The low temperature structure of low density ethylene monolayers physisorbed on the graphite basal plane has been examined by molecular dynamics calculations with an intermolecular potential based on atom–atom interactions. The simulations predict that the ethylene molecules are arranged in a herringbone with a centered rectangular unit cell of dimensions 4.95 Å × 7.05 Å. In this structure, the molecular C=C axes are parallel to the surface, and are oriented at 60° angles from each other, while the molecular planes are tilted some 55° from the plane of the surface. The structure was found to be essentially independent of the assumed corrugation of the graphite surface.

MICHAEL A. MOLLER et MICHAEL L. KLEIN. Can. J. Chem. **66**, 774 (1988).

Utilisant des calculs de dynamique moléculaire avec un potentiel intermoléculaire basé sur des interactions atome–atome, on a étudié la structure à basse température de monocouches d'éthylène de faible densité adsorbées physiquement sur le plan de base du graphite. Les simulations prédisent que les molécules d'éthylène seront arrangées sous une forme en arête de poisson possédant une unité cellulaire rectangulaire centrée de dimensions 4,95 × 7,05 Å. Dans cette structure, les axes moléculaires C=C sont parallèles à la surface et sont orientés à des angles de 60° les uns des autres, alors que les plans moléculaires sont déplacés de 55° par rapport au plan de la surface. On a trouvé que la structure est essentiellement indépendante du plissement supposé de la surface du graphite.

[Traduit par la revue]

1. Introduction

There has been a significant amount of effort, both experimental and theoretical, to characterize the phases of simple molecules adsorbed on graphite, and to construct the corresponding phase diagrams. To date a wide variety of structures have been identified. Much of this diversity in structure is due to the shape of the adsorbed molecule, and molecules with similar shapes often produce similar structures and similar phase diagrams. For example, small, aspherical molecules such as N_2 (1), C_2H_4 (2), C_2H_6 (3), C_2N_2 (4), and C_6H_{14} (5) all form herringbone structures on graphite at low coverages. For polar molecules like N_2 and C_2N_2, the herringbone structure arises from the electrostatic quadrupole–quadrupole interactions, whereas for the hydrocarbons it is a consequence of aspherical shape.

Computer simulation molecular dynamics (MD), or Monte Carlo (MC) calculations are particularly suited to the study of physisorbed *molecular* systems. Such simulations can give additional details about the structures of the various phases that are not readily obtainable from diffraction experiments. Molecular dynamics has the added advantage that it can be used to study time-dependent properties such as vibrational frequencies, and hence dynamical properties of adsorbed molecules. In combination with scattering and thermodynamic experiments, MD is thus a powerful technique for the study of physisorbed systems (6).

One molecule, ethylene (C_2H_4), has been the object of considerable interest since the discovery of its incomplete wetting (7) and continuous melting (8) behavior on graphite. Ethylene adsorbed on graphite has been examined by several experimental methods, including both elastic and inelastic neutron scattering (9, 10), synchrotron X-ray diffraction (11, 12), nuclear magnetic resonance (nmr) (13, 14), and calorimetry (8, 15).

These experiments have shown that overlayers of ethylene form two main structural phases at low temperature. If we define a coverage of $n = 1.0$ to be a registered triangular $\sqrt{3} \times \sqrt{3}$ R30° monolayer, then at coverages below $n = 0.8$ ethylene forms the so-called low density (LD) phase. Published diffraction data suggest a triangular lattice for this phase, with a nearest neighbor (n-n) distance of 4.65 Å (9). For $n > 1.05$, ethylene forms the high-density (HD) phase, which is a triangular lattice with n-n distance of 4.22 Å. Calculations suggest that in the HD phase the C=C bonds are aligned perpendicular to the plane of the surface, while in the LD phase the C=C bonds are aligned parallel to the plane of the surface (2). Between $n = 0.8$ and $n = 1.05$ a two-phase (HD + LD) region exists (9, 15). A variety of experiments indicate that both the LD and HD phases have a transition at about 35 K from an ordered herringbone to a phase in which the molecules are rotationally disordered (13–15).

Molecular dynamics has been used previously to probe the behavior of C_2H_4 on graphite (2, 16, 17). These calculations employed atom–atom intermolecular potentials fitted to bulk crystal properties (18), and admolecule–surface interactions (19) fitted to the heat of adsorption (2). The low-temperature structure, the rotator phase, and melting have all been studied (2, 16, 17) with a flat surface model, which ignored the corrugation of the graphite basal plane (19). The calculated low temperature structure was not in agreement with the close-packed triangular lattice deduced for the experimental measurements mentioned above. In particular, the structure was found to be based on a two-molecule centered rectangular cell, approximately $1 \times \sqrt{2}$ rather than $1 \times \sqrt{3}$ characteristic

of a triangular lattice. Since these earlier calculations were performed on a flat surface model, the question arises as to whether or not it is the surface corrugation of graphite that causes LD ethylene to adopt triangular $1 \times \sqrt{3}$. We tackle this question with new MD simulations, which explicitly include the corrugation of the graphite surface (19).

2. MD calculations

To examine the effect of the surface corrugation on the low temperature structure, MD simulations were performed on three different models. In most of the simulations, the intermolecular potential was taken as the sum of individual atom–atom exp-6 potentials (8), with the same set of Williams (W) parameters as in the previous study (2). One simulation was performed using a different set of potential parameters, which was taken from the methane potential of Severin and Tildesley (ST) (20). The molecule–surface potentials were also taken as the sum of atom–atom potentials, which were converted to Lennard-Jones (L-J) form and approximated by a Fourier expansion as in the method of Steele (19), keeping the first two terms of the expansion. This procedure gives an analytic form for the *atom*-corrugated surface potential, which contains the two terms $V_0(z)$ and $V_1(x,y,z)$. Here, V_0 is the flat surface approximation for the total potential, and V_1 is a correction term that contains the lateral variation in the potential due to the corrugation. All of the MD calculations were run at 20 K for 20 ps, after a short equilibration period. We have employed the same MD algorithm as in earlier work (2), and a timestep of 2.5 fs, which gave excellent energy conservation.

For the simulations on the flat surface ($V_1 = 0$), we used a system of 96 molecules that was started in a triangular lattice at a coverage of $n = 0.84$. The system was kept at constant spreading pressure, which meant that the sides of the box were allowed to fluctuate with time (21). In this way, the system could relax to its equilibrium structure (2).

The simulations on the corrugated surface ($V_1 \neq 0$) could not be run at constant spreading pressure. Systems with periodic boundary conditions require the potential to be continuous at the boundaries. Therefore MD studies of the corrugated surface model were run at constant area. This was a serious limitation for a simulation that was supposed to allow the system to relax to its equilibrium configuration (*including surface coverage*). So, instead of using a full simulation box, we employed a patch of ethylene molecules placed at the center of a box of fixed area approximately double the size of the patch. The patch contained 108 molecules in a box of dimensions $20 \times 12\sqrt{3}a$, where $a = 4.26$ Å is the unit cell length for the $\sqrt{3} \times \sqrt{3}$ R30° triangular structure. The starting configuration for the molecules in this simulation was the equilibrated structure from the MD calculations on the flat surface.

It has been noted (22) that the Steele method (19) of incorporating the corrugation does not take into account the fact that the carbon atoms in the graphite basal plane are more polarizable within the plane of the surface than normal to it. It was estimated (22) that the actual size of the corrugation is almost double the amount given by the Steele method. Joshi and Tildesley (23) made a thorough study of the melting of N_2 on graphite, and have derived a more realistic form for the corrugated surface potential, which we have employed here.

Finally, we mention that we have made no allowance for the so-called substrate mediated McLachlan interaction, which has been shown to be important for atomic systems (24, 25). In the latter case, these effective 3-body forces weaken the adatom–adatom interactions by about 15%. It remains to adapt the theory to treat molecular as opposed to atomic systems.

3. Results and discussion

The MD results for the different systems are compared with each other and with the experimental results in Table 1. The most important finding is that the corrugation seems to have little effect on the structure. We now discuss each system separately.

3.1 Flat surface

The simulation on the flat surface was essentially a duplication of the previous work (2), but here we present more details. In the present calculations, the system rapidly evolved from a triangular lattice to a rectangular unit cell in a time of 4 ps. We therefore present averages over the last 5-ps segment of the 10-ps MD run. The calculated molecule–surface potential energy E(m-s) is very close to the experimental value of −20.3 kJ/mol (16), corrected to 20 K (see Table 1). Figure 1 shows the radial distribution function $G(R)$ for the centers of mass of the molecules. The inset shows $G(Z)$, the distribution of the carbon atoms of the ethylene in the z-direction, which is normal to the surface. The $G(R)$ has its first three peaks at 4.30, 4.92, and 7.05 Å, which correspond to the three smallest intermolecular distances in the quasi two-dimensional solid. In a triangular lattice, the first two peaks would be degenerate.

Figure 2(a) shows the instantaneous configuration of the system at the end of the simulation at 20 K. The system forms a stable herringbone, with individual molecules exhibiting only a small amount of rotational (librational) motion within the plane of the surface. From this snapshot, and from the $G(R)$ peak positions, we can deduce the following structure for the solid. The ethylene formed a herringbone structure, with a rectangular unit cell of dimensions 4.92 Å × 7.05 Å, corresponding to a coverage of $n = 0.904$, or 0.0577 Å^{-2}.

The C=C bonds of the molecules were aligned parallel to the surface plane, since $G(Z)$ shows only one peak. For the molecule at the corner of the unit cell, the molecular axis makes an angle of 30° with $\boldsymbol{a}$. The molecular axis of the molecule at the center of the cell makes an angle of −30° with $\boldsymbol{a}$. The planes of the molecules do not lie flat (parallel to the surface), but are inclined an average of 62° from the plane of the surface. This compares to a tilt of 35°, found from static calculations (9) that had assumed a triangular lattice at a coverage of $n = 0.85$. The higher tilt is likely a consequence of the higher coverage in our system. In the MD structure, the ethylene molecular axes make an angle of 60° with each other, as opposed to 90° expected for an ideal herringbone that arises from interacting point quadrupoles.

The above structure would produce a strong neutron scattering peak at 1.56 Å^{-1}, and weak ones at 1.78, 2.55, and 2.96 Å^{-1}. The peak position of 1.56 Å^{-1} agrees exactly with the experimental result (9), which was used to index the triangular lattice at a coverage of 0.83. The peak at 1.78 Å^{-1} was not observed. Also, the experiments show only a single peak at 2.70 Å^{-1}, whereas the present simulations at $n = 0.9$ have a double peak, due to the rectangular unit cell.

In summary, these new calculations confirm that the calculated low temperature LD monolayer structure for ethylene on graphite is not triangular.

3.2 Corrugated surface

The MD simulation on the corrugated surface was run for 20 ps. The motivation for this was that we wished to run long

TABLE 1. Molecular dynamics results for ethylene on graphite

[b]Data taken from ref. 16 and corrected to 20 K.

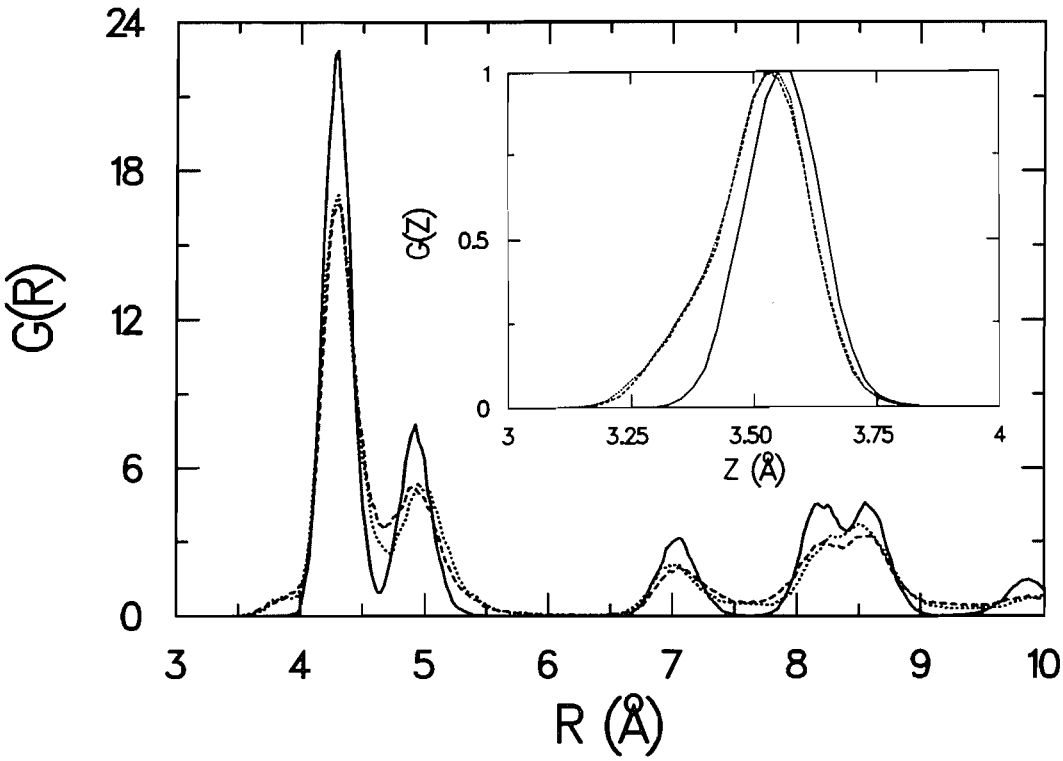

FIG. 1. Pair distribution function $G(R)$ for ethylene overlayers physisorbed on graphite. The inset shows the single particle distribution $G(Z)$ for the carbon atoms of the ethylene molecules in the direction perpendicular to the surface. The solid curve is for the system on a flat surface, the dashed curve is for the patch on a corrugated surface, and the dotted curve is for the patch on a corrugated surface with the anisotropic potential.

enough to allow for local relaxation of molecular orientations, etc. The determination of the true equilibrium structure of a patch would likely require a prohibitively long computation.

The results of the simulation on the corrugated surface are presented in Table 1. Once again, E(m-s) is very close to the experimental value. In this case, by considering only those molecules in the center of the patch, the molecule–molecule potential energy E(m-m) has been adjusted to approximately eliminate the edge effects. Figure 1 shows the $G(R)$ for the centers of mass, and $G(Z)$ for the carbon atoms of the ethylene. Figure 2(b) is a snapshot of the system at the end of the simulation. The $G(R)$ for the corrugated surface is virtually identical to the $G(R)$ for the flat surface. The peaks are somewhat more spread out because of the molecules at the edge of the patch. Unlike the flat surface model, $G(Z)$ is asymmetric and displaced inward, because the ends of the ethylene molecules tend to settle into the centers of the graphite hexagons. Since the ethylene is incommensurate, the effect of the corrugation to some extent is averaged out.

The small shoulder in $G(R)$ at about 3.85 Å deserves mention. This shoulder is due to pairs of canted molecules with their molecular planes and C=C axes aligned parallel to each other. In Fig. 2(b), there are several pairs of molecules arranged in this way. This happens near the edge of the patch, where each molecule has an incomplete set of only a few neighbors.

The $G(R)$ peak positions are at 4.30, 4.90, and 7.06 Å. This corresponds to a centered rectangular unit cell of dimensions 4.90 Å × 7.06 Å, which is a coverage of $n = 0.907$. It is otherwise identical to the unit cell of the flat surface simulations. From the snapshot of the system in Fig. 2(b), it can be seen that the ethylene structure is rotated about 4° with respect to the graphite lattice. This particular structure would produce a strong neutron scattering peak at 1.56 Å^{-1}, and weak ones at 1.78, 2.55, and 2.96 Å^{-1}. Such a pattern is indistinguishable from the pattern deduced from the flat surface simulations.

Because the structures for the flat and corrugated surfaces were so similar, it was natural to consider whether the latter calculation was run for sufficiently long times or if initiating the corrugated surface calculations from the final flat surface structure had prejudiced the calculations. Accordingly, two new

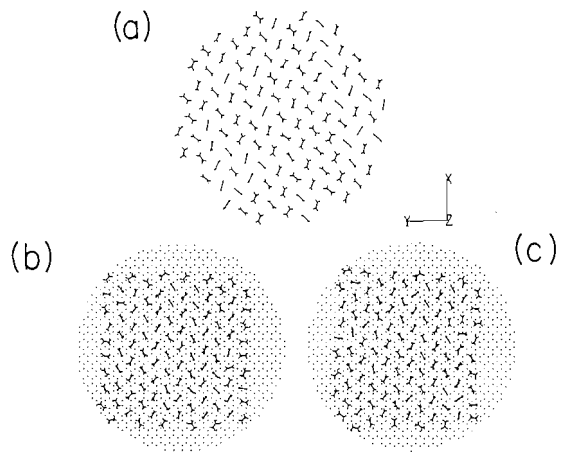

FIG. 2. Top views of the instantaneous configurations for each system at the end of the simulation runs; (a) a section of the system on the flat surface, (b) the patch on the corrugated surface, and (c) the patch on the corrugated surface with the anisotropic potential. The dots represent the positions of the carbon atoms in the first layer of the graphite.

calculations were performed on the corrugated surface starting from structures that were dilated by 2% and 5% in both the x and y directions. In both cases, the MD calculation yielded the same final structure as in Table 1.

3.3 Corrugated surface (anisotropic potential)

The above results show that the surface corrugation had little influence on the low temperature structure of ethylene on graphite. However, recent work has demonstrated the inadequacy of the isotropic form of the atom–surface potential. Both N_2 (23) and C_2H_4 (17), when simulated with the isotropic atom–surface potential, have melting temperatures which are at least 9 degrees below the corresponding experimental values. This observation has been attributed to the fact that the isotropic potential produces a corrugation that is too small. To remedy this, Joshi and Tildesley used the anisotropic potential with two parameters, γ_A and γ_R, which are derived from the polarizability of the graphite atoms (22). The case $\gamma_A = \gamma_R = 0$ corresponds to the isotropic potential. We have taken the values $\gamma_A = 0.4$ and $\gamma_R = -1.05$, which were found to give the correct melting temperature for N_2 on graphite (23). The maximum variation in the ethylene–graphite potential rises from about 50 K to about 95 K when the isotropic form is replaced by the anisotropic form.

The results of the simulation with the anisotropic potential are shown in Table 1. Surprisingly, the enhanced corrugation of this potential seems to have almost no effect on the ethylene structure. The corrugation is not able to produce a triangular lattice. The $G(R)$ and $G(Z)$ for this system are shown in Fig. 1. Figure 2(c) shows a snapshot of the system at the end of the simulation. The peak positions for $G(R)$ are 4.30, 4.98, and 7.03 Å. This corresponds to a centered rectangular unit cell of dimensions 4.98 Å × 7.03 Å, and a coverage of $n = 0.898$. It is otherwise identical to the unit cell for the system on the corrugated surface.

This structure would produce a strong neutron scattering peak at 1.55 $Å^{-1}$, and weaker peaks at 1.79, 2.52, and 2.96 $Å^{-1}$. Again, this is indistinguishable from the results on the other two surfaces.

3.4 A different potential

The agreement between the flat and corrugated surface

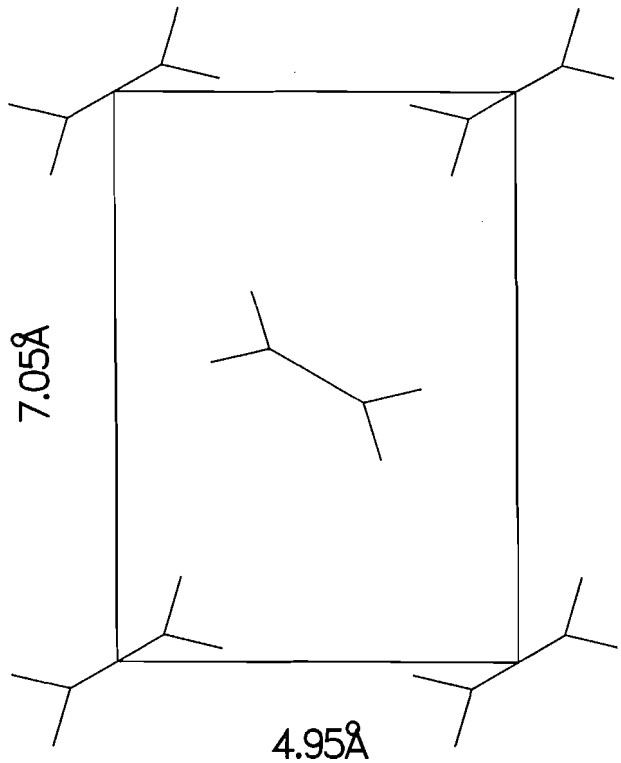

FIG. 3. Unit cell for low temperature ethylene on graphite deduced from the simulations. The molecules are arranged with their C=C axes parallel to the plane of the surface, and rotated 30° with respect to ***a***. The molecular planes are canted 55° away from the plane of the surface.

models suggests that the monolayer structure of ethylene is really not triangular when the coverage is about 0.9. This is a higher surface density than was used in the neutron measurements of ref. 9. The discrepancy between the calculated and measured density for the LD phase may be due to the fact that the Williams intermolecular potential was too attractive. We therefore performed a new simulation with a radically different potential (20). This potential was fitted to experimental properties of *methane* adsorbed on graphite, namely the rotational barrier heights, second virial coefficients, and the isotropic enthalpy at zero coverage (20). In contrast, the parameters used earlier in this study, which were taken from Williams (19), were fitted to the properties of bulk hydrocarbons. On a flat surface, the ST potential produced a herringbone with a unit cell of 5.35 Å × 7.35 Å, which is less dense than both the experimental and earlier simulation results. We conclude that this is not an appropriate potential for ethylene adsorbed on graphite, and unfortunately does not resolve the apparent discrepancy between our model and experiment.

4. Conclusion

We have presented the results of MD simulations of ethylene on graphite, both on a flat surface, and on a corrugated surface. The corrugation appears to have little effect on the low temperature structure, even when the anisotropic surface potential was used. The calculations predicted that ethylene forms the low temperature structure shown in Fig. 3, with a unit cell of 4.95 Å × 7.05 Å, rotated by 4° with respect to the substrate. This would produce diffraction peaks at 1.56, 1.78, 2.52, and 2.96 $Å^{-1}$. To this point, only peaks at 1.56 and 2.70 $Å^{-1}$, which correspond to a triangular lattice, have been seen in the diffraction experiments, at $n = 0.83$. The present

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/07/12
For personal use only.

simulations predict that, at $n = 0.9$, these peaks should be split. If this discrepancy with experiment is confirmed, it could mean that the Williams potential alone is inadequate for surface calculations on substrate supported molecules due to the neglect of substrate mediated interactions.

The fact that the corrugation had such little effect on the structure was quite unexpected, given the large effect it had on the melting temperature (17). Therefore, we will be conducting future investigations into the effect of the corrugation on the dynamical properties of the liquid phase of submonolayer ethylene on graphite.

Received August 21, 1987

This paper is dedicated to Professor James A. Morrison

TORSTEN HVIDT, WALTER A. SZAREK, and DAVID B. MACLEAN. Can. J. Chem. **66**, 779 (1988).

The (*R*) and (*S*) isomers of β-amino-α-methylene-γ-butyrolactone hydrochloride (4-amino-dihydro-3-methylene-2(3*H*)-furanone hydrochloride) have been synthesized from (*R*)- and (*S*)-tryptophan, respectively. A key step is the ozonolysis of *N*,*O*-diacetyl-2-amino-3-(3′-indolyl)-1-propanol. (*S*)-β-Amino-α-methylene-γ-butyrolactone hydrochloride has been synthesized also by an analogous route starting with (*S*)-phenylalanine.

TORSTEN HVIDT, WALTER A. SZAREK et DAVID B. MACLEAN. Can. J. Chem. **66**, 779 (1988).

Utilisant les (*R*)- et (*S*)-tryptophanes comme produits de départ, on a synthétisé respectivement les isomères (*R*) et (*S*) du chorhydrate de la β-amino α-méthylène γ-butyrolactone (chlorhydrate de l'amino-4 dihydro méthylène-3 (3*H*)-furannone-2). Une étape clé est l'ozonolyse du *N*,*O*-diacétyl amino-2 (indolyl-3′)-3 propanol-1. Utilisant la (*S*)-phénylalanine comme produit de départ, on a synthétisé le chlorhydrate de la (*S*)-β-amino α-méthylène γ-butyrolactone de la même manière.

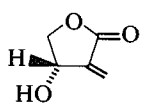
Introduction

The α-methylene-γ-butyrolactone system, found in many natural products, has stimulated much research because of the interesting biological properties (1–5). Most of the synthetic effort has been directed towards the preparation of lactones substituted with alkyl groups at the β and (or) γ positions. Only a few examples of α-methylene-γ-butyrolactones bearing a heteroatom at the β position are known (6–10); one example is tulipalin B (**1**), which has fungicidal properties (2*a*) and



1

cutaneous allergenic activity (2*b*). However, to our knowledge an α-methylene-γ-butyrolactone bearing a nitrogen substituent attached to the ring has not been described. In this article we report the synthesis of enantiomerically pure β-amino-α-methylene-γ-butyrolactone hydrochlorides (4-amino-dihydro-3-methylene-2(3*H*)furanone hydrochlorides) (see **10**) and their *N*-acetyl derivatives (see **11**). In addition to the potential biological activity of **10** and **11**, the varied functionality in the new compounds should make them of interest as intermediates in the synthesis of complex natural products.

Results and discussion

The synthetic route developed for the (*R*) and (*S*) isomers of β-amino-α-methylene-γ-butyrolactone started with (*R*)- and (*S*)-tryptophan, respectively, and involved no chromatographic separations. The conversion of (*S*)-tryptophan (**2**) into the (*S*) isomer **10** is shown in Scheme 1. Treatment of **2** with thionyl chloride in methanol at reflux temperature (11) afforded the ester **3** in quantitative yield. Reduction of **3** using sodium borohydride in aqueous ethanol gave the alcohol **4**, which, on treatment with acetic anhydride and pyridine at room temperature, afforded *N*,*O*-diacetyl-2-amino-3-(3′-indolyl)-1-propanol (**5**) in crystalline form. A solution of **5** in aqueous acetic acid was subjected to a stream of ozone in oxygen for 14 h; oxidative processing, followed by heating of the product in the presence of 2 *N* hydrochloric acid, afforded a syrupy material whose ^{1}H nmr spectrum indicated that it consisted predominantly of the lactone **6**. An analytically pure sample of **6** eventually could be obtained. (The synthesis of **6** was achieved previously (12*a*) by way of reduction of *N*-benzoylasparagine methyl ester using lithium aluminum hydride; also, recently, the carbobenzyloxy derivative of **6** was synthesized (12*b*) by way of the selective reduction of *N*-(carbobenzyloxy)-L-aspartic anhydride.) Treatment of the crude syrupy material with benzophenone imine (13) in dichloromethane gave the imino derivative **7** in crystalline form; this derivative proved to be particularly useful for the subsequent transformations. The conversion of **5** into **7** was achieved in an overall yield of 35%.

The α-methylene function was introduced into **7** in two stages, namely by treatment with sodium hydride and then ethyl formate to give the sodium salt of the α-formyl lactone (**8**), followed by heating a solution of **8** in tetrahydrofuran at reflux temperature in the presence of paraformaldehyde to give the α-methylene lactone **9** in crystalline form. This method of synthesis of α-methylene lactones has been reported by Murray and Reid (14). Hydrolysis of **9** using 1 *N* hydrochloric acid – diethyl ether gave the amine hydrochloride **10**, which, on treatment with acetic anhydride, 4-*N*,*N*-dimethylaminopyridine, and triethylamine in dichloromethane, afforded (*S*)-β-acetamido-α-methylene-γ-butyrolactone (**11**).

The same reaction sequence has been employed for the synthesis of (*R*)-β-acetamido-α-methylene-γ-butyrolactone from (*R*)-tryptophan. Also, (*S*)-phenylalanine has been employed to obtain (*S*)-β-(diphenylmethylene)amino-γ-butyrolactone (**7**) by an analogous route (see Scheme 2). In this case, **7** was obtained in 45% yield (based on *N*,*O*-diacetyl-2-amino-3-phenyl-1-propanol (**14**)), whereas, in the case of the synthesis starting with (*S*)-tryptophan, **7** was obtained in 35% yield (based on **5**).

SCHEME 2

The work described in this article provides a useful route to the synthesis of α-methylene-γ-butyrolactones bearing a heteroatom at the β position. For example, starting with commercially available (*S*)-2-hydroxy-3-phenylpropanoic acid should afford (*S*)-tulipalin B (**1**). Also, the synthetic utility of **10** is being explored for the synthesis of nitrogen heterocycles.

Experimental

The ^1H nmr spectra were recorded on a Bruker AM400 spectrometer. Tetramethylsilane (TMS) was used as the internal standard for samples examined in organic solvents, and sodium 4,4-dimethyl-4-silapentan-1-sulfonate (DSS) for samples examined in aqueous solution; chemical shifts are reported in ppm (δ) downfield from the signal of TMS. The symbols, s (singlet), d (doublet), t (triplet), q (quartet), m (multiplet), and br (broadened), are used to report the multiplicity and shape of signals. The ^{13}C nmr spectra were recorded on the same instrument at 100.6 MHz. The solvent was used as internal standard when spectra were recorded in $CDCl_3$ (77.00 ppm) or CD_3OD (49.00 ppm); *tert*-butyl alcohol (32.27 ppm) was used as the internal standard for samples examined in aqueous systems. The chemical shifts of all signals are reported relative to TMS; all data were obtained in SEFT experiments. EI mass spectra were recorded on a VG ZAB-E mass spectrometer at an ionizing voltage of 70 eV. Infrared (ir) spectra were recorded on a Bruker IFS 85 FTIR instrument. Optical rotations were measured on a Perkin–Elmer 241 polarimeter in a 1-dm tube at 27 ± 3°C.

Melting points were determined on a Fisher–Johns melting point apparatus and are uncorrected. Silica gel 60 F_{254}, Merck, was used for thin-layer and column chromatography. Elemental analyses were performed by Canadian Microanalytical Services, Ltd., New Westminster, B.C.

(*R*) and (*S*) are used to designate the configuration of chiral centres, which are situated at C-2 for compounds **2**–**5** and **12**–**14**, and at C-3 for compounds **6**–**11**.

Methyl tryptophanate hydrochloride (3)

Tryptophan (25 g, 0.128 mol) was added to a solution of thionyl chloride (11 mL, 0.152 mol) in dry methanol (350 mL) and the resulting mixture heated under reflux for 18 h. The mixture was then evaporated to dryness, affording in quantitative yield a crystalline product that was used without purification in the next step. Recrystallization from methanol – diethyl ether gave an analytical sample; (*R*) isomer: mp 204–205°C; $[\alpha]_D$ −16.7° (*c* 1.5, methanol); (*S*) isomer: mp 203.5–205.0°C; $[\alpha]_D$ +17.1° (*c* 1.2, methanol) (lit. (15) mp 213.5–214.0°; $[\alpha]_D$ +17.1° (*c* 2.0, methanol)); (lit. (16) mp 200–201°C; $[\alpha]_D$ +16.3° (*c* 2.0, methanol)); ^1H nmr (CD_3OD) δ: 3.42 (dd, 1H, *J* = 15.1 and 7.0 Hz, H-3), 3.46 (dd, 1H, *J* = 15.1 and 5.5 Hz, H-3), 3.77 (s, 3H, OMe), 4.32 (apparent t, 1H, *J* = 6.4 Hz, H-2), 7.06 (t, 1H, *J* = 7.5 Hz, H-5′), 7.13 (t, 1H, *J* = 7.5 Hz, H-6′), 7.23 (s, 1H, H-2′), 7.40 (d, 1H, *J* = 8.0 Hz, H-7′), 7.54 (d, 1H, *J* = 8.0 Hz, H-4′); ^{13}C nmr (CD_3OD) δ: 27.5 (C-3), 53.6, 54.6 (C-2, OMe), 107.4 (C-3′), 112.7 (C-7′), 118.8, 120.3, 122.9 (C-4′, C-5′, C-6′), 125.7 (C-2′), 128.2 (C-4a′), 138.2 (C-7a′), 170.8 (C=O).

2-Amino-3-(3′-indolyl)-1-propanol (4)

To a solution of **3** (30 g, 0.178 mol) in a 1:1 (v/v) mixture (350 mL) of water and ethanol was added slowly with stirring a solution of sodium borohydride (23.1 g, 0.612 mol) in 100 mL of the same solvent. When the addition of borohydride was complete the mixture was heated to boiling under reflux for 18 h. The solution was evaporated under reduced pressure to remove ethanol, and the residual aqueous solution treated first with sodium hydroxide to hydrolyze esters of boric acid and then with sodium chloride to saturate the solution before exhaustive extraction with ethyl acetate. The extract was washed with water, dried over anhydrous Na_2SO_4, and evaporated

to dryness, affording 16.2 g (72%) of **4** as a glassy solid, which was used without purification in the next step. The product could not be induced to crystallize. (*S*) Isomer: $[\alpha]_D$ −19° (*c* 1.0, methanol) (lit. (17) mp 84–85°C; $[\alpha]_D$ −20.5° (*c* 1.0, methanol)); ^{1}H nmr (CD_3OD) δ: 3.05 (dd, 1H, *J* = 14.5 and 6.5 Hz, H-3), 3.11 (dd, 1H, *J* = 14.5 and *J* = 7.5 Hz, H-3), 3.51 (m, 1H, H-2), 3.59 (dd, 1H, *J* = 11.5 and 6.0 Hz, H-1), 3.75 (dd, 1H, *J* = 11.5 and 3.6 Hz, H-1), 7.04 (dt, 1H, *J* = 7.6 and 1.0 Hz, H-5′), 7.12 (dt, 1H, *J* = 7.6 and 1.0 Hz, H-6′), 7.17 (s, 1H, H-2′), 7.37 (apparent dt, 1H, *J* = 7.6 and ~1.0 Hz, H-7′), 7.58 (apparent dt, 1H, *J* = 7.6 and ~1.0 Hz, H-4′); ^{13}C nmr (CD_3OD) δ: 26.4 (C-3), 55.0 (C-2), 62.1 (C-1), 109.6 (C-3′), 112.5 (C-7′), 119.0, 120.1, 122.7 (C-4′, C-5′, C-6′), 125.0 (C-2′), 128.4 (C-4a′), 138.3 (C-7a′).

N,O-*Diacetyl-2-amino-3-(3′-indolyl)-1-propanol* (***5***)

A solution of **4** (15.5 g, 0.082 mol) in dry pyridine (70 mL) was treated with acetic anhydride (23 mL, 0.245 mol). The resulting solution was kept at room temperature for 14 h; isolation of the product in the usual manner afforded 22.0 g (98%) of **5** as a syrup that slowly crystallized. Recrystallization from ethyl acetate – hexanes gave an analytical sample. (*R*) Isomer: mp 124.5–125.5°C; $[\alpha]_D$ +4.5° (*c* 0.8, methanol); (*S*) isomer: mp 125.5–126.0°C; $[\alpha]_D$ −4.4° (*c* 0.6, methanol); ^{1}H nmr ($CDCl_3$) δ: 1.96 (s, 3H, NAc), 2.10 (s, 3H, OAc), 2.97 (dd, 1H, *J* = 14.5 and 7.2 Hz, H-3), 3.05 (dd, 1H, *J* = 14.5 and 5.4 Hz, H-3), 4.06 (dd, 1H, *J* = 11.2 and 4.8 Hz, H-1), 4.13 (dd, 1H, *J* = 11.2 and 6.0 Hz, H-1), 4.56 (m, 1H, H-2), 5.71 (br d, 1H, *J* = 8.0 Hz, *H*NAc), 7.04 (s, 1H, H-2′), 7.14 (t, 1H, *J* = 8 Hz, H-5′), 7.21 (t, 1H, *J* = 8 Hz, H-6′), 7.37 (d, 1H, *J* = 8 Hz, H-7′), 7.66 (d, 1H, *J* = 8 Hz, H-4′), 8.22 (br s, 1H, NH); ^{13}C nmr (CD_3OD) δ: 20.7 ($NCOCH_3$), 22.7 ($OCOCH_3$), 27.8 (C-3), 50.5 (C-2), 66.3 (C-1), 111.6 (C-3′), 112.2 (C-7′), 119.2, 119.7, 122.3 (C-4′, C-5′, C-6′), 124.1 (C-2′), 128.8 (C-4a′), 138.0 (C-7a′), 172.7 (C=O), 173.0 (C=O). *Anal.* calcd. for $C_{15}H_{18}N_2O_3$: C 65.68, H 6.61, N 10.21; found, (*R*) isomer: C 66.10, H 6.72, N 10.45; found, (*S*) isomer: C 65.63, H 6.58, N 10.10.

β-*Amino-γ-butyrolactone hydrochloride* (***6***)

A stream of ozone in oxygen (0.4 mmol/min of O_3) was passed through a vigorously stirred solution of **5** (4.0 g, 0.015 mol) in 86% acetic acid, at room temperature, for 14 h or until the solution became colorless. Hydrogen peroxide (30 mL, 30%) was then added and the colorless solution allowed to stand at room temperature. After 3 days the excess of peroxide was destroyed by adding a small amount of 10% Pd/C. The peroxide-free mixture was filtered to remove catalyst, and the filtrate was evaporated under vacuum below 40°C. The last traces of acetic acid were removed by adding water to the residue and evaporating again; this process was repeated several times. The residual reddish oil was applied to a column (3 × 28 cm) of Amberlite IR410 ion-exchange resin (OH^- form); the column was washed with water and eluted with 2 *N* hydrochloric acid. The eluate was heated under reflux for 2 h to hydrolyze the acetyl groups. The hot solution was treated with DARCO C, the mixture was filtered, and the filtrate evaporated to dryness. The residue was dried to constant weight over phosphorus pentoxide at 0.2 Torr (1 Torr = 133.3 Pa). The ^{1}H nmr spectrum of the crude product indicated that it consisted mainly of **6**, and the product was used as such in the preparation of **7** described below. An analytical sample of **6** was obtained from a preparation starting with (*S*)-phenylalanine; details of the characterization are given below.

β-*(Diphenylmethylene)amino-γ-butyrolactone* (***7***)

The crude product **6** (2.86 g) prepared above, suspended in dichloromethane (50 mL), was treated with benzophenone imine (13) (4.16 mL, 0.025 mol). The mixture was stirred at room temperature overnight, filtered free of suspended solids, and the filtrate evaporated to dryness. The oily, reddish residue was triturated with diethyl ether and the insoluble matter removed by filtration. The filtrate was washed with a saturated solution of sodium chloride, dried over anhydrous sodium sulfate, and evaporated to dryness. The crystalline residue was recrystallized from diethyl ether – hexanes, affording 1.41 g (35% based on **5**) of **7**; another 0.07 g of **7** was isolated from the mother liquor. (*R*) Isomer: mp 123.0–123.5°C; $[\alpha]_D$ +10.3° (*c* 1.2, chloroform); (*S*) isomer: mp 123.0–123.5°C; $[\alpha]_D$ −10.5° (*c* 1.1, chloroform); ν_{max}(KBr): 1712 (lactone) cm^{-1}; ^{1}H nmr (CD_3OD) δ: 2.52 (dd, 1H, *J* = 17.5 and 3.5 Hz, H-α), 2.77 (dd, 1H, *J* = 17.5 and 7.0 Hz, H-α), 4.29 (m, 2H, H-γ), 4.40 (m, 1H, H-β), 7.16–7.59 (m, 10H, Ph); ^{13}C nmr ($CDCl_3$–CD_3OD, 2:1 (v/v)) δ: 36.3 (C-α), 57.3 (C-β), 73.8 (C-γ), 127.1, 127.9, 128.4, 128.6, 128.8, 130.5, 135.7, 138.4 (Ph), 170.1 (C=N), 176.7 (C=O). *Anal.* calcd. for $C_{17}H_{15}NO_2$: C 76.96, H 5.70, N 5.28; found, (*R*) isomer: C 77.24, H 5.73, N 5.36; found, (*S*) isomer: C 76.90, H 5.73, N 5.27.

β-*(Diphenylmethylene)amino-α-methylene-γ-butyrolactone* (***9***)

A sample of sodium hydride (0.14 g, 5.8 mmol) obtained from a 50% suspension in mineral oil was prepared by washing twice with hexanes. The hydride was suspended in dry diethyl ether (20 mL) and treated successively with absolute ethanol (2 drops), dry ethyl formate (0.45 mL, 5.6 mmol), and **7** (1.4 g, 5.3 mmol); the resulting suspension was stirred for 16 h at room temperature. The suspended solid (crude **8**) was recovered by filtration and washed thoroughly with anhydrous diethyl ether. A ^{1}H nmr spectrum of the crude product indicated that reaction had proceeded in the expected manner; the salt was not further characterized.

The sample of crude **8** prepared above, in dry tetrahydrofuran (20 mL), was treated with paraformaldehyde (0.48 g, 16 mmol). The resulting suspension was heated under reflux for 3 h with the temperature adjusted in a manner that minimized separation of paraformaldehyde on the walls of the condenser. The suspension was cooled and filtered, and the separated solids washed well with dry tetrahydrofuran. The filtrate was evaporated to dryness, affording an oily residue that was adsorbed on a short column of silica gel; elution of the column with 15:1 (v/v) toluene – ethyl acetate gave crystalline **9** (0.758 g, 52% from **7**). Recrystallization from diethyl ether – hexanes gave an analytical sample. (*R*) Isomer: mp 117.5–120.0°C; $[\alpha]_D$ −32.7° (*c* 1.5, chloroform); (*S*) isomer: mp 117.5–120.0°C; $[\alpha]_D$ +33.2° (*c* 1.0, chloroform); ν_{max}(KBr): 1764 (lactone) cm^{-1}; ^{1}H nmr (CD_3OD) δ: 4.27 (dd, 1H, *J* = 9.0 and 5.4 Hz, H-γ), 4.46 (dd, 1H, *J* = 9.0 and 7.8 Hz, H-γ), 4.79 (m, 1H, H-β), 5.69 (d, 1H, *J* = 2.4 Hz, H-β′), 6.28 (d, 1H, *J* = 2.5 Hz, H-β′), 7.25–7.61 (m, 10H, Ph); ^{13}C nmr ($CDCl_3$–CD_3OD, 1:1 (v/v)) δ: 59.8 (C-β), 70.9 (C-γ), 124.0 (C-β′), 127.1, 128.0, 128.5, 128.7, 129.0, 130.7, 135.4, 138.3 (Ph), 137.1 (C-α), 169.9 (C=N), 172.0 (C=O). *Anal.* calcd. for $C_{18}H_{15}NO_2$: C 77.96, H 5.45, N 5.05; found, (*R*) isomer: C 77.99, H 5.48, N 5.06; found, (*S*) isomer: C 78.15, H 5.43, N 5.05.

β-*Amino-α-methylene-γ-butyrolactone hydrochloride* (***10***)

To a solution of **9** (0.32 g, 1.2 mmol) in diethyl ether (15 mL) was added aqueous 1 *N* hydrochloric acid (1.4 mmol). The two-phase system was vigorously stirred until the starting material had disappeared (~4 h); the progress of the reaction was monitored by tlc using 15:1 (v/v) toluene – ethyl acetate. When the reaction was complete, the aqueous phase was separated and washed several times with diethyl ether. Evaporation of the aqueous phase under vacuum, keeping the bath temperature below 40°C, gave a crystalline residue in quantitative yield. (*R*) Isomer: mp > 120°C (dec.); $[\alpha]_D$ +85.7° (*c* 0.5, water); (*S*) isomer: mp > 135°C (dec.); $[\alpha]_D$ −85.2° (*c* 0.6, water); ν_{max}(KBr): 1748 (lactone) cm^{-1}; ^{1}H nmr (CD_3OD) δ: 4.35 (dd, 1H, *J* = 10.7 and 2.8 Hz, H-γ), 4.68 (dd, 1H, *J* = 10.7 and 7.5 Hz, H-γ), 4.77 (m, 1H, H-β), 6.33 (d, 1H, *J* = 1.2 Hz, H-β′), 6.60 (d, 1H, *J* = 1.9 Hz, H-β′); ^{13}C nmr (D_2O) δ: 50.3 (C-β), 71.6 (C-γ), 133.7 (C-α), 134.0 (C-β′), 172.8 (C=O); ms (EI) *m/z* (%): 113 (12), 96 (24), 84 (13), and 67 (100). *Exact Mass* calcd. for $C_5H_7NO_2$: 113.0477; found (hrms): 113.0464.

β-*Acetamido-α-methylene-γ-butyrolactone* (***11***)

A suspension of **10** (0.2 g, 1.33 mmol) in dichloromethane (5 mL) was treated with triethylamine (0.41 mL, 2.9 mmol), acetic anhydride (0.30 mL, 3.2 mmol), and 4-*N*,*N*-dimethylaminopyridine (1 mg). The mixture was stirred for 3 h and then the solution was poured into 3 equivalents of dilute hydrochloric acid. The organic phase was

separated and the aqueous phase, after saturation with sodium chloride, extracted six times with 5-mL portions of ethyl acetate. The combined organic extract was washed with a saturated solution of sodium chloride and dried over anhydrous Na_2SO_4. The organic phase was evaporated to dryness, yielding a crystalline residue (78%) that was further purified by flash chromatography or by recrystallization from ethyl acetate – hexanes. (*R*) Isomer: mp 75–77°C; $[\alpha]_D$ +89.8° (*c* 0.4, chloroform); (*S*) isomer: mp 75–77°C; $[\alpha]_D$ −90.8° (*c* 0.3, chloroform); ν_{max}(KBr): 1764 (lactone) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 2.07 (s, 3H, Ac), 4.10 (dd, 1H, *J* = 10.0 and 4.5 Hz, H-γ), 4.64 (dd, 1H, *J* = 10.0 and 7.5 Hz, H-γ), 5.23 (m, 1H, H-β), 5.96 (d, 1H, *J* = 2.3 Hz, H-β′), 6.35 (br s, 1H, NH), 6.42 (d, 1H, *J* = 2.6 Hz, H-β′); ^{13}C nmr ($CDCl_3$) δ: 22.7 ($NCOCH_3$), 47.6 (C-β), 71.6 (C-γ), 125.9 (C-β′), 135.2 (C-α), 169.2, 170.4 (C=O). *Anal.* calcd. for $C_7H_9NO_3$: C 54.19, H 5.85, N 9.03; found, (*R*) isomer: C 53.87, H 5.85, N 8.83; found, (*S*) isomer: C 53.98, H 5.88, N 8.90.

(S)-Methyl phenylalanate hydrochloride (12)

This compound was prepared from (*S*)-phenylalanine in quantitative yield by the procedure already described for the preparation of **3** from **2**; mp 159–160°C; $[\alpha]_D$ +18.9° (*c* 2.0, methanol) (lit. (18) mp 157–160°C; $[\alpha]_D$ +18.6° (*c* 4.5, methanol)); ^1H nmr (D_2O) δ: 3.24 (dd, 1H, *J* = 14.5 and 7.5 Hz, H-3), 3.36 (dd, 1H, *J* = 14.5 and 5.7 Hz, H-3), 3.84 (s, 3H, OMe), 4.44 (apparent t, 1H, *J* ≃ 6.7 Hz, H-2), 7.28–7.49 (m, 5H, Ph); ^{13}C nmr (D_2O) δ: 38.2 (C-3), 56.2, 56.7 (C-2, OMe), 130.7, 131.8, 131.9, 136.3 (Ph), 172.6 (C=O).

(S)-2-Amino-3-phenyl-1-propanol (13)

This compound was prepared from **12** in 74% yield using the procedure described for the preparation of **4** from **3**; mp 90–91°C; $[\alpha]_D$ −25.3° (*c* 3.1, chloroform) (lit. (19) mp 89–90°C; $[\alpha]_D$ −25.8° (*c* 2.2, chloroform)); ^1H nmr ($CDCl_3$) δ: 2.53 (dd, 1H, *J* = 13.5 and 8.5 Hz, H-3), 2.79 (dd, 1H, *J* = 13.5 and 5.2 Hz, H-3), 3.12 (m, 1H, H-2), 3.38 (dd, 1H, *J* = 10.5 and 7.0 Hz, H-1), 3.63 (dd, 1H, *J* = 10.5 and 4.0 Hz, H-1), 7.19–7.34 (m, 5H, Ph); ^{13}C nmr ($CDCl_3$) δ: 39.6 (C-3), 54.2 (C-2), 64.9 (C-1), 126.4, 128.5, 129.1, 138.0 (Ph).

(S)-N,O-Diacetyl-2-amino-3-phenyl-1-propanol (14)

This compound was prepared from **13** in quantitative yield by the procedure described for the preparation of **5** from **4**; mp 122–123°C; $[\alpha]_D$ −14.1° (*c* 1.5, chloroform); ^1H nmr ($CDCl_3$) δ: 1.97 (s, 3H, NAc), 2.12 (s, 3H, OAc), 2.81 (dd, 1H, *J* = 13.8 and 7.5 Hz, H-3), 2.89 (dd, 1H, *J* = 13.8 and 6.1 Hz, H-3), 4.03 (dd, 1H, *J* = 11.2 and 4.4 Hz, H-1), 4.09 (dd, 1H, *J* = 11.2 and 5.5 Hz, H-1), 4.43 (m, 1H, H-2), 5.59 (br d, 1H, NH), 7.19–7.33 (m, 5H, Ph); ^{13}C nmr ($CDCl_3$) δ: 20.8, 23.2 ($NCOCH_3$, $OCOCH_3$), 37.4 (C-3), 49.4 (C-2), 64.7 (C-1), 126.7, 128.5, 129.1, 136.9 (Ph), 169.6, 170.9 (C=O); ms (EI) *m/z* (%): 236 ($M+1$)$^+$ (6), 235 (M^+) (2), 176 (31), 144 (28), 134 (14), 120 (34), 102 (64), 91 (26), 84 (100). *Exact Mass* calcd. for $C_{13}H_{17}NO_3$: 235.1209; found (hrms): 235.1211.

Preparation of (S)-β-(diphenylmethylene)amino-γ-butyrolactone (7) from 14

Compound **14** was subjected to ozonolysis for 18 h and the ozonolysis product was processed under conditions identical with those used in the ozonolysis of **5**. The crude product **6**, isolated from the ozonolysis mixture, was converted to **7** in the manner described above. The yield of **7** based on **14** was 45%; mp 123–124°C; $[\alpha]_D$ −10.1° (*c* 1.3, chloroform).

Crystalline (S)-β-amino-γ-butyrolactone hydrochloride (6)

In one experiment, in which ozonization of **14** was incomplete, a crystalline product separated spontaneously (after a prolonged period of standing in an open vessel) from the crude syrup obtained on processing of the ozonolysis mixture. The syrupy crystals were triturated with absolute ethanol, and the crystals were recovered by filtration. The crystals were a mixture of **6** and **13**, which was resolved by chromatography on silica gel using *n*-butylalcohol–water – acetic acid (5:1:1 (v/v)) as eluant to afford a sample of crystalline **6**; recrystallization from methanol – diethyl ether gave an analytically pure sample; mp > 180°C (dec.); $[\alpha]_D$ −54.4° (*c* 0.6, water) (lit. (12) mp 185–186°C); ^1H nmr (D_2O) δ: 2.78 (dd, 1H, *J* = 19.0 and 2.5 Hz, H-α), 3.21 (dd, 1H, *J* = 19.0 and 8.5 Hz, H-α), 4.36 (m, 1H, H-β), 4.53 (dd, 1H, *J* = 11.1 and 4.5 Hz, H-γ), 4.72 (dd, 1H, *J* = 11.1 and 6.5 Hz, H-γ); ^{13}C nmr (D_2O) δ: 35.3 (C-α), 49.9 (C-β), 73.9 (C-γ), 180.1 (C=O). *Anal.* calcd. for $C_4H_8NO_2Cl$: C 34.93, H 5.86, N 10.18; found: C 35.08, H 5.89, N 9.94.

Heats of vaporization and gaseous molar heat capacities of ethanol and the binary mixture of ethanol and benzene

JIN-QUAN DONG, RUI-SEN LIN, AND WEN-HSING YEN[1]
Department of Chemistry, Zhejiang University, Hangzhou, China

Received September 14, 1987

This paper is dedicated to Professor J. A. Morrison

JIN-QUAN DONG, RUI-SEN LIN, and WEN-HSING YEN. Can. J. Chem. **66**, 783 (1988).

A combined system of the Newsham vaporization calorimeter and the Pitzer gaseous heat capacity flow calorimeter were reconstructed with modifications. Both calorimeters were calibrated with benzene, the liquid standard, and were found to be acceptable for measurements, with deviations of 0.4% and 0.9%, respectively. Heats of vaporization of pure ethanol under five pressures and binary mixtures of ethanol and benzene under normal pressure were determined. Gaseous molar heat capacities of pure ethanol under three pressures and of binary mixture of ethanol and benzene at two temperatures were also determined, with anomalies due to association noted. Association of ethanol molecules in the vapor phase was discussed and analyzed, with heats of association and entropy change of association calculated.

JIN-QUAN DONG, RUI-SEN LIN et WEN-HSING YEN. Can. J. Chem. **66**, 783 (1988).

Introduisant des modifications, on a reconstruit un système combinant le calorimètre à vaporisation de Newsham et le calorimètre à écoulement pour capacité calorifique gazeuse de Pitzer. On a calibré chacun de ces calorimètres à l'aide du benzène, le liquide standard, et on les a trouvés acceptables pour effectuer des mesures; les déviations sont respectivement de 0,4 et 0,9%. On a déterminé les chaleurs de vaporisation de l'éthanol pur sous cinq pressions ainsi que d'un mélange binaire d'éthanol et de benzène sous pression normale. On a aussi déterminé les capacités calorifiques molaires gazeuses de l'éthanol à l'état pur sous trois pressions différentes ainsi que d'un mélange binaire d'éthanol et de benzène à deux températures; on a noté des anomalies dues à l'association. On discute et analyse l'association des molécules d'éthanol en phase vapeur et on a calculé les chaleurs d'association ainsi que les changements d'entropie dus à l'association.

Introduction

Among investigations in chemical thermodynamics, liquid–vapor equilibrium research are of great importance in theory as well as in application. Systems involving normal liquids can be treated generally with simple activity corrections, but systems involving associated liquids demand special attention and relevant treatment. Associated liquids, though rather limited in number, constitute many systems important both to natural phenomena and industrial production. Alkanols, ethanol in particular, are liquids most frequently encountered.

Liquid–vapour equilibrium studies are usually undertaken with determinations of constituent concentrations under specific physical conditions, and they were investigated with data reported extensively in literature. However, heat capacities of the liquid phase and the vapor phase, and heats of vaporization of the liquid phase, were only occasionally reported.

A binary system of ethanol and benzene was selected to be studied. Prior to obtaining results on the binary system, pure ethanol and pure benzene were studied for primary data to be used in ultimate comparison and analysis. Pure benzene was employed in the calibration of the Newsham (1) vaporization calorimeter and in the calibration of the Pitzer (2) gaseous heat capacity flow calorimeter with modifications proposed by Hales *et al.* (3). Data for the binary system of cyclohexane and benzene are included for comparison.

Experimental

Apparatus

A schematic drawing for the calorimeters is given in Fig. 1, with the Newsham vaporization calorimeter and the Pitzer gaseous heat capacity flow calorimeter occupying, respectively, the right and left portions of the figure.

The Newsham vaporization calorimeter consists of inner vaporization chamber (I) with heater (H_1), outer vaporization chamber (D), and electric heating envelop (C), with liquids fed by reservoir (B) and feed-back condenser (F). Temperatures of liquids in the inner and the outer vaporization chambers are measured with platinum resistance thermometers (T_v and T_e).

Liquids are heated to boiling in the outer vaporization chamber before entering the inner vaporization chamber through a capillary, with the inner vaporization chamber double-walled, silvered, and under vacuum. The inner vaporization chamber is immersed and protected by the vapor and liquid of the outer vaporization chamber. Nichrome heater of 16 ohms is regulated for steady evaporation.

The Pitzer gaseous heat capacity flow calorimeter consists of a U-tube, through which the gaseous flow is heated with heater (H_2), with the temperatures of vapors measured with platinum resistance thermometers (T_1, T_2, and T_3). The U-tube, enclosed in silvered and evacuated container, is placed in a thermostat, which in turn is enclosed in an electric oven, kept at some 5°C lower than the thermostat. The inlet and outlet vapor temperatures, for which accurate values are not required, are monitored with nickel chromium and nickel silicon thermocouples (TC_1 and TC_2).

Vapors from the Newsham vaporization calorimeter pass through a spiral to be brought to the temperature of the thermostat before entering the U-tube. A nichrome heater of 30 ohms is employed.

Vapor samples of 5–10 g are collected through condenser (G) into receiver (E) for flow measurements.

The platinum resistance thermometers of 46 ohms each were certified with temperature precisions of 0.01°C.

The system is equipped with two external connections: one for evacuation as well as pressure control, and the other for filling-in with air or nitrogen. Glass valves marked 1 to 5 were lubricated with vacuum grease which should not introduce measurable quantities of impurity.

The pressure regulator is shown in Fig. 2, filled with a conducting sulfuric acid solution, acting as a control switch when solution level changes with pressure of the system. Pressure fluctuations were less than 0.5 mm Hg.

Materials

All liquids, ethanol, benzene, and cyclohexane, were purified by fractional distillation from analyzed reagent quality. Normal boiling points and refractive indices were observed and compared with values

[1]Author to whom correspondence may be addressed.

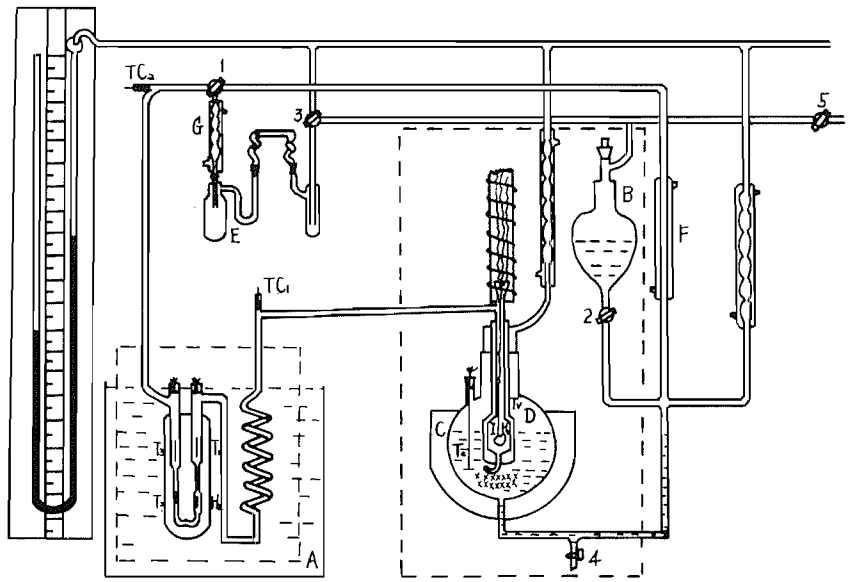

FIG. 1. Schematic drawing of the Newsham vaporization calorimeter and the Pitzer gaseous heat capacity flow calorimeter.

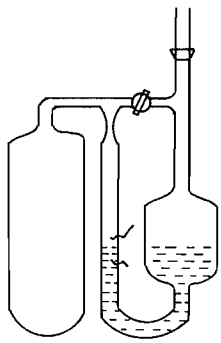

FIG. 2. The pressure regulator.

cited in literature (4). Purities were determined by gas chromatographs. All data are presented in Table 1.

Measurements

All energy inputs and temperature measurements were done electrically with voltage readings on $5\frac{1}{2}$-digit Fluke 8520A voltmeter. The potential difference is measured with a precision of 10^{-6} V. The temperatures on the platinum resistance thermometers were thus given with precisions of 0.005°C, with a working current of 1 mA.

Procedure

The Newsham vaporization calorimeter and the Pitzer heat capacity flow calorimeter constitute one combined system, but measurements may be conducted independently with liquids circulating through the entire system.

Before introducing liquids into the system, the thermostat for the Pitzer heat capacity flow calorimeter, the thermostat for the pressure regulator (kept constant at 25°C), and the entire vapor circuit were brought to the various desired temperatures. The vapor circuit was kept some 5°C above the condensation temperature of the liquids in order to maintain their vapor state. After introducing liquids, the heating rate on the outer vaporization chamber and the pressure regulator were so adjusted to steady boiling. Vapor was brought into circulation when heat was supplied to the inner vaporization chamber. Steady state between the vapor and liquid phases may be reached in 0.5 h for pure liquids and in 1.5 h for mixtures. Different flow rates may be maintained by varying the heating rate in the inner vaporization chamber. Actual operation disclosed that the temperature in the outer vaporization chamber was 0.1°C higher than that in the inner vaporization chamber.

144.0	307.40	33.390	33.384	33.326

[a]1 Torr = 133.32 Pa.

Heats of vaporization were measured in duplicates or triplicates at three or more different flow rates in the range of 0.015–0.100 g/s. These apparent heats of vaporization were plotted against reciprocal flow rates to obtain the true heat of vaporization at infinite flow rate with uncalled-for heating effects eliminated.

Heat capacities were measured at three or more different flow rates under each set of pressure and temperature conditions. Platinum resistance thermometers (T_2 and T_3) readings were recorded at steady states both before and during heating. Time for attaining the steady state varied in the range of 10–30 min with different flow rates. Heat inputs were adjusted for an increase of some 3°C in temperature.

Results

Prior to its application for studies on other liquids and binary mixtures, the Newsham vaporization calorimeter was first calibrated with the standard substance, benzene. Its heats of vaporization were determined under six different pressures,

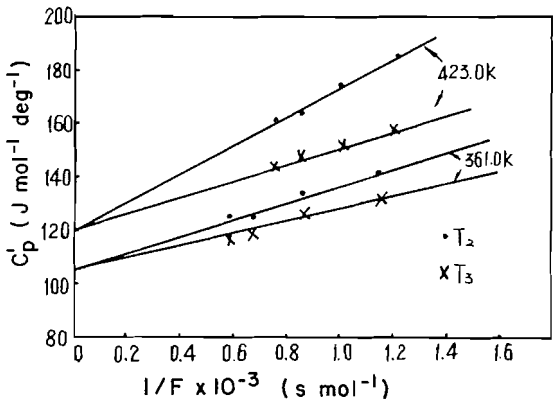

FIG. 3. Inverse flow rate dependence of apparent gaseous molar heat capacities of benzene.

from 760 to 144 Torr. The results are tabulated and compared with values cited in literature (5, 6), as presented in Table 2. Deviations amounted to less than ±0.4%, thus assuring the calorimeter feasibly reliable.

The experimental data were then correlated and represented for use in subsequent analyses by a Thiesen-type equation, as

$$[1] \quad \Delta H = 46.650(1 - T/562.1)^{0.4216}$$

where ΔH, T, and 562.1 are the heat of vaporization, the boiling temperature, and the critical temperature, respectively, of benzene. The corresponding temperatures T for specified pressures are obtained by the Antoine equation (7), because readings on the calorimeter were not as precise enough for calculations.

Similarly, the Pitzer heat capacity flow calorimeter was also calibrated with the standard substance, benzene. Selected molar heat capacities were determined under five different pressures, from 760 to 144 Torr, and at eight different temperatures, from 323.0 to 423.0 K. The results are tabulated in Table 3. These molar heat capacities are not values measured directly, but obtained indirectly through extrapolation of finite flow-rate results taken simultaneously on the two platinum resistance thermometers, T_2 and T_3, to infinite flow-rate, as exemplified in Fig. 3. The introduction of the two thermometers and the graphical extrapolation were directed to the total elimination of energy losses during actual heatings.

In Table 3, molar heat capacities of benzene in the ideal gas state, i.e., at zero pressure, at different temperatures are included. They are deduced individually from equations of the form, as

$$[2] \quad C_p^0(T) = C_p(T) + A(T)_p$$

where $C_p(T)$ and $A(T)$ are molar heat capacity under pressure p and temperature-dependent constant, all at the corresponding temperature T. The molar heat capacities of benzene in the ideal gas state were correlated with the equation,

$$[3] \quad C_p^0 = -78.777 + 0.690T - 5.290 \times 10^{-4}T^2$$

By this equation, interpolated molar heat capacities of benzene in the ideal gas state are compared with values cited in literature (6, 8), as presented in Table 4. Deviations, averaging 0.9%, appeared monotonously smaller than literature values. Intrinsic defects of the flow calorimeter and purity of benzene probably contributed to the systematic errors.

Heats of vaporization of cyclohexane were next determined under four different pressures, from 760 to 190 Torr. The results are tabulated and compared with values cited in literature (9), as presented in Table 5. The experimental data were again represented by a Thiesen-type equation, as

$$[4] \quad \Delta H = 45.057(1 - T/553.4)^{0.4022}$$

Heats of vaporization of ethanol were finally determined under five different pressures, from 760 to 190 Torr. The results are tabulated and compared with values cited in literature (10), as presented in Table 6. The experimental data were again

represented by a Thiesen-type equation, as

[5] $\Delta H = 55.273(1 - T/516.2)^{0.3090}$

Selected molar heat capacities of ethanol were also determined under three different pressures, 760.00, 506.67, and 253.33 Torr, and at relevant temperatures, from 330.8 to 418.4 K. The results are tabulated in Table 7, and graphically presented in Fig. 4.

Molar heat capacities of ethanol under 760 Torr are plotted in Fig. 5, together with corresponding values reported by Sinke and De Vries (11), Strömsöe, Rönne, and Lydersen (12), and Barrow (13), with good agreements. Comparing with the molar heat capacities of benzene under 760 Torr, as shown in Table 3, the behavior of ethanol is anomalous, with values decreasing to a minimum before increasing with increase in temperature, instead of the general trend of values increasing with increase in temperature.

The Newsham vaporization calorimeter is successfully employed in the determination of heats of vaporization of pure liquids, maintaining the liquid and vapor phases at identical temperatures. But, it fails theoretically to give correct heats of vaporization of binary mixtures, because the boiling points (of the liquid phase) and the dew points (of the vapor phase) of mixtures at identical compositions would in no case become identical. However, it may suffice for measurements if the binary components have comparable normal boiling points and comparable heats of vaporization, minimizing and even cancelling out discrepancies.

Benzene, with 353.25 K and 30.625 kJ mol^{-1}, and cyclohexane, with 355.80 K and 30.013 kJ mol^{-1}, was chosen as the exceptional pair for study on the feasibility of the Newsham vaporization calorimeter in the determination of heats of vaporization of binary mixtures. Heats of vaporization of the binary mixture at different mole fraction (x) of benzene were determined under three different pressures, 760, 570, and

380 Torr. The results are tabulated in Table 8. (The mole fraction (x) of benzene is determined by the observed refractive index of the recirculating mixture, with the refractive index converted to composition by interpolation on the known refractive index – composition curve.)

Ethanol and benzene, the ultimate study of this work, was finally examined in the Newsham vaporization calorimeter. Heats of vaporization of the binary mixture at different mole fraction (x) of ethanol were determined under the normal pressure of 760 Torr. The results are tabulated in Table 9. (The mole fraction (x) of ethanol is similarly determined with refractive index.)

Ethanol and benzene was the only binary mixture studied in the Pitzer heat capacity flow calorimeter. Molar heat capacities of the binary mixture at different mole fraction (x) of ethanol were determined under the normal pressure of 760 Torr and at two different temperatures, 365 and 395 K. The results are tabulated in Table 10, and graphically presented in Fig. 6.

Discussion

Associated liquids and normal liquids are quite different, exhibiting many divergent properties, some of which are listed in Table 11. Ethanol, an associated liquid, has a boiling point comparable to those of normal liquids, benzene and cyclohexane, but its normal heat of vaporization is not much larger. But the Thiesen-type equation constants (A and B) of ethanol are very much different from the comparable ones of benzene and cyclohexane. These differences denote for ethanol higher

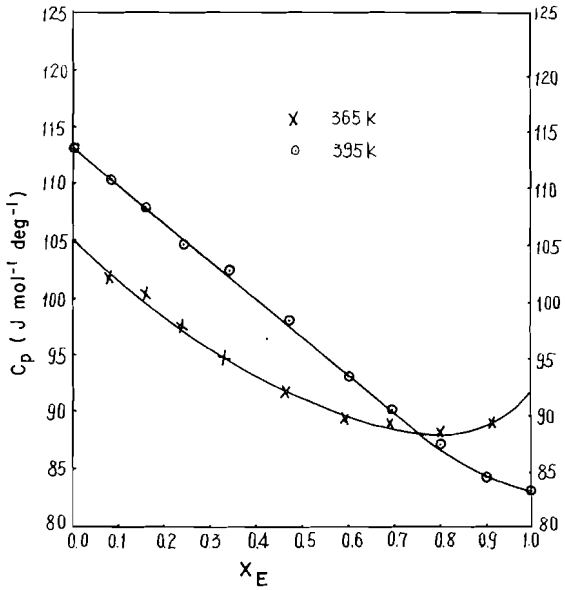

FIG. 6. Variation of gaseous molar heat capacities of mixture of ethanol and benzene with mole fraction at 365 and 395 K.

TABLE 11. Some properties of ethanol, benzene, and cyclohexane

	Value		
Parameter	C_2H_5OH	C_6H_6	c-C_6H_{12}
T_b (K)	351.45	353.25	355.80

B	0.3090	0.4216	0.4022

heats of vaporization at lower temperatures and faster rate of diminution toward a lower critical temperature. These larger heats of vaporization clearly suggest that the excess energy over the normal heats of vaporization is necessary to convert the extensively associated liquid into non-associated liquids composed of free molecules.

The three gaseous molar heat capacity curves of ethanol in Fig. 4 all consist of two sections, one on the left descending steeply with a turn toward the minimum, and another on the right extending almost linearly outward from the minimum. The curves seem to have a tendency to coalesce when extended further to higher temperatures. The molar heat capacities of ethanol at 440 K under the three different pressures all amount to approximately 87 J mol^{-1} K^{-1}, corresponding to 10.5R.

According to the statistical mechanical theories on molecular motions, the gaseous molar heat capacity of non-linear molecules at constant pressure is the sum total of molar heat capacities due to molecular translations, molecular rotations and molecular vibrations (including other vibration-like motions), together with the usual increment of C_p over C_v. With translations and rotations accounted-for classically, the molar heat capacity of ethanol due to vibrations at 440 K amounts to some 6.5R.

A difference of 0.2R can be estimated from the curves between molar heat capacities at 420 K under pressures of 760.00 and 253.33 Torr. This small difference indicates that

molecular interactions contribute only slightly in the higher temperature region, but become more important with decrease in temperature.

A value of $11.7R$ is found for the total molar heat capacity at 360 K from the curve under the pressure of 760.00 Torr, and $9.7R$ is found for the molar heat capacity due to molecular motions (including molecular interactions) at 360 K from the linear extension of the high temperature section of the same curve. This difference of $2.0R$ is obviously not of physical origin but of chemical source. Considering liquid ethanol being highly associated, an assumption that gaseous ethanol is composed of free molecules as well as associated molecules in different stages may be reasonable and correct.

With this additional information, vaporization of ethanol should be deemed as a process, by which the associated liquid is converted not just to free molecules, but to free molecules together with associated molecules in different stages with proportions varying with temperature and pressure. Large gaseous molar heat capacities of ethanol at lower temperatures and higher pressures may then be thought of as energy increments due to physical changes in molecular motions and due to chemical changes as manifested by molecular "dissociation".

Weltner and Pitzer (14) measured the gaseous molar heat capacities of methanol, and observed similar anomalies as ethanol. They proposed the existence of duo- and quarto-associated molecules among free molecules in gaseous methanol. Similar proposals were put forward by Barrow (13), McKetta and co-workers (15–19), and Hales *et al.* (3), for other alkanols. Pitzer's assumptions are as follows: (*1*) only two types of association, duo- and quarto-molecules, existing in the gaseous phase; (*2*) all molecules, free and associated, considered to be in the ideal gas state; (*3*) heats of association and entropy change of association assumed to be constant and independent of temperature; (*4*) very few associated molecules coexisting with free molecules, considered to be negligible in comparison.

With these assumptions, chemical equations for the two associations are:

[6] $2A \rightleftharpoons A_2$

[7] $4A \rightleftharpoons A_4$

The respective equilibrium constants, K_2 and K_4, as expressed with partial pressures, are

[8] $K_2 \approx d/p$

[9] $K_4 \approx q/p^3$

where p, d, and q are the total pressure, moles of duo- and quarto-molecules, with moles of single molecules before association taken as 1. The total number of moles n is

[10] $n = 1 - d - 3q$

[11] $n = 1 - K_2p - K_4p^3$

Introducing n into van der Waals equation and neglecting a/v^2,

[12] $pV = n(RT - bp)$

[13] $pV = RT + (b - RTK_2)p - 3RTK_4p^3$

is obtained, where b is the co-volume, with simplification by neglecting second-order terms. Comparing with virial equation,

[14] $v = RT/p + B + Dp^2$

with the p term omitted, and using thermodynamic relationships,

[15] $RT \ln K = -\Delta G$

[16] $\Delta G = \Delta H - T\Delta S$

virial constants in term of ΔH's and ΔS's are given by

[17] $B = b - RT \exp(\Delta S_2/R) \exp(-\Delta H_2/RT)$

[18] $D = -3RT \exp(\Delta S_4/R) \exp(-\Delta H_4/RT)$

From thermodynamic relationships,

[19] $(\partial S/\partial p)_T = -(\partial V/\partial T)_p$

[20] $(\partial S/\partial T)_p = C_p/T$

heat capacity changes with pressure, as

[21] $\partial(C_p/T)/\partial p = -(\partial^2 V/\partial T^2)_p$

Differentiating [14] with B and D substituted, and then integrating [21],

[22] $C_p = C_p^0 + ap + cp^3$

is obtained, where a and c are symbols standing for

[23] $a = (\Delta H_2^2/RT^2) \exp(\Delta S_2/R) \exp(-\Delta H_2/RT)$

[24] $c = (\Delta H_4^2/RT^2) \exp(\Delta S_4/R) \exp(-\Delta H_4/RT)$

Equations [23] and [24] are converted into logarithmic equations, as

[25] $\ln a + \ln(RT^2) = [2 \ln(\Delta H_2) + (\Delta S_2/R)] - (\Delta H_2/RT)$

[26] $\ln c + \ln(RT^2) = [2 \ln(\Delta H_4) + (\Delta S_4/R)] - (\Delta H_4/RT)$

C_p values at given temperatures of gaseous ethanol were read from the three pressure curves in Fig. 4 by interpolation, and they were used in solving [22] to give C_p^0, a and c constants for the relevant temperatures. Logarithmic values of a and c for various given temperatures were plotted according to [25] and [26], respectively, against reciprocal temperatures as linear lines to obtain ΔH's (from slopes) and ΔS's (from intercepts). All solutions were performed through mathematical recursions on computers.

Calculated results are as follows:

for the duo-associations,

$$\Delta H_2 = -15.20 \pm 0.12 \text{ kJ mol}^{-1}$$

$$\Delta S_2 = -70.7 \pm 0.6 \text{ J mol}^{-1} \text{ K}^{-1}$$

for the quarto-associations,

$$\Delta H_4 = -97.2 \pm 0.8 \text{ kJ mol}^{-1}$$

$$\Delta S_4 = -321 \pm 3 \text{ J mol}^{-1} \text{ K}^{-1}$$

These values agree very well with those reported by Barrow (13).

Comparing with hydrogen bond energies of 20–25 kJ mol^{-1}, duo-associations with a smaller energy are obviously weaker, but quarto-associations with energies of four-fold may be thought of as composed of four hydrogen bonds, forming an eight-membered ring of hydrogen and oxygen atoms.

For a binary mixture of mole fraction (x), its vaporization starts from the liquid state at the lower boiling point (T_b), and stops in the gaseous state at the higher dew point (T_d). To specify the temperature for its heat of vaporization, a single intermediate temperature (T_i), other than T_b and T_d, must be assigned.

The vaporization process may be resolved into five steps: (*1*) separating the binary liquid solution into two pure liquids at T_b; (*2*) warming the pure liquids separately from T_b to T_i;

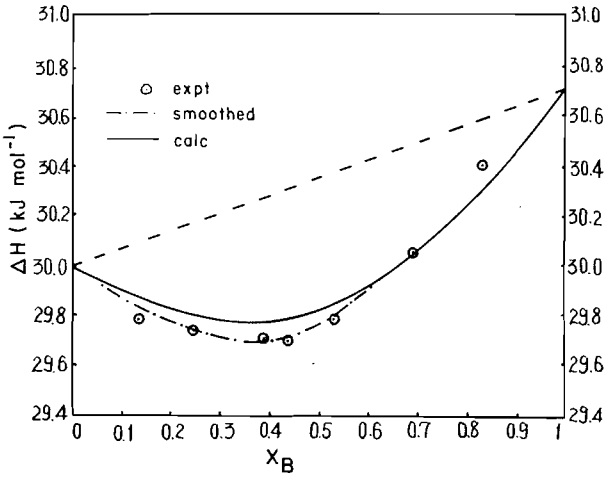

FIG. 7. Variation of heats of vaporization of mixture of benzene and cyclohexane with mole fraction under 760 Torr.

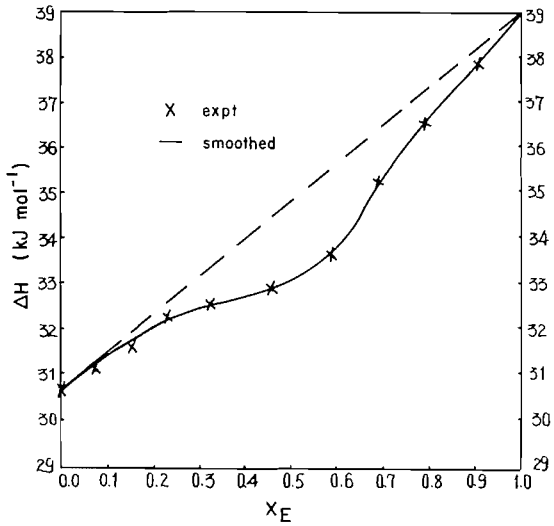

FIG. 8. Variation of heats of vaporization of mixture of ethanol and benzene with mole fraction under 760 Torr.

(*3*) vaporizing the pure liquids into pure gases separately at T_i; (*4*) warming the pure gases separately from T_i to T_d; (*5*) mixing the two pure gases into binary gaseous solution at T_d.

Making use of the relevant data found in literature, heats of vaporization of the binary mixture of benzene and cyclohexane at different mole fraction (x) under a pressure of 760 Torr were theoretically evaluated by adding together the separate calculations undertaken according to the afore-mentioned steps. The results are graphically presented in Fig. 7, as a companion curve to testify the validity of the Newsham vaporization calorimeter to be a reliable instrument for measuring heats of vaporization of liquid mixtures, with experimental results also presented for comparison. Good agreement provides proof of its usefulness. A similar calculation for the system ethanol–benzene has not yet been carried out.

Among the five heat effects in the proposed vaporization process, the heat of vaporization at T_i, $\Sigma x_i \Delta H_{vi}(T_i)$, which is different from $\Sigma x_i \Delta H_{vi}(T_{bi}^0)$, as represented by the dashed line in Fig. 7, constitutes almost the entire heat of vaporization of the binary mixture, $\Delta H_v(T_b - T_d)$. The heat of mixing of liquids at T_b, ΔH_m^L, the negative heat effect of step (1), comes next in magnitude, about 2% of the total, while the heat of mixing of gases at T_d, ΔH_m^G, is very small, if not negligible. The mixings in both phases, in the present case of benzene and cyclohexane, take place endothermically with absorption of heat. The warming-up of the liquid mixture from T_b to T_i and the gaseous mixture from T_i to T_d varies with the composition of the binary mixture, starting from 0 when pure and reaching a maximum at medium compositions, because of the lens-like T_b–T_d intervals between the liquidus and the vaporus curves. The sum total of the heat effects in steps [2] to [4] may be approximately equal to that represented by the dashed line in Fig. 7, and the droop in the experimental heat of vaporization curve should then be due to the evolution of heat in separating the liquids from solution.

Heats of vaporization of the binary mixture of ethanol and benzene at 760 Torr of Table 9 are graphically represented in Fig. 8. Due to pronounced differences in the heats of vaporization of pure ethanol and pure benzene, a side-wise protrusion instead of a droop appears in the experimental heat of vaporization curve of ethanol and benzene. The maximum differences in values on the experimental heats of vaporization curves from those on the dashed lines are very significant, with 1850 J mol^{-1} for ethanol and benzene, and 530 J mol^{-1} for benzene and cyclohexane. Evidently, a simple explanation as that for the binary mixture of benzene and cyclohexane will not suffice. Molecular association of ethanol molecules must be seriously considered. Dissociation of associated liquid ethanol and mixing of the partially dissociated ethanol molecules and benzene molecules both contribute to the heat and mixing of liquid ethanol and liquid benzene, with absorption of heat in larger quantities necessary for dissociation. Dissociation of associated ethanol molecules and mixing of ethanol molecules and benzene molecules also contribute to the heat of mixing of gaseous ethanol and gaseous benzene, with absorption of heat in smaller, though not insignificant, quantities. These considerations may thus explain the slanting lines of deviation from the dashed line at extreme compositions and the bulge at medium compositions.

The gaseous molar heat capacity – composition curves of the binary mixture of ethanol and benzene at 365 and 395 K are strikingly different from each other, as shown in Fig. 6. The curve at 395 K protrudes slightly from the diagonal connecting the heats of vaporization of pure liquids. However, the curve at 365 K droops very strongly from another similar diagonal.

From the gaseous molar heat capacity – temperature curve of ethanol under 760 Torr in Fig. 4, its gaseous molar heat capacity at 395 K is located on the right linear section, while that at 365 K is located on the left descending section. According to afore-mentioned discussions, gaseous ethanol at 395 K consists of free molecules with few or no associated ones, and gaseous ethanol at 365 K consists of free molecules as well as associated ones.

The almost linear gaseous molar heat capacity – composition curve of ethanol and benzene at 395 K denotes that the gaseous mixture is composed of free molecules quite at the ideal gas state, with non-ideality noticeable at increasing ethanol compositions. The drooping curve at 365 K denotes that change in ethanol molecularity plays a significant role in the gaseous molar heat capacity of ethanol and benzene, with changes in molecular motions and "dissociation" of ethanol molecules taking place simultaneously.

The derivation of the rotational potential function from atom–atom potentials. III. Borohydride compounds

DAVID SMITH

Pennsylvania State University, Department of Chemistry, Hazleton Campus, Hazleton, PA 18201, U.S.A.

Received August 25, 1987

This paper is dedicated to Professor James A. Morrison

DAVID SMITH. Can. J. Chem. **66**, 791 (1988).

The rotational potential functions for the borohydride ion embedded in potassium and rubidium halides are derived from atom–atom potentials of the Buckingham (exp-6) type. The librational frequencies computed from the potential functions are in good agreement with the observed frequencies. The potential functions for rubidium and potassium borohydrides derived from the atom–atom potentials yield librational frequencies that are about 10% higher than the observed values. Since the entropy of transition for potassium and rubidium borohydrides is less than expected, there is a possibility that there is some ordering of the borohydride ions above the transition temperature. An experimental method is presented for studying the ordering of the borohydride ions based on the difference in the ground level degeneracy of a tetrahedral ion in ordered and disordered states.

DAVID SMITH. Can. J. Chem. **66**, 791 (1988).

Utilisant des potentiels atome–atome du type de Buckingham (exp-6), on a obtenu les fonctions du potentiel de rotation de l'ion borohydrure intercalé dans des halogénures de potassium et de rubidium. Les fréquences de libration calculées à partir des fonctions de potentiel sont en bon accord avec les fréquences expérimentales. Les fonctions de potentiel des borohydrures de rubidium et de potassium qui ont été obtenues à partir des potentiels atome–atome fournissent des fréquences de libration qui sont 10% plus élevées que les valeurs expérimentales. Puisque l'entropie de transition des borohydrures de potassium et de rubidium est plus faible que prévue, il est possible qu'au dessus de la température de transition les borohydrures soient ordonnés. On présente une méthode expérimentale pour étudier la mise en ordre des ions borohydrures; cette méthode est basée sur la différence dans la dégénérescence de l'état fondamental d'un ion tétraédrique dans les états ordonné et désordonné.

I. Introduction

The rotational potential functions have been derived for ammonium chloride compounds (1) and ammonium fluoride compounds (2). The rotational potential functions have been used to compute the hindered rotational energy levels of the ammonium ion in the solids studied. From the energy levels, the librational frequencies, tunneling frequencies, activation energies, rotational heat capacities, and thermal expansions may be determined. In this paper, the rotational potential functions of the borohydride ion embedded in potassium and rubidium halides are derived. The term that makes the greatest contribution to the potential function is the repulsion term. In ammonium compounds, the attractive terms usually make the largest contribution to the potential function.

II. Theory

The rotational potential function has been derived (from atom–atom potentials) by Yasuda for the case of solid methane (3). The interaction between the atoms in a solid with one of the hydrogen atoms of a reference borohydride ion is given by

$$[1]\quad \Phi_{H-X}(R_{ik}) = A_{H-X}\exp(-\alpha_{H-X}R_{ik}) - C_{H-X}/R_{ik}^{6} - q_H q_X/R_{ik}$$

The effective charge on a hydrogen atom of the reference borohydride ion is given by q_H. The value of q_H is set equal to -0.20 electron units (4). The effective charge on an atom X is given by q_X. The interaction between the hydrogen atoms on the reference borohydride ion with other BH_4^- ions considers the other BH_4^- ions as simple spherical ions. In this paper, the parameter C is determined by using the values of C for metal–metal interactions and halide–halide interactions given in ref. 5 and the borohydride–borohydride interaction given in ref. 6. Using the equation

$$[2]\quad C = \sqrt{c_{++}c_{--}}$$

the value of C for the alkali metal ions and halide ions with the borohydride ion can be determined. The value of α in the repulsion term of eq. [1] is set at 1.8 Å, because this value gave the best results. The value of A in the repulsion term is determined by using the equation

$$[3]\quad A_{H-X} = b\exp\{\alpha(r_X + r_{BH_4})\}$$

where $b = 10^3$ and r represents the ionic radius. The values of the ionic radii used in this paper are given in Table 1. The parameters in eq. [1] are also given in Table 1. The values of A_{K-H} and A_{Rb-H} were adjusted to give the best possible match between the observed and computed librational frequencies. The value of A_{K-H} given in Table 1 is essentially the same value that results from using eq. [3], but the value of A_{Rb-H} given in Table 1 is somewhat less than 10% lower than that computed using eq. [3].

III. Analysis of borohydride compounds

The potential function for the motion of the borohydride ion embedded in alkali halides is

$$[4]\quad V(\omega) = \beta B\{\beta_4 V_4(\omega) + \beta_6 V_6(\omega)\}$$
$$\beta_4^2 + \beta_6^2 = 1$$

The rotational constant, B, of the borohydride ion is 3.95 cm^{-1}. Expressions for $V_4(\omega)$ and $V_6(\omega)$ are given in ref. 7. In eq. [4], β is a dimensionless field strength parameter related to the barrier to rotation. Higher terms in the potential function are very small.

In Table 2, the contributions to $\beta_4\beta$ and $\beta_6\beta$ are given for BH_4^- embedded in KCl. The largest contribution to the parameters comes from the repulsion term for the interaction of BH_4^- with the alkali metal ion. The values of the parameters in eq. [4] are given in Table 3. In Table 4, the observed and calculated librational frequencies are compared. The results are favorable for the borohydride ion embedded in alkali halides, but are about 10% high for the alkali borohydrides.

TABLE 1. Parameters in the atom–atom potentials[a]

Interaction	$-C \times 10^{-5}$ ($cm^{-1}/Å^6$)	$A \times 10^{-5}$ (cm^{-1})	r_x (Å)
Cl–H	2.6	8.4	1.81
Br–H	3.6	11.0	1.96
I–H	5.25	16.0	2.16
BH_4–H	2.0	10.0	1.93
K–H	1.3	3.55	1.33
Rb–H	1.8	4.3	1.48

[a]The value of α is 1.8 Å for all the interactions.

$RbBH_4$	RT	−171.2	1.000	−0.015

[a]RT stands for room temperature.

There is a lambda (λ) point transition in the observed heat capacities of all the alkali metal borohydrides (11(*a*) $NaBH_4$; (*b*) KBH_4; (*c*) $RbBH_4$; (*d*) $CsBH_4$). The entropy of the transition is about $R \ln 2$ in $NaBH_4$, but about half that value in the other alkali metal borohydrides (12). The lower entropy of transitions in the heavier alkali metal borohydrides has been attributed to the partial disordering of the borohydride ion, while in $NaBH_4$ the borohydride ion is totally disordered above the transition temperature (13). If the borohydride ion is partially ordered above the transition temperature, a $\beta_3 V_3(\omega)$ term would be introduced into the potential function, eq. [4]. This would further increase the librational frequencies of the borohydride ions in KBH_4 and $RbBH_4$. Why does the rotational potential function derived from atom–atom potentials give values for the librational frequency that are higher than the observed values? In the study of linear molecules in inert gas matrices, a model by Manz and Mirsky that takes into account

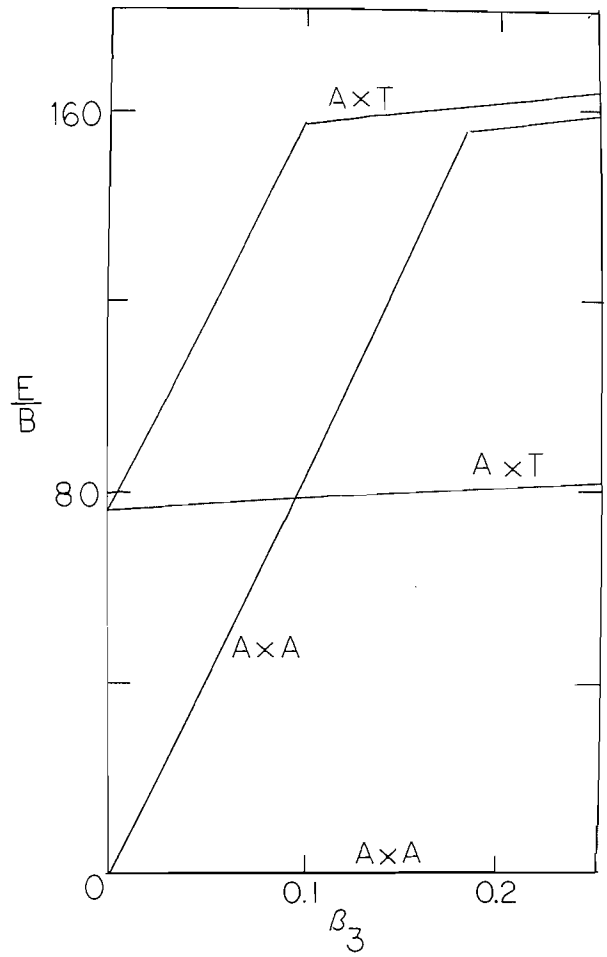

FIG. 1. The effect of β_3 on the lower energy levels with nuclear spin symmetry *A*. The other terms in the potential function are given in Table 3 for $RbBH_4$. The librational frequency varies from 77*B* to 82*B* as β_3 increases from 0 to 0.25.

the relaxation of the lattice near the impurity molecules has been used to interpret the results (14). There would be no purpose in applying such a theory to potassium and rubidium borohydrides, since the degree of order of the borohydride ions above the transition temperature is unknown and therefore the parameters in the rotational potential function are uncertain. The parameters given in Table 3 for KBH_4 and $RbBH_4$ are derived assuming total disorder of the borohydride ions above the transition temperature.

A method of studying the order of tetrahedral ions in solids is based on the difference in the ground level degeneracies of a tetrahedral ion in an ordered and in a disordered state. In a disordered state the ground level comprises five states with a total degeneracy, including nuclear spin, of 32, while in an ordered state there are three states with a total degeneracy of 16. The site symmetry of the tetrahedral ion in the disordered state is O_h, while in the ordered state it is T_d. The difference in the potential function of these two states is that there is a $\beta_3 V_3(\omega)$ in the ordered state. When $\beta_3 = 0$, there are two states with nuclear spin symmetry *A* in the ground level, while if $\beta_3 \neq 0$, there is only one state with *A* symmetry in the ground level. As a small β_3 term is added to a potential such as given in eq. [4], the two states with *A* symmetry will split, as is illustrated in Fig. 1. If the value of β_3 is large enough, the second state with nuclear spin symmetry *A* will eventually

[c]See ref. 9.
[d]See ref. 10.

become part of the third librational level; i.e., the total harmonic quantum number will be equal to 2. The effect is illustrated in Fig. 1. However, for small values of β_3, one of the two states with A nuclear spin symmetry will have an energy somewhere between the ground librational level and the third librational level. So it is possible that when β_3 is less than about 0.10, there will be a state with A symmetry that will have an energy less than the librational frequency. There are states with T and E nuclear spin symmetry that will behave in the same manner as the state with A nuclear spin symmetry.

The effect described above may be investigated by a spectroscopic study of $RbBH_4$ at liquid nitrogen temperatures. Since the degree of ordering above the transition temperature is probably small, the value of β_3 will be small. If the effect described above is not observed in the pure substance, addition of RbBr to $RbBH_4$ will weaken the interaction between the borohydride ions and therefore lower the value of β_3. A similar study could be carried out on the ammonium halides below their transition temperature: by adding a rubidium halide to the ammonium halide, the interaction between the ammonium ions will be weakened.

IV. Results

The rotational potential function has been derived for the borohydride compounds using only three parameters, the value of α, the charge on the hydrogen atom of the borohydride ion, and the values of A_{K-H} and A_{Rb-H}. The latter parameters take on values that are close to those computed using eq. [3]. The charge on the hydrogen atoms of the borohydride ion does not have a significant effect on the derived potential function. If q_H is set at -0.15 rather than -0.20 electron units, a small adjustment of the values of A_{K-H} and A_{Rb-H} will yield essentially the same results for the parameters in the potential function.

The electrostatic term makes about the same contribution to the rotational potential function in borohydride compounds as in ammonium compounds. The repulsion term, however, makes a much larger contribution to the rotational potential function in borohydride compounds than in ammonium compounds because of the larger size of the BH_4^- ion. The B—H distance is about 1.26 Å as opposed to about 1.04 Å for N—H.

As with the previous two papers in this series, the question of the transferability of the atom–atom potentials for the major interaction is determined by the fit of the properties computed from the rotational potential functions to experiment (1, 2). Just as in ref. 2, where the results indicated that the transferability of the hydrogen–fluorine interaction is appropriate, so in this paper the good agreement between the computed and observed librational frequencies indicates that the transferability of the alkali metal – hydrogen interaction is appropriate. The use of a constant value of α for all the repulsive interactions in this paper follows the pattern set in ref. 1. All of the repulsive interactions considered in this paper are small, except for the alkali metal – hydrogen interaction, so the values of α for the weak interactions do not make a significant change in the resultant rotational potential function.

This paper is dedicated to Professor James A. Morrison

LEE D. HANSEN, STANISLAW L. RANDZIO, LAURA LEWIS, EDWIN A. LEWIS, and DELBERT J. EATOUGH. Can. J. Chem. **66**, 794 (1988).

Results of calorimetric measurements of the heat of mixing of distillates from distillation of an H-coal liquefaction product are reported. The measurements were made at 373 K with mixing ratios such that the resultant mixture was the same as before distillation. The heat of mixing, which was endothermic in all cases, was found not to be a result of hydrogen bond formation. Intermolecular interactions of aromatic compounds are the probable source of the heats of mixing observed.

LEE D. HANSEN, STANISLAW L. RANDZIO, LAURA LEWIS, EDWIN A. LEWIS et DELBERT J. EATOUGH. Can. J. Chem. **66**, 794 (1988).

On rapporte les résultats de mesures calorimétriques de la chaleur de mélange de distillats obtenus par distillation d'un produit de liquéfaction H-charbon. On a fait les mesures à 373 K, avec des rapports de mélange tels que le produit qui en résulte est le même que celui qui existait avant la distillation. Il ne semble pas que la chaleur de mélange, qui est endothermique dans tous les cas, provienne de la formation d'une liaison hydrogène. Il est probable que la chaleur de mélange observée est due aux interactions intermoléculaires des produits aromatiques.

Introduction

The design and optimization of processes for the liquefaction of coal and the upgrading of coal liquefaction products will require a knowledge of the thermodynamic properties of coal liquid fractions (1). The liquids derived from hydrogenation of coal contain high concentrations of multi-ring aromatic compounds and of polar organic compounds with functional groups capable of forming hydrogen bonds (2–4). As a result of strong intermolecular interactions among these aromatic and polar compounds (5–8), correlation procedures previously developed for petroleum fractions usually cannot be used for estimation of the thermodynamic properties of coal liquid distillates (9). The development of improved correlation procedures requires thermodynamic data for coal liquefaction products at temperatures and pressures relevant to post-liquefaction separation processes such as distillation.

Heat capacities and enthalpies of coal liquids have been collected for distillates covering the whole range of boiling temperatures of liquids obtained from different coals (7–13). The measured enthalpy and specific heat values for coal liquids are larger than those predicted from conventional correlation procedures (9) because of the strong intermolecular interactions mentioned above. Eatough *et al.*[2] have successfully correlated the heat capacity of three different sets of coal distillates with an equation that uses the Watson–Nelson parameter (14) and a parameter describing hydrogen bonding between nitrogen bases and phenols. Allen *et al.*[3] have successfully used group contribution methods to predict the heat capacities of these same coal liquids. The results of these studies demonstrate that data directly related to the formation of hydrogen bonds and other strong intermolecular interactions in coal liquids are needed to predict the physical and thermodynamic properties of the liquids from easily measured parameters.

The distillation of a coal liquid results in changes in the intermolecular interactions, so that the properties of the distillate may be quite different from those predicted from correlations based only on the distillation temperature, the distillate density, and Watson characterization factor, K_W. A case in point is the observation that distillate fractions from coal liquids sometimes have much lower boiling points than distillation temperatures (7). The ΔH values for re-forming the liquid from the several distillates should be useful in identifying and quantifying any strong intermolecular interactions that affect the distillation curve. This paper reports experimental data on the heat of re-forming an H-coal liquid from distillate fractions taken along the distillation curve.

Experimental

Materials

A blend of products from the H-coal liquefaction process was distilled into fractions boiling in 28 K or 42 K increments by Chevron Research Company. Fractions were obtained over the boiling range from 478 to 728 K and also from the start of boiling to 478 K. Samples of distillate cuts were provided to BYU by the Pittsburgh Energy Technology Center (PETC). Selected physical and chemical properties of the 28 K cuts as determined at PETC are listed in Table 1. A more complete description of the samples and the methods used for characterization is given elsewhere.[3] For the purposes of this study, the still bottoms (728 +) were ground to a fine powder with an agate mortar and pestle.

Calorimetric measurements

Measurements of the heat of mixing of the distillates were made in a Setaram C80 calorimeter. The mixing cells supplied with the calorimeter were modified for these experiments as shown in Fig. 1. The total volume of the mixing space was reduced to about 2 cm^3 and the mixing space was centered in the cell. The vapor space never exceeded about 0.5 cm^3. The reduction in the cell volume was necessary because of the small quantities of the distillate cuts that were available. One sample was placed in the holder, 7, and covered with a thick metallic lid, 6. The holder, 7, was then put into the calorimetric cell cylinder, 8, and closed with a Teflon seal, 4, and the bottom screw, 10. The second sample was then placed in the calorimetric cell cylinder directly on the metallic lid, 6, and sealed with a second Teflon seal, 4,

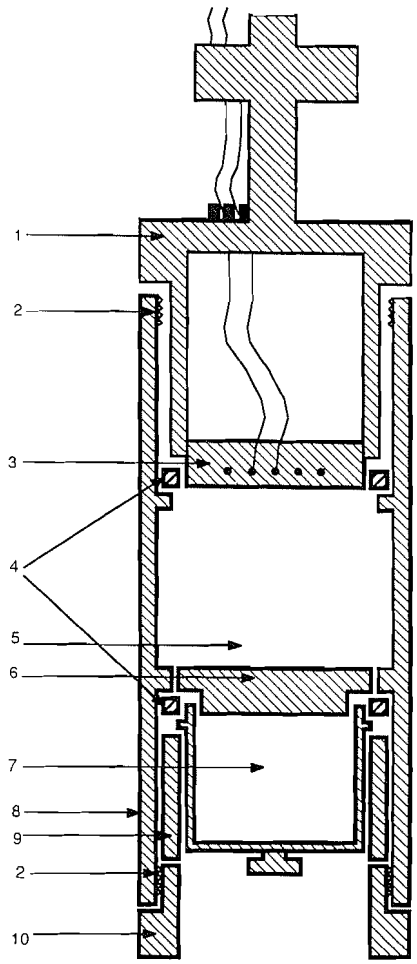

FIG. 1. Schematic diagram of the small volume calorimetric mixing cell. The parts of the cell are (1) upper screw, (2) threaded portion of cell cylinder, (3) calibration heater, (4) Teflon seals, (5) upper sample compartment, (6) lower sample compartment lid, (7) lower sample compartment, (8) cell cylinder, (9) spacer ring, and (10) bottom screw.

and the upper screw, 1. The screw, 1, also contained a miniature calibration heater, 3, made from Omegaclad thermocouple wire. With this design, the calibration heater was in direct thermal contact with the liquid in the cell. This design minimized the dependence of the calorimetric calibration constant on the distribution of the heat produced in the calorimetric cell (15).

The calorimeter output data were digitized at 10-s intervals with a Keithley 195A voltmeter and stored in a Commodore 64 computer. After a calorimetric experiment, the data were transferred to a Vax computer and integrated numerically to obtain the total heat produced in the experiment.

The electrical calibrations were checked by measuring the heat of mixing of *m*-cresol with quinoline. The heat of mixing for these chemicals is known from previous calorimetric measurements (5). The two calibrations disagreed by less than 1%. Since the *m*-cresol/quinoline system contains the most volatile materials used in this study, the vapor space in the mixing cell apparently does not result in any significant error.

The standard Setaram procedure of rotating the calorimeter was used to mix the liquids. Rotation of the calorimeter was repeated several times to insure that chemical equilibrium had been reached. The rotation itself produced negligible thermal effect.

All results reported here were collected at 373 K to decrease the viscosity of the high-boiling distillate fractions. Also, the products of mixing were collected and examined visually to insure that complete mixing had taken place during the experiment. The mixing process was slow compared to the mixing of *m*-cresol and quinoline, as judged by the calorimetric data. Attempts were made to perform measurements at 473 K to further decrease the viscosity of the liquids, but a large exotherm was observed with every rotation of the calorimeter. At 373 K this exotherm was not observed. The design of the mixing cell did not allow for the elimination of oxygen from the mixing space and we believe the exotherm seen at 473 K was due to oxidation of the coal liquid.

In the first series of nine duplicate measurements, we began by mixing the still bottoms (728+) with the highest boiling fraction (686–728) to obtain a mixture designated M686+. The M686+ mixture was mixed with the next higher boiling fraction (644–686) in the second experiment to form a mixture designated M644+. The experiments were continued in this way with successively lower boiling fractions until the final mixing of the M478+ mixture with the lowest boiling fraction, i.e., 478−.

TABLE 2. Heat of re-forming an H-coal liquid from distilled fractions

Experiment		Weight ratio of lower boiling fraction to higher boiling fraction	Heat of mixing[a] (J/(g of mixture))
Series I

[a]All heat of mixing effects are endothermic. Uncertainties are ±0.2 J/g for the zero values and between ±0.1 and ±0.05 J/g for the rest of the values.

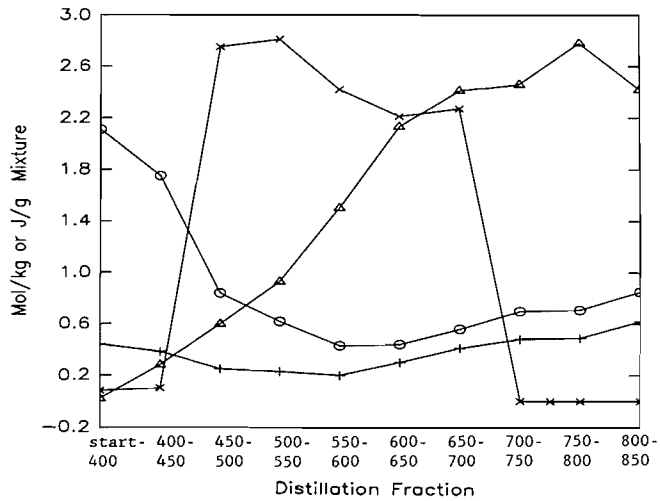

FIG. 2. Heat of re-forming (×) and concentrations (mol/kg) of aromatic hydrocarbons (△), phenols (○), and nitrogen bases (+) as a function of the distillation temperature.

The second series of three duplicate measurements was done in the same way except that 28 K fractions were used and the final mixture was an M700+ mixture. The measurements were performed in such a manner as to re-form the coal liquid as it existed prior to distillation. The mass ratios at which the particular distillate samples were mixed are listed in Table 2. These ratios were calculated from the mass balance of the distillation process determined by Chevron Research Company.

Results

The results of the measurements of the heat of re-forming of the H-coal liquids are given in Table 2. The precision of the calorimetric measurements was limited by the amount of material available for study and also by the very slow evolution of heat during the calorimetric experiments, which was a result of the high viscosity of the samples. The lower limit of detection for the two higher boiling samples where no detectable heat was observed was about 0.2 J/(g mixture). The uncertainty in the other data is about 0.05 to 0.1 J/(g mixture). Most of the data are the mean values of two measurements. A graphical presentation of the heat of mixing data as a function of the midpoint boiling temperature of the lower boiling distillate is given in Fig. 2.

The concentrations of phenols, azaarenes (e.g., pyridine, quinoline, and related compounds), hydrogenated azaarene (e.g., tetrahydroquinoline), and multi-ring aromatic compounds in each of the distillates are given in Table 1 and shown graphically in Fig. 2.

Discussion

To elucidate the factors that determine the heat of mixing values, both specific interactions such as hydrogen bonding and nonspecific intermolecular interactions caused by dispersive forces must be taken into account. The hydrogen bond interactions in a distillate include those resulting from the self-association of the phenols and from association of the phenols with nitrogen bases (5, 6). The effect of these hydrogen bonding interactions on the observed heats of mixing can be predicted by using the thermodynamic quantities for hydrogen bonding in the model system *m*-cresol–tetralin–quinoline–tetrahydroquinoline. The thermodynamic parameters determined for this model system have been used to predict correctly the heat capacity of distillates of coal liquefaction products (see footnote 2), thus showing that the model system provides an accurate portrayal of the thermodynamics of hydrogen bonding in coal liquids. The enthalpy values for the formation of hydrogen bonded complexes between quinoline and *m*-cresol and for the self-association of *m*-cresol are all strongly exothermic (5, 6). However, the heat of mixing of *m*-cresol and quinoline with multi-ring compounds such as tetralin (6) and large polynuclear aromatic compounds (16) is near zero.

If the heat absorbed on mixing the distillate fractions is due to changes in hydrogen bonding, the total hydrogen bonding must decrease as the samples are mixed. Furthermore, data on the model system (5, 6) predict that the change in the hydrogen bonding content must be about 0.1 mol/kg to account for the heat effect. However, calculations based on the free energies of hydrogen bonding reactions in the model system (6) indicate that the changes in hydrogen bond content in the mixing experiments are only about 0.005 mol/kg. Thus, the observed heats of mixing for the various distillate cuts are not controlled by changes in hydrogen bonding during mixing.

The negligible change in the amount of hydrogen bonding is a result of two factors. First, for many of the distillate fractions, the concentrations and ratios of acidic and basic species are approximately constant from fraction to fraction. Second, the heat of self-association of phenols (5, 6) effectively compensates for the decrease in the heat of acid–base interaction for those fractions in which the amount of phenol increases with decreasing boiling point (see Fig. 2). The only conclusion that can be made at the present time is that the heat of mixing is highest for those experiments which have the greatest change in the concentration of multi-ring aromatic hydrocarbons. This suggests that the observed heat of mixing reflects significant changes in non-hydrogen bonded molecular interactions, which occur on mixing the various distillate fractions. This conclusion is in agreement with a previous study (17) of the polarizability of coal liquefaction product distillates which concluded that "van der Waals forces are the dominant intermolecular forces in the H-coal and Wilsonville distillates." Also, data on heats of mixing of pure compounds (18) show that heats of mixing of aliphatic hydrocarbons are generally much smaller than the heat effects observed in this study, but that heats of mixing

of aromatic compounds are of the same order of magnitude. Thermodynamic data on appropriate model coal liquids are needed to further define the nature of these interactions.

Computer simulation versus experiment: the structure of orientationally disordered neopentane

WOLFGANG BREYMANN,[1] PHILIPPE DEPONDT, AND ROBERT M. PICK

Département de Recherches Physiques (UA CNRS n° 71), Université Pierre et Marie Curie, Paris, France

Received August 11, 1987

This paper is dedicated to Professor J. A. Morrison

WOLFGANG BREYMANN, PHILIPPE DEPONDT, and ROBERT M. PICK. Can. J. Chem. **66**, 798 (1988).

A method to confront computer simulations to real nature is reported. "Experimental" results calculated from the simulation are analyzed through the same model as the actual experiments. The same terms are thus used to describe the simulated and the real sample; they can then be compared, with some reliability, to one another and also to the corresponding quantities obtained directly from the microscopic information provided by the simulation. The method is applied to neutron diffraction experiments performed on orientationally disordered neopentane ($C(CD_3)_4$) single crystals, a system for which a realistic molecular dynamics simulation has also been performed. Our method turns out to be a severe test both for the simulation and the models used to interpret the experiments.

WOLFGANG BREYMANN, PHILIPPE DEPONDT et ROBERT M. PICK. Can. J. Chem. **66**, 798 (1988).

On expose une méthode pour confronter une simulation par ordinateur à la réalité. Des résultats "expérimentaux" calculés à partir de la simulation sont analysés à l'aide des mêmes modèles que les véritables expériences. On utilise ainsi les mêmes termes pour décrire les échantillons simulés et véritables; ceux-ci peuvent alors être comparés entre eux aussi bien qu'avec les grandeurs correspondantes directement calculées à partir des données microscopiques obtenues dans la simulation. Cette méthode est appliquée à des expériences de diffraction de neutrons sur des monocristaux de néopentane ($C(CD_3)_4$) présentant un désordre d'orientation, système pour lequel une simulation de dynamique moléculaire réaliste a aussi été réalisée. Cette technique s'avère être un test sévère à la fois pour la simulation et pour les modèles utilisés pour l'interprétation des expériences.

I. Introduction

The comparison of information supplied by a molecular dynamics simulation and actual experimental results obtained on the same system may end up being a somewhat difficult task, when no flagrant disagreement between both sets of results occurs, since the two points of view are extremely different. Indeed, once a computer simulation is performed, the successive positions and velocities of each particle of the system are known, so that one may choose to study independently any given aspect of the problem at hand, the only limitations being the size of the sample and the duration of the simulation. The experimental data, on the other hand, are always a mixture of several contributions. Subsequently, they have to be interpreted by using models which are more or less adequate and thus provide information which is more or less reliable. To be specific, the simulation of an orientationally disordered crystal can provide separately, for instance, the orientations of the molecules and the displacements of the molecular centers of mass, while both quantities, among others, will play a role simultaneously, e.g., in a diffraction experiment or in an inelastic neutron scattering experiment performed on the real crystal.

A first step towards this comparison is the use of the microscopic information obtained during the simulation to compute what should have been the experimental result (e.g. Bragg peak intensities, or neutron inelastic spectra), if the experiment had been performed on the simulated system. One may then find out the extent of agreement (or disagreement) between the simulated and the real experiment; this method has been used, for instance, by Klein and co-workers (1) in the case of inelastic neutron spectra obtained in the plastic phase of KCN. Unfortunately, since the experimental data have, generally, no simple, directly understandable physical meaning, such a comparison remains rather qualitative.

A second step may be achieved if one analyses the simulated experiment through the same model(s) as the real one. Then three sets of physical parameters exist to describe the two systems, real and simulated: (*1*) physical parameters obtained by analyzing the experimental data via a given model; (*2*) physical parameters obtained by analyzing the simulated experimental data via the same model; and (*3*) the last set is obtained by computing directly these parameters from the microscopic data of the simulation.

The comparison between (*1*) and (*2*) is a precise test of the extent to which the simulation is realistic. Since it is made in terms with a direct physical meaning, it may also indicate which aspects of the simulation fail to be realistic. The same comparison performed between (*2*) and (*3*) is, conversely, a test of the validity of the model used for analyzing the experiments; any discrepancy between (*2*) and (*3*) means that a similar discrepancy between (*1*) and (*3*) is not a severe test on the validity of the simulation. It gives a measure of the uncertainties existing on the parameters extracted from (*1*).

The present paper illustrates this fairly general method with the example of the orientationally disordered, or plastic, phase of neopentane ($C(CH_3)_4$) in which the molecular centers of mass form a f.c.c. Bravais lattice, while the tetrahedral molecules perform large amplitude rotations. Structural information supplied by a molecular dynamics simulation (2) on the one hand, and by neutron elastic diffraction experiments (3, 4) on the other, have been compared. The simulation shows a situation in which the molecules perform frequent reorientations from one orientational potential well to another equivalent one. The corresponding most probable orientations are D_{2d}, i.e. with one molecular $\bar{4}$ axis parallel to a 4-fold crystal axis and the two other $\bar{4}$ axes parallel to 2-fold crystal axes, giving six equivalent but physically distinct wells. This agrees with the experiment so that one is apt to become interested in more detailed structural aspects.

The structure of the plastic phase is usually described in terms of the orientational probability density function (o.p.d.f.)

$P(\Omega)$, which is the probability that the molecular reference frame can be deduced from the crystal frame through a rotation Ω, where Ω represents the corresponding set of Euler angles. In the case of the computer simulation, $P(\Omega)$ can be evaluated directly since the orientation of each molecule is known independently of other quantities, its center of mass position for instance. On the other hand, the experimental data consist of a set of Bragg peak intensities; they contain a combination of at least orientational and translational effects, assuming one is able to eliminate scattering by the cryostat[2] and the incoherent contribution caused by the remaining hydrogen atoms in $C(CD_3)_4$. As it has been shown in (5), $P(\Omega)$ can be expanded on a set of symmetry adapted functions, and the resulting expansion coefficients, as well as an isotropic Debye–Waller factor related to the molecular center of mass translations, appear in a calculated structure factor, which, in turn, is fitted to the data.

We want to compare in detail an actual orientational probability function supplied by the simulation with the sets of parameters which are provided by the model. We are interested in particular in knowing how well the maxima of $P(\Omega)$ are defined and what is the amount of translational disorder as shown by the Debye–Waller factor. The rest of this paper is devoted to the calculation of the two sets of parameters (*2*) and (*3*) relative to the simulation and to their comparison with set (*1*).

II. Numerical simulation of a neopentane crystal

The simulation is described in detail elsewhere (2) so we will give only a short summary here.

The simulated sample[3] consists of 864 molecules located on a f.c.c. lattice corresponding to a sample of $6 \times 6 \times 6$ unit cells. Each molecule is described by its 17 atoms and considered as rigid. As the molecule of neopentane is electrically neutral and fairly isotropic, the electrostatic forces can be neglected. Therefore, only Buckingham atom–atom potentials between all the atoms of the nearest neighbour molecules have been taken into account (6). The mass and moment of inertia of $C(CH_3)_4$ are quite large, so that quantum effects can be neglected. Three runs have been performed at, respectively, 135 K,[4] 175 K, and 230 K.

The result of such a simulation is a set of positions and orientations of each molecule as a function of time, allowing one to compute any pertinent physical quantity; those of interest are, here, $P(\Omega)$ and the Debye–Waller factor.

III. Computation of Bragg peak intensities

A coherent neutron scattering experiment yields (7):

$$[1] \qquad I(\boldsymbol{Q}) = \int_0^\tau \left| \sum_{n,j} f_j \{\exp i\boldsymbol{Q}(\boldsymbol{R}_n + \boldsymbol{u}_n(t) + \boldsymbol{r}_{nj}(t))\} \right|^2 \mathrm{d}t$$

where $\boldsymbol{R}_n$ is the equilibrium position of the center of mass of molecule n, $\boldsymbol{u}_n(t)$ is the displacement at time t of the center of mass of the same molecule, $\boldsymbol{r}_{nj}(t)$ is the position at time t of atom j relative to the molecular center of mass n, f_j is the coherent scattering length of atom j, $\boldsymbol{Q}$ is the scattering vector, the symbol $\Sigma_{n,j}$ stands for $\Sigma_{n=1}^{N}\Sigma_{j=1}^{\nu}$, N and ν being the number of molecules and atoms in the sample and molecule, and τ is the duration of the experiment.

In eq. [1], the usual thermal average is replaced by an explicit time summation as time appears explicitly in a simulation, but eq. [1] holds as well for the real system as for the simulation.

Equation [1] may be rewritten as

$$[2] \qquad I(\boldsymbol{Q}) = \int_0^\tau \left(\sum_{n,j} f_j \{\exp i\boldsymbol{Q}[\boldsymbol{R}_n + \boldsymbol{u}_n(t) + \boldsymbol{r}_{nj}(t)]\} \sum_{n',j'} f_{j'}^* \{\exp -i\boldsymbol{Q}[\boldsymbol{R}_{n'} + \boldsymbol{u}_{n'}(t) + r_{n'j'}(t)]\} \right) \mathrm{d}t$$

In a Bravais lattice, $\exp i\boldsymbol{Q}\boldsymbol{R}_n$ is equal to 1 if $\boldsymbol{Q}$ belongs to the reciprocal lattice.[5] We see thus that $\boldsymbol{R}_n$ and $\boldsymbol{R}_{n'}$ are, in principle, irrelevant quantities in [2], but since we want to make sure that, in the simulated sample, the f.c.c. extinctions actually do occur, we shall keep these terms.

In a disordered system, correlations between different molecules may exist, but the corresponding correlation lengths are short (approximately 20–30 Å) compared to the macroscopic size of the real sample (at least 1 mm) so that for a given value of n, among the N values of n', only a small number are sensitive to correlation effects. These may then be neglected, which yields:

$$[3] \qquad I(\boldsymbol{Q}) = \int_0^\tau \sum_{n,j} f_j \{\exp i\boldsymbol{Q}[\boldsymbol{R}_n + \boldsymbol{u}_n(t) + \boldsymbol{r}_{nj}(t)]\} \mathrm{d}t \int_0^\tau \sum_{n',j'} f_{j'}^* \{\exp -i\boldsymbol{Q}[\boldsymbol{R}_{n'} + \boldsymbol{u}_{n'}(t) + \boldsymbol{r}_{n'j'}(t)]\} \mathrm{d}t$$

$$= \left| \int_0^\tau \sum_{n,j} f_j \{\exp i\boldsymbol{Q}[\boldsymbol{R}_n + \boldsymbol{u}_n(t) + \boldsymbol{r}_{nj}(t)]\} \mathrm{d}t \right|^2$$

Passing from [1] to [3] is an important step, because neglecting short range correlations, whatever their nature, is possible only because of the large size of the sample. On the other hand, the size of the simulated sample (approx. $(100\ \text{Å})^3$) is not large enough to neglect these correlations, and indeed we have verified their importance in the following manner: the intensity given by eq. [1] should be equal to zero for $\boldsymbol{Q}$ not belonging to the reciprocal lattice of the f.c.c. Bravais lattice. Furthermore, if $\boldsymbol{Q}$ is a reciprocal lattice vector, the existence of centers of symmetry in the f.c.c. lattice implies that in eq. [1], the summation over n and j should not contain an imaginary part. Neither of these tests turned out to be verified with a meaningful accuracy for the simulated sample, which means that [1] cannot be used since we want to compare computed

[2]The experiments were performed between 150 and 253 K.

[3]In order to avoid confusing double meanings, the word "model" will be used only for the models with which the experiments are interpreted, while the simulated model will be called "sample".

[4]Although the real crystal is not in the plastic phase at 135 K, the simulated crystal is, since the constraints of the constant volume simulation prevent orientational ordering.

[5]As we index these vectors in the simple cubic lattice, $\exp i\boldsymbol{Q}\boldsymbol{R}_n$ is in fact equal to 1 only for those reciprocal lattice vectors which satisfy the Miller indices parity rule.

Bragg peak intensities to actual experimental data obtained on large samples for which short range correlations are extremely small. We have thus used eq. [3], in which the correlations have been deliberately eliminated.

As in a simulation we use discrete time steps, we must now transform eq. [3] into:

$$[4]\quad I(\boldsymbol{Q}) = \left| \sum_{n,j} f_j \sum_{k=1}^{\theta} \{\exp i\boldsymbol{Q}[\boldsymbol{R}_n + \boldsymbol{u}_n(k.\delta t) + \boldsymbol{r}_{nj}(k.\delta t)]\}\delta t \right|^2$$

where δt is the time step length in the summation and $\theta = \tau/\delta t$ is the number of time steps.

δt could be chosen to be equal to the simulation step length (1/60 ps) but two successive steps in the simulation are strongly correlated and thus carry almost the same information. Therefore, very little loss of information will occur if δt is chosen to be equal to 1 ps, i.e. a typical correlation time for a single molecule orientation.

Using the composite index $m \equiv k,n$ and writing

$$[5]\quad \rho_{mj} \equiv \boldsymbol{R}_n + \boldsymbol{u}_n(k.\delta t) + \boldsymbol{r}_{nj}(k.\delta t)$$

yields

$$[6]\quad F(\boldsymbol{Q}) = \frac{1}{M} \sum_{m=1}^{M} \sum_{j=1}^{\nu} f_j \exp i\boldsymbol{Q}\cdot\rho_{mj}$$

and

$$[7]\quad I(\boldsymbol{Q}) = M|F(\boldsymbol{Q})|^2\delta t^2$$

with $M = N\cdot\theta = N\tau/\delta t$, and where $F(\boldsymbol{Q})$ is the average single molecule structure factor (SMSF) which is the quantity that appears in most models for diffraction experiments.

Summing up, the procedure leading from eq. [1] to eqs. [6] and [7] means that we have used ergodicity to replace an experiment lasting for τ = 60 ps on a sample with N = 864 molecules by an instantaneous experiment on a much larger sample with M = 51840 molecules. This new sample has now the correct average structure of a real crystal. Indeed, Table 1 shows that the imaginary part of $F(\boldsymbol{Q})$ and the intensity of the forbidden Bragg reflexions are equal to zero with a very good accuracy.

Finally, in order to estimate the standard deviations of our intensity computations, several equivalent reflexions have been taken into account.

IV. Analysis of the Bragg peak intensities

Table 1 exhibits the simulated and experimental Bragg peak intensities. It is clear that a direct comparison is fruitless; thus justifying the procedure described in the Introduction.

(a) Model

In the rigid molecule approximation, the SMSF writes, for molecules on a Bravais lattice:

$$[8]\quad F(\boldsymbol{Q}) = \int P(\boldsymbol{u},\Omega) \sum_{j=1}^{\nu} f_j\{\exp i\boldsymbol{Q}[\boldsymbol{u} + \boldsymbol{r}_j(\Omega)]\}\mathrm{d}\boldsymbol{u}\mathrm{d}\Omega$$

where $P(\boldsymbol{u},\Omega)$ is the probability of finding the molecule with orientation Ω and a center of mass displacement $\boldsymbol{u}$.

Following ref. 9, $P(\boldsymbol{u},\Omega)$ can be expressed as

$$[9]\quad P(\boldsymbol{u},\Omega) = P(\boldsymbol{u})[P(\Omega) + \boldsymbol{P}^{(1)}(\Omega).\boldsymbol{u} + \ldots.]$$

Combining eq. [8] and the first term of eq. [9] provides the zeroth order translational contribution which may be rewritten as (8):

$$[10]\quad \int P(\boldsymbol{u})\mathrm{e}^{i\boldsymbol{Q}.\boldsymbol{u}}\mathrm{d}\boldsymbol{u} = \langle \mathrm{e}^{i\boldsymbol{Q}.\boldsymbol{u}}\rangle = \mathrm{e}^{-(1/2)Q^2\langle u^2\rangle}$$

thus supplying the usual Debye–Waller factor related to the molecular center of mass displacements.

The orientational probability $P(\Omega)$ is expanded on a set of symmetry adapted functions:

$$[11]\quad P(\Omega) = \sum_{l,\lambda,\lambda'} \frac{2l+1}{8\pi^2} A_l^{\lambda\lambda'} \mathcal{R}_l^{\lambda\lambda'}(\Omega)$$

where $\mathcal{R}_l^{\lambda\lambda'}(\Omega)$ is a symmetry adapted function, l is related to the number of nodes of $\mathcal{R}_l^{\lambda\lambda'}(\Omega)$ as in the case of the spherical harmonics $Y_l^m(\theta,\varphi)$, and λ (or λ') labels the irreducible representations of the site (or molecular) symmetry point group (10).

It is easily shown (5) that, when limiting $P(\boldsymbol{u},\Omega)$ to its lowest order term, the SMSF is completely expressed in terms of $\langle u^2\rangle$, $A_l^{\lambda\lambda'}$, and functions depending only on $\boldsymbol{Q}$, f_j, and on the molecular geometry. In the case of a tetrahedral molecule in a cubic lattice, symmetry considerations restrict the $A_l^{\lambda\lambda'}$ coefficients, for the lowest values of l, to A_4^{11}, A_6^{11}, A_8^{11}, and A_{10}^{11} (proper definitions of these coefficients are given in ref. 10). When including the second term of [9], new coefficients related to rotation-translation coupling appear in $F(\boldsymbol{Q})$.

In a plastic crystal, the Bragg peak intensities decrease very rapidly when $|\boldsymbol{Q}|$ increases, due to the large value of $\langle u^2\rangle$, so that the number of independent reflexions which may be used is always small (32 at most for $C(CD_3)_4$) thus limiting the number of fitting parameters. In the analysis of the experimental data, we restricted ourselves to $\langle u^2\rangle$, the four $A_l^{\lambda\lambda'}$ coefficients for $l \leqslant 10$ and to the three lowest translation–rotation coupling coefficients. The latter three parameters have no obvious physical meaning and will consequently not be discussed in the present work.

The Bragg peak intensities obtained from the simulated sample were analyzed following the same procedure.

(b) Direct calculations

The Debye–Waller factor and the expansion coefficients $A_l^{\lambda\lambda'}$ can also be obtained directly from the simulation. The translational term $\langle u^2\rangle$ relative to the molecular centers of mass is:

$$[12]\quad \langle u^2\rangle = \frac{1}{\tau}\int_0^{\tau} \frac{1}{N}\sum_{n=1}^{N} u_{rn}^2(t)\mathrm{d}t$$

where $u_{rn}(t)$ is the projection of $\boldsymbol{u}_n(t)$ on an arbitrary direction $\hat{\boldsymbol{r}}$.

$P(\Omega)$ may be written directly, following the definition of the o.p.d.f.:

$$[13]\quad P(\Omega) = \frac{1}{\tau}\int_0^{\tau} \frac{1}{N}\sum_{n=1}^{N} \delta(\Omega - \Omega_n(t))\mathrm{d}t$$

where $\Omega_n(t)$ is the orientation of molecule n at time t. Applying the orthogonality relation of the symmetry adapted functions to eq. [11] and using eq. [13] yields:

$$A_l^{\lambda\lambda'} = \frac{1}{\tau}\int_0^{\tau} \frac{1}{N}\sum_{n=1}^{N} \mathcal{R}_l^{\lambda\lambda'*}(\Omega_n(t))\mathrm{d}t$$

which can be computed.

V. Results

As mentioned in the Introduction, we now have three sets of parameters which describe the same system in the same terms and can be compared with one another; this comparison leads to interesting results both for the Debye–Waller factor and the o.p.d.f.

(a) Debye–Waller factor

Figure 1 shows the thermal dependence of the three Debye–Waller factors. The two results relative to the simulation coincide almost perfectly, which means that the model used to analyze $I(\boldsymbol{Q})$ is reliable as far as $\langle u^2 \rangle$ is concerned. On the other hand, the experimental values are significantly smaller than the simulated ones. This may be caused by two different effects.

(i) Corrections to the experimental data

No thermal diffuse scattering (TDS) correction has been performed on the experimental data. As the correction increases with the Miller indices, this could lead to an overestimation of the Bragg peak intensities for large momentum transfers, thus to an experimental Debye–Waller factor smaller than the actual one. Nevertheless, the TDS correction is clearly very small for the more intense Bragg peaks, and could be important only for the weak peaks for which the standard deviation is already comparatively large, and have then a small weight in the fitting procedure; the inclusion of the TDS correction is thus not likely to alter significantly the Debye–Waller factor obtained from the experiment.

Similarly, other corrections such as absorption and multiple

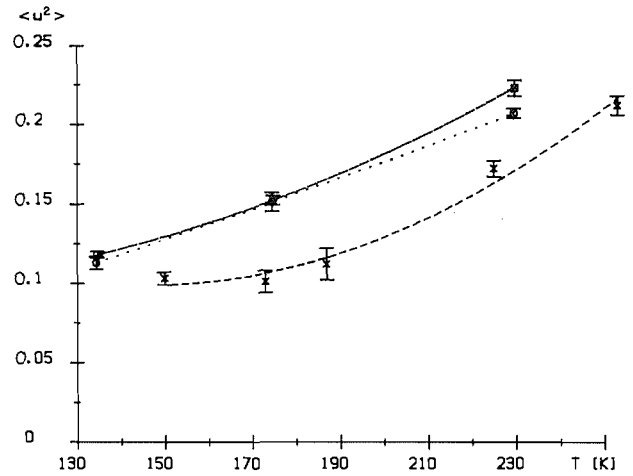

FIG. 1. Thermal dependence of the Debye–Waller factor. Crosses (× ×): experimental data analyzed through the o.p.d.f. expansion model; circles (○○○): simulated data, analyzed with the same model as above; boxes (□□□): calculated directly from the simulation.

scattering were not performed but simply included in the error bars.

(ii) Weakness of the potential

The potentials used in the simulation have been optimized on crystallographic and calorimetric data (6), and then tested on the harmonic dynamics of molecular crystals (11), that is, for usual interatomic distances in crystals. Nevertheless, in ODIC phases, some of these distances will become much shorter (particularly for H–H interactions) during the reorientation processes. The simulation is thus sensitive to a range of distances at which these potentials may be inaccurate. The comparison between the experiment and the simulation suggests strongly that they are, in fact, too weak at short distances.

The general behaviour of the three Debye–Waller factors shown in Fig. 1 is however quite comparable; in particular, one must stress that this factor is much larger than what one expects from the translational phonon contribution (3). There exists, in neopentane, an intrinsic, orientationally induced, contribution to the Debye–Waller factor which dominates it, and which increases with temperature.

(b) Orientational probability distribution functions

Figures 2*a*, *b*, and *c* show the thermal dependence of A_4^{11}, A_6^{11}, and A_8^{11}, respectively. The great accuracy of the coefficients obtained directly, compared to that of the fitted coefficients, may be noticed, along with their linear dependence with temperature. On the other hand, if the differences between the three methods are within error bars for A_4^{11} and A_8^{11} due to their small numerical values, A_6^{11} which has the largest absolute value shows a significant difference between the direct calculation and the fitted values. These results may be discussed from two different view points: (*1*) The fact that A_6^{11} is strongly negative while A_4^{11} is small, both in the direct calculation and in the analysis through the model, is important because this is the signature of an o.p.d.f. with maxima in D_{2d} orientations (3): the model thus provides the correct most probable molecular orientations. (*2*) From a quantitative point of view, the comparison between the two values obtained for A_6^{11} for the same sample on the one hand, as well as that of the respective sizes of the error bars on the other, shows that the analysis of the

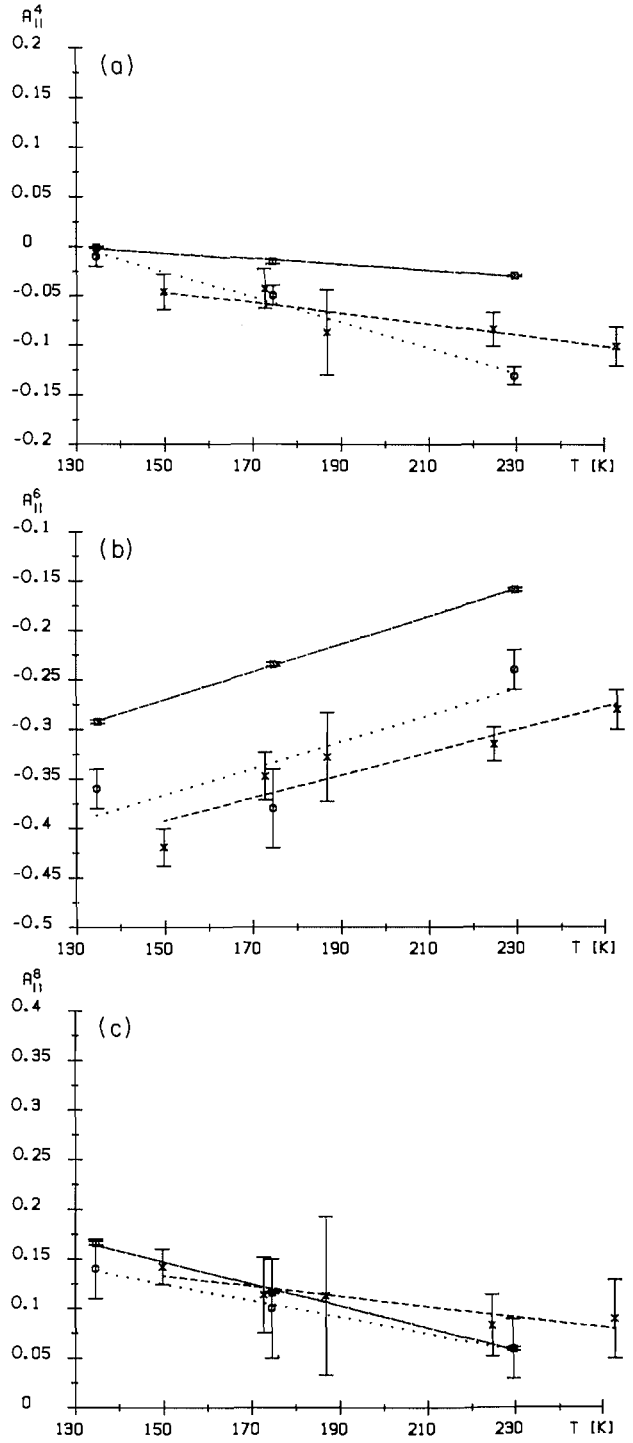

FIG. 2. Thermal dependence of the o.p.d.f. expansion coefficients. Same as above; (*a*) coefficient A_4^{11}; (*b*) coefficient A_6^{11}; (*c*) coefficient A_8^{11}.

data through this model does not describe $P(\Omega)$ properly.[6] The reasons for this inaccuracy lie mainly in two of the assumptions of the model: (*a*) $P(\Omega)$ is a smooth enough function of the

[6]The coefficients A_l^{λ} are quite uncorrelated because the spherical Bessel functions $j_l(kr)$ which enter in the calculation of the SMSF (5) select, for each value of l, different regions of the reciprocal space. There is thus no way of decreasing in a systematic way the differences between the two sets of values.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/07/12
For personal use only.

orientation so that one may restrict oneself to low values of l; (b) the mean center of mass displacements are small enough for any term in the expansion of the second term of $P(\boldsymbol{u},\Omega)$ beyond the linear one, to be neglected.

It is very likely that none of these assumptions is correct. The large values of $\langle u^2 \rangle$ tend to contradict point (b). Furthermore, the analysis of the experimental data using the TLS model (4) suggests that most of the molecules are in fact much more localized around the D_{2d} orientations than can be described by an expansion of the o.p.d.f. truncated at $l = 10$, thus contradicting point (a). The fitting procedure tends to overcome this difficulty by producing a $P(\Omega)$ which is smoother than in reality, thus making the model somewhat unreliable in this respect.

VI. Conclusion

We have confronted the point of view of Laplace's creature[7] to an actual experiment by performing a simulated "experiment" and then comparing it to real size experimental data. This is, in itself, not unusual (13) but the simulated data were also analyzed through the model which was used to interpret the experiments. This is a demanding test both for the simulation and for the model so that their shortcomings are vividly revealed: (*1*) The expression of the SMSF through a Debye–Waller factor and an expansion of the o.p.d.f. seems to be able to provide reliable information about the translational disorder since one obtains identical values for $\langle u^2 \rangle$ in the simulated sample, whether calculated directly or through the model. The values of the expansion coefficients of the o.p.d.f. in terms of symmetry adapted functions are, however, clearly unreliable in this case contrary to what has been found for adamantane (14) in the case of small Debye–Waller factors. (*2*) The simulation shows at least an excess in translational disorder compared to the real crystal. This discrepancy is very likely related to the short range behaviour of the atom–atom potentials used in the simulation, a conclusion which could not have been reached by simply computing the Bragg peak intensities for the simulated sample and comparing them with the experimental ones.

[7] "Une intelligence qui pour un instant donné connaitrait toutes les forces dont la nature est animée et la situation respective des êtres qui la composent" ("An intelligence which for a given instant would know all the forces by which nature is driven and the respective locations of the beings of which it is composed") (12).

It would have been most desirable to perform a similar comparison between the simulated crystal and the real crystal, making use of the TLS model (4) mentioned in section V. The direct calculation of the pertinent quantities (i.e. $\langle \theta_i^2 \rangle$, where θ_i is a molecular rotation around an axis i) is, however, much more difficult than for the o.p.d.f. expansion coefficients and therefore beyond the scope of this work.

From a more general point of view, two aspects emerge from this specialized study of neopentane: (*1*) The method we have presented here for comparing experimental data with a molecular dynamics simulation allows us to use the complementarity of these two techniques more efficiently than previously: it reveals the weakness of the simulation as well as those of the models used for analysing the experiments.

(*2*) This technique involves the computation of simulated experimental data. The production of such data may imply the use of rather sophisticated techniques because of the inherent differences between the simulated and real samples, such as, in the present case, the size of the sample and the duration of the experiment.

Energetics of order/order transitions in nucleic acids[1]

H. H. KLUMP

Department of Biochemistry, Cape Town University, Republic of South Africa

Received September 8, 1987

This paper is dedicated to Professor James A. Morrison

H. H. KLUMP. Can. J. Chem. **66**, 804 (1988).

Besides the temperature induced canonical helix to random coil transition, which serves as a prototype of an order/disorder transition, there is a second group of conformational changes in helical polynucleotides, which will be termed order/order transitions. Depending on the environmental conditions and the sequence of the polynucleotides involved, there are four alternative reaction schemes: (*i*) The inversion of the helical handedness from a right-handed to a left-handed conformation, (*ii*) the disproportionation of a double helix into a single strand and a triple helix, (*iii*) the addition of a single strand to a double helix, and (*iv*) the single/double strand displacement reactions, that is, the displacement of one of the two strands of the helix by a matching single-stranded polynucleotide or the mutual exchange of one strand each between two helical structures. The first three reactions are considered reversible while the last reaction is irreversible; that is, one cannot regain the initial state by inversing the course of the change, here the change in temperature. Both ribo and deoxyribo polynucleotides can undergo these reactions. In the following paper at least one example is given for each of these reactions.

H. H. KLUMP. Can. J. Chem. **66**, 804 (1988).

La température induit une transition de l'hélice canonique en bobine au hasard qui est le prototype d'une transition ordre/désordre; en plus de cette transition, il existe un deuxième groupe de changements conformationnels des polynucléotides hélicoïdaux qu'on appelle transitions ordre/ordre. Suivant les conditions du milieu et la séquence des polynucléotides impliqués, il y a quatre schémas réactionnels possibles : (*i*) l'inversion de la chiralité de l'hélice d'une conformation droite vers la gauche; (*ii*) la dismutation de la double hélice en un brin unique et en une triple hélice; (*iii*) l'addition d'un brin unique à une double hélice et (*iv*) les réactions de déplacements simple/double brins, c'est-à-dire les réactions de déplacements de l'un de deux brins de l'hélice par un polynucléotide approprié à brin unique ou par l'échange mutuel d'un brin de chacune de deux structures hélicoïdales. On considère que les trois premières réactions sont réversibles alors que la dernière serait irréversible, c'est-à-dire qu'on ne pourrait revenir à l'état initial en inversant le changement, dans notre cas, la température. Les ribo- et désoxyribo-polynucléotides peuvent subir ces réactions. Dans ce travail, on décrit au moins un exemple de chacune de ces réactions.

[Traduit par la revue]

Introduction

Three biological reactions of fundamental importance, namely (*i*) the replication and (*ii*) the transcription of the DNA double helix and (*iii*) the crossing over of DNA sequences between two chromosomes are considered to require strand separation prior to the consecutive steps in these processes. The investigation of the helix–coil transition of double-stranded synthetic and (or) native polynucleotides (1) has been taken as an adequate approach to gain insight into the kinetics (2) and the energetics (3) of the opening of the DNA double helix.

However, these model reactions can only serve as a first approximation, for the final state of the DNA under native conditions is always an ordered conformation, mostly a double helix, and sometimes a triple helix. Thus, it is important to develop a set of reaction schemes that is capable of modelling the in vivo reactions. Prerequisite to cope with this task of designing the appropriate model reactions is the evaluation of a sufficiently large body of experimental data such as the transition temperature (T_m) and stoichiometry of helical polynucleotide complexes as functions of the environmental conditions (4). From these data it will be possible to construct a series of phase diagrams. These diagrams will have two useful applications (cf. Fig. 1*a*,*b*). From the diagram, the conformational state of the polynucleotides in the system at any arbitrary set of external conditions (temperature, cation concentration) can be taken simply by inspection. From the behavior of the phase boundaries, the physical effects responsible for the phase transitions can be assessed. The different order/order transitions have different prerequisites (5). In general (24) only strictly alternating purine–pyrimidine sequences are observed from the normal right-handed conformation into a left-handed form (6).

High counterion concentrations of simple monovalent cations and (or) low concentrations of additional transition metal ions are also required. Chemical modifications of the 5′ position in the pyrimidine ring, e.g., by methyl or bromine groups, are capable of facilitating the inversion (7). Addition of organic solvents, which compete for the bound water in the small helix groove, will favour the left-handed helix (8).

The type of order/order reactions favoured is determined only by the thermodynamic stabilities of the final state of products. For example, poly(A)·poly(U) is the stable complex formed in the 1A/1U mixture. At moderately high sodium concentrations (9) (300 mM) this complex rearranges itself at elevated temperatures into poly(A)·2 poly(U), liberating one half of the poly(A) strands. As will be shown in the following, this triple-strand formation can also be brought about by simply adding the extra polypyrimidine as a single strand. Only recently Fresco and co-workers (25) demonstrated a new triple helical complex, consisting of poly(A)·poly(U) and another poly(A) strand of intermediate length. This 2 poly(A)·poly(U) helix is only formed under stringent conditions. It cannot be obtained by thermal disproportionation of the initial poly(A)·poly(U) double helix. Thus we do not include this particular complex in the order/order reactions. This disproportionation reaction occurs also in the poly(I)·poly(C) system (11), but here the competitive formation of the four-stranded poly(I) helix at high counterion concentration will eventually abolish the triple strand altogether. We will discuss this in more detail later in the paper.

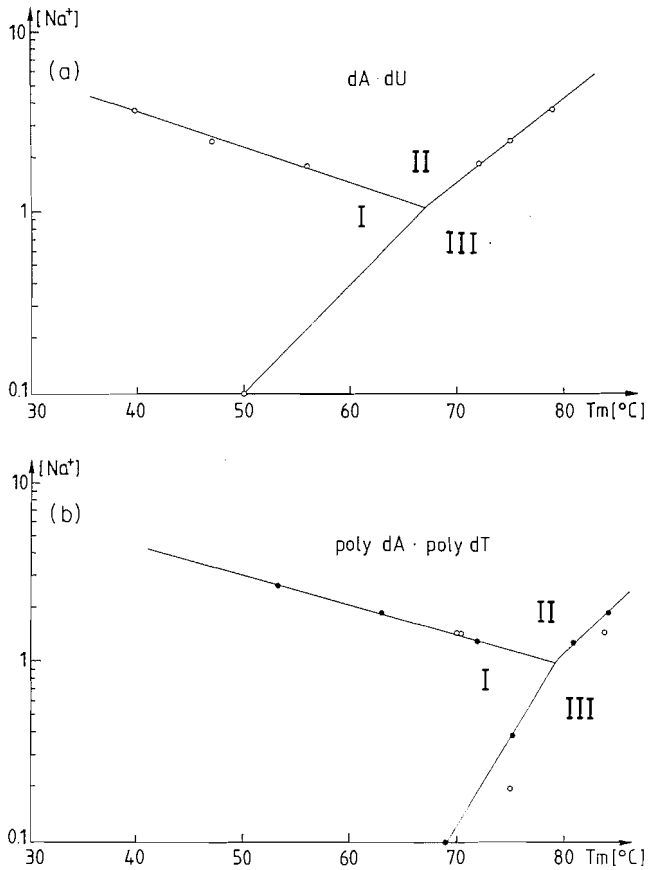

FIG. 1. (a) Phase diagrams of poly(dA)·poly(dU), i.e., transition temperature as a function of cation concentration. Region I represents the stability range of the double helix, region II represents the stability range of the triple helix, and region III is the range of the coiled single strands. (b) Phase diagram constructed from the data of poly(dA)·poly(dT). The assignment of the regions is as in (a).

The evaluation of a complete set of state diagrams for all polynucleotide systems gives an exact overview of the conditions for the preference of any particular double helical polynucleotide complex, and will allow prediction of the potentially irreversible displacement reactions (12).

Another important question to be approached experimentally in this paper is the relative stability of ribo, deoxyribo, and hybrid helices. The data set presented here will allow us to group the different helical complexes according to their thermodynamic stability. The exact enthalpy values per base pair for the different conformational changes are determined by differential scanning calorimetry (13).

Materials and methods

The polynucleotides investigated were purchased from Pharmacia PL-Biochemicals, Freiburg, W. Germany, and used without further purifications. The alternating ribopolymers and poly[d(A-brC)]·poly-[d(G-T)] were furnished by T. Jovin, MPI for Biophysical Chemistry, Göttingen, in the context of cooperative research into alternating ribo and deoxyribo polynucleotides. Some of the results have already been published elsewhere (26). All buffers applied were prepared from double distilled water and the inorganic substances were of analytical reagent grade. The pH of all solutions was set to pH 7.2 by adding the appropriate amount of either HCl or NaOH. Polymer concentrations were calculated from the absorbance at 260 nm, determined with an ultraviolet spectrophotometer, Perkin–Elmer model 124.

Optical melting curves were also measured with the Hitachi–Perkin–Elmer double beam ultraviolet spectrophotometer model 124 and recorded on a Hewlett–Packard model 1800 *xy*-recorder. Temperature signals were taken direct from the solution in the reference cuvette by a resistance thermometer. The voltage of this device was fed into the *x*-axis of the recorder.

Calorimetric measurements were performed with the help of an adiabatic differential scanning calorimeter, type DASM-1, from Mashpriborintorg, Poustshino, Moscow region, USSR. In principle, the instrument plots the difference in heat capacity between solvent and solution. Any transition that is brought about by increasing temperature will absorb heat, causing the apparent heat capacity of the solution to be greater than that of the solvent. The extra energy that has to be put into the solution, to bring the temperature difference between the sample and reference as close to zero as possible, corresponds to the enthalpy change due to the reaction under study. Details of this procedure and of the design of the instrument are given in the literature (13).

Results

Disproportionations

Figures 1*a* and 1*b* give the state diagrams of two polynucleotide systems, the poly(dA)·poly(dT) and the poly(dA)·poly(dU) systems. The transition temperatures are plotted as a function of the sodium concentration. For comparison we show also the reinvestigated, most extensively studied system that undergoes a disproportionation reaction, the poly(A)·poly(U) system (14) (cf. Fig. 2*a*). To obtain the two branches of the state diagram at elevated sodium concentrations the uv absorbance at 280 nm is plotted as a function of temperature. The unanimous observation in all three systems is a drop in absorbance that is shifted to lower temperatures with increasing cation concentration for the first step, and the rise in absorbance that shows the opposite behaviour for the second step. The first transition is due to the disproportionation of two double helices into a triple helix and a partly stacked polypurine single strand. The second transition reflects the thermally driven denaturation of the triple helix into random coils of single-stranded poly(dU) and poly(dA), for example, at elevated temperature. Figure 2*b* gives the corresponding heat capacity scan from the differential microcalorimeter for poly(A) and poly(U). The area under the small peak represents the transition enthalpy ΔH of the order/order transition (disproportionation) and the area under the large peak represents the transition enthalpy for the order/disorder transition (denaturation of triple helix). Both transitions are reversible, i.e., on lowering the temperature below the upper transition the three-stranded helix of polypurine · 2 polypyrimidine is reestablished, and on passing the lower transition temperature the complex rearranges again to form the double helical complexes of polypurine·polypyrimidine.

This also holds for hybrid helices like poly(rA)·poly(dU). For example, Table 1 gives the energetics of the disproportionation reactions, reinvestigated with the help of the advanced instrumentation.

