The DQF–COSY spectra were recorded using the sequence written by Dr. J. Keeler and software developed by him for phase sensitive acquisition, using a V77-200 data system on a Varian XL-200 instrument (10).[3] In all cases, 32 transients were accumulated for 256 values of the evolution period, with a spectral width of 700 Hz in both dimensions. The recycle time was 4 s and the acquisition time, AT, was 1.45 s. A 2048 × 1024 data matrix was used. Processing: Lorentz to Gauss with RE = 1, AF = 0.87 and RE = 1, AF = 0.06 in f_2 and f_1, respectively. The 90° pulse widths were 12.5 μs for ^{13}C and 8 μs for ^1H.

MATTEO ADINOLFI, GASPARE BARONE, MARIA MICHELA CORSARO, LORENZO MANGONI, ROSA LANZETTA, and MICHELANGELO PARRILLI. Can. J. Chem. **66**, 2787 (1988).

Eight novel oligoglycosides, Muscarosides G–N **3–10**, have been isolated from the bulbs of *Muscari armeniacum* and *Muscari botryoides*, in addition to known Muscarosides A–C **12–14** and scillascilloside D-1 **11**. Their structure was elucidated mainly by spectral analysis (FAB–MS and 1D- and 2D-nmr spectroscopy) and, in some cases, degradative chemical study. The aglycone of **3–10** is the spirocyclic nortriterpenoid **1** or **2**. The monose units of their di-, tri-, tetra-, or hexasaccharide chain are β-D-glucopyranose, α-L-arabinopyranose, α-L-rhamnopyranose, β-D-galactopyranose, α-L-arabinofuranose, and β-D-apio-D-furanose.

MATTEO ADINOLFI, GASPARE BARONE, MARIA MICHELA CORSARO, LORENZO MANGONI, ROSA LANZETTA et MICHELANGELO PARRILLI. Can. J. Chem. **66**, 2787 (1988).

À partir des bulbes du *Muscari armeniacum* ainsi que du *Muscari botryoides*, on a isolé huit nouveaux oligoglycosides, les muscarosides G–N, **3–10**, en plus des muscarosides A–C, **12–14**, et du scillascilloside D-1, **11**, déjà connus. Afin d'élucider leurs structures, on a principalement fait appel à des analyses spectrales (SM–FAB ainsi que spectroscopie rmn en 1D et 2D) et, dans quelques cas, à des études impliquant une dégradation chimique. L'aglycone des composés **3–10** est le nortriterpénoïde spirocyclique **1** ou **2**. Les unités de monose de leurs chaînes di-, tri-, tétra- ou hexasaccharides sont formées de β-D-glucopyrannose, de α-L-arabinopyrannose, de α-L-rhamnopyrannose, de β-D-galactopyrannose, de α-L-arabinofurannose et de β-D-apio-D-furannose.

[Traduit par la revue]

The bulbs of *Muscari comosum* Miller (Liliaceae) have been shown (1–4) to contain six oligoglycosides, named Muscarosides A–F. Their spirocyclic nortriterpenoid aglycones belong to the eucosterol group and the glycone moieties are constituted by four to six units of glucose, arabinose, and rhamnose or apiose. This study was extended to bulbs of other *Muscari* species, namely *M. armeniacum* Leicht and *M. botryoides* Miller, affording the isolation and structure elucidation of eight novel glycosides, Muscarosides G–N, all of them structurally related to Muscarosides A–F. In particular, Muscarosides G **3**, J **6**, K **7**, L **8**, and M **9** (see Chart 1) were obtained from *M. armeniacum*, in addition to known Muscarosides A **12** and B **13**, whereas Muscarosides H **4**, I **5**, and N **10** were isolated from *M. botryoides*, besides the known Muscarosides A **12** (1), B **13** (2), and C **14** (3) and scillascilloside D-1 **11**, already found (5) in the bulbs of another Liliacea, *Scilla scilloides*.

The structures of the novel Muscarosides G–N were elucidated by spectral analysis (^{1}H and ^{13}C nmr spectroscopy and fast atom bombardment mass spectrometry) with the aid of chemical work, whenever a sufficient amount of material was available. The known glycosides **11–14** were identified by comparison of their spectral data with those reported in refs. 1–5.

In the upfield part of the ^{1}H spectra (Table 1) of Muscarosides G **3**, H **4**, J **6**, and L **8** the signals of four tertiary, one secondary, and one primary methyl group are observed. In addition, the signals of one methylene group appear centered at δ 2.43–2.47 as four lines of the A_2 part of an A_2X_3 system, correlated by scalar coupling with the primary methyl group, and the signals of a second methylene group appear centered at δ 2.37–2.39 and δ 3.03–3.05 as an AB quartet. The close similarity between these ^{1}H nmr data and those (see Table 1) obtained for the aglycone of Muscaroside B **13** indicated that Muscarosides G **3**, H **4**, J **6**, and L **8** also possess eucosterol **1** as their aglycone moiety. This was confirmed by comparison of the ^{13}C nmr shifts of the aglycone carbons of Muscarosides G **3**, H **4**, J **6**, and L **8** with the ^{13}C data for eucosterol **1**, both free and linked in Muscaroside B **13** (Table 2). Analogously, the presence, in the ^{1}H nmr spectrum, of the signals of three tertiary, one secondary, and one primary methyl group, as well as the signals of one methylene group at δ 2.50–2.51 as four lines of the A_2 part of an A_2X_3 system, and the absence of an AB quartet at δ 2.3–3.2 indicated, by comparison with the nmr data for the aglycone protons of Muscaroside C **14** that (23*S*)-17,23-epoxy-3β, 30,31-trihydroxy-27-nor-5α-lanost-8-en-24-one **2** was the aglycone moiety of Muscarosides I **5**, K **7**, H **9**, and N **10**. The ^{13}C data (Table 2) were in accordance with this conclusion.[2]

The negative-ion FAB–MS spectrum (Scheme 1) of Muscaroside G **3** exhibited an ion peak at m/z 1367 $(M - H)^-$,

[2]In a previous paper (3), the chemical shifts of the aglycone carbons of Muscaroside C **14** in pyridine-d_5 were compared to those of **2** in chloroform-d_1, on the assumption, supported by literature (7), that the different solvents did not affect the chemical shifts of Muscaroside aglycones highly. The observed differences between **14** and **2** for carbons 5 and 30 were therefore ascribed to glycosidation, whereas they are mainly due to solvent effect, since they almost completely disappear if the spectrum of **2** in pyridine-d_5 (6) (Table 2) is considered. On the other hand, the 8-ppm upfield shift of the carbon 30 of free **2** on going from pyridine-d_5 to chloroform-d_1 is hardly explained and deserves investigation.

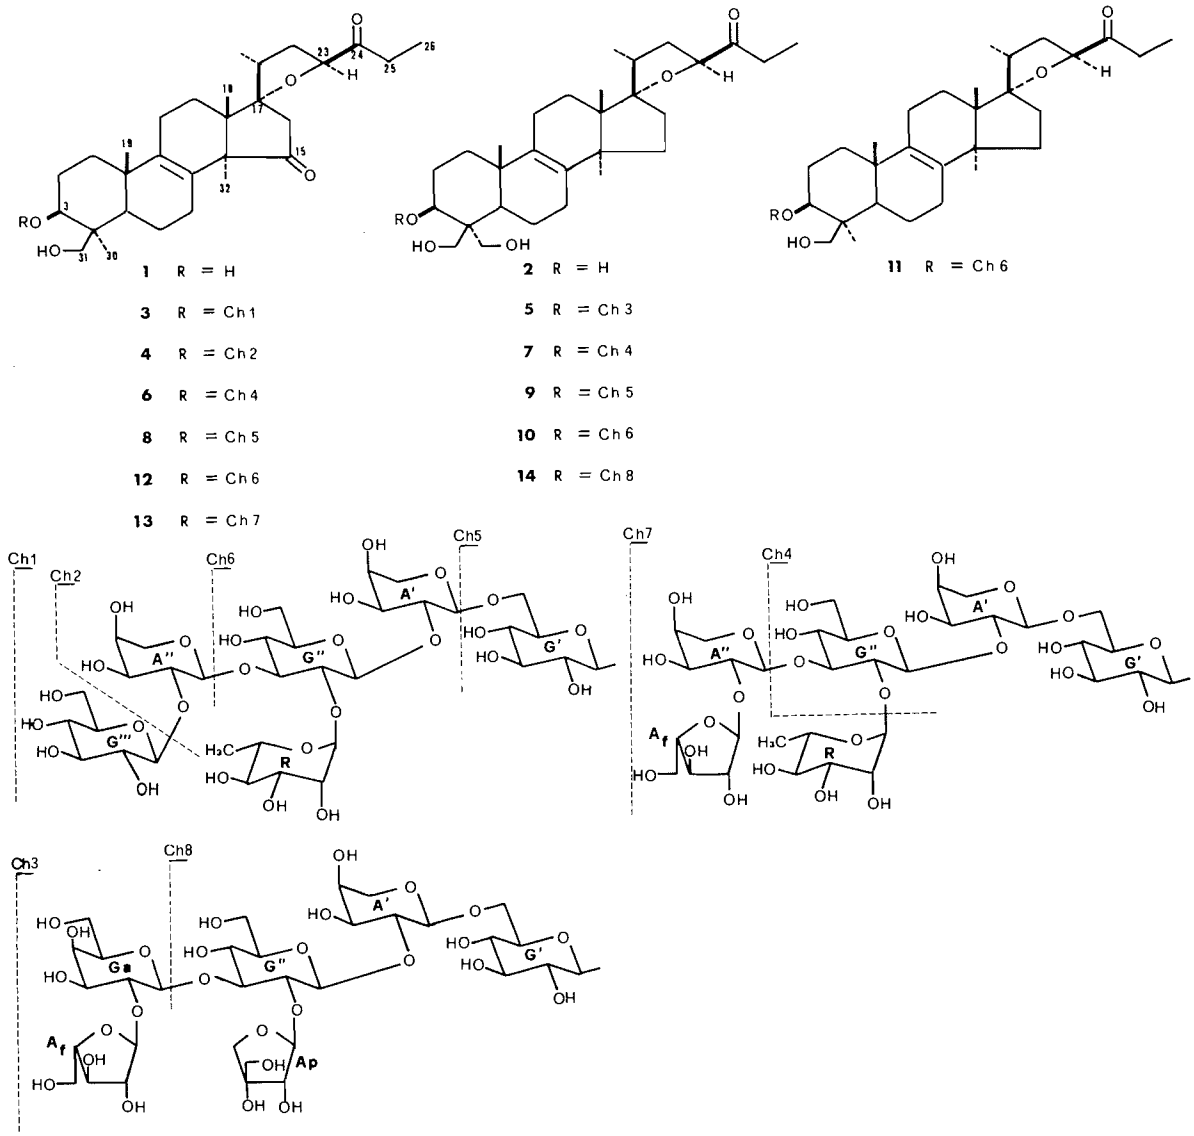

CHART 1.

which, together with ^{13}C and ^{1}H nmr data, suggested the molecular formula $C_{63}H_{100}O_{32}$. The corresponding molecular weight of 1368 daltons was confirmed by the presence of the peak at m/z 1391, formed by cationization of the molecule with Na^+, in the positive-ion spectrum.

Acid hydrolysis (7% H_2SO_4) of Muscaroside G **3** gave rhamnose, arabinose, and glucose, identified by tlc and hplc of the water-soluble fraction of the hydrolysate through comparison with authentic samples of the monosaccharides. A 1:2:3 molar ratio of the monoses was established on calibration of the hplc peak integrated areas against known concentrations. The monose-containing water-soluble fraction of the hydrolysate was perbenzoylated with benzoyl chloride and pyridine and the pure perbenzoates (α-anomers (8)) of rhamnose, glucose, and arabinose were isolated by hplc. Identity in chirality and amplitude of their circular dichroism (cd) curves with those of the perbenzoates (α-anomers) obtained from authentic samples of L-rhamnose, D-glucose, and L-arabinose established the absolute configuration D of all three glucopyranose units and the absolute configuration L of both arabinopyranose units and of the rhamnopyranose unit in the sugar chain of Muscaroside G **3**.

The comparison of the ^{13}C chemical shifts of Muscaroside G (Table 3) with those of reference methyl glycosides revealed the attachment position in the sugar chain (through the glycosidation shifts) and the configuration at the anomeric centres. Thus, the glycone moiety of Muscaroside G was found to consist of one terminal α-rhamnopyranose unit (1, 12), one terminal β-glucopyranose unit, one nodal β-glucopyranose unit linked at its positions 2 and 3, one inner β-glucopyranose unit linked at its position 6, and two inner α-arabinopyranose units, both linked at their position 2 (1, 13, 14). The glycosidation shift (+9.0, Table 2) observed for the C-3 carbon of the aglycone moiety showed that the sugar chain was linked at this carbon. The values of the coupling constants $^{3}J_{H\text{-}1,H\text{-}2}$ listed in Table 1 were in accordance with the configuration of the anomeric centres as determined from the ^{13}C data.

The determination of the glycone sequence was arrived at mainly on the basis of the negative-ion FAB–MS data (Scheme 1). The peak at m/z 633, due to the loss of two hexoses, two pentoses, and rhamnose, indicated that the inner glucose is directly linked to the aglycone. The peak at m/z 765 (= 633 + 132) shows that one inner arabinose is linked to this

glucose unit. The subsequent unit is nodal glucose, as indicated by the very low intensity, due to secondary fragmentation, of the peak at m/z 927, corresponding to the loss of the terminal rhamnose, the terminal glucose, and the remaining inner arabinose unit. The peaks at m/z 1073 $[M - H - (162 + 132)]^-$ and m/z 1221 $[M - H - 146]^-$ may be explained only by locating the second inner arabinose between the terminal and the nodal glucoses. Finally, the small value (+2.9, Table 3) of the glycosidation shift of the 2-carbon of the nodal glucose confirmed that rhamnose is linked to this unit, and identified that carbon as its attachment position (15). Consequently, the linkage location of the other branch of the chain was established at carbon 3. The structure **3** for Muscaroside G was also supported by comparison of the ^{13}C data with those of Muscaroside B **13**, which differs from **3** only in having a terminal arabinofuranose in place of a terminal glucopyranose in its sugar chain.

Muscaroside H **4**, positive-ion FAB–MS m/z 1229 $(M + Na)^+$, negative-ion FAB–MS m/z 1205 $(M - H)^-$, was shown, upon application of the chemical procedure and the cd method already used for **3**, to possess a sugar chain constituted by one L-rhamnose, two D-glucose, and two L-arabinopyranose units. This was confirmed by comparison of the negative-ion FAB mass spectra of the two Muscarosides (see Scheme 1), which accorded with a glycone chain for the former identical to that of the latter, apart from the lack of the terminal hexose. Support to the structure **4** thus assigned to Muscaroside H was given by comparison of the ^{13}C spectrum with those of **12** and **3** (Table 3), which particularly confirmed the positions of the interglycosidic linkages, and by analysis of the ^{1}H nmr spectrum (Table 1). The assignment of the nmr resonances of the anomeric carbons of **4** was confirmed through the use of 2D-heteronuclear carbon–proton shift correlation.

Muscaroside I **5** is unique in having a galactopyranose unit in its chain, as shown by the result of acid hydrolysis of the glycoside, which afforded that carbohydrate as well as glucose, arabinose, and apiose with the molar ratio 1:2:2:1. The negative-ion FAB mass spectrum of Muscaroside I showed peaks at m/z 1355 $(M - H)^-$, 1223 $(M - H - 132)^-$, 1091 $[M - H - (2 \times 132)]^-$ (very low relative intensity), 1061 $[M - H - (132 + 162)]^-$, 929 $[M - H - ((2 \times 132) + 162)]^-$ (very low relative intensity), 767 $[M - H - ((2 \times 132) + (2 \times 162))]^-$, and 635 $[M - H - ((3 \times 132) + (2 \times 162))]^-$, which indicated a branched-chain hexasaccharide moiety, -hex-

ose-pentose-hexose(-pentose)-hexose-pentose. The comparison between the glycone-carbon chemical shifts of Muscaroside I and those of known **13** and **14** (Table 3) suggested the chain ara·*p*(1→2)-gal·*p*(1→3)(api·*f*(1→2))-glu·*p*(1→2)-ara·*p*(1→6)-glu·*p*-. The mode of galactopyranose linkage in Muscaroside I **5** was regarded as β on the basis of the $^3J_{H\text{-}1,H\text{-}2}$ (8.1 Hz) for the anomeric proton.

The sugar chain of both Muscaroside J and Muscaroside K was immediately established as constituted by one pentose and two hexose units from the positive-ion FAB–MS spectra, which displayed the (aglycone + (2 × 162) + 132 + Na)$^+$ peak at *m/z* 951 and *m/z* 953, respectively. The ^{13}C nmr data for the sugar moieties of Muscarosides J and K were almost identical (Table 3) and were consistent with a trisaccharide chain glu·*p*(1→2)-ara·*p*(1→6)-glu·*p*-, which, on the other hand, constitutes the sequence of the first three monoses linked to the aglycone in all so-far isolated Muscarosides, both those from *M. comosum* (1, 4) and those from *M. armeniacum* and *M. botryoides*. Structures **6** and **7** for Muscaroside J and K, respectively, were also supported by ^1H nmr data (Table 1).

Structures **8** and **9** with a disaccharide ara·*p*(1→6)-glu·*p*-chain were attributed to Muscarosides L and M quite similarly, consistent with the pseudomolecular-ion (aglycone + 132 + 162 + H)$^+$ peak at *m/z* 767 and *m/z* 769, respectively, exhibited by the positive-ion FAB mass spectra, and with the ^{13}C and ^1H nmr data listed in the tables.

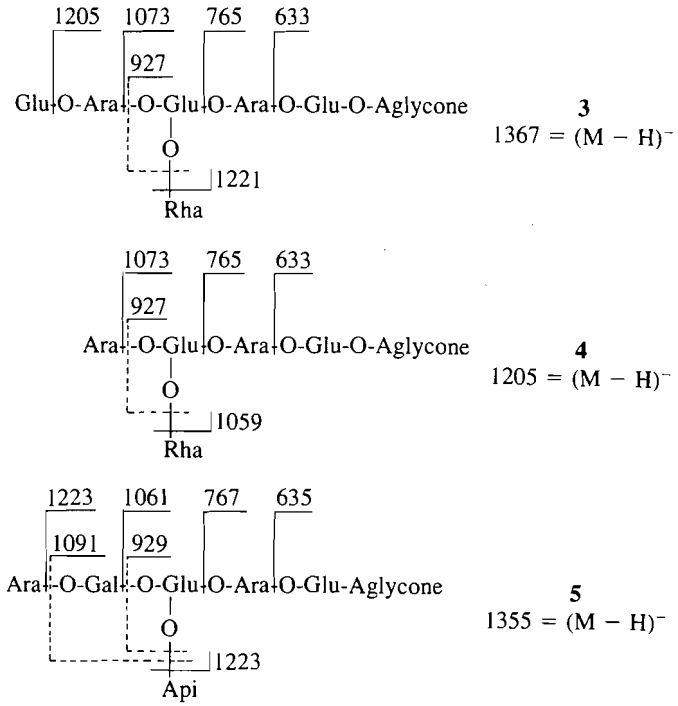
Muscaroside N was identified as having a rha·*p*(1→2)-glu·*p*(1→2)-ara·*p*(1→6)-glu·*p*- chain identical with that of Muscaroside A **12** on the basis of the positive-ion FAB mass spectrum (pseudomolecular-ion peak at *m/z* 1099 (M + Na)$^+$) and of the ^{13}C nmr data for the sugar moiety (Table 3), which were quite similar to those of **12**.

Experimental[3]

The ^1H (270 MHz) and ^{13}C (67.88 MHz) nmr spectra were taken on a Fourier transform Bruker instrument WH270 with an Aspect 2000 computer with 48K memory (32K data). Two-dimensional carbon–proton shift correlations for Muscaroside H **4** were performed by choosing polarization transfer delays equal to average one-bond couplings of *J*(CH) = 140 Hz. Exponential multiplication in the ^{13}C domain and Gaussian resolution enhancement in the ^1H domain were applied to a 256 × 1024 data matrix prior to Fourier transformation.

Mass spectra were recorded with a Kratos MS50 instrument

[3]With the assistance of Italo Giudicianni.



SCHEME 1. Negative FAB–MS fragmentation (— primary, --- secondary) patterns of Muscarosides G **3**, H **4**, and **15**.

equipped with a FAB source. The circular dichroism curves were recorded with a JASCO A500 dichrograph. The hplc was performed with a Varian 5060 instrument using a Waters R401 differential refractometer as the detector. The preparative and the thin-layer chromatography were carried out on precoated silica gel plates (Merck F_{254}, 2 mm and 0.25 mm, respectively). Merck silica gel 60 H was used for column chromatography.

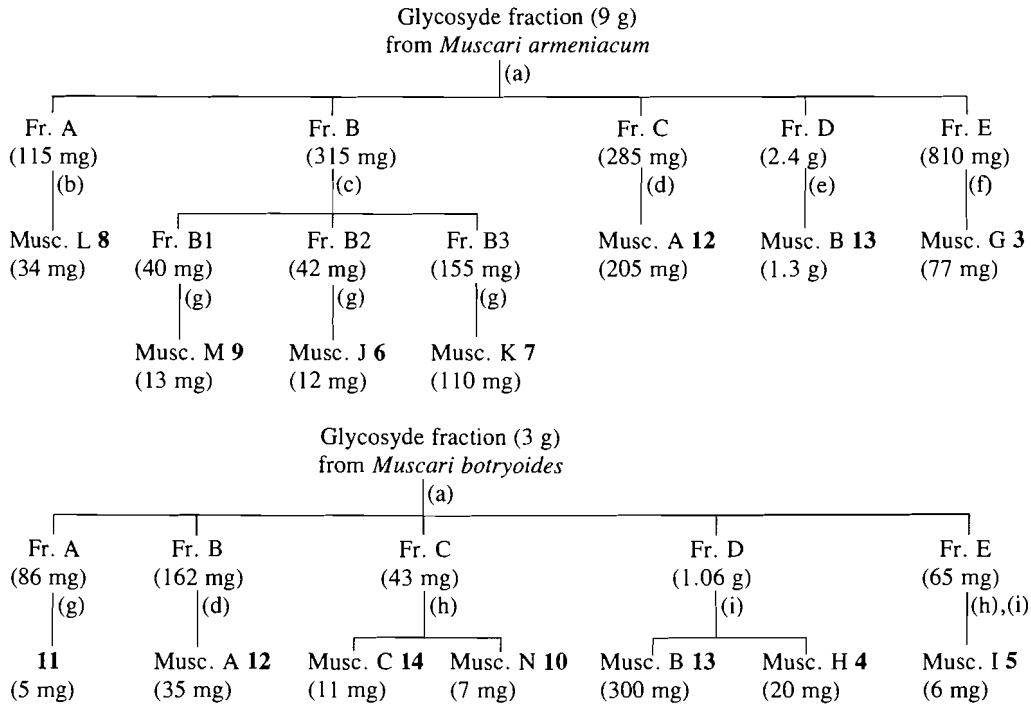
Isolation of Muscarosides

Fresh bulbs (18 kg) of *Muscari armeniacum* Leicht (purchased from Stassen Italiana, Como, Italy, and authenticated by the Botanical Garden of the University of Naples) were homogenized in a mechanical stirrer, freeze-dried, and extracted in a Soxhlet with light petrol (12 h), ethyl ether (12 h), and with methanol (12 h). The methanol extract was evaporated (40 g), dissolved in water (600 mL), and chromatographed on an Amberlite XAD-2 (800 g) column. Elution with methanol gave a crude glycoside mixture (9 g).

A similar procedure was adopted to obtain the crude glycoside mixture (3 g) from fresh bulbs (2 kg) of *Muscari botryoides* Miller (collected in May 1985 near Formia, Italy, and authenticated by the Botanical Garden of the University of Naples).

The glycoside mixtures were fractionated as detailed in Chart 2.

The spectral data (negative and (or) positive FAB–MS, ^1H and ^{13}C nmr spectroscopy) of novel Muscarosides G–N, **3**–**10**, are reported in the text, in Scheme 1, and in Tables 1–3. The known Muscarosides A **12**, B **13**, and C **14** were identified by comparison (^1H and ^{13}C nmr spectra, tlc, hplc) with authentic samples (1, 3). Glycoside **11** was recognized to be the known scillascilloside D-1, isolated from *Scilla scilloides*, as it exhibited ^1H and ^{13}C nmr data that were practically identical with those reported in ref. 5.



(a) Silica gel column chromatography on a Chromatospac Prep10 apparatus (Jobin Yvon); solvent: 7:3 chloroform–methanol.
(b) Preparative hplc on a Lichrosorb RP-18 (7 μm) column, 3:2 methanol–water, 5 mL min^{-1}.
(c) Preparative chromatography on silica gel plates (2 mm); solvent: 13:7:1 chloroform–methanol–water (3 runs).
(d) Preparative hplc on a Lichrosorb RP-18 (7 μm) column, 3:1 methanol–water, 5 mL min^{-1}.

Acid hydrolysis of Muscaroside G **3**

A sample of Muscaroside G **3** was hydrolyzed with 7% H_2SO_4 and the water-soluble fraction of the hydrolysate was analyzed by tlc and hplc following the procedure described in ref. 4, establishing the presence of rhamnose, arabinose, and glucose in a 1:2:3 molar ratio.

Perbenzoylation of the hydrolysate from Muscaroside G **3**

Perbenzoylation of the water-soluble fraction of the above hydrolysate, isolation of pure perbenzoates of rhamnose, arabinose, and glucose, and measurement of the amplitudes (−12, +71, and +12, respectively) of their circular-dichroism split curves were carried out following the procedure described in ref. 4.

Acid hydrolysis of Muscaroside I **5**

A sample of Muscaroside I **5** was hydrolyzed with 7% H_2SO_4 and the water-soluble fraction of the hydrolysate was analyzed by tlc and hplc following the procedure described in ref. 4, establishing the presence of galactose, glucose, arabinose, and apiose in a 1:2:2:1 molar ratio.

Received February 28, 1988

MIRTHA NASSETTA, RITA H. DE ROSSI, and JUAN J. COSA. Can. J. Chem. **66**, 2794 (1988).

The effect of α-, β-, and γ-cyclodextrins on the quantum yield for the formation of *o*- and *p*-aminoacetophenone from the photolysis of acetanilide at 254 nm was determined. There is an increase in the ratio of *o*/*p* products when cyclodextrins are added and the total quantum yield is about the same as in water in the presence of γ-CD, higher with β-CD, and lower with α-CD. The association constants between acetanilide and CD were determined and the values are 22.7 M^{-1} and 30.7 M^{-1} for α- and β-CD respectively. The quantum yields for the formation of *o*- and *p*-aminoacetophenone were measured. The rearrangement occurs in water and in the included acetanilide. The quantum yields for the formation of *o*-aminoacetophenone and *p*-aminoacetophenone from the included substrate could be calculated for α- and β-cyclodextrin. Comparing these values with those obtained in water, it is concluded that there is some steric inhibition for rearrangement at the *para* position when α-cyclodextrin is the host, whereas with β-cyclodextrin the less polar microsolvent effect is responsible for the increase in the total quantum yield relative to water.

MIRTHA NASSETTA, RITA H. DE ROSSI et JUAN J. COSA. Can. J. Chem. **66**, 2794 (1988).

On a déterminé l'influence des α-, β- et γ-cyclodextrines sur les rendements quantiques des réactions conduisant à la formation des *o*- et *p*-amino acétophénones, par photolyse de l'acétanilide à 254 nm. Lorsqu'on ajoute des cyclodextrines, on observe une augmentation du rapport des produits *o*/*p* et le rendement quantique global est pratiquement le même que celui observé dans l'eau en présence de γ-CD, plus élevé qu'avec de la β-CD et plus faible qu'avec de l'α-CD. On a déterminé les constantes d'association de l'acétanilide avec les CD et on a obtenu des valeurs de 22,7 M^{-1} et 30,7 M^{-1} respectivement pour l'α- et la β-CD. On a mesuré les rendements quantiques pour la formation des *o*- et *p*-amino acétophénones. La transposition se produit dans l'eau ainsi qu'avec de l'acétanilide inclus. On peut calculer les rendements quantiques pour la formation des *o*- et *p*-amino acétophénones à partir de substrats inclus dans l'α- ainsi que la β-cyclodextrine. Lorsqu'on compare ces données avec celles obtenues dans l'eau, on peut conclure que, lorsque l'α-cyclodextrine est l'hôte, il existe une certaine inhibition stérique à la transposition vers la position *para*; par ailleurs, lorsqu'on utilise de la β-cyclodextrine, l'effet de microsolvant moins polaire est responsable de l'augmentation de rendement quantique par rapport à l'eau.

[Traduit par la revue]

Introduction

Cyclodextrins are cyclic oligomers of α-D-glucose with 6, 7, or 8 glucose units (α-, β-, or γ-cyclodextrins) and are able to form inclusion complexes with a great variety of organic as well as inorganic compounds (1). As a result of the interaction, the reactivity of the included substrate changes and, when parallel reactions take place, the presence of the host may change the proportion of the various products formed (2).

Some examples are the halogenation of anisole (3) and the iodination (4), carboxylation (5), or formylation of phenoxide ion (6). It has been reported that in the photo-Fries rearrangement of acetanilide in the presence of β-cyclodextrin there is a significant increase in the *para* relative to the *ortho* product (7), and that there is an increase in the yield of rearrangement products. The change in selectivity was attributed to steric inhibition for the reaction at the *ortho* position. On the other hand, a very high *ortho* selectivity was recently reported for the photo-rearrangement of phenyl esters and anilides in solution and in the solid state, for reactions carried out in the presence of α- and β-cyclodextrins (8).

We considered it of interest to carry out a kinetic study of the photo-rearrangement of acetanilide in the presence of α-, β-, and γ-cyclodextrins to determine whether the change in product ratio was due to a decrease in reactivity at the *ortho* position or to an increase in reactivity at the *para* position. We were surprised to find that in the presence of α- and β-cyclodextrin there is an increase in the *ortho* rather than in the *para* product, but we believe that our results are consistent with what is known about the mechanism of photo-Fries reactions (*vide infra*).

Results and discussion

The photolysis of acetanilide has been extensively studied in protic as well as in non-protic solvents (9). The main photolysis products are *o*- and *p*-aminoacetophenone. The quantum yield of these products is not affected by oxygen, piperylene, initial concentration of reactants, and radiation intensity. These results suggest that the excited state responsible for the photorearrangement is a singlet (9*a*). The absorption band of acetanilide centered at 239 nm suffers a small bathochromic shift when α- or β-CD is added, indicating some type of association (10). No changes in the spectra are observed with γ-CD. A similar shift in the wavelength maximum is observed when the solvent is changed from water to dioxane, indicating that the acetanilide is in a less polar environment.

From the changes in the optical density at the λ_{max} of the difference spectrum, the equilibrium constant for the association was determined (11). The values obtained are 22.7 ± 0.1 and 30.7 ± 0.1 M^{-1} for α- and β-CD, respectively. The value for the equilibrium constant for the association of acetanilide and α-CD is in good agreement with that obtained by other authors by nmr (12), namely 20 M^{-1}.

In the presence of α-, β-, or γ-CD the ratio of quantum

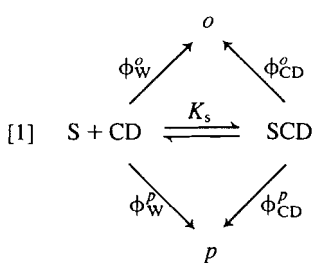
20	1.45	4.42	3.31

[a] T = 25°C. Solvent, water. $[Substrate]_0 = 3 \times 10^{-4}$ M.
[b] Initial concentration of α-cyclodextrin. Conversion was kept below 3%. Quantum yields are calculated using a solution of acetanilide as actinometer.
[c] Observed quantum yield for the formation of *para* product.
[d] Observed quantum yield for the formation of *ortho* product.
[e] Ratio of concentration of *ortho*- and *para*-aminoacetophenone.
[f] Calculated using ferrioxalate as actinometer.

yields for the formation of *ortho*- and *para*-aminoacetophenone increases. But there is not a big change in the total quantum yield of product formation (the data are summarized in Tables 1–3). In one reaction, in the presence of β-CD, the solution was photolyzed up to 40% and was analyzed by gas chromatography to determine whether any aniline was formed. Within the limits of the detection of our instrument (~1%), aniline was not formed. In the same reaction we compared the yield of *ortho*- and *para*-aminoacetophenone, determined spectrophotometrically and by gas chromatography, and we found the same value within experimental error (see experimental section).

We also carried out an experiment using similar concentrations of acetanilide and β-cyclodextrin as those reported in a previous work (7) and we found that the concentrations of *ortho* and *para* products are similar to those obtained in water (see last run in Table 2). The measured ratio of concentrations of *o*- and *p*-aminoacetophenone is similar to that reported by Chenevert and Raymond (7). We believe that the reason for their interpretation, that β-cyclodextrin increased the amount of the *para* product relative to the *ortho*, is that they obtained a value of 3.8 for the *o*/*p* ratio in water. This value is larger than that previously reported in the literature (9, 13) and than our own values (Tables 1–3).

Similar results were obtained when degassed solutions were used. The changes observed in quantum yields in the presence of cyclodextrins are not large, but it is important to note that the association constants are quite weak and, due to solubility limitations for the host, the fraction of complexed substrates under extreme conditions is less than 30%. Therefore, the photochemical reaction must be taking place in both environments. The kinetic scheme may be represented as in eq. [1],



where S is acetanilide, CD is the cyclodextrin, SCD is the inclusion complex, *o* is *o*-aminoacetophenone, *p* is *p*-aminoacetophenone, ϕ^o_W, ϕ^p_W and ϕ^o_{CD}, ϕ^p_{CD} are the quantum yields for the formation of products in water and in CD respectively, and K_s is the binding constant for acetanilide.

The observed quantum yields for *ortho* ϕ^o_{exp} or *para* ϕ^p_{exp} products are described in eq. [2] (14, 15), where ϵ_c/ϵ_w is an approximate correction factor for the differences in light absorption by the complexed and uncomplexed acetanilide. This value is 1.2 for α- and β-CD and was determined from the absorbance at 254 nm of solutions of acetanilide in the presence of the appropriate cyclodextrin and from the calculated fraction of complexed substrate.

$$[2] \quad \phi^{o(p)}_{exp} = \frac{\phi^{o(p)}_w + (\epsilon_c/\epsilon_w)\phi^{o(p)}_{CD} K_s[CD]}{1 + K_s[CD]}$$

Equation [2] can be rearranged to eq. [3]:

$$[3] \quad \frac{1}{\phi^{p(o)}_W - \phi^{o(p)}_{exp}} = \frac{1}{\phi^{o(p)}_W - \epsilon_c/\epsilon_w \phi^{o(p)}_{CD}} + \frac{1}{[\phi^{o(p)}_W - \epsilon_c/\epsilon_w \phi^{o(p)}_{CD}] K_s[CD]}$$

In Table 1 it can be observed that while ϕ^o_{exp} remains approximately constant, ϕ^p_{exp} decreases when the concentration of α-CD increases. A plot (not shown) of the left-hand side of eq. [3] vs. $[CD]^{-1}$ for the *p*-aminoacetophenone yields a straight line. From the intercept of this plot, $\phi^p_{CD} = (0.3 \pm 0.4) \times 10^{-3}$ is calculated. The ratio of slope over intercept yields $K_s = (37 \pm 18)$ M^{-1}, in fair agreement with the spectrophotometric value.

Alternatively, eq. [2] can be rearranged to eq. [4]:

$$[4] \quad \phi^{o(p)}_{exp} = \phi^{o(p)}_W + \left[\frac{\epsilon_c}{\epsilon_w}\phi^{o(p)}_{CD} - \phi^{o(p)}_W\right] \frac{K_s[CD]}{1 + K_s[CD]}$$

From a plot of ϕ^p_{exp} vs. the fraction of complexed acetanilide (using the spectrophotometric value of K_s), ϕ^p_{CD} is calculated as $(0.2 \pm 0.2) \times 10^{-3}$. Although in both cases the error in the calculated value is quite high, it is smaller in the latter treatment. Since there is not a marked trend in the values of ϕ^o_{exp}, we estimated ϕ^o_{CD} using eq. [2] for each experimental point. The average value is $(1.9 \pm 0.8) \times 10^{-3}$.

In Table 2 the data for the reactions in the presence of β-CD are shown. It can be seen that there is a change in the product ratio mainly due to changes in the quantum yield for the formation of the *ortho* product. We attempted to fit the data using eq. [3] but there was a poor linear correlation; however, the value of K_s that can be estimated from the ratio of the slope and the intercept is similar to that determined spectrophotometrically. We estimated ϕ^o_{CD} and ϕ^p_{CD} for each experiment from eq. [2] using the K_s determined spectrophotometrically and the value $\epsilon_c/\epsilon_w = 1.2$. These values show that the quantum yield for the formation of the *para* product is somewhat lower in the included substrate than in water, whereas the quantum yield for the formation of the *ortho* product in the substrate included in CD is about 50% higher than in water.

The experimental *o*/*p* ratios for the reactions in the presence of γ-CD (Table 3) show a tendency to behave similarly to those for β-CD but, since the equilibrium constant for the association could not be determined and the changes in $\phi^{o(p)}_{exp}$ with the concentration of γ-CD are barely outside the experimental error, it was not possible to calculate ϕ^o_{CD} and ϕ^p_{CD}.

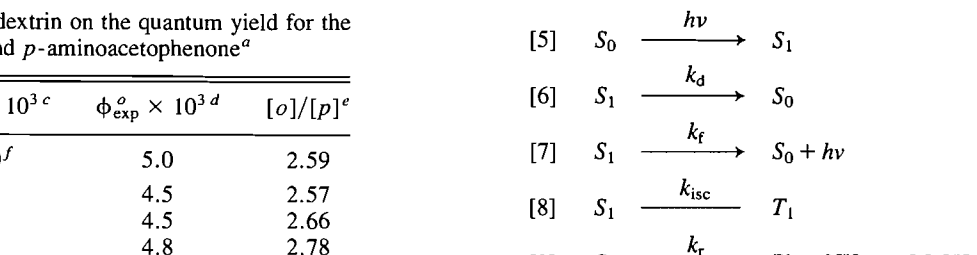
It has been reported that the mechanism of the photo-Fries rearrangement of acetanilide may be described in Scheme 1, where S_0, S_1, and T_1 represent the ground state, first singlet, and first triplet excited state respectively.

The total quantum yield is highly dependent on the hydrogen-bonding ability of the solvent with the substrate (16).

Equation [9] is accepted as the initial process of the photo-Fries reaction, followed by rearrangement of the radical pair within the solvent cage (Scheme 2) (9*b*).

We assume that the photophysical and photochemical primary processes of acetanilide, given in Scheme 1, are not appreciably altered by association with CD, and we have no reason to believe they are. To explain the observed changes in quantum yields in the reactions that occur inside the cavity of the cyclodextrins or in the bulk solution (Table 4), we must consider the various factors that may induce changes in quantum yields. These are (*a*) hydrogen bonding, (*b*) steric hindrance for migration of the acetyl radical to the *ortho* and *para* positions, (*c*) escape of radicals from the solvent cage (this is not an important reaction under our experimental conditions since we could not detect aniline), (*d*) back recombination of the geminate radical pair to regenerate acetanilide.



SCHEME 1

It is known that reaction [9] is strongly dependent on the hydrogen bonding ability of the solvent (9). The quantum yield of products decreases when the hydrogen bonding ability of the solvent increases. For instance, the total quantum yield is 7×10^{-3} in water, 3.1×10^{-2} in ethanol, and 8×10^{-2} in ethyl ether. On the other hand, the *ortho*/*para* ratio increases from 1.2 in ethyl ether to 2.5 in water (9*a*).

Our results show that the total quantum yield of products is about the same as in water in the presence of γ-CD (Table 3), somewhat higher with β-CD (Table 2), and somewhat lower with α-CD (Table 1).

The changes observed in the uv spectra of solutions of acetanilide in the presence of α- and β-CD indicate that acetanilide is in a less polar microenvironment; therefore under these conditions the quantum yield of product formation should be larger, whereas the *ortho*/*para* ratio should be lower, than in water.

It was determined that in the complex of acetanilide with α-CD, the benzene ring penetrates the cavity and the *ortho* positions are sterically hindered due to interactions with the cyclodextrin ring system (12). In this way, it is possible to explain the decrease in the ϕ^o_{CD} for the reactions carried out in the presence of α-CD. The larger decrease in the value of ϕ^p_{CD} can also be explained on the basis of steric inhibition for the migration of the acetyl group to the *para* position. We suggest that the decrease in total quantum yield is due to an increase in the rate of the back reaction. The phenomenon of "cage combination" is well known (17). This effect is observed in systems involving two radicals simultaneously produced in

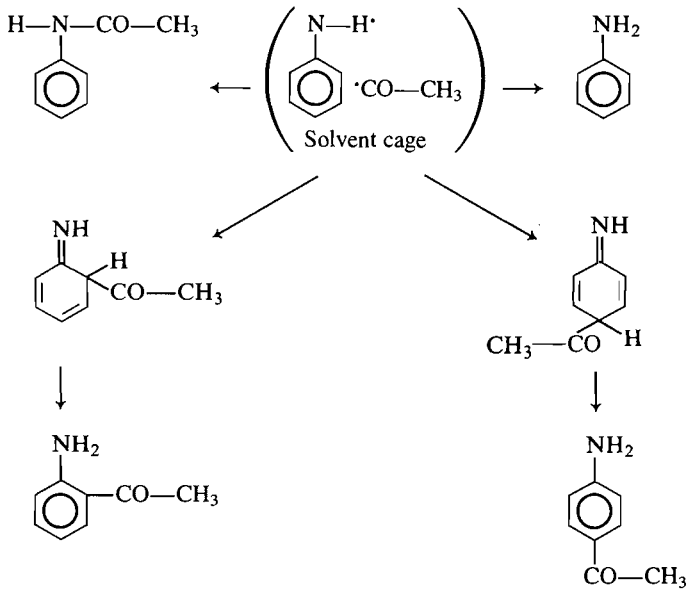

SCHEME 2

solution at the same location and is strongly dependent on the solvent viscosity. The cavity of the α-CD may present an increased microviscosity and therefore the migration of the acetyl radical is somehow impeded. On the other hand, studies regarding the location of substituted benzene derivatives in the cavity of β-CD (18) indicate that the aromatic ring does not penetrate the cavity very deeply, so that the *ortho* position may not be sterically hindered for reaction, while we would expect some steric inhibition for migration of the acetyl radical to the *para* position, consistent with the value of $\phi^p_{CD}/\phi^p_W = 0.8$. The observed $\phi^o_{CD}/\phi^o_W = 1.5$ may be due to the less polar microenvironment where the reaction is taking place.

In Table 4 the values for the quantum yield for the formation of *ortho* and *para* aminoacetophenone in the presence of cyclodextrins are summarized. Although the values have a considerable error, the results indicate that there is a significant increase in the formation of the *ortho* product relative to the *para* product, when the rearrangement takes place in the cavity of α- and β-CD. The lack of a comparable effect upon the addition of γ-CD is reasonable if it does not bind acetanilide, as suggested by the absorption spectrum, or if γ-CD allows several water molecules to share the cavity with acetanilide.

Experimental

Photolysis methods

A set of reactions was carried out in a quartz reactor where solutions of acetanilide 2×10^{-4} M in water, with or without cyclodextrin, were irradiated with an immersion type low-pressure mercury lamp (254 nm) during 120 min. The yield of products was determined spectrophotometrically as indicated below. Bubbling nitrogen through the solution did not change the results.

A solution containing 6×10^{-4} M acetanilide and 1.5×10^{-2} M β-CD and one without β-CD were photolyzed up to 40% conversion. The solutions were analyzed spectrophotometrically, giving 31.56% of *ortho* and 10.06% of *para* aminoacetophenone for the former and 26.77% of *ortho* and 10.41% of *para* aminoacetophenone for the latter. Then they were extracted three times with 10-mL portions of ether. The combined ether extracts were dried with calcium chloride, concentrated, and analyzed by gas chromatography. The gc analysis was performed on a Varian Aerograph series 1400 instrument using a 1.5 mts, OV 101 on 3% Chromosorb GHP column, using β-naphthol as internal standard giving 32.16% and 11.04% of *o*- and *p*-aminoacetophenone respectively for the former and 28.00% and 12.41% of *o*- and *p*-aminoacetophenone respectively for the latter. No aniline was detected in this analysis. In all cases the photoproducts were compared to those of known mixtures of authentic samples.

TABLE 4. Association constants of acetanilide with cyclodextrins, and calculated quantum yields for the formation of *o*- and *p*-aminoacetophenone from the complexed acetanilide

Cyclodextrin	K_s, M^{-1} [a]	$\phi^o_{CD} \times 10^3$	$\phi^p_{CD} \times 10^3$
α[b]	22.7 ± 0.1	1.9 ± 0.8	0.2 ± 0.2
β[c]	30.7 ± 0.1	7.4 ± 0.8	1.6 ± 0.4
γ[d]		5	2
Water		5.0 ± 0.2	2.0 ± 0.1

[a]All determinations were done at 25°C in water. $[\text{Acetanilide}]_0 = 3 \times 10^{-4}$ M.
[b]Concentration range $(4–20) \times 10^{-3}$ M.
[c]Concentration range $(2–14) \times 10^{-3}$ M.
[d]Concentration range $(4–18) \times 10^{-3}$ M.

Quantum yield determinations

Aqueous solutions of 3×10^{-4} M acetanilide and the required amount of CD contained in square quartz cuvettes were placed in a merry-go-round apparatus and irradiated with a low-pressure mercury lamp (254 nm). Every 20 minutes the lamp was covered to stop irradiation and the spectra of the solutions were taken. The yield of photoproducts was determined by measuring the absorption at 312 and 357 nm, which are the λ_{max} of *o*- and *p*-aminoacetophenone respectively. In all cases the conversion was below 10%. To calculate the yield we use eqs. [10] and [11]:

$$[10] \quad C_1 = A_1 \frac{\epsilon_{22}}{\epsilon_{11}\epsilon_{22} - \epsilon_{12}\epsilon_{21}} + A_2 \frac{-\epsilon_{21}}{\epsilon_{11}\epsilon_{22} - \epsilon_{12}\epsilon_{21}}$$

$$[11] \quad C_2 = A_1 \frac{-\epsilon_{12}}{\epsilon_{11}\epsilon_{22} - \epsilon_{12}\epsilon_{21}} + A_2 \frac{\epsilon_{11}}{\epsilon_{11}\epsilon_{22} - \epsilon_{12}\epsilon_{21}}$$

where ϵ_{11} and ϵ_{21} are the extinction coefficients at 357 nm of *p*- and *o*-aminoacetophenone respectively; ϵ_{12} and ϵ_{22} are the extinction coefficients at 312 nm of *p*- and *o*-aminoacetophenone; A_1 and A_2 are the observed values of the absorbance at these two wavelengths; and C_1 and C_2 are the observed values of concentration of *p*- and *o*-aminoacetophenone. The concentration so calculated was plotted vs. time, and the ratios of the slopes for the *o*- and *p*-aminoacetophenone are the values of the *o*/*p* ratio reported in Tables 1–3.

The quantum yields were determined using the solution of acetanilide in water as acetinometer. The quantum yield for the acetanilide solution was checked using the ferrioxalate actinometer (19). The value obtained is the same as that reported in the literature (9, 13).

Equilibrium constant determinations

The spectrum of solutions containing 1.4×10^{-4} M acetanilide and variable concentrations of α- or β-CD was run and the spectrum of the cyclodextrin and that of acetanilide were subtracted. This difference spectrum has its maximum at 230 nm. The equilibrium constant for the association was determined from the measurement of the change in optical density as a function of cyclodextrin concentration (11).

For personal use only.

Marine brown algae belonging to the family Dictyotaceae are known to be a rich source of bioactive terpenoids that possibly act as feed deterrent against herbivorous marine animals. Previous work on *Dilophus ligulatus* (Kütz.) Feldm. (Syn. *D. Spiralis* (Montagne) Hamel) has afforded diterpenoids **1**–**3** (1–3), one of which (**2**) possesses antibiotic properties (4). A further secondary metabolite, crenuladial **4**, active against *Aeromonas hydrophila*, *Staphylococcus aureus*, and *Micrococcus luteus*, has been now isolated from the more polar fractions of the chloroform extract of this alga.

Crenuladial **4** was obtained as an optically active oil, $[\alpha]_D$ +27.3°. Its elemental composition was established as $C_{22}H_{34}O_5$ by combustion analysis. In the mass spectrum the molecular ion was not discernible, the ion at highest mass being observed at *m/z* 360 ($M^+ - H_2O$). Diagnostically important fragments were observed at *m/z* 342 ($M^+ - (H_2O \times 2)$), 318 ($M^+ - CH_3COOH$), 300 ($M^+ - H_2O - CH_3COOH$), 282 ($M^+ - (H_2O \times 2) - CH_3COOH$), 109 ($C_8H_{13}$), and 69 ($C_5H_9$); the last two ions were considered to be strongly suggestive, based on the known fragmentation of diterpenoids from Dictyotaceae seaweeds (5, 6), of the 1,5-dimethyl-4-hexen-1-yl side chain. The ir spectrum showed intense hydroxyl (3400 cm^{-1}) and ester (1740 cm^{-1}) absorptions. In both ^1H and ^{13}C nmr spectra of **4** the majority of signals were broadened and ill-defined; the few sharp ones were readily assigned to the terminal portion of the side chain (1.70, s, 3H; 1.61, s, 3H; 5.10, t, 1H; 25.7, q (C-15); 17.7, q (C-16); 131.9, s (C-14); 124.6, d (C-13); 32.0, d (C-10); 25.6, t (C-12)). Signal broadening was substantially affected neither by acetylation (which afforded triacetate **5**, $C_{26}H_{38}O_7$, in the ir spectrum of which the OH absorption had disappeared) nor by measuring the spectra at low (−40°C) or high (100°C) temperature. Also, 2D nmr techniques (H,H and H,C correlations) were moderately informative.

As elucidation of the structure of **4** by spectroscopic means appeared unfeasible, the possibility of chemical correlation to known compounds was considered. The tricyclic nature of **4**, deduced from the molecular formula and ^{13}C nmr data, together with the probable presence of a cyclopropane ring (broad signals at δ 0.01 (H-8a) and 0.92 (H-7), and 8.5 ppm (C-8)) suggested a close relationship with a group of marine diterpenoids (crenulides and crenulacetals (5–8)) isolated from brown algae of the family Dictyotaceae as well as from sea hares that presumably feed on them. That two of these compounds, namely crenulacetals C and D (6), also show severe broadening of the nmr signals due to "mobility" of the conformations of the ring system lent support to the conjecture that crenuladial could be structurally related to them.

Sodium borohydride reduction of **4** gave compound $C_{22}H_{36}O_4$, which exhibited well-defined ^1H and ^{13}C nmr spectra (Tables 1 and 2), interpretable in terms of structure **6**. During the chromatographic purification of **6** on Si gel the formation of a small amount of a dehydration product, **7**, was observed. Definite confirmation of the structure of diol **6** was obtained by acetylation, which afforded triacetate **8**. Identification is based on comparison of ^1H nmr data with those reported in the literature (partial) for a semisynthetic compound obtained from acetoxycrenulide **9**, by reduction ($LiAlH_4$) followed by acetylation (8). This correlation definitely settled the gross structure of **6**, while its stereochemistry remained undefined since the value of the optical rotation of **8** has not been reported. To solve the question, **6** was treated with MnO_2 to give a compound that had physical properties (ms, ir, uv, ^1H and ^{13}C nmr) identical with those of acetoxycrenulide **9** (7, 8). The optical rotation was +21.5°, which closely compares with the value (+20.5°) reported for semisynthetic acetoxycrenulide obtained from the natural 1,9-dihydroxycrenulide by $NaBH_4$ reduction followed by acetylation (8), and therefore the stereochemistry at C-3, -4, -6, -7, and -9 was assumed to be the same.

In the light of the above results, the ^1H and ^{13}C nmr features of **4** could be interpreted as summarized in Tables 1 and 2, and the new algal metabolite described as the cyclic monohydrate of the hypothetical dialdehyde, **10**, that has been proposed as the precursor of crenulacetals (6). The isolated material, although homogeneous in many different chromatographic systems, is actually a mixture of isomers, possibly in equilibrium through the free aldehyde **10**, differing in the stereochemistry at

C-18 and C-19, as indicated by the presence in the ^{13}C nmr spectrum of no less than four hemiacetal resonances in the range 102–105 ppm.

Experimental

Mass spectral measurements were obtained at 70 eV with a Kratos MS-50S spectrometer. The ir and uv spectra were obtained using Perkin–Elmer 330 and Perkin–Elmer 684 spectrophotometers respectively. Optical rotations were taken on a Beckman DB-GT polarimeter. The alga was collected in February 1986 off the south coast of Sicily (Portopalo).

Isolation of compound 4

Freeze-dried alga (200 g) was extracted three times with CH_2Cl_2. Evaporation of the solvent afforded an oily residue (12 g), which was chromatographed on Si gel (5 × 100 cm; increasing concentrations of Et_2O in C_6H_{14} as the eluent). Fractions of 100 mL were collected and pooled according to their tlc profiles. Compound **4**, eluted in fractions 40–45, was purified by successive chromatographies on LiChroprep Si 60, using as solvent Et_2O–C_6H_{14}, 3:2 vol/vol and then Me_2CO–C_6H_{14}, 1:4 vol/vol, to give 300 mg of pure **4**.

Crenuladial (**4**): $[\alpha]_D$ ($CHCl_3$) +27.3°; ir ν(CCl_4): 3400, 2930, 1740, 1450, 1360, 1250, 1115, 1030, 835 cm^{-1}; hrms, *m/z* calcd. for $C_{22}H_{32}O_4$: 360.2300; found: 360.2305 ($M^+ - H_2O$, 6%); ms, *m/z* (rel. int.): 342 ($M^+ - (H_2O \times 2)$, 2%), 318 ($M^+ - CH_3COOH$, 16%), 300 ($M^+ - CH_3COOH - H_2O$, 13%), 285 ($M^+ - CH_3COOH - H_2O - CH_3$, 13%), 282 (6%), 275 (8%), 257 (11%), 244 (7%), 228 (9%), 218 (28%), 202 (10%), 189 (49%), 176 (18%), 173 (15%), 161 (26%), 159 (16%), 147 (21%), 145 (30%), 133 (24%), 131 (16%), 123 (14%), 121 (15%), 119 (20%), 109 (50%), 105 (26%), 95 (26%), 93 (20%), 91 (33%), 82 (35%), 79 (28%), 69 (100%). *Anal.* calcd. for $C_{22}H_{34}O_5$: C 69.81, H 9.05; found: C 69.85, H 9.08. The ^1H and ^{13}C nmr data are given in Tables 1 and 2.

Acetylation of 4 to give 5

Acetylation (Ac_2O/Py) of **4** (100 mg) and conventional work-up afforded, after chromatographic purification (LiChroprep Si 60, Et_2O/C_6H_{14}, 3:7 vol/vol, as the eluent), 110 mg of triacetate **5**;

ir $\nu(CCl_4)$: 2910, 1740, 1445, 1215, 1175, 1080, 1025, 1000, 965, 925 cm^{-1}; hrms, *m/z* calcd. for $C_{26}H_{38}O_7$: 462.2602; found: 462.2609 (M^+, 0.4%); ms, *m/z* (rel. int.): 402 ($M^+ - CH_3COOH$, 3%), 362 (10%), 342 ($M^+ - (CH_3COOH \times 2)$), 318 (12%), 300 (13%), 283 (22%), 282 (20%), 257 (8%), 245 (8%), 239 (8%), 227 (9%), 218 (16%), 191 (20%), 176 (14%), 161 (13%), 145 (10%), 109 (30%), 105 (12%), 95 (12%), 91 (14%), 69 (75%), 67 (18%), 55 (30%), 43 (100%), 41 (51%). The ^{1}H and ^{13}C nmr data are given in Tables 1 and 2.

*Reduction of **4** to give **6** and **7***

$NaBH_4$ (50 mg) was added to a solution of **4** (50 mg) in EtOH (2 mL) and the mixture kept at room temperature for 4 h. H_2O (2 mL) was added and the solution extracted with Et_2O. The ether extract was evaporated to give a crude product that was purified by chromatography (LiChroprep, Et_2O/C_6H_{14}, 2:3 vol/vol), thus affording 30 mg of pure **6**. In the course of the chromatographic purification of **6** formation of small amounts of the less polar compound **7** was observed.

*Compound **6***: ms, *m/z* (rel. int.): 304 ($M^+ - CH_3COOH$, 2%), 286 ($M^+ - CH_3COOH - H_2O$, 8%), 271 ($M^+ - CH_3COOH - H_2O - CH_3$, 11%), 255 (13%), 243 (10%), 213 (17%), 201 (22%), 175 (58%), 159 (38%), 145 (42%), 133 (41%), 121 (32%), 119 (42%), 109 (100%), 95 (34%), 82 (27%), 69 (61%). The ^{1}H and ^{13}C nmr data are given in Tables 1 and 2.

Compound 7: ms, *m/z* (rel. int.): 344 (M^+, 18%), 302 (4%), 284 ($M^+ - CH_3COOH$, 32%), 269 ($M^+ - CH_3COOH - CH_3$, 24%), 241 (44%), 213 (20%), 202 (100%), 187 (58%), 173 (64%), 159 (40%), 147 (44%), 131 (26%), 119 (26%), 109 (28%), 105 (20%), 101 (22%), 95 (24%), 88 (36%), 81 (22%), 69 (30%). The ^{1}H and ^{13}C nmr data are given in Tables 1 and 2.

*Acetylation of **6** to give **8***

Acetylation (Ac_2O/Py) of **6** (20 mg) gave, after chromatography on LiChroprep Si 60 (Et_2O–C_6H_{14}, 2:3 vol/vol), 18 mg of pure **8**; ms, *m/z* (rel. int.): 328 ($M^+ - (CH_3COOH \times 2)$, 3%), 286 (16%), 271 (11%), 268 (41%), 255 (23%), 253 (47%), 243 (22%), 225 (34%), 215 (20%), 213 (53%), 211 (28%), 200 (30%), 199 (48%), 197 (22%), 189 (26%), 186 (42%), 175 (70%), 173 (52%), 171 (40%), 161 (28%), 159 (70%), 157 (57%), 149 (19%), 147 (37%), 145 (53%), 143 (28%), 133 (33%), 131 (30%), 121 (19%), 119 (37%), 109 (100%), 107 (29%), 105 (27%), 95 (20%), 93 (18%), 82 (24%), 69 (33%), 43 (14%). The ^{13}C nmr data and a full set of ^{1}H nmr data are given in Tables 1 and 2 because those reported in the literature are insufficient.

*MnO_2 oxidation of **6** to give **9***

MnO_2 (60 mg) was added to a solution of **6** (40 mg) in C_6H_{14} (3 mL) and the suspension was stirred overnight at room temperature. The precipitate was filtered off and the solution was evaporated to give 40 mg of residue, which was purified by chromatography (Lichroprep Si 60, Et_2O/C_6H_{14}, 3:7 vol/vol) to give 30 mg of a compound, identified by comparison of its physical properties (uv, ir, ms, ^{1}H and ^{13}C nmr) with those reported in the literature for acetoxycrenulide (**9**); $[\alpha]_D$ +21.5° ($CHCl_3$) (lit. (7) $[\alpha]_D$ +13.0°; (8) $[\alpha]_D$ +13.4°, +20.5°).

Proton and carbon nuclear magnetic resonance spectra

The nmr spectra were recorded at 200 MHz (^{1}H) and 50 MHz (^{13}C), respectively, using a Bruker AC-200 instrument equipped with a carbon-13–proton dual probe head, an Aspect 3000 data system, and a 160 MByte Disk cartridge. One-dimensional proton and carbon-13 Fourier transform nmr spectra with sweep widths and transmitter frequencies optimized for the lowest possible digital resolution

[a]Measured in $CDCl_3$; chemical shifts (δ) are reported in ppm, TMS as internal standard.

[b]Owing to severe broadening, only part of the peaks have been assigned.

[c,d]Values with identical superscript within each column may be interchanged.

[e]At least four discernible peaks are observed in the 102–105 ppm region, attributable to C-18 and C-19 resonances for different stereoisomers.

(Hz/data point) were obtained for 32 K free induction decay signals. Gaussian resolution enhancements for proton nmr and exponential multiplication for carbon-13 nmr were applied before performing Fourier transformations; LB (line broadening) constants were adapted to the digital resolution. Two-dimensional proton–proton shift correlations were performed using the commercially available microprogram COSY without delay. Sine-squared shaping functions without shifts were applied before Fourier transformations in both dimensions. Two-dimensional carbon-13–proton shift correlations were performed using the commercially available microprogram XHCORR by polarization transfer via J_{CH}. Relaxation delays were 0.8 s; incremented delays were adapted to the individual proton chemical shift ranges of each sample, optimized as described above. Polarization transfer delays ($1/2J_{CH}$ = 0.0036 s and $1/2^{2,3}J_{CH}$ = 0.07 s) were adapted to the expected averages of one-bond couplings (J_{CH} = 150 Hz) for CH correlation and two- or three-bond couplings ($^{2,3}J_{CH}$ = 7.5 Hz) for long-range CH correlations. 1024 × 256 data matrices were applied for the carbon-13 and proton chemical shift domains. Shifted ($\pi/4$) sine-squared shaping functions were applied prior to Fourier transformations in both domains.

Antimicrobial activity

In the course of fractionation, antimicrobial activity was followed by the paper disc – agar diffusion assay using *Staphylococcus aureus* as test organism. The minimum inhibitory concentrations (MICs, μg/mL) against *S. aureus* (75), *Micrococcus luteus* (75), and *Aeromonas hydrophyla* (>100) were determined by the conventional agar dilution method for compounds **4–8**. Compounds **5–8** were totally inactive. All test strains were grown in Mueller Hinton medium incubated at 37°C for 18 h.

Received May 5, 1988

MICHEL BARBIER, MICHEL DEVYS, and DENISE PARISOT. Can. J. Chem. **66**, 2803 (1988).

A dihydrofusarubin O-ethyl ether from a strain of the fungus *Nectria haematococca* (Berk. and Br.) Wr. is reported. On the basis of spectrographic data, the stereochemistry **4** is proposed for the pyran ring of this new substance, which thus represents an isomeric form of the previously reported O-ethyl ether **3***b*.

MICHEL BARBIER, MICHEL DEVYS et DENISE PARISOT. Can. J. Chem. **66**, 2803 (1988).

Un éther éthylique de la dihydrofusarubine a été obtenu à partir d'une souche du champignon *Nectria haematococca* (Berk. and Br.) Wr. Sur la base des données spectrographiques, la stéréochimie **4** est proposée pour le cycle pyrannique de cette nouvelle substance qui représente ainsi un isomère de l'éther éthylique précédemment décrit **3***b*.

Introduction

Nectria haematococca (Berk. and Br.) Wr., the teleomorph of the fungus *Fusarium solani*, produces in vitro a wide series of naphthoquinone pigments related to fusarubin **1**. Over the last six years, we have isolated and identified 12 of these metabolites from selected mutants or the wild strain. Six were new compounds, namely, nectriafurone (1) (the first reported naturally occurring isofuranonaphthoquinone), anhydrofusarubin lactone (1), 5-deoxyfusarubin, 5-deoxyanhydrofusarubin (2), 13-hydroxynorjavanicin (3), and fusarubinoic acid (4). Biosynthetic experiments on 5-deoxyfusarubin and the corresponding anhydro derivative, from *Nectria haematococca*, have shown that these two compounds, and probably the others also, are derived from a heptaketide (2). Indeed, as fusarubinoic acid is probably the initial product arising from cyclization of the heptaketide, it seems likely that it is a common intermediate in the formation of the other metabolites, a hypothesis requiring experimental verification.

Pyranonaphthoquinones of the fusarubin type **1** are typical pigments of *Fusarium* species (5–8) and have shown interesting antibiotic (5–7), insecticidal (9), and phytotoxic (6, 10, 11) activities.

In the present publication, we report on the isolation and properties of a new dihydrofusarubin O-ethyl ether (7, 8, 12) from *Nectria haematococca*.

Results

A new dihydrofusarubin O-ethyl ether was discovered by chance, when anhydrofusarubin epoxide was prepared from an anhydrofusarubin **2** sample previously obtained from *Nectria haematococca*.

Examination by tlc of the product from the reaction between *m*-chloroperbenzoic acid and crude anhydrofusarubin revealed the presence of another metabolite with the same R_f value, which fluoresced in the uv at 366 nm, and was now visible because anhydrofusarubin had been converted to a derivative with different chromatographic behaviour. The epoxidation reaction was unfortunately required for the isolation of the new metabolite, because attempts to separate it from anhydrofusarubin by tlc using a wide variety of solvent systems were unsuccessful. The new substance was obtained in crystalline form, and its structure established through the usual spectrographic methods. The ms spectrum is consistent with the presence of an O-ether group. The molecular ion at m/z 336 is accompanied by characteristic fragments at $M - OCH_2CH_3^+$ and $M - CH_3CH_2OH^+$ (base peak). The uv spectrum is identical to that reported for a dihydrofusarubin O-ethyl ether previously obtained from *Fusarium martii*, and the appearance of signals for the methylene protons for the new substance at 3.50 ppm instead of 5.00 ppm was the only significant difference in their proton nmr spectra. That the newly found dihydrofusarubin O-ethyl ether was different from the previously reported substance was finally confirmed by the rotatory power, determined in the same solvent as published (found, +67 instead of +125).

The agreement between the proton chemical shifts and spin–spin coupling constants for H-3, H-4, H-13, and H-14 of metabolites **4** and **3***b* (7) indicates that the substituents attached to C-4 and C-13 of compound **4** have the same relative configurations as in **3***b*. This and other structural features of the dihydrofusarubins, including evidence that the tetrahydropyran ring exists in a chair conformation, have been reported in detail in previous communications (7, 8). Furthermore, the structural similarity of compounds **4** and **3***b* as established by nmr, combined with the observation that their specific rotations have the same sign but differ in magnitude, indicates that the compounds are diastereoisomers. From the nmr evidence it can be readily deduced that the substituents attached to the ketal centre in compounds **4** and **3***b* have different configurations, thereby establishing structure **4** for the new metabolite.

Experimental

The melting points were determined under the microscope of a Kofler apparatus and are corrected. The ^1H nmr spectrum was obtained with a Bruker 400 MHz apparatus and the ms with an AEI MS 50 spectrometer. The rotatory power was determined with an automatic polarimeter (Perkin–Elmer) and the uv spectrum with a Lambda-5 uv spectrophotometer (Perkin Elmer). Thin-layer chromatography was carried out on Schleicher–Schüll SiO_2 fluorescent films for analytical purposes, and on 20 × 20 cm plates, 1 mm thickness, for preparative

use; chromatograms were examined under a Desaga uv lamp at 336 nm in the dark, and the substance was isolated from the scraped SiO_2 layer by extraction with ethyl acetate.

Isolation of the new dihydrofusarubin O-ethyl ether

The "*58*-red" mutant of *Nectria haematococca* was grown at 26°C in the dark for 12 days on synthetic agar medium as previously (1) reported. The agar medium was extracted with acetone and the concentrate reextracted with ethyl acetate according to the method of Bell *et al.* (13). The ethyl acetate residue dissolved in chloroform was applied to a Sephadex LH-20 column packed in $CHCl_3$–MeOH, 49:1, and the pigments were eluted with this same solvent (1). The first fraction to be eluted was a violet product containing anhydrofusarubin (**2**) as the major compound. The new dihydrofusarubin O-ethyl ether was isolated from this fraction after epoxidation. One hundred milligrams of isolated fraction **2** were dissolved in 5 mL anhydrous $HCCl_3$ and 150 mg of *m*-chloroperbenzoic acid in 2 mL $CHCl_3$ were added. The reaction mixture was kept at 0°C and the epoxidation was followed by tlc (hexane–CH_2Cl_2–MeOH 29:29:2), starting anhydrofusarubin R_f 0.60. The reaction was found to be complete after 6 h, showing the presence of a fluorescent spot in uv at the R_f of the now absent violet anhydrofusarubin **2**. (The corresponding epoxide, ms *m/z* 304, was found at R_f 0.30 as a red product.) After this reaction, the dihydrofusarubin O-ethyl ether was isolated by preparative tlc in the same solvent system; yield 4 mg (representing 4% of the mixture).

Physical properties of the isolated substance

The orange product was crystallized from CH_2Cl_2, giving small orange-red prisms, mp 137–141°C (2 mg); uv ($CHCl_3$), λ_{max}, nm (log ε): 242 (4.2), 275 (3.70), 305 (3.65), 390 (3.70), with shoulders at 370 and 415; ^1H nmr ($CDCl_3$, TMS reference), δ ppm: 1.47 (CH_3, C-1, 3H, s), 2.40 (H-C3, 1H, dd, $J_{ax} - J_{eq}$ 15 Hz, $J_{ax} - J_{H\text{-}C4}$ 12 Hz), 1.80 (H-C3, dd, $J_{eq} - J_{H\text{-}C4}$ 4 Hz), 3.50 (H-C4, 1H, ddd, $J_{H\text{-}C4}/J_{H\text{-}C13}$ 13 Hz), 12.0 (phenolic proton at C-7, 1H, s), 3.95 (OCH_3 at C-8, 3H, s), 6.60 (H-C9, 1H, s), 12.10 (phenolic proton at H-C10, 1H, s), 2.97 (H-C13, 1H, ddd), 3.80 (H-C14, 1H, dd, $J_{ax} - J_{eq}$ 13 Hz, $J_{ax}/J_{H\text{-}C13}$ 7 Hz, $J_{eq}/J_{H\text{-}C13}$ 5 Hz), 4.20 (H-C14, 1H, dd, $J_{eq}/J_{H\text{-}C13}$ 5 Hz), 3.50 (q, 2H, CH_2 at C-16, $J_{H\text{-}C16}/J_{H\text{-}C17}$ 6 Hz), 1.20 (t, 3H, CH_3 at C-17, $J_{H\text{-}C17}/J_{H\text{-}C16}$ 6 Hz. ms *m/z*: 336, 8%, M^+ ($C_{17}H_{20}O_7$); 291 $(M - OC_2H_5)^+$, 46%; 290 $(M - C_2H_5OH)^+$, 100%.

The minute amounts of substance that we were able to isolate did not permit determination of the ^{13}C nmr spectra.

The numbering system used in this publication corresponds to the natural (heptaketide) origin of the molecule.

Reduction of dimethyl 3-hydroxy-4,4,8-trimethyl-6-oxo-*cis*-bicyclo[3.3.0]octa-2,7-diene-1,2-dicarboxylate (**8**) with lithium and ammonia gives dimethyl 3-hydroxy-4,4,*exo*-8-trimethyl-6-oxo-*cis*-bicyclo[3.3.0]oct-2-ene-1,2-dicarboxylate (**9**), which on acetylation, reduction with sodium borohydride, and methanolysis gives dimethyl 3,*exo*-6-dihydroxy-4,4,*exo*-8-trimethyl-*cis*-bicyclo[3.3.0]oct-2-ene-1,2-dicarboxylate (**12**). This on 2-decarbomethoxylation followed by treatment with lithium acetylide in the presence of cerium trichloride gives methyl 3-ethynyl-3,*exo*-6-dihydroxy-4,4,*exo*-8-trimethyl-*cis*-bicyclo[3.3.0]octane-1-carboxylate (**21**), which on hydration, diacetylation, and treatment with tri-*n*-butyltin hydride and azoisobutyronitrile is converted to methyl *exo*-6-acetoxy-3-acetyl-4,4,*exo*-8-trimethyl-*cis*-bicyclo[3.3.0]octane-1-carboxylate (**31**). Methanolysis of **31**. *tert*-butyldimethylsilylation, and reaction with potassium *tert*-butoxide in *tert*-butyl alcohol gives *exo*-4-*tert*-butyldimethylsilyloxy-*exo*-2,6,6-trimethyl[5.3.1^{1,5}]undecane-8,10-dione (**35**). This on treatment with lithium aluminum hydride followed by oxidation and hydrogenation provides the corresponding 10-deoxo compound, **39**. Reaction of this with methyllithium, dehydration, and desilylation with hydrogen fluoride in acetonitrile gives a mixture of (±)-α-biotol (**1**) and (±)-β-biotol (**2**); desilylation with hydrogen chloride in methanol gives solely (±)-**1**.

PETER YATES, RUPINDER S. GREWAL, PETER C. HAYES et JEFFERY F. SAWYER. Can. J. Chem. **66**, 2805 (1988).

La réduction de l'hydroxy-3 triméthyl-4,4,8 oxo-6 bicyclo[3.3.0]octadiène-2,7 dicarboxylate-1,2 de diméthyle *cis* (**8**) par le lithium et l'ammoniac conduit à l'hydroxy-3 triméthyl-4,4,8-*exo* oxo-6 bicyclo[3.3.0]octène-2 dicarboxylate-1,2 de diméthyle *cis* (**9**) qui, par une acétylation suivie d'une réduction par le borohydrure de sodium et d'une méthanolyse, conduit au dihydroxy-3,6-*exo* triméthyl-4,4,8-*exo* bicyclo[3.3.0]octène-2 dicarboxylate-1,2 de diméthyle *cis* (**12**). Ce composé, par une décarboxyméthylation en 2 suivie d'un traitement par l'acétylure de lithium en présence de trichlorure cérique, fournit l'éthynyl-3 dihydroxy-3,6-*exo* triméthyl-4,4,8-*exo* bicyclo[3.3.0]octane carboxylate-1 de méthyle (**21**) qui, par une hydration suivie d'une diacétylation et d'un traitement par l'hydrure de tri-*n*-butylétain et l'azoisobutyronitrile, est transformé en acétoxy-6-*exo* acétyl-3 triméthyl-4,4,8-*exo* bicyclo[3.3.0]octane carboxylate-1 de méthyle (**31**). La méthanolyse du produit **31**, suivie d'une *tert*-butyldiméthylsilylation et d'une réaction avec le *tert*-butylate de potassium dans l'alcool *tert*-butylique, fournit le *tert*-butyldiméthylsilyloxy-4-*exo* triméthyl-2-*exo*-6,6 [5.3.1^{1,5}]undécanedione-8,10 (**35**). Ce composé, soumis à un traitement par l'hydrure double de lithium et d'aluminium, puis à une oxydation et une hydrogénation, conduit au composé désoxo-10 correspondant, **39**. La réaction du composé **39** avec le méthyllithium, suivie d'une déshydratation et d'une désilylation par le fluorure d'hydrogène dans l'acétonitrile, livre un mélange des (±)-α-biotol (**1**) et (±)-β-biotol (**2**); une désilylation par le chlorure d'hydrogène dans le méthanol ne conduit qu'au (±)-**1**.

Introduction

α-Biotol (**1**) and β-biotol (**2**), the *exo*-4-hydroxy derivatives of the prototypical cedranoid sesquiterpenes, α-cedrene (**3**) and β-cedrene (**4**), respectively (3), were isolated in 1968 from the alcoholic portion of the essential oil of the wood of *Biota orientalis* (4). These alcohols are minor components of the oil, cedrol (**5**) being one of the major components. Their gross structures were assigned on the basis of chemical and spectroscopic methods (4). To establish the relative stereochemistry at C-4, α-biotone (**6**), formed by oxidation of **1**, was reduced with sodium borohydride to a mixture of **1** and 4-epi-α-biotol (**7**).

[2]Author to whom correspondence may be addressed.

Comparison of the ^{1}H nmr chemical shifts for the C-12 methyl group in the two epimeric alcohols with that for α-cedrene suggested the configurations at C-4 in **1** and **7** to be those shown.

Four partial syntheses of **1** or **7** have been reported (5–9), but there have been no previous total syntheses of the biotols. We describe here total syntheses of (±)-α- and (±)-β-biotol by a route that we have designed for the synthesis of cedranoid sesquiterpenes of various levels of oxidation — a pathway that we have earlier used in a new synthesis of α-cedrene (10).

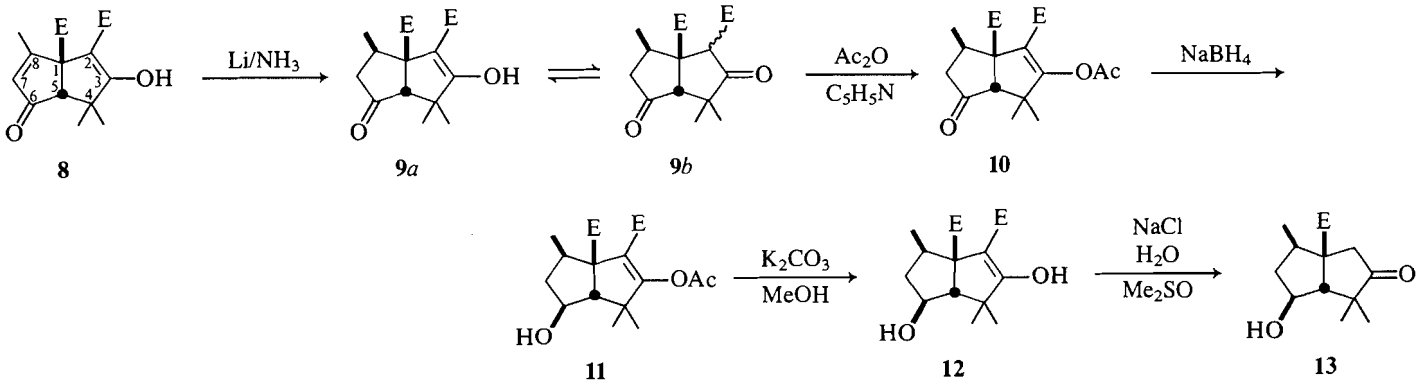
Results and discussion

Rings A and B. Construction of bicyclo[3.3.0]octanone 13

The key step in our route to the bicyclo[3.3.0]octane system of rings A and B is the photosensitized oxa-di-π-methane rearrangement of a bicyclo[2.2.2]octanone to a tricyclo [3.2.1.0^{2,8}]octanone. The utilization of this reaction in the synthesis of the bicyclo[3.3.0]octanone **8** has been reported earlier from these Laboratories (11).

Compound **8** was converted to the ketol **13** by the route shown in Scheme 1; the gross structural assignments for compounds **9**–**13** were corroborated by their ir, ^{1}H nmr, and ^{13}C nmr spectra[3] (see Experimental). Reduction of **8** with lithium/ammonia gave the dihydro compound **9**. The ^{1}H and ^{13}C nmr spectra of this product showed that it exists in solution in $CDCl_3$

[3]The ^{13}C nmr spectroscopic assignments will be discussed elsewhere.

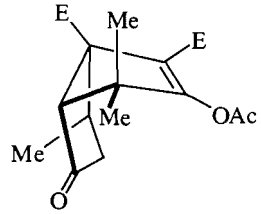


SCHEME 1

as a mixture of the enol and keto tautomers **9***a* and **9***b*, with the latter predominating. This is uncommon, since we have usually observed in the cases of related dimethyl 3-oxobicyclo[3.3.0]octane-1,2-dicarboxylates prepared in this and earlier work (10, 11) that the enol forms are so predominant that the keto forms cannot be detected spectroscopically.

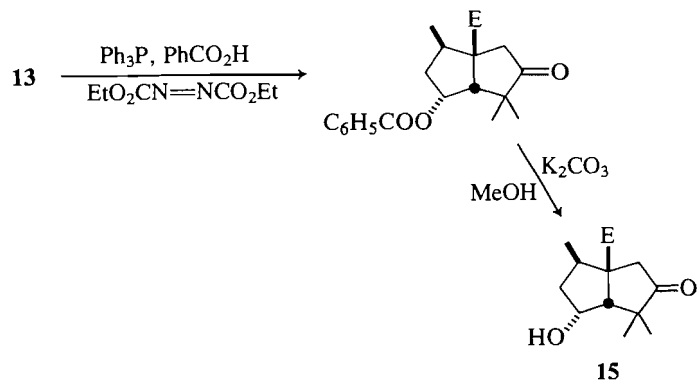
Compound **9** was converted with acetic anhydride and pyridine to the enol acetate **10** to protect the C-3 carbonyl group so that the C-6 carbonyl group could be reduced selectively. This reduction was carried out with sodium borohydride in methanol to give a single product **11** in quantitative yield. Compound **11** in methanol was treated with potassium carbonate to give **12**, whose ^{1}H nmr spectrum showed the presence of the enol tautomer alone. Monodecarbomethoxylation of **12** with sodium chloride and wet dimethyl sulfoxide (12) gave hydroxy keto ester **13**.

The relative configuration of compound **13**, and thus the relative configurations of compounds **8**–**12** also, was established by X-ray crystallography (1). The *exo* disposition of the C-8 methyl group was expected on the basis of our earlier work (11). However, the *exo* disposition of the C-6 hydroxyl group was not anticipated. This showed that the sodium borohydride reduction of **10** gave a product with an *exo* hydroxyl group. In general, such reactions of bicyclo[3.3.0]octan-2-ones proceed with preferential attack on the *exo* face of the ketone to give the *endo* alcohol (13). The exclusive formation of the *exo* product in the case of **10** may result from two factors: (*i*) reduced steric hindrance to *endo* attack because of an increased fold angle between the rings resulting from the presence of the ethylenic bond, and (*ii*) increased hindrance to *exo* attack because of the *exo* C-8 methyl group (1). These factors apply only if this methyl group has a pseudoaxial disposition and the *endo* geminal methyl group a pseudoequatorial disposition, as shown in **14**.



14

For spectroscopic comparison, we converted **13** to its C-6 epimer **15** by treatment with triphenylphosphine, benzoic acid, and diethyl azodicarboxylate (14) followed by methanolysis (Scheme 2). The ir and ^{1}H nmr spectra of **13** and **15** may be



SCHEME 2

compared with those of the *endo*-6-hydroxy-*endo*-8-methyl isomer **18**, which was obtained previously (11) by the route shown in Scheme 3. It may be noted that in this case sodium borohydride reduction of the α,β-unsaturated ketone **16** (carried out in the presence of cerium trichloride (15)) gave alcohol **17**. This diastereomer, whose relative configuration was established by an X-ray crystallographic determination of the relative configuration of **18** (1), was the only product detected. The contrasting stereochemical course of this reduction reaction relative to the stereochemical course of the sodium borohydride reduction of **10** is attributable to the planarity of the enone ring in **16**.

Comparison of the ^{1}H nmr spectra of **13** and **15** shows that the C-6 proton signal of **13** appears at higher field than that in **15** ($\Delta\delta = 0.33$). This is analogous to the case of the *exo* and *endo* bicyclo[3.3.0]octan-2-ols, **19** and **20** (13*b*), where the signal of the *endo*-2 proton of **19** appears at δ 3.73 while that of the *exo*-2 proton of **20** appears at δ 4.09 ($\Delta\delta = 0.36$).

Construction of ring C. Synthesis of the tricyclic β-diketone 35

Our next aim was to add a two-carbon chain at C-3 in the hydroxy ketone **13** that would permit closure of ring C in the biotols. This was first attempted with lithium acetylide as in the synthesis of α-cedrene (10); however, only starting material was recovered. Lithium acetylide – ethylenediamine complex (16) was also without effect. It is considered that these reactions were unsuccessful because of the formation of the lithium enolate of **13**, which returned the starting material upon work-up.

Recent observations by Imamoto *et al.* (17) have provided a solution to problems encountered during attempted nucleophilic addition to readily enolizable ketones. They found that organocerium reagents react cleanly with easily enolizable ketones to

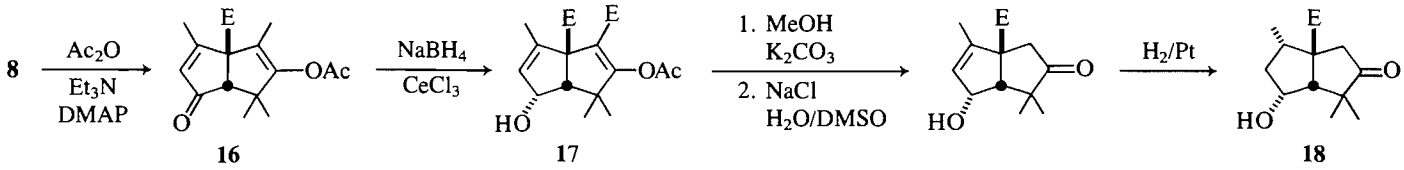
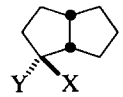


SCHEME 3



19 X = OH, Y = H
20 X = H, Y = OH

afford addition products. In the present case the organocerium reagent was prepared by reaction of lithium acetylide (prepared from *n*-butyllithium and acetylene) with anhydrous cerium(III) chloride at −78°C in tetrahydrofuran. Reaction of this with hydroxy ketone **13** gave the propargylic alcohol **21** in 73% yield. At least two equivalents of the reagent had to be used since the hydroxyl substituent reacts with one equivalent. The structure of this product was established by comparison of its ir and ^{1}H nmr spectra with those of the analogous propargylic alcohol **23**, which was an intermediate in the synthesis of α-cedrene (10) (Table 1).

The relative configuration at C-3 in **21** was not established. It is thought to involve the *exo* placement of the ethynyl group, resulting from attack of acetylide on the *exo* face of the bicyclic system. However, this is of no consequence insofar as the final synthetic goals are concerned. Terashima and co-workers (18) have used 2-trimethylsilylethynylcerium(III) to synthesize propargylic alcohols from ketones and we investigated its use in the present case. However, treatment of **13** with this reagent gave the *bis* adduct **22** rather than the (trimethylsilyl)ethynyl analogue of **21** (Scheme 4).

The identity of compound **22** was established from its composition, $C_{22}H_{36}O_3Si_2$, and its spectra. Its ir spectrum shows a hydroxyl-stretching band at 3.15 μm and a weak band at 4.68 μm attributable to the acetylenic-stretching vibration. It also exhibits a carbonyl-stretching band at 5.76 μm. However, there was no signal corresponding to a methoxyl group in either the ir or nmr spectra. The ^{1}H nmr spectrum of **22** shows two distinct nine-hydrogen singlets at δ 0.15 and 0.16, indicating the presence of two trimethylsilyl groups. Three signals corresponding to the C-methyl groups appear at δ 1.04 (s), 1.18 (s), and 1.30 (d, J = 6.8 Hz). Two broad one-proton singlets at δ 1.56 and 3.70 are attributable to two hydroxyl protons, as

[a]The nmr spectra were recorded at 200 or 400 MHz unless otherwise indicated; their signals have relative areas in accord with the assignments; J values are given in Hz.
[b]The nmr spectrum of **23** was recorded at 60 MHz (10).
[c]The OH proton signals overlap with the CH multiplets at δ ~ 2.

confirmed by their absence after deuterium exchange. The ^{13}C nmr spectrum shows 18 signals; the SFORD spectrum includes quartets at δ −0.4 and −0.5 ppm, attributable to the methyl groups of the two trimethylsilyl groups, and four singlets at δ 89.8, 90.8, 104.6, and 105.7, assignable to the four acetylenic carbons.

This product must result from attack of the cerium reagent at the carbonyl group of the ester, followed by further attack of the reagent on the resulting acetylenic ketone (an excess of the reagent was used). It is interesting to find that this reagent, unlike lithium acetylide, attacks the ester group, although both reactions were carried out under similar conditions. The reason for the preferred attack at the ester rather than the ketone group is uncertain; it may involve prior complexation of the silicon atom with the oxygen atom of the ketonic carbonyl or the methoxyl group.

Our next aim was to convert the propargylic alcohol **21** to the methyl ketone **32** preparatory to closure of ring C. In our synthesis of α-cedrene (10) the analogous transformation of **23** to **25** had been carried out by the route shown in Scheme 5. However, this route is made unattractive by the low yield in the conversion of **23** to **24**, which results from competing methyl migration. We therefore adopted an alternative route in which **21** was converted to **26** by mercuric oxide-catalyzed hydration, which in turn was acetylated with acetic anhydride/DMAP to give the diacetate **27** (with acetic anhydride/pyridine, **26** gave

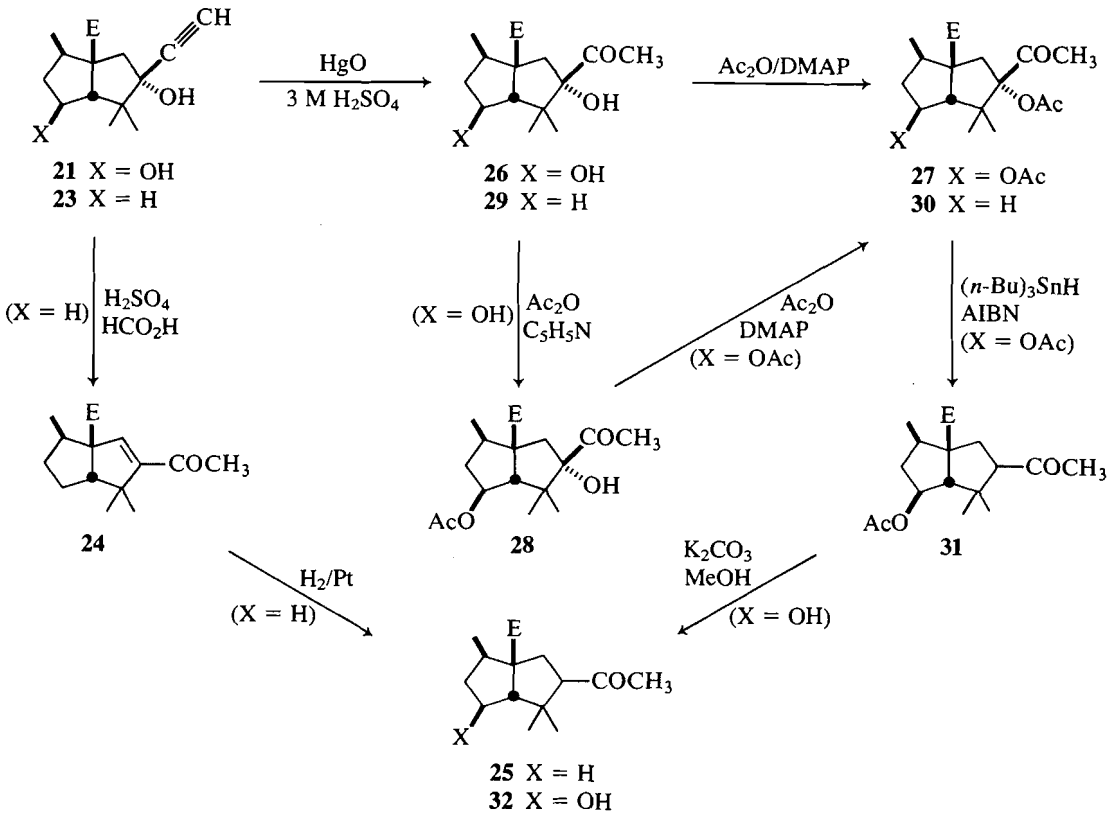
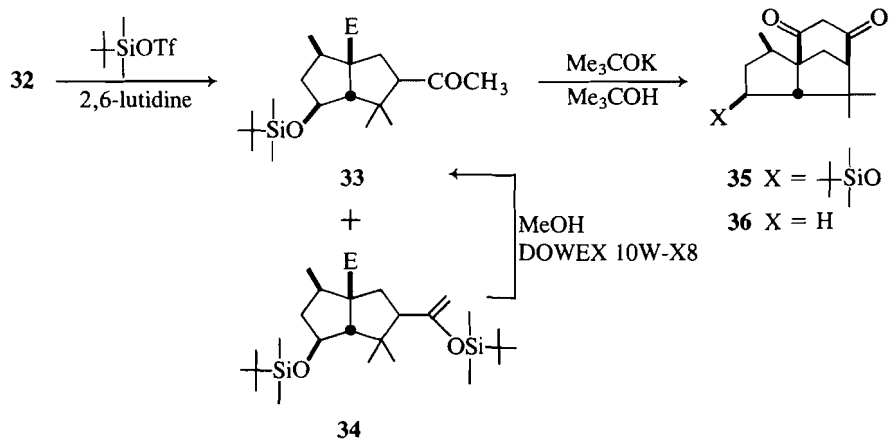


SCHEME 5



SCHEME 6

the monoacetate **28**; this could be converted to **27** with acetic anhydride/DMAP).

It was next necessary to remove selectively the 3-acetoxyl group of **27**. We had previously unsuccessfully attempted to carry out in the α-cedrene series (10, 19) an analogous transformation of **30**, the acetate of **29**, the hydration product of **23**. Treatment of **30** with a variety of reducing agents had been tried, including zinc and acid and chromous salts. In the case of **27**, amalgamated zinc and calcium/ammonia (20) were tried with equal lack of success. However, treatment of **27** with tri-*n*-butyltin hydride in the presence of azoisobutyronitrile (AIBN) in boiling toluene (21) gave the desired reduction product **31** in high yield, which was converted to the corresponding alcohol **32**.

The gross structures assigned to compounds **26**–**28** and **31** and **32** are confirmed by their ir and ^{1}H nmr spectra and their ^{13}C nmr spectra[3] and the relationship of these to the spectra of compounds **29** and **30** (Tables 2 and 3). Their relative configurations follow from that assigned to their precursor **13** (*vide supra*). No assignment of stereochemistry is made at C-3 in compounds **31** and **32**, but as will be seen from the sequel this is not critical.

It was planned to close ring C via a base-catalyzed intramolecular Claisen condensation involving the δ-keto ester system of **32**, as utilized originally by Stork and Clarke (22) and later by Yates and Stevens (10) in the synthesis of α-cedrene. However, it seemed wise to protect first the hydroxyl groups of **32**; this was done by treatment with *tert*-butyldimethylsilyl triflate and

2,6-lutidine at 0°C to give **33**,[4] whose spectra are compared with those of **32** in Table 3. Reaction of **33** with potassium *tert*-butoxide in *tert*-butyl alcohol gave the tricyclic β-diketone **35** (Scheme 6), whose ir and ^{1}H nmr spectra are given in Table 4. These show that **35** exists in deuterochloroform as the unenolized form, giving rise in its ^{1}H nmr spectrum to two doublets for the two nonequivalent protons on the α-methylene group of the β-diketone system. The analogous β-diketone **36** prepared in the synthesis of α-cedrene similarly exists in the unenolized form, but in this case the analogous methylene

[4]When the reaction was carried out at room temperature a mixture of **33** and the disilyloxy compound **34** was obtained; the latter could be converted to **33** by methanolysis.

protons give rise to a singlet (10), presumably because of a greater rate of exchange.

It may be noted that the formation of such a product is possible, whatever the configuration at C-3 in **33**, since equilibration of the *trans* acetyl ester to the *cis* acetyl ester can occur under the reaction conditions.

Manipulation of Ring C. Synthesis of the biotols

Following the procedure of Stork and Clarke (22) in the cedrene series, we treated **35** with lithium aluminum hydride in boiling ether and were happy to find that the somewhat unusual course of reduction observed by these workers in the case of **36** was duplicated, giving a mixture of the allylic and saturated alcohols, **37** and **38**, respectively (Scheme 7). Oxidation of this mixture with chromium trioxide – pyridine followed by hydrogenation gave the single saturated ketone **39**. This was treated with methyllithium to give the cedrol analogue **40**. The relative configuration at C-8 was assigned as shown, based on analogy with previously observed conversion of **36** to cedrol (**5**) itself by this route (22).

Dehydration of **40** with thionyl chloride and pyridine gave a mixture of the endocyclic and exocyclic alkenes **41** and **42**, which upon desilylation with hydrogen fluoride in acetonitrile gave a 2:1 mixture of (±)-α-biotol (**1**) and (±)-β-biotol (**2**) (Scheme 8). These were separated by chromatography on silica and the identity of (±)-**1** was established by direct comparison of its ir and ^1H nmr spectra (Table 5) and ^{13}C nmr spectrum with those of a sample of (−)-**1** of natural provenance.[5] The spectra of (±)-**2** were in accord with those published (4) for natural β-biotol (**2**). When the mixture of **41** and **42** was desilylated with hydrogen chloride in methanol, isomerization of the double bond also occurred and the only product obtained was (±)-**1** (Scheme 9).

Oxidation of (±)-**1** gave (±)-α-biotone (**6**), which on reduction with lithium aluminum hydride gave a 1:1 mixture of (±)-**1** and (±)-4-epi-α-biotol (**7**). These were separated by

chromatography on silica and their identity was established by direct comparison of their ir and ^{1}H nmr spectra (Table 5) and ^{13}C nmr spectrum with those of the corresponding naturally occurring compounds.[5]

These syntheses of the biotols and our earlier syntheses of α-cedrene (10) and bicyclo[3.3.0]octane intermediates with a carboxy substituent at the carbon destined to become C-2 in the derived cedranoids (24) give promise of the attainment of our goal of a general synthetic route for cedranoids of various levels of oxidation.

Experimental

Melting points (mp) were taken on a Fisher–Johns melting point apparatus and are uncorrected.

Analytical thin-layer chromatography was performed with silica gel plates (0.25-mm thickness) from Merck. Preparative thin-layer chromatography was performed on 20 × 20-cm plates coated with 0.25, 1.0, or 2.0 mm of Silica Gel 60 containing a fluorescent indicator (Merck). Bands were scraped off the plate and stirred with ethyl acetate and the extracts were filtered and concentrated. Column chromatography was carried out on silica gel (Grace Davison, grade 923, 100–200 mesh). Flash chromatography was performed on 40–60 μm silica gel (Merck, grade 60, 230–400 mesh, 60 Å mean pore diameter).

Unless otherwise specified, infrared (ir) of solutions in chloroform were recorded on a Perkin–Elmer 137 or 337 spectrometer or a Nicolet 5DX Fourier transform spectrometer. Band positions in microns (μm) are reported relative to the 6.24-μm band of polystyrene. The intensities of the bands are denoted as strong (s), medium (m), or weak (w).

Proton magnetic resonance (^{1}H nmr) spectra of deuterochloroform solutions (unless otherwise specified) were recorded on a Varian T-60 spectrometer; spectra reported at 200 and 400 MHz were recorded on Varian XL-200 and XL-400 spectrometers, respectively. Signal positions are reported on the delta (δ) scale in parts per million (ppm) downfield from tetramethylsilane as an internal standard. Spectra run at 200 and 400 MHz were referenced to either the chloroform signal at 7.24 ppm or the tetramethylsilane signal at δ 0.00 ppm. Signal multiplicities are denoted as singlet (s), broad singlet (br s), doublet (d), triplet (t), quartet (q), multiplet (m), doublet of doublets (dd), doublet of triplets (dt), and doublet of doublet of doublets (ddd). Coupling constants (*J*) are given in hertz (Hz). Carbon-13 magnetic resonance (^{13}C nmr) spectra of deuterochloroform solutions were recorded on a Varian CFT-20 Fourier transform spectrometer or a Varian XL-200 or XL-400 spectrometer. The chemical shifts are reported on the delta (δ) scale in ppm and are referenced to the signal for the middle line of deuterochloroform at 77.0 ppm. Signal multiplicities were determined from single-frequency off-resonance decoupled (SFORD) spectra or from APT or DEPT (25) experiments. In the cases where an APT spectrum was obtained, the chemical shifts are denoted as "e" (no or two attached protons) or "o" (one or three attached protons) (26).

Low resolution mass spectra (ms) were obtained either at 60 eV on a Bell and Howell CEC 21-490 single focussing mass spectrometer or a VG 70-2505 mass spectrometer. Peaks are reported in mass-to-charge units (*m*/*z*) and the relative abundances in parentheses. Exact mass measurements were determined from high resolution mass spectra

[5]We are most grateful to Dr. Pierre Brun, Université d'Aix-Marseille, for providing these spectra and a preprint of his comprehensive paper on the ^{13}C nmr spectra of cedrane derivatives (23).

obtained on either an AE1 MS-3074 double focussing mass spectrometer with a DS-50 Data System or a VG 70-250S mass spectrometer.

*Dimethyl 3-hydroxy-4,4,*exo*-8-trimethyl-6-oxo-*cis*-bicyclo[3.3.0]oct-2-ene-1,2-dicarboxylate (**9**)*

Lithium (304 mg, 43.8 mg-atom) was added to a stirred solution of **8** (11) (4.00 g, 13.6 mmol) in dry tetrahydrofuran (60 mL) and liquid ammonia (distilled from sodium; 200 mL) at −78°C under an argon atmosphere. After 15 min the reaction mixture was treated with solid ammonium chloride (2.5 g) and the ammonia was allowed to evaporate. Water (20 mL) was added and the mixture was extracted with ethyl acetate (3 × 30 mL). The combined organic extracts were washed with saturated aqueous sodium chloride (20 mL) and dried over anhydrous sodium sulfate. The solvent was removed and the residue was chromatographed on a silica gel column with ethyl acetate/hexanes (1:3) as eluent to give **9** (1.64 g, 41%) as a clear, colorless oil; ir λ_{max}: 5.77 (s), 6.01 (m), 6.16 (m) μm; ^{1}H nmr (200 MHz) spectrum includes signals at "δ": 1.01, 1.04, 1.07, 1.09, 1.23, 1.25, 3.69 (s), 3.70 (s), 3.82 (s), and 10.9 (br s); ^{13}C nmr spectrum inclues signals at δ: 14.6, 16.7, 21.8, 23.0, 27.3, 29.7, 36.0, 38.7, 43.7, 45.4, 47.3, 49.0, 51.1, 51.6, 52.5, 61.3, 61.4, 61.6, 63.0, 167.5, 170.1, 171.7, 173.4, 181.2, 212.5, 214.4, 215.0; ms *m/z*: 296 (15), 194 (100). *Exact Mass* calcd. for $C_{15}H_{20}O_6$: 296.1260; found: 296.1251.

*Dimethyl 3-acetoxy-4,4,*exo*-8-trimethyl-6-oxo-*cis*-bicyclo[3.3.0]oct-2-ene-1,2-dicarboxylate (**10**)*

A mixture of compound **9** (2.20 g, 7.42 mmol), freshly distilled acetic anhydride (17 mL), and dry pyridine (1.7 mL) was stirred at room temperature for 19 h under argon. The acetic anhydride and pyridine were evaporated and the residue was dissolved in dichloromethane (25 mL). This solution was washed with saturated aqueous sodium bicarbonate (15 mL), followed by water (15 mL). The aqueous layer was reextracted with dichloromethane (3 × 25 mL). The combined organic solutions were dried over anhydrous magnesium sulfate and the solvent was evaporated. The residue was passed through a short silica gel column with ethyl acetate/hexanes (1:3) as solvent and eluent to give **10** (2.40 g, 96%) as a clear, colorless oil; ir (NaCl) λ_{max}: 5.67 (s), 5.80 (s), 6.06 (m) μm; ^{1}H nmr (200 MHz) δ: 1.01 (s, 3H), 1.16 (d, *J* = 7.0 Hz, 3H), 1.23 (s, 3H), 2.23 (s, 3H), 2.25–2.38 (m, 1H), 2.58 (dd, *J* = 15.7, 7.8 Hz, 1H), 2.87 (s, 1H), 3.02 (dd, *J* = 15.7, 7.2 Hz, 1H), 3.70 (s, 3H), 3.74 (s, 3H); ^{13}C nmr δ: 16.4 (o), 20.3 (o), 21.6 (o), 27.7 (o), 37.5 (o), 45.9 (e), 47.3 (e), 51.1 (o), 51.8 (o), 61.5 (o), 63.1 (e), 117.6 (e), 161.5 (e), 163.5 (e), 166.9 (e), 172.5 (e), 214.5 (e); ms *m/z*: 338 (4), 296 (26), 237 (100). *Exact Mass* calcd. for $C_{15}H_{20}O_6$ (M − C_2H_2O): 296.1260; found: 296.1268.

*Dimethyl 3-acetoxy-*exo*-6-hydroxy-4,4,*exo*-8-trimethyl-*cis*-bicyclo[3.3.0]oct-2-ene-1,2-dicarboxylate (**11**)*

Sodium borohydride (0.35 g, 9.25 mmol) was added to ketone **10** (2.40 g, 7.09 mmol) in methanol (120 mL) at 0°C. After the mixture had been stirred at 0°C for 20 min the solution was neutralized with 5% hydrochloric acid (20 mL). Methanol was removed and the residue was extracted with dichloromethane (3 × 40 mL). The combined organic extracts were washed with water (15 mL) and dried over anhydrous magnesium sulfate. Evaporation gave alcohol **11** (2.41 g, 100%) as a colorless, viscous oil; ir (NaCl) λ_{max}: 2.86 (m), 5.65 (s), 5.78 (s), 6.02 (m) μm; ^{1}H nmr (400 MHz) δ: 1.10 (s, 3H), 1.16 (d, *J* = 6.7 Hz, 3H), 1.18 (s, 3H), 1.63–1.73 (m, 1H), 2.04–2.10 (m, 1H), 2.26 (s, 3H), 2.26–2.34 (m, 1H), 2.37 (br s, 1H, absent after treatment with deuterium oxide), 2.55 (d, *J* = 9.0 Hz, 1H), 3.69 (s, 3H), 3.71 (s, 3H), 4.13 (m, 1H); ^{13}C nmr δ: 16.0 (q), 18.7 (q), 20.6 (q), 28.2 (q), 39.8 (d), 43.6 (t), 44.3 (s), 51.0 (q), 51.7 (q), 62.2 (s), 63.8 (d), 73.3 (d), 118.5 (s), 163.5 (s), 163.8 (s), 167.5 (s), 174.9 (s); ms *m/z*: 341 (10), 239 (100). *Exact Mass* calcd. for $C_{17}H_{25}O_7$: 341.1600; found: 341.1628.

*Dimethyl 3-*exo*-6-dihydroxy-4,4,*exo*-8-trimethyl-*cis*-bicyclo[3.3.0]oct-2-ene-1,2-dicarboxylate (**12**)*

A solution of alcohol **12** (2.41 g, 7.08 mmol) in methanol (80 mL) was treated with potassium carbonate (0.96 g) and the mixture was stirred at room temperature for 2.5 h under an argon atmosphere. Dilute hydrochloric acid (5%; 20 mL) was added and the methanol was evaporated. The residue was extracted with dichloromethane (3 × 40 mL). The combined organic extracts were dried over anhydrous sodium sulfate and the solvent was removed to give **12** (2.10 g, 99%) as an oil; ir λ_{max}: 3.09 (w), 5.76 (s), 6.02 (s), 6.15 (m) μm; ^{1}H nmr δ: 1.12 (s, 3H), 1.12 (d, *J* = 6.4 Hz, 3H), 1.30 (s, 3H), 1.43–2.27 (m, 4H), 2.51 (d, *J* = 9.2 Hz, 1H), 3.70 (s, 3H), 3.80 (s, 3H), 4.11 (m, 1H), 10.80 (br s, 1H); ^{13}C nmr δ: 16.0 (q), 18.9 (q), 28.3 (q), 40.7 (t), 43.8 (d), 44.2 (s), 51.1 (q), 51.6 (q), 61.0 (s), 64.8 (d), 73.9 (d), 102.5 (s), 170.8 (s), 175.7 (s), 180.5 (s); ms *m/z*: 298 (3). *Exact Mass* calcd. for $C_{15}H_{22}O_6$: 298.1410; found: 298.1434.

Methyl exo*-6-hydroxy-4,4,*exo*-8-trimethyl-3-oxo-*cis*-bicyclo[3.3.0]octane-1-carboxylate (**13**)*

A mixture of compound **12** (2.10 g, 7.04 mmol), sodium chloride (1.18 g, 20.2 mmol), and distilled water (4 mL) in reagent grade dimethyl sulfoxide (75 mL) was heated at 85°C for 19 h under argon. Dimethyl sulfoxide was removed under high vacuum and water (10 mL) was added to the residue. The resulting mixture was extracted with dichloromethane (3 × 40 mL). The combined organic extracts were washed with water (2 × 15 mL) and dried over anhydrous sodium sulfate, and the solvent was removed. The residue was chromatographed on silica gel with a 1:2 mixture of ethyl acetate and hexanes as eluent to give **13** (1.04 g, 62%) as a colorless viscous oil, which was crystallized from a 1:3 mixture of ethyl acetate and hexanes to give **13** as colorless rhombs, mp 63.5–64.0°C; ir λ_{max}: 3.03 (w), 5.75 (s) μm; ^{1}H nmr (400 MHz) δ: 0.98 (d, *J* = 6.6 Hz, 3H), 1.07 (s, 3H), 1.14 (s, 3H), 1.68–1.83 (m, 2H), 2.19 (d, *J* = 19.2 Hz, 1H), 2.18 (m, 1H), 2.55 (br s, 1H, absent after treatment with deuterium oxide), 2.67 (d, *J* = 6.6 Hz, 1H), 3.25 (d, *J* = 19.2 Hz, 1H), 3.78 (s, 3H), 4.04 (m, 1H); ^{13}C nmr δ: 14.9 (o), 19.1 (o), 28.3 (o), 43.1 (e), 44.2 (o), 44.9 (e), 48.1 (e), 52.2 (o), 55.2 (e), 63.7 (o), 74.1 (o), 176.3 (e), 219.9 (e); ms *m/z*: 240 (10), 140 (100). *Anal.* calcd. for $C_{13}H_{20}O_4$: C 64.98, H 8.39; found: C 64.85, H 8.49.

Methyl endo*-6-hydroxy-4,4,*exo*-8-trimethyl-3-oxo-*cis*-bicyclo[3.3.0]octane-1-carboxylate (**15**)*

To a solution of hydroxy ketone **13** (29 mg, 0.119 mmol), triphenylphosphine (96.5 mg, 0.368 mmol), and benzoic acid (30.9 mg, 0.253 mmol) in dry tetrahydrofuran (3 mL) under argon was added diethyl azodicarboxylate (42.0 mg, 0.241 mmol). The mixture was stirred at room temperature for 48 h. Removal of tetrahydrofuran under reduced pressure afforded the crude product, which was chromatographed on a silica gel plate with 1:3 ethyl acetate/hexanes as eluent to give *methyl* endo*-6-benzoyloxy-3-oxo-4,4-*exo*-8-trimethyl-3-oxo-*cis*-bicyclo[3.3.0]octane-1-carboxylate* (27.8 mg, 68%) as a solid, which was recrystallized from hexanes to give crystals, mp 136–138°C; ir λ_{max}: 5.77 (s), 5.82 (s) μm; ^{1}H nmr (400 MHz) δ: 0.96 (s, 3H), 1.00 (d, *J* = 7.1 Hz, 3H), 1.08 (s, 3H), 1.76 (dt, *J* = 2.8, 13.5 Hz, 1H), 2.20 (dd, *J* = 13.5, 5.7 Hz, 1H), 2.36 (m, 1H), 2.37 (d, *J* = 19.8 Hz, 1H), 3.18 (d, *J* = 4.2 Hz, 1H), 3.65 (d, *J* = 19.8 Hz, 1H), 3.78 (s, 3H), 5.48 (m, 1H), 7.40–7.82 (m, 5H); ^{13}C nmr δ: 15.4 (o), 18.3 (o), 26.7 (o), 41.8 (e), 47.0 (o), 47.6 (e), 47.9 (e), 52.3 (o), 55.3 (e), 61.1 (o), 78.0 (o), 128.7 (o), 129.5 (o), 129.7 (e), 133.3 (o), 165.8 (e), 176.2 (e), 218.8 (e); ms *m/z*: 344 (1), 140 (80), 105 (100). *Exact Mass* calcd. for $C_{20}H_{24}O_5$: 344.1624; found: 344.1633.

A mixture of this product (21.6 mg, 0.0627 mmol) and potassium carbonate (14.9 mg) in methanol (2 mL) was stirred at room temperature for 48 h under argon. Methanol was evaporated and water (2 mL) was added to the residue. The mixture was extracted with dichloromethane (3 × 15 mL) and the extracts were dried over anhydrous sodium sulfate. After evaporation, the residue was chromatographed on a silica gel plate with ethyl acetate/hexanes (1:3) as solvent and eluent to give hydroxy ketone **15** (13.9 mg, 92%) as a colorless oil; ir λ_{max}: 3.03 (w), 5.76 (s), 5.81 (s) μm; ^{1}H nmr (400 MHz) δ: 0.87 (s, 3H), 0.99 (d, *J* = 7.1 Hz, 3H), 1.23 (s, 3H), 1.58 (br s, 1H, absent after treatment with deuterium oxide), 1.61 (dt, *J* = 2.5, 13.0 Hz, 1H), 1.88 (dd, *J* = 13.0, 6.1 Hz, 1H), 2.26 (d, *J* = 19.6 Hz, 1H), 2.50 (m, 1H), 2.85 (d, *J* = 3.7 Hz, 1H), 3.45 (d, *J* = 19.6 Hz, 1H), 3.72 (s, 3H), 4.37 (m, 1H); ^{13}C nmr δ: 15.9 (o), 18.8 (o), 26.5

*Methyl 3-ethynyl-3-*exo*-6-dihydroxy-4,4,*exo*-8-trimethyl-*cis*-bicyclo[3.3.0]octane-1-carboxylate (**21**)*

Acetylene was bubbled into a solution of *n*-butyllithium in hexanes (2.00 M; 10.0 mL, 20.0 mmol) in anhydrous tetrahydrofuran (45 mL) at −78°C for 1 h. This solution was added to a suspension of anhydrous cerium(III) chloride in tetrahydrofuran at −78°C (cerium(III) chloride heptahydrate (7.44 g, 20.0 mmol) was heated with stirring at 140°C under reduced pressure (0.1 Torr; 1 Torr = 133.3 Pa) for 3 h and then cooled; dry tetrahydrofuran (50 mL) was added with stirring under argon and stirring was continued overnight at room temperature). The resulting organocerium reagent was stirred at −78°C for 0.5 h and then a solution of hydroxy ketone **13** (0.890 g, 3.70 mmol) in dry tetrahydrofuran (12 mL) was added. The mixture was stirred at −78°C for 4 h and then saturated aqueous ammonium chloride (18 mL) was added. The mixture was allowed to warm to room temperature and filtered through Celite, and the resultant solids were washed with dichloromethane. The combined organic solutions were dried over anhydrous sodium sulfate and the solvent was evaporated. Trituration of the residue with hexanes containing 5–10% ethyl acetate gave propargylic alcohol **21** (0.72 g, 73%) as a solid. Recrystallization from a 1:3 mixture of ethyl acetate and hexanes gave white needles, mp 159–160°C; ^{13}C nmr δ: 14.5 (q), 16.8 (q), 29.0 (q), 42.6 (d), 43.4 (t), 47.1 (t), 47.9 (s), 51.7 (q), 60.8 (s), 67.1 (d), 73.5 (d), 74.9 (d), 81.6 (s), 84.5 (s), 177.0 (s). *Anal.* calcd. for $C_{15}H_{22}O_4$: C 67.65, H 8.33; found: C 67.63, H 8.37.

exo*-6-Hydroxy-1-[1-(1-hydroxy-1-(2-(trimethylsilyl)-1-ethynyl))-3-(trimethylsilyl)-2-propynyl]-4,4,*exo*-8-trimethyl-*cis*-bicyclo[3.3.0]octan-3-one (**22**)*

Anhydrous cerium(III) chloride (prepared by heating cerium(III) chloride heptahydrate (934 mg, 2.51 mmol) as above for 4 h) was suspended in dry tetrahydrofuran (10 mL) and the suspension was stirred overnight at room temperature under argon. A solution of 2-trimethylsilylethynyllithium, which was prepared by adding *n*-butyllithium in hexanes (2.00 M; 1.25 mL, 2.50 mmol) to a solution of trimethylsilylacetylene (308.2 mg, 3.139 mmol) in tetrahydrofuran (8 mL) at −78°C, was stirred at −78°C for 15 min. This solution was added to the suspension of cerium(III) chloride at −78°C with a cannula. The mixture was stirred at −78°C for 1 h, giving a solution of 2-trimethylsilylethynylcerium(III) chloride. Then a solution of hydroxy ketone **13** (197 mg, 0.819 mmol) in dry tetrahydrofuran (4 mL) was added at −78°C. The mixture was stirred at −78°C for 3 h, and then treated with water (10 mL). The mixture was extracted with dichloromethane (3 × 40 mL). The combined extracts were dried over anhydrous sodium sulfate and concentrated. Chromatography of the residue on a silica gel plate with ethyl acetate/hexanes (1:3) as solvent and eluent gave **22** (201.5 mg, 61%) as a solid. Recrystallization from hexanes gave a white solid, mp 77.5–79.0°C; ir λ_{max}: 3.10 (w), 4.68 (w), 5.76 (s) μm; ^{1}H nmr (400 MHz) δ: 0.15 (s, 9H), 0.16 (s, 9H), 1.04 (s, 3H), 1.18 (s, 3H), 1.30 (d, *J* = 6.8 Hz, 3H), 1.56 (br s, 1H, absent after treatment with deuterium oxide), 1.72–1.90 (m, 2H), 2.20–2.35 (m, 1H), 2.35 (d, *J* = 18.1 Hz, 1H), 2.87 (d, *J* = 18.1 Hz, 1H), 2.88 (br s, 1H), 3.70 (br s, 1H, absent after treatment with deuterium oxide), 4.28 (m, 1H); ^{13}C nmr δ: −0.5 (q), −0.4 (q), 15.1 (q), 22.3 (q), 27.8 (q), 44.2 (d), 45.5 (t), 47.1 (t), 47.8 (s), 57.8 (s), 64.6 (d), 69.3 (s), 73.0 (d), 89.8 (s), 90.8 (s), 104.6 (s), 105.7 (s), 221.6 (s); ms *m/z*: 404 (1), 134 (100). *Anal.* calcd. for $C_{22}H_{36}O_3Si_2$: C 65.29, H 8.97; found: C 65.10, H 8.98.

*Methyl 3,*exo*-6-dihydroxy-4,4,*exo*-8-trimethyl-3-(1-oxoethyl)-*cis*-bicyclo[3.3.0]octane-1-carboxylate (**26**)*

A mixture of propargylic alcohol **21** (0.72 g, 2.70 mmol), mercuric oxide (0.16 g, 0.74 mmol), and sulfuric acid (3 M; 10.7 mL) in tetrahydrofuran (20 mL) was stirred at room temperature for 4 days under argon. Solid sodium bicarbonate was added until the solution had a pH of 8, and the solvent was evaporated. Water (15 mL) was added and the mixture was extracted with ethyl acetate (3 × 40 mL). The combined organic extracts were dried over anhydrous sodium sulfate and the solvent was removed to give dihydroxy ketone **26** (0.72 g, 94%) as a solid. This was recrystallized from 10% ethyl acetate in hexanes to give white needles, mp 175–176°C; ^{13}C nmr δ: 14.5 (q), 16.9 (q), 28.0 (q), 28.7 (q), 41.9 (t), 42.1 (d), 43.1 (t), 48.5 (s), 51.8 (q), 61.1 (s), 68.8 (d), 74.8 (d), 90.9 (s), 177.3 (s), 211.6 (s); ms *m/z*: 284 (5), 163 (100). *Anal.* calcd. for $C_{15}H_{24}O_5$: C 63.36, H 8.51; found: C 63.33, H 8.53.

*Methyl 3,*exo*-6-diacetoxy-4,4,*exo*-8-trimethyl-3-(1-oxoethyl)-*cis*-bicyclo[3.3.0]octane-1-carboxylate (**27**)*

A solution of diol **26** (0.686 g, 2.41 mmol), 4-(dimethylamino)pyridine (1.19, 9.74 mmol), and freshly distilled acetic anhydride (2.20 mL) in dichloromethane (20 mL) was stirred at room temperature for 20 h under argon. The mixture was washed with saturated aqueous sodium bicarbonate (15 mL) and saturated aqueous sodium chloride (15 mL). The aqueous layers were reextracted with dichloromethane (3 × 20 mL). The combined organic solutions were dried over anhydrous sodium sulfate and the solvent was evaporated. The residue was chromatographed on silica gel column with ethyl acetate/hexanes (1:3) as solvent and eluent. The diacetate **27** (0.58 g, 65%) was obtained as a clear, colorless oil; ^{13}C nmr δ: 14.7 (o), 17.6 (o), 21.2 (o), 21.3 (o), 26.8 (o), 26.9 (o), 39.1 (e), 39.4 (e), 43.8 (o), 46.1 (e), 51.9 (o), 58.5 (e), 64.9 (o), 75.8 (o), 97.4 (e), 170.3 (e), 170.7 (e), 176.1 (e), 203.3 (e); ms *m/z*: 337 (3), 223 (100). *Exact Mass* calcd. for $C_{18}H_{25}O_6$ (M − OCH_3): 337.1651; found: 337.1656.

Methyl exo*-6-acetoxy-3-hydroxy-4,4,*exo*-8-trimethyl-3-(1-oxoethyl)-*cis*-bicyclo[3.3.0]octane-1-carboxylate (**28**)*

A solution of diol **26** (48.8 mg, 0.172 mmol), distilled acetic anhydride (1 mL), and pyridine (0.08 mL) in dichloromethane (3 mL) was stirred at room temperature for 20 h under argon. The mixture was washed with saturated aqueous sodium bicarbonate (10 mL) and saturated aqueous sodium chloride (10 mL). The aqueous layers were reextracted with dichloromethane (3 × 25 mL). The combined organic solutions were dried over anhydrous sodium sulfate and the solvent was evaporated to give **28** (56.0 mg, 100%) as a viscous oil; ^{13}C nmr δ: 14.4 (q), 16.8 (q), 21.2 (q), 27.9 (q), 28.2 (q), 39.4 (t), 42.0 (t), 42.4 (d), 48.2 (s), 51.8 (q), 60.0 (s), 64.8 (d), 76.6 (d), 90.8 (s), 170.6 (s), 176.9 (s), 210.9 (s); ms *m/z*: 327 (50), 223 (100), 163 (95). *Exact Mass* calcd. for $C_{17}H_{26}O_6$: 326.1729; found: 326.1718.

This monoacetate was converted to diacetate **27** under conditions analogous to those used for the formation of **27** from **26**.

Methyl exo*-6-acetoxy-4,4,*exo*-8-trimethyl-3-(1-oxoethyl)-*cis*-bicyclo[3.3.0]octane-1-carboxylate (**31**)*

A solution containing diacetate **27** (304 mg, 0.826 mmol), azoisobutyronitrile (36.7 mg, 0.223 mmol), tri-*n*-butyltin hydride (0.42 g, 1.44 mmol), and dry toluene (10 mL) was boiled under reflux under argon for 6 h. The solvent was removed and the residue was chromatographed on silica gel with ethyl acetate/hexanes (1:3) as solvent and eluent to give monoacetate **31** (233 mg, 91%) as a clear, colorless oil. Crystallization from hexanes gave white crystals, mp 75.0–75.5°C; ^{13}C nmr δ: 14.6 (q), 21.2 (q), 23.0 (q), 24.2 (q), 31.7 (q), 35.5 (t), 38.5 (t), 42.9 (d), 43.3 (s), 51.7 (q), 58.4 (s), 58.6 (d), 64.1 (d), 75.0 (d), 170.5 (s), 175.9 (s), 208.1 (s); ms *m/z*: 311 (60), 147 (100). *Anal.* calcd. for $C_{17}H_{26}O_5$: C 65.78, H 8.44; found: C 65.73, H 8.47.

Methyl exo*-6-hydroxy-4,4,*exo*-8-trimethyl-3-(1-oxoethyl)-*cis*-bicyclo[3.3.0]octane-1-carboxylate (**32**)*

A mixture of monoacetate **31** (315.5 mg, 1.016 mmol) and potassium carbonate (145.8 mg, 1.055 mmol) in methanol (20 mL) was stirred at room temperature for 17 h under argon. The methanol was evaporated and water (15 mL) was added to the residue. The resulting mixture was extracted with dichloromethane (4 × 25 mL) and the combined organic extracts were dried over anhydrous magnesium sulfate. The solvent was removed to give alcohol **32** (273 mg, 100%) as a solid, which was recrystallized from 10% ethyl acetate in hexanes to give white needles, mp 95.5–96.0°C; ^{13}C nmr δ: 14.5 (q), 23.2 (q),

Methyl exo-*6-(*tert-*butyldimethylsilyloxy)-4,4,*exo-*8-trimethyl-3-(1-oxoethyl)-*cis-*bicyclo[3.3.0]octane-1-carboxylate (33) and methyl* exo-*6-(*tert-*butyldimethylsilyloxy)-3-[1-(*tert-*butyldimethylsilyloxy)ethenyl]-4,4,*exo-*8-trimethyl-*cis-*bicyclo[3.3.0]-octane-1-carboxylate (34)*

(*i*) A solution containing alcohol **32** (161 mg, 0.601 mmol), 2,6-lutidine (175.0 mg, 1.633 mmol), and *tert*-butyldimethylsilyl triflate (179.8 mg, 0.680 mmol) in dry dichloromethane (10 mL) was stirred at 0°C for 3 h under argon. Saturated aqueous sodium bicarbonate (10 mL) was added and the layers were separated. The aqueous layer was reextracted with dichloromethane (3 × 25 mL) and the combined organic solutions were dried over anhydrous magnesium sulfate. The residue, after evaporation, was chromatographed on a silica gel column with ethyl acetate/hexanes (1:3) as solvent and eluent to give silyl ether **33** (225.5 mg, 98%) as a solid. The silyl ether was recrystallized from hexanes to give a crystalline solid, mp 75.0–76.5°C; ^{13}C nmr δ: −4.9 (q), −3.7 (q), 14.5 (q), 17.6 (s), 23.6 (q), 24.5 (q), 25.7 (q), 31.4 (q), 35.4 (t), 42.2 (t), 42.4 (d), 43.5 (s), 51.4 (q), 58.5 (s), 58.9 (d), 68.0 (d), 74.3 (d), 176.6 (s), 208.9 (s); ms *m/z*: 325 (100). *Anal.* calcd. for $C_{21}H_{38}O_4Si$: C 65.92, H 10.01; found: C 66.19, H 10.09.

(*ii*) A solution containing alcohol **32** (60 mg, 0.965 mmol), dry 2,6-lutidine (258.5 mg, 2.41 mmol), and *tert*-butyldimethylsilyl triflate (383 mg, 1.45 mmol) in dry dichloromethane (10 mL) was stirred at room temperature for 3 h under argon. Work-up and chromatography as in (*i*) gave the silyl ether **33** (169 mg, 46%) and its silyl enol ether **34** (208.4 mg, 43%) as oils. The disilyloxy compound has ir λ_{max}: 5.80 (s), 6.18 (w) μm; ^{1}H nmr δ: 0.07 (s, 6H), 0.18 (s, 6H), 0.76 (s, 3H), 0.90 (s, 9H), 0.93 (d, 3H), 0.96 (s, 9H), 1.07 (s, 3H), 1.20–1.26 (m, 7H), 3.67 (s, 3H), 4.07 (m, 3H). When a solution of this product (208 mg, 0.419 mmol) in methanol was passed through a Dowex 10W-X8 plug it gave **33** (overall yield 85%).

exo-*4-(*tert-*Butyldimethylsilyloxy)-*exo-*2,6,6-trimethyltricyclo[5.3.1.0^{1,5}]undecane-8,10-dione (35)*

Keto ester **33** (165 mg, 0.431 mmol) in dry *tert*-butyl alcohol (8 mL) was treated with potassium *tert*-butoxide (0.77 g, 6.9 mmol). This mixture was heated under reflux for 1.5 h. *tert*-Butyl alcohol was evaporated. Water (2 mL) and dichloromethane (15 mL) were added. The resulting emulsion was passed through Celite and the solution was dried over anhydrous magnesium sulfate. The residue left after evaporation of dichloromethane was passed through a short silica gel column with ethyl acetate as solvent and eluent to give solid dione **35** (144.5 mg, 96%), which was recrystallized from 5–10% ethyl acetate in hexanes to give a crystalline solid, mp 152–153°C; ^{13}C nmr δ: −5.0 (q), −3.9 (q), 14.6 (q), 17.7 (s), 25.6 (q), 25.9 (q), 28.1 (q), 36.4 (t), 39.6 (d), 42.0 (s), 46.9 (t), 52.3 (t), 65.1 (s), 66.7 (d), 67.1 (d), 73.5 (d), 204.9 (s), 207.8 (s); ms *m/z*: 335 (3), 293 (100). *Exact Mass* calcd. for $C_{16}H_{25}O_3Si$ (M − $C(CH_3)_3$): 293.1573; found: 293.1565.

exo-*4-(*tert-*Butyldimethylsilyloxy)-*exo-*2,6,6-trimethyltricyclo[5.3.1.0^{1,5}]undec-9-en-8-ol (37) and* exo-*4-(*tert-*butyldimethylsilyloxy)-*exo-*2,6,6-trimethyltricyclo[5.3.1.0^{1,5}]undecan-8-ol (38)*

A mixture of dione **35** (118 mg, 0.335 mmol) and lithium aluminum hydride (69.5 mg, 1.83 mmol) in dry ether (40 mL) was boiled under gentle reflux for 20 h. Saturated aqueous sodium sulfate (2 mL) was added and then the mixture was dried with anhydrous sodium sulfate. The mixture was filtered and the resulting solids were washed with ethyl acetate. The combined organic solutions were concentrated to give a mixture of alcohols **37** and **38** (111 mg, 98%) as an oil; ir λ_{max}: 2.97 (w), 6.18 (w) μm; ^{1}H nmr spectrum of the mixture includes signals at δ: 0.05 (s), 0.92 (s), 3.52–4.25 (m), 4.67 (m), 5.40 (m), 6.12 (m).

exo-*4-(*tert-*Butyldimethylsilyloxy)-*exo-*2,6,6-trimethyltricyclo[5.3.1.0^{1,5}]undecan-8-one (39)*

Chromic anhydride (98 mg, 0.98 mmol) was added to cold, dry pyridine (6.7 mL) under argon. The mixture was stirred at room temperature for 10 min and the mixture of alcohols **37** and **38** (111 mg, ~0.33 mmol) in pyridine (1 mL) was added and the mixture was stirred for 20 h at room temperature. The pyridine was evaporated, water (10 mL) and ethyl acetate (25 mL) were added, and the layers were separated. The aqueous layer was reextracted with ethyl acetate (3 × 25 mL) and the combined organic solutions were dried over anhydrous sodium sulfate. Evaporation and passage of the residue through a silica gel plug with ethyl acetate as solvent and eluent gave a mixture of exo-*4-(*tert-*butyldimethylsilyloxy)-*exo-*2,6,6-trimethyltricyclo[5.3.1.0^{1,5}]undec-9-en-8-one and* exo-*4-(*tert-*butyldimethylsilyloxy)-*exo-*2,6,6-trimethyltricyclo[5.3.1.0^{1,5}]undecan-8-one* (94 mg, 85%) as an oil; ir λ_{max}: 5.86 (m), 5.97 (s) μm. The ^{1}H nmr spectrum of the mixture includes signals at δ: 0.06 (s), 0.88 (s), 4.10 (m), 5.73 (d, *J* = 10 Hz), 7.47 (d, *J* = 10 Hz).

The mixture (94 mg, ~0.28 mmol) in absolute ethanol (15 mL) containing 10% palladium on carbon (35.5 mg) was hydrogenated for 1 h at room temperature. Filtration and evaporation gave crude ketone **39**. Chromatography on a silica gel plate with ethyl acetate/hexanes (1:3) as solvent and eluent gave **39** (83 mg, ~89%) as a clear, colorless oil. The overall yield from diketone **35** was 74%. Compound **39** has ^{13}C nmr δ: −4.9 (q), −3.8 (q), 15.2 (q), 17.8 (s), 25.5 (q), 25.8 (q), 26.2 (q), 32.0 (t), 36.2 (t), 39.1 (d), 41.5 (s), 41.8 (t), 46.5 (t), 52.0 (s), 65.6 (d), 67.8 (d), 73.4 (d), 213.8 (s); ms *m/z*: 336 (5), 279 (100). *Exact Mass* calcd. for $C_{20}H_{36}O_2Si$: 336.2484; found: 336.2476.

exo-*4-(*tert-*Butyldimethylsilyloxy)-*exo-*2,6,6,*endo-*8-tetramethyltricyclo[5.3.1.0^{1,5}]undecan-*exo-*8-ol (40)*

To a solution of ketone **39** (83 mg, 0.247 mmol) in dry ether (10 mL) was added methyllithium in hexanes (1.4 M; 6.0 mL), 8.4 mmol) under argon. The mixture was heated under reflux for 5 h. Water (10 mL) was added and the layers were separated. The aqueous layer was reextracted with ethyl acetate (3 × 25 mL) and the combined organic solutions were dried over anhydrous sodium sulfate. The solvent was evaporated and the residue was chromatographed on silica with ethyl acetate as eluent to give alcohol **40** (83 mg, 95%) as a solid, mp 65.0–67.0°C; ^{13}C nmr δ: −4.9 (q), −3.7 (q), 15.3 (q), 17.8 (s), 25.8 (q), 27.8 (q), 28.3 (q), 30.0 (q), 31.6 (t), 34.7 (t), 38.6 (d), 42.5 (s), 42.7 (t), 46.5 (t), 51.8 (s), 61.6 (d), 64.8 (d), 73.6 (d), 75.0 (s); ms *m/z*: 335 (16), 295 (100). *Exact Mass* calcd. for $C_{21}H_{39}OSi$ (M + H − H_2O): 335.2766; found: 335.2780.

exo-*4-(*tert-*Butyldimethylsilyloxy)-*exo-*2,6,6,8-trimethyltricyclo[5.3.1.0^{1,5}]undec-8-ene (41) and* exo-*4-(*tert-*butyldimethylsilyloxy)-*exo-*2,6,6-trimethyl-8-methylenetricyclo[5.3.1.0^{1,5}]undecane (42)*

Thionyl chloride (0.16 mL) was added to a cold (0°C) solution of alcohol **40** (38 mg, 0.107 mmol) in pyridine (2 mL) under argon. The reaction mixture was stirred for 1.5 h at 0°C. Water (10 mL) was added and the mixture was extracted with ethyl acetate (3 × 25 mL). The combined extracts were dried over anhydrous sodium sulfate and the solvent was evaporated. The residue was passed through a short silica gel column with ethyl acetate as solvent and eluent to give a 2:1 mixture of **41** and **42** (29 mg, 81%) as an oil; ir λ_{max}: 6.08 (w) μm. The ^{1}H nmr (400 MHz) spectrum of **41** includes signals at δ: 0.00 (s), 0.02 (s), 0.84 (s), 0.91 (d, *J* = 7.6 Hz), 1.01 (s), 1.06 (s), 1.64 (m, vinyl methyl), 4.00 (ddd, *J* = 7.9, 6.9, 5.5 Hz), 5.19 (m) and the ^{1}H nmr (400 MHz) spectrum of **42** includes signals at δ: 0.01 (s), 0.05 (s), 0.86 (s), 0.88 (d, *J* = 7.6 Hz), 0.96 (s), 1.05 (s), 4.04 (ddd, *J* = 9.3, 8.1, 5.5 Hz), 4.48 (m), 4.56 (m).

(±)-α-Biotol (1)

The mixture of compounds **41** and **42** (20.0 mg, 0.060 mmol) was treated with a solution (6 mL) of 5% hydrogen chloride in methanol under argon and this mixture was stirred at room temperature for 2 h. Saturated aqueous sodium bicarbonate (10 mL) was added and the mixture was extracted with ethyl acetate (3 × 25 mL). The extracts

were dried over anhydrous sodium sulfate and the solvent was evaporated. The residue was chromatographed on a silica gel plate with 25% ethyl acetate in hexanes as solvent and eluent to give (±)-α-biotol (**1**) (9.1 mg, 69%), mp 68–70°C; ^{13}C nmr δ: 15.8 (q), 24.7 (q), 25.8 (q), 27.9 (q), 38.8 (t), 39.6 (d), 41.0 (t), 46.5 (t), 46.6 (s), 52.6 (s), 55.6 (d), 68.9 (d), 73.8 (d), 118.6 (d), 140.4 (s).

*(±)-α-Biotol (**1**) and (±)-β-biotol (**2**)*

A solution of 5.2% hydrofluoric acid in acetonitrile was prepared from a standard solution of 52% aqueous hydrofluoric acid. The former solution (7 mL) was added to a mixture of silyl ethers **41** and **42** (14.0 mg, 0.0418 mmol) under argon. The solution was stirred at 0°C for 1.75 h and then allowed to warm to room temperature during 15 min. Saturated aqueous sodium bicarbonate (10 mL) was added and the mixture was extracted with ethyl acetate (3 × 10 mL). The combined extracts were dried over anhydrous sodium sulfate and the solvent was evaporated. The residue was chromatographed on a silica gel plate with 1:3 ethyl acetate/hexanes as solvent and eluent to give (±)-α-biotol (**1**) (4.5 mg) and (±)-β-biotol (**2**) (2.2 mg) in a combined yield of 77%. (±)-β-Biotol has mp 95–97°C; ^{13}C nmr δ: 14.9 (q), 26.2 (q), 26.3 (q), 29.0 (t), 33.7 (t), 39.5 (d), 41.1 (s), 45.5 (t), 46.6 (t), 53.1 (s), 61.1 (d), 65.1 (d), 73.6 (d), 108.1 (t), 151.0 (s).

*(±)-α-Biotone (**6**)*

To a suspension of pyridinium chlorochromate (31.1 mg, 0.144 mmol) in dichloromethane (1.5 mL), was added (±)-α-biotol (**1**) (13.2 mg, 0.0599 mmol) in dichloromethane (1.5 mL). The mixture was stirred at room temperature for 3 h. Water was added and the mixture was extracted with dichloromethane (3 × 10 mL). The combined extracts were dried over anhydrous sodium sulfate and passed through Celite to give (±)-α-biotone (**6**) (13.1 mg, 100%) as an oil; ir λ_{max}: 5.78 (s) μm; ^{1}H nmr δ: 0.93 (d, J = 8.0 Hz, 3H), 1.00 (s, 3H), 1.20 (s, 3H), 1.70 (m, 3H), 1.50–3.00 (m, 9H), 5.20 (m, 1H).

*(±)-α-Biotol (**1**) and (±)-4-epi-α-biotol (**7**)*

(±)-α-Biotone (**6**) (9.9 mg, 0.045 mmol) and lithium aluminum hydride (11.6 mg, 0.306 mmol) in dry ether (5 mL) were heated under reflux for 5 h under argon. Saturated aqueous sodium sulfate (0.5 mL) was added and the solution was dried with anhydrous sodium sulfate. The mixture was filtered and the solids were washed with ethyl acetate. The combined filtrates were concentrated and the residue was chromatographed on a silica gel plate with ethyl acetate/hexanes (1:3) as solvent and eluent to give (±)-α-biotol (**1**) (3.2 mg) and (±)-4-epi-α-biotol (**7**) (3.3 mg) in a total yield of 65%. (±)-4-Epi-α-biotol (**7**) has mp 57–59°C; ^{13}C nmr δ: 15.8 (q), 24.7 (q), 27.4 (q), 28.7 (q), 37.3 (d), 38.7 (t), 41.7 (t), 44.7 (t), 49.7 (s), 53.1 (s), 56.5 (d), 62.1 (d), 73.7 (d), 119.1 (d), 140.3 (s).

Received May 31, 1988

J. B. STOTHERS AND ALBERT STOESSL. Can. J. Chem. **66**: 2816 (1988).

Incorporation experiments with [1,2-$^{13}C_2$]acetate establish that the biosynthesis of kotanin, a dimeric 5-methylcoumarin, proceeds through a polyketide pathway and, therefore, represents an exception to Turner's rule regarding the relative lengths of the uncyclized residues of polyketide chains. The previous ^{13}C signal assignments are also revised.

J. B. STOTHERS ET ALBERT STOESSL. Can. J. Chem. **66** 2816 (1988).

Des expériences d'incorporation du acétate [$^{13}C_2$-1,2] ont permis de démontrer que la biosynthèse de la kotanine, un dimère de la méthyl-5 coumarine, se produit par le biais d'un polycétide et qu'elle correspond donc à une exception à la régle de Turner concernant les longueurs relatives des résidus non-cyclisés des chaines polycétides. On a aussi revisé les attributions antérieures des signaux relatifs au ^{13}C.

Fungal metabolites whose structures are in real or apparent breach of Turner's rule (1) that "the uncyclized residues from the methyl ends of polyketide chains are never shorter than residues from the carboxyl end of the chain" include marticin (**1**) from *Fusarium martii* (2), colletruncoic acid methyl ester (**2**) from *Colletotrichum truncatum* (3), kotanin (**3**) and demethyl kotanin (**4**) from *Aspergillus clavatus* (4, 5), orlandin (**5**) from *A. niger* (6), siderin (**6**), the monomer of kotanin, from *A. variecolor* (7, 8), and the desertorins A, B, and C (**7–9**, respectively) from *Emericella desertorum* (*A. nidulans* group) (9). Another group of compounds comprises the benzoisochromane quinones, such as actinorhodin (10) and granaticin (11), whose relevant structural moieties (12) have been shown to be of polyketide origin by extensive biosynthetic studies (10, 11). The latter compounds, however, are metabolites of actinomycetes, that is, prokaryotic organisms which may not be encompassed by the rule. Of the true fungal metabolites marticin has been proven (2, 12) to be of mixed polyketide and tricarboxylic acid cycle origin, which accounts for the apparent anomaly. Of the others, only siderin (**6**) has been the subject of an experimental biosynthetic study. It was found (7) that *A. variecolor* cultures incorporated sodium [2-$^{14}C_1$]acetate into **6** with 0.75% efficiency. Kuhn–Roth degradation of the labelled siderin placed 25.8% of its total radioactivity into the 5-methyl group and the excess, over the expected result of uniform incorporation (20% at each of 5 sites), was very plausibly ascribed to the starter effect as frequently seen in polyketide biosynthesis. Unfortunately, lack of material precluded further degradative experiments that could have rendered this conclusion certain. Alternative interpretations of the data, therefore, could not be entirely discounted. For instance, it might be envisaged that the coumarin nucleus is derived from shikimate, while non-uniform incorporation of acetate via formate into the C- and the two O-methyl groups could account for the activity data.

To test these concepts, we undertook an incorporation study with the readily available *A. niger*, applying [1,2-$^{13}C_2$]acetate together with L-[1-$^{14}C_1$]phenylalanine as potential precursors, in the expectation of isolating orlandin (**5**) as the labelled product. In a preliminary cold run, however, chromatography of the culture extract furnished crystalline kotanin (**3**) in good yield. This compound had not been reported previously as a metabolite of *A. niger*. Other fractions from the chromatogram were complex and, in the absence of an authentic specimen, orlandin could not be detected in them with certainty. Further work on this aspect seemed unnecessary because it was clearly advantageous, in subsequent runs, to add diazomethane to the crude extracts to convert any **4** and **5** into **3**. In fact, in the final incorporation experiment described below, kotanin was present only in small amounts before, but was isolated in good yield after, methylation.

Our ^{13}Cmr spectrum of natural kotanin agreed well with that originally reported (6) but the specific signal assignments required reconsideration in the light of a comparison of the proton-coupled and decoupled spectra together with the results reported earlier for siderin and related coumarins (13). These data led to reassignment of six of the nine skeletal carbon signals, each arising from fully substituted carbons. In the coupled spectrum, the signals at δ_C 153.5 and 163.0 remain as singlets, albeit slightly broadened, which is indicative of the absence of vicinal $^{13}C-^1H$ coupling and consistent with their assignment to C-9 and C-2, respectively. In contrast, the signals at δ_C 107.4 and 108.5 appear as multiplets in the coupled spectrum, the former as a broadened doublet, J = 5.5 Hz, and the latter as a nine-line pattern, $\nu_{\frac{1}{2}}$ = 22.5 Hz. It follows that the 107.4-ppm signal arises from C-8 with one vicinal $^{13}C-^1H$ coupling to H-6 and the δ_C 108.5 pattern is that of C-10 exhibiting vicinal coupling with H-3, H-8, and the 5-methyl protons. The carbons bearing methoxyl groups at δ_C 159.5 and 169.8 each gave rise to a doublet of quartets in the coupled spectrum through geminal coupling to the neighbouring proton and vicinal coupling with the methoxyl protons; these signals were not unequivocally assigned until the spectrum of the labelled sample was recorded. While our work was in progress a different assignment of the kotanin spectrum was reported (9), which also requires revision.

An attempt to achieve incorporation of labelled precursors into **3** on the shredded wheat medium of Cutler *et al.* (6) was abortive. Several fully liquid media were therefore compared as to the kotanin yield and the most promising, Czapek–Dox

[1]Part 137 of ^{13}Cmr studies; for Part 136 see ref. 15, for Part 135, ref. 16.

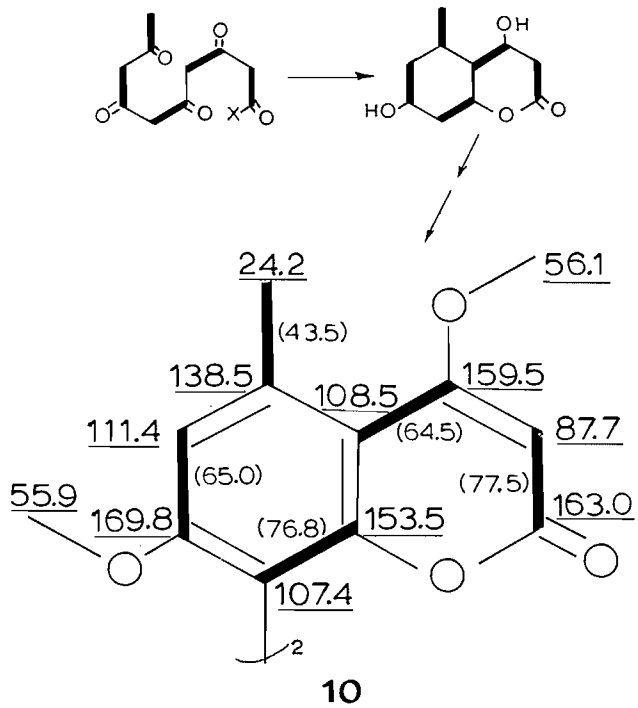
solution modified by the addition of corn steep liquor, was chosen for the critical experiment. The crystalline kotanin isolated therefrom gave a ^{13}C spectrum in which each of the original signals was flanked by a pair of weak satellite peaks indicative of incorporation of five intact acetate units, since the separations of the satellite peaks readily permitted pairing of each of the 10 signals in an unequivocal manner as shown in **10**, in which the J_{CC} values are given in Hz in parentheses. The relative intensities of the satellite peaks and the central signals showed that the specific enrichment level was very low, 0.18 ± 0.01%, but the labelling pattern of intact acetate units is unequivocal evidence that the metabolite is generated through a polyketide pathway as shown in Fig. 1.

An additional complication arose, however, because the ^{13}C-labelled sample of kotanin also exhibited low levels of radioactivity, which reached a constant value, 4 ± 2 dpm/mg, on repeated recrystallization. This corresponds to a specific incorporation rate of about 0.05% at each of two sites and an incorporation efficiency of 0.003%. For comparison, the specific enrichment of 0.18% ^{13}C, at each of 20 sites as determined from the ^{13}Cmr spectrum, represents an incorporation efficiency of 0.01%. The incorporation of radioactivity from phenylalanine could be due to its breakdown by fungal agency to acetic acid with subsequent incorporation into kotanin. Another similar experiment gave analogous results. The activity of the available kotanin was much too low (ca. 50 dpm in the total recrystallized sample) to allow verification of this surmise by degradative studies. In contrast, the labelling pattern revealed by the ^{13}C spectrum is consistent only with a polyketide origin of kotanin, in accord with the earlier conclusion of Holker and co-workers (7) with respect to siderin



10

FIG. 1. Probable biosynthetic route to kotanin.

biosynthesis in *A. variecolor*. However, siderin and many other 5-methylcoumarins are also known as metabolites of higher plants (14). It would be highly interesting to determine whether the polyketide route is also operative in these cases.

Experimental

General purpose solvents were redistilled before use. Evaporations were done at the reduced pressure of the water aspirator. Thin-layer chromatography (tlc) was done on precoated sheets of silica gel (Macherey–Nagel Polygram Sil G/UV_{254}, 0.25 mm) with MeOH/$CHCl_3$ (2:98 v/v) as solvent and uv light (254 nm) and (or) vanillin (0.5% in 60% phosphoric acid) for detection. Column chromatography was performed as described by Cutler *et al.* (6). Melting points were determined on a Kofler hot stage and are uncorrected. Optical rotations were measured with a Perkin–Elmer 241 photoelectric polarimeter. Radioactivities were determined on a Beckman LS 9000 scintillation counter utilizing an Omnifluor (New England Nuclear, Boston, MA; 4 g in toluene (1 L) and ethylene glycol monomethyl ether (800 mL)) scintillation cocktail. Ultraviolet spectra were recorded in 96% EtOH with a Shimadzu UV 240 spectrophotometer. A Varian XL-200 instrument was used to obtain the ^{1}Hmr spectra in $CDCl_3$ solution with TMS as internal reference. The ^{13}Cmr spectra were recorded on a Varian XL-300 system using the same solutions. The coupled spectrum of **3** was obtained with the gated decoupling technique.

Aspergillus niger, accession number ATCC 36626, was purchased from the American Type Culture Collection, Rockville, MD, and routinely maintained on potato-dextrose agar in Petri dishes at 20–24°C. Preparative culture media were inoculated by direct transfer of spores, with a needle, from stock cultures. All operations with viable fungal cells were done aseptically in a biohazard cabinet type IIA. Sodium [1,2-$^{13}C_2$]acetate, 99.1% ^{13}C, was obtained from Isotec Inc., Miamisburg, OH, and L-[1-$^{14}C_1$]phenylalanine from New England Nuclear, Boston, MA.

Preliminary experiments were carried out as described by Cutler *et al.* (6) with a cake (25 g) of shredded wheat (Nabisco) and nutrient solution (50 mL, ref. 6) per flask (Erlenmeyer, 500 mL). On column chromatography (6) of the product from one flask, crystalline kotanin (30 mg) was obtained by concentration of fractions 35–40 (50 mL each, EtOAc/C_6H_6, 3:2). After recrystallization (H_2O/HOAc), the compound had mp > 350°C; $\lambda_{max}(\epsilon)$: 316(19 000 sh), 306(23 450), 296(19 400 sh), 235(18 800 sh), 207(52 400); ^{1}Hmr ($CDCl_3$) δ: 6.72(s, 1H, H-6), 5.51(s, 1H, H-3), 3.93(s, 3H, OMe), 3.80(s, 3H, OMe), 2.71(s, 3H, 5-Me); ^{13}Cmr (see text).

The experiment was repeated with 6 cultures of *A. niger* on medium supplemented with sodium [1,2-$^{13}C_2$]acetate (42 mg, 99.1% ^{13}C) and L-[1-$^{14}C_1$]phenylalanine (41.5 mg, 3.4×10^6 dpm) in each 50 mL of nutrient solution. On extraction after 9 days growth, the cultures afforded only 9.3 mg of crystalline **3** on chromatography of the methylated extract (see below); there was no evidence of ^{13}C satellite signals in its ^{13}C spectrum and its radioactivity (347 dpm/mg) decreased to 42 dpm/mg after two recrystallizations.

Further preliminary experiments with several completely liquid media indicated that the best yields of **3** were realized on a Czapek–Dox medium amended with corn steep liquor ($NaNO_2$, 1.5 g; KCl, 0.3 g; $MgSO_4 \cdot 7H_2O$, 0.3 g; $FeSO_4 \cdot 7H_2O$, 0.006 g; K_2HPO_4, 0.6 g; $CuSO_4$, 0.002 g; $ZnSO_4 \cdot 7H_2O$, 0.006 g; sucrose, 120.0 g; corn steep liquor (Sigma, St. Louis, MO), 12 mL; H_2O to 600 mL), as estimated by two-dimensional tlc (MeOH/$CHCl_3$, 1:10, and EtOAc/toluene/HCOOH, 3:6:1 v/v). However, the rate of kotanin production in these experiments, as determined after methylation, was found to be variable and not a reliable guide for the planned incorporation experiment.

Main experiment

A batch of Delong flasks (250 mL), each containing 40 mL of amended Czapek–Dox medium, were inoculated and monitored, by extraction of one flask at a time, until a distinct spot for kotanin was first observed on tlc of the methylated extract (day 8). Twelve of the cultures were then treated with 4 mL/flask of a solution containing, in 100 mL, sodium (1,2-$^{13}C_2$]acetate (420 mg, 99.1 at.% ^{13}C), L-phenylalanine (413 mg), and L-[1-$^{14}C_1$]phenylalanine (0.006 mg, 2 μCi). The treatment was repeated (4 mL/flask) on day 10 and growth was terminated by the addition of MeOH (100 mL/flask) on day 11. After standing for two days, the supernatant was decanted from the mycelia, which were extracted twice more by steeping in MeOH. The combined supernatants were concentrated until aqueous (ca. 300 mL) and then extracted with $CHCl_3$ (3 × 100 mL). The extracts were combined, evaporated, redissolved in MeOH (20 mL), and treated with ethereal diazomethane (3 × 5 mL, added over 1 h). The product was chromatographed as before to yield crystalline **3** (12.5 mg), which gave the ^{13}C spectrum discussed in the text. On successive recrystallizations from MeOH/$CHCl_3$, the apparent specific radioactivity decreased from 24 dpm/mg to a constant value of 4 ± 2 dpm/mg.

L. MAGDZINSKI and B. FRASER-REID. Can. J. Chem. **66**, 2819 (1988).

The formation of *C*-alkyl derivatives from 1,6:2,3-dianhydro-*manno*-pyranose precursors has been examined. Regioselectivity at C2 is excellent when the C4 substituent is benzyloxy. However, with CH_3, reaction at C2 and C3 occurs, although the ratio of products can be altered substantially depending on the nature of the nucleophile and the reaction conditions.

L. MAGDZINSKI et B. FRASER-REID. Can. J. Chem. **66**, 2819 (1988).

On a examiné la possibilité de former des dérivés *C*-alkylés à partir du dianhydro-1,6:2,3 *manno*-pyrannose. La régiosélectivité au niveau C2 est excellente lorsque le substituant en C4 est un benzyloxy. Avec un substituant CH_3, la réaction se produit toutefois en C2 et en C3; le rapport des produits peut être modifié d'une façon importante en faisant varier la nature du nucléophile ainsi que les conditions de la réaction.

[Traduit par la revue]

The use of 2,4-di-*C*-methyl-pyranose derivatives (e.g., **II**) as chirons (1) in the synthesis of propionate-derived natural products represented by **I** was pioneered by Hanessian *et al.* in their seminal approach to the synthesis of erythronolide (2). Several related contributions have appeared since then (3–8) and among these, 1,6-anhydro sugars (e.g., **III**), first exploited by Kelly and Roberts (6), and Kochetkov *et al.* (7), have been found to be particularly appealing (see for example ref. 8). Thus, the unique topological properties of these derivatives usually engender high stereoselectivities, a fact that had been established previously by the extensive studies of Cerny and Stanek (9).

In the early approaches to the fragment **I**, the anomeric center of **II** was invariably a site for chain elongation (i.e., C1a of **I**) via attachment of the group R. In an alternative approach, we have disconnected the C2 site of **I** differently, in that the C2-CH_3 group is derived from the anomeric carbon (path b), chain elongation being pendant to the ring, as in **V**. This simple change in strategy facilitated the development of the concept of pyranosidic homologation, which we have described elsewhere (10, 11) as a method for assembling multiple contiguous chiral centers with predictable stereoselectivity and easily verified configurations. For this plan, 1,6-anhydro derivatives (e.g., **V**) could serve as intermediates in which the substituent at C2 would need to be more complex than CH_3. In this manuscript, we describe some of our work directed at such chirons.

Epoxide **2** is readily available from levoglucosan, **1**, in two steps (12), and its copper-induced reactions with allyl Grignard reagents had been described by Kelly and Roberts (6) prior to our own work. Accordingly, reaction of **2** with methylmagnesium chloride and cuprous iodide in tetrahydrofuran at 0°C gave **3** in 91% yield.

However, the presence of a functionalized alkyl substituent at C4 was deemed worthy of exploration because of the number of synthetic options that would be opened thereby. Unfortunately, reactions of **2** with a variety of sodium, lithium, or aluminum alkyls were either sluggish or gave complex mixtures probably due to cleavage of the sulfonyl ester, and isomerization to the more stable 2,3-epoxide, **4** (9). Indeed, derivatives of **4** were isolated from some of these reactions.

The sulfonyl group in **2** was therefore removed by sodium–ammonia reduction and the product **5** (13) was treated with ethylvinyl ether to give the α-ethoxyethyl derivative **6**. Reaction of the latter with excess 2-lithio-1,3-dithiane required 11 days and gave **7***a* in only 38% yield. Fortunately, the reaction of **6** with excess bis-diethyl-(trimethylsilylalkynyl)-alane (14) for 30 min at 80°C gave **8***a* in the excellent yield of 96%.

The feasibility of introducing a second alkyl group at C2 of the compounds in Scheme 1 was next considered and, for this purpose, the 4-*C*-methyl product **3** was the most available substrate. Reaction of the latter with sodium methoxide afforded the 2,3-*manno*-epoxide **9** in 86% yield after distillation. Treatment of **9** with methylmagnesium chloride in the presence of cuprous iodide did give the dimethyl compound **10** in 66% yield.

In contrast to this encouraging result, the reactions of **9** with more functionalized nucleophiles proved to be more complex, the regioselectivity and yields being found to be vey dependent on the reaction conditions. For example, reaction with the Grignard reagent **11***c* (prepared from the silylated propargyl ether **11***b*) gave epoxide ring opening at C2 and C3, the products **12***a* and **13***a* being formed quantitatively in 3:2 ratio. The alkynyl alane that had worked so well to give **8** (Scheme 1) was next examined, but several modifications had to be made before optimum selectivity and yields were achieved. For example, reaction of *tert*-butyldimethylsilylpropargyl ether **11***b* with butyllithium, followed by 3 equivalents of diethylaluminum chloride, generated a mixture that reacted with **9** at 80°C in 24 h to give **12***a* and **13***a* in a 2:3 ratio with an excellent total yield of 94%. Further experimentation showed that the ratio of **12***a* and **13***a* could be changed to 7:1 by using equimolar amounts of the alkynyl alane and increasing the temperature to 110°C. Unfortunately, the yield in the latter reaction was also reduced.

Attempts at rationalizing the selectivity at C2 or C3 in reactions of *manno*-2,3-epoxides (e.g., **9**) have been advanced by Cerny and Stanek on the basis of HASB arguments (9). More polarizable "soft" bases (e.g., I^-) attack these substrates predominantly at C3, while "hard" bases (e.g., OH^-) attack at

SCHEME 3

C2, leading to *trans*-diaxial openings. Copper catalyzed addition of methyl magnesium bromide occurred exclusively at C2; however, the regioselectivity in organometallic reactions is dependent on the metal. This is clear with the magnesium and aluminum propargyl derivatives in Scheme 2.

The effect of the C4 substituent on regioselectivity was apparent when the reaction of the *O*-benzyl analog **14** (12*a*) was examined (Scheme 3). Thus, reaction with alane **11***e* in toluene at 80°C for 2 h gave **15***a* in quantitative yields. Similarly, the unprotected propargyl derivative **11***a* (M = $AlEt_2$) also reacted stereoselectively, but the product was a mixture of **15***b* and **16** in 71 and 7% yields, respectively. However, in both cases reaction was observed only at C2, and in both cases the reaction was much more rapid than in the 4-*C*-methyl derivative. These differences in rate and stereoselectivity in the reactions of **9** and **14** with the same alkynyl alane can be rationalized by evoking electronic influence by the C4 oxygen of **14**.

Data from ^1H nmr and ^{13}C nmr for selected compounds, shown in Tables 1 and 2, were very helpful in making structural assignments. The rigid bicyclic framework allows many long-range couplings, including through-the-ring-oxygens (J_{14}, J_{15}, J_{16}, and J_{25}). These long-range couplings, in addition to the small diequatorial pyranosidic proton couplings, support the triaxial assignments at C2, C3, and C4 encountered in most of the 1,6-anhydro-β-D-glucopyranoses shown in Table 1 (9). In addition, the J_{23} = 10.0 Hz coupling seen in **13** independently

confirms its structure and is consistent with "diequatorial" epoxide ring opening of **9**. The ^{13}C nmr data (Table 2) indicated that C5 was very sensitive to substitution at C4. The assignments were verified by off-resonance broad-band decoupling of both sides of the proton spectrum.

Experimental

General

Melting points were determined in capillary tubes using a Buchi model 510 melting point apparatus and are uncorrected. Elemental analyses were performed by Dr. F. Kasler, University of Maryland. The ir spectra were recorded on a Perkin–Elmer model 298 instrument using sodium chloride plates for thin films of liquids, syrups, or solids in Nujol mulls. Optical rotations were detemined at the sodium D line using a Perkin–Elmer 241 polarimeter. The ^{1}H nmr spectra were determined on the following spectrometers: Varian EM-360 A, Varian XL-100, or Varian XL 200. Unless otherwise stated, the solvent used was $CDCl_3$ with internal tetramethylsilane or $CHCl_3$ as the standard. The coupling constants were verified by homonuclear decoupling experiments. For the purpose of ^{1}H nmr interpretation, compound structures have been numbered in the schemes. Low resolution mass spectra were obtained using a Varian MAT-CM7 or a Bell and Howell 21-492 instrument and high resolution mass spectra (hrms) were performed at the Research Triangle Park, North Carolina, with a VG707OF instrument. The progress of all reactions was monitored by thin-layer chromatography (tlc), which was performed on aluminum plates precoated with silica gel HF-254 (0.2-mm layers) containing a fluorescent indicator (Merck, 5539), with detection by uv (254 nm), charring with sulfuric acid spray. Flash chromatography was performed using Kieselgel 60 (230–400 mesh, E. Merck).

*1,6-Anhydro-4-deoxy-4-*C*-methyl-2-*O*-p-toluenesulfonyl-*β*-*D*-glucopyranose, 3*

To a mixture of purified (15) cuprous iodide (800 mg, 0.4 mmol) and methylmagnesium chloride (2.9 M in THF, 60 mL, 160 mmol) in dry THF (200 mL) at −44°C under argon was added solid **2** (12) (12.0 g, 40 mmol). After 2 h at 20°C, the reaction was complete and the mixture was cooled to 0°C, diluted with ether (400 mL), and poured slowly onto 5 M NH_4Cl (400 mL). The ether–THF layer was washed with a 10% ammonium hydroxide, NH_4Cl solution, dried ($MgSO_4$), filtered, and evaporated to yield a yellow semisolid, which was recrystallized from ether – petroleum ether to give the title compound as white plates, mp 91.5–92.0°C, 11.4 g (91%); $[\alpha]_D^{25}$ −54.2° (*c* 1.00, $CHCl_3$); ^{1}H nmr

(200 MHz), δ: 1.30 (d, J = 7.5 Hz, 3H, C4-CH_3), 1.81 (bq, J = 7.5 Hz, 1H, H4), 2.30 (bs, 1H, OH, D_2O ex), 2.50 (s, 3H, φCH_3), 3.64 (quintet, J = 1.0 Hz, 1H, H3), 3.72 (dd, J = 7.6, 5.0 Hz, 1H, H6x), 4.08 (d, J = 7.6 Hz, 1H, H6n), 4.21 (q, J = 1.0 Hz, 1H, H2), 4.31 (bd, J = 5.0 Hz, 1H, H5), 5.31 (bs, 1H, H1), 7.82 and 7.37 (2 × d, J = 2.3 Hz, 4H, φH); ^{13}C nmr (200 MHz), δ: 145.2 (φC1), 133.8 (φC4), 130.0 (φC2 and φC5), 127.9 (φC3 and φC4), 99.1 (C1), 79.2 (C2), 76.8 (C5), 72.1 (C3), 68.4 (C6), 38.8 (C4), 21.6 (φCH_3), and 17.5 (C4-CH_3); ms: 314 (M, 0.5), 297 (0.5), 279 (1), 243 (2), 227 (7), 159 (70), 155 (60), 113 (32), 101 (58), 91 (70), 85 (69), 71 (42), 55 (75), and 43 (100). *Anal.* calcd. for $C_{14}H_{18}O_6S$: C 53.49, H 5.77, S 10.20; found: C 53.65, H 5.98, S 10.50.

*1,6:3,4-Dianhydro-2-*O*-α-ethoxyethyl-*β*-D-galactropyranose (**6**)*

To an *efficiently* stirred solution of the sulfonate **2** (1.0 g, 2.1 mmol) in dry DME (100 mL) and liquid ammonia (100 mL) at −78°C was added just enough sodium (in 20-mg pieces) to produce a persistent blue color. The addition and stirring were at such a rate as not to allow any large accumulation of sodium metal. At the first sign of the blue color, excess solid ammonium chloride was added. The mixture was diluted with dry ether, refluxed for 5 min, and filtered through Celite 503 (Celite, Baker). The Celite was washed with DME (20 mL) and the combined organic phases evaporated to give compound **5** as white prisms (0.340, 72%); mp 69.0–70.5°C (lit. (13) mp 67–69°C); $[\alpha]_D^{25}$ −83.3° (c 1.46, H_2O) (lit. (13) $[\alpha]_D$ −80°). Treatment of the epoxy alcohol **5** (2.0 g, 13.9 mmol) with ethyl vinyl ether (10 mL, 100 mmol), and pyridinium p-toluenesulfonate (0.1 g) (16) in dry CH_2Cl_2 (20 mL) gave a new material (R_f 0.50, 50% EtOAc – petroleum ether). The mixture was washed successively with sodium bicarbonate solution, water, and brine, dried (K_2CO_3), processed, and chromatographed (30% EtOAc – petroleum ether) to afford the title compound, **6**, as a colorless liquid, bp 100°C/0.06 Torr (1 Torr = 133.3 Pa); 2.4 g (80%); $[\alpha]_D^{25}$ −53.6° (c 0.81, $CHCl_3$); ^1H nmr (200 MHz), δ: 5.28 and 5.19 (2 s, 1:1, 1H, H1), 4.83 (m, 2H, H5 and H1′), 4.00 (d, J = 7.0 Hz, 1H, H6n), 3.78 (s, 1H, H2), 3.63 (m, 3H, H4 and H1″), 3.51 (dd, J = 7.0, 3.4 Hz, 1H, H6x), 3.16 and 3.09 (2 × d, J = 2.5 Hz, 1:1, 1H, H3), 1.40 (d, J = 6.6 Hz, 3H, H2′), and 1.26 (t, J = 6.8 Hz, 3H, H2″). *Anal.* calcd. for $C_{10}H_{16}O_5$: C 55.54, H 7.45; found: C 55.34, H 7.64.

*1,6-Anhydro-4-deoxy-2-*O*-α-ethoxyethyl-4-*C*-(2-trimethylsilyleth-1-ynyl)-*β*-D-glucopyranose (**8**a)*

To a stirred solution of trimethylsilylacetylene (707 mg, 7.2 mmol) in dry toluene (20 mL) at −78°C was added dropwise a solution of n-butyllithium (6.6 mmol). After warming to 20°C, THF (ca. 0.2 mL) was added to dissolve a gelatinous precipitate, the reaction was recooled to −78°C, and Et_2AlCl (6 mmol) was added. The mixture was warmed to 20°C for 45 min, causing a thick white precipitate to form. The temperature was raised to 80°C and epoxide **6** added. After 30 min, tlc (2% MeOH–CH_2Cl_2) indicated completion, and the product was isolated by usual work-up procedures. Column chromatography (60% EtOAc – petroleum ether) gave the title compound (**8***a*) as a colorless liquid, bp 100°C/0.06 Torr; 588.6 mg (96%); $[\alpha]_D^{25}$ −30.5° (c 1.12, $CHCl_3$). Acetylation gave **8***b* as a colorless liquid, bp 80°C/0.06 Torr; $[\alpha]_D^{25}$ −21° (c 0.39, $CHCl_3$); ^1H nmr (60 MHz), δ: 5.52 and 5.46 (2 × d, J = 2.0 Hz, 1H, H1), 5.10 (m, 1H, H3), 4.50 (m, 2H), 4.10 (m, 1H, H2), 3.95 (d, J = 7.0 Hz, 1H, H6n), 3.60 (m, 4H), 2.07 (s, 3H, Ac), 1.30 (m, 6H), and 0.15 (s, 9H, $SiCH_3$). *Anal.* calcd. for $C_{17}H_{28}O_6Si$: C 57.28, H 7.92; found: C 57.29, H 8.14.

*1,6-Anhydro-2-*O*-α-ethoxyethyl-4-deoxy-4-*C*-(1,3-dithian-2-yl)-*β*-D-glucopyranose (7*a*)*

Reaction of epoxide **6** (250 mg, 1.6 mmol) with 1,3-dithianyllithium (5 mmol) in 10 mL dry HMPA at 4°C for 11 days gave a new material (tlc R_f 0.27, 50% EtOAc – petroleum ether; NBS–fluorescein (17) spray positive for thioether) and residual starting **6** (R_f 0.55). The mixture was diluted with ether, washed with water, dried ($MgSO_4$), filtered, evaporated, and chromatographed to yield the title compound (**7***a*) as a pale yellow syrup. The α-ethoxyethyl group was removed by treatment with 80% acetic acid at 60°C for 16 h and the resulting diol, **7***b*, was acetylated to the diacetate **7***c* as a pale yellow syrup, 172.0 mg; $[\alpha]_D^{25}$ −7.6 (c 1.18, $CHCl_3$); ^1H nmr (60 MHz), δ: 5.40 (bt, J = 1.0 Hz, 1H, H2), 5.32 (bs, 1H, H1), 4.98 (bd, J = 5.0 Hz, 1H, H5), 4.55 (bs, 1H, H3), 4.14 (d, J = 10.0 Hz, 1H, H2′), 4.04 (d, J = 7.0 Hz, 1H, H6n), 3.73 (dd, J = 7.0, 5.0 Hz, 1H, H6x), 2.78 (m, 4H, H4′ and H6′), 2.12 (d, J = 10.0 Hz, 1H, H4), 2.04 (s, 6H, Ac), and 1.98 (m, 2H, H5′). *Mol. Wt.* (hrms) calcd. for $C_{14}H_{20}O_6{}^{32}S_2$: 348.0701; found: 348.0703.

*1,6:2,3-Dianhydro-4-deoxy-4-*C*-methyl-*β*-D-mannopyranose (**9**)*

Treatment of **3** (11.4 g, 36.4 mmol) with sodium methoxide (4.0 g) in 30 mL dry MeOH and 300 mL $CHCl_3$ for 16 h produced a clean product (tlc R_f 0.45, 2% MeOH–CH_2Cl_2). After diluting with $CHCl_2$ (600 mL), the organic phase was washed with water, dried ($MgSO_4$), filtered, and evaporated. The resulting pale yellow liquid was distilled to give the title compound (**9**) as a colorless liquid, bp 90°/0.1 Torr; $[\alpha]_D^{25}$ −24.6° (c 1.57, $CHCl_3$); ^1H nmr (100 MHz), δ: 5.68 (d, J = 1.8 Hz, 1H, H1), 4.13 (m, J = 4.2, 22, 1.0, 0.5 Hz, 1H, H5), 3.76 (m, 2H, H6), 3.38 (dt, J = 1.8, 1.8, 0.5 Hz, 1H, H2), 2.88 (dd, J = 1.8, 1.0 Hz, 1H, H3), 2.11 (bq, J = 7.5 Hz, 1H, H4), and 1.23 (d, J = 7.5 Hz, 3H, CH_3); ^{13}C nmr (100 MHz), δ: 97.8 (C1), 73.3 (C2), 68.3 (C6), 53.5 (C2), 51.3 (C3), 34.2 (C4), and 16.4 (CH_3). *Anal.* calcd. for $C_7H_{10}O_3$: C 59.14, H 7.09; found: C 58.58, H 7.24.

*1,6-Anhydro-2,4-dideoxy-2,4-di-*C*-methyl-*β*-D-glucopyranose (**10**)*

To a solution of methylmagnesium chloride (2.9 M in THF, 8.5 mL, 25 mmol) and cuprous iodide (100 mg, 0.5 mmol) in 10 mL dry THF was added epoxide **9** (1.5561 g, 3.9 mmol) at −44°C. After 5 h, tlc (2% MeOH–CH_2Cl_2) showed that reaction was complete. Work-up as for **3** and chromatography (50% EtOAc – petroleum ether) provided the title compound **10** as a colorless liquid, bp 60°/0.06 Torr; 407.0 mg (66%); $[\alpha]_D^{25}$ −62.4° (c 0.82, $CHCl_3$); ^1H nmr (200 MHz), δ: 5.28 (bs, 1H, H1), 4.22 (bd, J = 5.0 Hz, 1H, H5), 4.11 (dd, J = 7.2, 0.8 Hz, 1H, H6n), 3.68 (dd, J = 7.2, 5.0 Hz, 1H, H6x), 3.30 (bd, 1H, H3), 2.50 (bs, 1H, OH, D_2O ex), 2.89 (H2), and 2.87 (H4) (2 × bq, J = 7.5 Hz, 2H), and 1.20 (C2-CH_3) and 1.07 (C4-CH_3) (2 × d, J = 7.5 Hz, 6H); ^{13}C nmr (100 MHz), δ: 104.4 (C1), 76.8 (C5), 74.6 (C3), 67.9 (C6), 42.2 (C2), 40.4 (C4), 18.5 (C4-CH_3), and 15.9 (C2-CH_3). *Mol. Wt.* (hrms) calcd. for $C_8H_{14}O_3$: 158.0942; found: 158.0945.

tert-*Butyldimethylsilyl propargyl ether (**11**b)*

To a solution of propargyl alcohol **11***a* (22.5 g, 0.4 mol), imidazole (60 g, 0.88 mol), and 4-dimethylaminopyridine (2 g) in dry CH_2Cl_2 (500 mL) at 0°C was slowly added *tert*-butyldimethylsilyl chloride (64 g, 0.4 mol). After stirring for 18 h at 25°C, the mixture was poured into water and the CH_2Cl_2 phase washed with water and bicarbonate solution, then dried (Na_2SO_4), filtered, and evaporated. The pale yellow liquid was distilled and the fraction boiling at 155–165°C redistilled through glass rings to give *tert*-butyldimethylsilyl propargyl ether (**11***b*) as a colorless liquid, 51.7 g (76%), bp 161–163°/760 Torr; ^1H nmr (60 MHz), δ: 4.25 (d, J = 2.0 Hz, 2H), 2.32 (t, J = 3.0 Hz, 1H), 0.86 (s, 9H), and 0.03 (s, 6H). *Anal.* calcd. for $C_9H_{18}OSi$: C 63.43, H 10.66; found: C 62.56, H 11.06.

*1,6-Anhydro-2,4-dideoxy-4-*O*-methyl-2-*C*-(3-*tert*-butyldimethylsilyloxyprop-1-nyl)-*β*-D-glycopyranose (**12**a) and 1,6-anhydro-3,4-dideoxy-4-*C*-methyl-3-(3-*tert*-butyldimethylsilyloxyprop-1-ynyl)-*β*-D-altropyranose (**13**a)*

To a stirred solution of TBDMS-propargyl ether **11***a* (4.66 g, 27.4 mmol), in 40 mL dry toluene at −78°C under argon, was added dropwise n-BuLi (27.4 mmol). After warming to 20°C for 30 min, the solution was cooled to −78°C, and 1.3 M Et_2AlCl (6.0 mmol) was added. After stirring for 16 h at 20°C, the epoxide **9** (780 mg, 5.47 mmol), dissolved in 15 mL toluene, was added to the white mixture and the mixture was heated to 100°C. After 20 h, the starting material **9** was completely converted to new material and the mixture was cooled to 0°C and poured into concentrated NH_4Cl solution. EtOAc and Celite were added and the mixture was filtered and washed well with EtOAc. Customary work-up and column chromatography (50% EtOAc – petroleum ether) provided a colorless liquid containing a 7:1 mixture of compounds **12***a* and **13***a*. The major isomer, **12***a*, could be purified by removal of the TBDMS group with fluoride and chromatography (EtOAc) to give the diol **12***b* as a pale yellow syrup,

bp 125°/0.1 Torr; 704.9 mg (65.7% from **9**); $[\alpha]_D^{25}$ +29.5° (*c* 0.43, $CHCl_3$); ^1H nmr (200 MHz), δ: 5.56 (s, 1H, H1), 4.33 (bd, J = 5.0 Hz, 1H, H5), 4.26 (d, J = 2.0 Hz, 2H, H3′), 4.20 (d, J = 7.5 Hz, 1H, H6n), 3.25 (m, 2H, H3 and H6x), 2.76 (bs, 1H, H2), 1.93 (bq, J = 7.0 Hz, 1H, H4), 1.60 (bs, 2H, OH, D_2O ex), and 1.32 (d, J = 7.0 Hz, 3H, C4-CH_3); ms, *m/e*: 198 (*M*, 0.2). *Anal.* calcd. for $C_{10}H_{14}O_4$: C 60.59, H 7.12; found: C 59.95, H 7.00. The regioisomers could be separated by column chromatography (30% EtOAc – petroleum ether) after acetylation to give the corresponding acetates as syrups:

(*a*) **12***c*: ^1H nmr (100 MHz), δ: 5.52 (bs, 1H, H1), 4.78 (quintet, J = 1.2 Hz, 1H, H3), 4.34 (d, J = 2.0 Hz, 2H, H3′), 4.32 (bd, J = 5.2 Hz, 1H, H5), 4.15 (d, J = 7.0 Hz, 1H, H6n), 3.78 (dd, J = 7.0, 5.3 Hz, 1H, H6x), 2.73 (bs, 1H, H2), 1.07 (s, 3H, Ac), 1.84 (bq, J = 7.5 Hz, 1H, H4), 1.37 (d, J = 7.5 Hz, 3H, C4-CH_3), 0.92 (s, 9H, 6Bu), and 0.12 (s, 6H, $SiCH_3$); ^{13}C nmr (100 MHz), δ: 169.5 (C=O), 100.9 (C1), 82.4 (C2′), 81.2 (C1′), 76.1 (C5), 73.5 (C3), 67.7 (C6), 51.7 (C3′), 37.8 (C4), 36.6 (C3), 25.7 (*t*$BuCH_3$), 21.2 ($AcCH_3$), 18.2 (*t*BuC), 17.6 (C4-CH_3), and −5.1 ($SiCH_3$).

(*b*) **13***c*: ^1H nmr (200 MHz), δ: 5.36 (bs, 1H, H1), 4.78 (dd, J = 10.0, 1.0 Hz, 1H, H2), 4.32 (bd, J = 5.3 Hz, 1H, H5), 4.25 (d, J = 2.0 Hz, 2H, H3′), 3.82 (d, J = 7.0 Hz, 1H, H6n), 3.80 (dd, J = 7.0, 5.3 Hz, 1H, H6x), 3.10 (dd, J = 10.0, 4.5 Hz, 1H, H3), 2.07 (s, 3H, Ac), 1.93 (m, 1H, H4), 1.27 (d, J = 7.5, 3H, H4-CH_3), 0.92 (s, 9H, *t*Bu), and 0.12 (s, 6H, $SiCH_3$); ^{13}C nmr (100 MHz), δ: 16.95 (C=O), 99.4 (C1), 82.3 (C2′), 82.0 (C1′), 77.2 (C5), 71.9 (C2), 68.3 (C6), 51.6 (C3′), 37.2 (C4), 82.0 (C1′), 77.2 (C5), 71.9 (C2), 68.3 (C6), 51.6 (C3′), 37.2 (C4), 30.7 (C3), 25.7 (*t*$BuCH_3$), 20.8 ($AcCH_3$), 18.2 (*t*BuC), 14.2 (C4-CH_3), and −5.1 ($SiCH_3$).

*1,6-Anhydro-4-*O*-benzyl-2-deoxy-2-*C*-(3-*tert*-butyldimethylsilyloxy-prop-1-nyl)-β-*D*-glucopyranose (**15**a)*

To a stirred solution of freshly distilled TBDMS-propargyl ether **11***b* (29.0 g, 170.8 mmol), in dry toluene (300 mL) at −78°C under argon, was added dropwise *n*-butyllithium (170.8 mmol). The solution was warmed to 0°C for 1 h. On cooling to −78°C, Et_2AlCl (106.8 mmol) was added to the dark yellow solution. After stirring for 36 h at 25°C, the light yellow mixture was warmed to 80°C and the epoxide **14** (18) (9.90 g, 42.25 mmol) was added as a solid. After 45 min, a new compound (R_f 0.48, 2% MeOH–CH_2Cl_2) had formed. The mixture was cooled to 0°C, 5 M NH_4Cl (30 mL) was carefully added, followed by Celite (30 g) and EtOAc (400 mL). The resulting mixture was filtered through Celite, the solid washed with EtOAc, and the combined organic phases evaporated and chromatographed to remove residual **11***b* (25% EtOAc–petroleum ether). The title compound, **15***a*, was obtained as a pale yellow liquid, bp >150°C/0.06 Torr; 16.9 g (99.1%); $[\alpha]_D^{25}$ +38.8° (*c* 2.36, $CHCl_3$); ^1H nmr (200 MHz); δ: 7.30 (m, 5H, ϕ), 5.52 (bs, 1H, H1), 4.52 (ABq, J = 12.5, Δδ = 0.09 ppm, 2H, CH_2ϕ), 4.54 (bd, J = 5.5 Hz, 1H, H5), 4.27 (d, J = 2.5 Hz, 2H, C3′), 3.94 (dd, J = 7.5, 0.5 Hz, H6x), 3.92 (ddd, J = 7.0, 2.5, 2.0 Hz, 1H, H3), 3.63 (dd, J = 7.5, 5.5 Hz, 1H, H6x), 3.32 (ddd, J = 2.5, 1.5, 1.0 Hz, 1H, H4), 2.67 (bt, J = 2.5 Hz, 1H, H2), 2.49 (d, J = 7.0 Hz, OH, D_2O ex), 0.82 (s, 9H, *t*Bu), and 0.03 (s, 6H, $SiCH_3$); ^{13}C nmr (200 MHz) δ: 139.0, 128.4, 127.7 (aromatic carbons), 101.8 (C1), 82.3 (C2′), 81.3 (C1′), 80.0 (C4), 75.2 (C5), 71.6 (ϕCH_2), 70.4 (C3), 66.0 (C6), 52.0 (C3′), 39.9 (C2), 25.9 (*t*Bu, CH_3), 19.7 (*t*Bu, C), and −5.0 ($SiCH_3$).

*Preparation of 1,6-anhydro-4-*O*-benzyl-2-deoxy-2-*C*-(3-hydroxypropynyl)-β-*D*-glucopyranose **15**b and 1,6-anhydro-4-*O*-benzyl-2-*O*-(prop-2-ynyl)-β-*D*-glucopyranose **16***

To a stirred solution of propargyl alcohol **11***a* (0.20 mL, 280 mg, 5 mmol) in 20 mL dry toluene was added dropwise a solution of *n*-butyllithium in hexane (1.0 M, 10 mL, 10 mmol) at −78°C under argon. The mixture was warmed to 20°C for 30 min until a transparent solution developed. It was sometimes necessary to add a few drops of tetrahydrofuran to redissolve a precipitate. On recooling to −78°C, a solution of diethylaluminum chloride in hexane (1.4 M, 4.5 mL, 6.3 mmol) was added and the resulting white mixture warmed to 20°C. After 18 h, this mixture was heated to 80°C and a solution of the epoxide **14** (18) (234 mg, 1 mmol) in 5 mL toluene was added. After 2 h, the reaction was cooled to 20°C, poured onto 5 M NH_4Cl (30 mL), diluted with 30 mL EtOAc, and filtered through Celite. The solid residue was washed with EtOAc and the aqueous phase extracted with EtOAc. The combined organic phases were dried over magnesium sulfate, filtered, and evaporated. Column chromatography on silica gel provided:

(*a*) (50% EtOAc–petroleum ether) **16** as a colorless oil, bp 110°C/0.1 Torr; 20.6 mg (7%); $[\alpha]_D^{25}$ −23.2° (*c* 1.56, $CHCl_3$); ir: 34.80 (sb), 2120 cm^{-1}; ^1H nmr (200 MHz), δ: 7.34 (m, 5H, PhH), 5.47 (bs, 1H, H1), 4.65 (ABq, J_{AB} = 12 Hz, Δδ = 0.04 ppm, 2H, CH_2Ph), 4.51 (bd, J = 5 Hz, 1H, H5), 4.28 (d, J = 2.0 Hz, 2H, H1′), 3.82 (m, 1H, H3), 3.80 (d, J = 7.5 Hz, 1H, H6n), 3.62 (dd, J = 7.5, 5.3 Hz, 1H, H6x), 3.42 (d, J = 4.0 Hz, 1H, H2), 3.29 (d, J = 4.3 Hz, 1H, H4), 2.46 (bs, 1H, OH, D_2O ex), and 2.42 (t, J = 2.0 Hz, H3′); ms, *m/e* (%): 290 (M^+, 0.5).

To test whether α-amino acids can be efficient chiral auxiliaries in asymmetric Diels–Alder reactions, the chiral dienophile *N*-acryloyl-L-phenylalanine methyl ester was made to react with cyclopentadiene. Diastereofacial selectivity is to a great extent dependent on the Lewis acid used to promote the reaction; whereas moderate excesses of the (1*R*, 2*R*)-cycloadduct were achieved with $AlCl_3$, the reaction did not show diastereofacial selectivity when titanium catalysts were used. Moreover, with $Ti(^iPrO)_4$ a transesterification reaction, which leads to the isopropyl ester and competes with the Diels–Alder reaction, was observed. In spite of the structural similarity of this dienophile to the acrylate of (*S*)-ethyl lactate, it behaved very differently in the titanium-catalyzed reactions.

MARIA P. BUENO, CARLOS CATIVIELA, JOSÉ A. MAYORAL, ALBERTO AVENOZA, PAULA CHARRO, MIGUEL A. ROY et JOSÉ M. ANDRÉS. Can. J. Chem. **66**, 2826 (1988).

Afin de déterminer si les acides α-aminés peuvent être des auxiliaires chiraux efficaces dans des réactions de Diels–Alder asymétriques, on a fait réagir le cyclopentadiène avec le dièNophile chiral suivant: l'ester méthylique de la *N*-acryloyl-L-phénylalanine. La sélectivité diastéréofaciale dépend beaucoup de l'acide de Lewis utilisé pour promouvoir la réaction; alors que le $AlCl_3$ nous permet d'obtenir de légers excès du cycloadduit-(1*R*, 2*R*), on n'a pas détecté de sélectivité diastéréofaciale lorsqu'on a utilisé des catalyseurs de titane. De plus, avec le Ti(i-PrO)$_4$, on a observé une réaction de transestérification qui entre en compétition avec la réaction de Diels–Alder et qui conduit à la formation de l'ester isopropylique. D'un point de vue structural, ce dièNophile ressemble beaucoup à l'acrylate du (*S*)-lactate d'éthyle; malgré ces ressemblances, les deux se comportent très différemment au cours de réactions catalysées par le titane.

High levels of diastereofacial selectivity have been achieved in asymmetric Diels–Alder additions of prochiral 1,3-dienes to dienophiles with a removable, chiral-directing auxiliary (1). However, it is interesting to test whether chiral reagents, both enantiomers of which are inexpensive and easily available, can be efficient chiral auxiliaries in this kind of reaction. In this context, reactions of acrylates (2) and fumarates (3) of several derivatives of chiral hydroxy acids with cyclopentadiene are reported to proceed with good selectivity, mainly when $TiCl_4$ is used to promote the reaction. The results obtained are explained by the formation of a dienophile–$TiCl_4$ chelate complex, which amplifies diastereofacial discrimination (4). Also several *N*-acryloyl and *N*-crotonyl compounds, such as the *N*-acyloxazolidones (5) and the *N*-acylsultams (6) derived from camphor, have been used as chiral dienophiles.

In spite of their availability, inexpensive natural α-amino acids, which have been used in a lot of asymmetric reactions (7), have not been tested as chiral auxiliaries in asymmetric Diels–Alder reactions. In view of that, we have studied the reaction between cyclopentadiene and *N*-acryloyl-L-phenylalanine methyl ester (**1**).

The chiral dienophile was easily obtained by reaction of L-phenylalanine with acryloyl chloride (8), followed by methylation with BF_3–MeOH complex. *N*-acryloyl-L-phenylalanine methyl ester **1** was made to react with cyclopentadiene under several conditions, using a molar relationship dienophile: diene = 1:6 (Scheme 1). The results of the reactions were determined by hplc and are shown in Table 1.

No significant solvent effect was found for the reaction of cyclopentadiene with dienophile *N*-acryloyl-L-phenylalanine methyl ester **1**, the slight changes in *endo*/*exo* selectivity conforming to the pattern found by Berson *et al.* (9) for reactions of acrylates with cyclopentadiene.

As expected, the use of $AlCl_3$ as a catalyst caused a remarkable increase in both the reaction rate and *endo*/*exo* selectivity. When the reaction temperature was lowered the *endo*/*exo* ratio increased, but diastereofacial selectivity was not noticeably modified for reaction temperatures below 0°C.

Helmchen and co-workers have previously reported (2*a*) that the use of $TiCl_4$ to promote the reaction between cyclopentadiene and the acrylate of (*S*)-ethyl lactate causes a high diastereofacial differentiation, mainly with 0.75 equiv. of Lewis acid. In spite of the structural similarity between the dienophile used by these authors and *N*-acryloyl-L-phenylalanine methyl ester **1**, in our case this catalyst gave low diastereofacial selectivity for all tested molar ratios of catalyst:dienophile.

To increase diastereofacial selectivity, a less effective titanium catalyst, $Ti(^iPrO)_4$, was tested. The relationship between the areas of the hplc peaks corresponding to the *endo* products **2***a*:**2***b* followed an unexpected pattern, since it increased with increasing reaction temperatures. A careful analysis showed that the peak corresponding to **2***a* was contaminated by a new product, which was obtained by reaction of *N*-acryloyl-L-phenylalanine methyl ester with $Ti(^iPrO)_4$ and identified as

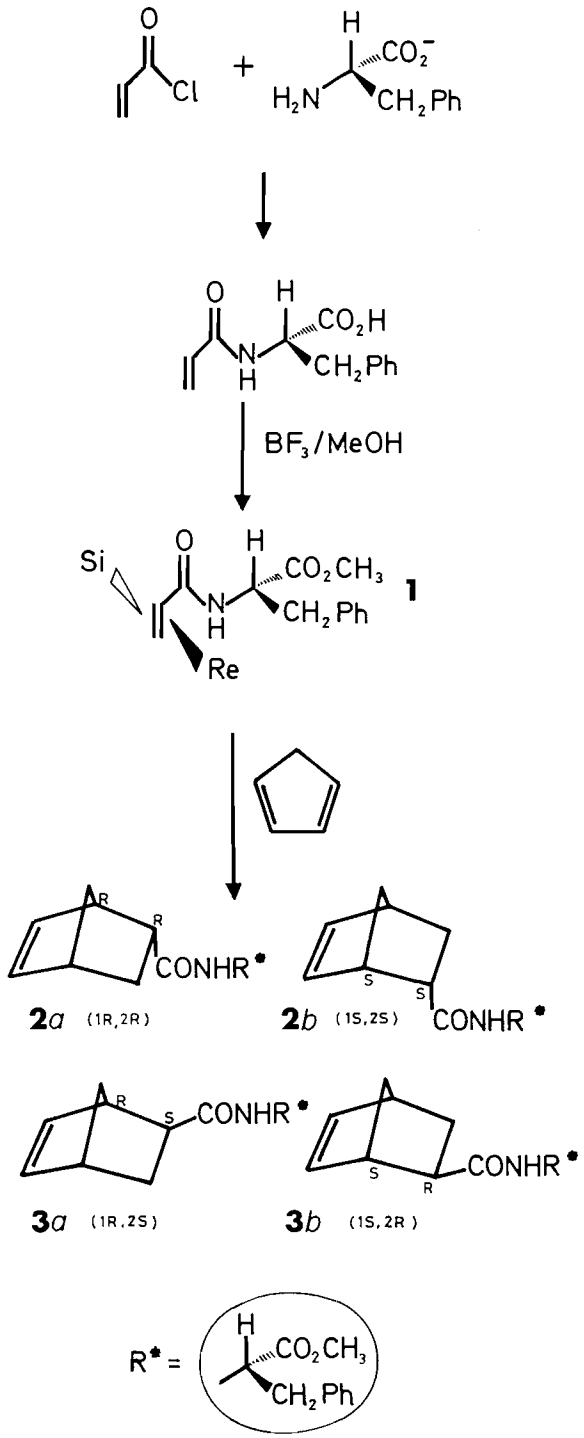

SCHEME 1

N-acryloyl-L-phenylalanine isopropyl ester **4**. The proportion of this product increases with the reaction time and temperature (Scheme 2).

When the reaction was carried out at −25°C the formation of the isopropyl ester **4** was minimized, and the ratio of **2***a*:**2***b* approached that obtained with $TiCl_4$. Neither the Diels–Alder reaction nor ester formation occurred at still lower reaction temperatures.

N-Acryloyl-L-phenylalanine isopropyl ester **4** was made to react, in CH_2Cl_2 at −40°C, with 6 equiv. of cyclopentadiene using 1.1 equiv. of $AlCl_3$ to promote the reaction. In comparison to the reaction between *N*-acryloyl-L-phenylalanine methyl

ester **1** and cyclopentadiene under the same conditions, a similar *endo*/*exo* ratio (35.4:1) but a lower diastereofacial selectivity (54:46) were obtained.

The low diastereofacial selectivities obtained with titanium catalysts suggest that the coordination of **1** with this kind of catalyst does not lead to a chelate complex, similar to that postulated by Helmchen *et al.* for the acrylate of (*S*)-ethyl lactate – $TiCl_4$ complex. However, the formation of *N*-acryloyl-

[c]The peak corresponding to **2***a* is contaminated by a small amount of *N*-acrylolyl-L-phenylalanine isopropyl ester **4**.

L-phenylalanine isopropyl ester **4** indicates that, in spite of the greater basicity of the amide moiety, there may be some degree of coordination to the ester moiety.

To determine the absolute configuration of the major product, *endo*- and *exo*-5-norbornen-2-carboxylic acids, which were prepared by reaction of acrylic acid with cyclopentadiene followed by iodolactone separation, were used to prepare *endo* and *exo* cycloadducts **2** and **3**. The *endo* mixture was separated into its components by means of column chromatography on silica gel, using n-C_6H_{14}/Et_2O (1:3) as eluting agent. By treatment of **2***a* or **2***b* with 20% aqueous NaOH only the ester moiety was hydrolysed and, after 2 h, partial epimerization was observed. Treatment of **2***a* and **2***b* with aqueous mineral acids led to a complex mixture of products, probably due to Wagner–Meerwein type rearrangements (10). In view of this, **2***a* and **2***b* were hydrogenated and converted without epimerization into both enantiomers of the *endo*-norbornan-2-carboxylic acid, **6***a* and **6***b*, by acid hydrolysis. The absolute configurations of these acids were determined by comparing their specific rotations with those given in the literature (11). Under these conditions **2***a* gave (1*S*, 2*R*, 4*R*) norbornan-2-carboxylic acid and **2***b* (1*R*, 2*S*, 4*S*) norbornan-2-carboxylic acid, with optical rotations $[\alpha]_D^{26}$ (EtOH) of +30° (*c* 1.2) and −30° (*c* 1.2) respectively (Scheme 3).

In all cases the Diels–Alder reaction led predominantly to the (1*R*, 2*R*)-*endo* diastereomer **2***a*, which comes from the attack of the cyclopentadiene on the Si face of the dienophile **1**. This result can be explained on the basis of reactive conformer **1**, with antiplanar enoate conformation, which is similar to those postulated for complexes (**7**) of "classical" chiral acrylates with only one center capable of coordination (1*a*) (Scheme 4). The preferential attack on the Si face of the dienophile **1** suggests a possible electronic effect of the phenyl group (12).

SCHEME 4

Experimental

The ^1H nmr spectra were recorded at 80 MHz with a Bruker model WP 80 CW spectrometer and at 200 MHz with a Varian model XL 200 spectrometer in $CDCl_3$ with Me_4Si as internal standard. High pressure liquid chromatography was performed using a Hewlett–Packard model 1090 M chromatograph; specific rotations were measured with a Perkin–Elmer model 241-MC polarimeter. Melting points were determined on a Buchi 510 apparatus and are uncorrected.

The chiral dienophile **1** was easily obtained by reaction of L-phenylalanine with acryloyl chloride (8) followed by methylation with BF_3–MeOH complex.

A. Diels–Alder reactions

1. Without a catalyst

One millimole of **1** and 6 mmol of cyclopentadiene were stirred under nitrogen in 25 mL of the appropriate solvent and at the temperature specified (Table 1). After the corresponding time the solvent was removed under reduced pressure and the residue was dissolved in methanol. The solution was filtered and evaporated under reduced pressure to give a solid, which was analyzed by hplc.

2. With a catalyst

One millimole of **1** and the corresponding amount of the catalyst were stirred in 20 mL of dry CH_2Cl_2 under nitrogen at the appropriate temperature for 1 h. A solution of cyclopentadiene (6 mmol) in 5 mL of dry CH_2Cl_2 at the same temperature was then added. The mixture was stirred for the adequate time (Table 1) and treated with a cold 10% aqueous NaOH solution in the case of $AlCl_3$ or 15% aqueous NaOH solution in the case of titanium catalyst. The organic layer was dried with anhydrous sodium sulfate, filtered, and evaporated under reduced pressure to give a solid, which was analyzed by hplc.

B. Synthesis of N*-acryloyl-L-phenylalanine isopropyl ester 4*

One millimole of **1** and 1.1 mmol of $Ti(^iPrO)_4$ were stirred in 25 mL of dry CH_2Cl_2 under nitrogen at the appropriate temperature for the chosen time. The mixture was then treated with a 15% NaOH solution and the organic layer was dried with anhydrous sodium sulfate, filtered,

For personal use only.

and evaporated under reduced pressure to give a solid, which was analyzed by hplc.

To obtain an analytically pure sample of **4**, the reaction was carried out with 2 mmol of $Ti(^iPrO)_4$ at room temperature for 72 h, and the solid obtained after the treatment was recrystallized from diethyl ether/*n*-hexane; mp 81–83°C; nmr ($CDCl_3$) δ: 1.12 (d, 3H), 1.22 (d, 3H), 3.12 (dd, 2H), 4.9 (m, 2H), 5.5 (dd, 1H), 6.1 (m, 3H), 7.25 (m, 5H). *Anal.* calcd. for $C_{15}H_{19}NO_3$: C 68.94, H 7.33, N 5.36; found: C 69.29, H 7.07, N 5.43.

C. Alternative synthesis of methyl-N-(endo-*bicyclo[2.2.1]hept-2-carbonyl)-L-phenylalaninates* **2**a *and* **2**b

Ten millimoles of *endo*-bicyclo[2.2.1]hept-5-en-2-carboxylic acid and 15 mmol of thionyl chloride in dry chloroform were refluxed for 3 h. After this time the solution was evaporated under reduced pressure and the residue was distilled at 14 Torr (1 Torr = 133.3 Pa) to give 80% of the corresponding acyl chloride. This compound was dripped into a solution of 8 mmol of L-phenylalanine in 10 mL of 10% aqueous sodium hydroxide previously cooled in an ice bath (if a precipitate appeared, a little more water was added). After 3 h the stirred solution was acidified with 6 N hydrochloric acid; the precipitate was filtered and recrystallized from water to give a 65% yield of *N*-(*endo*-bicyclo[2.2.1]hept-5-en-2-carbonyl)-L-phenylalanine. Five millimoles of this compound were refluxed with BF_3–MeOH complex for 2 h. The solution was washed with sodium acid carbonate solution and extracted several times with ether. The organic layer was separated and dried over anhydrous sodium sulfate. After removing the organic solvent a white oil appeared (yield 90%), which was passed through a chromatographic column of silica gel, using *n*-hexane/Et_2O = 1:3 as eluting agent, to give both diastereoisomers. These were recrystallized from *n*-hexane to give analytically pure samples of methyl-*N*-(*endo*-bicyclo[2.2.1]hept-5-en-2-carbonyl)-L-phenylalaninate **2***a* and **2***b*. mp (**2***a*) 114–116°C; nmr (**2***a*) ($CDCl_3$) δ: 1.23–1.40 (m, 3H), 1.88 (m, 1H), 2.82–2.89 (m, 2H), 3.00–3.20 (m, 3H), 3.73 (s, 3H), 4.85 (m, 1H), 5.74 (m, 1H), 6.18 (m, 1H), 7.08–7.32 (m, 5H). *Anal.* calcd. for $C_{18}H_{21}NO_3$: C 72.22, H 7.07, N 4.68; found: C 71.96, H 7.20, N 4.93. For **2***b*: mp 80–82°C; nmr ($CDCl_3$) δ: 1.24–1.45 (m, 3H), 1.92 (m, 1H), 2.81–2.90 (m, 2H), 3.00–3.20 (m, 3H), 3.73 (s, 3H), 4.83 (m, 1H), 5.85 (m, 1H), 6.18 (m, 1H), 7.06–7.38 (m, 5H). *Anal.* found: C 72.52, H 7.33, N 4.21.

Two millimoles each of **2***a* and **2***b* in 20 mL of methanol were hydrogenated at room temperature and atmospheric pressure using 10% Pd/C as catalyst until completion of the reaction (tlc). In 1 h the hydrogenation was completed, the catalyst filtered off, and the solvent removed under reduced pressure to give white solids, **5***a* and **5***b*, in quantitative yield. *Anal.* calcd. for $C_{18}H_{23}NO_3$: C 71.73, H 7.69, N 4.65; found for **5***a*: C 71.54, H 7.99, N 4.15; found for **5***b*: C 71.45, H 7.96, N 4.28.

To identify the major product in the Diels–Alder reaction, 1 millimole each of **5***a* and **5***b* in 5 mL of 6 N hydrochloric acid were refluxed for 24 h. After this time the solution was extracted with ether and the organic layer was dried over anhydrous sodium sulfate and evaporated to give both *endo* bicyclo[2.2.1]heptan-2-carboxylic acids **6***a* and **6***b* whose specific rotations were measured, $[\alpha]_D^{26}$ (**6***a*) +30° (*c* 1.2, EtOH) and $[\alpha]_D^{26}$ (**6***b*) −30° (*c* 1.2, EtOH), and compared with the literature value, $[\alpha]_D$ 30.6° (*c* 1.2, EtOH) (11).

Étude de la flash thermolyse du méthyl-5 azido-2 thiadiazole-1,3,4 par spectroscopie photoélectronique (HeI) et calculs quantiques[1]

I. B'Shary, C. Guimon, M. Grimaud et G. Pfister-Guillouzo
Université de Pau et des Pays de l'Adour, Laboratoire de physico-chimie moléculaire, Unité Associée 474, Avenue de l'Université, 64000 Pau, France

Reçu le 11 mars 1988

I. B'Shary, C. Guimon, M. Grimaud et G. Pfister-Guillouzo. Can. J. Chem. **66**, 2830 (1988).

La flash thermolyse du méthyl-5 azido-2 thiadiazole-1,3,4 sous pression réduite (10^{-2} mbar) a été suivie par spectroscopie photoélectronique ultraviolette (HeI). Elle conduit à l'obtention du thiocétène $H_2C{=}C{=}S$ accompagné d'acide cyanhydrique HCN et d'azote N_2. La formation de ces molécules montre que le thiadiazolo-nitrène instable subit une ouverture de cycle pour donner une thione linéaire **4** qui se réarrange thermiquement dans les produits finals. Ce dernier réarrangement est analysé théoriquement à l'aide de la méthode semi-empirique MNDO.

I. B'Shary, C. Guimon, M. Grimaud, and G. Pfister-Guillouzo. Can. J. Chem. **66**, 2830 (1988).

The flash thermolysis of 5-methyl 2-azido 1,3,4-thiadiazole (vapour phase: 10^{-2} mbar) was studied by ultraviolet photoelectron spectroscopy (HeI). The products detected ($H_2C{=}C{=}S$, HCN, and N_2) suggest that the unstable thiadiazole-nitrene undergoes a ring opening to form a linear thione **4**, which generates the thiocetene $H_2C{=}C{=}S$. This step was theoretically analysed by the MNDO method.

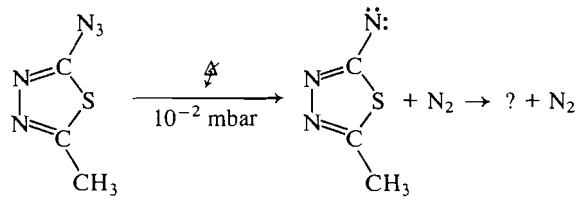
Les azotures sont utilisés depuis de nombreuses années comme précurseurs de molécules à courte durée de vie aussi bien par photolyse que par thermolyse car, perdant relativement facilement une molécule d'azote, ils génèrent un nitrène instable qui se réarrange aussitôt en composés stables ou métastables

$$R{-}N_3 \xrightarrow{\Delta \text{ ou } h\nu} R{-}\ddot{N}{:} + N_2 \rightarrow ? + N_2$$

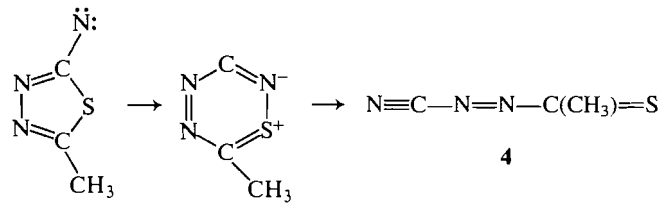
Dans le cadre d'une étude des réarrangements thermiques de nitrènes en série hétérocyclique en particulier sur le pyridino-nitrène-2 (1) et triazolo-1,2,4 nitrène-3 (2), nous avons examiné l'évolution du méthyl-5 thiadiazolo-2 nitrène **2** issu de la thermolyse éclair du méthyl-5 azido-2 thiadiazole-1,3,4 en phase vapeur et sous pression réduite ($\sim 10^{-2}$ mbar) :



1 **2**

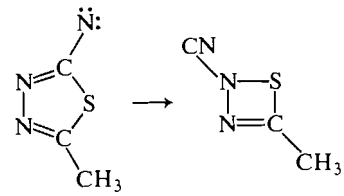
Si d'une part on admet la validité de l'hypothèse de la conservation de spin (3–5) (réaction se déroulant entièrement à l'état singulet) et si d'autre part on ne considère que les réactions monomoléculaires du fait de la faible pression, trois processus de réarrangement sont généralement proposés (3).

(a) L'extension de cycle déjà observée à basse température dans le cas des cycles à six chaînons (6, 7) conduit à un cycle de structure mésoionique à six chaînons **3**, très instable dans nos conditions opératoires, qui pourrait alors s'ouvrir pour donner le composé linéaire **4** :



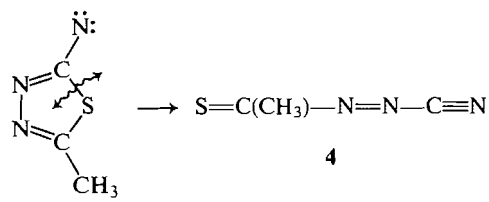
2 **3** **4**

(b) La contraction de cycle a également été mise en évidence dans le cas des cycles à six chaînons du type pyridine ou pyrimidine (1, 3, 8–10) pour lesquels on obtient des cycles à 5 chaînons. Dans notre cas, ce processus conduit à un cycle à quatre chaînons **5** évidemment beaucoup moins stable :



2 **5**

(c) L'ouverture de cycle a été postulée dans la décomposition d'azotures hétérocycliques du même type que **1** tel que l'azido-5 triazole-1,2,4 (11) et l'azido pyrazole (12, 13). Ici, comme l'extension de cycle, ce processus conduit au composé **4** :



2 **4**

Les composés métastables issus de ces réarrangements peuvent eux mêmes évoluer en produits plus stables thermodynamiquement. Ainsi, nous montrons dans ce travail que la

1. Partie 36 de «Application de la spectroscopie photoélectronique aux propriétés moléculaires». Partie 35, ref. 2.

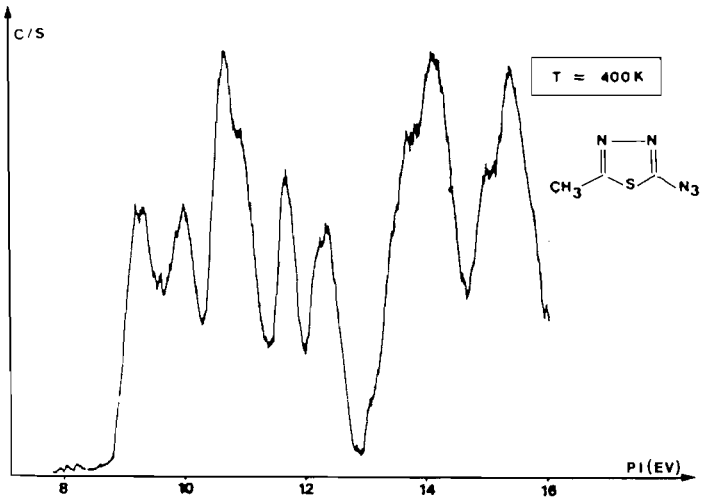


FIG. 1. Spectre photoélectronique du méthyl-5 azido-2 thiadiazole-1,3,4 avant thermolyse (400 K).

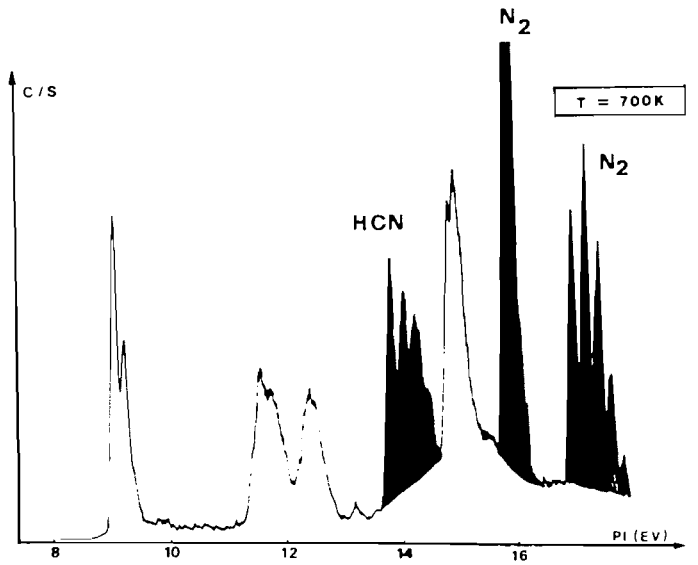

FIG. 2. Spectre photoélectronique du méthyl-5 azido-2 thiadiazole-1,3,4 après thermolyse (700 K). Les parties noires sont les bandes de HCN et de N_2.

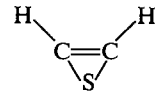
décomposition thermique du méthyl-5 azido-2 thiadiazole-1,3,4 conduit à l'obtention du thiocétène en deux étapes principales (ouverture du cycle pour former **4**, puis décomposition de **4** en $CH_2{=}C{=}S + N_2 + HCN$). Ce chemin de réaction a été analysé à l'aide de la méthode semi-empirique MNDO.

Résultats expérimentaux

Le méthyl-5 azido-2 thiadiazole-1,3,4 dont le spectre photoélectronique (HeI) est présenté dans la figure 1, commence à se décomposer à partir de 600 K pour donner le thiocétène **5** $CH_2{=}C{=}S$, l'acide cyanhydrique HCN et l'azote N_2 (bandes hachurées dans la figure 2). Ce spectre reste inchangé jusqu'à 1200 K où l'on observe l'apparition de CS_2.

Ces dernières années la structure du thiocétène déterminée par spectrométrie microondes (14–18) et son spectre infrarouge (17–19) ont intéressé de nombreux auteurs. En général sa synthèse a été effectuée soit par photolyse, soit par pyrolyse du thiadiazole-1,2,3 non substitué. Outre le thiocétène, ce précurseur est susceptible de donner également le thiirène



et l'éthényl mercaptan $HC{\equiv}C{-}SH$ (17, 20) qui sont cependant moins stables que leur homologue allénique (21–24).

Le spectre photoélectronique (figure 2) du thiocétène est tout à fait en accord avec celui réalisé par Bock *et al.* (21). La séquence des états ioniques donnée par le calcul d'interaction de configurations (cf. partie théorique) confirme l'ordre des valeurs propres du calcul SCF donné par la méthode MNDO (tableau 1). Contrairement au cas des molécules ne comprenant que des atomes de la seconde période ou même celui de composés comme l'iminosilylène et l'iminogermylène (26), le calcul d'interaction de configurations (CIPSI) donne des résultats relativement distants des valeurs expérimentales (sous estimation de 0,2 à 0,6 eV selon les potentiels d'ionisation). Cette observation avait déjà été relevée lors de plusieurs études concernant des composés sulfurés (27, 28). Il avait alors été montré que l'origine se situait dans un effet de base puisque l'élargissement de celle-ci améliorait considérablement les résultats quantitatifs. Nos résultats présentent toutefois une fiabilité qualitative certaine aussi bien au niveau de l'ordre des premiers états ioniques que de leur caractère. Ils montrent en particulier que les deux premiers d'entre eux $^2B_1$ et $^2B_2$ ainsi que le quatrième $^2A_1$ (dans une moindre mesure toutefois) sont relativement purs puisque issus à près de 90% d'une seule configuration correspondant au départ d'un électron respectivement des orbitales b_1 ($n_S - \pi_{C=C}$), b_2 ($\pi'_{C=S}$) et a_1 (σ_{CCS}). Par contre le troisième état ionique $^2B_1$, s'il a une configuration majoritaire (~70%) associée à l'orbitale monooccupée b_1 ($\pi_{CC} + n_S$), montre un mélange de configurations plus prononcé, les deux plus importantes (14% et 5%) correspondant à des effets de corrélation spécifique de l'ion, c'est-à-dire des déterminants décrivant des monoexcitations du premier état ionique. Les deux configurations suivantes (3% et 1%) correspondent à un effet de polarisation (déterminants décrivant des simples et des doubles excitations de l'état ionique étudié).

Ces deux effets ayant tendance à abaisser la valeur des potentiels d'ionisation calculés, il faut toutefois remarquer que ces calculs semblent les surestimer puisque toutes les valeurs théoriques sont inférieures aux valeurs expérimentales, celle se rapprochant le plus (0,27 eV) étant la valeur du deuxième potentiel pour lequel les effets électroniques ont le moins d'importance (0,51 eV d'écart entre $-\epsilon_i$ et le potentiel calculé après IC).

Chemin de reaction

Si, comme nous l'avons précisé dans l'introduction, nous admettons que, du fait de la faible pression ambiante, les réactions de réarrangement sont unimoléculaires et sont favorisées par un mouvement nucléaire minimal, l'obtention du thiocétène n'est explicable que par la formation intermédiaire du composé **4**. Ceci implique qu'à la suite du départ de N_2 et de la formation du nitrène, la première étape, très rapide, correspond à une ouverture du cycle. En général, cette ouverture demande moins d'énergie que la scission du groupement azido qui est l'étape déterminante au niveau énergétique et qui détermine la température pour laquelle commence le processus de dégradation thermique (2, 29). Cette température est d'ailleurs sensiblement plus basse dans ce type d'hétérocycles

$^2B_2$	11,67	$\pi'_{C=S}$	11,56	11,05	11,32
$^2B_1$	13,15	$\pi_{C=C} + n_S$	13,68	11,67	12,14
$^2A_1$	15,19	σ_{CCS}	16,05	14,07	14,55

(entre 600 et 700 K) que dans les azotures linéaires saturés (26, 30) (entre 800 et 1100 K) et est voisine des azotures linéaires insaturés comme l'azoture de vinyle (31) (650 K). Il semble donc que la conjugaison fragilise ce groupement tout en stabilisant le nitrène résultant. Nous nous sommes plus particulièrement intéressés aux processus de réorganisation du nitrène présentés dans l'introduction.

Les calculs ont été effectués à l'aide de la méthode MNDO à laquelle a été ajoutée une recherche du col (point selle) le plus bas reliant deux minima de l'hypersurface de potentiel (cf. partie théorique). Dans l'optimisation énergétique des minima (matrice des dérivées secondes avec aucune valeur propre négative) et des points selles (une seule valeur propre négative) ont été pris en compte tous les paramètres géométriques.

Nous avons tout d'abord vérifié le mode d'ouverture du cycle. Comme nous l'avons noté, cette ouverture peut soit passer par l'intermédiaire cyclique à six chaînons **3**, soit être directe. Dans ce but nous avons effectué d'une part un calcul MNDO sur ce cycle intermédiaire **3** et d'autre part la recherche du col reliant le nitrène **2** au composé linéaire **4**.

Le calcul (figure 3) montre que ce cycle est de type mésoionique avec un atome de soufre très positivé (charge nette de 0,54 e$^-$) et un atome d'azote négatif. De plus l'analyse théorique (figure 5) met en évidence que l'ouverture directe du nitrène est favorisée. En effet l'énergie d'activation de la réaction d'ouverture (différence énergétique entre le col et le nitrène de départ) est de 75 kJ mol^{-1} alors que le cycle à six chaînons **3** est moins stable que le nitrène de 96 kJ mol^{-1} et donc à 21 kJ au dessus du col direct entre **2** et **4**.

D'après les calculs MNDO, la forme stable de **4** n'est pas plane, le soufre et le groupement méthyl se trouvant de part et d'autre (angle dièdre de 76°) du plan formé par le reste du squelette (N≡C—N=N—C) (figure 4). Il n'est cependant pas exclu que ce résultat soit du à un artefact de la méthode de calcul.

Les deux formes correspondant aux configurations où les doubles liaisons N=N et C=S se trouvent en position *syn* ou *anti* sont en fait des points selles et sont respectivement à 11,6 et 30,6 kJ mol^{-1} au dessus du minimum (figure 5). Il semble donc que l'ouverture du cycle nitrène **2** débute dans le plan (allant vers la forme *syn* de **4**) puis qu'il y ait rotation autour de la simple liaison N—C. Or, l'analyse de l'hypersurface de potentiel associée aux mouvements nucléaires de **4** pour former les composés observés expérimentalement (CH_2=C=S, HC≡N, N_2) a montré que le chemin de réaction passe par la forme *anti* de **4** (figure 5). À partir de ce point, tous les atomes lourds restent dans le plan moléculaire. Nous montrons dans la figure 6 la structure de l'état de transition ET dont l'énergie totale indique une barrière d'activation conséquente de 382 kJ mol^{-1}. La hauteur de cette barrière s'explique par la scission de trois liaisons et en particulier celle de C—H. En effet, la

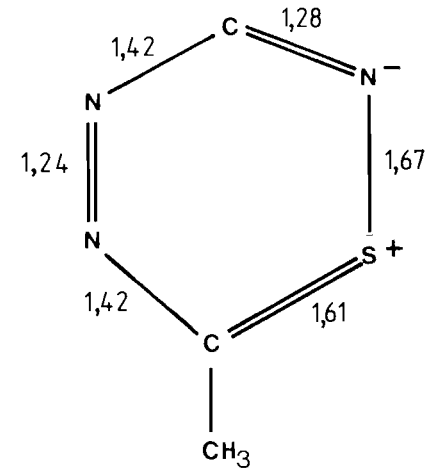

FIG. 3. Structure calculée (MNDO) du composé **3**.

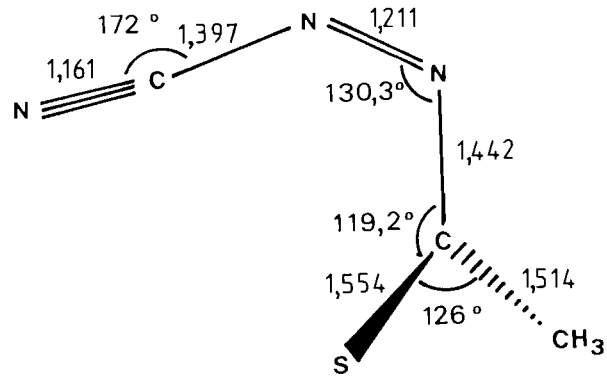

FIG. 4. Structure calculée (MNDO) du composé **4**.

structure de ET montre une pré-formation de HCN et seulement étirement des liaisons C—N. La seconde partie de cette étape (allant vers les trois molécules séparées) consiste en l'éloignement progressif de N_2 alors que les entités HCN et H_2CCS aboutissent à une structure stable (H—C≡N et H_2C=C=S) principalement par une évolution des angles définis par leurs liaisons.

Nous avons examiné en outre le chemin décrivant un processus non concerté. Celui-ci comprend plusieurs étapes, à savoir la coupure radicalaire d'une liaison C—N (→ $H_3CCS^\cdot$ + $NNCN^\cdot$), puis une seconde scission générant une molécule d'azote ($NNCN^\cdot \rightarrow N_2 + CN^\cdot$) et enfin une réaction radicalaire pour former le thiocétène ($H_3CCS^\cdot + CN^\cdot \rightarrow HCN + H_2CCS$). Il s'avère que ce processus n'est pas favorisé énergétiquement par rapport à la réaction concertée, du fait essentiellement de la très haute instabilité des radicaux et en particulier de $CN^\cdot$. En

outre, il est vraisemblable que ce type de réaction donnerait des produits parasites que nous n'avons jamais observés.

Conclusion

Lors de ce travail, nous avons montré que la décomposition thermique du méthyl-5 azido-2 thiadiazole-1,3,4 aboutissait à la formation de thiocétène accompagné d'azote et d'acide cyanhydrique. Après l'analyse des états ioniques de cette molécule, nous avons analysé le processus de cette réaction. Seul un mécanisme d'ouverture du cycle après formation initiale du thiadiazolonitrène peut rendre compte des produits observés expérimentalement. La thione linéaire ainsi formée se réarrange spontanément à la température de la pyrolyse (~700 K) par départ de N_2 intracyclique et migration d'un hydrogène du groupement méthyl sur le carbone du groupement cyano.

Partie expérimentale et théorique

L'azido-2 méthyl-5 thiadiazole-1,3,4 a été synthétisé suivant une variante de la méthode de Claramunt *et al.* (32):

formation à −10°C, à partir de l'amino-2 méthyl-5 thiadiazole-1,3,4, du phosphate de diazonium correspondant

obtention de l'azido-2 méthyl-5 thiadiazole-1,3,4 par action sur le phosphate de diazonium, de l'azoture de sodium

purification par chromatographie sur colonne de silice et recristallisation dans la chlorure de méthylène ($t°_{fus}$ = 93,5°C)

caractérisation par absorption dans l'infrarouge ($\nu_{as}N_3$ = 2145 cm^{-1}) en solution dans CH_2Cl_2.

Les spectres photoélectroniques ont été enregistrés sur un spectromètre modèle 0078 de « Photo Electron Spectrometer Laboratories Ltd » et calibrés à l'aide des doublets $^2P_{1/2}$ et $^2P_{3/2}$ du xénon et de l'argon. Pour réaliser la flash pyrolyse nous avons utilisé une sonde à « température variable » (33) permettant de chauffer la vapeur jusqu'à 1300 K pendant quelques fractions de seconde dans un tube de céramique situé à proximité immédiate de la chambre d'ionisation. Cette distance très courte permet d'obtenir le spectre photoélectronique de composés à courte durée de vie (~0.1 s) ou des produits issus de réarrangements moléculaires.

Les chemins de réaction décrivant le passage d'un minimum de l'hypersurface de potentiel à un autre (matrice des dérivés seconde à 0 valeur propre négative) ont été calculés par la méthode MNDO (34) qui présente l'avantage de donner, pour un coût raisonnable, une qualité des résultats qui s'approche de celle des méthodes *ab initio* (double

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/07/12
For personal use only.

zeta) (35, 36) plus élaborées. De plus dans le cas particulier des nitrènes hétérocycliques une étude parallèle (à paraître) effectué sur la décomposition thermique du tétrazole nous a montré que les résultats MNDO étaient quantitativement proches et qualitativement similaires aux résultats *ab initio* avec interaction de configurations. Pour ces calculs nous avons utilisé un algorithme de recherche de point selle (37–39) qui nous permet de trouver le col le plus bas situé sur le chemin reliant deux minima de l'hypersurface de potentiel.

Les données spectroscopiques ont été comparées aux valeurs des potentiels d'ionisation pris comme la différence énergétique entre les divers états ioniques et l'état fondamental. À la suite du calcul SCF effectué grâce au programme HONDO (40) sur une base de type 4.31G* (orbitales *d* de polarisation sur le soufre), une interaction de configuration, conduite sur l'état fondamental du thiocetene ainsi que sur ses premiers états ioniques, a été réalisée à partir d'un programme (41) utilisant l'algorithme CIPSI (42).

Une fonction variationnelle d'ordre zéro est construite à partir d'une sélection itérative des déterminants les plus importants, les autres étant pris en considération au travers d'une perturbation au second ordre de Möller–Plesset. Le nombre de déterminants entrant dans la fonction d'onde variationnelle est de 60, celui généré dans le calcul perturbationnel étant compris entre 6×10^5 et 10^6.

La structure moléculaire utilisée pour ces calculs est tirée d'une optimisation de l'énergie totale prenant en compte tous les paramètres géométriques grâce à un processus de minimisation à métrique variable avec évaluation du gradient selon l'algorithme de Broyden–Fletcher–Goldfard–Shanno (43) inclus dans le programme « Monstergauss » (44, 45), la base choisie étant identique aux calculs précédents.

Computational study of heterocyclic thione ligands. Part I. Five-membered heteroatomic thiones possessing an α-nitrogen heteroatom

GEORGE S. KAPSOMENOS AND PERICLES D. AKRIVOS

Department of General and Inorganic Chemistry, P.O.B. 135, GR-540 06 Thessaloniki, Faculty of Chemistry, Aristotelian University of Thessaloniki, Greece

Received September 30, 1987[1]

GEORGE S. KAPSOMENOS and PERICLES D. AKRIVOS. CAN. J. CHEM. **66**, 2835 (1988).

A SCF-MNDO study is made of the equilibrium between the "thiol" and "thione" tautomers of four species possessing a five-membered heterocyclic ring, where nitrogen and oxygen or sulfur are the α-heteroatoms. Based on the computationally derived $\Delta(\Delta H_f)$ values for each pair of forms, evidence is presented for the possibility of co-occurrence of the two forms in solution. The tautomerism is particularly interesting in this class of compounds, since it offers the possibility for a sulfur, nitrogen, or sulfur and nitrogen coordination. The nucleophilicity of each specific site in both forms is discussed in terms of net atomic charges and the HOMO constitution of the molecules. Results concerning the study of metal complexes are generally in accordance with these considerations, since the preference for a specific donation scheme is governed by an HSAB criterion.

GEORGE S. KAPSOMENOS et PERICLES D. AKRIVOS. CAN. J. CHEM. **66**, 2835 (1988).

On étudie par la méthode SCF-MNDO l'équilibre entre les tautomères thioniques et thioliques des quatre espèces possédant un anneau hétérocyclique penta atomique avec des atomes d'azote, d'oxygène ou de soufre en position α. On met en évidence la possibilité de coexistence des deux formes en solution, basée sur un calcul des valeurs $\Delta(\Delta H_f)$ pour chaque couple de formes. La tautomérie est particulièrement intéressante dans cette classe des composés parce qu'elle offre la possibilité de coordination par l'intermédiaire de l'atome de soufre, d'azote ou d'azote et soufre en même temps. On discute le charactère nucléophile de chaque coté spécifique pour les deux formes en termes des charges atomiques nettes et de la constitution HOMO des molécules. Les resultats concernant l'étude des complexes métalliques sont géneralement en accord avec ces considérations parce qu'un critère HSAB gouverne la préférence pour un schema particulier de coordination.

Introduction

Heterocyclic thiones possessing α-heteroatoms show a variety of bonding modes toward different metal ions; this coordination behaviour has been reviewed quite recently (1). In particular, five-membered heterocyclic thiones with N in the α-position reveal a coordination potential, which is affected by several factors, predominantly by prototropic tautomerism occurring in the ligand, and in particular, which tautomer–(Fig. 1) is present in solution immediately prior to the metal-ligand bond formation (2). Though structural analysis (3) and ^{1}H NMR results concerning the free ligands account for the predominance of the thione form (Fig. 1*a*), the NMR studies of complexes (4) indicate the presence of —SH groups and therefore support a through nitrogen coordination (i.e. ligand structure as in Fig. 1*b*). This is the case of benzo-1,3-thiazoline-2-thione, benz-1,3-oxazoline-2-thione and a series of related ligands (5).

Thus, the suggested prototropic migration taking place between heterocyclic N and exocyclic S gains importance considering the plethora of bonding schemes toward different metal centres. An equilibrium in solution between the "thiol" and "thione" forms or the predominance of one of them would possibly account for the aforementioned observations.

Therefore, a quantum chemical calculation of the energy stabilization of one form relative to the other would be of interest since evidence should be provided for the possibility of coexistence of both forms in solution. The need for such a determination has led to the proposition of several empirical models, among which that of Duus (6), where the percent occurrence of each form emerges from an analysis of the UV–Vis and EPR spectra of the studied compounds.

Furthermore, in a series of analogous compounds, the role of a second heteroatom may be investigated along with the influence of substitutions such as a double bond or a delocalized π-system on the "thionic" character of the compounds under discussion.

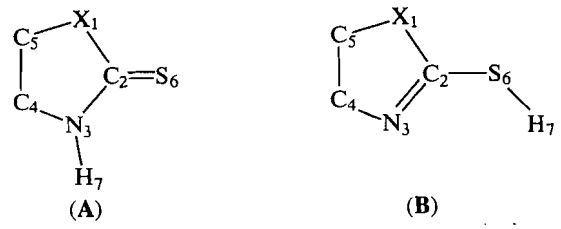

FIG. 1. The atomic numbering scheme in the five-membered heterocyclic ring for the "thione" (**A**) and the "thiol" (**B**) tautomers discussed.

