suggests that X is an isomer of **6** and the latter confirms that the isopropylidene portion is absent from X as it is from **6**. Although compound X remains an unknown, it is clearly not **13** and it cannot be derived from **14**. Thus, reaction [4] appears to be excluded.

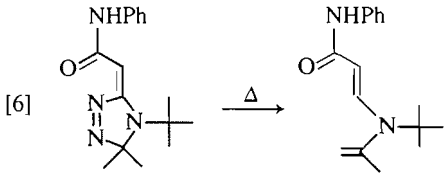
Analogy for the proposed mechanism is found in the reactions of triazoline **15** with methacrylonitrile and with methyl methacrylate (2), reaction [5], except that the precursor of **17** and **18** is a true zwitterion (**16**) and not just a polar structure such as **1**.



The very facile hydrolysis of **5** that was pointed out earlier is shared by **18***b* but not by **18***a*, suggesting that there may be bifunctional catalysis involving both the 2-substituent and the 5-carbomethoxy functional group of **5** and **18***b*.

3,4-Dicarboalkoxypyrroles are common while 4,5-dicarboalkoxypyrroles are rare. Methods for the synthesis of the less common 4,5 isomers (5*b*, 5*c*, 7–9) are unsuitable for the preparation of 2-alkylamino-4,5-dicarboalkoxypyrroles such as **5** and **6**, which seem to be the first members of that family. Reductive removal of the 1-amino substituent of **6** should be facile, as it is for other 1-aminopyrroles (10).

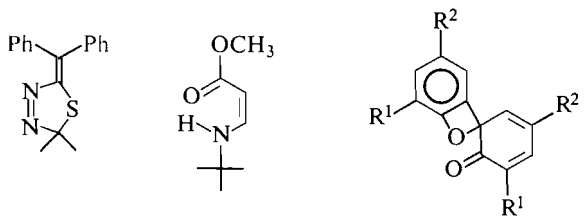
Thermolysis of **3** in solution led to formation of **19** (reaction [6]) in solvent-dependent yields. In methanol the yield was 53%



[6] **3** → **19**

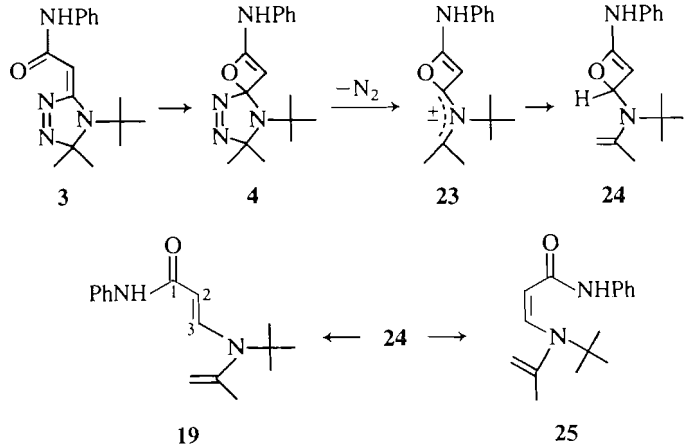
but in benzene, or in methyl acrylate, the yields reached 85%. The *E*-configuration at the internal double bond of **19** was assigned on the basis of the 12-Hz coupling constant between the vinyl hydrogen atoms.

A mechanism that accounts for the transformation of **3** to **19** must accommodate the following observations. First, the decomposition of **3** occurs with first-order kinetics in both benzene and in methanol without the accumulation of intermediates to levels detectable by ^{1}H nmr spectroscopy. Second, the reaction is 2.3 times faster in benzene than in methanol at 80°C and both rate constants are probably larger than that for thermolysis of model compound **20** (11), which decomposes in 45–60 min at 165°C. From the activation parameters (log A = 13.6, E_a = 29.6 kcal mol^{-1}) for thermolysis of **3** in methanol (see Experimental), decomposition at 165°C would be complete (>98%) in less than 1.0 min. Fourth, thermolysis of **3** in CH_3OD affords **19**, which is fully deuterium labelled at C3 (Scheme 3). Finally, aniline and **21** are coproducts (10–21% each) of the thermolysis of **3** in methanol.