Additions

The triple-strand formation can also be brought about by addition of a matching polypyrimidine single strand to the polypurine–polypyrimidine double helix. The separate polynucleotide species can be mixed at room temperature and at low cation concentration. By raising the cation concentration above a threshold concentration the triple helix formation can be triggered (cf. Fig. 3). The energetics of this reaction can be followed with the help of a differential isothermal scanning

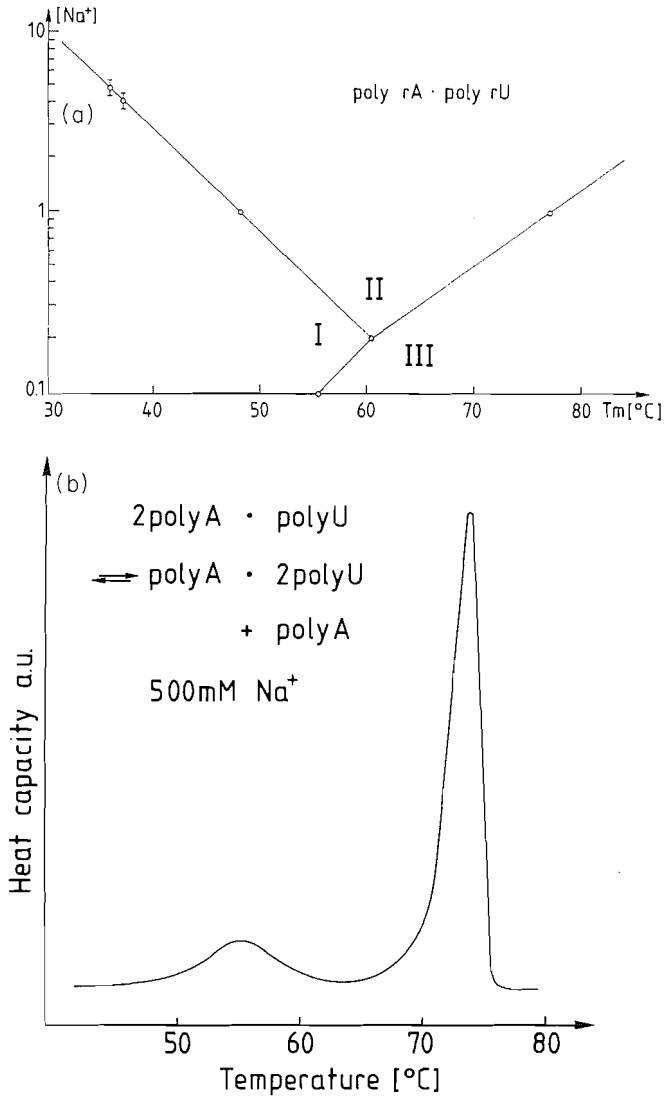

FIG. 2. (a) Phase diagram of poly(A)·poly(U) (assignments as in Fig. 1). (b) Heat capacity of poly(A)·poly(U) at 500 mM Na^+, as a function of temperature. Left peak is due to the disproportionation reaction, right peak represents the enthalpy change accompanying the triple-helix coil transition.

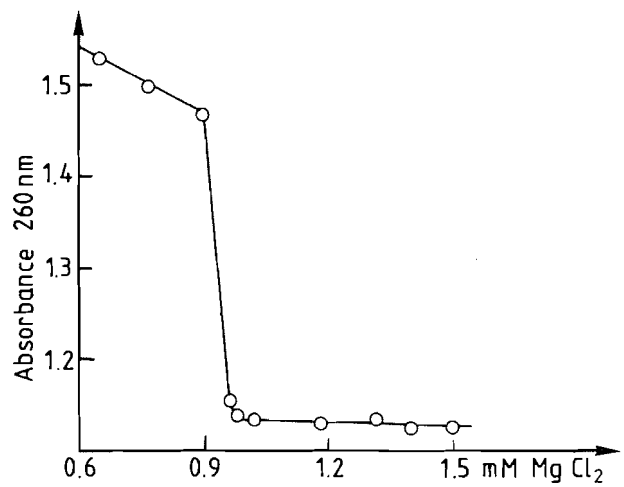

FIG. 3. Triple-strand formation as a function of the Mg^{2+} concentration for poly(U)·poly(A) plus poly(dT).

titration calorimeter to compensate for the heat due to the concentration change of the cations, an effect that is much larger than the heat of adding the third strand to the preexisting double strand (10).

Mixed three-stranded DNA–RNA complexes in which the three strands differ have been reported to occur in vivo, and have been suggested as intermediates in the transfer of information between the nucleic acids (11). The triple-strand formation via addition is included here only for comparison with the other order/order reactions. It does not contain new experimental results.

Coil–helix displacement reactions

Chamberlin and Patterson (11) were the first to study extensively the coil–helix displacement reactions in the poly(I)·poly(C) system. It was demonstrated that the order of thermal stability of the I–C homopolymer pairs could be used to predict relative stabilities of helical complexes, and the displacement reactions were followed spectroscopically at low temperatures. Here we show that the same general scheme also holds for the poly(A)·poly(U) system. Since we were interested in the energetics of these reactions in the first place, the displacement was brought about by raising the temperature just above the thermal transition of the less stable helical complex. At this point the synchronous helix–coil transition of the weaker complex and the helix formation of the more stable complex occurs. The heat capacity change at this temperature is the differential effect of the two reactions. The displacement reaction is facilitated by raising the cation concentration. The reactions observed in the poly(A)·poly(U) system are the following:

$$\text{poly(dA)·poly(rU)} + \text{poly(dU)} \rightarrow \text{poly(dA)·poly(dU)} + \text{poly(rU)}$$

$$\text{poly(dU)·poly(rA)} + \text{poly(rU)} \rightarrow \text{poly(rA)·poly(rU)} + \text{poly(dU)}$$

$$\text{poly(dA)·poly(rU)} + \text{poly(rA)} \rightarrow \text{poly(rA)·poly(rU)} + \text{poly(dA)}$$

$$\text{poly(dU)·poly(rA)} + \text{poly(dA)} \rightarrow \text{poly(dA)·poly(dU)} + \text{poly(rA)}$$

Experimentally the denaturation of the appropriate hybrid helix was forced by raising the temperature continuously through the transition interval while either the change in optical density or in heat capacity was scanned as a function of the temperature. The denaturation of the hybrid helices is a reversible process. In the second run the same polymer solution was mixed with one equivalent of the single-stranded homopolymer in 100 mM NaCl and heated continuously at a constant heating rate of 0.8°/min. Each of the reactions was observed to occur either at 44 or 46°C, the transition temperatures of the hybrid helices.

When two samples that contain one of the alternative hybrids are combined and heated to a temperature just above the transition of the least stable hybrid, concerted replacement reaction takes place. The correct measure of the stability of helical conformations is the free energy ΔG_s of a given state s, and, if all components are in their standard states, the standard free energy ΔG^0_s can be used instead. Whether a given reaction will occur is determined exclusively by the change in the standard free enthalpy (not by the change in enthalpy or by the relative magnitude of T_m) (3). This holds in general but there are exceptions to the rule. If ΔS is constant, then ΔG can be

replaced by ΔH for the following considerations. For the helix single-strand exchange let us focus on the following reaction:

$$\text{poly(rA)}\cdot\text{poly(dT)} + \text{poly(dA)} \rightleftharpoons \text{poly(dA)}\cdot\text{poly(dT)} + \text{poly(rA)}$$

The scheme presented below represents the different steps of a Born–Harber circular process. The initial state is represented by the three separated single strands. In the first step the formation of the hybrid helix poly(rA)·poly(dT) is considered. The formation enthalpy results in 30.9 kJ per mol of base pairs (mbp). In the second step the poly(rA) strand is displaced by the poly(dA) strand. The displacement enthalpy amounts to 1.5 kJ·mbp^{-1}. In the third step the poly(dA)·poly(dT) double strand is denatured to give back the initial state. The denaturation enthalpy is 32.4 kJ·mbp^{-1}. The sum of the formation enthalpy and the displacement enthalpy equals the denaturation enthalpy of the most stable helical complex in the system. The assumption is that the formation enthalpy and the denaturation enthalpy of a certain double helix are identical.

poly(rA) + poly(dT) + poly(dA)

$\Delta H = 30.9$ kJ·mbp^{-1}
$T_m = 69$°C

poly(rA)·poly(dT) + poly(dA)

$\Delta H = 32.4$ kJ·mbp^{-1}
$T_m = 74$°C

$\Delta H_d = 1.5$ kJ·mbp^{-1} | poly(dA)·poly(dT) + poly(rA)

We can evaluate the free enthalpy change accompanying the displacement (ΔG^0_d) because $T_m = \Delta H^0/\Delta S^0$, and both T_m and ΔH^0 are experimentally accessible quantities. The only assumption that has to be made is that the transition enthalpy ΔH is temperature independent. This assumption seems to be justified because of the almost undetectable small value of ΔC_p. ΔS^0 is also given from the experimental values using the Gibbs–Helmholtz equation (5).

We therefore obtain the standard free enthalpy of formation of poly(rA)·poly(dT) according to the following equation, first applied to nucleic acids by Tinoco (27).

$$\Delta G^0_{dAdT} = \Delta H^0_{rAdT} - T\Delta S^0_{rAdT} = \Delta H^0_{rAdT}(1 - T/T_{m\,rAdT})$$

The exact corresponding equation holds for ΔG^0_{rAdT}. It immediately follows that

$$\Delta G^0_d = \Delta G^0_{dAdT} - \Delta G^0_{rAdT}$$

The quantitative evaluation of the displacement free enthalpy change at 25°C under standard conditions yields $\Delta G^0_d = 0.6$ kJ per base pair in the system given above.

Because ΔH^0 is negative for all known duplex formations, ΔG^0_d is also negative if $T_{m\,dAdT} > T_{m\,rAdT}$, which in fact is correct. The double helix with the higher T_m will be favoured in a helix displacement reaction. The results also demonstrate the general observation that RNA/RNA duplexes are more stable than DNA/DNA duplexes, while the relative stability of RNA/DNA hybrids is less predictable.

Helix/helix displacement reactions

The same approach can be made for a mutual displacement of strands between two metastable hybrid complexes.

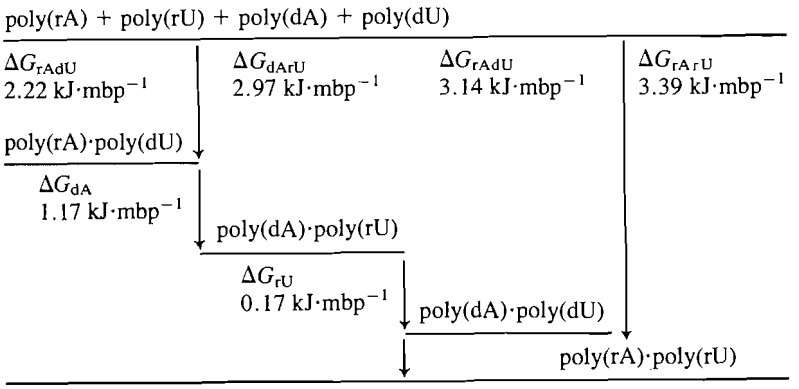
To demonstrate this case we will consider the following system:

$$\text{poly(dA)}\cdot\text{poly(rU)} + \text{poly(rA)}\cdot\text{poly(dU)} \rightleftharpoons \text{poly(dA)}\cdot\text{poly(dU)} + \text{poly(rA)}\cdot\text{poly(rU)}$$

In a 100 mM NaCl solution the hybrid helices have a transition temperature of 46°C / 44°C respectively and the poly(rA)·poly(rU) melts at 55.5°C, 5.5° higher than the DNA analogue poly(dA)·poly(dU) ($T_m = 50.0$°C). The corresponding transition enthalpies are 31.6 kJ·mbp^{-1} for poly(dA)·poly(dU), 30.6 kJ·mbp^{-1} for poly(dA)·poly(rU), 28.6 kJ·mbp^{-1} for poly(rA)·poly(dU), and finally 32.2 kJ·mbp^{-1} for poly(rA)·poly(rU). According to

the formalism given above the free enthalpy for the formation of each of the four double helical complexes is calculated. The displacement reaction can be illustrated by the following thermodynamic cycle: The initial state is given by the four separate single strands. In the first step the least stable helix poly(rA)·poly(dU) is formed. In the second step the poly(dA)·poly(rU) helix is formed. An increase of the environmental temperature above the melting temperature of the least stable helix sets one ribo and one desoxyribo strand free. The single ribo strand now displaces the desoxy strand from the second helix and the displaced strand finally reassociates with the residual desoxy strand.

The concerted formation of the final double helical states is equivalent to the independent formation of these species from isolated single strands, as given on the right-hand side of the following scheme. Hence a travel around the circle results in the initial state.



This scheme demonstrates that for the adenine/uridine (poly(A)·poly(U)) system all necessary thermodynamic quantities are known, which enables us to correlate the ΔG^0_d with the T_m parameters. The enthalpy change around the thermodynamic cycle is obviously zero, as the theory requires.

Inversion of handedness in DNAs and RNAs

The left-handed DNA or Z-DNA structure is characterized by a dinucleotide repeat. Thus it is convenient to consider sequences of $2n$ base pairs (bp) as present in the canonical alternating polynucleotides poly[d(G-C)], e.g., to adopt the Z form under certain experimental conditions. This has been demonstrated by crystallographic and solution studies (15). The state with all bp in the B form is taken as the reference state.

A logarithmic dependence of the apparent equilibrium constant K on NaCl concentration was initially observed in the study of poly[d(G-C)] (16). Cooperative transitions were also observed with poly[d(G-C)] undergoing B–Z transitions in the presence of organic solvents either alone or as cosolvents at very low salt concentrations. It is noticeable that the NaCl-induced B–Z transition of poly[d(G-C)] is essentially isoenergetic; i.e., the enthalpy change is less than 0.3 kcal·mbp^{-1} (from calorimetric and from spectroscopic equilibrium-kinetic studies). The reaction has to be entropy driven and is probably dominated by interionic interactions (17). In all other situations, i.e., in mixed solvents or under the influence of bound di- or oligovalent cations and other conformationally selective ligands, the B–Z transition of poly[d(G-C)] can also be induced by temperature variations at constant solvent composition. The latter is also true for DNA sequences methylated at the 5′ position of the cytosine moiety (18). Such substitutions lead to a selective stabilization of the left-handed conformation of the two canonical alternating purine–pyrimidine families, poly[d(G-C)] and poly[d(A-C)]·poly[d(G-T)] (19). With temperature dependent transitions, the apparent spectroscopically determined van't Hoff transition enthalpy change (for an unknown size of the cooperative unit) given by the following equation where n represents the number of strands (27),

$$\Delta H_{vH} = (n + 1)RT_m^2(d\theta/dT)$$

is related to the intrinsic transition enthalpy per base pair (determined by calorimetry). In the case of long polymers described by means of the infinite lengths Ising model

$$\Delta H_{vH} = m\Delta H_{cal}$$

where m is the calculated length of the cooperative unit. The thermodynamic parameters for the temperature dependent B–Z transitions in DNA polymers, obtained from van't Hoff analysis of spectroscopic data and from some directly obtained calorimetric data, are presented in Table 2.

Several conclusions can be drawn from the following information:

(*i*) DNAs with 5′ cytidine substitutions (methyl, halogen) in both sequence families show a similar transition enthalpy ΔH per base pair of ca. 4.2 kJ per mol of base pairs, derived from spectroscopic measurements, which is very close to the directly determined value from adiabatic scanning microcalorimetry (4.2 kJ·mpb^{-1} for poly[d(G-m5C)] (cf. Table 3).

(*ii*) The halogen substituents are more effective than a methyl group in stabilizing the Z form, i.e., it requires less enthalpy to turn the handedness around.

(*iii*) The cooperative lengths, i.e., junctional free energies, vary from one polymer to another, i.e., are DNA-sequence specific as well as a function of environmental conditions. Thus reported values for the cooperative length m for poly[d(G-C)] duplexes range from 25 bp to 100–1000 bp. Three recent estimates for the methylated polymer are 180, 226, and 110 bp.

Energetics of the A–Z RNA transition

Very recently it was successfully demonstrated for the first time that corresponding inversions of helical handedness occur also in double-stranded RNAs (2), contradicting a statement of Drew and Dickerson (19), which in an apodictic way states that it is immediately clear that there is nothing like a Z-RNA

because of the 2′-OH group of the ribose ring. This statement seems to be premature in the light of the results presented here for a series of nonmodified poly(G-C) and the methylated and halogenated analogs. The results of the calorimetric measurements are compiled in Table 3. The polymers were obtained from T. Jovin and the details of this investigation have been published as a cooperative paper (26).

The experimental conditions of the calorimetric investigation correspond to the conditions mentioned in the next paragraph.

Ultraviolet spectroscopy

Ultraviolet (uv) spectroscopic studies have shown that poly(G-C) in aqueous solution containing 4 M $NaClO_4$ can be reversibly converted into a left-handed Z-RNA by raising the temperature to 60°C. This conversion temperature will linearly decrease as a function of the logarithmic increase of the perchlorate concentration up to 110°C. The uv melting curves are shown in Fig. 4. Above this temperature the order/order transition merges with the helix–coil transition. The reversibility and cooperativity of the helix/helix conversion facilitates the investigation and the quantitative evaluation of the transition. The van't Hoff enthalpy, which can be derived from the temperature dependence of the degree of transition, i.e., the fraction of polymer strands that populates the left-handed conformational state, is calculated to 820 kJ per mol of the cooperative unit (20). From the ratio of the two enthalpies the size of the cooperative unit (bp) can be determined to amount to about 200 bp. Very similar results are obtained for the poly(G-m5C) and for poly(G-br5C) (cf. Table 3).

Discussion

The fundamental cellular reactions such as replication, transcription, and exchange of genetic material between two chromosomes will be fully explainable with the help of the thermodynamic state functions applied to the base/base interactions in the plane of the complementary Watson–Crick base pairs and (or) along the single strands. The proteins involved are assumed to speed up the reactions but they will not influence the equilibrium between the states of the nucleic acids involved. These proteins are catalysts in the chemical sense. Hence once the activation energy is supplied the reaction has to go spontaneously to the new equilibrium state.

Unfortunately it is impossible to check the hypothesis with native DNA sequences, for the amount of material needed to pick up the physical signals surpasses the limits of biochemical isolation techniques. The difficulties can be avoided by the help of selected model systems. To be able to select the best model system it is advisable to investigate all polynucleotides available. Figures 5*a*–*d* give the four matrices that demonstrate all possible double helical complexes in the poly(A-U), poly(A-T), poly(G-C), and poly(I-C) systems. We have collected all state diagrams either from the literature or from carefully recorded absorbance/temperature scans at different environmental conditions. The details of these measurements will be given elsewhere.[2]

To discuss the unique features of order/order transitions in a given context rather than to review all published data, we will choose the four A-U homopolymer helices and the strictly alternating A-U sequence. The five A-U polymers in solution form stable double helical structures. The degree of hyperchromicity and the sharp melting profile indicate that in the ordered complexes there is a maximum degree of orientation, presumably due to the strict pairing of each adenine residue with a uridine residue. They show, however, marked differences in thermal stability. The occurrence of displacement reactions between randomly coiled polypyrimidines or partly stacked polypurines and the homopolymer helices to form a double helix of even greater thermal stability indicates differences in the thermodynamic properties of the individual double helices. These considerations assume that the final state of all the polynucleotides under study is a randomly coiled conformation, which is reasonable for high temperatures. It is also assumed that the transition entropies (21) are close for all double helix/coil transitions in these systems. As was shown recently by the author, this can safely be assumed. The entropy change per base pair reflects primarily the gain in rotational freedom along the backbone single strands upon the denaturation of the helix. Hence differences in T_m correspond to differences in the transition enthalpy ΔH, and, if we assume that ΔH is temperature independent, to differences in the free enthalpy change. This is a hint that there is some difference in the three-dimensional arrangement of the different helical complexes.[3] A similar situation was found for the I-C homopolymers (11). It is also observed that the thermodynamic stability of the double-stranded RNAs is always bigger than the stability of the corresponding DNAs. The spontaneous course of the helix/helix displacement reaction, such as poly(dA)·poly(rU) +

FIG. 5. Matrix of possible helical complexes of I-C, A-U, A-T, and G-C homonucleotides. (+) represents the observed binary complexes. Numbers given are transition temperatures in °C at neutral pH and at the sodium concentration given in the bottom line (mostly 100 mM with the exception of 10 mM for G-C systems). (+H) refers to acid pH below pH 5, and (4) refers to the four-stranded complexes.

poly(rA)·poly(dU) rearranging to give poly(rA)·poly(rU) + poly(dA)·poly(dU) indicates that the free energy of the mixture of the hybrids is greater than that of the mixture of pure DNA- and RNA-like homopolymer helices.

This is also true for the I-C homopolymers. The displacement of one strand of the hybrid helix by an additional single strand of either type of polynucleotide to yield a homopolymer helix is caused by the same underlying principle. We can conclude that the displacement of the mRNA from the coding strand of the DNA is based on this thermodynamic phenomenon.

The addition of a matching single strand to the homopolymer helix at elevated cation concentrations is thermodynamically driven. The loss in conformational entropy of the single strand upon binding to the double helix is compensated by the gain in stacking and H-bonding energy once the electrostatic repulsion is sufficiently decreased by the shielding of the phosphate groups by cations. Whether the triple-strand formation is possible is also dependent on the tendency of the homopolymer to form ordered secondary structures. Poly(I), for example, has a high tendency to form four-stranded helices at moderate counterion concentration, preventing it from binding as a third strand to poly(I)·poly(C) (cf. Fig. 5). This tendency of self-complementary structure formation is extreme for poly(G). All investigations on structures that contain poly(G) are obscured by this behaviour (22).

The temperature-driven disproportionation reactions are com-

For personal use only.

pletely reversible and also strictly follow the laws of thermodynamics. Whether a disproportionation occurs is governed by the same rules as the addition of a third strand to the double helix. In this case the third strand only originates from the second helix. As is shown for the order/order transitions in general, the disproportionation temperature decreases with increasing cation concentration. This also holds for the inversion of the handedness of the helical complexes formed from a strictly alternating sequence.

For quite a while it was thought that the inversion was only possible for the deoxypolymers. Now we have a growing list of various copolymers that can form the left-handed helix under appropriate conditions, i.e., high counterion concentration and reduction of water activity (8). The energy required for the inversion is surprisingly low (about 4 kJ per mol of base pairs).

The only reason that the polymer is not flipping between the two conformational states is the fact that the inversion is a highly cooperative process. There is only one inversion centre in each double strand, and its formation requires a large activation energy to start (cf. the size of the cooperative unit m).

Summing up the results reported in this paper, it can be stated with confidence that systems presented here are capable of modelling the order/order transitions of nucleic acids proposed for replication, transcription, or chromosomal crossing over.

Acknowledgments

The author acknowledges the constant support throughout these investigations by the Deutsche Forschungsgemeinschaft and Fonds der Chemischen Industrie. The alternating polynucleotides used are the gift of Professor T. Jovin and will be used for further cooperative investigations. The series of melting experiments to set up the four matrices were conducted by J. Siepmann, whose expert technical assistance is gratefully acknowledged.

This paper is dedicated to Professor J. A. Morrison

TADEUSZ LUTY and JOHN C. RAICH. Can. J. Chem. **66**, 812 (1988).

Structural transformations in solid iodine under high pressure are analyzed from the point of view of symmetries of possible charge density distortions coupled to phonons. The transition from the high pressure atomic phase to the low pressure molecular phase is interpreted in terms of phonon softening and formation of molecular bonds and is seen as a condensation of a charge density distortion wave coupled to a phonon mode.

TADEUSZ LUTY et JOHN C. RAICH. Can. J. Chem. **66**, 812 (1988).

Dans le but d'examiner les symétries des distorsions possibles dans les densités de charges couplées aux phonons, on a étudié les transformations structurales de l'iode solide, sous pression. On interprète la transition de la phase atomique à haute pression vers la phase moléculaire à basse pression en fonction d'un ramollissement du phonon et de la formation de liaisons moléculaires et on la considère comme une condensation d'une onde de distorsion de la densité de charge qui est couplée avec un mode phonon.

1. Introduction

Solid iodine has been the subject of many experimental and theoretical studies in part because of its interesting properties under pressure. The dynamical properties of the crystal are of particular interest because they appear to have characteristics intermediate between those of molecular solids and of metals. This intermediate character of solid iodine is evident from experimental studies, which indicate an insulator–metal transition at about 16 GPa (1). According to recent X-ray crystal structure analysis, the insulator–metal transition is followed by a structural phase transition associated with molecular dissociation at 21 GPa (2). It has been known for a long time that there is a chemical bond formation involving $5p$ electrons of nearest iodine molecules in the crystal under atmospheric pressure (3). A common opinion is that the intermolecular bond is of a charge transfer nature, that is, a dative structure involving ionic and covalent bonds between nearest atoms of different molecules is formed. Theoretical studies of the lattice dynamics (4, 5) demonstrated the importance of charge distribution of the intermolecular bond.

Structural studies of iodine under pressure (2) stimulated this theoretical effort to construct a model for charge density distortions and lattice dynamics which gives a phenomenological explanation for the observed structural changes.

The generally accepted viewpoint is that the application of pressure changes the balance between intermolecular charge-transfer interactions and intramolecular covalent bonds, so that the crystal becomes metallic and molecular dissociation follows. Because of the relatively simple crystal structures, it is believed that the pressure-induced transformations in solid iodine can serve as a model to study charge density distortions in molecular crystals caused by applied pressure. The current studies elucidate the transition between the metallic bond and the ionic-covalent bond, so far only weakly suggested by McMillan (6) within the charge density wave concept. The transformation of solid iodine under pressure can be viewed as a solid state chemical reaction ($2N\ I \rightleftharpoons I_2$). Thus, it is believed that concepts needed to understand the transformation in solid iodine will also be useful for an understanding of solid state reactions (dimerization, polymerization) in more complicated systems.

Very recently the description of molecular dissociation of iodine at $p > 21$ GPa became controversial. On the basis of Mössbauer effect measurements (10) it has been argued that "up to 30 GPa the I_2 molecules remain the building blocks of the high pressure structural modifications". The need for assuming a "zig-zag" structure is stressed in ref. 10. We hope that the analysis presented in this paper will provide a compromise (a polymeric structure) between the two interpretations of the transition.

In the present paper we start with a brief description of the iodine crystal structures and phase transitions under pressure. In section 3 we formulate the 16-bond model and determine the possible order parameters for the phase transformations. The next section is devoted to demonstrating that the 16-bond model is equivalent to a 2-bond model in reciprocal space. It is shown that the order parameters can be identified with amplitudes of charge density distortion waves. Finally, we consider the coupling of the charge density distortion waves to phonons.

2. Structures of solid iodine

The low-pressure (LP), molecular phase of iodine is orthorhombic, space group D_{2h}-$Cmca$, with two I_2 molecules per primitive unit cell (7). The iodine molecules form layered structure in the (bc) plane, as shown in Fig. 1. When pressure is applied to the crystal the iodine molecules tilt around the crystallographic a axis in such a way that the angle between the two translationally nonequivalent molecules in the (bc) plane comes closer to $\pi/2$. In the range of stability of the molecular phase ($p < 21$ GPa) no change in the intramolecular bond length has been observed (2) although an insulator–metal transition occurs at about 16 GPa (1). This purely electronic transition is

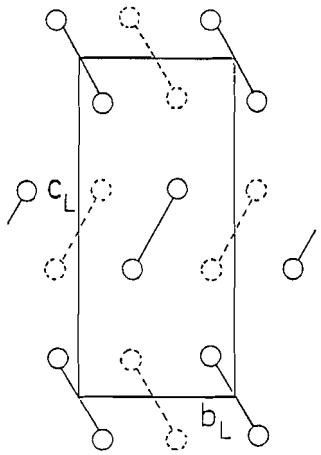

FIG. 1. The (bc) planes of the molecular phase, stable at atmospheric pressure, of solid iodine.

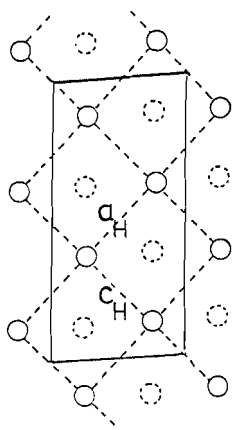

FIG. 2. The iodine atoms on the (ac) plane of the atomic phase at 30 GPa, according to ref. 2.

followed, according to ref. 2, by the first-order structural phase transition at 21 GPa which is essentially molecular dissociation.

The high-pressure (HP), monoatomic phase forms a body-centred orthorhombic lattice, space group D_{2h}-$Immm$, with one iodine atom per primitive unit cell (2). The structure of the phase at 30 GPa according to ref. 2 is shown in Fig. 2. In terms of the basic vectors of the molecular (LP) phase the atomic phase forms a monoclinic structure. If the larger unit cell of the LP phase is considered, the HP monoatomic structure appears as a shear strained LP molecular structure when projected on the (bc) plane. The distortion angle α can be expressed in terms of the strain, $e_{yz} = e_4$, and the basic vectors of the atomic phase, a_H and c_H,

$$[1] \qquad e_4 = \text{ctg}\,\alpha = \frac{c_H^2 - a_H^2}{2a_H c_H}$$

Relationships between crystal axes of the LP phase (a_L, b_L, and c_L) and those of the HP phase (a_H, b_H, and c_H) are:

$$[2] \qquad \begin{aligned} a_L &= b_H \\ b_L &= a_H + c_H \\ c_L &= 2c_H - 2a_H \end{aligned}$$

Recent X-ray diffraction studies of solid iodine have revealed that it undergoes two additional phase transitions, one at about 45 GPa to a face-centred tetragonal structure (11) (space group D_{4h}-$I4/mmm$) and the other at 55 GPa to a face-centred cubic structure (12) (space group O_h-$Fm3m$). The formation of the tetragonal structure (VHP phase) can be seen as decreasing the shear strain defined in eq. [1], when the pressure increases to approximately 45 GPa. In the present paper this very high pressure tetragonal phase is labeled VHP. Electronic band structure calculations have been performed for the tetragonal structure (8).

A comparison of the atomic positions in the LP and HP phases is the basis for a phenomenological model of the LP $\longleftrightarrow$ HP transition (2). The model uses atomic displacements as order parameters without any reference to charge density distortions. The present study also offers a simple phenomenological model for the transition and also combines the charge density distortions and phonon instabilities.

3. 16-Bond model

In the considerations which follow we treat the tetragonal VHP phase as the parent phase. Following arguments of Takemura and co-workers (2) it will be assumed that the dimerization of the iodine atoms occurs primarily in the ($a_H c_H$) or ($b_L c_L$) plane as the applied pressure is decreased. Hence, we believe that a two-dimensional model will be adequate to describe the essential features of the phase transitions. The other basic assumption of the postulated model is that we describe the electronic bonds in solid iodine in a manner similar to the description used by Blinc *et al.* (9) for hydrogen bonding.

Let us consider the VHP tetragonal phase. Each atom has four nearest neighbors in the ($a_H c_H$) plane. In the plane the unit cell is a square and electronic densities (or probabilities) in the four bond directions are equal. This situation is shown schematically in Fig. 3*a*. The HP phase results from the VHP phase by an application of a shear strain resulting in $c_H \neq a_H$ and electronic densities which are different in the orthogonal directions. The schematic of the electron densities for this case is given in Fig. 3*b*. For the diagrams of Fig. 3 the lengths of the lines indicate the strengths of the bonds and not the lengths of the bonds. One would expect an inverse relationship between bond strengths and bond lengths or interatomic distances.

The molecular LP phase has a larger unit cell than the VHP or HP phases with four atoms in the (bc) plane in each unit cell. The strengths of the bonds with nearest neighbors for a typical atom in the molecular phase are shown schematically in Fig. 3*c*.

In order to describe all possible phases of iodine in terms of Brillouin zone center instabilities we consider the unit cell shown in Fig. 4. This unit cell contains eight atoms in the crystal plane, hence is twice as large as needed to describe the molecular phase. The two-dimensional basis is a square lattice. From Fig. 4 it is clear that two choices for unit cells are possible.

In the following we shall consider the 16-bond model as represented in Fig. 4. We assume that the electronic interaction energy for two-particle interactions can be written in the form

$$[3] \qquad U_2 = \frac{1}{2}\sum_{\alpha\beta} a_{\alpha\beta} n_\alpha n_\beta$$

where n_α is the occupation probability for the αth bond in the unit cell. Unit cell indices are neglected in eq. [3] because the chosen cell is the largest one and $a_{\alpha\beta}$ is the interaction parameter summed already over the unit cells. In eq. [3], $\alpha, \beta = 1, 2, \ldots, 16$. The form of the interactions can be justified

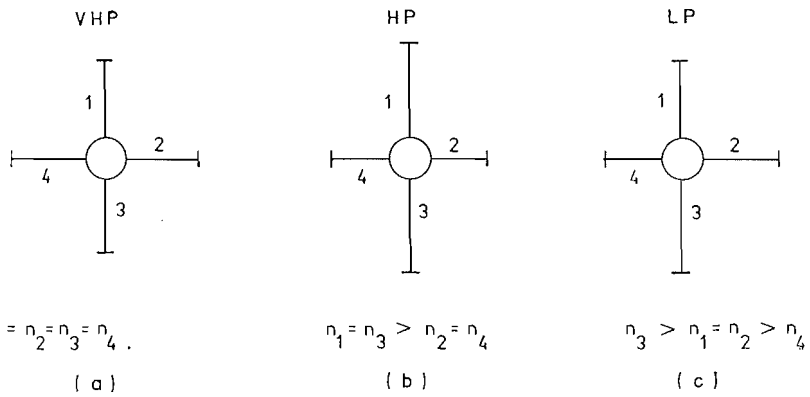

FIG. 3. A schematic representation of electronic densities in four directions around an iodine atom in the (*a*) atomic tetragonal VHP, (*b*) atomic orthorhombic HP, and (*c*) molecular LP phases.

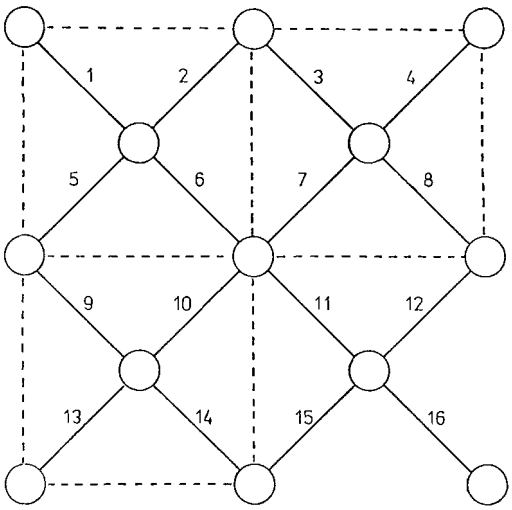

FIG. 4. The 8-atom two-dimensional unit cell with 16 interatomic bonds.

on the basis of Coulomb interactions between bond charge distributions.

We postulate that structural phase transitions in solid iodine are a consequence of changes in occupation probabilities of interatomic bonds. The changes will correspond to eigenvectors of the interaction matrix $\{a_{\alpha\beta}\}$. For the 16-bond model the eigenvectors will transform according to following irreducible representations of the D_{4h} point group: $2A_{1g}$, $2A_{2g}$, $2B_{1g}$, $2B_{2g}$, $4E_u$. The eigenvectors with A_{1g} symmetry correspond to trivial solutions. Hence, all possible changes in the bond occupation probabilities corresponding to the various phases of solid iodine must be linear combinations of eigenvectors with A_{2g}, B_{1g}, B_{2g}, and E_u symmetries. Because we limit ourselves to the two observed phases of solid iodine, an inspection of the schematic representation of HP and LP phases in Figs. 3*b* and 3*c* allows us to reject eigenvectors with A_{2g} and B_{2g} symmetries. None of the distributions shown in these figures is symmetric with respect to the four-fold axis as A_{2g} symmetry requires or with respect to diagonal symmetry planes (σ_d) required by the B_{2g} representation. Therefore, we can conclude that the changes in bond occupation probabilities, which will drive the structural changes to the HP and LP phases must transform according to B_{1g} and E_u representations.

An eigenvector corresponding to B_{1g} symmetry has the form,

$$\begin{aligned}[4]\quad &\delta n_1 = \delta n_3 = \delta n_6 = \delta n_8 = \delta n_9 = \delta n_{11} = \delta n_{14} \\ &\qquad = \delta n_{16} = \delta n \\ &\delta n_2 = \delta n_4 = \delta n_5 = \delta n_7 = \delta n_{10} = \delta n_{12} = \delta n_{13} \\ &\qquad = \delta n_{15} = -\delta n\end{aligned}$$

Here δn denotes a change in the occupation probability n of a particular bond. From the eigenvector [4] an order parameter of B_{1g} symmetry can be constructed as follows:

$$[5]\quad \eta = \{n_1 + n_3 + n_6 + n_8 + n_9 + n_{11} + n_{14} + n_{16} - n_2 - n_4 - n_5 - n_7 - n_{10} - n_{12} - n_{13} - n_{15}\}$$

Now, it is seen that a distortion in the bond probabilities which is of B_{1g} symmetry can be directly assigned to that observed in the HP orthorhombic phase. The corresponding configuration of bonds associated with a given iodine atom for that phase is shown in Fig. 3*b*.

We expect that the LP molecular phase can be described by changes in the bond occupation probabilities from those of the parent phase which transform according to the E_u representation. The eigenvector with this symmetry has the form:

$$\begin{aligned}[6]\quad &\delta n_1 = \delta n_7 = \delta n_9 = \delta n_{15} = \delta l \\ &\delta n_3 = \delta n_5 = \delta n_{11} = \delta n_{13} = \delta n \\ &\delta n_2 = \delta n_4 = \delta n_6 = \delta n_8 = \delta n_{10} = \delta n_{12} = \delta n_{14} \\ &\qquad = \delta n_{16} = \delta m\end{aligned}$$

It follows from the form of the interaction energy, given by eq. [3], that the eigenvalue problem to be solved has the form:

$$[7]\quad \sum_{\beta} (a_{\alpha\beta} - \lambda\delta_{\alpha\beta})\delta n_\beta = 0$$

For example, if interactions between bond charges are limited to nearest neighbors, the eigenvalue problem with eigenvectors [6] can be simplified to:

$$\begin{bmatrix} -\lambda & 2a & 2a \\ a & 2a-\lambda & a \\ 2a & 2a & -\lambda \end{bmatrix} \cdot \begin{bmatrix} \delta l \\ \delta m \\ \delta n \end{bmatrix} = 0$$

where a is the nearest neighbor interaction strength. The solutions for the eigenvalues and eigenvectors for the nearest

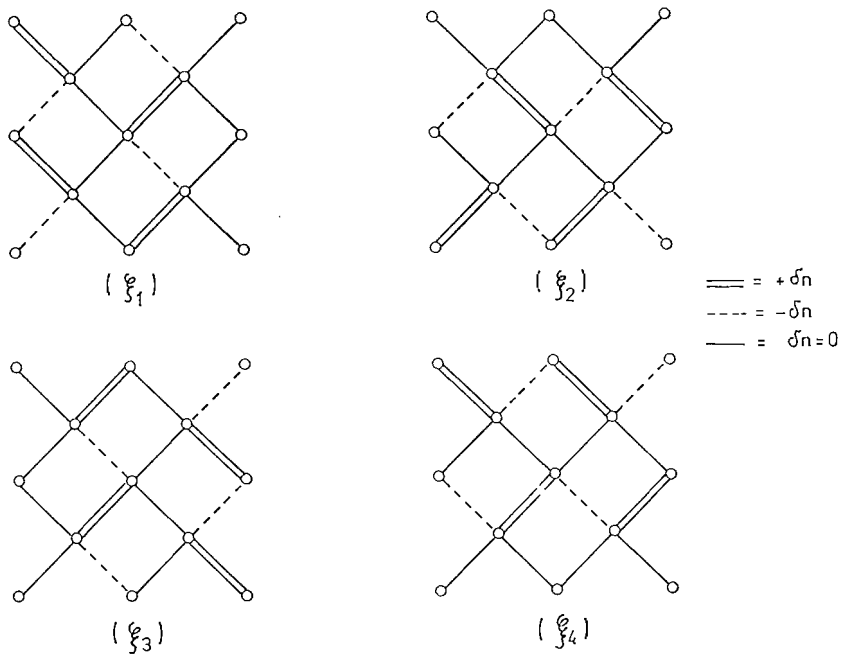

FIG. 5. A representation of the four-component order parameter ξ representing four possible domains of the molecular phase.

neighbor case are:

$$[8a] \quad \lambda = 4a, \qquad \frac{1}{\sqrt{3}}[1, 1, 1]$$

$$[8b] \quad \lambda = -2a, \qquad \frac{1}{\sqrt{2}}[1, 0, -1]$$

$$[8c] \quad \lambda = 0, \qquad \frac{1}{\sqrt{3}}[1, -1, 1]$$

Although the eigenvalues change when further neighbors are considered, the symmetry of the eigenvectors given by eqs. [8a], [8b] and [8c] does not.

The first solution to the eigenvalue problem, eq. [8a], must be rejected because bond-charge conservation condition,

$$\delta l + 2\delta m + \delta n = 0$$

is not fulfilled. For the second solution, eq. [8b], the eigenvector has the form of eq. [6] with $\delta l = -\delta n$, and $\delta m = 0$. For that case the following order parameter of E_u symmetry can be constructed,

$$[9a] \quad \xi_1 = \{n_1 + n_7 + n_9 + n_{15} - n_3 - n_7 - n_{11} - n_{16}\}$$

It is easy to verify that the order parameter ξ_1 is orthogonal to the order parameter η and satisfies the charge conservation condition. As there are four possible choices of equivalent eigenvectors of the form [6], one can construct three additional equivalent order parameters,

$$[9b] \quad \xi_2 = \{n_6 + n_8 + n_{13} + n_{15} - n_5 - n_7 - n_{14} - n_{16}\}$$

$$[9c] \quad \xi_3 = \{n_2 + n_8 + n_{10} + n_{16} - n_4 - n_6 - n_{12} - n_{14}\}$$

$$[9d] \quad \xi_4 = \{n_1 + n_3 + n_{10} + n_{12} - n_2 - n_4 - n_9 - n_{11}\}$$

The distortions in bond occupation probabilities corresponding to E_u symmetry and represented by the four-component order parameter ξ correspond to the distortion shown in Fig. 3c. This figure schematically represents the bonds around an iodine atom in the molecular phase. Four components of the order parameter lead to four equivalent structures which represent distortions with E_u symmetry from the assumed parent phase, the tetragonal VHP phase. The structures are represented in Fig. 5. It is seen that an increase in a bond occupation probability, corresponding to a positive δn, can be identified with a formation of a chemical bond which will cause the dimerization of the atomic phase and the formation of the molecular phase of iodine.

The third solution [8c] of the eigenvalue problem [7] also has E_u symmetry. This distortion in the bond occupation probabilities corresponds to the eigenvector of eq. [6] with $\delta m = -\delta l = -\delta n$. The order parameter which corresponds to this eigenvector is the four component order parameter ξ with the components:

$$[10a] \quad \xi_1 = \{n_1 + n_3 + n_5 + n_7 + n_9 + n_{11} + n_{13} + n_{15} - n_2 - n_4 - n_6 - n_8 - n_{10} - n_{14} - n_{16}\}$$

$$[10b] \quad \xi_2 = \{n_1 + n_2 + n_3 + n_4 + n_9 + n_{10} + n_{11} + n_{12} - n_5 - n_6 - n_7 - n_8 - n_{13} - n_{14} - n_{15} - n_{16}\}$$

$$[10c] \quad \xi_3 = -\xi_1$$

$$[10d] \quad \xi_4 = -\xi_2$$

A graphical representation of the order parameter is shown in Fig. 6. It is seen that the charge density distortions characterized by the order parameter ξ correspond to polymerization of the iodine atoms leading to molecular chains $(I)_n$. Thus, the possibility for polymerization and the formation of a polymerized phase is permitted by the present model. It is quite possible that this is the "zig-zag" chain phase postulated in ref. 10 as an intermediate phase which exists in the pressure range $16 < p < 21$ GPa. One should notice that this postulated "polymeric" phase has the same symmetry as the molecular phase so that the metal–insulator transition at 16 GPa would indeed be iso-structural.

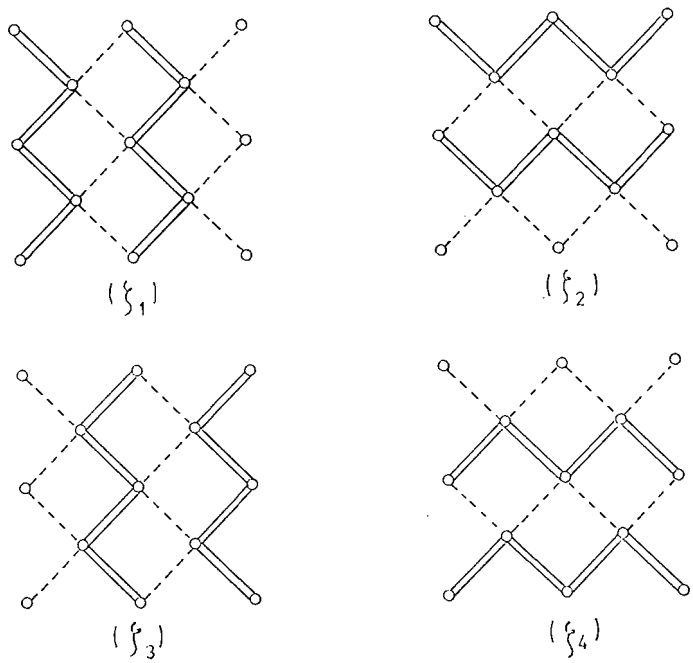

FIG. 6. A representation of the four-component order parameter ξ representing four domains possible of a hypothetical polymerized phase of iodine.

4. Bond charge density distortion waves

The distortions in the bond occupation probabilities discussed for the 16-bond model will now be reinterpreted as bond charge density distortion waves. For this purpose we start with the VHP tetragonal phase and choose the smallest unit cell as the elementary unit. As before, we limit our discussion to a two-dimensional square lattice. The unit cell contains one iodine core and two electron charge densities, $\rho_\alpha(\boldsymbol{l})$. Here $\alpha = x,y$, and $\boldsymbol{l}$ denotes the unit cell vector. Charge densities are assigned to the nearest neighbor interatomic bonds only. Distortions in the charge densities at the wavevector $\boldsymbol{q}$

$$[11] \quad \delta\rho_\alpha(\boldsymbol{q}) = \sum_{\boldsymbol{l}} \delta\rho_\alpha(\boldsymbol{l}) \exp(i\boldsymbol{q}\cdot\boldsymbol{l})$$

will cause a change in the electronic part of the crystal internal energy

$$[12] \quad \delta U = (1/2)\sum_{\alpha\beta}\sum_{\boldsymbol{q}} \delta\rho_\alpha(\boldsymbol{q})\phi_{\alpha\beta}(\boldsymbol{q})\delta\rho_\beta(-\boldsymbol{q})$$

where

$$[13] \quad \phi_{\alpha\beta}(\boldsymbol{q}) = \sum_{\boldsymbol{l},\boldsymbol{l}'} \chi^{-1}_{\alpha\beta}(\boldsymbol{l},\boldsymbol{l}')\exp[i\boldsymbol{q}\cdot(\boldsymbol{l}-\boldsymbol{l}')]$$

and $\chi_{\alpha\beta}(\boldsymbol{l},\boldsymbol{l}')$ is the charge density response in unit cell $\boldsymbol{l}$ to a scalar potential in unit cell $\boldsymbol{l}'$ and χ is a simplified version of an electronic susceptibility $\chi(\boldsymbol{r},\boldsymbol{r}')$.

For our two-dimensional square lattice with one atom in a unit cell, the matrix $\boldsymbol{\phi}(\boldsymbol{q})$ has form

$$[14] \quad \boldsymbol{\phi}(\boldsymbol{q}) = \begin{bmatrix} a(\boldsymbol{q}) & b(\boldsymbol{q}) \\ b(\boldsymbol{q}) & a(\boldsymbol{q}) \end{bmatrix}$$

A condition for the crystal to be stable and to support the charge density distortion described by eq. [11] is that the eigenvalues

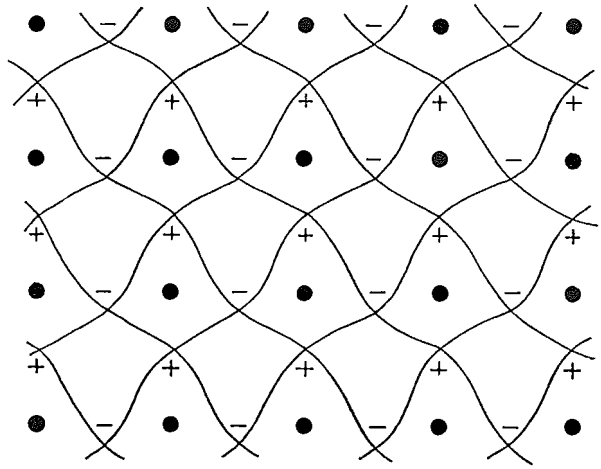

FIG. 7. The bond charge density distortion wave of B_{1g} symmetry in the tetragonal phase of solid iodine.

of the matrix $\boldsymbol{\phi}(\boldsymbol{q})$,

$$[15a] \quad \phi_A(\boldsymbol{q}) = a(\boldsymbol{q}) + b(\boldsymbol{q})$$

$$[15b] \quad \phi_B(\boldsymbol{q}) = a(\boldsymbol{q}) - b(\boldsymbol{q})$$

have to be positive definite. Eigenvectors which correspond to the above eigenvalues are

$$[16a] \quad \delta\rho_A(\boldsymbol{q}) = [\delta\rho(\boldsymbol{q}),\delta\rho(\boldsymbol{q})]$$

$$[16b] \quad \delta\rho_B(\boldsymbol{q}) = [\delta\rho(\boldsymbol{q}),-\delta\rho(\boldsymbol{q})]$$

Because of the charge conservation condition, the totally symmetric eigenvector, $\delta\rho_A(\boldsymbol{q})$ is trivial, $\delta\rho(\boldsymbol{q}) = 0$. Hence, we are only interested in charge density distortions described by the anti-symmetric eigenvector [16*b*]. The distortions corresponding to the wavevector $\boldsymbol{q}$ will transform according to one of the irreducible representation of the corresponding wavevector group $G(\boldsymbol{q})$.

A. Γ-point, $\mathbf{q} = 0$

At the center of the Brillouin zone distortions can be classified according to the D_{4h} point group. The charge density distortion described by the eigenvector [16*b*],

$$[17] \quad \delta\rho_B(\boldsymbol{q} = 0) = [\delta\rho, -\delta\rho]$$

transforms according to the B_{1g} representation and is shown schematically on Fig. 7. It is clearly seen that the distortion corresponds to changes in the bond occupation probabilities of the same symmetry for the 16-bond model. Therefore, the amplitude of the charge density distortion wave, $\delta\rho_B(\boldsymbol{q} = 0)$, can be identified with the order parameter η, introduced in section 3.

B. Δ-direction, $\mathbf{q} = (\pi/2a, \pi/2a, 0)$

The wavevector group for the Δ-direction is isomorphic with the C_{2v} point group. Charge density distortions corresponding to the eigenvector [16*b*] in this direction will transform according to the B_1 representation of the C_{2v} group. The changes in occupation probabilities described by the order parameter ξ will correspond to the charge density distortion wave of B_1 symmetry for the wavevector $\boldsymbol{q}_0 = (\pi/2a, \pi/2a, 0)$. The "bond structures" shown in Fig. 5 and described by the order parameters ξ can now be seen as patterns of the charge density distortion waves for wavevector $\boldsymbol{q}_0$. One of the latter patterns is illustrated in Fig. 8. Thus, the amplitude of the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/07/12
For personal use only.

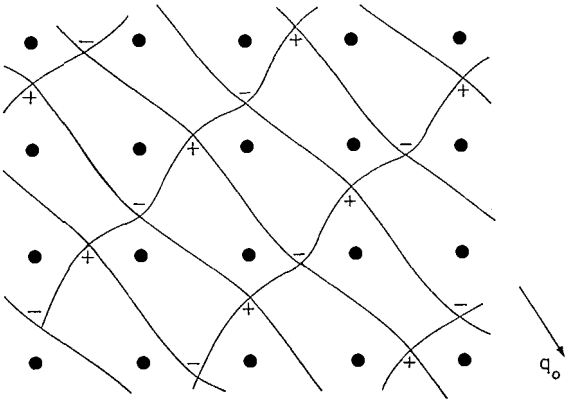

FIG. 8. The bond charge density distortion wave with wavevector $q_0 = (\pi/2a, \pi/2a, 0)$ in the tetragonal phase of iodine.

charge density distortion wave in the Δ-direction can be identified with the order parameter ξ, keeping in mind that $\delta\rho(q_0)$ transforms according to the B_1 irreducible representation of the C_{2v} point group.

The distortions of the bond charge densities described here are coupled to phonons. This coupling leads to indirect interactions between iodine atoms. The indirect interaction produces a softening of certain phonon modes of the tetragonal phase, as described in the next section.

5. Dynamics of the tetragonal phase (two-dimensional model)

Propagating phonon modes are described by quantum numbers (qj), representing the wavevector q and branch index j, with polarization vectors $w(qj)$ and frequency $\omega(qj)$. The frequencies are given by the eigenvalues of the dynamical matrix $\mathbf{D}(q)$, through the solution of the eigenvalue problem

$$[18] \quad m\omega^2(qj)w_\alpha(qj) = \sum_\beta D_{\alpha\beta}(q)w_\beta(qj)$$

In eq. [18], m is the atomic mass and the indices α,β represent the Cartesian components. For the two-dimensional square lattice with one atom per unit cell there are two branches ($j = 1, 2$) for every wavevector.

The force constants which make up the dynamical matrix can be viewed as coming from two separate contributions. The first can be thought of as arising from the forces between "bare" atoms and a second contribution comes from the indirect interaction between the "bare" atoms mediated by charge density distortions. It follows from considerations in the previous section that the amplitudes $\delta\rho_\mu(q)$, $\mu = A,B$, of the bond charge density distortion waves can be chosen as the most natural approximation for the electronic variables. Introducing phenomenological coupling constants $A_{\alpha\mu}(q)$ between the atomic displacement in the α direction and the charge density distortion wave of type μ with wavevector q, the following expression for the dynamical matrix is obtained

$$[19] \quad D_{\alpha\beta}(q) = D^{(0)}_{\alpha\beta}(q) - \sum_\mu A_{\alpha\mu}(q)\phi_\mu^{-1}(q)A_{\beta\mu}(-q)$$

where $\phi_\mu(q)$ are the eigenvalues of the inverse electronic susceptibility, given by eq. [15]. $D^{(0)}_{\alpha\beta}(q)$ is the part of the dynamical matrix which comes from direct interactions between "bare" atoms. The form of eq. [19] is a consequence of the adiabatic approximation: whatever lattice displacement exists at a given time, the charge density distortion amplitudes $\delta\rho_\mu$ instantly adjust themselves to minimize the electronic energy. On introducing the renormalized coupling constants,

$$[20] \quad A_\mu(qj) = \sum_\alpha w_\alpha(qj)A_{\alpha\mu}(q)$$

the expression for the renormalized phonon frequencies is

$$[21] \quad \omega^2(qj) = \omega_0^2(qj) - \frac{1}{m}\sum_\mu A_\mu(qj)\phi_\mu^{-1}(q)A_\mu(-qj)$$

As a consequence of the adiabatic approximation we obtain a useful relation between the amplitudes of the charge density distortion waves, $\delta\rho_\mu(q)$, and the amplitude of the phonon modes, $Q(qj)$,

$$[22] \quad \delta\rho_\mu(q) = -\phi_\mu^{-1}(q)A_\mu(qj)Q(qj)$$

Four acoustic modes the relation reads

$$[23] \quad \delta\rho_\mu(0) = -\phi_\mu^{-1}(q)A_{\mu,\alpha\beta}e_{\alpha\beta}$$

where the components of the strain tensor, $e_{\alpha\beta}$, conveniently describe displacements of atoms due to acoustic phonons

$$[24] \quad e_{\alpha\beta} = \lim_{q\to 0}(Nm)^{-1/2}iq_\beta Q(q_\beta,\alpha)$$

In eq. [24], $Q(q_\beta,\alpha)$ is the acoustic mode amplitude with eigenvector polarized in the α direction and wavevector in the β direction.

Relations [22] and [23] put restrictions on the coupling constants $A_\mu(qj)$. It is clear that only phonon modes or strain components and charge density distortions of the same symmetry can couple bilinearly. We now consider phonons in the two-dimensional tetragonal lattice of solid iodine in the long-wave length limit $q \to 0$ and in the Δ-direction of the Brillouin zone.

A. $\mathbf{q} \to 0$ limit

For a lattice with one atom per unit cell, the dynamical problem in the limit $q \to 0$ reduces to the equations of motion of elasticity theory. The dynamical matrix is expressed in terms of the isothermal elastic constants $c_{\alpha\gamma\beta\delta}$ as

$$[25] \quad D_{\alpha\beta}(q) = \sum_{\gamma\delta} c_{\alpha\gamma\beta\delta}q_\gamma q_\delta$$

For the two-dimensional lattice, the eigenvalues of the elastic constant matrix are

$(1/2)(c_{11} + c_{12})$ with eigenvector $(e_1 + e_2)$ of A_{1g} symmetry,

$(1/2)(c_{11} - c_{12})$ with eigenvector $(e_1 - e_2)$ of B_{1g} symmetry,

$4c_{66}$ with eigenvector (e_6) of B_{2g} symmetry.

Here the Voigt notation for elastic constants and strain components is used.

In the previous section the charge density distortion wave at $q = 0$ is shown to be of B_{1g} symmetry. It follows from eqs. [19] and [25] that the eigenvalue of the effective dynamical matrix can be expressed as

$$[26] \quad (1/2)(c_{11} - c_{12}) = (1/2)(c^0_{11} - c^0_{12}) - \phi_B^{-1}(0)A^2_{B,7}$$

Here $A_{B,7}$ is the coupling constant between the charge density distortion wave and the strain $e_7 = (e_1 - e_2)$. Note that e_7 also has B_{1g} symmetry. c^0_{11} and c^0_{12} are elastic constants of the crystal due to "bare" interatomic interactions only. The relation

$$[27] \quad \delta\rho_B(q = 0) = -\phi_B^{-1}(0)A_{B,7}e_7$$

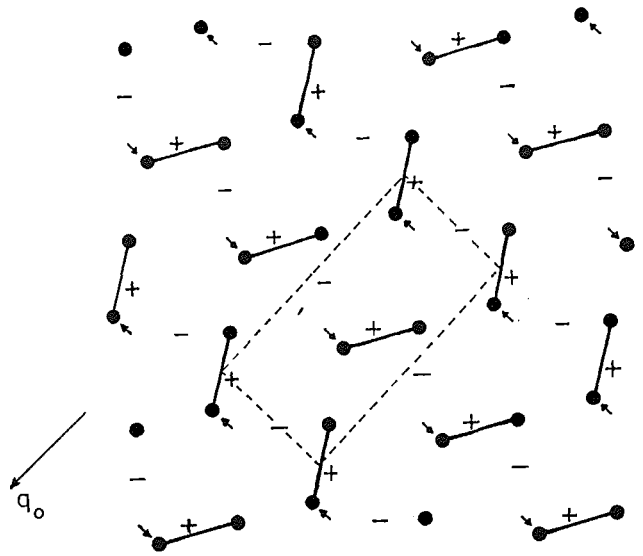

FIG. 9. The formation of the molecular phase of iodine as a result of simultaneous condensation of the bond charge density distortion wave (characterized by increases (+) and decreases (−) in the bond charges) and the transverse phonon mode (characterized by atomic displacements indicated by the arrows), both of B_1 symmetry.

indicates how the amplitude of the charge density distortion wave adjusts to the crystal strain. It is clear from eq. [26] that for sufficiently large coupling constant the eigenvalue $(1/2)(c_{11} - c_{12})$ of the elastic constant matrix vanishes. At that point the crystal is unstable against a homogeneous deformation and will distort continuously to a new structure with symmetry indicated by the e_7 strain. The new structure is orthorhombic and the strain can be used as the primary order parameter to describe the VHP → HP phase transition as the pressure is decreased. Although the strain e_7 is a primary order parameter, the transition is driven by distortions of the electronic charge distributions.

B. Δ-direction

In this direction the two phonon branches of the square lattice of the VHP phase of iodine are classified according to symmetries A_1 and B_1 of the C_{2v} point group. The A_1 phonon corresponds to a longitudinal mode and B_1 represents a transverse mode. It follows from the previous discussion that the frequency of the transverse mode depends on the coupling of the B_1 phonon to the charge density distortion wave of the same B_1 symmetry,

$$[28] \qquad \omega^2_{B_1}(\Delta) = \omega^2_{0,B_1}(\Delta) - \frac{1}{m}|A_B(\Delta)|^2\phi_B^{-1}(\Delta)$$

Again, we expect that the phonon with the wavevector $q_0 = (\pi/2a, \pi/2a, 0)$ will show a tendency to go soft due to indirect interactions mediated by charge density distortion waves of B_1 symmetry. Therefore, we assume that the amplitude of the B_1 phonon at q_0 will be an order parameter for the phase transition to the molecular phase of iodine (iodine dimerization). It has to be stressed that the B_1 phonon at q_0 corresponds to the transverse wave which is used in ref. 2 to explain the HP → LP phase transition. There is, however, an important difference between our approach and that of ref. 2. Here, no additional longitudinal wave with wave vector $q = 2q_0$ is needed to explain the structural changes during the iodine dimerization. The reason is that the transverse bond charge density distortion wave with wave vector q_0 automatically produces simultaneously a longitudinal charge density wave with $q = 2q_0$. Moreover, the dimerization of the iodine atoms in our model is due to the condensation of the phonon mode of B_1 symmetry and, triggered by it, the condensation of the bond charge density distortion wave of the same symmetry. This wave, together with the corresponding atomic displacements, helps to form the chemical bond between iodine atoms. This is visualized schematically in Fig. 9.

The proposed phenomenological model correctly predicts structural changes for transitions VHP → HP and VHP → LP. The model also suggests a possible mechanism which causes the instabilities of the (parent) tetragonal atomic VHP phase leading to the HP and LP phases. The observed sequence of the transformations VHP ⇢ HP ⇢ LP which requires an analysis of thermodynamical properties is not a topic for discussion in this paper.

6. Discussion

On the basis of the present model the phase transformations in solid iodine under high pressure can be explained as follows.

$$\text{Atomic phase} \underset{\text{dissociation}}{\longleftarrow\!\!\!\longrightarrow} \text{molecular phase}$$

can be interpreted in terms of a coupling between a bond charge density distortion wave and a transverse phonon. The driving force for the transformation is the electron–phonon coupling and the instability has a two-dimensional Peierls character. The dimerization results from the condensation of the transverse phonon mode which goes soft as a result of indirect interatomic interactions mediated by charge density distortion waves. The charge density fluctuation coupled to the transverse phonon results in increased electronic charge densities between certain atoms. The displacements corresponding to the soft phonons bring these atoms closer together resulting in chemical bonds between certain iodine atoms and the molecular phase appears.

Polymorphs of rubidium nitrate and their crystallographic relationships

M. SHAMSUZZOHA AND B. W. LUCAS[1]

Department of Physics, University of Queensland, St. Lucia, Brisbane, Queensland, Australia 4067

Received September 4, 1987

This paper is dedicated to Professor J. A. Morrison

M. SHAMSUZZOHA and B. W. LUCAS. Can. J. Chem. **66**, 819 (1988).

The crystal structure relationships between the four thermal polymorphs (IV – 437 K – III – 492 K – II – 564 K – I) of $RbNO_3$ are discussed. Trigonal IV, $a = 10.55(2)$, $c = 7.47(2)$ Å at 298 K, $Z = 9$, and space group $P3_1$ (or its enantiomorph $P3_2$) has Rb atoms arranged on a pseudocubic sublattice defined by $(1/3)[10.\bar{1}]$, $(1/3)[01.\bar{1}]$, $(1/3)[11.1]$ and related segments. The ordered NO_3 groups are enclosed within respective pseudocubes and form close to ideal 8-fold anion–cation coordination with the surrounding Rb atoms. At IV → III, each of the appropriate $(1/3)\langle 10.1\rangle$ and $(1/3)\langle 11.1\rangle$ segments of IV (forming the Rb atom sublattice) transform to a cell edge of an ideal s.c. lattice of Rb atoms, $a = 4.39(1)$ Å, $Z = 1$, and space group $Pm3m$. The orientationally disordered NO_3 groups in III form another close to ideal 8-fold anion–cation coordination with the Rb atoms. At III → II, the s.c. lattice of III changes to form a larger b.c.c. lattice, $a = 8.84(3)$ Å, $Z = 8$, in II. A parallel-axes unit cell relationship, i.e. $\langle 100\rangle_{III} // \langle 100\rangle_{II}$ and $2(a)_{III} = (a)_{II}$, exists between III and II. The NO_3 group in II is postulated to form a close to ideal 8-fold anion–cation coordination with the surrounding Rb atoms. At II → I, II transforms to a f.c.c. lattice, $a = 7.32$ Å, $Z = 4$, and space group $Fm3m$. The NO_3 group in I forms a close to ideal 6-fold anion–cation coordination with the surrounding Rb atoms. It is suggested that $(1/2)[1\bar{1}1]$, $(1/2)[11\bar{1}]$, $(1/2)[\bar{1}11]$ and related segments in II, which form a trigonal Rb atom sublattice, $a = 7.65(3)$ Å and $\alpha = 109.47°$, after II → I, transform to orthogonal cell edges of the cubic lattice of I.

M. SHAMSUZZOHA et B. W. LUCAS. Can. J. Chem. **66**, 819 (1988).

On discute des relations qui existent entre les structures cristallines de quatre polymorphes thermiques (IV – 437 K – III – 492 K – II – 564 K – I) du $RbNO_3$. A 298 K, dans la forme trigonale IV, avec $a = 10{,}55(2)$ et $c = 7{,}47(2)$ Å, $Z = 9$ et groupe d'espace $P3_1$ (ou son énantiomorphe $P3_2$), les atomes de Rb sont arrangés dans un sous-réseau pseudo-cubique défini par $(1/3)[10.\bar{1}]$, $(1/3)[01.\bar{1}]$ et $(1/3)[11.1]$ et des segments apparentés. Les NO_3 ordonnés sont enfermés dans des pseudo-cubes et ils forment, avec les atomes de Rb qui les entourent, une coordination anion–cation octuple pratiquement idéale. Lors de la transition IV → III, chaque segment approprié $(1/3)\langle 10.1\rangle$ et $(1/3)\langle 11.1\rangle$ du composé IV (ils forment le sous-réseau de l'atome de Rb) se transforme en une arête de la cellule d'un réseau idéal cubique simple d'atomes de Rb, avec $a = 4{,}39(1)$ Å, $Z = 1$ et groupe d'espace $Pm3m$. Dans la forme III, les atomes de Rb et les groupements NO_3, qui sont désordonnés du point de vue de l'orientation, forment une autre coordination anion–cation octuple pratiquement idéale. Lors de la transition III → II, le réseau cubique simple de III se transforme en un réseau cubique centré plus grand, avec $a = 8{,}84(3)$ Å, $Z = 8$. Entre les formes III et II, il existe une relation d'unité cellulaire à axes parallèles, c'est-à-dire $\langle 100\rangle_{III} // \langle 100\rangle_{II}$ et $2(a)_{III} = (a)_{II}$. Dans la forme II, on postule que le groupement NO_3 et les atomes de Rb forment une coordination anion–cation octuple pratiquement idéale. Lors de la transition II → I, la forme II se transforme en un réseau cubique à face centrée avec $a = 7{,}32$ Å, $Z = 4$ et groupe d'espace $Fm3m$. Dans I, le groupement NO_3 et l'atome de Rb forment une coordination anion–cation sextuple pratiquement idéale. On suggère que, après la transformation II → I, les segments $(1/2)[1\bar{1}1]$, $(1/2)[11\bar{1}]$, $(1/2)[\bar{1}11]$ et apparentés de la forme II — qui forment un sous-réseau trigonal avec l'atome de Rb avec $a = 7{,}65(3)$ Å et $\alpha = 109{,}47°$ — se transforment en arêtes orthogonales du réseau cubique de I.

Introduction

For solids which exhibit phase transitions, information on the crystal structures of the polymorphs is useful in understanding the relationships between them and the mechanisms of the changes. At atmospheric pressure, $RbNO_3$ undergoes the thermal polymorphic phase transitions (1, 2):

$$IV - 437\ K - III - 492\ K - II - 564\ K - I$$

The IV → III transition has been studied (2) by single crystal X-ray diffraction methods, with IV reported to be trigonal, $a = 10.48$, $c = 7.45$ Å, $Z = 9$, and space group $P3_112$ (or its enantiomorph $P3_212$), and III, cubic $a = 4.37$ Å, $Z = 1$. The observation of transformation of the $\langle 00.1\rangle$- and $\langle 10.1\rangle$-axes single crystal diffraction patterns of IV to the corresponding $\langle 111\rangle$- and $\langle 100\rangle$-axes diffraction patterns of III, suggested the unit cell relationships shown in Fig. 1.

Crystallographic studies of the III → II transition were originally made by X-ray powder diffraction methods (3, 4), with III reported to be cubic, $a = 4.37$ Å, and $Z = 1$, and II to be trigonal, $a = 5.48$, $c = 10.71$ Å, and $Z = 3$. Brown and McLaren (2) proposed, from X-ray powder diffraction, II to be tetragonal, $a = 6.19(3)$, $c = 8.74(6)$ Å, and $Z = 6$, and suggested a simple unit cell relationship between III and II, where $\sqrt{2}\,(a)_{phase\ III} = 6.16$ Å $= (a)_{phase\ II}$, $2(a)_{phase\ III} = 8.74$ Å $= (c)_{phase\ II}$. The II → I transition was also studied by X-ray powder diffraction methods (2) with I suggested to have a f.c.c. lattice, $a = 7.32$ Å and $Z = 4$.

The structural relationships between phases III, II, and I have been considered (5–7) and were regarded as a progressive transition conversion from a CsCl-type to a NaCl-type lattice (Fig. 2). The interaxial angle of the trigonal unit cell for II is between 70 and 78°, while the trigonal angles of 90 and 60° correspond to CsCl- and NaCl-type lattice, respectively.

The availability of more recently determined crystal structure details for the various phases of $RbNO_3$ allow further consideration of the structural relationships between the various polymorphs.

Structure of $RbNO_3$ (IV) and its behaviour at the onset of the IV → III transition

The IV crystal system was established as trigonal by early single crystal X-ray diffraction studies (8), although its Laue group remained uncertain long after. Laue photographs taken

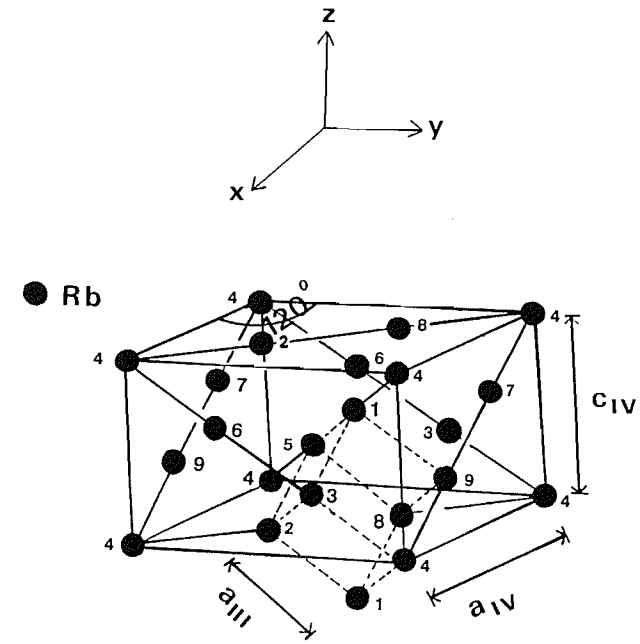

FIG. 1. The relationship between the unit cells of phases IV and III in $RbNO_3$; Rb atoms only are shown (groupings 1,2,3; 4,5,6; 7,8,9 represent symmetry-related atoms, generated by the equivalent positions of the space group $P3_1$) (2,11).

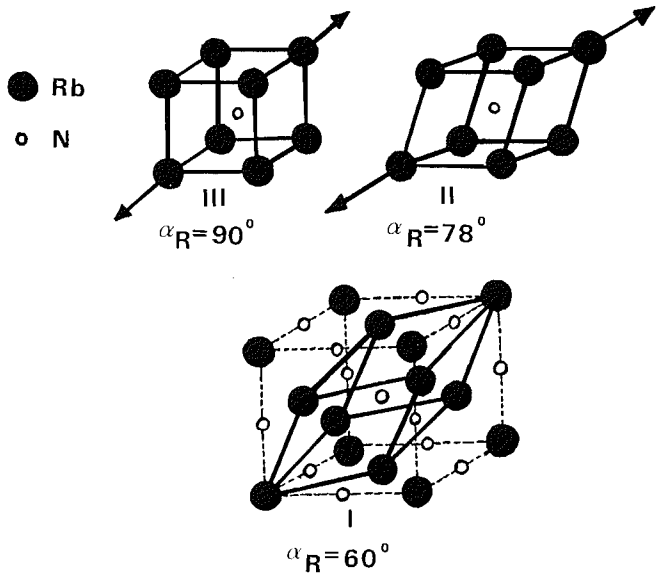

FIG. 2. The structural relationships between III (CsCl-type), II (trigonal), and I (NaCl-type) $RbNO_3$. Large circles represent Rb atoms, small circles, N atoms; the O atoms are not shown. The arrows indicate the direction of the elongation of the trigonal cell, α_R is the trigonal angle (6).

with the X-ray beam along the trigonal axis were reported to exhibit a mirror plane parallel to the 3-fold axis, indicating a Laue group $\bar{3}m$ (2, 8, 9). However, the discovery of optical activity (10) and pyroelectricity along the trigonal axis (9) suggested a point group 3 and Laue group $\bar{3}$. The ambiguity was resolved when the crystal structure, determined by 3-dimensional single crystal neutron diffractometry (11), indicated only an *apparent* mirror plane and the Laue group could be uniquely assigned $\bar{3}$. The structure (Fig. 1) has $a = 10.55(2)$, $c = 7.47(2)$ Å at 298 K, $Z = 9$, space group $P3_1$ (or its

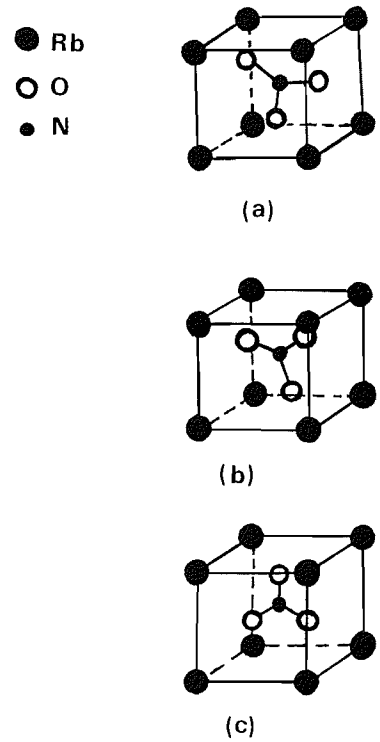

FIG. 4. Three possible orientational models of a planar NO_3 group within a cubic array of Rb atoms in III. The plane of the NO_3 group (*a*) bisects the unit cell edge, (*b*) is normal to the cubic body diagonal, (*c*) is parallel to a face of the surrounding Rb atom cube.

enantiomorph $P3_2$). The Rb atoms form a pseudocubic sublattice with each NO_3 group (of the type shown in Fig. 4(*c*)) in close to ideal 8-fold anion–cation coordination with its surrounding Rb atoms.

From the viewpoint of the IV → III transition, the Rb atom sublattice is significant since its behaviour approaching the IV → III transition temperature is expected to act as a precursor to the forthcoming change and have influence on the resultant lattice of the higher temperature phase. In this respect, the structure of IV determined just below the IV → III transition temperature of 403 K (11) provides useful information on the behaviour of the Rb atom sublattice. The structure, along with that at room temperature, indicates the Rb atom pseudocubic sublattice to have dimension ranging between $a = 4.07(1)$ to 4.62(1) Å and $\alpha = 85.9(2)$ to 95.8(2)° at 298 K and $a = 4.12(1)$

to 4.53(1) Å and α = 86.9(2) to 93.8(2)° at 403 K (11); the Rb atom sublattice is closer to an ideal cubic lattice at 403 K than at 298 K. This behaviour of the Rb atom sublattice of IV does tend to anticipate its forthcoming change to the cubic symmetry of III (2, 3) at the higher temperature phase.

Structure of $RbNO_3$ (III) and IV → III transition

From early X-ray powder diffraction studies III was reported to have a structure with s.c. cell, a = 4.37 Å and Z = 1, although the NO_3 group orientation was uncertain (3). A single (essentially planar) NO_3 group cannot be fitted into the unit cell for any possible cubic space group; this can only be achieved if orientational disorder is introduced.

The first suggestion incorporating such disorder involved "free rotation" about its centre of mass (3). However, the experimentally observed entropy change at the IV → III transition is 2.15 cal mol^{-1} K^{-1} (5), which is too small to allow such extreme disordering. Strϕmme (12) proposed a III crystal structure with finite equivalent-orientational disorder of the NO_3 group. The structure, with a = 4.37 Å, Z = 1 and space group $Pm3m$, was based on X-ray powder diffraction (13). The Rb atoms were at cell corners, while the NO_3 group was orientationally disordered over mainly aragonite-type (each NO_3 group plane normal to a body diagonal of the surrounding Rb atom cube) and partly calcite-type (each NO_3 group plane bisects a cell edge of the surrounding Rb atom cube) configurations. Recently, powder (14) and single crystal (15) neutron diffraction studies concluded that a 12-fold orientationally disordered model for the NO_3 group (each NO_3 group plane being parallel to a face of the surrounding Rb cube) is preferable to an 8-fold disordered model (pure aragonite-type configuration). This model is compatible with the observed single crystal X-ray diffuse scattering intensity patterns that occur perpendicular to the reciprocal lattice axes (17, 18).

The structure has a = 4.39(1) Å, Z = 1, and space group $Pm3m$, the Rb atom at the corners of a cubic unit cell with a N atom close to its centre. The oxygen atoms of the orientationally disordered NO_3 group lie essentially on a spherical shell of radius equal to the N—O bond length about the cell centre. The NO_3 group in its orientationally disordered state forms close to an ideal 8-fold anion–cation coordination with the Rb atoms.

The lattice relationship between the two phases (11, 15) is shown in Fig. 1. In IV, (1/3)[10.1], (1/3)[01.1], and (1/3)[11.1] and related segments define the pseudocubic sublattice cell, which, at the IV → III transition, transforms to the cell of an ideal s.c. lattice of Rb atoms in III.

Structure of $RbNO_3$(II) and III → II transition

X-ray powder diffraction data of II have been indexed on the basis of *three* different crystal systems, viz trigonal (3, 6, 14), tetragonal (2), and cubic (16). Single crystal diffraction methods to determine the crystal system have not been successful so far, as various reports (2, 19, 20, 21) indicate that single crystals (grown in IV) fragment during the III → II transition, and are unsuitable for single crystal diffraction studies in II. It has been reported, however, that single crystals of $RbNO_3$ grown from the melt can be cooled through the I → II transition to phase II, to give distinct single crystal X-ray diffraction patterns (20, 21). Owing to experimental difficulties in determining various crystallographic axes of such transformed crystals, the resultant single crystal diffraction data have not clearly established the appropriate crystal system of II.

The unit cells of the proposed trigonal, tetragonal, or cubic

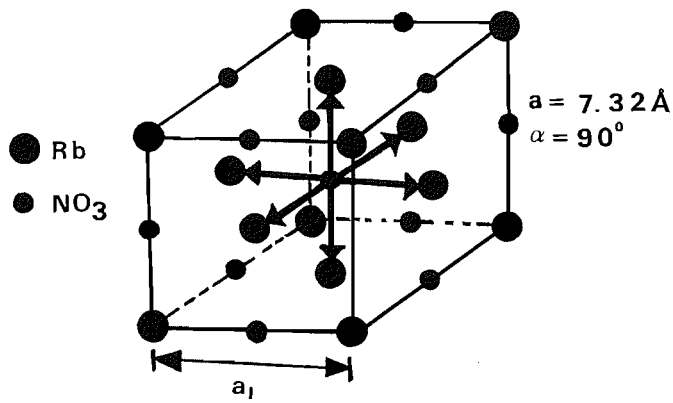

FIG. 5. The unit cell contents of I (14). The large circles represent Rb atoms, small circles the NO_3 groups.

crystal systems are geometrically closely related and this makes difficult discrimination (22) between the fit to the observed X-ray diffraction powder pattern, although as III has been established to have a cubic crystal system (14, 15), a lowering of crystal symmetry to trigonal or tetragonal with higher temperature phase appears unlikely. Antiferroelectricity has been reported for II (23–25), which requires arrangements of antiparallel dipoles within the unit cell. These dipoles would occur as a consequence of the relative displacements between the Rb^+ and NO_3^- units within the unit cell, which is not likely to occur in the crystal structures within the possible space groups $R3$, $R32$, $R3m$, $R3c$, $R\bar{3}m$, $R\bar{3}c$, belonging to the suggested trigonal crystal system. In fact, the determined crystal structure of II by Ahtee and Hewat (14), does not show such antipolar structure; rather, the NO_3 group (in aragonite-type configuration) is disordered over two orientations inside a Rb atom trigonal unit cell with space group $R\bar{3}m$. On the other hand, the cubic crystal system (structure yet to be determined) potentially could have such antiparallel dipoles in the unit cell.

Recent studies suggest that II has a b.c.c. lattice, with Z = 8 and possible space group: $I23$, $I2_13$, $Im3$, $I432$, $I\bar{4}3m$, or $Im3m$ (16). For these space groups, the 8 Rb atoms of the unit cell can only define a b.c.c. lattice if occupying the positions: 0,0,0; $\frac{1}{2},\frac{1}{2},\frac{1}{2}$; $0,\frac{1}{2},\frac{1}{2}$; $\frac{1}{2},0,\frac{1}{2}$; $\frac{1}{2},\frac{1}{2},0$; $\frac{1}{2},0,0$; $0,\frac{1}{2},0$; $0,0,\frac{1}{2}$ in the unit cell. A b.c.c. unit cell of such atomic occupancy may be considered comprised of eight cubic subcells of Rb atoms (Fig. 3) each with a = 4.42(3) Å. If Rb...O distances are kept somewhat greater than the sum of their effective atomic radii 2.88 Å (26), each of the eight planar NO_3 groups of the unit cell can only occupy positions surrounded by one Rb atom cubic subcell. The orientation of the NO_3 group inside the II unit cell according to the observed entropy change of 1.35 cal mol^{-1} K^{-1} (5) at the III → II transition is likely to be disordered. The most probable configuration of the NO_3 groups which could satisfy orientational disordering as well as antiparallel displacements of the NO_3 group in the neighbouring sites of the unit cell are shown in the structural models Fig. 4 (*a*), (*b*), and (*c*). These structural models can be fitted to various space groups suggested for this phase, but only a proper experimental analysis can define the appropriate space group and configuration of the NO_3 group. Since each of these structural models suggests a close to an ideal 8-fold anion–cation coordination, it is reasonable to hypothesize close to an ideal 8-fold anion–cation coordination structure for II.

The lattice of II along with its suggested structure presents an understanding of the Rb lattice rearrangement which takes place

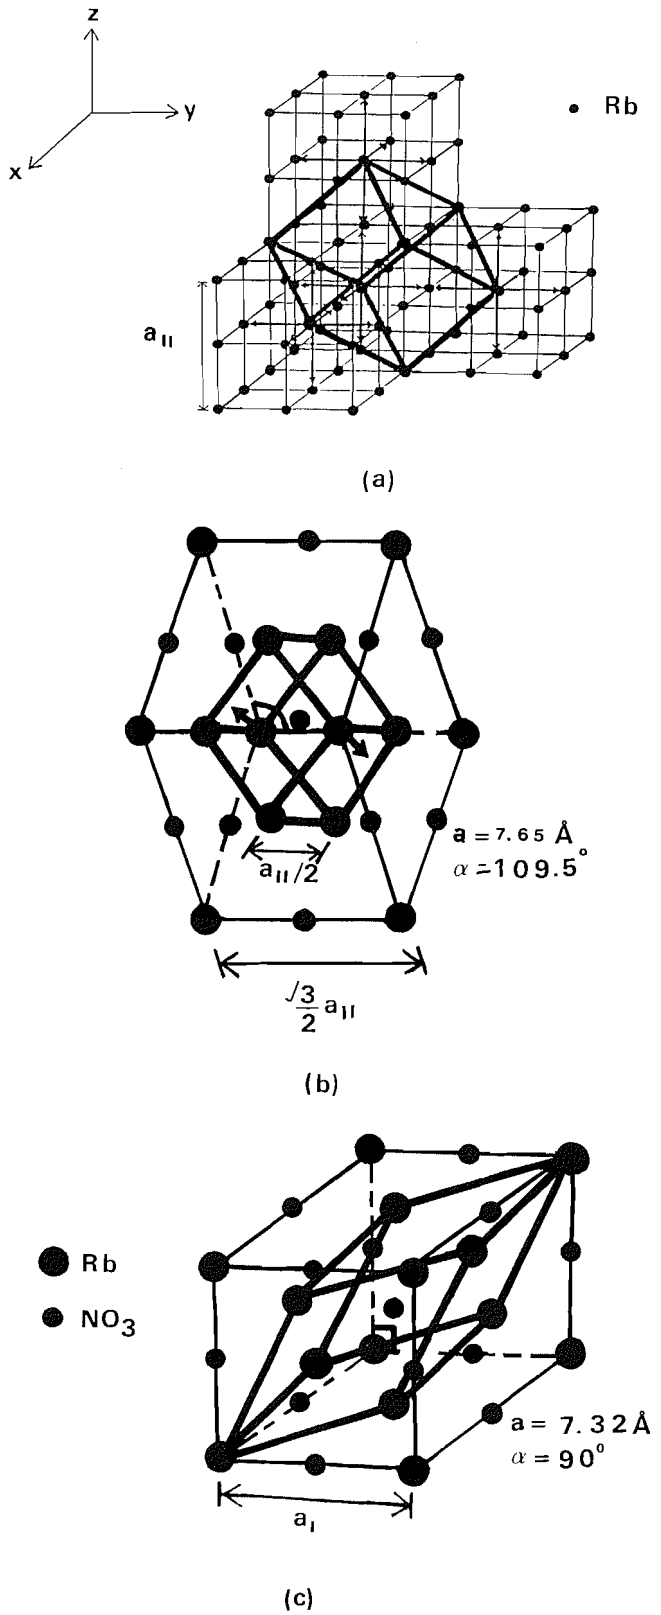

FIG. 6. Lattice transformation processes during the II → I transition. (*a*) (1/2)[1$\bar{1}$1], (1/2)[11$\bar{1}$], (1/2)[$\bar{1}$11] of II form a trigonal subcell (represented by thicker lines). The (101),110), and (011) of II correspond to (100), (010), and (001) of the trigonal subcell. (*b*) The trigonal subcell described in (*a*) is shown separately, with the arrows showing the <111>-direction of elongation. (*c*) Illustrates a NaCl-type cubic unit cell of I.

at the III → II transition (Fig. 3). Eight s.c. unit cells of III combine during the III → II transitions to form a larger b.c.c. unit cell. This results in a parallel-axes unit cell relationship between the two phases, i.e. $<100>_{\text{phase III}} // <100>_{\text{phase II}}$ and $2(a)_{\text{phase III}} = (a)_{\text{phase II}}$.

Structure of $RbNO_3$(I) and II → I transition

Phase 1 has been reported to have a f.c.c. lattice with a = 7.32 Å and Z = 4 (2, 6, 14, 20, 21). Its crystal structure was originally suggested to have the Rb atoms and NO_3 groups forming a NaCl-type cation–anion arrangement. Single crystal X-ray (21) and neutron powder (14) diffraction studies also concluded a similar structure with an aragonite-type configuration of the orientationally disordered NO_3 groups. The structure (14), with a = 7.32(2) Å, Z = 4 and space group $Fm3m$, is shown in Fig. 5; the NO_3 group (small circles) form a close to ideal 6-fold anion–cation coordination with the Rb atoms.

The lattices of II and I and their suggested structures clearly indicate that at the II → I transition, a close to ideal 8-fold anion–cation coordination in II transforms to a close to ideal 6-fold anion–cation coordination in I; a possible lattice conversion mechanism is shown in Fig. 6. For the II lattice, (1/2)[1$\bar{1}$1], (1/2)[11$\bar{1}$], (1/2)[$\bar{1}$11], and related segments (Fig. 6(*a*)) form a trigonal sublattice (Fig. 6(*b*)), with a = 7.65(3) Å, α = 109.47°, Z = 4. The anion–cation coordination in this unit subcell is 8-fold (a NO_3 group represented by small circle within a CsCl-type II $RbNO_3$ cubic subcell of dimension a = 4.41(3) Å, outlined by thick lines in Fig. 6(*b*), is surrounded by eight equidistant Rb atoms). At the transition, the trigonal lattice effectively dilates along the shortest <111>-type direction and transforms to the f.c.c. unit cell (Fig. 6(*c*)) of I. For the b.c.c. unit cell of II, this elongation process is accomplished (*a*) by a homogenous dilation along ±<110> and a simultaneous contraction along ±<100> on the respective {110} planes and (*b*) by a homogenous elongation along the appropriate <111> directions. This results in the transformation of $\{110\}_{\text{phase II}}$ to the corresponding $\{100\}_{\text{phase I}}$.

Discussion

The transitions IV – III – II for $RbNO_3$ are accomplished by very small changes of the Rb atom sublattices from pseudocubic to cubic. The NO_3 groups in these structures change from being orientationally ordered to disordered and have a similar 8-fold anion–cation coordination. The reported tendency for single crystals to fragment at the III → II transition could result from a change of the NO_3 group configuration, rather than the previously suggested Rb atom sublattice.

At the II → I transition, a major Rb atom sublattice rearrangement takes place and no simple unit cell relationship exists between the two phases. The suggested lattice transformation, in accordance with Buerger's (27) proposal, is accomplished by an homogenous dilation along one of the trigonal axes of the CsCl-type phase II structure. The crystals in I are soft and plastic (19, 20), which could account for the sublattice rearrangement at the transition without single-crystal fragmentation.

Microcalorimetry and thermochemistry of alloys

JEAN PIERRE BROS

Thermodynamique des systèmes métalliques, Université de Provence, Centre Saint-Charles, Place V. Hugo, 13331 Marseille CEDEX 3, France

Received September 28, 1987

This paper is dedicated to Professor James A. Morrison

JEAN P. BROS. Can. J. Chem. **66**, 824 (1988).

High temperature microcalorimetry is a very fruitful technique for increasing our knowledge of the thermochemistry of multicomponent alloys. As a good example, calorimetric results obtained for the Al + Bi + Ga system have been selected. Using a Calvet microcalorimeter and the indirect drop method, enthalpies of formation were measured over the entire concentration range between 725 and 1170 K and several points of the phase diagram were deduced from these calorimetric results. By means of a computer program, the Al + Bi + Ga equilibrium phase diagram was calculated and thus a thermodynamic description can be predicted. Making use of some simplifying hypotheses, the results indicate a satisfactory agreement between the experimental and the calculated liquid miscibility gap.

JEAN P. BROS. Can. J. Chem. **66**, 824 (1988).

Avec l'énergie libre de Gibbs, la fonction enthalpie de formation, obtenue par calorimétrie directe, joue un rôle important dans l'étude thermodynamique des alliages; pour le système Al + Bi + Ga, les résultats expérimentaux choisis constituent un bon exemple. En effet, par microcalorimétrie haute température, les chaleurs de formation à pression constante ont été mesurées sur tout le domaine de composition à diverses températures ($725\ K < T < 1170\ K$). De plus, dans certaines conditions, ces mesures permettent d'accéder directement aux coordonnées de quelques points du diagramme d'équilibre des phases. À l'aide d'un programme de calcul et de quelques hypothèses simplificatrices, ces résultats ont conduit, avec une précision satisfaisante, à la localisation de la lacune de miscibilité ternaire à l'état liquide de cet alliage.

[Traduit par la revue]

Introduction

The Gibbs free energy of reaction is the most interesting of the thermodynamic functions, but its experimental determination is often difficult. The direct measurement of the heat of reaction at constant pressure plays an important role in the study of reactions between substances in condensed phases, for which the entropy changes are generally small. Enthalpies of reaction are usually obtained by calorimetry. This direct technique, very simple in principle and using several kinds of apparatus, permits determination of the enthalpies of reaction, of dissolution, of phase transition, etc., as well as the molar heat capacities. A detailed description of the different types of calorimeters, a criticism of experimental techniques, and much useful information are contained in the literature, and particularly in Metallurgical thermochemistry, by Kubaschewsky and Alcock (1). Since the publication of this book the number of experimental studies concerning alloys has increased very rapidly. In most cases, enthalpies of formation have been obtained directly by using a high temperature microcalorimeter, the characteristic feature of which is one or two experimental cell(s) completely surrounded by several hundred thermocouples. Groups of researchers using this kind of apparatus are so numerous (for example, Kleppa in Chicago, Collinet in Grenoble, Castanet and Gambino in Marseille, Topor in Moscow, Hertz in Nancy, Hayer and Komarek in Vienna, Predel in Stuttgart) that it is difficult to draw up an exhaustive list.

The main purposes in the determination of the enthalpies of formation of alloys are, on the one hand, to obtain knowledge of the liquid and solid metallic states and, on the other hand, to predict the stability of the metallic phases. Such information can also be used in the study of industrial processes.

To highlight the advantages of microcalorimetric measurements in the field of thermochemistry of alloys, some typical results carried out for binary, or multicomponent, alloys are presented in the second part of this paper. In the following section a description of the calorimeters and the experimental techniques used are reviewed.

Experimental

In general, thermodynamic studies of alloys are performed over a wide temperature range and the choice of the calorimeter depends upon this temperature range of investigation. Between 0 and 1000°C the microcalorimeter described by Calvet and Prat in 1955 (2) is most often employed. Several authors have adapted this apparatus to solve specific problems (for example by changing the cell volume or the number and the nature of thermocouples) but the principle remains the same.

Apparatus

A complete description of the Calvet high temperature microcalorimeter, operable up to 1100°C, has been published by Gaune-Escard (3). The central alumina block (120 mm in diameter) surrounded by two large cylindrical shields in pure alumina is located in a cylindrical furnace heated by four Kanthal resistors (one on the bottom, two on the vertical wall, and one on the cover). Two very similar thermopiles are fixed in the central block. Each thermopile consists of a thin cylindrical alumina tube (16.9 mm in diameter and 80 mm high), closed at the bottom, surrounded by 396 (Pt/Pt + Rh 10 wt.%) thermocouples. About 80% of the external surface of this alumina tube is covered by the junctions of regularly arranged thermocouples.

These two thermopiles are connected differentially to eliminate thermal perturbations due to the furnace. One of the cells is called the "laboratory cell", the other one the "reference cell". The temperature of the calorimeter is regulated or linearly programmed by an electronic device, the sensing element of which is a platinum resistance (100 Ω at 0°C).

The electromotive force (E) of these two piles is recorded versus time (t) by using a millivoltmeter. In the absence of thermal effect in the cells the base line recorded is a straight line parallel to the time axis. When a thermal effect (Q) is developed in one cell a thermogram ($E = f(t)$ curve) is recorded; the area delimited by this curve and the baseline is proportional to the heat effect (Q). Generally the determination of this surface is made either by using a manual planimeter (e.g., an OTT planimeter) or by a trapezoid method. Now automatic data acquisition systems are available. They consist of an amplifier, a scanner, a

For personal use only.

millivoltmeter, and a microcomputer: the emf values measured at constant frequency are entered in the computer; and from these data the area of the thermogram is computed. The integration procedure includes a correction method to take into account the derivation of the baseline.

The nature of the materials and of the thermocouples used to build a microcalorimeter depends on the temperature range investigated. At low temperature a metallic block and shields can be used, as well as other kinds of thermocouples.

Techniques

The experimental techniques worked out in calorimetry for the determination of enthalpies of formation of alloys are numerous. For all of them, the main problem is the elimination of secondary effects arising generally from evaporation of the components, from metal–atmosphere interactions, from solvent– or solute–crucible reactions, from difficulties of mixing, etc. To solve these specific problems various devices have been created.

In ref. 1 the so-called "drop method" has been described by Kubaschewski. This method consists of dropping into the liquid metal (A), or into the liquid alloy (A + C), considered as a solvent and maintained at the experimental temperature T_E, a known amount (m) of the metal B previously stabilized at temperature T_0 (generally the room temperature). This very simple technique has been applied to the Calvet calorimeter. At constant pressure P, the recorded thermal effect ($Q_P = \Delta H$) corresponds to the following relation:

$$Q_P = m/M_B \times \left[\int_{T_0}^{T_{B,fus}} C_{p,Bsol} dT + \Delta H_{B,fus} + \int_{T_{B,fus}}^{T_E} C_{p,Bliq} dT \right] + Q'_P$$

in which M_B, $C_{p,Bsol}$, $C_{p,Bliq}$, $T_{B,fus}$ and $\Delta H_{B,fus}$ are respectively the atomic mass, the molar heat capacity in solid and liquid state, and the temperature and enthalpy of fusion of B. From the experimental value (Q_P), the first, second, and third terms must be subtracted to obtain Q'_P and, accordingly, to calculate the enthalpy of formation (ΔH_M). Unfortunately, for some alloys, the uncertainty in these corrective terms is larger than the value of ΔH_M. Of course the accuracy of these evaluations is not great, particularly when the enthalpy of mixing becomes very small (or tends towards zero).

To reduce these inconveniences (4, 5) we developed the "indirect" drop method that allows us to minimize or to cancel the corrective terms. The added metal (B) is stopped during its drop in the funnel (G) until thermal equilibrium is reached (Fig. 1). The mixing is performed by opening the funnel by means of a magnetic device that lifts the tube (T) up and down. If the funnel and the crucible are at the same temperature the recorded thermal effect corresponds directly to the enthalpy of mixing. A small alumina piece (S) fastened to the magnetic device (Fig. 1-*B*) allows the final liquid alloy to be stirred. This microcalorimetric cell is connected to a vacuum pump (V_1) and to a purified argon circuit (V_2) by a lateral valve (V). For both drop methods, direct and indirect, metallic samples are introduced in the calorimeter by using a special tap (R) and their drop is directed towards the crucible or the funnel by the tube (T). This manual introducer is now replaced by an automatic device, the main parts of which are a vertical disk holding several "nacelles" containing the samples of metal and an electric motor. This apparatus is maintained at constant temperature (room temperature) under a purified argon atmosphere. The partial rotation of the disk, monitored by a microcomputer, brings the nacelle to the top of the drop tube: in this position the nacelle turns around automatically and the sample drops into the experimental crucible. The choice of indirect or direct drop method depends on the intensity and on the sign of the experimental thermal effect.

The break-off ampoule method described earlier by Wittig and Huber (6) has been used to obtain the enthalpy of formation of liquid alloys (Hg + Ga, for example) by microcalorimetry (7). The Pyrex or quartz ampoule has to be thin enough to break with a single soft press. The thermal effect arising from the ampoule breakoff must be very small and reproducible. To measure the enthalpy of formation of Tl + Te alloys (the vapor tension of the second metal is very large) Castanet *et al.* (8) modified this technique: the ampoule containing the more volatile metal and the second metal are enclosed in a gastight syringe. The ampoule is broken by the vertical shift of the piston of the syringe and the mixing process takes place in a small volume. In this method the two components are at the same temperature and the recorded heat effect leads directly to the enthalpy of formation.

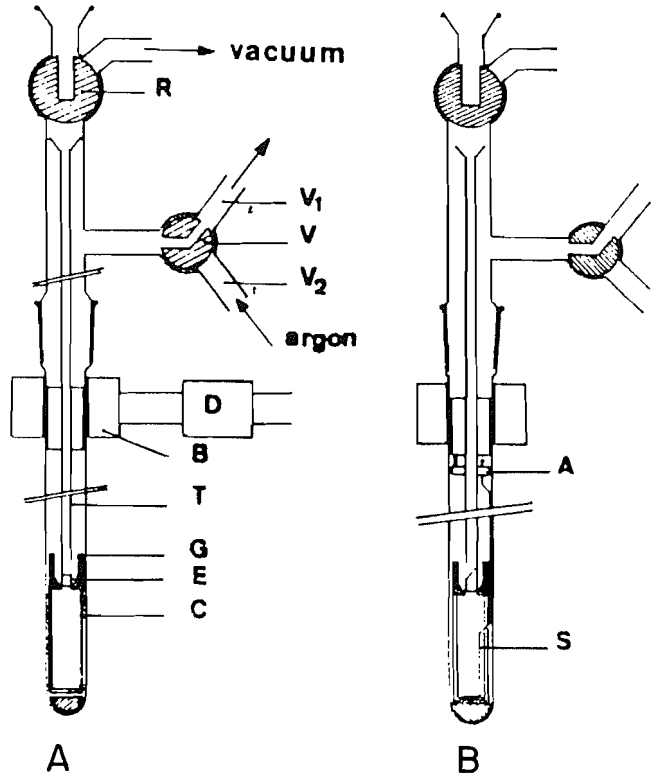

FIG. 1. Calorimetric device used for the indirect drop method; R, introducing tap; V, three-way tap; T, drop tube; G, funnel; C, experimental crucible; B and D, electromagnetic device; S, stirrer (Fig. 1-*A*).

The measurement of the heat of formation of the Ga + In liquid alloys was performed with a simple device. In the calorimetric cell the indium sample is suspended above the bath of gallium by a thin quartz wire. The mixing takes place when the wire comes down. Such a method is used only when vapor tensions of the metals are weak.

Experimental precautions

Careful attention must be paid to obtain reliable results: (*i*) All the experiments are performed under vacuum or under a purified argon atmosphere. Before each experiment the cell, tube, and crucible are degassed. (*ii*) The calorimetric cell is made of quartz; the nature of the crucible (quartz, graphite, alumina) depends on the chemical reactivity of the components of the alloy and on the experimental temperature. (*iii*) The purity of all the metals used during these experiments is about 99.999%.

Calibration

The calorimeter must be calibrated under experimental conditions either by the Joule effect or by drops of alumina or pure metal.

(*a*) By the Joule effect: the lower part of the experimental crucible is surrounded by a small resistance that generates a well-known thermal effect. This calibration, operable up to 900 K, requires precise measurements of time, intensity, and resistance.

(*b*) By drops of alumina or pure metal: at the beginning of each experiment some pieces of metal (A) are added to the liquid bath (A) and thermal effects so released allow calculation of the calibration

constant. During and at the end of each experiment, drops of NBS alumina crystals permit a second calibration.

Accuracy

A study of the accuracy of calorimetric results (9) leads to the following conclusions: the standard deviation of the calibration experiments is about 1.5% and the uncertainty in the final value for the enthalpies of mixing is estimated to be ±3% at 1000 K.

The experimental temperature is measured at ±0.5°C by using a (Pt/Pt + Rh 10 wt.%) thermocouple located between the two thermopiles in the center of the calorimetric block.

Results

To highlight the interest in calorimetric measurements for the field of thermochemistry of alloys, some results provided by a complete study of ternary Al + Ga + X systems (5) have been assembled. As an example, we have selected the Al + Bi + Ga system; from the equilibrium phase diagram of the three limiting binary systems a large tenary miscibility gap can be predicted.

Al + Bi system

The phase diagram compiled by Hultgren *et al.* (10) shows a large miscibility gap in the liquid state. The coordinates of the eutectic and critical points are respectively $x_{Bi} = 0.9944$ with $T_E = 543$ K and $x_{Bi} = 0.175$ with $T_C = 1323$ K. At the monotectic temperature, $T_M = 940$ K, the limiting molar fractions of the gap are respectively $x_{Bi} = 0.0055$ and 0.84.

Bi + Ga system

Predel (11), from DTA experiments, found a miscibility gap in this system. At the monotectic temperature T_M the limiting molar fractions of the miscibility gap are $x_{Bi} = 0.615$ and 0.085. The coordinates of the critical and eutectic points are respectively $x_{Bi} = 0.30$ with $T_C = 535$ K and $x_{Bi} = 0.0022$ with $T_E = 302.5$ K.

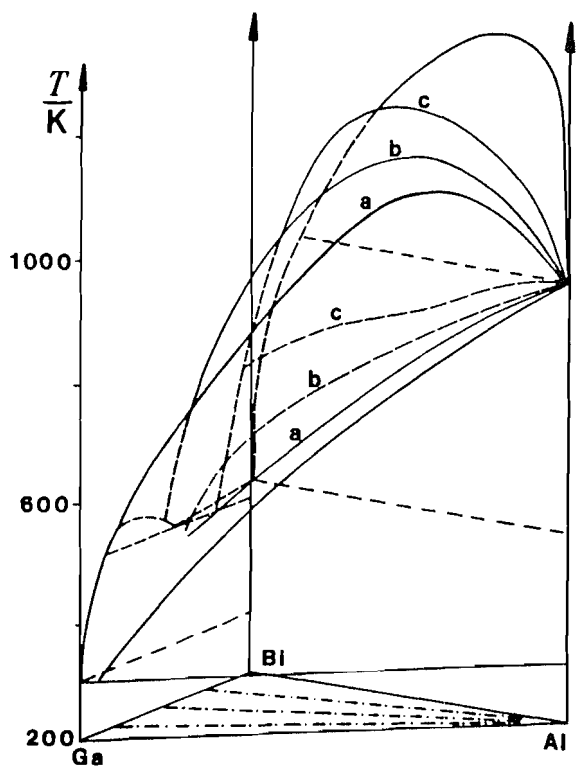

FIG. 4. Experimental equilibrium phase diagram of the Al + Bi + Ga system; a, b, and c correspond to the three sections $x_{Bi}/x_{Ga} = 1/3$, 1/1, and 3/1.

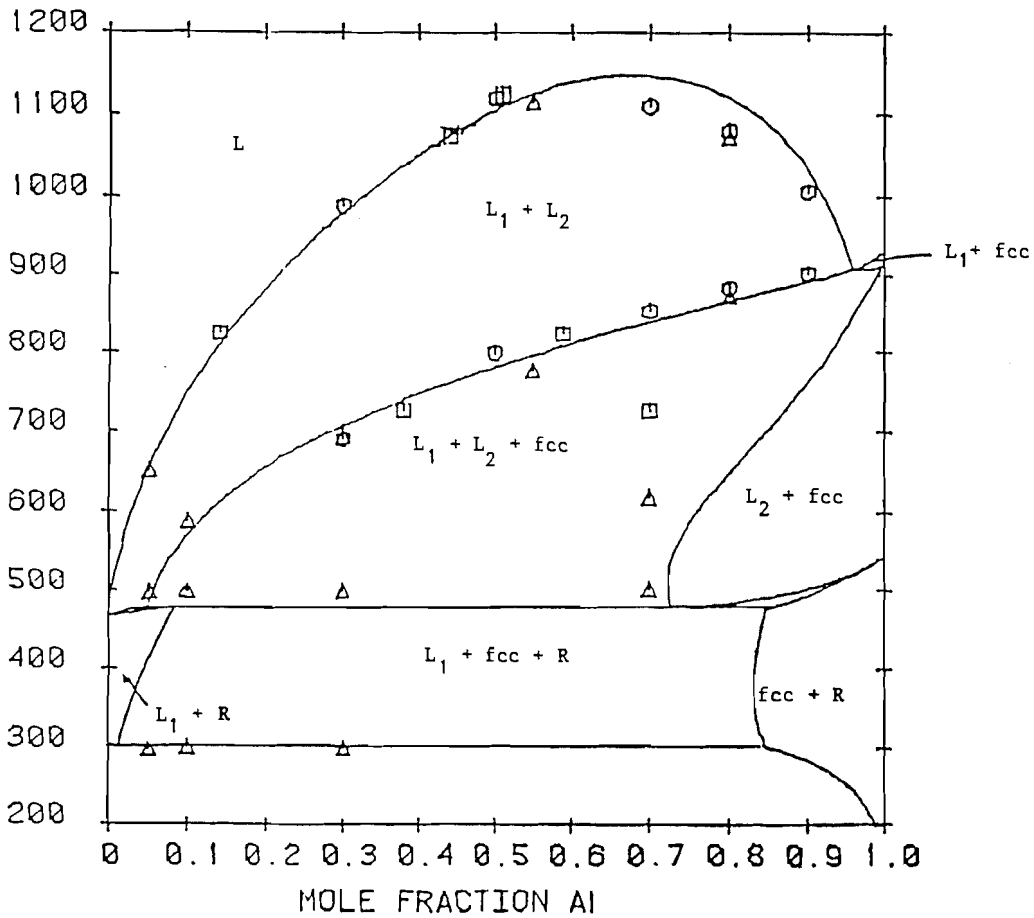

FIG. 5. Vertical section (x_{Ga}/x_{Bi} = 1/1) of the Al + Bi + Ga ternary phase diagram. Continuous lines correspond to the calculated temperatures; experimental points are obtained by microcalorimetry (□), potentiometry (◇), and differential thermal analysis (△).

Al + Ga system

The phase diagram exhibits a eutectic point (T_E = 299.6 K and x_{Ga} = 0.973) very near pure gallium. At the eutectic temperature the solid solubility of gallium in aluminium is about 8.8 at.%. On the other hand the solubility of aluminium in solid gallium is not exactly known (5).

Al + Bi + Ga

The enthalpy and Gibbs free energy of formation of this system are not available and its equilibrium phase diagram is unknown.

Using a high temperature microcalorimeter, enthalpies of formation of binary and ternary liquid alloys have been measured over large concentration ranges and at several temperatures: 725, 817, 823, 948, 972, 981, 985, 1073, 1123, 1136, 1142, and 1170 K (12). Six sections were investigated: three by dropping bismuth pieces in Al + Ga liquid alloys with x_{Al}/x_{Ga} = 1/3, 1/1, and 3/1 and three by adding aluminium samples in Bi + Ga liquid mixtures with x_{Bi}/x_{Ga} = 1/3, 1/1, and 3/1. From these results a complete description of the enthalpy of formation of Al + Bi + Ga liquid alloy can be given on the basis of the Bonnier (12) or Muggianu (14) equations with a ternary term obtained by using the least-squares method. Moreover, these calorimetric measurements allow us to obtain some points on the equilibrium phase diagram. As an example, at 823 K, the change from a one-liquid phase equilibrium to a two-liquid phase equilibrium ($L \longleftrightarrow L_1 + L_2$) is pointed out on the curve $\Delta H_M = f(x)_{x_A/x_C=ct}$ by a break point (B) followed by a straight line (Fig. 2); at the point C, the appearance of a solid phase corresponds, on the $\Delta H_M = f(x)_{x_A/x_C=ct}$ curve, to a straight line running to the enthalpy of fusion of the pure phase. The second curve obtained at 1123 K does not show any discontinuity; it corresponds to the formation of a monophase liquid alloy over the entire concentration range of aluminium. Between A and B no significant temperature variation of the enthalpy of formation of this liquid alloy is observed.

REMARK: when the phase diagram exhibits a definite compound or a solid phase, a sharp discontinuity appears on the enthalpic curve obtained by calorimetry. The triangle (A, B, C) (Fig. 6) corresponds to the precipitation of a solid phase in Al + Ga + Sb liquid alloys at 1185 K.

Calorimetric results obtained at 1123, 981, 972, and 823 K along the section x_{Al}/x_{Ga} = 1/1 are shown in Fig. 3. Linear parts correspond to the crossing of the ternary miscibility gap. All the coordinates of the break points obtained by calorimetry are collected in Table 1.

Several equilibrium temperatures were obtained from experiments performed with a Calvet microcalorimeter transformed into a differential enthalpic analyzer (DEA). For this purpose the electronic regulator was replaced by a linear temperature programmer; so modified, this apparatus becomes a very sensitive differential enthalpic analyser. Its very slow heating rate (about 12 K min^{-1}) permits a clear separation of the thermal effects.

We studied 16 alloys selected on the ternary sections (x_{Bi}/x_{Ga} = 1/3, 1/1, and 3/1). When the temperature was increasing, two endothermic peaks were recorded: the first one between 295 and 298 K and the second one, sometimes split in two parts, between 494 and 508 K. All these temperatures were obtained with a mean accuracy of ±3K.

Results collected in Table 2 show the presence of two invariant horizontal planes corresponding to the coexisting phases: (*i*) liquid + Bi(sol) + Ga(sol) + aluminium-rich solid solution at about 297 K; (*ii*) liquid 1 + liquid 2 + Bi(sol) + aluminium-rich solid solution at about 497 K.

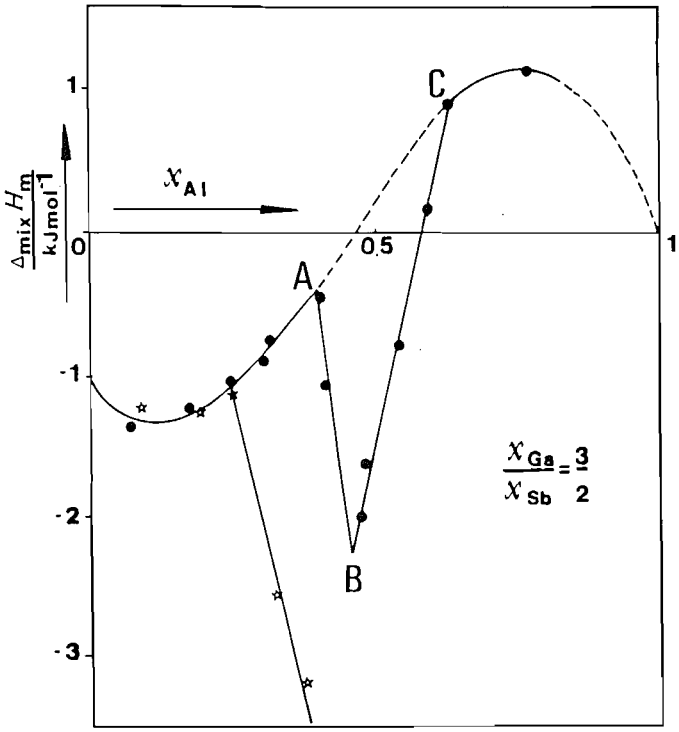

FIG. 6. Enthalpies of formation of the Al + Ga + Sb system along the section x_{Ga}/x_{Sb} = 3/2, obtained respectively at 1143 K (☆) and 1185 (●).

From all the thermodynamic data (13, 14) the equilibrium phase diagram was calculated (Fig. 4) by means of a computer program developed by Jansson (15). On the vertical section (x_{Bi}/x_{Ga} = 1/1), experimental temperatures have been reported and a good agreement was found with calculated values as represented by the continuous line (Fig. 5), except in the solid-rich aluminium region.

Conclusion

To improve our knowledge of the thermodynamic properties of multicomponent alloys, high temperature calorimetry is a very fruitful method. For ternary alloys (Al + Bi + Ga, Al + Ga + In, Al + Ga + Sn, Bi + Ga + Zn, etc.) this technique permits us to determine, from the same set of data, the enthalpies of formation on the one hand and several points of the equilibrium phase diagram on the other hand. Moreover, the temperatures of the phase transitions of these alloys have been obtained with the same calorimeter transformed into a differential enthalpic analyzer. Using a special computer program the complete set of the thermodynamic properties of formation can be predicted and the equilibrium ternary phase diagram deduced.

Ionic conductivity of pure and doped sodium chloride crystals

IRENE E. HOOTON AND P. W. M. JACOBS
Department of Chemistry, The University of Western Ontario, London, Ont., Canada N6A 5B7

Received September 24, 1987

This paper is dedicated to Professor J. A. Morrison

IRENE E. HOOTON and P. W. M. JACOBS. Can. J. Chem. **66**, 830 (1988).

New measurements are reported for the ionic conductivity of well-annealed crystals of pure NaCl, NaCl doped with Sr^{2+} ions, and NaCl doped with S^{2-} ions. Analysis of these data leads to the conclusions (*i*) that the Schottky defect model is entirely adequate for NaCl (in contrast to KCl); and (*ii*) that the activation energy for the migration of anion vacancies is 0.74 eV. This last result is in agreement with values derived from the analysis of conductivity and diffusion data for pure NaCl and NaCl doped with Sr^{2+}, and with theoretically-calculated values, but at variance with results from recent measurements on quenched sulphide-doped crystals.

IRENE E. HOOTON et P. W. M. JACOBS. Can. J. Chem. **66**, 830 (1988).

On a effectué de nouvelles mesures de conductivité ionique de cristaux bien recuits de NaCl pur, de NaCl dopé avec des ions Sr^{2+} et de NaCl dopé avec des ions S^{2-}. Une analyse de ces données permet de conclure (*i*) que le modèle de défaut de Schottky est entièrement satisfaisant pour le NaCl (et ceci est en opposition avec ce qui est observé avec le KCl) et (*ii*) que l'énergie d'activation pour la migration des lacunes des anions est de 0,74 eV. Ce dernier résultat est un bon accord avec les valeurs qu'on peut obtenir à partir d'une analyse des données de conductivité et de diffusion du NaCl pur et du NaCl dopé par du Sr^{2+} ainsi qu'avec les valeurs calculées sur une base théorique; toutefois, elles diffèrent des résultats qui dérivent de mesures récentes effectuées sur des cristaux trempés, dopés au sulfure.

[Traduit par la revue]

Introduction

The experimental study of the transport properties of ionic crystals is the principal source of data from which both the mechanisms of ion transport and numerical values of the thermodynamic properties of the crystal defects can be deduced. Doping with aliovalent ions alters the relative contributions of different species to the transport process and so is a considerable aid in data analysis. Since the early work of Koch and Wagner (1) cation doping of alkali and silver halides has been employed to accentuate the contribution of cation vacancies to the transport process. Indeed, since even nominally pure alkali halide crystals invariably contain divalent cation impurities, a rough upper bound to the cation vacancy migration energy can be obtained from measurements of the ionic conductivity, σ, by plotting the data in the Arrhenius form, $\log \sigma T$ against T^{-1} with T the thermodynamic temperature, and determining the slope of the curve in the extrinsic region. While salts like $CaCl_2$ are quite soluble in the alkali chlorides to the extent of several hundred parts per million (ppm), the corresponding situation with respect to divalent anion doping is far less satisfactory. Nevertheless, Chandra and Rolfe (2–5) have successfully doped KCl, KBr, KI, and RbI with CO_3^{2-}. Bénière, Bénière, and Chemla (6) found the maximum solubility of SO_4^{2-} in KCl to be only 36.4 ppm but even so SO_4^{2-}-doped crystals were employed in detailed studies of KCl both by themselves (7) and by Acuña and Jacobs (8, 9). Unfortunately, the solubility of SO_4^{2-} in NaCl is less than 2 ppm so similar procedures are not possible. However, Na_2S is soluble in NaCl (Baba, Ikeda, and Yoshida (10, 11), and Cook and Dryden (12, 13)) and so NaCl:S^{2-} crystals have been used in this work in an attempt to increase the anion transport number at high temperatures. The relatively low and roughly temperature-independent anion transport number in pure NaCl are major difficulties in the successful computer analysis of ionic conductivity data for pure NaCl (14, 15). Indeed, even after a very careful and detailed analysis of conductivity data for pure NaCl and NaCl:Sr^{2+}, Allnatt, Pantelis, and Sime (14) decided that no useful conclusions about the anion vacancy (av) parameters could be drawn from their work. Computer analysis of data for two pure crystals (14) yielded enthalpies of anion vacancy migration of 1.43 eV and 1.75 ± 0.18 eV, but the Arrhenius plot of the anion diffusion coefficient calculated from their defect parameters had much too high a slope, although it was intersected at about 1000 K by a plot of Laurance's experimental data. In marked contrast, they were able to fix the cation vacancy (cv) migration energy at 0.65 ± 0.01 eV and their calculated Na^+ diffusion was in excellent agreement with the experimental measurements of Nelson and Friauf (17).

In their analysis of conductivity and diffusion data for KCl, Acuña and Jacobs (8, 9) were able to determine a set of defect parameters that fitted consistently eight different sets of transport measurements, namely the conductivity of pure, Sr^{2+}-doped and SO_4^{2-}-doped KCl; cation diffusion in pure KCl and KCl:Sr^{2+}; anion diffusion in pure and Sr^{2+}-doped KCl; and SO_4^{2-}-diffusion in KCl:SO_4^{2-}, but only by a model that included small concentrations of cation and anion interstitials in addition to the conventional Schottky-defect model. One of the objects of this work was to determine if Frenkel defects also occur in NaCl. The other objective was to determine from conductivity measurements the energy and entropy for anion vacancy migration. This had not proved to be practicable from measurements on NaCl and NaCl:Sr^{2+} alone (14) and our intention therefore was to utilize measurements on NaCl:S^{2-} as well.

The anion migration problem in NaCl

It is true that information about the anion vacancy defect parameters can be determined from measurements of anion diffusion and this has been done for NaCl. The earliest measurements used the sectioning technique and were made by Chemla (18) over a limited temperature range. Laurent and Bernard (19) made similar measurements over an extended range and found an Arrhenius energy E_1 of 2.23 eV. A quite different method that involved measuring the rate of exchange of chlorine between the crystal and a circulating gas was developed by Morrison and associates (20–24). Among the advantages of this method are the fact that measurements can be

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/07/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/07/12
For personal use only.

carried out to much lower temperatures than with the sectioning technique and that measurements at a number of different temperatures can be made with the same specimen. Patterson, Rose, and Morrison (20) found an Arrhenius energy E_2 of 1.67 eV in the low-temperature regime; later Harrison, Morrison, and Rudham (21) found the Arrhenius plot of log D against T^{-1} to comprise two parts, with a "knee" at about 500°C and energies of $E_1 = 2.29 \pm 0.03$ eV at high T and $E_2 = 1.61 \pm 0.04$ eV at low T. Lidiard (25) pointed out that E_2 could not correspond to diffusion by single vacancies since at low temperatures the naturally-occurring divalent cation impurity would depress the concentration of single anion vacancies. He suggested that the species responsible for Cl^- transport at low temperatures was the vacancy pair (vp) and that this might be confirmed by diffusion experiments on crystals doped with divalent cations. Soon afterwards, Morrison and Rudham (22) found Cl^- diffusion in KCl to be insensitive to divalent-cation doping, thus providing the first experimental evidence that anion transport at low temperatures was indeed due to vacancy pairs. Laurance (16), using the sectioning technique, found Arrhenius energies of 2.12 eV for pure NaCl and 2.49 eV for Ca^{2+}-doped NaCl (in the intrinsic region) thus confirming that pairs contribute to anion transport in NaCl.

The fact that anion diffusion in NaCl must be partitioned between that due to pairs and to single vacancies, complicates data analysis, but Barr, Morrison, and Schroeder (24) were able to separate the contributions from pairs and singles and found that in the intrinsic region, the Arrhenius energy for the motion of single anion vacancies (av) was $E_{av} = 1.92$ eV while $E_{ap} = 2.37$ eV. Despite minor differences in actual numbers, a pattern of consistency had now emerged in the diffusion measurements, but E_{av} must still be separated into $\frac{1}{2}h_S + \Delta h_{av}$ where h_S is the enthalpy of Schottky defect formation and Δh_{av} the enthalpy of migration of an anion vacancy. Barr, Morrison, and Schroeder (24) used the then-determined experimental value of 2.02 eV for h_S by Etzel and Maurer (26), which gave $\Delta h_{av} = 0.91$ eV. This value of h_S is too low by current standards, so that 0.91 eV would be an upper bound.

The most complete analysis of the transport properties of NaCl is that of Bénière, Chemla, and Bénière (7) using measurements of anion and cation diffusion (obtained using the sectioning technique) and of the ionic conductivity of pure NaCl and NaCl:Sr^{2+}. Their self-consistent set of defect parameters included $\Delta h_{av} = 0.77$ eV. And if we use their value for h_S, 2.44 eV, with the Arrhenius energy $E_{av} = 1.92$ eV determined by the exchange-gas method (24) we find $\Delta h_{av} = 0.70$ eV, essentially in agreement both with the value of Bénière *et al.* (7) and the value of 0.71–0.72 eV for the energy of anion vacancy migration Δu_{av} (at 0 K) calculated by lattice simulation techniques (27), which represents a lower bound to Δh_{av}. (For an explanation of why an experimental enthalpy determined over a range of temperatures of ~800–1000 K may be compared with a theoretical energy at 0 K, see, for example, refs. 28 and 29.)

The situation with respect to the anion vacancy migration energy was therefore beginning to look fairly satisfactory by 1976, but three years later Cook and Dryden (12, 13) reported a migration enthalpy for anion vacancies in NaCl of 1.24 ± 0.05 eV, determined from impedance measurements on quenched crystals of NaCl:S^{2-}. The model used to analyze their data is that the separated S^{2-} ions and anion vacancies present at high temperatures reform complexes at lower T by the diffusion of anion vacancies to immobile S^{2-} ions. This model leads to second-order kinetics for the isothermal decay of conductivity, in agreement with experiment. Quenching to different final temperatures provides sufficient data to determine the anion migration enthalpy. The temperature dependence of the conductivity of freshly quenched material was also measured over a rather narrow range (~345–385 K) limited at the upper end by the requirement that no significant time-dependence occur during the time required to make the measurement and at the lower end by the sensitivity of the electrical measurement. Essentially the same value for Δh_{av} was obtained from these measurements as from their data on the kinetics of the decay of conductivity.

In this paper we also report measurements of the ionic conductivity of NaCl:S^{2-}, but these were made on well-annealed rather than quenched crystals.

Experimental technique

The ionic conductivity of NaCl crystals was measured using a quartz conductivity cell similar to that described by Acuña and Jacobs (8, 30). The only materials in the high temperature zone of the furnace, apart from the sample, are alumina, mica, quartz, Pt, and Pt–Rh. The electrical conductivity of the cell was measured using one of three bridges: a Wayne-Kerr B905, a General Radio 1621, or a General Radio 1689, according to the desired frequency range or the resistance of the specimen. Most measurements were made with the B905 at 1.02 and 10.2 kHz, with frequent checks to confirm that polarization resistance was negligible at the higher frequency. Temperature control was effected by a Trirect MK2 controller with a Pt resistance thermometer sensor. The temperature at each face of the crystal was measured by Pt/Pt–Rh thermocouples. The lead resistance was measured but these corrections proved to be negligible, even at the highest temperatures. Crystal dimensions were measured with a Mitutoyo Profile Projector Type PJ-250 before and after a run to confirm the absence of crystal deformation. The general technique including thorough annealing of the crystals followed closely that described previously (8, 31). The data were processed initially on a DEC 11/24 computer and plotted on an HP 7225B plotter. Non-linear least-squares analysis of the final data in the form of log σT as a function of T was carried out on a mainframe computer (Cyber 825).

Large crystals of pure NaCl containing about 1 ppm of residual divalent cation impurity were purchased from the Harshaw Chemical Co. Doping of these with Sr^{2+} or S^{2-} was effected by diffusion of $SrCl_2$ or Na_2S into small crystals (cleaved from the original blocks of pure NaCl) in graphite boats in a slow stream of argon at 750°C for periods of 2 weeks. The boats were machined from reactor-grade graphite (Ultra-carbon UF-4S) and then soaked twice in concentrated nitric acid to dissolve any metal fragments from machining. They were then soaked several times in distilled water and finally heated overnight in a stream of argon in the furnace tube used for the diffusion anneals. The particular boat used for the diffusion anneals had been used at least 15 times for growing NaCl crystals from ultra-pure NaCl powder of at least 4N7 purity so that any residual NaCl-soluble impurities would have been leached out of the graphite by the molten salt. Na_2S solutions were prepared in a glove bag under argon, the appropriate amount placed on the crystals in the glove bag, and the crystals then transferred rapidly to the furnace tube which was being flushed with argon. The crystal containing 7.1 ppm S^{2-} was kindly given to us by Dr. J. S. Dryden. This had been grown from molten NaCl containing Na_2S (12).

Results

Arrhenius plots of the ionic conductivity of undoped (Harshaw) NaCl in the form log σT against T^{-1} display the typical segmented form characteristic of alkali halides with the "knee" at about 480°C. A typical example is illustrated in Fig. 1. However. the intrinsic region is remarkably straight with no evidence (to the eye) of the curvature so characteristic of KCl (8, 33), indicating either that the cation transport number is

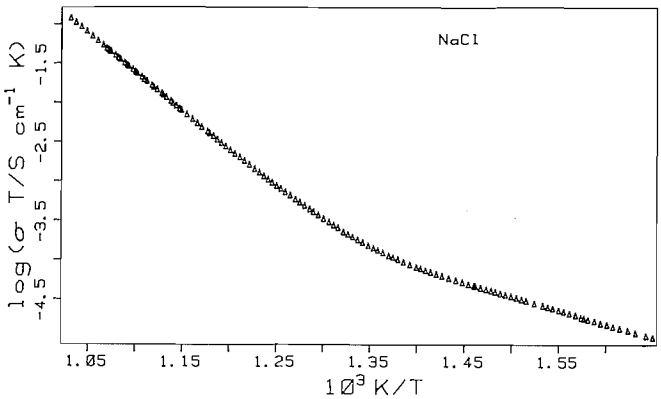

FIG. 1. Arrhenius plot of the ionic conductivity of undoped NaCl.

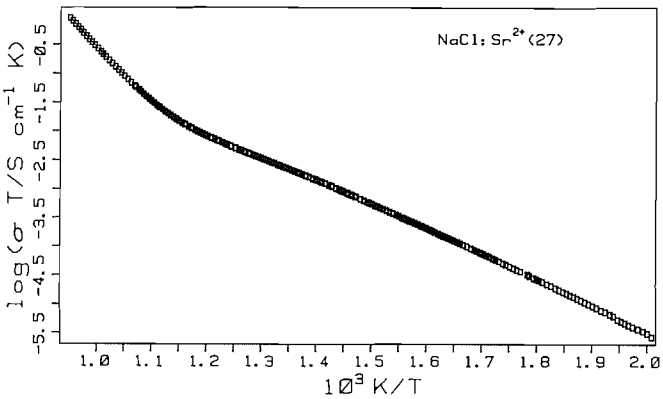

FIG. 2. Arrhenius plots of the ionic conductivity of NaCl containing 27 ppm of Sr^{2+} ion.

much greater than that of the anion, or that the Gibbs energies of migration of cation and anion vacancies must be very similar. The extrinsic part of the conductivity curve is also rather straight because of the low level of divalent cation impurity (~1 ppm) and the limited temperature range before the conductivity became too low to measure accurately.

Figure 2 shows the Arrhenius conductivity plot for NaCl doped with 27 ppm of Sr^{2+}. The extrinsic conductivity has been increased so that the knee is now centred at ~615°C. Curvature of the conductivity plot in the extrinsic region is clearly evident, due to association between Sr^{2+} and cation vacancies (cv). The high density of data is typical of this investigation. At several points the temperature was held constant for 8 h to test for precipitation, which finally occurred to a small extent at 515 K. The curve contains data determined both with T decreasing and T increasing and the excellent reproducibility verifies that the data refer to a crystal in thermal equilibrium.

A plot of log σT against T^{-1} for an NaCl:S^{2-} crystal containing 8.6 ppm of S^{2-} is shown in Fig. 3, along with the corresponding plot of a pure NaCl Harshaw crystal. The conductivity of these two crystals was measured in a double cell so that the two crystals were at the same temperature during each measurement. We note immediately that the conductivity of the pure crystal is decreased in the intrinsic region by doping with S^{2-}. Because the product of the concentrations of anion and cation vacancies is constant at constant T, doping with S^{2-} will have the effect of replacing some cv by av. The consequent lowering in σ tells us the mobility of the av is slightly lower than that of the cv. Because the concentration of dopant is only 8.6 ppm this effect decreases as T increases, and when $\exp(-g_S/2kT)$, where g_S is the Gibbs energy of formation of

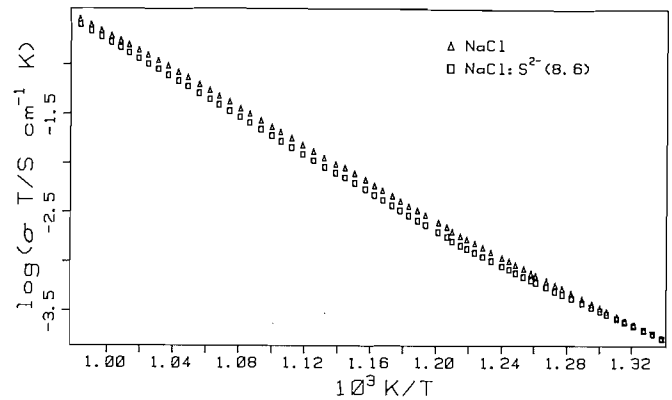

FIG. 3. Arrhenius plots of the ionic conductivity of NaCl and of NaCl containing 8.6 ppm of S^{2-} ion, measured in a double cell.

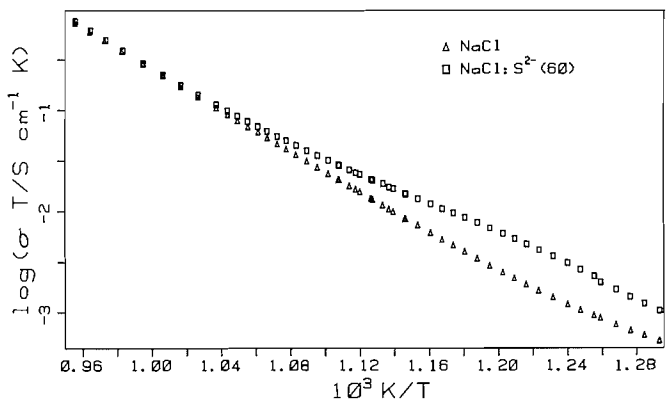

FIG. 5. Arrhenius plots of NaCl and of NaCl containing 60 ppm of S^{2-} ion (double cell).

a Schottky defect, becomes comparable with the concentration of S^{2-}, the curves converge. As $c_{S^{2-}} > c_{M^{2+}}$, where M^{2+} denotes the residual divalent cation impurity in the Harshaw NaCl (almost certainly largely Ca^{2+}) the two conductivity curves converge also as T decreases, as is to be expected because of the slightly higher knee-temperature for NaCl:S^{2-}.

At higher S^{2-} concentrations, the lowering of the intrinsic conductivity should lessen, until eventually the enhanced concentration of anion vacancies more than compensates for their lower mobility and the conductivity curve for NaCl:S^{2-} lies above that for pure NaCl. These effects are illustrated in Figs. 4 and 5. Figure 4 shows the conductivity curves for pure Harshaw NaCl and for NaCl:S^{2-} containing 19 ppm of the

dopant. We note the same lowering of conductivity as in Fig. 3 but the effect is less pronounced, as is to be expected. The knee for the doped crystal occurs at some 20 K higher than that for pure NaCl and the initial extrinsic slope is greater for the anion-doped crystal than for pure NaCl. These initial slopes correspond to Arrhenius energies of 1.03 eV and 0.67 eV, respectively,and represent rough upper bounds for the migration enthalpies Δh_{av} and Δh_{cv}. However, the absence of an upwards curvature in the intrinsic conductivity curve for pure NaCl shows that the cv and av mobilities do not differ by several tenths of an eV (cf. KCl, ref. 8) so that we conclude that in NaCl:S^{2-} av and S^{2-} ions are strongly associated, as was also true for SO_4^{2-} ions in KCl (8, 9).

Figure 5 shows the conductivity plots for pure NaCl and NaCl:S^{2-} containing 60 ppm of the divalent impurity. We observe the raised knee temperature and enhanced extrinsic conductivity so typical of doped crystals. The extrinsic region for NaCl:S^{2-} has a negative curvature, which might be taken as indicating a temperature-dependent association of S^{2-} and av. However, as there is already considerable association between S^{2-} and av at $c_{S^{2-}} = 19$ ppm and the initial slope of the extrinsic curve in Fig. 5 is greater than the corresponding slope in Fig. 4, it is possible that the marked downward curvature below 830 K is already indicating some precipitation of Na_2S. At 795 K the conductivity of NaCl:S^{2-} dips sharply, due to precipitation of some of the Na_2S. (The lower curve for pure NaCl is smoothly continuous confirming that this effect is characteristic of the doped crystal and not due to some error in temperature measurement, which would affect both curves equally.)

Data analysis

Non-linear least-squares analysis of the conductivity data were carried out on the basis of two models. The first one tried, and the one finally favoured, supposes that: (*i*) a perfectly pure crystal would contain Schottky defects; (*ii*) that Harshaw NaCl contains a residual divalent cation impurity (which is probably Ca^{2+}); (*iii*) that divalent cations and cv may associate to form complexes; (*iv*) that in NaCl:S^{2-}, the divalent S^{2-} ions associate with av to form complexes. The anion-doped crystals were assumed to contain the same level of divalent cation impurity as the undoped Harshaw crystals, namely 1.2 ppm. One might expect pairing of M^{2+} and S^{2-} ions on nn sites, but as long as the resultant complexes do not have a temperature-dependent degree of association, this has no effect on the analysis. The S^{2-} concentrations quoted would simply be reduced by 1.2 ppm.

Data points taken at temperatures lower than those at which precipitation was first observed in the conductivity plot were removed in the initial analysis. After preliminary fitting, a pronounced increase in the residuals at temperatures just above a precipitation discontinuity were interpreted as indicating the onset of precipitation (even though this might not be evident in the Arrhenius plot) so these points were removed and the analyses repeated. For example, this procedure led to the lower limit of data accepted for least squares analyses for the data plotted in Fig. 5 being set at 842.5 K, slightly above where the detectable increase in curvature commences and well above the obvious precipitation at 795 K. Early precipitation during runs carried out with decreasing T is a problem in anion-doped crystals because of the lower solubility of S^{2-} and we erred on the side of caution in ensuring that the $c_{S^{2-}}$ parameter really could be regarded as constant.

By substituting the conservation conditions in the equilibrium equations (30) the number of unknown defect concentrations can be reduced to one, and the resulting fourth-order algebraic equation solved for initially chosen values of the parameters (enthalpies, entropies, and dopant concentrations). The conductivity is calculated and the parameters are then varied systematically so as to minimize RSS, the weighted residual sum of squares, where

$$[2] \quad \mathrm{RSS} = \sum_i [\{\sigma_i(\text{calcd.}) - \sigma_i(\text{expt.})\}/\sigma_i(\text{expt})]^2$$

and σ_i means $\sigma(T_i)$. For pure or cation-doped crystals, the variable in the fourth-order equation was chosen to be c_{cv} and for anion-doped crystals, c_{av}. Because of the large number of parameters (14) in this model, the fitting of the conductivity was performing in the following cycle. First, the pure-crystal data was fitted, with only the Schottky defect formation parameters and the impurity concentration variable, the other parameters being fixed. Next the data for cation-doped crystals was analyzed with only the cv migration and association parameters and the impurity concentration variable. Finally, the data for anion-doped crystals was analyzed with only the av migration and association parameters and the impurity concentration variable. This sequence was repeated until no further decrease in RSS occurred. The fixed parameters were then released and the fitting cycles continued until a final set of parameters was obtained for each crystal. These parameters, together with their average values, are given in Table 1.

In Model 2, the perfectly pure crystal was supposed to contain Frenkel defects on the cation sublattice, in addition to Schottky defects. The fitting of the data to this model was no more satisfactory than achieved with Model 1 — sometimes the s.d. was a little better and sometimes it was worse. One would expect cation interstitials to be most important in crystals doped with a divalent anion impurity and the fact that no significant improvement could be achieved makes it plain that the case for a significant concentration of cation interstitials in NaCl is "not proven", at least for these data. A modification of Model 2 which included both anion and cation interstitials gave worse fittings than the Schottky defect model.

Discussion

Mechanism of ion-transport

The first conclusion to be drawn from the computer analysis of these conductivity data is that the Schottky defect model is adequate for NaCl. The existence of cation Frenkel defects had been tentatively suggested previously (33), as a possible means of accounting for the unsatisfactory fitting of the conductivity of NaCl to the Schottky model, but later it was realized that this was due to the use of a steepest-descent algorithm which has unsatisfactorily slow convergence. Our results do not prove that Frenkel defects do not form in NaCl, but they do show that it is not necessary to include cation and/or anion Frenkel defects in fitting the conductivity. This is in marked contrast to KCl where the inclusion of Frenkel defects on both sub-lattices was shown to be essential in order to account for the transport data. A definitive experiment would be the measurement of the anion diffusion coefficient as a function of the concentration of added Sr^{2+}, analogous to that performed by Fuller (34) for KCl. An increase in D_{Cl^-} at high Sr^{2+} concentrations would be a clear indication of the presence of anion interstitials (8). The analogous experiment for D_{Na^+} seems not to be possible at present because of the low concentration of divalent anions that can be dissolved in NaCl.

TABLE 1. Defect parameters for NaCl, derived from non-linear least-squares analysis of ionic conductivity data[a]

Parameter	Value										Average value

[a]The following symbols for defect thermodynamic quantities are used; k denotes the Boltzmann constant. h_S, enthalpy of formation of a Schottky defect; s_S, entropy of formation of a Schottky defect; Δh_{cv}, enthalpy of migration of a cation vacancy; Δs_{cv}, entropy of migration of a cation vacancy; Δh_{av}, enthalpy of migration of an anion vacancy; Δs_{av}, entropy of migration of an anion vacancy; h_{ck}, enthalpy of association between an M^{2+} cation and a cation vacancy; s_{ck}, entropy of association between an M^{2+} cation and a cation vacancy; h_{ak}, enthalpy of association between an S^{2-} anion and an anion vacancy; s_{ak}, entropy of association between an S^{2-} anion and an anion vacancy; c_M, site fraction of divalent cation impurity in ppm; c_X, site fraction of divalent anion impurity in ppm. The temperature range refers to the data actually used in the least squares analysis and may be slightly smaller than the temperature range covered by the experimental data, for reasons that are explained in the text. Numbers in parentheses indicate that the parameter was held constant at that value.

[b]Association parameters for Sr^{2+}.

[c]Association parameters for naturally-occurring impurity, almost certainly Ca^{2+}.

Vacancy migration parameters

The cation vacancy migration enthalpy Δh_{cv} is 0.626 eV, in satisfactory agreement with the previous experimental values of 0.65 ± 0.01 eV (14) and 0.69 eV (7) and the calculated values of 0.66–0.67 eV (35) and 0.66 eV (36). The anion vacancy migration enthalpy is 0.744 eV, well below the upperbound of 1.03 eV set by the slope of the conductivity curve for doped NaCl in Fig. 4 and in excellent agreement with the value of 0.77 eV obtained by Bénière *et al.* by fitting conductivity, cation diffusion and anion diffusion, but in disagreement with Cook and Dryden's (12, 13) value of 1.24 eV derived from conductivity measurements on $NaCl:S^{2-}$. Their value was obtained by measuring the conductivity of quenched crystals at fixed temperatures. Such crystals are supersaturated with Na_2S and the danger exists that precipitation may occur during the run and remain undetected. If $c_{S^{2-}}$ is not constant, the value of Δh_{av} from the slope of the conductivity plot will be too high by an unknown amount. Also, the av association parameters h_{ak}, s_{ak} in Table 1 indicate a considerable degree of association p (for example, p = 0.515–0.637 for $c_{S^{2-}}$ = 60 ppm in the range 960–845 K) and this will also raise the slope of the conductivity plot. Cook and Dryden (12) also measured the rate of isothermal decay of conductivity in quenched crystals and found second-order kinetics, as expected for the association of av with free S^{2-} ions. Such measurements could also in principle be affected by precipitation, but this would upset the second-order kinetics which were well-obeyed over about three half-lives. The order of a reaction is notoriously difficult to determine and requires measurements of the fractional change in concentration α covering at least 90% of the extent of reaction, and this range of α was practically realized in the measurements referred to. We have no clear explanation, then, of why Cook and Dryden's experiments on the decay of conductivity (12) yield a much higher migration enthalpy than do our measurements on well-annealed crystals, but we note the difficulties in ensuring that precipitation is not occurring during measurements, and the relatively few temperatures at which the decay in conductivity could be followed, and the need to separate the polarization and conductance losses.

The small difference between the migration enthalpies of cv and av obtained in this work (0.18 eV) is consistent with the extreme linearity of the intrinsic conductivity plots which display no visible upward curvature (Fig. 1), in marked contrast to KCl (8, 9, 32). Finally, if we calculate from our parameters the Arrhenius energy expected for single av diffusion, we find $\frac{1}{2}h_s + \Delta h_{av}$ = 1.95 eV, in good agreement with the single-vacancy value of 1.92 eV derived by Barr, Morrison, and Schroeder (24).

Temperature-dependent uv spectroscopy has been used to determine the differential salt effect of tetramethylammonium chloride (Me_4NCl) and sodium chloride (NaCl) on the thermal stabilities of a series of deoxyoligonucleotide duplexes that systematically differ in base composition and sequence. This approach has allowed us to resolve the AT-specific effect of Me_4N^+ from the more general, non-specific cation effects of Me_4N^+ versus Na^+. Our results reveal that in the absence of AT-specific effects, Me_4N^+ (relative to Na^+) significantly reduces the thermal stability of duplex structures. We offer an interpretation of this differential salt effect in terms of the influence of the condensed cation on water structure at the surface of the duplex. We also observe an AT-specific effect of Me_4N^+ which results in an increased thermal stability for AT-containing duplexes in Me_4NCl relative to NaCl. This specific effect which is governed by mass action is found to be uninfluenced by base sequence and to be a linear function of the percent AT base pairs in the duplex.

LUIS A. MARKY, KENNETH S. BLUMENFELD et KENNETH J. BRESLAUER. Can. J. Chem. **66**, 836 (1988).

On a utilisé la spectroscopie uv à température variable pour déterminer l'effet différentiel de sel des chlorures de tétraméthylammonium (Me_4NCl) et de sodium (NaCl) sur les stabilités thermiques d'une série de duplex de désoxyoligonucléotides qui diffèrent d'une façon systématique dans la composition de la base ainsi que dans la séquence. Cette approche nous a permis de différencier entre l'effet spécifique au AT du cation Me_4N^+ des effets cationiques plus général mais non spécifiques du Me_4N^+ vs Na^+. Nos résultats révèlent que, en l'absence d'effets spécifiques au AT, le Me_4N^+ (par rapport au Na^+) réduit d'une façon importante la stabilité thermique des structures des duplex. On offre une interprétation de cet effet différentiel de sel en fonction de l'influence du cation condensé sur la structure de l'eau à la surface du duplex. On a aussi observé un effet du Me_4N^+ qui est spécifique au AT et qui provient d'une augmentation, dans le Me_4NCl par rapport au NaCL, de la stabilité thermique des duplex contenant du AT. On a trouvé que ces effet spécifique, qui est soumis à la loi d'action de masse, n'est pas influencé par la séquence de la base et qu'il est une fonction linéaire du pourcentage des paires de bases AT dans le duplex.

Introduction

The effect of added salt on the stability of helical polynucleotides is well documented and generally depends on the nature of the cationic species (1–4). Cations can exert their stabilizing or destabilizing influences through specific and/or non-specific interactions with the polymer. Examples of non-specific interactions include general electrostatic effects (e.g. cation condensation and screening) as well as the resulting perturbation of local water structure surrounding the polymer. Essentially all cations in aqueous solution manifest such non-specific effects to varying degrees. By contrast, a specific salt effect involves a direct interaction in which the cation influences helix stability by actually "binding" to a specific site of the helical structure. Not all cations are capable of interacting in this manner. Such specific and non-specific salt effects on polymer transitions have been the subject of previous investigations with particular attention given to salts that are capable of eliminating the usual dependence of melting temperature on base composition (5–9).

In this paper we report the first resolution of an overall salt effect accompanying an oligonucleotide transition into its specific and non-specific components. The details of both interactions are discussed in terms of current theories. In addition, the oligomeric salt effects are compared with polymer data.

Our approach involves comparing the effect of two different cations on the thermal stability of a series of deoxyoligonucleotide duplex structures that systematically differ in base composition and sequence.

Experimental

Materials

All measurements reported in this paper were carried out in pH 7 phosphate buffer solutions containing either NaCl (0.1 or 1.0 *M*) or Me_4NCl (0.1 or 1.0 *M*).

Each of the self-complementary deoxyoligomers was characterized spectroscopically (nmr and uv) and chromatographically. The purities were verified by hplc. The hexamer d(ATGAT) was synthesized by a modified diester method as previously described (12). The hexamer d(GCGCGC) and octamer d(GGAATTCC) were synthesized by Collaborative Research Waltham, MA and were kind gifts from Drs. Douglas Turner and Dinshaw Patel, respectively. The dodecamer d(CGCGAATTCGCG) was synthesized by Dr. K. Itakura at the City of Hope using a modified triester method and was provided by Dr. Dinshaw Patel. The poly (dA-dT) was obtained from PL Biochemicals, Inc., purified by dialysis against distilled water, and obtained in dry form by lyophilization.

All the oligomers were desalted by chromatography on Sephadex G-10 and dialyzed exhaustively against water. Membranes having a molecular weight cutoff of 1000 daltons were used for the dialysis.

Me_4NCl obtained from Fisher (reagent grade) was purified by recrystalizing the salt twice from distilled water and then drying approximately 24 h at 100°C. The dry solid was washed twice with purified diethyl ether and the ether removed by drying for 24 h in a vacuum desiccator (13, 14). One of these cations, tetramethylammonium ion (Me_4N^+) can interact both specifically (with AT base pairs) and non-specifically (5–10) while the other, sodium ion (Na^+) only interacts in a non-specific manner (1, 11). Thus, by examining the differential effect of these two cations on the thermal stabilities of a series of oligomer duplexes of varying AT-content we have been able to isolate the contributions from the specific and non-specific interactions.

poly d(AT)	100	63.1	80.6	61.8	74.9	1.3	5.7

Methods

Ultraviolet spectroscopy

The absorbance vs. temperature profiles were measured at 260 nm by using a temperature-programmable, thermoelectrically controlled Perkin-Elmer 575 spectrophotometer interfaced to a Tektronix 4051 computer for data acquisition and analysis. The temperature was increased continuously from 5 to 95°C at a rate of 0.5°C/min. Repetitive runs revealed the melting temperature, t_m, to be reproducible to better than ±0.5°C. Since the melting temperatures, t_m's, for these oligomers are concentration dependent, precautions for this effect were taken into account as follows: Aqueous stock solutions of equal concentrations were prepared for all oligomers. Aliquots of each oligomer stock solution were diluted with the appropriate buffers to yield solutions of equal concentrations (~0.1 m*M* in phosphate). In this way comparisons between t_m values for a given oligomer in NaCl versus Me_4NCl were not influenced by concentration effects.

Results and discussion

The four self-complementary deoxyoligomers examined in this investigation are (in order of increasing AT content): d(GCGCGC); d(CGCGAATTCGCG); d(GGAATTCC); d(ATGCAT) as well as the self-complementary polymer poly d(AT).

Temperature-dependent uv profiles were determined for each of these duplex structures at 0.1 and 1.0 *M* concentrations of Me_4NCl and NaCl. Typical uv melting curves are shown in Fig. 1. The resulting melting temperature data, t_m, are listed in Table 1. The final column gives the differential effect on t_m of the two salts at both concentrations investigated. The trends in these data are most clearly seen by examination of Fig. 2 in which Δt_m (t_m in Me_4NCl − t_m in NaCl) is plotted against the % AT base pairs present in each duplex structure.