Computational details

The results presented and discussed in this report emerged by carrying out MNDO-SCF calculations (7) as implemented in the MNDOC ensemble of programs (8). The parameters used for sulfur were those proposed by Dewar and McKee (9*b*). These were recently revised by Dewar and Reynolds (9*d*), but their improved set is particularly important when dealing with compounds having SS bonds and will not alter the main conclusions herein obtained, as will be discussed presently. The approximation used has proved to be effective in studies analogous to the present one (9, 10), giving, in general, results comparable or parallel to those of *ab initio* studies, which if used in the present case, would have been impractical.

The relevant internal coordinates of the studied compounds have been fully optimized by means of the DFP algorithm included in the above mentioned package. Table 1 includes all the final internal coordinates, whereas Fig. 1 presents the numbering scheme of the basic five-membered ring in both tautomeric forms considered. The only structural constraint used in the case of the benzo-derivatives, is the assumption of an ideal benzene ring.

Discussion

Calculations on the thione forms of the discussed compounds directly taken from crystallographic data (3, 11) led to unrealistic $\Delta(\Delta H_f)$ compared to theoretical data (10, 12) and also to experimental suggestions (1), so the comparison will be made between the optimized structures.

Table 1 presents in brackets the experimental values (16) for the geometries of some of these compounds. The main conclusion is a general underestimation of bond distances, a result also noted by Dewar *et al.* (9*b*, *d*). Thus, in the lengths of SH and SC bonds the errors are ca. 0.027 and 0.045 Å, respectively.

Regarding the effect of the second heteroatom on the thionic character of the exocyclic group, substitution of O by S generally leads to shorter SC bonds as can be seen from the results also contained in Table 1. This is apparently a consequence of the more electronegative character of O relative to S. Thus, oxygen "attracts" electron density from the neighbouring carbon atom, subsequently enhancing the polarity of the SC bond. The atomic net and p_π charges presented in Fig. 2 indicate, as expected, that this electron withdrawing is associated with the σ-rather than the π-system of the molecules. Further evidence for this charge withdrawing ability of oxygen relative to sulfur is the case of **2** and **4** (hereafter, each specific molecule will be referred to by using the notation used in Fig. 2) and the π-system involving C(2), N(3), C(4), and C(5) in each of them. The bond distances and atomic p_π charges associated with these systems strongly suggest an enhanced electron donating character for sulfur. The additional charge provided to C(5) in **4**, certainly provokes a stronger C(5)—N(4) p_π overlap and in an indirect way a weaker N(4)—N(3) and a stronger N(3)–C(2) one.

The concept of coordination to a metal ion, is generally understood in terms of the net atomic charges and the partitioning of the HOMO of the ligands. The net charges (Fig. 2) are indicative for a preference for nitrogen donation in the case of thiol forms while in the thione ones, the thioketo sulfur atom possesses a negative charge comparable, though less than that of nitrogen. The effect of the second heteroatom on the charge resident on N may be readily explained in a qualitative way, based on the same arguments as in the dependence of the SC bond character on the same factor (*vide supra*). The effect of the substituent at the 4- and 5-position of the heterocyclic ring on the nitrogen atom on going from the thiol to the thione tautomers is a depression in the amount of its net charge. This effect is less pronounced in the case of the benzo-compounds, thus providing grounds for the argument that the N charge reduction is related to the capacity of the system to transform the CN bond from a single one in the thione tautomer to a double one in the thiol one. Apparently this capacity is rather limited in the case of the benzo-compounds owing to the fact that the C(5)—C(4) bond possesses only partial double bond character.

The enhanced role of the thioketo S atom in the coordination of the thione tautomeric forms is also indicated by the constitution of the HOMOs of the ligands under study, which

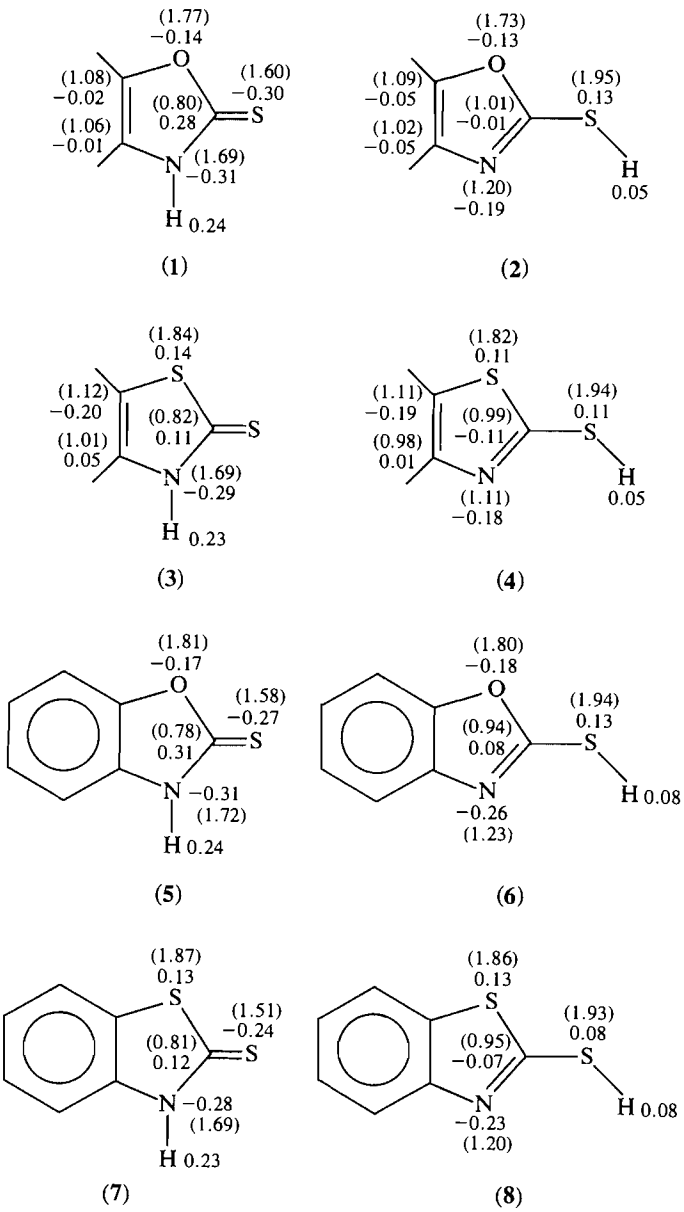

FIG. 2. The atomic net and p_π charges (in parentheses) for compounds **1**–**8**.

are responsible for the electron donation to the metal ions. It is quite evident that in the thione tautomers, sulfur donation is the main phenomenon, while in the thiol ones, nitrogen participation in the HOMOs gains in importance and in the benzo-compounds exceeds even that of sulfur. In every case, the HOMO is extensively delocalized over the entire molecule, especially in the region of the double bond or the aromatic system. The HOMO eigenvalues presented in Table 2, along with the coefficients by which N and S participate in them, suggest, as would have been expected, that the thiol tautomers are harder (13) than their thione counterparts, i.e. **2** will preferably attack an electrophilic metal site via the nitrogen atom, whereas **1** would most probably adopt a through-sulfur coordination scheme. Of course, in such a limited series of compounds, with the HOMO eigenvalues lying within a rather small energy margin, one cannot propose a strict classification according to the HSAB (14, 15) criterion, but only discuss the relative hardness or softness of the compounds. Nevertheless, the relative hardness of the thiols with respect to the corresponding thiones, as it follows from their HOMO eigenvalues is in accordance with the more significant nitrogen participation in their HOMOs relative to that of their thione analogues.

TABLE 3. Heats of formation (corrected) and their difference for the the tautomeric forms of the studied compounds in kJ mol^{-1}

1	2	3	4
−16.83	27.13	146.02	202.84
43.96		56.82	
5	**6**	**7**	**8**
42.81	107.43	190.44	284.22
64.62		57.78	

Moreover, the question arises whether the ligands discussed will act toward metal centres in their thiol or thione forms. To go into such a question we present in Table 3 the difference in the energies of formation of the tautomeric forms. The $\Delta(\Delta H_f)$ values computed for the discussed compounds are presented in Table 3.

The thione form should be the prevailing one for benz-1,3-oxazoline-2-thione, since it is more stable than its tautomeric form by 64.6 kJ mol^{-1}. The preference for the thione form should be lower in the case of benzo-1,3-thiazoline-2-thione, since the thione forms are calculated to be more stable than their thiol counterparts by 57.8 and 56.8 kJ mol^{-1}, respectively. Some larger amounts of "thiol" should be present in the case of 1,3-oxazoline-2-thione as the thione is favoured by only 43.9 kJ mol^{-1}. Based on the above results, one would expect the compounds to ligate through the exocyclic sulfur atom, while the benzo-derivatives may also act in a bridging fashion through both S and N atoms as has been argued in a few instances.

The mean error in enthalpies of formation calculated by the MNDO method is ca. 44 kJ mol^{-1}, as pointed out by Dewar and McKee (9*b*). However, this is the case when the complete list of molecules presented by these authors is considered. This list contains molecules with SS bonds as well as molecules for which one must, probably, include *d* functions in the basis set. If we exclude such molecules, the average error is much smaller (ca. 12.5 kJ mol^{-1}) and our conclusions still apply. It must also

For personal use only.

be noticed that for the final enthalpies we have applied the corrections proposed by the above authors.

Thus, it could be suggested that the thione form of the compounds prevails initially in solution. A hard metal site could, however, provoke a prototropic migration from nitrogen to sulfur forcing the ligand to coordinate mainly through nitrogen, while a soft metal would coordinate to the thioketo sulfur atom of the thione form. Complexes that have been prepared in neutral media express bonding modes that are in accordance with these MNDO predictions, but the NH hydrogen atom is very labile and even in slightly alkaline media will be eliminated in favour of the corresponding anionic species which have attracted much more interest than the neutral ones.

Acknowledgement

The authors wish to express their thanks to Professor Dr. W. Thiel for his useful comments regarding the use of the MNDOC package of programs.

Structure and reactivity in highly halogenated ketazines

ELLEN C.K. LAI, DONALD MACKAY,[1] NICHOLAS J. TAYLOR, AND KENNETH N. WATSON[2]

The Guelph–Waterloo Centre for Graduate Work in Chemistry, Department of Chemistry, University of Waterloo, Waterloo, Ont., Canada N2L 3G1

Received July 21, 1987[3]

ELLEN C.K. LAI, DONALD MACKAY, NICHOLAS J. TAYLOR, and KENNETH N. WATSON. Can. J. Chem. **66**, 2839 (1988).

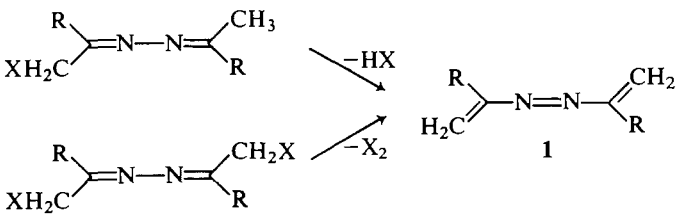
The azines of acetophenone and its mono- and di-chlorinated derivatives show a bathochronic shift in the yellow region, but the azine of trichloroacetophenone is colorless. Similar trends are observed in the brominated analogs and in the chlorinated propiophenone azines. The colorless tetrachloropropiophenone azine (**13**) is shown by X-ray analysis to be nonplanar at the azine atoms (N—N torsion angle, 126.7°). Hexachloroacetophenone azine (**9**) undergoes displacement of all its chlorines with NaOMe to give the hexamethoxy compound **16**, also colorless. With acid, **16** gives the yellow planar (X-ray) ketazine diester **20**. These reactions appear to be general for the trichloromethyl group in azines, but not for the α,α-dichloroalkyl group, attempts at the sequence **13** to **28** proving unsuccessful.

ELLEN C.K. LAI, DONALD MACKAY, NICHOLAS J. TAYLOR et KENNETH N. WATSON. Can. J. Chem. **66**, 2839 (1988).

Les azines de l'acétophénone et de ses dérivés mono- et di-chlorés présentent un effet bathochrome vers la région jaune; toutefois, l'azine de la trichloroacétophénone est incolore. Des tendances semblables ont été observés avec les analogues bromés ainsi qu'avec les azines de la propiophénone chlorée. Faisant appel à la diffraction des rayons-X, on a démontré que, au niveau des atomes de l'azine (angle de torsion N—N de 126,7°), l'azine incolore de la tétrachloropropiophénone (**13**) n'est pas plane. Sous l'influence du NaOMe, tous les atomes de chlore de l'azine de l'hexachloroacétophénone (**9**) subissent des réactions de substitution qui conduisent au composé hexaméthoxy, **16**, qui est aussi incolore. En milieu acide, le composé **16** conduit au cétazine diester, **20**, qui est jaune et plan (diffraction des rayons-X). Ces réactions semblent générales pour le groupement trichlorométhyle des azines. Toutefois, ce n'est pas le cas pour les groupements α,α-dichloroalkyles; en effet, des essais effectués en vue de transformer le composé **13** en **28** se sont avérés infructueux.

[Traduit par la revue]

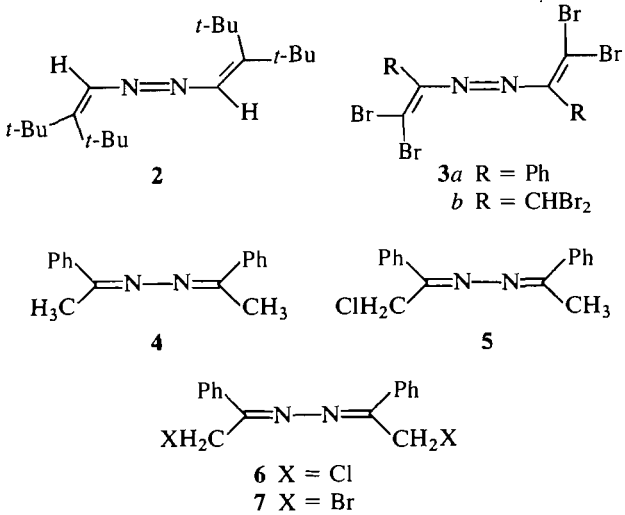
In conjunction with our studies on conjugatively unsaturated azo compounds (1, 2), we became interested in the halogenation of azines as potential routes to the terminally unsubstituted 3,4-diazatrienes **1** (methylene analogs of azodiacyls), e.g. as in Scheme 1.



SCHEME 1

Compounds of type **1** have so far not been described though the fully substituted examples **2** and **3** have been prepared (3, 4). We chose acetophenone azine **4** as a starting point for this chemistry.

Both α-chloro (**5**) and α,α′-dichloroacetophenone azine (**6**) have been observed in the mixture obtained when the parent azine is treated with one equivalent of Cl_2 in CCl_4 (5), but neither has been characterized. We attempted to synthesize **5** by reaction of acetophenone hydrazone and chloroacetophenone and obtained only a mixture of **4**, **5**, and **6**. Azine formation is clearly reversible under these conditions. The dichloro-azine **6** was made in a modest yield by the acid-catalyzed reaction of α-chloroacetophenone and hydrazine (2:1). The dibromo analogue **7** is available from the known reaction of acetophenone azine with Br_2 in methanol (6), conditions which give only coupling products in the analogous reaction with Cl_2 (7).



Attempts to dehalogenate **6** or **7** or to dehydrohalogenate **5** (as in Scheme 1) to 2,5-diphenyl-3,4-diaza-1,3,5-triene (**1**, R=Ph) have so far been unsuccessful, but some of the physical and chemical properties of the halogenated acetophenone azine and propiophenone azine are of sufficient interest to warrant reporting on here.

The chlorination of these azines has been studied in some detail (5). In the case of acetophenone azine either 1,4-addition to give the azo compound **8**, or substitution, occurs cleanly, depending on solvent and temperature (Scheme 2). One equivalent (5), or an excess, of Cl_2 in methylene chloride at −70°C gives **8**. In carbon tetrachloride only substitution is observed, 6 equivalents of Cl_2 giving the hexachloro compound **9** at room temperature (5). Lower levels of Cl_2 gave the expected mixtures of partially chlorinated azines. One equivalent gave mainly **5** and **6**, but also starting material and small

[c]Reference 4.

amounts of more highly chlorinated products; for example methine absorption is observed in the ^{1}Hmr spectrum ($CDCl_3$) at δ 7.2, possibly due to compound **10**, as well as peaks for the other expected symmetric and unsymmetric products.

Two spectroscopic trends concerning acetophenone azine and its symmetrically chlorinated derivatives intrigued us. The yellow color of acetophenone azine (λ_{max}, cyclohexane, 290 nm) deepens on dichlorination (compound **6**: λ_{max}, 309 nm). We could not purify the tetrachloro derivative **10** from the mixture of chlorinated isomers, but solutions rich in it were yellow; it has been described, without details, as a yellow product obtained by the photolysis of *N*,*N*-dichloro-α-phenylethylamine (8). The fully chlorinated compound **9**, however, is *colorless* (λ_{max}, 244 nm). The bromo derivatives, inherently deeper in color, show the same trend: the dibromo compound **7** is orange, the tetrabromo compound **11** has not been prepared, and the hexabromo compound **12** is pale yellow. The absorption spectroscopy data for all these and related azines are given in Table 1.

Propiophenone azine is yellow, but its tetrachloro derivative **13** (5) is colorless. The α,α′-dichloropropiophenone azine has not been reported.

The second feature of note was found in the phenyl region of the ^{1}Hmr spectra. In both acetophenone azine and propiophenone azine, and in all but their fully halogenated derivatives, the *ortho* protons appeared downfield of and fully resolved from the *meta* and *para* protons, the expected pattern in a phenyl group attached to a conjugatively electron-withdrawing group. By contrast, in the fully halogenated azines **9**, **12**, and **13** separation of the *o* peaks from the others was very much less (the phenyl peak of **12** was a singlet); their Ph nmr absorptions are also given in Table 1. A similar collapse of the ring aryl protons to a singlet has been observed in the spectrum of α,α-dichloroalkylarylketimines (9).

The abrupt change in both these properties with the introduction of the last halogen atoms made us wonder whether in fact structures **9** and **13** were correct, and if instead a profound structural change had occurred at this last step. For example, in the case of tetrachloroacetophenone azine a final 1,4-addition followed by oxidative cyclization would give the cyclic hexachloro azo compound **14**, which, like **8**, would be colorless. The latter has only a very slight separation of the *o* from the *m* + *p* protons in its nmr spectrum.

An alternative possibility was that the extended conjugation responsible for the yellow color in the azines **5**–**7**, **10**, and **11** was destroyed in the fully halogenated azines **9**, **12**, and **13**, by twisting of the two halves around the N—N bond. This in fact appears to be the case.

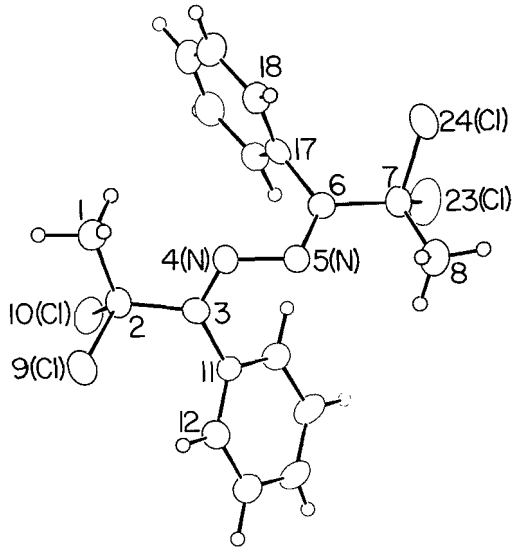

FIG. 1. ORTEP drawing of tetrachloropropiophenone azine, **13**.

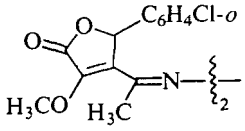
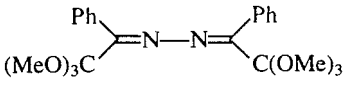
The X-ray crystallographic analysis of the propiophenone azine derivative **13** (Fig. 1, ORTEP II plot, C.K. Johnson, Oak Ridge National Laboratory, Oak Ridge, TN, 1976) shows it to have the *E,E* configuration with an N—N torsion angle of 126.5(5)°. Bond lengths and angles are shown in Table 2. As expected from the space group of the crystal (See Table 5, experimental section) the molecule has no symmetry element, and differences exist between corresponding angles and distances on either side of the N to N bond. For example the torsion angles for C(2)C(3)N(4)N(5) and C(7)C(6)N(5)N(4) are 178.6(5)° and 179.1(5)° respectively, and for C(11)C(3)N(4)N(5) and C(17)C(6)N(5)N(4) they are 175.2(5)° and 176.9(5)°.

A search of the X-ray crystallographic literature shows that of six ketazines on record (10–14),[4] all of them colored, three have a locally planar arrangement around the C=N—N=C portion (10–12). C to N and N to N bond lengths and the N—N torsion angle of these six ketazines and of **13** are shown in Table 3. We expected that in the planar azines delocalization through the C=N—N=C system would lead to longer C to N and shorter N to N bonds than in the twisted azines. There is in fact no such discernible pattern. From bond length data at least, the evidence for delocalization between the two halves of a planar azine is much weaker than it is from ultraviolet–visible spectroscopy.

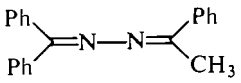
One of the planar ketazines cocrystallizes in a red modification along with one of the nonplanar ketazines that is yellow (10, 15). They are both *E,E* forms of the lactone derived azines **15**,



15



16



17

and are alleged to differ structurally only in the torsion angle at N—N, despite their non-identical ^{1}Hmr and solution ir and uv spectra (15). In fact the crystal structure diagrams of these show them to be stereoisomers (chiral ring carbon), the red compound being the *meso* and the yellow the *racemic*. Both of these have extended conjugation in each separate half of the molecule, accounting for the yellow color in the nonplanar form. One of the other two nonplanar azines, that of benzylidene acetone (13), likewise has extended conjugation. The remaining nonplanar ketazine, that of 4,4′-dihydroxyacetophenone, which is described as pale yellow (14), has a hydrogen-bonded water molecule in the crystal; the origin of the color is not obvious.

While trichloroacetophenone gives the haloform reaction with aqueous NaOH (to benzoate ion), or with NaO-*t*-Bu in cyclohexene (to *tert*-butyl benzoate) (16), its azine **9** proved remarkably resistant to alkali, being largely recovered after a 10-h reflux.

With NaOMe in refluxing MeOH, substitution of all six chlorines in **9** occurred to give the hexamethoxy compound **16**. The conversion of CCl_3 into $C(OR)_3$ is a venerable reaction when the reacting carbon is part of a locally saturated system (17), but examples are also known where the reacting carbon is next to a conjugatively electron-withdrawing function, for example in the conversion of 2-trichloromethylimidazoles into the imidazole ortho esters (18, 19). In related cases conversion of CCl_2OR into $C(OR)_3$ adjacent to ester groups leads to trialkoxyacetate esters (hemiorthooxalates) (20–24), and from them trialkoxyacetamide derivatives (22, 23).

We tried with ^{1}Hmr spectroscopy to monitor the sequence of introduction of the MeO groups into **9**, using a range of NaOMe concentrations and reaction times. Twelve different methoxy shifts are possible in principle in the mixture of nine products formed when **9** is substituted one to six times with MeO

[4]A total of 22 azine crystal structures (three for benzaldehyde azine) were found in the CRYSTOR database as of August 1986. Those not referenced here consist of azines in which either or both of the nitrogen attached groups are derived from aldehydes or from less common carbonyl derivatives (e.g., thio- or chloro-carbonyl). We thank Dr. S.R. Gough, Services Coordinator, Scientific and Technical Information, Ottawa, for undertaking this search for us.

groups.[5] The nmr spectra were complex under all conditions and we were unable to analyze them. Methoxy absorptions occurred in three regions, representing mono- (near δ 4.0), di- (near δ 3.4), and tri- (near δ 3.0; δ 3.05 for **16**) substitution on a given carbon (Cl thus has a more deshielding effect than MeO on a geminal MeO group); each of these regions has a possible maximum of four peaks.

To try to simplify the problem we synthesized the mixed azine **17** (25) and chlorinated it (3–4 equivalent Cl_2 at room temperature) to **18**, a colorless, rather unstable, solid. Replacement of the chlorines (3–4 equivalents MeO^- in refluxing MeOH) proceeded smoothly to the oily **19**. Low levels of MeO^- (one equivalent) produced rapid buildup (Scheme 3) of the mono- (δ 3.99) but much less of the di- and tri-methoxy derivatives (δ 3.25, 3.09; ratio ca. 8:2:3). In a reaction with 3 equivalents of NaOMe, growth of the trimethoxy derivatives was very rapid and the amount of di- was always less than that of the mono-methoxy derivative (ca. 6:1:10 after 3 h reflux). These results suggest that both k_1 and k_3 are considerably larger than k_2. This may simply reflect a mechanistic change (e.g., S_N2 to S_N1) between the first and third steps, but no detailed kinetic studies were carried out, and we can only assume that the same relative rate effects pertain to both ends of the hexachloro compound **9**.

The solid colorless **16**, which like **13** presumably has a significant torsional angle round the N—N bond, is the azine of methyl benzoylorthoformate. As expected for an orthoformate (26), it was rapidly converted in acidic MeOH into a yellow crystalline solid, $C_{18}H_{16}N_2O_4$, mp 140–141°C, which showed

[5]This number is that predicted for the *E,E* azine only. In none of this work did we have evidence for the presence of any other stereoisomer.

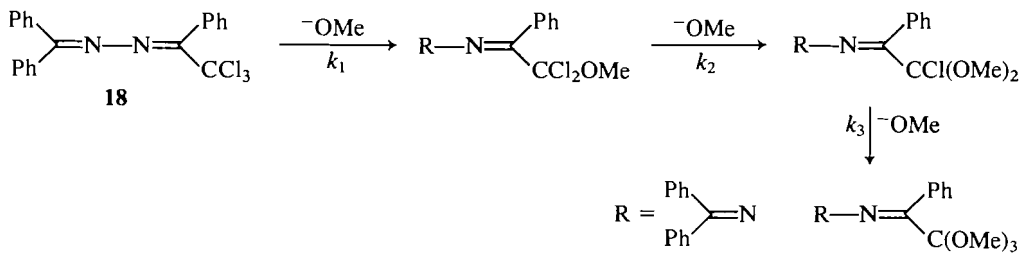

SCHEME 3

equivalent MeO groups at δ 4.00 and strong and weak bands at 1746 and 1609 cm^{-1} in its ir spectrum (CCl_4), attributed to C=O and C=N. An X-ray crystal structure determination showed this compound to be the planar *Z,Z* diester **20** (Fig. 2), the azine of methyl benzoylformate. Its imine stereochemistry is opposite to that found in **13**. Selected bond lengths and angles are shown in Table 4 (see also Table 3). Molecular dimensions are identical in both halves of the molecule, which has an inversion centre. The C to N and N to N bond lengths in this planar azine are not significantly different than those in the twisted azine **13**.

The functional groups found in **16** and **20**, the azine of an α-keto orthoester and of its derived carboxylate ester, are to the best of our knowledge the first examples of their kind in the literature. The closest analogies to **16** are the aforementioned imidazole (18, 19), ester, and carboxamate (20–24) derivatives and, in particular, α-imino ortho esters synthesized from the hydrazonium salts of pyruvaldehyde acetal (27).

The trimethoxy azine **19** similarly gave the yellow ester **21**, mp 118–118.5°C, on treatment with acidic MeOH.

Treatment of **16** with acidic EtOH rapidly gave a mixture of the diesters **20** and **22** (ca. 0.5:1). There was no evidence of the mixed diester **23** in the nmr spectrum (unless its alkoxy peaks coincided with the corresponding ones in **20** and **22**), a surprising result. The diester **22** was formed directly from **16**, and not by way of **20**, which was stable to these conditions over a long time. An authentic sample of **22** was made by transesterification of **20** with NaOEt in EtOH.

Hydrazone exchange could be effectively used to liberate the

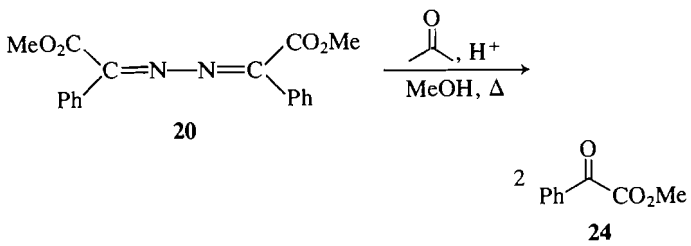

SCHEME 4

keto ester **24** from its azine **20**, by refluxing the latter in acetone in the presence of MeOH containing HCl (Scheme 4). Attempts to reconvert **24** into **20** using hydrazine (0.5 equivalents) showed that the azine was only one of several products that could not be readily separated.

In the general case of a perhalogenated phenyl alkyl ketone, the sequence analogous to **9** → **16** → **20** would result in the formation of the azine of an α-diketone, **25** → **26** → **27** (Scheme 5). With tetrachloropropiophenone azine (**13**), however, reaction with NaOMe–MeOH was very complex. The product mixture had a larger number of MeO peaks in it, and it was not particularly simplified on addition of dilute acid. There was no clear evidence of the presence of the expected azine of phenylmethylglyoxal, **28**. Related chemistry describing the reactions of α,α-dichloroalkylarylketimines with NaOMe–MeOH was similarly complex, mixtures of unsaturated halogenated and methoxylated ketones being produced (9). In light of the well-established synthesis of ketones by reaction of Grignard reagents with simple ortho esters ($RC(OEt)_3 + R'MgX \rightarrow RC(R')(OEt)_2 \rightarrow RCOR'$) an alternative route to **28** from the trimethoxy compound **16** seemed feasible. The latter, however, proved quite inert to an excess of either methylmagnesium iodide or methyllithium.

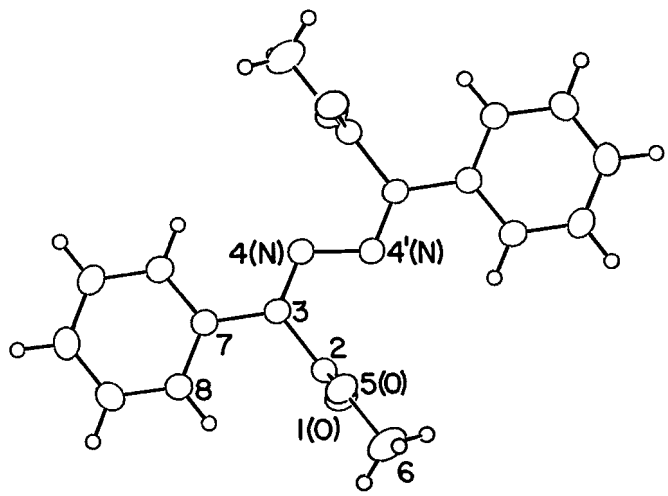

FIG. 2. ORTEP drawing of methyl benzoylformate azine, **20**.

Experimental

The following spectrometers were used: for infrared, a Perkin Elmer 983, samples being run in Nujol mulls or in solution in CCl_4 or $CHCl_3$; for ultraviolet, a Unican SP 800 with cyclohexane as solvent; for ^1H and ^{13}C nmr, a Bruker WP 80 or AM 250 ($CDCl_3$ as solvent). Melting points are uncorrected. Elemental analyses were done by Guelph Chemical Laboratories, Guelph, Ontario.

Magnesium sulfate was used as drying agent for solutions in organic solvents. The uv and ^1Hmr data for compounds **4–7**, **9**, **12**, **13**, **16**, and **20** are listed in Table 1. Hexachloroacetophenone azine (**9**) and tetrachloropropiophenone azine (**13**) were prepared as described by Malament and McBride (5), and dibromoacetophenone azine by the method of Tsuge *et al.* (6).

Attempted synthesis of α-chloroacetophenone azine (5)

Acetophenone hydrazone (4.4 g, 32.5 mmol) and α-

27

SCHEME 5

chloroacetophenone (5.0 g, 32.5 mmol) were dissolved in EtOH (50 mL) and the solution cooled in ice over 3 h. Colorless crystals (an inorganic salt, probably hydrazine hydrochloride) were filtered off. The filtrate was kept overnight, and evaporated to a small volume to give a precipitate (2.0 g), consisting of a mixture of acetophenone azine, and the symmetrical and unsymmetrical azines **6** and **5**.

α,α′-Dichloroacetophenone azine (6)

α-Chloroacetophenone (10 g, 65 mmol), freshly distilled anhydrous hydrazine (1.0 g, 33 mmol), and 12 M hydrochloric acid (2.7 mL, 33 mmol) were dissolved in ethanol (50 mL), and kept for 12 h in the dark. The crystalline **6** was filtered off and recrystallized from ethanol (5.4 g, 55%), mp 138–139°C: ν (Nujol): 1603 (C=N) cm^{-1}; ^{1}Hmr, δ: 4.67 (4H, s, CH_2), 7.27–8.07 (10H, m, 2Ph). *Anal.* calcd. for $C_{16}H_{14}Cl_2N_2$: C 62.97, H 4.62, N 9.18, Cl 23.23; found: C 63.21, H 4.59, N 9.22, Cl 23.45%.

Stability of hexachloroacetophenone azine to aqueous alkali

To solid chlorinated azine **9** (0.15 g, 0.34 mmol) was added 2 M aqueous NaOH (2 mL, 4 mmol) and the whole was refluxed. The azine (mp 108–109°C) became semisolid. After 10 h, the mixture was cooled, cold carbon tetrachloride (1 mL) was added down the condenser, and the organic phase separated and dried. The ^{1}Hmr spectrum of the residue obtained on evaporation was that of **9** only. Chloroform was not present.

Hexamethoxyacetophenone azine (16)

To a solution of hexachloroacetophenone azine (**9**) (5.0 g, 11.3 mmol) in MeOH (50 mL) was added NaOH (5.5 g, 136 mmol, 12 equiv.). The whole was heated to a clear solution and refluxed for 17 h. The residue upon evaporation was treated with water and methylene chloride and the water layer shaken out with further methylene chloride. The combined organic extracts were dried and evaporated to give an oil, which crystallized on addition of hexane. Recrystallization from hexane gave colorless **16** (64%), mp 81–82°C: ν (Nujol): 1624 (C=N) cm^{-1}; λ_{max} (cyclohexane): 238 nm; ^{1}Hmr, δ: 3.05 (18H, s, MeO), 7.25–7.35 (10H, br s, 2 Ph); ^{13}Cmr, δ: 49.5 (CH_3), 112.5, 127.3, 128.2, 128.7 (Ph), 132.6 (C=N), 149.9 ($C(OMe)_3$). *Anal.* calcd. for $C_{22}H_{28}N_2O_6$: C 63.44, H 6.78, N 6.73; found: C 63.59, H 7.15, N 6.63%.

NaOH dissolved in a large excess of MeOH is mostly converted into NaOMe. In smaller scale preparations of **16** sodium dissolved in MeOH was used.

Reaction of hexachloroacetophenone azine with a limited amount of NaOMe

The azine **9** (0.30 g, 0.67 mmol) was kept at room temperature in 0.1 M NaOMe in MeOH (7.6 mL, 1.1 equiv.). Aliquots were taken periodically, evaporated, and their residues shaken out with water and methylene chloride. The contents of the organic layer were examined by ^{1}Hmr spectroscopy. The product from a half-hour reaction showed (as well as a large amount of unreacted **9**) MeO peaks at δ 2.90 and 3.40; after 18 h, peaks at δ 2.95, 3.36, 3.45, 3.49, 3.72, 3.98. These very likely represent an increasing degree of MeO substitution with increasing field, i.e., δ 2.95 and 3.98 are MeO resonances for a tri- and mono-methoxy substituted carbon. Detailed assignments were not possible.

Mixed azine 17

Benzophenone hydrazone (28) (5.0 g, 26 mmol) and acetophenone (3.05 g, 26 mmol) were stirred together in chloroform (10 mL) at room temperature for 5 h. Evaporation and crystallization of the residue from hexane gave long yellow needles, mp 103.5–105°C (lit. (25) mp 105°C); ^{1}Hmr, δ: 2.40 (3H, s, CH_3), 7.26–7.80 (15H, m, 3Ph).

Trichloroazine 18

The mixed azine **17** (0.50 g, 1.7 mmol) in CCl_4 (5 mL) was treated dropwise and with stirring with a solution of Cl_2 (0.49 g, 6.8 mmol, 4 equiv.) in CCl_4 (20 mL). After 1 h the solvent was removed and the colorless solid residue was recrystallized from pentane giving needles of **18** (63%), mp 73–75°C; ν (Nujol): 1590 (C=N) cm^{-1}; ^{1}Hmr, δ: 7.22–7.42 (15H, m, 3 Ph). This compound was rather unstable and slowly discolored at room temperature.

Trimethoxyazine 19

The trichloro compound **18** (0.50 g, 1.2 mmol) was refluxed in a solution of 0.10 M NaOMe in MeOH (48 mL, 4 equiv.) for 30 h. Evaporation, addition of ether and water, and an ether extraction work-up gave the product as a pale yellow oil; ^{1}Hmr, δ: 3.10 (9H, s, 3 OCH_3), 7.02–7.55 (15H, m, 3 Ph).

It was used directly in the synthesis of the ester **21**.

Reaction of trichloroazine 18 with limited amounts of NaOMe

A refluxing solution of **18** (0.20 g, 0.50 mmol) in 0.10 M NaOMe in MeOH (4.8 mL, 1 equiv.) was sampled at intervals, aliquots being evaporated and the residues shaken out with water and ether. The ^{1}Hmr spectra of the residue were taken. Typical result: at 2 h 35 min, δ 3.09, 3.25, 3.99, possibly due to $C(OMe)_3$, $CCl(OMe)_2$, $CCl_2(OMe)$ in a ratio of ca. 8:2:3; at 4 h 20 min the peaks at 3.09 and 3.25 had disappeared (after consumption of base the solution probably becomes slightly acidic, causing formation of the ester **21**, whose absorption is not readily distinguishable from the peak at 3.99. The latter may be more stable to acid than the di- or tri-methoxy compounds).

In a similar experiment compound **18** (0.60 g, 1.49 mmol) was refluxed in 0.10 M NaOMe in MeOH (44.3 mL, 3 equiv.) and the reaction monitored before completion, as above. The growth of the trimethoxy compound was very rapid after the initial stages. The dimethoxy compound was the least abundant component at all times. After 3 h, work-up of a sample led to the mono-, di-, and trimethoxy compounds in a molar ratio of ca. 6:1:10.

Methyl benzoylformate azine (20)

One drop of 1 M HCl was added to a solution of hexamethoxyacetophenone azine (0.134 g, 0.32 mmol) in MeOH (2 mL). The colorless solution immediately became deep yellow, and the yellow azine separated within minutes. Evaporation and recrystallization of the residue from MeOH gave large deep yellow prisms (0.094 g, 90%), mp 140–141°C: ν (CCl_4) 1746 (C=O), 1609 (C=N) cm^{-1}; λ_{max} (cyclohexane): 308 nm; ^{1}Hmr, δ: 4.00 (6H, s, OCH_3), 7.40–7.85 (10H, m, 2 Ph); ^{13}Cmr, δ: 52.2 (CH_3), 128.2, 129.0, 131.4, 132.3 (Ph), 162.5 (C=N), 165.9 (C=O). *Anal.* calcd. for $C_{18}H_{16}N_2O_4$: C 66.66, H 4.97, N 8.64; found: C 66.74, H 5.26, N 8.50%.

Mixed azine ester 21

The oily trimethoxyazine **19**, prepared as described above (0.10 g, 0.26 mmol), was dissolved in MeOH (2 mL) and acidified with 1 drop of 12 M HCl. The solid that precipitated was recrystallized from MeOH as yellow prisms (88%), mp 118–118.5°C; ν (Nujol): 1720 (C=O), 1650 (C=N) cm^{-1}; ^{1}Hmr, δ: 3.97 (3H, s, OCH_3), 7.3–7.5, 7.5–7.9 (15H, two multiplets, 3 Ph); m/e 342 (M^+). *Anal.* calcd. for $C_{22}H_{18}N_2O_2$: C 77.19, H 5.26, N 8.19; found: C 77.30, H 5.36, N 8.10%.

*Conversion of hexamethoxy compound **16** into the dimethyl and the diethyl esters (**20**+**22**)*

The hexamethoxy compound **16** (0.40 g, 0.96 mmol) dissolved in ethanol (5 mL) was treated with 2 drops of 12 M HCl. The solution, which immediately turned yellow, was kept at room temperature for 0.5 h and evaporated. The residue (93%) was shown by ^{1}Hmr spectroscopy to consist of **20** and **22** in a ratio of 1:2. This mixture was converted as described below into the pure diethyl ester **22**.

*Stability of dimethyl ester **20** to acidic ethanol*

The ester **20** (0.10 g, 0.31 mmol) was dissolved in ethanol (60 mL) and 2 drops of 12 M HCl were added. The solution was kept at room temperature and monitored over 4 days, by work-up and nmr analysis of samples. There was no reaction.

*Transesterification of dimethyl ester **20***

The ester (50 mg, 0.15 mmol) was kept at room temperature for 1 h in 1 M NaOEt in ethanol (2 mL). Evaporation and extraction of the residue with water – methylene chloride gave from the dried organic layer a mixture shown by ^{1}Hmr spectroscopy to be starting material **20** and the diethyl ester **22** in a ratio of about 1:1.

The 1:2 mixture (0.10 g), prepared as described above in acidic ethanol, was stirred at room temperature for 6 days in ethanol (3 mL) containing a catalytic amount of NaOEt (5 drops of 0.1 M in ethanol). Evaporation and a water – methylene chloride work-up gave a yellow solid whose ^{1}Hmr spectrum showed ethoxy peaks only. Recrystallization from ethanol gave **22** as yellow prisms, mp 135–137°C: ν (CCl_4): 1743 (C=O), 1609 (C=N) cm^{-1}; ^{1}Hmr, δ: 1.45 (6H, t, J = 7.1 Hz, CH_3), 4.50 (4H, q, OCH_2), 7.39–7.86 (10H, m, 2 Ph). *Anal.* calcd. for $C_{20}H_{20}N_2O_4$: C 68.18, H 5.68, N 7.95; found: C 68.60, H 5.91, N 8.01%.

*Hydrazone exchange of diester **20** with acetone*

To a solution of **20** (0.10 g, 0.31 mmol) in acetone (3 mL) were added MeOH (0.02 g, 0.62 mmol) and 12 M HCl (0.07 mL, 0.62 mmol), and the whole was refluxed for 2 h. Evaporation gave a pale yellow oil (55%; considerable ester loss by volatilization) whose ^{1}Hmr spectrum was the same as that of an authentic sample of methyl benzoylformate: δ: 3.98 (3H, s, OCH_3), 7.48–8.10 (5H, m, Ph).

*Attempted synthesis of diester **20** from methyl benzoylformate*

Methyl benzoylformate (0.40 g, 2.4 mmol) and 95% hydrazine (0.040 mL, 1.2 mmol) were kept in MeOH (1 mL) for 24 h, with periodic monitoring of the reaction by thin-layer chromatography. This showed **20** to be one of several products. Evaporation gave a yellow oil whose ^{1}Hmr spectrum confirmed the presence of **20** as a minor product.

*Attempted synthesis of phenylmethylglyoxal azine (**28**) from **16***

The hexamethoxy compound **16** (45 mg, 0.11 mmol) in ether (5 mL) was treated with a large excess of ethereal methylmagnesium iodide. After 1 h, the solution was filtered and worked up to give only the starting material.

A similar reaction using methyllithium led also to the recovery of **16**.

X-ray analyses

Crystals of both **13** and **20** were grown from methanol. Details of the crystal data, intensity collection, and refinement are given in Table 5. The intensity data were collected on a Syntex $P2_1$ diffractometer using graphite monochromated MoKα radiation. Accurate cell constants for

each were determined using 15 general reflections ($23 < 2\theta < 30°$) well distributed in reciprocal space. Intensities were measured by the θ–2θ scan technique with background counts being made at the beginning and end of each scan for a total of half the scan time. The stability of the crystals was checked by monitoring the intensities of standard reflections every 100 measurements. Only minor variations were observed. The data were corrected for Lorentz and polarization effects but not for absorption. Both structures were solved by direct methods (MULTAN80) and refined by full-matrix least-squares methods; the function minimized was $\Sigma w\|F_o|-|F_c\|^2$. All hydrogen atoms were located in difference Fourier syntheses and included in the refinement in unconstrained isotropic form. In the final cycles of refinement, empirical weighting schemes of the form $A\text{-}B|F_o|+C|F_o|^2$ were applied to give constant error in the various ranges of F_o, the coefficients being derived from Ranger.

Interlayer ammine complexes of metal uranyl phosphates

RAFAELA POZAS-TORMO, SEBASTIÁN BRUQUE GAMEZ, MARÍA MARTINEZ-LARA, AND LAUREANO MORENO-REAL[1]

Dpto. Quimica Inorgánica, Universidad de Málaga, Apartado 59, E-29071 Malaga, Spain

Received April 22, 1988

RAFAELA POZAS-TORMO, SEBASTIÁN BRUQUE GAMEZ, MARÍA MARTINEZ-LARA, and LAUREANO MORENO-REAL. Can. J. Chem. **66**, 2849 (1988).

The solids derived from HUP by substituting metallic ions for protons, take up Lewis base molecules (like NH_3 and $C_4H_9NH_2$) in the interlamellar space. The diffractograms of these inclusion compounds indicate that the host crystallinity was preserved.

The infrared spectroscopy of the Ni, Co, Cu, Zn, and Cd intercalates revealed that part of the sorbate was protonated in the interlaminar space while the other part displaced the water in their coordination spheres. However, in the Mn derivative, no coordinated or free Lewis base could be detected: it was all in the protonated form.

RAFAELA POZAS-TORMO, SEBASTIÁN BRUQUE GAMEZ, MARÍA MARTINEZ-LARA et LAUREANO MORENO-REAL. Can. J. Chem. **66**, 2849 (1988).

On peut insérer des molécules de bases de Lewis (comme le NH_3 et le $C_4H_9NH_2$) dans l'espace interlamellaire des solides que l'on obtient lorsqu'on remplace les protons des HUP par des ions métalliques. Les diffractogrammes de ces composés d'inclusion indiquent que la cristallinité de l'hôte est préservée.

Les spectres infrarouges des produits intercalés comportant du Ni, du Co, du Cu, du Zn ou du Cd révèlent que, dans l'espace interlamellaire, une portion du sorbate est protonée alors que l'autre portion a déplacé l'eau de ses sphères de coordination. Toutefois, dans les dérivés du Mn, on n'a pas pu détecter de base de Lewis soit libre ou coordonnée; elles étaient toutes sous la forme protonée.

[Traduit par la revue]

1. Introduction

$H_3OUO_2PO_4.3H_2O$ (HUP) is a member of the large family of uranium–mica compounds with the general formula $M^{n+}(UO_2PO_4)_n^{n-}.zH_2O$, where M may be a mono-, di-, or trivalent cation. HUP crystallizes in the tetragonal system in which the interlayer distance is 8.8 Å. In electrochemical studies, uranyl hydrogen phosphate was shown to have a high protonic conductivity ($0.4\ \Omega^{-1}\ m^{-1}$ at 290 K). The solids derived from HUP by substituting metallic ions for protons show lower conductivity (1). Other authors have systematically studied the effect that certain chemical substitutions of HUP have on its luminescence (2, 3).

Recently we prepared some *d* and *f* metal derivatives of HUP by ion-exchange topotactic reactions (4, 5). All the resulting solids were isostructural and their tetragonal lattices remained intact during the cationic substitution. The structure of metal uranyl phosphates consists of negatively charged layers of $(UO_2PO_4)_n^{n-}$ separated by sheets of water containing the compensating cations. The environments of these cations are compatible with their corresponding hexaaquocations and their electronic spectra show the vibronic transition bands of the UO_2 moiety in addition to the electronic absorption bands of the metal ions (4). All of the intercalation reactions, ionic exchange, solvation or neutralization, modified the photoluminescent properties (2, 3) and the proton conductivities of these solids (1).

These layered compounds are suitable systems to study changes in optical properties based on different coordination around the interlaminar cations. Some basic substances like ammonia and butylamine modify the system of the intracrystalline space and change the observed behavior of their diffuse reflectance spectra. The processes occurring within the solid during intercalation of the above molecules have elements of similarity with the formation of complex cations in aqueous media.

2. Experimental

The metal uranylphosphates $M(H_2O)^n[UO_2PO_4]_2$ (M = Mn^{2+}, Ni^{2+}, Co^{2+}, Cu^{2+}, Cd^{2+}, and Zn^{2+}) (MUP) were prepared according to the method described by Pozas Tormo *et al.* (4). Table 1 gives the composition, M:U:P molar ratio, and the color of these solids.

The intercalation complexes were prepared by exposing MUP to a saturated atmosphere of: (*1*) *n*-butylamine vapour (NBA), and (*2*) a concentrated solution of aqueous ammonia (24% w/w) in a desiccator for 2 weeks. The products were then evacuated at room temperature and kept for 3 to 5 days in a desiccator containing H_2SO_4 (98%) to remove the physically adsorbed basic molecules. The prepared samples were stored in an atmosphere of controlled humidity (H_2SO_4 40% w/w).

The composition of the intercalates was determined: nitrogen by Kjeldahl microanalysis and water content by thermal analysis.

The new materials were characterised by (*1*) infrared spectroscopy using the KBr disk method in a Perkin Elmer 883 instrument; (*2*) X-ray diffraction with CuKα monochromated radiation in a Siemens D-501 powder diffractometer; (*3*) thermogravimetric analysis in a Rigaku Thermoflex apparatus with a heating rate of 10 K/min in air and using calcined Al_2O_3 as reference; and (*4*) visible diffuse reflectance spectroscopy using barium sulfate as white reference in a Kontron UVIKON 810 instrument fitted with an integrating sphere attachment.

3. Results

The metal uranyl phosphates retained ammonia and *n*-butylamine (NBA) when they were exposed to the above mentioned Lewis base vapours. The sorption of NH_3 and NBA diminishes the degrees of hydration of the host solids and this suggests that the observed retention of the nitrogenated species in each case occurred by displacement of interlaminar water. Details of the composition of the new materials are given in Table 2.

Under the experimental conditions employed, no more than two molecules of NBA were retained by each metallic cation, but in the complexes containing NH_3, the retention was observed to be greater, possibly because the size of the NH_3 molecule is smaller than that of the NBA so that less energy was required for its interlaminar diffusion and at the same time the process was faster.

X-ray diffraction data

The sorption of NH_3 or $C_4H_9NH_2$ vapours by the layered MUP host lattices took place in the interlaminar spaces because the $00l$ and hkl reflections were modified while those of $hk0$ remained unchanged. This indicated a topotactic intercalation.

The d_{002} interlaminar distances of the MUP + NH_3 complexes (Fig. 1*B*) are smaller than those of the starting phosphates (Fig. 1*A*) (4). Although the substitution of H_2O by NH_3 (both molecules are similar in size) should not produce noticeable variations in the basal spacings, the observed contraction in *ca.* 1 Å, is due to the smaller number of sorpted molecules (see Tables 1 and 2). On the other hand, as Fig. 1*C* shows, the MUP + NBA derivatives displayed mixtures of phases around 14.5 and 9 Å; the latter possibly due to the unchanged MUP phases in which the NBA did not penetrate, or to phases in which the amine intercalated with the carbonated chain parallel to the $[UO_2PO_4]_n^{n-}$ layers. In every case, the 9 Å reflection is of much lower intensity than that at 14.5 Å. The 14.5 Å phase is the consequence of the presence of the NBA alkyl chain being oriented perpendicularly to the laminar plane, similarly to that which occurs in $C_4H_9NH_3UO_2PO_4 3H_2O$, described by us (4).

Tables 3 and 4 display a selection of the most intense reflections and the corresponding Miller indices of the MUP + NH_3 and MUP + NBA derivatives.

The diffractograms of the MUP + NBA complexes (Fig. 1*C*), in contrast to those of MUP + NH_3, are rather diffuse in the 2θ high angle zone, probably due to stacking disorder. The pattern shown in Fig. 1*C* indicates a well-defined *c*-spacing and ***ab*** plane, because the $00l$ and $hk0$ reflection lines are sharp. Nevertheless, the effect of defective stacking on the pattern provokes a widening of certain diffraction lines in a characteristic fashion, as is reported for layered silicates (6).

Thermal analysis

Two or three endothermic effects were observed in the thermograms of the MUP + NH_3 complexes. In the TG these were accompanied by weight loss between room temperature and 200°C. This corresponds to the elimination of the water molecules or the NH_3 coordinated to the cation, or both. Between 200 and 700°C two endothermic effects were observed which were similar to those reported by Schaekers (7) for the decomposition of ammonium uranyl phosphate; they are consistent with the following reactions of the $NH_4UO_2PO_4$ component of the complexes:

[1] $NH_4UO_2PO_4 \rightarrow HUO_2PO_4 + NH_3$

[2] $HUO_2PO_4 \rightarrow (UO_2)P_2O_7 + H_2O$

The DTA–TG recording of the $Co(NH_3)_{3.2}(H_2O)_{4.2}[UO_2PO_4]$ complex is shown in Fig. 2*A*.

The MUP + NBA derivatives exhibited similar behaviour, but in these cases, between 200–500°C, the elimination of amine was accompanied by an exothermic effect, the result of the combustion of organic residues (Fig. 2*B*).

Infrared ir spectra

The infrared spectroscopy gave valuable information about the shapes adopted by the guest species. The first remarkable characteristic of the infrared spectra (Fig. 3 and Tables 5 and 6) was the appearance of bands at 1400 and 1470 cm^{-1} that indicate the unequivocal presence of the NH_4^+ ion in all MUP + NH_3 compounds. Baran and Botto (8) assign these to the $\nu_4(\delta_S)$ deformation vibrations of the NH_4^+ group in the ammonium uranyl phosphates. The MUP + NBA intercalates displayed a similar picture; bands due to the deformation vibrations of the NH_3^+ group were observed between 1495 and 1575 cm^{-1} in the spectra of all the samples and this fact confirms the existence of the alkylammonium species.

The presence of the coordinated NH_3 species was also detected in the infrared spectra of all intercalates, except the Mn derivative, by the bending vibrations (symmetric (δ_S), towards 1260 cm^{-1}; degenerate (δ_d) at 1620 cm^{-1}; and rocking (ρ_r) between 600 and 750 cm^{-1}). The first of these was very sensitive to the coordination of ammonia to the metallic ions because the frequencies at which this vibration appeared in this type of complex was in the order of 300 cm^{-1} higher than in the free molecule (9). Moreover, the presence of a band assignable to the ρ_r (NH_3) mode confirms the existence of the ammine complexes because this band is not present in the free NH_3 molecule. The vibration band towards 1620 cm^{-1} (δ_d of the ammonia) is not diagnostic, because the δHOH band of the water present in the compound overlaps it.

Diffuse reflectance

The replacement of the water molecules by NH_3 or NBA around the metallic ions displaces the bands produced by the *d–d* transitions to higher frequencies. Only the intercalates of Co^{2+}, Ni^{2+}, and Cu^{2+} exhibit this phenomenon; the other intercalates (Mn^{2+}, Zn^{2+}, and Cd^{2+}) have complete, or semi-

complete outer shells and so *d–d* transitions are forbidden by Laporte and spin rules. Consequently, these bands do not appear in the visible spectrum.

Narrow bands due to vibronic transitions of a UO_2^{2+} moiety were observed in the 300–500 nm region (10). However, these were not seen in the manganese intercalates because the MnUP + RNH_2 solids (R = Bu or H) have strong absorption in all regions of the visible spectrum: they are almost black. Figure 4 shows the diffuse reflectance spectra of the nickel derivatives.

4. Discussion

The sorption of the Lewis base molecules may be produced by (*1*) The presence of ions by transition metals with water in the coordination sphere which may be replaced by relatively stronger ligands (R—NH_2; R = Bu or H) in the spectrochemical series, in an anation process and (*2*) The strong acidity of the interlaminar coordinated water produced by the polarizing action of two electrostatic fields, that of the M^{2+} cation, and that of the $[UO_2PO_4]_n^{n-}$ layer.

These two effects might produce (*a*) the partial substitution of water by R—NH_2 (R = Bu or H)

[3] $[M(OH_2)_n]^{2+} + NH_3 \rightarrow [M(OH_2)_{n-1}NH_3]^{2+} + H_2O$

and (*b*) the insertion of R—NH_2 and its subsequent protonation to form RNH_3^+ ions (R = Bu or H) via dissociation of the water and protonation of the Lewis base. The latter reaction involves a decrease of the charge on the metallic cation and the appearance of additional RNH_3^+ ions as compensators of the layer charge, according to the following reaction:

[4] $[M(OH_2)_n]^{2+} + NH_3 \rightarrow [M(OH_2)_{n-1}OH]^+ + NH_4^+$

However, reactions [3] and [4] could be coupled to give

[5] $[M(OH_2)_n]^{2+} + zNH_3 \rightarrow [M(OH_2)_{n-z}(NH_3)_{z-1}OH]^+ + NH_4^+$

The reactions with $C_4H_9NH_2$ occur in a way similar to that of NH_3.

The cations $[M(OH_2)_{n-z}(NH_3)_z]^{2+}$ and $[M(OH_2)_{n-z}(NH_3)_{z-1}OH]^+$ should show a similar electronic spectrum to those of the aqueous cations. The R—NH_2 ligand (R = H, C_4H_9) is somewhat stronger than water in the spectrochemical series so that the bands must be displaced to lower wavelengths. This effect may be partially compensated by the presence of OH^- in the coordination sphere. Nevertheless, in the diffuse reflectance spectra of CuUP + NH_3, there is a net shift of the 675 nm band (transition $^2E \leftarrow {}^2B_{1g}$; aqueous cation) to 540 nm (ammine complexes). In the case of nickel uranylphosphate, the shift is from 650 nm to 625 nm (Fig. 4). These facts, together with the color changes observed, support the existence of ligand molecules, different from water, in the proximity of the metallic ions.

Although the techniques employed do not permit an exact estimate of the coordination symmetry, the slight changes in the spectra and the very small numbers of nitrogenated molecules detected suggest that the octahedrical conformation established in the aquation process persists (4, 11).

Infrared spectroscopy of the Ni, Co, Cu, Zn, and Cd intercalates revealed that part of the sorbate was protonated in the interlaminar space while the other part displaced the water in their coordination spheres. However, in the Mn derivative, no coordinated or free Lewis base could be detected: it was all in the protonated form.

When the manganese uranyl phosphate absorbs RNH_2 (R = H, or C_4H_9) it forms a very dark brown product and this suggests that the interlaminar cation is oxidised, as occurs in basic solutions of Mn^{2+} when exposed to air. As the manganese ammine complexes are usually only slightly stable in humid atmospheres, the insertion of RNH_2 might create the basic medium required for oxidation, according to the following

[7] $2Mn(OH)_2(n-2)H_2O + (1/2)O_2 \rightarrow 2MnOOH(n-2)H_2O + H_2O$

black

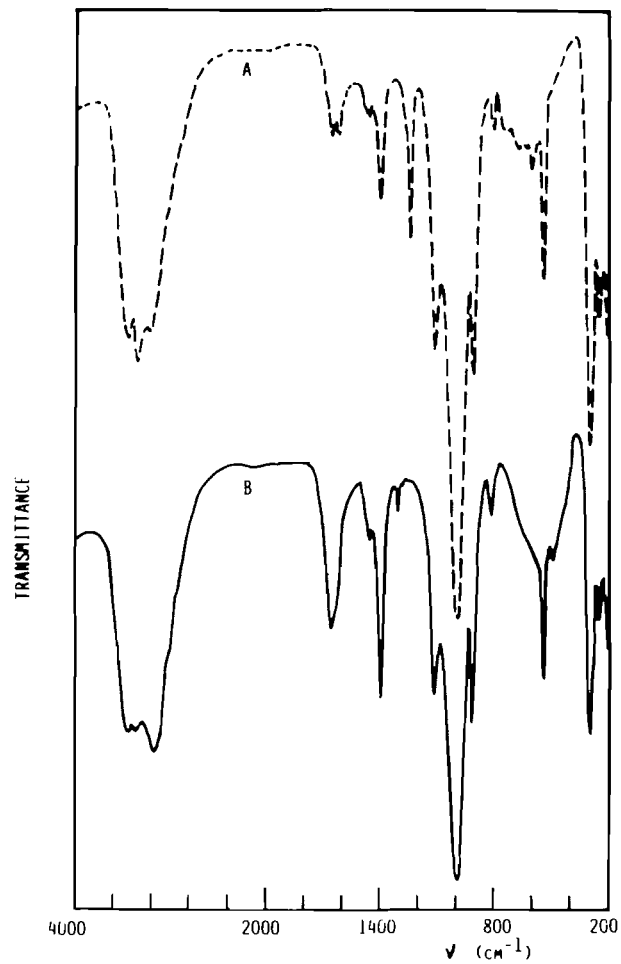

FIG. 3. Infrared spectra of (*A*) $Cu(NH_3)_{3.6}(H_2O)_{3.8}[UO_2PO_4]_2$ and (*B*) $Mn(NH_3)_2(H_2O)_6[UO_2PO_4]_2$.

Reactions [6] and [7] are thermodynamically more favourable than [3] and [4] so that the formation of the complex is hindered. Consequently, in the ir spectra, the bands due to the δ_s and ρ_r of the NH_3 united to the cation are absent (Fig. 3*B*). The stoichiometries determined for MnUP + NH_3 and MnUP + NBA reactions lend support to the above hypothesis, in the sense that two molecules of either NH_3 or NBA were absorbed for each manganese ion as required for reactions [6] and [7].

The above argument means that the resultant product of the retention of NH_3 or NBA by $Mn(H_2O)_n[UO_2PO_4]_2$ should be

considered an inclusion compound of Mn(III) oxohydroxide in a matrix of $RNH_3\ UO_2PO_4$ (R = H or C_4H_9). The diffractograms of these inclusion compounds were surprisingly well defined, indicating that the host crystallinity was preserved. However, the insertion of a mono-layer between the matrix layers prevented the intended diffractometric examination of $MnOOH \cdot H_2O$ because the necessary three-dimensional regularity no longer existed. *The ESR spectra showed poorly defined broad lines due to spin–lattice and spin–spin interactions. For this reason, it was impossible to confirm the existence of Mn(III) in the compounds. However, the XPS data show the existence of manganese in oxidation states greater than +2.*

Received March 24, 1988

GUILLERMO LÓPEZ-CUETO and CARLOS UBIDE. Can. J. Chem. **66**, 2855 (1988).

The reaction between hexacyanomanganate(IV) and arsenic(III), in acidic media, proceeds with a stoichiometry $\Delta[Mn(IV)]/\Delta[As(III)] = 1$. The reaction in sulfuric acid media has been followed spectrophotometrically at 387 nm, where the Mn(IV) cyanide complex has an absorption maximum, and shows a first-order dependence on the hexacyanomanganate(IV) concentration, viz., $-d[Mn(IV)]/dt = k[Mn(IV)]$, the value of k being dependent on the acidity and the arsenic(III) concentration. At As(III), 0.1 *M*; H^+, 0.16 *M*; ionic strength, 2.0; and *T*, 30°C, the value of the rate constant was found to be $k = (1.04 \pm 0.06) \times 10^{-5}$ s^{-1}. The proposed mechanism, through three parallel pathways, explains satisfactorily the experimental results observed.

GUILLERMO LÓPEZ-CUETO et CARLOS UBIDE. Can. J. Chem. **66**, 2855 (1988).

La réaction de l'hexacyanomanganate(IV) et l'arsenic(III), en milieu acide, se produit avec une stoechiométrie de $\Delta[Mn(IV)]/\Delta[As(III)] = 1$. Opérant dans un milieu d'acide sulfurique, on a suivi la réaction par spectrophotométrie à 387 nm, la longueur d'onde d'absorption maximale du complexe de cyanure de Mn(IV); on a observé que la réaction est du premier ordre par rapport à la concentration d'hexacyanomanganate(IV), soit $-d[Mn(IV)]/dt = k[Mn(IV)]$ dans laquelle k dépend de l'acidité ainsi que de la concentration en arsenic(III). A une concentration de As(III) de 0,1 *M*, de H^+ de 0,16 *M*, une force ionique de 2,0 et une *T* de 30°C, on a observé que la valeur de la constante de vitesse est égale à $k = (1{,}04 \pm 0{,}06) \times 10^{-5}$ s^{-1}. Le mécanisme proposé, impliquant trois voies parallèles, explique correctement les données expérimentales obtenues.

[Traduit par la revue]

Introduction

Manganese(IV) is a strong Lewis acid and in aqueous solutions is only soluble in the form of coordination compounds (1). In aqueous solutions, the relatively few Mn(IV) known complexes have a strong tendency to hydrolyze in neutral as well as acidic media (2–5). On the other hand, transient soluble species of Mn(IV) have been detected on the permanganate oxidations in neutral or basic media (6–8). Kinetic and mechanistic studies with soluble species of Mn(IV) in acidic media are rather scarce in the literature (9).

Hexacyanomanganate(IV) is produced in acidic solutions by disproportionation of hexacyanomanganate(III) (10) ($Mn(H_2O)_6^{2+}$ and HCN are also produced). At room temperature the reaction is quite fast and quantitative, and the hexacyanomanganate(IV) formed is a relatively inert complex in acidic media, but slowly decomposes to yield Mn(II) and $(CN)_2$. The kinetics of the latter reaction has been studied and a mechanism has been proposed (11). In acidic media, arsenic(III) reduces hexacyanomanganate(IV), the reaction rate being slow. In this paper the kinetics of this reaction is studied and a mechanism is proposed.

Experimental

Apparatus

A Shimadzu UV-260 spectrophotometer with 1.0-cm fused-silica cells was used for the kinetic measurements. A water bath circulator Selecta Tectron Digiterm was used for the cells' temperature control. When pH measurements were required, a Radiometer PHM 82 pH-meter with a combined glass – silver chloride electrode was used.

Reagents

All chemicals were of analytical reagent grade (Merck or Riedel-de-Haën) and doubly distilled water was used throughout. Potassium hexacyanomanganate(III) was prepared and characterized as described previously (11); hexacyanomanganate(IV) was formed in the reaction mixture by the disproportionation of hexacyanomanganate(III), this reaction proceeding to completion in less than three minutes under the reaction conditions. A 0.4 *M* solution of sulfuric acid (standardized with Na_2CO_3) was used to adjust the H^+ concentration. Solid $NaAsO_2$ (99.0% against MnO_4^- previously standardized with As_2O_3) and $NaNO_3$ were used as received.

Stoichiometry measurements

The stoichiometry of the reaction was determined by means of the following procedure: in a 250 mL volumetric flask, a measured amount of arsenic(III) between 0.990 and 1.423 mmol was dissolved with 30 mL of 0.15 *M* H_2SO_4, two drops of 10^{-2} *M* KI were added as a catalyst and finally 0.08 g of $K_3Mn(CN)_6$ (accurately weighed) were added with the aid of 20 mL of 0.15 *M* H_2SO_4 (whenever $K_3Mn(CN)_6$ is taken into acidic solution HCN is produced, so *care* should be taken). After the reaction had proceeded to completion — and no colour was detected (10–15 min) — 15 mL of 6 *M* HCl and one drop of 0.002 *M* KIO_3 were added; finally, the remaining arsenic(III) was determined by titration with a 0.02 *M* MnO_4^- standard solution.

Kinetic measurements

Solutions were prepared in a dark 250 mL standard flask by mixing the required amounts of sodium arsenite, sodium nitrate (to adjust the ionic strength), 0.4 *M* sulfuric acid and water up to 220–230 mL. The resulting solution was kept in a thermostatic bath for 30 min; the required amount of $K_3Mn(CN)_6$ was then added with stirring and the volume was quickly adjusted with water to 250 mL. The solution was stirred again ($K_3Mn(CN)_6$ dissolves very quickly) and transferred to a spectrophotometric cell. The kinetic curve at 387 nm (where the $Mn(CN)_6^{2-}$ shows an absorption maximum) was recorded for about 60 min using water as a reference.

The temperature in the cell was kept constant within ±0.2°C during each run.

The value of the observed rate constant (k_{obs}) was calculated by plotting ln A vs. time ($A_\infty = 0$) and by applying linear regression analysis. This value includes the decomposition reaction constant (k_{dec}) (11); when the value of the rate constant for the Mn(IV)–As(III) reaction (k) had to be calculated, the rate constant for the decomposition — estimated or known from previous work (11) — was subtracted. With the exception of the variable studied the initial conditions were Mn(IV), 2.5×10^{-4} M; As(III), 0.1 M; H^+, 0.16 M; I, 2.0; T, 30°C (customary working conditions).

Results and discussion[2]

Stoichiometry

Because the reaction between hexacyanomanganate(IV) and arsenic(III) proceeds slowly and, at the same time, hexacyanomanganate(IV) decomposes at a comparable rate, the stoichiometry of the Mn(IV)–As(III) reaction can be determined only in the presence of a suitable catalyst.

We have found that iodide notably accelerates the reaction. In the presence of iodide concentrations as low as 2×10^{-5} M the reaction rate is high enough to render the hexacyanomanganate(IV) decomposition negligible. Concentrations of iodide higher than 2×10^{-5} M were not allowed as significant amounts of Mn(IV) are reduced. The reaction stoichiometry was determined by using excess arsenic(III). Varying the [As(III)]/[Mn(IV)] initial ratio from 8.00 to 11.48, the stoichiometry was found to be $\Delta[Mn(IV)]/\Delta[As(III)] = 1.01 \pm 0.01$ (six determinations). The oxidation products were not positively identified, but no spectral evidence was found of Mn(II)–As(III) associations and a flat spectrum is obtained at equilibrium;[3] therefore, the reaction can probably be represented by the equation

$$[1] \quad Mn(CN)_6^{2-} + H_3AsO_3 + 4H_3O^+ + 3H_2O = Mn(H_2O)_6^{2+} + H_3AsO_4 + 6HCN$$

Effect of hexacyanomangate(IV) concentration. Reaction order

Plots of ln A vs. time were linear for at least three half lives, the slope being independent of the initial concentration of $Mn(CN)_6^{2-}$. This shows a first order dependence on the hexacyanomanganate(IV) concentration. Decomposition of $Mn(CN)_6^{2-}$, which takes place simultaneously, is also a pseudo-first order reaction (11), and hence, the rate law below must be followed:

$$[2] \quad \text{Rate} = -\frac{d[Mn(IV)]}{dt} = k_{obs}[Mn(IV)] = (k_{dec} + k)[Mn(IV)]$$

From the slope values, k_{obs} can be evaluated. Under the customary working conditions and for Mn(IV) concentrations ranging from 1 to 3×10^{-5} M, it has been found that $k_{obs} = (7.68 \pm 0.05) \times 10^{-5}\ s^{-1}$ (five runs). The experimental value for k_{dec} under these conditions is $(6.64 \pm 0.03) \times 10^{-5}\ s^{-1}$ (6 runs), and the rate constant for the Mn(IV)–As(III) reaction will be

$$k = (1.04 \pm 0.06) \times 10^{-5}\ s^{-1}$$

The rate constant is independent of the Mn(II) concentration, at least at the concentration levels in which it is produced during the reaction.

Effect of the ionic strength on k_{obs}

In the range of ionic strength from 0.3 to 2.8 a very slight positive primary salt effect was found for the whole reaction, but no attempt was made to obtain conclusions about the Mn(IV)–As(III) reaction because the decomposition reaction shows a similar effect.

Effect of the As(III) concentration and acidity

In Fig. 1 values of k_{obs} have been plotted versus the arsenic(III) concentration for different H_3O^+ concentrations. The effects of both variables can be represented as follows: for [As(III)] from 3×10^{-2} to 0.20 M (maximum concentration tested), plots of k_{obs} vs. [As(III)] were linear and showed positive slopes (m) and intercepts (b) both of whose values decrease as the acidity increases. Figures 2 and 3 show the linear dependence of both m and b with respect to the reciprocal of the H_3O^+ concentration; for $[As(III)] < 3 \times 10^{-2}$ M, k_{obs} rapidly decreases and approaches the value of k_{dec} measured in the absence of As(III). The following equation

$$[3] \quad k_{obs} = k_{dec} + A[As(III)] + B\frac{[As(III)]}{[H_3O^+]} + \frac{C[As(III)]}{(1 + D[As(III)])[H_3O^+]}$$

represents satisfactorily the results observed for both high and low As(III) concentrations. Thus, at very low As(III) concentrations, k_{obs} approaches k_{dec} and, at zero As(III) concentration

$$[4] \quad k_{obs} = k_{dec}$$

On the other hand, when [As(III)] is high enough

$$[5] \quad k_{obs} = k_{dec} + A[As(III)] + B\frac{[As(III)]}{[H_3O^+]} + \frac{E}{[H_3O^+]}$$

where $E = C/D$.

From Figs. 2 and 3 the values for A, B, and E can be estimated. For $T = 30$°C and $I = 2$, $A = 9.2 \times 10^{-5}\ s^{-1}\ M^{-1}$, $B = 3.9 \times 10^{-7}\ s^{-1}$, and $E = 2.4 \times 10^{-7}\ s^{-1}\ M$.

Values of k_{obs} were calculated from eq. [5] and compared with the experimental ones, the mean of the quotient k_{calc}/k_{obs} being 1.006 and the standard deviation 0.031 (24 runs).

Reaction mechanism

According to eq. [3], the hexacyanomanganate(IV)–arsenic(III) reaction must proceed through three parallel pathways. The following reaction scheme is proposed to explain the kinetic results:

$$[6] \quad Mn(CN)_5(CNH)^- + H_2O \overset{K_a}{\rightleftharpoons} Mn(CN)_6^{2-} + H_3O^+$$

$$[7] \quad Mn(CN)_5(CNH)^- + As(OH)_3 \xrightarrow{k_1} [Mn(CN)_4(CNH)—CN—As(OH)_3]^-$$

$$[8] \quad Mn(CN)_6^{2-} + As(OH)_3 \xrightarrow{k_2} [Mn(CN)_5—CN—As(OH)_3]^{2-}$$

$$[9] \quad Mn(CN)_6^{2-} \underset{k_{-3}}{\overset{k_3}{\rightleftharpoons}} Mn(CN)_6^{2-}*$$

$$[10] \quad Mn(CN)_6^{2-}* + As(OH)_3 \xrightarrow{k_4} [Mn(CN)_5—CN—As(OH)_3]^{2-}$$

[2]Tables of observed and calculated rate constants, and the effect of ionic strength and temperature on rate constants may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

[3]Nevertheless, when pH is higher than 3 a change in the uv spectrum seems to be produced, and above pH 7 the spectrum is clearly different, the solution shows an orange–pink colour and no precipitate is observed. This can probably be due to some kind of manganese–arsenic association in these less acidic solutions.

[11] $[Mn(CN)_4(CNH)—CN—As(OH)_3]^- + 3H_3O^+ + 4H_2O \xrightarrow{fast} Mn(H_2O)_6^{2+} + 6HCN + H_3AsO_4$

[12] $[Mn(CN)_5—CN—As(OH)_3]^{2-} + 4H_3O^+ + 3H_2O \xrightarrow{fast} Mn(H_2O)_6^{2+} + 6HCN + H_3AsO_4$

$Mn(CN)_5(CNH)^-$ is a species partially protonated on the nitrogen of one of the coordinated cyano groups, as previously reported (11) and stated for some other cyano complexes (12). Reactions [7] and [8] follow the equilibrium step [6] and they are the limiting steps of two of the three aforementioned parallel pathways. They correspond to bimolecular interactions of $As(OH)_3$ (which is proposed as predominant species rather than $HAsO_2$ in line with previous work (13)) with both the protonated and the deprotonated species of the Mn(IV) cyano complex. They would probably originate binuclear cyanide-bridged species, previous to the transfer of two electrons, that

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/07/12
For personal use only.

would be accompanied by a CN^+ group transfer.[4] The oxidation reactions of As(III) may take place through either one or two electron steps. The former case is quite usual with one electron oxidizing agents, including cerium(IV) (14) and some cyanocomplexes as octacyanomolybdate(V) (15), hexacyanoferrate(III) (16) and octacyanotungstate(V) (17); arsenic(IV) is then produced as an intermediate species. On the other hand, two-electron steps are not so common as one-electron steps. We have not found in the literature two-electron oxidations of arsenic(III) with cyanocomplexes, but they can be found when the stable oxidation states of the oxidant are two units apart, as it happens with the platinum(IV)–arsenic(III) reaction (18).

The kinetics of the third pathway depends on reactions [9] and [10]. We have not found spectral evidence on the existence of the intermediate $Mn(CN)_6^{2-}$ * in step [9], but the formation of such an intermediate has been postulated in order to explain the experimental results. Stanghellini *et al.* (19) proposed a step as [9] to interpret the kinetics of the reaction between bis(cyclopentadienylcarbonylnickel) with diphenylacetylene. In that work, the intermediate proposed was a complex in which a $\pi \rightarrow \sigma$ conversion of some ligand–metal bonds was produced. In our reaction, the species $Mn(CN)_6^{2-}$ * would be an intermediate in which the charge transfer from CN^- to Mn(IV) would not have completely taken place.

Reactions [11] and [12] are fast and therefore none of them exert influence on the rate law. These two reactions will probably proceed through consecutive bimolecular steps.

From the proposed mechanism, and by applying the steady-state assumption for the $Mn(CN)_6^{2-}$ * species, the following rate law is derived:

$$[13]\quad \text{Rate} = -\frac{d[Mn(IV)]}{dt} = \left\{ k_1 \frac{[As(III)]}{1 + \frac{K_a}{[H_3O^+]}} + k_2 \frac{[As(III)]}{1 + \frac{[H_3O^+]}{K_a}} + \frac{k_3 k_4 [As(III)]}{(k_{-3} + k_4[As(III)])\left(1 + \frac{[H_3O^+]}{K_a}\right)} \right\} [Mn(IV)]$$

and, if we consider that Mn(IV) cyanide complex predominates as the monoprotonated form,[5] that is to say $K_a \ll [H_3O^+]$, eq. [13] reduces to

$$[14]\quad \text{Rate} = \left\{ k_1[As(III)] + k_2 K_a \frac{[As(III)]}{[H_3O^+]} + \frac{k_3 \frac{k_4}{k_{-3}} K_a [As(III)]}{\left(1 + \frac{k_4}{k_{-3}}[As(III)]\right)[H_3O^+]} \right\} [Mn(IV)]$$

where the pseudo first-order constant is

$$[15]\quad k = k_a + k_b + k_c = k_1[As(III)] + k_2 K_a \frac{[As(III)]}{[H_3O^+]} + \frac{k_3 \frac{k_4}{k_{-3}} K_a [As(III)]}{\left(1 + \frac{k_4}{k_{-3}}[As(III)]\right)[H_3O^+]}$$

This equation, in which k_a, k_b, and k_c are the pseudo first-order constants of the three parallel pathways, agrees with the experimental results found for the Mn(IV)–As(III) reaction, where $A = k_1$, $B = k_2 K_a$, $C = k_3 k_4 K_a / k_{-3}$, and $D = k_4 / k_{-3}$. The third term will take two limiting forms depending on the value of the As(III) concentration:

(*i*) For $(k_4/k_{-3})[As(III)] \gg 1$

$$[16]\quad k_c = \frac{k_3 K_a}{[H_3O^+]}$$

That is to say, k_c will be independent of the As(III) concentration. This takes place for $[As(III)] \geq 3 \times 10^{-2}$. Step [10] is rapid and the reaction rate is limited by the rate of formation of the intermediate (step [9]).

(*ii*) For $(k_4/k_{-3})[As(III)] \ll 1$

$$[17]\quad k_c = k_3 \frac{k_4}{k_{-3}} K_a \frac{[As(III)]}{[H_3O^+]}$$

From this, at low As(III) concentrations ($[As(III)] < 3 \times 10^{-2}\ M$), k_c will depend linearly on the As(III) concentration. In these conditions, step [10] is slow (rate determining).

Effect of temperature on k_{obs}

A plot of ln k_{obs} vs. $1/T$ between 20 and 50°C gives an apparent activation energy of 76.1 ± 1.4 kJ mol^{-1}. For the decomposition reaction, E_a = 74.9 kJ mol^{-1}; hence, a value higher than 76.1 kJ mol^{-1} can probably be estimated for the Mn(IV)–As(III) reaction, but attempts to calculate it more accurately were unsuccessful owing to decomposition of hexacyanomanganate(IV). When a plot of ln (k_{obs}/T) vs. $1/T$ was made, the apparent activation enthalpy and entropy were found to be 78.6 ± 1.5 kJ mol^{-1} and 30.4 ± 4.8 J mol^{-1} K^{-1}, respectively.

[4]We are indebted to one of the reviewers for pointing out the possibility of a CN^+ group transfer, what is more convincing than our original proposition.

[5]In an earlier paper (11) on the decomposition of the hexacyanomanganate(IV) we assumed the predominant species of Mn(IV) to be $Mn(CN)_6^{2-}$. The inconsistency is only apparent, because we could have supposed that the $Mn(CN)_5(CNH)^-$ species was predominant in the decomposition reaction, without changing the deduced rate law, by considering the equilibrium reaction:

$$Mn(CN)_5(CNH)^- + H_3O^+ \overset{K}{\rightleftharpoons} Mn(CN)_4(CNH)_2 + H_2O$$

instead of

$$Mn(CN)_6^{2-} + H_3O^+ \overset{K}{\rightleftharpoons} Mn(CN)_5(CNH)^- + H_2O$$

Steric effects in the diastereoselective reduction of β-ketosulfones[1,2]

The stereochemical course of the reduction of ketones adjacent to a chiral center normally shows some diastereoselectivity (described by Cram's rule), the degree of which is dependent on the structure of the ketone and on the reaction conditions; the selectivity in acyclic species is often not very great. In this paper, we describe the sodium borohydride reduction of four acyclic β-ketosulfones, containing a chiral center at the α position, in which the products are formed with high diastereoselectivity. Reasons for this selectivity became apparent when we were able to show that these ketosulfones apparently exist predominantly in the same conformation in solution as in the solid state. This conformation requires that the preferred trajectory for nucleophilic attack on the carbonyl group leads to reaction on the *re* face, to yield the *threo* diastereomer of the β-hydroxysulfone. The results that led to these conclusions were obtained from structural studies by X-ray crystallography, as well as by detailed ^{1}H and ^{13}C nuclear magnetic resonance spectroscopy. In some cases, the latter spectra were run both in solution and in the solid state.

J. Stuart Grossert, H. Ranjith W. Dharmaratne, T. Stanley Cameron et Beverly R. Vincent. Can. J. Chem. **66**, 2860 (1988).

La degré de diastéréosélectivité (décrit par la règle de Cram) de la réduction de cétones adjacentes d'un centre chiral dépend de la structure de la cétone ainsi que des conditions de la réaction; la sélectivité des espèces acycliques est souvent faible. Dans ce travail, on décrit la réduction par le borohydrure de sodium de quatre β-cétosulfones acycliques, contenant un centre chiral en position α, qui donnent lieu à une haute diastéréosélectivité. Les raisons de cette sélectivité sont devenues apparentes lorsqu'on a pu montrer que la conformation principale de ces cétosulfones est la même à l'état solide qu'en solution. Cette conformation implique que l'attaque nucléophile sur le groupement carbonyle se produit préférentiellement selon une trajectoire d'attaque sur la face *re* qui conduit au diastéréoisomère *thréo* de la β-hydroxysulfone. Les résultats qui ont permis de proposer cette conclusion ont été obtenus à l'aide d'études de structures par diffraction des rayons-X ainsi que par résonance magnétique nucléaire du ^{1}H et du ^{13}C. Dans quelques cas, on a déterminé ces derniers spectres tant en solution qu'à l'état solide.

[Traduit par la revue]

Introduction

The fact that the two π faces of a carbonyl group adjacent to a chiral center are diastereotopic and hence that a nucleophilic attack on the carbonyl group will lead to an excess of one diastereomer in the product was first reported by Fischer in 1894 (1). The phenomenon is much more familiar when described by Cram's rule, which is well documented (2, 3).

Stereoselectivity is not usually very high in the case of normal acyclic molecules in which the energy barriers to carbon–carbon bond rotation are low, and in which the effects are simply steric. However, selectivity can be markedly improved in the case of α-hydroxy ketones, or similar molecules in which two adjacent groups can chelate with a cation. The carbonyl group is now part of a cyclic system, and the stereoelectronic requirements for the addition of a nucleophile to the carbonyl group (4–7) are such that much greater stereoselectivity is possible (8–10). Indeed, the correct choice of nucleophile, solvent, and substrate can give reactions with either chelation or nonchelation control leading to diastereomeric excesses of better than 95:5. By contrast, when the chiral center is located at a distance from the carbonyl group, even in a vinylogous manner, stereoselectivity is not observed (11).

In the absence of chelation or some other situation that constrains the carbonyl group, it is not easy to interpret and predict the direction of the diastereoselectivity during the addition of a nucleophile to an acyclic carbonyl group. Indeed, Cram's rule is based on the assumption that a particular conformation of the chiral carbonyl compound will predominate in solution and that addition to the carbonyl is favoured from a particular direction, based on steric grounds (cf. **1***a*). Other explanations, such as that due to Felkin and co-workers (cf. **1***b*) (12), have been offered and have been discussed at length (2, 4, 7, 8). One major difficulty in assessing the reactivity of acyclic carbonyl compounds is to decide what is the major conformer in solution. Even if this conformer can be identified, the Curtin–Hammett principle may apply, which renders predictions hazardous, if not useless.

In connection with other work,[4] we had occasion to prepare the *acyclic* β-hydroxysulfone **5** and we report here that it can be obtained, with remarkable diastereoselectivity, by reduction of the corresponding β-ketosulfone **4**. This led us to carry out the physical measurements on the structures of these and related molecules, with the result that we are able to present in this paper a plausible rationale for this unusual behaviour of acyclic molecules.

Results and discussion

Preparation of the molecules

The preparation of the ketosulfone **2** (see Scheme 1) is unremarkable, and can be effected from readily available starting materials. The alkylation reaction, **6** → **2** was found to be somewhat sluggish, but could be done effectively under phase-transfer conditions, especially using an ultrasonic bath to assist with the stirring (13). Preparation of the analogous *tert*-butylsulfonyl compound **8** proceeded similarly via **7**, care being needed in temperature control during the oxidation step

leading to **7** (eq. [1]). The chlorination steps **2** → **4** and **8** → **10** were readily accomplished by the modification of an earlier procedure (14).

[1] $PhCOCH_2Cl \xrightarrow[2.\ H_2O_2 + cat., in MeOH]{1.\ Bu^tSH,\ ^-OH,\ PTC} PhCOCH_2SO_2Bu^t$ (7)

Reduction of the ketones **2**, **4**, **8**, and **10** was carried out in a mixed solvent system, containing a mildly acidic buffer that was essential in the case of **4** to prevent the base-catalyzed cleavage of the α-chloro-β-ketosulfones (15, 16). Otherwise, **5** was found to be contaminated with benzyl alcohol, from which purification was difficult. When **2** was reduced, we were able to observe the presence of *only* the *threo* diastereomer (3); in the case of **4** the ratio of stereoisomers produced was reproducibly at least 19:1 in favour of the *threo* form, for **8**, 9:1, and for **10**, ca. 5:2.

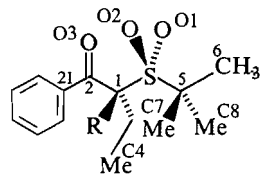
Structural and spectroscopic features

Structural features of the compounds **2–11** were readily apparent from standard spectroscopic techniques but, desiring an unequivocal proof of the stereochemistry in **5**, we resorted to X-ray crystallography. Crystal data for the compounds **2–5** are recorded in Table 1, selected bond lengths and angles in Table 2, and selected torsion angles in Table 3.[5] Figures 1–4 contain stereoscopic drawings to show the geometry of these four molecules.[6]

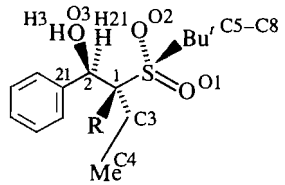
[5]Sets of positional parameters and isotropic thermal parameters (Tables 5–8), of the complete anisotropic thermal parameters (Tables 9–12), of the structure factor tables (Tables 13–16), and full details of distances, bond angles, and torsion angles (Tables 17–20) and the structure determinations (Tables 21–24) may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

Crystal data and bond lengths and angles for these compounds have also been deposited with the Cambridge Crystallographic Data Centre, and can be obtained on request from the Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, Cambridge CB2 1EW, U.K.

[6]The stereoscopic drawings were produced by the SNOOPI program, a part of the CHEMGRAF system (Chemical Designs, Oxford, U.K.).



8, R = H (H11) **10**, R = Cl



9, R = H (H11) **11**, R = Cl (*a* = *threo*; *b* = *erythro*)

Examination of the structures reveals that most features of the molecules **2–5** are unexceptional, apart from a few details worthy of comment. For instance, the two S—O bond lengths in both **2** and **3** are significantly different. Normally, the S—O bond lengths in a sulfone are equivalent (17–19), with a few cases being known in which they are significantly different (18–20), the differences generally being ascribed to factors that are not clearly understood.

An understanding of these factors is not readily achieved. For example, when the structures of known sulfones are considered, there does not appear to be evidence to support electrostatic forces due to adjacent polar bonds (18), or to implicate π–π interactions between a carbonyl group or a phenyl ring and the sulfonyl group (18, 20). An attempt to shed light on the phenomenon by examining the infrared stretching frequencies of the relevant functional groups is hampered by the fact that both the S—O symmetric and antisymmetric stretching vibrations are not obviously assignable to bands in the normally accepted wave-number ranges (21) for most of the molecules described in this paper. However, it is interesting to examine the C=O stretching frequencies in **2**, **4**, **7**, **8**, and **10**. These range from 1670 cm^{-1} in **10** to 1688 cm^{-1} in **8**, which can be compared with the frequencies found in other benzoyl derivatives. Thus, alkyl phenyl ketones absorb between 1684 and 1695 cm^{-1}, and the wave number increases with adjacent, inductive, electron-withdrawing groups to about 1710 cm^{-1} in $PhCOCHCl_2$ (22). By contrast, the β-ketosulfones show bathochromic shifts, characteristic of conjugation and a weaker C=O bond. X-ray crystal data show no unequivocal lengthening of these bonds, but any possible lengthening could be masked by uncertainties in the bond lengths. A definitive explanation of this phenomenon awaits further work.

In the case of **3**, a more straightforward explanation is available: the S—O(2) bond is the longer bond, and this oxygen atom is only 2.5 Å away from H(3) of the hydroxyl group, which is typical of a very weak hydrogen bonding interaction (23). Hydrogen bonding to sulfonyl groups is not common (24), although evidence for its presence has been observed previously (25). Again, the infrared spectrum was not especially helpful since it shows a strong band at 1142 cm^{-1}, close to the region for the sulfone S—O symmetrical stretch, but there is no obviously assignable band for the antisymmetric stretch, at the normally expected frequency just above 1350 cm^{-1} (21). However, the hydroxyl proton is coupled to a vicinal methine proton, the implications of which are discussed below.

In the case of **4**, the X-ray results show that there are two nonidentical molecules in each unit cell, but the differences

between them are not sufficient to warrant their inclusion in Table 2; complete details are given in the tables that have been deposited.[5]

Apart from the cases discussed above, the infrared spectrum for each molecule showed the expected absorption bands. The mass spectra are consistent with the various structures. Fragmentation of the molecular ions formed in the mass spectra of all the β-ketosulfones is characterized by a very facile cleavage of these ions. In the cases of **2** and **4** the cleavage processes are simple and as expected (16, 18). In the cases of the *tert*-butylsulfonyl compounds, **7**, **8**, and **10**, another major fragmentation pathway appears, viz. migration of a hydrogen atom (presumably in a McLafferty rearrangement), followed by loss of a total of 120 daltons, which corresponds to $Me_2C{=}CH_2$ + SO_2 (i.e., the *tert*-butylsulfonyl group). The resulting radical cation then fragments further in expected pathways. These three molecules also show a prominent ion at 57 daltons.

The fragmentation patterns of the β-hydroxysulfones are

much more complex, with major fragmentation pathways of the molecular ions from **3** and **5** being outlined in Scheme 2. The molecular ions from **9** and **11** fragment similarly in some ways, although not with the loss of $Bu^tSO_2^{\bullet}$; rather, a major fragmentation pathway appears to involve the sequential loss of the elements of $Me_2C{=}CH_2$, SO_2, and H_2O. However, due to the complex nature of the fragmentations, it is not possible to make a detailed assessment of their pathways using a low-resolution spectrum and the intensities of isotope peaks, even with the observation of some metastable peaks. This assessment must await further study.

We have carried out detailed nmr studies on the four

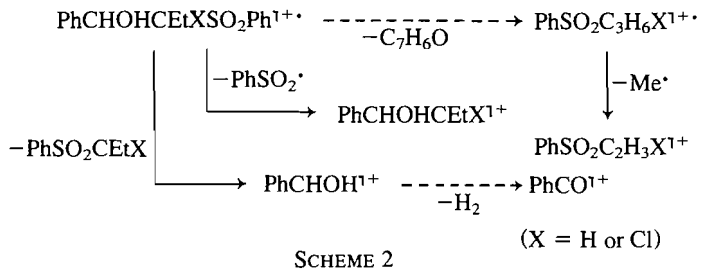

SCHEME 2

molecules, **2–5**. These include proton nmr spectra in solution, and carbon-13 nmr spectra in solution and in the liquid phase. Relevant results are presented in Table 4. Solution nmr spectral data for **8–11** are presented in Table 5. All molecules also showed appropriate resonances for the aromatic protons and carbon atoms, in the expected chemical shift ranges; these could not be correlated with any structural properties of the molecules that are relevant to the work reported here, and are therefore not included in this paper. The first point to note is that the chemical shifts in both the solution and the solid-state carbon-13 spectra are very similar in the case of **2** and not quite so similar in the case of **4**. This suggests that these molecules exist largely in the same conformations in these two states. Also, the proton–proton coupling constants of **8** and **9** are remarkably similar to those of **2** and **3**, thus suggesting very similar solution conformations for these four molecules.

The H31–H11 and H32–H11 coupling constants in **2** are typical of those for *anti* and *gauche* conformations (26), respectively, which is evidence that only one conformer about the C1—C3 bond is predominant in solution. The torsion angles for these atoms from the X-ray crystal structure are 178(7)° and 64(7)°; although these are imprecise, they confirm that the solution conformation of this bond is very similar to the solid-state conformation. Since only one conformer of the ethyl group (C1—C3 bond) is appreciably populated, it is likely that the same will be true for the C11—S1—C1—C2—C21 backbone of the molecule and, given the bulky and polar substituents about this part of the molecule, that it will be subject to bond rotation barriers. A modified form of the Karplus–Conroy equation given by Günther (eq. [2]) (26) can

$$[2] \quad \cos\phi = [1 + (40^3J - 79)^{0.5}]/20$$

be used to correlate the torsion angle (ϕ) with vicinal proton coupling constants. The experimental values of these constants give torsion angles of 2° and 63°, which are within the error limits of the angles found from the X-ray determinations.

§Estimated precision = ±0.05 Hz.

Alternatively, the Altona equation (eq. [3]) for 3 substituents (27) takes into account both substituent electronegativity and orientation; it has been used successfully to describe the conformations of acyclic methylsulfonyl compounds in solution (28).

$$[3]\quad {}^3J_{HH} = 13.22\cos^2\phi - 0.99\cos\phi + \Sigma\Delta\chi_i\{0.87 - 2.46\cos^2(\xi_i\phi + 19.9|\Delta\chi_i|)\}^7$$

Application of this equation to a molecule such as **2** presents difficulties because of uncertainties in the values of group electronegativities, χ_i, especially for sulfones. For example, published group electronegativities for the phenylsulfonyl group are 2.9 (29), 4.10 (30), or 3.014 (31), whereas the methylsulfonyl group is given as 2.83 (28), 3.1 (29), or 2.998 (31) and the benzoyl group as 3.42 (30) or 2.681 (31). Clearly, the $PhSO_2$ group is more electronegative than an $MeSO_2$ group, since the pK_a values of $PhSO_2Me$ and $MeSO_2Me$ are 29.0 and 31.1, respectively (32); furthermore, Creary *et al.* (33) have recently shown that the $PhSO_2$ group is strongly electron-withdrawing, in an inductive manner. We have therefore chosen to use Langler's electronegativities (30) in the Altona equation for describing coupling constants in **2** (as outlined in footnote 7, even though these are probably too large relative to other electronegative functional groups, such as CF_3), from which we obtained torsion angles of 175° and 59°, which again agree with the X-ray results. The use of the electronegativities from ref. 31 gave torsion angles of 166° and 59°, which are in poorer agreement with, but still close to, the results for the solid state. Presumably, a similar solution conformation pertains in the case of the chloroketosulfone, **4**. Application of the Altona equation [3] to the C1—C3 bond in **8** presented further difficulties when χ values of 3.4 (PhCO) and 3.1 (Bu^tSO_2) (values from refs. 29 and 30) were used, as the equation then did not yield a large enough value for the *trans* coupling constant (only 11.15 Hz, whereas the experimental value is 11.33 Hz). The use of the group electronegativities due to Inamoto and Masuda (31), assuming that a *tert*-butylsulfonyl group has a similar electronegativity to a methylsulfonyl group, leads to torsion angles of 56° and 170° for the coupling constants of 3.55 and 11.33 Hz, respectively. This discussion serves to illustrate the difficulties that are encountered when attempts are made to quantify the electronic properties of sulfonyl groups; the values suggested for the above torsion angles must be considered to be approximate.

It is reasonable to expect that the β-hydroxysulfones **3**, **5**, **9**, and **11** will be more likely to experience bond rotations in solution, as restrictions to rotations will now be mostly steric, since these molecules have lost the electronic conjugation effects associated with the benzoyl groups of **2**, **4**, **8**, and **10**. Application of the Altona equation for four substituents (27) to the coupling constant between H11 and H21 in **3** (χ = 4.02 for $PhSO_2$, other values from ref. 29) provided a torsion angle of 177°, which compares favourably with the angle derived from the X-ray data, viz. 172(5)°. A similar application of this equation for the value obtained from **9** (χ = 3.05 for Bu^tSO_2) leads to a torsion angle of 176°. Thus, the conformation of the C2—C1—S1 backbone in these four β-hydroxysulfones is probably similar in solution to what it is in the solid state. The coupling constants between H11 and H21 and the chemical shifts of H21 in **3** and **9** are quite similar to the values given for the *threo* diastereomer of PhCHOHCHMeTs prepared by Truce and Klinger (34), using a condensation between a sulfonyl-stabilized carbanion and benzaldehyde.

The vicinal coupling constants of 5.71 and 4.86 Hz between H11 and H31,32 could not be related using eq. [3] to the approximately 60° torsion angles obtained from the X-ray structure of **3**. Rather, it became apparent that the relationship between the coupling constants was that which would be expected from a mixture of the three possible conformers arising from rotation about the C1—C3 bond. Depending on how the coupling constants were assigned, the proportions of the conformers are 37:25:38 or 40:32:28, the first number representing the conformer present in the solid state. Application of a similar procedure to the same coupling constants from **8** leads to a conformer population of 53:17:30. These proportions must be regarded as qualitative. Comparison of the solution and solid-state ^{13}C nmr spectra of **3** (Table 4) reveals only slight differences between the resonances, differences of a similar order of magnitude to those in the case of **2**. These examples

[7]The following values for the substituents $PhSO_2$, PhCO, and Me were used: χ_i = 4.1, 3.4, 2.3; ξ_i = +1, −1, +1, respectively, with the substituents in the given order, when applying this equation to coupling constants from **2**.

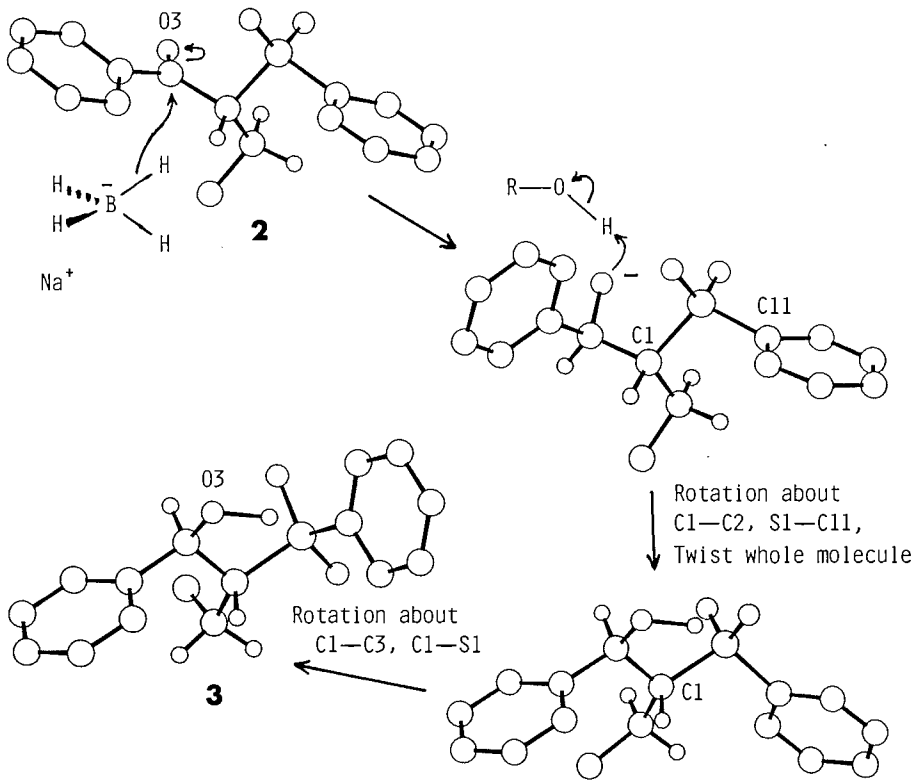

FIG. 5. A simulation of the step-by-step geometry changes required in the conversion of **2** into **3**.

serve as a further example that care must be taken when attempting to draw conclusions from comparisons between nmr spectra in these two phases (35).

A further point of interest is that the nmr spectra of **3**, **5**, **9**, and **11***a*,*b* showed coupling between the hydroxyl and the carbinol protons. In **3**, the splitting is shown unequally on the two proton resonances that are somewhat broadened, implying that the hydroxyl proton is undergoing slow exchange. However, in the other molecules, the resonances are sharply defined and the vicinal coupling constant of 3.86 Hz in **5** implies that the relationship between H3 and H21 is primarily *gauche* (36). It is likely that the greater population of this *gauche* orientation is due to weak hydrogen bonding between the hydroxyl proton and one of the sulfonyl oxygen atoms (25).

The solid-state spectra of **4** and **5** both show their resonance for Cl as a complex multiplet of relatively broad lines. This is due to a phenomenon of dipolar coupling between the carbon-13 and the two chlorine isotopes. The phenomenon is the subject of continuing interest.[8]

Mechanistic aspects of the reduction reaction

We are aware of four other reports in which diastereoselectivity in the reduction of β-ketosulfones has been observed. Bordwell and co-workers have reported (37) that the carbonyl group of 2-benzenesulfonylcyclohexanone is stereoselectively reduced by sodium borohydride; similarly, Bohlmann and Haffer (38) found that reduction of an acyclic methyl sulfone ($PhCOCMeClSO_2Me$) gives a mixture of chlorohydrins in a 7:3 ratio. More recently, Julia *et al.* (39), in a search to improve the Julia olefin synthesis (40–42), have studied the reduction of the acyclic β-ketosulfones, **12**, with three hydride-type reducing agents. Sodium borohydride gave high yields, but was relatively nonstereoselective (55–74%), lithium tri-*sec*-butylborohydride gave rather lower yields, but in some case better stereoselectivity (38–100%), and lithium aluminum hydride gave somewhat better yields and quite good selectivity (72–91%).

$RCOCHR'SO_2R''$ R = Ph or Bu^t; R′,R″ = alkyl
(12)

Interestingly, only in the case of **12**, R = Bu^t, R′ = R″ = Me, was the reduction fully stereoselective, and only by using the tributylborohydride. The authors do not provide full details in their note, nor do they provide a rationalization for the stereoselectivity that they found. The fourth report (43) is concerned with the reduction of cycloalkanones that contain a 3-arylsulfonyl group, and the reductions are only partially stereoselective.

The results discussed in this paper show quite clearly that when the carbonyl and sulfonyl groups are sufficiently proximate, the polar electronic fields about them interact to cause one conformer about the CO—C—SO_2 bonds to be predominant. When the β-ketosulfone includes both a benzoyl group and a phenylsulfonyl group, as in **2** and **4**, extra conjugation or polar effects are imposed; rotation about this bond is then probably completely hindered (at room temperature). Furthermore, in **2** and **4**, one of the sulfonyl oxygen atoms is located close enough to the trajectory normally followed by a nucleophile adding to the *si* face of the carbonyl group so that this reaction is kinetically disfavoured. The preferred reaction path is thus attack at the *re* face, leading to the *threo* diastereomer.[9]

It was intriguing to find that the actual conformation of the products (**3** or **5**) from reduction of **2** or **4**, respectively, can be

[8]R. E. Wasylishen and M. McKinnon, to be published.

[9]Alternatively, **3** can be described as the *RS*(1*l*,2*u*) diastereomer, whereas **5** is *RS*(1*l*,2*l*) (44).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/07/12
For personal use only.

arrived at quite simply by assuming the hydride attack on the *re* face of the carbonyl (which includes a rehybridization of the carbonyl carbon atom), followed by partial rotations about three C—C bonds. This view of the reaction can be simulated using molecular models, or by the molecular drawing properties of the CHEMGRAF system, as shown in Fig. 5. Although we recognize that this approach is speculative and that it cannot suggest the order in which the events might have happened, the structures in Fig. 5 represent a plausible representation for the reaction pathway of the stereoselective reduction at the carbonyl group.

Conclusions

The stereoselective reduction of these β-ketosulfones can be described by the Felkin modification of Cram's Rule (4, 7). It is not readily apparent whether the stereoselectivity is due to a low-lying σ* orbital from the adjacent C—SO_2 bond (7), or whether the effect is simply a steric control on the reagent trajectory, arising from the particular conformation adopted by these β-ketosulfones.

We suggest that the diastereoselectivity shown by this reaction system has significant synthetic potential as a stereoselective synthesis of heavily substituted styrenes, using the Julia synthesis (40–42). We are exploring the potential of such a synthesis.

Experimental

General

Thin-layer chromatography was carried out on E. Merck or Brinkmann silica sheets with fluorescent indicator, which were developed with dichloromethane. Aqueous solutions were worked up by extraction with the requisite organic solvent, which was washed two or three times with water, dried over anhydrous sodium sulfate, and rotary evaporated using a water-aspirator vacuum. The compounds were all purified by recrystallization from the solvent given. Melting points were taken with a Fisher–Johns apparatus and are uncorrected. Infrared spectra were run as KBr pellets on a Perkin–Elmer model 283 spectrophotometer. Mass spectra were recorded on a CEC 21-104 magnetic sector spectrometer, equipped with a modified scan system (45) and IBM-PC control and data system,[10] at 70 eV, source temperature of ca. 150°C, using a glass direct-injection probe.

Proton nmr spectra were run in $CDCl_3$ solutions, referenced to TMS, on a Nicolet 360 NB nmr spectrometer typically using a spectral window of 4000 Hz, an acquisition time of 4–8 s, and transformed using 32- or 64K data points. Carbon-13 nmr spectra for **2**–**5** were recorded in $CDCl_3$ solutions, referenced to TMS, on a Varian CFT-20 spectrometer, using 35° pulses, a spectral window of 4505 Hz, an acquisition time of 0.5 ms, and were processed using 8K data points. The ^{13}C solution nmr spectra for **8**–**11** were recorded on the Nicolet spectrometer with SW = 20 000 Hz, AT = 400 ms, and a 16K Fourier transform. All lines observed in each spectrum could be interpreted in terms of the structure of the molecule. Solid-state carbon-13 nmr spectra were recorded on powdered samples (ca. 0.4 g) packed into cylindrical rotors made from alumina, using a Bruker MSL-200 spectrometer operating at 50.3 MHz while the sample was spun (magic-angle) at 4.5–5 kHz. Cross polarization was accomplished using the Hartmann–Hahn match with 90° pulses of about 4 μs and contact times of 2–3 ms. Data tables of 8K points were collected over a sweep width of 13.5 kHz and spectra were signal-averaged for at least 100 transients using recycle times of 2–3 s. A sensitivity enhancement corresponding to 15 Hz of line broadening was applied before Fourier transformation. The chemical shifts were referenced with respect to external adamantane, which has shifts of 29.50 ppm (*C*H) and 38.56 ppm (CH_2) with respect to TMS (46). All the nmr data are recorded in Tables 4 and 5.

[10]B. Millier and J. S. Grossert, unpublished work in this department.

Details by which data for the X-ray crystal structure determinations were acquired have been published recently (17); all structures were refined using the CRYSTALS system (issue V).

Preparation of 2-phenylsulfonyl-1-phenylethanone, 6

Sodium benzenesulfinate and phenacyl chloride were refluxed in absolute ethanol and worked up to give **6** as colourless needles (95% ethanol, >80% yield), mp 91–92°C (lit. (47) mp 96°C).

Preparation of 2-phenylsulfonyl-1-phenylbutanone, 2

A mixture of **6** (5.20 g, 20 mmol), iodoethane (16 mL, 200 mmol), benzyltriethylammonium bromide (0.7 g), sodium hydroxide (1.60 g, 40 mmol), dichloromethane (40 mL), and water (20 mL) was stirred in an ultrasonic bath for 4.5 h. After cooling, dichloromethane (100 mL) was added and the mixture worked up to give **2** as white needles (95% ethanol, 3.5 g, 60%), mp 91–92°C; ir ν_{max}: 1667 (s), 1448 (m), 1305 (m, br), 1267 (s), 1145 (s), 745 (s), 679 (m), 559 (s) cm^{-1}; ms *m/z*: 288 ($M^{+\cdot}$, 3.2), 260 (2.4), 224 (6.4), 147 (3.4), 146 (6.4), 105 (100), 91 (2.3), 77 (32) daltons.

Preparation of 2-phenylsulfonyl-1-phenylbutanol, 3

A mixture of **2** (1.10 g, 3.82 mmol), NaH_2PO_4 (0.360 g, 3 mmol), $NaBH_4$ (0.152 g, 4.02 mmol), dimethoxyethane (15 mL), and water (3 mL) was stirred for 1 h at room temperature, after which it was poured into 10% NH_4Cl solution (25 mL) and extracted with diethyl ether. Regular work-up gave **3** as fine white needles (1:1 hexane–dichloromethane, 0.82 g, 74%), mp 135–137°C; ir ν_{max}: 3500 (s), 1449 (m), 1283 (s), 1142 (s), 759 (s), 729 (s), 692 (s), 628 (m) cm^{-1}; ms *m/z*: 292 (2.25), 291 (6.38), 290 ($M^{+\cdot}$, 33.8), 184 (100), 169 (93), 149 (17), 148 (32), 107 (35), 105 (14), 91 (32), *m** at 117.0, 146.5, 155.5 daltons.

Preparation of 2-chloro-2-phenylsulfonyl-1-phenylbutanone, 4

A solution of **2** (1.19 g, 4.13 mmol) in dry toluene (40 mL) was dropped on to NaH while stirring (0.20 g of 50% oil dispersion, oil removed by washing with dry ligroin, 4.17 mmol) and the mixture was then heated under nitrogen for 5 h (90°C oil bath). At this point, *N*-chlorosuccinimide (0.70 g, 5.2 mmol) was added in one portion, and heating continued for a further 5 h, after which the mixture was allowed to stand at room temperature overnight before being worked up with diethyl ether and water to give **4** as brilliant colourless prisms (1:1 hexane – diethyl ether, 1.30 g, 97%), mp 58–60°C; ir ν_{max}: 1678 (m), 1450 (m), 1315 (m), 1232 (s), 1153 (s), 763 (s), 682 (s), 568 (s) cm^{-1}; ms *m/z*: 324 ($M^{+\cdot}$, 1.00), 322 (2.52), 183 (2.13), 181 (6.39), 141 (1), 125 (1), 117 (1), 115 (1), 105 (100), 77 (33) daltons.

Preparation of threo*-2-chloro-2-phenylsulfonyl-1-phenylbutanol, 5*

A mixture of **4** (3.26 g, 10.1 mmol), NaH_2PO_4 (1.152 g, 9.6 mmol), $NaBH_4$ (0.384 g, 10.2 mmol), dimethoxyethane (48 mL), and water (10.6 mL) was reacted and worked up as for **3** (above) to give **5** as fine white needles (1:1 diethyl ether – dichloromethane, 2.90 g, 88%), mp 130–133°C; ir ν_{max}: 3495 (s), 1448 (m), 1303 (s), 1285 (s), 1148 (s), 1062 (s), 731 (s), 555 (s) cm^{-1}; ms *m/z*: 326 (5.75), 324 ($M^{+\cdot}$, 14.9), 220 (22.3), 218 (60.1), 205 (11.4), 203 (30), 185 (4.4), 183 (12.8), 147 (37), 143 (21), 125 (10), 119 (12), 107 (100), 105 (36), 91 (63), 79 (30), 78 (23), 77 (67), *m** at 189.5 daltons.

Preparation of 2-tert*-butylsulfonyl-1-phenylbutanone, 8*

Phase-transfer condensation of phenacyl chloride (15.4 g, 0.1 mol) and *tert*-butylthiol (9.0 g, 0.1 mol) in an analogous manner to that described for the preparation of **2** gave relatively clean *tert*-butyl phenacyl sulfide (20.6 g), part of which was recrystallized to give needles, mp 143–145°C (from ethanol), ms *m/z* 208 ($M^{+\cdot}$, 11), 152 (23), 105 (100) daltons. A methanolic solution of the sulfide (5.0 g, 24 mmol) was oxidized with excess 30% H_2O_2 in the presence of ammonium molybdate catalyst following the method of Schultz *et al.* (48) to give crude 2-*tert*-butylsulfonyl-1-phenylethanone (**7**). This was purified by recrystallization from absolute ethanol to form **7** as needles (4.2 g, 73%), mp 77–78°C; ir ν_{max}(KBr): 1681 (s), 1452 (s), 1339 (m), 1238 (s), 1017 (m), 710 (s), 704 (s), 576 (s) cm^{-1}; ^1H nmr δ($CDCl_3$): 1.4 (s, 9H), 4.5 (s, 2H), 6.9–8.0 (m, 5H); ms *m/z*:

240 ($M^{+\cdot}$, 0.6), 184 (0.9), 176 (5), 120 (100), 118 (3), 105 (19), 91 (9), 78 (6), 77 (14), 57 (94), *m** at 150, 92.0, 82.2, 46.9 daltons.

Ethylation of **7** (2.8 g, 11.6 mmol) was carried out by phase-transfer condensation with iodoethane (3.6 g, 23 mmol), as described above for **2**, to give crude **8**; several recrystallizations (ethanol) gave **8** as white needles, mp 188–189°C (1.63 g, 55%); ir ν_{max}(KBr): 2980 (m), 1688 (s), 1287 (s), 1269 (s), 1217 (s), 1110 (s), 747 (s), 685 (s) cm^{-1}; ms *m/z*: 150 (0.77), 149 (11.4), 148 (100, $M^{+\cdot} - 64 - 56$), 147 (17), 133 (36), 120 (5), 105 (49), 91 (3), 77 (28), 57 (70), *m** 97.5 daltons.

Preparation of threo-*2*-tert-*butylsulfonyl-1-phenylbutanol, **9***

A mixture of **8** (420 mg, 1.57 mmol), NaH_2PO_4 (138 mg, 1.15 mmol), and $NaBH_4$ (60 mg, 1.57 mmol) in EtOH–Et_2O–water (11 mL, 5:5:1) was stirred vigorously for 1 h, at room temperature. Regular work-up with water and Et_2O gave homogeneous (by tlc) material, which by ^1H and ^{13}C nmr was a mixture (ca. 9:1) of the *threo* and *erythro* diastereomers (400 mg, 95%). Recrystallization (CH_2Cl_2–hexane, 1:1) gave **9** as white prisms, mp 67–69°C; ir ν_{max}: 3500 (s), 2990 (m), 1470 (m), 1271 (s), 1239 (s), 1100 (s), 697 (s), 555 (s) cm^{-1}; ms *m/z*: 270 ($M^{+\cdot}$, 3.4), 214 (0.25), 205 (0.1), 187 (0.1), 164 (9), 150 (2.5), 149 (19), 148 (22), 147 (2), 133 (10), 132 (45), 131 (7), 117 (23), 108 (38), 107 (22), 105 (7), 91 (24), 79 (9), 77 (11), 57 (100), *m** at 146.0, 104.0 daltons.

Preparation of 2-tert-*butylsulfonyl-2-chloro-1-phenylbutanone, **10***

A sample of **8** (2.0 g, 7.46 mmol) was chlorinated with NaH and NCS, as for the preparation of **4**, to give **10** as colourless needles (Et_2O–hexane, 1:1, 1.55 g, 68%), mp 74–75°C; ir ν_{max}(KBr): 2985 (m), 1670 (s), 1308 (s), 1301 (s), 1236 (s), 1121 (s), 759 (s), 618 (s) cm^{-1}; ms *m/z*: 302 ($M^{+\cdot}$, 0.28), 184 (26), 183 (11), 182 (77), 169 (8), 167 (23), 147 (6), 131 (4), 105 (100), 77 (45), 57 (80), *m** at 153.6, 119.0 daltons.

Preparation of 2-tert-*butylsulfonyl-2-chloro-1-phenylbutanol, as a diastereomeric mixture, **11**a + b*

A mixture of **10** (800 mg, 2.65 mmol), NaH_2PO_4 (250 mg, 2.17 mmol), and $NaBH_4$ (127 mg, 3.4 mmol) was reacted in the usual way in DME (10 mL) and water (1 mL) to give **11** as a crystalline mixture (785 mg, 97%); ir ν_{max}(KBr): 3450 (s), 2930 (m), 1457 (s), 1285 (s), 1120 (s), 1095 (s), 1085 (s), 1048 (s), 697 (s), 660 (s), 555 (s) cm^{-1}; ms *m/z*: 306 (1.2), 304 ($M^{+\cdot}$, 3.3), 200 (1), 198 (3), 185 (1), 183 (4), 168 (7), 166 (21), 148 (10), 147 (13), 142 (15), 131 (11), 107 (26), 105 (20), 91 (19), 77 (16), 57 (100) daltons.

Substitution reactions adjacent to sulfonyl groups are known to proceed with difficulty, and there is evidence to suggest that these may not necessarily proceed by an S_N2 pathway. The mechanism of these reactions could be studied in principle by using the conversion of α-chloro-β-hydroxysulfones of known configuration into α,β-epoxysulfones of known configuration. This paper describes results in which this has been attempted. However, the stereochemical aspects of the epoxide formation could not be assigned unequivocally because of the intervention of a very facile "retro-aldol" process when the chlorohydrins are subjected to treatment with bases, although the experimental results do suggest that the reaction does proceed in a regular S_N2-like manner, with inversion at carbon. The X-ray crystal structures of two highly substituted α,β-epoxysulfones are presented, thus putting the structures, including stereochemistry, of a range of these compounds on firm ground.

J. Stuart Grossert, Subramanian Sotheeswaran, H. Ranjith W. Dharmaratne et T. Stanley Cameron. Can. J. Chem. **66**, 2870 (1988).

Il est connu que les réactions de substitution sur des carbones voisins de groupements sulfonyles ne se produisent qu'avec difficulté et il existe des données suggérant que ces réactions ne procèdent pas nécessairement par une voie S_N2. En principe, on peut étudier le mécanisme de ces réactions en utilisant la transformation d'α-chloro β-hydroxysulfones de configurations connues en α,β-époxysulfones de configurations connues. Dans ce travail, on décrit les résultats de telles études. Toutefois, dû au fait qu'un processus «rétro-aldolique» facile intervient lorsque les chlorohydrines sont soumises à un traitement par les bases, on n'a pas pu attribuer sans équivoque les aspects stéréochimiques de la formation de l'époxyde même si les résultats expérimentaux suggèrent que la réaction se produit de fait par le biais d'une réaction régulière S_N2, avec inversion au niveau du carbone. On présente les structures cristallines déterminées par diffraction des rayons-X de deux α,β-époxysulfones fortement substituées; on établit donc avec certitude les structures, y compris leur stéréochimie, d'un large éventail de ces composés.

[Traduit par la revue]

Introduction

Substitution reactions adjacent to sulfones are known to be both difficult and complex in mechanism. Generally, the reactions occur when thiolate nucleophiles attack α-chloro- or bromosulfones (eq. [1]) (1–6), whereas most other nucleophiles give rise to reductive dehalogenation rather than to substitution reactions (eq. [2]) (1, 4, 7–11). This being the

[1] $RCHClSO_2R' + R''S^- \rightarrow RCHSR''SO_2R' + Cl^-$

[2] $RCHClSO_2R' + Nu^- + HA \rightarrow RCH_2SO_2R' + NuCl + A^-$

case, it is possible to envisage an alternative pathway for the substitution reactions to occur, as outlined in eq. [3] (4, 12, 13), although possible difficulties with this concept have been pointed out (4). We have been able to show that this pathway is indeed operative when thiolate anions attack an α-halo-β-ketosulfone in tetrahydrofuran solutions (14). Both we and Hendrickson have suggested that a similar pathway could be operative in the Ramberg–Bäcklund reaction (15). So far as we are aware, there is clear experimental evidence for an S_N2 reaction process only in the case of reactions involving regular types of nucleophiles, such as halide ions, and triflate or N_2^+ leaving groups (cf. eq. [4]) (16, 17).

[3] $RCHClSO_2R' + R''S^- \rightarrow R^-CHSO_2R' + R''SCl \rightarrow RCHSR''SO_2R' + Cl^-$

[4] $ArSO_2CH_2OSO_2CF_3 + Nu:^- \rightarrow ArSO_2CH_2Nu$

By contrast, a small group of reactions that result in an intramolecular expulsion of chloride or bromide ions are well known to be facile. The first is the Ramberg–Bäcklund reaction, which has been thoroughly reviewed (18, 19). A second group of reactions is those in which an internal oxygen or sulfur nucleophile displaces a chlorine or bromine atom α to a sulfonyl group, the products being 5-membered rings with two or more heteroatoms. The recorded examples (20–22) proceed relatively easily and efficiently.

The final reaction in this group concerns the formation of α,β-epoxysulfones from the corresponding chlorohydrins (23) and is the basis of the work described in this paper. Bohlmann and Haffer prepared a diastereomeric mixture of sulfonyl chlorohydrins, **1** and **2**, and found that these could be converted into a mixture of epoxysulfones **3** and **4**. The major diastereomer (**1**) could be crystallized out of the mixture, and converted into the major epoxysulfone, **3**. These authors assigned a configuration to this epoxysulfone from the chemical shifts of groups in its proton nmr spectrum. Then, from the above conversion, the authors assigned the configurations of the chlorohydrins (23): "Da 15 aus 12 entsteht, ist damit auch die Konfiguration der epimeren Chlorhydrine geklärt, denn die Bildung von 15 dürfte zweifellos als innere S_N2-Reaktion mit Inversion ablaufen". This argument is not necessarily flawless, since the configuration of the epoxysulfone **3** is in fact not readily determined by correlation of chemical shift values with stereochemistry. Furthermore, in the light of the results from work done (*vide supra*, 11–13) since Bohlmann and Haffer wrote this sentence, it is no longer so clear-cut that the formation of the epoxysulfones, **3** and **4**, *necessarily* proceeds from **1** and **2** via an internal S_N2 process.

In parallel with the work by Bohlmann and Haffer, Vogt and

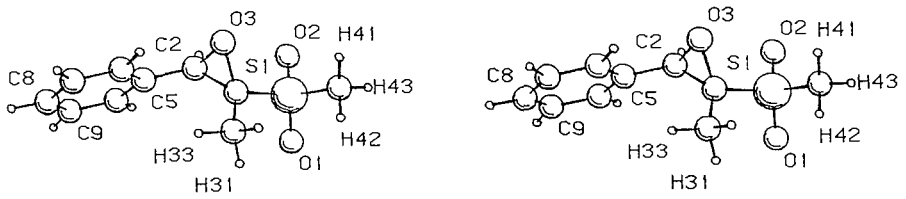

FIG. 1. A stereoscopic view of the crystal structure of *E*-1,2-epoxy-2-methylsulfonyl-1-phenylpropane (**3**).

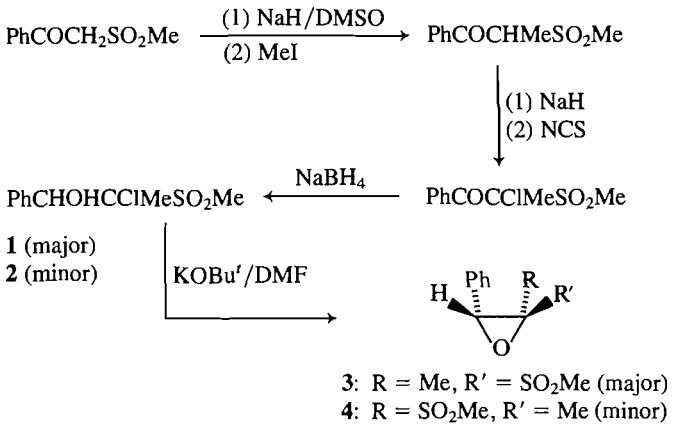


SCHEME 1

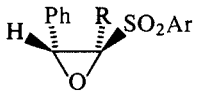
Tavares synthesized α,β-epoxysulphones, **5**, by a Darzens-type of condensation and found that only the *trans* stereoisomer was formed (24). Their assignment of stereochemistry was based on known vicinal proton–proton coupling constants in oxiranes, but the differences in these constants between the *cis* and *trans* isomers are in fact too small to permit unambiguous assignments (25), and caution is required. Since this time, the Darzens type reaction has been extended by the use of phase-transfer conditions (26), but no further work has apparently been done to confirm the stereochemistry of the oxirane rings.

We have demonstrated that it is possible to prepare highly substituted α-chloro-β-hydroxysulfones (27) of known stereochemistry. The purpose of the work described here was to take these and other chlorohydrins and convert them into α,β-epoxysulfones, at the same time determining unambiguously the stereochemistry of the relevant species by the use of ^{1}H nmr spectroscopy and X-ray crystallography. From this stereochemical knowledge, it should then be possible to describe the mechanism of displacement reactions α to the sulfonyl group as occurring with inversion or with retention of configuration, the former being required by an S_N2-type process, the latter by a process as outlined in eq. [3].

Results and discussion

The preparation and structures of the chlorohydrins and epoxysulfones

To gain an understanding of the reactions involved, as well as to take advantage of modern spectroscopic and structural techniques, we repeated the preparations of a few key compounds. Thus Bohlmann's diastereomeric mixture of chlorohydrins **1** and **2** (23) was prepared by a different reaction sequence, as outlined in Scheme 1. The reactions used in this synthesis are directly analogous to those described in the previous paper (27). Treatment of these molecules with potassium *tert*-butoxide in DMF solution gave an oily mixture from which the *E*-epoxysulfone, **3**, could be recovered. Its physical properties agreed with those found by Bohlmann and Haffer (23), and we resorted to X-ray crystallography to determine its stereochemistry unambiguously.[4,5] We did not succeed in isolating the *Z* epoxide, **4**, which may have been present in the crude product from the reaction, but this was not isolated by Bohlmann and Haffer either. The result of this determination was to confirm the stereochemistry of **3** (see Fig. 1)[6] that was assigned by Bohlmann and Haffer. It has also given substance to the stereochemistry of a range of other α,β-epoxysulfones, such as **5***a* and *b*, that have been prepared by Vogt and Tavares (24). We prepared **5***c* as an unstable, crystalline material, using



5

a: R = H, Ar = *p*-tolyl
b: R = Me, Ar = *p*-tolyl
c: R = H, Ar = Ph

the phase-transfer-catalyzed technique (26) for the Darzens condensation. A nuclear Overhauser experiment on the two protons directly attached to the epoxide ring showed that these are *trans* to each other, which again confirmed the previous literature assignments of stereochemistry in these epoxysulfones.

Having established that the published stereochemistry of these epoxysulfones was indeed firmly grounded, we turned our attention to the stereochemical relationship between them and their precursor chlorohydrins. We had prepared the *threo* chlorohydrin, **6**, and had established its stereochemistry unequivocally (27). When this was subjected to the same basic

[4]Crystal data for **3**: $C_{10}H_{12}O_3S$, F.W. = 212.35, orthorhombic, a = 15.122(3), b = 10.039(2), c = 6.986(1) Å; Z = 4; V = 1060.5(3) Å^3; d_c = 1.329(1) g cm^{-3}; space group $Pca2_1$; $F(000)$ = 448e; μ = 2.32 cm^{-1}; Mo-K_{α_1} radiation, λ = 0.70926 Å; 1000 unique reflections were collected, of which 846 with $I > 3\sigma(I)$ were used; R = 0.0311, R_w = 0.0313.

[5]Selected bond lengths, bond angles, and torsion angles for compounds **3** and **21** are recorded in Table 3. Sets of positional parameters and isotropic thermal parameters (Tables 5, 6), of the complete anisotropic thermal parameters (Tables 7, 8), of the structure factor tables (Tables 9, 10), and full details of distances, bond angles, and torsion angles (Tables 11, 12) and the structure determinations (Tables 13, 14) may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

Crystal data and bond lengths and angles for these compounds have also been deposited with the Cambridge Crystallographic Data Centre, and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, Cambridge CB2 1EW, U.K.

[6]This stereoscopic drawing was produced by the SNOOPI program, a part of the CHEMGRAF system (Chemical Designs, Oxford, U.K.).

conditions (including reaction concentration) that Bohlmann and Haffer had used, the exclusive product was the *E*-α,β-epoxysulfone, **7**, as shown in eq. [5].

[5] 
6 (*threo*) **7**

An epoxide with this stereochemistry could not have been formed directly from **6** *by a reaction pathway involving the normal stereoelectronics expected for the conversion of a chlorohydrin into an epoxide (28).* We were unable to produce crystals of **7** of an adequate quality, suitable for an X-ray diffraction experiment, and while its stereochemistry was quite convincingly given by the very similar chemical shifts of the benzylic ring methine proton in **7** and **3**, we wished to obtain as unequivocal as possible a picture of the reactions that were involved in the formation of these epoxysulfones. The fact that the formation of **7** from **6** was not a direct process was readily apparent when we found that it was possible to prepare the *erythro* diastereomer, **10** (see eq. [6]), and we were then able to show that this also could be converted very readily into the same epoxysulfone, **7**, that had been made from **6**. It was thus necessary to obtain clear evidence for the stereochemistry of **7**, or to obtain the stereochemical evidence needed with another chlorohydrin and epoxysulfone pair.

[6] $PhSO_2CHClEt$ (**8**) $\xrightarrow[(2)\ PhCHO,\ cold]{(1)\ Bu^nLi}$  $\xrightarrow[DMF]{KOBu^t}$ **7**

10 (*erythro*)

This was sought in several ways. The compounds **11**, having a methyl in place of the ethyl group in **6** and **10**, could be prepared, but only as an inseparable mixture of diastereomers. We prepared these in two ways. In the first instance, the chlorosulfone **9** (which is readily available from phenyl ethyl sulfide, by chlorination and oxidation) could be condensed with benzaldehyde at low temperatures to yield **11**, which contained an excess of the *erythro* diastereomer, eq. [7].

In the second instance, the β-ketosulfone, **14**, was prepared from propiophenone via **12** and **13**. Reduction of **14** with sodium borohydride again led to a mixture of **11***a* + *b*, but with the *threo* diastereomer, **11***a*, predominating. This sequence of reactions is outlined in Scheme 2.

[7] $PhSO_2CHClMe$ (**9**) $\xrightarrow[(2)\ PhCHO,\ -60°C]{(1)\ Bu^nLi}$ $PhCHOHCClMeSO_2Ph$

(**11***b*, major)
(*erythro*)

Treatment of a diastereomeric mixture of the chlorohydrins, **11**, with potassium *tert*-butoxide, as before, led to a single epoxysulfone, **15**, the nmr spectra of which (Table 2) implied an *E* stereochemistry, the same as that of **3** and **7**. The same epoxysulfone could be prepared by a Darzens condensation, under phase-transfer conditions (26), from the chlorosulfone **9** and benzaldehyde, as in eq. [8].

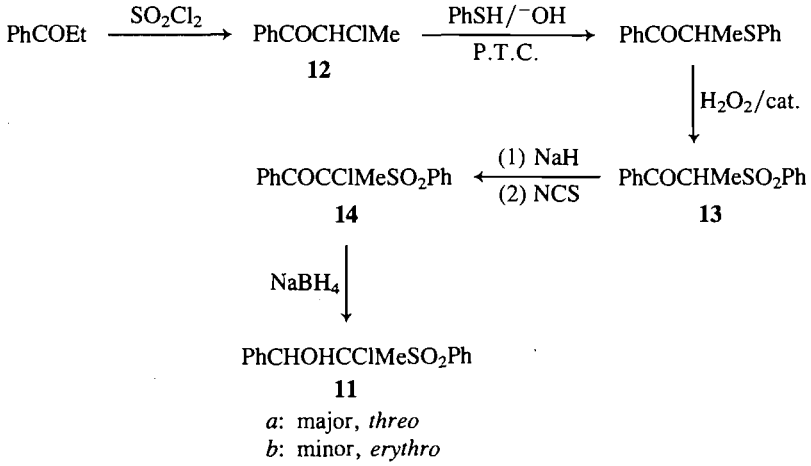
[8] $PhCHOHCClMeSO_2Ph$ (**11**) $\xrightarrow[DMF]{KOBu^t}$ 
15

P.T.C. ^-OH, PhCHO

$PhSO_2CHClMe$ (**9**)

These reactions and their products showed great similarity to those of the ethyl series, viz. **6** or **10** → **7**. However, they still did not provide unequivocal evidence for the stereochemical path of the reaction leading to formation of the epoxysulfones. The fact that either **6** or **10** could lead to a single product was highly suggestive of a common intermediate, which must involve a cleavage reaction that is the reverse of eq. [7] and involves the intermediacy of a chloroalkyl phenylsulfonyl carbanion, $^-$:CClRSO$_2$Ph. We reasoned that this cleavage reaction could perhaps be disfavoured by employing an alkylsulfonyl residue in place of the phenylsulfonyl moiety (29), and proceeded to explore the chemistry of the equivalent compounds leading to **7** and **15**, but instead incorporating the *tert*-butylsulfonyl group. This was chosen to provide a reasonable degree of steric hindrance around the sulfonyl group so as to afford adequate diastereoselectivity in the reduction of the appropriate β-ketosulfones (27).

The preparation of **18** was straightforward (Scheme 3), starting from 2-chloropropiophenone (**12**), which was condensed with *tert*-butyl mercaptan, followed by oxidation of the β-ketosulfide to the sulfone **16**. This could be chlorinated in the



SCHEME 2

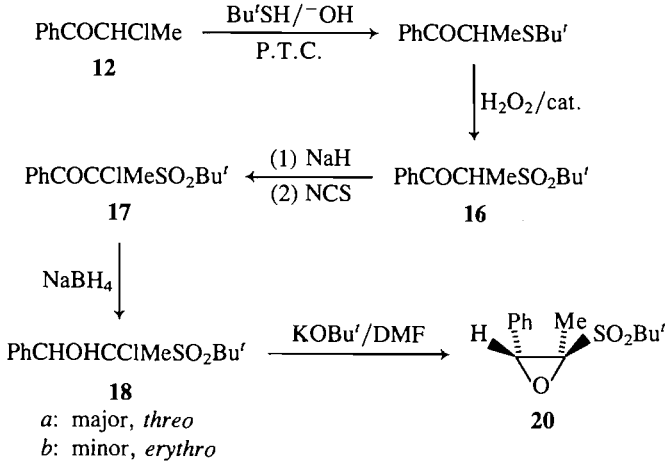
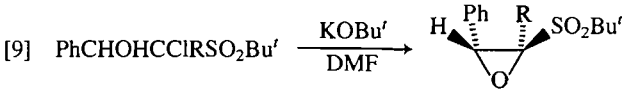


SCHEME 3

usual way to **17**, which on reduction with sodium borohydride gave the chlorohydrin **18** as a mixture of diastereomers, the *threo* form, **18***a*, again being predominant. The corresponding ethyl derivative, **19**, was also prepared (27), again as a mixture of diastereomers. When **18** and **19** were subjected to the regular basic conditions used for epoxide formation, the epoxysulfones **20** and **21**, respectively, were cleanly formed, as outlined in eq. [9].



18: R = Me
19: R = Et
20: R = Me
21: R = Et

The structures of these species were apparent from the close similarities of all the nmr spectra as seen in Tables 1 and 2. However, we were successful in growing crystals of **21** that were suitable for X-ray diffraction,[5,7] which confirmed the *E* stereochemical designation for this molecule, as depicted in Fig. 2.[6]

Spectroscopic and structural features

All molecules were carefully characterized by a full range of standard spectroscopic methods. It quickly became apparent that the most useful method for the detection and positive identification of the diastereomeric mixtures of chlorohydrins was high-field proton and carbon-13 nmr spectroscopy. The resonances of each species, as well as of the associated epoxysulfones and the chlorosulfones, such as **8** or **9**, are adequately dispersed about the chemical shift scale so as to permit ready, and positive, observation of significant quantities of any of these species within a given mixture.

An examination of Table 1 shows that the chemical shifts of most protons in the diastereomeric pairs of chlorohydrins show clear-cut differences, characteristic of each diastereomer. For example, the resonance of the carbinol methine proton is downfield in the *threo* diastereomer in each pair, except for **18**. This serves to underline the need for care, and the use of a range of both compounds and structural evaluations in assigning the stereochemistry of these species. Many of the spectral features discussed in detail in the accompanying paper (27) appear in these molecules, except for the epoxysulfones, and thus do not warrant further detailed discussion. The ring stereochemistry of the epoxysulfones **3**, **5***c*, and **21** has been determined unequivocally and an inspection of Table 2 shows that the same stereochemistry must pertain to **3**, **7**, **15**, **20**, and **21**, given the similarities of the chemical shifts of their ring carbons and protons.

Fragmentation patterns in the mass spectra of most stereoisomers are usually quite similar. This is so in the case of the *threo* and *erythro* diastereomers **6** and **10**, with the exception of the ion at *m/z* 142, which is quite insignificant in **6**, yet is a major ion in the spectrum of **10**. A mass spectrum at high resolution is required to identify the composition of this ion,

*Footnotes as per Table 1.

but it is likely to be $PhSO_2H^{\cdot+}$, which could arise by the interaction of the $PhSO_2$ group and a proximate proton, followed by a cleavage reaction, either from the molecular ion of **10** or from a higher energy daughter ion in the fragmentation process. The relevant proton would be proximate to the sulfonyl group only in the *erythro* diastereomer, and further work on clarification of this interesting reaction is under way.

So far as we are aware, only Bohlmann and Haffer (23) have discussed the mass spectrometry of α,β-epoxysulfones, in which they have produced some interesting speculation for a fragmentation pathway. The spectra of **7** and **21** on the one hand and **15** and **20** on the other are quite similar. The phenylsulfonyl compounds lose m/z 141 ($PhSO_2$), but the *tert*-butyl compounds lose both the elements of $C_4H_8SO_2$ and $C_4H_9SO_2$, probably in two-step processes, transfer of a proton from the *tert*-butyl group in the first case being energetically favourable. Thus, the spectra of both **7** and **21** have strong ions at 147 daltons, which appear to fragment further as outlined in eq. [10]. Evidence for these steps comes from the shape of the

$$[10]\quad \underset{m/z\ 147}{C_{10}H_{11}O^{+}} \xrightarrow[-C_2H_4]{} \underset{119}{C_8H_7O^{+}} \xrightarrow[-CO]{} \underset{91}{C_4H_7^{+}} \rightarrow\rightarrow$$

metastable ions associated with them, the ion at ca. 97.0 daltons being broad, whereas the ion at ca. 69.9 daltons is quite sharp and has a very similar shape to the ion associated with the loss of CO from $PhCO^{+}$, as observed in many benzoyl compounds. These ions have a very similar shape in the spectra of both molecules. The spectra of **15** and **20** are somewhat more complex, although both molecules give m/z $M^{+\cdot}$ – "RSO_2", viz. ions at 133 daltons. These appear to fragment further to ions at 105 and 79 daltons, with metastable ions that appear to support these processes.

All four epoxy sulfones show strong evidence of rearrangements occurring in the molecular ions, in addition to the cleavages described above. The formation of ions at 232 and 231 daltons in the fragmentation of **7** and **15**, and 212 daltons in **20**, is evidence of oxygen-to-carbon migration by the sulfonyl group in the molecular ion. This is confirmed by the presence of significant ions at 125 daltons ($PhSO^{+}$), as these ions are not normally very strong in the mass spectra of regular phenylsulfonyl compounds (14). There is also methyl-to-carbon migration in the molecular ions of **15** and **21**, as shown by the strong ions at 105 daltons in these species, whereas the corresponding ions in the ethyl derivatives **7** and **21** occur at 119 daltons. The fragmentations proposed here can be deduced by a careful examination of low-resolution spectra and accompanying metastable ions. However, the processes are complex and confirmatory evidence will have to be acquired from detailed high-resolution spectra and precursor-ion studies.

As far as we have been able to determine, the structures of the two α,β-epoxysulfones, **3** and **21**, are the first crystal structures of this particular complex functionality. One bicyclic structure having some similarities has been studied by Sands (30). In fact, even the reported number of *tert*-butylsulfonyl structure determinations is limited, one example being that of a chiral α-chlorosulfone (31). The bond lengths and angles about the key parts of **3** and **21** (see Table 3) are within the normal ranges for the relevant combinations of atoms (32–34). Perhaps the only noteworthy feature of the two structures is the significant difference between the C1—O3 and C2—O3 bond lengths in **3**. There is no obvious explanation for this difference. Compounds **3** and **21** are substituted styrene oxides and their crystal structures are of interest in connection with work in another area,[8] viz. the stereoelectronic effects associated with substitution reactions at a benzylic carbon atom (35). A particular aspect of this reaction concerns the nucleophilic attack on substituted styrene oxides (36), in which it has been shown that phenyl-

†Constrained during refinement.

oxirane is significantly less reactive towards nucleophilic attack than is oxirane itself. The preferred regiochemistry for this reaction is β to the phenyl ring, in contrast to the normal reactions of benzylic halides, and the phenomenon has been attributed to conformational preferences of the phenyl ring with respect to the oxirane ring (35, 36). Calculations suggest that the preferred conformation of phenyloxirane has an O—$C_{benzylic}$—C_{ipso}—C_{ortho} torsion angle of 0° (37), whereas the optimum geometry for reactivity towards nucleophiles requires this angle to be about 90°. The equivalent torsion angle is 3.7° and 7° in **3** and **21**, respectively, but is 24° in 4′-nitrophenyloxirane (32); however, the mechanism of nucleophilic attack on this latter oxirane does not appear to have been reported (35).

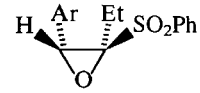
Mechanistic aspects of the epoxide formation

When we found that either chlorohydrin **6** or **10** could be converted into **7**, it was abundantly clear that this reaction system was not going to provide the answer to the stereochemical question that we had posed, viz., "Does a nucleophilic substitution reaction α to the sulfonyl group proceed with inversion or with retention of configuration at the electrophilic carbon?" We have studied the conversion of these chlorohydrins into **7** under a range of conditions, summarized in Table 4, which leads to the conclusion that the reaction of the chlorohydrins with base in dry *N*,*N*-dimethylformamide must involve more than one reaction process. At higher reaction concentrations, epoxide formation predominates; otherwise the reaction (cf. eqs. [5] or [9]) leads to a substantial quantity of the cleavage products, benzaldehyde and the appropriate α-chlorosulfone. It is remarkable how facile the formation of the epoxysulfones is, when compared to intermolecular displacement reactions adjacent to sulfones, and that even the briefest treatment of **6** or **10** with potassium *tert*-butoxide in DMF leads to complete destruction of the chlorohydrin, such as in entries 1, 2, and 9 (Table 4). The argument made by Bohlmann and Haffer (23) that the configuration of the chlorohydrins **1** and **2** could be deduced from the configuration of the epoxysulfone, **3**, is thus unfounded, although it was quite reasonable at the time when it was made (38).

The fact that the relevant reaction was complicated by a "retro-aldol"-type process, the reverse process of that depicted in eqs. [6] or [7], was proved by carrying out crossover experiments in which the chlorohydrins **6** and **10** were reacted under the regular basic conditions in the presence of *p*-tolualdehyde, as depicted in eq. [11]. The crossover epoxide,

[11] $PhCHOHCClEtSO_2Ph + p\text{-TolCHO} \xrightarrow[DMF]{KOBu^t}$

6 or **10**



+ $PhSO_2CHClEt$

8

7: Ar = Ph
22: Ar = *p*-tolyl

22, was clearly visible in the product mixture because of its characteristic peaks in both the ^1H nmr and mass spectra. We reasoned that this cleavage process would be facilitated by the phenylsulfonyl group, which would strongly stabilize the carbanion $^-$:$CEtClSO_2Ph$, **23** (29), and that this stabilization would be decreased by the use of a sterically hindered *tert*-butylsulfonyl group. Hence, the two series of compounds, **16**–**21**, were prepared. However, this group must still stabilize the carbanion adequately to permit the retro-aldol process, since the diastereomer mixtures **18** and **19** gave only the *E*-epoxysulfones, **20** and **21**, respectively. We have been able to show that the *erythro* chlorohydrin diastereomer, **10**, could be prepared from reacting the carbanion **23** with benzaldehyde in a relatively nonpolar solvent (THF) at low temperature, and that the proportion of **6** being formed increased at higher temperatures. This observation may be interpreted as the salt of **10** being a kinetic product whereas the salt of **6** is a thermodynamic product. Truce and Klingler (39) have also reported some diastereoselectivity in related addition reactions between non-halogenated α-sulfonyl carbanions and aldehydes, with the *erythro* form being found to be in excess.

The structure of **23** can be depicted as shown in Scheme 4 (34), which illustrates three of the six possible orientations for the aldehyde in the condensation outlined in eq. [6]. It is noteworthy that this orientation appears to describe the least sterically hindered transition state, which in fact leads to **10** after work-up. The intermediate alkoxide should be lithiated in tetrahydrofuran, but is undoubtedly largely ionized in *N*,*N*-dimethylformamide, which would explain why **10** can be isolated from the former solvent, and why the latter favours epoxide formation. Furthermore, deprotonation of **6** in DMF must lead to the equilibria shown in Scheme 5, and we venture to suggest that the actual epoxide formation takes place via the anion of **10**, by means of an internal displacement process that has the stereoelectronics of an S_N2 reaction (28, 38). This

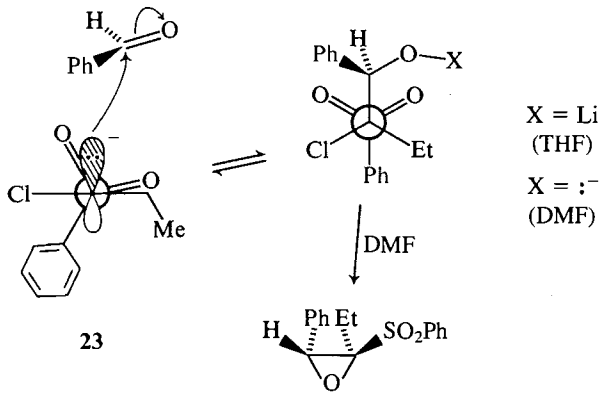

SCHEME 5

reaction would be greatly facilitated by the intramolecular nature of the reaction and the steric crowding about the epoxide ring (40). We also draw the reader's attention to the striking similarities between the crystal structures of the chlorohydrin **6** (27) and the two epoxysulfones, **3** and **21**. If the structure of **10** is indeed similar to that of **6**, but with the chloro and ethyl groups interchanged, the internal nucleophilic displacement process for epoxide formation from these halohydrins appears to be very favourable indeed.

Experimental

General

Most details have been provided previously (27). Proton nmr spectra were run either on a Varian T-60 spectrometer or, when analysis of complex spin systems or reaction mixtures required the extra dispersion, on a Nicolet 360 NB spectrometer, operating at 361.05 MHz. These spectra were analysed using a LAOCOON program, adapted locally to run on an IBM-XT computer. All expected lines were present in the high-field spectra. Carbon-13 nmr spectra were run either on a Varian CFT-20 or the Nicolet 360 NB spectrometers. X-ray crystal structures were determined by collection of data using a Nonius CAD-4 four-circle diffractometer; data were processed by published procedures (34). Chromatography was done using products of the E. Merck Co.; some tlc also was done using Brinkmann silica plates on polyester film. Anhydrous tetrahydrofuran (THF) was prepared by standing it over P_2O_5, distillation from P_2O_5, storage over $NaAlH_4$, and, before use, distillation from $NaAlH_4$ under an N_2 atmosphere. Dry *N,N*-dimethylformamide (DMF) was ACS grade, dried over 4A molecular sieves. Regular work-up procedures were to extract thoroughly the quenched reaction mixture with dichloromethane, or with diethyl ether in the case of any reaction that employed DMF or DMSO as solvents. The organic solvent was washed with dilute acid and (or) base, as appropriate, and water or saturated brine, dried with anhydrous magnesium sulfate, and rotary evaporated under water-aspirator vacuum.

Preparation of 2-chloro-2-methylsulfonyl-1-phenylpropanol as a mixture of diastereomers, 1 and 2

Sodium hydride (50% oil dispersion, 0.97 g, 20 mmol) was washed free of oil with dry ligroin, mixed with a solution of 2-methylsulfonyl-1-phenylethanone (3.6 g, 18 mmol) in dry DMSO, and heated under dry nitrogen for 60 min, using an oil bath at 55°C. The mixture was cooled, methyl iodide (2.7 g, 19 mmol in DMSO, 10 mL) was added carefully, and heating was resumed for a further 250 min, at 60–65°C. Work-up was effected by pouring into excess water, followed by a regular extraction procedure, some residual starting material (0.5 g) being removed by a wash with 2% NaOH solution, to give 2-methylsulfonyl-1-phenylpropanone, 2.1 g, 63%, mp 54–55°C (lit. (41), mp 56–57.5°C), >95% pure, by ^{1}H nmr.

The methylated sulfone prepared above (212 mg, 1 mmol) in dry benzene (5 mL) was added to washed NaH (50 mg of 50% oil

suspension, 1 mmol) and the resulting slurry was heated in an oil bath (80°C) for 4 h. Solid *N*-chlorosuccinimide (133 mg, 1 mmol) was added and heating at 90°C was continued for a further 3 h. Regular work-up was done by pouring into water and extraction with ether to give 2-chloro-2-methylsulfonyl-1-phenylpropanone (170 mg), contaminated by some starting material. Preparative tlc gave the pure chloroketosulfone, 120 mg, 48%, mp 68–70°C (lit. (23) mp 72.5–73°C).

Reduction of this chloroketosulfone (120 mg, 0.49 mmol) with $NaBH_4$ in dioxane–water, following the published procedure (23), gave a mixture of chlorohydrins, **1** and **2** (70 mg, 58%), in a ratio of 7:3.

*Preparation of 1,2-epoxy-2-methylsulfonyl-1-phenylpropane, as a mixture of diastereomers **3** and **4***

The diastereomeric mixture of **1** and **2** prepared above (660 mg, 2.66 mmol) in dry DMF (4 mL) was treated with 0.665 M Bu^{t}OK in dry DMF (4.0 mL) at 0°C, as per the procedure of Bohlmann and Haffer (23). The product was an oily mixture of epoxides, from which several recrystallizations (ether–ligroin) gave clean **3**, 130 mg, 23%, mp 111–112°C (lit. (23), mp 112–112.5°C).

Preparation of E-*1,2-epoxy-1-phenyl-2-phenylsulfonylethane, **5**c*

Chloromethyl phenyl sulfone (42) (285 mg, 1.5 mmol), benzaldehyde (191 mg, 1.8 mmol), and dimethylethylhexadecylammonium bromide (30 mg) were dissolved in acetonitrile (0.4 mL) and mixed with NaOH solution (50%, 1 mL). After vigorous stirring for 45 min, the reaction mixture was worked up with ether and water to give crude **5***c* (330 mg, 85%), which was recrystallized (CCl_4–ligroin) to give needles that decomposed with time, mp 104–105°C; for nmr spectra, see Table 2, but the ^{1}H nmr spectrum also showed aromatic resonances at δ: 7.25 (5H, s), 7.32–8.02 (5H, m); irradiation in the range of δ 4.18–4.28 produced a 5% increase in the intensity of the signal at δ 4.52; ms *m/z*: 260 (39), 231 (57), 167 (13), 165 (7), 141 (7), 125 (30), 119 (100), 91 (35), 77 (30) daltons.

Preparation of E-*1,2-epoxy-1-phenyl-2-phenylsulfonylbutane, **7***

A stirred solution of *threo*-2-chloro-1-phenyl-2-phenylsulfonylbutanol, **6**, (27) (324 mg, 1 mmol), under N_2 in dry DMF (3 mL), was cooled in an ice bath and carefully treated with Bu^{t}OK in DMF (0.5 mL of 2.0 M solution), so that the temperature did not rise above 5°C. The mixture was stirred for 5 min and worked up by adding NH_4Cl solution (10 mL of 10%) and extraction with ether. Regular procedures gave **7** as a semisolid that was homogeneous on tlc (248 mg, 86%). Crystalline material, as fine needles, mp 44–46°C (from ether–hexane), was best obtained by passage of this material through a short column of neutral alumina (25% CH_2Cl_2 in ligroin); ir (KBr) ν_{max}: 1322 (m), 1317 (m), 1310 (m), 1143 (s), 1079 (s), 714 (m), 590 (m), 556 (m) cm^{-1}; for nmr spectra, see Table 2; ms *m/z*: 288 ($M^{+\cdot}$, 4), 232 (14), 231 (7), 167 (3), 147 (85), 125 (16), 119 (10), 91 (100), 90 (12), 89 (10), 77 (25), *m** = 96.9, 69.9. *Exact Mass* calcd. for $C_{16}H_{16}O_3$: 288.082; found, for $M^{+\cdot}$ *m/z*: 288.082 daltons.[9]

*Preparation of α-chloropropyl phenyl sulfone, **8***

An ethanolic solution (2 mL) of 2-chloro-1-phenyl-2-phenylsulfonylbutanone (27) (290 mg, 0.9 mmol) was hydrolyzed by the addition of aqueous NaOH (0.5 mL, 2 M solution) and stirring for 60 min at 20°C. The solution was poured into water and worked up in a regular way with ether to give a crude product, from which the pure (tlc) chlorosulfone, **8** (130 mg, 66%), could be obtained as white needles after chromatography (25% CH_2Cl_2 in ligroin on neutral alumina), followed by recrystallization (ether–hexane), mp 57–58°C; ir (KBr) ν_{max}: 1450 (m), 1318 (s), 1151 (s), 1075 (s), 748 (s), 682 (m), 586 (s), 538 (s); ^{1}H nmr δ($CDCl_3$): 1.142 (3H, t of A_3MNX, ^3J = 7.27 Hz), 1.847 (1H, $^2J_{MN}$ = 14.40 Hz), 2.465 (1H), 4.599 (1H, $^3J_{MX}$ = 10.59 Hz, $^3J_{NX}$ = 3.01 Hz); ^{13}C nmr δ($CDCl_3$): 10.7 (CH_3), 24.6 (CH_2), 76.5 (*C*HCl), 129.1, 130.1, 134.5 (*C*H of Ph), 135.5 (*C*S of Ph); ms *m/z*: 220 ($M^{+\cdot}$, 0.6), 218 ($M^{+\cdot}$, 1.6), 143 (97), 142 (78), 141 (9), 125 (15), 94 (17), 79 (14), 78 (98), 77 (100), 51 (45) daltons.

*Preparation of α-chloroethyl phenyl sulfone, **9***

Ethyl phenyl sulfide (2.06 g, 15 mmol) was chlorinated by refluxing for 2 h with freshly distilled SO_2Cl_2 (2.16 g, 15.8 mmol, added slowly) in dichloromethane. Rotary evaporation of the solution at room temperature gave an oil (2.0 g, 78%) that was homogeneous by tlc, and was the α-chloroethyl sulfide by ^{1}H nmr; δ($CDCl_3$): 1.8 (3H, d, *J* = 8 Hz), 5.3 (1H, q), 7.4 (5H, s). A solution of this sulfide (686 mg, 4 mmol) in dry ether was cooled in an ice bath and carefully treated with *m*-chloroperoxybenzoic acid (85%, 1.72 g, 8.5 mmol) so that the temperature did not rise above 5°C. The mixture was stirred (ice bath, 16 h) and then worked up ($NaHSO_3$ and $NaHCO_3$ washes) to give a solid (700 mg, 85%) that was homogeneous on tlc (benzene), and was recrystallized (benzene) to give **9** as fine needles, mp 54–55°C; ir (KBr) ν_{max}: 2967 (m), 1450 (m), 1314 (s), 1150 (s), 1052 (m), 745 (s), 685 (s), 533 (s) cm^{-1}; ^{1}H nmr δ($CDCl_3$): 1.80 (3H, d, *J* = 7 Hz), 4.75 (1H, t, *J* = 7 Hz), 7.6 (5H, m);[10] ms *m/z*: 204 ($M^{+\cdot}$, 6), 160 (3), 141 (100), 125 (29) daltons.

Preparation of erythro-*2-chloro-1-phenyl-2-phenylsulfonylbutanol, **10***

A stirred solution of the chlorosulfone, **8** (335 mg, 1.52 mmol), in dry THF (5 mL) was cooled to −70°C, treated cautiously with *n*-BuLi (0.76 mL of 2.2 M solution), and kept cold for 15 min, after which distilled benzaldehyde (163 mg, 1.53 mmol) in dry THF (3 mL) was added slowly. The reaction was kept for a further 60 min (during which time the temperature was allowed to rise to −50°C), quenched by the addition of ice-cold NH_4Cl solution, and worked up in a regular way using an extraction with ether. The crude, oily solid (470 mg) was a mixture of chlorohydrins **10** and **6** in a ratio of ca. 4:1. Column chromatography with 20% CH_2Cl_2 in hexane gave pure **10** (330 mg, 67%), as fine colourless needles from CH_2Cl_2–hexane, mp 110–112°C; ir ν_{max}(KBr): 3465 (s), 1455 (m), 1305 (s), 1148 (s), 1074 (s), 1057 (s), 700 (m), 579 (s) cm^{-1}; nmr spectra in Table 1; ms *m/z*: 326 (4.8), 324 ($M^{+\cdot}$, 12.4), 220 (20), 218 (52), 205 (11), 203 (29), 185 (3), 183 (8), 153 (6), 147 (32), 143 (38), 142 (20), 129 (8), 125 (14), 119 (11), 107 (97), 106 (21), 105 (49), 91 (46), 79 (32), 78 (50), 77 (100), *m** at 189.5 daltons.

*Preparation of 2-chloro-1-phenyl-2-phenylsulfonylpropanol, **11***

*(a) By condensation reaction from **9***

In a similar way to the previous preparation, the chlorosulfone, **9** (prepared in a similar way to **8**), was reacted with *n*-butyllithium and benzaldehyde on a 0.7-mmol scale, to give the *erythro* hydroxysulfone (**11***b*) as the major product (ca. 3:2, by ^{1}H nmr) of a diastereomer mixture, obtained as needles, mp 148–154°C (from ether–ligroin), nmr spectra in Table 1, ms *m/z*: 312, 310 ($M^{+\cdot}$) daltons.

*(b) From 2-chloropropiophenone, **12***

Propiophenone (26.6 g, 0.2 mol) was chlorinated by stirring with a 20% molar excess of freshly distilled sulfuryl chloride in CH_2Cl_2 for 3 h at room temperature. Removal of the solvent and distillation of the crude product *in vacuo* gave pure **12** (28 g, 83%). A mixture of **12** (13.3 g, 0.079 mol), thiophenol (8.7 g, 0.079 mol), and Bu^t_4NBr (0.5 g) was stirred vigorously for 12 h in CH_2Cl_2 (75 mL) and NaOH solution (75 mL of 1.9 M). Regular work-up gave crude PhCOCHMeSPh (15 g, 78%), 3.0 g (12.4 mmol) of which was oxidized in methanol with excess 30% H_2O_2 in the presence of ammonium molybdate catalyst following the method of Schultz *et al.* (43) to give $PhCOCHMeSO_2Ph$, **13**, as colourless needles, mp 78–79°C (2.8 g, 82%, from CH_2Cl_2–EtOH, 1:9); ^{1}H nmr δ($CDCl_3$): 1.57

[9]We thank Dr. L. Ramaley for this accurate mass measurement.

[10]The *upfield* shift of the methine proton when an α-chloroalkyl sulfide is oxidized to the corresponding sulfone appears to be a general phenomenon: J. S. Grossert and S. Sotheeswaran, Abstract no. A 12.0, Eleventh Int. Symp. Org. Chem. of Sulphur, Lindau, FRG, 1984, and to be published. The phenomenon does not appear to have been described in the chemical literature, and must arise from a shielding cone around the sulfonyl group.

For personal use only.

(3H, d, J = 6.95 Hz), 5.19 (1H, q, J = 6.95 Hz), 7.4–8.0 (10H, m); ^{13}C nmr δ($CDCl_3$): 12.9 (Me, q), 65.0 (*C*H, d), 128–137 (Ar C), 192.2 (C=O); ms m/z: 274 ($M^{+\cdot}$, 4), 210 (8), 141 (1), 133 (1), 116 (2), 106 (7.8), 105 (100), 77 (29) daltons.

A sample of **13** (2.74 g, 10 mmol) was then chlorinated with NaH and NCS (10 mmol each) in dry toluene following a previously described procedure (27) to give crude 2-chloro-1-phenyl-2-phenylsulfonylpropanone, **14** (2.16 g, 96%), which could be purified by chromatography on silica gel (1:1 ligroin in CH_2Cl_2) and recrystallization (ether–hexane) to give **14** as small colourless prisms, mp 62–64°C; ms m/z: 310 (1.0), 308 ($M^{+\cdot}$, 2.6), 169 (1.6), 167 (4.2), 141 (4.9), 139 (6.6), 106 (7.5), 105 (100), 103 (5), 91 (1.0), 89 (2.5), 77 (29) daltons. Reduction of this material (1.6 g, 5.2 mmol) with $NaBH_4$ in DME–water containing NaH_2PO_4, as described previously (27), gave **11** (1.55 g, 95%) as a mixture of diastereomers (*threo*:*erythro*, ca. 9:1 by proton nmr). Recrystallization (ether–CH_2Cl_2) gave pure *threo*, **11***a*, mp 193–194°C; nmr spectra in Table 1; ms m/z: 312 (7.3), 310 ($M^{+\cdot}$, 19), 206 (17), 204 (45), 171 (2.4), 169 (7.6), 143 (14), 141 (4), 139 (9), 133 (29), 125 (6), 115 (5), 107 (100), 105 (43), 79 (22), 78 (17), 77 (37), 53 (15) daltons.

Conversion of the erythro *chlorohydrin, **10**, into the epoxysulfone, **7***

A solution of the chlorohydrin, **10** (72 mg, 0.23 mmol), in dry DMF (1 mL) was treated with a solution of potassium *tert*-butoxide in dry DMF (0.23 mL of 1.0 M solution) as for the conversion of **6** into **7**. The product was a semisolid (65 mg), which by high-field ^{1}H nmr spectroscopy was a mixture of epoxysulfone, **7**, and chlorosulfone, **8** (ca. 4:1). Recrystallization (ether–hexane) gave pure **7** (mp 45–48°C), identical to the substance prepared from **6**, by tlc, ^{1}H nmr, and ms.

*Conversion of the chlorohydrins, **11**, into the epoxysulfone, **15***

A diastereomeric mixture of chlorohydrins, **11** (*erythro*:*threo* = 3:2, 78 mg, 0.25 mmol), was reacted with KOBu^t as in the previous experiment. The residue (50 mg) gave *E*-1,2-epoxy-1-phenyl-2-phenylsulfonylpropane, **15**, as needles, mp 109–110°C (from CCl_4–ligroin); for nmr data, see Table 2. This sample was identical (mp, mmp, ^{1}H nmr) to another sample of **15** that was prepared by a phase-transfer-mediated Darzens condensation, in the way described for the preparation of **5***c*. This sample also had an ms recorded, m/z: 274 ($M^{+\cdot}$, 2), 233 (2), 232 (9), 231 (7), 168 (2), 167 (3), 134 (10.6), 133 (100), 126 (15), 125 (17), 105 (92), 90 (11), 89 (11), 79 (13), 77 (30), m^* = 196.5, 83.6 daltons. *Anal.* calcd. for $C_{15}H_{14}O_3S$: C 65.67, H 5.14%; found: C 65.55, H 5.16%.

*Preparation of 2-*tert*-butylsulfonyl-1-phenylpropanone, **16***

2-Chloropropiophenone (**12**, 14.2 g, 0.84 mol) and *tert*-butylthiol (7.68 g, 0.85 mol) were reacted together under phase-transfer conditions (as described in the previous paper) to yield an oil that, on purification by chromatography over silica gel in 1:1 hexane–dichloromethane, gave 2-*tert*-butylsulfenyl-1-phenylpropanone, oil, (16 g, 88%); ^{1}H nmr δ($CDCl_3$): 1.3 (9H, s), 1.6 (3H, d, J = 7 Hz), 4.3 (1H, q, J = 7 Hz), 7.2–8.0 (5H, m); ms m/z: 222 ($M^{+\cdot}$, 15), 166 (6), 134 (5), 118 (5), 117 (65), 105 (83), 77 (35), 61 (39), 57 (100) daltons. Oxidation of this β-ketosulfide (6.0 g, 27 mmol) with H_2O_2 in MeOH in the presence of ammonium molybdate catalyst (43), as described previously, gave a solid that was recrystallized (CH_2Cl_2–EtOH, 1:9) to give **16** as colourless needles (5.7 g, 83%), mp 119–120°C; ir ν_{max}: 2995 (m), 1685 (s), 1290 (s), 1284 (s), 1245 (s), 1108 (s), 988 (s), 951 (s), 726 (s) cm^{-1}; ^{1}H nmr δ($CDCl_3$): 1.43 (9H, s), 1.74 (3H, d, J = 7.05 Hz), 5.14 (1H, q, J = 7.05 Hz), 7.4–8.1 (5H, m); ^{13}C nmr δ($CDCl_3$): 14.52 (*Me*CH), 24.21 (Me_3C-), 60.27 (*C*HMe), 60.49 (Me_3C-), 128.84, 129.04 (*o*- and *m*-*C* of Ph), 133.82 (*p*-*C*), 136.25 (quart. *C* of Ph), 193.00 (*C*=O); ms m/z: 254 ($M^{+\cdot}$, 0.22), 198 (0.07), 180 (0.15), 135 (10.3), 134 (100), 133 (23), 115 (1), 105 (44), 77 (27), 57 (66), m^* = 132.2, 83.2 daltons.

*Preparation of 2-*tert*-butylsulfonyl-2-chloro-1-phenylpropanone, **17***

Chlorination of **16** (3.0 g) was carried out as described previously (27), which resulted in crude material that after purification by chromatography over silica gel (hexane–CH_2Cl_2, 1:1) gave pure **17** as white needles, mp 67–69°C (1.46 g, 43%, CH_2Cl_2–hexane); ir ν_{max}: 1680 (s), 1668 (s), 1305 (s), 1242 (s), 1228 (s), 1185 (s), 1120 (s), 950 (s), 737 (s), 690 (s), 555 (s) cm^{-1}; ^{1}H nmr δ($CDCl_3$): 1.53 (9H, s), 2.29 (3H, s), 7.4–8.3 (5H, m); ^{13}C nmr δ($CDCl_3$): 25.74 (Me_3C-), 28.36 (*Me*CCl), 69.15 (Me_3C-), 90.17 (MeCCl), 128.04, 130.66 (*o*-and *m*-*C* of Ph), 133.39 (*p*-*C*), 134.81 (quart. *C* of Ph), 193.07 (*C*=O); ms m/z: 288 ($M^{+\cdot}$, 0.21), 232 (0.13), 170 (26.4), 168 (79.6), 139 (3), 105 (67), 103 (8), 92 (5), 90 (14), 77 (33), 57 (100), m^* = 115.0 daltons.

*Preparation of 2-*tert*-butylsulfonyl-2-chloro-1-phenylpropanol, **18***

Reduction of **17** (1.46 g, 5.1 mmol) was carried out in the same way as described for the preparation of **11***a*. Work-up gave crude material (1.4 g) that was chromatographed on silica gel (hexane–CH_2Cl_2, 1:1) to give **18** (953 mg, 65%) as a mixture of diastereomers (*threo*:*erythro* = ca. 7:2, by ^{1}H nmr), needles, mp 72–73°C (ethanol); ir ν_{max}: 3465 (s), 1288 (s), 1116 (s), 1095 (s), 1070 (s), 726 (s), 697 (s), 636 (s) cm^{-1}; nmr spectra in Table 1; ms m/z: 292 (1.3), 290 ($M^{+\cdot}$, 3.4), 184 (2), 169 (2), 154 (5), 152 (15), 134 (5), 133 (9), 130 (5), 128 (13), 107 (29), 105 (13), 79 (8), 77 (9), 57 (100), m^* = 114.5, 84.0 daltons.

*Conversion of the chlorohydrins, **18**, into the epoxide, **20***

The mixture of chlorohydrins **18** (390 mg, 1.0 mmol) was reacted with base as described for the preparation of **7**. Regular work-up gave crude product that was a mixture of **20** and Bu^tSO_2CHClMe (269 mg); repeated recrystallization (ligroin) gave **20** as fine colourless needles, mp 56–58°C; ir ν_{max}: 3010 (m), 2980 (m), 1295 (s), 1120 (s), 874 (s), 760 (s), 690 (s), 578 (s) cm^{-1}; nmr spectra in Table 2; ms m/z: 254 ($M^{+\cdot}$, 0.41), 212 (0.54), 135 (10), 134 (100), 133 (97), 105 (83), 91 (19), 90 (14), 89 (11), 79 (11), 77 (19), 57 (90), m^* = 101.5, 83.3 daltons.

*Conversion of the chlorohydrins, **19**, into the epoxide, **21***

The mixture of chlorohydrins **19** (439 mg, 1.442 mmol) was reacted with base as described for the preparation of **7**. Regular work-up gave crude product that was a mixture of **21** and Bu^tSO_2CHClEt (481 mg); repeated recrystallization (ligroin) gave **21** as fine colourless needles, mp 71–72°C; ir ν_{max}: 2995 (m), 1467 (m), 1458 (m), 1305 (s), 1122 (s), 768 (s), 683 (s), 580 (s) cm^{-1}; nmr spectra in Table 2; ms m/z: 149 (11), 148 (94), 147 (74), 119 (14), 105 (8), 92 (11), 91 (100), 90 (14), 89 (10), 77 (9), 57 (90) daltons.

Conversion of chlorohydrins into epoxides in the presence of p*-tolualdehyde — crossover experiments*

The typical procedure was the same as for the preparation of the epoxysulfone **7** from the chlorohydrins **6** or **10**, with the exception that the one mole equivalent of freshly distilled *p*-tolualdehyde was added to the solution of chlorohydrin in DMF before the KOBu^t was added. After regular work-up, the crude product was filtered through a short column of silica gel using 20% hexane in CH_2Cl_2 and the resulting oil was analyzed by ^{1}H nmr spectroscopy. Two experiments were carried out:

(*a*) Chlorohydrin **6** (150 mg, 0.46 mmol) in DMF (2.0 mL), plus *p*-tolualdehyde (55 mg, 0.46 mmol), plus KOBu^t (0.46 mL of 1.0 M solution in DMF) gave an oil, the ^{1}H nmr spectrum of which clearly showed the presence of three compounds in a mixture, viz. **7**:**22**:**8** in a ratio of ca. 8:5:12; **22** could be distinguished by its resonances at δ 2.35 (s, aryl C*H*$_3$) and 4.82 (s, epoxy ring C*H*). The mass spectrum of the oil varied with time, but clearly showed the required pattern of ions characteristic of **7** and **8**, together with ions at m/z 302, 246, 245, and 161, characteristic of **22**.

(*b*) Chlorohydrin **10** (128 mg, 0.39 mmol in 1.5 mL of DMF) reacted as above, giving a crude product (133 mg) that yielded an oil (70 mg) after chromatography. This oil had essentially the identical ^{1}H nmr spectrum (at 361.05 MHz) to that from the previous experiment, with the ratio of **7**:**22**:**8** = ca. 4:3:8.

Intramolecular sensitization in salicylatotetraammine cobalt(III) complex

LUIS VASQUEZ, CARLOS ANDRADE, AND IRMA CRIVELLI[1]
Department of Chemistry, Faculty of Sciences, Universidad de Chile, Casilla 653, Santiago, Chile

Received October 20, 1987[2]

LUIS VASQUEZ, CARLOS ANDRADE, and IRMA CRIVELLI. Can. J. Chem. **66**, 2880 (1988).

Luminescence studies show that the fluorescence of salicylic acid and its anionic species is quenched when they belong to the coordination sphere of the Co(III) and no new emission appears even in glass at 77 K. The metallic center seems to provide new and efficient non-radiative deactivation paths for the ligand centered states.

Irradiation in the intraligand bands of the complex, in aqueous solution, leads to photoredox reaction generating Co^{2+} species characteristic of the charge transfer cobalt photochemistry. Results are discussed in terms of an efficient intramolecular sensitization or intramolecular energy transfer from states centered in the ligand to LMCT state centered at the metal.

LUIS VASQUEZ, CARLOS ANDRADE et IRMA CRIVELLI. Can. J. Chem. **66**, 2880 (1988).

Des études de luminescence démontrent que la fluorescence de l'acide salicylique et de ses espèces ioniques est piégée lorsqu'ils font partie de la sphère de coordination du Co(III); on n'observe aucune nouvelle émission, même dans un verre à 77 K. Le centre métallique semble fournir des voies de désactivation non-radiactives nouvelles et efficaces pour les états centrés sur le ligand.

L'irradiation, en solution aqueuse, dans les bandes intra-ligands du complexe, provoque une réaction photorédox conduisant à la formation d'espèces Co^{2+} caractéristiques de transferts de charges lors la photochimie du cobalt. On discute des résultats en fonction d'une sensibilization intramoléculaire efficace ou d'un transfert intramoléculaire d'énergie d'états centrés dans le ligand vers l'état LMCT centré au niveau du métal.

[Traduit par la revue]

Introduction

Different reactions result from CTTM and LF excitations in transition metal complexes (1, 2). Particularly, a variety of reaction modes have been observed for Co(III) complexes. There have been different approaches in evolving general patterns of photochemical behaviour, not only from a mechanistic point of view but also from excited state models (2, 3); although it has been recognized that the molecular properties (reactivity, energy, ...) of the excited states and some molecular processes (radiative and non-radiative relaxation, excited state distortions, ...) are relevant, the complete characterization of the excited state manifolds and the communication between excited states is not an easy task (4, 5). The lack of luminescence for cobalt complexes other than Co(III) cyanides (6) has made the access to this kind of information more difficult. Furthermore, Endicott *et al.* (7) with regard to the possibility of a meaningful use of the sensitization technique conclude that "there is no clear way to relate intermolecular energy transfer studies to intrinsic processes which take place within the molecular charge transfer state in coordination compounds."

Intramolecular energy transfer in metalloorganic bichromophore has been reported for some Rh(III) (8) and for heterobimetallic Co(III)–Cr(III) (9) and Ru(II)–Rh(III) complexes (10). In all cases the energy transfer results in metal-centred reactions characteristic of ligand field excited states of Rh(III), Cr(III), and Ru(II)–Rh(III), respectively. Through intramolecular energy transfer processes it is possible to get information about the possibility and competivity of the different inter- and intraconfigurational non-radiative relaxation processes within the excited state manifolds.

The present report is concerned with the intramolecular sensitization of redox reactions characteristic of CTTM excited states in Co(III) complexes, reactions which characterize Co(III) photochemistry.

Experimental

Preparations

Salicylatotetraamminecobalt (III) ion (Complex **I**) was prepared by adding slowly with continuous stirring 8.8 g of $[Co(NH_3)_4CO_3]NO_3$ (11) to a 40°C solution of 19 g salicylic acid in 100 mL of butanol 40%. The reaction mixture was stirred at 40–45°C for 12 h, cooled, and filtered. The solid was washed several times with ethanol to eliminate the excess of salicylic acid and the complex precipitated as salicylate. *Anal.* calcd. for $[Co(NH_3)_4O_2CC_6H_4O]C_6H_4(OH)CO_2$: Co 14.7, N 14, C 42, H 5.2; found: Co 13.5, N 13.97, C 39.22, H 4.99.

Cobalt content was determined gravimetrically (12). The salicylato species present as ligand in the complex was determined by measuring the concentration of the free ligand after a full hydrolysis of the complex (0.1 *M* $HClO_4$) by (*a*) emission, (*b*) spectrophotometrically adding $FeCl_3$ and measuring the absorbance at 515 nm (13).

Tridistilled H_2O was used in the preparation of all solutions. pH was adjusted using $HClO_4$ (Mallinckrodt 70%) and the ionic strength with $NaClO_4$ (Merck) when needed. Salicylic acid (Aldrich gold label) was used without further purification. All other reagents were of adequate grade.

Photolysis procedures

The light source was a water-cooled Phillips HPL-400 W (Hg) mounted in a conventional optical bench with adequate collimating lenses. A UG-11 Schott glass filter and a F-254 interference filter were used for irradiation at the 303 and 235 nm bands of the complex, respectively.

Photolysis were carried out in 0.1 *M* $HClO_4$ solutions, at complex concentrations which provided essentially total light absorption in a 5-cm cylindrical cell. Photolysis experiments were run without deoxygenating the solutions. Concurrent thermal hydrolysis reaction was negligible ($k = 1.09 \times 10^{-5}$ s^{-1}, 60°C, pH = 1, $I = 0.6$ *M* in $NaClO_4$ (14) at the irradiation conditions. Absolute light intensities were determined by ferrioxalate actinometry.

Analytic procedures: The salicyclic acid quantum yields, (ϕ_{sal}) were determined by emission analysis of diluted photolyzed solutions. The corresponding cobalt(II) quantum yields ($\phi_{Co(II)}$) were obtained using a modification of Kitson's method (15): 25 mL of the solution prepared by dissolving 546 g of NH_4SCN in 1 L of 1:5 water/acetone solvent, were added to an appropriate volume of the photolyzed solution, diluted to 50 mL with distilled water and the absorbance recorded at

625 nm. For quantum yield determinations photolysis were not carried out beyond 15–25% reaction.

Gas chromatography, absorption and emission spectrometry were used for identification of the other products. Cation exchange resin (H^+ form) was used to separate the eventual aquo complex species.

Emission procedures

A Perkin Elmer MPF-2A spectrofluorimeter was used for emission and quenching experiments. The emission properties of the $[Co(NH_3)_4O_2CC_6H_4O]^+$ ion were determined by dissolving the solid in NaAc–HAc buffer (pH = 5) and passing through an anionic exchange resin (Bio-Rad Analytical grade AG:X8 in ClO_4^+ form) to eliminate the salicylate counterion.

The fluorescence quantum yields were measured in modular equipment consisting of 1000 W Hanovia Xe–Hg lamp, a Hilger Monospek 1000 excitation monochromator, a Perkin Elmer E-1 emission monochromator, an EMI 9559 OB photomultiplier tube detector and a power supply from a Perkin Elmer E-11 spectrophotometer, using 9,10-dichloroanthracene as standard reference.

Calculations

Quantum yields of the photolysis products were calculated for each photolysis run since the inner filter effect of the salicylic acid formed as photoproduct, continuously added to the base inner filter effect of the salicylic counterion. The quantum yields reported were obtained by extrapolation to zero irradiation time.

Corrections for partial light absorption were taken into account in calculations where required (particularly UG-11 filter photolysis). Quantum yields of fluorescence were calculated using the original expression (16) corrected by the ratio of the refractive indexes.

Results

Figure 1 shows the absorption spectra of the free salicylic ligand and $[Co(NH_3)_4OCOC_6H_4O]^+$ ion. Electronic absorption spectra of some cobalt amine complexes are given in Table 1. Emission characteristics of the ligand and its anionic species are shown in Table 2. Table 3 summarizes the quantum yields of the main photoproducts obtained when aqueous solution of Complex **I** (0.001 *M*, μ = 0.1 $HClO_4$, pH = 1) is irradiated at 235 and 300 nm bands (F-254 and UG-11 filters, respectively).

The bands of the salicylic acid and the anionic forms are associated with $\pi-\pi^*$ and $n\pi-\pi^*$ transition and the emission is characterized as fluorescence (17). The absorption intraligand bands remain practically unchanged in the salicylic cobalt complex, but the emission of the bound ligand is quenched and new emissions are not observed even at 77 K. It may be seen from Table 1 that the aquo and oxalate complexes present a *d–d* band around 350 nm. A similar ligand field transition may be present in the 300 nm range for Complex **I**; however, the contribution to the total band absorption will be at least two orders of magnitude smaller than the transition observed for the ligand in the same spectral region. Therefore the 300 nm band is dominated by an intraligand band.

The free ligand band at 235 nm is also observed in Complex **I**, on top of the beginning of the ~200 nm band, maintaining the same maximum and minimum, which suggests it to be an intraligand band.

The free salicylic acid, whose quantum yields are given in Table 3 is related to the photoredox process through which Co(II) is formed (i.e., is a consequence of the kinetic lability of the Co(II) formed) since we were not able to find $[Co(NH_3)_4(H_2O)_2]^{3+}$. Although a small amount of CO_2 was found as a photolysis product, the identification of phenol was unsuccessful due to interference by minimum amounts of salicylic acid or its anionic species. The same problem was

faced after separation of the products through an ion exchange column. The irradiation conditions (pH = 1, $HClO_4$) made it impossible to measure any NH_3 production by pH changes. The identification of photolysis product was not pursued further since our main purpose was not mechanistic.

The emission of an aqueous acidic solution of $C_6H_4(OH)CO_2H$ ($\simeq 10^{-3}$–10^{-5} M) was not affected by addition of Co^{2+}, $[Co(NH_3)_4(H_2O)_2]^{2+}$ or $[Co(NH_3)_4O_2CC_6H_4O]^{+}$ ions, at least at the initial irradiation concentrations or at the final concentrations of the photoproducts formed during the reaction.

Discussion

The data of Table 1 and Fig. 1 suggest that the absorbance properties of the two chromophores, $Co(NH_3)_4^{3+}$ and $OC_6H_4CO_2^{2-}$, seem to add to give the spectral characteristics of Complex **I**, without major perturbation, and that the bands at 300 and 235 nm are essentially intraligand bands. A general spectral feature common to Co(III) amine complexes with carboxylate ligands is to show ligand bands around 500 nm ($\epsilon \simeq 100\ M^{-1}\ cm^{-1}$) and intense charge transfer bands ($\epsilon > 5 \times 10^3\ M^{-1}\ cm^{-1}$) in the UV region, therefore possible overlap of intraligand and LMCT absorptions must be analized for the salicylate–Co(III) complex. The only changes observed in the 235 nm centered band, are the relative increase of the absorption in the 245–260 nm range and around the minimum at 225 nm in relation to the spectra of the free ligand. The first change may be explained by an apparent 245–260 nm band, — obtained by Gaussian analysis — having an ϵ(250 nm) $\simeq 3 \times 10^3\ M^{-1}\ cm^{-1}$, and the second considering the overlap with the higher energy band tail. However, the apparent band at 245–260 nm, may just be artificial and the small change only a consequence of a broadening of the complex 235 nm band as compared to the free ligand spectra. The extinction coefficient observed for this apparent band, which is in the region of the CT bands, does not have the right value for a Co(III)–carboxylate CT band. Therefore we believe that the CT band is probably under the 200 nm band, and that the 235 and 300 nm bands appear to be essentially intraligand bands. On other hand, the emission of the $OC_6H_4CO_2^{2-}$ moiety is quenched on coordination to the Co(III) chromophore and Complex **I** is not luminescent. Although this result may be expected, since the lack of luminescent properties of Co(III)d^6 complexes as compared to $3d^3$ and $4d^6$–$5d^6$ complexes is known, the presence of a redox process when the intraligand bands of Complex **I** are irradiated, may give more information about the mechanism which accounts for the lack of luminescence in Co(III) low ligand field complexes. Literature accounts have emphasized the possibility of fast radiationless dissipation of excitation energy through the ligand field states manifold and (or) an inefficient intersystem crossing to the lowest ligand field triplet, the emitting state in luminescent Co(III) complexes (2, 6). The results obtained here suggest that for Complex **I**, the new deactivation non-radiative path provided to the intraligand excited states involves an energy transfer process.

Since the salicylic acid fluorescence (at 295°C and 0.1 M $NaClO_4$) is not modified by the presence of $[Co(NH_3)_4(H_2O)_2]^{3+}$ nor $[Co(NH_3)_4O_2CC_6H_4O]^{+}$ at the experimental irradiation conditions, the intermolecular energy transfer does not seem to be efficient; therefore the energy transfer must be an intramolecular process, or intramolecular sensitization.[3]

Irradiation at 254 and 300 nm bands yields the same products; however, the quantum yield values at 254 nm are greater than at 300 nm; i.e., ϕ_{redox} increasing going from the lower to the higher energy intraligand band. Nevertheless, the $\phi_{sal}/\phi_{Co^{2+}}$ ratio is the same for both bands, suggesting that the energy transfer process populates the same excited state, responsible for the photoreaction which is CT in nature.

[3]Way and Filipescu (18) have assigned a redox process for the $|Co(NH_3)_4C_2O_4|^{+}$ complex to a ligand field band centered at 350 nm with a $\phi_{Co^{2+}} = 0.2$. However ϵ(intraligand)/$\epsilon(d$–$d) \simeq 50$ and $\phi_{Co^{2+}} = 0.4$ (Table 2, 300 nm) for Complex **I**; hence the assumption that a ligand field transition band would be the photochemically active, would require a $\phi_{Co^{2+}} \simeq 20$, after filter effect correction, which is not a reasonable value.

Considering that $\phi_{Co^{2+}} > \phi_{sal}$, and the value itself of both quantum yields, it seems that Complex **I** is only in part reduced to Co(II) by the salicylic ligand. Therefore the process should start by two different primary photochemical acts (19). This suggestion does not exclude the possibility that the complete photoreduction mechanism may involve chemical reduction of the complex by radical species derived from the primary act. However, as it was mentioned above, we were unsuccessful to identify other products besides salicylic acid and small amounts of CO_2, thus any mechanistic interpretation of the results would only be speculative. Considering that fluorescence is the only deactivation process observed in the free ligand (20) and that the emission wavelength is independent of the excitation energy, as may be expected from Kasha's rule (21), the energy transfer must take place from the intraligand fluorescent state. Should this occur, not only equal quantum yield ratios would have been observed on irradiation at both λ_{exc} (254 and 300 nm), but also $\phi_{Co^{2+}}$ and ϕ_{sal} independent values should have moved in the same direction of ϕ_f if ϕ_f is dependent on λ_{exc}. Table 2 shows the ϕ_f measured for salicylic acid and the two anionic species; ϕ_f for both, totally protonated and completely ionized species, is constant (the first is at the limit of detection); for the monoprotonated species ϕ_f increases as the λ_{exc} increases, which is in the opposite direction of the products quantum yield changes (Table 3).

The results indicate that the transfer process is in competition with the relaxation processes to the fluorescent state within the intraligand manifold initially populated. Furthermore, they may suggest the existence of several competitive deactivation processes taking place in the CT manifold populated by the energy transfer process.

The possibility of direct excitation contribution to the same intermediate state when the irradiation in made at 254 nm band may be considered; in this case the absolute quantum yields may be expressed as:

$$\phi_{sal,Co(II)} = a\phi^{d(254)}_{sal,Co(II)} + b\phi^{ET(254)}_{sal,Co(II)}$$

where $\phi_{sal,Co(II)}$ is the total quantum yield for salicylic acid or Co(II), $\phi^{d(254)}_{sal,Co(II)}$ the corresponding quantum yield for direct population of the excited state and $\phi^{ET(254)}_{sal,Co(II)}$ is related to the excited population by energy transfer; *a* and *b* are coefficients which express the contribution of the charge transfer and intraligand bands, respectively, to the total absorption ($a + b = 1$).

The spectra of Complex **I** around the 235 nm centered band was examined above and based on it, two possible contribution to $\phi^{d(254)}_{sal,Co(II)}$ may be considered: one is absorption in the region of overlap with the higher energy band tail and the second is absorption in the 250–260 nm zone (apparent band). The first one in negligible on account of: number of intensity of the irradiation lamp lines, the cut-off point of the F-254 filter and the ending point of higher energy band tail. Considering now the absorption in the apparent band region (250–260 nm) and assuming that is in part a LMCT absorption, its contribution is only about 13.5% of the total; taking a limiting unfavorable condition (imply from Table 2), $\phi^{ET(254)}_{Co,sal} = \phi^{ET(300)}_{Co,sal}$, will result that $\phi^{d(254)}_{Co(II)} \simeq 4$ and $\phi^{d(254)}_{sal} \simeq 1.5$ which are unrealistic values for Co(III) photochemistry, even considering free radicals participation (2, 23). Therefore it is unlikely that irradiation through the F-254 filter may involve direct population of a LMCT, or at least will be negligible in our system.

In summary, the fluorescence quenching of the free ligand by the metal when it is coordinated to the $Co(NH_3)_4^{3+}$ chromophore, together with the presence of a redox process when the intraligand bands are irradiated, indicate that the initial intraligand excitation is followed by intramolecular transfer or intramolecular sensitization to a final LMCT state centered at the metal and reveal that for Complex **I** the new deactivation paths for the ligand upon coordination to the metal involve more than fast non-radiative paths through ligand field states to the ground state of the complex, i.e., involves energy tranfer or intramolecular sensitization processes which populate a LMCT state.

The total efficiency (tranfer plus redox processes) seems to be greater when the irradiation is made at the higher energy intraligand band. In this case the results suggest that the energy transfer is in competition with relaxation processes within the intraligand manifold initially populated. The fact that the quenching of the ligand fluorescence by the metallic center results in a redox process instead of a substitutional or new emission agrees with the considerations made by Yamamoto (6) about a possible relation between photochemical behaviour and luminescence in Co(III) complexes.

The multiphoton spectra of the 1,3-*trans*-butadiene molecule from *AB-initio* and configuration interaction calculations

MARCO ANTONIO CHAER NASCIMENTO

Instituto de Quimica, Departamento de Fisico-Quimica, Universidade Federal do Rio de Janeiro, Rio de Janeiro, RJ 21910, Brasil

Received February 3, 1988

MARCO ANTONIO CHAER NASCIMENTO. Can. J. Chem. **66**, 2884 (1988).

The multiphoton spectra of the 1,3-*trans*-butadiene is investigated using highly correlated wave-functions. On the basis of computed transitions energies, intensities and polarization ratios, assignments are made to the first members of five Rydberg series and to a valence ($\pi \rightarrow \pi^*$) state. The results are in good agreement with the experimental results.

MARCO ANTONIO CHAER NASCIMENTO.Can. J. Chem. **66**, 2884 (1988).

On a étudié la spectre multiphotonique du butadiène-1,3 *trans* en faisant appel à des fonctions d'onde hautement corrélées. Sur la base des énergies et des intensitiés de transition calculées ainsi que des rapports de polarisation, on a fait des attributions aux premiers membres de cinq séries de Rydberg et à un état de valence ($\pi \rightarrow \pi^*$). Les résultats sont en bon accord avec les données expérimentales.

1. Introduction

The electronic spectra of linear polyenes have been the subject of intensive experimental and theoretical studies since they were first prepared in the early 1930's. Recently there has been a revival of interest in the subject, partly because of its relation to the chemistry of visual pigments (1, 2).

The 1,3-*trans*-butadiene molecule (hereafter butadiene), being the first and the smaller of the polyenes, has received the greatest attention of both theoreticians and experimentalists (3). This molecule has now been studied using such techniques as vacuum ultraviolet (4), electron impact (5–7) and multiphoton spectroscopy (8–12), and also *ab-initio* calculations (13–15).

The electronic spectrum of butadiene is very complex and most of the observed peaks have been assigned to Rydberg series. Many of the optically forbidden Rydberg transitions appear as weak vibronic transitions in the one-photon spectra of the molecule, and their correct characterization is difficult. Such dipole forbidden transitions are more easily recognized by variable angle electron impact (5–7) and multiphoton ionization spectroscopy (8–12). The latter method presents the advantage that polarization studies can be conducted to determine the symmetry of the excited states (16).

In this article we present the results of extensive *ab-initio* calculations of transition energies, intensities (for both linear and circularly polarized radiation) and polarization ratios for the first members of the two-photon allowed Rydberg states of butadiene, and also for the $2\ ^1A_g$ ($\pi \rightarrow \pi^*$) valence state. These parameters are then used to assign the observed transitions in the multiphoton spectra of the compound.

2. Computational details

All the calculations were carried out using the Dunning (17) valence double-ζ (DZ) contraction of Huzinaga (18) double-ζ ($9s/5p,4s$) gaussian basis set, augmented with diffuse basis functions of either $3s$, $3d_\sigma$, or $3d_\pi$ ($\zeta_{3s} = 0.023$, $\zeta_{3d} = 0.015$) character on each carbon atom, in order to provide an adequate description of the Rydberg excited states.

With the molecule in the yz plane, we used the experimentally determined ground-state geometry (19) in all the calculations.

To understand the symmetry of the Rydberg states being described, it is important to recall that the molecular designation of the atomic orbitals in butadiene is $3s = a_g$; $3d = a_g\ (\sigma)$, $b_g\ (\pi)$. The two-photon allowed Rydberg states will have the overall symmetries B_g ($\pi\ (1b_g) \rightarrow 3s$, $3d_\sigma$) and A_g ($\pi\ (1b_g) \rightarrow 3d_\pi$).

The ground-state, $X\ ^1A_g$, was solved self-consistently at the GVB(5/PP) (20) level (correlating the three σ and the two π bonds) and the orbitals generated were used for the CI calculations of the ^1A_g valence states.

For the $3s$ Rydberg state, the valence basis set was augmented with a diffuse s basis function on each carbon atom. Using this augmented basis set and the natural orbitals from the ground-state calculation (properly recombined into symmetry orbitals), we performed an improved virtual calculation (IVO, 21) to obtain the starting guess for the $3s$-like excited orbital. Using the first IVO of a_g ($3s$) symmetry, we solved self-consistently for the ^1B_g ($1b_g(\pi) \rightarrow 3s$) Rydberg state.

Similarly, for the $3d_\sigma$ and $3d_\pi$ states, the valence basis set was augmented either with d_σ or d_π -like basis functions, and IVO calculations were performed to obtain the starting excited orbitals for the self-consistent calculations. With the proper IVO's, we solved self-consistently for the ^1B_g ($1b_g(\pi) \rightarrow 3d_\sigma$) state at the HF level, and for the ^1A_g ($1b_g(\pi) \rightarrow 3d_\pi$) state at the GVB(3/PP) level. For the latter state we used, in addition to the IVO orbital, the orbitals corresponding to the GVB(3/PP) of the ground-state, because we do not expect that correlating the σ orbitals will cause any constraints in the description of the π states.

Because the ^1B_g ($3d_\sigma$) and the ^1A_g ($3d_\pi$) Rydberg states are not the lowest states of these particular symmetries, their self-consistent wave-functions will not represent *pure* Rydberg states. Nevertheless, the self-consistent orbitals generated will be adequate to describe diffuse open-shell states. The final description of these Rydberg states is obtained as higher roots of CI calculations.

We have considered two different types of CI calculations, referred as full π-CI and all-valence CI calculations (22). Both calculations follow very closely the ones presented in a previous publication (14). The major difference is that in the latter paper all the Rydberg states were constructed from four off-centre s-like basis functions while in the present calculation they were constructed from s or d basis centered on each carbon atom. Reference 14 should be consulted for a detailed description of these calculations.

As discussed in ref. 14, the correct description of the $2\ ^1A_g$

state requires the inclusion of σ correlation, while the Rydberg states can be well described at the full π-CI level. Therefore, the full π-CI results cannot be used for comparison purposes. These calculations have been performed as part of a process to select configurations for the all-valence CI calculations. A selection process is necessary because the number of configurations becomes quite large as we consider singles and doubles excitations in the σ space while simultaneously performing a full CI in the π space.

In the all-valence CI calculations we allowed all but the carbon 1*s*-like orbitals to participate in the treatment. Since the calculation is identical for all the states considered, we limit ourselves to the description of the general strategy used.

The π space, for each state, is the same considered in the π-CI calculations (14). To the σ occupied orbitals from the SCF calculations on each of the states considered we added the respective virtual σ orbitals associated to the C—C and C—H bonds of each state.

Starting from the respective HF or GVB type wave-functions, we considered the lists of configurations used in the π-CI calculations of the various states described above, and selected from the lists those configurations contributing an energy lowering[1] of 0.001 hartrees or more. From these configurations we allowed single excitations in the π space times single + double excitations in the σ space. To the new lists we added the respective lists of configurations used in the π-CI calculations. The final lists were then used to perform the all-valence CI calculations.

Using these all-valence CI wave-functions we computed transition energies and the two-photon transition rates from the expression (16)

$$[1]\quad \tau_{fi} = CF^2(h\nu)^2 \sum_f^{\alpha} \sum_i^{\beta} |\ M_{fi}^{\alpha\beta}|^2$$

considering up to six terms in the expansion. The intermediate virtual states were obtained at the same level of CI treatment. In eq. [1], C is a constant, F^2 the photoionization flux (in photons/cm^2 s) and α and β the degrees of degeneracy of the states $|f>$ and $|i>$, respectively, and M_{fi} is the second order matrix element

$$[2]\quad M_{fi} = \sum_k <f|\hat{e}\cdot r|k><k|\hat{e}\cdot r|i> / (E_{k'} - h\nu)$$

In eq. [2] the summation index runs over all the intermediate states of energy $E_{k'}$ relative to the initial state $|i>$.

We have considered the possibility that configurations which do not contribute appreciably to the variationally determined wave-function energies could still be important when computing the transition moment matrix elements. In order to verify that possibility we have considered calculations, for the $2\ ^1A_g$ and 3*s* states, which included all the configurations contributing a coefficient as small as 10^{-8} in the full π-CI wave-functions. The results of these calculations clearly indicated that the energy-based selection criterium described above could be safely used to compute the two-photon transition rates.

3. Results and discussion

Table 1 shows the results of the calculations at the all-valence CI level. Except for the $2\ ^1A_g$ state (for which σ correlation is very important) the results do not differ appreciably from the ones obtained at the full π-CI level. Table 2 contains information about the number of configurations used in the all-valence CI calculations.

The $3d_\pi$ (^1A_g) states were obtained as higher roots in the respective CI calculations, in order to project out the ground and the $2\ ^1A_g$ valence states. The first root corresponds to a dominantly closed shell valence state, the second root is also dominantly a valence state and exhibits the doubly-excited dominant configuration characteristic of the $2\ ^1A_g$ state.[2] Finally, the third and fourth roots are dominantly single excited diffuse configurations corresponding to the $3d_\pi$ Rydberg states. The designation of these states as $3d_{xz}$ and $3d_{xy}$ follows from the fact that the excited orbitals of the strongly dominant configurations exhibit amplitude plots analogous to the $3d_{xz}$ and $3d_{xy}$ atomic orbitals respectively.

The $3d_\sigma$ (^1B_g) state obtained as second root in the CI calculation for the 3*s* Rydberg state is very similar to the one

[1]We call "energy lowering" of a configuration the energy increase that would result from deleting the configuration from the CI list without readjusting the coefficients of the remaining configurations.

[2]The dominant configuration in the CI calculation of the $2\ ^1A_g$ state, using either localized or delocalized π orbitals (13, 14), exhibits four open shell orbitals with electrons singlet coupled. We have interpreted that (14*a*), using the exciton model, as being the result of a double excitation (one excitation per double bond). In the exciton notation that corresponds to a *TT* state.

TABLE 2. Number of spatial configurations used in the all-valence CI calculations

State	Number of configurations
$2\,^1A_g$	2176
$3d_{xy}$	3944
$3d_{xz}$	3944
$3s$	1972
$3d_z^2$	2142
$3d_{yz}$	2142

obtained as the second root in the CI calculation of the $3d$ state. On the other hand, the first root of the last calculation is a very poor description of the $3s$ Rydberg state, showing, as expected, that the shape of the $3s$ orbital cannot be well described by d-like functions, except in the core region.

Because of the complexity involved, we restricted the calculations of two-photon transition rates to the $3s$, one $3d_\sigma$ and one $3d_\pi$ Rydberg states, besides the $2\,^1A_g$ valence state. From Table 1 one should, in principle, observe at least six transitions in the MPI spectra in the region 6.2–7.8 eV.

Johnson (8) was the first to examine the MPI spectra of butadiene in the region 5.29–6.79 eV. He observed a single transition in this region, with origin at 6.21 eV, and assigned it tentatively to the $3s$ Rydberg state. Berg *et al.* (9) have also examined the MPI spectra in the region about 6.2 eV. They also detected one single transition, at 6.21 eV, with polarization ratio $\Omega = 1.4$–1.6. Vaida *et al.* (10) recorded the MPI and thermal lensing spectra of the molecule between 6.2 and 6.5 eV and concluded, from pressure broadening studies, that the transition should correspond to a Rydberg state. From the results shown in Table 1 we assign this transition to the $3s$ Rydberg state, because the excellent agreement between the theoretical and experimental results for the transition energy and Ω.

Mallard *et al.* (11) have examined the MPI spectra of butadiene in the region 7.5–9.2 eV. They observed a series of transitions that they assigned to the various members ($4s$–$12s$) of the s (B_g) Rydberg series, converging to the first ionization potential (IP) of the molecule. More recently, Taylor *et al.* (12), based on polarization studies (16), reassigned these transitions. The first one, at 7.62 eV, was assigned to the $3d_\pi$ (^1A_g) state (consistent with $\Omega < 1$) and the others to higher members of this series. Polarization studies conducted for the observed peaks indicated that they should all correspond to states of A_g symmetry. From the results in Table 1, one sees that the only Rydberg states, predicted by the calculations, to occur in this region, are the $3d_\pi$ (^1A_g) states. The first members of the two series are very close in energy and cannot be distinguished by polarization studies since they have the same symmetry. As the principal quantum number increases, the two series become degenerated what definitely prevents the identification of the different components. Once more, there is an excellent agreement between the theoretical and experimental results. Thus, we assigned the observed transitions to the members of the d_π series converging to the first IP.

None of the experimental studies covered the region from 7.0 eV to 7.4 eV, where the $2\,^1A_g$ valence and the $3d_\sigma$ Rydberg states are predicted to occur.

From Table 1, the two-photon intensities of the observed transitions to the $3s$ and $3d_\pi$ states, relative to the intensity of the $2\,^1A_g$ transition, indicate that the last state should be observable once an experiment conducted at the proper energy is performed. Nevertheless, because the MPI spectra involve a two-photon resonance three-photon ionization process, it is possible that the resonant two-photon $2\,^1A_g$ valence state would not leave enough to enable subsequent ionization. Therefore, it is possible that in spite of its intensity the $2\,^1A_g$ state may not be detected by MPI spectroscopy. This state has been observed in the electron impact (EI) spectra of the molecule (5, 6).

On the other hand, one expects the $3d_\sigma$ states to have life-times comparable to the other observed by Rydberg states. However, if we compare the relative intensities, one sees that the two-photon intensities to the ^1A_g ($3d_{xy}$) state relative to the ^1B_g ($3d_{yz}$) state are 8.26 and 45.12 for circularly and linearly polarized light, respectively. Thus, the ^1B_g states should be much more difficult to detect. We encountered a similar situation in the MPI spectra of the 1,3,5-*trans*-hexatriene molecule, where the in-plane $3p_\sigma$ Rydberg states are not observed but the $3p_\pi$ is clearly identified, in agreement with the theoretical calculations (23). The $3d_{yz}$ state has been observed in the EI spectra of the butadiene molecule (5).

Finally it is interesting to notice that while various members of the nd_π series have been observed (12), only the first one of the ns series has been detected. Based on the quantum defect for the $3s$ state, it is easy to show that the higher members of this series should lie very close in energy to the nd_π states. However, the polarization studies (12) clearly indicate that none of the other peaks observed in the MPI spectrum correspond to members of the s series. The reason for not observing the higher members of this series could be that either their lifetimes or their transition rates drop very rapidly with the quantum number. The last possibility goes contrary to the common belief that Rydberg transitions with precursors (ns) should be more intense than the ones without precursors (nd).

4. Conclusions

The results of the calculations indicate that the multiphoton (two-photon resonance three-photon ionization) spectrum of butadiene, below the first IP, consists of a series of Rydberg transitions (ns, nd_σ, nd_π) and possibly of a valence $\pi \rightarrow \pi^*$ ($2\,^1A_g$) state. The $3d_\sigma$ states should be difficult to observe because of their small two-photon transition rates whereas the two-photon resonant $2\,^1A_g$ valence state may be too short-lived to be detected in the MPI experiment. The calculations are in good agreement with the available experimental results.

S. KAPUR, N. C. MATHUR, K. MCMANUS, A. L. PINCOCK, and J. A. PINCOCK. Can. J. Chem. **66**, 2888 (1988).

Rate constants for the pyrolysis of the indenyl diazo compounds, **5***a*–**5***e*, in methanol have been determined and correlated with σ^+, giving a $\rho^+ = -0.76$. The product of this pyrolysis reaction is the methyl ether resulting from trapping at the carbenic centre. The mechanism proposed for this process involves rate-determining unimolecular loss of nitrogen by the allowed nonlinear pathway to form the singlet σ^2 carbene. Evidence presented implies that this singlet state is more stable than the p^2 state despite the difference in aromatic stabilization of the two.

S. KAPUR, N. C. MATHUR, K. MCMANUS, A. L. PINCOCK et J. A. PINCOCK. Can. J. Chem. **66**, 2888 (1988).

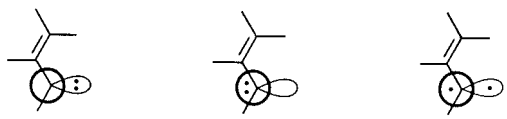
Opérant dans le méthanol, on a déterminé les constantes de vitesse pour la pyrolyse des composés diazoindényles, **5***a*–**5***e*, et on a établi une corrélation avec σ^+ conduisant à une valeur de ρ^+ de −0,76. Le produit de cette réaction de pyrolyse est l'éther méthylique provenant d'un piégeage par le centre carbénique. L'étape déterminante du mécanisme proposé pour ce processus implique une perte unimoléculaire d'azote par la voie non-linéaire permise et elle conduit à la formation d'un carbène σ^2 singulet. Des données qui sont présentées impliquent que cet état singulet est plus stable que l'état p^2 malgré la différence de stabilisation aromatique des deux.

[Traduit par la revue]

Introduction

We have recently been studying the thermal chemistry of vinyldiazo compounds as a simple and direct way to learn about the electronic structure of the carbene generated, eq. [1] (1–3).

[1] 
Vinyl carbenes, as singlets and in planar geometry, have three low lying states: **1** (2π or σ^2) (4–6), **2** (4π or p^2), and **3** (3π or p). As well, there is a triplet state corresponding to **3** that

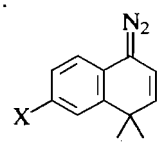


1 **2** **3**

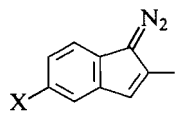
is normally the most stable of all four electronic configurations. Nevertheless, in any given chemical reaction, the triplet state may not be the first formed of the four possibilities. For instance, in the thermal decomposition of vinyldiazo compounds the rate-determining transition state for loss of nitrogen will be energetically a reflection of the structure of the developing singlet state. An examination of substituent effects on these reactions has been particularly revealing.

Rate constants for the pyrolysis of ring substituted diphenyldiazomethanes gave a parabolic-type Hammett plot where all substituted compounds react faster than the unsubstituted case (7, 8). A set of phenyldiazobutenes showed the same effect (2). These results were interpreted in terms of the rate-determining transition state resembling the carbene **1**, which is zwitterionic in the sense that the σ-system is electron rich and the π-system electron deficient. Rotation of the benzene ring at the carbene carbon allows conjugation with either the σ- or π-system. Thus, electron-donating substituents stabilize the transition state by conjugation with the electron deficient σ-system and electron-withdrawing ones with the electron rich π-system. These studies do not rule out the possibility that the transition state resembles carbene **2** since the same arguments can be applied.

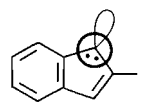
Loss of nitrogen from a diazo carbon is analogous to the cheletropic reactions described by Woodward and Hoffmann (9) in which there are two geometrically different modes. The linear mode leads directly to the carbene **2** (3) and, since **2** is not the ground state singlet, this pathway can be described as thermally forbidden. If the restriction on a linear dissociation geometry is removed then the starting material can proceed directly by a nonplanar transition state to the carbene **1** and this pathway is thermally allowed. A test of these two pathways is possible and proves that the nonlinear pathway is preferred (3). Thus pyrolysis of the set of ring substituted compounds, **4**, showed a linear Hammett plot with a $\rho^+ = -0.84$. The substituents can only conjugate with the π-system at the carbene center because of restricted rotation in the rigid ring system. The negative ρ value and correlation with σ^+ confirms the formation of carbene **1**.



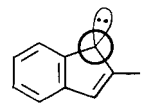
4



5*a* (X = CH_3O)
5*b* (X = CH_3)
5*c* (X = H)
5*d* (X = Br)
5*e* (X = NO_2)



6



7

We were interested in examining the magnitude of the preference for this nonlinear pathway and here report on the thermal kinetics for the loss of nitrogen from a series of 1-diazoindenes, **5***a*–**5***e*. This set of diazo compounds was chosen with the idea that the transition state for carbene formation might reflect the generation of **6** (analogous to **2**) rather than **7** (analogous to **1**) and thus the linear pathway would

be preferred. This suggestion is based on the fact that **6** has aromatic stabilization because it is a 10π-electron system whereas **7** has only 8π electrons.

Results and discussion

Synthesis of diazoindenes

The diazo compounds were prepared by pyrolysis of the corresponding sodium salts of the tosylhydrazones, **8***a*–**8***e*, in refluxing hexane, eq. [2]. This proved to be easier than

[2] 
a, $TsNHNH_2$; b, $NaOCH_3$; c, Δ, hexane

the previous cases examined (1–3) because the diazoindenes formed are somewhat more stable thermally and decompose only very slowly at this temperature. The tosylhydrazones were prepared from the corresponding 2-methylindenones, **9***a*–**9***e*, eq. [2]. The 2-methyl derivatives were chosen in preference to the unsubstituted indenones because of the known tendency towards polymerization of unsubstituted indenones (10, 11) and because a convenient synthetic route to **9***a*–**9***d* is available (11). Thus, **9***c* is known and **9***a*, **9***b*, and **9***d* were prepared by the same method, eq. [3]. The nitro compound, **9***e*, could not

[3] 
a, $Zn/CH_3CHBrCO_2Et$; b, NaOH; c, $SOCl_2$; d, $AlCl_3$; e, C_5H_5N

[4] 
10

a, $Cu(NO_3)_2$; b, CrO_3; c, Br_2; d, $LiBr/LiCO_3/DMF$

be prepared this way because Friedel–Crafts cyclizations are unsuccessful for strongly deactivated rings. However, nitration (12) and oxidation of 2-methylindane gave a mixture of nitroindanones from which the 5-nitro isomer **10** could be obtained in low yield after careful chromatography, eq. [4]. The structure of this isomer was confirmed by nmr spectral comparison with the closely related indanones that do not have the methyl group at C-2. Thus, even at 60 MHz, **10** could be seen to have an identical ^1H nmr spectrum in the aromatic region to the known 5-methylindanone (13) and quite different from that of the 6-methyl isomer (14). Bromination followed by dehydrobromination then gave **9***e*. Details of the syntheses are given in the experimental section.

Products of the thermal decomposition of diazoindene, 5c (X = H)

Samples from the pyrolysis of **5***c* (X = H) at 110°C in 5% pyridine in methanol were analyzed by gc/ms. These samples were identical to those used for infinity values in kinetic runs (see below). The major product was the methyl ether, **11**, as expected based on the usual trapping of the carbene by methanol (1–3) as shown in eq. [5]. Isolation of this ether from these very

[5] 
11

dilute samples was impossible but its structure was confirmed by independent synthesis as in eq. [6].

[6] 
12

a, Br_2/CH_3OH; b, $LiBr/LiCO_3/DMF$

Thus, bromination of 2-methylindene in methanol gave the dibromide and the bromoether, **12**, both as single stereoisomers that are probably (although not confirmed) the ones resulting from *anti* addition. Bromination of indene itself in methanol gives exclusively *anti* addition (15). Dehydrobromination then gave **11**, which had a retention time and mass spectrum identical to the kinetic sample. Details are given in the experimental section.

In addition to the ether, **11**, a minor component observable in the gc/ms scans of samples from the pyrolysis of **5***c* was a compound of molecular weight 207 corresponding to the carbene plus pyridine. That pyridine is a good trap for carbenes has been suggested from recent flash photolysis experiments where an ylid was formed by reaction of naphthylmethyl carbene with the pyridine nitrogen (16). If sodium methoxide (1.8×10^{-2} M) was used as the base instead of pyridine, the only observable product was the ether, **11**. The rate constant of decomposition of **5***c* (see below) was very similar for these two conditions: $7.8 \pm 0.3\ s^{-1}$ in 5% pyridine/methanol and $6.5 \pm 0.3\ s^{-1}$ with 1.8×10^{-2} M $NaOCH_3$ in methanol.

Rates of the thermal decomposition of the diazoindenes

The rates of thermal decomposition of **5***a*–**5***e* in 5% pyridine/methanol were monitored spectrophotometrically as described in the experimental section. The pyridine was added to the methanol to quench, as described previously (1), any possible acid catalysis. The reactions all exhibited good first-order kinetics and plots of $\log(A - A_\infty)$ versus time gave the following rate constants and mean deviations ($s^{-1} \times 10^5$) at 110°C: **5***a*, 22.9 ± 0.3; **5***b*, 9.8 ± 0.2; **5***c*, 7.8 ± 0.3; **5***d*, 5.12 ± 0.06; **5***e*, 1.39 ± 0.05.

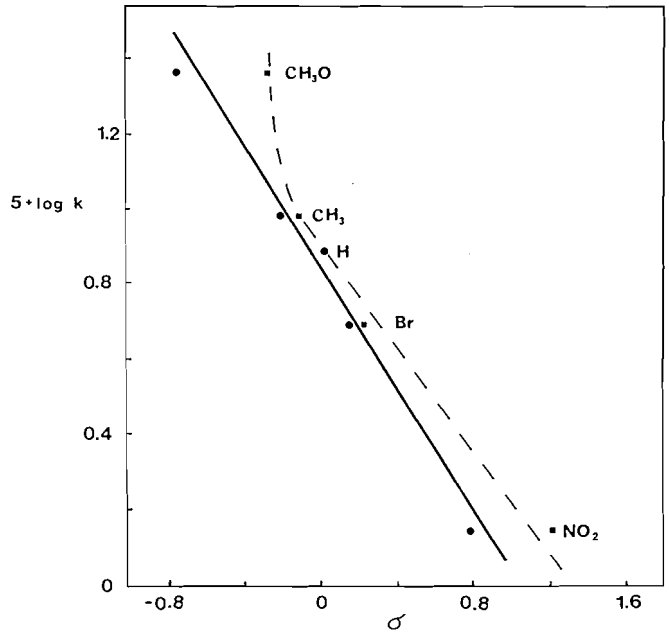

FIG. 1. Hammett plots for the rate constants for the thermal decomposition of the diazoindenes, **5***a*–**5***e*, in methanol at 110°C. ● are for σ^+ values and ■ for σ^-.

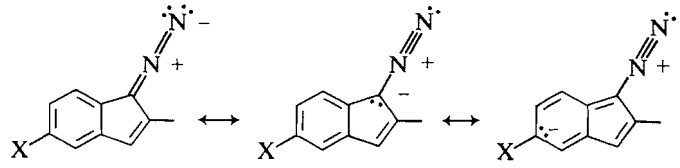
In this and our previous studies, we have assumed that rate constants such as these are measuring the rate of unimolecular decomposition of the diazo compound to the singlet carbene and are not complicated by some bimolecular component from the solvent system that would not be detected kinetically. The product information above supports this assumption since the rate of decomposition of the diazo compound, **5***c*, is similar with either pyridine or sodium methoxide as the base, even though the product composition changes. Moreover, measurement of the rate constant of decomposition as a function of temperature for **5***c* (104°C, 4.18×10^{-5} s^{-1}; 116°C, 13.5×10^{-5} s^{-1}; 123°C, 31.1×10^{-5} s^{-1}) gave the following activation parameters: $\Delta H^{\ddagger} = 30 \pm 1$ kcal/mol and $\Delta S^{\ddagger} = 1 \pm 4$ eu. We have also measured the activation parameters for the decomposition in 6% triethylamine/methanol for the diazotetralin, **4** (X = H), described previously (3): $\Delta H^{\ddagger} = 26 \pm 1$ kcal/mol and $\Delta S^{\ddagger} = 3 \pm 2$ eu. The low entropy of activation values are similar to all those reported previously for unimolecular diazo compound decompositions (1, 2, 17, 18) and point out that these decomposition rates are controlled almost entirely by enthalpy effects.

As expected for a process where a dipolar but neutral starting material like **5** proceeds to a carbene (also neutral), substituent effects are small. The total rate spread in going from **5***a* (X = CH_3O) to **5***e* (X = NO_2) is only a factor of 16. Analysis of these substituent effects may therefore be difficult although there is no doubt that electron-donating substituents favor the reaction.

Hammett plots for these kinetic results versus σ^+ and σ^-, the two substituent constants that allow direct resonance interaction with the reaction site, are shown in Fig. 1. The σ^+ plot is clearly better, giving a $\rho^+ = -0.76 \pm 0.06$ ($r = 0.990$). The σ^- plot gives a similar $\rho = -0.70 \pm 0.12$ ($r = 0.955$) but a much lower correlation coefficient. The line on the graph for σ^- is not the least-squares line but rather a line that emphasizes the deviation of the point for **5***a* (X = CH_3O).

The main objective of this work was to analyze substituent effects for the rate-determining transition state and to compare



the results for these indenyl compounds with those for the related tetralin derivatives, **4**, which were correlated with a $\rho^+ = -0.84$. The two are remarkably similar and suggest that the two sets of compounds have very similar mechanisms for thermal loss of nitrogen.

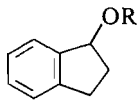
In the analysis of systems of this type there has been concern that ground-state substituent effects play an important role in the linear free energy correlations and that these effects might be as important as, or more important than, the transition state effects (2, 3, 7, 8). An examination of important resonance contributors that describe the charge distribution in these indenyl diazo compounds, **5**, shows why this is a concern. Obviously, electron-withdrawing groups should stabilize **5**. This should make **5***e* (X = NO_2) the least reactive, as observed. This ground-state stabilizing effect should be correlated with σ^-; however, in both this and the previous rigid system studied (3) the rate data correlate better with σ^+.

One way of examining the importance of ground-state resonance delocalization of this type is by measurement of the ^{13}C chemical shift of the diazo carbon (8). Although we have been unable to prepare enough material to do this for the very weak signal observed for the quaternary carbon of the set of indenyldiazo compounds, **5**, we have done so for the set of diazo tetralins, **4**. Thus ^{13}C chemical shifts (8) in CD_3CN relative to TMS for the diazo carbons in **4** are as follows: X = CH_3O, 61.4; X = CH_3, 61.7; X = H, 61.9; X = Br, 62.2; X = NO_2, 64.3 ppm. They obviously follow the expected deshielding order and, in fact, correlate with σ^-, giving $\rho^- = 1.85$ ($r = 0.997$). A very similar correlation has been observed for substituted diphenyldiazomethanes (8). The fact that ground-state delocalization is well accounted for by such a ρ^- correlation and that the rate constants for thermal decomposition are not fitted well by σ^- increases our confidence that analysis of the kinetic results for thermal decomposition is a useful way of assessing the transition state structure.

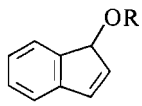
The σ^+ correlation for these thermal reactions is then best rationalized by increasing positive charge in the π orbital at the diazo carbon, and therefore the transition state is a reflection of the indenyl carbene being initially generated in the σ^2 configuration, **7**. Therefore, either the aromatic p^2 configuration, **6**, is less stable than the σ^2 one, **7**, or the driving force for nonlinear loss of nitrogen is large. Note that this discussion is only concerned with the rate-determining transition state for these pyrolysis reactions. The ground state of indenyl carbene is a σp triplet (19) but it can be trapped as a singlet using high concentrations of alkenes (20).

An estimate of the energy required to convert **6** and **7** can be made from some related ground-state chemistry. The destabilizing antiaromatic effect of having a positive charge in an indenyl ring system can be approximated by the solvolysis of **13** and **14**, which have estimated relative rates of 10^5 in favor of **13** forming the more stable cation (21). This corresponds to a free energy difference at 25°C of 6.8 kcal/mol. In contrast, the energetic advantage of having a negative charge in an indenyl ring system can be evaluated from the pK value (= 20.1) of indene, resulting in an estimated aromatic stabilization energy of 20 kcal/mol (22). Thus, approximately 27 kcal/mol of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/07/12
For personal use only.



13



14

π-energy are lost as a pair of electrons is removed from the π-system.

Opposed to this loss of energy as **6** (p^2) is converted to **7** (σ^2) is the gain in energy resulting from putting that pair of electrons in the more stable orbital. An estimate of this value is available from MO calculations on methylene itself (23). The vertical excitation energy from the $1'A_1$ to the $2'A_1$ state (analogous to excitation from **7** to **6**) is dependent on the H—C—H angle but increases from about 55 kcal/mol at 130°C, 72 kcal/mol at 120°C, to 105 kcal/mol at 100°C. This suggests that the energetic advantage of having the electron pair in the more stable σ orbital overcomes any disadvantage resulting from aromaticity factors. Supporting this estimate are calculations, including CI, on cyclopentadienylidene, which indicate that the 4π electronic configuration at a geometry with two localized π-bonds is 33 kcal/mol more stable than the 6π configuration at a geometry of an equilaterial pentagon (24). From these considerations, the apparent conclusion is that the ground-state singlet of indenyl carbene has the σ^2 configuration, **7**.

The conclusion as to the mechanism of the thermal decomposition of the indenyldiazo compounds **5** in methanol is that the reaction proceeds by rate-determining unimolecular loss of nitrogen by the allowed nonlinear pathway to form the carbene **7**. Substituent effects reflect the increased positive charge in the π-system during the conversion from starting material to transition state. The carbene is then trapped in a rapid second step to yield the methyl ether, **11**.

Experimental

The 60-MHz nmr spectra were recorded on either a Varian T-60 or EM-360 spectrometer using TMS as the internal standard. The 360-MHz nmr spectra were recorded on a Nicolet spectrometer. The ir spectra were recorded on a Perkin–Elmer 283B spectrometer using the 1620 cm^{-1} polystyrene absorption as a calibration. Mass spectra (70 eV) were recorded on a Dupont CEC-21-104 mass spectrometer and are reported as *m/e* (relative intensity). Except for the molecular ion peak, only peaks greater in intensity than 10% of the base peak are reported. The uv spectra were recorded on a Varian Carey 219 spectrometer. Melting points were taken on a Fisher–John apparatus and are uncorrected.

Combustion analyses were performed by Canadian Microanalytical Service Ltd., New Westminster, BC.

Preparation of 2-methylindenones, **9**a, **9**b, **9**c, *and* **9**d was by the method of Floyd and Allen (11): **9***a* (X = CH_3O), 25% based on 3-methoxybenzaldehyde; **9***b* (X = CH_3), 6% based on 3-methylbenzaldehyde; **9***c* (X = H), 18% based on benzaldehyde, mp 41–43°C (lit. (11) mp 45–47°C); **9***d* (X = Br), 28% based on 3-bromobenzaldehyde.

Preparation of 5-nitro-2-methylindenone, **9**e

2-Methylindanone was prepared as described previously (12) in 55% yield based on propiophenone, bp 91–92°C at 2.5 Torr (lit. (12) bp 65–66°C at 0.6 Torr) (1 Torr = 133.3 Pa). *2-Methylindane* was prepared by Clemmenson reduction of the ketone. To 67 g of amalgamated zinc in 310 mL of concentrated hydrochloric acid was added 35.0 g (0.24 mol) of 2-methylindanone and the mixture refluxed for 18 h. The mixture was then filtered and the filtrate extracted with ether. The ether layer was washed with water and saturated $NaHCO_3$ solution and then dried ($MgSO_4$), evaporated, and distilled to give 29 g (0.22 mol, 91%) of 2-methylindane, bp 200–202°C (lit. (12) bp 66–68° at 11 Torr).

2-Methyl-5-nitroindane and 2-methyl-4-nitroindane (12): A solution of 5.7 g (43 mmol) of 2-methylindane in 350 mL of acetic anhydride was cooled to 0°C and 7.5 g of $Cu(NO_3)_2 \cdot 3H_2O$ was added. The mixture was stirred for 1 h at 0°C and then for 3 h at ambient temperature. The mixture was poured into 500 mL of ice water and left stirring overnight. The mixture was then extracted with chloroform and the extract washed with water and then saturated $NaHCO_3$, dried over $MgSO_4$, and concentrated to give 6.9 g of crude nitroindanes. These indanes could be separated in low yield by flash chromatography using benzene eluant and silica gel. The faster eluting component (R_f 0.20) was assigned as the 4-nitro isomer and the second (R_f 0.16) as the 5-nitro isomer based on the observation of one lowfield aromatic hydrogen for the 4-nitro (δ 7.8–8.1) and two (δ 7.8–8.0) for the 5-nitro case. Because of the difficulty in this separation the mixture was oxidized before separation.

2-Methyl-5-nitroindanone, ***10***: To a solution of 0.93 g (5.3 mmol) of the mixed nitroindanes in 8.4 mL of acetic acid and 1.0 mL of water was added dropwise a solution of 2.5 g of chromium trioxide in 6.7 mL of acetic acid. The mixture was stirred at room temperature for 60 h, and was then poured into water and extracted with chloroform. The extract was washed with water and saturated $NaHCO_3$, dried over $MgSO_4$, and concentrated to give 1.3 g of crude nitroindanones and starting nitroindanes. Material of this type was chromatographed on a gravity column using silica gel and dichloromethane to separate the nitroindanones (795 mg) from the rest. This material could be recrystallized from methanol to give 195 mg (1.03 mmol, 19%) of pure 2-methyl-5-nitroindanone, mp 104–105°C; nmr ($CDCl_3$), δ: 1.4 (3H, d, J = 8 Hz), 2.7–3.2 (2H, m), 3.3–3.9 (1H, dd, J = 18 Hz, 8 Hz), 7.9 (1H, d, J = 8 Hz), 8.15–8.45 (2H, m).

2-Bromo-2-methyl-5-nitroindanone: To a solution of 75 mg (0.43 mmol) of the nitroindanone in 1 mL of CCl_4 was added 0.062 mL of bromine in 1 mL of CCl_4. This reaction can be monitored by titration to the faint end-point red colour of bromine. Evaporation of the CCl_4 gave 105 mg (0.41 mmol) of the bromoketone that was pure enough to use in the next step directly; nmr ($CDCl_3$), δ: 2.03 (3H, s), 3.4–4.3 (2H, dd, J = 19 Hz), 7.9–8.5 (3H, m).

2-Methyl-5-nitroindenone, **9**e: A mixture of 95 mg of LiBr, 82 mg of $LiCO_3$, and 160 mg (0.62 mmol) of the bromoindanone in 1.4 mL of DMF was heated to 130–140°C under a nitrogen atmosphere for 3 h. The mixture was then poured into 13 mL of water and extracted with 2 × 6 mL of ether. The extract was washed with 2 × 10 mL of water, dried over $MgSO_4$, and concentrated to give 46 mg (0.27 mmol, 43%) of **9***e*, which was used directly for the preparation of the tosylhydrazone; nmr ($CDCl_3$), δ: 1.97 (3H, s), 7.33 (1H, s), 7.47 (1H, d, J = 8 Hz), 7.82 (1H, s), 8.13 (1H, d, J = 8 Hz).

5-Nitroindanone: This compound was prepared by chromic acid oxidation of 5-nitroindane as described in the literature (13), mp 133–134°C (lit. (13) mp 131–133°C); nmr (360 MHz, $CDCl_3$), δ: 2.84 (m, 2H), 3.28 (m, 2H), 7.90 (d plus extensive long-range coupling, J = 8.4 Hz, H7), 8.23 (d plus extensive long-range coupling, J = 8.4 Hz, H6), 8.35 (complex multiplet H4).

6-Nitroindanone: This compound was prepared by nitration of indanone as described in the literature (14), mp 72–74°C (lit. (14) mp 74°C); nmr (360 MHz, $CDCl_3$), δ: 2.84 (m, 2H), 3.28 (m, 2H), 7.66 (dd, J = 8.4 Hz, 0.6 Hz, H4), 8.45 (dd, J = 8.4 Hz, 2.3 Hz, H5), 8.58 (dd, J = 2.3 Hz, 0.6 Hz, H7).