20 **21** **22**

The mechanism in Scheme 3 appears to fit the facts well. Electrocyclic ring closure of **3** and **4** is allowed thermally. Although analogous cyclizations of butadienes to cyclobutenes are rare, theoretical studies by Epiotis (12) indicate that closure of diene components that are "push–pull" polarized should be facilitated. Moreover, oxetes are recognized intermediates, or final products in favourable cases. Benzoxetes (**22**, for example) from oxidation of 2,4-disubstituted phenols, can be isolated (13). The solvent dependence of rates of electrocyclic reactions are small, in general (14), and the faster rate of decomposition of **3** in benzene, relative to that in methanol, can be explained readily in terms of greater solvation of the ground state **3** than of the transition state for going to **19**, by



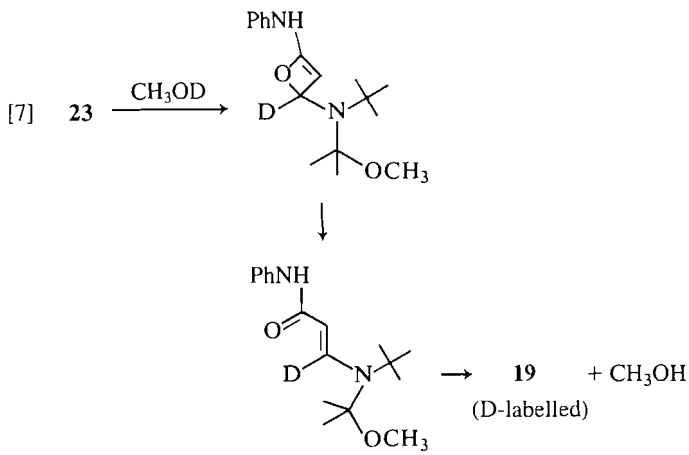
3 **4** **23** **24** **19** **25**

SCHEME 3

methanol. The entropy of activation ($\Delta S^{\ddagger} \simeq 1.5$ eu, methanol) is reasonable for a process involving a combination of decreased solvent ordering and increased substrate ordering as the oxete ring develops.

The remainder of Scheme **3** is relatively straightforward and well precedented. Facile cycloreversion of **4** to form **23** is analogous to loss of N_2 from some other Δ^1-1,2,4-triazolines with tetracoordinate C-3 and C-5 (2). Ylide **23** might well gain some stabilization from delocalization within the 4-membered ring, which is aromatic with respect to one of the ylide's contributing structures. The ylide must be slow to react with dipolarophiles, as yields of **19** from thermolysis of **3** in methyl acrylate were comparable to those obtained from thermolysis of **3** in benzene.

1,4-Sigmatropic shifts such as that which converts **23** to **24** are well known (15), as are electrocyclic ring openings of the type **24** to **19**. It is not surprising that the opening is unidirectional, although either **19** or **25** is allowed by (formal) conrotatory ring opening. Moreover, the deuterium labelling of **19**, when **3** is decomposed in CH_3OD, is readily explained in terms of interception of **23** by proton transfer from solvent (reaction [7]). Finally the formation of aniline and **21**, from



[7] **23** → **19** (D-labelled) + CH_3OH

heating of **3** in methanol, can be accommodated if it is assumed that an enaminic oxete like **24** can add methanol to the double bond. Such addition, followed by elimination of aniline and electrocyclic ring opening, constitutes formal anilide methanolysis (reaction [8]), and offers an explanation for the formation of **21** under conditions that **19** withstood in a control experiment. We see no reason why **19** should not serve as an

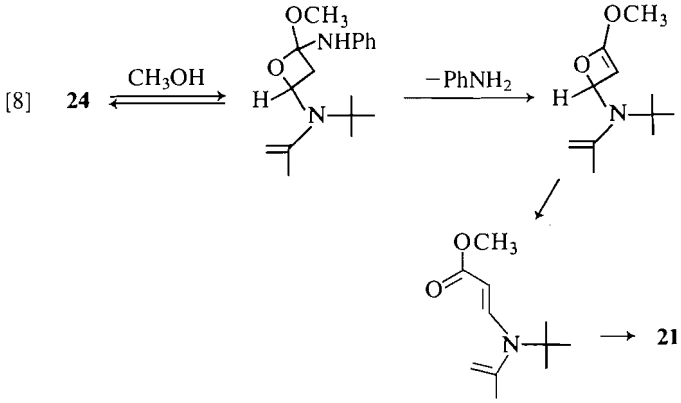
[a]The numbers in parentheses are tentative assignments and refer to the arbitrary numbering schemes given with the structures.
[b]Abbreviations: ei = electron impact, lr = low resolution, hr = high resolution.
[c]Neat film.



adequate model for estimating the rate of anilide methanolysis of **3**.