Several significant features should be noted: (*1*) Δt_m is a linear function of the % AT present in the duplex. (*2*) Δt_m values are negative for oligomers with less than about 50% AT base pairs. (*3*) The 0.1 and 1.0 M salt data have different slopes in Fig. 1 but converge to a common point at zero percent AT base pairs. (*4*) Within experimental error, the polymer data fall on the lines extrapolated from the oligomer results.

In the sections that follow, we elaborate on each of these observations.

Non-specific effect

The specific Me_4N^+ effect depends on the presence of AT base pairs (5–7). Thus, we can selectively eliminate this specific interaction and thereby compare the non-specific effects of the two cations by examining an oligomer that forms a duplex void of AT base pairs; namely, the self-complementary hexamer d(GCGCGC). Inspection of Table 1 reveals that the Δt_m for this oligomer is about −5°C at both salt concentrations. Thus, based solely on non-specific effects, Me_4N^+ causes a significantly larger destabilization of helical structure than Na^+. At this point one should be reminded that our operational definition of non-specific salt effects is intentionally very broad for the purposes of the desired resolution. The definition includes all differential salt effects except those associated exclusively with

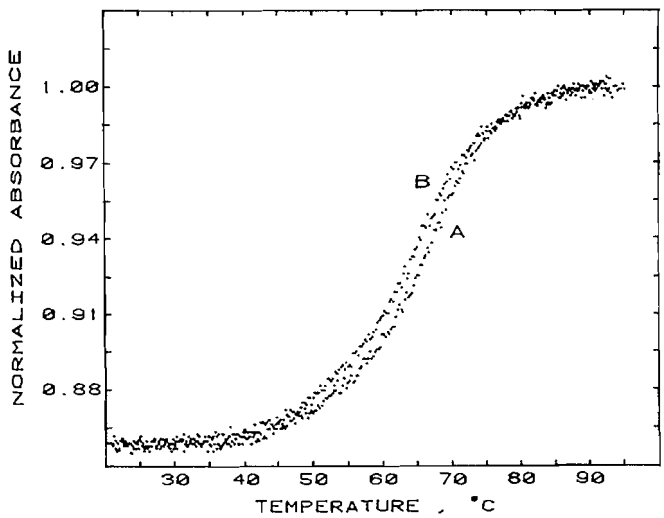

FIG. 1. Typical absorbance vs. temperature profiles for d(CGCGAATTCGCG) in 1 *M* NaCl (A) and 1 *M* Me_4NCl (B).

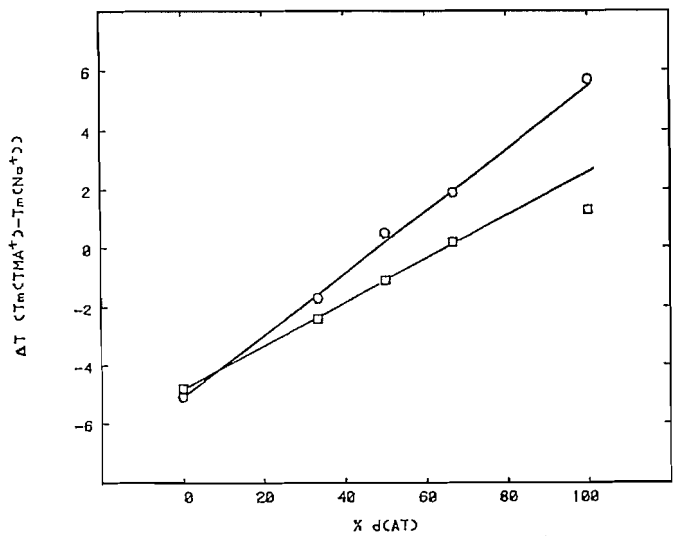

FIG. 2. Differences in the t_m values of the oligomer duplexes in Me_4NCl and NaCl solutions (□, 0.1*M*; ○, 1.0 *M*) plotted against the percent AT base pairs in the duplex structure $\Delta t = t_m$ (Me_4NCl) − t_m (NaCl).

d(ATGCAT)	67	+5.0	+7.0
poly d(AT)	100	+6.1	+10.8

the specific interaction of AT base pairs with Me_4N^+. With these definitions, we can isolate and define the AT-specific effect of Me_4N^+ without also attempting to resolve the many contributions to the non-specific, differential salt effect.

Due to the complexity and multiplicity of possible non-specific interactions, a unique molecular interpretation for the observed differential salt effect is quite difficult. Therefore, we simply present below one possible "explanation" as a basis for further discussion.

Consider that the diffuse hydration sphere surrounding a nucleic acid can act as a destabilizer of helical structure by providing local water molecules which compete with base pairing for hydrogen bonding. When a cation is added to an aqueous, polyion solution, the cation will condense onto the polyion surface to produce an effective local cation concentration in excess of one molar (1, 11). This high local cation concentration is independent of the concentration of the cation in solution (1). Such a high local cation concentration will significantly effect the water structure near the vicinity of the polyion surface which in turn will effect the stability of the polyion structure.

Specifically, when Na^+ ions condense with DNA double helices, they tie-up significant amounts of water molecules (as waters of hydration) in the vicinity of the duplex structure. By contrast, Me_4N^+ ions are not significantly hydrated. Consequently, when Me_4N^+ ions condense with DNA duplexes, they do not "tie up" (electrostriction) water molecules in the vicinity of the double helix. Thus, in Me_4N^+ solutions (in contrast to Na^+ solutions) water molecules close to the surface of the duplex are available to compete with interstrand base pairing thereby resulting in lower duplex melting temperatures in Me_4N^+ solutions compared with Na^+ solutions. We recognize that this "explanation" is rather simplistic and present it only as a basis for further discussion. Clearly, additional data are required before a more sophisticated explanation of non-specific, differential salt effects can be proposed.

Specific effect

To isolate and define the AT-specific stabilizing effect of Me_4N^+ versus N^+, we investigated the differential salt effect on a series of oligomers containing various AT/GC ratios. Inspection of the data in Table 1 and Fig. 2 reveals that the Me_4N^+-induced specific effect serves to stabilize the AT-containing helices. This contrasts with the non-specific Me_4N^+ effect described above which we showed results in lower t_m values relative to Na^+. Thus, the nearly zero values observed for Δt_m at about 50% AT base pairs results simply from a balancing of the opposing specific and non-specific effects of Me_4N^+ relative to Na^+. A similar effect previously has been observed with DNA polymers (7–9).

The specific effect can be more clearly seen if we isolate it by subtracting the constant background of −5°C contributed by the non-specific interaction. The data derived in this fashion are shown in Table 2. From these "corrected" data, we calculate a specific, Me_4N^+-induced stabilization relative to Na^+ of 0.1°C per % AT base pair at 1 M salt concentration.

It should be noted that the linear relationship between Δt_m and % AT base pairs holds despite considerable heterogeneity of base sequence in the oligomers studied. This strongly suggests that the specific interaction between the Me_4N^+ cation and the AT base pair is a highly local phenomenon that is not influenced by either nearest neighbor effects or the location of the AT base pair (terminal vs. interior).

Inspection of Fig. 1 further reveals that the 0.1 and 1.0 *M* lines are of different slope. This is consistent with a picture in which the specific binding of Me_4N^+ to AT base pairs is governed by mass action. In contrast, the non-specific salt effect associated with cation condensation should show no mass action behavior at these overall concentrations (1, 11). This prediction is supported by the observation that for d(GCGCGC), where no specific effects are possible, the Δt_m data are identical for 0.1 and 1.0 *M* salt concentrations.

Finally, one should note that the Δt_m data for poly d(AT) fall on the same lines as the oligomer results. Thus, we can conclude that for these two cations the polymer and oligomer salt effects are comparable. This suggests that the base composition of an oligomer or polymer can be determined by measuring the difference in t_m values in Me_4NCl and NaCl. However, more systems need to be investigated before such an approach can be used with confidence.

This paper is dedicated to Professor James A. Morrison

LIONEL G. HARRISON and BEVERLEY R. GREEN. Can. J. Chem. **66**, 839 (1988).

Computer simulations are described for simple models of kinetically cooperative competition between two or more a priori equally matched antagonists. These might be optically enantiomeric molecules, crystal defects in two phases, differentiation states of biological cells, etc. The models give a perspective on the relationship between the reaction–diffusion theory of pattern formation, homeogenetic induction between biological cells, and the currently popular "cellular automaton" computer programmes. The models express self-activation without inhibition. Therefore, they do not have all that is needed for indefinitely long stabilization of pattern by reaction–diffusion, as first established in the Turing activator–inhibitor model and used later in most reaction–diffusion models. But by the same token, boundaries between disparate regions do not reach stable positions, but must move until they finally reach the edges of the system and disappear. Therefore, these models are convenient for studying aspects of boundary movement in the régime of small-number statistics. To see this without artefacts from array geometry, we use hexagonal arrays in place of the more popular square ones.

We conclude that the behaviour of these models in one respect contrasts with and in another resembles the expected deterministic behaviour in large-number statistics. Regions totally surrounded by an antagonist often grow, while deterministically they must shrink. On the other hand, boundaries tend to straighten, as they would deterministically. In a system of overall rectangular habit, with or without periodic edge conditions making it a cylinder or a torus, boundaries tend to align with the shorter dimension, making a pattern of "square stripes".

LIONEL G. HARRISON et BEVERLEY R. GREEN. Can. J. Chem. **66**, 839 (1988).

On décrit des similations par ordinateur de modèles simples de compétitions, coopératives d'un point de vue cinétique, entre deux ou plusieurs antagonistes qui sont a priori équilibrés. Ces antagonistes peuvent être des molécules optiquement énantiomères, des défauts cristallins dans deux phases, des états de différentiation de cellules biologiques, etc. Les modèles donnent une perspective sur la relation qui existe entre la théorie de réaction–diffusion des motifs de formation, l'induction homéogénétique entre les cellules biologiques et les programmes d'ordinateurs «automatons cellulaires» qui sont actuellement très populaires. Les modèles expriment l'auto-activation sans inhibition. Ils n'ont donc pas tout ce qu'il faut pour la stabilisation à long terme du motif de réaction–diffusion, tel qu'il a été établi originalement dans le modèle activant–inhibiteur de Turing et qui a été utilisé ultérieurement dans la plupart des modèles de réaction–diffusion. En conséquence, les frontières disparaissent entre les régions disparates qui n'atteignent pas des positions stables mais qui doivent toutefois se déplacer jusqu'à ce qu'elles atteignent enfin les bords et qu'elles disparaissent. Ces modèles sont donc utiles pour étudier des aspects du mouvement aux frontières dans un régime de statistiques des petits nombres. Afin de voir ceci sans artefacts provenant de la géométrie matricielle, on utilise une matrice hexagonale plutôt ques les matrices carrées qui sont plus populaires.

On en conclut que le comportement de ces modèles contraste par certains points avec le, et par d'autres points ressemble au, comportement déterministe qu'on peut attendre dans les statistiques des grands nombres. Des régions qui sont totalement entourées par un antagoniste croissent souvent, alors que d'un point de vue déterministe elles devraient retrécir. Par ailleurs, les frontières tendent à devenir droites, comme on pourrait s'y attendre sur une base déterministe. Dans un système d'habitude globalement rectangulaire, avec ou sans conditions de bord periodique les transformant en cylindre ou en tore, les frontières tendent à s'aligner sur la dimension la plus courte et à former un motif de «bandes carrées».

Kinetic cooperativity

Fifty-five years ago, when James James Morrison Morrison was probably thinking about going down to the end of the town (1), Mills (2) published a proposed kinetic mechanism for spontaneous optical resolution. In essence, this was the production of chiral substances by stereospecific autocatalysis of higher kinetic order than the first in product concentration. The simplest illustration is second-order autocatalysis, whereby, if the ratio of enantiomers is at one moment 2:1, the ratio of rates of formation is 4:1, so that kinetic effects are taking the system away from racemic equilibrium and towards resolution. Essentially identifying autocatalysis with the growth of a living tissue, Mills concluded that "the optical activity of living matter is an inevitable consequence of its property of growth".

This concept was elaborated, and in more than one instance independently rediscovered, by a number of workers (2–11). At least two such accounts, Frank (3) and Harrison (7), mentioned the possibility of patterns of oppositely resolved regions as an intermediate stage on the way to resolution. Frank pointed out that a boundary between two such regions would advance in the direction towards which it was concave (Fig. 1). If one thinks of a boundary in the form of a closed loop, this behaviour has paradoxically contrasted aspects. First, on a flat surface (Fig. 1*a*), there will be progress towards resolution by "mopping-up" of surrounded areas. Second, if a boundary is closed by going right around the curved surface of a cylinder, it will tend to straighten out (Fig. 1*b*). This process tends to slow down its movement along the cylinder and impede resolution.

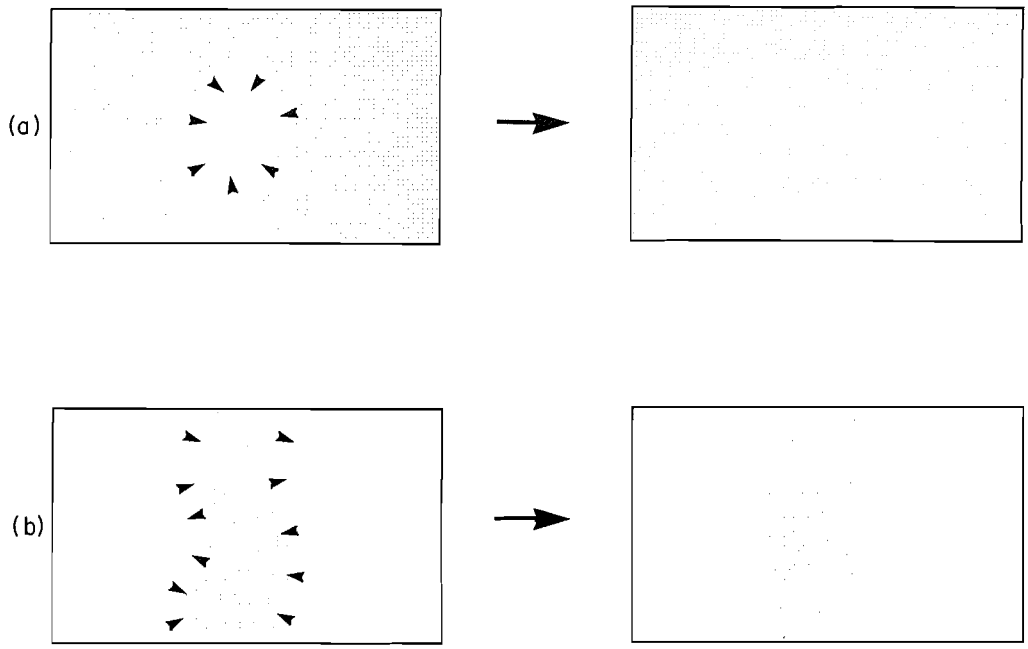

FIG. 1. Sketch to illustrate deterministic movement of boundaries in a kinetically cooperative model for optical resolution, the movement being always into the concavity of the boundary, so that (a) surrounded regions vanish; (b) boundaries running into edges of the region (or right around a cylinder, if periodic boundary conditions are applied to top and bottom edges) tend to straighten.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/07/12
For personal use only.

The difference between the two cases, topologically, is that in the first the integrated concavity *in the surface* is a full turn, while in the second, the integrated concavity is zero, the turn to close the loop being made *by the surface itself*. Anyone interested in phase transitions will also notice that the first kind of behaviour is just the opposite of nucleation.

The Mills mechanism, for a diffusible substance, can give rise to transient pattern. But, especially in relation to the morphogenesis of living organisms, there is much interest in putative mechanisms for formation of stable pattern. For generality of perspective on all possible mechanisms, the word "stable" must here be understood as an indication of chronological persistence without a priori implications as to whether the system is in a thermodynamic equilibrium or whether it is being kinetically maintained out of equilibrium. For the latter possibility, hypothetical patterning mechanisms are generally discussed under two headings: "reaction–diffusion theory" and "dissipative structure". The former term specifies a field with a 35-year history, starting from Turing's equations (12). The latter term is that of the Prigogine school (13, 14) for a more general category. One of us (15) has suggested that "kinetically maintained structures" is a clearer term.

Reaction–diffusion theory has been extensively discussed in relation to biological morphogenesis (16–22) but is still far from being generally accepted by experimental biologists; see recent review by one of us (23). Equations of the reaction–diffusion type have also appeared in the theory of kinetics of phase transitions (24–26). Most reaction–diffusion equations have nonlinearities in the reaction-kinetic terms that correspond, mechanistically, to some kind of kinetic cooperativity. Quite often, the most important nonlinearity takes the form of a squared concentration, being the simplest form to assume in instances where anything above the first power of concentration would do the job, just as in Mills' suggestion for optical resolution. For instance, the Gierer–Meinhardt equations, which are the form of reaction–diffusion theory so far most closely applied to specific instances of biological development, contain terms for rates of formation, destruction,and diffusive transport of an activator A and an inhibitor H. The rate of formation of A is dominated by a term proportional to A^2/H. Likewise, the Brusselator mechanism of the Prigogine school includes the step:

[1] $Y + 2X \rightarrow 3X$

which again has kinetics second order in the autocatalyst X.

The Turing equations appear at first glance an exception. For an activator X and an inhibitor Y, they contain only linear terms in the variables U and V that represent departures from a spatially uniform steady state X_0, Y_0, i.e.,

[2] $U = X - X_0$ and $V = Y - Y_0$

The equations are

[3a] $\partial U/\partial t = k_1U + k_2V + D_X\nabla^2U$

[3b] $\partial V/\partial t = k_3U + k_4V + D_Y\nabla^2V$

where D_X and D_Y are diffusivities of the species X and Y. Terms such as k_1U, however, representing an equal tendency for X to depart from X_0 either upwards or downwards, need for their simplest explanation a mechanism containing kinetic cooperativity. Thus if X is fomed by second-order autocatalysis and destroyed by first-order decay:

[4] $dX/dt = k_fX^2 - k_dX$

there is an unstable steady state:

[5] $X_0 = k_d/k_f$

and the rate of departure from it in either direction is

[6] $dU/dt = k_dU + k_fU^2$

At small U, the linear term is dominant, but only because the other term contains a squared concentration.

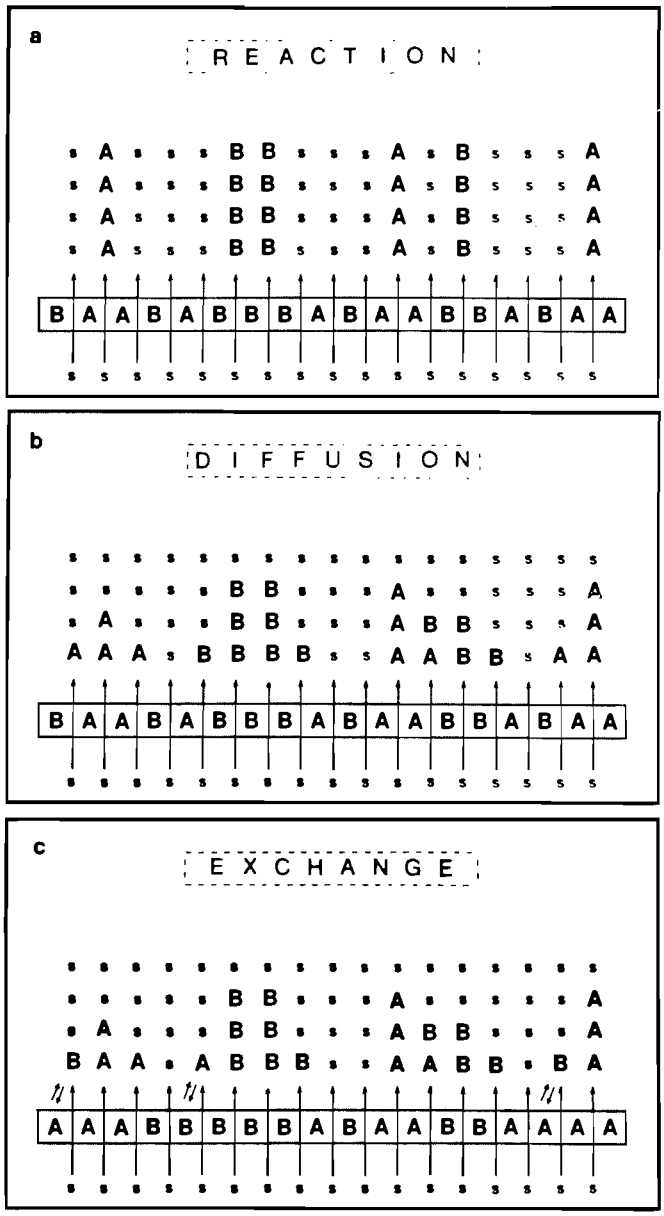

FIG. 2. Excerpts from a simulation (15) of the optical resolution model in one dimension. The row of 18 boxes is a catalyst bed. Reactant "s" flows upwards in solution. Each arrow is a potential catalytic site, activated only if it has the same enantiomer (A or B) adsorbed in boxes on both sides of it, for stereospecific catalysis of production of the same enantiomer. Product in solution diffuses sideways and exchanges back onto the catalyst bed. This simulation leads to increasingly long patches of A's and B's and was continued until there were 9 B's on the left and 9 A's on the right.

If A and B are optical enantiomers, the Mills mechanism for spontaneous resolution may be written formally in terms of the optical asymmetry

[7] $$X = A - B$$

[8] $$dX/dt = dA/dt - dB/dt = k_f(A^2 - B^2) = k_f(A + B)X$$

Circumstances are easily envisaged in which the asymmetry X can change rapidly while the total concentration $(A + B)$ remains constant, or almost so. In that kind of situation, complete nonlinear equations may be quite complicated, but the dominant behaviour as the system starts to depart from the racemic state is the linear relation of rate of departure of X from zero in either direction as shown in eq. [8] if $(A + B)$ is regarded as constant.

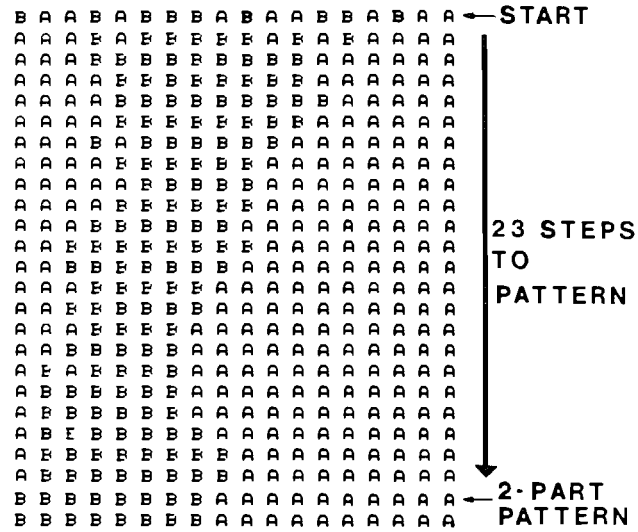

FIG. 3. Results from a computer programme (Appendix A) for one-dimensional optical resolution. In repeated runs, a patch of B's on the left and A's on the right almost invariably forms, but their relative sizes are not reproducible. Each row shows the composition of the adsorbed layer on the catalyst bed (Fig. 2) after one sequence of the operations shown in Fig. 2.

"Automata", boundaries, and the stochastic regime

One of us (15) published a very simple reaction–diffusion simulation in one dimension, in which a row of 18 objects, 9 A's and 9 B's, initially chaotically arranged, developed into an orderly two-part pattern. It was indicated that the dynamic rules of the model could be followed not only without mathematical knowledge but even without knowledge of how to read or write, beyond the ability to put down half a dozen symbols on paper. The simulation was done in half an hour with pencil and paper, and converted by manual draughtsmanship into about 50 frames for an animated film. This procedure, without use of a digital computer, makes it particularly obvious to the person doing it that no numerical calculation whatever has been done. Figure 2 shows a few stages from the sequence.

This model, which is essentially the Mills model for optical resolution, is quite easily programmed for a microcomputer (Appendix A). From a starting row of A's and B's set up either by a random number generator or in whatever initial pattern the operator wishes to choose, the computer examines a pair of adjacent sites. If both are occupied by A, a position one or two places to the left or right, at random, and with a probability distribution for one or two places representing a diffusivity, is converted to A (if it was not A already); similarly for the B's. The readout displays the appearance of the row as this operation is carried out repeatedly (Fig. 3).

Such computation lacks the expository power of the kind of graphic presentation shown in Fig. 2 for showing the chemical–mechanistic nature of the model. But the use of a computer lets one see very quickly two features of the dynamics that were mentioned but not illustrated in the earlier account (15): (*i*) The symmetrical two-part pattern is not always achieved, but something approximating it usually arises if the same input is used repeatedly. This is because the dynamics of the model pick up long-range biases in the input. For the specific example of an

For personal use only.

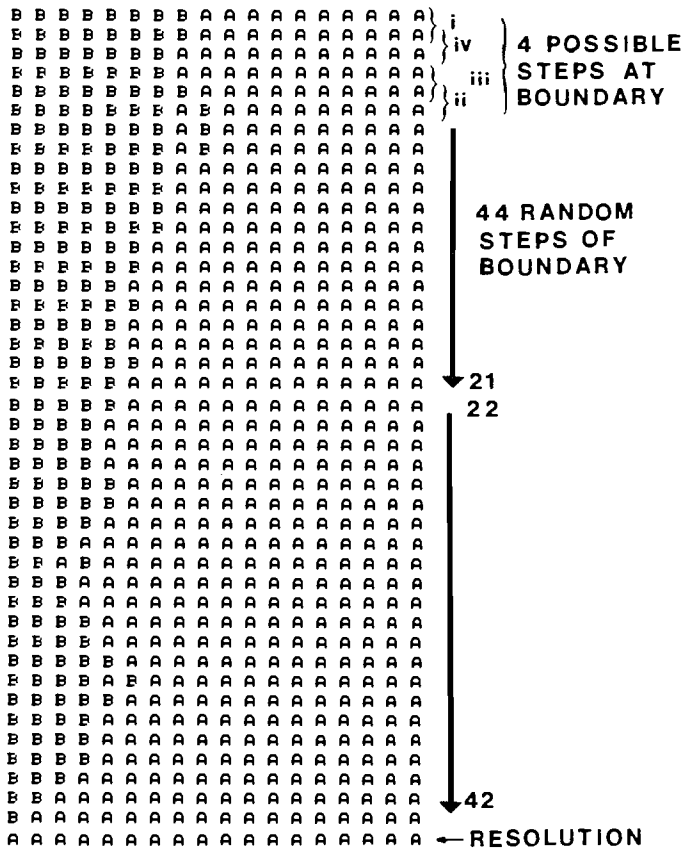

FIG. 4. Continuation of the simulation in Fig. 3. The boundary between *A*-resolved and *B*-resolved regions occasionally becomes "fuzzy" for a short time (possible step ii) but essentially becomes a diffusible entity executing a random walk by unit jumps left (iv) or right (iii), leading to eventual resolution.

input (Figs. 2 and 3), this initial arrangement happened to have 5 *B*'s and 4 *A*'s in the left-hand half, and the reverse in the right-hand half. The developing output always amplifies this bias, but not always to precisely the same extent. (*ii*) When a two-part pattern has been established, the boundary between the two parts starts to execute a random walk, whereby it must eventually reach either the left- or right-hand end of the row. The system has then achieved resolution as all *A*'s or all *B*'s. Figure 4 shows one such random walk, in which resolution took somewhat less than the expectation value of 64 steps.

The main purpose of this paper is to establish that it is useful to regard a boundary between disparate regions as an entity in its own right with significant properties. Some of these are seen only if the region has at least two spatial dimensions, as discussed in the next section, because the boundary then has a shape and such properties as the curvature that governs the deterministic behaviour discussed above in relation to Fig. 1.

In small-number statistics, the above one-dimensional case has led to the concept of a boundary as a randomly walking or diffusible entity. This study can be extended to two dimensions with quite unsophisticated computations to show that, with array sizes rather similar to those of arrays of cells in developing biological organisms, boundary movement displays a peculiar mixture of stochastic and deterministic aspects.

This behaviour is related not only to array size directly, but also to concentration profile, which depends both upon array size and upon the nonlinearities in the kinetic model. Most discussion in deterministic terms of pattern-forming models such as those of Turing, Gierer and Meinhardt, and the Prigogine school (and Frank's suggestion illustrated in Fig. 1) take concentrations of chemical species to be continuous functions of position. If, for instance, a concentration X varies sinusoidally with position so that its departure U from the uniform steady-state X_0 is

$$[9] \quad U = U_0 \sin (2\pi s/\lambda - \delta)$$

where s is the position and λ the wavelength, then

$$[10] \quad \partial^2 U/\partial s^2 = (4\pi^2/\lambda^2)U$$

The implication of this rather well-known formula for the present purpose is that if at any point along the distribution one knows the value of both U and its second derivative, one knows the wavelength. Thus every small region of a self-organizing system in a certain sense "knows" what its wavelength is; and if there is a condition such as no-flux across the ends of the system, so that the ends must be antinodes of the chemical waveform, regions within the system likewise in a certain sense know how far they are from the ends. Thus movement of the pattern in relation to the ends of the system is not random, but deterministic. In a Mills-type optical resolution model, with a diffusible chiral product turning the mechanism into reaction–diffusion, long-wave components will grow in amplitude faster than short-wave components (15), so that, even in one dimension, short regions will tend to be systematically eliminated. A central boundary ($U = 0$, separating a U-positive from a U-negative region), once displaced from the centre, will tend to continue to move in the same direction rather than executing a random walk.

All the above discussion is quite inapplicable to a square-wave pattern of oppositely resolved regions, with constant concentration in each and sharp boundaries between them. In that case, no small region of the pattern knows where it is in relation to the ends of the system. Nor are there differing finite values of wavelength to distinguish one region from another. In the sense of eq. [10], wavelength is everywhere infinite. Thus if internal boundaries move at all, they must move randomly, because they totally lack spatial information.

The model used in Figs. 2, 3, and 4 is strongly nonlinear, as discussed in ref. 18, especially section 2.3 containing equation 12 of that paper. The nonlinearities tend to lead to square-wave (i.e., patch-resolved) patterns, and do so particularly quickly if a rather small number of points are used in a simulation, so that the simulation has very limited ability to represent concentrations as anything like continuous variables.

The optical resolution model as presented here clearly resembles the kind of algorithm known as a "cellular automaton", in which elements of a one- or two-dimensional array change according to the values of neighbouring elements. Such algorithms, some of them having remarkable pattern-forming ability, have been designed for computers large and small. They have been discussed in popular language, for recreational purposes (27, 28), and also for scientific purposes, sometimes with minimal mathematics (29) and sometimes in mathematical language that might overwhelm the biological experimentalist, even when the problems addressed are in developmental biology (30). (From a rapidly growing literature, the references cited here are those which are most accessible to such an experimentalist, or which directly address problems related to theories of biological development.) One popular application, which is essentially an optical resolution model, is the "voting game" (29, 33). In this, array elements are adherents of political parties trying to persuade neighbours to change their allegiance. Simulations usually lead to the one-party state.

Wolfram (29) states that simple cellular automaton rules can capture the essential features of the usual partial differential equations of nonlinear chemical reaction–diffusion systems, citing Greenberg, Hassard, and Hastings (31) and Madore and Freedman (32). To a biochemically minded biologist who would like to interpret the model as a simulation of chemical processes at the molecular level, the correspondence may not be at all obvious, for the good reason that it is not there in most of the automaton models. An automaton model usually consists of an array of rectangular boxes, each labelled with one of a limited number of letters, numbers, or colours. In relation to a biological system, does each box represent a cell or a molecule? When a box induces a neighbour to change to the same label as itself, is this autocatalysis, diffusion, or homeogenetic induction, in which living cells cause neighbours to differentiate like themselves?

Two diagnostic tests are straightforward. First, if the programme nowhere uses a random number generator and the output shows no hint of stochastic behaviour, diffusion has not been simulated at the molecular scale. Second, if boxes that have not yet changed can be in one of two states, inducible (excitable) or refractory (quiescent), the state being time dependent, then the boxes represent not merely a biological cell, but a special kind of cell: the excitable cell, such as a neuron. Both of Wolfram's references to automaton models for reaction–diffusion systems are to this kind of model.

Such models are more promising for moving patterns of excitation in neuronal networks (brainwaves) than for most of the pattern-forming phenomena of development. Both papers also describe modelling of the moving spiral patterns of the Belousov–Zhabotinskii reaction when it is carried out in a Petri dish. This is a solution system without gross cellular compartmentalization. But its mechanism is a complex one. The Oregonator model of Field and Noyes (34–36) shows this complexity. It is a three-morphogen model; most reaction–diffusion models have only two morphogens. Such models as the Oregonator express the most kinetically significant steps in a reaction mechanism. Automaton models are at a farther remove: their cell-to-cell interactions are not unit steps in the chemical mechanism.

Nonstochastic automata for less specialized cell types (without refractory behaviour) may be relevant to homeogenetic induction, in which, for example, a false nervous system is propagated from a neural plate transplant (37–39) and, in plants, a new cambium ring forms by differentiation of wound-response callus tissue (40). But even in such cases, automata may give an overoptimistic impression of the ability of induction, unaided by long-range controls, to direct the spatial orientation of elongated or dendritic extensions of a tissue. In the automaton simulations, these directions are determined with zero error limits, and are strongly dependent on the configuration of the starting cluster. Any realistic introduction of random disturbances could lead to serious dead-reckoning errors in the navigation of the path of induction across the tissue.

At the *molecular* level, stochastic behaviour so dominates that it, in a sense, reverses its nature. Instead of being a nuisance as a disturber of order, it provides the means of communication that permits long-range control of order, across the full spatial scale of the system. The simulations described in this paper are designed to illustrate this in the simplest possible way, and to clarify how automaton-like rules with a little randomness abbreviate a reaction–diffusion mechanism at the molecular level when the mechanism is rudimentary and very little abbreviation has to be done.

Boundary movement in two dimensions

A boundary in two dimensions is not just a point. It has a shape, and hence has much more interesting properties. Its movement, in simulations, may be compared with the curvature-dominated deterministic behaviour in Fig. 1. Much biological pattern formation is in fact essentially two-dimensional, in single layers of cells or on the surfaces of individual cells. But what one learns from two dimensions is likely also to have some relevance in the three-dimensional world of phase transitions.

Using essentially a two-dimensional Mills model (but sometimes with more than two a priori equally matched antagonists), we conclude principally that small patches tend to grow or shrink stochastically, but that boundaries tend to straighten once they extend right across the system. Also, they tend to align with the shorter dimension of the system.

Such computations are within the scope of "computer recreations" for the microcomputer. Thus besides giving conclusions, as is usual in a research paper, we may invite readers to repeat the experiments. Actual running of such a programme gives a clearer indication of its kinetics than a few excerpts from the output can convey. Because of this, and also because of the very interdisciplinary nature of our topic, we find that we cannot clearly separate a pedagogic objective from the usual objective of presenting research results, in writing this paper.

In two dimensions, as previously in one dimension, we are using a model of such mechanistic simplicity that it lacks the power to stabilize a pattern of disparate parts indefinitely long or with a precisely reproducible geometry from repeated uses of the same disorderly input. When, however, the pattern has been reduced to a small number of parts with long boundaries between them, further progress towards uniformity is usually very slow. To stabilize pattern indefinitely long needs additional features in the kinetics of the model, but, in a sense, their task of stopping boundary movement altogether is not onerous.

These additional features are, of course, the presence of an inhibitor, and its diffusion at a faster rate than the self-enhancing activators, as first proposed by Turing and put into most later elaborations of reaction–diffusion theory for pattern formation (12–18). This sort of kinetic feature is likely to be necessary not only for theories of stable pattern, but also (Koga, personal communication) for further progress in the understanding of nucleation kinetics in phase transitions, for which the present level of knowledge is expressed in refs. 24–26 . For some computer programmes relevant to formation of stable pattern, see Meinhardt (17).

The kinetic principles of the model used here are the same as those used in one dimension. But the entire plane of the output must now show the array at one time-step, i.e., the whole picture is analogous to a single row in Fig. 3 or Fig. 4. For correspondence to Fig. 2, the flow direction of reactant "s" and products in solution is the third dimension, out of the plane of the diagram.

In two dimensions, the array can be quite large, and one may want to see output for time-steps shorter than that required for one systematic survey of the whole array for pairs. To show how the entire array is developing on a shorter time-scale, and to improve the correspondence to events on a molecular scale, it is best to visit points of the array in a random sequence in the computation procedure.

Most cellular automaton models use a square array, in which the neighbours of one square are considered to be either the four squares sharing sides with it (von Neumann neighbourhood, Fig. 5*a*) or those together with the four diagonal neighbours (Moore neighbourhood, Fig. 5*b*). For the present purpose, we

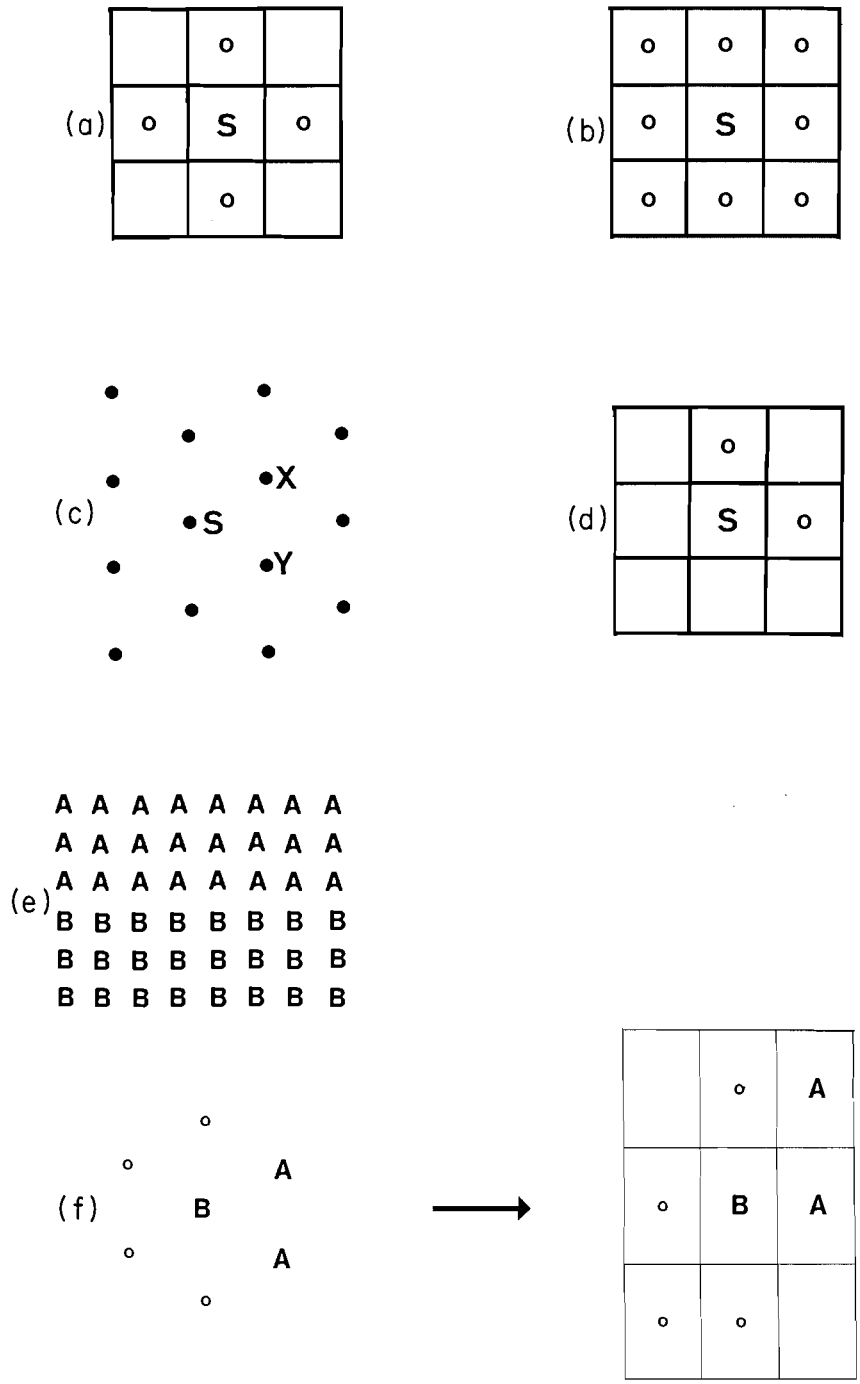

FIG. 5. Local geometries in cellular automaton calculations, relevant to two-dimensional models with bimolecular kinetic cooperativity. (a) von Neumann neighbourhood of a site S, marked by four o's; (b) Moore neighbourhood of site S; (c) close-packed hexagonal array, in which X and Y are two nearest neighbours of site S and are also nearest neighbours of each other; (d) the "two-nearest-neighbours" catalyst in a square array; (e) the artificial restriction of boundary movement in the square array; this boundary cannot move, because no letter has a diagonal pair of neighbours that are both the other letter; (f) the hexagonal array, which is free from this artificial restriction, nonconformally mapped into a rectangular array for ease of display on a microcomputer.

have found it more convenient to programme for a close-packed hexagonal layer (Fig. 5*c*). This change is not at all trivial in regard to movement of the boundaries, as explained below. Each site in the array has six nearest neighbours, and adjacent nearest neighbours are also nearest neighbours of each other, in contrast to the square array. In the programme, a site S is chosen at random, one of its nearest neighbours is chosen, also at random, and the next neighbour clockwise around the hexagon is checked for whether it has the same label as the first neighbour. If so, the site S is given the same label as that pair. This is a back-to-front way of representing an adjacent pair acting as an autocatalyst, and the product of the catalysis diffusing away a short distance in either direction from the centre of the catalytic pair. There is just sufficient random choice in this programme for a proper representation of reaction–diffusion with a fairly low diffusivity, or a high

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/07/12
For personal use only.

reaction rate. If, for instance, each catalyst pair processes molecules at a typical rate for enzyme catalysis, $100–1000\,s^{-1}$, and the nearest neighbour separation is 5 Å, then the diffusion distance of one nearest neighbour spacing per processing time of one molecule would correspond to a diffusivity of $10^{-13}–10^{-12}\,cm^2\,s^{-1}$.

The hexagonal array avoids all ambiguities about what arrangements should be regarded as neighbours, and thereby avoids a pitfall in certain obvious choices in the square array. Suppose, for instance, that one chose a site S in the square array and changed it to the same label as two of the von Neumann neighbours touching each other cornerwise (Fig. 5*d*). If, at any stage in the computation, a boundary between regions of two different labels has become linear, it can never change (Fig. 5*e*). This might be a good model for some aspects of crystal growth, in which flat surfaces will not grow and persistent steps are necessary catalysts for growth. But it is probably not a good model for the biological growth situations of morphogenesis. In the hexagonal array, this trap is simply not there to fall into. Computations with our programme will show boundaries repeatedly straightening out and then breaking up again into disorderly configurations.

A hexagonal array with a few thousand sites corresponds rather closely to a living system of great current importance in developmental biology: the *Drosophila* egg after nuclear division 13. The egg should then contain, ideally, 8096 nuclei. About 6000 of these, arranged in a single ellipsoidal layer close to the surface of the egg, are involved in a striped segmentation pattern, which can be revealed at this stage by selective fluorescent staining of particular gene products related to well-known mutations (41, 42). The pattern of the nuclei is roughly close-packed hexagonal. Various interesting problems of a physicochemical nature arise in this patterning process. It is not yet clear to what extent reaction–diffusion on a molecular scale may be involved, and on the other hand to what extent the particles of the system can be thought of in terms of small-number statistics as the 6000 nuclei, communicating by homeogenetic induction (43, 44). Within a 1-h period, at constant number of nuclei, the system changes, by formation of cell membranes, from a single cell with thousands of nuclei all in the same continuous cytoplasm to thousands of cells, each with one nucleus. The striped pattern arises before cellularization, while some patterns within the stripes arise immediately after cellularization. One might expect the cellularization to lead to a switch from large-number to small-number statistics, and hence possibly from deterministic to stochastic regimes of behaviour. But the actual behaviour observed is remarkably precisely deterministic throughout.

Clearly, a full explanation of the observed phenomena will involve a complex set of activator–inhibitor interactions, and the formation of stripes requires particular kinds of nonlinearity in the dynamics. But the striped pattern can be made visible at early stages because of alternating character (gene-off, gene-on) in the stripes for certain genes known as the "pair rule" genes, e.g., the gene associated with the *fushi tarazu* ("not enough segments") mutation. If the "off" and "on" states are approached by rather similar kinetics, in terms of quantitative values of rate constants, as seems to be implied in the inductive scheme of Meinhardt (43), then the dynamics of establishment of the alternating stripes may contain much that is kinetically isomorphous with the Mills mechanism for optical resolution. Computer simulations of this very rudimentary model may throw some light on certain limited but important aspects of the processes, especially in regard to the formation, positional stabilization, and straightness of boundaries between disparate regions.

Here, we present a programme for such simulations (Appendix B), some results (Fig. 6), and the suggestion that anyone interested in this topic (as well as many other instances of sharp and potentially mobile boundaries between disparate regions in living organisms or inanimate condensed systems) may gain a certain perspective on such processes by setting up microcomputer programmes of this kind and doing a few computer experiments with them. For a programme to be fairly quickly executed by a microcomputer, we have not tried to show the hexagonal array undistorted in the output. Instead, we have mapped it on to a rectangular array. In the mapping, the six neighbours of a site become the four von Neumann neighbours and two of the diagonals of the Moore neighbourhood (Fig. 5*f*). This is a nonconformal mapping in which one diameter of the hexagons has been arranged at 45° across the diagram, and a stretch of a factor of $3^{1/2}$ made in this direction, if the rectangles are squares. The ones in our display (Fig. 6) are not squares, but have diagonals at about 60° to the horizontal. It may occur to the reader that, because of this special shape of the rectangles, we could have represented a hexagonal array alternatively, without distortion, by using only alternate rectangles, i.e., one colour only of a chequerboard pattern. The centres of these rectangles would be a hexagonal array, but the rectangles themselves would still misrepresent which relative positions are nearest neighbour and which are not.

In this mapping, a region with boundaries following no special directions and therefore tending to become circular should appear as an ellipse with major axis inclined at 60° to the right. We have usually imposed boundary conditions as vertical and horizontal lines *in the map*. Thus, a change from undirected regions to regions responding to boundary conditions should appear as a change from inclined boundaries to vertical or horizontal ones.

Simple computer experiments, and some results

The programme suggested here (Appendix B) will produce an output of at most $23 \times 79 = 1817$ coloured rectangular patches on an IBM PC screen. The initial distribution need not have only two colours, suggesting two enantiomers. Up to 14 colours can be used, to represent morphogenetic substances, differentiation states of cells, allegiance to political parties, and so forth. Figure 6*a* has only 4 initial colours, for clarity in halftone. Numbers of cells of the order of this array size are common in developing sheets of cells. Expansion by a factor of two in both directions gives, roughly, the number of nuclei in *Drosophila* at the developmental stage mentioned above. But if the rectangle is regarded as representing the prolate ellipsoidal *Drosophila* blastoderm opened out, it should be noted that the *long* dimension (horizontal) represents the circumference on the short-axis radius, while the *short* dimension represents the long-axis length. The segmentation pattern would be a set of horizontal stripes, and this model will not produce such a pattern. If this model generates anything resembling stripes, they will be more or less square, with vertically oriented boundaries traversing the short dimension of the field (Fig. 6*a*).

The main interest in these simple computations is to gain some impression of the balance between deterministic and stochastic aspects of the shapes and movements of boundaries between disparate regions, for small-number statistics relevant to assemblies of biological cells and perhaps to aspects of the

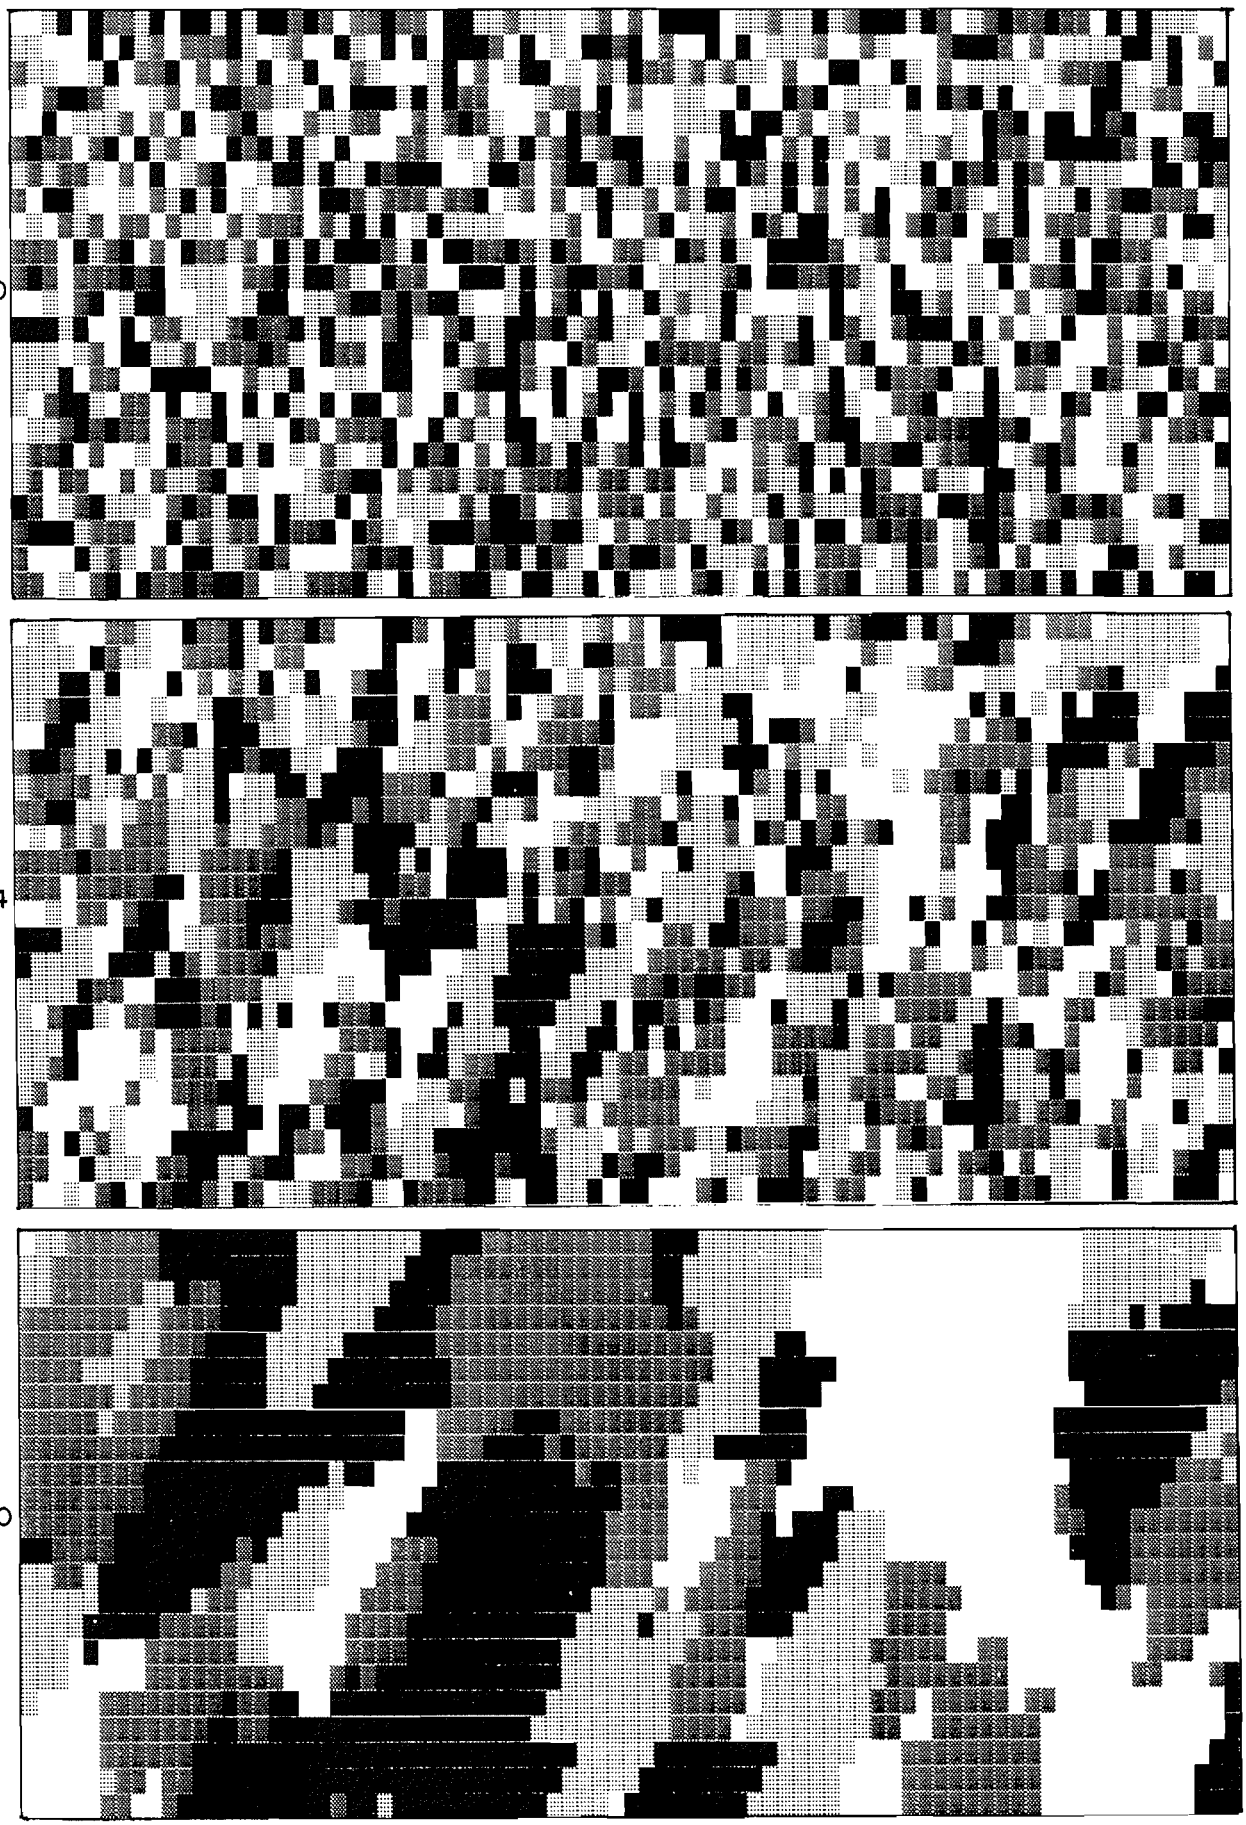

FIG. 6. Two-dimensional analogue of Figs. 3 and 4 but with four starting colours. Each rectangular diagram represents the adsorbed layer on the catalyst surface at one time, corresponding to one row in Fig. 3 or 4. Numbers are approximate total running times of the programme in an IBM PC microcomputer, in minutes.

kinetics of phase transitions. Our principal conclusions may be given as a contrast and comparison to the two kinds of large-number deterministic behaviour shown in Fig. 1 for two different topologies of boundaries: (*a*) Small regions with a boundary loop closed in the surface with a full-turn concavity behave stochastically: they are as likely to grow larger as to diminish. (*b*) Boundaries running right across the region from one edge to the opposite one, or forming a closed loop around the curved surface of a cylinder, if periodic boundary conditions have been used at opposite edges to wrap the rectangle into a cylinder, have a strong tendency to straighten (but "prominences" will repeatedly erupt from them, usually to disappear fairly quickly). (*c*) From a 14-colour start, several colours are eliminated quite quickly. But, although the ultimate destiny of the whole field is to become uniform in colour, the movement of boundaries becomes extremely slow by the stage at which there are only two colours left and boundaries run right across the system. In general, the model behaves substantially more deterministically than one might intuitively expect. Some of the experiments that one may carry out on such a model are as follows:

1. *Run the programme several times with the same input*

Response to imbalances in numbers of labels in various regions is usually more striking in two dimensions than in one. Some regions very reproducibly block out with the same label every time, though the shape of the block will not be exactly reproducible. The effect remains quite remarkable with up to 14 different colours used for the labels.

2. *Run the programme with both no-flux boundaries and wrap-around (periodic, cyclic) boundary conditions*

The latter, applied at top and bottom and sides, effectively convert the array into a torus (doughnut). Usually, in the early stages of a simulation, there is a strong suggestion of sloping lines as regional boundaries, indicating that there are no preferred directions. As the simulation continues, the regions tend to straighten out their boundaries into directions parallel to the boundaries of the whole array. This tendency is, however, no less with wrap-around boundary conditions than with no-flux boundaries. Thus, the directions to which the patterns respond are those in which the overall length or width of the array is specified.

3. *The worm that turns*

Make an array much wider than it is high—a horizontal "worm". Start, not with a random arrangement, but with an orderly pattern of two or more longitudinal stripes. As the simulation proceeds, these will break up into smaller blocks and gradually reorganize into vertical stripes. Murray (22) showed that nonlinear two-morphogen models for pattern formation tend to respond in this way to the dimensions of the pattern-forming area, accounting for the common occurrence of striped tails in mammals. This model shows the same response quite clearly, though with less regularity to the patterns formed, even though the model is so much cruder than a two-morphogen one.

Acknowledgements

We wish to thank Dr. T. C. Lacalli for stimulating comments and criticism, and NSERC Canada for financial support.

In this account, we honour James A. Morrison by showing that concepts from the fields of physical chemistry, which he long encouraged, have wider application to other experimental fields, such as developmental biology. One of us (L.G.H.) wishes to thank Dr. Morrison for such meticulous instruction, many years ago, in the writing of papers, that Dr. Morrison would hardly permit anything to be written except when he was present and participating in the task. This led to the following commentary (45):

> James James Morrison Morrison
> Works at the N.R.C.
> He takes great care with his papers
> Great care with his papers takes he.
> James James Morrison Morrison
> Says to his Fellows, says he:
> "You must never write down
> A verb or a noun
> Unless you do it with me."

Appendix A: one-dimensional programme

This programme is for the type of simulation shown in Figs. 3 and 4, but is not restricted to only two competing letters (see example below programme). Diffusivity may be changed by altering the threshold values of P. The programme is in BASIC and was used on an IBM PC computer.

The following example shows three quite different results obtained in three separate runs, all starting from the same input, which uses six different letters (a, b, c, x, y, z).