Preparation of tosylhydrazones **8**a, **8**b, **8**c, **8**d, *and* **8**e

The indenones were all relatively unstable (polymerization?) and were best converted directly to the tosylhydrazones. The procedure was the same for each and an example is given for **8***c*. To 1.10 g (8.2 mmol) of the indenone and 1.51 g of tosylhydrazine in 40 mL of methanol were added 5 drops of concentrated hydrochloric acid. The mixture was left to stand at 5°C overnight and the precipitate (1.4 g, 6.9 mmol,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/07/12
For personal use only.

84%) collected. Pure samples could be obtained by recrystallization from methanol.

2-Bromo-1-methoxy-2-methylindane, ***12***

To 0.5 g (3.9 mmol) of 2-methylindene (12) in 10 mL of methanol was added dropwise 0.2 mL of bromine until the colour of unreacted bromine persisted. The solution was concentrated *in vacuo* to give a residue that, by nmr analysis, was a mixture containing 1,2-dibromo-2-methylindane (50%) and 2-bromo-1-methoxy-2-methylindane (50%). Flash chromatography on silica gel using hexane as eluant gave 0.42 g (43%) of the bromoether; nmr, δ: 1.80 (s, 3H), 3.27 (s, 2H), 3.40 (s, 3H), 4.77 (s, 1H), 7.0–7.2 (m, 4H).

3-Methoxy-2-methylindene, ***11***

The bromoether **12**, 0.42 g, was dissolved in 5 mL of dry DMF; 0.169 g of lithium bromide and 0.144 g of lithium carbonate were added and the reaction heated to 140°C for 3 h. The mixture was then poured into 100 mL of water, extracted with 2 × 100 mL of ether, and the extracts washed with 2 × 100 mL of water, dried over $MgSO_4$, and concentrated to give 0.12 g (44%) of crude **11**, which could be purified by bulb-to-bulb distillation: nmr, δ: 2.01 (d, J = 1 Hz, 3H), 3.00 (s, 3H), 4.80 (s, 1H), 6.33 (bs, 1H), 6.9–7.3 (m, 4H); mass spectrum: 160 (255), 146 (39), 145 (382), 130 (64), 129 (48), 128 (78), 117 (192), 116 (83), 115 (332), 102 (45), 91 (97), 89 (82), 86 (22), 79 (36), 78 (24). This compound had gc/ms identical to infinity samples from kinetic runs.

Preparation of diazoindenes ***5***a, ***5***b, ***5***c, ***5***d, *and* ***5***e

The procedure used was the same for all and an example is given for **5***c*. The tosylhydrazone, **8***c* (400 mg, 1.28 mmol), was dissolved in 8 mL of dichloromethane and 0.22 g (4.0 mmol) of sodium methoxide was added. The mixture was stirred for 15 min and then the dichloromethane was evaporated under vacuum and 40 mL of hexane was added. After refluxing for 4 h the mixture was filtered and the hexane evaporated under vacuum to give 0.13 g (0.83 mmol, 65%) of 1-diazo-2-methylindene **5***c*; ir: 2055 cm^{-1}; nmr ($CDCl_3$), δ: 2.35 (3H, s), 6.10 (1H, s), 7.1–7.6 (4H, m).

Spectral data for the other diazoindenes are as follows: **5***a*; ir: 2050 cm^{-1}; nmr ($CDCl_3$), δ: 2.33 (3H, d, J = 1 Hz), 3.85 (3H, s), 6.07 (H3, q, J = 1 Hz), 6.77 (H6, dd, J = 8 Hz, 2 Hz), 7.03 (H4, d, J = 2 Hz), 7.29 (H7, d, J = 8 Hz); **5***b*; ir: 2050 cm^{-1}; nmr ($CDCl_3$), δ: 2.33 (3H, d, J = 1 Hz), 2.40 (3H, s), 6.07 (H3, q, J = 1 Hz), 6.95 (H5, d, J = 8 Hz), 7.17–7.42 (H4, H7, m); **5***d*; ir: 2060 cm^{-1}; nmr ($CDCl_3$), δ: 2.35 (3H, d, J = 1 Hz), 6.05 (H3, q, J = 1 Hz), 7.15–7.55 (3H, m); **5***e*; ir: 2055 cm^{-1}; nmr (360 MHz, $CDCl_3$), δ: 2.41 (3H, d, J = 1.3 Hz), 6.26 (H3, q, J = 1.3 Hz), 7.44 (H7, d, J = 8.6 Hz), 8.03 (H6, dd, J = 8.6 Hz, 2.1 Hz), 8.30 (H4, d, J = 2.1 Hz).

Kinetics of the thermal decomposition of diazoindenes ***5***a, ***5***b, ***5***c, *and* ***5***e

The concentration of the diazoindenes in 5% pyridine in methanol was adjusted to give an absorbance near 1.0 at the maximum: **5***a*, 338 nm; **5***b*, 326 nm; **5***c*, 322 nm; **5***d*, 328 nm; and **5***e*, 300 nm. Samples were then purged with nitrogen, sealed in ampoules wrapped with aluminum foil, and placed in a constant temperature bath. Kinetic samples were withdrawn and quenched by immersion in an ice bath. Rate constants were obtained from the slope of the linear log ($A - A_\infty$) versus time plots and the values are reported in the text.

A reformulation of the Sinanoglu–Reisse semi-empirical approach to describe the cavity formation process in liquids is proposed. The energy of cavity formation is regarded as a strictly potential energy corrected for short range order effects in the liquid state. Deviations from the Corresponding States Principle quantified by the Pitzer acentric factor are considered to describe these short range order effects.

The influence of the cavity shape on the calculation of its energetics is emphasized as well as the need for a realistic description of the dependence of the microscopic surface tension on the size and shape of the cavities. The proposed method is successfully applied to binary mixtures of *n*-alkanes at infinite dilution.

JOAQUIM J. MOURA-RAMOS, MADALENA S. DIONÍSIO, RAQUEL C. GONÇALVES et HERMÍNIO P. DIOGO. Can. J. Chem. **66**, 2894 (1988).

On propose une nouvelle formulation de l'approche semi-empirique de Sinanoglu–Reisse pour décrire le processus de formation de cavités dans des liquides. L'énergie de formation de la cavité est considérée strictement comme une énergie potentielle corrigée pour les effets d'ordre à courte distance dans l'état liquide. Les déviations par rapport au Principe des Etats Correspondants sont quantifiées par le facteur acentrique de Pitzer et sont utilisées sous cette forme pour décrire ces effets d'ordre à courte distance.

On démontre l'importance de la forme de la cavité sur le calcul de son énergie ainsi que la nécessité de posséder une description réaliste de la relation entre la tension superficielle microscopique et la taille et la forme des cavités. La méthode proposée a été appliquée avec succès à l'étude de mélanges binaires de *n*-alcanes à dilution infinie.

The importance of the energetics of cavity formation to elucidate the solvent effect on chemical processes has been strongly emphasized (1–3). The thermodynamic parameters ΔX associated with a chemical process A $\rightarrow$ B at infinite dilution are, in principle, solvent dependent and we may write $\Delta X_0 = \bar{X}_{BO} - \bar{X}_{AO}$ in the solvent S_0 and $\Delta X = \bar{X}_B - \bar{X}_A$ in the solvent S. The $\bar{X}$ are partial molar quantities at infinite dilution. Since $(\bar{X}_B - \bar{X}_A) - (\bar{X}_{BO} - \bar{X}_{AO}) = (\bar{X}_B - \bar{X}_{BO}) - (\bar{X}_A - \bar{X}_{AO})$,

$$[1] \qquad \delta(\Delta X) = \Delta(\delta \bar{X})$$

The operators δ (solvent effect) and Δ (process) are thus permutable (4). Equation [1] shows the relationship which exists between the solvent effect on ΔX and the thermodynamic transfer quantities $\delta \bar{X}$, and is at the origin of a generalised use of these transfer quantities in order to interpret the observed solvent effects (5–7). Nevertheless, $\delta \bar{X}$ are complex quantities, which reflect both solute–solvent and solvent–solvent interactions. To obtain information about the molecular structure of a solute it would be necessary to accede directly to the solute–solvent interaction and this is an important point when solvent effect studies are carried on in order to characterise short-lived species like electronic excited states or transition states.

The thermodynamic quantity $\delta \bar{X}_A$ for the transfer of a solute A from one solvent, S_0, to another, S, at infinite dilution, may be described as a sum of at least two terms[2]

$$\delta \bar{X}_A = (\delta \bar{X}_A)_c + (\delta \bar{X}_A)_i$$

where $(\delta \bar{X}_A)_c$ is a cavity contribution which depends on the size and shape of the solute A but reflects only the cohesive forces of the solvents (solvent–solvent interactions), and $(\delta \bar{X}_A)_i$ is a solute–solvent interaction contribution which depends on the polarity and the polarizability of the solute and of the solvent molecules. Only the last term gives information about the structure of the solute. Since thermodynamic transfer quantities are generally easy to obtain experimentally, the calculation of the energetics of cavity formation would make it possible to accede directly to the solute–solvent interaction term, and that is why this is an important feature in the context of solvent effect studies.

Two different methods are available in the literature for calculating the energetics of cavity formation in liquids: the Scaled Particle Theory (SPT) and a semi-empirical method based on the concept of microscopic surface tension of the solvent. The SPT is a statistical theory of liquids based on a hard

[1]Author to whom correspondence should be addressed.

[2]We neglect here an eventual contribution from the reorganization of the solvent in the cosphere of the solute. This contribution should be taken into account when structured solvents (particularly water) are involved. We also assume that the separation term, which describes the dispersion of the solute molecules in the solvent, is a pure solute property and does not depend on the solvent.

sphere potential, which was developed by Reiss *et al.* (8, 9) and applied to solubility problems by Pierotti (10–12). The second approach, which describes the cavity formation process as a work against the surface forces of the solvent, was qualitatively proposed a long time ago by Uhlig (13) and Eley (14) and has been quantitatively developed by Sinanoglu (3, 15) and Reisse *et al.* (2, 16). Since both methods have been criticized on different grounds (17, 18), we decided to reinvestigate this problem. In this paper we reconsider the thermodynamic formulation of the Sinanoglu–Reisse approach and we propose a new method for the calculation of the enthalpy of cavity formation.

The enthalpy of cavity formation: the basic equation

If the cavity formation process is described as a work against the surface forces of the liquid, $dW = \sigma_0 dS$, where dW is the infinitesimal work to create the infinitesimal surface dS[3] and σ_0 is the macroscopic surface tension of the liquid. This generalised work is a Gibbs energy if the process takes place at constant temperature and pressure so that the enthalpy of cavity formation can be obtained by derivation using the Gibbs–Helmholtz relationship. We thus have

$$[2] \quad H_c = N_A \sigma_0 A_0 S$$

with

$$[3] \quad A_0 = 1 - T\left(\frac{1}{\sigma_0}\frac{d\sigma_0}{dT} + \frac{2}{3}\alpha_0\right)$$

where N_A is the Avogadro's number, α_0 the solvent isobaric thermal expansion coefficient (see comment on p. 311 of ref. 3), S the surface of the cavity, and H_c the molar enthalpy of cavity formation.[4]

The cavities we are dealing with in this context are microscopic cavities (cavities of molecular size). As shown by Tolman (19), Kirkwood and Buff (20), and Koenig (21), the surface tension at the curved surfaces of these cavities is different from the macroscopic surface tension. To take into account the high curvature of these cavities we must multiply $\sigma_0 A_0$ (the enthalpy part of the surface tension) by a corrective factor K_h which depends on the size and the shape of the cavity. Then eq. [2] becomes

$$[4] \quad H_c = N_A \sigma_0 A_0 S K_h$$

This basic equation shows different forms according to the shape of the cavity. For spherical cavities $S = 4\pi r^2$, where r is the radius. If we take $V = N_A 4\pi r^3/3$, where V is the molar volume, we have

$$[5] \quad H_c/\text{J mol}^{-1} = 40.84 \sigma_0 A_0 V^{2/3} K_h$$

The factor 40.84 contains constants and unit conversion factors in order to obtain H_c in J mol^{-1} by introducing σ_0 in dyn cm^{-1} and V in cm^3 mol^{-1}. Since the relationship between the surface of a cylinder, S_{cyl}, and that of a sphere with the same volume, S_{sph}, is

$$[6] \quad \frac{S_{cyl}}{S_{sph}} = 0.4897\frac{V^{1/3}}{r} + 0.9266\frac{r^2}{V^{2/3}}$$

where r is the radius of the cylinder in Å and V is expressed in cm^3 mol^{-1}, the enthalpy of cavity formation for cylindrical cavities will be given by:

$$[7] \quad H_c/\text{J mol}^{-1} = 40.84 \sigma_0 A_0 K_h\left(\frac{0.4897V}{r} + 0.9266r^2\right)$$

An equivalent equation can be easily obtained for disc-shaped cavities.

The microscopic surface tension and its dependence on the size and shape of the cavity

The surface tension of spherical interfaces was studied by Tolman (19) based on Gibbs theory and a quasi-thermodynamic approach to the interface. He showed that the curvature dependence of the surface tension is appreciable for droplets and bubbles smaller than 10^{-6} cm radius, and obtained for this dependence the following equation:

$$[8] \quad \ln K = \ln\frac{\sigma(r)}{\sigma} = \int_{\infty}^{r} \frac{\left(\frac{2\delta}{r^2}\right)\left(1 + \frac{\delta}{r} + \frac{1}{3}\frac{\delta^2}{r^2}\right)}{1 + \left(\frac{2\delta}{r}\right)\left(1 + \frac{\delta}{r} + \frac{1}{3}\frac{\delta^2}{r^2}\right)} dr$$

where $\sigma(r)$ is the surface tension at the curved surface, σ_0 the macroscopic surface tension, r the radius of the sphere, and δ is the difference between the radius of the equimolar surface (for which adsorption is zero) and the radius of the surface of tension.[5,6] This equation was also obtained by Kirkwood and Buff (20) using the radial distribution function method, and by Ahn *et al.* (23) from the liquid partition function derived from the Significant Structure Theory. It is doubtful that the value of δ remains constant and independent of the radius of curvature for droplets and bubbles so small that r is of the same order as δ. Since δ is an unknown function of r, it is usual to consider it as a constant (24–26). If δ lies between 3 and 5 Å (and this is the case for most organic liquids (26–28)), the calculation of the Tolman integral leads to a curvature dependence which can be described by the equation

$$[9] \quad K = 1 + \left(\frac{V_0}{V}\right)^{2/3}(K_0 - 1)$$

previously proposed by Sinanoglu (15). We will consider this equation to describe the variation of K_h with the size of spherical cavities.[5]

As pointed out by different authors (25, 27), the Tolman integral (calculated assuming δ constant) underestimates K for small (molecular sized) cavities. To calculate K and K_h a semi-empirical method was thus proposed (2, 16, 29, 30). According to this method attention is focused on a reference cavity which corresponds to that occupied by a single molecule in the pure liquid. For the reference cavity we may write

$$[10] \quad H_{c0}/\text{J mol}^{-1} = 40.84 \sigma_0 A_0 V_0^{2/3} K_{h0}$$

[3] If the volume of the system changes during the process of creation of the new surface there will be a volume work which must be added to the surface work. Nevertheless, this volume work can be neglected at moderate pressures.

[4] From now on subscript zero indicates a solvent property; quantities without subscript are solute properties.

[5] This corrective factor K which may be used in Gibbs energy calculations is not the same as K_h (the corrective factor for the enthalpy part of the surface tension, $\sigma_0 A_0$). Nevertheless, it can be shown that both exhibit the same dependence on the curvature of the cavity (22).

[6] The δ value is positive for a droplet and negative for a bubble.

if spherical and

$$[11]\quad H_{c0}/\mathrm{J\ mol^{-1}} = 40.84\sigma_0 A_0 K_{h0}\left(\frac{0.4897V_0}{r} + 0.9266r^2\right)$$

if cylindrical.

To obtain K_{h0} it was suggested to identify H_{c0}, the reference cavity formation enthalpy, with the vaporization enthalpy of the pure liquid, H_{v0} (2, 16, 29, 30):

$$[12]\quad H_{c0} = H_{v0}$$

In this context the energy required to bring a molecule from the bulk to the surface (cavity formation) is considered to be the same as the one required to bring the molecule from the surface to the vapour phase (vaporization) (31, 32). The idea underlying this statement is that a given molecule has, at the surface, a number of nearest neighbours which is half the neighbours it has in the bulk.

The model developed by Prigogine and Saraga (33, 34) in which not all the surface lattice sites are occupied by molecules, the density at the surface being less than that in the underlying liquid, seems to confirm this approach. This modification of the cell model named incomplete-monolayer model gives good agreement between calculated and experimental surface tension if 30% of empty surface lattice sites are considered. Since for a compact structure (for example, a face-centered cubic lattice) the number of nearest neighbours is twelve in the bulk and nine at the surface of maximum compacity (six in the surface monolayer and three in the adjacent one), the Prigogine and Saraga results support the idea that the number of nearest neighbours in the bulk is approximately the double of that at the surface. (See appendix for another approach of this problem.)

Although this is an important point we must realise that the cavity formation process and the vaporization process are apparently very different in nature. During the cavity formation process molecules remain in the liquid state, while in the vaporization process molecules undergo a phase transition in which the molecular degrees of freedom are strongly changed: the liberational or quasi-vibronic modes of movement in the liquid change to translational degrees of freedom in the gas and the internal rotations, as well as the other contributions to the energy of molecules, can be dramatically changed in the phase transition.[7] Since the specific heat at constant volume, C_v, is a measure of the degrees of freedom of the molecules in a macroscopic assembly (35), the quantity $T\Delta C_v = T(C_{vg} - C_{vl})$ (where g and l refer to the gas and the liquid, respectively) may be taken as the contribution of the change of the degrees of freedom to the vaporization energy. In this context $H_v - T\Delta C_v$ would be the potential energy of vaporization (the enthalpy associated with the break of intermolecular interactions which takes place in the vaporization process) and consequently this is the quantity, and not H_v itself, that should be compared with the enthalpy of cavity formation.[8]

The influence of the molecular shape on thermodynamic properties is another debatable matter as regards the identification of the cavity formation and vaporization processes. The success of the Prigogine–Flory–Patterson theory to predict the thermodynamic excess properties of liquid mixtures containing hydrocarbon molecules of different sizes and shapes is well known. However, some inconsistencies are observed for mixtures containing long-chain *n*-alkanes which can be explained by postulating the existence in these liquids of a short range order or a correlation of molecular order (37). This correlation of molecular order is broken in the vaporization process but remains in the reference cavity formation process. Long chain *n*-alkanes strongly deviate from the Corresponding States Principle (CSP) (38, 39), and the short range order is certainly at the origin of these deviations. The CSP states that the variation of the reduced saturated pressure as a function of the reduced temperature is expressed by a single curve for a large number of substances. This means that liquids complying with the CSP have the same vaporization enthalpy at the same reduced temperature. Deviations from the CSP can be quantified by using the so-called Pitzer acentric factor, ω (38, 40). Originally ω was proposed to represent the acentricity of the shape or the nonsphericity of the molecules. Nevertheless, ω rises also with polarity. At present the acentric factor is widely used as a parameter which is a measure of the short range order in liquids and this short range may be caused by the anisotropy of the molecular shape or by the dipole correlation.

We will show now that the quantity $H_v/(1 + \omega) = H_v^*$ represents the vaporization enthalpy that a substance would have if it complied with the CSP (if correlation of molecular order effects were absent). Assuming a constant vaporization enthalpy, the integrated Clapeyron–Clausius equation in reduced variables takes the form

$$[13]\quad \ln p_r = \frac{H_v}{RT_c}\left(1 - \frac{1}{T_r}\right)$$

where T_c is the critical temperature and p_r and T_r are, respectively, the reduced vapour pressure and the reduced temperature. The fact that this simple equation holds for many fluids depends on a fortunate coincidence that errors from assuming a constant heat of vaporization and ideal gas behaviour tend to cancel each other (39). For fluids complying with the CSP the reduced vapour pressure curve is the same so that the quantity H_v/RT_c has the same value for these substances: 5.3650 according to the Rowlinson equation (41). For substances deviating from the CSP it is necessary to introduce a third parameter in order to account for their properties. The parameter which has been most extensively studied is the Pitzer acentric factor, ω, defined as (38)

$$[14]\quad \omega = [1 - \log_{10} p_r]_{T_r = 0.7}$$

and, hence, eq. [13] becomes

$$[15]\quad \ln p_r = \frac{H_v}{(1 + \omega)RT_c}\left(1 - \frac{1}{T_r}\right)$$

[7] In order to relate the energy of cavity formation with the vaporization energy Sinanoglu (29) considers a term named ΔE_{idf} which describes the change in the internal degrees of freedom (idf) of the molecules associated with the vaporization process. He is thus conscious of the different nature of the two processes (vaporization and cavity formation). Nevertheless he does not suggest any method for estimating this term and in practical applications he always neglects it.

[8] This has some analogy with Ben-Naim's preoccupation (36) of defining the solvation process of a solute in a solvent as the process of transferring the solute from a fixed position in the gas phase into a fixed position in the liquid solution at constant temperature and pressure.

The comparison between eqs. [15] and [13] suggests that the quantity $H_v/(1 + \omega) = H_v^*$ may be regarded as the vaporization enthalpy a substance would have if it complied with the CSP.

As the process of making a reference cavity takes place with no short range molecular order change in the liquid, we propose the use of the CSP vaporization enthalpy, H_v^*, instead of H_v, to calculate the reference cavity formation enthalpy. Thus eq. [12] must be replaced by:

$$[16] \quad H_{c0} = H_{v0}^* - T\Delta C_{v0}$$

The combination of eq. [16] with [10] or [11] enables us to calculate K_{h0} from the experimental properties of the pure liquids:

$$[17] \quad K_{h0} = \frac{H_{v0}^* - T\Delta C_{v0}}{40.84\sigma_0 A_0 V_0^{2/3}}$$

for spherical reference cavities, and

$$[18] \quad K_{h0} = \frac{H_{v0}^* - T\Delta C_{v0}}{40.84\sigma_0 A_0 \left(\frac{0.4897 V_0}{r} + 0.9266 r^2\right)}$$

for cylindrical reference cavities. Having this reference value for K_h and postulating some dependence of K_h on the size of the cavity (for example, eq. [9] for spheres) K_h values for any cavity may be obtained. The dependence of K_h on the size of cavity is an important problem which has been oversimplified in the literature dealing with the energetics of cavity formation. In fact, eq. [9] has been used for all cavities independently of their shape. Nevertheless, most of the organic molecules are not spherical. The molecules of *n*-alkanes in the liquid state, for instance, are in extended conformations such that the cavities occupied by each molecule are much more like cylinders than like spheres. Furthermore, the reference cavities for *n*-alkanes will differ in length but should have similar radii. These are relevant features because the difference between the surface area of the *n*-alkanes and that of a sphere of equal volume would increase rapidly (42) with the lengthening of the hydrocarbon chain. In addition, since the cylinders are of similar radii, the cavities of *n*-alkanes must have similar curvatures and thus similar values of K_h.

To use eqs. [7], [11], and [18] for cylindrical cavities we must choose the value of r, the radius of the cylinder. For *n*-alkane molecules we assumed $r = 3.5$ Å[9] and hence:

$$[19] \quad H_c/\text{J mol}^{-1} = 40.84\sigma_0 A_0 K_h(0.140V + 11.3509)$$

$$[20] \quad H_{c0}/\text{J mol}^{-1} = 40.84\sigma_0 A_0 K_{h0}(0.140V + 11.3509)$$

$$[21] \quad K_{h0} = \frac{H_{v0}^* - T\Delta C_{v0}}{40.84\sigma_0 A_0(0.140V_0 + 11.3509)}$$

[9]The value of r could be obtained from the plot of the molecular volume, v, against the molecular surface area, s, since between these quantities we have the relationship $v = (sr/2) - \pi r^3$. If we use the Bondi method (43) to calculate the Van der Waals volume and the Valvani method (44) to calculate the molecular surface area we obtain for *n*-alkanes $r = 1.9$ Å. Nevertheless, this is a very strong underestimation. As pointed out by A. Y. Meyer in his beautiful paper on the size of molecules (45), "This choice (of Van der Waals volumes) makes molecules as small as conceivably admissible". In fact, a Van der Waals *n*-alkane has a volume which is nearly one half the volume the molecule really occupies in the liquid at room temperature. The value of 3.5 Å seems reasonable if we compare it with the radius calculated from molar volumes of small molecules for which the spherical shape approximation is valid: acetone, $r = 3.1$ Å at 25°C; propane, $r = 3.1$ Å at the boiling point; *n*-butane, $r = 3.4$ Å at the boiling point; *n*-pentane, $r = 3.6$ Å at 25°C; neopentane, $r = 3.7$ Å at 25°C.

Table 1 lists the selected physical properties of the pure liquid *n*-alkanes required for the calculations. Table 2 shows the K_h values for reference cavities in these liquids calculated from eq. [21]. It is interesting to note that K_{h0} is nearly constant in the *n*-alkane series which means that the curvature of the cylindrical reference cavities does not change with the size of *n*-alkane molecules as predicted. This physically founded behaviour was not observed when previous methods of calculating K_{h0} (15, 16) were used. It is also interesting to observe that the K_{h0} values for *n*-alkane are not very different from the value $K_{h0} = 0.57$ we obtain for cyclohexane using the spherical approximation (eq. [17]). Thus if, for example, cyclohexane is dissolved in hexadecane the use of eq. [9] to estimate the microscopic surface tension of the solute cyclohexane cavity would lead to a strong underestimation of K_h. A better solution for this situation would be to consider $K_h = K_{h0}$. The previous comments emphasize how important it is to recognize the variation of the microscopic surface tension with the size and shape of the cavity in order to calculate the energetics of cavity formation.

The effect of the solute and solvent molecular size and shape of H_c

With respect to the K_h dependence on the size and the shape of the cavity, we will consider essentially two different situations: (*1*) eq. [9] describes the variation of K_h with the size of the cavity for spherical cavities in spherical solvents; (*2*) K_h will be taken as independent of the size of the cavity so that $K_h = K_{h0}$ for cylindrical cavities and for moderate sized spherical cavities in large cylindrical solvents. This leads to several alternative formulations to calculate the enthalpy of cavity formation:

(*a*) Spherical cavity in a spherical solvent. If we substitute eqs. [9] and [17] in [5] the result is:

$$[22] \quad H_c/\text{J mol}^{-1} = 40.84\sigma_0 A_0(V^{2/3} - V_0^{2/3}) + H_{v0}^* - T\Delta C_{v0}$$

(*b*) Spherical cavity in a cylindrical solvent. Substituting [21] in [19] yields:

$$[23] \quad H_c/\text{J mol}^{-1} = \frac{0.140V + 11.3509}{0.140V_0 + 11.3509}(H_{v0}^* - T\Delta C_{v0})$$

(*c*) Cylindrical cavity in a spherical solvent. From eqs. [17] and [19] one obtains:

$$[24] \quad H_c/\text{J mol}^{-1} = \frac{0.140V + 11.3509}{V_0^{2/3}}(H_{v0}^* - T\Delta C_{v0})$$

K_h for the cylindrical cavity was taken as being equal to K_{h0} for the spherical reference cavity of the solvent. This kind of choice must be discussed in each particular case.

(*d*) Spherical cavity in a cylindrical solvent. If we consider K_h varying according to eq. [9], from [5] and [21] we obtain:

$$[25] \quad H_c/\text{J mol}^{-1} = 40.84\sigma_0 A_0(V^{2/3} - V^{2/3}) + \frac{V_0^{2/3}}{0.140V + 11.3509}(H_{v0}^* - T\Delta C_{v0})$$

As discussed before, the description which is implicit in eq. [25] does not fit many real systems. In some cases, $K_h = K_{h0}$ was found to be the most appropriate. H_c is then given by:

$$[26] \quad H_c/\text{J mol} = \frac{V^{2/3}}{0.140V_0 + 11.3509}(H^*_{v0} - T\Delta C_{v0})$$

To test the adequacy of eqs. [22]–[26] we decided to focus our attention on binary mixtures of *n*-alkanes at infinite dilution (the next paragraphs should clarify the reasons for this option). Among these apolar molecules in such conditions there are neither solute–solute interactions nor directional or specific solute–solvent interactions. We must note, however, that particularly in the higher alkanes we can find strong deviations from CSP.

As enthalpy is a state function, the dissolution enthalpy at infinite dilution, H_d, of a liquid solute in a solvent can be factorised as:

$$[27] \quad H_d = H_s + H_c + H_i$$

where H_s corresponds to the enthalpy associated with the separation (or dispersion) of the solute molecules in the solvent, H_c is the enthalpy of cavity formation (which depends on the solute size and shape, but reflects only the solvent–solvent interactions), and H_i is the solute–solvent interaction enthalpy. We neglect here a reorganization term which would be present in structured solvents (particularly in water) and which would describe a change of the solvent structure in the cybotactic region of the solute. For a pure liquid $H_c = -H_i/2$ since H_c and H_i are potential energies and, as pointed out earlier, the number of nearest neighbours of a given molecule in the bulk is twice this number at the surface. For a binary mixture this will also be true provided the solute and the solvent interaction potentials are similar. Alkane–alkane mixtures are the systems which can most probably fulfill this condition as confirmed by different approaches (37, 59). Thus, we may write:

$$[28] \quad H_s - H_d = H_c$$

If the solute and the solvent are the same (dissolution of a liquid in itself) H_d will be zero and eq. [28] becomes $H_{s0} = H_{c0}$ suggesting that the so-called separation process and the cavity formation proess are energetically equivalent processes. This is reasonable since in the dispersion of the solute molecules in the solvent, as well as in the cavity formation process, there is no phase transition: both processes involve only changes in the potential interaction energy of the molecules. For the separation process we can thus write $H_s = H^*_v - T\Delta C_v$ and eq. [28] becomes

$$[29] \quad H^*_v - H^*_{v0} - T\Delta C_v + T\Delta C_{v0} - H_d = H_c - H^*_{v0} + T\Delta C_{v0}$$

In eq. [29] all quantities except H_c are obtained experimentally. H_c can be calculated by eqs. [22]–[26] or by the scaled particle theory. Experimental H_d values for different *n*-alkane/*n*-alkane systems are presented in Table 3. Figure 1 presents the results obtained by calculating H_c from eq. [22].

[a] K_{h0} calculated from eq. 21.

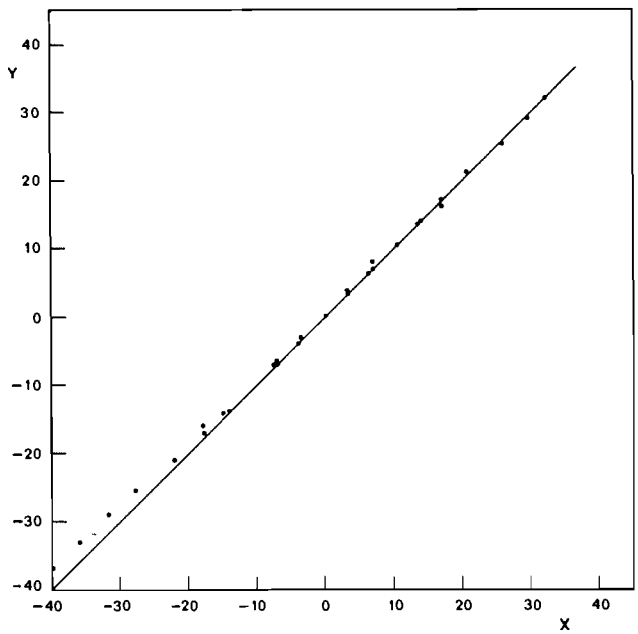

FIG. 1. Comparison between the calculated points and the theoretically predicted behaviour (line). The H_c values have been calculated from eq. [22]. Y and X are in kJ mol^{-1}.

Figure 2 shows similar results obtained by calculating H_c using different equations from [23] to [26].

In these figures Y (the ordinate) corresponds to the left-hand side of eq. [29] and X to the right-hand side, the straight-line representing the theoretical behaviour predicted by this equation.

From Figs. 1 and 2 we observe that calculated points are closely correlated with predicted behaviour (straight line). From Fig. 1 we conclude that eq. [22] (spherical approximation with K_h varying according to eq. [9]) is a good approach to H_c except for systems in which the solute is small compared with the solvent. The small but systematic deviations observed in these cases are due, as explained before, to an underestimation of K_h. Figure 2 shows that eqs. [23], [24], and [26] also lead to good values of H_c when realistically applied to particular systems. We may also note that the systematic deviations observed in

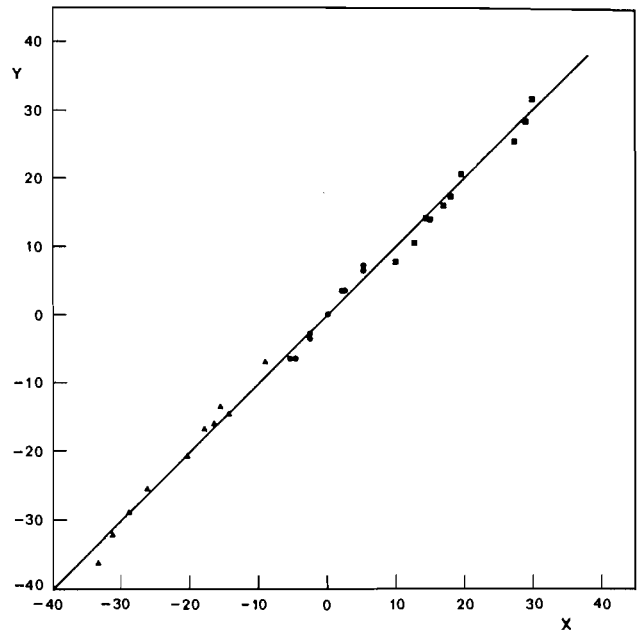

FIG. 2. Comparison between the calculated points and the theoretically predicted behaviour (line). The H_c values have been calculated by eqs. [26] (triangles), [23] (discs), and [24] (squares). Y and X are in kJ mol^{-1}.

Fig. 1 are now vanished. On the left-hand side of Fig. 2, the triangles correspond to the solution of the smaller *n*-alkane in the long *n*-alkane solvents and eq. [26] was used to calculate H_c (spherical cavity in cylindrical solvent). The squares on the right-hand side of the same figure represent systems composed of large solutes dissolved in the smaller *n*-alkane solvents and eq. [24] was used to calculate H_c (cylindrical cavity in a spherical solvent). The intermediate points correspond to systems well described by the eq. [23] (cylindrical cavity in a cylindrical solvent). Figure 2 shows a close correlation between the calculated points and the predicted behaviour.

It is interesting to compare our results with the ones obtained by the scaled particle theory. According to this theory the heat, H_c, involved in creating a cavity in a liquid to accommodate the solute molecule is related to the hard-sphere diameters, σ, of the solute and the solvent molecules. There are several methods proposed in the literature to estimate these hard-sphere diameters. In Table 4 we list the σ values for *n*-alkanes obtained by Reiss *et al.* (9) from vaporization enthalpies and by Wilhelm and Battino (68) from gas solubility data. The two sets of σ values are indeed very similar but the calculated enthalpies of cavity formation are very different when we use one set or the other. This strong dependence of H_c on the hard-sphere diameters of the solute and the solvent has been emphasized before (17) and it is illustrated in Figs. 3 and 4. In these figures Y and X have the same meaning as in the previous figures but now H_c has been calculated by the scaled particle theory. The points in the Fig. 3 correspond to H_c values from hard-sphere diameters in ref. 68. To obtain the points of Fig. 4 H_c has been calculated with the hard-sphere diameter values from ref. 9. The discrepancy between the results obtained with the two sets of σ values is large, particularly when the solute is small compared with the solvent. On the other hand, some methods of estimation of σ (for example, the use of the Stearn and Eyring equation (69)) yield results which are not physically acceptable, leading to H_c values which decrease with the size of cavity in the same

[a]From the enthalpy of vaporization, according to the equation given by Reiss *et al.* (9).
[b]From ref. 68.
[c]Extrapolated or interpolated value from: $\sigma/Å = 3.697 + 0.4196n - 8.019 \times 10^{-3} n^2$ where *n* is the number of carbon atoms, using hard-sphere diameters from ref. 68.

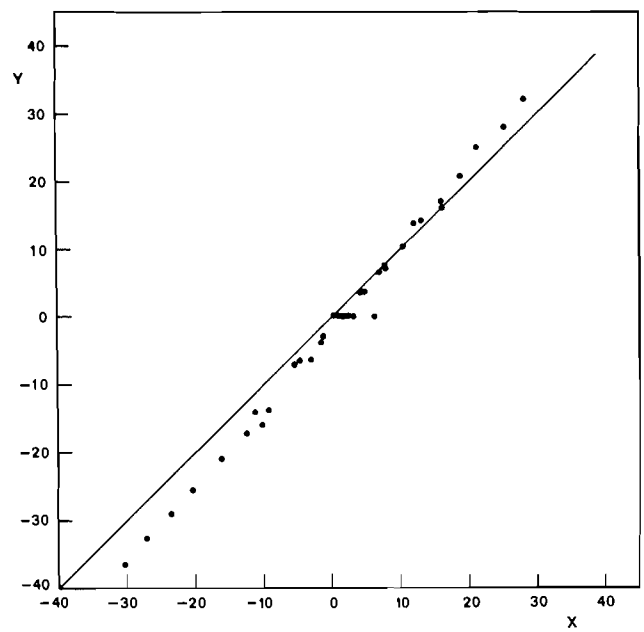

FIG. 3. Comparison between the calculated points and the theoretically predicted behaviour (line). The H_c values have been calculated from the scaled particle theory using hard-sphere diameters from ref. 68. *Y* and *X* are in kJ mol^{-1}.

solvent. It is difficult to assess the reliability limits of the scaled particle theory application. It has been pointed out before (17) that the application of the scaled particle theory is restricted to systems with no orientational molecular correlations or, otherwise stated, to systems composed of nearly spherical and apolar molecules. Nevertheless, using hard-sphere diameters from ref. 68, the discrepancies observed relative to the behaviour predicted by eq. [29] are not very large and they could probably be minimised by a suitable choice of the hard-sphere diameter values. It is obvious that this high sensitivity of H_c on the σ values is a strong handicap of the scaled particle theory. The semi-empirical method we propose here to calculate the energetics of cavity formation is more promising since it does not present this kind of sensitivity to molecular parameters and it allows a detailed description of the system under study (the shape of the solute cavity and of the reference cavity, the curvature of the surface cavities, ...).

Conclusions

The new method we proposed to calculate the enthalpy of cavity formation is based, as previous methods suggested in the literature, on a comparison between the vaporization process and the reference cavity formation process. Nevertheless, we showed that the identification of these two processes is not correct due to their different physical nature. The vaporization enthalpy is viewed as being composed of different contributions:

$$H_v = H_p + H_k + H_0$$

(*1*) a potential energy contribution, $H_p = H_v - T\Delta C_v$, due to the break of intermolecular interactions between neighbouring molecules; (*2*) a kinetic energy contribution, H_k, due to the change in the degrees of freedom of molecules in the vaporization process. (*3*) an order contribution $H_0 = H_v - H_v/(1 + \omega)$ which describes the destruction of the short-range order in the vaporization process of liquids deviating from the Corresponding States Principle. The reference cavity enthalpy formation H_{c0} is taken as a strictly potential energy corrected for order effects when they are present:

$$H_{c0} = H_p - H_0 = \frac{H_v}{1 - \omega} - T\Delta C_v$$

We emphasized the importance of taking into account the molecular shape of the solute and the solvent for calculating the energetics of cavity formation. We also emphasized the importance of describing correctly the dependence of the microscopic surface tension on the size and the shape of the solute cavities. In this context, we deduced different equations for calculating the enthalpy of cavity formation for real systems.

By applying these equations to binary mixtures of *n*-alkanes at infinite dilution we think that our new method for calculating the enthalpy of cavity formation constitutes a considerable improvement when compared with the other methods proposed in the literature.

Appendix

Consider an assembly of N molecules in the liquid state. N_b of these molecules are in the bulk and $N_s = N - N_b$ are at the surface. Consider also that C_b is the number of nearest neighbours of a molecule in the bulk, C_s is this number at the surface, and that ϕ is the pair potential interaction energy. The total potential energy of the assembly will be:

$$[A1] \quad U = \tfrac{1}{2}(N_b\phi C_b + N_s\phi C_s) = \tfrac{1}{2}\phi[(N - N_s)C_b + N_sC_s] = \tfrac{1}{2}\phi[NC_b + N_s(C_s - C_b)]$$

and the potential energy per molecule will be:

$$u = \frac{U}{N} = \tfrac{1}{2}\phi\left[C_b + \frac{N_s}{N}(C_s - C_b)\right]$$

and the molar potential energy of vaporization will be:

$$[A2] \quad U_m = \tfrac{1}{2}\phi\left[N_AC_b + \frac{N_AN_S}{N}(C_s - C_b)\right]$$

Let us suppose now that $C_s = m + n$ where m is the number of nearest neighbours a surface molecule has on the surface monolayer and n the number of nearest neighbours it has on the adjacent monolayer. If we bring a molecule from the surface to the gas phase, the m neighbours will have now $C_s - 1$ neighbours and the n molecules in the adjacent layer will have $C_b - 1$ neighbours. The potential energy of the assembly after removing the molecule from the surface monolayer will be

$$U' = \tfrac{1}{2}\phi[m(C_s - 1) + n(C_b - 1) + (N_s - m - 1)C_s + (N_b - n)C_b]$$

because $N_s - m - 1$ molecules at the surface and $N_b - n$ molecules in the bulk did not change their number of neighbours. The change of the potential energy associated with the removal of one molecule from the surface to the gas phase will thus be

$$U - U' = C_s\phi$$

and the molar potential energy of vaporization will be:

$$[A3] \quad U_m = N_A(U - U') = N_AC_s\phi$$

Comparing [A2] and [A3] we obtain

$$N_AC_s = \tfrac{1}{2}N_AC_b + \frac{1}{2}\frac{N_AN_s}{N}(C_s - C_b)$$

or

$$[A4] \quad \frac{N_s}{N} = \frac{2C_s - C_b}{C_s - C_b}$$

From [A4] it comes out that $C_s = (1/2)C_b$ if N_s/N is very small, which is the case for a macroscopic system in which the number of molecular monolayers in the bulk is big compared to unity.

Model studies of competing hydrolysis and epimerization of some tetrapeptides of interest in amino acid racemization studies in geochronology

MICHAEL E. MOIR AND ROBERT J. CRAWFORD
Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received March 23, 1988

MICHAEL E. MOIR AND ROBERT J. CRAWFORD. Can. J. Chem. **66**, 2903 (1988).

The processes of epimerization of individual peptide units in proteins and the concurrent cleavage of peptide bonds are modelled by heating some tetrapeptide and tetrapeptide derivatives to 148.5°C in pH 6.8 phosphate buffer. An excess of D-proline was observed during the heating of L-prolyl-L-leucylglycylglycine. The D/L ratio of proline attains a maximum value of 2.1 after 90 minutes. The excess D-proline is attributed to the formation of a 2.3:1 mixture of diketopiperazines *cyclo*-(D-prolyl-L-leucyl) and *cyclo*-(L-prolyl-L-leucyl). These two species account for most of the leucine and proline in the final mixture after the tetrapeptide is no longer detectable. Only small amounts of prolylleucine can be detected after 50 hours. It is suggested that the above tetrapeptide undergoes internal aminolysis. Leucine in the tetrapeptide glycyl-L-leucylglycylglycine racemizes three times faster than in L-prolyl-L-leucylglycylglycine. This demonstrates that an amino acid residue in a peptide chain does have an effect upon the rate of epimerization of a neighbouring peptide residue. A discussion of the geochemical implications of the results is included.

MICHAEL E. MOIR ET ROBERT J. CRAWFORD. Can. J. Chem. **66**, 2903 (1988).

Afin de développer un modèle des processus d'épimérisation des unités peptidiques de protéines et du clivage apparenté des liaisons peptidiques, on a chauffé des tétrapeptides ainsi que leurs dérivés à 148,5°C, dans un tampon de phosphate, à un pH de 6,8. Lorsqu'on a chauffé le L-prolyl-L-leucylglycylglycine, on a observé la formation d'un excès de D-proline. Le rapport de D/L proline atteint une valeur maximale de 2,1 après 90 minutes. On attribue la formation d'un excès de D-proline à la formation d'un mélange 2,3:1 des dicétopipérazines *cyclo*-(D-prolyl-L-leucyl) et *cyclo*-(L-prolyl-L-leucyl). Ces deux espèces peuvent expliquer la formation de la plus grande partie de la leucine ainsi que de la proline présentes dans le mélange final, même lorsqu'on ne peut plus détecter la présence du tétrapeptide. On ne peut détecter la présence que de faibles quantités de prolylleucine après 50 heures. On suggère que le tétrapeptide utilisé subit une aminolyse interne. La leucine du tétrapeptide glycyl-L-leucylglycylglycine se racémise trois fois plus rapidement que dans le L-prolyl-L-leucylglycylglycine. Ce résultat démontre que le résidu d'acide aminé d'une chaîne peptidique influence la vitesse d'épimérisation du résidu voisin. On présente une discussion des implications géochimiques de nos résultats.

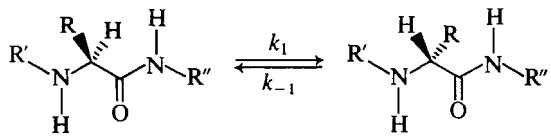
Introduction

Abelson's discovery of amino acids in fossils (1) has led to the use of the pseudo-first-order rate constant for racemization of the amino acids as a geochronometric tool. With the development of chiral phases for capillary column gas chromatography, the analytical technique has become sensitive enough that the enantiometric purity of nanogram quantities of the amino acid derivatives can be assessed. The process of amino acid racemization (slow at ambient temperature) is now widely used for dating fossils (2). Radiocarbon dating also is used often. In its most recent variation (3) it is generally considered to be accurate to between 30 and 50 ky bp. Geological dating by amino acid racemization is in fact peptide unit epimerization, in that generally the reaction occurs at one of the α carbons of a peptide unit, resulting in a peptide diastereomer being produced. Hydrolysis, derivatization, and GC analysis result in the comparison of the amounts of D and L isomers of the individual amino acids. The interconversion depicted in Scheme 1 begins after the death of the organism (except in those tissues which are not repaired) and has a half-life at ambient temperature varying from about 20 to 300 ky depending on the particular amino acid used for dating (4). There is often considerable disagreement between the ages obtained by the $^{14}C/^{13}C$ accelerator mass spectrometry method and those obtained from the analysis of enantiomeric amino acids (5). Despite these difficulties, the ease of sample preparation and the low initial capital cost of the amino acid method make it attractive for large volumes of samples when compared to the accelerator mass spectrometry method. The method does have value for relative dating, i.e., in deciding the relative age of a



SCHEME 1

series of samples within fossil beds or other deposits (6). In this paper we investigate three of the problems that may cause difficulty in attempting to use the amino acid method to obtain absolute dates. They are (*a*) the possibility of concomitant hydrolysis affecting the peptide epimerization rate, (*b*) the effect of neighbouring peptide units upon the rate of epimerization, and (*c*) the possibility that peptide epimerization rates cannot be calculated in the conventional manner. Equation [1] describes amino acid racemization exactly.

$$[1]\quad \ln\left[\frac{1 - K'[\mathrm{D}]/[\mathrm{L}]}{1 + [\mathrm{D}]/[\mathrm{L}]}\right]_t - \ln\left[\frac{1 - K'[\mathrm{D}]/[\mathrm{L}]}{1 + [\mathrm{D}]/[\mathrm{L}]}\right]_{t=0} = -(k_1 + k_{-1})t$$

For those amino acids which have only one asymmetric centre, $k_1 = k_{-1}$ and thus the right hand side becomes $-2kt$. For those amino acids for which racemization produces diastereomers (epimerization), the value of K' must be determined (for L-isoleucine epimerization of the α carbon produces D-alloisoleucine and $K' = 1.25$ (7)).

The use of amino acids racemization as a tool for geological dating has created the need to understand better the racemization of peptides and proteins. Racemization of a peptide has generally been treated as if it were occurring in discrete amino

acids. For the purpose of geological dating and stratigraphy, the first-order (or pseudo-first-order) rate law has been assumed to be operating for amino acids, peptides, proteins, and protein hydrolysates of changing composition. This simplification minimizes both the asymmetry of the peptides and the competing cleavage of peptide bonds. Since the initiation of our work Mitterer and Kriausakul (8) have demonstrated that the process of epimerization in peptides obeys first-order kinetics by separating the substrate from the hydrolysis mixture for the tripeptide L-Ile-Gly-Gly. The presence of more than one epimerizing centre has not been adequately addressed, particularly with respect to the potential for diastereomer formation from another chiral peptide unit within the protein.[1]

The epimerizations of tetrapeptides and their N-terminal and C-terminal derivatives were studied so as to model the protein situation. By studying model systems some of the properties of peptides that can complicate the interpretation of peptide epimerizations used for geochemical dating may be evaluated. Generally, in model studies, the rate constants have been taken from an examination of the individual amino acids from a protein hydrolysate. With the advent of convenient high performance liquid chromatography (HPLC) systems, it is possible to separate the amino acids from the di-, tri-, and tetrapeptides and thus obtain kinetic data on each species.

Experimental

Materials

Commercial peptides were found to be pure by electrophoresis (3000 V, pH 1.8, 45 min) and HPLC and required no further purification. Benzyl chloroformate, DMSO, *N*-methyl morpholine, isobutylchloroformate, and aniline were purified by distillation *in vacuo*. Ethyl acetate was purified by washing with sodium carbonate, water, and saturated sodium chloride, and then drying with anhydrous potassium carbonate followed by distillation from 3A molecular sieves. The water used for lyophilization was deionized, doubly distilled, and deionized again. Derivatives of peptides were prepared according to Bodanszky (10); examples of the synthetic preparations follow.

N-*Benzyloxycarbonyl-L-proline-L-leucylglycylglycine (1)*

L-Pro-L-Leu-Gly-Gly (**2**) (Bachem, Torrance, CA) (146.2 mg, 0.427 mmol) was dissolved in 20 mL water containing sodium bicarbonate (1.53 g). Benzyl chloroformate (2.0 mL, 14 mmol) was added and the mixture was mechanically stirred for 5 h at room temperature. Reaction times in excess of this caused significant hydrolysis of the starting material. The excess benzyl chloroformate was extracted three times with diethyl ether, the pH adjusted to 4, and the solution was then extracted three times with 25 mL of ethyl acetate. After drying the combined extracts, the solvent was evaporated and the white solid recrystallized from ethyl acetate/petroleum ether to give crystals of **1**, 125 mg (62%), mp 204–205°C. The product was characterized by its ^{1}Hmr and FAB-MS (11).

N-*Benzyloxycarbonyl-L-prolyl-L-prolyl-L-leucylglycylglycine anilide (3)*

A solution of **1** (57.3 mg, 0.12 mmol) in ethyl acetate (25 mL) was cooled to −15°C and enough DMSO was added to keep the solution homogeneous. *N*-Methylmorpholine (15 mL, 0.144 mmol) was added by syringe, followed immediately by isobutylchloroformate (20 L, 0.144 mmol). After 5 min, aniline (15 mL, 0.12 mmol) was added and the mixture was stirred for 1 h at −15°C, followed by additional stirring at room temperature for 6 h. After successive washes with sodium carbonate, water, 1 M HCl, and water, the organic layer was dried over magnesium sulfate. Evaporation of the solvent gave a white solid, which was recrystallized from ethyl acetate/petroleum ether to give 34.5 mg (56%) of **3**, mp 115–118°C. The product was characterized by its ^{1}Hmr and FAB-MS spectra (11).

L-Prolyl-L-leucyl-glycylglycine anilide (4)

A sample of **3** (50.8 mg, 0.919 mmol) was dissolved in 45% HBr in acetic acid (2 mL) and stirred for 30 min. The solution was evaporated to dryness and lyophilized several times with water. Upon dissolution in 1 mL ethanol the derivative was precipitated with methylene chloride and the solid filtered and washed with methylene chloride. This procedure was repeated until the material obtained was white. The anilide **4** was obtained as a white solid, 34.4 mg (87%), mp 160°C (dec.). The product was characterized by its ^{1}Hmr and FAB-MS spectra (11).

Using analogous procedures, *N*-benzyloxycarbonyl glycyl-L-leucylglycylglycine (**5**), mp 140°C, was synthesized from commercially available glycyl-L-leucylglycylglycine (**6**); N-benzyloxycarbonyl glycyl-L-leucylglycylglycine anilide (**7**), mp 160–162°C, was produced from **5**; glycyl-L-leucylglycylglycine anilide (**8**), mp 180°C, was produced from **7**; glycyl-L-prolyl-L-leucylglycine (**9**), mp 183–185°C, was produced from commercially available *N*-benzyloxycarbonyl glycyl-L-prolyl-L-leucylglycine (**10**); *N*-benzyloxycarbonyl glycyl-L-prolyl-L-leucylglycine anilide (**11**), mp 191–193°C, came from **10**; and glycyl-L-prolyl-L-leucylglycine anilide (**12**), mp 160°C, came from **11**. Each of these products was characterized by its ^{1}Hmr and FAB-MS spectra (11).

Procedure for studying reaction kinetics

Kinetic runs were carried out in a phosphate buffer (pH 6.8, 25°C) with a total phosphate concentration of 0.050 N. Two millilitres of ca. 10 mM peptide solution were placed in a glass tube and sealed after five freeze–pump–thaw cycles. The tubes were placed in a thermostated oil bath at a temperature of 148.5 ± 0.05°C. The bath was found to be stable to this precision for a period exceeding the maximum time required for the kinetic runs.

Eight to ten samples were analyzed for the disappearance of substrate peptide, the appearance of new species, and the extent of racemization in these components. Samples were removed from the heating bath at times between 5 and 300 min. The hydrolysis mixture of partially racemized material was separated by TLC or HPLC.

The hydrolysis mixture was separated on silica gel TLC plates (Whatman LK6DF, 250 μm) developed with 4:1:1 *n*-butanol:acetic acid:water. The components in the mixture were visualized with ninhydrin reagent (90 mL of a 0.3 wt.% aqueous solution of ninhydrin, and 10 mL of a solution of 3 g cadmium acetate in 300 mL acetic acid and 150 mL water) or with a UV lamp. The components in the mixture were isolated by scraping off the appropriate section of silica gel followed by extraction with 5.5 M HCl. After filtering the acid extracts (2 μm Metricel) the samples were derivatized and the extent of racemization measured.

Separation of the hydrolysis mixture by HPLC was accomplished using a C-18 reversed phase radial compression column (Waters Associates) connected to a Perkin–Elmer Series 2 liquid chromatograph solvent delivery system. The components of the hydrolysis mixture were detected by UV absorption at 230 nm using a Perkin–Elmer LC-55B UV detector. The separation was performed isocratically using 0.1 M ammonium acetate (pH 7) containing 10% acetonitrile. Ammonium acetate was purified by sublimation. The water used for the separation was deionized and distilled from potassium permanganate. HPLC grade acetonitrile (Caledon) was used untreated. The solvent mixture was degassed by bubbling helium through it for 2 min.

Typically, 1 mL of the reaction mixture was separated by repetitive injections of 100 mL. The hydrolysis fragments were collected manually as they eluted from the column after passing through the UV detector. Six fractions were collected for the hydrolysis and racemization studies of L-prolyl-L-leucylglycylglycine:

1. LL* + DD tetrapeptide
2. DL + LD tetrapeptide

[1]This is not to be confused with those cases wherein a second chiral centre is contained within the peptide unit, e.g., as in isoleucine; such cases have been well described in ref. 9.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/07/12
For personal use only.

3. LL + DD + DL + LD tetrapeptide[2]
4. DL + LD DKP
5. LL + DD DKP
6. DL + LD + LL + DD DKP[2]

*e.g., DL refers to the sequence D-Pro-L-Leu in the peptide. DKP = diketopiperazine.

In the case of glycyl-L-leucylglycylglycine, three fractions were collected:

1. initial fraction containing dipeptides
2. substrate enantiomers
3. *c*-(gly-L-leu) + *c*-(gly-D-leu)

For all three peptides, a portion of the total hydrolysis mixture was saved to obtain a measurement of racemization of the total hydrolysate. The HPLC solvent was removed from the fraction in a centrifugal biodryer. The identity of the hydrolysis components was determined by FAB-MS and by NMR spectroscopy. The extent of racemization of the separated components was subsequently determined by GC.

The dipeptide Pro-Leu and its diastereomer have similar retention times to the tetrapeptide L-prolyl-L-leucylglycylglycine and its diastereomer. From the measurement of the rate of formation of the DKP's it appeared that the tetrapeptide was hydrolyzing to the DKP with little or no incidence of the dipeptides. However, at long reaction times, the DKP's could be opening to the dipeptides, thus complicating the kinetic picture (12). To test this idea and to determine if the DKP's were in equilibrium with each other, the DKP's were separated from the reaction mixture, heated under the same conditions, and then separated again by HPLC. It was found that the DKP's were in equilibrium with each other and with the dipeptides. The dipeptides were found to be present in the equilibrating mixture to an amount not exceeding ca. 10% of the total. It was assumed that the DKP's were essentially stable to the reactions conditions and that the dipeptides were not significantly affecting the rate constant for hydrolysis derived from the measurement of the disappearance of the substrate. Sample chromatograms and conditions are shown for L-prolyl-L-leucylglycylglycine (Fig. 1).

Identification of hydrolysis products

The dried eluate from chromatography was analyzed by FAB-MS in the case of the peptides or by chemical ionization mass spectroscopy (CI) in the case of the DKP. The absolute configuration of the α carbons of the hydrolysis mixture was determined by GC analysis of the derivatives.

The hydrolysis of L-prolyl-L-leucylglycylglycine yielded three major components. The component having the shortest retention time after the substrate was found to have an $M + 1$ peak at mass 343. GC analysis showed that it consisted of D-proline, L-leucine, and glycine. Although it is tempting to assign the structure D-prolyl-L-leucylglycylglycine to this component, there is a potential complication. The formation of cyclic tetrapeptide(10) from the substrate followed by hydrolysis could in principle yield four isomeric tetrapeptides: Pro-Leu-Gly-Gly, Leu-Gly-Gly-Pro, Gly-Gly-Pro-Leu, or Gly-Pro-Leu-Gly.[3] The sequence of the peptide units was determined by examining the NMR chemical shifts at pH 1.00, 6.40, and 9.18. The removal of charge is predicted to have an effect on the chemical shift of those protons near to the centre of charge (13). A comparison of the change of chemical shift as function of pH for the starting material and the unknown tetrapeptide demonstrates identical behaviour, thus the structure D-prolyl-L-leucylglycylglycine is assigned to this component from the heating experiment.[4] The CI mass spectra of the other two components in the hydrolysis mixture each showed an $M + 1$ peak at mass 211, corresponding to *c*-(prolylleucyl). The component with the shorter retention time was shown by GC analysis to consist of D-proline and L-leucine while the other consisted of L-proline and L-leucine. The proton NMR and MS of authentic *c*-(L-prolyl-L-leucyl) and the latter component were identical. The spectra of the former component was consistent with *c*-(D-prolyl-L-leucyl).

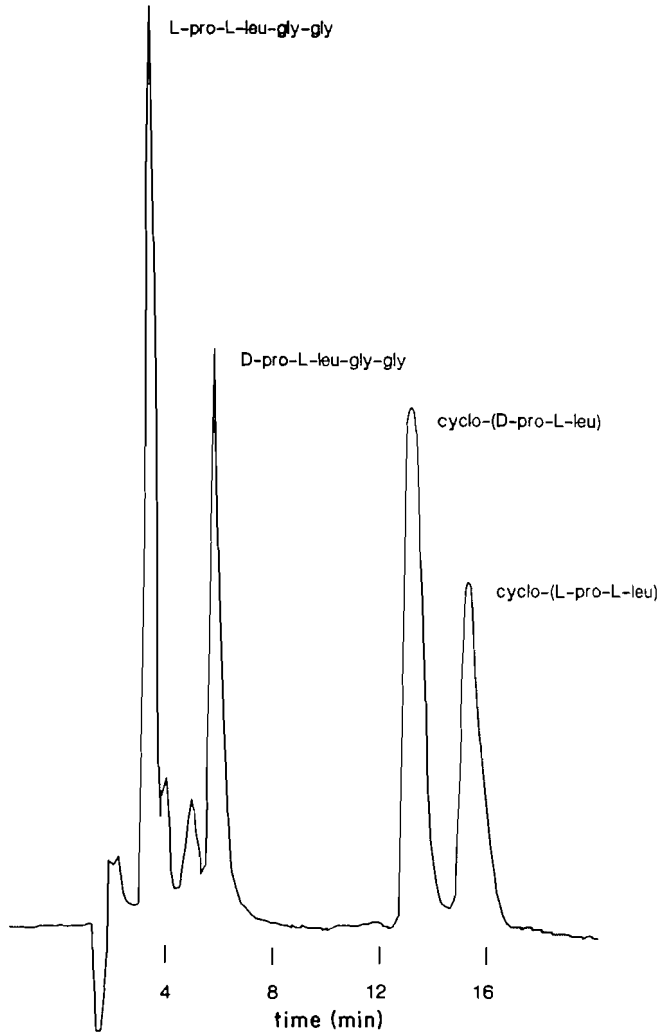


FIG. 1. HPLC trace of the mixture produced after heating L-Pro-L-Leu-Gly-Gly for 30 min at 148.5°C, pH 6.8. Chromatographic conditions: reversed phase C-18 column (Waters), 0.1 M NH_4OCOCH_3, 10% CH_3CN, 1.2 mL/min.

There were also three major components from the heating of L-prolyl-L-leucine, two of which correspond to the DKP's *c*-(D-prolyl-L-leucyl) and *c*-(L-prolyl-L-leucyl) obtained from heating of the tetrapeptide. The CI mass spectrum of the other component eluting after the substrate had an $M + 1$ peak at mass 229. GC analysis of this compound showed that it consisted of D-proline and L-leucine. Again, the sequence of the peptide units is ambiguous and was determined from the pH dependence of chemical shift in the proton NMR (13).

The component with the longest retention time, from the heating experiment with glycyl-L-leucylglycylglycine, gave a CI mass spectrum with an $M + 1$ peak at mass 170. The proton NMR and mass spectra of this compound were identical to the spectra obtained for authentic *c*-(glycyl-L-leucyl). The proton NMR spectrum of the least retained component indicated that it was a mixture. The composition was tentatively assigned to a mixture of glycine and leucine containing dipeptides.

[2]Fractions 3 and 6 were obtained by combining the column effluent from fractions 1 and 2 and fractions 4 and 5 respectively.

[3]It is assumed that the peptide Pro-Gly-Leu-Gly is not possible. The formation of this peptide requires the breaking of the Pro-Leu and Gly-Gly peptide bonds followed by the condensation of Pro, Gly, and Leu-Gly. This seems highly improbable.

[4]The nonobservance of any tripeptide is noteworthy. Presumably this is due to the preferential formation of diketopiperazines by internal aminolysis rather than peptide hydrolysis to yield a tripeptide.

Results and discussion

To determine the effect of neighbouring peptide units on the rate of epimerization of a peptide, it is necessary to separate the peptide from the mixture of products from hydrolysis. In an exploratory experiment thin-layer chromatography was used to attempt to separate the components of the mixture after heating a buffered aqueous solution of the model peptides. Extensive cleavage of the starting tetrapeptide occurs before any significant degree of epimerization of the reactant occurs. This last point underscores the limitation of studies that focus on the racemization of the total hydrolysis mixture. The assignment of the experimentally determined rate constant to the substrate accounts for only a small amount of the material in the hydrolysis mixture, if amino acid chirality is the parameter being measured.

Separation of the hydrolysis mixture is also not without hazards. In the case of a peptide with several chiral centres, there could be several separable diastereomers of the original peptide. Analysis of the component having the same retention time as the original peptide will likely result in a rate of epimerization that will certainly be lower than the rate of epimerization for all of the diastereomers combined. Therefore, it is important to be sure that the substrate and its diastereomers are not separated from each other or that they can be identified in the chromatogram. For experimental purposes, especially for determining epimerization rate constants for a protein, it is far better to try to achieve the former situation.

Despite the problems associated with separation, conclusions are possible from heating experiments on model peptides using TLC as the separation technique. The data in Table 1 were collected by isolating a fraction from the TLC plate having the same R_f as the substrate. Aside from the substrate, the identity of each spot on the TLC is not known. The important observation is the large variation in the D/L ratios in the components from the hydrolysis of peptides containing more than one chiral centre.

The one peptide that cannot suffer from the problems of diastereomers is the tetrapeptide containing only one chiral centre, glycyl-L-leucylglycylglycine. The tetrapeptide was heated at 148.5°C at pH 6.8 and the hydrolysis mixture separated by TLC. Five distinct components were detected (Table 2); that corresponding to the substrate was isolated and its D/L ratio measured. Equation [1] ($K' = 1.00$) is appropriate if there are no reversible processes, other than racemization, involving the substrate. Figure 2 shows the quality of fit obtained, demonstrating that the racemization process does follow pseudo-first-order kinetics described by eq. [1]. Similarly we observed that the other TLC spots that contained leucine had D/L ratios greater than that of the original substrate, and thus any rate constant derived from an analysis of the total sample would yield a rate constant faster than that of the tetrapeptide (Table 3).

Racemization and disappearance of L-prolyl-L-leucylglycylglycine

A goal of this work was to model the racemization of protein, using peptides having more than one chiral centre. Separation by TLC was incapable of resolving the complex hydrolysis mixture from peptides of this type. HPLC was considered to be the analytical method of choice since the experimental parameters could be controlled better than for TLC. For subsequent studies, HPLC was used exclusively for separation of peptide decomposition[5] mixtures.

The predominant feature of the racemization of L-prolyl-L-

[5]The generic term "decomposition" will be used to describe both the hydrolysis and cyclization.

leucylglycylglycine is the occurrence of an excess of D-proline in the total hydrolysate and in the diketopiperazine isolated during the decomposition of the substrate (Fig. 3). Excess D-proline has been observed in similar systems. For example *N*-benzyloxycarbonyl-L-alanyl-L-phenylalanyl-L-proline treated with acetic anhydride and sodium acetate gives *N*-(*N*-benzyloxycarbonyl-L-alanyl)-*c*-(L-phenylalanyl-D-prolyl) (**13**) (14). Also, phenylacetyl- L-alanyl-L-phenylalanyl-L-prolyl-*p*-nitrophenyl ester treated with NaH in DMF at 0°C for 2 h gives **14**, *N*-(phenylacetyl-L-alanyl)-*c*-(L-phenylalanyl-D-prolyl) (15). Earlier, a 90:10 ratio of *c*-(L-Phe-D-Pro):*c*-(L-Phe-L-Pro) was formed by treating *c*-(L-Phe-L-Pro) with 0.5 N NaOH at room temperature for 15 min (16), see Scheme 3. In the early studies of ergot alkaloids (17), D-proline was isolated from the alkaline hydrolysate in the form *c*-(D-prolyl-X) (X = Leu, Phe,

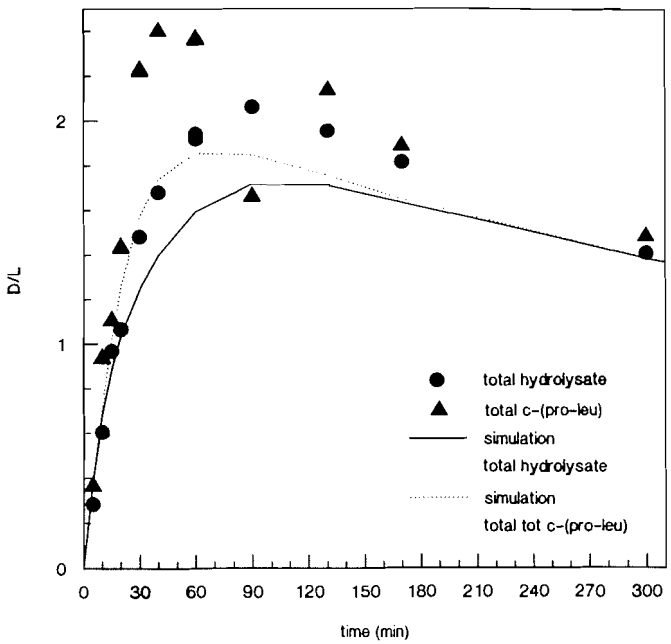

FIG. 3. Racemization of the proline peptide unit in the total hydrolysate and total *c*-(Pro-Leu) isolated during the decomposition of L-Pro-L-Leu-Gly-Gly, 148.5°C, pH 6.8, 8.45 mM. The *N*-pentafluoropropionyl isopropyl esters of D- and L-proline could not be baseline resolved by GC. Immediately after a sample run, a standard D/L proline derivative mixture having a D/L ratio close to that of the sample was injected into the GC. The observed D/L ratio for the sample was subsequently adjusted. The dotted and solid lines show the computer simulation produced for total *c*(-Pro-Leu) and total hydrolysate respectively using the experimentally derived rate constants (Table 4). The details of the assumptions used to obtain the rate constants are given in the text. The computer simulation is based on the pathways given in Scheme 2.

TABLE 3. Leucine epimerization rate constants for components isolated by TLC[a] during the decomposition of glycyl-L-leucyl-glycycl-glycine (148.5°C, pH 6.8, 7.71 mM)

Component (R_f)	10^5 k (s^{-1})
Leucine (0.40±0.03)	1.10±0.08
Glycylleucine (0.36±0.03)	4.93±0.79[b]

Glycylleucylglycylglycine (0.25±0.02)[c]	2.30±0.33
Glycylleucylglycylglycine (0.20±0.03)[c]	2.40±0.15

[a]Separation performed on Whatman LK6DF 250 μm silica gel. Mobile phase, *n*-butanol:acetic acid:water, 4:1:1.

[b]Only the first seven points (of the data in Table 2) were used to calculate the rate constant.

[c]Both the leading and trailing edge of this spot were sampled.

Val). This caused confusion regarding the stereochemistry of proline in these alkaloids (18). It was later discovered that in the alkaloids, proline was in the L form. By using only 1 equivalent of base to hydrolyze the alkaloids, the DKP containing L-proline can be obtained. Addition of more base epimerizes the DKP to the thermodynamically more stable *c*-(L-leucyl-D-prolyl) (18).

Scheme 2 shows the pathways consistent with our observations of L-prolyl-L-leucylglycylglycine. There is sufficient information available to estimate the 10 rate constants, eight of

which are independent. The disappearance of L-prolyl-L-leucylglycylglycine and its diastereomer D-prolyl-L-leucylglycylglycine and the appearance of *c*-(L-prolyl-L-leucyl) and its diastereomer *c*-(D-prolyl-L-leucyl) are shown in Fig. 4. The rate constants k_5 and k_6 (Scheme 2) can be seen from Fig. 4 to be equal since, after approximately 20 min, the diastereomers are disappearing at the same rate. The facile formation of DKP is not unexpected. Dipeptide esters and amides are known to cyclize, especially when one of the peptide units is proline or N-methylated (19). Adding together the concentrations of the diastereomers of prolylleucylglycylglycine and plotting the natural logarithm of the concentration versus time should yield a straight line with slope $-k_5$ or $-k_6$ (Fig. 5). A similar

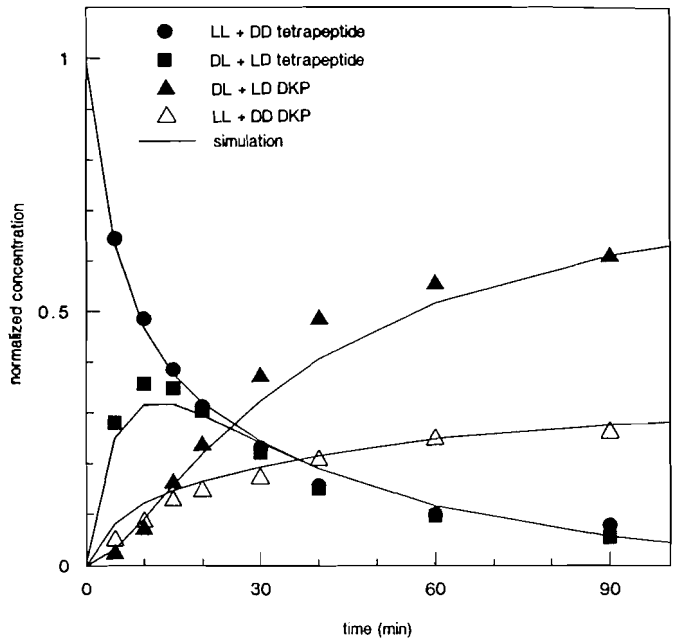

FIG. 4. Decomposition of L-Pro-L-Leu-Gly-Gly, 148.5°C, pH 6.8, 8.45 mM. As in Fig. 3, the solid line shows the result of the computer simulation.

treatment[6] of the data for the DKP's yields the same rate constant if there is no competing hydrolysis of the tetrapeptide.[7]

Figure 4 shows that the diastereomers L-prolyl-L-leucylglycylglycine and D-prolyl-L-leucylglycylglycine achieved the same concentration after 20 min. This phenomenon can be expressed as

$$[2] \quad \frac{\text{DL} + \text{LD}}{\text{DD} + \text{LL}} = 1.0$$

and requires that $k_{-1} = k_1$ and $k_2 = k_{-2}$, where, for example, DL refers to the concentration of D-prolyl-L-leucylglycylglycine. The D/L ratio for the proline of the tetrapeptide unit never exceeded unity (Fig. 6). The fact that $k_5 = k_6$, $k_1 = k_{-1}$, and $k_2 = k_{-2}$ significantly simplifies the extraction of the rate constants depicted in Scheme 2. The procedure for extracting the rate constants can be summarized as follows:

1. Since there is no evidence for a preferred diastereomer in the recovered tetrapeptides, k_1 and k_2 can be obtained from the appropriate plots using eq. [1].

[6]The complete derivation of the kinetics applicable to Scheme 2 and Fig. 5, and an appropriate computer program written in Microsoft Basic Version 3.2 may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., K1A 0S2.

[7]There are two pieces of evidence to support this: (1) A test sample of L-prolyl-L-leucylglycylglycine (2.99 mg/mL) was extracted with 3 × 5 mL CH_2Cl_2 after 60 min of heating at 148.5°C. Material weighing 3.2 ± 0.2 mg was isolated, having the same 200-MHz ^{1}Hmr spectrum as the DKP and with mass 210 (M + 1 in CI mass spectrum). This constituted an 86 ± 5% yield in good agreement with the expected result. (2) The total eluate from the HPLC up to the elution of L-prolyl-L-leucylglycylglycine (the first major peak) was collected. By GC analysis this was found to contain mostly glycine, with a Gly/Pro/Leu ratio of 1:0.06:0.01. The relative amount of glycine is larger than this since the derivatization/analysis procedure depletes the glycine derivative more than it does Pro or Leu.

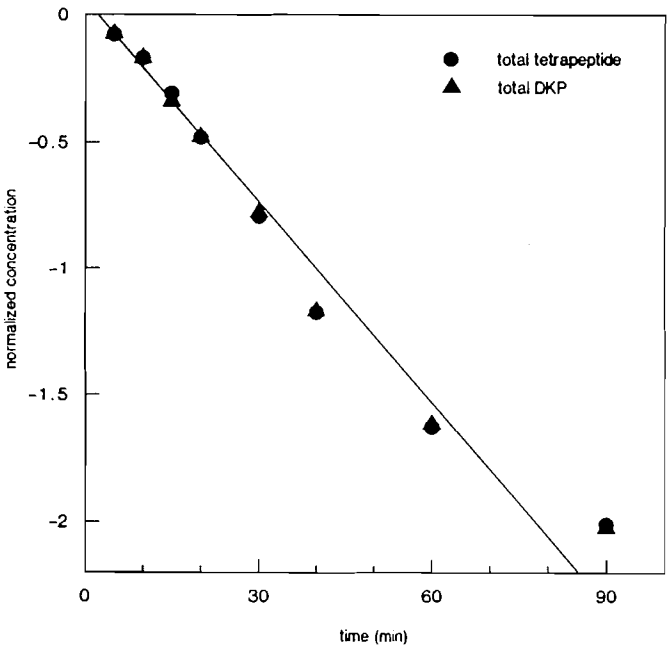

FIG. 5. Decomposition of L-Pro-L-Leu-Gly-Gly, 148.5°C, pH 6.8, 8.45 mM. For Pro-Leu-Gly-Gly the ordinate is $-\ln(c)$ where c is the normalized concentration of total tetrapeptide. For c-(Pro-Leu) the ordinate is $-\ln(1-c)$ where c is the normalized concentration of diketopiperazine. The solid line was produced by linear regression analysis.

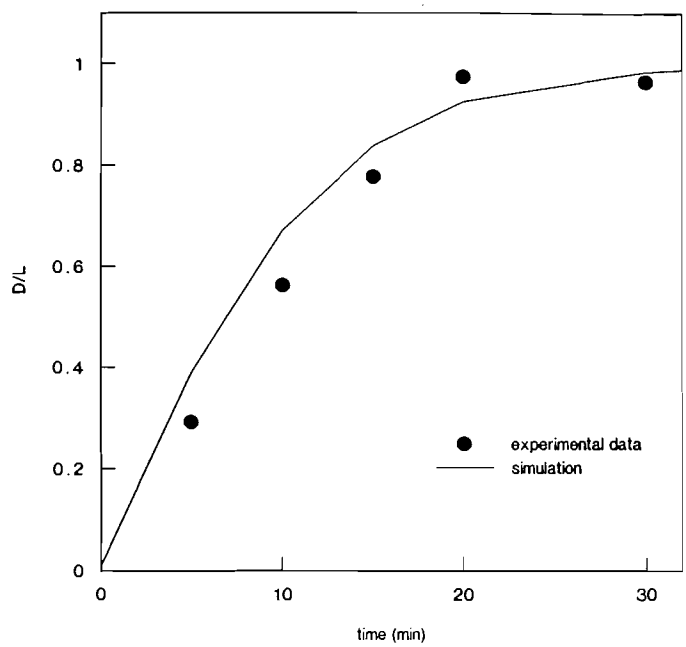

FIG. 6. Racemization of the proline peptide unit in the total tetrapeptide isolated during the decomposition of L-Pro-L-Leu-Gly-Gly, 148.5°C, pH 6.8, 8.45 mM. As in Fig. 3, the solid line shows the result of the computer simulation.

2. Obtain k'_1/k'_{-1} by measuring (DL + LD)/(DD + LL) at long reaction times.
3. Plot $\ln((1\text{-D/L})/(1 + \text{D/L}))$ versus time for the peptide unit undergoing epimerization to yield $k'_1 + k'_{-1}$.
4. Plot $\ln((1\text{-D/L})/(1 + \text{D/L}))$ versus time for the other racemizing centre. Using the slope, m, of this plot, k'_2 can be obtained from eq. [3]:

$$[3] \quad k'_2 = \frac{-m(m + k'_1 + k'_{-1})}{1 + K + 4k'_1}$$

k'_{-2} is obtained from $k'_{-2} = k'_2K$.

There are two weaknesses to this method; firstly, accuracy of $k'_1 + k'_{-1}$ is sensitive to the precision of the data and the number of data points taken around time zero. Also, the determination of "around time zero" and "long reaction times" is somewhat arbitrary. Secondly, a choice must be made between using a small number of data points and the precision of the individual data point. For example, using data at time 5, 10, and 15 min will yield a value of $k'_1 + k'_{-1}$ that will be less than the true value and probably less than that obtained from the first two data points. It is also a better approximation of the true average slope.

The experimentally determined rate constants for L-prolyl-L-leucylglycylglycine are given in Table 4. The consistency of the kinetic model was tested by substituting the experimental values in a computer program simulating Scheme 2. Overall the agreement is quite good (11). As expected, the major discrepancy is associated with the rate constant for epimerization of the proline peptide unit ($k'_1 + k'_{-1}$) in the DKP. The computer simulations using the experimentally determined values are superimposed on the experimental data in Figs. 3, 4, and 6.

TABLE 4. Experimentally determined rate constants for L-Pro-L-Leu-Gly-Gly and L-Pro-L-Leu (148.5°C, pH 6.8)

Rate constant	L-Pro-L-Leu-Gly-Gly[a] (10^4 s^{-1})	L-Pro-L-Leu[b] (10^4 s^{-1})
$k_1=k_{-1}$	13.4±0.8[d]	3.58±0.15
$k_2=k_{-2}$	0.083±0.015	0.0046±?
$k_5=k_6$	4.03±0.30	1.72±0.06
k'_1	10.4±1.0	13.9±1.5
k'_{-1}	4.52±0.45	6.97±0.66
k'_2	0.202±0.015[c]	0.235±0.030
k'_{-2}	0.436±0.036	0.540±0.069

[a]Rate constants k_1, k_{-1}, k_2, and k_{-2} refer to the tetrapeptide; k'_1, k'_{-1}, k'_2, and k'_{-2} refer to the diketopiperazine.
[b]Rate constants k_1, k_{-1}, k_2, and k_{-2} refer to the dipeptide; k'_1, k'_{-1}, k'_2, and k'_{-2} refer to the diketopiperazine.
[c]From $m = (5.60 \pm 0.43) \times 10^{-5}$ s^{-1} leucine epimerization, eq. [3]; $(5.65 \pm 1.12) \times 10^{-5}$ s^{-1} including proline epimerization.
[d]The rate constants are quoted as averages of several measurements. The error is reported at the 95% confidence level.

The maximum D/L ratio of the proline predicted using the experimentally determined rate constants is about 1.86 (at 40 min)) Fig. 3). If the decomposition of the tetrapeptide was instantaneous (i.e., the starting condition was pure c-(L-prolyl-L-leucyl)) the maximum predicted is 1.92 (at 50 min). Therefore an underestimate of the rate constant k'_1 or k'_{-1} cannot be completely responsible for the discrepancy in $k'_1 + k'_{-1}$. The most likely source of error lies with the model used to extract the rate constant (Scheme 2) for it does not account for the presence of species other than the tetrapeptide and the diketopiperazine. Other species in the mixture that yield D-proline could account for the discrepancy in $k'_1 + k'_{-1}$ and the maximum D/L ratio observed for the diketopiperazine and the total hydrolysate. The dipeptide L-prolyl-L-leucine was thought to be a logical candi-

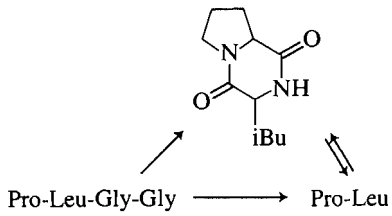
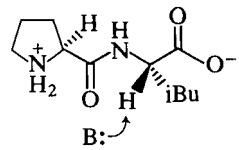


SCHEME 4

date for another species that could be found in the hydrolysis mixture from L-prolyl-L-leucylglycylglycine since it could be formed according to Scheme 4.

Figure 7 shows a plot of the D/L ratio of the proline peptide units at various reaction times when a sample of L-prolyl-L-leucine is used as the reactant, and the D/L ratio of both the total reaction mixture and that of the DKP isolated from the reaction mixture are measured. The rate constants were extracted in a similar manner as for L-prolyl-L-leucylglycylglycine above and are given in Table 4. A computer simulation using these values was performed and the agreement is shown in Fig. 7 and in a plot of the L-prolyl-L-leucine decomposition data (Fig. 8). A comparison of the rate constants for L-prolyl-L-leucylglycylglycine and for L-prolyl-L-leucine shows three noteworthy features:

1. The rate of cyclization (dehydration) of L-prolyl-L-leucine to the corresponding DKP is slower than the rate of production of the DKP from L-prolyl-L-leucylglycylglycine.
2. Proline racemization is slower for L-prolyl-L-leucine than for L-prolyl-L-leucylglycylglycine. These two observations indicate that the dipeptide cannot be giving rise to the underestimate of $k'_1 + k'_{-1}$ in the DKP.
3. Leucine racemization in the dipeptide is at least an order of magnitude slower than in the tetrapeptide. Removal of the proton at the asymmetric centre of the dipeptide may be inhibited by the electrostatic repulsion between the carboxylate anion and the developing negative charge in **15**.



15

To probe the influence of ring-opening of the DKP to prolylleucine, pure *c*-(L-prolyl-L-leucyl) was epimerized under the decomposition reaction conditions. The rate constant was found to be $2.03 \times 10^{-3}\,s^{-1}$, essentially the same value obtained from both L-prolyl-L-leucylglycylglycine and L-prolyl-L-leucine. These results suggest that the rate-determining step in the racemization of proline from L-prolyl-L-leucylglycylglycine is at the DKP stage and that the cyclization of the L-prolyl-L-leucine can be ignored. This implies that the DKP is, in this instance, arising directly from the tetrapeptide.

Racemization of glycyl-L-leucylglycylglycine

A time study of the racemization and hydrolysis behaviour of glycyl-L-leucylglycylglycine was carried out for comparison with the study on L-prolyl-L-leucylglycylglycine. The species in the hydrolysis mixture are the substrate, glycyl-L-leucylglycylglycine, the DKP *c*-(glycylleucyl), and at least two other components. Spiking the mixture with authentic dipeptides indicated that these components were probably Gly-Leu, Leu-Gly, and Gly-Gly.

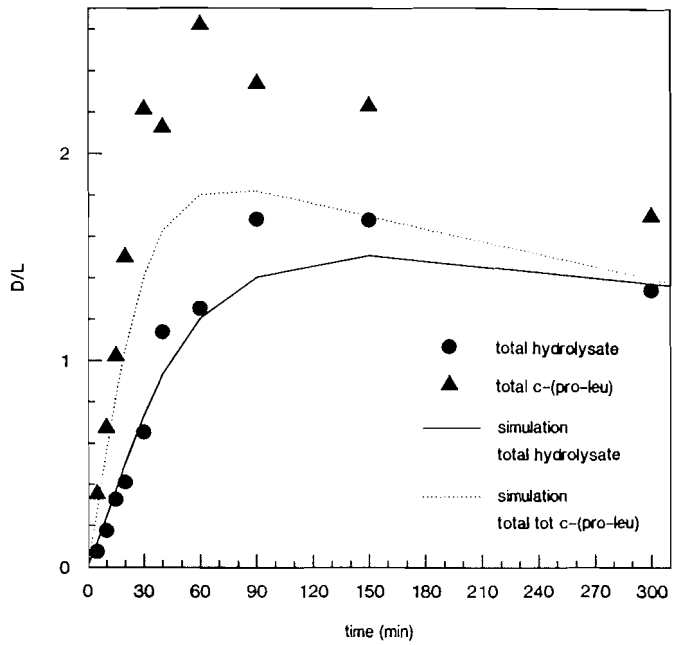


FIG. 7. Racemization of the proline peptide unit in the total hydrolysate and total *c*-(Pro-Leu) isolated during the decomposition of L-Pro-L-Leu, 148.5°C, pH 6.8, 9.01 mM. As in the case of L-Pro-L-Leu-Gly-Gly, the proline D/L ratios were corrected (see Fig. 3). The dotted and solid lines show the computer simulation produced for total *c*-(Pro-Leu) and total hydrolysate respectively using the experimentally derived rate constants (Table 4). The details of the assumptions used to obtain the rate constants are given in the text. The computer simulation is based on the pathways given in Scheme 2.

The source of DKP in this experiment is ambiguous since in the early stages there is more dipeptide than DKP.[8] Some of the DKP must ultimately come from the dipeptides arising from hydrolysis of the tetrapeptide.

There are three important findings from this experiment. First, a DKP is formed during the heating of another tetrapeptide. Second, the racemization rate of the substrate $(2.57 \pm 0.08) \times 10^{-5}\,s^{-1}$ does not resemble that of the total hydrolysis mixture $(4.53 \pm 0.11) \times 10^{-5}\,s^{-1}$ (Figs. 9 and 10). This further demonstrates that the epimerization rate constant of a peptide cannot be measured by the initial slope of a plot using eq. [1]. Third, the racemization of glycyl-L-leucylglycylglycine is about three times faster than the rate of epimerization of the leucine peptide unit in L-prolyl-L-leucylglycylglycine. This demonstrates that neighbouring peptide units have a significant effect on epimerization rates, and that such factors must be considered in using amino acid racemization rates as a geochronometric tool.

Racemization of peptide derivatives

In several previous studies (20), attempts have been made to explain the way in which the position of the peptide unit along the peptide chain affects the rate of racemization. It has been suggested that proximity to the termini increased the rate of racemization. By use of the N-terminal *N*-benzyloxycarbonyl and C-terminal anilide derivatives of the tetrapeptides glycyl-L-leucylglycylglycine, L-prolyl-L-leucylglycylglycine, and glycyl-L-prolyl-L-leucylglycine, this idea was tested. Tetrapeptides were considered to be better protein models than di- or

[8]Glycyl-L-leucylglycylglycine decomposes with a first-order rate constant of $(1.8 \pm 0.4) \times 10^{-4}\,s^{-1}$.

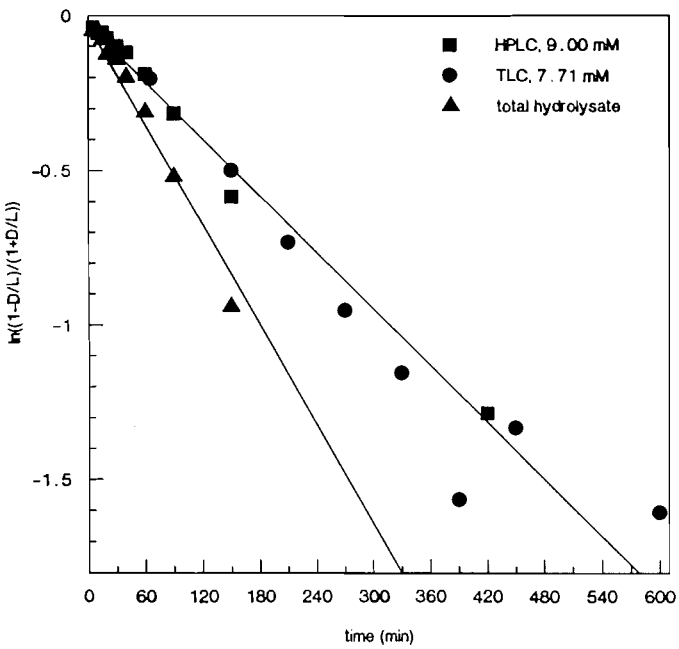

FIG. 9. Racemization of the leucine peptide unit in Gly-Leu-Gly-Gly isolated during the decomposition of Gly-L-Leu-Gly-Gly, 148.5°C, pH 6.8, 9.00 mM. Data from the separation by TLC and HPLC are combined in this plot. The solid line was produced from the HPLC data by linear regression analysis.

tripeptides. Also, the N-, C-, and N- and C-blocked peptides were taken to model the C-terminal, N-terminal, and interior portions of the peptide respectively.

The compounds were heated under the same conditions used in the time studies (Table 5). Since hydrolysis consumes the unblocked parent peptides quite rapidly, the degree of observed racemization is small in some cases.

Assuming that the epimerization follows eq. [1], the rate constants can be estimated. Placing a *N*-benzyloxycarbonyl

group on the N-terminus decreases the rate of epimerization of the leucine peptide unit. N-Benzyloxycarbonyl has the added effect of reducing hydrolysis. Conversely, addition of a C-anilide has little effect. It does not significantly change the rate of epimerization of leucine nor does it prevent hydrolysis. The results for proline as shown in Table 6 are essentially the same as for leucine. The rate decreases caused by the *N*-benzyloxycarbonyl group can be explained in three ways:

1. Free NH_2 can act as a base in **14**. When blocked with the *N*-benzyloxycarbonyl group, the nitrogen is not so readily able to remove the proton from the asymmetric centre of either the adjacent peptide or a peptide unit of another molecule. Since peptides are present at neutral pH as zwitterions there would be very little free NH_2. It would be tempting to eliminate the above pathway for this reason. However, since DKP formation

[b]Calculated using eq. [1].

requires an unprotonated amino function **15** and since DKP formation is so predominant, elimination of the above pathway is not justified. Indeed, the ability to cyclize to give a DKP may be reflected by an enhanced rate of racemization.

2. The removal of the positive charge from nitrogen by substitution eliminates the inductive stabilization of the incipient carbanion.

3. The presence of the hydrophobic *N*-benzyloxycarbonyl group disrupts the solvation shell so that the approach of water, acting as a base to remove the chiral proton, is impeded. When the N-terminus is not blocked, racemization may be aided by more tightly packed solvent molecules.

Since the anilide derivatives are amines, at pH 6.8 they will be predominantly in the protonated form (21). Therefore, it is not surprising that the anilide derivative behaves in the same way as the parent tetrapeptide, giving both relatively rapid racemization and a large amount of DKP. The derivatives can then be grouped according to their racemization behaviour. Those derivatives that racemize relatively quickly have positively charged nitrogen termini. The derivatives with blocked nitrogen termini racemize more slowly regardless of the charge on the C-terminus. The derivative with a protected nitrogen terminus (e.g., *N*-benzyloxycarbonyl-L-prolyl-L-leucylglycylglycine) will be mostly in the form of an anion (19).

Since the anion on the C-terminus does not appear to increase the rate of racemization, the anion cannot be acting as a base. It is noteworthy that the presumed increase in solvation of the anion (compared with the uncharged derivative) is also ineffective in promoting racemization. On the contrary, the leucine peptide unit of derivatives blocked only at the C-terminus racemizes more slowly than those derivatives having both termini blocked (Table 5). It appears that the presence of a carboxylate anion inhibits formation of an anion at the asymmetric centre. This is consistent with the slower rate of racemization observed for L-prolyl-L-leucine compared with L-prolyl-L-leucylglycylglycine.

The racemization of the peptide units in the total hydrolysate is given in Table 7 for leucine and in Table 8 for proline. The behaviour is the same as the substrates with one exception. The D/L ratio for the proline peptide in the total hydrolysate reaches a value of 1.97 for L-prolyl-L-leucylglycylglycine and 1.94 for L-prolyl-L-leucylglycylglycine anilide. This indicates that L-prolyl-L-leucylglycylglycine anilide is decomposing by internal aminolysis to give the DKP, *c*-(L-prolyl-L-leucyl). The DKP then epimerizes to the thermodynamically preferred diastereomer *c*-(D-prolyl-L-leucyl) (22).

The above experiments demonstrate that proximity to a protonated nitrogen enhances the rate of racemization. Conversely, proximity to a carboxylate anion decreases the rate of racemization. This does not mean that the rate of racemization for the individual peptide units in a peptide or peptide chain will increase monotonically from the C-terminus to the N-terminus. It is not justified to ignore possible rate enhancement/retardation by a nearby charge centre that is not a terminus (e.g. $-NH_3^+$ of lysine or $-CO_2^-$ of glutamic acid). Further complicating the picture, a uniform distribution of water along the peptide chain should not be assumed. Hare observed little racemization in bones heated at 157°C for 3 days under anhydrous conditions, while there was essentially complete racemization in the presence of water (22). By analogy, a lower rate of racemization is expected for peptide units in a region of peptide where water is excluded. Clearly, because of the individual structural characteristics of each protein, it is difficult to generalize protein racemization behaviour based on any one model study.

Summary

The general goal of this work was to investigate some of the unique properties of peptides that can complicate the interpretation of peptide racemization measurements used for dating fossils. It was found that the leucine peptide unit in glycyl-L-leucylglycylglycine racemizes about three times faster than in L-prolyl-L-leucylglycylglycine. The result helps to explain the variation in the D/L ratio in fossils of the same radiocarbon age

but of different species. The range of reported D/L ratios in fossil shells spans at least a factor of two (23).

Peptide derivatives blocked at the nitrogen terminus were observed to racemize 6 to 25 times more slowly than the unblocked parent peptides. This suggests that interior peptide units racemize more slowly than terminal units and that the racemization rate is dependent on the proximity to the nitrogen terminus.

D/L ratios of greater than unity were observed. The occurrence of this phenomenon is a major deviation from the pseudo-first-order kinetics found for amino acids and assumed previously to be operating for proteins (20). Anomalously high D/L ratios (but not greater than unity) have been reported for alanine, glutamic acid, and aspartic acid and this is attributed to the addition of D-alanine and D-glutamic acid from the peptidoglycan from the cell wells of bacteria (24). Preferential epimerization of one peptide unit provides another mechanism for high D/L ratios.

Amino acid dating has the potential to be an important tool for geologists because of its simplicity and speed of analysis. The uncertainty in age determination is thought to be primarily due to an unknown temperature history (25) but this work has shown that there is uncertainty in the chemistry as well. The utility of the method may lie in restricting the kinds of peptide units used for analysis, namely, the peptide units in the interior of the protein. If rapid preferential epimerization is confined to DKP's, and provided that it occurs in only DKP's and near nitrogen termini, the chemical variability could potentially be controlled by judicious selection of the higher molecular weight fraction of the protein hydrolysate.

Strong cooperative protonation of a small tris-urea cryptand[1]

PIERRE G. POTVIN[2] AND MAN HUNG WONG
Department of Chemistry, York University, 4700 Keele Street, North York, Ont., Canada M3J 1P3

Received June 6, 1988

PIERRE G. POTVIN and MAN HUNG WONG. Can. J. Chem. **66**, 2914 (1988).

A small bicyclic cryptand **3** bearing urea groups along the 7-atom bridges was synthesized in 22% yield by a novel tripod–tripod coupling procedure. Protonation and complexation studies are reported and compared with results with polyoxa-[2]-cryptands and [3]-cryptand **6**. These show that **3** is a moderate base, a weak metal ion binder, but a two-proton binder exhibiting strong positive cooperativity ($pK_{a_2} > pK_{a_1}$) and fast proton exchange kinetics. As demonstrated by molecular mechanics calculations, an inward rotation of the carbonyl groups to form hydrogen bonds to cryptated protons was invoked to explain the cooperativity.

PIERRE G. POTVIN et MAN HUNG WONG. Can. J. Chem. **66**, 2914 (1988).

On décrit la synthèse, par une nouvelle méthode de couplage tripode–tripode avec un rendement de 22%, du cryptand bicyclique **3** portant le long des bras des groupements urées. On rapporte les résultats d'études de protonation et de complexation de ce cryptand, comparés à ceux obtenus avec les polyoxa-[2]-cryptands et le macrotricycle **6**. Il résulte que **3** est une base peu forte qui lie faiblement les ions métalliques, mais qui lie réversiblement et en échange rapide deux protons avec une coopérativité prononcée ($pK_{a_2} > pK_{a_1}$). Ce phénomène de coopérativité est expliqué par une rotation des groupements carbonyles vers l'intérieur de la cavité pour former des liaisons hydrogènes avec les protons complexés, tel que demontré par des calculs de mécanique moléculaire.

[Traduit par la revue]

Introduction

In protonations of simple diamines, the second protonation step is more difficult than the first ($pK_{a_2} < pK_{a_1}$), with the difference depending on the distance between the two protonation sites. The polyoxa-[2]-cryptands (1), each possessing tertiary amino sites at the bridgehead positions, also obey this rule but display a form of cooperative proton binding in that the pK_{a_2} values increase with decreasing cavity size in spite of increasing electrostatic repulsions between the bridgeheads in the diprotonated forms. In this report, we describe a small cryptand, to our knowledge the first polyurea-[2]-cryptand, that appears to not obey this rule and display strongly cooperative binding (i.e., $pK_{a_2} > pK_{a_1}$). Its synthesis is a novel one-step macrobicyclization from acyclic precursors. With the help of molecular mechanical calculations, we can rationalize the observed cooperativity in terms of protonation-induced conformational changes involving the carbonyl groups.

Experimental

General

DMF was dried (anhydrous $MgSO_4$) and distilled before use. CH_2Cl_2 was hplc grade and used without further purification. 1,1′-Carbonyl diimidazole (CDI), from Aldrich, was recrystallized from THF. Tris(2-aminoethyl)amine **1**, 98% pure from Aldrich, was dried under high vacuum at room temperature for 3 h before use.

Melting points were determined on a Fisher–Johns apparatus and are uncorrected. Infrared (ir) spectra were run on a Unicam SP 3-200 ir spectrometer. Nuclear magnetic resonance (nmr) spectra were run either in $CDCl_3$ with $CHCl_3$ as internal reference (at 7.26 ppm in ^1H spectra, and at 77.00 ppm for ^{13}C spectra), or in D_2O with *t*-BuOH as internal reference (at 1.20 ppm in ^1H spectra and 30.07 ppm in ^{13}C spectra). The instrument, a Bruker AM-3000, operated at 300.13 MHz (^1H) or 75.5 MHz (^{13}C). *J*-resolved ^1H–^{13}C correlation spectroscopy was used to establish signal assignments. Analyses were performed by Guelph Chemical Laboratories Ltd.

pH-Metric titrations

Titrations were run in a jacketted flask at 25°C on 4 mL of titrate solutions. Titrant was added via a Metrohm 635 automatic burette under control of a Metrohm 636 Titroprocessor equipped with a micro combination glass electrode (Metrohm). The electrode was standardized with buffer solutions at pH 4, 7, and 10 (Fisher). The delivery of titrant was programmed to allow 20 s between increments and full stabilization of the electrode emf before recording the pH directly. The increment size was programmed to decrease with increasing slope of the pH vs. volume curve to obtain a maximum point density within a reasonable amount of time. Titrant was carbonate-free 0.10004 N NaOH prepared by dilution of a packaged concentrated solution (BDH) and standardized with potassium acid phthalate. Acids used in the titrate were 0.09977 N HCl (similarly prepared by dilution of a packaged concentrate) or 0.09843 N $HClO_4$, and both were standardized with the NaOH solution.

The recorded titrant volume vs. pH data were treated using a locally modified version of the program BEST (2). The major differences from the original are that the measure of "fit" used in the refinement was the standard deviation between calculated and experimental pH curves, that duplicate titrations were treated together to obtain a single set of protonation constants and a single standard deviation, and that a Gauss–Newton iteration algorithm was used.

Molecular mechanics calculations

The program MACROMODEL (W. C. Still, Columbia University), version 1.5 with the MM2 force field, was used to calculate minimum energy structures for **3** and its protonated forms. Using constraints at input on the urea geometries and on the orientation of the bridgehead lone pairs or added protons in all possible combinations, the (local) minimum energies were calculated for each possible conformer associated with a minimum, and the lowest of these was retained as the (global) minimum energy conformer. Refinement was considered complete if the drop in energy between iterations was ≤ 1 kJ mol^{-1}. All *in,out* combinations (conformers) were associated with shallow or nonexistent local minima, i.e., were so unstable that the refinement routine converted them to a more stable form (usually *in,in*). For the hypothetical Li^+ and Na^+ complexes of **3**, *in,in* all-*Z,Z* structures were created with the facilities of MACROMODEL, then reformatted for calculation by MMX, version 87.1 with the MM2 and MMP1 force fields, with the program MODEL (both due to K. Gilbert, Serena Software, P.O. Box 3076, Bloomington, Indiana), defining the M—O and M—N bonds as dative and the metals as coordinatively unsaturated. The force field was modified to define Li^+ and Na^+ as monopositive hard spheres (bond stretching force constants were set to

1000) with radii 0.68 and 1.00 Å, respectively. Standard bond lengths (Li—O, 2.08 Å; Li—N, 2.18 Å; Na—O, 2.40 Å; Na—N, 2.50 Å) were assumed, and all bending and torsional force constants were set to 0. Refinement was considered complete when the drop in total energy was ≤ 1 kcal mol^{-1}.

1,4,6,9,12,14,19,21-Octaaza-5,13,20-trioxobicyclo[7,7,7]eicosatriane (3)

Tris(2-aminoethyl)amine **1** (0.50 mL, 3.34 mmol) was dissolved in DMF (10 mL) in a volumetric flask. A 5-mL aliquot of this solution was added to a stirred solution of CDI (0.8 g, 4.93 mmol) in DMF (2 mL) over a period of 5 min. This reaction mixture was then transferred into another 10-mL volumetric flask and topped up with DMF to total 10 mL. The remaining triamine solution in the former volumetric flask was also diluted with DMF to make 10 mL total volume. Both solutions were transferred into two 10-mL syringes each fitted with a 12-in. needle of identical bore. These were then mounted on a syringe pump, and the needles were inserted through side arms of a dry, Ar-flushed three-neck flask and under the surface of a volume of fresh DMF (200 mL). The pumping rate was preset to 0.135 mL min^{-1} (ca. 1 drop s^{-1}) and vigorous magnetic stirring was maintained during the addition. After completion, the solvent was removed on a rotatory evaporator, leaving an amber oil that was then heated at 70°C under high vacuum for 4 h to sublime away most of the imidazole side-product. The residue was partially purified, first by chromatography on a short column of Al_2O_3 (eluting with CH_3OH), then by precipitation from a methanolic solution with Et_2O. The solid product was then recrystallized from EtOH to afford 136 mg of **3** (22% yield), mp 292°C; ir (KBr): 1570 (C=O), 1530 (asym N–H bend), 1470 (sym N—H bend) cm^{-1}; ^1H nmr ($CDCl_3$): 5.84 (bs, 1H, NH), 3.18 (bm, 2H, CH_2CH_2NHCO), 2.54 (t, 2H, $J = 4.9$ Hz, CH_2CH_2NHCO); ^1H nmr (D_2O, in square brackets with excess D_3PO_4): 3.07 [3.49] (t, 2H, $J = 5.0$ Hz, CH_2CH_2NHCO), 2.52 [3.35] (t, 2H, $J = 5.11$ Hz, CH_2CH_2NHCO) ppm; ^{13}C nmr (D_2O, in square brackets with excess D_3PO_4): 161.26 [161.69] (s, CO), 51.42 [58.89] (t, $J = 133.0$ Hz, CH_2CH_2NHCO), 37.51 [35.33] (t, $J = 138.7$ Hz, CH_2CH_2NHCO) ppm. *Anal.* calcd. for $C_{15}H_{30}N_8O$: C 48.63, H 8.16, N 30.25; found: C 48.98, H 8.37, N 30.37%. ms (*m/e*): 370 (M^+), 371 (MH^+).

Titrated solutions were 1.28×10^{-2} M in **3**, 3.74×10^{-2} M in $HClO_4$, and 0.101 M in $NaClO_4$, or 1.02×10^{-2} M in **3**, 2.95×10^{-2} M in $HClO_4$, and 0.116 M in KBr.

Tris(5-ethyl-3,5-diaza-4-oxo-heptyl)amine 4

Diethylamine (1.99 mL, 19.2 mmol) was added to a stirred solution of CDI (3.11 g, 19.2 mmol) in CH_2Cl_2 (30 mL). The reaction mixture was stirred at room temperature for 15 min, then triamine **1** (0.96 mL, 6.41 mmol) was combined with the above mixture. After 2 h, solvent and imidazole were removed as before. The residue was purified as before, and was treated with decolourizing charcoal. The product **5** (yield 1.54 g, 65.90%) was obtained as a light amber solid that resisted attempts at recrystallization; ir (KBr disk): 3350 (N–H str), 1650 (C=O), 1600 (N–H bend) cm^{-1}; ^1H nmr ($CDCl_3$): 3.14 (m, 6H, CH_2CH_3, CH_2CH_2NHCO), 2.58 (t, 2H, $J = 7.0$ Hz, CH_2CH_2NHCO), 1.07 (t, 18H, $J = 7.0$ Hz, CH_2CH_3) ppm; ^{13}C nmr ($CDCl_3$): 157.45 (s, CO), 54.90 (t, $J = 134.9$ Hz, CH_2CH_2NHCO), 40.75 (t, $J = 136.1$ Hz, CH_2CH_3), 38.48 (t, $J = 137.7$ Hz, CH_2CH_2NHCO), 13.50 (q, $J = 126.5$ Hz, CH_2CH_3) ppm; ms (*m/e*): 444 (MH^+), 443 (M^+).

Tritrated solutions were 6.31×10^{-3} M in **4**, 2.00×10^{-2} M in HCl, and 0.150 M in KNO_3.

1,9-Dimethyl-1,4,6,9,12,14,19,21-octaaza-5,13,20-trioxobicyclo-[7,7,7]eicosatrianium diiodide 5

Cryptand **3** (24.6 mg, 66 μmol) was treated with CH_3I (2 mL) in DMF (3 mL) and CH_2Cl_2 (2 mL), then allowed to reflux overnight. Solvents were then removed and the residue washed with CH_2Cl_2 (10 mL) to afford 31.7 mg of a pale yellowish hygroscopic solid (73% yield); ^1H nmr (D_2O): 3.49 (bt, 6H, CH_2CH_2NHCO), 3.36 (bt, 6H, CH_2CH_2NHCO), 3.22 (s, 6H, NCH_3) ppm; ^{13}C nmr (D_2O): 162.07 (CO), 58.93 (CH_2CH_2NHCO), 55.77 (NCH_3), 34.67 (CH_2CH_2NHCO) ppm.

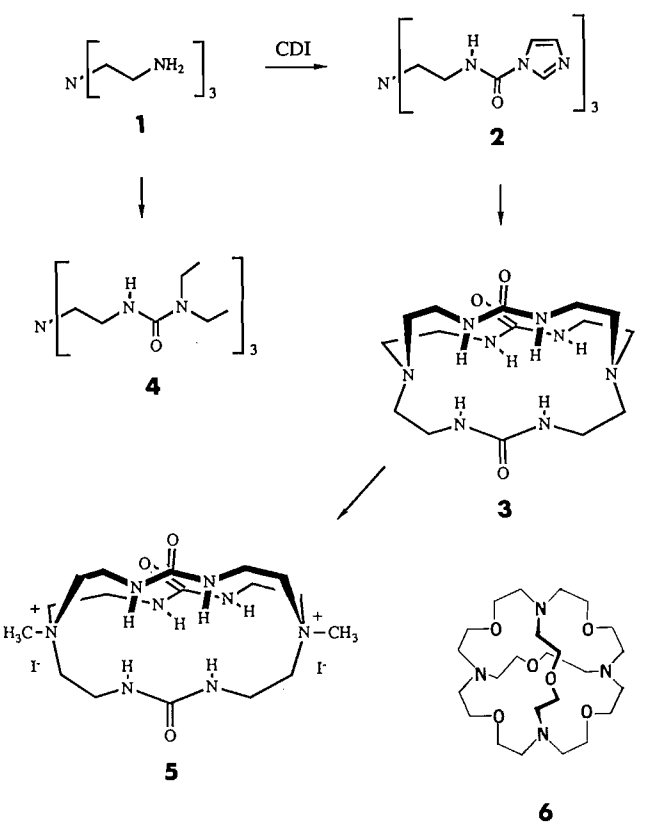
Results

The addition of one part of tris(2-aminoethyl)amine **1** to three parts of carbonyl diimidazole (CDI) cleanly provided the tris(carbamylimidazole) **2**, as made evident by nmr spectra. In a one-pot preparation, simple addition of a second equivalent of **1** provided cryptand **3** in 11% yield. With a high dilution apparatus, where syringes containing equimolar DMF solutions of preformed **2** and of **1** were slowly pumped into a volume of pure DMF such that the initial concentrations of the first aliquots were ca. 4×10^{-6} M or lower (the needle tips were held in the solution), the yield improved to 22%. The cryptand **3** was crystalline and soluble in organic solvents and H_2O.

Compound **4**, a model for the first protonation site of **3**, was prepared in two steps by the reaction of equal parts of diethylamine and CDI, followed by treatment of the resulting nonisolated intermediate with one-third equivalent of **1**. The dimethiodide salt **5** of **3** was prepared as a model for the *out,out* diprotonated form of **3**, by overnight reflux of **3** with excess CH_3I in a mixture of DMF and CH_2Cl_2.

The nmr, ir, and mass spectra of **3**, **4**, and **5** were entirely in accord with the assigned structures. Interestingly, the upfield CH_2 resonance of **3** correlated with the downfield CH_2 resonance, and was displaced further upfield upon diprotonation or dimethylation. The nmr spectra of **5** in D_2O were not significantly different from those of **3** in the presence of excess D_3PO_4.

pH-Metric base titrations were performed on acidic solutions of **3** at 25°C and μ 0.15 M, using $NaClO_4$ or KBr as background electrolytes. The calculated values for pK_{a_1} and pK_{a_2} with the former salt (7.81 and 7.96, respectively) were very similar to those with the latter salt (7.84 and 7.92, respectively), indicating the absence of complexation of Na^+. The pK_a of **4**, obtained by similar titration, was found to be 7.64 (with KNO_3 as background electrolyte). Additionally, titrations of **3** in the



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/07/12
For personal use only.

presence of various salts revealed that complexation of Li^+, Na^+, and F^- was very weak or nonexistent in H_2O.

Molecular mechanical calculations were performed on **3** and both of its protonated forms, exploring all possible conformations of the urea groups in combination with *in* or *out* bridgehead electron pairs or attached protons. The minimum energy form of **3** (see Fig. 3A), the *in,in Z,Z;Z,Z;E,Z* form, had three close contacts (≤2 Å) between oxygen on one bridge and urea NH on another bridge, while, in comparison, the next most stable conformer (some 43.5 kJ mol^{-1} more energetic), the *in,in* all-*Z,Z* form, had only two, and the *out,out* analogue of the latter (some 101 kJ mol^{-1} more energetic) had none. The minimum energy form of $(\mathbf{3}\cdot H)^+$ was *in,in* all-*Z,Z* with one such close contact and two others between oxygens and the added proton. In contrast, the *out,out* analogue had none of either kind. In the minimum energy form of $(\mathbf{3}\cdot H_2)^{+2}$, also *in,in* all-*Z,Z*, all six distances between oxygens and added protons were ≤1.95 Å.

The largest inscribed spherical cavity (radius 0.98 Å) was defined by the carbonyl carbons in the minimum energy form of **3**, and the interbridgehead distance was 5.65 Å. These values were larger for *in,in* or *out,out* all-*Z,Z* forms, reflecting the looser networks of hydrogen bonds in these structures. As expected, the protonated forms were compressed along the C_3 axes (down to 4.42 Å interbridgehead distance in $(\mathbf{3}\cdot H_2)^{+2}$) and expanded at the midsections.

Calculations were also attempted on hypothetical Li^+ and Na^+ inclusion complexes of *in,in* all-*Z,Z* **3**. In the resulting structures, the interbridge hydrogen bonding networks were broken as the cavities were compressed along the C_3 axes, and expanded at the midsections. Interbridgehead distances decreased to 4.50 Å with Na^+ and to 4.30 Å with Li^+, shorter than the sums of the appropriate radii (5.00 Å for Na^+ and 4.36 Å for Li^+). As the with the free ligand, the carbonyl groups were still largely tangent to the cavities and the largest inscribed spherical cavities were again enclosed by the carbonyl carbons instead of the oxygens, indicating poor alignment of the carbonyls with the metals. The shortest Li—O distance (2.66 Å, avg. 3.02 Å) indicated poor contact, while better contact was made with Na^+ (shortest Na—O distance 2.40 Å, avg. 2.78 Å).

Discussion

In our synthesis of **3**, the key formation of the necessary intermediate **2** amounted to a transformation of a triamine into a tris-electrophile, to our knowledge the first such transformation. This proceeded well with CDI, without intramolecular cyclization into ureas, but not with oxalyl 1,1′-diimidazole (ODI) (3). Both reagents were known to produce acylimidazoles in reaction with carboxylic acids, the latter with fragmentation and elimination of CO as well as CO_2 (3), but we obtained symmetrical diamides in reaction of either reagent with two equivalents of 2-phenylethylamine (4). Unfortunately, a DMF-insoluble gum was produced in reaction of ODI with one-third equivalent of **1**, undoubtedly containing intra- and intermolecular oxalyldiamide linkages. Presumably, the individual imidazole substitution steps proceeded at very different rates with CDI, but at similar rates with ODI. This was confirmed in an experiment using millimolar $CDCl_3$ solutions of 2-phenylethylamine and of CDI, monitoring the reaction by ^1H nmr spectroscopy. The first imidazole substitution step was essentially complete upon mixing, while the second reaction with a second equivalent of 2-phenylethylamine required 1.5–2 h for completion (4). Further, an asymmetric tris-urea, compound **4**, could be prepared by taking advantage of that difference in rates, while only a symmetric oxalyldiamide could be formed.

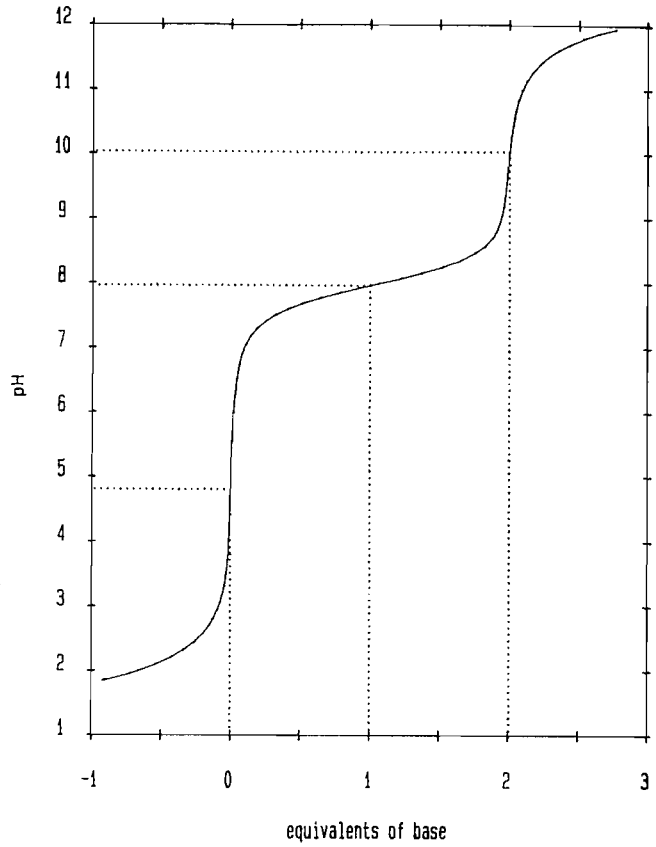


FIG. 1. Titration of 4 mL of 1.28×10^{-2} M **3** and 3.74×10^{-2} M $HClO_4$ with 0.10004 N NaOH. Plot of pH vs. added equivalents of base measured from the point where the excess acid (0.92 equiv.) was fully titrated.

The coupling of **2** and **1** proceeded well even when no special precautions were taken, and in surprisingly high yield for a non-templated tripod–tripod coupling reaction.[3] Even with very slow addition of dilute solutions ("high dilution conditions"), it is unlikely that high dilutions were maintained throughout the addition, as the reaction was probably too slow to have reached completion between increments. Nevertheless, a significant gain in yield resulted.

The cryptand **3** is a small cage molecule whose cavity size was expected to be intermediate between those of the polyoxa-[2]-cryptands [1.1.1] and [2.2.2]. Like these, **3** can be expected to have the bridgehead lone pairs *in* or *out* and to form inclusion complexes. As the former formed a weak complex with Li^+ (pK_{Li^+} ca. 2.2) (6), and as the latter formed a strong complex with K^+ (1), we sought evidence of Li^+ or Na^+ binding by **3**. However, the ^1H and ^{13}C nmr spectra in D_2O of **3** changed little in the presence of a large excess of LiCl. pH-Metric titrations in the presence of excess Na^+ or Li^+ confirmed this lack of binding, although complexation may occur in organic solvents. However, strongly cooperative protonation was clearly evident in the shape of the titration curve (Fig. 1), where, from the point where excess acid had been titrated (near pH 4.9), no further inflection occurred until two equivalents of base had been added (near pH 10). The cryptand therefore behaves as two equiva-

[3]For an example of a Cs^+-templated tripod–tripod coupling, see ref. 5.

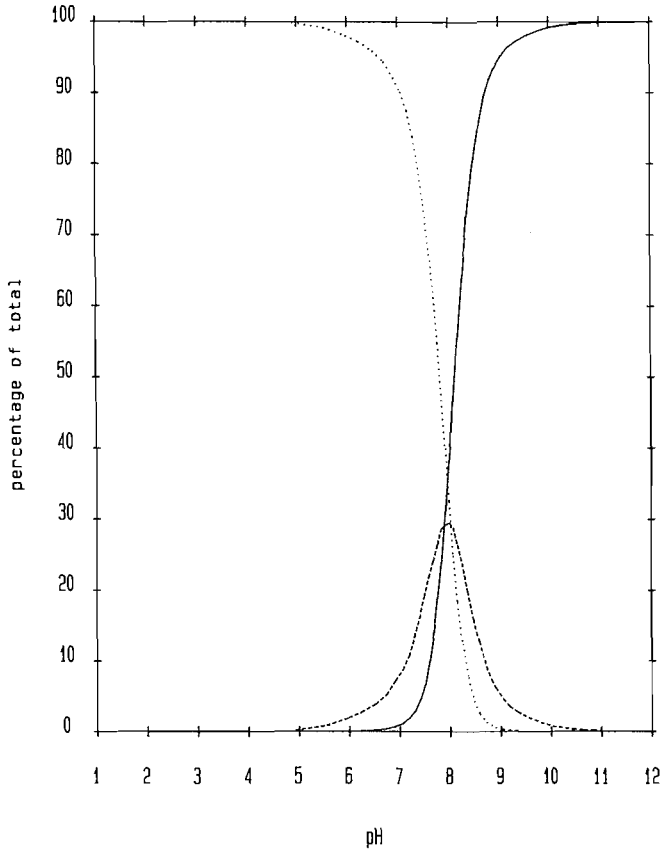

FIG. 2. Plots of the concentrations of **3** (solid line), $(\mathbf{3}\cdot H)^+$ (dashed line), and $(\mathbf{3}\cdot H_2)^{2+}$ (dotted line) against pH, calculated using pK_a values obtained with $NaClO_4$ as background electrolyte (see experimental section).

lents of a monobasic ligand of pK_a near 8 (half-titration point). Both pK_a's were indeed calculated to be near 8, but the pK_{a_2} values were in fact slightly larger than the pK_{a_1} values. The differences (0.15 log units with $NaClO_4$ as background electrolyte, 0.08 with KBr) were significant, as the pH-metric titration technique is usually considered to provide binding and protonation constants accurate to ±0.05 log units (1). The pH profile of the calculated species concentrations (Fig. 2) revealed that the monoprotonated species, $(\mathbf{3}\cdot H)^+$, was minor throughout the pH range and maximal at pH near 8. Normally, the calculated formation constants for minor species are considered suspect, since the pH calculated therefrom at all titration points and the standard deviation over the whole data set are little affected by errors in the concentrations of minor species arising from errors in their formation constants. Therefore, it was possible that the minority status of $(\mathbf{3}\cdot H)^+$ introduced calculational uncertainty in the values of pK_{a_1}. However, these were close to the pK_a measured for **4** (7.64), which we considered to be a good model for the first protonation site in **3**. Indeed, **4** could be expected to be less basic than **3** because it is less rigid and less preorganized for hydrogen bonding, and because *in,in* orientation of the bridgehead lone pairs of **3** would increase the electron density in its cavity. Hence, the calculated pK_a values of **3** appeared reasonable.

This kind of positive cooperativity could also be inferred from the protonation behaviour of the polyoxa-[2]-cryptands (1). In this series, the values for pK_{a_1} increase with decreasing cavity size (see Table 1). At the extremes, the smallest member

TABLE 1. Protonation constants for polyoxa-[2]-cryptands (ref. 1). (25°C, μ 0.05 M, H_2O)

Cryptand	pK_{a_1}	pK_{a_2}
[3.3.3]	7.70	6.96
[3.3.2]	8.16	7.31
[3.2.2]	8.50	7.33
[2.2.2]	9.60	7.28
[2.2.1]	10.53	7.50
[2.1.1]	10.64	7.85

of the series ([1.1.1]) is an extraordinarily strong base whose pK_{a_1} value could not be measured in aqueous solution (7), and the largest member ([3.3.3]) has pK_{a_1} (7.70) near those of the monoprotonation models *N*-ethylmorpholine (7.62, ref. 8*a*) and triethanolamine (7.8, ref. 8*b*). Increasingly rigid and progressively smaller cryptand cavities become more and more basic through increasing electron density within the cavity, and better stabilize the protonated forms through hydrogen bonding with the ether oxygens. But such hydrogen bonding also orients the ether oxygen lone pairs inward, and this adds more and more electron density near the second bridgehead as the cavity size decreases. There is therefore an increasingly efficient preorganization of the second protonation site as a result of the first protonation step and the values for pK_{a_2} also increase with decreasing cavity size (at least for the cryptands of Table 1), in spite of increasing Coulombic repulsion between the protonated bridgeheads. However, the increased basicity in the second protonation site never fully overcomes the Coulombic repulsion and pK_{a_2} remains much smaller than pK_{a_1}, unlike the values for **3**.

A more dramatic instance of protonation cooperativity ($pK_{a_1} - pK_{a_2} = 0.7$ with slow exchange) was witnessed with spheroidal [3]-cryptand **6** (9). ^{17}O nuclear magnetic resonance studies indicated that the diprotonated macrotricycle formed a water cryptate in its all-*in* form, with a tetrahedral array of hydrogen bonds. Thus, both the first proton and water are effectors in this case, and the diprotonated form is stabilized by the complexed water molecule (10). However, it is unlikely that the same be true of **3** because of the small cavity.

Rather, a conformational change similar to that occurring in the polyoxa[2]-cryptands can be invoked to explain the cooperativity observed in the protonation of **3**, involving the carbonyl oxygens as the only possible sources of new electron density. Indeed, the carbonyls must not be contributing much electron density at the first protonation site of the free ligand since **3** (pK_{a_1} 7.81) is considerably less basic than [2.2.2] (pK_{a_1} 9.60, ref. 1), the closest polyoxa analogue. Yet they must contribute more new electron density at the second site in $(\mathbf{3}\cdot H)^+$ than the ether oxygens in $([2.2.2]\cdot H)^+$ since $(\mathbf{3}\cdot H)^+$ is more basic (pK_{a_2} 7.96) than $([2.2.2]\cdot H)^+$ (pK_{a_2} 7.28, ref. 1) or even the lower homologues $([2.2.1]\cdot H)^+$ (pK_{a_2} 7.50, ref. 1) or $([2.1.1]\cdot H)^+$ (pK_{a_2} 7.85, ref. 1), probably as a result of inward orientation enforced by H-bonding to the first added proton held *in*. Hydrogen-bonding of *in* $N\text{-}H^+$ to the carbonyl oxygens of **3**, forming seven-membered rings, is likely geometrically less favourable than to the ether oxygens of the polyoxa-cryptands, forming five-membered rings, but electronically more favourable since the carbonyls are stronger dipoles and, in any case, evidently more effective at increasing the basicity of the second site.

Such a conformational change would not be likely were

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/07/12
For personal use only.

protonation to have occurred *out,out* since H-bonding with the carbonyls would then be impossible. We therefore sought experimental confirmation of this change by looking for conformational differences, through nmr spectral differences, between *in,in* and *out,out* diprotonation, using salt **5** as a model for *out,out* $(\mathbf{3}\cdot H_2)^{+2}$. Unfortunately, this was inconclusive, as the spectral displacements upon diprotonation (presumed to occur *in,in*) were in the same directions and of similar magnitudes as upon dimethylation (presumed to occur exclusively *out,out*).

However, molecular mechanical calculations of the minimum energy structures of **3**, $(\mathbf{3}\cdot H)^+$, and $(\mathbf{3}\cdot H_2)^{+2}$ (presented in cross-sectional views in Fig. 3) were in agreement with the proposed conformational change. In the least energetic form of the free ligand (Fig. 3A), the bridgehead lone pairs were both *in* and the urea groups lay tangent to the cavity, not well preorganized for H-bonding. This explains the similarity in basicity between **3** and **4**. The preferred geometries of the urea groups (two were *Z,Z* and one was *E,Z*) seemed determined by the number and the strengths of the interbridge hydrogen bonds that could be achieved. As expected, the calculated interbridgehead distance (5.6 Å) was intermediate between those in [2.2.2] (6.87 Å, ref. 11) and [1.1.1] (estimated at 3.5 Å, ref. 7). The calculated radius of the largest enclosed sphere was 0.98 Å, large enough for Li^+, and perhaps for Na^+ with lengthwise compression of the cavity. Indeed, calculations on the hypothetical Li^+ and Na^+ complexes revealed that the interbridgehead distance did diminish, but that the carbonyl groups could not turn sufficiently inwards for good alignment of the dipoles with the cationic spheres.

In both $(\mathbf{3}\cdot H)^+$ and $(\mathbf{3}\cdot H_2)^{+2}$, the bridgehead lone pair or the added protons were *in* and all three urea groups had *Z,Z* geometries. Importantly, two of the carbonyl groups of $(\mathbf{3}\cdot H)^+$ (Fig. 3B) were found twisted inward, forming two hydrogen bonds with the *in* $N-H^+$ and one with the urea N–H on the third bridge. In $(\mathbf{3}\cdot H_2)^{+2}$ (Fig. 3C), all three carbonyl groups were similarly twisted inward, forming six hydrogen bonds with both *in* $N-H^+$ groups. In so doing, the cavity was compressed along its length, making the cavity more spherical for more room for the carbonyl oxygens. In contrast, the *out,out* analogues of $(\mathbf{3}\cdot H)^+$ and $(\mathbf{3}\cdot H_2)^{+2}$ underwent no such change.

Solvation effects could not be taken into account in these calculations, and would be expected to somewhat affect the structural picture painted above, particularly with regard to the preferred geometries of the urea groups when these are not involved in hydrogen bonds to cryptated protons. However, the hydrogen bonding patterns found in the protonated species should not be significantly altered by the inclusion of solvent effects, since bulk or partially included H_2O molecules could not compete with the more strongly dipolar carbonyls, internal hydrogen bonding is entropically favoured, and the cooperativity cannot satisfactorily be explained by solvation effects. Also, it must also be cautioned that, although the structures of Fig. 3 appear reasonable, the number of possible conformers involved is likely very large, and it is difficult to ensure that the global minimum has been found without refinement of a large number of trial structures, a very laborious task, or without dihedral angle drivers (12) or a stochastic procedure such as that of Saunders (13).

Four other features of **3** are worthy of comparison with other proton cryptands ([1.1.1], **6**, and 1,6-diazabicyclo[4.4.4]tetradecane, a catapinand synthesized by Alder *et al.* (14, 15)): **3** is much more easily synthesized and a milder base; it excludes

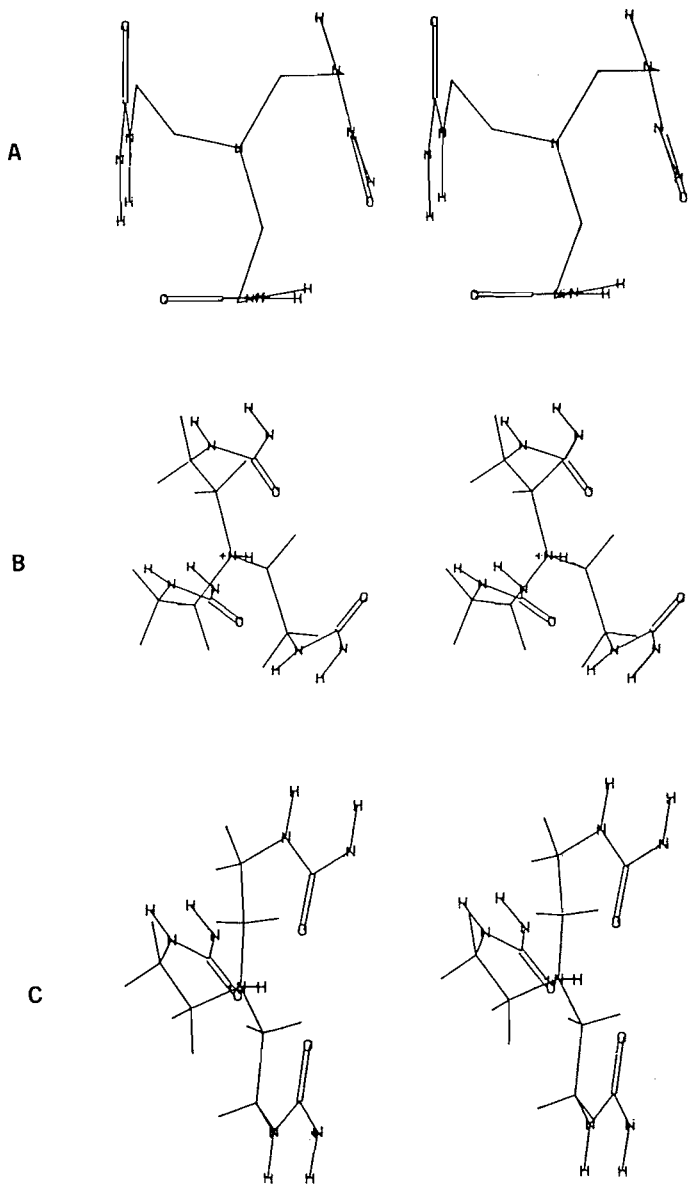

FIG. 3. Calculated minimum energy structures of (A) **3**, (B) $(\mathbf{3}\cdot H)^+$, and (C) $(\mathbf{3}\cdot H_2)^{2+}$ shown as stereoviews of cross sections of the cavities. Labels for methylene hydrogens and some C—H bonds have been omitted for clarity.

metal ions, and there was no evidence of slow proton exchange kinetics with **3** (i.e., protonation was easily reversed). In conclusion, compound **3** appears to be the first of a new class of proton cryptand. We are currently exploring its possible application in the selective transport or detection of one or another isotope of hydrogen, and are applying the bicyclization method to the preparation of larger polycarbonyl cryptands.

The conditions pertaining to triplet excited state ketone-sensitized photoreduction of $Ni(acac)_2$ under hydrogen were shown to serve as a method for light-promoted hydrogenation of olefins with clean chemospecificity. For example, the double bond in the bicyclic system was preferentially hydrogenated over the other double bond in dicyclopentadiene and in 5-methylenebicyclo-[2.2.1]heptene. This photohydrogenation could be run under a wide range of conditions and was apparently a homogeneous catalytic process; in a late stage of photohydrogenation, concurrence of heterogeneous catalytic processes was not ruled out. The Ni(I) complexes of tetrahydrofuran and olefins generated from the photoreduction of $Ni(acac)_2$ were shown to react with hydrogen to give nickel hydride complexes. By analogy with the generally accepted reaction pattern, coordinated olefins in these nickel hydride complexes probably spontaneously undergo intramolecular addition to give Ni–alkyl complexes. It is suggested that these Ni–alkyl complexes are photoexcited to generate a vacant coordination site so that the reaction with hydrogen can proceed to give products and regenerate a nickel hydride catalyst.

CHOW, Y. L., LI, H., et YANG, M-S. Can. J. Chem. **66**, 2920 (1988).

On a démontré que les conditions permettant d'effectuer la photoréduction du $Ni(acac)_2$, sensibilisée par l'état excité triplet de la cétone et effectuée sous l'influence de l'hydrogène, peuvent servir de méthode pour effectuer des hydrogénations d'oléfines amorcées par la lumière et présentant une grande chémospécificité. Par exemple, on a pu effectuer l'hydrogénation préférentielle de la double liaison du système bicyclique par rapport à l'autre double liaison du dicyclopentadiène et du méthylène-5 bicyclo[2,2,1]heptène. Cette photohydrogénation, qui est apparemment un processus catalytique homogène, peut être réalisée dans diverses conditions expérimentales; dans la dernière portion de la photohydrogénation, il est possible que des processus catalytiques hétérogènes interviennent d'une façon concurrente. On a démontré que les complexes du Ni(I) avec le tétrahydrofuranne et les oléfines qui sont produits lors de la photoréduction du $Ni(acac)_2$ réagissent avec l'hydrogène pour donner des complexes d'hydrure de nickel. Par analogie avec le processus généralement accepté pour cette réaction, on croit que les oléfines coordonnées aux complexes d'hydrure de nickel subissent spontanément une addition intramoléculaire conduisant à des complexes de Ni–alkyle. On suggère que ces complexes de Ni–alkyle sont photoexcités pour générer un site de coordination vacant qui permet à la réaction avec l'hydrogène de procéder pour donner les produits et pour régénérer un catalyseur d'hydrure de nickel.

Introduction

We have described the sensitized photoreduction of $Ni(acac)_2$ by triplet excited state ketones to give Ni(I) complexes and acetylacetone (acacH) and proposed a mechanism to explain the observations (1). The basic reaction pattern involves an interaction of a triplet excited ketone with $Ni(acac)_2$ to generate a coordinatively unsaturated Ni(I) complex with 17-electrons in the bonding shell and concurrent oxidation of a H-atom donor by radical pathways. Transient Ni(I) complexes decompose to metallic nickel or to Ni(0) complexes in the presence of a suitable ligand. It has been shown (2) that reduction conditions could be varied considerably as long as a ketone sensitizer with high triplet energy (e.g. acetone, xanthone, or benzophenone, etc) and a H-atom donor are present in an irradiated solution.

$$Ni(acac)_2 + RCH_2OH \xrightarrow[L]{\text{Xanthone, } h\nu} L_2Ni(acac) + RCHO + CH_3COCH_2COCH_3$$

$$\downarrow$$

$$NiL_4 + Ni(acac)_2$$

We have reported in a preliminary communication (3) that hydrogen can act as a H-atom donor not only in the photoreduction but also in the interaction with transient Ni(I) complexes to give nickel–hydride (Ni–H) complexes. We wish to report that the photoreduction conditions under slow purging of H_2 also serves as catalytic hydrogenation of simple olefins. Among metal catalysed olefin reactions (4–8), Ni–H complexes are good homogeneous catalysts for skeletal rearrangements (9, 10), isomerization (11–13), oligomerization (14–18), and hydrogenation (19, 20) of olefins under moderate pressure and temperature. Examples of light-promoted catalysis with other metal complexes in hydrogenation of olefins are also known and nicely summarized in recent reviews (7, 8).

Results

Irradiation of a benzene solution containing $Ni(acac)_2$ and xanthone (as a sensitizer) under hydrogen through a Pyrex filter caused reduction as shown by the disappearance of the 630 nm band of $Ni(acac)_2$ and by the change of the green solution to a yellow photolysate. Similar irradiation of solutions containing 10–50 fold excess of a simple olefin caused the photoreduction and concurrent hydrogenation of the olefin. Interruption of irradiation stopped the hydrogenation process and the conversion of photolysate to the original green colour occurred if air was leaked in. The percentage yields of hydrogenation products were determined quantitatively by GC analysis against an internal standard (Table 1). The structures of these products were either obtained by direct comparison with authentic samples or deduced from their spectral data. The sensitized photohydrogenation could be run in any kind of apparatus with a variety of configuration ranging from a Hanovia photocell to a test tube. Unoptimized results using various configurations of apparatus under different conditions are summarized in Table 1.

While unconjugated dienes with straight chains were hydrogenated without selectivity, 5-methylenebicyclo[2.2.1]heptene

[a] Xanthone, as a sensitizer, was added at the level of a 50% excess of $Ni(acac)_2$ concentrations that are in the range of 0.004–0.007 *M*.

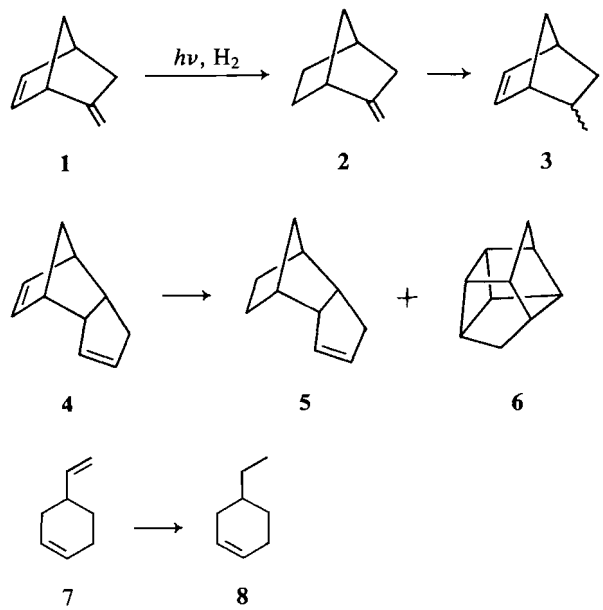
[b] These experiments use Method II; others use Method I and ordinary Hanovia photolysis apparatus.

[c] Use toluene as solvent to avoid the overlap of GC peaks in benzene.

(**1**) and dicyclopentadiene (**4**) were selectively reduced at the bicyclic olefinic bond exclusively and hydrogenation of the other olefinic bonds (i.e. those of **2** and **5**) did not occur before the dienes **1** and **4** were consumed. The caged hydrocarbon **6** was shown to be formed from **4** by the competing sensitized photocycloaddition (21). Indeed, it was found that the caged product **6** could be prepared by acetone- or xanthone-sensitized photocyclization which occurred even more efficiently by benzene-sensitized process using a Corex filter. During the photohydrogenation of Oct-1-en-3-ol, no 3-octanone was detected; 3-octanone was unaffected under the conditions. Amides, nitriles, carboxylates, and aldehydes were also shown to resist hydrogenation under these conditions. As a control experiment, when similar ingredients in benzene 2-propanol (9:1 v/v ratio) were photolysed under nitrogen, $Ni(acac)_2$ was photoreduced to Ni(0) metal but olefins were not hydrogenated.

For those experiments with a total product yield of less than 100%, oxetanes from the photocycloaddition of triplet excited xanthone to olefins could be detected by GC–MS analysis; these oxetanes were not isolated. In photohydrogenation of **1** (Table 1), a higher concentration of $Ni(acac)_2$ retarded the oxetane formation but the formation of hydrogenation products also became slower. It was obvious that triplet excited state xanthone preferentially interacted with $Ni(acac)_2$ in the initial phase to generate hydrogenation catalysts and thus prevented the alternative oxetane formation.

$Ni(acac)_2$ was rapidly reduced in a mixture of acetone and 2-propanol where the former was sensitizer and the latter a H-atom donor (1). Similar solutions containing an excess of either norbornene or **4** underwent photohydrogenation rapidly under hydrogen, but not under nitrogen, to give the expected products shown in Table 1. However, under these conditions, black precipitates of metallic nickel started to form rapidly as hydrogenation proceeded and was particularly rapid and severe



for 2-propanol concentrations higher than 25% (by volume) in 2-propanol–acetone mixtures. When benzone was added as a cosolvent in acetone–2-propanol mixtures, the deposition of metallic nickel was delayed in proportion to the benzene concentration. Typical results of the photohydrogenation of olefins in acetone–2-propanol–benzene mixtures are shown in Table 2. The photohydrogenation of 4-vinylcyclohexene (**7**) cleanly gave ethylcyclohexene (**8**) as shown by GC–MS analysis.

Dicyclopentadiene **4** was used as a model compound to study suitable conditions for photohydrogenation in acetone 2-propanol–benzene mixtures. The hydrogenation product **5** was contaminated by the sensitized photocycloaddition product **6**,

[c] The saturated dicyclopentadiene (tetrahydro-**4**) was obtained in 5%.

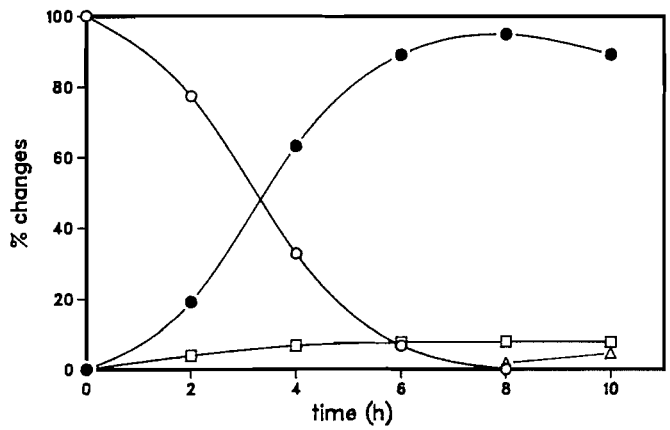

FIG. 1. Photohydrogenation of dicyclopentadiene **4** (0.029 *M*) and $Ni(acac)_2$ (0.0056 *M*) in a mixture of acetone, 2-propanol, and benzene (12:3:10 by volume): (Δ)% yields of tetrahydro-**4**.

particularly in the low concentration range of $Ni(acac)_2$ (Table 3). At a relatively high concentration of $Ni(acac)_2$, the formation of **6** was suppressed but the photohydrogenation of **4** to **5** was also retarded in the initial stage since triplet state acetone was preferentially intercepted by $Ni(acac)_2$. The photohydrogenation pattern under optimum conditions (Fig. 1) indicated that the photohydrogenation of **5** commenced at the point where **4** was totally consumed and that caged product **6** was formed in the initial stage.

Similar photohydrogenation of **4** in acetone–THF (4:1 by volume) remedied these problems; only a trace amount of **6** was formed (Table 3) and the precipitation of Ni(0) metal was much slower, occurring only in a much later stage of prolonged photolysis. The secondary hydrogenation of **5** started only when all **4** was consumed (Fig. 2). The interruption of irradiation caused the cessation of the photohydrogenation which restarted immediately on resumption of irradiation as shown in Fig. 3. Undoubtedly, irradiation was a necessary ingredient for the present catalytic hydrogenation. The long induction period required (see Figs. 2 and 3) indicated that the photoreduction of $Ni(acac)_2$ must precede and was obviously much more efficient than the photohydrogenation. The photohydrogenation of some bisolefins in acetone THF solution gave monohydrogenated products cleanly (Table 2) with only traces of side-products such as **6** and oxetanes.

Taking advantage of transient isotropic ESR signals exhibited by Ni(I) complexes in solution (1, 22–27), the xanthone-

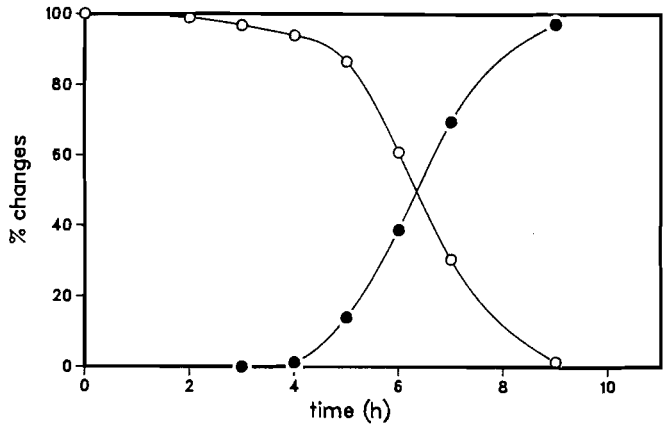

FIG. 2. Photohydrogenation of dicyclopentadiene **4** (0.051 *M*) and $Ni(acac)_2$ (0.001 *M*) in a mixture of acetone–THF (4:1 by volume): (Δ)% yield of tetrahydro-**4**.

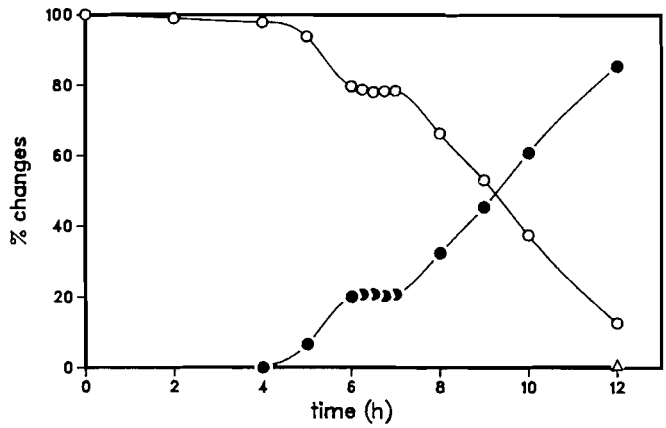

FIG. 3. The same conditions as in Fig. 2 except the dark reaction at the 6–7 h period.

sensitized photoreduction of $Ni(acac)_2$ was investigated with ESR spectroscopy. Photolysis of a solution of $Ni(acac)_2$, xanthone, and tri-*n*-butylphosphine, $P(n\text{-}Bu)_3$, in benzene 2-propanol (19:1 v/v) in the ESR cavity gave a signal at $g = 2.155$, $\Delta H_{pp} = 35$ gauss whether the solution was saturated with hydrogen or nitrogen. In pure benzene (without 2-propanol), photolysis of a similar solution under hydrogen gave a similar signal (Fig. 4) but that under nitrogen gave neither a signal nor photoreduction. Similar solutions in toluene were photolysed either under hydrogen of nitrogen to give a comparable signal, $g = 2.158$, $\Delta H_{pp} = 31$ gauss. These experiments clearly established that hydrogen could act as a H-atom donor in the photoreduction of $Ni(acac)_2$. However, hydrogen at the saturation concentration in benzene was a less efficient H-atom donor than alcohols or toluene since the estimated time required to reach a photostationary state in Fig. 4 was at least 2.5 times longer than those of other cases.

In the absence of $P(n\text{-}Bu)_3$, xanthone-sensitized photoreduction of $Ni(acac)_2$ in a benzene–2-propanol (19:1) mixture or in toluene under nitrogen generated a broad signal of colloidal nickel, $g = 2.286$, $\Delta H_{pp} = 920$ gauss (Fig. 5) (28): these photolysates soon deposited nickel metal. Similar photoreductions in benzene-2-propanol either in the presence of an olefin or hydrogen exhibited neither ESR signals of colloidal nickel nor those of Ni(I) complexes: the photolysate was bleached and remained clear for considerable times. This indicated that through ligation with an olefin and/or reaction with hydrogen some kinds of soluble nickel complexes were maintained in the solution.

The Ni(I) complexes generated in the sensitized photoreduction of $Ni(acac)_2$ decomposed rapidly as shown by the decays of their ESR signals reported previously (1). Because of the proportional variations of the Ni(I) ESR signal (i.e. the peak-to-peak line widths are the same, see Fig. 4), the concentrations of Ni(I) complexes, or their ESR intensities, are proportional to the peak-to-peak amplitudes of the first derivative waves (29). Thus signal heights can be monitored with respect to times at the peak position to represent the formation by photolysis and decay of Ni(I) complexes in the dark as shown in Fig. 6. For a solution placed in the ESR cavity, such generation and decay curves could be repeated several times.

The decay curves of Ni(I) ESR signals were analysed as a double exponential pattern, i.e., a mixture of bimolecular and unimolecular reactions on the basis of our previous findings (1); that is,

$$-(dA/dt) = k_1A + k_2A^2$$

where dA is the decreases of signal heights during time dt, and k_1 and k_2 are the first and second order rate constants. Its integrated form is

$$\ln [(k_1 + k_2A)A_0/(k_1 + k_2A_0)A] = k_1t$$

or

$$A = A_0k_1/[(k_1 + k_2A_0) \exp (k_1t) - k_2A_0]$$

Using computer best fit to simulate the data points of decay curves, k_1 and k_2 are obtained (Table 4). Under N_2, the first-order rate constants are negligibly small showing that the decay curves are dominated by the second order kinetics. Indeed when these curves are analysed with single second order kinetics, the values (values in parentheses in Table 4) are very close to those obtained by the double exponential analysis. The first order rate constants of the decay curves in THF under hydrogen show substantial increases from those under nitrogen and also the dependency on the amount of hydrogen present in the sealed tubes. These k_1 values should represent a bimolecular reaction of Ni(I) complexes and hydrogen; because the concentration of hydrogen (7×10^{-3} *M*) (30) must be orders of magnitude higher (30) than the concentration of the former, a first order pattern is obtained. It should be mentioned that k_2 values in these experiments are not absolute values since the concentration of Ni(I) complexes could not be determined and ESR signal amplitudes varied from one series of experiments to the other according to ESR settings.

Xanthone-sensitized photolysis of $Ni(acac)_2$ in C_6D_6 under hydrogen showed a weak signal at −15.2 ppm which was assigned to Ni–H resonance by reference to the published ^1H NMR data of known Ni–H complexes (31–34).

Discussion

We have established that sensitized photoreduction of $Ni(acac)_2$ with triplet excited state ketones under hydrogen can serve as a system to cause catalytic hydrogenation of olefins added *in situ*. The efficiency of this photohydrogenation is necessarily dependent, among other factors, on the rate of photon input. Eventual precipitations of metallic nickel further complicate quantitative studies of this process and prevent the measurements of quantum yields and turn over rates. The method is simple and shows chemospecificity toward unconjugated olefins; it can also

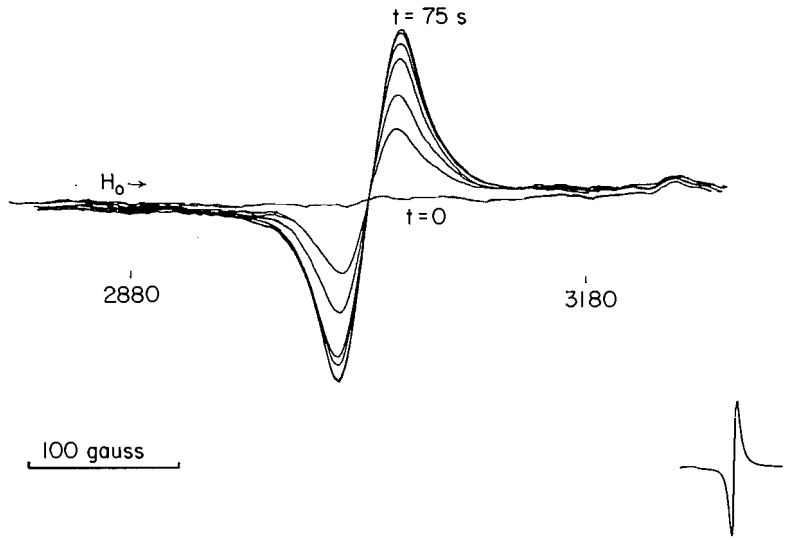

FIG. 4. ESR spectra recorded at every 15 s intervals in irradiation of benzene solution containing $Ni(acac)_2$ (0.010 *M*), xanthone (0.015 *M*), and $P(n\text{-}Bu)_3$ (0.050 *M*) saturated with hydrogen.

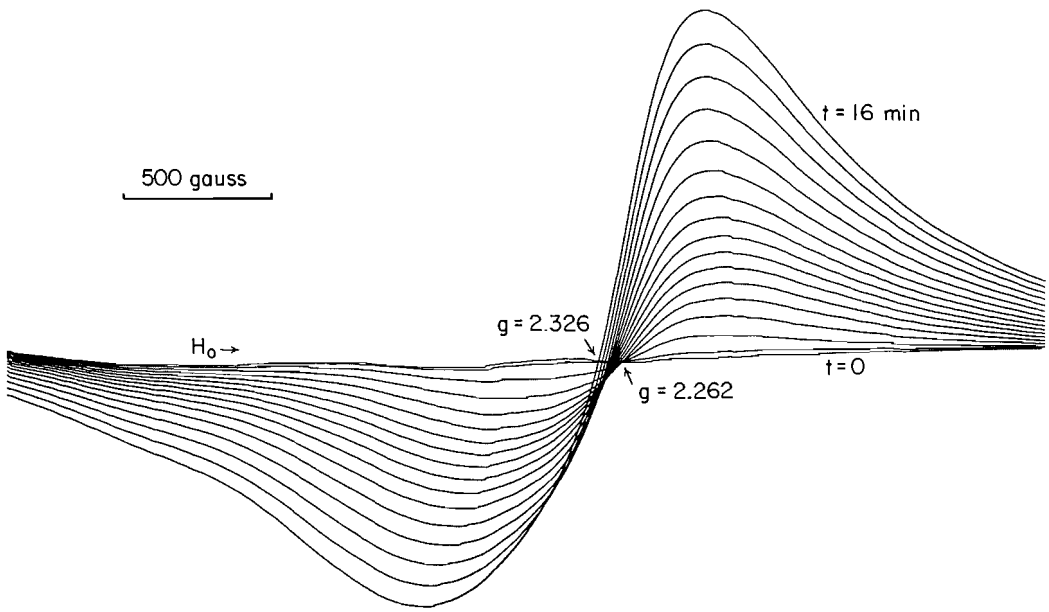

FIG. 5. ESR spectra recorded at one minute intervals in irradiation of $Ni(acac)_2$ (0.010 *M*) and xanthone (0.015 *M*) in benzene 2-propanol (19:1 v/v) under nitrogen.

tolerate many functional groups that do not interact with triplet excited states of ketones.

The overall reaction can be divided into three inter-related consecutive chemical events for mechanistic discussions. First of all, a triplet excited ketone promotes the sensitized photoreduction of $Ni(acac)_2$ in the presence of a H-atom donor and a ligand to give Ni(I) complexes, $Ni(acac)L_2$. Second, $Ni(acac)L_2$, being complexes with the 17-electron valence shell configuration, react with hydrogen rapidly to form monohydridonickel complexes, $H\text{–}Ni(acac)L_2$, that should have a stable 18-electron configuration. Third, light promotes hydrogenation of olefins using Ni–H complexes as catalytic vehicles.

The basic mechanism of sensitized reduction has been described in our previous publication (1). In this study, hydrogen is shown to be a H-atom donor to the proposed charge transfer complex either by H-atom transfer to acetylacetonyl radicals, or by other mechanisms mediated by the Ni-atom. The high H—H bond energy of 104 kcal/mol in comparison to much lower C—H bond energy (35) suggests that the latter pathway is more likely to be involved. Acetone possesses a high triplet excited state energy (78 kcal/mol) and a high volatility, making it an acceptable sensitizer; its drawback are low absorptivity in the >300 nm region and self-quenching reaction of its triplet state ($k_{sq} = 3 \times 10^6\ M^{-1}\ s^{-1}$) (36). The low reactivity to form the corresponding oxetanes with olefins under the photohydrogenation conditions (see Table 2) is an added advantage for the present purpose.

Many transient Ni(I) complexes have been identified in a variety of reductions of divalent nickel species in the presence of phosphines (22–27), and some stable Ni(I) complexes have been isolated and analysed by spectroscopy and X-ray crystallography (37, 38). The Ni(I) species generated in this sensitized photoreduction are sufficiently stabilized by good coordinating ligands, such as phosphines, THF, and diglyme, to permit the

[a] Solutions containing $Ni(acac)_2$ (0.010 *M*), xanthone (0.015 *M*) with or without additional ligand were irradiated at the cavity temperature of 24 ± 1°C.

[b] The rate constants in the parentheses were calculated on the assumption of purely second order reactions for entire decay curves. Since the absolute concentrations of Ni(I) complexes are unknown, they are represented by the unit of ESR spectra.

[c] These rate constants are averages of several determinations; others are standard deviations from best fit calculations.

[d] This kinetic determination was carried on the above sample preirradiated for 10 min.

detection by ESR spectroscopy; by analogy with the well established Ni(I) complexes reported (22–27, 37–38), these are assumed to have molecular formula of $Ni(acac)L_2$. The photoreduction in the presence of an olefin (using ethene C_2H_4 as a model) obviously also forms a soluble Ni(I) complex, $Ni(acac)_2(C_2H_4)_2$ (**9**), since colloidal nickel is not formed and a clear photolysate is maintained. The lack of the corresponding Ni(I) ESR signals probably means that such complexes are not as stable as those of phosphines and possess lifetimes too short to be detected under the ESR conditions. Acetone, alcohols, and benzene are weak ligands and probably form unstable Ni(I) complexes that are rapidly decomposed thermally or photolytically to give Ni(0) precipitates.

Although interactions with hydrogen to form nickel hydrides should be a key step in hydrogenation and other related processes, the present case (eq. [2]) is the first unambiguous proof of the reaction between Ni(I) complexes and hydrogen. Some Ni–H complexes appear to have remarkable stability and

[1] $Ni(acac)_2 + CH_2{=}CH_2 \xrightarrow[SH]{h\nu} Ni(acac)(C_2H_4)_2 + acacH$ (**9**)

[2] $Ni(acac)(C_2H_4)_2 + H_2 \longrightarrow H{-}Ni(acac)(C_2H_4)_2$ (**9** → **10**)

[3] $H{-}Ni(acac)(C_2H_4)_2$ (**10**) $\rightleftharpoons$ $CH_3CH_2{-}Ni(acac)(C_2H_4)$ (**11**), $h\nu(?)$; **10** → C_2H_6; **11** → $H_2 + C_2H_4$

their formations from Ni(II) or Ni(0) complexes by other methods are also known (31–34). Since $Ni(acac)L_2$ complexes have the 17-electron configuration, their reaction with hydrogen as in eq. [2] is expected to be spontaneous and to generate 18-electron Ni–H complexes, although the mechanism remains unknown. The failure of $Ni(acac)L_2$, where L = phosphines, to react with hydrogen supports the presence of steric hindrance since certain Ni(I) complexes with bulky phosphine ligands are stable enough to be isolated.

The bimolecular reaction of Ni(I) complexes as demonstrated by kinetic ESR studies (Table 4) is proposed to be the disproportionation shown in eq. [4]. Indeed, a freshly bleached $Ni(acac)_2$ solution in benzene 2-propanol regains the faint green color under nitrogen when irradiation is stopped. Equation [5]

[4] $2Ni(acac)L_2 \rightarrow NiL_4 + Ni(acac)_2$

[5] $NiL_4 + acacH \rightarrow H{-}Ni(acac)L_2 + 2L$

[6] $NiL_4 \rightarrow$ "Colloidal Ni" $\rightarrow$ "Ni metal"

shows an alternative route to form Ni–H complexes and has analogies in the prototropic generation of Ni–H bonds from Ni(0) complexes (37, 38); $Ni(1,5\text{-}COD)_2$ is known to react with acetylacetone to give a compound analogous to **11**, (η^1,η^2-cyclooctenyl) (acetylacetonato)nickel(II), either directly or via **10** (17, 18). The decomposition of NiL_4 to form colloidal and

metallic nickel may compete under the irradiation conditions. As the photohydrogenation proceeds smoothly while the photolysate remains clear, and shows ESR isotropic signals as well as H NMR signals, it appears to occur in the homogeneous phase where soluble Ni complexes **9**–**11** are probably involved and photoexcitation is required. However, we have not excluded the possibility that metallic and colloidal nickel, formed in the processes, may also act as heterogeneous catalysts in hydrogenation concurrently. The question on heterogeneous *versus* homogeneous catalysis, particularly for hydrogenation, has become a current interest (39–42) as catalytic reactions of transition metal and their derivatives figure more prominently in chemical industry. Although in recent years, several proposals have been put forward to differentiate homogeneous *versus* heterogeneous reaction processes (39–42), characterization and identification of colloidal metals (or metal sols) in reaction mixtures are not straightforward. Regardless of heterogeneous or homogeneous processes, the present photohydrogenation method works and is useful in some specific applications with excellent chemical selectivity. Leaving this question aside for future investigation, we continue to discuss the photohydrogenation as a homogeneous catalytic reaction.

The catalytic cycle of homogeneous photohydrogenation with nickel monohydride complexes is depicted in eq. [3] by analogy with the commonly accepted (4, 5) intramolecular addition of the Ni–H bond across a coordinated olefinic bond and hydrogenolysis to regenerate Ni–H complex **10**. Elimination of a Ni–H moiety in Ni–alkyl complexes, such as **11**, is apparently facile at ambient temperature or even lower (10–20): such processes are the source of Ni–H catalysed isomerization of olefins (9–12). The hydrogenolysis of **11** requires a vacant coordination site to accommodate oxidative addition of hydrogen followed by reductive elimination to give products and the regeneration of **10**. Without elaborating the mechanistic details, the role played by light energy is assigned to the photoexcitation of **11**, either by a direct or sensitized route, to promote the **11**—**10** transformation.

On the basis of the proposed mechanisms, the observed chemoselectivity of hydrogenation can be explained: (*i*) any functional groups possessing weak coordination properties with Ni(I) centers scarcely have a chance to undergo reduction (e.g., carbonyl, ester, cyano, amide groups), and (*ii*) better coordinating carbon–carbon double bonds should be preferentially hydrogenated; e.g., norbornene type vs. other olefinic bonds in intramolecular competitions in **1** and **4**. The latter point is further confirmed from an observation that the hydrogenation of dicyclopentadiene (**4**) is completely stopped in the presence of four equivalents of P(*n*-Bu)$_3$. Obviously, P(*n*-Bu)$_3$, being a better coordinating ligand, has displaced the olefin from **9** and/or **10**; a probable Ni(I) complex, Ni(acac)[P(*n*-Bu)$_3$]$_2$ (corresponding to **9**) reacts feebly with hydrogen in benzene as shown in Table 4. The observed clean chemoselectivity in the present photohydrogenation is the consequence of a complex overall effect consisting of various factors, such as the ability of olefins to coordinate, the facility of nickel complex **11** to undergo hydrogenolysis, and other steric and excitation factors. Furthermore, the addition of a Ni–H bond to an unsymmetrical olefinic bond should be regioselective by analogy with catalysed oligomerization of terminal olefins (14–17). This question will not be considered as it does not show in the products.

The present photohydrogenation depends on acetone-sensitized photoprocess as the key step to pump the reaction. Any substrates that can quench triplet excited ketone efficiently, say with $k_q \geq 10^9\ M^{-1}\ s^{-1}$, are not suitable substrates since they can compete efficiently to retard the processes of generating catalytic species **10** and **11**. Conjugated dienes and α,β-unsaturated carbonyl compounds are among those substrates that could not be used because of low triplet excited state energy (43). However, it is known that the former can be reduced to monoolefins by a thermal catalytic process of Ni–H complexes (20). It is interesting to note that **4** can be sensitized to undergo photocyclization to give caged compound **6** and that benzene is the most efficient sensitizer. Furthermore, triplet excited state acetone preferentially interacts with Ni(acac)$_2$ in THF even in the presence of **4** as shown in Table 3 and Fig. 2. This may arise from modifications of Ni complexes through loose coordination with solvent molecules.

Experimental

General conditions and materials

The experimental conditions and apparatus were the same as those described in ref. 1. The olefins (Aldrich) were distilled and stored under N_2. Reagent grade solvents were distilled.

Photolysis methods

Hanovia medium pressure mercury lamp 450 or 200 watts placed on a Pyrex Hanovia type cooling unit was used as the source.

Method I: A common Hanovia type irradiation cell was used to accommodate about 200 mL photolysates.

Method II: Solution was placed in a flat round cell (30–50 mL) with side arms for a gas tube inlet and an outlet connected to a condenser. The cell is placed facing the lamp housing in a running water bath.

Method III: A Pyrex test tube (10–20 mL) containing a solution was capped with a septum. A long needle extending to the bottom served as a gas inlet and a short needle extending to the upper space served as a leak. The tube was placed close to the lamp housing in upright position. Both of them were immersed in a running water bath.

Electron spin resonance spectra and signal decays

A solution necessary for photolysis was placed in a quartz ESR tube, up to 2 cm height (ca. 1.5 mL), which was capped with a septum at the top. The solution was purged with H_2 or N_2 with two needles. On removal of needles, the septum was sealed with wax paper. The cavity temperature in an equilibrated state was 24 ± 1°C.

For signal decay studies, the magnetic field was set at the maximum height of the first derivative wave, and scanned against time at the cavity temperature 24 ± 1°C. While the pen was running at a fixed speed, irradiation began until the signal reached the stationary state in 10–15 s. The irradiation beam was blocked to commence the decay as shown in Fig. 6. The data points read from these decay curves were analysed as follows: (*1*) according to a pure first or second order reaction by means of the "MINITAB" program of the MTS Computing System of SFU, and (2) according to double exponential decays of first and second order reactions on the bases of eq. [2], using the "MINUIT" program of Professor P. Percival (Chemistry Department, Simon Fraser University).

Photohydrogenation

Photohydrogenation of olefins was run with one of the apparatus described above. Aliquots of samples (2 mL) were removed at intervals and filtered through a short basic alumina (ca. 4 g) column, which was washed with benzene (2 mL). The filtrate was mixed with an internal standard solution of methylenedioxybenzene (0.05 *M*, 1.0 mL) and was brought to exactly 5 mL. This solution was injected in GC for quantitative analysis.

In the preparative photohydrogenation of **1** and **4**, the products **2**, **5**, and **6** were isolated with preparative GC (10% Carbowax 20 M on Anakrom Q, 0.25 in × 3 ft). Their physical data were as follows: **2** (45): MS *m/e*(%) 110(10, M^+), 95(4), 82(32), 67(86), 54(54), and 41(100); ^{1}H nmr($CDCl_3$), 4.82(s, $J_{\frac{1}{2}}$ = 0.7 Hz, 1H) 4.57(s, J = 0.7 Hz. 1H), 2.68(d, J = 1.2 Hz, 1H), 2.35(d, J = 1.2 Hz, 1H), 2.16 (d, J = 17.3 Hz, 1H), 1.90 (d, J = 17.3 Hz, 1H), 1.58(m, 2H), and 1.28(m,

4H) ppm. **5**: MS, *m/e*(%), 134(5, M^+), 66(100), 65(40); ^{1}H nmr; 5.60 (AB quartet and further coupling, J = 7, 2H), 2.99(m, 1H), 2.53(m, 1H), 2.27(m, 1H), 2.20(m, 2H), 2.12(m, 1H), 1.46 (AB quartet and further coupling, J = 8 Hz, 2H) and 1.20(m, 4H) ppm. **6**: MS, *m/e*(%), 132(8, M^+), 117(48), and 66(100); ^{1}H nmr, 2.75(m, 2H), 2.55(m, 4H), 2.47(m, 2H), 1.62(d, J = 11.3 Hz, 2H), and 1.23(d, J = 11.3, 2H) ppm.

In a prolonged irradiation, the fully hydrogenated product from **1** and **4** were not isolated but were identified by GC–MS to show the molecular ion peaks at *m/e* 112 and 136, respectively.

For photohydrogenation of hexa-1.5-diene, oeta-1,7-diene, octa-1-en-3-ol, and norbonene, the products 1-hexene, hexane, 1-octene, octane, norbornene, and 3-octanol were identified from their GC–MS spectra and co-injection in GC analysis with authentic samples.

Ethylcyclohexene (**8**) was isolated as a sample containing 15% 4-vinylcyclohexene (**7**) by preparative GC. This sample showed typical olefinic protons at 5.6 ppm (m, 2H) but no ABX system of the vinyl group at 5.9 and 5.0 ppm, and MS spectral pattern as follow (45); *m/e*(%) 110(M^+, 20), 95(17), 81(100), 67(30), 54(40), and 41(25).

DAVID E. WILLIAMS, RAYMOND J. ANDERSEN, JOHN F. KINGSTON, and ALEX G. FALLIS. Can. J. Chem. **66**, 2928 (1988).

The minor metabolites of both Pacific and Atlantic Ocean specimens of the cold water soft coral *Gersemia rubiformis* have been investigated. Pacific coast animals yielded two new pseudopterane diterpenoids, isogersemolides A (**11**) and B (**12**), and four new cembrane diterpenoids, isoepilophodiones A (**13**), B (**14**), and C (**15**) and rubifol (**16**). Atlantic coast animals yielded 3-acetoxy-β-cubebene (**17**). The proposed structures of all the new metabolites are based on spectroscopic analysis and chemical interconversions.

DAVID E. WILLIAMS, RAYMOND J. ANDERSEN, JOHN F. KINGSTON et ALEX G. FALLIS. Can. J. Chem. **66**, 2928 (1988).

On a examiné les métabolites mineurs d'échantillons, provenant de l'océan Atlantique ainsi que de l'océan Pacifique, du corail mou vivant en eau froide *Gersemia rubiformis*. Les animaux du Pacifique ont fourni deux nouveaux diterpénoïdes du pseudoptérane, les isogersémolides A (**11**) et B (**12**) ainsi que quatre nouveaux diterpénoïdes du cembrane, les isoépilophodiones A (**13**), B (**14**) et C (**15**) ainsi que le rubifol (**16**). Les animaux de l'Atlantique ont fourni de l'acétoxy-3 β-cubébène (**17**). Les structures qui sont proposées pour les métabolites sont toutes basées sur des analyses spectroscopiques ainsi que sur des interconversions chimiques.

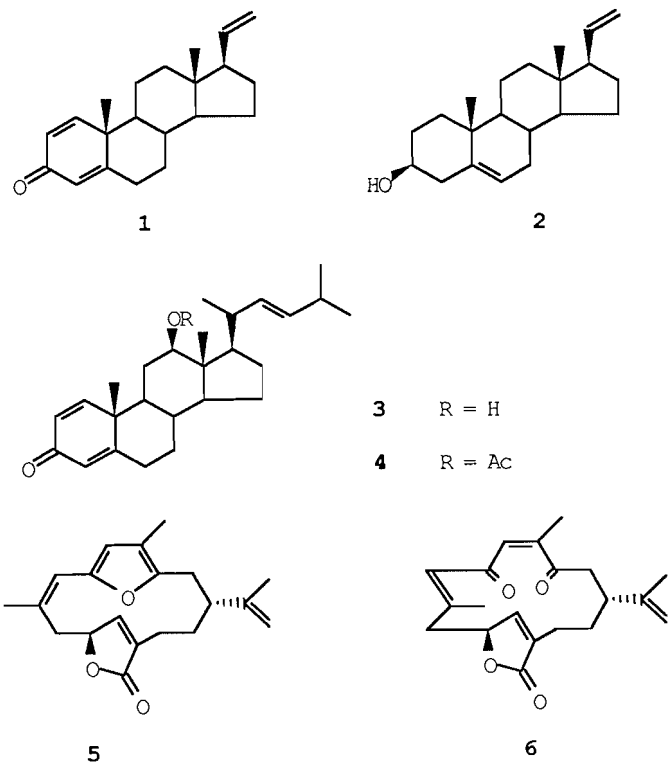
Tropical reef environments, particularly in the Indo-Pacific, are populated by a large variety of soft corals. In contrast to the tropical diversity of soft corals, the cold waters off both the eastern and western Canadian coasts harbour an extremely limited number of soft coral species (1).

Gersemia rubiformis, commonly referred to as the "sea raspberry", is one soft coral that can be collected in abundance from Canadian waters. Our previous chemical studies on *G. rubiformis* revealed that Atlantic specimens have entirely different chemistry than Pacific specimens. Atlantic Ocean samples of *G. rubiformis*, collected off the shores of Newfoundland, contained the two pregnane derivatives **1** and **2** (2) as well as the two C26 steroids **3** and **4** (3). Pacific Ocean collections of *G. rubiformis*, acquired off the northern end of Vancouver Island, yielded the cembrane diterpenoids rubifolide (**5**) and epilophodione (**6**), the pseudopterane diterpenoid gersemolide (**7**) (4), the gersolane diterpenoid gersolide (**8**) (5), and the cuprane sesquiterpenoids tochuinyl acetate (**9**) and dihydrotochuinyl acetate (**10**) (6). Our continuing investigations of the minor metabolites of both east and west coast specimens of *G. rubiformis* have resulted in the isolation of six new diterpenoids, **11**–**16**, from the Pacific animals, and one new sesquiterpenoid, **17**, from the Atlantic animals. We now wish to report the structures of these new *G. rubiformis* metabolites.



Pacific coast specimens

Samples of *G. rubiformis* were collected by hand using SCUBA (−5 to −15 m) around the Gordon Islands off the northern tip of Vancouver Island. Freshly collected soft coral was immediately immersed in methanol and extracted at room temperature for 2–3 days. The organic soluble portion of the methanol extract was fractionated by sequential application of silica gel flash, silica gel preparative thin-layer (tlc), radial thin-layer, and normal and reverse phase high performance (hplc) chromatographies to give pure metabolites.

Isogersemolide A (**11**) was obtained from methanol as colourless needles (mp 121–124°C). It showed a parent ion in the HREIMS at 328.1669 daltons appropriate for a molecular formula of $C_{20}H_{24}O_4$ (ΔM = −0.6 mmu), identical to that of gersemolide (**7**). The ^{13}C nmr spectrum of **11** (Table 2) showed resonances that could be assigned to eight olefinic carbons, two ketone carbonyls, and one lactone carbonyl. Six of the olefinic carbons and all three of the carbonyl carbons could be accounted

for by methyl substituted enedione (^{1}H nmr δ: 2.08 (d, J = 1.2 Hz, 3H), 6.21 (q, J = 1.2 Hz, 1H), α,β-unsaturated-γ-lactone (^{1}H nmr δ: 7.02 (dd, J = 0.6, 0.6 Hz, 1H) and 5.92 (d, J = 0.6 Hz, 1H)), and isopropenyl (^{1}H nmr δ: 1.72 (bs, 3H), 4.76 (bs, 1H), and 4.86 (bs, 1H)) residues similar to those found in gersemolide (**7**) (4). The two remaining olefinic carbon atoms and two additional olefinic methyl resonances apparent in the ^{1}H nmr of **11** (δ 2.01, s, 3H; 2.06, s, 3H) were assigned to a C7—C17 double bond and carbons 18 and 19 of the second isopropyl residue of a pseudopterane diterpene. Irradiation of the methyl resonance at δ 2.08 (C16) failed to induce an observable nOe (nuclear Overhauser enhancement) in the H5 olefinic resonance (δ 6.21), suggesting that the C4—C5 olefin had the *E* configuration. The chiral centers at C1 and C8 in isogersemolide A (**11**) were assigned the same relative configurations as the corresponding centers in gersemolide (**7**).

Isogersemolide B (**12**), also isolated as colorless needles (<1.5 mg), gave a parent ion at 328.1684 daltons in the HREIMS, indicating that it had a molecular formula of $C_{20}H_{24}O_4$ (ΔM = +0.9 mmu) as well. The ^{1}H nmr data for **12** showed a strong resemblance to those displayed by isogersemolide A (**11**) (Table 1), suggesting that the two metabolites had the same constitution but that they differed in some stereochemical sense. This hypothesis was confirmed by treatment of **11** with a catalytic amount of iodine in benzene/ethyl acetate, resulting in the formation of a 3:1 mixture of the geometric isomers **11** and **12**, as evidenced by ^{1}H nmr and tlc analysis. The assignment of the *Z* configuration to the C4—C5 alkene in isogersemolide B (**12**) was based on the observation of an nOe between H5 (δ 6.11) and the C16 methyl protons (δ 2.14), and on the observation of a 1.6-Hz allylic coupling between H5 and the C16 methyl protons in **12** and a 1.2-Hz allylic coupling between the same protons in **11**. It is generally observed that *cis* allylic coupling is larger than *trans* allylic coupling (7).

Isogersemolides A (**11**) and B (**12**) are formally related to gersemolide (**7**) by combinations of an allylic rearrangement and geometric isomerism. These interrelationships could be demonstrated by gently refluxing gersemolide (**7**) in formic acid/ethyl acetate to give a mixture of **7**, **11**, and **12** (30:20:3), as indicated by ^{1}H nmr and tlc.

Isoepilophodione A (**13**) was isolated as a pale yellow oil that gave a parent ion at 328.1686 daltons in the HREIMS appropriate for a molecular formula of $C_{20}H_{24}O_4$ (ΔM +1.1 mmu). Examination of the ^{1}H and ^{13}C nmr spectra (Tables 1 and 2) of **13** indicated the presence of the α,β-unsaturated-γ-lactone, methyl substituted enedione, trisubstituted olefin, and isopropenyl substructures found in epilophodione (**6**) (4). The strong similarity in the spectral data of **13** and **6** suggested that they were simply stereoisomers of each other, differing in the configuration of either one or both of the C4—C5 and C7—C8 olefins. Treatment of epilophodione (**6**) with iodine in benzene/ethyl acetate gave a mixture of **6**, **13**, and **14**, confirming that isoepilophodione A (**13**) and epilophodione (**6**) were geometric isomers of each other. The observation of a strong nOe between H7 (δ 6.07) and the C19 methyl protons (δ 1.99) established the *Z* configuration for the C7—C8 olefin in **13**. There was no demonstrable nOe between H5 (δ 6.68) and the C18 methyl protons (δ 2.16), implying that the C4—C5 olefinic configuration was *E*. Epilophodione (**6**) and isoepilophodione A (**13**), therefore, have the same relationship to each other as do the previously reported metabolites lophodione (**23**) and isolophodione (**24**) (8).

Isoepilophodione B (**14**) was isolated as a pale yellow oil that was shown by HREIMS (M^+ 328.1670; ΔM −0.5 mmu) to possess the same $C_{20}H_{24}O_4$ molecular formula as epilophodione and isoepilophodione A. Many of the resonances in the room temperature ^{1}H nmr spectrum of **14** were very broad, making it impossible to extract much structural information. Fortunately, however, isomerization of either epilophodione (**6**) or isoepilophodione A (**13**) with iodine in benzene/ethyl acetate gave

isoepilophodione B (**14**) as one component of the equilibrium mixture. Thus, isoepilophodione B (**14**) had to be one of the remaining geometric isomers of epilophodione, i.e., with the C4—C5 and C7—C8 double bonds in either the *E,E* or *Z,Z* configurations. Irradiation of the C19 methyl protons at δ 2.06 induced an nOe into the H7 olefinic proton at δ 6.25, and irradiation of the C18 methyl protons at δ 1.88 induced an nOe into the H5 proton at δ 6.21, demonstrating that both double bonds in **14** had the *Z* configuration.

The broadening of several resonances in the ^{1}H nmr spectrum of isoepilophodione B (**14**) was attributed to the slow interconversion of two low energy conformations of the molecule. Heating the nmr sample to 50°C failed to resolve the problem and it resulted in partial decomposition of the metabolite. Cooling the nmr sample to −40°C froze out two distinct conformations in a ratio of 4:1, producing sharp signals that could be assigned to both conformers.

Isoepilophodione C (**15**), isolated as a clear oil, was also shown by HREIMS (M^+ 328.1671, $C_{20}H_{24}O_4$; ΔM −0.4 mmu) to be isomeric with epilophodione. Methyl substituted ene dione, α,β-unsaturated-γ-lactone, and isopropenyl residues were again readily apparent in the ^{1}H and ^{13}C nmr spectra of **15** (Tables 1 and 2). Additional ^{13}C nmr resonances at δ 125.3 and 143.7, and ^{1}H nmr resonances at δ 5.90 and 6.08 were tentatively assigned to a C8—C19 exocyclic methylene functionality. A pair of SINEPT experiments (9), optimized for polarization transfer through two- and three-bond ^{1}H,^{13}C couplings of 7 Hz, confirmed the placement of the C8—C19 double bond and aided the assignment of the ^{13}C nmr spectrum (Table 2). Application of a selective pulse to the ^{1}H resonance at δ 3.73, assigned to one of the C7 methylene protons, gave polarization transfer into carbon resonances at δ 128.3 (C5), 143.7 (C8), and 196.9 (C6). Irradiation of the exocyclic methylene proton resonating at δ 5.90 (H19a) gave polarization transfer into carbon resonances at δ 48.3 (either C7 or C9) and 143.7 (C8). A strong nOe between H5 and the C18 methyl protons established the *Z* stereochemistry for the C4—C5 double bond. Additional decoupling and nOe experiments were completely consistent with the proposed structure and they facilitated complete assignment of the ^{1}H nmr spectrum (Table 1). Isoepilophodione A (**13**) gave isoepilophodione C (**15**) as one component of an equilibrium mixture upon treatment with refluxing formic acid/ethyl acetate.

Rubifol (**16**) ($C_{20}H_{26}O_5$; HREIMS M^+ 346.1785, ΔM +0.4 mmu) was isolated as colorless needles from methanol. As was the case with the other *G. rubiformis* cembranoid diterpenes, the ^{1}H and ^{13}C nmr spectra (Tables 1 and 2) of **16** clearly revealed the presence of the methyl substituted ene dione, α,β-unsaturated-γ-lactone, and isopropenyl fragments common to these metabolites. Clearly absent from the nmr data of **16** were resonances that could be assigned to a C7—C8 or C8—C19 olefin. Instead there was a new resonance at δ 80.7(C) in the ^{13}C nmr spectrum and a methyl singlet at δ 1.20 in the ^{1}H nmr spectrum of **16** that could be assigned to a tertiary carbinol carbon (C8) bearing a methyl substituent (C19). An alcohol stretching band at 3509 cm^{-1} in the ir spectrum of **16** supported the presence of the alcohol functionality. The alcohol accounted for the fifth oxygen atom in the molecular formula of rubifol. Irradiation of the C19 methyl protons at δ 1.20 induced nOe's into both H7a (δ 2.47) and H7B (δ 3.37). Irradiation of H7b (δ 3.37) in turn induced nOe's in H5 (δ 6.31) as well as H7a (δ 2.47) and the C19 methyl protons (δ 1.20). Decoupling and nOe experiments also demonstrated the expected connectivity from H9a and H9b continuously around the ring to H2a and H2b. It was not possible to unambiguously determine the relative configuration at C8 from the nOe data. We have assumed that the relative configurations at C1 and C10 in rubifol (**16**) and in the other new cembranoid metabolites **13**, **14**, and **15** are the same as the relative configurations of the corresponding centers in gersemolide (**7**) and gersolide (**8**). The relative stereochemis-

tries of **7** and **8** were determined by X-ray diffraction analysis (4, 5).

Atlantic coast specimens

East coast samples of *G. rubiformis* were collected by hand using SCUBA at Admiral's Cove and Bay Bulls, Newfoundland. Freshly collected specimens were immediately frozen and stored at −5°C until needed. Thawed material was homogenized in a Waring blender with methanol and the resulting homogenate was kept at room temperature for up to 3 days. The organic soluble portion of the methanol extract was fractionated by sequential application of silica gel flash, normal phase, and reverse phase high performance chromatographies to give pure samples of the known steroids **1**–**4** (2,3) and the new sesquiterpenoid **17**.

3-Acetoxy-β-cubebene (**17**) was obtained as a clear oil that failed to give a parent ion in the EI mass spectrum. The ^{13}C nmr spectrum of **17** showed resonances for 17 carbons (Table 3). An APT experiment (10) demonstrated that the molecule contained three quaternary, six methine, four methylene, and four methyl carbons and therefore 26 protons attached to carbon. An ir absorption at 1732 cm^{-1}, ^{13}C nmr resonances at δ 21.6(CH_3), 76.1(CH), and 170.4(C═O) (Table 3), and ^1H nmr resonances at δ 5.39 (d, J = 8.0 Hz, 1H) and 2.01 (s, 3H) (Table 3) all indicated the presence of a secondary acetate functionality in **17**. There was no spectral evidence for additional heteroatom containing functionalities, leading to the conclusion that **17** had a molecular formula of $C_{17}H_{26}O_2$ requiring five units of unsaturation. A strong fragment ion at m/z 202.1713 daltons ($C_{15}H_{22}$; ΔM −0.9 mmu) in the mass spectrum of **17**, corresponding to the facile loss of acetic acid from the parent molecule, confirmed the molecular formula. Evidence for four methyl residues, in addition to the acetate methyl, was apparent in the ^1H nmr spectrum of **17** (three methyl doublets, and one exocyclic methylene), indicating that the molecule was a sesquiterpene acetate.

Two other structural fragments could be readily recognized from the spectral data of **17**. A shielded one-proton multiplet at δ 0.58 in the ^1H nmr spectrum suggested a cyclopropyl ring. The base peak observed at m/z 159 daltons in the mass spectrum of **17** corresponded to a loss of acetic acid followed by a loss of a

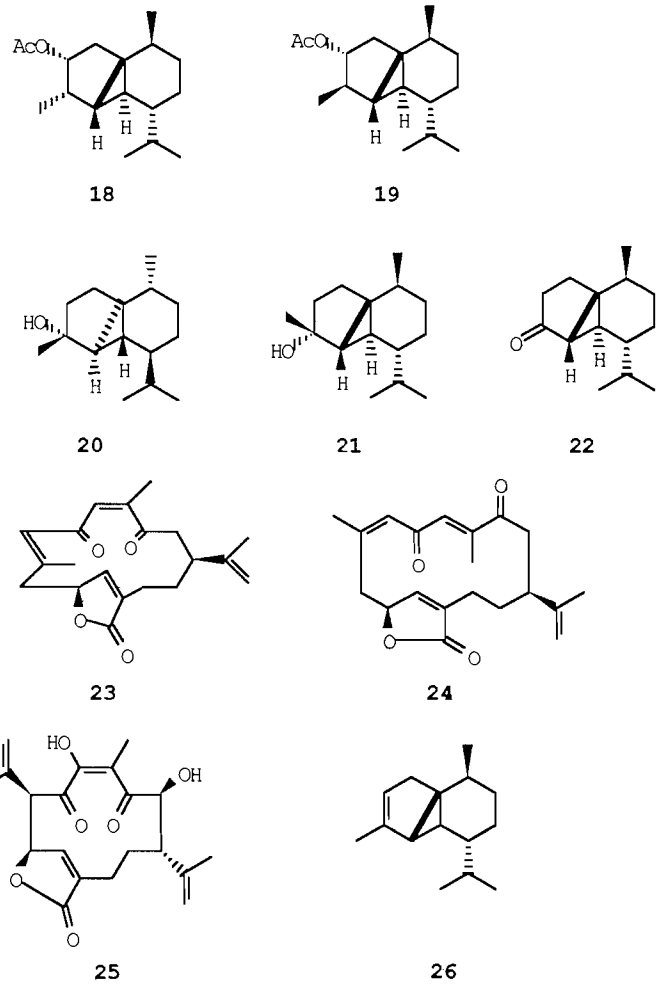
[a]The assignments may be interchanged.

C_3H_7 fragment. That observation, coupled with the presence of three methyl doublets in the ^1H nmr spectrum, provided evidence for an isopropyl residue.

The cubebene sesquiterpenoid structure **17** effectively accommodated all the identified structural fragments and observed spectral features of the metabolite. In concert with the proposed structure, irradiation of the carbinol methine proton at δ 5.39 (H3) sharpened the two exocyclic methylene resonances at δ 5.01 (H11a) and 5.05 (H11b) and simplified H2a (δ 2.38) to a doublet (J = 14.4 Hz). Irradiation of H2a (δ 2.38) collapsed the carbinol methine (H3, δ 5.39) to a broad singlet and also collapsed H2b (δ 1.54) to a singlet.

3-Acetoxy-β-cubebene (**17**) decomposed to give a complex mixture of very polar compounds when it was exposed to nmr solvents or subjected to routine laboratory manipulations. Hydrogenation of **17** gave an inseparable mixture of two stable dihydro epimers **18** and **19** in a ratio of 4:1. Decoupling and nOe experiments (see Experimental) conducted on the major isomer of the mixture supported the constitution of **17** and established that the relative stereochemistry at C3, C5, and C6 was as shown. A comparison of the ^{13}C nmr data for **17** with those reported for the related compounds **20** (11) and **21** (12) and with those which we recorded for the synthetic model compound **22** (13) showed excellent agreement (Table 4). In particular, the



resonances assigned to the methyl groups at C13, C14, and C15 have virtually identical chemical shifts in all three molecules, supporting our stereochemical assignments for C7 and C10.

The ^1H nmr resonance assigned to H6 (δ 0.58) in **17** displayed a complex coupling pattern that could not be readily explained on the basis of its vicinal proximity to only two other protons. The resonance assigned to H6 in the ^1H nmr spectrum of the model compound **22** showed an identical coupling pattern. Presumably the additional splittings observed in the H6 multiplets are the result of long-range scalar couplings facilitated by the strain and rigidity of the cubene ring system.

Discussion

Tropical soft corals and gorgonians are well known to be a very rich source of novel terpenoid metabolites (14). Our examination of the chemistry of *G. rubiformis* has shown that cold water soft corals are equally capable of elaborating a wide spectrum of interesting terpenes that are structurally related to those found in their tropical relatives. For example, two of the diterpenes found in Pacific specimens of *G. rubiformis*, gersemolide (**7**) and epilophodione (**6**), are close structural analogues of kallolide C (**25**) (15) and lophodione (**23**) (8) isolated from the tropical gorgonians *Pseudopterogorgia kallos* and *Lophogorgia alba*. Similarly, 3-acetoxy-β-cubebene (**17**), isolated from Atlantic specimens of *G. rubiformis*, is closely related to α-cubebene (**26**) isolated from several tropical gorgonians belonging to the genus *Pseudoplexaura* (16). The major difference between the tropical and cold water coelenterates is the observed concentration of the terpenoids. Rubifolide (**5**), the most abundant metabolite in *G. rubiformis*, is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/07/12
For personal use only.

present at a concentration of 2×10^{-4}% dry weight, while kallolide A, the most abundant metabolite of *P. kallos*, is present at a concentration of 3×10^{-1}% dry weight (15). The lower concentration of secondary metabolites in *G. rubiformis* appears to be typical of most cold water organisms.

The co-occurrence of cembrane, pseudopterane, and gersolane diterpenoids in the Pacific specimens of *G. rubiformis* suggests that all three carbon skeletons share a common biogenetic origin. Fenical has suggested that the pseudopterane skeleton is formed via a ring contraction of cembrane precursor (17) and it seems likely that the pathway to the gersolane skeleton also passes through a cembrane intermediate.

Pacific Ocean specimens of *G. rubiformis* contain secondary metabolites that are completely different than the metabolites present in Atlantic Ocean specimens. The reason for the difference is unclear; however, a reexamination of the taxonomy of *G. rubiformis*, taking into account the chemical information now available, is a necessary starting point in the quest for an explanation.

Experimental

The nmr spectra were recorded on Varian XL 300 and Bruker WH-400 spectrometers. Deutero chloroform was used as a solvent for recording all nmr spectra and Me_4Si was used as an internal standard. Low resolution mass spectra were recorded on an AEI MS902 spectrometer and high resolution mass spectra were recorded on an AEI MS50 spectrometer. The ir spectra were recorded on a Perkin Elmer 1710 Fourier transform spectrometer. The uv spectra were recorded on a Bausch and Lomb Spectronic 2000 instrument. Optical rotation measurements were recorded on a Perkin Elmer 141 polarimeter. A Fish–Johns apparatus was used to determine melting points and the reported vaues are uncorrected.

Merck silica gel (230–400 mesh) was used for flash chromatography and Merck silica gel 60 PF-254 with $CaSO_4 \cdot 1/2H_2O$ was employed in radial tlc (Harrison Research Chromatotron model 7924). Whatman Magnum-9 Partisil 10 or Whatman Magnum 9 Partisil 10 ODS-3 columns were used for preparative hplc.

Collection data

Specimens of *G. rubiformis* were collected by hand using SCUBA around exposed rocky reefs (−1 to −5 m) located within the Gordon Group of Islands, British Columbia, and at Admiral's Cove, Cape Broyle, and Bulls Bay, Newfoundland.

Isolation of metabolites from British Columbia specimens

Freshly collected animals (1.5 kg dry wt.) were homogenized with methanol in a Waring blender and left at room temperature for up to 3 days. The homogenized material was filtered through Celite and the solids were reextracted twice with fresh methanol. Evaporation of the combined methanol extracts *in vacuo* gave an aqueous suspension (1 L) that was sequentially extracted with hexanes (4 × 250 mL), dichloromethane (2 × 250 mL), and ethyl acetate (2 × 250 mL). The organic extracts were dried over sodium sulfate, combined, and evaporated *in vacuo* to give a dark red oil (33 g). Silica gel flash chromatography, employing a step gradient from 1:20 ethyl acetate/hexanes to 1:10 methanol/ethyl acetate, was used to separate the red oil into Fraction A (2.1 g, eluted with 1:20 ethyl acetate/hexanes), Fraction B (3.3 g, eluted with 1:4 ethyl acetate/hexanes), Fraction C (2.3 g, early part of material eluted with ethylacetate), and Fraction D (2.2 g, late part of material eluted with ethyl acetate).

Preparative silica gel tlc of Fraction C (5% methanol/dichloromethane) gave a series of close running uv active bands (R_f's 0.71–0.83) that were collected as a group to give a mixture (485 mg total) of gersemolide (**7**), isogersemolides A (**11**) and B (**12**), isoepilophodiones A (**13**), B (**14**), and C (**15**), rubifol (**16**), and gersolide (**8**). Radial tlc separation of the mixture (two-step gradient: (*i*) 1:1 dichloromethane/hexanes; (*ii*) 1:1:1 diethyl ether/hexanes/dichloromethane) gave fraction 1 (314 mg) containing **7**, **11**, **12**, **14**, **15**, and **16** and fraction 2 (24 mg) containing only **13** and fat. Normal phase hplc (3:3:1 diethyl ether/hexanes/dichloromethane) and reverse phase hplc (3:2 methanol/water) were used to separate fraction 1 into pure isogersemolide A (**11**) (3 mg), isogersemolide B (**12**) (1 mg), isoepilophodione B (**14**) (78 mg), isoepilophodione C (**15**) (17 mg), and rubifol (**16**) (8 mg). Reverse phase hplc (3:2 methanol/water) was used to obtain pure isoepilophodione A (**13**) (9 mg) from fraction 2.

Isolation of 3-acetoxy-β-cubebene (17) from Newfoundland specimens

Freshly collected Atlantic specimens of *G. rubiformis* (250 g dry wt.) were frozen and stored at −5°C until needed. Defrosted animals were homogenized with methanol in a Waring blender and the homogenized material was left at room temperature for 3 days before being filtered through Celite. The solids were reextracted twice with fresh methanol. Evaporation of the combined methanol filtrates *in vacuo* gave an aqueous suspension (300 mL) that was partitioned between brine (200 mL) and ethyl acetate (6 × 175 mL). The combined ethyl acetate layers were dried over sodium sulfate and concentrated *in vacuo* to give a dark orange-brown oil (4 g). Fractionation of the oil by silica gel flash (1:20 ethyl acetate/hexanes), normal phase hplc (1:40 ethyl acetate/hexanes), and reverse phase hplc (8:1:1 methanol/water/dichloromethane) gave pure 3-acetoxy-β-cubebene (**17**) (5 mg).

Isogersemolide A (11): colorless needles (MeOH), mp 121–124°C; $[\alpha]_D^{25}$ −225° (*c* 0.37, CH_2Cl_2); R_f 0.77 (silica gel, 1:20 MeOH/CH_2Cl_2); uv (MeOH) λ_{max}: 205 (ε 4700), 242(sh) nm; ir (CH_2Cl_2): 3017, 2960, 2930, 2855, 1761, 1695, 1672, 1645, 1607, 1458, 1379, 1175, 1045, and 871 cm^{-1}; ^1H nmr, see Table 1; ^{13}C nmr, see Table 2; LRMS, *m/z* (rel. intensity): 328 (M^+, 30), 310(10), 300(15), 283(27), 67(100).

Isogersemolide B (12): colorless needles (1:1 Et_2O/MeOH); $[\alpha]_D^{25}$ −27° (*c* 0.02, CH_2Cl_2); R_f 0.75 (silica gel, 1:20 MeOH/CH_2Cl_2); uv (MeOH) λ_{max}: 218 (ε 3050), 237(sh) nm; ^1H nmr, see Table 1; LRMS, *m/z* (rel. intensity): 328(M^+, 100), 310(25), 283(60), 201(38), 189(38), 173(50).

Isomerization of isogersemolide A (11) with iodine

To a stirred room temperature solution of isogersemolide A (**11**) (2 mg) in ethyl acetate (2 mL) was added 5 drops of a solution prepared by adding one crystal of iodine to 10 mL of benzene. The reaction was quenched after 16 h by adding 5 mL of an aqueous sodium bisulfite solution followed by repeated extraction with ethyl acetate (3 × 5 mL). Evaporation of the combined ethyl acetate layers *in vacuo* gave 1.3 mg of an oil that contained a 3:1 mixture of isogersemolide A (**11**) and isogersemolide B (**12**), as evidenced by ^1H nmr and tlc analysis.

Isomerization of gersemolide (7) with formic acid

A solution of gersemolide (**7**) (2 mg), ethyl acetate (4 mL), and formic acid (3 drops) was gently refluxed for 16 h under nitrogen. The cooled reaction mixture was neutralized with 5% sodium bicarbonate solution (10 mL) and extracted with ethyl acetate (2 × 5 mL). Evaporation of the ethyl acetate fraction *in vacuo* gave 1.5 mg of an oil that contained a 30:20:3 mixture of gersemolide (**7**), isogersemolide A (**11**), and isogersemolide B (**12**), as evidenced by ^1H nmr and tlc analysis.

Isoepilophodione A (13): pale yellow oil; $[\alpha]_D^{25}$ +138° (*c* 0.55, CH_2Cl_2); R_f 0.71 (silica gel, 1:20 MeOH/CH_2Cl_2); uv (MeOH) λ_{max}: 246 (ε 12 800), 208 (ε 16 200) nm; ir (CH_2Cl_2): 3070, 2985, 2936, 2845, 1761, 1681, 1648, 1619, 1605, 1445, 1380, 1276, 1065, and 1026 cm^{-1}; ^1H nmr, see Table 1; ^{13}C nmr, see Table 2; LRMS *m/z* (rel. intensity): 328(M^+, 4), 310(3), 178(21), 151(26), 135(25), 121(28), 107(30), 82(100).

Isoepilophodione B(14): pale yellow oil; $[\alpha]_D^{25}$ +298° (*c* 0.40, CH_2Cl_2); R_f 0.77 (silica gel, 1:20 MeOH/CH_2Cl_2); uv (MeOH) λ_{max}: 267 (ε 14 400), 212 (ε 13 100) nm; ir (CH_2Cl_2): 2982, 2935, 2875, 1758, 1683, 1643, 1620, 1610, 1443, 1381, 1260, 1120, 1105, 1064, 1026, and 882 cm^{-1}; ^1H nmr, see Table 1; ^{13}C nmr, see Table 2; LRMS *m/z* (rel. intensity): 328(M^+, 11), 82(100).

Isoepilophodione C(15): clear oil; $[\alpha]_D^{25}$ −170° (*c* 0.26, CH_2Cl_2); R_f 0.75 (silica gel, 1:20 MeOH/CH_2Cl_2); uv (MeOH) λ_{max}: 230 (ε 2500) nm; ir (CH_2Cl_2): 2982, 2942, 2868, 1756, 1689, 1643, 1614, 1441, 1380, 1335, 1102, 1091, 1042, and 948 cm^{-1}; ^1H nmr, see Table 1; ^{13}C nmr, see Table 2; LRMS *m/z* (rel. intensity): 328(M^+, 8), 310(6), 150(100), 121(27), 109(28), 82(60).

Rubifol (16): colorless needles (MeOH), mp 127–130°C; $[\alpha]_D^{25}$ −41° (*c* 0.38, CH_2Cl_2); R_f 0.76 (silica gel, 1:20 MeOH/CH_2Cl_2); uv (MeOH) λ_{max}: 230 (ε 6700), 207 (ε 10 300) nm; ir (CH_2Cl_2): 3509, 2980, 2934, 2869, 1756, 1700, 1671, 1644, 1610, 1447, 1382, 1338, 1200, 1094, and 1042 cm^{-1}; ^1H nmr, see Table 1; ^{13}C nmr, see Table 2; LRMS *m/z* (rel. intensity): 346(M^+, 2), 328(5), 151(89), 140(45), 133(33), 109(54), 91(62), 82(100).

Isomerization of epilophodione (6) and isoepilophodione A (13) with iodine

Epilophodione (**6**) (7 mg) and isoepilophodione A (**13**) (3 mg) were independently isomerized with iodine according to the procedure described above for the isomerization of isogersemolide A (**11**). The reaction with epilophodione (**6**) gave a 2:1:4:1 mixture of epilophodione (**6**), isoepilophodione A (**13**), isoepilophodione B (**14**), and an unidentified compound, as evidenced by tlc and ^1H nmr analysis. Isomerization of isoepilophodione A (**13**) gave a 1:3:2 mixture of **6**, **13**, and **14**.

Isomerization of epilophodione A (13) with formic acid

Eilophodione A (**13**) was isomerized with formic acid according to the procedure described above for gersemolide (**7**). The reaction gave a 3:1:1 mixture of isoepilophodione A (**13**), isoepilophodione B (**14**), and isoepilophodione C (**15**), as evidenced by tlc and ^1H nmr analysis.

3-Acetoxy-β-cubebene (17): clear oil; $[\alpha]_D^{25}$ +29° (*c* 0.24, CH_2Cl_2); R_f 0.34 (silica gel, 1:20 EtOAc/hexane); uv (MeOH) λ_{max}: 207 (ε 6100) nm; ir (CH_2Cl_2): 3057, 2962, 2934, 2875, 1732, 1609, 1464, 1374, 1246, and 1023 cm^{-1}; ^1H nmr, see Table 3, ^{13}C nmr, see Table 3; LRMS *m/z* (rel. intensity): 202(M^+ − 60, 18), 159(100), 157(74), 142(38), 131(59), 117(50), 105(56), 91(69), 77(38), 69(29), 60(26), 54(41).

Hydrogenation of 3-acetoxy-β-cubebene (17)

The fractions from the flash chromatography of a crude Newfoundland *G. rubiformis* extract that contained 3-acetoxy-β-cubebene (**17**) (75 mg) were added to methanol (10 mL) containing a catalytic amount of palladium on charcoal. The solution was stirred for 13 h at room temperature under balloon pressure of hydrogen gas. The palladium catalyst was removed via sintered glass filtration and the methanol was evaporated to give a crude mixture of the epimers **18** and **19**, fats, and steroids. The crude mixture was fractionated by normal phase hplc (1:40 EtOAc/hexanes) to give a fraction that contained only the inseparable epimers **18** and **19** (5 mg); ^1H nmr ($CDCl_3$, major isomer **18** only) δ: 0.54 (m, 1H), 083 (m, 1H), 0.88 (d, *J* = 7 Hz, 3H), 0.94 (d, *J* = 7 Hz, 3H), 1.03 (d, *J* = 7 Hz, 3H), 2.01 (s, 3H), 5.12 (t, *J* = 7 Hz, 1H); LRMS *m/z* (rel. intensity, of mixture): 264(M^+, 1), 204(12), 161(100), 133(10), 119(30), 105(50), 91(23), 81(24).

Coordination compounds of indium. Part 44. The oxidation of indium(I) halides by tetrahalogeno-*ortho*-quinones

THEODORE A. ANNAN AND DENNIS G. TUCK[1]

Department of Chemistry and Biochemistry, University of Windsor, Windsor, Ont., Canada N9B 3P4

Received May 6, 1988

THEODORE A. ANNAN and DENNIS G. TUCK. Can. J. Chem. **66**, 2935 (1988).

The reaction of indium(I) halides (InX; X = Cl, Br, I) with tetrahalogeno-*ortho*-quinones ($Y_4C_6O_2$; Y = Cl, Br) gives the oxidative addition product $Y_4C_6O_2InX$. These compounds have been isolated as adducts with neutral bidentate donor ligands (*N*,*N*,*N'*,*N'*-tetramethylethanediamine (tmen), 1,10-phenanthroline) or as salts of the anionic complexes $[Y_4C_6O_2InCl_2]^-$ or $[Y_4C_6O_2In(Cl)Br]^-$. The number of coordinated tmen molecules, and hence the structure, depends on the method of preparation. Infrared, ^1H NMR, and ^{13}C NMR spectroscopy all confirm that these products are all substituted-catecholato derivatives of indium(III), and the structure of these various neutral or anionic derivatives is discussed. The temperature dependence of the ^{13}C NMR spectra shows that the dynamic behaviour of these compounds (in d_6-dmso) is similar to that observed in previous studies of indium(III) chelate complexes.

THEODORE A. ANNAN et DENNIS G. TUCK. Can. J. Chem. **66**, 2935 (1988).

La réaction des halogénures d'indium(I) (InX; X = Cl, Br, I) avec des tétrahalogéno *o*-quinones ($Y_4C_6O_2$; Y = Cl, Br) conduit à des produits d'addition oxydative $Y_4C_6O_2InX$. On a isolé ces composés sous la forme d'adduits avec des ligands donneurs bidentates neutres (*N*,*N*,*N'*,*N'*-tétraméthyléthanediamine (tmen), phénanthroline-1,10) ou sous la forme de sels de complexes anioniques $[Y_4C_6O_2InCl_2]^-$ ou $[Y_4C_6O_2In(Cl)Br]^-$. Le nombre de molécules de tmen qui se coordonnent et, en fin de compte, la structure dépendent de la méthode de préparation. Les spectres infrarouges ainsi que rmn du ^1H et du ^{13}C confirment tous que ces produits sont tous des dérivés catécholato-substitués de l'indium(III); on discute des structures de ces divers dérivés neutres ou anioniques. La variation des spectres rmn du ^{13}C avec la température démontre que le comportement dynamique de ces composés (dans le dmso-d_6) est semblable à celui observé au cours d'études antérieures sur des complexes de l'indium(III) chélaté.

[Traduit par la revue]

Introduction

The oxidation of indium(I) compounds by various inorganic or organic substrates has been demonstrated in a number of studies. For example, the oxidative addition of various alkyl halides to indium(I) iodide or bromide yields the appropriate $RInX_2$ compounds (1–6), whilst oxidation of cyclopentadienylindium(I) (CpIn) by iodine gives $CpInI_2$ (7). Both CpIn (8) and indium(I) halides (9) react with 1,2-bis(trifluoromethyl)dithiete by cleavage of the S—S bond, forming indium(III) derivatives containing a C_2S_2In ring. A related type of M—M cleavage involves the reaction of InX with $Co_2(CO)_8$ to give $XIn[Co(CO)_4]_2$ (10), and similar reactions with dimeric manganese and iron carbonyls have also been reported (11, 12). The discovery that indium(I) halides have significant solubility in mixtures of aromatic solvents and neutral bases (13) allowed the range of these oxidative reactions to be extended. The overall mechanism which was proposed to explain the reaction, or absence of reaction, between InX and various M—M or M—X bonded compounds (14–16) involves the lone pair of electrons on indium(I) being donated to M to form the appropriate M—In bond, with a concomitant rearrangement and transfer of the remaining ligands.

The use of *ortho*-quinones for the oxidation of transition metal ions has been the subject of many publications, but few analogous studies with Main Group metals have been reported. In a recent paper (17), we showed that the oxidation of stannous halides (SnX_2) by tetrahalogeno-*ortho*-quinones ($Y_4C_6O_2$: Y = Cl, Br) gives the corresponding tin(IV) catecholates $Y_4C_6O_2SnX_2$. The present paper demonstrates that solutions of indium(I) halides in organic solutions containing strong donors react with these same substituted *ortho*-quinones to give indium(III)-catecholato compounds, which have been isolated as adducts with neutral bidentate or anionic donors.

Experimental

General

Indium(I) halides were prepared as in earlier work (13). Tetrahalogeno-*o*-quinones, *N*,*N*,*N'*,*N'*-tetramethylethanediamine (tmen), 2,2'-bipyridine (bpy), and 1,10-phenanthroline (phen) were used as supplied. Solvents were dried by conventional methods, and stored over drying agents. All reactions were carried out in an atmosphere of dry nitrogen.

Indium analysis were by atomic absorption spectrophotometry using an IL 251 instrument, and microanalysis was carried out by Guelph Chemical Laboratory. The presence of the strongly coloured *o*-quinone in acidified aqueous solution prevented the use of the Volhard method for halogen analysis. Proton nmr spectra were recorded on a Varian EM 360 instrument, and ^{13}C spectra on a Bruker AC 300L instrument. Infrared spectroscopy involved the use of samples in KBr discs with a Nicolet 5DX instrument. Conductivity measurements were made with a YSI Model 31 bridge, and a conventional cell calibrated with aqueous KCl solution.

Preparation of adducts of $Y_4C_6O_2InX$ (Y = Cl, Br; X = Cl, Br, I)

(*i*) With tmen. The same general method was used throughout for the initial reactions, followed by isolation procedures which varied depending on the particular system. In a typical experiment, 3 mmol of InX (X = Cl, Br, I) was suspended in 25 mL of toluene/methylene chloride (1:1, v/v) and the mixture cooled to about −40°C. When tmen (ca. 2 mL, 13 mmol) was syringed in, the characteristic reddish colour of solutions of InX in such systems was observed. With the temperature still at ca. −40°C, an equimolar amount of tetrachloro-*ortho*-quinone in the same toluene/methylene chloride mixture (25 mL) was added dropwise over a period of 1 h. Stirring was continued for an hour, and the solution was then allowed to warm up slowly to room temperature, with further stirring for another 1 h. The resultant clear red–wine solution was filtered and the volume of the filtrate reduced by 60% *in vacuo*; addition of diethyl ether or petroleum ether then yielded

For personal use only.

a brown precipitate for X = Cl or Br. With X = I, an oily material was obtained at this stage, and a solid product was formed only after lengthy trituration with cold petroleum ether. All products were washed twice with either petroleum ether or diethyl ether (20 mL), and dried *in vacuo*, and identified as $Cl_4C_6O_2InX.n$tmen (n = 1.5, 2) (see Table 1 for analytical results).

(*ii*) Since it seemed probable that the use of excess tmen in the above procedure affected the composition of the final adduct, a different preparative approach was investigated. Indium(I) halide (InX, ca. 3 mmol) was suspended in a solution of tetrahalogeno-*ortho*-quinone (3 mmol) in 50 mL of a toluene/methylene chloride mixture (1:1, v/v) at room temperature. The red colour of the *o*-quinone was discharged after stirring for ca. 6 h, with complete consumption of the indium monohalide. At this stage, tmen (0.45 mL, 3 mmol) was syringed into the reaction mixture, and stirring continued for 1 h, after which the now light yellow solution was filtered to remove any traces of solid impurity. The isolation procedure was that described above. The final products were the 1:1 adducts $Y_4C_6O_2InX$.tmen.

(*iii*) Equimolar amounts (ca. 3 mmol) of InX and tetrahalogeno-*ortho*-quinones were stirred together in methylene chloride at room temperature; complete reaction occurred over a period of 4–6 h. Addition of an equimolar amount of 1,10-phenanthroline quantitatively precipitated the 1:1 adduct $Y_4C_6O_2InX$.phen.

(*iv*) Anionic derivatives of $Y_4C_6O_2InX$ were also prepared. Equimolar quantities of InCl and $Y_4C_6O_2$ (ca. 3 mmol) were stirred together in tetrahydrofuran (thf) at room temperature for 3 h. The resultant solution was filtered to remove traces of unreacted material, and the filtrate run into a solution of either Ph_4PCl or Et_4NBr (3 mmol) in methanol (5 mL). The resultant mixture was stirred (3 h), and the solvents were removed *in vacuo* to yield a dark brown oily residue, which was redissolved in the minimum amount of acetonitrile (5–10 mL). Addition of diethyl ether (100 mL) produced an oily deposit, which on trituration over several days at room temperature gave a colorless solid, $Ph_4P[Y_4C_6O_2InCl_2]$ or $Et_4N[Y_4C_6O_2In(Cl)Br]$, which was collected and dried *in vacuo*.

(*v*) An alternative route to these anionic species involved formation of the $Y_4C_6O_2^{2-}$ anion by treating a solution of *o*-$Br_4C_6(OH)_2$ (2.0 g, 4.7 mmol) in thf (20 mL) with a suspension of NaH (0.22 g, 9.2 mmol) in the same solvent. Evolution of hydrogen occurred. The resultant light brown solution was treated dropwise with a solution of $InCl_3$ (1.05 g, 4.7 mmol) in thf (25 mL), and the mixture refluxed gently for 1 h. The white precipitate of NaCl was removed by filtration, and the filtrate treated with equimolar quantities of Ph_4PCl or Et_4NBr. The products were isolated as in (*iv*) above.

In each case, the products were characterized by elemental analysis, and by ir and nmr spectroscopy, and in the case of the anionic species by molar conductivity measurements.

Results and discussion

Preparative

The compounds listed in Table 1 are all neutral or anionic adducts of substituted-catecholato-indium(III) halides species, which themselves are formed in the redox reaction.

[1] 
This process is exactly analogous to that identified in the reaction of SnX_2 with these same tetrahalogeno-*o*-quinones, producing the tin(IV) compounds $Y_4C_6O_2SnX_2$ (17). Both reactions are formally oxidative addition processes, involving the transfer of a pair of electrons. A study of the reaction of SnX_2 with 3,5-di-*tert*-butyl-*ortho*-quinone (TBQ) has revealed clear evidence from electron spin resonance spectroscopy that such reactions actually involve two distinct one-electron transfers via the appropriate semiquinone (18), and we have found that the pale yellow solutions observed in the synthesis (e.g., method (*ii*) of Preparation above) are also esr-active, although these systems are not as conveniently investigated as are those with TBQ.

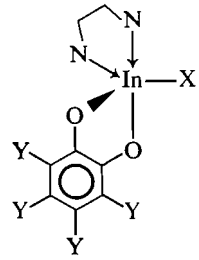
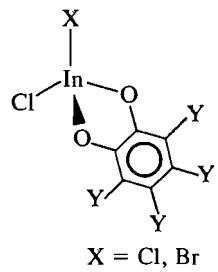
The adducts prepared with equimolar quantities of phen or tmen can be readily formulated as the five-coordinate species **1**



1



X = Cl, Br

2

and this is in keeping with the spectroscopic evidence (see below). This coordination state has been established for a number of indium(III) compounds, and must now be regarded as one of the standard stereochemical forms of the element. Relevant examples include Ph_3SnInX_2.tmen (16), $InCl_3.2Ph_3P$ (19), $(R_2E)_2InX.L_2$ (E = S, Se) (15), $EtInX_2$.tmen (20), L_2InX (L = 2-[(dimethylamino)methyl]phenyl ligand) (21), $In^{III}(dthz)_3$ (dthz = dithizone) (22), Me_2InCl (23), $(MeInCl_2)_2$ (24), and Me_2InBr (25). Unlike the higher adducts of tmen (see below), these compounds typically have low conductivities in *N*,*N*′-dimethylformamide (dmf) (see Table 2), in keeping with the neutral formulation shown.

It is also possible to prepare anionic derivatives of $Y_4C_6O_2InX$, in which indium(III) is four-coordinate (structure **2**); many such complexes are known. The structure of these particular complexes is confirmed by their synthesis via the disodium salt of the tetrahalogeno-catechol as shown in Scheme 1.

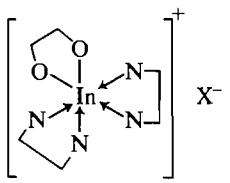
[a] m*M* concentration.

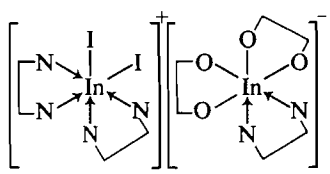
[b] The expected range for 1:1 electrolytes in dmf is 65–90 $ohm^{-1}\,cm^2\,mol^{-1}$ and in $C_6H_5NO_2$ 20–40 $ohm^{-1}\,cm^2\,mol^{-1}$ (36).

Complexes obtained by this route were identical in all respects with those synthesised from InX + *ortho*-quinone. Anionic indium(III) catecholates have been previously prepared in aqueous media by Bevillard (26), and were characterized as anionic complexes, e.g., $[In(O_2C_6H_5)_3]^{3-}$. Investigations by Srivastava and Mohan (27) with aqueous solutions of indium(III) nitrate showed that it is possible to isolate compounds in which the indium:catecholate ratio is 1:1, 1:2, or 1:3, depending on the pH of the reaction mixture. The present work appears to be the first preparation of catecholato–halogeno mixed ligand anionic complexes.

Finally we note that the use of excess tmen in the $Cl_4C_6O_2$/InX reaction gives rise to the compounds $Cl_4C_6O_2InX.n$tmen (X = Cl, Br, n = 2; X = I, n = 1.5). The conductivities of these complexes in nitrobenzene identify them as 1:1 electrolytes in solution, and we therefore propose the structures **3** and **4**.



3, X = Cl, Br



4

The structure of indium(III) species isolated from solution frequently depend upon the solution conditions (28), and the present results are in keeping with this observation. Structures similar to that shown in **4** have been proposed to explain the behaviour of the indium(III) halide adducts $InX_3.1.5$bpy (X = Cl, Br, I) (29).

Vibrational spectroscopy

A comparison of the infrared spectra of the indium(III)–catecholato complexes with those of the parent *ortho*-quinones and the corresponding diols shows marked changes in the ν(C=O) and ν(C—O) regions. The substituted tetrahalogeno-*ortho*-quinones have strong absorptions at 1670 and 1641 cm^{-1} while in the corresponding diol *o*-$Br_4C_6(OH)_2$, ν(C—O) is at 1445 and 1270 cm^{-1}. The complexes typically show strong absorptions in the 1440 cm^{-1} region, supporting the identification of these products as catecholato derivatives.

TABLE 3. Far infrared spectra of some indium(III)–catecholato complexes (in cm^{-1})

Compound	ν(In—N)	ν(In—O)	ν(In—X)
$Cl_4C_6O_2InCl.tmen$	480(m)	400(w)	270(s,br)
	454(m)		
$Cl_4C_6O_2InCl.2tmen$	476(m)	426(m)	—
	458(m)

$Br_4C_6O_2InI.phen$	290(s)	424(s)	185(s)

[a] ν(In—N) obscured by broad In—Cl band.

The vibrational spectra in the far infrared region are presented in Table 3. The tmen adducts have weak to medium bands between 450 and 520 cm^{-1}, readily assigned to ν(In—N) from earlier work (30), while the ν(In—N) absorptions of the phenanthroline adducts are in good agreement with reported values for $InX_3.1.5$phen (X = Cl, Br, I), which fall in the range 270–220 cm^{-1} (29). The assignment of ν(In—X) and ν(In—O) follows the analysis of the spectra of $InX_2(acac)L_2$ (X = Cl, Br, I, L = phen, bpy) (31), and the ν(In—X) values are in general agreement with those reported for other indium(III) halides (32). The identification of ν(In—O) has been the subject of discussion, with frequencies between 450 cm^{-1} and 180 cm^{-1} being proposed; in the present work, a band at ca. 420 cm^{-1} is observed in all the compounds prepared, and is tentatively assigned to this mode.

The tmen adducts $Cl_4C_6O_2InX.2$tmen do not show any infrared absorption in the ν(In—X) region, in agreement with the ionic structure **3** proposed, while the compound $Cl_4C_6O_2InI.1.5$tmen has two bands in the far ir spectrum at 177 and 152 cm^{-1}, assigned as ν_{as}(In—I) and ν_s(In—I). The presence of two ν(In—I) modes supports the structure **4**, rather than a mononuclear structure.

Nuclear magnetic resonance spectroscopy

The ^1H nmr spectra, some typical examples of which are presented in Table 4, serve to confirm the presence of the coordinated bidentate ligand (phen or tmen), and also establish that the species in question are diamagnetic. The resolution of the spectra of the 1,0-phenanthroline adducts was hampered by their low solubility in dimethyl sulphoxide, but the proton

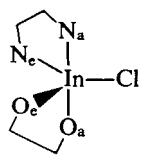
[a]Y = Cl, Br; X = Cl, Br, I. There were no significant differences between individual members of any given group of these compounds.
[b]In ppm, relative to Me_4Si.

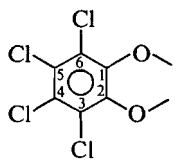
resonances are typical of those observed in related phen complexes.

The ^{13}C NMR spectra also proved to have considerable diagnostic value. Table 5 shows the relevant features of some typical compounds; comparisons with previously published values for the tetrahalogeno-*o*-quinones, the analogous diols and the neutral bidentate ligands (17) again confirm the assignments proposed.

As in the tin(IV) compounds, there are substantial shifts from (say) the *o*-quinone $Cl_4C_6O_2$ (C1, C2 168.8; C3, C6 143.7; C4, C5 131.9 ppm) to the various indium(III) complexes, for which the values are close to those in *o*-$Cl_4C_6(OH)_2$ (C1, C2 143.0; C3, C6 122.5; C4, C5 119.5 ppm). These results then confirm the identification of these products, and again establish the change from *o*-quinone to *o*-catecholate on reaction with InX. There are small but significant differences between the present results and those for the analogous tin(IV) species. The C1, C2 resonances are approximately 4 ppm higher in the indium(III) compounds, while C3, C6 and C4, C5 are 2–3 ppm lower, and similarly the ^{13}C resonances of tmen are 2–3 ppm higher in the indium(III) complexes than in the tin(IV) analogues.

These spectra also serve to identify the structures of the species present in dimethyl sulphoxide solution. We consider first the molecule $Cl_4C_6O_2InCl.tmen$, which is formulated from infrared and conductivity results as the five-coordinate monomeric neutral species.





The room temperature (295 K) spectrum showed double resonances for each of the three pairs of the carbons on the catecholato ring, at 158.4 and 157.7 (C1, C2), 120.4 and 120.3 (C3, C6), and 119.4 and 118.9 (C4, C5) ppm from Me_4Si. These values are significantly different in frequency from those quoted in Table 5, due to (*i*) the presence of tmen rather than phen as the neutral ligand and (*ii*) the different coordination number at indium(III) (see below). As the solution warmed up, these signals coalesced, and the coalescence temperatures and other derived kinetic data are shown in Table 6. The $\Delta G^{\ddagger}$ values obtained from the three sets of results by standard methods (33) are essentially identical, at 70.3 kJ mol^{-1}. Before considering the mechanistic implications of this temperature dependence, it is worth noting that the tmen region is too complicated to allow a similar analysis. There are two pairs of diastereotopic CH_3 groups on the different nitrogen atoms of the bidentate ligand (51.9, 49.4 ppm) and similarly these are two

TABLE 6. Temperature dependence of ^{13}C NMR spectrum of $Cl_4C_6O_2InCl.tmen$

Sites	ν (Hz)	$\Delta\nu$	K_c (s^{-1})	T_c (K)	$\Delta G^{\ddagger}$ (kJ mol^{-1})
C1	7968.6	32.7	145.3	≥353	≥70.3
C2	7935.9				
C3	6058.9	6.6	29.1	333	70.6
C6	6052.3				
C4	6006.5	21.2	93.9	343	69.5
C5	5985.4				

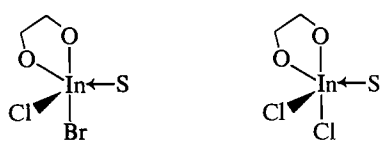
CH_2 resonances (60.3, 59.4 ppm). All these signals show the appropriate coalescence behaviour, but it was not possible to assign the resonances to the individual CH_3 (or CH_2) groups unambiguously, so that a detailed analysis of these results has not been attempted. An approximate treatment shows that here again $\Delta G^{\ddagger} \approx 65 \pm 10$ kJ mol^{-1}.

The most probable mechanism for the dynamic nmr involves the breaking of an N → In bond to give a quasi-tetrahedral species.

[2] 
$\mathbf{A_1}$ $\mathbf{B}$ $\mathbf{A_2}$

A similar mechanism has been established for indium(III) derivatives of the 2-[(dimethylamino)methyl]phenyl ligand (34), and for ligand exchange between InL_3 and HL (HL = various β-diketones) (35). In fact, the $\Delta G^{\ddagger}$ values of 70.3 kJ mol^{-1} deduced above is close to the values found in the latter work, where the rate-controlling process to which this relates was identified as the rotation of a monodentate β-diketonate ligand coordinated to indium. The analogous process in the present work would be the motion of the monodentate tmen ligand in the four-coordinate intermediate B, thus leading to the transformation $\mathbf{A_1} \rightleftarrows \mathbf{A_2}$, so that 70.3 kJ mol^{-1} is the rearrangement energy of this intermediate.

The spectra reported in Table 5 do not show any temperature dependence, which is also in keeping with the proposed structures. The spectra of the anionic complexes $[Y_4C_6O_2InCl_2]^-$ give singlets for the C1 + C2, C3 + C6, and C4 + C5 sites, so that the catecholate ligand is symmetrical within experimental error, while in the $[Y_4C_6O_2In(Cl)Br]^-$ series C1 and C2 are separated by ca. 1 ppm. Given the strong donor properties of the solvent dimethyl sulphoxide, it seems likely that the species in solution in both cases is a five-coordinate solvate. The relative electronegativities of the ligating atoms are in the order O > Cl > Br, but in arriving at the most probable structure one must allow the catecholate ligand to span equatorial and axial sites of a trigonal bipyramid, given that the O—In—O bite angle must be close to the value of 81.5(2)° in the analogous tin system (17). Given the usual arguments of VSEPR theory, the most probable structure for the solvated $[Y_4Cl_6O_2In(Cl)Br]^-$ anion is **5**.



5 **6** S = dmso

All forms of **5** must produce a stereotopic distinction between C1 and C2 of the catecholate, so that rapid solvent exchange cannot make these sites degenerate. For the solvate of $[Y_4C_6O_2InCl_2]^-$, rapid solvent exchange would render C1 and C2 homotopic, as they are in the four-coordinate parent anions of both **5** and **6**. The effect is a short-range one, being confined to C1 and C2, as shown by the results in Table 5.

Finally we note that those compounds which are 1:1 electrolytes in nitrobenzene (Table 2) (i.e., $Cl_4C_6O_2InX.2tmen$, X = Cl, Br, and $Cl_4C_6O_2InI.1.5tmen$) show only single resonances for all related pairs of carbon atoms in both the catecholate and tmen ligands. We assume that these compounds are also dissociated in dmso into the ionic species shown earlier as **3** and **4**. For the six-coordinate cation $[Cl_4C_6O_2In(tmen)_2]^+$ of species **3**, a process in which one of the tmen ligand undergoes uncoupling and recoupling via a five-coordinate intermediate cannot change the NMR spectrum irrespective of the rates involved.

[3] 
Both initial and final stages are identical, so that the NMR spectra reveal nothing about this exchange process. Similar arguments apply to the ions proposed for the iodo complex **4**.

In sum then, the ^{13}C NMR spectra of these complexes examined are in good agreement with the structures proposed from the vibrational spectra, and are also in keeping with earlier results on the rearrangement processes for indium(III) complexes in solution.