Although alternative mechanisms are conceivable, including initial C—N bond rupture as in Scheme 4, they fall short on several counts. First, and most telling, is the fact that analogous triazolines do not lose N_2 under similar conditions (1, 2), and that the thiadiazoline analogue (**20**) already mentioned above (11) decomposes with loss of N_2 only at a much higher temperature. Second, formation of a dipolar intermediate (**25**) in the rate-determining step (Scheme 4) should be facilitated, not retarded, in a more polar solvent. Third, an ylide of the type **26** (Scheme 4) would be expected to have an allenic structure with orthogonal π-systems as shown in that scheme. In benzene, where the H-transfer does not involve the solvent, 1,4-sigmatropic shifts to afford both **19** and its geometric isomer **27**, possibly with the latter predominating, would be required. For the above reasons, we favour the mechanism of Scheme 3.

Experimental

The ^1H and ^{13}C nmr spectra were recorded on a Varian EM-390 spectrometer and on a Bruker WP80/90 spectrometer, respectively. Infrared spectra were obtained with a Perkin–Elmer model 283 instrument. They are calibrated against the 1601.4 cm^{-1} band of polystyrene. Ultraviolet spectra were taken with a Hewlett–Packard model 8451A diode array spectrophotometer. Mass spectra were recorded on either a VG 70-70F or a VG-ZAB-E spectrometer. Centrifugal chromatography was carried out on a Chromatotron 7924T instrument equipped with silica coated glass plates (coating 2 mm thick, 12 cm in radius, Merck Kieselgel 60, PF_{254}) using distilled solvents. Analytical thin-layer chromatography (tlc) involved plastic backed silica plates (Merck Kieselgel 60, F_{254}) of 0.2 mm thickness. Benzene was distilled from P_2O_5 and stored over 4Å molecular sieves. Methanol, Baker Analyzed, was used as received. The synthesis and spectra of **1** and **3** have been described (1, 2).

*Thermolysis of **1***

Fumaratotriazoline **1** (369 mg, 1.2 mmol) was added to methanol (100 mL). Dissolution of **1** occurred during heating to the reflux temperature. Periodic withdrawal of aliquots of the boiling solution, and analysis by tlc, showed that no more **1** remained after 48 h. Cooling and evaporation of the solvent with a rotary evaporator was followed by centrifugal chromatography of the residue in two portions. Elution with ethyl acetate (15%) in light petroleum afforded pyrroles **6** and **5** in that order, combined yields (from both portions) of 13 and 78%, respectively. On silica tlc plates, developed with 50% ethyl acetate in light petroleum, **6** and **5** had R_f values of 0.40 and 0.22, respectively. Both were oils at room temperature. Spectroscopic data are in Table 2.

*Hydrolysis of **5***

Pyrrole **5** (10 mg) was dissolved in ether (0.5 mL) and the solution was transferred to a watch glass from which the ether was evaporated in ca. 5 min. Ten minutes after the ether had evaporated, analysis of the residue by ir revealed that little, if any, **5** remained and that **6** was the major product. For ir spectra, see Table 2.

*Thermolysis of **3** in methanol*

Amidotriazoline **3** (120 mg, 0.42 mmol) in methanol (5 mL) was heated at the reflux temperature for 6 days. Cooling, concentration, and centrifugal chromatography (15% ethyl acetate in light petroleum) afforded **19** (47 mg, 0.18 mmol), 43%, as a white solid, mp 163–164.5°C (from acetone in petroleum ether), R_f 0.58 (ethyl acetate), spectra in Table 2.

Direct analysis by gc of a similar thermolysate from **3** in methanol showed that both aniline and **21** were present in 11–14% yield. An authentic sample of **21** prepared from methylpropiolate and *tert*-butyl amine (16) had R_f 0.21 (10% ethyl acetate in petroleum) and gave the published ^1H nmr data (16). Crude **21**, from thermolysis of **3** and concentrated by chromatography, gave the ^1H nmr spectrum of authentic **21** except for extraneous signals from impurities in the former. Spectra of **21** are in Table 2.

*Thermolysis of **3** in benzene*

Heating of **3** (120 mg) in benzene (5 mL) at the reflux temperature for 3 days afforded **19** in 85% yield, estimated by integration of the ^1H nmr spectrum.

Unknown X

Properties of X: R_f 0.80 (15% ethyl acetate in petroleum); uv ($CHCl_3$), nm (log ε): 256 (4.03); ir ($CDCl_3$), cm^{-1}: 1702 (br); ^1H nmr (90 MHz, $CDCl_3$) δ: 1.53 (s, 9H), 2.69 (s, 3H), 3.72 (s, 3H), 6.37 (d, J = 3 Hz, 1H), 6.66 (d, J = 3 Hz, 1H); ms (ei), m/z (%): 269 (8), 219 (7), 195 (53), 149 (26), 139 (67), 124 (34), 108 (100), 107 (47), 69 (42).

*Kinetics of thermolysis of **3***

Medium-walled nmr tubes were charged with **3** and with enough solvent to give solutions at the concentrations given in Table 3. The