                                   782  rounds of reaction-diffusion.
```

Appendix B: two-dimensional programme

This programme was used to generate output like Fig. 6. By using the fact that colours are numbered in BASIC, it is possible to generate patterns with up to 14 colours, using the COLOR command without any characters. The programme is called MONDRIAN because of the resemblance of some of its output to the style of that designer. A compiled version is available on request from the authors.

Lattice and molecular dynamics

ALEC R. JANZEN[1] AND JOHN W. LEECH
Guelph–Waterloo Program for Graduate Work in Physics, Waterloo Campus, Waterloo, Ont., Canada N2L 3G1

Received September 2, 1987

This paper is dedicated to Professor J. A. Morrison

ALEC R. JANZEN, and JOHN W. LEECH. Can. J. Chem. **66**, 852 (1988).

A frequency analysis is made of a molecular dynamical (MD) simulation of crystalline CS_2. At 20 K the peak MD frequencies agree with those calculated using lattice dynamics (LD). However, they are not as dominant as might be expected. At 150 K the peak frequencies are generally not the LD ones. Experience with the Fermi–Pasta–Ulam linear chain problem suggests the reason may be obscuring of fundamental by combination frequencies in highly anharmonic situations.

ALEC R. JANZEN, et JOHN W. LEECH. Can. J. Chem. **66**, 852 (1988).

Utilisant une simulation de dynamique moléculaire (DM), on a efectué une analyse des fréquences du CS_2 cristallin. A 20 K, les fréquences principales en DM correspondant bien avec celles qui ont été calculées en utilisant la dynamique des réseaux (DR). Toutefois, elles ne sont pas aussi dominantes qu'ont aurait pu l'espérer. A 150 K, les fréquences principales ne sont généralement pas celles prévues par la DR. Une expérience avec le problème de la chaîne linéaire de Fermi–Pasta–Ulam suggère que ce résultat est peut être dû à l'obscurcissement de la fréquence fondamentale par des fréquences de combinaison dans des situations hautement inharmoniques.

Introduction

Lattice and molecular dynamical investigations of crystalline solids both attempt to determine details of the vibrational behaviour of mathematical models of those solids. The two methods differ in approach and are limited in different ways. Most notably lattice dynamics (LD) cannot, except with great computational effort, deal with anharmonic details of the motion, and molecular dynamics (MD) can only take into consideration samples of extremely small size. Wisdom suggests treating them as complementary methods in which case it seems important to check their degree of overlap by determining what predictions are common to both. Surprisingly little effort seems to have been devoted to this task. The primary aim of the present investigation was to answer the question "do lattice and molecular dynamical methods predict the same basic frequencies of vibration?"

Crystalline CS_2 was chosen as the substance whose model properties were to be investigated. This is because satisfactory highly equilibrated LD models were available from previous work (1, 2). Specifically model VIII of ref. 1 was selected. This is a simple Lennard–Jones 12–6 model whose details are given in Table 2. As far as harmonic LD is concerned this model behaves essentially the same as a number of others assuming different Lennard–Jones potentials (e.g. IV, V, and VII of ref. 1). However, since our investigation began, model VIII of ref. 1 has been investigated by Impey and Klein (4) together with another model (I of ref. 1 but taken from work by Tildesley and Madden (5)) using the "new" molecular dynamics (NMD). Their finding was that model VIII was unstable and developed, in the course of an MD run, into a lattice of much lower symmetry. Their other model, indistinguishable from model VIII in its LD and conventional MD behaviour, persisted in the same lattice form but changed its lattice parameters by appreciable amounts. Our MD method was the conventional one and was unable to identify these properties since the sample was constrained as to lattice type and specific dimensions though the inclinations of the molecules with respect to the crystal axes were free to change.

[1]Present address: Physics Department, Brock University, St. Catharines, Ont., Canada L2S 3A1.

The MD model

CS_2 forms a face-centred orthorhombic crystal with two molecules per unit cell. The non-primitive orthorhombic cell containing 4 molecules is shown in Fig. 1 and its parameters appropriate to 0 and 150 K are given in Table 1. The melting point at atmospheric pressure is variously quoted as 161.7 (6) and 173 K (7). The parameters of the Lennard-Jones type potential functions taken from ref. 1 and used here are given in Table 2.

The simulated crystal consisted of 108 molecules in $3 \times 3 \times 3$ non-primitive unit cells. The use of periodic boundary conditions confined the wave vectors employed to those shown in Fig. 2. When evaluating the interaction of a given molecule i with its neighbour j only the periodic image closest to i is considered. This limits the range of interaction to a maximum of one half the smallest dimension of the simulated crystal. In our work the potential cut off was 7 Å.

In the MD simulations molecule positions were specified in terms of the cartesian coordinates of their centres of mass together with quaternion parameters representing orientation.

The numerical method employed was a Störmer-based one in which positions, velocities, and accelerations at the various steps are related by:

$$[1a] \quad x_{l+1} = x_l + hv_l + (h^2/12)(7a_l - a_{l-1})$$

$$[1b] \quad a_{l+1} = a[x_{l+1}, (l+1)h]$$

$$[1c] \quad v_{l+1} = v_l + (h/12)(5a_{l+1} + 8a_l - a_{l-1})$$

The time step length h was 2×10^{-14} s corresponding to 1/14 of the period of the highest expected frequency (3.65 THz).

The initial configuration of the molecules in the 20 K simulation was that of static equilibrium of the crystal except that (for reasons concerning equilibrium and discussed in ref. 1) the molecular orientation to the crystal y-axis was 45.6° and not the experimentally measured 48.2°. In ref. 1 a number of LD models were investigated and a general tendency to equilibrate at the new 45.6° inclination was discovered.

The molecules were assigned computer-generated random values of linear and angular momentum. These were constrained to (*a*) zero total linear momentum for the whole

crystal,(b) zero angular momentum of the crystal about its centre of mass, (c) zero total spin angular momentum for each of the four types of molecule in the non-primitive unit cell, and (d) a total KE for each component of motion calculated to produce a temperature of approximately 20 K (it was actually found to be 18.6 K on equilibriation). The initial conditions represent a specialized state not conforming to a Boltzmann distribution.

The 150 K simulation configuration was that determined experimentally (3) and shown in Table 1.

Results for 20 K

An immediate consequence of the small size of the simulated crystal is the restriction of the normal modes of vibration to those corresponding to just 54 different wave vectors. Of these 16 form the irreducible set corresponding to distinct wave vectors. If LD and MD treatments overlap in the way expected the frequencies predicted by LD (approx. 16 × 10 in number)

should be the dominant ones present in the motions calculated by MD.

A selection of spectra obtained by discrete fourier transformation (DFT) of our MD results (8) corresponding to a temperature of approximately 20 K is shown in Fig. 3. The spectra represent the space–time DFT's of the x component of linear momentum. (Momentum was chosen as the quantity of interest, rather than the customary displacement, because linear momentum can be compared directly with angular momentum. In contrast it is difficult to identify an "angular displacement vector" to compare with its linear counterpart.) Superimposed are vertical lines representing the predicted LD frequencies (1). The correspondence between these vertical lines and principal features of the spectra is seen to be generally good though identification of the LD frequencies from the MD curves alone is sometimes difficult owing to the existence of other principal maxima. Higher frequency peaks are systematically somewhat greater than the corresponding LD frequencies according to the relation (9):

$$[2] \quad \omega' = (2/h)\sin^{-1}(h\omega/2)$$

between the actual frequency of a vibration (ω) and the value

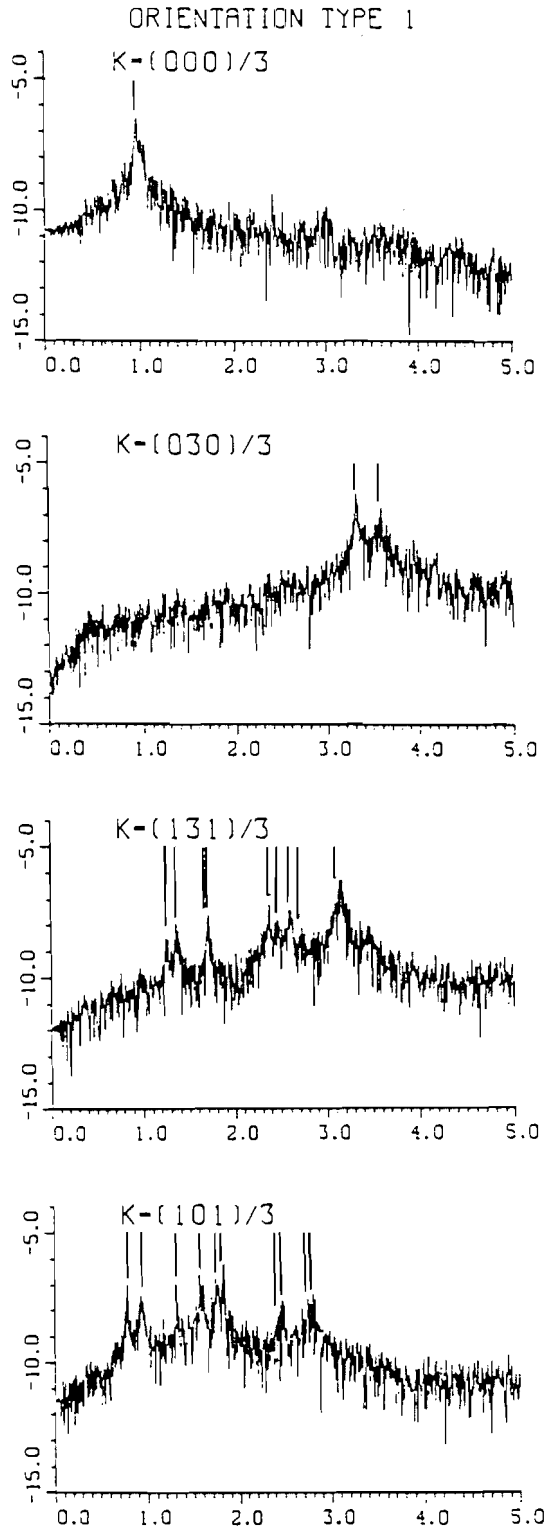

FIG. 3. Sample spectra for CS_2 at 20 K showing log (intensity) vs. frequency in THz for x component of linear momentum.

(ω') determined using a Störmer based-numerical method employing a calculational step length h. In the present case an actual frequency 3.46 THz would be determined as 3.50 THz.

A further correspondence with LD findings is that the CS_2 molecules appear to equilibriate at $45.7 \pm 2.1°$ with the crystal y axis in agreement with the LD values of 45.6°.

The MD spectra are perhaps surprising in that they do not show the LD frequencies dominating the other features as might be expected from the normal view that 20 K is a low temperature.

As a preliminary to the present investigation a simpler 1-D problem was considered. This is reported in ref. 9. The model there was a 16-particle Fermi–Pasta–Ulam (FPU) ring of identical particles interacting anharmonically through a potential function containing quadratic and cubic terms of the form:

$$[3] \quad E = \sum_{n=1}^{16} \dot{x}_n^2/2 + y_n^2/2 + y_n^3/3$$

where $y_n \equiv x_{n+1} - x_n$ and $x_{n+16} \equiv x_n$. The initial conditions consisted of a displacement only of the 16th particle. The amplitude of this displacement determined the degree of anharmonicity.

Spectra of the motion using space–time DFT's were obtained for each of 4 degrees of anharmonicity including zero. They each consisted of a principle maximum, only minutely different from the corresponding harmonic frequency, together with combination frequencies whose amplitudes increase with the degree of anharmonicity. Figure 4 (taken from Fig. 6 of ref. 9) shows a selection of spectra corresponding to the greatest degree of anharmonicity considered ($x_n(0) = 0.5 \times \delta_{16,n}$). The anharmonic structure is complex but it was shown that each feature corresponds to a distinct combination frequency and that the motion is reversible to 1 part in 10^{11} after 8 000 steps of calculation. This extreme reversibility can be traced to the use of what is essentially the Feynman algorithm in the calculation of velocities and displacements. Its consequence is that details of the motion are dependent upon initial conditions as well as upon details of the interaction potential.

The 3D MD runs simulating CS_2 are *not* reversible. There are two reasons for this: (*a*) the calculational algorithm used to determine the velocities is not reversible although that for the displacements is, (*b*) the use of quaternions in the simulation of the angular part of the motion involves a normalisation procedure at each step which also destroys reversibility. It follows that the motion is not strictly determinate as is that of the FPU ring though properties such as the interpretation of subsidiary structure of the spectra as combination frequency amplitudes must still be approximately valid.

Evidence for irreversibility lies in a slow decay with time of the energy of the assembly. This decay is almost entirely in the KE which reduces by 15 parts in 18 800 (i.e. ~0.1%) over 13 000 calculational steps.

The use of MD in simulating the properties of a thermodynamic system implies the hope that some form of irreversibility is present to the extent that thermal equilibrium is simulated though the commonly observed secular decay is unwelcome. It would thus be inappropriate to employ a completely reversible method but the identification of a suitable irreversible one is not obvious.

A measure of the approach to thermal equilibrium is through consideration of fluctuations. Using an obvious generalisation of the result obtained in ref. 10, the KE fluctuations in an "MD ensemble" in thermal equilibrium are given by:

$$[4] \quad (\delta K/K)^2 = 2/\nu N - k/C_V$$

where N is the number of particles each with ν degrees of freedom. For our ensemble assuming a harmonic solid the prediction is that $(\delta K/K)^2 = 1/540$. The observed value is 1/518. The difference could be explained by a C_V value of 574 K instead of the harmonic solid value of 540 K. However, this runs counter to the usual finding that anharmonicity lowers the value of the specific heat. An alternative explanation is that

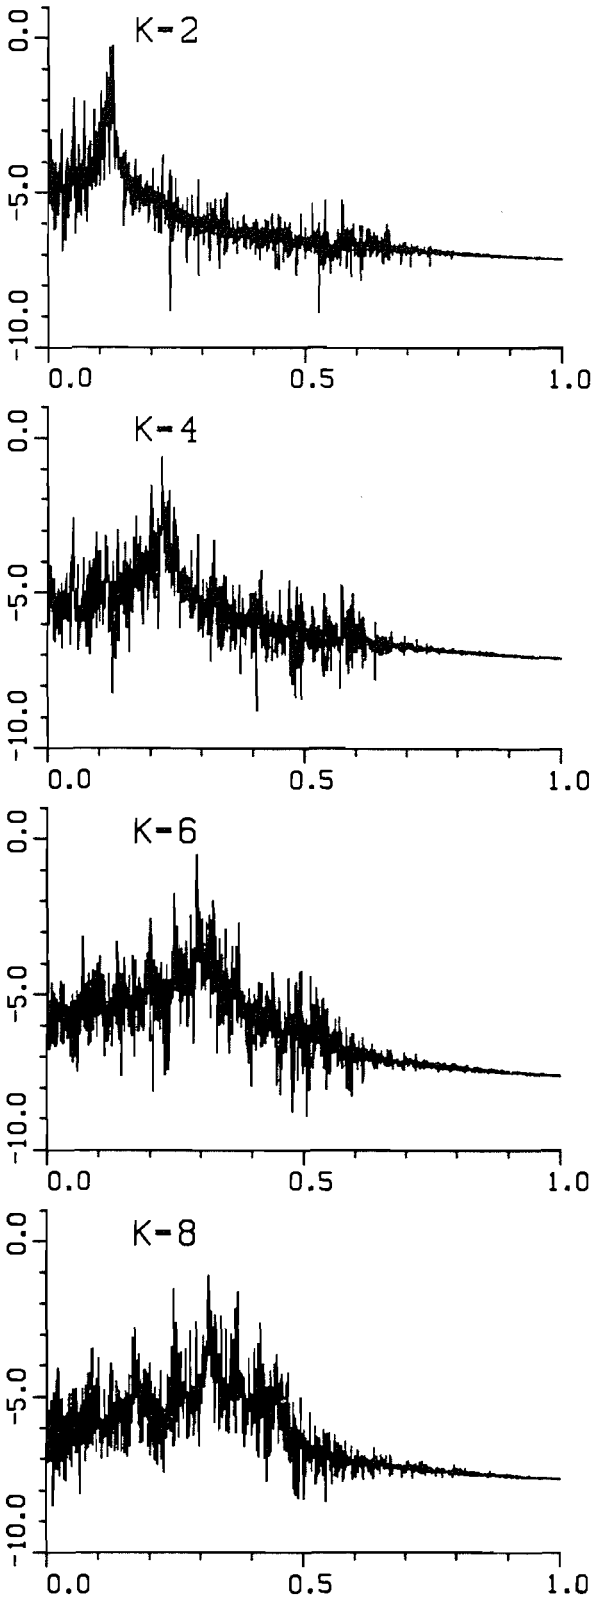

FIG. 4. Sample spectra for FPU linear chain with 16 members, showing log (intensity) vs. frequency for displacement.

fewer than 540 degrees of freedom are operative. This suggests that thermal equilibrium has not been completely attained.

A statistical analysis was made also of the KE fluctuations associated with various components of motion of individual molecules of the ensemble. Several averages over 1000 time steps of the KE associated with the T_x and R_x components of molecules numbers 1, 26, 51, and 76 were calculated. These averages each confirm the 18.8 K "temperature" of the ensemble. However, the individual values of $(\delta K/K)$ lie outside the 95% confidence limits of the value $\sqrt{2/1000}$ predicted by supposing thermal equilibrium in 25 of 40 cases. This may correspond with the motion being a correlated one approximating to a deterministic one consisting of normal modes together with the various possible sum and difference frequencies as was found with the FPU problem.

The conclusion concerning the 20 K simulation is that the motion is a complex correlated one in which the LD normal modes are observable but not dominant, and that it does not correspond to complete thermal equilibrium.

Results for 150 K

Figure 5 shows a selection of spectra relating to an MD run with mean KE corresponding to approximately 150 K. The curves have obvious broad maxima but only in a few cases, for instance $\boldsymbol{k} = (0, 0, 0)$, was there any obvious correlation with calculated LD frequencies.

As at 20 K the 150 K calculations were found not to be reversible even after as few as 20 calculational steps. A secular decrease of some 0.5% over 13 000 steps was found in the KE. Fluctuations in the KE were determined as at 20 K. The findings were that, for the whole sample, $(\delta K/K)^2 = 1/564$ consistent with all 540 degrees of freedom being operational and C_V being less than the harmonic value (by about 4%) as would be expected with anharmonic motion. Determination of the fluctuations for individual degrees of freedom over 1000 steps showed 17 cases of 40 investigated exceeding the 95% confidence limit again suggesting the existence of correlated motions.

The general conclusion concerning the 150 K MD calculations is that, except in two particulars, they are consistent with the behaviour of a simulated CS_2 crystalline sample in thermal equilibrium. The exceptions are the secular decay of amplitudes and the general lack of agreement between the broad but reasonably well defined peaks of the MD frequency curves for various wave numbers and the corresponding LD frequencies

The secular decay is an undesirable feature commonly met with in MD simulations. Since algorithm [1] is known to be drift-free when applied to a single anharmonic oscillator (11), we attribute this decay to quaternion normalisation. Normalisation introduces an irreversible error of the order of the truncation error ($O(h^4)$ in the case of algorithm [1]) at each step. This is many orders of magnitude above the level of double-precision roundoff, which might otherwise be blamed for the energy decay.

The frequency disagreement is not found in the single case of $\boldsymbol{k} = (0, 0, 0)$. Here the calculated LD and MD frequencies (at approximately 1.0, 2.0, and 2.3 THz) are in agreement. The 2.0 THz value is confirmed by neutron and optical methods (12, 13). The effects of anharmonicity are sometimes discussed in terms of frequency shifts and it is conceivable that the predicted LD frequencies are not good indications of those to be observed under the highly anharmonic conditions present at 150 K. There is, however, no obvious pattern to the shifts other than that the MD maxima are at larger frequencies than what appears to be their LD counterparts. There is also no universal correspondence between the numbers of MD maxima and the numbers of LD frequencies.

Further experimental observations using neutron diffraction and/or optical techniques could be helpful in deciding between the 2 sets of predictions but are unlikely to be made at the rather specialized wave-vectors in question. Incomplete neutron dif-

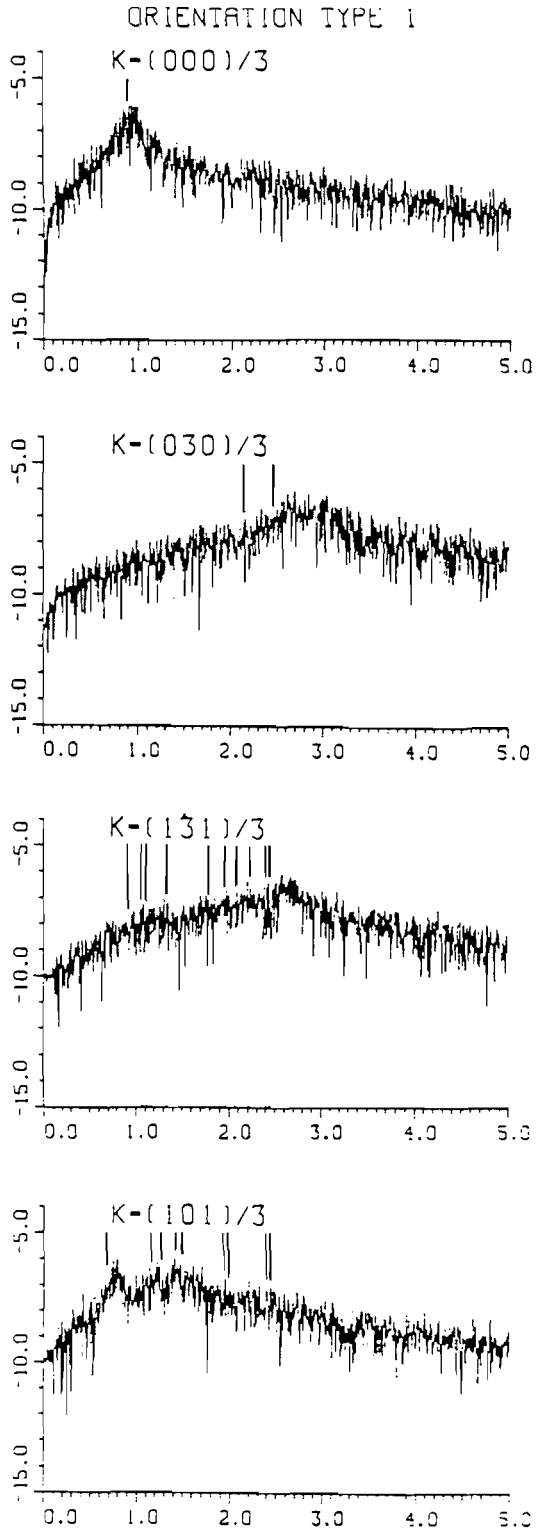

FIG. 5. Sample spectra for CS_2 at 150 K showing log (intensity) vs. frequency in THz for x component of linear momentum.

fraction evidence (12) concerning the point $k = (0, 1, 0)$ seems to favour the LD rather than the MD predictions.

Analogy with the FPU problem findings suggests regarding all the detailed structure of the 3D CS_2 frequency curves as combination frequency amplitudes. The observed growth of structure in the FPU case indicates this may ultimately dominate the normal modes thus giving rise to effectively shifted frequencies. In this way the dominant details of the spectra would be determined by incidental (anharmonic) features of potential functions designed merely to reproduce the original normal mode frequencies and disagreement with observable spectra would not be surprising.

Conclusion

Investigation of an MD model for crystalline CS_2 at 20 K shows good agreement with LD investigation of the same model though some degrees of freedom appear to be inoperative and the LD frequencies do not seem as dominant as might be expected.

The same model at 150 K agrees with LD predictions at $k = (0, 0, 0)$. Predicted broad maximum frequencies for other points in k-space are in disagreement with LD ones but little experimental evidence is available as a check. Previous investigation of the FPU linear chain suggests that combination frequency amplitudes have increased to the extent that they dominate the harmonic ones. The net effect is an apparent shifting of the harmonic frequencies. Since, however, the degree of apparent shift depends upon the anharmonic details of potential functions which are designed merely to reproduce the low temperature harmonic frequencies there is no guarantee that the predicted shifts are correct. The meager evidence available suggests otherwise.

Multiphoton absorption (MPA) by ethanol has been studied using pulsed HF and CO_2 lasers. For the same laser fluence, a CO_2 laser excites the ethanol molecule to a much higher energy than an HF laser. The multiphoton decomposition (MPD) of methanol has been studied using the $9P(16)$ CO_2 laser line for pulse widths of 10 and 60 ns. The major decomposition channel produces C_2H_4 and H_2O. However, other decomposition channels, resulting in the products CH_3CHO, C_2H_6, CH_4, and C_2H_2, are also studied and the channel ratios are found to vary with laser pulse width and with pressure. The mechanistic implications of these results are discussed.

Utilisant des lasers pulsés au HF et au CO_2, on a étudié l'absorption multiphotonique (AMP) de l'éthanol. Pour un même flux de laser, un laser au CO_2 excite la molécule d'éthanol à un plus haut niveau d'énergie qu'un laser au HF. Utilisant la raie $9(P)16$ du laser au CO_2 avec des largeurs de pulsation de 10 et de 60 ns, on a étudié la décomposition multiphotonique (DMP) du méthanol. Le chemin principal de décomposition conduit principalement à du C_2H_4 et à du H_2O. Toutefois, on a aussi étudié d'autres voies de décomposition conduisant au CH_3CHO, au C_2H_6, au CH_4 et au C_2H_2 et on a trouvé que les rapports des diverses voies varient avec la longeur de la pulsation du laser et avec la pression. On discute des implications mécanistiques de ces résultats.

[Traduit par la revue]

1. Introduction

A series of molecules, ROH, has proven to be very useful for studying Multiphoton Absorption (MPA) and Decomposition (MPD) (1, 2). The highly anharmonic -OH stretch mode can be pumped by an HF laser, and the weakly anharmonic -CO stretch mode by a CO_2 laser. For methanol, pumping into the -CO stretch mode rather than the -OH mode reduces the fluence needed to achieve MPD by about a factor of 100. The anharmonicity bottlenecking for pumping of the -OH stretch mode by an HF laser can be reduced in two ways: (*a*) R can be chosen to have a large density of states. For example, the fluence required to achieve collisionless HF laser-induced MPD of methanol (R = CH_3) is about 30 000 J/cm^2 compared to 800 J/cm^2 for ethanol (R = CH_3CH_2). (*b*) Collisions dramatically reduce the fluence required to achieve MPD. Effect (*a*) is greatest for molecules such as methanol having relatively low densities of states. Consequently, comparison studies of MPA and MPD of methanol and ethanol provide insight into the MPD process. Previously, we studied the MPA and MPD of methanol. Here we report a comprehensive study of the MPA and MPD of ethanol.

The first part of the present paper reports MPA results for ethanol with both HF and CO_2 lasers. The MPD of ethanol vapour was first studied by Selwyn, Back, and Willis (1) in 1978, using a pulsed HF laser at a wavelength of 2.744 μm. Danen (2), in a brief study with a pulsed CO_2 laser, showed by experiments with ethanol–propanol mixtures that the decomposition at pressures less than 0.13 kPa was selective, and thus involved unimolecular decomposition of isolated molecules, while more detailed experiments by Gandini and Back (3) with a CO_2 laser showed some significant differences from the earlier HF laser study. Interest in the system has continued, with results reported from China (4), Japan (5), Brazil (6), USSR (7, 8), and England (9),[4] mostly using pulsed CO_2 lasers, but with two further HF laser studies (8, 9).[4]

Previous studies have discussed the pyrolysis and the MPD of ethanol in terms of the following primary processes:

[1] $CH_3CH_2OH \rightarrow CH_2CH_2 + H_2O$

[2] $\rightarrow CH_3 + CH_2OH$

[3] $\rightarrow CH_3CHO + H_2$

[4] $\rightarrow CH_4 + CH_2O$

[5] $\rightarrow CH_3CH_2 + OH$

There is no direct evidence about the energy barriers for any of these reactions. However, barriers for [1], [3], and [4] are expected to be sizeable, while those for [2] and [5] will be close to the strength of the bond that is broken. For all of the MPD studies previously performed, and also for those to be reported here, the major reaction under all conditions is dehydration, reaction [1]. However, at high fluences or high pressures of ethanol, reactions [3] and [5], and several other processes, also

occur. The results of the MPD studies differ from those of the pyrolysis studies in that channel [1] is the predominant primary channel for MPD but free radical chain mechanisms yielding CH_3CHO and H_2 (11) dominate for thermal decomposition. Unimolecular dehydration has been observed in the pyrolysis of several alcohols (10), but not in ethanol. Danen (2) estimates E_1 = 297 kJ/mol, while Tsang (12) estimated Arrhenius parameters $A_1 = 10^{14}\ s^{-1}$ and E_1 = 320 kJ/mol, based on an analogy between the alcohols and alkyl chlorides. In a recent *ab initio* calculation, Yamabe *et al.* (13) concluded that reaction [1] was the lowest energy path for the decomposition of ethanol, with $A_1 = 1.7 \times 10^{14}\ s^{-1}$ and E_1 = 298 kJ/mol. There is less information about reaction [3], with only the calculations of ref. 13, which yielded values of $A_3 = 3.1 \times 10^{14}\ s^{-1}$ and E_3 = 469 kJ/mol. There is no information at all about reaction [4]. Three chemical activation studies produced C_2H_5OH in vibrationally excited states and the subsequent decomposition of these provides insight into the decomposition channels of ethanol. The first of these studies involves the insertion of $O(^1D)$ atoms into a C—H bond of C_2H_6 to give C_2H_5OH with excess vibrational energy of about 607 kJ/mol, and studies in several laboratories (14, 15) found products that could be entirely accounted for by the reactions of free radicals resulting from channels [2] and [5]. Tsang (12) compared these results with theoretical calculations that predicted rate constants for reactions [1], [2], and [5] of 2.5×10^9, 55×10^9, and $26 \times 10^9\ s^{-1}$ respectively for molecules of this energy. With "strong collision" deactivation, decomposition of partially relaxed ethanol molecules of reduced energy would have been minimal; the expected occurrence of 3% of reaction [1] would not have been easily detected, especially as C_2H_4 could also be formed by disproportionation of ethyl radicals from reaction [5]. Thus chemically activated ethanol created by reaction of $O(^1D)$ with C_2H_6 is not well suited to give information about reaction [4] (or other molecular dissociations), which cannot compete with reactions [2] and [5] because of the much lower frequency factors of the molecular channels. The second chemical activation system, the reaction of $CH_2(^1A_1)$ with CH_3OH, is complicated by insertion of CH_2 into both C—H and O—H bonds, with the latter yielding predominantly CH_3OCH_3 (16, 17).[5] The C_2H_5OH formed by insertion in the C—H bond had an excess vibrational energy of 418 kJ/mol, but at the lowest pressure employed (0.17 kPa) was apparently completely stabilized; no C_2H_4 formation was reported. Studies at lower pressures would be desirable, as the relatively low energy would favour observation of reaction [1], but this may present some experimental difficulties. Finally, the third system, which was actually not interpreted as involving chemical activation, may offer some evidence for the occurrence of reactions [1], [3], and [4]. The reaction of H atoms with C_2H_5OH in a flow-discharge system at pressures of 0.27–2.0 kPa gives C_2H_4, H_2O, CH_3CHO, CH_4, and C_2H_6 as important products (18). While these were explained by the authors by a sequence of abstraction reactions, it seems possible that the sequence:

[6] $H + C_2H_5OH \rightarrow C_2H_4OH + H_2$

[7] $H + C_2H_4OH \rightarrow C_2H_5OH^* \rightarrow$ Products

could account for the products observed, especially the C_2H_4, although the authors argued against it (18). This chemical activation system merits further exploration, especially as the low-energy channel, reaction [1], would be favoured and also perhaps reactions [3] and [4] would be favoured relative to reactions [2] and [5], for which the energy of $C_2H_5OH^*$ would be close to threshold.

The dependence of the relative rates of these primary processes on pressure and fluence is not yet fully understood, nor is the difference between the results with HF and CO_2 lasers. The present measurements of absorption and decomposition using a short-pulse (10 and 60 ns) CO_2 laser, in which there are effectively no collisions during the pulse, were undertaken to explore the pressure and fluence dependence under these conditions, to separate the effects of collisions on the absorption and the decomposition, and to distinguish between the effects of fluence and intensity.

2. Experimental

The ethanol used was prepared as follows. A 15-g sample of 4A molecular sieve was activated by heating at 550°C for 1 h. After the molecular sieve was cooled to room temperature, 50 mL of anhydrous alcohol was added slowly. This sample was stored in a sealed vessel for several weeks and the water content was determined by a Karl–Fischer titration to be less than 0.05% by weight. Small aliquots were transferred on a glass vacuum line equipped with greaseless stopcocks for use in MPA experiments. The samples were regularly degassed by repeatedly freezing in liquid nitrogen and pumping.

Both the HF and CO_2 lasers have been described elsewhere (19, 21). MPA photoacoustic results and the corresponding calibrations by transmission were recorded on a microcomputer-based data acquisition system (22). In the transmission experiments cells of 31.9, 88.9, and 300.2 cm length equipped with NaCl windows were used for the HF laser experiments and the 88.9-cm cell was used with the CO_2 laser. The results were analyzed as previously described (22). Cells used for the MPD experiments were made from 22 mm inside diameter Pyrex tubing, 10 cm long. NaCl windows were fitted to the ends at about a 5 degree angle (to prevent reflections back into the lasers). The laser beam was focussed at the centre of the cells using BaF_2 lenses of focal lengths 50 or 100 cm with the fluence at each pulse length adjusted using calibrated CaF_2 filters. Analysis of products and ethanol depletion was done on a Hewlett–Packard 5700A gas chromatograph with flame ionization detection. The Poropak T-18 column, 3 mm diameter × 2.44 m length stainless steel, was held at 60°C for 4 min and then heated at 16 degrees per minute to 140°C and held at that temperature. Calibrations of peak areas were obtained from authentic samples and checked frequently.

3. Results and discussion

3.1 HF laser MPA of ethanol

The results of both the transmission measurements and the calibrated photoacoustic measurements with HF laser irradiation are summarized in Table 1. The uncertainties quoted are for 95% confidence intervals for the linear least-squares fits. These indicate the precision of the measurements but, for the photoacoustic results, uncertainties in the calibration give an accuracy of about a factor of 2 in reported excitation. For HF laser measurements, the fluence available for transmission measurements is low and these results do not overlap with the photoacoustic results. A sample measurement at 400 Pa is shown in Fig. 1. At higher pressures the gap between transmission and photoacoustic results decreases, while it increases at lower pressures.

The HF laser $P_1(7)$ photons at 3644.16 cm^{-1} are absorbed by the OH stretching mode, a rather weak absorption feature in the infrared spectrum of ethanol (23). The excitation, given as $\langle n \rangle$, the average number of photons absorbed per molecule, showed no measurable dependence on the pressure of ethanol. Measurements of other molecules such as CDF_3 (24, 25), CH_3OH (26), and cyclobutanone (27) showed a first-order relaxation as $P\tau$,

[5] Also, H. M. Frey, private communication.

TABLE 1. Absorption of HF and CO_2 laser radiation by C_2H_5OH. The observations have been fitted to the form $\log \langle n \rangle = a + b \log \phi$. The fluence, ϕ, is the fluence at beam center (24)

the product of pressure and laser pulse duration, increased. This was interpreted as rotational relaxation giving access to a larger fraction of the molecules. For the experiments reported here, the smallest $P\tau$ product was 8000 Pa ns whereas the other systems mentioned were seen to be essentially fully relaxed at a $P\tau$ of 4000–8000 Pa ns. Presumably, if it had been possible to use lower pressures than 27 Pa, a pattern similar to that of the other molecules might have been observed. In section 3.2, a test of this hypothesis for a different excitation mode using the shorter CO_2 laser pulses is reported.

Previous work (28) on the MPA of HF laser photons by ethanol was not calibrated by transmission; the response of the microphone was taken to be the same for all the alcohols studied and calibrations were performed only with methanol. The present experiments show that the microphone response varies less with pressure in ethanol than in methanol. The pressure dependence previously reported is not seen when separate calibration experiments with ethanol are done; however, the behaviour with changing fluence is the same. For fluences above about 1 J/cm^2, the slope of $\log \langle n \rangle$ against log fluence is greater than one, indicating that molecules, once excited, are excited further more easily than in the ground state.

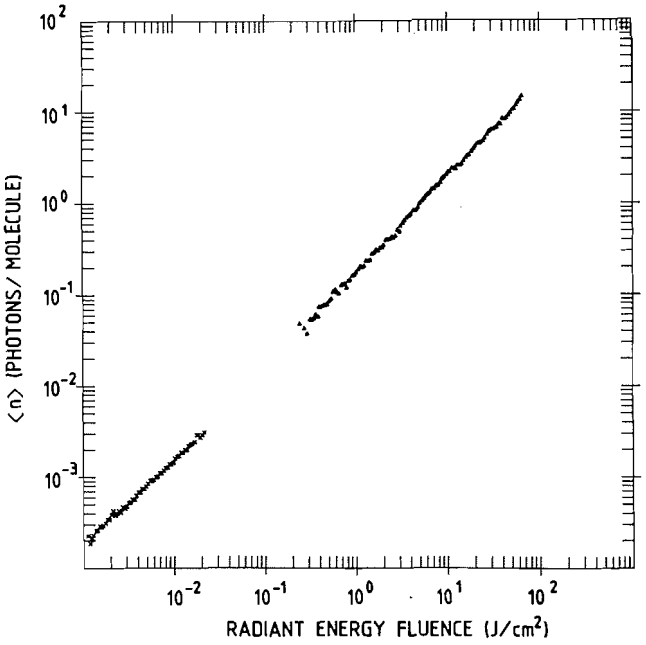

FIG. 1. The MPA of the HF laser $P_1(7)$ line by 0.4 kPa ethanol using a pulse of width 300 ns. The transmission results (×) are extrapolated from the low fluence range to the higher fluences of the photoacoustic results (△) and are used for calibration of the latter.

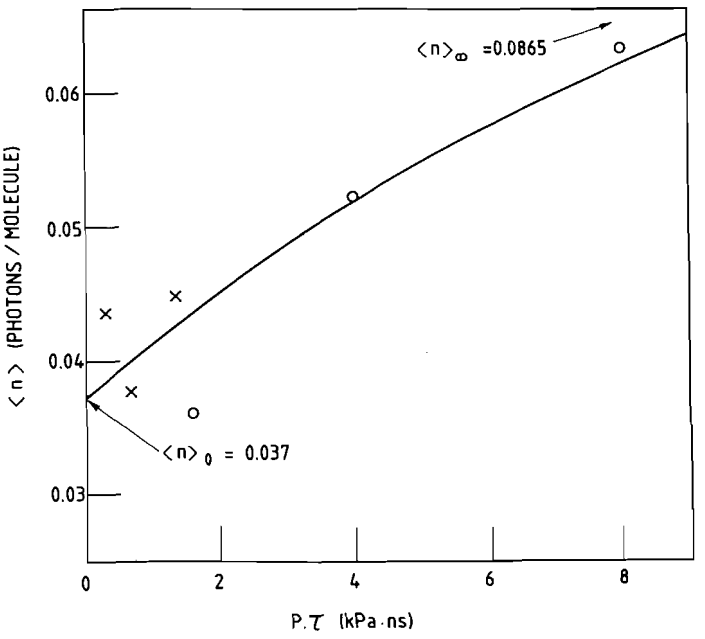

FIG. 2. The dependence of $\langle n\rangle(\phi)$ on $P\tau$ (where P is ethanol pressure and τ is laser pulse duration) for MPA of the CO_2 9P(16) laser line by ethanol. (×) τ = 10 ns, (○) τ = 60 ns. The fluence, ϕ, is the fluence at beam centre (24).

3.2 CO_2 laser MPA of ethanol

Measurements with smooth CO_2 laser pulses of 10 and 60 ns FWHM were made at low pressures to investigate the region of pressure pulse width below 8000 Pa ns, the lowest accessible with the present HF laser. The results are summarized in Table 1. An increase in excitation with increasing $P\tau$ was observed for the region studied. The results at each value of $P\tau$, for a fluence at beam centre of 0.02 J/cm^2, were fitted to eq. [8] characteristic of the relaxation model used with other molecules (24, 27)

$$[8]\quad \langle n\rangle(P\tau) = \langle n\rangle_\infty + (\langle n\rangle_0 - \langle n\rangle_\infty)\exp[-kP\tau]$$

Values of $\langle n\rangle_0$, $\langle n\rangle_\infty$, and k were found to be 0.037, 0.0865, and 8.9 × 10^{-5} Pa^{-1} ns^{-1}, respectively. Figure 2 shows the results at 0.02 J/cm^2 and the curve for the relaxation model. For CO_2 laser excitation, rotational relaxation of ethanol occurs at a rate comparable to other molecules. At 8000 Pa ns, the excitation has reached over 75% of its asymptotic value. The lack of pressure dependence with HF laser irradiation is consistent with this relaxation time.

For each pressure and pulse width, the CO_2 laser excitation of ethanol showed a bend in the plot of log $\langle n\rangle$ vs. log fluence at about 4 J/cm^2. At these fluences, a pressure rise was observed in the microphone cell, which was attributed to decomposition of the ethanol. The ethanol was replaced frequently to ensure the concentration did not change. Separate decomposition experiments showed measurable decomposition at these fluences. Thus we cannot determine from these experiments whether the observed bend is caused by some bottleneck to further absorption or whether some of the absorbed energy is being used for chemistry and therefore is not contributing to the pressure pulse measured by the microphone.

3.3 Comparison of HF and CO_2 laser excitation

For this comparison, we cannot simply look at $\langle n\rangle$, since the HF photons used are 3.5 times as energetic as the CO_2 photons. Thus we have multiplied $\langle n\rangle$ for the HF laser by 3.5 to compare the average energy of excitation of the ethanol molecules by each laser. Figure 3 shows such a comparison for the photoacoustic measurements at 27 Pa using the HF laser, with data for the CO_2 laser at two pulse lengths. The CO_2 laser results are independent of laser pulse length indicating no dependence on intensity or bandwidth. (The relative bandwidths of the CO_2 laser pulses has been determined by measuring the collisionless MPA of SF_6. This is described elsewhere (29).) The average level of excitation of an ethanol molecule is about an order of magnitude lower for an HF laser than for a CO_2 laser at the same fluence. At fluences high enough for decomposition to occur, the difference in the photoacoustic signal is not so large, but this might be a consequence of the type of measurement and not a true difference in the behaviour of the molecule. Any effect of the larger $P\tau$ for the HF laser would decrease the difference in excitation.

The lowest pressure used for the HF laser, 27 Pa, is still sufficiently high to allow access to most of the molecules by rotational hole filling. The complementary measurements with the CO_2 laser support this interpretation. At low pressures, we found that excitation of ethanol is at least a factor of 3 easier using a CO_2 laser than with an HF laser. Even though 3.5 times as many photons must be absorbed, the larger cross section at the CO_2 laser frequency more than compensates. The cross section at 3644 cm^{-1} increases slightly with the level of excitation, as determined in earlier work. Ethanol is an example of a large molecule with several vibrational modes that can be excited, and it is probably the strength of the absorption, rather than the magnitude of the vibrational quanta, that determines the easiest way to excite the molecule.

3.4 MPD studies

3.4.1 Reaction products

As in previous MPD studies, the major product under all conditions was C_2H_4 (54–99%), presumably accompanied by

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/07/12
For personal use only.

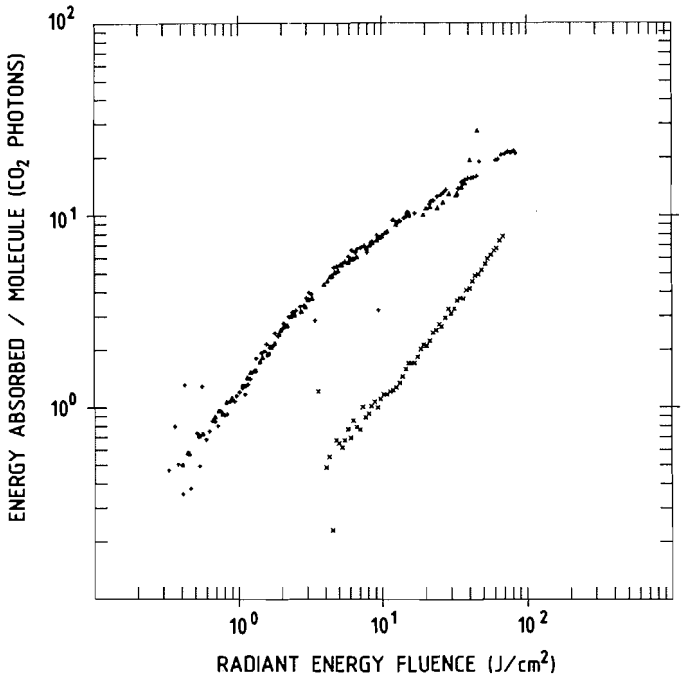

FIG. 3. A comparison of the excitation levels reached pumping ethanol with either an HF or a CO_2 laser. To compare energies of excitation, $\langle n \rangle$ for the HF laser has been multiplied by 3.5 and is still lower than the CO_2 laser excitation of the same fluence. CO_2 laser; (△) τ = 10 ns, (+) τ = 60 ns. HF laser: (×) τ = 300 ns.

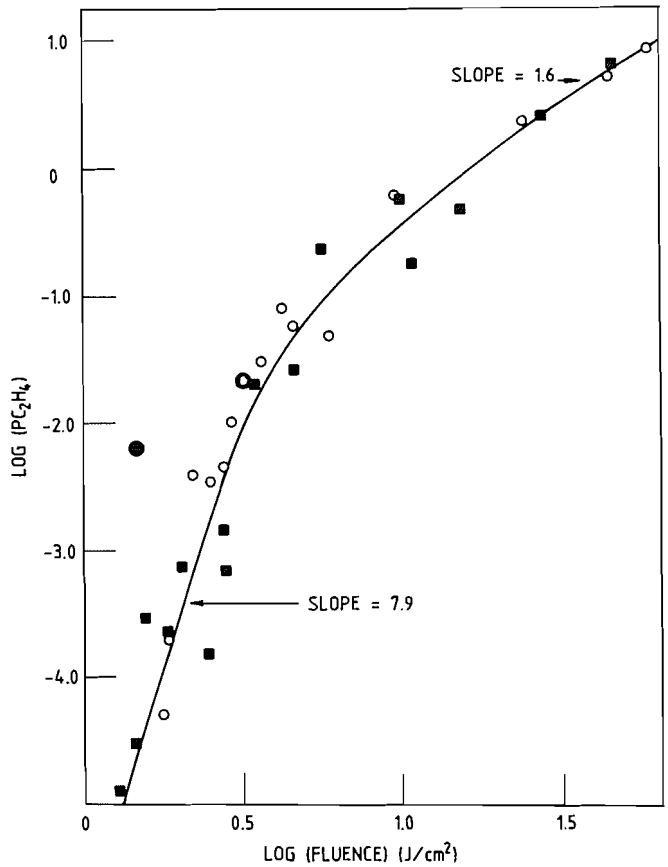

FIG. 4. The probability of decomposition of C_2H_5OH to form C_2H_4 versus laser fluence for the CO_2 laser, $9P(16)$ line. (■) τ = 60 ns, (○) τ = 10 ns and (●) is an average for 6 experiments.

H_2O, which was not measured. Minor products in approximately diminishing order of importance were CH_3CHO, C_2H_6, CH_4, C_2H_2, and C_3H_6, while even smaller yields of ethylene oxide, propane, and several other C_3 and C_4 hydrocarbons were detected but were not measured systematically. Product yields, expressed as partial pressures generated per pulse in the reaction vessel, are given in Table 2 for a variety of experimental conditions. Also given are the ratios of the minor products to C_2H_4, and values of $P_{C_2H_4}$, the probability of decomposition to form C_2H_4 in a single pulse for a molecule of C_2H_5OH in the reaction zone. The latter was taken to be the central cylindrical portion of the focussed beam with dimensions given by radius = $0.5f\theta$, and length = 2(radius × f)/R, where f = focal length of lens, θ = divergence in radians, and R = radius of unfocussed beam. Reaction volumes thus obtained were 0.331 and 0.021 cm^3 for f = 100 and 50 cm respectively. Values of $P_{C_2H_4}$ were approximately corrected for depletion of C_2H_5OH in the reaction vessel over the course of multipulse experiments, taking C_2H_4 formation as a rough measure of depletion (ignoring other products). No correction was made for depletion in the reaction zone during a single pulse, and complete renewal between pulses of the reagent in the reaction zone from the bulk of the reaction vessel was assumed.

3.4.2 Dependence on fluence and intensity

Figure 4 shows the dependence of $P_{C_2H_4}$ on fluence at constant pressure of 0.13 kPa for two pulse lengths, 10 and 60 ns, for the CO_2 laser $9P(16)$ line. A strong dependence is seen at low fluence, with the slope of the log–log plot about 8. The dependence becomes less at high fluence as $P_{C_2H_4}$ approaches unity, corresponding to decomposition of all the molecules in the reaction zone in a single pulse. At the highest fluence, above about 20 J/cm^2, values of $P_{C_2H_4}$ exceed unity, indicating decomposition outside the central cylindrical zone; this is confirmed by the final slope of 1.6, close to the value of 1.5 expected for this situation (30). Within the experimental scatter, values of $P_{C_2H_4}$ appear to be independent of pulse duration, and hence, at a given fluence, independent of intensity or bandwidth.

Figure 5 shows how the four minor products, CH_3CHO, C_2H_6, CH_4, and C_2H_2, expressed as ratios to C_2H_4, varied with fluence. Only the smoothed curves are shown here to minimize congestion. All the individual data points are given in Table 2. In each case a marked increase of the ratio with increasing fluence was observed, with a definite dependence on pulse length, and hence, at a given fluence, on intensity; values of product ratios are significantly higher for the 10-ns pulse.

3.4.3 Dependence on pressure

The pressure dependence of $P_{C_2H_4}$ at 9(±1) J/cm^2 shows a downward trend at higher pressures, which can probably be accounted for by attenuation of the laser radiation in the central reaction zone by the absorption in the converging beam between the front window and the reaction zone. There is again no significant difference between the 10-ns and 60-ns pulses. A series of experiments at a higher fluence of about 50 (±8) J/cm^2 showed no trend of $P_{C_2H_4}$ with pressure.

The ratios CH_4/C_2H_4, C_2H_2/C_2H_4, and CH_3CHO/C_2H_4 all show an upward trend with pressure for irradiation at both 9 and 50 J/cm^2, and all four product ratios show a significant dependence on pulse length.

3.4.4 Primary processes

As in previous MPD studies, reaction [1] is always the most important, ranging from ~99% of the decomposition at the lowest fluence to ~54% at the highest fluence and pressure. In

these experiments and previous work (3, 6), yields of C_2H_4 were unaffected by the addition of O_2, an efficient radical scavenger; hence it is most probably formed in a simple unimolecular dehydration. Reaction [3] is generally the third most important, varying from about 1 to 24% of reaction [1]. In the present experiments it was followed by measuring the acetaldehyde. In previous work (3), only H_2 was measured; neither H_2 nor CH_3CHO was affected by the addition of O_2, so again a simple unimolecular elimination is suggested. Reaction [4], similarly, is postulated as before (3), because yields of CH_4 were unaffected by O_2. Reaction [2] is suggested as a source of CH_3 radicals that form C_2H_6 by combination. Their removal by reaction with O_2 accounts for the observed suppression of C_2H_6 formation. From the yield of ethane, and recognizing that perhaps half of the CH_3 radicals combined with CH_2OH, the extent of reaction [2] may be taken as 4 times the yield of ethane, making reaction [2] the second most important primary process, rising to as much as 80% of reaction [1] at the highest fluence. Reaction [5] probably occurs to a minor extent, accounting for the small yields of propane and butane observed, formed by recombination reactions of C_2H_5 and CH_3. Evidence for reaction [5] also comes from the direct observation of OH in the system at high fluence (7).

3.4.5 Secondary processes

Propylene is always a very minor product (<3% of C_2H_4); the source is not clear, but several secondary reactions involving C_2H_4 or CH_3CHO can be suggested.

Acetylene, also a minor product, shows a strong dependence on fluence. Its yield does not depend on conversion, but it could be formed by secondary decomposition of C_2H_4 during a single pulse, perhaps by multiphoton absorption by vibrationally excited C_2H_4 product.

The yield of CH_3CHO relative to C_2H_4 declines with increasing extent of reaction; this could be due to direct decomposition by absorption of laser radiation, or perhaps by secondary attack by CH_3 or other radicals, and is probably responsible for the CO reported as a product in some studies (5, 6, 9). Carbon monoxide was not a significant product in a previous investigation of the system (3), and no analysis was made for it in the present experiments. The possibility that CH_3 radicals were formed by the decomposition of CH_3CHO is not supported by the fluence dependence of C_2H_6 formation, and the primary dissociation, reaction [2], remains the most probable source of CH_3.

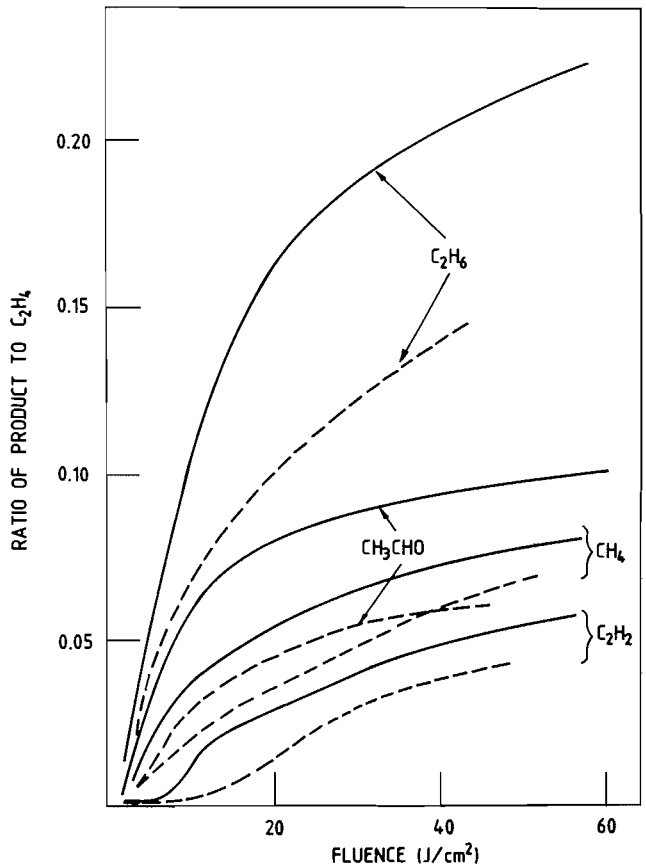

FIG. 5. The product ratios for C_2H_6, CH_3CHO, CH_4, and C_2H_2 compared to C_2H_4. For each product the solid line is a smooth curve of results using a 10-ns pulse and the dashed line is for a 60-ns pulse.

3.4.6 Energies and relative rates of primary processes

The energetics of reactions [1]–[4] are summarized in Fig. 6. There is no direct experimental information about the energy barriers for any of these reactions.

The present data, notably the dependence of product ratios on fluence and pulse length, and all previous MPD studies support the conclusion that reaction [1] is the lowest-energy channel, in accord with empirical (12) and theoretical (13) predictions. The relative rates of reactions [3] and [2], however, do not support the relatively high barrier of 469 kJ/mol suggested for the

For personal use only.

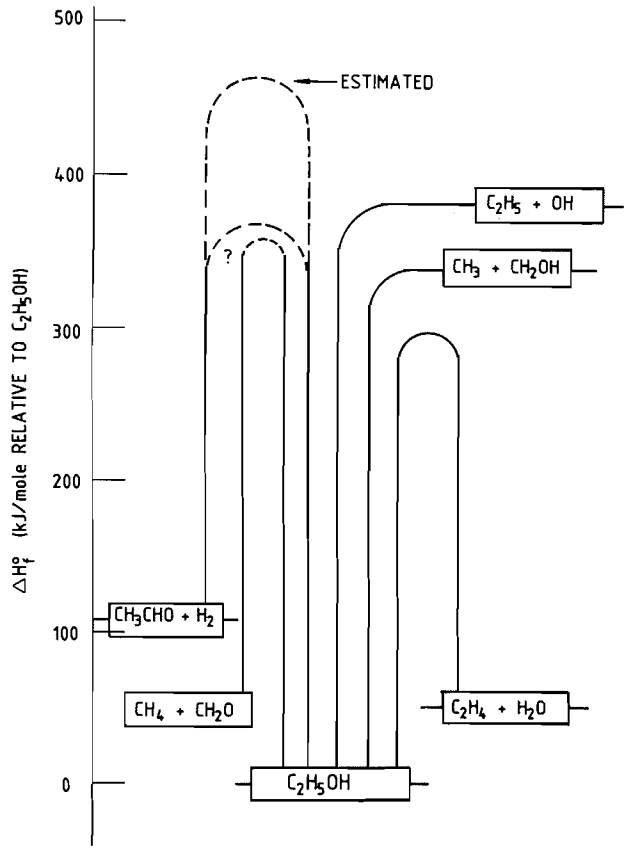

FIG. 6. The energetics of reactions [1]–[4]. Dashed lines indicate uncertainty in the activation energies of the channels.

former (13); the similar fluence dependence of reactions [3] and [4] to that of reaction [2] in fact points to similar activation energies for all three. The activation energy for reaction [2] must be close to its endothermicity (343 kJ/mol), while a frequency factor of $A_2 = 10^{16.4}$ s^{-1} has been estimated by Tsang (12).

Independent confirmation of the occurrence of reactions [1]–[5], and estimates of their relative rates, is obviously desirable. Reaction [1] appears well established, with Arrhenius parameters probably close to those estimated by Danen (2) and Tsang (12), and there seems little doubt about reactions [2] and [5]. Reactions [3] and [4] are more suspect, with high barriers predicted for both (13). Evidence for their occurrence as simple unimolecular processes relies heavily on the lack of effect of O_2 on H_2, CH_4, and CH_3CHO production, and it is just possible that free-radical reactions occurring with vibrationally hot species in the reaction zone, unsusceptible to scavenging by O_2, might account for these products.

3.5 Mechanism of the MPD decomposition

The lack of dependence of $P_{C_2H_4}$ on pulse duration suggests that little or no collisional deactivation took place during the pulse, not unexpected at these pressures and pulse lengths. Hence, to a first approximation the total energy deposited during the pulse, rather than its rate of deposition, determined the number of molecules pumped to levels capable of decomposition by reaction [1]. The enhancement of the higher-energy channels described by reactions [2]–[4], relative to reaction [1], with the 10-ns pulse (Fig. 5) shows, however, that the *energy* of the decomposing molecules does depend on intensity as well as fluence. This implies that there was appreciable decomposition via reaction [1] during the pulse in competition with up-pumping by the laser radiation, so that at higher intensity, higher energy levels were attained before decomposition. One might therefore expect some decrease in $P_{C_2H_4}$ as reactions [2]–[4] became significant; the extent of the latter reactions, however, was only a small fraction of that of reaction [1], except at the highest fluence, and the corresponding decrease in $P_{C_2H_4}$ would hardly have been noticed in Fig. 4; there may also have been a small countervailing enhancement of reaction [1] itself at the higher intensity.

The dependence of $P_{C_2H_4}$ and the product ratios on pressure is more complex. The decomposition can be considered the sum of two processes, the first a collision-free decomposition of excited molecules during and shortly after the pulse, the second a decomposition of molecules whose energy content and distribution have been modified by collisions, largely after the pulse. The first must be independent of pressure; the second will be affected by pressure and will merge at long times and high pressures into a bulk thermal decomposition. The ratio of the first process to the second will decrease with increasing pressure. The factors affecting the relative efficiencies of the collision-free and collision-modified processes are manifold and complex, involving the energy distributions of the decomposing molecules in each, the radiation intensity, the pulse length, and the mechanism and rate of cooling after the pulse, the last factor depending in turn on the dimensions of the reaction zone. In two previous studies (3, 6), the overall probability of decomposition clearly declined with increasing pressure, indicating a lesser efficiency for collision-modified processes; in the present experiments there is little change in $P_{C_2H_4}$ with pressure, as noted earlier, which combined with the increasing product ratios leads to a modest *increase* in the overall decomposition probability. This is in agreement with the MPA observations shown in Fig. 2 where more energy is absorbed per molecule in the laser beam. The increase in energy absorbed does not just get collisionally spread and degraded to heat but is used to cause chemical reaction. What is clear, however, from this and all previous studies, is that reactions [2]–[4] increase with respect to reaction [1] with increasing pressure. This would appear to indicate a higher average energy for the molecules decomposing in collision-modified reactions compared with collision-free decomposition.

This paper is dedicated to Professor J. A. Morrison

VENKAT BHETHANABOTLA and WILLIAM STEELE. Can. J. Chem. **66**, 866 (1988).

Molecular dynamics computer simulations are reported for O_2 physisorbed on the graphite basal plane at 45 K. Surface coverages ranged from the low density monolayer through the compressed monolayer up to roughly two layers. Thermodynamic properties, orientational distribution functions, and two-dimensional structure factors are presented. The time-dependent translational motion is characterized both by computer-generated trajectory plots and by evaluation of the mean square in-plane displacements as a function of time. It is concluded that the O_2 orientations shift from predominantly surface-parallel to surface-perpendicular as the first layer density increases, in agreement with deductions from experiment. The structure factors indicate that some translational ordering is present in the fluid phases and that the bilayer is a composite made up of a solid monolayer plus a fluid overlayer; these observations are in agreement with recent experimental studies of this system.

VENKAT BHETHANABOTLA et WILLIAM STEELE. Can. J. Chem. **66**, 866 (1988).

On rapporte les résultats de simulations par ordinateur de la dynamique moléculaire du O_2 physiquement adsorbé sur du graphite basal plan, à 45 K. Les taux de surface qui sont couverts vont de la monocouche à faible densité à pratiquement des doubles couches, en passant par la monocouche comprimée. On présente les propriétés thermodynamiques, les fonctions de distribution d'orientation ainsi que les facteurs de la structure bidimensionnelle. On a caractérisé le mouvement de translation qui varie avec le temps par le biais de diagrammes de trajectoires obtenus à l'aide d'un ordinateur ainsi que par une évaluation des valeurs quadratiques moyennes des déplacements dans le plan en fonction du temps. On en conclut que, au fur et à mesure qu'on augmente la densité de la première couche et conformément aux déductions qui ont été faites en se basant sur les expériences, les orientations du O_2 passent d'une position principalement parallèle à la surface à une position perpendiculaire à la surface. Les facteurs de structure indiquent qu'il existe un certain ordre de translation dans les phases fluides et que la double couche est une composite formée d'une monocouche solide et d'une couche superficielle liquide; ces observations sont en accord avec les études expérimentales récentes effectuées dans ce système.

[Traduit par la revue]

1. Introduction

The structures and transitions of the low temperature solid and liquid phases in monolayer O_2 adsorbed on the graphite basal plane are currently a subject of considerable interest (1–9). Experimental studies reveal considerable differences between oxygen and the analogous N_2 monolayer/graphite system (1). We have undertaken molecular dynamics computer simulations of both materials adsorbed on a model graphite substrate in an attempt to better understand the reasons for the contrasting behavior. It appears that simple models of the intermolecular interactions can be found for these systems which produce simulated thermodynamic and dynamic properties in reasonably good agreement with experimental data. In these models, the sizes and shapes of N_2 and O_2 are similar, but the electrostatic quadrupole moments, which are known from independent measurements, are quite different. This difference seems to be capable of accounting for much of the contrasting monolayer phase behavior. In previous work, molecular dynamics simulations of O_2 layers were undertaken at fixed density but temperatures varying from 15–60 K (2). One such scan was done for a solid layer that filled only half the surface at low temperature. The structure of this film was found to be an orientationally ordered centered-rectangular lattice at low temperature, in agreement with X-ray and L.E.E.D. measurements. As temperature increased, the solid expanded slightly, melted to a two-dimensional liquid and eventually, vaporized to a two-dimensional gas. Furthermore, the model potential used for the O_2/solid interaction produced a strong preference for orientation parallel to the surface at temperatures up to ~60 K. A similar temperature scan at a larger areal density showed the same low temperature ordering but different phase behavior at higher temperature due in part to the fact that the adsorbed monolayer is being studied essentially at constant density whereas the patches (actually infinitely long strips after periodic boundary conditions are imposed) are not restricted in this way. It is not surprising to find that melting of the filled-surface monolayer occurs at a higher temperature than the patch and is no longer a first order phase change. Of greater interest is the fact that molecular orientation is affected by the increase in density — melting is here accompanied by an increase in the number of molecules with a significant tilt angle relative to the surface. Inasmuch as experiments indicate the presence of several slightly different phases of surface-tilted molecules at high monolayer densities, we have carried out a simulation scan of density at a fixed temperature in order to learn more about the properties of the high density monolayer and the bilayer of O_2 adsorbed on graphite. This paper reports the results obtained for such a scan taken at 45 K with areal densities taken in the region of the θ phase observed in L.E.E.D. experiments (5) (more precisely, in the region of liquid – θ-phase coexistence). It has been suggested that this phase is ordered but incommensurate. These simulations confirm the existence of unusual behavior in this part of the phase diagram and help elucidate the properties of the θ-phase by providing information concerning both the distribution of molecular orientation relative to the surface and the translational dynamics of the monolayer.

2. Details of the simulation

The work reported here is an extension of the previous simulation study of this system (2). Thus, the intermolecular interactions and the simulation algorithm were kept the same in

0.1145	1.000	4 000	20 000
0.1908	0.699	9 000	9 750

order to allow comparisons between the two sets of results. The O_2–O_2 and the O_2–graphite energies were modelled as pairwise sums of Lennard–Jones site–site interactions. Values of the well-depth and size parameters used are listed in Table 1. The molecular dynamics was based on a predictor-corrector algorithm, with molecular orientations specified by quaternions and with periodic boundary conditions in the x,y directions parallel to the surface. No molecules were observed to leave the adsorbed phase under the conditions of these simulations. Coverages studied and numbers of timesteps during equilibration and during computation are listed in Table 2. A timestep of 0.0049 ps was used throughout, so that the durations of the computational parts of the simulations were from 48 to 98 ps. Reduced units are used so that distances are reduced by 2.46 Å, the lattice spacing for the graphite basal plane, and energies are reduced by the ϵ_{gs}, the site–site well-depth for the C—O site interaction. Note that the densities listed in Table 2 can be converted to multiples of the registered lattice density by dividing by 0.0636 Å^{-2}. In these simulations, the number of O_2 molecules was 192 for the most part (208 were taken in the run at ρ = 0.0735 Å^{-2}); coverages were varied by changing the size of the simulation cell. In all but the highest density, the molecules were initially placed in an orientationally ordered monolayer. During the equilibration period, in-plane disordering was essentially complete and the out-of-plane orientational ordering, while not lost, changed significantly from the initial surface-parallel configuration. The initial configuration for the highest coverage studied was set with 120 molecules in layer 1 and 72 in layer 2, both in an ordered configuration (consequently, layer 2 was initially a patch that covered ~2/3 of the surface). As time went on, layer 2 spread out into a fluid phase distributed over the entire surface (detailed evidence for this will be presented below) and seven molecules changed from layer 1 to layer 2. Because layer changes produce large temperature jumps in a small number of molecules running in a constant energy simulation, a constant temperature algorithm due to Evans *et al.* (10) was employed. As it turned out, no molecules changed layers during the computational parts of the simulations (all layer changes observed were actually during the equilibration stage in the high-coverage system). To ensure thermodynamic equilibrium, it would have been desirable to run long enough for such interchanges to occur in the bilayer film but the temperature chosen was apparently somewhat too low and the duration of the simulation not long enough for this to happen. The fact that molecules were squeezed out of the first layer during equilibration indicates that the configurations observed are at least close to equilibrium.

Equilibrium properties evaluated in these simulations included a number of average potential energies, the structure factor $S(\boldsymbol{k})$, and the distributions of in-plane and out-of-plane orientation angle. In particular, the total potential energy of an

TABLE 3. Average O_2–O_2 interactions per molecule (divided by ϵ_{gs})

	Average number		
ρ (Å^{-2})	Layer 1	Layer 2	Between layers 1 and 2
0.0735	−9.39	—	—
0.0954	−13.35	—	—
0.1145	−15.04	—	—
0.1908	−15.17	−10.51	−5.66

adsorbed O_2 molecule was divided into the average molecule–solid energy $\langle u^*_{gs}\rangle$, and the average molecule–molecule energy $\langle u^*_{mm}\rangle$. For the bilayer system, u_{mm} was further subdivided by evaluating the interaction of a molecule in the nth layer with its neighbors in the same layer ((11) or (22)) and with its neighbors in a different layer (12). Results of this calculation are given in Table 3.

The structure factor is defined the usual way for a two-dimensional phase:

$$S(\boldsymbol{k}) = \langle \exp i\boldsymbol{k}\cdot\boldsymbol{\tau}_{12}\rangle$$

where $\boldsymbol{\tau}_{12}$ is the center-of-mass separation of a pair of molecules (both in the same layer) and the two-dimensional wave vector $\boldsymbol{k}$ is restricted to fit into the simulation box. (That is, $\exp(i\boldsymbol{k}\cdot\boldsymbol{r})$ must be the same function in each member of the infinite array of box images produced by the periodic boundary conditions.)

Two orientational distribution functions were simulated: the distribution of in-plane angle and the distribution of cos β where β is the angle between a molecular axis and the normal to the surface. Of these, only $P(\cos\beta)$ indicated significant ordering and thus, plots shown here are limited to that function. Note that $P(\cos\beta)$ for the bilayer system was evaluated separately for first and for second layer molecules.

3. Results

Considerable insight into the properties of these simulated films can be gained by viewing the trajectories of the center-of-mass (c.o.m.) motions of the O_2 molecule, projected onto the surface. These are shown for time intervals of 50 ps in Fig. 1a for three of the monolayer systems. However, one must also view the distribution of the orientation of the molecular axes relative to the surface to understand the changes in film structure with density. Appropriate plots are shown in Fig. 2. Taken together with Fig. 1a, we see that the O_2 layer at ρ = 0.076 Å^{-1} is characterized by relatively random c.o.m. motion with most of the molecules parallel to the surface. As density increases to 0.0954, the c.o.m. motion becomes much more solid-like, with

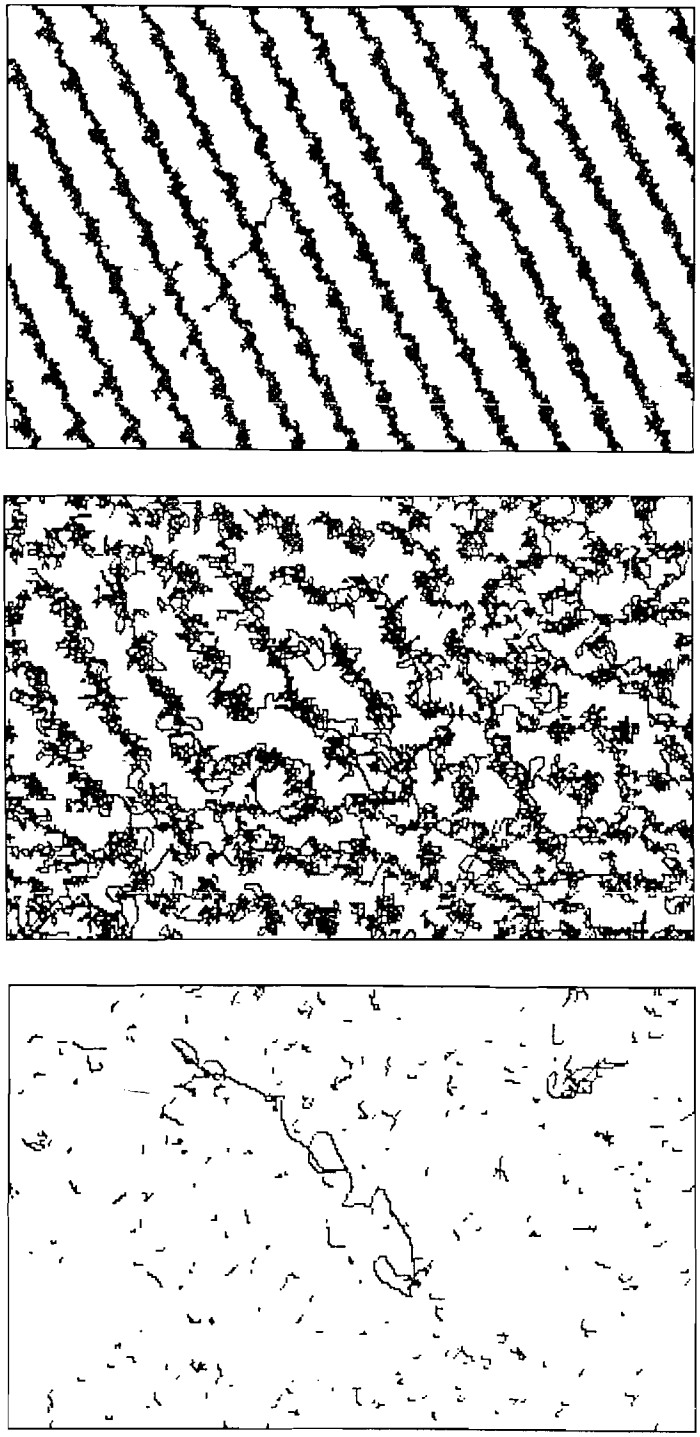

FIG. 1. Projections in the plane of the computer-generated trajectories of the O_2 molecules are shown here for four of the surface coverages studied. Part (*b*) shows results for the highest density ($\rho = 0.1908$ Å^2). At the highest density, molecules may be found in three layers, and trajectories are shown for each layer separately in part (*b*). The fully solidified layers "float" slowly across the surface — an artifact of the simulation model which provides no mechanism for pinning the solids in place.

some "skating" motion of the entire solid. (This is a physically unrealizable consequence of the perfectly periodic surface — in reality, pinning at a defect will certainly occur.) Note, however, the change in orientational distribution to one where a significant fraction of the molecules are standing on end. At a density of 0.01145, the change to a hexagonal solid-like layer of molecules oriented nearly perpendicular to the surface is complete. The average potential energies of the molecules in the first layer that are shown as a function of density in Fig. 3 are readily understood in terms of this picture. The reduced gas–solid energy drops from the "patch" value of −32.8 to −23.7 as the molecules are forced to reorient from mainly parallel to mainly perpendicular with increasing density (6). At the same time, the O_2–O_2 interaction becomes more attractive because the well-depth for pairs of molecules parallel to each other (but perpendicular to the surface) at optimum separation

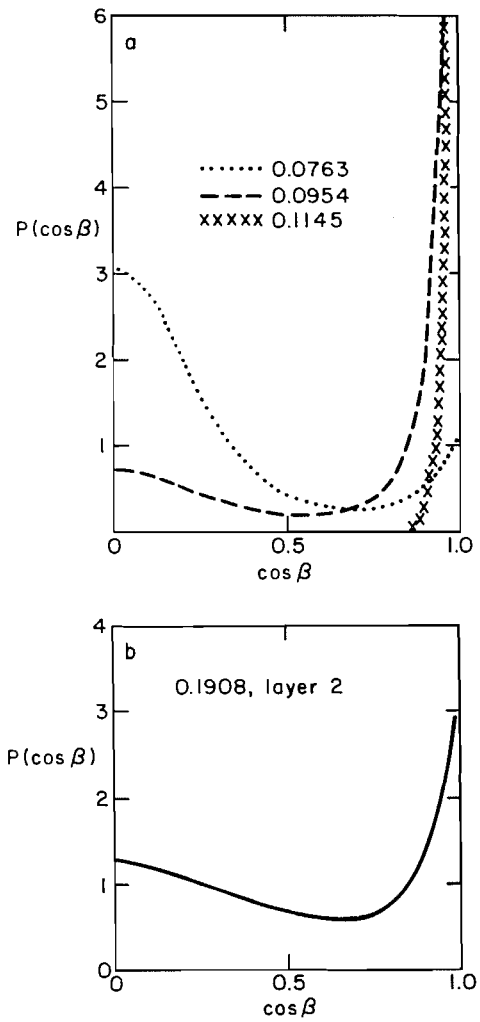

FIG. 2. Distributions of the cosine molecular orientation angle relative to the surface normal are shown here for the first layer molecules at four of the densities simulated. The distributions become extremely sharp at cos β = 1.0 for the two highest densities considered and actually go off-scale for ρ = 0.0954, 0.1145, and 0.1908 Å^{-2} (first layer). Part (*b*) shows the orientational distribution for the second layer molecules in the 0.1908 system.

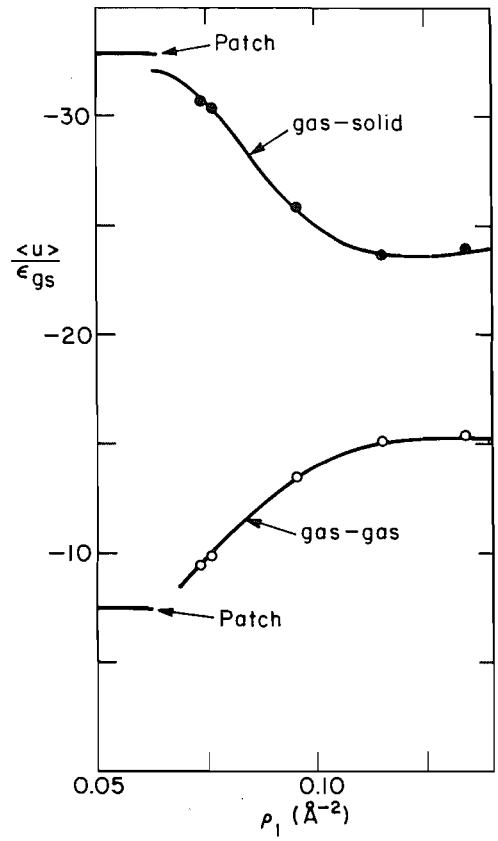

FIG. 3. Average potential energies per first layer particle are plotted here as a function of the first layer density. Circles show the simulation data and curves are drawn as an aid to the eye. At densities lower than ~0.07 Å^{-2}, patches of adsorbed molecules form with indicated energies obtained in a previous study (2).

distance is deeper than for pairs of molecules randomly oriented in the plane of the surface.

At the highest surface coverage considered (ρ = 0.1908 Å^2), the first layer is somewhat compressed (see Table 2), but considerable second and even some third layer adsorption occurs, as shown by the trajectory plots in Fig. 1b. The first layer is a well-organized solid of molecules perpendicular to the surface. Figure 3 indicates that both the O_2–solid and the O_2–O_2 interaction in this layer are little changed in going from ρ_1 = 0.1145 to ρ_1 = 0.135. (Presumably the alterations in energy with changing orientation and distance are balanced to give a negligible net change in energy in this range.)

According to the L.E.E.D. data, most of these simulations were carried out in a region in the phase diagram corresponding to two-phase equilibrium between fluid and θ-phase, where the θ-phase is an incommensurate phase exhibiting weak six-fold diffraction peaks. Thus, we have evaluated structure factors for these films in an effort to see whether the model system reproduces the observations. The three-dimensional views of $S(\boldsymbol{k})$ shown in Fig. 4 indicate that this is the case. The first picture shows the weak ring observed for a true two-dimensional fluid at 65 K. At the lower temperature of the systems studied here, peaks are observed with six-fold symmetry even at the low densities. These peaks sharpen considerably and move outwards as the first layer density increases. Specifically, the k^* values for the maxima in $S(\boldsymbol{k})$ occur at 0.705, 0.74, 0.84, and 0.91 for ρ = 0.0735, 0.0765, 0.0954, and 0.1145, respectively. For the highest coverage, the maximum in $S(k)$ for the first layer occurs at 0.90. The difference between this value and that for ρ* = 0.1145 is probably not significant. It could well be produced by a small mis-match of the lattice with the cell dimensions.

These structure factors are more-or-less equivalent to a mapping of the simulated L.E.E.D. patterns. The peaks sharpen considerably when a solid is formed but do appear to confirm the θ-phase suggested by Fain and co-workers (5).

Figure 5 shows the surface-averaged two-dimensional c.o.m. density ρ*(z*) for four of the densities considered. These plots confirm the description suggested by the energies and orientational distributions. The surface-parallel molecules at

FIG. 4. Pictures of the two-dimensional structure factors $S(\boldsymbol{k})$ for these systems are shown here, together with a reference diagram obtained for the two-dimensional fluid at 65 K (near the two-dimensional critical point). Part (*b*) shows the separate structure factors for the first and second layer molecules present at ρ = 0.1908 Å^2.

$\rho = 0.076$ Å^{-2} form a reasonably compact layer at $z^* = 1.3$, with a shoulder in $\rho^*(z^*)$ at ~ 1.55. As the surface coverage increases, the first layer molecules split into two groups which can be characterized as surface-parallel and surface-perpendicular. For instance, the areas under the peaks for $\rho = 0.0954$ Å^{-2} indicate $\sim 3/4$ perpendicular, whereas the first-layer molecules are essentially all perpendicular at the two highest densities. Note that the shift in layer center-of-mass position z^* as orientation changes should be (and is) equal to half the reduced molecular length of 0.48.

The results shown so far indicate a possible two-phase equilibrium made up of molecules predominantly perpendicular to the surface (up) and parallel (down). However, if these molecules segregate into separate phases, one would expect to find a predominance of up–up and down–down pairs and few up–down pairs (which would occur only along the edges of each phase). This can be studied by determining the center-of-mass pair correlation functions $g(\tau)$ for the three types of molecular pair. We have simulated this function by defining an "up" molecule to have orientation angle less than 45° and "down" to be those with angle greater than 45°. For a random distribution of such molecules, one expects that $g(\tau)$ or, more precisely, the areas under the peaks in this function will be identical for all three cases, whereas phase separation would give $g(\tau)$ nearly equal to zero for the up–down correlation (no neighbors of the other kind). The plots in Fig. 6 show clearly that the number of up–down nearest neighbors is far from zero and in fact, the nearest neighbor peaks have nearly the same areas, indicating a random distribution in the surface layer. The shapes of the peaks change slightly, with the widths and positions of $g(\tau)$ for up–up pairs indicating well-ordered hexagonal array. The peaks are broadened and move out slightly when one or both molecules in the pair lies down. This is not surprising, since rotation in the plane of the surface is relatively free and would give an effective molecular size which is somewhat larger and less well-defined than for a molecule standing on end.

We have also investigated whether or not these phases are fluid by determining the nature of the translation parallel to the surface. The time-dependence of the mean square displacements are shown in Fig. 7. The first layer molecules at the two highest coverages show the characteristic behavior of a solid-like layer (consistent with the trajectory plots of Fig. 1), whereas linear increases with time that indicate diffusional motion are observed at the smaller two coverages.

4. Discussion

Evidently, these simulations indicate the presence of an unusual monolayer phase at densities between ~ 0.07 and ~ 0.11 Å^{-2}. Above 0.11 Å^{-2}, a solid hexagonal phase forms with the molecules orientationally perpendicular to the surface. At densities less than 0.07 Å^{-2}, a fluid phase forms with the molecules orientationally ordered parallel to the surface. In the intermediate regime (θ-phase), the structure factors indicate weak but distinct hexagonal ordering relative to the graphite substrate, in agreement with the L.E.E.D. experiments. However, the mean square displacements are those expected for a fluid phase, not a solid. It is legitimate to suggest that the order observed might be a residual effect of the initial conditions of the simulation which would disappear in a sufficiently long run. Although this hypothesis cannot be strictly proven incorrect, there are several counter-arguments. For instance, the initial configuration is a centered rectangular lattice with all molecules parallel to the surface. Both the symmetry and the orientations change during the equilibration period. Support for the presence

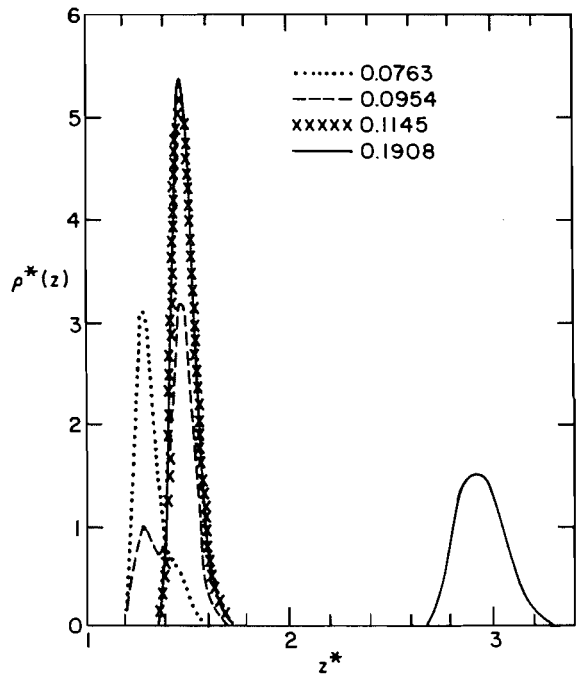

FIG. 5. Center-of-mass two-dimensional densities for four surface coverages are shown as a function of reduced distance from the surface z^*. Reduced density $\rho^*(z^*) = \rho(z)a^2$, with $a = 2.46$ Å.

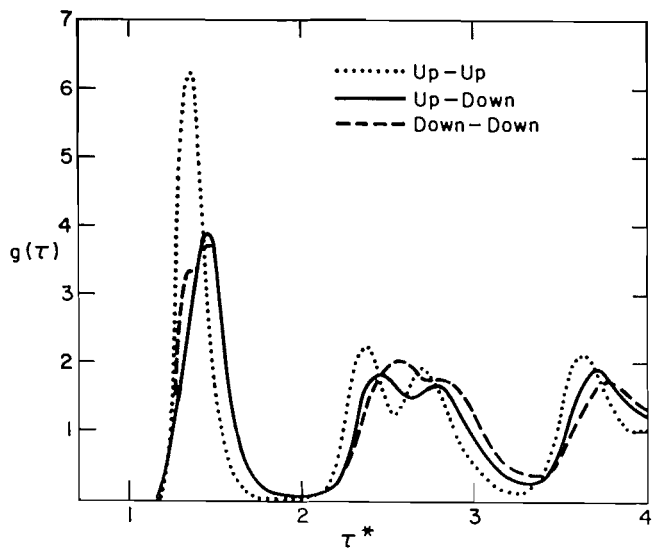

FIG. 6. Pair correlation functions for the orientationally distinct molecules in the layer with $\rho = 0.0954$ Å^{-2} are plotted here as a function of the reduced center-of-mass separation distance in the plane of the surface. A molecule in a hexagonal array has 6 neighbors at the nearest neighbor distance τ_{nn}, 6 at $\sqrt{3}\tau_{nn}$, 6 more at $2\tau_{nn}$, etc. For the up–up function, $\tau_{nn}^* = 1.35$; a second peak occurs at 2.35 (expected value = 2.34) and a third at 2.71 (expected = 2.70). Areas under the peaks in $\pi g(\tau)\tau$ are roughly constant.

of an equilibrium layer also comes from the mean square displacements. If one extrapolates the curve in Fig. 7*a* for 0.0954 Å^{-2} to a time interval of 50 ps, one finds a root mean displacement of ~2 Å, which should be sufficiently large to remove all memory of the initial configuration. (For $\rho =$ 0.0763 Å^{-2}, the r.m.s. displacement is ~6 Å after 50 ps.) In fact, the most significant disagreement with experiment is not a lack of structure, but too much structure, especially at the

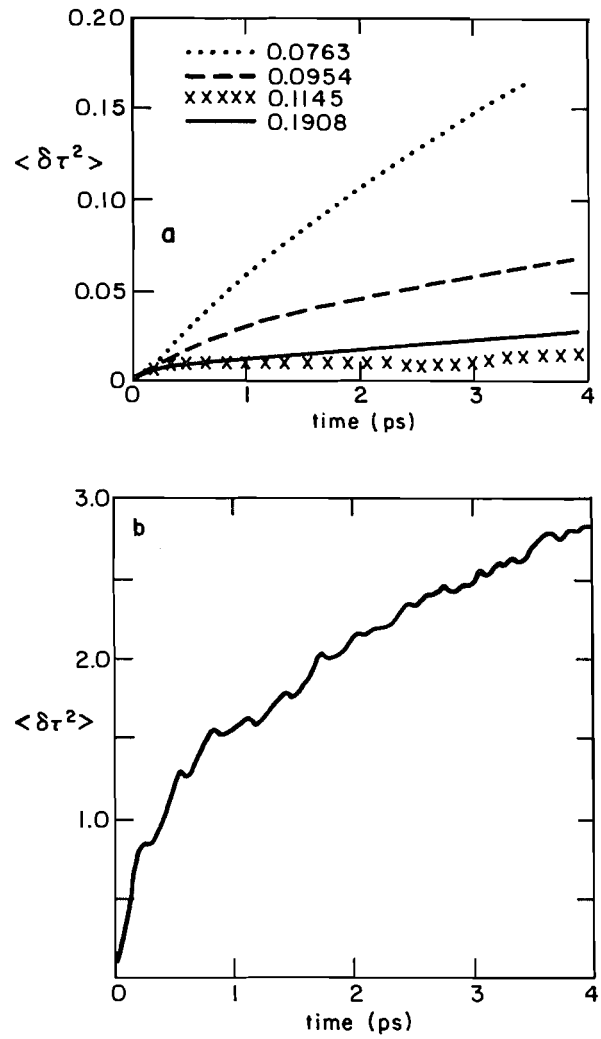

FIG. 7. Mean square displacements (in reduced units) in the plane of the surface are shown for first layer molecules at several coverages (part (*a*)) and for the second layer molecules at the highest coverage (part (*b*)). The oscillations in the curve of part (*b*) are probably of no physical significance. The slow upward drifts of the two lowest plots in part (*a*) reflect the floating of these solid layers across the surface (see Fig. 1).

lowest density. One should remember that O_2–O_2 interaction was not perfectly modelled in this study — in particular, there are indications that the well-depths of the site–site potential used here is ~20% too deep (11). If so, this is equivalent to simulating the real O_2 at a temperature ~20% less than the nominal 45 K used, which should be characterized by more ordering than that observed experimentally at 45 K.

Although we have not yet made an exhaustive study of the bilayer system, the results obtained so far appear to indicate a fluid second layer coexisting with the solid monolayer. Weak orientational ordering in the second layer fluid is observed together with orientational distribution showing some evidence of a mixture of parallel and perpendicular molecules. Indeed, the second layer at this coverage behaves as a poorly defined θ-phase. Additional simulations of thick O_2 films are being carried out at various temperatures in an attempt to characterize the melting and possibly the wetting behavior of these systems.

Rate expressions are derived for hydrogen transfer between two molecules in a solid, typical examples being hydrogen abstraction by methyl radicals in solid methane and in glassy methanol. These expressions are based on two-dimensional potential-energy surfaces describing the motion of the hydrogen atom along with that of the atoms between which it is transferred. A diabatic rate expression, based on the Golden Rule, is compared with an adiabatic rate expression, based on transition-state theory with a tunneling correction. In both cases, the two degrees of freedom must be treated quantum-mechanically rather than classically. For the adiabatic case, this leads to a new expression in which the barrier permeability is averaged over the wavefunction of the slow motion. The result differs from the Golden-Rule expression but yields similar rate constants. Numerical estimates are presented to illustrate the temperature and isotope dependence of these rate constants. The concept of a tunneling path is shown to break down at low temperature, so that the conventional one-dimensional tunneling approach becomes invalid.

PHILIP D. PACEY et WILLEM SIEBRAND. Can. J. Chem. **66**, 875 (1988).

On a dérivé des équations représentant la vitesse du transfert d'hydrogène entre deux molécules dans un solide; l'enlèvement d'hydrogène par des radicaux méthyles dans du méthane solide et dans du méthanol vitreux en sont des exemples typiques. Ces équations sont basées sur des surfaces d'énergie potentielle en deux dimensions qui décrivent le mouvement de l'atome d'hydrogène ainsi que ceux des atomes entre lesquels le transfert se produit. On compare une équation de vitesse diabatique qui est basée sur la «règle d'or» avec une équation de vitesse adiabatique qui est basée sur la théorie des états de transition avec une correction pour l'effet tunnel. Dans les deux cas, on doit faire appel à la mécanique quantique plutôt qu'à la mécanique classique pour traiter des deux degrés de liberté. Dans le cas adiabatique, ceci conduit à une nouvelle expression dans laquelle on fait une moyenne de la barrière à la perméabilité sur toute la fonction d'onde du mouvement lent. Le résultat est différent de celui obtenu à l'aide de l'expression dérivée de la «règle d'or»; toutefois, on obtient des constantes de vitesse qui sont semblables. On présente des évaluations numériques pour illustrer l'influence de la température et des isotopes sur ces constantes de vitesse. On montre que le concept de trajet de tunnel ne tient pas à basse température; il en résulte que l'approche conventionnelle par effet tunnel à une dimension devient invalide.

[Traduit par la revue]

I. Introduction

In this contribution we consider transfer of a hydrogen atom between two molecules in a solid at low temperatures. A typical example would be hydrogen exchange between a methane molecule and a trapped methyl radical in solid methane. Theoretically more complicated but experimentally more accessible is the equivalent reaction of methyl and methanol (1–14). In both cases hydrogen transfer is opposed by a high potential-energy barrier which reduces the rate of transfer over its top to negligible values at the low temperatures where these materials are solid. However, hydrogen is light enough to transfer by quantum-mechanical tunneling, a process that can take place even at 0 K.

The general characteristics of this tunneling process are well known (15). Its rate depends on the mass and energy of the tunneling particle and on the width and height of the barrier. However, in practice, it is not so simple to relate the barrier parameters to the known structural and energetic parameters of the system. While it is often possible to find a one-dimensional barrier that reproduces a set of observed tunneling rate constants, measured at different temperatures and perhaps for different hydrogen isotopes, in most cases the physical significance of the corresponding barrier height and width remains obscure. Instead of explaining the observed tunneling rates, such an analysis only presents the data in a different form.

Classically, the barrier represents the potential energy of the tunneling particle along the reaction coordinate. For intermolecular transfer, this coordinate always involves at least two degrees of freedom, namely one that describes the motion of the hydrogen atom relative to the heavier atoms between which it is exchanged and another that describes the motions of these heavier atoms relative to each other (16–19). At low temperatures these motions behave quantum-mechanically so that the concept of a reaction coordinate becomes irrelevant: the constraints imposed by the uncertainty principle will dominate those imposed by classical turning points. The two (or more) degrees of freedom governing the tunneling must then be treated separately.

If the tunneling is slow, the interaction causing the transfer is weak and can be treated simply as a perturbation. The rate of tunneling can then be expressed in terms of the Golden Rule (16, 18, 19). This makes it easy to include an arbitrary number of degrees of freedom, provided they are adiabatically separable. It has been shown that a two-dimensional Golden-Rule treatment can account satisfactorily for the rates of many hydrogen-tunneling reactions (18), including those of hydrogen abstraction by methyl radicals in glassy methanol (1). In this

approach the barrier does not enter directly; instead the transfer is described as a transition between reactant and product eigenstates which are derived from spectroscopic data. In principle, the coupling driving the transfer can be calculated quantum-chemically (20). However, this calculation requires a diabatic basis set, leading to crossing potentials. Standard quantum-mechanical methods are based on adiabatic basis sets, leading to avoided crossings. The problem is aggravated if the coupling is not weak so that higher-order terms must be included. In most Golden-Rule treatments of tunneling available to date, the coupling is parametrized rather than calculated.

Hence it remains worthwhile to pursue the alternative method based on transition-state theory (15, 21) which allows the use of standard quantum-chemical potentials. However, its usual form is based on classical approximations which fail at low temperature (22). For our purpose we need an adaptation suitable to describe tunneling in low-temperature solids. To this end, the motion of the hydrogen atom is described in terms of a two-dimensional potential-energy surface, derived from quantum-chemical calculations (20) in conjunction with spectroscopic and thermochemical data (1). The two degrees of freedom determining this surface are assumed to be adiabatically separable and treated quantum-mechanically. The results are compared with the Golden-Rule expression previously fitted to experimental data (1, 3).

II. Model system

We consider reactions of the type

[1] $$CH_3^{\bullet} + CH_3X \rightarrow CH_4 + {}^{\bullet}CH_2X$$

where X = H or OH. We also consider these reactions with H replaced by D. For simplicity, we restrict our calculations to symmetrical potentials (i.e., to X = H) for which quantum-chemical computations are available (20). These computations refer to the system $H_3C....H....CH_3$ and determine the structure of the transition state but not the complete surface. Their results are therefore combined with parameters derived from experimental data. The harmonic CH-stretch frequency and CH-bond dissociation energy are readily available from spectroscopic and thermochemical measurements (23). For the CC-stretching mode, we use the parameters derived previously (1) for the methyl–methanol system. Starting from these parameter values, we use the method of ref. 22 to construct a potential-energy surface. A typical result is illustrated in Fig. 1.

Actually, this construction involves some compromise, since the CC interaction used is valid only for small amplitudes. To obtain a realistic potential in the transition-state region, we would have to include a steep repulsion term. Since such a term is missing from the simplified approach of ref. 22, the resulting barrier is considerably lower than quantum chemical calculations indicate. However, this does not affect the final results significantly, since the transition-state region hardly contributes to the low-temperature transfer rate.

To compensate to some extent for the absence of a repulsive term, Fig. 1 is calculated with an electronic coupling term that does not depend on the CC distance. It has been shown previously that this does not affect the form of the result but only rescales some parameters (19). It follows that the potential surface in Fig. 1 is of limited accuracy in regions where high accuracy is not necessary for our purpose. The skewed-axes plot illustrates the motion of a spherical atom along this surface. However, the actual motion of the hydrogen atom will be shown to be quite different.

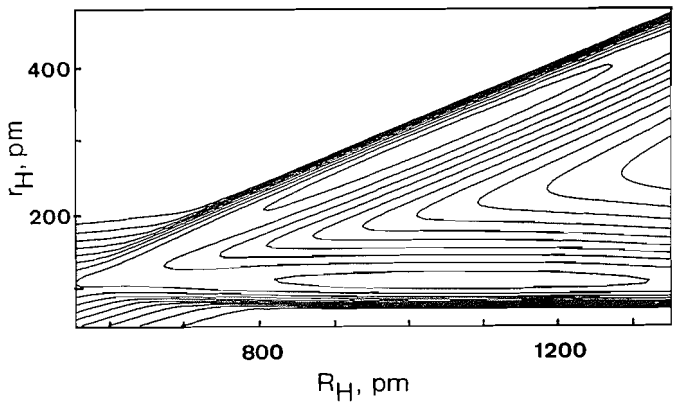

FIG. 1. Skewed and mass-weighted contour diagram of a potential-energy surface for transfer of H from CH_4 to $CH_3^{\bullet}$. The axes are scaled for an effective mass equal to the hydrogen mass. The elongated oval contours have the lowest energy, 20.5 kJ/mol above the minima, and represent the loci of classical turning points of the two-oscillator system with zero-point energy. Successive contours are mutually separated by 41 kJ/mol. The surface, calculated by the method of ref. 22, is based on the following parameter values: D_{CH} = 472.4 kJ/mol, $\bar{r}_A = \bar{r}_B$ = 108 pm, $\bar{R}$ = 395 pm, m = 1.008 g/mol, M = 15.04 g/mol, $\bar{J}$ = 34 kJ/mol, ω = 3289 cm^{-1}, Ω = 130 cm^{-1}.

To calculate hydrogen transfer rate constants, we do not use this potential surface directly, but start from the original parameters from which the surface is deduced. Where appropriate, we shall use analytical approximations to the potentials, so as to obtain simple expressions for the rate constants. In this way we can demonstrate the qualitative features of the method without having to rely on detailed numerical calculations. For the same reason, we restrict ourselves to resonant transitions in which the quantum numbers v and V of the CH and CC oscillators do not change. Since we consider only low-temperature transitions, we set $v = 0$, so that the temperature dependence of the transfer will be governed by the rate constants and Boltzmann populations of the levels $V = 0, 1, 2, \ldots$.

Given the strong dependence of the tunneling rate on the transfer distance (1), it is likely that transfer will only take place when the C...H...C system is collinear or nearly so. In principle, the tunneling rate will thus depend on the rotational and librational states of the molecules in the lattice. For simplicity, we assume that, on the timescale of the transfer, the methyl radicals and groups and/or the methane molecules are "freely" rotating and tumbling. Then the rotational degrees of freedom will introduce only temperature-independent statistical factors, compensated in part by the statistical factors representing the number of nearest-neighbor molecules of each radical. All of these factors we shall ignore for the present purpose.

III. Golden-Rule approach

The model allows a simplified version of the Golden-Rule treatment of refs. 1 and 18. The probability per second of a transition from an initial state $|i\rangle$ to a final state $|f\rangle$ is given by the diabatic rate constant

[2] $$k_{fi}^{d} = (2\pi/\hbar)|U_{fi}|^2\delta(\epsilon_f - \epsilon_i)$$

where U_{fi} is the matrix element coupling the states and the δ function signifies energy conservation. States $|i\rangle$ and $|f\rangle$ are represented by products of two harmonic oscillator wavefunctions

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/07/12
For personal use only.

[3] $|i\rangle = \chi_v(r - \bar{r}_A)\chi_V(R - \bar{R})$

$|f\rangle = \chi_w(r - \bar{r}_B)\chi_W(R - \bar{R})$

characterized by frequencies ω and Ω. For the present model, the vibrational quantum numbers are $v = w = 0$ and $V = W$. R is the instantaneous CC distance with an equilibrium value $\bar{R}$, r is the instantaneous hydrogen position and $\bar{r}_A$ and $\bar{r}_B$ are the hydrogen equilibrium positions before and after transfer, respectively. Since the CH and CC coordinates r and R are collinear, we have $\bar{r}_B - \bar{r}_A = R - 2\xi$, where ξ is the equilibrium CH distance. We have assumed that the two vibrations are adiabatically separable; we further assume that the coupling operator J, representing the interaction between the donor (A) and acceptor (B) carbon atoms, does not depend on r. Then we obtain

[4] $U_{fi}(V) = \langle\chi_V(R - \bar{R})|J(R)S_{00}(R)|\chi_V(R - \bar{R})\rangle$

$S_{00}(R) = \langle\chi_0(r - \bar{r}_B)|\chi_0(r - \bar{r}_A)\rangle$

$= \exp\{-[\frac{1}{2}q(R - 2\xi)]^2\}$

where $q = (m\omega/\hbar)^{1/2}$. Taking

[5] $J = \bar{J}\exp[-z(R - \bar{R})]$

where z is the characteristic orbital radius expressed in units of the Bohr radius, we can solve the integral analytically (19)

[6] $U_{fi}(V) = \bar{J}\exp[2z(\bar{R} - 2\xi) + 2z^2/q^2]\int|\chi_V|^2\exp[-\frac{1}{4}q^2(R - 2\xi + 2z/q^2)^2]dR$

$= \bar{J}(1 - g)^{1/2}\exp[-\gamma^2 + 2z(\bar{R} - 2\xi) + 2z^2/q^2]\sum_{K=0}^{V}\frac{V!}{K![(V - K)!]^2}(g/2)^{V-K}H_{2(V-K)}(\gamma)$

where

[7] $g = q^2/(q^2 + 4Q^2)$

$\gamma = [qQ/(q^2 + 4Q^2)^{1/2}](\bar{R} - 2\xi + 2z/q^2)$

$Q = (M\Omega/\hbar)^{1/2}$

and $H_{2(V-K)}(\gamma)$ are Hermite polynomials. As usual, we replace the δ function in eq. [2] by a density of states, ρ_0. We then obtain

[8a] $k^d(V) =$

$$k^d(0)\left\{\sum_{K=0}^{V}\frac{V!}{K![(V - K)!]^2}(g/2)^{V-K}H_{2(V-K)}(\gamma)\right\}^2$$

[8b] $k^d(0) =$

$$(2\pi/\hbar)\bar{J}^2\rho_0(1 - g)\exp[-2\gamma^2 + 4z(\bar{R} - 2\xi + z/q^2)]$$

In this form, the treatment is suitable for qualitative purposes only. A more accurate form of these equations has been explored elsewhere (1, 3).

IV. Semi-classical approach

Semi-classically, the adiabatic rate constant of transfer through a one-dimensional barrier $U(r)$ is given by the frequency with which the hydrogen atom impinges on the barrier multiplied by the barrier permeability (15, 24, 25)

[9] $k^a(E) = (\omega/2\pi)P(E)$

$P(E) = \exp\{(-2/\hbar)\int_s(2m)^{1/2}[E - U(r)]^{1/2}dr\}$

where E is the energy of the atom and s is its path inside the barrier. This formulation has been the starting point for some very elaborate treatments (26–28) presumed to be capable of producing accurate numerical results. However, for our purpose we prefer to use a more traditional approach adapted so as to produce analytical results of the same type as those of the simplified Golden-Rule approach. This will allow a direct comparison of the two methods in a physically transparent form. To this end we identify ω in eq. [9] with the CH-stretch frequency and replace the actual barrier, depicted in Fig. 1, by a symmetrical Eckart barrier (15, 29)

[10] $U(r) = U_0/\cosh^2(\pi r/\lambda)$

which allows us to express the permeability in analytical form (15, 29):

[11] $P(E) = \dfrac{\sinh^2 b}{\sinh^2 b + \cosh^2 a}$

where

[12] $a = [(\lambda/\hbar)^2 2mU_0 - 4\pi^2]^{1/2} \simeq (\lambda/\hbar)(2mU_0)^{1/2}$

$b = (\lambda/\hbar)(2mE)^{1/2}$

To relate the Eckart barrier to our potential, we set $E = E_0 = \frac{1}{2}\hbar\omega$ and take the barrier width for $U(r) = \epsilon_0$ equal to the tunneling distance $R - 2\xi$. The barrier height $U_0(R)$ is taken from quantum-chemical calculations (20). The barrier width parameter $\lambda(R)$ is then given by

[13] $\lambda(R) = \frac{1}{2}\pi(R - 2\xi)/\text{arc cosh}\,[2U_0(R)/\hbar\omega]^{1/2}$

$\simeq \pi(R - 2\xi)/\ln[8U_0(R)/\hbar\omega]$

where the last step is valid if $2U_0(R) \gg \hbar\omega$. Substitution in eq. [12] yields

[14] $a(R) = \pi(R - 2\xi)qL/2\ln(2L)$

$b(R) = \pi(R - 2\xi)q/2\ln(2L)$

$L = [2U_0(R)/\hbar\omega]^{1/2}$

from which we obtain an expression for the rate constant as a function of ϵ_0 and R.

So far our treatment is basically standard. Conventionally one now proceeds by choosing a representative value of R, for instance the value corresponding to the classical turning point (15, 21). However, in the present case this would be improper since the oscillators are in low quantum states so that we are far from the classical region. Instead, we calculate the probability that a given R is realized by standard quantum mechanics, viz.

[15] $p_V(R) = |\chi_V(R - \bar{R})|^2$

The tunneling rate constant for an energy $\epsilon_0 = \frac{1}{2}\hbar\omega$ and a vibrational quantum number V is thus

$$[16]\quad k^a(\epsilon_0;V) = \int p_V(R)k^a(\epsilon_0,R)\mathrm{d}R = (\omega/2\pi)\int|\chi_V|^2P(\epsilon_0,R)\mathrm{d}R$$

$$P(\epsilon_0,R) = \frac{\sinh^2[\pi q(R-2\xi)/2\ln(2L)]}{\sinh^2[\pi q(R-2\xi)/2\ln(2L)] + \cosh^2[\pi qL(R-2\xi)/2\ln(2L)]}$$

To evaluate this integral, we need an expression for $L(R)$ and thus for $U_0(R)$. In our model, this potential ridge varies between $U_0(R_0)$, where R_0 is the transition state value, and $U_0(\infty) = D_{CH}$, the CH bond dissociation energy. For R near R_0, we use quantum-chemical results to obtain $U_0(R_0)$ as well as the harmonic frequency ω_0. To extrapolate to $R \rightarrow \infty$, we use a Morse potential:

$$[17]\quad U_0(R) = U_0(R_0) + \Delta U\{1 - \exp[-(M\omega_0^2/2\Delta U)^{1/2}(R - R_0)]\}^2$$

where $\Delta U = D_{CH} - U_0(R_0)$. After substitution into eq. [16], the resulting integral can be evaluated numerically.

However, in our case we can obtain a simple analytical approximation. For realistic R values, we have

$$[18]\quad a(R) \gg b(R) \gg 1$$

so that the hyperbolic functions in eq. [16] can be approximated by exponentials:

$$[19]\quad P(\epsilon_0,R) \simeq \exp\{2[b(R) - a(R)]\} = \exp[-\pi q\eta(R - 2\xi)]$$

where

$$[20]\quad \eta = [L(R) - 1]/\ln[2L(R)]$$

Within the range of R values for which significant transfer takes place, L is a number in the range 2.5–4.5, so that $\eta = 1.3 \pm 0.3$. Since η varies slowly with R, we shall approximate it by a constant, implying that $P(\epsilon_0,R)$ is approximated by an exponential function of R. We thus obtain

$$[21]\quad k^a(\epsilon_0;V) = (\omega/2\pi)\int_{-\infty}^{\infty}|\chi_V|^2\exp[-\pi q\eta(R - 2\xi)]\mathrm{d}R$$

which can be integrated analytically to yield

$$[22]\quad k^a(\epsilon_0;V) = k^a(\epsilon_0;0)\sum_{K=0}^{V}\frac{V!\sigma^{2(V-K)}}{2^{V-K}K![(V-K)!]^2}$$

$$k^a(\epsilon_0;0) = (\omega/2\pi)\exp[-\sigma Q(\bar{R} - 2\xi - \sigma/4Q)]$$

where

$$[23]\quad \sigma = \pi\eta q/Q \simeq 4q/Q$$

In practice, it may be advisable to apply this result only as a semi-empirical equation in which η is an adjustable parameter close to unity. In this form, it can be used to obtain relative rate constants as a function of temperature and isotopic species.

V. Comparison

Resonant hydrogen tunneling leads to splitting of the corresponding energy levels. In terms of the Golden-Rule approach this splitting is given by

$$[24]\quad \Delta\epsilon^d = 2|U_{fi}|$$

Semi-classically, the splitting can be represented by (30)

$$[25]\quad \Delta\epsilon^a = (\hbar\omega/\pi)P^{1/2}$$

Since

$$[26]\quad |U_{fi}| = (2\hbar k/\pi\rho)^{1/2}$$

and

$$[27]\quad P^{1/2} = (2\pi k/\omega)^{1/2}$$

these formulas are equivalent (31) for one-dimensional tunneling with $\rho = 1/\hbar\omega$.

For two-dimensional tunneling of the type considered, we obtain from eq. [24]

$$[28]\quad \Delta\epsilon_V^d = 2|\langle V|J(R)S_{00}(R)|V\rangle|$$

and from eq. [25]

$$[29]\quad \Delta\epsilon_V^d = (\hbar\omega/\pi)|\langle V|P(\epsilon_0,R)|V\rangle|^{1/2}$$

These results are no longer equivalent, since the integration over $\chi_V(R - \bar{R})$ enters in a different manner. The integral $\langle V|P|V\rangle$ represents an averaging procedure and should not be interpreted as a transition matrix element. Thus for an asymmetric barrier corresponding to a transition from χ_V to χ_W, the integral $\langle V|JS_{00}|V\rangle$ in [28] becomes $\langle W|JS_{00}|V\rangle$, but the integral $\langle V|P|V\rangle$ in [29] becomes $\frac{1}{2}|\langle V|P|V\rangle + \langle W|P|W\rangle|$. Although standard transition-state theory does not consider the final state explicitly, this averaging is imposed by the principle of microscopic reversibility.

The same differences are observed between the diabatic and adiabatic rate constant expressions [8] and [22]. Clearly the R coordinate is treated differently in the two approaches. In the Golden-Rule approach, it is treated on the same footing as the r coordinate. In the transition-state approach, the two coordinates are treated differently, such that r is the reaction coordinate and R modifies the barrier. This is thus an "oscillating barrier" treatment. Both treatments are approximate, but they involve different approximations so that their results will not be identical.

VI. Quantitative aspects

In our adiabatic approach, the tunneling rate constant $k^a(\epsilon_0;V)$ is expressed as an integral over all tunneling paths, each characterized by a single-path rate constant $k^a(\epsilon_0,R;V)$, which in turn is expressed as the product of a probability $\chi_V^2(R - \bar{R})$ and a permeability $P(\epsilon_0,R)$:

$$[30]\quad k^a(\epsilon_0;V) = \int_{-\infty}^{\infty}k^a(\epsilon_0,R;V)\mathrm{d}R$$

$$k^a(\epsilon_0,R;V) = (\omega/2\pi)P(\epsilon_0,R)|\chi_V(R - \bar{R})|^2$$

All of these quantities are plotted in Fig. 2. The permeability $P(\epsilon_0,R)$ is a nearly exponential function of R for relevant R values, so that eq. [19] with constant η should be a satisfactory approximation for our model. The single-path rate constants $k^a(\epsilon_0,R;V)$ peak well outside the classical region delimited by the inner turning points shown in Fig. 2. The effective R value denoted by $\tilde{R}$ and defined by

$$[31]\quad k^a(\epsilon_0,V) = (\omega/2\pi)\int_{-\infty}^{\infty}P(\epsilon_0,R)\delta(R - \tilde{R})\mathrm{d}R/\tilde{R} = (\omega/2\pi)P(\epsilon_0,\tilde{R})$$

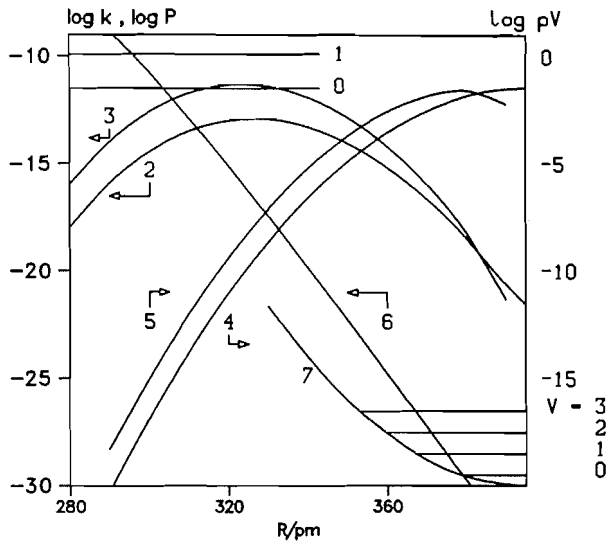

FIG. 2. Adiabatic rate constants of hydrogen transfer from CH_4 to $CH_3^{\bullet}$ and their components plotted as a function of R, the instantaneous CC distance. The rate constants $k^a(\epsilon_0;0)$ and $k^a(\epsilon_0;1)$, calculated from eq. [16], are labeled 0 and 1, respectively. Their R-dependent components $k^a(\epsilon_0,R;0)$ and $k^a(\epsilon_0,R;1)$, defined by eq. [30], are labeled 2 and 3, respectively. The curves labeled 4 and 5 depict the squared harmonic wavefunctions $\chi_0^2(R-\bar{R})$ and $\chi_1^2(R-\bar{R})$, respectively. Curve 6 depicts $P(\epsilon_0,R)$ defined by eq. [16], and curve 7 depicts the harmonic CC stretch potential, showing the classical turning points associated with vibrational quantum numbers $V = 0$–3. Parameter values are taken from ref. 1, except that the exothermicity ΔE has been taken equal to zero, and, from ref. 2 for the transition-state region: $\omega/2\pi = 1.41 \times 10^{13}\,s^{-1}$, $R_0 = 267$ pm, $U_0(R_0) = 357$ kJ/mol, $\Delta U = 98$ kJ/mol, $\bar{R} = 395$ pm, $\xi = 1.08$ pm, $(M\omega_0^2/2\Delta U)^{1/2} = 0.0123\,pm^{-1}$, $q = 0.0899\,pm^{-1}$, $Q = 0.0626\,pm^{-1}$.

is found to be about 9 pm smaller than the inner turning points for $V = 0$ and 1. If $\bar{R}$ is replaced by the turning point value, the resulting rate constants would be too small by about 10^5. Hence turning points do not provide a useful definition of the barrier for low quantum numbers.

The rate constants $k^a(\epsilon_0;0) = 3.2 \times 10^{-12}\,s^{-1}$ and $k^a(\epsilon_0;1) = 1.2 \times 10^{-10}\,s^{-1}$ depicted by horizontal lines at the top of Fig. 2 are obtained by numerical integration of eq. [16]. The corresponding approximate results, obtained from eq. [22] are $k^a(\epsilon_0;0) \simeq 2.2 \times 10^{-12}\,s^{-1}$ and $k^a(\epsilon_0;1) \simeq 4.0 \times 10^{-11}\,s^{-1}$, for $\eta = 1.3$. These results are about six orders of magnitude smaller than the rate constants observed at 5 K for the methyl–methanol system (1) and would be too small to be measured by conventional methods. This discrepancy is thought to be mostly due to the assumption of zero exothermicity, a conclusion supported by Golden-Rule results obtained earlier (1, 8). Since the exothermicity ΔE for the methyl–methanol system is about 26 kJ/mol (32), resonant transitions $vV \rightarrow wW$ with $w - v = 1$ or $W - V = 10$–20 would be expected. It is clear that these would have much higher rates than the $w - v = W - V = 0$ transitions calculated here. Hence our calculations predict that hydrogen exchange between methyl radicals and methane molecules in solid methane, where ΔE vanishes by symmetry, will be extremely slow and probably unobservable. This prediction does not depend on the details of the potential. It should be realized, however, that for quantitative calculations of rate constants, very accurate potentials are required. The formulas presented here should be used only for qualitative purposes.

Qualitatively, the present expressions for the temperature and isotope dependence of the adiabatic rate constants are compatible with the diabatic results obtained earlier (1, 3) and hence with the experimental data to which they were fitted. Thus $k^a(T)$ assumes a constant value in the limit $T \rightarrow 0$ and increases nonexponentially with temperature due to the gradual population of the low-frequency oscillator levels. Since the experimental data show a good deal of scatter at low temperatures, we compare the predictions of eq. [16] with those of the Golden-Rule *calculations* of ref. 1. In both cases the temperature dependence of $k(T)$ is negligible for $T < 25$ K. The ratio $k(50\text{ K})/k(25\text{ K})$ is given as 2.4 by eq. [16] and as 3.2 by ref. 1. The ratio of the rate constants for hydrogen and deuterium transfer $k_H(50\text{ K})/k_D(50\text{ K})$ is given as 1.2×10^5 by eq. [16] and 1.5×10^4 by ref. 1. While the agreement is not quantitative, it is satisfactory if the difference between the potentials is taken into account.

VII. One-dimensional tunneling

Conventionally hydrogen transfer is treated as a one-dimensional tunneling problem (15). It is therefore of interest to inquire whether our two-dimensional treatment can be reduced to one dimension by the introduction of suitable approximations. In terms of our formalism, the one-dimensional rate constant for fixed $R = \bar{R}$ would be given by eq. [31] with ϵ_0 replaced by $E = \epsilon_0 + (V + \frac{1}{2})\hbar\Omega$. For a high barrier, eq. [19] can be rewritten in the generalized form

$$[32] \quad P(E;\bar{R}) \simeq \exp\,[-\pi q\tilde{\eta}(E)(\bar{R} - 2\xi)]$$

where

$$[33] \quad \tilde{\eta}(E) = 2[(U_0/E)^{1/2} - 1]/\ln(4U_0/E)$$

is a generalization of eq. [20]. We now set this one-dimensional rate constant equal to the corresponding two-dimensional rate constant for $V = 0$ and 1. Using eqs. [21]–[24], we obtain

$$[34a] \quad \tilde{\eta}(0) = \eta(\bar{R} - 2\xi - \pi q\eta/4Q^2)/(\bar{R} - 2\xi)$$

$$[34b] \quad \tilde{\eta}(1) \simeq \tilde{\eta}(0) - \frac{4\ln[\pi q\eta(\bar{R} - 2\xi)]}{\pi q(\bar{R} - 2\xi)}$$

where $\tilde{\eta}(0) = \tilde{\eta}(\frac{1}{2}\hbar\omega + \frac{1}{2}\hbar\Omega)$ and $\tilde{\eta}(1) = \tilde{\eta}(\frac{1}{2}\hbar\omega + \frac{3}{2}\hbar\Omega)$. If $\tilde{\eta}(E)$ varies slowly with E, i.e., if $E \ll U_0$ we can set

$$[35] \quad \tilde{\eta}(0) \simeq \tilde{\eta}(1) \simeq \eta$$

yielding

$$[36] \quad \bar{R} = \bar{R} - \pi q\eta/4Q^2$$

However, this makes $\bar{R}$ and thus the barrier width isotope dependent since q varies as $m^{1/4}$. Moreover, it would imply that the second term at the right-hand side of eq. [34*b*] is small. This is not generally true, however; for our model parameters it is about 0.3 and thus not negligible compared to $\tilde{\eta}(0)$ which is of order unity. The same argument is readily extended to $\tilde{\eta}(2)$, $\tilde{\eta}(3)$, etc. Hence eqs. [34] and [35] are not mutually consistent; specifically [34] contradicts the assumption $E \ll U_0$ and requires a strongly curved $\ln P$ against R plot instead of the nearly linear plot of Fig. 2. Thus to fit the temperature dependence of the transfer rate constant with a one-dimensional barrier, this barrier must be equated with a cut through the adiabatic surface that does not pass through the top (i.e., the quantum-chemical transition state). Since the position of the cut cannot be identified in the one-dimensional picture, the corresponding barrier height remains an empirical quantity.

Moreover there is no guarantee that it is the same for hydrogen and deuterium: for our system, the hydrogen barrier yields a deuterium transfer rate constant that is much too small compared to the hydrogen rate constant, due to the isotope dependence of $\bar{R}$. Comparison of the Golden-Rule barriers of refs. 1 and 22 with reported one-dimensional barriers for the same reactions (9) confirms these conclusions.

As a further illustration, we compare the rate constants $k^a(\frac{1}{2}\hbar\omega;1)$ and $k^a(\frac{1}{2}\hbar\omega + \hbar\Omega;0)$, which differ in the way the thermal energy quantum $\hbar\Omega$ is distributed over the two degrees of freedom. In a one-dimensional treatment, they are thus indistinguishable. However, application of eq. [16] or eq. [24] readily shows that $k^a(\frac{1}{2}\hbar\omega;1) \gg k^a(\frac{1}{2}\hbar\omega + \hbar\Omega;0)$ for our model.

We therefore conclude that a two-dimensional analysis of hydrogen transfer data is much more informative and meaningful than the conventional one-dimensional analysis. If high accuracy is not required, the extra effort involved in including the second dimension is minimal, as the present calculations show.

VIII. Discussion

We have shown that conventional transition-state theory, corrected for tunneling, can be used to calculate the rate of hydrogen transfer between molecules in low-temperature solids, provided at least two relevant degrees of freedom are included and treated quantum-mechanically rather than classically. In the proper limit this method is a convenient alternative to the Golden-Rule approach. The physical pictures associated with the two methods are different. In the Golden-Rule method the transfer is described as a transition between two zeroth-order diabatic eigenstates mediated by a coupling. This is basically a time-dependent perturbation method. In transition-state theory, the transfer is described as tunneling through an adiabatic potential-energy barrier. This is basically a time-independent approach, the permeability being derived from a time-independent Schrödinger equation (29). To turn this into a time-dependent description, one needs to localize the system at a given initial time at one side of the barrier: this requires a "classical" assumption. However, the actual treatment of the degrees of freedom involved in the tunneling must be quantum-mechanical rather than classical in order to produce valid results in the low-temperature region.

This implies that the classical notion of a distinct tunneling path is lost at low temperatures, since many different paths contribute. Alternatively, one can say that the path taken is fuzzy as befits a quantum particle. Of course, the concept of a tunneling path is alien to the Golden-Rule treatment. Here the transfer rate is limited by vibrational overlaps, i.e., by the Franck–Condon principle. Transfer occurs during those statistically rare events where the amplitudes of all relevant degrees of freedom are large and in phase, such that the instantaneous hydrogen position could have arisen from either the reactant or product state with comparable probability. In this picture the proton transfers because quantum mechanics allows it to stray occasionally very far from its origin.

Of course, these are elementary pictures which tend to get blurred in more sophisticated treatments. It is possible to overcome the apparent handicaps of the two theories and get accurate results but this requires elaborate computations and extensive numerical testing. This is impractical in the case of complex systems or limited data sets, for which the traditional one-dimensional tunneling method remains the most popular approach. We hope that the present contribution offers some insight into the merits and limitations of that approach and the available alternatives.

This paper is dedicated to Professor James A. Morrison

JAMEY K. HOVEY, LOREN G. HEPLER, and PETER R. TREMAINE. Can. J. Chem. **66**, 881 (1988).

Calorimetric and densimetric measurements have led to apparent molar heat capacities and volumes for aqueous solutions of the mixed electrolytes $[(CH_3)_4N]_4EDTA + (CH_3)_4NOH$, $Na_4EDTA + NaOH$, and $K_4EDTA + KOH$, and single electrolytes Na_2H_2EDTA and $[(CH_3)_4N]_3[HEDTA]$ at 25°C. We have analyzed these results in terms of Young's rule and Pitzer's ion interaction model to obtain standard state partial molar heat capacities and volumes of $EDTA^{4-}(aq)$, $HEDTA^{3-}(aq)$, $H_2EDTA^{2-}(aq)$, $NaEDTA^{3-}(aq)$, and $KEDTA^{3-}(aq)$ at 25°C. For these calculations it was also necessary to evaluate the "relaxation" contribution to the measured heat capacities of some solutions. The partial molar heat capacities obtained here have been used with enthalpies from previous investigations for calculations of several equilibrium constants over wide ranges of temperature; volumes can be used for similar calculations of the effects of pressure.

JAMEY K. HOVEY, LOREN G. HEPLER et PETER R. TREMAINE. Can. J. Chem. **66**, 881 (1988).

Des mesures calorimétriques et de densités ont permis d'obtenir les capacités et les volumes molaires apparents de solutions aqueuses des électrolytes mixtes $[(CH_3)_4N]_4EDTA + (CH_3)_4NOH$, $Na_4EDTA + NaOH$ et $K_4EDTA + KOH$ ainsi que des électrolytes simples Na_2H_2EDTA et $[(CH_3)_4N]_3[HEDTA]$, à 25°C. Dans le but d'obtenir les capacités calorifiques et les volumes molaires partiels dans l'état standard des ions $EDTA^{4-}(aq)$, $HEDTA^{3-}(aq)$, $H_2EDTA^{2-}(aq)$, $NaEDTA^{3-}(aq)$ et $KEDTA^{3-}(aq)$, à 25°C, on a analysé ces résultats en fonction de la règle de Young et du modèle de Pitzer pour les interactions ioniques. Pour faire ces calculs, il est nécessaire d'évaluer la contribution de la «relaxation» aux capacités calorifiques de quelques-unes de ces solutions. On a utilisé les capacités molaires partielles ainsi obtenues en conjonction avec des enthalpies obtenues au cours d'études antérieures pour calculer plusieurs constantes d'équilibre, sur un large éventail de températures; les volumes peuvent aussi être utilisés pour faire des calculs semblables relativement aux effets de la pression.

[Traduit par la revue]

Introduction

Aqueous solutions of EDTA (ethylenediaminetetraacetic acid and its salts) have found use in many applications, as discussed previously (1, 2). As a result of our own and other investigations we now have reasonably complete thermodynamic data for aqueous complexes of EDTA with several cations. On the other hand, we are missing potentially valuable thermodynamic data for complexes of EDTA with some other important cations and for the acid dissociation species $HEDTA^{3-}(aq)$, and $EDTA^{4-}(aq)$. In this latter connection, the speciation (3) of EDTA solutions at 25°C as a function of pH at 0.1 molar ionic strength is illustrated in Fig. 1.

Thermodynamic measurements carried out with constant ionic strength media of alkali metal salts are complicated by the formation of alkali metal ion – EDTA complexes (4, 5). Similarly, investigations with the highly alkaline solutions that are required to obtain most of the EDTA as the $HEDTA^{3-}(aq)$ and $EDTA^{4-}(aq)$ anions are also complicated by the formation of EDTA complexes with the cations that inevitably accompany hydroxide ions.

Several investigations of equilibrium constants and enthalpies of reaction involving solutions of EDTA have been carried out over a limited temperature range near 25°C, thereby permitting calculations of ΔC_p^0 values by way of

$$[1] \qquad (\partial \ln K/\partial T)_p = \Delta H^0/RT^2$$

and

$$[2] \qquad (\partial \Delta H^0/\partial T)_p = \Delta C_p^0$$

Accurate values of ΔC_p^0 would allow both ΔH^0 and $\ln K$ to be extrapolated to temperatures beyond the range of the original measurements. Unfortunately, the magnification of errors and uncertainties associated with differentiation, and also the complications mentioned above, cause many ΔC_p^0 values from eq. [2] to have very large uncertainties. We have therefore carried out the calorimetric measurements of heat capacities that are described in this paper. We have also measured densities that lead to new apparent and partial molar volumes. Analysis of our experimental data to obtain the desired standard state partial molar properties of specified ions is complicated because all of the solutions investigated have contained at least one cationic species and two anionic species.

Experimental

Water to be used for all experiments was filtered through activated charcoal and then passed through a Milli-RO4/Milli-Q reagent grade mixed bed ion exchange and activated carbon system to yield water with resistivity greater than 18 MΩ cm.

Solutions of NaCl (Fisher certified, ACS) were prepared by mass

[1]Alberta Research Council contribution no. 1571.

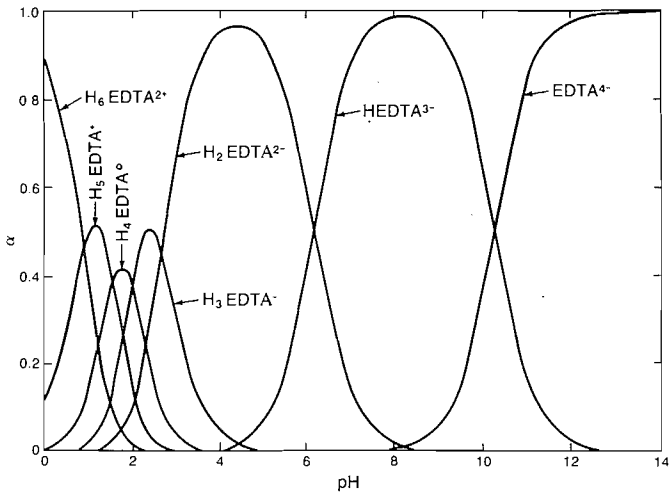

FIG. 1. Speciation of aqueous EDTA at 25°C and $I = 0.10$ molar.

after drying the salt at 110°C for several hours. Crystalline H_4EDTA (Fisher certified, ACS) was dried at 140°C for several hours to yield material that has been described (6) as a primary standard. Aqueous solutions of NaOH (50%) and KOH (1 molar) were obtained from Fisher (certified, ACS). Aqueous solutions of $(CH_3)_4NOH$ (25%) were obtained from both Fisher (certified) and Alfa (certified purity 99.9999%). The solution from Alfa was used without further purification, but the sample from Fisher was purified by passing it through an anion exchange column with resin in the hydroxide form to remove chloride and other anionic impurities. All hydroxide solutions were standardized by titration against potassium hydrogen phthalate. A solution of Na_2H_2EDTA was prepared by dissolving the salt (Fisher certified, ACS) in pure water and then standardized by titration against standard solutions of zinc chloride (6). A solution of $[(CH_3)_4N]_3[HEDTA]$ was prepared by adding a weighed amount of $(CH_3)_4NOH$ (Alfa) solution to a weighed amount of H_4EDTA, followed by adjustment to pH = 8.30 with a very dilute solution of $(CH_3)_4NOH$. Further solutions were prepared by dilution of this solution with very dilute $(CH_3)_4NOH$. Stock solutions of known stoichiometric compositions of $[(CH_3)_4N]_4EDTA + (CH_3)_4NOH$ (Alfa and Fisher), $Na_4EDTA + NaOH$, and $K_4EDTA + KOH$ were prepared by adding weighed amounts of standardized hydroxide solutions to weighed amounts of dried H_4EDTA. Further solutions were prepared by dilution with standardized hydroxide solutions. All of these alkaline solutions were prepared under nitrogen and then stored in nitrogen filled desiccators containing silica gel and Ascarite pellets to minimize carbonate contamination.

Densities were measured relative to water at 25.00 ± 0.01°C with a Sodev 03D vibrating tube densimeter (7), which was calibrated with pure water and a standard solution of NaCl. Heat capacities were measured relative to water with a Sodev CP-C Picker flow microcalorimeter (8). Temperatures were controlled (constant to ±0.001°C) with a Sodev CT-L circulating bath and monitored with calibrated thermistors. For the density and specific heat capacity of water at 25°C we used the values (9, 10) 0.997047 g cm^{-3} and 4.1793 J K^{-1} g^{-1}, respectively. Daily evaluation of the calorimetric heat loss correction factor (11) by way of measurements on standard solutions of NaCl led to $f = 1.006 \pm 0.002$.

Results and calculations

$[(CH_3)_4]_4NEDTA$

The Picker vibrating tube densimeter and calorimeter measure $[(c_p d/c_{p,1}^0 d_1^0) - 1]$ and $(d - d_1^0)$, in which c_p and $c_{p,1}^0$ are the specific heats of solution and of pure water, and d and d_1^0 are the densities of solution and of pure water, respectively. It is most useful to express our experimental results for mixed electrolyte solutions of $[(CH_3)_4N]_4EDTA + (CH_3)_4NOH$ as "experimental" apparent molar properties (${}^\Phi V_\Sigma^{exp}$, ${}^\Phi C_{p,\Sigma}^{exp}$) that are defined by

$$[3] \qquad {}^\Phi Y_\Sigma^{exp} = (Y_{sol} - n_1 Y_1^0)/(n_2 + n_3)$$

Here, Y_{sol} is the extensive property (volume or heat capacity) of a specified quantity of solution, Y_1^0 is the property (volume or heat capacity) of one mole of pure solvent (water), and n_1, n_2, and n_3 are the amounts (moles) of water and of solutes 2 (M_4EDTA) and 3 (MOH) in the specified quantity of solution.

For solutions containing molalities of solutes represented by m_2 and m_3, the equations that define ${}^\Phi V_\Sigma^{exp}$ and ${}^\Phi C_{p,\Sigma}^{exp}$ are given by

$$[4] \qquad {}^\Phi V_\Sigma^{exp} = [(1 + m_2 M_2 + m_3 M_3)/d_{sol} - 1/d_1^0]/(m_2 + m_3)$$

and

$$[5] \qquad {}^\Phi C_{p,\Sigma}^{exp} = [c_{p,sol}(1 + m_2 M_2 + m_3 M_3) - c_{p,1}^0]/(m_2 + m_3)$$

where M_2 and M_3 are the molar masses of the solutes. These experimental results are listed in Table 1.

At high pH values nearly all of the dissolved EDTA is in the $EDTA^{4-}(aq)$ form, as shown in Fig. 1. There is evidence (3), however, that $EDTA^{4-}(aq)$ at high concentrations of $(CH_3)_4NOH$ (>0.1 molal) forms complexes or ion pairs (small stability constant) with $(CH_3)_4N^+(aq)$. We have calculated the speciation of our solutions with the assumption that the rather uncertain equilibrium constant is exactly correct and have found that the amount of complex present in our solutions is so small as to have negligible effect upon the results we have obtained by extrapolation to infinite dilution. Consequently, we describe here only the simpler calculations based on neglect of ion pair or complex formation of $(CH_3)_4N^+(aq)$ with $EDTA^{4-}(aq)$.

Because the high pH solutions in which most of the dissolved EDTA is in the form of $EDTA^{4-}(aq)$ contain two anionic species (the $EDTA^{4-}(aq)$ of present interest and also $OH^-(aq)$), it is necessary to make use of some model for the excess thermodynamic properties of mixed electrolyte solutions to permit extraction of the desired properties of $EDTA^{4-}(aq)$ from the experimental quantities defined by eq. [3]. Because our solutions contained relatively large amounts of "extra" electrolyte and also because the electrolytes are of different charge types, we have used two methods of carrying out these calculations. One method is based on Young's rule and the other is based on Pitzer's ion interaction model.

Young's rule (12) expresses the apparent molar properties of a mixture of electrolytes in terms of properties (at an ionic strength equal to the total ionic strength of the solution) of the solute components of the mixture. Young's rule can be expressed as

$$[6] \qquad {}^\Phi Y_\Sigma = \Sigma(m_i/\Sigma m_i){}^\Phi Y_i + \delta$$

where m_i is the molality of the ith solute, ${}^\Phi Y_i$ is the corresponding apparent molar property, and δ is an excess mixing term. For solutions containing two solutes whose molalities are denoted by m_2 and m_3, δ has the form

$$[7] \qquad \delta = k_{23}[m_2 m_3/(m_2 + m_3)^2]I = k_{23} F_2 F_3 I$$

in which k_{23} is a binary interaction coefficient, $F_i = m_i/\Sigma m_i$, and I is the total molal ionic strength. Equations [6] and [7] can also be applied to systems in which one of the solutes dissociates or complexes to form other species. In such cases m_i refers to

TABLE 1 (*concluded*)

*m_2 is the stoichiometric (total) molality of EDTA from all species and m_3 is the stoichiometric molality of base.

†$^{\phi}Y^{exp}$ used in the heading represents $^{\phi}Y_{\Sigma}^{exp}$ for solutions containing $[(CH_3)_4N]_4$EDTA, Na_3[NaEDTA], and K_3[KEDTA].

the molality of each species rather than to the stoichiometric molality of each component.

Apparent molar properties of strong electrolytes can be represented to moderate concentrations by Debye–Hückel equations of the type

$$[8] \qquad {}^{\phi}Y = \bar{Y}_2^0 + A_Y\omega I^{1/2} + B_Y I + C_Y I^{3/2} + \ldots$$

in which $\bar{Y}_2^0$ is the value of $^{\phi}Y$ at infinite dilution, A_Y is derived from the Deybe–Hückel theory (13, 14), and B_Y and C_Y are adjustable parameters. The ionic strength I and the "valence factor" ω are defined and related by

$$[9] \qquad I = \omega m = 0.5\Sigma m_i z_i^2$$

We have made calorimetric and densimetric measurements leading to apparent molar heat capacities and volumes of solutions of $(CH_3)_4NOH$ prepared with material from Alfa and from Fisher and have reported (15) the results obtained for the solutions from Alfa. Apparent molar volumes for the solutions from Fisher are in good agreement with those for the solutions from Alfa, with both of the infinite dilution values showing good agreement with the value calculated from properties of $(CH_3)_4NCl$, NaCl, and NaOH. The apparent molar heat capacity at infinite dilution derived from the measurements on solutions from Alfa is also in good agreement with the value that can be calculated from heat capacities for the other electrolytes mentioned above. The result from the Fisher salt differs from this value by 11 J K^{-1} mol^{-1}. As a result, we have weighted the data obtained from measurements on solutions from Alfa more heavily than those obtained from solutions from Fisher.

In Table 2 we report the results of least-squares fits of eq. [8] to heat capacities and volumes of solutions of $(CH_3)_4NOH$ and other "auxiliary" electrolytes to be considered later. We have used the parameters in Table 2 with our experimental results (Table 1) in fitting eqs. [6]–[8] to obtain the desired standard state properties of $EDTA^{4-}$(aq) and other parameters as listed in Table 3. Results of different fits (different parameters set equal to zero) are mostly in good agreement. Uncertainties in the desired values of $\bar{C}_p^0$ are larger than for most of our other investigations because the solutions contained relatively large amounts of the auxiliary electrolyte and also because of the uncertainty in the product ωA_J for highly charged electrolytes such as $[(CH_3)_4N]_4$EDTA. We have plotted in Figs. 2 and 3 the results of our fits with Young's rule as presented in this section, and with the Pitzer model which follows. These plots illustrate some of the model dependency of the fitted results as well as some of the uncertainties in our data. We have estimated that *total* uncertainties (chemical, our measurements, Debye–Hückel slopes, and fitting model) in $\bar{V}^0$ and $\bar{C}_p^0$ for $EDTA^{4-}$(aq) are ±2 cm^3 mol^{-1} and ±25 J K^{-1} mol^{-1}, respectively.

Na_3[NaEDTA] and K_3[KEDTA]

We have listed results of our measurements on solutions labelled Na_3[NaEDTA] and K_3[KEDTA] in Table 1, with experimental quantities and compositions defined as previously specified. Analysis of these results to obtain the desired standard state properties of $NaEDTA^{3-}$(aq) and $KEDTA^{3-}$(aq) requires consideration of mixed electrolyte effects as in the previous section. It is also necessary to consider detailed speciation and contributions of "chemical relaxation" to the measured heat capacities. Calculations with the stability constants from Daniele *et al.* (3) show that complexes of type $MEDTA^{3-}$(aq) are the principal species, but concentrations of $EDTA^{4-}$(aq) are too large to be ignored.

Concentrations of the various species have been obtained with equilibrium constants from Daniele *et al.* (3) by way of calculations based on eq. [10] as follows:

$$[10]\qquad \underset{(1-\alpha)m_2}{MEDTA^{3-}(aq)} = \underset{(3+\alpha)m_2 + m_3}{M^+(aq)} + \underset{\alpha m_2}{EDTA^{4-}(aq)}$$

The equilibrium properties of EDTA species have usually been based on a standard state having an ionic strength equal to 0.1 molar rather than the usual infinite dilution reference state. We denote the 0.1 molar reference state by the superscript † instead of ^{0} for the infinite dilution state.

Results obtained by Daniele *et al.* (3) for ionic strengths from 0.02 to 1.0 molar have been summarized by the equation

$$[11]\qquad \log K(I) = \log K^\dagger - z\{I^{1/2}/(2 + 3I^{1/2}) - (0.1)^{1/2}/[2 + 3(0.1)^{1/2}]\} + C(I - 0.1) + D[I^{3/2} - (0.1)^{3/2}]$$

We have listed values of $\log K^\dagger$, z, C, and D in Table 4 to allow easy calculation of the equilibrium constants and note that the small numerical differences between molality and molarity are less than the uncertainties in $K(I)$. Results of these speciation calculations are summarized in Table 5. We have corrected our measured apparent molar heat capacities for relaxation contributions to these functions as detailed in Appendices I and II. We subsequently have fitted expressions of type [6] and [8], using data from Roux *et al.* (16) for NaOH and KOH, and our calculated values for the hypothetical Na_4EDTA and K_4EDTA as listed in Table 3 for $[(CH_3)_4N]_4EDTA$. These calculations have also made use of auxiliary data for $(CH_3)_4NCl$, NaCl, and KCl (7, 11, 17–19) listed in Table 2, along with eq. [7] extended to three electrolytes as in

$$[12]\qquad \delta = k_{23}F_2F_3I + k_{24}F_2F_4I + k_{34}F_3F_4I$$

to obtain standard state and other parameters. The relative concentrations of the species in the solutions containing $NaEDTA^{3-}$(aq) allow us to ignore interactions of the uncomplexed $EDTA^{4-}$(aq) anion, which simplifies eq. [12] to eq. [7] in this case. On the other hand, analysis of the experimental data for solutions in which $KEDTA^{3-}$(aq) was an important anion is more complicated because of the larger number of non-negligible parameters to be included in the fit. Results of all of these calculations for solutions containing $NaEDTA^{3-}$(aq) and $KEDTA^{3-}$(aq) are given in Table 6. We have plotted our data and the resultant fits for these solutions in Figs. 3 and 4. Again these plots show our fits to Young's rule as described here and as calculated from the Pitzer ion interaction model, which follows directly below.

The basic equation in the Pitzer treatment that we now use considers the excess free energy to result from long-range electrostatic interactions (given by Debye–Hückel theory) and

TABLE 3. Conventional standard state (infinite dilution) partial molar volumes, heat capacities, B_Y, C_Y, and k_{23} parameters for solutions of $[(CH_3)_4N]_4EDTA + (CH_3)_4NOH$ derived using Young's rule approach* †

*The ± values correspond to the statistical estimates of the uncertainties from our least-squares fits.

†Values of the important parameters $\bar{V}^0$ and $\bar{C}_p^0$ depend on the fitting equation that is used. We have adopted the values marked §. Based on the differences between fits and other factors discussed in the text, we assign total uncertainties to be ±2 $cm^3\ mol^{-1}$ and ±25 $J\ K^{-1}\ mol^{-1}$ for $\bar{V}^0$ and $\bar{C}_p^0$.

‡We have assumed that k_{23}^J is the same as that for the Fisher solutions, which had a wider variation in m_2 and m_3.

short-range binary and ternary interactions. The model yields the following general equation for a mixture of any number of electrolytes (48–50)

$$[13]\quad \frac{G^{EX}}{RT} = f(I) + 2\sum_c\sum_a m_c m_a(B_{ca} + EC_{ca}) + \sum_c\sum_{c'} m_c m_{c'}(\theta_{cc'} + \sum m_a\psi_{cc'a}/2) + \sum_a\sum_{a'} m_a m_{a'}(\theta_{aa'} + \sum m_c\psi_{caa'}/2)$$

Here c and a refer to individual cationic and anionic species, $f(I)$ is the Pitzer form of the extended Debye–Hückel equation

$$[14]\quad f(I) = -A_\phi(4I/1.2)\ln(1 + 1.2I^{1/2})$$

and E is given by

$$[15]\quad E = \sum m_c z_c$$

Combination and rearrangement of our equations for the experimental apparent molar properties and appropriate derivatives of eq. [13] leads to the "Pitzer expressions" that we apply to our results for solutions of $[(CH_3)_4N]_4EDTA + (CH_3)_4NOH$:

$$[16]\quad {}^\phi V_\Sigma = [1/(m_2 + m_3)][(A_V I/1.2)\ln(1 + 1.2I^{1/2}) + m_2\bar{V}_2^0 + m_3\bar{V}_3^0 + 2RT(m_c m_2 B_2^V + m_c^2 m_2 C_2^V + m_c m_3 B_3^V + m_c^2 m_3 C_3^V + m_2 m_3\theta_{23}^V)]$$

$$[17]\quad {}^\phi C_{p,\Sigma} = [1/(m_2 + m_3)][(A_J I/1.2)\ln(1 + 1.2I^{1/2}) + m_2\bar{C}_{p,2}^0 + m_3\bar{C}_{p,3}^0 - 2RT^2(m_c m_2 B_2^J + m_c^2 m_2 C_2^J + m_c m_3 B_3^J + m_c^2 m_3 C_3^J + m_2 m_3\theta_{23}^J)]$$

In these equations m_c refers to the molality of the common cation, given by $m_c = 4m_2 + m_3$. The contributions of non-ideal ternary interactions to the excess properties have been neglected because previous experience has suggested that such interactions are unimportant in the relatively dilute solutions under consideration.

Similar more complicated expressions that are applicable to solutions of M_3[MEDTA] + MOH are as follows:

$$[18]\quad {}^\phi V_\Sigma = [1/(m_2 + m_3)][(A_V I/1.2)\ln(1 + 1.2I^{1/2}) + m_2\bar{V}_2^0 + m_3\bar{V}_3^0 + m_4\bar{V}_4^0 + 2RT(m_c m_2 B_2^V + m_c^2 m_2 C_2^V + m_c m_3 B_3^V + m_c^2 m_3 C_3^V + m_c m_4 B_4^V + m_c^2 m_4 C_4^V + m_2 m_3\theta_{23}^V + m_2 m_4\theta_{24}^V + m_3 m_4\theta_{34}^V)]$$

$$[19]\quad {}^\phi C_{p,\Sigma} = [1/(m_2 + m_3)][(A_J I/1.2)\ln(1 + 1.2I^{1/2}) + m_2\bar{C}_{p,2}^0 + m_3\bar{C}_{p,3}^0 + m_4\bar{C}_{p,4}^0 - 2RT^2(m_c m_2 B_2^J + m_c^2 m_2 C_2^J + m_c m_3 B_3^J + m_c^2 m_3 C_3^J + m_c m_4 B_4^J + m_c^2 m_4 C_4^J + m_2 m_3\theta_{23}^J + m_2 m_4\theta_{24}^J + m_3 m_4\theta_{34}^J)]$$

Again for systems in which one of the solute components dissociates, m_2, m_3, and m_4 refer to the molality of different species rather than to the molality of the stoichiometric component, as is the case elsewhere in this paper.

This application of the Pitzer model to solutions of a single electrolyte $M_{\nu_M}X_{\nu_X}$ leads (51) to

$$[20]\quad {}^\phi V = \bar{V}^0 + \nu|z_M z_X|(A_V/2b)\ln(1 + bI^{1/2}) + 2\nu_M\nu_X RT[mB^V + m^2(\nu_M z_M)C^V]$$

and

$$[21]\quad {}^\phi C_p = \bar{C}_p^0 + \nu|z_M z_X|(A_J/2b)\ln(1 + bI^{1/2}) - 2\nu_M\nu_X RT^2[mB^J - m^2(\nu_M z_M)C^J]$$

in which $\nu = \nu_M + \nu_X$, $b = 1.2$, C^Y is an adjustable parameter, and B^Y is a function of ionic strength that has the form

$$[22]\quad B^Y = \beta^{(0)Y} + 2\beta^{(1)Y}[1 - (1 + \alpha I^{1/2})\exp(-\alpha I^{1/2})]/\alpha^2 I$$

Here $\beta^{(0)Y}$ and $\beta^{(1)Y}$ are adjustable parameters and $\alpha = 2$.

We have fitted equations of type [16]–[22] to our experimental data for mixed electrolytes as listed in Table 1 (with auxiliary data from Tables 5 and 7) to obtain the desired

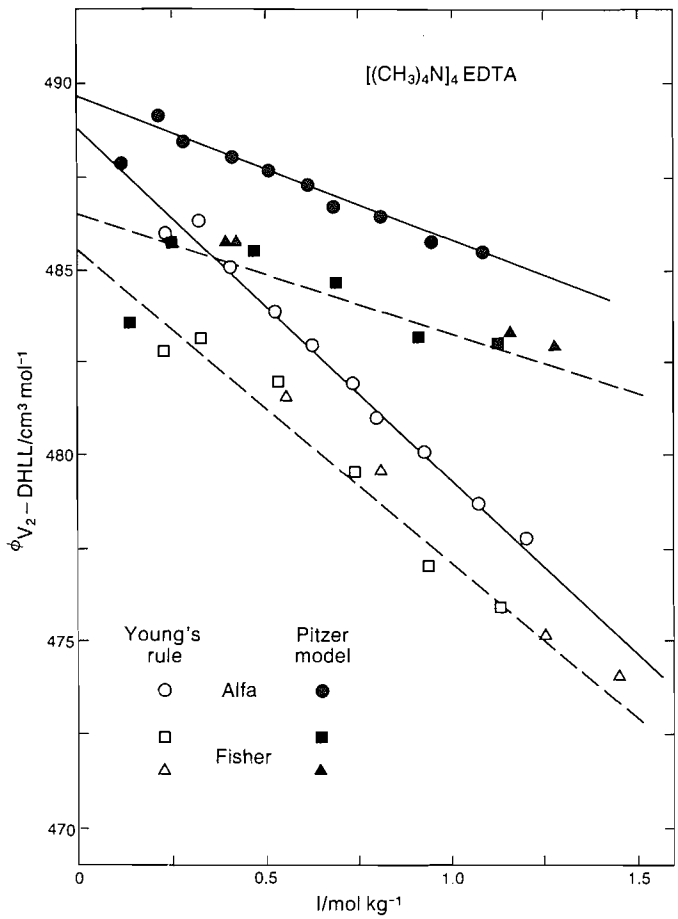

FIG. 2. Apparent molar volumes for $[(CH_3)_4N]_4EDTA$ minus the Debye–Hückel limiting law (DHLL) contribution against ionic strength (I) as calculated from both Young's rule and the Pitzer model. Our selected fits to the Pitzer model were mathematically manipulated to produce linear fits with ionic strength and subsequently do not represent true ionic strength values but rather ωm_2, but do show the desired "goodness" of fit.

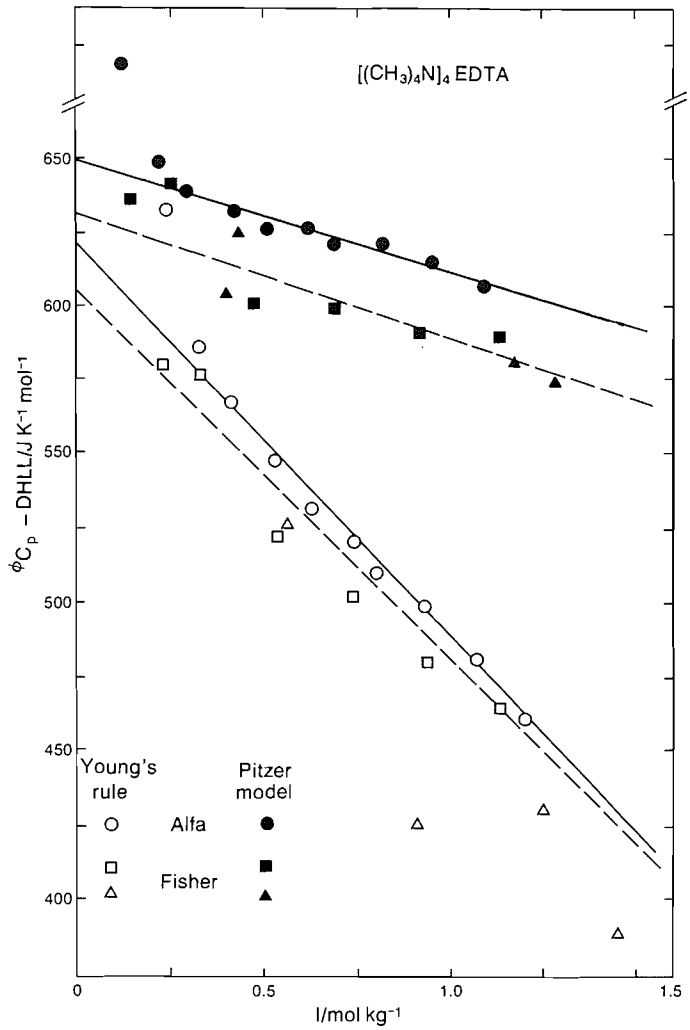

FIG. 3. Apparent molar heat capacities for $[(CH_3)_4N]_4EDTA$ minus the Debye–Hückel limiting law (DHLL) contribution against ionic strength (I) as calculated from both Young's rule and the Pitzer model. The plotted ionic strength values from the two models are different (see Fig. 2 caption).

parameters that are listed in Table 8. Plots of our fits to these data are given in Figs. 2–5.

$[(CH_3)_4N]_3HEDTA$ and Na_2H_2EDTA

We express our experimental results for solutions of Na_2H_2EDTA and $[(CH_3)_4N]_3HEDTA$ as experimental apparent molar properties ($^{\phi}V^{exp}$, $^{\phi}C_p^{exp}$) defined by

$$[23] \qquad {}^{\phi}Y^{exp} = (Y_{sol} - n_1 Y_1^0)/n_2$$

in which meanings of symbols have been specified previously. These experimental results are listed in Table 1.

The important equilibria in solutions of $[(CH_3)_4N]_3HEDTA$ are

$$[24] \qquad \underset{(1-\alpha-\beta)m_2}{HEDTA^{3-}(aq)} + H_2O(l) = \underset{\alpha m_2}{H_2EDTA^{2-}(aq)} + \underset{(\alpha-\beta)m_2}{OH^-(aq)}$$

and

$$[25] \qquad \underset{(1-\alpha-\beta)m_2}{HEDTA^{3-}(aq)} + \underset{(\alpha-\beta)m_2}{OH^-(aq)} = \underset{\beta m_2}{EDTA^{4-}(aq)} + H_2O(l)$$

The experimental apparent molar heat capacities and volumes contain contributions from the $H_2EDTA^{2-}(aq)$ and $EDTA^{4-}(aq)$ anions as well as the $HEDTA^{3-}(aq)$ anion that is the principal species of interest here. The experimental apparent molar heat capacities also contain relaxation contributions associated with the equilibria described by eqs. [24] and [25]. Evaluations of the relaxation contributions are presented in Appendices I and II.

TABLE 4. Equilibrium constant data for $Na^+(aq)$ and $K^+(aq)$ complexation with $EDTA^{4-}(aq)$, from Daniele *et al.* (3) for use in eq. [11]

	$M^+ + EDTA^{4-} = MEDTA^{3-}$		$nH^+ + EDTA^{4-} = H_nHEDTA^{n-4}$		
Property	Na^+	K^+	n = 1	n = 2	n = 3

[27] $H_2EDTA^{2-}(aq) = H^+(aq) + HEDTA^{3-}(aq)$
$(1 - \alpha - \beta)m_2 \quad (\alpha - \beta)m_2 \quad \alpha m_2$

and

[28] $H_2EDTA^{2-}(aq) + H^+(aq) = H_3EDTA^-(aq)$
$(1 - \alpha - \beta)m_2 \quad (\alpha - \beta)m_2 \quad \beta m_2$

The experimental apparent molar heat capacities and volumes contain contributions from the $HEDTA^{3-}(aq)$ and $H_3EDTA^-(aq)$ anions as well as $H_2EDTA^{2-}(aq)$, which is of principal interest here, and the apparent molar heat capacities also contain relaxation contributions associated with the equilibria represented by eqs. [27] and [28]. Appendices I and II describe evaluation of these relaxation contributions from equilibrium constants and enthalpies of reaction.

Concentrations of all species in these solutions have been calculated from equilibrium constants given by Daniele *et al.* (3) and Sweeton *et al.* (52) in combination with our eqs. [27] and [28], with results summarized in Table 9.

The experimental apparent molar properties are expressed as appropriate sums as done previously in eq. [26]:

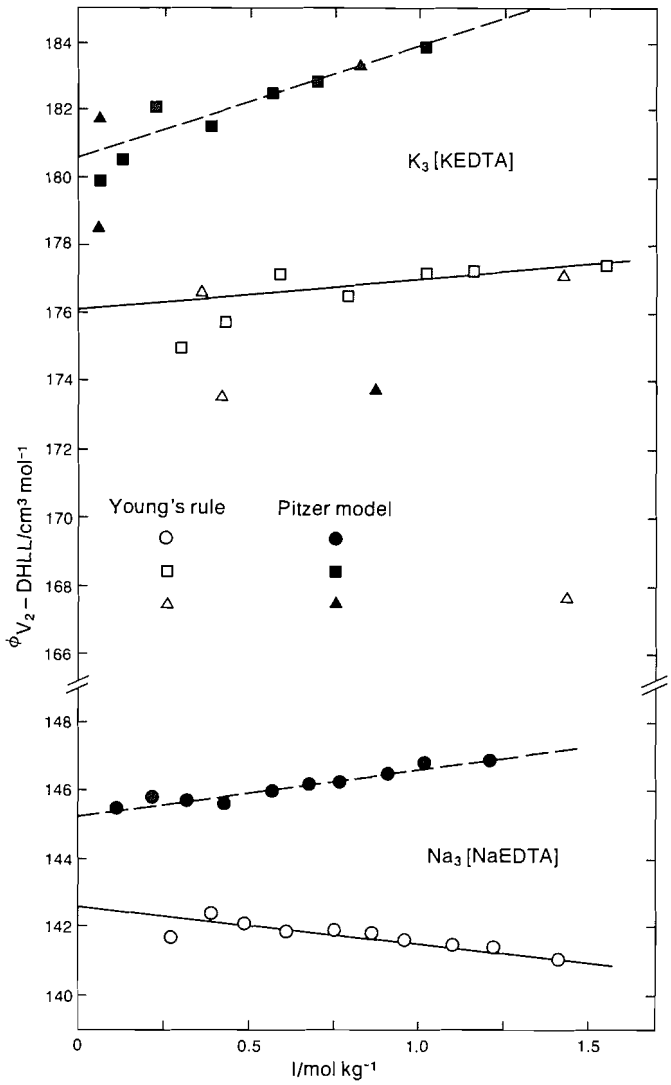

FIG. 4. Apparent molar volumes for Na_3[NaEDTA] and K_3[KEDTA] minus the Debye–Hückel limiting law (DHLL) contribution against ionic strength (I) as calculated from both Young's rule and the Pitzer model. The plotted ionic strengths from the two models are different (see Fig. 2 caption). △ represent higher $OH^-/KEDTA^{3-}$ ratios.

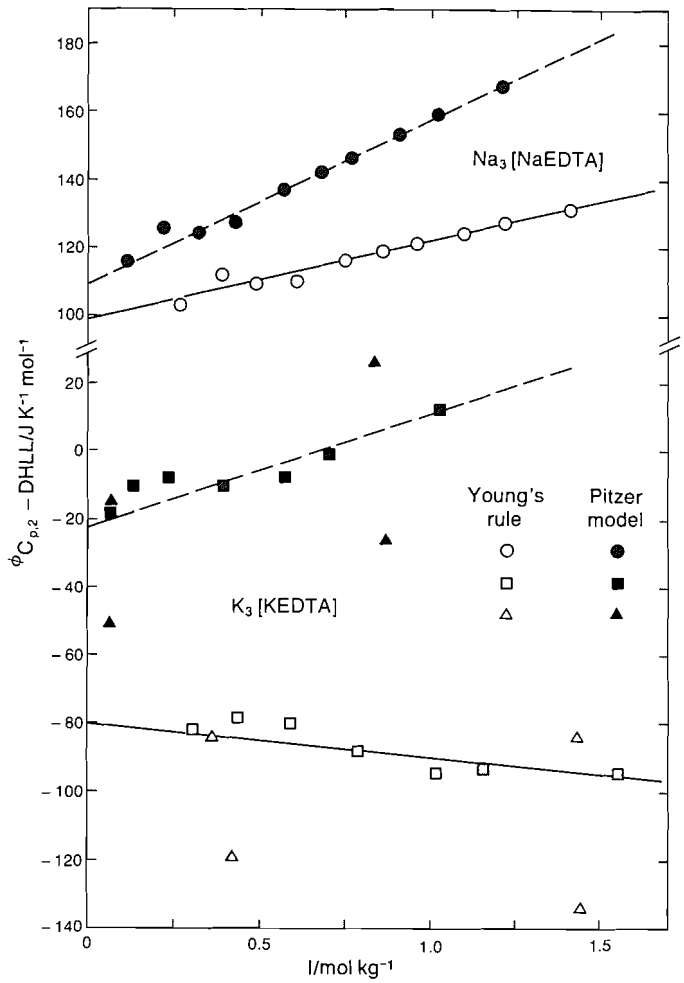

FIG. 5. Apparent molar heat capacities for Na_3[NaEDTA] and K_3[KEDTA] minus the Debye–Hückel limiting law (DHLL) contribution against ionic strength (I) as calculated from both Young's rule and the Pitzer model. The plotted ionic strengths from the two models are different (see Fig. 2 caption). △ represent higher $OH^-/KEDTA^{3-}$ ratios.

[29] $$^{\phi}Y^{exp} = (1 - \alpha - \beta)^{\phi}Y(2Na^+ + H_2EDTA^{2-}) + \alpha^{\phi}Y(3Na^+ + HEDTA^{3-}) + \beta^{\phi}Y(H_3EDTA^-) + (2\beta - \alpha)^{\phi}Y(Na^+) + (\alpha - \beta)^{\phi}Y(H^+)$$

To make use of eq. [29] we have used the standard state heat capacity and volume of Na^+(aq) as listed in Table 10. Properties of $3Na^+$(aq) + $HEDTA^{3-}$(aq) have come from our measurements and calculations based on eq. [26]. There are two indirect routes to the required properties of H_3EDTA^-(aq). In our previous work (1) we combined $d\Delta H/dT$ results (cited in Appendix II) for the ionization of H_2EDTA^{2-}(aq) with our measured heat capacities for H_2EDTA^{2-}(aq) to obtain a value (large uncertainty) for the heat capacity of H_3EDTA^-(aq). Another route is to estimate the desired standard state properties for H_3EDTA^-(aq) on the basis of the now reliably known properties for other EDTA species and trends observed for a few other systems. In this latter way (see Fig. 8) we have estimated $\bar{V}^0 = 159\ cm^3\ mol^{-1}$ and $\bar{C}_p^0 = 210\ J\ K^{-1}\ mol^{-1}$ for H_3EDTA^-(aq). Fortunately, because β values used in eq. [29]

are small, the uncertainties in these estimated values do not cause much uncertainty in the desired properties of $2Na^+(aq) + H_2EDTA^{2-}(aq)$. Finally, using auxiliary results mentioned here, we have fitted eqs. [8] and [29] to our experimental apparent molar properties listed in Table 1 to obtain the desired properties of $2Na^+(aq) + H_2EDTA^{2-}(aq)$ that are listed in Table 11. Figs. 6 and 7 show plots of our fits of eq. [8] to our experimental data.

Selections of ionic properties

For calculation of the temperature and pressure dependence of thermodynamic quantities (such as standard equilibrium constants) we use partial molar heat capacities and volumes (identical to the corresponding apparent molar properties at infinite dilution). It is most convenient to tabulate these standard state quantities as the conventional ionic properties, based on $\bar{Y}^0(H^+, aq) \equiv 0$.

Our selections of values for these conventional standard state quantities for $HEDTA^{3-}(aq)$ and for $H_2EDTA^{2-}(aq)$ are straightforward, based on our results in Table 11 in combination with properties listed in Table 10 for $Na^+(aq)$ and $(CH_3)_4N^+(aq)$. Results of these calculations are listed in the bottom half of Table 10.

Our applications of Young's rule and the Pitzer model to extraction of standard state properties of $[(CH_3)_4N]_4EDTA$ from experimental results for solutions of $[(CH_3)_4N]_4EDTA + (CH_3)_4NOH$ have led (Tables 3 and 8) to a small difference between the desired $\bar{V}^0$ values and to a substantial difference between the two $\bar{C}^0_p$ values that "should" be identical. In addition to this difference that comes from the two methods of data analysis, there are also different results from the two stock solutions that we have used. Because there is no clear reason for selecting any one value of $\bar{C}^0_p$ or $\bar{V}^0$ as best, we have decided to use a weighted average of the various results, with appropriate consideration of the uncertainties. In this way we have selected $\bar{V}^0 = 488 \pm 2\ cm^3\ mol^{-1}$ and $\bar{C}^0_p = 630 \pm 20\ J\ K^{-1}\ mol^{-1}$ as the best available values of these thermodynamic properties for $[(CH_3)_4N]_4EDTA(aq)$. These selected values then lead in straightforward fashion to the conventional ionic properties listed in Table 10 for $EDTA^{4-}(aq)$.

As can be seen in Tables 6 and 8, the two different methods of data analysis lead to somewhat different values for the properties of $Na_3[NaEDTA](aq)$ and $K_3[KEDTA](aq)$ at infinite dilution. These differences are due mostly to the differences in the properties of $[(CH_3)_4N]_4EDTA$ derived from the two methods of data analysis. Here we have used the average values to obtain $\bar{V}^0 = 143.9 \pm 1\ cm^3\ mol^{-1}$ and $\bar{C}^0_p = 104 \pm 15\ J\ K^{-1}\ mol^{-1}$ for $Na_3[NaEDTA](aq)$ and $\bar{V}^0 = 178 \pm 2\ cm^3\ mol^{-1}$ and $\bar{C}^0_p = -51 \pm 25\ J\ K^{-1}\ mol^{-1}$ for $K_3[KEDTA](aq)$. These values lead to the conventional ionic standard state properties for $NaEDTA^{3-}(aq)$ and $KEDTA^{3-}(aq)$ that are listed in Table 10.

Many of the published thermodynamic results (equilibrium constants and enthalpies) for aqueous EDTA systems refer to solutions having constant ionic strength (mostly 0.1 molar), rather than to the infinite dilution condition that is appropriate to the selected ionic properties cited earlier in this section. We have therefore used our results to obtain partial molar heat

capacities and volumes applicable to 0.1 M solutions by way of

[30] $\quad \bar{Y} = {}^{\Phi}Y + I(\partial {}^{\Phi}Y/\partial I)$

Results of these calculations are listed in Table 12, and related conventional properties of ionic species are listed in Table 10.

The only previous direct calorimetric investigation of heat capacities of EDTA solutions pertinent to our present work was our investigation (1) of solutions of H_2EDTA^{2-}(aq). We note, however, that Vasil'ev *et al.* (46, 55–59) have measured enthalpies of several reactions involving EDTA in moderately concentrated solutions over narrow (mostly 20°) ranges of temperature, with results that lead with eq. [2] to ΔC_p values for these same reactions. These ΔC_p values can be combined with results of our previous direct heat capacity measurements (1, 2) to provide estimates for the $\bar{C}_p^0$ of $EDTA^{4-}$(aq). We have used and will use some of these ΔH values in thermodynamic calculations, but we do not use their ΔC_p values for reasons that follow. Vasil'ev *et al.* have estimated that uncertainties in their derived ΔC_p values are about ± 50 J K⁻¹ mol⁻¹. We believe that this estimate of uncertainties is optimistic because of

†These values are estimates at the infinite dilution reference state.