Anodic oxidation of lead in aqueous carbonate solutions. II. Film formation and dissolution in the pH range 9 to 14

D. W. SHOESMITH, M. G. BAILEY, and P. TAYLOR

Geochemistry and Waste Immobilization Division, Whiteshell Nuclear Research Establishment, Pinawa, Man., Canada R0E 1L0

Received May 2, 1988

D. W. SHOESMITH, M. G. BAILEY, and P. TAYLOR. Can. J. Chem. **66**, 2941 (1988).

The anodic oxidation of lead has been studied in aqueous carbonate solutions at pH values in the range $9 \leq pH \leq 14$. The solid films formed on the electrode surface have been identified by X-ray diffractometry. The dissolution and film formation processes have been studied by a number of electrochemical techniques at rotating disk electrodes. The anodic oxidation process can be divided into two distinct regions. In the main anodic oxidation process, a variety of surface phases is formed. The nature of the phase formed is pH-dependent. Plumbonacrite ($Pb_{10}O(OH)_6(CO_3)_6$) formation is observed at all pH values and predominates at $pH \geq 13$. At $pH < 11$, cerussite ($PbCO_3$) is the predominant phase, whereas at intermediate pH values, hydrocerussite ($Pb_3(OH)_2(CO_3)_2$) predominates. The dissolution rate of Pb^{2+} species from the electrode surface is directly proportional to the solubility of the predominant phase present. At more positive potentials, a reactivation, involving increased dissolution and a further stage of film formation, is observed. Litharge (PbO) is observed to grow underneath the initially formed basic lead carbonates. Dissolution occurs either by the field-assisted dissolution of the base-layer on the electrode or by metal dissolution through faults in the base-layer.

D. W. SHOESMITH, M. G. BAILEY et P. TAYLOR. Can. J. Chem. **66**, 2941 (1988).

Opérant dans des solutions aqueuses de carbonate et à des pH allant de 9 à 14, on a étudié l'oxydation anodique du plomb. On a utilisé la diffraction des rayons-X pour identifier les films solides qui se forment à la surface de l'électrode. Faisant appel à un certain nombre de techniques électrochimiques impliquant des électrodes à disque tournant, on a étudié les processus de formation et de dissolution du film. On peut diviser les processus d'oxydation anodique en deux régions distinctes. Dans le processus principal d'oxydation anodique, il se forme une grande variété de phases superficielles. La nature de la phase qui se forme dépend du pH. On observe la formation de la plumbonacrite ($Pb_{10}O(OH)_6(CO_3)_6$) à tous les pH; cette formation prédomine à un $pH \geq 13$. A un $pH \leq 11$, la cérusite ($PbCO_3$) est la phase prédominate alors qu'à des pH intermédiaires, l'hydrocérusite ($Pb_3(OH)_2(CO_3)_2$) prédomine. La taux de dissolution des espèces Pb^{2+} à partir de la surface de l'électrode est directement proportionnel à la solubilité de la phase prédominate qui est présente. A des potentiels plus positifs, on observe une réactivation impliquant une dissolution accrue ainsi qu'un autre stage de formation de film. On a observé que du litharge (PbO) se forme sous la couche de carbonates basiques de plomb qui se forment au départ. La dissolution se produit soit par une dissolution, aidée par le champ, de la couche de base de l'électrode soit par une dissolution du métal à travers les défauts de la couche de base.

[Traduit par la revue]

Introduction

Lead carbonates occur (or are expected) as corrosion products on artifacts as diverse as wine-bottle tops (1), bullets used in the American Civil War (2), water pipes (3, 4), and nuclear waste containers (5). Surprisingly little is known, however, about the electrochemistry of lead in carbonate solutions. As part of a program to understand the corrosion behaviour of lead in aqueous carbonate solutions, we have been studying its oxidation under electrochemical conditions. In a previous paper (6), we presented our results on the anodic oxidation of lead in 1.0 mol L^{-1} potassium carbonate solutions at pH = 12. Experiments were confined to the potential range where Pb^{2+} species were formed. The formation of higher oxidation states was not considered because oxidation does not proceed to these states under natural corrosion conditions.

We have extended our electrochemical and X-ray diffraction studies to cover the region $9 \leq pH \leq 14$. Also, our measurements of the corrosion potential (E_{CORR}) of lead in carbonate solutions (5) yielded values in the range $-0.540\ V < E_{CORR} < -0.350\ V$. Consequently, we have studied the dissolution and film formation processes occurring on lead at potentials up to 0 mV (vs. SCE). This value is over 0.600 V more positive than our previous anodic limit (6).

Experimental

Details of our electrochemical and X-ray diffraction (XRD) procedures have been described previously (6). All the experiments were performed at rotating disk electrodes of surface area ~1.6 cm^2. All potentials were measured, and are quoted, against the saturated calomel electrode. Unless otherwise stated, all experiments were performed in 1.0 mol L^{-1} potassium bicarbonate solutions. All solutions were originally made up with bicarbonate and the pH adjusted to the desired value with potassium hydroxide.

Results

(a) Cyclic voltammetry

Figure 1 compares the form of the voltammograms recorded at pH = 9.8 (A) and pH = 13.9 (B) at an electrode rotation rate (ω) of 16.7 Hz. The form of these voltammograms is similar to that observed at pH = 12, shown in Fig. 1 of ref. 1. The shoulder, observed on the negative side of the main anodic peak at pH = 12, is not so prominent at pH = 9.8 and is apparently absent at pH = 13.9. At pH = 9.8, two peaks are observed on the cathodic sweep, corresponding to the reduction of a base-layer (peak X) and a deposited-layer (peak Y). This assignment of peaks X and Y was discussed in ref. 7. At pH = 9.8, peak X shows no tendency to split into two, as observed at pH = 12; this suggests the base-layer is composed of a single phase. At pH = 13.9, the main anodic peak occurs at a more negative potential. Only peak X, corresponding to reduction of a single-phase base-layer, is observed on the reverse cathodic scan. The absence of reduction peak Y at pH = 13.9 shows that dissolution to form Pb^{2+} species is not accompanied by redeposition of an upper-layer on the electrode surface.

At pH = 13.9, the current passes through a minimum and rises again for potentials (E) > −0.6 V, eventually forming a

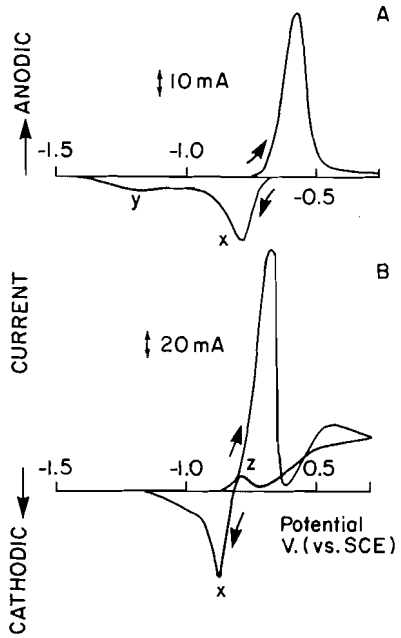

FIG. 1. Cyclic voltammograms recorded in 1.0 mol L^{-1} K_2CO_3 at a scan rate of 20 mV s^{-1}: (*A*) pH = 9.8, (*B*) pH = 13.9.

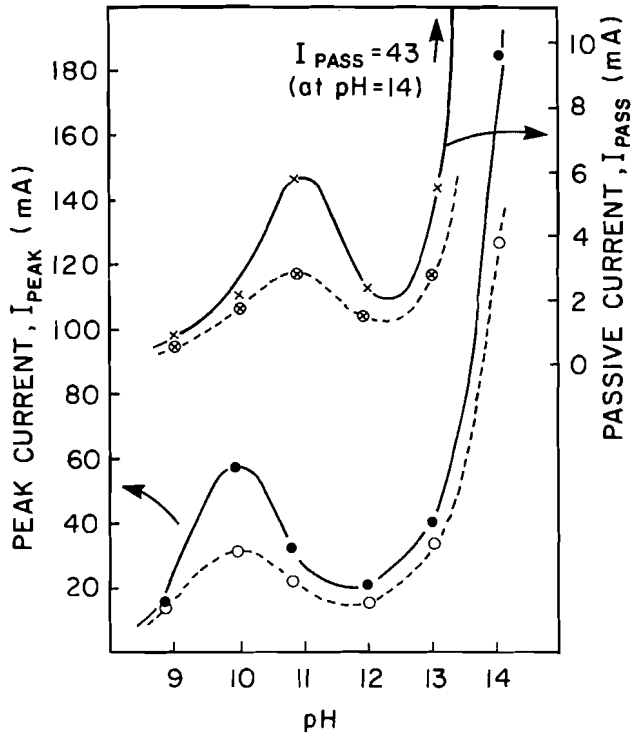

FIG. 2. Peak current (I_{PEAK}) and the passive current (I_{PASS} at −0.250 V), taken from voltammograms recorded at 20 mV s^{-1}, plotted as a function of pH: —, ω = 16.7 Hz; --- ω = 1.67 Hz.

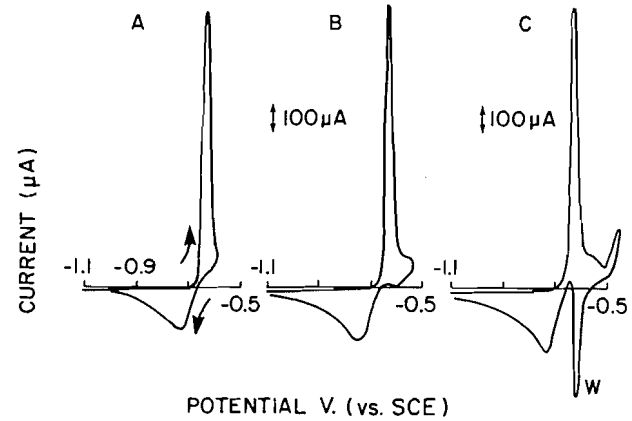

FIG. 3. Cyclic voltammograms, from −2.0 V to various anodic limits, recorded at 1.0 mV s^{-1} in 0.1 mol L^{-1} $NaClO_4$ plus 5×10^{-3} mol L^{-1} K_2CO_3 (pH = 10).

second, very broad peak at ~ −0.45 V. On the reverse cathodic scan, the current remains anodic and yields a small anodic peak (*Z* in Fig. 1*B*) at ~ −0.79 V. This anodic current and peak Z are symptomatic of a reactivation process, whereby the film formed at the main anodic peak is partially dissolved at more anodic potentials.

Figure 2 shows the peak current, I_{PEAK}, for the main anodic peak, and the current at −0.25 V, I_{PASS}, plotted as functions of the pH at which the voltammogram was recorded. The solid and dashed lines show the values obtained at ω = 16.7 and 1.67 Hz, respectively. A maximum in I_{PEAK} occurs around pH = 10, when the current is most sensitive to ω. For I_{PASS}, a similar peak occurs at pH ~11, again when the current is most sensitive to ω. Both I_{PEAK} and I_{PASS} increase substantially at pH > 13.

At lower carbonate concentrations, the size of the main anodic peak in the voltammogram (I_{PEAK}) is reduced by over two orders of magnitude. Figure 3 shows a series of scans, to various anodic limits, recorded in 0.1 mol L^{-1} $NaClO_4$ plus 5×10^{-3} mol L^{-1} K_2CO_3 (pH = 9.9), at ω = 33.3 Hz. When the anodic limit of the scan is extended into the reactivation region ($E > -0.5$ V), an additional, very sharp cathodic peak (W) appears in the reverse scan, Fig. 3 (*B* and *C*). The voltammograms of Fig. 3 were recorded at a scan rate of 1 mV s^{-1}, because peak W is most prominent at slow scan rates. Peak W can be attributed to the reduction of a further surface film formed in the activation region. This dependence on scan rate suggests the extent of formation of this layer is determined by the time spent in the reactivation region, $E > -0.5$ V.

(b) X-ray diffraction of anodically formed films

Figure 4 shows the identity of the phases formed after 60 min of potentiostatic oxidation at a potential on the positive side of the main anodic peak. This potential varies from −0.680 V at pH = 13.9 to −0.600 V at pH = 9. The vertical lines in Fig. 4 represent the stability boundaries between the indicated phases (7). Because the formation of the individual phases is compared on the basis of the height of a single diffraction peak for each phase, the data of Fig. 4 can only be considered semi-quantitative. The formation of plumbonacrite ($Pb_{10}O(OH)_6(CO_3)_6$) is observed over the whole potential range and it is the only detectable phase formed at pH > 13. The amount formed varies very little over the range 9 ≤ pH ≤ 12. Cerussite ($PbCO_3$) is formed at pH < 11, but is replaced by hydrocerussite ($Pb_3(OH)_2(CO_3)_2$) in the range 11 ≤ pH ≤ 13. Some hydrocerussite was also formed at pH = 10. Around pH = 12 to 13, traces of massicot/litharge (PbO) are observed, and traces of another phase, possibly $KOH{\cdot}2PbCO_3$ (8) are obtained around pH = 10 to 11. The same distribution of products is observed at more positive potentials around the current minimum after the main peak, i.e., in the potential range −0.600 to −0.450 V. Both hydrocerussite and cerussite predominate in the pH ranges within which they are the stable phases (7).

If the anodically formed films are stripped from the electrode

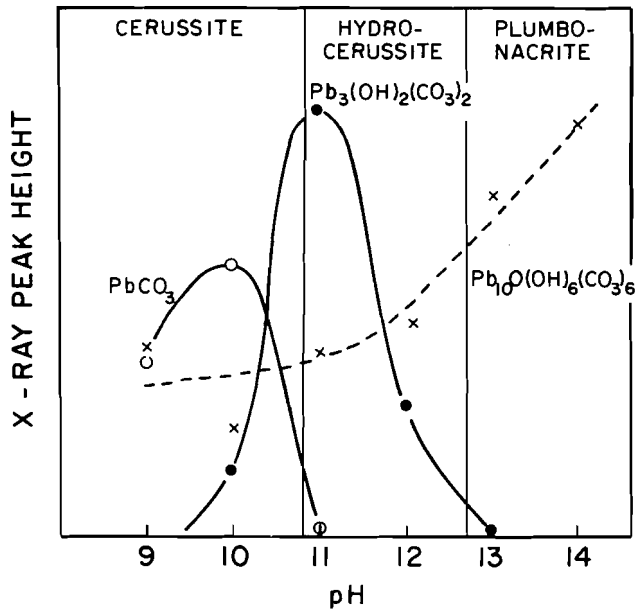

FIG. 4. Nature of the phases formed, determined from X-ray peak heights (6) as a function of pH after potentiostatic oxidation on the positive side of the main anodic peak (Fig. 1) for 60 min in 1.0 mol L^{-1} K_2CO_3; the vertical lines represent the stability boundaries between the basic lead carbonate phases.

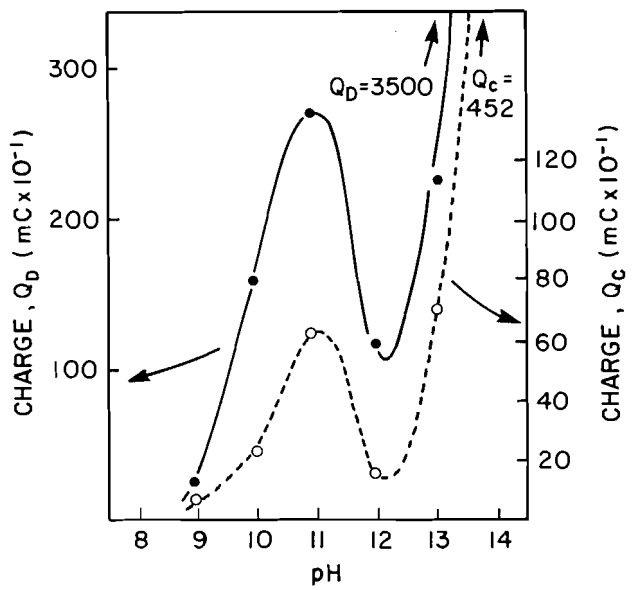

FIG. 5. The charge due to dissolution (Q_D) and the charge due to film formation (Q_C) as functions of potential for oxidation under the conditions given in the legend to Fig. 4. The Q_D and Q_C values noted on the figure are the respective values achieved at pH = 14.

surface by cathodic stripping voltammetry two cathodic reduction peaks are observed at all pH values below 13. The form of the cathodic stripping voltammograms (CSVs) is similar to the cathodic sections of the voltammograms obtained at pH = 12 (Fig. 1 of ref. 1) and is consistent with the voltammograms of Fig. 1, which show the reduction of both a base-layer (peak X) and a recrystallized layer (peak Y) at pH = 9.8, but only the reduction of a base-layer at pH = 13.9. Apparently no recrystallization is observed at pH $\geq$ 13, consistent with the rapid increase in lead solubility at pH values above 13 (see below).

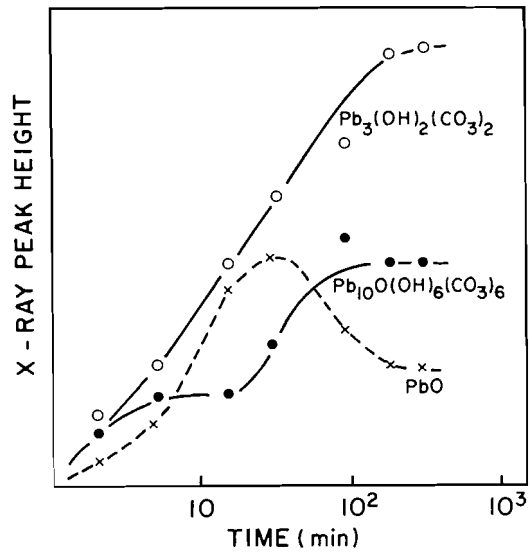

FIG. 6. Distribution of phases, expressed as X-ray peak heights (6), as a function of the duration of potentiostatic oxidation at 0 V in 1.0 mol L^{-1} K_2CO_3 at pH = 12.

This evidence confirms that plumbonacrite constitutes the base-layer over the whole pH range, and that it is formed via a solid-state reaction directly on the electrode but not by deposition from solution. When deposition occurs at pH < 13, it leads to the formation of hydrocerussite and/or cerussite.

Figure 5 shows the charge due to dissolution, Q_D, and the charge due to film formation, Q_C, for a one-hour oxidation at the same potentials used to record the data of Fig. 4. The value of Q_C was obtained by integration of the CSV recorded after completion of oxidation. The total anodic charge consumed, Q_A, was obtained by integration of the current recorded during oxidation, and Q_D is given by the difference, $Q_A - Q_C$. Both Q_D and Q_C possess a maximum around pH = 11, a minimum around pH = 12, and very large values at high pH.

At more positive potentials in the reactivation region, i.e., $E > -0.5$ V, more complex behaviour is observed. This is illustrated by the distribution of phases, as a function of the duration of oxidation at 0 V (pH = 12), shown in Fig. 6. Three phases are observed: plumbonacrite and hydrocerussite, which were observed at more negative potentials (6); and litharge (PbO), a phase not observed in significant amounts at lower potentials. After 16 h, hydrocerussite is the predominant phase. The formation of litharge is initially as extensive as hydrocerussite formation, but the amount present decreases after about 20 min. Plumbonacrite forms in two stages, the second stage coinciding with the disappearance of litharge.

Figure 7 shows the extent of plumbonacrite formation for three different potentials. The data for −0.720 and −0.640 V are taken from ref. 7, and for 0 V, from Fig. 6. The common curve for all three potentials at short times is consistent with the rapid formation of a plumbonacrite base-layer. The second stage of plumbonacrite formation observed at 0 V is distinct from this initial process, suggesting a different mechanism for its formation.

(c) Potentiostatic oxidation in the reactivation region

The current in the potential region positive to the main anodic peak (i.e., $E > -0.5$ V) is dependent on the electrode rotation speed, but independent of potential. This is demonstrated by the data of Figs. 8 and 9.

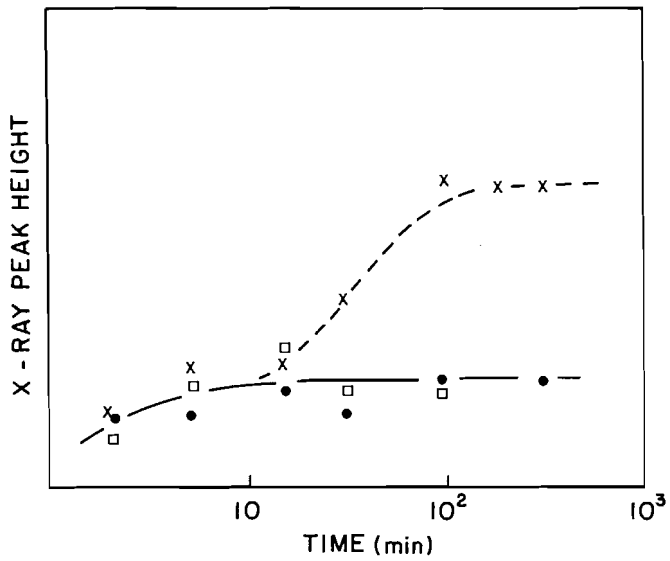

FIG. 7. The extent of plumbonacrite ($Pb_{10}O(OH)_6(CO_3)_6$) formation (as X-ray peak height) as a function of the duration of oxidation at three different poentials: ○, −0.726 V; □, −0.640 V; ×, 0 V.

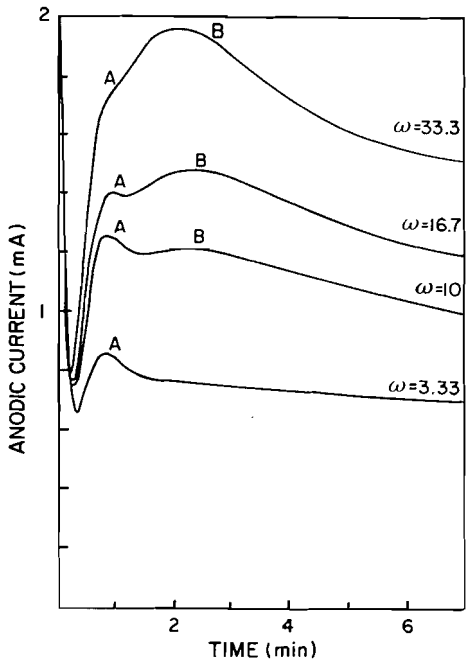

FIG. 8. Current–time plots recorded at a potential of −0.480 V in 1.0 mol L^{-1} K_2CO_3 (pH ~ 10) for various values of electrode rotation speed (ω).

Figure 8 shows a series of current–time curves recorded at $E = -0.480$ V, in 1.0 mol L^{-1} K_2CO_3 at a pH of 9.96, for various values of ω. The current for times < 20 s is large, but falls rapidly with time and is almost independent of the electrode rotation rate. This is consistent with the rapid growth of a base-layer on the electrode surface. No attempt was made to investigate the form of the current at such short times. At more negative potentials, $-0.740 \leq E \leq -0.700$ V, however, a peak is observed in the current transient, suggesting base-layer formation may be a nucleation and growth process.

For ω = 3.3 Hz, a peak (A in Fig. 8) is observed at $t \sim 60$ s; subsequently, the current falls slightly, eventually achieving a

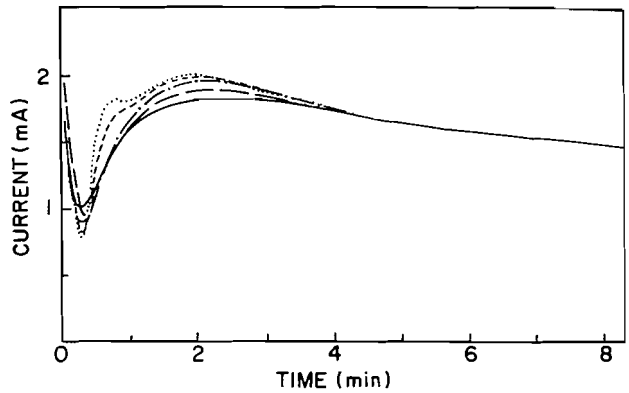

FIG. 9. Current–time plots recorded at ω = 33.3 Hz in 1.0 mol L^{-1} K_2CO_3 (pH ~ 10) for various values of potential in the reactivation region: —, −0.60 V; – –, −0.550 V; -·-·-, 0.525 V; ---, −0.48 V; ····, −0.46 V.

constant value for $t \geq 420$ s. The size and position of this peak are independent of ω. Peak A, however, is eventually swamped, at higher values of ω, by a second, much broader peak, B, as shown in Fig. 8. Peak A becomes sharper at more positive potentials, but is not observed at more negative potentials, Fig. 9. This behaviour is consistent with the nucleation and growth of a film for potentials greater than ~ −0.500 V. Peak B, however, is independent of potential (Fig. 9) as expected for a film breakdown process.

For all values of ω, the current eventually levels off at a constant value for $t > 420$ s, Fig. 9. These steady-state currents are plotted according to the Levich relationship for a system jointly controlled by transport and surface reaction kinetics (9, 10) in Fig. 10. These data confirm that the current in this potential region (-0.650 V $\leq E \leq -0.480$ V) is potential-independent but rotation-rate (ω) dependent. Similar data, exhibiting the same trends, were obtained for other pH values in the range $9 \leq$ pH ≤ 14. When the currents are compared at the same value of ω for various values of pH, a plot identical in form to that obtained voltammetrically for I_{PASS} (Fig. 2) is obtained.

Using the relationships developed previously (11) and estimating solubility values from the calculations of Taylor and Lopata (7), we can calculate a value for the average diffusion coefficient (D_{AVER}) for Pb^{2+} species from the slope of Fig. 10. If we assume that the deposited cerussite layer present at pH = 10, Fig. 4, controls the dissolution rate, we obtain a value for D_{AVER} of $\sim 4 \times 10^{-2}$ cm^2 s^{-1}. If we assume that an underlying base-layer of plumbonacrite or litharge controls dissolution, then a minimum value for D_{AVER} of $\sim 3 \times 10^{-4}$ cm^2 s^{-1} is obtained. Both these values are too large to be meaningful; the maximum expected value for solution-transport of dissolved Pb^{2+} species is $\sim 10^{-5}$ cm^2 s^{-1}. This suggests that dissolution in this region is not controlled by the solubility of the basic carbonate phases present on the electrode surface.

(d) Solubility and stability relationships

Figure 11 shows the computed equilibrium dissolved lead activities for the four individual phases observed on our electrodes, at a constant total carbonate activity of 1.0 mol L^{-1}. This figure was calculated from the thermodynamic data compilation of Taylor and Lopata (7), according to which the solution species $Pb(OH)_3^-$ and $Pb(CO_3)_2^{2-}$ dominate the solubility over the pH range $8 \leq$ pH ≤ 14 in 1 mol L^{-1} carbonate/bicarbonate solution.

Ferri *et al.* (12) have recently redetermined the speciation of

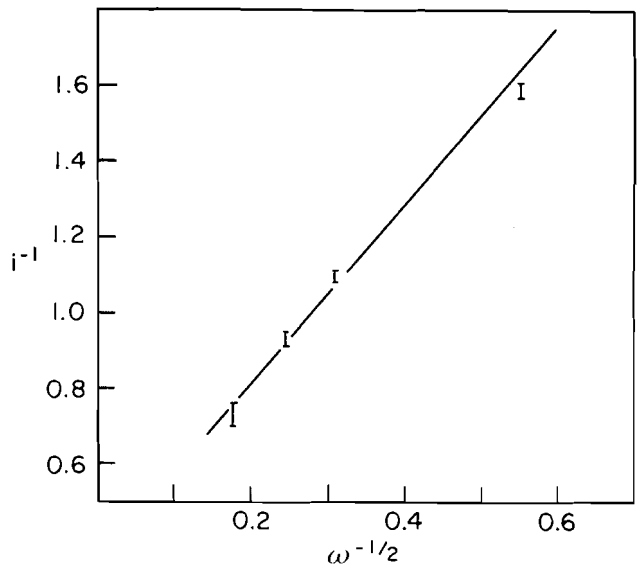

FIG. 10. Steady-state currents (i) under potentiostatic oxidation conditions as a function of electrode rotation rate (ω) plotted according to the Levich equation. Each data bar contains a data point for four different potentials in the range −0.650 V to −0.480 V in 1.0 mol L^{-1} K_2CO_3 (pH ~ 10).

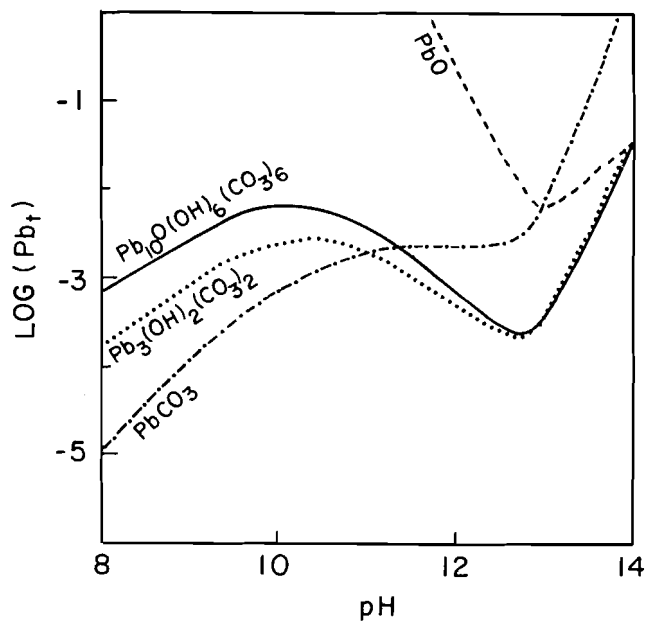

FIG. 11. Computed equilibrium dissolved lead activities, $\{Pb(CO_3)_2^{2-}\}$ + $\{Pb(OH)_3^-\}$, as a function of pH for the four phases shown, at a total dissolved carbonate activity of 1 mol L^{-1} (derived from ref. 7).

lead in alkaline carbonate solutions. Their stability constants for $Pb(CO_3)_2^{2-}$ and $Pb(OH)_3^-$ are in good agreement with earlier work (as summarized in ref. 7), but they detected an additional species, $Pb(OH)(CO_3)^-$. Their data were obtained at high ionic strength, and so are not readily incorporated into Fig. 11, which is based on Gibbs energies and refers to a hypothetical standard state of zero ionic strength. In 1 mol L^{-1} carbonate solution, $Pb(OH)(CO_3)^-$ is a major species only between pH 12 and 13, exceeding $Pb(OH)_3^-$ and $Pb(CO_3)_2^{2-}$ combined by no more than a factor of two (12). Its inclusion would therefore result in somewhat shallower minima in the dissolved lead activity curves for PbO and the basic lead carbonates, and a less pronounced inflection for $PbCO_3$, than in Fig. 11. The following discussion is based only on solubility trends, and so is not substantially affected.

Discussion

The voltammograms of Fig. 1 show that the anodic oxidation process can be divided into two distinct regions: (*i*) the main anodic oxidation region for $E \leq -0.5$ V; and (*ii*) a reactivation region at more positive potentials, where increased dissolution of the electrode occurs. The pH dependence of the current I_{PASS} (reactivation region), Fig. 2, has the same general form as the solubility curve, Fig. 11. The maximum in the value of I_{PEAK} (Fig. 2), however, does not coincide with that in the solubility curve. This indicates the value of I_{PEAK} is determined, at least in part, by processes other than dissolution. Potentiostatic transients recorded at potentials on the negative side of the main anodic peak have a form suggesting film formation by a nucleation and growth process. Consequently, it is possible that, under voltammetric conditions, the position and height of the main anodic peak (I_{PEAK}) is determined as much by film formation as by dissolution processes.

The distribution of phases with pH, Fig. 4, at potentials in the vicinity of the main anodic peak is similar to that predicted thermodynamically, and the extent of dissolution (Q_D, Fig. 5) varies with pH in a similar manner to the solubility, Fig. 11. Thus, we can claim that the dissolution rate in this potential region is directly proportional to the solubility of the predominant surface phase present. The similarity in Q_D (the extent of dissolution) and Q_C (the extent of film formation) as a function of pH shows that dissolution and film formation are directly related at a constant electrode rotation speed, i.e., under constant convective conditions. In the CSV obtained after potentiostatic oxidation both peak X, for the reduction of a base-layer, and peak Y for the reduction of a redeposited layer (see Fig. 1) are observed. The predominance of peak Y indicates that the majority of the film is present in the recrystallized form. Consequently, as the dissolution rate increases, the rate of redeposition/recrystallization back onto the electrode surface increases. As demonstrated previously at pH = 12, recrystallization competes with solution transport for the soluble Pb^{2+} species produced by dissolution. The extent of recrystallization decreases as the rate of transport of soluble Pb^{2+} species to the lead-free bulk of solution is increased by increases in electrode rotation rate.

The peak in the plot of Q_C versus pH (Fig. 5) coincides with the predominance of hydrocerussite ($Pb_3(OH)_2(CO_3)_2$) and/or cerussite ($PbCO_3$) on the electrode surface. Hence, we can conclude that both these phases are formed by recrystallization from solution. Film formation in this manner is more likely to yield the thermodynamically stable phase because its formation will be independent of the electrochemically applied field. It is not possible to decide which of these two phases forms directly from solution. The interconversion of these two phases has been shown to be fast and reversible (7). Consequently, our observation that the thermodynamically stable phase is present is not surprising.

For pH > 13, plumbonacrite is the thermodynamically stable phase, and the only phase observed experimentally. Its formation at lower pH values (8 to 13) and its identification with the base-layer reduction process are consistent with our claim in ref. 1 that plumbonacrite is formed directly on the electrode surface. It appears to be kinetically stabilized by the high rate of anodic formation of Pb^{2+} species. The potentiostatic transients indicate

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/07/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 196.1.178.254 on 09/07/12
For personal use only.

that its formation may be controlled by a nucleation and growth process. A similar mechanism of formation has been demonstrated for lead sulphate (13) and lead chloride (14) films. Plumbonacrite appears to be kinetically stabilized by the anodic injection of Pb^{2+} species from the underlying metal into the surface film.

It is interesting that at pH = 12 (6), the base-layer appears to possess a sandwich structure with hydrocerussite growing on top of an initially formed layer of plumbonacrite. This dual structure was explained on the basis of the close crystallographic relationship between these two phases which allows epitaxial growth of one phase on the other. Also, the curves of Fig. 11 show that, for pH $\geq$ 12, there is almost no difference in solubility between these two phases. For more alkaline pH values ($\geq$ 13), only plumbonacrite is formed, Fig. 4, despite the observed closeness in solubility, Fig. 11. This suggests that hydrocerussite formation is inhibited when the OH^-/CO_3^{2-} concentration ratio increases.

The potentiostatic transients of Fig. 8 show that the behaviour in the reactivation region is complex. The potential and electrode rotation rate dependencies of peaks A and B suggest that breakdown of the film grown at short times is accompanied by the formation of a further film (peak A) and the eventual establishment of a steady-state involving dissolution and continued recrystallization. The broad peak B can be attributed to film breakdown, leading to a surge in current due to dissolution. The slow decrease in current to an eventual steady-state after approximately 7 min can be attributed to further growth of the porous deposited layer. The data of Fig. 6 show that the additional film formed is litharge and the continued growth at longer times can be attributed to deposition of hydrocerussite from solution.

The formation of litharge could be explained as follows. When rupture of the initially formed plumbonacrite/hydrocerussite film occurs, presumably as a result of stress in this rapidly formed layer, the subsequent metal dissolution process will be extremely rapid. Hence, the local concentration of dissolved Pb^{2+} in the faults in the base-layer will be high. If the transport of CO_3^{2-} into the fault is limited, perhaps because of the presence of the upper-layer of hydrocerussite, then the carbonate concentration at the electrode surface will be much lower than the bulk concentration. If carbonate depletion is sufficiently large, then PbO could be stabilized with respect to plumbonacrite (7).

This explanation is supported by the voltammogram of Fig. 3, which shows a further stage of film formation at low carbonate concentrations. This film is reduced on the reverse cathodic scan before the main anodic film, Fig. 3*C*, indicating that it is formed under the basic lead carbonate layer. A similar peak was observed by Buchanan *et al.* (15) in borate solutions at pH = 9; and was attributed to the reduction of a tetragonal PbO (litharge) layer formed in the reactivation region. These authors confirmed their claim by photocurrent spectroscopy.

When litharge formation becomes extensive, Fig. 6, the outer areas of the film will be exposed to more concentrated carbonate solutions. Under these conditions, the oxide becomes unstable with respect to plumbonacrite and converts, at least partially, to the latter phase (see Fig. 6) as shown by Taylor and Lopata (7):

$$10PbO + 9H_2O + 6CO_3^{2-} \rightarrow Pb_{10}O(OH)_6(CO_3)_6 + 12OH^-$$

This reaction would explain the second stage of plumbonacrite formation only observed at very positive potentials, Fig. 6. This stage is distinct from the initial formation of this phase as a base-layer which occurs at all potentials over the range −0.726 to 0 V.

The analysis of the steady-state currents in the reactivation region shows that they are not proportional to the solubility of the phases present. The independence of the currents on potential, Fig. 9, suggests a constant field across the dissolving film. This is consistent with a film thickness (x) that increases with potential (E) and maintains the electric field ($\Delta E/\Delta x$) in the film constant. The dependence of the currents on electrode rotation rate confirms that transport processes are important. Reasonable values for the diffusion coefficient of Pb^{2+} species can only be obtained if we assume the surface films are more soluble than indicated by thermodynamic calculations. Such values can be explained by a dissolution process involving either (*a*) a field-assisted dissolution of the plumbonacrite (or litharge) base-layer or (*b*) metal dissolution through pores, or other faults, in the base-layer.

Fragmentation of alkoxide ions following collisional activation. An energy-resolved study

ROGER S. MERCER and ALEX G. HARRISON
Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received December 31, 1987[1]

ROGER S. MERCER and ALEX G. HARRISON. Can. J. Chem. **66**, 2947 (1988).

The collisionally activated dissociation reactions of the C_2 to C_5 alkoxide ions have been studied for collisons occurring at 8 keV kinetic energy and also over the range 5 to 100 eV kinetic energy. The alkoxide ions fragment by 1,2-elimination of H_2 and/or an alkane. Thus, primary alkoxide ions fragment by elimination of H_2 only, secondary alkoxide ions show elimination of H_2 and alkane molecules, while tertiary alkoxide ions show elimination of alkanes only. In alkane elimination, loss of CH_4 is much more facilie than loss of larger alkanes. For secondary alkoxide ions, where more than one elimination reaction occurs, the energy dependence of fragmentation has been explored over the collision energy range 5 to 100 eV. The results are interpreted in terms of a step-wise mechanism involving formation of an anion-carbonyl compound ion–dipole complex, followed by proton abstraction by the H^- or alkyl anion leading to the final products. The relative importance of the reaction channels is determined by the relative stabilities of these ion–dipole complexes.

ROGER S. MERCER et ALEX G. HARRISON. Can. J. Chem. **66**, 2947 (1988).

On a étudiée les réactions de dissociation des ions alcoolates C_2 à C_5 activées par des collisions se produisant à une énergie cinétique de 8 keV ainsi qu'à des énergies cinétiques allant de 5 à 100 eV. Les ions alcoolates se fragmentent par une élimination-1,2 de H_2 et/ou d'alcane. Ainsi, les ions alcoolates primaires se fragmentent uniquement par une élimination de H_2; par ailleurs, les ions alcoolates secondaires présentent de l'élimination de H_2 ainsi que celle de molécules d'alcanes alors que les ions alcoolates tertiaires ne présentent que de l'élimination d'alcanes. Lors de l'élimination d'alcanes, la perte de CH_4 est beaucoup plus facile que celle des alcanes plus volumineux. Dans le cas des alcoolates secondaires où il se produit plus d'une élimination, on a évalué la relation qui existe entre l'énergie de collision (de 5 à 100 eV) et le type de fragmentation. On interprète les résultats en fonction d'un mécanisme par étape impliquant la formation d'un complexe ion–dipôle d'un composé anion-carbonyle, suivie par l'enlèvement d'un proton par un H^- ou par un anion alkyle, conduisant aux produits. On a déterminé l'importance relative des diverses voies réactionnelles en se basant sur les stabilités relatives de ces complexes ion–dipôles.
[Traduit par la revue]

Introduction

Studies of the fragmentation of gaseous ions have long been invaluable sources of information concerning the structures and chemistry of such species (1, 2). This information is even more useful if the internal energy of the fragmenting ions is known and can be varied in a controlled fashion; such energy-resolved studies permit the establishment of break-down graphs expressing the variation of fragment ion yields with internal energy. Energy-resolved data for odd-electron molecular cations can be obtained with high precision by photoelectron/photoion coincidence (PEPICO) experiments (3–5) and, with reduced precision, by charge exchange experiments (6–8). Energy-resolved data, not restricted to molecular cations, also can be obtained from mass-resolved studies of the single-photon photodissociation of gaseous ions by varying the wavelength of the incident photons (9, 10). More qualitative data on the energy dependence of ionic fragmentation reactions can be obtained from energy-resolved (ERMS) collisional experiments (11–13), from angle-resolved (ARMS) collisional experiments (13, 14), and from field ionization kinetics (FIK) measurements (15, 16), the latter also being limited to odd-electron molecular cations. With this extensive armoury of techniques, the study of the energy dependence of the fragmentation of organic cations is a well-established field.

However, the same cannot be said for the study of the energy dependence of the fragmentation of organic anions. Techniques such as PEPICO and FIK are not applicable to anions, while charge exchange methods have not been developed. It should be possible to obtain energy-resolved data for anions by single-photon laser photodissociation experiments, however, such studies have not been reported. Angle-resolved collisional mass spectrometry (ARMS) requires specialized equipment not readily available; in addition, there have been some questions raised concerning the interpretation of the results (17, 18). Thus, the simplest, and most accessible, method of obtaining at least qualitative data on the energy dependence of the fragmentation reactions of gaseous anions appears to be low, variable collision energy collisional mass spectrometry (ERMS). In such studies the collision-induced dissociation (CID) mass spectra of the ions of interest are recorded as a function of collision energy over the range from ~2 to 100 or 200 eV. It is clear from positive ion studies that, at these low collision energies, the kinetic energy transformed into internal energy increases with increasing collision energy (13, 19–23), although the relationship between collision energy and mean internal energy is unknown and appears to vary from system to system and the kinetic to internal energy transfer appears to reach a maximum at higher collision energies (22, 23). A recent communication from this laboratory (24) has reported such an ERMS study for the fragmentation of a number of simple ester enolates and has compared the results obtained with the energy-resolved results obtained earlier (25), over the collision energy range 0 to 150 eV, using Fourier-transform mass spectrometric methods. The present paper reports an energy-resolved study of the collision-induced dissociation of simple alkoxide ions. Boand *et al* (26) have recorded the 8 keV CID mass spectra of a few alkoxide ions. They observed elimination of H_2 and/or small alkanes from the activated alkoxide ions; from limited isotopic labelling they concluded that specific 1,2-eliminations were responsible for the fragmentation reactions occurring. This conclusion is supported by the more recent isotopic labelling studies of Bowie and co-workers (27, 28) who also concluded, from *ab initio* calculations and a study of isotope effects, that the elimination reactions proceeded by a step-wise mechanism involving intermedi-

ate formation of a long-lived complex of H^-/CH_3^- and a carbonyl compound. The conclusions that the elimination reactions are specifically 1,2-eliminations and that they occur in a stepwise fashion are in agreement with the conclusions reached by Brauman and co-workers (29–31) from a study of the infrared multiphoton dissociation of a variety of alkoxide ions. Base on this evidence we have interpreted the results obtained in the present work for larger alkoxide ions in terms of specific 1,2-elimination reactions.

The multi-photon photodissociation experiments (29–31) explore threshold fragmentation reactions while our low energy collisional experiments explore higher energy fragmentation reactions as well, thus probing the energy dependence of possible competing fragmentation reactions. We also have determined the CID mass spectra following activation by 8 keV collisions; the comparison of the results obtained with the low energy CID mass spectra provides information on the relative internal energies achieved by the two methods of activation.

Experimental

Experiments were carried out using a VG Analytical ZAB-2FQ mass spectrometer, which has been described in detail previously (32). In brief, the ZAB-2FQ is of BEQQ geometry in which a reversed-geometry (BE) double-focussing mass spectrometer precedes a third stage consisting of a deceleration lens system, an r.f.-only quadrupole collision cell and a quadrupole mass analyzer. The instrument also contains a collision cell in the second field free region (between the magnetic and electric sectors) which allows high energy CID experiments to be carried out.

In all cases, the alkoxide ions were prepared by reaction of the appropriate alcohol with $[OH]^-$ in a chemical ionization source operating at 200°C. The $[OH]^-$ was produced by electron impact on a $10\%N_2O/90\%CH_4$ mixture at a pressure of $\sim 1.5 \times 10^{-5}$ Torr as read by an ionization gauge on the pumping line from the ion source region. The alcohols were commercial samples of high purity and were used as received. They were admitted through a heated capillary inlet system held at 130°C.

Low energy collisional experiments were performed by mass selecting the appropriate ion using the double focussing (BE) portion of the instrument, decelerating the ion beam from 8 keV to the desired collision energy (5–100 eV) and allowing the ion beam to undergo collision with N_2 gas in the r.f.-only quadrupole at a pressure $\sim 1.5 \times 10^{-7}$ Torr as indicated by the ionization gauge situated on the pumping line for the quadrupole region. Spectra were obtained as a function of collision energy by varying the potential of the r.f.-only quadrupole with respect to the ion source and scanning the analyzer quadrupole in a mass selective fashion.

For the high energy collisional experiments the ion of interest was selected by the magnetic sector and underwent collision, at 8 keV kinetic energy, with He in a collision cell located between the magnetic and electric sectors. The ionic fragmentation products were analyzed by their kinetic energy by scanning the voltage applied to the electric sector. The He pressure, as measured by an ionization gauge on the pumping lead for the region, was $\sim 1.5 \times 10^{-7}$ Torr, which gave ~50% attenuation of the main beam, although a significant part of this apparent reduction may correspond to collisional electron detachment.

Results and Discussion

Table 1 compares the CID mass spectra observed after collision with He at 8 keV collision energy and after collision with N_2 at 30 eV collision energy for the C_2 through C_5 alkoxide ions. With one exception, the primary alkoxide ions show only loss of H_2 in both the high and low energy CID mass spectra. The exception is *i*-butoxide (entry 5) where a minor loss of CH_4 is observed in the low energy CID mass spectra; Bowie and co-workers (28) also reported loss of H_2 and CH_4 from this alkoxide ion following 8 keV excitation, although the relative importance of the two reactions was not indicated. Fragmentation of the

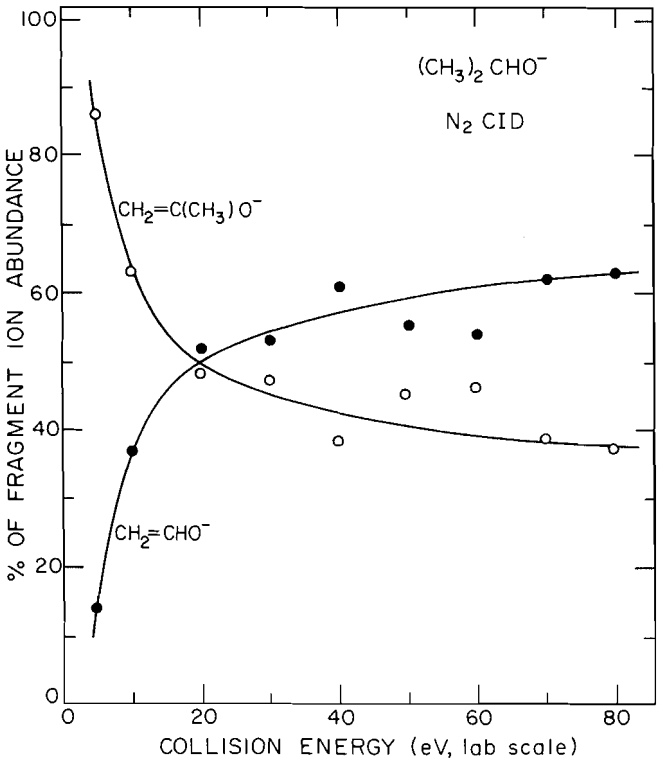

FIG. 1 Breakdown graph for *i*-propoxide (*m/z* 59).

$CH_3CD_2O^-$ anion resulted in elimination of HD only, in agreement with results of Hayes *et al.* (28) and with a specific 1,2-elimination reaction.

In contrast to the primary alkoxide ions, secondary alkoxide ions show more than one fragmentation pathway. The simplest of the secondary ions is isopropoxide (entry 3) which shows elimination of both H_2 and CH_4 in both the low energy and high energy CID mass spectra. These two fragmentation reactions were reported by Bowie and co-workers (28), although their relative importance was not indicated. They also reported that CD_3H was eliminated from $(CD_3)_2CHO^-$, a reaction inconsistent with the proposed 1,2-elimination. We observe elimination of CD_4 (and HD) from $(CD_3)_2CHO^-$, consistent with a specific 1,2-elimination reaction. In contrast with the collisional studies, Brauman and co-workers (30) have reported that the infrared multiphoton photodissociation of isopropoxide results in elimination of H_2 only. Figure 1 shows the dependence of fragmentation of isopropoxide ions on collision energy over the range 5 to 80 eV, laboratory scale. At the lowest collision energies elimination of H_2 is the dominant fragmentation reaction indicating that this reaction has the lower critical reaction energy and will be the channel observed when threshold reactions are probed by multiphoton activation. However, with increasing collision energy (and presumably, increasing energy deposition in the ion) elimination of CH_4 increases rapidly in importance up to ~40 eV collision energy beyond which there is little change in relative yields.

Scheme 1 summarizes the possible fragmentation reactions of the *i*-propoxide ion and gives for each possible set of products the enthalpy relative to the reactant ion. The scheme has been constructed on the basis of the step-wise mechanism proposed by Bowie and co-workers (27, 28) and Brauman and co-workers (29–31). Although the simple bond fission products (H^- and CH_3^-) were not observed they are included in this and following

schemes because they provide information relevant to the energies of the intermediate ion–dipole complexes. The necessary thermochemical data used in deriving the relative enthalpies in the schemes are summarized in Table 2. As shown in the scheme, elimination of CH_4 is the thermochemically favoured reaction (indeed it is essentially thermoneutral), however, both the present results and the earlier photo-dissociation results (30) indicate that elimination of H_2 is the favoured reaction energetically, presumably because the intermediate ion–dipole complex $[H^-\text{---}(CH_3)_2CO]$ is lower in energy than the ion–dipole complex $[CH_3^-\text{---}CH_3CHO]$ (the site of the negative charge in these complexes and those shown in later schemes is uncertain. The available evidence (28, 30) favours the structure shown). The stabilization of these complexes, relative to the separated products $H^- + (CH_3)_2CO$ and $CH_3^- + CH_3CHO$, should arise

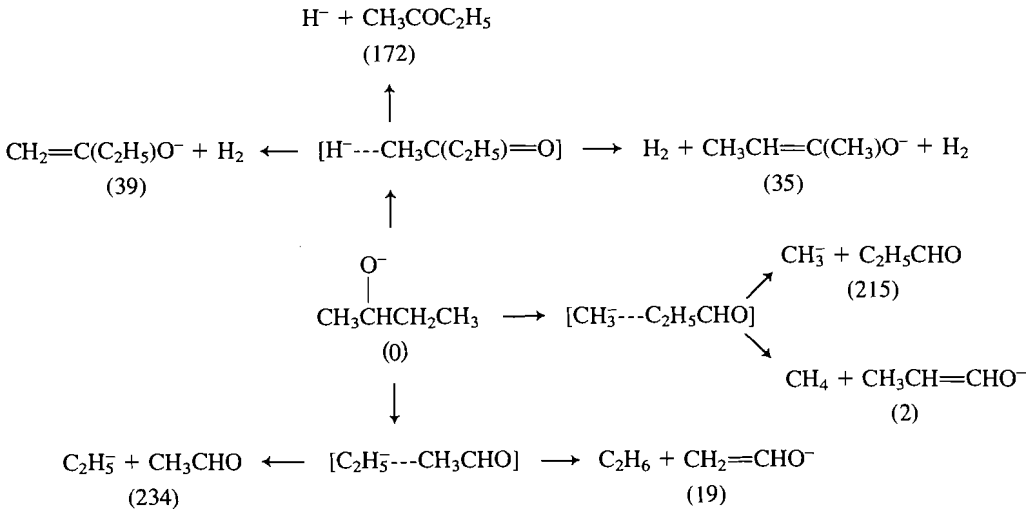

SCHEME 2

primarily from ion–dipole interactions and, since the dipole moments (33) of $(CH_3)_2CO$ (μ = 2.89 D) and CH_3CHO (μ = 2.72 D) are similar, the stabilization energies should be similar. (This should be true for all ion/dipole complexes discussed in this work since all the carbonyl compounds have similar dipole moments.) Thus, since H^- + $(CH_3)_2CO$ is lower in energy than CH_3^- + CH_3CHO, the [H^----$(CH_3)_2CO$] complex should be the lower energy ion–dipole complex. However, in view of the rapid rise in importance of the CH_4 elimination reaction with increasing collision energy, it appears that the critical energy for CH_4 elimination must be only slightly greater than that for H_2 elimination; in addition there may be entropic effects which favour CH_4 elimination.

The *s*-butoxide ion (entry 6) also fragments by more than one channel, exhibiting elimination of H_2, CH_4, and C_2H_6 in the low energy CID and the former two in the high energy CID. Boand *et al.* (26), in high energy CID experiments, have observed H_2, CH_4 and, in low yield, C_2H_6 elimination. Figure 2 shows the dependence of the fragmentation of *s*-butoxide on collision energy over the range 5–80 eV, while Scheme 2 presents a fragmentation scheme giving the enthalpy of products relative to the *s*-butoxide ion. Although elimination of H_2 is the least favourable reaction thermochemically, it clearly is the most favourable reaction energetically. Two H_2-elimination products are possible and are of similar final enthalpies; the present work provides no information on the relative importance of these two reactions. Although elimination of methane is an essentially thermoneutral reaction, the [CH_3^- --- C_2H_5CHO] complex is less stable than that leading to H_2 elimination and CH_4 elimination is less important than H_2 elimination at all collision energies; it is not clear why CH_4 elimination is not as important in this system as in the *i*-propoxide system. Elimination of C_2H_6 is of only minor importance at all collision energies despite the fact that the ΔH for the reaction is only ~19 kJ mol^{-1}. There is no reliable evidence that alkyl anions other than CH_3^- are stable gas phase species. Indeed DePuy and co-workers (34) have estimated a gas-phase acidity for C_2H_6 of 761 kJ mol^{-1}, which leads to an electron affinity of −37.7 kJ mol^{-1} for C_2H_5. For comparison, the electron affinity of CH_3 is 7.5 kJ mol^{-1} (35). Using the $\Delta H°$ acid for C_2H_6, the enthalpy of the hypothetical products [$C_2H_5^-$ + CH_3CHO] is calculated to be ~234 kJ mol^{-1} relative to the *s*-butoxide ion; thus, assuming equal ion–dipole stabilization in the intermediate complexes, the [$C_2H_5^-$---CH_3CHO] complex will be the highest in energy in agreement with the low yield of C_2H_6 + CH_2=CHO^-.

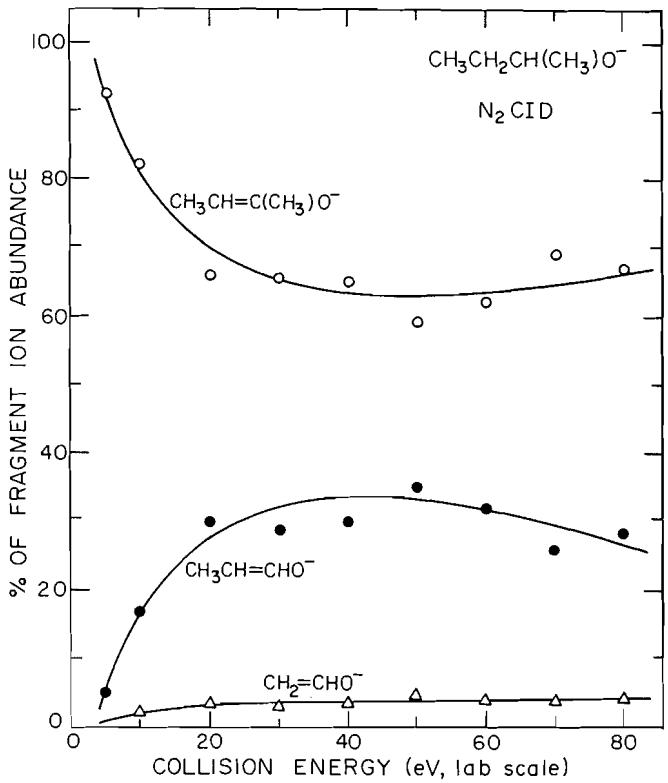

FIG. 2 Breakdown graph for *s*-butoxide (*m/z* 75).

The same arguments apply for the 3-pentoxide ion (entry 14, Table 1) where C_2H_6 elimination is of only minor importance relative to H_2 elimination over the entire collision energy regime (Fig. 3) even though elimination of C_2H_6 is the more favourable reaction thermochemically (Scheme 3). An interesting observation is the low yield of CH_2=CHO^- (*m/z* 43) at high collision energies corresponding to elimination of C_3H_8 from the 3-pentoxide ion.

Fragmentation of the 2-pentoxide anion (entry 11) involves elimination of H_2, CH_4 and, in low yield, C_3H_8; the breakdown

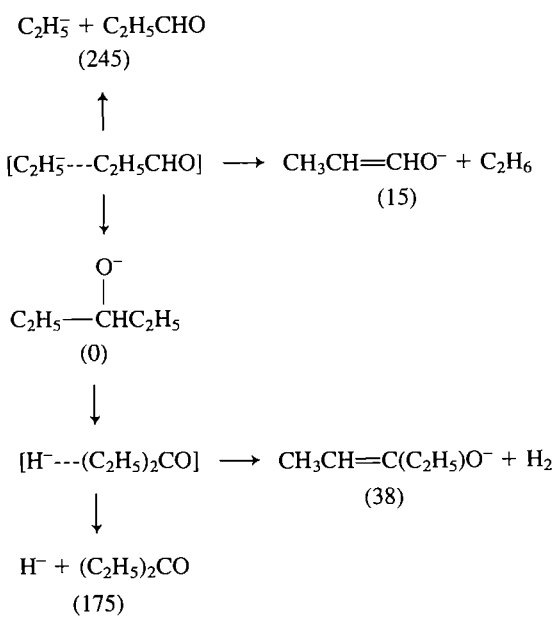

SCHEME 3

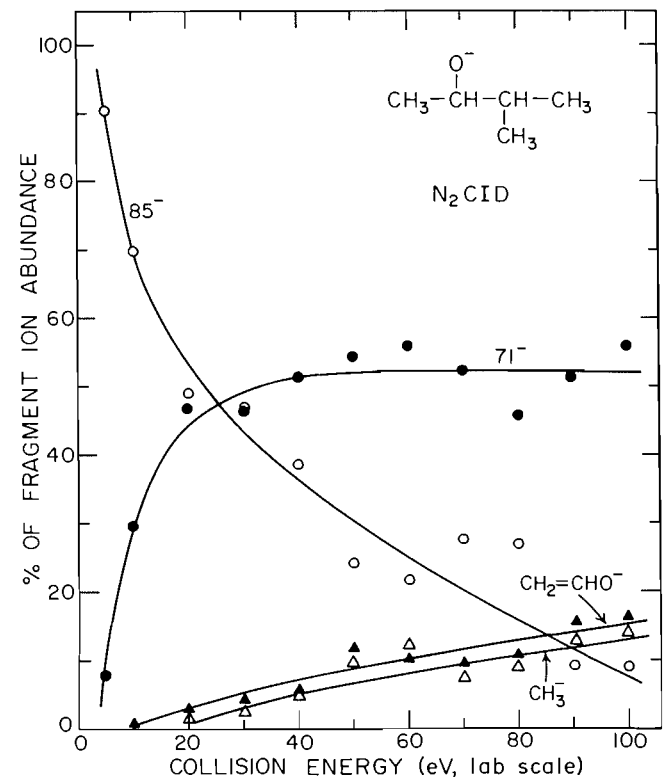

FIG. 5 Breakdown graph for 3-methyl-2-butoxide (*m/z* 87).

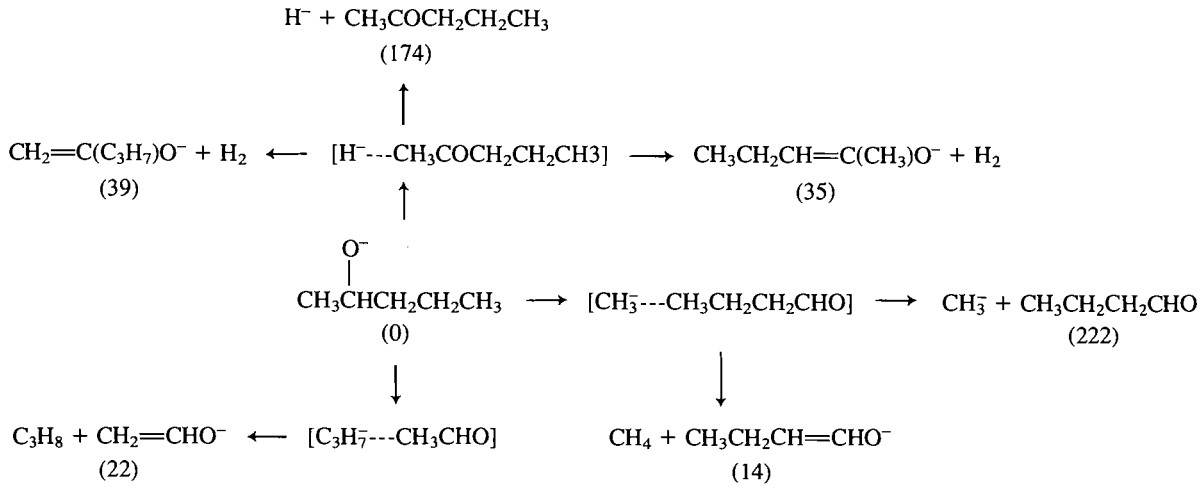
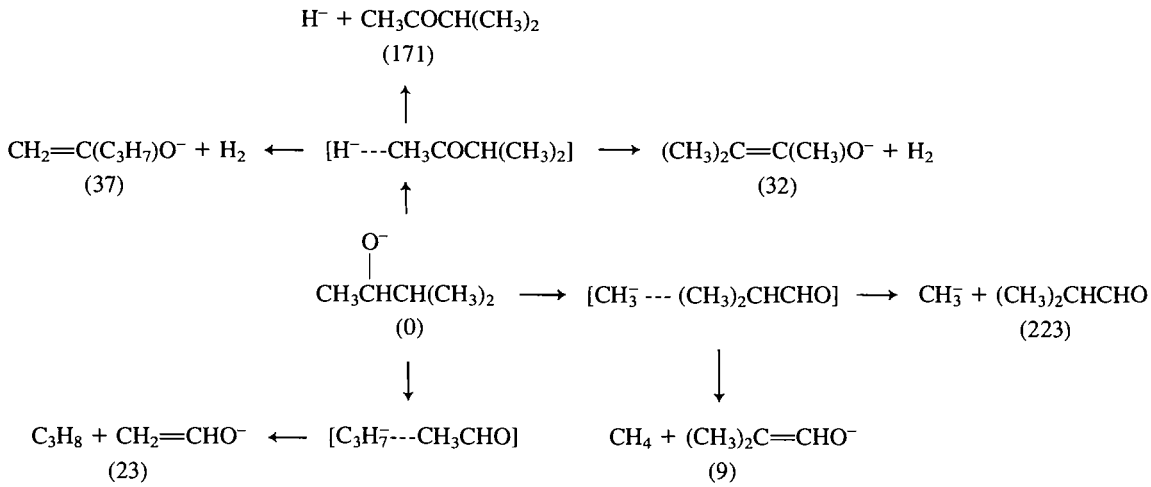
graph is shown in Fig. 4 while the thermochemical data are summarized in Scheme 4. Clearly elimination of H_2 is the favoured reaction at low internal energies and must have the lowest critical reaction energy even though it is the least favourable reaction thermochemically. This is in agreement with the expected energies of the intermediate ion–dipole complexes. By analogy with other alkyl anions (34) $(CH_3)_2CH^-$ is not expected to be stable and the intermediate $[(CH_3)_2CH^-$---$CH_3CHO]$ complex will be quite high in energy leading to only minor reaction by this mode. One should note that H_2 elimination can lead to two products of similar stability; the present work provides no information on the relative importance of these two channels (Scheme 5).

In contrast to the 2-pentoxide ion, collision-induced dissociation of the 3-methyl-2-butoxide ion (entry 12, Fig. 5) results in



SCHEME 4



SCHEME 5

much more significant elimination of CH_4 although elimination of H_2 is the favoured reaction at low internal energies. The increased importance of CH_4 elimination may result from the fact that the final step involves abstraction of a tertiary hydrogen; the *ab initio* calculations suggest (28) that either step may be rate determining. This is the only system where formation of CH_3^- is observed in significant yield. We do not believe that this product arises by primary fragmentation of the alkoxide ion, but rather that it arises by further fragmentation of the ion formed by H_2 elimination, viz.

The evidence, admittedly weak, for this proposal is the continual decrease in relative intensity of the *m/z* 85⁻ ion with increasing collision energy, in contrast to the other systems studied.

1,2-Elimination from tertiary alkoxide ions must result in alkane elimination. Thus as reported previously (28, 29, 31), *t*-butoxide (entry 7) eliminates CH_4, while the *t*-pentoxide ion (entry 13) shows elimination of CH_4 and, in minor yield, C_2H_6.

Comparison of the results in Table 1 for the 8 keV collision-induced dissociation reactions with the low energy CID results, particularly the breakdown graphs, leads to the conclusion that, on the whole, in the high energy system those ions which fragment to form detectable products are of lower internal energy than those fragmenting after 30 eV or higher energy collisions. Similar conclusions were reached in the study of ester enolate ions (24). It is likely that the alkoxide ions receiving higher internal energies in the 8 keV collisions suffer electron detachment since high energy collisional activation is believed (36) to involve electronic excitation.

A redetermination of the ultraviolet photoelectron spectrum of (*Z*)-2-methyl-1,3-pentadiene; evidence that twisted conformers predominate in the gas phase

NICK HENRY WERSTIUK AND GEORGE TIMMINS

Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received May 11, 1988

NICK HENRY WERSTIUK and GEORGE TIMMINS. Can. J. Chem. **66**, 2954 (1988).

A redetermination of the ultraviolet photoelectron spectrum of (*Z*)-2-methyl-1,3-pentadiene (**1***a*) has resulted in a correction of the spectrum published by Masclet and co-workers. MMX and AM1 calculations on **1***a* predict that twisted *s-cis* conformations should be populated preferentially in the gas phase; this is in keeping with the experimentally determined π_-, π_+ splitting of 1.55 ± 0.05 eV.

NICK HENRY WERSTIUK et GEORGE TIMMINS. Can. J. Chem. **66**, 2954 (1988).

On a redéterminé le spectre photoélectronique ultraviolet du méthyl-2 pentadiène-1,3-(*Z*) (**1***a*) et il en résulte que l'on doit corriger le spectre publié antérieurement par Masclet et ses collaborateurs. En se basant sur des calculs MMX et AM1 effectués sur la molécule **1***a*, on peut prédire que, en phase gazeuse, les conformations *s-cis* croisées sont privilégiées; ces prédictions sont en accord avec le couplage π_-, π_+ de 1,55 ± 0,05 eV qui a été déterminé expérimentalement.

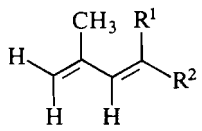
We have undertaken a systematic study of the effect of methyl and ethyl substituents on butadiene conformation by ultraviolet photoelectron spectroscopy (UPS) and the computational methods MMX and AM1. Our aim is to carry out conformational analysis of dienes computationally by calculating the heats of formation as a function of the 2—3—4—5 dihedral angle — we chose to use MMX and AM1 initially because of their ease of usage and the low computational costs — to calculate the π_-, π_+ splittings for the predicted preferred conformations and the *s-trans* planar conformers and to compare these values to the experimentally obtained splittings. Through such comparisons, we hope to establish whether or not a combination of UPS-AM1/MMX will be useful generally for studying conformational isomerism of alkyl-substituted polyenes in the gas phase. Since structure determines conformational behaviour, it may be possible also in certain cases to use this methodology to elucidate the structure of highly substituted dienes and polyenes. In this connection, when we reviewed the photoelectron (pe) spectroscopy of the pentadienes, we were surprised to find that Masclet and co-workers (1)[1] reported that the lowest three ionization energies of (*Z*)-2-methyl-1,3-pentadiene (**1***a*) and (*E*)-2-methyl-1,3-pentadiene (**1***b*) are identical within experimental error; this is not what would be expected on the basis of the results of MMX calculations.[2] Figures 1(*A*) and 1(*B*) show ΔH_f as a function of the C1—C2—C3—C4 dihedral angle calculated by MMX for **1***a* and **1***b*, respectively. AM1 yields similar data.[3] Both computational methods predict that the (*Z*)-diene should exist in twisted conformations in gas phase at ambient temperature. For this reason and the fact that there is renewed interest (3,4) in the conformation of dienes, a topic which occupied the attention of experimentalists and theoreticians for several decades,[4] we undertook to redetermine the pe spectra of **1***a* and **1***b*.



1

a, $R^1 = CH_3$; $R^2 = H$

b, $R^1 = H$; $R^2 = CH_3$

In addition to the MMX study,[5] which shows that planar *s-trans* **1***a* is 20 kJ higher in energy than *s-trans* **1***b* (Fig. 1), AM1 calculations also established that planar *s-trans* **1***b* is 12.5–16.5 kJ higher in energy than planar *s-trans* **1***b* depending on the conformations of the =CH—CH_3 units. This difference must be due mostly to a 1,3-CH_3,CH_3 steric interaction. On the assumption that $\Delta\Delta S \simeq 0$ for rotation about C2—C3, according to MMX twisted *s-cis* conformers should predominate over twisted *s-trans* conformers by approximately 4:1. Since the planar *s-trans* conformer is expected to be the stablest structure of (*E*)-isomer **1***b* — the results of MMX calculations summarized in Fig. 1(*B*) are in accord with this expectation — the spectra of **1***a* and **1***b* should be different; the π_-, π_+ splitting of (*Z*)-isomer **1***a* should be less than the splitting of (*E*)-isomer **1***b*.

[1]The authors reported only the three lowest ionization energies of **1***a* (8.43, 10.49, and 11.53 eV) and **1***b* (8.42, 10.46, and 11.50 eV).

[2]MMX, Version 87.200 of PCMODEL: A molecular mechanics package including MM2 (Allinger-QCPE 395), MMP1 Pi (Allinger-QCPE 318), MODEL parameters (Still) plus more atoms and constants by K.E. Gilbert and J.J. Gajewski, Indiana University. Available from Dr. K.E. Gilbert, Serena Software, P.O. Box 3096, Bloomington, IN, 47402.

[3]AM1 of AMPAC; Austin Method 1 Package (QCPE 506) (2).

[4]See ref. 3 for a comprehensive list of pertinent references.

[5]The C1—C2—C3—C4 dihedral angle was incremented and the geometry was optimized at each stage. The heats of formation were reproducible to ±0.4 kJ/mol regardless of the increment (15° or 30°) or the starting dihedral angle (0° or 180°). MMX87.200 predicts the difference in energy between planar *s-trans*-1,3-butadiene and the planar *s-cis* conformer (calcd. 10.0 kJ/mol, obsd. 10.4 to 12.9 kJ (5,6)) and the barrier to rotation (calcd. 24.4 kJ/mol, obsd. 16.3 to 19.6 kJ (5,6)) with better accuracy than AM1 (3.4 and 9.0 kJ, respectively).

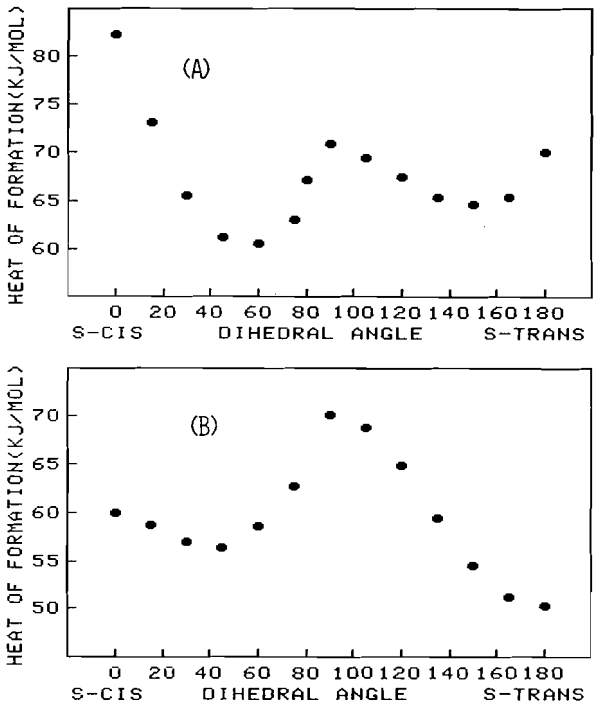

FIG. 1. Heat of formation (ΔH_f) as a function of C1—C2—C3—C4 dihedral angle: (*A*), **1***a*; (*B*), **1***b*.

Nevertheless, the pe spectrum of a sample of what supposedly was the (*Z*)-diene **1***a* obtained from Aldrich Chemical Co.,[6] did indeed exhibit bands at 8.42, 10.46, and 11.50 eV, identical within experimental error to the values for **1***a* and **1***b* reported by Mascalet and co-workers (1); however, the 500 MHz ^{1}H nmr spectrum of the major component of this commercial material[6] corresponded closely to the ^{1}H nmr spectrum of the (*E*)-diene. That the major component is, in fact, the (*E*)-isomer was established by the fact that it was photochemically isomerized to **1***a*, which turns out to be the *minor* component (~2%) of the commercial material.[6,7,8,9] Photoisomerization of (*E*)-dienes to (*Z*)-dienes is well documented in the literature (7). The correct pe spectra of the (*Z*)- and (*E*)-pentadienes **1***a* and **1***b* are given in Fig. 2(*A*) and 2(*B*), respectively. As expected (*vide supra*), the spectra are different; the MMX and AM1 predictions are supported by these experimental results. The difference between the maxima of the lowest ionization energy bands of **1***a* (8.65 ± 0.025 and 10.20 ± 0.025 eV) is 1.55 ± 0.05 eV. This splitting correlates well with the difference of 1.50 eV between the eigenvalues of π_- and π_+ calculated by AM1[10] for a *s-cis* conformer twisted by 40°. It should be pointed out that it is conceivable that MMX and AM1 overestimate the 1,3-CH_3,CH_3 steric interaction and underestimate the "resonance" stabilization; if this is the case, then twisted *s-trans* conformers would predominate. That the π_+, π_- splitting calculated by AM1 for a *s-trans* conformer twisted

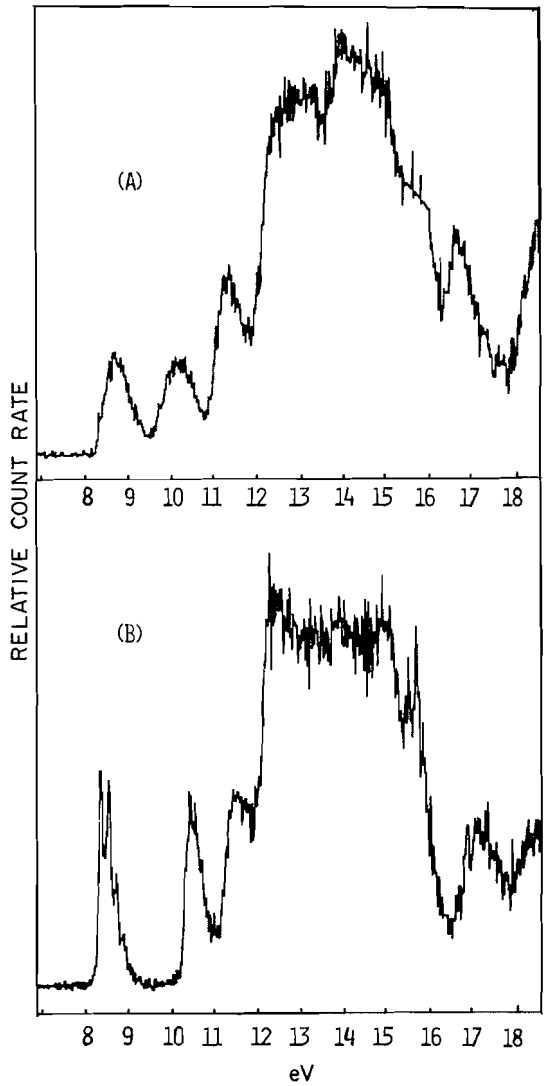

FIG. 2. Ultraviolet photoelectron spectra: (*A*), **1***a*; (*B*), **1***b*.

[6]The commercial sample was described as a mixture of 80% of (*Z*)-diene **1***a* and 20% of (*E*)-diene **1***b*. Analysis by gc at ambient temperature on a 1,2,3-tris (2-cyanoethoxy)propane (TCEP) column, known to be especially useful for separating alkenes, established that three components with relative retention times of 1:1.40:1.55 were present in a ratio of 1:39:10. The major components were isolated by preparative gc on a TECP column. High-field ^{1}H nmr spectroscopy along with analytical gc analysis on the TCEP column established that the dienes were >95% pure.

[7]The commercial sample was dissolved in pentane (0.1 *M*), containing acetophenone (0.01 *M*), the solution was degassed with nitrogen and photolyzed at 300 nm in a Rayonet reactor. After 9 h, the ratio of the areas of the three peaks corresponding to the starting components[4] was 1:1.84:0.87. The dienes were isolated by preparative gc on a TCEP column and shown to be >95% pure by analytical gc using a TCEP column and by high-field ^{1}H nmr. The component of lowest retention time is the (*Z*)-diene **1***a*. The component of longest retention time which was supposedly the (*E*)-diene was identified as 4-methyl-1, 3-pentadiene by its mass spectrum, its 500 MHz ^{1}H nmr spectrum, and by its pe spectrum. The component of intermediate retention time is **1***b*.

[8]We thank Dr. W. Leigh for suggesting photochemical isomerization of **1***b* as a route to **1***a*.

[9]We have notified Aldrich Chemical Co. of our findings.

[10]AM1 accurately predicts the splittings for planar *s-trans* dienes. The splittings (2.35, 2.53, 2.46, and 2.43 eV) calculated for (*Z*),(*Z*)-2,4-hexadiene, (*E*),(*E*)-2,4-hexadiene, (*E*),(*Z*)-2,4-hexadiene, and 2,5-dimethyl-2,4-hexadiene which are *s-trans* and planar, correlate very well with the experimental values (2.35, 2.47, 2.42, 2.46 eV) (1).

by 40° is similar to the splitting for the *s-cis* conformer twisted by 40° indicates that this possibility must be considered and eventually excluded. However, we presently favour our initial interpretation because MMX accurately predicts the barrier to rotation and the difference in energy between the planar *s-trans* and *s-cis* conformers of butadiene.[3] The π_-, π_+ ionization energy bands of **1***a* are broad, unlike the corresponding bands of **1***b*; this is in keeping with our view that a wider range of conformers (twisted *s-cis* and twisted *s-trans*) are populated at ambient temperature for **1***a* than for **1***b* as predicted by MMX and AM1. AM1 predicts a splitting of 2.14 eV for planar *s-trans*-**1***a*. A π_-, π_+ splitting of 2.04 eV for the (*E*)-isomer which turns out to be the major component of the commercial material is consistent with a planar *s-trans* structure; AM1 predicts a splitting of 2.09 eV for this conformer.

We will report on other examples of the application of UPS-AM1/MMX to the structure elucidation of alkyl-substituted dienes in the near future.

B. Mario Pinto, Blair D. Johnston, Raymond J. Batchelor, Frederick W. B. Einstein, and Ian D. Gay. Can. J. Chem. **66**, 2956 (1988).

The synthesis and characterization of the novel selenium coronands, 1,3,7,9-tetraselenacyclododecane **1***a*, 1,3,7,9,13,15-hexaselenacyclooctadecane **2***a*, the corresponding β-*gem*-dimethyl derivatives **1***b*, **2***b*, and 1,5,9,13-tetraselenacyclohexadecane **3**, and 1,5,9,13,17,21-hexaselenacyclotetracosane **4** are described. X-ray crystallographic analysis of **1***a* reveals three independent molecules that exist in two distinct conformations, one molecule having approximate two-fold symmetry together with two molecules (of similar conformation) each having crystallographic $\bar{1}$ symmetry. The conformations are denoted as [3333] or [66]. Whereas one resembles that of cyclododecane and tetrathia-12-crown-4 with respect to torsion angles, the other resembles that of tetraoxa-12-crown-4. The solid state CP-MAS ^{77}Se and ^{13}C nmr spectra are interpreted in light of the crystallographic information. Crystal structure: formula $Se_4C_8H_{16}$; fw = 428.05; monoclinic, $P2_1/c$; $Z = 8$; $a = 15.823(2)$ Å, $b = 5.534(1)$ Å, $c = 27.962(5)$ Å, $\beta = 92.26(1)°$; $V = 2446.6$ Å^3; $T = 200$ K; $R = 0.027$ for 2162 observed data ($I \geq 2.5\sigma(I)$).

B. Mario Pinto, Blair D. Johnston, Raymond J. Batchelor, Frederick W. B. Einstein et Ian D. Gay. Can. J. Chem. **66**, 2956 (1988).

On décrit la synthèse et la caractérisation de nouveaux coronands du sélénium, le tétraséléna-1,3,7,9 cyclododécane, **1***a*, l'hexaséléna-1,3,7,9,13,15 cyclooctadécane, **2***a*, et les dérivés correspondants portant des groupements *gem*-diméthyles en β, **1***b* et **2***b*, ainsi que le tétraséléna-1,5,9,13 cyclohexadécane, **3**, et l'hexaséléna-1,5,9,13,17,21 cyclotétracosane, **4**. Une analyse cristallographique à l'aide de rayons-X effectuée sur le composé **1***a* révèle que trois molécules indépendantes existent sous deux conformations distinctes, l'une possédant une symétrie approximativement binaire alors que les deux autres (de conformation semblable) possèdent une symétrie cristallographique de $\bar{1}$. On dénote les conformations par [3333] ou [66]. Alors que, par rapport aux angles de torsion, l'une ressemble à celle du cyclododécane et du tétrathia-12-couronne-4, l'autre ressemble à celle de la tétraoxa-12-couronne-4. A la lumière des informations cristallographiques, on peut facilement interpréter les spectres rmn CP-MAS à l'état solide du ^{77}Se et du ^{13}C. Structure cristalline: formule $Se_4C_8H_{16}$; MF = 428,05; monoclinique, $P2_1/c$; $Z = 8$; $a = 15,823(2)$ Å, $b = 5,534(1)$ Å, $c = 27,962(5)$ Å, $\beta = 92,26(1)°$; $V = 2446,6$ Å^3; $T = 200$ K; $R = 0,027$ pour 2162 données observées avec $I \geq 2.5\sigma(I)$.

[Traduit par la revue]

The study of synthetic ionophores such as crown ethers, coronands, cryptands, and podands is of current interest (1), both from a structural viewpoint as well as a means of modelling the more complex natural host–guest complexes present in antibiotics and membrane transport systems. While macrocyclic polyoxaethers (the crown ethers) have been extensively studied, and investigation of the corresponding polythiaethers is also well documented (2), extension of this type of chemistry to the corresponding third-row analogues is virtually unknown.[2] We now

Reaction of propane-1,3-bisselenolate **5** in liquid ammonia and THF with dibromomethane gave, in addition to 1,3-diselenane (10%), **1***a* (10%), and **2***a* (5%) as colorless solids, and similar treatment of 2,2-dimethylpropane-1,3-bisselenolate yielded crystalline **1***b* and **2***b*.[3] Extension of this approach to the preparation of coronands containing only three-carbon bridges was more successful.[4] Thus, treatment of **5** with 1,3-dibromopropane afforded, in one step, **3** (40%), **4** (15%), and 1,5-diselenacyclooctane **6** (17%).[3] The structures of **1**–**4** were deduced by mass spectrometry and by ^1H and ^{13}C nmr spectroscopy.[3,5]

Selenium coronands **1**–**4**, in addition to their potential as agents for complexing transition metals,[6] are interesting candidates for conformational analysis.[7] By way of example, we present herein the conformational analysis of **1***a* in the solid state. It is noteworthy that the solid state conformations of sulfur coronands show significant differences from those of their oxygen counterparts (7).

Interestingly, the structure of **1***a*[8] contains three crystallographically independent molecules that exist in two distinct conformations. Whereas ring A has no crystallographic symmetry but has an approximate two-fold axis normal to the molecular plane, rings B and C lie on centres of inversion and have similar conformations. Figure 1 illustrates the different ring types. Ring A has corners formed by two consecutive *gauche* torsion angles of the same sign as in cyclododecane (8) and 1,4,7,10-tetrathia-12-crown-4 **7** (7), and can be denoted as [3333] in Dale's notation (9). In contrast, ring B (and C) has two such torsional sequences at opposite corners (with C as the pivotal atom) while the remaining corners (with Se as the pivotal atom) are formed by consecutive *gauche* torsion angles of opposite sign as in 1,4,7,10-tetraoxa-12-crown-4 **8** (10), and is denoted as [66] in Dale's notation (9). An additional feature of interest in the conformations of **1***a* is the location of the selenium atoms at both side and corner positions of the quadrilateral. In contrast, the oxygen analog, 1,3,7,9-tetraoxacyclododecane, has been shown

[3]A complete set of data may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

[4]Similar attempts to synthesize two-carbon bridged analogues were totally unsuccessful, the reactions being complicated by the extrusion of ethylene.

[5]All compounds gave satisfactory combustion microanalysis (C, H) data. The actual structures were confirmed by simulation of the isotopic clusters for parent ions in the isobutane CI mass spectra.

[6]For the preparation of acyclic oligoselena ethers and their complexes with transition metals, see ref. 6.

[7]**1** and **2** contain an additional conformational feature of interest, the Se—CH_2—Se anomeric effect (Pinto *et al.* (13)).

by nmr spectroscopy to exist in solution preferentially in a [3333] conformation with the oxygen atoms occupying side positions across corners (11). The preference of the selenium atoms for the corner positions in **1***a* is similar to that of the sulfur atoms in **7** but contrasts with the preference of oxygen for the side positions in **8**.

The asymmetric unit of **1***a* is comprised of 8 Se and 16 C atoms. The solid state CP-MAS ^{77}Se nmr spectrum[3] consists of six resolved resonances (δ 209–130) of relative intensity 1:1:1:2:1:2, some of which exhibit Se–Se coupling. The linewidth of the peak at highest field is such that the individual unresolved resonances must be of considerably larger linewidth than the others. We note that Se(101) and Se(107) show the largest thermal motion, and assign the highest field peak to these atoms (12). The solid state CP-MAS ^{13}C nmr spectrum of **1***a*[3] is also consistent with the proposed structure. The resonances at δ 19.8, 17.6, and 11.2, of intensities 1:1:2, are assigned to the carbons of the four independent Se—CH_2—Se units. The high-field shifts appear to be characteristic of this structural unit (13). Structurally, each of these four atoms has one *gauche* and one *anti* Se—C*—Se—C arrangement, the atoms being distinguished by differences in the torsion angles. The angles for C*(102) and C*(108) are not significantly different, suggesting the assignment of the peak at δ 11.2 to these atoms. Finally, we note the implications of the magnitudes of the *gauche* torsion angles and the carbon chemical shifts in Se—C—Se units for the study of selenium anomeric interactions.

A study of thermodynamic acidities of carbon acids by AM1

NICK HENRY WERSTIUK
Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received May 17, 1988

NICK HENRY WERSTIUK. Can. J. Chem. **66**, 2958 (1988).

Monocyclic carbon acids **1–8** have been studied by the semiempirical computational method AM1 in an attempt to develop a methodology for estimating p*K*s. The results indicate that there is a good correlation between $[\Delta H_f(R^-) - \Delta H_f(R\text{-}H)]$ obtained computationally and the p*K*s measured in DMSO. The p*K*s of **9***a*, **9***b*, **10**, **11** (tetronic acid), and the dioxolane dione **12** are predicted on the basis of this correlation.

NICK HENRY WERSTIUK. Can. J. Chem. **66**, 2958 (1988).

Dans le but de développer une méthodologie appropriée à l'évaluation des p*K*, on a utilisé la méthode de calculs semi-empiriques AM1 pour étudier les acides carboniques monocycliques **1–8**. Les résultats indiquent qu'il existe une bonne corrélation entre la valeur $[\Delta H_f(R^-) - \Delta H_f(R\text{-}H)]$ obtenue par calculs et les valeurs de p*K* mesurés dans le DMSO. Utilisant cette corrélation, on a pu prédire correctement les valeurs des p*K* des composés **9***a*, **9***b*, **10**, **11** (acide tétronique) ainsi que de la dioxolanedione **12**.

Our interest in the synthesis and homoenolization of monoketones and diketones has led to a number of significant contributions to the area of carbanion chemistry (1–7). For studies of this type, it would be useful to have an economical, easy-to-use, graphics-based computational methodology to probe the thermodynamic acidities of carbon acids. This would greatly facilitate the design of unusually acidic polycyclic multicarbonyl compounds and their thione analogues. A combination of the MM2-based molecular modelling packages MACROMODEL (8) and MODEL (9) and the semiempirical computational package AMPAC (10, 11) meets these requirements. MACROMODEL and MODEL provide an interactive graphics environment to generate good input geometries for optimizations using the AM1 or MNDO Hamiltonian of AMPAC; MODEL also has the facility to interconvert MODEL and MACROMODEL geometry files, to generate input files for AMPAC, and to read geometries from AM1/MNDO output files. In principle then, fairly large molecules can be studied with minimum effort at a reasonable cost. The pKs of a wide range of carbon acids are documented in the chemical literature. This communication reports the results of an AM1 study of a series of monocyclic compounds **1**–**13**; Meldrum's acid (MDA) (**1**), which exhibits an enhanced acidity, has been the subject of a number of studies recently (12–14).

The enthalpy change for ionization of a carbon acid in the gas phase (eq. [1]) is given by eqs. [2] and [3].

[1] $\mathrm{R{-}H \rightarrow R^- + H^+}$

[2] $\Delta H = [\Delta H_f(R^-) + \Delta H_f(H^+)] - \Delta H_f(\text{R-H})$

[3] $\Delta H = [\Delta H_f(R^-) - \Delta H_f(\text{R-H})] + \Delta H_f(H^+)$

If a series of structurally similar substrates are studied, then $[\Delta H_f(R^-) - \Delta H_f(\text{R-H})]$ and ΔH should correlate with the solution pK of R-H if the entropy of ionization in solution (ΔS_i) and the degree of ion-pairing remain essentially constant through the series. $\Delta H_f(R^-)$ and $\Delta H_f(\text{R-H})$ (Table 1) were obtained computationally using AM1,[1] and $\Delta H_f(H^+)$ was taken as 364.2 kcal/mol, the sum of one half the H_2 bond energy and the hydrogen atom ionization energy. Figure 1 shows a plot of ΔH versus pK for the series **1**–**8** measured in DMSO (12). The correlation, which spans nearly 20 pK units, establishes that this methodology may be useful generally for estimating thermodynamic acidities. The equation[2] for this line (—) is given in eq. [4]. While the pKs as a whole deviate from the

[4] $\Delta H = 1.75\ \mathrm{p}K + 315.0$

least-squares line, the correlation (----) involving the cyclic lactones **1** (MDA), **2**, **3**, **4**, and **5** is excellent.

Based on the correlation developed herein, bis-lactone **9***a*, the unsubstituted analogue of MDA that could not be prepared by Arnett and Harrelson (12), should exhibit a pK of 5.8. This result provides support for Arnett's analysis that the enhanced

[b] See ref. 12.

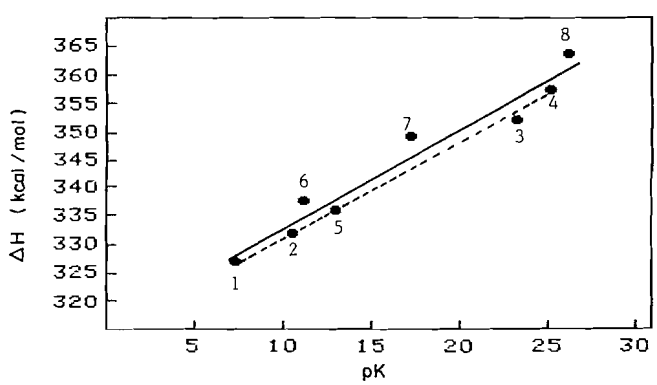

FIG. 1. Plot of ΔH versus pK of carbon acids **1**–**8**.

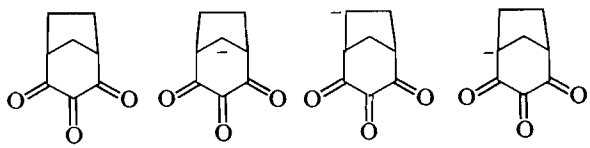
[1] All structures were generated using MACROMODEL and the geometries were optimized using the MM2 force field of this package. The MACROMODEL files were converted to MODEL files, which were used to generate the AMPAC input files. The geometries of the carbon acids and the corresponding anions were fully optimized using the AM1 Hamiltonian of AMPAC. All computations were carried out on a VAX 11/780 computer.

[2] The pK can be related to ΔG_i^0 ($\Delta G_i^0 = 2.303RT - (\mathrm{p}K + \log 14)$) according to the equation described by Arnett and Venkatasubramaniam (15).



13

ΔH_f(kcal/mol)	−92.5	−90.2	−83.4	−84.9

FIG. 2. ΔH_f of **13** and isomeric anions.

acidity of MDA—the stablest conformation is the boat—is not due to buttressing of the axial hydrogen at C5 by the axial methyl at C2. Furthermore, the seven-membered bis-lactone **9***b*, which also could not be prepared by Arnett (12), is predicted to have a pK of 7.7 in DMSO. According to MM2 of MACROMODEL and AM1, the stablest structure of **9***b* is a boat conformation. Bis-amide **10**, the diaza analogue of MDA, is predicted to have a pK of 15.7.

Based on a study of cyclopentanone, cyclopentane-1,3-dione, 2-methylcyclopentane-1,3-dione, 2-oxotetrahydrofuran (γ-butyrolactone), and tetrahydrofuran-2,4-dione (tetronic acid) (**11**), **11** is predicted to be more acidic (estimated $pK^{DMSO} = 5$) than MDA.[3] The accuracy of this value is established by the relative acidities of MDA and **11** in aqueous solution; MDA exhibits a pK of 4.83 (12) and **11** exhibits a pK of 3.76 (17). It is noteworthy that replacement of a *single* methylene of cyclopentane-1,3-dione by an oxygen yields a stronger acid than MDA. Perhaps this is an indication that additional factors, other than those already proposed (12–14), are important in determining the acidity of multicarbonyl heterocycles such as MDA. According to AM1, 1,2-dioxolone-3,5-dione (**12**) should be unusually acidic and should exhibit a pK of approximately −1.5; in this case the anion may be aromatic.

The results of a study of the isomeric anions derived from bicyclo[3.2.1]octane-2,3,4-trione (**13**) illustrate the potential utility of this methodology for studying homoenolizations. According to AM1 (the ΔH_fs are shown in Fig. 2), **13** should homoenolize faster at C8 than at C7. In fact, based on $[\Delta H_f(R^-) - \Delta H_f(R\text{-}H)]$, the p$K$ of **13** at C8 should be ~30.

AM1 studies of other series of carbon acids including hydrocarbons are planned. Tetronic acid (**11**), **12**, and the corresponding anions will be studied at the *ab initio* level to accurately determine the electron populations (18, 19) and the σ and π densities (20).

[3]Cyclopentanone (ΔH, 365.3; pK^{DMSO} = 25.6 (15)) and cyclopentane-1,3-dione (ΔH, 339.9; pK^{DMSO} = 10 estimated from the pK of 2-methylcyclopentane-1,3-dione (16)) were used as reference points for a plot for the 5-membered ring compounds. These points define a line that is parallel to the plot for the 6-membered ring series, but the intercept (323.6 kcal) is displaced upward by 8.6 kcal from the intercept (315.0 kcal) for the 6-membered ring series. An initial study of 1-methylcyclohexene, 1-methylcyclopentene, 1-methylcyclobutene, and the corresponding exocyclic isomers indicates that AM1 overestimates the strain in endocyclic cycloalkenes as ring size decreases. The upward displacement of the plot may be due to a computational differential destabilization of the 5-membered ring enolates. Using an intercept of 323.6 and a slope of 1.75, the pKs of γ-butyrolactone (ΔH, 360.1), **11** (ΔH, 332.3), and **12** (ΔH, 320.9) are predicted to be 20.8, 5.0, and −1.5, respectively.

The correspondence between Hückel theory and *ab initio* atomic charges in allyl ions

TOM S. SLEE[1] AND PRESTON J. MACDOUGALL[2]
Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received July 4, 1988

TOM S. SLEE and PRESTON J. MACDOUGALL. Can. J. Chem. **66**, 2961 (1988).

Atomic charges for the allyl cation and anion are reported, as defined by the quantum theory of atoms in molecules. An interesting feature of these charges is that they differ considerably from expectations based on simple π orbital models. The reasons for the difference are investigated and it is shown that the charges are both compatible with and understandable in terms of simple orbital models.

TOM S. SLEE et PRESTON J. MACDOUGALL. Can. J. Chem. **66**, 2961 (1988).

On rapporte les charges atomiques des cations allyles et des anions telles que définies par la théorie quantique des atomes dans les molécules. Une caractéristique intéressante de ces charges réside dans le fait qu'elles diffèrent considérablement des valeurs prévues à partir des modèles d'orbitale π simple. On étudie les raisons de cette différence et on montre que la nature des deux charges la justifie. Les modèles d'orbitale simple permettent de comprendre ce fait.

Atomic charges for the allyl cation and anion are reported, as defined by the quantum theory of atoms in molecules. An interesting feature of these charges is that they differ considerably from expectations based on simple π orbital models. The reasons for the difference are investigated and it is shown that the charges are both compatible with and understandable in terms of simple orbital models.

The theory of atoms in molecules defines an atom in a molecule from quantum mechanics (1), and has been recently reviewed (2). An atom is defined as the union of a nucleus and its basin. An atomic basin is just the region of space traversed by all paths of steepest ascent in the total charge density, which terminate at a given nucleus. Any two bonded atoms share, and are separated by, an interatomic surface. They are also linked by a ridge of charge density, or bond path, which exhibits a minimum at the point of intersection with the interatomic surface. This is called the bond critical point.

Integrations of the total charge density and the density of all π molecular orbitals (where molecular symmetry permits) over this basin yield average atomic electron populations, $N(A)$, and their π components, $N_\pi(A)$, respectively (3). Although the π component of an atom's average electron population is definable only within the context of molecular orbital theory (unlike the total population), it is found here to be extremely useful in establishing a correspondence between simple orbital models and the total charge distribution. The total charge on an atom is defined as $q(A) = Z(A) - N(A)$. The π charge on a formally sp^2 carbon is defined as $q_\pi(A) = 1 - N_\pi(A)$, to correspond with the Hückel model.

The total charges and π charges for the allyl cation and anion are shown in Table 1, along with the positions of the bond critical points. The charges are obtained using a 6-31G** basis set (4) augmented by diffuse *s* and *p* functions on carbon, which provides a good description of the electron distribution in such systems (5). Predictions made on the basis of the Hückel model are in remarkable agreement with the π charges in these systems, with the terminal CH_2 groups each having a π charge of +0.50 in the cation and −0.53 in the anion. The total atomic charges illustrate the consequences of the Hückel model's neglecting the σ orbital contributions to the atomic charge.

The relationship between π charges and total charges can be qualitatively understood using an approach described in detail elsewhere (6). Perturbations of electron distributions affect the charges of atoms in two ways (to first order). The "basin" contribution is the change in the density evaluated over the volume of the *unperturbed* atom, while the "surface" contribution arises from the change in volume of the atom as it is perturbed, and can be approximated by the product of the total charge in the surface $N(S)$ and the distance through which the bond point moves, δx_c.

$$[1] \quad \delta N(A) = \delta N(A^0) + N(S)\delta x_c$$

Changes in the π distribution contribute directly to the change in the total population only through the basin term. The surface term is determined by the bond point position, which in turn is dictated by the σ density (7). It is this surface term which is largely responsible for the discrepancy between the π and total atomic charges.

The large π charge on the terminal CH_2 groups in the allyl cation will increase their electronegativity, and hence they will withdraw σ electrons from the central CH group. The polarisation of the CC σ bond produces a large shift in the bond point position towards the central carbon atom, and so the surface contribution to the net change in population is substantial. Thus, the *total* charge on the terminal CH_2 groups will be considerably more negative than π orbital models predict, and the total charge on the central CH group will be correspondingly more positive. Table 1 verifies these predictions. The total charges in the allyl anion can be explained in exactly the same manner, although the simple Hückel model does not predict the slight positive π charge on the central CH group.

The charges on the formally positive carbons of simple alkyl cations can be explained in an identical manner to the allyl ions, and are reported in Table 2 (8). Simple orbital models correctly predict that in the methyl cation the central carbon will have a π charge of +1.0, and that as hydrogens are replaced by methyl groups this positive π charge will decrease in magnitude. The total charge on the formally positive carbon is determined partly by the π contribution, but also by the changes induced in the σ distribution (partially due to the electronegativity difference between sp^2 and sp^3 carbons in this case) which modify the positions of the bond points. The slightly non-planar CH_2 group in the ethyl cation leads to a contamination of the "π" orbital,

and a consequent uncertainty in the value of the "π" charge in this group. All other species are planar around the central carbon.

The quantum theory of atoms in molecules also allows the calculation of π charges and total charges in heteroatomic systems. For example, in difluoromethylene (singlet) the π population on carbon is 0.152, and the total charge is +1.552, showing that the inductive electron withdrawing effect of fluorine far outweighs its weak π donating ability (9). The greater π donating ability of the amino group compared to fluorine is shown by the π population of 0.232 on the carbon in aminomethylene (singlet). The weaker inductive electron withdrawing ability is reflected in the total charge on the amino group, which is −0.598.

In conclusion, it has been shown that the apparently counter-intuitive total atomic charges in allyl ions and other related systems are understandable in terms of simple orbital models, as long as the correspondence between the two is treated properly. The verification of Hückel theory expectations by *ab initio* π orbital charges emphasises the importance of the σ framework in determining the total atomic charges in unsaturated hydrocarbons (7).

Phosphoranylation de polyols : Voie d'accès aux phosphates d'intérêt biologique. I. Cas du myo-inositol

BRIGITTE DUTHU, DOURAID HOUALLA[1] ET ROBERT WOLF

Université Paul Sabatier de Toulouse, Unité associée au Centre national de la recherche scientifique n° 454, 118 route de Narbonne, 31062 Toulouse CEDEX, France

Reçu le 26 janvier 1988

BRIGITTE DUTHU, DOURAID HOUALLA et ROBERT WOLF. Can. J. Chem. **66**, 2965 (1988).

Nous décrivons une méthode originale de phosphorylation du myo-inositol non protégé, qui fournit plusieurs myo-inositol phosphates à la fois. Le schéma réactionnel comporte une phosphoranylation totale ou partielle du cyclitol, à l'aide de l'aminobicyclophosphane **8**, suivie d'une oxydation des bicyclophosphoranes à liaison P—H obtenus et d'une hydrolyse acide des phosphates neutres qui en résultent. Dans le cas de la tris-phosphoranylation nous avons identifié, parmi les fractions séparées par HPLC, le myo-inositol-1,2(cycl) phosphate **22**, le myo-inositol-1 phosphate **23** et le myo-inositol-2 phosphate **24**.

BRIGITTE DUTHU, DOURAID HOUALLA, and ROBERT WOLF. Can. J. Chem. **66**, 2965 (1988).

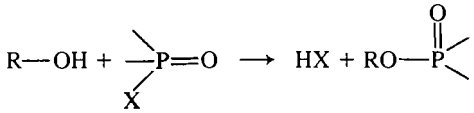
An original method for the phosphorylation of an unprotected myo-inositol is described, which yields several myo-inositol phosphates at the same time. The reaction proceeds via a partial or complete phosphoranylation of the cyclitol by means of the aminobicyclophosphane **8**, followed by oxidation of the resulting bicyclophosphoranes bearing a P—H bond and acid hydrolysis of the neutral phosphates thus formed. In the case of the tris-phosphoranylation we identified, among the HPLC fractions, the myo-inositol-1,2-(cycl)phosphate **22**, the myo-inositol-1-phosphate **23**, and the myo-inositol-2-phosphate **24**.

Introduction

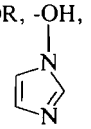
Des polynucléotides aux phospholipides, les constituants et métabolites du système biologique que l'on peut considérer comme des phosphates de polyols se comptent par centaines, ce qui explique l'intérêt que les chimistes et biochimistes portent au problème de la phosphorylation des polyols.

Schématiquement la phosphorylation d'un alcool a été réalisée jusqu'à présent essentiellement par deux voies :

1. Voie de Khorana et coll. (1) : Action d'un dérivé du phosphore tétracoordonné possédant déjà le groupement phosphoryle P=O :

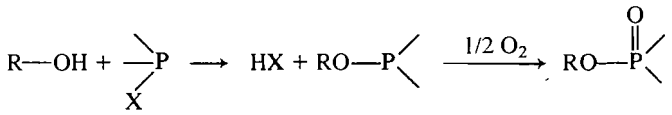


X étant un groupement nucléofuge: Cl, OR, -OH, $(RO)_2P(O)$



etc. ...

2. Voie de Caruthers (2) : Action d'un dérivé du phosphore tricoordonné, suivie d'une oxydation :



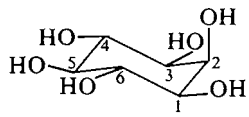
X = Cl, NR_2, RC(O)O-

Les phosphates biologiquement intéressants sont des monoesters ou diesters auxquels on accède par hydrolyse des phosphates neutres obtenus par ces deux procédés.

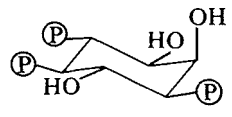
Appliquées aux polyols, chacune de ces deux méthodes a ses avantages et inconvénients.

Le myo-inositol **1** voit son intérêt renouvelé depuis la mise en évidence du rôle du D-myo-inositol-1,4,5 tris-phosphate **2** et d'autres myo-inositol phosphates, comme les dérivés **3** et **4**, dans le mécanisme de régulation du calcium intracellulaire (3–5).

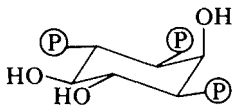
1. Auteur à qui adresser toute correspondance.



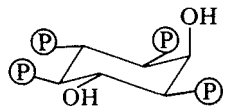
1



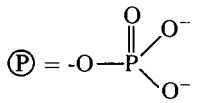
2



3



4



Le D-myo-inositol-1,4,5 tris-phosphate, ainsi qu'un certain nombre de myo-inositol phosphates, sont extraits du cerveau de bovins par voie enzymatique (6). Quelques-uns sont disponibles, depuis peu, dans le commerce à des prix forts élevés (7). La synthèse chimique de tels composés en fournissant des quantités relativement importantes de produits et surtout en permettant l'accès à des dérivés marqués ou modifiés, revêt par conséquent une importance considérable. Une dizaine de synthèses ont été décrites récemment. Elles nécessitent toutes l'obtention préalable du myo-inositol protégé, optiquement actif ou non, la phosphorylation étant faite soit par la méthode de Khorana (8–12) soit par celle de Caruthers (13–17).

Nous décrivons une méthode originale et générale de phosphorylation des polyols, appliquée à l'obtention de différents phosphates de myo-inositol. Elle s'appuie sur l'aptitude exceptionnelle des bicyclophosphanes **5**[2] à additionner les alcools pour donner des alcoxybicyclophosphoranes à liaison P—H stables **6** (18) :

2. La nomenclature de ces composés est la suivante : **5**, 2,8-dioxa 5-aza 1-phospha^{III} bicyclo[3,3,0]octane; **6**, 1-alcoxy 2,8-dioxa 5-aza 1-phospha^{V} bicyclo[3,3,0]octane. Pour des raisons de commodité, nous les appellerons bicyclophosphanes pour **5** et bicyclophosphoranes pour **6**.

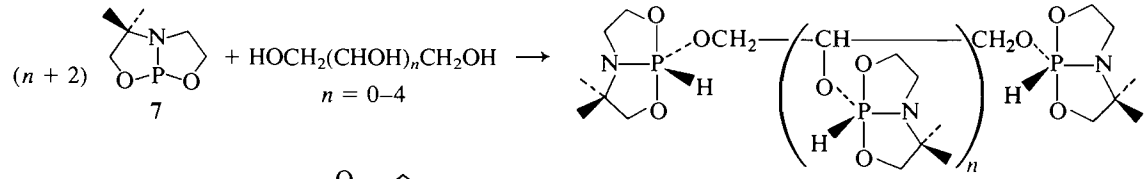
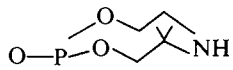
5 6



7 6′



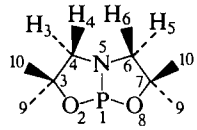
6″

Nous avons montré avec une série d'alditols (HO—CH_2—(CHOH)$_n$—CH_2OH (n = 0, 1, 2, 3, 4)) qu'on peut facilement introduire autant de groupes bicyclophosphoranes qu'il y a de fonctions alcool dans le polyol et que les per-bicyclophosphoranes **6′** obtenus sont en équilibre avec des entités dans lesquelles le groupe phosphorane est passé sous sa forme tautomère phosphite **6″** (19).

Nous nous sommes alors attachés à réaliser la phosphorylation du myo-inositol sans protection préalable, en effectuant une phosphoranylation totale ou partielle de ce dernier, suivie d'une oxydation des bicyclophosphoranes obtenus et d'une hydrolyse acide des esters neutres qui en résultent. Les produits de la réaction sont séparés par HPLC.

Résultats et discussion

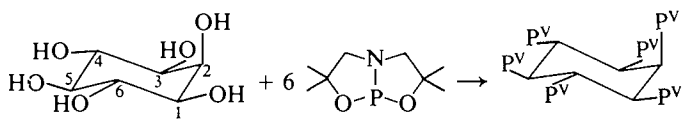
Ces expériences ont été conduites avec, comme agent de phosphoranylation, le bicyclophosphane **8** qui se distingue de son analogue **7** par la présence de deux substituants CH_3 sur chacun des carbones 3 et 7 au lieu de deux groupes CH_3 sur le seul carbone 6. L'intérêt de cette substitution apparaîtra par la suite.



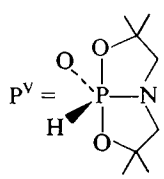
8

1. Per-phosphoranylation

La per-phosphoranylation du myo-inositol a été effectuée soit dans le toluène (phase hétérogène), soit dans le diméthyl sulfoxyde (DMSO) (phase homogène).



1 8 9



Elle nécessite 6–14 h de chauffage à 80°C dans le premier cas, 1/2 h d'agitation à la température ambiante dans le second.

En outre, nous avons vérifié à l'aide de la RMN ^{31}P que dans ces conditions le DMSO n'oxyde pas les dérivés phosphorés obtenus (20).

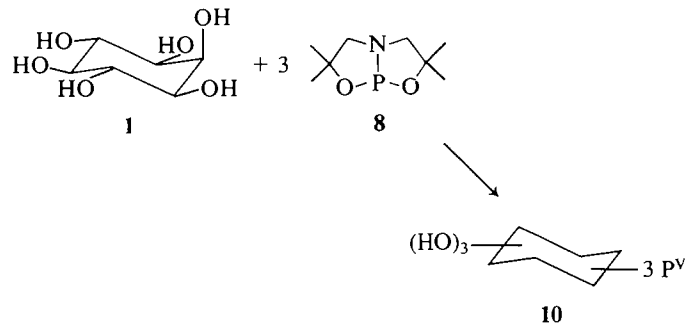
La formation du per-phosphorane **9** est attestée par (*i*) la disparition, dans le spectre de RMN ^{31}P du mélange réactionnel, du singulet correspondant au bicyclophosphane **8** (δ = 163 ppm) et son remplacement par un ensemble de doublets entre −38 et −46 ppm avec un couplage $^1J_{P-H}$ de l'ordre de 800 Hz (figure 1); (*ii*) l'absence dans le spectre infrarouge de toute absorption de vibration OH; (*iii*) la présence dans le spectre de masse (désorption de champ) d'un pic à M^+ = 1314, correspondant à l'addition de 6 molécules de bicyclophosphane **8** (masse moléculaire = 189) sur le myo-inositol.

Du point de vue stéréochimique, la présence dans le myo-inositol d'un plan de symétrie passant par les carbones C_2 et C_5 se traduit par l'existence dans le per-phosphorane **9** de quatre sites de phosphoranylation différents (P_1 P_3), P_2, (P_4 P_6) et P_5. En fait, le spectre de RMN ^{31}P comporte au moins cinq pics identifiables au lieu des quatre attendus (figure 1). Cela traduit l'existence d'équilibres tautomères phosphorane–phosphite, comparable à ce qui a été observé avec les polyols linéaires (19) et qui donne ipso-facto des phosphoranes originaux. On détecte dans le spectre du produit **9** (figure 1) un signal peu intense (inférieur à 10%), situé à 134 ppm, qui correspond à la résonance du noyau de phosphore des phosphites (21). La formation de ces phosphites est également attestée par la présence dans le spectre infrarouge de deux absorptions à 3235 cm^{-1} et 3450 cm^{-1}, attributables à ν_{N-H} associé et ν_{N-H} libre.

2. Phosphoranylation partielle

Comme exemple de phosphoranylation partielle du myo-inositol, nous avons choisi la tris-phosphoranylation. Celle-ci a été réalisée de deux manières :

1. Action du bicyclophosphane **8** sur le myo-inositol en solution dans le DMSO. À la fin de la réaction le spectre de



1 8 10

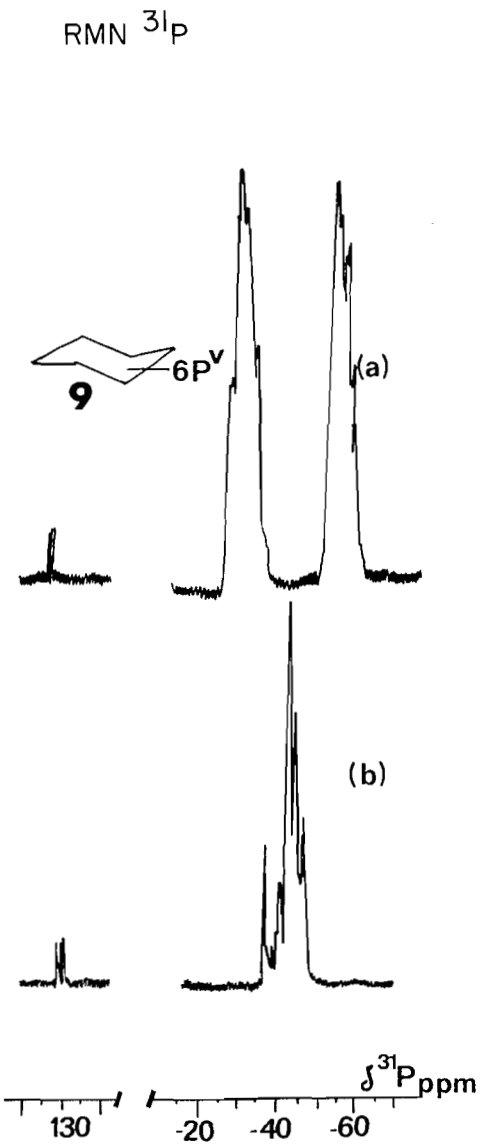

FIG. 1. Spectre de RMN ^{31}P, (a) proton non découplé; (b) proton découplé du per-phosphorane de myo-inositol **9**.

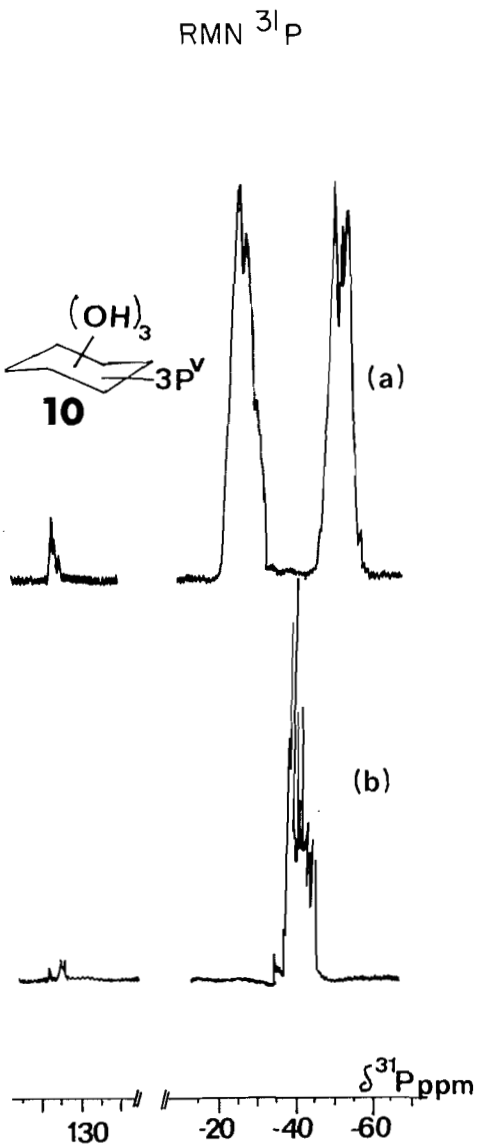

FIG. 2. Spectre de RMN ^{31}P, (a) proton non découplé; (b) proton découplé du myo-inositol tris-phosphorane **10**.

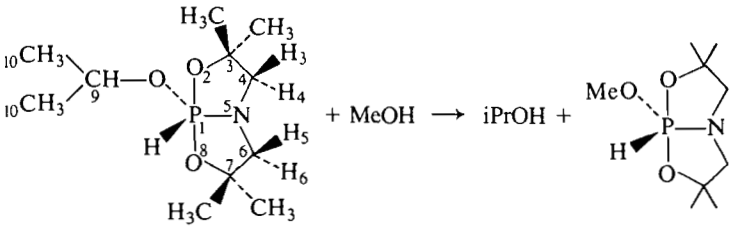
RMN ^{31}P comporte à -40 ppm un ensemble de doublets ($^1J_{P-H}$ = 815 Hz) qui, par irradiation du proton, donnent naissance à 16 pics identifiables. Notons là également, la présence d'un signal peu intense (~10%) à 134 ppm, attribuable aux phosphites tautomères (figure 2).

La complexité de ce spectre s'explique par des considérations stéréochimiques. La fixation de trois atomes de phosphore sur le myo-inositol donne naissance à 12 stéréoisomères identifiables par RMN qui comportent 32 noyaux de phosphore différents. Ce nombre peut encore être augmenté par la présence de phosphites tautomères. Bien plus, on ne peut exclure dans cette réaction la formation d'entités correspondant à la fixation d'un nombre d'atomes de phosphore différent de 3 (1, 2, 4, 5, 6) ce qui ajoute à la complexité du spectre.

2. Méthanolyse du per-phosphorane **9**. En effet, nous avons préalablement montré que l'action du méthanol sur l'isopropyl-



11

20

$\delta^{31}P = 51{,}0$ ppm

lophosphane à se fixer sur le myo-inositol et à en être retiré lui confère des caractéristiques d'un bon groupement protecteur.

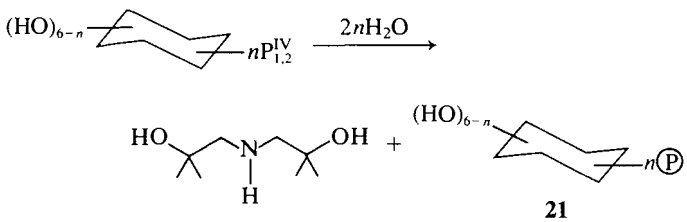
3. Oxydation – sulfuration

L'oxydation par le tertiobutylhydroperoxyde (22) des phosphoranes **9** et **10** en solution dans le DMSO a été effectuée à la température ambiante. Dans les deux cas, les spectres de RMN $^{31}P\{^1H\}$ des mélanges réactionnels montrent la disparition totale des signaux des phosphoranes et phosphites tautomères et leur remplacement par un groupe majeur situé entre 10 et 20 ppm, attribuable aux composés **13** et **14** (23), et un groupe mineur, situé entre −16 et 0 ppm, attribuable aux dérivés **15** et **16** (23). Bien entendu, le nombre de pics représentant les produits d'oxydation est bien plus grand dans le cas du produit **10** que dans celui du dérivé **9**, ce qui traduit le fait que le composé **9** est un isomère unique possédant quatre noyaux de phosphore différents alors que le dérivé **10** peut représenter un mélange de 12 isomères comportant au total 32 noyaux de phosphore différents.

Nous avons montré ensuite que l'action du soufre élémentaire transforme quantitativement les phosphoranes **9** et **10** en deux types de dérivés thiophosphorylés : les produits majeurs **17** et **18** d'une part et les produits mineurs **19** et **20** d'autre part, dont les paramètres de RMN ^{31}P sont tout à fait comparables à ceux de composés analogues relevés dans la littérature (23, 24).

4. Hydrolyse

L'hydrolyse des phosphates neutres a pour but d'accéder aux monoesters selon la réaction :



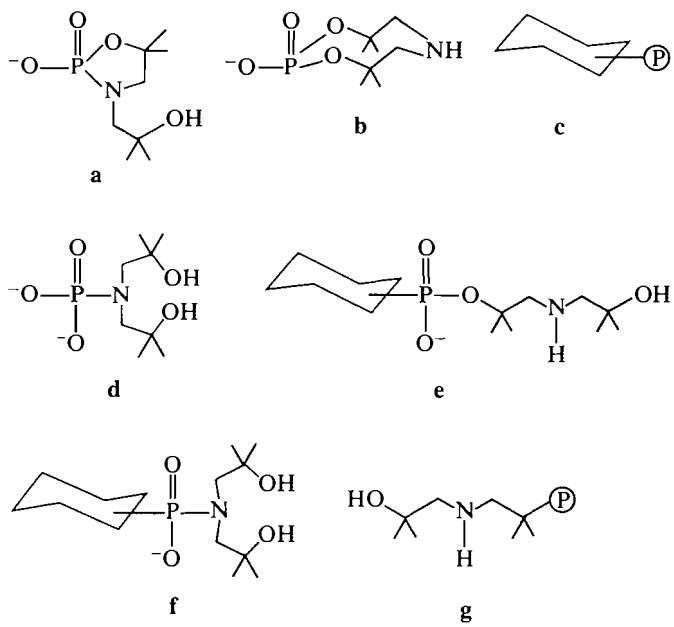
21

L'hydrolyse acide conduisant à un alcool tertiaire étant plus rapide que celle conduisant à un alcool secondaire (25), l'utilisation du bicyclophosphane **8** permet de réduire le taux de déphosphorylation du myo-inositol.

Nous avons effectué cette réaction sur les produits d'oxydation **14** et **16** des tris-phosphoranes **10**. À la température ambiante, la réaction est quasi-instantanée. Le spectre de RMN ^{31}P du mélange réactionnel continue à présenter deux groupes de signaux, entre −16 et 0 ppm d'une part et entre 10 et 16 ppm d'autre part, mais ce dernier groupe n'est plus aussi prédominant comme dans le spectre des produits de départ. En outre les déplacements chimiques sont sensiblement différents de ceux pointés dans le spectre du mélange des produits **14** + **16.**

Ce mélange réactionnel a été soumis à une séparation par chromatographie liquide à haute performance (HPLC) sur une résine échangeuse d'anions dans les conditions expérimentales d'Irvine *et al.* (26). Celles-ci permettent, par la modification de la force ionique à l'aide d'un gradient de formiate d'ammonium, de séparer les phosphates du myo-inositol en fonction du nombre de leurs atomes de phosphore qui est en relation directe avec la concentration du formiate d'ammonium. On conclut que les fractions 1–16 correspondent surtout aux molécules à un atome de phosphore, les fractions 17–22 aux molécules à deux atomes de phosphore et les fractions suivantes aux molécules à trois atomes de phosphore. Nous avons collecté au total 48 fractions et enregistré leurs spectres de RMN ^{31}P (pH = 3,5).

L'étude de ces spectres montre que seules les 22 premières fractions contiennent des molécules phosphorées, ce qui veut dire que les entités séparées contiennent seulement un ou deux atomes de phosphore. L'hydrolyse ne s'est donc pas limitée aux liaisons P—O—C et P—N—C, liant le phosphore au reste



a **b** **c** **d** **e** **f** **g**

≪aminodiol≫, mais elle a également touché les liaisons P—O—C inositol. Dans ces conditions, l'hydrolyse partielle des phosphates **14** et **16** peut conduire à 7 types de molécules (**a**–**g**) qui se distinguent par l'allure du signal de résonance du phosphore : singulet pour **b** et **g**, doublet pour **c** et **e** et multiplet pour **a**, **d** et **f**. Les fractions recherchées sont celles qui correspondent aux entités **c**. Nous en avons relevé trois :

Fraction 5

Le spectre de RMN ^{31}P (figure 5) comporte un doublet qui se

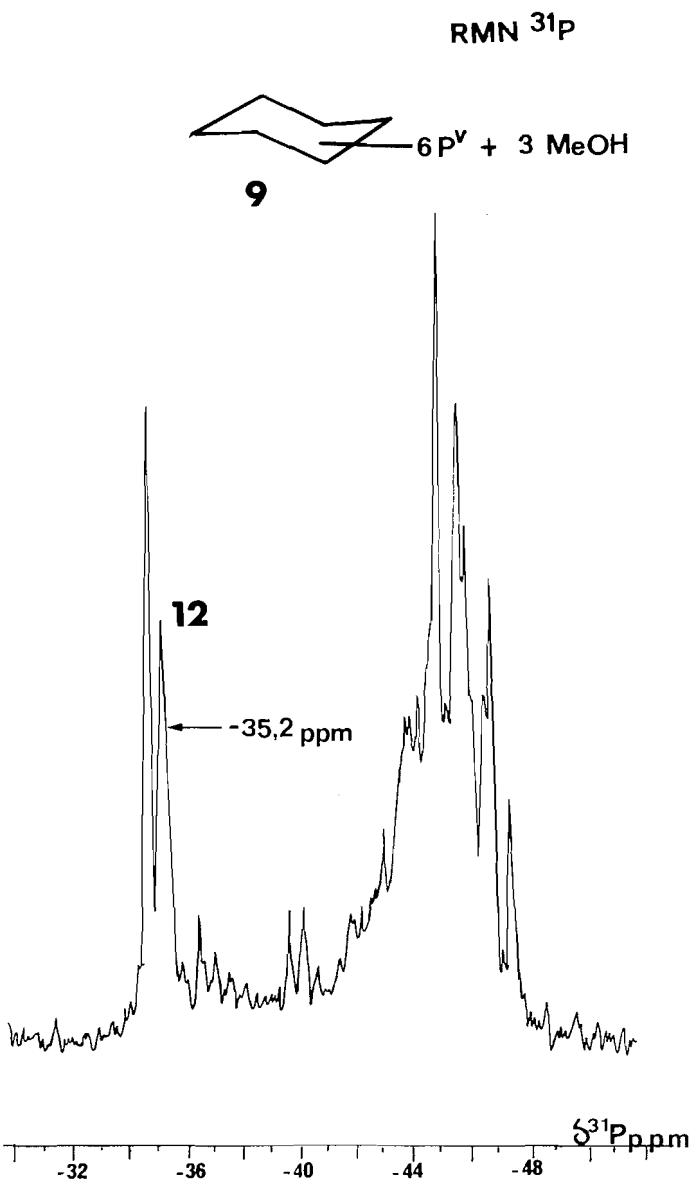

FIG. 4. La méthanolyse du per-phosphorane de myo-inositol **9** conduit à une augmentation du nombre de phosphoranes de myo-inositol (voir fig. 1) et à la formation du méthoxybicyclophosphorane **12** : $\delta = -35,2$ ppm valeur légèrement différente de celle lue sur la figure 3 en raison de la modification du milieu.

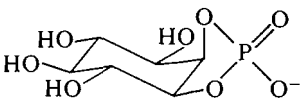
transforme en singulet par découplage des protons : $\delta^{31}P$, 15,8 ppm; $^3J_{P—O—C—H}$, 20,1 Hz. Ces paramètres sont quasi identiques à ceux du myo-inositol-1,2(cycl) phosphate **22** : $\delta^{31}P$, 16,5 ppm; $^3J_{P—O—C—H}$, 20 Hz (27). L'identification est parachevée en comparant le spectre de RMN ^1H de cette fraction (figure 6) à celui d'un échantillon authentique du produit **22**, récemment publié dans la littérature (28).



22

Fraction 7

Le spectre de RMN ^{31}P (figure 7) comporte un signal unique: $\delta^{31}P$, 0,20 ppm; $^3J_{P—O—C—H}$, 7,6 Hz; cette fraction a été

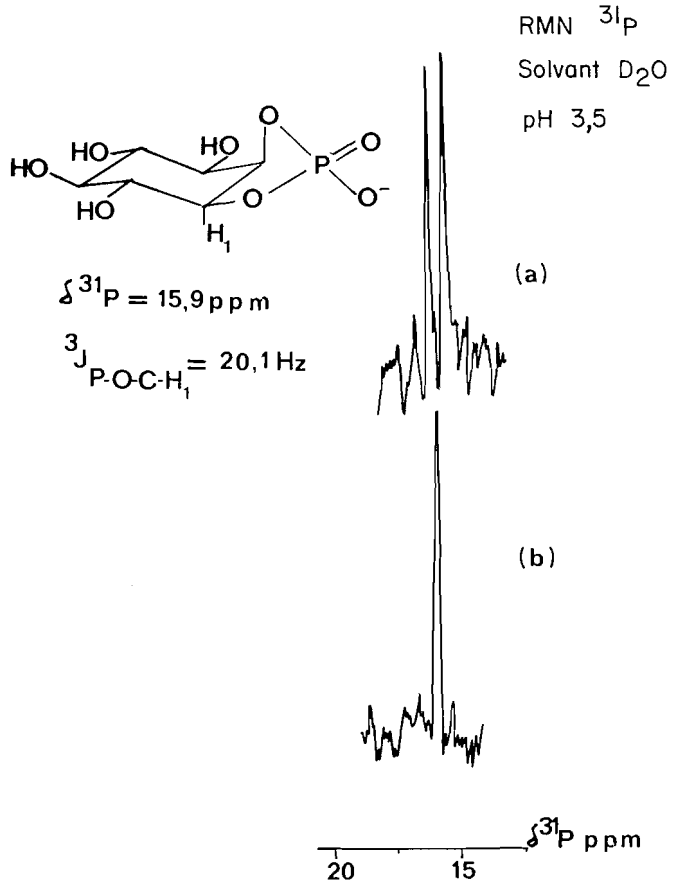


FIG. 5. Spectre de RMN ^{31}P, (a) proton non découplé; (b) proton découplé de la fraction 5 obtenue lors de la séparation par HPLC des produits d'hydrolyse de phosphates **14** et **16**. Nombre d'accumulations : 104.

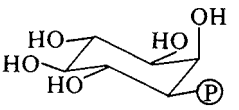
identifiée comme étant le myo-inositol-1 phosphate **23** en comparant son spectre de RMN ^1H à celui d'un échantillon authentique (28) (figure 8).



23

La valeur de $\delta^{31}P$: 0,20 ppm à pH 3,5 diffère de celle relevée dans la littérature : 4,75 ppm à pH 8. Toutefois la différence est conforme à ce qui a été généralement observé dans les phosphates de myo-inositol : un blindage quand la valeur du pH diminue (29). En revanche, les constantes de couplage $^3J_{P—O—C—H}$ 7,6 Hz et 7,3 Hz (littérature) sont quasiment identiques.

Le spectre de résonance ^{13}C de cette fraction 7 est reproduit en figure 9. Il montre que les six noyaux de carbone sont devenus tous différents par suite de la fixation du groupe phosphate sur le carbone 1 (ou sur le carbone 3 suivant l'énantiomère considéré). Par comparaison avec les déplacements chimiques des noyaux de carbone du myo-inositol[3] d'une part et compte tenu de l'effet bien connu de déblindage du noyau de carbone touché par la phosphorylation (29, 30), le spectre peut être

3. Dans le myo-inositol, les noyaux de ^{13}C ont les déplacements chimiques suivants : $C_1C_3 = 72,4_4$ ppm, $C_2 = 72,1_8$ ppm, $C_4C_6 = 71,1_5$ ppm, $C_5 = 74,3_5$ ppm (solvant D_2O) (ce travail).

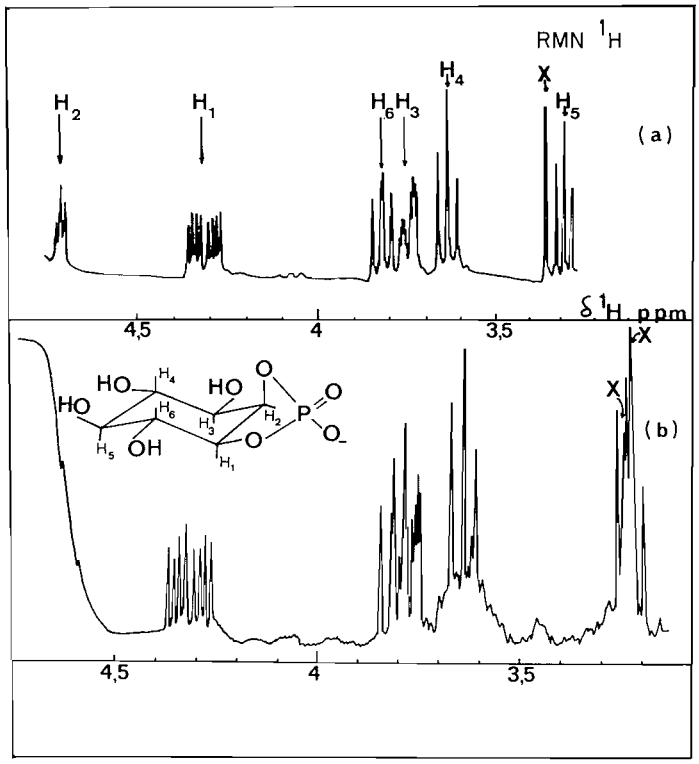


FIG. 6. Spectres de RMN ^{1}H, (a) d'un échantillon authentique de myo-inositol-1,2(cycl)phosphate publié par Cerdan *et al.* (28); (b) de la fraction 5 obtenue lors de la séparation par HPLC des produits d'hydrolyse des phosphates **14** et **16**. Nombre d'accumulations : 16. Le signal du proton H_2 est masqué par le signal OH de H_2O, $\delta > 4,5$ ppm. × = impureté.

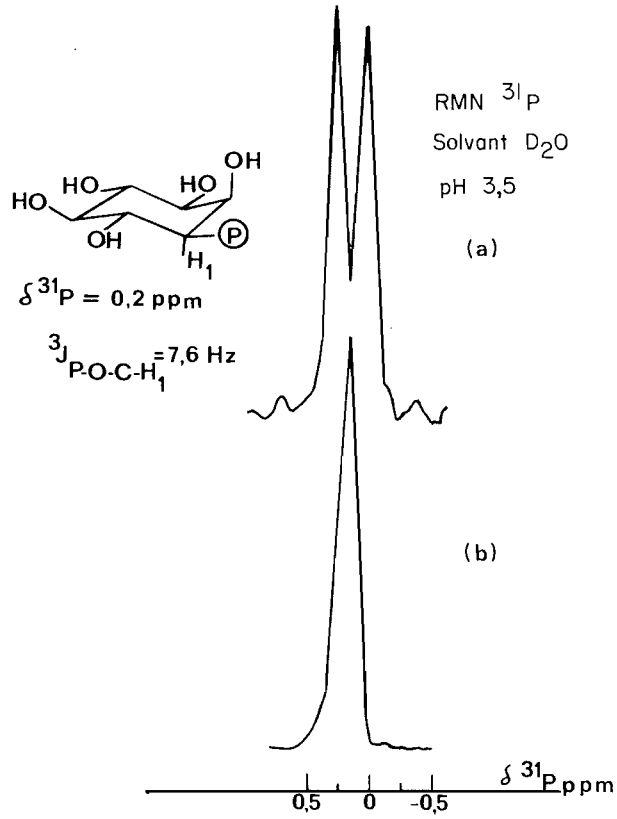

FIG. 7. Spectre de RMN ^{31}P, (a) proton non découplé; (b) proton découplé de la fraction 7 obtenue lors de la séparation par HPLC des produits d'hydrolyse des phosphates **14** et **16**. Nombre d'accumulations : 64.

analysé de la façon suivante : le doublet à δ 75,5$_7$ ppm, $^2J_{C\text{-}P}$ 5,8 Hz, correspond au carbone C_1; le doublet à δ 74,0$_5$ ppm, avec un écart de 0,8 Hz entre ses branches, est attribué au carbone C_5 présentant un couplage à travers quatre liaisons avec le phosphore : $^4J_{C\text{—}C\text{—}C\text{—}O\text{—}P}$ 0,8 Hz ; les singulets à δ 72,3 ppm et δ 70,8 ppm sont attribuables respectivement aux carbones C_3 et C_4; le doublet à δ 71,6 ppm, $^3J_{C\text{—}P}$ 5,8 Hz, peut être attribué aussi bien au carbone C_2 qu'au carbone C_6. Il en est de même du doublet à δ 71,2$_5$, $^3J_{C\text{—}P}$ 1,6$_5$ Hz.

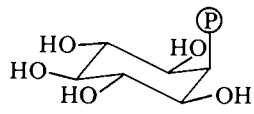
Cette ambiguïté peut être levée en tenant compte d'une part du fait que les variations des constantes de couplage $^3J_{C\text{—}C\text{—}O\text{—}P}$ en fonction des angles dièdres C—C—O—P suivent une loi (31) comparable à celle qui existe pour les constantes de couplage $^3J_{H\text{—}C\text{—}O\text{—}P}$ (32) et, d'autre part, en considérant la valeur non nulle du couplage $^4J_{C5\text{-}P}$. Cette dernière donnée implique en effet que les quatre liaisons C_5—C_6, C_6—C_1, C_1—O et O—P sont dans le même plan (règle du M), ce qui entraîne un empêchement à la rotation autour de la liaison C_1—O. Ceci peut résulter d'une liaison hydrogène intramoléculaire entre le groupement phosphoryle P=O et l'hydroxyle porté par le carbone C_6 ou C_2. La liaison O—P peut donc être soit du côté du carbone C_6 soit du côté du carbone C_2 par rapport au plan perpendiculaire au plan moyen du cycle et passant par C_1 et C_4. L'examen d'un modèle moléculaire montre que dans le premier cas ((**A**): projection de Newman suivant O—C_1), l'angle dièdre C_6—C_1—O—P serait presque nul et l'angle dièdre C_2—C_1—O—P voisin de 120°, alors que dans le second (**B**) les valeurs des mêmes angles dièdres seraient voisines de 180° et 60° respectivement. Seule cette dernière situation rend bien compte des

A **B**

valeurs expérimentales des constantes de couplage. L'attribution définitive est donc : $\delta^{13}C_2$ 71,2$_5$ ppm, $^3J_{C2\text{-}P}$ 1,6$_5$ Hz ; $\delta^{13}C_6$ 71,6 ppm, $^3J_{C6\text{-}P}$ 5,8 Hz.

Fraction 8

Le spectre de cette fraction (figure 10) comporte deux doublets d'inégale intensité : δ ^{31}P 1,9 ppm, $^3J_{P\text{—}O\text{—}C\text{—}H}$ 7,5 Hz ; δ ^{31}P 0,38 ppm, $^3J_{P\text{—}O\text{—}C\text{—}H}$ 7,2 Hz. L'analyse de son spectre de RMN ^{1}H montre qu'elle est constituée d'un mélange de myo-inositol-1 phosphate **23** et de myo-inositol-2 phosphate **24**. On y



24

relève, en effet, les deux signaux caractéristiques du proton H_2 de ces deux entités (cf. réf. 28) : un triplet à δ 4,08 ppm correspondant au proton H_2 de **23**, un doublet de triplet à δ 4,35 ppm correspondant au proton H_2 de **24**.

Le spectre de RMN ^{13}C de cette fraction (figure 11) confirme la présence de ces deux entités. Il est facile d'y reconnaître les six signaux (ombrés) correspondant aux noyaux de carbone de **23**. Le reste du spectre comporte quatre signaux dont les intensités relatives sont comme 1.1.2.2. Cette allure est celle prévue

pour les signaux ^{13}C du myo-inosotol-2 phosphate **24**. Tout comme le myo-inositol, ce dernier admet comme plan de symétrie le plan perpendiculaire au plan moyen du cycle et passant par C_2 et C_5. Ainsi les paramètres de RMN ^{13}C de **24** sont les suivants : C_1C_3, δ 72,8_4; C_2, δ 77,4_5, $^2J_{C2-P}$ 5,8 Hz; C_4C_6, δ 71,1_1; C_5, δ 74,5_2.

La séparation de ces monophosphates dans l'ordre que nous venons de décrire concorde avec les résultats récemment publiés par Binder *et al.* (33). Ainsi, parmi les produits à un atome de phosphore obtenus dans cette réaction, nous avons caractérisé trois myo-inositol monophosphates qui peuvent avoir un intérêt biologique. L'analyse des fractions à deux atomes de phosphore dans le but de détecter des myo-inositol bis-phosphates se poursuit actuellement.

Conclusion

Nous avons mis au point une méthode de phosphorylation du myo-inositol qui diffère de toutes celles rapportées dans la littérature (8–17, 35) par le fait qu'elle n'exige pas la protection préalable du myo-inositol.

Ce procédé à trois étapes seulement : phosphoranylation du myo-inositol, oxydation des phosphoranes et hydrolyse des phosphates neutres ainsi obtenus, permet d'accéder en une seule préparation à plusieurs phosphates de myo-inositol, ce qui est illustré par l'obtention des myo-inositol phosphates **22**, **23** et **24** en partant des tris-phosphoranes **10**. L'obtention, toujours en une seule opération, d'autres phosphates de myo-inositol biologiquement intéressants, comme les tris ou les tetrakis-phosphates, devient ainsi concevable moyennant une adéquation du degré de phosphoranylation du myo-inositol et une recherche de conditions d'hydrolyse qui protègeraient la liaison P—O de l'inositol. C'est ce que nous nous proposons d'étudier dans un proche avenir.[4]

Partie expérimentale

Méthodes spectroscopiques

Les spectres de RMN ^1H, ^{13}C et ^{31}P ont été enregistrés avec différents appareils Bruker : W.P 60, A.C 80, W.H. 90, W.M. 250 et A.M. 300 WB.

Les déplacements chimiques, exprimés en parties par million du champ inducteur (ppm) sont mesurés avec une précision de ±0,02 ppm pour ^1H, ±0,03 ppm pour ^{31}P et ^{13}C (références : TMS pour ^1H et ^{13}C, H_3PO_4 à 85% pour ^{31}P). Les constantes de couplage, exprimées en Hz, sont mesurées avec une précision de ±0,2 Hz.

Les spectres IR ont été enregistrés à l'aide d'un spectrographe Bruker I.F.S. 110 fonctionnant en transformée de Fourier (cuves de 200–1000 μm, 50–1000 accumulations). Résolution ±0,5 cm^{-1}.

Préparations

1. Le bicyclophosphane 8

Le 3,3,7,7-tetramethyl 2,8-dioxa 5-aza 1-phospha^{III} bicyclo [3,3,0]octane (bicyclophosphane *8*) a été obtenu selon une procédure que nous avons décrite précédemment (18, 34).

L'oligomérisation bien connue de ce composé a été réduite en mélangeant les solutions des réactifs goutte à goutte et non en une seule fois, comme c'était le cas précédemment. La pureté du produit obtenu a été vérifiée par RMN ^{31}P, ^1H et ^{13}C. Elle se situe en général entre 95 et 100%. Rdt, 45%. RMN ^{31}P (32, 44 MHz, toluène-d_8) : s 163 ppm; ^1H (80 MHz, C_6D_6): 1,21_6 ppm (s, 6H, CH_3), 1,30_8 ppm (s, 6H, CH_3), 2,73 et 2,99 ppm (2 quadruplets AB, 4H, $H_3H_4H_5H_6$, $^2J_{H3H4} = {}^2J_{H5H6} = -11,5$ Hz; $|{}^3J_{H3P}| = |{}^3J_{H5P}| = 8$ Hz; $|{}^3J_{H4P}|\,|{}^3J_{H6P}| = 9,3$ Hz); $^{13}C\{^1H\}$ (20,15 MHz, toluène-d_8): 28,5 (s, C_9), 30,5_2 (d, C_{10}, $^3J_{CP} = 3,2$ Hz)[5]; 64,20 (d, C_4, C_6, $^2J_{C—N—P} = 3,8$ Hz), 82,0_7 (d, C_3, C_7 $^2J_{C—O—P} = 10,5$ Hz) ppm.

2. Phosphoranes de myo-inositol

Les per-phosphoranes ainsi que les tris-phosphoranes de myo-inositol ont été préparés selon le même protocole expérimental dont voici un exemple. Une solution de 14,4 mg (0.08×10^{-3} mol) de myo-inositol dans 5 mL de DMSO est ajoutée en une fois à 90,7 mg ($0,48 \times 10^{-3}$ mol) de bicyclophosphane **8** (45,8 mg soit $0,24 \times 10^{-3}$ mol dans le cas de la tris-phosphoranylation). Au bout d'une dizaine de minutes d'agitation à la température ambiante, l'examen du spectre de RMN ^{31}P du mélange réactionnel montre que la réaction est terminée (voir Résultats et discussion).

*3. Le 3,3,7,7-tétraméthyl-1 isopropyloxy-2,8 dioxa-5 aza-1 phospha^V [3,3,0] bicyclooctane **11***

Une solution de 30 mg ($0,5 \times 10^{-3}$ mol) d'isopropanol, fraîchement distillé, dans 0,25 mL de toluène a été ajoutée en une fois à une solution de 94,5 mg ($0,5 \times 10^{-3}$ mol) du bicyclophosphane **8** dans 0,25 mL du même solvant. Le spectre de RMN ^{31}P enregistré 10 min après le mélange des réactifs montre que la réaction est terminée. Le produit n'a pas été isolé. Il a été caractérisé par RMN ^1H, ^{31}P et ^{13}C. RMN ^{31}P (32,44 MHz, toluène-d_8) : −37,27 ppm (d, $^1J_{P-H} = 791,5$ Hz); $^{31}P\{^1H\}$: −37,23 ppm (s); ^1H (300 MHz, toluène-d_8) : 1,18_5 ppm (d, 6H, CH_3 (10), $^3J_{H—C—C—H} = 6,2$ Hz), 1,21 ppm (s, 6H, CH_3 (11 ou 12)), 1,28_5 ppm (s, 6H, CH_3 (12 ou 11)), 2,49_7 et 2,56_6 ppm (2 quadruplets AB, 4H, H_3, H_4, H_5, H_6, $^2J_{H3H4} = {}^2J_{H5H6} = -8,2$ Hz; $|{}^3J_{H3\text{ ou }H_4P}| = 15$ Hz; $|{}^3J_{H4\text{ ou }H3P}| = 12,8$ Hz), 4,59_4 ppm (m, 1H H_9, $^3J_{H—C—O—P} = 10,7$ Hz); $^{13}C\{^1H\}$ (20,1_5 MHz, toluène-d_8) : 24,1_7 (d, C_{10}, $^3J_{C—C—O—P} = 5,9$ Hz), 29,1_7 (s, C_{11}), 29,6_3 (d, C_{12}, $^3J_{CP} = 5$ Hz), 55,5_9 (d, C_4, C_6, $^2J_{C—N—P} = 19$ Hz), 68,5_9 (d, C_9, $^2J_{C—O—P} = 6,4$ Hz), 70,0_8 (d, C_3, C_7, $^2J_{C—O—P} = 5,8$ Hz) ppm.

4. Oxydation

Au mélange réactionnel issu de la per-phosphoranylation (105,1 mg ($0,08 \times 10^{-1}$ mol) du composé **9** en solution dans 5 mL de DMSO) on ajoute 43,20 mg ($0,48 \times 10^{-3}$ mol) de tertiobutylhydroperoxyde, t-C_4H_9OOH, fraîchement redistillé (Eb_{10} = 28°C). Une agitation pendant 2 h à la température ambiante suffit pour conduire au mélange des phosphates neutres **13** et **15**. Le mélange des phosphates **14** et **16** est obtenu par le même procédé. Seule la quantité de tertiobutylhydroperoxyde est divisée par 2.

5. Sulfuration

Une solution de 131,4 mg ($0,1 \times 10^{-3}$ mol) du per-phosphorane de myo-inositol **9** dans 5 mL de DMSO est mélangée à 19,2 mg ($0,075 \times 10^{-3}$ mol) de fleur de soufre S_8. La dissolution de ce dernier dans le mélange réactionnel nécessite un chauffage à 40°C pendant 20–30 min. Un contrôle par RMN de ^{31}P montre que la sulfuration est terminée. Dans le cas des tris-phosphoranes **10** la quantité de fleur de soufre est réduite de moitié.

*6. Hydrolyse des phosphates neutres **13** + **15** ou **14** + **16***

L'addition à la température ambiante de la quantité stoechiométrique d'une solution d'acide chlorhydrique 1 N au mélange réactionnel des produits **13** + **15** ou **14** + **16** en solution dans le DMSO conduit à une solution dont le pH est égal à 5. À ce pH, la réaction est lente; au bout de 6 h, les modifications du spectre de RMN ^{31}P sont quasiment nulles. Nous avons vérifié qu'en diminuant le pH par addition de quantité

4. Pendant le temps qui s'est écoulé entre l'envoi du manuscrit et la réception des avis des rapporteurs, nous avons identifié, parmi les fractions à 2 atomes de phosphore, le myo-inositol-1,4 bis-phosphate. Cette identification a été réalisée en comparant le spectre de RMN ^1H de la fraction séparée à celui d'un échantillon authentique publié dans la littérature (28).

5. L'étude conformationnelle des bicyclophosphanes de ce type nous montre que la molécule se présente comme un toit à deux pentes, les doublets libres du phosphore et de l'azote étant sur le toit. Les cycles pentagonaux adoptent une conformation enveloppe bloquée, les atomes de carbone C_3 et C_7 étant à la pointe des rabats, lesquels sont orientés en *trans* par rapport aux doublets libres du phosphore et de l'azote (géométrie *endo–endo* (34)). L'existence d'une relation de type Karplus (31) pour le couplage $^3J_{P\text{-}O\text{-}C\text{-}C}$ explique l'existence ou non d'un couplage détectable entre le phosphore et les carbones C_9 et C_{10}. Pour le premier l'angle dièdre P—O—C_9 est voisin de 90°, alors que l'angle dièdre P—O—C—C_{10} est voisin de 150°.

croissante de solution d'acide chlorhydrique, la réaction est accélérée. À pH 2 elle est quasiment instantanée. Aussi les hydrolyses de ces phosphates ont été effectuées en portant directement à 2 la valeur du pH de la solution par addition de la quantité nécessaire de solution d'acide chlorhydrique 1 N.

7. Séparation par HPLC

Le mélange réactionnel de l'hydrolyse des phosphates neutres est évaporé à sec sous 10^{-2} Torr (1 Torr = 133.3 Pa). Le résidu est repris par un minimum d'eau puis filtré sur 0,22 μm millipore.

La séparation HPLC est réalisée sur colonne échangeuse d'anion Whatman Partisil Sax 10. Le gradient employé est analogue à celui de Irvine *et al.* (26). Le pH des solutions tampons est ajusté à 3,5 avec l'acide chlorhydrique et non de l'acide orthophosphorique pour permettre le contrôle par RMN. Tout au long de la séparation, le débit est de 3 mL/min et les fractions sont collectées toutes les minutes.

Remerciements

Les auteurs tiennent à remercier les responsables et personnels techniques des services spécialisés du Groupe régional de mesures physiques de Toulouse : Mme Bon, MM. Commenges, Dall'ava, Pelletier, Servin et Tran le Trang (RMN), Mme Bouissou (IR) et M. Roussel (spectrométrie de masse) pour l'enregistrement des spectres qui ont servi au cours de ce travail. Ils tiennent également à remercier Mme et Monsieur Cavadore du Centre de recherche de biochimie macromoléculaire du C.N.R.S. à Montpellier qui ont apporté une contribution décisive à la mise au point des séparations chromatographiques.

Penta-*O*-acetyl-D-glucose diethyl dithioacetal monoxide **3** was obtained by oxidation of penta-*O*-acetyl-D-glucose diethyl dithioacetal **2** with 3-chloroperbenzoic acid. By reaction of **3** with sodium methoxide in methanol and further acetylation, 3,4,6-tri-*O*-acetyl-2,5-anhydro-D-mannose-diethyl dithioacetal monoxide **8** and the reduction product 3,4,6-tri-*O*-acetyl-2,5-anhydro-1,1-bis(ethylthio)-1-deoxy-D-arabino-hex-1-enitol **4** were obtained. Reduction of **8** yielded the corresponding dithioacetal derivative **9**, which was converted to 3,4,6-tri-*O*-acetyl-2,5-anhydro-D-mannose diethyl acetal **11**.

L'oxydation du diéthyl dithioacétal du penta-*O*-acétyl-D-glucose **2** par l'acide chloro-3 perbenzoïque conduit au monoxyde du diéthyl dithioacétal penta-*O*-acétyl-D-glucose **3**. La réaction du composé **3** avec le méthanolate de sodium dans le méthanol, suivie d'une acétylation, conduit au monoxyde du diéthyl dithioacétal tri-*O*-acétyl-3,4,6 déhydro-2,5 D-mannose **8** et au produit de réduction, le tri-*O*-acétyl-3,4,6 anhydro-2,5 bis-éthylthio-1,1 déoxy-1 D-arabino-hexène 1 itol **4**. La réduction du composé **8** conduit au dérivé dithioacétal correspondant **9** que l'on transforme en diéthyl acétal tri-*O*-acétyl-3,4,6 anhydro-2,5 D-mannose.
[Traduit par la revue]

Introduction

One of the best-known methods to obtain 2,5-anhydro aldehydo sugars is the nitrous acid deamination of 2-amino-2-deoxy-D-glucose to yield 2,5-anhydro-D-mannose **1** (1). However, because of the nature of **1**, the utility of this method is seriously diminished; nevertheless the crystalline 2,5-anhydro-D-mannitol was obtained (2) by a reduction procedure, although this compound lacks the potentiality of a carbonyl group. In our laboratories this synthesis was modified by *in situ* protection of the aldehyde group, preparing several 2,5-anhydro-D-mannose dithioacetal derivatives (3), and using them in a further synthesis of C-nucleoside analogues (4).

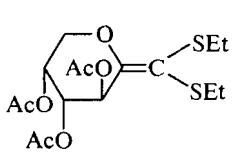
In the literature the oxidation of dialkyl dithioacetal sugar derivatives with peracid yields the corresponding sulfoxides and sulfones, and on some occasions the unsaturated product from the elimination between C-1 and C-2 is isolated (5). From disulfone derivatives of aldose diethyldithioacetals, the formation of side products of 2,6-anhydro hexose and heptose and of 2,5-anhydro pentose derivatives has been postulated (6). However, those anhydro derivatives have not been fully characterized or used in synthesis.

In this work we present a new method of obtaining 2,5-anhydro-D-mannose derivatives from D-glucose. At the same time, 2,5-anhydro-D-gluco- or manno-ketene dithioacetal derivatives are isolated.

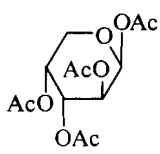
Results and Discussion

Oxidation of penta-*O*-acetyl-D-glucose diethyl dithioacetal **2** with 3-chloroperbenzoic acid yields penta-*O*-acetyl-D-glucose diethyl dithioacetal monoxide **3** as a mixture of isomers. During the reaction, two new chiral centers are formed.

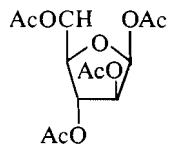
By reaction of **3** with an excess of sodium methoxide in methanol and subsequent acetylation of the reaction mixture;



5



6



7

two products are isolated by column chromatography with a large R_f (tlc) difference (R_{f1} 0.75; R_{f2} 0.25 (hexane:ether 1:1)).

The first product is identified as 3,4,6-tri-*O*-acetyl-2,5-anhydro-1-deoxy-1,1-bis(ethylthio)-D-arabino-hex-1-enitol **4**.

Firstly, we concentrated our attention on the structural determination of the ring size of **4**. To solve this question we used both ^1H and ^{13}C nmr data, and molecular mechanics calculations.

Molecular models for a six-membered ring in the $^4C_1$ conformation show that the H-5,6 and H-5,6′ angles are 180° and 80° approximately. These angles must show a large and a small coupling constant, respectively. However, in the $^1C_4$ conformation, the H-5,6 and H-5,6′ angles are the same, about 60°, but the H-3,4 angle is 180°. The coupling constant $J_{3,4}$ must be large. Molecular models for a five-membered ring show that the C-3,4 and C-4,5 angles are 90°, therefore $J_{3,4}$ and $J_{4,5}$ must be small. Molecular mechanics calculations have been performed for a related compound of **4**, compound **16** (see Fig. 1). The reason for choosing this compound is the structural similarity between **4** and **16**, and the impossibility for doing such a calculation on **4**, due to the lack of parameterization on the S—C_{sp^2}—S group. Molecular mechanics calculations show angles for H—C3—C4—H and H—C4—C5—H of 94.6° and −91.4° respectively. Theoretical $^3J_{HH}$ calculations show $J_{3,4} = -0.12$ and $J_{4,5} = 0.47$ Hz. The final conformation obtained by molecular mechanics is shown in Fig. 1, and the atomic Cartesian coordinates in Appendix 1. Experimentally (see experimental part) the compound **4** shows $J_{3,4}$ and $J_{4,5}$ as less than 1 Hz.

Similarly, we can obtain inferential data from the ^{13}C nmr spectra. As can be seen, both structures **4** and **5** show close analogies to 1,2,3,4-tetra-*O*-acetyl-β-D-arabino furanose **7** and 1,2,3,4-tetra-*O*-acetyl-β-D-arabino pyranose **6**, respectively; therefore we can compare the 2,3,4, and 5 carbon ^{13}C nmr absorptions in structures **6** and **7** with those corresponding to

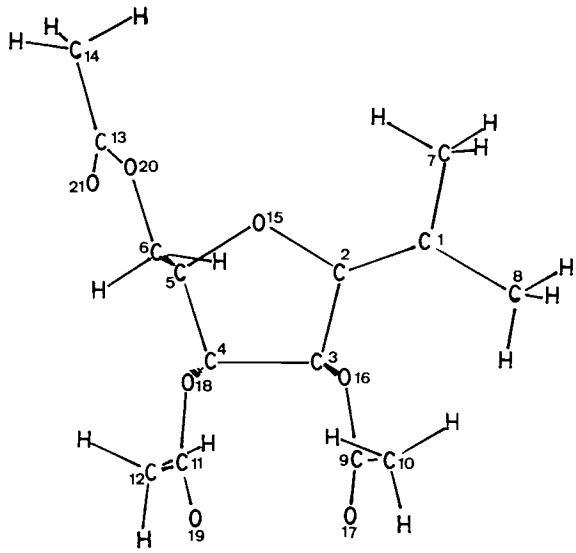

FIG. 1. Final conformation for **16**, obtained by molecular mechanics calculations.

TABLE 1. Carbon-13 nmr data

Compound	C—2	C—3	C—4	C—5	Reference
6	67.3	68.7	66.9	62.9	7
7	75.4	74.8	79.7	64.5	7

carbons 3,4,5, and 6 in structures **5** and **4**, respectively, as shown in Table 1.

The experimental data obtained for these compounds are C-3: 76.3; C-4: 74.7; C-5: 84.6; and C-6: 62.1, in complete accordance with those of compound **7** and in agreement with a five-membered ring structure.

The synthesis of **4** from **3** implies a reduction of the ethylsulfinyl to a ethylthio group. We explain this formation, as shown in Scheme 2.

Oxidation of C-2 could be an internal Moffatt oxidation upon treatment with acetic anhydride in pyridine (8); posterior cyclization leads to the hemiacetal and, after acetylation and acetic acid elimination, product **4** was formed.

The second product was 3,4,6-tri-*O*-acetyl-2,5-anhydro-D-mannose diethyl dithioacetal monoxide **8**. Its ^{1}H nmr shows the existence of three acetyl groups and two methyl groups from ethylthio groups. The above data are consistent with the existence of a ring. After several, very careful column chromatographic separations, only one pure compound could be isolated (yield 1.3%). Its spectroscopic and physical data are in agreement with one isomer of structure **8**; from the ^{1}H and ^{13}C nmr data we can conclude its structure: in ^{1}H nmr only two peaks appear, corresponding to two methines bonded to acetate groups (H-3 and H-4). The methylene at C-6 appears as a doublet, and is located at very low field, in agreement with having a five-membered ring and being bonded to an acetate group. It is also possible to say that one of the sulfur atoms is oxidized to a sulfoxide group; the signals corresponding to both methyls, in the ethylthio and ethylsulfinyl groups, appear at different field as two triplets, and the two H's of the methylene of the ethylsulfinyl group are diastereotopic, appearing as two sets of signals at different field. All the above arguments can be confirmed using ^{13}C nmr data. The methyls from the ethylthio and ethylsulfinyl groups appear at 14.96 and 7.13 ppm respectively, and the methylenes from the same groups at 28.06 and 43.19 ppm respectively. The absorptions of C-3, C-4, and C-5 appear at values in accordance with compound **7** (see Table 1), in agreement with a five-membered ring.

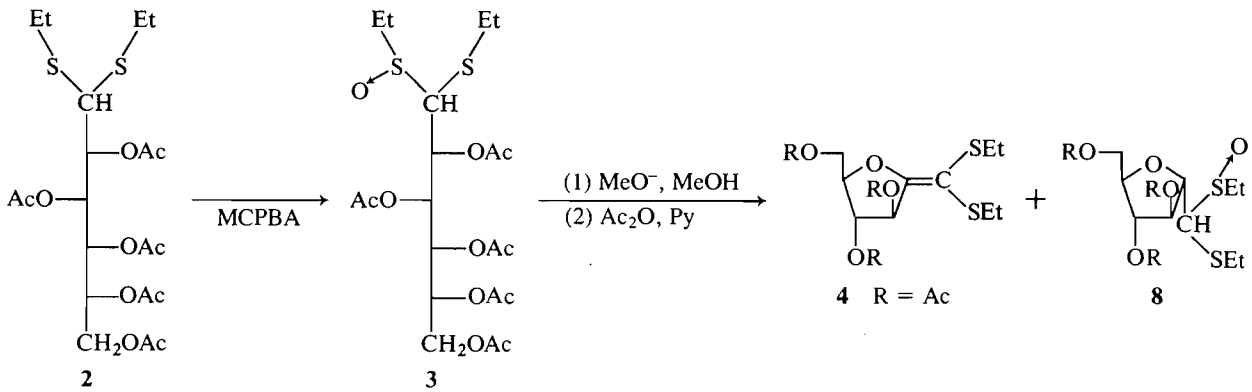
From the above-mentioned column chromatographic separation, fractions consisting of mixtures of several isomers of **8** in different yields could be obtained, except for the compound mentioned (**8**). The hplc separation of these fractions shows that they are mixtures of four different compounds, representing more than 90% of the mixture. The retention times (RT) and the yields from **3** are as follows: (a) 7.5 min, 22.3%; (b) 8 min, 13.3%; (c) 8.8 min, 9.8%; (d) 11 min, 7.1%. The compound isolated by column chromatography corresponds to an RT of 8 min.

Reduction of **8** yields 3,4,6-tri-*O*-acetyl-2,5-anhydro-D-mannose diethyl dithioacetal **9**. Its structure could be determined chemically as follows: hydrolysis of **9** yields 3,4,6-tri-*O*-acetyl-2,5-anhydro-D-mannose **10**, which, without purification, was treated with triethyl orthoformate in ethanol to yield 3,4,6-tri-*O*-acetyl-2,5-anhydro-D-mannose diethyl acetal **11**.

We obtained **11** by the following unequivocal method: acetylation of 2,5-anhydro-D-mannose di-*n*-propyl dithioacetal **12** yields the triacetate derivative **13**, which upon hydrolysis and subsequent reaction with ethyl orthoformate produces a compound with spectroscopic values identical to **11**.

Compound **8** can be formed by an intramolecular nucleophilic attack of OH at C-5 on the double bond between C-1 and C-2, as shown in Scheme 2. This double bond in **14** is activated by the presence of the sulfoxide group (9).

The above conclusions have been confirmed by reaction of **3**



2 **3** **4** R = Ac **8**

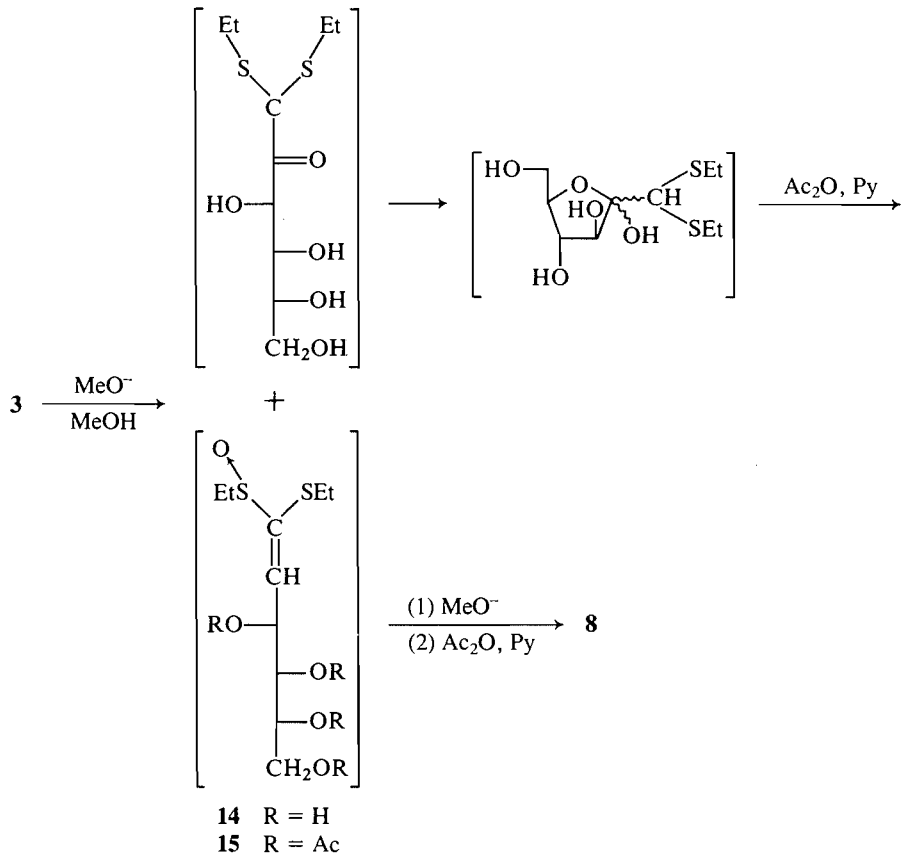
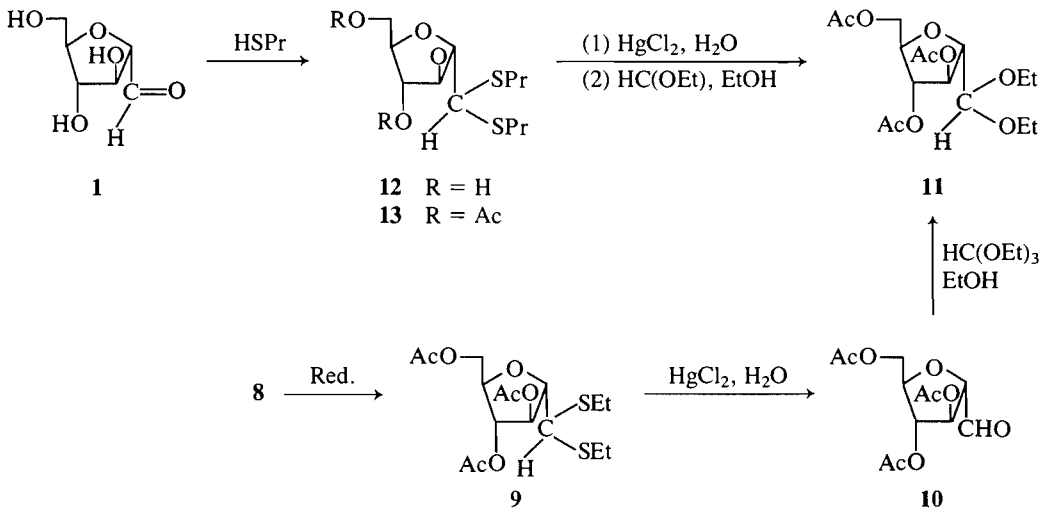


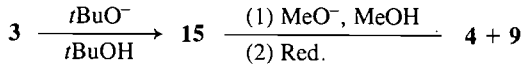
SCHEME 2



SCHEME 3

with potassium *tert*-butoxide to yield 3,4,5-tri-*O*-acetyl-1,2-dideoxy-1-ethylthio-1-ethylsulfinyl-hex-1-enitol **15**.

Integration of the ^{1}H nmr spectrum of **15** shows four acetyl groups and a vinyl proton, which is in accordance with a linear molecule. When **15** is treated with sodium methoxide, followed by acetylation and reduction, a mixture of **4** and **9** is obtained.



SCHEME 4

The presence of **4** in the reaction mixture can be explained by addition of the methoxide ion to the double bond and subsequent oxidation and elimination in a mechanism similar to the one shown in Scheme 2.

Experimental

General methods

Organic solutions were dried over anhydrous $MgSO_4$. Solvents were evaporated under diminished pressure below 40°C. Column chromatography was carried out on Silica Gel 60 (Merck, 70–230 mesh, ASTM). Optical rotations were measured with a Perkin–Elmer 141

automatic polarimeter. The ^1H nmr and ^{13}C nmr spectra were recorded for solutions in $CDCl_3$ (internal Me_4Si), using a Bruker WP-80-SY or a Bruker AM-300, and ir spectra with a Perkin–Elmer 983-G spectrometer. Elemental analyses were realized on a Perkin–Elmer 240C or on a Carlo Erba 1106. The hplc separations were carried out on a Waters-501, using a Pyrkle IA column, with 80:20 isopropanol–hexane as a mobile phase at 0.8 mL/min, monitoring at 230 nm.

Calculations

The energetic minimizations were performed by an MMPM program from Serena Software.[5] The inputs for the MMPM program were carried out using the STRP program.[5] A value of 10 for the effective dielectric constant has been chosen. Theoretical $^3J_{HH}$ calculations were performed by application of the generalized Karplus equation (10), using the program from Osawa and Jaime (11).

*2,3,4,5,6-Penta-*O*-acetyl-*D*-glucose diethyl dithioacetal* **2**

Ethanethiol (50 mL) was added dropwise to a stirred solution of D-glucose (50 g) in hydrochloric acid (43 mL) at room temperature. After 30 min ice was added up to precipitation of the corresponding dithioacetal. The solid was filtered and washed with ice-water, $NaHCO_3$ solution, and ethanol. A white solid (69 g) was obtained. After acetylation in the usual manner with acetic anhydride and pyridine, 2,3,4,5,6-penta-*O*-acetyl-D-glucose diethyl dithioacetal **2** (197 g) was obtained (12).

*2,3,4,5,6-Penta-*O*-acetyl-*D*-glucose diethyl dithioacetal monoxide* **3**

A solution of 3-chloroperbenzoic acid (4.34 g) in CH_2Cl_2 (70 mL) was added dropwise to a solution of penta-*O*-acetyl-D-glucose diethyl dithioacetal (9.92 g) in CH_2Cl_2 (100 mL), stirred at −10°C for 20 min. The reaction mixture was treated with $NaHCO_3$ and water, dried, and the solvent removed to leave 2,3,4,5,6-penta-*O*-acetyl-D-glucose diethyl dithioacetal monoxide **3** (10.5 g) as a mixture of the possible diasteromers observed by the ^1H nmr spectrum. It was not possible to resolve this mixture after several attempts using column chromatography.

Reaction of **3** *with sodium methoxide*

Sodium methoxide in methanol was added dropwise, until pH was basic, to a solution of 2,3,4,5,6-penta-*O*-acetyl-D-glucose diethyl dithioacetal monoxide **3** (1.3 g) in methanol (15 mL), stirred for 1 h at room temperature. After 30 min, acid Amberlite IR-45 resin was added until pH 7, and the mixture stirred for 1 h. This mixture was filtered and the solvent evaporated to leave a syrup, which, upon acetylation (acetic anhydride and pyridine), produced a mixture (1.29 g). After purification by column chromatography (hexane:ethyl acetate 3:1 to ethyl acetate and to ethyl acetate:acetone 9:1) two products were obtained:

(*i*) 3,4,6-Tri-*O*-acetyl-2,5-anhydro-1,1-bis-ethylthio-1-deoxyhex-1-enitol **4** (100 mg); $[\alpha]_D$ +17.1(*c* 0.4, Cl_3CH); ir ν_{max} (cm^{-1}): 1747, 1620, 1448, 1369, and 1227; ^1H nmr, δ(ppm): 6(s, 1H, H-3), 5.05 (dd, 1H, $J_{3,4} = J_{4,5} < 1$ Hz, H-4), 4.56 (dt, 1H, H-5), 4.34 (dd, 1H, $J_{6,6'} = 12$ Hz, $J_{5,6} = 6$ Hz, H-6), 4.24 (dd, 1H, $J_{5,6'} = 5$ Hz, H-6′), 2.5–2.9 (m, 4H, 2S—CH_2—CH_3), 2.14 (s, 3H, COCH_3), 2.10 (s, 6H, 2COCH_3), 1.25 (t, 3H, $J = 7$ Hz, SCH_2CH_3), and 1.20 (t, 3H, $J = 7$ Hz, SCH_2CH_3); ^{13}C nmr, δ(ppm): 170, 169.3, and 168.7 ($3COCH_3$), 158.3 (C-2), 104.5 (C-1), 84.6, 76.3, and 74.7 (3CH, C-5, 3, and 4, respectively), 62.1 (CH_2, C-6), 27 and 26.6 ($2CH_2$, SCH_2CH_3), 20.5 and 20.4 ($3CH_3$, $COCH_3$), 14.4 and 14.1 ($2CH_3$, SCH_2CH_3). *Anal.* calcd. for $C_{16}H_{24}O_7S_2$: C 48.96, H 6.16; found: C 48.92, H 6.30.

(*ii*) 3,4,6-Tri-*O*-acetyl-2,5-anhydro-D-mannose diethyl dithioacetal monoxide **8** (539 mg). After several and very careful column chromatography separations using hexane–ether as eluent, a fraction with only one pure isomer (17 mg) could be isolated. Liquid, $[\alpha]_D$ +13.7 (*c* = 1.1, $CHCl_3$); ir ν_{max} (cm^{-1}): 2968, 2933, 1740, 1447, 1371, 1229, 1047, 970, and 908; ^1H nmr, δ(ppm): 5.59 (dd, 1H, $J_{2,3} = 6.59$, $J_{3,4} = 4.52$ Hz,H-3), 5.31(t, 1H, $J_{4,5} = 4.54$ Hz, H-4), 4.65 (dd, 1H, $J_{1,2} = 1.78$ Hz, H-2), 4.29(q, 1H, $J_{5,6} = J_{5,6'} = 4.23$ Hz, H-5), 4.21 (d,2H, H-6 and H-6′), 3.89 (d, 1H, H-1), 3.2–3.04 (m, 1H, H-a of the methylene in the ethylsulfinyl group), 2.9–2.68 (m, 3H, H-b of the methylene of the ethylsulfinyl group and the methylene of ethylthio group), 2.06, 2.07, and 2.09 (3s, 9H, 3CO—CH_3), 1.39 (t, 3H, $J = 7.49$ Hz, CH_3—CH_2—SO), 1.29 (t, 3H, $J = 7.45$ Hz, CH_3—CH_2—S); ^{13}C nmr, δ (ppm): 170.72, 170.32 (3C, *CO*—CH_3), 80.56, 78.69, 78.58, and 77.83 (4CH, C-2, C-3, C-4, and C-5), 67.62 (CH, C-1), 63.14 (CH_2, C-6), 43.19 (CH_2, SO—CH_2—CH_3), 28.06 (CH_2, S—CH_2—CH_3), 20.85 and 20.71 ($3CH_3$, CO—CH_3), 14.56 (CH_3, CH_3—CH_2—S), and 7.13 (CH_3, CH_3—CH_2—SO).

The remaining fractions were mixtures of different isomers.

*Reduction of 3,4,6-tri-*O*-acetyl-2,5-anhydro-*D*-mannose diethyl dithioacetal monoxide* **8**

$TiCl_4$ (0.25 mL) was added to a stirred and cooled suspension of powdered Zn (273.7 mg) in anhydrous diethyl ether (2 mL). After 2 min a solution of **8** (539 mg) in CH_2Cl_2 (2 mL) was added. The reaction mixture was poured into water and extracted twice with diethyl ether. The combined organic layers were dried over $MgSO_4$ and the solvent removed to leave a mixture that was purified by column chromatography (hexane:ether 10:1 to 2:1), giving 3,4,6-tri-*O*-acetyl-2,5-anhydro-D-mannose diethyl dithioacetal **9** (151 mg); $[\alpha)_D$ +41.3 (*c* 1.01, Cl_3CH); ir, ν_{max} (cm^{-1}): 1745, 1451, 1370, 1225, 1045, and 900; ^1H nmr, δ(ppm): 5.55 (dd, 1H, $J_{2,3} = 5$ *Hz*, $J_{3,4} = 4$ Hz, H-3), 5.12 (t, 1H, H-4), 4.37–4.12 (m, 4H, H-2, 5, 6, and 6′), 4.00 (d, 1H, $J = 6$ Hz, H-1), 2.7 (q, 4H, $J = 7$ Hz, SCH_2CH_3), 2.05 (s, 9H, COCH_3), 1.25 (t, 6H, SCH_2CH_3); ^{13}C nmr, δ (ppm): 170.3, 169.8, 169.6 (3C, $COCH_3$), 85.4, 80.53, 79.2, and 78.02 (4CH, C-2, 5, 3, and 4, respectively), 62.8 (CH_2, C-6), 52.8 (CH, C-1), 25.02 and 24.8 ($2CH_2$, SCH_2CH_3), 20.05 ($3CH_3$, $COCH_3$), 14.25 ($2CH_3$, SCH_2CH_3). *Anal.* calcd. for $C_{16}H_{26}O_7S_2$: C 48.71, H 6.64; found: C 48.58, H 6.74.

*Hydrolysis of 3,4,6-tri-*O*-acetyl-2,5-anhydro-q2d-mannose diethyl dithioacetal* **9**

A mixture of **9** (199 mg), acetone (2 mL), water (0.15 mL), HgO (344 mg), and $HgCl_2$ (344 mg) was stirred for 2 h at room temperature. Then the solvent was removed, $CHCl_3$ (50 mL) was added, and the mixture was filtered through Celite. The chloroform solution was washed with a solution of KI and water, dried, and the solvent removed to leave 3,4,6-tri-*O*-acetyl-2,5-anhydro-aldehydro-D-mannose **10** (145 mg); ^1H nmr, δ (ppm): 9.67 (s, H, aldehyde). This compound was used without further purification.

*3,4,6-Tri-*O*-acetyl-2,5-anhydro-*D*-mannose diethyl acetal* **11**

Ethyl orthoformate (0.5 mL) and Amberlite IR-45 resin were added to a solution of **10** (145 mg) in ethanol (1 mL) and stirred at room temperature for 24 h. The reaction mixture was filtered and solvent removed to leave a syrup that was purified by column chromatography (ethyl ether:hexane 2:1) to give 3,4,6-tri-*O*-acetyl-2,5-anhydro-D-mannose diethyl acetal **11** (106 mg); $[\alpha]_D$ +24.85 (*c* 1.02, Cl_3CH); ir, ν_{max} (cm^{-1}): 2985, 1746, 1370, 1230, and 1060; ^1H nmr, δ (ppm): 5.36 (t, 1H, $J_{3,2} = J_{3,4} = 4$ Hz, H-3), 5.05 (m, 1H, H-4), 4.51 (d, 1H, $J_{1,2} = 5$ Hz, H-1), 4.10–4.25 (m, 3H, H-5, 6, and 6′), 4.02 (dd, 1H, H-2), 3.85–3.30 (m, 4H, OCH_2CH_3), 2.02 (s, 9H, CH_3CO), 1.15 and 1.16 (2t, 6H, $J = 7$ Hz, OCH_2CH_3); ^{13}C nmr, δ(ppm): 170.4, 169.7, and 169.5 (3C, $COCH_3$), 111.5 (CH, C-1), 82.63, 80.93, 78.3, and 77.9 (4CH, C-2, 5, 3, and 4, respectively), 63.6, 63.08, and 62.3 ($3CH_2$, C-6 and OCH_2), 20.6 (CH_3, $COCH_3$), and 15.08 (CH_3, OCH_2CH_3). *Anal.* calcd. for $C_{16}H_{26}O_9$: C 53.03, H 7.23; found: C 52.97, H 7.29.

*Synthesis of 2,5-anhydro-*D*-mannose di-*n*-propyl dithioacetal* **12**

Treatment of 2,5-anhydro-D-mannose **1** with *n*-propanethiol as described for the synthesis of 2,5-D-mannose dialkyl dithioacetal (3) produces **12**. Solid, mp 64–65°C; $[\alpha]_D$ +51.9 (*c* 1, $CHCl_3$); ir, ν_{max} (cm^{-1}): 3400, 3000, 2900, and 1060; ^1H nmr, δ (ppm): 3.8–3.5 (br, 2H, 2OH), 3.35–3.1 (m, 1H, OH), 3.0–2.25 (7H, H-1, 2, 3, 4, 5, 6,

[5]MMPM is an addition to MM2 (Allinger, QCPE 395) and MMP1 (Allinger, QCPE 318), by K. E. Gilbert and J. J. Gajewski, Indiana University. STRP is used to generate an input file.

and 6′), 1.15–0.9 (m, 4H, $2CH_3$—CH_2—CH_2), 0.9–0.65 (t, 6H, $2CH_3$). *Anal.* calcd. for $C_{12}H_{24}O_4S_2$: C 48.64, H 8.17; found: C 48.99, H 8.17.

*Synthesis of 3,4,6-tri-*O*-acetyl-2,5-anhydro-*D*-mannose diethyl acetal **11** from 2,5-anhydro-q2d-mannose di-*n*-propyl dithioacetal **12***

2,5-Anhydro-D-mannose di-*n*-propyl dithioacetal **12** was acetylated by the usual procedure (pyridine – acetic anhydride). The reaction mixture was purified by column chromatography (hexane:ether) to give **13** in quantitative yield. Hydrolysis of **13** following the same procedure as for **9** gave the corresponding aldehyde **10**; ^{1}H nmr, δ(ppm): 9.67 (s, H, aldehyde). Treatment of this aldehyde, without any purification, with triethyl orthoformate and ethanol under the same conditions as above, after column chromatography yielded a product with the same physical and spectroscopic properties as those presented by **11**.

*Reaction of **3** with potassium* tert-butoxide

Potassium *tert*-butoxide (218 mg) in *tert*-butanol was added dropwise to a stirred solution of **3** (1 g) in *tert*-butanol (40 mL), and refluxed for 10 min. Then Amberlite IR-45 resin was added until acid pH. The solution was filtered and the solvent evaporated to give a mixture that, upon acetylation by the usual method and after column chromatography (ethyl ether), rendered **15** (510 gmg) as a mixture of the possible isomers; ^{1}H nmr, δ (ppm): 6.65 and 6.60 (2d, $J_{2,3}$ = 8 Hz, H-2), 6.25 (dd, 1H, $J_{3,4}$ = 2 Hz, H-3), 5.50–5.20 (m, 2H, H-4 and 5), 4.3–4.1 (m, 2H, H-6 and 6′), 3.25–2.5 (m, 4H, SCH_2CH_3 and $SOCH_2CH_3$), 2.1–1.9 (m, 12H, $4COCH_3$), 1.45–1.00 (m, 6H, SCH_2CH_3 and $SOCH_2CH_3$).

*Reaction of **15** with sodium methoxide in methanol*

Sodium methoxide in methanol was added dropwise until permanent basic pH to a solution of **15** (510 mg) in methanol (15 mL), which was then stirred for 30 min at room temperature. Amberlite IR-45 resin was added until pH 7. This was filtered and evaporated, giving a mixture that was acetylated in the usual manner. The acetylated mixture (335 mg) was reduced with $TiCl_4$ and Zn, under the same conditions as **8**, yielding, after purification by column chromatography, a mixture of **4** and **9**.

Received April 22, 1988.

PENELOPE W. CODDING, MARIA B. SZKARADZINSKA, ALEKSANDER W. ROSZAK, LORRAINE J. AHA, TIMOTHY J. HAGEN, and JAMES M. COOK. Can. J. Chem. **66**, 2981 (1988).

The crystal and molecular structures of two ligands for the benzodiazepine (BZ) receptor, *t*-butyl β-carboline-3-carboxylate, **I** ($C_{16}H_{16}N_2O_2$), and 2-(methoxycarbonyl)canthin-6-one, **II** ($C_{16}H_{10}N_2O_3$), are reported. The *t*-butyl β-carboline compound has high affinity for the receptor and is an antagonist; in contrast, the canthin-6-one has a 10-fold lower affinity for the receptor and no determinable *in vivo* activity. The space group for **I** is $P2_1/c$ with $a = 11.756(1)$, $b = 11.2324(8)$, $c = 11.964(1)$ Å, and $\beta = 105.99(1)°$. For **II**, the space group is also $P2_1/c$ with $a = 9.317(1)$, $b = 7.964(1)$, $c = 17.180(3)$ Å, and $\beta = 104.173(7)°$. The orientation of the alkyl-carboxylate side chain is different in the two molecules and may be related to the difference in affinity and *in vivo* activity of the ligands. In addition, the packing arrangements in the two structures are dominated by π-stacking interactions; and, in the case of the *t*-butyl compound, by hydrogen bonding.

PENELOPE W. CODDING, MARIA B. SZKARADZINSKA, ALEKSANDER W. ROSZAK, LORRAINE J. AHA, TIMOTHY J. HAGEN et JAMES M. COOK. Can. J. Chem. **66**, 2981 (1988).

On rapporte les structures cristallines et moléculaire de deux ligands du récepteur de la benzodiazépine (BZ) : la β-carboline carboxylate-3 de *tert*-butyle, **I**, ($C_{16}H_{16}N_2O_2$) et la (methoxycarbonyle)-2 canthinone-6, **II**, ($C_{16}H_{10}N_2O_3$). Le composé β-carboline de tert-butyle a une grande affinité pour le récepteur et son antagoniste; la canthinone-6, au contraire a une affinité 10 fois plus faible pour le récepteur et son activité in vivo n'est pas décelable. Le composé **I** appartient au groupe d'espace $P2_1/c$ avec $a = 11,756(1)$, $b = 11,2324(8)$, $c = 11,964(1)$ Å et $\beta = 105.99(1)°$. Le composé **II** appartient également au groupe d'espace $P2_1/c$ avec $a = 9,317(1)$, $b = 7,964(1)$, $c = 17,180(1)$ Å, et $\beta = 104,173(7)°$. L'orientation de la chaine latérale alkyle-carboxylate est différente dans les deux molécules et peut être reliée à la différence d'affinité et d'activité in vivo des ligands. De plus des interactions π-entassement domine l'entassement des deux structures; et, dans le cas du composé *tert*-butyle ce sont des liaisons hydrogènes.qui dominent.

[Traduit par la revue]

Introduction

The benzodiazepine receptor found in brain tissue mediates anticonvulsant, anxiolytic, hypnotic, and sedative effects (1). This receptor is part of a macromolecular complex that includes both the γ-aminobutyric acid (GABA) receptor and the chloride anion channel (2, 3). Ligands for the benzodiazepine receptor exert their action by modulating the apparent potency of GABA at the GABA receptor. Ligands which interact with the benzodiazepine receptor demonstrate effects that range, in a continuous fashion, from full agonists to inverse agonists. Antagonists are in the center of this continuum of effects, while partial agonists and partial inverse agonists lie to either side of the midpoint (4). Agonists reduce anxiety and convulsions, antagonists elicit no biological response, and inverse agonists promote anxiety and convulsions (5). In essence, inverse agonists enhance neuronal firing while agonists decrease it.

Many compounds other than the 1,4-benzodiazepines have affinity and biological effect at the benzodiazepine receptor. Derivatives of the β-carbolines span the entire range of biological actions. Indeed, minor changes in the alkyl group on the 3-carboxylate substituent are known to modify the activity from inverse agonist for a methyl group to antagonist for a propyl group (6). A bulky alkyl group, as in the *t*-butyl compound presented herein, also produces an antagonist; the *t*-butyl compound has high affinity for the receptor (K_i = 10 n*M*) and antagonizes the anticonvulsant and anti-punishment effects of diazepam (7).

Two models for the recognition of and the differential response to ligands that are as dissimilar as benzodiazepines and β-carbolines have been derived from the pharmacological data. In one model, a conformational difference in the receptor site is assumed, such that in one conformation the agonist ligand binds more tightly and has the effect of increasing GABA transmission; in the other conformation, inverse agonists bind preferentially and decrease the efficacy of GABA (5, 8). Following this reasoning, antagonists would bind to either conformation and cause no shift in the latent response to GABA. In the other model, some photolabeling studies have been interpreted in terms of two separate but interacting sites, one that recognizes benzodiazepines (agonists) and one that recognizes antagonists and β-carboline inverse agonists (9).

Since no experiment has, as yet, actually established which of these explanations is correct, studies of the structures of ligands for the benzodiazepine receptor have been done in several laboratories (10–12) to attempt to find a structural discrimination between these two models. Thus far, the structural information has led to proposals for the differences between agonists and non-agonists (10), to a model containing two interacting sites (11), and, recently, to a description of the recognition site for inverse agonist ligands (13 *a* and *b*). Three features of the β-carbolines have been invoked as key to receptor recognition. The first is a requirement for a planar aromatic system (14) and

*The reflections used in the refinement included the observed reflections and those unobserved reflections for which $F_c^2 > 2.5\sigma(I_o)$.

near coplanarity of the 3-carboxylate group (15). Also, two hydrogen bonding groups have been implicated in activity: the indole N—H function as a donor and either the pyridyl N atom or the carbonyl O atom of the side chain (or both) as an acceptor (10, 13*a*, *b*). In the crystal, inverse agonist β-carbolines have similar conformations which place the carbonyl O atom *cis* to the N atom of the pyridyl ring. In contrast, a similar 3-substituted β-carboline which is an antagonist, the 3-(methoxycarbonyl) amino β-carboline (12), has the opposite conformation.

The β-carbolines presented in this work are the high affinity antagonist, *t*-butyl ester (**I**), and 2-(methoxycarbonyl)canthin-6-one (**II**) which has an affinity similar to clinically useful benzodiazepines, i.e., K_i = 100 n*M* (16). The structure of **I** was determined to gain more information regarding the side chain conformation common to antagonist ligands. The canthin-6-one structure was undertaken to look for a structural explanation for the fact that this compound has receptor affinity even though the N—H indole function is blocked. Comparison of both of these structures to those of other known receptor ligands will help to further characterize the recognition site and to define the differences for recognition of inverse agonists vs. antagonists.

Experimental

Samples were prepared in the Wisconsin laboratory and recrystallized in the Calgary laboratory from pyridine (**I**) and from a chloroform–methanol mixture (**II**) by a slow evaporation. X-ray intensity data were collected at room temperature on an Enraf-Nonius CAD-4F automated diffractometer with Ni-filtered CuKα radiation, λ(CuKᾱ = 1.54178 Å), using an ω/2θ scan mode. The cell parameters and orientation matrix were determined by least-squares refinements of the angular positions of 25 reflections with θ values in the range 16–45° for **I** and 22–28° for **II**. During the data collection the intensities of three reflections were measured every 2000 s of exposure of the crystal to X-ray radiation; these reflections showed no significant variation in intensity. The crystal data are given in Table 1. Lorentz and polarization corrections were applied; absorption corrections were not deemed necessary. The intensities were converted into normalized structure factors (E values) by application of a K-curve.

Both structures were solved by direct methods using MULTAN78 (17); the most probable phase sets were used to calculate E maps that revealed the positions of all but two of the non-hydrogen atoms of **I** and all of the non-hydrogen atoms of **II**. The remaining atoms of **I** were located in a difference Fourier synthesis calculated from the phases of the partial structure. After isotropic refinement of the parameters of the non-hydrogen atoms, most of the hydrogen atoms were located in difference Fourier syntheses. All hydrogen atoms were included in the model at idealized positions. The parameters varied in the final refinement cycles consisted of the coordinates of all the atoms, the anisotropic thermal parameters of the non-hydrogen atoms, and the isotropic thermal parameters of the hydrogen atoms except for those in methyl groups. The methyl hydrogen atoms were held in fixed positions with U_{iso} equal to 120% of the U_{eq} of the C atoms to which they were bonded. All calculations were done with the XRAY76 system of programs (18) implemented on a Honeywell computer. The atomic scattering factors used were those of Cromer and Mann (19) for the non-H atoms and of Stewart *et al.* (20) for the hydrogen atoms.

The atomic coordinates[3] for **I** are given in Table 2 and for **II** are given in Table 3, with the atoms labeled as in Figs. 1 and 2, respectively. The bond distances and bond angles are given in Table 4.

[3]The anisotropic thermal parameters, the hydrogen atom parameters, least squares planes data, the lists of observed and calculated structure factors, and the REFCODES from the Database search may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

Results

The β-carboline portion of **I** and the canthin-6-one portion of **II** are both planar: the standard deviations for the planes are 0.022 Å for 13 atoms in **I** and 0.022 Å for 16 atoms in **II**.[3] Also, in both structures, the ester side chains are in extended conformations and are nearly coplanar with the aromatic systems. In **I**, the angle between the plane of the β-carboline and the plane containing C(3), C(31), O(34), O(32), and C(33) is 10.5(3)°; in **II**, the angle between the canthin-6-one and the corresponding atoms of the ester side chain is 6.1(2)°. These conformations facilitate the formation of an extended π system over the side chain and the polycycle. Such extended systems have been found in all 3-substituted β-carbolines (21–24) except the 3-(methoxycarbonyl) amino β-carboline (12).

The major difference between these two structures is in the orientation of the ester side chain. In the canthin-6-one (**II**) structure, the side chain is oriented so that the ester carbonyl oxygen atom is *trans* to the pyridine N atom: the N(2)—C(3)—C(31)—O(34) torsion angle is 173.9(2)°. In **I**, the side chain is in the opposite orientation (*cis*) so that the carbonyl oxygen atom is adjacent to the pyridine N atom: the torsion angle N(2)—C(3)—C(31)—O(34) is −9.0(3)°. Muir and Codding (21) examined the orientation of ester side chains to pyridine rings by surveying the conformations found in 18 similar molecular fragments tabulated in the Cambridge Crystallographic Database (25). The eighteen examples consisted of 10 with *cis* conformations and 8 with the *trans* conformation found in the canthin-6-one crystal structure reported here. The approximately equal populations of the two conformers suggest that the two forms have similar potential energies. Interestingly, the *cis* arrangement for the side chain has been found in all of the ester-containing benzodiazepine receptor ligands except the canthin-6-one. The *cis* compounds include R015-1788 (10), an

antagonist which forms no hydrogen bonds in the crystal, and several ligands which form three-center hydrogen bonds, including the antagonist, 6-*N*-benzyl-β-carboline methyl ester (22), and the inverse agonists, β-carboline methyl ester (21) and β-carboline ethyl ester (23).

The two molecules reported in this paper have different crystal packing arrangements. The packing in the *t*-butyl β-carboline ester is determined by the formation of three-center H-bonds. Similar hydrogen bonding patterns have been found in both the methyl- (21) and ethyl- (23) ester crystal structures. The unique feature of the *t*-butyl packing arrangement is the formation of closely stacked dimers which facilitates strong π–π interactions. In the dimers, the entire polycyclic ring system is stacked such that the two molecules face in opposite directions and are aligned **A** ring over **C** ring with a dimer–dimer separation of 3.422(6) Å. Neither of the inverse agonist β-carboline esters (21, 23) show such extensive π interactions; however, both esters show partial π stacking which involves the **A** ring. Such interactions involving the **A** ring are postulated to be important to receptor binding (10, 11). The only other type of π-stacking observed in β-carboline crystals involved stacking of the side chain over the five-membered ring: this was observed for the low affinity *N*-ethyl-3-carbamoyl-β-carboline (24).

In contrast to the H-bonding found in the β-carboline esters, the packing of the canthin-6-one molecules is determined solely by π-stacking interactions. The canthin-6-one molecules are stacked in columns that are aligned to form sheets held together by van der Waals interactions. The distances between adjacent molecules in the stacks are 3.453(5) Å and 3.472(5) Å for the two molecules related by the centers of symmetry: 0,0,0 and 1/2,0,0, respectively. Molecules in a single sheet are aligned so that there are two types of van der Waals interactions, one between interleaved ester side chains and the other between the edges of the **A** and **D** rings. Although there are no hydrogen bonding interactions in the lattice of **II** because there are no hydrogen bond donors in the crystal, such interactions are found in the other crystal structure of a canthin-6-one, amarorine hydrate (26). The π-stacking in the amarorine crystals is similar to that found in crystals of **II**; in addition, a water molecule serves as a hydrogen donor and the acceptor atom is the pyridyl N atom (the N(2) atom in **II**), an atom that is held to be important for interactions with the benzodiazepine receptor (10, 11, 13*a*, *b*).

Discussion

Intermolecular contacts that are observed in crystals have been used as models for the interactions of receptors with ligands (10, 11, 27). The three-center hydrogen bond found in the crystal lattice of the *t*-butyl β-carboline is found in the structures of all β-carboline-3-carboxylate ester crystal structures and has been invoked as a model for the interaction of the pyridyl-ester portion of the molecule with the benzodiazepine receptor (10, 13*a*, *b*, 21). A novel feature of the three-center hydrogen bond is that the position of the donor, relative to the two acceptors: the pyridyl N atom and the carbonyl O atom, can vary over a wide range of values. Indeed, the bonding possibilities range from a two-center H bond to the N atom, through a range of positions that form a three-center H bond, finally to a two-center H bond to the carbonyl O atom. The variation in H bond geometries observed in the β-carbolines is shown in Table 5. Although these are all three-center bonds, they range from a bond that is stronger to the N(2) atom than to O(34) in the case of the 6-*N*-benzyl structure, to a bond that is stronger to the carbonyl O atom, as evidenced by shorter O(34)···N(9) distances than N(2)···N(9) distances, in the methyl and ethyl esters. The *t*-butyl β-carboline forms the most symmetrical three-center bond.

According to models for the interaction of the ligand with the receptor (10, 11, 13*a*, *b*), this H-bond donor position determines the distance between two postulated recognition points on the receptor: one that binds an aromatic ring, the **A** ring of the β-carboline or benzodiazepine(III), and a second that donates a hydrogen atom to a H-bond acceptor on the ligand. Previously (10, 23), the separation between the two recognition points on the ligands has been found to lie in the range 4.72–4.95 Å for benzodiazepine agonists. This value for agonist ligands is much shorter than that for the antagonist and inverse agonist β-carbolines, imidazobenzodiazepines, and pyrazoloquinolinones. If, for the ester ligands, both the *cis* conformation and the position of the H-bond acceptor as the midpoint of the N(2)···O(34) group are assumed, the separation between recognition points on the ligand varies from 6.06(1) Å for RO15-1788 to an average of 6.50(5) Å for the β-carboline esters. The analogous separation for an inverse agonist pyrazoloquinolinone, CGS-8216 (23), is 6.10(1) Å. Unfortunately, the variability in the position of the H-bond acceptor point obscures any determination of a specific distance between ligand features that would distinguish inverse agonists from antagonists. It is clear,

however, that the receptor can recognize ligands of different size and that size may, at least, be important to distinguishing between agonist or inverse agonist activity.

The *trans* conformation of the ester side chain that was found in the canthin-6-one crystal has also been observed in two non-ester benzodiazepine receptor ligands: the *N*-ethyl-3-carbamoyl-β-carboline **IV** (24), which has low benzodiazepine receptor affinity (28), and 3-(methoxycarbonyl)amino-β-carboline **V** (12), which produces 50% antagonism of diazepam (**III**) binding at a concentration of 71 n*M* (29). Because our examination (24) of the tabulated geometries of pyridyl–carbamoyl fragments showed that *trans* is the only observed conformation, and because the carbamoyl-β-carboline has low receptor affinity (28), we have proposed (24) that this *trans* conformation is not the binding conformation. Thus, models for the receptor–ligand interaction have assumed a *cis* conformation for the ester side chain (9, 13*a*, *b*). For this proposal to be valid, the side chains of both the canthin-6-one, **II**, and the methoxycarbonylamino compound **V** must have alternative conformations to those found in the crystal structures.

To evaluate the conformational freedom of the pyridyl-methoxycarbonyl amino fragment; the Cambridge Crystallographic Database (25) was searched for the variety of conformations found for the fragment. Like the ester side chain (21, *vide infra*), the methoxycarbonyl amino side chain is found in both *cis* and *trans* conformers: of the nine fragments found in the database, six were *trans* as found in the β-carboline crystal structure (12) and three were *cis* (the REFCODES for this search are in the deposited information[3]). However, unlike the ester case, in the methoxycarbonyl amino search all of the *cis* conformers were stabilized by molecular interactions: either by an intramolecular hydrogen bond or by complexation to a metal ion. This finding suggests that the *cis* conformer of the methoxycarbonyl amino side chain is less stable than the *trans* form. To determine the energy required to stabilize the *cis* conformer, the GAUSSIAN86 molecular orbital program (31) was used to calculate the difference in energy between the *cis* and *trans* forms of the β-carboline (**V**). The *cis* conformer is 4.8 kcal/mol less stable than the *trans* form. This energy would be required to convert the observed (12) *trans* conformer to a *cis* conformer which could form a three-center hydrogen bond at the receptor site; such energies are available from the formation of the three-center H-bond. Therefore, the higher affinities of the canthin-6-one (**II**) and the methoxycarbonylamino compound (**V**) over that of the carbamoyl compound (**IV**) may be due to the facile formation of the *cis* conformer that, it is assumed (9, 13*a*, *b*, 30), binds to the receptor site.

Alternatively, these molecules could retain the *trans* conformation and bind in a different orientation from that proposed for the *cis* β-carboline esters. This possibility is most likely for the canthin-6-one because the usual binding orientation, i.e., N(2) and O(34) as acceptors and N(9)—H as donor, causes the **D** ring to interfere with the hypothesized (9, 13*a*, *b*) N—H donor position and, indeed, places a group of opposite polarity (the carbonyl O(17) atom) in the position normally occupied by the N—H. Thus, the **D** ring in the canthin-6-one may select for binding to the receptor in an "opposite" orientation by using the observed *trans* conformation and the carbonyl O atom, O(34), as the sole hydrogen bond acceptor. To assess this possibility, the overall shapes of the *t*-butyl β-carboline antagonist (**I**) and of the canthinone (**II**) were compared to the shape of the potent, 1,4-benzodiazepine antagonist, RO15-1788(10). Comparisons of the fit of the canthin-6-one in this "opposite" orientation and the *t*-butyl β-carboline ester in a normal orientation, both to RO15-1788, are shown in Fig. 3*a* and *b*. The separation between the midpoint of the **A** ring of the canthin-6-one and O(34) is 6.749(2) Å which is ca. 0.25 Å longer than the separation between the **A** ring and the midpoint between N(2) and O(32), the binding point of a "normal" β-carboline orientation. In either orientation, this ligand cannot form a H-bond to the receptor through the indole N—H; this interaction is thought to be necessary for inverse agonist activity (13*a*, *b*).

Neither of the other two *trans* ligands, *N*-ethyl-3-carbamoyl-β-carboline (**IV**) or 3-(methoxycarbonyl)amino-β-carboline (**V**), have good superpositions in the "opposite" orientation. In addition to poor fit in the side chain region, another difference is that this alternative orientation places the indole N—H function of the β-carbolines in the same position as the carbonyl oxygen atom, O(21), of RO15-1788. In contrast, the canthin-6-one superposition shown in Fig. 3*a* places two similar functionalities, the two carbonyl O atoms, O(21) from RO15-1788 and O(17) from the canthin-6-one, in the same position. Thus, the canthin-6-one may be unique in its ability to bind in either of the *trans* or *cis* conformations.

The canthin-6-one, **II**, was screened in whole animal studies (32) and did not demonstrate potent *in vivo* activity: the canthin-6-one did not antagonize the anticonvulsant effects of diazepam, nor did it show any inverse agonist activity. The lack of *in vivo* activity may be due either to a low *in vivo* affinity so that the biological effect is small or to an inability of the compound to reach the benzodiazepine receptor via the blood–brain barrier. This latter argument is supported by the results of a CNDO (33) calculation of the electronic properties of both the *t*-butyl ester β-carboline and the canthin-6-one. These calculations indicate

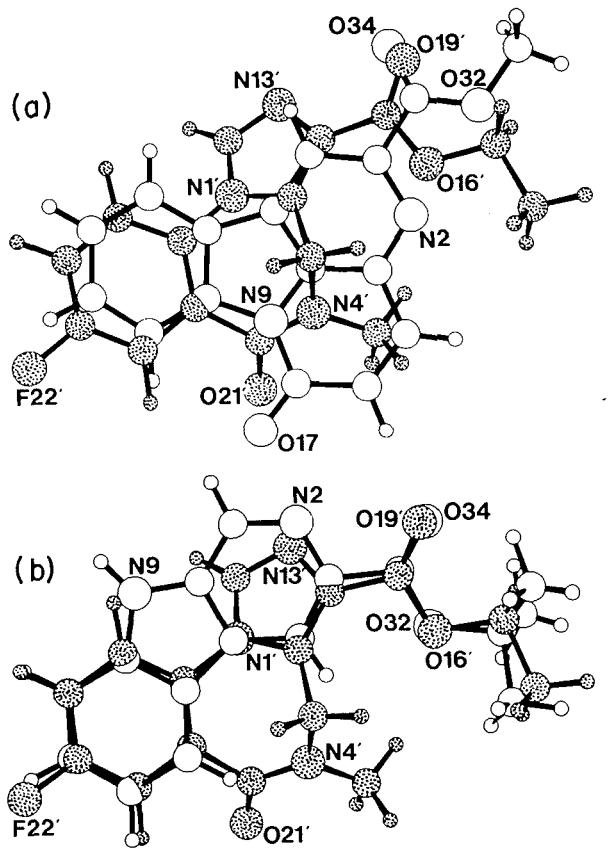

FIG. 3. (*a*) Superposition of the structure of compound **II** (open circles) in the "opposite" orientation with the structure of the antagonist, RO15-1788 (stippled circles, 10). (*b*) Superposition of compound **I** (open circles) in the normal orientation with RO15-1788 (stippled circles). In both drawings, the points of overlap were the **A** rings and the carbonyl O atoms. The least squares superpositions of the molecules were calculated with the program PROFIT (35) and the drawings were made with the program PLUTO (36).

that, while the individual atomic charges are similar in the two structures, the dipole moments are quite different. The β-carboline ester has a large dipole moment of 4.46 debye while the canthin-6-one is much less polar with a dipole moment of 1.38 debye. This difference in relative polarity may indicate that the biological transport characteristics of the two ligands are quite different or that electrostatic orientation of the two ligands in the binding site could be different.

In summary, the structure of the *t*-butyl ester, **I**, supports the hypothesis that the presence of a hydrogen bond acceptor site on the ligand (the pyridyl N atom) is an important criterion for receptor affinity (10, 11, 13*a*, *b*, 30) and that substituents and conformations that enhance the acceptor function enhance affinity. The *cis* conformation of the ester side chain, which will enhance the proposed hydrogen bond formation between N(2) and the receptor by forming a three-center H-bond involving the carbonyl O atom as a secondary hydrogen acceptor, has been found in **I** and in another antagonist, 6-N-benzyl methyl ester (22) as well as in the inverse agonist esters (21, 23), all high affinity ligands. The methoxycarbonyl amino β-carboline antagonist (12), which crystallized with a *trans* side chain conformation, is shown to have an accessible *cis* conformation (*vide infra*); thereby supporting the hypothesized importance of the proposed *cis* interaction. Comparison of the inverse agonist β-carboline esters with the structure of the antagonist, **I**, indicates that the difference between ligands which elicit different biological effects is mainly a difference in molecular volume. The larger size of the antagonist compounds may preclude complete occupation of the inverse agonist site, in the case of the two interacting site model, or preclude the complete conformational change to the inverse agonist-elicited receptor shape in the case of the induced conformation model. Taken together, these two features, the similar hydrogen bonding patterns and the different sizes, suggest that inverse agonists and antagonists can occupy, if somewhat differently, a common binding site (10, 13*a*, *b*).

The affinity of the canthin-6-one may be due to the highly planar aromatic system, a feature that is known to be necessary for binding (14, 15). The low polarity of the molecule may either affect transport or may preclude proper orientation in the binding site so that the molecule simply occupies the binding pocket without forming specific hydrogen bonds and, therefore, without eliciting any biological response. Interestingly, the canthin-6-one fits the current structural models for the recognition site better in a reversed orientation rather than in the orientation adopted by ligands that do have *in vivo* activity.

In summary, the structures presented here support the hypotheses that size and the formation of specific H-bonds are important criteria for receptor affinity (10, 11, 13*a*, *b*) and activity; however, they do not clearly discriminate between the two models for the benzodiazepine receptor. Further characterization of benzodiazepine receptor ligands is underway to define the geometric and electrostatic characteristics of the recognition site, particularly as to the discrimination between inverse agonists and agonists.

Naphthaloyl group: a new selective amino protecting group for deoxynucleosides in oligonucleotide synthesis

ARCHANA DIKSHIT, MANJULA CHADDHA, R. K. SINGH, AND KRISHNA MISRA[1]

Nucleic Acids Research Laboratory, Department of Chemistry, University of Allahabad, Allahabad-211 002, India

Received November 18, 1987[2]

ARCHANA DIKSHIT, MANJULA CHADDHA, R. K. SINGH, and KRISHNA MISRA. Can. J. Chem. **66**, 2989 (1988).

The naphthaloyl group has been found to be a selective amino protecting group for deoxycytidine, deoxyadenosine, and deoxyguanosine in oligodeoxyribonucleotide synthesis. All three protected monomers obtained (78–85%), being six-membered cyclic imides, were fairly stable. These protected monomers were used successfully for the preparation of dimers (phosphodiester approach) and tetramers (phosphotriester approach) in solution as well as solid phase, respectively. The group acted as a purification tool due to its high lipophilicity. No adverse effect has been observed either on the glycosidic bond (depurination) or the internucleotidic bond during its removal. The monomeric units were characterized by UV, NMR, and elemental analyses whereas the tetramers were characterized by enzymatic hydrolyses with snake venom phosphodiesterase followed by alkaline phosphatase.

ARCHANA DIKSHIT, MANJULA CHADDHA, R. K. SINGH, et KRISHNA MISRA. Can. J. Chem. **66**, 2989 (1988).

On a trouvé que le groupe naphtaloyle constitue un groupe protecteur sélectif de la fonction amine de la déoxycytidine, de la déoxyadénosine et de la déoxyguanosine dans la synthèse de l'oligodéoxyribonucléotide. Les trois monomères protégés obtenus (78–85%) sont des imides cycliques à six chainons assez stables. On a utilisé avantageusement ces trois monomères protégés dans la préparation des dimères (approche phosphodiester) et des tétramères (approche phosphotriesters) en solution aussi bien qu'en phase solide respectivement. La grande lipophilicité de ce groupe en fait un outil de purification. On n'a pas observé d'effets contraires ni sur la liaison glycosidique (dépurination) ni sur la liaison internucléotidique lors de la déprotection. On a caractérisé les unités monomères par ultraviolet, par résonance magnétique nucléaire et par analyse élémentaire tandis que l'hydrolyse enzymatique par le phosphodiestérase du venin de serpent suivie d'une phosphatase alcaline ont permis de caractériser les tétramères.

Introduction

The importance of synthetic oligodeoxyribonucleotides in molecular biology (1–5) has long attracted attention to the refining of chemical synthetic methods. The most important aspect of chemical syntheses of oligodeoxyribonucleotides is the selective protection of different nucleophilic sites of the monomer building blocks, and amino protection is one of them. The amino protecting groups remain in place throughout the course of the synthesis and, therefore, are extremely important. Several groups have been used for the protection of the amino function (5–10) but selective protection of the amino group, despite repeated attempts, is still a challenging and important problem. Notable success has been achieved only in the case of deoxycytidine (11–14). We have now successfully used naphthaloyl as a new selective amino protecting group for the protection of all three deoxynucleosides, i.e., dA, dG, and dC. The protected monomers are found to be compatible with conditions for the synthesis of oligodeoxyribonucleotides, as evidenced by good yields of dimers and tetramers synthesized in solution phase and solid phase, respectively.

Experimental

Nucleosides, nucleotides, dimethoxytrityl chloride, 5′-*O*-dimethoxytritylthymidine-3′-*O*-chlorophenyl phosphate (triethylammonium salt), mesitylenesulfonyl-3-nitro-1,2,4-triazole, triisopropylbenzene sulfonyl chloride (TPSCl), 1,1,3,3-tetramethylguanidine, 4-nitrobenzaldoxime, 1-methylimidazole, DCC, Fmoc-glycine, ninhydrin, and acenaphthene were purchased from Fluka, Sigma, and Cruachem Chemical Co. The enzymes, snake venom phosphodiesterase (EC 3.1.4.1., *Crotalus durissus*) and alkaline phosphatase (EC 3.1.3.1., *Escherichia coli*), were purchased from Sigma Chemical Co. Naphthalic anhydride was prepared by dichromate oxidation of acenaphthene (15). Composite polydimethylacrylamide/kieselguhr support was used for solid phase synthesis, which was carried out on a dual column DNA bench synthesizer (OMNIFIT Ltd., Cambridge). HPLC separations were made on an LKB Ultrapac TSK DEAE-35W column (7.5 × 150 mm) and UV absorption was measured on a Hitachi 220 S spectrophotometer. Elemental analyses were carried out using a Carlo Erba 1106 analyser.

All the tlc analyses were done on silica gel G (Merck) using solvent system *a* (CH_2Cl_2/CH_3OH ; 9:1,v/v) or *b* (CH_2Cl_2/CH_3OH ; 9.5:0.5, v/v).

General preparation of N-*napthaloyldeoxynucleosides (N-nph-dNS)*

Each deoxynucleoside (1 mmol) was dried by evaporation *in vacuo* with pyridine (3 mL), twice. It was then suspended in dry pyridine (10 mL) and naphthalic anhydride (1 mmol) was added. Triethylamine (0.02 mL) was used as a catalyst. The flask was sealed and shaken in the dark at 70°C for 7 h, the mixture was evaporated to a gum *in vacuo*, poured into water (10 mL), and extracted with dichloromethane (4×5 mL). The organic layer was backwashed with water, dried over Na_2SO_4, and filtered. This organic part yielded 55, 55, and 50% of the N-protected derivatives of dC, dA, and dG, respectively. The aqueous layer was repeatedly coevaporated to dryness with pyridine, the residue reacted with naphthalic anhydride (1 mmol), and, after an appropriate time, it was extracted with dichloromethane. The combined dichloromethane solution was evaporated to dryness *in vacuo* and the residue was subjected to silica gel column chromatography. Elution was done with CH_2Cl_2/ CH_3OH of increasing polarity (Scheme 1). Data obtained are given in Table 1.

Conditions for removal of naphthaloyl group

Conditions for the removal of the naphthaloyl group were worked out by treating the N-protected derivatives with 40% ammonia at 30, 50, and 70°C. Reaction was quenched after 1, 2, 3, 4, 5, and 6 h duration. After hydrolysis, the mixtures were analysed for deprotected 2′-deoxynucleosides by preparative tlc and subsequent estimation by UV spectroscopy. Ammonia (40%) at 50°C for 4 h showed the best result and was taken to be the optimal condition for removal of the group, although the initial rate of hydrolysis varied in each case (Table 2).

General preparation of 5′-O-dimethoxytrityl-N-naphthaloyl-deoxynucleosides (5′-O-DMTr-N-nph-dNS)

The corresponding trityl derivatives were prepared by treating dried N-nph-dNS (1 mmol) with DMTrCl (1.2 mmol) in pyridine (10 mL) at room temperature (25–30°C) (Table 3). After completion of the reaction (as checked by tlc), the clear solution was evaporated to a gum *in vacuo*. Ice-cooled water (10 mL) was added and it was extracted with ethyl acetate (3×10 mL). The organic layer was dried over Na_2SO_4, concentrated, and applied to an alumina column, eluting with CH_2Cl_2/CH_3OH of increasing polarity. Yield, R_f, and λ_{max} of different derivatives are shown in Table 3.

General method for preparation of N,3′-diacetyldeoxyadenosine-5′-phosphate (pdA-N,3′-O-Ac_2)

Deoxyadenosine-5′-phosphate (1 mmol) was dried by evaporation *in vacuo* three times with dry pyridine (2 mL). The residue was placed in dry pyridine (5 mL), acetic anhydride (5 mL) added, and the solution stirred at room temperature. After 3 h, the reaction was checked for completion, by tlc, and methanol (5 mL) was added. The reaction mixture was evaporated to a gum. The gum was dissolved in a minimum amount of water, which was washed with ether. The aqueous solution was evaporated to a gum. The process of evaporation was repeated twice with 10% aqueous pyridine. The residue thus obtained was dissolved in dry pyridine, concentrated, and added dropwise to dry ether (5 times the volume of concentrated pyridine solution); the white precipitate was filtered, washed with ether, and dried under vacuum (yield, 90%; λ_{max} 272 nm).

TABLE 3. Preparation and characterization of 5′N-protected units

	Reaction time (h)	Yield (%)	R_f	λ_{max} (nm)
5′-O-DMTr-N^4-nph-dC	3	90	0.42 (*a*)	292,303,312
5′-O-DMTr-N^6-nph-dA	2	94	0.47 (*b*)	271–273
5′-O-DMTr-N^2-nph-dG	1.5	95	0.45 (*b*)	262–264

a and *b* refer to solvent systems (see text).

General procedure for dimer preparation

All three 5′-O-DMTr-N-naphthaloyldeoxynucleosides (1 mmol) and N,3′-diacetylated-5′-phosphates of dA (2 mmol) were evaporated *in vacuo* three times with dry pyridine and suspended in pyridine (5 mL). Triisopropyl benzenesulfonyl chloride (4 mmol) was added and the mixture stirred. After 4 h at room temperature (22–25°C), water (5 mL) was added while cooling the flask in an ice-bath (Scheme 2).

Purification of dimers

Purification of dimers was carried out on a DEAE cellulose (HCO_3^-) ion-exchange column. Elution was done by tris-HCl buffer (pH 8.3, 0.1 M) using a linear gradient of NaCl (0.05–0.15 M) and columns were monitored at 300, 270, and 260 nm in the case of CpA, ApA, and GpA, respectively. The desired fractions were pooled and evaporated to dryness *in vacuo*.

Dry residue dissolved in concentrated ammonia (40%) was kept sealed at 50°C for 4 h. It was then evaporated carefully, *in vacuo*, to dryness. Acetic acid (80%) was added to the flask and left at 25–30°C for 30 min. Acid was evaporated *in vacuo* and the residue dissolved in a minimum amount of water, diluted to twice the initial volume, and extracted four times with ether. The aqueous layer was lyophilized and stored under dry conditions. The dimers were obtained in 62–68% yield.

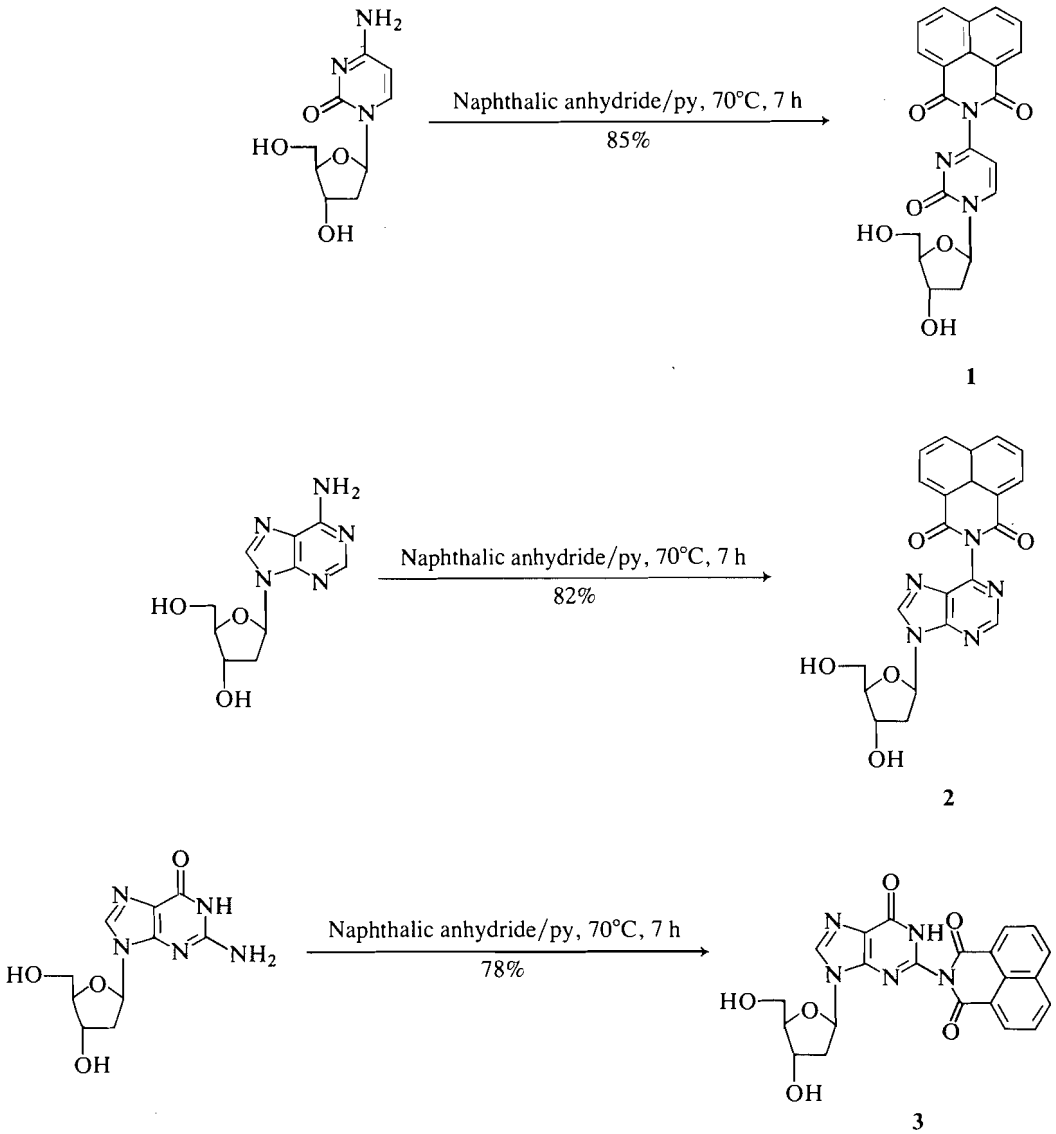

SCHEME 1. Preparation of cyclic imides of deoxynucleosides (dC, dA, and dG).

Preparation of 5'-O-DMTr-N-nph-dNS-3'-O-succinate

To 5'-O-DMTr-N-nph-dNS (0.5 mmol) dissolved in pyridine (2.5 mL) were added triethylamine (0.2 mL) and succinic anhydride (0.55 mmol). The reaction mixture was worked up as usual (14) to give the final product. Yield, 70–75%.

Preparation and purification of tetramers d(TTTC), d(TTTA), and d(TTTG)

5'-O-DMTr-N-nph-dNS-3'-O-succinate was linked to the support (kieselguhr/polydimethylacrylamide, 500 mg) with the help of the spacer, i.e., ethylenediamine and two glycine units, using Gait's procedure (16). Loading was estimated to be 68, 65, and 57 μmol g^{-1} in the case of dC, dA, and dG, respectively.

This functionalized resin (100 mg each) was placed in the column of the DNA bench synthesizer and allowed to stand in DMF for 5 min. Synthesis, deprotection, and purification of the tetramers were carried out by the usual procedure (14) (Fig. 1). Yield of d(TTTC), d(TTTA), and d(TTTG) was 72.6, 70.0, and 66.4%, respectively (Scheme 3).

Enzymatic hydrolysis of tetramers

Each tetramer (0.4 A_{260} units) dissolved in 0.1 M Tris-HCl buffer, pH 8.5 (0.5 mL), was first digested with snake venom phosphodiesterase (5 μg, 37°C, 2 h) and then incubated with alkaline phosphatase (5 μg, 37°C, 1 h). The nucleosides thus obtained were separated (Fig. 2) using 0.1 M triethylammonium acetate, pH 7.0 (A), and acetonitrile (B). A gradient elution using 6% B over 20 min at a flow rate of 0.5 mL min^{-1} was achieved. After separation, quantification was made at 260 nm on the basis of peak areas and extinction coefficients of the nucleosides (E_{260} : dT, 8800; dC, 7300; dA, 15 400; and dG, 11 700).

Results and discussion

The naphthaloyl group has been used for protection of the exocyclic amino function of all three deoxynucleosides, i.e., dA, dG, and dC, when cyclic imides were obtained (Scheme 1). These cyclic imides have been well characterized by elemental analyses, and by their UV and NMR spectra. There was no indication of any free -NH or -COOH group.

The absolute selectivity observed during protection under controlled experimental conditions for all three deoxynucleosides is of utmost importance. It eliminates the two-step procedure of protection whereby, first, a fully protected derivative is formed that on subsequent and selective hydrolysis gives the desired product (Khorana's procedure) (17), and it also avoids the need for prior silylation (Jones' procedure) (18). This selectivity may be explained as most probably due to the formation of stable cyclic imides, which drives the reaction predominantly in this direction.

A literature survey reveals that, so far, acid chlorides have been employed for acylation of the exocyclic amino function of deoxynucleosides. Because of the slow reaction between anhydride and amino function (cf. chloride and amino function), more selectivity can be observed. Thus, the use of anhydride is certainly advantageous, due also to its stable nature and easy storage. Furthermore, use of acid chlorides is well known to yield isomeric imides, while anhydrides are reported to exclude the formation of any such isomers (19). In this respect the use of the naphthaloyl group is more advantageous and convenient as compared to the phthaloyl group.

Other advantages envisaged for this group are its bulkier nature and higher lipophilicity. These are important considerations for N-acyl protecting groups. The naphthaloyl group has found extensive use in preparation of smaller blocks via solution phase methodology where column purification of those fully protected blocks after each condensation step is necessary. Because of high lipophilicity, the group helps in purification. It has been observed that phosphodiester oligomers have a tendency to become less soluble in organic solvents with increasing chain length due to polar effects (20). This can make experimental procedure difficult in connection with solvent extractions and adsorption chromatographic methods. However, naphthaloyl derivatives are highly soluble in organic solvents due to the hydrophobic nature of the group and are, therefore, well suited for adsorption chromatography as well as for purification of protected oligonucleotides by reversed phase HPLC (21). Thus, the group acts as a purification handle.

The protected monomer units have been found sufficiently stable. In the case of adenosine, the imidazole ring opened when the phthaloyl group was used for amino protection, under the reaction conditions of oligonucleotide synthesis (7), and thus many problems were created. But in the present case no ring opening was observed. This, in all probability, was due to the formation of a more stable six-membered ring in the cyclic imides in place of a five-membered ring as in the case of phthaloyl derivatives.

Conditions for removal of the naphthaloyl group are comparatively milder and speed of reaction is faster. It can be removed by concentrated ammonia (40%) at 50°C in 4 h (cf. the benzoyl group, 40% ammonia, 50°C, 5 h), although the initial rate of hydrolysis is different in the case of different nucleosides.

To adjudge the efficiency of the group in preparation of small blocks and oligonucleotides by solution and solid phase methods, different dimers and tetramers have been prepared by the phosphodiester and triester approach, respectively. An overall yield of 62–68% in the case of dimers and 66–72% in the case of tetramers was obtained, which is almost comparable

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 122.72.124.2 on 09/07/12

to the yields reported in the literature, thereby indicating the suitability of the group in both approaches, viz., solution and solid phase.

To confirm the structure of the tetramers, enzymatic hydrolysis with snake venom phosphodiesterase followed by alkaline phosphatase was carried out. After HPLC analysis, the cleavage pattern of the tetramers clearly indicated the presence of deoxynucleosides in a 3:1 ratio in each case (Fig. 2). The peak assignment, based on the retention time, was confirmed by direct comparison with authentic samples of deoxynucleosides. HPLC analyses clearly showed the absence of any base modification.

Modelling the binding step in dopamine receptor–antagonist interactions

ALAIN BOUDON, JAN SZYMONIAK, JACQUES R. CHRÉTIEN,[1] and JACQUES-EMILE DUBOIS

Institut de Topologie et de Dynamique des Systèmes de l'Université Paris VII, associé au CNRS, 1 rue Guy de la Brosse, 75005 Paris, France, and Laboratoire de Chimiométrie, Université d'Orléans, B.P. 6759, 45067 Orleans Cedex 2, France

Received July 5, 1988

ALAIN BOUDON, JAN SZYMONIAK, JACQUES R. CHRÉTIEN, and JACQUES-EMILE DUBOIS. Can. J. Chem. **66**, 2995 (1988).