inadequate allowance for the magnification of uncertainties associated with differentiation and also because of additional uncertainties in extrapolating their results to the standard states of present interest (infinite dilution or 0.1 molar or 0.1 molal). The only previous investigation of volumes of $H_2EDTA^{2-}(aq)$ was our work (1).

Thermodynamics of ionization reactions of EDTA

One of the principal purposes of this work has been to obtain partial molar heat capacities and volumes of species of EDTA, with a view toward using these results in thermodynamic calculations as described in the next section. Here (and in Appendix II) we are concerned with selecting the values of various thermodynamic properties (K, ΔH, etc.) associated with the following ionization reactions of aqueous EDTA:

[31] $H_6EDTA^{2+}(aq) = H^+(aq) + H_5EDTA^+(aq)$

[32] $H_5EDTA^+(aq) = H^+(aq) + H_4EDTA(aq)$

[33] $H_4EDTA(aq) = H^+(aq) + H_3EDTA^-(aq)$

[34] $H_3EDTA^-(aq) = H^+(aq) + H_2EDTA^{2-}(aq)$

[35] $H_2EDTA^{2-}(aq) = H^+(aq) + HEDTA^{3-}(aq)$

[36] $HEDTA^{3-}(aq) = H^+(aq) + EDTA^{4-}(aq)$

[37] $H_6EDTA^{2+}(aq) = 6H^+(aq) + EDTA^{4-}(aq)$

Equilibrium constants (K) and enthalpies (ΔH) for each of these reactions [31]–[37] have been selected as summarized in Appendix II. Our experimental results lead to accurate values of ΔC_p and ΔV for reactions [35] and [36] and to less accurate values of ΔC_p and ΔV for reaction [34], as discussed earlier. We regard these ΔC_p values as more reliable than those that can be obtained by way of application of $d\Delta H/dT$ to the enthalpy of reaction data of Vasil'ev *et al.* (26, 34–39). The only experimental route that we have to ΔC_p for reaction [37] is by application of $d\Delta H/dT$ to the enthalpies of reaction measured in concentrated solution by Vasil'ev *et al.* (38). Finally, we have used the ΔC_p values mentioned above in constructing plots of ΔC_p against n (or alternatively against $\log K$, which yields a reasonably linear relationship) for ionization of $H_nEDTA^{n-3}(aq)$ and have thereby *estimated* the "missing" ΔC_p values for reactions [31]–[33]. We have made similar plots for ΔV values against $\log K$ for the ionization reactions [34]–[36] to *estimate* values for eqs. [31]–[33]. All of the selected (based on experimental and estimated results) thermodynamic quantities ($K^\dagger$, $\Delta H^\dagger$, $\Delta C_p^\dagger$, and $\Delta V^\dagger$) for reactions [31]–[37] are collected in Table 13. We have also listed selected values for complexation of $Na^+(aq)$ and $K^+(aq)$ with $EDTA^{4-}(aq)$ in Table 13.

Extrapolations of equilibrium constants to higher temperatures

Equilibrium constants vary with temperature according to the van't Hoff equation [1] and the Kirchhoff equation [2] and vary with pressure according to

[38] $$(\partial \ln K/\partial p)_T = -\Delta V^0/RT$$

We begin by combining eqs. [1] and [2] with the specification that ΔC_p is (approximately) independent of temperature to obtain

[39] $$\ln K_T^\dagger = \ln K_{298}^\dagger + \Delta H_{298}^\dagger[(1/298.15) - (1/T)]/R + \Delta C_p^\dagger[\ln (T/298.15) - 1 + (298.15/T)]/R$$

Here we have written this equation in terms of the 0.1 molar reference state that is commonly used for EDTA studies. Experience has shown that eq. [39] provides a more accurate representation of the temperature dependence of equilibrium constants over wide ranges of temperature than does the simpler equation based on integration of [1] with the pretence that ΔH is independent of temperature ($\Delta C_p = 0$).

In obtaining eq. [39] we have specified that $\Delta C_p^\dagger$ is (approximately) independent of temperature because we have no direct evidence about the possible temperature dependence of this quantity for the reactions of present interest. Experience (23,

25	−1.2	−1.51	−1.96	−2.68	−6.19	−10.39	1.04
37	−1.2	−1.53	−2.00	−2.75	−6.10	−10.27	0.99
50	−1.2	−1.57	−2.01	−2.79	−5.97	−10.11	0.94
75	−1.2	−1.67	−2.08	−2.91	−5.82	−9.90	0.86
100	−1.2	−1.79	−2.17	−3.04	−5.71	−9.75	0.82
125	−1.3	−1.93	−2.27	−3.18	−5.65	−9.65	0.79
150	−1.4	−2.08	−2.38	−3.33	−5.61	−9.58	0.77
175	−1.5	−2.24	−2.51	−3.48	−5.60	−9.54	0.77
200	−1.6	−2.41	−2.66	−3.66	−5.63	−9.55	0.78
250	−1.9	−2.76	−2.97	−4.02	−5.74	−9.62	0.81

*The uncertainties in these values depend on the uncertainties in the values of log $K^\dagger$ at 25°C and in our extrapolation. Experience has shown that errors in log K due to the extrapolations increase to about ±0.5 at 250°C.

60, 61) has shown that ΔC_p values for "isocoulombic" reactions (symmetric with respect to number and charges of ions) are much more nearly independent of temperature than for electrically asymmetric reactions. We therefore focus our attention on reactions [31], [32], and the following reactions that are related to [33]–[36], all of which are either isocoulombic or pseudo-isocoulombic:

[40] $EDTA^{4-}(aq) + H_2O(l) = HEDTA^{3-}(aq) + OH^-(aq)$

[41] $HEDTA^{3-}(aq) + H_2O(l) = H_2EDTA^{2-}(aq) + OH^-(aq)$

[42] $H_2EDTA^{2-}(aq) + H_2O(l) = H_3EDTA^-(aq) + OH^-(aq)$

[43] $H_3EDTA^-(aq) + H_2O(l) = H_4EDTA(aq) + OH^-(aq)$

Equilibrium constants, $\Delta H^\dagger$, and $\Delta C_p^\dagger$ values for reactions [40]–[43] are related to corresponding values for reactions [33]–[36] by $K^\dagger$, $\Delta H^\dagger$, and $\Delta C_p^\dagger$ for the ionization of water; we take $K^\dagger$ and $\Delta H^\dagger$ values from earlier investigations (45, 62), and have used the values in Table 10 to calculate $\Delta C_p^\dagger$. We have used all of these quantities and applied eq. [39] to all of the ionization reactions of EDTA, and have reported the results in Table 14.

Integration of eq. [38] leads to

[44] $$\ln K_p^\dagger = \ln K_1^\dagger - (p-1)(\Delta V^\dagger/RT)$$

where $\ln K_1^\dagger$ represents the value of the logarithm of $K^\dagger$ at 1 bar (100 kPa), and $\ln K_p^\dagger$ the value at a pressure p. Although the effect of pressure on equilibrium constants is small at pressures up to the saturation pressure of water at 200°C, we have included this effect in the values listed in Table 14, calculated using saturation pressures of water from Haar *et al.* (24).

Results of similar calculations for the isocoulombic exchange reaction involving $NaEDTA^{3-}(aq)$ and $KEDTA^{3-}(aq)$ given by

[45] $K^+(aq) + NaEDTA^{3-}(aq) = KEDTA^{3-}(aq) + Na^+(aq)$

are listed along with the ionization constants in Table 14.

Appendix I

Relaxation contributions to heat capacities of mixed electrolyte solutions

There have been several accounts (20–23, 25)[2] of the contributions of chemical relaxation to heat capacities of aqueous solutions of electrolytes, but none has dealt with the kinds of mixed electrolyte effects encountered here. We therefore provide the following treatment.

The total enthalpy of a system containing k components can be expressed (21) by

$$[I\text{-}1] \qquad H = \sum_k n_k H_k$$

in which n_k and H_k represent the number of moles and the partial molar enthalpy of the kth component. Differentiation with respect to temperature leads to

$$[I\text{-}2] \qquad C_p = (\partial H/\partial T)_p = \Sigma n_k (\partial H_k/\partial T)_p + \Sigma H_k (\partial n_k/\partial T)_p$$

In this equation the first summation term represents the "compositional" or "species" contribution to the heat capacity and the second summation term represents the contribution to the heat capacity due to the change in distribution (chemical relaxation) of species induced by the change of temperature that is necessary for heat capacity measurements. The last term (relaxation contribution to the heat capacity) must be subtracted from the measured heat capacity to obtain the compositional contribution of the chemical species of interest.

Evaluation of the relaxation contribution for mixed aqueous electrolyte solutions of present interest can begin along the lines of an earlier investigation (20) by expressing the heat capacity C_p of a solution (containing 1 kg of water) as a sum of compositional or species and relaxation contributions denoted by superscripts sp and rel as in

$$[I\text{-}3] \qquad C_p(\text{sol}) = (\partial H/\partial T)_p^{\text{sp}} + (\partial H/\partial T)_p^{\text{rel}}$$

Combination of this equation with our defining eq. [3] gives (see ref. 20)

$$[I\text{-}4] \qquad {}^{\Phi}C_{p,\Sigma}^{\text{exp}} = [(\partial H/\partial T)_p^{\text{sp}} - C_p(\text{H}_2\text{O})]/(m_2 + m_3) + (\partial H/\partial T)_p^{\text{rel}}/(m_2 + m_3)$$

A start on the evaluation of the relaxation term in [I-4] is provided (20) by

$$[I\text{-}5] \qquad (\partial H/\partial T)_p^{\text{rel}} = [\partial H/\partial(\alpha m_2)]_p [\partial(\alpha m_2)/\partial T]_{p,m} = m_2 \Delta H (\partial\alpha/\partial T)_{p,m}$$

in which α is the fractional extent of the reaction, m_2 is the stoichiometric molality of the reacting electrolyte, and ΔH is the molar enthalpy of the reaction. Now we write

$$[I\text{-}6] \qquad {}^{\Phi}C_{p,\Sigma}^{\text{rel}} = [m_2/(m_2 + m_3)]\Delta H (\partial\alpha/\partial T)_{p,m}$$

for the contribution of chemical relaxation to the apparent molar heat capacities that come directly from our calorimetric measurements. Evaluation of $(\partial\alpha/\partial T)_{p,m}$ is done in terms of the equilibrium constant K, the temperature dependence of K as in eq. [1], activity coefficients, and the temperature dependence of the activity coefficients. Because of limitations imposed by the available data, we have ignored the distinction between ΔH and ΔH^0 (related to the temperature dependence of activity coefficients) and have used K values that refer to specified concentrations and that have been expressed in terms of concentrations of various species.

Solutions of Na_3[NaEDTA] and K_3[KEDTA]

The equilibrium reaction to be considered in connection with these solutions was represented by eq. [10] in the main text. Mathematical manipulation of K for reaction [10] expressed in terms of α in combination with eq. [1] leads to

[I-7] $$(\partial\alpha/\partial T)_m = K\Delta H(1-\alpha)/[RT^2(3m_2 + 2\alpha m_2 + m_3 + K)]$$

We have used K values (given as a function of ionic strength) from Daniele *et al.* (3) as listed in Table 4, and $\Delta H = -8.5$ kJ mol^{-1} (Appendix II) to evaluate the relaxation contributions to the heat capacities of solutions of Na_3[NaEDTA] + NaOH as listed in Table A1. Because $\Delta H \simeq 0$ for the corresponding reaction involving K^+(aq), the relaxation contribution for these solutions is nearly zero.

Solutions containing $HEDTA^{3-}$(aq) and H_2EDTA^{2-}(aq)

The relaxation components of the experimental apparent molar heat capacities of solutions containing $HEDTA^{3-}$(aq) and H_2EDTA^{2-}(aq) are given by the usual expressions for coupled reactions (α and β defined in terms of eqs. [24], [25], and [27], [28]):

[I-10] $${}^{\Phi}C_{p,\alpha}^{rel} = \Delta H_\alpha(\partial\alpha/\partial T)_m$$

[I-11] $${}^{\Phi}C_{p,\beta}^{rel} = \Delta H_\beta(\partial\beta/\partial T)_m$$

Mathematical manipulations with equilibrium constants for two coupled equilibria in combination with eq. [1] lead to complicated expressions for $(\partial\alpha/\partial T)_m$ and $(\partial\beta/\partial T)_m$ that are similar in principle to those for other systems of coupled equilibria (21).[2] We have selected values of ΔH (Appendix II) to be used in eqs. [I-8], [I-9] to find that the relaxation components of the heat capacities are negligibly small for solutions in which $HEDTA^{3-}$(aq) is the principal species of interest, and have also obtained the non-negligible relaxation contributions to the heat capacities of solutions of H_2EDTA^{2-}(aq) as listed in Table A2.

Appendix II

Selections of thermodynamic data

Previous selections (1) of "best" equilibrium constants from Anderegg (5) for the ionization reactions of H_4EDTA(aq) at 25°C and 0.1 molar ionic strength have been extended by accepting the equilibrium constants reported by Daniele *et al.* (3). The equilibrium constant data for the two protonation reactions of H_4EDTA(aq) are much less certain than the other values. We have chosen the value listed by Anderegg (5) for the first protonation of H_4EDTA and have considered the recommendations of Anderegg (5) and Vasil'ev *et al.* (26) in estimating $\log K^{\dagger} = -1.2 \pm 0.6$ for protonation of H_5EDTA^+(aq), by considering the trends in all of the other equilibrium constants of H_4EDTA(aq) at 0.1 molar.

Several investigations (3, 5, 27–32) have led to values of the equilibrium constant for association of Na^+(aq) with $EDTA^{4-}$(aq); we have used the results of Daniele *et al.* (3). The chosen equilibrium constants for association of K^+(aq)

For personal use only.

with $EDTA^{4-}(aq)$ reported by Daniele *et al.* (3) are in good agreement with results from others (28, 30, 31).

We have revised some previous (1) choices for $\Delta H^{\dagger}$ values for the ionization of $H_4EDTA(aq)$. We have averaged selected direct calorimetric values (many cited by Christensen *et al.* (33)) obtained usually at 0.1 molar (some values were corrected to 0.1 molar from equations given by the respective authors) and 25°C (Vasil'ev *et al.* (26, 34–39), Christensen *et al.* (40), and Kugler and Carey (41)) and also values at 20°C (Tillotson and Staveley (42) and Anderegg (43)) corrected to 25°C using our $\Delta C_p^{\dagger}$ values listed in Table 13. Values reported by Christensen *et al.* (40) seemed inconsistent with other results and were not included in the averages.

For association of $Na^+(aq)$ with $EDTA^{4-}(aq)$ we have several reported (33, 44–46) $\Delta H^{\dagger}$ values and have chosen to use the value from Vasil'ev *et al.* (46) to which we have assigned an uncertainty of about ± 2 kJ mol^{-1}. For association of $K^+(aq)$ with $EDTA^{4-}(aq)$ we have $\Delta H^{\dagger} \simeq 4$ kJ mol^{-1} (after correcting for the effect of temperature on the molarity (42) in the van't Hoff eq. [1]) (large uncertainty) from equilibrium constants at several temperatures (3) and $\Delta H^{\dagger} = 0 \pm 2$ kJ mol^{-1} from calorimetric measurements by Vasil'ev *et al.* (46); we have chosen to use this latter value, which leads to a negligible relaxation contribution to the heat capacity. All of these $\Delta H^{\dagger}$ values used in our calculations are listed in Table 13.

The structures and dynamics of SF_6: new insights

B. M. POWELL AND G. DOLLING

Atomic Energy of Canada Research Company, Chalk River Nuclear Laboratories, Chalk River, Ont., Canada K0J 1J0

Received August 24, 1987

This paper is dedicated to Professor J. A. Morrison

B. M. POWELL and G. DOLLING. Can. J. Chem. **66**, 897 (1988).

The structural and dynamical properties of the orientationally disordered solid SF_6 have been studied. The present understanding of this state is discussed in terms of the microscopic nature of the orientational disorder, the influence of steric repulsion, and the concept of orientational frustration. A possible mechanism is considered for the phase transition to an ordered structure.

I. Introductory review

In addition to the two well-established states of condensed matter, solid and liquid, there exist several other states or phases which are intermediate between these extremes. They exhibit particular characteristics which can be said to derive from *both* the solid and liquid states. One such intermediate state is that of an orientationally disordered solid (OD). This state may exist in solids containing charged ions such as CN^-, SO_4^{2-}, but also exists in solids composed of rather small, often globular and electrically neutral molecules, coupled by intermolecular potentials that are weakly anisotropic. In such molecular solids there are extra orientational degrees of freedom in addition to the usual three translational degrees of freedom. As the molecular liquid is cooled, the translational and orientational degrees of freedom do not necessarily condense out at the same temperature. If the translational degrees condense first and the anisotropic part of the intermolecular potential is too weak to impose orientational order at that temperature, then the resulting solid may have the molecular centres of mass ordered on a crystal lattice, as in a true crystalline solid, but the molecular orientations may remain disordered, as in a liquid. This state of condensed matter is called an orientationally disordered solid.

The existence of a class of molecular solids whose properties might be due to orientational disorder has been known for a long time (1). These solids were originally termed "plastic crystals" by Timmermans and their characteristics have been reviewed more recently (2). However, it is only during the last decade or so that the microscopic nature of the disorder has been studied and elucidated in detail.

In this Introduction we review the present understanding of the OD phase for a particular molecular solid, sulphur hexafluoride (SF_6). New results are discussed in Section II and some conclusions concerning our understanding of this phase are drawn in Section III.

The existence of a phase transition at 96 K in solid SF_6 was first observed in calorimetric measurements (3) and subsequently confirmed by nmr observations (4). From the temperature dependence of the nmr lineshape it was determined that the molecules were undergoing reorientational motion in the high temperature phase. The crystal structure of this phase was shown by X-ray diffraction to be body-centred cubic (4). Later detailed nmr measurements (5) confirmed the reorientational motion of the high temperature phase, but also indicated a second phase transition at $\approx$45 K. The data showed that two inequivalent sites must exist in the low temperature phase and that reorientation of at least some molecules sets in between 45 K and the transition at 96 K. The conclusion from these studies was that the high temperature phase of SF_6 was probably orientationally disordered, but the detailed nature of the disorder remained obscure.

a. Crystal structure and orientational disorder

The high-temperature phase extends from 96 K to the sublimation point at 223 K, an exceptionally large temperature range. Its detailed crystal structure was elucidated by neutron powder diffraction methods (6, 7). Well-defined Debye–Scherrer peaks were observed whose positions could be indexed on the basis of a bcc unit cell. The intensities were analyzed by writing the structure amplitude as the product of a term due to the molecular centre of mass (including a translational Debye–Waller factor) and a term due to a rotational form factor. The latter term was then expanded in a series of symmetry adapted functions. Since SF_6 is cubic (point group symmetry O_h) the appropriate functions are the Kubic Harmonics. These particular functions were introduced into crystal structure analysis by Seymour and Pryor (8) and independently employed by Press and Hüller in their detailed analysis of methane (9). For the octahedral symmetry of SF_6 the four lowest order terms are the zeroth, fourth, sixth, and eighth harmonics. Analysis of the neutron diffraction data in terms of these functions showed that the fourth order harmonic was dominant. Dolling *et al.* (7) showed that the probability distribution describing the orientation of the molecule is determined directly by the coefficients of the expansion in symmetry-adapted functions. This "orientational distribution function" for SF_6, determined from the neutron diffraction data, is shown in Fig. 1.

The distribution function has a maximum along the cubic axes, i.e. the S—F bonds are preferentially aligned along these directions. However, the function has significant values as much as 20° away from these axes. The reason for this can be understood from the unit cell and molecular dimensions. If the S—F bonds are aligned precisely along the cube axes then the closest F atoms in molecules adjacent along these directions will overlap. Such perfect alignment will thus be prevented by steric repulsion. No other maxima in the orientational distribution were found and hence the molecular and site symmetries are the same. High temperature measurements on SF_6 (at 200 K) showed the same qualitative features as those near the transition but extensive diffuse scattering was also observed (7). Analysis

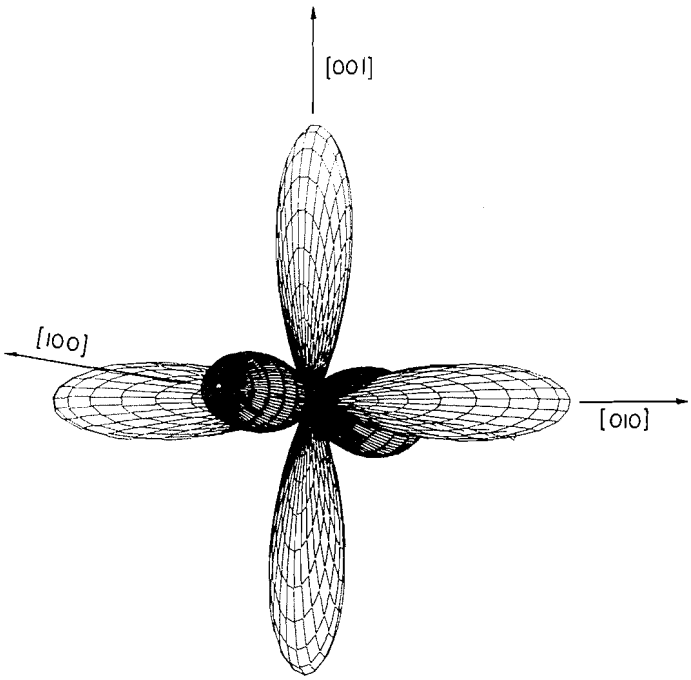

FIG. 1. Orientational distribution function of S—F bonds in SF_6 at 100 K.

of this scattering in terms of randomly oriented SF_6 molecules showed significant discrepancies with the neutron data. These were interpreted as evidence for orientational correlations. Thus the picture of the SF_6 crystal structure emerging from these measurements is one in which the molecular centres of mass lie on an ordered bcc lattice; steric repulsion prevents orientational ordering of the molecules and the preferential cubic axis alignment indicated by the orientational distribution function is merely the time-averaged molecular orientation. The reorientation is not "free", however, and orientational correlations exist between neighbouring molecules.

This experimentally determined picture of SF_6 has been augmented by extensive molecular dynamics simulation (MDS) calculations. The calculations for SF_6 were carried out on an ICL Distributed Array Processor at the University of Edinburgh with a large simulation sample (4096 molecules). The intermolecular potential was written as a summation over pairwise F–F interactions between F atoms in the origin molecule and those in the nearest and next nearest neighbour molecules of the bcc lattice. The F–F interaction is represented by a Lennard–Jones potential. The model is thus as simple as possible while retaining enough essential features to resemble the real SF_6 crystal. The calculations (10, 11) confirmed the experimental orientational distribution function and showed that the molecules were undergoing rotational diffusion. There did not appear to be any well-defined collective librational excitations. Particularly revealing were calculations of the intermolecular potential as a function of separation between pairs of SF_6 molecules with different relative orientations. These showed that when the molecules are aligned parallel to the cube axes the force between the molecule at the origin and its nearest neighbour (the body centred molecule) is attractive, while the force between the origin molecule and its next-nearest neighbour (along the cubic axis) is repulsive (the steric repulsion mentioned previously). The intermolecular potentials are shown in Fig. 2. Thus nearest neighbour interactions favour orientational ordering while next-nearest neighbour interactions oppose this. The competition between these interactions means that the origin molecule does not feel a well-defined orientational potential. Dove and Pawley (11) called this competition "orientational frustration", and suggested that it was the origin of the orientational disorder. At high temperatures the orientational frustration is resolved dynamically, producing an average crystal lattice of high symmetry. The concept of orientational frustration enables a classification of OD crystals into two categories. For orientationally frustrated solids the competing interactions prevent neighbouring molecules from ordering simultaneously, whereas in other OD solids each molecule is either randomly oriented, e.g. CD_4 (9), β-N_2 (12), or resides in one of a finite number of symmetry-related orientations, e.g. CBr_4 (7), adamantane (13).

b. Collective excitations

It is evident that the particular nature of the OD phase will have a significant effect on the character of the intermolecular collective excitations. For a normal molecular solid the intermolecular modes will generally be of mixed translational–librational character. If the solid has high symmetry, then pure translational or pure librational modes may exist for particular directions of propagation. The intermolecular mode dispersion relations can be measured by inelastic neutron scattering techniques and the measurements for HMT (14) show results typical of a normal, high symmetry molecular solid. In an OD phase, however, the absence of long-range orientational order means that well-defined, purely librational modes cannot propagate through the crystal; they will always be rapidly damped out. This intuitive picture has been confirmed by the failure of inelastic neutron scattering measurements to observe well-defined librational modes in OD crystals: it has also been confirmed, in the case of SF_6, by the MDS calculations (11).

Since long range positional order does exist in the OD phase, it would be expected that pure translational modes and mixed modes with predominantly translational character will be largely unaffected by the orientational disorder. Consequently measurements of the long wavelength acoustic modes would be expected to yield well-defined excitations, becoming broadened perhaps as they acquire increasing librational character.

In order to investigate the excitation spectrum for SF_6, inelastic neutron scattering measurements were made on a single crystal at 200 K (15). The experiment concentrated on observing the translational acoustic modes and measurements were made along three high-symmetry directions. Typical results are shown in Fig. 3. Although there is some evidence of discrete structure in the distributions, the dominant feature is the intense, generally featureless scattering at low frequencies. The qualitative characteristics of the experimental distributions are largely independent of momentum transfer and measurements at 100 K showed few differences from those at 200 K. The distributions resemble those expected from overdamped modes and imply very strong rotational–translational coupling. They are in contrast to analogous measurements on other OD solids (12, 13, 16, 17), which generally show well-defined acoustic modes, even when superimposed on a background due to an overdamped librational mode.

These results were completely unexpected, for SF_6 was considered one of the more normal or "more crystalline" of the OD crystals. The only theory of excitations in an orientationally disordered phase is that of Michel and Naudts (18). It was developed originally for the alkali cyanides (18), but has been successfully applied to CBr_4 (17) and β-N_2 (12). It is essentially

a mean field theory, and since steric repulsion is clearly of crucial importance in the concept of orientational frustration, its applicability to SF_6 is uncertain. In view of this uncertainty, the neutron scattering data were analyzed by means of MDS calculations (15). The same simulation sample used to investigate the static properties of SF_6 (10, 11) was utilised and the simulation was allowed to run for a total of 16 000 time steps (80 ps). From this, the dynamical structure factor $S(\boldsymbol{Q}, \omega)$ was calculated for the same momentum transfers, $\boldsymbol{Q}$, used in the neutron measurements. After convoluting the calculated $S(\boldsymbol{Q}, \omega)$ with the experimental resolution, the calculated lineshapes could be directly compared with those measured experimentally. The comparison is shown in Fig. 4. Although there are quantitative discrepancies, the overall qualitative agreement is very good, evidence that the concept of orientational frustration is a valid interpretation of the orientational disorder in SF_6.

c. Orientational ordering and the phase transition

The phase transitions to the low temperature phase of OD crystals are usually first order and the low temperature crystal structures are usually of low symmetry. Consequently a critical test of our understanding of the behaviour of these solids is the ability to explain how (or indeed if!) the ordered low temperature phase arises from the disordered high temperature phase as the temperature is lowered. An essential requirement for this is a knowledge of the low temperature crystal structure, which, in the case of SF_6, was until very recently quite uncertain and a matter of some dispute.

Neutron powder diffraction data (19) indicated the structure to be of low symmetry and showed that it must be very similar at 20 K and 75 K. However, all efforts to find unit cell parameters to index these diffraction data failed. This failure implied that the symmetry of the low temperature phase could be no higher than triclinic. However, electron diffraction data (20) obtained between 45 K and 96 K could be analyzed in terms of a hexagonal cell containing three molecules. These measurements also indicated that at lower temperatures the hexagonal cell distorted to one of monoclinic or lower symmetry. The apparent conflict between the neutron and electron diffraction data immediately below the transition remained unresolved for several years. The two crystal structures observed by electron diffraction could, however, be reproduced by MDS calculations (21). While these suggested that the crystal structure at the lowest temperatures was triclinic, space group $P\bar{1}$, with three ordered molecules in the unit cell, at temperatures just below the transition a trigonal structure was found in which only two-thirds of the molecules are ordered. These two structures are shown in Fig. 5, which is taken from ref. 21. However, subsequent attempts to use this information in the analysis of the neutron diffraction data proved unsuccessful.

II. New results and speculations

The lineshape calculations referred to in Section I(*b*) and shown in Fig. 4 suggest a more complex structure for the excitation spectrum in SF_6. For wave-vectors smaller than those investigated by the neutron scattering experiments, the indications are that well-defined, long wavelength, acoustic modes do indeed exist. In a recent high-resolution inelastic neutron scattering experiment on a single crystal of SF_6, these well-defined modes were observed. Some results are shown in Fig. 6. These data are at present being analyzed (22), following Dove and Lynden-Bell (23), to give information about both the rotational–translational coupling and the correlation functions in SF_6.

The uncertainty concerning the low temperature structure of SF_6 referred to in Section I(*c*) has been resolved recently with the development of a new procedure to index diffraction data, starting from trial structures suggested by molecular packing considerations (24). When applied to the neutron data from SF_6, it succeeded in indexing the pattern in terms of a triclinic unit cell (25). The analysis determined the unit cell parameters with sufficient accuracy that a complete refinement was possible. The detailed crystal structure of SF_6 at 23 K and 85 K has recently been determined from new neutron diffraction data (26). At both temperatures the structure was found to be triclinic, space group $P\bar{1}$, with three ordered molecules in the unit cell, in agreement with the MDS calculations (21). But no evidence for a hexagonal phase below 96 K could be found. It is possible that the intermediate hexagonal phase observed by electron diffraction is restricted to the very thin surface layers that are probed by the electron beam. We believe that it does not exist in bulk SF_6 at any temperature.

The phase transition thus involves a dramatic lowering of symmetry, from cubic to triclinic. However, the triclinic structure can be derived from the cubic by distortions in two stages accompanying the onset of orientational order. First the bcc cell transforms to a hexagonal cell with the hexagonal axis along a cubic <111> direction. This stage involves a significant molecular displacement and a contraction along this direction (26). The MDS calculations (21) show that below 96 K the molecules order along <111> directions, the ordering direction in the cubic OD phase. But since the contraction along this direction causes a closer approach of next nearest neighbour molecules (the "disordering" interaction in the OD phase), not all molecules are able to order. The calculations show that two adjacent rows along <111> can order, but in the next row the molecules remain orientationally disordered. Thus, of the three molecules in the hexagonal cell, two will be ordered and one will remain disordered. The second state of the transition then involves a shear of the hexagonal cell to form the triclinic cell. The shear is perpendicular to the basal plane and appears to involve tilting the hexagonal axis towards the $[1\bar{1}0]$ direction. Since the triclinic structure is fully ordered, this second stage must be associated with the orientational ordering of the remaining third of the molecules. The relation between the cubic, hexagonal and triclinic cells is shown in Fig. 7. Since the hexagonal phase is not observed by the neutron diffraction experiments it appears that in bulk samples of SF_6 both ordering effects occur together at the transition at 96 K; the separation of the two stages seen by electron diffraction may be a purely surface phenomenon.

III. Concluding remarks

The last decade has seen very substantial advances in our understanding of the orientationally disordered state of condensed matter. This is particularly true for the case of SF_6. It has been brought about to a large extent by the application of neutron scattering techniques to the problem and by the increasing availability of large scale molecular dynamics simulation calculations to interpret experimental data. As a result we now know the microscopic nature of the orientational disorder in some detail. Its origin is neither statistical in nature nor large-amplitude thermal fluctuations, but is determined by steric repulsion effects, and may be understood in terms of the concept of orientational frustration. Its character thus differs markedly from the disorder in many other OD crystals.

MDS calculations allow many of the single molecule prop-

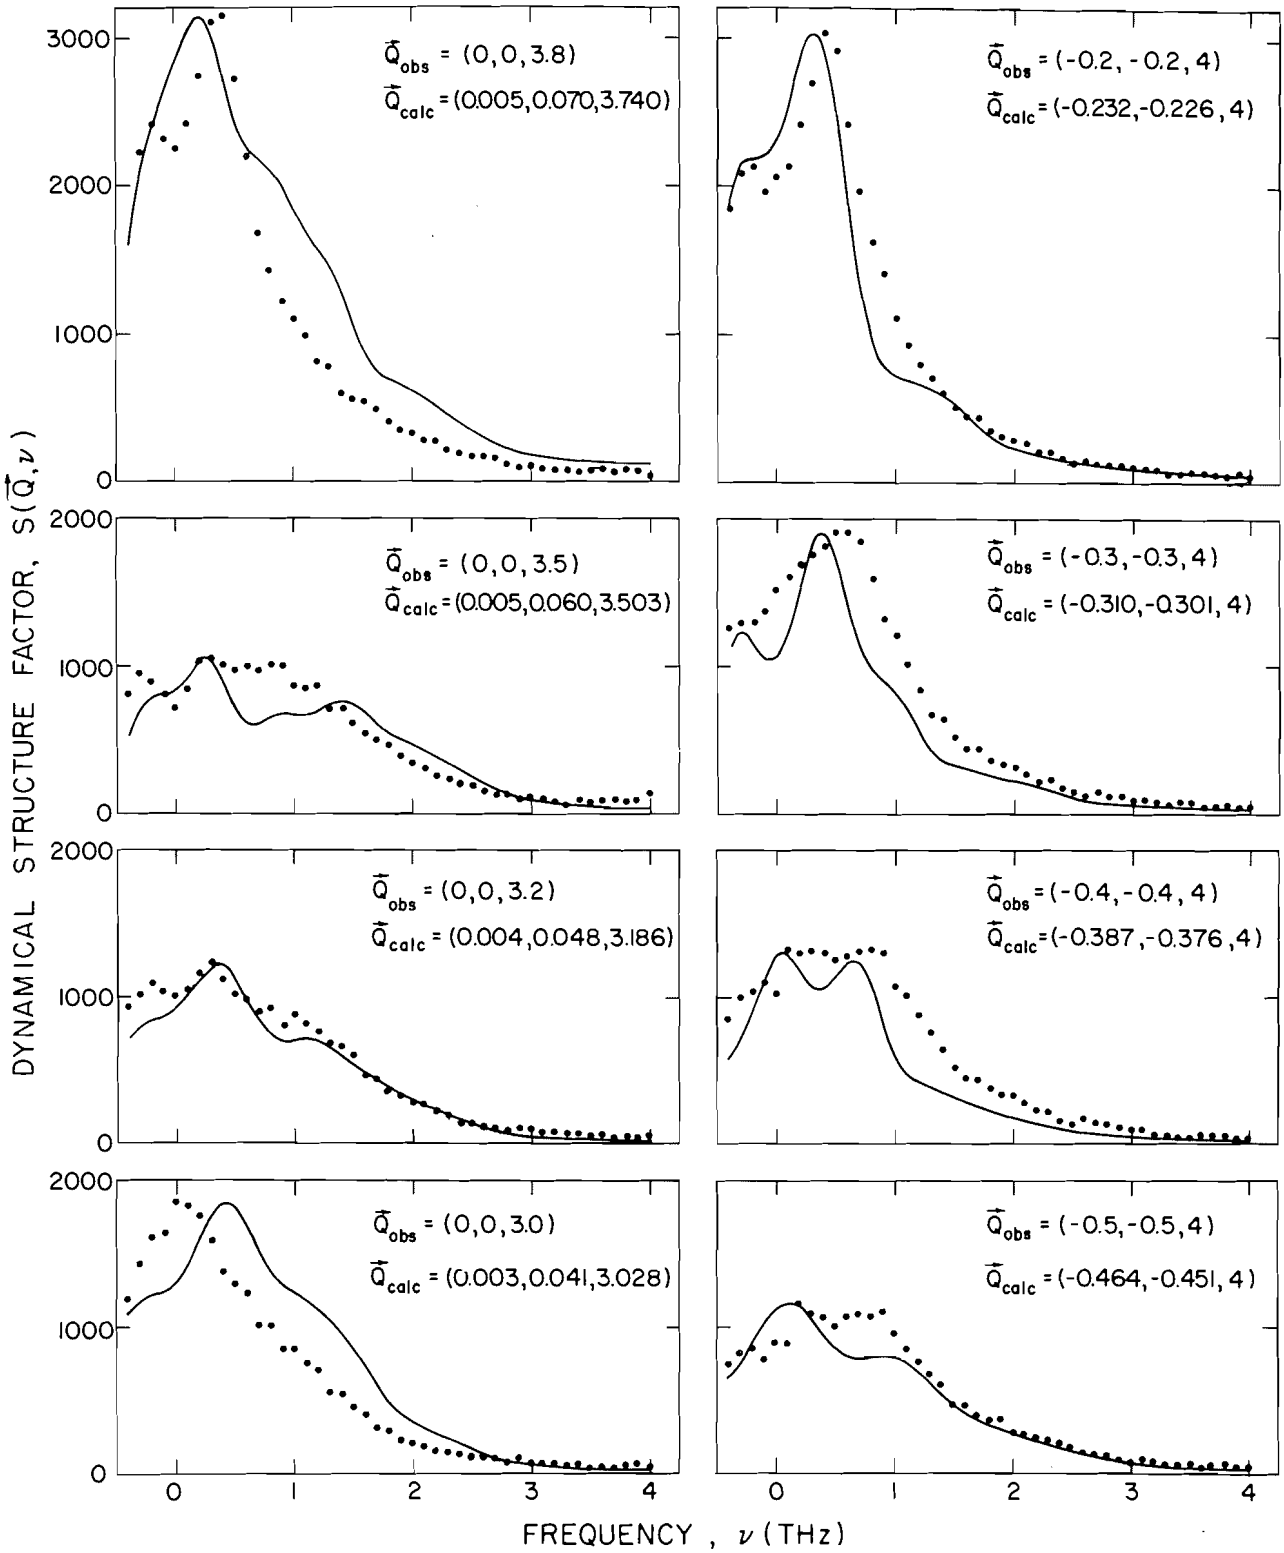

FIG. 4. Comparison of dynamical structure factors measured by inelastic neutron scattering with those obtained from MDS calculations. The points are observed and the line is the calculation.

erties (e.g. the autocorrelation functions, orientational distribution function, near neighbour correlations) to be understood, as well as the overdamped collective excitations observed by neutron scattering. The crystal structure of the low temperature phase is now known in detail and the transition can be understood, qualitatively at least, in terms of orientational ordering. For a quantitative understanding of the characteristics of the OD phase, however, more work is required.

Elucidation of the details of the collective excitation spectrum is a particularly difficult problem. The prediction of well-defined collective excitations at smaller wave-vectors and their subsequent observation show that the collective excitation spec-

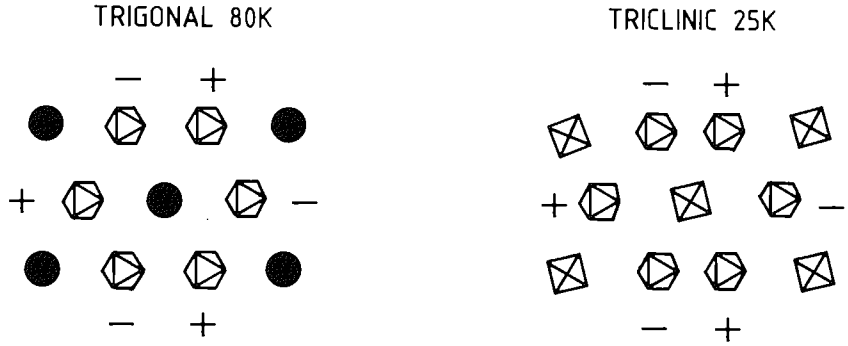

FIG. 5. The ordering in SF_6 at 25 K and 80 K suggested by the simulation calculations (21). The filled circles indicate orientationally disordered molecules. The structures are viewed along the [111] direction of the high temperature cubic phase. The structure of the latter would be similar to that shown at 80 K, but *all* molecules would be disordered.

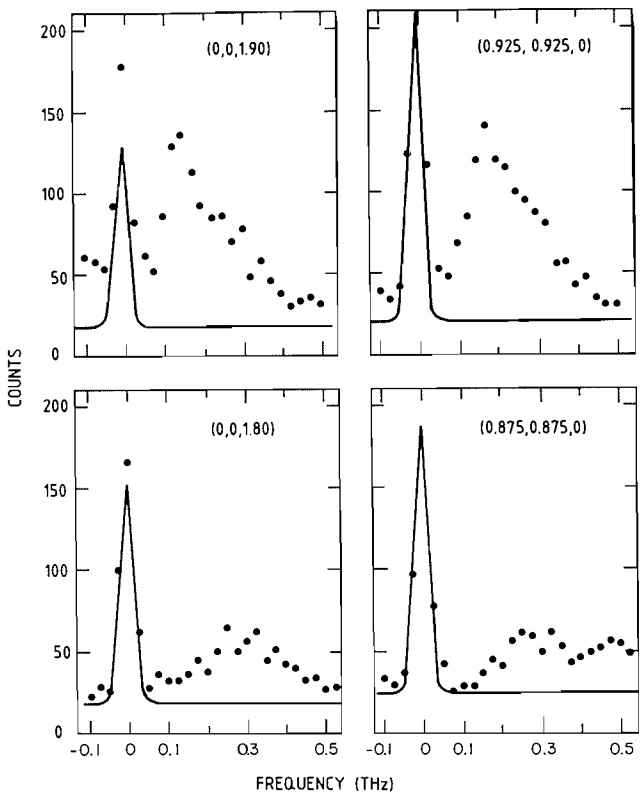

FIG. 6. High-resolution neutron scattering results from SF_6 at small propagation vectors. The line is the background from the container.

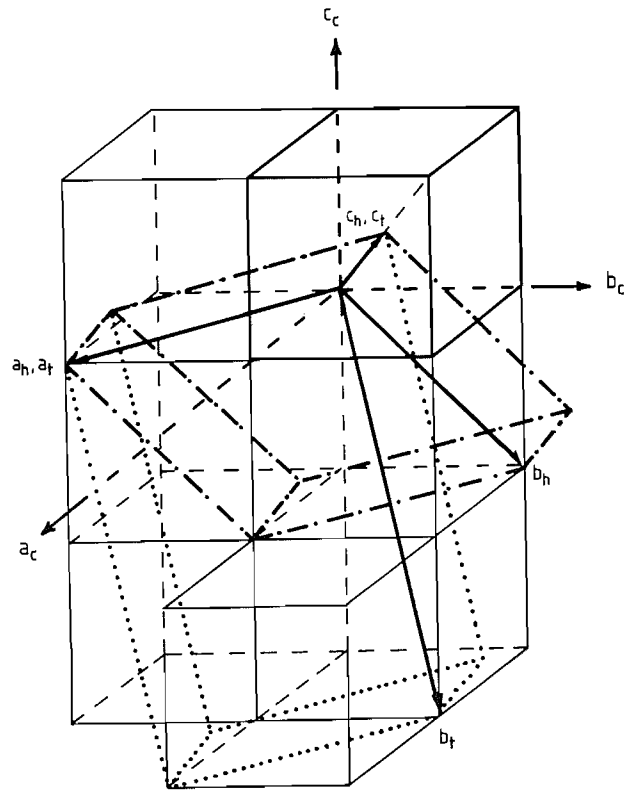

FIG. 7. The relationship between the cubic, hexagonal and triclinic cells suggested by the simulation calculations (21, 26). The subscripts c, h, t refer to cubic, hexagonal, and triclinic, respectively. The axes specifying the unit cells are shown by the bold vectors. The cubic, hexagonal, and triclinic cells are outlined by solid, dot–dash, and dotted lines, respectively, and the original cubic lattice is shown by faint lines.

trum is quite complex. It appears to be determined by the relative magnitudes of two effects: (*i*) the strength of the rotational–translational coupling and (*ii*) the separation between the relaxational frequencies of the translational and orientational correlation functions. The rotational–translational coupling parameter has recently been calculated for SF_6 by MDS (27). For the centro-symmetric SF_6 molecule it is a maximum at the zone centre and decreases to zero at the zone boundary. It is found to be rather independent of temperature and of the specific translational and rotational displacements considered. Relaxational frequencies have also been calculated recently (28). The translational relaxational frequency ("undamped" phonon) is zero at the zone centre and increases to values comparable with the orientational frequencies near the zone boundary. The interplay of these two effects means that there are several regimes of behaviour for the collective excitations as a function of propagation vector (28).

The relationship between orientational ordering and the phase transition lacks a quantitative basis at present and the conditions under which either the hexagonal or the triclinic phases are formed are not entirely clear. Finally, the applicability of the concept of orientational frustration to other OD crystals and other rotational–translational coupled systems remains to be explored. In many respects our increased insight into the nature of the orientationally disordered state has merely served to reveal further complexities in this intermediate phase of condensed matter.

Enthalpies of mixing of ternary alkane mixtures with branched chain components

WEI-GUO SHEN AND ARTHUR G. WILLIAMSON[1]

Department of Chemical and Process Engineering, University of Canterbury, Christchurch, New Zealand

Received September 10, 1987

This paper is dedicated to Professor James A. Morrison

WEI-GUO SHEN and ARTHUR G. WILLIAMSON. Can. J. Chem. **66**, 904 (1988).

Measurements at 25°C are reported for the enthalpies of mixing of 2-methyl pentane with *n*-dodecane and with each of three pseudo *n*-dodecanes prepared from equimolar mixtures of *n*-undecane + *n*-tridecane, *n*-decane + *n*-tetradecane, and *n*-octane + *n*-hexadecane respectively. Measurements for mixtures of the equimolar decane + tetradecane mixture with each of the other three branched hexane isomers are also reported. The results are compared with the work of Benson and co-workers for binary mixtures of *n*-dodecane with the same hexanes. The deviations of 1–2% from the principle of congruence are similar to those reported previously for the ternary *n*-alkane mixtures.

WEI-GUO SHEN et ARTHUR G. WILLIAMSON. Can. J. Chem. **66**, 904 (1988).

Opérant à 25°C, on a mesuré les enthalpies de mélange du méthyl-2 pentane avec le *n*-dodécane ainsi qu'avec chacun des trois pseudo *n*-dodécanes qui ont été préparés respectivement à partir de mélanges équimolaires de *n*-undécane + *n*-tridécane, *n*-décane + *n*-tétradécane et *n*-octane + *n*-hexadécane. On rapporte aussi les résultats des mesures effectuées à l'aide du mélange équimolaire de décane + tétradécane avec chacun des trois autres isomères ramifiés de l'hexane. On compare ces résultats avec ceux obtenus par Benson et ses collaborateurs pour des mélanges binaires du *n*-dodécane avec les mêmes hexanes. On a observé des déviations de 1 à 2% du principe de la congruence et ces déviations sont semblables à celles rapportées antérieurement pour des mélanges tertiaires de *n*-alcanes.

[Traduit par la revue]

Introduction

The principle of congruence (1) has been applied to many binary systems and a few multicomponent systems (2, 3) of *n*-alkanes and the experimental results are in excellent agreement with the values predicted from the principle. The study has been extended to excess volumes of ternary mixtures obtained by mixing a pseudo *n*-dodecane with hexane isomers (4). This work reports the excess molar enthalpies of pseudo *n*-dodecane (10:14) [0.500 *n*-decane + 0.500 *n*-tetradecane] + 2-methyl pentane (2-MP), + 3-methyl pentane (3-MP), + 2,3-dimethyl butane (2,3-DMB), + 2,2-dimethyl butane (2,2-DMB), of pseudo *n*-dodecane (11:13) [0.500 *n*-decane + 0.500 *n*-tridecane], and of pseudo *n*-dodecane (8:16) [0.500 *n*-octane + 0.500 hexadecane] + 2-MP.

Experimental

Excess molar enthalpies were measured with an isothermal dilution calorimeter of the type described by Costigan *et al.* (5). The volume of the glass calorimeter vessel was 59.41 (±0.06) cm^3 and the volume of mercury displaced from the vessel into the pipette was 32.59 (±0.015) cm^3. The pipette level was adjusted so that there was always a positive pressure on the calorimeter vessel of 2–3 kPa above atmospheric pressure. Injections were made with a motorized burette with an estimated uncertainty of ±0.01 cm^3 per injection. The difference between the cumulative volume of the injections and the volume of displaced mercury was always less than 0.15 cm^3 and the corresponding error in mole fraction for a binary mixture was less than ±0.001. The water bath temperature was maintained at a constant temperature (±0.0004 K) and monitored with a thermistor and a bridge arrangement similar to that used in the calorimeter. The temperature was measured with a platinum resistance thermometer (Rosemount Model WS104) and a Rosemount ac bridge (Type VLF 51A).

Branched hexanes were "Aldrich" materials with quoted purities better than 98% for 2,2-DMB, 97% for 2,3-DMB, and 99% for 2-MP and 3-MP. *n*-Alkanes were Koch-Light, "puriss" grade (99% minimum purity). All chemicals were taken from freshly opened bottles without further purification. Gas–liquid chromatographic analysis of the materials with chain length less than C_{10} suggested that the actual purities were significantly better than the quoted minimum purities. Our past experience has been that despite the quoted minimum purities of the alkanes from these sources being only 98 or 99%, the consistency of measurements made with the materials as supplied indicates that such impurities as are present have a negligible effect on enthalpies of mixing and volumes of mixing with other alkanes. The densities of all these chemicals were measured with a Mettler DMA60/DMA602 vibrating tube densimeter and are compared with literature values in Table 1. Pseudo *n*-dodecanes were prepared by weighing the *n*-alkanes into stoppered flasks. The density of each batch of newly prepared pseudo *n*-dodecane was measured before it was used to prepare ternary mixtures, as is listed in Table 2. The differences in the densities of four preparations of pseudo *n*-dodecane (10:14) were less than $\pm 3 \times 10^{-5}$ g cm^{-3}, which corresponds to a maximum error of ±0.001 in mole fraction. The measured densities of pseudo *n*-dodecane (8:16) indicated no significant change in composition between runs (Nos. 6 and 7 in Table 2). The discrepancies in the excess enthalpies in the composition-overlap region were less than 1 J mol^{-1}. The equipment and method were checked by measurements of the system x *n*-dodecane + $(1 - x)$ 2-MP, which were compared with the previous published results of Benson and co-workers (6).

Results and discussion

The measured excess molar enthalpies of (x *n*-dodecane + $(1 - x)$ 2-MP) and six ternary systems are listed in Table 3. The results for (x *n*-dodecane + $(1 - x)$ 2-MP) shown in Fig. 1 agree with those of Benson and co-workers (6) within 0.5 J mol^{-1} at $x = 0.5$. Although Benson's measurements are significantly smoother than ours, we believe that the agreement justifies direct comparison of our measurements with the corresponding binary data from Benson within ±0.5 J mol^{-1}.

An equation of the type:

$$[1] \quad H^E/(\text{J mol}^{-1}) = x(1-x)\sum_{j=1}^{m} A_j(1-2x)^{j-1}$$

where x is the mole fraction of *n*-dodecane or pseudo *n*-dodecane, was fitted to each set of results by the method of least squares with all points weighted equally.

The parameters for these representations and their standard

	7	0.74633

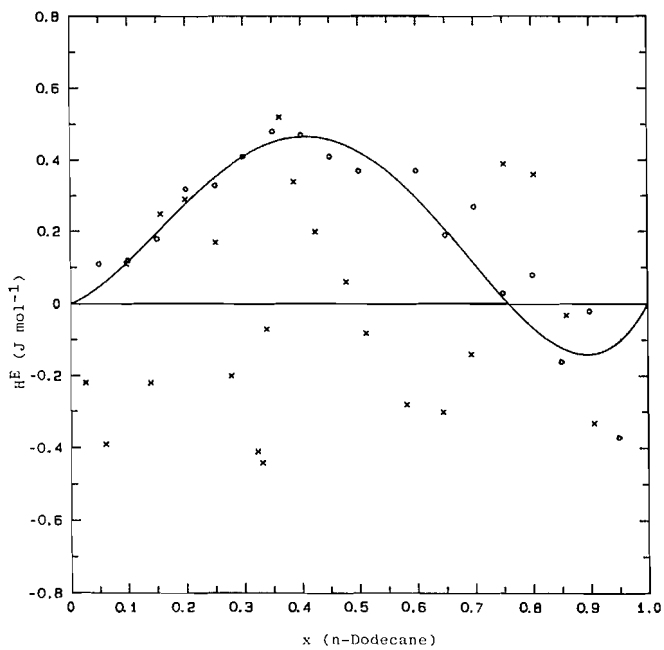

FIG. 1. Deviations of enthalpies for *n*-dodecane and 2-MP: (—) H^E calculated with eq. [1] (Benson) − H^E calculated with eq. [1] (this work); (x) H^E Exp. (this work) − H^E calculated with eq. [1] (this work); (○) H^E Exp. (Benson) − H^E calculated with eq. [1] (this work).

deviations:

$$[2] \quad R = [\Sigma r/(n-m)]^{1/2}$$

where $r = H^E$ (eq. [1]) − H^E experimental, and n = the number of experimental points, are listed in Table 4.

The excess molar enthalpies of mixtures of pseudo *n*-

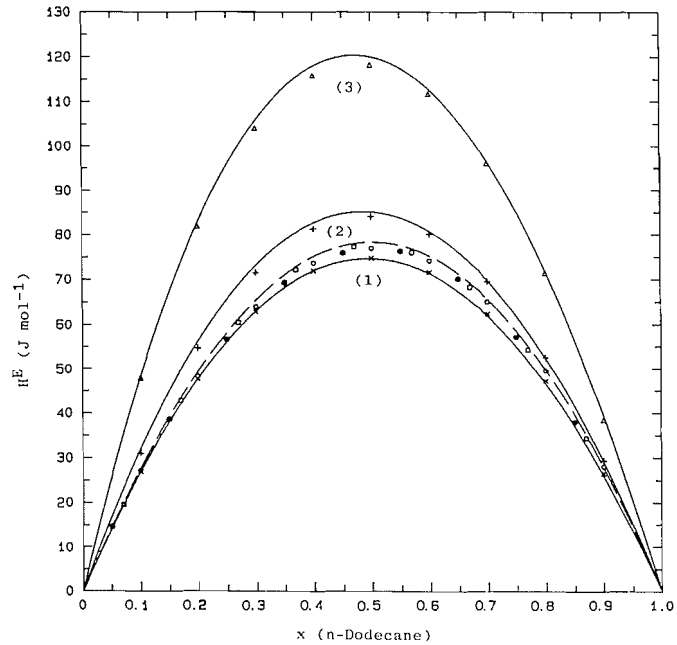

FIG. 2. Excess enthalpies for *n*-dodecane and isomers of hexane. (------) Equation [1] with parameters from Table 4, system 2, for *n*-dodecane + 2-MP. (———) Equation [1] with parameters from Table 4 for (1) *n*-dodecane + 3-MP (system 6), (2) *n*-dodecane + 2,3-DMB (system 8), (3) *n*-dodecane + 2,2-DMB (system 10). Experimental results: (○) pseudo *n*-dodecane (10:14) + 2-MP; (×) pseudo *n*-dodecane (10:14) + 3-MP; (+) pseudo *n*-dodecane (10:14) + 2,3-DMB; (△) pseudo *n*-dodecane (10:14) + 2,2-DMB; (*) pseudo *n*-dodecane (11:13) + 2-MP; (□) pseudo *n*-dodecane (8:16) + 2-MP.

dodecane and of *n*-dodecane with hexane isomers are compared in Fig. 2. The curves are from values calculated by eq. [1] with the parameters optimized from this work for *n*-dodecane + 2-MP (dotted curve), and from Benson for *n*-dodecane + the other three hexane isomers (solid curves). The points are the experimental values for the ternary mixtures.

The magnitudes of the excess molar enthalpies for pseudo *n*-dodecane + hexane isomers decrease in the order: 2,2-DMB > 2,3-DMB > 2-MP > 3-MP, just as Benson and co-workers (6) observed from their measurements for *n*-dodecane + hexane isomers.

The results of this study are very similar to those previously obtained for ternary *n*-alkane mixtures, namely, that the behaviour of multicomponent mixtures is almost the same as that

of the congruent binary mixtures, but that the excess enthalpies of the multicomponent mixtures are usually lower than those of the binaries by an amount only marginally greater than the experimental accuracy of the measurements. The excess volumes of the same ternary mixtures at 25°C (4) showed no significant deviation from those of congruent binaries.

We had hoped that the excesss thermodynamic properties of mixing of ternary mixtures of the branched system with binary *n*-alkane mixtures might reveal larger deviations from congruence than those of the congruent binary *n*-alkane plus branched chain systems. This was expected to arise from the different experimental behaviours of the long and short alkanes with the branched chains compared with that of the congruent intermediate chain length system. As can be seen by comparison of the current results with the *n*-alkane results, this is not so. As yet we have not been able to find systems in which major deviations from simple congruence occur.

Received August 17, 1987

This paper is dedicated to Professor J. A. Morrison

N. S. SULLIVAN. Can. J. Chem. **66**, 908 (1988).

We discuss the orientational ordering in solid ortho–para hydrogen mixtures. Following a brief sketch of the properties of the ortho and para hydrogen modifications and the long-range ordering of an assembly of $J = 1$ quantum rotors (ortho-H_2), we consider the nature of the purely local ordering seen in random dilute ortho–para mixtures. Measurements of the quasi-static glass order parameter and the mean correlation time for the molecular alignments are interpreted in terms of a rapid but continuous freezing of the orientational fluctuations.

N. S. SULLIVAN. Can. J. Chem. **66**, 908 (1988).

On discute de la mise en ordre de l'orientation qui s'établit dans des mélanges solides d'hydrogènes ortho et para. Après avoir présenté une brève ébauche des propriétés des formes ortho et para de l'hydrogène et de la mise en ordre d'un groupe de $J = 1$ rotors quantiques (H_2 ortho), on considère la nature de la mise en ordre purement locale qui est observée dans des mélanges ortho–para dilués au hasard. On interprète les résultats des mesures du paramètre d'ordre vitreux quasi-statique et du temps moyen de corrélation des alignements moléculaires en fonction d'un gel rapide mais continu des fluctuations des orientations.

I. Introduction

Solid hydrogen is the simplest molecular solid that exists in nature and the search for a detailed understanding of the many-body properties at low temperatures has held the interest of researchers in both theory and experiment for many years (for a review of the properties of solid hydrogen, see ref. 1). The reason for this is that the ordering of the rotational degrees of freedom of the molecules can be understood from first principles considerations. The interaction Hamiltonians are believed to be well-known and studies of the ordering of the molecular orientations provide a rich testing ground for interesting new regimes of collective behavior. This has been seen in recent nmr studies (2, 3) which have led to the observation of a new phase — the "quadrupolar glass" phase for dilute samples of ortho hydrogen. This regime of purely local ordering is believed to result from the combined effects of frustration and disorder which are thought to be universal features of the magnetic spin glasses. In this sense the dilute ortho mixtures resemble a quantum rotor spin-glass at low temperatures.

In this paper, we will give a short description of the long range periodic orientational ordering for samples rich in ortho molecular species and then discuss the outstanding problems concerning the nature of the purely local ordering in random dilute ortho–para H_2 mixtures. We will present recent measurements of the quasi-static glass order parameter and of the quadrupolar correlation time (inferred from nmr relaxation) which show that the molecules go through a rapid but continuous freezing of their orientational fluctuations on cooling into the glass regime. The transition appears to be that of a dynamic gel and not a thermodynamic phase transition.

II. Fundamentals

There are two distinct molecular species of hydrogen (ortho and para) that arise from the two ways that the total wave function can be antisymmetrised (as required by the exclusion principle). For *ortho hydrogen* the nuclear wave function is symmetric ($I_{total} = i_1 + i_2 = 1$), and for *para hydrogen* the nuclear wave function is antisymmetric ($I_{total} = 0$), the corresponding orbital wave functions are antisymmetric (orbital angular momentum J odd) and symmetric (J even), respectively (see Table 1). The different J states are widely separated in energy. The rotational kinetic energy $E_J = B_J J(J+1)$ with $B_J = 85.6$ K, and the $J = 1$ and $J = 2$ rotational states are 171 K and 510 K above the $J = 0$ ground state, respectively. We therefore only need to consider the lowest rotational states, $J = 1$ and $J = 0$ in the solid. Furthermore, the anisotropic interactions between the molecules which can mix the different J states are very weak ($V_{aniso} \sim 1$ K), J is therefore a good quantum number and we may consider the ortho–para solids as mixtures of quantum rotors. The order/disorder transitions seen at low temperatures are those of an interacting array of $J = 1$ rotors, and thus a problem of fundamental interest in solid state physics.

TABLE 1. Symmetries of nuclear and orbital wave functions of ortho and para species

Parameter	Value	
	ortho-H_2	para-H_2
$\chi_{nuclear}$	Even, $I = 1$	Odd, $I = 0$
ϕ_{orb}	Odd, $J = 1, 3, 5 \ldots$	Even, $J = 0, 2, 4 \ldots$

The conversion of ortho molecules to the para ground state ($J = 0$) is very slow because it is doubly forbidden; two symmetries need to be broken simultaneously, the symmetry of the nuclear wave function and that of the orbital wave function, in order to convert an ortho molecule into a para molecule. In the pure solid this conversion is induced by the intermolecular magnetic interactions which lead to a bimolecular rate constant of 1.9% per hour. This rate is sufficiently slow that we may consider the ortho species as stable on the time scale of ordinary experiments. On the other hand, over a few weeks or months, the experimenter may explore a wide range of ortho concentrations continuously by simply allowing a sample to age at constant low temperature.

The $J = 1$ molecules are not spherically symmetric; they have end-on symmetry and hence no permanent electric dipole moment, but they do have a small electric quadrupole moment. There is therefore a weak electrostatic quadrupole–quadrupole (EQQ) interaction between ortho molecules which depends on

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/07/12
For personal use only.

their relative orientations (4). At high temperatures the molecules are free to rotate about fixed sites, but at low temperatures the ortho molecules adopt mutual orientations to minimize their EQQ interactions. The resulting states lead to a rich phase diagram of oriented structures as a function of ortho concentration.

For high ortho concentrations one observes first-order phase transitions to a periodic ordering of the quadrupolar alignments in a Pa_3 configuration. As the ortho molecules are replaced by inert para molecules, there is a small perturbation of the orientations in the neighbourhood of the para molecule for small dilutions, but at a critical concentration of approximately 55% for hydrogen, the long range periodic ordering is lost. At low concentrations one finds a random ordering of the molecular axes and of the degree of ordering from site to site. This has been referred to as a "quadrupolar glass" (5). The experimentally established phase diagram is illustrated in Fig. 1. In the following we will try to understand the underlying physics of these two different types of ordering in terms of the properties of the quadrupolar interactions which drive the transitions.

The intermolecular electrostatic interactions between two rigid molecules can be written down easily using a standard multipolar expansion, the quadrupole–quadrupole term is the first in the expansion for symmetric diatomic molecules and is given by (4)

$$[1]\quad V_{12}^{QQ} = \frac{20\pi}{9}(70\pi)^{1/2}\Gamma_{12} \times \sum_{m_1 m_2} C^{224}_{m_1 m_2 m} Y_2^{m_1}(\Omega_1) Y_2^{m_2}(\Omega_2) Y_4^{m}(\Omega_{12})^*$$

Ω_1 and Ω_2 designate the polar angles ($\Omega_1 = \alpha_1, \beta_1$) specifying the orientation of the molecules with respect to some arbitrary reference frame. Ω_{12} specifies the orientation of the intermolecular vector $\boldsymbol{R}_{12}$ (connecting the centers of mass). $C^{224}_{m_1 m_2 m}$ is a Clebsch–Gordon coefficient and the strength of the interaction is measured by

$$[2]\quad \Gamma_{12} = \frac{6e^2Q^2}{25R_{12}^5} \simeq 0.85\ \text{K}$$

Q is the electric quadrupole moment of the molecule. The next highest-order interaction is the hexadecapole–quadrupole interaction, $V^{QH} \simeq 0.02\, V^{QQ}$, at the nearest neighbour separation (6).

Since J is a good quantum number for solid hydrogen we can replace the spherical harmonics Y_1^m by their irreducible operator equivalents O_1^m in the manifold $J = 1$, using

$$[3]\quad \langle JM|Y_l^m|JM\rangle = \alpha_{(J=1)}\langle JM|O_l^M|JM\rangle$$

with

$$[4]\quad \alpha = -\tfrac{2}{5}$$

and

$$O_i^0 = \frac{1}{\sqrt{6}}(3J_Z^2 - 2)$$

$$O_i^{\pm 1} = \mp\tfrac{1}{2}(J_Z J_\pm + J_\pm J_Z)$$

$$O_i^{\pm 2} = \tfrac{1}{2}(J_\pm)^2$$

i labels the lattice sites. The operators O_l^m are formulated in the local molecular reference frame, and are related to the laboratory frame by

$$(O_2^m)^1 = \sum_n D^2_{mn}(\chi_i) O_2^n(i)$$

where the $D^2_{mn}(\chi_i)$ are the rotation matrices specifying a rotation through the Eulerian angles $\chi_i = (\alpha_i, \beta_i)$ for molecule i.

The quadrupole–quadrupole interaction can therefore be written in the simple form

$$V_{ij}^{QQ} = \sum_{m,n} \zeta_{ij}^{mn} O_i^m O_j^n$$

where the lattice constants and interaction strength are collected in the factor

$$[5]\quad \zeta_{ij}^{mn} = \frac{(70\pi)^{1/2}}{3}\Gamma_{ij} \times \sum_{m'n'} C^{224}_{m'n'} [Y_4^{m',+n'}(\Omega_{ij})]^* D^{(2)}_{mm'}(\chi_i) D^{(2)}_{n'n}(\chi_j)$$

χ_i *and* χ_j are the Eulerian angles specifying the orientation of the local symmetry axes of the molecules (i and j) with respect to the laboratory frame (which will be fixed relative to the crystal axes).

Anisotropic forces other than the quadrupole–quadrupole and quadrupole–hexadecapole interactions do occur. These include the anisotropic components of Van der Waals and valence forces (8), but theoretical estimates place their strengths well below the EQQ interaction. Indirect interactions (4) mediated by phonons are also believed to be very weak but they are long-ranged (R^{-3}) and are expected to dominate the short-range interactions at very low concentrations ($x < 1\%$). In the following treatment of the long-range ordering we will neglect all but the quadrupolar interaction.

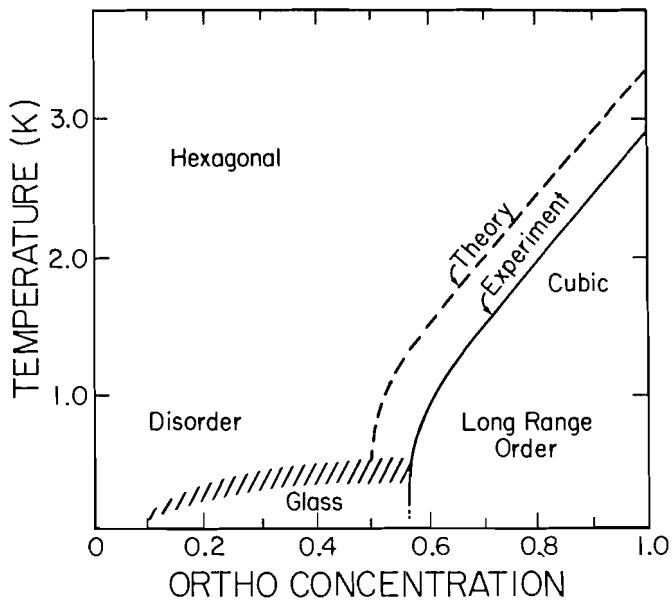

FIG. 1. Phase diagram for the orientational ordering seen in solid ortho–para hydrogen mixtures. The hatched region designates the continuous growth of local ordering on cooling into the glass phase.

III. Orientational ordering for high ortho concentrations

We are interested here in the nature of the order/disorder transition on a fixed lattice. The ground-state configuration has been shown (9) to be a Pa_3 configuration in which the fcc lattice is divided into four interpenetrating simple cubic sublattices: in each sublattice the molecules are aligned parallel to a body-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113.on 09/07/12
For personal use only.

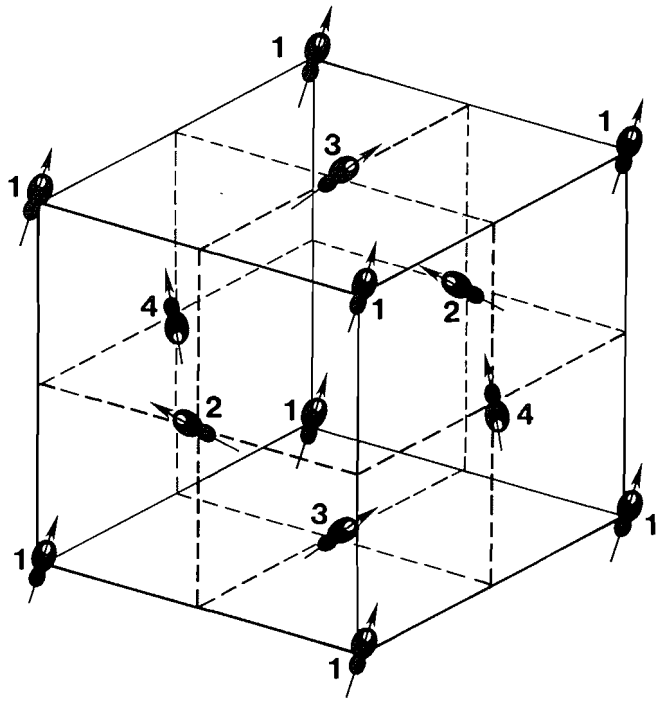

FIG. 2. The Pa_3 configuration showing the four interpenetrating simple cubic sublattices.

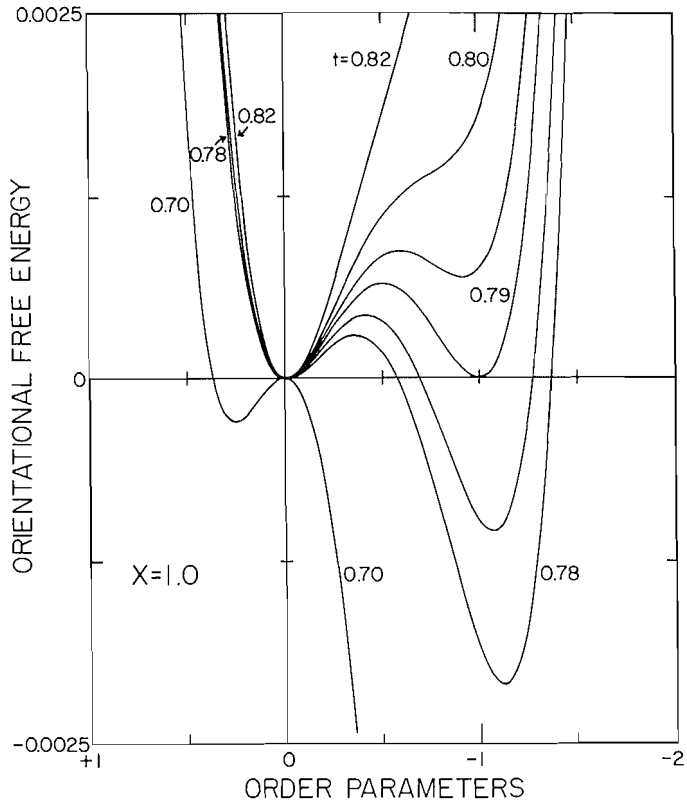

FIG. 3. Calculated orientational free energies $F(S)$ as functions of the order parameter for several temperatures near the transition temperature. The ortho concentration $X = 1.0$. The reduced temperatures $t = T/T_b$ where $T_b = 19\Gamma_{12}/4 \ln 2$ is the mean field transition temperature. A first order transition occurs at $t_c = 0.79$.

diagonal of the fcc lattice, a different body-diagonal being associated with each sublattice (Fig. 2). This structure has been well verified experimentally (10) and in the following we will develop the theory of the ordering, taking the axes of the Pa_3 system as fixed local reference frames, and treat the quantum mechanical alignment $S_i = \langle 3J_j^2 - 2\rangle_i$ (evaluated with respect to the local axes Z_i) as the relevant thermodynamic variable. The parameter S_i is an appropriate measure of the local orientational order at site i. $S_i(T) \rightarrow 0$ if all states in the manifold $J = 1$ are equally populated and $S_i \rightarrow -2$ at low temperatures if the ground state corresponds to $J_{z_i} = 0$.

In order to calculate the variation of S as a function of the temperature we will use Kirkwood's method of restricted traces (11) which will give the mean-field approximation as a zeroth-order approximation. The virtue of the method is that, treated to higher orders of approximation, it includes the contribution of correlations arising from "flip–flop" terms such as $\langle O_i^n O_j^n\rangle_{m,n\neq 0}$ which are important for an assembly of quantum rotors.

In the method of restricted traces one calculates the partition function $Z = \text{tr}\,[\exp(-\beta H)]$ assuming a fixed value of S, i.e. we write

$$[6] \quad Z = \sum_{\{S\}} \text{tr}_S'(e^{-\beta H})$$

where tr′ refers to the trace calculated subject to the constraint that S is fixed. The sum $\sum_{\{S\}}$ over the range of S will be sharply peaked at the value of S (say S_0), which minimizes the free energy, and Kirkwood's approximation consists of neglecting all terms in the sum except for $S = S_0$. The calculations can be simplified by noting that

$$[7] \quad \log Z = \log \langle e^{-\beta H}\rangle_S + \log W(S)$$

where $\langle\ \rangle_S$ denotes the expectation value subject to the constraint $S = 1/N\Sigma_i\langle 3J_{Z_i}^2 - 2\rangle$, and $W(S)$ is the number of configurations with fixed S.

$$[8] \quad \log W(S) = \frac{1}{3N}\{-(2+S)\log(2+S) - (1-S)\log(1-S) + (2+S)\log 2 + 3\log 3\}$$

The temperature-dependent term of $\log Z$ is calculated using the high temperature expansion

$$\log\langle e^{-\beta H}\rangle = \sum_{n=1}^{\infty} (-\beta)^n M_n/n!$$

where the first two cumulants are $M_1 = \langle H\rangle$ and $M_2 = \langle H^2\rangle - \langle H\rangle^2$. Since $\zeta_{ij} \propto R_{ij}^{-5}$, we restrict i and j to nearest neighbours; i and j must therefore belong to distinct sublattices and we can vary $\langle O_i\rangle$ and $\langle O_j\rangle$ independently in the calculation of $\langle H\rangle$. We find $M_1 = 6x\gamma S^2$ where N is the number of lattice sites, Z is the co-ordination number, and $\gamma = 19\Gamma/72$ for the Pa_3 structure.

In the mean-field approximation we limit the expansion to the first cumulant. The orientational free energy per particle is given by

$$[9] \quad F(S) = \tfrac{1}{3}k_B T[(2+S)\log(2+S) + (1-S)\log(1-S) - S\log 2] + 6X\gamma S^2$$

This is minimised as a function of S when

$$[10] \quad 36\beta|\gamma|S = \log\left(\frac{2+S}{2-2S}\right)$$

At large β (low temperature), the solution is given by $S_0 = -2$,

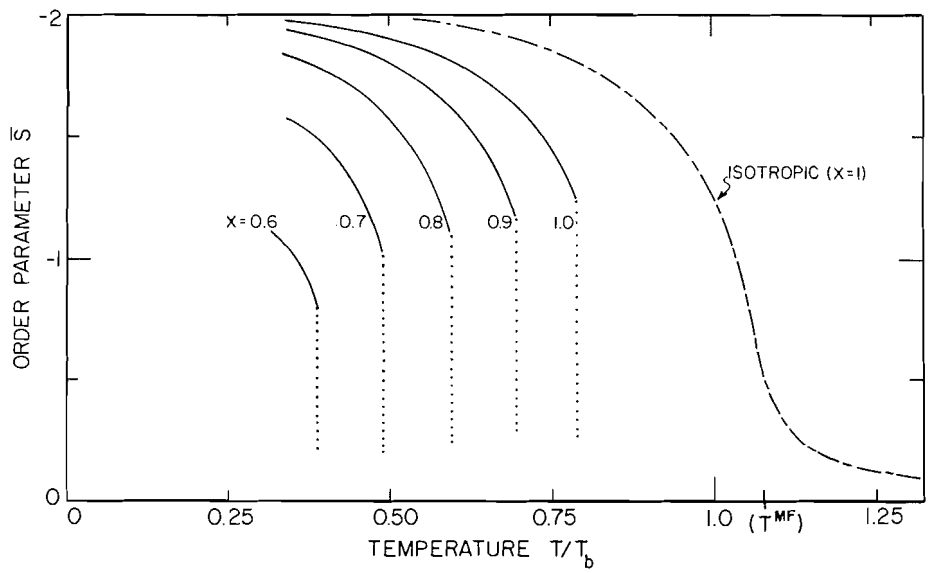

FIG. 4. Temperature dependence of the equilibrium values of the order parameter obtained from the free energy minima (such as those seen in Fig. 3) for several ortho concentrations. The broken vertical lines indicate first-order phase transitions. The dashed line gives the variation calculated for an isotropic quadrupolar interaction for $X = 1.0$.

and as β is reduced (rising temperature), S_0 increases toward -1 where there is a discontinuous jump to the value $S = 0$ at the critical temperature

$$[11] \quad k_B T_c = \left(\frac{19\Gamma}{4 \ln 2}\right) X$$

This is a factor of two higher than the experimental values at high ortho concentrations and there is no evidence for the critical behaviour near $X_c = 0.55$.

The inclusion of higher-order correlations in the evaluation of the free energy modifies the predicted phase diagram for periodic ordering quite drastically. The reason for this is that the critical concentration for propaging the 4-sublattice structure is much higher than the simple site percolation concentration (12). The importance of the correlations can be seen by extending the above calculations to include the second cumulant M_2. If we consider, at first, only the isotropic terms of the Hamiltonian, i.e.

$$H = \frac{1}{2} \sum_{(ij)} \zeta_{ij}^{00} O_i^0 O_j^0$$

then

$$M_2^{iso} = \frac{1}{4} \sum_{\{ijkl\}} \zeta_{ij}^{00} \zeta_{kl}^{00} \{\langle O_i^0 O_j^0 O_k^0 O_l^0 \rangle - \langle O_i^0 O_j^0 \rangle \langle O_k^0 O_l^0 \rangle\}$$

Summing over three types of terms: (*i*) 4-particle terms with all indices different $(ij) \neq (kl)$, (*ii*) 3-particle terms with one comon index $i = k, j \neq l$, and (*iii*) 2-particle terms $i = k$ and $j = l$; one finds (13)

$$[12] \quad M_2^{iso} = 6Nx^2\gamma^2(2 - S - S^2)[2 - S - (2x - 1)S^2]$$

It should be noted that the sign of the correlation term (in square brackets) changes sign at $X = 50\%$. This is a major contribution to the critical behavior at X_c in this approximation. The anisotropic terms in M_2 have also been calculated (13).

$$M_2^{aniso} = 27Nx^2\gamma^2 S(0.88 - 1.51S)$$

The free energy functionals $F(S)$ (per particle) for different temperatures calculated as a function of S using the above values for M_2 are illustrated in Fig. 3. One observes a first-order transition with a jump in the equilibrium value of the order parameter S_0 at the critical temperature $T = T_c$. Below T_c, S_0 approaches -2 as $T \rightarrow 0$ for large X. One finds only second-order transitions if the anisotropic interactions are neglected.

Explicit calculations of $F(S)$ for several values of ortho concentration lead to the temperature dependence of S_0 shown in Fig. 4. The corresponding variation of the critical temperatures with ortho concentration is given in Fig. 5. While the calculated phase diagram for the transitions to the periodically ordered structures is in reasonably good qualitative agreement with the experimental observations, the results should be taken with caution. The inclusion of second-order approximations has a very significant influence on the phase diagram, and it is important to check that third-order corrections make only a small correction.

IV. Quadrupolar glass regime

The low temperature – low concentration region of the phase diagram has been referred to as a quadrupole glass regime in analogy to the spin glasses such as $Eu_xSr_{1-x}S$ (14). No true phase transition to the glass region has been detected and most of the current research effort is devoted towards understanding the nature of the onset of local ordering on cooling from the high temperature disordered para-orientational phase. The crystal lattice remains hcp (15) in the glass-like region and this is to be contrasted with the behaviour for high ortho concentrations. (For $X > 55\%$, the onset of orientational ordering triggers a crystal transformation from the hcp phase to the fcc phase, but subsequent small thermal cycles leaves the cubic phase stable and the order/disorder transitions to the Pa_3 structure can be considered to occur on an fcc lattice.)

One of the key concepts underlying the physics of the quadrupolar glass phase, and the spin glasses in general, is the inherent frustration in the system, and in our case the interacting quadrupoles. The minimum energy configuration for a pair of quadrupoles is a "Tee" configuration with the molecular axes mutually perpendicular. While this can be satisfied for a square

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/07/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/07/12
For personal use only.

array, it is impossible to arrive at a configuration with all quadrupoles mutually perpendicular in any other lattice. The quadrupolar interaction is topologically incompatible with the symmetry of the supporting lattice. It is the introduction of disorder, by the replacement of quadrupole-bearing ortho molecules by para molecules in the frustrated system, that leads to the glass phase. As stressed by Klenin (16), the frustration is especially severe for quadrupoles on an hcp lattice because the ground state is a Pc_{21} structure (17) with some molecules almost parallel to their neighbors (i.e. highly frustrated) while others are almost perpendicular (i.e. negligible frustration). In contrast to the cubic structure, the frustration is now highly inhomogeneous. This inhomogeneity imposes additional constraints and this renders the nucleation of long-range periodic ordering especially difficult. Even if they can be nucleated, possible clusters of periodic orientational ordering will be fragile with respect to random site dilution, and it is not surprising that only local ordering is achieved below the critical concentration.

There is another important feature of the hexagonal structure. For the non-cubic structure, the random occupation of lattice sites by the quadrupoles leads to the existence of local electric field gradients, the field conjugate to the local order parameter. The ordering of a random dilute hcp lattice is therefore analogous to that of the local dipolar ordering in spin glasses in the presence of random internal magnetic fields. These fields may not only smear out a transition, but even exclude any meaningful transition on cooling from the para-orientational phase.

Fictitious model

Some limited insight into the collective nature of the local freezing in the glass phase can be obtained from a fictitious model (18, 19) which assumes a Gaussian distribution of interaction strengths for the quadrupoles. This is of course not the situation in solid hydrogen but it is useful in that it does lead to a glass-like ordering for the quadrupoles. If we consider the truncated Hamiltonian

$$H = \frac{1}{2}\sum_{(ij)} \zeta_{ij} O_i^0 O_j^0$$

with a Gaussian probability distribution

$$[13] \quad P(\zeta_{ij}) = \left(\frac{1}{2\pi\tilde{\zeta}^2}\right)^{1/2} [\exp - (\zeta_{ij} - \zeta_0)^2/2\tilde{\zeta}^2]$$

for the ζ_{ij} where ζ_0 is the mean value and $\tilde{\zeta}^2$ the variance, then the free energy can be evaluated in terms of an average over an ensemble of n replicas, following the technique of Edwards and Anderson (20).

$$\tilde{F} - -k_B T \lim_{n\to 0} \frac{1}{n} (\overline{Z^n} - 1)$$

is calculated in terms of the quadrupolar glass order parameter

$$Q = \overline{6\langle (O_i^0)_\mu (O_i^0)_\nu \rangle}$$

where μ and ν label different replicas of the random array and the bar designates a configurational average. The average local molecular alignment is $S = \sqrt{6}\,\langle O_i^0 \rangle$.

Minimising F with respect to S and Q we find

$$S = \left(\frac{1}{2\pi}\right)^{1/2} \int e^{1/2y^2} F(\eta)\, dy$$

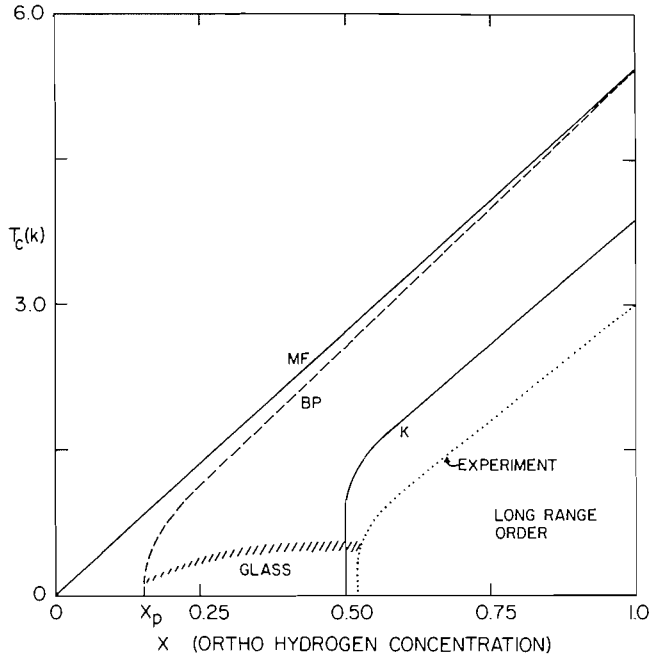

FIG. 5. Comparison of the observed concentration dependence of the critical temperatures with various theoretical treatments. MF, molecular field approximation; BP, first order Bethe–Peierl's approximation; K. Kirkwood's method of restricted traces.

where

$$F(x) = \frac{2e^x - 2e^{-2x}}{2e^x + e^{-2x}} \quad \text{and} \quad \eta = \beta[\tilde{\zeta}(ZQ)^{1/2} y + \zeta_0 ZS]$$

and

$$Q = (2 - S) - \left(\frac{1}{2\pi}\right)^{1/2} \int e^{-1/2y^2} F'(\eta)\, dy$$

$$[F'(x) = \partial/\partial_x F(x)]$$

For the case $\tilde{\zeta} = 0$ (i.e. fixed interactions) we find $Q = 2 - S$, as it should, and at the transition $\eta = \eta_0 = \beta\tilde{\zeta}_0 ZS$ with $S = F(\eta_0)$ or $36\beta_c\zeta_0 S = \ln (2 + S)/(2 - 2S)$ which is just the molecular field result obtained in section II above.

In the opposite limit of very broad distributions ($\tilde{\zeta} \gg \zeta_0$), we find at low temperature that

$$Q = \frac{5}{2} - \frac{27}{2} e^{B^2} \operatorname{efrc}(B)$$

where $B = 3\beta\tilde{\zeta}(ZQ/2)^{1/2}$ and erfc (t) is the complementary error function. Expanding the error function one finds that there is no solution except the trivial solution for

$$k_B T > k_B T_g = \frac{5}{27}\sqrt{\frac{5\pi}{3}}\, Z\tilde{\zeta} \simeq 0.4 Z^{1/2}\tilde{\zeta}$$

A rough estimate of the magnitude of $\tilde{\zeta}$ for a system similar to solid hydrogen can be made by averaging the angle dependent interaction constants of the EQQ potential over all possible orientations for an hcp lattice. This gives $k_B T_g \simeq 0.7X^{1/2}$ K. The glass transition temperatures $T_g(X)$ for this fictitious model are shown in Fig. 4 and they correspond to the temperature region for which one observes a rapid but continuous growth of local orientational order. The inclusion of a distribution of random crystal fields in the model would smear out any transition and

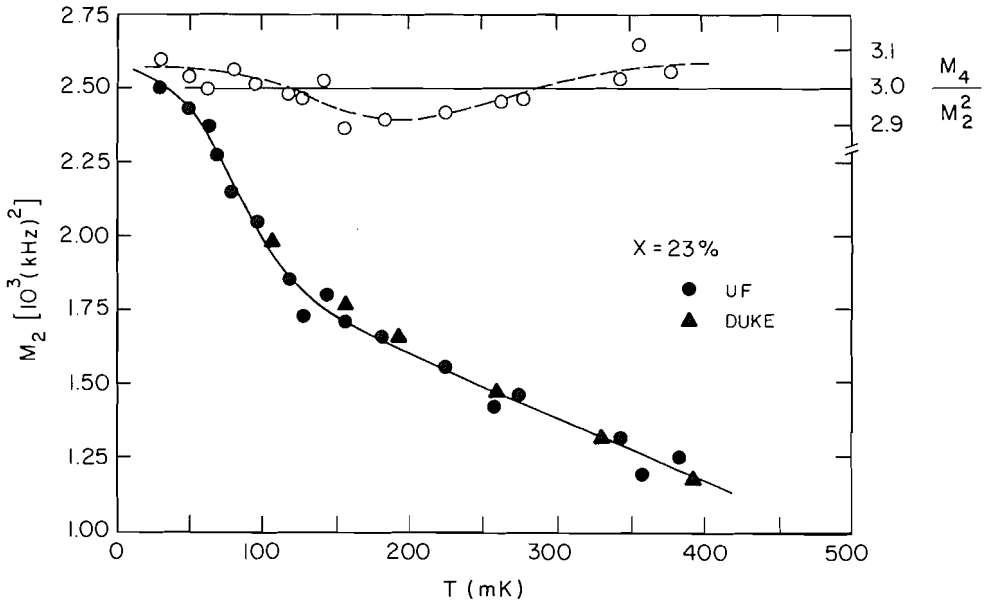

FIG. 6. Temperature dependence of the intramolecular second moment M_2 of the nmr spectra for ortho concentration $X = 23\%$. M_2 is directly proportional to the Edwards–Anderson glass order parameter.

this would give a first approximation to the behavior in solid hydrogen.

The value of S obtained at low temperatures for a broad distribution of ζ_{ij} is small, $|S| \simeq 0.5$, and this is in qualitative agreement with the experimental values. Experimentally one observes a broad distribution of local molecular alignments and S is the mean value.

Monte Carlo simulations of the ordering of classical quadrupoles have been carried out (21, 22) and they are also consistent with a continuous random freezing of the quadrupole fluctuations.

Goldbart and Scherrington (23) have considered the Parisi replica-symmetry breaking scheme for a set of m-dimensional uniaxial quadrupoles. They find that for three dimensions there is a phase transition to an *isotropic glass* at a critical temperature, $T_{\text{crit}} \sim \langle\zeta^2\rangle^{1/2}$, but there is a *further* transition at very low temperatures to a canted long-range ordered phase.

V. Nuclear magnetic resonance measurements and discussion

The local order parameters can be observed directly by nmr techniques. The reason for this is that the intramolecular nuclear dipole–dipole interaction between the protons of an ortho-H_2 molecule does not average to zero if the molecule has a preferred alignment. Each molecule contributes a doublet to the nmr spectrum with a frequency splitting

$$\Delta\nu_i = \pm D[\tfrac{1}{2}S_i P_2(\cos\theta_i) + \tfrac{3}{4}\eta_i \sin^2\theta_i \cos 2\phi_i]$$

where θ_i, ϕ_i) are the polar angles defining the orientation of the applied magnetic field with respect to the local symmetry axes of molecule i. S_i is the *alignment* and $\eta_i = \langle J_{x_i}^2 - J_{y_i}^2\rangle$ the eccentricity. For axial symmetry (as is usually assumed) $\eta_i = 0$. ($D = 173.1$ kHz.)

In the long-range ordered phase the order parameters S_i have the same value S_0 at each site and the resulting nmr lineshape is the well known Pake doublet (24) with two cusps separated by $(1/2)\,DS_0$. The temperature dependent S_0 exhibits a jump at the critical temperatures indicated in Fig. 1 for $x > 55\%$. In the glass regime one observes a completely different nmr spectrum which has been interpreted as a superposition of Pake doublets due to a broad distribution of local order parameters S_i (2, 3).

While there has been agreement on the existence of a broad distribution of S_i in the quadrupolar glass regime, there has been a serious controversy concerning the temperature dependence of the onset of the glass-like ordering. The first observations at Saclay (5) reported sharp transitions while subsequent studies at Duke (2) showed only a continuous evolution with temperature. It was suggested that the difference was related to sample preparation techniques; the Saclay group using powdered specimens while the Duke group grew single crystals. The results presented here from a new series of experiments in Florida agree with the conclusions of the Duke group. Furthermore, we have extended the temperature range explored down to 34 mK well below the limits of all of the previous studies (typically 100 mK).

We have measured the Edwards–Anderson glass order parameter defined by

$$Q_{\text{EA}}(T) = [\langle 3J_Z^2 - J^2\rangle_i^2]_c$$

for the quadrupolar system. This is determined directly from the nmr data because Q_{EA} is given by the second moment of the order parameter distribution function and hence proportional to the intramolecular component of the dipolar second moment of the nmr line shape

$$M_2^{\text{intra}} = \tfrac{9}{20} D^2 Q_{\text{EA}}(T)$$

Typical results for the variation of M_2 are shown in Fig. 6. The temperature dependence is featureless with no hint of either a thermodynamic phase transition or a dynamical transition down to the lowest temperatures attained (~34 mK).

The molecular dynamics in the glass-like regime has been explored by studies of nuclear spin–lattice relaxation T_1 which measures the spectral densities of the molecular motion. The results show that T_1 has a strong spectral inhomogeneity (25) across the nmr spectrum, and this has been interpreted in terms of collective excitations, or *para-librons* (25, 26), in large clusters of well-defined short-range order. The characteristic quadrupolar fluctuation rates τ_Q^{-1} estimated from the T_1

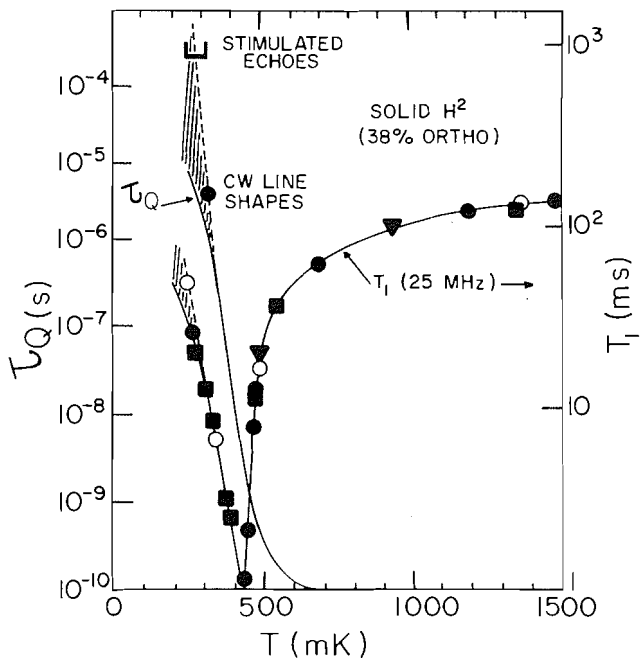

FIG. 7. Rapid dynamical freezing in the quadrupolar glass phase. The characteristic quadrupole fluctuation rates τ_Q^{-1} are deduced from the nuclear spin–lattice relaxation times T_1.

measurements are shown in Fig. 7. The rates decrease very rapidly, but smoothly, on cooling into the glass-regime.

As a result of the new measurements discussed above there is now a consensus concerning the nature of the onset of local ordering in the glass phase. The rapid quenching of the molecular reorientation rates and the continuous growth of the Edwards–Anderson glass parameter show that there is a collective dynamic gel of the molecular reorientation rates as the temperature is lowered. The qualitative picture of a glass-like phase (5) at low temperatures with both the local symmetry axes *and* the degree of local alignment S_i varying from site to site is basically correct.

A light scattering and calorimetric study was made of micelle formation by a polystyrene-*b*-hydrogenated polyisoprene in a binary mixture. The polymer 0.42 weight percent PS, is unassociated in cyclopentane (*c*-C5) but forms micelles with a PS core in *n*-pentane, a non-solvent for PS. Light scattering measurements and heats of mixing, obtained over the binary composition range at a polymer concentration higher than the c.m.c., show that the solution changes from the unassociated to the micellar state for solutions richer in pentane than 0.4 volume fraction. Using heats of mixing of the corresponding homopolymers, the heat of micellization is found to be $-5.1 + 0.3$ J g^{-1}, a value which supports the model of an enthalpy driven process of micellization.

KAREL PROCHÁZKA, HÉLÈNE DELCROS et GENEVIÈVE DELMAS. Can. J. Chem. **66**, 915 (1988).

Utilisant la calorimétrie et la diffraction de la lumière, on a étudié la formation de micelles par un polystyrène-*b*/polyisoprène hydrogéné, dans un mélange binaire. Dans le cyclopentane (*c*-C5), le polymère contenant 0,42 pourcent en poids de PS n'est pas associé; toutefois, dans le *n*-pentane qui n'est pas un solvant pour le PS, il forme des micelles avec un coeur de PS. Des mesures de diffraction de la lumière et de chaleurs de mélanges, réalisées sur un éventail de concentrations de la région binaire et à des concentrations en polymère plus grandes que la c.m.c., ont permis de montrer que, dans le pentane contenant une fraction molaire supérieure à 0,4, la solution passe d'un état qui n'est pas associé à un état micellaire. Utilisant les chaleurs de mélange des homopolymères correspondants, on a trouvé que la chaleur de micellisation est de $-5,1 \pm 0,3$ J g^{-1}; cette valeur est en accord avec le modèle d'un processus de micellisation d'origine enthalpique.

[Traduit par la revue]

Introduction

Block copolymers when dissolved in a solvent which is good for one of the corresponding homopolymer and a nonsolvent for the other, associate reversibly and form spherical micelles (1). As predicted by the "closed association" mechanism (2), the micelles are in equilibrium with the molecularly dissolved copolymer (unimer). The mass, size, structure, size distribution, and micellization equilibrium of block copolymer micelles have been studied by different techniques such as viscosimetry, osmometry, sedimentation velocity analysis, size exclusion chromatography (SEC) (3, 4), elastic light scattering, and electron microscopy (see ref. 1). New techniques such as neutron scattering (5, 6) and light scattering photon correlation spectroscopy (7, 8) have also been applied successfully to block copolymer micellar systems. From these studies, the micelles are found to be quite uniform in weight, size, and composition while the micellar mass and micelle-to-unimer ratio depends on the copolymer composition, the thermodynamic quality of the solvent, and the temperature.

With simplifying assumptions, the thermodynamic parameters associated with the micellization, namely, the free energy and enthalpy of micelle formation have their usual expressions:

$$\Delta G_m = RT \ln (\text{c.m.c.})$$

$$\Delta H_m = -RT^2 \, \mathrm{d} \ln (\text{c.m.c.})/\mathrm{d}T$$

The study of the temperature dependence (9*a*) of the c.m.c. of polystyrene-*b*-polyisoprene block copolymer in *n*-hexadecane lead to a value of ΔH_m in good agreement with that determined calorimetrically (9*b*). The aim of the present paper was to study the formation of micelles in a similar copolymer, polystyrene-*b*-hydrogenated polyisoprene (PS-*b*-h·PIP) by light scattering in a mixture of two solvents having each a different quality for PS and to measure directly ΔH_m in the same system.

Experimental

Materials

Polymers

The polystyrene-*b*-hydrogenated polyisoprene two-block copolymer (G 1701 Shell Chemical Co., U.S.A.) was characterized by nmr, light scattering analysis in benzene, and size exclusion chromatography (SEC) in tetrahydrofuran. From these measurements, the copolymer is found to have a M_w of 105 000, an average weight fraction of polystyrene $w = 0.42$ and a narrow molar mass distribution as indicated by SEC analysis.

The homopolymer polystyrene a standard from Pressure Chemical Co., Pittsburgh, U.S.A., with $M_w = 2100$ and $M_w/M_n = 1.1$ was studied in the present work and through heats of dilution in ref. 10. The results for polypropylene (PP) were obtained previously (11) on an atactic sample obtained by solvent extraction from a partially crystalline PP followed by purification (12).

Using DSC, the T_g of the PS standard was found around 75°C but that of the copolymer was not clearly defined. However, the heat of transition from the glass to the liquid $\Delta H_{\text{glass–liquid}}$ of the PS part of the copolymer must be similar in magnitude to that of the homopolymer.

Solvents

Pentane and benzene (99% pure, from Aldrich Co., Milwaukee), cyclopentane (spectrograde, from BDH, Toronto) were used without purification.

Apparatus

Light scattering

A KMX-6 Low Angle Light Scattering Photometer, with a low power helium laser (Chromatix, U.S.A.) was used. No extrapolation to zero angle of the light scattering $G(\theta)$ was made since the scattering angle is low (3–4°). If G_0 is the signal of the primary beam transmitted through the sample, the scattered factor R_0 is

$$R_0 = \text{constant } G(\theta)/G_0$$

The constant is obtained from a compound whose Rayleigh factor is known. The molar mass can be calculated from the standard equation:

$$[1] \quad Kc/R_0 = 1/M_w + 2A_2c$$

c is the polymer concentration, K and A_2 have their usual definition. In the case of micellar solutions, M_w is the micelle molecular mass usually written as M_w^{app}. The solutions were clarified by filtration via Fluoropore filters (0.2 m, Millipore Corp., Bedford, U.S.A.) and their concentrations ranged from 0.1 to 5×10^{-3} g cm^{-3}.

Calorimetry

The heats of dissolution were measured with a differential tilting Tian-Calvet calorimeter (Setaram, France) with cells similar to those described earlier (12). The polymer is placed on a support and immersed under mercury. The rest of the cell is filled with the solvent. Polymer and solvent are brought into contact after equilibrium by rotating the calorimeter. Due to its specific features (size of the heat-sink block, differential setting, good temperature regulation), the calorimeter has an excellent stability in time. Teflon plugs assure a good vapor-tightness even with volatile solvents. The concentrations were between 0.3 and 0.5%. The heat evolved per run was between 20 and 400 mJ.

Choice of the solvent

Cyclopentane is a good solvent for PP which may be taken as a model for hydrogenated polyisoprene and a medium quality solvent for PS. *N*-Pentane, a non-solvent for PS and a good solvent for PP, dissolves the copolymer but favors micelles with a PS core. The presence of micelles in the pentane solutions is revealed by the bluish color of dilute solutions of the copolymer. When cyclopentane is added to the solution, the color vanishes, indicating a change in the structure of the solution. The dissolution of the polymer even in *n*-pentane is achieved in less than 3 h for concentrations around 0.5%. A longer time of dissolution found, for instance, with methyl ethyl ketone (which gives micelles with a hydrogenated polyisoprene core) will lead to important errors in the evaluation of the heats since the heat flow due to the dissolution and micelle formation is small.

Results and discussion

Light scattering

Figure 1 shows the values of Kc/R_0 versus the copolymer concentration, the different curves corresponding to different solvent compositions. In pure cyclopentane ($\varphi_{c\text{-}C5} = 1.0$) and cyclopentane-rich solvents ($\varphi_{c\text{-}C5} = 0.8$), the curves are typical of a monomolecular solution with a positive virial coefficient. They extrapolate to the inverse of the value of the molecular weight found in benzene, M_w. For intermediate solvent compositions ($\varphi_{c\text{-}C5} = 0.45$ and 0.50), the concentration dependence of Kc/R_0 is typical of a closed association, the c.m.c. being estimated, respectively, at 0.5 and 2.9×10^{-3} g cm^{-3}. In the pentane-rich solutions and in pure pentane Kc/R_0 does not vary with concentration down to $c < 10^{-4}$ g cm^{-3}. In more concentrated polymer concentration M_w^{app} can be evaluated from the plateau of Kc/R_0. The curve in Fig. 2 corresponds to M_w^{app} at $c = 4 \times 10^{-3}$ g cm^{-3} chosen as such because it is similar to the concentration used for the heats of dissolution experiments (0.3–0.5% or $3–5 \times 10^{-3}$ g cm^{-3}). By extrapolating the curve, one finds that at that polymer concentration, the micelles start to form in solutions with $\varphi_{c\text{-}C5} < 0.60$. For $\varphi_{c\text{-}C5} = 0.5$, where

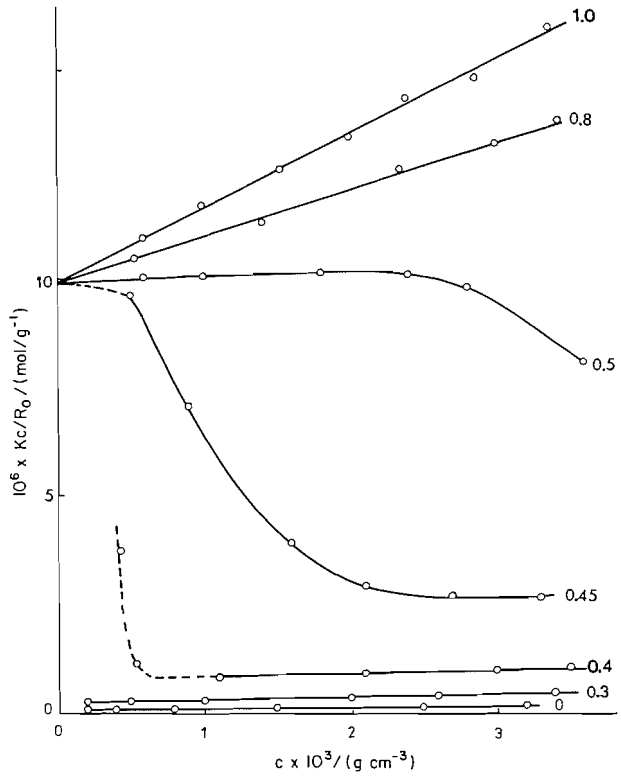

FIG. 1. A plot of Kc/R_0 against concentration for the polystyrene-*b*-h-polyisoprene copolymer in a series of cyclopentane/pentane mixtures at 25°C. The values of $\varphi_{c\text{-}C5}$ are indicated on each curve. For four concentrations $0.45 < \varphi_{c\text{-}C5} < 1.00$, the extrapolation at $c = 0$ gives the molar mass of the unassociated polymer (105 000). In solutions richer in pentane, the higher molar mass is indicative of a micellar solution. The dotted lines correspond to measurements in very dilute solutions where the state of aggregation of the molecules is changing with concentration.

Kc/R_0 is not independent of c, M_w^{app} has been estimated by extrapolating two points at lower concentrations. For two concentrations 0.45 and 0.50, the values of M_w^{app}, cannot be read accurately on Fig. 2 but correspond, respectively, to 365 000 and 150 000.

As the solvent refractive indices differ by less than 0.05, the possible preferential adsorption which could occur in the mixed solvent should not change significantly the value of the refractive index increment dn/dc (included in K of eq. [1]). Consequently, the value of (dn/dc) at constant solvent compostion has been used instead of that at constant chemical potential of low molecular mass components.

Calorimetry

The heat of micellization, ΔH_{micel} can be obtained directly by measuring, ΔH_{diss}, the heat of dissolution of the sample at increasing polymer concentration. A rapid change of heat is expected when the c.m.c. is reached. Alternatively, in a mixed solvent such as *c*-C5 and *n*-C5, ΔH_{diss} may be obtained at different solvent compositions using always the same polymer concentration. Micellization in solution should be marked by a noticeable change in ΔH_{diss} with $\varphi_{c\text{-}C5}$. Since the very small c.m.c. would not allow precise determination of the heat of micellization, the second method has been chosen, using a polymer concentration above the c.m.c.

In Fig. 3, the different ΔH_{diss} in J g^{-1} are plotted against $\varphi_{c\text{-}C5}$. Curve 1 is that obtained for the copolymer. It is to be noted that

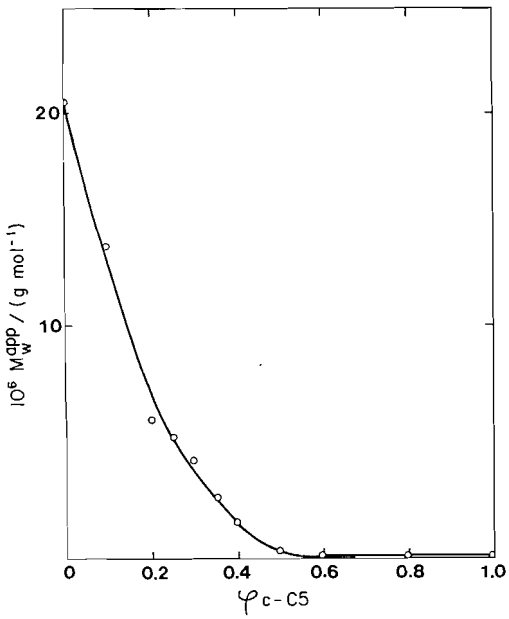

FIG. 2. Apparent molar mass of the polystyrene-*b*-h·polyisoprene versus $\varphi_{c\text{-}C5}$ obtained from light scattering data at $c = 4 \times 10^{-3}$ g cm^{-3}. M_w^{app} is already higher than M_w at $\varphi_{c\text{-}C5} = 0.50$ (150 000) and 0.45 (365 000).

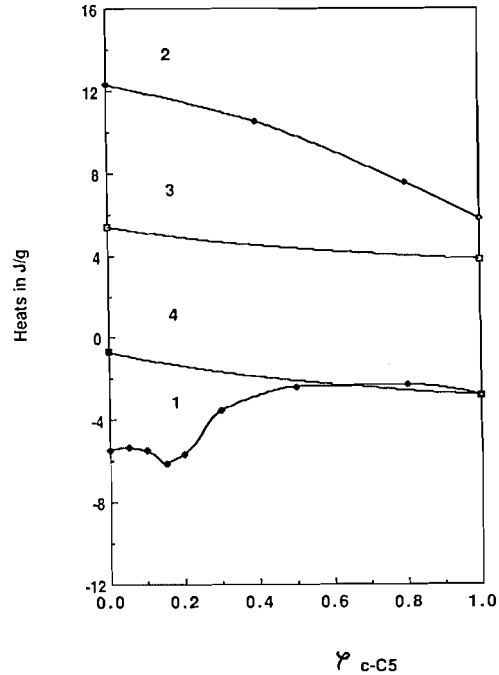

FIG. 3. Heats of dissolution of PS and the copolymer versus $\varphi_{c\text{-}C5}$. *Curve* 1: ΔH_{diss} of the copolymer; *curve* 2: ΔH_{diss} for a standard PS (molar mass = 2100). The corresponding curve for pure PP has not been put on the graph but would run as a straight line between −2.3 J g^{-1} for *c*-C5 and −4.0 J g^{-1} for *n*-C5; *curve* 3: ΔH_1diss of the copolymer as calculated with eq. [5] from the experimental heats of PP (ref. 12) and PS (curve 1); *curve* 4: identical to curve 2 but displaced by $\Delta H_{glass\text{-}liquid}$ (−6.1 J g^{-1}). ΔH_{micel} is taken s the maximum difference, in the region of the micellar structure, between curves 1 and 4, namely −5.1 J g^{-1}.

the change of heat starts at the same $\varphi_{c\text{-}C5}$ as that found in Fig. 2 for the increase of M_w^{app} by light scattering. The ΔH_{micel} is associated with the difference between the value in cyclopentane-rich solutions (−2 J g^{-1}) and the values in the micellar solutions (about −6 J g^{-1}) so that ΔH_{micel} has a value of −4 J per g of micelle by simple reading of the experimental ΔH_{diss}. However, to have a more refined data, one has to evaluate the ΔH_{diss} of the polymer in the hypothetical case where no micelle would form. The other calorimetric measurements have been made with that aim and are detailed below.

The ΔH_{diss} for an homopolymer come chiefly from the contribution, $\Delta H_{contact\text{-}interchange}$ which has its origin in the replacement of solvent–solvent contacts and polymer–polymer contacts by solvent–polymer contacts. A second contribution which is exothermic, $\Delta H_{glass\text{–}liquid}$ is to be counted if the polymer is a glass and a third ΔH_{micel} when association occcurs. Assuming that these contributions are additive, one can write:
Homopolymer:

[2] $\Delta H_{diss} = \Delta H_{contact\text{-}interchange}$

Homopolymer (glass):

[3] $\Delta H_{diss} = \Delta H_{contact\text{-}interchange} + \Delta H_{glass\text{–}liquid}$

Copolymer (glass) forming micelles:

[4] $\Delta H_{diss} = \Delta H_{contact\text{-}interchange}(w) + \Delta H_{glass\text{–}liquid} + \Delta H_{micel}$

In eq. [4], $\Delta H_{contact\text{-}interchange}$ (w) can be obtained as an approximation by making a weight average of the values for the two corresponding homopolymers. If *w* is the weight fraction of PS in the copolymer one has:

[5] $\Delta H_{contact\text{-}interchange}(w) = w\Delta H_{contact\text{-}interchange,\ PS} + (1 - w)\Delta H_{contact\text{-}interchange,\ h.PIP}$

In the range of $\varphi_{c\text{-}C5}$ where the molecules asociate, $0.00 < \varphi_{c\text{-}C5} < 0.60$, all the terms of eq. [4] contribute while for $0.6 < \varphi_{cC5} < 1.0$, the last term is absent. ΔH_{micel} is expected to be negative since non-favorable polymer–solvent contacts are replaced by good polymer–polymer contacts in the core of the micelle and solvent–solvent contacts outside.

Heats of dissolution of PS, PP, and copolymer in cyclopentane, $\Delta H_{glass\text{-}liquid}$ for PS

In curve 2 of Fig. 3, one sees that ΔH_{diss} of PS varies between 5.7 and 12.3 J g^{-1} over the whole concentration range. In order to separate the two terms of eq. [3], we can use the heat of dilution of PS in cyclopentane which has been measured over the concentration range of polymer φ_p such as $0 < \varphi_p < 0.7$. The heat $\Delta H_{contact\text{-}interchange,\ PS}$ is calculated to be 11.0 J g^{-1}. Considering that from the contact-interchange energy point of view, the hydrogenated part of PIP is similar to PP (or a random ethylene–propylene copolymer rich in PP), one can use here, the heat $\Delta H_{contact\text{-}interchange,\ PP}$ found to be −2.3 J g^{-1} (11). Using eq. [5], the calculation for the copolymer in cyclopentane gives:

[5a] $\Delta H_{contact\text{-}interchange}(w)$ (J g^{-1}) $= 0.58(-2.3) + 0.42 \times (11.0) = 3.3$

The difference between 3.3 and the experimental value (−2.8) is due to $\Delta H_{glass\text{–}liquid}$ which can be calculated to be $-(3.3 - (-2.8)) = -6.1$ J.

Heats of dissolution of PS, PP, and copolymer in n*-pentane*

To obtain $\Delta H_{contact\text{-}interchange,\ PS,\ n\text{-}C5}$ from the experimental heat of dissolution of PS in pentane (12.3 J), one should add 6.1 J. One obtains 18.4 J g^{-1}. $\Delta H_{contact\text{-}interchange,\ PP,\ n\text{-}C5}$ has been

estimated to two ways either by extrapolating from the values in higher alkanes (11) and also from comparison from the result in *n*-C5 of atactic polybutene-1 (12). The two methods give very similar results averaged to $-4.0\ J\ g^{-1}$. Using again eq. [5], one finds for the copolymer in pentane:

[5b] $$\Delta H_{\text{contact-interchange}}(w) = 0.58 \times (-4.0) + 0.42 \times (18.4) = 5.40$$

The values in [5*a*] and [5*b*] make the pure solvent points of curve 3. Since the difference of heats is small enough a linear interpolation between these points is used for the copolymer in the mixed solvent.

In order to compare to the experimental values, one has to add to curve 3, $\Delta H_{\text{glass-liquid}}$ ($-6.1\ J\ g^{-1}$), which gives curve 4.

The exothermic heats found for PP and the EP copolymers and used in the above equation include the free-volume term which comes from the difference in expansion coefficients of the polymer and solvent (13, 14). This negative term may become dominant when the free volume term is large (volatile solvents) and when $\Delta H_{\text{contact-interchange}}$ is small (mixture of a non-polar polymer with a non-polar chemically similar solvent). In order to simplify the terminology in eqs. [2]–[5], only the interactional term $\Delta H_{\text{contact-interchange}}$ and not the free volume term has been listed.

It is reasonable to assume that averaging ΔH_{diss} of the two polymers will take care also of the free volume contribution.

The different contributions to the heats in *c*-C5 and *n*-C5 can be seen qualitatively in the trace of the heat versus time during the dissolution. Although the total heats become more and more negative in the pentane-rich concentrations as seen in Fig. 3, the heat starts endothermic for these solutions at the beginning of the dissolution and changes to exothermic at a fraction (10–15%) of the dissolution time. In *c*-C5-rich solutions, the heat is always exothermic due mainly to the dominance of $\Delta H_{\text{glass-liquid}}$.

ΔH_{micel}, which is the difference between the experimental curve for the copolymer (curve 1) and that found for the copolymer without micellization (curve 4) in the pentane-rich solvent, is found to be $-5.1\ J\ g^{-1}$ at its maximum (-4.8 in pure pentane). The incertitude on this value has different origins: the error in the experimental ΔH_{diss} may be at most 0.15 J in the pentane-rich region due to the slower speed of dissolution. The error in assuming a linear relationship betwen ΔH_{diss} and the solvent composition (curve 4) can be estimated from previous work on homopolymers in mixed solvents (15). In the case of random mixing, the deviation from linearity is calculated to depend on the magnitude of the heat of mixing of the two solvents but is found experimentally smaller than calculated when the polymers have a large surface to volume ratio as is the case for PS. It is then reasonable to asssume that the errors coming from this simplification and those implicit in eq. [5] do not exceed 0.15 J so that $\Delta H_{\text{micel}} = -5.1 \pm 0.3\ J\ g^{-1}$. This result is higher than that found directly from the change of ΔH_{diss} (curve 1) versus concentration because in the first evaluation, account was not taken of the increase of ΔH_{diss} when the bad solvent *n*-pentane is added.

When expressed by gram of PS, ΔH_{micel} increases to 12.1 J per g of PS (5.1/0.42). This is to be compared to the value found in *n*-hexadecane for polystyrene-*b*-polyisoprene whose PS chain has a molecular weight of 7 000 (9*b*), namely, $44\ kJ/7 \times 10^3 = 6.7$ J. The larger value found in the present system is due both to the worse quality of *n*-pentane than *n*-hexadecane for the PS sequence and to the high molar mass of PS in the present sample (42,000 instead of 7,000). The smaller value of the c.m.c. for the system PS-*b*-hydrogenated PIP + (*n*-C5 + *c*-C5) compared to that for the system PS-*b*-PIP + *n*-hexadecane is in line with its larger ΔH_{micel}. Forming a micelle corresponds in reverse to dissolving a polymer in a bad solvent. The heat of dissolution of a polymer (atactic, liquid) in a θ solvent gives a good model for the heat one should recover when the micelle is formed. For instance ΔH_{diss} of PIB in benzene at 25°C near phase separation has been found to be $19\ J\ g^{-1}$ (15*a*) which is higher but of the same order of magnitude that ΔH_{micel} found presently. The sign and the value of ΔH_{micel} for this PS-*b*-h·PIP confirm the previous conclusion of the importance of the enthalpic origin of the stability of these block-copolymer micelles.

Energies of the phases of ice at low temperature and pressure relative to ice Ih[1]

Y. Paul Handa, D. D. Klug, and Edward Whalley
Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6

Received November 18, 1987

This paper is dedicated to Professor J. A. Morrison

Y. Paul Handa, D. D. Klug, and Edward Whalley. Can. J. Chem. **66**, 919 (1988).

The enthalpy of transformation to ice Ic of ice II, IX, V, VI, and VIII that have been recovered at 77 K and ambient pressure, and of the transformation of ice Ic to Ih, has been measured in a heat-flow calorimeter. The enthalpy of transformation of ice Ic to Ih depends on the high-pressure phase used to make the ice Ic. The thermodynamics of the transformation of ice IX, which was made by cooling ice III at 0.3–0.7 K s^{-1}, to ice III shows that the ice IX was fully orientationally ordered to the precision of the experiments.

Y. Paul Handa, D. D. Klug, et Edward Whalley. Can. J. Chem. **66**, 919 (1988).

Utilisant un calorimètre à écoulement de chaleur, on a mesuré les enthalpies de transformation en glace Ic des glaces II, IX, V, VI et VIII, récupérées à 77 K et à pression ambiante, ainsi que de la transformation de la glace Ic en glace Ih. L'enthalpie de transformation de la glace Ic en glace Ih dépend de la nature de la phase à haute pression qui a été utilisée pour faire la glace Ic. Les propriétés thermodynamiques associées à la transformation de la glace IX, préparée par refroidissement de la glace III à 0,3–0,7 K s^{-1}, en glace III démontre que, à la précision des expériences, la glace IX est complètement ordonnée d'un point de vue de l'orientation.

1. Introduction

Ice forms a wide range of crystalline (1–13) and amorphous (4, 14, 15) phases. The energies of these phases at zero temperature and pressure are excellent tests of proposed intermolecular potentials of water (ref. 16 and references quoted there). They have been estimated in the past from the enthalpies of the spontaneous transformation of the high-pressure phases, as recovered at low temperatures and pressures, to ice Ic (17, 18), and from the equilibrium pressures, temperatures, and volume changes as extrapolated to zero temperature (ref. 16).[2] When measuring the enthalpies of some order–disorder transformations of the various phases of ice at ambient pressure, the enthalpies of transformation of several crystalline phases to ice Ic and of ice Ic to Ih were measured; a preliminary account of some of the measurements of ice V and VI has been published (19). The enthalpy of the transformations at ambient pressure is, of course, the difference of energy between the phases at the temperature of the transformation, and so the energy of transformation from the high-pressure phase to ice Ih can be obtained. These enthalpies of transformation are reported in this paper.

As the energy of ice Ih at zero pressure relative to the vapor is well known throughout its range of stability, the energies of the high-pressure phases relative to the vapor can be obtained. The principal immediate use of these energies will be to test and adjust intermolecular potentials of water, both two-body and multi-body potentials, and to adjust the phase boundaries to more accurate locations.

2. Experimental methods

Ice II, IX, V, VI, and VIII were made by placing 1.5–2.7 g of degassed water in an indium cup, which was then capped with indium, and the ice and the indium were pressurized in a piston-cylinder apparatus having an inside diameter of 12.5 mm. The course of the compression was followed by measuring the displacement of the piston relative to the cylinder to 2 μm by a dial gauge. Samples of ice II were made by compressing ice Ih to 3.5 kbar at about 200 K and were identified by the pressure and change of volume at the transformation from ice Ih. Samples of ice III, V, and VI were made in similar ways by compressing ice Ih to 4, 6, and 9 kbar respectively at 240 K, and samples of ice VII were made at 22 kbar and 280 K. All samples were cooled under pressure in about 5 min by immersing them in liquid nitrogen, when ice IX, V, and VI, each having an uncertain degree of order, and ice VIII were formed. They were stored in liquid nitrogen.

The calorimetric measurements were made at ambient pressure by placing the experimental sample in its indium cup in the sample cell of an automated Setaram model-BT Tian-Calvet heat-flow calorimeter (20) that had been cooled to 77 K. A reference cup whose mass was identical to that of the sample cup to ±10 mg, except that it was empty, was placed in the reference cell of the calorimeter, and the two cells were flushed with helium. The calorimeter was operated in the scanning mode using a scan rate of 10 K h^{-1}. The water in the sample cup was weighed at the end of each run. The details of the calorimeter, the operational technique, and the methods used to analyze the raw data are described elsewhere (20). The temperature was measured with a platinum thermometer located just outside the measurement cell, and represents the sample temperature except during a thermal event, when the sample temperature is slightly different.

3. Results

Representative scans of ice II, IX, V, VI, and VIII are plotted in Figs. 1–5, in which endothermic and exothermic peaks point upwards and downwards, respectively. Each has at least two transformations, one being the transformation from the high-pressure phase to ice Ic, which occurs in the range 120–160 K, and the other the transformation of ice Ic to Ih, which occurs near 200 K, as is marked on the figures.

All samples of ice II and VIII have weak exothermic transformations at about 105 K, which is outside the range of the curves in Figs. 1 and 5, and ice V and VI have moderate endothermic transformations at about 125 and 140 K, respectively. The exotherms are probably caused by irreversible transformations from a partly orientationally disordered state that was frozen in during the cooling. This was confirmed by recooling the samples to 80 K and reheating to 105 K; the exotherms were not observed. The endotherms of ice V and VI have already been reported briefly (19) and they and the two exo-

[1]NRCC No. 28593.

[2]In ref. 16 the lattice energy of ice VIII in Table VII should be −60.70 kJ mol^{-1} instead of −62.4 kJ mol^{-1}, and the last sentence should be omitted.

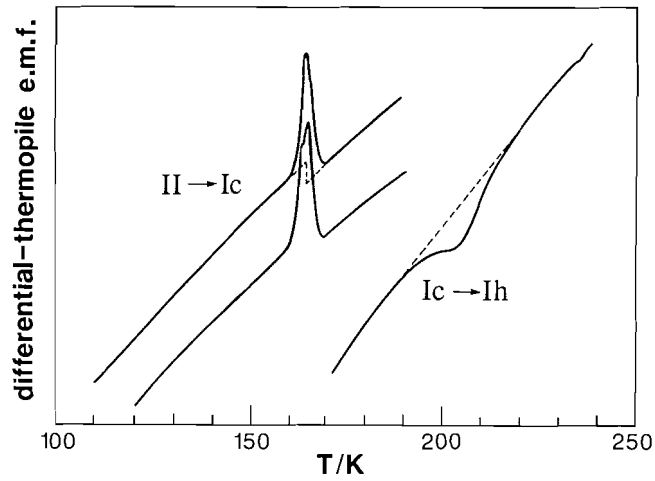

FIG. 1. Thermal e.m.f. of the differential thermopile during the transformation of ice II to ice Ic and then to ice Ih, plotted against temperature, for two experiments in order to show the different shapes of the endotherms at the transformations of ice II to Ih. The dashed lines are the assumed base lines of the transformations.

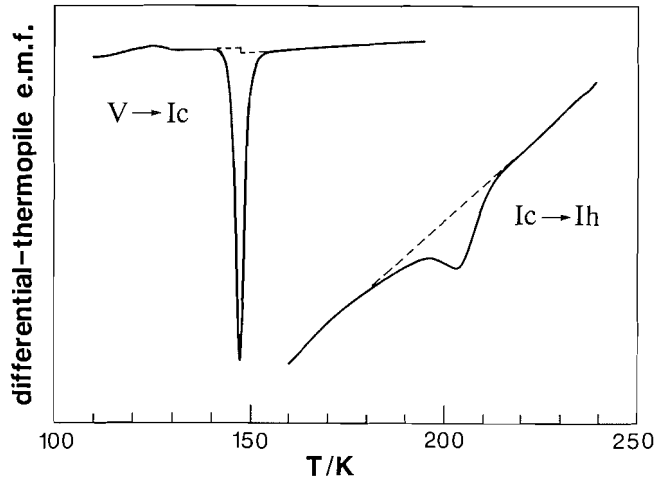

FIG. 3. Thermal e.m.f. generated between the sample cell and the reference cell when ice V transforms to ice Ic and then to ice Ih, plotted against temperature. Part of the transformation of ice VI to Ic is drawn on an enlarged ordinate in order to show clearly the disordering transformation near 135 K.

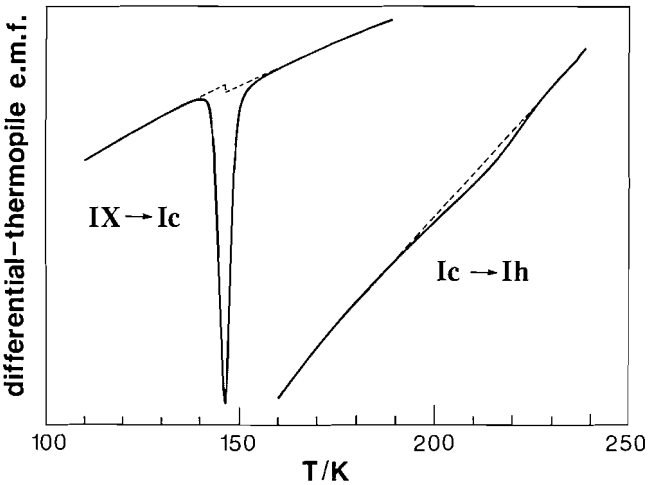

FIG. 2. Thermal e.m.f. generated between the sample cell and the reference cell when ice IX transforms to ice Ic and then to ice Ih, plotted against temperature.

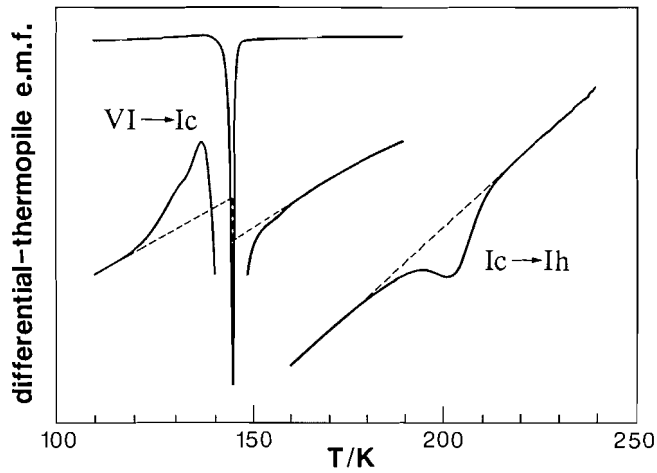

FIG. 4. Thermal e.m.f. generated between the sample cell and the reference cell when ice VI transforms to ice Ic and then to Ih, plotted against temperature.

therms will be reported in detail in later papers. Five samples of ice II, two of ice IX, four of ice V, two of ice VI, and two of ice VIII were measured. The enthalpy of the transformations to ice Ic and of ice Ic to Ih are summarized in Tables 1 and 2, respectively.

The transformation of ice II to Ic sometimes produced a symmetric peak in the calorimeter scans, and sometimes produced peaks with small irregularities, as is illustrated in one of the scans in Fig. 1. The cause of the irregularities is not known, but they seem to have no significant influence on the enthalpies of transformation. The enthalpies of transformation seem to fall into two reasonably well defined groups, the first three samples averaging 57.4 ± 1 J mol^{-1} and the last two samples having the value 48.1 J mol^{-1}. All five are consistent with the average value of 54 ± 5 J mol^{-1}, and the two groups are tentatively considered to differ insignificantly.

Two measurements of the enthalpy of transformation of ice IX to Ic were made, and the average value is -340 ± 3 J mol^{-1}, which agrees well with the earlier and less accurate value (17). Ice IX is partly ordered (9, 17, 21–25) but the degree of order of our samples is not known *a priori*. The endothermic contribution from the disordering transformation is included in the observed enthalpy of transformation. Yamamuro and others (26) have recently described making ice IX by applying 2.5 kbar of helium pressure to either the liquid or the ice I at about 250 K. They cooled the samples to 77 K and released the helium. When the samples were heated, an endothermic transformation occurred. In the present experiments, ice II transformed to ice Ic endothermically but ice IX transformed to ice Ic exothermically, which agrees with the earlier data (17). It seems likely that Yamamuro and others (26) made not ice IX, but ice II, as Rabideau and co-workers showed (27) when helium was the pressurizing fluid.

The endothermic transformations of both ice V and VI in the range 106–132 K and 120–141 K, respectively, are probably due to disordering of the molecular orientations. The endotherm in ice V depended upon the conditions and had a maximum value (19) of 229 ± 10 J mol^{-1} and seems to be quite well separated from the exotherm of the transformation of ice V to Ic, whose enthalpy change is -915 ± 45 J mol^{-1}, as is clear in Fig.

VIII	1	117.5	124.4	174.7	−2685	−2667±25	−2340 at ~125 K
	2	117.6	123.0	176.3	−2649		

[a]Approximately, T_i and T_f are, respectively, the temperatures at which the thermal effect appeared to start and end and T_t is the apparent transformation temperature, all as defined in ref. 39.

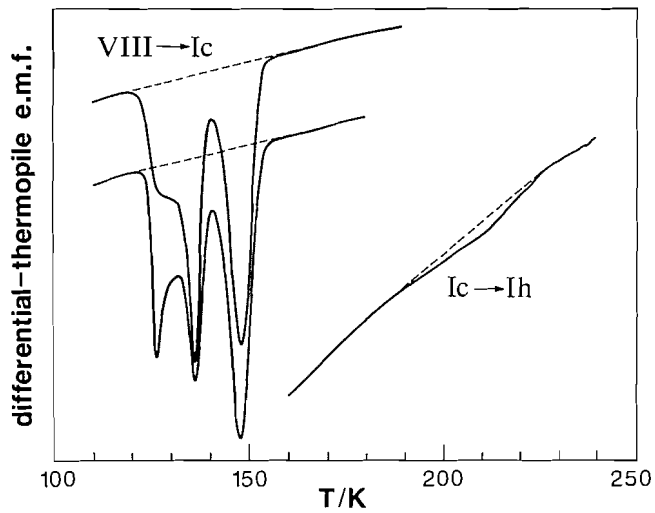

FIG. 5. Thermal e.m.f. generated between the sample cell and the reference cell when ice VIII transforms to ice Ic and then to Ih, plotted against temperature. Two scans are plotted in order to illustrate the difference in the shape of the exotherm of the transformation of ice VIII to Ic.

3. It seems likely that ice V is fully disordered before its transformation to ice Ic.

The endotherm of ice VI clearly overlaps the exotherm caused by the transformation of the partly ordered ice VI to Ic, as is shown in Fig. 4, and could not be properly separated from it in these experiments. The endotherm and exotherm occur with an average apparent enthalpy change of 115 ± 2 and −1404 ± 20 J mol^{-1}, but the endotherm is probably more positive and the exotherm more negative than they seem to be because of the overlap. What we know about the true value of the exotherm is discussed in Section 4.4.

The transformation of ice VIII to ice Ic that is drawn in the lower curve of Fig. 5 has three distinct exotherms, which can be approximately separated into peaks whose areas are listed in Table 3. In the transformation represented by the upper curve of Fig. 5, the peak at the lowest temperature seems to have broadened to become only a shoulder of the center peak, but the areas of the three features are consistent with the areas under the curve in the lower part of the figure. The average area under all the features is −2667 ± 25 J mol^{-1}. All the enthalpies of transformation are consistent with the less accurate values that were measured in a simple apparatus over 20 years ago (17, 18).

The enthalpy of transformation of ice Ic to Ih depends on the phase that the ice Ic was made from. It was about −35 ± 5 J mol^{-1} when either ice II, ice VIII, or the low-density amorph was the source of the ice Ic, was about −13 ± 4 J mol^{-1} when ice IX was the source, and was about −50 ± 5 J mol^{-1} when either ice V or VI was the source. The differences between the enthalpy changes are so great that they are well outside the experimental uncertainties.

Four possible causes of the differences are the formation of ice Ic with a substantial fraction of stacking faults, the formation of regular stacking variants that are intermediate between ice Ih and Ic, a transformation of ice Ic to Ih that releases some of its heat too slowly to detect, and formation of ice Ic having grains that are small enough to have an energy of some tens of joules per mole. Stacking variants are known in the closely related system ammonium fluoride (28), phase I of which is isomorphous with ice Ih, but have never been reported in the phases of ice. Stacking faults are known to occur in ice Ih (29) but seem not to have been identified in the numbers needed to explain differences in energy of transformation of as much as 40 J mol^{-1}. Stacking faults in ice Ic have not yet been reported but probably exist in small numbers. The formation of small grains is certainly possible, so that the interfacial energy accounts for

	2	176.5	216.7	−53.1	
Ice VIII	1	186.7	228.0	−33.9	−34.5± ~1
	2	186.0	228.0	−35.1	
Low-density amorphous ice[d,e]	1			−38.4	
	2			−30.6	−35±4
	3			−35.5	

[a] T_i and T_f are defined in Table 1.
[b] The transformation of sample 3 of ice IX to ice Ic was not measured, and so the sample is not included in Table 1. It was annealed in the calorimeter at 146–150 K for 1 h in order to eliminate any perturbation of the initial baseline for the transformation of ice IX to Ic.
[c] These values have already been reported briefly in ref. 40 and are listed here for comparison.
[d] The low-density amorphous ice was made by heating high-density amorphous ice that had itself been made by compressing ice Ih at 77 K to about 13 kbar (14).
[e] These values have already been reported (39) and are listed here for comparison.

the difference in the energies of transformation of ice Ic to Ih. But then a correlation between the volume and heat changes at the transformation to ice Ic might be expected, but none is apparent. As the ice Ih forms at temperatures as high as 220 K, it seems likely that the grains are quite large and so have only a small interfacial energy. If the average interfacial energy between the grains of ice Ic were about 10 nJ mm^{-2} and the average grain had dimensions of about 100 nm, which varied from sample to sample depending on the origin, then the difference in the transformation energies of ice Ic to Ih could be explained.

It will be assumed tentatively that this explanation is correct, and that the ice Ih that is made (at about 225 K) has a large enough grain size that the interfacial energy is small. Then, the enthalpies of transformation of the high-pressure phases to ice Ih can be obtained accurately. The values so obtained are summarized in Table 4. They agree reasonably well with the changes of enthalpy at zero temperature as obtained from the phase relations and from simple thermal measurements (16–18).

4. Discussion

4.1 Transformation of ice II to Ih

The difference of internal energy U on the equilibrium line II–Ih, U_{Ih}–U_{II} (3), changes linearly with the temperature from −68.6 J mol^{-1} at 238.2 K to −53.5 J mol^{-1} at 198.2 K. If the line is extrapolated linearly to 162 K, the change of energy is −40 J mol^{-1}. The difference between this value and the 18 J mol^{-1} that is reported in Table 4 is, presumably, accounted for by the effect of temperature and pressure on the internal energy, but the existing data for this and other equilibrium lines are insufficient to evaluate the effect.

The enthalpy of transformation of ice II to ice Ih is 18 ± 5 J mol^{-1} at 162 K. Its sign disfavors the transformation, so the transformation must be driven by an increase in the entropy. Because ice II is orientationally ordered and ice Ih is not (30–32), the change of configurational entropy at the transformation is approximately (R) ln (3/2), where R is the gas constant and 3/2 is approximately the number of orientational configurations per molecule (33), i.e. 3.37 J K^{-1} mol^{-1}. The change of Gibbs function G at the transformation at ~200 K is

$$[1] \quad G_{Ih} - G_{II} = H_{Ih} - H_{II} - T(S_{Ih} - S_{II}) = -656 \pm \sim 16 \text{ J mol}^{-1}$$

so the transformation is predicted to go in the observed direction.

The pressure p_e at which ice II and Ih are at equilibrium is described by the equation

$$[2] \quad p_e = -\Delta_e A/\Delta_e V$$

where A is the Helmholtz function and subscript e means at thermodynamic equilibrium. At zero temperature, eq. [2] becomes

$$[3] \quad p_e = -\Delta_e U/\Delta_e V$$

Because the difference of enthalpy is 18 ± 5 J mol^{-1} at 162 K and ambient pressure, and because the heat capacity of ice II,

TABLE 3. Enthalpy of transformation ΔH of ice VIII to ice Ic at zero pressure, and approximate enthalpies of transformation of the three peaks.

Sample no.	Total ΔH J mol^{-1}	Peak 1 T_p[a] K	Peak 1 ΔH[b] J mol^{-1}	Peak 2 T_p[a] K	Peak 2 ΔH[b] J mol^{-1}	Peak 3 T_p[a] K	Peak 3 ΔH[b] J mol^{-1}
1	−2685	126	−620	136	−810	147	−1250
2	−2649	128	−520	136	−880	148	−1250

[a] T_p is the temperature at which the e.m.f. of the thermopile reached a maximum.
[b] The enthalpies of the peaks were obtained by resolving the peaks graphically.

TABLE 4. Enthalpies of transformation ΔH of the high-pressure phases of ice to ice Ih

Phase of ice	T[a] K	ΔH J mol^{-1}
Ice II	162	18±5
Ice IX	143	−353±6
Ice V	144	−966±6
Ice VI	143	−1454±20
Ice VIII	124	−2702±25

[a] T is the average of the temperatures T_t reported in Table 1, rounded to the nearest integer.

which has not yet been measured, is probably greater than that of ice I, the difference of energy of ice II and ice Ih at zero temperature is greater than 18 ± 5 J mol^{-1}. The volume of ice II is less than that of ice I by 3.5 cm^3 mol^{-1} at about 100 K and ambient pressure (30–32). If the unknown difference of thermal expansivity of ice Ih and II is neglected, the equilibrium pressure at zero temperature is −51 ± ~20 bar, and so ice II is the most stable phase of ice at zero temperature and pressure. Bridgman (3) pointed out 75 years ago that the equilibrium line between ice II and Ih extrapolated to about zero temperature and pressure, and Whalley (16) estimated from Bridgman's measurements that the intercept of the line on the pressure axis was 0.14 ± 0.2 kbar, which agrees with the present, more accurate, result.

The equilibrium temperature T_e is defined by the equation

[4] $$T_e = \Delta_e H/\Delta_e S$$

The value of the enthalpy change at zero pressure can be taken as that at 162 K without a great uncertainty, and is about 18 J mol^{-1}. From this, the entropy change, which has already been discussed, and eq. [4], the equilibrium temperature at zero pressure is about 5 K.

Some years ago it was pointed out (34) that if ice II were the stable phase of ice at zero temperature and pressure, and if ice Ih and II had the same configurational entropy, our world would be vastly different from what it is and, in particular, that life as we know it could not exist. We are indeed fortunate that ice Ih is disordered and ice II is not.

4.2 Transformation of ice IX to Ih

The difference of enthalpy between ice IX and Ih at ambient pressure, is, according to Table 4,

[5] $$H_{Ih} - H_{IX} = -353 \pm 7 \text{ J mol}^{-1} \text{ at } 143 \text{ K}$$

The difference of enthalpy between ice III and Ih can be obtained from the position and slope of the equilibrium line and the difference of volume between ice III and Ih. Then the thermodynamics of the transformation of ice III to ice IX can be determined, in order to determine the configurational entropy of ice IX.

An estimate of the enthalpy of transformation of ice Ih to ice III can be obtained from the slope of the ice Ih–III equilibrium line and the volume change across it, according to the Clausius–Clapeyron equation

[6] $$H_{III} - H_{Ih} = T\left(\frac{\partial p}{\partial T}\right)(V_{III} - V_{Ih})$$

The slope of the equilibrium line is (35) −2.58 ± 0.02 bar K^{-1}, which replaces Bridgman's (3) value, whose line is much too strongly curved.

The change of volume on the equilibrium line at 238 K and 2120 bar is

[7] $$V_{III} - V_{Ih} = -3.53 \pm \sim 0.02 \text{ cm}^3 \text{ mol}^{-1}$$

which is the average of Bridgman's (3) and Gagnon's (36) values. It follows that

[8] $$H_{III} - H_{Ih} = 217 \pm \sim 3 \text{ J mol}^{-1} \quad \text{at} \quad 238 \text{ K} \quad \text{and} \quad 2120 \text{ bar}$$

This value can be reduced to zero pressure by the equation

[9] $$\left(\frac{\partial \Delta H}{\partial p}\right)_T = \Delta V - T\left(\frac{\partial \Delta V}{\partial T}\right)_p$$

The first term on the right-hand side of eq. [9] can be integrated, assuming a difference of compressibility of 3 ± ~1 Mbar^{-1}, to

[10] $$(H_{III} - H_{Ih})(p = 0) - (H_{III} - H_{Ih})(p = 2120 \text{ bar}) = 751 \pm \sim 6 \text{ J mol}^{-1} \quad \text{at} \quad 238 \text{ K}$$

The second term of eq. [9] is of the magnitude of 1 J mol^{-1} if the difference of thermal expansions of ice Ih and III is a third of the thermal expansion of ice Ih, and can be neglected. Then, from eqs. [8] and [10]

[11] $$(H_{III} - H_{Ih})(p = 0) = 968 \pm 7 \text{ J K}^{-1} \text{ mol}^{-1} \quad \text{at} \quad 238 \text{ K}$$

This value can be reduced to 143 K by means of the equation

$$\left(\frac{\partial \Delta H}{\partial T}\right)_p = \Delta C_p$$

where ΔC_p is the difference of heat capacities at constant pressure. The difference of heat capacities can be estimated approximately from the peak infrared frequency of the librations of ice Ih and III or IX, i.e. 840 (37) and 812 cm^{-1} (38), respectively, ignoring the translational vibrations because their frequencies are not known well enough. If the librations are approximated by a single frequency then at ambient pressure

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/07/12
For personal use only.

[12] $(H_{III} - H_{Ih})(238\ K) - (H_{III} - H_{Ih})(143\ K) = 25 \pm \sim 10\ J\ mol^{-1}$

It follows from eqs. [11] and [12] that at ambient pressure

[13] $H_{III} - H_{Ih} = 943 \pm \sim 12\ J\ mol^{-1}$ at 143 K

It further follows from eq. [13] and the difference of enthalpy between ice Ih and IX of $-353 \pm 6\ J\ mol^{-1}$ that

[14] $H_{III} - H_{IX} = 590 \pm \sim 13\ J\ mol^{-1}$ at 143 K and ambient pressure

The enthalpy of the transformation of ice III to ice IX, as measured in a high-pressure differential scanning calorimeter (21) that was cooled at the rate 0.01–0.04 K s^{-1}, was $-230 \pm \sim 50\ J\ mol^{-1}$, which is less than half the value that is determined in this work. The cause of the discrepancy is not immediately obvious.

If W_{III} and W_{IX} are the numbers of configurations per molecule in ice III and IX respectively, then

[15] $RT \ln W_{III}/W_{IX} = 590 \pm \sim 13\ J\ mol^{-1}$

If the transformation temperature T is taken as about 173 K (9, 21) which is where a major part of the transformation occurs, although the transformation occurs over the range 200–165 K, then

[16] $W_{III}/W_{IX} = 1.51 \pm 0.02$

which is, within the experimental precision, equal to the value for fully disordered ice III and fully ordered ice IX within the ice rules. The ice IX made in this work seems, therefore, to be fully ordered.

4.3. Transformation of ice V to ice Ih

The transformation of fully disordered ice V to ice Ih occurs at 144 K with an enthalpy change of $-966 \pm 6\ J\ mol^{-1}$.

4.4 Transformation of ice VI to ice Ih

If ice VI had no orientational disorder, the maximum enthalpy change at the disordering transformation would be RT ln (3/2) or 470 J mol^{-1} at 140 K. The enthalpy of transformation is at least 115 J mol^{-1}. If ice VI were fully ordered, then about -355 J mol^{-1} should be added to the enthalpy of the transformation of ice VI to Ic. The enthalpy of transformation of ice VI, as made in this work, to Ic could, then, be as high as about 1760 J mol^{-1} and as low as 1405 J mol^{-1}.

4.5. Transformation of ice VIII to ice Ih

The transformation of fully ordered ice VIII to Ic occurred in three distinct exothermic peaks in one sample, and in the second sample the lowest-temperature peak seems to have broadened to form a shoulder on the low-temperature side of the center peak. The characteristic temperatures and the enthalpy changes in each peak are summarized for the two samples in Table 3.

The cause of the three features is not known; the principal possibilities are samples that are reproducibly inhomogeneous, and samples that sequentially transform from ice VIII to two other phases and finally to ice Ic. Reproducible inhomogeneity seems unlikely, and a sample of ice VIII that was held at 125 K for 21 h and then had its X-ray powder pattern taken at about 90 K was about half ice VIII and half ice Ic, and there was no evidence of intermediate phases (18).

A new method for calculating the rotational tunnelling splitting for three-dimensional rotors

GÜNTER VOLL AND ALFRED HÜLLER

Department of Theoretical Physics, University of Erlangen, 8520 Erlangen, Glückstraße 6, West Germany

Received September 15, 1987

This paper is dedicated to Professor James A. Morrison

GÜNTER VOLL and ALFRED HÜLLER. Can. J. Chem. **66**, 925 (1988).

We present a recursion method for calculating the rotational part of the wave function and the rotational tunnelling splitting ω for three-dimensional rotors. This Pocket Recursion Method (PRM) is designed to include the case of splittings that are smaller than 10^{-2} μeV. The PRM combines two advantages: fast convergence and accuracy. Applications to the various $(NX_4)_2SnCl_6$ model potentials are shown (X = H, D). For the Smith potential, the calculated isotope shift agrees well with the recent experimental results. Applications to other rotational tunnelling systems are straightforward.

GÜNTER VOLL et ALFRED HÜLLER. Can. J. Chem. **66**, 925 (1988).

On présente une méthode récursive permettant de calculer, pour des rotors tridimensionnels, la portion rotationnelle de la fonction d'onde et la levée de la dégénerescence (ω) dûe à l'effet tunnel rotationnel. On a développé cette méthode récursive de poche (MRP) de façon à inclure les cas où les séparations entre les niveaux sont plus petits que 10^{-2} μeV. La MRP présente deux avantages : une convergence rapide et une bonne précision. On présente des applications à divers potentiels modèles du $(NX_4)_2SnCl_4$ (X = H, D). Dans le cas du potentiel de Smith, le déplacement isotopique qui a été calculé est en bon accord avec les données expérimentales rapportées récemment. Des applications à d'autres systèmes présentant une levée de la dégénerescence dûe à l'effet tunnel rotationnel sont immédiates.

1. Introduction

1.1 A qualitative picture of rotational tunnelling

A molecule in a solid experiences an angle-dependent potential (1–3). The moment of inertia J of the rotor determines the natural energy unit, termed "rotational constant", $B = \hbar^2/(2J)$, where $\hbar$ denotes Planck's constant; Table 1 gives the values of B for some molecules.

In this section we develop a qualitative picture of rotational tunnelling at zero temperature, using as an example a tetrahedral molecule, like CH_4 or NH_4, in a tetrahedral crystal field (Fig. 1). For tetrahedral molecules the orientational potential can be divided into at least 12 disjointed identically shaped regions, according to the invariance of the rotor with respect to the 12 rotations that are the symmetry operations of the tetrahedral symmetry group T. We call the regions "potential pockets" (4). For a tetrahedral crystal field there are just 12 pockets and the symmetry within a pocket is high (4): the rotations around the three twofold symmetry axes of the molecule are energetically equivalent; the same is true for the rotations around the four threefold symmetry axes.

For high (in units of B) and broad potential barriers the orientational probability distribution of the quantum rotor is sharply peaked at the potential minima. A real valued ("ansatz") wave function, which is peaked in a single pocket, is called a "pocket state" (4). We take 12 pocket states, denoted by $|1\rangle$, $|2\rangle$, ..., $|12\rangle$, of identical shape, each centered in one of the 12 pockets (Figs. 2–4). The rotations of the tetrahedral group transform the pocket states into each other. The pocket states are neither eigenstates of the Hamiltonian, nor orthogonal to each other.

The orientations that differ by one of the molecule's symmetry operations are indistinguishable. Consequently, approximate eigenstates of the Hamiltonian can be constructed as linear combinations of the 12 pocket states. The eigenstates are classified according to the irreducible representations A, T, and E of the tetrahedral group; there are two E-symmetric functions, nine T-functions, and one A-function (4). Functions of the same symmetry type are energetically degenerate. As an example, we give one (unnormalized) eigenstate of each symmetry approximated by the appropriate linear combination of pocket states (4) (Fig. 4):

TABLE 1. The order of magnitude of some rotational constants $B = \hbar^2/(2J)$. J denotes the moment of inertia of the rotor; $\hbar$ is Planck's constant; k_B is Boltzmann's constant

Molecule	B
$-CH_3$, NH_4^+, CH_4	$8Kk_B$: 0.7 meV
$-CD_3$, ND_4^+, CD_4	$4Kk_B$: 0.3 meV
H_2	$85Kk_B$: 7.3 meV
D_2	$43Kk_B$: 3.7 meV

$$|A\rangle \approx \sum_{i=1}^{12} |i\rangle$$

[1] $$|T_x\rangle \approx |1\rangle - |2\rangle - |3\rangle + |4\rangle$$

$$|E^-\rangle \approx |1\rangle + |2\rangle + |3\rangle + |4\rangle - |6\rangle - |8\rangle - |10\rangle - |12\rangle$$

We choose $\langle i|i\rangle = 1$ to simplify the notation; for the diagonal matrix element of the Hamiltonian H we write $e_i = \langle i|H|i\rangle$. By construction of the set of pocket states, all e_i are equal and are denoted e. Because of the tetrahedral crystal field, there are only two types of overlaps and off-diagonal elements of the Hamiltonian (4): the matrix elements linking pocket states that differ by a 120° rotation around the respective symmetry axis of the molecule (e.g., the pair ($|4\rangle$, $|5\rangle$)); Fig. 4) are all equal and are denoted by $b = \langle 4|5\rangle$ and $h = \langle 4|H|5\rangle$; analogously, the matrix elements between 180° adjacent pocket states are all equal and we write $\bar{b} = \langle 4|1\rangle$ and $\bar{h} = \langle 4|H|1\rangle$. The eigenenergies are approximated in terms of these matrix elements as follows (the upper index "ps" stands for "calculated

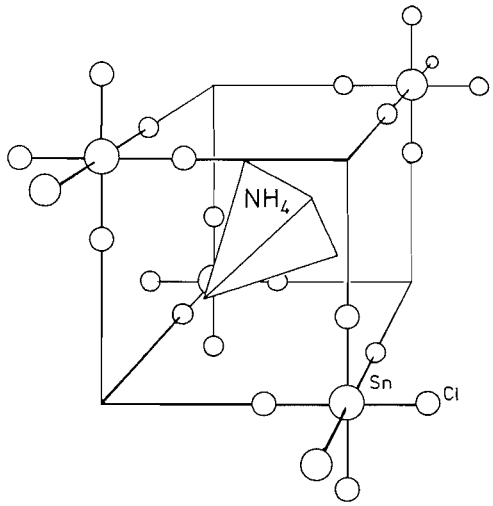

FIG. 1. $(NH_4)_2SnCl_6$. The NH_4 rotor sits in a crystal field of tetrahedral symmetry.

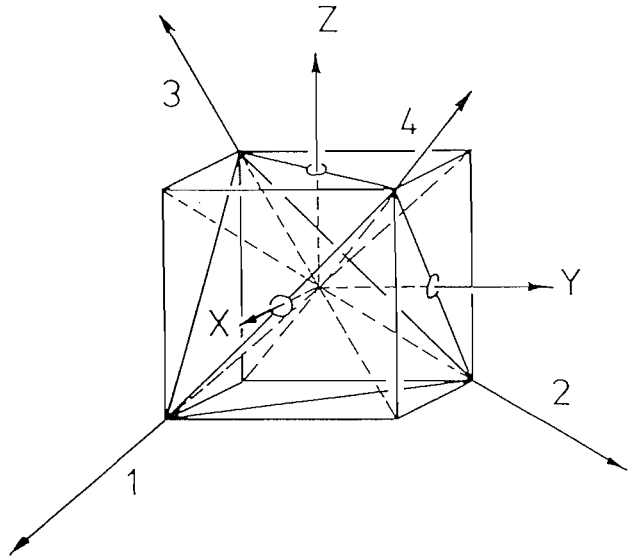

FIG. 2. The choice of the space-fixed coordinate system (XYZ) relative to the standard orientation of the tetrahedral rotor. In its standard orientation the rotor has minimal potential energy in a H_{11}^3-type potential (Fig. 5).

with pocket states"):

$$E_E = \frac{\langle E^-|H|E^-\rangle}{\langle E^-|E^-\rangle} \approx \frac{e - 4h + 3\tilde{h}}{1 - 4b + 3\tilde{b}} = E_E^{ps}$$

[2] $$E_T = \frac{\langle T_x|H|T_x\rangle}{\langle T_x|T_x\rangle} \approx \frac{e - \tilde{h}}{1 - \tilde{b}} = E_T^{ps}$$

$$E_A = \frac{\langle A|H|A\rangle}{\langle A|A\rangle} \approx \frac{e + 8h + 3\tilde{h}}{1 + 8b + 3\tilde{b}} = E_A^{ps}$$

The energy differences $\omega(TA) = E_T - E_A$ and $\omega(ET) = E_E - E_T$ characterize the fine structure of the librational ground state multiplet; they are called tunnelling energies or "tunnelling splittings", if the splittings are smaller than roughly 10^{-1} B (Table 1). We note several important aspects: The degeneracy between A, T, and E states is lifted by the overlap matrix elements (h, $\tilde{h}$, b, and $\tilde{b}$) of adjacent pocket states. The tunnelling splittings decrease with increasing potential barrier height. For high potential barriers, the 180° terms contribute far less to the tunnelling energy than the 120° terms (Fig. 5) and we can neglect the former: $1 \gg b \gg \tilde{b}$ and $|d| \gg |\tilde{d}|$ with $\tilde{d} = \tilde{h} - e\cdot\tilde{b}$ and $d = h - e\cdot b$ characterizing[1] the respective contributions to the splitting; this is the case in which we are interested:[2]

[3] $$E_E \approx e + 4|d|$$
$$E_T \approx e \qquad \text{for} \quad |d| \gg |\tilde{d}|$$
$$E_A \approx e - 8|d|$$

So far we have not explicitly stated the assumption used above, eq. [1]: A priori, we need three different sets of pocket states, one for each symmetry label. In eq. [1] we used instead only one common set. In the case of a high potential barrier, eq. [3], we therefore obtain a ratio $R = \omega(TA)/\omega(ET)$ equal to 2. The experimental results for tiny tunnelling splittings show that the value of R is close to 2 (1.96; ref. 5). Variational calculations, using free rotor states as a basis, also support the assumption made, as they show that R approaches quickly the value 2 (Sect. 3) with increasing potential barrier height.[3]

1.2 Bonding interpretation

The energy values E_A^{ps}, E_T^{ps}, and E_E^{ps} are obtained by inserting the linear combination, eq. [1], of the pocket states into the definition, eq. [2], of the eigenenergies E_A, E_T, and E_E, but can also be understood in more detailed terms by what we call a "bonding interpretation" of the (real valued) wave functions: In each of the linear combinations (eq. [1]) the pockets are either occupied with positive or negative amplitude ($s_i = \pm 1$) or they are empty ($s_i = 0$); the s_i are simply the coefficients in the linear combinations. The bond between two different pockets i and j is said to be "symmetric" if $s_i s_j = +1$, or to be "antisymmetric" if $s_i s_j = -1$, or to be open if $s_i s_j = 0$. Antisymmetric bonds correspond to nodes of the wave function in the potential barrier region leading to a stronger localization of the rotor and consequently to an increase of the energy of the state relative, instead, to a state with an open bond. Symmetric bonds correspond to a doubling of the amplitude of the wave function under the barrier, thus leading to a relative decrease of the energy. Both the increase and the decrease of the energy have the same absolute value. This simple counting scheme leads to the following structure of the energy formulas (eq. [2]):

[4] $$E^{ps} = \frac{\Sigma_{i,j} s_i s_j \langle i|H|j\rangle}{\Sigma_{i,j} s_i s_j \langle i|j\rangle} \qquad \text{with} \quad i,j = 1, \ldots, 12$$

We assume pocket no. 4 (Fig. 4) to be occupied ($s_4 = +1$). For each of the eigenstates, all occupied ($s_i \neq 0$) pockets can be treated equivalently (Sect. 1.1). Therefore, the corresponding pocket states $\langle i|$ in eq. [4] may be replaced by $\langle 4|$, s_i by $s_4 = +1$, and the summation over i yields the same factor both in the numerator and in the denominator and drops out. We obtain:

[1]Note the invariance of d (and $\tilde{d}$) with respect to energy shifts $H \rightarrow H + \Delta$: $e \rightarrow e + \Delta$, $h \rightarrow h + b\cdot\Delta$, $b \rightarrow b$ and therefore $d \rightarrow d$.

[2]The ground state needs to be A-symmetric, therefore $d \leq 0$.

[3]Th. Brückel, private communication.

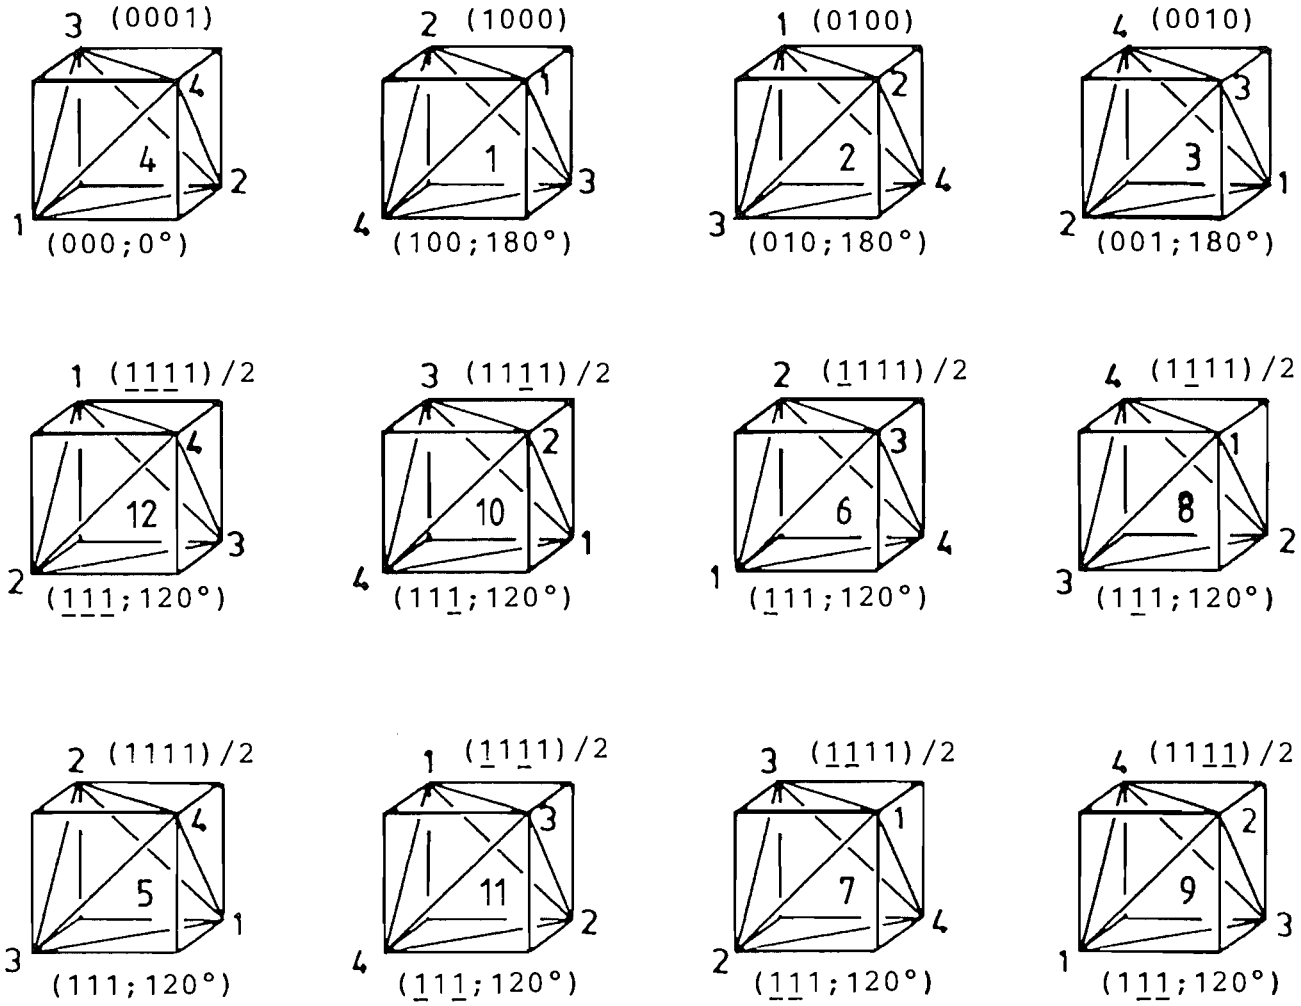

FIG. 3. There are always 12 energetically equivalent orientations of a tetrahedral rotor. The orientations of minimal potential energy in a H_{11}^3-type potential are given both in quaternions $q = (q_1,q_2,q_3,q_4)$ and in the form (rot. axis; rot. angle), referring to the standard orientation (0, 0, 0, 1), respectively (000;0°). The enumeration of the orientations follows Fig. 4.

$$[5] \qquad E^{ps} = \frac{\Sigma_j s_j \langle 4|H|j\rangle}{\Sigma_j s_j \langle 4|j\rangle} \qquad \text{with} \qquad j = 1, \ldots, 12$$

Inserting for the s_j the coefficients of the linear combinations, eq. [1], and specializing for the case of tetrahedral crystal symmetry (Sect. 1.1), we obtain the energy formulas (eq. [2]).

The bonding interpretation will be useful for the construction of so-called *artificial states* (Sect. 1.4).

1.3 Earlier methods and their drawbacks

Various attempts have been made to calculate the tiny tunnelling splittings ω/B. All of them are variational calculations. Two main methods exist, reflecting the two limiting cases of vanishing and infinitely high potential barriers. In the first case, free rotor functions (6), and in the second, pocket functions are used as a basis (4). The obvious choice of a pocket function is to take eigenfunctions of the harmonic oscillator (7). Power law functions have also been tried for some technical advantages (8).

All theoretical methods are confronted with the basic problem that two complementary aspects are involved in the lower part of the experimentally interesting and accessible range from $\omega \approx 100$ μeV (n-scattering (9)) down to $\omega \approx 30$ neV (nmr (10)), namely accuracy vs. fast convergence. Even for the highly symmetric tetrahedral crystal field, at a potential barrier height of about $100B$ (at the saddle; Fig. 5), the Free Rotor Method (FRM) needs functions up to an angular momentum l of at least $l_{max} = 16$ to yield satisfying convergence of the calculated energies $E(l_{max})$ on the scale of the tunnelling splitting (6). The FRM would need considerably more functions for the case of a nonsymmetric crystal field and (or) a stronger potential.

The Pocket State Method (PSM) suffers from the fact that all variational parameters are used to approximate the eigenfunction in the region of the potential minimum, whereas one also needs a good approximation in the saddle point region (Fig. 5) of the potential. The PSM is unreliable. This can be seen by inspecting the local fulfillment $A(q;\phi,E)$ of the stationary Schrödinger equation (SSE), which is defined by

$$[6] \qquad A(q;\phi,E) = \frac{(H\phi)(q) - E\cdot\phi(q)}{B\cdot\phi(q)}$$

For an eigenfunction ψ of the Hamiltonian H with eigenvalue E_ψ, the SSE $(H\psi)(q) = E_\psi\psi(q)$ is satisfied for any orientation q of the rotor, that is, $A(q;\psi,E_\psi) = 0$ for all q. Figure 6 shows $A(q;\phi,E_\phi)$ for rotations leading directly from an orientation

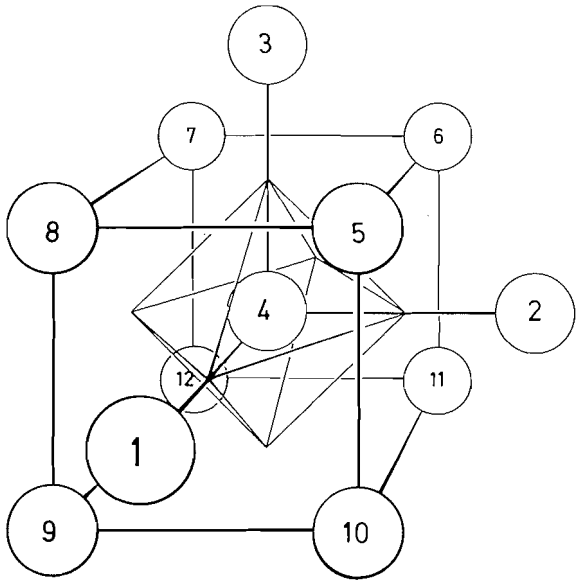

FIG. 4. The enumeration of the 12 pockets and pocket functions is shown in the configuration space (CS). Any point in CS corresponds to an orientation of the (rigid) rotor in real space (RS). The origin of the coordinate system in CS lies in the center of pocket no. 4 and corresponds to the standard orientation of the rotor (Fig. 3). The CS coordinate axes (100), (010), and (001) are chosen through the centers of the pockets no. 1, no. 2, and no. 3. The (space-fixed) axis of rotation (xyz) in RS (Fig. 2) corresponds to the direction xyz in CS, while the rotation angle in RS is represented by a certain distance along the xyz direction in CS. Note that the drawing shows the correct topology of CS, but the same rotation angle in RS leads to different distances in the drawing, depending on the axis of rotation. The boundary of the central pocket is shown as an octahedron.

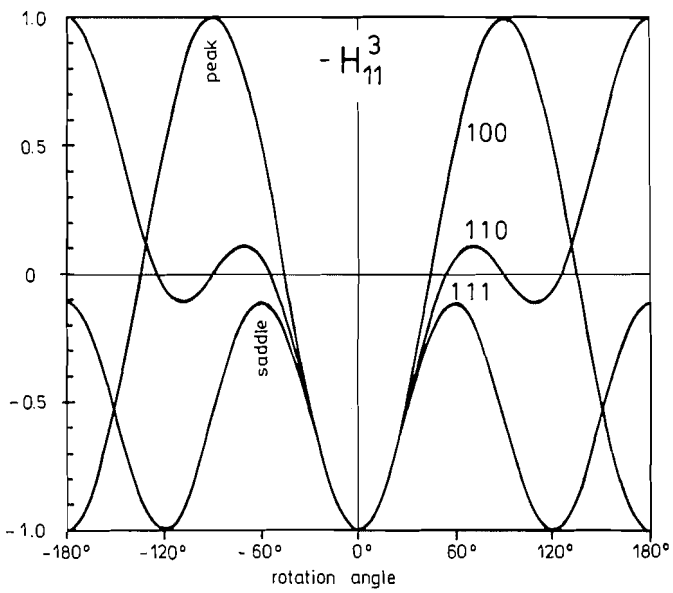

FIG. 5. The first nontrivial cubic rotator function of tetrahedral symmetry is $H_{11}^3(q)$ (eq. [11]). The shape of $-H_{11}^3$ is plotted for three axes of rotation, (100), (110), and (111), starting from the center (at 0°) of pocket no. 4 (Fig. 4); e.g., the rotation around the (111) axis leads through the centers of the pockets no. 5 (at 120°) and no. 12 (at −120°). From a (space-fixed) axis of rotation (xyz) (with $x^2 + y^2 + z^2 = 1$) and the rotation angle Θ, we get $\rho = \sin(\Theta/2)$ and the quaternion $q = (\rho x, \rho y, \rho z, \sqrt{1-\rho^2})$.

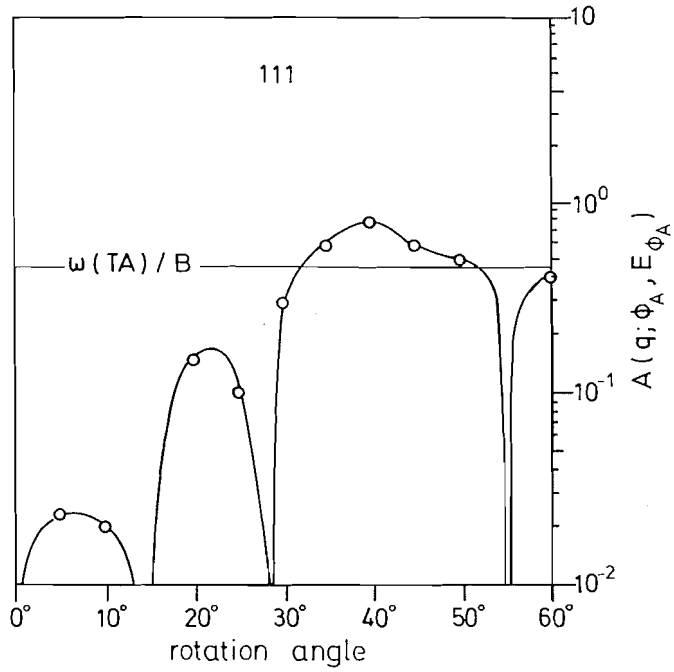

FIG. 6. The local fulfillment $A(q;\phi_A,E_{\phi_A})$ (eq. [6]) of the stationary Schrödinger equation is shown for rotations around the (111) axis; ϕ_A is an optimized variational wave function, using a combination of pocket and free rotor functions ($l_{max} = 6$) (Sect. 1.3); $E_A = \langle\phi_A|H|\phi_A\rangle/\langle\phi_A|\phi_A\rangle$ where H is the Hamiltonian. The potential is of the simple H_{11}^3 type. The potential strength in this example is quite low ($A_{11}^3 = -30B$), but nevertheless the calculated tunnelling splitting $\omega(TA)/B$ is not reliable: the fluctuations $(|\phi_A|^2 \cdot A)(q)$ around E_{ϕ_A}/B reach 20% of $\omega(TA)/B$ at rotation angles of only 20°. Consequently, we cannot consider ϕ_A to be a good approximation to the A eigenfunction in the saddle point region of the potential (around (111;60°)), which is decisive for the value of the tunnelling splitting.