Modelling of the binding step in dopamine receptor–antagonist interactions was undertaken using sixteen antagonists belonging to the following five chemical series: phenothiazines, thioxanthenes, butyrophenones, benzamides, and benzisoxazoles. The Lower Unoccupied Molecular Orbitals (LUMOs) of the antagonists used for these interactions were compared using a similarity τ_{ij} index, which enabled us to define the characteristic orbital forms of the active molecules. The result of the intersection of these representative orbital forms was the form common to the antagonists' LUMOs. This form corresponds to the orbital form of the indole's Higher Occupied Molecular Orbital (HOMO), and thus suggests that the aromatic binding site of the dopamine receptor is part of a tryptophan type structure.

ALAIN BOUDON, JAN SZYMONIAK, JACQUES R. CHRÉTIEN et JACQUES-EMILE DUBOIS. Can. J. Chem. **66**, 2995 (1988).

La modélisation de l'étape de liaison des interactions récepteur dopaminergique–antagoniste est entreprise sur seize antagonistes appartenant à cinq séries chimiques: les phénothiazines, les thioxanthènes, les butyrophénones, les benzamides et les benzisoxazoles. Une comparaison des orbitales moléculaires vacantes les plus basses (LUMO) des antagonistes mises en jeu lors de l'interaction, est effectuée à l'aide de l'indice de similitude τ_{ij}. Elle permet de préciser les formes des orbitales caractéristiques des molécules actives. L'intersection de ces formes orbitales représentatives aboutit à la forme commune des LUMO des antagonistes. Cette forme commune correspond à la forme de l'orbitale HOMO de l'indole; elle suggère que le site de liaison aromatique du récepteur dopaminergique fait partie de la structure de type tryptophane.

Introduction

Neuroleptic compounds, which are dopamine receptor–antagonists, include a wide variety of chemical series: phenothiazines, thioxanthenes, butyrophenones, benzamides, benzisoxazoles... Despite this structural diversity each antagonist contains an aromatic ring linked to an alkyl amine chain with three or four nodes betwen the nitrogen atom and the aromatic ring. The antagonists act on two primary sites of the dopamine receptor (1), whose exact structure has not yet been determined.

Several studies stress that the proper positioning of the chain's nitrogen atom in relation to the aromatic ring is essential for a strong affinity between the antagonist and the receptor. In the case of the rigid molecules in the butaclamol series, a slight modification of the positioning of the ring eliminates activity (2). Receptor mapping studies provided the receptors' topography, most importantly the three-dimensional location of the zones corresponding to the two primary sites (3, 4). The superposition of the pharmacophores (N atom-chain – aromatic ring) — corresponding to the antagonists with flexible chains and belonging to a different series — was accomplished with only slight modifications of the chain's conformation (5). Comparative conformational analysis allows us to locate the nitrogen orbital's vectoral position relative to the orbital of the aromatic system (6). Geometric models of the receptor obtained from such research do not, however, inform us about the nature of the interactions.

Recently it was demonstrated that the energy of the lower unoccupied molecular orbital (ϵ_{LUMO}) was correlated with the biological activity for different series of antagonists (7, 8); biological activity increases with the decrease of the LUMO energy. An excellent correlation exists, for example, between activity (C_1) and the ϵ_{LUMO} for sixteen 2-substituted phenothiazines belonging to three series: promazine, perazine, and phenazine (8). These results have been formalized in terms of the LUMO antagonist – HOMO receptor (L_a–H_r) principle, which denotes the participation of the antagonist's aromatic ring LUMO and the receptor's aromatic binding site HOMO in the complex formation.

The L_a–H_r principle led us to examine more closely the role played by the antagonist's LUMO, with the object of modelling the interactions of the antagonists with the dopamine receptor.

Our investigations are based on several primary assumptions. First, the factors relating to drug transport play a minor role so the activity differences reflect essentially events occurring at the receptor. The validity of this assumption is confirmed by several studies (9, 10). Second, the charge-transfer interactions are an important feature in stabilizing the drug–receptor complex. Third, the antagonist's unoccupied orbital (LUMO) acts as an electron acceptor in charge-transfer interactions. Since the receptor has not been isolated, the latter two assumptions cannot be verified through direct experimentation at the present time. However, these conditions seem to prevail in the current study, in light of theoretical considerations.

If a major portion of the stabilization energy ΔW for the drug–receptor complex is provided by charge-transfer interactions (11) in which the drug acts as an electron acceptor, ΔW may be expressed approximately by the Mulliken equation (12)

$$\Delta W = Q - \kappa/(\epsilon_a - \epsilon_d - \lambda)$$

where Q is the energy of interaction between the drug and receptor exclusive of charge-transfer, $\epsilon_a - \epsilon_d$ is the energy gap between the donor (receptor) Φ_d and acceptor Φ_a molecular orbitals, and λ is a term which depends upon the degree of overlap between Φ_d and Φ_a. Significant charge-transfer contributions to ΔW exist only when Φ_d and Φ_a exhibit complementary features in the overlap region with regard to local symmetry and density distribution. If this were not the case, k would become negligible (12). If the distribution of density in the critical regions of the pharmacophore remained essentially constant for a given series of drug molecules, the values of Q, k, and λ would not be expected to change greatly. As a result, the stability of the drug–receptor complex appears to depend pri-

marily on the energy (ϵ_a) of the molecular orbital Φ_a. This stability is enhanced if Φ_a is a low-energy unoccupied molecular orbital and Φ_d is a high-energy occupied molecular orbital.

Consider a homogeneous group of 2-substituted phenithiazine molecules which will orientate in the same way according to the field of the receptor and where the contribution of the second interaction on the side of the chain's nitrogen atom is weighed: a very good correlation exists between ϵ_{LUMO} and antagonist activity (8). This correlation is characterized by a negative slope. It therefore fulfills the conditions of a $\Delta W = f(\epsilon_a)$ relationship, and is consistent with the expectation that a reduction of the energy of the orbital acceptor stabilizes the drug–receptor complex when charge-transfer interactions play an important role (13).

The relationship between activity and the single ϵ_{LUMO} for the aromatic binding site interaction indicates only a slight variation of the overlap factor. This lets us assume that the LUMOs corresponding to the aromatic rings of active phenothiazines have similar characteristics with regard to local symmetry and density distribution. This supposed similarity among the LUMOs (Φ_a) of the active phenothiazines related to the HOMO (Φ_d) of the receptor's aromatic binding site also assures conditions favorable for a significant contribution by charge-transfer interactions to ΔW.

The activity of the non-phenothiazine series of antagonists also increases with the reduction in LUMO's energy (8). It could be assumed that LUMOs corresponding to these antagonists show a likeness to LUMOs of the phenothiazines, just as it may be assumed that they resemble each other. We may now ask, what is the extent and content of this similarity in the case of a group of structurally heterogeneous antagonists?

In the present work we would like to focus attention on the dopamine receptor–antagonist MOs' overlap factor. We will study the distribution of the LUMO density among the aromatic parts of a series of antagonists, while assuming that the LUMO acts as an electron acceptor in charge-transfer interactions dominating the stabilization of the complex.

Because of the rudimentary nature of our model (assumption that the contribution of the N-atom interaction is constant for the non-variable alkyl-chain analogues, approximation of the frontier orbital approach, limitations imposed by the quality of the biological data ...) we did not attempt to establish a quantitiative structure–activity relationship. The reasoning and final conclusions remain semi-quantitative.

In order to systematize our approach, the following procedure was taken. A preliminary comparison of the LUMO density distributions was carried out using a τ_{ij} similarity index. This methodology applied by Cheney *et al.* (14, 15) in studies on drug–receptor charge-transfer interactions using frontier MOs was adopted for our ends. Applying these results as a point of departure, we conducted a more extensive analysis, seeking, above all, to determine the characteristics shared by the antagonists' LUMOs. Moreover a comparison of the series of antagonists was always preceded by an analysis of the LUMO density distribution of the homogeneous series of phenothiazines.

We examined the overlap factor to determine the shape of the aromatic binding site of the dopamine receptor (HOMO) through an indirect approach of receptor mapping.

Methods

Calculations were performed on a VAX-11/780 computer under VMS. Wave functions and electron densities were calculated by the Gaussian 80 program (QCPE 446) operating in the

SCHEME 1

STO-3G* minimal basis set. As in our previous investigation, standard bond lengths and valency angles (16) were used. No geometrical optimiztions were performed. Molecular orbitals are written as linear combinations of the basis functions, using the following equation:

$$[1] \quad \Phi_i = \sum_r^N C_{ri}\Psi_r$$

N is the number of basis function Ψ_r, and C_{ri} is an expansion coefficient on atom r. Optimization of the molecular wave function was performed using a standard self-consistent field (SCF) procedure (17, 18).

The similarity τ_{ij} index (14) is used to express the correlation between MOs from two molecules, A and B.

$$[2] \quad \tau_{ij} = \left|\sum_r^n C_{rI}^A \times C_{rj}^B\right|$$

C_{ri}^A represents the coefficient of Ψ_r in the ith MO (LUMO in this case) of molecule A (**I** to **V**, Scheme 1). In this case, only corresponding structural moieties in molecules A and B, i.e., C atoms of the aromatic rings are taken into account and give rise to significant terms in eq. [2]. If Φ_r in the aromatic part of molecule A has no counterpart in the aromatic part of molecule B, the value of C_{rj}^B is considered to be zero. The τ_{ij} similarity index (Table 1) is calculated for two different molecules (A ≠ B), with respect to only the density contribution made by the aromatic ring. The value of τ_{ij} then varies from 0 to 1, depending on the degree of similarity between the density distribution over

the corresponding carbon atoms of two aromatic rings.[2] However, in the case of a comparison within the ring itself (**I***a*–**I***a*, etc.) τ_{ij} is not calculated with respect to the ring (for this would invariably give a τ_{ij} value of 1) but rather to the electron density of the whole molecule. In this event, τ_{ij} expresses the absolute value of the aromatic ring's LUMO density. The electron density values for sixteen model compounds are then given in the diagonal of the τ_{ij} matrix in Table 1.

Determination of the common LUMO form was done by intersecting the LUMOs previously defined by τ_{ij} analysis. Intersections were constructed on corresponding atoms of comparative aromatic rings starting from the carbon atom linked to the aliphatic fragment. The wave function Φ was calculated in a plane parallel to the aromatic ring at a distance of 0.5 Å (~1 Bohr). The intersection Λ yielded the smallest common Φ value.

Supposing that Φ_A and Φ_B are wave functions calculated at any point on the plane,

$$\text{If } \Phi_A \times \Phi_B > 0$$

$$\Lambda = 0$$

The results of the intersections in graphic terms are given in Fig. 1, indicating points on the plane for which $|\Phi| \geq 0.06$.

The chlorpromazine index C_l is the relative measure of the phenothiazines' neuroleptic activity ($C_l = 1$ for the chlorpromazine). The C_l values of the antiapomorphine test for the promazine analogues, corresponding to model phenothiazines **I***a*–*h* (Scheme 1), were derived from ref. 19. They are as follows: $C_l = 0.03$ for **I***a*, 1.0 for **I***b*, 0.25 for **I***c*, 0.01 for **I***d*, 0.25 for **I***e*, 1 for **I***f*, 0.20 for **I***g*, 4.0 for **I***h*. The C_l values for the promazine chain analogues of model thioxanthenes **II***a* and **II***b* are 0.06 for **II***a* and 1.0 for **II***b* (19). Binding test values for the active analogues of model series **III**–**V** are given in the text.

Results and discussion

In order to study the distribution of the LUMO density among the aromatic fragments of a series of antagonists, we chose sixteen model compounds from the following five chemical series: phenothiazines (**I**), thioxanthenes (**II**), butyrophenones (**III**) benzamides (**IV**), and benzisoxazoles (**V**). They are aromatic (tricyclic) parts corresponding to the non-variable alkyl-chain analogues of different levels of activity (see Methods). The eight phenothiazines (**I***a*–**I***h*) differ by the nature of their substituents and positions. The influence of the disubstitution in the same aromatic ring (**I***f*) or both aromatic rings (**I***g*) will be observed. The four non-phenothiazine series (**II**–**V**) are each represented by two differently substituted compounds.

As already explained (see Methods), the τ_{ij} index and the intersection procedure require an equivalence of carbon atoms in the two aromatic rings compared. In fact, it may be assumed that the location of the antagonist's aromatic ring in relation to the corresponding site on the receptor does not vary much at the time of the binding interaction. This supposition follows from geometric constraints related to the second simultaneous interaction, that of the alkyl chain's nitrogen atom (see Introduction). More precisely, doing away with the equivalence of carbon atoms in the compared aromatic rings amounts to rotating one ring at least 60 degrees, which corresponds to the displacement of one atom, or a C_1–$C_{2'}$ interaction instead of a C_1–$C_{1'}$. Even this minimum rotation would bring about significant conformational constraints in the chain, due to the nitrogen atom's fixed position to the aromatic ring (2–6).

The LUMO electron density

The LUMO electron density is a localized electronic property whose role in the interaction of the antagonists' aromatic ring with the aromatic binding site of the dopamine receptor will be considered. The values for the sixteen model compounds are given in the diagonal of the τ_{ij} matrix in Table 1. The LUMO electron density is generally concentrated at the aromatic rings, to the detriment of the heteroatoms S and N for the phenothiazines. Thus the LUMO electron density values are 0.49 for each of the two aromatic rings of *N*-methylphenothiazine **I***a*, which represents 98% of the total density. Substitution of the aromatic ring by an electroacceptor (**I***b*, **I***c*, **I***d*, **I***h*) strongly increases its electron density.

Two groups of compounds will be examined. The first group is composed of compounds with high electron densities ranging from 0.63 to 0.92. This group includes five phenothiazines (**I***b*, **I***c*, **I***d*, **I***f*, **I***h*) and all of the butyrophenones, benzamides, and benzisoxazoles. The second group, which contains compounds with low electron densities ranging from 0.34 to 0.53, includes the other three phenothiazines (**I***a*, **I***e*, **I***g*) and the two thioxanthenes.

It is not possible to establish a close relationship between activity and electron density to the exclusion of other important parameters like the ϵ_{LUMO} (8). Nevertheless, the biological activity of the first group's phenothiazines was generally greater than that of the second, except for the inactive 4-Cl-*N*-methylphenothiazine **I***d*. This compound's low activity is undoubtedly due to a very unfavorable overlap factor which will be discussed further on.

The important role played by the electron density is demonstrated by 2-Cl,8-CF_3-*N*-methylphenothiazine **I***g* of the second group. Compound **I***g* has a chlorpromazine index ($C_l = 0.20$) (19) corresponding to a relatively low activity, though a favorably low ϵ_{LUMO} (8) was observed (5.97 eV). The lowering of the activity of compound **I***g* is explained by the fact that its electron density is distributed between the two substituted rings, giving values of 0.53 for the CF_3-substituted ring (Table 1) and 0.41 for the Cl-substituted ring. Indeed, when compared to the electron density of the monosubstituted phenothiazine ring as in active compound **I***b* (0.81), the relatively lower values of the electron densities of the two aromatic rings weaken the potential interactions with the receptor's aromatic binding site. The other two phenothiazines of the second group (**I***a* and **I***e*) have similarly low electron densities which contribute to decreased activity. The difference in activity for these two compounds (C_l **I***a* = 0.03; C_l **I***e* = 0.25) are probably due to the favorable orientation vector of 2-MeO-*N*-methylphenothiazine **I***e* as already observed.

Degrees of similarity of the LUMO form

The distribution of the LUMO density of an aromatic ring will be referred to as the orbital form. The similarity index τ_{ij} (Table 1) indicates the degree of orbital form similarities for any two molecules. Comparison of τ_{ij} of sixteen molecules **I**–**V** (Scheme 1) serves to screen the LUMO having the characteristic form of active antagonists. For clarity, the τ_{ij} data of Table 1

[2]For tricyclic molecules **I** and **II** the substituted aromatic ring is considered.

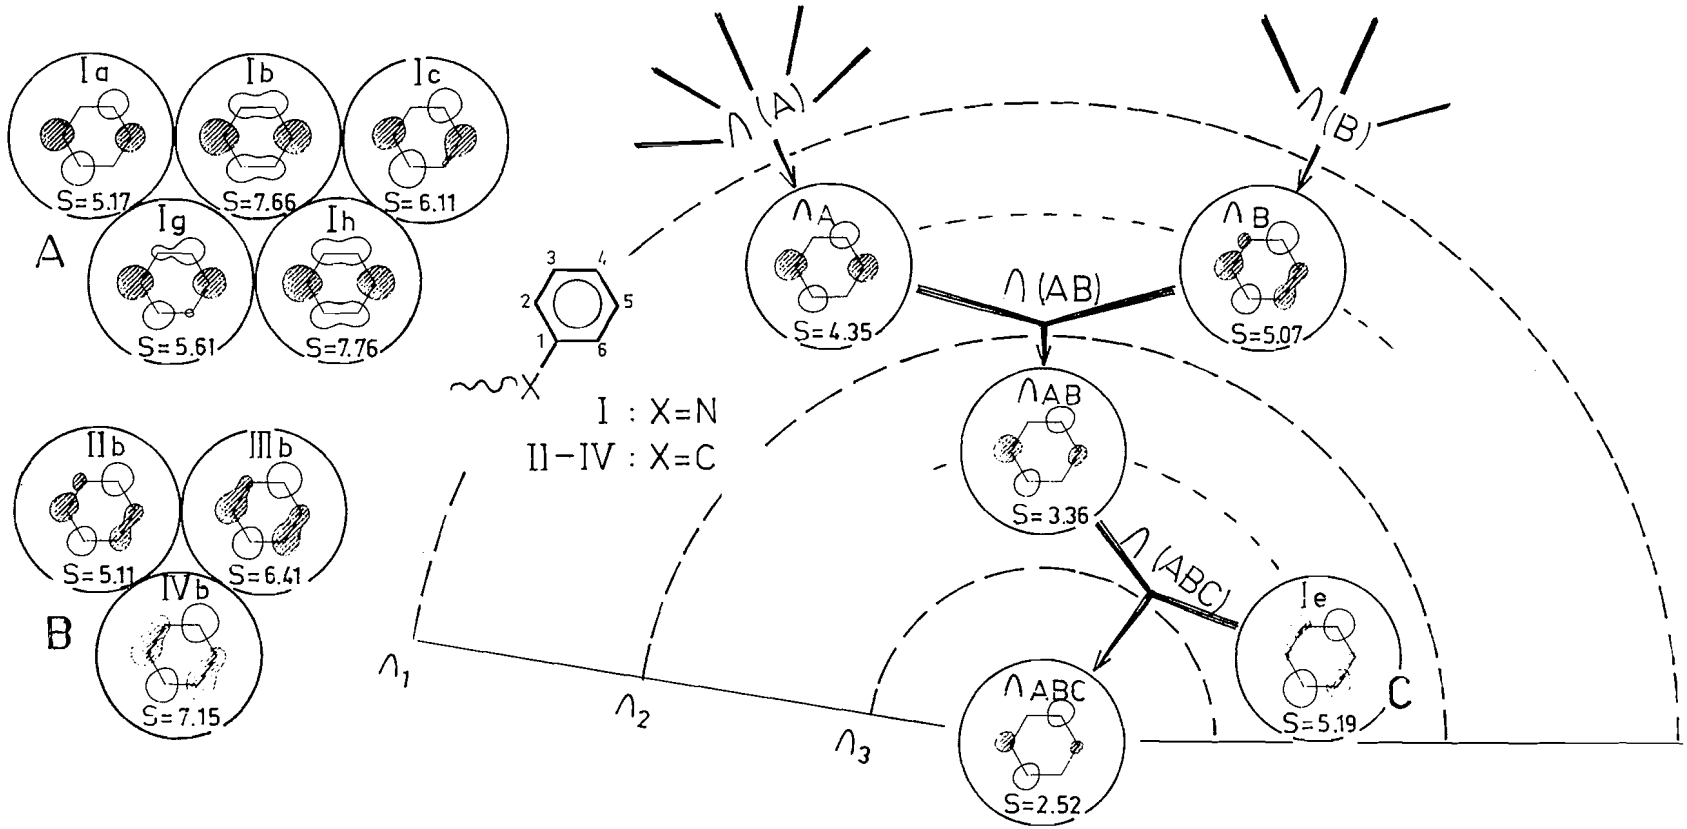

FIG. 1. Graphic representation of the intersections of the dopamine antagonist LUMO orbital forms. The intersections are made on the corresponding carbon atoms of the aromatic rings (where the C_1-atom of the ring is linked to the aliphatic fragment —×~). A represents the LUMO orbital forms of phenothiazines, B the LUMO orbital forms of the non-phenothiazine antagonists, and Λ_{ABC} the orbital form common to all four antagonist series. The S surfaces (Å^2) are indicated in a plane 0.5 Å (~1 Bohr) above the aromatic ring.

should be separated into three correlating zones: orbital forms for phenothiazine/phenothiazines (PP), orbital forms for phenothiazine/non-phenothiazines (PN), and orbital forms for non-phenothiazine/non-phenothiazines (NN). It is important to note that the orbital form of a phenothiazine may be better, equally or less well correlated with the orbital form of other phenothiazines (zone PP) than with the orbital forms of non-phenothiazine compounds (zone PN).

In other words, the two zones PP and PN of the τ_{ij} values which characterize the orbital forms of phenothiazines may exhibit the following three trends: (*1*) $\tau_{ij\,(PP)} \simeq \tau_{ij(PN)}$, (*2*) $\tau_{ij\,(PP)} > \tau_{ij\,(PN)}$, (*3*) $\tau_{ij\,(PP)} < \tau_{ij\,(PN)}$.

The first trend is represented by three phenothiazines, *N*-methylphenothiazine, 3-Cl-, and 2-Cl,8-CF_3-*N*-methylphenothiazine (**I***a*, **I***c*, **I***g*) showing a homogenous dispersion of their τ_{ij} values in the PP and PN zones. Generally, relatively high τ_{ij} values ($\tau_{ij} \simeq 0.4$–0.6) are observed for these compounds. Contrary to this general tendency, low τ_{ij} values are observed for **I***a* when compared with phenothiazine **I***d*, as well as with benzisoxazoles **V***a* and **V***b*, compound **I***c* when compared with phenothiazines **I***d* and **I***f*, and compound **I***g* when compared with benzisozazoles **V***a* and **V***b*.

In the second trend, there is a better correlation of the orbital forms between phenothiazines (as represented by **I***b*, **I***h*, and **I***f*) than between phenothiazines and non-phenothiazines. For 2-Cl-*N*-methylphenothiazine **I***b* and 2-CF_3-*N*-methylphenothiazine **I***h*, τ_{ij} values of the PP zone are only moderately higher than those of the PN zone. However, for 2,4-dichloro-*N*-methylphenothiazine **I***f*, the discrepancy increases with values ranging from 0.3 to 0.8 in the PP zone, and from 0.02 to 0.1 in the PN zone, with the exception of benzisoxazoles **V***a* and **V***b*.

The third trend, $\tau_{ij\,(PP)} < \tau_{ij\,(PN)}$, deals with the orbital forms of the phenothiazines which are less well correlated with other phenothiazines than with the non-phenothiazine compounds. This is illustrated by 2-MeO-*N*-methylphenothiazine **I***e* whose relatively high τ_{ij} values (~0.3–0.6) are nevertheless slightly lower in the PP zone than in the PN zone.

In general, the differences of the τ_{ij} of phenothiazines for zones PP and PN are weak (**I***b*, **I***h*, **I***e*) or nonexistent (**I***a*, **I***c*, **I***g*), with the exception of only two 4-substituted chlorinated compounds: 4-chloro- and 2,4-dichloro-*N*-methylphenothiazine (**I***d* and **I***f*, respectively). It must be noted that the virtually inactive phenothiazine **I***d* exhibits low τ_{ij} values (0.1–0.2) with most of the other model compounds. Only three of the fifteen τ_{ij} values, corresponding to compounds **I***b*, **I***h*, and **I***f* with heavy orbital density, present τ_{ij} values greater than 0.6. The relatively good correlation of **I***d* with the orbital form of the benzisoxazoles ($\tau_{ij} \simeq 0.5$) is obviously related to the special properties of their LUMOs.

Search for a LUMO form common to the dopamine antagonits

The LUMO form is only one of the parameters responsible for antagonist activity related to the interaction at the aromatic binding site. Therefore the selection of optimal LUMO forms — those that best resemble the hypothetical HOMO form of the receptor's binding site — cannot be made merely by distinguishing the active and inactive molecules. Another important parameter, ϵ_{LUMO}, must also be taken into account. Indeed the orbital forms of molecules demonstrating very low activity cannot be considered as representative of the optimal form, just as the LUMO forms of two molecules of comparable, medium activity are not necessarily representative to the same degree. It was in view of the complexity of this problem that the preliminary τ_{ij} analysis was carried out by comparing the similarity of the orbital forms. This quantitative comparison of each LUMO form with all of the others (corresponding to phenothiazine and non-phenothiazine antagonists with different levels of activity) was made in order to facilitate selecting the optimal orbital forms. It is important to note that the orbital forms corresponding to active antagonists of different chemical series show a strong resemblance. This justifies delineating a characteristic shape common to all of them. The contribution of phenothiazine and/or non-phenothiazine antagonists to this common form is demonstrated in a step-by-step approach (Fig. 1) in which three groups (A, B, and C) are considered.

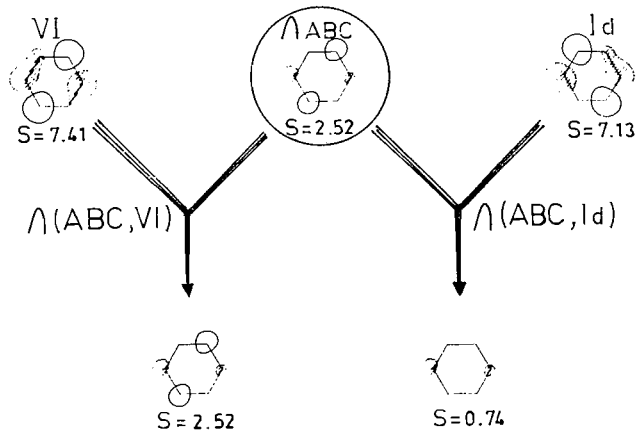

FIG. 2. Graphic representation of the intersections of the LUMO orbital form common to the antagonists (Λ_{ABC}) with the LUMO orbital forms of **I***d* and **VI**. The Λ_{ABC} is as different from the LUMO orbital form of the inactive **I***d* as it is similar to that of the active compound **VI**, which does not belong to the **I–V** series (Scheme 1).

Group A includes five of the eight phenothiazines studied (**I***a*, **I***b*, **I***c*, **I***g*, and **I***h*). In this group the phenothiazine orbital forms correlate well with both the other phenothiazines and the non-phenothiazines.

Two phenothiazines, **I***d* and **I***f*, are considered as non-representative of the optimal form. 4-Cl-*N*-Methylphenothiazine **I***d* is inactive ($C_I = 0.01$ for the promazine analogue) and it is significant that its orbital form is poorly correlated with the orbital forms of the active antagonists (preceding section). The activity of the promazine analogue of 2,4-dichloro-*N*-methylphenothiazine **I***f* is comparable to that of the analogue of 2-chloro-*N*-methylphenothiazine **I***b* (chlorpromazine, $C_I = 1$). However, its LUMO energy ($\epsilon_{LUMO} = 6.0$ eV) is appreciably lower and therefore, more favourable than the LUMO energy of **I***b* ($\epsilon_{LUMO} = 6.5$ eV) (8). We can assume that the favorable effect of **I***'s* ϵ_{LUMO} *is offset by its orbital form which is less representative than that of* **I***b*. This assumption is all the more probable when considering the fact that τ_{ij} are scattered for compound **I***f*. The degree of similarity between **I***f*'s LUMO form and the active non-phenothiazine antagonists' LUMO forms is clearly lower than that of compound **I***f* and the phenothiazines.

2-MeO-*N*-Methylphenothiazine **I***e* behaves as a distinctive phenothiazine compound in that, as indicated above, its orbital form displays a better likeness to that of the non-phenothiazine antagonists than to that of the phenothiazines (see Table 1). It is for this reason that it is considered separately as belonging to Group C.

Group B includes three non-phenothiazine antagonists which belong to three different chemical series: thioxanthene **II***b*,

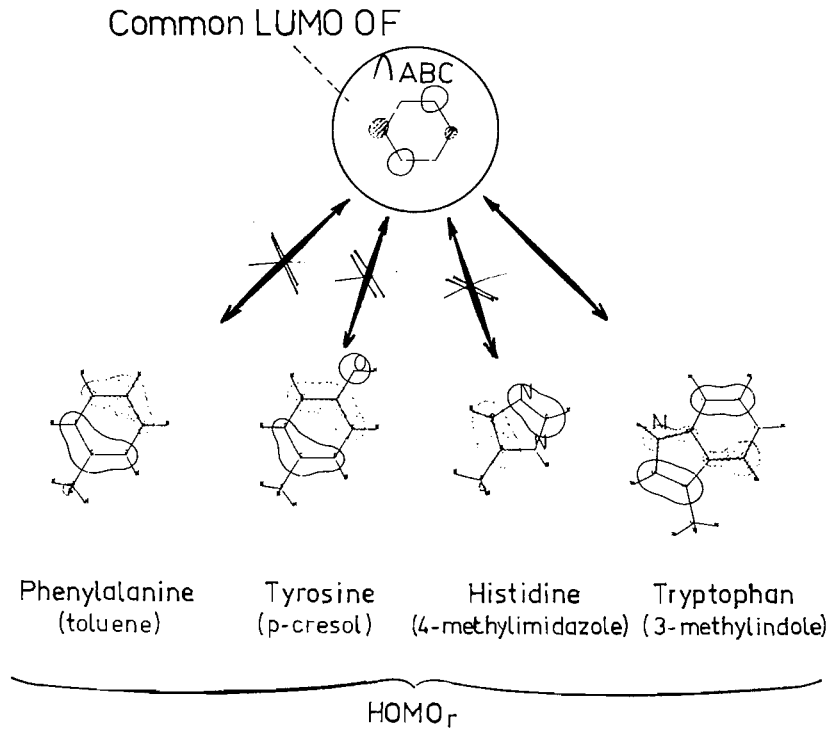

FIG. 3. Comparison of the LUMO orbital form common to the antagonists Λ_{ABC} with the HOMO orbital forms of the amino acid aromatic residues, phenylalanine, tyrosine, histidine, and tryptophan. Only the HOMO orbital form of the indolic part of the tryptophan ressembles Λ_{ABC}.

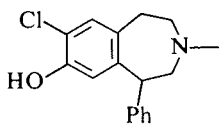
benzamide **IV***b*, and butyrophenone **III***b*. Compound **II***b* corresponds to a promazine analogue that is more active (C_l = 1) (19) than **II***a* (C_l = 0.06). As would be expected from its greater activity, **II***b*'s τ_{ij} values are generally higher than **II***a*'s (Table 1). Similarly, **IV***b*, which corresponds to a more active analogue (metoclopramide [^3H] spiperone IC_{50} = 57) (1) than **IV***a* (sulpriride, [^3H] spiperone IC_{50} = 570), is characterized by higher τ_{ij} values with the phenothiazines than **IV***a*. 4-*F*-Butyrophenone **III***b*'s analogue (haloperidol) is only slightly more active ([^3H] haloperidol IC_{50} = 8.5) (1) than the non-substituted **III***a*'s analogue ([^3H] haloperidol IC_{50} = 7.7). **III***b* is characterized by a slightly lower ϵ_{LUMO} (ϵ_{LUMO} **III***b* = 5.7) (8) than **III***a* (ϵ_{LUMO} **III***a* = 5.9), but the two have practically the same τ_{ij} values. Either of these forms — that of **III***a* or **III***b* — could therefore be used. The orbital form of **III***b*, a 4-*F*-substituted derivative whose analogues are frequently found among the neuroleptics, was chosen. The two benzisoxazoles, 6-*F*-benzisoxazole **V***a*, whose analogue is an active compound (IC_{50} = 6.7), and 6-MeO-benzisoxazole **V***b*, whose analogue is practically inactive (IC_{50} = 2800) (20), have similar τ_{ij} values. These values are often more elevated with inactive than with active molecules (for example, τ_{ij} values of **V***a* and **V***b* are 0.03 and 0.07, respectively, with the active phenothiazine **I***b*, but 0.53 and 0.55 with the inactive phenothiazine **I***d*). Furthermore, ϵ_{LUMO} of **V***a* is only slightly lower (ϵ_{LUMO} **V***a* = 5.5 eV) (8) than that of **V***b* (ϵ_{LUMO} = 5.57 eV). Unlike LUMOs of **V***a* and **V***b* with their unusual properties, the orbitals Next to LUMO (NLUMO) demonstrate a strong resemblance to LUMOs of the active molecules of series **I–IV**. It is assumed that in the case of benzisoxazoles, the NLUMO participates in the interaction with the aromatic binding site of the receptor. For the sake of coherence, these orbital forms are not considered in the comparison with LUMO forms **I–IV**. The LUMOs of the benzisoxazoles, however, are disregarded in the search for a common LUMO form of active antagonists.

Looking at the progressive contribution of the groups in Fig. 1, the intersections Λ of the orbital forms of groups A and B are represented by the forms Λ_A and Λ_B, respectively. These common forms are very close to the original orbital forms as indicated by their surface areas. Area $S(\Lambda_A)$ = 4.35 Å^2 is quite similar to the minimal area corresponding to the orbital form of compound **I***a* (S_{Ia} = 5.17 Å^2) and area $S(\Lambda_B)$ = 5.07 Å^2 is close to the minimal value S_{IIb} = 5.11 Å^2 for compound **II***b*. The two common forms Λ_A and Λ_B differ by their orbital density at carbon atoms 3 and 6, which equal zero in the common phenothiazine form Λ_A. Form Λ_B exhibits a lower density at carbon atom 5 than form Λ_A.

In the second step Λ_2, the intersection Λ(AB) between forms Λ_A and Λ_B yields their common form as Λ_{AB}. Its surface S_{AB} is only 28% weaker than the average surface of its predecessors ($S_{A/B} = S_A + S_B/2$. In fact Λ_{AB} retains the essential characteristics of Λ_A and Λ_B, and in particular, a strong orbital density at atoms 1 and 4. Comparison of the orbital form of 2-MeO-*N*-methylphenothiazine **I***e* Λ_C) with forms Λ_B and Λ_{AB} confirms the distinctiveness of this molecule. The orbital form of **I***e*, intermediate between the orbital form of the phenothiazines (A) and the non-phenothiazines (B), becomes a step closer to the latter.

The intersection Λ_3 between forms Λ_{AB} and Λ_C ends with the form Λ_{ABC}. This form, which retains between 35 to 50% of the LUMO density of each of the nine molecules belonging to the four different chemical series, will be considered representative of all the antagonists studied. Λ_{ABC} is characterized by a strong orbital density at atoms 1 and 4, and by a weaker density at atoms 2 and 5. It is noteworthy that a structurally analogous but inactive molecule, 4-Cl-*N*-methylphenothiazine **I***d*, has a very



VI

different LUMO form than the proposed common Λ_{ABC} form (Fig. 2). On the other hand, SCH-23390 **VI**, the D-1 selective antagonist (21) which does not belong to the four series in question, is characterized by the orbital form similar to the common Λ_{ABC} form.

Conclusion

It has been observed that the LUMO form of the dopaminergic antagonists, aside from its energy ϵ_{LUMO}, is an important parameter of the binding step, that is to say, of the antagonist activity vis-a-vis the dopamine receptor. A common orbital form of the antagonists has been proposed, Λ_{ABC}, which insures the maximum overlap between the frontier orbitals, the antagonist's LUMO (L_a) and the receptor's HOMO (H_r). Λ_{ABC} may be used in view of a non-classic DRUG DESIGN, which is not only unlimited to a homogenous and known series of compounds, but is also a means of "receptor mapping". In fact, sticking to the L_a–H_r principle (7, 8), the form of the HOMO receptor should have characteristics similar to the common Λ_{ABC} form.

Assuming that the aromatic binding site is an aromatic residue of the amino acid fragment of the polypeptide chain (22), the HOMO orbital form which corresponds to the aromatic fragments most likely to be the aromatic binding site (phenylalanine (Phe), tyrosine (Tyr), histidine (His) and tryptophan (Try)) has been examined. As shown in Fig. 3 only the HOMO orbital form of the indolic fragment (Try) is suitably superimposed on the commor antagonist form Λ_{ABC} to the exclusion of all other forms different from Λ_{ABC}. Thus the aromatic part corresponding to the aromatic binding site of the dopamine receptor is assumed to have a tryptophan structure.

$Fe(CO)_3$ and Rh(acac) complexes of ergosteryl and 7-dehydrocholesteryl acetates: A high field nuclear magnetic resonance study

RICHARD E. PERRIER and MICHAEL J. MCGLINCHEY[1]
Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received May 17, 1988

RICHARD E. PERRIER and MICHAEL J. MCGLINCHEY. Can. J. Chem. **66**, 3003 (1988).

The 500 MHz ^1H and 125 MHz ^{13}C spectra of ergosteryl and 7-dehydrocholesteryl acetate were recorded in C_6D_6 and $CDCl_3$ and assigned using two-dimensional NMR techniques. It is shown that incorporation of an $Fe(CO)_3$ or a Rh(acac) moiety onto the ring B diene system affects the chemical shifts of neighbouring protons and carbons. These changes are discussed in terms of the anisotropic properties of the organometallic fragments.

RICHARD E. PERRIER et MICHAEL J. MCGLINCHEY. Can. J. Chem. **66**, 3003 (1988).

Les spectres rmn ^1H et ^{13}C de l'ergostéryle et de l'acétate de déhydro-7-cholestéryle ont été obtenus dans différents solvants deutérés: C_6D_6 et $CDCl_3$. Les spectres rmn ^1H ont été enregistré sur un spectromètre 500 MHz et les spectres rmn ^{13}C sur un spectromètre 125 MHz. Les techniques de la rmn à 2 dimensions ont été employées pour l'étude de ces molécules. Dans cette publication, nous montrons que l'incorporation d'une unité $Fe(CO)_3$ ou Rh(acac) dans le système cyclique du diène B affecte les déplacements chimiques des protons et des carbons voisins. Puis, nous tentons d'établir une corrélation entre ces changements de déplacements chimiques et les propriétés anisotropiques des fragments organométalliques.

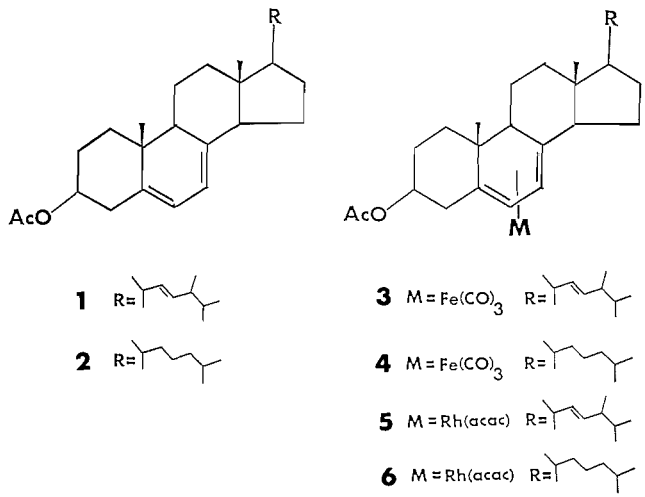
Introduction

With the advent of high field NMR spectrometers and the ease of applicability of two-dimensional NMR techniques, it is now possible to completely and unambiguously assign all the protons and carbons of complex molecules. These new techniques have facilitated the determination of the structure of numerous biologically important molecules in solution without having to resort to X-ray crystallographic techniques. Typically, steroidal systems provide a plethora of protons and carbons which, in principle, can provide a wealth of structural information.

For years, the only unequivocal assignments one could obtain from the ^1H spectra of steroids were limited to methyl, olefinic, or other protons whose signals were significantly deshielded relative to TMS because of substitution. The rest of the spectrum was often complicated by severe peak overlap as the remaining protons were distributed in a narrow spectral range (0.5 to 2.5 ppm). It was not until Hall and Sanders (1, 2) undertook an exhaustive study using a combination of ^1H 2D *J*-resolved spectroscopy and nOe difference measurements at high field that the overlapping problem was overcome. Since this initial paper, numerous other reports of the ^1H spectra of steroids have appeared in the literature (3–16). In contrast, the ^{13}C NMR spectra of steroids have been exhaustively studied and excellent compilations are now available (17, 18).

Another aspect of steroid chemistry which has gained prominence recently has been the incorporation of organometallic moieties onto the steroidal framework. For example, the $Fe(CO)_3$ fragment coordinates to the C(5)—C(6)—C(7)—C(8) diene unit of ergosterol esters, **1**; this cheap and readily available organometallic moiety has been utilized as a temporary protecting agent in order to synthesize modified steroids which would have been difficult to prepare by normal methods (19, 20). Allyl palladium complexes (21, 22) and $Cr(CO)_3$ moieties (23, 24) have also been exploited for synthetic purposes. The potential of inorganic salts, such as $RhCl_3$, or of organometallic reagents, e.g., $Cr(CO)_6$, to bring about the selective migration of double bonds in ergosterol has been noted by Barton (25, 26). Finally, in the bio-organometallic field, Jaouen and colleagues have demonstrated that steroidal hormones labeled with metal carbonyls can be used to assay receptor sites (27); this latter discovery promises to have an enormous impact on the early detection and treatment of breast cancer.



In this paper, we report the ^1H and ^{13}C NMR spectra for 3β-acetoxyergosta-5,7,22 triene (ergosteryl acetate), **1**, and for the closely related steroid, 3β-acetoxycholesta-5,7 diene (7-dehydrocholesteryl acetate), **2**; we also present the spectra of their $Fe(CO)_3$ and Rh(acac) derivatives **3** through **6**. The aim of this work was to investigate the effects induced by the organometallic moiety on the neighbouring protons and carbons of the steroid skeleton. Such effects are not limited merely to steric interactions which can alter the conformation of the steroid but can also include diamagnetic anisotropic contributions to the chemical shifts of proximate nuclei.

Results and discussion

In our earlier studies on organometallic derivatives of steroidal hormones, we were able to incorporate a tricarbonylchromium group into the aromatic A ring of estradiol and a series of related estrogenic steroids (28). The $Cr(CO)_3$ unit can complex either on the α or β face of the hormone and by using high field NMR spectroscopy, we were able to show that the two diastereomers **7***a* and **7***b* could be distinguished. More recently, we have prepared organometallic tetrahedral clusters of the type

$(RC{\equiv}CR')Co_2(CO)_6$, **8**, and $(RC{\equiv}CR')Cp_2Mo_2(CO)_4$, **9**, where the R group is steroidal (29). In those cases, the hormonal steroids used were the commercially available mestranol and an isomer 17α-propynylestradiol. Once again, by using a high field spectrometer, it was possible to show that the effects brought about by the incorporation of these organometallic fragments were localized primarily on protons of the C and D rings. Continuing in this vein, we prepared the $Fe(CO)_3$ complexes of ergosteryl acetate and 7-dehydrocholesteryl acetate with the goal of determining the influence of diamagnetic anisotropy of metal carbonyl ligands on the neighbouring ^1H and ^{13}C nuclei of the steroidal skeleton. In addition, the analogous Rh(acac) complexes were synthesized since the detection of coupling to ^{103}Rh ($I=1/2$) could help to resolve any ambiguities in assignments.

As pointed out by others (3–16, 30), it is still not trivial to assign all the proton resonances in complex steroids even taking advantage of the full armamentarium of 2D techniques currently available. Since there are over 40 protons in each of the compounds and the ^{13}C NMR spectra of the 3β-acetate esters of ergosterol and of 7-dehydrocholesterol were already known (17, 31), the initial phase of our investigation involved the measurement of heteronuclear ^1H–^{13}C shift correlated spectra (32). These experiments were performed in conjunction with APT (33) (Attached Proton Test) spectra to distinguish between C or CH_2 and CH or CH_3 resonances. Figure 1 illustrates the result of such an experiment with correlations between carbons and their attached protons presented as contours; thus methine carbons, such as C-14, exhibit a single contour peak while methylene carbons, for example C-4, show correlations to both of the protons attached to the same carbon atom.

The ^1H assignments were further determined using the ^1H–^1H COSY experiment (32) which enabled the ^1H–^1H connectivities to be established through the scalar couplings between protons. Figure 2 shows the result of a COSY experiment and is presented as a contour plot; the one-dimensional spectrum lies along the diagonal and coupling between two spins is manifested by off-diagonal contours. However, the ^1H–^1H COSY experiment does not directly distinguish between α and β protons in a given methylene group. This distinction can be achieved using nOe difference spectroscopy measurements, allylic couplings (e.g., H-4β/H-6), and the observation of couplings between particular protons and other substituents whose position is unambiguously known. Typically, H-12α shows a clear correlation in the COSY spectrum with the 18-methyl group which is situated anti-periplanar to it. These data, together with the magnitude of the coupling constants and the usual Karplus considerations (34, 35) led to the assignments listed in Tables 1 and 2.

Not surprisingly, the ^1H assignments for 7-dehydrocholesteryl acetate, **2**, are rather similar to those of **1** until one reaches the sidechain which lacks the double bond present in ergosteryl acetate, as well as the C-28 methyl group. Thus the ^{13}C resonances for C-22 and C-23 appear at ≈36 and 24 ppm, respectively, in 7-dehydrocholesteryl acetate rather than at 135 and 132 ppm, as in **1**. These differences are also manifested in the ^1H spectrum whereby the vinylic and allylic hydrogens at C-20 through C-24 in **1** are now more typical of the alkane environments in **2**.

The data were obtained in benzene-d_6 as well as in deuteriochloroform not merely in an attempt to place different protons in environments with less spectral overlap but also to investigate an ingenious proposal advanced by Ustynyuk *et al.* (36). They had suggested the possibility of differentiating protons in a methylene pair situated proximate to an organometallic fragment by recording the spectrum in an isotropic medium and in one which could exhibit the aromatic solvent induced shift (ASIS) effect (37). They reasoned that the bulk of the metal and its associated ligands would hinder the approach of the anisotropic solvent to the complexed face of the molecule. Hence, one might be able to deduce the site of complexation of the metal because the protons proximal to it would not experience the ASIS effect. For the non-complexed steroids, as shown in Table 1, there are indeed some noticeable changes in the spectra of **1** and **2** when they are recorded in $CDCl_3$ and C_6D_6. In benzene

one observes a general tendency for the protons attached to carbons 1, 2, 9, and 11 to be shielded relative to their resonance positions in chloroform. In contrast, the protons in the sidechain are generally more shielded when dissolved in $CDCl_3$.

Generally, our assignments for the protons and carbons in the molecules **1** through **6** are in good agreement with the shifts reported in the literature for related systems (30). Figure 3 shows the high field region of the 500 MHz ^1H NMR spectra of ergosteryl acetate, **1**, and of its $Fe(CO)_3$ and Rh(acac) complexes, **3** and **5**, respectively. It is readily apparent from Table 1 and Fig. 3 that the protons which experience the greatest shifts upon complexation are those of the diene unit, viz., H-6 and H-7; their ^1H signals move upfield by as much as 1 ppm. Such large shifts to low frequency are entirely typical of coordinated olefinic systems and provide unequivocal evidence of the site of complexation. One would expect the $Fe(CO)_3$ and Rh(acac) moieties to coordinate onto the α face of the steroid and thus avoid any steric problems with the methyl substituent at C-10. This scenario has been verified by the X-ray crystal structure determination of the $Fe(CO)_3$ complex of 7-dehydrocholesteryl acetate, **4** (results forthcoming), which shows (see Fig. 4) that the metal is attached to the α face of the steroid.

It is noticeable that in $CDCl_3$ solution the 4α hydrogens in both of the $Fe(CO)_3$ complexes, **3** and **4**, are markedly shielded relative to their absorption positions in their precursors **1** and **2**, respectively, while their 4β counterparts are but little affected. Furthermore, we see that, when the solvent is changed to benzene-d_6, the 4α proton positions are actually deshielded as are their 4β partners; apparently, the ASIS effect does not seem to have manifested itself in these particular systems. We have previously noted that protons sited close to metal carbonyl fragments can exhibit sizeable upfield shifts. The carbonyl ligand resembles the alkyne or nitrile linkage in that its cylindrical symmetry and multiple bond character gives rise to a marked diamagnetic anisotropy. Protons which are positioned along, or close to, the multiple bond axis lie in the shielding

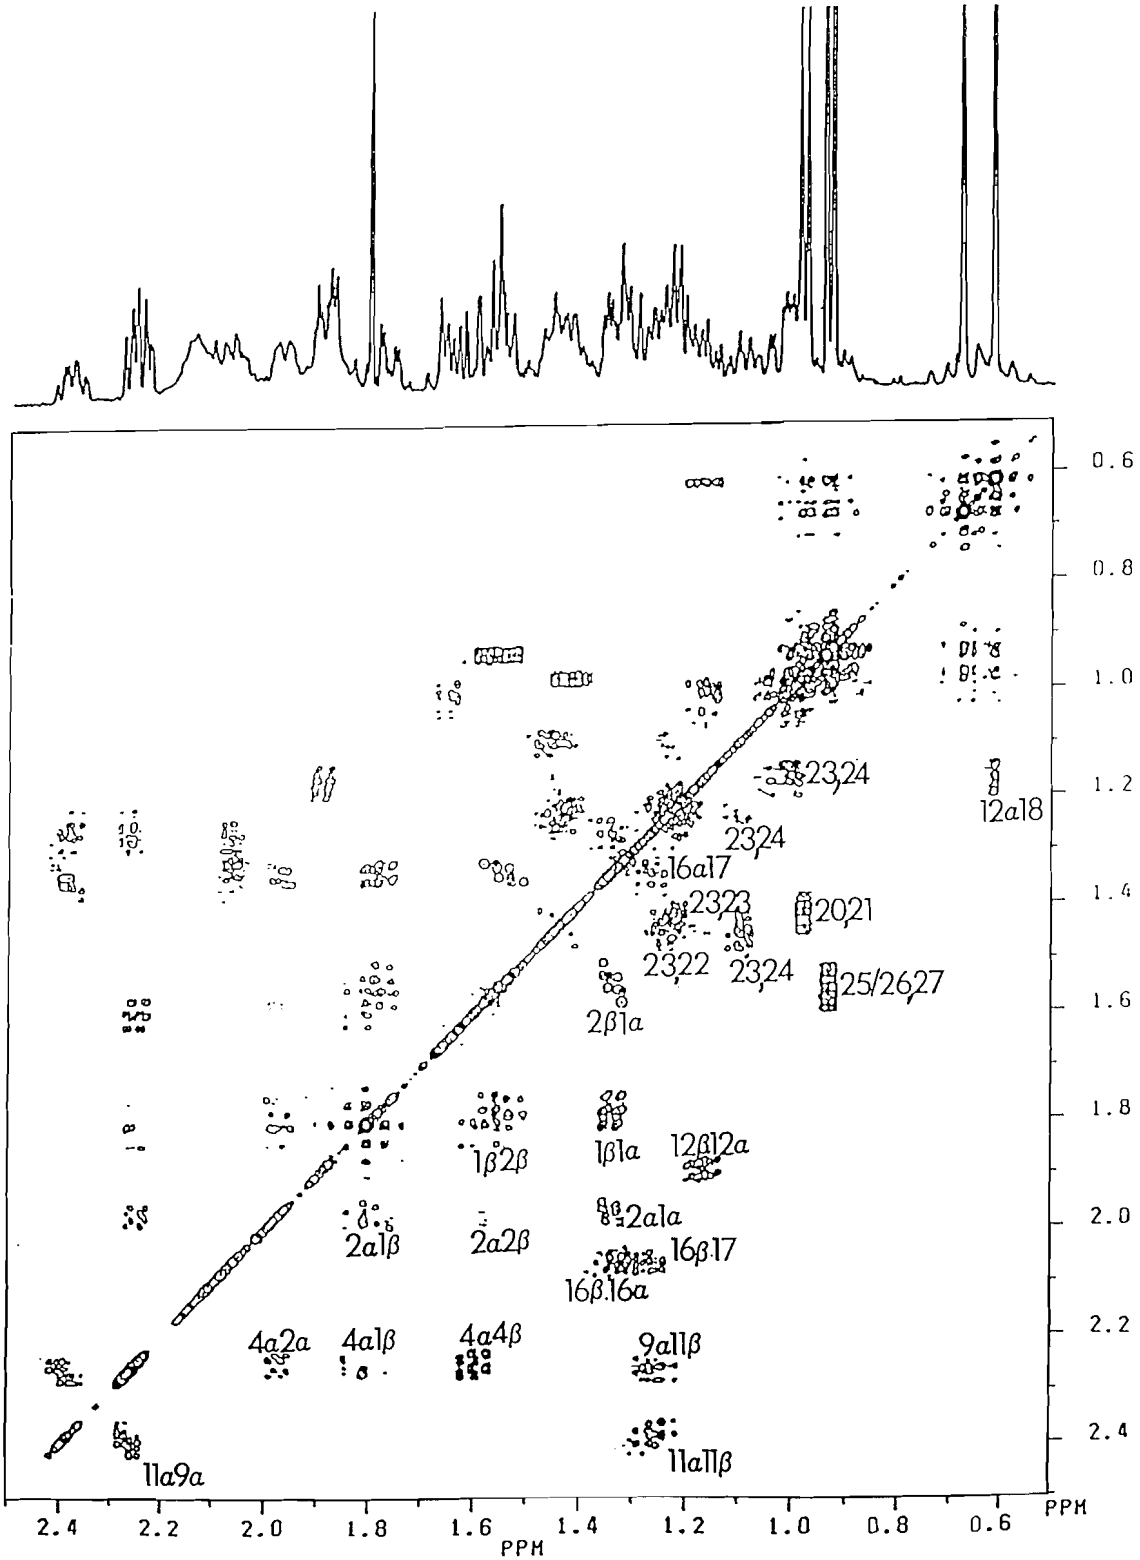

FIG. 2. 500 MHz 2-D NMR spectrum of **6** recorded in C_6D_6. Expanded contour plot of a portion of the matrix for a COSY 45 experiment. The matrix has been symmetrized.

zone while nuclei sited close to the plane perpendicular to the triple bond are deshielded (38, 39). Since we have recently obtained crystallographic data on **4** this allows the correlation of the chemical shift changes observed upon complexation with the geometric relationships between the proton positions and the cones of anisotropy of the metal carbonyl ligands. From these data we have determined that both the 4α and 4β protons are positioned within the shielding zone of a terminal CO ligand, thus their ^1H signals should move to low frequency relative to their resonance positions in the uncomplexed ligand.

When the Rh(acac) moiety is bonded to the diene unit, the effects are again localized primarily to the protons proximate to

the metal. This time there are some rather dramatic shifts. Thus the 4α and 4β protons suffer upfield shifts in excess of 0.5 ppm while the 1α and 11α hydrogens are deshielded by somewhat smaller amounts. One might speculate that these effects are rationalizable on the basis of a pseudo-aromatic ring current induced in the planar Rh–acac ring. It is well established that metal–acetylacetonate complexes are susceptible to electrophilic attack by, for example, bromine at the γ-H position. If the plane of the Rh–acac ring approximately bisects the C-6 C-7 bond then this would place the 4α and 4β protons in the shielding zone while the H-11α proton would be deshielded just like the aromatic protons in benzene itself. These results suggest that the Rh(acac) fragment is bound in a π fashion to the C(6)—C(7) double bond and σ bond formation occurs to C(5) and C(8), rather than the usual interaction of square planar rhodium with the π-donating C(5)—C(6) and C(7)—C(8) double bonds. We hope to resolve this point crystallographically.

Turning now to the ^{13}C NMR data for the molecules **1** through **6**, the effect of coordination is once again localized to carbons of the diene system, namely C-5, C-6, C-7, and C-8. In all cases, the organometallic moiety induces a very large upfield shift (≈ 40–60 ppm) in their ^{13}C signals while the other remaining ^{13}C signals are relatively unchanged. These observations are not unprecedented, as Butler and co-workers (40) have reported that the resonances of the arene ring carbons in estradiol and estrone 3-methyl ether are shifted upfield upon complexation to a $Cr(CO)_3$ group. Figure 5 shows the vinylic sections of the 125 MHz ^{13}C NMR spectra of **1**, **3**, and **5**. In these APT spectra (33) the carbon atoms with directly bonded hydrogens, viz., C-6 and C-7, have negative phase while the unsubstituted carbons at C-5 and C-8 have positive phase. The very dramatic low frequency shifts of the coordinated carbons are clearly evident. For the Rh complexes, it was gratifying to observe the appropriate Rh coupling (≈ 15 Hz) in the ^{1}H decoupled ^{13}C spectrum.

To conclude, we report the complete ^{1}H and ^{13}C NMR assignments for ergosteryl acetate, 7 dehydrocholesteryl acetate and their respective $Fe(CO)_3$ and Rh(acac) derivatives. In future reports we shall describe the reactions of these steroids and their metal complexes with alkynes to yield initially Diels–Alder adducts and ultimately ansa steroids.

Experimental

Nuclear magnetic resonance spectra were recorded on a Bruker AM 500 spectrometer. The 500 MHz ^{1}H and 125.7 MHz ^{13}C spectra were

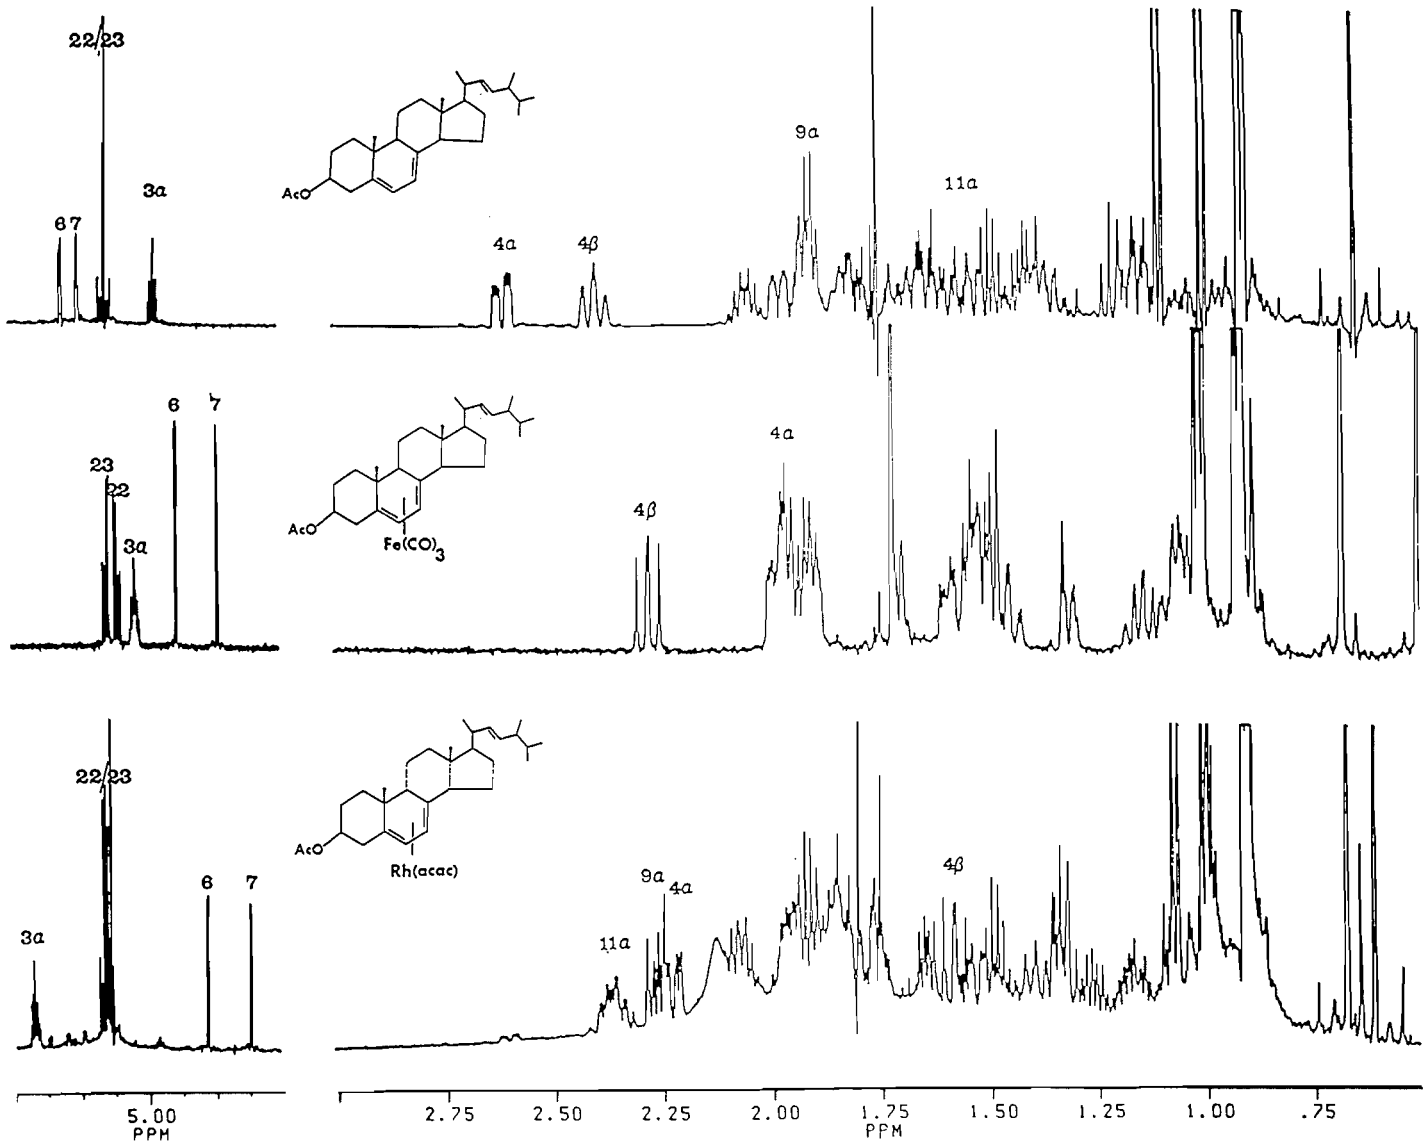

FIG. 3. Sections of the 500-MHz ^{1}H NMR spectra of molecules **1**, **3**, and **5**.

acquired using a 5 mm dual frequency ^{1}H/^{13}C probe. The samples were dissolved in C_6D_6 and $CDCl_3$ to a final volume of 0.6 mL which resulted in concentrations of approximately 0.09 *M*. Chemical shifts are reported relative to tetramethylsilane using the residual C_6H_6 signal (7.15 ppm) and $CHCl_3$ signal (7.24 ppm) as internal references. Proton spectra were acquired in 16 scans over a 3000 Hz spectral width in 32K data points, processed using Gaussian multiplication for line enhancement and zero filled to 64K before transformation.

Homonuclear chemical shift correlation (COSY) experiments were carried out in the absolute value mode by using the pulse sequence: delay – (π/2, ^{1}H) – t_1 – (π/4, ^{1}H) – acquisition. A 2-s relaxation delay was used: the π/2 pulse was 18 μs. The spectra were acquired in 8 scans for each of 256 FID's which contained 1024 data points in f_2. The data were zero filled once in the t_2 domain and yielded a 512 × 512 matrix after transformation. The transformed matrix was symmetrized.

Heteronuclear chemical shift correlated spectra were obtained by using the pulse sequence: delay – (π/2, ^{1}H) – (t_1/2) – (π, ^{13}C) – (t_1/2) – Δ_1 – (π/2, ^{1}H; π/2, ^{13}C) – Δ_2 – acquisition with decoupling. A 2-s relaxation delay was used and the delay times $\Delta_1 = \frac{1}{2}J$ and $\Delta_2 = \frac{1}{4}J$ were calculated from a compromise value of ^1J(C,H) = 125 Hz. The π/2, ^{1}H pulse was 18 μs and π/2, ^{13}C pulse was 7.3 μs. The spectral width in the t_2(carbon) domain was 17857 Hz (140 ppm) and in the t_1(proton) domain was 3000 Hz. The spectra were acquired containing 4K data points in f_2 for each of 256 FID's. Zero filling twice in f_2, followed by 2-D transformation created a 2K × 512 data matrix. Gaussian enhancement of the data was applied.

Ergosterol and 7-dehydrocholesterol were purchased from Aldrich and converted into their corresponding acetates using the procedures described by Stansbury (41). Their $Fe(CO)_3$ complexes were prepared via literature procedures (20). All syntheses were carried out under an atmosphere of nitrogen and all solvents were dried using standard procedures.

*Synthesis of ergosteryl acetate Rh(acac), **5**, and 7-dehydrocholesteryl acetate, **6***

Bis[(chloro)(ergosteryl acetate)rhodium(I)] and bis[(chloro)(7-dehydrocholesteryl acetate)rhodium(I)] were prepared according to the procedure of Barton (25). To the appropriate RhCl dimer (0.5 g) in Et_2O (25 mL) was added acetylacetone (0.1 mL). The solution was cooled to −20°C in an ice–salt water bath and 6 *M* KOH (1 mL) was added. After stirring for 1 h, the solution was warmed to room temperature and extracted with Et_2O (2 × 25 mL). The orange Et_2O layer was concentrated and dried over $MgSO_4$. After filtration, the solution was cooled to −78°C (dry ice – acetone) and a light yellow precipitate was

The photochemical nucleophile–olefin combination, aromatic substitution reaction (Part 2): methanol – cyclic olefins, 1,4-dicyanobenzene[1]

DONALD R. ARNOLD[2] AND MILES S. SNOW
Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3

Received May 10, 1988

DONALD R. ARNOLD and MILES S. SNOW. Can. J. Chem. **66**, 3012 (1988).

Direct irradiation of acetonitrile–methanol (3:1) solutions of 1,4-dicyanobenzene and the cyclic olefins, cyclohexene, 1-methylcyclohexene, norbornene, and 2-methylnorbornene, leads to formation of regio- and stereoisomers of the 1:1:1 (alcohol:olefin:aromatic) adducts. This reaction can be photosensitized by electron transfer; addition of electron donors, biphenyl or phenanthrene, to the irradiation mixture generally increases the efficiency and yield of adduct formation. The efficiency of the reaction and the ratio of isomeric adducts are also affected by the addition of salts, particularly magnesium perchlorate. All of the possible regio- and stereoisomers from cyclohexene and 1-methylcyclohexene have been identified, two from cyclohexene and four from 1-methylcyclohexene. Three of the four possible isomers from norbornene were characterized; the *endo,endo* isomer was not detected. There are eight possible isomers from 2-methylnorbornene; six were detected and five have been isolated and identified. The two sterically hindered isomers, those having both the 4-cyanophenyl and the methoxy groups in the *endo* position, and *exo*-3-(4-cyanophenyl)-*endo*-2-methoxy-*exo*-2-methylnorbornane, were not characterized. The structures of the products were established largely on the basis of the ^{1}H and ^{13}C nuclear magnetic resonance spectra. The mechanism of the reaction is discussed, with emphasis on those factors that may affect the product ratio. The most striking observation is that the reaction is regioselective when magnesium perchlorate is added to the irradiation mixture.

DONALD R. ARNOLD et MILES S. SNOW. Can. J. Chem. **66**, 3012 (1988).

L'irradiation directe du dicyano-1,4 benzène et des oléfines cycliques : le cyclohexène, le méthyl-1 cyclohexène, le norbornène et le méthyl-2 norbornène en solution dans le mélange acétonitrile–méthanol (3:1) conduit à la formation des régioisomères et des stéréoisomères des adduits 1:1:1 (alcool : oléfine : aromatique). Cette réaction peut-être photosensibilisée par transfert d'électrons; l'addition de donneurs d'électrons : le biphényle ou le phénantrène, au mélange irradié augmente généralement l'efficacité et le rendement de la formation d'adduits. L'addition de sels, le perchlorate de magnésium en particulier, affecte l'efficacité de la réaction et le rapport des adduits isomères. On a identifié tous les régioisomères et les stéréoisomères possibles du cyclohexène et du méthyl-1 cyclohexène, deux pour le cyclohexène et quatre pour le méthyl-1 cyclohexène. On a caractérisé trois des quatre isomères possibles du norbornène; on n'a pas décelé l'isomère *endo,endo*. Le méthyl-2 norbornène a huit isomères possibles; on en a décelé six, et cinq d'entre eux ont pu être isolés et identifiés. On n'a pas caractérisé les deux isomères stériquement encombrés, ceux ayant les deux groupes cyano-4 phényle et méthoxy en position *endo* et le (cyano-4 phényle)-3-*exo*-méthoxy-2-*endo*-méthyl-2-*exo* norbornane. On a établi les structures des produits en se basant essentiellement sur les spectres de résonance magnétique nucléaire du ^{1}H et du ^{13}C. On discute du mécanisme de la réaction en mettant l'accent sur les facteurs qui peuvent affecter le rapport des produits. La régiosélectivité de la réaction due à l'addition de perchlorate de magnésium dans le mélange irradié constitue l'observation la plus remarquable.

[Traduit par la revue]

Introduction

When a solution of 1,4-dicyanobenzene (**1**) and 2,3-dimethyl-2-butene (**2**) in acetonitrile–methanol (3:1) is irradiated, the 1:1:1 (alcohol:olefin:aromatic) adduct (**3**) is obtained in good yield (70%) (reaction [1]). This reaction and some similar reactions involving 1,2-dicyanobenzene and 2-methylpropene (**5**) (Table 1, reactions [2] and [3]) reported at the same time (2) were among the first examples of photochemical nucleophile–olefin combination, aromatic substitution (photo-NOCAS) (3).[3] Two new chemical bonds are formed during this process, which in one simple operation yields a more complex, bifunctional product from readily available starting materials. This reaction will have significant synthetic utility, particularly if it is general and if the product is formed (or can be made to form) regio- and stereoselectively.

Our previous work has shown that this reaction occurs not only upon direct irradiation of **1**, but in some cases also upon photosensitization (electron transfer). Phenanthrene (**4**) and biphenyl (**8**) have been used as photosensitizers.

The proposed mechanism is shown in Scheme 1, where steps 1–5 indicate the events that occur upon direct irradiation (2), and steps 6 and 7 occur instead of step 2 when the reaction is photosensitized (electron transfer) by an additional electron donor (2, 4, 5). Competing with product formation is deactivation by back electron transfer from the radical anion to the radical cation (steps 2d and 8).

Another variation in reaction conditions involves the addition of salts to the irradiation mixture. Salts, particularly magnesium salts, are known to have a profound effect on photosensitized (electron transfer) reactions; they extend the lifetime of radical ions generated in this way (6). Apparently, the magnesium cation forms a complex with the radical anion, which slows down the deactivating back electron transfer from the radical anion to the radical cation (6*b*).

Consideration of each step in this sequence provides an initial basis for predicting the scope, the limitations, and the regio- and stereoselectivity of this reaction. For example, the free-energy for the electron transfer process (step 2b or b′) must be negative (or less than ca. 5 kcal mol^{-1} endergonic) to allow a significant formation of radical ions. Involvement of step 3 directs the regioselectivity of the process in that the olefin will be attached to the aromatic at the more heavily substituted site. Step 4 requires the reduction potential of the intermediate radical to be greater (more negative) than the reduction potential of the

aromatic; otherwise, electron transfer from the aromatic radical anion to the radical will occur and addition of methanol to the olefin will result instead of aromatic substitution.

We have begun a detailed study of this reaction to test these predictions and to determine which nucleophiles, olefins, and aromatic compounds can participate. This report describes the reaction of methanol and 1,4-dicyanobenzene (**1**) with several cyclic olefins (cyclohexene (**9**), 1-methylcyclohexene (**10**), norbornene (**11**), and 2-methylnorbornene (**12**)). These olefins were specifically chosen so that the regio- and stereoselectivity of each of the key steps of the overall process could be determined.

A question of particular interest in these experiments is whether the ratio of isomeric products is dependent upon the alternative modes of activation, direct or photosensitized (electron transfer), or upon the presence of added salts. If upon direct irradiation the combination of methanol with the olefin occurs at the exciplex or radical ion pair stage, specific interactions resulting from the associated 1,4-dicyanobenzene (**1**) or the dicyanobenzene radical anion ($\mathbf{1}^{\bullet-}$), with the olefin or the olefin

D = Phenanthrene (**4**) or biphenyl (**8**).

SCHEME 1. The mechanism (abbreviated) for the photo-NOCAS reaction. Electron-donating photosensitizers, D in steps 6–8, are phenanthrene (**4**) or biphenyl (**8**).

radical cation, may influence the regio- and stereoselectivity of this and subsequent steps. On the other hand, combination of methanol with the olefin radical cation formed by photosensitization (electron transfer) presumably involves either the freely solvated olefin radical cation, or the olefin radical cation complexed with the photosensitizer. This difference could be reflected in the ratio of regio- and stereoisomeric products.

Another facet to be considered is the addition of salts to the irradiation mixture, which might increase the relative amount of products resulting from reaction of the solvated radical cation. Furthermore, the regio- and stereoselectivity of the radical – radical anion coupling step (step 4) might now reflect the fact that the radical anion is complexed with the added cation.

Results

The irradiation and product isolation procedures were straightforward and operationally simple. A solution of 1,4-dicyanobenzene (**1**) and an excess of the olefin in acetonitrile–methanol (3:1) was irradiated through a Pyrex filter with a mercury vapor lamp. For the photosensitized (electron transfer) reactions an additional electron donor, phenanthrene (**4**) or biphenyl (**8**), was added to the solution. The effect of added salt was tested by dissolving the salt (0.3 M), magnesium perchlorate, lithium perchlorate, or tetraethylammonium perchlorate, in the solution. Some of these solutions were also irradiated after the addition of photosensitizer.

Progress of the reaction was followed by gas chromatography with a mass selective detector (gc/ms). The products were isolated by column chromatography. The yields of photo-NOCAS products, reported in Table 1, were determined by gas chromatography with a flame ionization detector (gc/fid). They are based upon dicyanobenzene, the limiting reagent, when the reaction was more than 80% complete. The error in the tabulated yields may be as much as 10% of the value listed. The ratios of products, on the other hand, are more accurate, less than 5% error. The ratio of products was not dependent upon the extent of conversion and agreed with the ratio obtained upon isolation. Structural assignments were based primarily on a detailed analysis of the nuclear magnetic resonance (^{1}H and ^{13}C nmr) spectra, which are described in the next section.

The only previous report (2) of regioselectivity in the photo-NOCAS reaction was the result of the addition of methanol to 2-methylpropene (**5**) followed by substitution on 1,4-dicyanobenzene (**1**). Direct irradiation gave a low yield of 2-(4-cyanophenyl)-1-methoxy-2-methylpropane (**6**) (Table 1, reaction [3]), the *anti*-Markovnikov adduct.[4] The other regioisomer, 1-(4-cyanophenyl)-2-methoxy-2-methylpropane (**7**), was not detected. We now find that biphenyl (**8**) is an effective photosensitizer for this reaction; the efficiency of the reaction and the yield of adduct(s) are much improved. Under these conditions (reaction [4]) the Markovnikov adduct (**7**) was formed as a minor product (3% of the photo-NOCAS products). Such a small amount of **7** would have gone undetected in the earlier work when the yield of photo-NOCAS product(s) was low.

The reaction that combines methanol with cyclohexene (**9**) and substitutes on 1,4-dicyanobenzene (**1**) was carried out by direct irradiation and also was photosensitized by biphenyl (**8**) (Table 1, reactions [5] and [6]). Phenanthrene (**4**) was not effective as a photosensitizer for this reaction. Product formation was more efficient upon photosensitization with **8**; the required irradiation time was greatly reduced. The *trans* isomer was favoured over the *cis* isomer under both irradiation conditions. The ratio of *cis* to *trans* isomers was essentially independent of mode of activation (**13**-*c*:**13**-*t*, 1:5 direct; 1:6 photosensitized).

The effect of added magnesium perchlorate on the ratio of

[4]The designation of adducts **7** as Markovnikov and **6** as *anti*-Markovnikov is based upon the original definition; by the Markovnikov rule of orientation for the addition of hydrogen halides to olefins, the anion (methanol in this case) combines with the less hydrogenated of the ethenoid carbon atoms (7). No mechanistic information is implied.

stereoisomers formed upon both direct and sensitized (**8**) irradiation was also small (**13**-*c*:**13**-*t*, 1:5.5. direct; 1:4 photosensitized) (Table 1, reactions [7] and [8]). The most obvious effect of the addition of magnesium perchlorate to the irradiation mixture was the greatly decreased yield of photo-NOCAS products. The major reactions under these conditions were addition of methanol to the cyclohexene (8), and the allylic radical substitution (2). Reaction [8] gave a 70% yield of 3-(4-cyanophenyl)cyclohexene.

Reaction with 1-methylcyclohexene (**10**) was carried out by both direct irradiation and by photosensitization with phenanthrene (**4**) and with biphenyl (**8**) (Table 1, reactions [9], [10], and [11]). The yield of photo-NOCAS products was 66% (combined yield of isomers) upon direct irradiation and was highest (77%) when **8** was used as a photosensitizer. All four isomeric adducts were obtained under all of these irradiation conditions. The product ratio from the photosensitized reactions was essentially independent of the sensitizer (**4** or **8**) used.

The reaction was somewhat more regioselective upon sensitized irradiation, favouring the *anti*-Markovnikov adducts ((**15**-*c* plus *t*):(**14**-*c* plus *t*), 1:4 direct; 1:6 photosensitized). The stereoselectivity of the reaction favours the *trans* isomer of both of the regioisomers upon both modes of activation. While the *cis*:*trans* isomer ratio of the *anti*-Markovnikov adduct was essentially independent of mode of activation (**14**-*c*:**14**-*t*, 1:12 direct; 1:16 photosensitized), the ratio of isomeric Markovnikov adducts (**15**) varied. Sensitized irradiation led to relatively more of the *cis* isomer although the effect was not large (**15**-*c*:**15**-*t*, 1:3 direct; 1:2 photosensitized).

The addition of magnesium perchlorate to the sensitized (**8**) irradiation had a profound effect on the product ratio. *Adduct formation was regioselective*; neither of the Markovnikov adducts was detected. The stereoselectivity for formation of the *anti*-Markovnikov adducts was also affected by the addition of this salt (**14**-*c*:**14**-*t*, 1:7 with added salt and 1:15 without). Again in this case, the overall yield of photo-NOCAS products decreased upon the addition of magnesium perchlorate to the irradiation mixture. The major competing reaction was formation of the methylcyclohexene allylic radical substitution products.

In marked contrast to the results obtained upon addition of magnesium perchlorate, the addition of lithium or tetraethylammonium perchlorate to the sensitized (**8**) irradiation had little effect on the product ratio. The overall yield of photo-NOCAS products was also relatively unaffected by the addition of these salts. In fact, the addition of lithium perchlorate increased the yield of photo-NOCAS adducts.

In the case of norbornene (**11**) (Table 1, reactions [15]–[19]), three of the four possible stereoisomeric adducts have been identified; the most sterically hindered *endo,endo* isomer was not detected. The ratio of stereoisomers was dependent upon mode of activation. While the isomer bearing the methoxy group in the *exo* position and the 4-cyanophenyl group in the *endo* position (**16**) was the major product under both conditions, direct irradiation and photosensitized, the other *trans* isomer (**17**) was a significant product and the *cis* isomer (**18**) was a relatively minor product upon direct irradiation (**18**:**17**:**16**, 1:3.9:5.1 direct irradiation; 1:1.5:4.4 photosensitized (**8**)).

Addition of magnesium perchlorate to both the direct and sensitized (**8**) irradiation mixtures led to relatively more of the *exo*-(4-cyanophenyl)-*endo*-methoxy isomer; **17** was the major photo-NOCAS product obtained upon direct irradiation when magnesium perchlorate had been added (**18**:**17**:**16**, 1:16:2). The overall yield of photo-NOCAS products was again lower than that obtained upon irradiation in the absence of added salt.

Methylnorbornene (**12**) is not commercially available. Several procedures for the syntheses of this compound were tried; the method eventually chosen was the cuprous ion promoted oxidative bis-decarboxylation of 2-methylbicyclo[1.2.2]heptane-2,3-dicarboxylic acid (9, 10).

The photo-NOCAS reaction could conceivably yield eight isomeric adducts with 2-methylnorbornene; six have been detected (gc/ms) and the five major products, those formed in greater than 1% yield, were isolated and characterized (Table 1, reactions [20]–[24]). Neither of the sterically hindered isomers, those having both the methoxy and the 4-cyanophenyl groups in the *endo* position, were among the isolated products. The other missing isomer was the *trans*-Markovnikov adduct with the methoxy group in the *endo* position.

The five relatively abundant isomeric adducts were formed in a ratio that was again dependent upon mode of activation. The major product under all conditions was the *trans anti*-Markovnikov adduct with the 4-cyanophenyl group in the *endo* position (**19**). The next most abundant isomer was the *cis exo-anti*-Markovnikov adduct **20**; photosensitization using either **4** or **8** (Table 1, reactions [21] and [22]) led to relatively more of this isomer (**19**:**20**, 2:1 direct irradiation; 1.5:1 photosensitized). Again in this case, as with 1-methylcyclohexene (**10**), the reaction was more regioselective upon photosensitization, favouring the *anti*-Markovnikov adducts ((**22** + **23**) : (**19** + **20** + **21**), 1:8 upon direct irradiation; 1:20 photosensitized).

The addition of magnesium perchlorate to the irradiation mixture had an effect on this reaction similar to that observed with 1-methylcyclohexene. The Markovnikov products, **22** and **23**, were missing from the photolysis mixture when magnesium perchlorate had been added. There was also an effect upon the ratio of the isomeric *anti*-Markovnikov products (**21**:**20**:**19**, 1:5:10 direct irradiation; 1:0.8:1 with added salt). The yield of photo-NOCAS products again was decreased by the addition of this salt.

The photo-NOCAS adducts were major products from all of these reactions. There were other products, from competing reactions, that are not listed in the table. These products were not isolated and completely characterized in every case; however, tentative structural assignments, based on gc/ms (retention time and mass spectrum), were made for several of them.

The ethers (e.g., methoxycyclohexane and 1-methoxy-2-methylcyclohexane), resulting from addition of methanol to the olefin, were usually detected. Formation of these products is not reflected in the reported yields because the yields are based upon the consumption of **1** and the olefins were present in excess. Yields based upon olefin were generally poor (<25%). No systematic effort was made to improve this yield; however, there was significantly less of these ether side products when phenanthrene (**4**) was used as photosensitizer. For example, the yield of photo-NOCAS products, based upon 1-methylcyclohexene (**10**), was 8% in reaction [11] involving direct irradiation, and 15% in reaction [10], which was photosensitized with **4**.

The dicyanobenzene–olefin one-to-one adducts (e.g., 3-(4-cyanophenyl)cyclohexene), resulting from substitution of the allylic radical of the olefin on the dicyanobenzene radical anion, were also formed in significant amounts in the reactions involving cyclohexene and 1-methylcyclohexene.

The product formally resulting from the addition of hydrogen cyanide to phenanthrene (9-cyano-9,10-dihydrophenanthrene) was usually observed when **4** was used as photosensitizer, and 2-cyano- and 4-cyanobiphenyl were detected when **8** was used. The photo-NOCAS products incorporating cyanide ion instead of methanol (e.g., 1-cyano-2-(4-cyanophenyl)cyclohexane) were usually produced in small amounts. The products formally resulting from the addition of the cyanomethyl radical to the olefin, followed by substitution on the dicyanobenzene radical anion (the isomeric 2-cyanomethyl-3-(4-cyanophenyl)norbornanes), were produced in significant amounts in the reactions involving the norbornenyl ring system. The product resulting from the addition of acetonitrile, that is, involving the intermediate cyanomethyl radical, to the olefin was a major product in the case of norbornene (2-*exo*-(cyanomethyl)norbornane). Details concerning the characterization of these minor products are given in the experimental section.

Structural assignments

The structural assignments for the photo-NOCAS products were based largely on an analysis of the ^1H and ^{13}C nmr spectra (11, 12). For the cyclohexene adducts the assignments were straightforward. Using accepted chemical shift correlations, the peak in the region of 3.3 ppm can be assigned to the hydrogen on the cyclohexane ring and adjacent to the methoxy group; the benzylic hydrogen will adsorb at lower frequency, near 2.6 ppm. From the established conformational free-energy values of these substituents (*A* values: methoxy, 0.60; phenyl, 2.9 (13)), the more bulky 4-cyanophenyl ring will adopt the equatorial position. The relationship of the benzylic hydrogen and the hydrogen adjacent to the methoxy group, C*H*—OCH_3, will be axial–axial in the *trans* adduct and axial–equatorial in the *cis* adduct. Vicinal hydrogen axial–axial coupling (8–13 Hz) is significantly larger than axial–equatorial coupling (2–6 Hz) and the configuration of substituted cyclohexanes can be assigned using this criterion.

For the isomer assigned the *cis* configuration (**13**-*c*), the vicinal couplings of the benzylic hydrogen at 2.70 ppm are 12.9, 3.5, and 2.9 Hz, corresponding to one axial–axial and two axial–equatorial couplings. The methoxy group must be axial; the configuration is therefore *cis*. Coupling of the signal due to the hydrogen adjacent to the methoxy group at 3.47 ppm was unresolved.

The isomer assigned the *trans* configuration (**13**-*t*) shows the methine hydrogen adjacent to the methoxy group as a multiplet at 3.26 ppm. The observed vicinal couplings of this hydrogen are 10.4, 10.4, and 4.1 Hz. This hydrogen must be axial with two axial–axial couplings and one axial–equatorial coupling. The couplings of this hydrogen to the benzylic hydrogen at 2.59 ppm is 10.4 Hz, axial–axial. Therefore, both the 4-cyanophenyl and the methoxy group are equatorial, that is, *trans*.

The structural assignments for the methylcyclohexene adducts were somewhat more involved. The regiochemistry was initially assigned on the basis of the chemical shift of the low-field aliphatic hydrogen adjacent to either the 4-cyanophenyl or the methoxy group. The adducts resulting from Markovnikov addition must have a benzylic hydrogen; this structure was assigned to those isomers having multiplets at higher field, at 2.45 and 2.85 ppm. The isomers with the lower-field multiplets, at 3.38 and 3.43 ppm, indicative of hydrogen adjacent to the methoxy group, are taken to be the *anti*-Markovnikov adducts.

In both of the Markovnikov adducts the vicinal couplings of the benzylic hydrogens are axial–axial and axial–equatorial (*cis* (**15**-*c*), 12.8 and 3.4 Hz; *trans* (**15**-*t*), 12.1 and 4.2 Hz), which indicates the 4-cyanophenyl group is equatorial.

The distinction between the *cis* and *trans* Markovnikov adducts (**15**-*c* and **15**-*t*) was made on the basis of the magnitude of the vicinal coupling constants ($^3J_{C-H}$) between the benzylic hydrogen (axial) and the carbon of the methyl group, as determined from the coupled ^{13}C nmr spectra (one of the central lines of the quartet). This coupling ($^3J_{C-H}$) follows a Karplus relationship similar to that pertaining to vicinal hydrogen–hydrogen coupling ($^3J_{H-H}$), dependent on the dihedral angle of the coupled nuclei (14). In general, the magnitude of $^3J_{C-H}$ is ca. 0.6 that of the analogous $^3J_{H-H}$.

In the ^{13}C nmr coupled spectrum of the isomer assigned the *cis* Markovnikov structure (**15**-*c*), the observed couplings were determined from one of the central lines of the quartet that is centered at 23.37 ppm. The width of this line at half-height was approximately 5 Hz. This could only result from several small couplings, e.g., two axial–equatorial and one equatorial–equatorial. Reasonable values for these couplings would be 2–3 Hz.

Analysis of the ^{13}C nmr spectrum provides additional support for the regiochemical assignment, that is, the Markovnikov structure **15**-*c*. The resonance due to the benzylic carbon at 55.28 ppm is a doublet ($^1J_{C-H}$, 123 Hz) and the signal due to the quaternary carbon (the carbon bearing the methyl and methoxy group) is a singlet at 74.10 ppm.

The structural assignment for the *trans* Markovnikov adduct (**15**-*t*) was more obvious because of the larger $^3J_{C-H}$ couplings. Selected proton resonance frequencies were irradiated and the ^{13}C nmr was observed. The axial–axial coupling of the methyl carbon, at 16.66 ppm, to the benzylic hydrogen, at 2.85 ppm, was found to be 5 Hz; the other axial–axial coupling was 6 Hz. An additional 3-Hz coupling was found for the remaining axial–equatorial hydrogen interaction.

Again, an analysis of the ^{13}C nmr spectrum supports the Markovnikov structural assignment of this isomer (**15**-*t*). The signal due to the benzylic carbon at 51.89 ppm is a doublet ($^1J_{C-H}$ coupling of 126.5 Hz). This is a typical coupling constant for an sp^3 carbon bearing alkyl substituents.

Similar reasoning was used to establish the stereochemical assignments for the *anti*-Markovnikov adducts. In the ^1H nmr spectra of one of these isomers the peak due to the hydrogen adjacent to the methoxy group at 3.38 ppm is an apparent triplet with a relatively small 4.4-Hz splitting. This coupling pattern must be due to an axial–equatorial and an equatorial–equatorial interaction, both of which are small and coincidentally identical in this case. This is the expected pattern for the hydrogen adjacent to the methoxy group of the *cis anti*-Markovnikov adduct **14**-*c*.

In the other *anti*-Markovnikov adduct, the 3.43-ppm peak for the hydrogen adjacent to the methoxy group is observed as a doublet of doublets with coupling constants of 10 and 4 Hz. This is indicative of the large axial–axial and a smaller axial–equatorial hydrogen–hydrogen interaction expected of the *trans anti*-Markovnikov adduct **14**-*t*.

Analysis of the coupled ^{13}C nmr spectra of these isomers supports these assignments. Consider first the spectrum of the isomer assigned the *cis anti*-Markovnikov structure (**14**-*c*). The width, at half-height, of one of the central lines of the quartet assigned to the methyl carbon at 27.12 ppm is 12 Hz. This broad

[a]Oxidation potentials measured at a platinum electrode relative to the saturated calomel electrode (SCE) using tetraethylammonium perchlorate (0.1 M TEAP) as electrolyte in acetonitrile.

[b]Based upon the Weller equation (ref. 15); $E_{0,0}$(**1**) 97.6 kcal mol^{-1}, $E^{red}_{1/2}$ (**1**) −1.66 V, the Coulombic attraction term was taken to be 1.29 kcal mol^{-1} (2).

[c]Reference 2. The potentials reported in this paper, versus silver/silver nitrate (Ag/0.1 M $AgNO_3$) were related to SCE by adding 0.34 V.

[d]Reference 16. Lithium perchlorate (0.1 M $LiClO_4$) was used as the electrolyte in these determinations.

[e]Reference 8.

[f]Reference 17. Lithium perchlorate (0.1 M $LiClO_4$) was used as the electrolyte in these determinations.

peak is the result of the overlap of lines split by the 5-, 3-, and 3-Hz couplings of the axial–axial and two axial–equatorial vicinal hydrogen–carbon interactions present in this isomer. The chemical shift of the quaternary benzylic carbon is 43.09 ppm (singlet) and the doublet signal ($^1J_{C-H}$, 136 Hz) due to the carbon adjacent to the methoxy group is at 84.85 ppm.

The ^{13}C nmr spectrum of the isomer assigned the *trans anti*-Markovnikov structure (**14-***t*) shows $^3J_{C-H}$ couplings of the vicinal hydrogens to the methyl group of 6, 6, and 3 Hz. This is similar to the coupling pattern observed for the *trans* Markovnikov adduct **15-***t* and is indicative of an axial methyl group coupled to two axial and one equatorial hydrogens. The signal due to the carbon bearing the methoxy group is a doublet (83.82 ppm, $^1J_{C-H}$ 142.3 Hz) and the benzylic carbon shows up as a singlet (43.43 ppm).

The structures of the three adducts from norbornene (**16**, **17**, and **18**) were established by applying similar reasoning. Analyses of both the ^1H and ^{13}C nmr spectra indicate that the norbornane carbon framework is intact; there was no indication of skeletal rearrangement.

The structural assignment for the *exo–exo* product **18** was based on a vicinal coupling of the hydrogen adjacent to the methoxy group (3.50 ppm), C*H*—OCH_3, and the benzylic hydrogen (2.91 ppm) of 7.0 Hz, typical coupling for *endo–endo* vicinal hydrogen interaction. The $^4J_{H2_{endo}-H7_{anti}}$ is small (1.7–2.6 Hz (11)) and in this case it was not observed.

The assignment of the *endo*-(4-cyanophenyl)-*exo*-methoxy product **16** was also based on the observed coupling of the signal due to the hydrogen adjacent to the methoxy group (3.43 ppm). Couplings of this hydrogen were assigned to an *endo–exo* vicinal (3.5 Hz) and a $^4J_{H2_{endo}-H7_{anti}}$ (1.5 Hz) interaction.

The signal at 3.65 ppm, due to the hydrogen adjacent to the methoxy group on the other *trans* addition product, *exo*-(4-cyanophenyl)-*endo*-methoxy (**17**), also had coupling attributed to an *exo–endo* hydrogen interaction (4.4 Hz). This hydrogen was split further by the $^2J_{H1-H2_{endo}}$ (4 Hz) coupling.

The ^{13}C nmr spectra of all three of these isomers are consistent with these structural assignments.

The methodology used for the structure determination of the adducts of 2-methylnorbornene was a combination of that used for the norbornene and methylcyclohexene adducts. Analyses of both the ^1H and ^{13}C nmr spectra indicate that the norbornane ring system is intact in all five isomers.

The regiochemistry of the major product **19** was established as *anti*-Markovnikov on the basis of chemical shift considerations in both the ^1H and ^{13}C nmr spectra. The low-field signal in the aliphatic region of the ^1H nmr spectrum at 3.47 ppm is indicative of a hydrogen adjacent to the methoxy group, C*H*—OCH_3.

The stereochemistry at this carbon was established as that with the hydrogen in the *endo* position because of the observed four-bond coupling, 1.6 Hz, to the *anti* hydrogen at C7. In the ^{13}C nmr spectrum, the observed line width (one of the central lines of the quartet) of the signal due to the methyl carbon (26.81 ppm) is relatively sharp; the width at half-height is only 6.3 Hz. Such a small combined coupling establishes that this methyl is in the *exo* position.

In the ^{13}C nmr spectrum of this isomer (**19**), the signal due to the carbon adjacent to the methoxy group at 90.85 ppm is a doublet, $^1J_{C-H}$, 142 Hz; the signal due to the benzylic carbon at 54.74 ppm is a singlet.

The structural assignment, *trans-endo*-(4-cyanophenyl)-*exo*-methoxy-*anti*-Markovnilov (**19**), is consistent with both the ^1H and ^{13}C nmr spectra.

The second most abundant isomer (**20**) was also shown to have the *anti*-Markovnikov structure and the hydrogen adjacent to the methoxy group, C*H*—OCH_3, is also *endo*. The chemical shift of this hydrogen is 3.05 ppm and it is coupled to the hydrogen, $H7_{anti}$, by 1.8 Hz in this case. There is, however, a large difference in the coupled carbon spectra of these two major isomers. The observed splitting of one of the central lines of the quartet due to the methyl carbon measures 4.5 Hz in this isomer. The line width at half-height is 11 Hz. This relatively large coupling constant indicates that the methyl group is in the *endo* position and is coupled ($^3J_{C-H}$) to the *endo* hydrogen adjacent to the methoxy group.

One of the remaining minor products was also established as having the *anti*-Markovnikov regiochemistry, *exo*-(4-cyano-

phenyl)-*endo*-methoxy (**21**). The low-field signal at 3.68 ppm, due to the hydrogen adjacent to the methoxy group, C*H*—OCH_3, is split by 3.8 Hz. This coupling results from the interaction of this hydrogen, $H2_{exo}$, with the vicinal hydrogen H1.

In the ^{13}C nmr spectrum of this isomer, the lines of the quartet due to the carbon of the methyl group (23.36 ppm) are narrow, less than 1.6 Hz wide at half-height. This observation leads to the conclusion that the methyl group must be *endo*, so that coupling to the hydrogen $H2_{exo}$ is small.

Analysis of the ^{13}C nmr spectrum confirmed the regiochemical assignment of this isomer (**21**). The signal due to the carbon adjacent to the methoxy group at 89.03 ppm is a doublet, coupled by $^1J_{C-H}$ 143.8. Hz. The peak assigned to the benzylic carbon at 48.30 ppm is a singlet.

The two remaining minor products were established as Markovnikov adducts on the basis of the chemical shift of the low-field hydrogen; one occurs at 2.47 ppm and the other at 3.11 ppm. This is in the region expected for a benzylic hydrogen.

One of these adducts was shown to have the *exo*-(4-cyanophenyl)-*exo*-methoxy configuration (**22**). The benzylic hydrogen (2.47 ppm) had a small but observable coupling to the hydrogen in the *anti* position on C7; thus this hydrogen was assigned as *endo*.

In the ^{13}C nmr spectrum of this isomer, the observed splitting of one of the central lines of the quartet due to the carbon of the methyl group (19.39 ppm) was 4.0 Hz. This was attributed to coupling involving $H2_{endo}$ and the carbon of the methyl group in the *endo* position.

Support for the regiochemical assignment comes from the ^{13}C nmr spectrum of this isomer (**22**). The signal due to the carbon adjacent to the methoxy group is a singlet (84.69 ppm), while a doublet peak centered at 61.67 ppm ($^1J_{C-H}$, 129.2 Hz) is observed for the benzylic carbon.

The other Markovnikov adduct was established as the *endo*-(4-cyanophenyl)-*exo*-methoxy isomer (**23**). The signal due to the benzylic hydrogen (3.11 ppm) was split by a 3.4-Hz coupling to the hydrogen at C4, and is therefore in the *exo* position.

The ^{13}C nmr spectrum of this isomer shows the lines of the quartet due to the carbon of the methyl group (19.19 ppm) are relatively sharp (<4.5 Hz) with little coupling and therefore the orientation of the methyl group must be *exo*. The signal due to the carbon adjacent to the methoxy group occurs at 83.50 ppm and is a singlet. The signal due to the benzylic carbon at 58.83 ppm is a doublet, coupled by 126.7 Hz ($^1J_{C-H}$).

The consistent pattern that emerges from analysis of the spectra of all of these isomers gives us confidence in all of the structural assignments.

Discussion

Direct and photosensitized irradiations

Salient features of the mechanism of the photo-NOCAS reaction were introduced in the first paper in this series (2). The new results generally are consistent with that proposal (Scheme 1).

Reactions carried out by direct irradiation, without added donor, involve excitation of the 1,4-dicyanobenzene **1**. The ultraviolet absorption spectrum of **1** extends to 300 nm, beyond the short wavelength cutoff due to absorption of Pyrex (280 nm). Previous studies have shown that the fluorescence of **1** is quenched at nearly the diffusion controlled rate by simple olefins (2). The intersystem crossing process from singlet **1** is relatively slow. It is therefore reasonable that steps 2a and (or) 2b involve the single excited state of **1** upon direct irradiation.

Table 2 is a list of the calculated free-energy change, based upon the Weller equation (15), for the electron transfer process between the excited singlet state of **1** and the olefins studied. Step 2b is significantly exergonic for all of the cyclic olefins studied; the rate of electron transfer will be diffusion controlled. Only with 2-methylpropene (**5**) is the calculated free-energy change for the electron transfer step positive, and the photo-NOCAS reaction is in fact inefficient in this case (2).

The alternative mode of activation, photosensitization (electron transfer), occurs in those reactions in which another donor, phenanthrene (**4**) or biphenyl (**8**), has been added (steps 6 and 7). In the case of added **4**, the major light-absorbing species is the phenanthrene (step 6b). The ultraviolet absorption spectrum of phenanthrene extends to 360 nm. Electron transfer from the singlet excited state of phenanthrene to 1,4-dicyanobenzene is an exergonic process (-7.8 kcal mol^{-1}) and is known to be a rapid (diffusion controlled) process (18). In the case of added biphenyl (**8**), it is the singlet excited state of **1** that accepts an electron from **8** (step 6a). The ultraviolet absorption spectrum of **8** does not extend much beyond 290 nm. Electron transfer from **8** to the excited singlet state of **1** is spontaneous (-19 kcal mol^{-1}).

Of the examples listed in Table 1 several show that the efficiency of the reaction and yield of photo-NOCAS product(s) are greatly improved by the addition of the photosensitizer. In many of these cases, secondary electron transfer from the olefin to the radical cation of the added donor is spontaneous, or only slightly endergonic, and therefore formation of the olefin radical cation should be rapid (step 7) (4, 5).

There are some cases, however, where the reaction is improved in spite of the fact that the oxidation potential of the photosensitizer is significantly less than that of the olefin. For example, reaction [5], where the addition of biphenyl (**8**) to the irradiation mixture improves the reaction with 2-methylpropene (**5**), even though the oxidation potential of **8** is 19 kcal mol^{-1} less than that of **5**, and reaction [16], where phenanthrene (**4**) improves the reaction with norbornene (**11**) even though the oxidation difference ($E_{1/2}$(**11**) $-$ $E_{1/2}$(**4**)) is $+12$ kcal mol^{-1}.

To complete the analysis, there are examples where addition of the photosensitizer does not significantly improve the reaction; in fact, there are some examples where the added donor even quenches the reaction. For example, phenanthrene (**4**) quenches the reaction with 2-methylpropene (**5**); the oxidation potential difference ($E_{1/2}$(**5**) $-$ $E_{1/2}$(**4**)) is 23 kcal mol^{-1} (2). Yet, biphenyl (**8**) improves this reaction (reaction [4]); the oxidation potential difference ($E_{1/2}$(**5**) $-$ $E_{1/2}$(**8**)) is 19 kcal mol^{-1}. And, while the addition of **8** improves the reaction with cyclohexene (**9**) (reaction [6]) (the oxidation potential difference ($E_{1/2}$(**9**) $-$ $E_{1/2}$(**8**) is 11 kcal mol^{-1}), **4** is ineffective (the oxidation potential difference ($E_{1/2}$(**9**) $-$ $E_{1/2}$(**4**)) is 15 kcal mol^{-1}).

From this limited number of examples we conclude that the photosensitizer may improve the reaction even though it has an oxidation potential significantly (as much as 20 kcal mol^{-1}) lower than that of the olefin. As the difference in oxidation potential becomes greater, the effectiveness of photosensitization decreases. The relative oxidation potentials of the olefins and photosensitizers are plotted in Fig. 1.

The fact that an added donor can function as a photosensitizer even though it has an oxidation potential significantly lower than the olefin makes it unlikely that a simple electron transfer, forming the olefin radical cation, is involved. We suggest that there is formation of a bimolecular radical cation complex involving the olefin and the added donor (4*d*). Even though such a complex might have most of the charge and spin density on the

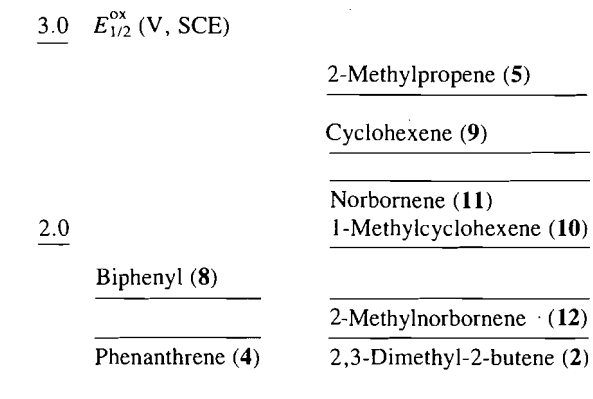

FIG. 1. The relative oxidation potentials of the photosensitizers and olefins studied.

component with the lower oxidation potential, the olefin component could still be reactive toward methanol. The analogous dimeric radical cations of polynuclear aromatic compounds are well known and the radical cation complex of benzene–ethylene has recently been characterized (19).

In those reactions that are more efficient upon photosensitization, the product ratios are essentially the same with both photosensitizers. We make the assumption that under these conditions the olefin radical cation is formed away from the 1,4-dicyanobenzene radical anion ($\mathbf{1}^{\bullet -}$) and is either freely solvated or is involved in a mixed radical cation complex with the donor. In fact, termolecular complexes cannot be ruled out (5). The increased efficiency may be the result of a slower back electron transfer process within the initially formed radical anion – photosensitizer radical cation pair.

The representation of step 3 shown in the scheme is oversimplified in that it only shows reaction of methanol occurring with the olefin radical cation. The extent of the association of the radical cation with the radical anion $\mathbf{1}^{\bullet -}$ or with an added donor is not indicated. In those reactions induced by direct irradiation, along the increasing stages of radical ion pair separation, where does reaction with methanol occur? And, in the photosensitized reactions, does the added donor play a role in this step?

There are small but significant differences in the ratio of isomers formed upon direct irradiation and photosensitized. The most significant, consistent, difference is that the reaction is more regioselective upon photosensitization, favouring the *anti*-Markovnikov adducts. We believe that this is the result of reaction occurring at different stages of radical cation – radical anion pair separation, and that complexation of the olefin radical cation with the added donor is involved.

Let us consider first the possibility that reaction occurs while the radical ion pair is still in an electronic excited state, that is, at the exciplex stage. Formation of the radical ion pair with **1** and 2-methylpropene is endergonic and the photo-NOCAS reaction is very inefficient, and yet the fluorescence of **1** is quenched by 2-methylpropene at nearly the diffusion controlled rate. The quenching process, in this case, may involve formation of an exciplex that does not go on to a reactive radical ion pair stage (2).

The formation (step 2a) and stability of the exciplex is favoured by nonpolar solvents while polar solvents favour the direct formation (step 2b) of the radical ion pair and providc an efficient deactivation pathway for the exciplex to the radical ion pair (step 2b′). The irradiation of cyanoaromatic compounds in the presence of olefins in nonpolar solvents generally leads to cycloadducts (1-azetines and (or) cyclobutanes); this reaction does involve the exciplex (20, 21).

If exciplexes were involved, in the case of norbornene (**11**) and 2-methylnorbornene (**12**), the favoured orientation of the exciplex would have the 1,4-dicyanobenzene (**1**) on the *exo* side. If reaction occurred by bonding within the exciplex, product formation should reflect this structure. While there is, in fact, relatively more of the *exo*-(4-cyanophenyl) isomer (**17**) formed upon direct irradiation in the reaction involving norbornene (**11**), the major isomer in every case has the methoxy group in the *exo* position and the (4-cyanophenyl) group *endo* (**16**, **19**, and **23**).

The evidence is against the exciplex as the reactive intermediate in the photo-NOCAS reaction in polar solvents.

The possibility that coupling between the radical anion and the radical cation within the radical ion pair precedes the addition of methanol should be addressed. This mechanism has been suggested for some related reactions (21*e*, 22). Coupling between the radical anion and the radical cation should lead to the more stable zwitterionic (or diradical) intermediate, and ultimately to the Markovnikov adducts. This mechanism should be more likely upon direct irradiation. The results show that direct irradiation does give relatively more of the Markovnikov adduct(s) in comparison to sensitized irradiation; however, the *anti*-Markovnikov adduct(s) are still the major products. Coupling of the radical anion and the radical cation prior to, or concerted with, reaction with methanol may account for some of the Markovnikov adducts, but this cannot be the dominant mechanism.

The relevant question then becomes, can the rate of reaction of methanol with the olefin radical cation, while still part of the radical ion pair, be fast enough to compete with solvent separation of the pair? The rate of separation of several radical ion pairs, similar to those involved here and also in acetonitrile, has been measured to be ca. 5×10^8 s^{-1} (23). The rate constant for reaction of olefin radical cations with methanol varies with the structure of the olefin. With 1,1-diphenylethylene the rate constant is 1.6×10^9 M^{-1} s^{-1}; more stable and sterically hindered radical cations react more slowly (23). The olefins used here are not stabilized by conjugation with phenyl rings and it is therefore possible that reaction of the radical cation with methanol (ca. 6 M) occurs at the radical ion pair stage, in competition with solvent separation.

Reaction of the olefin radical cation with a nucleophile may appear deceptively simple at first. This is, however, an interesting process that has received relatively little attention. The initial product of step 3 is the β-alkoxy alkyl radical *protonated on the oxygen*, a distonic radical cation. Most of our knowledge of this process comes from electrochemical studies (24) and from studies of ion–molecule reactions in the gas phase (25). Two possible mechanisms have been suggested: direct attack of the nucleophile on the radical cation with covalent bond formation, leading directly to the distonic radical cation, and initial formation of an ion–dipole π-complex. Either of these mechanisms could lead ultimately to the β-alkoxy alkyl radical; however, deprotonation from oxygen may not be fast enough, even in this polar solvent, to compete with reaction with the radical anion. This mechanism would be similar to the termolecular electrophilic addition to olefins (Ad_E3) (26).

A single electron shift from the nucleophile to the radical cation cannot lead directly to nucleophilic addition (27).

The intermediate radical shown as the ultimate result of step 3 is the same as would be obtained upon addition of an alkoxy

radical to the neutral olefin. The factors that influence the regioselectivity of radical addition to olefins are well known; both polar and steric effects are important (28). The factors that influence the regioselectivity of the addition of methanol to the radical cation of an unsymmetrical olefin are not yet defined. For example, the regioselectivity may depend upon the extent of separation of the radical ion pair formed upon direct irradiation, and upon the nature of the radical cation complex in the photosensitized reactions.

Methanol adds to the radical cation of 1,1-diphenylethylene to give exclusively the resonance stabilized radical (29). The previously reported photo-NOCAS reaction of methanol combining with 2-methylpropene (**5**) and then substituting on 1,4-dicyanobenzene (**1**) (reaction 3) also implicated the involvement of the more stable radical intermediate. An argument based upon steric factors could also explain these results. Both of these examples involve terminal olefins with large differences in both radical stability and in steric hindrance to approach at the alternate ends of the olefin. It was not clear how regioselective the reaction would be when the difference between the two ends of the olefin was less pronounced than in these earlier examples.

The reactions reported here with 1-methylcyclohexene (**10**) and 2-methylnorbornene (**12**) indicate that addition of methanol to these unsymmetric olefin radical cations, where the intermediate is either a secondary or tertiary radical, is not very regioselective. The reaction is somewhat more regioselective, favouring the *anti*-Markovnikov adducts, upon photosensitization. The largest effect of sensitization is observed in the case of 2-methylnorbornene (**12**) where there is significantly more of the *cis anti*-Markovnikov isomer (**20**) (reaction 21). In this reaction the ratio of *anti*-Markovnikov to Markovnikov adducts is relatively high (20:1). We offer the tentative explanation that it is the initial proximity of the radical anion, in those reactions involving direct irradiation, which leads to relatively more Markovnikov addition.

There is surprisingly little variation in the stereoselectivity as a function of mode of activation. The major differences involve the reactions of norbornene (**11**) and 2-methylnorbornene (**12**); there is relatively more of the *trans* adduct *with the methoxy in the* endo *position* (**17** and **21**) produced upon direct irradiation. This observation can also be explained in terms of reaction of the radical ion pair. The olefin radical cation would be attacked by the methanol on the side opposite from the radical anion; if the radical anion was blocking the preferred *exo* side, the methanol would be forced to attack from the *endo* side.[5]

There is no reason to expect the reaction to be stereoselective if step 4 involves the coupling of the β-alkoxyradical to the 1,4-dicyanobenzene radical anion free from the radical ion pair. Chemical (31) and spectroscopic (32) evidence indicates that "bridging" is of little importance in this type of radical. The suggestion has been made that bridging is more important in the distonic radical cation (25*d*). In these cyclic systems there should be a preference for formation of the *trans* adduct, by coupling of the β-methoxycyclohexyl radical at the less hindered *pseudo-equatorial* position with the methoxy group in the equatorial position. In fact, the *cis*:*trans* ratio of 1:5–6 observed in the case of cyclohexene is comparable to the ratio (1:2.5) of β-chlorocyclohexyl *tert*-butyl ethers obtained upon addition of *tert*-butyl hypochlorite to cyclohexene (33).

If step 4 follows directly after step 3 as a continuation of the reaction of the radical ion pair formed upon direct irradiation, these two reactants are still part of the solvent cage and coupling is likely to occur. If, however, the radical is formed away from the radical anion, the very low concentration of both of these species, and the fact that they are reactive (particularly for coupling and disproportionation of the radical), might make the required encounter improbable. Small amounts of the radical coupling and disproportionation products are in fact among the side products. It therefore seems likely that the high yield of the photo-NOCAS products results from a buildup of the relatively stable radical anion $\mathbf{1}^{\bullet -}$, to the point where the probability of an encounter with the reactive radical becomes significant. This is an example of a reaction controlled by "internal suppression of fast modes" (5*i*, 34).

Another interesting aspect of step 4 involves identification of the factors that influence the position, on the radical anion, at which coupling occurs. The results support the hypothesis that coupling occurs at the position of greatest spin density. This is also the position that minimizes the localization energy in the resulting anion (2, 20).

The driving force for step 5 is the rearomatization of the phenyl ring. If step 4 occurs at a position on the aromatic ring other than that bearing the cyano group, or if the driving force for rearomatization is insufficient, as in polynuclear aromatics, then the anion can be protonated and addition will occur instead of substitution (2, 21*a*, 21*e*).

A minor product under most irradiation conditions was the photo-NOCAS product incorporating cyanide ion, instead of methanol, as the nucleophile. Presumably this product arises from the addition of cyanide ion, generated in the final aromatization step (step 5), in competition with methanol in step 3 of the scheme.

The effects of added salts

The addition of salts (0.3 M), particularly magnesium perchlorate, has a profound effect on both the yield and the ratio of photo-NOCAS products. The yield is adversely affected; the amount of ethers resulting from addition of methanol to the radical cation of the olefin is increased. The amount of the allylic radical substitution products is also increased. *The photo-NOCAS reaction is regioselective when magnesium perchlorate has been added; only the* anti-*Markovnikov products are formed*. Both of these effects may result from a stabilization of the radical anion by the magnesium cation, causing a decrease in reactivity and increased selectivity.

Flash photolysis studies have shown that the lifetime of radical cations can be significantly increased by the addition of magnesium cation. The explanation given was that stabilization of the radical anion inhibits the deactivating back electron transfer (6*b*). Other cations were not as effective.

The reaction of methanol with the olefin radical cation may occur without any influence being exerted by the 1,4-dicyanobenzene radical anion $\mathbf{1}^{\bullet -}$ when it is stabilized by the magnesium cation. This would imply that the uncomplexed radical anion $\mathbf{1}^{\bullet -}$ is involved in the step that determines the regiochemistry in the absence of magnesium cations. Involvement of $\mathbf{1}^{\bullet -}$ directs the addition in favour of the Markovnikov adduct(s). This is consistent with the conclusion reached earlier: in the absence of added salts there is an addition step that is analogous to the Ad_E3 mechanism, resulting in an increase in the relative amount of Markovnikov addition. When magnesium salt is added to the irradiation mixture the radical anion is deactivated, the reaction becomes analgous to the Ad_E2 mechanism, and the reaction is regioselective, i.e., *anti*-Markovnikov.

[5]There is still some debate over the cause of the generally preferred *exo* attack on norbornene (see ref. 30, and the references therein).

The addition of other salts (lithium perchlorate and tetrabutylammonium perchlorate) had much less effect. Lithium perchlorate had a noticeable effect in some cases, increasing the yield of photo-NOCAS products incorporating methanol (reaction 13). Formation of the side product involving cyanide addition was greatly reduced when lithium perchlorate was added to the irradiation mixture; hence, the yield of the methanol adducts was increased. This may result from lithium cation scavenging the cyanide anion.

Perspective

Not too many years ago the major (only) reaction considered to be generally useful in a synthetic strategy for alkylation of an aromatic ring would have involved the electrophilic aromatic substitution mechanism (S_E2Ar). Recent years have seen a significant increase in our understanding of the mechanism, if not the routine application, of several alternative methods for achieving this objective. Some of these newer methods involve radical ions, both the radical cation and the radical anion, of the aromatic compound (35).[6]

It is already obvious from these few examples that the photo-NOCAS reaction will also have significant synthetic utility. The limitations of the reaction, many of which are now predictable in terms of the mechanism, are no more severe or restrictive than those imposed by the S_E2Ar mechanism. The differences observed in the ratio of regio- and stereoisomeric products, as a function of mode of activation and complexation, encourage us to predict that ways will be found to control this aspect of the reaction as well.

Experimental

General Information

The ^1H and ^{13}C nmr spectra were recorded on a Nicolet 360 NB nmr spectrometer coupled to an Oxford Instruments superconducting magnet and a Nicolet 192 kword data acquisition system, a Varian CFT-20, or an EM-360L spectrometer, and are reported in parts per million to high frequency from TMS. Coupling constants are reported as absolute values; the signs of the couplings were not determined. Infrared spectra (ir) were recorded on an air-purged Perkin–Elmer 180 grating infrared spectrometer or a Pye Unican SP3-200 and are reported in wavenumbers relative to the 1601.4 cm^{-1} absorption of polystyrene. Mass spectra (ms) were recorded on a Hewlett–Packard 5970 series mass selective detector and are reported as *m/z* (relative intensity). Exact mass determinations were done on a Du Pont CEC 21-110B mass spectrometer. Elemental analyses were performed by Canadian Microanalytics Services Inc. The melting points were determined using a Cybron Corporation Thermolyne melting point apparatus and are corrected.

Product analyses were determined by gas chromatography (gc) using either a Hewlett–Packard (HP) 5890 gc, fitted with a 5% phenyl methyl silicone fused silica WCOT column (25 m × 0.20 mm, 0.33-μm film thickness), coupled to an HP 5970 mass selective detector (ms), or a Hewlett–Packard 5890 gc, fitted with a DB-1701 or DB-225 fused silica WCOT column (30 m × 0.25 mm, 0.25-μm film thickness), with a flame ionization detector (fid). The digital signal from the fid was transmitted to a HP 3392A integrator and the data were acquired by software developed at the Department of Chemistry, Dalhousie University, using a Commodore PC-II.

Compounds that were obtained as liquids were purified prior to analysis by preparative gas chromatography using a Varian Aerograph 90-P and a 3/8 in. × 10 ft aluminum column, column "A". Column A was packed with 5% SE-52 on Chromosorb A 60/80 NAW. Column "B" was used for the purification of the olefins for the electrochemistry experiments; it was a 3/8 in. × 10 ft aluminum column packed with 40% SE-30 on Chromosorb W 60/80 NAW. Preparative medium-pressure liquid chromatography (mplc) was carried out using a 2.5 cm × 1 m column packed with tlc grade silica gel (without binder) (Merck) at 15 psi (helium) (1 psi = 6.9 kPa). The chromatograms were developed with a hexanes – methylene chloride linear gradient and the eluant was monitored, collected by a uv spectrometer-fraction collector.

Materials

Solvents were fractionally distilled. Acetonitrile (Fisher ACS grade) was distilled successively from sodium hydride and phosphorus pentoxide, and was then passed through a column of basic alumina, refluxed over calcium hydride for 24 h (under a nitrogen atmosphere), and fractionally distilled. The 1,4-dicyanobenzene (**1**) (Aldrich) was purified by treatment with Norite in methylene chloride, followed by sublimation and recrystallization from 95% ethanol. Tetraethylammonium perchlorate (TEAP) (Aldrich) was recrystallized (three times) from 95% ethanol and dried in a vacuum oven (12 h, 80°C, 10 Torr (1 Torr = 133.3 Pa)) before use.

Irradiations

Irradiations were carried out using a CGE 1-kW medium-pressure mercury vapor lamp contained in a water cooled quartz immersion well. The temperature was maintained at 10°C. The solvent was acetonitrile–methanol (3:1) at a typical concentration of **1** of 0.1 M, and olefin of 0.2 M. The concentration of photosensitizer (electron transfer) was 0.02 M. Solutions were placed in 2 cm i.d. Pyrex tubes (large scale) or 5 mm Pyrex nmr tubes, flushed with dry nitrogen, and sealed. Reaction mixtures (large scale) were chromatographed by mplc, taking ca. 10-mL fractions. For quantitative studies, changes of the ratio between starting material and products were followed by gc/fid. Variation in the fid response was taken into account (37).

Cyclic voltammetric measurements

Oxidation potentials were obtained by cyclic voltammetry using an apparatus similar to that previously described (*1a*). The working electrode was a platinum sphere (1 mm diameter), while the counter electrode was a platinum wire. The reference electrode was a saturated calomel electrode (SCE), which was connected to the solution by a Luggin capillary. The electrolyte was TEAP (0.1 M) and the solvent was acetonitrile. Substrate concentrations were typically 0.005 M. If the anodic wave was not reversible, the half-wave potential was taken as 0.028 V before the anodic peak potential (38).

2-Methylbicyclo[2.2.1]heptane-2,3-dicarboxylic acid

This dicarboxylic acid was prepared by the method of Beckmann and Schaber (9). Freshly distilled cyclopentadiene (108 g, 1.63 mol) was dissolved in 500 mL of ethyl acetate at 0°C. To this solution was added 112 g (1 mol) of citraconic anhydride (Aldrich) in 5-mL aliquots. The reaction was kept at 0°C overnight and was then allowed to warm to room temperature. Gas chromatographic analysis indicated the reaction was 93% complete based on consumed citraconic anhydride.

This solution was added to a 1-L flask containing 2 g of 5% palladium on charcoal (Engelhard). The flask was evacuated and charged with hydrogen. This mixture was stirred for 5 days; reaction was complete. The reaction mixture was filtered through Celite 545 and the solvent was evaporated. The residue was added to 500 mL 15% KOH. After 12 h, tricyclo[5.2.1.$0^{2,6}$]decane was removed by filtration. Concentrated hydrochloric acid was added to the filtrate until pH 2. The product, 2-methylbicyclo[2.2.1]heptane-2,3-dicarboxylic acid, precipitated and was isolated by filtration, washed with water, and dried.

Yield 190 g (96%), mp 142–144°C (lit. (9) mp 143°C).

*2-Methylnorborn-2-ene (**12**)*

The 2-methylnorborn-2-ene was prepared by oxidative bis-decarboxylation of 2-methylbicyclo[2.2.1]heptane-2,3-dicarboxylic acid using a procedure developed by Paquette and co-workers (10). To a 250-mL round bottom flask, equipped for distillation with a receiver in Dry Ice and under a nitrogen atmosphere, was added 9.9 g (0.05 mol) of 2-methylbicyclo[2.2.1]heptane-2,3-dicarboxylic acid, 15.6 g (0.10

[6]An analogous reaction, the photochemical electrophile–olefin combination, aromatic substitution (photo-EOCAS) reaction, might also be developed into a useful synthetic procedure (36).

mol) 2,2′-dipyridyl (Aldrich), 15.0 g (0.10 mol) red cuprous oxide, 3 g powdered glass, and 75 mL of distilled quinoline. The stirred mixture was heated at 140°C for 1.5 h, and then the temperature was increased to 180°C for 72 h. The distillate was purified by washing, first with 10% hydrochloric acid, then with water, and was dried with magnesium sulphate. The yield of **12** was 2.54 g (47%) as a colourless liquid. Analysis of this product by gc indicated the purity was 97% (impurity, 2-methylenenorbornane). The reactor was recharged repeatedly with the original quantity of 2-methylbicyclo[2.2.1]heptane-2,3-dicarboxylic acid and one quarter of the amount of cuprous oxide (0.05 mol) with little effect on the overall yield.

Infrared (SP3-200) ν: 2940(vs), 2840(m), 1430(m), 790(m); ^{1}H nmr (60 MHz, $CDCl_3$) δ: 5.5(s, 1H), 2.75(s, 1H), 2.6(s, 1H), 1.75(d, 3H, ^4J=2 Hz), 1.70–0.9(m, 6H); ^{13}C nmr (20 MHz, $CDCl_3$) δ: 145.3, 128.2, 48.2, 46.5, 42.4, 26.9, 24.2, 15.0; ms *m/z*: 108(20), 91(12), 80(100), 79(73), 77(21). The ^{1}H nmr spectra of **12** has been reported (39).

Formation of the cyclohexene adducts

A solution of 3.30 g (0.04 mol) cyclohexene (**9**), 3.00 g (0.02 mol) biphenyl (**8**), and 2.50 g (0.02 mol) 1,4-dicyanobenzene (**1**) in 200 mL acetonitrile–methanol (3:1) was degassed with nitrogen for 15 min and irradiated for 90 h. The volatile components of the photolysate, removed by distillation, included unreacted **9** and methoxycyclohexane (analyzed by gc/ms). The nonvolatile residue (8.50 g) was partially separated by standard column chromatography using hexanes as the eluent; **8** was recovered in 97% yield. The solvent was changed to diethyl ether, which eluted the photo-NOCAS isomers as a mixture of yellow oil and crystals (5.79 g). This mixture was separated by mplc.

Fraction no. 140–157: 482 mg of 3-(4-cyanophenyl)cyclohexene (2); ir (PE-180) ν : 3020(w), 2930(s), 2860(m), 2840(w), 2220(s), 1600(s), 1500(m), 830(s); ^{1}H nmr (60 MHz, $CDCl_3$) δ: 7.6–7.1(dd, 4H), 6.1–5.5(m, 2H), 3.6–3.3(m, 1H), 2.3–1.5(m, 6H).

Fraction no. 161–175: 80 mg of a 1:1 mixture of 2- and 4-cyanobiphenyl. The 4-cyanobiphenyl (mp 87°C) was identified by comparison with an authentic sample prepared by the reaction of the diazonium salt of 4-cyanoaniline with benzene in the presence of base (40). The other product, with similar retention time and fragmentation pattern (gc/ms), was assigned the structure *ortho*-cyanobiphenyl; ^{1}H nmr (361.08 MHz, $CDCl_3$) δ: 7.76–7.24(m); ms *m/z*:179(100), 178(25), 152(5), 151(5), 77(3).

*Formation of the 1-methylcyclohexene (**10**) adducts*

Dicyanobenzene (**1**) (2.50 g, 20 mmol) and biphenyl (**8**) (1.80 g, 12 mmol) were dissolved in 200 mL of acetonitrile–methanol (3:1). This solution was distributed between six Pyrex irradiation tubes and degassed. To each tube was added 1-methylcyclohexene (**10**) (0.65 mL in each (33 mmol total)). After irradiation for 20 h, gc analysis indicated that **10** was essentially consumed. The volatile components were removed by distillation leaving a mixture (6.74 g) of yellow-orange oil and some crystals. The distillate contained a small amount of unreacted **10**, *cis*- and *trans*-1-methoxy-2-methylcyclohexane, and 1-methoxy-1-methylcyclohexane. These ethers were identified by direct comparison (gc/ms) with authentic samples prepared from the corresponding alcohols (Aldrich). The nonvolatile residue was filtered through glass wool to yield a yellow-orange oil containing the photo-NOCAS products; the crystalline material was unreacted **1** (200 mg). The oil was partially separated by column chromatography; **8** (1.30 g) was eluted with hexane and the photo-NOCAS products (2.96 g) came off in methylene chloride. The photo-NOCAS products were isolated by mplc.

Fraction no. 153–189: 195 mg of allylic radical substitution products. These products were identified on the basis of gc/ms (retention time and fragmentation pattern) in comparison with the analogous products from **9**.

Fraction no. 190–207: 100 mg of a mixture of the radical substitution products and **15**-*c*.

Fraction no. 208–216: 42 mg pure **15**-*c*.

Fraction no. 217–241: 600 mg of a mixture of **14**-*t* and **14**-*c*.

Fraction no. 242–258: 828 mg pure **14**-*t*.

Fraction no. 259–272: 310 mg of a mixture of **14**-*t* and **15**-*t*.

Fraction no. 273–288: 205 mg pure **15**-*t*.

Fraction no. 289–310: 180 mg of impure **15**-*t*.

*Formation of adducts with norbornene (**11**)*

A solution of 1,4-dicyanobenzene (**1**) (2.5 g, 20 mmol), norbornene (**11**) (9.0 g, 96 mmol), and biphenyl (**8**) (1.8 g, 12 mmol) in 250 mL of acetonitrile–methanol (3:1) was purged with nitrogen and irradiated (60 h). The volatile components of the reaction mixture were distilled. Analaysis of the distillate by gc/ms indicated that *endo-* and *exo*-2-methoxynorbornane were present. The nonvolatile components were partially separated by flash chromatography using a 40 cm × 2 cm silica gel column, eluting with methylene chloride (100-mL fractions). Fraction no. 4 (1.35 g) was mainly **8** with some 2-(cyanomethyl)norbornane; fraction no. 5 (1.38 g) was pure 2-(cyanomethyl)norbornane; fraction no. 6–13 contained the photo-NOCAS products. The yield of photo-NOCAS isomers was 2.20 g. When the amount of recovered **1** was taken into account, the yield was 78%. Fractions no. 5–13 were combined and the products were partially separated by mplc using the hexanes – methylene chloride gradient.

Fraction no. 57–64; trace of **8**.

Fraction no. 155–175; 124 mg of 2-cyanomethylnorbornane.

Fraction no. 220–244; 794 mg of a mixture of **16**, **17**, **18**, and **1**.

Fraction no. 245–257; 548 mg of pure **16**.

Fraction no. 258–290; traces of the isomeric 2-(cyanomethyl)-3-(4-cyanophenyl)norbornanes. Structures were tentatively assigned on the basis of gc/ms (retention time and fragmentation pattern).

The structure of *exo*-2-(cyanomethyl)bicyclo[2.2.1]heptane was established by comparison with an authentic sample prepared by refluxing a solution of acetonitrile, norbornene, and dibenzoyl peroxide for 4 days. This is a known compound (41); ir (PE-180) ν: 2950(s), 2870(m), 2240(m), 1460(m), 1425(m); ^{1}H nmr (361.08 MHz, $CDCl_3$) δ: 2.29–2.12(m, 4H), 1.88–1.78(m, 1H), 1.63–1.45(m, 3H), 1.34–1.27(m, 1H), 1.27–1.07(m, 4H); ms *m/z*: 135(2), 95(79), 68(100), 67(100).

Fraction no. 220–244 was rechromatographed (mplc) using methylene chloride as eluent. Traces of unreacted **1** were separated in earlier fractions, then a mixture of **18** and **17** was eluted, followed by a mixture of **18** and **16**, and finally some pure **16**. Pure **17** was obtained from an enriched fraction by preparative gc using column A.

Acknowledgments

This work was supported by grants from the Natural Sciences and Engineering Research Council of Canada and from the Petroleum Research Fund administered by the American Chemical Society. We thank Dr. D. L. Hooper at the Atlantic Regional Magnetic Resonance Centre at Dalhousie University for the high-field nmr spectra and for help in the preparation of the manuscript. We are also grateful to Mr. B. M. Millier for developing the data acquisition system interfaced with the gc/fid and to Dr. L. Ramaley for the exact mass determinations.

Hydrolysis of *p*-nitrophenyl alkanoates in aqueous organic solvent mixtures. The dispersal of aggregates and the uncoiling of *n*-alkyl chains

OSWALD S. TEE[1] AND JOHN A. ENOS[2]

Department of Chemistry, Sir George Williams Campus, Concordia University, Montréal, P.Q., Canada H3G 1M8

Received May 14, 1988

OSWALD S. TEE and JOHN A. ENOS. Can J. Chem. **66**, 3027 (1988).

Rate constants have been measured for the hydrolysis of six *p*-nitrophenyl alkanoates (C2, C4, C6, C8, C10, and C12) in basic aqueous media containing up to 80% (v/v) of the cosolvents: ethylene glycol (EG), 2-methoxyethanol (2ME), 1,2-dimethoxyethane (DME, glyme), bis(2-methoxyethyl) ether (diglyme), or DMSO. Addition of these cosolvents reduces and ultimately removes hydrophobic aggregation and coiling of the longer chain alkanoates, with the ether-type solvents (2ME, DME, and diglyme) being more efficient than EG or DMSO. Once the rate-lowering effects of aggregation and coiling have been removed by addition of a cosolvent, the rates of hydrolysis of the C4–C12 esters are all virtually the same, in a given medium. Thus, the apparent "steric size" of the C4–C12 (and even C16) acyl chains does not differ significantly in basic *p*-nitrophenyl ester hydrolysis. Addition of DMSO brings about rate increases that are greater in a carbonate buffer (pH 10.48) than those in 0.05 M NaOH solution, and these increases are larger than those observed for ethyl acetate in 0.05 M NaOH solution. None of the rate increases rise as quickly as the enhanced basicity of aqueous DMSO media.

OSWALD S. TEE et JOHN A. ENOS. Can J. Chem. **66**, 3027 (1988).

On a mesuré les constantes de vitesse pour l'hydrolyse de six alcanoates de *p*-nitrophényle (C2, C4, C6, C8, C10 et C12) en milieu aqueux basique contenant jusqu'à 80% (v/v) de cosolvants : l'éthylène glycol (EG), le méthoxy-2 éthanol (2ME), le diméthoxy-1,2 éthane (DME, glyme), l'éther bis-(méthoxy-2 éthyle) (diglyme), ou le DMSO. L'addition de ces cosolvants réduit et à la limite fait disparaître l'aggrégation hydrophobique et l'enroulement des plus longues chaînes d'alcanoates; les cosolvants de type éther (2ME, DME et diglyme) sont plus efficaces que le EG ou le DMSO. Dès que les cosolvants font disparaître l'aggrégation et l'enroulement, responsables de la diminution des vitesses, les vitesses d'hydrolyse des esters de C4–C12 sont à toutes fins pratiques identiques dans un milieu donné. Ainsi, il n'y a pas de différence significative dans la « dimension stérique » apparente des chaînes acyles de C4–C12 (et même C16) lors de l'hydrolyse basique des esters *p*-nitrophényles. L'addition de DMSO provoque des augmentations de vitesse qui sont supérieures dans un tampon de carbonate (pH 10,48) à celles que l'on note dans une solution de NaOH 0,05 M, et ces augmentations sont supérieures à celles observées pour l'acétate d'éthyle dans une solution de NaOH 0,05 M. Les vitesses n'augmentent pas aussi rapidement que l'accroissement de la basicité du milieu aqueux contenant du DMSO.

[Traduit par la revue]

A change of solvent may affect reaction rates in various ways, depending on the reaction and the species involved (1). Dramatic changes in rate may be seen with reactions that involve heterolytic steps, due to the large free energies for the transfer of ions from hydroxylic solvents to non-hydroxylic solvents (1, 2). Indeed, the effects of ion solvation very often obscure the contributions of more subtle types of solvent–solute interactions (1–3). Thus, when a solvent change involves water, alterations in hydrophobic interactions (4) may be masked by the larger effects of ion solvation (1, 2). On the other hand, in the absence of heterolysis, significant hydrophobic effects may be apparent. Thus, Diels–Alder reactions, which are not generally sensitive to solvent, show large rate enhancements on transfer of the reaction to water because of the tendency of the reactants to aggregate in aqueous solution (5).

Obviously, hydrophobic effects in a heterolytic process may be apparent in a series of substrates in which the reaction centre remains constant, but alkyl groups are varied. Thus, hydrophobic aggregation was established in a long-chain *p*-nitrophenyl alkanoate (PNPA) by comparing, in part, the rates of hydrolysis of the dodecanoate and acetate esters (6). Likewise, the reactions of PNPA esters with nucleophiles can be enhanced by hydrophobic attractions, the effect increasing with lengths of the alkyl chains of the reactants (7).

However, the use of PNPAs in such studies must be exercised carefully because of the aggregation of long-chain esters, even at spectrophotometric concentrations (8). Guthrie showed that the rates of hydrolysis of the C6, C8, and C10 esters are not very different *if* the substrate concentrations are kept low enough to ensure that the esters are in a monomeric state (8). Also, since the reactivities of the monomeric esters decrease (modestly) from C6 to C12, it was concluded that coiling of the alkyl chains occurs in water (8, 9).

Recently, Jiang and co-workers studied the effect of organic cosolvents on the hydrolysis of long-chain PNPAs (10). Their principal intent was to probe the aggregation and coiling of *n*-alkyl chains in an aqueous environment and they have presented a variety of evidence that coiling does occur with longer chains (>C12) (10, 11). Further, the effects of most cosolvents can be related to their lipophilicities (10*b*).

The present study extends the former studies to medium chain lengths (C2–C12), other solvent mixtures, and different reaction conditions.[3] It was designed to provide background for future work on solvent effects on the cleavage of esters by cyclodextrins. These complexing agents bind guests hydro-

[2]Undergraduate participant.

[3]Jiang *et al.* (10*a*) measured rate constants for the hydrolysis of four PNPA esters (C2, C8, C12, and C16) in 30% (v/v) and 50% (v/v) aqueous organic solvents at 40°C (and *not* at 35°C, as given in the Experimental). A 0.02 M carbonate aqueous buffer (pH 9.65 in water) was *diluted* with organic cosolvent (details supplied by Prof. Jiang). Thus, their buffer concentrations were not constant and were lower than ours. The cosolvents used were *t*-BuOH, MeCOMe, MeCN, EtOH, dioxane, DME, DMF, 2ME, DMSO, and EG. In their most recent work (10*b*) the effects of initial ester concentration were extensively explored and the use of a "critical aggregate concentration" was introduced, similar to, but distinct from, a critical micelle concentration.

phobically (12, 13) and they exert varying effects on the cleavage of aryl alkanoates, depending on the aryl group (12, 14, 15) and the length of the alkyl chain (16, 17).[4] In one case a change from water to 60% aqueous DMSO enhances the efficiency of ester cleavage by β-cyclodextrin (18) but the origin and generality of this effect has not been established. Also, we are intrigued by the possibility that coiled *n*-alkyl chains may fit into cyclodextrin cavities better than extended ones.

Results and discussion

We have measured the rates of hydrolysis of *p*-nitrophenyl acetate (C2), butanoate (C4), hexanoate (C6), octanoate (C8), decanoate (C10), and, to a limited extent, the dodecanoate (C12) in basic aqueous media (a carbonate buffer or NaOH solution) containing varying amounts of the following organic cosolvents: dimethyl sulphoxide (DMSO), glyme (1,2-dimethoxyethane, DME), diglyme (bis(2-methoxyethyl) ether), 2-methoxyethanol (2ME), or ethylene glycol (EG).[3]

Table 1 presents rate constants for the hydrolysis of the acetate in a carbonate buffer and in dilute NaOH solution, as a function of DMSO content. For the reaction in buffer the rates rise more steeply than in simple base, but the origin of this difference is not clear. It may be due to the unknown effect of added DMSO on the bicarbonate–carbonate buffer system or to an enhanced contribution from buffer catalysis (7*a*).

In both buffer and NaOH solution the rate increases are quite modest when compared to the effects of DMSO and other dipolar aprotic solvents on simple nucleophilic substitutions (1–3). Likewise, the rate increases with added DMSO are not simply due to elevations of the activity of hydroxide ion since the basicity rises much more quickly (2, 19) than do the rate constants in Table 1. As discussed in detail by others (2, 20), the effects of DMSO on the rates of ester hydrolyses in base are composite; there are significant changes in the solvation energies of the ester *and* of the transition state, as well as of hydroxide ion. Moreover, the magnitude of the changes varies with the structure of the ester (20).

In Table 1 there is also a comparison with data for the hydrolysis of ethyl acetate in aqueous DMSO, taken from the literature (21). As seen there, in 50 mM NaOH the rate increases for *p*-nitrophenyl acetate are greater than for ethyl acetate. This difference may simply reflect solvation differences between the aryl and alkyl esters and their respective transition states (20) but it may also arise from the mechanistic difference between the two esters: with the phenyl ester the rate-limiting step is formation of the tetrahedral intermediate, whereas for the ethyl ester loss of the leaving group is rate limiting (4*a*, 22). Furthermore, there may be differential effects on leaving-group abilities since the effects of DMSO on the pK_as of water, ethanol, and phenols are not the same (ref. 1*a*, p. 300; ref. 2).

Table 2 shows the effects of different solvent mixtures on the cleavage of *p*-nitrophenyl acetate in 0.05 M NaOH. The organic solvents were chosen for their abilities to solvate cations well and their varied abilities to solvate anions. In all cases the rates of hydrolysis are elevated relative to wholly aqueous solution but the increases are quite modest. In the case of the two alcohols (EG and 2ME, both $pK_a = 14.8$ (22*b*)), there may be a contribution to ester cleavage from attack by their anions since the anion of 2ME is six times more reactive than OH^- towards *p*-nitrophenyl acetate in water (22*b*).[5] For our purposes, the data in Table 2 delineate the phenomenological effects of the cosolvents on PNPA ester hydrolysis, devoid of hydrophobic effects such as aggregation or coiling (8–11).

In Table 3 there is a comparison of rate constants for the hydrolysis of the C2, C4, C6, C8, and C10 PNPA esters in a carbonate buffer containing 0 and 40% DMSO. The rates for the C8 and C10 esters in water are somewhat lower, presumably due to coiling and the onset of solute aggregation (8–10).[6] In 40% DMSO both coiling *and* aggregation are removed, apparently, since the C4, C6, C8, and C10 esters all react at much the same rate. Similar behaviour has been observed for the C8 and C12 esters (but not the C16 ester) in 50% DMSO (10).

As a referee has noted, the acetate (C2) ester is more reactive than the others in any given medium (Table 3; see also Tables 4

[b]Solution slightly turbid due to the insolubility of NaOH.

[4]As well as the 4-carboxy-2-nitrophenyl alkanoates reported in ref. 17, we are also studying the cleavage of 2-carboxy-4-nitrophenyl esters, *m*-nitro and *p*-nitrophenyl alkanoates, and of 4-chloro and 5-chloro aspirin homologues (cf. ref. 15) by α-and β-cyclodextrin.

[5]Such a contribution has been posited for the cleavage of PNPAs in aqueous methanol mixtures (10*b*).

[6]With 4-carboxy-2-nitrophenyl alkanoates C4–C8 there is no diminution in the hydrolysis rates in water (17) nor with their 2-carboxy-4-nitrophenyl isomers (O. S. Tee and X.-X. Du. Unpublished work).

[a]At 25°C, in 0.05 M NaOH. $[Ester]_0$ = 0.05 mM for the C4 and C6 esters; 0.01 mM for the C8, C10, and C12 esters. Analogous data for the C2 ester are presented in Table 2; it reacts 2–3 times faster in any given medium.

[b]Very small absorbance change due to biphasic kinetic behaviour (see Experimental).

and 5). Such behaviour has been observed by other workers (8–10), with other aryl esters (17),[4] and with alkyl esters (23). It is entirely consistent with known steric effects on the hydration of carbonyl groups (ref. 1*a*, p. 663), a reasonable model for hydrolysis via a tetrahedral intermediate (4*a*, 22).

The effects of 50% (v/v) of the cosolvents on the rates of hydrolysis of medium-chain PNPA esters in 0.05 M NaOH solution are presented in Table 4. Where measurable, the rate constants for the C4, C6, C8, C10, and C12 esters in a particular solvent mixture are almost exactly equal. Thus, as seen with the buffer/DMSO data in Table 3 and as anticipated from earlier work (8–11), the addition of large amounts of organic solvents removes the rate-lowering effects of aggregation and coiling. However, the abilities of the various cosolvents differ: the ether-type solvents (2ME, DME, and diglyme), which are, presumably, less hydrophilic than EG or DMSO, are more efficient at removing hydrophobic effects from the C10 and C12 esters (Table 4). Consistent with this view, Jiang *et al.* (10*b*) have recently found that the effects of most cosolvents are related to their lipophilicities.

These results concur with those of Jiang *et al.* (10), to the extent that there is overlap.[3] At the 50% (v/v) level, all of their solvents, except EG and DMSO, reduce hydrophobic interactions such that the C8, C12, and the C16 esters react at the same rates in a given water–solvent mixture (10). Thus, combining the results of our study and theirs, the rates of basic hydrolysis of PNPA esters with acyl chain lengths from C4 to C16 are all virtually the same in aqueous solvent mixtures with sufficient organic cosolvent to remove hydrophobic effects.

TABLE 5. Pseudo first-order rate constants for the hydrolysis of *p*-nitrophenyl alkanoates in aqueous DMSO mixtures[a]

	k^{obs} (s^{-1})				
% DMSO (v/v)	C2	C4	C6	C8	C10

80	36.1	15.7	14.2	14.8	12.1

[a]At 25°C, in 0.05 M NaOH. $[Ester]_0$ = 0.05 mM for the C2, C4, and C6 esters; 0.01 mM for the C8 and C10 esters.

[b]Small absorbance change, biphasic behaviour (see Experimental).

[c]Very small absorbance change.

Finally, we have studied the effects of different amounts of DMSO on the basic hydrolysis of the PNPAs (Table 5). Provided sufficient DMSO is added to disrupt aggregation and remove biphasic kinetic behaviour (see Experimental), the rate constants for all the esters beyond C2 approach the same value. The minimum amount of DMSO that is sufficient for this purpose increases with the length of the acyl chain, as one might expect.[7]

The present study supplements the findings of earlier workers (8–10) and consolidates their conclusions about the hydrophobic aggregation and coiling of *n*-alkanoate chains. It seems clear that beyond the acetate, and up to at least the C16 case (10), there is no significant increase in the apparent steric effect of the alkyl chain in basic PNPA ester hydrolysis *if* the effects of hydrophobic aggregation *and* coiling are removed by an organic cosolvent (Tables 3–5).[8]

Our results also provide a valuable base of information for further studies of the interactions of alkyl chains with cyclodextrins. Initial work on aryl alkanoate cleavage has already revealed some novel features (17).

Experimental

The PNPA esters were obtained from Sigma Chemical Co., except for the acetate; it was purchased from Aldrich, as were the organic solvents, which were of the highest grade available. Stock solutions (0.01 or 0.10 M) of the esters were prepared in HPLC grade methanol and a few microlitres of these were diluted to the desired strength with the chosen media. The final reacting solutions contained 0.2 or 0.5% (v/v) MeOH.

For the reactions in carbonate buffer, the solution was made from 5 mL of 0.5 M aqueous $NaHCO_3$ and 2 mL of 1.0 M aqueous NaOH to which were added water and DMSO in the amounts required to bring the total volume to 100 mL; the final buffer concentration was 0.025 M. In 100% water the buffer had a pH of 10.48. Reactions were initiated by adding a few microlitres of stock ester solution to a cuvette containing 2 mL of buffer, at 25°C in the cell-holder. Ester concentrations were 0.10–0.01 mM, depending on the chain length.

For the experiments in NaOH solutions, the reactant solutions were prepared just before use. Standard 1.0 M NaOH in water was diluted with water and organic solvent to give a 0.10 M solution in the desired mixture. If the base solution showed any turbidity due to the low solubility of NaOH it was not used. After mixing in the stopped-flow

[7]However, coiling persists with esters having very long chains, even in aqueous DMSO with a high DMSO content (10, 11).

[8]Recently, Menger and Venkataram (24) defined a scale of "Microscopic Hydrophobicity Parameters", based on the disruption of aggregates of the C12 ester by substituted trimethylammonium ions, and using hydrolysis kinetics as the probe.

apparatus, [NaOH] was 0.05 M and $[ester]_0$ was 0.05 mM or 0.01 mM (for the C8, C10, and C12 esters).

For the slow reactions a conventional uv–visible spectrophotometer was used; the fast reactions in NaOH solutions were followed using a stopped-flow apparatus interfaced to a microcomputer (15). In both cases, the appearance of the *p*-nitrophenolate ion was monitored at 405 nm and the observation cells were kept at 25.0±0.1°C. Whenever possible, the reactions were followed to 80–90% completion and an infinity reading was obtained after 10 half-lives. The pseudo first-order rate constants were evaluated in the normal way (15).

With longer esters, in solutions of high water content, biphasic kinetic behaviour was often observed, as reported by others (8, 10, 24). If the faster process, due to monomeric ester, was dominant, the initial absorbance change was followed as far as its first-order behaviour persisted, and an infinity value was estimated by the Kezdy–Swinbourne method (25). However, when the slower reaction of aggregated ester was more significant, so that the initial "fast" absorbance change was small, the kinetic run was abandoned. The problem of biphasic kinetics[9] diminishes and eventually disappears as more organic cosolvent is added (Tables 4 and 5) (8–10).

Nature of the oil/water interface and equilibrium surfactant aggregates in systems exhibiting low tensions

ROBERT AVEYARD,[1] BERNARD P. BINKS,[2] THOMAS A. LAWLESS,[3] AND JEREMY MEAD[4]
School of Chemistry, University of Hull, Hull, England, HU6 7RX

ROBERT AVEYARD, BERNARD P. BINKS, THOMAS A. LAWLESS, and JEREMY MEAD. Can. J. Chem. **66**, 000 (1988).

Oil/water interfacial tensions are reported for systems containing pure alkane, aqueous sodium chloride, and a pure anionic surfactant, either Aerosol OT or *p*-dihexylbenzene sodium sulphonate (DHBS). Evidence is produced to support the claim that monolayer adsorption at the oil/water interface can produce ultralow tensions ($\sim 1\ \mu N\ m^{-1}$), and that the presence at the interface of a third, surfactant-rich phase is not necessary. The aggregation of DHBS and its distribution between oil and aqueous phases of various salinities have been investigated. It has been confirmed that the behaviour of DHBS in these respects is similar to that of Aerosol OT, as might be expected from its molecular structure. The sizes of microemulsion droplets in equilibrium with planar adsorbed monolayers have been determined, and related to the tensions of the plane oil/aqueous phase interfaces using simple existing theory.

ROBERT AVEYARD, BERNARD P. BINKS, THOMAS A. LAWLESS, et JEREMY MEAD. Can. J. Chem. **66**, 000 (1988).

On rapporte les tensions interfaciales des systèmes huile/eau contenant un alcane pur, une solution aqueuse de chlorure de sodium et un surfactant anionique à l'état pur: l'aérosol OT ou le *p*-dihexylbenzènesulphonate de sodium (DHBS). On fournit des preuves qui confirment le fait que l'adsorption monocouche à l'interface huile/eau peut produire des tensions très faibles ($\sim 1\ \mu N\ m^{-1}$), et qu'il n'est pas nécessaire d'avoir à l'interface une troisième phase riche en surfactant. On étudie l'aggrégation du DHBS et sa répartition entre l'huile et les phases aqueuses dont on fait varier la salinité. On confirme que dans ces conditions, compte tenu de sa structure moléculaire, le comportement du DHBS est analogue à celui de l'aérosol OT. On a déterminé la taille des gouttelettes de microémulsion en équilibre avec les monocouches planes adsorbées et on la relie aux tensions de l'interface plan huile/phase aqueuse en faisant appel à la théorie existante.

[Traduit par la revue]

A number of studies have been made in recent years of systems which contain oil, aqueous electrolyte, and surfactant and which exhibit ultralow oil/water interfacial tensions ($<10^{-2}$ mN m^{-1}), e.g. refs. 1–7. These tensions can often be made to pass through a minimum as the temperature, electrolyte concentration, nature of the oil phase, or the concentration of a further surface-active material (e.g. cosurfactant) is varied (6–8). The minimum in tension occurs under conditions around which a surfactant-rich third or "middle" phase (intermediate in density between oil and aqueous phases) is formed. The tension between the middle phase and one of the other two ("outer") phases is lower than the oil/water tension and appears to be associated with a thick interface (3). Our concern here however is with the nature of the oil/water interface and of the surfactant aggregates which form in oil or aqueous phases at equilibrium.

It has been claimed recently (9), on the basis of data obtained using sodium di-(2-ethylhexyl)sulphosuccinate (AOT) as the surfactant, that ultralow tensions are associated with the presence of a third phase between oil and aqueous phases, and that a single adsorbed monolayer of surfactant does not give rise to very low tensions. Other workers, however, (3, 4, 10) believe that tensions at least as low as 10^{-3} mN m^{-1} can be associated with monolayer adsorption. Here we present evidence supporting the latter view, based on measurements on systems containing alkane, aqueous NaCl, and AOT. We also present new data concerning interfacial tensions, and surfactant distribution and aggregation in systems containing *p*-dihexylbenzene sodium sulphonate (DHBS).

Experimental

Materials

The origins and purities of the samples of alkanes, AOT, water, and sodium chloride used have been described elsewhere (6, 7). The *p*-dihexylbenzene sulphonate preparation was carried out as follows. A Friedel–Crafts arylation of *n*-hexylbenzene with caproyl chloride and anhydrous aluminium chloride catalyst produced a mixture of the *o*- and (mainly) *p*-ketones. These were reduced to dihexylbenzene using amalgamated zinc and concentrated HCl. The product contained 12.5% *o*- and 82.5% *p*-isomers. This was sulphonated at 5°C using chlorosulphonic acid, and neutralised with sodium carbonate. The *o*-isomer carried over unsulphonated and was removed by preparative HPLC. The purified *p*-isomer was >99% pure by HPLC and TLC and the ^1H and ^{13}C nmr spectra were consistent with the required structure. The sulphonation stage and purification were carried out by Dr. N. Stewart at the BP Research Centre, Sunbury.

Methods

Interfacial tensions

Interfacial tensions were measured using a Krüss spinning-drop tensiometer (SITE 04) for low tensions and a Krüss K10 automatic tensiometer (with both Wilhelmy plate and du Nouy ring attachments) for higher tensions (>3 mN m^{-1}), as previously described (6, 7). In addition, low tensions were also determined by a surface laser light-scattering technique (11) at the BP Research Centre, Sunbury, in conjunction with Dr. A. R. Goodall. Aqueous and oil phases were all preequilibrated and pipetted into sample cells. All the interfaces were observed to be mirror-like with no visible sign of the presence of a third phase, even when a third phase was present prior to placing the two outer phases into the cell. Light from a He–Ne laser (λ = 632.8 nm) was passed through the oil phase and the scattered light, which was mixed with light reflected from the glass cell walls, was detected by a photomultiplier. The intensity correlation function was measured using a 64 channel multibit autocorrelator (Malvern Instruments) and analysed using a cumulant expansion that fitted the data to a single exponential (12). The necessary bulk viscosities and densities were measured with Ubbelohde viscometers and a Paar DMA 55 densimeter respectively.

Absorbance measurements

These were made on aqueous surfactant solutions in cuvettes with a path length of 1 cm, thermostatted at 25°C, using a Perkin Elmer 550 uv/visible spectrophotometer.

Determination of oil and surfactant concentration in aqueous phases

Analysis for AOT and heptane in aqueous phases in equilibrium with excess heptane phase was made using HPLC. A Waters Novapak C18 column was used in conjunction with a mobile phase containing 95% methanol and 5% water. The AOT concentrations were detected by absorbance at 220 nm (using a Waters 481 uv detector) and heptane concentrations by refractive index (Waters differential refractometer 401). Monitoring of the two detectors and evaluation of peak areas was performed using a Comus Instruments twin channel data acquisition and integration system.

Distribution of DHBS between aqueous and heptane phases

The distribution of DHBS was determined as a function of NaCl concentration in the aqueous phase. Aqueous solutions of NaCl were shaken with heptane; the surfactant was initially in either phase. The resulting emulsions were allowed to separate for several days in a thermostat and then samples were collected from both phases. Surfactant concentrations in each of the phases were determined by titration with hyamine (13). Concentrations of water in heptane were measured using a Baird and Tatlock automatic Karl-Fischer titrator (AF3). Hydrodynamic radii of the water droplets in the heptane phase were determined by photon correlation spectrometry (p.c.s.) as described elsewhere (6) using a Malvern Instruments PCS 100 spectrometer and a Malvern K7027 correlator.

Results and Discussion

Nature of interface exhibiting low tensions

As pointed out by Puig *et al.* (9) AOT at low concentrations in water first aggregates (at the cmc) to form micelles and then, at higher concentrations forms liquid crystals. In the presence of 0.017 and 0.068 *M* NaCl, however, only liquid crystallites appear to form and solutions are visibly turbid. In salt solutions the onset of turbidity occurs for the surfactant concentration at which the slope of the surface tension – ln (concentration) plot changes. Puig *et al.* claim that when a pure hydrocarbon is brought into contact with a turbid surfactant solution the dispersed crystallites in the vicinity of the interface take up oil and form a middle phase, the presence of which produces the observed ultralow interfacial tensions. It is observed that in the absence of salt the aqueous surfactant is optically clear and ultralow tensions are not given at the oil/water interface. Puig *et al.* further report that in systems containing salt there is a "precipitous" drop of interfacial tension (with octane as the oil phase) from about 1 mN m^{-1} at the surfactant solubility limit (~ 0.01 wt.% in 0.068 *M* NaCl) to around 10^{-3} mN m^{-1}, which they say is indicative of a change in the mechanism of tension lowering from monolayer adsorption (at high tension) to lowering by the third phase.

We have prepared aqueous solutions of AOT in 0.017 and 0.068 *M* NaCl by two different methods. In one case (method 1) surfactant was dissolved in water and NaCl added, and in the other (method 2) surfactant was dissolved in an aqueous solution of NaCl. Absorbance values at 600 nm of solutions in 0.068 *M* NaCl made up by each of the methods are shown in Fig. 1. Clearly the method of preparation has a profound effect on the size of the aggregates formed. Absorbances quoted by Puig *et al.* fall between the two extremes shown in Fig. 1. We have found that absorbances of solutions prepared by method 2 decrease over a period of several weeks and become equal to absorbances of similar solutions prepared by method 1.

In systems of current interest, however, the aqueous phases are brought into contact with hydrocarbon. Irrespective of how

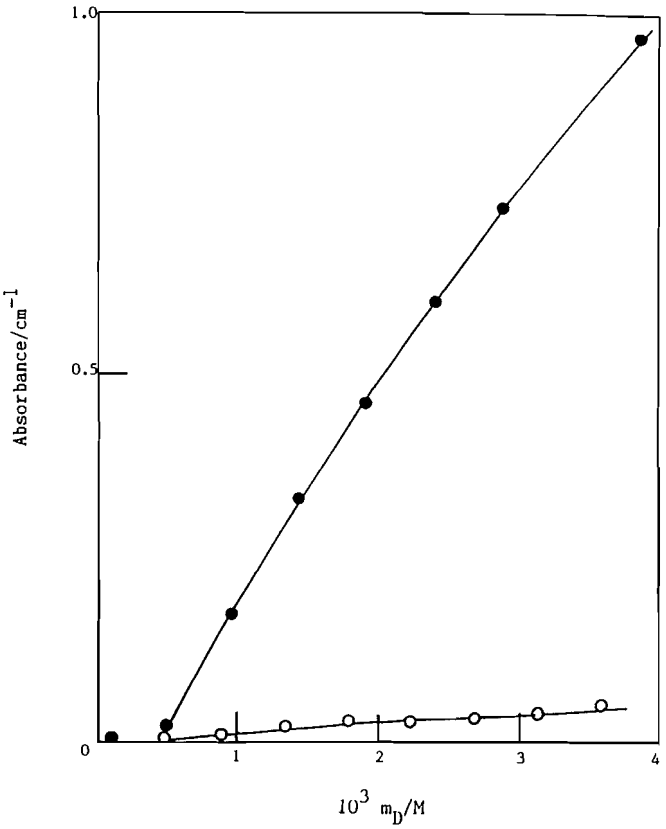

FIG. 1. Absorbance of solutions of AOT, concentration m_D, in 0.0684 *M* aqueous NaCl. Symbols ○ and ● are for solutions prepared by methods 1 and 2, respectively (see text).

the aqueous phases are prepared, when they are shaken with (say and equal volume of) heptane and left to separate, both phases are optically clear with absorbances of less than 0.003 cm^{-1}. Further, we show later (and elsewhere (6)) that the equilibrium aggregates in these systems are microemulsion droplets (oil-in-water or water-in-oil depending on salt concentration) and not liquid crystallites. The droplets themselves are not surface-active; it is found (10) that the oil/water tension is the same in systems containing droplets and those without droplets but otherwise identical.

With regard to the "precipitous" fall in tensions observed around the solubility limit, we have determined tensions in systems containing AOT with heptane and 0.0513 *M* NaCl where tensions range from 25 down to $<10^{-3}$ mN m^{-1}. These data are presented as log (tension, γ) versus ln (surfactant concentration, m_D) in Fig. 2*a*, and plotted in this fashion it does indeed appear that the tensions fall drastically just below the aggregation point. We have however obtained a number of tensions between 1 and 10^{-3} mN m^{-1} and when these data are plotted (as is usual) as γ versus ln m_D a straight line results (Fig. 2*b*). From the slope the area per AOT molecule, obtained by use of the appropriate form of the Gibbs equation (14) is found to be 0.66 ± 0.04 nm^2, in respectable agreement with the value of 0.72 ± 0.02 nm^2 obtained by fitting all the data from tensions of 25 mN m^{-1} down. These areas are consistent with monolayer adsorption down to tensions of at least 5×10^{-2} mN m^{-1}.

As mentioned, at and above the aggregation point the tension remains constant in the range of m_D investigated; we denote this tension γ_c. In Fig. 3 log γ_c is plotted against the salt concentration, m_s, for systems containing AOT, aqueous NaCl,

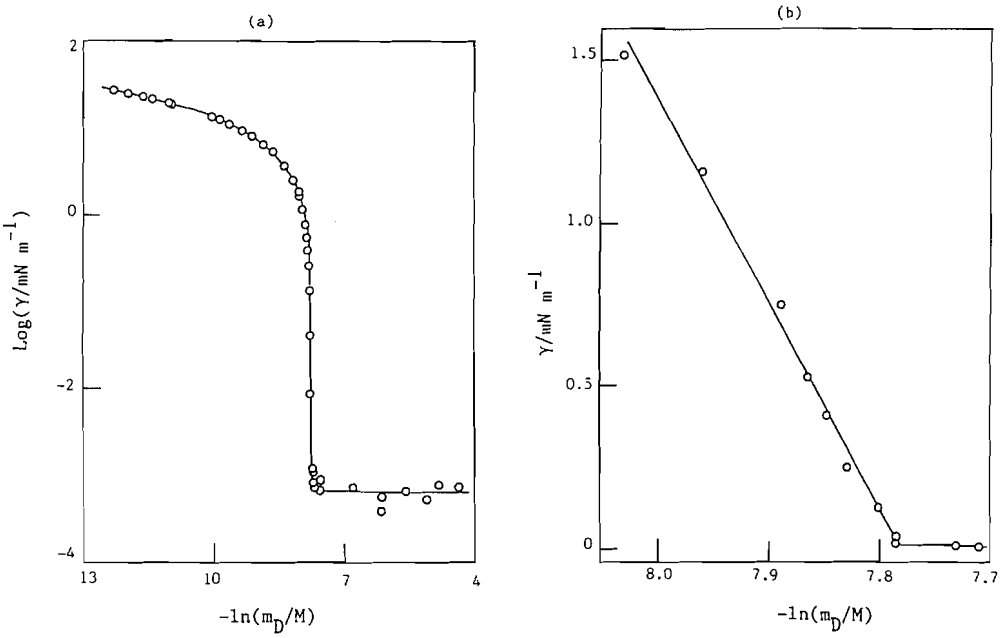

FIG. 2. Variation of tension with surfactant concentration, m_D, in systems containing AOT, heptane, and 0.0513 *M* NaCl at 25°C (*a*) log γ against ln m_D; (*b*) γ against ln m_D for tensions of 1.5 mN m^{-1} and lower.

and heptane at 25°C. Included in the plot are values obtained in three different ways. First, results are shown for systems in which pure heptane was introduced into aqueous surfactant (prepared by methods 1 and 2) which had not previously been equilibrated with the heptane. When $\gamma_c < 0.01$ mN m^{-1} a coating was initially observed to form around the oil drop; the coating was quite fluid and the drop shape responded rapidly to changes in the rotation frequency of the tensiometer capillary. Eventually, the coating became detached from the drop leaving an apparently clean oil/water interface; tensions recorded were those for such clean interfaces. We also prepared equilibrium systems in which heptane was shaken with aqueous NaCl (the AOT being initially in either phase) and left in a thermostat at 25°C to separate. For salt concentrations around 0.05 *M* a third "middle" phase was formed; in such cases the oil and aqueous phases only were removed and introduced into the tensiometer. The tensions so obtained were in close agreement with those for the non-equilibrated systems described above. Thirdly, tensions in equilibrated systems were determined by surface light scattering. The interfaces in these experiments were visibly very clean and completely mirror-like, as mentioned, and the tensions were in good accord with all the other tensions, as seen in Fig. 3.

We conclude from the foregoing that the oil/water interfaces exhibiting low tensions investigated here contain a saturated monolayer of surfactant and not a thick intervening layer of a third phase. It is relevant to note that if a third phase were present the measured tension would presumably be close to the sum of the tensions between the third phase (δ) and the oil phase (α), and the third phase and aqueous phase (β). For such systems at equilibrium Widom (15) has shown that

$$[1] \qquad \gamma_{\alpha\beta} \leq \gamma_{\alpha\delta} + \gamma_{\beta\delta}$$

Thus if the "interface" contained a third phase at equilibrium and the measured tension ($\gamma_{\alpha\delta} + \gamma_{\beta\delta}$) were ultralow it follows from eq. [2] that $\gamma_{\alpha\beta}$ must also be ultralow. Indeed, for systems consisting of sodium dodecyl sulphate, aqueous NaCl, toluene, and butanol Cazabat *et al.* (16) have shown that $\gamma_{\alpha\beta}$ is

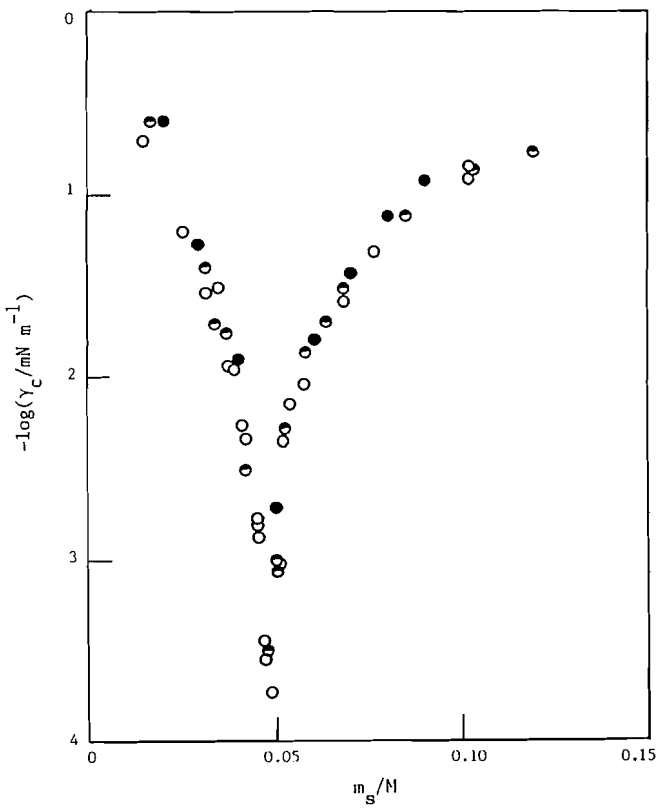

FIG. 3. Variation of γ_c with salt concentration in systems containing AOT, heptane, and aqueous NaCl at 25°C. Tensions from light scattering on pre-equilibrated systems are represented by ●.

effectively equal to the higher of $\gamma_{\alpha\delta}$ and $\gamma_{\beta\delta}$, the lower of the two being very low indeed.

We finally mention in this section the recent warnings of Good *et al.* (17, 18) that the spinning-drop method of measuring

(*b*) Variation of γ_c with m_s for the aqueous solution/heptane interface (○) and aqueous solution/dodecane interface (●).

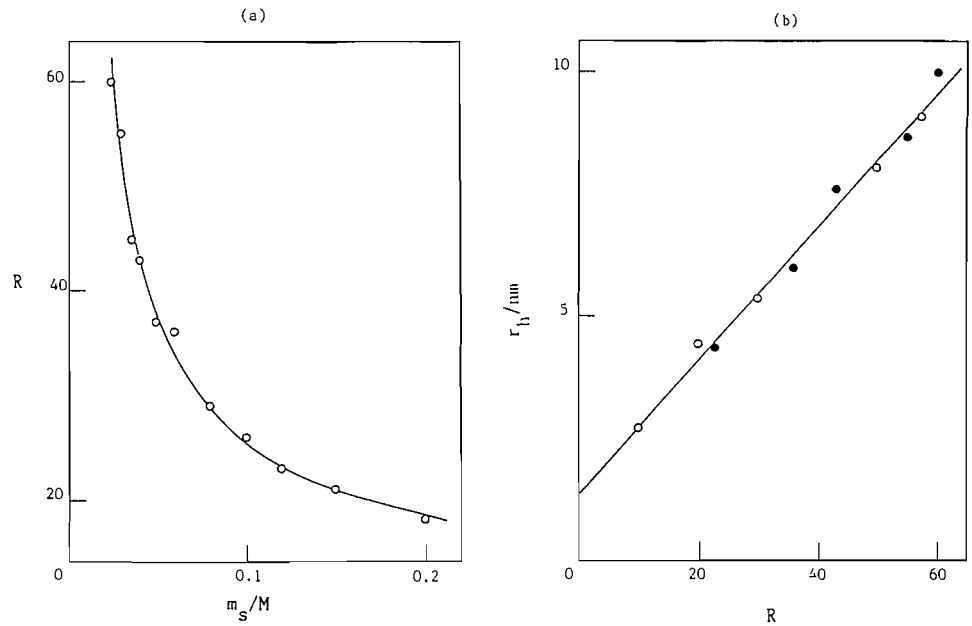

FIG. 5. Variation of R with salt concentration and hydrodynamic radius in systems containing aqueous NaCl, heptane, and DHBS at 25°C. (*a*) *R* as a function of m_s, (*b*) r_h as a function of *R*. Symbols ● are for w/o microemulsions in equilibrium with excess aqueous phase and ○ are for "made-up" w/o microemulsions (see text).

interfacial tensions may not be valid for systems, such as those of present interest, in which one phase is a microemulsion. It is clear however from the level of agreement between tensions measured using the spinning-drop method and those determined by surface light scattering (Fig. 3), that the spinning-drop tensiometer yields correct tensions for the systems studied here.

Tensions and distribution in systems containing DHBS

We briefly summarise here tension and surfactant distribution data for DHBS, which were obtained to confirm that the behaviour resembled that of AOT in otherwise similar systems. Both are twin-tailed anionic surfactants and the origins of the observed behaviour (for AOT) have already been discussed in terms of effective molecular geometry of the surfactant as well as in thermodynamic terms (6).

In Fig. 4*a* are shown tensions for the air/0.0513 *M* NaCl surface and heptane/0.0513 *M* NaCl interface as a function the DHBS concentration, m_D. Tensions become effectively constant (γ_c) at the aggregation point (cmc) and show no minima, consistent with the surfactant sample being free from surface-active impurities. The variation of γ_c for the heptane/solution interface with m_s is shown in Fig. 4*b*, together with results for

*γ_c in parentheses are interpolated values from data in Fig. 3; r_h in parentheses are interpolated from data in Fig. 5*b*.

the dodecane/solution interface. The γ_c for both interfaces pass through a minimum; as with AOT the minimum for the longer chain alkane is broader, at a higher tension, and at a higher salt concentration ($m_s \sim 0.06$ *M*) than for the shorter chain alkane (where $m_s = 0.02$ *M*). This reflects the stronger penetration of heptane into the chain region of the surfactant monolayer (7). Both minima occur at a lower value of m_s than for AOT, probably resulting from the smaller head group size (relative to the chain cross-sectional area) of the DHBS (7).

We have confirmed that in the heptane + aqueous NaCl system, for $m_s < 0.02$ *M* DHBS resides totally in the aqueous phase and for $m_s > 0.02$ *M*, the surfactant transfers to the oil phase leaving the aqueous phase close to the cmc. A third, surfactant-rich phase forms in the region of $m_s = 0.02$ *M*.

Relation between aggregate size and γ_c

When surfactant is present in the heptane phase, water is also present. If we suppose that the surfactant aggregates consist of monodisperse water droplets (19), radius r_c, coated with an adsorbed monolayer of surfactant, then (6, 20, 21)

$$[2] \qquad r_c = 3R\nu_w A_D^{-1} = r_h - t$$

where $R = ([H_2O]/[DHBS])$ in oil, it being assumed that all the surfactant in the oil is adsorbed at droplet surfaces. The volume of a water molecule in a droplet is ν_w, and A_D is the area occupied by a surfactant molecule at the drop surface. The hydrodynamic radius, r_h, of the droplet differs from r_c by an amount t which is expected to be approximately equal to the surfactant molecular length.

It is seen from Fig. 5*a* that for $m_s > 0.02$ *M* in systems containing DHBS R (and hence by eq. [2] r_h) decrease as m_s increases and (Fig. 4*b*) γ_c increases.

The hydrodynamic radii, r_h, have been determined by photon correlation spectroscopy as described previously (6). According to eq. [2], if A_D and t are independent of drop size a plot of r_h versus R should be linear and A_D and t may be obtained from the slope and intercept, respectively. Such a plot is shown in Fig. 5*b* for the w/o microemulsions containing DHBS in equilibrium with excess aqueous phase (filled circles); some microemulsions of known R were also prepared by addition of water to a solution of DHBS in heptane. The r_h in such "made-up" systems

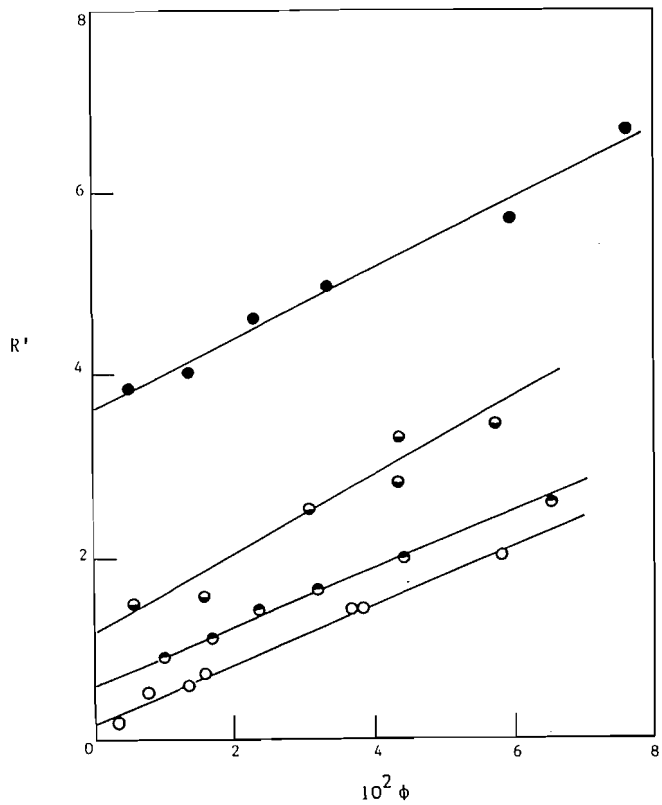

FIG. 6. Variation of R' with droplet volume fraction ϕ for heptane-in-aqueous NaCl microemulsions, stabilised by AOT, for various salt concentrations, m_s. Symbols ○, ◓, ◒, and ● are for m_s of, respectively, 0, 5, 15, and 25 *mM*.

are denoted by open circles. Values of A_D and t of 0.66 ± 0.02 nm^2 and 1.4 ± 0.1 nm respectively were obtained from the plot. The value of A_D is very similar to that, 0.69 nm^2, for the plane interface obtained from the linear part of the graph shown in Fig. 4*a* and the application of the Gibbs equation (14). We list values of r_h of water droplets in oil and corresponding values of γ_c for systems containing AOT and DHBS in Table 1.

In addition to characterising the w/o microemulsions we have

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 122.72.124.2 on 09/07/12
For personal use only.

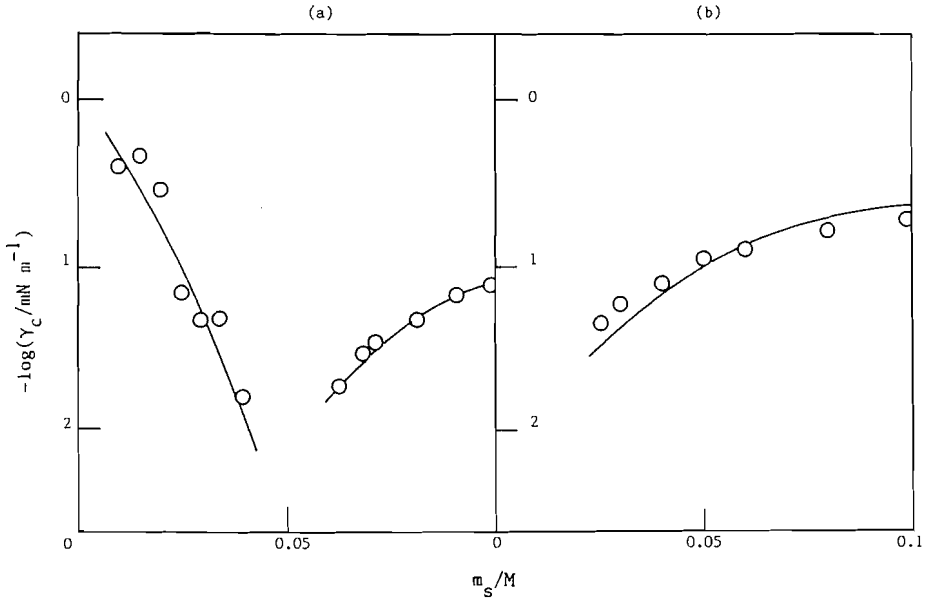

FIG. 7. Tensions γ_c calculated from eq. [3] (○). Full lines represent experimental data. (*a*) Systems containing AOT. Circles on left hand limb (low m_s) obtained using $K/kT = 0.29$, and those on right hand limb using $K/kT = 0.77$. (*b*) Systems containing DHBS. Circles obtained using $K/kT = 0.58$.

also estimated the sizes of oil droplets in heptane/aqueous NaCl microemulsions, stabilised by AOT, in equilibrium with excess heptane. For $m_s < 0.05$ *M* AOT aggregation occurs in the aqueous phase, the heptane phase remaining free of surfactant. Heptane and aqueous NaCl ($m_s < 0.05$ *M*) phases were allowed to come to equilibrium in the presence of AOT above its aggregation point at 25°C. The aqueous phases were then analysed for heptane and AOT using HPLC (see Experimental section). Knowing the cmc at various salt concentrations in the presence of heptane (6) the amount of surfactant at the droplet surfaces can be calculated. The ratios R' (= [heptane]/[aggregated AOT] in aqueous phase) were obtained as a function of AOT concentration (and hence of dispersed phase volume fraction, ϕ) for various salt concentrations. Sample plots of R' against ϕ are shown in Fig. 6. The dependence of R' on ϕ (which presumably arises largely as a result of repulsive forces between the electrical double layers surrounding the droplets) is striking, and in contrast to the situation for w/o microemulsions where R is effectively independent of droplet concentration (6). We will consider here values of R' at infinite dilution of droplets, i.e. the intercepts (R') of plots such as those in Fig. 6. By assuming a value for the area per surfactant molecule at the drop surface (A_D), the core radii have been calculated as $3R'_\infty v_h/A_D$ where v_h is the volume per heptane molecule in the droplets (0.24 nm^3). A value of A_D of 0.52 nm^2 has been used, being that obtained from aggregation numbers determined by a time-resolved fluorescence method (22). The droplet radii, r_h, and the tensions γ_c are listed in Table 1 along with the values for w/o microemulsion systems.

The value of γ_c depends in part on the tendency of the surfactant film to bend, as does the size of the droplets which are in equilibrium with the plane monolayer. It can be appreciated therefore that γ_c and drop radius are related (4). The bending tendency of the film may not be the only important factor in the determination of drop size, however (23, 24). The radius r is perturbed from its spontaneous value r_o as a result of the entropy of mixing the droplets with the medium. This entropy effect favours the formation of a greater number of droplets with radius $< r_o$. At higher volume fractions of dispersed phase, droplet interactions may also modify the drop size and γ_c. In the dilute systems studied here, however, these interactions may be assumed to be negligible. Also we find γ_c is within experimental error independent of surfactant concentration. A possible reason for this is that the effect of the dispersion entropy on γ_c is negligible in our systems. If so the major contributions to γ_c may well be due to the bending energy and we may write as an approximation (4)

$$[3] \qquad \gamma_c \simeq 2K/r^2$$

where K is a rigidity coefficient, having dimensions of energy (25). Equation [3] can only be expected to hold if the interfacial thickness (i.e. t) is considerably smaller than r. Our concern here is to test if the equation predicts the trends in γ_c with radius (and hence m_s) with a reasonable value of K.

Meunier (10) has measured K at plane interfaces directly, using ellipsometry, in systems containing SDS, butanol (cosurfactant), toluene, and aqueous NaCl. Although K is expected to depend on salt concentration Meunier reports that for salinities between 8 and 10%, where w/o microemulsions form with drop radii of between 12 and 18 nm, K/kT only varies between 0.5 and 0.75. We might therefore expect that in the region of the minimum in γ_c (where r is largest) eq. [3] will reasonably represent the trend in experimental data with a single value of K, at least for a given microemulsion type. In what follows we have used hydrodynamic radii in the calculations. The lines in Fig. 7*a* represent the experimental data for AOT (as shown in Fig. 3) and the points are calculated from eq. [3] using values of r_h in Table 1 with $K/kT = 0.29$ for systems containing o/w microemulsions and $k/kT = 0.77$ for those containing w/o microemulsions. Results for DHBS are shown in Fig. 7*b*; points were obtained using $K/kT = 0.58$. These values of K are similar to those quoted by Meunier (for monolayers of SDS + butanol) and agreement between experiment and theory is not unreasonable.

We finally mention that Fletcher (26) has recently considered tensions and drop sizes in more concentrated systems in which γ_c varies with droplet concentration.

Solvent effect on the solution, ionization, and structure of aminosulfonic acids

ROBERT L. BENOIT, DANIELLE BOULET, AND MONIQUE FRÉCHETTE
Département de Chimie, Université de Montréal, C.P. 6128, Succ. A. Montréal (Qué.), Canada H3C 3J7

Received May 31, 1988

ROBERT L. BENOIT, DANIELLE BOULET, and MONIQUE FRÉCHETTE. Can. J. Chem. **66**, 3038 (1988).

We have determined thermodynamic parameters for the solution and ionization in dimethylsulfoxide and water of four aminosulfonic acids: $NH_2(CH_2)_nSO_3H$ with $n = 0$, 1, and 2, and $NH_2C_6H_4SO_3H$. Potentiometric and calorimetric methods were used. The solubilities of the four acids in Me_2SO are either nearly equal to or lower than in water, but the enthalpies of solution are 15–40 kJ mol^{-1} more exothermic in Me_2SO. The three aliphatic acids are much weaker ($2.1 \leq \Delta pK_a \leq 5.5$) in Me_2SO than in water and their heats of ionization are some 30 kJ mol^{-1} more endothermic in Me_2SO. The discussion of our results is based on comparisons with corresponding data for related substituted amines and ammonium ions, and sulfonic acids and sulfonate ions. We conclude that the four aminosulfonic acids are mostly present as zwitterions in Me_2SO just as in water.

ROBERT L. BENOIT, DANIELLE BOULET et MONIQUE FRÉCHETTE. Can. J. Chem. **66**, 3038 (1988).

On a déterminé des paramètres thermodynamiques pour la dissolution et l'ionisation dans le diméthylsulfoxyde et l'eau de quatre acides aminosulfoniques: $NH_2(CH_2)_nSO_3H$ avec $n = 0$, 1 et 2 et $NH_2C_6H_4SO_3H$. On a utilisé des méthodes potentiométriques et calorimétriques. Les solubilités des quatre acides dans le Me_2SO sont soit voisines soit plus faibles que dans l'eau, mais les enthalpies de solution sont de 15–40 kJ mol^{-1} plus exothermiques dans le Me_2SO. Les trois acides aliphatiques sont nettement plus faibles ($2{,}1 \leq \Delta pK_a \leq 5{,}5$) dans le Me_2SO que dans l'eau et leurs chaleurs d'ionisation sont quelques 30 kJ mol^{-1} plus endothermiques dans le Me_2SO. La discussion de nos résultats est basée sur des comparaisons avec des données correspondantes pour des composés analogues, des amines et ions ammonium substitués et des acides sulfoniques et ions sulfonates. On conclut que les quatre acides aminosulfoniques sont essentiellement présents sous forme de zwitterions dans le Me_2SO comme dans l'eau.

Introduction

Aminosulfonic acids are bifunctional compounds of general interest because of their structural relation to amino acids. In addition, sulfamic acid, H_2NSO_3H, and particularly some of its N-substituted derivatives (cyclamates) (1) as well as biologically important taurine, $H_2NCH_2CH_2SO_3H$, are of specific interest.

The aminosulfonic (AS) acids are generally regarded as being zwitterionic in the solid state and in aqueous solution (1, 2), just like the amino acids, but little is known about the structure of the acids in non-aqueous solvents (3). In dimethylsulfoxide (Me_2SO) for example, the non-ionic form may prevail since it has been shown that addition of Me_2SO to aqueous solutions of some amino acids shifts the tautomeric equilibrium towards the non-ionic form (4, 5). Some meagre literature data on sulfamic acid in Me_2SO might also be taken as pointing in this direction. First, the pK_a of H_2NSO_3H increases from 1.0 in water (2) to a reported 6.5 in Me_2SO (6). Considering that related CH_3SO_3H, a strong acid in water, has a 1.7 pK_a in Me_2SO, the above 6.5 pK_a value is not incompatible with a non-ionic structure for H_2NSO_3H in Me_2SO. Second, the large pK_a increase from 1.0 to 6.5 for H_2NSO_3H when passing from water to Me_2SO would seem to be at odds with an $^+H_3NSO_3^-$ structure in Me_2SO since the pK_a of substituted ammonium ions ^+H_3NR are nearly the same in both solvents (7). Finally, the very high solubility of H_2NSO_3H both in water and Me_2SO, when contrasted with the high solubility of glycine $H_2NCH_2CO_2H$ in water and near insolubility in Me_2SO, might indicate that Me_2SO solvates the zwitterionic structure $^+H_3NCH_2CO_2^-$ poorly and would then favour a non-ionic structure for H_2NSO_3H.

It would be interesting to ascertain whether AS acids are zwitterionic or not in Me_2SO, and this can be achieved by comparing the solution and ionization thermodynamics of AS acids and simpler analogues in Me_2SO and water. Data for the solution and ionization in water of sulfamic acid, taurine, and sulfanilic acid being already available (2), we have obtained data for aminomethanesulfonic acid in water and for the four AS acids in Me_2SO.

[1]LiA being a strong electrolyte its ΔH_s should be approximately linear in square root of concentration, but because of the low concentrations used this effect is within our experimental errors.

Experimental

Materials

Sulfamic acid (Baker) was dried under vacuum at room temperature for 3.5 h. Aminomethanesulfonic acid and taurine (both from Aldrich) were recrystallized from ethanol–water mixtures. After washing with cold ethanol, the acids were dried at 80°C for 2.5 h. Sulfanilic acid (Fisher) was recrystallized from water and dried under vacuum at 80°C for 2.5 h. Titrations of the acids, in water or Me_2SO, with standard aqueous NaOH indicated a purity of 99.3 ± 0.3% for NH_2SO_3H, 100.0 ± 0.5% for $NH_2CH_2SO_3H$, 100.2 ± 0.3% for $NH_2CH_2SO_3H$, and 99.1 ± 0.2% for $NH_2C_6H_4SO_3H$.

Lithium salts of the acids were prepared. Lithium sulfamate was first obtained by adding solid sulfamic acid to an aqueous 0.1 *M* Li_2CO_3 solution to reach pH 2.98. The salt was recrystallized from methanol–chloroform mixtures and then dried under vacuum at 80°C for 1.5 h. Acidimetric titrations in Me_2SO showed a purity of 98.8 ± 0.2%. Lithium taurinate and lithium sulfanilate were prepared by adding the solid acids to aqueous 0.1 *M* LiOH solutions to reach pH 11.40 and 8.36, respectively. The salts were washed with ethanol and dried under vacuum at 70°C for 3 h. Acidimetric titrations of $NH_2CH_2CH_2SO_3Li$ in water showed a purity of 100.0 ± 0.2%. Purity of $NH_2C_6H_4SO_3Li$ was checked by comparing its UV spectra in aqueous 0.1 *M* HCl and NaOH with the corresponding spectra of pure sulfanilic acid. Results indicated a purity of 88.2 ± 0.7% and Karl Fischer titrations showed that the materials contained 11.9 ± 0.8% water.

Dimethylsulfoxide (Anachemia) was used as received. Trifluoromethanesulfonic acid (Aldrich) was distilled under reduced pressure.

Potentiometry

Potentiometric titrations of Me_2SO solution of the lithium salts (6×10^{-3} to 3×10^{-2} *M*) with standard 0.1 *M* CF_3SO_3H in Me_2SO were carried out at 25.0 ± 0.1°C in a thermostated cell as previously described (8). The glass electrode was calibrated before each run with standard 0.1 *M* CF_3SO_3H to give a 59 ±1 mV slope ($r = 0.9998$) in a

ΔE vs. pH plot. Since we were not successful in preparing pure $NH_2CH_2SO_3Li$, we proceeded differently to study the ionization of aminomethanesulfonic acid. First, we carried out a titration of a Me_2SO solution of 0.05 M lithium taurinate with a Me_2SO solution of 0.02 M aminomethanesulfonic acid. Second, we added standard 0.1 M CF_3SO_3H to a Me_2SO solution containing both lithium taurinate and aminomethanesulfonic acid (6×10^{-3} to 1×10^{-2} M).

Calorimetry

The calorimetric work involved the determination at 25.00 ± 0.01°C of heats of solution, heats of protonation of the salts, and heats of deprotonation of the acids using an LKB model 8725-2 isoperibol calorimeter as previously described (8).

The heats of solution of sulfamic acid, lithium sulfamate, and lithium sulfanilate, in Me_2SO and water, as well as those of lithium taurinate and aminosulfonic acid in water, were measured. We also determined the heats of protonation of lithium sulfamate, lithium sulfanilate, and lithium taurinate in 0.1 M CF_3SO_3H in Me_2SO. We obtained as well the heats of deprotonation of sulfamic acid, aminomethanesulfonic acid, taurine, and sulfanilic acid in Me_2SO containing 0.02 M or 0.05 M of a strong base (tetramethylguanidine or lithium taurinate) as well as the heat of solution of aminomethanesulfonic acid in 0.01–0.10 M aqueous NaOH.

The heats of mixing of 0.5–1.0 mL of a standard 0.2 M lithium taurinate solution in Me_2SO with 100 mL of 0.1 M CF_3SO_3H in Me_2SO and with 100 mL of 0.007 M sulfanilic acid in Me_2SO were measured, as well as the heat of mixing of 0.5–1.0 mL of a standard 0.11 M aminomethanesulfonic acid in Me_2SO with 100 mL of 0.05 M lithium taurinate in Me_2SO.

The amounts of acid or salt dissolved or reacted (1×10^{-4} to 6×10^{-3} mol) were deduced from the weights of the glass ampoules. For each determination, three to six separate experiments were made at different concentrations.

Results

Solubilities and solution enthalpies

The solubilities of the AS acids in Me_2SO and water are given in Table 1 and are expressed in molarity (mol L^{-1}) or molality. The heats of solution, Q, of the AS acids and their lithium salts were plotted against the number of moles dissolved. The plots were linear[1] and the least-squares slopes gave the molar enthalpies of solution ΔH_s; in water (ΔH_{sw}) and in Me_2SO (ΔH_{ss}).

[1] $HA(c) = HA(s \text{ or } w)$ $\quad \Delta H_{ss}(HA) \text{ or } \Delta H_{sw}(HA)$

[2] $LiA(c) = A^-(s \text{ or } w) + Li^+(s \text{ or } w)$ $\quad \Delta H_{ss}(LiA) \text{ or } \Delta H_{sw}(LiA)$

Because aminomethanesulfonic acid, taurine, and sulfanilic acid dissolved too slowly in Me_2SO, their heats of solution were obtained indirectly by dissolving the acids in Me_2SO solution of a strong base, B (tetramethylguanidine or lithium taurinate), according to

[3] $HA(c) + B(s) = A^-(s) + BH^+(s)$

We then substracted from these values the enthalpies of protonation of B (−85.8 ± 0.4 kJ mol^{-1} and −67.8 ± 0.7 kJ mol^{-1} for tetramethylguanidine (9) and lithium taurinate, respectively), to obtain the enthalpies for

[4] $HA(c) = H^+(s) + A^-(s)$

Finally, we subtracted from these latter values the enthalpies of ionization for

[5] $HA(s) = H^+(s) + A^-(s)$

to give the enthalpies of solution ΔH_{ss} (eq. [1]).

The heat of solution of lithium taurinate in Me_2SO was also obtained indirectly by subtracting the heat of protonation of the taurinate ion from the heat of protonation of the solid salt in Me_2SO solutions of 0.1 M CF_3SO_3H.

No effect of concentration on ΔH_{ss} or ΔH_{sw} was observed, so that the ΔH_s values were taken as being equal to ΔH_s^0. Our ΔH_s^0 values with their standard deviations are given in Tables 1 and 2.

TABLE 2. Solution enthalpies of lithium aminosulfonates at 25°C

Lithium salt	ΔH_s^0 (kJ mol^{-1})	
	H_2O	Me_2SO
NH_2SO_3Li	+0.79±0.07	−17.5±0.3

$NH_2C_6H_4SO_3Li \cdot 1.34H_2O$	+15.8±0.2	−14.3±0.6

Ionization constants

The ionization constants of the AS acids in Me_2SO were obtained from the potentiometric neutralization data using a program previously described (8). Corrections were made for the effect of ionic strength which varied between 0.005 and 0.025 M. Our pK_a values are given in Tables 3 and 4 together with literature data.

Ionization enthalpies

The heats of protonation of solid lithium sulfamate and lithium sulfanilate in 0.1 M CF_3SO_3H in Me_2SO were plotted against the number of moles dissolved. The least-squares slopes

of the linear plots gave the protonation enthalpies of the salts, ΔH_{ps} (LiA), according to [6].

[6] $LiA(c) + H^+(s) = HA(s) + Li^+(s)$

By combining ΔH_{ps}(LiA) with ΔH_{ss}^0(LiA) (eq. [2]), we obtained the ionization enthalpies of the corresponding acids in Me_2SO, ΔH_{is}(HA) according to [5] with

[7] $\Delta H_{is}(HA) = \Delta H_s^0(LiA) - \Delta H_{ps}(LiA)$

The ΔH_{is} of sulfanilic acid was also obtained from the heat of mixing of an Me_2SO solution of lithium taurinate with an Me_2SO solution of sulfanilic acid. These heats were first corrected for the slight ionization of the sulfanilic acid in Me_2SO. Then we subtracted the heat of protonation of the taurinate ion to yield values of $\Delta H_{is} = +23.0 \pm 0.5$ kJ mol^{-1} in fair agreement with the previous value $+24.0 \pm 0.8$.

The ionization enthalpy of taurine in Me_2SO was determined first by dissolving sulfamic acid in an excess of lithium taurinate in Me_2SO. From the resulting heats of reaction, which correspond to eq. [3], we subtracted the heats of solution and of ionization of sulfamic acid to yield the ionization enthalpy of taurine. Second, we added aliquots of a standard Me_2SO solution of lithium taurinate to an excess of 0.1 *M* CF_3SO_3H in Me_2SO. The heat of dilution of the taurinate solution being negligible, we obtained the heat of ionization of taurine directly. The plot of the two series of heats of ionization against the number of moles of taurine ionized was linear and the slope gave the ΔH_{is} of taurine in Table 3.

For aminomethanesulfonic acid, we determined the heats of mixing of aliquots of a standard Me_2SO solution of the acid in an excess of 0.05 *M* lithium taurinate in Me_2SO. The correction for the dilution of the aminomethanesulfonic acid solution was negligible and we subtracted the heat of protonation of the taurinate ion to obtain the ΔH_{is} of aminomethanesulfonic acid.

The heat of ionization of aminomethanesulfonic acid in water was obtained from the heat of solution of the acid in aqueous 0.01 to 0.1 *M* NaOH according to

[8] $HA(c) + OH^-(w) = A^-(w) + H_2O$

Then we added to this value the heat of ionization of water ($\Delta H_i(H_2O) = +55.8$ kJ mol^{-1} (10)) and subtracted the heat of solution of aminomethanesulfonic acid in water. The ionization enthalpy of aminomethanesulfonic acid in water, ΔH_{iw}, was obtained from the slope of the linear plot of the heats against the number of moles of acid ionized.

All our ΔH_i(HA) values are taken to be equal to ΔH_i^0(HA) because no concentration dependence was observed in the concentration range used and because no effect of the ionic strength between 0 and 0.1 *M* was observed for sulfanilic acid and taurine. A small ionic strength effect was observed for aminomethanesulfonic acid, but it was within our experimental error. Our ΔH_i^0 values are given in Tables 3 and 4 with their standard deviations and some literature data.

Enthalpies of transfer from water to Me_2SO

The enthalpies of transfer of the acids from water to Me_2SO, ΔH_{ws}^0(HA), correspond to

[9] $HA(w) = HA(s)$

These values were calculated from

[10] $\Delta H_{ws}^0(HA) = \Delta H_{ss}^0(HA) - \Delta H_{sw}^0(HA)$

The enthalpies of transfer of A^- from water to Me_2SO, $\Delta H_{ws}^0(A^-)$, were calculated by means by eq. [11]:

[11] $\Delta H_{ws}^0(A^-) = \Delta H_{is}^0(HA) - \Delta H_{iw}^0(HA) + \Delta H_{ws}^0(HA) - \Delta H_{ws}^0(H^+)$

	ΔH^0_{ws} (kJ mol^{-1})
$NH_3^+C_6H_4SO_3^-$	−26.3
$NH_2C_6H_4SO_3^-$	+5.2
$NH_3^+C_6H_5$	−37.4[a]
$NH_2C_6H_5$	−11.2[a]
$C_6H_5SO_3^-$	+16.4[b]
C_6H_6	0.3[c]

[a]Reference 30.
[b]Unpublished result.
[c]Reference 32.

The value of $\Delta H^0_{ws}(H^+)$, −25.5 kJ mol^{-1}, is based on the tetraphenylarsonium tetraphenylborate (tatb) extrathermodynamic assumption (11).

The $\Delta H^0_{ws}(A^-)$ values calculated from eq. [11] can be compared to those obtained from data on the solution of lithium salts and eq. [12].

[12] $\Delta H^0_{ws}(A^-) = \Delta H^0_{ss}(LiA) - \Delta H^0_{sw}(LiA) - \Delta H^0_{ws}(Li^+)$

$\Delta H^0_{ss}(LiA)$ and $\Delta H^0_{sw}(LiA)$ are given in Table 2 and $\Delta H^0_{ws}(Li^+)$, the enthalpy of transfer of Li^+, is taken as −27.4 kJ mol^{-1} (12). The values thus obtained for ΔH^0_{sw} of $NH_2SO_3^-$ and $NH_2CH_2CH_2SO_3^-$ are 3.7 kJ mol^{-1} less endothermic than the values obtained through eq. [11]. This difference is not unreasonable considering our experimental errors and those involved in the calculation of ΔH^0_{sw} for H^+ and Li^+ (12). For the sake of consistency we have kept the values obtained through eq. [11]. These ΔH^0_{ws} values for A^- are given in Tables 5 and 6 together with those for HA and related compounds.

Discussion

Solution data

If we first consider the solution in Me_2SO of the three aliphatic acids, the data in Table 1 show a solubility decrease from sulfamic acid to aminomethanesulfonic acid and taurine. The corresponding free energies of solution can only be estimated since there are no data on the activity coefficients of the acids. Such approximate free energies when combined with the solution enthalpies in Table 1 show that the decrease in the acids solubility with the increasing length of the carbon chain is the result of a complex balance between the enthalpy terms becoming less negative and favorable, and entropy terms becoming less negative and unfavorable. The low solubility of sulfanilic acid in Me_2SO is mainly due to a large negative entropy of solution opposing a favorable enthalpy term.

Clearly, in water there is no definite trend in either the solubility or the solution enthalpy data. Since the enthalpy terms are large and positive, there is a large and positive and favorable entropy of solution, thus contrasting the negative entropy of solution in Me_2SO.

It is not possible to gain from our solution data any information on the structure of the AS acids in Me_2SO because of the absence of data in Me_2SO on known zwitterionic compounds, sulfonic acids and substituted ammonium ions as well as on the sublimation of the AS acids.

Ionization data

While we have not tabulated the ionization entropies ΔS^0_{is} and ΔS^0_{iw} which can be calculated from the ionization data in Table 3, it is worth noting that there is a good pK_{aw} (or ΔG^0_{iw}) − ΔH^0_{iw} linear correlation for the three aliphatic AS acids in water so that ΔS^0_{iw} is also linearly related to ΔG^0_{iw} and ΔH^0_{iw}. The corresponding correlation is only fair in Me_2SO. Such linear correlations are often observed for the ionization of structurally related acids (13).

The pK_a data in Tables 3 and 4 show that both in Me_2SO and water the three aliphatic AS acids become progressively weaker when the carbon chain is lengthened, while the ionization becomes more endothermic. The aliphatic acids, but not sulfanilic acid, are also considerably weaker in Me_2SO than in water. Interestingly, the pK_{as} of taurine in Me_2SO, 11.1, is very close to that of ethylammonium ion $NH_3^+CH_2CH_3$, 10.9, and far from that of methanesulfonic acid CH_3SO_3H, 1.7. We can therefore conclude that taurine must be present in Me_2SO as the zwitterion $NH_3^+CH_2CH_2SO_3^-$ and not as non-ionic $NH_2CH_2CH_2SO_3H$. Clearly the electron-attracting effect of the SO_3^- group, 2 carbons away from $—NH_3^+$, must be small, while the electron-donating effect of the $—NH_2$ group, two carbons away from $—SO_3H$, could certainly not account for a pK increase from 1.7 to 11.1.

An argument similar to the previous one can be used to assign the structure $NH_3^+CH_2SO_3^-$ to aminomethanesulfonic acid in Me_2SO. However, for sulfamic acid it is becoming difficult to choose between NH_3^+ SO_3^- and NH_2SO_3H on the strength of a comparison between its pK_{as} 6.30, and those of CH_3SO_3H, 1.70, and $NH_3^+CH_3$, 11.0. Fortunately, the comparison of pK_a of the three aliphatic AS acids in Me_2SO and water helps us to decide on the structure of sulfamic acid in Me_2SO. The plot in Fig. 1 of pK_{as} against pK_{aw} for the three acids gives a good straight line $pK_{as} = (0.57 \pm 0.02)pK_{aw} + (5.95 \pm 0.15)$ (r = 0.9991). This linear correlation makes us conclude that since the AS acids are zwitterionic in water, they must also be so in Me_2SO, the linear correlation reflecting the effect on $—NH_3^+$ of stronger electron-withdrawing substituents when going from $CH_2CH_2SO_3^-$ to $CH_2SO_3^-$ and SO_3^-. It is interesting to note that the slope of the straight line, which is the ratio of the Hammett ρ values for the $—NH_3^+$ series in Me_2SO and water, is unexpectedly lower than 1. For the uncharged acids, substituted benzoic acids (14) and phenols (15) the ρ_s/ρ_w values are, respectively, 2.5 and 2.0, and for substituted anilinium ions ρ_s/ρ_w 1.6. The lower value of ρ_s/ρ_w for the aminosulfonic acids reflects in a complex manner differences in ΔG^0_{ws} of both the zwitterionic acids and the anions. The linear correlation between ΔH^0_{is} and ΔH^0_{iw} (Fig. 1) is not as good as the pK_{as}–

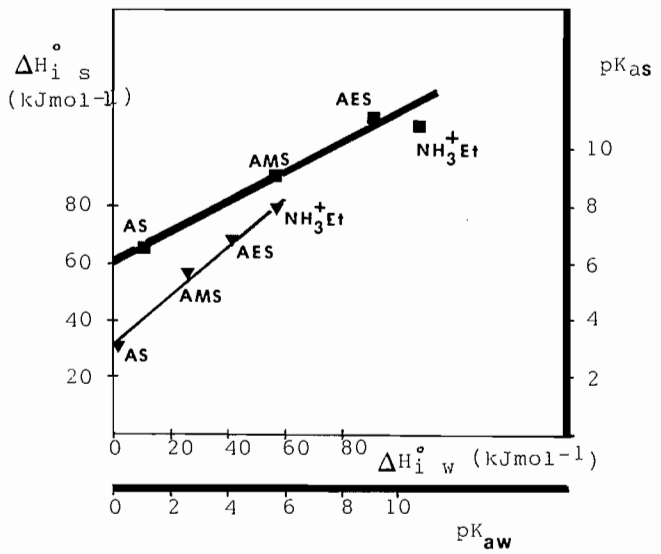

FIG. 1. Correlation between ionization parameters of aminosulfonic acids in Me_2SO and water (AS: sulfamic acid; AMS: aminomethanesulfonic acid; AES: taurine; NH_3^+Et, ethylammonium ion).

pK_{aw} correlation but the point corresponding to $NH_3^+CH_2CH_3$ falls on the line.

As for sulfanilic acid, it comes as no surprise that the ionization data do not follow the correlation for the aliphatic AS acids. Comparing the ionization data in Me_2SO for $NH_2C_6H_4SO_3H$ with those for related $NH_3^+C_6H_5$, $NH_3^+C_6H_4Cl$, and $C_6H_5SO_3H$ (Table 4) strongly suggests that sulfanilic acid is also zwitterionic in Me_2SO. It is worth noting that the $—SO_3^-$ group which is more electron-attracting than —Cl in water, on the basis of pK_{aw} (see also ref. 16) in Table 4, would have a value near 0 in Me_2SO clearly demonstrating the influence of the solvent on a negatively charged substituent.

Transfer parameters

The transfer free energies and enthalpies of HA and A^- are useful parameters to rationalize the change of pK_a (free energies) and enthalpies of ionization when passing from water to Me_2SO. The values can also be compared to thermodynamic functions of transfer of other single ions (11).

The values of the energies of transfer $\Delta G^0_{ws}(HA)$, which are approximate in the absence of activity coefficients data on the AS acids in Me_2SO, are either near 0 or slightly positive (+10 kJ mol^{-1}). Then, the values of $\Delta G^0_{ws}(A^-)$ calculated from an equation similar to [11] are between +40 and +50 kJ mol^{-1} for aliphatic A^- and +25 kJ mol^{-1} for $NH_2C_6H_4SO_3^-$. We conclude from these values that the pK_a increase of the aliphatic AS acids, when passing from water to Me_2SO, is mainly due to a destabilization of A^- in Me_2SO opposed by stabilization of H^+ ($\Delta G^0_{ws}(H^+) = -19.0$ kJ mol^- (11)) and a slight destabilization of $HA^{\pm}$ in Me_2SO. For sulfanilic acid, the much smaller increase of pK_a on going from water to Me_2SO is a consequence of the comparatively smaller destabilization in Me_2SO of $NH_2C_6H_4SO_3^-$ (ΔG^0_{ws} = +25 kJ mol^{-1} instead of +40 – +50 kJ mol^{-1} for aliphatic A^-). This is in line with the known stronger affinity of Me_2SO for aromatic compounds over aliphatic compounds. Our approximate values of $\Delta G^0_{ws}(A^-)$ are comparable to reported values for negative ions such as Cl^- (+40 kJ mol^{-1}), and $CH_3CO_2^-$ (+50 kJ mol^{-1}) (17) which are poorly solvated in Me_2SO because this solvent has no hydrogen bond donor properties.

Turning now to the enthalpies of transfer ΔH^0_{ws} listed in Tables 5 and 6, the data show a strong enthalpy stabilization of aliphatic AS acids in Me_2SO, which however, becomes less pronounced when the length of the carbon chain increases. This stabilization may be attributed to the substituted $—NH_3^+$ structure and the much greater H-bond acceptor properties of Me_2SO compared with water (cf. Taft–Kamlet solvatochromic parameter β: 0.76, Me_2SO; 0.17, H_2O). Conversely, the anions A^- are enthalpy destabilized in Me_2SO and increasingly so from $NH_2SO_3^-$ (+12.8) to $NH_2CH_2SO_3^-$ (+26.8) and $NH_2CH_2CH_2SO_3^-$ (+35.9 kJ mol^{-1}). Although Krishnan and Friedman (18) found small (0.1 kJ mol^{-1}) additive ΔH^0_{ws} terms for the water —Me_2SO transfer of $—CH_2—$ groups in amines and alcohols series, that was only for long carbon chains, if not, terminal polar group interfered as would be the case with our series $NH_2(CH_2)_nSO_3^-$. Attempts were made to determine whether other group additivity rules could be used to estimate ΔH^0_{ws}. Thus, when we add the ΔH^0_{ws} contribution of $CH_3SO_3^-$ (+28.5 kJ mol^{-1}) to those of NH_2CH_3 (+18.4) and $NH_3^+CH_3$ (−29.7), we might obtain approximate values for $NH_2CH_2CH_2SO_3^-$ (+47) and $NH_3^+CH_2CH_2SO_3^-$ (−1). These calculated ΔH^0_{ws} can be contrasted with the experimental values of +35.9 and −15.6 kJ mol^{-1} for $NH_2CH_2SO_3^-$ and $NH_2CH_2CH_2SO_3H$, respectively. The differences between the two sets of values, 13 ± 2 kJ mol^{-1}, could be roughly accounted for by noting that the calculated values include the transfer of two terminal $—CH_3$ groups (ΔH^0_{ws} ($—CH_3$) ~ +5 kJ mol^{-1}) which should be replaced by $—CH_2—$ group with smaller transfer contributions (18). At any rate, and however crude these comparisons may be, they serve to confirm our contention that the three aliphatic AS acids are zwitterionic in Me_2SO. Proceeding similarly with sulfanilic acid, we take $\Delta H^0_{ws}(C_6H_5SO_3^-) = +16.4$ kJ mol^{-1} to which we add for $NH_2C_6H_5$, −11.2 and for $NH_3^+C_6H_5$ −37.4 kJ mol^{-1} to obtain for $NH_2C_6H_4SO_3^-$, +5.2, and for $NH_3^+C_6H_4SO_3^-$, −21.0 kJ mol^{-1} (since $\Delta H^0_{ws}(C_6H_6) \sim 0$ kJ mol^{-1}). The experimental values are +5.2 and −26.3 kJ mol^{-1} for $NH_2C_6H_4SO_3^-$ and $NH_2C_6H_4SO_3H$, respectively. The fair agreement for sulfanilic acid provides us with our strongest argument for the assignment of a zwitterionic structure.

It is clear that our conclusion that the four aminosulfonic acids are present as zwitterions in Me_2SO does not preclude the presence of low concentrations of the non-ionic forms. It is notoriously difficult to determine the equilibrium constant of such tautomeric forms, as is apparent for glycine (19, 20). The selection of the model compounds, whether alkyl esters or $—NR_3^+$ derivatives, and possibly the method used, whether thermodynamic or spectroscopic, may also lead to different results as exemplified in the case of 4-aminobenzoic acid in water (21, 22) where the percentage of zwitterion found varies between 17 and 1%.

NOTE ADDED IN PROOF: Our recent ^{13}C nmr work confirms the ionic structure of three of the four AS acids.

Experimental and theoretical investigation of C-nitroso rotation in 2-nitrosoimidazoles

JUDY L. BOLTON, MICHAEL R. PETERSON, AND ROBERT A. MCCLELLAND[1]

Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received May 30, 1988

JUDY L. BOLTON, MICHAEL R. PETERSON, and ROBERT A. MCCLELLAND. Can. J. Chem. **66**, 3044 (1988).

1-Methyl-2-nitrosoimidazole exhibits broadened ^1H nuclear magnetic resonance signals at room temperature. The concentration independency of this spectrum as well as the linearity of the 700-nm absorbance with concentration rules out equilibrating nitroso monomer – nitroso dimer. It is suggested that there are equilibrating s-*cis* and s-*trans* nitroso monomer rotational isomers. At −59°C two sets of signals in a 3:1 ratio are observed. Analysis of CH_3 chemical shifts in terms of the magnetic anisotropy of the nitroso group suggests that the s-*trans* is the major isomer. The broadening observed at higher temperatures leads to a barrier for rotation (from the *trans* isomer) of 12.4 kcal mol^{-1}. *Ab initio* calculations with 2-nitrosoimidazole using the 3-21G basis set show that the fully planar s-*cis* and s-*trans* forms are minima, with the s-*trans* more stable by 2.5 kcal mol^{-1}, and a barrier to rotation (from the s-*trans*) of 13.0 kcal mol^{-1}. These results are in good agreement with those from solution phase. Various factors suggest that the π conjugative interaction between the nitroso group and imidazole ring is relatively unimportant.

JUDY L. BOLTON, MICHAEL R. PETERSON et ROBERT A. MCCLELLAND. Can. J. Chem. **66**, 3044 (1988).

Le méthyl-1 nitroso-2 imidazole présente en énlargissement des signaux de résonance magnétique nucléaire du ^1H à la température ambiante. L'absence de relation entre le spectre et la concentration aussi bien que la relation de proportionnalité existant entre la concentration et l'absorption à 700 nm écartent la posibilité d'un équilibre monomère nitroso – dimère nitroso. On suggère qu'il y a un équilibre entre les isomères rotationnels s-*cis* et s-*trans* du monomère nitroso. On observe à −59°C deux groupes de signaux dans un rapport 3:1. L'analyse des déplacements chimiques en fonction de l'anisotropie magnétique du groupe nitroso suggère que l'isomère s-*trans* est majoritaire. L'élargissement des signaux observé à plus haute température conduit à une barrière à la rotation de 12.4 kcal mol^{-1} (pour l'isomère *trans*). Les calculs *ab initio* effectués avec le nitroso-2 imidazole en utilisant l'ensemble de base 3-21G montrent que les formes totalement planes s-*cis* et s-*trans* sont minimales. La forme s-*trans* est plus stable de 2.5 kcal mol^{-1} avec une barrière à la rotation de 13.0 kcal mol^{-1}. Ces résultats s'accordent parfaitement avec ceux obtenus en solution. Divers facteurs suggèrent qu l'interaction π conjuguée entre le groupe nitroso et le cycle imidazole joue un rôle relativement peu important.

[Traduit par la revue]

Extensive studies of the 2-nitroimidazole radiosensitizers have revealed a number of biological and biochemical effects that are associated with reductive metabolism (1–6). The implication is that biological reduction is producing some reactive species that interacts with cellular components. In our investigations into the chemical origins of these effects, we have prepared 1-methyl-2-nitrosoimidazole (7), the two-electron reduction derivative of the model nitroimidazole 1-methyl-2-nitroimidazole. A search of the chemical literature reveals that 2-nitrosoimidazoles are unknown, a small number of 4 (5)-nitroso-5 (4)-phenylimidazoles being the only reported examples of the nitrosoimidazole class (8–11). 1-Methyl-2-nitrosoimidazole is indeed highly cytotoxic *in vitro* and, pending further studies, is a candidate for the biologically active reduction product (7, 12, 13). The compound, a green solid, was isolated in pure form and identified by various methods: C,H,N analysis, mass spectrum, uv–vis spectrum, and ^1H nmr spectrum (7). The latter, when recorded at 60 MHz, showed signals consistent with a substance containing the NCH_3 group and two nonequivalent H4-, H5-imidazole hydrogens. Examination of the 400 MHz spectrum recorded at ambient temperature revealed, however, that these signals were significantly broadened. Our initial assumption was that this was associated with equilibrating nitroso monomers and dimers,

[1] 
as has been characterized for nitrosobenzenes (14–17). This paper presents our examination of this phenomenon, at both the experimental and theoretical level. As will be shown, our initial premise was incorrect. The nmr broadening is in fact associated with interconverting C—NO rotamers of the monomeric nitrosoimidazole.

Experimental

1-Methyl-2-nitrosoimidazole was prepared as described previously (7). The nmr experiments were carried out at 400 MHz with a Varian XL-400 nmr spectrometer. The uv–visible spectra were recorded with a Varian 2390 spectrophotometer.

Ab initio computations were carried out with the split-valence 3-21G basis set (18) within the Hartree-Fock formalism (19) using the analytic gradient (20) of the SCF energy with respect to the internal geometrical parameters. The Optimally Conditioned (OC) minimization technique (21) was used to determine the optimal geometry at each minimum. The VAO5AD sum of squares technique (22) was used for the transition state optimizations and to confirm the order of the minima obtained with the OC method. The order of a critical point is equal to the number of negative eigenvalues of the Hessian or force constant matrix (second derivatives of the energy with respect to the internal geometrical parameters). The order of minima must be zero, whereas transition states have order one. Optimizations were terminated when the gradient length,

$$\left[|g| = \left(\sum_i^n (\delta E/\delta q_i)^2/n \right)^{1/2} \right]$$

where q_i are the internal parameters and the sum is over the n optimized parameters, was reduced to below 5×10^{-4} mdyn. All computations were performed on the Gould 32/9705 computer system at the University of Toronto with the MONSTERGAUSS *ab initio* program (23).

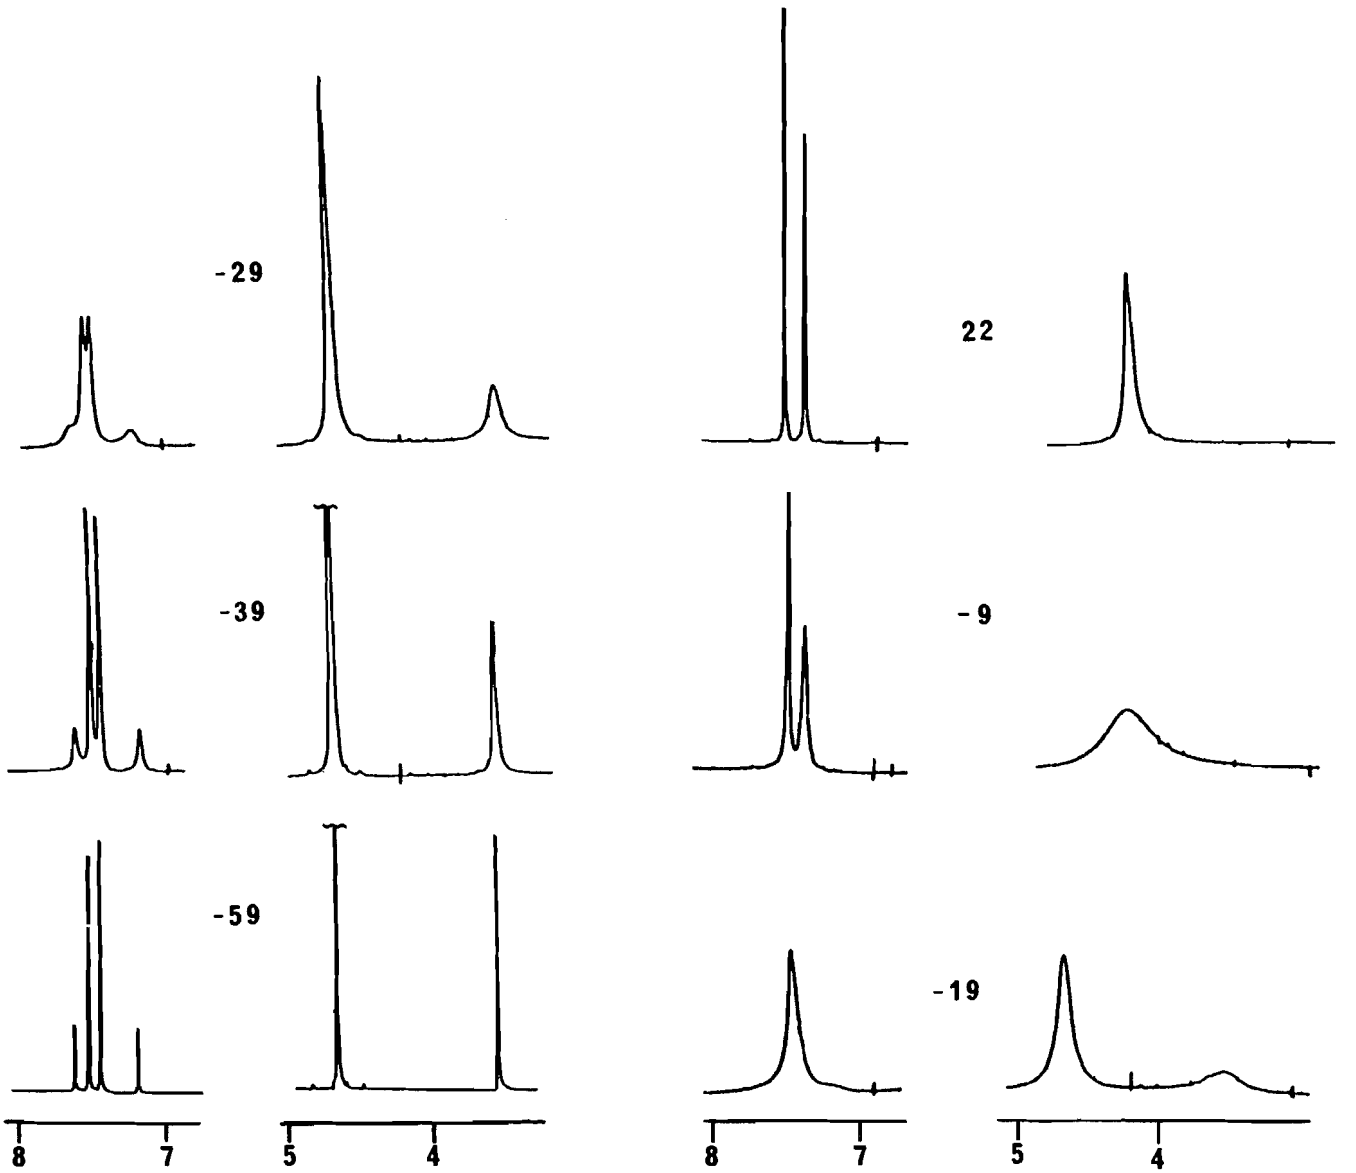

FIG. 1. Temperature dependence of the 400-MHz ^{1}H nmr spectrum of 1-methyl-2-nitrosoimidazole (5 mM) in CD_2Cl_2.

Results and discussion

Monomer–dimer Equilibration

The uv–visible spectrum of 1-methyl-2-nitrosoimidazole in CH_2Cl_2 exhibited three peaks, with λ_{max} at 280 nm ($\epsilon = 2.0 \times 10^3$ M^{-1} cm^{-1}), 355 nm ($\epsilon = 2.0 \times 10^4$ M^{-1} cm^{-1}), and 700 nm ($\epsilon = 45$ M^{-1} cm^{-1}). The weak band around 700 nm is characteristic of monomeric C-nitroso compounds (15), and is obviously the absorption that causes the green color of the solid. Since dimeric C-nitroso compounds lack this visible absorption band, the presence of the dimer in solutions of C-nitroso compounds can be demonstrated by examination of the concentration dependence of the absorption spectra. In particular, as the concentration is increased and the relative amount of dimer at equilibrium increases, the apparent extinction coefficient of the visible band (optical density/concentration) should decrease. With 1-methyl-2-nitrosoimidazole in CH_2Cl_2, however, the optical density at 700 nm is linear in concentration up to 25 mM, the highest concentration investigated. Thus we conclude that this compound exists principally (>90%) as the monomer, at least up to this concentration in this solvent. Similar experiments in methanol and water lead to the same conclusion, although the precision of the optical density measurements is less because the compound is not indefinitely stable in these solvents (7).

The ambient temperature 400 MHz ^{1}H nmr spectrum showing the broadened singlets is shown in one of the panels of Fig. 1. This spectrum was recorded in a 5 mM solution in CD_2Cl_2, where the evidence of the visible absorption spectroscopy is that principally monomer should be present. Increasing the concentration, in this case up to 100 mM, had no effect on the shapes of the peaks in the nmr spectrum. The conclusion therefore is that the broadening is not being caused by equilibrating monomer and dimer.

C-Nitroso rotamers. Variable temperature nuclear magnetic resonance

This leaves as an explanation some form of conformational equilibration. An examination of the structure of this relatively rigid molecule suggests that this would involve rotamers about the C2—NO bond.

[2] 
s-*trans* s-*cis*

We define these as s-*cis* and s-*trans* with respect C2=N3 bond as shown in eq. [2]. As indicated by the dipolar resonance contributor of the s-*cis* form, the C2—NO bond is expected to have partial double bond character because of conjugation of the electron-rich imidazole ring and the electron-withdrawing nitroso group. (A similar dipolar contributor can obviously be written for the s-*trans* form.)

The results of a variable temperature nmr investigation are shown in Fig. 1. As the temperature is decreased the signals broaden further, but then there is a separation and, by −59°C, two species are clearly indicated. The major isomer has peaks at δ 7.47 and δ 7.39 corresponding to the imidazole hydrogens and δ 4.65 for the N-methyl, while the minor isomer has signals at δ 7.57, 7.13, and 3.52. The ratio of the major to minor isomer as determined by integration is 3:1.

A tentative assignment of the s-*trans* as the major isomer can be made upon consideration of the magnetic anisotropy of the nitroso group. The major isomer has its methyl signal 1.13 ppm downfield from the corresponding signal of the minor isomer, and it is in the *trans* form, which has the methyl group closer to the nitroso bond, that the hydrogens are most deshielded. Through the use of the appropriate formula for the anisotropy effect with nitroso group parameters (24), we calculated that a freely rotating methyl group has its hydrogens on average deshielded by 0.23 ppm in the *cis* isomer, and by 1.42 ppm in the *trans*. The difference between the two, 1.19 ppm, is remarkably close to the experimental difference.

The ^{13}C nmr spectrum, recorded in $CDCl_3$ at ambient temperature, also showed broadened signals, at 34.4, 126.3, 132.4, and 169.0 ppm. The signal at 169.0 ppm was weak and can be assigned to the quaternary C2 carbon. A proton coupled spectrum revealed that the signal at 126.3 ppm had small coupling to the methyl hydrogens, and this is therefore C5.

The broadening of the separate N—CH_3 signals can be related to the exchange rate constant by the equation $k = \pi(h\text{-}h_0)$ where h is the line width at half-height and h_0 is the linewidth in the absence of exchange (25). The four nmr spectra obtained below the coalescence point (Fig. 1) were analyzed with this equation. The temperature variation in the rate constants was then treated in the normal fashion to give the activation parameters listed in Table 1. The free energy difference between the two isomers also listed in this table was calculated from their 3:1 ratio at −59°C.

Ab initio *computations*

In order to examine the situation at the theoretical level we carried out *ab initio* calculations with the 3-21G basis set, using the simpler parent 2-nitrosoimidazole as the model. The initial

[3] 
TABLE 1. Activation parameters for nitroso group rotation in 1-methyl-2-nitrosoimidazole

	Major isomer (s-*trans*)	minor isomer (s-*cis*)
$\Delta H‡$, kcal mol^{-1}	12.4	12.2
$\Delta S‡$, cal mol^{-1} K^{-1}	0.1	0.4

$\Delta G°$ (−59°C), kcal mol^{-1}	0.5	

calculations proceeded with the constraint that the imidazole ring atoms lay in a common plane, and the geometry was optimized in both the s-*cis* and s-*trans* configurations. A check of the critical point order revealed that the calculated geometries did represent true minima (order = 0). The geometry was also optimized for the C—NO torsional transition state. The requirement here is that the critical point order be unity. The results are summarized in Table 2, with the atom numbering corresponding to that given in eq. [3].

Similar calculations were also performed on the non-heterocyclic analog, 2-nitrosoethylene.

[4] 
s-*trans* s-*cis*

In this case the transition state for in-plane rotation or nitrogen inversion was also optimized. Results are tabulated in Table 3. Nitrosoalkenes have been isolated, but only when there are bulky substituents at the β-carbon (26). Simple nitrosoalkenes such as nitrosoethylene have only been observed in solution and (or) trapped with various reagents (27, 28). Several theoretical calculations of nitrosoethylenes have been reported (28–30), but none of these have examined the *cis* and *trans* isomerization. *Ab initio* calculations have been carried out at the STO-3G and at the 4-31G level but the geometry was not reported (29). The energies found (−203.99559 hartrees (STO-3G), −206.34914 hartrees (4-31G)) lie on either side of the one calculated in this paper, as is expected for these basis sets.

Considering that the calculations refer to isolated (gas phase) molecules, the nitrosoimidazole results show good correspondence with the experimental results for the 1-methyl derivative. The calculation predicts that the s-*trans* form is the more stable isomer, although the difference in stability, 2.5 kcal mol^{-1}, is larger than that seen experimentally. This discrepancy could be related to solvation differences between the two isomers; there is a slight difference in the calculated dipole moments (see later). Moreover there may be a methyl–nitroso steric interaction in the 1-methylimidazole that would destabilize the s-*trans*

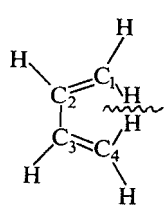
form relative to the s-*cis* form. The calculated barrier for nitroso rotation, 13.0 kcal mol^{-1} from the s-*trans* form, also shows good agreement with experiment (12.1 kcal mol^{-1}). The calculated transition state has the nitroso group 3° from the perpendicular to the imidazole ring, with the oxygen slightly to the NH side.

The situation with the nitrosoethylene is quite similar. The s-*trans* isomer is again calculated to be more stable. This conformational preference is also observed, both experimentally and theoretically, with 1,3-butadiene (31). One explanation for this trend in the latter case is that the s-*cis* conformation incorporates an unfavorable eclipsed interaction involving the C2 and C3 hydrogens; there is as well van der Waals repulsion between hydrogens at C1 and C4. However, these arguments cannot be applied to either nitrosoethylene or 2-nitrosoimidazole, where such interactions do not exist. An alternative explanation is that there is a diminished electron delocalization in the structures with the s-*cis* double bonds. Evidence for this can be seen in the calculated geometries, which generally have shorter double bonds and longer single bonds for the s-*cis* isomer. Thus, for example, the N=O bond is shorter by 0.0085 Å in s-*cis* nitrosoimidazole, with the difference 0.0017 Å in nitrosoethylene. Elongated C—N single bonds can be observed, the C—NO bond 0.0024 Å longer in s-*cis* nitrosoimidazole than in s-*trans*, and 0.0179 Å in the nitrosoethylene isomers. 1,3-Butadiene also shows similar trends, particularly in the C2—C3 bond, which is 0.0127 Å longer in the s-*cis* form (31).