of minimal potential energy across the potential saddle to a neighbouring minimum; $E_\phi = \langle\phi|H|\phi\rangle/\langle\phi|\phi\rangle$ is the energy associated with the optimized variational wave function ϕ, resulting from a sophisticated ansatz that combines pocket states and free rotor states.[4] The pocket states are used to approximate the sharp peaks of the eigenfunction around the potential minimum, with the effect that the difference to the eigenfunction ought to be a slowly varying function. The difference was thought to be accurately representable by only a few free rotor functions ($l_{max} = 6$). The result is disappointing, as can be seen from the figure: for rotation angles Θ of only 20°, $A(q;\phi,E_\phi)$ already reaches the order of magnitude of the tunnelling splitting ω/B. Now the amplitude of the (real valued) wave function at $\Theta = 20°$ amounts to 60% of its maximal value; consequently the local fluctuations $|\phi^2 \cdot A|$ around the mean value E_ϕ are large on the scale of the tunnelling energy. The calculated ω value is not reliable even for the small potential barrier height of only $30B$!

The drawbacks of the variational methods pose the problem of designing a fast converging, but nevertheless accurate, method to be able to make reliable theoretical predictions for the very interesting situations of low crystal field symmetry (e.g., CH_4 adsorbed on graphite surfaces) and for the experimentally measured tunnelling splittings close to the neV range.

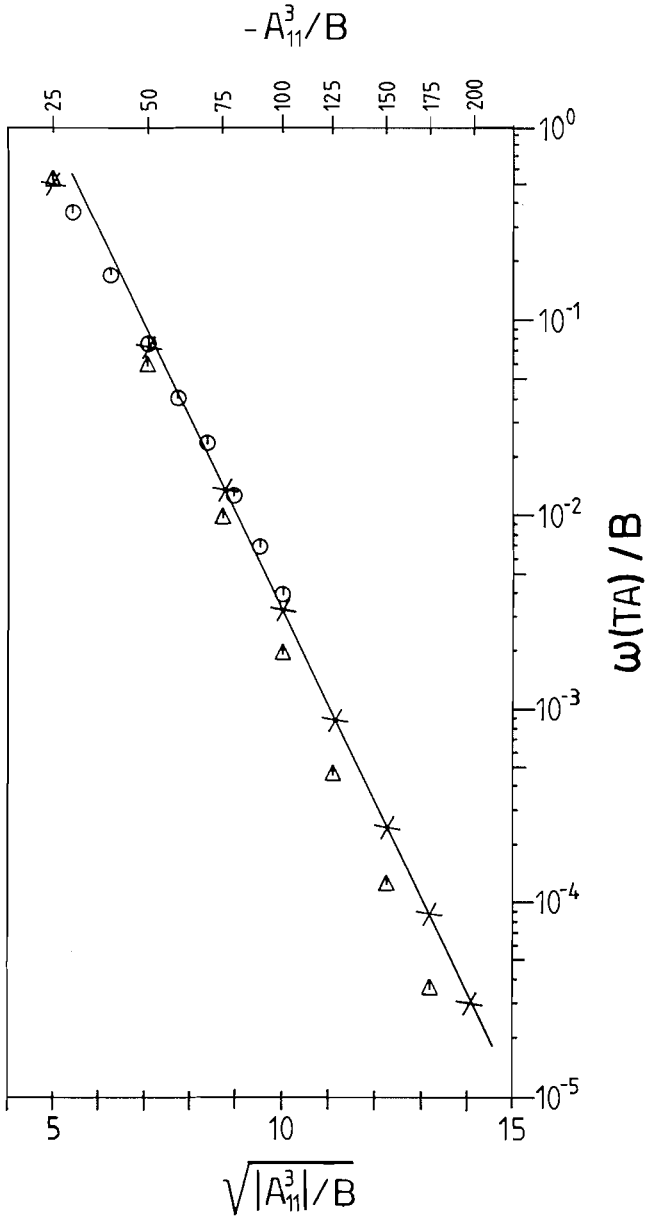

FIG. 7. Asymptotically, the tunnelling splitting ω decreases exponentially with increasing square root of the potential strength. This behaviour can be expected by considering simple one-dimensional examples. By our calculations the expected behaviour is confirmed to hold for the three-dimensional case, too, if the potential strength is larger than about $50B$. The plot compares the results of several methods. The PRM results for $\omega(TA)$ ($l_{max} = 10$) are shown by the crosses; the straight line is fitted only to results for the interval $50B < -A_{11}^3 \leq 150B$. The splittings for $-A_{11}^3 > 150B$ should lie exactly on the straight line, but are distributed a little bit around it. This is not surprising, as the PRM with $l_{max} \leq 10$ is not able to deal with potential strengths of more than about $150B$ (Fig. 11). The triangles show the results of Hüller and Kroll (13); the circles show the values which Smalley (see footnote 4, Sect. 1.3) obtained. Surprisingly (Fig. 8), the available results of Hüller and Raich (7) coincide with the PRM values.

1.4 Asymptotic behavior and extrapolation

With growing potential strength all methods run into similar difficulty in achieving the desired relative accuracy for an increasingly small tunnelling splitting. In the FRM (3, 6, 11, 12) a rising number of basis states (up to $l_{max} = 32$) has to be used to comply with the demands. The Pocket Recursion Method (PRM; Sect. 2) gives reliable results up to $V_0 \approx 150B$ using only very few terms in the ansatz of the recursion wave function (Sect. 3). By V_0 we denote the difference between the values of rotational potential at the saddle point and the center of the pocket (Fig. 5). See Fig. 7 for a one-parameter model and Fig. 13 for several three-parameter potentials, for which $V_0 = -8A_{11}^3/9 - 40A_{11}^4/27 - 140A_{11}^6/243$. For $V_0 = 150B$ the tunnelling splitting is several times $10^{-4}B$, yet we want to go further down to at least $10^{-5}B$. Luckily, there exists an additional aspect: explicit calculations for simple one-dimensional problems reveal the asymptotic behavior of the tunnelling splitting ω with increasing potential strength V_0.

$$[7] \quad \ln(\omega/B) \sim \alpha\sqrt{V_0/B} + \beta \qquad \alpha < 0$$

Our pocket recursion calculations verify eq. [7] for the three-dimensional case, where the linear dependence begins at potential strengths of about $50B$ (Fig. 7). Therefore we have the broad range of potential strengths from $50B$ to $150B$ to calculate accurately the parameters α and β for a given potential function, a fact that allows the extrapolation of the tunnelling energy for very high potential barriers (Figs. 7 and 13).

2. Pocket Recursion Method (PRM)

2.1 Program

The partition of the potential into fully equivalent pocket regions implies calculating the spectrum of the Hamiltonian in a single pocket. This can be done by finding just that part of each eigenfunction which is in the pocket chosen. To reach that goal we need exact constraints, termed "continuation conditions", characterizing the eigenfunctions of the Hamiltonian. The constraints ought to be as close as possible to the pocket center. There are two types of constraints, corresponding to symmetric and antisymmetric bonds (Sect. 1.2): for short we term them "sb condition" and "asb or node condition". Their locations are found from symmetry considerations (Sect. 2.3) of the eigenfunctions of the Hamiltonian.

Now we imagine a wave function (eq. [1]) to be expanded around a pocket center:

$$[8] \quad \psi(q_1,q_2,q_3,\rho) = \sum_{l=0}^{\infty} \sum_{m=-l}^{l} f_{lm}(\rho) K_{lm}(q_1,q_2,q_3)$$

The excursion from the center is denoted by $\rho = \sin(\Theta/2)$, where Θ is the rotation angle; (q_1,q_2,q_3) with $q_1^2 + q_2^2 + q_3^2 = \rho^2$ denotes the space-fixed axis of rotation. These coordinates are intimately related to the quarternions: any quaternion on the sphere $S^3 = \{q \in \mathcal{R}^4 | \Sigma_{i=1}^4 q_i^2 = 1\}$ corresponds to an orientation of the rotor relative to a standard orientation $q^s = (0,0,0,1)$ (Fig. 2); note $q_4 = \cos(\Theta/2)$; henceforth we abbreviate the quadrupel (q_1,q_2,q_3,ρ) by $r(q)$. The K_{lm} are the cubic harmonics (see Appendix 1) and the $f_{lm}(\rho)$ are polynomials in ρ:

$$[9] \quad f_{lm}(\rho) = \sum_{n=0}^{\infty} g_n^{(lm)} \rho^n$$

We now calculate the function $(H\psi)(r(q))$, where H is the Hamiltonian, and insert it into the stationary Schrödinger equation (SSE) $(H\psi) - E\psi = 0$, which then appears as a vanishing linear combination

$$[10] \quad \sum_{l=0}^{\infty} \sum_{m=-l}^{l} \sum_{n=0}^{\infty} \Lambda_n^{(lm)} \rho^n K_{lm}(q_1,q_2,q_3) = 0$$

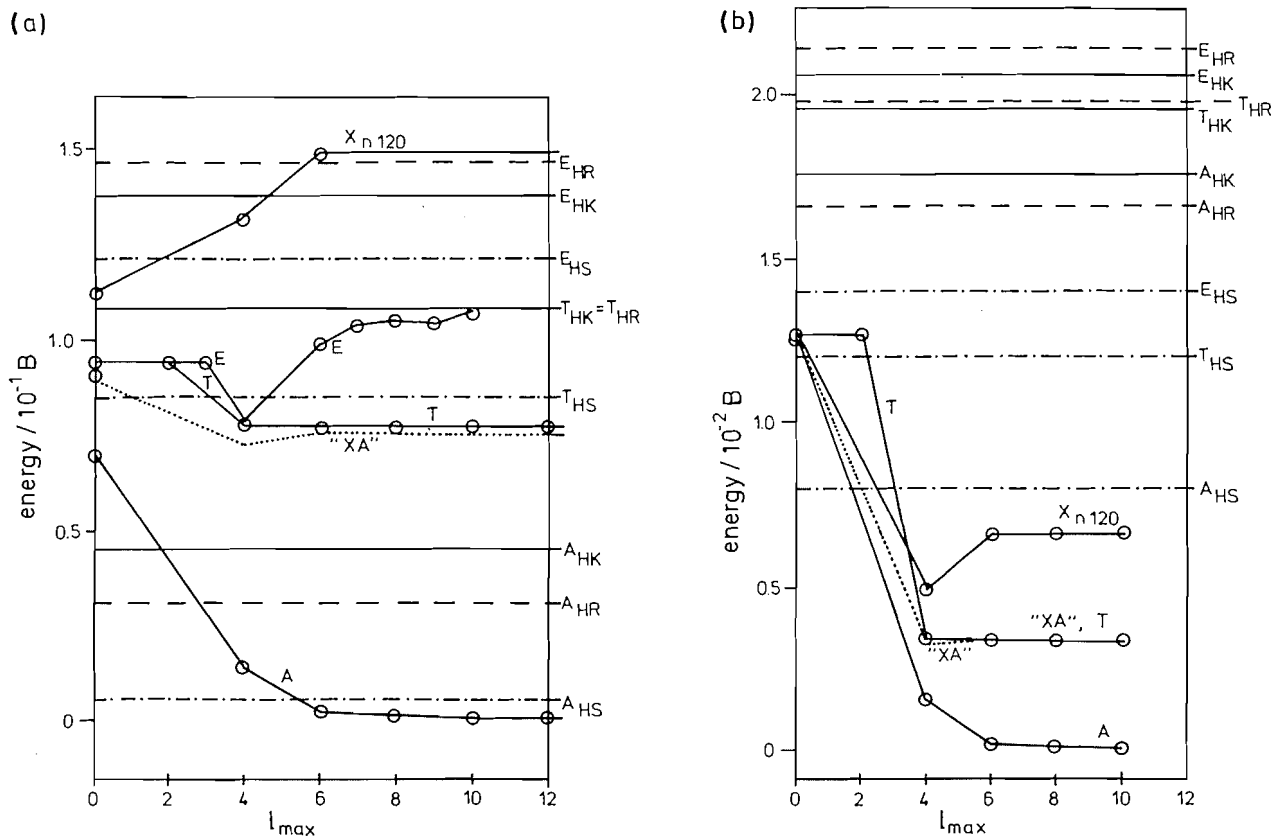

FIG. 8. The convergence of the PRM energies with increasing number of terms in the PRM ansatz for both $A^3_{11} = -50B$ and $-100B$. Also marked are results of earlier pocket state calculations (indices: K, Kroll; R, Raich; S, Smalley; H, Hüller). For $A^3_{11} = -100B$ the earlier results differ by more than the value of the splitting from the correct results. (a) $A^3_{11} = -50B$: The energy of the E recursion function does not converge on the scale of the tunnelling splitting (Sect. 3), but can be substituted by $E_A + (3/4)(E_{X_{n120}} - E_A)$, eq. [18], for the case of very strong potentials. To test the validity of that substitution, we check whether eq. [19] is satisfied (dotted "XA" line) by the X_{n120} energy value. The visible (relative to $\omega(TA)$) difference between the XA and T results indicates that $A^3_{11} = -50B$ cannot be considered to be a very strong potential. (b) $A^3_{11} = -100B$: XA and T values become indistinguishable on the scale of the tunnelling splitting. The fast convergence is remarkable.

with coefficients $\Lambda_n^{(lm)}$ that are functions of the yet unspecified energy E and the starting coefficients $g_0^{(lm)}$ of the polynomials $f_{lm}(\rho)$, eq. [9]. Only the $f_{lm}(\rho)$ for symmetry-allowed K_{lm} are nonvanishing. To let the linear combination, eq. [10], vanish for any rotation axis and angle, it is necessary to set the coefficients $\Lambda_n^{(lm)}$ to nil. Recursion relations for the $g_n^{(lm)}$ follow (Sect. 2.2). The choice $g_0^{(00)} = 1$ uses the freedom of normalization.

The "set of recursion parameters" $(E, \{g_0^{(lm)}\}_{l=1,\ldots,\infty}^{m=-l,\ldots,l})$, for which the recursion wave function satisfies the continuation condition of an eigenstate, contains the corresponding eigenvalue E. If we use only a finite number l_{max} of terms in the ansatz [8], the continuation condition cannot be fulfilled exactly; consequently E is not an exact eigenvalue. But we find the function $E(l_{max})$ (Fig. 8) to be rapidly convergent, except for the E-symmetric case (Sect. 3). The parameter n_{max}, at which the summation in [9] is broken off, is easy to handle and is chosen large enough not to influence the results; typically $n_{max} \geq 60$ and ≥ 150 for potential strengths of $50B$ and $100B$, respectively (Sect. 4).

2.2 An example of a recursion relation

To illustrate the details of our program outlined above, we now derive the recursion relation for an isotropic ansatz function ($l_{max} = 0$ in eq. [8]) used in the specific example of a tetrahedral molecule in the simplest tetrahedral potential, an H^3_{11}-potential function (Fig. 5):

$$[11]\quad H^3_{11}(q) = 16\sum_{i=1}^{4} q_i^6 - 20\sum_{i=1}^{4} q_i^4 + 5 \quad \text{with} \quad q \in S^3$$

The potential then reads $V(q) = A^3_{11} \cdot H^3_{11}(q)$. With $A^3_{11} \leq 0$, one of the 12 potential minima lies at $q^s = (0,0,0,1)$, which corresponds to the standard orientation of the rotor (Fig. 2). The potential can be expressed in the form of expansion [8]:

$$[12]\quad H^3_{11}(q_1,q_2,q_3,\rho) = V_{00}(\rho)K_{00}(q_1,q_2,q_3) + V_{41}(\rho)K_{41}(q_1,q_2,q_3) + V_{61}(\rho)K_{61}(q_1,q_2,q_3)$$

with $V_{00}(\rho) = 1 - 8\rho^2 + 16\rho^4 - \frac{64}{7}\rho^6$; $V_{41}(\rho) = -20(1 - \frac{12}{11}\rho^2)/N_{41}$; $V_{61}(\rho) = 48/N_{61}$; $N_{41} = 5\sqrt{21}/4$, $N_{61} = 231\sqrt{26}/8$; note $K_{00} \equiv 1$. The potential is invariant with respect to the change $\rho \rightarrow -\rho$, which means that clockwise and counterclockwise rotations around any axis are energetically equivalent. Therefore all odd expansion terms vanish in the ansatz [8] of the recursion function:

$$[13]\quad \phi_0 = f_{00}(\rho)\cdot K_{00}(q_1,q_2,q_3) = f_{00}(\rho) = \sum_{n=0}^{n_{max}} g_{2n}^{(00)}\rho^{2n}$$

The operator $\hat{T}$ of the kinetic energy (see A.2) applied to the isotropic ansatz reads

$$[14]\quad \hat{T}\phi_0 = \frac{B}{4}\left(\left(\rho^2\frac{\partial^2}{\partial\rho^2} + 3\rho\frac{\partial}{\partial\rho}\right) - \left(\frac{\partial^2}{\partial\rho^2} + \frac{2}{\rho}\frac{\partial}{\partial\rho}\right)\right)f_{00}(\rho)$$

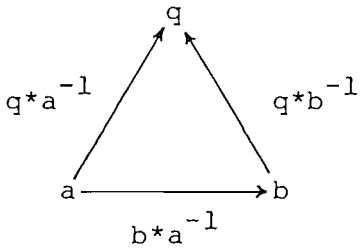

FIG. 9. The orientation q is said to lie on the middle between the orientations a and b, if the rotation angles from a to q and from b to q are equal. A necessary condition for equal rotation angles is $(q*a^{-1})_4 = (q*b^{-1})_4$, where a, b, and q are the respective quaternions, * denotes the quaternionic multiplication (14).

Inserting the isotropic ansatz ϕ_0 into the SSE therefore yields for the coefficients $\Lambda^{(00)}_{2n}$ (eq. [10]):

$$\Lambda^{(00)}_{2(n-1)} = \left\{ \left(n(n-1)g^{(00)}_{2(n-1)} - n\left(n+\frac{1}{2}\right)g^{(00)}_{2n} \right) \right.$$

$$[15] \quad + \frac{A^3_{11}}{B}\left(g^{(00)}_{2(n-1)} - 8g^{(00)}_{2(n-2)} + 16g^{(00)}_{2(n-3)} - \frac{64}{7}g^{(00)}_{2(n-4)} \right)$$

$$\left. - \frac{E}{B}g^{(00)}_{2(n-1)} \right\} \rho^{2n-2} \quad \text{with} \quad g^{(00)}_m = 0 \quad \text{for} \quad m < 0$$

Setting the coefficients $\Lambda^{(00)}_{2(n-1)}$ of $\rho^{2n-2}\cdot K_{00}$ to nil yields $g^{(00)}_{2n}$ in terms of the $g^{(00)}_{2n'}$ of lower order ($n' < n$), thus establishing a recursion relation for $g^{(00)}_{2n}$.

2.3 Continuation conditions

All orientations $q \in S^3$, which are the same rotation angle apart from two given orientations $a, b \in S^3$, satisfy the condition (Fig. 9)

$$[16] \quad \sum_{i=1}^{4} q_i(a_i - b_i) = 0$$

and are said to lie on the "middle" $M_{a,b}$ of (a,b): $M_{a,b} = \{q \in S^3 | \sum_{i=1}^4 q_i(a_i - b_i) = 0\}$. Let a and b be the centers of different pockets, and φ_a and φ_b the respective pocket functions. As we have already pointed out (Sect. 1.1), φ_a and φ_b are identically shaped, but centered at different orientations. Therefore $\varphi_a + \varphi_b$ satisfies the sb condition (Sect. 2.1), whereas $\varphi_a - \varphi_b$ has nodes in all points of $M_{a,b}$. In this way we consider all pairs of contributing pocket functions for a given eigenfunction, sorting out (e.g., below) the type (node or sb condition) and locality of the exact continuation conditions. They are listed in Table 2 for a tetrahedral molecule in a tetrahedral crystal field and are easy to adapt for other symmetries of the surrounding.

As an example for the procedure described above, we derive the continuation conditions for the E-symmetric state $|E^-\rangle$, eq. [1]: The pocket function centered in pocket i is denoted $\varphi_i(r(q)) = \langle r(q)|i\rangle$ with $r(q)$ ($q \in S^3$) describing the orientation of the rotor (Sect. 2.1). From the list of linear combinations [1] and the numbering convention given by Fig. 4, we easily get a very useful illustration (Fig. 10a) of the E-state.

Applying any symmetry operation of the tetrahedral group to the E-state shown (Fig. 10a) would only rotate the E-state, but would not fundamentally change the picture, because all pocket functions φ_i have the same shape (Sect. 1.1). Therefore, all we need to discuss is which are the continuation conditions between the central pocket function φ_4 and all its neighbours φ_i ($i \neq 4$), and whether or not the continuation condition for any pair (φ_4, φ_i) ($i \neq 4$) is disturbed by any other φ_j ($j \neq i$).

In our case of a tetrahedral rotor in a tetrahedral crystal field, the discussion is once again simplified, because many axes of rotation are equivalent (Sect. 1.1). For the three pairs $(\varphi_4, \varphi_i)_{i=1,2,3}$ we obviously have the sb condition on the respective middles $M_{4,i}$ (the faces of the cube in Fig. 10a), and the presence of the other pocket functions φ_j ($j \neq 1, 2, 3, 4$) does not conflict with that finding, because each of them is symmetric with respect to each $M_{4,i}$ ($i = 1, 2, 3$). For the four pairs $(\varphi_4, \varphi_k)_{k=6,8,10,12}$ we find the asb condition to hold on the respective middles $M_{4,k}$. Note that, e.g., the functions $\varphi_1 - \varphi_8$, $\varphi_2 - \varphi_6$, and $\varphi_3 - \varphi_{12}$ are antisymmetric with respect to $M_{4,10}$ and therefore they do not spoil the asb condition on $M_{4,10}$; the same holds for any $M_{4,k}$ ($k = 6, 8, 10, 12$). Figure 10b summarizes our discussion; it shows the locations of the continuation conditions for the E-state (eq. [1]).

2.4 Artificial states

The PRM offers a unique opportunity: we can perform our program for any continuation condition we want; and there is a meaningful choice on the basis of the bonding interpretation (Sect. 1.2). As an example we choose the amplitude in one pocket to be positive nonvanishing ($s_4 = +1$), as usual (Sect. 1.2), and assume antisymmetric bonds to each 120° adjacent pocket (Fig. 4); the bonding interpretation then predicts the energy

$$[17] \quad E_{X_{n120}} \approx e + 8|d| \qquad \text{for} \qquad |d| \gg |\tilde{d}|$$

for the artificial wavefunction X_{n120} in the case of high potential barriers, that is, if the 180° overlaps are negligible compared to the 120° terms (eq. [3]). The artificial function X_{n120} cannot be extended to the full sphere S^3 without violating either the SSE or the natural boundary conditions of 2π periodicity for the threefold rotation axes. Therefore X_{n120} cannot appear in the FRM and PSM calculations (Sect. 1.3). But it can be used successfully in the PRM, because the PRM does not work on the whole sphere S^3. The interesting aspect is that the energy $E_{X_{n120}}$ has a fixed relation to the eigenvalues sought:

$$[18] \quad \omega(XA) = E_{X_{n120}} - E_A \approx \frac{4}{3}(E_E - E_A)$$

$$\text{for} \qquad |d| \gg |\tilde{d}|$$

The PRM calculations of the energy $E_{X_{n120}}$ of the artificial function show (Fig. 8) that $E_{X_{n120}}$ converges very quickly with increasing order $l_{\max}$ in the ansatz [8]. The ansatz itself is the same as for an A-symmetric function, because we merely substitute the symmetric 120° bonds of the A-state (Table 2) by antisymmetric bonds and because of the irrelevance of the 180° bonds with respect to the tunnelling energy in our case of strong potentials. The importance of the artificial function X_{n120} for the PRM is illustrated by the discussion in Sect. 3.

3. Test of the Pocket Recursion Method

In this section we discuss the features and the quality of the PRM results in detail, using again the simple H^3_{11}-potential function (Fig. 5). The PRM results for the energy $E_S(l_{\max})$ (with $S = A, T, E$) are presented in Fig. 8 for a medium potential strength of $A^3_{11} = -50B$. Obviously, $E_E(l_{\max})$ does not converge on the scale of the tunnelling splitting. The reason is simple: the ansatz of the recursion function does not contain enough terms ($l_{\max} \leq 8$; Sect. 2.1) to satisfy the E-symmetric continuation conditions. To understand that, consider a 120°

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/07/12
For personal use only.

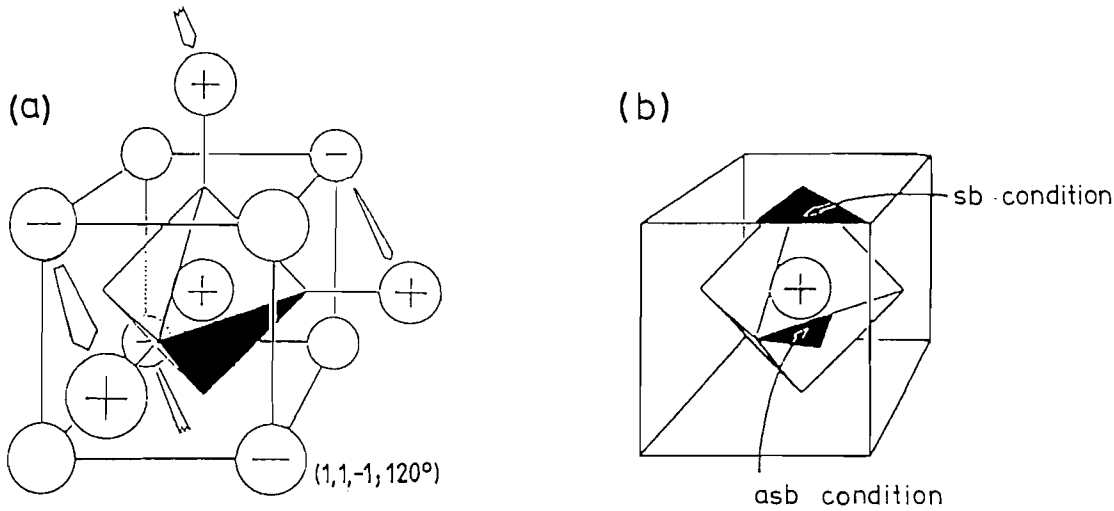

FIG. 10. (a) The E-state used in the PRM calculations (Fig. 8) is shown. The middle between the central and the $(1,1,-1;120°)$ pocket is also the middle between the pairs of pockets connected in the drawing. (b) The irreducible regions where sb and asb conditions have to be imposed on the recursion wave function for the case of a crystal field of tetrahedral symmetry. For a less symmetric crystal field, the irreducible regions would be larger.

TABLE 2. The continuation conditions given here for the $X_{n_{120}}$ recursion function and those of A, T, and E symmetry have to be rotated, using the operations of the tetrahedral symmetry group T, to obtain the full restrictions. Notation: In $M_{c,i}$ (Sect. 2.3) i stands for the quaternion coordinate of the center of pocket no. i (e.g., $i = 2 \Leftrightarrow (0,1,0,0)$; Fig. 3) and $c = (0,0,0,1)$ is taken to emphasize the central pocket (no. 4). Because of the 2:1 homomorphism (15) between SU_2 and SO_3, the two quaternions of opposite sign correspond to exactly the same physical orientation of a rigid body, but in calculations one has to be careful; therefore "$-c$" appears

Symmetry	Continuation condition
A	sbc on $M_{c,5} \cup M_{-c,5}$
$X_{n_{120}}$	asbc on $M_{c,5} \cup M_{-c,5}$
T	asbc on $(M_{c,1} \cup M_{-c,1}) \cap M_{3,2}$
	sbc on $M_{c,3} \cup M_{-c,3}$
E	asbc on $M_{c,10} \cup M_{-c,10}$
	sbc on $M_{c,3} \cup M_{-c,3}$

neighbouring (relative to pocket no. 4; Fig. 4) pocket P_{120}, in which the E-symmetric eigenstate ψ_E [1] has one of its maxima (e.g., no. 6; Fig. 4). We recall (Sect. 2.3) that the center of P_{120} lies on the middle $M_{4,i}$ of each pair $(\varphi_4,\varphi_i)_{i=1,2,3}$ of 180° adjacent pocket functions. To fulfill the sb condition in P_{120} for a recursion parameter that is equal or close to the eigenvalue of the E-state ψ_E, it is necessary for the recursion function to have maximal amplitude in P_{120}. With $l_{max} = 8$ we reach only 60% of the required amplitude. In the case of E symmetry, larger values of l_{max} would contradict the requirement for a fast converging method, because too many (more than 9) cubic harmonic functions K_{lm} would be symmetry allowed and would therefore be needed in the ansatz [8] of the recursion function. Consequently the number of adjustable parameters would become larger than we consider to be reasonable. From eq. [18] and Fig. 8 it is clear that we can overcome the difficulty by calculating $E_{X_{n120}}$.

Except for $E_E(l_{max})$, all PRM results converge quickly (Fig. 8), but this is not a sufficient condition for identifying the PRM energies with the eigenvalues sought. How reliable are the PRM energies? To answer this question, let us compare the PRM results with the FRM results[3,5] for $l_{max} = 21$ (Table 3), which are surely very good approximations (upper bounds) for the exact eigenenergies at medium potential strengths of about $50B$. The FRM results ($l_{max} = 21$) for a potential strength of $1400\,Kk_B$ (with $B = 8.381\,Kk_B$ we get $|A^3_{11}| \approx 50B$) were made available to us.[3] After all, the PRM results for E_A and E_T for $10 \leq l_{max} \leq 12$, $l_{max} = 8$, respectively agree very well with the FRM output for $l_{max} = 21$ (Table 3). The $E_{XA}(l_{max})$ values in Table 3 are obtained from

$$[19] \quad E_{XA} = \frac{E_{X_{n120}} + E_A}{2} \approx E_T \qquad \text{for} \qquad |d| \gg |\tilde{d}|$$

and ought to be (eqs. [3], [17]) equal to E_T, if the 180° overlap $\tilde{d}$ is negligible relative to the 120° overlap d. For $A^3_{11} \approx -50B$, the FRM shows that the ratio R (Sect. 1.1) is about 1.97, which means that $\tilde{d}$ cannot be neglected with respect to d; therefore we expect and see E_{XA} to deviate visibly from E_T in Fig. 8a. For stronger potentials, like $A^3_{11} = -100B$ (Fig. 8b), $E_{XA}(l_{max} = 10)$ and $E_T(l_{max} = 8)$ are equal within less than 1% of the tunnelling splitting. The fast convergence is remarkable (Fig. 11): for $E_T(l_{max} = 6)$, the $\omega(XA)$ value, eq. [18], deviates only 3% from its value for $l_{max} = 10$. This allows a reasonable approximation of the tunnelling energy with only three functions K_{lm}, namely K_{00}, K_{41}, and K_{61}, in the ansatz [8] of the recursion function, which means that only three recursion parameters (Sect. 2.1) are needed.

The local fulfillment $A(q;\phi,E_\phi)$ of the SSE by the optimal recursion functions also looks very promising. As can be seen by comparing Figs. 6 and 12, even the isotropic ansatz is as good as the sophisticated ansatz of Hüller and Smalley (Sect. 1.3); $A(q;\phi,E_\phi)$ hardly depends on the potential strength but strongly on l_{max} (Fig. 12). Table 4 gives a brief survey

[5]The different normalization of the potential functions in ref. 6 and in this work leads to the factor $\sqrt{(2l+1)/(8\pi^2)}$ in the calculation of A^l_{mn} from their potential strength.

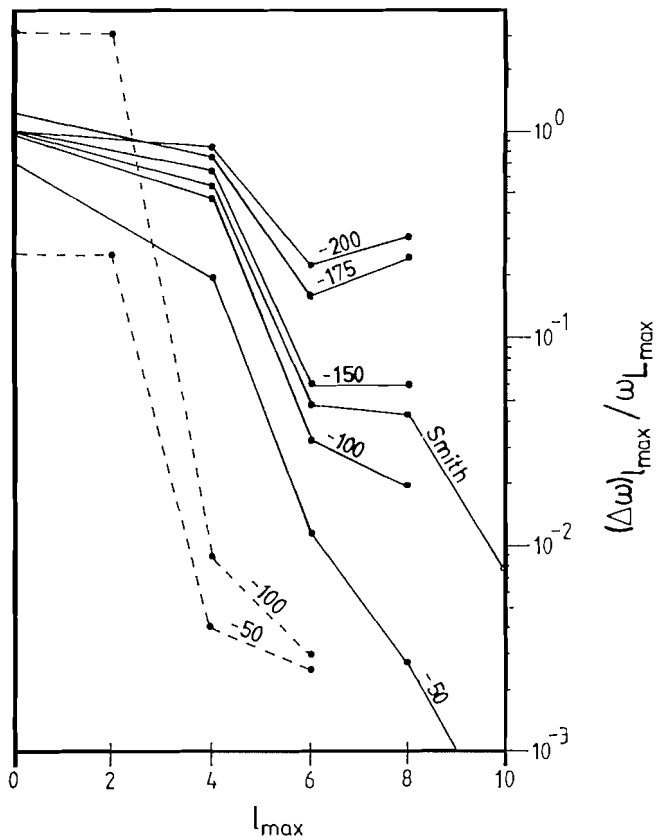

FIG. 11. The convergence of the tunnelling splitting $\omega_{l_{max}}$ towards the value $\omega_{L_{max}}$ obtained in the highest order L_{max} that we used (L_{max} = 10 and 12, respectively) in the PRM (Sect. 2.1); $(\Delta\omega)_{l_{max}} = \omega_{L_{max}} - \omega_{l_{max}}$. The respective potentials are indicated by the A^3_{11}/B values for the case of a simple H^3_{11} potential; "Smith" stands for the potential given in Table 5. The dashed lines show the convergence of $\omega_{l_{max}}$ using the PRM for T- and A-symmetric wave functions, whereas the solid lines connect the values obtained by using the artificial state X_{n120} (Sect. 2.4) instead of the T-state.

of the local fluctuations around the recursion parameter E_{ϕ_A} (Sect. 1.3), using the optimal A recursion function ϕ_A for $A^3_{11} = -50B$: The main fluctuations around $E_{\phi_A}(l_{max} = 10)$ occur in the saddle point region of the potential and they are very small on the scale of the tunnelling energy (Fig. 8a). Therefore we regard $E_{\phi_A}(l_{max} = 10)$, resulting from the PRM, to be reliable; the same holds for the energies of the optimized recursion functions ϕ_T and $\phi_{X_{n120}}$ and consequently it also holds for the tunnelling energies calculated by the PRM.

4. Application to $(NH_4)_2SnCl_6$ model potentials

We examine three different sets (Table 5) of potential parameters for ammonium hexachlorostannate ($(NH_4)_2SnCl_6$). The potentials are given as linear combinations of cubic rotor functions H^l_{mn} (see A.4):

[20] $$V(q) = A^3_{11}\cdot H^3_{11}(q) + A^4_{11}\cdot H^4_{11}(q) + A^6_{11}\cdot H^6_{11}(q)$$

Using the PRM, we calculate (Table 6; Fig. 13) the tunnelling splitting $\omega(TA)/B$ as a function of the potential strength V_0/B (Table 5) for each model potential; V_0 denotes the height of the potential saddle point relative to the potential at the center of the pocket. The numerical values of the tunnelling splitting for protonated and deuterated rotors are given in Table 6. The values are obtained as follows: In the first step, we calculate the tunnelling splittings $\omega(TA)$ for at least three potentials of the type $a\cdot V(q)$, which differ only in the value of the factor a. The calculations for $a = 1$ are shown by S, M, and V in Fig. 13. Secondly, we use the χ^2 method to find an optimal straight line through the points $(V_0, \omega(TA))$ obtained for each potential. The splittings calculated for $V_0 \leq 50B$ were not included in the χ^2 procedure; they indicate the lower limit of the potential strengths for which the asymptotic behaviour, eq. [7], is valid. The parameters α and β of eq. [7], which are obtained from the χ^2 algorithm, are given in Table 6 and allow extrapolation of the tunnelling splittings for potential barriers that are even higher than those for which the PRM (with $l_{max} \leq 10$) still yields reliable results. If we assume that deuteration of the rotor does not change the rotational potential function, then only the rotational constant B is affected: $B_d = B_p/2$. Consequently one can read, from Fig. 13, the tunnelling splitting of the deuterated rotor at an effective potential strength V_0/B_d, which has twice the value of the protonated case. The predicted values of the tunnelling splitting are shown in Fig. 13, again in units of B_d.

A recent nmr experiment (19) reveals a tunnelling splitting of $2\pi\hbar(7.5 \pm 0.5)$ MHz for the deuterated rotor in a $(ND_4)_2SnCl_6$ single crystal. The PRM results for the Smith potential agree fairly well with the experimental values of the tunnelling splitting for both protonated and deuterated rotors.

5. Comparison of the model potentials

For a comparison of the different model potentials (Table 5), we scale their strengths such that the theoretically predicted value of the tunnelling splitting for the protonated rotor equals the experimentally measured value (Table 6). For the scaled potentials, we derive from eq. [7] the predicted values of the splitting for the deuterated rotor (Table 7). The isotope shift can be characterized by the parameter β (eq. [7]), or by $\sigma(\beta)$

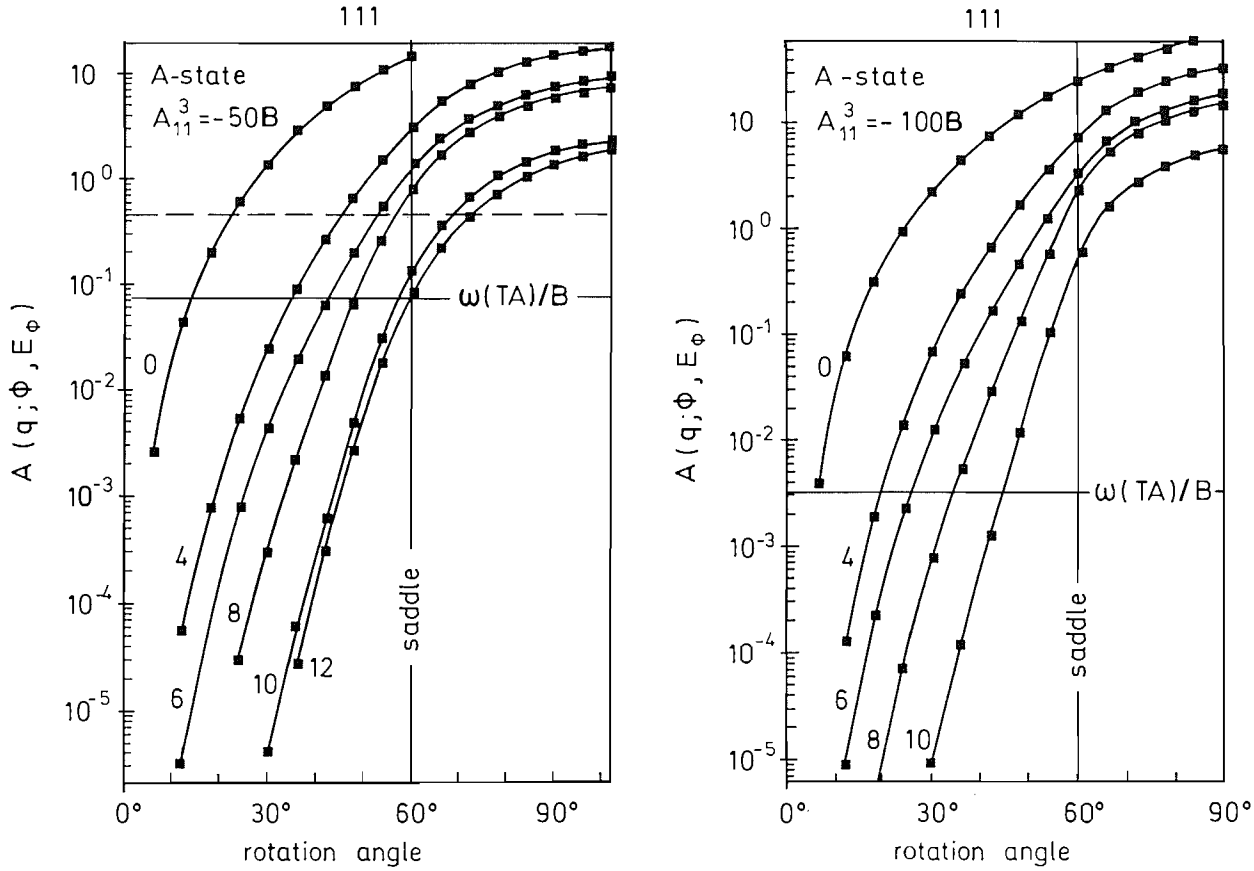

FIG. 12. The deviation $B \cdot A(q;\phi,E_\phi)$ (Sect. 1.3) of the local energy $(H\phi)(q)/\phi(q)$ (H = Hamiltonian) from the recursion parameter E_ϕ for an optimized A-symmetric wave function $\phi(q)$ is given for two potential strengths A_{11}^3 and different orders l_{max} of the PRM. The deviation depends strongly on l_{max} and weakly on the potential strength. The final results of the PRM tunnelling splitting calculations are also shown. The splitting for $A_{11}^3 = -30B$ is indicated by the dashed line. By comparison with Fig. 6 we see that even the isotropic ($l_{max} = 0$) recursion wave function yields results that are as good as the sophisticated ansatz ($l_{max} = 6$) of Hüller and Smalley (Sect. 1.3).

TABLE 4. The deviation $(\phi^2 A)(q)$ (eq. [6]) of the local energy from the recursion parameter E_ϕ for an optimized (real-valued) A-symmetric recursion function $\phi(q)$ ($l_{max} = 10$) at a potential strength of $A_{11} = -50B$. The maximal amplitude of the function ϕ is set to unity. The ϕ amplitude is maximal at the center (0°) of the central pocket. The biggest fluctuations occur around (111;60°), which is the locus of the saddle point of the potential (Fig. 5)

Rot. angle	20°	30°	40°	60°	90°
Rot. axis	All	All	All	111	100
$\phi(q)$	0.6	0.3	0.1	0.04	10^{-3}
$A(q;\phi,E_\phi)$	10^{-11}	10^{-7}	10^{-5}	4×10^{-3}	1
$(\phi^2 A)(q)$	10^{-11}	10^{-8}	10^{-7}	10^{-5}	10^{-6}

TABLE 5. $(NH_4)_2SnCl_6$ model potentials (8, 16, 17). V_0 is chosen to be the height of the potential saddle point relative to the center of the central pocket. Recently Smith (18) proposed a further potential. We have not performed a calculation for this set of parameters

		Smith	Müller	Vogt
Potential parameters	A_{11}^3/B	−132.84	−95.60	−49.70
	A_{11}^4/B	0	−27.90	−61.47
	A_{11}^6/B	42.70	46.80	55.24
Potential strength	V_0/B	92.5903	99.3481	103.4189

defined as follows:

$$[21] \quad \frac{\omega_d}{B_d} = \sigma \cdot \left(\frac{\omega_p}{B_p}\right)^{\sqrt{2}} \quad \text{with} \quad \sigma = e^{\beta(1-\sqrt{2})}$$

Only the scaled Smith potential yields an isotope shift that agrees with the experimentally observed one. But the results for the other model potentials are not far off, despite the fact that their parameters (Table 5) are quite different.

If we express the potential in the form

$$[22] \quad V(q) = A_{11}^3 \cdot (H_{11}^3(q) + C_{11}^4 \cdot H_{11}^4(q) + C_{11}^6 \cdot H_{11}^6(q)) \quad \text{with} \quad C_{11}^4 = A_{11}^4/A_{11}^3,\ C_{11}^6 = A_{11}^6/A_{11}^3$$

there are clearly lines of constant isotope shift in the (C_{11}^4, C_{11}^6)-parameter space. The model potentials of Smith, Müller, and Vogt type (Table 5) are lying almost on a straight line in the (C_{11}^4, C_{11}^6) plane. If we assume a linear dependence of the parameter σ of the isotope shift on C_{11}^4 and C_{11}^6

$$[23] \quad \sigma(C_{11}^4, C_{11}^6) = s_0 + s_1 \cdot C_{11}^4 + s_2 \cdot C_{11}^6$$

inside the narrow band in (C_{11}^4, C_{11}^6) space that is determined by the Smith-, Müller-, and Vogt-type potentials, we find $s_0 = 0.0246$, $s_1 = -0.3591$, and $s_2 = -0.5376$. For the experimental value of the isotope shift (Table 7) we then get the straight line $C_{11}^6 = -0.33 - 0.67 C_{11}^4$. The point (0,0) characterizes the H_{11}^3-type potentials and is far outside the band. The value derived above for s_0 gives the isotope shift for the H_{11}^3-type potentials ($\sigma = 0.025$), which is only one fourth of

TABLE 6. The PRM results for the model potentials of Table 5 compared to the experimental values (5, 19). The value of the rotational constant B of the NH_4 rotor is taken to be 8.381 Kk_B (6). For the deuterated rotor, we assume B to be equal to 8.381 $Kk_B/2$. The asymptotic behaviour (eq. [7]) for the H^3_{11}-type potentials is given as well

		PRM results				Experimental results
		Smith	Müller	Vogt	H^3_{11}	
Asymptotic behaviour	α	−0.9827	−0.9489	−0.8620	−1.133	
	β	3.9170	4.1002	4.1671	5.645	
$\omega(TA)/B$						
protonated rotor		3.93×10^{-3}	4.71×10^{-3}	10.07×10^{-3}		$(4.1\pm0.5)\times10^{-3}$
deuterated rotor		7.82×10^{-5}	9.37×10^{-5}	26.7×10^{-5}		$(8.6\pm0.6)\times10^{-5}$

TABLE 7. The results for the scaled model potentials. The scaling is such that the PRM value of the tunnelling splitting for the protonated rotor equals the experimentally measured one ($4.1\times10^{-3}B$). The predicted values (eq. [7]) (Table 6) of the tunnelling splitting for the deuterated rotor are compared to the experimental results. The values of the rotational constants are taken from Table 6. The values of the shift parameter σ (eq. [21]) are determined from the β values given in Table 6

		Theoretical results				Experimental results
		Smith	Müller	Vogt	H^3_{11}	
Scaled strength	$\tilde{V}_0$	91.7192	102.2367	125.6228		
$\omega(TA)/B$ deuterated rotor		8.33×10^{-5}	7.72×10^{-5}	7.51×10^{-5}		$(8.6\pm0.6)\times10^{-5}$
Shift parameter	σ	0.1974	0.1830	0.1780	0.096	0.2037

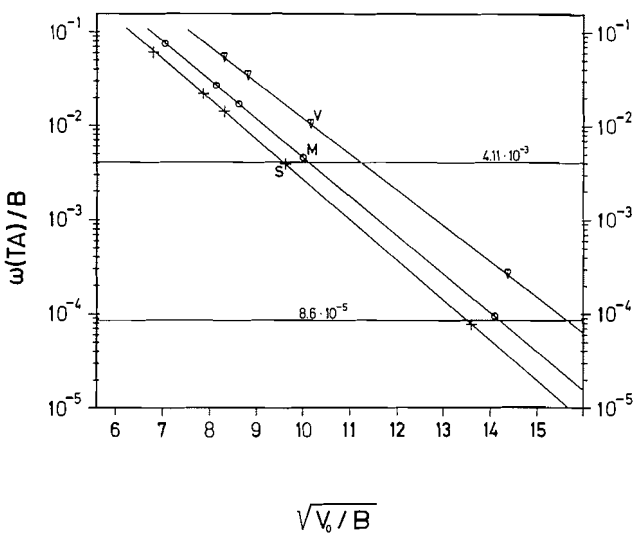

FIG. 13. The dependence of the logarithm of the tunnelling splitting $\omega(TA)$ on the square root of the potential strength V_0 turns out to be linear above $V_0 = 50B$ (Fig. 7). Therefore we can predict the splitting for a deuterated rotor in a given potential. The PRM predictions of the splittings for the three potentials of Table 5 (S, Smith; M, Müller; V, Vogt) are compared with the experimental values for the protonated ($4.1\times10^{-3}B_p$ (5)) and deuterated rotor ($8.6\times10^{-5}B_d$ (19)). The Smith potential is obviously the best choice. Notation: $V_0 = V$(potential saddle) − V(center of the pocket).

the value calculated directly (Table 7). This indicates that the function $\sigma(C^4_{11},C^6_{11})$ rises, going from any of the model potentials of Table 5 towards the H_{11}-type potentials.

The simultaneous analysis (8) of the librational frequency and the tunnelling splitting for the protonated rotor yields the straight line $C^6_{11} = -0.30 - 0.62C^4_{11}$. Unfortunately, it is almost parallel to the straight line derived above from the value of the measured isotope shift. Thus the isotope shift and the librational frequency do not lead to an independent determination of the potential parameters. However, it is satisfying to observe the consistency: the two straight lines are very close together.

Further useful information on the rotational potential might be drawn from an experimental determination of the librational frequencies in the deuterated sample. Unfortunately, due to the much smaller neutron scattering cross section of deuterium, the librational excitations are less intense and it has not been possible to separate them from the other lattice modes.[6]

Appendix

A.1 *Cubic harmonics*

The cubic harmonics (CH) $K_{lm}(q_1,q_2,q_3)$ (note: $\Sigma_{i=1}^{3} q^2 = \rho^2$; $l = 0, 1, 2, \ldots$, and $-l \leq m \leq l$, with $m \in \mathfrak{Z}$) form a complete orthogonal basis for the continuous functions defined on the sphere $S^2(\rho)$ with radius ρ. The CH are symmetry adapted to the cubic symmetry (20). To allow easy comparison of the explicit expressions used here and those listed elsewhere (20–23) we give K_{00}, K_{41}, and K_{61} explicitly:

$$K_{00}(q_1,q_2,q_3) = 1$$

$$K_{41}(q_1,q_2,q_3) = N_{41}\cdot\left(\sum_{i=1}^{3} q_i^4 - \frac{3}{5}\rho^4\right)$$

[24] $$\text{with} \quad N_{41} = \frac{5\sqrt{21}}{4}$$

$$K_{61}(q_1,q_2,q_3) = N_{61}\cdot\left(q_1^2q_2^2q_3^2 + \frac{1}{22N_{41}}K_{41}\cdot\rho^2 - \frac{1}{105}\rho^6\right)$$

$$\text{with} \quad N_{61} = \frac{231\sqrt{26}}{8}$$

With the abbreviation $\partial_i = \partial/\partial q_i$ and the use of the summation convention ($i = 1, 2, 3$), we summarize several important facts about the CH:

1. "harmonic" means: $\partial_i\partial_i K_{lm}(q_1,q_2,q_3) = 0$

2. K_{lm} is homogeneous of degree l: $K_{lm}(\lambda q_1,\lambda q_2,\lambda q_3) = \lambda^l\cdot K_{lm}(q_1,q_2,q_3)$. It follows that $q_i\partial_i K_{lm}(q_1,q_2,q_3) = l\cdot K_{lm}(q_1,q_2,q_3)$.

3. Using properties 1 and 2, and the product rule, one can easily see that K_{lm} is an eigenfunction of the angular part of the three-dimensional Laplacian (A.3) with the eigenvalue $-l(l+1)\cdot\rho^{-2}$. This property, together with symmetry considerations, provides a simple method of generating the K_{lm} as polynomials in q_1, q_2, and q_3 (degree l).

4. The K_{lm} are orthogonal in the sense:

[25] $$\frac{1}{4\pi}\oint_{S^2(\rho)} dq_1dq_2dq_3K_{lm}K_{jn} = \delta_{lj}\delta_{mn}\cdot\rho^{l+j+3}$$

5. A very useful formula (24):

[26] $$\frac{1}{4\pi}\oint_{S^2(\rho)} dq_1dq_2dq_3q_1^{2a}q_1^{2a}q_3^{2c} = \frac{(2a-1)!!(2b-1)!!(2c-1)!!}{(2a+2b+2c+1)!!}\cdot\rho^{2a+2b+2c+3}$$

where $a,b,c \in \mathcal{N}$. The integral would be zero if at least one exponent were odd.

6. The CH can be expressed as linear combinations of the spherical harmonics. These linear combinations are listed in ref. 22 up to $l_{max} = 12$ and in ref. 23 up to 21.

A.2 *The kinetic energy operator*

The mathematical description of the orientation of a rigid body obviously involves the rotation group SO_3. Instead, we can use the (unitary) group SU_2, because of the isomorphism between SO_3 and the quotient group $SU_2/\{\iota,-\iota\}$.[7] The SU_2 group manifold is the sphere S^3 ($\subset \mathfrak{R}^4$); antipodes of S^3 correspond to the same physical orientation of the body.

It follows that the physical rotation of a (rigid) body is equivalent to the motion of a mass point confined to S^3. This illustrates that the operator $\hat{T}$ of the kinetic energy (abandoning the translational degrees of freedom) is proportional to the angular part of the four-dimensional Laplacian (A.3). The explicit expression [25] for $\hat{T}$ is highly symmetric if it is written[8] in the Cartesian coordinates of the S^3 points ($q_iq_i = 1$):

[27] $$\hat{T} = -\frac{B}{4}(\partial_i\partial_i - 3q_i\partial_i - q_iq_j\partial_i\partial_j) \quad \text{with} \quad i,j = 1,2,3,4$$

The Cartesian coordinates of the S^3 points constitute the so-called elements of the (real) quaternion $q = (q_1,q_2,q_3,q_4)$.

Another set of coordinates $(q_1,q_2,q_3,\rho) = r(q)$ with $\rho = \sqrt{1-q_4^2}$ ($\Sigma_{i=1}^{3} q_i^2 = \rho^2$ follows) is more appropriate to be used in expansions around the standard orientation $q^s = (0,0,0,1)$, $r(q^s) = (0,0,0,0)$, respectively. By means of the chain rule, one can easily apply $\hat{T}$ to functions of the new coordinates. We give a very useful formula:

[28] $$\hat{T}f(\rho)K_{lm}(q_1,q_2,q_3) = \frac{B}{4}K_{lm}(q_1,q_2,q_3)\hat{U}_lf(\rho)$$

[7] The identity element of SU_2 is denoted ι and is written $(0,0,0,1)$ in the quaternionic representation; $-\iota \Leftrightarrow (0,0,0,-1)$.

[8] We use the summation convention; ∂_i denotes the partial derivative with respect to q_i.

where the operator $\hat{U}_l$ is defined as follows:

$$[29]\quad \hat{U}_l = (\rho^2 - 1)\frac{\partial^2}{\partial\rho^2} + \left((2l+3)\rho - 2\frac{l+1}{\rho}\right)\frac{\partial}{\partial\rho} + l(l+2)$$

The proof of eq. [28] is based on the properties no. 2 and no. 3 (A.1) of the cubic harmonics K_{lm}.

A.3 *Angular part of the* d*-dimensional Laplacian*

Let $x_1, \ldots, x_d$ be the Cartesian coordinates in $\mathcal{R}^d$ and denote the partial differentiation with respect to x_i by ∂_i; we use the summation convention. The d-dimensional Laplacian then reads $\partial_i\partial_i$. Its radial part (15) is given by

$$[30]\quad R_{(d)} = \frac{1}{r^{d-1}}\frac{\partial}{\partial r}\left(r^{d-1}\frac{\partial}{\partial r}\right)$$

where $r^2 = x_i x_i$. Applying the chain rule, we obtain $R_{(d)}$ expressed in Cartesian coordinates:

$$[31]\quad R_{(d)} = \frac{1}{r^2}\cdot((d-1)x_i\partial_i + x_i x_j \partial_i\partial_j)$$

The difference $\partial_i\partial_i - R_{(d)}$ constitutes the angular part of the d-dimensional Laplacian.

A.4. *The cubic rotor functions* H^3_{l1}, H^4_{l1}, *and* H^6_{l1}

The $(NH_4)_2SnCl_6$ model potentials (Table 5) are given as linear combinations of the following cubic rotor functions (21):

$$H^3_{11}(q) = 2^4\sum q_i^6 - 2^2\cdot 5\sum q_i^4 + 5$$

$$H^4_{11}(q) = \frac{2^4\cdot 5}{3}\sum q_i^8 - \frac{2^4\cdot 5\cdot 7}{3^2}\sum q_i^6 + \frac{2^2\cdot 5\cdot 7}{3}\sum q_i^4 + \frac{2^6\cdot 5\cdot 7}{3}q_1^2q_2^2q_3^2q_4^2 - \frac{91}{3^2}$$

$$[32]\quad H^6_{11}(q) = \frac{2^5\cdot 7\cdot 11}{3}\sum q_i^{12} + \frac{2^6\cdot 7\cdot 11}{3}[q_1^6(q_2^6+q_3^6+q_4^6) + q_2^6(q_3^6+q_4^6) + q_3^6q_4^6] - 2^5\cdot 7\cdot 11\sum q_i^{10} + 2^3\cdot 3^2\cdot 5\cdot 7\sum q_i^8 - 2^5\cdot 3\cdot 5\cdot 7\cdot q_1^2q_2^2q_3^2q_4^2 - \frac{2^6\cdot 5\cdot 7}{3}\sum q_i^6 - 2\cdot 3\cdot 5\cdot 7\sum q_i^4 + \frac{241}{3}$$

Notation: Σ abbreviates $\Sigma_{i=1}^4$.

Phase transitions in the organic semiconductor dipropylamine tetracyanoquinodimethane: DPA $TCNQ_2$

ANDRÉ D. BANDRAUK, KIM D. TRUONG, AND MARCEL AUBIN
Groupe de Recherche sur les Semiconducteurs et Diélectriques, Faculté des Sciences, Université de Sherbrooke, Sherbrooke (Qué.), Canada J1K 2R1

Received September 29, 1987

This paper is dedicated to Professor J. A. Morrison

ANDRÉ D. BANDRAUK, KIM D. TRUONG, and MARCEL AUBIN. Can. J. Chem. **66**, 938 (1988).

Dipropylamine tetracyanoquinodimethane, DPA $TCNQ_2$, is by stoichiometry a 1:2 organic salt giving rise to a $\frac{1}{4}$ filled band quasi one dimensional electronic system. Conductivity measurements indicate the presence of at least three phase transitions. A dominant transition at 215 K shows simultaneous large discontinuities in both electric and magnetic properties. Infrared measurements suggest a structural change at 215 K related to conduction electron–molecular vibration interactions in view of the appearance of A_g TCNQ modes in the infrared spectrum. Deuteration of the donor $\overset{+}{N}$—H bond lowers the main transition temperature by 5 K but maintains the same physical properties as in the nondeuterated compound.

ANDRÉ D. BANDRAUK, KIM D. TRUONG, et MARCEL AUBIN. Can. J. Chem. **66**, 938 (1988).

Le dipropylamine tétracyanoquinodiméthane (DPA $TCNQ_2$) est un sel organique de stoechiométrie 1:2 qui donne lieu à un système électronique quasi-unidimensionnel comportant une bande qui n'est remplie qu'au $\frac{1}{4}$. Des mesures de conductivité suggèrent la présence d'au moins trois transitions de phases. Une transition dominante à 215 K présente des discontinuités simultanées importantes tant dans les propriétés électriques que magnétiques. Des mesures infrarouges permettent de voir apparaître les modes A_g du TCNQ et suggèrent qu'il se produit un changement de structure à 215 qui est relié à des interactions de vibration de conduction électron–molécule. La deutération de la liaison donneur N—H diminue par 5 K la température d'apparition de la transition principale; toutefois, on retrouve les mêmes propriétés physiques que celles du produit non-deutéré.
[Traduit par la revue]

Introduction

Investigation of organic charge transfer salt has proven to be very useful for an adequate understanding of the physical properties of low dimensional electronic systems. In particular the organic salts of the strong acceptor TCNQ give rise to varied stoichiometries and hence unusual fillings of the quasi one dimensional electronic bands arising from the segregated stacking of the acceptor molecules face-to-face in the crystal. This geometry produces quasi one dimensional π-electron networks, and thus gives rise to highly anisotropic electric and magnetic properties of these systems (1).

Of current interest is the influence of the counterions, i.e., donors in the case of TCNQ salts, on these properties. As an example, we have been able to show via Resonance Raman Spectroscopy of crystals of the ternary system TMAITCNQ (trimethylammonium iodide TCNQ) that a semimetal–semiconductor phase transition occurring in this system involves coupling of a chain of I_3 counterions to the conducting $TCNQ^-_{2/3}$ stacks (2). In other examples, we have found hydrogen-bonding to be a determining factor for the occurrence of parallel or non-parallel stacking of acceptors in the crystal (3–5).

In the present case we investigate the electric and magnetic properties of a 1:2 organic charge transfer salt of dipropylamine (DPA) with TCNQ. One expects as a result of the stoichiometry that each TCNQ will acquire a ¼ electric charge and crystallize in one dimensional arrays of $TCNQ^{-\frac{1}{2}}$ ions separated by the donor, as occcurs in the well studied TEA (triethylamine) (6) and MEM (methylethylmorpholinium) $TCNQ_2$ systems (7, 8). In the limit of weak electronic correlations ($U \rightarrow 0$, where U is the on-site electronic repulsion in the Hubbard model (9)), such systems have $\frac{1}{4}$ filled electronic bands and are expected to undergo an electronic instability, called the electronic Peierls transition leading to a phase transition between a metallic and a semiconducting state. The metallic state is characterized by a nearly temperature-independent conductivity whereas the semiconducting state has an activated conductivity. In the lower temperature semiconducting state one expects tetramerization ($2k_F$ periodicity, where k_F is the metallic state Fermi level) of the uniform metallic stacks, with two electrons per tetrameter. Large electron–electron repulsion (U) will suppress this tendency to form tetramers with the end result that a dimerized structure ($4k_F$) will be preferred. This has been observed in MEM $TCNQ_2$ at high temperatures. Of note is that the magnetic susceptibility remains unaffected in the above compound at the $4k_F$ or metal–dimer phase transition, although a large conductivity change is observed, and the electronic spin system behaves as an antiferromagnetic system in the dimerized phase (hopping of alternating spins between the dimers). This antiferromagnetic behaviour of dimerized chains with one charge per dimer is also well documented in the TMTSF (tetramethylselenofulvalene) salts where the now positive organic chains can give rise to superconductivity at low temperatures (10). Common to all these systems is the appearance of a magnetic phase transition at much lower temperatures than the first transition described above. At these low temperatures, one finds a disappearance of the magnetic susceptibility accompanied by a slight tetramerization. This is called a spin–Peierls transition ($2k_F$), since it is clear that it is the magnetic (spin energies) which drive the quasi one-dimensional electronic system to this new instability.

Theoretical studies of finite rings of degenerate electronic systems show that the electronic repulsion U regulates the temperature of the $4k_F$ and $2k_F$ phase transitions (11). At large U, one expects the $4k_F$ electronic transition to occur at high temperatures, whereas the $2k_F$ magnetic transition should occur at very low temperatures. This is the case of MEM $TCNQ_2$ (7–9, 11). Our studies on the DPA $TCNQ_2$ system, reported below, indicate an important phase transition at 215 K. Of note is that we found both electric and magnetic properties to change simultaneously at that temperature, contrary to the MEM

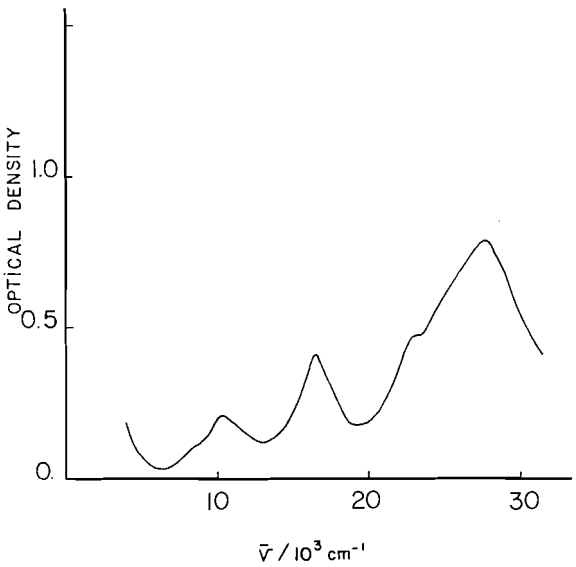

FIG. 1. Electronic absorption spectrum of DPA $TCNQ_2$ crystals in KBr pellets at room temperature.

$TCNQ_2$ case where the sharp electronic conductivity variation occurs at 335 K and the magnetic susceptibility essentially vanishes at 19 K. We report in the remainder of this paper the details of this finding on the DPA compound.

Experimental results

(i) Preparation

DPA $TCNQ_2$ was synthesized from the monoiodide of dipropylamine mixed with recrystallized TCNQ in distilled acetonitrile. The resulting reaction

[1] $H_2(CH_3—CH_2—CH_2)_2\overset{+}{N}I^- + 2TCNQ \rightarrow H_2(CH_3CH_2CH_2)_2\overset{+}{N}[TCNQ_2]^- + \frac{1}{3}I_3^-$

gave in solution black needles. Chemical analysis of the recrystallized needles confirmed the 1:2 stoichiometry between the dipropylamine (DPA) donor and the TCNQ acceptor (theoretical % value in parentheses):

C = 70.51 (70.59; H = 4.86 (4.70); N = 24.78 (24.70)

Deuteration of the nitrogen in DPA was achieved by preparing the monoiodide with DI acid, giving DPAd $TCNQ_2$.

(ii) Spectra

Ultraviolet, visible, and ir spectra were obtained from pressed KBr pellets of the compound, following the procedures in our previous work (3). In Fig. 1 we illustrate the electronic spectrum. The strong bands at 27800 cm^{-1} and 16500 cm^{-1} are usually attributed to TCNQ localised electronic excitations. The lower bands at 10200 cm^{-1} and ~3000 cm^{-1} are attributed to charge transfer bands between the TCNQ ions (12). The low energy electronic band at 3000 cm^{-1} is typical of mixed valence systems, and presages nonnegligible conductivities.

In Fig. 2 we illustrate the infrared spectra at room temperature and at 150 K, i.e., below the phase transition. A noticeable sharpening and splitting is observed below the transition temperature. Prominent vibrations appear at 150 K at frequencies 2170, 1560, 1410 cm^{-1}. These are usually attributed to TCNQ A_g modes, which are activated by conduction – electron vibration couplings (13, 14). These and other vibrations are tabulated in Table 1.

TABLE 1. $TCNQ^{-1/2}$ vibrations in DPA $TCNQ_2$ at 298 K and 150 K

*(s) = strong.

(iii) Electrical properties

The electrical resistivity was measured on single crystals along the needle axis using standard four probe silver contacts (4).

The resistivity of DPA $TCNQ_2$ was found at room temperature to be 0.07 Ωm, increasing gradually upon lowering the temperature. Such behaviour is characteristic of a semiconductor, possessing an electronic energy gap E_g, for which we can write

[2] $$\ln \rho = \ln A + \frac{E_g}{2kT}$$

In Fig. 3 we present a graph of ln ρ vs. $10^3/T$. Three transitions are readily identified at 215, 245, and 302 K. The gap energies can be determined from eq. [2] as:

$$E_g\,(T \geq 302\text{ K}) = 0.14\text{ eV}$$

$$E_g\,(280\text{–}302\text{ K}) = 0.81\text{ eV}$$

$$E_g\,(215\text{–}245\text{ K}) = 0.33\text{ eV}$$

$$E_g\,(T \leq 215\text{ K}) = 0.3\text{ eV}$$

The largest resistivity change occurs at T_c = 215 K, with an increase of 6.1 Ωm at 214 K to 31.5 Ωm at 216 K.

Measurements were also performed, Fig. 4, on single crystals of the deuterated compound DPAd $TCNQ_2$, where deuteration of the $\overset{+}{N}$—H bond is expected to occur following the preparation described above. Room temperature conductivity is similar to the nondeuterated compound, 0.09 vs. 0.07 Ωm. The largest conductivity change is similar, 7.7 Ωm at 209 K and 39.3 Ωm at 212 K. The corresponding phase transition now occurs at T_c = 210 K as opposed to 215 K for the nondeuterated compound.

Changes in slope for ρ (eq. [2]), are observed also at 255 K and 295 K. The corresponding activation energies for the deuterated compound are:

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/07/12
For personal use only.

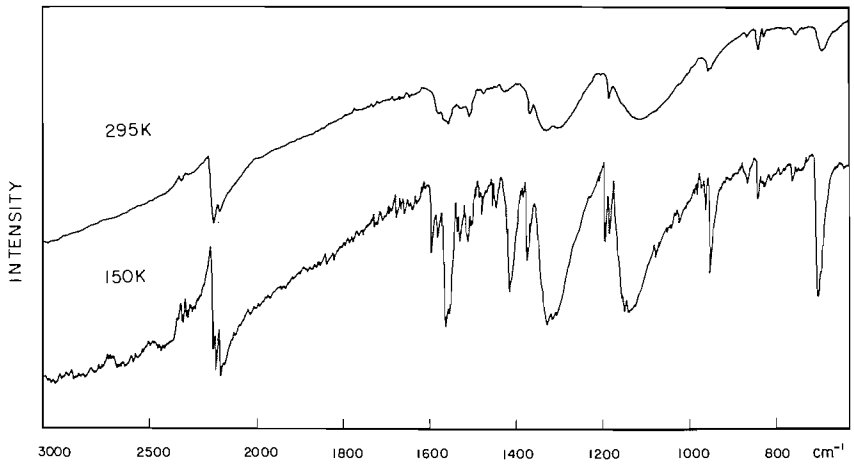

FIG. 2. Infrared spectra of DPA $TCNQ_2$ in KBr pellets at 295 and 150 K.

$$E_g\,(T \geq 295\text{ K}) = 0.2\text{ eV}$$
$$E_g\,(260\text{–}290\text{ K}) = 0.7\text{ eV}$$
$$E_g\,(210\text{–}250\text{ K}) = 0.17\text{ eV}$$
$$E_g\,(T \leq 210\text{ K}) = 0.15\text{ eV}$$

When compared to the nondeuterated compound, we note that the transition temperatures are now lowered by about 5 K in the deuterated compound. In particular, the low temperature E_g is about *half* of that observed in the nondeuterated compound.

(*iv*) *Electron spin resonance*

Integrated intensities are reported in Figs. 5 and 6 for the nondeuterated and deuterated compounds respectively. Measurements were performed on fine powders of the sample as a function of temperature between 140 and 360 K, with a temperature precision of ±5 K. A strong signal is observed at room temperature with a g factor of 2.0021 and there was no evidence of fine structure. The integrated intensity of the signal decreases monotonically from 295 to 220 K. Between 210 and 200 K an abrupt decrease in intensity is observed. At lower temperatures, the temperature variation becomes regular again. The esr spectrum actually consists of two lines below the transition temperature T_c = 215 K, which gradually merge into one line at the transition. This suggests that in the low temperature phase one is observing inequivalent TCNQ's.

The sharp variation of the esr line and intensity around the same temperature where a sharp decrease in conductivity occurs, i.e., at T_c = 215 K is indicative of an abrupt change in magnetic activation energy. We shall assume an activated form for the esr intensity, which is characteristic of linear chains of spins with antiferromagnetic alternating interactions (15, 16),

$$[3] \quad I = (C/T)\exp -(J/kT)$$

where J is the exchange energy between neighbouring spins. Alternatively one could have chosen the exact expression for the magnetic susceptibility of a localized singlet–triplet system (9),

$$[4] \quad \chi_{ST} = \frac{C}{T}\,[3 + \exp(2J/kT)]^{-1}$$

For large J or low T, this expression also describes an activated behaviour, as in the antiferromagnetic expression [3]. Fitting eq. [3] to Fig. 5 above and below the transition temperature, T_c

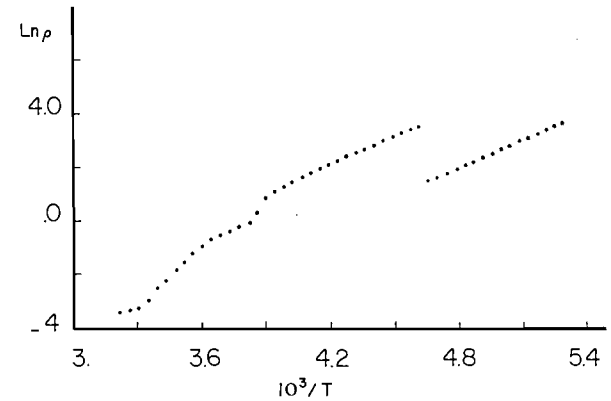

FIG. 3. Temperature dependence of resistivity ρ (Ωm) for DPA $TCNQ_2$.

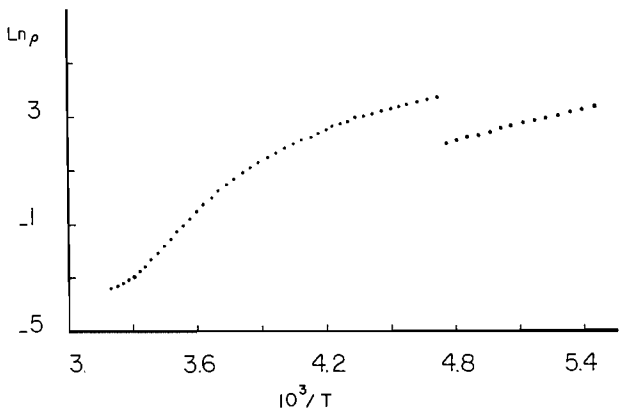

FIG. 4. Temperature dependence of resistivity ρ (Ωm) for deuterated DPAd $TCNQ_2$.

= 215 K we obtain for DPA $TCNQ_2$:

$$J(T \geq T_c) = 0.018\text{ eV}; \qquad J(T \leq T_c) = 0.044\text{ eV}$$

and for DPAd $TCNQ_2$, T_c = 210 K (Fig. 6),

$$J(T \geq T_c) = 0.013\text{ eV}; \qquad J(T \leq T_c) = 0.044\text{ eV}$$

Clearly, in both nondeuterated and deuterated compounds the magnetic excitation energies J are similar, and the low temperature phase exhibits a larger exchange energy.

Discussion

The conductivities of both the deuterated and nondeuterated compounds indicate three distinct regions of electronic behaviour: a high temperature semiconducting phase above 300 K with small activation energy, an intermediate phase between 300 and 250 K with a large anomalous activation energy and a low temperature semiconducting phase below 215 K with moderate activation energy. It is only in this low temperature phase that the conduction activation energies of the deuterated and nondeuterated compounds differ by a factor of 2, suggesting the importance of hydrogen bonding between donor and acceptor chains at low temperatures.

It is also only the lower temperature phase transition T_c (210, 215 K) which shows simultaneous discontinuities in electric and magnetic properties. We emphasize that both electronic conductivities and esr signals change abruptly when crossing below T_c, indicating that these are sharp transitions. The other two transitions occurring at higher temperatures are less well defined, and may probably be continuous transitions due to the gradual onset of order in the donor chain, as in the case of MEM $TCNQ_2$ (7, 8). These may be second-order transitions, for which the quoted activation energies may not be physical. Further clarification of this region is required.

Preliminary X-ray studies of our compound indicate that the TCNQ chains are slightly dimerized and that the donor DPA molecules are indeed disordered at room temperature (17). Thus our treatment in the previous section of the room temperature phase as an antiferromagnet with electrons exchanging dimer sites concurs with the stoichiometry of the system and the X-ray data, leading to a low exchange energy. At the lower temperature, a tripled exchange energy is observed, suggesting stronger interactions, as a result of increased overlap between adjacent molecules in a contracting lattice. The onset of sharp A_g modes in the infrared spectrum below T_c and the complication of the spectrum is further suggestive of a structural transition whereby the electrons are more localized (13, 14).

Our compound behaves in many respects like another 1:2 TCNQ salt, DMM (dimethylmorpholinium) $TCNQ_2$ in its monoclinic phase (18). This compound exists at room temperature in the form of dimerized TCNQ chains (19). At high temperatures (475 K), a transition is observed suggestive of a $4k_F$ transition to uniform chains as in MEM $TCNQ_2$. Below T_c = 260 K, the chains are tetramerized, indicative of a spin–Peierls or $2k_F$ transition (20). At temperatures below T_c, two lines are observed in the esr spectrum which gradually merge at T_c. We have observed this same phenomenon in DPA $TCNQ_2$ which suggests the appearance of inequivalent TCNQ's at the lower temperatures.

However, contrary to the present DPA compound, DMM $TCNQ_2$ does *not* show a discontinuity in its esr intensity at T_c, i.e., the spin–Peierls transition does not seem to be observed in the temperature dependence of the magnetic susceptibility in the latter. This is explained as due to weak coulomb correlations U or large hopping (transfer), t, of electrons between adjacent sites (18), i.e., the system behaves like an antiferromagnet. Following this argument, we would conclude that DPA $TCNQ_2$ is a large U and small t system, as in MEM $TCNQ_2$. If such were the case, one would have expected conductivity and magnetic susceptibilities anomalies to occur at much different temperatures. Thus DPA $TCNQ_2$ does not follow this simple rule which distinguishes $4k_F$ and $2k_F$ transitions.

In conclusion, we emphasize that DPA $TCNQ_2$, a semiconductor, exhibits simultaneous discontinuities in its electrical and magnetic properties at T_c = 210 K. This is indicative of simultaneous electronic and spin–Peierls transitions. A similar phenomena has been observed recently in the compound $(BEDT\text{–}TTF)_3(ClO_4)_2$ (BEDT–TTF = bis(ethylenedithiols)-tetrafulvalene) which undergoes a metal–insulator phase transition at 171 K with simultaneous sharp drops in conductivity and magnetic susceptibilities (21). The origin of this phase transition is not known. Both compounds above, indicate from their magnetic data a strong localisation of the spins at low temperatures. The dynamics of the accomanying structural transition

which induces a simultaneous large change in the conductivity and magnetic susceptibility needs to be further explored by careful temperature dependent X-ray and nmr studies of the present and analogous systems.

A variety of investigations has been undertaken on hydrogen sulphide hydroquinone clathrates, with the aim of achieving a better understanding of the motions of the guest molecules and of the phase transition near 8 K. Measurements have been made, over a wide temperature range including the phase transition, of heat capacities on H_2S, D_2S, and HDS clathrates, dielectric constants perpendicular and parallel to the trigonal axis of single crystal specimens, incoherent quasi-elastic neutron scattering, and neutron diffraction. All of the data are consistent with the H_2S molecular dipole being able to rotate rather easily about an axis parallel to the trigonal crystal *c* axis. Rotations about the other axes are much more difficult. The rotation about the trigonal axis is almost free at high temperatures but there is evidence for three preferred orientations at temperatures just above the phase transition. No discrete energy states are observed at any temperature due to strong guest–cage and guest–guest interactions. The experiments provide direct evidence that the phase transition is associated with a cooperative freezing out of the dipole reorientations.

HARUTOSHI UKEGAWA, TAKASUKE MATSUO, HIROSHI SUGA, ALAN J. LEADBETTER, RICHARD C. WARD et JON W. CLARK. Can. J. Chem. **66**, 943 (1988).

Afin de parvenir à une meilleure compréhension des mouvements des molécules hôtes ainsi que de la phase de transition autour de 8 K, on a entrepris une série d'études sur les clathrates du sulfure d'hydrogène/hydroquinone. Opérant sur un large éventail de températures, y compris celle de la transition de phase, on a fait des mesures relatives aux capacités calorifiques des clathrates du H_2S, du D_2S ainsi que du HDS, aux constantes diélectriques perpendiculaire ainsi que parallèle à l'axe trigonal d'échantillons de cristaux uniques, à la dispersion neutronique quasi-élastique incohérente ainsi qu'à la diffraction des neutrons. Toutes les données sont en accord avec le fait que le dipôle moléculaire du H_2S pourrait effectuer des rotations faciles autour d'un axe parallèle à l'axe trigonal-*c* du cristal. Les rotations autour des autres axes sont beaucoup plus difficiles. À des températures plus élevées, la rotation autour de l'axe trigonal est pratiquement libre; toutefois, juste au-dessus de la transition de phase, il semble exister trois orientations préférées. À cause des fortes interactions qui existent soit entre l'hôte et la cage ou entre l'hôte et l'hôte, aucun état d'énergie défini n'a pu être observé sur tout l'éventail de températures étudiées. Les expériences fournissent toutefois des preuves directes à l'effet que la transition de phase est associée avec une élimination coopérative des réorientations des dipôles.

[Traduit par la revue]

Introduction

In the hydroquinone clathrate compounds, various kinds of small molecules are encaged in nearly spherical cavities of free diameter ca. 0.4 nm (1). The cavity wall, formed by six benzene rings on the side and two six-membered rings of hydrogen-bonded oxygen atoms top and bottom, is rather rigid and retains otherwise volatile guest molecules firmly in the cavities. The rigidity of the cavity wall is demonstrated by the formation of non-stoichiometric clathrate solutions Q_3G_x (where Q is the hydroquinone and G the guest molecule) of the same structure over a wide range of values of x, and also by the constancy of the unit cell size for guest molecules smaller than methanol (2). The translational vibrations of the guest molecule in such a cavity are highly anharmonic and may be described as a rattling motion. For diatomic and polyatomic guest molecules, their rotational vibration is also anharmonic, approaching free rotation in the low-barrier limit. These properties, which depend on the interaction of a guest molecule with a host cavity, have been studied calorimetrically and spectroscopically (3–5).

Occurrence of phase transitions in the hydroquinone clathrate compounds was first reported for the methanol and hydrogen cyanide compounds (6, 7). The role played by the guest–guest interaction was stressed there. In these compounds, the guest–host interactions are also important, as the appreciable dielectric loss indicates the presence of a barrier to rotation whose origin is primarily the guest–host interaction. Various aspects of the guest–host and guest–guest interactions and their connection to the molecular motion have been reviewed in refs. 8 and 9.

The rigidity of the host lattice gives rise to the possibility of studying the properties of an assembly of small molecules in an unusual situation: the guest molecules are quasi-free to move and rotate in the cavity but they can also interact with each other through angle-dependent potentials without coming in direct contact with each other (10). In the present paper, we report calorimetric, dielectric, and neutron scattering studies of the hydroquinone clathrates of H_2S, D_2S, and HDS guest mole-

cules. These were undertaken with a view to reaching a better understanding of the behaviour of the enclathrated molecules and of the phase transitions that occur when the guest molecules are polar (11). Some of the experimental results on the H_2S compound have been published elsewhere (10).

Experimental

Sample preparation

All the samples were prepared according to the method described in ref. 2. For the D_2S clathrate $[C_6H_4(OD)_2]_3\cdot(D_2S)_x$, the hydroxyl group of hydroquinone was deuterated by repeated recrystallization from D_2O. D_2S was prepared from Al_2S_3 according to the reaction :

$$Al_2S_3 + 6D_2O \rightarrow 2Al(OD)_3 + 3D_2S$$

The D_2S clathrate was then prepared in the same way as for the normal compound with care being taken to avoid contamination from atmospheric moisture. The half-deuterated clathrate $[C_6H_4(OH)(OD)]_3\cdot(HDS)_x$ was also prepared, using an equimolar mixture of the normal and hydroxyl-deuterated hydroquinone and half-deuterated hydrogen sulphide. The latter was prepared from Al_2S_3 and an H_2O–D_2O mixture. The half-deuterated clathrate thus prepared had H_2S, HDS, and D_2S as the guest molecules with the statistical ratio 1:2:1.

The heat capacity measurement showed the presence of water occluded in the sample crystal. The amount of water impurity determined from the heat capacity peak due to its melting was 0.23 mass percent for the hydrogenous compound and 0.13 mass percent for the deuterated compound, and these were taken into account in the heat capacity reduction.

The extent of deuteration was examined by Raman spectroscopy. The Raman active ν_1 occurred at 2588 cm^{-1} for the H_2S and at 1875 cm^{-1} for the D_2S clathrate. For the half-deuterated clathrate, the guest spectra also occurred at 2588 and 1875 cm^{-1} with nearly the same intensities, but both were broader than the spectrum of the single component clathrate. From the absence of the H–SD stretching frequency in the clathrate of the D_2S clathrate, the deuteration was estimated to be better than 96%.

For the neutron diffraction experiment, a completely deuterated specimen $[C_6D_4(OD)_2]_3\cdot(D_2S)_x$ was also prepared. The ring protons were exchanged with deuterons in a refluxing deuteroxide solution acidified with deuterated sulphuric acid. Ten grams of hydroquinone was deuterated twice, each time using 100 cm^3 of 99.8% D_2O and 1–2 cm^3 of concentrated D_2SO_4. The proton nmr on the hydroquinone sample dissolved in deuterated acetone showed that the deuteration level was 92%. The deuteration of the hydroxyl group and the preparation of D_2S were carried out as described above. A partially deuterated clathrate sample $\{[C_6D_4(OH)_2]_3\cdot(H_2S)_x\}$ for the incoherent quasi-elastic neutron scattering experiment was prepared using ring deuterated hydroquinone kindly supplied by Professor G. W. Gray, Hull University.

The occupancies x of the cavities were determined from elemental analysis for C, H (D), and S.

Single crystals of the H_2S clathrate for the anisotropic dielectric measurement were grown from pressurized aqueous solutions cooled from 80 to 20°C in 2 weeks. Crystals ~8 × 8 × 8 mm^3 with no particular anisotropic growth were obtained.

Calorimetric and dielectric measurements

The two calorimeters used in the present work have been described elsewhere (12, 13). The rhodium–iron thermometer was calibrated on the temperature scale EPT-76 and the platinum thermometer on IPTS-68.

The dielectric constant was measured using a General Radio 1620 transformer bridge. Since the sample was free from dielectric loss at all temperatures, it was measured at 1 kHz only. The samples cut parallel and perpendicular to the crystallographic c axis were placed in a doubly thermostated cryostat cooled with liquid helium. Gold foils attached to the crystal faces with Apiezon grease were used as electrodes.

Neutron diffraction and quasi-elastic scattering

The neutron diffraction measurements were made using a freshly powdered sample of material with the aromatic hydrogens approximately 92% deuterated and the remaining hydrogens better than 95% deuterated. The cage occupancy was 96 ± 2%. The high resolution powder diffractometer (14) at the spallation neutron source ISIS was used for the measurements; the sample-detector distance was 1 m, giving a resolution $\Delta d/d \sim 10^{-3}$. Measurements were made at 3.8, 6.5, 12, 30, and 150 K.

Incoherent neutron quasi-elastic scattering measurements were made on two separate samples; both were slab-shaped samples scattering 10% of the incident neutrons. One was completely hydrogenous, with a cage occupancy of 80%, and was investigated using the 1N6 spectrometer at the Institute Laue–Langevin, Grenoble. The other sample had the aromatic hydrogen deuterated to better than 95% with an H_2S cage occupancy of 90% and the measurements were made using the IN5 spectrometer. The energy resolution of the two instruments was determined using the scattering from a vanadium plate. For IN5 the incident wavelength was 7.0 Å giving a maximum elastic scattering vector Q_{el} = 1.60 $Å^{-1}$ with a resolution of 20 μeV (FWHM); measurements were made at 5, 10, and 15 K. For IN6 the wavelength was 5.1 Å with a resolution varying from 75 μeV (FWHM) at Q_{el} = 0.4 $Å^{-1}$ to 140 μeV (FWHM) at Q_{el} = 2.1 $Å^{-1}$; measurements were made at 5, 10, 15, 87, and 180 K.

Results and discussion

Heat capacity

The heat capacity data are given in the Appendix; Tables A1–A4, H_2S clathrate $T \leq 20$ K; Table A5, HDS clathrate, $T \leq 15$ K; Table A6, D_2S clathrate $T \leq 30$ K; Table A7, H_2S clathrate $T \leq 300$ K; Table A8, D_2S clathrate $T \leq 300$ K. The heat capacities have been normalized to three moles of hydroquinone. They therefore represent different amounts of the guest species, depending on the stoichiometry.

The heat capacities of the H_2S and D_2S clathrates are shown in Fig. 1 for the higher temperature region. They are free from anomalies at temperatures above 10 K. The heat capacity of the D_2S clathrate is larger than that of the H_2S clathrate because of the mass effect. The heat capacities of the H_2S clathrates for $T \leq 20$ K have been given graphically in ref. 10. They have peaks between 7 and 8 K for occupancies x larger than 0.9. The regions of the heat capacity peaks are shown in Fig. 2 on an enlarged scale for the H_2S, D_2S, and HDS clathrates. The heat capacity peaks occur at 7.61, 7.80, and 7.72 K for the H_2S, D_2S, and HDS compounds, respectively. On the assumption that the transition temperature depends linearly on the occupancy, the transition temperatures of the fully occupied clathrate are calculated to be 8.01, 8.48, and 8.04 K for the H_2S, D_2S, and HDS. The isotope effect on the transition temperature is quite small. The transition temperatures are summarized in Table 1 together with the previous data on the other clathrates (10).

Dielectric constant

The dielectric constants were measured on single crystals of the H_2S clathrate with x = 0.95. They are very anisotropic, as shown in Fig. 3. The orientational polarization characterized by the strong temperature dependence contributes only to $\varepsilon_\perp$, where the polarization perpendicular to the c axis is measured. The largest value ($\varepsilon_\perp$ = 7.82) is found at 14.2 K. $\varepsilon_\parallel$ changes very little with temperature, always being between 3.4 and 3.8. The maximum temperature for $\varepsilon_\perp$ is much higher than the temperature of the heat capacity peak, 7.61 K. However, the strong increase of $\varepsilon_\perp$ around this temperature must be associated with the phase transition. The $\varepsilon_\perp$ value is significantly larger

D_2S	0.92	7.80±0.05
HDS	0.96	7.72±0.06

than $\varepsilon_{\parallel}$ at 4.2 K, which shows that a part of the dipolar polarization responds to the applied field even at this low temperature.

The strong anisotropy of the dielectric constant indicates that the guest dipoles have a strong preferential orientation perpendicular to the trigonal c axis, which is normal to the plane containing the hydroxyl rings. The dipole reorientation is thus essentially confined within the *ab* plane although no details are determined about the motion in this plane nor concerning

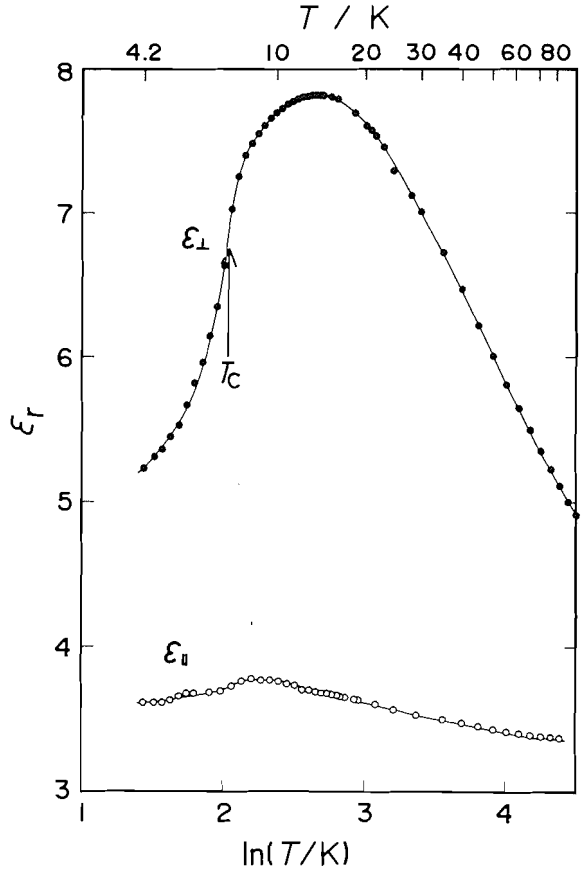

FIG. 3. Dielectric constants of single crystals of $[C_6H_4)OH)_2]_3{\cdot}(H_2S)_{0.95}$ measured perpendicular ($\varepsilon_\perp$) and parallel ($\varepsilon_\parallel$) to the c axis.

molecular orientation about the dipolar axis. The dielectric result is consistent with the nonpolar structure found at 295 K (15).

The different temperatures of the ε and heat capacity maxima have also been found in the HCl clathrate compound,[4] for which the maximum occurred at 20 K, and the heat capacity peak at 12.3 K. This may be related to the anisotropic structure of the clathrates in which the nearest neighbour guests form a chain that runs along the c axis.

Rotational heat capacity and entropy

The experimental heat capacity is the sum of the guest and host contributions. By making the assumption that these are additive, subtraction of the known host heat capacity (17) from the total gives the guest heat capacity shown in Fig. 4. At high temperatures, the curve was reproduced well by the following equation:

$$[1] \quad C = 3C_E(\theta = 104.5\,K) + 2C_E(\theta = 249.8\,K) + \tfrac{1}{2}R$$

The first Einstein term represents the rattling motion in the close space limit, the second term describes two of the three rotational degrees of freedom, and the last the third rotational degree of freedom. This very anisotropic rotational motion is indicated by a calculation of the rotational barrier (see below) and by the dielectric results. At lower temperatures, the heat capacity expression [1] fails to apply for two reasons: the clas-

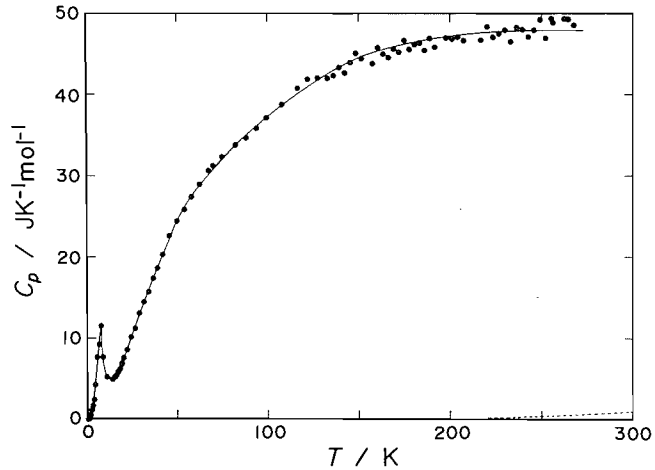

FIG. 4. Molar heat capacity of H_2S enclathrated in $[C_6H_4(OH)_2]_3\cdot(H_2S)_{0.95}$.

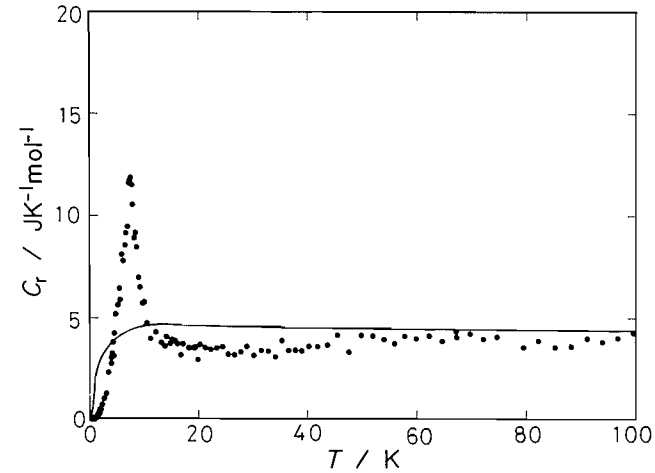

FIG. 5. Rotational heat capacity of H_2S enclathrated in $[C_6H_4(OH)_2]_3\cdot(H_2S)_{0.95}$ about the c axis. Experimental (. . .) and uniaxial free rotation (———).

sical value $\frac{1}{2}R$ of the rotational heat capacity cannot be used, and the guest–guest interaction becomes significant compared to the thermal energy. The rotational heat capacity calculated by subtracting the first two terms of eq. [1] from the guest heat capacity given in Fig. 4 is drawn in Fig. 5, where the one-dimensional rotator heat capacity is also plotted for the sake of comparison. The moment of inertia used in the calculation was 1.25×10^{-46} kg m^2. This value assumes that the guest molecule rotates in the cavity about the point of the lowest guest–host potential energy (see below). The discrepancy between the experimental and calculated heat capacities is of course caused by the phase transition arising from the guest–guest interaction that is not taken into account in the theoretical curve.

The entropy due to the orientational disordering was calculated from the rotational (or orientational) heat capacity plotted in Fig. 5. Figure 6 shows the entropy curves for the different occupancies normalized to 1 mole of H_2S. The entropy value at 15 K, where the main part of the heat capacity anomaly has finished, is 9.5 J K^{-1}mol^{-1}. The number of states occupied at this temperature is equal to exp (9.5/8.3144) = 3.13. In the free rotation model, the uniaxial rotation of H_2S occupies one of the three states: $m = 0$ and $m = \pm 1$ where m is the rotational quantum number. However, in the neutron scattering experiment no discrete excitations were observed at any temperature but only broad quasi-elastic wings above the transition, which indicates that the rotational states are extremely broadened. In terms of a classical order–disorder picture, the number of states 3.13 indicates that the guest H_2S has three equivalent orientations in the high temperature phase. The rhombohedral symmetry ($R\bar{3}$) of the crystal certainly appears consistent with this interpretation.

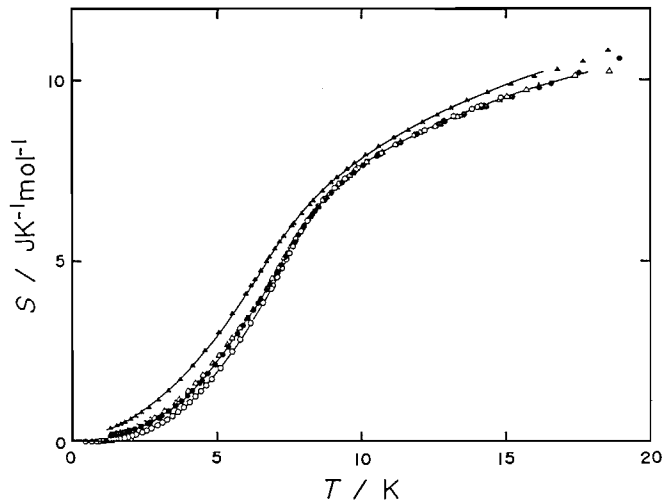

FIG. 6. Molar entropies of enclathrated H_2S in $[C_6H_4(OH)_2]_3\cdot(H_2S)_x$. —▲— $x = 0.85$; —△— $x = 0.92$; —○— $x = 0.95$; —●— $x = 0.96$.

Isotope effect

The general behaviour of the H_2S, D_2S, and HDS clathrates is very similar. In particular, the transition temperatures are essentially the same, in view of the probable variation of the occupancies. There would potentially be two aspects of the isotope substitution. One is that the rotational energy levels are closer together for D_2S than for H_2S. The other is that all the free rotational energy levels are available to HDS molecules whereas there is a restriction for H_2S and D_2S due to the symmetry requirement of the states. The experimental observation that there is no significant isotope effect shows that neither of these effects operates in the actual situation. From the first, one can argue that the moment of inertia of the guest molecule in the cavity may be larger than the free-rotator value because the host–guest interaction forces the guest molecule to rotate about a centre away from the molecular centre of mass. This causes the mass of the sulphur to dominate the rotational properties of the three isotopic species, thus diminishing the possible isotope effect. From the second, the absence of an isotope effect indicates that the rotational motion that exchanges H and D does not take place. The dielectric measurement alone could not exclude this possibility of the rotation of the H_2S molecule about its bisector axis, but the neutron scattering results described below also support the conclusion that it does not occur.

Incoherent neutron quasi-elastic scattering

Typical results for the higher Q-values are shown in Fig. 7 for temperatures of 5 and 10 K. All the results are dominated by the scattering from the protons and for both samples most of the protons are static and thus contribute only elastic scattering. Hence, for the fully hydrogenous sample only approximately 10% of the observed scattering carries useful information, and by deuteration of the aromatic hydrogens this could only be increased to 25%.

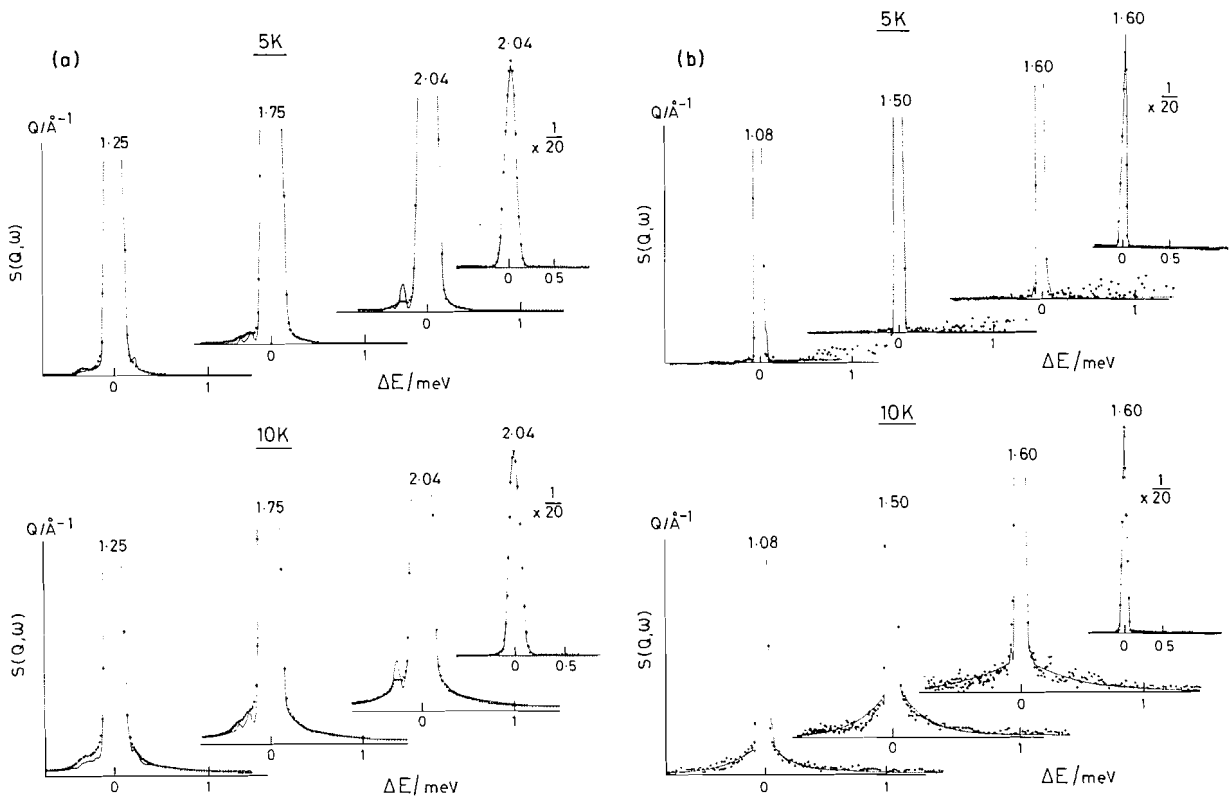

FIG. 7. Quasi-elastic neutron scattering results on H_2S enclathrated in (a) $[C_6H_4(OH)_2]_3 \cdot (H_2S)_{0.8}$ and measured on IN6 at ILL. The energy loss peaks are scattering from the cryostat. (b) $[C_6D_4(OH)_2]_3 \cdot (H_2S)_{0.9}$ measured on IN5 at ILL.

Nevertheless, the results very clearly show a distinct quasi-elastic broadening above the transition, which completely disappears below it, and no discrete inelastic peaks are seen at any temperature. At 5 K and also at 87 and 180 K the data were indistinguishable from the measured resolution function. For the low temperature this means that there are no excitations in the meV range and no stochastic motions faster than approximately 10^9 s^{-1}. For the higher temperatures the result means that the rotational/rattling motions of the H_2S molecules are fast enough to give a very broad quasi-elastic component indistinguishable from the background. The free rotational energy levels of H_2S extend from 1.7 meV upwards and the fact that no such excitations were observed, but only quasi-elastic broadening, shows that the rotational states are completely smeared out by collisional broadening through guest–host interactions and by the strongly fluctuating potential resulting from guest–guest interactions, which are comparable with thermal energies at temperatures just above the transition.

Unfortunately, because the signal from the H_2S protons is relatively weak, and also because for the higher-resolution IN5 experiment technical problems restricted the data collection time, neither the elastic incoherent structure factor nor the temperature dependence of the quasi-elastic broadening could be reliably determined. Nevertheless, the scattering is certainly consistent with rotation of the H_2S molecules about a single axis with a radius of ca. 1 Å. The correlation time τ_1 determined from a fit of a model of uniaxial rotation (18) is 2.0 ± 0.3 ps so that the rotation of the molecules is very rapid even at 10 K.

The INQES results therefore confirm unequivocally that the phase transition is associated with the freezing-out of the H_2S dipole reorientational motion. In the disordered phase the strong interactions of the guest molecules with other guests, and with the cage, make the motions essentially stochastic, although the geometrical details are not directly determined. Finally, because the freezing-out of the dipole motions does not of itself affect possible reorientational motion about the dipole axis, then the fact that no such motion is observed below the transition implies that these rotations are very much slower than the dipole reorientation itself, at least at low temperatures. This is in agreement with the results of model calculations presented below.

Neutron diffraction

A portion of the time-of-flight diffraction pattern at four temperatures is shown in Fig. 8. A full analysis of these results will be published later and at this stage only a brief discussion is given. The data at 150 K are completely in agreement with the X-ray structure (15, 19) except for the contribution of the sulphur hydrogens, which should be located by the neutron data. With decreasing temperature the lattice contracts anisotropically, the contraction from ambient temperature to 12 K being about 1% along *a* and 3% along *c*, which accounts for the observed splitting of some of the diffraction peaks at 12 K. This is consistent with a rapid rotation of the H_2S dipole in the *ab* plane and with a strong decrease in the amplitude of the rattling motion along *c* as the temperature decreases. At the transition, the freezing-out of the dipole motions causes a distortion of the lattice in the *ab* plane but very little change in the *c*-direction. This is shown by the splitting of most of the diffraction peaks from the high temperature phase into two or three components at low temperatures. Apart from these splittings, however, no new reflections appear, showing that the structural change associated with the ordering of the H_2S molecules does not involve an increase in the unit cell size but is confined to distortions of the high temperature unit cell amounting to 2 or 3 parts in 10^3.

Calculation of the guest–host interaction energy

It was stated in the introduction that the rigid host lattice provides a restricted space in which the guest molecule may rotate. In this section we present a simple calculation of the guest–host potential energy as a function of the rotation angles. The interaction energy was calculated as the sum of atom–atom potentials for which the following form was assumed (20):

$$V(r) = \frac{A \exp[-Br]}{r^D} - \frac{C}{r6}$$

where r is the interatomic distance and the parameters A, B, C, and D are given in Table 2.

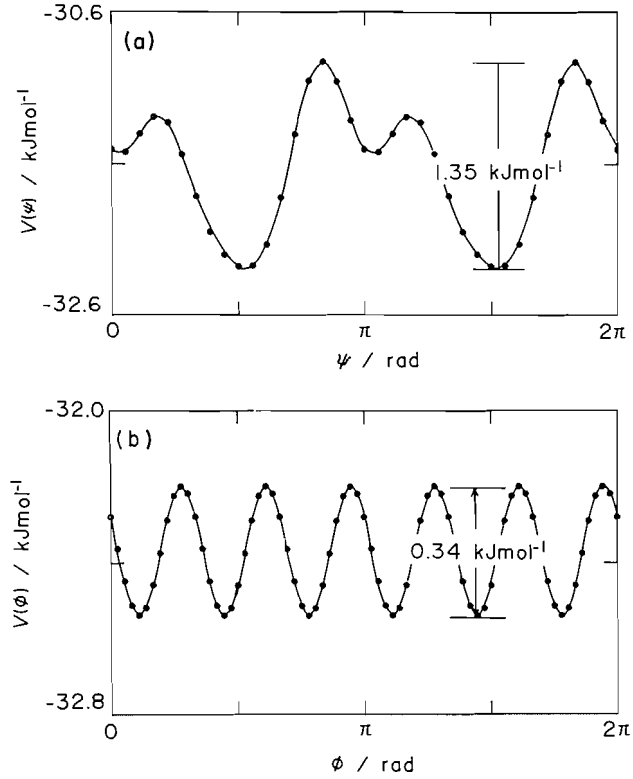

FIG. 9. (a) Potential energy of H_2S as a function of the rotation angle ψ (see text). The axis of rotation is the molecular bisector axis and is perpendicular to the c axis (i.e., $\theta = \pi/2$). $\psi = 0$ corresponds to the molecular plane being parallel to c. (b) Potential energy of H_2S as a function of the rotation angle ϕ (see text). The molecule lies flat in the ab plane and rotates about the c axis.

The sum was taken for all the pairs made by each of the three atoms of the guest H_2S and each of the atoms of the six benzene rings and the two six-membered rings of the hydrogen-bonded oxygen atoms that form the cage. Two of the potential curves are shown in Fig. 9.

First the guest molecule was moved translationally along the crystallographic a axis (as defined in ref. 19), keeping the dipolar axis parallel to the a axis and the proton–proton vector parallel to the c axis. The lowest energy was found at the position where the S atom was 0.045 nm away from the centre of the cavity. The rotational barrier was then calculated around this position. For the calculation, the molecular orientation was specified by the polar and azimuthal angles (θ, ϕ) of the dipolar axis, measured from the c and a axes, respectively, and the rotation angle ψ about the dipolar axis. The zero of the ψ angle was taken at the position where the proton–proton vector lies in the ac plane.

The potential energy calculated as a function of ψ for $\theta = \pi/2$ and $\phi = 0$ is plotted in Fig. 9(a). Two equivalent minima occur at $\psi \sim \pi/2$ and $3\pi/2$. The barrier height is 1.35 kJ mol^{-1}. The minima correspond to the molecule lying approximately flat in the ab plane. Rotation of the dipolar axis from $\theta = 0$ to π, keeping $\phi = 0$ and $\psi = \pi/2$, also gave a minimum near $\theta = \pi/2$ with a barrier height of approximately 1.35 kJ mol^{-1}. The potential energy as a function of ϕ for $\theta = \pi/2$ and $\psi = \pi/2$ is plotted in Fig. 9(b). This represents the rotation of the molecule lying flat in the ab plane about the c axis. This calculation gives six potential minima with a barrier height of 0.34 kJ mol^{-1} and an average energy of −32.37 kJ mol^{-1}. The similar rotation of the molecular dipole about the c axis but with the molecular

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/07/12
For personal use only.

plane perpendicular to the *ab* plane (i.e., $\theta = \pi/2$, $\psi = 0$) gave an average potential energy of -31.50 kJ mol^{-1} and a very small barrier, 0.014 kJ mol^{-1}.

These calculations show first that the barriers to rotation are smaller than those in ordinary molecular crystals by a factor of about $\frac{1}{10}$ to $\frac{1}{1000}$. This is a reasonable result in view of the special nature of the clathrate compound where the guest molecules rotate in the space secured by the host lattice. The second conclusion is that even though the rotational potential surface is very flat it does have minima and maxima differing by about 1 kJ mol^{-1}. The difference will be significant at low temperatures (<100 K) where the molecules will preferentially occupy the low energy orientations, which implies that the plane of the molecule and hence the dipole axis tends to be located in the *ab* plane. This explains the anisotropic dielectric response found experimentally at low temperatures.

Anisotropic potentials have also been obtained by explicit calculations of the energy using the Lennard–Jones (8) and electric multipole (16) interactions for N_2, O_2, and other larger guest molecules.

These potential barriers, calculated here, represent lower limits because of the neglect of the possible formation of hydrogen bonds and of dipole–dipole interactions with other guest molecules. However, the calculation clearly demonstrates the anisotropy of the rotational motions. Furthermore, estimates of the reorientation frequency about the bisector axes based on this potential show that while the correlation time will be about 1 ps at 100 K, it has increased to more than 1 ns below 20 K and would not be seen in the neutron scattering data, as was the case in practice.

Conclusions

All of the results presented are consistent with strongly anisotropic rotational motions of the H_2S molecules in the clathrate cages at temperatures above the 8 K phase transition. The guest dipoles are located in the crystallographic *ab* plane and rotate very rapidly ($\omega \sim 5 \times 10^{11}$ s^{-1} at 10 K) about an axis parallel to *c*. Rotations about the other axes are much more difficult. The heat capacity analysis shows that this motion is nearly free rotation at high temperatures, but the transition entropy implies that there are three distinguishable states just above the transition although the potential calculations suggest six. It would in fact not be surprising to find some such localization of the molecular orientations at low temperatures in the disordered phase and it is interesting to note that the existence of three orientations (but not six) would remove the centre of symmetry, giving space group $R3$, as for the HCl clathrate, rather than $R\bar{3}$.

The neutron scattering results confirm that the phase transition is associated with the freezing-out of the H_2S dipole reorientations and show that the molecular motions immediately above the transition are essentially stochastic in nature, in accord with the expected strong interactions with the cage and with other guest molecule dipoles.

What remains now to be determined are the precise locations of the H_2S molecules through the transition, which will provide the essential structural information required to model the phase transition. Analysis of the high resolution powder diffraction data currently in progress is expected to provide this information.

Monte Carlo simulation of chlorine adsorbed on graphite

SOONG-HYUCK SUH AND SEAMUS F. O'SHEA
Department of Chemistry, University of Lethbridge, Lethbridge, Alta., Canada T1K 3M4
Received November 17, 1987
This paper is dedicated to Professor J. A. Morrison

SOONG-HYUCK SUH and SEAMUS F. O'SHEA. Can. J. Chem. **66**, 955 (1988).

Monte Carlo calculations are reported for patches of molecular chlorine adsorbed on the basal plane of graphite. A variety of combinations of intermolecular and molecule–surface potentials have been tested, and the resulting structural predictions cover a wide range of behaviour. None of the combinations employed here can explain the recent experimental observations, but it is clear that at least some could be adjusted to do so. However, the lack of thermodynamic data concerning the interaction between the molecules and the surface presents a major obstacle. Further experiments which give information about the energetics of the system are needed before a definitive account of the structure and dynamics can be given.

SOONG-HYUCK SUH et SEAMUS F. O'SHEA. Can. J. Chem. **66**, 955 (1988).

On a effectué des calculs de Monte Carlo sur des plaques de chlore moléculaire adsorbées sur le plan basal du graphite. On a évalué un grand nombre de combinaisons des potentiels intermoléculaires et molécule/surface; les prédictions relatives à la structure qui en résultent couvrent un large éventail de comportements. Aucune des combinaisons utilisées dans ce travail ne peut expliquer les résultats expérimentaux observés récemment; mais il est évident que quelques-unes pourraient être ajustées pour le faire. Toutefois, le manque de données thermodynamiques concernant l'interaction entre les molécules et la surface présente un obstacle important. De nouvelles expériences qui pourraient donner des informations concernant les énergies du système sont nécessaires avant qu'une explication définitive de la structure et de la dynamique puissent être données.

Introduction

James A. Morrison and his collaborators were among the pioneers in high precision surface calorimetry, including the study of the heats of adsorption of linear molecules of various surfaces (1–6). Physisorption of simple molecules on well characterized surfaces continues to be of interest, and recent papers include a number on the adsorption of linear molecules on the basal plane of graphite (5–24). While most of this work has dealt with molecular nitrogen (5, 7–15), oxygen (17–24), and with carbon monoxide (6, 16), a recent paper (25) describing an experimental study of the adsorption of molecular chlorine provides the opportunity to address a new system which may display some novel and interesting features. The basis for this expectation lies in the history of the study of solid three-dimensional (3-D) chlorine.

Because of the apparent simplicity of the structures of the homonuclear diatomic molecules, and of the solids composed of them, theorists have devoted a considerable amount of effort to constructing intermolecular potentials capable of accounting for the observed solid structures, thermodynamics, and dynamics. The ideas used for other systems are based heavily on experience gained in the study of nitrogen and Scott (26) gives a good account of early work in this area. In spite of some early successes, the general picture is fairly gloomy: at present there is not a single diatomic system for which we have an intermolecular potential of the quality of those available for the interaction of spherical systems, such as pairs of rare gas atoms.

Nonetheless, there are many approximate potentials which are effective in accounting for a restricted range of phenomena for a given element. The present work concerns a particularly interesting case, that of molecular chlorine. In early studies of the solid the site–site model, particularly in the form of two "atoms" interacting by means of Lennard–Jones interactions (2LJ), proved both popular and, to a limited extent, successful (27–31). 2LJ may be augmented by electrostatic interactions, written as the interaction of simple point multiples (26, 30), of "many-point-charges" (32), or of "distributed-multipole" arrangements (33). The simplest problem should be that of finding a model which would yield a structure of the solid consistent with the one observed experimentally. For the halogens, including chlorine, this proved to be substantially more difficult (27–31) than, e.g., for nitrogen (26). Indeed, the difficulties encountered in the case of chlorine have led to innovative suggestions (34, 35) concerning methods of representing the potential. Almost simultaneously two groups proposed to solve the problem of the structure of solid chlorine by using an atom–atom model which consists of anisotropic atoms. Burgos *et al.* (34) used the conventional LJ model for the atom–atom interactions but scaled the resulting value by a function combining the usual isotropic part with angular terms of some chosen multipole interaction, such as quadrupole–quadrupole. The resulting potential gives the correct structure and lattice frequencies for the crystal. Price and Stone (35) combined a detailed distributed-multipole model of the electrostatics with an anisotropic exponential repulsion and the best available estimates of the (isotropic) dispersion coefficients to give a more complicated model potential which also provides the correct stable structure. No further refinements have been introduced since, but Price (36) has recently published a very interesting analysis of the anisotropic atom model; she follows the method of English and Venables (30) in examining the relationship of atom–atom potentials to crystal structure.

The recently reported (25) X-ray study of the structure of chlorine adsorbed on graphite seems to indicate that 2-D solid chlorine will prove every bit as intriguing as has the 3-D one. The relevant results of that study are as follows: the solid is incommensurate; it is almost rectangular with a unit-cell angle of (97.54 ± 0.16°) and unit cell spacings of a = (4.033 ± 0.009) Å and b = (3.548 ± 0.008) Å; the lattice spacings are very insensitive to both temperature and coverage; the layer is so dense that the molecules must be standing with their bond axes close to the normal to the surface; above monolayer coverage, and certainly above about one and one third monolayers, formation of the second layer competes with bulk crystalliza-

tion; the 2-D critical and triple temperatures are believed to be higher than those in 3-D, in contrast to the usual case of the 2-D values being about 50% of the 3-D ones. The authors also show the close similarity between 2-D and 3-D solids. A setting of the 2-D unit cell similar to that used for layers in the 3-D cell yields lattice constants only slightly different from the 3-D values and a cell area which is almost identical. These are the essential features for which explanations are sought.

It is correct to say that any system consisting of adsorbent plus adsorbate constitutes a mixture, and therefore poses particularly difficult problems for anyone attempting a detailed explanation of its structures and dynamics. The source of the difficulty is that one must not only provide an accurate representation of the interactions among the adsorbate molecules but also a balanced account of the adsorbate–adsorbent interactions. In the present case little enough is known about the interactions among chlorine molecules, but essentiatlly nothing is known about the chlorine–graphite interaction. The work described here is a first attempt at explaining the structure and dynamics of the system, undertaken more to identify the features which need continued further study than in any hope of providing immediate answers. The treatment of the molecule-surface interaction is the simplest possible, using a sum of atom–atom Lennard–Jones interactions. This approach works well for rare gases on graphite (37). Even at this level of simplicity the lack of data, experimental and theoretical, prevents us from determining the two necessary parameters for chlorine on graphite.

Three versions of the intermolecular interaction were used together with two simple models of the molecule–surface interaction to investigate various aspects of the system. The temperatures and coverages studied are fairly restricted, but serve to highlight important aspects of the phase behaviour related to the experimental results. The models are introduced in the next section, and the calculations are described in the following one. The paper concludes with a discussion and suggestions for future work.

Interaction potentials

In their systematic study of the (classical) structures of diatomic solids English and Venables (30) used the two centre Lennard–Jones (2LJ) model

$$[1]\quad V_{\text{mol-mol}} = 4\epsilon \sum_i^2 \sum_j^2 \left[\left(\frac{\sigma}{R_{ij}}\right)^{12} - \left(\frac{\sigma}{R_{ij}}\right)^{6} \right]$$

R_{ij} is the distance between site i in one molecule and site j in the other; the sites either coincide with the atomic positions or are very close to them. English and Venables used a ratio of bondlength (d) to atomic diameter (σ) of $d/\sigma = 0.63$, and the well depth for atomic interactions was $\epsilon/k = 282$K. Singer and co-workers (38) used a similar value of d/σ, but with a range of ϵ values, the smallest being $\epsilon/k = 178.3$ K. We have used one of the Singer potentials which has $d/\sigma = 0.632$ and a well depth of $\epsilon/k = 256.6$ K.

The second intermolecular potential (PS) is that due Price and Stone (35), and it is also based on an atom–atom model, but the atoms are now anisotropic. The general form of the non-coulombic part of the interatomic potential is

$$[2]\quad V_{\text{a-a}} = c \exp\{-\alpha(\Omega)[R_{ij} - \rho(\Omega)]\} - \frac{A}{R_{ij}^6}$$

The angle dependence of the repulsive parameters is given by

TABLE 1. Potential parameters

(*a*) Lennard–Jones atom–atom potential for Cl_2–Cl_2

$\sigma = 3.198$ Å $\quad \epsilon/k = 256.6$ K $\quad d = 2.020$ Å

−1.4566	−1.0100	0.0	1.0100	1.4566

Moments of the PC model referred to the centre of mass:

$Q_2 = 2.688\, ea_0^2$ $Q_4 = 84.35\, ea_0^4$ $Q_6 = 872.2\, ea_0^6$ $Q_8 = 7457\, ea_0^8$

(*d*) Lennard–Jones atom–atom potential for Cl_2–graphite interaction

LB: $\sigma = 3.299$ Å $\quad \epsilon/k = 84.76$ K
FH: $\sigma = 3.299$ Å $\quad \epsilon/k = 50.49$ K

$$\alpha(\Omega) = \alpha_0 + \alpha_1[S_{202} + S_{022}]$$

$$[3]\quad \rho(\Omega) = \rho_0 + \rho_1[S_{303} + S_{033}] + \rho_2 S_{110}$$

The S functions are the angle-dependent terms appearing in expansions of pair properties of linear molecules in terms of the orientation angles of the bond vectors. In the convention followed here the relevant S functions are

$$S_{101} = z_1 \cdot \hat{\boldsymbol{R}}$$

$$S_{011} = z_2 \cdot \hat{\boldsymbol{R}}$$

$$S_{110} = z_1 \cdot z_2$$

$$[4]\quad S_{202} = (3S_{101}^2 - 1)/2$$

$$S_{022} = (3S_{011}^2 - 1)/2$$

$$S_{303} = (5S_{101}S_{202} - 2S_{101})/3$$

$$S_{033} = (5S_{011}S_{022} - 2S_{011})/3$$

$\hat{\boldsymbol{R}}$ is a unit vector pointing from site 1 to site 2 and z_1 and z_2 give the directions of the molecular bonds. It is very important to note that the convention used by Price and Stone (35) for the unit vectors along the bond is opposite to that commonly used; they use z_i to represent a vector pointing *from* the site *towards* the molecular centre. The electrostatic component of the intermolecular potential is also represented by an atomic model, but the atoms each carry a series of multipoles, from dipole to hexadecapole, so that the resulting series for each site–site interaction is formidable. The requisite values of the parameters are given in Table 1.

The third model (2LJPC) combines Price–Stone electrostatics with the 2LJ model, giving a potential which has simple isotropic atom–atom interactions and very detailed electrostatics. To simplify the evaluation of the potential and reduce the long computation times encountered with the PS model, we

constructed a "5-q" type (32) equivalent of the PS electrostatics. Point charges were placed on the atoms (q_1 at $\pm d/2$), symmetrically outside the atoms (q_2 at $\pm z$), and at the molecular centre ($-2q_1 - 2q_2$). The 5-q model was calibrated to fit the first three moments of the molecular charge distribution measured with respect to the centre of symmetry. These were obtained by transferring the moments of the "ATOM" model of Price and Stone (35) to the centre; an ambiguity in sign relating to the coordinate system was resolved by requiring that the molecular quadrupole moment have the value given in their "MOL" model. The fourth moment of the distribution is well reproduced by our point charges; see Table 1 for details. We calculated the charge model for the slightly larger bondlength value used with the Singer potential (38). Figure 1 shows some typical curves of the intermolecular potential as a function of intermolecular separation at fixed orientation for four models: 2LJ, PS, 2LJ + PS electrostatics (method of moments), and 2LJPC; the last two are plotted together in Fig. 1 and it is clear that the differences between them are not physically significant.

The interaction of the molecules with the surface is also written as a sum of atom–atom terms. Individual chlorine atoms interact with the carbon atoms of the graphite substrate by means of a Lennard–Jones potential. We used two models which differ only in the well depth parameters. The σ values for the molecule–surface interaction ($\sigma_{Cl—C}$) are found from those for the pure elements by means of the Lorentz combining rule (39)

$$[5] \quad \sigma_{Cl—C} = \frac{\sigma_{Cl—Cl} + \sigma_{C—C}}{2}$$

The value used for carbon is $\sigma_{C—C}$ = 3.4 Å. The well depth parameter can be found from the Bertholet rule (39)

$$[6] \quad \epsilon_{Cl—C} = \sqrt{\epsilon_{Cl—Cl}\epsilon_{C—C}}$$

The well depth may also be estimated by the Fender–Halsey rule (39, 40)

$$[7] \quad \epsilon_{Cl—C} = \frac{2\epsilon_{Cl—Cl}\epsilon_{C—C}}{\epsilon_{Cl—Cl} + \epsilon_{C—C}}$$

This approach gives values of $\epsilon_{Cl—C}$ which are closer to the lesser of the ϵ's for the pure systems, $\epsilon_{C—C}$ = 28 K; here it results in a drop of almost exactly 40% in $\epsilon_{Cl—C}$, from 84.76 to 50.49 K. Evidence concerning the usefulness of alternatives to the Bertholet rule is mixed. In 3-D fluid mixtures this rule has proved more effective than the geometric mean rule when the disparity between the well depths of the pure systems is large (39). However, the possibility of using combining rules other than Lorentz–Bertholet was discussed and rejected by Steele (37) in his work on the adsorption of rare gases on graphite.

The gas–surface interaction energy was calculated by means of the Fourier method introduced by Steele (41, 42), and, as usual, only the leading two terms of the series are used; the first represents the laterally averaged (flat) part of the potential, and the second term gives the dominant part of the corrugation. We used the Euler–MacLaurin representation give by Steele (37) for the flat part, and constructed an accurate analytical approximation to the z-dependence of the corrugation amplitude. In many calculations the second term was omitted, so that the surface was treated as being atomically flat. In any event, for the graphite substrate the corrugation term is very much smaller than the flat part, being about 1.5% in the region of the minimum; the maximum barrier to translation is a few tens of degrees.

Calculations

The calculations were implemented using the conventional Metropolis algorithm (43) for Monte Carlo simulation of the (N, V, T) ensemble, and production calculations were done on the CYBER 205 supercomputer at the University of Calgary. Typical calculations involved 5–10 $\times$ 10^5 steps of equilibration followed by 5–20 $\times$ 10^5 steps of accumulating data to form thermal averages of thermodynamic and structural quantities. Because the equilibration "times" are long at low temperatures most of the results reported here are for runs of 2 $\times$ 10^6 steps; the results of the first and second halves of the run were juxtaposed to ensure that the data are stable. Calculations were made for temperatures of 100, 160, 200, and 240 K. For each intermolecular potential a series of calculations was made using the Lorentz–Bertholet (LB) model and subsequent calculations incorporated the Fender–Halsey (FH) model. Most calculations were made on finite patches of 127 molecules, started from hexagonal configurations. A few calculations were done at a coverage of 0.5 monolayers (based on the $\sqrt{3} \times \sqrt{3}R30°$ structure), using 126 molecules with periodic boundary conditions. The cutoff for the intermolecular potential is 14.2 Å in the case of periodic systems, but many calculations were made without a potential cutoff for the finite patches. No systematic differences are evident between the patches with and without a cutoff.

Results

The pair energy curves of Fig. 1 are very useful for interpreting the results of the simulations. The cross (both molecules perpendicular to the intermolecular axis and to one another) configuration is the most stable for each of the three potentials. The optimum binding energy for 2LJ and 2LJPC interactions is noticeably greater (by $\approx$200 K) than for PS, and it is generally true that the binding energies are smaller for PS than for the others for the important configurations. Another important difference is that the parallel configuration (both molecules perpendicular to the intermolecular axis and parallel to one another) is more stable in 2LJ and 2LJPC than many other configurations, but this is not the case for PS. In fact, an even more stable configuration for 2LJ and 2LJPC is one in which the molecules are parallel but make an angle of about 70° to the intermolecular axis; at the minimum in the pair energy curve for these configurations the intermolecular separation is relatively small, about 3.5 Å. The T configuration is relatively favourable for all models, and this is the interaction which stabilizes the herringbone structure of solid nitrogen on graphite. Finally, the colinear arrangement is very unfavourable for the PS model and less so for the other two. These pair interactions compete with one another and with the molecule surface energy to determine the structure of the overlayer. For an isolated molecule the optimum structure is lying flat on the surface. The extra energy needed to make a molecule stand up must come either from the random thermal energy or from enhanced pair interactions in the upright position.

At 100 K the 2LJ–LB combination produces a compact but non-uniform solid structure. Many molecules stand up, but many also lie flat on the surface (Fig. 2) in a defective version of the herringbone structure. Here, at least in isolated patches, only some molecules can achieve the dense upright configurations, while the remaining molecules surround them with the

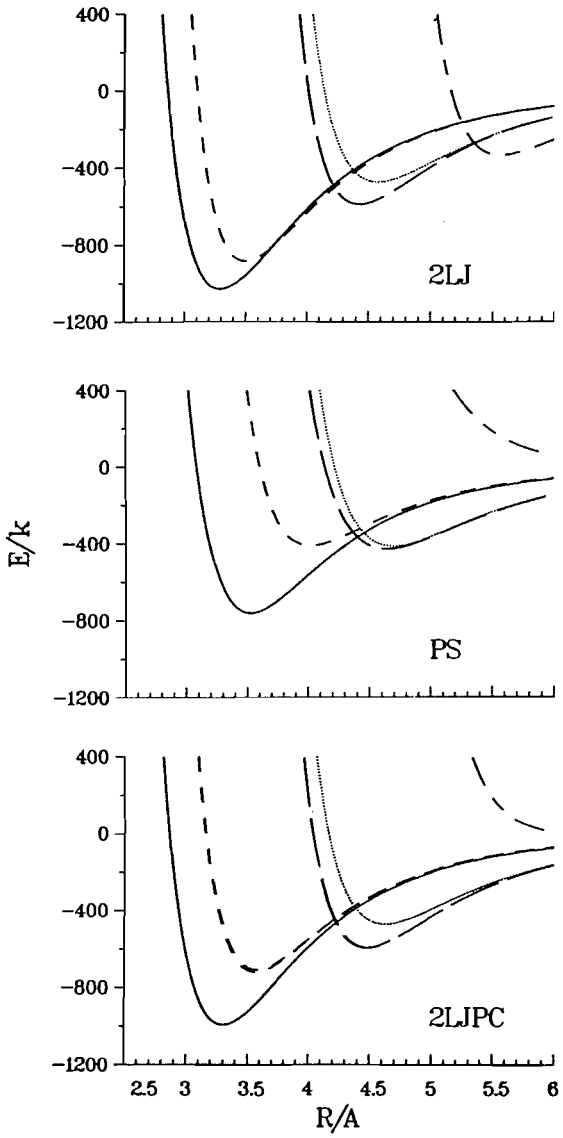

FIG. 1. The intermolecular pair potential as a function of the separation of the centres of mass at fixed orientation. For each model the solid line represents the cross configuration, the small dashes the parallel configuration, the large dashes the canted (45°) parallel configuration, the dots the T configuration, and the alternating dashes the linear configuration, respectively. In the case of 2LJPC two sets of results are plotted, one calculated with the method of moments and the other with the point charge representation; for most curves the results are indistinguishable. See the text for details.

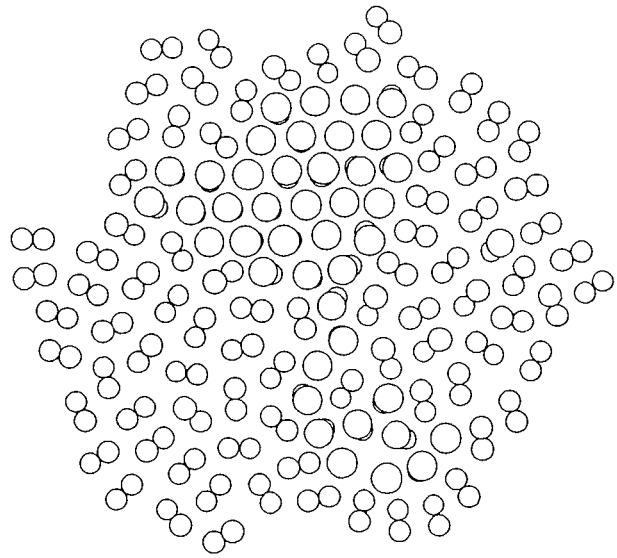

FIG. 2. The final configuration of the calculation for the 2LJ–LB model at 100 K. The radius of the atom increases with its height above the surface.

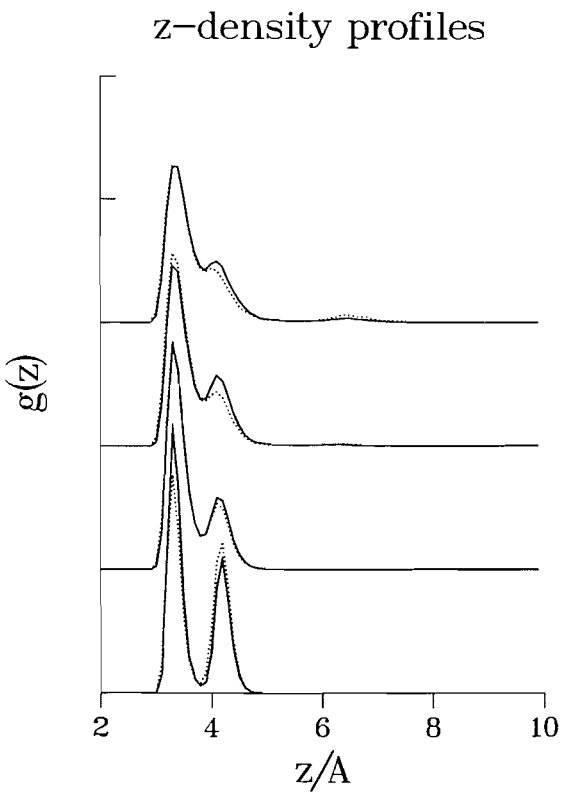

FIG. 3. The density profile as a function of the height of the centres of mass of the chlorine molecules above the graphite basal plane. The solid lines were calculated using the flat LB surface, and the dotted lines using the corrugated LB surface, both in combination with the 2LJ intermolecular potential. From bottom to top the data refer to temperatures of 100, 160, 200, and 240 K, respectively.

lower density flat structure; at lower temperatures one might expect the fraction of upright molecules to increase to some limiting value, unless another structure intervenes in the low temperature limit. The periodically replicated system at a coverage of 0.5 gives very similar results, showing that coverage is unimportant, at least for these parameters and conditions. When the system is heated to 160 and 200 K, the structure melts but remains compact. The thermal agitation destroys the dense upright rafts and, although a few of the molecules do stand up, the dominant structure is flat, as can be seen from the z-profile of the molecular centres of mass (Fig. 3). At 100 K there is a double peak, with one at the height (3–3.3 Å) appropriate to a layer flat on the surface and the other on the high-z side (≈4 Å) where one would expect to find the centres of mass of molecules which are standing up. At 160 and 200 K the second peak is much smaller. At 240 K a very small peak also appears at the bilayer position, $z \approx 6$–7 Å.

Raising the temperature to relatively high values produces two paradoxical kinds of behaviour: the spreading of the patch

to form a 2-D vapour, and promotion of molecules to form a partial bilayer in the patch. Ultimately every patch must evaporate because in the absence of an equilibrium vapour, both 2-D and 3-D, a patch can at best be metastable. Here, because of the limited calculations we can perform, we can detect only a massive and rapid evaporation of the patch which shows that the system has become completely unstable. The strong surface potential here favours 2-D evaporation. For 2LJ–LB this does not appear to happen up to 240 K, but there are indications that it is starting to happen at 240 K. Once it begins it probably happens rapidly, because the loss of coherence of the patch reduces the potential which prevents spreading. As the molecules spread they are largely parallel to the surface, reflecting the greater stability of this orientation for an isolated molecule. The existence of the corrugation term has relatively little effect on any of the dominant aspects of the behaviour of the patch, except that the density appears to be slightly larger for the flat case at low temperature; for obvious reasons it is impossible to determine the density of a finite patch precisely. The energies are entirely consistent with the observed structural behaviour; at low temperature the molecule–molecule energy favours the dense upright rafts at the expense of surface energy, and the collapse of the rafts at high temperature results in a net gain in surface energy and a greater loss of molecule–molecule energy. The formation of a partial bilayer, which can be detected in Fig. 3, provides a mechanism whereby the evaporation of a molecule to the 3-D vapour can occur in stages, each of which has a lower energy cost. For the strong LB surface potential a staged mechanism is probably necessary at the temperatures studied here.

No evidence of molecules standing up in any systematic way was found when the PS model was used to represent the intermolecular interactions. There are some important differences between PS and 2LJ in relative stabilities of different configurations, but the reduction in overall binding energy is probably the most important point here. The surface potential is strong enough to tip the balance in favour of T configurations, easily achieved in herringbone-like structures, rather than the parallel structures employed by a molecules in a layer which is predominantly standing up. The PS–LB (flat) system appears to be solid at 160 K, although there are some structural defects including occasional attempts to promote molecules to the second layer. The corrugated equivalent appears to be melted, but is still very compact. At 200 K there are clear signs that the system has become dilated and highly disordered, but it has not yet evaporated; at 240 K the system is even more dilated and shows weak indications of second layer molecules. Further calculation may well show that one or both of these systems would evaporate. In general, this model shows little tendency to have the molecules standing upright at any temperature studied here.

The 2LJPC–LB combination produces a result closer to PS–LB than to 2LJ–LB. Some molecules stand upright, but they are relatively few, and the effect of raising the temperature is to reduce the number upright (Fig. 4). By 160 K the structure is so defective that it almost certainly liquid. At 200 K the system is less dense but still compact, and at 240 K it shows evidence of fragmenting. The number of molecules standing up is slightly increased, but the separate peaks indicating two local minima have broadened to give a single peak with a pronounced shoulder on the high-z side. There is less evidence of promotion here than in the case of 2LJ–LB, probably because the intermolecular interactions in 2LJ favour upright molecules

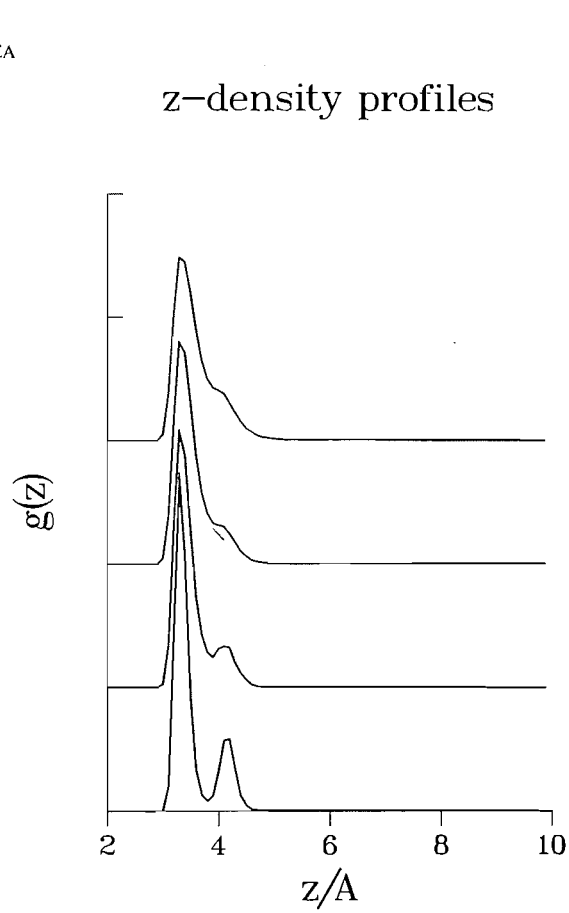

FIG. 4. The z-density profile for the 2LJPC–LB combination, following the conventions of Fig. 3.

more, and these are both precursors to and stabilizers of promotion.

It was at this stage that we introduce the FH model. As one might expect on the basis of the reduced well depth for the molecule–surface interaction, the influence of the surface is substantially reduced. At 100 K a patch of 2LJ molecules is very compact, with most of the molecules in the centre of the patch standing almost vertical, although many of those immediately at the edge are lying down. As the temperature is raised the system again becomes more disordered, but now the molecules continue to stand up, and the tendency to promote to the second layer is substantially greater (Fig. 5) than for any of the LB models. At 240 K the system is best described as a droplet sitting on the surface, and many of the molecules in the droplet are almost vertical, particularly those in the upper layer. Clearly, reducing the net binding to the surface tips the behaviour towards that found in layers of the 3-D solid (30), or what might be expected in 3-D droplets.

In this regime of reduced surface binding the PS model continues to predict flat herringbone structures (Fig. 6). The z-profile for the centre of mass positions shows virtually no molecules standing upright at 100 K, and heating the system to 160 K melts it, but produces only a slow growth in the number of upright molecules. The shape of the peak shows that the upright position is not a well defined local minimum, probably because the upright molecules are isolated from one another in a disordered environment. There are indications of molecules being promoted at higher temperatures, and of the patch evaporating laterally (2-D). By 240 K it has also started to evaporate off the surface.

The 2LJPC–FH combination yields results closely resem-

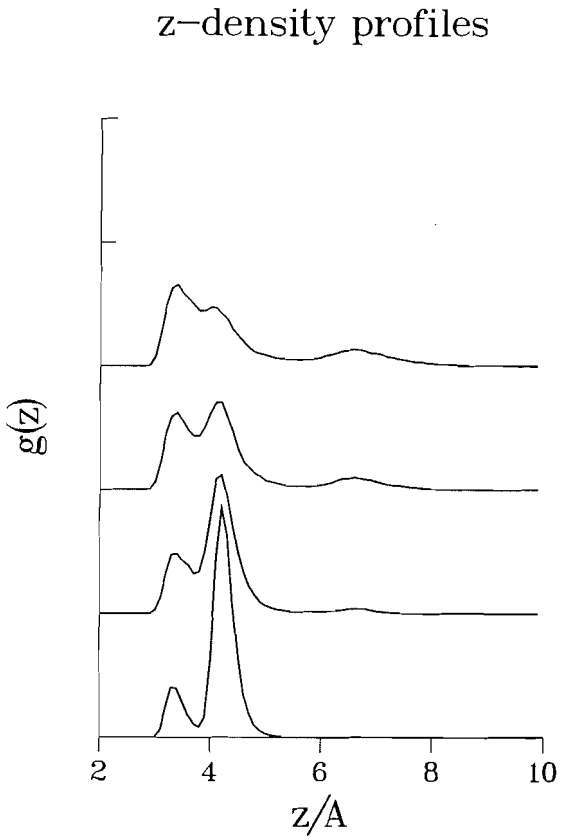

FIG. 5. The z-density profile for the 2LJ–FH combination, following the conventions of Fig. 3.

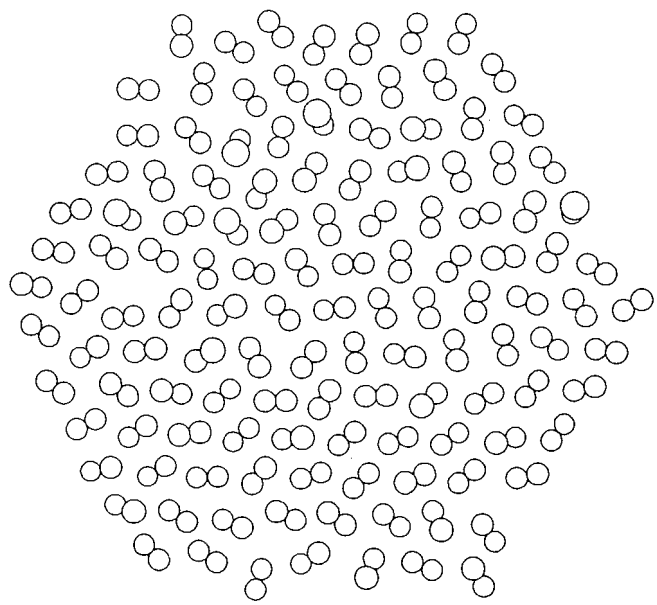

FIG. 6. The final configuration of the calculation for the PS–FH model at 100 K.

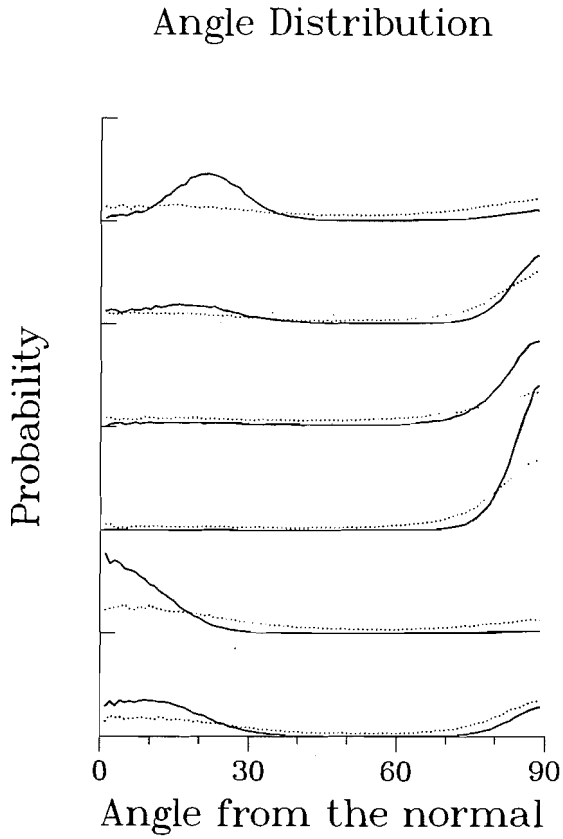

FIG. 7. The probability density for the angle of orientation of the bond axis measured from the normal to the surface. From bottom to top the data are for the 2LJ–LB, 2LJ–FH, PS–LB, PS–FH, 2LJPC–LB, and 2LJPC–FH, respectively. The solid lines were calculated for T = 100 K, and the dotted ones for 200 K.

bling those of 2LJ–FH. The low temperature structure is dominated by molecules standing upright in a dense mesh. One point of interest here is that the upright molecules are now canted at an angle of about 20° to the normal, a characteristic of the 2LJPC model which can also be seen in the 2LJPC–LB case (Fig. 7). Heating it to 160 K melts the system, and reduces the number of molecules standing up; some molecules are promoted to the second layer, where they tend to stand up. At 200 K the system forms a dense droplet (Fig. 8) having a lower layer which is mainly lying down and a top layer which has a significant number of upright molecules. At 240 K the droplet is still surprisingly compact, with only a few molecules separating from the main body.

Discussion

The main point which emerges from this survey of interaction potentials is that within this range of choices it is possible to produce a considerable variation in behaviour. The structures due to the 2LJ and PS models are sharply different whatever the surface potential, and 2LJPC lies somewhere between, closer to 2LJ in the FH case and to PS in the LB case. The balance between 2LJ-like and PS-like behaviour in 2LJPC is determined by the surface potential. A strong surface potential gives flat herringbone configurations which are PS-like in their behaviour, and a weaker surface permits some molecules to stand up and use the 2LJ-like parallel configurations (Fig. 1). The fact that 2LJPC is sometimes more like 2LJ than PS shows that the anisotropy due to the electrostatic interaction is important but not dominant, a result that is consistent with the work of Price and Stone on the 3-D solid (35). PS has a smaller well depth for configurations in which the molecules are parallel and nearly normal to the intermolecular vector, and this militates against the formation of rafts of upright molecules. As far as surface potentials are concerned, the weakening of the interaction with

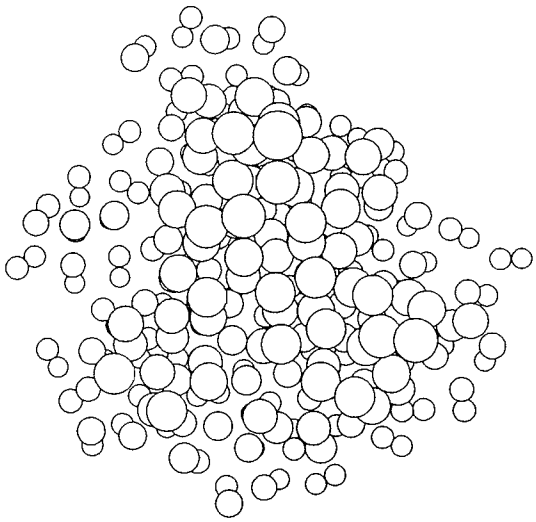

FIG. 8. The final configuration of the calculation for the 2LJPC–FH model at 200 K.

the surface in going from LB to FH results in a shift from a situation which is clearly more favourable to wetting, towards one in which wetting is probably incomplete.

The observed behaviour can almost certainly be rationalized by some combination of the molecule–molecule and molecule–surface interactions studied here. The 2LJ and 2LJPC models both predict upright rafts of molecules, as observed experimentally (25). However, in the 2LJ case the molecules stand vertical, leading inevitably to a regular triangular structure of the kind obtained for rare gases on graphite (41). 2LJPC leaves the molecules standing with a polar angle of 20° and a spacing of about 3.6 Å, in general agreement with the observed data. This canted structure seems more likely to yield a non-triangular lattice. We have not pursued this point, feeling that the uncertainties in the surface potential are so large that refining the models at this stage would be futile. The 2LJPC–FH combination apparently gives non-wetting behaviour (Fig. 8) when the temperature is high enough to melt the system, but appears to wet, at least incompletely, at low temperatures. The question of wetting behaviour is complex and difficult (44), and must also await further refinement of the molecule–surface interactions.

One important aspect neglected in the present paper is the role of surface mediation (45, 46) in modifying interactions among the molecules. The effects of surface mediation on the structure can be predicted, at least qualitatively. It reduces the attractive interactions between atoms at equal heights above the surface, by as much as 16–20% for atoms near the optimum height, while increasing the attraction between atoms more or less vertically above one another. The dominant effect that can be expected is a reduction in the effective well depth for intermolecular interaction, and a consequent increase in the relative importance of molecule–surface interactions. The second aspect deals with the competition between different overlayer structures. Inspection of the pair geometries of important configurations shows that this effect, although reducing attraction forces between molecules, does so differentially, favouring configurations in the following order: upright pairs, one upright plus one flat, flat and parallel, flat T, and, least of all, flat linear; bilayer configurations are actively favoured. Thus, surface mediation of interactions is likely to promote wetting by increasing the relative importance of molecule–surface interactions, to favour upright structures in the monolayer, and to favour bilayer formation over bulk condensation (because of the rapid decay of this mechanism with height above the surface).

The fact that the range of models treated here appears to be able to support a rich variety of phase behaviour is a mixed blessing. It is clear that progress towards a reliable explanation of the observations cannot be made until further experimental information becomes available. Of particular interest is the heat of adsorption, especially the limiting isosteric heat. This can be obtained from the analysis of isotherms in the Henry's Law region. We have calculated Henry's Law coefficients K_H for both molecule–surface models used here, and obtained the isosteric heat from the slope of ln (K_H) vs. $1/T$ (47). The resulting values for the low temperature, low coverage limit are 2970 K for LB and 1730 K for FH (24.7 and 14.4 kJ/mol, respectively). The experimental precision is such that it should be relatively easy to determine which is the more appropriate value; in fact, these values probably set limits to the true isosteric heat. While the isosteric heat would be useful, a detailed thermodynamic investigation of the kind done for nitrogen on graphite (5, 12) would be even more helpful in unravelling the details of this complex system.

Structural, spectroscopic, and electron paramagnetic resonance studies on two solid phases of bis-dipropylammonium tetrachlorocuprate(II) (DPACC)

MARCUS R. BOND,[1] TIMOTHY J. JOHNSON, AND ROGER D. WILLETT
Chemical Physics Program, Washington State University, Pullman, WA 99163-4620, U.S.A.

Received September 17, 1987

This paper is dedicated to Professor James A. Morrison

MARCUS R. BOND, TIMOTHY J. JOHNSON, and ROGER D. WILLETT. Can. J. Chem. **66**, 963 (1988).

Bis-dipropylammonium tetrachlorocuprate(II) exists in two known crystalline phases. Below 330 K (β phase) the crystal is orthorhombic *Pbca* with cell constants (at 293(1) K) a = 13.029(2) Å, b = 15.252(3) Å, c = 20.997(2) Å, V = 4175.5(9) Å^3. The crystal undergoes a phase transition at 330 K to the α phase, which is monoclinic $P2_1/n$ with cell constants (at 342(1) K) a = 13.277(4) Å, b = 10.280(3) Å, c = 16.362(13) Å, β = 104.31(5)°, V = 2164(2) Å^3. The β phase consists of discrete, distorted tetrahedral $CuCl_4^{2-}$ anions, which are surrounded by dipropylammonium cations. Hydrogen bonding between the anions and cations results in a two-dimensional network of linked anions coplanar with the c-glide plane of the unit cell. The terminal carbon of one of the dipropylammonium chains assumes the higher energy *gauche* conformation while all other carbon and nitrogen atoms are found in the *anti* conformation. The local geometry of the α phase is very similar to that of the β phase. Powder electron paramagnetic resonance measurements in both phases confirm the persistence of the β phase anion geometry in the α phase. The disorder and increased thermal motion of the alkyl groups of the cation account for observed differences between the crystal structures of the two phases. This phase transition is similar to those found in long chain monoalkylammonium metal halide layer compounds that involve "melting" of the alkyl chain. Near infrared – visible spectra at 77 and 295 K show two distinct peaks at 12 700 and 9800 cm^{-1} in the first case and a very broad band maximizing at 11 200 cm^{-1} in the latter case. The highest-energy d–d transition correlates well with those of other $CuCl_4^{2-}$ anions of varying tetragonal distortion from tetrahedral geometry. The present data are used in conjunction with earlier data to develop the correlation between the highest-energy d–d transition and the distortion from tetrahedral symmetry.

MARCUS R. BOND, TIMOTHY J. JOHNSON et ROGER D. WILLETT. Can. J. Chem. **66**, 963 (1988).

Le tétrachlorocuprate(II) de bis-dipropylammonium existe sous deux phases cristallines connues. En-dessous de 300 K (phase β), le cristal est orthorhombique, groupe d'espace *Pbca* avec (à 293(1) K) a = 13,029(2), b = 15,252(3) et c = 20,997(2) A et V = 4175,5(9) Å^3. Le cristal subit une transition de phase à 330 K qui le transforme en phase α, monoclinique, groupe d'espace $P2_1/n$ avec (à 342(1) K) a = 13,277(4), b = 10,280(3) et c = 16,362(13) Å, β = 104,31(5)° et V = 2164(2) Å^3. La phase β comprend des anion tétraèdres déformés de $CuCl_4^{2-}$ qui sont entourés de cations dipropylammonium. Les liaisons hydrogènes entre les anions et les cations conduisent à la formation d'un réseau bidimensionnel d'anions coplanaires liés au plan de glissement c de la cellule unitaire. Le carbone terminal d'une des chaînes du groupement dipropylammonium se trouve dans une conformation *gauche* d'énergie élevée; tous les autres atomes de carbone et d'azote se retrouvent dans une conformation *anti*. La géométrie locale de la phase α est trés semblable à celle de la phase β. Des mesures de resonance paramagnétique électronique effectuées sur des poudres confirment que la géométrie de l'anion de la phase β persiste dans la phase α. Le désordre ainsi qu'une augmentation du mouvement thermique des groupements alkyles du cation expliquent les différences qui sont observées entre les structures cristallines des deux phases. Cette transition de phase est semblable à celle qui est observée dans les couches d'halogénures de monoalkylammonium métalliques à longues chaînes impliquant la «fonte» de la chaîne alkyle. Les spectres proche-infrarouge – visible, déterminés à 77 et 295 K, présentent deux bandes distinctes à 12 700 et 9800 cm^{-1} dans le premier cas et une bande très large avec maximum à 11 200 cm^{-1} dans le deuxième cas. Il existe une bonne corrélation entre la transition d–d de haute énergie et celles d'autres anions du $CuCl_4^{2-}$ présentant des distorsions variées par rapport à la géométrie tétraédrique. On utilise ces données de concert avec d'autres obtenues antérieurement pour développer une corrélation entre la transition d–d de haute énergie et la distorsion par rapport à la symétrie tétraédrique.

[Traduit par la revue]

Introduction

Compounds of the A_2CuX_4 (A = monopositive cation, X = halide) system have been found to exhibit a number of interesting phase transitions. The $(RNH_3)_2CuX_4$ systems are known to crystallize as layers of corner-sharing CuX_6^{4-} octahedra with the alkylammonium cations sandwiched between the layers (1). The long chain alkylammonium compounds, in particular, undergo phase transitions involving the "melting" of the alkyl groups while leaving the copper halide layers rigid (1, 2). When bulkier cations are used, these systems are known to crystallize as isolated CuX_4^{2-} ions surrounded by the cations. A number of these compounds exhibit thermochromic phase transitions (e.g., the diethylammonium and *N*-methylphenethylammonium salts) in which the coordination geometry of the copper(II) ion changes (3). The $[(CH_3)_4N]_2CuX_4$ systems exhibit commensurate–incommensurate phase transitions that involve rotation of the CuX_4^{2-} tetrahedra (4).

White and co-workers (5) recently studied the thermal properties of the $[(C_nH_{2n+1})_2NH_2]_2CuCl_4$ salts (n = 2–6) by differential scanning calorimetry and found that the title compound undergoes a solid–solid phase transition at 330 K with ΔH_{trans} = 4.26 kJ mol^{-1}. This transition has also been observed by Tomovic *et al.* (6). There has also been continued interest in correlating the d–d transition energies of tetrahedrally coordinated Cu(II) ions with varying degrees of tetragonal distortion (7, 8). The purpose of this paper is to report the crystal structures and spectroscopic properties of two solid phases of bis-dipropylammonium tetrachlorocuprate(II) (DPACC) (the α phase existing between the transition temperature at 330 K and the melting point at 353 K, the β phase existing below 330 K), and to correlate the maximum d–d transition energy of the room

temperature phase with that of other distorted tetrahedral $CuCl_4^{2-}$ ions.

Experimental

Synthesis

Crystals of DPACC were grown by slow evaporation of an ethanolic solution containing stoichiometric amounts of dipropylammonium chloride and anhydrous copper(II) chloride. The dipropylammonium chloride was prepared by neutralizing dipropylamine (Aldrich, 99%) with concentrated HCl, recrystallizing the product from water, and washing with acetone. The light green crystals, which often grow as large (~1 cm^3) plates, exhibit a gradual thermochromism (green to yellow with increasing temperature). Samples for immediate use may be quickly prepared by fusing together stoichiometric quantities of the reagents at ~100°C with stirring. The sample for spectroscopic study was prepared in this manner.

Crystal data, β phase

$C_{12}H_{32}Cl_4CuN_2$ fw = 395.75

Orthorhombic, *Pbca*(no. 61) (systematic absences: $0kl$, $k = 2n + 1$; $h0l$, $l = 2n + 1$; $hk0$, $h = 2n + 1$; $h00$, $h = 2n + 1$; $0k0$, $k = 2n + 1$; $00l$, $l = 2n + 1$); at 293 K: $a = 13.029(2)$ Å, $b = 15.252(3)$ Å, $c = 20.997(2)$ Å, $V = 4175.5(9)$ Å^3 (from 25 reflections in the range $29° < 2\theta < 30°$) (ref. 9); $Z = 8$, $\rho_{calc} = 1.30$ g/cm^3, $F(000) = 1720$ e.

Structure determination, β phase

Radiation, Mo $K\alpha_1$, $\lambda = 0.70926$ Å (graphite monochromator); light-green, block-shaped crystal, 0.35 mm × 0.35 mm × 0.43 mm, glued to a glass fiber. Reflections (Nicolet R3m/E four-circle diffractometer, 0.85° ω scans, scan speed: 4.88–29.3°/min): total (to $2\theta = 45°$; $0 \le h \le 14$; $0 \le k \le 16$; $0 \le l \le 22$) 3095, 6 rejected as asymmetric; total unique, 2718; total used ($|F_o| \ge 3\sigma(|F_o|)$), 1858. Check reflections ($\bar{2}\,\bar{4}\,5$, $\bar{6}\,0\,4$, $\bar{7}\,1\,6$) collected every 100 reflections, variations within counting statistics. Lorenz polarization corrections and crystal decay correction based on a curve fitted to the intensities of the standard reflections were applied. Empirical absorption correction assuming ellipsoidal crystal shape ($\mu = 15.6$ cm^{-1}; limits of transmission, 0.38–0.42; $R_{merge} = 0.0176$ (before), 0.0095 (after)). Isotropic extinction correlation made; $F = F_{calc}/[1.0 + 0.002 \times X \times F^2/\sin(2\theta)]^{0.25}$, X refined to 0.00013. Weighting scheme: $w^{-1} = \sigma^2(F_o) + g|F_o|^2$, g refined to 0.0. Temperature factor: $T = \exp[-2\pi^2(h^2a^{*2}U_{11} + k^2b^{*2}U_{22} + l^2c^{*2}U_{33} + 2klb^*c^*U_{23} + 2hla^*c^*U_{13} + 2hkab^*U_{12})]$.

Structure solution and refinement were achieved using the SHELXTL package of programs provided by Nicolet (10) (scattering factors from ref. 11). The structure was solved using direct methods and refined using a blocked cascade least-squares method. Copper and chlorine atom positions were identified from the E-map produced from direct methods, while positions of the remaining non-hydrogen atoms were identified from subsequent electron density difference maps. The hydrogen atoms were also located on the electron density difference map and were included in the refinement but constrained to a C—H distance of 0.096 Å, an N—H distance of 1.034 Å, and an idealized geometry. Anisotropic thermal parameters are refined for all non-hydrogen atoms and a common isotropic thermal parameter was refined for the hydrogen atoms. Final refinement with 186 least-squares parameters gave $R = 0.0512$ and $R_w = 0.0318$ (0.0825 and 0.0343, respectively, for all data). Goodness of fit = 1.429, $|\Delta/\sigma|_{mean} = 0.005$, $|\Delta/\sigma|_{max} = 0.023$. The excursions on the final electron density difference map ranged from −0.338 to 0.366 e/Å^3.

Positions and equivalent isotropic thermal parameters for non-hydrogen atoms are listed in Table 1, anisotropic thermal parameters in Table 2, and interatomic distances and angles in Table 3. An ORTEP plot of the formula unit with atom labels is shown in Fig. 1, while a stereographic diagram of the structure is shown in Fig. 2. Tables of observed and calculated structure factors and hydrogen atom positions are included in the supplementary material.[2]

[2]Copies of these tables and figures may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

was measured with an iron–constantan thermocouple prior to mounting the crystal. Fluctuations of a few tenths of a degree Kelvin in the temperature were observed while driving the diffractometer angles. Reflections (Syntex $P2_1$ four-circle diffractometer upgraded to Nicolet P3F specifications, 1.0° ω scans, scan speed: 3.91–29.3°/min): total (to $2\theta = 40°$; $0 \leq h \leq 12$; $0 \leq k \leq 9$; $-15 \leq l \leq 15$) 2300, 3 rejected as asymmetric, 1 rejected due to background imbalance; total unique, 2018; total used ($|F_o| \geq 3\sigma(|F_o|)$), 1431. After measuring 1080 reflections the crystal was found to have moved slightly (due, presumably, to a small amount of surface melting). The temperature was then lowered to 342(1) K and data collection resumed on the same crystal. Reflection intensities are assumed to be relatively unchanged by the temperature drop since the intensities of the standard reflections were the same, within counting statistics, immediately before and after the temperature change. Check reflections ($\bar{5}\ \bar{3}\ 0$, $\bar{1}\ 2\ \bar{5}$) were collected every 45 reflections with an approximate 17% decrease in intensity over the course of the data collection. The rate of intensity loss was unaffected by the above mentioned temperature drop. A crystal decay correction based on a curve fitted to the intensities of the check reflections over time was applied as were Lorenz polarization corrections. Empirical absorption correction assuming ellipsoidal shape ($\mu = 15.0\ cm^{-1}$; limits of transmission, 0.70–0.84; $R_{merge} = 0.0359$ (before), 0.0133 (after)). Intensities of equivalent reflections were averaged ($R_{merge} = 0.0158$). Weighting scheme: $w^{-1} = \sigma^2(F_o) + g|F_o|^2$, $g = 0.00006$. Temperature factor: $T = \exp[-2\pi^2(h^2a^{*2}U_{11} + k^2b^{*2}U_{22} + l^2c^{*2}U_{33} + 2klb^*c^*U_{23} + 2hla^*c^*U_{13} + 2hka^*b^*U_{12})]$.

Structure solution and refinement were achieved using the SHELXTL package of programs provided by Nicolet (12) (scattering factors from ref. 11). The structure was solved using direct methods and refined using a blocked cascade least-squares method. Copper and chlorine atom positions were identified from the *E*-map produced following direct methods. Positions of the remaining non-hydrogen atoms were identified from subsequent electron density difference maps. An unusually large thermal parameter on C(6) suggested disorder of the atom. The disordered atom (C(6a)) was refined with the following constraints: C(5)—C(6a) distance ~1.49 Å; C(4)—C(6a), C(6)—C(6a) distance ~2.43 Å; S.O.F.(C(6a)) + S.O.F.(C(6)) = 1(S.O.F. = site occupation factor, S.O.F. C(6) refined to 0.86(2)). The hydrogen atoms were not visible on the electron density difference map but reasonable positions were calculated, with the exception of the hydrogen atoms bonded to C(6) or C(6a), constraining the atoms to a C—H distance of 0.96 Å, an N—H distance of 1.034 Å, and an idealized geometry. Anisotropic thermal parameters were refined for all non-hydrogen atoms, except C(6a), and the hydrogen atom thermal parameters were fixed at 1.2 times the equivalent isotropic thermal parameter of the carbon or nitrogen atom to which the hydrogen atoms

are bonded. Final refinement with 177 least-squares parameters gave $R = 0.0557$ and $R_w = 0.0413$ (0.0823 and 0.0430, respectively for all data). Goodness of fit = 1.661, $|\Delta/\sigma|_{mean} = 0.006$, $|\Delta/\sigma|_{max} = 0.022$. The excursions on the final electron density difference map ranged from −0.304 to 0.358 e/Å^3.

Positional and equivalent isotropic thermal parameters for non-hydrogen atoms are listed in Table 1, anisotroic thermal parameters in Table 2, and interatomic distances and angles in Table 3. An ORTEP plot of the formula unit with atom labels is shown in Fig. 3, while a stereographic diagram of the structure is shown in Fig. 4. Tables of observed and calculated structure factors and hydrogen atom positions are included in the supplementary material.[2]

Electron paramagnetic resonance spectroscopy

Electron paramagnetic resonance (epr) spectra were measured on a Varian E-3 X-band spectrometer. The finely powdered samples were packed in a 1 mm diameter glass tube. Temperature control was attained via circulation of heated Dow–Corning 200 Fluid around the sample tube. The sample tube was contained in a larger, vacuum-jacketed quartz tube, which was connected by rubber tubing to a reservoir in which returning fluid was collected and heated. Circulation of the fluid was achieved with a centrifugal pump. Sample temperature was measured by an iron–constantan thermocouple placed in the fluid ~8 cm upstream from the sample. Variations in thermocouple voltage indicated that temperature fluctuation was within ±1 K of the desired temperature.

Optical spectroscopy

Ultraviolet–visible – near infrared spectra were recorded using a Cary Model 14 spectrophotometer. The DPACC samples were melted to thin films held between two quartz plates. A specially constructed device was used to record both high and low temperature spectra; a chromel–alumel thermocouple served to measure the temperature.

Results

Crystal structure of the β phase

The structure of the β phase of DPACC consists of discrete $CuCl_4^{2-}$ anions and dipropylammonium cations. Since all atoms sit on general positions in the unit cell, there is no inherent symmetry within the individual ions. The geometry of the $CuCl_4^{2-}$ ion can be described as a tetragonally distorted tetrahedron with idealized D_{2d} point symmetry, i.e., a tetrahedron compressed along one of its S_4 axes. The anion geometry is

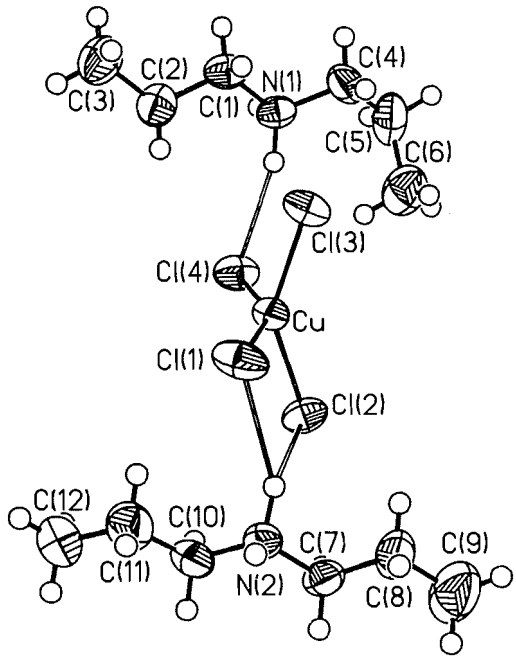

FIG. 1. View of a formula unit in the β phase of DPACC. Open bonds are hydrogen bonds.

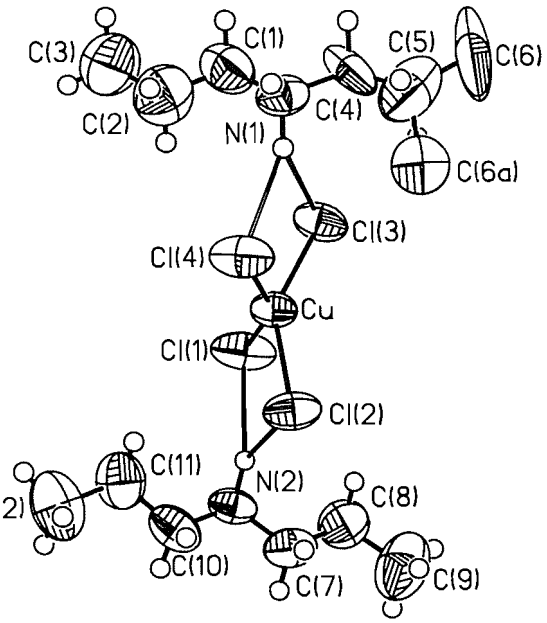

FIG. 3. View of the formula unit in the α phase of DPACC. Open bonds represent hydrogen bonds. C(6) was refined in two positions with C(6a) having an isotropic thermal parameter and a refined occupancy of 14(2)%.

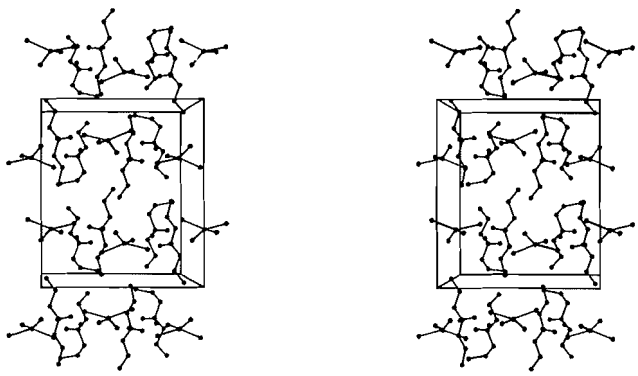

FIG. 2. Stereoview of the β phase of DPACC with the *b*-axis vertical, the *a*-axis horizontal, and the *c*-axis out of the plane of the paper. The box represents the boundaries of the unit cell. Only half of the unit cell along the *c*-axis is depicted. Chain 1 (N(1)) is the chain with a *gauche* configuration, and makes an angle with the normal to the *xz* plane of 29°. Only amino protons are shown for clarity.

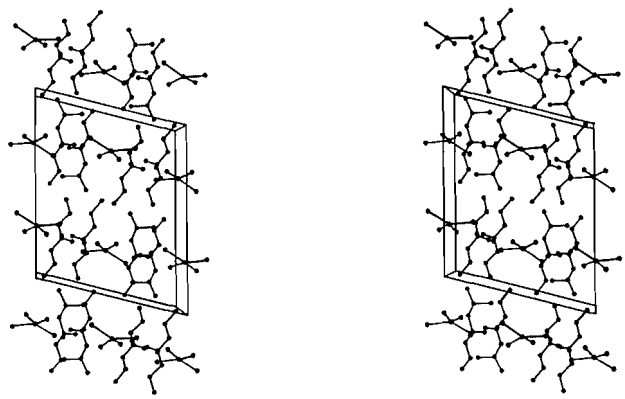