The barrier to nitroso rotation in nitrosoethylene was calculated as 9.5 kcal mol^{-1} (from the s-*trans* isomer). As in the imidazole, the transition state was just slightly off the perpendicular. The barrier to in-plane nitrogen inversion was also computed for the ethylene, and found to be 55.1 kcal mol^{-1}. From this much larger number we conclude that the *trans–cis* isomerization proceeds via rotation. The smaller barrier for the nitrosoethylene as compared to the nitrosoimidazole is not unexpected since the latter should have a stronger π interaction between the nitroso group and adjacent π system. What is perhaps surprising is that the difference between the two is not greater. This may indicate that the nitroso – imidazole π interaction is not that important, and there are in fact several other signs that this may be the case. As shown in Fig. 2, which provides some pertinent bond lengths, the imidazole rings in s-*trans* and s-*cis*-2-nitrosoimidazole are not particularly distorted from imidazole itself. There are some small bond length differences in the direction expected for a nitroso plus imidazole resonance interaction, but these are small, particularly compared to the very large distortions for the imidazole-stabilized nitrenium ion (32) where there is a large delocalization. A comparison of the torsional transition state and the planar forms

also exemplifies the point. The former, with the nitroso group perpendicular, can have no conjugative interaction, and yet its geometry is very similar. There are small increases and decreases in bond length during the rotation, in particular a lengthening of the C—NO bond at the transition state, but the changes are small. A final indicator is the direction and magnitude of the dipole moment. Imidazole itself has a significant dipole oriented along the line from N1 to N3. The introduction of the nitroso group shifts the dipole towards this group, but the resultant can in fact be roughly ascribed as the vector sum of the imidazole dipole and C-nitroso dipole. This applies to both the planar and perpendicular forms, leading to the conclusion that π-delocalizations in the former are not causing significant distortions in the electron distribution. It can be noted that *ab initio* calculations with nitrobenzene (33) and various nitroimidazole[2] have pointed to the same conclusion, namely the relative unimportance of a resonance interaction between the nitro group and adjacent ring.

Electron spin resonance study of the structure of some σ* disulfur radical cations

L. BONAZZOLA, J.P. MICHAUT, AND J. RONCIN

Laboratoire de physico-chimie des rayonnements,[1] bat. 350, Université de Paris-Sud, 91405 Orsay CEDEX, France

Received May 30, 1988

L. BONAZZOLA, J.P. MICHAUT, and J. RONCIN. Can. J. Chem. **66**, 3050 (1988).

The radical cations generated by exposure to ^{60}Co γ rays, at 77 K. of dilute solutions of 1,4-dithiane, 1,5-dithiacyclooctane, and thiirane in freon matrices, have been investigated by ESR spectroscopy. The relation between the g_{iso} value and the S—S σ bond length is studied quantitatively.

L. BONAZZOLA, J.P. MICHAUT et J. RONCIN. Can. J. Chem. **66**, 3050 (1988).

Les cations provenant de l'irradiation γ à 77 K de solutions diluées, en matrices de fréons, de 1,4-dithiane, 1,5-dithiacyclooctane et de thiirane, sont étudiés par spectroscopie RPE. La relation entre la valeur de g_{iso} et la longueur de la liaison σ S—S est étudiée quantitativement.

Introduction

It is well known that exposure of dilute solutions of organic sulfides in freon matrices (1, 2) at 77 K to ^{60}Co γ rays gives the parent radical cations. These cations may react with neutral molecules to form dimer cations characterized by an intermolecular sulfur–sulfur σ bond. When a second sulfur is present in the parent molecule, an intramolecular radical cation complex can be observed if it is not prevented by steric factors. From liquid phase studies, it has been shown (3*a*) that the unpaired electron of dithia cations is generally located in an antibonding σ* orbital. Asmus *et al.* (4) found a correlation of optical absorption data in liquid phase with the structure of inter and intramolecular dithia cations: a redshift in the absorption seems to be associated with an increasing distance between the two sulfur atoms. Other liquid phase studies (3*b*, 5) indicate that the *g* factors determined from ESR spectra of the dimer cations $R_2SSR_2^+$ are dependent upon the size of the alkyl substituents. For a given medium and temperature, the *g* factor increases with the bulk of R: for $((CH_3)_2S)_2^+$, $g = 2.0102$: the *g* value becomes 2.0112 for $(Pr_2^iS)_2^+$ and 2.0122 for $(Bu^tSPr^i)_2^+$.

The present work is concerned with the correlation of the *g* values of dithia radical cations with their structure and in particular with the S—S σ bond distance. We focused our attention on two compounds: 1,4-dithiacyclohexane $S(CH_2)_2S(CH_2)_2$ and thiirane $S(CH_2)_2$. The first gives a cation characterized by an intramolecular S—S bond. Its absorption spectrum has been reported by Asmus *et al.* (4); its ESR spectrum in $CFCl_3$ matrix (1) leads to an uncertain g tensor (two of the three principal values are given by the authors). The second compound (thiirane) generates a dimer cation with an intermolecular S—S σ bond. To our knowledge, no data relative to the optical absorption of the dimer cation $((CH_2)_2S)_2^+$ are reported in literature. Nevertheless, the maximum absorptions (9) in liquid phase, of $((CH_3)_2S)_2^+$, $((CH_3CH_2)_2S)_2^+$, and $((CH_2)_4S)_2^+$, occur at the same wavelengths (470 nm). A similar maximum absorption is then expected for the thiirane dimer cation. The *g* value of $((CH_2)_4S)_2^+$ has been measured by Gilbert *et al.* (3*a*) in liquid phase (2.0102). The dimer radical cation of thiirane has been studied by Quin *et al.* (2) in freon matrices. They found a g_{iso} value of 2.0120. This value is unexpectedly high with respect to the values relative to $((CH_3)_2S)_2^+$ (2.0102) (5) and to $((CH_2)_4S)_2^+$ (2.0102). A change for *g* from 2.0102 to 2.0120 means a shift of the center of the spectrum of 3 gauss, which is outside the experimental error. Results concerning 1,5-dithiacyclooctane cation are also given in this paper because some information concerning its structure may be obtained from the comparison of its **g** tensor with those of 1,4-dithiane and thiirane cations.

Experimental

Samples were prepared from commercially available 1,4-dithiane, 1,5-dithiacyclooctane, and ethylene sulfide (Aldrich). Fluorotrichloromethane was purified before use. Dilute solutions (0.3% volume fraction) in freon (1,1,2-trichlorotrifluoromethane, fluorotrichloromethane) were degassed, frozen to 77 K, and then exposed to ^{60}Co γ rays (0.5 Mrads). Electron spin resonance spectra were recorded on a Brucker ER 200 D spectrometer equipped with a RMN gaussmeter. The spectrometer was calibrated with a Hewlett Packard 5342A frequency counter. The experimental spectra were simulated by using a computer program developed in the laboratory.

Results

Figures 1*a* and 2*a* show the spectra obtained from 1,4-dithiane trapped in $CFCl_2CCl_2F$ matrix registered at 80 and 110 K, respectively. The spectra simulated by using the parameters in Table 1 are given in Figs. 1*b* and 2*b*. The spectra in Figs. 1*a* and 2*a* are assigned to 1,4-dithiane radical cation. Warming from 80 to 110 K causes a softening of the matrix and a subsequent reversible spectral change leading to a nonet due to rapid reorientation of the cation. The motion of the cation averages out the g tensor to 2.0118 (spectrum II*a*) which is exactly the value found independently for g_{iso} from the spectrum I*a*. The isotropic coupling constant of 4.4 G (spectrum II*a*) to eight equivalent protons, agrees with the approximate value (1) proposed by Symons *et al.* It has been shown (2) that the radical species generated from thiirane–$CF_2ClCFCl_2$ solutions is the dimer cation, Its spectrum is given in Fig. 3*a*, and is simulated in Fig. 3*b*. It can be seen from the ESR parameters in Table 1 that the *g* and *A* values determined by Quin *et al.* (2) correspond to $A_\perp$ and $g_\perp$ parts of A and g tensors. Our g tensor is in good agreement with measurements in liquid phase (5) for $((CH_2)_4S)_2^+$.

Figure 4*a* shows the spectrum of 1,5-dithiacyclooctane cation trapped in $CFCl_3$ matrix. It indicates coupling to four equivalent protons. The isotropic coupling of 13.8 gauss corresponding to the measured tensor (see Table 1 and simulated spectrum in Fig. 4*b*) does not agree with liquid phase studies by Brown *et al.* (6). The hyperfine couplings observed by these authors are dependent on the method of generation of the

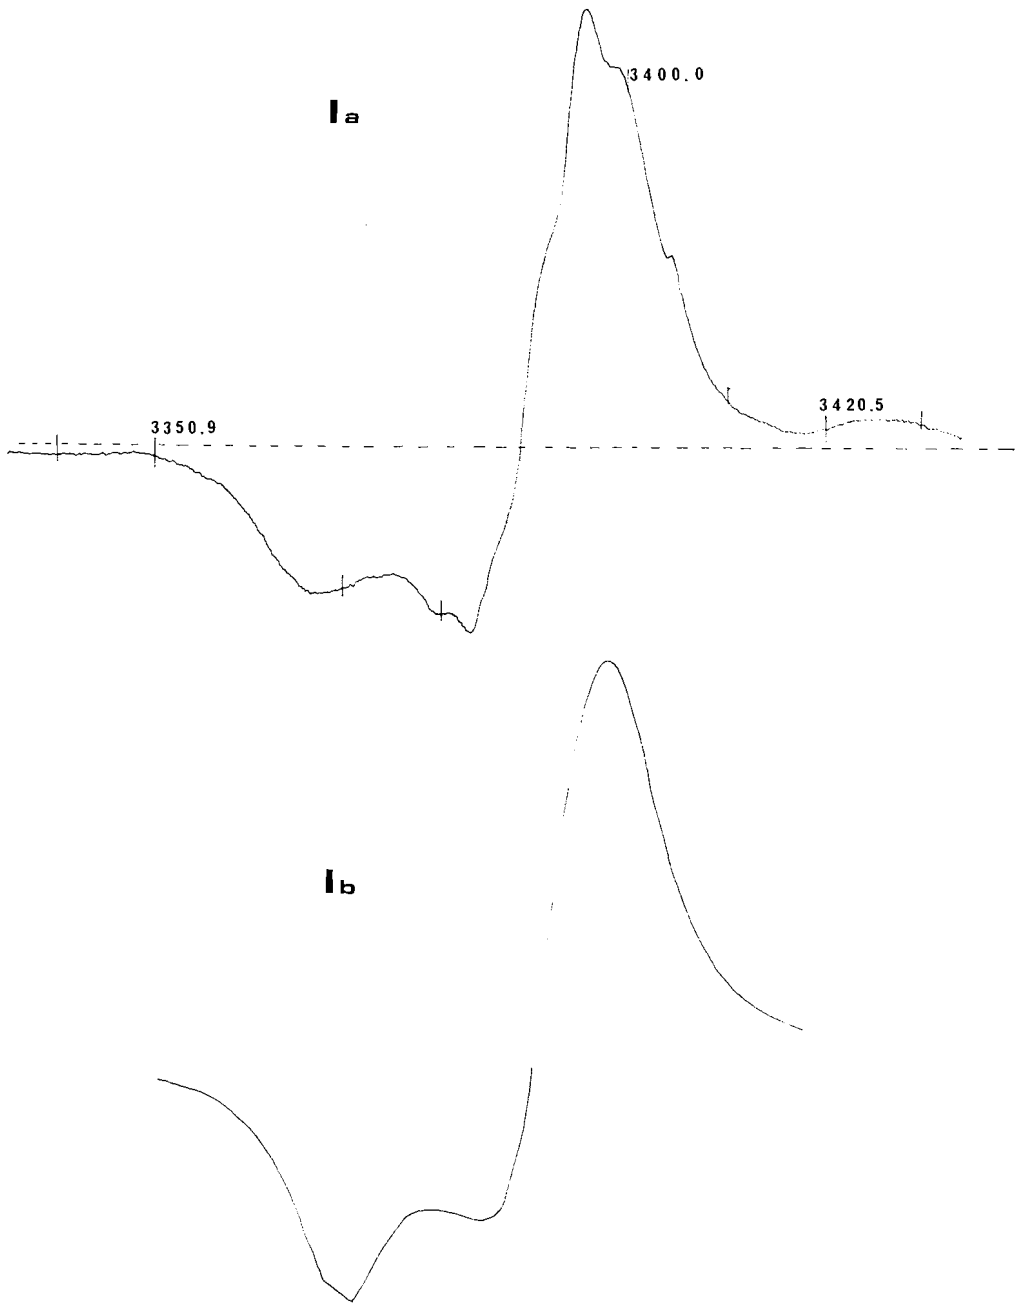

FIG. 1. (*a*) Electron spin resonance spectrum of 1,4-dithiane cation trapped in $CFCl_2CCl_2F$ matrix, registered at 80 K; (*b*) computer simulation of spectrum I*a*.

radical. In H_2SO_4, a five-line spectrum due to four equivalent protons is observed ($A_H = 9.9 \pm 0.2$ G), and in other media, the spectrum is due to the interaction of the unpaired electron with two pairs of equivalent protons ($A_{1H} = 11.2 \pm 0.1$ G; ($A_{2H} = 16.4 \pm 0.1$ G). The coupling of 13.8 gauss to four equivalent protons found in this work is the mean value of the above two couplings. The observed equivalence of the protons is not due to the line width (9.3 G) because the experimental spectrum would have been different: the second line of the spectrum should have been 5 G broader than the first one.

Discussion

As stated by Gara *et al.* (5) and Peterson *et al.* (3*b*), an increase in *g* values for a series of dithia cations is related to an increase of the S—S σ bond length. Optimized geometries for the neutral parent molecule and the radical cation of 1,4-dithiane have been determined by Momose *et al.* (7) (by using an STO 3G basis set and the gradient method for the search of stable conformation). The S—S bond length is found to be of 3.11 Å. The boat structure (7) is confirmed by ESR data: the coupling to eight equivalent protons (spectrum II*a*) would not have been possible with a chair conformation. Then, from our experimental *g* values. the S—S distance in the cation $(S(CH_2)_2)_2^+$ is expected to be less than 3.11 Å. We have performed a geometry optimization of thiirane dimer cation (Fig. 5) with a minimal STO 3G basis set and a minimization procedure using the gradient of the potential energy as described by Iver and Komornicki (8): the calculated value of the S—S bond length is 2.61 Å. Despite the known limitation of minimal basis set calculations, there is a clear trend of increasing

magnitudes for S—S bond length from thiirane dimer cation to dithiane cation. Similarly, the position of the maximum absorption, reflecting the σ/σ^* energy difference, is expected to increase with S—S distance. To our knowledge the maximum absorption for thiirane dimer cation has not been measured, but it is probably not very different from that of $((CH_2)_4S)_2^+$ cation (470 nm) (9). A λ_{max} value of 650 nm has been found for dithiane cation (4). From the maximum of absorption of 1,5-dithiacyclooctane cation (400 nm) (4), a g_{iso} value inferior to 2.0097 is expected, which disagrees with the value found in this work (2.0128). The many possible conformations of this cation do not allow a geometry optimization because of computational expense. Nevertheless, some information relative to the structure of this cation can be obtained from its ESR spectrum: the coupling of the unpaired electron to four equivalent protons indicates a twist boat–chair conformation with four hydrogens in the plane SSC. For this conformation, a close approach of the two interacting sulfur atoms does not seem possible as in liquid phase (4) where two structurally favorable five-ring systems are established (giving a maximum degree of orbital overlap along S—S coordinate). The most likely structure in liquid phase consists of two *cis*-fused five-membered rings with limited fluxional character (6). The inequivalence of protons in some media may be due to the effect of the counter ions, In solid phase, steric hindrance probably makes the most stable conformation impossible.

Conclusion

Two radical cations exhibiting a S—S three-electron σ intramolecular bond (1,4-dithiane and 1,5-dithiacyclooctane cations) and one radical exhibiting a S—S three-electron intermolecular σ bond (thiirane dimer cation) have been studied by ESR spectroscopy. It appears that a precise measurement of g_{iso} may give a very good indication of the S—S bond length. The chair conformation of the dithiane cation, expected from calculation is confirmed. The equilibrium structure of 1.5-dithiachlorooctane cation in solid phase can be deduced from ESR data.

Kinetics of hydrolysis of aromatic bicycling disulfonyl dichlorides

PRZEMYSŁAW SANECKI AND EDWARD ROKASZEWSKI
Faculty of Chemistry, I. Lukasiewicz Technical University, 35-959 Rzeszów, Poland

Received July 12, 1988

PRZEMYSŁAW SANECKI and EDWARD ROKASZEWSKI. Can. J. Chem. **66**, 3056 (1988).

Hydrolysis of 16 compounds ClO_2S—Ar—B—Ar—SO_2Cl (B, bridge) in 20% H_2O, 80% v/v CH_3CO_2H, 0.5 mol dm^{-3} CH_3CO_2Na at 298.15 K has been investigated by a polarographic method. From plots of the hydrolysis, pseudo-first-order rate constants for two consecutive reactions $A \xrightarrow{k_1} A_1 \xrightarrow{k_2} A_2$ have been computed and the influence of -SO_2Cl groups, bridges B, and SO_3^- groups on the reactivity of -SO_2Cl groups has been discussed. The ratio of rate constants k_2/k_1 ranges from 0.45 to 30, depending on the structure. Log $(k_1/(2k_H))$ correlated linearly with $\sigma^{m,p}_{B\text{-}C_6H_5}$ and log (k_2/k_1) correlated linearly with ΔpK for the analogous diamine series H_2N—Ar—B—Ar—NH_2.

PRZEMYSŁAW SANECKI et EDWARD ROKASZEWSKI. Can. J. Chem. **66**, 3056 (1988).

Opérant à 298,15 K, en solution dans un mélange 20:80 (v/v) de H_2O/CH_3CO_2H contenant 0,5 mol dm^{-3} de CH_3CO_2Na, et faisant appel à une méthode polarographique, on a étudié l'hydrolyse de 16 composés du type ClO_2S—S—Ar—B—Ar—SO_2Cl (pont, B). À partir des courbes d'hydrolyses, on a calculé les constantes de pseudo-premier ordre des deux réactions consécutives $A \xrightarrow{k_1} A_1 \xrightarrow{k_2} A_2$; on discute de l'influence des groupements -SO_2Cl, des ponts B ainsi que des groupements SO_3^- sur la réactivité des groupements -SO_2Cl. Selon la structure, les rapports des constantes de vitesse k_2/k_1 varient de 0,45 à 30. On a établi une corrélation linéaire entre le log $(k_1/2k_H)$ et le $\sigma^{m,p}_{B\text{-}C_6H_5}$ ainsi qu'entre le log (k_2/k_1) et le ΔpK de la série des diamines analogues H_2N—Ar—B—Ar—NH_2.

[Traduit par la revue]

Introduction

In our previous paper (1) a continuous or semicontinuous polarographic method was applied to the investigation of the hydrolysis kinetics of 10 substituted benzenesulfonyl chlorides X—C_6H_4—SO_2Cl and seven disulfonyl dichlorides $C_6H_{4-n}(CH_3)_n(SO_2Cl)_2$. This method, together with the appropriate computing procedure, made possible the determination of rate constants k_1 and k_2 for the consecutive hydrolysis of disulfonyl compounds. The Hammett correlation was carried out, a reaction mechanism proposed, and the influence of -SO_2Cl and -SO_3^- groups on the reactivity of an unreacted -SO_2Cl group was discussed.

In this paper analogous investigations of a new series of 16 bicyclic disulfonyl dichlorides ClO_2S—Ar—B—Ar—SO_2Cl are reported. Compounds of this type are interesting as monomers for the synthesis of linear polysulfonates (2). The aim of this paper was to determine their reactivities in a model reaction running according to the nucleophilic substitution mechanism. Hydrolyses of some compounds of this type have previously been investigated in a different medium to give a single rate constant k (3).

Experimental

Chemicals

The compounds investigated were synthesized by means of classical methods. Numbers of compounds and their formulas are given in Table 1.

1: mp 128–129°C (lit. (4) mp 128–129°C).

2: mp 152–154°C (CH_3CO_2H); the compound after reduction with $SnCl_2$ + HCl gives dithiol, mp 78–80°C (CH_3OH), identical with dithiol obtained from 4,4′-diaminodiphenyl-2,2-propane by replacement of -NH_2 groups with SH groups; Cl in compound **2**, calcd.: 18.03%; found: 18.10%.[1]

3: mp 146.5–147°C (lit. (5) mp 146°C).

4: mp 126–128°C (lit. (6) mp 126–128°C).

5: mp 209–210°C (CH_3CO_2H) (lit. (3) mp 99–100°C (?); Cl calcd.: 18.695%; found: 18.62%.

6: mp 224–225°C (lit. (7) mp 225–226°C).

7: mp 157–158°C (lit. (8) mp 155–156°C, (9) mp 157–158°C).

8: mp 210–211°C (lit. (10) mp 203°C).

9: mp 218–219°C (lit. (11) mp 218°C).

10: mp 183–184°C; obtained by oxidation of **7** with the stoichiometric amount of $KBrO_3$ in CH_3CO_2H solution at 25°C, Cl calcd.: 17.76%; found: 17.75%.

11: mp 220–221°C (lit. (12) mp 222°C).

12: mp 140.5–141°C (crystallization: twice from CS_2, twice from CCl_4, 5 times from $CHCl_3$ + CCl_4) (lit. (13) mp 134°C).

13: mp 176–177°C (lit. mp 177–178°C);[2] obtained by oxidation of **4** with an excess of $KMnO_4$ in CH_3CO_2H solution at 35°C.

14: mp 185.5–186°C (CH_3CO_2H); obtained by chlorosulfonation of C_6H_5—Se—C_6H_5 with Cl—SO_2OH at 120°C by analogy to chlorosulfonation of C_6H_5—S—C_6H_5; Cl calcd.: 16.48%; found: 16.42%.

15: mp 174–175°C (lit. (9) mp 174–175°C).

16: mp 238–239°C (lit. (3) mp 238°C).

The positions of the -SO_2Cl groups in compound **14** (not described in the literature) as well as **5** and **12** were checked by ir spectroscopy.

Melting points were determined with the use of a Boëtius apparatus. Compounds **1–4** and **6–9** were obtained from the Department of Organic Synthesis, University of Lublin. The other substances were purified as in ref. 1. Apparatus and rate measurements were as in ref. 1.

Kinetic investigations were carried out in 20% H_2O, 80% v/v CH_3CO_2H; $c_{CH_3CO_2Na} = 0.5$ M; $c_{oClO_2S—ArBArSO_2Cl} = 8.5 \times 10^{-4}$ M ($c_{oSO_2Cl} = 1.7 \times 10^{-3}$ M) at 298.15 K.

Kinetics

A system of two irreversible consecutive first-order reactions $A \xrightarrow{k_1} A_1 \xrightarrow{k_2} A_2$ is described by the well-known set of differential equations. Based on the instantaneous concentrations of the -SO_2Cl groups, constants k_1 and k_2 can be determined by means of an iterative computing method (1).

Results and discussion

Hydrolysis of 14 compounds of the ClO_2S—Ar—B—Ar—SO_2Cl type, containing different divalent bridges, as well as of two derivatives with two divalent bridges (in the shape of five-

[a] $\sigma_{CH_2X} = 0.36\ \sigma_X$.
[b] $\sigma_X \cong \sigma^m_{-CH_2—C_6H_5}$.
[c] $\sigma_X \cong \sigma^m_{-C_6H_5}$.

membered rings: compounds **6** and **7**) has been examined (Table 1). All the compounds contain structurally equivalent $-SO_2Cl$ groups and hydrolyze according to the following mechanism (1):

$$-SO_2Cl + CH_3CO_2^- \xrightarrow{k_1 \text{ or } k_2} -SO_2OCOCH_3 + Cl^-$$

$$-SO_2OCOCH_3 + H_2O + CH_3CO_2^- \xrightarrow{\text{fast}} -SO_3^- + 2CH_3CO_2H$$

The reactivity of the first $-SO_2Cl$ group (k_1) depends on the donor or acceptor influence of the bridge -B- and, in contrast, the reactivity of the second $-SO_2Cl$ group (k_2) in the intermediate product ClO_2S—Ar—B—Ar—SO_3^- (A_1) depends additionally on the negative charge localization centre and on the degree of delocalization of the charge in A_1. The numerical order of the compounds in Table 1 corresponds to the order of increase for k_1.

Treating a single bond joining two aromatic rings in the diphenyl derivative (compound **8**) as a standard bridge (B = —) the remaining compounds can be divided into two groups: those with deactivating bridges (**1**–**7**) and those with activating bridges (**9**–**16**). The hydrolysis of compound **8** (diphenyl derivative) is close to that of the unsubstituted compounds C_6H_5—SO_2Cl, if the statistical factor is taken into account:

$$k_{-C_6H_4SO_2Cl(4)} = k_1/2 = 4.25 \times 10^{-5}\ s^{-1}$$

$$k_{C_6H_5—SO_2Cl} = k_H = 3.54 \times 10^{-5}\ s^{-1}$$

After hydrolysis of the first $-SO_2Cl$ group some distinct changes in the hydrolysis rate of the second group can be observed. The ratio of k_1/k_2 changes from 0.45 (-B- = -N=N-) to about 30 (compounds **6**, **7**, **14**). The computing procedure allowed us to distinguish k_1 and k_2 when their ratio is $0.03 < k_1/k_2 < 30$.

With regard to k_2 we get a new series (order of k_2 increase) for the intermediate products ClO_2S—Ar—B—Ar—SO_3^- (A_1), i.e., **3**, **11**, **9**, **2**, **4**, **5**, **1**, **8**,**6**, **7**, **12**, **10**, **13**, **15**, **14**, **16**. The second series differs from the first one in the position of bridges in compounds **1**, **9**, **11** and in the sequence of the neighbouring bridges.

All -B—Ar—SO_2Cl and -B—Ar—SO_3^- groups can be treated as complex substituents for which σ constants are not known. They can be estimated from the previously determined Hammett correlations for mono-ring compounds (1):

[1] $$\log (k_X/k_H) = 1.42\ \sigma_X - 0.087$$
$$n = 13,\ r = 0.9852$$

It was taken into account that

$$\log (k_X/k_H) = \log (k_1/(2k_H)), \quad -X = -B—C_6H_4—SO_2Cl$$

$$\log (k_X/k_H) = \log (k_2/k_H), \quad -X = -B—C_6H_4—SO_3^-$$

For the substituents $-X = -B—C_6H_4—SO_2Cl$, constants σ_X become more and more positive (from 0.01 to 0.62), in the order in which the compounds occur in Table 1. The substituents $-X = -B—C_6H_4—SO_3^-$ are characterized by a wider range of σ_X variation, i.e., 0.14–1.27, and generally $\sigma_{BC_6H_4SO_3^-}$ does not correlate linearly with $\sigma_{BC_6H_4SO_2Cl}$. With a set of literature σ constants for the substituents of type -B—C_6H_5 (14, 15) it is possible to determine an indirect correlation, $\log (k_1/(2k_H)) = f(\sigma_{BC_6H_5})$, to get (Fig. 1):

[2] $$\log (k_1/(2k_H)) = (0.859 \pm 0.143)\ \sigma_{BC_6H_5} + (0.110 \pm 0.056)$$
$$n = 9,\ r = 0.983,\ s_0 = 0.0035, \text{ for } t_{0.05,7}$$

Compounds **6** and **9** with two bridges could be included in this

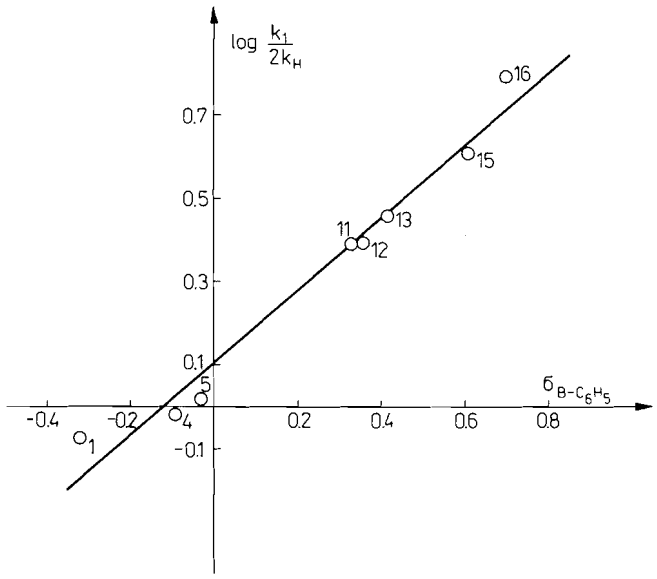

FIG. 1. Relationship of log $(k_1/(2k_H))$, for the first hydrolysis step of disulfonyl dichlorides, to Hammett $\sigma_{BC_6H_5}$ constants—analogous to $\sigma_{BC_6H_5SO_2Cl}$ constants.

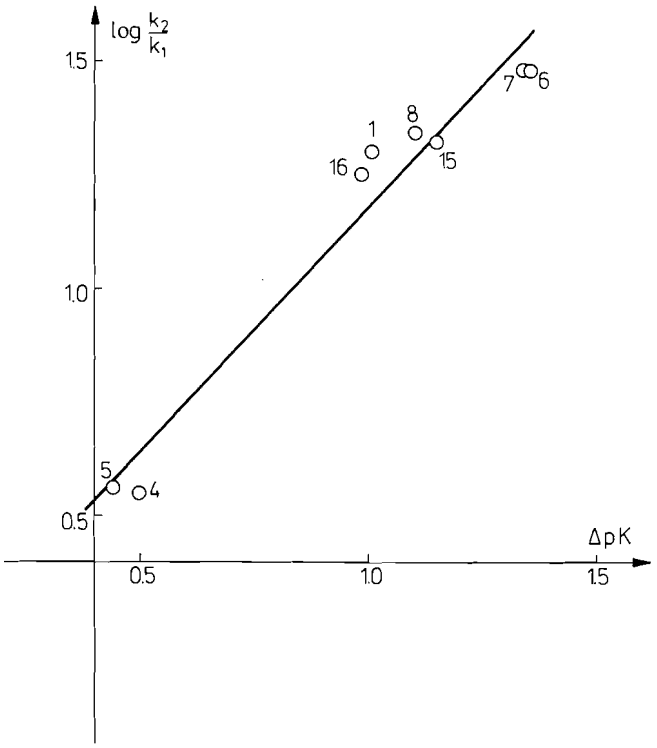

FIG. 2. Relationship of log (k_2/k_1), for the hydrolysis of disulfonyl dichlorides, to $\Delta pK = \log (K_{a_2}/K_{a_1})$ for deprotonation reactions of conjugated acids of analogous diamines (16).

correlation after assuming that the decisive influence is exerted by the bridge situated in the *meta* position in relation to the $-SO_2Cl$ group. This operation corrects only the correlation coefficient. Equation [2] together with [1] give an interstructural correlation [3]:

[3] $\sigma^{m,p}_{BC_6H_4SO_2Cl} = 0.606\ \sigma^{m,p}_{BC_6H_5} + 0.139$

From the data of Table 1 it follows that $\sigma^{p}_{OC_6H_4SO_2Cl} = -0.05$, $\sigma^{p}_{SC_6H_4SO_2Cl} \cong 0.15$, $\sigma^{p}_{SeC_6H_4SO_2Cl} = 0.45$. Equation [3] makes possible the evaluation of $\sigma^{p}_{SC_6H_5} = 0.02$ and $\sigma^{p}_{SeC_6H_5} = 0.52$. The hydrolysis reaction of the first $-SO_2Cl$ group is well described by eq. [2]. The analogous correlation $\log (k_2/k_H) = f(\sigma_{BC_6H_5})$ is fulfilled only for six out of the nine compounds previously taken into consideration. The intermediate products created from the compounds with $-CH_2-$, $-(CH_2)_2$, and $-N=N-$ bridges (**4**, **5** and **11**, respectively), as well as from **9**, do not fulfill the correlation:

[4] $\log (k_2/k_H) = (0.778 \pm 0.173)\cdot\sigma_{BC_6H_5} + (1.762 \pm 0.080)$

$n = 6$, $r = 0.9874$ $s_0 = 0.0539$, for $t_{0.05,4}$

For six intermediate products, A_1 (from compounds **1**, **8**, **12**, **13**, **15**, **16**), two additional structural correlations (eqs. [5] and [6]) are fulfilled:

[5] $\sigma_{BC_6H_4SO_3^-} = 0.548 \cdot \sigma_{BC_6H_5} + 1.302$

[6] $\sigma_{BC_6H_4SO_3^-} = 0.956 \cdot \sigma_{BC_6H_5SO_2Cl} + 1.149$

However, these correlations are not of a general character.

The correlations and abnormalities observed raise the question as to whether all the initial compounds and their intermediates react according to the same mechanism, and if it is possible to determine a more general correlation with regard to where the specific interactions occur. A correlation of this type can be determined by a comparison of relative reactivities of $-SO_2Cl$ groups in A and A_1 with the relative basicities of analogous amines $H_2N—Ar—B—Ar—NH_2$ and $H_2N—Ar—B—Ar—NH_3^+$. Taking into account the acidity constants of the suitable conjugated acids given in ref. 16 we get the following dependence:

[7] $\log (k_2/k_1) = \rho_r \log (K_{a2}/K_{a1}) + \delta_r = \rho_r\, \Delta pK + \delta_r$

where $\Delta pK = pK_{a1} - pK_{a2}$; $\rho_r = 1.073 \pm 0.230$; $\delta_r = 0.100 \pm 0.239$; $n = 8$, $r = 0.9777$, $s_0 = 0.087$, for $t_{0.05,6}$. This is a directly proportional correlation $(k_2/k_1 \cong K_{a2}/K_{a1})$ and it includes compounds **4** and **5** (Fig. 2).

The negative charge of the SO_3^- group changes the reactivity of the unreacted SO_2Cl group in the same way as the positive charge of the protonated amine group changes the acidity of the second protonated amine group in the transition state or the equilibrium state, respectively:

$$[(^-O_3S—)\ ClO_2S—Ar—B—Ar—SO_2Cl \ldots {}^-OCOCH_3]^{\neq} \xrightarrow{(k_1 \text{ or } k_2)} \ldots$$

$$(H_2N\text{-})\ {}^+H_3N—Ar—B—Ar—NH_3^+ + H_2O \xrightleftharpoons{(K_{a1} \text{ or } K_{a2})} \ldots$$

This fact suggests the same hydrolysis mechanism and indirectly confirms the fact that the anion is an intermediate product of hydrolysis A_1 as in ref. 1.

Acknowledgment

The authors wish to express their gratitude to Professor Wawrzyniec Podkościelny for samples of compounds investigated in this paper. The work was supported in part by the MRI-11 and CPBP 01.15 projects.

Crystal chemistry of tetraradial species. Part 2. Crystal structures of Et_4NI, $Ph_4PBr \cdot H_2O$, and $Ph_4PBr \cdot 2H_2O$[1]

BEVERLY R. VINCENT,[2] OSVALD KNOP,[3] ANTHONY LINDEN, T. STANLEY CAMERON, AND KATHERINE N. ROBERTSON

Received May 26, 1988

BEVERLY R. VINCENT, OSVALD KNOP, ANTHONY LINDEN, T. STANLEY CAMERON, and KATHERINE N. ROBERTSON. Can. J. Chem. **66**, 000 (1988).

The crystal structure of Et_4NI ($I\bar{4}$, a = 8.860(2) Å, c = 6.933(1) Å, Z = 2) has been redetermined and those of $Ph_4PBr \cdot H_2O$ ($P\bar{1}$, a = 10.005(3) Å, b = 10.659(2) Å, c = 10.697(4) Å, α = 102.61(2)°, β = 83.39(3)°, γ = 108.09(3)°, Z = 2) and $Ph_4PBr \cdot 2H_2O$ (*Pnma*, a = 16.255(4) Å, b = 10.810(4) Å, c = 12.667(9) Å, Z = 4) have been determined for the first time. In the Et_4NI structure Et_4N^+ cations in an extended S_4 conformation and I^- anions are arranged in a zincblende-type packing. The two hydrate structures are ionic and very similar. The anion in the monohydrate is a centrosymmetric cyclic dimer $[Br_2(OH_2)_2]^{2-}$; in the dihydrate the anion, which is an almost planar infinite $[Br^-(OH_2)_{4/2}]_\infty$ chain $\| b$, appears to be of a novel type. If the H_2O molecules are not considered, the ion packing in both hydrates may be regarded as of the *anti*-NiAs type. The ion packing in R_4EX structures and the conformation of the Et_4N^+ ion in crystals are discussed in some detail.

BEVERLY R. VINCENT, OSVALD KNOP, ANTHONY LINDEN, T. STANLEY CAMERON et KATHERINE N. ROBERTSON. Can. J. Chem. **66**, 000 (1988).

On a déterminé de nouveau la structure cristalline du composé Et_4Ni ($I\bar{4}$, a = 8,860(2) Å, c = 6,933(1) Å, Z = 2) et on a déterminé pour la première fois les structures cristallines du $Ph_4PBr \cdot H_2O$ ($P\bar{1}$, a = 10,005(3) Å, b = 10,659(2) Å, c = 10,697(4) Å, α = 102,61(2)°, β = 83,39(3)°, γ = 108,09(3)°, Z = 2) et du $Ph_4PBr \cdot 2H_2O$ (*Pnma*, a = 16,255(4) Å, b = 10,810(4) Å, c = 12,667(9) Å, Z = 4). Dans la structure du Et_4NI, les cations Et_4N^+, dans une conformation étendue de type S_4, et les anions I^- sont disposés selon un entassement de type blende. Les deux structures hydrate sont ioniques et sont très voisines. Dans le monohydrate, l'anion est un dimère cyclique centrosymétrique $[Br_2(OH_2)_2]^{2-}$; dans le dihydrate l'anion, qui est quasiment une chaîne plane infinie $[Br^-(OH_2)_{4/2}]_\infty \| b$, semble être d'un nouveau type. Si on ne tient pas compte des molécules d'eau, on peut considérer l'entassement des ions dans les deux hydrates comme étant de type *anti*-NiAs. On discute de l'entassement des ions dans les structures de type R_4EX et de la conformation de l'ion Et_4N^+ dans les cristaux.

[Traduit par la revue]

In this series of investigations we are interested in discovering how the idealized symmetry (T_d or subgroup) of tetraradial[4] $XL_4^{n\pm}$ species is reflected in the crystallographic symmetry when $XL_4^{n\pm}$ is incorporated in a crystal, on its own (n = 0) or in combination with another, not necessarily tetraradial species, and in particular how the packing type is affected by the size and complexity of $XL_4^{n\pm}$ in simple chemical combinations. In the present contribution to the systematic crystal chemistry of such species we report the results of a redetermination of the structure of Et_4NI and of determinations of the structures of $Ph_4PBr \cdot H_2O$ and $Ph_4PBr \cdot 2H_2O$. Although Ph_4PBr rather than its hydrates was originally the compound to be investigated, we were unsuccessful in our attempts to obtain crystals of the anhydrous bromide (see Experimental).[5]

The crystal data of the title compounds are assembled in Table 1. Details of the structure determinations and a list of material deposited will be found under Experimental.

Et_4NI

The structure was partially determined by Wait and Powell (2) from a projection based on visually estimated photographic intensities of 57 independent *hk*0 reflections. The determination utilized the fact that the signs of the $F(hk0)$ were all determined by the contribution from the I atoms and were all positive. With I at 2(*a*) − 000 etc. and N at 2(*d*) − ½0¼ etc. of $I\bar{4}$ they obtained x = 0.633, y = −0.048 for C(1) and x = 0.558, y = −0.190 for C(2) (converted to the setting of Table 2). They did not determine z of either atom, their main concern being with the conformation of the cation skeleton, which they presumed could be derived without this information. The H atoms were not considered.

The present redetermination (Tables 1 and 2) confirms the general features of the structure as reported in ref. 2. However, the coordinates of C(2) given there appear to correspond to C(2) attached to C(1) ($\frac{1}{2} + y, \frac{1}{2} - x, \frac{1}{2} - z$) and not to C(1) with x, y, z of Table 2.

The overall arrangement is shown in Fig. 1. The cation/anion packing is of the 4:4 coordinated, zincblende[6] type, with the cation in an extended S_4 conformation[7] and with the $NC(1)_4$ tetrahedron slightly flattened along the S_4 axis, C(1)NC(1′) = 111.4° (cf. Table 3). Each of the five H atoms has a nearest I neighbour at a distance which ranges from 3.18 to 3.72 Å (Fig. 1). Two of these distances, H(11)···I(1, 0, 0) = 3.18(4) Å and H(22)···I($\frac{1}{2}, \frac{1}{2}, \frac{1}{2}$) = 3.24(4) Å, are slightly but not significantly shorter than the sum of the van der Waals radii, 3.35 Å. The closest H···H approach within the cation is H(11)···H(23) ($\frac{1}{2} + y; \frac{1}{2} - x; \frac{1}{2} - z$) = 2.07(8) Å, with H(11)···H(12) ($\frac{1}{2} - y; x - \frac{1}{2}; \frac{1}{2} - z$) = 2.37(8) Å next. The intercation H···H distances all exceed 2.4 Å, twice the van der Waals radius of the H atom.

$Ph_4PBr \cdot H_2O$

The positional parameters are listed in Table 4 and interatomic distances and bond angles in Table 5.

[1]Reference 1 is considered as Part 1.

[3]To whom correspondence may be addressed.

[4]We use the term "tetraradial" in preference to "tetrahedral", which has also other, quite different connotations.

[5]Much the same difficulty was experienced with Et_4NCl (3, 4). However, the crystal structure of Ph_4PBr was in the meantime determined by Alcock *et al.* (5), who were able to crystallize the anhydrous compounds from mixtures of MeOH and MeCN.

[6]Not wurtzite as stated in ref. 2.

[7]Taking the S_4 axis as the z axis, z(N) = 0, $|z[C(2)]| > |z[C(1)]|$.

[e]$I > 2\sigma(I)$.

The structure consists of Ph_4P^+ cations of symmetry C_1 and centrosymmetric cyclic $[Br^-{}_2(OH_2)_2]$ anions (Figs. 2 and 3), and as such it may be viewed as being of a distorted *anti*-CdI_2 packing type, $[Ph_4P^+]_2[Br_2(OH_2)_2]^{2-}$. Alternatively, if the H_2O molecule is disregarded, the packing may be described as a distorted *anti*-NiAs type arrangement, $Ph_4P^+Br^-$. The hydrogen bonding in the cyclic anion is discussed in more detail below.

Comparison of the $Ph_4P^+ \cdots Br^-$ geometry with that of the covalent Ph_4EX (E = Sb, Bi) species (cf. ref. 6) shows that the $P \cdots Br$ distance, 5.821(2) Å, is far in excess of the $Sb \cdots X \sim 3.3$ Å limit for pentacoordination (even though the C(21)PBr angle, 156°, is still acceptable for a distorted trigonal bipyramid with C(21) as the axial and C(11), C(31), and C(41) as the equatorial carbon atoms), and the means of the $C_{ax}PC_{eq}$ and $C_{eq}PC_{eq}$ angles, 110.1(15)° and 108.9(17)°, respectively, are statistically indistinguishable from each other and from the tetrahedral angle. There is thus no doubt that the crystal is ionic.

The internal CCC angles in the phenyl rings are all within 3 esd's of 120°. Specifically, the means of the C(6)C(1)C(2) and C(3)C(4)C(5) angles are 119.7(4)° and 120.0(5)°, respectively, indicating that within the accuracy of the structure determination the rings are undistorted by bonding to the P atom.

$Ph_4PBr \cdot 2H_2O$

The positional parameters are given in Table 6 and interatomic distances and bond angles in Table 7.

This orthorhombic structure also is ionic. The Ph_4P^+ cation is of symmetry C_s, with ring 2 perpendicular to and ring 3 in the mirror plane (Fig. 2). The Br atom is at an inversion centre and coordinated by four oxygens. The $Br^+ \cdots H_2O$ bonds connect the bromide ion and the water molecules to form almost planar infinite $[Br^-(OH_2)_{4/2}]_\infty$ anion chains $\| b$ (Fig. 3); the hydrogen bonding aspects of these chains are discussed below.

The cation/anion packing in the dihydrate is an orthorhombic distortion of the *anti*-NiAs packing if only the Ph_4P^+ and Br^- ions are considered. The $P \cdots Br$ separation, 6.233(3) Å, is 0.4 Å larger than in the monohydrate.

Comparison of $Ph_4PBr \cdot H_2O$ and $Ph_4PBr \cdot 2H_2O$

As is evident from Fig. 2, the two structures are very similar. The main difference is in the linking of the $[Br_2(OH_2)_2]^{2-}$ ions in the monohydrate by the additional water molecule to form the infinite $[Br^-(OH_2)_{4/2}]_\infty$ bands in the dihydrate. In the monohydrate the planes of the anion rings are all parallel, whereas in the dihydrate the orientations of the bands alternate. Similarly, in the monohydrate all the cations are related by parallel translations; in the dihydrate, the cation orientations alternate.

The relationship of the orthorhombic unit cell D of the dihydrate to the triclinic unit cell M of the monohydrate is illustrated in Fig. 2: $2M \rightarrow D$, $\boldsymbol{a}^D \rightarrow \boldsymbol{c}^M - \boldsymbol{a}^M$, $\boldsymbol{b}^D \rightarrow \boldsymbol{b}^M$, $\boldsymbol{c}^D \rightarrow \boldsymbol{c}^M + \boldsymbol{a}^M$. Conversely, M corresponds to a pseudo-hexagonal subcell H of D: $\boldsymbol{a}_1{}^H = \frac{1}{2}(\boldsymbol{c}^D + \boldsymbol{a}^D) \rightarrow \boldsymbol{c}^M$, $\boldsymbol{a}_2{}^H = \frac{1}{2}(\boldsymbol{c}^D - \boldsymbol{a}^D) \rightarrow \boldsymbol{a}^M$, $\boldsymbol{c}^H = \boldsymbol{b}^D \rightarrow \boldsymbol{b}^M$. To take account of the alternating orientations of the ions in the dihydrate in relation to the monohydrate structure, the symmetry of the dihydrate structure may be represented by the dichromatic group $62/448$, $Pn'ma' - Pnma|P2_1/m$, which relates to $P\bar{1}$ of the monohydrate via $P\bar{1} \subset P2_1/m$.

The phenyl rings in the two hydrates are planar to better than $\sigma = 0.005$ Å; ring 3 in the dihydrate is in a mirror plane and hence planar by symmetry. The conformations of the Ph_4P^+

Br	0618.7(5)	2444.7(5)	1223.1(5)	503
O	0676(4)	−0758(4)	1675(3)	768

cations in the two structures are closely similar (Fig. 2), the main difference being that rings 1 and 4 in the dihydrate are related by reflection whereas in the monohydrate they are not, and rings 2 and 3 in the dihydrate are mutually perpendicular whereas in the monohydrate they form an angle of 100°. The P atom is coplanar by symmetry with ring 3 of the dihydrate. In the other cases it is 0.26 Å or less out of the plane of the ring.

Hydrogen bonding

A centrosymmetric cyclic anion dimer of the type $[X_2^-(OH_2)_2]$ (X = Cl, Br), such as that present in the $Ph_4PBr\cdot H_2O$ structure, is not an unusual feature of low hydrates or organic onium halides (e.g. refs. 3, 7, 8), where it occasionally competes with helical or near-planar $[X^-(OH_2)_{2/2}]$ chains (8). However, the infinite flat $[Br^-(OH_2)_{4/2}]_\infty$ anion of $Ph_4PBr\cdot 2H_2O$ appears to be of a hitherto unreported type. It may be regarded (Fig. 3) as a superposition of two planar centrosymmetric zigzag

chains, ···Br···O(1)···Br···O(1)··· and ···Br···O(2)···Br···O(2)···, which share the Br atoms; the planes of the two chains form an angle of 11°. The symmetry of these flat bands is almost *pmam* and approaching *pmmm*. The oxygen atoms are located in mirror planes bisecting the HOH angles, so that the symmetry of the water molecules is C_{2v}. Although the H_w atoms have not been located with any accuracy, the BrOBr angles (Table 7) are close to the HOH angle in the free water molecule, which indicates that the O—H_w···Br^- bonds are practically linear.

The O···Br^- distances in both hydrates, between 3.40 and 3.57 Å (Tables 5 and 7), fall in the upper half of the O···Br range observed in hydrates, 3.25–3.58 Å (7–9), and well below the estimated cut-off O···Br distance, 3.92 Å, for O—H···Br interactions (9). The BrOBr angle in the cyclic $[Br_2^-(OH_2)_2]$ anion in the monohydrate is only 94.7°. Whether this rather small angle and the rather long O···Br^- distances are attributable to the bulkiness of the cation cannot be ascertained at present.

Ion packing in $R_4E^+X^-$ structures

Inspection of Fig. 2 reveals two conspicuous gross features present in both Ph_4PBr hydrate structures: the Br^- ions are situated in or close to the $10\bar{1}$ planes of the "orthohexagonal" cells[8] (or the 100 planes of the "hexagonal" cells, i.e. the tabulated triclinic cell M of the monohydrate and the pseudohexagonal subcell H of the dihydrate); and the cations are arranged in columns parallel to b and related, within each column, by inversion or by a 2_1 axis to form infinite cation helices. The $10\bar{1}$ planes confine the cation skeletons to parallel slabs, so that the two structures may be viewed as layer structures, the layers defining in a natural manner the pseudohexagonal cells. These features are strongly reminiscent of the structure of Ph_4SbBr (6), the covalent character of the Sb—Br bond in this compound notwithstanding, and in fact can be shown to be common to a whole family of onium salts and their pro-cation congeners.

In $R_4E^+X^-$ structures all the common AB packing types are represented (Table 8). The occurrence of planes occupied exclusively by anions (or the central atoms of anions) is a natural consequence of the zincblende, CsCl, NiAs, and *anti*-NiAs packing arrangements (Fig. 4). In the two last-named arrangements, which are based on the hexagonal aristotype symmetry $P6_3mc$, the anion planes are $||1\bar{1}00$ or (in *anti*-NiAs) $11\bar{2}0$; they correspond to the anion planes of the two Ph_4PBr hydrates, which accounts for the layer-like character of these structures. Although Ph_4SbBr ($P2_1/n$) is not ionic, the Br atoms (involved

[8]This is the $[\boldsymbol{c}^M - \boldsymbol{a}^M, \boldsymbol{b}^M, \boldsymbol{c}^M + \boldsymbol{a}^M]$ cell of the monohydrate and the D cell of the dihydrate. In the dihydrate the Br^- ions may be described as lying in the $10\bar{1}$ *or* the 101 planes of the D cell.

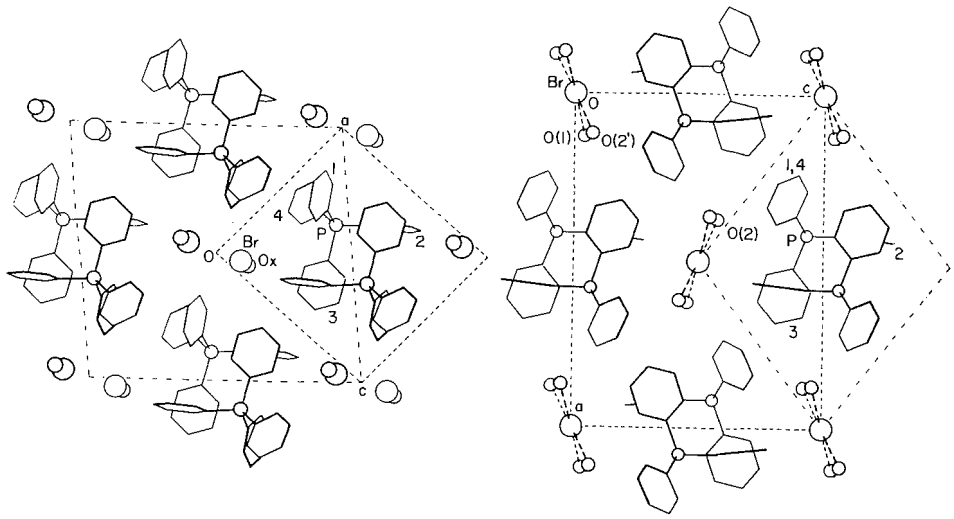

FIG. 2. Structures of the two hydrates of Ph_4PBr. The projections are oriented so as to display the matching features of the two structures. Broken lines, unit cell of Table 1; dash–dot lines, sub- or supercell related to the *anti*-NiAs or *anti*-CdI_2 packing (see text). (*Left*) $Ph_4PBr \cdot H_2O$: projection along *b* on (010). (*Right*) $Ph_4PBr \cdot 2H_2O$: projection on (010). Rings 1 and 4 are related by mirror planes at $y = \pm\frac{1}{4}$, ring 2 is perpendicular to (010), ring 3 is in the mirror plane at $y = \frac{1}{4}$.

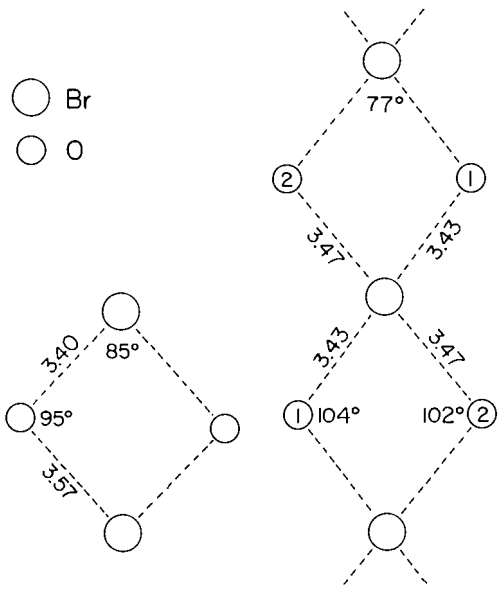

FIG. 3. Hydrogen bonding schemes in the two hydrates of Ph_4PBr. (*Left*) $Ph_4PBr \cdot H_2O$: isolated centrosymmetric $[Br_2(OH_2)_2]^{2-}$ rings. (*Right*) $Ph_4PBr \cdot 2H_2O$: almost planar infinite $[Br^-(OH_2)_{4/2}]_\infty$ anion chains parallel to *b*.

in long Sb—Br bonds) are located almost exactly in the $1\bar{1}00$ planes of the monoclinic, pseudohexagonal unit cell. These planes correspond to the $1\bar{1}00$ planes of the *anti*-NiAs structure and contain only the Br atoms (cf. Fig. 6 of ref. 6), in accord with the view (6) that the Ph_4SbBr structure represents a transitional stage between covalent and ionic R_4EX.

In the wurtzite-type packing ($P6_3mc \subset P6_3/mmc$) the anion planes ($11\bar{2}0$ or $|||100$) in addition accommodate all the cations (or the central atoms of the cations), so that this arrangement lacks the layer-like features. The Me_3SbX_2 ($P\bar{6}2c \subset P6_3/mmc$; X = Cl, Br, I) structure is quite similar in this respect if one allows for the covalent character of the Sb—X bonds (Fig. 4). It is interesting that in Ph_4SbCl (also a covalent structure, cf. ref. 6) the Cl atoms, compared with Ph_4SbBr, are considerably farther away from the $10\bar{1}$ planes of the monoclinic cell than the Br atoms in Ph_4SbBr. In this regard the Ph_4SbCl structure may be viewed as intermediate between the *anti*-NiAs and the wurtzite ion packing; it again represents a transitional stage between covalent and ionic R_4EX structures.

In zincblende-type ion packing in Et_4NI ($I\bar{4}$) and related structures (Table 8) may be compared with the *molecular* packings in, for example (10), $C(SMe)_4(I)$ ($P\bar{4}2_1c$) and $C(CH_2OH)_4$ ($I\bar{4}$). In all three cases the tetragonal bc unit cell can be transformed into a fc setting by a 45° rotation about a tetragonal axis and taking $a\sqrt{2}$ as the base edge of the fc unit cell. The structures can then be formulated as [A][B] = $[Et_4N^+][I^-]$, $[C(SMe)_4][\square]$ (no hydrogen bonding), and $[C(CH_2OH)_4][\square]$ (with intermolecular hydrogen bonding): the octahedral interstices in the fc sublattice of contacting A units are occupied by the smaller ion (I^-) in the case of Et_4NI or are vacant, as in the molecular crystals. The smaller ion thus constitutes "stuffing" in the A framework. The series may be completed by adding $LiNH_2 = [NH_2^-][Li^+]$ ($I\bar{4}$)[9] (10), which represents a reverse of the Et_4NI packing. This classification scheme can be extended to include a variety of other structures containing tetraradial units.

Conformation of the Et_4N^+ (= E) ion in crystals

The highest-symmetry skeletal conformation of $N[C(1)H_2C(2)H_3]_4^+$ not in severe conflict with H–H repulsions would be the flat form of D_{2d} ($z(N) = 0$, $z[C(1)] > 0$, $z[C(2)] \sim 0$; principal axis taken as the *z* axis), but this conformation has so far not been reported, nor has a D_{2d} site symmetry for the N atom of E. Site symmetries at N compatible with possible E geometries will be the subgroup symmetries of D_{2d}, viz. S_4, D_2, C_{2v}, C_2, C_s, and C_1. However, these site symmetries do not necessarily imply an unambiguously positioned single conformation, for they may represent volume- or time-averaged symmetries (or both) or two or more E conformations in orientational disorder. When the crystallographic site symmetry

[9]The $LiNH_2$ structure is related to the zincblende structure through $F\bar{4}2'm' - F\bar{4}2m|F\bar{4}$, $F\bar{4}2m \subset F\bar{4}3m$: $c \sim 2a$, upper and lower half of the unit cell each constitutes a tetragonally distorted ZnS cell.

is not a subgroup symmetry of D_{2d}, E at such sites is disordered of necessity.

The various observed conformational situations are listed in Table 9. I is seen that a site of S_4 symmetry occupied by a single, uniquely oriented E conformation of S_4 symmetry is found only in EI, although the single E(1) conformation in E_2SnCl_6, at a site of C_2 symmetry, simulates the S_4 symmetry quite closely. In both cases the conformation is of the extended[7] type, as it also is in E_2InCl_5 at the site of symmetry S_4, where an S_4 conformation can occur in either of two equivalent orientations differing in C(1) positions. The flat form deriving from D_{2d} is observed at C_{2v} sites, and D_2 is simulated by E(1) and E(2) in $ECl \cdot H_2O$, at sites of symmetries C_2 and C_1, respectively. The volume-averaged symmetry simulated at an N site can be as high as C_{4h}, D_{2d}, and D_{4h}, and the alternative orientations need not be populated equally (cf. Table 9). In an extreme case of orientational disorder, that in $E_2[W_2Ni_3(CO)_{16}]$ (48), no indication of the atoms of E was observed in electron-density maps, although here the presence of the heavy scatterer W may be partially to blame.

Clearly for a single, uniquely oriented E conformation to occur at a given E site the anion size and shape must not be conducive to producing, at that site, a potential that is flat or contains equivalent minima. The last-named requirement is likely to be in conflict with N being accommodated at special positions of high symmetry, which would explain why ordered single conformations, such as that observed in EI, occur relatively rarely.

Experimental

Material

Et_4NI. Commercial material (Aldrich) was recrystallized from water.

Ph_4PBr. Crystallization of Ph_4PBr from water is reported (49) to give $Ph_4PBr \cdot 2H_2O$, which can be completely dehydrated to a white powder by drying *in vacuo*; no other hydrate or solvate is mentioned in ref. 49. To obtain *crystals* of anhydrous Ph_4PBr, oven-dried commercial Ph_4PBr (Aldrich) was therefore dissolved in (*a*) absolute EtOH, (*b*) dried MeCN, (*c*) dried $MeNO_2$, and the solutions were allowed to crystallize at room temperature by evaporation through pinholes. The good-quality crystals from *a* were shown by structure analysis to be the dihydrate (see below). Solution *b* yielded finer, more powdery dihydrate, unsuitable for single-crystal diffraction. Crystallization from *c* began only when the solvent had almost completely evaporated (similar to *b*) and gave quite large, clear, colourless crystals which turned out to be the hitherto unreported $Ph_4PBr \cdot H_2O$; they did not appear to alter on standing in air. An attempt was therefore made to obtain crystals of the anhydrous salt by refluxing (Dean-Stark trap) the oven-dried commercial material in sodium-dried benzene and subsequent crystallization. However, the bromide did not dissolve in benzene even when the liquid was boiling. In yet another attempt a sample of the dried commercial material was dissolved in a hot mixture of dry acetone and benzene. Crystals separated this time from a *large* volume of solution, but they again proved to be the dihydrate. Finally, a sample was dehydrated in a container which was capped while hot and subsequently opened in a dry-box, the sample was dissolved in dried CH_2Cl_2, and the solution was transferred to a special glass apparatus where the solvent was distilled off slowly in a closed system until crystals appeared. A crystal, visually of very good quality, was mounted in a capillary in a dry-box but turned out to be the dihydrate. After these discouraging results further attempts to obtain crystals of the anhydrous bromide were abandoned.

Infrared spectrum of $Ph_4PBr \cdot 2H_2O$

To gain an idea of the behaviour of the two H_2O molecules in $Ph_4PBr \cdot 2H_2O$ we examined the room-temperature FT-ir spectra of the undeuterated and weakly deuterated compound. The undeuterated dihydrate has OH stretching absorptions at ~3560 (broad shoulder, probably accidental water), 3498(sh), 3473, 3450, and 3427 cm^{-1}, and HOH bending absorptions at 1631(sh) and 1616 cm^{-1}. Since in the spectrum of the weakly deuterated sample only two isotopically isolated ν(OD) absorptions appeared, at 2567.0 and 2550.9 cm^{-1} ($\langle\nu(OH)\rangle/\langle\nu(OD)\rangle$ = 1.353), in accord with the expectation for two nonequivalent H_2O molecules of symmetry C_{2v} (cf. refs. 9 and 50), the complexity of the ν(OH) absorption must be attributed to coupling of the two molecules in the flat $[Br^-(OH_2)_{4/2}]_\infty$ anion chains. The similarity in the hydrogen bonding of the two molecules (cf. Fig. 3) is confirmed by the small difference in the decoupled ν(OD) component frequencies, 16 cm^{-1}. This would correspond, on a rough estimate (9), to a difference of ca. 0.02 Å in the O···Br distances, which is of the same order of magnitude as the difference between the observed O···Br distances (Table 7), 0.04(1) Å. The ν(OD) values are practically the same as those in $SrBr_2 \cdot H_2O$ (51), and the ν(OH) frequencies in the undeuterated sample are similar to those in $SrBr_2 \cdot H_2O$ and $BaBr_2 \cdot H_2O$ at room temperature (51), and about 40 cm^{-1} higher than in $BaBr_2 \cdot 2H_2O$ (52).

Routine low-resolution ir spectra revealed small differences in the

δ(OH) absorption regions of the two hydrates which served for characterization in the preparative work.

Structure determination

The crystals were sealed in glass capillaries. A CAD-4 four-circle diffractometer (ω:2θ scans; 20°C) was used in the data acquisition. Lorentz, polarization, and empirical absorption corrections (53) were applied. Scattering factors for neutral or ionized atoms and corrections for anomalous scattering were taken from ref. 54. The structures were solved using the SHELX (55) and CRYSTALS (56) systems. After the nonhydrogen atoms had been located, full-matrix least-squares ($w\Delta|F| = \min.$) refinement was carried out with isotropic temperature factors until R was reduced to a reasonably low value. The hydrogen atoms were then placed, consistent with the difference maps, and the refinement was continued with anisotropic factors on the nonhydrogen atoms and isotropic factors on the hydrogens. The final difference maps were in all three cases featureless. The anisotropic temperature factor is defined as $T = \exp[-2\pi^2(U_{11}h^2a^{*2} + U_{22}k^2b^{*2} + U_{33}l^2c^{*2} + 2U_{23}klb^*c^* + 2U_{13}hla^*c^* + 2U_{12}hka^*b^*)]$.

Et_4NI. Systematic absences: hkl, $h + k + l$ odd. $R_{merg} = 7.2\%$. Iodine and N atoms placed as in ref. 2. A Fourier map phased with I^- and N revealed the positions of C(1) and C(2), and a difference map after anisotropic refinement of the I, N, and C atoms revealed the positions of the five H atoms. The CH_3 in the final refinement was free. The least-squares weights were $w = 0.0405/(\sigma^2|F| + 0.006F^2)$.

$Ph_4PBr \cdot H_2O$. Systematic absences, none. $R_{merg} = 2.4\%$. The Br and P atoms were located from a Patterson map. A Fourier map revealed the positions of the remaining nonhydrogen atoms. Of the 1860 unique reflections with $I > 3\sigma(I)$ thirteen suffered from extinction and were omitted from further refinement. The H atoms were observable in a difference map and were allowed to refine freely after placement. The least-squares weights were $w^{-1} = \sigma^2|F| + 0.01996F^2$.

$Ph_4PBr \cdot 2H_2O$. Systematic absences: $h00$ and $hk0$, h odd; $0k0$, k odd; $00l$, l odd; $0kl$, $k + l$ odd. $R_{merg} = 2.1\%$. The Br and P atoms were located from a Patterson map and the remaining nonhydrogen atoms from a Fourier map. Only one H_w on each oxygen could be located; the phenyl hydrogens were refined in one cycle and then fixed. Weighting scheme, $w^{-1} = \sigma^2|F| + 0.01F^2$.

Sulfonyl esters 1: The reduction of tribromophenyl sulfonates with mercaptide anions

KATHLEEN ANNE DURKIN, RICHARD FRANCIS LANGLER,[1] AND NANCY ANN MORRISON

Department of Chemistry, Florida Institute of Technology, Melbourne, FL 32901-6988, U.S.A.

Received April 29, 1988

KATHLEEN ANNE DURKIN, RICHARD FRANCIS LANGLER, and NANCY ANN MORRISON. Can. J. Chem. **66**, 3070 (1988).

2,4,6-Tribromophenyl sulfonates have been shown to undergo unusually efficient reduction by mercaptide anions in hexamethylphosphoramide. The reduction products include the sulfinate anion derived from the sulfonate ester and the disulfide derived from the mercaptide anions.

KATHLEEN ANNE DURKIN, RICHARD FRANCIS LANGLER et NANCY ANN MORRISON. Can. J. Chem. **66**, 3070 (1988).

On démontre que les anions mercaptures dans l'hexaméthylphosphoramide provoquent une réduction anormalement efficace des tribromo-2,4,6 sulfonates. Les produits de la réduction comprennent entre autres l'anion sulfinate qui dérive de l'ester sulfonate ainsi que le disulfure provenant des anions mercaptures.

Introduction

Recently, we have observed the sulfonyl transfer reaction shown in eq. [1].

[1] $$CF_3CH_2OSO_2CH_3 + PhCH_2SH \xrightarrow[CH_3OH]{CH_3ONa} CH_3OSO_2CH_3 \longrightarrow PhCH_2SCH_3$$ 27%

Methyl methanesulfonate is an intermediate in this reaction (1). Subsequently, a study of sulfonate esters as reagents for the one-pot condensation of mercaptans and alcohols to furnish sulfone precursors was initiated. Equation [2][2] presents one such reaction.

[2] $$PhOSO_2CH_3 + CH_3C_6H_4SH + CH_3CH_2OH \xrightarrow[HMPA]{NaH} CH_3C_6H_4SCH_2CH_3 \xrightarrow{m\text{CPBA}} CH_3C_6H_4SO_2CH_2CH_3$$ 58% (overall)

Equation [2] presents what has become our routine screening procedure for sulfonate esters, which might be successful in condensing alcohols with mercaptans.

Results and discussion

The first goal in this study was to improve the yield of *p*-tolyl ethyl sulfide (eq. [2]) by modification of the sulfonate ester structure. It seemed likely that the initial transesterification would produce the intermediate ethyl methanesulfonate more efficiently if the phenoxy group were replaced with a better leaving group. An obvious strategy would involve the introduction of electron-withdrawing groups onto the phenoxy phenyl ring. However, as shown in eq. [3], powerful electron-withdrawing groups attached to the phenoxy phenyl ring can promote preferential attack at a ring carbon, thereby suppressing the desired behaviour.

[3] $$O_2NC_6H_4OSO_2CH_3 + CH_3C_6H_4SH + CH_3CH_2OH \xrightarrow[HMPA]{NaH} CH_3C_6H_4SC_6H_4NO_2$$ 50%

$$CH_3C_6H_4SCH_2CH_3$$ 4%

A subsequent experiment examined a sulfonate ester in which the phenoxy ring substituents were somewhat less effective anion stabilizers, in an attempt to suppress nucleophilic attack at the ring carbon.

[4] $$CH_3C_6H_4SH + CH_3CH_2OH + Br_2C_6H_2OSO_2CH_3 \xrightarrow[HMPA]{NaH} (CH_3C_6H_4S)_2 + CH_3C_6H_4SCH_2CH_3$$ 63% 0%

The surprising result presented in eq. [4] (contrast with eqs. [2] and [3]) might be rationalized in the simple ionic terms shown in Scheme 1. While the second step in Scheme 1 invokes a well-documented reaction (2), the first step is questionable. It seems unlikely that such a modest change in sulfonate ester structure would so dramatically alter the propensity for a soft base (RS^-) to attack a hard acid site (sulfonyl sulfur).[3] Despite subsequent examination of a variety of sulfonate esters, the tribromophenoxy systems remain unique in their propensity for clean oxidation of mercaptide anions to disulfides.

Table 1 presents the results of a modest survey of mercaptan dimerization using 2,4,6-tribromophenyl methanesulfonate.

Another feature of the proposed overall transformation pictured in Scheme 1 is the formation of a sulfinate anion. To confirm the presence of methanesulfinate anions in our reaction mixtures, we have carried out the following trapping experiment.

Sulfinate anions may be generated by reduction of sulfonyl chlorides or by reaction of an organometallic reagent with SO_2

[5] $$CH_3C_6H_4SH + Br_2C_6H_2OSO_2CH_3 \text{ (1)} \xrightarrow[(2)\ PhCH_2Cl]{(1)\ NaH} PhCH_2SO_2CH_3$$ 32%

(6). Commonly, yields are moderate. Consequently, new and mild methodology for the preparation of sulfinate anions might be useful. Since sulfones have proven to be useful and versatile synthetic intermediates, particularly for the production of alkenes and dienes (see ref. 7 for some examples), a preliminary exploration of sulfone preparation via sulfinate anions generated from 2,4,6-tribromosulfonates seemed warranted.

Prior to initiating this series of reactions, we wished to simplify the work-up somewhat. Reactions carried out as outlined in eq. [5] afford substantial amounts of *p*-tolyl disulfide in crude products (see eq. [3] and Table 1). Disulfide isolated in the crude product requires larger chromatography columns to purify products, thereby wasting time and chemicals. After a few trials with thioglycolic acid, *o*-mercaptobenzoic acid, and 3-mercaptopropionic acid, the latter was selected as the routine reducing agent. Work-up is significantly simplified because product disulfide-diacid is conveniently removed by extraction with aqueous base. Equation [6] presents an example of this modified procedure.

[6] $HS(CH_2)_2CO_2H$ +  **2**

$$\xrightarrow[(2)\ CH_3I]{(1)\ NaH} PhSO_2CH_3 + [(HO_2C(CH_2)_2S)_2]$$

37%

Table 2 presents the results of our survey of some simple sulfone preparations using this procedure. Although the results in Table 2 might indicate some potential for useful methodology, it is clear that some questions need to be answered to determine whether further improvements can be expected.

The most interesting of these equations concerns the substituent effect exerted by the bromine atoms. *A priori*, two arguments seemed reasonable. Firstly, the *ortho* bromine atoms might crowd the sulfonate-bearing ring carbon, which would

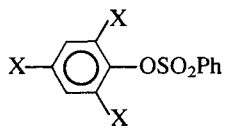
[a]Yield per step assuming a two-step synthesis. This yield is the average yield/step for the actual two-step synthesis, (*i*) sulfonate ester reduction and (*ii*) sulfinate anion alkyation. It also permits convenient comparison with the traditional two-step synthetic approach (*i*) mercaptan alkylation and (*ii*) sulfide oxidation.

[b]See ref. 4.

shift nucleophilic attack to sulfonyl sulfur, leading to disulfide via thiosulfonate intermediacy (vide Scheme 1). Alternatively, the halogens might lower the lowest unoccupied molecular orbital energy sufficiently to facilitate an electron transfer reaction. To distinguish between these possibilities, each of the sulfonate esters **3***a*–**3***c* have been subjected to the reaction conditions shown in eq. [6].



3*a* X = I
3*b* X = CH_3
3*c* X = Cl

The trimethyl system **3***b* gave no phenyl methyl sulfone, suggesting that steric effects do not play a dominant role in these reactions. In contrast, the trichloro ester **3***c* and the triiodo ester **3***a* were successfully transformed into phenyl methyl sulfone, albeit in somewhat poorer yields (32% and 24% respectively). An electron transfer mechanism appears to be a reasonable mechanistic possibility.

The most perplexing of the problems posed by the results disclosed thus far is this: how can the yields of the sulfones (see Table 2) be so much lower than the yields of the disulfides (see Table 1)? Since (*i*) the disulfides are formed in good to excellent yields and (*ii*) little or no starting sulfonate ester is recovered,[4] it seemed likely that near-complete reduction of the sulfonate esters (**1** or **2**) had occurred, producing sulfinate anions in good yield.

It was routine to observe a combined total of less than 10% of (*i*) the tribromophenyl ether derived from tribromophenoxide ions and the electrophile and (or) (*ii*) the disulfide-diester derived from 3-mercaptopropionic acid. Consequently, the eq. [6] reaction was repeated with twice as much electrophile, to ensure that fewer sulfinate anions would be left unreacted.

The results presented in eq. [7] suggest that there are significant amounts of tribromophenoxide ions and biscarboxylate dianions that do not react under normal reaction conditions. However, the eq. [7] sulfone yield (cf. 37% for eq. [6]) suggests that there is *not* a significant pool of unreacted sulfinate anions remaining at the end of a typical run.

The next point addressed was the possibility that there might have been significant air oxidation of sulfinate anions, which

[7] 
would consume our reagent and produce the corresponding sulfonate anions. The sulfonate anions would be much less nucleophilic[5] and would presumably go unreacted to be lost during the work-up. When carried out under an atmosphere of nitrogen, the eq. [6] reaction furnished the same sulfone yield.

Another possibility involves disproportionation of sulfinate anions as shown in eq. [8].

[8] $3PhSO_2^- \longrightarrow PhS^- + 2PhSO_3^-$

We decided to test for this possibility by using a trap that is specific for mercaptide anions. α-Chlorosulfones have long been known to be very resistant to nucleophilic displacement of chlorine (9). Mercaptide anions are unique in their propensity for accomplishing such substitutions (10). Phenyl mercaptide anions will react with our trap in HMPA, as shown below.

[9] $PhSNa + ClCH_2SO_2CH_3 \xrightarrow[HMPA]{\Delta} PhSCH_2SO_2CH_3$ 57%

The results of an attempt to trap a sulfinate-anion-derived disproportionation product are presented in eq. [10]. Given eqs. [9] and [10], there must be less than 2% disproportionation occurring *at elevated temperature* (100°C). Since these reactions are routinely carried out at ambient temperatures, it is very unlikely that disproportionation is a serious problem here.

[10] 
Since sulfinate anions are ambident nucleophiles, we have considered another potential complication in the preparation of sulfones using our scheme. If some sulfinate anions attack the

[4]Any sulfonate ester present in the reaction mixture can be isolated from HMPA nearly quantitatively by our work-up (1).

[5]Sulfonate anions do have some nucleophilicity (8).

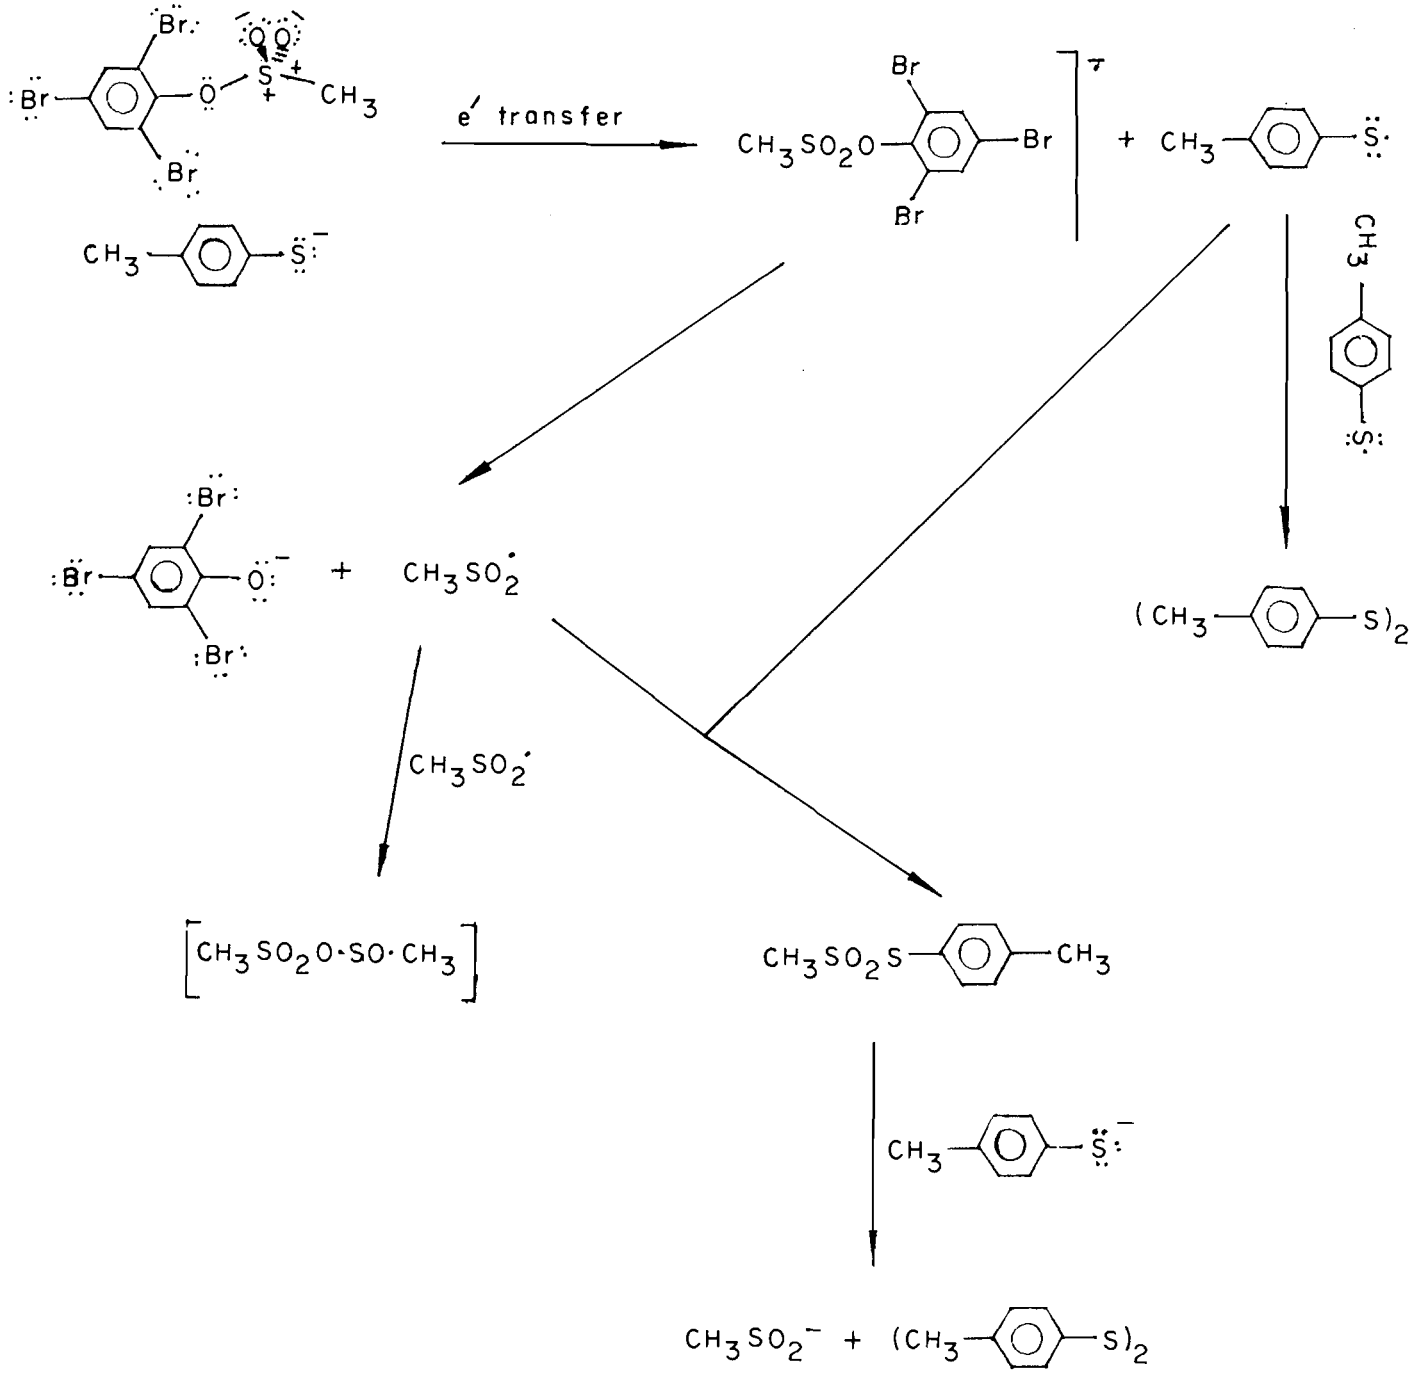

SCHEME 2

electrophile using oxygen rather than sulfur, the product mixture would include a sulfinate ester as well as a sulfone. The sulfinate ester might be hydrolyzed during work-up and lost in the aqueous phase during extraction. Both sulfone and sulfinate ester formation by sulfinate anion alkylation are well-known processes (ref. 3, p. 143). Nucleophilic attack by sulfur is apparently enhanced when reactions are conducted in hydroxylic solvents (11*a*).

The eq. [6] reaction has been repeated with a variation: immediately prior to the addition of methyl iodide, the reaction mixture (50 mL HMPA) was diluted with 10% water in isopropanol (100 mL). After the addition of methyl iodide, the usual work-up afforded phenyl methyl sulfone in 37% yield. Clearly, the hydroxylic solvents did not alter the outcome of the reaction.

If thiosulfonates are indeed principal intermediates in these reactions (see Scheme 1), they must be reduced by mercaptide anions to furnish substantially higher yields of disulfides than sulfinate anions. Experimental confirmation of this conclusion is shown by our results in eq. [11].

$$[11]\quad PhSO_2SPh \xrightarrow[(2)\ CH_3I]{(1)\ PhSNa/HMPA} \underset{57\%}{(PhS)_2} + \underset{30\%}{PhSO_2CH_3}$$

Assuming an electron transfer mechanism as suggested earlier, a reasonable fate for intermediate sulfonyl radicals would be formation of a sulfinate–sulfonate mixed anhydride. Sulfinate–sulfonate mixed anhydrides should not lead to sulfinate anions under our reaction conditions. Sucn anhydrides have been proposed for reactions involving sulfonyl radicals (11*b*,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 122.72.124.2 on 09/07/12
For personal use only.

11*c*). A complete pathway proposal that accounts for our results is presented in Scheme 2. Presumably, the sulfinate–sulfonate mixed anhydride (or products derived therefrom) would be smoothly hydrolyzed during work-up.

Experimental

General

The ir spectra were recorded on a Perkin–Elmer 237B grating spectrophotometer. Ultraviolet spectra were run on a Beckman DU-2 spectrophotometer. The nmr spectra were obtained on a Varian EM360A instrument using TMS as the internal standard. Melting points were determined on a Mel-Temp capillary melting-point apparatus and are uncorrected.

Preparation of p-*tolyl ethyl sulfone*

A solution of absolute ethanol (0.6317 g, 13.7 mmol) in HMPA (10 mL)[6] was added dropwise to a slurry of NaH (0.672 g, 28.0 mmol) in HMPA (30 mL). The mixture was stirred at ambient temperature for 20 min. A solution of *p*-tolyl mercaptan (1.707 g, 13.7 mmol) in HMPA (10 mL) was added dropwise over 15 min. Upon completion of the addition, the reaction mixture was stirred at ambient temperature to permit complete evolution of H_2. Phenyl methanesulfonate (2.377 g, 13.8 mmol) was added and the reaction mixture stirred at ambient temperature for 2 h.

The reaction mixture was poured into a 2-L Erlenmeyer containing water (400 mL), 10% HCl (5 mL), and diethyl ether (150 mL). The mixture was vigorously shaken and transferred to a separatory funnel. The layers were separated and the aqueous layer washed with diethyl ether (two 100-mL portions).

The combined organic layers were concentrated and the residue poured into a 2-L Erlenmeyer containing water (100 mL) and diethyl ether (100 mL). The layers were separated, the aqueous washed with diethyl ether (two 100-mL portions), and the combined ether layers washed with 2.5% NaOH (100 mL).

The crude product (*p*-tolyl ethyl sulfide) was dissolved in chloroform (100 mL) and the reaction mixture cooled with an ice/water bath. *m*CPBA (85%, 8.500 g) was added in small portions over 2 h. The reaction was permitted to return to ambient temperature while stirring overnight. Chloroform (100 mL) was added and the resultant solution washed with 2.5% NaOH (100-mL aliquots) until the aqueous pH remained basic. The organic layer was dried ($MgSO_4$) and concentrated.

The crude was chromatographed on silica gel (200 g) employing 1:1 methylene chloride/carbon tetrachloride elution (100-mL fractions). Fractions 19–38 were combined and concentrated, affording clean *p*-tolyl ethyl sulfone (1.468 g, 8.08 mmol, 58%), which was identical with authentic material by ir, nmr and double-spotted tlc.

Attempted condensation of p-*tolyl mercaptan and ethanol using* p-*nitrophenyl methanesulfonate*

Sodium hydride (0.678 g, 28.2 mmol), absolute ethanol (0.630 g, 13.7 mmol), *p*-tolyl mercaptan (1.729 g, 13.9 mmol), and *p*-nitrophenyl methanesulfonate (3.001 g, 13.8 mmol) were reacted in hexamethylphosphoramide as described under Preparation of *p*-tolyl ethyl sulfone. The crude product obtained by ether extraction was chromatographed on silica gel (200 g). Thirty fractions (100 mL each) of hexanes followed by 10 fractions of chloroform (100 mL each) were collected.

Fractions 9 and 10 were combined and concentrated, affording *p*-tolyl disulfide (0.048 g, 0.19 mmol). Fractions 12 and 13 were combined and concentrated, yielding clean *p*-tolyl ethyl sulfide (0.070 g, 0.46 mmol).

Fractions 28–35 were combined and concentrated, affording *p*-nitrophenyl *p*-tolyl sulfide (1.307 g, 5.3 mmol, 50%). The nitrosulfide was recrystallized from methanol. It had mp 78–80°C; R_f 0.41 (carbon tetrachloride development); ir ($CHCl_3$): 1520 and 1340 cm^{-1}; uv (CH_3OH): 223(ε 13 706), 257 (s, ε 4826), and 340 nm (ε 13 513); nmr ($CDCl_3$) δ: 8.03 (2H,d), 7.30 (6H,m), and 2.40 (3H,s). *Anal.* calcd. for $C_{13}H_{11}N_2S$: C 63.65, H 4.51; found: C 63.93, H 34.38.

Preparation of 2,4,6-trisubstituted phenyl sulfonates ***1***, ***2***, ***3***a *and* ***3***b

2,4,6-Trisubstituted phenol (15.2 mmol) was dissolved in dry pyridine (25 mL) and triethyl amine (15.2 mmol). The reaction mixture was cooled with an ice/water bath and the appropriate sulfonyl chloride (15 mmol) added dropwise over 5 min. The ice/water bath was removed and the reaction mixture stirred at ambient temperature for 1 h.

Water (50 mL) was added and the resultant mixture washed with chloroform (three 50-mL aliquots). The combined organic layers were extracted with 2.5% HCl (100-mL aliquots) until the aqueous pH remained acidic. The organic layer was dried and concentrated. The residue was recrystallized from methanol.

Recrystallized $Br_3PhOSO_2CH_3$ **1** (62%, mp 80–81°C) had ir ($CHCl_3$): 1385 and 1185 cm^{-1}: nmr ($CDCl_3$) δ: 3.50 (3H,s) and 7.73 (2H,s). *Anal.* calcd. for $C_7H_5Br_3O_3S$: C 20.56, H 1.23; found: C 20.66, H 1.16.

Recrystallized Br_3PhOSO_2Ph **2** (50%,[7] 85.7–86.6°C) had ir ($CHCl_3$): 1190 and 1390 cm^{-1}; nmr ($CDCl_3$) δ: 8.06 (2H,m) and 7.70 (3H,m); ms *m/e*: 474 (1.1%), 472 (3.4%), 470 (3.3%), 468 (1.1%), 141 (12%), and 77 (100%). *Anal.* calcd. for $C_{12}H_7Br_3O_3S$: C 30.60, H 1.49; found: C 30.60, H 1.29.

Recrystallizeed I_3PhOSO_2Ph ***3a*** (44%, mp 120.1–126.6°C) had ir (KBr); 1380 and 1180 cm^{-1}; nmr (DMSO-d_6) δ: 8.20 (2H,s) and 7.80 (5H,m); ms *m/e*: M^+ 612 (95%), 471 (100%), and 77 (77%). *Anal.* calcd. for $C_{12}H_7I_3O_3S$: C 23.55, H 1.15; found: C 23.64, H 1.03.

Crude $(CH_3)_3PhOSO_2Ph$ ***3b*** (5.009 g) was chromatographed on silica gel (400 g) employing 3:2 carbon tetrachloride/methylene chloride (100-mL fractions) for elution. Fractions 13–18 were combined and concentrated, affording clean trimethyl sulfonate ***3b*** (3.206 g, 58%). Recrystallized ***3b*** had mp 48.7–49.6°C; ir ($CHCl_3$): 1370 and 1175 cm^{-1}; nmr ($CDCl_3$) δ: 8.00 (2H,m), 7.65 (3H,m), 6.80 (2H,s), 2.26 (3H,s), and 2.06 (6H,s); ms *m/e*: M^+ 276 (9.8%) and 135 (100%). *Anal.* calcd. for $C_{15}H_{16}O_3S$: C 65.19, H 5.83; found: C 65.47, H 5.85.

Preparation of 2,4,6-trichlorophenyl benzenesulfonate ***3***c

Sodium metal (1.167 g, 50.7 mmol) was dissolved in methanol (250 mL). 2,4,6-Trichlorophenol (10.000 g, 51.0 mmol) was added and the methanol completely evaporated. Acetone (250 mL) was added to the residue. Benzenesulfonyl chloride (9.068 g, 51.5 mmol) was added dropwise to the solution. The reaction mixture was stirred at ambient temperature for 19 h. Chloroform (300 mL) was added and the resultant solution washed with 2.5% sodium hydroxide (100 mL). The organic layer was dried ($MgSO_4$) and concentrated. The residue was recrystallized, affording clean trichlorosulfonate ***3c*** (11.773 g, 69%, mp 64.9–65.8°C). The trichlorosulfonate had ir ($CHCl_3$): 1390 and 1190 cm^{-1}; nmr ($CDCl_3$) δ: 8.00 (2H,m), 7.65 (3H.m), and 7.30 (2H,s). *Anal.* calcd. for $C_{12}H_7Cl_3O_3S$: C 42.69, H 2.08; found: C 42.66, H 1.92.

Reaction of mercaptans with 2,4,6-tribromophenyl methanesulfonate ***1***

The conversion of benzenethiol into diphenyl disulfide will be used to illustrate the procedure that furnished the results in Table 1.

Benzenethiol (1.34 g, 12.1 mmol) in HMPA was added dropwise to a suspension of sodium hydride (0.296 g) in HMPA (25 mL). Upon completion of the addition, the reaction mixture was stirred for 5 min to permit complete evolution of H_2. The tribromomesylate (2.512 g, 6.1 mmol) was added and the reaction mixture stirred at ambient temperature for 0.5 h. The reaction mixture, initially opaque, became a pale yellow homogeneous solution within a minute after adding the mesylate.

The crude was obtained by the same extraction procedure described under "Preparation of *p*-tolyl ethyl sulfone". The crude was crystalline diphenyl disulfide (1.34 g, 6.1 mmol, 100%). After recrystallization

[6]HMPA is hexamethylphosphoramide $[(CH_3)_2N]_3PO$. HMPA is toxic and carcinogenic.

[7]Yield includes second crop.

from methanol, the product was shown to be identical to authentic disulfide by mp, mixture mp, tlc, and nmr.

*Reduction of tribromosulfonate **1** with* p*-tolyl mercaptide anions*

A solution of *p*-tolyl mercaptan (4.064 g, 32.7 mmol) in HMPA (10 mL) was added dropwise to a suspension of sodium hydride (0.842 g, 35.1 mmol) in HMPA (30 mL). Upon completion of the addition, the reaction mixture was stirred at ambient temperature for 35 min. The tribromosulfonate **1** (6.552 g, 16.0 mmol) was added and the reaction mixture stirred at room temperature for 1 h. Benzyl chloride (2.078 g, 15.8 mmol) was added dropwise and the reaction mixture stirred at room temperature for 60 h.

The reaction mixture was poured into a 2-L Erlenmeyer containing water (400 mL), 10% HCl (5 mL), and diethyl ether (100 mL). The mixture was vigorously shaken and transferred to a separatory funnel. The layers were separated and the aqueous washed with ether (two 100-mL portions). The combined ether layers were concentrated and poured into water (100 mL). The mixture was washed with diethyl ether (three 100-mL aliquots). The combined organic layers were washed with 2.5% sodium hydroxide (100 mL), dried ($MgSO_4$), and concentrated, affording crude product (5.364 g).

Half of the crude was chromatographed on silica gel (268 g) employing chloroform elution (100-mL fractions). Fractions 13–19 were combined and concentrated, yielding clean benzyl methyl sulfone (0.440 g, 2.58 mmol, overall yield 32.6%). The chromatographed sulfone was recrystallized from methanol and shown to be identical to authentic material by nmr, double-spotted tlc, melting point, and mixture mp.

One-pot sulfone preparations

The conversion of benzyl chloride into benzyl phenyl sulfone will be used to illustrate the procedure that furnished the results presented in Table 2.

A solution of 3-mercaptopropionic acid (0.934 g, 8.8 mmol) in HMPA (10 mL) was added dropwise to a suspension of sodium hydride (0.432 g, 18.0 mmol) in HMPA (30 mL). Upon completion of the addition, the reaction mixture was stirred at ambient temperature for 0.5 h. The tribromosulfonate **2** (2.037 g, 4.3 mmol) was added and the reaction mixture stirred at ambient temperature for 1 h. A solution of benzyl chloride (0.590 g, 4.6 mmol) in HMPA (10 mL) was added dropwise and the reaction mixture stirred at room temperature for 18 h.

Crude product (0.911 g) was obtained using the extraction procedure outlined under "Reduction of tribromosulfonate **1** with *p*-tolyl mercaptide anions". The crude was chromatographed on silica gel (91 g) employing 3:2 carbon tetrachloride/methylene chloride (90-mL fractions). Fractions 7–16 were combined and concentrated, yielding benzyl phenyl sulfone (0.576 g, 2.5 mmol, 57%). Recrystallized product was shown to be identical to authentic material by double-spotted tlc, nmr, mp, and mixture mp.

Preparation of 2,4,6-tribromophenyl methyl ether

A solution of 2,4,6-tribromophenol (1.023 g, 3.09 mmol) in HMPA (25 mL) was added dropwise to a slurry of sodium hydride (0.053 g, 2.21 mmol) in HMPA (15 mL). The reaction mixture was stirred at ambient temperature for 1 h. A solution of methyl iodide (0.325 g, 2.29 mmol) in HMPA (10 mL) was added dropwise to the reaction mixture.

Crude ether (0.6006 g) was obtained using the extraction procedure outlined under "Reduction of tribromosulfonate **1** with *p*-tolyl mercaptide anions." Crude tribromoether was recrystallized from methanol, affording clean ether (0.464 g, 1.34 mmol, 58.5%). The clean ether had mp 87.2–88°C; nmr ($CDCl_3$) δ: 7.66 (2H,s), and 3.85 (3H,s). *Anal.* calcd. for $C_7H_5Br_3O$: C 24.38, H 1.46; found: C 24.59, H 1.44.

Preparation of $(CH_3O_2C(CH_2)_2S)_2$

Sodium metal (2.076 g, 90.2 mmol) was dissolved in methanol (100 mL). A solution of 3-mercaptopropionic acid (4.467 g, 42.1 mmol) in methanol (10 mL) was added dropwise to the reaction mixture. Upon completion of the addition, the reaction mixture was stirred at ambient temperature for 0.5 h. Iodine (5.390 g, 21.2 mmol) was added and the reaction mixture stirred for 10 min. Concentrated sulfuric acid (2.4 mL) was added and the reaction mixture refluxed for 16 h.

The reaction mixture was diluted with chloroform (300 mL) and the resultant solution washed with 2% sodium thiosulfate (100-mL aliquots) until the organic layer became colorless. The organic layer was dried ($MgSO_4$) and concentrated. The residue was rectified at reduced pressure, affording homogeneous disulfide-diester (3.253 g, 13.6 mmol, 64.6%, 134°C/6.5 Torr; 1 Torr = 133.3 Pa). The diester-disulfide had ir ($CHCl_3$); 1740 cm^{-1}; nmr ($CDCl_3$) δ: 3.70 (3H,s), 2.93 (2H,t), and 2.73 (2H,t). *Anal.* calcd. for $C_8H_{14}O_4S_2$: C 40.31, H 5.92; found: C 40.33, H 6.08.

Preparation of phenyl methyl sulfone with excess methyl iodide

A solution of 3-mercaptopropionic acid (1.379 g, 13.0 mmol) in HMPA (10 mL) was added dropwise to a suspension of sodium hydride (0.652 g, 27.1 mmol) in HMPA (30 mL). The reaction mixture was then stirred at room temperature for 0.5 h. The tribromophenyl benzenesulfonate **2** (3.080 g, 6.5 mmol) was added and the reaction mixture stirred for 1 h. A solution of methyl iodide (1.868 g, 13.1 mmol) in HMPA (10 mL) was added dropwise and the reaction mixture stirred overnight.

Crude product (1.629 g) was obtained by employing the extraction procedure outlined under "Reduction of tribromosulfonate **1** with *p*-tolyl mercaptide anions". The crude was recrystallized from methanol. affording clean 2,4,6-tribromophenyl methyl ether (0.351 g). The mother liquor concentrate was chromatographed on silica gel (118 g) employing 3:2 carbon tetrachloride/methylene chloride elution (30 100-mL fractions). Fraction 3 was concentrated, yielding more 2,4,6-tribromophenyl methyl ether (0.157 g). After recrystallization, the tribromophenyl methyl ether (total yield 23%) was shown to be identical to authentic material by nmr, double-spotted tlc, mp, and mixture mp. Fractions 21–36 were concentrated and combined, affording a mixture (0.675 g) that contained phenyl methyl sulfone (0.383 g, 2.45 mmol, 38%) and $(CH_3O_2C(CH_2)_2S)_2$ (0.292 g, 1.22 mmol, 18.7%). The composition of the mixture was determined by nmr using the procedure previously described (12). The identity of the components in the mixture was confirmed by double-spotted tlc and by the addition of authentic samples of each, which caused increases in the intensity of the appropriate nmr signals.

Preparation of $PhSCH_2SO_2CH_3$

A solution of thiophenol (0.473 g, 4.3 mmol) in HMPA (15 mL) was added dropwise to a suspension of NaH (0.101 g, 4.2 mmol) in HMPA (15 mL) over 15 min. The reaction mixture was stirred at ambient temperature for 30 min. A solution of 1-chloro-2-thiapropane-2,2-dioxide (13) (0.509 g, 3.9 mmol) in HMPA (10 mL) was added dropwise to the reaction mixture. The reaction mixture was heated at 100°C for 1.5 h.

Crude product (0.552 g) was obtained with the extraction procedure outlined under "Reduction of tribromosulfonate **1** with *p*-tolyl mercaptide anions". The crude was chromatographed on silica gel (55 g) using chloroform elution (50-mL fractions). Fractions 6–11 were concentrated and combined, affording clean $PhSCH_2SO_2CH_3$ (0.462 g, 2.3 mmd. 57.5%). Upon recrystallization, the product was shown to be identical to authentic sulfone-sulfide (9) by mp, mixture mp, nmr, and double-spotted tlc.

Preparation of $PhSO_2CH_2SO_2CH_3$

A solution of $CH_3SO_2CH_2SPh$ (0.507 g, 2.5 mmol) in chloroform (50 mL) was cooled with an ice/water bath. *m*-Chloroperoxybenzoic acid (1.122 g, 85%) was added in small portions over 15 min. The ice/water bath was removed and the reaction stirred at ambient temperature overnight.

Chloroform (200 mL) was added and the resultant solution washed with 2.5% sodium hydroxide solution (100-mL aliquots) until the aqueous pH remained basic. The organic layer was dried ($MgSO_4$) and concentrated. The crude disulfone (0.316 g) was recrystallized from methanol, affording clean disulfone (0.234 g, 1.0 mmol, 40%), mp 140–143°C. The disulfone had ir ($CHCl_3$): 1340 and 1145 cm^{-1}; nmr ($CDCl_3$) δ: 8.00 (2H,m), 7.70 (3H,m), 4.60 (2H,s), and 3.30 (3H,s);

ms *m/e*: 234 (2.5%), 125 (19.5%), 107 (92%), and 77 (100%). *Anal.* calcd. for $C_8H_{10}O_4S_2$: C 41.01, H 4.30: found C 41.14, H 4.30.

Trapping a disproportionation product

A solution of 3-mercaptopropionic acid (1.884 g, 17.7 mmol) in HMPA (10 mL) was added dropwise to a suspension of sodium hydride (0.792 g, 33.0 mmol) in HMPA (30 mL). The reaction mixture was stirred at ambient temperature for 0.5 h. The tribromobenzenesulfonate **2** (4.049 g, 8.6 mmol) was added and the reaction mixture stirred at ambient temperature for 1 h. A solution of $ClCH_2SO_2CH_3$ (1.120 g, 8.7 mmol) in HMPA (15 mL) was added. The reaction mixture was heated at 90°C for 1.5 h.

Crude product (0.364 g) was obtained by employing the extraction procedure outlined under "Reduction of tribromosulfonate **1** With *p*-tolyl mercaptide anions". The crude was chromatographed on silica gel (25 g) employing chloroform elution (25-mL fractions). Fractions 6 and 7 were combined and concentrated, affording impure sulfone-sulfide (0.055 g). The impure sample contained $PhSCH_2SO_2CH_3$ (0.013 g) and $ClCH_2SO_2CH_3$ (0.042 g) as established by nmr using our previously described procedure (12).

The sulfone-sulfide was converted to disulfone to facilitate removal of the contaminating chlorosulfone. Impure sulfone-sulfide (0.041 g) was dissolved in chloroform (6.5 mL) and cooled with an ice/water bath. *m*-Chloroperoxybenzoic acid (85%, 0.211 g) was added and the reaction mixture stirred overnight.

After base washing, the dried layer was concentrated and chromatographed on silica gel (50 g) employing chloroform elution (50-mL aliquots). Fractions 10–13 were concentrated, combined (0.018 g), and rechromatographed on silica gel (100 g) employing chloroform elution (50-mL fractions). Fractions 25–28 were concentrated and combined, yielding clean $PhSO_2CH_2SO_2CH_3$ (0.012 g, 0.05 mmol). This material was identical to that described in the previous experiment by nmr, ir, mp, and mixture mp.

Reduction of benzenethiosulfonate with phenyl mercaptide anions

A solution of benzene thiol (0.895 g, 8.1 mmol) in HMPA (10 mL) was added dropwise to a slurry of sodium hydride (0.219 g, 9.1 mmol) in HMPA (20 mL) over 10 min. The reaction mixture was stirred at ambient temperature for 1 h. Benzenethiosulfonate (2.030 g, 8.1 mmol) was added and the reaction mixture stirred at room temperature for 1 h. A solution of methyl iodide (1.173 g) in HMPA (10 mL) was added dropwise over 5 min. The reaction mixture was stirred at ambient temperature for 18 h.

Crude product (2.092 g) was obtained using the extraction procedure outlined under "Reduction of tribromosulfonate **1** With *p*-tolyl mercaptide anions". The crude was chromatographed on silica gel (209 g) employing 3:2 carbon tetrachloride methylene chloride (31 100-mL fractions) followed by chloroform (100-mL fractions). Fractions 5–8 were combined and concentrated, yielding diphenyl disulfide (0.504 g, 2.3 mmol, 56.9%). Fractions 9–12 furnished unchanged thiosulfonate (0.073 g). Fractions 27–37 were combined and concentrated, affording phenyl methyl sulfone (0.382 g, 2.4 mmol, 30.1%), which was identical to authentic material by nmr, tlc, and mp.

Received November 25, 1987[1]

This paper is dedicated to Professor C. A. McDowell on the occasion of his 70th birthday

HIROKAZU SAKAMOTO, TAKEJI TAKUI, and KOICHI ITOH. Can. J. Chem. **66**, 3077 (1988).

A theory is presented for the sideband structure produced by a general multiple-modulation scheme with arbitrary combination of p-tuple field modulation, q-tuple frequency modulation, and r-tuple amplitude modulation for integral p, q, and r. A general formula describing the multiple-modulation effects is analytically derived using a density matrix formalism under the assumption of negligible saturation; an equivalent result is obtained from the phenomenological Bloch equation. The general formula reveals that field and frequency modulations are equivalent for the sideband production, even in the presence of amplitude modulation. Two particular cases, viz., r-tuple amplitude modulation and double field modulation are dealt with to show the validity and applicability of the general formula.

HIROKAZU SAKAMOTO, TAKEJI TAKUI et KOICHI ITOH. Can. J. Chem. **66**, 3077 (1988).

On présente une théorie pour la structure de bande secondaire produite par un schéma de modulation multiple générale avec une combinaison arbitraire de modulation de champ p-tuple, de modulation de fréquence q-tuple et un modulation d'amplitude r-tuple pour des valeurs entières de p, q et r. On a déduit une formule générale qui décrit les effets de modulation multiple en faisant appel a un formalisme de matrice dense et en supposant une saturation négligeable; on obtient un résultat équivalent à partir de l'équation phénoménologique de Bloch. La formule générale révèle que les modulations de champ et de fréquence sont équivalentes en ce qui a trait à la production de la bande secondaire, même en présence d'une modulation d'amplitude. On a envisagé deux cas particuliers, par exemple la modulation d'amplitude de r-tuple et la modulation de champ double, dans le but de démontrer la validité et l'applicabilité de la formule générale.

[Traduit par la revue]

I. Introduction

Modulation is one of the most useful techniques for improving sensitivity in various branches of spectroscopy. As a time-dependent perturbation to a physical system, modulation is also useful for examining dynamical features of the system, e.g., molecular spin dynamics. It is well known that when a modulation frequency is larger than a spectral linewidth sidebands generally appear. Karplus was the first to propose a quantum mechanical modulation theory for sideband production (1); he treated Stark effect in microwave spectroscopy using a density matrix formalism. This theory has been extended by Smaller to the case of Zeeman modulation in NMR (2), and was later generalized by Macomber and Waugh to cover a wide range of phenomena (3).

Anderson (4) and Haworth and Richards (5) have attempted another approach using the phenomenological Bloch equation for spin systems under the influence of either field or frequency modulation, and they have shown the equivalence of sideband structures induced by the two modulation schemes. Later, Kim (6) re-examined this problem using a density operator method and concluded that field modulation led to the same sideband structure as predicted previously from the Bloch equation (4, 5) while frequency modulation did not. Subsequently, Dulčić ans Rakvin (7) have claimed the equivalence of the two modulations and have pointed out that the answer to the controversy is to be found in the understanding of the detection scheme.

On the other hand, Miyagawa *et al.* (8) have demonstrated that field modulation is an excellent technique for the accurate measurement of the amplitude of a radio-frequency (rf) field applied to a sample in electron–nuclear double resonance (ENDOR) experiments, and they have developed a methodology of the measurement using a first-order time-dependent perturbation theory for isolated spins.

All the theoretical treatments above have been limited to the single modulation. Islam and Miyagawa have recently extended their theory to double-modulation schemes (9); they also obtained the equivalent sideband structures produced by field and frequency modulations. We have independently made a preliminary report on a general theory of sideband production by multiple modulation in magnetic resonance, and have demonstrated, as one of its potential applications, simultaneous measurements of two rf amplitudes at a sample site in electron–nuclear–nuclear triple resonance (TRIPLE) experiments (10). On the experimental side, Ravkin *et al.* (11) have recently reported a new double-modulation spectroscopic technique, observing sharp sidebands with a linewidth equivalent to the individual spin-packet from an inhomogeneously broadened ESR line; this methodology was also applied to the investigation of rotational motions of nitroxide spin-labeled polymers (12).

In this paper we extend the density matrix formalism for a single modulation scheme (6, 13) to the case of simultaneous application of field, frequency, and amplitude modulations, presenting a general theory which interprets multiple-modulation effects on magnetic resonance. It is shown that both the density matrix formalism and the phenomenological Bloch equations predict identical multiple-modulation effects if thermal equilibrium is maintained. The equivalence of field and frequency modulations is re-examined from the view point of general multiple modulation including amplitude modulation. The general formula derived here may serve as a basis for application of multiple modulation to possible new spectroscopic techniques as well

as to available spectroscopies, since it has no restriction on the number of modulations or on the types of modulation schemes. Experimental examinations of the theoretical predictions will be presented in a later paper.

II. General expression for sideband production by multiple modulation

A. Modulation fields

To describe a general scheme of multiple modulation, we introduce simultaneous application of three types of modulations: the p-tuple field modulation with the frequencies of ω_1^1 to ω_1^p, the q-tuple frequency modulation with those of ω_2^1 to ω_2^q, and the r-tuple amplitude modulation with those of ω_3^1 to ω_3^r, as defined by the formula

$$[1]\quad \boldsymbol{H}'(t) = H'\left[\boldsymbol{x}\left(1 + \sum_{\gamma=1}^{r} \Omega_3^\gamma \cos \omega_3^\gamma t\right) \cos\left\{\omega t - \sum_{\beta=1}^{q} (\Omega_2^\beta/\omega_2^\beta) \sin \omega_2^\beta t\right\} + \boldsymbol{y}\left(1 + \sum_{\gamma=1}^{r} \Omega_3^\gamma \cos \omega_3^\gamma t\right) \times \sin\left\{\omega t - \sum_{\beta=1}^{q} (\Omega_2^\beta/\omega_2^\beta) \sin \omega_2^\beta t\right\}\right] + \boldsymbol{z}\left(\sum_{\alpha=1}^{p} H_1^\alpha \cos \omega_1^\alpha t\right)$$

Here, the field modulation is applied to a static magnetic field taken to be along the z axis, while the frequency and amplitude modulations to a radiation field (for magnetic resonance) which is rotating in the xy plane with the amplitude H' and the frequency ω; H_1^α denotes the amplitude of the α-th field modulation, Ω_2^β a deviation of the β-th frequency modulation, and Ω_3^γ a degree of the γ-th amplitude modulation. It should be mentioned here that the phases of all these modulations can be neglected, since they have no influence on the sideband structure in our phenomenological treatment. Expressions including the phases and their effects are described in the Appendix.

B. Density matrix approach

We follow the density matrix formalism developed by Abragam (13) for a system with a "simple line" and consider a spin system with a Hamiltonian $\hbar\mathcal{H}_0$ which is not only free from interactions with other spin systems but also weakly coupled to a heat bath (lattice), and to which an rf perturbation $\hbar\mathcal{H}'(t)$ with a frequency ω is applied. Assuming that a pair of its unperturbed states $|a\rangle$ and $|b\rangle$ coupled by $\hbar\mathcal{H}'(t)$ has an energy difference ω_{ab} which is different from any other energy difference $\omega_{\alpha\beta}$ such that $|\omega_{ab} - \omega_{\alpha\beta}| \gg \omega - \omega_{ab}|$ and $|\mathcal{H}'(t)|$, and that the correlation time τ_c of the spin system is short enough to satisfy $|\mathcal{H}'(t)|\tau_c \ll 1$, we can write the equation for the density matrix $\rho(t)$ of this system as

$$[2]\quad d\rho/dt = -i[\mathcal{H}_0 + \mathcal{H}'(t), \rho(t)] - \Gamma(\rho - \rho_{eq})$$

Here, ρ_{eq} is the density matrix of the spin system in thermal equilibrium at a temperature T before the application of the perturbation, and is given by

$$[3]\quad \rho_{eq} = \exp(-\hbar\mathcal{H}_0/kT)/\mathrm{Tr}\,[\exp(-\hbar\mathcal{H}_0/kT)] \sim [1 - \hbar\mathcal{H}_0/kT]/A = 1/A - q\mathcal{H}_0$$

in the high temperature approximation ($kT \gg \hbar\mathcal{H}_0$). Here A is the number of degrees of freedom of the spin system and $q = (\hbar/kT)/A$. The term $-\Gamma(\rho - \rho_{eq})$ in eq. [2], which represents a relaxation of the spin system, is given by

$$[4]\quad [-\Gamma(\rho - \rho_{eq})]_{ab} = -\rho_{ab}/(T_2)_{ab}$$

for a simple line corresponding to the $|a\rangle \leftrightarrow |b\rangle$ transition. Here $(T_2)_{ab}$ stands for the transverse relaxation time characteristic of this transition (13).

When the radiation field given by eq. [1] is applied to the spin system, the time-dependent perturbation $\hbar\mathcal{H}'(t)$ can be written

$$[5]\quad \mathcal{H}'(t) = \left(1 + \sum_{\gamma} \Omega_3^\gamma \cos \omega_3^\gamma t\right)\left[D^- \exp\left[i\left\{\omega t - \sum_{\beta} (\Omega_2^\beta/\omega_2^\beta) \sin \omega_2^\beta t\right\}\right] + D^+ \exp\left[-i\left\{\omega t - \sum_{\beta} (\Omega_2^\beta/\omega_2^\beta) \sin \omega_2^\beta t\right\}\right]\right] + \sum_{\alpha} [F_\alpha \exp(i\omega_1^\alpha t) + F_\alpha^+ \exp(-i\omega_1^\alpha t)]$$

where we define

$$[6]\quad \begin{aligned} &S_\pm = S_x \pm iS_y \\ &D^- = -\gamma_e H' S_-/2,\ D^+ = -\gamma_e H' S_+/2,\ F_\alpha = F_\alpha^+ = -\gamma_e H_1^\alpha S_z/2 \end{aligned}$$

with the abbreviation

$$[7]\quad \langle b|D^-|a\rangle = \langle a|D^+|b\rangle^* = d$$

We introduce a reduced density matrix $\sigma(t) = \rho(t) - \rho_{eq}$ and consider the case where the rf power is low enough so that the two diagonal matrix elements ρ_{aa} and ρ_{bb} have their thermal equilibrium values. Then the departures from these values, σ_{aa} and σ_{bb}, vanish, and eq. [2] can be reduced to the following differential equation for the off-diagonal element σ_{ba} using eqs. [3]–[7]:

$$[8]\quad d\sigma_{ba}/dt + \left[-i\left(\omega_0 + \sum_{\alpha} \Omega_1^\alpha \cos \omega_1^\alpha t\right) + 1/T_2\right]\sigma_{ba} = iq\, d\omega_0\left(1 + \sum_{\gamma} \Omega_3^\gamma \cos \omega_3^\gamma t\right) \exp\left[i\left\{\omega t - \sum_{\beta} (\Omega_2^\beta/\omega_2^\beta) \sin \omega_2^\beta t\right\}\right]$$

where $\omega_0 = -\gamma_e H_0$, $\Omega_1^\alpha = -\gamma_e H_1^\alpha$, and $T_2 = (T_2)_{ab}$. We now look for the solution for eq. [8] of the following form

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 122.72.124.2 on 09/07/12

$$[9]\quad \sigma_{ba}(t) = Z(t)\exp\left[i\left\{\omega t + \sum_{\alpha}(\Omega_1^{\alpha}/\omega_1^{\alpha})\sin\omega_1^{\alpha}t\right\}\right]$$

The substitution of eq. [9] into eq. [8] yields the transformed differential equation for $Z(t)$

$$[10]\quad dZ/dt + [i(\omega - \omega_0) + 1/T_2]Z = iq\,d\omega_0\left(1 + \sum_{\gamma}\Omega_3^{\gamma}\cos\omega_3^{\gamma}t\right)\exp\left[-i\left\{\sum_{\alpha}(\Omega_1^{\alpha}/\omega_1^{\alpha})\sin\omega_1^{\alpha}t + \sum_{\beta}(\Omega_2^{\beta}/\omega_2^{\beta})\sin\omega_2^{\beta}t\right\}\right]$$

This equation can be analytically solved to give

$$[11]\quad \sigma_{ba}(t) = (q\,d\omega_0 T_2)\exp(i\omega t)\sum{}'\prod_{\alpha}J_{n_\alpha}(\Omega_1^{\alpha}/\omega_1^{\alpha})\prod_{\alpha'}J_{n_{\alpha'}}(\Omega_1^{\alpha'}/\omega_1^{\alpha'})\prod_{\beta}J_{k_\beta}(\Omega_2^{\beta}/\omega_2^{\beta})$$
$$\times\left\{\frac{\left(\omega - \omega_0 - \sum_{\alpha}n_\alpha\omega_1^{\alpha} - \sum_{\beta}k_\beta\omega_2^{\beta}\right)T_2 + i}{1 + \left(\omega - \omega_0 - \sum_{\alpha}n_\alpha\omega_1^{\alpha} - \sum_{\beta}k_\beta\omega_2^{\beta}\right)^2 T_2^2}\exp\left[i\left(\sum_{\alpha'}n_{\alpha'}\omega_1^{\alpha'} - \sum_{\alpha}n_\alpha\omega_1^{\alpha} - \sum_{\beta}k_\beta\omega_2^{\beta}\right)t\right] + \sum_{j=\pm1}\sum_{\gamma}\frac{\Omega_3^{\gamma}}{2}\right.$$
$$\left.\times\frac{\left(\omega - \omega_0 - \sum_{\alpha}n_\alpha\omega_1^{\alpha} - \sum_{\beta}k_\beta\omega_2^{\beta} - j\omega_3^{\gamma}\right)T_2 + i}{1 + \left(\omega - \omega_0 - \sum_{\alpha}n_\alpha\omega_1^{\alpha} - \sum_{\beta}k_\beta\omega_2^{\beta} - j\omega_3^{\gamma}\right)^2 T_2^2}\exp\left[i\left(\sum_{\alpha'}n_{\alpha'}\omega_1^{\alpha'} - \sum_{\alpha}n_\alpha\omega_1^{\alpha} - \sum_{\beta}k_\beta\omega_2^{\beta} - j\omega_3^{\gamma}\right)t\right]\right\}$$

where $J_{n_\alpha}(\Omega_1^{\alpha}/\omega_1^{\alpha})$, $J_{n_{\alpha'}}(\Omega_1^{\alpha'}/\omega_1^{\alpha'})$, and $J_{k_\beta}(\Omega_2^{\beta}/\omega_2^{\beta})$ are the Bessel functions of the first kind and Σ' denotes the summation over three indices n_α, $n_{\alpha'}$, and k_β from $-\infty$ to ∞. Here α and α' are integers ranging from 1 to p, β runs over the integral values from 1 to q, and γ over those from 1 to r, where p, q, and r denote the number of the field, frequency, and amplitude modulations, respectively.

Equation [11] is the general formula for an ensemble of mutually-noninteracting spin systems in the presence of the multiple-modulation fields simultaneously applied; this describes sideband structures induced by arbitrary combinations of multiple modulations. Naturally, eq. [11] contains the terms corresponding to the various combination bands characterized by

$$\sum_{\alpha}n_\alpha\omega_1^{\alpha},\ \sum_{\beta}k_\beta\omega_2^{\beta},\quad \text{and}\quad \pm\omega_3^{\gamma}$$

whose intensity distributions can be predicted through the Bessel functions using the experimentally-given modulation indices, $\Omega_1^{\alpha}/\omega_1^{\alpha}$, $\Omega_2^{\beta}/\omega_2^{\beta}$, etc.

C. The Bloch equation approach

We now describe the behavior of magnetization of an ensemble of spin systems in the presence of multiple-modulation fields in terms of the phenomenological Bloch equation

$$[12]\quad \frac{d\boldsymbol{M}}{dt} = \gamma_e(\boldsymbol{M}\wedge\boldsymbol{H}) - \frac{M_x\boldsymbol{i} + M_y\boldsymbol{j}}{T_2} - \frac{M_z - M_0}{T_1}\boldsymbol{k}$$

which is referred to the laboratory frame defined by the unit vectors, $\boldsymbol{i}$, $\boldsymbol{j}$, and $\boldsymbol{k}$. The resultant magnetic field $\boldsymbol{H}$ is given by

$$[13]\quad \boldsymbol{H} = \boldsymbol{H}_0 + \boldsymbol{H}'(t) = H_0\boldsymbol{k} + \boldsymbol{H}'(t)$$

where $\boldsymbol{H}_0$ is the static magnetic field applied along $\boldsymbol{k}(\|z)$ and $\boldsymbol{H}'(t)$ is the time-dependent radiation field given by eq. [1].

Substituting eqs. [1] and [13] into [12], we obtain the components of the Bloch equation for the magnetization:

$$[14]\quad dM_x/dt = \gamma_e\left[M_y\left(H_0 + \sum_{\alpha}H_1^{\alpha}\cos\omega_1^{\alpha}t\right) - M_zH'\left(1 + \sum_{\gamma}\Omega_3^{\gamma}\cos\omega_3^{\gamma}t\right)\sin\left\{\omega t - \sum_{\beta}(\Omega_2^{\beta}/\omega_2^{\beta})\sin\omega_2^{\beta}t\right\}\right] - M_x/T_2$$

$$[15]\quad dM_y/dt = \gamma_e\left[M_zH'\left(1 + \sum_{\gamma}\Omega_3^{\gamma}\cos\omega_3^{\gamma}t\right)\cos\left\{\omega t - \sum_{\beta}(\Omega_2^{\beta}/\omega_2^{\beta})\sin\omega_2^{\beta}t\right\} - M_x\left(H_0 + \sum_{\alpha}H_1^{\alpha}\cos\omega_1^{\alpha}t\right)\right] - M_y/T_2$$

$$[16]\quad dM_z/dt = \gamma_e\left[M_xH'\left(1 + \sum_{\gamma}\Omega_3^{\gamma}\cos\omega_3^{\gamma}t\right)\sin\left\{\omega t - \sum_{\beta}(\Omega_2^{\beta}/\omega_2^{\beta})\sin\omega_2^{\beta}t\right\}\right.$$
$$\left. - M_yH'\left(1 + \sum_{\gamma}\Omega_3^{\gamma}\cos\omega_3^{\gamma}t\right)\cos\left\{\omega t - \sum_{\beta}(\Omega_2^{\beta}/\omega_2^{\beta})\sin\omega_2^{\beta}t\right\}\right] - (M_z - M_0)/T_1$$

where M_0 denotes the magnetization in thermal equilibrium, T_1 the longitudinal relaxation time, and T_2 the transverse relaxation time. From eqs. [14] and [15], we obtain the differential equation for the transverse magnetization $M_+ = M_x + iM_y$,

$$[17]\quad dM_+/dt + \left[-i\left(\omega_0 + \sum_{\alpha}\Omega_1^{\alpha}\cos\omega_1^{\alpha}t\right) + 1/T_2\right]M_+ = i\gamma_eH'\left(1 + \sum_{\gamma}\Omega_3^{\gamma}\cos\omega_3^{\gamma}t\right)M_z\exp\left[i\left\{\omega t - \sum_{\beta}(\Omega_2^{\beta}/\omega_2^{\beta})\sin\omega_2^{\beta}t\right\}\right]$$

where $\omega_0 = -\gamma_e H_0$. For a sufficiently small radiation field satisfying $|\gamma_e H'| \ll 1/T_1$, viz., for negligible saturation, we may replace M_z by M_0 in eq. [17]. Equation [17] is then mathematically equivalent to eq. [8] derived in the preceding section except for the multiplying constant factor on the right-hand side. Therefore, under negligible saturation the solution for the Bloch equation should have the same form as that for eq. [11] derived by the density matrix formalism.

III. Effect of amplitude modulation on the equivalence of field and frequency modulations

It is widely known that in the absence of frequency modulation the transverse magnetization is written, in terms of the rotating frame with an rf frequency ω, as $M_x + iM_y = (\tilde{M}_x + i\tilde{M}_y)\exp(i\omega t)$. Radio frequency detection is normally carried out with reference to an rf voltage proportional to $\exp(i\omega t)$ which is supplied either as a permanent leakage voltage from the driving rf field when the rf bridge, the cross-coil system, or the resonant cavity is unbalanced, or as a reference voltage with a well-defined phase when the bridge or its equivalent is completely balanced. The stationary components $\tilde{M}_x$ and $-(\gamma_e/|\gamma_e|)\tilde{M}_y$ then give the dispersion and absorption modes, respectively. Analogously, in the presence of amplitude and frequency modulations, the rf-detected signal is given by the stationary components with reference to the *amplitude- and frequency-modulated* rf voltage which is in this case the driving rf field. Since we have shown in the preceding section that $\sigma_{ba}(t)$ is mathematically equivalent to $M_+ = M_x + iM_y$ for negligible saturation, we can write the rf-detected signal as

$$[18]\quad \tilde{\sigma}_{ba}(t) = \sigma_{ba}\left\{1 + \sum_{j=\pm1}\sum_{\gamma}\frac{\Omega_3^\gamma}{2}\exp[i(-j\omega_3^\gamma)t]\right\}\exp\left[-i\left\{\omega t - \sum_{\beta}(\Omega_2^\beta/\omega_2^\beta)\sin\omega_2^\beta t\right\}\right]$$

Using eqs. [11] and [18], and the identity

$$[19]\quad \exp(i\omega t) = \exp\left[i\left\{\omega t - \sum_{\beta}(\Omega_2^\beta/\omega_2^\beta)\sin\omega_2^\beta t\right\}\right]\sum_{k_\beta}\prod_{\beta}J_{k_\beta}(\Omega_2^\beta/\omega_2^\beta)\exp(ik_\beta\omega_2^\beta t)$$

we obtain as the stationary component of the reduced density matrix corresponding to $\tilde{M}_x$ and $-(\gamma_e/|\gamma_e|)\tilde{M}_y$

$$\begin{aligned}[20]\quad \tilde{\sigma}_{ba}(t) = (q\,d\omega_0 T_2)&\left\{1 + \sum_{j=\pm1}\sum_{\gamma}\frac{\Omega_3^\gamma}{2}\exp[i(-j\omega_3^\gamma)t]\right\}\sum{}'\prod_{\alpha}J_{n_\alpha}(\Omega_1^\alpha/\omega_1^\alpha)\prod_{\alpha'}J_{n_{\alpha'}}(\Omega_1^{\alpha'}/\omega_1^{\alpha'})\prod_{\beta}J_{k_\beta}(\Omega_2^\beta/\omega_2^\beta)\prod_{\beta'}J_{k_{\beta'}}(\Omega_2^{\beta'}/\omega_2^{\beta'})\\
&\times\left\{\frac{\left(\omega-\omega_0-\sum_\alpha n_\alpha\omega_1^\alpha-\sum_\beta k_\beta\omega_2^\beta\right)T_2+i}{1+\left(\omega-\omega_0-\sum_\alpha n_\alpha\omega_1^\alpha-\sum_\beta k_\beta\omega_2^\beta\right)^2T_2^2}\exp\left[i\left(\sum_{\alpha'}n_{\alpha'}\omega_1^{\alpha'}-\sum_\alpha n_\alpha\omega_1^\alpha+\sum_{\beta'}k_{\beta'}\omega_2^{\beta'}-\sum_\beta k_\beta\omega_2^\beta\right)t\right]\right.\\
&+\sum_{j=\pm1}\sum_\gamma\frac{\Omega_3^\gamma}{2}\frac{\left(\omega-\omega_0-\sum_\alpha n_\alpha\omega_1^\alpha-\sum_\beta k_\beta\omega_2^\beta-j\omega_3^\gamma\right)T_2+i}{1+\left(\omega-\omega_0-\sum_\alpha n_\alpha\omega_1^\alpha-\sum_\beta k_\beta\omega_2^\beta-j\omega_3^\gamma\right)^2T_2^2}\\
&\left.\times\exp\left[i\left(\sum_{\alpha'}n_{\alpha'}\omega_1^{\alpha'}-\sum_\alpha n_\alpha\omega_1^\alpha+\sum_{\beta'}k_{\beta'}\omega_2^{\beta'}-\sum_\beta k_\beta\omega_2^\beta-j\omega_3^\gamma\right)t\right]\right\}\end{aligned}$$

where Σ' now denotes the summation over the indices n_α, $n_{\alpha'}$, k_β, and $k_{\beta'}$ ($\alpha, \alpha' = 1, 2, \ldots, p$; $\beta, \beta' = 1, 2, \ldots, q$) from $-\infty$ to ∞. The real and imaginary parts of $\tilde{\sigma}_{ba}(t)$ correspond to the dispersion and absorption modes, respectively.[2] They contain a.c. components which are further phase-sensitively detected with reference to the modulation frequencies or to their harmonics, yielding sideband structures. The d.c. component also yields different sideband structures.

Equation [20] shows that the effects of the field and frequency modulations appear equivalently not only in the first term in the parentheses of the right-hand side but also in the second term which arises from the amplitude modulation. Thus the problem of their equivalence mentioned before can be answered in a more generalized way: *for sideband production, the field and frequency modulations are equivalent even in the presence of amplitude modulation.*

IV. Special cases of multiple modulation

It can be shown that the general expression eq. [11], or equivalently eq. [20], completely reproduces the formulas reported so far by several authors (4–9, 11). We deal with two particular cases here as applications of the general formula of multiple-modulation effects.

A. Multiple amplitude modulation

This modulation scheme has not been studied so far. Ignoring other modulation effects in eq. [20], we find for the rf-detected signal due to the r-tuple amplitude modulation with the frequencies ω_3^γ ($\gamma = 1, 2, \ldots, r$)

[2]"Dispersion" and "absorption" modes indicate here the phase relation on the rf-detection and do not mean the lineshapes characteristic of the original Bloch equation.

$$[21]\quad \bar{\sigma}_{ba}(t) = (q\,\mathrm{d}\omega_0 T_2)\left\{1 + \sum_{j=\pm 1}\sum_{\gamma}\frac{\Omega_3^{\gamma}}{2}\exp\left[i(-j\omega_3^{\gamma})t\right]\right\}\left\{\frac{(\omega-\omega_0)T_2 + i}{1+(\omega-\omega_0)^2T_2^2} + \sum_{j=\pm 1}\sum_{\gamma}\frac{\Omega_3^{\gamma}}{2}\frac{(\omega-\omega_0-j\omega_3^{\gamma})T_2 + i}{1+(\omega-\omega_0-j\omega_3^{\gamma})^2T_2^2}\exp\left[i(-j\omega_3^{\gamma})t\right]\right\}$$

The sideband structure observed after the phase-sensitive detection at ω_3^{γ} is given by the coefficient of $\exp(\pm i\omega_3^{\gamma}t)$ including the phase where the real and imaginary parts correspond, respectively, to the dispersion and absorption modes. Thus eq. [21] shows that the sideband is composed solely of the two first bands at $\omega_0 \pm \omega_3^{\gamma}$ for each γ in addition to the center band at ω_0. Furthermore, their intensity is simply proportional to the degree Ω_3^{γ} of the γ-th amplitude modulation. These simple modulation effects contrast with those of the field modulation and/or frequency modulation in which various overtones and/or combination bands with complex intensities appear in the sideband structures. In view of the complexity resulting from other modulation schemes the multiple amplitude modulation has its own right because of its extreme simplicity. An application of this modulation scheme will be presented elsewhere.

B. Double field modulation

For this modulation scheme eq. [20] reduces to

$$[22]\quad \bar{\sigma}_{ba}(t) = (q\,\mathrm{d}\omega_0 T_2)\sum{}'\, J_{n_1}(\Omega_1/\omega_1)J_{n_2}(\Omega_2/\omega_2)J_{n_1'}(\Omega_1/\omega_1)J_{n_2'}(\Omega_2/\omega_2)\,\frac{(\omega-\omega_0-n_1\omega_1-n_2\omega_2)T_2 + i}{1+(\omega-\omega_0-n_1\omega_1-n_2\omega_2)^2T_2^2} \times \exp\left[i(n_1'\omega_1 + n_2'\omega_2 - n_1\omega_1 - n_2\omega_2)t\right]$$

where Σ' denotes the summation over the indices n_1, n_1', n_2, and n_2' from $-\infty$ to ∞. For brevity, we use Ω_α and ω_α instead of Ω_1^α and ω_1^α in eq. [20], neglecting the subscript for field modulation. Evidently, sideband structures produced by the double field modulation are much more complex than those by single field modulation as shown in eq. [22] which involves a linear combination of the products of the four Bessel functions.

If the absorption mode is selected for the rf-detection, the detected signal is given by the imaginary part of eq. [22]:

$$[23]\quad I_m[\bar{\sigma}_{ba}(t)] = (q\,\mathrm{d}\omega_0 T_2)\sum{}'\, J_{n_1}(\beta_1)J_{n_1'}(\beta_1)J_{n_2}(\beta_2)J_{n_2'}(\beta_2)\rho(\omega-\omega_0-n_1\omega_1-n_2\omega_2)[\cos\{(n_1'-n_1)\omega_1 + (n_2'-n_2)\omega_2\}t + T_2(\omega-\omega_0-n_1\omega_1-n_2\omega_2)\sin\{(n_1'-n_1)\omega_1 + (n_2'-n_2)\omega_2\}t]$$

where $\beta_1 = \Omega_1/\omega_1$, $\beta_2 = \Omega_2/\omega_2$, and $\rho(x) = (1 + x^2T_2^2)^{-1}$. Equation [23] derived as a special case agrees, except for the symbols and the trivial proportional constants, with eq. [61] in ref. 9 and eq. [1] in ref. 11 which have been derived by Miyagawa *et al.* for double field modulation using the first-order time-dependent perturbation theory.

One of the potential applications of the sideband production by the double field modulation is to measure simultaneously accurate amplitudes of two different rf radiation fields in TRIPLE experiments, in which measurement of the rf field strengths at the same site is important for studying spin dynamics. Although the basic principle of the measurement is an extension of that in ENDOR experiments proposed by Miyagawa *et al.* (8, 9) the complete analysis of the double field modulation effect and the sideband structure is much more complicated. Details of the analysis and the experimental examination will be published shortly.

V. Conclusion

A general description of multiple modulation in terms of the density matrix and the phenomenological Bloch equation has led to the general formula predicting the multiple-modulation effects and the sideband structure in the case of negligible saturation. This formula reveals, as an answer to the controversy reported previously (6, 7), that for sideband production the field and frequency modulations are equivalent even in the presence of the amplitude modulation. It is shown that multiple amplitude modulation produces far simpler sideband structures than any other modulation scheme. Application to the double field modulation has led to the formula equivalent to those derived previously by the time-dependent perturbation theory (9, 11).

Appendix

In order to perform the general treatment of modulation, one should take into account the phases of its individual frequency components, since these phases do not generally coincide. Introduction of the phases, however, does not affect the discussion in the text. Hence, we have omitted them to simplify the expressions. In this Appendix, we make a brief comment on their role in multiple modulation.

If we introduce the phases θ_1^α, θ_2^β, and θ_3^γ, respectively, for the field, frequency, and amplitude modulations. Equations [1] and [8] are rewritten as

$$[A1]\quad \boldsymbol{H}'(t) = H'\left[\boldsymbol{x}\left\{1 + \sum_{\gamma=1}^{r} \Omega_3^\gamma \cos(\omega_3^\gamma t + \theta_3^\gamma)\right\} \cos\left\{\omega t - \sum_{\beta=1}^{q} (\Omega_2^\beta/\omega_2^\beta) \sin(\omega_2^\beta t + \theta_2^\beta)\right\}\right.$$
$$\left. + \boldsymbol{y}\left\{1 + \sum_{\gamma=1}^{r} \Omega_3^\gamma \cos(\omega_3^\gamma t + \theta_3^\gamma)\right\} \sin\left\{\omega t - \sum_{\beta=1}^{q} (\Omega_2^\beta/\omega_2^\beta) \sin(\omega_2^\beta t + \theta_2^\beta)\right\}\right] + \boldsymbol{z}\left\{\sum_{\alpha=1}^{p} H_1^\alpha \cos(\omega_1^\alpha t + \theta_1^\alpha)\right\}$$

$$[A2]\quad \mathrm{d}\sigma_{ba}/\mathrm{d}t + \left[-i\left\{\omega_0 + \sum_{\alpha} \Omega_1^\alpha \cos(\omega_1^\alpha t + \theta_1^\alpha)\right\} + 1/T_2\right]\sigma_{ba} = iq\,\mathrm{d}\omega_0\left[1 + \sum_{\gamma} \Omega_3^\gamma \cos(\omega_3^\gamma t + \theta_3^\gamma)\right]$$
$$\times \exp\left[i\left\{\omega t - \sum_{\beta} (\Omega_2^\beta/\omega_2^\beta) \sin(\omega_2^\beta t + \theta_2^\beta)\right\}\right]$$

The Bloch equation equivalent to eq. [A2] can be derived by the same procedure as in the text. Equation [A2] can also be analytically solved to give

$$[A3]\quad \sigma_{ba}(t) = (q\,\mathrm{d}\omega_0 T_2)\exp(i\omega t)\sum{}' \prod_{\alpha} J_{n_\alpha}(\Omega_1^\alpha/\omega_1^\alpha) \prod_{\alpha'} J_{n_{\alpha'}}(\Omega_1^{\alpha'}/\omega_1^{\alpha'}) \prod_{\beta} J_{k_\beta}(\Omega_2^\beta/\omega_2^\beta)$$
$$\times \left\{\frac{\left(\omega - \omega_0 - \sum_{\alpha} n_\alpha\omega_1^\alpha - \sum_{\beta} k_\beta\omega_2^\beta\right)T_2 + i}{1 + \left(\omega - \omega_0 - \sum_{\alpha} n_\alpha\omega_1^\alpha - \sum_{\beta} k_\beta\omega_2^\beta\right)^2 T_2^2} \exp\left[i\left\{\left(\sum_{\alpha'} n_{\alpha'}\omega_1^{\alpha'} - \sum_{\alpha} n_\alpha\omega_1^\alpha - \sum_{\beta} k_\beta\omega_2^\beta\right)t\right.\right.\right.$$
$$\left.\left.\left. + \left(\sum_{\alpha'} n_{\alpha'}\theta_1^{\alpha'} - \sum_{\alpha} n_\alpha\theta_1^\alpha - \sum_{\beta} k_\beta\theta_2^\beta\right)\right\}\right] + \sum_{j=+1} \sum_{\gamma} \frac{\Omega_3^\gamma}{2} \frac{\left(\omega - \omega_0 - \sum_{\alpha} n_\alpha\omega_1^\alpha - \sum_{\beta} k_\beta\omega_2^\beta - j\omega_3^\gamma\right)T_2 + i}{1 + \left(\omega - \omega_0 - \sum_{\alpha} n_\alpha\omega_1^\alpha - \sum_{\beta} k_\beta\omega_2^\beta - j\omega_3^\gamma\right)^2 T_2^2}$$
$$\times \exp\left[i\left\{\left(\sum_{\alpha'} n_{\alpha'}\omega_1^{\alpha'} - \sum_{\alpha} n_\alpha\omega_1^\alpha - \sum_{\beta} k_\beta\omega_2^\beta - j\omega_3^\gamma\right)t + \left(\sum_{\alpha'} n_{\alpha'}\theta_1^{\alpha'} - \sum_{\alpha} n_\alpha\theta_1^\alpha - \sum_{\beta} k_\beta\theta_2^\beta - j\theta_3^\gamma\right)\right\}\right]\Bigg\}$$

Equation [A3] is the most general expression for σ_{ba} because of the inclusion of the modulation phases. It can be seen that the phases appear in the form of $\exp i[\Omega(n_\alpha, n_{\alpha'}, k_\beta, j)t + \Phi(n_\alpha, n_{\alpha'}, k_\beta, j)]$, viz., they contribute only to the total phase shift Φ added to the periodic time-dependent term Ωt in the exponent. Suppose we make a phase-sensitive detection with reference to a particular frequency component $\Omega(n_\alpha, n_{\alpha'}, k_\beta, j) = \Omega_0$. The observed sideband then consists of the lines arising from all the terms with Ω_0 in eq. [A3]. These terms, however, have the same total phase shift because the coefficients of θ_1^α, θ_2^β, and θ_3^γ are identical with those of ω_1^α, ω_2^β, and ω_3^γ, respectively. Therefore, the role of the phases in multiple modulation is simply to change the optimum condition of phase adjustment in phase-sensitive detection of a sideband spectrum as in the case of single modulation.

Molecular recognition. VIII.[1] The binding of the β-D-galactopyranosyl residue of the Lewis b human blood group determinant by the lectin IV of *Griffonia simplicifolia* and by a monoclonal anti-Lewis b antibody. Evidence for intramolecular hydrogen bonding

RAYMOND U. LEMIEUX,[2] RÉMY CROMER,[3] AND ULRIKE SPOHR[4]

Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received May 25, 1988

RAYMOND U. LEMIEUX, RÉMY CROMER, and ULRIKE SPOHR. Can. J. Chem. **66**, 3083 (1988).

The 3b-deoxy, 4b-deoxy, 6b-deoxy, 6b-deoxy-6b-fluoro, 6b-chloro-6b-deoxy, and the 5b-des-hydroxymethyl derivatives of the Lewis b (αLFuc^d(1→2)βDGal^b(1→3)[αLFuc^c(1→4)]βDGlcNAc^a-OMe) human blood group determinant were synthesized in order to examine the involvement of the βDGal b unit in the binding of the Le^b-OMe tetrasaccharide both by the lectin IV of *Griffonia simplicifolia* and a hybridoma monoclonal anti-Le^b antibody. The replacement of the CH_2OH-5b group by hydrogen resulted in very weak binding by both the proteins, but the 6b-deoxy derivative was bound nearly as strongly as the parent compound in the case of the lectin but nine times more strongly in the case of the antibody. The 6b-fluoride was slightly more strongly bound than the 6b-deoxy derivative by both the proteins. On the other hand, the 6b-chloride was bound three times more strongly by the lectin but three times more weakly by the antibody than the 6b-deoxy derivative. The thermodynamic parameters for the binding of the 6b-deoxy derivative by the lectin as compared to those for Le^b-OMe confirmed that OH-6b interacts within the combining site of the complex. The results appear to require that for both proteins the CH_2OH-5b group becomes involved in nonpolar interactions within the combining site. It seems probable that OH-6b is accepted intramolecularly hydrogen bonded to O-5b in the case of the lectin but to OH-4b in the case of the antibody. The involvement of OH-3b, OH-4b, and OH-4c as the key polar grouping for the binding of Le^b-OMe by the lectin and of OH-3b and OH-2d in the case of the antibody was reported previously.

RAYMOND U. LEMIEUX, RÉMY CROMER et ULRIKE SPOHR. Can. J. Chem. **66**, 3083 (1988).

On a synthétisé les dérivés déoxy-3b, déoxy-4b, déoxy-6b, déoxy-6b-fluoro-6b, chloro-6b-déoxy-6b et des-hydroxyméthyl-5b du déterminant du groupe sanguin humain de type b de Lewis (αLFuc^d(1→2)βDGal^b(1→3)[αLFuc^c(1→4)]βDGlcNAc^a-OMe), dans le but de déterminer l'implication de l'unité b β-Gal dans le type de liaison du tétrasaccharide Le^b-OMe avec la léctine IV du *Griffonia simplicifolia* et avec un anticorps anti-Le^b monoclone hydrome. Le remplacement du groupe CH_2OH-5b par l'hydrogène a pour conséquence l'établissement d'un lien très faible avec les deux protéines; mais pour le dérivé déoxy-6b la liaison est presqu'aussi forte que celle du composé dont il dérive dans le cas de la léctine et neuf fois plus forte dans le cas de l'anticorps. La liaison du fluorure-6b avec les deux protéines est légèrement plus forte que celle du dérivé déoxy-6b. Par ailleurs, le chlorure-6b est lié trois fois plus fortement avec la léctine mais trois fois plus faiblement avec l'anticorps comparativement au dérivé déoxy-6b. Les paramètres thermodynamiques de la liaison du dérivé déoxy-6b avec la léctine comparés à ceux du Le^b-OMe confirment que le OH-6b interagit à l'intérieur du site de combinaison du complexe. Les résultats semblent indiquer que les deux protéines sont impliquées dans des interactions nonpolaires à l'intérieur du site de combinaison. Il existe probablement des liaisons hydrogènes intramoléculaires entre le groupe OH-6b et le O-5b dans le cas de la léctine mais ces liaisons hydrogènes impliqueraient cependant le groupe OH-4b dans le cas de l'anticorps. On a déjà rapporté l'implication des groupes OH-3b, OH-4b et OH-4c comme groupes polaires principaux dans le type de liaison du Le^b-OMe avec la léctine et de groupes OH-3b et OH-2d dans leur liaison avec l'anticorps.

[Traduit par la revue]

Introduction

The specific, non-covalent binding of oligosaccharides by antibodies and lectins in dilute aqueous solution is a remarkable phenomenon of great biological significance. Our approach to investigate the dominant forces for complex formation involves binding studies using a variety of synthetic oligosaccharides both as inhibitors in radioimmunoassays and as substrates when following changes in ultraviolet absorption that accompany the binding reactions (1–9). The latter technique has allowed the determination of thermodynamic parameters (2, 3, 6). To achieve information on the participation of the polar hydroxyl groups in the binding reactions, all possible monodeoxy derivatives are synthesized and, usually, also certain deoxy-halogeno compounds.

All the complexation reactions studied to date have been found to be enthalpy driven with a countervailing decrease in entropy (2, 3, 6). In all likelihood, the main reasons for the decreases in entropy are the need to order conformationally labile polypeptide chains to form the combining site, and the immobilization of the substrate within the complex including the structuring of water molecules.

In most of the cases so far studied, the binding has involved a cluster of two to three hydroxyl groups of the oligosaccharide in a polar interaction within the combining site. These clusters, termed the "key polar groupings" (10), are found at the edges of lipophilic surfaces that enter into nonpolar interactions with complementary counterparts of the protein combining sites. The key polar interactions are essential to the binding since modifications of the polar groupings that are involved produce essentially inactive compounds. In several instances, the key grouping is made up of hydroxyl groups stemming from different sugar units. However, its formation by hydroxyl groups from only one sugar unit, as in the substrates for the lectin I of *Ulex europaeus* (3) and the monoclonal anti-I antibody (1), has also been observed. The polar grouping may be involved in a highly specific interaction with charged groups of the receptor protein, and binding energies greater than 2.5

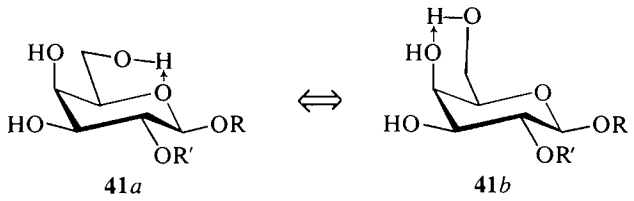
kcal/mol are lost on removing one of these hydroxyl groups (11). It remains to be established whether this loss in binding strength arises from a loss of the polar interaction that had involved the hydroxyl group or from the creation of a hydrophobic region that interacts unfavorably with the polar groups of the "gate" to the receptor site. In other words, it is possible that the key polar interactions are more concerned with guiding specificity than with the stability of the complex. More specific evidence in this regard is forthcoming from X-ray analyses of single crystals both for the lectin IV of *Griffonia simplicifolia*, and for its complexes with the Lewis b determinant and several of its derivatives (12).

We have often observed that the replacement of a hydroxyl group by hydrogen has no significant effect on the extent of the binding. This result could indicate that the hydroxyl group is not involved in the complexation. However, we have now found that although a structural change caused little change in free energy, the enthalpy and entropy terms may be profoundly affected (6). In some cases, deoxygenation or halogen substitution significantly strengthens the binding. In these instances, the decreases in entropy are much smaller and, therefore, the complexations appear to involve increased liberation of structured water molecules from hydrophobic environments in both the substrate and the protein. Such situations were found in studies of monoclonal anti-Le^b (4) and anti-B (5) antibodies and the lectin I of *Ulex europaeus* (3, 7) and it was proposed that these hydoxyl groups are intramolecularly hydrogen bonded for acceptance of the various oligosaccharides into nonpolar regions of the protein combining sites. Presumably, the hydroxyl group that becomes intramolecularly hydrogen bonded was previously bound by water and the return of these water molecules to bulk does not cause as great an increase in entropy as the liberation of water from about the deoxy derivative.

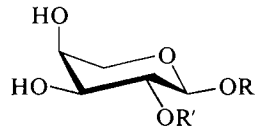
Fersht *et al.* (11) have suggested that the binding of tyrosyl adenylate may involve very weak hydrogen bonds with uncharged groups of the protein. We have preferred the intramolecular hydrogen bond proposal (13) because the improved binding resulting from deoxygenation of a hydroxyl group has occurred only when the hydroxyl group was sterically well disposed for intramolecular hydrogen bonding with a nearby proton-accepting atom.

This communication describes the synthesis of derivatives of the Lewis b blood group determinant modified in the βDGal unit and their use as probes for mapping the combining sites of the lectin IV of *Griffonia simplicifolia* (2, 9) and a monoclonal anti-Le^b antibody (4). The combining sites of these two Le^b-active proteins are different, since the anti-Le^b antibody distinguishes between the Le^b and Y (αLFuc(1→2)βDGal (1→4)[αLFuc(1→3)]βDGlcNAc) blood group determinants (4) whereas the lectin does not (2, 9). Furthermore, the key polar grouping in the binding by the lectin is formed by OH-3b and OH-4b of the βDGal unit and OH-4c of the αLFuc(1→4) unit of the Le^b tetrasaccharide (2), whereas in the case of the monoclonal antibody, the key polar group is provided by OH-3b of the βDGal unit and OH-2d of the αLFuc(1→2) unit (4).

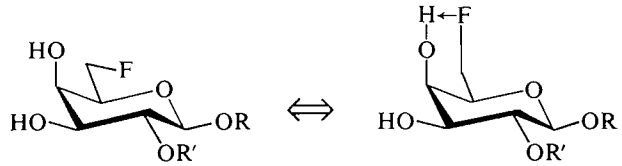
We have previously reported that the 6b-deoxy derivatives **40** of the Lewis-b tetrasaccharide (**41**) is nearly as strongly bound by the lectin as is the parent compound. The possibility therefore existed that the determinant was accepted into the combining site with OH-6b intramolecularly hydrogen bonded to O-5b as displayed in **41***a*. Since, in water, the formation of the intramolecular hydrogen bond shown in **41***a* is not likely extensive, the energy required for its formation may importantly



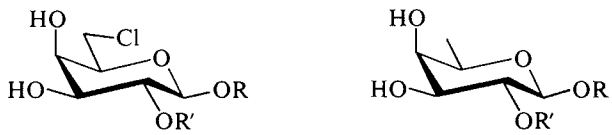
41*a* ⇔ **41***b*



37



38*a* ⇔ **38***b*



39 **40**

R = -3-[αLFuc(1 → 4)]βDGlcNAc-OMe
R′ = αLFuc-

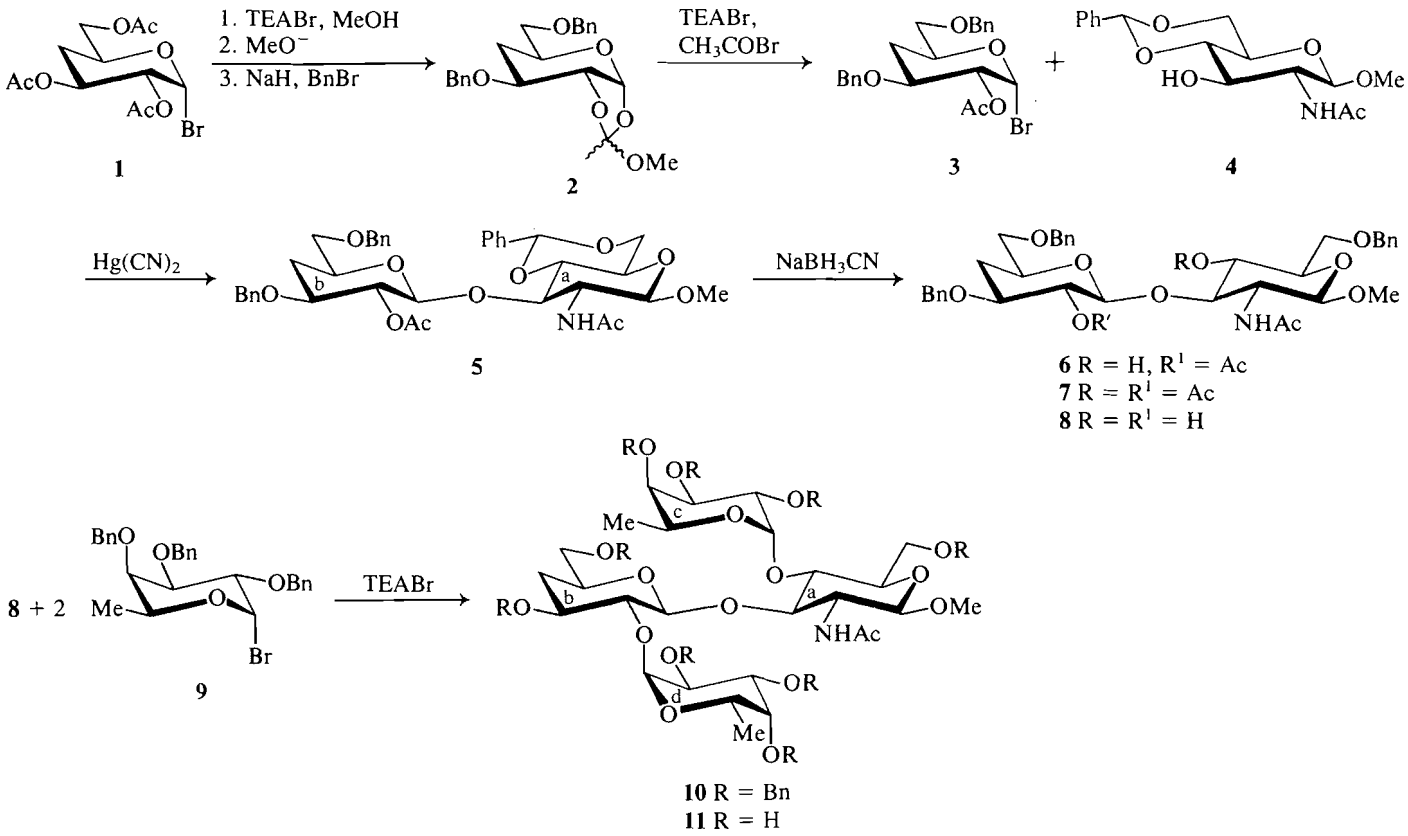
oppose complexation. The fluoride atom of the 6b-fluoride **38** will be hydrogen bonded to water and, therefore, should be accepted into a hydrophobic region of the combining site as the conformer **38***a* about as readily as **41**. On the other hand, the 6b-chloride **39** would be expected to be a superior inhibitor of the lectin–antigen interaction since the chloromethyl group is certainly more hydrophobic than the fluoromethyl group. Also, the chloromethyl group should offer better complementarity with the combining site than would the small methyl group of **40**. The situation could be expected to be quite different for binding by the anti-Le^b antibody, since in this case the 6b-deoxy derivative **40** was bound 18 times[5] more strongly than the parent (**41**) (4). It was proposed that the high activity displayed by **40** was related to the release of the need to form the conformer **41***b*, which, in spite of the intramolecular hydrogen bond, is known to be highly unstable. Should the OH-6b group be involved in the binding, substantial complementarity would be absent in binding the des-hydroxymethyl derivative **37** by either the lectin or the antibody.

Discussion

A. Synthesis

As displayed in Scheme 1, the disaccharide **8**, which has free hydroxyl groups at positions 4a and 2b, was prepared as a precursor for the synthesis of the 4b-deoxy-Le^b tetrasaccharide **11**. The first step was to synthesize the orthoester **2** from the glycosyl bromide **1** (14) using standard conditions (15). Treatment of **2** with acetyl bromide in the presence of tetraethylammonium bromide (16) then provided the glycosyl

[5]As will be seen later in this communication, we now find the binding to be nine times stronger. This finding does not materially affect the previous interpretation. The cause of the discrepancy remains unknown.



SCHEME 1. Synthesis of 4b-deoxy-Le^b-OMe (**11**).

bromide **3**. Condensation of **3** with the known alcohol **4** (17), under Helferich conditions (18) at room temperature, provided the crystalline disaccharide **5** in 80% yield. To deblock the 4a position (for subsequent fucosylation reaction) while keeping the 6a position protected, the benzylidene ring in **5** was reductively cleaved with sodium cyanoborohydride/hydrogen chloride as described by Garegg *et al.* (19). The resulting alcohol **6** was obtained crystalline in 93% yield and also characterized as its acetate **7**. The ^{1}H nmr spectrum fully supported the assigned structure. Zemplen deacetylation of **6** then provided the diol **8**, which was di-α-L-fucosylated under halide-ion-catalyzed conditions (20) using the fucosyl bromide **9** (21). The benzyl substituted tetrasaccharide **10** was isolated in 64% yield and subjected to catalytic hydrogenolysis over palladium-on-carbon to provide the 4b-deoxy-Le^b derivative **11** in 84% yield. The identity of the compound and its high purity were confirmed by ^{1}H and ^{13}C nmr spectroscopy (see Tables 1 and 2).

The preparation of the 3b-deoxy-Le^b tetrasaccharide (**16**) is outlined in Scheme 2. The precursor disaccharide **12** (P. Bird, O. Hindsgaul, and R. U. Lemieux, unpublished results) was prepared by reaction of methyl 2-acetamido-4,6-*O*-benzylidene-2-deoxy-β-D-glucopyranoside (**4**) with 2,4,6-tri-*O*-acetyl-3-deoxy-α-D-*xylo*-hexopyranosyl bromide (22) under Helferich conditions using mercuric cyanide in toluene–nitromethane (1:1) (83% yield), followed by reductive opening of the benzylidene ring with sodium cyanoborohydride/hydrochloric acid (19). Compound **12** was de-*O*-acetylated and the product was treated in *N*,*N*-dimethylformamide with α,α-dimethoxytoluene in the presence of *p*-toluenesulfonic acid (23). The crystalline 4b,6b-*O*-benzylidene derivative **13** was obtained and then acetylated to form **14**. The ^{1}H nmr spectrum of the diacetate **14** fully supported the structural assignment. Difucosylation of **13** with the benzylated fucosyl bromide **9** under halide-ion-catalyzed conditions then provided **15** in 84% yield. Hydrogenolysis in the presence of palladium-on-carbon afforded the desired 3b-deoxy-Le^b tetrasaccharide **16** in 83% yield.

To examine the possible involvement of the CH_2OH-5b group of the Le^b tetrasaccharide in its complexations with the lectin IV of *Griffonia simplicifolia* and the monoclonal anti-Le^b antibody, the L-Ara derivative **37** was synthesized as outlined in Scheme 3. Glycosylation of **4** (Scheme 1) with tri-*O*-acetyl-β-L-arabinopyranosyl bromide (**17**) (24) under Helferich conditions produced the β-linked disaccharide **21** in 62% yield. Reductive cleavage of the benzylidene ring of **21**, using sodium cyanoborohydride/hydrogen chloride (19), converted the benzylidene group to 6a-*O*-benzyl and liberated the hydroxyl at position 4a to thereby afford **24**. Zemplen deacetylation of **24** then provided methyl 2-acetamido-3-*O*-(α-L-arabinopyranosyl)-6-*O*-benzyl-2-deoxy-β-D-glucopyranoside, which was benzylidenated (23) to yield **28** as a mixture of diastereoisomeric 3b,4b-*O*-benzylidene derivatives. The free hydroxyl groups at positions 4a and 2b of **28** were then difucosylated to form the blocked tetrasaccharide **33** (76% yield). Removal of the benzyl and benzylidene groups by hydrogenolysis over palladium-on-carbon then provided the 5b-des-hydroxymethyl derivative **37** of the Le^b glycoside (**41**).

To study the involvement of OH-6b of Le^b-OMe (**41**) in the binding reactions, the 6b-deoxy-6b-fluoro-, 6b-chloro-6b-deoxy-, and 6b-deoxy-Le^b derivatives (**38**, **39**, and **40**, respectively), were synthesized following routes similar to that described for the synthesis of **37** (Scheme 3). Alcohol **4** was glycosylated using both 6-deoxy-6-fluoro-glycosyl bromide

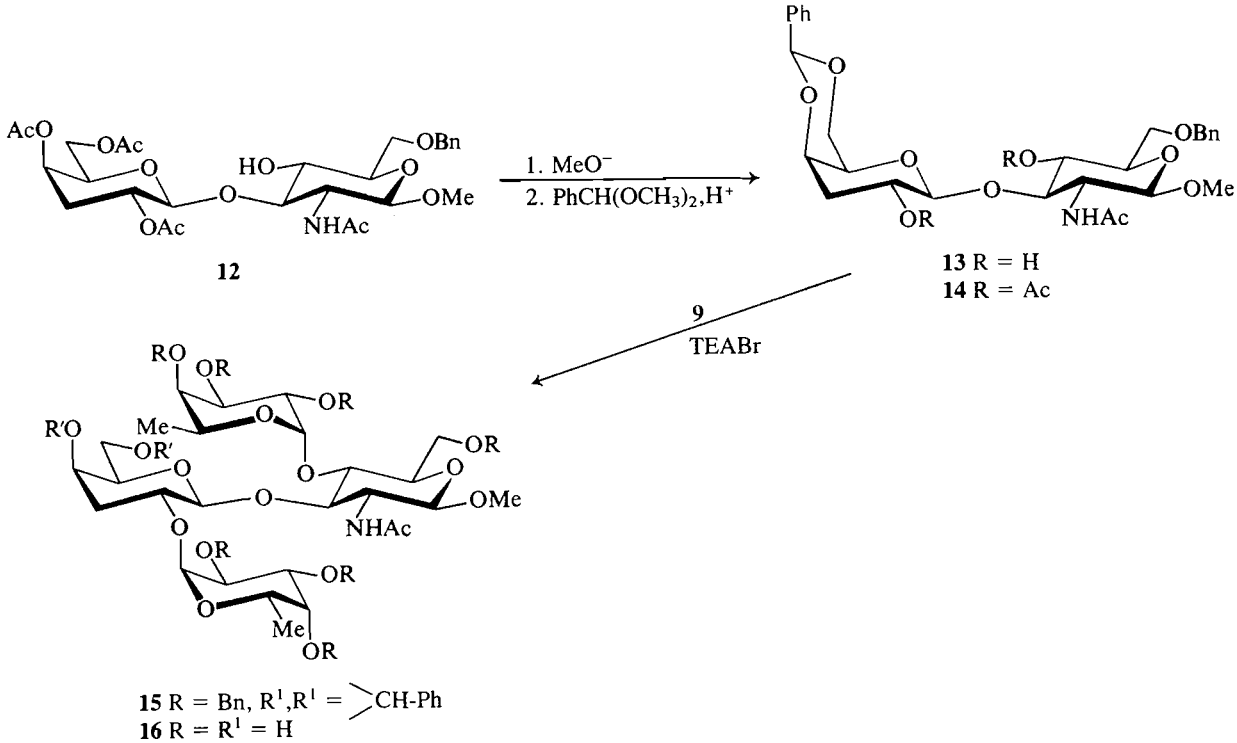
[a]0.05 M solutions in D_2O with dioxane as internal standard at 67.4 ppm were measured at 100 and 75 MHz at 295 K. The assignments were made by inspection using model compounds (26).

[b,c]The corresponding assignments of the chemical shifts are tentative and may be reversed.

[d]$J_{C6,F}$ 166 Hz, $J_{C5,F}$ 20 Hz, $J_{C4,F}$ 8 Hz.



SCHEME 2. Synthesis of 3b-deoxy-Le^b-OMe (**16**).

(**18**) (25) and the 6-chloro-6-deoxy-glycosyl bromide (**20**) under Helferich conditions to provide the disaccharides **22** and **23** in yields of 49 and 31%, respectively. Reductive opening of the benzylidene ring, as for **21**, provided the alcohols **25** and **26**. Similarly, the 6b-deoxy disaccharide **27** had been prepared (S. Narasimhan, P. Bird, O. Hindsgaul, and R. U. Lemieux, unpublished results). Conventional deacetylation of **25**, **26**, and **27** followed by benzylidenation afforded the precursor diols **29**, **30**, and **31** as diastereoisomeric mixtures in yields of 94, 77, and 75%. Structural proof was obtained by the ^{1}H nmr spectra of the corresponding di-*O*-acetates **29***a*, **30***a*, and **32** (see Experimental). Difucosylation of the diols **29**, **30**, and **31** furnished the blocked tetrasaccharides **34**, **35**, and **36** (66, 80, 80%). Hydrogenolytic debenzylation and debenzylidenation then led to the deblocked Le^b derivatives **38**, **39**, and **40**. The ^{1}H and ^{13}C nmr spectra are in complete agreement with the structural assignments (Tables 1 and 2).

B. Structural and conformational assignments

The ^{1}H and ^{13}C nmr parameters for Le^b-OMe and the various monodeoxy (**11**, **16**, **40**) and deoxy-halogeno (**38**, **39**) derivatives are reported in Tables 1 and 2 together with the 5b-des-hydroxymethyl derivative (**37**). The data clearly agree with the various structural assignments. A consideration of the conformational preferences for the modified determinants is required since it is intended to compare the energetics of the binding of the various compounds both by the lectin and by the antibody. Should the structural changes cause appreciable change in conformational preference, then the changes would have to be considered in any effort to interpret the relative potency.

Although the conformational preferences ϕ/ψ = 55°/10°, 55°/25°, 45°/15° about the glycosidic bonds involving the βDGal^b(1→3), αLFuc^c(1→4), and αLFuc^d(1→2) units, respectively, have been reported (27), we wish to review the salient points and to indicate how the conclusions then reached were reinforced by recent developments. In this regard, the ^{1}H chemical shifts for the reference glycoside, methyl α-L-fucopyranoside, measured under the conditions reported in Table 1 are reported in Table 3 since it was possible to assign the signals for the hydrogens with greater confidence and accuracy than was possible at 270 MHz (28).

As seen in Table 3, H-5c of the Le^b tetrasaccharide is deshielded by 0.80 ppm relative to H-5 of the αLFuc-OMe. This strong, specific interunit deshielding by O-3a and O-5b, first noted for the Lewis a trisaccharide (29), provided sufficient evidence for the conformational preference of the Lewis a portion of the tetrasaccharide. This conclusion was anticipated by HSEA calculation (30) and confirmed by nuclear Overhauser enhancement (nOe) studies (9). This orientation for the αLFuc c unit projects H-1c between the H-4a and the CH_2OH-5a groups of the βDGlcNAc unit and, therefore, should be somewhat deshielded relative to H-1 of methyl α-L-fucopyranoside. In fact (Table 3), the deshielding is by 0.24 ppm. Examination of the chemical shifts, reported in Table 1, for the hydrogens of the αLFuc c unit shows that the specific interunit deshieldings for the H-1c atom of the various derivatives of Le^b-OMe are essentially constant and the same as that for Le^b-OMe. This situation also applies to the chemical shifts for H-5c. The slight deshielding of this atom noted for the 3b (**16**) and 6b (**11**) deoxy derivatives is even greater than for Le^b-OMe and suggests even greater preference for the conformational assignment. Therefore, the chemical changes in the βDGal b unit do not appreciably affect the orientation of the c-fucose unit.

The ^{1}H nmr data show that the various modifications of the b unit also caused no significant change in the conformational preference of the d unit. As seen from Table 3, both H-1d and H-5d of Le^b-OMe experience specific interunit deshielding effects. In the case of H-1d, the deshielding of 0.37 ppm is assigned to a strong nonbonded interaction with O-3b. This

result agrees with the greater than 0.3-ppm interunit deshielding that Lemieux and Bock (31) found to be characteristic for the anomeric protons of certain α-glycopyranosides and assigned to nonbonded interaction with an equatorial oxygen in the aglycon. It was not surprising, therefore, to find that the signal for H-1d of 3b-deoxy-Le^b-OMe (**16**) is 0.33 ppm to higher field than that for Le^b-OMe. On the basis of this orientation for the d unit, H-5d should be in very near van der Waals contact with O-3a and therefore deshielded as compared to H-5 of αLFuc-OMe. The nOe data (9) agree with this conformational preference, which is that predicted by HSEA calculation. Consequently, the immunochemical data, including those for the 5b-des-hydroxymethyl derivative (**37**) (Tables 4, 5, and 6) will be considered on the basis of the HSEA conformer. The orientations of the OH-groups shown in Fig. 1 are all arbitrary but may be those in best accord with the binding studies.

The ^{13}C nmr chemical shifts reported in Table 2 are considered to be in good general accord with the conclusions reached above, on the basis of the ^1H nmr, as to the conformational preference. Nevertheless, the occurrence of chemical shift differences of as great as ±0.2 ppm for the carbon atoms of the βDGlcNAc[a], αLFuc[c], and αLFuc[d] units on making changes in the βDGal[b] unit are noteworthy. We expect that these arise from very slight changes in the hybridization (30) of the carbon atoms as the result of changes in the solvation shells caused by the chemical change.

R.U.L. takes umbrage from the statement (32) that we have assigned single conformations to oligosaccharides in solution. This is, of course, preposterous and was never done. Furthermore, it was disappointing that our paper on the conformational preference of the B blood group determinant (27) and the inference of the finding on the A determinant was ignored. Also, this publication (27) is our definitive paper on HSEA molecular modelling and this fact should not be obscured. What we do believe is that, as stated in our first publication on HSEA calculation (30) and reinforced in the more recent papers (27, 33), the *exo*-anomeric effect appears sufficiently strong to both narrow and deepen the potential energy well occupied by the preferred conformer to the extent that the nOe data well reflect the conformational preference indicated by the specific interunit deshielding effects. Why the HSEA conformer is often in fine agreement with the nmr data is surely of interest. However, we wish to reiterate that, although we have normally found this to be the case when D_2O was the solvent, there exists no reason to expect that it should be so. In the case of maltosides, the HSEA conformer is that suggested as most favorable by the nmr data when the solvent is D_2O but not when it is DMSO-d_6 (34).

C. *Immunochemical studies*

Our initial studies of the binding of the Lewis b determinant by the lectin IV of *Griffonia simplicifolia* allowed the conclusion that the β side of the tetrasaccharide (namely, the side of the core βD-Gal unit over which the two αLFuc units are extended) is extensively involved in the complexation reaction (2). Since the replacement of OH-6b of the βDGal unit by hydrogen had little effect on the strength of the association, the possibility existed that this hydroxyl group remained in contact with water and that the binding was restricted to the β side as displayed on the left in Fig. 1. However, we have now shown that the lipophilic surfaces that are presented by oligosaccharides may become extensively involved when bound both by antibodies (1, 4, 5, 8) and lectins (2, 3) and it was to be noted (2) that the α side[6] of the Le^b tetrasaccharide is extensively lipophilic in character. Consequently, the involvement of this α side seemed likely, especially since the OH-6b can be intramolecularly hydrogen bonded to O-5b (5). Thus, the hydroxyl group could more readily be accepted into a lipophilic cleft involving contact with both sides of the tetrasaccharide, as is depicted in Fig. 1.

That OH-6b is in fact involved in the binding was established by the thermodynamic data presented in Table 4. It is seen that in contrast to the complexation of the 6a-deoxy derivative of Le^b-OMe (9), the binding of the 6b-deoxy compound **40** involves thermodynamic parameters that differ very substantially from those for the Le^b-OMe tetrasaccharide. The differential change in enthalpy of 4.6 kcal/mol is well outside experimental error and clearly implicates OH-6b as directly involved in the complex. The decrease in entropy involved in the binding of **40** is 14.9 entropy units less than that for Le^b-OMe. The most obvious explanation would be that the binding of **40** involves a greater release of ordered water because of the greater hydrophobicity about the CH_3-5b group. On this basis, the OH-6b is accepted into a hydrophobic cleft presented by the lectin. The decrease in the change in enthalpy observed for **40** can be assigned, at least in part, to the loss in complementarity.

The importance of complementarity is well demonstrated by the observation that replacement of the CH_3-5b group of the 6b-deoxy-Le^b-OMe (**40**) by hydrogen provides a very weakly bound compound (**37**). As seen in Table 5, the differential change in free energy for compounds **40** and **37** amounts to 2.3 kcal/mol. The complementarity lost on preparing the 6b-deoxy compound **40** was somewhat restored on introducing a fluorine atom since the 6b-deoxy-6b-fluoro compound **38** is twice more potent an inhibitor than is **40**. The strong binding of the fluoride **38** cannot be attributed to a strictly hydrophobic effect since the fluorine atom is known to be somewhat hydrophilic in character. Also, the high activity of **38** precludes the possibility that OH-6b of Le^b-OMe becomes hydrogen bonded to the combining site as a proton donor. That OH-6b is actually merely involved as a space-filling group appears supported by the fact that the 6b-chloro-6b-deoxy derivative **39** is twice as potent an inhibitor as the parent Le^b-OMe compound and three times more potent than the 6b-deoxy compound (**40**). Thus, it appears most probable that OH-6b is accepted as hydrogen bonded to O-5b. The answer to this problem will be available when the X-ray structure for the lectin-Le^b-OMe complex is determined (12).

Table 6 reports the effects of changes in the βDGal b unit of

[6]Note that this side of the βDGal unit was mistakenly identified as the β side in our previous publication.

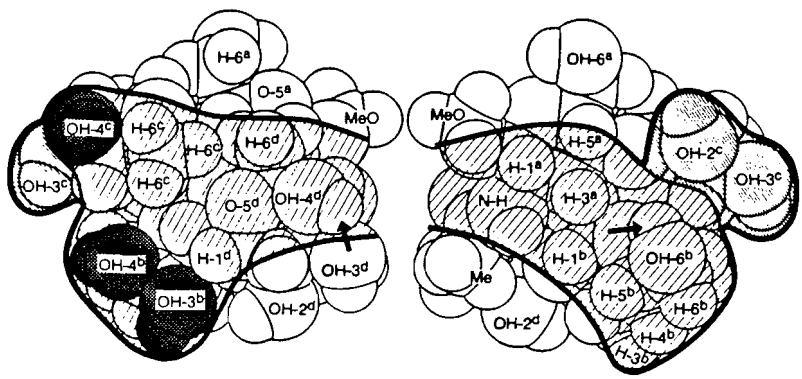

FIG. 1. Revised proposal for the binding of the Lewis b methyl tetrasaccharide by the lectin IV of *Griffonia simplicifolia* (2). The key polar grouping is presented by the cross-hatched hydroxyl groups. It is suggested that OH-4^d and OH-6^b are intramolecularly hydrogen bonded in order to participate in the binding of the lightly hatched surface in a lipophilic cleft. The regions left clear are known (9) to remain in contact with the water. The more darkly hatched OH-2^c and OH-3^c are considered to be engaged in peripheral interactions at the interface of the protein, the tetrasaccharide, and water.

Le^b-OMe on binding by the monoclonal anti-Le^b antibody. It was previously reported that OH-3b, along with OH-2d of the αLFuc(1→2) unit, provides the key polar interaction (4). As seen in Table 6, replacement of OH-4b by hydrogen strongly reduced the potency of the compound as an inhibitor of the binding of the Le^b-artificial antigen. As previously mentioned, the 6b-deoxy is much more strongly bound by the antibody than is Le^b-OMe and this result was attributed to the necessity of OH-6b being oriented as in conformer **41***b*. If so, OH-4b is required as the proton acceptor for the intramolecular hydrogen bond (OH-6b ← OH-4b).

The *syn*-axial-like relationship between OH-4b and OH-6b shown in **41***b* is surely energetically unfavorable (35). Consequently, for this orientation to occur there must exist an especially strong driving force to have the CH_2OH-5b group accepted into a hydrophobic environment. Indeed, this appears to be the case since, as seen in Table 6, the inhibition provided by the 6b-deoxy derivative **40** is nine times stronger. This high activity does not appear to be mainly related to the creation of a hydrophobic effect since the 6b-deoxy-6b-fluoro derivative **38** is even more potent (13 times more). This greater potency may arise because **38** can adopt conformation **38***b* more readily than Le^b-OMe can adopt **41***b*. Also, **38***b* should provide greater complementarity than does the 6b-deoxy derivative **40**.

It must be expected that prohibitive energy would be required for the chlorine atom of 6-chloro-6-deoxy-Le^b-OMe (**39**) to adopt the −Cl/O-5 conformation, and thereby come into a *syn*-axial-like interaction with the OH-4b hydroxyl. On the other hand, the combining site could adjust to allow acceptance of **39** in the +Cl/O-5 conformation. Especially, the strong binding of the chloride **39**, i.e., one third that of the 6b-deoxy derivative **40** but 3 times greater than Le^b-OMe, indicates that the CH_2OH-5b group is accepted at the bottom of a lipophilic cleft. If so, the replacement of this large group by hydrogen would lead to a large loss in complementarity and, therefore, the product **37** should be quite inactive. In fact, as seen in Table 6, the compound proved to be a poor inhibitor but only 10 times less potent than Le^b-OMe. As seen above, in the case of the lectin IV of *Griffonia simplicifolia*, **37** was inactive. The stronger binding of **37** by the anti-Le^b antibody is not surprising when it is considered that the driving force for complexation is so great that it can force the OH-6b group into an energetically unfavorable orientation for acceptance into the combining site. Presumably, the same strong driving force can act on **37** and force complex formation in spite of the loss in complementarity. In this regard, it is interesting to note that our probing studies indicate that the monoclonal anti-Le^b antibody accepts Le^b-OMe along an unusually large lipophilic surface (4). As previously suggested (10), it appears that it is the interaction between the complementary lipophilic surfaces that provides the main driving force for the complexation reaction.

Experimental

General methods

The ^{1}H nmr spectra were measured at 300, 360, and 400 MHz (Bruker AM 300, WM 360, and WH 400) with tetramethylsilane as internal standard for $CDCl_3$ solutions. Reference standard for D_2O solutions was acetone (2.225 ppm). The ^{13}C nmr spectra were recorded at 100 and 75 MHz (Bruker WH 400 and AM 300) using D_2O as solvent and 1,4-dioxane (67.4 ppm) as internal standard. Optical rotations were measured at room temperature (23 ± 1°C) in a 1-dm cell on a Perkin Elmer 241 polarimeter. Thin-layer chromatograms were performed on precoated plates of silica gel (60-F 254, E. Merck, Darmstadt) and visualized by spraying with 10% sulfuric acid in ethanol followed by heating. For column chromatography, silica gel 60 (230–400 mesh, E. Merck, Darmstadt) and distilled solvents were used. Solvents and reagents were purified and dried according to standard procedures. Melting points are uncorrected.

*2,3,6-Tri-*O*-acetyl-4-deoxy-α-*D*-*xylo*-hexopyranosyl bromide (**1**) (14)*

A solution of 45% (w/v) hydrogen bromide in glacial acetic acid (20 mL) was added to a solution of 1,2,3,6-tetra-*O*-acetyl-4-deoxy-D-*xylo*-hexopyranose (14) (1.3 g, 3.9 mmol) in dichloromethane (20 mL) with ice-bath cooling. The mixture was kept for 45 min at ice-bath temperature and was then diluted with dichloromethane and poured into ice-water. The organic layer was successively washed with water, aqueous sodium hydrogen carbonate, and water. Drying with sodium sulfate, evaporation, and drying of the residual material in an oil-pump vacuum provided crystalline bromide **1** (1.31 g, 95%); mp 77–79°C (lit. (14) mp 83–84°C (light petroleum)); $[\alpha]_D$ +197° (*c* 0.4, chloroform); ^{1}H nmr ($CDCl_3$) δ: 6.66 (d, 1H, H-1, $J_{1,2}$ 3.8 Hz), 5.39 (ddd, 1H, H-3, $J_{2,3}$ 9.5 Hz, $J_{3,4eq}$ 5.5 Hz, $J_{3,4ax}$ 11.5 Hz), 4.78 (dd, 1H, H-2), 4.38 (m, 1H, H-5, $J_{4eq,5}$ 2.0 Hz, $J_{4ax,5}$ 12.0 Hz, $J_{5,6}$ 4.5 Hz), 4.18 (d, 2H, H_2-6), 2.29 (ddd, 1H, H-4eq, $J_{4eq,4ax}$ 13.0 Hz), 2.12, 2.10, 2.07 (3s, each 3H, $3CH_3COC$), 1.70 (q, 1H, H-4ax).

*3,6-Di-*O*-benzyl-4-deoxy-1,2-*O*-(1-methoxyethylidene)-α-*D*-xylo-hexopyranose (**2**)*

A mixture of the acetylated bromo sugar **1** (14) (1.31 g, 3.71 mmol), tetraethylammonium bromide (1.2 g, 5.71 mmol), *sym*-collidine (1.52 mL), methanol (0.83 mL), and 4 Å molecular sieves (3 g) in nitromethane (13 mL) was stirred at room temperature for 10 h. It was then diluted with dichloromethane, filtered, and the solution washed with water prior to evaporation to dryness. The oily residue was treated with methanolic 0.17 N sodium methoxide (19.5 mL) for 45 min, evaporated, and dried in an oil-pump vacuum. The resulting material was dissolved in *N*,*N*-dimethylformamide (32 mL), sodium hydride (780 mg, approximately 50% dispersion in oil) was added, and the mixture kept at ice-bath temperature for 30 min. After the addition of benzyl bromide (1.56 mL, 13.1 mmol), it was stirred for another 30 min before pouring the mixture into ice-water. Extraction with dichloromethane, drying, and evaporation left an oily residue, the purification of which was achieved by chromatography on a column of silica gel (hexane–triethylamine 33:1, hexane – ethyl acetate – triethylamine 3:1:0.12) providing syrupy **2** (1.08 g, 73%). The ^{1}H nmr of this product showed it to consist of >90% of the main isomer. Repeated chromatography of a small sample gave the pure, slower migrating main isomer that was characterized; $[\alpha]_D$ +15.5°, $[\alpha]_{365}$ +45.4° (*c* 0.5, chloroform); ^{1}H nmr ($CDCl_3$) δ: 7.4–7.2 (m, 10H, 2Ph), 5.81 (d, 1H, H-1, $J_{1,2}$ 5.0 Hz), 4.71 and 4.63 (AB, 2H, CH_2Ph, J_{AB} 12.0 Hz), 4.59 (s, 2H, CH_2Ph), 4.26 (t, 1H, H-2, $J_{2,3}$ 5.0 Hz), 4.05 (m, 1H, H-5, $J_{4eq,5}$ 3.5 Hz, $J_{4ax,5}$ 9.5 Hz, $J_{5,6}$ 5.0 Hz), 3.8 (ddd, 1H, H-3, $J_{3,4eq}$ 6.0 Hz, $J_{3,4ax}$ 8.0 Hz), 3.68–3.47 (m, 2H, H-6, H-6′), 3.30 (s, 3H, CH_3O), 2.01 (ddd, 1H, H-4eq, $J_{4eq,4ax}$ 14.0 Hz), 1.68 (ddd, 1H, overlapped by CH_3C, H-4ax), 1.62 (s, 3H, CH_3C). *Anal.* calcd. for $C_{23}H_{28}O_6$: C 68.98, H 7.05; found: C 69.61, H 7.07.

*2-*O*-Acetyl-3,6-di-*O*-benzyl-4-deoxy-α-*D*-xylo-hexopyranosyl bromide (**3**)*

Acetyl bromide (300 μL, 4.06 mmol) was added to a mixture of compound **2** (840 mg, 2.10 mmol), tetraethylammonium bromide (210 mg, 1.0 mmol), and 4 Å molecular sieves (3 g) in dichloromethane (8 mL). The mixture was stirred for 45 min at room temperature, then decanted from the sieves and poured into a stirred mixture of aqueous sodium hydrogen carbonate, ice, and dichloromethane. The organic layer was washed with water, dried, and evaporated to leave **3** (880 mg, 93%) as a syrup; ^{1}H nmr ($CDCl_3$) δ: 7.4–7.2 (m, 10H, 2Ph), 6.72 (d, 1H, H-1, $J_{1,2}$ 3.5 Hz), 4.7 (dd, 1H, H-2, $J_{2,3}$ 9.5 Hz), 4.67 (s, 2H, CH_2Ph), 4.57 (s, 2H, CH_2Ph), 4.25 (m, 1H, H-5, $J_{4ax,5}$ 12.0 Hz, $J_{4eq,5}$ 2.5 Hz), 4.06 (ddd, 1H, H-3, $J_{3,4ax}$ 12.0 Hz, $J_{3,4eq}$ 5.0 Hz), 3.75–3.4 (m, 2H, H-6, H-6′), 2.22 (ddd, 1H, H-4eq, $J_{4eq,4ax}$ 13.0 Hz), 2.12 (s, 3H, CH_3O), 1.77 (q, 1H, H-4ax).

Methyl 2-acetamido-3-O-(2-O-acetyl-3,6-di-O-benzyl-4-deoxy-β-D-xylo-hexopyranosyl)-4,6-O-benzylidene-2-deoxy-β-D-glucopyranoside (5)

A mixture of methyl 2-acetamido-4,6-*O*-benzylidene-2-deoxy-β-D-glucopyranoside (**4**) (17) (480 mg, 1.48 mmol), mercuric cyanide (725 mg, 2.87 mmol), powdered calcium sulfate (500 mg), and 4 Å molecular sieves (1 g) in a mixture of toluene and nitromethane (1:1, 40 mL) was stirred under nitrogen, and a solution of bromide **3** (1.96 mmol) in toluene–nitromethane (1:1, 6 mL) was added. The completion of the reaction was indicated by tlc 20 min after the addition. The reaction mixture was filtered, and poured into a mixture of aqueous sodium hydrogen carbonate and dichloromethane. The organic layer was washed with water, dried, and evaporated. The crude reaction product was chromatographed on a column on silica gel (ethyl acetate, dichloromethane – 7% methanol) to provide pure crystalline **5** (825 mg, 80%). The analytical sample was recrystallized from dichloromethane – ethyl acetate; mp 205–207°C; $[\alpha]_D$ +9.6°, $[\alpha]_{365}$ +41° (*c* 0.5, chloroform); ^{1}H nmr ($CDCl_3$) δ: 7.5–7.2 (m, 15H, 3 Ph), 5.84 (d, 1H, NH, $J_{NH,2a}$ 7.0 Hz), 5.44 (s, 1H, C*H*Ph), 5.12 (d, 1H, H-1a, $J_{1a,2a}$ 8.5 Hz), 4.82 (dd, 1H, H-2b, $J_{1b,2b}$ 8.0 Hz, $J_{2b,3b}$ 9.0 Hz), 4.60 (d, overlapped by CH_2Ph and H-3a, H-1b), ~4.59 and 4.42 (AB, 2H, CH_2Ph, J_{AB} 12.0 Hz), 4.59 (t, overlapped by CH_2Ph and H-1b, H-3a, $J_{2a,3a} \sim J_{3a,4a}$ 9.0 Hz), 4.45 and 4.41 (AB, 2H, CH_2Ph, J_{AB} 12.0 Hz), 4.30 (dd, 1H, H-6a, $J_{6a,6a'}$ 10.5 Hz, $J_{6a,5a}$ 5.0 Hz), 3.71 (t, 1H, H-6a', $J_{6a',5a}$ 10.0 Hz), 3.67 (t, 1H, H-4a, $J_{4a,5a}$ 9.0 Hz), 3.52 (m, overlapped by CH_3O and H-3b, H-5a), 3.50 (s, 3H, CH_3O), 3.49 (overlapped by CH_3O and H-5a, H-3b, $J_{3b,4beq}$ 5.0 Hz), ~3.45–3.35 (m, H-6b, H-6b'), ~3.36 (m, H-5b), 3.04 (m, 1H, H-2a), 2.09 (ddd, 1H, H-4beq, $J_{4beq,4bax}$ 13.0 Hz, $J_{4beq,5b}$ 1.0 Hz), 1.96 (s, 6H, CH_3COOC, CH_3CONH), 1.46 (q, 1H, H-4bax, $J_{4bax,3b}$ 12.0 Hz, $J_{4bax,5b}$ 12.0 Hz). *Anal.* calcd. for $C_{38}H_{45}NO_{11}$: C 65.98, H 6.56, N 2.03; found: C 65.98, H 6.52, N 2.00.

Methyl 2-acetamido-3-O-(2-O-acetyl-3,6-di-O-benzyl-4-deoxy-β-D-xylo-hexopyranosyl)-6-O-benzyl-2-deoxy-β-D-glucopyranoside (6)

A mixture of compound **5** (685 mg, 0.99 mmol), sodium cyanoborohydride (1.8 g), 3 Å molecular sieves (3 g), and a few crystals of methyl orange in tetrahydrofuran (33 mL) was stirred at 0°C under nitrogen. Diethyl ether saturated with hydrogen chloride was added until the colour of the indicator turned red and gas evolution occurred. After hydrogen evolution ceased, tlc showed the reaction to be complete. The mixture was diluted with dichloromethane and poured into aqueous sodium hydrogen carbonate solution. The organic layer was washed with water, dried, and evaporated. Deionization with Amberlite MBl and column chromatography (silica gel, dichloromethane – 5% methanol) provided crystalline compound **6** (640 mg, 93%). The analytical sample was recrystallized from dichloromethane – ethyl acetate; mp 163–164°C; $[\alpha]_D$ +18.9° (*c* 0.9, chloroform); ^{1}H nmr ($CDCl_3$) δ: 7.4–7.2 (m, 15H, 3Ph), 5.69 (d, 1H, NH, $J_{2a,NH}$ 7.0 Hz), 4.89 (dd, 1H, H-2b, $J_{1b,2b}$ 7.5 Hz, $J_{2b,3b}$ 9.0 Hz), 4.85 (d, 1H, H-1a, $J_{1a,2a}$ 8.0 Hz), 4.62 and 4.46 (AB, 2H, CH_2Ph, J_{AB} 12.0 Hz), 4.60 (s, 2H, CH_2Ph), 4.53 and 4.50 (AB, 2H, CH_2Ph, J_{AB} 12.0 Hz), 4.41 (s, 1H, OH), 4.40 (d, 1H, H-1b), 4.33 (dd, 1H, H-3a, $J_{2a,3a}$ 10.0 Hz, $J_{3a,4a}$ 9.0 Hz), 3.49 (s, overlapped, CH_3O), 3.01 (m, 1H, H-2a), 2.10 (ddd, overlapped by CH_3CO, 1H, H-4beq, $J_{4beq,4bax}$ 13.0 Hz, $J_{3b,4beq}$ 5.0 Hz, $J_{4beq,5b}$ 1.0 Hz), 2.06, 1.96 (each s, each 3H, CH_3COOC, CH_3CONH), 1.52 (q, 1H, H-4bax, $J_{4bax,3b}$ 12.0 Hz, $J_{4bax,5b}$ 12.0 Hz). *Anal.* calcd. for $C_{38}H_{47}NO_{11}$: C 65.79, H 6.83, N 2.02; found: C 65.73, H 6.88, N 1.98.

Methyl 2-acetamido-4-O-acetyl-3-O-(2-O-acetyl-3,6-di-O-benzyl-4-deoxy-β-D-xylo-hexopyranosyl)-6-O-benzyl-2-deoxy-β-D-glucopyranoside (7)

A solution of compound **6** (30 mg, 0.04 mmol) in pyridine (1 mL) and acetic anhydride (0.5 mL) was kept at room temperature for 5 h. The mixture was poured into ice-water, extracted with dichloromethane, and evaporated. The resulting material was recrystallized from dichloromethane – ethyl acetate – hexane to provide the diacetate **7** (23 mg, 72%); mp 126–127°C, $[\alpha]_D$ +17° (*c* 0.4, chloroform); ^{1}H nmr ($CDCl_3$) δ: 7.4–7.2 (m, 15H, 3Ph), 5.85 (d, 1H, NH, $J_{2a,NH}$ 7.5 Hz), 4.89 (t, 1H, H-4a, $J_{3a,4a} \sim J_{4a,5a}$ 9.0 Hz), 4.81 (d, 1H, H-1a, $J_{1a,2a}$ 7.5 Hz), 4.76 (dd, 1H, H-2b, $J_{2b,3b}$ 9.0 Hz, $J_{1b,2b}$ 7.5 Hz), 4.60 and 4.44 (AB, 2H, CH_2Ph, J_{AB} 12.0 Hz), 4.52, 4.50 (2s, 4H, CH_2Ph), 4.42 (d, 1H, H-1b), 4.33 (t, 1H, H-3a, $J_{2a,3a}$ 8.0 Hz), 3.68 (m, 1H, H-5a), ~3.54 (m, H-3b, overlapped), 3.48 (s, CH_3O), 3.31 (m, 1H, H-2a), 2.13 (ddd, 1H, H-4beq, $J_{3b,4beq}$ 5.0 Hz, $J_{4beq,4bax}$ 13.0 Hz, $J_{4beq,5b}$ 1.0 Hz), 2.05, 1.92, 1.90 (each s, each 3H, $2CH_3COOC$, CH_3CONH), 1.5 (q, 1H, H-4bax, $J_{4bax,3b}$ 12.0 Hz, $J_{4bax,5b}$ 12.0 Hz). *Anal.* calcd. for $C_{40}H_{49}NO_{12}$: C 65.29, H 6.71, N 1.90; found: C 65.12, H 6.69, N 1.93.

Methyl 2-acetamido-6-O-benzyl-2-deoxy-3-O-(3,6-di-O-benzyl-4-deoxy-β-D-xylo-hexopyranosyl)-β-D-glucopyranoside (8)

Compound **6** (480 mg, 0.69 mmol) was treated with 0.17 N sodium methoxide in methanol (9 mL) for 16 h. The solution was made neutral with Amberlite IRC 50 H^+, evaporated to dryness, and the resulting product passed through a column of silica gel (dichloromethane – 7% methanol) to provide crystalline **8** (405 mg, 90%). Recrystallization from methanol gave the analytical sample; mp 170–172°C; $[\alpha]_D$ −4.5°, $[\alpha]_{365}$ −9.1° (*c* 1.1, chloroform); ^{1}H nmr ($CDCl_3$) δ: 7.4–7.2 (m, 15H, 3Ph), 6.07 (d, 1H, NH, $J_{2a,NH}$ 7.0 Hz), 4.72 (d, 1H, H-1a, $J_{1a,2a}$ 8.5 Hz), 4.66 and 4.65 (AB, 2H, CH_2Ph, J_{AB} 12.0 Hz), 4.67 (s, 2H, CH_2Ph), 4.56 and 4.51 (AB, 2H, CH_2Ph, J_{AB} 12.0 Hz), 4.24 (d, 1H, H-1b, $J_{1b,2b}$ 7.0 Hz), 4.07 (dd, 1H, H-3a, $J_{2a,3a}$ 9.0 Hz, $J_{3a,4a}$ 10.0 Hz), 3.54 (s, CH_3O), 3.41 (m, 1H, H-2a), 1.98 (s, CH_3CONH), ~1.98 (overlapped, H-4beq), 1.39 (q, 1H, H-4bax, $J_{4bax,4beq}$ 13.0 Hz, $J_{4bax,3b}$ 12.0 Hx, $J_{4bax,5b}$ 12.0 Hz). *Anal.* calcd. for $C_{36}H_{45}NO_{10}$: C 66.34, H 6.96, N 2.15; found: C 66.45, H 6.99, N 1.94.

2,3,4-Tri-O-benzyl-α-L-fucopyranosyl bromide (9) (21)

Bromide **9** was prepared freshly before use from 2,3,4-tri-*O*-benzyl-L-fucopyranose as described in ref. 9.

Methyl 2-acetamido-6-O-benzyl-2-deoxy-3-O-[3,6-di-O-benzyl-4-deoxy-2-O-(2,3,4-tri-O-benzyl-α-L-fucopyranosyl)-β-D-xylo-hexopyranosyl]-4-O-(2,3,4-tri-O-benzyl-α-L-fucopyranosyl)-β-D-glucopyranoside (10)

Bromide **9** (1.3 g, 2.99 mmol) dissolved in dichloromethane (3 mL) was added to a mixture of diol **8** (320 mg, 0.49 mmol), tetraethylammonium bromide (250 mg, 1.19 mmol), and 4 Å molecular sieves (3 g) in dichloromethane (3 mL) and *N*,*N*-dimethylformamide (0.9 mL). The mixture was kept stirring under nitrogen for 4 days, then methanol was added (0.5 mL) and stirring continued for a further 2 h. It was diluted with dichloromethane, filtered through a pad of Celite, washed with aqueous sodium hydrogen carbonate and water, dried, and evaporated. Purification was effected by column chromatography (silica gel, hexane – ethyl acetate 3:1, dichloromethane – ethyl acetate 2:1) to provide the title compound **10** (467 mg, 64%) as a white foam; $[\alpha]_D$ −75.4° (*c* 0.9, chloroform); ^{1}H nmr ($CDCl_3$) δ: 7.45–7.15 (m, 45H, 9Ph), 6.36 (d, 1H, NH, $J_{NH,2a}$ 8.5 Hz), 5.76 (d, 1H, H-1d, $J_{1d,2d}$ 3.5 Hz), 5.12 (d, 1H, H-1c, $J_{1c,2c}$ 3.5 Hz), 3.31 (s, 3H, CH_3O), 2.23 (ddd, 1H, H-4beq, $J_{4beq,4bax}$ 13.0 Hz, $J_{4beq,5b}$ 1.5 Hz, $J_{4beq,3b}$ 4.0 Hz), 1.66 (s, 3H, CH_3CONH), 1.41 (q, 1H, H-4bax, $J_{4bax,5b}$ 12.0 Hz, $J_{4bax,3b}$ 12.0 Hz), 1.14 (d, 6H, H_3-6c, H_3-6d, $J_{5c,6c} = J_{5d,6d}$ 6.5 Hz). *Anal.* calcd. for $C_{90}H_{101}NO_{18}$: C 72.80, H 6.86, N 0.94; found: C 72.51, H 6.78, N 0.97.

Methyl 2-acetamido-2-deoxy-3-O-[4-deoxy-2-O-(α-L-fucopyranosyl)-β-D-xylo-hexopyranosyl]-4-O-(α-L-fucopyranosyl)-β-D-glucopyranoside (11)

Compound **10** (288 mg, 0.19 mmol) in ethanol (9 mL) was hydrogenated over 5% palladium-on-carbon (288 mg) for 2 days at 100 psi (1 psi = 6.9 kPa). The catalyst was removed by filtration, the solvent evaporated and the resulting material precipitated from methanol – ethyl acetate to provide pure **13** (109.2 mg, 84%); $[\alpha]_D$ −131.7° (*c* 0.6, water). The ^{1}H and ^{13}C nmr data are reported in Tables 1 and 2.

*Methyl 2-acetamido-6-O-benzyl-3-O-(4,6-O-benzylidene-3-deoxy-β-D-xylo-hexopyranosyl)-2-deoxy-β-D-glucopyranoside (**13**)*

The triacetate **12** (600 mg, 1.00 mmol) was treated with methanolic 0.2 N sodium methoxide solution (13 mL) for 5 h. Deionization with Amberlite MB1, followed by evaporation to dryness, left a crystalline solid (374 mg), which was dissolved in acetonitrile (12 mL). α,α-Dimethoxytoluene (270 μL, 1.80 mmol) and *p*-toluenesulfonic acid monohydrate (20 mg) were added. A few minutes after the addition, the reaction product started to crystallize from the mixture and tlc indicated the reaction to be complete. A few drops of triethylamine were added and the mixture was kept in the fridge for 2 h before it was filtered to provide pure **13** (323 mg). Preparative tlc (dichloromethane – 7% methanol) of the mother liquor afforded an additional amount of **13** (48 mg, total yield 66%). The analytical sample was prepared by recrystallization from ethanol. No sharp melting point, but decomposition >240°C; $[\alpha]_D$ −56.7° (*c* 0.3, chloroform); ^{1}H nmr ($CDCl_3$, 1% dimethyl-d_6 sulfoxide) δ: 7.66 (d, 1H, NH, $J_{NH,2a}$ 7.5 Hz), 7.55–7.24 (m, 10H, 2Ph), 5.53 (s, 1H, C*H*Ph), 4.96 (d, 1H, H-1a, $J_{1a,2a}$ 8.5 Hz), 4.63 and 4.61 (AB, 2H, CH_2Ph, J_{AB} 12.0 Hz), 4.34 (d, 1H, OH-2b, $J_{OH,2b}$ 2.0 Hz), 4.23 (d, 1H, H-1b, $J_{1b,2b}$ 8.0 Hz), 3.99 (dd, 1H, H-3a, $J_{2a,3a}$ 10.0 Hz, $J_{3a,4a}$ 8.5 Hz), 3.90 (dd, 1H, H-6d, $J_{6b,6b'}$ 11.5 Hz, $J_{6b,5b}$ 1.5 Hz), 3.81 (m, 1H, H-2b), 3.69 (dd, 1H, H-6a, $J_{6a,6a'}$ 11.0 Hz, $J_{6a,5a}$ 5.5 Hz), 3.55 (s, overlapped, CH_3O), 3.22 (m, 1H, H-2a), 2.33 (ddd, 1H, H-3beq, $J_{3beq,3bax}$ 13.5 Hz, $J_{2b,3beq}$ 5.0 Hz, $J_{3beq,4b}$ 2.5 Hz), 1.97 (s, 3H, CH_3CONH), 1.68 (ddd, 1H, H-3bax, $J_{2b,3bax}$ 12.0 Hz, $J_{3bax,4b}$ 3.5 Hz). *Anal.* calcd. for $C_{29}H_{37}NO_{10}$: C 62.24, H 6.66, N 2.50; found: C 61.94, H 6.69, N 2.80.

*Methyl 2-acetamido-4-O-acetyl-3-O-(2-O-acetyl-4,6-O-benzylidene-3-deoxy-β-D-xylo-hexopyranosyl)-6-O-benzyl-2-deoxy-β-D-glucopyranoside (**14**)*

A solution of the diol **13** (40 mg, 0.07 mmol) in pyridine (0.8 mL) and acetic anhydride (0.4 mL) was kept at room temperature for 2 h. The usual work-up, followed by recrystallization of the resulting material from ethanol, provided the di-*O*-acetate **14** (36.0 mg, 79%); mp 119–120°C, $[\alpha]_D$ +2.8°, $[\alpha]_{365}$ +25° (*c* 0.6, chloroform); ^{1}H nmr ($CDCl_3$) δ: 7.55–7.25 (m, 10H, 2Ph), 5.80 (d, 1H, NH, $J_{NH,2a}$ 7.0 Hz), 5.47 (s, 1H, C*H*Ph), 5.00 (d, 1H, H-1a, $J_{1a,2a}$ 8.0 Hz), 4.94 (t, 1H, H-4a, $J_{3a,4a} \sim J_{4a,5a}$ 9.0 Hz), 4.86 (ddd, 1H, H-2b, $J_{1b,2b}$ 8.5 Hz, $J_{2b,3beq}$ 5.0 Hz, $J_{2b,3bax}$ 11.5 Hz), 4.56 and 4.53 (AB, 2H, CH_2Ph, J_{AB} 12.0 Hz), 4.51 (t, 1H, H-3a, $J_{2a,3a}$ 9.0 Hz), 4.25 (dd, 1H, H-6b, $J_{6b,6b'}$ 12.0 Hz, $J_{6b,5b}$ < 1.0 Hz), 4.05 (dd, overlapped by H-4b, H-6b', $J_{6b',5b}$ 1.5 Hz), 4.03 (br s, 1H, H-4b), 3.76 (m, 1H, H-5a, $J_{6a,5a}$ 2.5 Hz, $J_{6a',5a}$ 5.5 Hz), ~3.65, ~3.59 (m, 2H, H-6a, H-6a', $J_{6a,6a'}$ 10.5 Hz), 3.55 (s, 3H, CH_3O), 3.49 (br s, 1H, H-5b), 3.20 (m, 1H, H-2a), 2.50 (ddd, 1H, H-3beq, $J_{3beq,3bax}$ 13.5 Hz, $J_{3beq,4b}$ 2.5 Hz), 2.05, 2.04, 2.02 (3s, each 3H, 2CH_3COOC, CH_3CONH), 1.65 (ddd, 1H, H-3bax, $J_{3bax,4b}$ 3.5 Hz). *Anal.* calcd. for $C_{33}H_{41}NO_{12}$: C 61.58, H 6.42, N 2.18; found: C 61.59, H 6.53, N 2.31.

*Methyl 2-acetamido-6-O-benzyl-3-O-[4,6-O-benzylidene-3-deoxy-2-O-(2,3,4-tri-O-benzyl-α-L-fucopyranosyl)-β-D-xylo-hexopyranosyl]-2-deoxy-4-O-(2,3,4-tri-O-benzyl-α-L-fucopyranosyl)-β-D-glucopyranoside (**15**)*

A solution of bromide **9** (2.76 mmol) in dichloromethane (2.5 mL) was added to a stirred mixture of diol **13** (250 mg, 0.45 mmol), tetraethylammonium bromide (200 mg, 0.95 mmol), 4 Å molecular sieves (3 g) in dichloromethane (3 mL), and *N*,*N*-dimethylformamide (0.8 mL). After stirring for 24 h, the mixture was processed conventionally and separated on a column of silica gel using hexane – ethyl acetate (3:1) and dichloromethane – ethyl acetate (2:1) as eluents. The title compound **15** was obtained as a foam in 84% yield (524 mg); $[\alpha]_D$ −61.7° (*c* 0.6, chloroform); ^{1}H nmr δ: 7.55–7.15 (m, 40H, 8Ph), 6.26 (d, 1H, NH, $J_{2a,NH}$ 7.0 Hz), 5.56 (s, 1H, C*H*Ph), 5.09 (d, 1H, H-1c, $J_{1c,2c}$ 3.5 Hz), 3.44 (s, 3H, CH_3O), 3.09 (m, 1H, H-2a), 2.56 (m, 1H, H-3beq, $J_{3beq,3bax}$ 13.0 Hz), 1.74 (s, 3H, CH_3CONH), 1.56 (m, 1H, H-3bax, $J_{3bax,2b}$ 11.0 Hz, $J_{3bax,4b}$ 2.5 Hz), 1.15, 1.00 (each d, each 3H, H_3-6c, H_3-6d, $J_{5c,6c} = J_{5d,6d}$ 6.5 Hz). *Anal.* calcd. for $C_{83}H_{93}NO_{18}$: C 71.58, H 6.73, N 1.01; found: C 71.55, H 6.74, N 1.35.

*Methyl 2-acetamido-2-deoxy-3-O-[3-deoxy-2-O-(α-L-fucopyranosyl)-β-D-xylo-hexopyranosyl]-4-O-(α-L-fucopyranosyl)-β-D-glucopyranoside (**16**)*

The tetrasaccharide **15** (400 mg, 0.29 mmol) was hydrogenated for 3 days in the presence of 5% palladium-on-carbon as described for the preparation of compound **11**. The hydrogenation product was precipitated twice from methanol – ethyl acetate to provide pure **16** (160.2 mg, 83%); $[\alpha]_D$ −149.8° (*c* 0.9, water). The ^{1}H and ^{13}C nmr data are reported in Tables 1 and 2.

*2,3,4-Tri-O-acetyl-β-L-arabinopyranosyl bromide (**17**) (24)*

Bromide **17** was prepared from 1,2,3,4-tetra-*O*-acetyl-L-arabinopyranose (36) (3 g, 9.4 mmol) as described for the preparation of bromide **1**.

*2,3,4-Tri-O-acetyl-6-deoxy-6-fluoro-α-D-galactopyranosyl bromide (**18**) (25)*

Bromide **18** was prepared from 1,2,3,4-tetra-*O*-acetyl-6-deoxy-6-fluoro-D-galactopyranose (25) (1.7 g, 5.06 mmol) as described for the preparation of bromide **1**. Conventional work-up provided **18** (1.64 g, 88%) as a white powder; $[\alpha]_D$ −195.6° (*c* 0.4, chloroform); ^{1}H nmr ($CDCl_3$) δ: 6.72 (d, 1H, H-1, $J_{1,2}$ 4.0 Hz), 5.58 (br d, 1H, H-4, $J_{4,3}$ 3.5 Hz), 5.42 (dd, 1H, H-3, $J_{3,2}$ 10.5 Hz), 5.07 (dd, 1H, H-2), 4.60–4.32 (m, 3H, H-5, H-6, H-6'), 2.15, 2.12, and 2.02 (3s, each 3H, CH_3COOC). *Anal.* calcd. for $C_{12}H_{16}BrFO_7$: C 38.83, H 4.36; found: C 39.56, H 4.36.

*1,2,3,4-Tetra-O-acetyl-6-chloro-6-deoxy-D-galactopyranose (**19**)*

A mixture of 6-chloro-6-deoxy-D-galactose (37) (1.7 g, 8.56 mmol) in pyridine (50 mL) and acetic anhydride (8.3 mL) was kept at room temperature for 24 h. Conventional work-up provided the tetraacetate **19** (3 g, 96%) as a yellowish syrup in an α:β ratio of 0.75:1; ^{1}H nmr ($CDCl_3$) δ: 6.37 (d, 0.43H, H-1α, $J_{1,2}$ 3.0 Hz), 5.71 (d, 0.57H, H-1β, $J_{1,2}$ 8.5 Hz), 5.66, 5.59 (2 dd, 0.43H, H-4α, 0.57H, H-4β, $J_{4,3}$ 3.5 Hz, $J_{4,5}$ 1.5 Hz), 5.40–5.30 (m, 1.43H, H-2α, H-2β, H-3α, at 5.32), 5.11 (dd, 0.57H, H-3β, $J_{3,2}$ 10.5 Hz, $J_{3,4}$ 3.5 Hz), 4.27, 4.02 (2 ddd, 0.43H, H-5α, 0.57H, H-5β, $J_{5,6}$ 8.0 Hz, $J_{5,6'}$ 6.0 Hz, $J_{5,4}$ 1.5 Hz), 3.7–3.4 (2H, H-6α, H-6'α, H-6β, H-6'β), 2.18, 2.175, 2.015, 2.01 (4s, each 1.29H, 4CH_3COO from α isomer), 2.19, 2.13, 2.05, 2.005 (4s, each 1.71H, 4CH_3COO from β isomer). *Anal.* calcd. for $C_{14}H_{19}ClO_9$: C 45.83, H 5.22, Cl 9.67; found: C 46.01, H 5.22, Cl 9.43.

*2,3,4-Tri-O-acetyl-6-chloro-6-deoxy-α-D-galactopyranosyl bromide (**20**)*

Tetraacetate **19** (2.71 g, 7.39 mmol) was converted into bromide **20** as described for the preparation of compound **1**. Usual work-up provided **20** (2.67 g, 93%) as a syrup; ^{1}H nmr ($CDCl_3$) δ: 6.69 (d, 1H, H-1, $J_{1,2}$ 4.0 Hz), 5.66 (dd, 1H, H-4, $J_{4,3}$ 3.0 Hz, $J_{4,5}$ 1.0 Hz), 5.42 (dd, 1H, H-3, $J_{3,2}$ 10.5 Hz), 5.04 (dd, 1H, H-2), 4.43 (br t, 1H, H-5, $J_{5,6} = J_{5,6'}$ 7.0 Hz), 3.53 (m, 2H, H-6, H-6'), 2.20, 2.12, 2.05 (3s, each 3H, CH_3COO).

*Methyl 2-acetamido-4,6-O-benzylidene-2-deoxy-3-O-(2,3,4-tri-O-acetyl-α-L-arabinopyranosyl)-β-D-glucopyranoside (**21**)*

Alcohol **4** (1.76 g, 5.44 mmol) was reacted with 2,3,4-tri-*O*-acetyl-β-L-arabinopyranosyl bromide (24) **17** (2.77 g, 8.16 mmol) for 22 h at 40°C following the procedure used for the preparation of disaccharide **5**. Further processing of the reaction mixture in the usual way, followed by crystallization of the crude product from dichloromethane – ethyl acetate, afforded the title compound **21** (1.96 g, 62%); mp 203–204°C; $[\alpha]_D$ +4.4° (*c* 1.0, chloroform); ^{1}H nmr ($CDCl_3$) δ: 7.50–7.35 (m, 5H, Ph), 5.77 (d, 1H, NH, $J_{NH,2a}$ 7.0 Hz), 5.51 (s, 1H, C*H*Ph), 5.13 (m, 1H, H-4b), 5.07 (dd, 1H, H-2b, $J_{2b,3b}$ 8.5 Hz, $J_{2b,1b}$ 6.0 Hz), 5.03 (d, 1H, H-1a, $J_{1a,2a}$ 8.0 Hz), 4.93 (dd, 1H, H-3b, $J_{3b,4b}$ 3.5 Hz), 4.67 (d, 1H, H-1b), 4.59 (dd, 1H, H-3a, $J_{3a,4a}$ 10.0 Hz, $J_{3a,2a}$ 9.0 Hz), 4.35 (dd, 1H, H-6aeq, $J_{6aeq,6aax}$ 10.0 Hz, $J_{6aeq,5a}$ 4.5 Hz), 3.92 (dd, 1H,

H-5beq, $J_{5beq,5bax}$ 12.5 Hz, $J_{5beq,4b}$ 4.5 Hz), 3.78 (t, 1H, H-6aax, $J_{6aax,5a}$ 10.0 Hz), 3.64 (t, 1H, H-4a, $J_{4a,5a}$ 9.0 Hz), 3.55 (ddd, 1H, H-5a), 3.50 (s, 3H, CH_3O), 3.24 (dd, 1H, H-5bax, $J_{5bax,4b}$ 2.5 Hz), 3.10 (br td, 1H, H-2a), 2.10, 2.05, 2.01, 2.00 (4s, each 3H, $3CH_3COOC$, CH_3CONH). *Anal.* calcd. for $C_{27}H_{35}NO_{13}$: C 55.76, H 6.06, N 2.41; found: C 55.40, H 6.06, N 2.40.

Methyl 2-acetamido-4,6-O-benzylidene-2-deoxy-3-O-(2,3,4-tri-O-acetyl-6-deoxy-6-fluoro-β-D-galactopyranosyl)-β-D-glucopyranoside (22)

Compound **4** (1.1 g, 3.4 mmol) was reacted with bromide **18** (1.6 g, 4.3 mmol) at 50°C for 21 h as described for the preparation of disaccharide **5**. The resulting solid product was recrystallized from dichloromethane–ether to provide the pure disaccharide **22** (0.99 g, 1.62 mmol). More material (0.13 g, total yield 49%) was obtained by chromatography of the mother liquor on a column of silica gel (dichloromethane – 2% methanol); mp 233.5–234.5°C; $[\alpha]_D$ +10° (*c* 0.2, chloroform); ^{1}H nmr ($CDCl_3$) δ: 7.50–7.35 (m, 5H, Ph), 5.73 (d, 1H, NH, $J_{NH,2a}$ 7.0 Hz), 5.51 (s, 1H, C*H*Ph), 5.29 (dd, 1H, H-4b, $J_{4b,3b}$ 3.5 Hz, $J_{4b,5b}$ 1.0 Hz), 5.16 (dd, 1H, H-2b, $J_{2b,3b}$ 10.5 Hz, $J_{2b,1b}$ 8.0 Hz), 5.08 (d, 1H, H-1a, $J_{1a,2a}$ 8.5 Hz), 4.89 (dd, 1H, H-3b), 4.80 (d, 1H, H-1b), 4.70 (dd, 1H, H-3a, $J_{3a,2a}$ 10.0 Hz, $J_{3a,4a}$ 9.0 Hz), 4.33 (dd, 1H, H-6aeq, $J_{6aax,6aeq}$ 10.5 Hz, $J_{6aeq,5a}$ 5.0 Hz), 4.31 (ddd, 1H, H-6b, $J_{6b,F}$ ~ 47 Hz, $J_{6b,6b'}$ 9.5 Hz, $J_{6b,5b}$ 6.5 Hz), 4.27 (ddd, 1H, H-6b′, $J_{6b',F}$ ~ 47 Hz, $J_{6b',5b}$ 5.0 Hz), 3.79 (t, 1H, H-6aax, $J_{6aax,5a}$ 10.5 Hz), 3.72 (t, 1H, H-4a, $J_{4a,5a}$ 9.0 Hz), 3.61–3.50 (m, 2H, H-5a, H-5b), 3.50 (s, 3H, CH_3O), 3.05 (ddd, 1H, H-2a), 2.11, 2.03, 2.01, 1.96 (4s, each 3H, $3CH_3COOC$, CH_3CONH). CI ms (NH_3), *m/z*: 614 (2.9, $[MH]^+$), 582 (10, $[M - OMe]^+$).

Methyl 2-acetamido-4,6-O-benzylidene-2-deoxy-3-O-(2,3,4-tri-O-acetyl-6-chloro-6-deoxy-β-D-galactopyranosyl)-β-D-glucopyranoside (23)

The disaccharide **23** was prepared from alcohol **4** (586 mg, 1.8 mmol) by reaction with bromide **20** (891 mg, 2.3 mmol) at 45°C for 60 h following the procedure used for the synthesis of compound **5**. The crude reaction product was chromatographed on a column of silica gel (dichloromethane – 2% methanol) and recrystallized from dichloromethane–hexane to provide the title compound **23** (350 mg, 31%); mp 180°C; $[\alpha]_D$ +2.5° (*c* 0.8, chloroform); ^{1}H nmr ($CDCl_3$) δ: 7.50–7.40 (m, 5H, Ph), 5.71 (d, 1H, NH, $J_{NH,2a}$ 7.0 Hz), 5.52 (s, 1H, C*H*Ph), 5.40 (dd, 1H, H-4b, $J_{4b,3b}$ 3.5 Hz, $J_{4b,5b}$ 1.0 Hz), 5.13 (dd, 1H, H-2b, $J_{2b,3b}$ 10.5 Hz, $J_{2b,1b}$ 8.0 Hz), 5.08 (d, 1H, H-1a, $J_{1a,2a}$ 8.5 Hz), 4.91 (dd, 1H, H-3b), 4.77 (d, 1H, H-1b), 4.70 (dd, 1H, H-3a, $J_{3a,2a}$ 10.0 Hz, $J_{3a,4a}$ 9.0 Hz), 4.34 (dd, 1H, H-6aeq, $J_{6aeq,6aax}$ 10.5 Hz, $J_{6aeq,5a}$ 5.0 Hz), 3.78 (t, 1H, H-6aax, $J_{6aax,5a}$ 10.5 Hz), 3.69 (t, 1H, H-4a, $J_{4a,5a}$ 9.0 Hz), 3.58 (br ddd, 1H, H-5a), 3.51 (s, 3H, CH_3O), 3.47 (br t, 1H, H-5b, $J_{5b,6b}$ ~ $J_{5b,6b'}$ 7.0 Hz), 3.34–3.27 (m, 2H, H-6b and H-6b′), 3.05 (ddd, 1H, H-2a), 2.13, 2.02, 2.01 and 1.96 (4s, each 3H, $3CH_3COOC$, CH_3CONH). *Anal.* calcd. for $C_{28}H_{36}ClNO_{13}$: C 53.37, H 5.76, Cl 5.63, N 2.22; found: C 53.33, H 5.89, Cl 5.42, N 2.14.

Methyl 2-acetamido-6-O-benzyl-2-deoxy-3-O-(2,3,4-tri-O-acetyl-α-L-arabinopyranosyl)-β-D-glucopyranoside (24)

Compound **21** (1.70 g, 2.13 mmol) was reacted with sodium cyanoborohydride (4.11 g, 65 mmol) as described for the preparation of disaccharide **6**. Purification of the reaction product was achieved by column chromatography (dichloromethane – 5% methanol) and recrystallization from methanol–ether to provide **24** in 85% yield (1.45 g); mp 158°C; $[\alpha]_D$ +19.0° (*c* 0.5, chloroform); ^{1}H nmr ($CDCl_3$) δ: 7.35–7.30 (m, 5H, Ph), 5.63 (d, 1H, NH, $J_{NH,2a}$ 7.5 Hz), 5.26 (m, 1H, H-4b), 5.21 (dd, 1H, H-2b, $J_{2b,3b}$ 10.0 Hz, $J_{2b,1b}$ 7.5 Hz), 5.03 (dd, 1H, H-3b, $J_{3b,4b}$ 3.5 Hz), 4.76 (d, 1H, H-1a, $J_{1a,2a}$ 8.0 Hz), 4.62 (s, 2H, CH_2Ph), 4.48 (d, 1H, H-1b), 4.33 (br dd, 1H, H-3a, $J_{3a,2a}$ 10.0 Hz, $J_{3a,4a}$ 8.0 Hz), 4.05 (dd, 1H, H-5beq, $J_{5beq,5bax}$ 13.0 Hz, $J_{5beq,4b}$ 2.5 Hz), 3.51 (br s, 4H, with CH_3O), 3.11 (br td, 1H, H-2a), 2.14 and 2.10 (2s, each 3H, $2CH_3CO$), 2.01 (s, 6H, $2CH_3CO$). *Anal.* calcd. for $C_{28}H_{39}NO_{13}$: C 55.57, H 6.35, N 2.40; found: C 55.19, H 6.38, N 2.29.

Methyl 2-acetamido-6-O-benzyl-2-deoxy-3-O-(2,3,4-tri-O-acetyl-6-deoxy-6-fluoro-β-D-galactopyranosyl)-β-D-glucopyranoside (25)

Compound **25** was prepared from disaccharide **22** (1.0 g, 1.64 mmol) by reaction with sodium cyanoborohydride (2.3 g) as described for the preparation of compound **6**. Chromatography of the crude reaction product on a column of silica gel (dichloromethane – 2% methanol) and recrystallization from chloroform–ether provided the title compound **25** (663 mg, 66%); mp 144–145°C; $[\alpha]_D$ +6.9° (*c* 0.5, chloroform); ^{1}H nmr ($CDCl_3$) δ: 7.40–7.25 (m, 5H, Ph), 5.82 (d, 1H, NH, $J_{NH,2a}$ 8.0 Hz), 5.41 (br dd, 1H, H-4b, $J_{4b,3b}$ 3.5 Hz, $J_{4b,5b}$ 1.0 Hz), 5.24 (dd, 1H, H-2b, $J_{2b,3b}$ 10.0 Hz, $J_{2b,1b}$ 8.0 Hz), 5.03 (dd, 1H, H-3b), 4.74 (d, 1H, H-1a, $J_{1a,2a}$ 8.0 Hz), 4.63 (d, 1H, H-1b), 4.61 (s, 2H, CH_2Ph), ~4.45 (m, 2H, H-6b and H6b′, $J_{6,F}$ ~ $J_{6'F}$ ~ 45 Hz), 4.36 (1H, H-3a, overlapped by H-6b, H-6b′), 4.08 (m, 1H, H-5b), 3.87 (br d, 1H, H-6a, $J_{6a,6a'}$ 11.0 Hz, $J_{6a,5a}$ ~ 1.0 Hz), 3.73 (m, 2H, H-5a and OH-4a), 3.55–3.48 (m, 5H, H-6a′, H-4a, with CH_3O at 3.50), 3.17 (td, 1H, H-2a, $J_{2a,3a}$ 10.0 Hz), 2.15, 2.10, 2.03, 2.00 (4s, each 3H, 3 CH_3COOC, CH_3CONH). *Anal.* calcd. for $C_{28}H_{38}FNO_{18}$: C 54.63, H 6.22, N 2.28; found: C 54.30, H 6.23, N 2.45.

Methyl 2-acetamido-6-O-benzyl-2-deoxy-3-O-(2,3,4-tri-O-acetyl-6-chloro-6-deoxy-β-D-galactopyranosyl)-β-D-glucopyranoside (26)

Compound **26** was synthesized from disaccharide **23** (450 mg, 0.7 mmol) following the procedure used for the preparation of compound **6**. Chromatographic purification on a column of silica gel (dichloromethane – 2% methanol) and recrystallization from chloroform–ether afforded pure **26** (300 mg, 76%); mp 174–175°C; $[\alpha]_D$ +7.5° (*c* 0.2, chloroform); ^{1}H nmr ($CDCl_3$) δ: 7.35–7.30 (m, 5H, Ph), 5.79 (d, 1H, NH, $J_{NH,2a}$ 8.0 Hz), 5.48 (dd, 1H, H-4b, $J_{4b,3b}$ 3.5 Hz, $J_{4b,5b}$ 1.0 Hz), 5.22 (dd, 1H, H-2b, $J_{2b,3b}$ 10.5 Hz, $J_{2b,1b}$ 8.0 Hz), 5.01 (dd, 1H, H-3b), 4.78 (d, 1H, H-1a, $J_{1a,2a}$ 8.0 Hz), 4.61 (d, 1H, H-1b), 4.61 (s, 2H, CH_2Ph), 4.39 (m, 1H, H-3a), 3.95 (br t, 1H, H-5b, $J_{5b,6b}$ ~ $J_{5b,6b'}$ ~ 7.0 Hz), 3.87 (br d, 1H, H-6a, $J_{6a,6a'}$ 11.0 Hz), 3.75–3.45 (m, 9H, with CH_3O at 3.50), 3.11 (td, 1H, H-2a, $J_{2a,3a}$ 9.0 Hz), 2.16, 2.08, 2.02, 1.99 (4s, each 3H, $3CH_3COOC$, CH_3CONH). FAB ms, *m/z*: 654 (4.1, $[M + Na]^+$), 632 (2.0, $[M + H]^+$), 631 (0.2, M^+), 601 (2.2, $[M - OMe + H]^+$), 600 (6.8 $[M - OMe]^+$). An analytical sample was acetylated following standard conditions (pyridine, acetic anhydride). The resulting methyl 2-acetamido-4-*O*-acetyl-6-*O*-benzyl-2-deoxy-3-*O*-(2,3,4-tri-*O*-acetyl-6-chloro-6-deoxy-β-D-galactopyranosyl)-β-D-glucopyranoside was characterized by ^{1}H nmr spectroscopy: ^{1}H nmr ($CDCl_3$) δ: 7.40–7.30 (m, 5H, Ph), 5.72 (d, 1H, NH, $J_{NH,2a}$ 7.5 Hz), 5.48 (dd, 1H, H-4b, $J_{4b,3b}$ 3.5 Hz, $J_{4b,5b}$ 1.0 Hz), 5.08 (dd, 1H, H-2b, $J_{2b,3b}$ 10.5 Hz, $J_{2b,1b}$ 7.5 Hz), 4.98 (dd, 1H, H-3b), 4.94 (t, 1H, H-4a, $J_{4a,3a}$ = $J_{4a,5a}$ 9.0 Hz), 4.80 (d, 1H, H-1a, $J_{1a,2a}$ 7.5 Hz), 4.59 (d, 1H, H-1b), 4.54 (s, 2H, CH_2Ph), 4.41 (t, 1H, H-3a, $J_{3a,2a}$ 9.0 Hz), 3.81 (dt, 1H, H-5b, $J_{5b,6b}$ ~ $J_{5b,6b'}$ ~ 7.0 Hz), 3.71 (ddd, 1H, H-5a, $J_{5a,4a}$ 9.0 Hz, $J_{5a,6a}$ 6.0 Hz, $J_{5a,6a'}$ 3.0 Hz), 3.60–3.40 (m, 7H, H-6a, H-6a′, H-6b, H-6b′, with CH_3O at 3.49), 3.32 (td, 1H, H-2a), 2.15, 2.06, 2.02 (3s, each 3H, $3CH_3CO$), 1.97 (s, 6H, $2CH_3CO$).

Methyl 2-acetamido-6-O-benzyl-3-O-(3,4-O-benzylidene-α-L-arabinopyranosyl)-2-deoxy-β-D-glucopyranoside (28)

A solution of compound **24** (1.44 g, 2.47 mmol) in methanolic 0.05 N sodium methoxide (30 mL) was kept under argon for 5 h. After neutralization with Amberlite IRC 50 H^+ and evaporation to dryness, the residual powder was dissolved in *N*,*N*-dimethylformamide (5 mL) and acetonitrile (30 mL) and then treated with *p*-toluenesulfonic acid (100 mg, 5.26 mmol) and α,α-dimethoxytoluene (1.25 mL, 8.1 mmol) at room temperature for 1 day. The mixture was neutralized with triethylamine and evaporated to dryness. Purification was achieved by column chromatography on silica gel (dichloromethane – 4% methanol) to provide compound **28** (1.08 g, 77%) as a mixture of two diastereoisomers. A fraction containing the slower migrating isomer was evaporated and the residual material recrystallized from chloroform–ether and characterized; mp 174.5°C; $[\alpha]_D$ +22.5° (*c* 0.9,

chloroform); ^{1}H nmr ($CDCl_3$) δ: 7.60–7.20 (m, 10H, 2Ph), 6.25 (br d, 1H, NH), 5.95 (s, 1H, C*H*Ph), 4.66 (d, 1H, H-1a, $J_{1a,2a}$ 8.5 Hz), 4.60 (s, 2H, CH_2Ph), 4.35 (dd, 1H, H-5beq, $J_{5beq,5bax}$ 13.5 Hz, $J_{5beq,4b}$ 2.0 Hz), 4.00 (dd, 1H, H-3a, $J_{3a,2a}$ 10.0 Hz, $J_{3a,4a}$ 8.0 Hz), 3.55–3.44 (m, 5H, with CH_3O at 3.49), 3.39 (td, 1H, H-2a, $J_{2a,NH}$ 8.5 Hz), 1.98 (s, 3H, CH_3CONH). *Anal.* calcd. for $C_{28}H_{35}NO_{10}$: C 61.64, H 6.47, N 2.57; found: C 61.43, H 6.32, N 2.77.

*Methyl 2-acetamido-6-*O*-benzyl-3-*O*-(3,4-*O*-benzylidene-6-deoxy-6-fluoro-β-*D*-galactopyranosyl)-2-deoxy-β-*D*-gluco-pyranoside (**29**)*

Compound **25** (625 mg, 1 mmol) was deacetylated and benzylidenated as described for the preparation of diol **28**. Purification and partial separation of the two diastereoisomers of **29** was effected by column chromatography on silica gel (dichloromethane – 4% methanol). Total yield 94% (540 mg). A pure fraction of the more polar isomer was evaporated and the compound crystallized from dichloromethane – ethyl acetate – hexane; mp 184.5–185.5°C; $[\alpha]_D$ +10.9° (*c* 0.7, chloroform); ^{1}H nmr ($CDCl_3$) δ: 7.50–7.25 (m, 10H, 2Ph), 6.52 (d, 1H, NH, $J_{NH,2a}$ 8.0 Hz), 5.86 (s, 1H, C*H*Ph), 4.69 (m, 2H, H-6b, H-6b′, $J_{6b,F} \sim J_{6b',F} \sim$ 45 Hz), 4.60 (d, 1H, H-1a, $J_{1a,2a}$ 8.5 Hz), 4.29 (d, 1H, H-1b, $J_{1b,2b}$ 8.5 Hz), 3.73–3.45 (m, 8H, with CH_3O at 3.45), 1.94 (s, 3H, CH_3CONH). *Anal.* calcd. for $C_{29}H_{36}FNO_{10}$: C 60.30, H 6.28, N 2.42; found: C 60.06, H 6.25, N 2.48. An analytical sample of methyl 2-acetamido-4-*O*-acetyl-3-*O*-(2-*O*-acetyl-3,4-*O*-benzylidene-6-deoxy-6-fluoro-β-D-galactopyranosyl)-6-*O*-benzyl-2-deoxy-β-D-glucopyranoside (**29***a*) was prepared from the slower migrating isomer of diol **29** by acetylation (pyridine, acetic anhydride); ^{1}H nmr ($CDCl_3$) δ: 7.57–7.25 (m, 10H, 2Ph), 7.82 (s, 1H, C*H*Ph), 7.79 (d, NH, $J_{NH,2a}$ 7.5 Hz), 4.94 (t, 1H, H-2b, $J_{2b,3b} \sim J_{2b,1b}$ 6.5 Hz), 4.94 (t, 1H, H-4a, $J_{4a,3a} \sim J_{4a,5a}$ 9.5 Hz), 4.89 (d, 1H, H-1a, $J_{1a,2a}$ 7.5 Hz), 4.67 (d, 1H, H-1b, overlapped by H-6b and H-6b′), ~4.63 (m, 2H, H-6b, H-6b′, $J_{6b,F} \sim J_{6b',F} \sim$ 45 Hz), 4.53 (s, 2H, CH_2Ph, overlapped by H-6b and H-6b′), 4.45 (t, 1H, H-3a, $J_{3a,2a}$ 9.5 Hz), 4.36 (t, 1H, H-3b, $J_{3b,4b}$ 6.5 Hz), 4.25 (dd, 1H, H-4b, $J_{4b,5b}$ 2.5 Hz), 4.12 (dddd, 1H, H-5b, $J_{5b,F}$ 14.0 Hz, $J_{5b,6b}$ 7.0 Hz, $J_{5b,6b'}$ 5.0 Hz), 3.70 (ddd, 1H, H-5a, $J_{5a,6a}$ 5.5 Hz, $J_{5a,6a'}$ 3.5 Hz), 3.61–3.51 (m, 2H, H-6a, H-6a′), 3.50 (s, 3H, CH_3O), 3.15 (td, 1H, H-2a), 2.10, 2.0, 1.93 (3s, each 3H, $2CH_3COO$, CH_3CONH).

*Methyl 2-acetamido-6-*O*-benzyl-3-*O*-(3,4-*O*-benzylidene-6-chloro-6-deoxy-β-*D*-galactopyranosyl)-2-deoxy-β-*D*-glucopyranoside (**30**)*

Diol **30** was prepared from tri-*O*-acetate **26** (300 mg, 0.47 mmol) by deacetylation and subsequent benzylidenation as described for the preparation of compound **28**. Chromatographic purification on a column of silica gel (dichloromethane – 3% methanol) provided **30** (217 mg, 77%) as a diastereoisomeric mixture. A pure fraction of the less polar isomer was evaporated and the resulting material crystallized from chloroform–ether–hexane; mp 151–152°C; $[\alpha]_D$ +27.9° (*c* 0.3, chloroform); ^{1}H nmr ($CDCl_3$) δ: 7.44–7.24 (m, 1H, 2Ph), 6.10 (s, 1H, C*H*Ph), 6.04 (d, 1H, NH, $J_{NH,2a}$ 8.0 Hz), 4.62 (d, 1H, H-1a, $J_{1a,2a}$ 8.5 Hz), 4.58 (s, 2H, CH_2Ph), 4.42 (dd, 1OH, H-3b, $J_{3b,2b}$ 7.5 Hz, $J_{3b,4b}$ 5.5 Hz), 4.29 (d, 1H, H-1b, $J_{1b,2b}$ 8.5 Hz), 4.15 (dd, 1H, H-4b, $J_{4b,5b}$ 2.0 Hz), 4.04 (s, 1H, OH), 3.51 (s, 3H, CH_3O), 2.04 (s, 3H, CH_3CONH). *Anal.* calcd. for $C_{29}H_{36}ClNO_{10}$: C 58.63, H 6.11, N 2.36; found: C 58.24, H 6.11, N 2.66. An analytical sample of this isomer was acetylated conventionally (pyridine, acetic anhydride) to provide methyl 2-acetamido-4-*O*-acetyl-3-*O*-(2-*O*-acetyl-3,4-*O*-benzylidene-6-chloro-6-deoxy-β-D-galactopyranosyl)-6-*O*-benzyl-2-deoxy-β-D-glucopyranoside (**30***a*); ^{1}H nmr ($CDCl_3$) δ: 7.50–7.30 (m, 10H, 2Ph), 6.17 (s, 1H, C*H*Ph), 5.85 (d, 1H, NH, $J_{NH,2a}$ 7.5 Hz), 5.04 (t, 1H, H-2b, $J_{2b,1b} \sim J_{2b,3b}$ ~6.0 Hz), 5.00 (t, 1H, H-4a, $J_{4a,3a} = J_{4a,5a}$ 9.0 Hz), 4.96 (d, 1H, H-1a, $J_{1a,2a}$ 7.5 Hz), 4.64 (d, 1H, H-1b), 4.55 (s, 2H, CH_2Ph), 4.48 (t, 1H, H-3b, $J_{3b,4b}$ 6.0 Hz), 4.48 (t, 1H, H-3a, $J_{3a,2a}$ 9.0 Hz), 4.36 (dd, 1H, H-4b, $J_{4b,3b}$ 6.0 Hz, $J_{4b,5b}$ 2.0 Hz), 3.86 (dt, 1H, H-5b, $J_{5b,6b} \sim J_{5b,6b'} \sim$7.0 Hz), 3.80–3.66 and 3.60–3.56 (m, 5H, H-6b, H-6b′, H-6a, H-6a′, H-5a), 3.50 (s, 3H, CH_3O), 3.21 (td, 1H, H-2a), 2.21 (s, 3H, CH_3CO), 2.00 (s, 6H, $2CH_3CO$).

*Methyl 2-acetamido-6-*O*-benzyl-3-*O*-(3,4-*O*-benzylidene-6-deoxy-β-*D*-galactopyranosyl)-2-deoxy-β-*D*-glucopyranoside (**31**)*

The tri-*O*-acetate **27** (250 mg, 0.42 mmol) was converted into compound **31** by deacetylation and subsequent benzylidenation as described for the preparation of compound **28**. The resulting material was applied to a column of silica gel (dichloromethane – ethyl acetate 1:1, dichloromethane – 5% methanol) to provide solid **31** (175 mg, 75%). The ^{1}H nmr spectrum indicated the product to be a 1:1 mixture of *S* and *R* isomers of the 3,4-*O*-benzylidene acetal; $[\alpha]_D$ +2.1°, $[\alpha]_{365}$ +17.9° (*c* 0.5, dichloromethane); ^{1}H nmr ($CDCl_3$) δ: 7.5–7.2 (m, 10H, 2Ph), 6.62, 6.50 (each d, each 0.5H, NH, $J_{NH,2a}$ 7.5 Hz), 6.18, 5.90 (each s, each 0.5H, C*H*Ph), 4.72, 4.69 (each d, each 0.5H, H-1a, $J_{1a,2a}$ 8.5 Hz), 4.22, 4.21 (each d, each 0.5H, H-1b, $J_{1b,2b}$ 7.5 Hz), 3.50 (s, CH_3O), 2.01, 1.98 (2s, each 1.5H, CH_3CONH), 1.45, 1.40 (2d, each 1.5H, H3-6b, $J_{5b,6b}$ 6.5 Hz).

*Methyl 2-acetamido-4-*O*-acetyl-3-*O*-(2-*O*-acetyl-3,4-*O*-benzylidene-6-deoxy-β-*D*-galactopyranosyl)-6-*O*-benzyl-2-deoxy-β-*D*-glucopyranoside (**32**)*

A solution of diol **31** (25 mg, 0.05 mmol) in pyridine (0.6 mL) and acetic anhydride (0.3 mL) was kept at room temperature overnight. After work-up and evaporation to dryness, the reaction products was separated by preparative tlc (dichloromethane – 5% methanol, developed three times). Elution of the faster moving band provided one diastereoisomer (10.2 mg, 35.5%) as a solid; ^{1}H nmr ($CDCl_3$) δ: 7.55–7.25 (m, 10H, 2Ph), 6.16 (s, 1H, C*H*Ph), 5.89 (s, 1H, NH, $J_{NH,2a}$ 7.0 Hz), 4.99 (t, overlapped, 1H, H-2b, $J_{1b,2b}$ 6.5 Hz, $J_{2b,3b}$ 6.0 Hz), 4.99 (d, 1H, H-1a, $J_{1a,2a}$ 7.5 Hz), 4.97 (t, 1H, H-4a, $J_{3a,4a} = J_{4a,5a}$ 9.0 Hz), 4.56 (s, 2H, CH_2Ph), 4.53 (d, 1H, H-1b), 4.46 (t, 1H, H-3a, $J_{2a,3a}$ 9.0 Hz), 4.44 (t, 1H, H-3b, $J_{3b,4b}$ 6.0 Hz), 4.06 (dd, 1H, H-4b, $J_{4b,5b}$ 2.0 Hz), 3.80 (dq, 1H, H-5b, $J_{5b,6b}$ 6.5 Hz), 3.74 (m, 1H, H-5a), 3.63–3.54 (m, 2H, H-6a, H-6a′), 3.52 (s, 3H, CH_3O), 3.17 (m, 1H, H-2a), 2.12 (s, 3H, CH_3CO), 2.04 (s, 6H, $2CH_3CO$), 1.39 (d, 3H, H3-6b).

The lower band provided the solid second isomer (10.2 mg, 35.5%); ^{1}H nmr ($CDCl_3$) δ: 7.6–7.25 (m, 10H, 2Ph), 5.80 (s, 1H, C*H*Ph, overlapped by NH), 5.82 (d, 1H, NH, $J_{NH,2a}$ 7.0 Hz), 4.92 (t, 1H, H-4a, $J_{3a,4a} = J_{4a,5a}$ 9.0 Hz), 4.90 (d, overlapped by H-4a, 1H, H-1a, $J_{1a,2a}$ 7.5 Hz), 4.86 (t, 1H, H-2b, $J_{1b,2b}$ 7.0 Hz, $J_{2b,3b}$ 6.5 Hz), 4.58 (d, 1H, H-1b), 4.56 (s, 2H, CH_2Ph), 4.43 (t, 1H, H-3a, $J_{2a,3a}$ 9.0 Hz), 4.29 (t, 1H, H-3b, $J_{3b,4b}$ 6.5 Hz), 4.08 (dd, 1H, H-4b, $J_{4b,5b}$ 2.0 Hz), 3.92 (dq, 1H, H-5b, $J_{5b,6b}$ 6.5 Hz), 3.72 (m, 1H, H-5a), ~3.61, 3.66 (m, 2H, H-6a, H-6a′), 3.51 (s, 3H, CH_3O), 3.15 (m, 1H, H-2a), 2.09, 2.03, 1.97 (3s, each 3H, $2CH_3COOC$, CH_3CONH), 1.42 (d, 3H, H3-6b).

*Methyl 2-acetamido-6-*O*-benzyl-3-*O*-[3,4-*O*-benzylidene-2-*O*-(2,3,4-tri-*O*-benzyl-α-L-fucopyranosyl)-α-L-arabino-pyranosyl]-2-deoxy-4-*O*-(2,3,4-tri-*O*-benzyl-α-L-fuco-pyranosyl)-β-D-glucopyranoside (**33**)*

A solution of bromide **9** (5.8 mmol) in dichloromethane (5 mL) was added to a mixture of diol **28** (500 mg, 0.92 mmol), tetraethylammonium bromide (210 mg, 1 mmol), 4 Å molecular sieves (3 g) in dichloromethane (4 mL), and *N*,*N*-dimethylformamide (1 mL). The mixture was stirred for 40 h and then processed as described for the preparation of compound **10**. Column chromatography on silica gel (hexane – ethyl acetate 1:1, dichloromethane – ethyl acetate 3:1) afforded compound **33** (962 mg, 76%) as a mixture of two diastereoisomers. A pure fraction of the more polar isomer was characterized as a gum; $[\alpha]_D$ −65.5° (*c* 0.8, chloroform); ^{1}H nmr ($CDCl_3$) δ: 7.55–7.20 (m, 40H, 8 Ph), 6.14 (d, 1H, NH, $J_{NH,2a}$ 8.5 Hz), 5.93 (s, 1H, C*H*Ph), 5.51 (d, 1H, H-1d, $J_{1d,2d}$ 3.5 Hz), 5.02 (d, 1H, H-1c, $J_{1c,2c}$ 3.5 Hz), 3.32 (s, 3H, CH_3O), 1.67 (s, 3H, CH_3CONH), 1.10, 0.95 (2d, each 3H, H3-6c, H3-6d, $J_{5c,6c} = J_{5d,6d}$ 6.5 Hz). *Anal.* calcd. for $C_{82}H_{91}NO_{18}$: C 71.44, H 6.65, N 1.02; found: C 70.97, H 6.82, N 0.72.

Methyl 2-acetamido-6-O-benzyl-3-O-[3,4-O-benzylidene-6-deoxy-6-fluoro-2-O-(2,3,4-tri-O-benzyl-α-L-fucopyranosyl)-β-D-galactopyranosyl]-2-deoxy-4-O-(2,3,4-tri-O-benzyl-α-L-fucopyranosyl)-β-D-glucopyranoside (34)

Diol **29** (475 mg, 0.82 mmol) was reacted with bromide **9** (4.13 mmol) for 30 h according to the preparation of compound **10**. The crude product was applied to a column of silica gel (hexane – ethyl acetate, 1:1, dichloromethane – ethyl acetate, 3:1) to provide the title compound **34** (767 mg, 66%) as a mixture of two diastereoisomers. The slower migrating isomer was characterized. $[\alpha]_D$ −64.7° (*c* 0.6, chloroform); ^{1}H nmr ($CDCl_3$) δ: 7.43–7.20 (m, 40H, 8Ph), 6.40 (d, 1H, NH, $J_{NH,2a}$ 8.0 Hz), 5.99 (s, 1H, C*H*Ph), 5.52 (d, 1H, H-1d, $J_{1d,2d}$ 4.0 Hz), 5.11 (d, 1H, H-1c, $J_{1c,2c}$ 4.0 Hz), 3.29 (s, 3H, CH_3O), 1.65 (s, 3H, CH_3CONH), 1.13 (d, 6H, H3-6c, H3-6d, $J_{5c,6c} = J_{5d,6d}$ 6.5 Hz). *Anal.* calcd. for $C_{83}H_{92}FNO_{18}$: C 70.67, H 6.57, N 1.00; found: C 70.36, H 6.63, N 0.95.

Methyl 2-acetamido-6-O-benzyl-3-O-[3,4-O-benzylidene-6-chloro-6-deoxy-2-O-(2,3,4-tri-O-benzyl-α-L-fucopyranosyl)-β-D-galactopyranosyl]-2-deoxy-4-O-(2,3,4-tri-O-benzyl-α-L-fucopyranosyl)-β-D-glucopyranoside (35)

The tetrasaccharide **35** was prepared from diol **30** (235 mg, 0.40 mmol) and bromide **9** (3 mmol) as described for the preparation of compound **10**. Usual work-up after 42 h, followed by chromatography on a column of silica gel (hexane – ethyl acetate 1:1, dichloromethane – ethyl acetate 3:1) provided **35** as a mixture of two diastereoisomers (572 mg, 80%); $[\alpha]_D$ −60.2° (*c* 1.0, chloroform); ^{1}H nmr ($CDCl_3$) δ: 7.50–7.20 (m, 40H, 8Ph), 6.39, 6.31 (2d, 1H, NH, $J_{NH,2a}$ 8.0 Hz), 6.00, 5.91 (2s, 1H, C*H*Ph), 5.52, 5.50 (2d, 1H, H-1d, $J_{1d,2d}$ 4.0 Hz), 5.09, 5.04 (2d, 1H, H-1c, $J_{1c,2c}$ 4.0 Hz), 3.28, 3.27 (2s, 3H, CH_3O), 1.70, 1.65 (2s, 3H, CH_3CONH), 1.11, 1.08 1(2d, each 3H, H3-6c, H3-6d, $J_{6c,5c} = J_{6d,5d}$ 6.5 Hz). *Anal.* calcd. for $C_{83}H_{92}ClNO_{18}$: C 69.85, H 6.50, N 0.98, Cl 2.48; found: C 69.73, H 6.74, N 0.75, Cl 2.50.

Methyl 2-acetamido-6-O-benzyl-3-O-[3,4-O-benzylidene-6-deoxy-2-O-(2,3,4-tri-O-benzyl-α-L-fucopyranosyl)-β-D-galacto-pyranosyl]-2-deoxy-4-O-(2,3,4-tri-O-benzyl-α-L-fucopyranosyl)-β-D-glucopyranoside (36)

Bromide **9** (0.81 mmol) was reacted with diol **31** (140 mg, 0.25 mmol) as described for the preparation of compound **10**. After stirring for 20 h, more bromide **9** (0.57 mmol) was added and stirring continued for a further 20 h. Conventional processing and purification on a column of silica gel using hexane – ethyl acetate 1:1 as eluent provided the title compound **36** (279 mg, 80%) as a diastereoisomeric mixture; $[\alpha]_D$ −82.5° (*c* 0.7, dichloromethane); ^{1}H nmr ($CDCl_3$) δ: 7.55–7.21 (m, 40H, 8Ph), 6.38, 6.31 (each d, each 0.5H, NH, $J_{NH,2a}$ 7.5 Hz), 6.00, 5.92 (each s, each 0.5H, C*H*Ph), 5.57, 5.55 (each d, each 0.5H, H-1d, $J_{1d,2d}$ 3.5 Hz), 5.10, 5.04 (each d, each 0.5H, H-1c, $J_{1c,2c}$ 3.5 Hz), 3.34 (s, 3H, CH_3O), 1.68, 1.64 (each s, each 1.5H, CH_3CONH), 1.35, 1.32, 1.154, 1.148, 1.08, 0.92 (each d, each 1.5H, H3-6b, H3-6c, H3-6d, $J_{5b,6b} = J_{5c,6c} = J_{5d,6d}$ 6.5 Hz). *Anal.* calcd. for $C_{83}H_{93}NO_{18}$: C 71.58, H 6.73, N 1.01; found: C 71.57, H 6.74, N 0.81.

Methyl 2-acetamido-2-deoxy-4-O-(α-L-fucopyranosyl)-3-O-[2-O-(α-L-fucopyranosyl)-α-L-arabinopyranosyl]-β-D-glucopyranoside (37)

Compound **33** (200 mg, 0.15 mmol) was hydrogenated for 10 days over 10% palladium-on-carbon (100 mg) as described for the preparation of **11**. After filtration and evaporation, the crude product was applied to a column of Sephadex LH 20 and eluted with ethanol–water 1:1. Tetrasaccharide **37** was obtained as a light white powder (45 mg, 47%) after freeze-drying an aqueous solution; $[\alpha]_D$ −147.4° (*c* 0.4, water). The ^{1}H and ^{13}C nmr data are reported in Tables 1 and 2.

Methyl 2-acetamido-2-deoxy-3-O-[6-deoxy-6-fluoro-2-O-(α-L-fucopyranosyl)-β-D-galactopyranosyl]-4-O-(α-L-fucopyranosyl)-β-D-glucopyranoside (38)

A mixture of compound **34** (160 mg, 0.11 mmol) and 20% palladium hydroxide-on-carbon (160 mg) was hydrogenated for 22 h in the usual way. The reaction mixture was then treated as described for compound **37** and afforded the tetrasaccharide **38** (74 mg, 95%) as a light white powder; $[\alpha]_D$ −141.0° (*c* 0.4, water). The ^{1}H and ^{13}C nmr data are reported in Tables 1 and 2; ^{19}F nmr (367 MHz, D_2O, $CFCl_3$ as external standard set at 0) δ: −230.25 (ddd, F-6d, $J_{F,H6b}$ 47.8 Hz, $J_{F,H6b'}$ 45.5 Hz, $J_{F,H5b}$ 15.0 Hz).

Methyl 2-acetamido-3-O-[6-chloro-6-deoxy-2-O-(α-L-fuco-pyranosyl)-β-D-galactopyranosyl]-2-deoxy-4-O-(α-L-fuco-pyranosyl)-β-D-glucopyranoside (39)

Hydrogenolysis of compound **35** (150 mg, 0.1 mmol) was done over 10% palladium-on-carbon (75 mg) for 8 days in the usual way. The reaction mixture was then processed as described for **37** and afforded the title compound **39** (35 mg, 47%) as a light white powder; $[\alpha]_D$ −132.0° (*c* 0.5, water). The ^{1}H and ^{13}C nmr data are reported in Tables 1 and 2.

Methyl 2-acetamido-2-deoxy-3-O-[6-deoxy-2-O-(α-L-fucopyranosyl)-β-D-galactopyranosyl]-4-O-(α-L-fucopyranosyl)-β-D-gluco-pyranoside (40)

Compound **36** (200 mg, 0.14 mmol) was hydrogenated for 3 days over 5% palladium-on-carbon in the usual way. Precipitation of the resulting material from methanol – ethyl acetate provided the tetrasaccharide **40** (76 mg, 79%); $[\alpha]_D$ −129.4° (*c* 0.4, water). The ^{1}H and ^{13}C nmr data are reported in Tables 1 and 2.

FULVIO CACACE, M. ELISA CRESTONI, GIULIA DE PETRIS, SIMONETTA FORNARINI, and FELICE GRANDINETTI. Can. J. Chem. **66**, 3099 (1988).

Aromatic desilylation and detertbutylation by CH_5^+, $C_2H_5^+$, $i\text{-}C_3H_7^+$, and $t\text{-}C_4H_9^+$ ions have been studied in the gas phase by mass spectrometric and radiolytic techniques. The higher rate of desilylation than of dealkylation is traced to the step involving the formation of *ipso* arenium ions, protonated at the ring carbon bearing the $SiMe_3$ or the CMe_3 substituent. The latter has been shown by *ab initio* calculations at the SCF STO-3G level to selectively depress the basicity of the *ipso* position, hence the stability of the corresponding arenium ion relative to its protomers, e.g. the basicity of the *ipso* position of $PhCMe_3$ is lower by ca. 11 kcal mol^{-1} than of the *para* position. The $SiMe_3$ group has no comparable effect, very close basicities being computed for the *para* and the *ipso* position of $PhSiMe_3$. The different effects of the CMe_3 and $SiMe_3$ groups are traced to electronic and steric factors.

FULVIO CACACE, M. ELISA CRESTONI, GIULIA DE PETRIS, SIMONETTA FORNARINI et FELICE GRANDINETTI. Can. J. Chem. **66**, 3099 (1988).

Opérant en phase gazeuse et faisant appel à des techniques de spectrométrie de masse et de radiolyse, on a étudié les réactions de dé-*tert*-butylation et de désilylation aromatiques par les ions CH_5^+, $C_2H_5^+$, $i\text{-}C_3H_7^+$, et $tert\text{-}C_4H_9^+$. Le fait que la vitesse de désilylation est plus rapide que celle de la déalkylation est attribué à l'étape impliquant la formation des ions ipso arénium qui sont protonés au niveau du cycle carboné portant les substituants $SiMe_3$ ou CMe_3. Faisant appel à des calculs ab initio, en champ auto-cohérent, au niveau STO-3G, on a démontré que, par rapport à ses protomères, le dernier abaisse la basicité de la position *ipso* et, par conséquent, la stabilité de l'ion arénium correspondant; par exemple, la basicité de la position *ipso* du $PhCMe_3$ est environ 11 kcal mol^{-1} plus faible que celle de la position *para*. Le groupement $SiMe_3$ n'a pas d'effet semblable et les calculs fournissent des valeurs très comparables pour les positions *para* et *ipso* du $PhSiMe_3$. On attribue les effets différents des groupements CMe_3 et $SiMe_3$ à des facteurs électronique et stérique.

[Traduit par la revue]

Introduction

Electrophilic cleavage of aryl–silicon bonds, observed as early as in 1901 (1), has been characterized by the systematic work of Eaborn (2, 3) as a typical aromatic substitution, whose rate-determining step is the formation of the *ipso* σ complex.

We report here extension of the work to the gas phase by an integrated approach based on the coordinated application of mass spectrometric, radiolytic, and computational techniques (4). The same approach has recently allowed us to demonstrate the first example of the inverse process, the direct aromatic substitution by $SiMe_3^+$ (5, 6), unprecedented in solution, nor previously characterized in the gas phase.

In order to provide a proper perspective, and in view of the close correlations between carbon and silicon chemistry, a parallel investigation has been carried out of gas-phase aromatic detertbutylation, the subject of earlier detailed studies by chemical ionization mass spectrometry (CIMS) in the low-pressure range (7, 9).

Results

Radiolytic reactions

The *absolute* yields, measured by the G_{+M} values of the products, i.e. by the number of molecules formed per 100 eV, are reported for several representative systems in Table 1. Such absolute values are affected by large uncertainties, estimated around ±30%, owing to the severe problems associated with absolute dosimetric measurements, while *relative* yields can be determined with far better accuracy. To circumvent the problem, the experiments have been based on the competition of the unlabelled substrate of interest with a reference substrate, $p\text{-}CD_3\text{-}C_6H_4\text{-}t\text{-}C_4H_9$, whose products can easily be discriminated from their light isotopomers by GC/MS. Attack of the $C_nH_5^+$ (n = 1, 2) and $i\text{-}C_3H_7^+$ ions on *t*-butyltoluenes (TBT) and trimethylsilyltoluenes (TST) promotes several competing processes, i.e. (*i*) replacement of the XMe_3 group (X = C, Si) by H or by an alkyl group, Et or *i*-Pr, (*ii*) protonation-induced isomerization, and (*iii*) alkylation of the substrate without XMe_3 loss. Desilylation and detertbutylation are major reaction channels, whose ionic character is suggested by the presence of a radical scavenger (O_2) in the system, by the decrease of their yields caused by addition of nucleophiles that intercept ionic reactants and intermediates, and by the direct observation of the latter, in the CH_4 and C_3H_8 CI spectra of TBT and TST isomers (*vide infra*). A comparison between the relative rate of XMe_3 loss from TBT and TST substrates is reported in Table 2, showing that the reactivity of the latter is generally higher, the difference becoming quite large in passing from $C_nH_5^+$ to the milder $i\text{-}C_3H_7^+$ cation. With one exception, *m*-TST in CH_4, isomeric substrates fit into a regular pattern, their reactivity following the order *ortho* ≃ *para* > *meta*.

The addition of gaseous nucleophiles has mechanistically informative effects, illustrated in Table 1 in the case of MeOH and of NEt_3. While both additives depress the *absolute* yields by intercepting $C_nH_5^+$ and $i\text{-}C_3H_7^+$ ions, MeOH *enhances*, while NEt_3 strongly *reduces*, the predominance of desilylation over detertbutylation.

Table 3 provides a more detailed illustration of the reactions

promoted by the $C_nH_5^+$ attack on the TBT isomers. Consistent with the results in Table 1, the absolute yields of the proto-detertbutylation process are comparatively *lower* from *m*-TBT, while the extent of ethyldetertbutylation is approximately the same from the three isomers. The composition of the products shows that the Et group is not necessarily, nor even predominantly, found in the position formerly occupied by the *t*-Bu group, e.g. only 13% *p*-ethyltoluene is formed from *p*-TBT. Only in the case of *o*-TBT the isomerization process is significant, causing the shift of the *t*-Bu group mainly to the *para* position. The isomeric composition of the products from the replacement of the XMe_3 group of *p*-CH_3-C_6H_4-XMe_3 substrates by Et and *i*-C_3H_7 groups under different experimental conditions is reported in Table 4. The isomeric composition of cymenes from *p*-TBT and *p*-TST is considerably different and strongly dependent on the pressure, particularly in C_3H_8.

Alkylation of the substrate without loss of the XMe_3 group is significant only in the case of the TBT isomers. The orientation, illustrated in Table 5 for R = *i*-C_3H_7, reflects the operation of steric factors that hinder substitution ortho to the *t*-Bu group, as noted in earlier studies (10). The same factors are conceivably responsible for the migration of the *t*-Bu group that occurs, if to a limited extent, in the alkylation of *m*- and *p*-TBT.

Mass spectrometric evidence

The CH_4 CI spectra of TSB and of TST isomers are characterized by predominant loss of $SiMe_3^+$. In passing to milder Brønsted acids, the CI spectra of TSB, recorded in C_3H_8 and *i*-C_4H_{10} at a pressure of ca. 0.5 Torr, while significantly dependent on the source temperature, display most of the ionic intermediates whose formation is suggested by the radiolytic results. Thus, the C_3H_8 CI spectrum of TSB at 120°C is characterized by an abundant $SiMe_3^+$ peak at m/e = 73, and by its adduct with TSB, the $C_6H_5(SiMe_3)_2^+$ ion at m/e = 223. The $(M + H)^+$ adduct at m/e = 151 is detectable, albeit in low (<5%) abundances, while no isopropylated adducts could be detected.

Two typical *i*-C_4H_{10} CI spectra of TSB, recorded at 0.5 Torr at two different temperatures, are reported in Fig. 1. The *t*-butylated adduct at m/e = 207 is the base peak at 40°C,

accompanied by much lower abundances of the $(M + H)^+$ adduct at m/e = 151 and of $SiMe_3^+$. The latter becomes increasingly more significant as the source temperature is raised, becoming the most abundant peak at 100°C. The CH_4, C_3H_8, and i-C_4H_{10} CI spectra of the TST isomers are qualitatively similar to those of TSB.

As to *t*-butylbenzene (TBB) and the TBT isomers, their CI spectra have previously been reported (8, 11). The CH_4 spectra are dominated by the loss of t-Bu^+, while the protonated adduct is but a minor peak, accounting for less than 1% of the total ionization in CH_4 at 185°C, 0.5 Torr (8).

Metastable ion spectrometry

Despite the low abundances of protonated adducts in the CH_4 CI spectra of TBT and TST isomers, the study of their metastable decomposition has provided useful information. The intensity ratios of the metastable peaks from protonated TBT isomers are the same and show the same dependence on the CH_4 pressure. The transitions investigated include elimination of CH_3 from the XM_3 group (transition **I**) and of neutral toluene (transition **II**) from the $(M + H)^+$ ion.

The kinetic energy release data, i.e. the $T_{0.22}$, $T_{0.5}$, and $\langle T \rangle$ values, as well as the shape coefficient (12), are reported in Table 6, together with those of protonated TST isomers. The intensity ratios of the metastable peaks from the latter are the same, within the experimental error, irrespective of the particular isomer concerned, although the spectra are in general less reproducible than those of the TBT isomers, and as sensitive to pressure changes.

Furthermore, the low abundance of the protonated adducts from TST isomers restricts quantitative study to transition **I**. A comparison of the metastable decomposition **I** of the $(M + H)^+$ adducts from TBT isomers (ions *a*) and from TST isomers (ions *b*) reveals significant differences, both in the peaks shape and in the average kinetic energy release, $\langle T \rangle$. The metastable peaks from ions *a* (Fig. 2*a*) are not of pure Gaussian shape, being characterized by $n \neq 2$, although the difference (<0.4) is insufficient (12) to detect two competing fragmentation pathways. Their $\langle T \rangle$ values cluster around 50 meV, and increase in passing from the *meta* to the *ortho* and to the *para* isomer,

which, interestingly, fails to reflect any enhanced steric compression in the $(M + H)^+$ ion from *o*-TBT.

On the other hand, ions *b* give pure Gaussian-type metastable peaks (Fig. 2*b*) and a lower $\langle T \rangle$ value, ca. 40 meV, that is the same, within experimental errors, for all TST isomers.

Fragmentation **II** of ions *a* into neutral toluene and $t\text{-}Bu^+$ is characterized by pure Gaussian-type peaks ($n = 2$) and by the same value of $\langle T \rangle$, ca. 16 meV for the isomers investigated, *o*- and *p*-TBT.

Discussion

The reactants

The primary charged reactants are obtained both in CI mass spectrometry and in the radiolytic experiments from the ionization of the bulk gas. Methane, propane and isobutane give respectively $C_nH_5^+$ ($n = 1, 2$), $i\text{-}C_3H_7^+$ and $t\text{-}C_4H_9^+$, with G_{+M} values ranging from 2.9 to 3.3 as established by extensive radiolytic and mass spectrometric studies (13, 14). The ions undergo many unreactive collisions with the parent molecules, and can be regarded as fully thermalized before encountering an aromatic molecule. The heats of formation of the gaseous ions are the following: CH_5^+:216, $C_2H_5^+$:216, $i\text{-}C_3H_7^+$:191, $t\text{-}C_4H_9^+$:166 kcal mol^{-1} (unless specified otherwise, all thermochemical data have been taken from ref. 15).

The ionic reactions and their energetics

The processes promoted by the attack of the primary ionic reactants AH^+ ($A = CH_4, C_2H_4, C_3H_6, i\text{-}C_4H_8$) on the aromatic substrates are schematically represented in Scheme 1, where *a* denotes species containing the *t*-Bu group, and *b* those containing the $SiMe_3$ group.

Fruitful mechanistic discussion presupposes reasonably detailed information on the energetics of the processes and of the species involved, especially of key ionic intermediates. While many such ions have directly been detected by CI mass spectrometry, their energetics are frequently unknown and sometimes experimentally inaccessible, e.g. in the case of the *ipso* adducts **2** and **5** (in this example, and throughout the discussion, the term *ipso* refers exclusively to species protonated, or alkylated, at the ring carbon bearing the XMe_3 group). The problem is compounded by the lack of reliable data on *neutral* organosilicon compounds, whose combustion calorimetry is notoriously unreliable (16).

The above difficulties have prompted recourse to computa-

tional methods, whose results, suitably calibrated against experimental data and referred to a proton affinity (PA) of 181.3 kcal mol^{-1} of benzene (15), are reported in Table 7.

The computed values, in conjunction with the available experimental (15, 17) and theoretical (18) results, can be used to derive reasonably accurate estimates of the energetics of the processes of interest, reported in Table 8.

The result most significant to the present discussion is the different effect of the *t*-Bu and of the $SiMe_3$ groups on the basicity of the *ipso* position. In fact, while position 1 of TBB is less basic than position 4 by as much as 10.6 kcal mol^{-1}, positions 1 and 4 of TSB have nearly the same basicity. Another mechanistically significant result is the different stability of the **2***a* ions containing, respectively, a Me group in the meta and in the para position. As a consequence, unimolecular dissociation [3A] of the latter ion is *more endothermic* by ca. 9 kcal mol^{-1}.

As a final bonus, the STO-3G calculation allows calculation of the heat of formation of neutral TSB, whose experimentally measured value is uncertain. Combination of the experimental heat of formation of **2***a*, R = H (17), with the calculated PA value leads to a heat of formation of $PhSiMe_3$ of −26.6 kcal mol^{-1} that compares well with a value of −25 kcal mol^{-1} estimated according to the additivity approach, based on the heat of formation of $SiMe_4$ (16).

Protonation-induced detertbutylation and desilylation

The arguments planted earlier provide a satisfactory rationale for the mass spectrometric results, accounting, in particular, for the striking difference between the CI spectra obtained using isobutane, rather than methane or propane, as the reactant gas. In fact, owing to the inefficiency of collisional deactivation under CI conditions, most of the energy released in step 1 is stored in ions **1** and **2**, available to promote **1** → **2** isomerization and eventually loss of XMe_3^+ from ions **2**, a process favoured by the low pressure and the relatively high temperature of the CI ion source. This is the case of the reactions promoted by the $C_nH_5^+$ ions from CH_4, and by the i-$C_3H_7^+$ ions from C_3H_8, whose exothermicity exceeds the endothermicity of dissociation [3A], as shown in Table 8.

On the other hand, protonation by t-$C_4H_9^+$ is endothermic, or insufficiently exothermic, to allow XMe_3^+ loss from ions **2**, which accounts for the predominant formation of alkylated adducts, peculiar of the isobutane CI spectra.

The mechanistic picture is more complex in the radiolytic systems, where collisional deactivation is highly efficient, and the reactions can be assumed to obey thermal kinetics.

The paramount mechanistic feature of the radiolytic experiments, i.e. the higher rate of protolytic desilylation than of de-*t*-butylation, can reflect, in principle, operation of different factors, including: (*i*) the higher protonation rate of silylated substrates, (*ii*) the faster removal of $SiMe_3^+$ from **2***b* than of t-Bu^+ from **2***a* ions, (*iii*) the higher steady-state concentration of the *ipso*-protonated ions **2***b* than of **2***a*.

From the current theories of ion–molecule interactions, e.g. the ADO model, and from the kinetic data available on exothermic proton transfer reactions (19), the rate of protonation of silylated and *t*-butylated substrates is expected to be very close, and any difference largely inadequate to account for the higher rate of desilylation, particularly predominant in the C_3H_8 systems.

Factor (*ii*) can safely be discounted in the case of desilylation, that has been shown (5, 6) to be a fast process promoted by

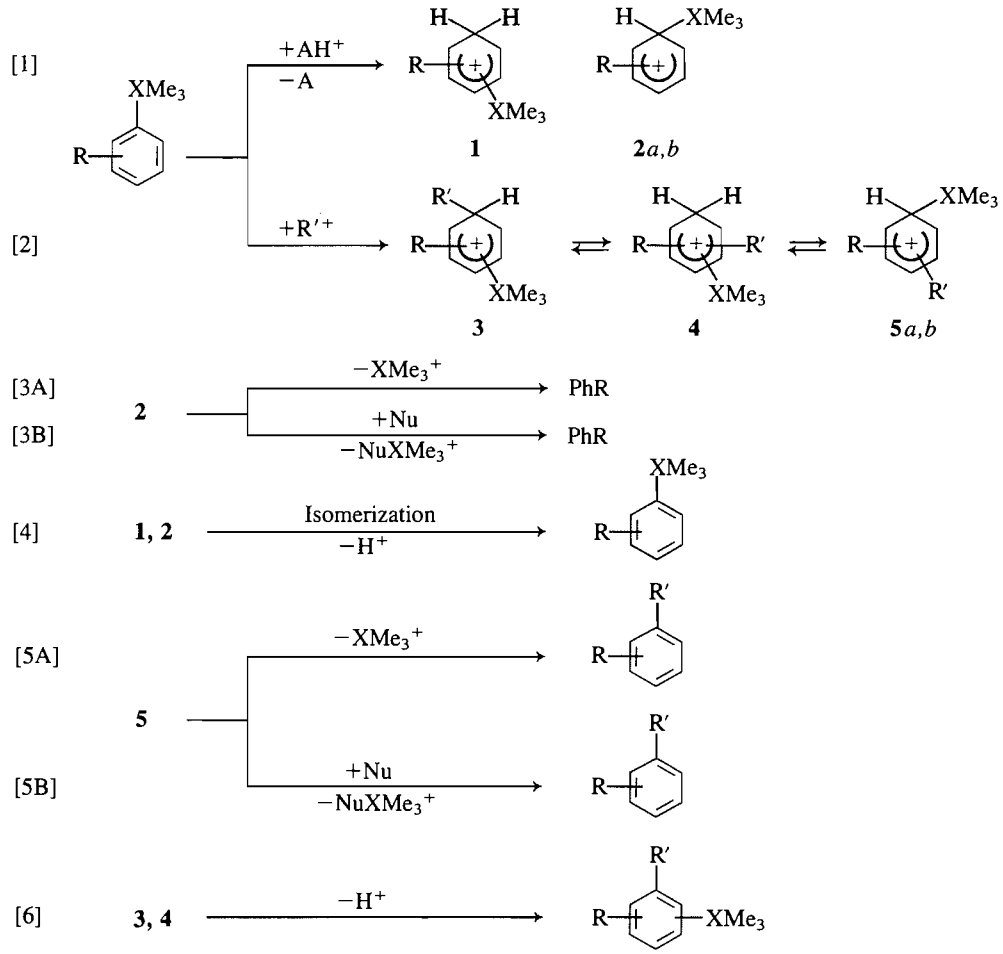
For personal use only.



SCHEME 1. Simplified scheme of the reactions promoted by the attack of AH^+ ions on the aromatic substrates.

oxygenated nucleophiles, either deliberately added, or formed in the radiolysis (H_2O, CH_2O, etc.), while gaseous NEt_3 promotes deprotonation, rather than desilylation of **2***b*. Such findings are consistent with the present results, in particular with the contrasting effects of added MeOH and NEt_3 on the desilylation rate.

The same conclusion can reasonably be extended to ions **2***a*, whose dealkylation rate *increases* in passing from *m*- to *p*-TBT. This trend is hardly consistent with a kinetically significant role of the dealkylation step, either occurring unimolecularly [3A] or promoted by nucleophiles [3B]. In fact, the activation energy of [3A] can be regarded as the sum of the two terms, the endothermicity of the dissociation and the activation energy of the reverse reaction, i.e. t-Bu^+ addition to toluene. Combination of such terms leads to a *lower* activation barrier for the unimolecular dealkylation of ion **2***a* containing a Me group in the position *meta*, rather than *para*, to the *ipso* carbon. In fact, the endothermicity of [3A] is higher by ca. 9 kcal mol^{-1} when ion **2***a* contains a Me group in the *para*, rather than in the *meta* position, while the activation energy of the reverse process, *t*-butylation of toluene, changes only by ca. 2 kcal mol^{-1} in passing from the *meta* to *para* positions, as deducted from intramolecular selectivity data (20). The role of the bimolecular process [3B], even in low-pressure systems, is independently supported by CI studies (9).

The same trend is expected for process [3B], e.g. t-Bu^+ transfer to H_2O from **2***a* ions is energetically allowed only when the Me group is in the *meta* position (Table 8). In summary, the overall dealkylation rate, if assumed to depend on steps [3A] or [3B], should *decrease* in passing from *m*-TBT to the *ortho* and *para* isomers, which conflicts with the experimental trend.

In passing, it is interesting to note that metastable loss of t-Bu^+ from protonated *o*-TBT does not involve a larger kinetic energy release than from protonated *p*-TBT, despite the large steric strain due to the *ortho* relation of the two alkyl groups (21). This is hardly surprising, in view of the intricate way the Me and *t*-Bu groups are entangled in *o*-TBT, as shown by conformational studies in solution (22). Under such conditions, according to the so-called "dynamic gearing" effect, the *t*-Bu group, receding from the ring plane as a result of *ipso* protonation and in the way to leave as a free t-Bu^+ ion, can be expected to possess, if anything, excess vibrational and especially rotational, rather than translational, energy.

The role of ipso *protonation*

Having disposed of other alternatives, it is appropriate to inquire whether the observed reactivity pattern reflects the abundance of the *ipso* adduct **2** in the population of interconverting (23*a*)[2] isomeric ions formed from the attack of AH^+, e.g.

[2]Low barriers to intraannular H^+ shifts in gaseous naphtalenium ions have recently been calculated by Filger and Grützmacher (23*b*) despite the fact that their MINDO approach notoriously overestimates the energy of the correspondent transition states.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 122.72.124.2 on 09/07/12

2

Clearly, a major role is played by the basicity of the *ipso* carbon relative to those of the other ring positions. If the PA of the *ipso* carbon is comparatively low, formation of **2** is hampered by unfavourable energetics, and its isomerization into more stable arenium ions is accelerated, thus reducing its steady-state concentration, hence the rate of XMe_3^+ removal via [3B]. A mechanistic model based on the different relative basicity of the *ipso* position of **2***a* and **2***b* accounts satisfactorily for the major experimental features. The SCF STO-3G results show, in the first place, that *t*-Bu group, unlike $SiMe_3$, *selectively* depresses the PA of the *ipso* position, which provides a straightforward explanation of the lower efficiency of protodetertbutylation. Secondly, the kinetic consequences of the (modest) stability differences among isomeric arenium ions can be expected to be particularly relevant when the latter are formed with a limited excess of internal energy. This accounts for the enhanced desilylation/detertbutylation ratio when the reactions are promoted by $i\text{-}C_3H_7^+$, a much milder acid than $C_nH_5^+$, as apparent from Table 8. Finally, the relative detertbutylation rate of TBT isomers, that increases in the order *meta* < *para* ≃ *ortho*, finds a reasonable explanation.

In fact, the basicity of the *ipso* position of *m*-TBT is not appreciably enhanced by the Me group, which instead increases the *ipso* PA of *o*- and *p*-TBT, hence the stability of the corresponding **2***a* ions. This accounts for the lowest relative rate of dealkylation of *m*-TBT. While the stabilizing effect of the Me group is comparable in the **2***a* ions from *p*- and *o*-TBT, formation of the *ipso*-protonated adduct from the latter is expected to be accelerated by the relief of the steric compression of coplanar Me and *t*-Bu groups (22).

The preceding discussion is based on the assumption that energetic factors, concerning in particular the relative stability of the protomers from reaction [1], control the kinetics of their isomerization, which is mechanistically relevant. In fact, since initial protonation largely occurs at sites other than the *ipso* position, the rate of formation of **2**, hence of XMe_3^+ loss, depends on the barriers to H^+ migration to the *ipso* carbon. Admittedly, purely energetics arguments bear only on the endothermicity of the process, whose *total* barrier includes an additional, unknown term, that corresponds to the activation energy of the inverse reaction. Accurate evaluation of the latter term is extremely difficult, especially in the case of *ipso*-protonated species. However, the published data show that the activation energies proper, i.e. not arising from unfavourable energetics, for intraannular H^+ migration in gaseous arenium ions are generally remarkably low (23), and their differences can hardly be expected to affect the relative heights of the total barriers predictable on energetic grounds. Thus, the total barrier to the significantly endothermic H^+ shift to the *ipso* carbon of $PhCMe_3$ can reasonably be estimated to be higher than the barrier to the thermoneutral, but otherwise analogous, process in protonated $PhSiMe_3$. The approximate character of such interpretation seems tolerable if restricted to purely comparative purposes, especially since in this framework the experimental observations, including the relative dealkylation rates of TBT isomers, find a satisfactory accommodation.

Alkylation-promoted detertbutylation and desilylation

The composition of the products, where the alkyl group R′ is not exclusively, nor predominantly, bound to the carbon formerly bearing the XMe_3 group, suggests initial attack to any activated ring position, followed by H^+, and possibly R'^+ shifts, eventually leading to the *ipso* protonated ions **5**, that undergo XMe_3^+ removal via process [5B]. While there are close similarities with the scheme suggested for protolytic reactions, the situation is more complicated in several respects. First, the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 122.72.124.2 on 09/07/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 122.72.124.2 on 09/07/12
For personal use only.

exothermicity of the alkylation is generally higher than of protonation, which enhances the rearrangement of the primary arenium ions and tends to level the reactivity of different substrates. Secondly, the stability of ions **5** reflects the cumulative effects of *two* substituents, the Me and the R′ groups, whose interplay depends on their respective positions.

Finally, the influence of isomerization process (4) and of the alkylation process (6) must be taken into account. In view of the complex nature of the problem, the discussion is limited to a few salient aspects.

The exothermic (24) addition of $i\text{-}C_3H_7^+$ to *p*-TST in C_3H_8 at 700 Torr is invariably followed by desilylation, yielding a mixture of cymenes whose composition, illustrated in Table 4, reflects the selectivity of the initial electrophilic attack. Clearly, H^+ shifts to the *ipso* position, whose basicity is not selectivity depressed by the $SiMe_3$ group, are energetically accessible to the arenium ions from [2], irrespective of the position of the $i\text{-}C_3H_7$ group, i.e. independently of the stabilization of **5***b* provided by R′ when bound to the *ortho* positions.

Comparison with the comparably exothermic addition of $i\text{-}C_3H_7^+$ to *p*-TBT, occurring under the same conditions, is informative. Owing to the selective depression by the *t*-Bu group of the basicity of the *ipso* carbon, its protonation via H^+ intramolecular shifts is energetically allowed only by the combined activating effects of *two* substituents, i.e. the *ortho* $i\text{-}C_3H_7$ and the *para* Me groups. This accounts for the predominant (80%) formation of *m*-cymene (Table 4). When alkylation occurs *meta* to the *ipso* carbon, the basicity of the latter is not appreciably enhanced by the $i\text{-}C_3H_7$ group, which makes formation of **5***a* energetically unfavourable. This depresses the rate of detertbutylation [5], allowing alkylation [6] to occur, but, significantly, only from the *meta* to the *t*-Bu group (Table 4). Such interpretation is supported by the pressure dependence of the products composition. At 100 Torr, collisional deactivation is less efficient, and the higher internal energy of the arenium ions from the exothermic addition (2) makes formation of **5***a*, and subsequent detertbutylation, much less dependent on the specific position attacked by $i\text{-}C_3H_7^+$. As a consequence, loss of $t\text{-}Bu^+$ becomes predominant and, significantly, the relative yield of *o*-cymene undergoes a tenfold increase with respect to that measured at 700 Torr.

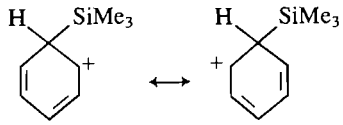
The same considerations apply to alkylation by $C_2H_5^+$ in methane, that displays the same typical composition of the detertbutylation products, and the same dependence on the CH_4 pressure, although the higher exothermicity of ethylation tends to depress the selectivity of the process with respect to isopropylation.

Conclusions

The salient result of the present study is the higher efficiency of desilylation than of detertbutylation of aromatic substrates following the attack of charged electrophiles. Such a finding extends to the gas phase a trend well established in solution, where facile aromatic desilylation is exploited as a synthetic tool (2).

Several lines of evidence identify the key difference between $SiMe_3$ and the *t*-Bu groups with their different effects on the basicity of the *ipso* carbon, hence on the stability of **2** and **2***b* relative to the respective isomers protonated at other positions.

Such a difference can be traced, in part, to electronic factors, since silicon, less electronegative than carbon, has a significant inductive effect and the $SiMe_3$ group is known to stabilize a β positive center, hence the mesomeric structures of the *ipso*



arenium ion **2***b*. The present study suggests operation of an additional steric factor that stabilizes **2***b* with respect to **2***a*. In the course of the SCF STO-3G calculations it has been noted that the aromatic ring of **2***a* (R = H) cannot be assumed to be rigorously planar, probably due to the significant steric repulsion between the bulky *t*-Bu substituent and the aromatic π system, that causes a destabilizing deformation of the latter. The greater length of the C—Si bond, 1.88 Å vs. 1.54 Å of the C—C bond, reduces the effective bulk of $SiMe_3$, hence the steric destabilization of **2***b*, which accounts, in part, for the fact that the PA of the *ipso* carbon bearing the $SiMe_3$ substituent is very close to the PA of the para position.

Experimental

Materials

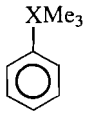
The gases, CH_4, C_3H_8, $i\text{-}C_4H_{10}$, O_2, NMe_3, were obtained from Matheson Gas Products Inc., with a stated purity of at least 99.9 mol%, and were used without further purification. The ethyltoluenes and cymenes used as substrates or chromatographic standards were obtained from commercial sources. The TBT and TST isomers were prepared from the corresponding Grignard reagents, obtained from the appropriate bromo- or iodo-toluenes, and *t*-butyl bromide or trimethylsilyl methanesulphonate. The analogous reaction involving *p*-bromo-*t*-butylbenzene and CD_3I was used to prepare labeled *p*-TBT, used as a reference competitive substrate in the radiolytic reactions. The crude products from the synthesis were purified by preparative GC, using a 4-m column, packed with Carbowax 20M (10% w/w) and KOH (2% w/w) on Supelcoport, repeating the operation until analytical GC of the purified samples failed to detect traces of unwanted impurities, in particular of PhMe. The identity of the products was confirmed by NMR and mass spectrometry.

Radiolytic reactions

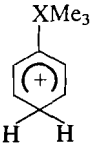
The gaseous samples were prepared using a greaseless vacuum line according to established procedures (25), by introducing the desired amounts of the reactants into carefully evacuated and outgassed 250-mL Pyrex vassels, equipped with fragile tips, that were cooled to −196°C and sealed-off. After thorough mixing of the reactants, the vessels were irradiated at 37°C to a total dose of 1.8×10^4 Gy, at a dose rate of ca. 6×10^3 Gy h^{-1}, in a 220 Gammacell from Nuclear Canada Ltd. The irradiated vessels were cooled to LN_2 temperature, their break-seal opened, and the contents, dissolved into ethyl acetate, analyzed by GC, using Perkin-Elmer Sigma 1 and Sigma 3 and Hewlett-Packard 5700 A chromatographs, equipped with FID and PID detectors. The products were identified by comparison of their capacity factors with those of authentic standards, using the following columns: (*i*) a 2-m long glass column, packed with SP 1000 (1% w/w) on Carbopack C, (*ii*) a 2-m long stainless steel column, packed with SP 2100 silicone fluid, deactivated with Carbowax 20 M. The yields of the products were deduced from the areas of the corresponding elution peaks, corrected for the individual response of the detector used, employing the internal-standard calibration method. In most cases, the identity of the products was confirmed by GC/MS, using a quadrupole HP 5985 A spectrometer and a HP 5970B mass selective GC detector from Hewlett-Packard. The same technique was used to measure the relative yields of $PhCH_3$ and $PhCD_3$ from the competitive reactions where methyl-d_3 *p*-TBT was used as the reference substrate.

CI and MIKE spectra

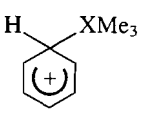
The CI spectra were recorded with the Hewlett-Packard 5985A quadrupole instrument, or a ZAB-2F magnetic spectrometer from VG-Micromass Ltd. Typical operating conditions of the latter instrument were as follows: reactant gas pressure 0.3 Torr, emission current



I*a,b*



II*a,b*



III*a,b*

1 mA, electron energy 50 eV, repeller potential 0 V, source temperature 180°C. The MIKE spectra were recorded as the average of 200 to 300 consecutive scans, at an energy resolution of 8 000 with a main-beam width of 1 eV.

Ab initio calculations

Standard quantum mechanical calculations were performed on the following species where *a* denotes X = C, *b* X = Si. The calculations were carried out, using a VM-CMS version of the Gaussian 80 package of programs (26), on an IBM 3090 computer. Geometry optimizations were carried out at the STO-3G level (27), and, limited to species *a*, single points were computed at the 4-31G level (28). Geometrical structures were considered to be optimized when the components of the gradient were less than 4.5×10^{-4} hartree/bohr, or hartree/rad^{-1}. The optimization at the SCF STO-3G level was carried out within the following constraints: (*i*) aromatic ring was assumed to be planar; (*ii*) C_s symmetry was assumed, with a plane perpendicular to the aromatic ring passing through the C_6—C_1—X—C_9 atoms; (*iii*) all C—H distances in the XMe_3 groups were considered to be identical.

Within the above constraints, stationary points were found corresponding to all species except **III***a* and **III***b*, that were not stationary on the energy surface. Analysis of the gradient vectors showed that for the latter species it is not correct to assume that the aromatic ring is rigorously planar. Single-point STO-3G calculations were carried out in correspondence of such corrugate situations, whose results showed that deformation of the aromatic ring has a great influence on gradient vectors, but does not appreciably affect total energies ($\Delta E < 10^{-3}$ au). Owing to the exceedingly high cost of the calculations required to achieve stationary points, such approximation was regarded as tolerable, and no further investigations of these regions of the potential energy surfaces were performed.

Received June 1, 1988

ADAM BECALSKI, WILLIAM R. CULLEN, MICHAEL D. FRYZUK, GEORG HERB, BRIAN R. JAMES, JAMES P. KUTNEY, KRYSTYNA PIOTROWSKA, and DIANNE TAPIOLAS. Can. J. Chem. **66**, 3108 (1988).

An extensive study involving achiral and chiral cyclopropanation of various isoprenoid units derived from the monoterpene thujone is presented. Carbenoid intermediates generated from ethyl and L-menthyl diazoacetates and various achiral and chiral copper catalysts are employed to achieve the desired cyclopropanation reaction. It is shown that high levels of enantiomeric excess can be achieved, particularly when L-menthyl diazoacetate and a chiral catalyst are employed. The resultant products are then converted to pyrethroid-like analogues.

ADAM BECALSKI, WILLIAM R. CULLEN, MICHAEL D. FRYZUK, GEORG HERB, BRIAN R. JAMES, JAMES P. KUTNEY, KRYSTYNA PIOTROWSKA et DIANNE TAPIOLAS. Can. J. Chem. **66**, 3108 (1988).

On présente une étude approfondie sur la cyclopropanation chirale et achirale de diverses unités isopropénoïdes provenant de la thujone. Dans le but de réaliser les cyclopropanations désirées, on a utilisé des carbénoïdes intermédiaires générés à partir des diazoacétates d'éthyle et de L-menthyle, en présence de divers catalyseurs chiraux et achiraux à base de cuivre. On montre qu'il est possible d'obtenir un grand excès d'énantiomère, particulièrement lorsqu'on utilise le diazoacétate de L-menthyle en présence d'un catalyseur achiral. On a réalisé la transformation des produits obtenus en dérivés du type pyréthroïde.

[Traduit par la revue]

Introduction

Pyrethroid-type insecticides comprise a highly important family of compounds with a wide diversity of application in the agricultural industry. Enormous efforts in various laboratories have provided a wide variety of structure–function relationships, and studies continue to potentiate activity while maintaining the well-established features of low mammalian toxicity. In the previous publication (2) in this series, we described utilization of thujone (**1**) in the synthesis of racemic analogs of pyrethroid insecticides. As biological activity of pyrethroid insecticides is closely related to the chirality of the cyclopropane ring (3), we set out to prepare optically active analogs to possibly maximize their insecticidal potency and to compare these data with the biological activity of the corresponding racemic material available from the earlier study.

Scheme 1 summarizes the overall sequence employed. The starting material, the methyl ester of *E*-α-thujaketonic acid (**4**), was synthesized with modification of the earlier described procedure (2). Via previously established methodology, α-thujaketonic acid **2**, obtained by the permanganate oxidation of **1**, was converted to the isopropenyl derivative **3** by Wittig reaction using methyltriphenylphosphonium bromide and potassium *tert*-butoxide in tetrahydrofuran. Conversion of **3** to **4** was achieved by thermal rearrangement of **3** to *E*-β-thujaketonic acid followed by esterification by CH_2N_2.

It had been shown earlier (2) that selective cyclopropanation of **4**, employing ethyl diazoacetate and copper sulfate, could be achieved with exclusive attack of the generated carbene occurring at the more reactive non-conjugated double bond. To achieve a potential entry into the chiral series, two diazoacetic esters, namely, ethyl diazoacetate and L-menthyl diazoacetate, prepared according to the literature procedure (4, 5) were employed along with five different copper catalysts. Two of these catalysts (A, B) were achiral while three continued a chiral ligand (C, D, E) (Scheme 2).

Cyclopropanation of the double bond by carbenoid addition is known to be promoted by catalysts containing various metals (6–9), e.g., ruthenium, palladium, rhodium, cobalt. We chose copper catalysts since they give high yields (10–12), and are inexpensive. Furthermore, Aratani *et al.* (10, 11, 13) had demonstrated successful chiral cyclopropanation of olefinic systems with high enantiomeric excess in the resultant cyclopropane analogues. In particular, catalysts C and D (Scheme 2) seemed well suited for our study.

Catalysts C and D have opposite configurations at the asymmetric centre and have different carbon chain lengths in the aryl ether group. Catalyst D with the butoxyaryl ether moiety is a free flowing powder while catalyst C with a C_8 unit is a very sticky gum and more difficult to handle.

Catalyst E, which gave excellent optical yields during cyclopropanation of styrene (14), was also included in the study for purposes of comparison.

Catalysts C and E were prepared according to the published literature procedures (13, 15). Catalyst D was obtained as a gift from Dr. Aratani while catalyst B was synthesized by condensation of salicylaldehyde with 2-aminoethanol and subsequent treatment of the resulting imine with NaOH and copper acetate.

The results of the various cyclopropanation experiments employing **4** as substrate, under varying conditions of temperature, solvent, and catalyst, are summarized in Table 1.

The ratio of the *trans* (see **6***a* and **6***b*) to *cis* isomers (**5***a* and **5***b*) was determined by hplc using a reverse phase C_{18} silica column and a mixture of water/methanol (10:90) as an eluent. In the case of experiment 5, gas–liquid chromatography was employed for analysis of the reaction products.

Determination of enantiomeric excess (e.e.) was done by ^1H nmr using a europium shift reagent. To illustrate the methodology, some detail of the procedure for the calculation of e.e. in the case of the diesters **5***a* and **6***a* and the keto-esters **11***a* and **12***a* is presented. In each case 10 mg of compound was dissolved in $CDCl_3$ and shift reagent was added portionwise (~10–15 mg) until optimal separation of the relevant signals of the enantiomers present was observed in the nmr spectrum. It

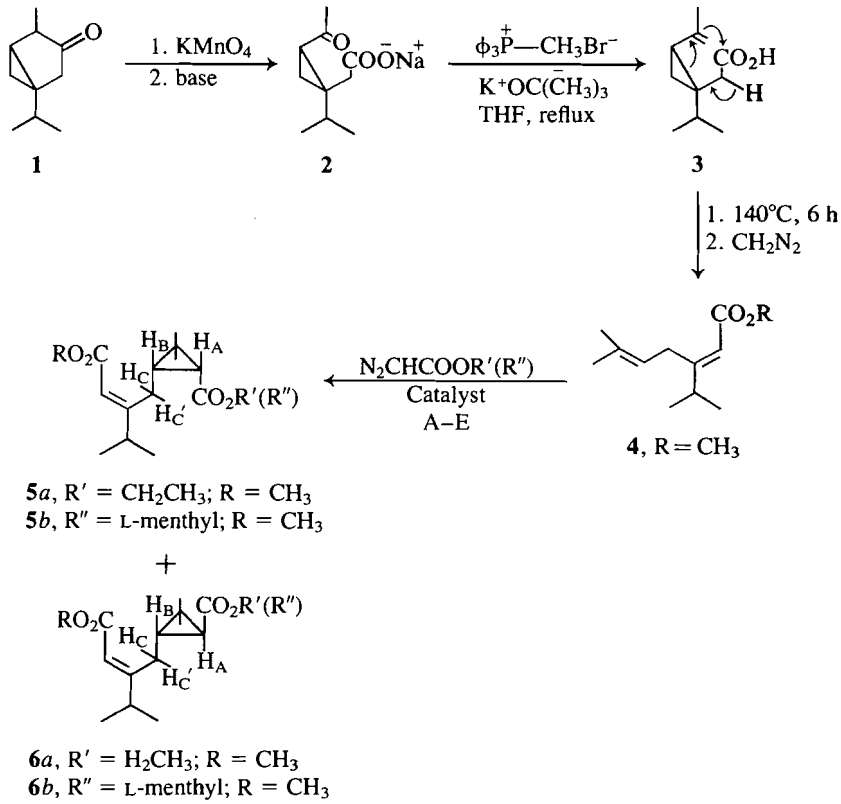
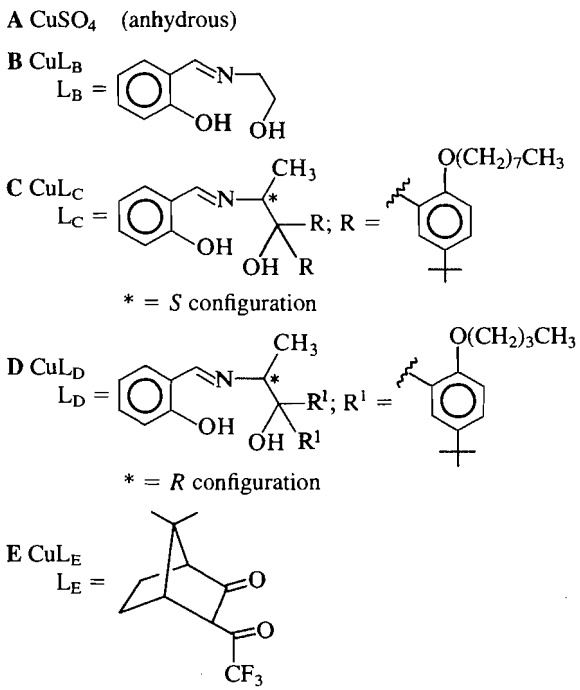


SCHEME 1

was shown (see Table 2) that different proton signals were shifted within the spectra of the different compounds, but these could be unambiguously analyzed for determination of enantiomeric excess present in the various reaction product mixtures.

As seen from Table 1, chemical yields vary only slightly in spite of considerable differences in the chemical structure of the catalysts.



SCHEME 2. Catalysts employed in cyclopropanation reaction.

In the case of achiral catalyst B, formation of the *trans* isomer **6** is favored over the *cis* isomer **5**. When the chiral catalysts C and D are employed, the *cis*/*trans* ratio of products is influenced by the ratio of ethyl diazoacetate to olefin (see experiments 1–4, Table 1) while with catalyst E, the ratio of reacting diazo compound and olefin appears to play no dominant role (see experiments 6 and 7, Table 1).

With respect to enantiomeric excess (e.e.) in *both* the *cis* and *trans* series obtained from chiral cyclopropanation of **4** with catalysts C and D, an excess of diazo ester is detrimental. For example, comparison of the results obtained with catalyst D (experiments 1 and 2, Table 1) reveals that a much higher e.e. value is obtained (78% versus 13.5% in the *cis* series) when a *low* ratio of diazo compound to substrate olefin is employed. A similar result is observed with catalyst C (experiments 3 and 4, Table 1). However, with catalyst E this effect is less pronounced.

It was reported (9) that use of "bulky" diazoacetates instead of alkyl diazoacetate in the cyclopropanation reaction results in increased optical yields of products.

Catalytic methods for metal carbene transformations have been extensively studied in various laboratories and excellent recent reviews (16, 17) are available. The mechanism of cyclopropanation using such methods has been presented with different models depending on the nature of the olefin and catalysts employed. Our results can be well explained by using the model of the cyclopropanation reaction as proposed by Aratani (18). Scheme 3 illustrates such a reaction mediated by catalyst C. The structure of the actual catalyst responsible for the asymmetric induction is proposed as a mononuclear cuprous complex such as **7**, in which copper carries a tetrahedral configuration and one of the four coordination sites is left vacant. Alkyl diazoacetate will attack the vacant site of **7** from the less hindered side (back side of the plane) to give the

carbon–copper complex **8**. Subsequent attack of the olefin **4** occurs again from the back side of the plane and will afford a mixture of metallocyclobutanes **9** and **10**, which then undergo rearrangement to form products **5** and **6** with regeneration of the active catalyst.

In the case of achiral catalyst B, formation of the *trans* isomer **6** is favored since its derivation, via the metallocyclobutane intermediate **10** (R = H, Scheme 3), is energetically preferred due to less severe steric interactions between R^1 and the ester group. These groups are in a *cis* relationship in **9** and in a more favorable *trans* relationship in **10**.

On the other hand, the *cis* isomer **5** should be favored over **6** when the chiral catalysts C and D are employed. In these cases, the steric interactions between R^1 and bulky R groups become most important. Such interactions are more severe in the metallocyclobutane intermediate **10** than in **9**. It should be noted that the rationalizations presented here assume that the product distribution follows the relative ground state stabilities of the two diastereomers, i.e., the most stable diastereomer generates the major enantiomeric product; this may not necessarily be so, and there are examples in asymmetric catalysis where the energetically *least* favoured form of two diastereomers leads to the major enantiomer in the product (25).

During the course of the cyclopropanation reaction, the molecule of carbene liberated from the diazoacetate ester can add to the double bond of **4** to form products **5** and **6** *or*, alternatively, can undergo a process of dimerization.

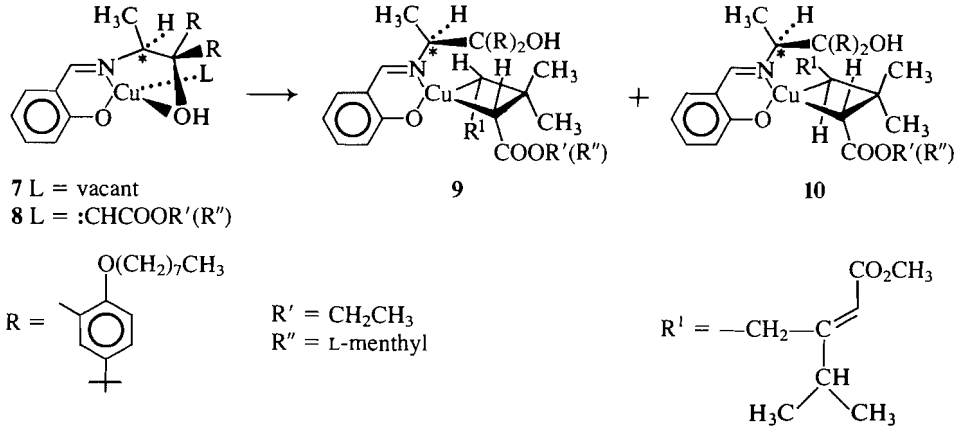
Indeed when an excess of diazoacetate ester is employed, the dimerization of carbene molecules and the formation of fumaric and maleic acid diesters (FDE and MDE respectively) becomes an important process. It is known that such molecules can coordinate strongly with copper (19, 20). It is therefore possible that the change in the *trans*/*cis* ratio, as observed in experiments 3 and 4, for example, may be a result of coordination of the catalyst or the resultant intermediate by FDE and (or) MDE.

When catalyst E is employed, the Aratani type model (intermediates **9** or **10**) is not applicable and the *trans* isomer **6** is formed as a major product regardless of the amount of diazo ester employed.

Enantiomeric/diastereomeric excess of compounds **5** and **6** varies a great deal depending on the nature of the catalyst and the reaction conditions. In our opinion, the huge difference in e.e. in experiments 1–5 is associated with the varied degree of coordination of the copper(I) atom by FDE and (or) MDE formed during the process of collapse of the metallocyclobutanes with resultant different geometry in the end product.

In previous studies done by Aratani's group, it was shown (18) that catalyst C gave slightly better optical yields of products than did catalyst D. It is a matter of interest to note that, in our

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 122.72.124.2 on 09/07/12
For personal use only.



SCHEME 3

experiment, catalyst C is also superior except in the case of the *cis* isomer **5***a* when excess of olefin **4** is used.

To achieve efficient chirality transfer from metallocyclobutanes **9** and **10** to the products, thus achieving high optical purity of **5** and **6**, formation of products of dimerization should be minimized (21).

Catalyst E was used for cyclopropanation of terminal olefins and an enantiomeric excess close to 100% was achieved (14). In our experiments, where the reaction was carried out with a substituted ethylene derivative, the surprisingly low e.e. suggests that this catalyst is very sensitive to the steric hindrance at the -C=C- bond.

In summary, the chiral esters produced in the course of the above described cyclopropanation reactions give entry to the family of chiral compounds shown in Scheme 4.

Diesters **5** and **6** were ozonized to afford ketones **11** and **12**. Separation of the *cis* and *trans* series and subsequent determination of enantiomeric and (or) diastereomeric excess could be achieved at either the diester *or* keto-ester stage.

In the case of the ethyl series, **5***a* and **6***a* were separated by preparative hplc on a silica column but purification can also be achieved by employment of C_{18} reverse phase columns and the use of a mixture of methanol and water (7:3) as eluent.

However, it is far more convenient to separate the corresponding ketones **11***a* and **12***a* after ozonolysis of the mixture of **5***a* and **6***a*, and work-up with zinc and acetic acid. In the case of the menthyl series, it is more practical to separate the mixture of **5***b* and **6***b* instead of **11***b* and **12***b*.

Ketones **11***b* and **12***b* were obtained by ozonolysis of esters **5***b* and **6***b* and reduction of the ozonide by dimethyl sulfide.

In the ethyl series, ketones **11***a* and **12***a* were reduced with sodium borohydride to afford, respectively, diastereomeric mixtures of alcohols **13** and **14**.

These alcohols were converted to olefins **17–22** via tosylation and subsequent elimination of *p*-toluenesulfonic acid under basic conditions.

Although synthesis of olefins **17**, **19**, **21** and **18**, **20**, **22** can be carried out in a "one-pot" process (for example, by heating the corresponding alcohols with TsCl in pyridine), it is more convenient to isolate the intermediate tosylates, as the tosyl group undergoes nucleophilic substitution by chloride anion in the course of the reaction and the corresponding chloride formed further complicates separation of the olefinic products.

In general, the intermediate tosyl derivatives **15** and **16** were prepared from alcohols **13** and **14** by the action of TsCl in CH_2Cl_2 in the presence of dimethylaminopyridine (DMAP).

The elimination reaction to afford the olefinic products was carried out using pyridine and 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) (22). When DBU was used as a base, yields were lower than those obtained when pyridine was the base employed. One-pot conversion of alcohols **13** and **14** to olefins via tosylate with DBU as a base also gave lower yields since the corresponding chlorides, formed as by-products, do not eliminate HCl at temperatures low enough to preserve the cyclopropyl ring in the resultant olefins.

Some attempts to increase yields of olefins **17** and **18**, which resemble more closely the natural pyrethroids, were made.

Using previously described reaction conditions (23, 24) ($(n\text{Bu})_4\text{NBr}$, 2,6-lutidine in acetone), which favor an elimination of TsOH toward formation of Saytzeff type products, we observed an increased yield of olefins **17** and **18** when compared to the reaction in which pyridine was used as a base.

Numerous attempts were made to separate, on a preparative scale, mixtures of the isomeric olefins **17**, **19**, **21** and **18**, **20**, **22** by means of chromatographic methods. Various combinations of solvents used with SiO_2, C_{18}-reverse phase hplc, or SiO_2 columns impregnated with $AgNO_3$ gave unsatisfactory results. Results obtained by utilizing analytical hplc suggest that such preparative separation will be very difficult. However, chromatography on SiO_2 columns impregnated with 15% $AgNO_3$ using an aromatic solvent (toluene) as an eluent gave partial resolution of the mixtures. We also showed that olefin **21** can be separated from olefins **17** and **19** by hplc on C_{18}-reverse phase columns using a mixture of methanol/water (80:20).

The resultant chiral cyclopropane analogues, as described above, will be evaluated for their potential in the agrochemical industry.

Experimental

Ultraviolet spectra were recorded on a Cary 15 spectrophotometer. Infrared spectra were recorded on a Perkin–Elmer 1710 spectrophotometer. The ^{1}H nmr spectra were recorded on one of the following instruments: Varian XI-300, Bruker WP-80, or Bruker WH-400 MHz. Deuteriochloroform was used as a solvent with TMS as internal standard. Mass spectra were recorded using a KRATOS MS50 apparatus. $[\alpha]_D$ measurements were made on a Perkin–Elmer 141 polarimeter. Microanalyses were carried out by Mr. P. Borda, Microanalytical Laboratory, University of British Columbia. Ethyl diazoacetate, chiral shift reagents, and 3-(trifluoroacetyl)-*d*-camphor were purchased from Aldrich. Anhydrous $CuSO_4$ was obtained from BDH. Starting materials were prepared according to the literature: L-menthyl diazoacetate (4, 5), catalyst C (13), catalyst E (14), *E*-β-thujaketonic acid methyl ester (2). Ligand for catalyst B was

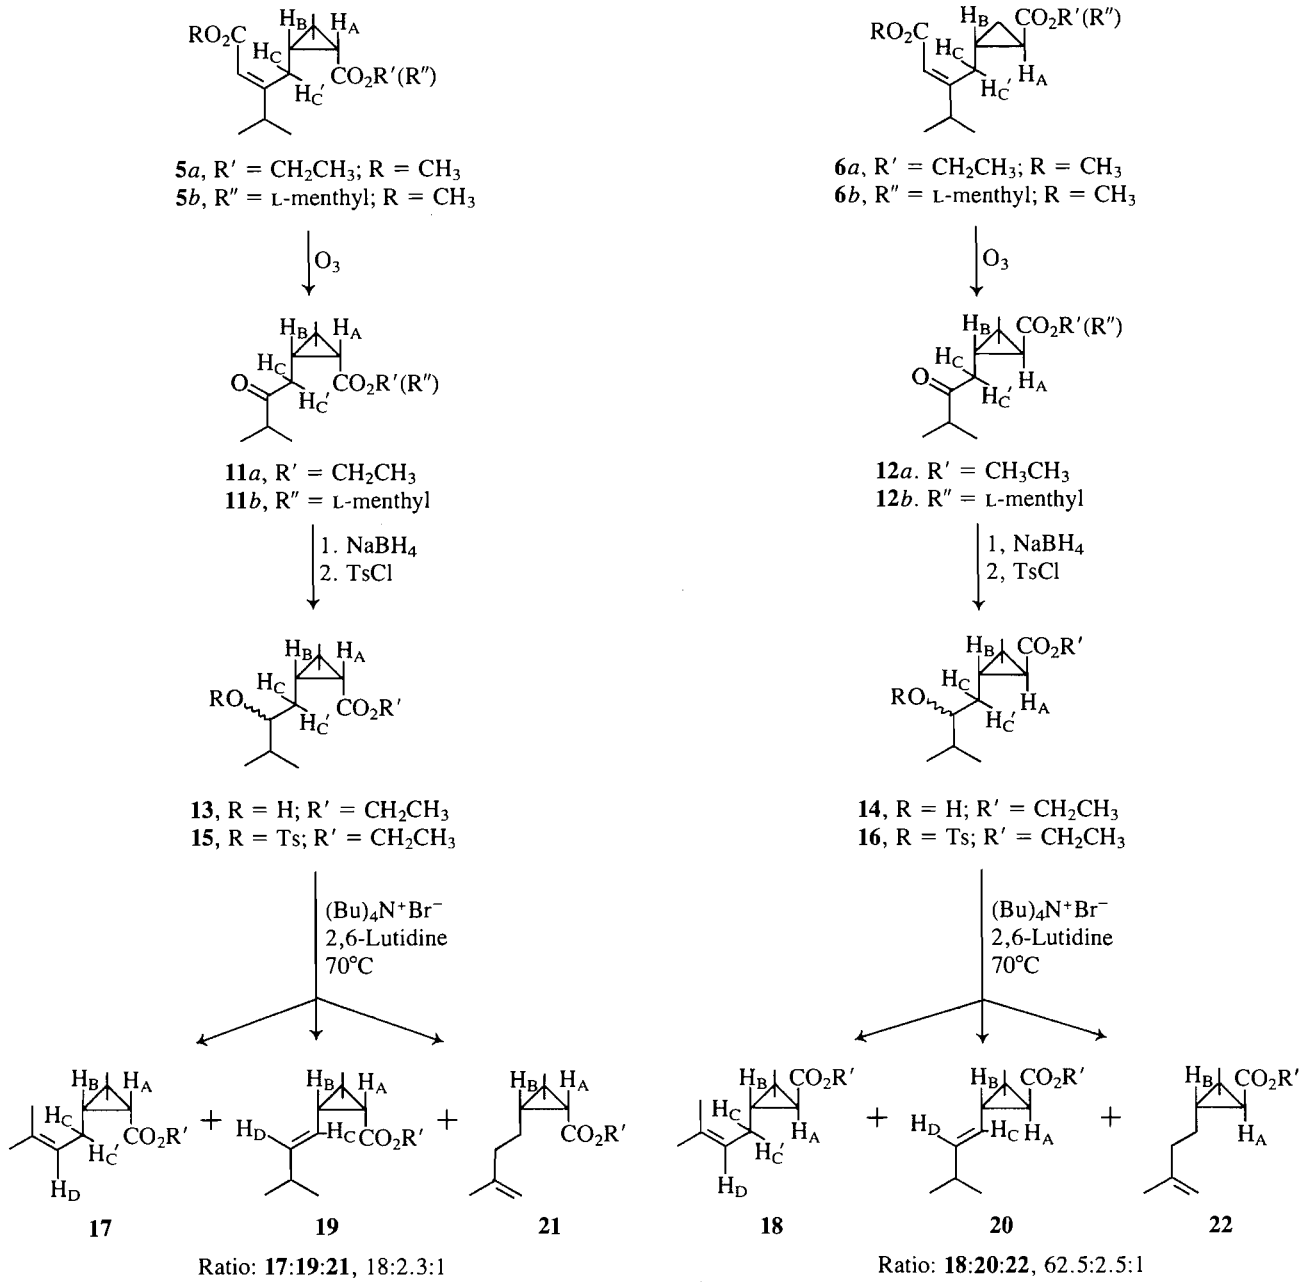

SCHEME 4

prepared from salicylaldehyde and 2-aminoethanol. Catalyst D was obtained from Dr. T. Aratani.

Isopropenyl derivative **3**

The sodium salt of isopropenyl acid **2** (14.4 g, 0.07 mol) was added to the suspension of the Wittig reagent prepared from triphenylmethylphosphonium bromide (50 g, 0.14 mol) and potassium *tert*-butoxide (16.8 g, 0.15 mol) in 1 L of THF and the resultant mixture was stirred under reflux for 20 h. After cooling, THF was removed *in vacuo*, and the residue was dissolved in a minimum amount of water and washed with ether. The aqueous layer was acidified with 10% hydrochloric acid and extracted with ether. This extract was washed with water, dried over Na_2SO_4, and concentrated *in vacuo* to give **3** (11.3 g, 89% yield).

Diesters **5**a *and* **6**a, **5**b *and* **6**b

See Table 1 for details.

Experiment 1

The solution of catalyst D (0.06 g, 0.092 mmol) and ester **4** (0.9 g, 4.6 mmol) in cyclohexane (4 mL) was heated to 75–80°C with vigorous stirring under an argon atmosphere and a few drops of the solution of ethyl diazoacetate (9 mL, 9.81 g, 86 mmol) in cyclohexane (9 mL) were added to initiate the reaction evidenced by evolution of nitrogen. Then the temperature was lowered to 40°C and the remainder of the solution of ethyl diazoacetate was added dropwise over a period of 8 h. After evaporation of solvent, the bulk of diethyl fumarate and diethyl maleate produced as by-products was removed by distillation (bulb-to-bulb, 40–50°C, 0.05 Torr; 1 Torr = 133.3 Pa). The remaining residual oil (3 g) was chromatographed on neutral alumina (500 g) using a mixture of toluene and ethyl acetate (40:1) as eluent to afford a mixture of **5***a* and **6***a* (1.17 g, 88%). Separation of *cis* **5***a* and *trans* **5***b* isomers was achieved by preparative hplc on the Waters Prep 500 instrument using two silica gel cartridges in series and 2% ethyl acetate in hexane as eluent to yield (*i*) pure *cis* isomer **5***a* (0.33 g), retention time ~75 min, bp ~60°C (bulb-to-bulb, 0.03 Torr); ir ν_{max} (neat): 1718, 1641, 1191, 1165 cm^{-1}; ^1H nmr δ: 5.7 (1H, s, =CH-), 4.1 (2H, m, CH_3CH_2COO-), 3.7 (3H, s, CH_3COO), 3.05 (1H, dd, $H_{C'}$, $J_{C'B}$ = 6.0 Hz), 2.9 (1H, dd, $H_{C'}$, $J_{CC'}$ = 13.7, J_{CB} = 6.0 Hz), 2.35 (1H, septet,

$(CH_3)_2CH$, J = 6.0 Hz), 1.5 (1H, d, H_A, J_{AB} = 8.6 Hz), 1.25 (4H, m, CH_3CH_2COO + H_B), 1.15 (6H, s, CH_3 cyclopropyl), 1.05 (6H, m, $(CH_3)_2CH$); ms m/z: 282 (M^+), 250, 237, 205, 153 (100). *Anal.* calcd. for $C_{16}H_{26}O_4$: C 68.05, H 9.28; found: C 67.95, H 9.33; (*ii*) pure *trans* isomer **6***a* (0.496 g), retention time ~90 min, bp ~60°C (bulb-to-bulb, 0.03 Torr); ir ν_{max} (neat): 1720, 1642, 1230, 1175 cm^{-1}; ^1H nmr δ: 5.7 (1H, s, =CH-), 4.1 (2H, m, CH_3CH_2COO-), 3.7 (3H, s, CH_3COO-), 2.9 (1H, dd, $H_{C'}$, $J_{C'B}$ = 6.0 Hz), 2.75 (1H, dd, $H_{C'}$, $J_{CC'}$ = 14.0, J_{CB} = 8.0 Hz), 2.5 (1H, septet, $(CH_3)_2CH$-, J = 6.0 Hz), 1.5 (1H, m, H_B), 1.35 (1H, d, H_A, J_{AB} = 6.0 Hz), 1.25 (9H, m, CH_3 cyclopropyl + CH_3CH_2COO-), 1.1 (6H, m, $(CH_3)_2CH$-); ms m/z: 282 (M^+), 250, 237, 205, 153 (100). *Anal.* calcd. for $C_{16}H_{26}O_4$: C 68.05, H 9.28; found: C 68.23, H 9.19; and (*iii*) a mixed fraction of **5***a* and **6***a* (0.26 g).

Experiment 2

The solution of catalyst D (0.04 g, 0.06 mmol) in 2 g of the ester **4** was heated with vigorous stirring to 75–80°C under an argon atmosphere and a few drops of the solution of ethyl diazoacetate (0.33 mL, 0.34 g, 3 mmol) in 3.9 g of **4** (total amount of the ester **4** employed in this reaction was 5.9 g, 30 mmol) was added to initiate the reaction evidenced by evolution of nitrogen. Then the temperature of the reaction was lowered to 40°C and the remainder of the solution of ethyl diazoacetate in **4** was added dropwise over a period of 8 h. The product of the reaction was separated from the excess of the substrate by column chromatography on silicia gel (500 g, 230–400 mesh), using a mixture of hexanes/ethyl acetate (80:1) as eluent. The mixture of **5***a* and **6***a* obtained (0.620 g, 70%) was separated by hplc, as described in experiment 1, to give pure **5***a* (0.32 g), pure **6***a* (0.19 g), and a mixed fraction (0.057 g).

Experiment 3

Procedure: As in experiment 1.
Work-up: As in experiment 1.

Experiment 4

Procedure: As in experiment 2.
Work-up: As in experiment 2.

Experiment 5

The solution of catalyst C (0.0966 g, 0.13 mmol) in the ester **4** (12.5 g, 63.8 mmol) was heated to 75°C and a dew drops of the solution of L-menthyl diazoacetate (1.43 g, 6.38 mmol) in cyclohexane (3 mL) was added with stirring to initiate the reaction evidenced by foaming and evolution of nitrogen. Then the temperature of the reaction was lowered to 40°C and the remainder of the solution of L-menthyl diazoacetate in cyclohexane was added dropwise at a rate of approximately 1 drop per 1–2 min. Subsequently, the reaction was heated to 80°C for 5 min and cooled to room temperature. Then the solvent was removed and the crude product was chromatographed on silica gel 60 (230–400 mesh) using toluene as eluent. Further separation and purification of the *cis*/*trans* products was achieved by repeated chromatography on silica gel 60 G (tlc grade) using toluene as eluent to give (*i*) pure *cis* isomer **5***b* (630 mg); bp ~120°C (bulb-to-bulb, 0.03 Torr); ir ν_{max} (neat): 1719, 1640, 1459, 1168 cm^{-1}; uv λ_{max} (MeOH): 223 (ε 16 265) nm; ^1H nmr δ: 5.70 (1H, br s), 4.68 (1H, ddd, J = 10.8, 4.4 Hz), 3.70 (3H, s), 3.10 (1H, dd, J = 13.8, 5.9 Hz), 2.90 (1H, dd, J = 13.8, 6.5 Hz), 2.31 (1H, septet, J = 7.0 Hz), 2.2–1.84 (2H, m), 1.68 (2H, m), 1.45 (1H, d, J = 8.6 Hz), 1.48 (1H, m), 1.36 (1H, m), 1.24 (3H, s), 1.16 (3H, s), 1.07 (3H, d, J = 6.8 Hz), 1.06 (3H, d, J = 6.8 Hz), 0.90 (6H, d, J= 7.0 Hz), 0.78 (3H, d, J = 7.0 Hz); ms m/z: 392 (M^+), 254, 236, 153 (100). *Exact Mass* (hrms) calcd. for $C_{24}H_{40}O_4$: 392.2926; found: 392.2926. *Anal.* calcd. for $C_{24}H_{40}O_4$: C 73.54, H 10.29; found: C 73.70, H 10.30; (*iii*) pure *trans* isomer **6***b* (510 mg); bp ~120°C (bulb-to-bulb, 0.03 Torr); ir ν_{max} (neat): 1719, 1641, 1460, 1170 cm^{-1}; uv λ_{max} MeOH): 220 (ε 15 360) nm; ^1H nmr δ: 5.68 (1H, br s), 4.66 (1H, ddd, J = 10.8, 10.8, 4.4 Hz), 3.68 (3H, s), 2.94 (1H, dd, J = 13.8, 5.4 Hz), 2.68 (1H, dd, J = 13.8, 8.9 Hz), 2.48 (1H, septet, J = 7.0 Hz), 1.94 (1H, m), 1.83 (1H, d, septet, J = 2.5, 6.9 Hz), 1.65 (2H, m), 1.48 (2H, m), 1.33 (1H, d, J = 5.4 Hz), 1.23 (3H, s), 1.19 (3H, s), 1.08 (3H, d, J = 6.9 Hz), 1.07 (3H, d, J = 6.9 Hz), 0.88 (3H, d, J = 7.0 Hz), 0.87 (3H, d, J = 7.0 Hz), 0.72 (3H, d, J = 6.9 Hz); ms m/z: 392 (M^+), 254, 222, 177, 153 (100). *Exact Mass* (hrms) calcd. for $C_{24}H_{40}O_4$: 392.2926; found: 392.2928. *Anal.* calcd. for $C_{24}H_{40}O_4$: C 73.54, H 10.29; found: C 73.70, H 10.35; and (*iii*) a mixed fraction of **5***b* and **6***b* (612 mg).

Experiment 6

Procedure: As in experiment 1, but temperature of the reaction was kept constant at 40°C throughout the entire experiment.
Work-up: As in experiment 1.

Experiment 7

Procedure: As in experiment 2, but temperature of the reaction was kept constant at 40°C throughout the entire experiment.
Work-up: As in experiment 2.

Experiment 8

The mixture of catalyst A ($CuSO_4$, 0.6 g, 3.8 mmol) and the ester **4** (2 g, 10.3 mmol) was heated to 100°C and then ethyl diazoacetate (neat, 9.28 g, 8.5 mL, 81 mmol) was added dropwise with stirring over a period of 8 h. The resulting oil was diluted with dichloromethane, filtered, and worked up further as in experiment 1.

Experiment 9

To the refluxing mixture of catalyst B (0.52 g, 2.3 mmol) and the ester **4** (2 g, 10.3 mmol) in cyclohexane (10 mL), ethyl diazoacetate (6.5 g, 6 mL, 56.6 mmol) was added dropwise over a period of 8 h. The resulting reaction mixture was worked up as in experiment 1.

Experiment 10

Procedure: As in experiment 8.
Work-up: As in experiment 1.

Experiment 11

Procedure: As in experiment 1.
Work-up: As in experiment 1.

Ketones **11**a *and* **12**a

A solution of a mixture of **5***a* and **6***a* (ratio **5***a*:**6***a* ≈ 2:1) (4.5 g) in dichloromethane (150 mL) was treated at −78°C with an excess of ozone for 30 min. Excess of ozone was removed by passing argon through the solution at −78°C and then the solution was allowed to warm to −20°C. At this temperature, 80% acetic acid (50 mL) and zinc powder (15 g) were added and the mixture was stirred at 0°C for 2 h and left overnight at 4°C. Then the solids were filtered off from the reaction mixture, and the filtrate was washed with water and saturated $NaHCO_3$, dried with Na_2SO_4, and concentrated *in vacuo*. Chromatography on silica gel (tlc grade), using a mixture of hexanes/ethyl acetate (20:1) as eluent, gave the isomeric ketones **11***a* (1.1 g, 92%); bp ~80°C (bulb-to-bulb, 0.03 Torr); ir ν_{max} (neat): 1720, 1172, 1136 cm^{-1}; ^1H nmr δ: 4.1 (2H, q, CH_3CH_2COO, J = 7.0 Hz), 2.9 (2H, dd, H_C + $H_{C'}$, $J_{CC'}$ = 18.0 Hz), 2.61 (1H, s, $(CH_3)_2CH$, J = 7.0 Hz), 1.54 (1H, d, H_A, J_{AB} = 8.9 Hz), 1.42 (1H, m, H_B, J_{BC} = 7.0, $J_{BC'}$ = 7.0 Hz), 1.3–1.18 (6H, m, CH_3 cyclopropyl + CH_3CH_2COO), 1.14 (3H, s, CH_3 cyclopropyl), 1.08 (6H, m, $(CH_3)_2CH$); ms m/z: 226 (M^+), 208, 180, 71 (100). *Anal.* calcd. for $C_{13}H_{22}O_3$: C 68.99, H 9.80; found: C 69.30, H 9.81; and **12***a* (2.4 g quant), bp ~90°C (bulb-to-bulb, 0.03 Torr); ir ν_{max} (neat): 1720, 1200, 1168 cm^{-1}; ^1H nmr δ: 4.1 (2H, m, CH_3CH_2COO), 2.7–2.58 (2H, m, $H_{C'}$, J_{BC} = 8.0, $J_{CC'}$ = 17.0 Hz), 1.64 (1H, m, H_B), 1.25 (6H, m, CH_3CH_2COO + CH_3 cyclopropyl), 1.23 (1H, d, H_A, J_{AB} = 5.5 Hz), 1.08 (9H, m, $(CH_3)_2CH$ + CH_3 cyclopropyl); ms m/z: 226 (M^+), 208, 180, 71 (100). *Anal.* calcd. for $C_{13}H_{22}O_3$: C 68.99, H 9.80; found: C 69.07, H 9.64.

Ketone **11**b

A solution of **5***b* (0.128 g) in dichloromethane (20 mL) was treated at −78°C with an excess of ozone for 30 min. Excess of ozone was removed by passing nitrogen through the solution at −78°C. Then dimethyl sulphide (10 molar excess) was added and the solution was allowed to warm up to room temperature and left overnight (14 h). The solvent was removed *in vacuo* and the crude reaction mixture was chromatographed on silica gel 60 G (tlc grade) to afford pure **11***b* (86 mg, 84% yield); bp ~140°C (bulb-to-bulb, 0.03 Torr); ir ν_{max} (neat):

Ketone **12b**

6*b* (0.1 g) was ozonized as above, to give pure **12***b* (81 mg, 91% yield); bp ~140°C (bulb-to-bulb, 0.03 Torr); ir ν_{max} (neat): 1713, 1459, 1201, 1169 cm^{-1}; ^1H nmr δ: 4.70 (1H, ddd, J = 10.8, 10.8, 4.4 Hz), 2.66 (1H, dd, J = 16.1, 6.1 Hz), 2.65 (1H, septet, J = 6.8 Hz), 2.41 (1H, dd, J = 16.1, 6.9 Hz), 1.99 (1H, m), 1.85 (1H, d, septet, J = 2.5, 6.8 Hz), 1.15 (4H, m), 1.23 (3H, s), 1.11 (6H, s and d, J = 6.8 Hz), 1.10 (3H, d, J = 6.8 Hz), 0.90 (6H, d, J = 6.8 Hz), 0.76 (3H, d, J = 6.5 Hz); ms m/z: 336 (M^+), 293, 262, 251, 198, 180, 110, 83 (100). *Exact Mass* (hrms) calcd. for $C_{21}H_{36}O_3$: 336.2665; found: 336.2640. *Anal.* calcd. for $C_{21}H_{36}O_3$: C 75.00, H 10.71; found: C 74.91, H 10.90.

Alcohol **13**

Reduction of **11***a* (0.64 g) with sodium borohydride (0.64 g) in ethanol (15 mL) for 30 min at 0°C gave alcohol **13** (0.61 g, 94%); ir ν_{max} (neat): 1725, 1134, 1093 cm^{-1}; ^1H nmr δ: 4.1 (2H, m, CH_3CH_2COO), 3.4 and 3.3 (1H, bs, $CH(OH)$), 1.9 (1H, m, $(CH_3)_2CH$), 1.7–1.25 (5H, m, H_A + H_B + H_C + $H_{C'}$ + OH), 1.25–1.15 (9H, CH_3CH_2COO + 2 × CH_3 cyclopropyl), 0.9 (6H, m, $(CH_3)_2CH$), most signals were doubled due to the presence of diastereoisomers; ms m/z: 210 ($M^+ - H_2O$), 182, 167, 139, 82 (100). *Exact Mass* (hrms) calcd.: 210.1620; found: 210.1616. *Anal.* calcd. for $C_{13}H_{24}O_3$: C 68.38, H 10.59; found: C 68.45, H 10.49.

Alcohol **14**

Reduction of **12***a* (0.64 g) with sodium borohydride (0.64 g) in ethanol (15 mL) for 30 min at 0°C gave alcohol **14** (0.59 g, 91%); ir ν_{max} (neat): 1724, 1202, 1165 cm^{-1}, ^1H nmr δ: 4.1 (2H, m, CH_3CH_2COO), 3.45 (1H, m, $CH(OH)$), 1.73–1.5 (3H, m, OH + $(CH_3)_2CH$, H_B), 1.5–1.35 (2H, m, H_C, $H_{C'}$), 1.3–1.1 (10H, m, CH_3CH_2COO + 2 × CH_3 cyclopropyl, H_A), 0.9 (6H, m, $(CH_3)_2CH$); ms m/z: 210 ($M^+ - H_2O$), 183, 143, 113, 55 (100). *Exact Mass* (hrms) calcd.: 210.1620; found: 210.1627. *Anal.* calcd. for $C_{13}H_{24}O_3$: C 68.38, H 10.59; found: C 68.60, H 10.59.

Tosylate **15**

p-Toluenesulphonyl chloride (0.17 g, 1.32 mmol) was added to the cool solution (ice bath) of the alcohol **13** (0.1 g, 0.44 mmol) and 4-dimethylaminopyridine (DMAP, 0.430 g, 3.52 mmol) in dichloromethane (2 mL) and stirred at 20°C under an argon atmosphere for 20 h. Then the solution was poured into ice, and extracted with dichloromethane. The organic layer was washed twice with cold 5% HCl and dried over Na_2SO_4 and $NaHCO_3$. Evaporation of the solvent yielded tosylate **15** (0.145 g, 87%), which was used in the next step without further purification; tlc gave one spot at R_f 0.4, hexanes/ethyl acetate 10:1; ^1H nmr δ: 7.7–7.2 (4H, m, ϕ), 3.55–3.40 (1H, m, C*H*OTs), 2.45 (3H, d, CH_3-ϕ). Most signals were doubled due to the presence of two diastereoisomers.

Tosylate **16**

The tosylate **16** was synthesized from the alcohol **14** following the procedure described above for tosylate **15**; ^1H nmr δ: 7.2–7.8 (4H, m, ϕ), 3.6 (1H, m, C*H*OTs), 2.5 (3H, s, CH_3-ϕ).

Olefins **17**, **19**, **21**

Tosylate **15** (0.150 g) was heated in dry pyridine (1 mL) at 110°C for 6 h. The mixture was cooled, poured into ice water, and extracted with ether. The extract was washed with cold 5% hydrochloride acid, dried over Na_2SO_4 and $NaHCO_3$, and concentrated *in vacuo*. The residual oil was chromatographed on a silica gel column using a mixture of hexanes/ethyl acetate (100:1) as eluent. After evaporation of the solvent, a mixture of **17**, **19**, and **21** (0.067 g, 81%) was obtained as a colorless oil. (Ratio of olefins by ^1H nmr, 10:3.2:1.) This oil was chromatographed on a silica gel column impregnated with $AgNO_3$ (15%) using a mixture of hexanes/toluene (1:3) as eluent. Fractions enriched in each olefin were collected and analysed by ^1H nmr and gc/hrma.

Olefins **17**, **19**, **21.** *Alternative preparation*

Tosylate **15** (0.57 g, 1.5 mmol), $(n\text{Bu})_4\text{NBr}$ (0.49 g, 1.5 mmol), and 2,6-lutidine (0.6 mL, 5 mmol) in anhydrous acetone (10 mL) were heated in a closed vessel at 70°C for 2 days. After the work-up, a mizture of olefins **17**, **19**, **21** (0.267 g, 89%, ratio 18:2.3:1) was obtained and separated as above.

Olefin **17**: ^1H nmr δ: 5.1 (1H, m, H_D), 4.1 (2H, m, CH_3CH_2COO), 2.3 (2H, m, H_C + $H_{C'}$), 1.65 (6H, ds, $(CH_3)_2$=C), 1.4 (1H, d, H_A, J_{AB} = 9.0 Hz), 1.25 (3H, t, CH_3CH_2COO), 1.22 (3H, s, CH_3 cyclopropyl), 1.2 (1H, m, H_B), 1.16 (3H, s, CH_3 cyclopropyl). *Exact Mass* (hrms) calcd.: 210.1620; found: 210.1637.

Olefin **19**: ^1H nmr δ: 5.68 (1H, dd, H_C, J_{CD} = 16.1, J_{CB} = 9.0 Hz), 5.57 (1H, dd, H_D, J = 6.2 Hz), 0.95 (6H, dd, $(CH_3)_2CH$). *Exact Mass* calcd.: 210.1620; found: 210.1619.

Olefin **21**: ^1H nmr δ: 4.7 (2H, m, CH_2=), 4.1 (2H, m, CH_3CH_2-COO), 2.0 (2H, m, CH_2), 1.8 (2H, m, CH_2), 1.72 (3H, s, CH_3—C=), 1.4 (1H, d, H_A, J_{AB} = 9.0 Hz), 1.25 (3H, t, CH_3CH_2COO), 1.23 (3H, s, CH_3 cyclopropyl), 1.2 (1H, m, H_B), 1.14 (3H, s, CH_3 cyclopropyl). *Exact Mass* (hrms) calcd.: 210.1620; found: 210.1642.

Olefins **18**, **20**, **22**

The olefins **18**, **20**, **22** were prepared following both procedures described above for the olefins **17**, **19**, **21**. When tosylate **16** was heated in pyridine, 87% yield was obtained (ratio of olefins 48:5:1). In reaction with $(n\text{Bu})_4\text{NBr}$ and lutidine, 93% yield was obtained (ratio of olefins 62.5:2.5:1). After separations on silica gel columns impregnated with $AgNO_3$ as above, fractions enriched in each olefin were collected and analysed by ^1H nmr and gc/hrms.

Olefin **18**: ^1H nmr δ: 5.1 (1H, m, -CH=), 4.1 (2H, m, CH_3CH_2-COO), 2.1 (2H, m, H_{3C} + $H_{C'}$), 1.68 (3H, s, CH_3—C=), 1.58 (3H, s, CH_3—C=), 1.35 (1H, m, $H_{B'}$, $J_{CB} \approx J_{C'B}$ = 7.6 Hz), 1.25 (3H, t, CH_3CH_2COO), 1.20 (3H, s, CH_3 cyclopropyl), 1.18 (1H, d, H_A, J_{AB} = 7.0 Hz), 1.15 (3H, s, CH_3 cyclopropyl). *Exact Mass* (hrms) calcd.: 210.1620; found: 210.1655.

Olefin **20**: ^1H nmr δ: 5.65 (1H, dd, H_D, J = 6.6, J_{CD} = 15.0 Hz), 5.10 (1H, dd, H_C, J_{BC} = 7.5 Hz), 4.1 (2H, m, CH_3CH_2COO), 2.25 (1H, m, $(CH_3)_2CH$), J = 6.6 Hz), 2.0 (1H, m, H_B), 1.45 (1H, d, H_A, J_{AB} = 5.3 Hz), 1.25 (3H, t, CH_3CH_2COO), 1.22 (3H, s, CH_3 cyclopropyl), 1.15 (3H, s, CH_3 cyclopropyl), 0.35 (6H, d, $(CH_3)_2CH$, J = 6.8 Hz). *Exact Mass* (hrms) calcd.: 210.1620; found: 210.1599.

Olefin **22**: ^1H nmr δ: 4.67 (2H, m, =CH_2). *Exact Mass* (hrms) calcd.: 210.1620; found: 210.1627.

Diastereoselective alkylation of glycinates. 4.[1] The role of the metal cation and additives

JOHN M. MCINTOSH AND KENNETH C. CASSIDY
Department of Chemistry and Biochemistry, University of Windsor, Windsor, Ont., Canada N9B 3P4

Received April 7, 1988

JOHN M. MCINTOSH and KENNETH C. CASSIDY. Can. J. Chem. **66**, 3116 (1988).

The alkylation of the sodium, potassium, zinc, and zirconium enolates of the *R*-camphor imine of *tert*-butyl glycinate have been examined and the stereochemical results compared with those obtained with the lithium enolate. No difference was noted for the sodium enolate but inferior chemical yields and stereoselectivities were obtained with the potassium enolate, perhaps due to its increased ionic character. Substituting TMEDA for HMPA in these reactions led in all but one case to reduced stereoselectivities. The results support and are interpreted in terms of the π-metal association model previously proposed.

JOHN M. MCINTOSH et KENNETH C. CASSIDY. Can. J. Chem. **66**, 3116 (1988).

On a étudié l'alkylation des énolates de sodium, de potassium, de zinc et de zirconium de l'imine du glycinate de *tert*-butyl du *R*-camphre et on a comparé les résultats stéréochimiques observés avec ceux obtenus avec l'énolate de lithium. On n'a noté aucune différence pour l'énolate de sodium; toutefois, on a obtenu des rendements chimiques et des stéréosélectivités inférieurs avec l'énolate de potassium et ces résultats sont peut-être dus à son plus grand caractère ionique. La substitution, dans ces réactions, du TMEDA par du HMPA provoque dans tous les cas, excepté un, une réduction des stéréosélectivités. Les résultats obtenus sont en accord avec et ils sont interprétés en fonction du modèle d'association π–métal qui a été proposé antérieurement.

Introduction

Recently we presented the results of the alkylation of the *R*-camphor imine of *tert*-butyl glycinate (**1**) with a variety of alkylating agents and showed that the stereochemical results can be nicely rationalized on the basis of electronic and steric effects (1–3). In particular, when π unsaturation is present in the electrophile in a position where it may interact with the enolate system, dramatically increased diastereoselectivities (de's) were observed. It was unclear, however, whether this effect was due to association of the electrophile π system with the π system of the enolate or with the coordination sphere of the metal cation of the enolate, which, in all cases, was lithium. Information on this point can be obtained by determining the effect of changing the metal cation on the stereoselectivity and yield of the reactions. In contrast to aldol reactions (4), this type of information is not routinely available for alkylation reactions. In a recent comprehensive review, Evans (5) classified one of the effects that controls alkylation stereoselectivity as "chelate-enforced chirality transfer" and gave a limited number of examples of the use of cations other than lithium. He also noted that chelation control in the alkylation of some amino acid derivatives is speculative because of the lack of information on enolate geometry. In our case, this uncertainty is absent since the C10 methyl group of camphor demands that the enolate have the *E* configuration. In this paper, the results of changing the metal cation are reported, as is the effect of changing the additive from HMPA (hexamethylphosphoramide) to TMEDA (tetramethylethylenediamine). The results are interpreted in terms of the reaction mechanism and the origin of the observed π effect.

A. Effect of the metal ion (Table 1)

In all cases reported to date, the enolate **2***a* was generated using one equivalent of LDA (lithium diisopropylamide) in THF solution and thus one equivalent of diisopropylamine (DIPA) was present during the alkylation reaction. Previous results had shown that one equivalent of HMPA was required to achieve satisfactory chemical yields, but that two equivalents had a deleterious effect on the de's obtained (2). Identical effects were obtained when this additive was introduced either prior to addition of the electrophile or coincident with it. These conditions will be referred to hereafter as "standard conditions". In either case, the enolate **2***a* was a homogeneous yellow solution.

When NaH was reacted with **1**, no reaction occurred unless a proton transfer reagent was added. To make the conditions as comparable as possible to those of the potassium enolate, one equivalent of *tert*-butyl alcohol was used. A homogeneous solution of **2***b* was obtained, which, upon alkylation with either allyl or benzyl bromide in the presence of HMPA, afforded **3** or **4** respectively. Both the chemical yield and diastereomeric

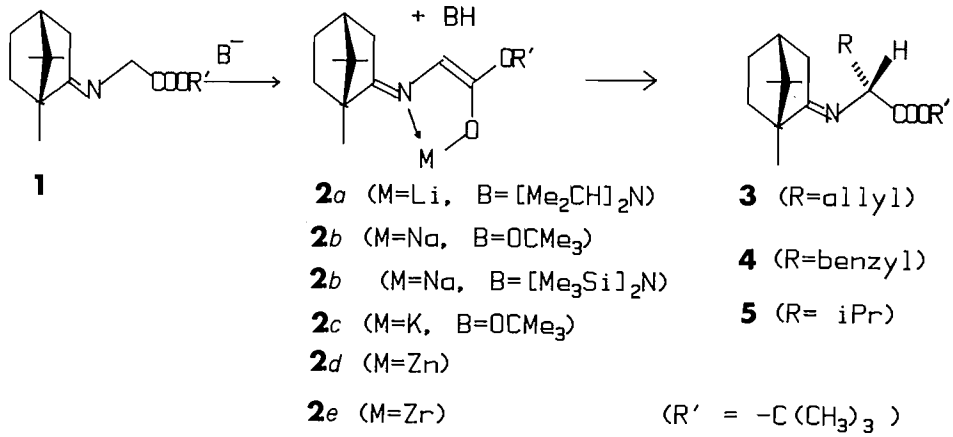

SCHEME 1

excesses obtained as determined by 300 MHz ^{1}H nmr measurements were indistinguishable from those obtained using enolate **2***a*. To better duplicate the reaction conditions used in the alkylation of **2***a*, the reactions were repeated using sodium hexamethyldisilazide as the base. The reactions of enolate **2***b*′ generated in this manner showed identical behavior to **2***a* and **2***b* (Table 1). Seebach and co-workers (6) have shown that the conjugate acid of the base used can have a significant effect on reactions of the enolate. The similarity of the reactions of **2***b* and **2***b*′ is reassuring.

The physical nature of enolate **2***c*, which was prepared using KO^{t}Bu, depended strongly on the temperature of its generation. At −20°C a precipitate formed immediately, which could not be stirred magnetically unless two equivalents of HMPA were added. When one equivalent of HMPA was added *simultaneously* with the base, a stirrable, but very turbid, heterogeneous mixture resulted. When enolate **2***c* was generated at −78°C in the presence of one equivalent of HMPA, a yellow-orange solution was formed, which persisted for approximately 15 min, at which time a precipitate formed. The process was not reversible. Enolate formation at −100°C, again in the presence of HMPA, gave a stable yellow-orange solution of enolate **2***c*. Alkylation of **2***c* generated at any of the above temperatures with allyl or benzyl bromide gave indentical results. (Alkylation with isopropyl iodide required a temperature of −20°C and therefore was necessarily conducted on the suspended enolate.) In every case, the chemical yield was low and the de values obtained with those electrophiles for which π association has been invoked (allyl and benzyl bromides) (1, 2) were severely reduced while that for isopropyl iodide, where no such association is possible, was unaffected.

The Zn^{2+} enolate (**2***d*) was prepared by exchanging Zn for Li at −78°C. When **2***d* was alkylated, poor chemical yields were obtained but the diastereoselectivities were comparable with those obtained under standard conditions. Finally, when enolate **2***a* was treated with one equivalent of Cp_2ZrCl_2 followed by either allyl or benzyl bromide, **3** and **4** were obtained. The de of the benzylated product **4** was unchanged whereas that of **3** increased slightly to 82%.

B. Effect of the additive

When one equivalent of TMEDA, a bidentate ligand, was used in place of HMPA with enolates **2***a*, **2***b*′, or **2***c*, alkylation with allyl or benzyl bromides or isopropyl iodide gave the results shown in Table 2. In the case of enolate **2***a* a severe reduction in the chemical yield and diastereoselectivity was observed for all three electrophiles, whereas very little effect was noted when enolates **2***b*′ and **2***c* were used.

Discussion

In the generation of enolates **2***b* and **2***c*, one equivalent of *tert*-butyl alcohol is generated. The corresponding conjugate acid formed in the Li case is diisopropylamine, which is also present in both **2***d* and **2***e*. The fact that the chemical yields and diastereomeric excesses obtained using **2***b* did not diminish significantly suggests that the presence of *tert*-butyl alcohol is, in itself, not deleterious and therefore not responsible for the reduced yields using **2***c*. Further support for this conclusion can be found in a comparison of the alkylations of enolates **2***b* and **2***b*′.

The solubility phenomenon described for enolate **2***c* is ascribed to aggregation effects. As initially generated, the enolate is monomeric and soluble. As the temperature increases, the rate of combination into insoluble aggregates increases, aided by the more ionic character of potassium. It may be that the enolate has changed to an extended one from which reduced de's might be expected. However, the low yield and selectivity obtained using **2***c* cannot be ascribed to the physical state of the enolate since, at −100°C, the homogeneous solution of **2***c* gave the same results as the heterogeneous mixture at −20°C and, also, alkylation with isopropyl iodide gave the same stereoselectivity as obtained with enolate **2***a*. The

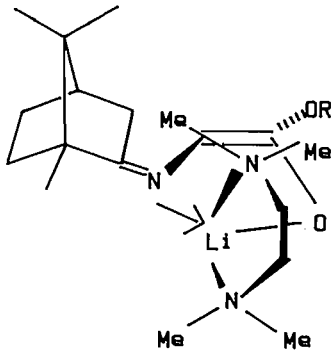

FIG. 1

use of two equivalents of HMPA in the reaction of **2***c* with benzyl bromide did not lead to significantly reduced de's. This stands in contrast to the results obtained with enolate **2***a*. Thus it seems that the aggregation state of enolate **2***c* may be responsible for the reduced chemical yields but not the lowered stereochemistry of the reaction.

The effect of the additive is especially interesting. As previously noted, whereas one equivalent of HMPA is required for acceptable yields in the alkylation of **2***a*, two equivalents significantly reduce the stereoselectivity. Lithium is known to be tetracoordinate in a tetrahedral geometry. Also, it is generally accepted that electronic forces operating beyond the first coordination sphere are weak and that alkali metal cations are seldom complexed by neutral ligands unless chelation can occur (7). Thus, coordinated HMPA in the lithium enolate should be much more easily displaced than should TMEDA. Complexation with TMEDA as shown in Fig. 1 should add significant steric bulk on both the *re* and *si* faces of the planar enolate system, making π association much less favorable and reducing the stereoselectivity of the reaction. Coordination to sodium should be even weaker and it appears that here HMPA and TMEDA are comparable. Both allow the interaction that leads to the enhanced stereoselectivity. When potassium is the counterion, the selectivity is reduced to a level that seems independent of the amount and nature of the additive. It is significant that this level of chiral induction is that observed with bulky aliphatic halides where no association of the kind invoked in our previous papers can occur. Of all the metal cations used in this study, potassium should be the most weakly complexing. The observed significant reduction in stereoselectivity suggests that the effect responsible for the correlation of diastereoselectivity with π unsaturation is π–metal, not π–π, coordination.

It should be noted also that the metal cations used in this study differ considerably in their atomic radii. It is possible that as the radius of the metal atom in the cyclic enolate increases, the metallocycle may begin to deviate significantly from planarity. The approach of the electrophile may then be along a path that does not efficiently discriminate between the *re* and *si* faces.

In summary, the following appear to rationalize the results. In the absence of a *chelating* additive and using enolate **2***a*, or using enolate **2***b* with either type of additive, an essentially covalent cyclic enolate ion of the type previously envisaged (Scheme 1) is formed. The function of HMPA in these cases may be to deaggregate the enolate (8). However, with the exception of the coordination of TMEDA to lithium, the coordination of any additive with the remaining two coordination sites on lithium or sodium must be so weak that little impediment to the association of the electrophile with the metal is present. The presence of TMEDA with lithium leads to an effective coordination that imposes larger steric requirements on the *re* face (and may destroy the cyclic nature of the enolate) and reduces the asymmetric induction.

When potassium is used, sufficient ionic character is imparted to the enolate to favor its aggregation and render it essentially insoluble in the organic medium. Even the presence of HMPA cannot prevent this, and the metallocycle structure of the enolate may have been destroyed. In the zinc and zirconium cases, strong cyclic chelation and π–metal association would be expected and the observed de's support this contention.

Experimental

The preparation of **1**, the general details for the formation and alkylation of enolate **2***a*, and the determination of the diastereomeric excesses (de's) have been published previously (1). The preparation and alkylation of enolates **2***b*-**2***e* are given below. The experiments using TMEDA as the additive were performed in an exactly analogous manner, substituting it for HMPA.

Enolate 2b

To a cold mixture of **1** (1.0 g, 3.77 mmol) and 1.1 equiv. of oil-free sodium hydride in 5 mL of dry THF was added 1 equiv. of *tert*-butyl alcohol under nitrogen. The mixture was stirred at 0°C for 0.5 h to afford a clear yellow solution of **2***b*. The solution was cooled to −78°C and a THF solution containing 1 equiv. of each of the alkylating agent and HMPA was added dropwise. After 1 h, the reaction was quenched at −78°C and work-up and purification were effected as previously reported (1). The results are shown in Table 1.

Enolate 2b′

A cold solution of **1** (1.0 g, 3.77 mmol) and 1 equiv. of HMPA in 5 mL of dry THF were added dropwise with stirring to 3.8 mL of a solution of sodium hexamethyldisilazide (1 M in THF). The solution was cooled to −78°C and alkylated as described above for enolate **2***b*.

Enolate 2c

To a cold solution of 0.43 g (3.8 mmol) of potassium *tert*-butoxide in 5 mL of dry THF was added a solution of **1** (1.0 g, 3.77 mmol) at −20°C in the same solvent. Immediate precipitation of the enolate caused the solidification of the mixture. It required the addition of 2 equiv. of HMPA to provide a heterogeneous but stirrable mixture that could be alkylated. If 1 equiv. of HMPA was added to the base *simultaneously* with **1**, a tractable slurry was obtained, which was cooled to −78°C and alkylated in the usual way. The results are given in Table 1.

Generation of the enolate at −78°C in the presence of 1 equiv. HMPA afforded **2***c* as a yellow-orange solution that precipitated after ca. 15 min. When enolate formation was carried out at −100°C, the enolate remained in solution.

Enolate 2d

To a solution of **2***a* in the THF generated in the usual way was added 1 equiv. of solution of anhydrous $ZnCl_2$ in ether. After stirring for 30 min, the solution had changed from orange to yellow. The solution was cooled to −78°C and the alkylation performed in the usual manner. The results are given in Table 1.

Enolate 2e

To a solution of **2***a* in dry, degassed THF was added a THF solution of 1 equiv. of Cp_2ZrCl_2 at −78°C under nitrogen. The color of the solution changed from orange to a dark red-brown. Alkylation and work-up were performed in the standard manner. The results are given in Table 1.

The reaction of $Pt^0(PCy_3)_2$ with triphenyltin hydride yields *cis*-H(Ph_3Sn)Pt(PCy_3)$_2$ as the initial product; isomerization to the *trans* isomer is accelerated by light, heat, and the presence of free phosphine. Both isomers have been characterized by multinuclear nmr spectroscopy; in particular, the $^{31}P\{^1H\}$ spectra in solution are correlated with the solid state CP/MAS ^{31}P nmr spectra and the crystal structure. The crystal structures of *trans*-H(X_3Sn)Pt(PCy_3)$_2$ X = Ph or Cl have been determined and the nature of the distortions produced by steric overcrowding is identified and discussed.

HOWARD C. CLARK, GEORGE FERGUSON, MARK J. HAMPDEN-SMITH, HEINZ RUEGGER et BARBARA L. RUHL. Can. J. Chem. **66**, 3120 (1988).

Le composé $Pt^0(PCy_3)_2$ réagit avec l'hydrure de triphénylétain pour donner le composé H(Ph_3Sn)Pt(PCy_3)$_2$ *cis* comme produit initial; la lumière, la chaleur et la présence de phosphine libre accélèrent l'isomérisation en isomère *trans*. On a caractérisé les deux isomères par spectroscopie de rmn à noyaux multiples. On a déterminé, en particulier, les rapports existants entre les spectres du $^{31}P\{^1H\}$ en solution, les spectres RMN de ^{31}P CP/MAS à l'état solide et la structure cristalline. On a déterminé les structures cristallines du composé H(X_3Sn)Pt(PCy_3)$_2$, X = Ph ou Cl et on a identifié la nature des distorsions produites par l'encombrement.

[Traduit par la revue]

Introduction

Compounds containing platinum(II)–tin(IV) bonds have been extensively investigated (1) largely because many of these systems function as effective homogeneous hydrogenation catalysts. A large number of such compounds have been fully characterized and a variety of preparative methods are available (2–6). A common method involves oxidative addition of organotin compounds to zerovalent tertiary phosphine complexes of Pt(II) (5), e.g.

[1] $(PPh_3)_2Pt(C_2H_4) + R^1R^2R^3R^4Sn \rightarrow R^1[R^2R^3R^4Sn]Pt(PPh_3)_2 + C_2H_4$

By this method, Pidcock and co-workers (5, 6) have prepared both *cis* and *trans* isomers of compounds $R^1[R^2R^3R^4Sn]$-$Pt(PPh_3)_2$ where R^{1-4} are alkyl, aryl, or halide, and where the nature of the group (R^1) transferred from tin to platinum depends on the nature of the various substituents on tin (R^1–R^4). Thus, the tin substrates $SnPh_4$, $SnPh_3Cl$, $SnPh_2Cl_2$, $SnMe_4$, and $SnMe_3Cl$ react with Pt(0) species via Sn—C bond cleavage, whereas $SnPhCl_3$, $SnMe_2Cl_2$, and $SnCl_4$ react via Sn—Cl bond cleavage. In such reactions, the *cis*-stereochemistry predominates when Sn—C cleavage occurs, but small amounts of *trans*-isomers are observed when Sn—Cl bond scission occurs. In these systems, a number of reaction pathways are possible; attempts to observe radical intermediates by esr spectroscopy were unsuccessful, perhaps surprising in view of the extensive radical chemistry of organotin compounds.

Previously, it was reported from this laboratory (3) that triphenyltin hydride reacts with a variety of bis(tertiaryphosphine) platinum(II) dihydrides to form bis-tin-, mono-tin-, or no tin- platinum products apparently depending on the steric bulk of the tertiary phosphine ligands. No tin–platinum product was isolated from the reaction of $HSnPH_3$ and $Pt^0(PCy_3)_2$ over a period of 1 h. More recently, however, we found[4] that $HSiPh_3$ reacts with $Pt^0(PCy_3)_2$ to form exclusively *cis*-H(Ph_3Si)Pt(PCy_3)$_2$ which could be quantitatively isomerized to the *trans* analogue by exposure to uv light. Clearly, the course of these reactions is influenced by the steric crowding at the platinum centre; indeed, given the steric bulk of the tricyclohexylphosphine ligand and of —SnX_3, these molecules must be severely distorted. We have therefore examined in more detail the reaction of $HSnPh_3$ with $Pt^0(PCy_3)_2$ to gain some better understanding of these reactions and have also determined the crystal structures of two molecules *trans*-H(SnX_3)Pt(PCy_3)$_2$, X = Ph or Cl, as a means of observing the steric overcrowding.

Experimental

All reactions were carried out using Schlenck apparati and techniques or adaptations of them, utilizing a dry nitrogen atmosphere and dry solvent. Our general preparative techniques have previously been described (7). Elemental analyses were carried out by Guelph Chemical laboratories.

(I) Preparation of trans-*H[Ph_3Sn]Pt(PCy_3)$_2$*

(i) From $HSnPh_3$ and $^0Pt(PCy_3)_2$

trans-$(PCy_3)_2PtCl_2$ (530 mg, 0.64 mmol) was reduced with sodium naphthalide according to the literature method (8). To the pale yellow hexane extract containing $Pt(PCy_3)_2$, 250 mg (0.71 mmol) of $HSnPh_3$ was added dropwise. The solution darkened slightly and after 3 h of stirring some white precipitate had been formed. The stirring was continued for a further 12 h, during which some of the white precipitate redissolved. The solution was filtered to yield 324 mg of a white solid, found to be *trans*-H[Ph_3Sn]Pt(PCy_3)$_2$ by ^1H and ^{31}P nmr spectroscopy

(see data below). Evaporation of the solvent from the supernatant, followed by washing with two 3 mL portions of cold *n*-pentane, led to isolation of a further portion of the *trans*-product (185 mg) to give an overall yield of 509 mg (0.46 mmol.), 72% based on $(PCy_3)_2PtCl_2$. *trans*-$H[Ph_3Sn]Pt(PCy_3)_2$ calculated for $C_{54}H_{82}P_2SnPt$: C 58.57, H 7.46; found: C 59.32, H 7.29. mp 158–162°C dec. ν(Pt—H) = 2050 cm^{-1}. Single crystals of *trans*-$H[Ph_3Sn]Pt(PCy_3)_2$ were grown by vapour diffusion between a benzene solution of the complex and external ethanol.

(ii) From $O_2Pt(PCy_3)_2$

$(PCy_3)_2PtO_2$ (97 mg, 0.12 mmol) was dissolved in 5 mL of benzene and an excess (100 μL) of Ph_3SnH was added. An immediate evolution of gas was observed and the solution was stirred for 1 h. The solvent was removed and the residue washed with two 4 mL portions of cold *n*-pentane to yield 115 mg of *trans*-$H[Ph_3Sn]Pt(PCy_3)_2$ (84.4%).

In an attempt to observe intermediates in this reaction, an nmr tube was charged with a known weight of $(PCy_3)_2PtO_2$ dissolved in 0.5 mL of $CDCl_3$. The solution was cooled to −60°C in the magnet and a ^{31}P nmr spectrum of the starting material was obtained at this temperature. One half of the stoichiometric amount of Ph_3SnH was added at −76°C and the tube quickly shaken and replaced into the cold magnet. On subsequent warming to −10°C, the ^{31}P nmr spectra taken at 10°C intervals revealed only the presence of starting material ($(PCy_3)_2PtO_2$) and final product (*trans*-$H[Ph_3Sn]Pt(PCy_3)_2$). No other phosphorus resonances were observed.

(II) Preparation of cis-*$H[Ph_3Sn]Pt(PCy_3)_2$*

trans-$Cl_2Pt(PCy_3)_2$ (1.00 g, 1.2 mmol) was reduced with 2 equiv. of sodium naphthalide and the hexane extract was transferred to a darkened Schlenk flask. $HSnPh_3$ was added (155 μL, 0.21 g, 0.6 mmol) and the solution was vigorously stirred in the dark for 3 h. During this period, a fine white precipitate formed which was separated by filtration. The white solid was found to be *cis*-$H[Ph_3Sn]Pt(PCy_3)_2$ (0.6243 g, 0.56 mmol) (93.3% yield based on $HSnPh_3$) by ^1H and ^{31}P nmr spectroscopy. The second equivalent of $HSnPh_3$ was added to the supernatant in room light and resulted in an immediate precipitation and yellowing of the solution. The mixture was stirred for a further 12 h (in room light), after which time the precipitate had redissolved. The solvent was reduced to a quarter of its original volume and the pale yellow solid filtered. This solid was found to be *trans*-$H[Ph_3Sn]Pt(PCy_3)_2$ by (^1H and ^{31}P nmr spectroscopy) (0.3422 g, 0.31 mmol). Total yield of *cis*- and *trans*-$H[Ph_3Sn]Pt(PCy_3)_2$ based on *trans*-$Cl_2Pt(PCy_3)_2$ starting material, 72.5%. *cis*-$H[Ph_3Sn]Pt(PCy_3)_2$: *Anal.* calcd. for $C_{54}H_{82}P_2SnPt$: C 58.78, H 7.46; found: C 58.84, H 7.76. Melting point 147–149°C dec. ν(Pt—H) = 2033 cm^{-1}.

(III) Preparation of trans-*$H[Cl_3Sn]Pt(PCy_3)_2$*

trans-$HClPt(PCy_3)_2$ (108 mg, 0.02 mmol) was dissolved in 15 mL of benzene and 50 mg (0.26 mmol) of $SnCl_2$ were added. The mixture was vigorously stirred as 0.2 mL of water was added to dissolve the tin(II) chloride. After stirring for 2 h the solution was filtered and the solvent was removed *in vacuo*. The white solid obtained was crystallized from a benzene/hexane mixture to give 208 mg (0.21 mmol) of *trans*-$H[Cl_3Sn]Pt(PCy_3)_2$, characterized by nmr spectroscopy, a yield of 92.1%, mp 183–186°C (dec), ν(Pt—H) 2115 cm^{-1}.

(IV) Nuclear magnetic resonance data

(*a*) Solution ^1H and ^{31}P nmr spectra were recorded on either Bruker AM 250 or WH400 nmr instruments. ^1H nmr spectra were referenced either to protio impurity of deuterated solvents, or to tetramethylsilane (TMS). ^{31}P nmr were referenced to external trimethylphosphate, and shifts were reported using the high frequency positive sign convention relative to phosphoric acid. The stereochemistry of *bis*-phosphine platinum(II) hydride species can readily be assigned from a partially proton-coupled ^{31}P nmr spectrum. In this experiment, the alkyl phosphine protons are decoupled at low decoupler power leaving the coupling of the hydride ligand essentially intact. The ^{31}P resonance of a phosphine ligand *trans* to a hydride ligand exhibits the large $J_{H—Pt_{trans}}$ of the order of 150 Hz while the value of $J_{H—P_{cis}}$ commonly lies in the range 20–35 Hz.

(*b*) The ^{31}P CP-MAS nmr spectra was acquired at 81.0 MHz on a Bruker CXP-200 instrument equipped with the standard CP-MAS probe, using the standard cross polarisation pulse program, PENMR.PPG. The Hartman–Hahn condition was set as described elsewhere (9). The magic angle was set by observing the ^{79}Br resonance of KBr and adjusting the angle to give maximum intensity to the spinning side bands. Typical acquisition parameters were as follows: spin rate, 3.5 to 4.0 kHz; 90° pulse, 6.0 μs; contact time, 0.5 ms; spectral width, 20 kHz centered on 0 ppm with respect to external 85% H_3PO_4; data table, 0.5 to 1K zero filled to 4K before Fourier transformation; recycle time, 10 s.

For the compounds prepared above, the following nmr data were recorded:

For *trans*-$H[Ph_3Sn]Pt(PCy_3)_2$: ^1H nmr (in C_6D_6): δ(hydride) = −5.84 ppm, $J_{H—P}$ = 13, $^1J_{H—Pt}$ = 918, $^2J_{H—Sn}$ = 698 Hz; ^{31}P nmr (in C_6D_6): δP = 43.3 ppm; $J_{P—Pt}$ = 2627, $J_{Sn—P}$ = 14.5; ^{119}Sn nmr (in C_6D_6): δSn = −21.8 ppm, $J_{Sn—Pt}$ = 9680 Hz.

For *cis*-$H[Ph_3Sn]Pt(PCy_3)_2$: ^1H nmr (in C_6D_6): δ(hydride) = −5.00 ppm, $^{cis}J_{H—P}$ = 18, $^{trans}J_{H—P}$ = 143, $J_{H—Sn}$ = 26, $J_{H—Pt}$ = 638 Hz; ^{31}P nmr (in C_6D_6): δP_A (*trans* to Sn) = 43.5, δP_B = 41.8, $J_{P_A—P_B}$ = 5, $J_{P_A—Pt}$ = 2568, $J_{P_B—Pt}$ = 2738, $J_{P_A—^{117}Sn}$ = 1750, $J_{P_A—^{119}Sn}$ = 1753, $J_{P_B—Sn}$ = 138 Hz.

For *trans*-$H[Cl_3Sn]Pt(PCy_3)_2$: ^{31}P nmr (in C_6D_6): δP = 44.5 ppm, $J_{P—Pt}$ = 2485, ^{119}Sn nmr (in C_6D_6): δSn = 134 ppm, $J_{^{119}Sn—H}$ = 752, $J_{Sn—P}$ = 11 242. ^1H nmr (in C_6D_6): δ(hydride) = −10.96 ppm (broad); $J_{H—Pt}$ = 1337.3 Hz. Solid State ^{31}P nmr data: for *trans*-$H[Ph_3Sn]Pt(PCy_3)_2$; δP_A = 40.0, δP_B = 44.3, $J_{P—P}$ = 354, $J_{P_A—Pt}$ = 2531, $J_{P_B—Pt}$ = 2683 Hz; for *trans*-$H[Cl_3Sn]Pt(PCy_3)_2$: δP ~41.3 ppm, $J_{P—Pt}$ = 2506 Hz.

(V) ^{31}P nmr tube experiments on cis/trans *isomerization*

These experiments were conducted in 5 mm nmr tubes by dissolving accurately weighed portions (25–35 mg) of solid in 0.5 mL of the appropriate solvent. The limit of solubility of *cis*-$H[Ph_3Sn]Pt(PCy_3)_2$ in benzene-d_6 is approximately 40 mg/0.6 mL (0.072 molar). The *trans*-isomer is very soluble, being even slightly soluble in *n*-hexane. Isomerization reactions, which were followed "in the dark" were run in the magnet (generally overnight) and spectra were recorded at various intervals. Temperatures were calibrated against methanol or ethylene glycol standard, where appropriate.

(VI) X-ray structure determinations for trans-*$H[Ph_3Sn]Pt(PCy_3)_2$ (I) and* trans-*$H[Cl_3Sn]Pt(PCy_3)_2$ (II)*

General crystallographic details for both molecules are given in Table 1. Accurate cell data were obtained by a least-squares treatment of the setting angles (25 for **I**, 12 for **II**) of reflections with θ between 10 and 15°, measured with graphite monochromatized Mo-Kα radiation, on a CAD4 diffractometer for **I** and on a Hilger & Watts Y290 four-circle diffractometer for **II**. The systematic absences for **I** (0*k*0) absent if $k = 2n + 1$) allow the space group to be $P2_1$ or $P2_1/m$; the former was chosen and confirmed by the successful analysis. Molecule **II** is triclinic; space group $P\bar{1}$ was assumed amd established by the analysis.

Both structures were solved via the heavy-atom method, and refined by full-matrix least-squares calculations (using SDP-Plus ref. 10 for **I** and SHELX ref. 11 for **II**). At intermediate stages in the analyses, difference maps revealed maxima in positions consistent with the expected locations of the phenyl and cyclohexyl hydrogen atoms; ripples at the Pt atoms precluded location of the hydrogen at these sites. The hydrogen atoms were then allowed for in geometrically idealised locations (C—H 1.08 A) and included but not refined in the final rounds of calculations in which all non-hydrogen atoms were allowed anisotropic motion. Molecule **I** occurs in the polar space group $P2_1$; at an intermediate stage in the analysis, calculations with the opposite hand gave R = 0.051, whereas the chosen model had R = 0.039. Refinement was then continued until convergence with this model. Final difference maps had no chemically significant features. Weights in the refinement were based on counting statistics with $w = 1/(\sigma - {}^2F_o + pF_o^2)$; scattering factors and anomalous dispersion correction factors were from ref. 12.

Refinement details are in Table 1. Tables 2 and 3 contain final fractional coordinates. Principal dimensions for **I** and **II** are given in Table 4. Tables of calculated hydrogen coordinates, all bond lengths and angles, anisotropic thermal parameters and structure factor listings are available as supplementary material.[5] Views of the molecules prepared with the aid of Ortep (ref. 13) are in Figs. 3 and 4.

Results and discussion

Addition of a 50% excess of the stoichiometric amount of $HSnPh_3$ to a hexane solution of $Pt^0(PCy_3)_2$ led to precipitation of analytically pure *trans*-$H[Ph_3Sn]Pt(PCy_3)_2$ over a period of 15 h at room temperature.

$$[2]\quad Pt^0(PCy_3)_2 + \text{excess } HSnPh_3 \xrightarrow{15\text{ h}} \textit{trans}\text{-}H[Ph_3Sn]Pt(PCy_3)_2$$

Evaporation of the solvent *in vacuo* led to recovery of a further portion of *trans*-$H[Ph_3Sn]Pt(PCy_3)_2$ after washing with cold pentane. This organotinplatinum species was characterized by a variety of spectroscopic methods and the structure was determined by X-ray crystallography.

The analogous trichlorostannate complex, *trans*-$H[Cl_3Sn]$-$Pt(PCy_3)_2$, was prepared by the following reaction:

$$[3]\quad \textit{trans}\text{-}HClPt(PCy_3)_2 + SnCl_2 \rightarrow \textit{trans}\text{-}H[Cl_3Sn]Pt(PCy_3)_2$$

By comparison with previous results[6] concerning the oxidative addition of organosilicon hydrides to $Pt^0(PCy_3)_2$, in which products of *cis* geometry were generally obtained, we were surprised to isolate a product of *trans* stereochemistry for the case of $HSnPh_3$. Formation of a *trans* product may arise from a reaction pathway involving a free radical mechanism or by isomerization of an unstable *cis* intermediate, amongst others. We have previously observed such a spontaneous *cis*→*trans*-isomerization process for *cis*-$H[Cl_3Si]Pt(PCy_3)_2$.[6] Using ^{31}P nmr spectroscopy to monitor reactions between $HSnPh_3$ and $Pt^0(PCy_3)_2$, we were able to observe formation of *cis*-$H[Ph_3Sn]$-$Pt(PCy_3)_2$, as an intermediate species. Over a period of

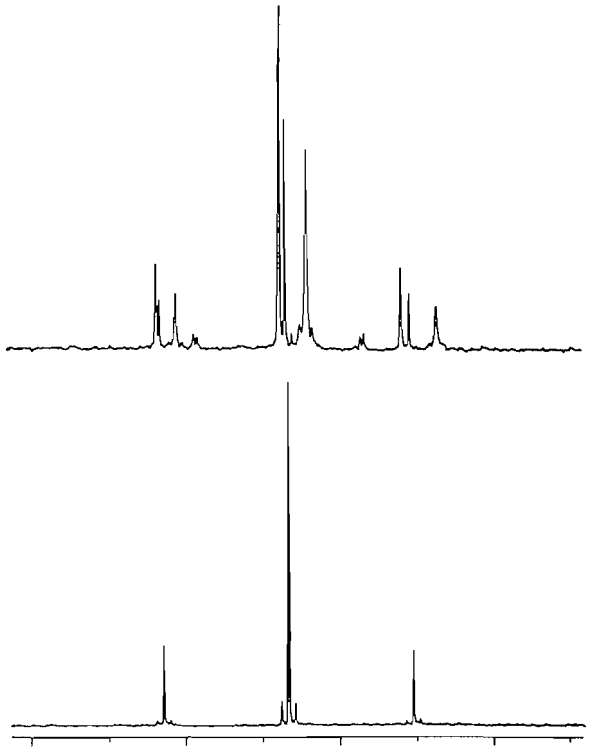

FIG. 1. $^{31}P\{^1H\}$ nmr spectra of (*a*) *cis*-$H[Ph_3Sn]Pt(PCy_3)_2$ and (*b*) after heating for 30 min at 60°C to form *trans*-$H[Ph_3Sn]Pt(PCy_3)_2$.

approximately 4 h at room temperature, the *cis* isomer completely rearranged to its *trans* analogue in these solutions. The *cis* isomer could also be observed on addition of half an equivalent of $HSnPh_3$ to a benzene solution of $(PCy_3)_2Pt(C_2H_4)$ at room temperature and was found to be stable in these solutions. The isolation of only the *trans* analogue from mixtures of excess $HSnPh_3$ and $Pt^0(PCy_3)_2$ is therefore thought to be due to isomerization caused either by one, or a combination, of the following factors; the presence of free PCy_3;[7] excess $HSnPh_3$ which after double oxidative addition to form a platinum(IV) intermediate could eliminate to form preferentially the *trans* isomer; or exposure to light. There are a number of precedents for each of these possibilities. The catalytic *cis–trans* isomerization of Pt(II) phosphine complexes caused by the presence of free phosphine is well known (16). With regard to the second possibility, there is both physical and chemical evidence for the formation of platinum(IV) intermediates in such reactions. Physical evidence, for example, comes from the direct observation of platinum(IV) intermediates by low temperature ^{31}P nmr spectroscopy during the reaction of various silanes with *trans*-$H_2Pt(PCy_3)_2$ (17) while chemical evidence derived from the mixtures of products obtained on addition of $HSnPh_3$, to *trans*-$H[CN(CH_2)_2]Pt(PCy_3)_2$. We have also found that irradiation of the complexes *cis*-$H[Ph_3Si]Pt(PCy_3)_2$ with a weak uv light source is very effective for quantitative isomerization of the *trans* analogues.

On addition of half the stoichiometric amount of $HSnPh_3$ to a hexane solution of $Pt^0(PCy_3)_2$ and stirring for 3 h *in the dark*, a white precipitate was formed. The ^1H and ^{31}P nmr spectra of this white solid showed it to be *cis*-$H[Ph_3Sn]Pt(PCy_3)_2$ and it was found to be analytically pure.

[4] $Pt^0(PCy_3)_2 + HSnPh_3 \rightarrow$ *cis*-$H[Ph_3Sn]Pt(PCy_3)_2$

Addition of the remaining one half equivalent of $HSnPh_3$ to the filtrate led to an immediate precipitation and a yellowing of the solution over a period of 12 h. *cis*-$H[Ph_3Sn]Pt(PCy_3)_2$ does not exhibit either of the fluxional processes observed for its silyl analogue at room temperature. However, on warming to $\geq 50°C$, the ^1H nmr resonance of the hydride ligand exhibits a similar lineshape to that of the complex *cis*-$H[Ph_3Si]Pt(PCy_3)_2$, characteristic of an exchange of ligand position with retention of P—H spin correlation. By comparison with the results obtained for some chelating diphosphine silyl platinum hydrides for which the same fluxional process was observed, we infer that for *cis*-$H[Ph_3Sn]Pt(PCy_3)_2$ the ligand position exchange process involves exchange of the tin and hydride ligands rather than the phosphine ligands. We also note that the corresponding lineshapes in the ^1H nmr spectra of *cis*-$H[Ph_3Si]Pt(PCy_3)_2$ and *cis*-$H[Ph_3Sn]Pt(PCy_3)_2$ occur at $+10$ and $+70°C$, respectively, which implies that a higher energy barrier to site exchange exists for the tin species compared to its silicon analogue. Attempts to observe the platinum(0) species, $Pt^0(PCy_3)_2$, in solutions of *cis*-$H[Ph_3Sn]Pt(PCy_3)_2$ at $+60°C$ by ^{31}P nmr spectroscopy in analogy to the oxidative addition – reductive elimination equilibrium observed for the silyl analogue according to eq. [5] have been unfruitful.

[5] *cis*-$H[Ph_3Si]Pt(PCy_3)_2 \rightleftharpoons Pt^0(PCy_3)_2 + HSiPh_3$

At temperatures greater than $+60°C$, the thermal isomerization of the *cis* species is too rapid to explore this phenomenon further. The possibility that at still higher temperatures, a Pt^{II}–Pt^0 equilibrium exists therefore cannot be precluded. On standing at room temperature in normal light, benzene solutions of pure *cis*-$H[Ph_3Sn]Pt(PCy_3)_2$ isomerize to the *trans* species over a period of about 20 h. On heating to $+60°C$ for less than 0.5 h in the dark, the *cis* isomer is completely transformed into the *trans* derivative as shown by the ^{31}P nmr spectra of Fig. 1. The *cis* → *trans* isomerization is not reversible; this is hardly surprising considering the anticipated severe steric interactions between the ligands of the *cis* isomer. In contrast, it is noteworthy that solutions of the silicon analogue, *cis*-$H[Ph_3Si]Pt(PCy_3)_2$ show no observable isomerization at temperature of up to $+60°C$.

This marked contrast between the apparent thermally allowed *cis*-to-*trans* isomerization of the tin derivative compared to the thermal stability of its *cis*-silyl analogue has led us to examine the mechanism of the isomerization reactions in more detail. In the case of *cis*-$H[Ph_3Sn]Pt(PCy_3)_2$, we can presumably exclude an ionic dissociative mechanism due to a lack of ionizable ligands. The presence of free phoshine may either accelerate or retard the rate of isomerization depending on the mechanism of the process.

We have made the following observations from ^{31}P nmr spectroscopy: (*i*) At room temperature, the addition of 1 equiv. of free PCy_3 to a benzene solution of analytically pure *cis*-

[7] Reduction of *trans*-$(Cy_3P)_2PtCl_2$ with sodium napthelide results in the production of substantial quantities of free PCy_3 as well as $Pt^0(PCy_3)_2$. We have found that increased yields of the platinum (0) species may be obtained by addition of 10–50% mole excess of PCy_3 to the *trans*-$(Cy_3P)_2PtCl_2$ mixture before reduction.

[a]Anisotropically refined atoms are given in the form of the isotropic equivalent thermal parameter defined as: $(4/3)[a^2B(1,1) + b^2B(2,2) + c^2B(3,3) + ab(\cos\gamma)B(1,2) + ac(\cos\beta) \times B(1,3) + bc(\cos\alpha)B(2,3)]$.

$H[Ph_3Sn]Pt(PCy_3)_2$ does not significantly alter the rate of isomerization compared to a benzene solution of pure *cis*-$H[Ph_3Sn]Pt(PCy_3)_2$ of similar concentration in the dark. The *cis* isomer is essentially unchanged after 20 h in C_6D_6 solution in the dark. (*ii*) The isomerization is faster in $CDCl_3$ (complete within 15 h) than C_6D_6 in the dark, and is accelerated at higher temperatures (in $CDCl_3$ completely isomerized in 2.5 h at 313 K in the dark). (*iii*) Addition of 1 equiv. of $HSnPh_3$ to benzene solutions of *cis*-$H[Ph_3Sn]Pt(PCy_3)_2$ resulted in a slight increase in the rate of isomerization. (*iv*) Changing the concentration of solutions of *cis*-$H[Ph_3Sn]Pt(PCy_3)_2$ did not alter the rate of isomerization, and so *inter*molecular mechanisms may be precluded. (*v*) A $CDCl_3$ solution of *cis*-$H[Ph_3Sn]Pt(PCy_3)_2$ exposed to room light had completely isomerized within (i.e. in less than) 5 h. (*vi*) Addition of 1 equiv. of PCy_3 to a $CDCl_3$ solution of the *cis* isomer of similar concentration as (*i*) at 313 K led to complete isomerization within 10 min.

On the preparative scale, a hexane solution containing a mixture of $Pt^0(PCy_3)_2$, excess $HSnPh_3$, and PCy_3 results in isolation of the *trans* isomer alone over a period of only 15 h. Since the observations (*i*), (*ii*), and (*iii*) above, all of which were followed by ^{31}P nmr spectroscopy, were made in the dark,

we also investigated the effect of exposure to light on solutions of *cis*-$H[Ph_3Sn]Pt(PCy_3)_2$. From these observations, it seems likely that the presence of light is responsible for the *cis*-to-*trans* isomerization in the preparative scale reaction rather than excess PCy_3 or $HSnPh_3$ at room temperature. However, from (*v*) above, it appears that the presence of free phosphine would accelerate rather than retard the isomerization process. The increase in rate with added phosphine implies intermediacy of a 5-coordinate species rather than prior phosphine dissociation (in which case added phosphine would reduce the rate of isomerization). The observation that the rate of isomerization is faster in a polar solvent than a non-polar solvent, (*iii*), is rather surprising since it was expected that the polar solvent would stabilize the more polar *cis* isomer.

Addition of a large excess of $HSnPh_3$ to a benzene solution of $(PCy_3)_2PtO_2$ resulted in a vigorous gas evolution and the ^1H and ^{31}P nmr spectra of the product showed it to be *trans*-$H[Ph_3Sn]Pt(PCy_3)_2$.

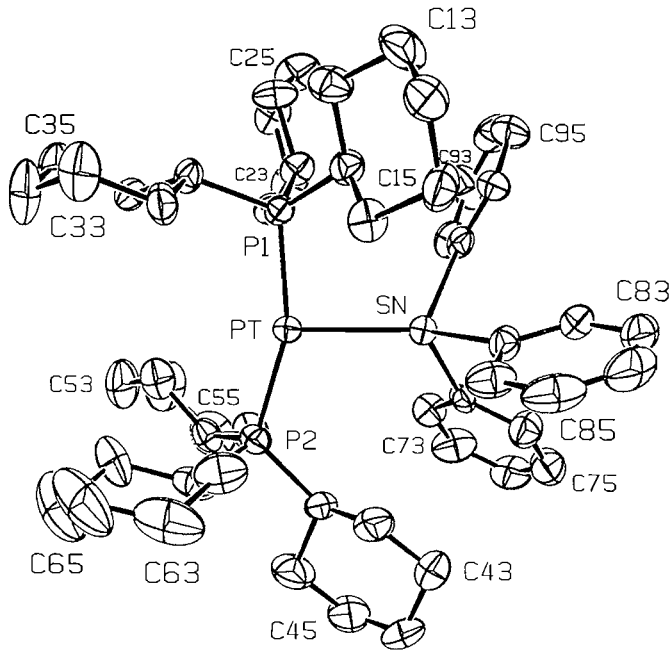

FIG. 3. A view of $H[Ph_3Sn]Pt(PCy_3)_2$ showing the crystallographic numbering scheme. Ellipsoids are at the 50% level.

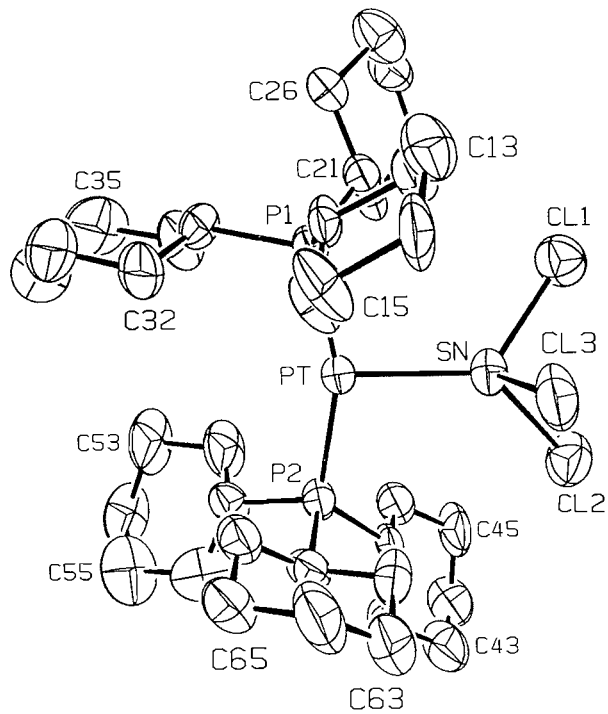

FIG. 4. A view of $H[Cl_3Sn]Pt(PCy_3)_2$ showing the crystallographic numbering scheme. Ellipsoids are at the 50% level.

[6] $(Cy_3P)_2PtO_2$ + excess $HSnPh_3 \rightarrow$ *trans*-$H[Ph_3Sn]Pt(PCy_2)_2 + O_2$

This reaction is extremely rapid at room temperature, and attempts to observe any intermediates by low temperature (−60°C) ^{31}P nmr spectroscopy in benzene and chloroform solutions were unfruitful. If the reaction proceeds via an oxidative addition – reductive elimination process, involving initial *cis* coordination of the $HSnPh_3$ moiety to platinum, elimination of dioxygen, followed by formation of a product with *trans* geometry due to severe inter-ligand repulsions

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 122.72.124.2 on 09/07/12
For personal use only.

(particularly between the two PCy_3 ligands) will most likely occur. If initial coordination of $HSnPh_3$ to the dioxygen complex is slow, but elimination of the O_2 is fast, the concentration of any intermediate will be too small to observe. Since no other products have been observed in this reaction,[8] and since it would be expected that the liberated oxygen would trap any intermediate tin radicals, a radical mechanism is unlikely but not completely excluded. A mechanism involving prior dissociation of a phosphine ligand (or oxygen molecule) is also possible provided the concentration of the free phosphine (or $Pt^0(PCy_3)_2$) is too small to be observed by ^{31}P nmr spectroscopy.

The ^{119}Sn nmr spectrum of *trans*-$H[Ph_3Sn]Pt(PCy_3)_2$ (proton coupled) was observed as a doublet of triplets with ^{195}Pt satellites centered at −21.8 ppm. The $^{119}Sn—^{195}Pt$ coupling constant of 9 680 Hz is somewhat smaller than those reported (18) for other compounds (e.g. 12 686 Hz for *cis*-$Ph[Ph_3Sn]Pt(PPh_3)_2$), and probably indicates the presence of a long tin–platinum bond caused by a combination of the high *trans* influence of the hydride ligand and severe steric interactions between the tin ligand and the PCy_3 ligands (see later). In the ^{119}Sn nmr spectrum of *trans*-$H[Cl_3Sn]Pt(PCy_3)_2$, the corresponding hydride resonance in the ^1H nmr spectrum and the ^{31}P nmr resonances were all broad at room temperature, probably due to one of the fluxional processes well known for such M—$SnCl_3$ derivatives. The value of $J_{Sn—Pt}$ of 11 242 Hz is smaller than other analogous compounds,[9] and is probably due to the high *trans* influence of the hydride ligand.

In this laboratory, it has previously been observed (19) that for compounds of *cis* geometry, e.g. *cis*-$(PPh_3)_2PtCl_2$, the single line (with platinum 195 satellites) observed in the solution ^{31}P nmr spectrum occurs as two distinct resonances in the solid state CP/MAS ^{31}P nmr spectrum due to the different environments of the two magnetically different phosphorus nuclei as shown by X-ray structural analysis (20). For the *trans* derivatives, however, only a single line (with platinum 195 satellites) was observed in the solid state ^{31}P nmr spectra. Similar results have recently been reported (21) for both palladium and platinum compounds, $(R_3P)_2MCl_2$. For the case of both *trans*-$H[R_3Sn]Pt(PCy_3)_2$, R = Ph or Cl, the single resonance observed in solution for the two magnetically equivalent phosphorus nuclei of each complex appeared as an AB spin system (with platinum 195 satellites) in the solid state ^{31}P nmr spectrum with the characteristic large $^2J_{P—P_{trans}}$ coupling of approximately 350 Hz (see Fig. 2).

Severe distortion of the intensities of the AB pattern are apparent, probably due to the similarity in shielding of both phosphorus nuclei. The non-equivalence of the phosphorus nuclei in these solid state ^{31}P nmr spectra can readily be appreciated by reference to the crystal structures of **I** and **II**. Also, the *small* difference in shielding of the ^{31}P nuclei in the solid state may be understood since the inequivalence is caused by different orientations of cyclohexyl rings. Recently, we have observed[9] that for other species such as *trans*-$Cl(X_3Si)Pt(PCy_3)_2$, where inequivalence of the ^{31}P nuclei is caused by spatial proximity to an electron-rich centre (i.e. chloride), there is a much more *distinct* difference in shielding. In some cases a chemical shift difference of over 15 ppm was observed.

Attempts to observe non-equivalence of the phosphorus nuclei of *trans*-$H[Ph_3Sn]Pt(PCy_3)_2$ in solution at low temperature (−90°C) by ^{31}P nmr spectroscopy could not be conducted due to the low solubility at this temperature.

In the solution $^{31}P\{^1H\}$ nmr spectrum of *cis*-$H[Ph_3Sn]Pt(PCy_3)_2$, the ^{31}P resonance of the PCy_3 ligand *trans* to the hydride is extensively broadened at room temperature. This feature is believed to be due to restricted rotation of this phosphine ligand about the Pt—P bond since it is "sandwiched" between two other sterically demanding ligands. A similar phenomenon was also observed for the *cis*-$H[R_3Si]Pt(PCy_3)_2$ analogues in which R = *ortho*- or *meta*-substituted benzyl. This broadening is field-dependent, these resonances being more broadened (in ppm) at higher field (S.F. = 161.9) than lower field (S.F. = 100.23 MHz) consistent with the above interpretation.

X-ray crystallographic characterization of both *trans*-$H[Ph_3Sn]Pt(PCy_3)_2$ and *trans*-$H[Cl_3Sn]Pt(PCy_3)_2$ were carried out in order to establish a positive basis for the non-equivalence of the phosphorus nuclei in the solid state ^{31}P nmr; to compare the relative "ligand volumes" of —$SnPh_3$ and —$SnCl_3$ ligands and to examine the ligand interactions in these compounds.

(i) trans-*$H[Ph_3Sn]Pt(PCy_3)_2$ (**I**)*

Allowing for location of the hydride ligand, the Pt atom has distorted square-planar geometry; the Pt atom is 0.082 Å out of the P_2Sn plane and the P—Pt—P angle is reduced to 160.24 (8)° (see Fig. 3) in order to accommodate the bulky $SnPh_3$ ligand. This angle is smaller than that of *trans*-$H[H_3Si]Pt(PCy_3)_2$ (166°) (17) but larger than the values for both *trans*-$[H(Ph_3P)Pt(PCy_3)_2]^+PF_6^-$ (155.2°) (22) and *trans*-$[H(PCy_2Ph)Pt(PCy_3)_2]^+PF_6^-$ (142.7°) (23). The Pt—P bond distances of 2.294(2) and 2.283(2) Å are significantly shorter than the sum of the covalent radii of Pt and P but comparable to those of other Pt(II)—phosphine complexes. The long Sn—Pt bond (2.6539(6 Å) reduces the steric interactions between the ligands to some extent and no doubt results from the *trans* influence of the hydride ligand. The tetrahedral geometry about tin is distorted with all Pt—Sn—C angles greater than the tetrahedral angle, in particular, the Pt—Sn—C(71) angle of 122.9(2)°. The geometry about the phosphorus ligands is also distorted, especially that of P2 where Pt—P(2)—C(41) = 121.2(3)°. The cyclohexyl rings of the phosphine ligands adopt a staggered conformation with respect to each other and also with respect to the phenyl rings of the triphenyltin ligand. All cyclohexyl rings possess a chair conformation and there are no significant *inter*molecular non-bonded contacts. However, there are a number of intramolecular non-bonded contacts between cyclohexyl hydrogens and platinum. The shortest interactions are between platinum and H222 (2.85 Å), H162 (2.99 Å) and H621 (3.03 Å), although these H...Pt distances are not as short as those observed in the species $Pd(PPt_tBu_2)_2$ (ca. 2.7 Å) (24). We have observed[9] a similar interaction between an *ortho*-phenyl hydrogen and platinum in the X-ray crystal structure of *trans*-$Cl(PhCl_2Si]Pt(PCy_3)_2$ (H...Pt = 2.94 Å) in which the square planar geometry about platinum is severely distorted. In the present case, however, the proposed H...Pt interaction does not cause significant distortion of the structure as would be apparent for example in the angles about carbon atoms C21, C11, or C61.

[8]The aromatic region of the ^1H nmr spectra gives a good indication of the purity of the tin containing species. The *ortho* phenyl protons of —$SnPh_3$ exhibit a three bond coupling to ^{119}Sn and occur at a characteristic shift position, e.g. 8.2 ppm, $^3J_{Sn—H}$ = for *cis*-$H[Ph_3Sn]Pt(PCy_3)_2$ and 7.57 ppm, $^3J_{Sn—H}$ = for $HSnPh_3$ (C_6D_6 solution).

[9]H. C. Clark, M. J. Hampden-Smith, E. Ferguson, and H. Raegger. Unpublished results.

(ii) trans-*H[Cl$_3$Sn]Pt(PCy$_3$)$_2$ (II)*

In this complex (Fig. 4) as in **I**, the Pt atom has distorted square-planar geometry; the Pt atom is 0.114 Å from the P_2Sn plane and the P—Pt—P is reduced to 159.0(2)°.

The Pt—Sn distance (2.600(2) Å) in this complex is shorter than that in **I**; it was anticipated that the Pt—Sn bond of **II** would be significantly shorter than that in **I** due to the increased electronegativity of the substituents on tin, as judged, for example by a comparison of $J_{H—Pt}$ values. The Pt—P bonds of **II** are slightly longer than those of **I**, an effect expected based on previous studies in which evidence was found for a *cis*-influence opposite in effect to the *trans*-influence in square planar complexes. Thus the —$SnCl_3$ ligand of **II** is expected to produce a shortening of the Pt—H bond compared to the $SnPh_3$ ligand of **I**, while the Pt—P bonds will be expected to be longer for **II** on the basis of the different *cis*-influence of the tin ligands. However, the observed Pt—P bond lengthening may also have some steric origin. Again, for **II** there are some intramolecular H...Pt interactions from hydrogens of the cyclohexyl rings; the shortest distances are 3.05 (H162), 3.02 (H522), and 2.97 Å (H662). As in the case of **I**, there is little if any distortion of the angles at adjacent carbon atoms indicating no significant Pt...H bonding interaction. Comparison of these interactions in **I** and **II** show that they all arise from hydrogen atoms attached to β-carbons of the cyclohexyl rings and it seems likely they arise from the forced spatial proximity due to the relative orientations and conformations of the cyclohexyl rings themselves.

While there is a marked similarity between the structures of **I** and **II** (Fig. 4), the most notable difference is the relative orientation of the two PCy_3 ligands labelled P2. Furthermore, if the angle P—Pt—P is taken as indicative of the bulk of the tin substituents, then the similarity in the values for $SnPh_3$ (160.2°) and $SnCl_3$ (159°) shows that the "coordinative" volume required by these two ligands *at the metal centre* is virtually identical (assuming the same D(Pt—Sn)). This is contrary to expectations based on both cone angle measurements (i.e. PCl_3 compared to PPh_3) and electronic effects.

Comparison of these structures indicates that bulky ligands, X, in the species *trans*-$HXPt(PCy_3)_2$ whose existence cannot be predicted on the basis of cone angle values, are accommodated by (25): (*i*) a significant reduction in the P—Pt—P angle; (*ii*) lengthening of the P—Pt bonds; and (*iii*) severe distortion of the Pt—P—C angles in the PCy_3 substituents. It is significant that these distortions occur while the planarity of the complex is apparently maintained, and also that the value of the Pt—P bond lengths do not exceed the sum of the covalent radii in either of these compounds. This may well be further evidence for π-back-bonding from phosphorus to platinum.

Configurationally dependent hydroxyl group effects on ^{13}C nuclear magnetic resonance chemical shifts of olefinic carbons in cyclic six-membered allylic alcohols

TEODORO S. KAUFMAN[1]

Instituto de Química Orgánica de Síntesis (CONICET-UNR), Facultad de Ciencias Bioquímicas y Farmacéuticas, Casilla de Correo 991, 2000 Rosario, Argentina

Received June 29, 1987

TEODORO S. KAUFMAN. Can. J. Chem. **66**, 3128 (1988).

The differences in chemical shifts of olefinic carbons, $\Delta\delta(sp^2)$, of pseudoequatorial and pseudoaxial six-membered allylic alcohols were correlated with the $\Delta\delta(sp^2)$ values of their parent olefins. The results obtained reflect configurationally dependent substituent effects, the magnitude of which could be used for the stereochemical assignment of the hydroxyl group in these compounds.

TEODORO S. KAUFMAN. Can. J. Chem. **66**, 3128 (1988).

On a établi une corrélation entre les différences de déplacements chimiques des carbones oléfiniques, $\Delta\delta(sp^2)$, des alcools allyliques à six chaînons pseudoaxial et pseudoéquatorial et les valeurs des $\Delta\delta(sp^2)$ des oléfines apparentées. Les résultats obtenus sont le reflet d'effets de substituants dépendant de la configuration dont l'amplitude pourrait être utilisée pour l'attribution stéréochimique du groupement hydroxyle de ces composés.

Introduction

The assignment of ^{13}C nmr chemical shifts from substituent effects and the interpretation of their variations obviously require a precise knowledge of these effects. Generally, these perturbations depend not only on the nature of the carbon frame to which the substituent is bonded, but also on the geometry of the molecule (electronic and steric effects).

The analyses of the ^{13}C nmr chemical shifts of selected model molecules in various classes of organic compounds have proved to be of great diagnostic and prognostic value in the elucidation of unknown structures. Cyclic six-membered allylic alcohols as a class, although common in organic synthesis as well as in the field of natural products (1, 2), are of special interest since they display ^{13}C nmr chemical shifts that are often difficult to predict and interpret, particularly in relation to the geometrical features of the molecule.

There are some scattered references in the literature to ^{13}C nmr studies of allylic alcohols (3–5) but, surprisingly, no systematic and comprehensive study is available concerning the role of the hydroxyl group on the chemical shifts of olefinic carbons.

Our aim was to investigate the chemical shift variations of the olefinic carbons in cyclic six-membered allylic alcohols as a function of the substituent orientation, and hence to try to delineate further the factors that influence these ^{13}C nmr chemical shifts.

During previous studies (6), it was shown that classifying allylic alcohols into pseudoaxial (the dihedral angle between the oxygen, the carbinyl carbon, and the olefinic carbon atoms approaches ±90°) and pseudoequatorial (the value of the same dihedral angle is in the range of ±30°) was more useful for studying hydroxyl group–double bond interactions in this class of compounds than the classification defined in ref. 7, which is based on the conformational class of the hydroxyl group.

A set of 33 allylic alcohols and their related olefins, corresponding to different chemical families, namely, steroids, mono-, bi-, and tri-cyclic terpenoids, was constructed using information available from the current literature (6, 8–10). The values of the ^{13}C nmr resonances and substituent-induced chemical shift differences of these alcohols and parent olefins are listed in Table 1.

The unequivocal assignments of the hydroxyl group orientation (Table 1) were made with the aid of Dreiding models, by measuring the dihedral angle formed by the oxygen, the carbinyl carbon atom, and both olefinic carbons. When data belonging to both epimers in an epimeric pair of alcohols were available (**1***b*–**1***c*, **2***b*–**2***c*, **3***b*–**3***c*, **4***b*–**4***c*, **5***b*–**5***c*, **6***b*–**6***c*,

[a]In ppm, downfield from internal TMS. Resonances were taken from refs. 6, 8, 9, and 10.
[b]Hydroxyl group: pa = pseudoaxial, pe = pseudoequatorial.

7*b*–**7***c*, **8***b*–**8***c*, **14***b*–**14***c*, and **16***b*–**16***c*), assignments were confirmed by the use of the empirical rule proposed in ref. 6.

Analysis of the data showed that the changes in the γ carbon atom resonances of the olefins due to the introduction of a hydroxyl group in the allylic position (Δδ(γ)), although representing mainly downfield shifts (4), did not appear to be related to the orientation of the allylic substituent. The same trend was observed during the examination of hydroxyl effects of pseudoaxial and pseudoequatorial alcohols on chemical shift differenes of the β carbon atoms (Δδ(β)). Particularly worth

noting was the relationship among the pairs of epimeric alcohols derived from the compounds **2***a* and **3***a*, which did not agree with the proposal of Delmont *et al.* that relates the $\Delta\delta(\gamma)$ value with the alcohol configuration (4).

It seemed reasonable to suppose that these results could be a consequence of the superposition of several effects simultaneously acting on both olefinic carbons. Evidence for strengthening this line of reasoning might be obtained if a correlation

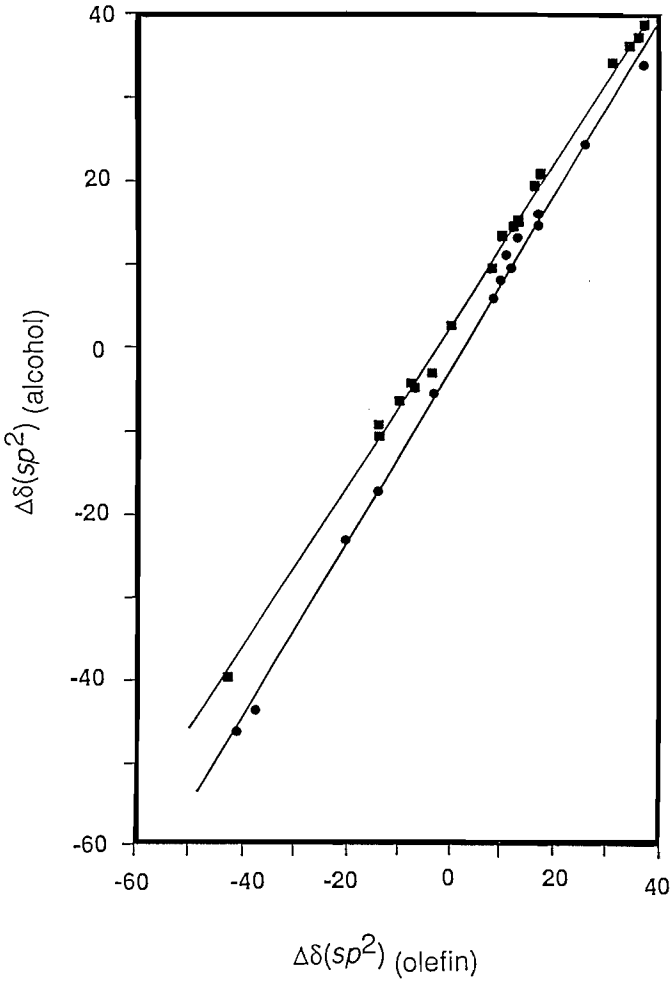

FIG. 1. Plot of $\Delta\delta(sp^2)_{(alcohol)}$ vs. $\Delta\delta(sp^2)_{(olefin)}$. (●) Pseudoequatorial alcohols; (■) pseudoaxial alcohols.

between parameters representing both sp^2 carbon atoms in the allylic alcohols and the parent olefins could be found.

Based on trends in chemical shift variations of the sp^2 carbons previously reported by Eggert and Djerassi (11), we have recently proposed a new empirical parameter called $\Delta\delta(sp^2)$, defined as the difference between the chemical shifts of the γsp^2 and βsp^2 carbon atoms relative to the hydroxyl group (eq. [1]). We have also demonstrated the usefulness of this parameter for the determination of the hydroxyl group stereochemistry in each member of a given pair of epimeric allylic alcohols (6).

$$[1] \quad \Delta\delta(sp^2) = \delta\gamma sp^2C - \delta\beta sp^2C$$

Considering that $\Delta\delta(sp^2)$, a measure of the difference of the perturbations exerted on both sp^2 carbon atoms, would take the olefin moiety as a unit, the $\Delta\delta(sp^2)$ values of alcohols and olefins were tested for linear regression by the least-squares method. The data, which are plotted in Fig. 1, adhered to eq. [2]; the complete sets of parameters for both straight lines, representing the behavior of pseudoaxial and pseudoequatorial allylic alcohols, are collected in Table 2.

$$[2] \quad \Delta\delta(sp^2)_{(alcohol)} = K + S\cdot\Delta\delta(sp^2)_{(olefin)}$$

It is interesting to note that the data displayed in Table 1 show a smooth progression from large negative $\Delta\delta(sp^2)$ values corresponding to alcohols bearing an unsubstituted γ carbon atom (**9***b*, **15***b*), to large positive values for compounds having

the hydroxyl group in the allylic position referred to an enol acetal double bond (**19***b*, **20***b*), in a range of 80 ppm.

Several other observations may be pointed out from these straight lines. The surprisingly precise correlations obtained by plotting the $\Delta\delta(sp^2)$ data contrast with the apparent independence of $\Delta\delta(\gamma)$ and $\Delta\delta(\beta)$ from substituent orientation, thus allowing a first approximation – complete description of each alcohol–olefin relationship by using only two parameters, namely K and S.

The zero ordinates, K, may be interpreted as the $\Delta\delta(sp^2)$ variations produced when a hydroxyl group replaces a pseudoequatorial or pseudoaxial hydrogen atom in the allylic position of an olefin, in which both sp^2 carbons display the same chemical shift.

On the other hand, S, the slope of the straight lines, describes the sensitivity of the olefinic carbons to changes in their chemical shift difference when the hydrogen–hydroxyl substitution is done.

Because the slopes are statistically different ($p < 0.05$), the observed differences in $\Delta\delta(sp^2)$ associated with pseudoaxial and pseudoequatorial alcohols depend on both K and S values. These linear relationships with slopes other than 1.0 suggest a constant relative enhancement or attenuation of $\Delta\delta(sp^2)_{(\text{alcohol})}$ in relation to $\Delta\delta(sp^2)_{(\text{olefin})}$, depending on the stereochemistry of the alcohol.

From the relative magnitudes of K and S, it is observable that the system presents a high activity associated with a first phenomenon (related to K), accompanied by a weak sensitivity associated with a second phenomenon (connected to S).

The above findings are indicative that at least two different, although simultaneously operating, mechanisms would be required to justify them. They are concordant with previous reports (12) ascribing these effects to geometry-dependent trough-space and trough-bond interactions between the oxygen lone pair and the olefin π-electrons.

The sets of additive parameters listed in Table 2 and the $\Delta\delta(sp^2)$ value of an olefin, when applied to eq. [2], allow the estimation of $\Delta\delta(sp^2)$ for the related pseudoequatorial or pseudoaxial allylic alcohols, providing a tool for the hydroxyl group stereochemical assignment by comparison of the resonances of the olefinic carbons of the alcohol with those of the parent olefin.

Almost all the geometric environments of the hydroxyl group are represented in this series, which includes 10 pairs of epimers, heterocyclic rings, double bonds bearing oxygen or sp^2 carbons in the homoallylic position, and tertiary alcohols. The fact that the hydroxyl group exerts essentially the same effect in different environments may be indicative that the transmission of the effect of this particular substituent is independent of the presence of the others.

Thus, the above observations seem to be general for cyclic six-membered allylic alcohols, and the estimated parameters S and K (Table 2), which appear to be independent of the double bond substitution pattern or substituents interacting with the olefinic carbon atoms, avoid the need of additional parameters to account for the effects of these factors (3, 4).

KEVIN G. MACDONALD, CHARLES MACLEAN, and E. A. SECCO. Can. J. Chem. **66**, 3132 (1988).

The ac conductivity and DSC calorimetry data reveal interesting solid state interactions and solid phase transition behavior in the Na_2SO_4–Cs_2SO_4 binary system. The $\beta \rightarrow \alpha$ solid transition of $NaCsSO_4$ is reported for the first time. These data indicate preferential reaction between Cs_2SO_4 and the high temperature phase I of Na_2SO_4, exemplifying the Hedvall effect, to form the compound $NaCsSO_4$ which further interacts with excess Na_2SO_4 or excess Cs_2SO_4 to form 1:1 association complexes, viz. $NaCsSO_4$:Na_2SO_4 and $NaCsSO_4$:Cs_2SO_4. These complexes appear to dissociate at low temperatures reminiscent of spinodal-type decomposition behavior. The reaction enthalpies of $NaCsSO_4$, $\beta \rightarrow \alpha$ transition of $NaCsSO_4$ and complex associations are reported.

The report contains two unexpected results: (*i*) a subdued higher ionic conductivity relative to its Rb_2SO_4 analogue and (*ii*) a conductivity drop accompanying the high temperature phase transition which is in strong contrast to all the other Na_2SO_4 – mixed alkali compositions.

KEVIN G. MACDONALD, CHARLES MACLEAN et E. A. SECCO. Can. J. Chem. **66**, 3132 (1988).

Les données de conductivité ca et de calorimétrie DSC se rapportant au système binaire Na_2SO_4–Cs_2SO_4 révèlent des interactions intéressantes dans l'état solide et des transitions de phase solide. On rapporte pour la première fois la transition $\beta \rightarrow \alpha$ du $NaCsSO_4$ à l'état solide. Ces données indiquent une réaction préférentielle entre le Cs_2SO_4 et la phase I à haute température du Na_2SO_4, mettant en évidence l'effect Hedvall, pour former le composé $NaCsSO_4$ qui par la suite interagit avec le Na_2SO_4 ou le Cs_2SO_4 en excès pour former des complexes d'association 1:1, par exemple $NaCsSO_4$–Na_2SO_4 et $NaCsSO_4$–Cs_2SO_4. Ces complexes semblent se décomposer à basses températures ce qui appelle un comportement de type spinodal. On rapporte les enthalpies de réaction du $NaCsSO_4$, de la transition $\beta \rightarrow \alpha$ du $NaCsSO_4$ et des complexes d'association.

Cette étude comporte deux résultats inattendus: (*i*) une plus grande conductivité ionique douce par rapport à son analogue Rb_2SO_4 et (*ii*) une chute de conductivité accompagnant la transition à haute température qui contraste beaucoup avec celle de tous les autres complexes métal alcalin–Na_2SO_4.

Introduction

Na_2SO_4 exhibits a sharp jump in ionic conductivity by a factor of 10 as it transforms to the high temperature phase Na_2SO_4(I). The phase transition is accompanied by a volume expansion of ~4%. Based on this volume expansion we reported recently on the mixed alkali and mixed anion effects of Na^+ ion conductivity (1). The enhanced ionic conductivity by a factor of 40 in $Na/RbSO_4$ compositions was attributed to lattice expansion, ceteris paribus, effected by the larger ionic radius Rb^+ incorporated in the Na^+ sublattice of Na_2SO_4. The lattice expansion within structural limits provides more "free" or "unoccupied" volume which facilitates inter-site mobility via a percolation-type or jump diffusion transport mechanism. This interpretation prompted us to pursue the effect of the still larger ionic radius Cs^+, $r_{Cs^+} = 181$ pm versus $r_{Rb^+} = 166$ pm, in the Na^+ sublattice. This paper presents ac electrical conductivity data and phase transition behavior along with transition enthalpies over the complete composition range in the Na_2SO_4–Cs_2SO_4 system.

Experimental procedure

The two compounds used were supplied by Alfa Products (Thiokol/Ventron Division, Danvers, MA) with the specified grade, Na_2SO_4 ultrapure and Cs_2SO_4 99.999$^+$%. All samples were prepared by fusing in air the requisite composition mixture of the respective compounds, previously well ground manually, at 50–75 K above its reported melting point (2) in a platinum crucible. There was no discernible weight loss after fusion. The fused product in each case appeared as a solid solution/reaction product and confirmed by its DTA effects. Except for the previously unreported transition at 395°C our recorded DTA effects up to 625°C are in qualitative agreement with the phase diagram (2).

Electrical conductivity measurements were made on compressed (force of 1.2×10^4 kg) polycrystalline sample in a stainless steel conductivity cell. The experimental procedure for these measurements as described earlier (1, 3), maintained the sample, whose surfaces were coated with graphite, by a spring-loaded support between stainless steel leads using two polished Pt discs as electrodes. Temperature was monitored within ±1 K by a standardized chromel–alumel thermocouple with a Keithley digital multimeter.

Thermal analyses of the samples were done on a DuPont 1090B Thermal Analyzer equipped with Disk Memory and Data Analyzer. Calorimetry measurements were carried out using gold pans with a differential scanning calorimeter DSC cell. The transition temperature T_t and transition enthalpy ΔH_t were obtained on samples up to 550°C in a flowing N_2 (ultrapure) atmosphere with ignited A_2O_3 as reference material.

Results and discussion

Ionic conductivity

The ionic conductivity, σ, in a solid phase is a composite quantity, $\sigma = nqu$ where n is the number of carriers of charge, q per unit volume, and u is the mobility of these charged carriers. The dependence of the ionic conductivity on temperature usually follows an Arrhenius-type expression,

$$[1] \quad \sigma T = \sigma_0 \exp(-Q_c/RT) = nq^2\lambda^2\gamma\nu/k \exp(-Q_c/RT)$$

the result of combining the Nernst–Einstein relation $\sigma/D = nq^2/kT$ and the diffusion equation $D = D_0 \exp(-Q_c/RT)$ where $D_0 = n\lambda^2\gamma\nu$. In this equation ν is the jump frequency, λ the inter-site distance, γ the inter-site geometric constant, and Q_c the apparent activation energy for mobility of the specific ion, k and R are fundamental constants.

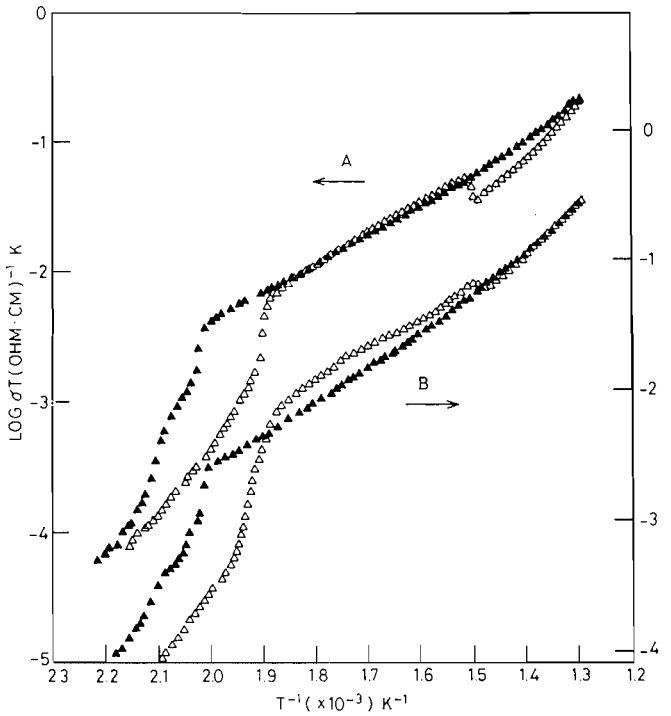

FIG. 1. Plots of log σT versus $(T/\mathrm{K})^{-1}$ of 3:1 mole ratio Na_2SO_4:Cs_2SO_4; *A* annealed at 500°C, *B* unannealed, △ heating, ▲ cooling.

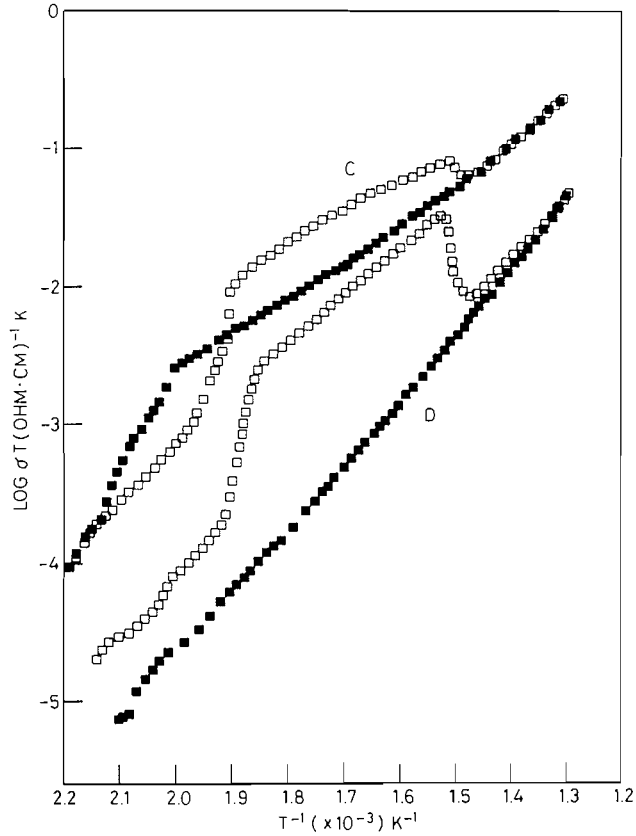

FIG. 2. Plots of log σT versus $(T/\mathrm{K})^{-1}$ of 1:1 mole ratio Na_2SO_4:Cs_2SO_4; *C* unannealed, *D* annealed at 500°C, □ heating, ■ cooling.

On the basis of eq. [1] typical heat and cool mode plots of log σT versus $(T/\mathrm{K})^{-1}$ representing Na_2SO_4-rich composition, 1:1 compound, and Cs_2SO_4-rich composition are presented. In Fig. 1 are given the plots for the 3:1 Na_2SO_4:Cs_2SO_4 samples: annealed in air at 500°C disc, *A*, and unannealed disc, *B*. Figure 2 gives the plots for the 1:1 Na_2SO_4:Cs_2SO_4, unannealed disc, *C* and annealed disc, *D*; Fig. 3 presents the plots for the 1:3 Na_2SO_4:Cs_2SO_4 unannealed disc. Figure 4 shows plots for unannealed discs, 9:1 Na_2SO_4:Cs_2SO_4, *F* and 1:9 Na_2SO_4:Cs_2SO_4, *G*.

The log σT (1 kHz) values at constant temperature of 282°C as a function of Cs^+:Na_2SO_4 composition are plotted in Fig. 5. The conductivity versus composition parallels the pattern for the Rb^+:Na_2SO_4 system at lower σ values. The Cs^+:Na_2SO_4 system is assumed to be hexagonal Na_2SO_4(I) phase incorporating Cs^+ in the cation sublattice. The activation energy values Q_c for the Na_2SO_4-rich compositions remain essentially constant at 44 ± 3 kJ/mol in excellent agreement with values for the Rb/Na_2SO_4 and Na_2SO_4/MoO_4 systems (1). Any additional "free" volume provided by the larger Cs^+ ion relative to Rb^+ ion does not effect a proportionate increase in Na^+ conductivity. This result suggests limits to the quest ion-free volume hypothesis.

All log σT versus T^{-1} plots of annealed and unannealed discs for Cs/Na_2SO_4 compositions up to 1:4 exhibit the normal positive conductivity response to the phase transition at 250 ± 10°C usually associated with the Na_2SO_4 III → I transition. Its appearance in the 1:1 compound $NaCsSO_4$ and Cs_2SO_4-rich compositions suggests break-down of the compound on cooling. On the other hand all log σT versus T^{-1} plots for Cs/Na_2SO_4 compositions between 1:4 and 4:1 show the unusual negative conductivity response to the new phase transition at 400 ± 5°C attributed to the compound $NaCsSO_4$. The normal hysteresis ΔT = 30°C for the 250°C transition is observed but the extended hysteresis ΔT = 140°C only appears

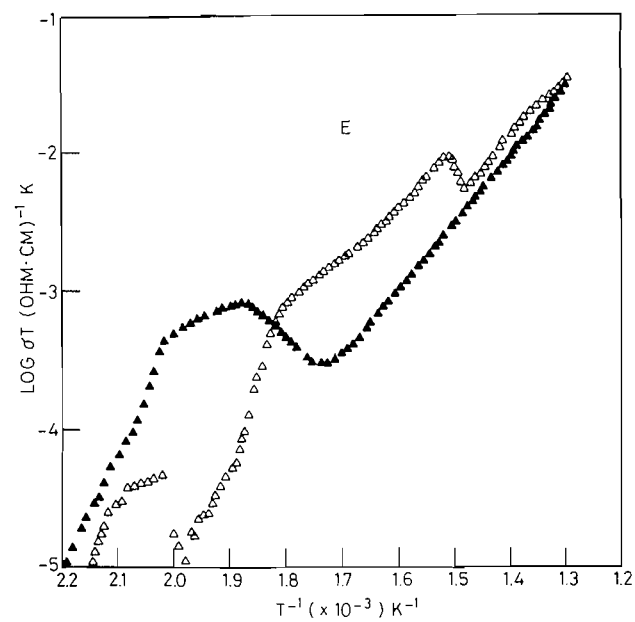

FIG. 3. Plots of log σT versus $(T/\mathrm{K})^{-1}$ of 1:3 mole ratio Na_2SO_4:Cs_2SO_4, △ heating, ▲ cooling.

for Cs/Na_2SO_4 compositions between 2:1 and 4:1 mole ratios. Annealing of the Na_2SO_4-rich samples at ~500°C prior to conductivity measurements had a negligible effect on σ and Q_c values. However, anneal of compound $NaCsSO_4$ lowered σ values and raised Q_c values. Furthermore, the Na_2SO_4 I → III

transition at 250°C is absent on cooling the annealed $NaCsSO_4$ disc.

The negative conductivity effect accompanying the 400°C phase transition parallels the $Pm3m \rightarrow Fm3m$ transition of CsCl (4, 5), the V → III single crystal of Na_2SO_4 (6), the β → α transition of Na_2WO_4 (7), the Ag_2SO_4–K_2SO_4 compositions (8) and the glass transition of $Na_4UO_2(SO_4)_3$ (9). Similar conductivity behavior occurs in melting AgI (10–12) and Na_2UBr_6 (5, 13). All systems exhibit an abrupt conductivity

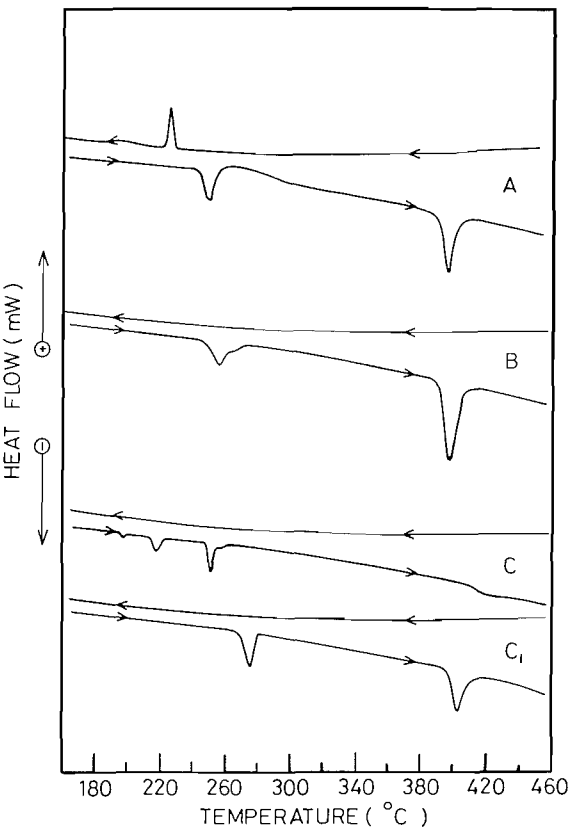

FIG. 6. Differential scanning calorimetry traces of Na_2SO_4:Cs_2SO_4 in mole ratios 3:1, A; 1:1, B; 1:3, C and C_1, first heat–cool cycle and second heat–cool cycle, respectively.

drop. Bogacz *et al.* (13) attributed Na_2UBr_6 behavior to melting of its anionic sublattice according to Ubbelohde's theory of independent melting of sublattices (14). Buerger (15) proposed a mechanism of dilatation for the $Pm3m \rightarrow Fm3m$ transformation in CsCl. The Na_2WO_4 result was interpreted as a switch over from intrinsic to extrinsic charge carrier, i.e. from Na^+ ions to Na^+ vacancies. The most striking structural characteristic accompanying the phase transition where a positive conductivity effect, i.e. conductivity jump, is observed as in solid AgI is the availability of substantially more than one site per conducting cation. On this same basis one can visualize a negative conductivity effect, i.e. conductivity drop, as observed in the above-cited cases, to be the result of a restriction in the number of sites, that is, a drop in the ratio of sites per mobile cation. Our interpretation for these cases, therefore, is a simple structural rearrangement of the whole lattice effecting a constriction of an open framework, rather than a melting of a specific sublattice. This restriction will affect ν, γ, and λ of eq. [1] to lower the overall ionic conductivity. The jump or drop in ionic conductivity during a solid phase transition as in $NaRbSO_4$ and $NaCsSO_4$ systems, respectively, represent the response of systems to perturbation, which can be used to probe and analyze the dynamics of molecular motions during lattice restructuring as in relaxation methods. However, attempts to develop theoretical models to adequately describe fast-ion conduction in the presence of a lattice phase transition have met with very limited, if any, success (16–18).

Differential scanning calorimetry

Figure 6 presents consistently typical heat and cool DSC traces for Na_2SO_4-rich, A, $NaCsSO_4$, B, and Cs_2SO_4-rich, C and C_1, compositions. Two thermal effects are evident in the

heat mode (*i*) a 255°C endotherm previously identified with the III → I transitions in Na_2SO_4 and (*ii*) a 395°C endotherm associated with a transition in $NaCsSO_4$. These T_t values are in excellent agreement with the conductivity data T_t values. The conspicuous absence of the 395°C exotherm in all cool traces suggests the existence of metastable states; only the reversible I → III transition in Na_2SO_4-rich compositions appears in the cool mode. The Cs_2SO_4-rich compositions show interesting behavior: only the characteristic endotherms of Na_2SO_4 at 210 and 255°C appear on the first heat-cool cycle, *C*. The second heating produces the endotherms at 275 and 395°C, C_1.

In Fig. 7 is given the transition enthalpy ΔH_t dependence on mole fraction of Cs_2SO_4. The 395°C endotherm maximum ΔH_t value occurs at 1:1 mole ratio, i.e. $NaCsSO_4$. However ΔH values for the 245°C peak of Na_2SO_4 exhibit accelerated decline relative to its fractional presence. The presence of Na_2SO_4 in the Cs_2SO_4 excess region, i.e. $x_{Cs_2SO_4} = 0.9$, suggests instability of $NaCsSO_4$ at low temperatures. The ΔH_t value for pure Na_2SO_4 given in Fig. 7 is for the III → I transition (6). Also the ΔH_t values for the 395°C peak associated with $NaCsSO_4$ show an accelerated rise relative to its fractional presence. The filled circles representing values obtained for the 275°C endotherm on the second heating of the Cs_2SO_4-rich compositions, Fig. 6 trace C_1, are found to fall on a straight line between pure Na_2SO_4 and pure Cs_2SO_4 values. The interpretation proposed for this behavior of Cs_2SO_4-rich compositions is another phase transition since Cs_2SO_4 has exhibited sporadic trimorphism instead of the usual dimorphism (2).

Assigning ΔH^E_{250} to the sum value of enthalpy to form $NaCsSO_4$ and the enthalpy of the association complex involving $NaCsSO_4$ and excess Na_2SO_4 I, we obtain the values in Table 1 which are plotted in Fig. 8. These data indicate preferential reaction of Cs_2SO_4 with Na_2SO_4 I, rather than Na_2SO_4 III, exemplifying the Hedvall effect (19). The maximum ΔH for complex association near $x_{Cs_2SO_4} = 0.25$ suggests a 1:1 complex, i.e. $NaCsSO_4$:Na_2SO_4. No complex association between $NaCsSO_4$ and excess Cs_2SO_4 is evident at 250°C.

The thermal effect at 400°C is attributed to the combined solid phase transition β → α in $NaCsSO_4$ and complex association of α-$NaCsSO_4$ with excess Na_2SO_4 or excess Cs_2SO_4. Taking ΔH_2 to be the sum of the enthalpy for the β → α transition and the complex association enthalpy the values in Table 2 are

[a]ΔH_1, expected enthalpy for the fraction of $NaCsSO_4$ $\beta \rightarrow \alpha$ transition using 4.45 kJ/mol for pure $NaCsSO_4$; ΔH_2, experimentally observed enthalpy for the composition cited; ΔH^E_{400}, enthalpy calculated for the association complex between α-$NaCsSO_4$ and excess Na_2SO_4 or excess Cs_2SO_4.

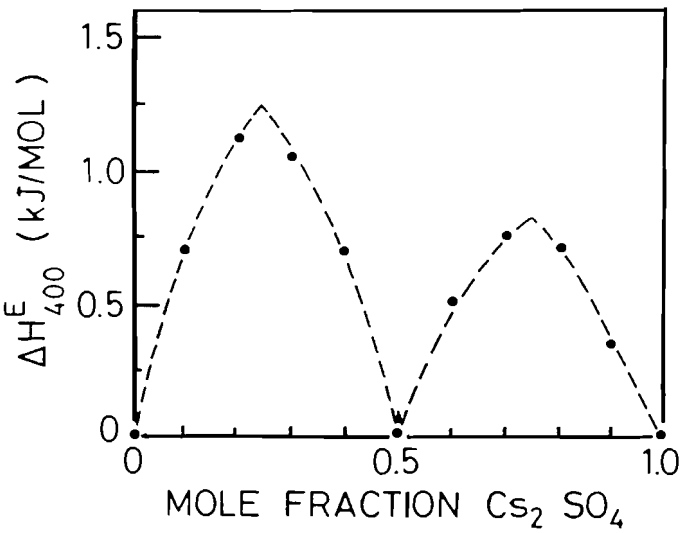

FIG. 9. Plot of ΔH^E_{400} versus mole fraction Cs_2SO_4 from Table 2.

obtained and plotted in Fig. 9. The maximum near $x_{Cs_2SO_4} = 0.25$ confirms the existence of the complex $NaCsSO_4$:Na_2SO_4 and the maximum near $x_{Cs_2SO_4} = 0.75$ suggests the existence of the complex $NaCsSO_4$:Cs_2SO_4.

The ac conductivity and DSC calorimetry data show the reaction products from Na_2SO_4 and Cs_2SO_4 to be relatively unstable. The conductivity drop associated with the I → III Na_2SO_4 transition is evident on cooling the compressed disc of $NaCsSO_4$ but no evidence of this transition appears on the cool mode DSC trace of the uncompressed sample. Furthermore, the presence of the III → I transition on the second heat mode DSC trace indicates behavior reminiscent of spinodal-type decomposition. The observation of V → III transition along with the III → I transition of Na_2SO_4 in the Cs_2SO_4-rich compositions, Fig. 6 trace *C*, suggests the stabilising action by Cs_2SO_4 where pure polycrystalline Na_2SO_4 can persist in metastable phase III for many months. The sporadic behavior and lack of reproducibility of some properties have been noted earlier for the Na_2SO_4–Cs_2SO_4 system (2). The spread and the lack of reproducibility in the conductivity data as evident in Fig. 5 is in strong contrast to the Na_2SO_4–Rb_2SO_4 system. Our observation on complex association is qualitatively consistent with solid solution in the Cs_2SO_4-rich region of the reported phase diagram (2) but the enthalpic effect at 400°C involving $NaCsSO_4$ is reported for the first time.

Substituent-induced chemical shifts and coupling constants in the ^{31}P, ^{13}C, and ^{1}H nuclear magnetic resonance spectra of *meta*- and *para*-substituted phenyl dimethylphosphinates (**1**), methylphenylphosphinates (**2**), and diphenylphosphinates (**3**) have been determined in $CDCl_3$ solvent. For all three series, a correlation of $\delta\,^{31}P$ with Hammett–Taft σ^0 (or σ) constants is preferred over σ^- on the basis of the correlation coefficient and standard deviations of the slope and intercept values. Electron-withdrawing substituents induce downfield shifts in $\delta\,^{31}P$, in contrast to the inverse trends observed for structurally related series of oxyphosphorus acids and their derivatives. It is proposed that electron-withdrawing substituents act to deplete the electron density on the aryl oxygen, thereby weakening a p_π–d_π bonding interaction between the aryl oxygen and phosphorus. The resultants loss of *d*-orbital density on phosphorus causes a downfield shift in $\delta\,^{31}P$ in each of the phosphinate series. Phenyl substituents attached directly to phosphorus in series **2** and **3** increase the phosphoryl p_π–d_π back-bonding interactions, either through inductive or resonance effects, which leads to shielding of the phosphorus atom, overriding the anticipated downfield shift through inductive electron withdrawal of the phenyl substituents in series **2** and **3**, relative to the methyls in series **1**. Trends in Hammett ρ values for the plots of $\delta\,^{31}P$ and $\delta\,^{13}C$ versus σ^0 and differences in the shielding of ^{13}C and ^{1}H nuclei of the methyl attached to phosphorus in series **1** and **2** suggest that the phenyl groups may interact in π bonding with the phosphorus atom through a resonance interaction.

E. J. DUNN, J. G. PURDON, R. A. B. BANNARD, K. ALBRIGHT et E. BUNCEL. Can. J. Chem. **66**, 3137 (1988).

Opérant dans le $CDCl_3$, on a déterminé les déplacements chimiques induits par les substituants ainsi que les constantes de couplage observés dans les spectres de résonance magnétique nucléaire du ^{31}P, du ^{13}C et du ^{1}H des diméthyl- (**1**), méthylphényl- (**2**) et diphényl- (**3**) phosphinates de phényles substitués en *méta* et en *para*. Dans les trois séries, on a établi une corrélation entre les valeurs des $\delta\,^{31}P$ et les constantes σ^0 (ou σ) de Hammett–Taft qui est meilleure que celle avec les constantes σ^- si l'on se base sur le coefficient de corrélation ainsi que sur les déviations standard de la courbe et les valeurs à l'origine. Les $\delta\,^{31}P$ sont déplacés vers les bas champs par les substituants électro-affinitaires et cet effet est l'inverse de celui que est observé avec les acides oxyphosphorés (ainsi que leurs dérivés) qui leur sont apparentés d'un point de vue structural. On suggère que les substituants électro-affinitaires agissent de façon à réduire la densité électronique sur l'oxygène de l'aryle et à provoquer un affaiblissement de l'interaction liante p_π–d_π entre l'oxygène de l'aryle et le phosphore. Dans chacune des séries de phosphinates, les $\delta\,^{31}P$ sont déplacés vers les bas champs par la diminution de la densité de l'orbitale *d* du phosphore que en résulte. Les substituants phényles qui sont attachés directement au phosphore dans les séries **2** et **3** augmentent les interactions de liaison en retour p_π–d_π, soit par des effets inductifs ou de résonance, et ils provoquent un blindage de l'atome de phosphore qui fait disparaître les déplacement vers les bas champs que l'on peut anticiper sur la base des substituants électro-affinitaires des séries **2** et **3** par rapport aux groupements méthyles de la série **1**. Les tendances dans les valeurs de ρ des courbes des valeurs de $\delta\,^{31}P$ et de $\delta\,^{13}C$ vs. σ^0 ainsi que dans les différences dans les blindages des noyaux de ^{13}C et de ^{1}H des groupements méthyles attachés au phosphore des séries **1** et **2** suggèrent que les groupements phényles peuvent interagir dans les liaisons π avec l'atome de phosphore par le biais d'une interaction de résonance.

[Traduit par la revue]

A unified theory of factors affecting chemical shifts and coupling constants is still in the developing stages for ^{31}P nmr (1, 2). Thus, relatively few studies of directly attached or remote substituent effects on $\delta\,^{31}P$, or of coupling constants to nuclei other than H, have been undertaken. Following the summaries of Gorenstein (1) and of Letcher and van Wazer (3), several factors have been identified as contributing to ^{31}P chemical shifts. These factors include hybridization of the phosphorus atom, electronegativity of attached ligands, π-bonding overlap, and σ-bonding angles (1–3).

An interesting observation has been made that, in series of structurally related P(V) esters and their derivatives, including substituted phenylphosphonic difluorides (4), ethyl α-diethylphosphonocinnamates, α-diethylphosphonocinnamonitriles (5), arylphosphonic dichlorides (6), phenylphosphonic acids (7), and alkyl phenyl phenylphosphonates (8), what may be termed an *inverse* chemical shift trend is observed; electron-withdrawing substituents act to shield the phosphorus nucleus. In a recent study (9), however, electron-withdrawing substituents on the ester phenyl ring of substituted phenyl diphenylphosphinates were shown to cause a *normal* or downfield shift in $\delta\,^{31}P$, as would be predicted for ^{13}C or ^{1}H. As well, ^{31}P chemical shifts were shown to correlate with Hammett σ or Hammett–Taft σ^0 substituent constants (9).

We have now extended the previous study to include the substituted phenyl dimethylphosphinates (series **1**) and substituted phenyl methylphenylphosphinates (series **2**). These series provide a useful extension of the previously studied phenyl

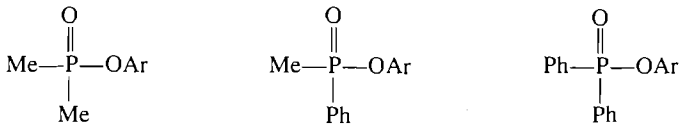
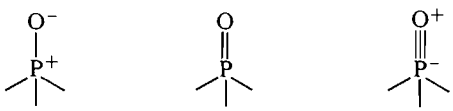
diphenylphosphinate series (**3**), in regard to nmr spectral parameters (chemical shifts, coupling constants), as well as chemical reactivities (10).



1 **2** **3**

In instances of *inverse* chemical shift trends, it has been argued that electron-withdrawing substituents act, inductively or through resonance, to decrease electron density around the phosphorus nucleus, thereby contracting the phosphorus *d* orbitals and increasing the phosphoryl P—O p_π–d_π bonding overlap to favour **4***b* over **4***a* and thus enhance the shielding of the phosphorus nucleus. It is noteworthy, however, that as a result of MO calculations, Schmidt and Gordon (11) have recently argued that the doubly bonded structure **4***b* is inappropriate, at least for phosphine oxide, and that structures of this type are more correctly represented by canonical forms **4***a* and **4***c*, with **4***a* being the dominant form:



4*a* **4***b* **4***c*

Moreover, the calculations indicate that increasing the electronegativity of the ligands attached to the phosphorus atom increases the contribution of the triply bonded structure (**4***c*) as a result of increased π back-bonding to the phosphorus atom (11). The partial triple bond of the phosphoryl group in phosphine oxide may be described as consisting of one σ bond and two mutually perpendicular, half π bonds formed by p_π–d_π overlap (12).

More recently, Streitwieser and co-workers (13, 14) have shown by *ab initio* MO calculations that, for H_3PO and $H_3PCH_2^-$, there is only a small degree of π back-bonding from O (or C) to P. It was also found that in compounds such as $H_2PO_2^-$, $H_2POCH_2^-$, $H_2P(CH_2)_2^-$, and PO_3^- there appears to be almost no allylic conjugation, suggesting that these bonds are best described as being very highly polar (e.g., $^-O—PH_2^+—O^-$).

The interaction between ligands attached to the phosphorus atom and the extent of π back-bonding is evident from studies of the gas-phase protonation of phosphine oxides and phosphoramides (15). It is shown that protonation of the phosphoryl oxygen causes a lengthening of the bonds of the attached ligands, due to a decrease in π back-bonding. Thus it is reasonable that the electronegativity of the attached ligands will have an effect on the extent of the π back-bonding in the phosphoryl group.

The measurement of the ^{31}P nmr chemical shifts in these types of compounds should yield direct evidence of differences in electron density on phosphorus as a result of changes in substituents either attached directly to or remote from the phosphorus atom. The observation of normal or inverse chemical shifts in a given system is therefore pertinent. To the best of our knowledge, the only other instance of a *normal* chemical shift trend in compounds of the type $R_2P(O)X$ has been reported by Schmidpeter and Brecht (16) for the series of phosphinyl derivatives **5**, where the varied substituent was directly attached to the phosphorus atom. $\delta^{31}P$ was found to correlate linearly with Hammett σ substituent constants, and electron-donating moieties (X) were found to increase shielding of the phosphorus nucleus. The diamagnetic shielding from increased electron density on phosphorus was thought to override all other factors in determining chemical shift trends for these compounds. Notably, all of the substituents studied possessed lone pairs of electrons capable of π back-bonding to phosphorus, making it difficult to assess whether the observed trend was due to diamagnetic shielding alone or to increased *d*-orbital occupancy on phosphorus as well.

5

In somewhat related studies with the $Ph_3P{=}NAr$ series, Bödeker *et al.* (17) and Pomerantz *et al.* (18) found normal chemical shift trends for *meta* and *para* substituents on the *N*-phenylimino moiety of the (*N*-phenylimino)triphenylphosphoranes. The latter workers found both chemical shifts (^{31}P, ^{13}C, ^{15}N) and one-bond phosphorus–carbon coupling constants ($^1J(PC)$), to correlate well with Hammett σ^- constants.

Antti Manninen (8) has reported on ^{31}P chemical shifts of derivatives of oxalates of 2-(*N*,*N*-dimethylamino)ethyl phenyl phenylphosphinates with both phenyl and phenoxy groups substituted in the *para* position. An inverse correlation of $\delta^{31}P$ vs. σ^0 was observed with substituents on the phenyl ring. No clear correlation with substituents on the phenoxy group was demonstrated, perhaps due to the limited range of substituents studied.

In light of the apparently anomalous effect of substituents on ^{31}P nmr chemical shifts, as described above, there is a need for further study into the factors that determine substituent-induced chemical shifts in phosphorus-containing compounds. Chemical shift (^{31}P, ^{13}C, ^1H) and coupling constant ($^1J(PC)$, $^2J(PH)$) data may provide additional information concerning the factors that determine chemical shifts for tetrahedral phosphorus and also factors pertaining to bonding and electronic effects in these families of compounds.

Results and discussion

Correlation of ^{31}P chemical shifts with substituent constants σ, σ^0, *and* σ^-

As stated in the introduction, in contrast to chemical shift trends observed in the majority of P(V) compounds, the series **3** was found to exhibit downfield shifts for electron-withdrawing substituents on the ester phenyl ring (9). This observation was interpreted (9) in terms of changes in the p_π–d_π overlap of the P—OAr bond. It was argued that electron-withdrawing substituents on the ester phenyl ring of **3** would act to deplete electron density on the aryl oxygen, resulting in a decrease in p_π–d_π interaction between phosphorus and the aryl oxygen. The results of the present work on series **1** and **2** allow for a comparison of the role of directly attached phenyl substituents in phosphorus bonding and provide further support for our arguments concerning p_π–d_π P—OAr bonding in these families of compounds.

^{31}P chemical shifts for the phosphinate esters **1**, **2**, and **3** are given in Table 1 along with Hammett σ, Hammett–Taft σ^0 and σ^- constants, and correlations. Correlation of $\delta^{31}P$ data to σ^0

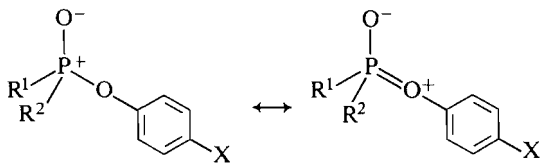
was generally preferred, on the basis of correlation coefficients (r) and standard deviations in slope and y-intercept, over σ and σ^-. However, the difference in correlation between σ and σ^0 does not appear statistically significant for any of the three series. Correlation to σ^0 was preferred, however, in related studies (7, 9). The correlation to σ^0 may be expected on the basis of the structural similarities of the phosphinates to the standard series of compounds defining σ^0 (19). The plot of $\delta^{31}P$ versus σ^0 is shown in Fig. 1 for the series, **1**, **2**, and **3**.

The correlation between $\delta^{31}P$ and σ^0 may be explained by considering the resonance structures **6** and **6***a* where R^1, R^2 = Me or Ph:



6 **6***a*

The resonance structure **6***a* results from donation of an electron pair in a *p* orbital on the phenoxy oxygen to a *d* orbital of the partially positive phosphorus atom (**6**). Electron-donating substituents (X) would enhance the contribution of resonance structure **6***a*, thereby resulting in increased *d*-orbital occupancy and hence increased shielding of the phosphorus nucleus. Conversely, decreased contribution from **6***a* would result from electron-withdrawing substituents on the phenoxy ring, leading to a decrease in electron density (deshielding) around the phosphorus atom.

The interesting observation follows, from the trends in the ^{31}P chemical shifts in the three families of compounds, that the phosphorus atom in the dimethylphosphinates (**1**) is deshielded relative to the methylphenylphosphinates (**2**) and the diphenylphosphinates (**3**), despite the fact that methyl substituents are inductively more electron donating than phenyl substituents. It is also seen (Fig. 1) that the magnitude of the slope, ρ, decreases upon phenyl for methyl substitution, i.e., along the series **1** → **2** → **3** (ρ values are 3.45, 3.18, and 2.89 respectively, see Table 1).

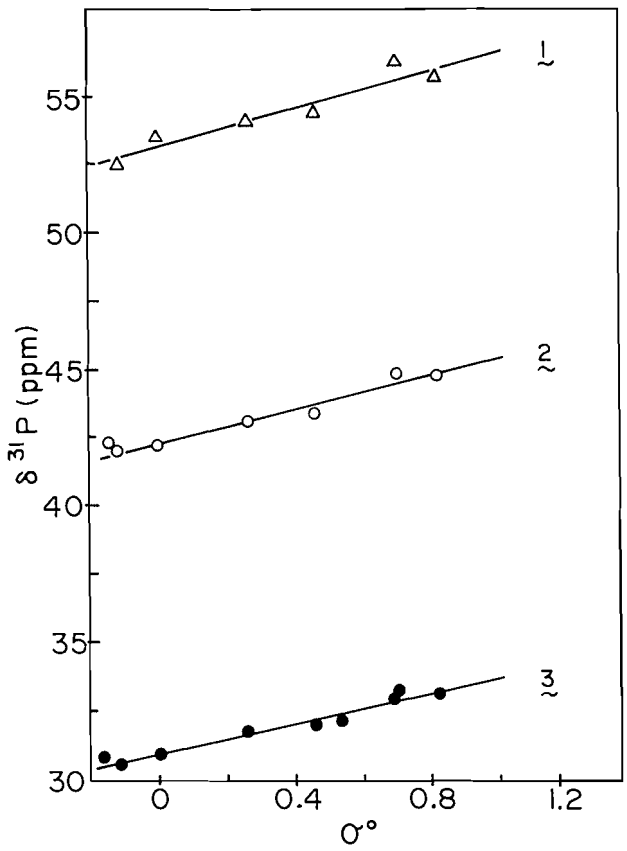


FIG. 1. Plot of $\delta^{31}P$ for phosphinate series **1**, **2**, and **3** versus Hammett–Taft σ^0 substituent constants.

Substitution of Me for Ph causes a large shielding effect around the phosphorus nucleus. For example, the difference in

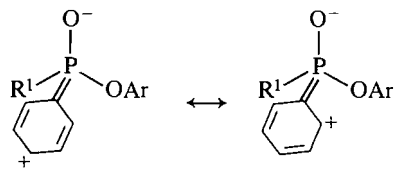
^{31}P chemical shifts for *p*-nitrophenyl diphenylphosphinate (**3***a*) and *p*-nitrophenyl dimethylphosphinate (**1***a*) is 22.5 ppm. The difference in chemical shift between the 4-NO_2 and 4-Me substituted compounds in series **1**, **2**, and **3** is, at most, 3.2 ppm. Therefore, the large increase in shielding of the phosphorus atom observed in series **3** (compared to **2** and **1**), as a result of the attached phenyl groups, may make changes in $\delta^{31}P$ less sensitive to smaller electron differences in the substituents attached to the phenoxy group.

The observed shielding effect of the phenyl groups, compared to the methyl groups, can be described in two ways. First, the phenyl rings inductively withdraw electrons from the phosphorus atom, which in turn increases the p_π–d_π back-bonding interaction of the phosphoryl oxygen, i.e., increased resonance contribution of **4***c* over **4***a*. Secondly, the *p* orbitals of the phenyl rings may be able to overlap with the *d* orbitals around the phosphorus atom through a resonance interaction.

Thus, whereas for series **1** only structures **6** and **6***a* ($R^1 = R^2$ = Me) are possible, for series **2** and **3** the phenyl groups may be involved via **6***b* and **6***c* as well. Contributions from **6***b* and **6***c* could be greater for the series **3** ($R^1 = R^2$ = Ph), where two phenyl groups are attached to phosphorus, relative to series **2**. For series **2** and **3**, the resulting effect of greater contribution by structures **6***b* and **6***c* may be to moderate the effects of the substituents in the ester moiety through electron withdrawal/donation of substituents via structures **6***a*, which would lead to smaller ρ values.



6*b* **6***c*

Hence electron-withdrawing substituents on the ester phenyl ring may act to weaken a π interaction of type **6***a* between the ester oxygen and phosphorus atom. In series **3**, and to a lesser extent series **2**, such weakening may be compensated for by increasing proportions of canonical forms **6***b* and **6***c*. In series **1**, however, there is no compensating effect by phenyl substituents, and the effect of the aryl oxygen–phosphorus π-bond weakening is seen to be greater, as reflected in the larger ρ values.

Correlation of ^{13}C and ^{1}H chemical shifts with the Hammett–Taft substituent constant σ^0

$\delta^{13}C$ and $\delta^{1}H$ values for the methyl moieties of series **1** and **2** are given in Table 2. On plotting the methyl $\delta^{13}C$ and $\delta^{1}H$ values in Table 2 versus σ^0 constants, a downfield shift in $\delta^{13}C$ and $\delta^{1}H$ is found with increasing electron-withdrawing ability of the ester phenyl substituents for **1** and **2**, as illustrated in Fig. 2 for $\delta^{13}C$. It is also seen that $\delta^{13}C$ and $\delta^{1}H$ for the methylphenylphosphinates (**2**) occur downfield of their dimethyl (**1**) counterparts.

The above observation of electron-withdrawing substituents on the phenoxy group inducing downfield shifts in $\delta^{13}C$ and $\delta^{1}H$ indicates that these substituents act to inductively withdraw electron density from the phosphorus atom and consequently from the attached methyl group. The higher resonance frequencies of series **1** as compared to **2** further implicate phenyl substituents in inductive electron withdrawal (relative to methyl substituents) from the phosphorus atom.

TABLE 2. ^{1}H and ^{13}C chemical shifts for the methyl substituents attached to phosphorus and ^{2}J(PH) and ^{1}J(PC) coupling constants for (*a*) the substituted phenyl dimethylphosphinate series (**1***a*–**1***f*) and (*b*) the substituted phenyl methylphenylphosphinate series (**2***a*–**2***f*), in $CDCl_3$ (shifts in ppm are quoted downfield of TMS, *J* is given in Hz)

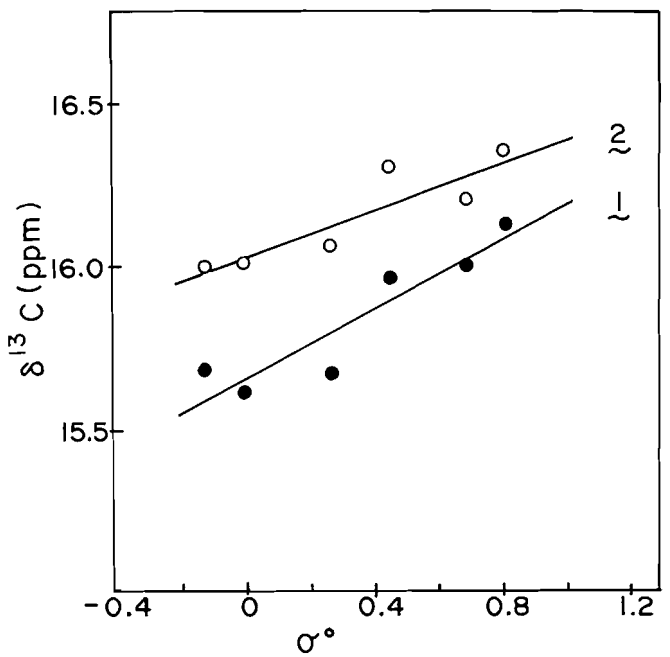

FIG. 2. Plot of $\delta^{13}C$ for the phosphorus-attached methyl group of series **1** and **2** esters versus Hammett–Taft σ^0 substituent constants.

The Hammett slope (ρ) may be taken as a measure of the sensitivity of phosphorus $\delta^{31}P$ and methyl $\delta^{13}C$ and $\delta^{1}H$ to substituent changes on the ester phenyl ring. The lower ρ values found for series **2** as compared with series **1** for both ^{13}C and ^{1}H are consistent with the argument for moderating effects of ester substituent changes by phenyl groups either through mesomeric forms **6***b* and **6***c* or by increased p_π–d_π back-bonding of the phosphoryl oxygen as a result of the inductive effect of the phenyl rings.

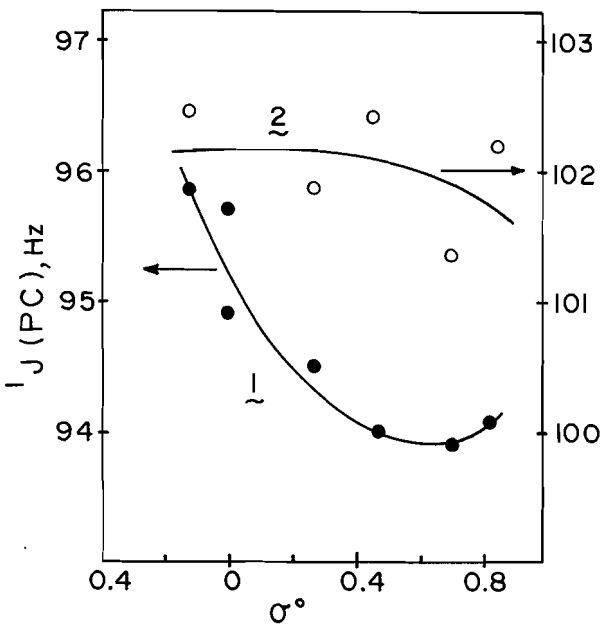

FIG. 3. Comparison of ^1J(PC) values for the methyl carbons of series **1** and **2**, plotted against Hammett–Taft σ^0 substituent constants. Series **1**, left-hand scale (●); series **2**, right-hand scale (○).

Correlation of one-bond P–C coupling constants (^{1}J(PC)) and two-bond P–H coupling constants (^{2}J(PH)) with σ^0

Plotted in Fig. 3 are the one-bond phosphorus – methyl carbon coupling constants ^1J (PC) for series **1** and **2** versus the σ^0 substituent constants (data in Table 2). ^1J(PC) values for series **2** remain approximately constant at ca. 102 Hz throughout the series. Series **1**, on the other hand, exhibits a decrease in ^1J(PC) from 95.86 Hz for **1***f* to ca. 93.90 Hz for **1***b*. ^2J(PH) coupling constants in series **1** assume approximately constant values of ca. 13.9 Hz, while in series **2** the values remain at ca. 14.5 Hz.

Duangthai and Webb (20), using calculations at the INDO level, have recently shown ^1J(PC) to be positive and completely dominated by the Fermi contact term for pentavalent phosphorus compounds, as is believed to be the case for ^1J(PC) and ^1J(PO) (21). Hence the magnitude of ^1J(PC) may be taken as a measure of the *s*-orbital density of the phosphorus – methyl carbon bond in **1** and **2**. If it is also assumed that the hybridization of the methyl carbon does not change noticeably within series **1** and **2**, then changes in ^1J(PC) are determined primarily by the hybridization of the phosphorus atom.

It follows from the above argument that the larger ^1J(PC) values for series **2** indicate that phosphorus in series **2** is involved in more extensive π bonding than in **1**. Thus, the relatively constant ^1J(PC) values found for series **2** can be taken to indicate that hybridization of the phosphorus atom does not change significantly within the series **2**, yet in series **1** hybridization is seen to change significantly. This observation may be explained in two ways. First, in series **2**, the larger phenyl group may present a steric barrier to significant C—P—C bond angle compression. This is not consistent with our previous arguments based on chemical shifts, since the sensitivity of the ^{31}P or methyl ^{13}C and ^{1}H nuclei to ester substituent changes is not expected to be lessened by a steric barrier to bond angle changes. Alternatively, the phenyl moiety of series **2** may enhance the p_π–d_π interaction of the phosphoryl oxygen with the phosphorus atom through contribution of structures such as **4***c*, **6***b*, and **6***c*. This interpretation is also consistent with the observation that the phosphoryl oxygen coupling constant ^1J(PO)) for $F_3P{=}O$ is much greater than in $H_3P{=}O$ (21).

Conclusions

An analysis of the ^{31}P chemical shift information for the series **1–3** shows that electron-withdrawing substituents on the ester phenyl ring of these phosphinates contribute to a deshielding of the ^{31}P nucleus, whereas directly attached phenyls act to shield the phosphorus nucleus, by promoting a p_π–d_π interaction of the phosphoryl oxygen with phosphorus and possibly by p_π–d_π overlap between the phenyl ring and phosphorus. The shielding effect brought about by a greater p_π–d_π interaction overrides the effect of inductive electron withdrawal by the phenyl group. The theory of Letcher and van Wazer (22) suggests that the difference in direct substituent effects may be due either to a change in π-bond overlap, or to the larger σ-bond angle in the methylphenyl series (**2**). Both of these arguments appear possible in light of the evidence presented.

Electron-withdrawing substituents on the ester phenyl ring may act, either inductively or through resonance, to deplete electron density on the aryl oxygen and thereby decrease a P—OAr p_π–d_π bonding interaction. The resultant decrease in *d*-orbital density induces a downfield shift in δ^{31}P. Phenyl moieties attached to phosphorus in **2** and **3** may moderate the effects of phenyl-ester substituent changes, either inductively or

through canonical structures **6***b* and **6***c*. Resonance donation of the type **4***c*, **6***b*, and **6***c* increases *d*-orbital occupancy on phosphorus (hence shielding the ^{31}P nucleus), overriding the effects of inductive electron withdrawal by phenyl substituents. Thus, differences in phosphorus *d*-orbital density in series **1–3** appear to play a major role in determining shielding of the ^{31}P nucleus in these series of compounds.

Experimental

Nuclear magnetic resonance spectra

All spectra were recorded on a Bruker AM400 nmr spectrometer. The 400-MHz ^{1}H and 101-MHz ^{13}C spectra were obtained in 5 mm o.d. nmr tubes in $CDCl_3$ solution with 0.5% tetramethylsilane (TMS) as internal reference. The ^{13}C nmr spectra were run in the ^{1}H-decoupled mode. The 162-MHz ^{31}P spectra were obtained in the PWRGATHT (^{1}H decoupled) mode on 0.1 M $CDCl_3$ solutions in 10 mm o.d. tubes and are quoted downfield with respect to 85% H_3PO_4 external reference.

Preparation of phosphinates

Substituted phenyl diphenylphosphinates were obtained from a previous study (9). Substituted phenyl dimethylphosphinates were prepared according to the method of Douglas and Williams (23). Substituted phenyl methylphenylphosphinates were prepared from the phosphinic chloride as described for **2***a* below as a representative example.

4-Nitrophenyl methylphenylphosphinate (**2***a*) was prepared by modification of the method of Raevskii *et al.* (24). To 3.10 g (0.022 mol) of 4-nitrophenol in a 50-mL solution of diethyl ether or benzene contained in a 100-mL 2-necked round-bottom flask under N_2 were added, in order, 3.25 mL (0.023 mol) of triethylamine and 3.96 g (0.022 mol) of methylphenylphosphinic chloride by syringe. The resulting yellow suspension was stirred at room temperature for 1 day, filtered under N_2 in a dry box to remove precipitated triethylamine hydrochloride, and concentrated on a rotary evaporator under reduced pressure, leaving behind a dark yellow oil. Acetone was added to triturate any methylphenylphosphinic acid; the resulting suspension was dried over $MgSO_4$ and filtered. Acetone was removed by rotoevaporation and the resulting partially crystalline mass was crystallized from ca. 20 mL of anhydrous diethyl ether by addition of petroleum ether (35/60) at room temperature. The product **2***a* was recrystallized twice from carbon tetrachloride.

Physical properties of the esters are provided in Table 3. Elemental analysis is included for compounds not previously reported. Melting points are uncorrected.

Diels–Alder reactions of 2-carbomethoxy-2-cyclohexen-1-one[1]

HSING-JANG LIU, TENG KO NGOOI, AND ERIC N. C. BROWNE[2]
Department of Chemistry, The University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received June 21, 1988

HSING-JANG LIU, TENG KO NGOOI, and ERIC N. C. BROWNE. Can. J. Chem. **66**, 3143 (1988).

Under stannic chloride catalysis, 2-carbomethoxy-2-cyclohexen-1-one (**5**) was found to undergo Diels–Alder reaction with a variety of dienes to give directly the *cis*-1-octalone system possessing a functionalized substituent at the angular position. With unsymmetrically substituted dienes, the adducts were those predicted on the basis of the normal rules (*ortho* and *para*) governing the orientation of Diels–Alder addition. In cases where differing secondary orbital overlap would affect the stereochemistry of the adducts, the major isomer in each case was that produced by secondary overlap of the diene with the ester carbonyl rather than the ketone carbonyl, presumably due in part to a steric effect. The degree of stereoselectivity was further shown to be dependent upon both the reaction temperature and the diene used and was generally enhanced when the reaction was carried out at lower temperatures or when a bulkier diene was involved.

HSING-JANG LIU, TENG KO NGOOI et ERIC N. C. BROWNE. Can. J. Chem. **66**, 3143 (1988).