FIG. 4. Stereoview of the α phase of DPACC with the *c*-axis vertical, the *a*-axis horizontal, and the *b*-axis into the plane of the paper. The box represents the boundaries of the unit cell. Chain 1 appears with a disordered terminal carbon and makes an angle of 17° with the normal to the *xy* plane. Only amino protons are shown for clarity.

fairly regular with an average Cu—Cl bond distance of 2.252(5) Å, an average *trans* Cl—Cu—Cl bond angle of 146.6(15)°, and an average *cis* Cl—Cu—Cl bond angle of 94.8(5)°. The dihedral angle of 46.0° between planes Cl(1)—Cu—Cl(3) and Cl(2)—Cu—Cl(4) indicates a geometry halfway between tetrahedral and square planar. Slight distortions of chloride atom pairs related by a twofold rotation about the distortion axis, i.e., Cl(1) and Cl(4), and Cl(2) and Cl(3), are found, which destroy rigorous D_{2d} symmetry. The Cu—Cl bond length in each pair is the same within error while the difference in average bond length between the pairs is on the order of 0.01 Å. Due to electronic repulsion, the pair with the shorter average bond length (Cl(1) and Cl(4)) possesses the larger *trans* Cl—Cu—Cl bond angle. Distortions from C_{2v} symmetry are indicated by the *cis* Cl—Cu—Cl angles. The smallest *cis* angle, Cl(1)—Cu—Cl(2), results from the symmetric, bifurcated hydrogen bond (*vide infra*) to both chloride ions causing the angle to close relative to the Cl(3)—Cu—Cl(4) angle (see Table 3). The bifurcated hydrogen bond to Cl(3) and Cl(4) is asymmetric (with a difference of 0.23 Å between the bond lengths), making the C_{2v} symmetry description only approximate. The dipropylammonium cations all exist in a staggered conformation with the carbon and nitrogen atoms *anti* (dihedral angle ~180°), with the exception of C(6), which is *gauche* with respect to N(1) (dihedral angle = 66.8°) (cf. Fig. 2).

Hydrogen bonding between the dipropylammonium cations and the tetrachlorocuprate anions creates a two-dimensional network of linked anions parallel to the *xz* plane and coplanar with the *c*-glide plane with adjacent layers related by inversion. This hydrogen bonding network is shown in Fig. 5 with hydrogen bond lengths and angles given in Table 4. The anions do not lie on the plane; rather, the copper ions are displaced ~0.7 Å from either side of the plane such that the least-squares plane of the copper ions defines the layer plane. The cations are situated

such that one of the hydrogen atoms bonded to nitrogen forms a bifurcated hydrogen bond with two chloride ions while the other amino hydrogen atom forms a single hydrogen bond to a chloride ion of a different $CuCl_4^{2-}$ group. The pair of chloride ions with extra hydrogen bonds (Cl(2) and Cl(3)) are the pair with the longer average Cu—Cl bond length. The anions in a layer are further arranged in columns parallel to the *c*-axis of the crystal. Neighboring ions in the column are related by a *c*-glide such that the orientation of a particular anion is the mirror image of its neighbors in the column while the next nearest neighbors in the column are related by a lattice translation along the *c*-axis.

Crystal structure of the α phase

While the gross features of the α phase structure are similar to those of the β phase, there are distinct differences, the most conspicuous of which is the change in lattice parameters. (Cell constants will henceforth be subscripted with an α or a β to distinguish between the two phases.) The b_α-axis corresponds to approximately one-half the c_β-axis, thus doubling the number of lattice translations. However, the b_α-axis is actually slightly *less* than one-half the length of the c_β-axis, indicating a macroscopic *contraction* along the c_β-axis of the crystal in passing into the high temperature phase. The γ_β angle increases from 90° to 104.31(5)°, the result of the layers moving parallel to the *a*-axis. The $b_\beta(c_\alpha)$-axis shows the largest increase above the phase transition and indicates an increased interlayer separation.

As a result of the halving of the c_β-axis, anions related by a *c*-glide in the β phase are related by a unit cell translation along the *b*-axis in the α phase. This causes the orientations of the anions in a given column to be the same, in contrast to the β phase where nearest neighbors in the column have mirror symmetry. Adjacent columns are related by the 2_1-axis parallel to *b* such that the orientations of anions in adjacent columns differ by a 180° rotation. If the anion is considered to possess D_{2d} symmetry, it is found for both phases that all of the anions are oriented such that the S_4-axis of the anion lies almost perpendicular to the layer plane, although there are minor deviations of the axis from this orientation that affect the epr spectra (*vide infra*). If the S_4-axis of a particular anion in the β phase is arbitrarily given a direction, it is then found that in the β phase the directions of the principal axes of its neighbors in the column point in the opposite direction due to the mirror symmetry. Thus, in the β phase the principal axes of one-half of the anions point in one direction while the axes of the other half point in the opposite direction. In the α phase the principal axes of the anions in a given column all point in the same direction; however, the axes of neighbouring columns in the layer point in the opposite direction, since they are related by a 180° rotation to the anions in the first column. Although the *total* number of anions found with a particular direction of their S_4 axes does not change between the two phases, the directions of the S_4 axes are reversed for one-half of the anions in going from the β to the α phase.

To understand the development of the monoclinic angle it is profitable to consider the relationship between the two layers found in a unit cell. As stated previously, the two layers in a unit cell are related by inversion in the β phase. Nearest neighbor columns in adjacent layers of the same unit cell are also related

by a center of inversion. For example, the nearest neighbor in the adjacent layer of a column whose axis passes through $x = 0.5641$ and $y = 0.2500$ is the column whose axis passes through $x = 0.4359$ and $y = 0.7500$, and the two are related by the inversion center at $x = 0.5000$, $y = 0.5000$, and $z = 0.5000$. The plane defined by these two column axes makes an angle of 102.4° with respect to the xz plane, which is very close to the value of the monoclinic angle, β_α. By symmetry these interlayer planes for all such pairs of columns are parallel; however, since lattice translations along the b_β-axis are perpendicular to the xz plane, none are coplanar. To achieve the c_α-axis translational symmetry, pairs of layers, other than the pair in the origin unit cell, must move in the x-direction until these interlayer planes are approximately coplanar. Referring to Fig. 2, the pair of layers that lie one positive b_β-axis translation from the origin unit cell layers must shift by 3.8 Å in the negative x direction, while the pair of layers that lie one negative b-axis translation away must shift 3.8 Å in the positive x direction. This produces a structure that has the approximate unit cell parameters of the α phase with the columns staggered about planes parallel to the yz-plane of that phase. The paired layers also shift by ~0.5 Å in the x direction relative to each other such that the plane defined by the pair of columns related by inversion makes a larger angle with the x-axis.

The molecular geometry of the α phase is very similar to that of the β phase. The $CuCl_4^{2-}$ ion exhibits pseudo D_{2d} symmetry (average Cu—Cl bond length = 2.248(10) Å, average *trans* Cl—Cu—Cl angle = 146.4(14)°, average *cis* Cl—Cu—Cl angle = 94.8(6)°). The *trans* chloride ion pairs have bond lengths that are equal within error while the difference between the average bond lengths of the pairs is 0.015 Å. Both of the bifurcated hydrogen bonds are symmetric in this phase, resulting in smaller *cis* angles between pairs of chlorides bonding to the same hydrogen atom than for the other pairs. For unknown reasons, the Cl(1)—Cu—Cl(2) angle is significantly smaller than the Cl(3)—Cu—Cl(4) angle. Hydrogen bonding links individual anions together in a manner analogous to that of the β phase to create a layer structure coplanar with the xy plane. Hydrogen bond lengths and angles for the α phase are listed in Table 4 with a view of the hydrogen bonding in Fig. 6. Adjacent layers are related by inversion, as in the β phase; however, the structure of the layers is somewhat different. Both dipropylammonium chains assume an *anti* configuration; however, C(6) is *gauche* relative to N(1) 14(2)% of the time (dihedral angle = 53.8°).

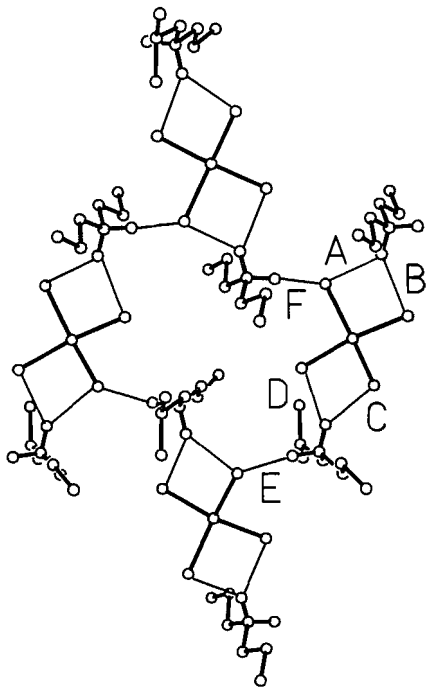

FIG. 6. View of the hydrogen bonding in a layer of the α phase of DPACC. The letters correspond to the letters in the far left column of Table 4, II.

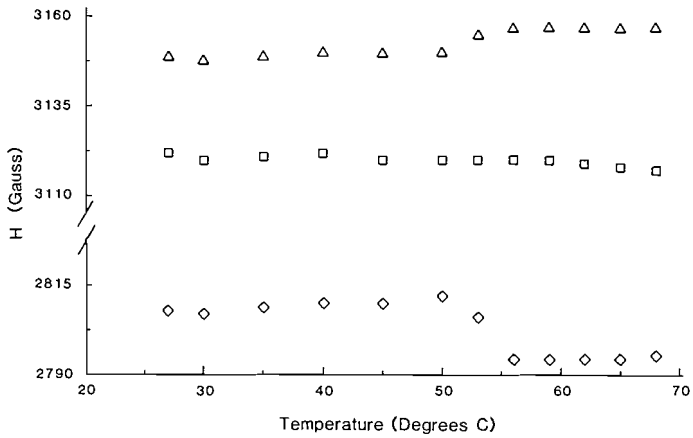

FIG. 7. $H_\parallel$ (◇), $H_{\perp,\min}$ (□), and $H_{\perp,\max}$ (△) (in gauss) versus temperature (in °C).

Electron paramagnetic resonance spectroscopy

Powder epr spectra were taken at temperatures between 27 and 68° C. Typical axial spectra were obtained for both phases with no indication of hyperfine interactions in the spectra. Two features were always found in the spectra corresponding to $g_\parallel$ (low field) and $g_\perp$ (high field), while the high temperature spectra often developed structure at intermediate fields resulting from a preferred orientation of the crystallites. Single crystal spectra exhibited only a single absorption line. This, coupled with the lack of hyperfine lines, indicates that sufficient exchange coupling exists between magnetically inequivalent anions to produce an exchange-averaged spectrum. Thus, the crystal g values represent geometric averages of the individual molecular g tensors. A plot of $H_\parallel$, $H_{\perp\min}$, and $H_{\perp\max}$ versus T is shown in Fig. 7, where $H_{\perp\min}$ is defined as the minimum in the derivative spectrum of the high field line. As the two figures show, there is very little difference between the spectra in the two phases. The most significant changes start at 56° C where $H_\parallel$ decreases by ~15 G while $H_\perp$ increases by ~5 G and broadens slightly. Although it is difficult to tell from the powder spectra, it appears that the width of the $g_\parallel$ peak does not change significantly. Since the copper chloride geometry is virtually identical in the two phases the similarity of the spectra in the two phases is not unexpected. The peak shift at the phase transition is easily explained by the change in anion (and, hence, g tensor) orientation between the two phases. Assuming D_{2d} symmetry for the anions, it is found in both phases that the S_4 axes of the anions are approximately perpendicular to the layer plane (*vide supra*); however, in both phases the anions are rotated by a small amount about an axis parallel to the a-axis (the S_4 axis corresponds to a principal axis of the g tensor of the anion). In the β phase the principal axis of an anion (assumed to be the normal to the least-squares plane calculated for the atoms of the anion)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/07/12
For personal use only.

forms an angle of 11° with respect to the normal to the layer plane, while in the α phase it forms an angle of 4° with respect to the normal. The anions on the eight general positions in the β phase and the four general positions in the α phase are oriented such that half of the principal axes are rotated in one direction while the other half are rotated an equal amount in the opposite sense. Due to exchange averaging the $g_{\|}$ value of the crystal is less than the $g_{\|}$ value for a single D_{2d} anion. Since the principal axes of the anions are more closely aligned in the α phase than in the β phase, an increase in the value of $g_{\|}$ (crystal) and a decrease in the value of $g_{\perp}$ (crystal) going from the β to the α phase is expected. It should also be noted that the orientations of the anions with respect to rotations about their principal axes differ from site to site; however, the anion g tensors have pseudo-axial symmetry (from the quasi-D_{2d} symmetry of the anion) and such differences should be of little consequence in the epr spectrum. No spectrum was observable in the melt due to extreme broadening of the line.

Optical spectroscopy

Visible – near infrared spectra of DPACC were studied as a function of temperature. At room temperature, in addition to charge-transfer bands at 26 100 and 29 200 cm^{-1}, one very broad peak was observed in the near infrared – visible region. At 25°C this highly asymmetric peak maximized at 895 nm (11 200 cm^{-1}), having a slight shoulder near 800 nm (12 500 cm^{-1}) and displaying a long red tail into the ir region. Lowering the temperature to 78 K removed much of this tail and resolved at least two bands within the room temperature envelope, one fairly sharp band at 790 nm (12 700 cm^{-1}) and a broader less intense band maximizing near 1020 nm (9800 cm^{-1}).

Attempts to record absorption spectra at higher temperatures resulted in either thermal- or photo-decomposition. If the sample remains in the beam the higher energy band decreases in intensity more quickly (resulting in an apparent red shift), and if left in the beam at higher temperatures for any length of time, both bands eventually extinguish. Reported peak positions are from spectra recorded from freshly prepared samples.

Discussion

Within the dipropylammonium chain the *gauche* conformation has a higher potential energy than the *anti* conformation; therefore, in the β phase the assumption of a *gauche* conformation by one of the chains must entail a lowering of the crystal packing energy. To understand the difference between the conformation of the two dipropylammonium chains in the β phase it is necessary to consider their positions in the structure and the manner in which this affects the energy of the crystal. Both chains lie with their lengths approximately perpendicular to the xz plane; however, the axis of chain 1 (N(1)) lies at an angle of 29(2)° with respect to the normal to the xz plane while the axis of chain 2(N(2)) lies at an angle of 13.0(4)°. (The angle for chain 1 was calculated by averaging the angles between the normal to the xz plane and the vectors between atoms in the sets {N1, C2, C5} and {C1, C3, C4}; the chain 2 angle was calculated in a similar manner.) The length of the projection of an ideal dipropylammonium chain (bond lengths = 1.5 Å, bond angles = 109.5° excluding hydrogen atoms) with an *anti* conformation onto its chain axis is 7.35 Å, while for a chain with one terminal carbon in a *gauche* conformation the corresponding length is only 6.12 Å (the bond to the *gauche* carbon is perpendicular to the chain axis). Since the interlayer spacing in the structure is 7.63 Å and the chains are offset by 0.6–0.8 Å from the center of the layer, chains with axes perpendicular to the layer are forced to extend into the neighboring layer. This is the case for chain 2, which, even though it is canted from the normal to the layer plane, has a length in the y direction of 7.25 Å ($b \times [y(C(9)) - y(C(12))]$). Chain 1, however, is canted at a much larger angle and has one terminal carbon *gauche*, resulting in a much smaller length in the y direction ($b \times [y(C(6)) - y(C(3))] = 5.47$ Å, well within the interlayer distance). Thus, assumption of the *gauche* conformation by C(6) allows the layers to be closer than would an *anti* conformation, lowering the crystal packing energy through increased van der Waals interactions between the layers.

In the α phase the dipropylammonium chains occur primarily in the *anti* conformation. Although disorder was refined only for C(6), the magnitude of the thermal parameters suggests that disorder is also possible for other carbon atoms. Assumption of the lower energy *anti* conformation and the increased entropy resulting from disorder of the alkyl chains appear to be the driving force behind the β → α phase transition. Preliminary nmr studies do show some resonance line shifting and motional narrowing with temperature; however, a more careful nmr study of the phase transition is necessary to quantify these results and determine the amount of cationic disorder at the phase transition. The following discussion will demonstrate that the structural changes accompanying the phase transition occur to accommodate the increased motion of the alkyl chains.

The increase in interlayer spacing from 7.63 to 7.93 Å allows greater freedom of movement for the alkyl groups, particularly for chain 1 of the β phase, which is now free to assume a completely *anti* configuration. This also allows the angle between the β phase, chain 1 axis, and the normal to the layer plane (the xz plane in the β phase) to decrease, i.e., chain 1 may now extend into the adjacent layers. Comparison of the stereoviews of the two phases in Figs. 2 and 4 illustrates the dramatic decrease in angle from 29° for chain 1 in the β phase to the smaller angles in the α phase (17(2)° for chain 1 and 14(1)° for chain 2). (It should be noted that due to the change in symmetry there is not a one-to-one correspondence between the numbered cation chains of the two phases.) Structurally, the decrease in chain angle causes a decrease in the component of the chain length in the z_{β} direction, which accounts for the previously mentioned macroscopic contraction of the crystal on passing into the α phase.

The development of the monoclinic angle can best be understood by considering the two phases individually. In the β phase chain 1 is contained within the layer while chain 2 (with the completely *anti* conformation) extends into both neighboring layers. From Fig. 2 it should be noticed that chain 2 lies on a line between two $CuCl_4^{2-}$ anions (the anions are related by a b_{β} translation) such that a *trans* chloride ion pair and a copper ion of a particular anion form the cap of a cavity into which a methyl group fits. Since each anion caps only two cavities, the terminal carbons of chain 2 occupy all of the possible cavities in the β phase. In the α phase both chains are *anti*, make approximately the same angle with the xy plane, and, therefore, extend into neighboring layers. The interlayer distance is quite a bit larger in the α phase, which does relieve crowding; however, the cations are staggered about the layer plane (just as in the β phase) such that one end extends further into a neighboring layer than the other. Shifting the pairs of planes in adjacent unit cells moves the β phase cavities into a position such that the more extended methyl groups of each chain fit into a cavity, as can be seen by comparison of Figs. 2 and 4.

TABLE 5. Comparison of the highest-energy d–d transition and geometrical parameters for complexes containing the $CuCl_4^{2-}$ anion

*For the cations, the following abbreviations have been used: (d-mampH)$^+$ = bis-[(+)-*N*,α-dimethylphenethylammonium]; $2NH_25PicH^+$ = 2-amino-5-picolinium (or 5-methyl-2-aminopyridinium); (NPhpipzH_2)$^{2+}$ = *N*-phenylpiperazinium; (cinH_2)$^{2+}$ = $(C_{19}H_{24}N_2O)^{2+}$ (cinchoninium); (metH)$^+$ = 1-methyl-4-oxo-3,3-diphenylhexyldimethylammonium (methadonium).

†For both the (cinH_2) and (d-mampH) salts the crystal structures have shown the $CuCl_4^{2-}$ anion to exist in two distinct conformations. The crystallographic data are taken as the average of the two.

Optical spectroscopy

The absorption bands observed at 26 100 and 29 200 cm^{-1} are of a greater relative intensity than those observed in the near-infrared region and are presumably due to chloride – copper ligand – metal charge transfer transitions (LMCT). However, our attention is focussed on the broad band in the near infrared maximizing at 11 200 cm^{-1}, not an atypical value for the d–d transitions of the $CuCl_4^{2-}$ ion. The Jahn–Teller theorem precludes a tetrahedral (T_d) geometry for the d^9 $CuCl_4^{2-}$ ion, and only in a few instances are the Cl–Cl steric repulsions overcome for the ion to assume a ligand field stabilizing square-planar (D_{4h}) geometry (27, 29). In most instances the ion assumes the intermediate geometry of a tetrahedron compressed along one of its S_4 axes having (approximate) D_{2d} symmetry. This has been observed here for the DPA salt, the anion geometry being essentially identical in both phases. The degree of distortion is conveniently measured by taking the average of the two Cl—Cu—Cl angles larger than 109.47°: an angle of 109.47° corresponds to tetrahedral gometry, 180.0° to a square-planar system. Typical values for $CuCl_4^{2-}$ fall in the range of 130–145°. The value obtained for the room temperature salt in this system is 146.6°.

Early work in this laboratory and by Lamotte-Brasseur recognized that the position of the highest-energy d–d band measured at room temperature correlated well with the distortion of $CuCl_4^{2-}$ from tetrahedral geometry: the greater the distortion from tetrahedral geometry, the further blue-shifted is the highest-energy (and indeed all of the) d–d transition(s) (14, 30). Such an empirical relation has subsequently been used in several different contexts (7, 20, 31). With several new $CuCl_4^{2-}$ structures now available, we wish to extend this analysis to include a great deal more data, and make available a convenient reference for other workers as to the probable geometry of the anion in systems containing $CuCl_4^{2-}$.

The criteria used in selecting data are three: First, the geometry about the copper must be four-coordinate. Care has been taken to exclude all systems having a contact interaction with a fifth or sixth ligand, such as in a 4 + 2 coordination geometry. Although we have included two $Cu_2Cl_6^{2-}$ dimers in the data, this is not a problem since most of the geometries are determined, at least in part, by chloride interaction with some neighboring cation, usually a proton. Thus, while the dimer interaction strongly affects the magnetic properties, it has little effect on the positions of the d–d bands. Second, both the crystal structure and the optical data should have been collected at room temperature. In many instances the geometry of the anion changes with temperature, shifting the positions of the absorption bands (thermochromism) (27, 30). Third, we use only the peak position of the highest-energy d–d band obtained from unpolarized room temperature absorption or diffuse reflectance data. Although the room temperature peak is normally an envelope of several vibronic peaks, and possibly two or more d–d peaks (as in this case), the data are this way internally consistent. Furthermore, this makes it more convenient, for example, for other workers considering whether an unusual geometry might be present, warranting a crystal structure.

The data used in the study are summarized in Table 5 along with the appropriate references. To measure the distortion, the average of the two largest Cl—Cu—Cl angles within the anion, Θ, was used. Other choices are possible, such as half this angle or the dihedral angle, but this is the most convenient. Figure 8 presents a plot of this empirical correlation. Considering the width of some of the d–d bands and the number of data included, the fit is very satisfactory. The data are fit by a least-squares line with slope 143 ± 6 cm^{-1} deg^{-1} and intercept −9600 ± 600 cm^{-1}. This corresponds to the highest-energy d–d transition having a value of approximately 6000 cm^{-1} for a tetrahedral geometry, a plausible value (7, 16, 36).

The low temperature spectrum resolves the broad room temperature d–d envelope into two peaks at 12 700 cm^{-1} and 9800 cm^{-1}. The dearth of optically resolved spectra for $CuCl_4^{2-}$ ions at large distortion angles (but not the square-planar limit) makes definitive assignment of the states difficult. That is, there exist only a few studies of $CuCl_4^{2-}$ using either polarized or cryogenic spectroscopic methods (17, 19). For the square-planar (D_{4h}) limit, however, a very detailed theoretical analysis

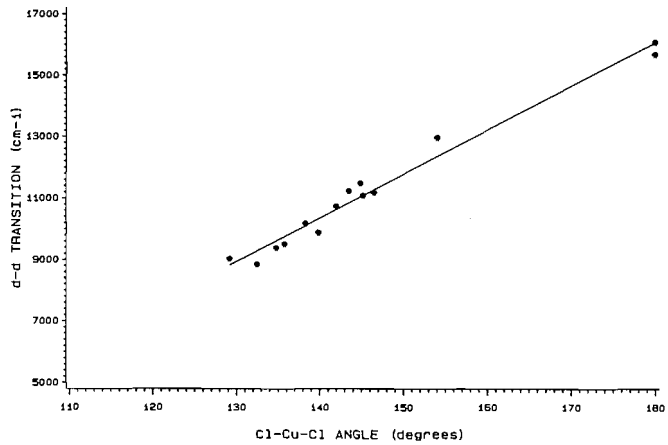

FIG. 8. A plot of the highest-energy d–d transition energy from the room temperature spectra versus the average of the two larger Cl—Cu—Cl angles in the $CuCl_4^{2-}$ anion. Data are from Table 5.

(32) and an extensive spectroscopic investigation including the thermal dependence and vibrational fine structure of the d–d transitions have been undertaken (33). In the distorted tetrahedral case, however, the energy level ordering is not as well understood. The early spectroscopic work of Ferguson on Cs_2CuCl_4 (17) and Furlani *et al.* (19) on $[(C_6H_5)CH_2N(CH_3)_3]CuCl_4$ has shown that the ordering of the term energies (ignoring spin-orbit coupling) in these systems is $^2B_2(xy) << {}^2E(xz, yz) < {}^2B_1(x^2 - y^2) < {}^2A_1(z^2)$, corresponding to a $^2B_2(xy)$ ground state. In the D_{2d} point group, the $^2B_2 \rightarrow {}^2E$ and $^2B_2 \rightarrow {}^2A_1$ transitions are dipole allowed and have been assigned as the lowest and highest-energy d–d bands, respectively, in these systems, while the forbidden $^2B_2 \rightarrow {}^2B_1$ was assigned as a weak band in the Cs_2CuCl_4 case only, assuming contribution from spin-orbit coupling effects and site group symmetry lowering. However, reference to Table 5 shows that both of these studies correspond to relatively small distortions from tetrahedral symmetry, whereas the DPACC system has a large distortion value ($\Theta = 146.6°$). Several theoretical studies have shown that the ordering of the ^2E and $^2B_1$ terms shifts near large θ values (8, 31, 32, 34, 35). Thus, we may assign the 12 700 cm^{-1} band as due to the $^2B_2 \rightarrow {}^2A_1$ transition, but may not definitively assign the 9800 cm^{-1} band. It is presumably due to the $^2B_2 \rightarrow {}^2E$ transition, but a combination of greater distortion from D_{2d} symmetry at low temperatures and differing enhancement mechanisms adding intensity to the $^2B_2 \rightarrow {}^2B_1$ excitation makes difficult the correct assignment of the transition.

Conclusions

The thermochromic phase transitions in several copper(II) chloride salts studied previously have involved a phase transition in which the coordination geometry of the copper(II) chromophore changed (3, 37). In each case, the driving force has been identified as the onset of thermal disorder of the organic counterion. In DPACC, virtually no change occurs in the coordination geometry about the copper. Rather, it exhibits a gradual thermochromism caused by a shifting of the d–d absorption bands that tail into the visible region. The phase transition in DPACC is much more similar to the melting transitions in monoalkylammonium metal chloride salts. These latter salts consist of an exclusively inorganic layer (corner-sharing MCl_6^{4-} octahedra), which is unaltered through the phase transition, and an organic layer sandwiched between inorganic layers. The amino groups of the alkylammonium chains are hydrogen bonded to the chloride ions in the layer while the alkyl groups extend away from the layer and are ordered below the transition temperature while extremely disordered above the transition temperature. DPACC is structurally similar in that there is a well-defined layer structure, although in this case the amino groups are intimately associated with the bonding in the layer, the alkyl groups extending away from the layer on both sides. The epr spectra show that if there is any fluctuation or dynamic disorder of the anion, it is occurring on a time scale much larger than the time scale of the epr experiment; thus the layers appear to be fairly rigid in both phases. Below the transition temperature the alkyl chains are well ordered while above the transition temperature the chains show a great deal of thermal motion and some disorder. This disorder is indicated by the large amount of thermal motion in the α phase of the terminal carbon atoms as compared to the nitrogen atoms (cf. Table 2). Since the alkyl chains in this compound have only three carbon atoms, compared to nine or more in other layer compounds exhibiting melting transitions, it could provide a clearer view of the motion of the alkyl chains in the different phases of this class.

Acknowledgments

We are grateful to Mark Pressprich for constructing the high temperature device for the X-ray diffractometer. We would also like to acknowledge the support of NSF Grant CHE-8408407 and of The Boeing Company for establishment of the X-ray diffraction facility. Thermal effects in polyelectrolyte ion exchange reactions: the Jahn–Teller effect

KANG SUN[1] AND GEORGE E. BOYD
Department of Chemistry, University of Georgia, Athens, GA 30602, U.S.A.

Received September 10, 1987

This paper is dedicated to Professor J. A. Morrison

KANG SUN and GEORGE E. BOYD. Can. J. Chem. **66**, 974 (1988).

Microcalorimetric determinations were made of the thermal effects accompanying the exchange of the divalent cations of Mn, Fe, Co, Ni, Cu, and Zn in dilute aqueous perchlorate solutions with Mg^{2+} ion initially bound in a crosslinked polyelectrolyte gel. The calorimetric measurements, together with microchemical equilibrium distribution determinations with the same cations, were employed to estimate the standard state Gibbs energy, enthalpy, and entropy changes associated with their ion exchange reactions.

All the transition elements were selectively absorbed relative to Mg^{2+} with the sequence being: Mn < Fe < Co < Ni > Cu > Zn, showing divalent Ni(II) cation to possess the greatest affinity for the polyelectrolyte phase. The sequence of standard state reaction enthalpy change, ΔH^0, revealed that Ni^{2+} also was the most exothermic of all 3*d* transition element cations. However, the ΔH^0 values became more negative in the order: Mn < Fe < Co < Ni > Cu < Zn, showing that Cu^{2+} ion behaved anomalously in being less negative than expected. This behavior (and that in the ΔS^0 values also) suggested that a destabilization of the octahedrally coordinated Cu^{2+} in aqueous solutions must occur, possibly because of Jahn–Teller effects on its d^9 electronic configuration when the cation is placed in an environment of cubic symmetry. Because of a thermodynamic compensation of the magnitudes of ΔH^0 and ΔS^0, the position of Cu^{2+} in the ΔG^0 value sequence was regular.

KANG SUN et GEORGE E. BOYD. Can. J. Chem. **66**, 974 (1988).

On a effectué des déterminations calorimétriques des effets thermiques qui accompagnent l'échange des cations divalents du Mn, du Fe, du Co, du Ni, du Cu et du Zn présents dans des solutions aqueuses diluées de perchlorate avec l'ion Mg^{2+} qui est lié initialement à un gel réticulé de polyélectrolyte. Afin d'évaluer les ΔG^0, ΔH^0 et ΔS^0 associés aux réactions d'échange de leurs ions, on a utilisé les mesures calorimétriques de concert avec des déterminations de la distribution de l'équilibre microchimique des mêmes cations.

Par rapport au Mg^{2+}, tous les éléments de transition sont absorbés sélectivement et la séquence observée Mn < Fe < Co < Ni > Zn démontre que le cation divalent Ni(II) possède l'affinité la plus grande pour la phase polyélectrolyte. La séquence des ΔH^0 révéle aussi que le Ni^{2+} est le plus exothermique des cations des éléments de transition 3*d*. Toutefois, les valeurs deviennent de plus négatives dans la séquence Mn < Fe < Co < Ni > Cu < Zn; ces résultats démontrent que le comportement du Cu^{2+} est anormal puisqu'il est moins négatif que prévu. Co comportement (ainsi que les valeurs de ΔS^0) suggérent que, dans des solutions aqueuses, il se produit une déstabilisation de l'ion Cu^{2+} qui est coordonné d'une façon octaédrique; cette déstabilisation est peut-être provoquée par les effets de Jahn-Teller sur sa configuration electronique d^9 lorsque le cation est placé dans un environnement de symétrie cubique. A cause d'une compensation thermodynamique des amplitudes des ΔH^0 et ΔS^0, la position du Cu^{2+} dans la séquence des valeurs de ΔG^0 est régulière.

[Traduit par la revue]

Introduction

Investigation into the causes of ion exchange equilibrium selectivity shown by ionogenic, high molecular weight organic polymers towards mobile cations or anions have produced much useful information since synthetic ion exchangers were first produced more than forty years ago. Quite frequently the preferential uptake of ions observed seems to be largely a reflection of the tendency for the electrostatic free energy of the system to be lowered. Electrostatic interactions between unlike charged ions and between like-charged ions in either or both the polyelectrolyte ion exchanger and in the external equilibrium mixed ion solution are usually the most evident. However, ion – polar solvent interactions in the exchanger and in the external solution may be of comparable importance particularly in aqueous systems. For example, the short-range structure of water is believed to be modified by the hydrophobic interaction of non-polar molecular ions leading to a strong preferential uptake of these species by ion exchangers.

There is some evidence also that the electronic configurations of ions such as in the tervalent rare earth cations may interact with their environment leading to small differences in relative ion exchange selectivity. The divalent cations of the 3*d* transition elements appeared to offer attractive possibilities for investigation in this connection. It is known that the d^9 configuration of Cu(II) makes its coordination symmetry subject to Jahn–Teller distortions when this species is placed in an environment of cubic symmetry. The unique properties of Cu(II) complexes appear to result from such a distortion (1). If Jahn–Teller distortions affect the character of the hydration of Cu(II), this might be mirrored in the thermodynamic property changes which accompany its ion exchange reactions.

Accordingly, an experimental program was undertaken to estimate the standard state Gibbs energy, enthalpy and entropy changes at 298 K which occur in the reactions of the divalent cations of Mn(II), Fe(II), Co(II), Ni(II), Cu(II), and Zn(II) with Mg^{2+} ion. Measurements of the enthalpy changes with a microcalorimeter proved particularly revealing with Cu(II), and this was ascribed to a Jahn–Teller distortion of the octahedral symmetry of hydrated Cu(II) ion. Enthalpy change values for the series were combined with Gibbs energy changes derived from equilibrium constant measurements to obtain ion exchange reaction entropy changes. A larger than expected (i.e. more positive) ΔS^0 value for Cu(II) was observed. In contrast, the magnitude of the ΔG^0 value for Cu(II) was not anomalous relative to the other 3*d* divalent cations. This study has appeared to confirm that calorimetric measurements, as well as X-ray crystallographic and spectroscopic observations can provide a sensitive probe for Jahn–Teller effects in ion exchange reactions.

Experimental

General remarks

The experiments were designed to yield measurements for use in the evaluation of the thermodynamic property changes occurring in the ion exchange reactions of the divalent cations, M^{2+}, of 3*d* transition elements between a polyelectrolyte gel and aqueous electrolyte mixtures at room temperature. Reactions involving the selective uptake of M^{2+} by the ion exchanger with Mg^{2+} as a "reference ion" in equilibrium constant and calorimetric determinations were studied systematically. Magnesium ion was chosen because of its relatively low affinity for the exchanger, because of its "rare gas" electronic structure, and because of its octahedral coordination in aqueous solutions. Purified perchlorate salts and dilute solutions (0.01 m) were used throughout to minimize the magnitudes of the corrections for aqueous phase nonideality. A moderately highly cross-linked polyelectrolyte gel was employed so as to enhance the selectivity differences between the M^{2+} cations, and to effectively eliminate absorption of ClO_4^{2-} ion by the gel. Thus, the normality of the aqueous phase remained strictly constant at $N = 0.02$ equiv. L^{-1} in all experiments. Care was exercised in the preparation of the electrolyte solutions, and homo-ionic salt-forms, MR_2 and MgR_2, of the exchanger, and in handling these in experiments and analysis. Details are described more fully elsewhere (2).

Chemicals and reagents

Stock solutions of the transition metal and magnesium perchlorates were made to approximately 1 *N* concentration with reagent grade $M(ClO_4)_2.6H_2O$ and pure water ($\kappa = 10^{-6}$ mho cm^{-1}). The pH of these solutions was adjusted to 3.0–3.5. The ferrous perchlorate solution was prepared specially, involving the addition of small amounts of ascorbic acid to reduce Fe(III) impurity and the stabilization of ferrous ion with ultra-pure iron wire.

Analytical grade cross-linked poly(styrene sulfonate), Dowex AG 50W-X8, was employed. Its exchange capacity was determined as 4.88 mequiv./g dry HR. The homo-ionic salt-forms, MnR_2, CoR_2, NiR_2, CuR_2, ZnR_2, and MgR_2, were prepared by treating the acid-form of the exchanger, HR, with 1 *N* MCl_2 solutions, respectively. Special measures were taken to prepare the FeR_2 form (2).

Chemical analyses were conducted to confirm that the conversion of MR_2 and MgR_2 from HR was at least 99.5% complete. Direct titrations of the MR_2 and MgR_2 preparations to determine their metal contents were carried out with standard 0.1000 *M* EDTA at pH = 10 using Eriochrome Black T or Murexide as indicators. The FeR_2 form was titrated with standard 0.1000 *N* $K_2Cr_2O_7$ using diphenylamine sulfonate as an indicator. The preparations were used in a partially hydrated, or "wet", state for convenience in handling. This conversion was accomplished by placing the salt-form in a humidistat, and bringing them to water vapor equilibrium with a saturated $Ca(NO_3)_2{\cdot}6H_2O$ solution.

Equilibrium distribution measurements

Mass law concentration-product quotients, K'_c for the transition metal – magnesium ion equilibria were determined with an ion exchange column technique. A cylindrical bed of approximately 1.5 g HR was formed in a glass column, and 10–15 "bed volumes" of 0.02 *N* $[(M^{2+} + Mg^{2+})ClO_4]_2$ mixtures with pre-determined M^{2+}/Mg^{2+} mole ratios of 0.25, 0.50, and 0.75 were passed through the bed. Equilibrium was assumed to have been reached when the pH of the influent and effluent solutions became identical. The metal ion mole ratio in the exchanger was determined by quantitative elution with 4 *N* H_2SO_4 followed by analysis of the eluate plus wash solution for its M^{2+} and Mg^{2+} contents separately. Numerical values of K'_c were computed from its definition:

$$[1] \quad K'_c = N_M M_{Mg}/N_{Mg} M_M$$

where *N* is the ion equivalent fraction in the exchanger and *M* is the ion molality in the aqueous mixture.

Calorimeter system and measurements

Design and other details on the solution microcalorimeter and its associated circuitry have been presented elsewhere (2, 3). Three features, however, may be of possible interest: (*a*) the response of the calorimeter was increased by reducing its thermal mass by using a specially constructed silvered-glass Dewar vessel with an inner wall of minimal (0.6 mm) thickness; (*b*) a reduction in the heat leak from the calorimeter to its surroundings was effected by leaving the top-most inch of the Dewar unsilvered; (*c*) the rate of the ion exchange reaction was increased significantly by using exchanger preparations consisting of small (i.e. 50–100 micron) spherical particles.

Measurement of ion exchange reaction thermal effects at 25.00 ± 0.05°C were conducted by filling the calorimeter with 500 mL of 0.02 *N* $M(ClO_4)_2$ or $Mg(ClO_4)_2$ solution weighed to ±0.1 g, and placing exactly determined weights of analyzed MgR_2 or MR_2 in sealed 3 mL cylindrical glass pipettes mounted on a suitable holder in the solution. When a steady-state temperature drift in the stirred solution was reached the pipette was opened. The thermal effect accompanying the mixing of the exchanger with the solution was complete within five minutes. Electric energy calibrations were made on the final state of the system with a precision of ±0.05%. Measurements of the heat of solution of NBS standard tris(hydroxylmethyl)aminomethane in 0.100 *N* HCl were conducted periodically to check on the overall performance of the calorimeter system.

The ion exchanger was recovered from the calorimeter and was subjected to chemical analysis to determine its ionic composition. Exhaustive elution with 4 *N* H_2SO_4 solution was used to release the M^{2+} and Mg^{2+} ions from the reacted exchanger. The concentrations of transition metal and magnesium ion in the various solutions and eluates from the calorimeter were estimated by titration with standardized 0.1000 *M* EDTA at pH = 10 using reagent Eriochrome Black T, Murexide and diphenylamine sulfonate as indicators. The equilibrium compositions of the exchanger, the final mixed aqueous electrolyte solution, and the number of milliequivalents of ion exchange reaction were computed from the analyses (2). Heats of partial exchange for the uptake of the preferred ion, M^{2+}, expressed in defined Joules equivalent^{-1}, Q^M_{Mg}, were calculated from the measured thermal effect and the estimated milliequivalents of reaction.

TABLE 1. Mass law concentration product quotient, K'_c, and heat of partial ion exchange, Q^M_{Mg}, for ion exchange reaction: $MgR_2 + M(ClO_4)_2 = MR_2 + Mg(ClO_4)_2$

	K'_c for $[M^{2+}]/[Mg^{2+}]$ =

Treatment of experimental data

Mass law concentration product quotients, $K'_c = K^M_{Mg}$, derived for the ion-exchange reaction which occurred in the calorimeter, and the corresponding heats of partial ion exchange, Q^M_{Mg}, are listed in Table 1. The magnitudes (Table 2) of the standard state Gibbs energy, enthalpy, and entropy changes, ΔG^0, ΔH^0, and ΔS^0 for the ion-exchange reactions at equilibrium at 298 K when the products and reactants are in their defined standard states may be derived from K'_c and Q^M_{Mg}. This hypothetical but defined magnesium-first transition series divalent cation equilibrium exchange reaction may be written as:

$$[2] \quad MgR_2{\cdot}nH_2O(a = 1, \text{equilibrium with } 0.02\,N\,Mg(ClO_4)_2) + M(ClO_4)_2(a = 1, aq) = MR_2{\cdot}mH_2O \; (a = 1, \text{equilibrium with } 0.02\,N\,M(ClO_4)_2) + Mg(ClO_4)_2\,(a = 1, aq) + (m - n)H_2O$$

TABLE 2. Thermodynamic property changes in the reaction at 298.0 K: $MgR_2 + M(ClO_4)_2 = MR_2 + Mg(ClO_4)_2$

M(II)	$-\Delta G^0$(J equiv.$^{-1}$)	ΔH^0(J equiv.$^{-1}$)	ΔS^0(J equiv. deg^{-1})	$T\Delta S^0$(J equiv.$^{-1}$)	K_a

The standard states of the hydrated exchanger salt forms, $MR_2 \cdot mH_2O$ and $MgR_2 \cdot nH_2O$, are defined when they are in vapor phase equilibrium with 0.02 N $M(ClO_4)_2$ and 0.02 N $Mg(ClO_4)_2$ solutions, respectively. The standard states for the mixed electrolyte solution phase are chosen as the usual ones which make ion activities approach corresponding molalities as the solute content of the solution becomes vanishingly small. The reference states for the solvent are chosen so that the activity of water, a_w, in each phase is the same and $a_w = 1$ for the pure solvent. It will be assumed that the anion, ClO_4^-, in the equilibrium electrolyte mixture was present in the gel phase of the exchanger to a negligible extent or, what is the same, that the total normality of the external electrolyte mixture remained constant during the ion exchange reactions. However, allowance is made for changes in the hydration of the exchanger.

The thermodynamic equilibrium constant, K_a, for reaction [2] may be estimated with the relation:

$$[3] \quad K_a = N_M f_M M_{Mg} \gamma_{Mg} / N_{Mg} f_{Mg} M_M \gamma_M$$

where f_M and f_{Mg} are the activity coefficients of the components MR_2 and MgR_2 in the ion exchanger, and γ_M and γ_{Mg} are the molal ionic activity coefficients in the equilibrium aqueous mixture. All of the quantities appearing on the right-hand side of eq. [3], except f_M and f_{Mg}, may be derived from experiment. Values of the activity coefficients for the ion components in the ion exchanger phase may be derived by application of Gibbs–Duhem equation to the three-component system. Substitution into eq. [3] leads to a result, eq. [4], for the standard state Gibbs energy change, ΔG^0, as derived by Gaines and Thomas (4)

$$[4] \quad \Delta G^0 = (-1/Z_{Mg}Z_M)RT(Z_{Mg} - Z_M) - (RT/Z_{Mg} - Z_M) \int_0^1 \ln K_c dN_{Mg} - RT \int_{a_w(M)}^{a_w(Mg)} n_w d \ln a_w$$

where Z_i is the cation charge, and K_c is defined by the equation:

$$[5] \quad K_c = K_c'(\gamma_{Mg}/\gamma_M) = K_c'[\gamma_\pm(Mg)/\gamma_\pm(M)]^6$$

The quantity, K_c, is a function only of the ionic composition of the ion exchanger (as are f_M and f_{Mg}), and is determined by K_c' which is known from chemical analysis, and by $\gamma_\pm(Mg)$ and $\gamma_\pm(M)$ which are the experimentally known mean molal activity coefficients for the salts $Mg(ClO_4)_2$ and $M(ClO_4)_2$ in the aqueous phase. The evaluation of the activity coefficient ratio in eq. [5] is described elsewhere (2), where it is shown also that the last term on the right-hand side of eq. [4] effectively vanishes.

A plot of K_c against N_M showed that K_c was a constant independent of the composition of the exchanger, so that eq. [4] further simplified to:

$$[6] \quad \Delta G^0 = -(1/Z_{Mg}Z_M)RT \ln K_c$$

The standard state enthalpy change, ΔH^0, for eq. [2] will be given by

$$[7] \quad \Delta H^0 = \Delta H + \Delta\phi_L + \Delta H_m$$

where ΔH is the integral or total enthalpy for the conversion of one equivalent of ion exchanger from MgR_2 to the first transition series metal salt form, MR_2, ΔH_m is the enthalpy of mixing in the aqueous phase, and $\Delta\phi_L$ is the relative apparent molal heat content difference (i.e., heat of dilution difference), $\phi_L[Mg(ClO_4)_2] - \phi_L[M(ClO_4)_2]$, for the magnesium and first transition series perchlorate solutions in their mixtures at 0.02 N. These concentrations are sufficiently low that the prediction, $\Delta\phi_L = 0$, from Debye–Hückel limiting law is a fair approximation. Relative apparent molal heat content values, ϕ_L, for $M(ClO_4)_2$ solutions at 0.02 N ($m = 0.01$) have been reported by Vanderzee (5–8) as 391, 389, 387, 387, 385, and 387 J equiv.$^{-1}$ for Mn, Fe, Co, Ni, Cu, and Zn perchlorates, respectively. The value for $Mg(ClO_4)_2$ is 387 J equiv.$^{-1}$ which was estimated by using an extended Debye–Hückel equation (9). Computations using these values confirm the approximation, $\Delta\phi_L = 0$, to be satisfactory within ±5 J equiv.$^{-1}$ which is about the same order as the error in the values of ϕ_L themselves. The enthalpy of mixing of $Mg(ClO_4)_2$ and $M(ClO_4)_2$ at $m = 0.01$ concentration was 4 mJ, which is negligible.

The magnitude of ΔH in eq. [7] is given by the area under the differential heat of exchange, $\overline{\Delta H}$, vs. composition curve:

$$[8] \quad \Delta H = \int_0^1 \overline{\Delta H} dN_M = \int_0^1 (dQ/dN_M) dN_M$$

where Q is the heat of partial ion exchange measured in the calorimeter experiments, and N_M is the equivalent fraction of M in the exchanger.

The quantity ΔH^0, eq. [7], is defined as the standard enthalpy change which accompanies the complete conversion of the homoionic exchanger MgR_2 in an ion exchange reaction to MR_2, each exchanger being in its respective standard state.

The entropy change, ΔS^0, for the standard state ion exchange reaction may be derived from the enthalpy and Gibbs energy change with the Gibbs–Helmholtz relation.

Results and discussion

Ion exchange equilibrium coefficients, K_c, for the first transition series divalent cations, M, initially in 0.02 N aqueous perchlorate solution with magnesium ion initially in the exchanger, are plotted in Fig. 1 against the atomic number, Z_M. Instead of a monotonically increasing value of K_c with Z_M, as for the exchange reactions of the alkali metal cations with Li^+ ion, or, for the alkaline earth cations with Mg^{2+}, the relative affinities (as measured by K_c) pass through a maximum for Ni^{2+} ion, and the sequence of "affinities" is Mn < Fe < Co < Ni > Cu > Zn. This atypical behavior of some of the 3d divalent

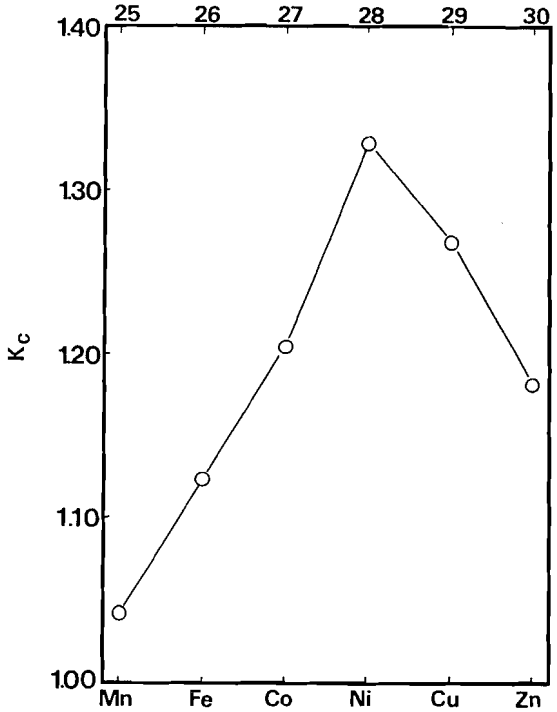

FIG. 1. Ion exchange equilibrium constants: $MgR_2 + M(ClO_4)_2 = MR_2 + Mg(ClO_4)_2$.

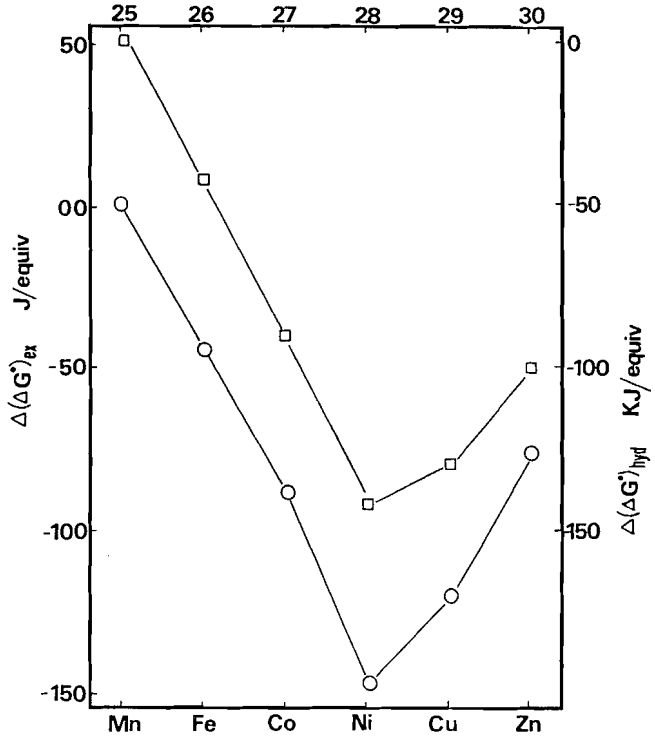

FIG. 2. ○ Standard Gibbs energy changes in ion exchange reactions, and □ Gibbs energy changes of hydration of divalent cations (the value of ΔG^0_{hyd} for Mn^{2+} was arbitrarily taken as zero).

cations had been noted earlier in this laboratory in unpublished studies with Co, Ni, Cu, and Zn ions in slightly more concentrated (0.03 *N*) perchlorate solutions using a virtually identical cation exchanger.[2] The sequence was Co < Ni > Cu > Zn. Sensitive thermometric titrations with EDTA using a Tronac 1200 isothermal solution microcalorimeter were employed in the K_c determinations. A small, linear dependence of K_c on N_{NiR_2} and N_{CuR_2} was observed in contrast with this research.

A plot (Fig. 2) of the standard state Gibbs energy change, ΔG^0, for the reactions of the transition element cations reveals a relatively large negative value for Ni^{2+} ion consistent with its strong preferential uptake by MgR_2. A comparison of the variations in ΔG^0, and the standard Gibbs energy change of ion hydration, ΔG^0_{hyd}, with atomic number (the value of ΔG^0_{hyd} for Mn^{2+} was arbitrarily taken as zero) may be made in Fig. 2. The qualitatively close correspondence may be understood on the basis of the crystal-field stabilization energies (CFSE) for 3*d* elements; Ni(II) ion should be stabilized more than any other ion in a weak octahedral field because it has greatest CFSE (12 *Dq*). The d^6, d^7, and d^9 ions have somewhat less stabilization energy, and the d^5 and d^{10} species have $Dq = 0$. Interestingly, there is no indication of the consequences of partially filled *d*-shell, or, of the effects of *d*-orbital splitting, in the values of ΔG^0.

By reason of the Gibbs–Helmholtz relation the sign and magnitude of ΔG^0 is determined by the signs and magnitudes of the standard enthalpy, ΔH^0, and entropy, $T\Delta S^0$, changes. Values of ΔH^0 from calorimetric measurements and values of $T\Delta S^0$ from ΔG^0 and ΔH^0 when plotted, Fig. 3, against Z_M also show unexpected features. The general trend of these quantities for the M(II) cations in their exchange reactions with Mg^{2+}

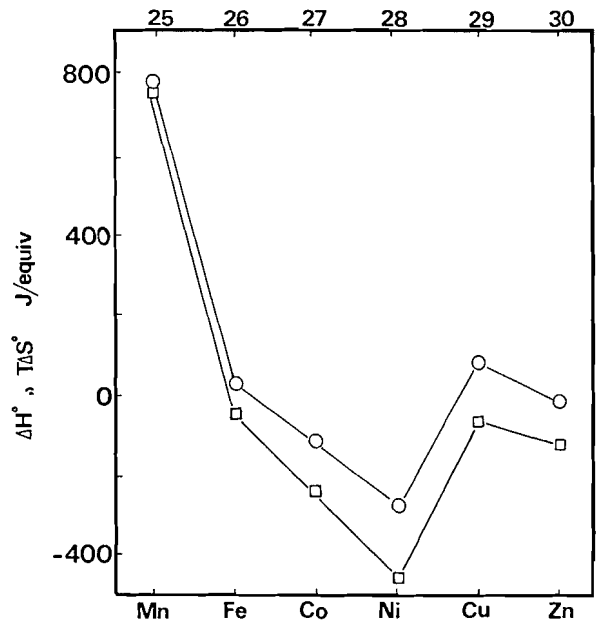

FIG. 3. □ Standard enthalpy changes and ○ standard entropy changes in ion exchange reactions.

seems normal up to Ni(II) ion, beyond which new interactions appear to set in which make ΔH^0 less negative and ΔS^0 more positive. Conceivably, changes in ion-solvent interaction may occur, in spite of the fact that the hydration enthalpies for the M(II) cations are large indicating strong ion–water forces (10). The exchange reaction of Cu(II) ion differed notably from the other 3*d* cations in that its preferential uptake was accompanied by an entropy increase, while the enthalpy change was negative.

Further, the positive ΔS^0 of reaction contributed significantly to the selective uptake.

The unique behavior of copper among the transition elements may possibly arise because its *d* electron configuration makes its hydrated ion subject to Jahn–Teller distortion. The existence of a well-defined, distorted $Cu(H_2O)_{4,eq}\cdot(H_2O)_{2,ax}$ octahedron in copper perchlorate solutions has been indicated by the X-ray diffraction researches of Magini (11). The Jahn–Teller theorem does not predict the details of the distortion, however. An elongation along one 4-fold axis occurs to produce a planar array of four short Cu—H_2O bonds and two long *trans*-bonds according to the X-ray results.

In dilute aqueous perchlorate solutions only water molecules are expected to enter the inner coordination spheres of 3*d* transition element cations. Although direct proof is lacking, it is likely that these ions also retain their primary hydration spheres when they are present inside the cation exchanger. The water contents of the MR_2 and MgR_2 salt-forms are certainly more than sufficient. Their environment, however, would be unlikely to possess cubic symmetry so that Jahn–Teller distortions are not expected. The structure of the cation exchanger gel phase is surely complex, and is very poorly understood. It has been likened to that of a concentrated aqueous electrolyte solution.

This research may be of general interest because it appears to demonstrate the feasibility of microcalorimetric methods in searching for Jahn–Teller and possibly other electronic effects in ion exchange reactions with organic polyelectrolytes. Thermal effects caused by *d*-orbital splitting are expected to be small, but existing microcalorimeters seem to be sensitive enough to detect and measure them quantitatively.

We present an algorithm for estimating dimensionality. It is based on a multivariate k nearest neighbor (k-NN) density estimator and shows explicitly that the dependence of k-NN distances on k does not follow pure power law behavior. We achieve very high efficiency ($\leq$2000 points for up to 20 dimensions) by abandoning the distribution free feature of our algorithm; it is *calibrated* for two distributions and tested on a number of strange attractors, the discretized Mackay–Glass system, and trajectories of 3, 10, and 20 coupled harmonic oscillators. The danger of embedding in higher dimensional spaces is demonstrated.

R. L. SOMORJAI et M. K. ALI. Can. J. Chem. **66**, 979 (1988).

On présente un algorithme permettant d'évaluer la dimensionnalité. Il est basé sur un évaluateur de densité à plusieurs variables sur k voisins les plus proches (k-VP) et il démontre explicitement que la dépendance des distances k-VP sur k ne suit pas une loi des puissances pure. On a réalisé une très grande efficacité ($\leq$2000 points jusqu'à 20 dimensions) lorsqu'on a abandonné la caractéristique non paramétrique de notre algorithme; celui-ci est *calibré* pour deux distributions et on l'a évalué sur un certain nombre d'attracteurs étranges, sur le système de Mackay–Glass discrétisé ainsi que sur les trajectoires de 3, 10 et 20 oscillateurs harmoniques couplés. On démontre les dangers qui découlent du plongement dans des espaces de dimensionnalité plus élevée.

In recent years the characterization of strange attractors has received much attention (1–8). Of special interest is the fractal dimensionality d. It is now recognized that for practical purposes the Balatoni–Rényi generalized dimension (9) d_q, $q \geq 0$, subsumes, for different q's, all currently used definitions of d (see, however, ref. 10).

Consider a strange attractor, embedded in d_E-dimensional Euclidean space, and let $\{x_i\}_{i=1}^n$ be n d_E-dimensional points of a time series on the attractor. We want to estimate from $\{x_i\}$ its dimensionality $d \neq d_E$. Box-counting methods are inefficient (11) for $d \geq 3$. All other published algorithms are based on some form of neighbor–distance relationship and, although more efficient, were tested mostly on systems with $d \leq 3$.

To devise a classification scheme for trajectories of both integrable and nonintegrable Hamiltonian systems of high dimension, we adopted an algorithm (12) that was developed for estimating the "intrinsic dimensionality" of a set of patterns typically encountered in discrimination analysis, pattern recognition, etc. (13–15), and improved its efficiency such that even for $d = 20$, 2000 points of $\{x_i\}$ give high accuracy. We sketch the derivation of the algorithm to make contact with current dimensionality estimators.

Consider our set $\{x_i\}$, $i = 1, 2, \ldots, n$ in Euclidean d_E-space. The x_i are sampled from an *unknown* distribution $p(x)$. The simplest estimator of $p(x)$, $\hat{p}(x)$ is (16)

$$[1] \quad \hat{p}(x) = (k/n)/V, \ \lim_{n\to\infty} (k/n) = 0$$

where k is the number of nearest neighbors (NN's) of x within a hypersphere of radius R_k about x. The volume is $V = V_d R_k^d$, where $V_d = \pi^{d/2}/\Gamma(d/2 + 1)$ is the volume of a unit d-dimensional hypersphere. Substituting into eq. [1] and taking logarithms (12) gives

$$[2] \quad \log R_k = (1/d)\{\log k - \log n - \log [V_d \hat{p}(x)]\}$$

Equation [2] cannot be used directly to estimate d because $\hat{p}(x)$ is not independent of k. Let $r_k(x)$ be the distance from x to its kth NN. If $p(x)$ is continuous and nonzero at x, then the density function for $r_k(x)$ for sufficiently large n and small $r > 0$ is (12) $f_{k,x}(r) = (d/r\Gamma(k))C^k \exp(-C)$, $C = np(x)r^d V_d$. The expected value of $r_k(x)$ is $E(r_k(x)) = [k/np(x)V_d]^{1/d}/G_{k,d}$, where $G_{k,d} = k^{1/d}\Gamma(k)/\Gamma(k + 1/d)$. If $\bar{r}_k$ is the sample-averaged distance to the kth NN over the set of points, $\bar{r}_k = (1/n)\sum_{i=1}^n r_k(x_i)$, then the expected value of this average is

$$[3] \quad E(\bar{r}_k) = (1/n)\sum_{i=1}^{n} E(r_k(x_i)) = G_{k,d}^{-1} k^{1/d} S_n$$

where S_n is independent of k. Taking logarithms of eq. [3] gives

$$[4] \quad \log G_{k,d} + \log E(\bar{r}_k) = (1/d)\log k + \log S_n$$

The term $\log G_{k,d}$ is in the range $0 \leq \log G_{k,d} \leq 0.12$ for all k and d, the maximum occurring for $k = 1$ and $d \simeq 2.17$ (12). The algorithm consists of replacing $E(\bar{r}_k)$ by $\bar{r}_k$ in eq. [4]. Using this observed value gives an estimator $\hat{d}$ of d:

$$[5] \quad \log G_{k\hat{d}} + \log \bar{r}_k = (1/\hat{d}) \log k + \log S_n$$

Plotting $\log \bar{r}_k$ vs. $\log k$ for $k = 1, 2, \ldots, k_{max}$ will give a least-squares fitted straight line with slope $1/\hat{d}$. One has to solve for $\hat{d}$ iteratively; the initial estimator $\hat{d}_0$ is obtained by setting $\log G_{k\hat{d}}$ to zero (12). Typically 4–5 iterations are sufficient for $\hat{d}$ to converge within 0.003. Note that $\hat{d}_0$ is frequently quite inaccurate.

The algorithm (and its other variants in the literature) is based on statistical methods for estimating probability densities via

multivariate k-NN estimators (17, 18). An important feature of the latter is that they are *nonparametric*, i.e., distribution free. This means in general that the efficiency of the algorithms is much less than optimal.

Since practical considerations limit the number of points n, it is essential to determine the optimum rate of convergence of $\hat{d}(n,k)$ to d with n and k. One necessary condition is $\lim_{n\to\infty}(k/n) = 0$. Another is that $k = k(n)$ be a sequence of positive integers such that $k \to \infty$ as $n \to \infty$. Then (17) the fastest rate at which the local mean square error of the estimated density decreases is $\sim n^{-\beta}$ if $k \sim n^{\beta}$, $\beta = 4/(4 + d)$. Furthermore, the *variance* of the estimated density is $0(1/k)$ and its *bias* is $0((k/n)^{2/d} + 1/k)$.

We tested the accuracy of the algorithm based on eq. [5] by applying it to various distributions of *known* dimensionality. In particular, uniformly distributed random points were generated from the interior of the unit d_E-sphere as well as from its surface, and from the unit d_E-torus, using the fast algorithms in ref. 12. Typically, for each dimension d_E, 10 samples of n = 250, 500, 1000, and 2000 points each were drawn and their apparent dimensionality determined via eq. [5]. The averages and their standard deviations were computed, each for $k = [m\sqrt{n}/4]$ $m = 9 - l$, l = 2(1)7 NN's ([ ] denotes the integer part). In Table 1 the results from the *surface* are recorded under d_{S2} and d_{S6}, for n = 2000 and m = 2, 6. Table 2 contains comparable data from the *interior* of the hyperspheres, d_{V2} and d_{V6}. Results for the d_E-torus are quite close to d_{V2} and d_{V6}.

A crude error analysis suggests that $(1/d)$ could be expanded in inverse powers of $\hat{d}$. In fact, the fitted values d^f in the tables were obtained by writing $1/d^2_E = \Sigma^3_{i=0}\, a_i/\hat{d}^i$ and determining by least-squares fitting the best a_i. The fitting errors are ± 0.24% over the four sets. Note that $a_i = a_i(n, k)$. For fixed n, low degree polynomials in k give excellent fits and, for fixed k, equally good fits with such polynomials in $1/n$ can be obtained. Thus reasonable interpolation is possible in the k–$1/n$ plane.

As expected (17), the variances of the estimated dimensions increase with d_E and decrease with both k and n. Furthermore, $\hat{d}$ increases only sublinearly with increasing d_E, rendering $\hat{d}$ less and less reliable. Thus the majority of dimensionality estimators in the literature would underestimate the true dimension of higher dimensional attractors. For fixed n, the larger the k, the slower the convergence of $\hat{d}(k, n)$ to d. The larger the n, the closer is $\hat{d}(k, n)$ to d.

In Table 3 we collect the results of applying our algorithm, both directly and after calibration, to a set of strange attractors.[3] These include the logistic map, with parameter = 4 (LOG4), Zaslawskii's map (ZASL), Henon's map (HENON), Rössler's equations (19) (RÖSS), and the Lorenz equations (20) (LOR). All of these are low ($d \leq 3$) dimensional attractors and the difference between $\hat{d}$ and d^f is small. The recorded results are averages over N subsets of 2000 points each of the appropriate time series of length $2000N$, where $3 \leq N \leq 50$, depending on the system. Our results compare quite favorably with data quoted in the literature (1, 3, 6–8): LOG4: 1.000 (exact); HENON: 1.21–1.28; RÖSS: 1.81; LOR: 2.05–2.10; ZASL: 1.22–1.80. The latter is particularly difficult to characterize in terms of its dimensionality, because of two distinct power law behaviors for small and large n (6). The latest study (7) gives d = 1.56. Note that most current methods require $10^4 \leq n \leq 10^6$ points on the attractor.

Inspection of Table 3 reveals the penalty one has to pay for efficiency: the fitted dimensionalities depend on the nature of the distribution. Fortunately, this dependence appears to be quite weak.

To further test this distribution dependence, we generated long trajectories for 3, 10, and 20 coupled harmonic oscillators on constant total energy surfaces. Thus the trajectories evolve in 6-, 20-, and 40-dimensional phase space, but because of integrability they are confined to the surface of at most 3-, 10-, and 20-dimensional tori, respectively. These are then the *maximum dimensionalities possible*. The results under HO-3, HO-10, and HO-20 indicate that the fitted dimensionalities are within 10% of the true ones. Furthermore, the d^f_S values are better than d^f_V fits for HO-3, and worse for HO-10 and HO-20. (It should be pointed out that it is increasingly more difficult to create *finite* trajectories in phase space that cover reasonably

[3]See ref. 4 for appropriate references for the strange attractors.

	8.85	10.60	11.39	8.78	10.06	10.77	20

densely and uniformly the surface of the d_E-torus as d_E increases, even with incommensurate relative frequencies, e.g., $1:\sqrt{2}:\sqrt{3}:\ldots\sqrt{p_i}$, p_i the ith prime. This may explain the underestimates.)

Finally, we applied the algorithm and the fitting scheme to the Mackey–Glass delay-differential equation (21) for τ = 23 and 100. Following ref. 4 we transformed the equation into a set of 1200 difference equations and embedded members of the time series produced into d_{EMB}-dimensional spaces. The results for τ = 23, denoted by MG23, are to be compared with (2.38, 2.43, 2.44) (ref. 4), 2.65(d_{EMB} = 10) (ref. 6), while for τ = 100 (MG100), with (5.8, 6.6, 7.2, 7.5) (ref. 4) and 12.6(d_{EMB} = 30) (ref. 6). Note that the d_V estimates give consistently higher dimensionalities than the d_S values, more in line with the results of ref. 4 for τ = 23. However, for τ = 100 the calibrated d^f increase linearly with d_{EMB} even for d_{EMB} = 20, thus displaying no sign of saturation (4).

The last column of Table 3 contains d_{EMB}, the dimension of Euclidean space in which the time series was embedded. For the HO systems this is $2f$, where f is the number of degrees of freedom. The infinite dimensional MG systems may have low dimensional attractors. Thus one increases d_{EMB} until d saturates. The d_{EMB}-dimensional points are $X_i = \{x(t_i), x(t_i + \tau), \ldots, x(t_i + (d_{EMB} - 1)\tau)\}$. The practical rationale for embedding is (22) that one has access only to a few components of a multidimensional time series. d_{EMB}-dimensional vectors X_i would then be formed and X-space would be used instead of x-space. τ is a judiciously chosen interval such that reasonable correlation exists amongst the components. The examples for LOG4 (2),[4] ZASL (8), and HENON (4, 6) show what may happen. ZASL (8) gives d's which are approximately twice as large as for ZASL (2); HENON (4, 6) are both smaller than HENON (2)! (Our simple construction uses d_{EMB} consecutive x_j's to form a d_{EMB}-dimensional vector, but the n vectors chosen are not necessarily consecutive.) Our principal conclusion is that embedding is a delicate process that requires more care than commonly believed. In particular, $\hat{d}$ as a function of d_{EMB} does not always behave predictably.

Our algorithm behaved erratically for the logistic map for $a = a_\infty = 3.5699\ldots$. The theoretical value for $d_2 = \sigma = 0.517$ (4). We found, with 2000 points ($d_{m=2}$, $d_{m=6}$) = (0.48, 0.45) for d_{EMB} = 1 (average of 25 sets), (0.40, 0.33; 2/12), (0.48, 0.44; 3/8), and (0.50, 0.47; 5/5). Inspection of individual $\hat{d}$ values that made up these averages reveals that for d_{EMB} = 1 the components cluster around 0.55, 0.50, 034, 0.21, 0.16.

The erratic behavior may be due to excessive fluctuations in the k–NN distances, which sample-averaging failed to smooth out. Rejection of outliers may then be beneficial and could be simply implemented by using the L_1 norm (instead of the L_∞ norm) for the distance calculations, as well as determining the best slope of log $\bar{r}_k$ vs. log k via L_1 fitting, using linear programming. This is robust against outliers, although computationally less efficient.

Both the construction and implementation of our algorithm argue for a probability measure dimension, σ in fact (5). This "information dimension" has recently been shown (10) to be invariant under "reasonable" changes of variables, a desirable property for a "dimension" to have. It was shown elsewhere (23) how to generalize the algorithm to obtain *moments* of the probability density. This will provide a measure of the nonuniformity of the distribution.

Other possible algorithms than the one based on eq. [5] follow from the theory. Thus assume that $(1/n)\,\Sigma_i\, p(x_i)^{-1/d}$ is very weakly dependent on n. Write $r(n,k,d) \equiv E(r_k)$. Then $T_1 \equiv r(n,k,d)/r(n',k,d) = (n'/n)^{1/d}$ for large n,n', $T_2 \equiv r(n,k,d)/r(n,k',d) = \Gamma(k')\Gamma(k + 1/d)/\Gamma(k)\Gamma(k' + 1/d)$. If $k' = k + 1$, $T_2 = k/(k + 1/d)$. Thus log T_1 vs. log (n'/n) is a straight line with slope $1/d$, and T_2 vs. $1/k$ has slope $-1/d$ for $kd \gg 1$. These alternatives were not tested.

In summary, we have presented explicit evidence that all the standard dimensionality algorithms that use variants of log r_k vs. log k depend on the distribution of the sample points and do not follow exact power laws. We demonstrated with examples the efficacy and need of *calibrating* dimensionality algorithms against *known* distributions of *known* dimensionality d, especially for d large, and used this calibration to show that embedding into higher dimensional spaces is a delicate process fraught with dangers.

[4]Numbers in parentheses denote the embedding dimension.

Received July 31, 1987

This paper is dedicated to Professor James A. Morrison

U. KÖHLER, H. H. MANTSCH, and H. L. CASAL. Can. J. Chem. **66**, 983 (1988).

The interaction of ascorbyl palmitate (AP) with phospholipid bilayers of 1,2-dipalmitoyl-*sn*-glycero-3-phosphocholine (DPPC), 1,2-dimyristoyl-*sn*-glycero-3-phosphoethanolamine (DMPE), and 1,2-dipalmitoyl-*sn*-glycero-3-phosphoethanolamine (DPPE) has been studied by variable temperature infrared spectroscopy. The incorporation of AP into these lipid bilayers induces a considerable increase in the gel to liquid-crystal phase transition temperature of the lipid. The increase in this temperature is dependent on the nature of the lipid head group, on the relative concentration of AP, and on its degree of ionization; i.e., smaller temperature increases are observed when AP is ionized, forming salts with cations (NH_4^+, Li^+, K^+, and Ca^{2+}). The stabilizing effect of the long chains in the bilayers plays an important role in inducing temperature increases. However, in the case of AP the present data also demonstrate that specific interactions at the polar head group serve to further stabilize the incorporation of AP into lipid bilayers. The infrared spectra demonstrate that in the case of DPPC:AP mixtures there are changes compatible with the formation of hydrogen bonds between the OH group at position 3 in AP and the ester carbonyl group at the *sn*-2 chain in DPPC. In the case of PE:AP mixtures the spectra are compatible with AP intercalated between PE head groups acting as a hydrogen bond bridge linking the phosphate and ammonium groups of two different PE molecules.

U. KÖHLER, H. H. MANTSCH et H. L. CASAL. Can. J. Chem. **66**, 983 (1988).

Utilisant la spectroscopie infrarouge à température variable, on a étudié les interactions entre le palmitate d'ascorbyle (PA) et des doubles couches de phospholipides de dipalmitoyl-1,2 *sn*-glycéro phosphocholine-3 (DPPC), de dimyristoyl-1,2 *sn*-glycéro phosphoéthanolamine-3 (DMPE) et de dipalmitoyl-1,2 *sn*-glycéro phosphoéthanolamine-3 (DPPE). L'introduction de PA dans ces doubles couches de lipides induit une augmentation considérable de la température de transition au cours du changement de phase gel – cristal liquide du lipide. L'augmentation de cette température dépend de la nature de la partie polaire du lipide, de la concentration relative de PA et de son degré d'ionisation; on observe des augmentations plus faibles de la température lorsque le PA est ionisé et qu'il forme des sels avec les cations (NH_4^+, Li^+, K^+ et Ca^{2+}). L'effet stabilisant des longues chaînes des doubles couches joue un rôle important en induisant des augmentations de température. Toutefois, dans le cas du PA, les données que nous avons obtenues démontrent que les interactions spécifiques des groupements polaires stabilisent aussi l'incorporation du PA dans les doubles couches de lipides. Les spectres infrarouges démontrent que, dans le cas des mélanges DPPC:PA, il se produit des changements qui sont compatibles avec la formation de liaisons hydrogènes entre le groupement OH en position 3 du PA et le groupement ester en position *sn*-2 de la chaîne du DPPC. Dans le cas des mélanges PE:PA, les spectres sont compatibles avec la présence d'un PA intercalé entre deux molécules de PE; le PA sert comme pont hydrogène reliant les groupements phosphate et ammonium de deux molécules différentes de PE.

[Traduit par la revue]

Introduction

The interaction of specific chemicals (often referred to as guest molecules) with biological membranes continues to be an active area of research with the general aim of understanding membrane-associated phenomena as well as characterizing the structures of these mesomorphic phases. In particular, the interaction of long-chain fatty acids and alcohols with phospholipids has received considerable attention (1–8). Generally, the presence of additives in lipid bilayers lowers the gel to liquid-crystal phase transition temperature (T_m) of the lipid. However, when fatty acids are mixed with lipid bilayers the modification of the thermal phase behaviour is dependent on the fatty acid chain length. In the case of long-chain fatty acids there is a marked increase of the gel to liquid-crystal phase transition temperature; on the other hand, short-chain compounds induce a decrease of T_m. These results are rationalized in terms of hydrogen bonding between the polar phospholipid head group and the carboxylate group of the guest fatty acid (cf. 9 and refs. therein). The different effects induced by fatty acids of different chain length emphasize the subtle balance of forces that regulate the phase behaviour of phospholipid bilayers: on the one hand, polar interactions (such as hydrogen bonding) at the head group may serve to stabilize the bilayer, thus inducing a higher T_m; on the other hand, when these polar interactions involve a concomitant bilayer disordering (such as that brought about by the presence of short chains), T_m decreases. Accordingly, "bulkier" guests also induce decreases in T_m (10).

In this report we describe the thermal phase behaviour of phospholipid bilayers of phosphatidylcholine (PC) and phosphatidylethanolamine (PE) mixed with ascorbyl palmitate (AP), a lipophilic derivative of vitamin C. AP provides an excellent model for the study of both polar interactions with the lipid head group and nonpolar interchain interactions with the lipid hydrocarbon core. The rationale behind the selection of the two classes of lipids used in this study, PC and PE, is their different hydrogen bonding capabilities. While both lipid head groups have the capability to serve as hydrogen bond acceptors (through the phosphate and the ester carbonyl groups), only PE has the additional capability of serving as hydrogen bond donor (via the NH_3^+ group). An investigation of these interactions at the molecular level is of particular interest, given the resemblance of AP to the important class of glycolipids (11). Furthermore, AP, which is a potent antioxidant by itself, also enhances the antioxidant potency of vitamin E, especially when mixed with lecithins (12–15).

Experimental

Materials and sample preparation

1,2-Dipalmitoyl-*sn*-glycero-3-phosphocholine (DPPC), 1,2-dipalmitoyl-*sn*-glycero-3-phosphoethanolamine (DPPE), and 1,2-dimyristoyl-*sn*-glycero-3-phosphoethanolamine (DMPE) were purchased from Sigma Chemical Co. (St. Louis, MO); 1,2-perdeuteriopalmitoyl-*sn*-glycero-3-phosphocholine (DPPC-d_{62}) was from Avanti Polar Lipids (Birmingham, AL), ascorbic acid (AA) from BDH Chemicals (Toronto, Canada), and ascorbyl palmitate (AP) from Aldrich Chemical Co. (Milwaukee, WI). The AP salts with different cations were prepared at pH 7 using standard procedures (16). Samples for infrared spectroscopy were prepared from the appropriate amounts of solid AA, AP or its salts, and DPPC, DMPE, or DPPE. The mixtures were hydrated by adding H_2O or D_2O (80% by weight) and warming to ca. 10°C above the corresponding T_m, vortexing while warm, and allowing to cool to room temperature; this procedure was repeated three times. Identical results were obtained with samples prepared by mixing the components as solutions in chloroform/methanol, followed by solvent evaporation and hydration.

Spectra and data processing

Infrared spectra at 2 cm^{-1} resolution were recorded with a Digilab FTS-15 FT-IR spectrometer. The samples (12 μm thickness) were held between ZnSe windows. Procedures for data collection and analysis have been described previously (17). Fourier self-deconvolution procedures were used to resolve broad band contours into their constituent bands (18, 19).

Results and discussion

The principal effect of the addition of AP into bilayers of either PC or PE is a pronounced elevation of the gel to liquid-crystal phase transition temperature. The changes in the lipid thermotropic phase behaviour were studied by variable-temperature infrared spectroscopy. At the same time, the infrared spectra reveal subtle changes at the molecular level. Therefore, we separate the presentation and discussion of our results into two main areas: the thermal phase behaviour of AP:lipid mixtures and the interpretation of spectral changes observed at the level of different functional groups.

Thermotropic phase behaviour of lipid:AP mixtures

The thermal phase behaviour of mixtures of AP with lipids was followed by measuring the temperature dependence of the wavenumber of the symmetric stretching mode, $\nu_s(CH_2)$ of the methylene groups of the fatty acyl chains (17). In these lipid:AP mixtures both the lipid and AP molecules contain fatty acyl chains that give rise to $\nu_s(CH_2)$ bands. It is well established that the wavenumber of the $\nu_s(CH_2)$ mode undergoes a shift of 2–3 cm^{-1} when bilayer lipid assemblies change from the gel phase to the liquid-crystalline phase (17). Similarly, in the case of AP the $\nu_s(CH_2)$ wavenumber increases when hydrated assemblies change from the coagel to the micellar state at 63°C.[2] Figure 1 shows typical plots illustrating the temperature dependence of the $\nu_s(CH_2)$ wavenumber of the following samples: (*i*) AP mixed with DPPC (1:1 molar ratio); (*ii*) AP mixed with DPPE (1:1 molar ratio); and (*iii*) the potassium salt of AP (APK) mixed with DPPC (1:1 molar ratio). The transition temperatures in Table 1 were determined by monitoring spectral changes of the vibrational modes of the fatty acyl chains. The same transition temperatures were found when monitoring the temperature dependence of vibrational modes in the polar head group region of both the lipid and AP molecules, indicating that the transition occurs concomitantly in the hydrocarbon core of the membrane and in the polar regions. The increase in T_m is dependent on the concentration of AP (Table 1); thus, T_m is 51°C for a 1:1 mixture of AP and DPPC and 46°C for a 1:5 mixture. We did not study samples with excess AP, and the possibility of compound (complex) formation with a specific stoichiometry was not investigated. Fatty acids are known to form 2:1 complexes with lipids such as PC (9, 10).

Since, as noted above, both the lipid and AP fatty acyl chains give rise to $\nu_s(CH_2)$ bands at the same wavenumber, the temperature dependence of this mode in lipid:AP mixtures contains information from both components. However, by using deuterated DPPC it is possible to separate spectroscopically the thermal events of the individual components of the mixture. Figure 2A shows the temperature dependence of the $\nu_s(CD_2)$ mode from the fully deuterated fatty acyl chains of DPPC-d_{62} in a 1:1 mixture with AP. The transition occurs at 47.5°C in the DPPC-d_{62}:AP mixture, while it is at 37°C for pure DPPC-d_{62} (21). The same transition temperature is obtained when monitoring the behaviour of the $\nu_s(CH_2)$ modes of the AP acyl chain in the same

DMPE	—	—	49
DMPE:AP	1:1	—	65

[a]Determined from the temperature dependence of the $\nu_s(CH_2)$ wavenumber in the case of T_m and from the temperature dependence of the $\delta(CH_2)$ mode in the case of T_p.

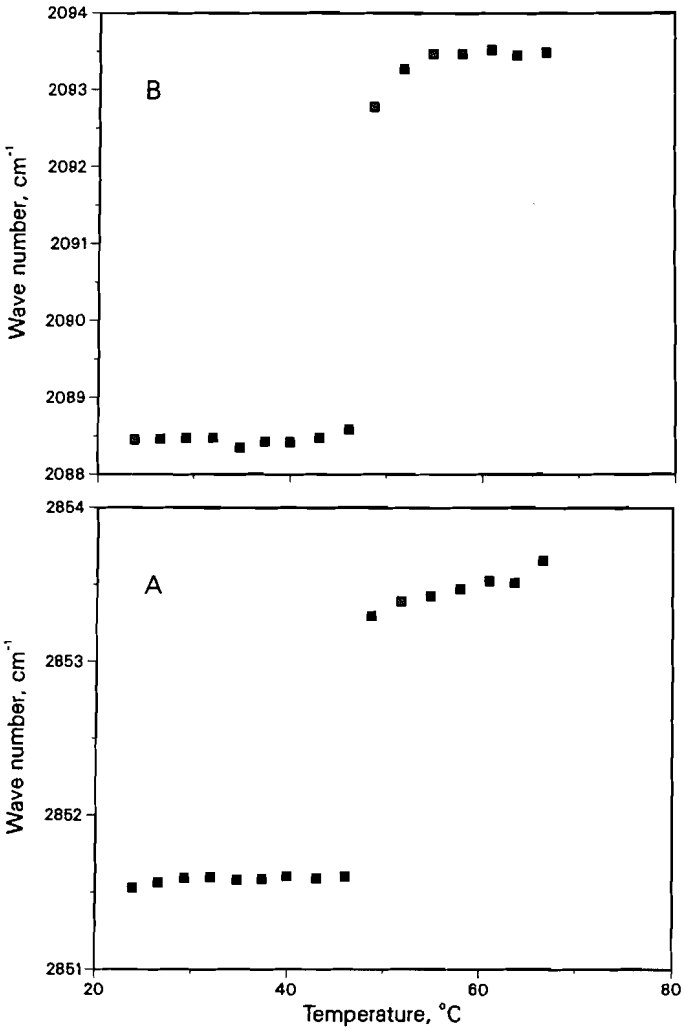

FIG. 2. Temperature dependence of the $\nu_s(CH_2)$ (A) and $\nu_s(CD_2)$ (B) wavenumbers in the infrared spectra of a DPPC-d_{62}:AP (1:1) mixture.

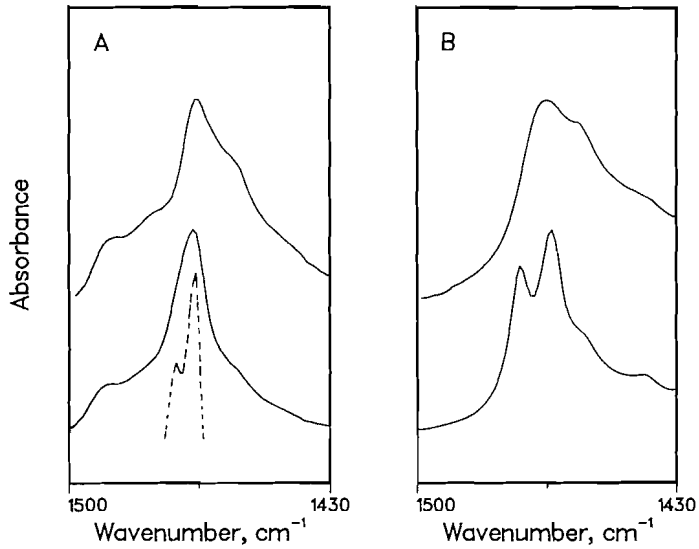

FIG. 3. A. The 1500–1430 cm^{-1} region of the infrared spectrum of a DPPC:AP mixture (1:1) at 20 and 60°C. The broken curve is the result of deconvolution with a Lorentzian line of 5 cm^{-1} full width at half height using a resolution enhancement factor of 1.8. B. The 1500–1430 cm^{-1} region of the infrared spectrum of a DMPE:AP mixture (1:1) at 20 and 70°C.

spectra (Fig. 2B). These data demonstrate that the conformational melting of DPPC and AP occurs at the same temperature; it is therefore concluded that DPPC mixes well with AP and that there is no phase separation. The increment of T_m in DPPC-d_{62} induced by AP is the same (approximately 10°C) as that induced by AP with nondeuterated DPPC, which indicates that the effects that lead to this increase of T_m must be primarily associated with interactions at the head group of the lipid molecules.

So far, the data indicate that the temperatures of the main phase transitions of PC and PE increase considerably due to the presence of AP. No "new" transitions are observed, suggesting that no phase separation occurs. This elevation of T_m has some features in common with the situation of fatty acids mixed with lipids. For example, fatty acids induce increases in T_m but their salts have a negligible effect; similarly, AP salts induce a smaller increase (Table 1). In contrast, palmitic acid (2:1 mixture) increases the T_m of DPPC by 20°C (to 61.5°C) (22) but has no effect on DPPE (9). On the other hand, AP increases the T_m of DPPE by 17°C (to 80°C, see Table 1) and that of DPPC by only 10°C. Thus, the interaction of AP with PCs and PEs is different from that of fatty acids and also different for these two classes of lipids.

Given that AP interacts differently with PC and PE, it is plausible to suggest that the differences between the head groups of PC and PE are responsible for the different interactions. This point is addressed in the next section.

The long palmitoyl chain of AP must be inserting within the hydrocarbon core of PC and PE bilayers, possibly causing changes in the packing of the fatty acyl chains. The pretransition of PCs at T_p is very sensitive to changes in the packing pattern of the fatty acyl chains as it involves primarily a change in packing from orthorhombic (below T_p) to hexagonal (above T_p). Infrared spectra, in particular the CH_2 scissoring vibrations $\delta(CH_2)$ of the acyl chains, are especially sensitive to the packing of polymethylene chains. This mode can be used to ascertain the packing pattern and therefore to determine the temperature of the pretransition (23). In the spectra of mixtures of DPPC with AP we find that the temperature dependence of the $\delta(CH_2)$ mode is the same as that of pure DPPC. From this temperature dependence we find that the pretransition temperatures of DPPC mixed with AP are all approximately 34°C. These temperatures are also given in Table 1.

Figure 3 shows the region 1500–1430 cm^{-1} of the spectra of a DPPC:AP mixture (1:1 molar ratio) and a DMPE:AP mixture (1:1 molar ratio). In the spectra of DPPC:AP at temperatures below T_p there are two bands at 1471 and 1468 cm^{-1} as in the spectrum of pure DPPC (see Fig. 4 of ref. 17 for comparison). The two bands collapse to one at 1468 cm^{-1} above T_p. The appearance of two bands for the $\delta(CH_2)$ mode is a consequence of correlation field splitting and demonstrates that there is interchain vibrational coupling of the fatty acyl chains, compatible with the acyl chains being packed in an orthorhombic-like subcell (23). In the spectrum of DPPC:AP in Fig. 3A the two component bands are separated by 3 cm^{-1} (1471 and 1468 cm^{-1}), whereas in spectra of pure DPPC recorded at the same temperature (20°C) the separation between the two component bands is larger (6 cm^{-1}; cf. Fig. 4 of ref. 17). As the separation between the component bands is related to the magnitude of the interchain potential, a smaller frequency separation indicates that this potential is weaker in the DPPC:AP mixture than in pure DPPC. The most ready explanation for a weaker coupling

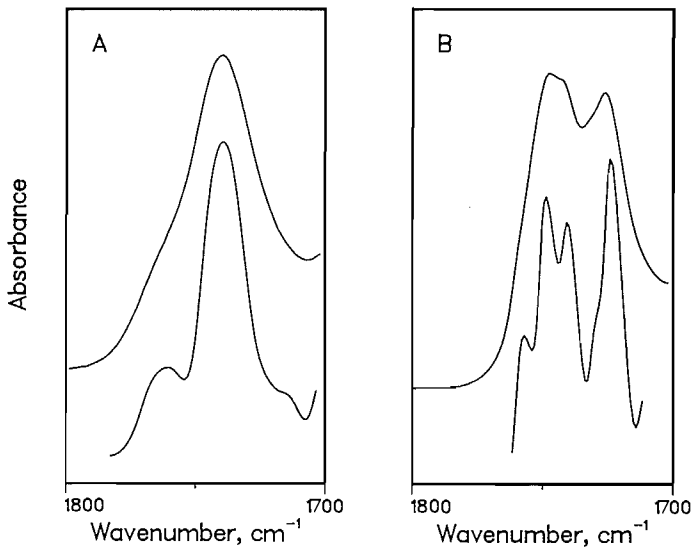

FIG. 4. A. The 1800–1700 cm^{-1} region of the infrared spectrum of a DPPC:AP mixture (1:1) at 20°C. B. The 1800–1700 cm^{-1} region of the infrared spectrum of a DMPE:AP mixture (1:1) at 20°C. In both cases, the bottom traces are the result of deconvolutions with a Lorentzian line of 18 cm^{-1} full width at half height using a resolution enhancement factor of 2.

is that in DPPC:AP the interchain distances are larger and therefore the packing of the fatty acyl chains is somewhat "looser" compared to that of pure DPPC, but that the pretransition is still present at approximately the same temperature. The fact that the incorporation of the AP acyl chains into the DPPC hydrocarbon core does not induce a large change in interchain interaction, but that the main transition temperature is increased by 10°C, suggests that interaction at other moieties must play an important role.

PEs show no pretransition comparable to that of PCs, and in the spectra of hydrated PEs the $\delta(CH_2)$ mode is split[3] at all temperatures below T_m. The frequency separation between the components of $\delta(CH_2)$ in PEs is 2–3 cm^{-1} (25). However, a much larger separation (8 cm^{-1}) is found in the spectra of the DMPE:AP mixture at 20°C where the bands are at 1472 and 1464 cm^{-1} (Fig 3B, bottom). Thus, in contrast to the case of DPPC the packing of the fatty acyl chains of PE is markedly affected by the presence of AP molecules. In the case of PEs the acyl chains are more closely packed in the presence than in the absence of AP; the opposite was found for PC:AP.

From the spectral characteristics of the fatty acyl chains (the CH_2 stretching and CH_2 scissoring modes) the thermal phase behaviour of AP mixed with PC and PE can be summarized as follows: The introduction of AP into DPPC bilayers increases the gel to liquid-crystal phase transition temperature by 10°C, does not affect the temperature of the pretransition, and modifies slightly the packing of the fatty acyl chains by inducing larger interchain interactions. The introduction of AP into PE bilayers increases the transition temperature by 16 to 17°C and induces a much tighter packing of the fatty acyl chains.

Molecular-level interactions

We now turn to the question of the molecular-level interactions giving rise to the thermal effects just described. Previous studies have established that a large increase of T_m in lipids is observed when there exists the possibility of intermolecular hydrogen bonding between the guest and lipid molecules (9, 10). It is with this in mind that we search for hydrogen bonding between PC and PE with AP.

A note on the possible states of ionization of the molecules involved is worth mentioning here since the thermal phase behaviour of lipids is affected by their state of ionization (26). All our experiments were carried out in nonbuffered dispersions prepared with D_2O; the pH of these preparations is between 6 and 7. The pK_a of AP must be the same as that of ascorbic acid (4.26) while the pK_a of DPPC is between 2 and 3 (9, 27). Therefore, AP cannot protonate DPPC. At the same time, the spectrum of ionized AP is completely different from that of AP and thus characteristic of the state of the sample. In particular, the C═O and C═C stretching bands of AP are diagnostic of the ionization state because changes in the charge density at position 3 are transmitted to these bonds.

It has been proposed that guests that are hydrogen bond donors (fatty acids, alcohols, amines) interact with lipids by forming hydrogen bonds to the lipid phosphate group (9, 10, and refs. therein). In the spectra of DPPC mixed with AP and AP salts the bands due to phosphate vibrations are the same as those in the spectra of pure DPPC. In particular, the antisymmetric O═P═O stretching band appears at 1220 cm^{-1} at all temperatures in spectra of DPPC, DPPC:AP, and mixtures of DPPC with salts of AP. The value of this wavenumber is characteristic of hydrated phosphate groups in lipids (28) and the fact that it is the same with and without AP suggests that here are no dramatic changes in the hydrogen bonding scheme of the phosphate group. Evidence for hydrogen bonding between AP and DPPC is found in the ester C═O stretching bands.

Figure 4A shows the 1800–1700 cm^{-1} region of the spectrum of DPPC:AP (1:1 molar ratio) at 20°C (i.e., gel phase). This spectrum of DPPC:AP is not a simple superposition of the spectra of DPPC and AP. For comparison, we recall the spectrum of pure DPPC; the ester C═O groups give two bands at 1740 and 1728 cm^{-1}, assigned to the C═O groups in the *sn*-1 and *sn*-2 chains respectively (29, 30). The difference in the two groups arises from the conformational nonequivalence of the two chains in the C2—C3 bonds. These two bands are observed in both the gel and liquid-crystal phases of DPPC at approximately the same frequencies. Meanwhile, the spectrum of pure AP shows three C═O stretching bands, at 1762 cm^{-1} (ascorbate C═O) and at 1747 and 1732 cm^{-1} (palmitate C═O). The spectrum of the 1:1 DPPC:AP mixture in the gel phase (Fig. 4A) shows three bands in this region, at 1764, 1739, and 1714 cm^{-1}. The band at 1764 cm^{-1} in the spectrum of the mixture results from the AP ascorbate moiety, while the bands at 1739 and 1714 cm^{-1} result from the palmitate groups of DPPC and AP.

The fact that the spectrum of the mixture is not a simple superposition of the spectra of DPPC and AP reveals that the lipid carbonyl groups are in a different environment when the molecules are mixed. In particular, the two DPPC C═O stretching bands at 1742 and 1728 cm^{-1} have merged into one band at 1739 cm^{-1}. The most likely explanation for this observation is that the conformational nonequivalence of the C2—C3 segments of the DPPC chains has been removed. Apparently, in the DPPC:AP mixture the two DPPC ester bonds have become equivalent. However, as discussed above, this has not brought about important changes in the packing characteristics of the fatty acyl chains.

In the spectrum of the DPPC:AP gel phase (Fig. 4A) there appears a third C═O stretching band at 1714 cm^{-1}. Extensive

[3]Different nonhydrated phases of PEs show different patterns for the $\delta(CH_2)$ mode (24). However, all our PE samples were well hydrated.

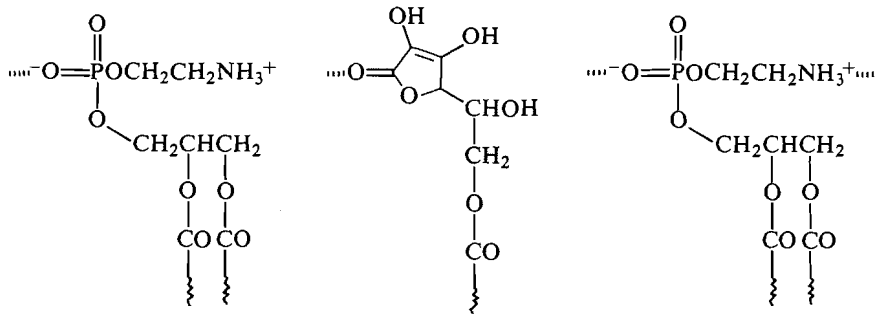

SCHEME 1

studies by Levin and co-workers (29, 30) established that C=O stretching bands below 1720 cm^{-1} occur when these C=O groups participate in strong hydrogen bonding. Thus, the appearance of this band at 1714 cm^{-1} strongly suggests that one (or two) of the DPPC ester C=O groups becomes hydrogen bonded in the presence of AP. AP has several OH groups that could serve as donors for this type of hydrogen bonding. In the spectra of DPPC mixed with AP salts, where the OH group at position 3 is ionized, the band at 1714 cm^{-1} does not appear and the DPPC C=O stretching bands are the same as in the spectra of pure DPPC. From this, it is possible to conclude that the OH group at position 3 of AP engages in hydrogen bonding to at least one of the DPPC ester carbonyl groups. Apparently, the formation of this hydrogen bond also induces a change in the conformation of the *sn*-2 chain in the C2—C3 segment. We emphasize that AP is not ionized; the spectral characteristics of ionized AP are not observed in these spectra of DPPC:AP mixtures; the AP OH bending modes (1400–1200 cm^{-1}) are observed and in a pattern that indeed suggests hydrogen bonding and not ionization. The C=C stretching band of AP is at 1677 cm^{-1}, again indicating hydrogen bonding and not ionization; this band appears at 1598 cm^{-1} in the spectra of ionized AP.

Thus, when the DPPC:AP mixture is in the gel phase below T_m there is hydrogen bonding between the OH group at position 3 of AP (donor) and at least one of the DPPC ester C=O groups (acceptor). The lack of change in the bands due to the phosphate group of DPPC cannot be taken as definitive evidence of lack of hydrogen bonding to this group. In the liquid-crystal phase of the DPPC:AP mixture the situation changes. The band at 1714 cm^{-1} (from the hydrogen-bonded C=O group) disappears and at the same time the AP C=C stretching band shifts from 1677 to 1682 cm^{-1}; these changes are compatible with the hydrogen bond between the AP 3-OH group and the ester C=O groups disappearing. Also, the DPPC C=O bands become the same as in pure DPPC and two bands are now observed at 1740 and 1728 cm^{-1}; the removal of the hydrogen bond is accompanied by the reestablishment of the conformational nonequivalence of the two DPPC ester carbonyl groups.

The C=O stretching bands observed in the spectra of the DMPE:AP mixture are completely different from those of the DPPC:AP mixture (compare Figs. 4A and 4B). Surprisingly, the C=O stretching bands of DMPE appear at almost the same wavenumbers as those in the spectra of pure DMPE. It appears that while AP induces a large increase in T_m of DPPE and DMPE, it does not lead to conformation changes in the C=O ester groups nor does it introduce new hydrogen bonds. At the same time, the $\delta(CH_2)$ bands in the spectra of DMPE:AP (Fig. 3B) demonstrate that in this mixture the fatty acyl chains are packed very tightly. Also, the bands due to the phosphate group are very similar in the spectra of the DMPE:AP mixture and in pure DMPE; thus in both cases the O=P=O asymmetric stretching bands are at 1220 cm^{-1}, characteristic of hydrated PE. The OH deformation bands of the ascorbyl moiety of AP are very different in the spectrum of the DMPE:AP mixture compared to those in pure AP, which is compatible with the fact that these groups are engaged in hydrogen bonding to PE. The C=O stretching band of AP in the DMPE:AP spectrum is at 1756 cm^{-1}, compared to 1768 cm^{-1} in pure AP, suggesting hydrogen bonding; the characteristics of the AP spectrum indicate that AP is not ionized. From these spectral characteristics we propose that in this case the AP C=O group serves as an acceptor while the NH_3^+ group of PE acts as the donor. At the same time, the OH group at position 3 of AP may serve as donor for a hydrogen bond to the phosphate group of PE. Scheme 1 shows a tentative model for these hydrogen bonds between PE and AP based on the spectral characteristics alone. In this model the AP molecule serves as a hydrogen-bond bridge between two PE molecules; moreover it implies that the insertion of this bridge in the already rigid network of PE hydrogen bonds serves to strengthen it further, which is reflected in a higher T_m of the DMPE:AP mixture (see Table 1). We also note that at the phase transition of these PE:AP mixtures large changes are observed in the position of the AP C=C stretching and ascorbate C=O stretching modes; the former shifts from 1670 to 1684 cm^{-1} while the latter shifts from 1756 to 1768 cm^{-1}, suggesting that the hydrogen bonding does not exist (or is much weaker) in the liquid-crystal phase.

Finally, a control experiment was carried out with a mixture of ascorbic acid (AA) and DPPC, also at a 1:1 molar ratio. The transition temperature of this mixture is 40°C, somewhat lower than that of pure DPPC (see Table 1). The spectra of the DPPC component of this mixture are very similar to those of DPPC and DPPC:AP in the liquid-crystal phase, but there are subtle changes in the bands due to AA, suggestive of a weak interaction between AA and DPPC. The lower T_m of the DPPC:AA mixture suggests that the weak interaction with AA leads to a spreading of the fatty acyl chains of DPPC, particularly since similar effects have been observed in mixtures of DPPC with carbohydrates (20). These results emphasize the importance of the insertion of the acyl chain of AP in the hydrocarbon core of lipid bilayers to yield a complex with altered thermotropic behaviour.

Conclusions

The incorporation of ascorbyl palmitate (AP) into bilayers of PC and PE induces a large increase of the gel to liquid-crystal phase transition temperature of the lipids. The nature of the phase transition in the lipid:AP mixtures is the same as in pure

For personal use only.

lipds and involves the conformational melting of both the lipid fatty acyl chains and the palmitoyl chains of AP. AP mixes with the lipid bilayers and there is no AP-induced phase separation. In the case of PC:AP mixtures the pretransition of the lipid bilayer is also preserved; since the pretransition involves primarily a change in acyl chain packing, we conclude that the insertion of AP molecules into the PC hydrocarbon core does not induce important changes in the packing of the lipid fatty acyl chains. In contrast to the increase in the temperature of the gel to liquid-crystal transition there is no increase in the temperature of the pretransition, suggesting that this event is controlled by interchain interactions alone. In the case of the PC:AP mixtures the spectra also reveal a much looser packing of the fatty acyl chains than in pure PC bilayers or in the PE:AP mixtures in the gel phase.

The results obtained with mixtures of AP salts and DPPC demonstrate that the acidic enol group at position 3 of the ascorbate moiety plays a dominant role in determining the interaction at the polar group of DPPC. The ester C=O stretching bands of DPPC reveal that there is a major conformational change involving these groups and there is evidence for the formation of hydrogen bonds between the enolic OH group of AP and the DPPC C=O groups. No such hydrogen bonds are formed between AP and PE. On the contrary, there is evidence that in the PE:AP mixtures the AP C=O moiety acts as the acceptor group while the PE NH_3^+ moiety acts as the proton donor; thus, the spectra of DMPE:AP are compatible with the ascorbate moiety of AP serving as a hydrogen-bond bridge between the NH_3^+ and PO_4^- groups of two PE molecules.

The thermotropic effects observed by incorporation of AP into PC and PE bilayers are similar to those observed when mixing long-chain fatty acids with PC. However, fatty acids induce only a small increment of T_m (1–2°C) when mixed with PE, in contrast with the 16–17°C increment observed with AP. Thus, different mechanisms of interaction at the molecular level are operational for the interaction of fatty acids and AP. When AP is ionized there are only small changes in the thermal phase behaviour of the lipids, similar to the effect of fatty acid salts. As a general point, the present data demonstrate that AP mixes well with PC and PE, and, that since the AP molecules are protected from ions in solution, the mixing of this lipophilic vitamin C with lipids may serve as a means of transport across membranes of this potent antioxidant. At the same time, incorporation of AP into bilayers containing PE may serve as a means of creating more rigid structures.

Apparent heat capacities have been measured for fifteen branched and cyclic alcohols in dilute *n*-decane solution at 25°C. The alcohols were 2-methyl-2-propanol, cyclohexanol, 3-methyl-3-pentanol, *trans*-, *cis*-, and mixed isomer 2-methylcyclohexanol, 1-methylcyclohexanol, 3-ethyl-3-pentanol, cyclooctanol, 3,7-dimethyl-1-octanol, 5-decanol, 4-propyl-4-heptanol, cyclododecanol, 5-butyl-5-nonanol, and 8-hexadecanol (in *n*-hexane). Excess heat capacities C_p^E throughout the concentration range were measured at 25°C for: 1-hexanol + *n*-hexadecane (*n*-C_{16}) and + 2,2,4,4,6,8,8-heptamethylnonane (br-C_{16}), 4-propyl-4-heptanol, and 1-decanol + *n*-decane, 3-methyl-3-pentanol + *n*-C_{16} and + br-C_{16} and at 27°C for cyclohexanol + *n*-C_{16} and + br-C_{16}. Also, for 3-methyl-3-pentanol + *n*-decane C_p^E was measured at 10, 25, 40, and 50°C. For a series of isomeric alcohols, the apparent molar heat capacities show a maximum against concentration which decreases and moves to higher alcohol concentration as the hydroxyl group on the alcohol becomes increasingly hindered, effectively reducing the alcohol self-association capabilities. This situation is also reflected by the heat capacities of the pure alcohols which increase strongly in magnitude in going from a linear 1-alcohol to an isomeric alcohol which has its hydroxyl group on a quaternary carbon atom. C_p^E of the mixtures are negative at low alcohol concentrations turning positive at increasingly higher alcohol concentrations as the steric hindrance on the hydroxyl group increases. Throughout most of the concentration range C_p^E for the branched or cyclic alcohols is considerably more positive than for the corresponding isomeric 1-alcohol. For the highly hindered 3-methyl-3-pentanol $C_p^E(T)$ passes through a maximum. All of the above behaviour is explained by the Treszczanowicz–Kehiaian model for self-associated liquids + inert solvents which has been applied to the present data. Equilibrium constants have been obtained for alcohol association and are sensitive to alcohol structure. At low alcohol concentrations, while for the linear 1-alcohols tetramers are the predominant species and dimer are almost absent, for the corresponding isomeric alcohols the concentration of tetramers is severely reduced and the lower species, i.e. trimers and dimers, are more important. For the highly hindered alcohols, monomers are the predominant species in dilute solution reflecting the decrease in self-association ability that steric hindrance of the hydroxyl group imposes on them.

Opérant à 25°C, on a mesuré les capacités calorifiques apparentes de quinze alcools ramifiés et cycliques en solutions diluées dans le *n*-décane. Il s'agit des alcools suivants : méthyl-2 propanol-2, cyclohexanol, méthyl-3 pentanol-3, les isomères *cis*- et *trans*- du méthyl-2 cyclohexanol, méthyl-1 cyclohexanol, éthyl-3 pentanol-3, cyclooctanol, diméthyl-3,7 octanol-1, décanol-5, propyl-4 heptanol-4, cyclododécanol, butyl-5 nonanol-5 et hexadécanol-8 (dans le *n*-hexane). Opérant à 25°C, on a mesuré les capacités calorifiques en excès, C_p^E, à toutes les concentrations pour les mélanges : hexanol-1 + *n*-hexadécane (*n*-C_{16}) et heptaméthyl-2,2,4,4,6,8,8 nonane (C_{16}-ram), propyl-4 heptanol-4 et décanol-1 + *n*-décane, méthyl-3 pentanol-3 + *n*-C_{16} et + C_{16}-ram; les mêmes valeurs ont été mesurées à 27°C pour les mélanges : cyclohexanol + *n*-C_{16} et C_{16}-ram. Pour le mélange méthyl-3 pentanol-3 + *n*-décane, on a mesuré les C_p^E à 10, 25, 40 et 50°C. Pour une série d'alcools isomères, la courbes des capacités calorifiques molaires apparentes en fonction de la concentration présente un maximum qui diminue et qui se déplace vers des concentrations d'alcool plus élevées au fur et à mesure que le groupement hydroxyle de l'alcool devient plus encombré et qu'il réduit effectivement les possibilités d'auto-association de l'alcool. Cette situation se reflète aussi dans le fait que les capacités calorifiques des alcools purs qui augmentent fortement lorsqu'on passe des alcools primaire linéaires vers des alcools isomères tertiaires. A de faibles concentrations en alcool, les C_p^E des mélanges sont négatives; elles deviennent positives lorsque les concentrations d'alcool augmentent et que l'empêchement stérique du groupement hydroxyle augmente. Sur l'ensemble des concentrations, les valeurs de C_p^E des alcools cycliques ou ramifiés sont beaucoup plus positives que celles des alcools primaire correspondants. Dans le cas du méthyl-3 pentanol-3 qui est hautement empêchée, la valeur de $C_p^E(T)$ passe par un maximum. Tous ces comportements peuvent être expliqués par le modèle de Treszczanowicz–Kehiaian qui a été développé pour les liquides auto-associés + les solvants inertes et que nous avons appliqué aux données obtenues. On a déterminé les constantes d'équilibre pour les associations d'alcools et on a mis en évidence qu'elle sont sensibles à la structure des alcools. A des concentrations faibles en alcools, les tétramères des alcools primaires sont les espèces prédominantes et les dimères sont pratiquement absents;

[1]A complete set of data may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

par ailleurs, pour les alcools isomères correspondants, la concentration des tétramères est sévèrement réduite et les trimères et les dimères deviennent importants. Dans les cas des alcools fortement empêchés, les monomères sont les espèces prédominantes en solution diluée; cette situation est le reflet du fait que la possibilité d'auto-association est diminuée par l'empêchement stérique qui est imposé à ces groupements hydroxyles.

[Traduit par la revue]

Introduction

Amongst different thermodynamic quantities, the heat capacity is unique in that it is a very sensitive indicator of structure in pure liquids and solutions (1). In particular, heat capacity measurements for 1-alcohol + inert solvent mixtures have proven to be very useful in understanding the self-association of alcohol molecules in solution (1, 2). It has been found that, with the exceptions of methanol and ethanol, the associational part of the apparent molar heat capacity ϕ_C(assoc) of all linear alcohols is independent of both alcohol and alkane chain length. As a consequence, values of ϕ_C(assoc) for different systems follow a single corresponding states curve when plotted against a new concentration variable, ψ_1, essentially the hydroxyl concentration in solution (3). This remarkable result is predicted by the Treszczanowicz–Kehiaian (TK) theory (4) for self-associated liquids + inert solvents with a unique equilibrium constant for H-bond formation. Tetramers were found to be the predominant species with trimers and dimers being almost absent. The adherence of all primary alcohols + inert alkane mixtures to a corresponding states ϕ_C(assoc) vs. ψ_1 curve implies that for these alcohols self-association is only governed by the concentration of hydroxyl groups in solution, i.e. for linear alcohols the availability of the hydroxyl group to form H-bonds with neighbouring alcohol molecules is the same and independent of the size of the linear hydrocarbon tail attached to it. It appeared then interesting to study the effect that the introduction of various degrees of steric hindrance of the hydroxyl group has on the self-association ability of an alcohol. The present work reports heat capacity data for a series of branched and cyclic, secondary and tertiary alcohols mixed with an inert hydrocarbon solvent.

The TK model for self-associated liquids + inert solvents

In the TK model each molecule is capable of two energy levels corresponding to the associated state and the dissociated monomer as indicated by Fig. 1. For a pure alcohol, at very low temperature the associational energy U(assoc) will be low because all the alcohol molecules will be associated through H-bonds; as the temperature is raised the energy will rise corresponding to dissociation of the H-bonds. In Fig. 1, room temperature (T') will correspond to a temperature where most of the alcohol molecules will still be associated forming H-bonds. For a highly concentrated mixture of an alcohol with an inert solvent (I in Fig. 1), it will be slightly easier to break up the H-bonds; there is now a greater entropic driving force towards the randomly dispersed alcohol molecules. Going to lower concentrations in the inert solvent, the driving force towards dissociation becomes greater giving curves II and III in Fig. 1. Taking the slope of the energy curves, i.e. $dU(\text{assoc})/dT$, the association heat capacity of the alcohol, ϕ_C(assoc), is obtained at the different concentrations as a function of T; this is indicated in the lower part of Fig. 1 where ϕ_C(assoc) curves have the form of "Schottky peaks" (5). ϕ_C(assoc) is given explicitly by the model (1) as

$$[1]\quad \phi_C(\text{assoc}) = \frac{\left(\frac{\Delta H^0}{T}\right)^2 \frac{1}{R}\left[\sum_{i=2} \frac{i-1}{i} K_i^{\varphi} \frac{{\varphi_A}^i}{\varphi_1}\left(i - 1 + \sum_{j\neq i}(i-j)K_j^{\varphi}{\varphi_A}^{j-1}\right)\right]}{\left[1 + \sum_{i=2} iK_i^{\varphi}{\varphi_A}^{i-1}\right]}$$

where ΔH^0 is the enthalpy change for the formation of a H-bond, φ_1 the alcohol volume fraction and K_i^{φ} the volumetric equilibrium constant for species i. Equation [1] assumes that the i-mers are linear, i.e. that they involve $i - 1$ H-bonds. In the event that the i-mers are cyclic, i.e. involve i H-bonds, $i - 1$ becomes i and eq. [1] and the $i \neq j$ summation drops out. The fraction of monomers φ_A in eq. [1] is the closest root to zero of the equation

$$[2]\quad \sum_{i=2} K_i^{\varphi}{\varphi_A}^i + \varphi_A - \varphi_1 = 0$$

which can be easily found using a numerical method. The TK model can predict the excess heat capacity ${C_p}^E$ starting from

$$[3]\quad {C_p}^E = x_{OH}(\phi_C - {C_p}^0)$$

with ϕ_C being the apparent heat capacity of the alcohol in solution and ${C_p}^0$ the value for the pure state. In using this equation we need only be concerned with that part of the heat capacity which is due to association since the internal C_p of the alcohol is eliminated and other inter-molecular contributions will be small. In eq. [3] ${C_p}^0$(assoc) is obtained using eq. [1] with $\varphi_1 = 1$ and $\varphi_A = {\varphi_A}^0$.

Parameters of the theory, i.e. ΔH^0 and K_i^{φ}, can be fitted in the least square sense to experimental $\phi_C(\text{assoc}) = \phi_C - \lim \phi_C(x_{OH} \rightarrow 0)$ where the infinite dilution apparent molar heat capacity represents the contribution to the heat capacity of the alcohol in the absence of any association, each alcohol molecule being isolated in an inert solvent. For linear alcohols (1, 3) tetramers turned out to be the predominant species; the K_4^{φ} were found to change rapidly with the 1-alcohol studied reflecting the inter-alcohol rather than inter-hydroxyl character of these volumetric equilibrium constants. However, these K_4^{φ} can be translated into a single equilibrium constant for H-bond formation in tetramers, K_4. In contrast, for the branched and cyclic alcohols reported in this work the K_i^{φ} values fitted to the experimental ϕ_C(assoc) using eq. [1] indicate that, compared to linear alcohols, the concentration of tetramers is severely reduced and the lower species, i.e. trimers and dimers, are more important. Furthermore, the K_i^{φ} no longer lead to common values of K_i for H-bonding in the multimers. Thus the present

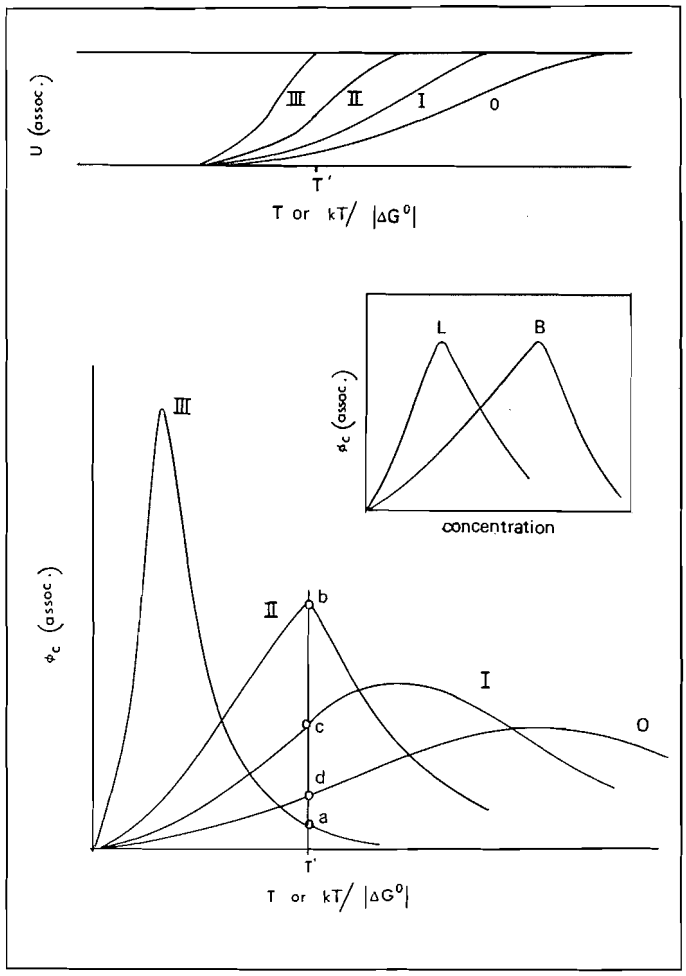

FIG. 1. Schematic representation of energy (upper diagram) and heat capacity (lower diagram) against $kT/|\Delta G^0|$ for an alcohol in the pure state (0) and at increasing dilution in an inert solvent (I, II, III). T' represents the experimental temperature.

systems deviate from the corresponding states scheme followed by the 1-alcohols where there is one dominant species. Different degrees of deviation are found to be related to the steric hindrance of the hydroxyl group which effectively decreases the alcohol self-association ability.

Experimental

Values for the apparent molar heat capacity ϕ_C of a series of branched and cyclic alcohols mixed with *n*-decane in the concentration range 0.1–10wt.% were determined at 25°C (*n*-hexane was used as solvent for 8-hexadecanol). Table 1 lists these alcohols together with their molar volumes, heat capacities, and ϕ_C at infinite dilution. Excess heat capacities C_p^E throughout the concentration range were measured for the following systems at 25°C: 1-hexanol + *n*-hexadecane (*n*-C_{16}) and + 2,2,4,4,6,8,8-heptamethylnonane (br-C_{16}), 4-propyl-4-heptanol and 1-decanol + *n*-decane, 3-methyl-3-pentanol + *n*-C_{16} and + br-C_{16}. At 27°C C_p^E was obtained for cyclohexanol + *n*-C_{16} and br-C_{16}. Also, for 3-methyl-3-pentanol + *n*-decane C_p^E was determined at 10, 25, 40, and 50°C. Heat capacity data both throughout the concentration range and in the dilute alcohol region may be purchased from the Depository of Unpublished Data.

All materials used in this work were obtained from either Aldrich Chem. Co. or Wiley Organics. Their stated purities range between 98 and 99.9%. Volumetric heat capacities were measured using a Picker Flow Microcalorimeter (Sodev, Sherbrooke, Quebec, Canada) and were transformed to a molar basis through solution densities obtained using a vibrating-cell densimeter (Sodev). The instrumentation and procedures have been described in the literature (7). The volumetric heat capacity of the liquid flowing through the working cell is measured against that of the reference cell. Solutions were prepared by weight and extreme care was taken during their preparation and handling in order to minimize evaporation losses. In the extremely dilute concentration range the heat capacity of each solution was determined using the pure solvent as reference. Heat capacity data for pure *n*-decane and *n*-hexane was taken from ref. 8. In the less diluted concentration range, where the heat capacity of the solutions differ greatly from that of the pure solvent, each solution acted as reference for the next as discussed in ref. 7. Heat capacities for pure alcohols were measured using as reference either 2-methyl-2-propanol or 1-decanol as indicated in Table 1; the heat capacity for pure 1-decanol was taken from ref. 1 and that for 2-methyl-2-propanol measured against *n*-decane. Heat capacities for pure *n*-C_{16} and br-C_{16} were taken from refs. 8 and 9, respectively, while those for *n*-decane at 10, 40, and 50°C were measured using benzene as reference; heat capacity data for benzene was taken from ref. 10. Through repetition of the present systems the precision appears to be ± 4 J K^{-1} mol^{-1} for ϕ_C in the dilute region, ± 5 to 6 J K^{-1} mol^{-1} for ϕ_C at infinite dilution and ± 0.1 J K^{-1} mol^{-1} for C_p^E.

Results and discussion

The Schottky peaks indicated in Fig. 1 can explain both the concentration and temperature dependences of ϕ_C(assoc). At T' = 25°C ϕ_C(assoc) is small for very low concentration (point *a* on curve III) because there is no structure in the solution, almost all the alcohol being dissociated; as the concentration increases (point *b* on curve II) ϕ_C(assoc) increases corresponding to increased structure due to the coming together of alcohol molecules into multimers over long distances. With further increases in concentration (point *c* in curve I) ϕ_C(assoc) decreases. Structure has decreased since although almost all alcohol molecules are associated into multimers they have come together over smaller distances. According to Fig. 1 then ϕ_C(assoc) must go through a maximum when plotted against concentration at constant temperature as indicated by the inset in Fig. 1. In Fig. 1 the maximum in ϕ_C against concentration at T' occurs at concentration II (point *b*). Compared to primary alcohols, secondary and tertiary alcohols form weaker H-bonds reflecting the fact that the hydroxyl group on the alcohol becomes increasingly hindered, effectively reducing the alcohol self-association capabilities. For secondary and tertiary alcohols the free energy of association ΔG^0 is less negative than for primary alcohols. In Fig. 1, the abscissa is more properly taken to be $kT/|\Delta G^0|$ rather than T itself, representing the ratio of the thermal energy to the H-bonding free energy. With this change the experimental temperature T' for a secondary or tertiary alcohol will correspond to a higher value of the $kT/|\Delta G^0|$ ratio in Fig. 1 than for a primary alcohol, and will act like a primary alcohol at $T > T'$. Figure 1 predicts then that for a secondary or tertiary alcohol ϕ_C(assoc) will have a maximum which will occur at higher alcohol concentration than for the corresponding isomeric primary alcohol. Then, in the inset in Fig. 1 curve L would correspond to ϕ_C(assoc) for a linear alcohol while curve B would be for a branched or cyclic alcohol. Figure 2 illustrates this situation through the experimental ϕ_C(assoc) at 25°C for 1-decanol and three of its isomers: another primary alcohol (3,7-dimethyl-1-octanol), a secondary alcohol (5-decanol) and a tertiary (4-propyl-4-heptanol). The introduction of two methyl groups along the hydrocarbon chain does not significantly affect the self-association ability of the primary alcohol. However, for the secondary and tertiary alcohols the maximum is progressively

displaced towards higher alcohol concentrations, i.e. ϕ_C(assoc) for these two alcohols correspond to ϕ_C(assoc) for 1-decanol at $T > 25$°C (as shown in Fig. 5 in ref. 1).

The excess heat capacities for 1-decanol and its three isomers mixed with *n*-decane at low alcohol concentration are shown in Fig. 3; C_p^E is negative at low alcohol concentrations becoming positive at increasingly higher alcohol concentrations as the steric hindrance of the hydroxyl group increases. C_p^E turns positive at $x_{OH} \sim 0.01$ (~1.1wt.%) for 5-decanol and at $x_{OH} \sim 0.03$ (~3.3wt.%) for 4-propyl-4-heptanol. According to eq. [3] C_p^E corresponds to the difference between two Schottky curves, one for the alcohol in solution and the other in the pure state. At very low alcohol concentration (curve III in Fig. 1) ϕ_C(assoc) < C_p^0(assoc) and hence $C_p^E < 0$; furthermore, as the difference between points *a* and *d* in Fig. 1 increases as $kT/|\Delta G^0|$ increases, C_p^E must become more negative as ΔG^0 is decreased through the substitution of a primary alcohol by a secondary or tertiary at constant temperature. This is illustrated by the results shown in Fig. 3. The negative C_p^E corresponds to a net breaking of H-bonds on passing from the pure alcohol to the solution which is so dilute as to contain only monomeric alcohol, this behaviour being completely general for all alcohol + inert mixtures. As the alcohol concentration is increased, the solution Schottky peak moves to higher $kT/|\Delta G^0|$ (curve II in Fig. 1) and here at T' ϕ_C(assoc) > C_p^0(assoc) producing $C_p^E > 0$. Since the difference between points *b* and *d* decrease as $kT/|\Delta G^0|$ increases in this concentration region C_p^E for a secondary or tertiary alcohol + an inert will be less positive than for the corresponding primary isomeric alcohol. This prediction has been corroborated by the experimental C_p^E results displayed in Fig. 4 for 4-propyl-4-heptanol and 1-decanol + *n*-decane and 3-methyl-3-pentanol and 1-hexanol + n-C_{16} at 25°C. The positive C_p^E indicates that the solution is extremely structured, corresponding to a localization of monomers into multimers, i.e. a process of order creation in solution through the formation of H-bonds. Finally, at higher alcohol concentration (curve I in Fig. 1) $C_p^E > 0$ but now since the difference between points *c* and *d* increases as $kT/|\Delta G^0|$ increases, C_p^E for a secondary or tertiary alcohol + an inert will be more positive than for the primary isomeric alcohol as indicated in Fig. 4, where the branched alcohols are seen to have a much larger C_p^E than for the corresponding linear isomers. In Fig. 1 it is also possible to move to the right along the $kT/|\Delta G^0|$ axis by increasing the temperature for any given alcohol + inert mixture; hence, three concentration regions also appear with the following characteristics: (*i*) $C_p^E < 0$ with $dC_p^E/dT < 0$ at very dilute, (*ii*) $C_p^E > 0$ with $dC_p^E/dT < 0$ at slightly higher concentrations, and (*iii*) $C_p^E > 0$ with $dC_p^E/dT > 0$ at higher alcohol concentration. These changes have been experimentally observed for 1-decanol + *n*-decane and are displayed in Figs. 8 and 9 in ref. 1. The above description of C_p^E behaviour in the three concentration regions, obtained either by changing T for a given alcohol + inert mixture or by changing the primary alcohol to a hindered alcohol at constant T, should be completely general for any alcohol mixed with an inert solvent.

The temperature dependence of C_p^E for branched or cyclic alcohols also follows from the Schottky curves in Fig. 1. Figure 5*a* shows Schottky peaks for a pure associated component and for a given concentration (say equimolar) in an inert solvent, while Fig. 5*b* shows C_p^E obtained through eq. [3] by the

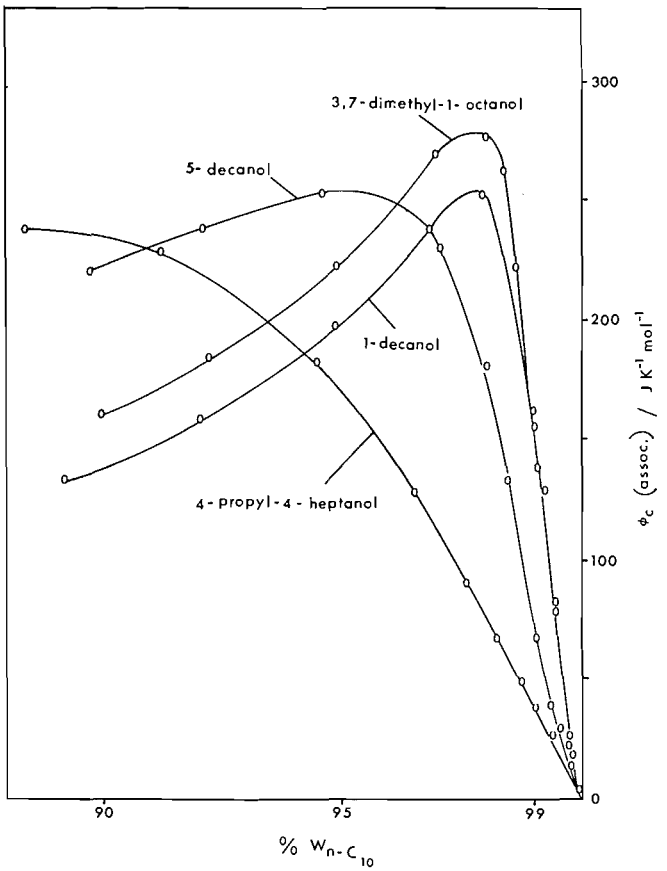

FIG. 2. Associational part of the apparent molar heat capacity for 1-decanol (from ref. 3), 3.7-dimethyl-1-octanol, 5-decanol, and 4-propyl-4-heptanol + *n*-decane at 25°C.

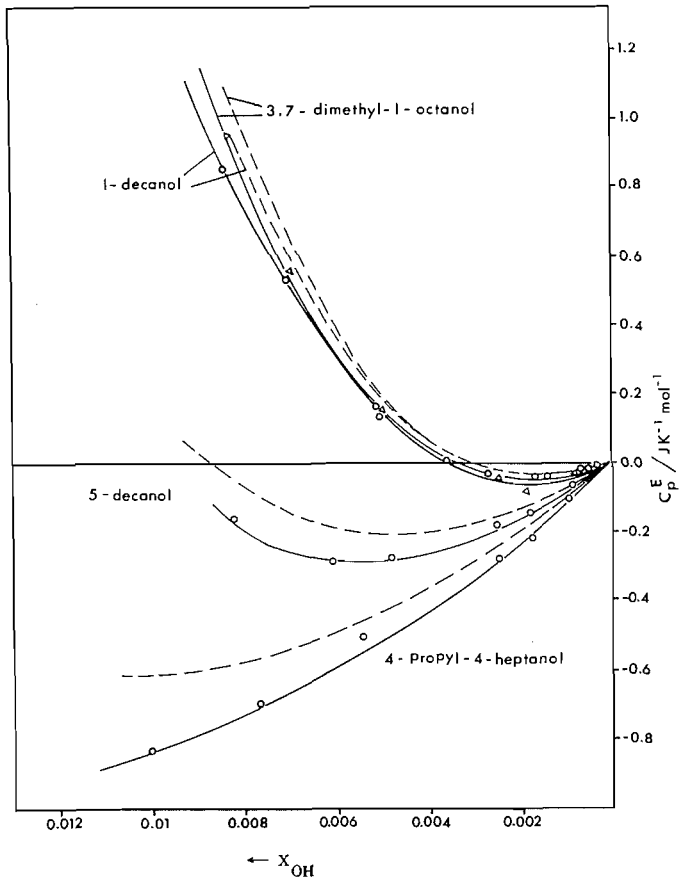

FIG. 3. Excess heat capacity for 1-decanol (from ref. 3), 3,7-dimethyl-1-octanol, 5-decanol, and 4-propyl-4-heptanol + *n*-decane at 25°C. Dashed lines are TK model calculations.

subtraction of the two curves in Fig. 5*a*. At constant temperature, it is possible to move from left to right along the horizontal axes in Fig. 5*a* or 5*b* by decreasing ΔG^0, i.e. by making the association weaker. For linear alcohols, where ΔG^0 is large, $C_p^E > 0$ and $dC_p^E/dT > 0$ but for secondary and tertiary alcohols where ΔG^0 is lower $C_p^E > 0$ and dC_p^E/dT changes from positive to negative as indicated by the shadowed area in Fig. 5*b*. The C_p^E data for the tertiary alcohol 3-methyl-3-pentanol + *n*-decane shown in Fig. 5*c* are an example of such behaviour; here, ΔG^0 has been reduced from that corresponding to the isomeric primary alcohol due to the steric hindrance of the hydroxyl group and hence the ratio $kT/|\Delta G^0|$ is increased for the usual temperature range. C_p^E is very large and dC_p^E/dT now changes sign from positive to negative within the temperature range studied, 10 to 50°C. The negative C_p^E region at low alcohol concentration is also visible. It is clear then that Fig. 1 provides a general framework for understanding heat capacity data for all alcohols.

The above qualitative arguments for ϕ_C(assoc) and C_p^E can be made quantitative through the use of the TK model whose parameters, i.e. the enthalpy change for the formation of a H-bond ΔH^0 and the volumetric equilibrium constants K_i^φ for each species i (i = 2, 3, and 4), were fitted to dilute ϕ_C(assoc) data using eq. [1] and are displayed in Table 2. Figures 3, 4, and 5*d* show C_p^E calculations using these parameters and eqs. [1] to [3]; note that although the TK model parameters were fitted to dilute alcohol concentration data, good predictions throughout the concentration range are obtained. In Fig. 5*d*, the theory is seen to give a semi-quantitative representation of C_p^E over a wide range of temperature. The reduction in self-association capabilities in going from the primary alcohol to the secondary or tertiary alcohols can also be observed in their pure component heat capacities. Table 2 reports values of the associational part of pure alcohol C_p, C_p^0(assoc) found by subtracting columns three and four in Table 1. Table 2 also gives theoretical C_p^0(assoc) values from eq. [1]. For a given carbon number C_p^0(assoc) increases strongly in magnitude in going from a linear 1-alcohol (C_p^0 and C_p^0(assoc) for 1-alcohols are given in ref. 3) to an isomeric alcohol which has its hydroxyl group in a quaternary carbon atom. For instance, C_p^0(assoc) for 1-decanol is 35 J K^{-1} mol^{-1} (3) whereas for 4-propyl-4-heptanol the corresponding value is 132 J K^{-1} mol^{-1}. This remarkable sensitivity of C_p^0(assoc) to steric hindrance corresponds to weaker H-bonding and a shift to higher $kT/|\Delta G^0|$ values along curve 0 in Fig. 1. The weaker H-bonding is also seen in higher thermal expansion coefficients for these alcohols. Theoretical C_p^0(assoc) values in Table 2 reproduce successfully the experimental trend but they are only qualitatively correct due to the fact that the TK parameters were fitted to dilute alcohol concentration data.

The evaluation of the volumetric equilibrium constant for every species allows the calculation of the volume fractions for each i ($\varphi_{A_i} = K_i^\varphi \varphi_A{}^i$). One of the most interesting results of applying the TK model to the experimental data for linear alcohols (1, 3) is that tetramers turned out to be the predominant species, dimers being almost absent even at very low alcohol concentration. For 1-decanol and 4-propyl-4-heptanol + *n*-

decane, Fig. 6 shows the distribution of tetramers, dimers, and monomers of the total alcohol present in solution, as a function of the weight percent of the solvent. At each concentration φ_1, the real volume fraction of alcohol in solution, represents 100%. The percentage for dimers for 1-decanol + *n*-decane is not shown since its values are extremely small. In contrast to the predominance of tetramers in the linear alcohol case, for the highly hindered tertiary alcohol monomers are the predominant species in this concentration range reflecting the decrese in self-association ability imposed by the steric hindrance of the hydroxyl group. At 2wt.% alcohol in Fig. 6, which corresponds to the highest concentration in Fig. 3, the solution contains ca. 93% of monomers and 7% dimers; the negative C_p^E in Fig. 3 in then due to the breaking of structure on passing from the pure alcohol to the solution which contains many monomers and just a few dimers. For this tertiary alcohol, the order-creation process in solution is delayed to higher concentrations where finally enough stucture, i.e. higher species like tetramers, has been created and C_p^E becomes positive.

Deviations from the predominance of one species (tetramers) found for all 1-alcohols (3) are seen for all the branched and cyclic alcohols listed in Table 2. In ref. 3, the experimentally determined volumetric equilibrium constants K_i^{φ} were found to be related to the more fundamental equilibrium constant for H-bond formation for linear *i*-mers $K_{i,L}$ through

$$[4] \quad (K_i^{\varphi})^{1/(i-1)}\bar{V} = i^{1/(i-1)}K_{i,L}(v\sigma\omega^2/z)$$

where $\bar{V}$ is the molar volume of the alcohol, z is the lattice coordination number, v is the molar volume of a segment in the lattice, σ the symmetry number, and ω a parameter which characterizes the flexibility of the chain. From eq. [4]

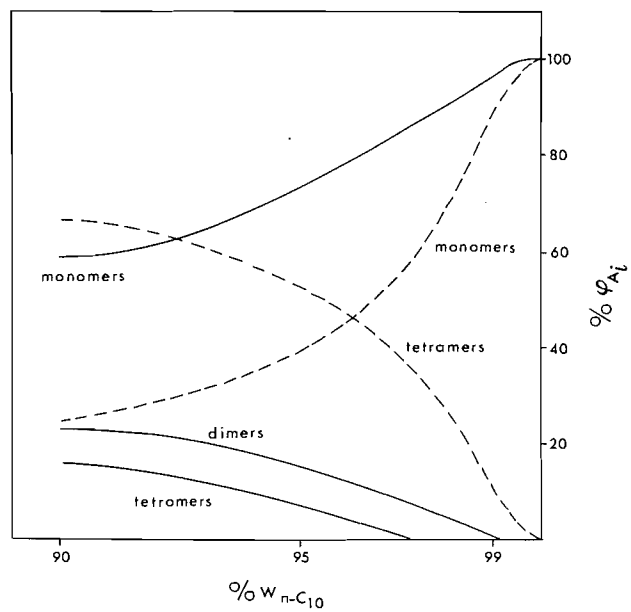

FIG. 6. Distribution in *i*-mers of the total alcohol present in solution for 4-propyl-4-heptanol + *n*-decane (full lines) and 1-decanol + *n*-decane (dashed lines) at 25°C.

$$[5] \quad \Delta G_i^+/RT = \Delta G_i^0/RT - \ln(v\sigma\omega^2/z)$$
$$= (\ln i)/(i-1) - \ln[(K_i^{\varphi})^{1/(i-1)}V]$$

where ΔG_i^0 is the free energy of association for species *i*. Calculation of ΔG_i^0 is, however, hampered by the difficulty in

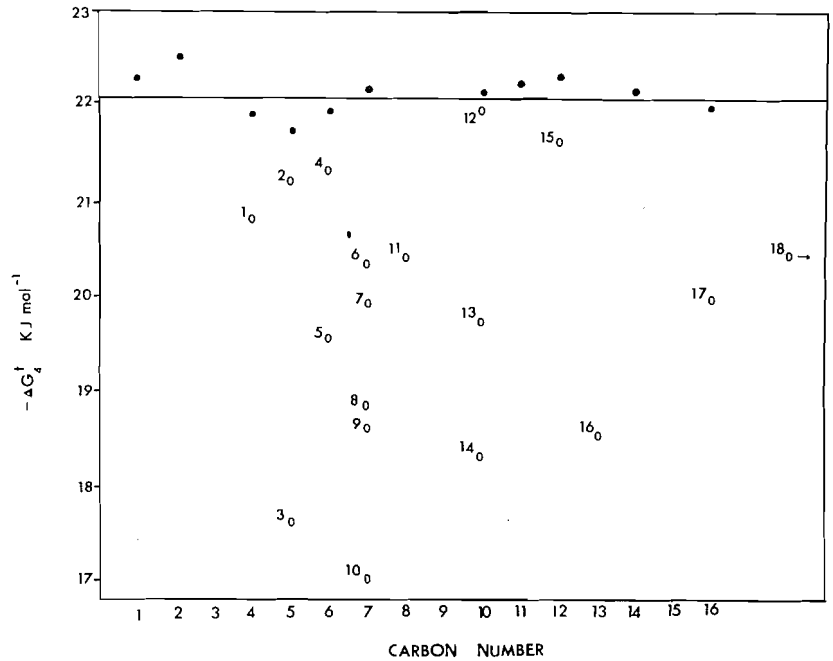

FIG. 7. $-\Delta G_4^+$ from eq. [5] against carbon number for linear alcohols (●) from ref. 3 and for branched and cyclic alcohols (○). Code is that indicated in Table 2. For alcohol number 18, i.e. cholesterol, the carbon number is 27.

choosing values for the quantities v, σ, ω, and z; nevertheless, to within the constant ln $(v\sigma\omega^2/z)$, comparison between different alcohols is possible through the calculation of ΔG_i^+ from eq. [5]. Figure 7 shows ΔG_4^+ values for 1-alcohols (3) and for all the branched and cyclic alcohols studied in this work. In this figure, all 1-alcohols are seen to have essentially the same ΔG_4^+ while secondary and tertiary alcohols depart from this behaviour. For a given carbon number $|\Delta G_4^+|$ decreases in going from the primary to the tertiary alcohol. As the steric hindrance of the hydroxyl group increases ΔG_4^+ becomes less negative reflecting the increasing difficulty for tetramer formation. In Table 2 almost all alcohols have $|\Delta H^0|$ values which are higher than the average $|\Delta H^0|$ for linear alcohols (28.9 kJ mol^{-1}) found in ref. 3 under the assumption of linear tetramers. The assumption of cyclic tetramers and no other i-mers gave $|\Delta H^0| = 3/4\ (28.9) = 21.7$ kJ mol^{-1}. In the present case we believe that due to steric hindrance cyclization of the i-mers should be less pronounced than in the case of the linear alcohols and hence $|\Delta H^0|$ must remain higher for the branched and cyclic alcohols than for the linear. The weakness of the H-bonds formed by cyclic and branched alcohols as compared to those present in linear alcohols emerges then from a larger negative entropy change which reduces $|\Delta G_4^+|$ below the value for the corresponding isomeric linear alcohol. It was unexpected that going from a linear to branched alcohol should entail changes of opposite sign in $|\Delta H^0|$ and $|\Delta S^0|$ and particularly that $|\Delta H^0|$ should be increased. However, we do not believe this result to be an artefact of the TK fitting. The maximum of the ϕ_C(assoc) vs. x_1 curve has essentially the same height for branched and linear alcohols (see for instance Fig. 2). This height is proportional to $(\Delta H^0/RT)^2$, where the proportionality constant increases with the size of the multimer (i). Linear alcohols are characterized by a predominance of tetramers with negligible dimers and trimers while the branched species, as seen in Table 2 and Fig. 6, shift substantially to dimers and trimers. Thus the same height of the ϕ_C(assoc) maximum for branched and linear alcohols means that $|\Delta H^0|$ must be higher for the branched species to compensate for the relatively larger dimer and trimer populations.

2-Methyl-2-propanol and n-butanol are amongst the most studied branched and linear alcohols. The alkyl inductive effect which is stronger for 2-methyl-2-propanol than for n-butanol indicates that the oxygen atom for 2-methyl-2-propanol should be more negative than for n-butanol while the hydrogen should be less positive. This is in agreement with the Kamlet–Taft parameters α (hydrogen bonding donor ability) and β (hydrogen bonding acceptor ability) which are (11) for 2-methyl-2-propanol $(\alpha, \beta) = (0.68, 1.01)$ and for n-butanol (0.79, 0.88). Thus the more basic oxygen of 2-methyl-2-propanol should increase $|\Delta H^0|$ and the less acidic hydrogen should produce the opposite effect making it difficult to decide on this basis the sign of the change in $|\Delta H^0|$. The majority of the reported values for $|\Delta H^0|$ have been obtained through nmr or ir measurements in CCl_4 (12). However, CCl_4 is not a truly inert solvent. For instance, C_p measurements in this laboratory for alcohols in CCl_4 give apparent $|\Delta H^0|$ values which are much lower than found with alkane solvents. An ir determination of $|\Delta H^0|$ for 2-methyl-2-propanol compared with methanol in hexadecane gives $|\Delta H^0|$ larger for 2-methyl-2-propanol (13*a*); however, the situation is reversed for 2-methyl-2-propanol compared with n-butanol in heptane (13*b*). The assertion that $|\Delta H^0|$ is higher is neither confirmed or denied by the literature. If indeed $|\Delta H^0|$ is larger for the branched alcohols then it implies that the H-bond itself is strengthened but steric hindrance between the branched alkyl groups increases $|\Delta S^0|$ sufficiently to produce a net decrease in $|\Delta G^0|$.

In Fig. 7, comparison between ΔG_4^+ values for cycloalkanols and other secondary alcohols such as 5-decanol and 8-hexadecanol indicate that cycloalkanols are able to form tetramers more easily. Comparison between different cycloalkanols also indicate that the size of the cyclic ring attached to the hydroxyl group does not seem to have a significant influence in the formation of tetramers. While in 5-decanol and 8-hexadecanol the hydroxyl group is attached to a carbon atom in the middle of a long hydrocarbon chain, in the cyclohexanols the more exposed hydroxyl group produces a more favourable molecular shape for the formation of higher H-bonded species like tetramers. It appears that as far as the hydroxyl group is not surrounded by bulky groups the alcohol is able to self-associate

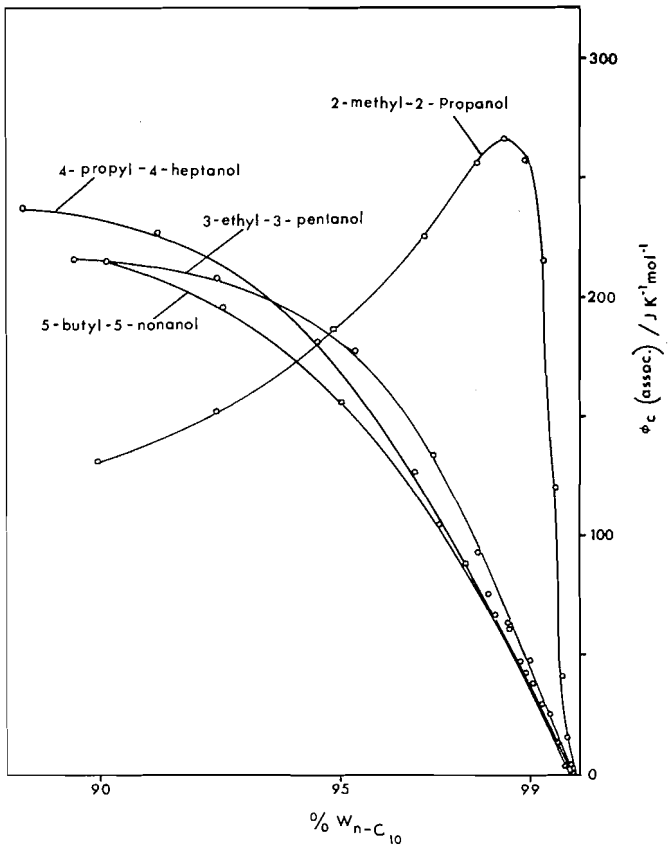

FIG. 8. Associational part of the apparent heat capacity for 2-methyl-2-propanol, 3-methyl-3-pentanol, 4-propyl-4-heptanol, and 5-butyl-5-nonanol + *n*-decane at 25°C.

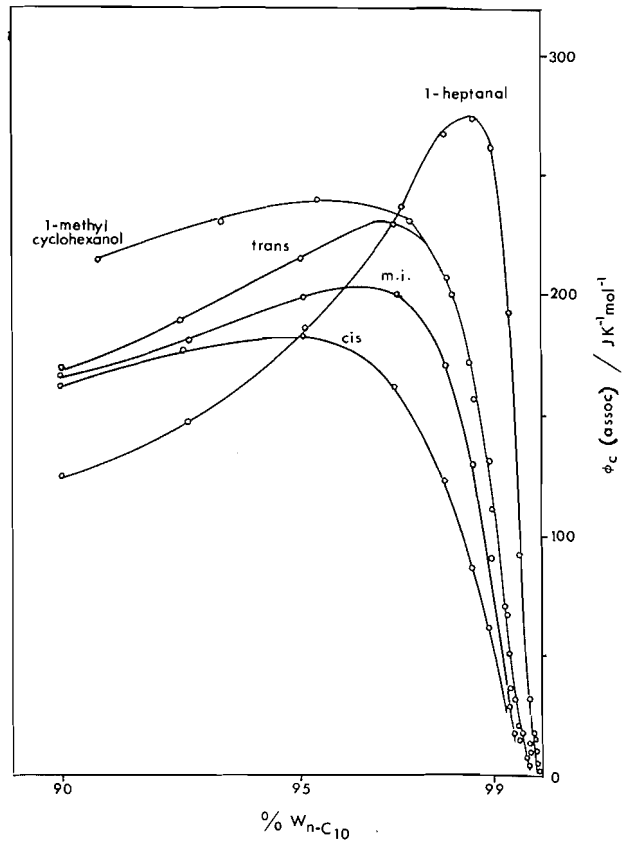

FIG. 9. Association part of the apparent heat capacity for 1-heptanol (from ref. 3), 1-methylcyclohexanol, *trans*-, *cis*-, and mixed isomers (m.i.) 2-methylcyclohexanol + *n*-decane at 25°C.

in dilute solution forming species higher than dimers; another example of this is given by cholesterol which, as indicated in Fig. 7, has a tetramer forming ability (14) comparable to that of cyclooctanol. Since more self-association has been observed (15) in using a hydrocarbon as solvent than when CCl_4 is used, the lower $|\Delta H^0|$ for cholesterol in Table 2 is a reflection of the solvent selection.

Amongst the tertiary alcohols in Fig. 7 and Table 2 the series 2-methyl-2-propanol, 3-methyl-3-pentanol, 4-methyl-4-heptanol, and 5-butyl-5-nonanol illustrates the effect of changing the molecular shape while keeping the same "degree of crowding" of the hydroxyl group. Starting with 2-methyl-2-propanol, the addition of CH_2 groups on the three hydrocarbon tails attached to the carbon where the hydroxyl is linked, changes the molecular shape from being spherical to a T-like shape. The ϕ_C(assoc) for these tertiary alcohols is shown in Fig. 8 where a substantial change on the self-association behaviour is observed when the spherical 2-methyl-2-propanol is substituted by either one of the three "tail extended *t*-butanols." This situation is reflected on the K_i^{φ} values in Table 2 which indicate that while for *t*-butanol tetramers are predominant and dimers almost absent, for the other three alcohols the formation of *i*-mers in this concentration region is almost totally hindered and monomers are by far the predominant species (see Fig. 6). In Fig. 8 there is no continuous progression of ϕ_C(assoc) curves in going from 2-methyl-2-propanol to 5-butyl-5-nonanol but it appears that the change in self-association is rather abrupt, indicating that the formation of higher species such as tetramers depend critically on the alcohol molecular shape being geometrically favourable.

The sensitivity with which the heat capacity responds to slight changes on the molecular shape and the steric hindrance of the hydroxyl group prompted the measurement of ϕ_C(assoc) for a series of isomeric methylcyclohexanols. These results are shown in Fig. 9 together with those for the corresponding linear alcohol (1-heptanol) from ref. 3. As expected, the methylcyclohexanols show a self-association behaviour which corresponds to that of 1-heptanol at $T > 25$°C. A ^{13}C nmr spectroscopy study (16) on the conformational equilibria in isomeric methylcyclohexanols has concluded that the dominating species are those where the CH_3 group is in the equatorial position. It appears then that the dominating species for *cis*- and *trans*-2-methylcyclohexanol are the ae and ee conformers, respectively (the first letter of each pair refers to the orientation of the hydroxyl group). Molecular models show quite readily that amongst these two alcohols the hydroxyl group is less hindered and hence more available for H-bond formation when it is in the equatorial position, i.e. that the *trans* isomer should have a better self-association ability than the *cis* isomer. This is confirmed by the results in Fig. 9 where ϕ_C(assoc) for the *trans* isomer show a higher maximum which occurs at lower alcohol concentration. This situation is also reflected in Table 2 where the *trans* isomer is seen to have a better ability for tetramer formation and in Fig. 7 where ΔG_4^+ is considerably more negative than for the *cis* isomer. Figure 9 also shows the results for a mixture of the *trans*- and *cis*-2-methylcyclohexanol ϕ_C(assoc) being, as expected, intermediate between those for each separate isomer. For 1-methylcyclohexanol ref. 16 indicates that the dominating species is the ae conformer; in this case the steric hindrance of the hydroxyl group is not only due to its axial position but also to the fact that the CH_3 is attached to the same carbon atom in the ring structure. Accordingly, in Fig. 9 ϕ_C(assoc) for this alcohol

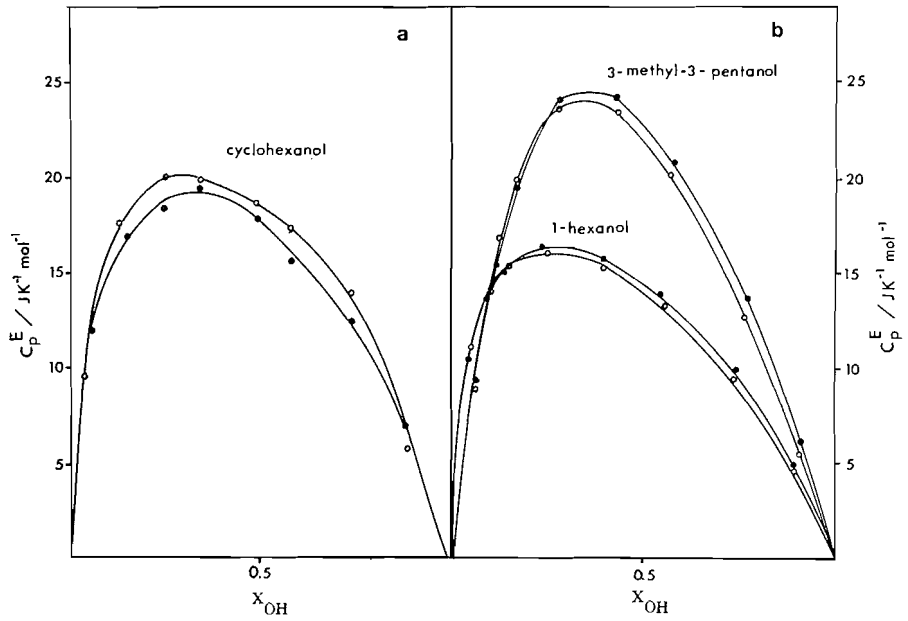

FIG. 10. Excess heat capacity for n-C_{16} (○) and br-C_{16} (●) mixed with (*a*) cyclohexanol at 27°C and (*b*) 3-methyl-3-pentanol and 1-hexanol at 25°C.

shows only a shallow maximum, its weak tetramer formation ability producing the least negative ΔG_4^+ of all the methylcyclohexanols studied.

Much thermodynamic work has been done studying the correlation of molecular orientation (CMO) in long chain n-alkanes (2). Changes in the thermodynamic functions X due to the presence of CMO are small and difficult to isolate, but they manifest themselves in the mixing (ΔX) or excess (X^E) functions. Furthermore, it has been found that increasing degrees of chain branching reduce the ability of the alkane to order in the pure or solution states, essentially eliminating the order contribution to ΔX or X^E for highly branched alkanes such as br-C_{16}. Amongst many different thermodynamic functions X, C_p^E has proven to be a good CMO-destruction indicator. The presence of CMO in the pure n-alkane increases the heat capacity of the pure liquid and, upon mixing with a spherical molecule, gives a negative contribution to C_p^E: at equimolar concentration C_p^E for n-C_{16} + cyclohexane is -6.7 J K^{-1} mol^{-1} while for br-C_{16} + cyclohexane it is only -0.5 J K^{-1} mol^{-1}. Since in studying alcohol + inert solvent mixtures the solvent used is often a hydrocarbon, it appeared interesting to assess the effect that the presence of CMO could have on the alcohol self-association. C_p^E was then measured for n-C_{16} and br-C_{16} mixed with 1-hexanol, 3-methyl-3-pentanol, and cyclohexanol the results being shown in Fig. 10. Surprisingly, it appears that for each alcohol C_p^E for the n-C_{16} mixtures is very close to that for the br-C_{16} mixtures, i.e. the alcohol does not appear to destroy the CMO between n-C_{16} molecules. On the other hand, results in Fig. 10 give support to an underlying assumption in this work and that with 1-alcohols (1, 3), namely, that the so-called physical contribution to the heat capacity for alcohol + inert hydrocarbon mixtures can be neglected. The use of the TK model in the form presented here for the analysis of heat capacity data is then fully justified.

Calorimetric determination of the deviation between the International Practical Temperature Scale 1968 and the Thermodynamic Temperature Scale