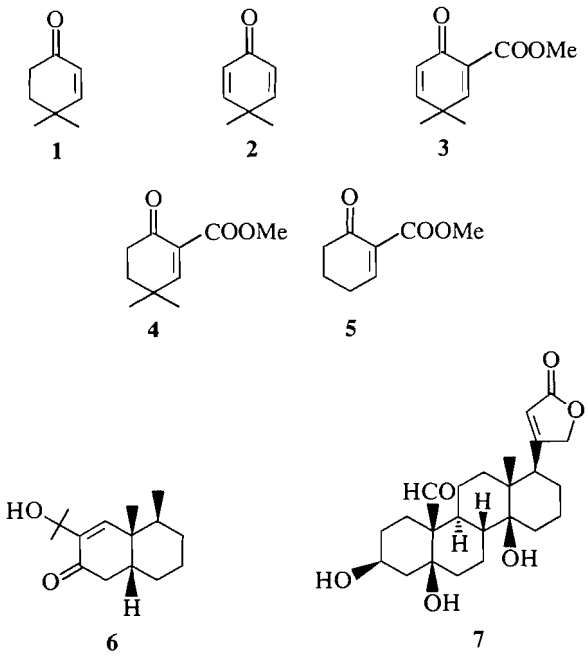
On a trouvé que, sous l'influence d'une catalyse par le chlorure stannique, la carbométhoxy-2 cyclohexène-2 one-1 (**5**) subit des réactions de Diels–Alder avec un grand nombre de dienes pour conduire directement au système de l'octalone-1-*cis* possédant un substituant fonctionnalisé en position angulaire. Lorsqu'on effectue la réaction avec des dienes qui ne sont pas substitués d'une façon symétrique, les adduits sont ceux que l'on peut prévoir en se basant sur les règles normales (*ortho* et *para*) régissant l'orientation de l'addition de Diels–Alder. Dans les cas où un recouvrement d'orbitales secondaires différent peut affecter la stéréochimie des adduits, l'isomère principal obtenu est toujours celui provenant du recouvrement secondaire du diène avec le carbonyle de l'ester plutôt qu'avec le carbonyle de la cétone; ce résultat est vraisemblablement dû à un effet stérique. On a démontré que le degré de stéréosélectivité dépend aussi de la température de la réaction ainsi que du diène utilisé; on a remarqué qu'il augmente généralement lorsqu'on opère à des températures plus basses ou lorsqu'un diène plus encombré est impliqué.
[Traduit par la revue]

Introduction

The poor results of attempts to achieve cycloadditions to cyclohexenones are well known in the field of Diels–Alder reactions (1–4). The catalytic effect of Lewis acids on Diels–Alder additions to α,β-unsaturated carbonyl compounds (5–8) was discovered long before it was applied to simple cyclic enones. Furthermore, while catalysis has made available a variety of adducts of cyclohexenones substituted on the dienophilic double bond,[3] cycloadditions to unsubstituted cyclohexenone continue to give poor results.

Wenkert and co-workers (9, 11–22) made an extensive study to systematize the Diels–Alder additions of a variety of simple cyclic enones. Liu and Browne (23–28) carried out an extensive study of the Diels–Alder reactions of 4,4-dimethyl-2-cyclohexen-1-one (**1**) and its derivatives **2**, **3**, and **4**. They observed improved rates and yields by the introduction of an additional electron-withdrawing group into the dienophilic moiety (as in **3**) as predicted by the Alder rule (29, 30). That study also indicates the potential of using different Lewis acid catalysts to effect different regiochemical outcomes in the reaction of isoprene with the dienone **3** (25).

Although conjugated cyclohexenones having an additional electron-withdrawing group attached to the dienophilic double bond have been observed to display improved dienophilicity in Diels–Alder reactions, few studies using such cyclohexenone derivatives have been reported. The compounds that were studied include examples substituted either at the α-carbon (24, 26, 28, 31) or the β-carbon (32–34) of the cyclohexenone. In the former case all of the enones explored were geminally substituted at the γ-carbon, blocking the facile enolization



1 2 3 4 5 6 7

towards that center. In spite of their broader synthetic utility, cycloadditions of enolizable analogs of cyclohexenone that have an electron-withdrawing α-substituent had not been reported prior to our first communication of this work (10).

We have examined the dienophilicity of 2-carbomethoxy-2-cyclohexen-1-one (**5**). The results as well as the structural assignments and mechanistic significance of the study will be discussed. A total synthesis of petasitolone (**6**) has been achieved (35) by a Diels–Alder addition to **5**. The use of enone ester **5** in a key Diels–Alder reaction for a synthetic study of the cardenolide strophanthidin (**7**) is under study in these laboratories (36).

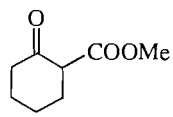
Results and discussion[4]

The effective preparation of 2-carbomethoxy-2-cyclohexen-1-one (**5**) has only recently been achieved since mild conditions for the carbon–carbon double bond formation have become available.[5] It could be prepared according to the two-step procedure of Reich *et al.* (40) or according to the method developed by Liotta *et al.* (41). We preferred the latter procedure for its simplicity and reproducibility. The starting 2-carbomethoxycyclohexanone (**8**) was treated with phenylselenenyl chloride pyridine complex (42) in methylene chloride. After an aqueous acid extraction of the reaction mixture to remove pyridine, the resulting selenide was oxidized with a solution of 30% aqueous hydrogen peroxide to give the required enone ester **5** in quantitative yield.

The enone ester **5** thus obtained was found to enolize and decompose rapidly,[6] but it was of good quality by ^{1}Hmr analysis. Attempts to distill this material led to reduced yield and it was more expedient to use the "crude" enone ester **5** in the Diels–Alder reaction without purification. A variety of conditions were initially examined for the Diels–Alder reaction of **5**. Thermal conditions did not give synthetically useful yields of adducts.[7] For example, when freshly prepared enone ester **5** was heated with 2,3-dimethyl-1,3-butadiene in benzene the adduct **9** was obtained in only 6% yield. Even with a more reactive diene the yields of adducts were not significantly improved. Thus reaction of enone ester **5** with 2-trimethylsilyloxy-1,3-butadiene (**10**) (44) carried out over a range of temperatures (20–120°C) gave at best 8% yield of the keto ester **11** after hydrolysis. A



8

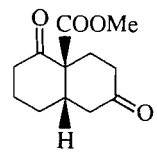
10



11

preliminary study indicated that various Lewis acids could be used to catalyze the Diels–Alder reaction of enone ester **5**. The results are summarized in Table 1. Stannic chloride usually gave the best yields of adducts and so, for further exploration of the scope of the Diels–Alder reactions of enone ester **5**, it was chosen as the Lewis acid catalyst. The results of this broader study are summarized in Table 2.

In general, the additions to **5** proceeded without operational difficulty and in moderate to good overall yield from **8** taking into account the 3 or 4 steps (selenation, oxidative elimination, cycloaddition, and, for the silyl enol ether derivatives, hydrolysis) required in the transformation. The structures of the adducts were established from their spectroscopic properties including ^{1}Hmr decoupling experiments, spectroscopic and chemical correlation with known compounds, and by degradation techniques previously developed in this laboratory (25–27). The usual orientational and stereochemical rules of Diels–Alder addition (27, 29, 45) were followed.

Structural assignments

Several of the adducts of **5** shown in Table 2 required more detailed analysis to unambiguously establish their structures. The chemical transformations used in the assignment of structures are summarized in Scheme 1. Ring junction stereochemistry was typically assigned on the basis of the *cis* principle (4, 27, 29, 45). In support of this general assignment, a reduction product **26** derived from **14**, **19**, or **22** was converted to the *cis*-fused natural product petasitolone **6** (35). We will discuss the regiochemical and stereochemical assignments of each group of adducts in turn.

The expected product of Diels–Alder reaction of **5** with 2-trimethylsilyloxy-1,3-butadiene **10** would have structure **11** after hydrolytic cleavage of the initially formed silyl enol ether **30**. Evidence in support of the regiochemical assignment was obtained from the high-field (400 MHz) ^{1}Hmr spectrum. A one-proton signal appeared at δ 3.11 with three coupling constants of 14, 7.0, and 3.5 Hz. This signal was assigned to the methine proton at the ring junction. The signal was coupled to a doublet at δ 2.29 (J = 7.0 Hz),[8] which integrated for two protons and was assigned to the methylene protons at C-5.[9] Clearly, these data are consistent with structure **11**. The regioisomeric adduct **31** would show no vicinal coupling to the ring junction proton for the methylene protons at C-8. Instead it would show a geminally coupled doublet for each proton, or a two-proton singlet if they were magnetically equivalent.

It is known that the Diels–Alder reaction with 2-substituted dienes can lead to regioisomeric mixtures of products (29, 45) or even complete orientational reversal (25). Therefore, it was important to prove that the addition of isoprene to enone ester **5** gave **12** and not the regioisomeric keto ester **29**. This simple structural proof has been detailed in a previous report (46).

Preliminary analysis of the spectral data indicated that the structure of the adduct of cyclopentadiene was either **13** or **32**. Conformational analysis showed that the keto ester **13** would have conformation **13***a*, in which a long-range *W*-coupling between the proton at C-4a and one of the protons on C-9 (H_x) would be expected in the ^{1}Hmr spectrum. On the other hand, in **32***a* no such *W*-coupling would be possible. Decoupling experiments of all isolable signals in the ^{1}Hmr spectrum led to assignment of all the protons on the bicyclo[2.2.1]heptene ring system of the adduct. The signal for the C-4a proton appeared at δ 2.52, with coupling constants of 12, 7.0, and 2.0 Hz, while the signal at δ 1.42 was assigned to the H_x proton on C-9. This

[4]For a preliminary communication see ref. 10.

[5]Although the corresponding ethyl ester was reported much earlier (37–39), the methods required were laborious or extreme.

[6]To slow decomposition and enolization, the crude oil was stored in a clean dry flask that had been pretreated with aqueous NH_4OH before drying. Usually freshly prepared **5** was used.

[7]A recent communication (43) reports successful thermal cycloaddition of a complex silyloxy diene to **5** (62% yield) in a synthetic strategy where acid catalysis would be incompatible with the required survival of the resulting silyl enol ether adduct.

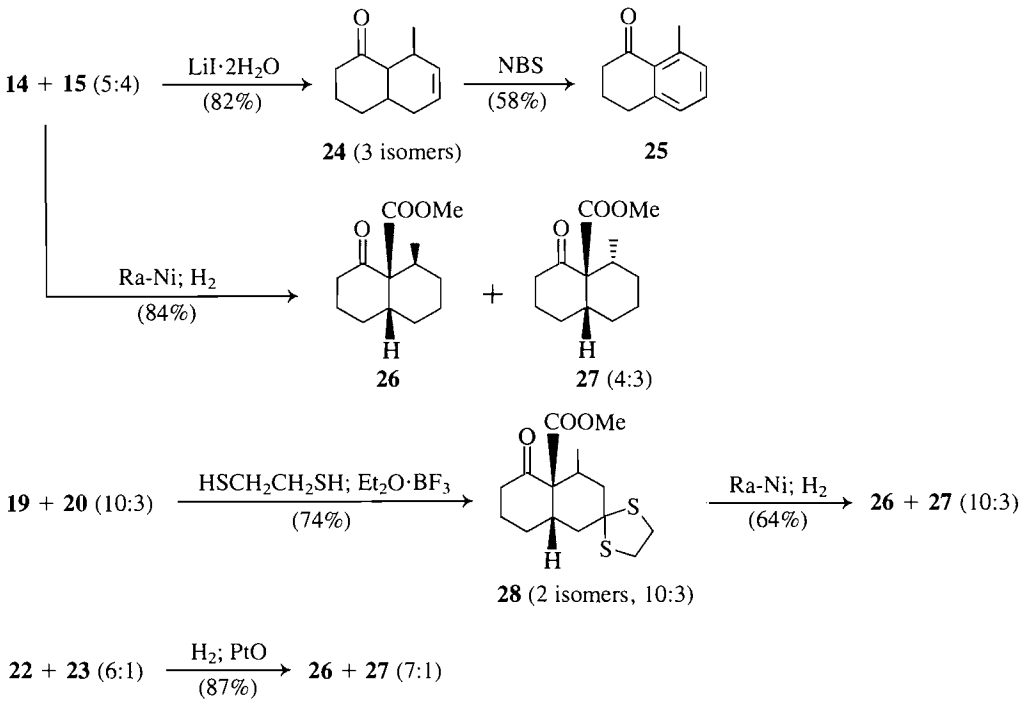
[8]This coupling was confirmed by irradiation of the signal at δ 3.11, which caused the signal at δ 2.29 to collapse to a singlet. Conversely, a doublet of doublets was observed at δ 3.11 on irradiation of the signal at δ 2.29.

[9]These two methylene protons have the same chemical shift in $CDCl_3$; however, when the ^{1}Hmr spectrum was run in deuterobenzene these same two protons showed different chemical shifts at δ 1.91 and 1.80. The signal at δ 1.91 showed coupling constants of 14.5, 5.5, and 1.0 Hz, while the signal at δ 1.80 gave coupling constants of 14.5, 8.5, and 1.5 Hz.

TABLE 1. Effect of different Lewis acid catalysts on Diels–Alder reactions of enone ester **5**[a]

Entry	Diene (10 equiv.)	Catalyst (0.5 equiv.)	Time (h)	Product	% Yield from **8**
1		$Et_2O{\cdot}BF_3$	3	**9**	38
		$SnCl_4$	1.5	**9**	61
		$FeCl_3$	1.5	**9**	42
2		$SnCl_4$	1.5	 **12**	61
		$FeCl_3$	2	**12**	46

[a]All reactions were run at 0°C using ether as the solvent.



SCHEME 1. Transformations of adducts, **14**, **15**, **19**, **20**, **22**, and **23**.

latter signal had coupling constants of 9.0, 2.0, and 1.0 Hz. Irradiation of the signal at δ 1.42 led to simplification of the signal at δ 2.52 to a doublet of doublets with coupling constants of 12 and 7.0 Hz. Conversely, irradiation of the signal at δ 2.52 led to the disappearance of the 2.0-Hz coupling constant for the signal at δ 1.42. This demonstrated coupling between the C-4a and C-9 H_x protons confirmed the assignment of structure **13** to the adduct.

To conclusively determine the regiochemistry of the addition of *trans*-piperylene, the 5:4 mixture of Diels–Alder adducts was converted to the corresponding aryl ketone derivative (Scheme 1) by the established method (25, 27, 46). Decarbomethoxylation of the mixture of adducts **14** and **15** by treatment with lithium iodide dihydrate in refluxing 2,4,6-collidine (40, 47) gave a mixture of three ketones **24**. The mixture of ketones was dehydrogenated with *N*-bromosuccinimide in refluxing carbon tetrachloride (48) to give a single aryl ketone in 58% yield. The aryl methyl signal in the ^{1}Hmr spectrum appeared as a singlet at δ 2.65. The absence of any signal above δ 7.30 as well as the presence of the *peri*-deshielded (49) aryl methyl signal indicated the assignment of structure **25** for the aryl ketone. The Diels–Alder adducts must then possess the regiochemistry shown in structures **14** and **15**.

The determination of the major epimer of the product mixture was made by chemical correlation of the major adduct to the known (35) compound **33**. The mixture of adducts was

[a]Reactions were carried out in ether except where otherwise stated.

[b]Since the reactions are not easily monitored while in progress, they were not examined for completion prior to quenching and work-up. Minimum times for completion and optimum yield were not determined.

[c]Ratios were determined by ^{1}Hmr integration.

[d]Hydrolytic cleavage of the silyl enol ether occurred during the work-up.

[e]This reaction was carried out in ether–dichloromethane (1:1).

hydrogenated with Raney nickel to give the chromatographically separable keto esters **26** and **27** in 84% total yield. The structure of the major keto ester **26** was confirmed by its conversion (35) in four steps to ketone **33**. This conclusively established the structure of the major Diels–Alder adduct of *trans*-piperylene as **14**. The minor adduct must have epimeric structure **15**.

At this stage it is useful to introduce several features of the ^{1}Hmr spectrum of the adducts **14** and **15** that were useful in determining the C-8 stereochemistry of the adducts in this

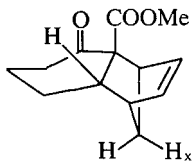
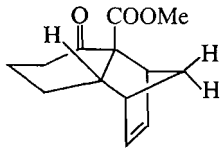
32



13*a*



32*a*

series. The secondary methyl group of **15** appeared at δ 1.17, strongly deshielded relative to the secondary methyl of **14** (δ 0.83). Conversely, the allylic methine proton at C-8 of **14** appeared at δ 2.92, strongly deshielded relative to the allylic methine proton at C-8 of **15** (δ 2.49).[10] These observations were attributed to deshielding of the C-8 proton or methyl, which is *trans* to the angular carbomethoxyl group in the adduct, by the ketone carbonyl. Consideration of the conformations of these adducts showed that adduct **15** would have possible conformations **15***a* and **15***b*, in which the preferred conformation **15***b* would have the C-8 methyl in the deshielding zone of the ketone carbonyl. Adduct **14** would have possible conformations **14***a* and **14**b, in which the preferred conformation **14***b* would have the C-8 proton in the deshielding zone of the ketone carbonyl. These ^{1}Hmr results have been consistently observed in similar decalin derivatives. For instance, in the ketone **34** (9), the secondary methyl group appears at δ 1.15, deshielded relative to the corresponding methyl group of **35** at δ 0.75. Similarly, in ketone **36** (27) the allylic methine proton on C-8 shows a signal at δ 3.06, strongly deshielded relative to the C-8 proton of **37** (δ 2.34), while the C-8 methyl of **37** appears at δ 1.38, shifted downfield relative to the corresponding methyl of **36** at δ 1.04.

Attempts to determine the regiochemistry of the Diels–Alder adducts of *trans*-2-methyl-1,3-pentadiene by the decarbomethoxylation–aromatization sequence (*vide supra*) were not successful. The other examples in the study (Table 2) indicated that the *ortho* and *para* rules were consistently followed and from these results we presume that the addition of *trans*-2-methyl-1,3-pentadiene to **5** followed the usual rules to give the C-8 epimeric keto esters **16** and **17**.

As indicated above, the ^{1}Hmr data were used to determine the C-8 stereochemistry of the keto esters **16** and **17**. In the spectrum of the 2:1 mixture of epimers, the allylic methine proton at C-8 of the major adduct appeared at δ 2.83, strongly deshielded relative to the C-8 proton of the minor adduct (δ 2.40),[11] while the C-8 methyl of the minor adduct appeared at δ 1.08, deshielded relative to the C-8 methyl of the major adduct (δ 0.73). These data confirmed the assignment of structure **16** to the major adduct and the C-8 epimeric structure **17** to the minor adduct.

The stereoselectivity in favor of keto ester **16** was improved by the use of a lower reaction temperature. At −30°C enone ester **5** reacted with *trans*-2-methyl-1,3-pentadiene under stannic chloride catalysis to give a 6:1 mixture of Diels–Alder adducts **16** and **17** respectively in 34% total yield. At even lower reaction temperature (− 78°C) the Diels–Alder reaction proceeded to give excellent 13:1 stereoselectivity in favor of **16**; however, the total yield of adducts was again only 37%.

trans-2-Trimethylsilyloxy-1,3-pentadiene (**18**) was prepared by the general method of Ohfune and Tomita (50) by trimethylsilyl chloride trapping of the enolate formed from *trans*-3-penten-2-one with lithium diisopropylamide at −78°C. The addition of **18** to enone ester **5** gave an inseparable mixture of Diels–Alder adducts tentatively identified as the C-8 epimeric diketones **19** and **20**.[12] Treatment of the mixture of adducts with 1,2-ethanedithiol and boron trifluoride etherate in methylene chloride at 0°C for 30 min furnished the mixture of thioketals **28**. Desulfurization of the thioketals **28** was accomplished with Raney nickel in refluxing ethanol. After chromatographic separation two products were obtained in a ratio of 10:3 and in a combined yield of 64%. The major product was identical to the saturated keto ester **26** previously obtained from **14** and the minor product was identical to the keto ester **27** derived from **15**. This transformation unambiguously established the structures of the Diels–Alder adducts as the epimeric diketones **19** and **20**, and that **19** was the major isomer. At a lower temperature (−50°C) the selectivity in favor of adduct **19** was increased to 7:1 (35).

Enone ester **5** reacted with *trans*-2-diethylphosphoryloxy-1,3-pentadiene (**21**)[13] at −30°C (35) to give a 6:1 mixture of adducts in 66% yield. These Diels–Alder adducts were also unambiguously identified (35) as the epimeric enol phosphates **22** and **23** by their transformation to the previously obtained chromatographically separable keto esters **26** and **27**, by hydrogenolysis of the mixture of adducts using platinum oxide as the catalyst (53, 54).

When the Diels–Alder reaction of **5** with **21** was carried out at −78°C, a similar stereoselectivity (6:1) in favor of **22** was observed; however, the yield was lower (45%). The use of methylene chloride as the solvent did not lead to any improvement in the result. For example, when the addition was run at −30°C in methylene chloride, a 6:1 ratio of **22** to **23** was again obtained in 50% yield.

endo *Selectivities of the additions*

Enone ester **5** has two dienophilic components, namely, the α,β-unsaturated ketone and the α,β-unsaturated ester moieties. Ordinarily, it would not be necessary to distinguish these two moieties except in cases where the *endo* rule applies. The factors determining which dienophilic moiety would control the reaction pathway are expected to be a function of the secondary

[10]The assignments for the allylic methine protons at C-8 (δ 2.92 and 2.49) were confirmed by the observation of significant sharpening of the signals upon irradiation of the adjacent methyl protons (δ 0.83 and 1.17).

[11]The assignments for the allylic methine protons at C-8 (δ 2.83 and 2.40) were confirmed by the observation of significant sharpening of the signals upon irradiation of the adjacent methyl protons (δ 0.73 and 1.08).

[12]Hydrolysis of the labile silyl enol ether of the initially formed Diels–Alder adducts occurred during the work-up.

[13]For a broader discussion of the Diels–Alder reactions of **21** and a related dienyl phosphate see refs. 51 and 52.

orbital overlap with the diene (27, 55). Additions of 1-substituted dienes to enone ester **5** gave predominantly the product resulting from addition with secondary overlap with the ester group ("ester-*endo*" transition state **B**) rather than with the ketone carbonyl ("keto-*endo*" transition state **A**).[14]

The bias in favor of transition state **B** may be of combined electronic and steric origins. The electronic effect promoted by a catalyst complexing more effectively with the ester group of the enone ester **5** would favor ester-*endo* addition via transition state **B** to give the various major adducts (**13**, **14**, **16**, **19**, and **22**). Addition via transition state **A** would encounter steric interaction between the diene and the nonreacting centers of the cyclohexenone ring of the dienophile. The presence of this steric effect was substantiated by the increased predominance of ester-*endo* adducts in cases where a bulky substituent was used at the C-3 position of the 1-substituted diene.

The formation of two C-8 epimeric adducts **14** and **15** in a ratio of 5:4 by addition of *trans*-piperylene to **5** at 0°C clearly was the result of addition via the two different transition states **14B** and **15A** respectively. The preferential formation of the adduct **14** can be attributed in part to a destabilization of transition state **15A** by steric interaction between the diene and the nonreacting centers of the cyclohexenone ring of the dienophile.[15] Addition via transition state **14B** would not encounter such a steric interaction.

This steric effect was evidently larger for the addition of *trans*-2-methyl-1,3-pentadiene. A larger product ratio (**16**:**17** = 2:1) was observed in favor of ester-*endo* addition via transition state **16B** to give the adduct **16**. Clearly, in the keto-*endo* addition via the competing transition state **17A**, a greater steric interaction would be encountered between the more bulky diene and the nonreacting centers of the ring of the dienophile.

The cases of *trans*-2-trimethylsilyloxy-1,3-pentadiene (**18**) and *trans*-2-diethylphosphoryloxy-1,3-pentadiene (**21**) again showed very good stereoselectivities in favor of the ester-*endo* adducts (**19** and **22**) resulting from additions via transition states **19B** and **22B** with significantly less addition via the sterically less favourable transition states **20A** and **23A**.

The addition of cyclopentadiene is also noteworthy. Its addition to enone ester **5** gave only the adduct **13** arising from ester-*endo* addition to **5**. Conformational analysis of the possible transition states revealed that in **36A** a severe steric interaction would be encountered between both the C-2 and C-3 protons of the diene and the nonreacting centers of the cyclohexenone ring of the dienophile. On the other hand, in **13B**, the methylene protons on C-5 of cyclopentadiene would be nearer the center of the cyclohexenone ring than to the nonreacting centers of the ring and would experience less steric interaction.

At lower reaction temperatures the stereoselectivity in favor of the ester-*endo* addition should be greater and this expectation was confirmed. For instance, in the case of *trans*-2-methyl-1,3-pentadiene, the stereoselectivity improved to 6:1 in favor of adduct **16** at −30°C compared to 2:1 at 0°C. This stereoselectivity was even greater at −78°C where a product ratio of 13:1 in favor of the ester-*endo* adduct **16** was obtained.

Conclusions

In conclusion, the development of enone ester **5** as a dienophile makes available a new method for the rapid construction of angularly substituted *cis*-decalin derivatives. The angular carbomethoxyl group of the resulting *cis*-decalin derivatives can either be removed or used as a reactive site for further elaboration of the adducts. Furthermore, the stereochemical outcome of the addition of 1-substituted dienes to **5** is opposite to that observed for the Lewis acid catalysed Diels–Alder additions to 2-cyclohexenone and 2-methyl-2-cyclohexenone. Thus the two processes are complementary in stereochemical control.

Experimental

General

Melting points were determined on a Kofler hot stage apparatus and are uncorrected. Elemental analyses were performed by the microana-

[14]We have adopted the terms keto-*endo* and ester-*endo* to distinguish transition states, orientations, and adducts that have, or result from, secondary orbital overlap with a particular functional group (here ketone and ester respectively) in cases where the *endo* rule of Diels–Alder addition applies. See introduction to ref. 27.

[15]A similar explanation has been offered to account for the relatively poor dienophilicity of cyclohexenones (4) and also to account for an orientational reversal in violation of the *para* rule in the Diels–Alder reaction (26, 27).

lytical laboratory of this department. Infrared (ir) spectra were recorded on a Perkin–Elmer model 457 or Nicolet 7-199 FT-IR spectrophotometer and, except where otherwise stated, were obtained on solutions in carbon tetrachloride. Proton nuclear magnetic resonance (^{1}Hmr) spectra were recorded on a Varian HA-100, HA-100/Digilab, Bruker WH-200 or WH-400 spectrometer, and, except where otherwise stated, were obtained on solutions in deuterochloroform with tetramethylsilane as internal reference. Carbon-13 nuclear magnetic resonance (^{13}Cmr) spectra were recorded on a Bruker HFX-90/Nicolet 1085 system, Bruker WH-200 or WH-400 spectrometer, and were obtained on solutions in deuterochloroform using tetramethylsilane as internal reference. The following abbreviations are used: s = singlet, d = doublet, t = triplet, q = quartet, and m = multiplet. Mass spectra (ms) were recorded using A.E.I. model MS9, MS12, or MS50 mass spectrometers. Unless otherwise stated, anhydrous magnesium sulfate was used for drying organic solutions. Crystalline samples were recrystallized and liquid samples were subjected to Kuhgelrohr distillation before submitting for elemental analysis. Flash chromatography (56) was routinely used for purification and separation of product mixtures.

Materials

Benzene, ether, tetrahydrofuran, and 1,2-dimethoxyethane were freshly distilled over lithium aluminum hydride. *n*-Hexane was purified by simple distillation for use in chromatographic purifications. Anhydrous stannic chloride was purchased from A. G. Fluka and used without further purification. Nitrogen or argon was passed through a purification train of Fieser's solution (57), saturated aqueous lead acetate, concentrated sulfuric acid, and potassium hydroxide pellets. Enone ester **5** was prepared from 2-carbomethoxycyclohexanone according to the reported procedures (40, 41). 2-Trimethylsilyloxy-1,3-butadiene (**10**) was prepared according to the procedure of Conia (44, 58). 1,3-Cyclopentadiene was prepared by thermal cracking of dicyclopentadiene and was used immediately after the distillation.

*General conditions for the Diels–Alder reaction of enone ester **5** using different Lewis acids (Table 1)*

Enone ester **5** (1.0 equiv.) and the diene (2,3-dimethylbutadiene or isoprene; 10 equiv.) were dissolved in ether at 0°C. The Lewis acid (boron trifluoride etherate, ferric chloride, or stannic chloride; 0.5 equiv.) was added. After stirring under an atmosphere of argon for 1.5–3 h as indicated, saturated aqueous sodium bicarbonate was added and the resulting mixture was extracted with methylene chloride. The organic extracts were dried, filtered, and concentrated. Purification of the residue by flash chromatography gave the product **9** or **12**. The results are summarized in Table 1.

*8aβ-Carbomethoxy-6,7-dimethyl-3,4,4aβ,5,8,8a-hexahydro-1(2H)-naphthalenone (**9**)*[16]

To a solution of enone ester **5** (531 mg, 3.45 mmol) and 2,3-dimethyl-1,3-butadiene (2.8 g, 34.4 mmol) in ether (10 mL) at 0°C and under an atmosphere of argon was added anhydrous stannic chloride (0.44 g, 1.70 mmol). After stirring for 1.5 h at 0°C, saturated aqueous sodium bicarbonate (50 mL) was added and the resulting mixture was filtered through Celite. The filtrate was extracted with methylene chloride and the organic extracts were washed with water, dried, filtered, and concentrated. Purification of the residue by flash chromatography on silica gel, eluting with 8% ethyl acetate in petroleum ether, gave keto ester **9** (499 mg, 61% yield), which crystallized on standing. Recrystallization from ether/*n*-hexane gave white crystals of pure keto ester **9**: mp 69–70°C; ir: 1743 (ester C=O) and 1717 (ketone C=O) cm^{-1}; ^{1}Hmr δ: 3.72 (s, 3H, -COOCH$_3$) and 1.64 (br s, 6H, 2 × -CH$_3$); ^{13}Cmr δ: 208.0, 172.8, 123.1, 121.7, 61.7, 52.2, 38.1, 37.6, 33.9, 33.5, 26.9, 23.9, 18.9, and 18.5; ms M$^+$: 236.1414 (calcd. for $C_{14}H_{20}O_3$: 236.1413). *Anal.* calcd. for $C_{14}H_{20}O_3$: C 71.16, H 8.53; found: C 71.02, H 8.58.

[16]The stereochemical designations and all other chemical names used in this section denote relative stereochemistry. All compounds used and obtained were racemic.

*8aβ-Carbomethoxy-2,3,4,4aβ,5,8,8a-octahydro-1,6-naphthalenedione (**11**)*

To a solution of enone ester **5** (568 mg, 3.69 mmol) and 2-trimethylsilyloxy-1,3-butadiene (**10**) (2.8 g, 18.5 mmol) in ether (20 mL) at 0°C and under an atmosphere of argon was added anhydrous stannic chloride (479 mg, 1.84 mmol). After stirring for 4 h water was added and the resulting mixture was extracted with methylene chloride. The organic extracts were combined, dried, filtered, and concentrated. Flash chromatography of the residue on silica gel, eluting with 20% ethyl acetate in petroleum ether, gave diketone **11** (212 mg, 27% yield). Recrystallization from ether/petroleum ether gave white crystals of pure **11**: mp 87–88°C; ir: 1736 (ester C=O) and 1714 (ketone C=O) cm^{-1}; ^{1}Hmr δ: 3.82 (s, 3H, -COOCH$_3$), 3.11 (ddd, 1H, J = 14 Hz, J' = 7.0 Hz, J'' = 3.5 Hz, C-4a H), and 2.29 (d, 2H, J = 7.0 Hz, 2 × C-5 H); ^{13}Cmr δ: 209, 206, 171, 60, 52, 43, 42, 38, 37, 29, 27, and 23; ms M$^+$: 224.1049 (calcd. for $C_{12}H_{16}O_4$: 224.1049). *Anal.* calcd. for $C_{12}H_{16}O_4$: C 64.27, H 7.19; found: C 64.13, H 7.18.

*8aβ-Carbomethoxy-5,8α-methano-3,4,4aβ,5,8,8a-hexahydro-1(2H)-naphthalenone (**13**)*

To a solution of enone ester **5** (428 mg, 2.78 mmol) and 1,3-cyclopentadiene (2.0 g, 30.3 mmol) in ether (20 mL) at −25°C and under an atmosphere of argon was added anhydrous stannic chloride (360 mg, 1.38 mmol). After stirring for 3 h water was added and the resulting mixture was extracted with chloroform. The organic extracts were washed with water, dried, filtered, and concentrated. Column chromatography of the residue on silica gel, eluting with 5–10% ether in petroleum ether, gave an impure fraction containing the adduct **13**. A second purification by column chromatography on neutral alumina (grade III), eluting with 20% ethyl acetate in petroleum ether, gave pure adduct **13** (174 mg, 29% yield). Recrystallization from *n*-hexane gave white crystals of pure **13**: mp 91–93°C; ir: 1730 (ester C=O) and 1709 (ketone C=O) cm^{-1}; ^{1}Hmr δ: 6.31 (dd, 1H, J = 5.5 Hz, J' = 3.0 Hz, C-6 H), 6.00 (dd, 1H, J = 5.5 Hz, J' = 3.0 Hz, C-7 H), 3.67 (s, 3H, -COOCH$_3$), 3.63 (m, 1H, C-8 H), 2.60 (m, 1H, C-5 H), 2.52 (ddd, 1H, J = 12 Hz, J' = 7.0 Hz, J'' = 2.0 Hz, C-4a H), and 1.42 (ddd, 1H, J = 9.0 Hz, J' = 2.0 Hz, J'' = 1.0 Hz, bridge -CH*H*-); ^{13}Cmr δ: 208.8, 171.1, 139.5, 138.8, 81.7, 52.5, 48.4, 47.5, 46.8, 45.9, 38.4, and 29.0; ms M$^+$: 220.1098 (calcd. for $C_{13}H_{16}O_3$: 220.1100).

*8aβ-Carbomethoxy-8β-methyl-3,4,4aβ,5,8,8a-hexahydro-1(2H)-naphthalenone (**14**) and 8aβ-carbomethoxy-8α-methyl-3,4,4aβ,5,8,8a-hexahydro-1(2H)-naphthalenone (**15**)*

(a) By Diels–Alder reaction at 0°C

To a solution of enone ester **5** (453, 2.94 mmol) and *trans*-piperylene (2.0 g, 29.4 mmol) in ether (20 mL) at 0°C and under an atmosphere of argon was added anhydrous stannic chloride (374 mg, 1.44 mmol). After stirring for 5 h water was added and the resulting mixture was extracted with methylene chloride. The organic extracts were washed with water, dried, filtered, and concentrated. Column chromatography of the residue on silica gel, eluting with 1–5% ether in petroleum ether, gave an impure mixture of adducts **14** and **15**. Further purification by column chromatography on neutral alumina (Woelm III), eluting with 10% ethyl acetate in petroleum ether, gave a mixture of pure adducts **14** and **15** (182 mg; 28% yield). The ^{1}Hmr spectrum of the mixture showed two sets of signals in an integral ratio of 5:4. One set, assigned to the major adduct **14**, showed signals at δ: 5.32 (m, 2H, -CH=CH-), 3.72 (s, 3H, -COOCH$_3$), 2.92 (m, 1H, -C*H*—CH$_3$), and 0.83 (d, 3H, J = 7.0 Hz, -CH—C*H*$_3$). The other set, assigned to the minor adduct **15**, showed signals at δ: 5.63 (m, 2H, -CH=CH-), 3.78 (s, 3H, -COOCH$_3$), 2.49 (m, 1H, -C*H*—CH$_3$), and 1.17 (d, 3H, -CH—C*H*$_3$). The mixture also showed the following spectral data: ir (film): 1743 (ester C=O) and 1717 (ketone C=O) cm^{-1}; ms M$^+$: 222.1256 (calcd. for $C_{13}H_{18}O_3$: 222.1256).

(b) By Diels–Alder reaction at −30°C

To a solution of enone ester **5** (331 mg, 2.15 mmol) and *trans*-piperylene (1.5 g, 22.0 mmol) in ether (10 mL) at −30°C and under an atmosphere of nitrogen was added anhydrous stannic chloride

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 122.72.124.2 on 09/07/12
For personal use only.

(2.86 mg, 1.09 mmol). After stirring for 6 h the reaction mixture was warmed to room temperature. Water was added and the resulting mixture was extracted with methylene chloride. The organic extracts were dried, filtered, and concentrated. Column chromatography of the residue on neutral alumina (grade III), eluting with 10% ethyl acetate in petroleum ether, gave an impure mixture of adducts **14** and **15**. A second chromatographic purification on neutral alumina (Woelm III), eluting with 10% ethyl acetate in petroleum ether, gave a pure 5:3 mixture (by ^{1}Hmr integration) of adducts **14** and **15** (164 mg, 34% yield).

(c) By Diels–Alder reaction at −78°C

To a solution of enone ester **5** (408 mg, 2.65 mmol) and *trans*-piperylene (1.8 g, 26.5 mmol) in ether (15 mL) at −78°C and under an atmosphere of nitrogen was added anhydrous stannic chloride (352 mg, 1.35 mmol). After stirring for 6 h the reaction mixture was warmed to room temperature. Water was added and the resulting mixture was extracted with methylene chloride. The organic extracts were combined, dried, filtered, and concentrated. Column chromatography of the residue on neutral alumina (Woelm III) gave an impure mixture of adducts **14** and **15**. A second purification on neutral alumina (Woelm III), eluting with 10% ethyl acetate in petroleum ether, gave a pure 5:3 mixture (by ^{1}Hmr integration) of adducts **14** and **15** (200 mg, 34% yield).

6-Methyl-3,4,4aβ,5,8,8a-hexahydro-1(2H)-naphthalenone, mixture of ketones 24

Finely divided anhydrous lithium iodide (101 mg, 0.74 mmol) was suspended in 2,4,6-collidine (5 mL) with vigorous stirring. Water (27 mg, 1.51 mmol) was added and the suspension dissolved on vigorous stirring. A 5:4 mixture of keto esters **14** and **15** (84 mg, 0.38 mmol) was added to the lithium iodide dihydrate solution. The mixture was heated to reflux for 1.5 h under an atmosphere of nitrogen. The reaction mixture was cooled to room temperature, poured into ice-cold aqueous 1.0 N hydrochloric acid, and extracted with methylene chloride. The extracts were washed with aqueous 1.0 N hydrochloric acid and water, dried, filtered, and concentrated. Flash chromatography of the residue on silica gel, eluting with a solution of 5% ether in petroleum ether, gave a mixture of three ketones **24** (51 mg, 82% yield). The mixture showed the following spectral data: ir (film): 1712 (ketone) cm^{-1}; ^{1}Hmr δ: 1.00, 0.99, 0.98 (each d, total 3H, each J = 7.0 Hz, -CH_3) and 5.56 (complex, total 2H, -CH=CH-); ms M$^+$: 164.1198 (calcd. for $C_{11}H_{16}O$: 164.1201).

8-Methyl-3,4-dihydro-1(2H)-naphthalenone (25)

A mixture of ketones **24** (51 mg, 0.31 mmol) was dissolved in carbon tetrachloride (10 mL). Benzoyl peroxide (5 mg, 0.02 mmol) and *N*-bromosuccinimide (110 mg, 0.62 mmol) were added. The reaction mixture was heated to reflux for 10 h under an atmosphere of nitrogen and cooled to room temperature. Filtration and concentration gave an oily residue, which was purified by flash chromatography on silica gel. Elution with 10% ether in petroleum ether gave aryl ketone **25** (29 mg, 58% yield): ir (film): 1690 (C=O) cm^{-1}; ^{1}Hmr δ: 7.30 (m, 2H, 2 × Ar-H), 7.10 (d, 1H, J = 7.0 Hz, Ar-H), 2.95 (t, 2H, J = 6.0 Hz, -CH_2CO-), 2.65 (t, 2H, J = 7.0 Hz, -CH_2C=), 2.63 (s, 3H, -CH_3), and 2.50 (m, 2H, -$CH_2CH_2CH_2$); ms M$^+$: 160.0891 (calcd. for $C_{11}H_{12}O$: 160.0888).

8aβ-Carbomethoxy-8β-methyl-3,4,4aβ,5,6,7,8,8a-octahydro-1(2H)-naphthalenone (26) and 8aβ-carbomethoxy-8α-methyl-3,4,4aβ,5,6,7,8,8a-octahydro-1(2H)-naphthalenone (27)

(a) From mixture of Diels–Alder adducts 14 and 15

A 5:4 mixture of Diels–Alder adducts **14** and **15** (540 mg, 2.43 mmol) and Raney nickel (grade W-2, ca. 5.0 g) were stirred together in ethanol (15 mL). After 7 h the reaction mixture was filtered and the organic filtrate was concentrated. Column chromatography of the residue on silica gel, eluting with 1% ethyl acetate in petroleum ether, gave pure keto ester **27** (198 mg; 36% yield) as a colorless oil: ir (neat): 1739 (ester C=O) and 1712 (ketone C=O) cm^{-1}; ^{1}Hmr δ: 3.79, (s, 3H, -$COOCH_3$) and 1.18 (d, 3H, J = 7.0 Hz, -$CHCH_3$); ms M$^+$: 224.1410 (calcd. for $C_{13}H_{20}O_3$: 224.1407). Continued elution gave the isomeric keto ester **26** (263 mg, 48% yield), which crystallized on standing: mp 37–39°C; ir: 1740 (ester C=O) and 1714 (ketone C=O) cm^{-1}; ^{1}Hmr δ: 3.72, (s, 3H, -$COOCH_3$) and 0.86 (d, 3H, J = 7.0 Hz, -$CHCH_3$); ms M$^+$: 224.1411 (calcd. for $C_{13}H_{20}O_3$: 224.1407). *Anal.* calcd. for $C_{13}H_{20}O_3$: C 69.91, H 8.99; found: C 69.77, H 9.01.

(b) From thioketals 28

To a solution of a 10:3 mixture of thioketals **28** (31 mg, 0.09 mmol) in dry ethanol (5.0 mL) was added Raney nickel (grade W-2, ca. 0.5 g) under an atmosphere of nitrogen. The mixture was heated to reflux for 5 h and then cooled to room temperature, filtered, and concentrated to give a light yellow oil, which was purified by column chromatography on silica gel. Elution with 2% ether in petroleum ether gave the minor keto ester **27** (3.0 mg, 14% yield). Continued elution gave the major keto ester **26** (11 mg, 50% yield).

8aβ-Carbomethoxy-6,8β-dimethyl-3,4,4aβ,5,8,8a-hexahydro-1(2H)-naphthalenone (16) and 8aβ-carbomethoxy-6,8α-dimethyl-3,4,4aβ,5,8,8a-hexahydro-1(2H)-naphthalenone (17)

(a) By Diels–Alder reaction at 0°C

To a solution of enone ester **5** (505 mg, 3.28) in ether (10 mL), at 0°C and under an atmosphere of argon, were sequentially added *trans*-2-methyl-1,3-pentadiene (808 mg, 9.85 mmol) and anhydrous stannic chloride (427 mg, 1.64 mmol). After stirring for 3 h water was added and the resulting mixture was extracted with methylene chloride. The organic extracts were dried, filtered, and concentrated. Column chromatography of the residue on silica gel, eluting with 5–10% ethyl acetate in petroleum ether, gave an impure mixture of adducts **16** and **17**. A second purification by flash chromatography, eluting with 6% ethyl acetate in petroleum ether, gave a mixture of pure adducts **16** and **17** (255 mg, 33% yield). The ^{1}Hmr spectrum of the mixture showed two sets of signals in an integral ratio of 2:1. One set was assigned to the major keto ester **16**: δ: 5.25 (m, 1H, =CH—), 3.63 (s, 3H, -$COOCH_3$), 2.83 (m, 1H, -C*H*—CH_3), and 0.73 (d, 3H, J = 7.0 Hz, -CH—CH_3). The other set was assigned to the minor keto ester **17**: δ: 5.15 (m, 1H, =CH—), 3.70 (s, 3H, -$COOCH_3$), 2.40 (m, 2H, -C*H*—CH_3), and 1.08 (d, 3H, J = 7.0 Hz, -CH—CH_3). The mixture also showed the following spectral data; ir (neat): 1740 (C=O ester) and 1716 (C=O ketone) cm^{-1}; ms M$^+$: 236.1413 (calcd. for $C_{14}H_{20}O_3$: 235.1413).

(b) By Diels–Alder reaction at −35°C

Enone ester **5** (574 mg, 3.73 mmol) and *trans*-2-methyl-1,3-pentadiene (0.92 g, 11.2 mmol) were placed in ether (10 mL) and cooled to −35°C. Anhydrous stannic chloride (485 mg, 1.86 mmol) was added. After stirring under an atmosphere of argon for 3 h the reaction mixture was warmed to room temperature. Water was added and the resulting mixture was extracted with methylene chloride. The combined organic extracts were dried, filtered, and concentrated. Column chromatography of the residue on silica gel, eluting with 5% ethyl acetate in petroleum ether, gave an impure mixture of adducts **16** and **17**. A second chromatographic purification on neutral alumina (Woelm III), eluting with 50% ether in petroleum ether, gave a 6:1 mixture (by ^{1}Hmr integration) of adducts **16** and **17** (299 mg, 34% yield).

(c) By Diels–Alder reaction at −78°C

To a solution of enone ester **5** (238 mg, 1.54 mmol) in ether (8 mL), at −78°C and under an atmosphere of argon, were sequentially added *trans*-2-methyl-1,3-pentadiene (380, 4.64 mmol) and anhydrous stannic chloride (201 mg, 0.77 mmol). After stirring for 6 h the reaction mixture was warmed to room temperature. Water was added and the resulting mixture was extracted with methylene chloride. The combined organic extracts were dried, filtered, and concentrated. Column chromatography of the residue on neutral alumina (Woelm III), eluting with 20–50% ether in petroleum ether, gave an impure mixture of adducts **16** and **17**. A second chromatographic purification on neutral alumina (Woelm III), eluting with 50% ether in petroleum ether, gave a 13:1 mixture (by ^{1}Hmr integration) of adducts **16** and **17** (136 mg, 37% yield). Fractional recrystallization of the mixture from ether/petroleum ether gave white crystals of pure **16**: mp 110–111°C; ^{1}Hmr δ: 5.24

(m, 1H, =CH—), 3.64 (s, 3H, -$COOCH_3$), 2.82 (m, 1H, -C*H*—CH_3), and 0.73 (d, 3H, J = 7.0 Hz, -CH—CH_3).

trans-2-*Trimethylsilyloxy-1,3-pentadiene (**18**)*

At −78°C and under an atmosphere of argon, *n*-butyllithium (56.7 mL of 1.5 M solution in *n*-hexane, 85.0 mmol) was added to a solution containing diisopropylamine (8.59 g, 84.9 mmol) in tetrahydrofuran (40 mL). After stirring for 15 min, a solution of *trans*-3-penten-2-one (6.48 g, 77.0 mmol) in tetrahydrofuran (20 mL) was added dropwise over 10 min through a pressure equalizing dropping funnel. After another 20 min, chlorotrimethylsilane (16.8 g, 154 mmol) was rapidly added. The resulting solution was allowed to warm to room temperature. *n*-Pentane was added to the reaction mixture and the resulting solution was washed with ice-cold distilled water (400 mL). The organic layer was dried, filtered, and concentrated. The residue was fractionally distilled under vacuum, collecting the fraction distilling at 56–62°C (16 Torr; 1 Torr = 133.3 Pa). The resulting colourless oil was the required diene **18** (6.7 g, 54% yield); ir: 2960, 1569, 1507, 1256, and 1048 cm^{-1}; ^{1}Hmr δ: 5.88, 5.30 (both m, total 2H, -CH=CH-), 4.07 (br s, 2H, =CH_2), 1.80 (m, 3H, =CH—CH_3), and 0.18 (s, 9H, -$Si(CH_3)_3$); ms M^+: 156.0968 (calcd. for $C_8H_{16}OSi$: 156.0971).

*8aβ-Carbomethoxy-8β-methyl-2,3,4,4aβ,5,7,8,8a-octahydro-1,6-naphthalenedione (**19**) and 8aβ-carbomethoxy-8α-methyl-2,3,4,4aβ,5,7,8,8a-octahydro-1,6-naphthalenedione (**20**)*

Enone ester **5** (179 mg, 1.16 mmol) was dissolved in ether (5 mL) and cooled to −30°C. *trans*-2-Trimethylsilyloxy-1,3-pentadiene (**18**) (560 mg, 3.59 mmol) and anhydrous stannic chloride (151 mg, 0.58 mmol) were sequentially added. After stirring at −30°C under an atmosphere of nitrogen for 4.5 h, the reaction mixture was warmed to room temperature and water was added. The resulting mixture was extracted with methylene chloride. The organic extracts were combined, dried, filtered, and concentrated and the crude residue was purified by flash chromatography. Elution with 10% ethyl acetate in petroleum ether gave a mixture of keto esters **19** and **20** (86 mg, 45% yield). The ^{1}Hmr spectrum of the mixture showed two sets of signals in an integral ratio of 10:3. The major set, assigned to **19**, showed signals at δ 3.73 (s, 3H, -$COOCH_3$) and 0.90 (d, J = 7.0 Hz, -CH—CH_3). The minor set, assigned to **20**, showed signals at δ 3.82 (s, 3H, -$COOCH_3$) and 1.15 (d, 3H, -CH—CH_3). The mixture of keto esters **19** and **20** also showed the following spectral data: ir: 1740 (ester C=O) and 1714 (ketone C=O) cm^{-1}; ms M^+: 238.1205 (calcd. for $C_{13}H_{22}O_4$: 238.1205).

6,6-Ethylenedithio-8aβ-carbomethoxy-3,4,4aβ,5,6,7,8,8a-octahydro-1(2H)-naphthalenone, mixture of thioketals 28

To a solution of a 10:3 mixture of **19** and **20** (171 mg, 0.72 mmol) in methylene chloride (5 mL) at 0°C were sequentially added 1,2-ethanedithiol (339 mg, 3.60 mmol) and boron trifluoride etherate (112 mg, 0.79 mmol). After stirring under an atmosphere of argon for 25 min, ice-cold 2.0 N aqueous sodium hydroxide solution was added and the resulting mixture was extracted with methylene chloride. The organic extracts were washed with water, dried, filtered, and concentrated. Column chromatography of the residue on silica gel, eluting with 20% ether in *n*-hexane, gave a 10:3 mixture of thioketals **28** (137 mg, 74% yield, based on consumed starting material). The ^{1}Hmr spectrum showed two sets of signals in an integral ratio of 10:3 and showed signals at δ: 3.80, 3.74 (each s, total 3H, -$COOCH_3$), 3.30 (complex, 4H, -SCH_2CH_2S-), 1.10, 1.02 (each d, total 3H, each J = 7.5 Hz, -CH—CH_3). The following spectral data were also recorded for the mixture of thioketals **28**: ir (film): 1740 (ester C=O) and 1713 (ketone C=O) cm^{-1}; ms M^+: 314.1008 (calcd. for $C_{15}H_{22}O_3S_2$: 314.1010). Continued elution gave a mixture of diketones **19** and **20** (31 mg, 18% recovery).

Received April 25, 1988

SHMUEL ALBERT and JOHN A. RIPMEESTER. Can. J. Chem. **66**, 3153 (1988).

^{19}F static and rotating frame spin–lattice relaxation times (T_1 and $T_{1\rho}$) as well as broadline NMR studies have been carried out on solid IF_6AsF_6 between 213 and 393 K. From the T_1– and $T_{1\rho}$–temperature behaviour, we inferred a phase transition at 350(±2) K and a supercooled high temperature phase. In both phases the second moments are consistent with a model where both IF_6^+ and AsF_6^- reorient about random axes. The T_1 and $T_{1\rho}$ data in the low temperature phase can be interpreted in terms of a single frequency factor $\tau_0 = 3.15(\pm0.2) \times 10^{-16}$ s and activation energy $E_a = 10.4(\pm0.4)$ kcal/mol for both cation and anion reorientation. At the temperature of the phase transition the ionic-reorientational frequencies become faster by ~ 2 orders of magnitude. In the high temperature phase T_1 and $T_{1\rho}$ are essentially independent of temperature which may be associated with a spin–rotation relaxation mechanism.

SHMUEL ALBERT et JOHN A. RIPMEESTER. Can. J. Chem. **66**, 3153 (1988).

Opérant à des températures allant de 213 à 393 K, on a déterminé les temps de relaxation spin–réseau statiques et de rotation du ^{19}F (T_1 et $T_{1\rho}$) et on a effectué des études rmn à bandes larges sur le IF_6AsF_6. En se basant sur le comportement des valeurs de T_1 et $T_{1\rho}$ en fonction de la température, on en a déduit qu'il existe une phase de transition à 350(±2) K ainsi qu'une phase à une température de surfusion. Dans chacune de ces phases, les moments secondaires sont en accord avec un modèle dans lequel les deux ions IF_6^+ ainsi que AsF_6^- se réorientent autour d'axes au hasard. On peut interpréter les données relatives aux T_1 et $T_{1\rho}$ de la phase à basse température en fonction d'un facteur de fréquence unique, $\tau_0 = 3{,}15(\pm0{,}2) \times 10^{-16}$ s et une énergie d'activation $E_a = 10{,}4(\pm0{,}4)$ kcal/mol pour les réorientations tant du cation que de l'anion. A la température de la transition de phase, les fréquences de la réorientation ionique augmentent par un facteur d'environ 100. Dans la phase à haute température, les valeurs de T_1 et $T_{1\rho}$ sont essentiellement indépendantes de la température qui pourrait être associée avec un mécanisme de relaxation spin–rotation.

[Traduit par la revue]

Introduction

The solid formed when AsF_5 reacts with IF_7 has been formulated as an ionic adduct consisting of discrete IF_6^+ and AsF_6^- ions (1, 2). Subsequent infrared, Raman, and powder X-ray studies (3, 4) have substantiated this suggestion. The ^{75}As NMR spectrum (5) of $IF_6^+AsF_6^-$ demonstrated that AsF_6^- ion is a regular octahedron in the room temperature solid. Mössbauer (6) and ^{127}I NMR (5) studies have shown that the IF_6^+ ion has octahedral symmetry. The room temperature crystal structure of $IF_6^+AsF_6^-$ is cubic, space group $Pa3$, with four formula units per unit cell, and a unit cell constant of 9.4935 ± 0.0005 Å (3). Magnetic field and temperature dependent ^{19}F broadline NMR studies (7) of IF_6AsF_6 have been carried out and have yielded information regarding chemical shift parameters and ionic mobility in the solid state.

To obtain further information on the cation and anion motions as well as the interactions in solid IF_6AsF_6, we have studied the temperature dependence of its ^{19}F static and rotating frame spin–lattice relaxation times, T_1 and $T_{1\rho}$, respectively. We also measured the limiting high temperature ^{19}F second moments and reevaluated them in terms of a motional model, chemical shift parameters, and ^{19}F–^{127}I indirect coupling constant.

Experimental

IF_6AsF_6 was prepared by condensing AsF_5 (Ozark Mahoning Co., Tulsa, OK) and IF_7 (Alfa Inorganic, Inc., Beverly, MA) in a cold trap using a Pyrex vacuum system. The solid mixture was allowed to react by first warming to the melting point of AsF_5, then to ~0°C. Excess reagent was removed by pumping at ~60°C. Further purification of the product was not necessary, as the 1:1 adduct is the only product (4). Portions of the solid were transferred under dry conditions to Pyrex sample tubes which were subsequently evacuated.

The ^{19}F T_1 and $T_{1\rho}$ of IF_6AsF_6 were measured between 213 and 394 K at a radio frequency of 25.3 MHz. For the $T_{1\rho}$ measurements a rf field amplitude of 9 G was utilized. The apparatus and techniques used for the measurements have been described previously (8). Broad line ^{19}F NMR spectra were recorded as first derivative of the absorption line at a frequency of 56.4 MHz. The measurements ranged between 295 K and ~360 K. The ^{19}F second moments were determined by conventional integration methods including modulation amplitude correction (8).

Results and discussion

Low temperature phase

Second moment

A line narrowing region was identified between 205 and 235 K in the plot of the ^{19}F second moment vs. temperature reported by Barr and Dunell (7). The limiting low temperature second moment data (77 to 200 K) have been interpreted in terms of a static structure (7). This is consistent with our analysis and calculations. We studied the ^{19}F NMR spectra above the line narrowing region between 295 and ~360 K, the limiting high temperature. Our second moment measured at 56.4 MHz was 2.94 ± 0.2 G^2 at 341 K. Considering the frequency of measurement our line shape and second moment are in good agreement with the experimental results of Barr and Dunell (7).

The limiting high temperature second moment, M_2, can be interpreted as a sum of the following three contributions:

[1] $M_2 = M_D + M_{IC} + M_{CS}$

where the various contributions to the ^{19}F second moment are due to: M_D, nuclear dipolar interactions partially averaged by motions of the IF_6 and AsF_6 octahedra (field independent); M_{IC}, indirect $^{127}I-^{19}F$ coupling (field independent); and M_{CS}, chemical shift difference between cationic and anionic fluorines (field dependent).

It is assumed here that the chemical shift anisotropy is averaged out by the motion.

Let us evaluate each of these second moment contributions. M_D is determined by the type of motion for which we propose a simple model. If we assume that both IF_6^+ and AsF_6^- groups reorient in a random manner such as to average out all intramolecular nuclear dipolar interactions we can calculate the second moment by taking all the fluorine nuclei to be at their respective ionic centers. Using the Van Fleck (9) second moment expression and counting contributions from ^{19}F, ^{75}As, and ^{127}I nuclei, we calculate M_D to be 1.43 G^2. It was found from solution NMR studies (10) that the $^{127}I-^{19}F$ indirect coupling is quite strong, the coupling constant being 2730 ± 15 Hz. This will contribute significantly to the field-independent ^{19}F second moment of IF_6AsF_6. This is supported by the indication that the IF_6^+ component of the spectrum has a greater line width than that of the AsF_6^- component. The second moment contribution due to indirect coupling is given by (11)

[2] $M_{IC} = (1/3)S(S+1)\sum_k A_{ik}^2$

where A_{ik} is the coupling constant between nuclei i and k expressed in gauss. Taking account only of the six $^{127}I-^{19}F$ couplings and the aforementioned coupling constant of 2730 Hz we find a M_{IC} of 0.68 G^2. We note that this is a maximum contribution for M_{IC}, as it depends on the ^{19}F spin state lifetimes. The ^{19}F spin exchange time depends on the $^{19}F-^{19}F$ dipolar interactions, and will be significantly longer in the presence of random intramolecular motion, than under rigid lattice conditions. Contributions from $^{75}As-^{19}F$ couplings are negligible.

A chemical shift difference of 143 ± 15 ppm was found (7) between the IF_6^+ and the AsF_6^- fluorines of IF_6AsF_6. This chemical shift difference yields a second moment contribution, M_{CS}, of 1.02 ± 0.2 G^2 at 56.4 MHz. The total calculated second moment, M_2, at this frequency becomes 3.13 ± 0.2 G^2, in good agreement with our experimental value of 2.94 ± 0.2 G^2.

If we extrapolate the field dependent second moment data of Barr and Dunell (7) to zero field, a field-independent second moment of ~1.9 G^2 is obtained. This value is in agreement with the field independent second moment that is determined to be 2.11 G^2 from the first two terms of eq. [1]. This implies that our motional model and analysis are consistent with the experimental results of ref. 7. Barr and Dunell (7) suggested that the 1.9 G^2 field-independent second moment corresponds to a situation where both ions reorient about more than one axis with the AsF_6^- motions more extensive than the IF_6^+ motions. However, the calculated second moments do not support this suggestion.

Spin–lattice relaxation times

The static and rotating frame ^{19}F spin–lattice relaxation times for IF_6AsF_6 are shown in Fig. 1 as semilog plots vs. inverse temperature. Both relaxation processes show exponential behavior. From the lowest temperature of measurement, T_1 and

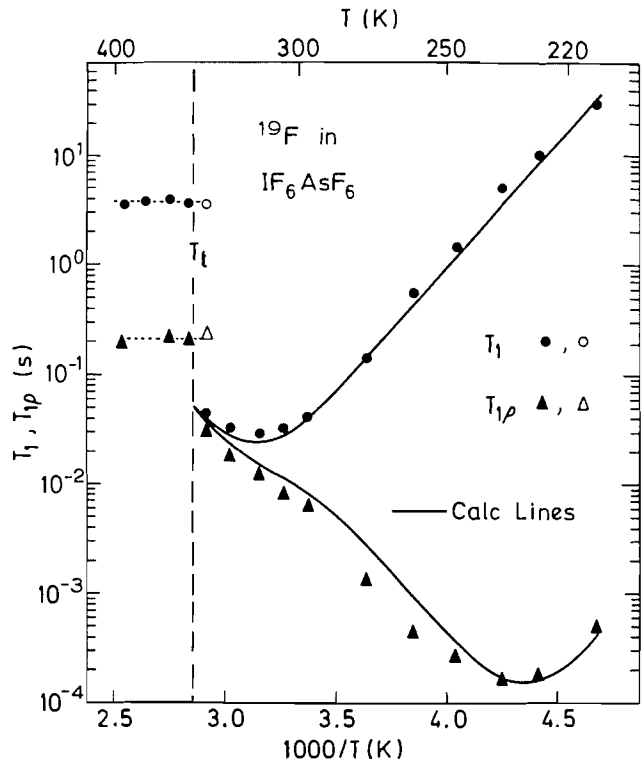

FIG. 1. A semilog plot of the ^{19}F static and rotating frame spin–lattice relaxation times, T_1 and $T_{1\rho}$, respectively, versus the inverse temperature measured at a frequency of 25.3 MHz in solid IF_6AsF_6. τ is the proposed phase transition temperature 350(±2) K. The open circle and triangle are measured in the supercooled high temperature phase. The solid curves were calculated by means of eqs. [3]–[14] as explained in the text.

$T_{1\rho}$ decrease with increasing temperature. Minima of 2.9(±0.2) × 10^{-2} and 1.6(±0.12) × 10^{-4} s are found at temperatures of 316 and 233 K for T_1 and $T_{1\rho}$, respectively. There is a discontinuity in these parameters at 350(±2) K, which we presume to be due to a phase transition.

In the low temperature phase of IF_6AsF_6 the dominant ^{19}F spin–lattice relaxation mechanism will be the modulation of the nuclear dipolar interactions by the random spherical reorientations of the IF_6^+ and AsF_6^- ions. The main contribution is from $^{19}F-^{19}F$ dipolar interactions (T_1^{FF}, $T_{1\rho}^{FF}$) and there will also be smaller contributions from $^{19}F-^{127}I$ (T_1^{FI}, $T_{1\rho}^{FI}$) and $^{19}F-^{75}As$ (T_1^{FAs}, $T_{1\rho}^{FAs}$) nuclear dipolar interactions as well as from the averaging of the chemical shift anisotropy [$(T_1)_{CSA}$, $(T_{1\rho})_{CSA}$]. We assume that the expression for T_1 can be written as a sum of these four individual contributions.

[3] $(T_1)^{-1} = (T_1^{FF})^{-1} + (T_1^{FI})^{-1} + (T_1^{FAs})^{-1} + (T_1)_{CSA}^{-1}$

According to BPP theory (12)

[4] $(T_1^{FF})^{-1} = \frac{2}{3}\gamma_F^2 \Delta M_{FF} g(\omega_F, \tau_c)$

where

[5] $g(\omega_F, \tau_c) = \tau_c/(1 + \omega_F^2\tau_c^2) + 4\tau_c/(1 + 4\omega_F^2\tau_c^2)$

In a similar vein we may write for the heteronuclear dipolar interactions (11) which give rise to the T_1^{FI} and T_1^{FAs} contributions:

[6] $(T_1^{FI})^{-1} = \frac{1}{2}\gamma_F^2 \Delta M_{FI} g(\omega_{FI}, \tau_c)$

where

$$[7]\quad g(\omega_{Fl}, \tau_c) = \tau_c/(1 + (\omega_F - \omega_l)^2\tau_c^2) + 3\tau_c/(1 + \omega_F^2\tau_c^2) + 6\tau_c/(1 + (\omega_F + \omega_l)^2\tau_c^2)$$

and $[T_1^{FAs}]^{-1}$ is obtained by substituting I for As. ΔM_{FF}, ΔM_{Fl}, and ΔM_{FAs} are the fractions of the fluorine dipolar second moment "averaged out" by the random motions of the IF_6^+ and AsF_6^- ions. The other symbols have their usual meaning. The chemical shift anisotropy contribution is given by (13)

$$[8]\quad (T_1)_{CSA}^{-1} = \frac{1}{15}\gamma_F^2 H_0^2 \Delta\sigma^2[\tau_c/(1 + \omega_F^2\tau_c^2)]$$

Similarly, $T_{1\rho}$ will be given by a sum of four contributions:

$$[9]\quad (T_{1\rho})^{-1} = (T_{1\rho}^{FF})^{-1} + (T_{1\rho}^{Fl})^{-1} + (T_{1\rho}^{FAs})^{-1} + (T_{1\rho})_{CSA}^{-1}$$

Assuming a weak collision limit we have for the nuclear dipolar interaction (14, 15)

$$[10]\quad (T_{1\rho}^{FF})^{-1} = \tfrac{2}{3}\gamma_F^2 \Delta M_{Fl} g_\rho(\omega_F, \tau_c, \omega_1)$$

$$[11]\quad (T_{1\rho}^{Fl})^{-1} = \tfrac{1}{4}\gamma_F^2 \Delta M_{Fl} g_\rho(\omega_{Fl}, \tau_c, \omega_1)$$

and $(T_{1\rho}^{FAs})^{-1}$ is obtained by substituting I for As. The spectral density functions are

$$[12]\quad g_\rho(\omega_F, \tau_c, \omega_1) = \tfrac{5}{2}\tau_c/(1 + \omega_F^2\tau_c^2) + \tau_c/(1 + 4\omega_F^2\tau_c^2) + \tfrac{3}{2}\tau_c/(1 + 4\omega_1^2\tau_c^2)$$

$$[13]\quad g_\rho(\omega_{Fl}, \tau_c, \omega_1) = 4\tau_c/(1 + \omega_1^2\tau_c^2) + \tau_c/[1 + (\omega_F - \omega_l)^2\tau_c^2] + 3\tau_c/(1 + \omega_F^2\tau_c^2) + 6\tau_c/(1 + \omega_1^2\tau_c^2) + 6\tau_c/[1 + (\omega_F^2 + \omega_l)^2\tau_c^2]$$

and $\omega_1 = \gamma H_1$.

The chemical shift anisotropy contribution is (13)

$$[14]\quad (T_{1\rho})_{CSA}^{-1} = \frac{1}{45}\gamma_F^2 H_0^2 \Delta\sigma^2[3\tau_c/(1 + \omega_F^2\tau_c^2) + 4\tau_c/(1 + \omega_1^2\tau_c^2)]$$

From the ^{19}F T_1 and $T_{1\rho}$ (Fig. 1) and second moment (ref. 7) variations with temperature it appears that the motions of both ions can be described by a single correlation time. We assume simple Arrhenius behaviour for the correlation time in terms of an inverse frequency factor, τ_0, and an activation energy, E_a, according to $\tau_c = \tau_0 \exp(E_a/RT)$. From the temperature of the T_1 minimum and the low temperature straight line portion of the semilog T_1 plot we derive values for $\tau_0 = 3.15(\pm0.2) \times 10^{-16}$ s and $E_a = 10.4(\pm0.4)$ kcal/mol. From our second moment calculations as well as Barr and Dunell's (7) we find ΔM_{FF}, ΔM_{Fl}, and ΔM_{FAs} to be 5.18, 0.95, and 0.38 G^2, respectively. An average value of the chemical shift anisotropy for the two ions of $\Delta\sigma = 333 \pm 20$ ppm, obtained by Barr and Dunell (7), was employed in the calculations of the CSA contribution to the spin–lattice relaxation times. Using these parameters and eqs. [3]–[14] we calculated the T_1 and $T_{1\rho}$ curves shown as solid lines in Fig. 1. There are some discrepancies between the calculated lines and the experimental data points at the T_1 minimum and at the high temperature side of $T_{1\rho}$ curve. To a good degree our T_1 and $T_{1\rho}$ data are consistent with the same motional parameters for both AsF_6^- and IF_6^+ ion reorientations. This is not surprising if we consider the crystal structure determined for IF_6AsF_6 at room temperature. The anions and cations are almost of equal size (considering the I—F and As—F bond lengths of ~ 1.85 Å and ~ 1.77 Å, respectively) and are arranged in an essentially close packed arrangement with six cations surrounding an anion and vice versa. The anions and cations will thus be in quite close contact, so that motions of one will affect the other. This implies that there is some degree of correlation between the motions of IF_6^+ and AsF_6^-. Correlation effects have not been taken into account in our simple motional model and this may explain the discrepancies between the calculated lines and experimental data points of Fig. 1.

Phase transition and high temperature phase

On heating IF_6AsF_6 samples from room temperature, a discontinuity in the ^{19}F T_1 and $T_{1\rho}$ behaviour was observed at 350(±2) K. The respective changes in T_1 and $T_{1\rho}$ are two and one order of magnitude. On cooling the samples from a temperature above the discontinuity point, no change in the relaxation times was noted until we reached a temperature of 329(±2) K, where both T_1 and $T_{1\rho}$ returned to their original values of the heating cycle. From this behaviour we conclude that a phase transition occurs at a temperature of 350(±2) K and that the high temperature phase supercools down to 329(±2) K. It is pertinent to point out that significant hysteresis of the phase transition temperature has also been found for $KAsF_6$ (29°C) (20) and $KSbF_6$ (38°C) (22). The T_1 and $T_{1\rho}$ times measured in the normal region of stability of the high temperature phase are shown in Fig. 1 to the left of the vertical dashed line. The T_1 and $T_{1\rho}$ measurements in the supercooled high temperature phase are presented in Fig. 1 as open circles and triangles and are consistent with the other T_1 and $T_{1\rho}$ data points in this phase.

On going through the phase transition, the line shape does not change. We measured the ^{19}F second moment as 56.4 MHz and a value of 3.32(±0.3) G^2 was obtained at 354 K, slightly larger than the second moment of 2.94(±0.2) G^2 observed in the low temperature phase. The signal-to-noise ratio attainable in this temperature region was poorer than that in the low temperature phase in accordance with the longer T_1 values. No new motions appear at the phase transition. The slightly larger second moment the high temperature phase may simply reflect the difference in the crystal structure between the high and low temperature phases, such as a change from one cubic structure to another cubic structure. The measured second moment in the high temperature phase is in good agreement with our calculated second moment of 3.13(±0.2) G^2. Accordingly, the high temperature phase is consistent with the simple motional model where both IF_6^+ and AsF_6^- reorient about random axes. The frequency of reorientation of the ions has increased by ~ 2 orders of magnitude on going from the low to the high temperature phase.

In the high temperature phase and its supercooled region the ^{19}F T_1 and $T_{1\rho}$ are essentially independent of temperature. T_1 is relatively long (~4 s) while $T_{1\rho}$ is shorter by a factor of ~20 (~0.2 s). This behaviour of T_1 and $T_{1\rho}$ can be interpreted in terms of an additional relaxation mechanism that becomes effective in the high temperature phase, with the net T_1 and $T_{1\rho}$ due to the dipolar and the additional mechanism essentially temperature independent. A possible relaxation mechanism is spin–rotation (16, 17). The fast reorientations of the octahedral IF_6^+ and AsF_6^- ions in the high temperature phase of IF_6AsF_6 may well be associated with spin–rotation relaxation. Similar behaviour of ^{19}F T_1 was found in the high temperature phases of

For personal use only.

$CsPF_6$, $RbPF_6$, and NH_4PF_6 where fast reorientations of PF_6^- ions take place (18, 19). It is of interest to note that spin–rotation relaxation also has been proposed for the high temperature phase of $KAsF_6$ as T_1 was found to decrease with increasing temperature (20). On the other hand, relaxation of the slightly larger SbF_6^- ions in the sodium and potassium salts could be explained by using dipole–dipole interactions only (21).

LEED and AES studies of chemisorption resulting from low exposures of C_2H_4, CO, and PH_3 to the (0001) surface of zirconium

J. R. LOU, P. C. WONG, AND K. A. R. MITCHELL

Department of Chemistry, University of British Columbia, 2036 Main Mall, Vancouver, B.C., Canada V6T 1Y6

Received March 30, 1988

J. R. LOU, P. C. WONG, and K. A. R. MITCHELL. Can. J. Chem. **66**, 3157 (1988).

Low-energy electron diffraction (LEED) and Auger electron spectroscopy (AES) have been used to study for the first time the chemisorption systems formed on the (0001) surface of zirconium by exposing to C_2H_4, CO, and PH_3 in the one to ten Langmuir regime. The adsorptions are done at room temperature, but there is subsequent heating to optimize the surface ordering. The main observations are as follows: (*i*) after heating C_2H_4-covered surfaces to effect hydrogen desorption, the remaining carbon can form two different ordered (1×1)-C structures; (*ii*) CO forms both (2×2)- and (1×1)-type structures; (*iii*) the temperature at which the bulk diffusion of oxygen becomes significant, as determined by AES, is about 40°C greater on a CO-treated surface than for an O_2-treated Zr(0001) surface; and (*iv*) heating a PH_3-covered surface can yield a weakly-ordered (3×3)-P structure. The observation (*iv*) contrasts with that for the analogous surface prepared previously with H_2S; the poorly developed (3×3)-P surface structure results from the fact that the temperatures required for surface ordering overlap with those which yield a loss of phosphorus from the surface region.

J. R. LOU, P. C. WONG et K. A. R. MITCHELL. Can. J. Chem. **66**, 3157 (1988).

Faisant appel à la diffraction électronique de faible énergie (LEED) et à la spectroscopie électronique de Auger (AES), on a étudié pour la première fois les systèmes de chemisorption formés à la surface (0001) du zirconium exposé au C_2H_4, au CO et au PH_3 dans l'un des dix régimes de Langmuir. On a réalisé les adsorptions à la température ambiante avec un chauffage subséquent pour optimiser l'ordonnance la surface. Les principales observations sont les suivantes : (*i*) après le chauffage des surfaces couvertes de C_2H_4, pour affecter la désorption de l'hydrogène, les atomes de carbone restants peuvent former deux différentes structures ordonnées de type (1×1)-C; (*ii*) le CO forme deux structures de type (2×2) et (1×1); (*iii*) la température à laquelle le gros de la diffusion de l'oxygène devient significative, telle que déterminée par AES, est plus élevée d'environ 40°C pour une surface traitée au CO que pour une surface de Zr(0001) traitée à l'oxygène et (*iv*) une surface couverte de PH_2 peut donner une structure P de type (3×3) faiblement ordonnée. L'observation (*iv*) contraste avec celle relative à la surface analogue préparée antérieurement avec du H_2S. La structure P de type (3×3) faiblement développée résulte du fait que la température requise pour l'agencement de la surface rejoint celles qui conduisent à une perte de phosphore à partir de la surface.

1. Introduction

Currently only very limited information is available for the structural details of well-characterized surfaces of hexagonal close packed metals after chemisorption with common reactive gas molecules. We have accordingly been undertaking a project to investigate the structural chemistry of the (0001) surface of zirconium with low-energy electron diffraction (LEED) (1–3), motivated both by some interesting early observations for the corresponding surface of titanium (4, 5) and by the general technological importance of the surface chemistry of zirconium (6, 7). Our interest in the Zr(0001) surface concentrates on the structures resulting from chemisorption, that is with coverages of the order of a monolayer formed by exposures to less than 10 Langmuir (1 L = 10^{-6} Torr s) of reactive gas.

The present paper describes the use of Auger electron spectroscopy (AES) and qualitative LEED for characterizing chemisorption systems formed by exposing a Zr(0001) surface at room temperature to C_2H_4, CO, and PH_3. It aims to provide a basis for future structural analyses, although here comparisons are made both with previous studies of the chemisorption of O_2 (2, 8), N_2 (3), and H_2S (9) on Zr(0001), and with relevant investigations for reactive adsorption on polycrystalline samples of this metal (10–13).

2. Experimental

The apparatus and cleaning procedures used were as described previously from this laboratory for a LEED crystallographic analysis for the clean Zr(0001) surface (14). Each adsorption study was made on a surface which showed a sharp (1×1) LEED pattern, with hexagonal symmetry at normal incidence, and for which no contaminants were apparent with AES measured by a cylindrical mirror analyzer. The exposures were made at room temperature, although commonly further heating was necessary to order the surface regions sufficiently for undertaking structural analyses with a diffraction technique. The experiments used high purity gases which were directed to the Zr(0001) surface via a nozzle. For various exposures of the adsorbing gas, the relative amounts of adsorbed species were assessed with appropriate Auger peak height ratios; specifically R_C, R_O, and R_P

$$R_C = A_{270}/A_{92}, \quad R_O = A_{510}/A_{92}, \quad R_P = A_{120}/A_{92}$$

for carbon, oxygen, and phosphorus respectively. In these defining equations A_{270}, A_{92}, A_{510}, and A_{120} are the Auger peak heights, respectively, for C at 270 eV, Zr at 92 eV, O at 510 eV, and overlapping P and Zr signals at 120 eV. In addition, since there are indications that the Zr Auger peak at 147 eV can be sensitive to adsorbates including hydrogen (9), we also used the peak height ratio

$$R_{Zr} = A_{147}/A_{92}$$

as a further surface monitor.

Quantitative assessments of LEED patterns, with regard to either diffracted beam intensity-versus-energy ($I(E)$) curves or spot profile analyses, were measured with a video LEED analyzer as described previously (15). After each adsorption experiment, the sample surface was cleaned by Ar^+ bombardment and re-ordered by raising the temperature to 600°C followed by immediate cooling (heating and cooling rates are approximately 1°C s^{-1}). All heating operations referred to here were done by flashing in this way to the stated temperature. The cleaned zirconium surface is characterized with $R_C = 0.00$, $R_O = 0.00$, $R_P = 0.74$, and $R_{Zr} = 1.40$.

3. Results and discussion

3.1. C_2H_4 adsorption

Exposure of a clean, ordered Zr(0001) surface to about 1 L of C_2H_4 at room temperature yielded a diffuse (1×1) LEED

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 122.72.124.2 on 09/07/12
For personal use only.

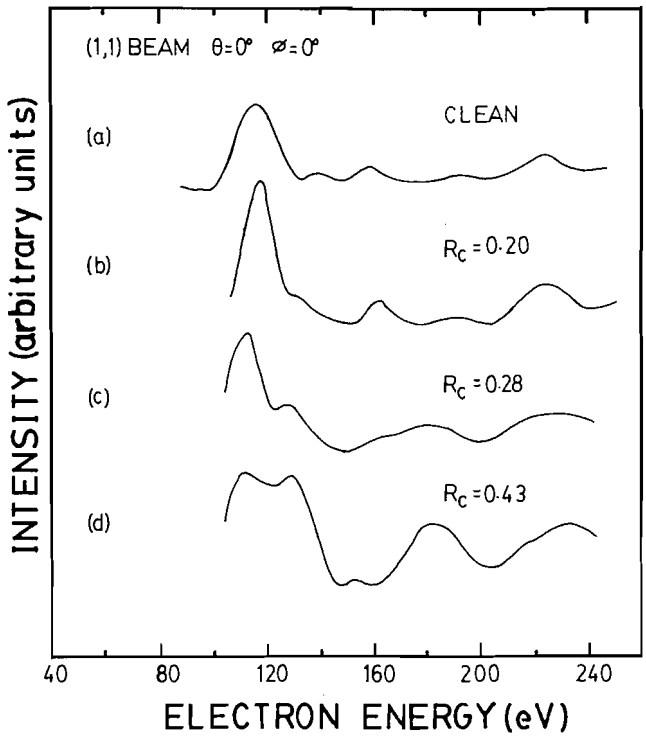

FIG. 1. Intensity-versus-energy curves for normal incidence measured for the (1,1) beam from: (*a*) clean Zr(0001); (*b*) Zr(0001)–(1×1)-C with $R_C = 0.20$ from C_2H_4 adsorption; (*c*) as (*b*) except $R_C = 0.28$; (*d*) as (*b*) except $R_C = 0.43$.

pattern with high background, and the AES results are summarized with $R_C = 0.20$ and $R_{Zr} = 1.20$. However, the latter changed to 1.34 upon heating to 400°C, an observation which, in conjunction with our previous report for H_2S chemisorption on Zr(0001) (9) and observations by Lin and Gilbert (13), appears to be associated with hydrogen desorption. With further brief heating to 470°C, a very sharp (1×1) LEED pattern was observed on cooling to room temperature; for this surface R_C and R_{Zr} remained at 0.20 and 1.34, respectively. Upon heating to above 600°C both R_C and R_{Zr} returned to the clean surface values, observations that we take to indicate the completion of hydrogen desorption and carbon diffusion to the bulk.

Similar observations were made for surfaces with a range of R_C values, which were varied according to the extent of the initial C_2H_4 exposure. Careful visual observations of the intensity distribution in the sharp (1×1) LEED patterns at normal incidence were compared with that of the clean Zr(0001) surface. As R_C was increased from zero, a new feature was established at $R_C = 0.20$, namely a bright region for the (1,1) beam between 132 and 136 eV. This differs from the clean surface where the (1,1) beam is dim for that particular energy range. This contrast is also apparent in the measured LEED $I(E)$ curves, as shown in Fig. 1.

The data in Fig. 2 give a suggestive indication from AES of carbon and hydrogen migration from the surface region. They apply to a C_2H_4-treated Zr(0001) surface for which R_C and R_{Zr} initially equal 0.33 (referred to as R_C^{init}) and 1.15, respectively; this surface was heated to a temperature T and then cooled back to room temperature for measuring the new Auger peak-height ratios (R_C^T and R_{Zr}^T). Two plots of the normalized carbon and zirconium ratios (R_C^T/R_C^{init} and $R_{Zr}^T/1.40$) obtained for successively increasing T are shown in Fig. 2. The first break in $R_{Zr}^T/1.40$ (Fig. 2(*b*)) at around 400°C appears to be associated with the desorption of hydrogen, while the second starting at 490°C results from carbon diffusion into the bulk (see Fig. 2(*a*)). The latter observation provides the basis for the choice noted above of heating to 470°C to encourage surface carbon ordering. The temperature at which the bulk diffusion of carbon becomes appreciable, according to Fig. 2, is approximately 50 and 250°C higher than the corresponding values found previously for nitrogen (3) and oxygen (8), respectively, when measured under comparable conditions.

The evolution of $I(E)$ curves from Zr(0001) surfaces which show (1×1) LEED patterns, and have increasing amounts of bonded carbon, was studied to $R_C = 0.43$, and representative curves for the (1,1) beam are given in Fig. 1. Changes from the clean surface are quite subtle until $R_C = 0.20$, but we believe that value corresponds to a well-defined (1×1)-C surface, whose structure is currently under investigation with LEED crystallography. Bigger changes occur as R_C increases beyond 0.20. With reference to the $I(E)$ curves in Fig. 1, the intensity

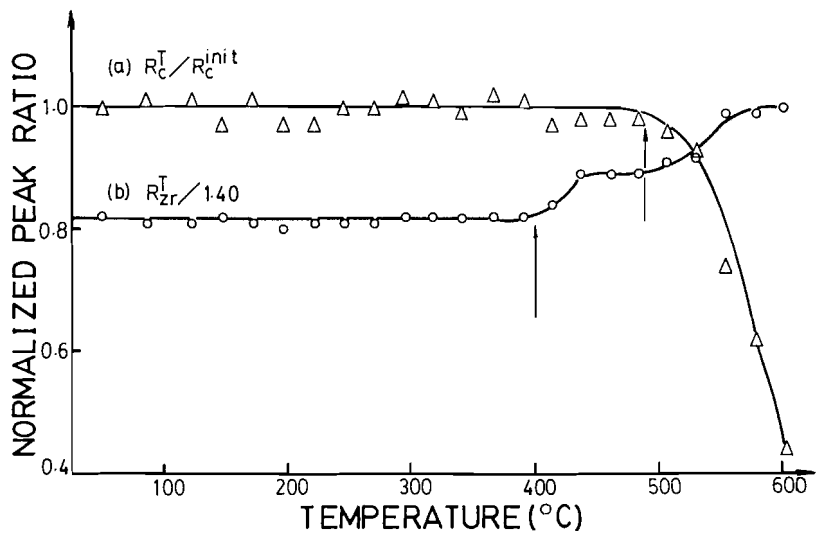

FIG. 2. Normalized Auger peak-height ratios (*a*) R_C^T/R_C^{init} and (*b*) $R_{Zr}^T/1.40$ as a function of temperature for C_2H_4 adsorbed on Zr(0001). The initial coverage corresponds to $R_C^{init} = 0.33$ and $R_{Zr}^{init} = 1.15$.

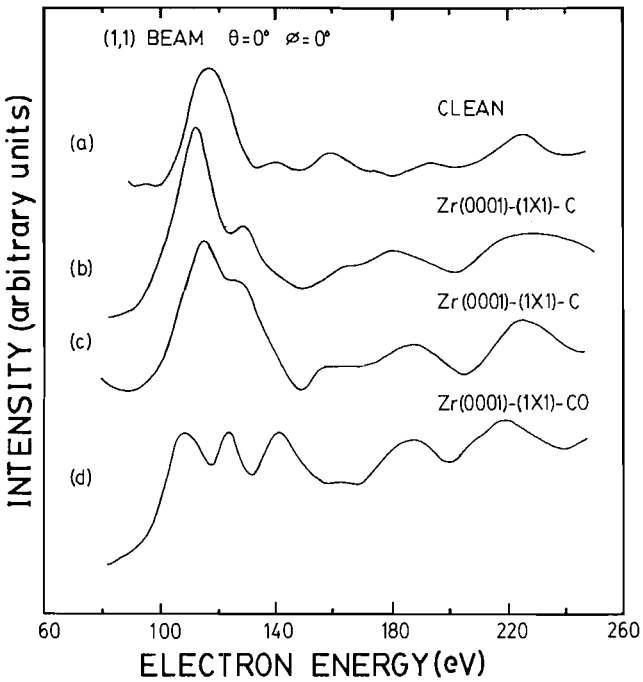

FIG. 3. Intensity-versus-energy curves for normal incidence measured for the (1,1) beam from: (*a*) clean Zr(0001); (*b*) Zr(0001)–(1×1)-C with $R_C = 0.28$ from C_2H_4 adsorption after heating; (*c*) Zr(0001)–(1×1)-C with $R_C = 0.26$ from CO adsorption after heating; (*d*) Zr(0001)–(1×1)-CO with $R_C = 0.44$ and $R_O = 0.18$.

of the carbon peak around 136 eV increases very significantly, while the peak which is at 118 eV for $R_C < 0.20$ shifts to lower energy and is reduced to 112 eV for $R_C = 0.43$. This evolution suggests a further (higher-coverage) (1×1)-C structure, although we have not studied this adsorption system beyond $R_C = 0.43$ and so we do not know whether that value completes the second structure. Nevertheless, it does correspond to a carbon coverage approximately twice that of the first (lower-coverage) (1×1)-C structure. The $I(E)$ curves measured for the intermediate coverages (e.g. $R_C = 0.28$) can be well reproduced by appropriately weighted mixtures of the curves for $R_C = 0.20$ and $R_C = 0.43$. That suggests the surfaces with intermediate coverages are made up of lower-coverage and higher-coverage (1×1) domains. By contrast, the $I(E)$ curves for $R_C = 0.28$ are not well modelled by mixtures of $I(E)$ curves for the clean and $R_C = 0.43$ surfaces, an observation which provides further support for $R_C = 0.20$ defining a completed (1×1)-C structure.

3.2. *CO adsorption*

Exposure of a clean, ordered Zr(0001) surface to about 1 L of CO at room temperature gave adsorption of both atomic constituents ($R_C = 0.28$, $R_O = 0.10$), but no extra LEED beams were immediately detectable. However, a poorly developed (2×2) pattern was observed on heating to 240°C, although on heating to 300°C the surface became depleted of oxygen and showed a sharp (1×1) LEED pattern. With greater initial exposures to CO only (1×1) patterns were found, and these patterns were best established after heating to 270°C. The $I(E)$ curve measured from such a Zr(0001)–(1×1)-CO surface ($R_C = 0.44$, $R_O = 0.18$) for the (1,1) beam at normal incidence is included in Fig. 3. This curve differs from the corresponding curves measured from either clean Zr(0001) or from the (1×1)-C structures; indeed it is also not adequately reproduced by weighted averages of measured curves from the (1×1)-O and (1×1)-C structures, and therefore it appears to identify a new ordered surface.

The onset of the effective surface depletion of both carbon and oxygen was assessed by following R_C and R_O values at room temperature after heating to progressively higher temperatures as described in 3.1. The data in Fig. 4 apply to a surface which was initially characterized with $R_C = 0.36$, $R_O = 0.18$; there is an initial depletion at around 120°C which appears to be associated with CO desorption (10). By contrast the bulk diffusion of oxygen and carbon becomes significant near to 270 and 490°C, respectively; interestingly the former value is increased by about 40°C over that measured previously for the Zr(0001)–O system (8), thereby suggesting the presence of some attractive C...O interactions within the surface region.

When the temperature of an ordered CO-treated (1×1) surface with $R_C = 0.44$, $R_O = 0.18$ is raised to 485°C and immediately cooled, it yields a surface which is characterized by $R_C = 0.26$, $R_O = 0.00$ and shows a sharp (1×1)-C LEED pattern. The $I(E)$ curves for this surface preparation can be

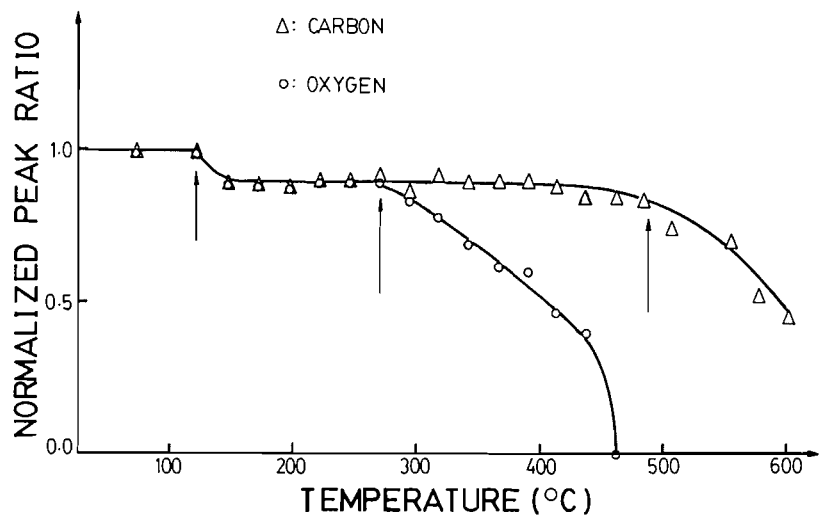

FIG. 4. Normalized Auger peak-height ratios as a function of temperature for both carbon and oxygen. The initial surface of Zr(0001) is characterized with $R_C = 0.36$ and $R_O = 0.18$ after exposure to CO.

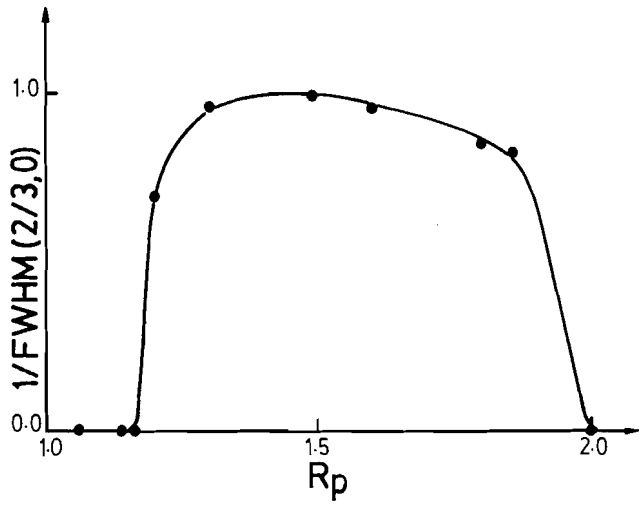

FIG. 5. Variation for a Zr(0001)–(3×3)-P surface of normalized 1/FWHM for the (2/3,0) beam at 92 eV as a function of phosphorus coverage resulting from increasing exposures to PH_3.

similar to those prepared from the adsorption of C_2H_4 as indicated in Fig. 3. When the surface with $R_C = 0.26$, $R_O = 0.00$ was re-exposed to oxygen, heated to 240°C, and cooled to room temperature, a faint (2×2) LEED pattern could be recovered. Since there is no evidence for carbon (Section 3.1), like nitrogen (3), forming a (2×2)-type structure on Zr(0001), it is natural to associate the existence of (2×2) patterns formed from CO adsorption especially with the presence of oxygen. Previous work has shown that oxygen forms (2×2)-type LEED patterns on Zr(0001) over the range of R_O values from 0.09 to 0.23 (8). Incidentally both (2×2) and (1×1) LEED patterns have also been observed with CO adsorption at Ti(0001) (16). Further, since oxygen has a strong tendency to form underlayer structures at both the (0001) surfaces of zirconium (2) and titanium (17), it is possible that the carbon plus oxygen structures involve oxygen beneath the carbon layer. Nevertheless the reverse is also possible (18); clearly this is a topic for further investigation with LEED crystallography and other structural probes.

3.3 PH_3 adsorption

AES shows that PH_3 readily adsorbs at room temperature on clean ordered Zr(0001) surfaces, although only diffuse (1×1) LEED patterns are found for exposures in the range 1–10 L. An initial empirical testing indicated that surfaces with $R_P > 2.0$ need heating to 555°C in order to get (3×3)-P LEED patterns on cooling back to room temperature, by which stage R_P is typically reduced to between 1.3 and 1.6. Such patterns were still found to be diffuse, and, unlike our experience with H_2S (9), it was not possible to measure $I(E)$ curves over a sufficiently useful energy range. Nevertheless some initial indications of the ordering process could be obtained by measuring the spot profiles with our video LEED analyzer. Figure 5 reports measurements of the reciprocal of beam width (defined as full-width at half-maximum (FWHM) height) for the (2/3,0) beam at 92 eV as a function of R_P. After each exposure to PH_3, the sample was heated to 555°C and cooled to room temperature before measuring R_P and 1/FWHM. Variation of the beam widths reflect variation in the size of the ordered regions that contribute to the (3×3) structure; specifically, larger values of 1/FWHM correspond to larger ordered regions (19).

Figure 6 reports measurements made with a PH_3-treated surface, for which the initial R_P value was 2.5. This assesses conditions both for phosphorus depletion from the surface region, as well as for the formation of (3×3) LEED patterns (the information in Fig. 6(*b*) complements that in Fig. 5). The initial depletion at around 100°C probably relates to PH_3 desorption, although the larger depletion in R_P which starts at 360°C may be associated with the desorption of hydrogen (either free or in combination with phosphorus). The latter step, judging by the 1/FWHM curves in Fig. 6(*b*), appears to initiate the (3×3)-P ordering which starts at around 420°C, although by 480°C there is a further phosphorus loss. In principle the latter could involve either bulk diffusion or desorption from the surface. Given that a similar effect is not observed for sulphur below 600°C (9), and that atomic phosphorus has a comparatively high bonding capability, the phosphorus loss starting at 480°C possibly relates to the desorption of species like P_4 or P_2 from the surface. Certainly this phosphorus loss, from whichever mechanism, acts in opposition to the formation

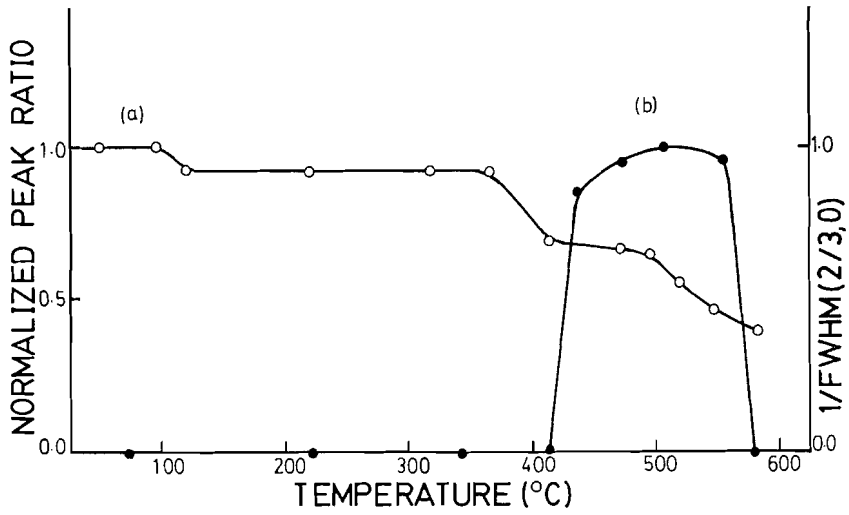

FIG. 6. (*a*) Normalized Auger peak-height ratio for phosphorus as a function of temperature. The initial Zr(0001) surface has been exposed to sufficient PH_3 to make the R_P value equal to 2.5. (*b*) Variation of normalized 1/FWHM for the (2/3,0) beam in the (3×3) LEED pattern at 92 eV for the same conditions as in (*a*).

of well-ordered (3×3)-P surface structures, although Fig. 6 does suggest that the latter may be optimized by heating at around 470°C. Also, for forming ordered structures, there may be advantages in introducing phosphorus to the Zr(0001) surface from a pure source rather than from PH_3. Such possibilities are to be investigated in further studies.

4. Concluding remarks

This paper reports the first study of the interaction between a clean and ordered (0001) surface of zirconium and the adsorbing gases C_2H_4, CO, and PH_3. All exposures are of the order of one L, and the emphasis is particularly to provide background information prior to making structural analyses with LEED crystallography. For this purpose it is important to identify optimal procedures for surface preparation, and this is done by following changes with exposure and heating in both AES and qualitative LEED patterns. An assumption is that the trends in Auger peak height ratios follow variations in surface concentrations, although strictly that requires the shape of the basic Auger peak to be constant (20). That peak shape effects (21) can occur is included in the assumption that some changes (e.g. in R_{Zr}) follow changes in hydrogen concentration. The desorption of hydrogen from polycrystalline zirconium at around 400°C has previously been recognized mass spectrometrically (13), and that emphasizes that additional characterization procedures (e.g. thermal desorption spectroscopy) would have been helpful for identifying desorbing species in the present work.

The reduced tendency for carbon to migrate below the Zr(0001) surface compared with nitrogen and oxygen reinforces previous estimates of bulk diffusion coefficients made by Foord *et al.* (10). The evolution of $I(E)$ curves after carbon adsorption suggests the existence of three successive (1×1) surfaces (including the clean surface), a feature that has not to our knowledge been reported previously. Another new structure designated Zr(0001)–(1×1)-C+O may involve underlayer oxygen, although we were not able to draw conclusions for the corresponding (2×2)-type structure. The poorly defined Zr(0001)–(3×3)-P surface recognized here likely has the same basic structure as that of the better ordered Zr(0001)–(3×3)-S system prepared previously (9). However, the ready loss of phosphorus from the former, compared with sulphur in its structure, apparently indicates that the limit to good ordering is set by ease of desorption, a condition which in turn may suggest that the surface structure is based on a phosphorus overlayer, rather than a phosphide-type (i.e. mixed Zr–P) region. Such clues are important in setting priorities for approaching the expensive multiple-scattering calculations required in the LEED structural analyses, especially for Zr(0001)–(3×3)-S.

Cyclopalladation of trimesitylarsine. The X-ray crystal structure for $[Pd(Asmes_2C_6H_2(CH_3)_2CH_2)Cl(PPh_3)]$

ELMER C. ALYEA,[1] GEORGE FERGUSON,[1] JOHN MALITO, AND BARBARA L. RUHL

Guelph-Waterloo Centre for Graduate Work in Chemistry, Guelph Campus, Department of Chemistry and Biochemistry, University of Guelph, Guelph, Ont., Canada N1G 2W1

Received May 13, 1988

ELMER C. ALYEA, GEORGE FERGUSON, JOHN MALITO, and BARBARA L. RUHL. Can. J. Chem. **66**, 3162 (1988).

The bulky trimesitylarsine ligand, $As(mes)_3$, undergoes facile cyclopalladation to yield the dimeric complex, $[Pd(Asmes_2C_6H_2(CH_3)_2CH_2)Cl]_2$, characterized by microanalysis, IR and ^1H NMR spectroscopy. This complex is very stable but readily undergoes bridge-cleavage reactions with tertiary phosphine ligands having ligand cone angles less than 170°. The crystal structure for the PPh_3 bridge-cleavage product is reported. This complex, $[Pd(Asmes_2C_6H_2(CH_3)_2CH_2)Cl(PPh_3)]$ is monoclinic, space group $P2_1/c$ with $a = 20.469(2)$, $b = 12.702(2)$, $c = 15.401(4)$ Å, $\beta = 98.46(1)°$, $V = 3961$ Å^3, $Z = 4$, $R = 0.0284$ and $R_w = 0.0305$. The Pd geometry is distorted square-planar with principal dimensions, Pd—Cl 2.395(1), Pd—P 2.318(1), Pd—C 2.056(3), and Pd—As 2.437(1) Å; As—Pd—Cl 96.5(1), Cl—Pd—P 90.9(1), P—Pd—C 93.7(1), As—Pd—C 78.9(1), As—Pd—P 172.6(1), and Cl—Pd—C 171.7(1)°. The average C—P—C angle (104.3(1)°) is smaller than expected and is rationalized on the basis of steric effects operative within the complex.

ELMER C. ALYEA, GEORGE FERGUSON, JOHN MALITO et BARBARA L. RUHL. Can. J. Chem. **66**, 3162 (1988).

Le ligand encombrant trimésitylarsine, $As(mes)_3$, subit une cyclopalladation facile conduisant au complexe dimère, $[Pd(Asmes_2C_6H_2(CH_3)_2CH_2)Cl]_2$, qui a été caractérisé par des microanalyses et par spectroscopie IR et RMN du ^1H. Ce complexe est très stable; toutefois, mis en présence de ligands phosphines tertiaires comportant des angles du cône de ligand inférieurs à 170°, il subit facilement des réactions de clivage de pont. On a déterminé la structure cristalline du produit obtenu par clivage de pont à l'aide de la PPh_3. Ce complexe, $[Pd(Asmes_2C_6H_2(CH_3)_2CH_2)Cl(PPh_3)]$, est monoclinique, groupe d'espace $P2_1/c$, avec $a = 20{,}469(2)$, $b = 12{,}702(2)$ et $c = 15{,}401(4)$ Å, $\beta = 98{,}46(1)°$, $V = 3961$ Å^3, $Z = 4$, $R = 0{,}0284$ et $R_w = 0{,}0305$. La géométrie du Pd est du type plan carré déformé et les principales dimensions du cristal sont : Pd—Cl 2,395(1), Pd—P 2,318(1), Pd—C 2,056(3) et Pd—As 2,437(1) Å; As—Pd—Cl 96,5(1), Cl—Pd—P 90,9(1), P—Pd—C 93,7(1), As—Pd—C 78,9(1), As—Pd—P 172,6(1) et Cl—Pd—C 171,7(1)°. L'angle C—P—C moyen (104,3(1)°) est plus faible que prévu et on rationalise ce fait sur la base d'effets stériques opérant à l'intérieur du complexe.

[Traduit par la revue]

Introduction

Tertiary phosphine complexes of the platinum group metals have proven valuable as homogeneous catalysts (1). Integral to the design and development of these catalysts are studies related to ligand modification affecting either or both the steric and electronic properties of the ligand in question. It has now become very clear that as the overall bulk of a tertiary phosphine ligand is increased, steric factors begin to play a dominating role often leading to new and unexpected effects (1*b*, 2, 3). For example, bulky phosphine ligands tend to promote internal metallation reactions (3, 4).

Trimesitylphosphine ($P(mes)_3$) is at the upper limit for phosphine steric bulk (2, 5) and shows transition metal chemistry dominated by steric factors (6) as does the trimesitylarsine analogue, $As(mes)_3$ (6*b*, 7). Both these ligands readily undergo relatively facile cyclopalladation and cycloplatination (8) and despite literature trends (3, 4), in each case, the former is the more facile of the two processes (8). These observations for $As(mes)_3$ are somewhat surprising in view of the limited examples of cyclometallated arsine complexes (9). Furthermore, in those cases involving platinum group metals (9, 10), only cycloplatination is observed.

We have pursued this cyclometallation chemistry of $As(mes)_3$ and in this paper, we present details for the synthesis and characterization of the stable complex, $[Pd(Asmes_2C_6H_2(CH_3)_2CH_2)Cl]_2$. We have placed special emphasis on the monomeric species produced by bridge-cleavage reactions and in particular the complex, $[Pd(Asmes_2C_6H_2(CH_3)_2CH_2)Cl(PPh_3)]$. The X-ray crystal determination for this complex appears to be the first such analysis for a cyclometallated arsine ligand.

Experimental

General

Trimesitylarsine was prepared by literature methods (11). Palladium dichloride (Johnson, Matthey and Mallory Ltd.) was used to prepare $PdCl_2(CH_3CN)_2$ by literature methods (12). All reactions were carried out under a dinitrogen atmosphere using standard Schlenk line techniques with solvents purified by standard methods.

Physical methods

Elemental analyses were performed by MHW laboratories, Phoenix, Arizona. Melting points were determined on a Gallenkamp Melting Point apparatus in unsealed capillary tubes and calibrated against a series of melting point standards. Infrared spectra (500–180 cm^{-1}) were recorded as Nujol mulls between polyethylene plates on a Perkin-Elmer 180 spectrophotometer. ^1H and ^{31}P NMR spectra were acquired on a Bruker WH-400 spectrometer operating in the pulsed FT mode at 400.13 and 161.98 MHz, respectively, at 297 K. Nuclear magnetic resonance samples were prepared in $CDCl_3$ with TMS and 80% H_3PO_4 as internal (^1H) and external (^{31}P) standards, respectively. Chemical shifts downfield of positions observed for the standards are considered positive.

Synthesis

$[Pd(Asmes_2C_6H_2(CH_3)_2CH_2)Cl]_2$

A mixture of $PdCl_2(CH_3CN)_2$ (0.080 g, 0.31 mmol) and $As(mes)_3$ (0.260 g, 0.60 mmol) in benzene (55.0 cm^3) was refluxed (20 h),

cooled, concentrated (to 10 cm^3), and *n*-hexane was added. Overnight refrigeration afforded a yellow precipitate which was isolated and recrystallized from chloroform/petroleum ether (BP 30–60°C) (1:3 v/v) to give yellow needles which were washed with cold petroleum ether and dried *in vacuo*, yield 0.16 g (94%). *Anal.* calcd. for $[Pd(Asmes_2C_6H_2(CH_3)_2CH_2)Cl]_2$: C 56.56, H 5.63; found: C 56.42, H 5.71. MP: 252–253°C (dec.).

$[Pd(Asmes_2C_6H_2(CH_3)_2CH_2)Cl(PPh_3)]$

A mixture of the dimer (0.11 g, 0.10 mmol) and triphenylphosphine (0.05 g, 0.20 mmol) was refluxed in benzene (50.0 cm^3, 1.5 h), cooled, concentrated (to 10 cm^3), and poured onto a silica-gel column (Baker 60–200 mesh, $CHCl_3/C_6H_6$, 1:1 v/v). The yellow fraction collected was reduced to dryness, washed with cold petroleum ether, and dried *in vacuo*, yield 0.14 g (84%). *Anal.* calcd. for $[Pd(Asmes_2C_6H_2(CH_3)_2CH_2)Cl(PPh_3)]$: C 64.68, H 5.67; found: C 64.51, H 5.77. MP: 238–241°C (to colourless, then black liquid).

X-ray crystallography

$[Pd(Asmes_2C_6H_2(CH_3)_2CH_2)Cl(PPh_3)]$

Pale yellow plates suitable for X-ray diffraction were grown by slow precipitation from chloroform/*n*-hexane (1:4 v/v) at ambient temperatures in the dark. Crystal data are as follows:

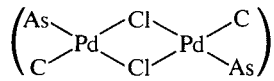
$C_{45}H_{47}AsClPPd$ $M = 835.6$

Monoclinic, $a = 20.469(2)$, $b = 12.702(2)$, $c = 15.401(4)$ Å, $\beta = 98.46(1)°$, $V = 3961$ Å, $Z = 4$, $D_c = 1.475$ g cm^{-3}, $F(000) = 1712$; MoK_α radiation, $\lambda = 0.71073$ Å, $\mu = 14.7$ cm^{-1}, space group $P2_1/c$ (from systematic absences $h0l$, $l = 2n + 1$, $0k0$, $k = 2n + 1$).

Accurate cell dimensions and crystal orientation matrix were determined on a CAD4 diffractometer by a least-squares treatment of 25 reflections with θ in the range 10–15° and an intensity data set collected to θ = 27° (see Table 1 for details). The data were corrected for Lorentz, polarization, and absorption effects and the structure solved via the Patterson heavy-atom method. Refinement was by full-matrix least-squares calculations, initially with isotropic and finally with anisotropic thermal parameters. At an intermediate stage in the refinement, a difference map showed maxima in positions consistent with the expected locations of all hydrogen atoms. In the final rounds of calculations, the hydrogen atoms were positioned on geometrical grounds (C—H 0.95 Å) and included (as riding atoms) in the structure factor calculations. A final difference map had no chemically significant features. Weights in the refinement process were derived from the counting statistics. Scattering factors and anomalous dispersion corrections were taken from refs. 13 and 14. Final fractional coordinates are given in Table 2 and details of molecular geometry are given in Table 3. All other data tables (hydrogen coordinates, thermal parameters, mean planes, structure factors) have been deposited. An ORTEP diagram of the molecule showing the crystallographic numbering scheme is in Fig. 1.

Results and discussion[2]

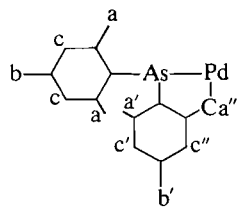
Cyclopalladation of $As(mes)_3$ seems to proceed in a similar but much slower manner than cyclopalladation of $P(mes)_3$ (8) to give the chlorobridged structure suggested by our ^1H NMR and IR data.



As^C = $Asmes_2C_6H_2(CH_3)_2CH_2$

The far-infrared spectrum shows two bands (280 and 252 cm^{-1}) assignable to the two "vibrational modes" of the bridging Pd—Cl bonds shown and there is no evidence for terminal Pd—Cl bonds. Two higher energy bands (365 and 350 cm^{-1}) have been assigned to Pd—As bonding modes. The *trans-anti* geometry shown is assigned on the basis of stereochemical arguments and solvent (8*c*) and X-ray (8*d*) studies of the related palladium and platinum complexes of $P(mes)_3$.

In comparison to the ^1H NMR spectrum for free $As(mes)_3$ (a, b, c: δ 2.12, 2.24, 6.77 ppm, relative integration 18:9:6), the spectrum for $[Pd(As\hat{}C)Cl]_2$ (a′, b′, b, a, a″, c″, c′, c: δ 1.81, 2.25, 2.34, 2.38, 3.41, 6.56, 6.74, 6.78 ppm, relative integration 3:3:6:12:2:1:1:4) indicates two types of mesitylene ring. The two proton peak at δ 3.41 ppm is diagnostic of orthometallation and the assignments made are based upon the labelling scheme given below.



We saw no evidence for formation of the 1:2 monomeric $[Pd(As(mes)_3)_2Cl_2]$ species reported earlier by other workers (15) but the 1:1 dimeric species, $[Pd(As(mes)_3)Cl_2]_2$, is observed (8*a*). This latter species undergoes facile cyclopalladation to form the more stable chlorobridged complex $[Pd(As\hat{}C)Cl]_2$. Solutions of the cyclopalladated complex are unaffected by treatment with O_2 or HX (X = H, F, Cl).

The bulky phosphine ligands, $P(t\text{-}Bu)_3$ and $P(mes)_3$ (θ = 182 and 212°, respectively) (2) will not cleave the $PdCl_2Pd$ bridge unit of $[Pd(As\hat{}C)Cl]_2$ even under rigorous reaction conditions while $P(o\text{-}tol)_3$ (θ = 194°) (2) does react with the dimer but leads to a complicated product mixture. Reaction with the less bulky PPh_3 however, leads clearly to the isolable bridge-cleavage product *trans*-$[Pd(As\hat{}C)Cl(PPh_3)]$.

The latter complex is also a stable compound in the solid state but will revert to the parent dimer over a period of weeks if left standing in solution. The far-infrared spectrum shows only one ν(Pd—Cl) band of relatively low energy at 275 cm^{-1}, consistent with this bond being *trans* to the Pd—C bond. The higher energy bands (365 and 349 cm^{-1}) attributable to Pd—As stretching modes have not shifted significantly relative to positions observed for $[Pd(As\hat{}C)Cl]_2$. The ^1H NMR spectrum (a′, b′, b, a, a″, a″, c″, c′, c: δ 1.81, 2.12, 2.28, 2.42, 2.61, 2.63, 6.11, 6.49, 6.85 ppm, relative integration

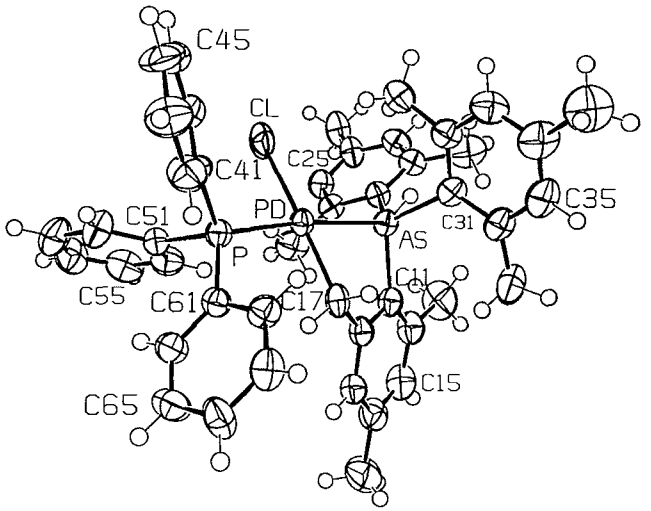

FIG. 1. A view of the [Pd(As—C)Cl(PPh_3)] complex with 50% probability ellipsoids and an indication of the numbering scheme. Phenyl ring carbons are numbered C*i*1–C*i*6 (*i* = 1–6); methyl carbons are numbered C*i*7–C*i*9 (*i* = 1–3).

3:3:6:12:1:1:1:1:4) shows the appropriate resonances due to bound PPh_3 (δ 7.63–7.58 ppm, relative integration 15). The two protons on the metallated carbon are now magnetically nonequivalent, perhaps due to the steric effects of the relatively bulky PPh_3 moiety present in a position *cis* to this carbon. Relative to the parent dimer, protons on the nonmetallated and metallated mesityl rings are more deshielded and shielded, respectively. This perhaps suggests a Pd—As bond which shortens at the expense of a lengthening Pd—C bond. That the latter should happen is reasonable since upon bridge-cleavage, the metallated carbon finds itself *trans* to a terminal rather than bridging Pd—Cl bond. Also, a steric effect induced by proximity of the relatively bulky PPh_3 ligand might be a factor here. Nevertheless, the *trans*-influence of PPh_3 is higher than that of a chloro group and one should expect an overall lengthening of the Pd—As bond upon cleavage. Unfortunately, the ν(Pd—As) positions measured for the monomer and dimer are virtually the same and do not allow a decision about which factor is dominant.

The Pd geometry in *trans*-[Pd(As⌒C)Cl(PPh_3)] (Fig. 1) is close to square-planar geometry. Deviations from the plane

defined by atoms P, Cl, As, and C(17) are P 0.063, Cl −0.055, As 0.066, C(17) −0.074, and Pd 0.067 Å. Atoms As and P have distorted tetrahedral coordination. For the As^C moiety, the average C—C ring (1.391(5) Å) and C—C methyl (1.509(5) Å) bond distances and corresponding bond angles are virtually identical to those observed for free $As(mes)_3$ (16).

The Pd—P bond length (2.318(1) Å) is shorter than those reported for *trans*-$[PdCl_2(PPh_3)_2]$ (2.337(1) Å) (17) or $[PdCl_2(PPh_3)_2]\cdot(1/2)p\text{-}C_6H_4Cl_2$ (2.349(1) Å) (18) and at the lower end of the range for *trans*-$[PdCl_2(PR_3)_2]$ complexes (2.310(5)–2.388(16) Å) (19). The average P—C bond length (1.828(3) Å), however, is exactly the same as that measured for noncoordinated PPh_3 (20) but longer than that observed for *trans*-$[PdCl_2(PPh_3)_2]$ (1.816(2) Å; range is 1.810(1)–1.820(1) Å) (17). It is worth noting that the As—C(11) bond distance (1.946(3) Å) of the metallated ring is shorter than either the As—C(21) or As—C(31) bonds and is shorter than that observed for the As—C bond distance in free $As(mes)_3$ (average 1.976(5) Å) (16). The Pd—As bond distance (2.437(1) Å) appears to be longer than that measured for the Pd—As bond distance in *trans*-$[PdCl_2(AsPh_3)_2]$, which is reported as 2.42 Å (21). Finally, the Pd—Cl bond (2.395(1) Å) is longer than those measured for other related systems (2.267(9)–2.326(4) Å) (17–19), in accord with our infrared data (see above).

The maximum cone angle measured for PPh_3 in *trans*-$[Pd(As^C)Cl(PPh_3)]$ is 154° which is comparable to a predicted value of 145° (2) in view of the different modes of measurement and the environmental dependence of ligand cone angles in general (22). In any case, the changes in C—P—C bond angles give more reliable information as to the effects of steric environment on coordinating PPh_3. The average C—P—C angle should increase upon coordination from the value (102.6°) (20) in free PPh_3 toward the ideal tetrahedral angle (109.5°). Instead, it is found to be 104.3(1)° which is smaller than the average C—P—C angle (105.0(1)°; range 104.0(1)–106.3(1)°) measured in the less sterically hindered *trans*-$[PdCl_2(PPh_3)_2]$ (17). Thus, the opening of the C—P—C angles in PPh_3 upon coordination in the bridge-cleavage of $[Pd(As^C)Cl]_2$ is effectively constrained by the crowded environment about Pd(II).

S. FLISZÁR, S. RIOUX, J. ANDZELM, C. MINICHINO, and E. C. VAUTHIER. Can. J. Chem. **66**, 3166 (1988).

The atomization energies of selected alkanes, alkyl radicals, and amines are deduced from Xα local spin density calculations of E, the total energy of a molecule in its potential minimum. Both the exchange-correlation energy, $\alpha(\partial E/\partial\alpha)$, and $\partial E/\partial\alpha$ itself obey, in a first approximation, simple atom-by-atom additivity rules. The appropriate α's for use in Xα(LSD) calculations of organic molecules thus appear as weighted averages and depend on the particular composition of each molecule. The at least approximate validity of this averaging procedure is illustrated by the accuracy of calculated atomization energies.

S. FLISZÁR, S. RIOUX, J. ANDZELM, C. MINICHINO et E. C. VAUTHIER. Can. J. Chem. **66**, 3166 (1988).

On a déduit les énergies d'atomisation d'une série d'alcanes, de radicaux alkyles et d'amines à partir des calculs de E, l'énergie totale d'une molécule à son minimum de potentiel, basés sur la densité locale de spin Xα. L'énergie totale de corrélation-échange $\alpha(\partial E/\partial\alpha)$ et $\partial E/\partial\alpha$ lui-même suivent, en première approximation une simple règle d'additivité atome-par-atome. Les valeurs appropriées de α utilisées dans les calculs de Xα(LSD) des molécules organiques sont des moyennes pondérées et dépendent de la composition particulière de chaque molécule. La précision des énergies d'atomisation calculées illustre pour le moins la validité approximative de cette procédure.

[Traduit par la revue]

Introduction

By far the most useful non-empirical alternatives to configuration interaction calculations are the methods rooted in density functional theory (DFT) (1, 2). Building on their success in numerous applications to inorganic chemistry (3), an area where the familiar wave function methods rapidly sink under the burden of formidable computational demands, we examine here the applicability of DFT to the "simpler" organic systems, particularly to the study of their atomization energies, keeping in mind that any presently known density functional approach involves approximations. The tests are meaningful in that they are conducted at a very demanding level, that approaching experimental accuracy.

Here we use the local spin density (LSD) approximation (4) and expand the molecular orbitals as a linear combination of gaussian type orbitals (LCGTO) for solving the LSD equations. The specific form of the latter depends on the treatment of exchange and correlation in electron-gas calculations. The Xα approach yields the following exchange energy (2, 5)

$$E_{X\alpha} = -\frac{3}{4}\alpha\left(\frac{81}{8\pi}\right)^{1/3}\int\rho(1)^{4/3}\mathrm{d}v_1$$

where α is treated as a variable parameter. The tentative hypothesis is that the LCGTO-Xα(LSD) method basically meets the required demands of accuracy. In other words, we assume that the energy should be right if α is properly selected.

This is where the problem lies. Ever since the appearance of the Xα method, the way of selecting α has been a fundamental problem. In this work we focus attention on this particular topic. On the basis of regularities which are observed for exchange-correlation energies, we develop a recipe permitting valid estimates of α and, thus, an assessment of the possibilities offered by LCGTO-Xα(LSD) calculations. Momentarily we concentrate on the description of this recipe and illustrate our approach with results obtained for a representative collection of saturated hydrocarbons, alkyl radicals, and amines. Extensions to other systems are contemplated at a later stage, e.g., to organic molecules containing oxygen.

The calculations are made for molecules at 0 K when all the atoms are stationary in their equilibrium positions. The total ground state energy is then

$$[1]\quad E = \sum_i E_i^{\mathrm{atom}} - \Delta E_a^*$$

where E_i^{atom} is the ground state energy of the isolated atom i and ΔE_a^* the atomization energy of that molecule. E is the target of our LCGTO-Xα(LSD) calculations. ΔE_a^* is convenient for comparisons with experimental results.

The evaluation of ΔE_a^* and E from experimental data

The energy of an isolated atom, E^{atom}, is taken (with the appropriate change in sign) as the sum of its ionization potentials. With the conversion factor 1 hartree = 27.2106 eV, we obtain from the tabulation given by Moore (6) $E_C^{\mathrm{atom}} = -37.8558$, $E_N^{\mathrm{atom}} = -54.6121$, and $E_H^{\mathrm{atom}} = -0.5$ au. These energies are used in calculations of E, eq. [1], together with the appropriate experimental ΔE_a^* results. The latter are deduced from eq. [2] (7)

$$[2]\quad \Delta E_a^* = \sum_i n_i[\Delta H_f^0(A_i) - \tfrac{5}{2}RT] + \mathrm{ZPE} + (H_T - H_0) - \Delta H_f^0$$

where ΔH_f^0 is the standard enthalpy of formation of the molecule in the gas phase and $\Delta H_f^0(A_i)$ that of the isolated atom A_i, with n_i = number of atoms A_i found in the molecule. We have used (8) $\Delta H_f^0(H) = 52.09$, $\Delta H_f^0(C) = 170.89$, and $\Delta H_f^0(N) = 113.0$ kcal atg^{-1}. ZPE is the zero point energy of the molecule (usually evaluated in the harmonic oscillator

Printed in Canada / Imprimé au Canada

For personal use only.

approximation) and $(H_T - H_0)$ its heat content. Most of the ZPE + $(H_T - H_0)$ and ΔE_a^* results considered in this work are conveniently tabulated elsewhere (7, 9, 10). The most important source of errors accompanying the evaluation of ΔE_a^* and, thus, of E originates in the experimental uncertainty associated with ΔH_f^0. Possible errors associated with ZPE + $(H_T - H_0)$ are expected (10) not to exceed ~0.2 kcal mol^{-1}.

Outline of LCGTO-Xα(LSD) calculations (11, 12)

The calculations were performed using the program developed by Dunlap, Connolly, and Sabin (12). Huzinaga's $(9s5p)$ basis (13) was used for carbon and nitrogen. Hydrogen was described by a $(5s)$ basis obtained from Dunning's $(3s)$ basis set (14). In this Xα method it is necessary to fit the charge density and the exchange potentials to sets of auxiliary Hermite gaussian functions. The Xα exchange potentials were fitted to the auxiliary functions following the criterion given by Dunlap *et al.* (12), i.e.,

$$\int \rho(\widetilde{\rho^{1/3}})d\tau = \int (\widetilde{\rho^{1/3}})^4 d\tau$$

where the tilde represents a fitted quantity. The sampling points for the exchange potentials were determined by taking each tenth point of the Herman–Skillman radial mesh (15) and an angular mesh consisting of the twelve vertices of a regular icosahedron (16). The selected auxiliary functions were $(9s5p3d)$ for carbon and nitrogen and $(5s5p)$ for hydrogen. Two s-type bond-centered auxiliary functions were also used, as suggested by Dunlap *et al.* (12).

The final value obtained for E, the energy of a molecule, obviously depends on α, where $\partial E/\partial\alpha = \partial E_{X\alpha}/\partial\alpha$ and

$$[3] \quad \frac{\partial E}{\partial \alpha} = \frac{E_{X\alpha}}{\alpha}$$

Now we turn our attention to this important point.

The selection of α

Slater's original treatment (17) of the exchange potential amounts to taking $\alpha = 1$ but Gáspár (5) and later Kohn and Sham (2) showed that $\alpha = 2/3$ is more appropriate. The more recent treatment of the exchange-correlation potential by Gáspár and Nagy (18) represents a generalization of the Slater and Gáspár–Kohn–Sham approaches and contains those as special cases. The theoretical α's deduced by Gáspár and Nagy are intermediate between 2/3 and 1. They offer a justification for the value $\alpha \simeq 0.7$ advocated by Baerends and Ros (19) for molecular calculations. For the calculation of accurate atomization energies, however, "approximate" α values are clearly insufficient because even a relatively minor error, $\Delta\alpha$, accompanying the selection of α results in a sizeable error, $\Delta\alpha(\partial E/\partial\alpha) = \Delta\alpha(E_{X\alpha}/\alpha)$, in the evaluation of E.

With this idea in mind, we examine first the α values which would duplicate the experimental energies, eq. [1]. Second, we examine the possibility of constructing these α's in a simple manner on the basis of structural features. Our approach is illustrated by means of a representative collection of molecules. Table 1 indicates (*i*) their total energies, E, obtained from eqs. [1] and [2] and the appropriate experimental data, (*ii*) the α values which duplicate these energies, and (*iii*) the corresponding $\partial E/\partial\alpha$ results, eq. [3]. Experimental geometries were used throughout the LCGTO-Xα(LSD) calculations of the alkanes and amines but additional verifications have indicated that equally consistent results can be obtained with the systematic use of theoretical (STO-3G and 4-31G) geometries. The geometries of the radicals were derived from 4-31G computations. For each molecule we have calculated the total Xα(LSD) energy using an initial guess, α^0, for α. This yields an approximate value of E, namely $E^0 = E^0(\alpha^0)$. Next, we have estimated an improved α value, $\alpha = \alpha^0 + \Delta\alpha$, using the experimental E of Table 1 and the formula

$$[4] \quad E = E^0 + \Delta\alpha(\partial E/\partial\alpha)$$

and repeated the procedure until convergence was attained. In practice, with a little experience as regards the initial guess, two calculations suffice. We tentatively proceed with the idea that, under proper circumstances, Xα-LSD calculation effectively mimic correlated calculations, although there is presently no formal justification for this contention.

The α's obtained for the individual molecules listed in Table 1 differ significantly from one another. Indeed, a recalculation using one single α value for the alkanes and the alkyl radicals, namely the best possible one, 0.778, leads to sizeable errors,

TABLE 1. Experimental energies (hartree) and corresponding α and $\partial E/\partial\alpha$ values of selected molecules[a]

Molecule	E	α	$\partial E/\partial\alpha$

[a]The energy of spiropentane was calculated from eqs. [1] and [2] using ZPE + $(H_T - H_0)$ = 73.56 kcal mol^{-1}, obtained in the harmonic oscillator approximation from experimental frequencies (20) and ΔH_f^0 = 44.25 kcal mol^{-1} selected by Cox and Pilcher (21). The appropriate ΔE_a^* energies for the other alkanes (7) and selected alkyl radical (9) were given earlier. In addition, we have used ΔH_f^0 = 51.1 ± 1.6 (cyclopropylcarbinyl radical) (22) and 51.2 ± 1.0 kcal mol^{-1} (cyclobutyl radical) (23); their ZPE + $(H_T - H_0)$ energies were estimated at 61.26 and 61.55 kcal mol^{-1}, respectively, by subtracting 8.85 kcal mol^{-1} from the ZPE + $(H_T - H_0)$ values of the corresponding hydrocarbons, following an empirical rule described elsewhere (9). For the nitrogen compounds we have used standard ΔH_f^0 results (21) and reported values for the ZPE + $(H_T - H_0)$ energies (10). The experimental geometry (24) of azirane was used, whereas those of piperidine and pyrrolidine are calculated (STO-3G) values.

averaging 13.5 kcal mol^{-1} for the alkanes and 10.7 kcal mol^{-1} for the radicals. Clearly, we have to account for the variations of α in these classes of compounds, even though they may seem small at first sight. For the aliphatic amines, in contrast, one singla α value could do, namely α = 0.776936 (average error = 0.23 kcal mol^{-1}).

Inspection of the results (Table 1) indicates that the $\partial E/\partial\alpha$ derivatives linearly depend on the numbers of atoms of each species found in the molecule. In writing

$$[5]\quad \frac{\partial E}{\partial\alpha} = \sum_i n_i\left(\frac{\partial E_i}{\partial\alpha}\right)$$

we express the idea that $\partial E/\partial\alpha$ is, at least to a good approximation, the sum of individual atomic contributions, $\partial E_i/\partial\alpha$. Equation [5] is, indeed, satisfied with $\partial E_H/\partial\alpha = -0.437$, $\partial E_C/\partial\alpha = -7.098$, and $\partial E_N/\partial\alpha = -9.105$ au (Table 2). In addition, it appears that our exchange-correlation energies, $\alpha(\partial E/\partial\alpha)$, are also linearly related to the n_i's, i.e.,

$$[6]\quad \alpha\left(\frac{\partial E}{\partial\alpha}\right) = \sum_i n_i\alpha_i\left(\frac{\partial E_i}{\partial\alpha}\right)$$

where each $\alpha_i(\partial E_i/\partial\alpha)$ plays the role of a local "atomic" contribution to $\alpha(\partial E/\partial\alpha)$, that of atom i, α_i being the corresponding "atomic" α. The genuine Xα-LSD results are well given by eq. [6] with $\alpha_H(\partial E_H/\partial\alpha) = -0.357$, $\alpha_C(\partial E_C/\partial\alpha) = -5.484$, and $\alpha_N(\partial E_N/\partial\alpha) = -7.011$ au (Table 2). Briefly, both $\partial E/\partial\alpha$ and $\alpha(\partial E/\partial\alpha)$ satisfy, in a first approximation, simple atom-by-atom additivity rules. As a consequence, it

[a]The ΔE_a^* values are indicated with a precision which is in many cases not warranted by our actual knowledge, particularly as regards the radicals (9). They are used here primarily to facilitate recalculations without being continually bothered by rounding-off errors. None of the conclusions reached in this paper critically depends on the precision of the data given here.

follows that

$$[7]\quad \alpha = \frac{\sum_i n_i\alpha_i(\partial E_i/\partial\alpha)}{\sum_i n_i(\partial E_i/\partial\alpha)}$$

showing that the molecular α can be understood as a weighted average governed by the composition of the molecule. We shall now test eq. [7] for its appropriateness as a source of sufficiently accurate α's for use in Xα(LSD) calculations of molecular energies.

Results

Here we examine the average molecular α's deduced from eq. [7]. These are used in LCAO-Xα(LSD) computations of E. The latter, in turn, give access to ΔE_a^*, eq. [1]. The theoretical atomization energies thus obtained, using 1 hartree = 627.51 kcal mol^{-1}, are compared in Table 3 with their experimental counterparts, eq. [2]. The $\partial E_i/\partial\alpha$ values for use in eq. [7] are those indicated earlier, as they were derived from eq. [5].

A statistical data analysis indicates that $\alpha_H = 0.816235$ and $\alpha_C = 0.772651$ minimize the errors of the ΔE_a^*'s computed for the hydrocarbons. The average deviation is 0.78 kcal mol^{-1}. For the radicals and the amines we have proceeded with the

TABLE 4. A comparison between theoretical and experimental strain energies[a]

Molecule	Strain energy, kcal mol^{-1}	
	Xα(LSD)	Exptl.

Spiropentane	59.2	60.2
Piperidine	0	0
Pyrrolidine	6.8	7.1
Azirane	31.7	28.1

[a]The "model" ΔE_a^* values with reference to cyclohexane (with zero strain energy) are deduced from $(1/6)\Delta E_a^*$ of cyclohexane times the number of CH_2 groups in the cycle. Strain energy is defined in each case as the difference between the "model" ΔE_a^* and the corresponding genuine value. For spiropentane we have estimated the contribution of the quaternary carbon from spiro [5,5]undecane (7), $\Delta E_a^* = 3102.24$ kcal mol^{-1}, less 10 cyclohexane-like CH_2 groups, at 167.57 kcal mol^{-1}. The "model" ΔE_a^* of spiropentane is obtained by adding 4 cyclohexane-like CH_2 contributions to that of the quaternary carbon and the strain energy is defined as above with respect to the genuine ΔE_a^*.

same α_H and α_C parameters plus, in a first approach, $\alpha_{C\cdot} = 0.773103$ (for the radical C atom) and $\alpha_N = 0.770076$ for nitrogen. The average deviations, 2.57 and 2.95 kcal mol^{-1} for the radicals and the amines, respectively, are acceptable considering that with $\partial E/\partial\alpha$ values ranging from -8 to -40 au an error of 0.001 in the estimate of α translates into a ~5–25 kcal mol^{-1} error for ΔE_a^*. A reevaluation of the results, however, reveals a regular trend in the errors made for the aliphatic amines, from a too small ΔE_a^* for NH_3 (by 6.76 kcal mol^{-1}) to a too large ΔE_a^* for $C_4H_9NH_2$ (by $\sim 2.7 \pm 0.1$ kcal mol^{-1}). This observation prompted us to examine the possibility that the parameters determined for the hydrocarbons are perhaps not exactly transferable to other classes of compounds. This may be so on physical grounds or only appear that way as a result of approximations involved in the present form and use of Xα(LSD) theory, not to forget possible superposition errors like those discussed for conventional *ab initio* calculations of ammonia and alkylamines (25) and, more generally, for computations involving hydrogen basis sets which are not adequately balanced (26). In either event, it requires only a modest correction in order to achieve a significant improvement of the results. Using now $\alpha_{C\cdot} = 0.774589$ and $\alpha_N = 0.771777$ in eq. [7], as well as the α_H and α_C values of the alkanes, we multiply the α's thus obtained by 0.99951 (radicals) or 0.999392 (amines). The averages of the errors which are now normally distributed, meaning that they do not follow any trend with molecular size, drop to 1.35 and 0.17 kcal mol^{-1} for the radicals and the aliphatic amines, respectively (Table 3). This fine-tuning is visibly important if we desire to approach experimental results as closely as possible. On the other hand, considering the smallness of the required correction, it is also clear that eq. [7] basically represents a valid approximation for α.

A good insight is offered by the cycloalkanes C_3H_6 to C_6H_{12}. Their thermochemical stabilities reflect an important destabilizing effect, the strain energy, accompanying the shrinking of a ring. Because all these cycloalkanes have the same composition, $(CH_2)_n$, they also have the same α, eq. [7], for use in our Xα(LSD) calculations. The quality of the results (Table 4) strongly suggests that the very strained cyclopropane and the strain-free cyclohexane are, indeed, to be treated in precisely the same manner in applications of eq. [7]. This, of course, implies the persistence, even in highly strained systems, of simple additivity as far as exchange-correlation energies are concerned. A similar conclusion holds true for the nitrogen-containing small cycles.

Conclusions

Postulating that the local spin density approximation in its present LCGTO-Xα(LSD) form effectively mimics correlated calculations[1] the results obtained for a variety of organic systems indicate that, as a rule, α differs from molecule to molecule. Inspection of the results reveals that both the exchange-correlation term, $\alpha(\partial E/\partial\alpha)$, and $(\partial E/\partial\alpha)$ itself behave, at least to a good approximation, as additive properties in that they are linearly dependent on the number of atoms of each chemical species found in a molecule. As a consequence, the appropriate α's for use in Xα(LSD) calculations appear as weighted averages depending on the composition of the molecules under scrutiny. These average α's, constructed from theoretical $\alpha(\partial E/\partial\alpha)$ and $(\partial E/\partial\alpha)$ values obtained for a representative collection of molecules, lead to satisfactory evaluations of atomization energies, thus demonstrating the at least approximate validity of our averaging procedure.[2] Numerical analyses reveal that the agreement between calculated and experimental atomization energies can be further improved if the average α's deduced for the alkyl radicals and the amines are systematically reduced by 0.049 and 0.061%, respectively. A formal justification for these corrections cannot be given but their very smallness suggests that our averaging procedure is basically efficient. The deviations between calculated and experimental results are, indeed, remarkably small (0.85 kcal mol^{-1} on the average) in situations where an error of 0.001 in the evaluation of α translates into a 5–30 kcal mol^{-1} error in atomization energy. It seems thus reasonable to hope that the present results may serve as useful guidelines in the search for accurate theoretical derivations of α in molecular systems, perhaps along the lines developed by Gáspár and Nagy which represent an important step in that direction.

[1]The Xα approach in itself contains only the exchange term, but the present Xα(LSD) calculations are meant to include correlation as well. For an alternate way of effectively incorporating correlation in LSD, see ref. 27.

[2]The use of the familiar exchange parameters α_{HF} given by Schwarz (28), i.e., 0.77725 for H and 0.75928 for C, obtained from an adjustment of the statistical total energies to the Hartree–Fock total energies of the isolated atoms, is not appropriate. They do, indeed, lead to large discrepancies depending on molecular size, ranging from ~104 (CH_4) to ~486 kcal mol^{-1} (C_6H_{12}). The results can be empirically improved if the average molecular α's obtained from these atomic parameters are systematically multiplied by 1.02162, but the average error still remains large, ~8 kcal mol^{-1}.

Excess partial molar enthalpies of water in water–*tert*-butanol mixtures

YOSHIKATA KOGA

Department of Chemistry, University of British Columbia, Vancouver, B.C., Canada V6T 1Y6

This paper is dedicated to Professor Charles A. McDowell on the occasion of his seventieth birthday

Received May 19, 1988

YOSHIKATA KOGA. Can. J. Chem. **66**, 3171 (1988).

The excess partial molar enthalpies of H_2O, $H_m^E(H_2O)$, in water–*tert*-butanol mixtures were measured at 30.00, 36.75, and 40.45°. Using the values of H_m^E(TBA) of the previous work (Y. Koga, Can. J. Chem. **66**, 1187 (1988)), the excess (integral) molar enthalpies of the solution, H_m^E, were calculated at 30.00°C, and compared with the literature values. The comparison was satisfactory. From the literature values of the excess free energy, the chemical potentials of each component were evaluated for the range, $x_{TBA} > 0.1$. With the measured values of the excess partial molar enthalpies, the excess partial molar entropies were also calculated. These partial molar thermodynamic quantities and their dependence on temperature and composition clearly support the following views: (*1*) in the intermediate region, $0.1 < x_{TBA} < 0.5$, the system is very close to a critical demixing, and (*2*) in the TBA-rich region, $x_{TBA} > 0.6$, TBA molecules in the solution are in almost the same environment as in the pure liquid, while H_2O molecules lose the hydrogen bond network completely and are dispersed in the TBA liquid structure.

YOSHIKATA KOGA. Can. J. Chem. **66**, 3171 (1988).

On a mesuré les enthalpies molaires partielles en excès du H_2O, $H_m^E(H_2O)$, dans des mélanges eau–*tert*-butanol à 30,00, 36,75 et 40,45°C. Utilisant les valeurs du H_m^E(TBA) de travaux antérieurs (Y. Koga, J. Can. Chem. **66**, 1187 (1988)), on a calculé les enthalpies molaires (intégral) en excès à 30,00°C, du H_m^E en solution et on les a comparées aux valeurs existantes. La comparaison s'est révélée satisfaisante. A partir des valeurs d'énergie libre répertoriées dans la littérature, on a évalué les potentiels chimiques de chaque composante dans l'intervalle de $x_{TBA} > 0,1$. On a également calculé les entropies molaires en excès à partir des valeurs mesurées des enthalpies molaires partielles en excès. Ces quantités thermodynamiques partielles en excès, leurs relations avec la température et la composition confirment nettement les faits suivants : (*1*) dans la région intermédiaire, $0,1 < x_{TBA} < 0,5$, le système est très près de la démixion critique, et (*2*) dans la région riche en TBA, $x_{TBA} > 0,6$, les molécules de TBA en solution sont à peu près dans le même environnement que dans le liquide pur; par ailleurs, les molécules de H_2O perdent complètement le réseau de liaisons hydrogènes et se dispersent dans la structure du TBA.

[Traduit par la revue]

Introduction

In the previous papers (called paper I (1) and II (2) hereinafter), results were reported on the excess partial molar enthalpies of *tert*-butanol (TBA) in TBA–H_2O mixtures, H_m^E(TBA). While this system had been investigated previously (3, 4), it was the first time that the *partial* molar enthalpies were measured directly for the TBA–water mixtures. Generally, evaluation of these quantities is possible by differentiating the existing values of excess (integral) molar enthalpies, H_m^E. One difficulty is, however, that differentiation magnifies errors and uncertainties, and the resulting values of the partial molar enthalpies are not accurate enough for detailed discussion. Indeed, the importance and usefulness of directly measured excess partial molar enthalpies have been demonstrated some time ago for ethanol–water and methanol–water mixtures (23). Thus it was chosen to measure the excess partial molar enthalpies directly for TBA–water mixtures in papers I (1) and II (2).

The results of papers I and II provided more direct information on the nature of solute–solvent and solute–solute interactions, and indicated clearly that there were two distinct regions bounded at about $x_{TBA} = 0.07$. The values of H_m^E(TBA) at $x_{TBA} \approx 0$ and the temperature dependence showed that TBA molecules not only form hydrogen bonds towards H_2O molecules for an enthalpy gain but also induce more hydrogen bondings among the solvent H_2O molecules for an equally, if not more, substantial enthalpy gain. The latter effect has been termed "iceberg formation", or in a more recent terminology, "structure enhancement of the solvent" (5–8). It was pointed out in paper II that such an effect was long range. At $x_{TBA} \approx 0.001$, the value of H_m^E(TBA) becomes less negative than that at a lower concentration, indicating that the solute–solute interaction is apparently repulsive. This suggests that already at this concentration TBA molecules have more enthalpic difficulty in settling into the solution, i.e. the structure enhancement by a previously settled TBA molecule spans a long range. If TBA molecules are distributed randomly among H_2O molecules without any preferential association, a TBA molecule is surrounded by $(1 - x_{TBA})/x_{TBA}$ molecules of H_2O, about 1000 molecules in this case at $x_{TBA} = 0.001$. Assuming that such H_2O molecules surround in a spherical fashion, the radius, n_r, in terms of number of molecule, would be about 6, $[(4/3)\pi 6^3 = 904]$.

As x_{TBA} increases and the TBA–TBA distance, $2n_r$, becomes smaller, the apparent solute–solute repulsion increases sharply to a threshold, beyond which such an apparent enthalpic repulsion diminishes rapidly to almost zero. As to the number, k, of H_2O molecules surrounding a TBA molecule in the form of $TBA(H_2O)_k$, the above threshold values corresponded to k = 16, 20, and 23 at 26.90, 45.17, and 59.49°C, respectively (2), in comparison with k = 15–19, 21, and 21–25 for 17.5, 24, and 63°C obtained from light scattering measurements (9, 10).

In the second region, $x_{TBA} > 0.1$, the values of H_m^E(TBA) become small with almost no dependence on composition and temperature, suggesting that the environment of TBA molecules in the solution is almost the same as that in pure TBA liquid. This is not inconsistent with closeness to a probable critical demixing, as pointed out previously (11–13).

In the present work, the excess partial molar enthalpies of H_2O in the solution, $H_m^E(H_2O)$, were measured directly at 30.00, 36.75, and 40.45°C. It was not expected that the values of $H_m^E(H_2O)$ and their dependence on composition and temperature might add any qualitatively newer insight into the nature of this solution, since H_m^E(TBA) and $H_m^E(H_2O)$ are

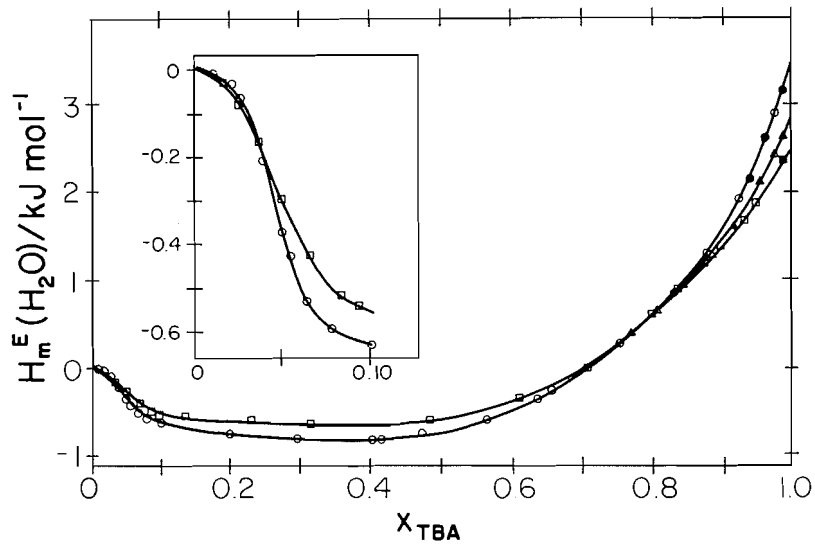

FIG. 1. The excess partial molar enthalpies of H_2O against the mole fraction. ●,○, 30.00°C; ▲,△, 36.75°C; ■,□, 40.45°C. Filled symbols, $\Delta n_{H_2O} = 0.03$ mol; open symbols, $\Delta n_{H_2O} = 0.05$ mol.

not independent, being related by the Gibbs–Duhem relation. However, the values of the measured $H_m^E(H_2O)$ together with those of $H_m^E(TBA)$ in papers I and II enable an accurate evaluation of the excess (integral) molar enthalpies, which will then be compared directly with the literature values (14, 15). This was the original purpose of the present work. It turned out, however, that the measured values of $H_m^E(H_2O)$ show a clearly different behaviour in another, the third region, $x_{TBA} > 0.6$, as will be shown below. Furthermore, an unexpectedly clearer indication was obtained for a precursor of a critical demixing in the intermediate range, $0.1 < x_{TBA} < 0.5$ when the chemical potentials were calculated from the existing excess molar free energy data (15) for the purpose of estimating the excess partial molar entropies. This will also be discussed below.

Experimental

The excess partial molar enthalpies were measured by means of an LKB Bromma 8700 precision calorimetry system, following the same procedure as described elsewhere (1, 2, 22). The results were calculated as $H_m^E(H_2O) = \Delta H/\Delta n_{H_2O}$, where ΔH is the enthalpy change of the mixture of about 100 mL due to the addition of a small amount of H_2O, Δn_{H_2O} (~0.05 mol). The above relation, $H_m^E(H_2O) = \Delta H/\Delta n_{H_2O}$, is correct if Δn_{H_2O} is sufficiently small in comparison with the total amount of the mixture. In the worst situation, i.e. at $x_{TBA} \approx 1$, where the total amount of the mixture is about 1 mol, several runs were performed with a reduced amount of H_2O increment (~0.03 mol). As shown below (Fig. 1), the data points with the two different sets of increments appear to lie on the smooth curve within the experimental error. This indicates that $\Delta n_{H_2O} = 0.05$ mol is sufficiently small for the entire concentration range. The experimental error in $H_m^E(H_2O)$ was estimated to be ± 0.015 kJ mol^{-1}.

Result and discussion

The measured values of $H_m^E(H_2O)$ are listed in Table 1 and plotted in Fig. 1. As is apparent from the figure, there is the third region, $x_{TBA} > 0.6$, where the composition dependence is different from those in the water-rich region, $x_{TBA} < 0.07$, and the intermediate region, $0.1 < x_{TBA} < 0.5$. The difference between the latter two regions was conspicuous in the composition dependence of $H_m^E(TBA)$, but the difference of the third TBA-rich region from the second intermediate region was not quite apparent in papers I and II. The excess partial molar heat capacities of H_2O, $C_p^E(H_2O)$, were calculated as $\{H_m^E(H_2O, T_1) - H_m^E(H_2O, T_2)\}/(T_1 - T_2)$ and listed in Table 2. Towards $x_{TBA} \approx 1$, the value of $H_m^E(H_2O)$ is positive, and the absolute values of $C_p^E(H_2O)$ are of the same magnitude as the heat capacity of pure H_2O with the negative sign. These may suggest that H_2O loses its hydrogen bond network completely and mixes into the solution as a single molecule. This point will be touched upon later, using the calculated excess partial molar entropies of TBA and H_2O.

Now that the values of $H_m^E(H_2O)$ and those of $H_m^E(TBA)$ at 30.00°C (2) are available, the excess (integral) molar enthalpies, H_m^E, of this solution are calculated and plotted in Fig. 2 together with the literature values (14, 15). The comparison appears satisfactory, and hence confidence can be placed on the values of $H_m^E(TBA)$ (1, 2) and those of $H_m^E(H_2O)$.

If the excess partial molar free energies of TBA and H_2O are available, the excess partial molar entropies can now be calculated. The latter quantities may shed more light on the nature of the solution. Kenttamaa *et al.* have measured among other quantities the isothermal vapour pressures of the mixtures (14). Their data, however, are spotty in terms of composition and temperature. Quitzsch *et al.* obtained isobars (16), while Okamoto *et al.* (17) measured the freezing points in a water-rich region ($x_{TBA} < 0.02$) and determined the second virial coefficient of the excess free energy. With only the second virial coefficient at 25°C, however, the excess free energies can be calculated accurately only in the very water-rich region, $x_{TBA} < 0.003$ (18). Thus all these data need various corrections to be applied before they become useful for the present purpose. On the other hand, Westmeier (15) reviewed in 1977 all the available data and compiled the best values of the excess molar free energies, G_m^E, at every 10 K from 273.15 to 373.15 K and from $x_{TBA} = 0.1$ to 0.9.

It is therefore elected to calculate the excess partial molar free energies, $G_m^E(H_2O)$ and $G_m^E(TBA)$, at 303.15 K from Westmeier's values of G_m^E for $0.1 < x_{TBA} < 0.9$. This will inevitably leave out the most interesting region, $x_{TBA} < 0.07$. More complete data are necessary for further discussion in that region.

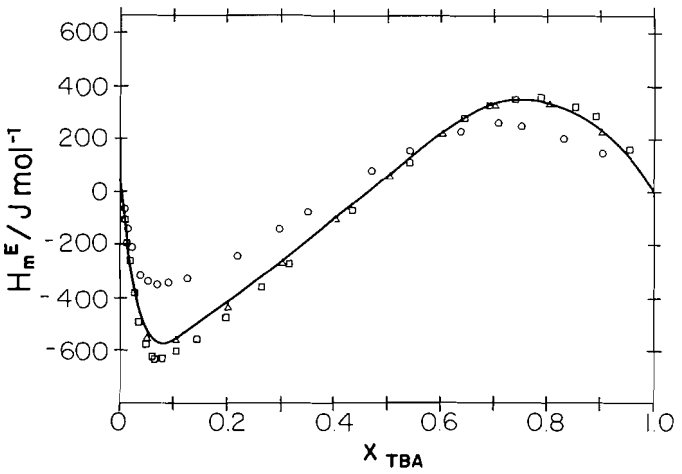

FIG. 2. The excess (integral) molar enthalpies against the mole fraction. △, Westmeier, 30°C, ref. 15; □, Kenttamaa, 26°C, ref. 14; ○, Kenttamaa, 40°C, ref. 14; smooth curve, 30.00°C, this work.

The values of G_m^E appear to vary smoothly and nearly symmetrically with composition (15). It may therefore be possible to curve-fit the following equation (19) to these data points,

$$[1] \quad G_m^E = x_{TBA}(1 - x_{TBA})\sum_j a_j(1 - 2x_{TBA})^{j-1}$$

Equation [1] serves only as an empirical formula, from which the excess partial molar free energy, $G_m^E(i)$, and the chemical potential, μ_i, (i = H_2O or TBA) can be calculated algebraically.

$$[2] \quad G_m^E(i) = G_m^E + (1 - x_i)(\partial G_m^E/\partial x_i)$$

and

$$[3] \quad \mu_i = G_m^E(i) + RT \ln x_i$$

where i = H_2O or TBA. The chemical potential for the standard states at x_i = 1.0 are taken to be zero hereinafter. The excess

FIG. 3. See text.

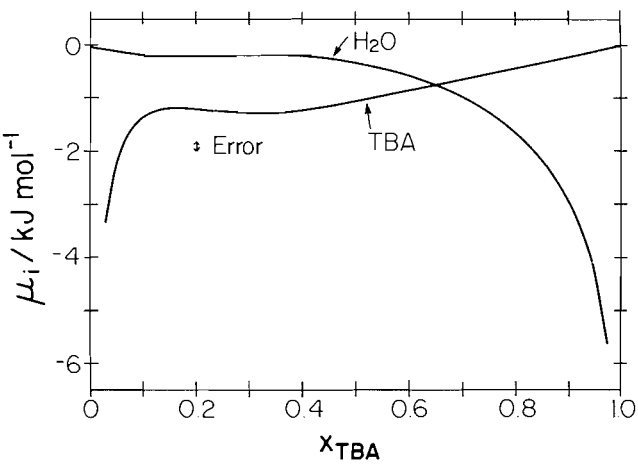

FIG. 4. Chemical potentials of TBA and H_2O against mole fraction, at 30.00°C, calculated using Westmeier's data, ref. 15. See text.

partial molar entropies, $S_m^E(i)$, are then calculated as

$$[4] \quad S_m^E(i) = \{H_m^E(i) - G_m^E(i)\}/T$$

Note in passing that, since the chemical potentials for the standard states, $x_i = 1.0$, are taken to be zero, μ_i, $G_m^E(i)$, and $S_m^E(i)$ can be written with the activity coefficients γ_i as,

$$[4b] \quad \mu_i = RT \ln x_i\gamma_i$$

$$[4c] \quad G_m^E(i) = RT \ln \gamma_i$$

and

$$[4d] \quad S_m^E(i) = -R \ln \gamma_i - RT(\partial \ln \gamma_i/\partial T)$$

Equation [1] with six terms was least-square-fitted to the data of G_m^E at 303.15 K (15). While the uncertainty of the data is quoted as ±150 J mol^{-1}, the fitted values were all within ±10 J mol^{-1} of the data. With the six coefficients of eq. [1] thus obtained, $G_m^E(i)$, μ_i, and $S_m^E(i)$ (i = H_2O or TBA) were calculated by eqs. [2], [3], and [4] and plotted in Figs. 3, 4, and 5, respectively.

In Fig. 3 are also plotted Kenttamaa's data at 25 and 50°C (14). The dotted lines at $x_{TBA} \approx 0$ are drawn using the appropriate values for the second virial coefficient taken from Perron *et al.* (20) for 25 and 50°C. As was suspected, eq. [1] with six terms is not satisfactory in the first region, $x_{TBA} < 0.07$. For further discussion in that region, more complete data for the excess partial molar free energy are necessary.

Figure 4 shows plots of chemical potential against composition. A striking feature is that in the range $0.15 < x_{TBA} < 0.4$, μ_{TBA} behaves as a three-valued function in x_{TBA} for a single value of μ_{TBA}. Although such a variation in μ_{TBA} is about the same magnitude as the estimated uncertainty, it is an indication of a phase separation, if genuine. It is, however, most likely to be an artifact due to a subtle incorrectness in the curvature of eq. [1] with the six terms in this range, since the measured concentration fluctuations are finite in the same range (9, 21). Namely, the structure factor at the zero momentum transfer, $S_{xx}(0)$, and the concentration fluctuations, $N\langle(\Delta x_i)^2\rangle$, are related to the derivative of the chemical potential as

$$[5] \quad S_{xx}(0) = N\langle(\Delta x_i)^2\rangle = RT(1 - x_i)/(\partial\mu_i/\partial x_i)$$

In Fig. 6, the values of $S_{xx}(0)$ measured by means of light scattering (9) and those obtained by small angle X-ray scattering (21) are shown together with the curve calculated by using eqs. [1], [3], and [5]. If there is a phase separation, the measured values of $S_{xx}(0)$ should be infinity. While a more complete set of data of $S_{xx}(0)$ or μ_i in this range is necessary, it seems safe to say that $S_{xx}(0)$ is large but finite. This means that μ_i is nearly but not constant in this range, suggesting closeness to a critical demixing.

Figure 5 shows the excess partial molar entropies, $S_m^E(i)$, calculated by eq. [4]. The partial molar enthalpies, $H_m^E(i)$, are also replotted. Since the data for $G_m^E(i)$ and hence those of $S_m^E(i)$ are not reliable in the first region, $x_{TBA} < 0.1$, nothing new is said about that region from the figure. For the second region, $0.1 < x_{TBA} < 0.5$, all that can be deduced from Fig. 5 have been more directly pointed out from Figs. 4 and 6. Thus the solution in this region at 30°C under the atmospheric pressure is very close to a critical demixing. In the third region, $x_{TBA} > 0.6$, the values of S_m^E(TBA) (not including the term, $-R \ln x_{TBA}$) stays zero (<1 J K^{-1} mol^{-1}) and those of H_m^E(TBA) are also nearly zero (<1 kJ mol^{-1}) with a small concentration dependence. These facts suggest that an additional TBA molecule in the solution in this composition range always settles in the environment that is almost exactly the same as in the pure liquid of TBA. On the other hand, as pointed out earlier, the values of $H_m^E(H_2O)$ and the temperature as well as the composition dependences seem to suggest that H_2O molecules lose the hydrogen bond network and are dispersed among TBA molecules as a single molecule, with a repulsion from TBA and a resulting attraction from H_2O molecules. H_2O molecules are still dispersed due to the gain in the ideal mixing entropy up to $x_{TBA} \approx 0.5$. The non-ideal part of the partial molar entropy, $S_m^E(H_2O)$, is also small (<7 J K^{-1} mol^{-1}) and almost constant as shown in Fig. 5, indicating an almost regular solution behaviour. When the concentration of H_2O increases to $x_{TBA} \approx 0.5$, the H_2O–H_2O attraction causes H_2O clusters to form possibly $TBA(H_2O)_k$ and in the second region the situation very close to a phase separation, between TBA and $TBA(H_2O)_k$, sets in.

While all these views presented here are not entirely new (3, 4), the present work provides some additional data to support such views within a limited power of the thermodynamic

quantities. Although much has been known about this solution, it appears still worthwhile to measure accurately the quantities that are proportional to the higher order derivatives of the free energy, in particular chemical potential and concentration fluctuations. Eventually it may become possible to formulate the free energy of this solution as a function of the mole fraction based on a physically reasonable model.

N. C. PAYNE, R. J. PUDDEPHATT, R. RAVINDRANATH, and I. TREURNICHT. Can. J. Chem. **66**, 3176 (1988).

Acetylide complexes of formula [*tert*-BuC≡CAu($R_2PCH_2PR_2$)], R = CH_3 (**6***a*) and C_6H_5 (**6***b*), have been prepared, and characterized by spectroscopic methods. These complexes undergo a fluxional process involving a three-coordinate Au(I) centre. Complex **6***a* dimerizes by a first-order process in chlorinated solvents, with substitution of the acetylide ligand by chloride ion, to form $[Au_2(\mu\text{-dmpm})_2]Cl_2\cdot 2H_2O$ (**7***a*). The crystal and molecular structures of **7***a* and the iodide salt **7***b* have been determined by single crystal X-ray diffraction methods. Both crystallize in the triclinic space group $P\bar{1}$ with $Z = 1$; unit cell dimensions are $a = 7.962(1)$, $b = 9.987(1)$, $c = 7.895(1)$ Å, $\alpha = 90.11$, $\beta = 109.13(1)$, and $\gamma = 112.84(1)°$ for **7***a*; $a = 8.243(1)$, $b = 9.057(1)$, $c = 8.167(1)$ Å, $\alpha = 90.23$, $\beta = 110.33(1)$, and $\gamma = 89.92(1)°$ for **7***b*. The analyses refined to final agreement factors on F of $R = 0.035$ based on 3225 unique reflections with $I > 3\sigma(I)$ for **7***a*, and $R = 0.030$ based on 2971 unique reflections with $I > 3\sigma(I)$ for **7***b*. The structures are closely related, with the cations containing an eight-membered centrosymmetric ring formed by the Au(I) centres and the bridging dmpm ligands. The Au...Au′ distances are 3.014(1) and 3.019(1) Å in **7***a* and **7***b*, respectively. In the solid state, the halide ions bridge the two Au centres, and, together with the water molecules, form a network of hydrogen bonds running at an angle of 104° to the eight-membered $Au_2P_4C_2$ rings.

N. C. PAYNE, R. J. PUDDEPHATT, R. RAVINDRANATH et I. TREURNICHT. Can. J. Chem. **66**, 3176 (1988).

On a préparé les complexes d'acétylure de formule [*tert*-BuC≡CAu($R_2PCH_2PR_2$)], dans lesquels R = CH_3 (**6***a*) et C_6H_5 (**6***b*), et on les a caractérisés par des méthodes spectroscopiques. Ces complexes subissent un processus de fluxion impliquant les centres tri-coordonnés Au(I). Dans les solvants chlorés, le complexe **6***a* se dimérise par un processus du premier ordre impliquant une substitution du ligand acétylure par l'ion chlorure et la formation de $[Au_2(\mu\text{-dmpm})_2]Cl_2\cdot 2H_2O$ (**7***a*). Faisant appel à des méthodes de diffraction des rayons-X sur un cristal unique, on a déterminé les structures tant cristallines que moléculaires des composés **7***a* ainsi que **7***b*. Chacun cristallise dans le groupe d'espace triclinique $P\bar{1}$ avec $Z = 1$; les dimensions de la maille sont $a = 7{,}962(1)$, $b = 9{,}987(1)$ et $c = 7{,}895(1)$ Å, $\alpha = 90{,}11$, $\beta = 109{,}13(1)$ et $\tau = 112{,}84(1)°$ pour **7***a* et $a = 8{,}243(1)$, $b = 9{,}057(1)$ et $c = 8{,}167(1)$ Å, $\alpha = 90{,}23$, $\beta = 110{,}33(1)$ et $\tau = 89{,}92(1)°$ pour **7***b*. Les structures ont été affinées sur F jusqu'à une valeur de $R = 0{,}035$ pour 3225 réflexions uniques avec $I > 3\sigma(I)$ pour **7***a* et jusqu'à une valeur de $R = 0{,}030$ pour 2971 réflexions uniques avec $I \geq 3\sigma(I)$ pour **7***b*. Les structures sont très apparentées alors que les cations contiennent un cycle centro-symétrique à huit chaînons formé par les centres Au(I) et les ligands dmpm qui forment le pont. Les distances Au...Au′ sont respectivement de 3,014(1) et 3,019(1) Å pour les composés **7***a* et **7***b*. A l'état solide, les ions halogénures forment un pont entre les deux centres Au et, avec les molécules d'eau, ils forment un réseau de liaisons hydrogènes avec un angle de 104° avec les cycles à huit chaînons de $Au_2P_4C_2$.

[Traduit par la revue]

Introduction

Diphosphine ligands such as $CH_2(PR_2)_2$ (R = Ph, dppm; R = Me, dmpm), $CH_2{=}C(PPh_2)_2$ (vdpp) $EtOCH_2CH(PPh_2)_2$ (edpp), or $CH_2CH_2C(PPh_2)_2$ (cdpp) are commonly used to bind two metal centres in close proximity (1–5). An interesting feature of the coordination chemistry of gold(I) with these ligands is the tendency of gold to adopt coordination number three in some cases. Known structures with dppm and related ligands are **1**–**4** (2–5).

In these complexes, the gold–halogen bonds are long and presumably weak but are still strong enough to give considerable distortion of the PAuP angle away from the normal 180° found for two-coordinate gold(I) and to have a major effect on the ^{197}Au Mössbauer parameters (2–5). In complexes **1** and **4** both gold(I) centres are three-coordinate, but the former has only terminal halides and is neutral while the latter has a bridging halide and is cationic. Complexes **2** and **3** each have one three-coordinate and one two-coordinate gold(I) centre, but in **2** the chloride ligand is approximately perpendicular to the eight-membered $Au_2P_4C_2$ ring whereas in **3** the chloride is approximately coplanar with this ring. In some cases, the structural changes are caused by subtle changes in the diphosphine ligand (e.g. **1***a*, **1***b*, **4**) (2–5). The reasons for the structures being different are not known, but the energy differences are small and the unsymmetrical complexes **2** and **3** are fluxional in solution (2–4).

We were interested in studying how the coordinating ability of the ligand X and the steric bulk of the diphosphine ligand affected the structures of complexes of the formula $\{AuX(R_2PCH_2PR_2)\}_n$ and chose to investigate the complexes with the ligand $Me_2PCH_2PMe_2$, dmpm, which is less bulky than the phenyl substituted ligands dppm, vdpp, and cdpp. Despite this lower steric effect, there was a report that the gold(I) chloride derivative possessed the ionic structure $[Au_2(\mu\text{-dmpm})_2]Cl_2$ (6) and this was confirmed during the course of the present work by an X-ray structure determination (structure **5** with very long Au..Cl distances) (7).

Experimental

^{1}H (200 MHz) and $^{31}P\{^1H\}$ NMR (121.4 MHz) were recorded using a Varian XL200 and Varian XL300 spectrometer. Chemical shifts are quoted with respect to TMS and H_3PO_4, respectively. Infrared spectra were recorded on a Bruker IR/32 FTIR spectrometer, and FAB mass spectra were recorded on a Finnigan MAT 8230 mass spectrometer. Elemental analyses were carried out by Guelph Chemical Laboratories, Guelph, Ontario. All experiments were carried out under a dry, oxygen-free dinitrogen atmosphere.

[Au(C≡C′Bu)(dmpm—P)]

To a yellow suspension of [AuC≡C′Bu] (0.350 g, 1.259 mmol) in acetone (10 mL) was added dmpm (0.1712 g, 1.257 mmol). An instant colour change from a yellow suspension to a white powder was

observed. The solution was stirred for 2 h. The white solid was filtered, dried under vacuum, and identified as [Au(C≡C^{t}Bu)(dmpm—P)]. Yield: 72%. MP: 165°C (dec); ir (Nujol): ν_{max} 2100 cm^{-1} [ν(C≡C)]; ^{1}H NMR in $CDCl_3$ at 20°C: δ1.19 (s, 9H, *t-Bu*); 1.77 (br.s, 12H, *Me*P); 2.93 (s, 2H, PCH_2P); ^{31}P{^{1}H} NMR: δ3.8 (br.s, P). ^{1}H NMR in CD_2Cl_2 at −80°C: δ1.08 (s, 9H, *t-Bu*); 1.70 and 1.88 (br.s, each 6H, *Me*P); 3.1 (m, 2H, PCH_2P). *Anal.* calcd. for $C_{11}H_{23}AuP_2$: C 31.9; H 5.60; found: C 29.8, H 5.47. Mass spectrometry: calcd. for $C_{11}H_{23}AuP_2$: *m/e* = 414; found *m/e* = 414; 333 (Parent − C≡C^{t}Bu).

[Au(C≡C'Bu)(dppm—P)]

[AuC≡C^{t}Bu] (0.2563 g, 0.922 mmol) was suspended in CH_2Cl_2 (3 mL). To this was added dppm (0.3543 g, 0.922 mmol) in CH_2Cl_2 (5 mL). After 3 h stirring, the product was precipitated by slow addition of pentane. The product was washed with diethyl ether and dried under vacuum. Yield: 68%. MP: 99°C (dec); ^{1}H NMR in CD_2Cl_2 at 20°C: δ1.25 (s, 9H, *t-Bu*); 3.25 (br.s, 2H, PCH_2P); 7.31 to 7.51 (m, 20H, PC$_6H_5$); ^{31}P{^{1}H} NMR at 20°C: —Au—P^a P^b; δ29.35 (br. s, P^a); −27.20 (br.s, P^b). Mass spectrometry calcd. for $C_{30}H_{29}AuP_2$: *m/e* = 662; found: *m/e* = 662; 384 (P − AuC≡C^{t}Bu); 278 (Parent − dppm).

[Au$_2$(μ-dmpm)$_2$]Cl$_2$·2H$_2$O

This complex was obtained by two different procedures. (*a*) To a yellow suspension of [AuC≡C*t*—Bu] (0.345 g, 1.241 mmol) in CH_2Cl_2 (10 mL) was added dmpm (0.169 g, 1.241 mmol). Immediately the solution turned milky. The solution was stirred for 3 h. On slow evaporation of solvent, colourless crystals were obtained and were characterized as [Au$_2$(μ-dmpm)$_2$]Cl$_2$·2H$_2$O. Yield: 75%. MP: 228°C (dec); ^{1}H NMR in CD_2Cl_2 at 20°C: δ1.84 (m, ^2J(PH) + ^4J(PH) = 7, 24H, *Me*P); 2.98 (quintuplet, ^2J(PH) + ^4J(PH) = 10, 4H, PCH_2P); ^{31}P{^{1}H} NMR at 20°C: δ5.6 (s, *P*). *Anal.* calcd. for $C_{10}H_{32}Au_2Cl_2O_2P_4$: C 15.53, H 4.17; found: C 15.94, H 3.85. (*b*) To a solution of [AuCl(SMe$_2$)] (0.305 g, 1.037 mmol) in CH_2Cl_2 (6 mL) was added dmpm (0.1412 g, 1.037 mmol) and the mixture was stirred for 3 h. On removal of solvents, a white solid was isolated. Yield: 70%. *Anal.* calcd. for $C_{10}H_{32}Au_2Cl_2O_2P_4$: C 15.53, H 4.17; found: C 15.30, H 3.96.

[Au$_2$(μ-dmpm)$_2$]I$_2$·2H$_2$O

A solution of NaI (0.051 g, 0.3402 mmol) in acetone (5 mL) was added to a suspension of [AuCl(SMe$_2$)] (0.1028 g, 0.3490 mmol) dissolved in acetone (5 mL). The contents were stirred at −78°C for 0.5 h. [AuI(SMe$_2$)] was then filtered into a Schlenck tube containing dmpm (0.049 g, 0.3602 mmol) and the contents were stirred at −78°C for 3 h. A pale yellow solid turning white on exposure to air was isolated. The product was washed with cyclohexane and dried under vacuum. Recrystallization in water gave colourless crystals. Yield: 60%. MP: 233°C (dec); ^{1}H NMR in CD_2Cl_2 at 20°C: δ1.71 (s, 24H, *Me*P); 2.44 (br.m, ^2J(PH) + ^4J(PH) = 8, 4H, PCH_2P); ^{31}P{^{1}H} NMR at 20°C: δ − 7.8 (s, *P*). *Anal.* calcd. for $C_{10}H_{32}Au_2I_2O_2P_4$: C 12.56, H 3.37; found: C 12.61, H 3.08. Mass spectrometry: *m/e* = 793 [P − (I, 2H$_2$O)], 657 [P − (dmpm, I)].

[Au$_2$(μ-dmpm)$_3$]Cl$_2$

To a solution of [AuCl(SMe$_2$)] (0.5114 g, 1.736 mmol) in CH_2Cl_2 (10 mL) was added dmpm (0.3544 g, 2.604 mmol). The contents were stirred for 3 h. A yellow solid was obtained which was filtered and dried under vacuum. Yield: 69%. ^{1}H NMR in CD_2Cl_2 at 20°C: δ1.76 (m, ^2J(PH) + ^4J(PH) = 8, 36H, *Me*P); 2.97 (br.m, ^2J(PH) + ^4J(PH) = 12, 6H, PCH_2P). ^{31}P{^{1}H} NMR at 20°C: δ3.24 (s, Au*P*). *Anal.* calcd. for $C_{15}H_{42}Au_2Cl_2P_6$: C 20.63, H, 4.85; found: C 20.30, H 4.86.

[Au$_2$(μ-dmpm)$_3$]I$_2$

The work-up procedure was similar to that of [Au$_2$(μ-dmpm)$_2$]I$_2$. The stoichiometries of the reagents used were as follows: NaI (0.0698 g, 0.4565 mmol). [AuCl(SMe$_2$)] (0.1029 g, 0.3493 mmol) and dmpm (0.0701 g, 0.5146 mmol). Yield: 73%. MP: 290°C (dec). ^{1}H NMR in CD_2Cl_2 at 20°C: δ1.71 (s, 36H, *Me*P); 2.40 (br.s, 6H, PCH_2P): ^{31}P{^{1}H} NMR at 20°C: δ − 8.5 (s, Au*P*). *Anal.* calcd. for $C_{15}H_{42}Au_2I_2P_6$: C 17.06, H 4.01; found: C 16.79, H 4.00.

Kinetic studies

The reaction kinetics of the conversion of the acetylide product **6***a* to chloride product **7***a* was followed by monitoring the decay of the MLCT band of **6***a*. [AuC≡C*t*—Bu(dmpm—P)] (0.0083 g, 2 × 10^{-5} *M*) was dissolved in $CHCl_3$ (10 mL) and was transferred to a 1 cm cuvette and placed in a cell compartment, thermostated at 25°C. The absorbance (at λ = 282 nm) was recorded at 20 min intervals for 5 h. Computer treatment of the data showed good first-order kinetics, with the rate constant, $k = 7.9 \times 10^{-5}$ s^{-1}.

X-ray data collection and reduction

Clear, colourless, bladed crystals of **7***a* were obtained by slow diffusion of pentane into a chloroform solution at room temperature. A preliminary photographic examination, employing Weissenberg and precession techniques, showed no symmetry other than triclinic. The crystal density was determined by neutral buoyancy in mixtures of $CHBr_3$ and CH_2Cl_2, and crystal data are summarized in Table 1.

The structure determination of **7***a* was undertaken first. Cell constants and an orientation matrix were refined from the angular settings at ±2θ for carefully centred high angle reflections (8). ω-Scans of intense low angle reflections indicated a satisfactory crystal quality (9). Intensity data were collected in two shells, employing variable scan rates within a maximum time per datum of 90 s in order to optimize counting statistics. Background estimates were made by extending the scan by 25% on each side. A Zr foil attenuator was used for extremely strong reflections. Four standard reflections were

monitored regularly. ω-Scans were again recorded after 4311 data had been collected, and, together with the standard reflections, showed no evidence for crystal deterioration.

The data were processed using the Enraf-Nonius Structure Determination Package, Version 3.0 (10), running on a PDP 11/23+ computer. Standard deviations were assigned on the basis of counting statistics, a starting value of 0.04 was chosen for *p* (11), and an absorption correction was applied (12). The equivalent reflections were averaged. In all, 3225 unique data with $I > 3\sigma(I)$ were available for solution and refinement.

Clear, colourless, bladed crystals of 7*b* were obtained by recrystallization from water solutions. Preliminary photography showed the crystals to belong to triclinic system. The crystal density was determined by neutral buoyancy in mixtures of $CHBr_3$ and 1,2-$C_2H_4Br_2$. Data collection and reduction procedure was similar to that for structure 7*a*. Again, no significant crystal deterioration occurred, and 2971 unique data with $I > 3\sigma(I)$ were available for the analysis. Full details for both studies are presented in Table 1.

Solution and refinement of the structures

7*a*: A statistical analysis of the data using the *N*(*Z*) test (13) suggested that the space group was *P*1. The positional parameters of the Au and P atoms were obtained from a three-dimensional Patterson synthesis. A series of least-square refinements and difference Fourier syntheses were used to locate the remaining six non-H atoms. At this stage it became apparent that the cation possessed a centre of symmetry, so the analysis was continued in space group $P\bar{1}$, with the cation placed on the centre at (0,0,0). Refinement of atomic parameters was by full-matrix least-squares techniques on *F*, minimizing the function $\Sigma w(|F_o| - |F_c|)^{1/2}$, where F_o and F_c are the observed and calculated structure factor amplitudes and *w*, the weighting factor, is given by $w = 4F_o/\sigma^2(F_o^2)$. Scattering factors for neutral, non-H atoms

*$U_{eq} = \frac{1}{3}\Sigma_i\Sigma_j U_{ij}\, a_i^*\, a_j^*\, \mathbf{a}_i\cdot\mathbf{a}_j$.

were taken from ref. 14, and the real components of anomalous dispersion were included for all atoms (14). Agreement factors $R_1 = \Sigma(||F_o| - |F_c||)/\Sigma|F_o| = 0.094$ and $R_2 = (\Sigma w(||F_o| - |F_c||)^2/\Sigma w|F_o|) = 0.129$ were achieved.

The 14 H atoms were located in a difference Fourier synthesis with peaks ranging from 1.4(2) to 0.7(2) e Å^{-3}, and included in ideal positions (C—H = 0.95 Å, sp^3 hybridization) in calculations of F_c, but were not refined. Positions for the methyl hydrogen atoms were optimized by a least-squares routine. The scattering factor values were taken from Stewart *et al.* (15). The hydrogen atoms on the water molecule were clearly visible in a difference Fourier, see Fig. 3. For the final cycles, positional and anisotropic thermal parameters were refined for all non-H atoms, and H atom positions were recalculated after each cycle. The model converged (3225 unique reflections for which $I > 3\sigma(I)$, 92 variables) with agreement factors $R_1 = 0.035$ and $R_2 = 0.047$.

In the final cycle no parameter shift exceeded 0.01 of its estimated standard deviation, and, with a p value of 0.06, the error in an observation of unit weight was 1.28 e. A total difference Fourier synthesis showed that the highest peak, with an electron density of 3.4(1) e Å^{-3} is situated 0.88 Å from the Au atom. A statistical analysis of R_1 and R_2 in terms of $|F_o|$, $\lambda^{-1}\sin\theta$, and classes of indices showed no unusual trends. There was no secondary extinction. Final positional and U equivalent thermal parameters for the non-H atoms are presented in Table 2. H atom parameters, anisotropic thermal parameters, selected torsion angles, weighted least-square planes, and structure amplitudes have been deposited.[2]

7*b*

Space group $P\bar{1}$ was assumed. The positional parameters of the Au atom were obtained from a three-dimensional Patterson synthesis, and the remaining eight non-H atoms were located from a series of least-squares refinements and difference Fourier syntheses. The 12 methyl H atoms were located with electron densities varying from 1.1(3) to 0.5(3) e Å^{-3}, and their idealized contributions included in the calculation of F_c; those on the water molecule could not be found. The refinement of 92 variables with 2971 unique observations ($I > 3\sigma(I)$) converged at $R_1 = 0.030$ and $R_2 = 0.054$. In the final cycle all parameter shifts were less than 0.01σ, and, with a p value of 0.06, the error in an observation of unit weight was 1.38 e. The highest peak in a difference Fourier synthesis is of electron density 1.8(1) e Å^{-3} is at a distance of 0.72 Å from the I atom. A statistical analysis of the structure factors showed no unusual trends. Final positional parameters of non-H atoms are given in Table 2. Hydrogen atom parameters, anisotropic thermal parameters, selected torsion angles and weighted least-squares planes, and structure factor amplitudes have been deposited.[2]

Results and discussion

The complexes [t-BuC≡CAuPR$_2$CH$_2$PR$_2$]

The above complexes **6***a*, R = Me and **6***b*, R = Ph were prepared by reaction of AuC≡C*t*—Bu with an equimolar amount of the corresponding diphosphine ligand. They were readily characterized by elemental analysis and mass spectroscopy and the structures were defined by the ^{1}H and ^{31}P NMR spectra. Both **6***a* and **6***b* gave a parent ion in the mass spectrum.

The complexes contain monodentate diphosphine ligands as shown by the variable temperature NMR spectra. Thus, complex **6***a* gave two *Me*P resonances in the low temperature ^{1}H NMR spectrum and **6***b* gave two ^{31}P resonances in the low temperature ^{31}P NMR spectrum. In the former case, the two resonances coalesced to a single resonance at room temperature indicating fluxionality according to eq. [1], but coalescences did not occur for **6***b* indicating slower fluxionality. The ^{31}P NMR chemical shifts for **6***b* were +29.4 ppm and −27.2 ppm, characteristic of coordinated and free phosphine atoms, respectively. Hence, in complexes **6**, it is clear that gold(I) is two-coordinate and that three-coordination occurs only in the transition state for exchange as shown in eq. [1]. Similar fluxionality of dppm ligands has been observed previously (16, 17), and monodentate phosphines also undergo exchange in gold(I) complexes, for example, the exchange of free and coordinated PMe_3 in [MeAuPMe$_3$] with PMe_3 (18).

[2]Hydrogen atom parameters, anisotropic thermal parameters, selected torsion angles and weighted least-squares planes, and structure amplitude tables for **7***a* and **7***b* may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

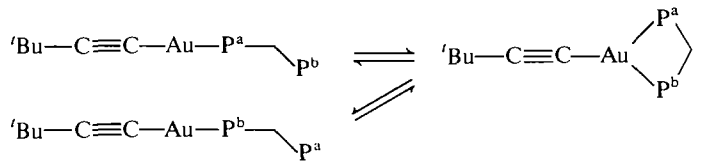
[1]



The complexes $[Au_2(\mu\text{-dmpm})_2]^{2+}$ and $[Au_2(\mu\text{-dmpm})_3]^{2+}$

The complex $[Au_2(\mu\text{-dmpm})_2]Cl_2$, **7***a*, was formed when complex **6***a* was recrystallized slowly from the chlorinated solvents $CHCl_3$ or CH_2Cl_2. Thus, although the gold–acetylide bond is usually considered strong (19), it is readily cleaved in these complexes. In $CHCl_3$ at 25°C the reaction was first order in the concentration of **6***a*, with an observed first order rate constant of 7.9×10^{-5} s^{-1}.

The complex **7***a* was prepared more rationally by reaction of $[AuCl(SMe_2)]$ with one equivalent of dmpm and, when recrystallized from $CHCl_3$/*n*-pentane, it formed the hydrate $[Au_2(\mu\text{-dmpm})_2]Cl_2 \cdot 2H_2O$, **7***a*. Similarly the iodide derivative was prepared from $[AuI(SMe_2)]$, made *in situ*, with dmpm and again it formed a hydrate $[Au_2(\mu\text{-dmpm})_2]I_2 \cdot 2H_2O$, **7***b*, when recrystallized from water. The structures of **7***a* and **7***b* were determined by X-ray diffraction methods.

Reaction of $[AuCl(SMe_2)]$ with either 1.5 or 2 equiv. of dmpm gave the yellow complex $[Au_2(\mu\text{-dmpm})_3]Cl_2$, **8**. This was obtained analytically pure and gave single resonances in the NMR spectra due to CH_3P, CH_2P_2, and ^{31}P groups, indicating a symmetrical structure. Slow crystallization of this complex **8** led to partial loss of dmpm and formation of $[Au_2(\mu\text{-dmpm})_2]Cl_2$ which is much paler yellow in colour. Hence an X-ray structure of **8** could not be obtained. However, the X-ray structure of the corresponding tetrafluoroborate salt, $[Au_2(\mu\text{-dmpm})_3](BF_4)_2$, has recently been reported (20).

Coordination number four is possible in gold(I) complexes (21) but there was no interaction of $[Au_2(\mu\text{-dmpm})_3]^{2+}$ with excess dmpm and, together with the observation that dissociation of dmpm from **8** occurs readily, this suggests that this binuclear system has little tendency to exceed coordination number three. In contrast, the isoelectronic $[Pt_2(\mu\text{-dmpm})_3]$ readily adds one or two triphenylphosphine ligands to give four-coordinate platinum (0) centres (22).

There are many examples of transition-metal binuclear complexes of the sterically less demanding dmpm ligand which

have been characterised by crystallographic methods (7, 20, 22–29). Each of them displays a different kind of molecular structure.

The crystal structures of compounds **7***a* and **7***b* consist of discrete $[Au_2(\mu\text{-dmpm})_2]^{2+}$ cations and two halide anions. The anions are located above and below the eight-membered ring formed by two gold atoms and the atoms of the bidentate ligands of the cation. A perspective view of the complex cation is presented in Fig. 2. Although the structures appear to be identical, the salts are not isomorphous. Each formula unit of the gold dimer in the crystal lattice is associated with two molecules of water of crystallization. The crystal structure contains polymeric chains made of discrete molecules linked together by hydrogen bonds formed between water molecules and the halide anions.

In the solid state the cationic dimers **7***a* and **7***b* have an exact C_i symmetry, the mid-point of the Au → Au′ vector coinciding with a crystallographic centre of inversion. The $Au_2P_4C_2$ ring adopts a chair conformation. In both structures, the metal atoms are spanned by two bridging dmpm ligands in a mutually *trans* arrangement. The Au...Au separations, 3.0143(3) Å in **7***a* and 3.0190(4) Å in **7***b*, fall well outside the range considered typical for Au—Au single bonds (ca. 2.757–2.780 Å) (30). However, the P...P bite distances of 3.084(2) Å in **7***a* and 3.116(3) Å in **7***b* are slightly larger than the Au...Au distance, suggesting a weak metal–metal interaction. The Au—P bond lengths in **7***a* and **7***b* are indistinguishable, averaging 2.302(2) Å. The halide anions are located approximately normal to the Au_2P_4 plane as indicated by the P—Au—X angles (see Table 3). The closest distances of approach between the gold atoms and the halide anions are 3.467(2), 3.534(2) Å in **7***a* and 3.590(1), 3.678(1) Å in **7***b*, clearly indicating that the interaction is essentially ionic, with little covalent character. In the analogous chloride, bromide and iodide dppm complexes, there is at least one covalently bonded halide atom with Au—Cl = 2.771(4)–2.963(4) Å in compounds **1**–**3** and Au—I = 3.127(3)–3.196(2) Å in **4** (2, 5). Each of the two water molecules forms two hydrogen bonds to chloride ions of two neighbouring unit cells.

It is interesting to speculate on the reasons for the different structures **1**–**5** being adopted by such similar complexes. It has been suggested that the Au_2dppm_2 ring, and the other rings with phenyl substituents on phosphorus, must twist (giving non-linear PAuP groups) in order to reduce steric hindrance between phenyl substituents and that this favours halide coordination above the $Au_2P_4C_2$ ring. Thus, steric effects would be responsible for the greater tendency of the halide to coordinate in dppm compared to dmpm complexes (7). However, this argument is contrary to the more general trend that increased steric hindrance usually leads to *lower* coordination numbers. In addition, there are now more structures which do not conform to the expected pattern; for example, in **3** the halide is coordinated in the plane of the $Au_2P_4C_2$ ring rather than above the ring (2–5). Therefore, it is more probable that the lower tendency of halide to coordinate in the dmpm compared to dppm complexes is primarily an electronic effect. However, since the energy differences between the different structural forms **1**–**5** are low, this conclusion is tentative. By examination of structures **1**–**5**, it is easy to see how either intramolecular or intermolecular halide exchange could occur easily in these complexes, as shown experimentally in several cases (2–5). Thus, interconversion of structures **1** and **5** leads to exchange of halide between gold centres while both halides remain weakly coordinated. Similarly, interconversion between structures **2**, **3**, and **4** leads to fluxionality while only one halide is coordinated throughout. Finally, conversion of **1** or **5** to **2**, **3**, or **4**, involving halide dissociation, would lead to intermolecular halide exchange.

Polarimetric and nuclear magnetic resonance studies of the complexation of mercury by thiols

MOHAMED M. SHOUKRY,[1] BRUCE V. CHEESMAN, AND DALLAS L. RABENSTEIN[2]
Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received February 11, 1988

MOHAMED M. SHOUKRY, BRUCE V. CHEESMAN, and DALLAS L. RABENSTEIN. Can. J. Chem. **66**, 3184 (1988).

The complexation of Hg(II) by glutathione has been studied by polarimetry under conditions of excess ligand with the objective of characterizing formation of the 3:1 complex, Hg(glutathione)$_3$. The optical rotatory power of solutions containing glutathione only and of solutions containing glutathione and Hg(II) at ratios of 2:1, 2.5:1, 3:1, and 4:1 was measured as a function of pH. Acid dissociation constants for the ammonium and thiol groups of glutathione and for the two ammonium groups of Hg(glutathione)$_2$ and the formation constant of the 3:1 complex (Hg(glutathione)$_2$ + glutathione $\rightleftarrows$ Hg(glutathione)$_3$) were determined from the pH dependence of the optical rotatory power. The value obtained for the formation constant, $K_f = 1.5 \times 10^3$, indicates that binding of the third ligand to form Hg(glutathione)$_3$ is much weaker than binding of the first two glutathione ligands. However, calculations indicate that binding is sufficiently strong that a significant fraction of Hg(II) is present as Hg(glutathione)$_3$ under physiological conditions. Equilibrium constants were also determined by polarimetry and by ^{13}C nuclear magnetic resonance for the displacement of one thiolate ligand by another (RSHgSR + R′SH $\rightleftarrows$ RSHgSR′ + RSH; RSHgSR′ + R′SH $\rightleftarrows$ R′SHgSR′ + RSH). The results indicate that, at pH 5.5 and at physiological pH, the relative stability increases in the order Hg(glutathione)$_2$ < Hg(penicillamine)$_2$ < Hg(mercaptoethylamine)$_2$. However, when competitive protonation of free ligand is accounted for, it is shown that the intrinsic stability of the complexes increases in the order Hg(penicillamine)$_2$ < Hg(mercaptoethylamine)$_2$ < Hg(glutathione)$_2$, which parallels the order of the Brønsted basicity of the thiolate ligands.

MOHAMED M. SHOUKRY, BRUCE V. CHEESMAN et DALLAS L. RABENSTEIN. Can. J. Chem. **66**, 3184 (1988).

Faisant appel à la polarimétrie et opérant dans des conditions impliquant un excès de ligand, on a étudié la complexion du Hg(II) par le glutathion dans le but de caractériser la formation du complexe 3:1, Hg(glutathion)$_3$. On a mesuré la variation, en fonction du pH, du pouvoir rotatoire optique de solutions ne contenant que du glutathion ainsi que de solutions contenant du glutathion et du Hg(II) à des rapports de 2:1, 2.5:1, 3:1 et 4:1. En se basant sur la relation entre le pouvoir rotatoire optique et le pH, on a déterminé les constantes de dissociation acide des groupements ammonium et thiol du glutathion ainsi que des deux groupements ammonium du complexe Hg(glutathion)$_2$ de même que la constante de formation du complexe 3:1 (Hg(glutathion)$_2$ + glutathion $\rightleftarrows$ Hg(glutathion)$_3$). La valeur obtenue pour la constante de formation, $K_f = 1{,}5 \times 10^3$, indique que la liaison du troisième ligand pour former le complexe Hg(glutathion)$_3$ est beaucoup plus facile que les liaisons des deux premiers ligands glutathion. Toutefois, des calculs indiquent que la liaison est suffisamment forte pour qu'un fraction importante du Hg(II) soit présent sous la forme Hg(glutathion)$_3$, dans des conditions physiologiques. Faisant appel à la polarimétrie ainsi que la résonance magnétique nucléaire du ^{13}C, on a aussi déterminé les constantes d'équilibre pour le déplacement d'un ligand thiolate par un autre (RSHgSR + R′SH $\rightleftarrows$ RSHgSR′ + RSH; RSHgSR′ + R′SH $\rightleftarrows$ R′SHgSR′ + RSH). Les résultats indiquent que, à un pH de 5,5 ainsi qu'au pH physiologique, les stabilités relatives augmentent dans l'ordre Hg(glutathion)$_2$ < Hg(pénicillamine)$_2$ < Hg(mercaptoéthylamine)$_2$. Toutefois, on démontre que, lorsqu'on tient compte de la protonation compétitive du ligand libre, la stabilité intrinsèque des complexes augmente dans l'ordre Hg(pénicillamine)$_2$ < Hg(mercaptoéthylamine)$_2$ < Hg(glutathion)$_2$ qui est parallèle à l'ordre de la basicité selon Brønsted des ligands thiolates.

[Traduit par la revue]

Introduction

Mercury(II) forms extremely stable, linear two-coordinate complexes with sulfhydryl-containing ligands (1–6). For example, stability constants for the Hg(glutathione)$_2$ and Hg(cysteine)$_2$ complexes at physiological pH and 25°C are reported to be 9×10^{40} and 2×10^{40} respectively (1). However, even though the thermodynamic stability of Hg(II)–thiol complexes is high, Hg(II)–thiol binding is labile, with the Hg(II) exchanging among thiol ligands. Consequently, in biological systems, Hg(II) exchanges among the multitude of thiol groups it encounters, with some ultimately combining with thiol groups of enzymes and other molecules that are dependent on free thiol groups for their activity.

In a recent ^{13}C nmr study of the kinetics of Hg(II) – thiol ligand exchange, we obtained evidence for the formation at physiological pH of complexes having the stoichiometry Hg(thiol)$_3$ when the thiol:Hg(II) ratio is greater than 2:1 (7).

[1] $$RS^- + RSHgSR \rightleftarrows Hg(SR)_3$$

$$K_f = \frac{[Hg(SR)_3^-]}{[RS^-][Hg(SR)_2]}$$

We proposed that the rapid exchange of thiol between the free and Hg(thiol)$_2$ forms proceeds via a mechanism involving Hg(thiol)$_3$ complexes. Even though the complexation of Hg(II) by sulfhydryl-containing amino acids and peptides has been the subject of a number of studies, including potentiometric studies with ligand:Hg(II) ratios greater than 2:1 (1, 4–6), this is apparently the first report of complexes of the stoichiometry Hg(thiol)$_3$ with sulfhydryl-containing amino acids and peptides.

Because of the potential importance of Hg(thiol)$_3$ complexes in accounting for the mobility of Hg(II) in biological systems, we have investigated the formation of the 3:1 complex with the sulfhydryl-containing tripeptide glutathione (GSH) by an independent technique, polarimetry. Glutathione was chosen for this study because it has been established previously that Hg(II) in human erythrocytes is complexed predominantly by glutathione (8), and GSH has been implicated in numerous other studies of the toxicology of Hg(II) (9–12).

We also report on the use of polarimetry to measure

equilibrium constants for the displacement of one thiol ligand by another.

[2] $RSHgSR + R'SH \leftrightarrows RSHgSR' + RSH$

$$K_1 = \frac{[RSHgSR'][RSH]}{[RSHgSR][R'SH]}$$

[3] $RSHgSR' + R'SH \rightleftarrows R'SHgSR' + RSH$

$$K_2 = \frac{[R'SHgSR'][RSH]}{[RSHgSR'][R'SH]}$$

[4] $RSHgSR + 2R'SH \rightleftarrows R'SHgSR' + 2RSH$

$$K_d = K_1K_2 = \frac{[R'SHgSR'][RSH]^2}{[RSHgSR][R'SH]^2}$$

Because of the extremely high stability of $Hg(thiol)_2$ complexes, it is difficult to measure accurate values for their stability constants. However, if displacement constants K_1 and K_2 can be measured, they will provide the relative affinity of various thiol ligands for Hg(II). Such information is of interest, e.g., in determining the relationship, if any, between the stabilities of Hg(II)–ligand complexes and the effectiveness of the ligands as therapeutic antidotes for mercury poisoning. Equilibrium constants were determined for the displacement of glutathione by penicillamine and for the displacement of penicillamine by mercaptoethylamine (cysteamine). Equilibrium constants for the displacement of glutathione by penicillamine were also determined by ^{13}C nmr spectroscopy for comparison with the polarimetric results.

Experimental

Glutathione, D-penicillamine, and mercaptoethylamine hydrochloride (Sigma) were used as received. All thiols were stored under an inert atmosphere below 4°C. Solutions of Hg(II) were prepared from analytical grade mercuric nitrate (J. T. Baker Chemical Co.). 1,4-Dioxane and D_2O were from BDH Chemicals Ltd. and Stohler Isotope Chemicals, respectively.

All solutions used in the polarimetric studies were prepared in water that had been purified by distilling it twice and then passing it through a Barnstead D8902 ultrapure mixed-bed ion-exchange resin. The solvent was deoxygenated by bubbling with nitrogen or argon before addition of thiol, to minimize oxidation by dissolved oxygen. Inert gas was also bubbled through the solutions during adjustment of pH and, in the nmr experiments, nmr tubes were flushed with gas before transfer of an aliquot of solution to the tube. In the polarimetric experiments to characterize the $Hg(glutathione)_3$ complex, 50 mL of solution containing 0.10 M glutathione, 0.3 M $NaNO_3$, and either 0.025, 0.0333, 0.040, or 0.050 M $Hg(NO_3)_2$ was prepared from solid glutathione and $NaNO_3$ and stock $Hg(NO_3)_2$ solution. The pH was initially adjusted to ~6 and then increased by adding ~10 M NaOH as the optical rotation was measured, as described below. In the polarimetric experiments to measure displacement equilibrium constants, 50 mL of solution containing 0.015 M $Hg(glutathione)_2$ or 0.015 M $Hg(penicillamine)_2$ and 0.3 M $NaNO_3$ were prepared from $Hg(NO_3)_2$ stock solution and solid $NaNO_3$ and glutathione or penicillamine. The pH was adjusted to 5.5 ± 0.1, and the optical rotation was measured as 0.491 M penicillamine was added to the $Hg(glutathione)_2$ solution and as 0.492 M mercaptoethylamine was added to the $Hg(penicillamine)_2$ solution. The penicillamine and mercaptoethylamine titrant solutions were prepared immediately before use. The pH was kept at 5.5 ± 0.1 during the titration by addition of ~10 M NaOH or HCl as necessary.

In the ^{13}C nmr experiments, a solvent mixture consisting of 5% D_2O/95% H_2O was used. Solid penicillamine was added to a pH 6.0 solution containing 0.10 M $Hg(glutathione)_2$ and 0.3 M KNO_3. Solution preparation was done in a water-jacketed titration cell at 25.0 ± 0.1°C. The cell was covered with a tightly fitting plastic lid with holes for glass and reference electrodes, a micropipet delivery tube, and argon inlet and outlet tubes. After each addition of penicillamine, the pH was adjusted to 6.0, and a sample was withdrawn for nmr measurements.

For the nmr experiments, pH measurements were made with an Orion model 701A pH meter equipped with a Phillips glass electrode (GAT 130) and a Phillips glass sleeve double junction Ag/AgCl reference electrode (R44/2-SD/12). For the polarimetric experiments, pH measurements were made with a Fisher Accumet 620 pH meter equipped with an Ingold combination electrode. The pH meters were calibrated with freshly prepared N.B.S. standard solutions having pH values of 4.008 (phthalate) and 6.865 (phosphate).

Polarimetric measurements were made with a Perkin–Elmer model 141 polarimeter using the 589-nm line of the sodium lamp. The polarimeter was calibrated using solutions of sucrose. The precision of the measurements is estimated to be ±0.002 degrees of arc. A water-jacketed cell of 100 mm length and 5 mL total volume was used. The solutions were contained in a water-jacketed titration cell (25.0 ± 0.1°C), which was connected to the polarimetric cell via Teflon tubing. Solution was transferred from the titration cell to the polarimetric cell and back to the titration cell through the Teflon tubing with a 10-mL syringe that was connected to one of the two Teflon transfer lines with a liquid chromatography sample injection loop. The pH of the solution was adjusted in the titration cell, and then the solution was circulated through the polarimetric cell with the syringe. Titrant was added with a 1-mL Mettler DV11 autoburette.

The ^{13}C nmr measurements were made at 90.56 MHz and 25°C on a Bruker WM-360 spectrometer. Sample temperature was maintained at 25°C by collecting free induction decays under conditions of inverse gated decoupling (nOe suppressed) with chilled air blowing over the sample tube in the probe to minimize sample heating. ^{13}C chemical shifts were measured relative to internal 1,4-dioxane, but are reported relative to tetramethylsilane (TMS). The resonance for 1,4-dioxane is at 67.40 ppm to high frequency from TMS.

Results and discussion

Characterization of Hg(glutathione)$_3$

The optical rotatory power (α_{obs}) of solutions containing 0.10 *M* GSH (A), 0.05 *M* $Hg(NO_3)_2$ and 0.10 *M* GSH (B), and 0.025 *M* $Hg(NO_3)_2$ and 0.10 *M* GSH (C) is plotted as a function of pH in Fig. 1. Since Hg(II) has a strong tendency to form linear, two-coordinate complexes with thiol ligands (1, 3–6), curve B in Fig. 1 corresponds to the optical rotatory power for the complex $Hg(glutathione)_2$. Curve D is the predicted optical rotatory power vs. pH for solution C if only the 2:1 complex and free GSH were present. At pH ~ 6, the predicted and observed curves are similar, indicating that these are the only species at this pH. However, at higher pH, α_{obs} is different from $\alpha_{predicted}$, which indicates the formation of other Hg(II)–GSH complexes. A similar variation was observed between experimental and predicted ^{13}C chemical shifts for GSH in solutions having GSH:Hg(II) ratios greater than 2:1 at pH > 6 (7). From studies in which the ^{13}C chemical shifts were measured as a function of the Hg(II):GSH ratio at constant pH, it was shown that the differences are due to formation of the 3:1 complex, $Hg(glutathione)_3$. Evidence for the formation of $Hg(SR)_3^-$ complexes, where R represents methyl and *tert*-butyl groups, in solution has also been obtained from vibrational spectroscopic studies (13). In another study, the crystalline mononuclear, three-coordinate mercury(II) thiolate $[NBu^n_4][Hg(SPh)_3]$ was prepared and its crystal structure determined (14).

The formation constant for $Hg(glutathione)_3$ was determined from the data in Figs. 1 and 2. First, however, the acid dissociation constants for GSH and $Hg(glutathione)_2$ were determined from the data in Curves A and B of Fig. 1. For GSH, the thiol and ammonium groups are titrated in the pH range

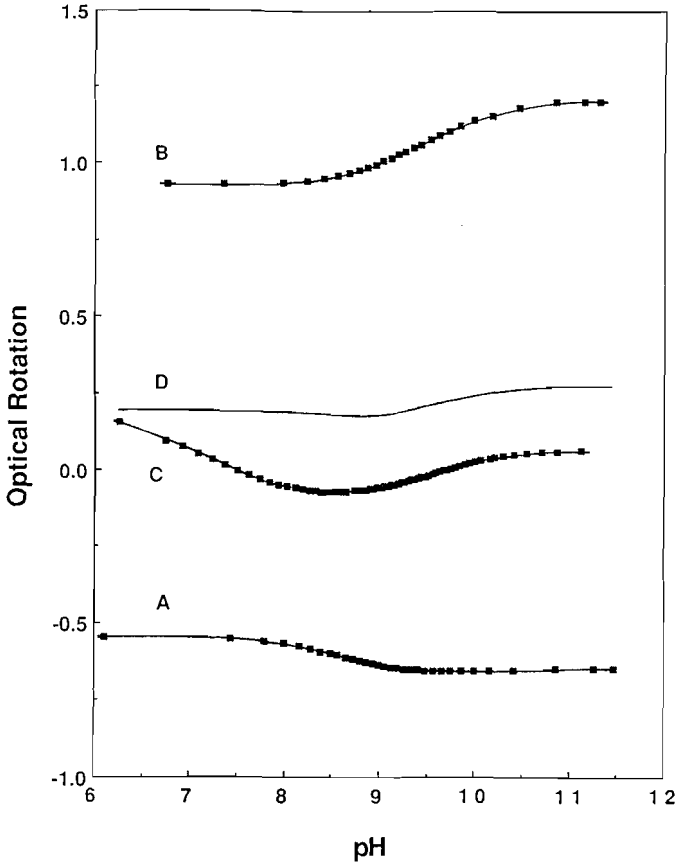

FIG. 1. pH dependence of the optical rotation of solutions containing (A) 0.100 M GSH, (B) 0.05 M $Hg(NO_3)_2$ and 0.100 M GSH, and (C) 0.025 M $Hg(NO_3)_2$ and 0.100 M GSH. Curve D represents the optical rotation expected for solution C if only free GSH and $Hg(glutathione)_2$ were present. The solid curves through the experimental points in A–C are theoretical curves calculated with acid dissociation and formation constants determined in this study.

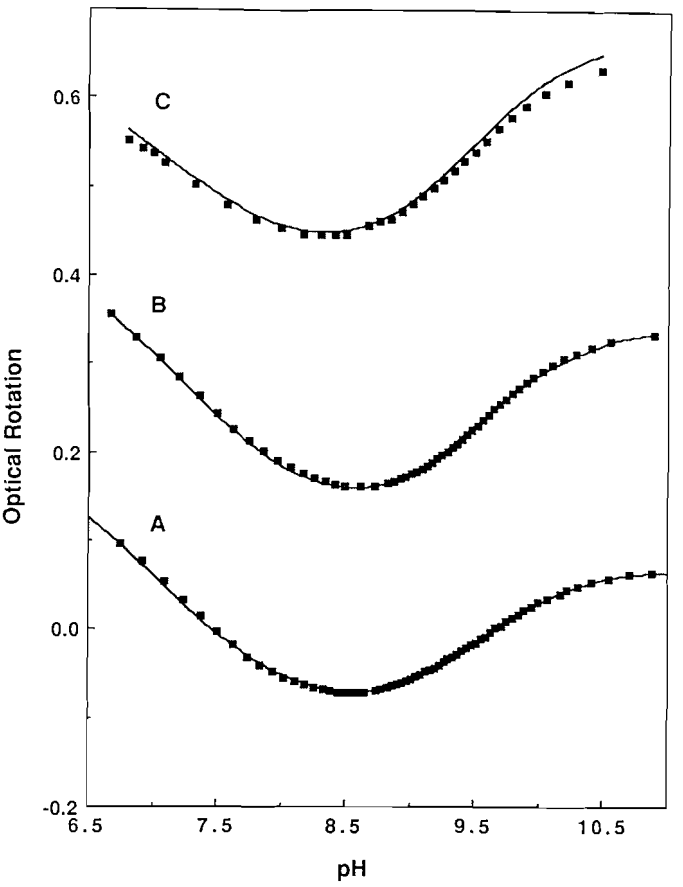

FIG. 2. pH dependence of the optical rotation of solutions containing (A) 0.025 M $Hg(NO_3)_2$ and 0.100 M GSH, (B) 0.0333 M $Hg(NO_3)_2$ and 0.100 M GSH, and (C) 0.04 M $Hg(NO_3)_2$ and 0.100 M GSH. The solid curves are theoretical curves calculated with the acid dissociation and formation constants determined in this study.

shown in Fig. 1, as given by eqs. [5] and [6],

[5] $H_2A^- \rightleftarrows H^+ + HA^{2-}$

$$K_3 = \frac{[H^+][HA^{2-}]}{[H_2A^-]}$$

[6] $HA^{2-} \rightleftarrows H^+ + A^{3-}$

$$K_4 = \frac{[H^+][A^{3-}]}{[HA^{2-}]}$$

where H_3A represents the triprotonated form of GSH. The contribution of each species to the total rotation, α_{obs}, at a given pH is the product of its concentration and its molar optical rotatory power:

[7] $$\alpha_{obs} = \alpha_A[A^{3-}] + \alpha_{HA}[HA^{2-}] + \alpha_{H_2A}[H_2A^-]$$

where α_A, α_{HA}, and α_{H_2A} are the molar optical rotatory powers of the species indicated. Substitution of eqs. [5] and [6] into [7] leads to:

[8] $$\alpha_{obs} = \frac{\alpha_A K_3 K_4 + \alpha_{HA} K_3[H^+] + \alpha_{H_2A}[H^+]^2}{[H^+]^2 + K_3[H^+] + K_3K_4}[GSH]_{total}$$

Since H_2A^- and A^{3-} are the only species present at pH 6–7 and pH > 11 respectively, values of $\alpha_{H_2A} = -5.431$ and $\alpha_A = -6.481$ deg·L·mol^{-1} were calculated directly from α_{obs} at these pH values. K_3, K_4, and α_{HA} were then determined by fitting the α_{obs} vs. pH data for GSH to eq. [8] using the nonlinear least-squares computer program KINET (15). The values obtained are $\alpha_{HA} = -6.691$ deg·L·mol^{-1}, $pK_3 = 8.58$, and $pK_4 = 9.54$. The solid line through the experimental points for GSH in Fig. 1 is the optical rotatory power vs. pH predicted using these parameters. The average values from three experiments are $pK_3 = 8.60 \pm 0.02$ and $pK_4 = 9.56 \pm 0.06$; these values are in excellent agreement with values determined by other techniques (16–18).

The optical rotatory power of the solution containing Hg(glutathione)$_2$ is pH dependent due to titration of the free ammonium group of each thiolate-coordinated ligand, as defined by eqs. [9] and [10].

[9] $Hg(AH)_2^{2-} \rightleftarrows H^+ + Hg(AH)(A)^{3-}$

$$K_5 = \frac{[H^+][Hg(AH)(A)^{3-}]}{Hg(AH)_2^{2-}}$$

[10] $Hg(AH)(A)^{3-} \rightleftarrows H^+ + Hg(A)_2^{4-}$

$$K_6 = \frac{[H^+][Hg(A)_2^{4-}]}{[Hg(AH)(A)^{3-}]}$$

where $Hg(AH)_2^{2-}$ represents the form of the complex with both amine groups protonated, etc. pK_5 and pK_6 were determined from the data in curve B of Fig. 1. Because the two ammonium

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 122.72.124.2 on 09/07/12
For personal use only.

groups are quite distant from each other in $Hg(AH)_2^{2-}$, each group is assumed to dissociate independently of the other and to have an acid dissociation constant that is independent of the protonation state of the other group. Thus, the macroscopic constants K_5 and K_6 are assumed to equal $2K_{NH_3^+}$ and $K_{NH_3^+}/2$ respectively, where $K_{NH_3^+}$ is the dissociation constant for the ammonium group. Substitution of these equations for K_5 and K_6 into the equation analogous to eq. [8] for $Hg(SG)_2$ gives an equation for α_{obs} in terms of $K_{NH_3^+}$ and the molar optical rotatory powers of $Hg(AH)_2^{2-}$, $Hg(AH)(A)^{3-}$, and $Hg(A)_2^{4-}$. Since $Hg(AH)_2^{2-}$ and $Hg(A)_2^{4-}$ are the only species present at pH 6–7 and pH > 11, respectively, values of $\alpha_{Ag(AH)_2} = 18.66$ deg·L·mol^{-1} and $\alpha_{Hg(A)_2} = 24.20$ deg·L·mol^{-1} were calculated directly from the α_{obs} vs. pH data at these pHs. Values of 9.34 and 20.94 deg·L·mol^{-1} were obtained for $pK_{NH_3^+}$ and $\alpha_{Hg(HA)(A)^{3-}}$ respectively from a nonlinear least-squares fit of the data in Fig. 1B. The solid line through the experimental points in Fig. 1B is the theoretical curve predicted with these parameters. The average value obtained for $pK_{NH_3^+}$ from three experiments is 9.33 ± 0.06. Values calculated for pK_5 and pK_6 from this value for $pK_{NH_3^+}$ are 9.03 and 9.63 respectively.

To determine the formation constant for the 3:1 complex, the optical rotatory power was measured as a function of pH for solutions containing GSH and Hg(II) at ratios of 2.5:1, 3:1, and 4:1 (Fig. 2). For these solution conditions, α_{obs} is given by eq. [11].

$$[11]\quad \alpha_{obs} = \sum_{i=0}^{2} \alpha_{H_iA}[H_iA] + \sum_{i=0}^{2} \alpha_{Hg(A)_2H_i}[Hg(A)_2H_i] + \sum_{i=0}^{3} \alpha_{Hg(A)_3H_i}[Hg(A)_3H_i]$$

The formation constant for $Hg(A)_3^{7-}$, defined by eq. [12],

$$[12]\quad A^{3-} + Hg(A)_2^{4-} \rightleftarrows Hg(A)_3^{7-}$$

$$K_{f3} = \frac{[Hg(A)_3^{7-}]}{[A^{3-}][Hg(A)_2^{4-}]}$$

was determined by fitting the data in Fig. 2 to an equation that gives α_{obs} in terms of the acid dissociation constants for H_3A, $Hg(AH)_2^{2-}$, and $Hg(AH)_3^{4-}$, the formation constant for $Hg(A)_3^{7-}$, the pH, and the total concentrations of Hg(II) and glutathione.[3] The equation was derived by appropriate substitutions into eq. [11]. Because the three $-NH_3^+$ groups of $Hg(AH)_3^{4-}$ are quite distant from each other and from the site of complexation, the acidity of each $-NH_3^+$ group was assumed to be independent of the protonation states of the other $-NH_3^+$ groups. The three macroscopic acid dissociation constants used for $Hg(AH)_3^{4-}$ in the formation constant calculations were calculated using the value determined above for $pK_{NH_3^+}$ for the $Hg(AH)_2^{2-}$ complex and the equations $K_7 = [H^+][Hg(A)(AH)_2^{5-}]/[Hg(AH)_3^{4-}] = 3K_{NH_3^+}$; $K_8 = [H^+][Hg(A)_2(AH)^{6-}]/[Hg(A)(AH)_2^{5-}] = K_{NH_3^+}$; and $K_9 = [H^+][HgA_3^{7-}]/[Hg(A)_2(AH)^{6-}] = K_{NH_3^+}/3$. The values obtained by fitting simultaneously the data from the three separate experiments in Fig. 2 using nonlinear least-squares methods are: $\log K_{f3} = 3.18 \pm 0.02$, $\alpha_{Hg(AH)_3} = 1.63 \pm 0.07$, $\alpha_{Hg(A)(AH)_2} = 3.74 \pm 0.11$, $\alpha_{Hg(A)_2(AH)} = 6.14 \pm 0.14$, and $\alpha_{HgA_3} = 9.17 \pm 0.08$. The value obtained for $\log K_{f3}$ is in excellent agreement with the average value of 3.23 obtained from ^{13}C nmr chemical shift data (7).

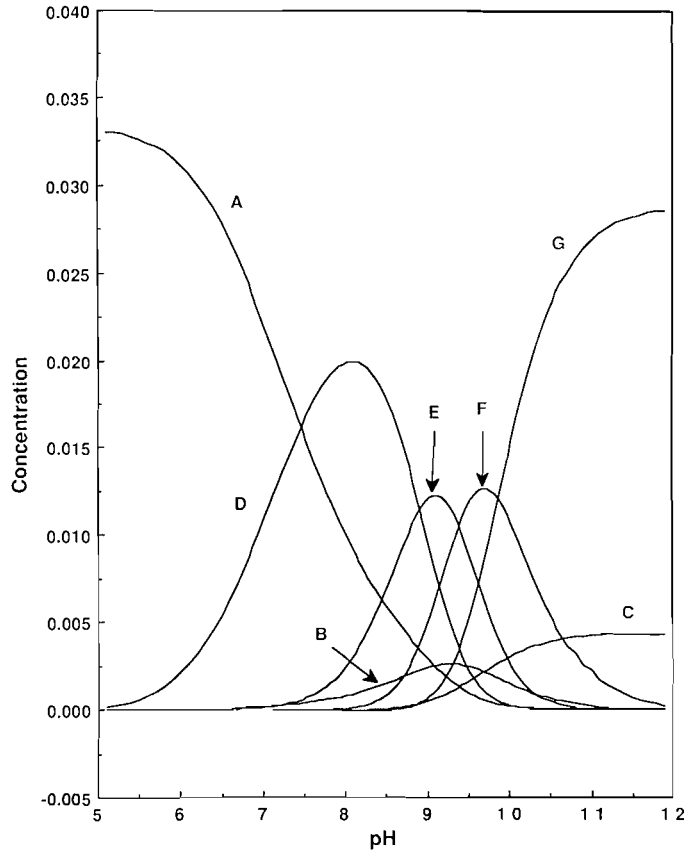

FIG. 3. pH dependence of the distribution of Hg(II) among its various complexes in a solution containing 0.0333 M $Hg(NO_3)_2$ and 0.100 M GSH. The curves were calculated using acid dissociation and formation constants determined in this study. The complexes are: (A) $Hg(AH)_2^{2-}$; (B) $Hg(A)(AH)^{3-}$; (C) HgA_2^{4-}; (D) $Hg(AH)_3^{4-}$; (E) $Hg(A)(AH)_2^{5-}$; (F) $Hg(A)_2(AH)^{6-}$; (G) HgA_3^{7-}.

Figure 3 shows the distribution of Hg(II) among its various complexes with GSH in a solution containing 0.100 M GSH and 0.0333 M Hg(II) (the conditions for curve C of Fig. 1). These curves were calculated using the formation constants and acid dissociation constants determined in this study and show that even though the formation constant for addition of the third ligand is much less than that for the formation of $Hg(AH)_2^{2-}$ (9×10^{40}) (1), it is large enough that a major fraction of the Hg(II) is present in the various 3:1 complexes. It is also of interest to use these results to predict the extent to which the 3:1 complexes will form in vivo. As an example, in human erythrocytes, where the GSH concentration is $\sim 2.2 \times 10^{-3}$ M and the pH ~ 7.4 (19), ~10% of the Hg(II) is predicted to be present as the $Hg(AH)_3^{4-}$ complex at total Hg(II) concentrations in the range 1×10^{-4} to 1×10^{-6} M. Thus, these results predict that, even at the somewhat lower GSH concentrations present in biological systems, a significant fraction of the Hg(II) will be present in the 3:1 complexed form. GSH has been identified as a major binding site for Hg(II) in intact human erythrocytes and has also been implicated in studies of the toxicology of Hg(II) (9–12).

[3]Equations used to determine the formation constant of $Hg(A)_3^{7-}$, the acid dissociation constants of $Hg(AH)_3^{4-}$, and the optical rotatory powers of $Hg(A)_3^{7-}$, $Hg(A)_2(HA)^{6-}$, $Hg(A)(AH)_2^{5-}$, and $Hg(AH)_3^{4-}$ may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

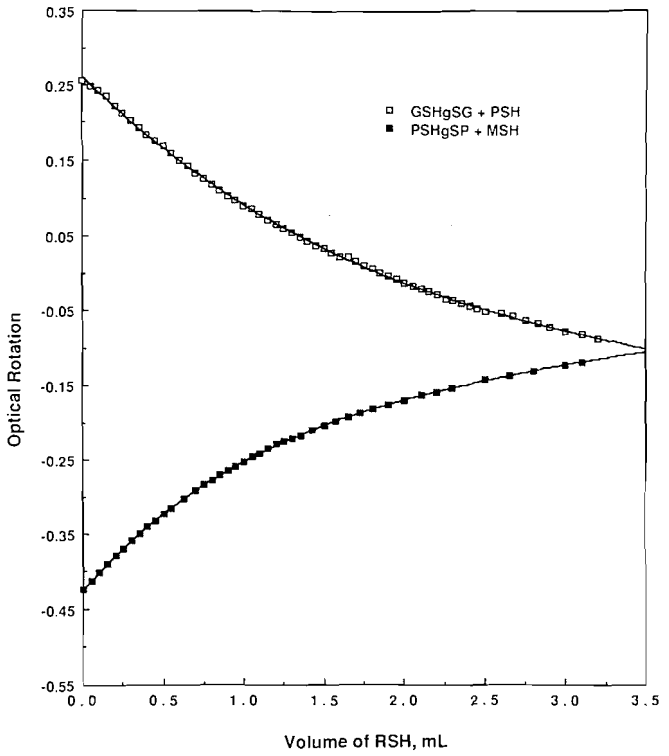

FIG. 4. The optical rotation of (A) a solution containing initially 0.015 M $Hg(NO_3)_2$ and 0.030 M GSH as a function of the volume of added 0.491 M penicillamine and (B) a solution containing 0.015 M $Hg(NO_3)_2$ and 0.030 M PSH as a function of the concentration of added 0.493 M mercaptoethylamine. Both solutions were kept at a constant pH of 5.5. The initial volume was 50 mL for both experiments. The solid curves through the experimental points are theoretical curves calculated using the displacement equilibrium constants determined in this study.

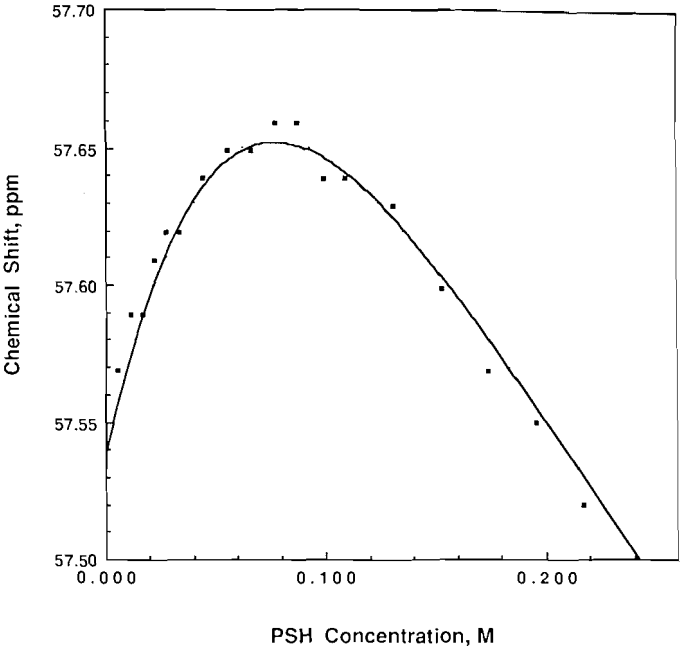

FIG. 5. The chemical shift of the C_α carbon of the cysteinyl residue of GSH in a solution containing 0.100 M $Hg(NO_3)_2$ and 0.200 M GSH as a function of the concentration of added penicillamine at pH 6. The solid curve is a theoretical curve calculated using the displacement constants determined from the ^{13}C chemical shift data.

Displacement equilibrium constants

To investigate the feasibility of using polarimetry to measure equilibrium constants for the displacement of complexed thiol ligand by free thiol ligand, as described by eqs. [2]–[4], the optical rotatory power was measured as solutions containing $Hg(SR)_2$ were titrated at constant pH with R′SH. Figure 4 shows results for (A) the titration at pH 5.5 of a solution containing 0.015 M Hg(glutathione)$_2$ with 0.491 M penicillamine and (B) the titration at pH 5.5 of a solution containing 0.015 M Hg(penicillamine)$_2$ with 0.493 M mercaptoethylamine. A pH of 5.5 was used since the results in curve C of Fig. 1 indicate there is little tendency to form the 3:1 complex at this pH. At pH 5.5, free ligands are in the amino and thiolate protonated forms, the amino groups of the complexed ligands are protonated, and carboxylic acid groups of the free and complexed ligands are deprotonated.

The observed optical rotation is described by eq. [13]:

$$[13]\quad \alpha_{obs} = \alpha_{RSHgSR}[RSHgSR] + \alpha_{RSHgSR'}[RSHgSR'] + \alpha_{R'SHgSR'}[R'SHgSR'] + \alpha_{RSH}[RSH] + \alpha_{R'SH}[R'SH]$$

Displacement equilibrium constants K_1 and K_2 (eqs. [2] and [3]) were determined by fitting the data in Fig. 4 to eq. [13] using nonlinear least-squares curve-fitting methods. The values used for α_{RSHgSR}, $\alpha_{R'SHgSR'}$, α_{RSH}, and $\alpha_{R'SH}$ in the curve fitting were calculated directly from α_{obs} measured for solutions containing only these species. The curve-fitting procedure involved first estimating values for equilibrium constants K_1 and K_2 (eqs. [2] and [3]) and $\alpha_{RSHgSR'}$. Then, using equations derived by combining the mass balance equations and the displacement equilibria, the concentrations of RSHgSR, RSHgSR′, R′SHgSR′, RSH, and R′SH were calculated using the estimated values for K_1 and K_2, and α_{obs} was predicted using these concentrations, the measured α values for RSHgSR, R′SHgSR′, RSH, and R′SH, and the estimated value for $\alpha_{RSHgSR'}$ at each added R′SH concentration. Using the nonlinear least-squares program KINET (15), the estimates for K_1, K_2, and $\alpha_{RSHgSR'}$ were then refined and the procedure repeated until the best fit between α_{obs} and $\alpha_{predicted}$ was obtained, as judged by the sum of the squares of the residuals.

The equilibrium constants obtained for the displacement of GSH by penicillamine using the data in Fig. 4A are $K_1 = 2.4 \pm 0.1$ and $K_2 = 0.41 \pm 0.01$. The solid curve through the experimental points in Fig. 4A is the predicted curve calculated using these parameters. The results obtained from a second experiment on the same system are $K_1 = 2.7 \pm 0.3$ and $K_2 = 0.47 \pm 0.03$. The equilibrium constants for the displacement of penicillamine by mercaptoethylamine ($\alpha_{R'SH}$ and $\alpha_{R'SHgSR'} = 0$) using the data in Fig. 4B are $K_1 = 4.4 \pm 0.03$ and $K_2 = 0.27 \pm 0.02$. The solid curve through the experimental points in Fig. 4B is the predicted curve calculated using these parameters.

To verify the results obtained by polarimetry, the equilibrium constants for the displacement of GSH by penicillamine were also determined by ^{13}C nmr spectroscopy. The chemical shifts of the ^{13}C resonances for GSH in pH 6.0 solutions containing 0.20 M GSH, 0.10 M $Hg(NO_3)_2$, and various concentrations of penicillamine were measured as a function of the penicillamine concentration. The exchange of glutathione among the various complexed and free forms is fast on the ^{13}C nmr time scale (20), and thus single, exchange-averaged resonances are observed for each of the carbons of glutathione. The chemical shift of the exchange-averaged resonance for the C_α carbon of the

cysteinyl residue of glutathione is plotted as a function of the penicillamine concentration in Fig. 5.

The exchange-averaged chemical shift for the Cys-C_β or Cys-C_α resonances is the weighted average of the chemical shifts of the various GSH species present, as described by eq. [14]:

$$[14] \quad \delta_{obs} = \delta_{RSHgSR} f_{RSHgSR} + \delta_{RSHgSR'} f_{RSHgSR'} + \delta_{RSH} f_{RSH}$$

where δ_{obs} is the observed chemical shift, RSH and R'SH represent GSH and penicillamine, respectively, and δ_{RSHgSR}, f_{RSHgSR}, etc. represent the chemical shifts and the fractional concentrations of GSH in the forms indicated by the subscripts. The displacement equilibrium constants were evaluated by non-linear least-squares curve fitting using a procedure analogous to that described above for their evaluation from polarimetric data. The values calculated from the chemical shift data for the Cys-C_α carbon are $K_1 = 2.1 \pm 0.1$ and $K_2 = 0.40 \pm 0.01$. The equilibrium constants were also calculated from the chemical shift data for the Cys-C_β carbon; the results are $K_1 = 2.0 \pm 0.1$ and $K_2 = 0.31 \pm 0.06$. The values determined by ^{13}C nmr are in good agreement with those determined by polarimetry.

The equilibrium constant for the complete displacement of one thiol ligand by another, K_d (eq. [4]), is the product of K_1 and K_2. Thus, for the displacement of GSH by penicillamine, $K_d = 1.12$, and for the displacement of penicillamine by mercaptoethylamine, $K_d = 1.19$. These equilibrium constants indicate that the relative stabilities of the $Hg(SR)_2$ complexes at pH 5.5 are in the order Hg(mercaptoethylamine)$_2$ > Hg(penicillamine)$_2$ > $Hg(GSH)_2$. Since the protonation states of the amino and thiol groups of the free ligands and the amino groups of the complexed ligands are essentially identical at pH 5.5 and 7.4, this also is the order of relative stabilities at physiological pH. The greater stability of Hg(penicillamine)$_2$ compared to that of Hg(glutathione)$_2$ is consistent with the effectiveness of penicillamine as a therapeutic antidote for mercury poisoning (21).

At pH 5.5, the free ligands are in the thiol form. Thus, to compare the intrinsic stabilities of the various complexes, it is necessary to account for the competitive protonation of the thiolate group (eq. [15]) since it is the thiolate form of the ligand that is complexed.

$$[15] \quad \begin{array}{ccc} RSHgSR + 2R'S^- & \rightleftarrows & R'SHgSR' + 2RS^- \\ \updownarrow H^+ & & \updownarrow H^+ \\ 2R'SH & & 2RSH \end{array}$$

$$K_d' = \frac{[R'SHgSR'][RS^-]^2}{[RSHgSR][R'S^-]^2}$$

Thus, the equilibrium constants determined above are conditional equilibrium constants for pH 5.5. Using values of pK_{SH} = 8.97, 8.05, and 8.37 for the microscopic acid dissociation constants of GSH, penicillamine, and mercaptoethylamine, respectively (18, 22, 23), K_d' is calculated to be 0.0162 for the displacement of GSH by penicillamine and 5.19 for the displacement of penicillamine by mercaptoethylamine. Thus, the relative order of intrinsic stability is Hg(glutathione)$_2$ > Hg(mercaptoethylamine)$_2$ > Hg(penicillamine)$_2$, which parallels the order of the Brønsted basicity of the thiolate ligands. Methylmercury(II) complexes of thiolate ligands show the same correlation between formation constant and Brønsted basicity of the thiolate ligand (22).

Page 1158, reference 29, insert "J." before "Chem. Soc."

Table 4. For radical **39**, the listed α-, β-, and γ-H(CH) splitting constants and *g*-value should be replaced by "20.25(2)", "26.17(2)", "1.56(3)", and "2.00323(2)", respectively. For radical **40**, the β-H(CH) splitting constant listed as "20.07(3)[d]" should be replaced by "18.46(2)[d], 22.68(4)[e]", and the listed δ-H(CH) splitting constant and the *g*-value should be replaced by "1.53(2)" and "2.00325(2)", respectively. The text in footnote *d* should be replaced by "β-CH_2OH group." and a new footnote, *e*, reading "β-CH_3 group." should be added.