GÜNTER ERNST,[1] GÜNTER BRÄUNING, AND JOON-FEN LAI

Institut für Technische Thermodynamik, Fakultät für Maschinenbau, Universität Karlsruhe, Kaiserstr. 12, 7500 Karlsruhe 1, Federal Republic of Germany

Received August 28, 1987

This paper is dedicated to Professor James A. Morrison

GÜNTER ERNST, GÜNTER BRÄUNING, and JOON-FEN LAI. Can. J. Chem. **66**, 999 (1988).

A flow calorimeter was constructed to measure the isobaric heat capacity c_p for dilute fluids for pressure $p \leqq 1500$ kPa and for temperature $-20 \leqq t$ (°C) $\leqq +200$. The special design features of the calorimeter facilitate measurements at extremely high accuracy. In this paper the measurements have been used to explore the metrology of the temperature. Measured values of c_p were compared with corresponding theoretical values calculated via statistical mechanics. From the comparison, the deviation between the International Practical Temperature Scale of 1968 and the (theoretical) Thermodynamic Temperature Scale has been obtained. The results of this metrology are in good agreement with those obtained with the PVT gas thermometer and those obtained by radiometry. The comparison establishes the accuracy of the calorimeter and, more important, the feasibility of c_p metrology, especially for probing local stretching or contraction of the International Practical Temperature Scale. The integration of this distortion, starting from the triple point of water, yields the deviation between the scales. It is, e.g., between 30 mK and 40 mK at the boiling point of water, according to our results.

GÜNTER ERNST, GÜNTER BRÄUNING et JOON-FEN LAI. Can. J. Chem. **66**, 999 (1988).

On a construit un calorimètre à écoulement dans le but de mesure la capacité calorifique isobare, c_p, de fluides dilués, à des pressions, p, allant jusqu'à 1500 kPa et à des températures allant de -20 à $+200$°C. Les caractéristiques spéciales du calorimètre permettent d'effectuer des mesures avec une très grande précision. Dans ce travail, on a utilisé les mesures pour examiner la métrologie de la température. On a comparé les valeurs de c_p mesurées avec les valeurs théoriques correspondantes calculées à l'aide de la mécanique statistique. Pour fins de comparaison, on a aussi déterminé la déviation entre l'échelle internationale de température pratique (1968) et l'échelle thermodynamique de température (théorique). Les résultats de cette métrologie sont en bon accord avec ceux obtenus soit avec le thermomètre à gaz PVT ou par radiométrie. Cette comparaison permet d'établir la précision du calorimètre et, encore plus important, la possibilité d'utiliser la métrologie c_p pour étudier des élongations ou des contractions locales de l'échelle internationale de température pratique. L'intégration de cette distorsion, commençant avec le point triple de l'eau, permet d'établir la déviation entre les échelles. Au point d'ébullition de l'eau, nos résultats suggèrent que cette déviation est de 30 à 40 mK.

1. Introduction

The PVT (Pressure–Volume–Temperature) gas thermometry of Guildner and Edsinger (1) and the radiometric thermometry of Quinn and Martin (2) established that differences exist between the International Practical Temperature Scale 1968 (IPTS-68) and the Thermodynamic Temperature Scale (TTS) that are much larger than were previously estimated to be the maximum possible errors in IPTS-68. It was demonstrated by Haar (3) that differences between the two temperature scales could be derived from corresponding differences between accurate values of the isobaric heat capacity c_p referred to each of these scales. (The c_p difference is proportional to the temperature derivative of the difference between the scales, so that a calorimetric method offers the potential for probing the local stretching and contraction of IPTS-68.) In this paper we explore differences between the temperature scales using this "new" metrology based on calorimetry.

We designed a state of the art flow calorimeter to measure c_p for dilute vapor states; the range includes values of pressure $\leq$1500 kPa and values of temperature $-20 \leq t$ (°C) ≤ 200. Measured values of c_p, which refer to the IPTS-68, are to be compared with corresponding theoretical values based on statistical mechanics. These theoretical values refer *ipso facto* to the TTS. If, as found by Guildner, the difference between values of temperature on the two scales amounts to several hundredths of a kelvin at the boiling point of water, then, for our metrology to be meaningful, the combined errors in the measured and theoretical values of c_p would have to be not larger than a few hundredths of a percent. An analysis of possible errors suggests that the calorimeter is capable of achieving results at this level of accuracy.

Xenon was selected to be the working fluid. Over the experimental range, the specific heat capacity of xenon for the ideal gas state is constant. The principal error source for the value of this constant is the possible error in the molecular gas constant and in the value used for the molecular mass of xenon.

Results based on the new metrology are consistent with those reported for conventional thermometry, and for radiometric thermometry.

This report includes six sections: The theoretical basis is described in Sect. 2; Sect. 3 contains a description of the calorimeter and the experimental procedure; estimates of possible error are given in Sect. 4; Sect. 5 includes experimental results; short conclusions are contained in Sect. 6.

2. Theoretical basis

We will consider numerical values of the temperature and of the ideal gas state heat capacity to explain the basic theory. The symbol T designates a numerical value of temperature on the IPTS-68 for a fluid in a particular thermodynamic state. The symbol θ designates the corresponding numerical value of temperature for the same state on the TTS. Thermodynamic quantities that are represented as a function of θ are to be determined via statistical mechanics. We define, for the

For personal use only.

particular thermodynamic state, the quantity μ as the deviation between the numerical values of the temperature on the TTS and on the IPTS-68:

$$[1] \quad \mu \equiv \theta - T$$

The specific enthalpy for the ideal gas state ($p = 0$) at a particular temperature is apparently independent of the temperature scale used:

$$[2] \quad \hat{h}^0(\theta) \equiv h^0(T)$$

The symbol ˆ is used to distinguish between the different mathematical dependencies on the generally different variables θ and T. (This difference between θ and T results from the transition to the numerical values of the temperature.) Differentiation of eq. [2] at constant pressure ($p = 0$) yields, for the numerical values of the ideal gas state, the specific heat capacity

$$[3] \quad \hat{c}_p^0(\theta) \cdot \frac{d\theta}{dT} = c_p^0(T)$$

The $dT/d\theta$ is the local stretching or contraction of the IPTS-68. Differentiation of eq. [1] yields

$$[4] \quad \frac{d\theta}{dT} = 1 + \frac{d\mu}{dT}$$

Equations [3] and [4] yield

$$[5] \quad \hat{c}_p^0(\theta) \cdot \frac{d\mu}{dT} = c_p^0(T) - \hat{c}_p^0(\theta)$$

Integration of eq. [5] yields

$$[6] \quad \mu(T_a) - \mu(273.16) = \int_{273.16}^{T_a} \frac{c_p^0(T) - \hat{c}_p^0(\theta)}{\hat{c}_p^0(\theta)} \cdot dT$$

where by definition of IPTS-68, $\mu(273.16) \equiv 0$.

If $\hat{c}_p^0(\theta)$ varies with θ, we can obtain it as a function of the integration variable T by means of a Taylor series expansion

$$[7] \quad \hat{c}_p^0(\theta) = \hat{c}_p^0(T) + \mu \cdot \frac{d\hat{c}_p^0}{d\theta}(T) + \ldots.$$

With the noble gas xenon as the working fluid, the ideal gas state specific heat capacity can be taken as constant. Thus eq. [6] is evaluated easily

$$[8] \quad \mu(T_a) = \frac{\overline{c_p^0}(T_a) - c_p^0}{c_p^0} \cdot (T_a - 273.16)$$

with c_p^0, used for $\hat{c}_p^0(\theta)$, as the numerical value of $(5/2) \cdot R \cdot M^{-1}$ (R = molecular gas constant; M = molecular mass) and $\overline{c_p^0}(T_a)$ from the extrapolation of the mean values determined experimentally with a temperature rise in the calorimeter from T_a to 273.16 or from 273.16 to T_a:

$$[9] \quad \overline{c_p^0}(T_a) = \frac{1}{T_a - 273.16} \int_{273.16}^{T_a} c_p^0(T) \cdot dT$$

3. Experimental

Detailed descriptions of the equipment and the experimental procedure have been reported (4–6).

Calorimeter

The calorimeter is a U-shaped tube, isolated by vacuum and a radiation shield (Fig. 1). The tube is made of stainless steel with 8 mm outer diameter and 0.15 mm wall thickness.

The gas is heated electrically. Its temperature is measured in front of and behind the heater. Mass flow rate m (≈ 0.2 g s^{-1}), heating power P (≈ 1 W), and temperature rise Δt (≈ 6 K) yield as a first approximation

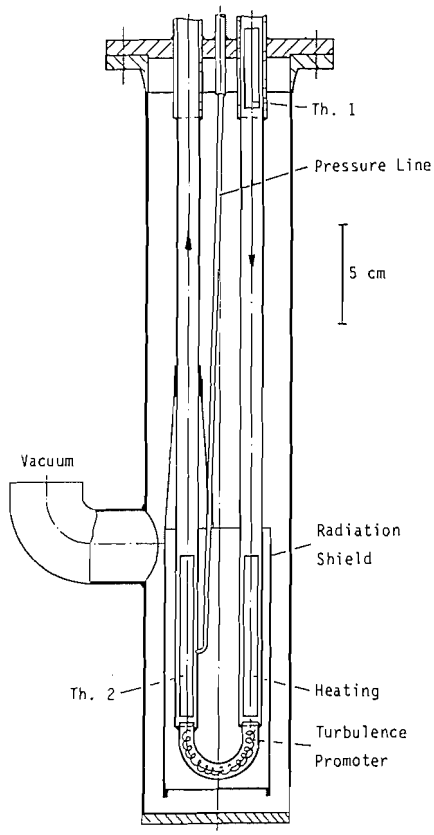

FIG. 1. Cross section of the calorimeter.

$$[10] \quad c_p = P \cdot m^{-1} \cdot \Delta t^{-1}$$

The coiled heating wire is connected with two leads at each end to the current circuit and to a digital voltmeter. The current is measured at a standard resistor in the circuit.

The resistance thermometers are platinum wires of 20 Ω at 0°C, wound strainfree and bifilar on Al_2O_3 crosses. The wires are in direct contact with the flowing gas. The resistance of the thermometers is measured with an A7 ac bridge from ASL, Leighton Buzzard, U.K.

The two thermometers were calibrated with water triple-point cells and with a platinum resistance thermometer from Leeds and Northrup Co., North Wales, PA, U.S.A. calibrated twice at the National Bureau of Standards, Gaithersburg, MD, U.S.A., in 1973, and once at the Physikalisch-Technische Bundesanstalt, Braunschweig, F.R.G. Several recalibrations at our institute, the last in November 1985, showed agreement within about 0.5 mK among the thermometers and between the termometers and the water triple-point cells.

The thermometers can be mounted and removed easily. This is convenient for recalibrating and exchanging. They are positioned in the tube at points where the temperature gradients in the tube and in the electrical leads are very small (Fig. 2). Therefore heat loss by conduction out of the control area is reduced. The radiation shield surrounding the heated part of the control area is fixed on the tube behind the end of the control area and is heated by the outflowing gas. Thus the shield is very close in temperature to the heated gas, so that the heat loss caused by radiation is further reduced.

The influence of the heat loss decreases with increasing mass flow rate m of the gas. If both m and the heating power P are increased so that the temperature rise Δt is unchanged, the heat loss is constant as a first approximation, but the ratio between heat loss and heating power decreases. More strictly, the heat loss decreases with increasing m even with unchanged Δt because the temperature profile in the tube and the electrical leads is modified by the gas flow and the temperature

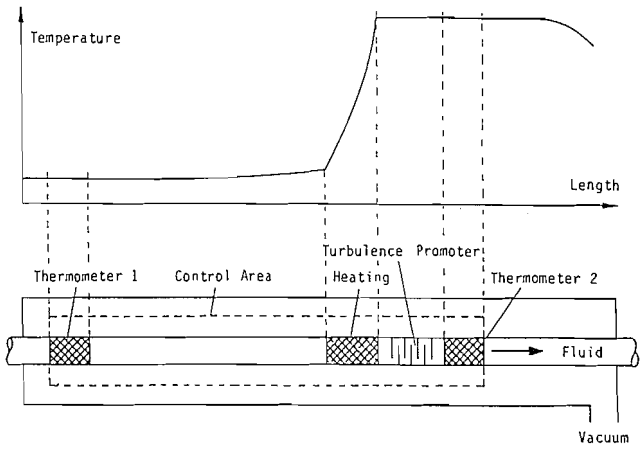

FIG. 2. Temperature profile along the tube of the calorimeter (simplified). Thermometers at points of low temperature gradient.

gradients at the thermometers decrease with increasing m (Fig. 2). If m is increased at constant p, Δt and, with it, the heat loss decrease. Results presented in Table 1 show no systematic influence of the mass flow rate m and, therefore, of the heat loss on the measured values of c_p. The scatter is within ±0.02%. For xenon with its low c_p, the temperature rise and, therefore, the heat loss relative to the heating power would be large without appropriate means for its reduction.

Flow system

The gas flow is produced at constant pressure by evaporating the liquid from a thermostated two-phase container (Fig. 3). The mass flow and the pressure in the calorimeter are adjusted with two needle valves, one before and one behind the calorimeter. The gas is condensed behind the second needle valve, alternatively in one of two condensers cooled with liquid air. A filled condenser is heated to push the liquid back into the two-phase container. Thus the apparatus can be used continuously. The mass flow rate m is measured by weighing the condensate in a small detachable condenser and measuring the collecting time.

Experimental procedure

Each c_p value is given by the difference between a main experiment and a blank experiment (Fig. 4). The main experiment is made with heating, an the blank experiment without. The heating power causes the temperature difference from 2b to 2m at the second thermometer Th2. The c_p, therefore, is assigned to the pressure p_2 measured at the second thermometer Th2 and to the mean temperature of the second thermometer.

$$[11] \quad \bar{t} = (t_{2b} + t_{2m})/2$$

This assignment is independent of the specific profiles of temperature and pressure along the tube of the calorimeter (Fig. 2)!

The experimental c_p is calculated from the difference of the temperature differences

$$[12] \quad \overline{c_p}(p_2, \bar{t}) = P \cdot m^{-1} \cdot ((t_2 - t_1)_m - (t_2 - t_1)_b)^{-1}$$

It is obvious that the first thermometer Th1 only checks the constancy of the temperature of the thermostat and yields the correction for slight changes between the blank and the main experiment (mK).

The difference $(t_2 - t_1)_b$ in the blank experiment for the most part includes the effects of Joule–Thomson cooling (and also changes in potential and kinetic energy). Thus subtracting the blank measurement largely eliminates this major limitation to the accuracy of flow calorimetry and yields the assignment of c_p to the constant pressure p_2. (With very large temperature rises (up to 200 K), the difference of the kinetic energy at Th2 between the blank and the main experiment causes a temperature difference at Th2 of about −15 ppm of $(t_2 - t_1)_m$, calculated with the recovery factor.)

The heating power in the leads to the heater in the calorimeter is not negligible. It is eliminated because it is also contained in the blank experiment: the same current as in the main experiment flows in the blank experiment through the current lead and the potential lead of one end of the heating wire. This potential lead has the same properties as the current lead at the other end of the heating wire. The heating power in the leads, therefore, is the same in the main experiment as in the blank experiment and the difference between the main and the blank experiment is the measured heating power delivered to the calorimeter from the heating wire.

4. Error analysis

Measurements

The possible error in the measurement of the heating power P is smaller than ±0.005%. The possible error in the measurement of the mass flow rate m is smaller than about ±0.005%. The temperature difference in eq. [12] can be written as

$$[13] \quad \Delta t = (t_{2m} - t_{2b}) - (t_{1m} - t_{1b})$$

It is apparent that many of the systematic errors in the individual temperature measurements cancel out. For the measurements with small temperature difference $\Delta t \approx 6$ K, this cancellation is nearly total, so that the possible error of Δt is estimated to be ±0.001 K, ±0.02% of Δt. The cancellation decreases with the size of the interval, so that for $\Delta t \approx 200$ K the possible error is approximately ±0.003 K, but as a percentage of Δt it is $< \pm 0.002\%$. This reduction of the relative uncertainty is the principal reason for basing the metrology on the measurements made at large temperature intervals.

The possible error in assigning c_p to p_2 and $\bar{t}$ is negligible over the pressure and temperature range of the measurements.

The direct experimental results for $\overline{c_p}$ (Table 2, Fig. 5) were calculated for each state as mean values from at least three measurements. They were fitted to linear isotherms for the extrapolation to $p = 0$. Their absolute distance from the isotherms is, on the average, 20 ppm of $\overline{c_p}$ with two extreme values of 80 and 120 ppm. The possible error constituted by the extrapolation to $p = 0$ at a 95% confidence level (following

TABLE 3. Deviation μ between the values of the temperature on the TTS and on the IPTS-68 (unit: K)

Temperature t_a (°C)	Mean value[a] $\overline{c_p^0}$	$d \times 10^{6b}$	$\mu \times 10^{3c}$

[a]Experimental mean value for the temperature rise in the calorimeter from t_a to ≈0°C or from ≈0°C to t_a: $\overline{c_p^0}$. Theoretical value: $c_p^0 = 0.158309\ (J\,g^{-1}\,K^{-1})$.
[b]Relative difference $d \equiv (\overline{c_p^0}(T_a) - c_p^0) \cdot c_p^{0-1}$ (eq. [8]).
[c]Deviation at t_a (=(T_a − 273.15)°C): μ = θ − T (eq. [1]).

Student's statistical test) is about ±50 ppm, or ±0.005%. The influence of uncertainties other than fitting with linear isotherms appears to be the major contributor to this source of possible error of $\overline{c_p^0}$.

The change in the kinetic energy at the thermometer 2 was found to be very small. It increases with increasing temperature difference in the calorimeter. The correction is 15 ppm for the largest temperature difference, $\Delta t = 200$ K. The possible error from this correction is negligible.

Another error results from the impurities in the xenon. According to the supplier, Deutsche L'Air Liquide, Düsseldorf, the sum of the impurities is below 30 mol-ppm. The principal impurity constituents are Ar, Kr, H_2, O_2, N_2, and H_2O. Their highest possible concentration would cause the $\overline{c_p^0}$, obtained from the experiments, to be too large by nearly 30 ppm. The values of c_p^0, therefore, were reduced by 15 ppm and ±15 ppm is the possible error we assign to impurities.

Measurements repeated after long time intervals confirmed that the xenon was not noticeably contaminated during the experiments. The average of the difference between the mean values and results taken at the different time intervals is 0.01%; the maximum difference (an outlier) is 0.035%. We conclude that there is no influence of time on the purity of the xenon or on the apparatus.

Uncertainty of $\hat{c}_p^0(\theta)$

Because xenon is a noble gas, $\hat{c}_p^0(\theta)$ is nearly constant $(=c_p^0)$; statistical mechanics yields $(5/2)\cdot R\cdot M^{-1}$ to within ±0.001% over the experimental range. The molecular gas constant is 8.3144 J mol^{-1} K^{-1} ± 30 ppm (7), so that the possible error in c_p^0 from this source is ±0.003%. The molecular gas constant, determined by Moldover *et al.* is about 8 ppm higher.[2] With this value, the deviation between the temperature scales at the normal boiling point of water would be about 1 mK higher (−38 mK; cf. Table 3).

The molecular mass of xenon was taken as 131.300 g mol^{-1} calculated with information from the supplier for the isotopic composition of naturally occurring xenon:

^{124}Xe: 0.096 mol%, 123.9061 g/mol
^{126}Xe: 0.090 mol%, 125.9042 g/mol
^{128}Xe: 1.920 mol%, 127.9035 g/mol
^{129}Xe: 26.440 mol%, 128.9048 g/mol
^{130}Xe: 4.080 mol%, 129.9035 g/mol
^{131}Xe: 21.180 mol%, 130.9051 g/mol
^{132}Xe: 26.890 mol%, 131.9042 g/mol
^{134}Xe: 10.440 mol%, 133.9054 g/mol
^{136}Xe: 8.870 mol%, 135.9072 g/mol

The uncertainty in the value for the molecular mass is ±15 ppm (8), so that the possible error in c_p^0 from this uncertainty is less than ±0.002%.

5. Experimental results and comparison of temperature scales

Table 4 lists the c_p values for xenon, which were determined in the measurements with a low temperature rise of about Δt = 6 K in the calorimeter. Summing up the uncertainties of the heating power P, the mass flow rate m, and the temperature difference Δt, one gets a maximum uncertainty for the c_p values of about ±0.05%.

The direct experimental values of the $\overline{c_p}$ for the intervals of the high temperature rises are contained in Table 2 and plotted in Fig. 5. These results were used for comparing the temperature scales. Their uncertainty from the uncertainties of P, m, and Δt, assuming a Gaussian law of errors, is about ±125 ppm at Δt = 10 K and about ±75 ppm at Δt = 200 K. As already mentioned, each value contained in Tables 1, 2, and 4 is based on at least 3 measurements.

Table 3 and Fig. 6 contain the results of the comparison for the temperature scales. The values of c_p^0 in Table 3 were determined by extrapolating the direct experimental results (Table 2). They were corrected for the possible influence of the impurities in the xenon used and for the influence of the kinetic energy change at Th2. The highest correction for both influences (at Δt = 200 K) is about one-half unit of the last digit of the numbers contained in Table 2 for the direct experimental results. The values of c_p^0 listed in Table 3 have one more digit than the values of $\overline{c_p}$ in Table 2.

The difference between $\overline{c_p^0}$ and c_p^0 is a small difference between two large numbers. Small relative uncertainties of these numbers, therefore, cause a high relative uncertainty in the small difference. The possible error of the relative difference between $\overline{c_p^0}$ and c_p^0 (eqs. [6], [8]; Table 3) and, therefore, of the deviation between the values of the temperature on the TTS and on the IPTS-68 is about ±30%. It was determined assuming a Gaussian law of errors for the following uncertainties:

from the direct experimental results: ±(75–125) ppm
from the extrapolation to p = 0: ±50 ppm
from the impurities: ±15 ppm
from the molecular gas constant: ±30 ppm
from the molecular mass of the xenon used: ±15 ppm

The hatched area in Fig. 6 represents the possible error of ±30% in the deviation between the temperature scales.

6. Conclusions

The results presented are in satisfactory agreement with results from the gas thermometric work of Guildner and

Edsinger (1) and the radiometric work of Quinn and Martin (2). The agreement is everywhere within the combined tolerances. This result is of particular importance, since this is a new method (PVT gas thermometry has been used for over a century). The differences between the numbers on the TTS and on the IPTS-68 are sufficiently large that they may be important for experimental work of the highest accuracy.

The one-electron potential, $\nabla^2\sqrt{\bar{\rho}(r)}/2\sqrt{\bar{\rho}(r)}$, appearing in the Schrödinger equation for the charge density is calculated for the neutral atoms from hydrogen to uranium, and the singly positive ions, from helium to barium and lutetium to radium. These computations, utilizing the nonrelativistic SCF wavefunctions of Clementi and Roetti and McLean and McLean, were performed in order to investigate the concept of shell structure as defined by this potential. $\nabla^2\sqrt{\bar{\rho}(r)}/2\sqrt{\bar{\rho}(r)}$ exhibits a number of zeros and extrema corresponding to classically allowed and forbidden regions, with its topology being very similar in nature to that of $\nabla^2\bar{\rho}(r)$. The significant difference is that $\nabla^2\sqrt{\bar{\rho}(r)}/2\sqrt{\bar{\rho}(r)}$ displays all seven shells in the heavier elements of the periodic table, whereas $\nabla^2\bar{\rho}(r)$ displays only five shells; i.e. compared with $\nabla^2\bar{\rho}(r)$, $\nabla^2\sqrt{\bar{\rho}(r)}/2\sqrt{\bar{\rho}(r)}$ has additional zeros and extrema at large distances corresponding to the two outer shells. The positions of these additional zeros and extrema, when plotted against atomic number Z, exhibit large deviations from the Bohr model of the hydrogen atom. The outermost zero-extremum is not displayed in the transition elements; i.e. where d-orbital filling is present. The model of classically allowed and forbidden regions is shown to provide an alternative definition of shell structure to that of the simple Bohr–Schrödinger theory of an atom. The odd-numbered zeros in $\nabla^2\sqrt{\bar{\rho}(r)}/2\sqrt{\bar{\rho}(r)}$ provide a topological feature capable of representing all shells. Furthermore, these zeros appear at precisely the atomic number as the corresponding shell predicted by the aufbau principle.

ROBIN P. SAGAR, ANDREW C. T. KU, VEDENE H. SMITH, JR. et ALFREDO M. SIMAS. Can. J. Chem. **66**, 1005 (1988).

Le potentiel d'un électron, $\nabla^2\sqrt{\bar{\rho}(r)}/2\sqrt{\bar{\rho}(r)}$, qui apparaît dans l'équation de Schrodinger pour la densité de charge, a été calculé pour les atomes neutres de l'hydrogène à l'uranium ainsi que pour les ions portant une seule charge positive, de l'hélium au baryum et du lutécium au radium. On a effectué ces calculs, qui utilisent les fonctions d'onde des champs auto-cohérents non-relativistes de Clementi et Roetti ainsi que de McLean et McLean, dans le but d'étudier la structure de couche définie par ce potentiel. Le potentiel $\nabla^2\sqrt{\bar{\rho}(r)}/2\sqrt{\bar{\rho}(r)}$ présente un certain nombre de zéros et d'extremums qui correspondent aux régions qui sont d'un point de vue classique permises et défendues et sa topologie est très semblable en nature à celle de la fonction $\nabla^2\bar{\rho}(r)$. La différence importante provient du fait que le potentiel $\nabla^2\sqrt{\bar{\rho}(r)}/2\sqrt{\bar{\rho}(r)}$ représente les sept couches des éléments lourds du tableau périodique alors que $\nabla^2\bar{\rho}(r)$ ne représente que cinq de ces couches; par exemple, si on compare $\nabla^2\bar{\rho}(r)$. avec le potentiel $\nabla^2\sqrt{\bar{\rho}(r)}/2\sqrt{\bar{\rho}(r)}$, ce dernier possède plus de zéros et d'extremums aux grandes distances qui correspondent aux deux couches extérieures. Lorsqu'on trace une courbe des positions de ces zéros et de ces extremums en fonction du numéro atomique Z, on observe de grandes déviations par rapport au modèle de Bohr pour l'atome d'hydrogène. Les zéros et les extremums extérieurs ne sont pas représentés dans les éléments de transition, c'est-à-dire lorsqu'on remplit les orbitales d. On démontre que, par rapport à la théorie simple de Bohr–Schrödinger d'un atome, le modèle classique impliquant des régions permises et défendues fournit une alternative à la définition de la structure des couches. Les zéros impairs du potentiel $\nabla^2\sqrt{\bar{\rho}(r)}/2\sqrt{\bar{\rho}(r)}$ fournissent une caractéristique topologique capable de représenter toutes les couches. De plus, ces zéros apparaissent précisément au numéro atomique de la couche correspondante prédite par le principe de aufbau.
[Traduit par la revue]

Introduction

Density functional theory (1) offers the possibility of reducing the N-electron problem into a more viable one-electron one. However, there are difficulties that are encountered such as N-representability, i.e. to guarantee that a computed density is representative of an ensemble of N fermions (2). In the case of the wavefunction, this N-representability is achieved by making the wavefunction antisymmetric with respect to exchange of coordinates of any two of the N indistinguishable fermions.

The Schrödinger equation for the electron density as proposed by Hunter (3) is of interest since this equation is an "exact dynamical model of the motion of a single electron in a many-electron system" (3). Thus, this particular Schrödinger equation is useful for the interpretation of molecular and atomic structure based on the potential,[1] $\{U(\boldsymbol{r}) - E\} = \nabla^2\sqrt{\rho(\boldsymbol{r})}/2\sqrt{\rho(\boldsymbol{r})}$, within which any one electron moves.

[1]This potential is defined in eq. [6].

The shell structure of atoms and ions has been previously discussed with regard to $D(r)$, the radial distribution function (5–8), $I(p)$, the radial momentum density (9), and more recently in conjunction with $\nabla^2\bar{\rho}(r)$, the Laplacian of the spherically averaged charge density (10). The topological features most indicative of a shell were the maxima in $D(r)$ and $I(p)$, and the odd-numbered zeros in $\nabla^2\bar{\rho}(r)$ (8–10). For the purposes of those studies a shell was defined within the independent particle model as the set of those orbitals having the same principal quantum number. Based on these criteria, the authors noted (8) that five shells at most were apparent in $D(r)$ and likewise, $\nabla^2\bar{\rho}(r)$ also exhibited five shells at most (10). It was also shown that all shells do not have expression in $D(r)$ and $\nabla^2\bar{\rho}(r)$, for all the studied atomic and ionic cases (8, 10). In fact, these authors noted that it was in particular the outer shells which were not expressed in $D(r)$ and $\nabla^2\sqrt{\bar{\rho}(\boldsymbol{r})}$ for all the studied atomic and ionic cases.

The potential $\{U(\boldsymbol{r}) - E\}$ which governs the motion of one

electron is related to $\nabla^2\rho(\boldsymbol{r})$ but differs by the additional term $-|\nabla\rho(\boldsymbol{r})|^2/[2\rho(\boldsymbol{r})]$ and division by $4\rho(\boldsymbol{r})$. Since this additional term makes a negative contribution to the potential $\{U(\boldsymbol{r}) - E\}$, Hunter has argued that the allowed regions of space would be increased and perhaps make the outer regions, and hence the outer shells, visible[2] (3).

In the present study we shall examine the nature of $\nabla^2\sqrt{\rho(\boldsymbol{r})}/2\sqrt{\rho(\boldsymbol{r})}$ in order to examine the concept of shell structure as defined within this potential for atoms and ions. Due to the nature of the square root operator, i.e. a nonlinear operator, the technique of examining the contributions from the various shells to the total, previously used in shell structure studies cannot be utilized (9, 10).

It was previously shown (8, 10) that the topological features (zeros and extrema) of $D(r)$ and $\nabla^2\bar{\rho}(r)$ (as functions of the nuclear charge Z) correlate very well with the functional dependence on Z predicted by the Bohr–Schrödinger model of the hydrogenic atom. Thus, this correlation with the hydrogenic atom shall also be investigated for $\nabla^2\sqrt{\rho(\boldsymbol{r})}/2\sqrt{\rho(\boldsymbol{r})}$.

Theoretical considerations

We adopt the notation of Hunter (3) and denote the electronic wavefunction for a particular stationary state k, by $\psi^k(\boldsymbol{r}', s', \boldsymbol{r}, s|\boldsymbol{R})$ where s and $\boldsymbol{r}$ are the spin and spatial coordinates respectively of a particular electron, $\boldsymbol{R}$ are the coordinates of the nuclei, and s' and $\boldsymbol{r}'$ are the spin and spatial coordinates of the remaining electrons. Since we are considering only the ground states of atomic systems, we shall suppress the index k and the nuclear vector $\boldsymbol{R}$. Thus we write $\rho(\boldsymbol{r})$ instead of $\rho^k(\boldsymbol{r}|\boldsymbol{R})$, etc.

The wavefunction can be factorised into

$$[1] \quad \psi(\boldsymbol{r}', s', \boldsymbol{r}, s) = \theta(\boldsymbol{r})\chi(\boldsymbol{r}', s', s|\boldsymbol{r})$$

and substituted into the N-electron Schrödinger equation, $\mathbf{H}\psi = E\psi$, premultiplied by $\chi(\boldsymbol{r}', s', s|\boldsymbol{r})$, and then integrated with respect to $\boldsymbol{r}'$, s', s in the manner described in ref. 4 to yield

$$[2] \quad \left\{-\frac{1}{2}\nabla^2 + U(\boldsymbol{r})\right\}\theta(\boldsymbol{r}) = E\theta(\boldsymbol{r})$$

where

$$[3] \quad U(\boldsymbol{r}) = \int\chi(\boldsymbol{r}', s', s|\boldsymbol{r})\mathbf{H}\chi(\boldsymbol{r}', s', s|\boldsymbol{r})\mathrm{d}\boldsymbol{r}'\mathrm{d}s'\mathrm{d}s$$

$\mathbf{H}$ refers to the N-electron Hamiltonian and Hartree atomic units are used here and throughout this paper.

By utilizing the relationship between the one-electron wavefunction $\theta(\boldsymbol{r})$, and the charge density $\rho(\boldsymbol{r})$,

$$[4] \quad \rho(\boldsymbol{r}) = N|\theta(\boldsymbol{r})|^2$$

Equation [2] can be changed (3) into an equation for the charge density

$$[5] \quad \left\{\frac{\nabla^2\rho(\boldsymbol{r})}{4} - \frac{|\nabla\rho(\boldsymbol{r})|^2}{[8\rho(\boldsymbol{r})]}\right\} + U(\boldsymbol{r})\rho(\boldsymbol{r}) = E\rho(\boldsymbol{r})$$

As noted by Hunter (3), this equation has the same potential energy function, $U(\boldsymbol{r})$, as eq. [2] for the charge density amplitude $\theta(\boldsymbol{r})$ but the kinetic energy has a different form.

[2]The statement by Hunter (3) "Thus, the attractive classically allowed regions computed from eq. [15] (eq. [6] of the present paper) are always larger than those predicted by $\nabla^2\bar{\rho}(r)$" is not strictly correct, because negative regions of $\nabla^2\bar{\rho}(r)$ are interpreted as regions of charge accumulation (11) rather than as classically allowed regions of space; i.e. the negative regions of $\{U(r) - E\}$ are larger than those of $\nabla^2\bar{\rho}(r)$, but their respective interpretations are different.

Equation [5] may be rearranged into

$$[6] \quad \{U(\boldsymbol{r}) - E\} = \left\{\frac{[\nabla^2\rho(\boldsymbol{r})]}{4\rho(\boldsymbol{r})} - \frac{|\nabla\rho(\boldsymbol{r})|^2}{[8\rho(\boldsymbol{r})^2]}\right\} = \frac{\nabla^2\sqrt{\rho(\boldsymbol{r})}}{2\sqrt{\rho(\boldsymbol{r})}}$$

The potential $\{U(\boldsymbol{r}) - E)\}$ governs the motion of a single electron. The region where this potential is negative is a classically allowed region of space and where it is positive is a classically forbidden region of space. As a result it provides a map of alternating allowed and forbidden regions. Hunter (3) has speculated that the number of these regions corresponds to the shell structure of an atom or an ion.

The physically meaningful charge density for atomic systems is spherical because an ensemble average must be taken over degenerate states. As a result we shall focus our attention on $\bar{\rho}(r)$ and $\nabla^2\sqrt{\bar{\rho}(r)}/2\sqrt{\bar{\rho}(r)}$. The latter will be computed from eq. [6]. The wavefunctions used for the computation of $\nabla^2\bar{\rho}(r)$, $\nabla\bar{\rho}(r)$ and $\bar{\rho}(r)$ were the non-relativistic self-consistent field wavefunctions of Clementi and Roetti (12) and of McLean and McLean (13). Published wavefunctions for the singly positive ions with open f-shells could not be found.

As discussed elsewhere (9), the Laplacian operator for the spherically averaged charge density expressed in spherical polar coordinates (10) is,

$$[7] \quad \nabla^2\bar{\rho}(r) = \frac{\partial^2}{\partial r^2}\bar{\rho}(r) + \frac{2}{r}\frac{\partial}{\partial r}\bar{\rho}(r)$$

The expression for the gradient of $\rho(\boldsymbol{r})$ in spherical polar coordinates is,

$$[8] \quad \nabla\rho(\boldsymbol{r}) = \frac{\partial}{\partial r}\rho(\boldsymbol{r})\hat{r} + \frac{1}{r}\frac{\partial}{\partial\theta_r}\rho(\boldsymbol{r})\theta_r + \frac{1}{r\sin\theta_r}\frac{\partial}{\partial\phi}\rho(\boldsymbol{r})\hat{\phi}_r,$$

which reduces to

$$[9] \quad \nabla\bar{\rho}(r) = \frac{\partial}{\partial r}\bar{\rho}(r)\hat{r}$$

for a spherically averaged charge density. Substitution of eqs. [7] and [9] into eq. [6] yields

$$[10] \quad \{U(r) - E\} = \frac{\nabla^2\sqrt{\bar{\rho}(r)}}{2\sqrt{\bar{\rho}(r)}} = \frac{1}{8\bar{\rho}(r)^2}\left\{2\bar{\rho}(r)\frac{\partial^2}{\partial r^2}\bar{\rho}(r) + \frac{4}{r}\bar{\rho}(r)\frac{\partial}{\partial r}\bar{\rho}(r) + \left(\frac{\partial}{\partial r}\bar{\rho}(r)\right)^2\right\}$$

The potential can thus be seen to be related to the various curvatures of $\bar{\rho}(r)$, the spherically averaged charge density, which has been the topic of a recent study (8).

Results and discussion

In Figs. 1 and 2 plots of the potential $\nabla^2\sqrt{\bar{\rho}(r)}/2\sqrt{\bar{\rho}(r)}$ for the neutral atoms Zn ($Z = 30$), Ga ($Z = 31$) and the singly positive ion Cl^+ ($Z = 17$) are presented. From eq. [10] and the MacLaurin expansion of $\bar{\rho}(r)$

$$[11] \quad \bar{\rho}(r) = \bar{\rho}(0)[1 - 2ZC_{en}r] + 0(r^2)$$

where C_{en} is the electron–nuclear cusp ratio (14)

$$[12] \quad C_{en} = -\lim_{r\to 0}\frac{\bar{\rho}'(r)}{2Z\bar{\rho}(r)}$$

we observe that if C_{en} is non-zero, the potential rises from negative infinity as r increases. C_{en} has the value one for the exact electron density as well as the exact Hartree–Fock $\bar{\rho}(r)$. For the present functions, C_{en} is approximately one (14). The

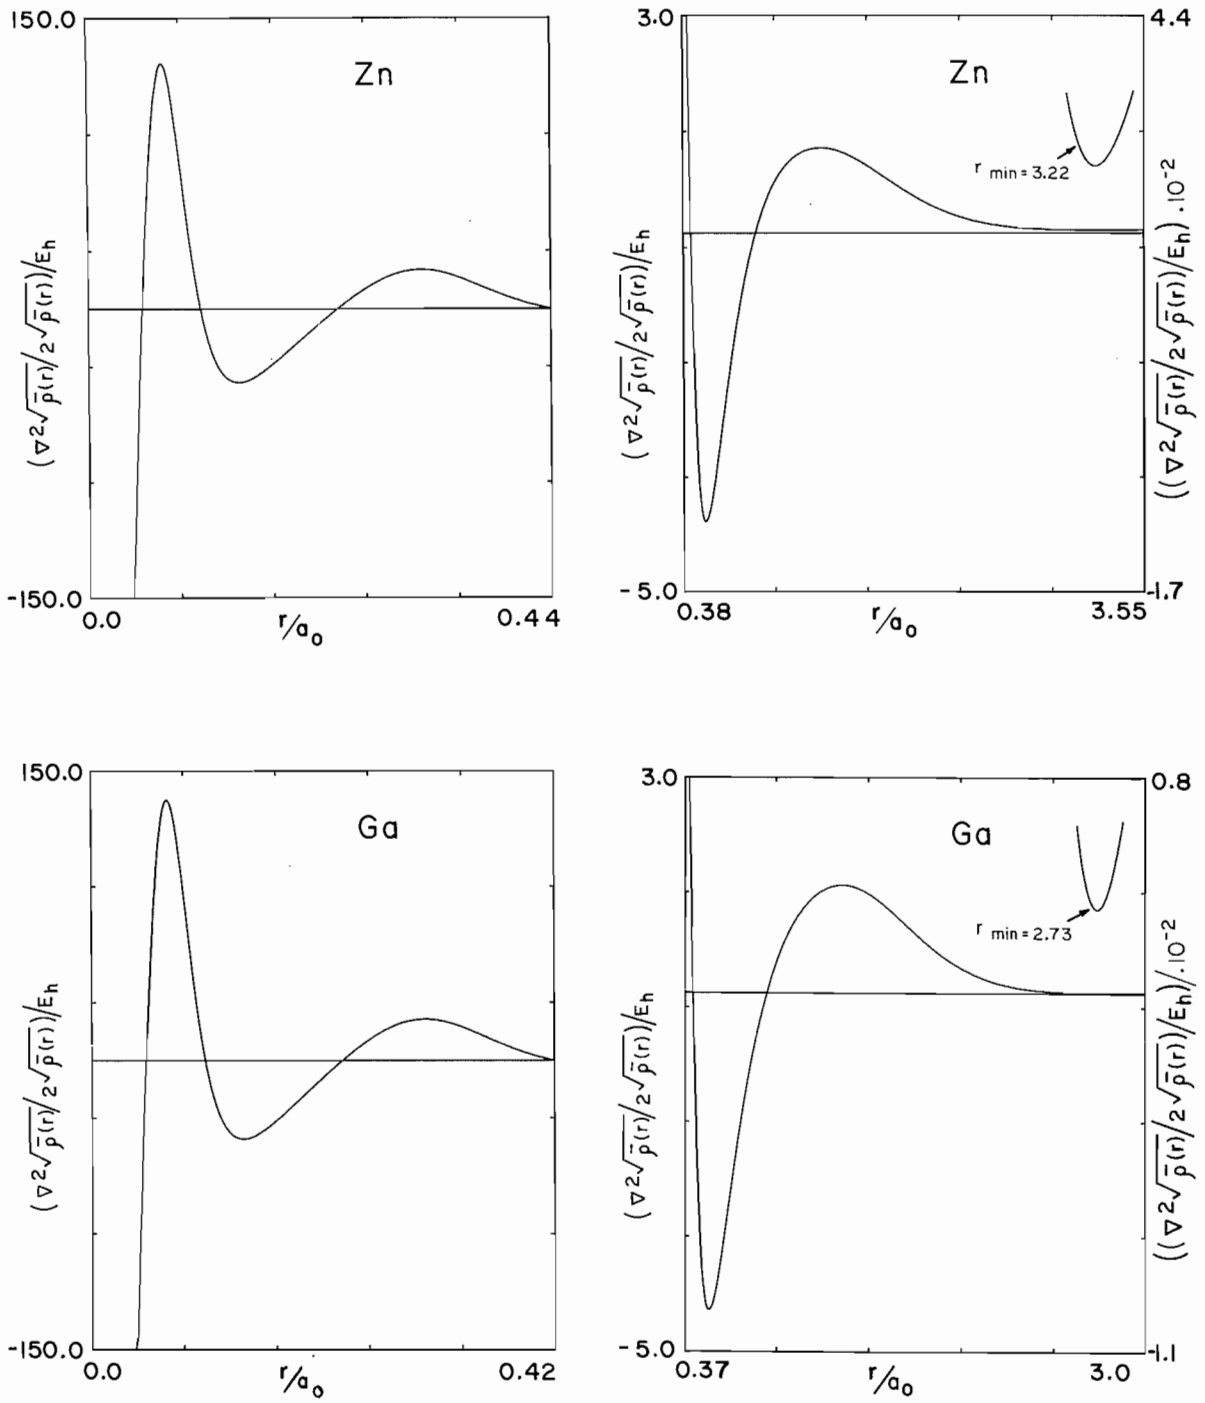

FIG. 1. The one-electron potential, $\nabla^2\sqrt{\bar{\rho}}(r)/2\sqrt{\bar{\rho}}(r)$, for the neutral atoms zinc ($Z = 30$) and gallium ($Z = 31$).

potential exhibits a number of zeros, maxima and minima, with the absolute value of the function becoming smaller at each successive extremal point. As $r \rightarrow \infty$, the potential $\{U(r) - E\}$ has the ionization potential of the system as its asymptotic value (3).

The topology of this potential greatly resembles that of $\nabla^2\bar{\rho}(r)$ (10), but differs in that the relative magnitudes of $\nabla^2\sqrt{\bar{\rho}}(r)/2\sqrt{\bar{\rho}}(r)$ from a particular maxima to a successive minima are not as great as that displayed by $\nabla^2\bar{\rho}(r)$.

The positions of the extrema in $\nabla^2\sqrt{\bar{\rho}}(r)/2\sqrt{\bar{\rho}}(r)$ are plotted against atomic number Z, for the atoms in Fig. 3 and the ions in Fig. 4. The extrema arbitrarily assigned to a particular shell have been joined in order to guide the eye, with the thicker lines corresponding to the maxima and the thinner ones to the minima. The first maximum shall be arbitrarily denoted as the K shell, with successive maxima denoted as L, M, N, etc. the minima located between two maxima will be denoted by the two letters corresponding to the two maxima between which the particular minimum is situated. These minima shall be arbitrarily considered to be reflections of regions between the shells, i.e. an intershell region.

As was previously demonstrated (8, 10) plots of this nature should yield roughtly first order hyperbolae according to the simple hydrogenic model (i.e. Bohr theory of an atom) which

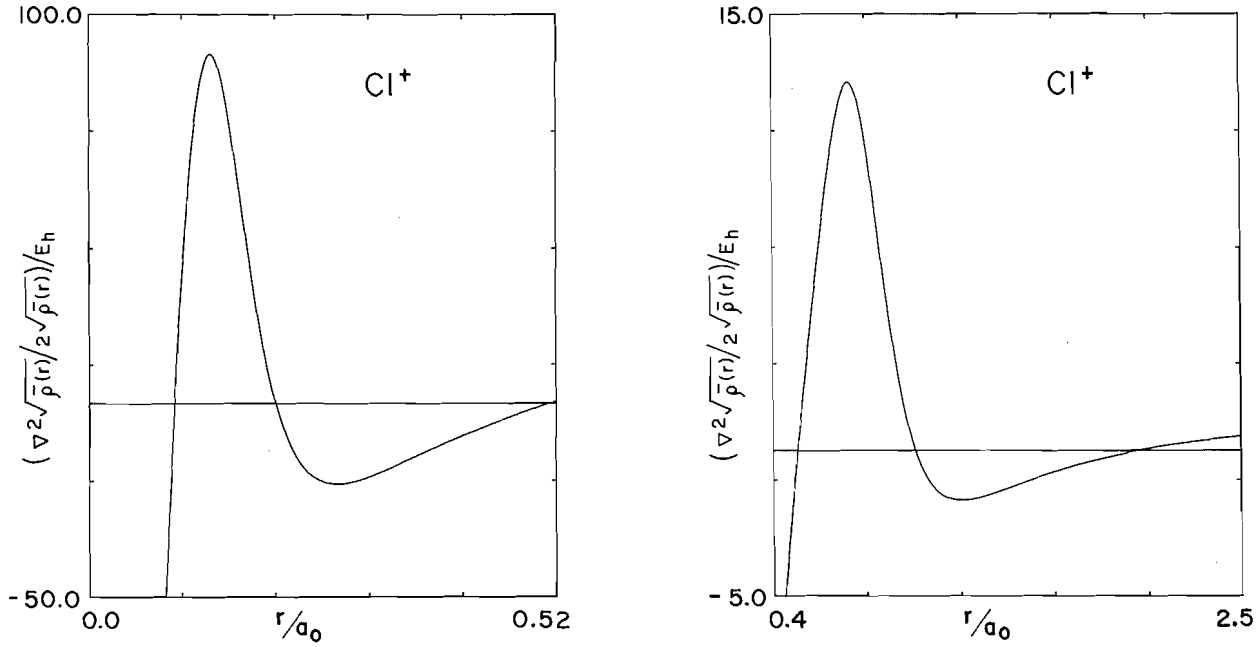

FIG. 2. The one-electron potential, $\nabla^2\sqrt{\bar{\rho}}(r)/2\sqrt{\bar{\rho}}(r)$, for the singly positive ion Cl^+ ($Z = 17$).

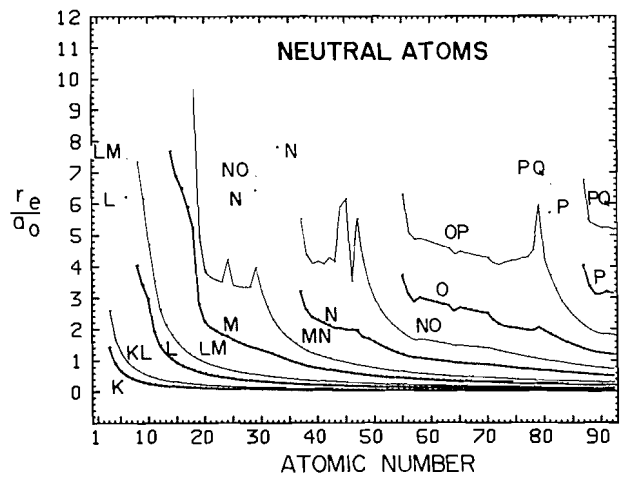

FIG. 3. The positions of the extrema of the one-electron potential $\nabla^2\sqrt{\bar{\rho}}(r)/2\sqrt{\bar{\rho}}(r)$, as a function of atomic number Z, for the neutral atoms. Those values belonging to a particular extremum (i.e. 1st, 2nd, 3rd) have been connected. The thicker lines connect those r-values for the maxima which have been arbitrarily classified acording to each shell (e.g. K, L, M, ---) while the thinner ones connect the minima that have been arbitrarily classified according to an intershell region (e.g. KL, LM, MN, etc.). Note that in this and the following figures the lines joining the points have no physical significance and are merely meant to guide the eye.

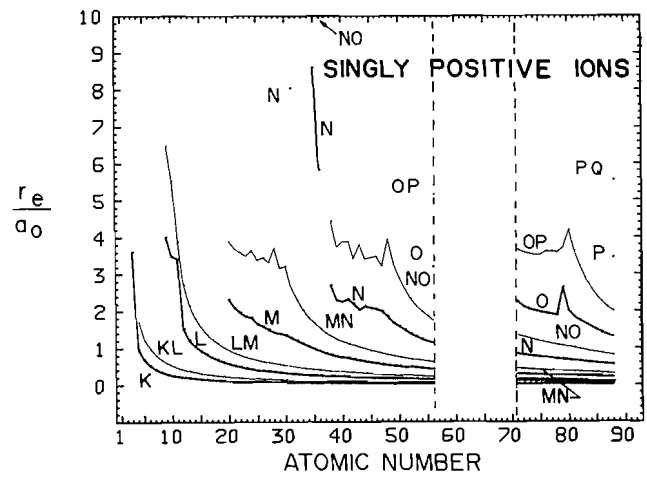

FIG. 4. The positions of the extrema of the one-electron potential $\nabla^2\sqrt{\bar{\rho}}(r)/2\sqrt{\bar{\rho}}(r)$, as a function of the atomic number Z, for the singly positive ions. Those values belonging to a particular extremum (i.e. 1st, 2nd, 3rd) have been connected. The thicker lines connect those r-values for the maxima which have been arbitrarily classified according to each shell (e.g. K, L, M, ---) while the thinner ones connect the minima that have been arbitrarily classified according to an intershell region (e.g. KL, LM, MN, etc.). Note that the gap $57 \leqq Z \leqq 70$ is due to the unavailability of published wavefunctions for ions with open f-shells.

specifies shells with radii equal to

$$[14] \quad \left(\frac{n^2}{Z}\right)\left(\frac{\hbar^2}{m_e e^2}\right)$$

where $\hbar$, m_e, e are the Planck–Dirac constant, mass and charge of the electron, respectively. However, it may be seen in Figs. 3 and 4 that there are significant deviations from a hyperbolic form, with the deviations becoming larger in the case of the outermost minima.

An examination of Fig. 3 also indicates that the L shell and the LM intershell region appear at the carbon atom ($Z = 6$) and are present for all atoms in the range ($6 \leqq Z \leqq 92$) with the only exception being the nitrogen atom. The N shell and the NO intershell regions are present for the range ($29 \leqq Z \leqq 92$) with breaks occurring at ($29 < Z < 33$) and ($33 < Z < 37$). The P shell and PQ intershell regions are present in the range ($81 \leqq Z \leqq 92$) with the only break occurring in the interval ($81 < Z < 87$). The remainder of the shell and intershell regions display no breaks, i.e. once a particular shell or intershell region is present at some value of the atomic number Z, it will remain present for all other

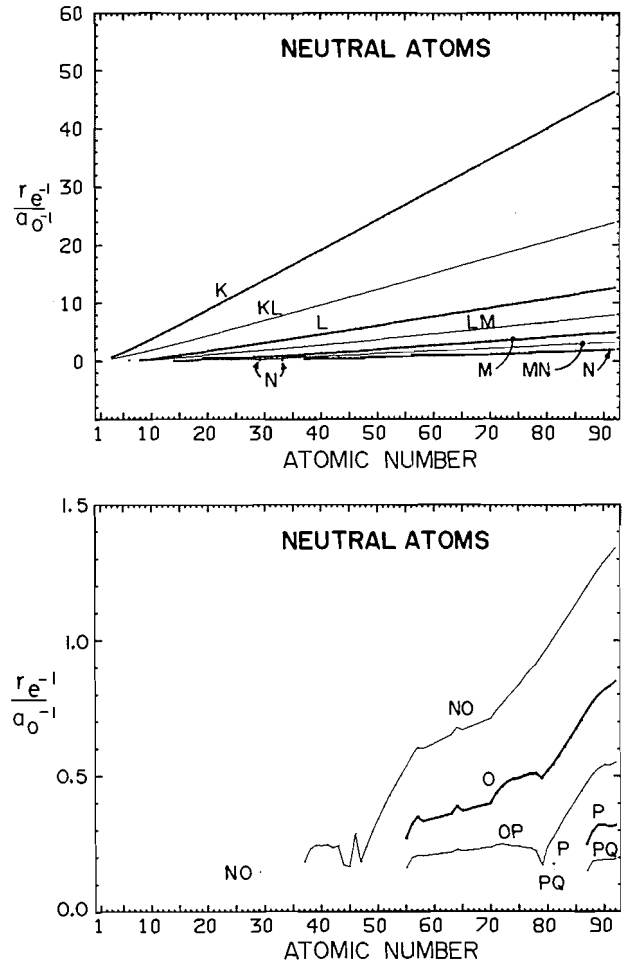

FIG. 5. Inverses of the positions of the extrema of the one-electron potential, $\nabla^2\sqrt{\bar{\rho}}(r)/2\sqrt{\bar{\rho}}(r)$, as a function of the atomic number Z, for the neutral atoms. Those values belonging to a particular extremum (i.e. 1st, 2nd, 3rd, etc.) have been connected. The thicker lines connect those r-values for the maxima which have been arbitrarily classified according to each shell (e.g. K, L, M, ---) while the thinner ones connect the minima that have been arbitrarily classified according to an intershell region (e.g. KL, LM, MN, etc.).

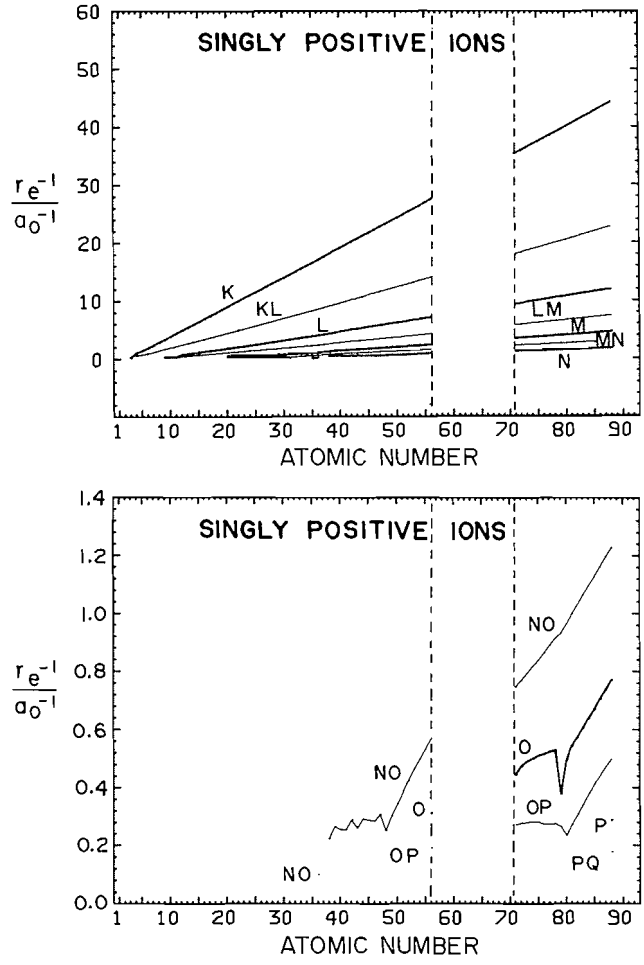

FIG. 6. Inverses of the positions of the extrema of the one-electron potential, $\nabla^2\sqrt{\bar{\rho}}(r)/2\sqrt{\bar{\rho}}(r)$, as a function of the atomic number Z, for the singly positive ions. Those values belonging to a particular extremum (i.e. 1st, 2nd, 3rd, etc.) have been connected. The thicker lines connect those r-values for the maxima which have been arbitrarily classified acording to each shell (e.g. K, L, M, ---) while the thinner ones connect the minima that have been arbitrarily classified according to each intershell region (e.g. KL, LM, MN, etc.). Note that the gap $57 \leqq Z \leqq 70$ is due to the unavailability of published wavefunctions for ions with open f-shells.

values of atomic number $Z' > Z$. It should be noted from Fig. 3 that there are at most twelve extrema displayed by $\nabla^2\sqrt{\bar{\rho}}(r)/2\sqrt{\bar{\rho}}(r)$ while a previous study on $\nabla^2\bar{\rho}(r)$ reported nine extrema at most (10).

For the ions, inspection of Fig. 4 indicates that the N shell is present in the interval ($31 \leqq Z \leqq 90$) for the ions studied, with a break occurring at ($31 < Z < 35$) and at ($35 < Z < 38$). The NO intershell region is present in the interval ($36 \leqq Z \leqq 90$) with the only break occurring at $Z = 37$. The O shell and the OP intershell region appear simultaneously in the interval ($51 \leqq Z \leqq 90$) with the assumption that these features are present in the interval ($51 < Z < 71$) where no data is available.

Figures 5 and 6 are plots of the inverses of the curves in Figs. 3 and 4 for the atoms and the ions, respectively. The large deviations from linearity in Figs. 5(b) and 6(b) where these curves correspond to the outermost extrema, i.e. at large r, is indicative of the failure of the Bohr theory at large r. Electronic shielding, previously explored (8) with regard to $D(r)$, can be used to explain why the curves in Figs. 5(a) and 6(a) exhibit marked linearity even though the curves in Figs. 3 and 4 show deviations from hyperbolae. Equation [14] indicates that if shielding were present, i.e. $Z = Z - s$, where s is a shielding parameter, then the intercepts and not the slopes would be affected. A least-squares fit was performed on the data points in Figs. 5(a) and (b) and figs. 6(a) and (b) for the atoms and the ions with the determined parameters tabulated in Tables 1 and 2 for the atoms and the ions, respectively. The values which are close to unity for R^2, the square of the correlation coefficient, for the extrema closer to the nucleus is supportive of the graphical evidence in Figs. 5(a) and 6(a) for the atoms and the ions. The comparatively large deviation from unity in R^2 for the curves in Figs. 5(b) and 6(b) supports the observation that the outer extrema are not directly related to the Bohr theory of an atom.

A similar analysis to that performed on the extrema was done for the zeros of $\nabla^2\sqrt{\bar{\rho}}(r)/2\sqrt{\bar{\rho}}(r)$. These results are presented in Figs. 7–10 for the neutral atoms and the ions. Inspection of Fig. 7 shows that there are at most thirteen zeros present for an atom in comparison with the maximum number of nine zeros previously reported for $\nabla^2\bar{\rho}(r)$ (10). These plots have been labelled according to the arbitrarily selected convention that the

[a]The same definitions have been used as in Table 1.
[b]Note that no fitting was performed for the 11th and 12th extrema since these are only present for Ra^+ ($Z = 88$) in the cases studied.

odd-numbered zeros (i.e. 1st, 3rd, etc.) be denoted as the shells and the even numbered zeros (i.e. 2nd, 4th, etc.) be denoted as an intershell region. The intershell regions have been labelled with two letters, with the first corresponding to the shell indicative of the $(n-1)$ zero and the second letter corresponding to the shell indicative of the $(n+1)$ zero, where n is the even-numbered zero being labelled. Figure 7 illustrates that while there are no breaks in the curves for the K, L, M shells and the KL, LM intershell regions, the MN intershell region and the N shell are present in the period ($19 \leqq Z \leqq 92$) but are not present in the intervals ($23 < Z < 25$) and ($25 < Z < 32$). The NO intershell region and the O shell are present in the period ($37 \leqq Z \leqq 92$) with a large break occurring in the interval ($39 < Z < 50$). The OP intershell region and the P shell are present in the period ($55 \leqq Z \leqq 92$) with a break occurring at ($72 < Z < 83$). As was previously noted for the case of the outer extrema, deviations from a hyperbolic form are also more evident for the outer zeros, i.e. as the distance from the nucleus increases. This further validates the notion that the topology of the potential $\nabla^2\sqrt{\bar{\rho}}(r)/2\sqrt{\bar{\rho}}(r)$ is dependent upon the extent of electronic shielding in a particular atom or ion. Most interestingly, these breaks are seen to occur in regions where the *d*-orbitals of the next innermost shell are being filled. Hence, the outermost shell is not visible.

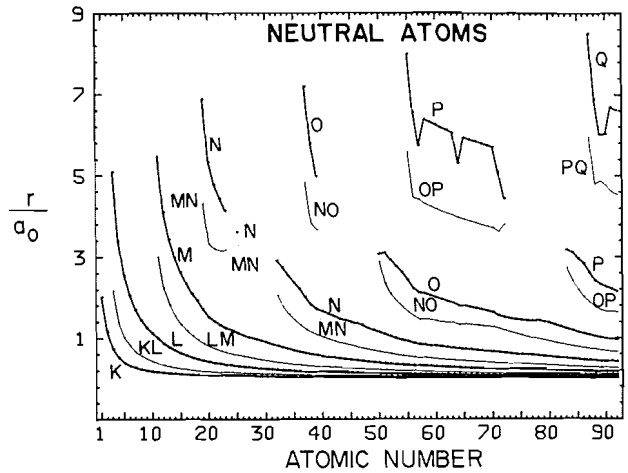

FIG. 7. The positions of the zeros in the one-electron potential, $\nabla^2\sqrt{\bar{\rho}}(r)/2\sqrt{\bar{\rho}}(r)$, as a function of the atomic number Z, for the neutral atoms. Those values belonging to a particular zero (i.e. 1st, 2nd, 3rd) have been connected. The thicker lines connect those r-values for the odd numbered zeros (1st, 3rd, etc.) which have been arbitrarily classified according to each shell (e.g. K, L, M, ---) while the thinner ones connect the even numbered zeros (2nd, 4th, etc.) that have been arbitrarily classified according to each intershell region (e.g. KL, LM, MN, etc.).

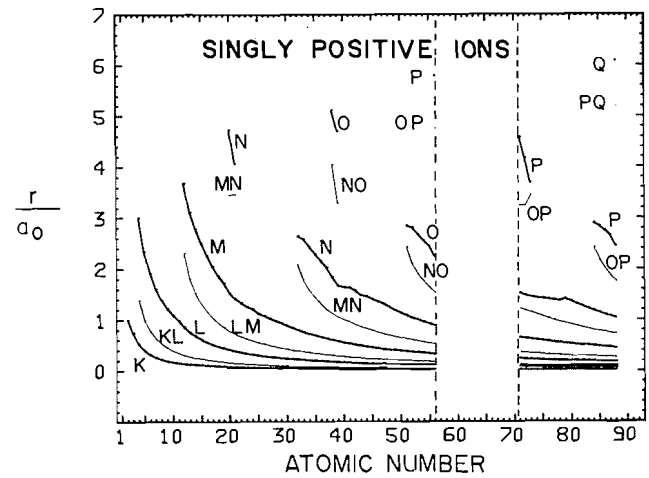

FIG. 8. The positions of the zeros of the one-electron potential $\nabla^2\sqrt{\bar{\rho}}(r)/2\sqrt{\bar{\rho}}(r)$, as a function of atomic number Z for the singly positive ions. Those values belonging to a particular zero (i.e. 1st, 2nd, 3rd) have been connected. The thicker lines connect those r-values for the odd numbered zeros (1st, 3rd, etc.) which have been arbitrarily classified according to each shell (e.g. K, L, M, ---) while the thinner ones connect the even numbered zeros (2nd, 4th, etc.) and have been arbitrarily classified according to each intershell region (e.g. KL, LM, MN, etc.). Note that the gap $57 \leqq Z \leqq 70$ is due to the unavailability of wavefunctions with open *f*-shells.

Figure 8 for the singly positive ions indicates that there are at most thirteen zeros present for the studied cases in comparison to the nine reported for $\nabla^2\bar{\rho}(r)$. The MN intershell region and the N shell are present in the period ($20 \leqq Z \leqq 90$) with a break occurring in the interval ($21 < Z < 32$). The NO intershell region and the O shell are present in the period ($38 \leqq Z \leqq 90$) with a break occurring at ($39 < Z < 51$). Consequently the OP intershell region and the P shell are present in the period ($56 \leqq Z \leqq 90$) with a break occurring at ($73 < Z < 84$). Figures 9 and 10 are the inverses of the curves presented in Figs. 7 and 8

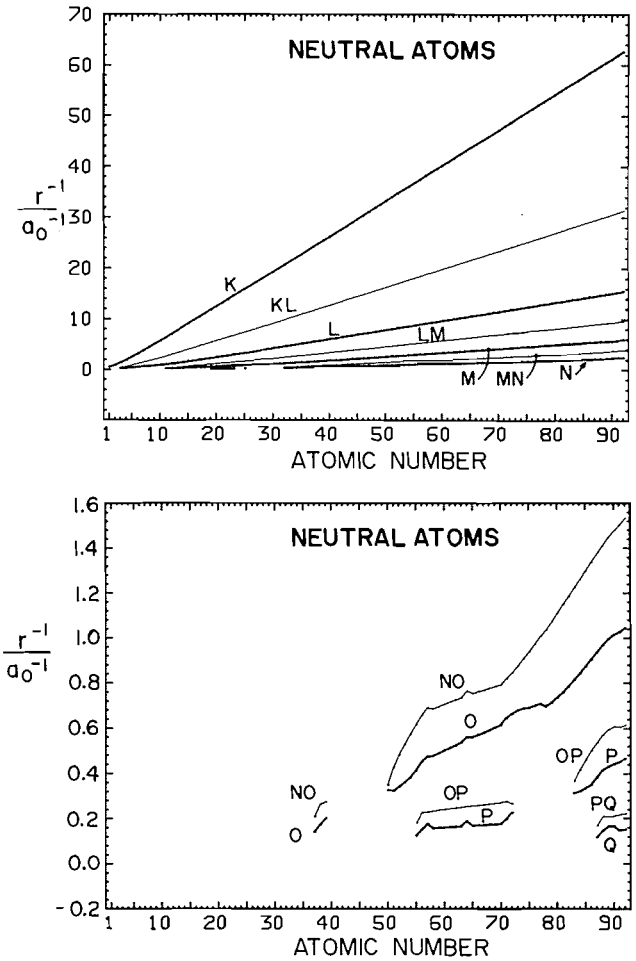

FIG. 9. The inverses of the positions of the zeros of the one-electron potential, $\nabla^2\sqrt{\bar{\rho}}(r)/2\sqrt{\bar{\rho}}(r)$, as a function of atomic number Z for the neutral atoms. Those values belonging to a particular zero (1st, 2nd, 3rd, etc.) have been connected. The thicker lines connect those r-values for the odd numbered zeros (1st, 3rd, etc.) which have been arbitrarily classified according to each shell (e.g. K, L, M, ---) while the thinner ones connect the even numbered zeros (2nd, 4th, etc.) that have been classified according to each intershell region (e.g. KL, LM, MN, etc.).

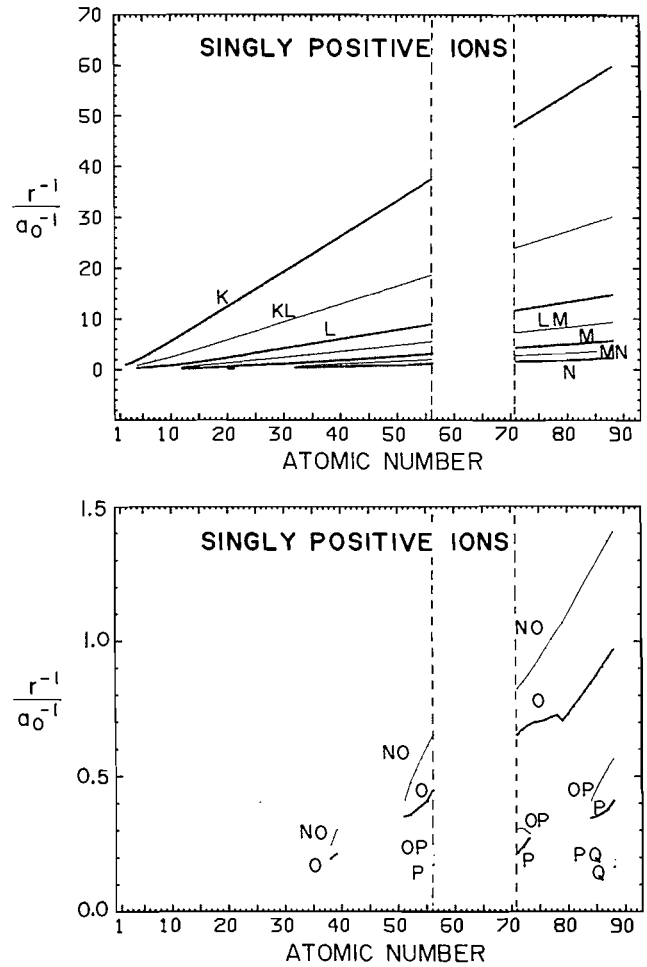

FIG. 10. The inverses of the positions of the zeros of the one-electron potential, $\nabla^2\sqrt{\bar{\rho}}(r)/2\sqrt{\bar{\rho}}(r)$, as a function of atomic number Z for the singly positive ions. The values belonging to a particular zero (1st, 2nd, 3rd, etc.) have been connected. The thicker lines connect those r-values for the odd numbered zeros (1st, 3rd, etc.) which have been arbitrarily classified according to each shell (e.g. K, L, M, ---) while the thinner ones connect the even numbered zeros (2nd, 4th, etc.) that have been arbitrarily classified according to each intershell region (e.g. KL, LM, MN, etc.). Note that the gap $57 \leqq Z \leqq 70$ is due to the unavailability of wavefunctions with open f-shells.

for the neutral atoms and the singly positive ions, respectively. Examination of Figs. 9(a) and 10(a) shows that there is marked linearity for the zeros closer to the nucleus, but the results in Figs. 9(b) and 10(b) are indicative that the Bohr theory of an atom fails more drastically at larger distances from the nucleus than at closer distances. Tables 3 and 4 contain the parameters from a least-squares linear regression analysis of the data points in Figs. 9(a) and (b) and Figs. 10(a) and (b), respectively. The values of close to unity for the square of the correlation coefficient for the inner zeros are supportive of the observed linearity, while the deviations from unity of the outer zeros further compliments the evidence of large deviations from the Bohr theory of an atom at larger values of r.

The classically allowed and forbidden regions model suggests that a shell may be defined as an interval where $\nabla^2\sqrt{\bar{\rho}}(r)/2\sqrt{\bar{\rho}}(r)$ is correspondingly negative and positive. Thus, the topological features present in this interval may be indicative of shell structure. Figures 7 and 8 show that all shells are present when the odd-numbered zeros are chosen as the topological feature indicative of a shell. Furthermore, these zeros appear at

precisely the atomic number predicted by the aufbau principle. In this manner the zeros of $\nabla^2\sqrt{\bar{\rho}}(r)/2\sqrt{\bar{\rho}}(r)$ would seem to be an indicative feature of shell structure within this framework.

Conclusions

The number of topological features (zeros, extrema) exhibited by the potential $\nabla^2\sqrt{\bar{\rho}}(r)/2\sqrt{\bar{\rho}}(r)$ are greater than the number displayed in $\nabla^2\bar{\rho}(r)$ and $D(r)$ for the larger atoms and ions. This means that a comparatively larger number of shells are visible in the potential. These features are seen to show significant deviations from the Bohr–Schrödinger theory which become greater for the outer extrema and zeros, i.e. as the distance from the nucleus increases. There are also breaks present in the curves of the positions of a particular zero or extremum plotted against atomic numbers. These breaks correspond to a particular topological feature being present at some atomic number Z, but then not being present at some higher atomic number Z'. They are seen to coincide with the filling of the d-orbitals corresponding to the next innermost shell. $\nabla^2\bar{\rho}(r)$ was shown to exhibit no breaks in the curves pertaining to the zeros, however breaks were observed in the curves of the extrema (9).

The fact that the computed potential $\nabla^2\sqrt{\bar{\rho}}(r)/2\sqrt{\bar{\rho}}(r)$ involves the use of a non-linear operator makes it difficult to perform a shell by shell analysis of this potential. This reasoning casts doubts on its ability to reveal the shell structure of an atom or an ion, if a shell is defined within the independent particle model as the set of those orbitals possessing the same principal quantum number. However, within the framework of classically allowed and forbidden regions, $\nabla^2\sqrt{\bar{\rho}}(r)/2\sqrt{\bar{\rho}}(r)$ is shown to correctly represent all shells, at the precise value of the atomic number predicted by the aufbau principle, when the odd-numbered zeros are used as the feature indicative of a shell.

Received September 3, 1987

This paper is dedicated to Professor James A. Morrison

ZHI CHENG SHI, ALINE AUROUX, and YOUNES BEN TAARIT. Can. J. Chem. **66**, 1013 (1988).

The acidity of synthetic HY samples dealuminated with silicon tetrachloride vapour at various temperatures is investigated using microcalorimetry. The work covers sample preparation, characterization, and acidic properties. The differential heats of ammonia adsorption versus coverage and the acidity spectra are described. The catalytic performance is measured in the hydrogen transfer reaction.

ZHI CHENG SHI, ALINE AUROUX et YOUNES BEN TAARIT. Can. J. Chem. **66**, 1013 (1988).

L'acidité d'échantillons de zéolithes HY désaluminées par traitement par $SiCl_4$ vapeur à différentes températures est déterminée essentiellement par microcalorimétrie. Ce travail recouvre la préparation, les caractéristiques et les propriétés acides de ces échantillons. Les chaleurs différentielles d'adsorption d'ammoniac en fonction du recouvrement ainsi que les spectres d'acidité sont présentés. Les performances catalytiques sont mesurées à partir d'une réaction de transfert d'hydrogène.

Introduction

Faujasite is one of the most open-structured zeolites. This important class of materials has been widely used in commercial chemical processes as well as in the petroleum industry. However, it is difficult to synthesize Y-type faujasite with a Si/Al ratio greater than 3. In the last few years the aluminium-deficient zeolites have been found to have increased chemical and thermal stability. To prepare and study aluminium-deficient zeolites, several techniques are now proposed for their preparation by dealumination of the low Si/Al analogs.

Recently Scherzer reviewed the important processes used in this field (1). Among them, dealumination by silicon tetrachloride vapour has become more and more popular because of its simplicity as a laboratory procedure. Furthermore, it has been reported that dealumination by $SiCl_4$ effects the removal of structural aluminium from any cationic form of Y-zeolite without excessive loss of crystallinity (2, 3).

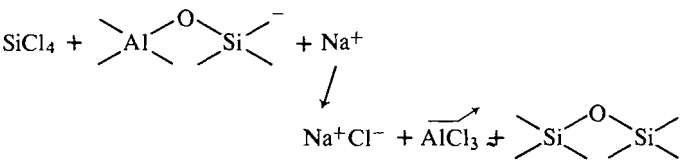
The present work will deal in detail with dealuminated Y-zeolite with Si/Al ratios up to 60. The work covers sample preparation, characterization, and acidic properties.

Experimental

Sample preparation

The parent zeolite used is Na-Y-zeolite from the Linde Division of Union Carbide Corporation, with a unit cell formula $Na_{56}(AlO_2)_{56}(SiO_2)_{136}$ and a Si/Al ratio of about 2.4. The NaY samples were calcinated at 400°C under a stream of dry nitrogen to ensure thorough dehydration and possibly dehydroxylation of residual silanol groups.

The dealumination procedure used in our study follows that proposed by Beyer and Belenykaja (3): the dehydrated samples were heated in the flow of a $SiCl_4 + N_2$ mixture obtained by bubbling dry N_2 through a saturator containing liquid $SiCl_4$ maintained at 0°C. The extent of dealumination was controlled by monitoring the temperature of the substitution reaction, which can be written as:



The reaction was allowed to continue for 1 h and the sample was then flushed for an additional 2-h period at the same temperature to remove excess reagent and possibly volatile reaction products. The substitution reaction temperature was varied between 250 and 450°C. At this latter temperature, total dealumination was eventually achieved.

The samples were subsequently cooled down to room temperature and divided into two parts. One part was washed by deionized water. The other part was boiled in an acidic (HCl) solution at a pH of 2 for 30 min (4). The operation was repeated 3 times. The samples washed only by deionized water were further subjected to ion exchange with NH_4Cl.

Structural characterization

Beyer reported (3) that during the dealumination reaction using $SiCl_4$, only part of the aluminium that leaves the framework positions escapes in the form of volatile aluminium chloride. $Na(AlCl_4)$, which is not volatile under the reaction conditions and is formed by melting NaCl with $AlCl_3$, remains in the zeolite cavity. Thus, in most cases, at least part of the extra-framework aluminium will be found with the dealuminated zeolite (5, 6).

Since these two kinds of aluminium have different properties, it is essential to know the distribution between the framework and the extra-framework aluminium.

Recent advances in ^{29}Si solid-state and ^{27}Al solid-state nmr have made possible the accurate determination of the framework aluminium content in faujasite-type zeolites (7). In the absence of solid-state nmr facilities, it is desirable to have other methods of estimating the framework aluminium. Fortunately, it has long been recognized that for a faujasite-type zeolite the unit cell size decreases with increasing Si/Al ratio (8).

Applications of infrared spectroscopy to zeolite structural problems have also been reviewed (9). The frequency shift of infrared stretching-mode bands with variation of the Si/Al ratio is known. A nearly linear decrease is shown for the position of the main asymmetric stretch band near 980–1100 cm^{-1}. Since the masses of Al and Si atoms are nearly the

same, the decrease in frequency with increasing Al concentration appears to be related to the variation in bond length and bond order. The increased length of Al—O bonds and decreased electronegativity of Al atoms result in a decrease in the force constant.

Correlations between the Si/Al ratio and ir absorptions and unit cell dimensions, using nmr data as the primary means, have been provided (10).

In our study ^{29}Si and ^{27}Al solid-state nmr were employed to determine the framework Si/Al ratio and we also utilized X-ray powder diffraction and ir to monitor the Si/Al ratios of the samples. For the ir structural analysis the zeolite wafer was prepared in a metallurgical die. The total wafer weighed 0.3 g, mixed with KBr. The percentage of the zeolite in a wafer was 0.1%. Before analysis by X-ray diffraction the zeolite sample was saturated with water at room temperature for 24 h.

Surface acid characterization

Many methods have been evolved for measuring the nature and the number of acid sites. Methods have been developed that distinguish between Brönsted and Lewis sites (11, 12) while others measure the total amount and distribution of various acid sites present.

Microcalorimetric measurements, associated with spectroscopic methods, appear to be the most reliable method to date to fully characterize the acidity of solid materials both qualitatively (nature, strength) and quantitatively (number, strength distribution, etc.). Strong bases such as piperidine, pyridine, ammonia, and butylamine have been used to determine the adsorption heats on zeolite HY (13–15).

In this study, microcalorimetry was employed to measure the acid sites quantitatively and also to determine their distribution. Dry ammonia was used as the molecular basic probe. Ammonia was adsorbed at 150°C to prevent physisorption. The zeolite sample in powder form, approximately 60 mg in weight, was pretreated in a quartz cell, first with oxygen by heating at 2°C per minute and holding at 350°C for about 4 h and then under vacuum (1.33 mPa) at the desired temperature (350°C or 600°C) for about 2 h. The pretreated sample was transferred to a SETARAM Tian–Calvet microcalorimeter of the twin conduction type maintained at constant temperature (150°C). The gaseous probe was then admitted to the zeolite sample in successive small doses of ~0.04 cm^3, the gas pressure before expansion and at equilibrium being measured for every dose by a Datametrics Barocel gauge of maximum pressure 200 Pa. Both the gas pressure and the thermogram were monitored graphically for every dose to determine the sorption equilibrium. The sorption process was followed both volumetrically and calorimetrically (with facilities for automation and computer processing) up to a final pressure of ca. 150 Pa.

Catalytic reaction

The hydrogen transfer reaction was selected as a catalytic test reaction, cyclohexene being employed as the reaction agent. We used a flowing type reactor with hydrogen as flowing gas.

Since the samples deactivate very quickly, after every 20 s of reaction time, the reaction was stopped by passing only the flowing gas through the reactor without the cyclohexene. The sample weighed about 50 mg. The gas flow was 3 L per hour, and the reaction temperature was 250°C. The reaction proceeded until the sample became stable. The products were analysed by chromatography.

Results and discussion

Structural analysis

Table 1 gives the results of structural analysis. The numbers in the first column (S-200, etc.) express the temperature of the dealumination reaction and thus represent degree of dealumination.

The results of the X-ray powder diffraction analysis show that all samples maintain good crystallinity, and that with increase of the Si/Al ratio the unit cell constant decreases.

The results of the ir spectra in the structural region also show the dependence of the ir wavenumber on the Si/Al ratio. With the increase of ir frequency, the Si/Al ratio increases. These results are in good agreement with those of the nmr analysis. Samples shown in the upper part of Table 1 were washed only by deionized water after the dealumination reaction; those shown in the lower part were subjected to acid leaching. It is interesting to note that ^{27}Al solid-state nmr shows that there is almost no extra-framework aluminium in samples washed by deionized water, in contrast to the samples leached with acid in which some extra-framework aluminium continues to be present.

Originally we hoped that acid leaching would remove the extra-framework aluminium formed during the dealumination process from the zeolite cavity without influencing the framework aluminium. In fact the acid leaching further removed the structural aluminium. The aluminium produced during acid leaching becomes the extra-framework aluminium remaining in the zeolite cavities. Probably these extra-framework aluminium atoms are retained in small cavities, so that they are difficult to remove.

Surface acid characterization

Figure 1 presents the curves of differential heats of NH_3 adsorption versus the adsorbed ammonia volume for the samples washed with deionized water, pretreated at 350°C before adsorption at 150°C. When the Si/Al ratio increases to a certain degree the initial differential heat increases. This means that more strong acid sites are formed. This is the case for S-200–S-375, which show initial heat increasing from 170 to 215 kJ

mol^{-1}. But for S-450 the initial differential heat decreases due to the excess dealumination. One should also notice that plain samples exhibited, for a given sample, essentially constant differential heats over a wide range of coverage with ammonia.

For a better appreciation of the acid strength scatter, Fig. 2 shows dn/dQ as a function of Q for the same samples. The vertical and horizontal coordinates stand for the numbers and the strengths of acid sites, respectively. It is found that after treatment at 350°C all samples except S-375 (and evidently S-450) show two peaks between 150 and 210 kJ mol^{-1}.

This behaviour is quite different from that of the parent sample, which has only one peak in the same range (see Fig. 3). Table 2 gives the positions of the two peaks (a) and (b). With increasing Si/Al ratio, the primary peak (a) first shifts to the right and then to the left. For sample S-350 this peak is rather flat. The second peak (b) always moves to the right with increasing Si/Al ratio. Referring to another study in ir spectroscopy, of the adsorption/desorption of pyridine onto the same samples (to

	Sample			
	SH-200	SH-300	SH-350	Parent zeolite
Si/Al (nmr)	5.72	7.25	9.02	2.43
Peak (a) position (kJ mol^{-1})	160	158	160	—
Peak (b) position (kJ mol^{-1})	—	188	—	176

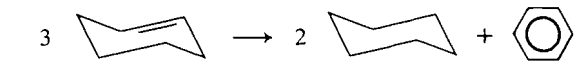
be published), it is suggested that the primary peak and the secondary peak should be attributed to 3640 cm^{-1} and 3540 cm^{-1} hydroxyl stretch modes, respectively.

Samples that have been acid leached (Fig. 4) show an additional feature in the histogram: the initial heats of NH_3 adsorption are essentially higher than usual for Brönsted-type acidity. Samples SH-200–SH-300 show initial heat between 220 and 240 kJ mol^{-1}. Moreover, the differential heats for a given sample decrease steadily until the value of the plateau characteristic of the unleached analogue is reached. It again seems reasonable to ascribe this behaviour to the presence of a pure zeolitic phase coexisting with an extra-framework aluminium phase having Lewis-type acidity characteristics. The corresponding acidity spectra of these acid-leached samples are given in Fig. 5 and the energy of the observed peaks is given in Table 3.

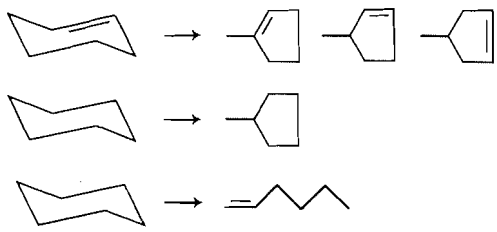
Catalytic reaction

The catalytic activity of samples was determined with respect to the cyclohexene transformation at 250°C. Under these conditions the cyclohexene reacts as follows:

Hydrogen transfer reaction:



Isomerization:



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/07/12
For personal use only.

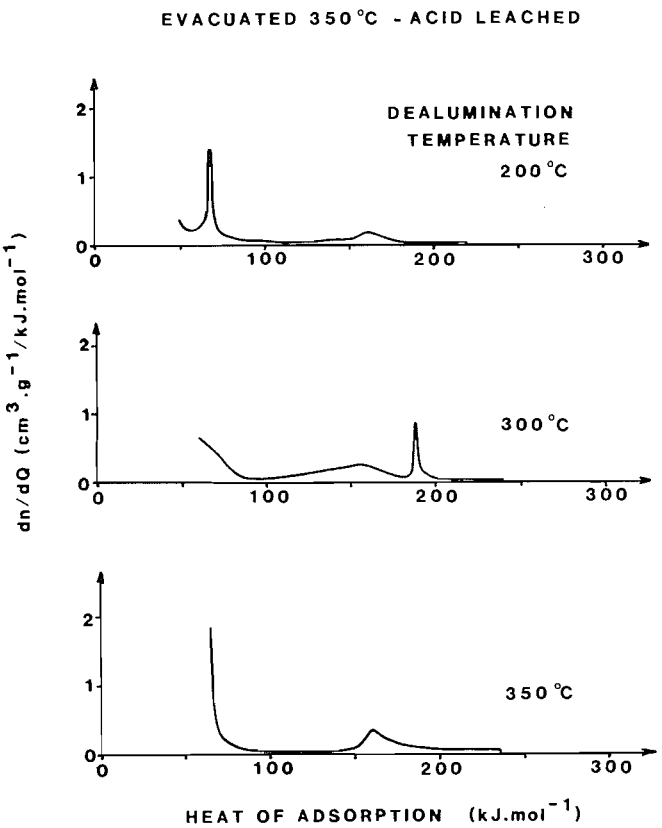


FIG. 5. Acidity spectra of dealuminated and acid leached H-Y samples.

All the compounds mentioned above are found in the product stream. From the reaction mechanism we can distinguish between intramolecular hydrogen transfer and intermolecular hydrogen transfer. Cyclohexane is considered as the product from intermolecular reaction and methylcyclopentene as that from intramolecular reaction. Methylcyclopentane and hexene can result from both intermolecular and intramolecular reaction. Table 4 shows the variation of selectivity at a conversion level of 23% for samples with different lattice aluminium content. The selectivity of the intermolecular reaction decreases and the selectivity of intramolecular reaction increases with decrease of lattice aluminium because the lower acid site density favors the intramolecular reaction.

Conclusions

1. Dealumination by $SiCl_4$ at moderate temperatures produces Y-zeolite having increased Si/Al ratio with good crystallinity and without having significant extra-framework aluminium.

2. The zeolite is always sensitive to acid. Acid leaching will probably remove framework aluminium.

3. Catalytic reaction of cyclohexene shows that the selectivity of both intermolecular and intramolecular hydrogen transfer reactions depends on the composition of the samples.

4. During dealumination, the type, number, and acidity of the OH groups varies. The total acidity for a certain zeolite depends on the nature, the strength, and the number of the acid sites. There is a maximum value of total acidity; microcalorimetric measurements show that it occurs at a Si/Al ratio of about 7 (sample S-300).

Molecular dynamics simulation of the phase transition in adamantane

A. S. TREW AND G. S. PAWLEY
Department of Physics, University of Edinburgh, King's Buildings, Edinburgh EH9 3JZ, U.K.

Received November 2, 1987

This paper is dedicated to Professor J. A. Morrison

A. S. TREW and G. S. PAWLEY. Can. J. Chem. **66**, 1018 (1988).

Phase changes in adamantane have been studied by MD simulation on the DAP computers, using a zero-pressure technique to simulate clusters of 128 and 256 molecules where each member interacts with all others via the rigid molecule model and the 6-exp atom–atom potential. The form of the potential has been modified to permit the use of the 16 hydrogen sites only, giving a 65% saving in the calculation times. This model is shown to give lattice dynamics of adamantane closely similar to results with potentials which are generally accepted.

Using this potential the system equilibrates into the correct low temperature phase ($P\bar{4}2_1c$) and on heating, a transition is observed at 210 ± 10 K to an $Fm3m$ phase where the molecules lie preferentially in the T_d orientations, as expected. Further heating beyond 240 ± 15 K removes all apparent orientational order, though the underlying lattice is still fcc. On recooling the cluster from 300 to 100 K the orientational distribution function developed a significant degree of order as determined through the calculation of a correlation function designed to show any local order. This order is consistent with the lowest phase structure, but would in itself be insufficient to suggest a particular crystal structure.

A. S. TREW et G. S. PAWLEY. Can. J. Chem. **66**, 1018 (1988).

Dans le but d'étudier les changements de phase de l'adamantane, on a fait appel à une simulation MD sur des ordinateurs DAP et on a utiliser une technique à pression zéro pour simuler des agrégats de 128 et 256 molécules dans lesquels chaque membre interagit avec tous les autres par le biais d'une molécule modèle et par le potentiel atome–atome au 6-exp. On a modifié la forme du potentiel pour permettre l'utilisation de seulement 16 sites d'hydrogène et on a ainsi sauvé 65% du temps de calcul. On démontre que ce modèle fournit des dynamiques du réseau de l'adamantane qui sont très semblables aux résultats obtenus avec des potentiels qui sont généralement acceptés.

Lorsqu'on utilise ce potentiel, le système s'équilibre et, à basse température, il atteint la bonne phase ($P\bar{4}2_1c$) par chauffage, on observe une transition à 210 ± 10 K qui conduit à une phase $Fm3m$ dans laquelle les molécules se trouvent préférentiellement, tel qu'attendu, dans les orientations T_d. Si on continue le chauffage au-delà de 240 ± 15 K, tout ordre apparent d'orientation est éliminé même si le réseau sous-jacent est encore fcc. En refroidissant l'agrégat de 300 à 100 K, la fonction de distribution de l'orientation présente un degré important d'ordre qui a été déterminé par le biais de calculs de la fonction de corrélation développée pour mettre en évidence l'ordre local. Cet ordre est en accord avec la structure de la phase la plus basse; toutefois, cet ordre serait insuffisant pour suggérer une structure cristalline particulière.

Introduction

There has been considerable interest for some time in the study of plastic crystals and their phase changes. Experimental measurements of deuterated adamantane using neutron coherent inelastic scattering when compared with model lattice dynamics calculations (1) suggested that simple atom–atom potentials would be appropriate for modelling. The use of these potential functions for molecular dynamics (MD) was then suggested as the obvious way to model the plastic phase. The computing power available at the time of these experiments was not sufficient for a serious attempt at a MD simulation, but now that very cost-effective computation can be done with parallel computers the problem becomes viable. In this paper we present the results of a MD investigation of the phase transition of adamantane in its deuterated form ($C_{10}D_{16}$) using the ICL Distributed Array Processor (DAP) (2).

A somewhat simpler problem was chosen to test the MD method for the modelling of plastic to crystalline phase transitions before embarking on adamantane. SF_6 was chosen because of its smaller size, and a simulation of a sample of 4096 molecules was done on the DAP. It was obvious at the outset that the conditions required of such phase transition studies included the control of the pressure of the system. A zero pressure simulation soon yielded a transition to a crystalline phase (3) which has now been shown to be found in nature (4). Another necessary condition for a physically acceptable simulation is that the behaviour of the sample should not be determined by the boundary conditions, whatever these conditions may be. For SF_6 these were cyclic conditions, and there was clearly no finite-size artefact as the crystal phase developed as a mass of crystallites. A similar study of the phase transition in *n*-butane (5) using the stress-free algorithm of Parrinello and Rahman (6) and recent unpublished work on adamantane both failed to give lower crystal phases, and another method is now sought to avoid any sample constraints resulting from cyclic conditions.

Adamantane, or tricyclo-(3,3,1,1)-decane is one of the best known of plastic crystals. It has been extensively studied experimentally (1, 7) and computationally (1, 8). It is a globular molecule displaying tetrahedral symmetry T_d consisting of an octahedron formed by six methylene groups from which four methine groups extend. X-Ray diffraction studies (9, 10) show that at low temperatures the crystal has a $P\bar{4}2_1c$ space group with $a = b = 6.60$ A, $c = 8.81$ Å, while above 208.6 K it transforms to a plastic phase with space group $Fm3m$, $a = 9.45$ Å. In the low temperature phase the molecules are oriented at an angle of 9° relative to the *a* or *b* axes (9) while in the plastic phase they are randomly distributed between the two T_d orientations (10). This is a rotationally frustrated state and so individual molecules will alternate dynamically between the two orientations. In addition, an ordered structure with space group $F43m$ has been reported at room temperature (11) but this is somewhat controversial and is thought to be due to the unusual annealing conditions for the crystals studied (10). The triple point of adamantane is 543 K but it sublimes easily even at room temperature as we find with our simulations.

We have chosen to perform MD calculations on a free cluster

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 176.9.209.113 on 09/07/12
For personal use only.

in order to remove as much as possible the constrictions of boundaries. The simulation is therefore stress-free; the gain in avoiding self-image boundary condition artefacts is off-set to some extent by having a large fraction of the sample molecules involved with the cluster surface. Nevertheless we expect that our experience with SF_6 clusters containing similar numbers of molecules will be reflected in the adamantane simulations (12). For a sample of 128 SF_6 molecules a phase change was clearly observed on cooling, this transition being exactly as observed in the cyclic boundary 4096 molecule simulation and was achieved in a fraction of the computer time. Diffraction patterns from larger cluster simulations of SF_6 have been compared with electron diffraction results using similar sized clusters, and give excellent agreement (13). These results lead us to conclude that there is a good proportion of molecules in orientations as found in the bulk, and that cluster simulations are well suited to the search for the solid state phase transitions we wish to study.

Earlier experiments had failed to find non-crystallographic structures from this molecular system (14), in contrast to the results from atomic clusters (15). Simulations have been done in search of icosahedral structures in very small molecular (16, 17) and atomic (16, 18) systems, on 2-dimensional (19) and 3-dimensional (20) atomic liquid clusters, and on water (21) using the model of Stillinger and Rahman (22).

Thus although the simulation of clusters is now new, their use in the search for bulk properties in the solid has been neglected. Although the quantity of bulk material is reduced in free clusters, the method gives the possibility of studying other phenomena. Surface effects are an obvious area of study, but any defect in the bulk can now be studied, from vacancies and interstitials to twinning and grain boundaries. The technique is surprisingly efficient on the DAP. Nevertheless, it is a computationally intensive method for very large systems when all possible interactions are calculated, and this usually limits the size of the cluster to a few hundred molecules. Algorithms giving more efficiency for the very large systems will require more computer storage than is currently readily available; storage will certainly increase in future machines and the method will become more generally feasible.

The simulations

The calculations were performed on the two ICL DAPs at Edinburgh University. These machines are SIMD arrays of 64 × 64 interconnected processing elements and are very well suited to problems which involve the calculation of many-body interactions. The present problem runs with about 90% efficiency. The DAP has a speed of 20 Mflops but as such figures are always misleading we prefer to state that in this type of work the DAP is roughly 30% more powerful than a Cray-1 running an appropriate algorithm (D. Tildesley, private communication).

To form the cluster, a spherical sample of molecules is created in the required initial crystalline state. Molecules are given translational and orientational order but with random linear and angular velocities obeying a gaussian distribution for the prescribed temperature. The interaction between each pair of atoms belonging to different molecules is then calculated and hence the resultant forces and torques on each molecule. These may then be used to predict the next configuration. Time integration is accomplished by use of the Beeman algorithm (23). This method is well known and extensively used and gives good energy stability in our calculations, provided that the time-step chosen is not too large. For all of this work, except immediately after initialisation of a new cluster, we have used a time-step of 0.015 ps. The systematic energy fluctuation is then typically at most 1 part in 10^6 per time-step. This is close to the precision expected from arithmetic round-off in performing the calculations.

Restrictions on the amount of computer time available effectively determine the number of molecules in the system. Clusters with 128 adamantane molecules were chosen as the largest practicable for general investigations on the ICL DAP. However, we have also performed a number of simulations with 256 molecules and find that there is no qualitative difference in the results from these and the smaller systems. This is in agreement with previous investigations of SF_6 (12) by the cluster method which showed that the phases and transitions produced were independent of the number of molecules but that transition temperatures increased with cluster size.

A brief description of how the DAP is used to perform these calculations will help in understanding the applicability of SIMD computers to these problems. For our 128 molecule problem let us think of the molecule information arranged as 128 component vectors both along and top and down the side of a 128 × 128 matrix. The components of this matrix can be used to contain the interaction between the row and column molecules, and the total force and torque on a particular molecule can then be found by summing the interactions by rows (or indeed by columns). Row summation is particularly easy on the DAP, as also is the row and column broadcasting needed before calculating the interactions at the various matrix elements. The matrix elements are the processing elements (PEs) of the DAP, and as the DAP has only 64 × 64 PEs (32 × 32 in the AMT DAP 510), the mapping just described has to be done in stages, but this gives us the opportunity of avoiding most of the double calculation implicit in the description above. In fact it is easy to avoid all double calculation except for the case where the number of molecules is N for a $N \times N$ DAP. For other mapping strategies the reader is referred to a paper devoted to SIMD mapping (24).

Let us now return to the adamantane simulations. As with previous investigations (1, 8) we assume a rigid molecule interacting via the 6-exp pairwise additive potential

$$[1] \quad V(i,j) = -A_{ab} r_{ij}^{-6} + B_{ab} \exp(-C_{ab} r^{ij})$$

where a and b indicate the species of the atoms at sites i and j, and r_{ij} is the distance between two atoms belonging to different molecules. Several studies have been undertaken to measure the A, B, and C parameters for the H—H, C—H, and C—C interactions, most notably by Williams (25) and Kitaigorodskii (26), both of which give similar lattice dynamics (cf. Figs. 1 and 2). In these calculations the deuterated form of the molecule is used but the standard H—H potential is assumed for D—D. Because of the large amount of computation necessary for a complex molecule such as adamantane we have derived a modified H—H potential which when used on its own for adamantane gives the lattice dynamics of Fig. 3. The corresponding modes are easily identified, and the frequencies for the "reduced" potential are nicely bracketed by those of Williams and Kitaigorodskii. The rationale behind the simplification of the potential is that the molecule trajectories are principally determined by the interactions between the deuteriums, and the interactions involving the carbon atoms, being somewhat screened by the deuteriums, do not contribute significantly to the motion. The immediate consequence of this modification is that it permits the use of a "reduced molecule" of 16 atoms thus diminishing the amount of computation by a factor of $(26/16)^2$. The smaller cluster there-

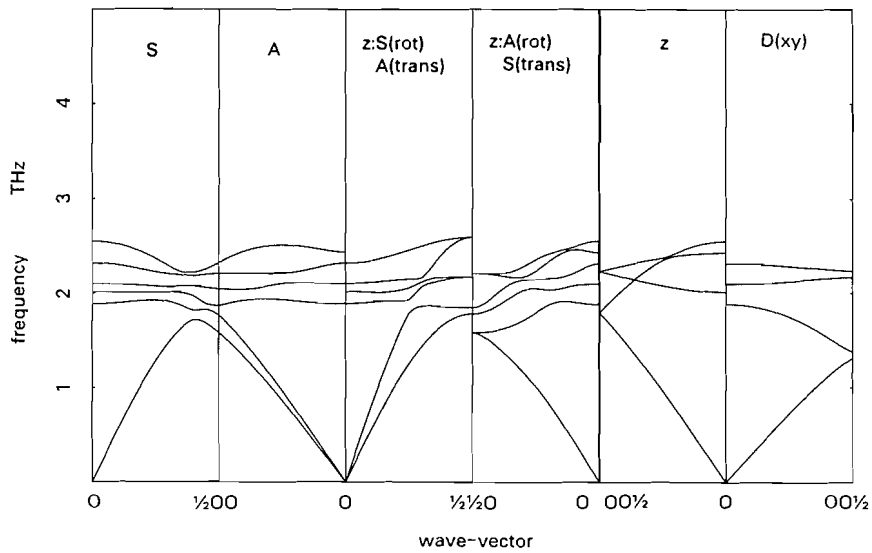

FIG. 1. Lattice dynamics calculations for the $P\bar{4}_1c$ phase of deuterated adamantane using the Williams (24) potential. The first four sections show the modes with wave-vectors in the ***a*–*b*** plane, the last two sections show modes with wave-vectors along the ***c*** axis. For (ξ00) modes S and A mean, respectively, symmetric and antisymmetric with respect to the diad axis perpendicular to ***c***. The representations for the (ξξ0) modes are distinguished by the *z* rotational and translational eigenvector components; when the former are symmetric, *S*(rot), then the latter are antisymmetric, *A*(*trans*), and vice versa. At (1/2, 1/2, 0) there are two representations, both doubly degenerate, in which *z* rotation and translation only occur in the two branches which are continuous over this boundary. For (00ξ), *z* denotes modes with eigenvectors along the ***c*** axis, *D*(*xy*) means a double degeneracy with eigenvectors in the ***a*–*b*** plane.

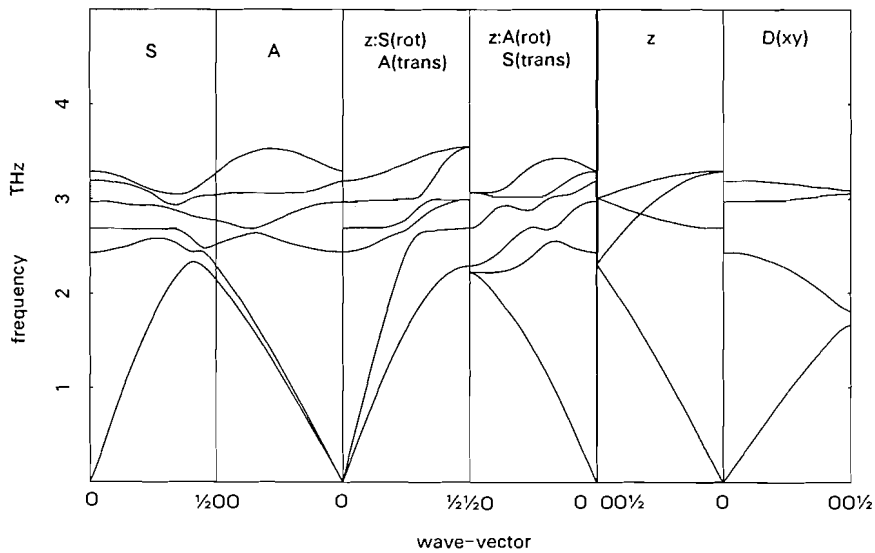

FIG 2. Lattice dynamics calculations for the $P\bar{4}_1c$ phase of deuterated adamantane using the Kitaigorodskii (25) potential. The representations correspond to Fig. 1.

fore necessitates the calculation of $16^2 \times 128^2/2$ (about 2.2 million) forces per time-step and takes approximately 7 s on the DAP.

The modified potential has parameters $A_{HH} = 128.25$ kcal mol^{-1} Å^{-6}; $B_{HH} = 94500.0$ kcal mol^{-1}; $C_{HH} = 4.86$ Å^{-1}.

On initialisation, or after a temperature change, it is necessary to let the cluster equilibrate. This is done in effect by placing the system in a heat bath at the desired temperature and allowing it to gain or lose energy as necessary for temperature equalisation. This is achieved by the usual velocity/angular-velocity scaling. Given that the system may have to undergo a phase change, equilibration is deemed to have occurred when the potential energy stabilises. This usually takes from 5 to 10 ps, i.e. 1 250 to 2 500 time-steps.

Analysis

We have used two basic techniques for analysing the clusters, an orientational and a structural analysis. These have been the working tools for understanding the simulations, and demonstrate the importance of graphics beyond that of result presentation.

(i) Orientational analysis

As the molecules have T_d symmetry it is possible to project four vectors from the centre of the molecule through the tetrahedral vertices and onto the surface of a sphere, marking the points of intersection by a dot. Groups of molecules with similar orientations will then produce clustering of dots on the sphere. In fact because of the symmetry of the structures found, all

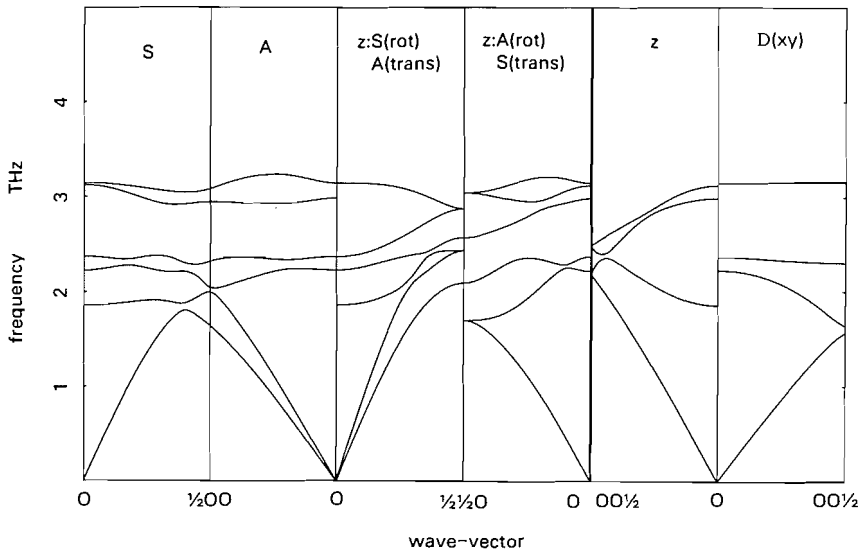

FIG. 3. Lattice dynamics for the $P\bar{4}_1c$ phase of the reduced molecule using the modified H—H potential. The representations correspond to Fig. 1.

necessary information is contained within one hemisphere and we can thus confine attention to this. On average each molecule will give two dots, though producing one or three is also possible. For representation in two dimensions the distance from the pole to each dot on the hemisphere is calculated and used as the radius for that dot on a plane, positioned at the same azimuthal angle. This gives an "equal-area" presentation, so that the density of dots on the plot corresponds exactly to the solid angle density of the orientational distribution function.

(ii) Structural analysis

Although the dot-plots give a good overall impression of the orientational state of the molecules in the cluster they contain no information about the translational structure. While powder diffraction patterns could be produced to investigate this, the calculations are computationally intensive and the small size of our cluster (radius ~20 Å) means that any features in the Fourier transform are rather broad. It is consequently difficult to measure lattice spacings accurately, and we therefore use the molecule radial distribution function both to derive lattice spacings and to show any translational order. This works well, giving a typical peak of about 0.2 Å full width at half maximum, and we are thus confident of the derived lattice spacings to about 0.1 Å.

Results

The $P\bar{4}2_1c$ to $Fm3m$ phase transition involves a change in the definition of the ***a*** and ***b*** lattice vectors by a 45° rotation about ***c***. In order to avoid confusion about the directions of ***a*** and ***b*** we prefer to fix these parallel to those in the cubic system. This has the effect of increasing the quoted tetragonal lattice parameters by a factor of $\sqrt{2}$ (6.60 → 9.33 Å). However, this convention has an added bonus later when we attempt to determine the direction of the local ***c*** axis.

Starting with an initial configuration at 100 K in the observed low-temperature phase, both the 128 and 256 molecule clusters equilibrated into the $P\bar{4}2_1c$ state within 5–10 ps but with a unit cell $a = b = 9.6$ Å, $c = 9.1$ A. This is approximately 3% larger than determined by X-ray diffraction studies of real crystals (9) — a discrepancy which is significant at the 1σ level. However, lattice statics investigations of the low temperature phase using the modified potential also show a similar increase in the crystallographic cell. We are therefore confident that this is not a consequence of the free-boundary condition technique used, or the small size of the sample. Figure 4 shows the dot plot representations and radial distribution functions of the cluster in the tetragonal phase after equilibration at 100 K. Examination of the orientational dot plot shows that the 9° orientation of the molecules relative to the tetragonal axes is reduced to 4 ± 1°. This may be correlated with the slight increase in cell size.

On heating to 220 K it was found that a phase change took place, as evident from Fig. 5. The new lattice has an fcc structure with $a = 9.9$ Å. This is a 6% increase on the experimental value, and the dot plot shows that the molecules have lost their orientation with respect to the tetragonal ***a, b*** axes. The molecules are therefore adopting the expected tetrahedral orientations. Inspection of individual molecules shows jumps between the two T_d orientations, but because of lack of computer time the statistics of reorientations are poor. We are, however, confident that both the observed low and high temperature phases have been simulated.

Determination of transition temperatures in these simulations is difficult to achieve precisely. One method for improving the accuracy is to overlay dot plots generated by the addition of configurations for different times at the same temperature. Unfortunately, calculation of sufficient data requires prohibitive amounts of computer time. Our best estimate of the transition temperature is 210 ± 10 K. It is not clear, given the uncertainty in this value and the interpretation difficulties on cooling, to determine whether there is hysteresis present on cooling.

Further heating of the fcc phase beyond 240 ± 15 K gave a second change. Although the new structure maintained its fcc lattice with the same lattice parameter the molecular orientations became disordered, c.f. Fig. 6. The increased random component in the radial distribution function is due to surface relaxation.

Recooling this phase to 100 K produced a structure with the same fcc lattice, $a = 9.9$ Å, but with a non-random orientational distribution — c.f. Fig. 7. A possible explanation is that the cluster has undergone the phase change back to the low temperature phase but is no longer a single crystal, rather a collection of crystallites distinguishable by the direction of their c axes.

In order to investigate any short range order in the ***c***-axis direction we consider each molecule site in turn and calculate the local lattice parameters by measuring the centre-to-centre distances to the next molecule along the cubic cell directions. Since the ***c*** axis is the shortest of the three axes for the tetragonal phase (in the cubic axial system) we may identify the smallest measured distance as defining the local ***c***-axis direction, provided that it is less than some limit, c_{max}, and that the data for the site are complete (i.e. all three local cell parameters can be found). Comparison of the state (***c***-axis direction) of a site with that of its nearest neighbours, next nearest neighbours etc. can then be used to form correlation functions on a variety of length scales.

It is simple to predict the expected number of agreements between sites on the basis of a random distribution of states. Let us suppose that we have a number of sites, some fraction, f, of which are assigned a state drawn randomly from k posssible states; in our case $k = 3$. If N comparisons are made, then, taking care not to double count, the expected number of agreements is

$$[2] \quad L = Nf^2/k$$

and hence the correlation function has a mean value, w, which is simply

$$[3] \quad w = L/N = f^2/k$$

with a standard deviation given by the binomial distribution of

$$[4] \quad \sigma = \{f^2(1 - f^2/k\}^{1/2}$$

A value of unity for the correlation function can occur only for a bulk sample because f is reduced by the virtue of the cluster surface. Figure 8 shows the observed correlation functions for the nearest and next nearest neighbours respectively. The curves are for configurations at 100 K (before heating, upper curve), 300 and 100 K (after cooling) together with those expected from random crystallite orientations, denoted r 300 K and r 100 K for the 300 K and 100 K (after cooling) configurations, respectively. These random curves are calculated from eq. [3] using the value of f determined for that particular cluster and value of

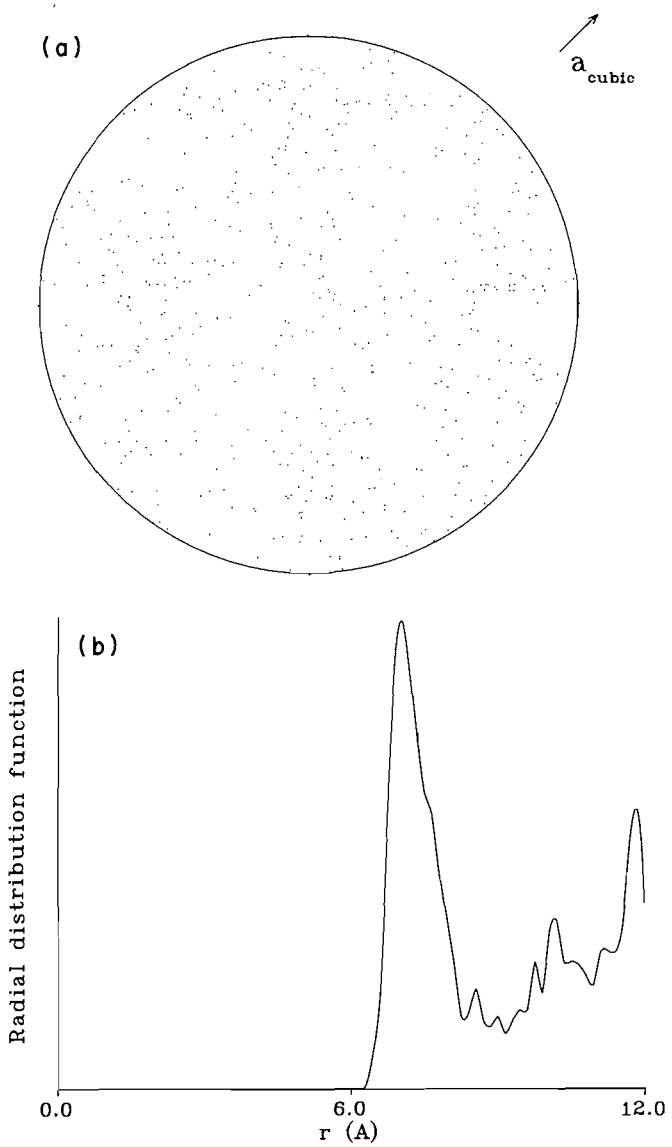

FIG. 6. (*a*) Dot plot of the plastic phase after heating to 300 K for the 256 molecule cluster. (*b*) Radial distribution function for the 256 molecule cluster at 300 K.

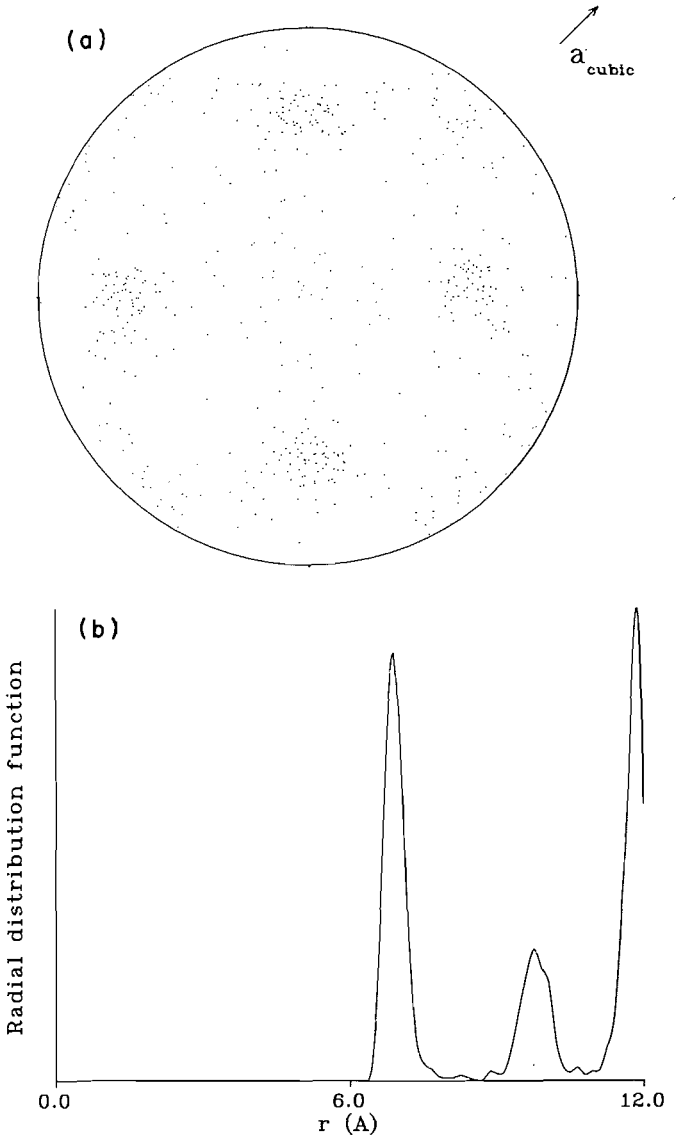

FIG. 7. (*a*) Dot plot of the $P\bar{4}_1c$ phase after cooling to 100 K from 300 K for the 256 molecule cluster. (*b*) Radial distribution function for the 256 molecule cluster cooled to 100 K.

c_{max}. Differences between random curves therefore reflect variations in the fraction of sites which are assigned *a* state. Both diagrams display the same general features. The error bars are $\pm\sigma$; those on the observed curves are calculated from observed temporal fluctuations, while those on the random curves are a combination of these errors with those calculated from eq. [4].

Examination of these figures shows the high degree of order in the structure before heating. Also clear are the relative displacements along the abscissa of the correlation functions after heating to those before heating. This is caused by the lattice expansion already noted.

A comparison of the correlation functions at 300 K with the random curves shows that the simulation curves remain above the levels expected, although this is not statistically significant at the 2σ ($P < 5\%$) level. This may be indicative of some slight local correlation but a direct search for crystallites in the fcc structure proved unsuccessful. On cooling, the level of correlation rises to become statistically significant at the 2σ level and a number of possible "crystallites" can be identified in the larger cluster, though these are small and contain only a few molecules each. While the correlation functions have not reproduced the original degree of order, this would not be expected even from a polycrystalline system when compared with a single crystal, because of the disorder at crystallite boundaries. It may be supposed that these boundaries also contribute to the larger potential energy of the recooled cluster which, at 100 K is 23% more than at the same temperature before heating. Unfortunately, the system is so small that examination of the spatial distribution of the molecule potential energies does not show localised minima corresponding to the crystallites.

Conclusions

A comprehensive MD study has been made of phase changes in adamantane using approximately 100 h of calculation time on the ICL DAPs at the University of Edinburgh. We have employed a H—H potential modified so that when used on its own with deuterated adamantane it gives lattice dynamics similar to those of Williams (25) or Kitaigorodskii (26) in both high and low temperature phases. This enables the use of a reduced molecule of 16 atoms with a consequent reduction in the necessary calculation by 65%.

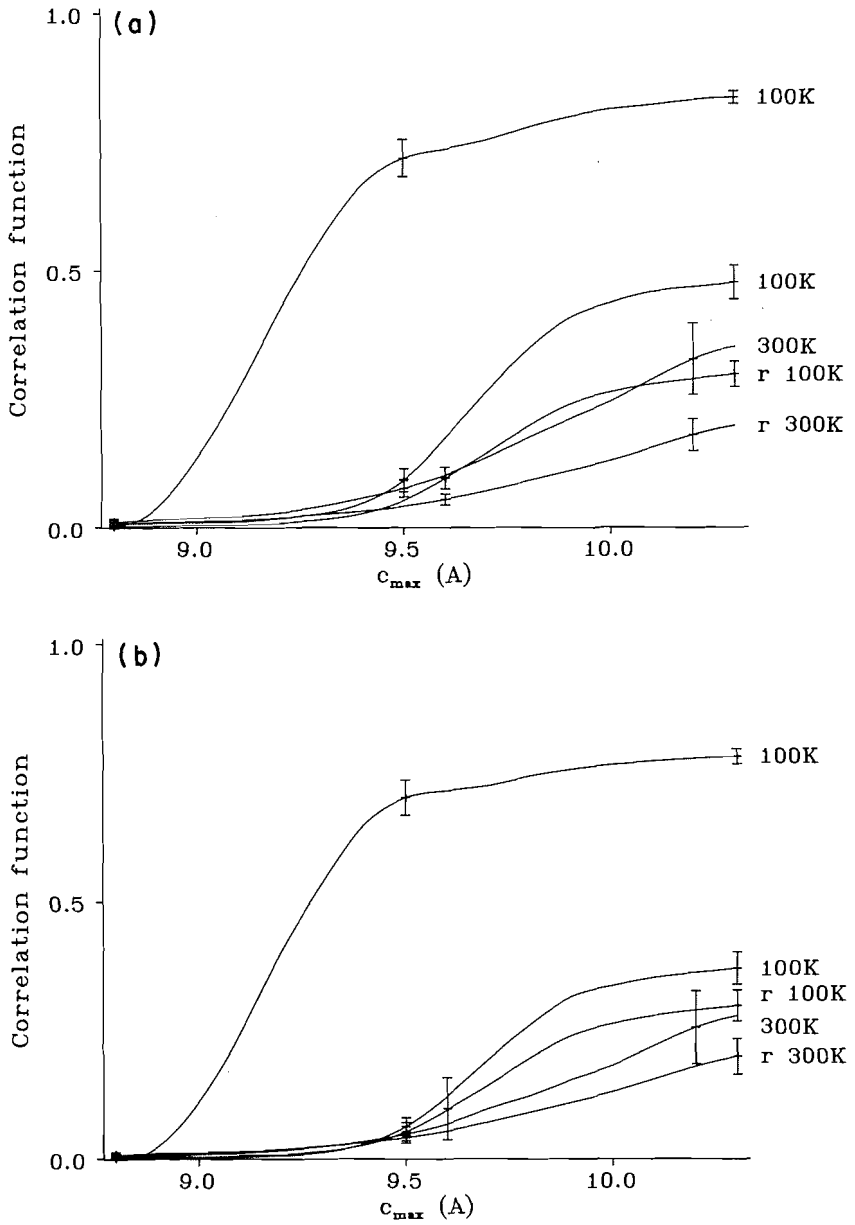

FIG. 8. (*a*) Correlation functions for the nearest neighbours plotted as a function of the minimum acceptable value of c, c_{max}. (*b*) Correlation functions for the next nearest neighbours plotted as a function of c_{max}.

Using this potential we observe the system to equilibrate into the correct low temperature phase ($P\bar{4}2_1c$) with lattice parameters only slightly larger than expected from lattice dynamics. This non-trivial achievement demonstrates that the modified potential and the reduced rigid molecule give a good model.

On heating the system a phase transition is observed at 210 ± 10 K (experimental value 208.6 K) to a rotationally frustrated phase on a fcc lattice. Further heating removed the orientational order though the translational structure was preserved until sublimation took place.

Recooling the cluster to 100 K gave regions which could be identified as a collection of crystallites rather than a single crystal. This is not surprising since the cubic phase is not uniaxial and therefore there are three possible directions for the new local *c*-axis. We suppose that given sufficient time for annealing at an optimum temperature, or equivalently a very much slower cooling rate through the transition, larger crystallites could have been formed. Unfortunately, this would require much more computer time than is currently practicable, though with the rapid improvements in computer technology will soon render such simulations feasible.

Future work will involve the search for local transient ordering in the plastic phase and a study of reorientations in both the rotationally frustrated and orientionally disordered structures. Furthermore it is hoped that future simulations will help in the interpretation of the inelastic neutron scattering experiments which initiated this work (1, 7).

BODHAN SKALSKI, GRAZYNA WENSKA, STEFAN PASZYC, and ZDZISLAW STEFANIAK. Can. J. Chem. **66**, 1027 (1988).

The intramolecular photocycloaddition of cytosine (Cyt) to 5-methoxyuracil (mo^5U) in Cyt-$(CH_2)_3$-mo^5Ura, a dinucleotide model compound, occurs upon irradiation with near ultraviolet light ($\lambda > 300$ nm) with the formation of an unstable cyclobutane dimer. The dimer undergoes spontaneous dark deamination with a rate constant $k = 9.0 \times 10^{-5}\ s^{-1}$ and $t_{1/2} = 128$ min, to give a related uracil derivative.

BODHAN SKALSKI, GRAZYNA WENSKA, STEFAN PASZYC et ZDZISLAW STEFANIAK. Can. J. Chem. **66**, 1027 (1988).

La photocycloaddition intramoléculaire de la cytosine (Cyt) sur le méthoxy-5 uracile (mo^5U) conduisant à la Cyt-$(CH_2)_3$-mo^5Ura, un composé modèle des dinucléotides, se produit par irradiation avec de la lumière pratiquement ultraviolet ($\lambda > 300$ nm) et avec la formation d'un cyclobutane dimère instable. Le dimère subit une désamination spontanée à l'abri de la lumière; la constante de vitesse $k = 9{,}0 \times 10^{-5}\ s^{-1}$, $t_{1/2} = 128$ min et la réaction conduit à un dérivé uracile apparenté.

[Traduit par la revue]

Introduction

It has been found recently that complexes of certain tRNAs with *Escherichia coli* or yeast ribosomes could be cross-linked upon irradiation with near uv light ($\lambda > 300$ nm) (1–5). This cross-linking results in covalent bond formation between the tRNA 5′-anticodon base 5-methoxy or (5-carboxymethoxy) uracil and cytosine-1400 of the rRNA (5). Based on the photoreversal of the cross-link by 254-nm light, the cyclobutane-type dimer was proposed as the structure of the photoproduct (2).

Since the available information on the photocycloaddition of cytosine to uracils, and on the stability of the resulting photodimers, is still limited (6), we decided to investigate this reaction using a model compound in which cytosine and 5-methoxyuracil are connected by a trimethylene chain.

Results and discussion

The Cyt-$(CH_2)_3$-mo^5Ura **6** was synthesized by a multistep synthesis (Scheme 1) in which the triazole derivative **5** was a key intermediate. In the first step the 1-(3-bromopropyl)uracil **1** (7) was transformed into pyridinium salt **2** by reacting with 4-chlorophenylphosphorodichloridate ($4ClPhOPOCl_2$) in the presence of pyridine (8). The synthetic procedure, identical to that applied previously for synthesis of other nucleobase-derived pyridinium salts (8, 9), led to the concentrated aqueous solution of pure **2**. The presence of a pyridinium cation in **2** was confirmed by ^1H nmr spectroscopy (see Experimental). Treatment of the aqueous solution of **2** with 1,2,4-triazole (3 equiv.), at room temperature for 48 h, gave crystalline 1-(3-chloropropyl)-4-(1,2,4-triazol-1-yl)uracil **3** in which the bromine of the bromopropyl chain was quantitatively replaced by chlorine, as revealed by ms analysis of the product. As we found, this replacement takes place during the phosphorylation reaction of **1** and does not occur when reaction is carried out in the presence of an excess (6 equiv.) of pyridine hydrobromide. In the next step the triazole derivative **3** was reacted with 5-methoxyuracil (10) in dry dimethylformamide in the presence of anhydrous K_2CO_3, to give a mixture of three products. The desired product, 1-[3-(5-methoxyurac-1-yl)propyl]-4-(1,2,4-triazol-1-yl)uracil **5**, was isolated by means of preparative tlc with a 30% yield.

The 4-(azol-1-yl) derivatives of uracils can be transformed into the related cytosine derivatives, or reversed to the parent heteroaromatic bases, depending upon the conditions applied (11). Thus, the triazole derivative **5** was converted into both Cyt-$(CH_2)_3$-mo^5Ura **6** by treatment with aqueous ammonia and into Ura-$(CH_2)_3$-mo^5Ura **7** using mild alkaline hydrolysis.

In the proton-coupled ^{13}C nmr spectrum of **7** the C(6) carbon of the 5-methoxyuracil residue (δ_C 126.9 ppm) is coupled with the protons of the trimethylene chain ($^3J_{C(6),H} = 3.6 \pm 06$, $^1J_{C(6),H} = 180.6 \pm 0.6$ Hz), indicating that in **7** and thus in its precursor **5** the mo^5Ura is alkylated at position N(1).

Irradiation of a deoxygenated, aqueous solution of **6** ($c = 1.3 \times 10^{-4}$), at room temperature with near uv light ($\lambda > 300$ nm), resulted in the loss of uv absorption at $\lambda = 270$ nm, characteristic of the 5,6 double bond in pyrimidine residues (Fig. 1). Simultaneous tlc and hplc analyses of the irradiated solution revealed the presence of only one photoproduct (74% conversion). This product appeared to be reversible to the parent compound **6** upon irradiation with short wavelength uv light ($\lambda = 254$ nm) (see curve 3 in Fig. 1).

The lack of uv absorption and photoreversal to the starting monomer, characteristic for cyclobutane dimerization of pyrimidine bases (6), pointed to the cyclobutane dimer as the structure of the photoproduct.

Unfortunately, the isolation and direct identification of the photoproduct in the pure state was not possible. The tlc and hplc analyses of the solution, within 6 h after irradiation, showed the gradual decay of the photoproduct with concomitant formation of a new compound. This dark transformation was followed by a further decrease in the uv absorption of the solution (curve 4 in Fig. 1).

Irradiation of the solution in which the dark transformation was completed with $\lambda = 254$ nm light resulted in the appearance of a new absorption band with the maximum blue-shifted ca. 5 nm compared to that for **6** (curve 5 in Fig. 1). A new product, identical chromatographically with the previously synthesized Ura-$(CH_2)_3$-mo^5Ura **7** (see Scheme 1) was detected in the solution.

Based on these observations, the following reaction pathway (Scheme 2) is proposed: **6** undergoes an intramolecular cycloaddition to form the cytosine cyclobutane dimer **8**, followed by the dark deamination process to give the uracil derivative **9**. It must be pointed out that spontaneous deamination is a general property of 5,6 saturated cytosine derivatives (6, 12).

To prove the proposed reaction scheme, the preparative scale irradiation of **6** ($c = 3 \times 10^{-4}$ *M*, 1 L) was performed. The

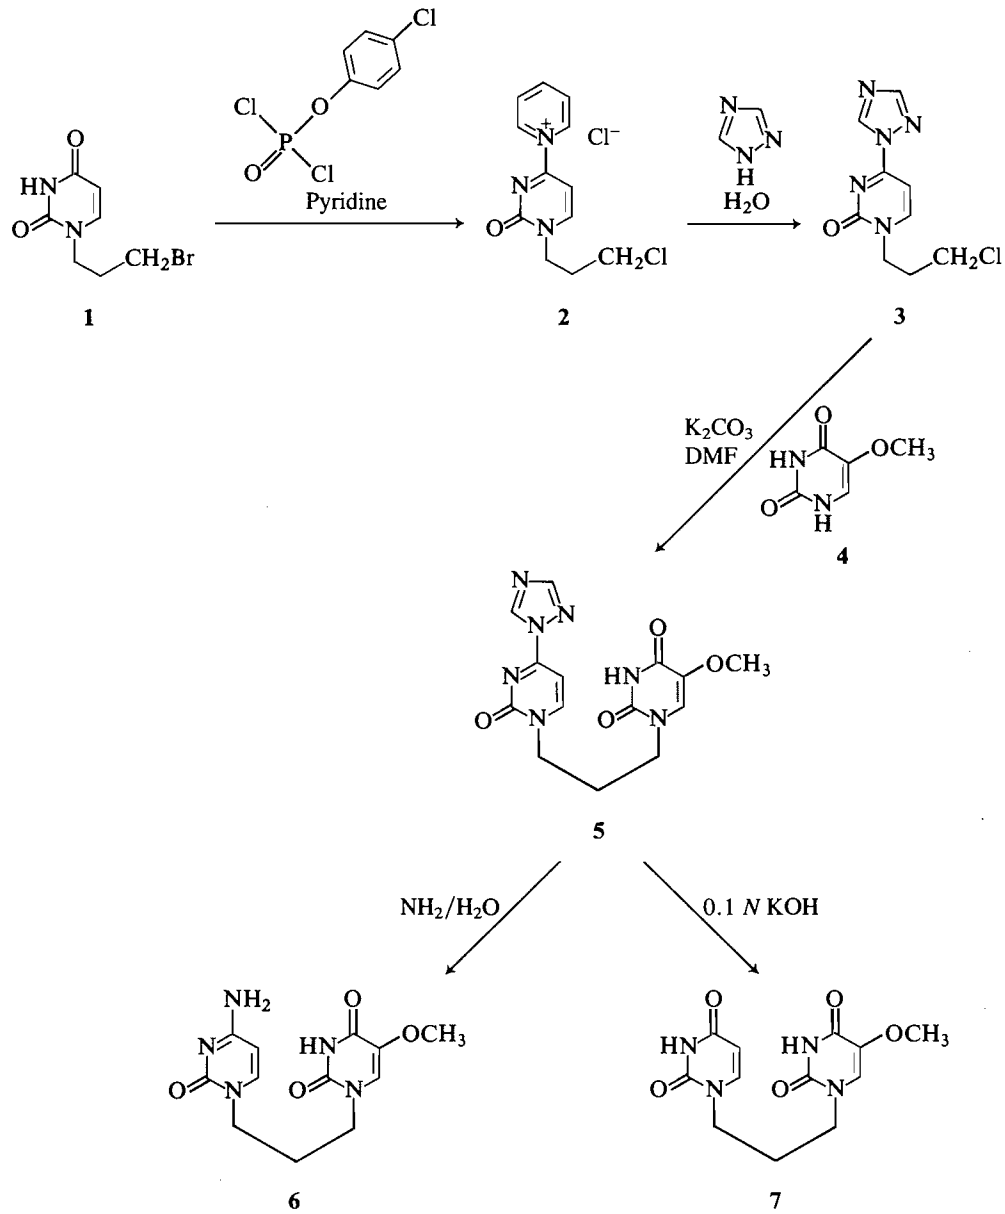

SCHEME 1

transformation product obtained from the primary photoproduct of Scheme 2 was isolated and identified (nmr, ms, uv, elemental analysis) as the Ura-$(CH_2)_3$-mo^{5}Ura cyclobutane dimer **9**. The structure of **9** was also confirmed by splitting the dimer by irradiating with $\lambda = 254$ nm light (see Scheme 2 and Fig. 2) and comparing the resulting monomer with an authentic sample of **7** obtained from **5** (Scheme 1). Analogously, **7** was converted into **9** by irradiation with $\lambda > 300$ nm light.

The dark deamination process **8** → **9** was studied by means of quantitative hplc analysis. It was found that the reaction proceeds according to first-order kinetics (Fig. 3) with a rate constant $k = 9.0 \times 10^{-5}$ s^{-1} and a half-life $t_{1/2} = 128$ min at room temperature.

The results of this work support the proposed mechanism for tRNA and rRNA photo cross-linking in view of possible cyclobutane dimer formation between cytosine and 5-methoxyuracil residues (1–5). It might be surprising that no deamination of the photoproduct was observed in cross-linked tRNA–rRNA complexes except for the very recent report on photo cross-linking of *E. coli* acetylvalyl tRNA and *Artemia salina* ribosomes, in which some conversion of cytosine into uracil was detected (13). However, it must be noted that most of the previous studies (1–5, 13) involved RNAs containing the carboxy analog of mo^{5}U, namely, cmo^{5}U. It is very likely that the nearby negative charge due to the carboxyl group and (or) the steric effects of the environment of the polynucleotide have inhibited the deamination reaction.

Experimental

Spectra were measured on a Carl Zeiss Jena uv–vis spectrophotometer, a JEOL 90 FX Fourier transform nmr instrument, and a JEOL MS-D-100 mass spectrometer. TMS and dioxane were used for δ_H chemical shift measurements. All δ_H values (ppm) are given relative to TMS. Melting points were taken on a Boetius apparatus and are uncorrected. Elemental analyses were made on a Perkin Elmer 240 analyser.

Thin-layer chromatography was performed on precoated silica gel $60F_{254}$ (Merck) plates in the following solvent systems: (a) isopro-

N-*[1-(3-Chloropropyl)pyrimidin-2(1*H*)-one-4-yl)pyridinium chloride, 2*

Dry 1-(3-bromopropyl)uracil **1** (3.5 g, 15 mmol) was dissolved in pyridine (50 mL) and treated with 4-chlorophenylphosphorodichloridate (5.6 mL, 30 mmol). The reaction mixture was left at room temperature for 12 h. The white precipitate containing pyridinium salt **2** and cocrystallizing pyridine hydrochloride was filtered off, washed with pyridine, and dissolved in water (50 mL). The aqueous solution was treated with charcoal, filtered, and neutralized with Dowex 1 resin (HCO_3^-) to pH 6.5. The resin was filtered off, and the solution concentrated under vacuum to one third of the initial volume and tested for the presence of the pyridinium salt by means of uv and ^{1}H nmr spectroscopy: uv (H_2O): 266 and 333 nm (max), 259 and 296 nm (min); δ_H (D_2O): 9.55 (m, $Py^{+\alpha}$-H), 8.89 (m, $Py^{+\gamma}$-H), 8.77 (d, ura 6-H), 8.39 (m, $Py^{+\beta}$-H), 7.37 (d, ura 5-H, J = 5 Hz), 4.30 (t, N-CH_2, J = 4.5 Hz), 3.74 (t, —CH_2Cl), 2.38 (m, —CH_2—).

*1-(3-Chloropropyl)-4-(1,2,4-triazol-1-yl)pyrimidin-2(1*H*)-one, 3*

Obtained as above, the concentrated aqueous solution of **2** was diluted with water to V = 50 mL, treated with 1,2,4-triazole (2.06 g, 30 mmol), and left overnight at room temperature. The reaction mixture was filtered to yield ca. 1.1 g of crude product. The filtrate was extracted with chloroform (3 × 30 mL). The solvent was evaporated and the residue combined with a crude solid and purified by chromatography on a silica gel column ($CHCl_3$/CH_3OH 10:1) to give 1.79 g of pure **3**, 50% yield estimated relative to the 1-(3-bromopropyl)uracil used; mp 171°C; uv (H_2O): 246 nm (12 400), 311 nm (8200): δ_H ($CDCL_3$): 9.24 and 8.12 (2s, triazole 3-H and 5-H), 7.94 (d, Ura 6-H, J = 7 Hz), 7.05 (d, Ura 5-H), 4.18 (t, N-CH_2, J = 6 Hz), 3.61 (t, —CH_2Cl, J = 6 Hz), 2.34 (m, —CH_2—); ms m/e (rel. int.): 239 (18), 204 (69), 190 (13), 177 (100), 176 (9), 163 (6), 162 (4), 149 (16), 148 (11). *Anal.* calcd. for $C_9H_{10}N_5OCl$: C 45.09, H 4.17, N 29.22; found: C 44.98, H 4.14, N 28.81.

*1-[3-(5-Methoxyurac-1-yl)propyl]-4-(1,2,4-triazol-1-yl)pyrimidin-2(1*H*)-one, 5*

5-Methoxyuracil (0.171 g, 5 mmol), 1-(3-chloropropyl)-4-(1,2,4-triazol-1-yl)uracil **3** (1.19 g, 5 mmol), anhydrous K_2CO_3 (1.4 g, 10 mmol), and dimethylformamide (100 mL) were stirred together, with the exclusion of moisture, at room temperature. After 24 h, the reaction mixture was filtered and concentrated to a small volume. The major product (R_f = 0.35 in system b and 0.19 in system c) was isolated by means of preparative tlc and recrystallized from 50% aqueous ethanol to give 0.52 g of **5**. Yield 30%; mp 239–241°C; uv (H_2O) 236 nm (11 600), 247 nm (13 700), 270 nm (8000), 291 nm (10 100); δ_H ($(CD_3)_2SO$): 9.42 (s, triazole 5-H), 8.49 (d, triazoloura 5-H), 8.38 (s, triazole 3-H), 7.36 (s, mo^5Ura 6-H), 6.95 (d, triazoloura 6-H), 3.95 (t, triazoloura N-CH_2), 3.72 (t, mo^5Ura N-CH_2), 3.58 (s, O-CH_3), 2.05 (m, —CH_2—); ms m/e (rel. int.): 345 (2), 204 (25), 203 (100), 190 (3), 177 (21), 176 (7), 169 (3), 167 (5), 164 (3), 149 (8), 148 (12), 135 (3), 126 (2), 121 (4), 112 (3), 110 (4), 109 (4), 108 (6), 96 (7). *Anal.* calcd. for $C_{14}H_{15}N_7O_4$: C 48.69, H 4.35, *N* 28.41; found: C 48.36, H 4.22, N, 28.19.

1-[3(Cytos-1-yl)propyl]-5-methoxyuracil, 6

Compound **5** (0.150 g, 0.43 mmol) was treated with aqueous ammonia (0.5 M, 150 mL) at room temperature. After 6 h the reaction mixture was concentrated under reduced pressure and the residue recrystallized from aqueous ethanol to give 0.11 g of **6**. Yield 87%; mp 283–286°C; uv (H_2O): 277 nm (14 800); δ_H (CF_3COOD): 7.62 (d, Cyt 6-H, J = 8 Hz), 7.06 (s, mo^5Ura 6-H), 6.20 (d, Cyt 5-H, J = 8 Hz), 3.93 (m, Cyt N-CH_2 and mo^5Ura N-CH_2), 3.76 (s, OCH_3), 2.54 (m, —CH_2—); ms m/e (rel. int.); 293 (18), 182 (9), 155 (3), 152 (8), 151 (13), 138 (33), 137 (5), 125 (16), 124 (36), 110 (43). *Anal.* calcd. for $C_{12}H_{15}N_5O_4$: C 49.15, H 5.12, N 23.89; found: C 48.66, H 5.04, N 23.80.

1-[3-(Urac-1-yl)propyl]-5-methoxyuracil, 7

Compound **5** (0.150 g, 0.43 mmol) was treated with a 0.1 M aqueous solution of sodium hydroxide (150 mL) at room temperature. After 6 h, the reaction mixture was neutralized to pH 7.2, concentrated under reduced pressure to ca. 1/3 of the initial volume, and filtered off. The white precipitate was recrystallized from aqueous ethanol (60%) to give 0.108 g of **7**. Yield 85%; mp 278–281°C; uv (H_2O): 272 nm (14 100); δ_H (CF_3COOD): 7.18 (d, Ura 6-H), 6.84 (s, mo^5Ura 6-H), 5.94 (d, Ura 5-H, J = 8 Hz), 3.64 (s and m, mo^5Ura N-CH_2, Ura N-CH_2, and OCH_3), 2.02 (m —CH_2—); δ_C (CF_3COOD): 169.26 (C═O), 154.03 (C═O), 152.35 (C═O), 149.54 (Ura 6-C), 139.24 (C═O), 126.94 (mo^5Ura 6-C), 103.81 (Ura 5-C), 122.55 (mo^5Ura 5-C), 58.62 (O-CH_3), 48.54 (N-CH_2), 29.14 (—CH_2—); ms m/e (rel. int.): 294 (48), 182 (13), 169 (15), 153 (100), 149 (16), 141 (5), 139 (9), 126 (20), 125 (17), 110 (16). *Anal.* calcd. for $C_{12}H_{14}N_4O_5$: C 48.98, H 4.76, N 19.04; found: C 48.32, H 4.37, N 18.68.

Irradiation of 6

The preparative scale photochemical reaction of **6** was carried out in a cylindrical Pyrex glass reactor using an immersed, water-cooled high-pressure mercury lamp TQ 150 (Original Hanau) equipped with a Pyrex cutoff filter (λ > 300 nm).

Compound **6** (90 mg, 0.3 mmol) was dissolved in water (1 L, c = 3 × 10^{-4} M). The solution was deoxygenated prior to the irradiation by purging with nitrogen, and then irradiated portionwise (130 mL) under a continuous flow of nitrogen. The reaction was monitored by taking the uv spectra of the samples of irradiated solution and was continued until no further decrease in absorption at 260 nm occurred (ca. 74% conversion after 30 min of irradiation). The irradiated portions were combined and left for 12 h at room temperature (pH 6.7) to allow for complete dark transformation of the primary photoproduct into compound **9**. Chromatography on silica gel (system b) followed by recrystallization of the isolated product from aqueous ethanol gave 0.054 g of photodimer **9**. Yield 59%; mp 307–312°C; δ_H (CF_3COOD): 4.31 (m, Ura N-CH and mo^5Ura N-CH), 4.05 (m, Ura 5-H, Ura 6-H, and mo^5Ura 6-H), 3.41 (s, OCH_3), 2.66 (m, —CH_2—), 1.98 and 1.47 (2 m, Ura N-CH and mo^5Ura N-CH); ms m/e (rel. int.): 294 (36), 182 (15), 169 (15), 153 (100), 152 (29), 149 (8), 139 (9), 126 (19), 125 (14), 110 (14). *Anal.* calcd. for $C_{12}H_{14}N_4O_5$: C 48.98, H, 4.76, N 19.04; found: C 48.52, H 4.43, N 18.98.

Irradiation of 7

The irradiation of **7** (60 mg, 0.2 mmol in 500 mL of water) and isolation of the photoproduct was performed in the same manner as for **6** (except for dark reaction step) to give 41 mg of the compound identical in all respects with photodimer **9** described above, 68% yield.

L'azote, site basique des amides encombrées ?

GEORGES GUIHENEUF,[1] JOSÉ-LUIS M. ABBOUD[2] ET ABDELJALIL LACHKAR
Laboratoire de chimie physique organique, Université Cadi Ayyad, BP S 15, Marrakech, Maroc

Reçu le 16 avril 1987[3]

GEORGES GUIHENEUF, JOSÉ-LUIS M. ABBOUD et ABDELJALIL LACHKAR. Can. J. Chem. **66**, 1032 (1988).

L'augmentation de la taille des substituants R des amides $R'CONR_2$ entraîne une élévation des constantes de complexation avec la molécule d'iode si R = CH_3. À l'inverse, lorsque R est un groupe alkyle différent de CH_3, les constantes diminuent jusqu'à un seuil critique d'encombrement de R et R'. Au-delà de cette limite les valeurs des constantes augmentent brutalement dans des proportions importantes. Ce comportement s'explique par un changement du site de fixation de l'iode. Alors que généralement le site basique des amides *N,N*-disubstituées est l'atome d'oxygène du carbonyle, les contraintes stériques en diminuant la conjugaison des groupes CO et NR_2 réduisent la basicité de l'oxygène et au-delà d'un seuil critique confèrent à l'atome d'azote un caractère basique proche de celui des amines. Cette interprétation est confirmée par la position de la bande de transfert de charge et par la comparaison avec les constantes de formation des complexes iode–amines et iode – composés carbonylés α-aminés.

GEORGES GUIHENEUF, JOSÉ-LUIS M. ABBOUD, and ABDELJALIL LACHKAR. Can. J. Chem. **66**, 1032 (1988).

If R = CH_3, an increase in the bulk of the R groups of the amides $R'CONR_2$ provokes an increase in the complexation constants with iodine. Conversely, if R is an alkyl group (but not a CH_3), the constants decrease up to a critical size for the bulkiness of R and R'. Above these limits, an abrupt increase of the constants is observed. This behaviour is rationalized in terms of a change in the point of fixation of the iodine. While the basic site of the *N,N*-disubstituted amides is the oxygen of the carbonyl, steric hindrance reduces the conjugation of the CO and NR_2 groups and hence the basicity of the oxygen; above the critical size and due to steric hindrance, the basicity of the nitrogen atom becomes similar to that of amines. This explanation is confirmed by the position of the charge transfer band and by a comparison with the formation constants of the complexes iodine–amines and iodine – α-amino carbonyl compounds.

Introduction

Les pivalamides *N,N*-disubstituées $(CH_3)_3CCONR_2$ sont moins basiques que les acétamides disubstituées CH_3CONR_2 correspondantes (1). Les effets électroniques des groupes méthyle et *tert*-butyle étant équivalents (2), la diminution des constantes d'association avec un acide de Lewis donné ne peut résulter que des contraintes stériques induites par les groupes $(CH_3)_3C$ et NR_2. Nous avons, dans un travail précédent (1), comparé les effets stériques des substituants $N(CH_3)_2$ et $N(C_2H_5)_2$ à l'aide de la différence des enthalpies libres de complexation des amides CH_3CONR_2 et $(CH_3)_3CCONR_2$ avec l'iode. En élargissant la gamme des substituants R à d'autres groupes plus encombrants, tel le cyclohexyle, nous avons observé que les constantes d'association des pivalamides avec l'iode deviennent très grandes. L'étude de divers substituants R nous a permis de déterminer l'origine de cette particularité.

Partie expérimentale

Les valeurs des constantes et des enthalpies libres de formation des complexes amides–iode, à 25°C en solution dans l'heptane, sont réunies dans le tableau 1. La similitude des conditions expérimentales autorise une comparaison directe avec nos résultats antérieurs (1, 3).

Lorsque les constantes sont inférieures à 1000 L mol^{-1}, nous utilisons la méthode décrite précédemment (3). Dans tous les cas où la valeur est supérieure à 1000 L mol^{-1}, la détermination est faite par des mesures spectrophotométriques sur la bande de transfert de charge (274 nm) dont le coefficient d'extinction molaire supérieur à 2×10^4 L mol^{-1} cm^{-1} autorise l'emploi de solutions très diluées. Pour éviter la formation des ions I_3^- il est nécessaire que la concentration en iode soit de l'ordre de 10^{-5} mol L^{-1} et que la concentration en donneur ne dépasse pas 5×10^{-4} mol L^{-1}; ces limites sont le résultat des nombreux essais auxquels nous avons procédé. Ces contraintes nous ont conduit à retenir la méthode proposée par Bellon (4). La solution d'iode est placée dans une cellule de 10 cm d'épaisseur et le spectre est enregistré, puis la solution de donneur est ajoutée par fraction de 0,1 cm^3, le volume total ajouté étant de 2 à 3 cm^3. Après chaque addition le spectre est enregistré. Les concentrations en iode et en donneur sont calculées en supposant les volumes additifs, ce qui, en raison de l'extrême dilution des solutions, ne peut entraîner d'erreur significative.[4] La valeur de la constante est ensuite déterminée par la procédure de Rose et Drago (5).

Mesures spectrophotométriques

Tous les spectres dans le domaine uv–visible ont été enregistrés sur un spectrophotomètre Cary 219. La température est maintenue constante par une circulation d'eau à partir d'un cryostat Lauda K2R.

Synthèse des produits

Les amides ont été préparées par action des amines convenables sur les chlorures d'acide correspondants; le composé $(C_6H_{11})_2NCH_2COOC_2H_5$ a été obtenu en faisant agir la dicyclohexylamine sur le chloroacétate d'éthyle. Tous les produits ont été purifiés par distillation, recristallisation ou sublimation.

Résultats et discussion

1. Influence du substituant R dans la série CH_3CONR_2

L'examen du tableau 1 met immédiatement en évidence l'augmentation des valeurs K_c ou $\Delta G°$ avec la taille du substituant NR_2: K_c est multipliée par deux en passant du groupe $N(CH_3)_2$ à $N(C_6H_{11})_2$. Nous trouvons ici une variation analogue à celle observée pour la basicité des alcools aliphatiques (6) pour lesquels la basicité augmente avec la longueur de la chaîne du substituant. Or la somme des effets inductif et de

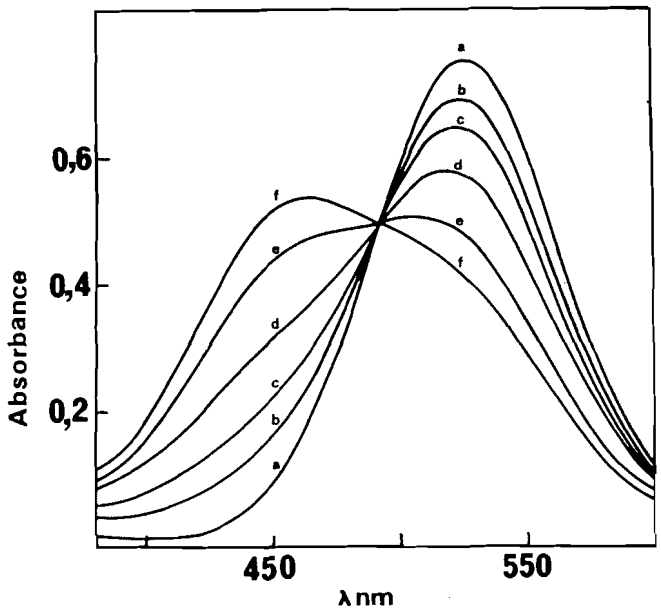

FIG. 1. Absorption de l'iode dans les mélanges iode–*N*,*N*-dicyclohexylacétamide (T = 298 K; solvant : heptane). $[I_2] = 8{,}3 \times 10^{-4}$ mol L^{-1}; $[CH_3CON(C_6H_{11})_2] \times 10^{-3}$ mol L^{-1} : (a) = 0; (b) = 2,8; (c) = 5,1; (d) = 9,6; (e) = 17,3; (f) = 23,7.

résonance demeure pratiquement constante alors que la polarisabilité augmente avec le nombre de groupes CH_2 (7). Il semble donc que l'augmentation de la basicité des amides *N*,*N*-disubstituées soit liée à la polarisabilité croissante du substituant NR_2.

Ces résultats confirment également l'absence de contrainte stérique notable entre les groupes NR_2 et CH_3, ceci indépendamment de la taiHe des groupes alkyles R; cette supposition, base de notre estimation des interactions stériques (1), trouve ainsi une justification supplémentaire.

Pour tous les composés de la série CH_3CONR_2, les spectres des solutions mixtes iode–amides, dans l'heptane, sont analogues. La figure 1 illustre ces spectres pour le complexe iode–*N*,*N*-dicyclohexylacétamide. Nous relevons les présences

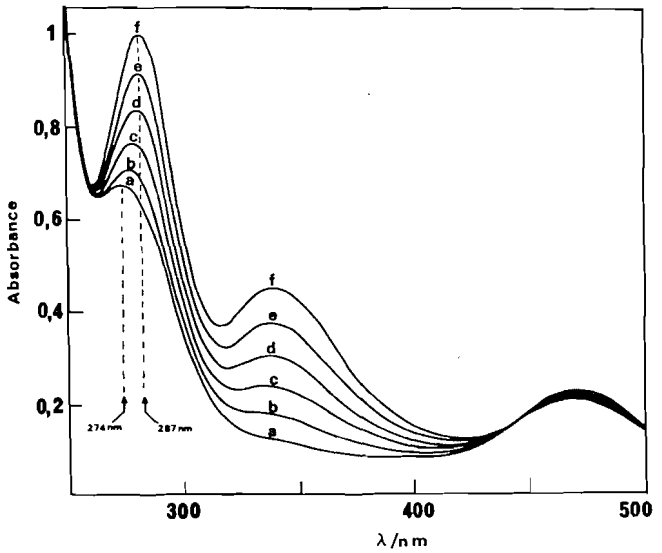

FIG. 2. Evolution de l'absorption d'un mélange iode–*N*,*N*-dicyclohexylpivalamide au cours du temps (T = 298 K; solvant : heptane). $[I_2] = 1{,}2 \times 10^{-5}$ mol L^{-1}; $[(CH_3)_3CCON(C_6H_{11})_2] = 10^{-4}$ mol L^{-1}. Temps : (a) = 0; (b) = 30 min; (c) = 60 min; (d) = 90 min; (e) = 120 min; (f) = 150 min.

de la bande de l'iode libre (520 nm) et de la bande de l'iode complexé (maximum au voisinage de 470 nm) dont l'intensité augmente avec la concentration en amide (la concentration en iode est maintenue constante). Hormis ces deux bandes il n'existe pas d'autre absorption caractéristique; en particulier il est impossible de mettre en évidence, dans le domaine de longueur d'onde accessible ($\lambda > 200$ nm), une absorption de transfert de charge.

2. Association I_2–$(CH_3)_3CCON(C_6H_{11})_2$

En choisissant des domaines de concentrations, pour l'iode et l'amide, identiques à ceux retenus précédemment (I_2, 10^{-3} mol L^{-1}; amide, 10^{-2} mol L^{-1}) les spectres enregistrés présentent des différences appréciables.

(a) La bande de l'iode complexé (470 nm) n'apparaît pas, quelle que soit la concentration en iode et en amide. De même, le point isobestique, présent sur le spectre de la figure 1, est absent.

(b) Une absorption intense se manifeste au voisinage de 350 nm dont l'intensité croît plus rapidement que la concentration en amide. Il ne peut donc s'agir d'une bande de transfert de charge, puisque dans cette hypothèse, les variations d'absorbance seraient inférieures à celles résultant de la relation de Beer–Lambert.

(c) Il n'existe pas de relation entre les variations d'absorbance aux différentes longueur d'onde et aucun résultat significatif ne peut être calculé pour les constantes K_c.

(d) Les spectres évoluent très rapidement dans le temps et nous avons remarqué la formation d'un précipité, même aux faibles concentrations.

Par ailleurs, et parallèlement à l'absorption située à 350 nm, une bande apparaît entre 280 et 300 nm. Ces deux bandes sont semblables aux bandes des ions I_3^- (8). Nous pouvons donc penser que des ions I_3^- se forment très rapidement dans le cas du complexe I_2–$(CH_3)_3CCON(C_6H_{11})_2$, même en solution dans l'heptane, qui ne favorise pas la formation de ces ions, et pour des solutions très diluées en iode et en donneur. C'est la première fois qu'un tel comportement des complexes iode – composés carbonylés est observé.

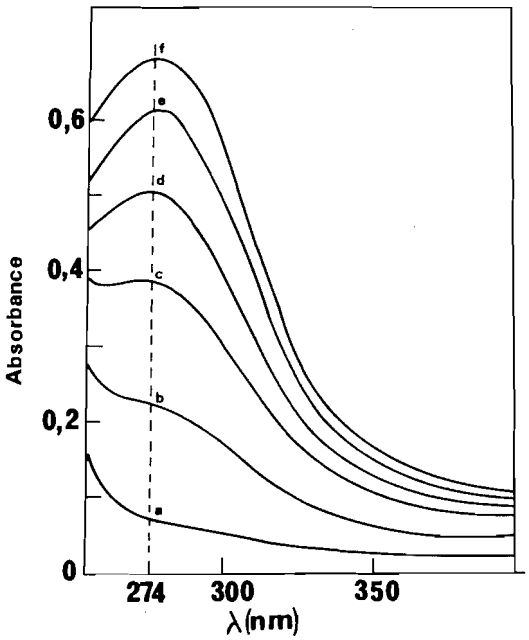

FIG. 3. Absorption des mélanges I_2–$(CH_3)_2CHCON(C_6H_{11})_2$ (T = 298 K; solvant : heptane). $[I_2] \times 10^5$ mol L^{-1} : (a) = 1,67; (b) = 1,65; (c) = 1,63; (d) = 1,615; (e) = 1,60; (f) = 1,58. $[(CH_3)_2CHCON(C_6H_{11})_2] \times 10^5$ mol L^{-1} (a) = 0; (b) = 2,88; (c) = 6,42; (d) = 9,70; (e) = 13,5; (f) = 16,1.

L'enregistrement des spectres en fonction du temps permet de préciser la suite des réactions (figure 2). Initialement, un choix convenable des concentrations ($I_2 = 1{,}2 \times 10^{-5}$ mol L^{-1}; amide = 10^{-4} mol L^{-1}) élimine la présence de la bande à 350 nm; en revanche, nous notons une absorption très intense à 274 nm. Au cours du temps, l'intensité de cette dernière bande diminue pendant qu'apparaissent les bandes à 350 nm et 287 nm. Ensuite, en laissant une durée suffisante d'évolution, les bandes à 350 et 287 nm disparaissent.

La bande située à 274 nm qui n'appartient ni à l'iode ni à l'amide doit être attribuée au complexe. L'existence d'une bande de transfert de charge dans ce domaine de longueur d'onde est tout à fait remarquable; en général il est impossible d'observer les transitions de transfert de charge des complexes iode – composés carbonylés.

L'évolution des spectres dans le temps conduit à proposer le processus suivant : dans un premier stade, il y a formation du complexe par transfert de charge identifié par la bande à 274 nm. Ensuite ce complexe évolue vers un complexe ionique avec apparition des ions I_3^- (bande à 290 et 350 nm). À ce jour, une évolution de ce type n'avait pas été observée pour les complexes CO..I_2 alors que des phénomènes semblables sont fréquents avec les complexes amines–iode (9); si nous prenons l'exemple du complexe iode–triéthylamine, la bande de transfert de charge, à 278 nm, présente au moment de la mise en solution disparaît ensuite progressivement. Nous remarquons la similitude des positions des bandes de transfert de charge pour les deux types de complexes iode–amine (278 nm) et iode–*N*,*N*-dicyclohexylpivalamide (274 nm).

Nous avons ensuite procédé à la recherche des conditions expérimentales et des concentrations permettant une détermination de la constante de formation du complexe initial. Ceci nous a conduit à modifier la méthode utilisée habituellement (cf. Partie expérimentale). En choisissant une concentration en iode très faible (10^{-5} mol L^{-1}) et en faisant varier la concentration en amide de 10^{-5} mol L^{-1} à environ 5×10^{-4} mol L^{-1} il est possible d'avoir des solutions qui n'évoluent pas significativement pendant le temps de l'expérience (1–2 h). Un exemple de spectre et donné sur la figure 3.

En exploitant la mesure de l'absorbance au maximum de la bande de transfert de charge, la valeur calculée de K_c est égale à 4300 L mol^{-1} ($\Delta G° = -21$ kJ mol^{-1}). Cette valeur est très supérieure à celle habituellement obtenues pour les complexes iode – composés carbonylés et est totalement incompatible avec la valeur K_c du complexe I_2–$CH_3CON(C_6H_{11})_2$: en raison de la contrainte stérique entre les groupes $(CH_3)_3C$ et $N(C_6H_{11})_2$, la constante devrait être inférieure à 30 L mol^{-1} pour le complexe I_2–*N*,*N*-dicyclohexylpivalamide.

Ces anomalies et l'analogie remarquée à plusieurs reprises avec les propriétés des complexes iode–amines, permettent de conclure à une complexation au niveau de l'atome d'azote de la *N*,*N*-dicyclohexylpivalamide.

Le site basique des amides *N*,*N*-disubstituées est toujours l'atome d'oxygène, aussi bien pour les complexes par transfert de charge (10, 11) que par liaison hydrogène (3). Il s'agit donc du premier exemple de fixation d'un acide de Lewis sur l'atome d'azote d'une amide acyclique. Cette particularité peut s'expliquer par l'effet stérique très grand du groupe $N(C_6H_{11})_2$. Pour les substituants $N(CH_3)_2$ et $N(C_2H_5)_2$, la substitution du groupe CH_3 par le groupe $(CH_3)_3C$ entraîne une diminution importante de K_c et de la stabilité du complexe. Cet abaissement est plus marqué avec $N(C_2H_5)_2$ en raison de l'effet stérique plus important du groupe éthyle. La contrainte stérique est levée soit par une ouverture de l'angle C—CO—N soit par une rotation du substituant NR_2 autour de la liaison C—N. Il en résulte une diminution de l'effet mésomère donneur du groupe NR_2 et un abaissement de la basicité du groupe carbonyle. Lorsque la contraite stérique devient très forte comme c'est le cas avec le substituant $N(C_6H_{11})_2$, l'angle de rotation peut devenir tel que la conjugaison entre les groupes CO et NR_2 est pratiquement absente. Le site le plus basique devient alors l'atome d'azote qui possède une basicité analogue à celle de l'azote d'une amine porteur d'un substituant attracteur par effet inductif et sans effet mésomère.

3. *Influence de l'encombrement stérique du substituant R′ de R′CON(C_6H_{11})$_2$*

Afin de confirmer l'interprétation proposée, nous avons fait varier l'encombrement du substituant noté R′ et avons déterminé les K_c de formation des complexes avec l'iode pour la série R′ = CH_3, CH_2CH_3, $CH(CH_3)_2$ et $C(CH_3)$. La substitution progressive des atomes d'hydrogène par des groupes méthyles s'accompagne d'abord d'une diminution de K_c, similaire à celle qui se produit en passant de $CH_3CON(CH_3)_2$ à $C_2H_5CON(CH_3)_2$. Puis une brutale inversion est provoquée par le groupe isopropyle, la constante K_c devient égale à 1350 L mol^{-1} et la bande de transfert de charge à 274 nm apparaît alors qu'elle était absente avec les composés précédents. La substitution par le groupe isopropyle donne un composé dont les propriétés de basicité sont les mêmes que celles de la *N*,*N*-dicyclohexylpivalamide. La valeur K_c moins élevée s'explique par une contrainte stérique moins forte qu'avec le *tert*-butyle et une conjugaison résiduelle entre les groupes CO et NR_2. Conformément aux prévisions faites à partir du modèle proposé, la basicité commence par diminuer, puis augmente au-delà d'un encombrement stérique « critique » des substituants. En fait, la basicité de l'oxygène continue à diminuer puisque la conjugaison s'affaiblit, mais la détermination expérimentale de sa valeur est impossible.

For personal use only.

4. Substitutions sur l'atome d'azote

La substitution des groupes alkyle de l'atome d'azote exerce également une influence sur la nature de l'association avec l'iode. Ainsi, pour les composés $(CH_3)_3CCON[CH(CH_3)_2]_2$ et $(CH_3)_3CCON[CH_2CH(CH_3)_2)]_2$, apparaît également une bande de transfert de charge vers 275 nm, mais pour avoir une intensité d'absorption significative il est nécessaire d'accroître les concentrations en iode et en amide. Dans ces conditions, la formation des ions I_3^- et l'évolution des solutions sont très rapides. Les constantes de formation des complexes ont été déterminées à partir de l'absorption de l'iode à 520 nm en nous assurant que les ions I_3^- ne perturbaient pas les mesures. Pour cela, nous avons été contraints de nous placer dans des domaines de concentrations où la proportion d'iode complexé est faible; la reproductibilité est alors moins satisfaisante que pour les autres valeurs de constantes. Toutefois, en raison des différences importantes entre les constantes, les écarts sont significatifs. Pour les deux composés, les constantes sont comprises entre 250 et 350 L mol^{-1}, le site basique est donc à nouveau l'atome d'azote, mais en raison de la conjugaison résiduelle, sa basicité et plus faible que celle de la *N,N*-dicyclohexylpivalamide. L'augmentation progressive des constantes avec l'encombrement stérique des substituants est parfaitement en accord avec une complexation sur l'azote provoquée par les contraintes stériques.

5. Comparaison avec les amines et les composés carbonylés α-aminés

La constante déterminée pour le complexe iodo–dicyclohexylpivalamide est compatible avec celles relevées dans la littérature pour les complexes iode – amines tertiaires. Dans l'heptane, à 20°C, ces valeurs sont, par exemple, de 13 804 L mol^{-1} pour le complexe I_2–$(CH_3)_2N(C_6H_{11})$ et de 2 344 L mol^{-1} pour I_2–$CH_3N(C_6H_{11})_2$ (12).

Pour confirmer cet accord, nous avons étudié le complexe I_2–$C_2H_5OCOCH_2N(C_6H_{11})_2$. L'encombrement autour de l'azote est proche de celui existant dans la *N,N*-dicyclohexylpivalamide et le groupe CH_2 élimine la conjugaison entre le carbonyle et l'azote. L'atome d'azote doit donc posséder des propriétés basiques proches de celles de l'azote de la *N,N*-dicyclohexylpivalamide. La bande de transfert de charge du complexe est située à 280 nm; les solutions évoluent également dans le temps avec disparition de la bande de transfert de charge et formation des ions I_3^- caractérisés par les bandes à 350 et 287 nm. La constante de complexation déterminée à partir de l'absorption de transfert de charge est se 3 800 L mol^{-1}, comparable à la valeur 4300 obtenue pour le complexe iode–*N,N*-dicyclohexylpivalamide.

L'ensemble des données spectrales, thermodynamiques et d'effets structuraux sur ces grandeurs vont dans le sens d'un changement du site basique dans les amides encombrées. Il faut remarquer que cette conclusion s'applique au cas de l'iode, acide mou dans la classification de Pearson (13, 14); elle ne peut pas être étendue, sans vérification expérimentale préalable, à des acides durs tels que les donneurs de liaison hydrogène.

Convolutive voltammetry with microelectrodes

A. R. HARMAN AND A. S. BARANSKI
Department of Chemistry, University of Saskatchewan, Saskatoon, Sask., Canada S7N 0W0

Received September 9, 1987

A. R. HARMAN and A. S. BARANSKI. Can. J. Chem. **66**, 1036 (1988).

Hemispherical microelectrodes prepared by electroplating of mercury on platinum microelectrodes were used in studies of fast charge transfer processes under convolutive voltammetry conditions. The algorithm used in the convolutive transformation was modified to account for spherical symmetry of diffusion. The sweep rate was varied from 0.1 to 220 V/s. Low sweep rate experiments were used to test the symmetry of the mass transport. It was found that the mass transport to (and inside) the electrodes can be described with good accuracy by the spherical symmetry diffusion. It was shown that the spherical convolution can be used to determine from cyclic voltammetric data the diffusion coefficient of a depolarizer and the number of electrons transfered to (or from) the depolarizer molecule in the electrode process.

At high sweep rates the technique was found useful in studies of fast electrode reactions. The technique was tested in the determination of kinetic parameters for Cd^{2+} reduction in aqueous solutions and *p*-dicyanobenzene reduction in DMF solutions. In both cases good agreement with values reported in literature was found. Properties of Hg/Pt microelectrodes were also studied using the ac impedance techniques. The ac impedance measurements were carried out at various frequencies (0.1 Hz to 100 kHz) in solutions containing 0.1 to 10^{-5} *M* of the supporting electrolyte.

A. R. HARMAN et A. S. BARANSKI. Can. J. Chem. **66**, 1036 (1988).

On a préparé des micro-électrodes hémisphériques en faisant de l'électrodéposition de mercure sur des micro-électrodes de plantine et on les a utilisées pour étudier les processus rapides de transfert de charge dans des conditions de voltampérométrie de convolution. On a modifié l'algorithme utilisé dans la transformation de convolution pour tenir compte de la symétrie sphérique de la diffusion. On a fait varier la vitesse de balayage de 0,1 à 220 V/s. On a utilisé les expériences aux basses vitesses de balayage pour vérifier la symétrie de la masse de transport. On a trouvé que la masse de transport vers les (et à l'intérieur des) électrodes peut être décrite avec une bonne précision en utilisant la diffusion de symétrie sphérique. On a démontré qu'on peut utiliser la convolution sphérique pour déterminer, à partir des données de la voltampérométrie cyclique, le coefficient de diffusion d'un dépolarisant ainsi que le nombre d'électrons qui sont transférés vers (ou de) la molécule dépolarisante dans le processus de l'électrode.

A des vitesses de balayage élevées, on a trouvé que la technique est utile dans des études de réactions à l'électrode qui sont rapides. On a vérifié la technique dans la détermination des paramètres cinétiques de la réduction du Cd^{2+} en solutions aqueuses ainsi que de la réduction du *p*-dicyanobenzène dans des solutions de DMF. Dans chacun des cas, on a trouvé une bonne corrélation avec les valeurs rapportées dans la littérature. Utilisant des techniques d'impédance en ca, on a aussi étudié les propriétés de micro-électrodes Hg/Pt. On a effectué des mesures d'impédance en ca à diverses fréquences (0,1 Hz à 100 kHz), dans des solutions contenant de 0,1 à 10^{-5} *M* d'électrolyte de support.

[Traduit par la revue]

Introduction

In most electrochemical measurements the rate of the process can be calculated directly from the value of the current flowing through the circuit. However, the determination of rate constants is more complicated because it requires knowledge of the concentration of reactants at the reaction site. The convolution method introduced by Oldham (1, 2) and independently by Saveant and co-workers (3–5) allows simple determination of the surface concentration of a depolarizer from the current–time dependence measured during an electrochemical experiment. Originally this method was based on semi-integration of current with respect to time and it was applicable to processes involving semi-infinite linear diffusion of reactants. Recently the method was extended to include spherical symmetry of diffusion (6). The spherical symmetry convolution can be easily applied to analysis of cyclic voltammetry curves obtained with spherical or hemispherical microelectrodes. Such electrodes can be readily produced by electroplating of mercury on platinum disk microelectrodes (7, 8). Cyclic voltammetry with microelectrodes (microvoltammetry) has several advantages. The solution resistance (R_s) of a hemispherical electrode can be described as:

$$[1] \quad R_s = 1/2\pi\kappa r$$

where κ is the electrical conductivity of the solution and r is the radius of the electrode.

The electrical capacitance of the electrode is proportional to its surface area:

$$[2] \quad C = 2\pi C_d r^2$$

where C_d is the specific capacitance of the metal–solution interface.

Consequently, the time constant of the electrode is

$$[3] \quad \tau = R_s C = C_d r/\kappa$$

In some cases it is possible to construct a cell with time constant lower than 10 ns. This, of course, means that very high sweep rates can be used in cyclic voltammetry experiments and, as a result, kinetics of very fast electrode reactions can be studied (9, 10).

Another important aspect of microvoltammetry is a significant reduction of the resistance polarization. This is apparent particularly at high sweep rates, when mass transport to a microelectrode resembles that to a conventional size electrode. In such a case the current is proportional to the surface area of the electrode. Since the solution resistance is inversely proportional to the radius, the resistance polarization of the electrode decreases with its radius. Recently it has been shown that microelectrodes can be successfully employed in electroanalysis in solvents of low dielectric constant (9), organic solvents without supporting electrolyte (11), organic glasses (11), and even in the gas phase (12).

Advantages of using microelectrodes in the study of the heterogeneous electron transfer kinetics are obvious. Since the mass transport becomes faster, and the solution resistance per surface area becomes smaller with a decrease in the size of an electrode, the activation resistance of the electrode reaction (connected in series with mass transport impedance and solution resistance) can be more precisely determined on small rather than on large electrodes. It was demonstrated that with microelectrodes the rate constants of fast electron transfer reactions ($k_s > 1$ cm/s) can be measured under both: steady-state conditions (i.e. slow sweep rates) (13, 14), and fast perturbation conditions (i.e. fast sweep rates) (9, 15).

The measurements reported in literature were done exclusively with solid microelectrodes: disk (9), ring (13, 14), and hemicyclindrical (15).

In this work the usefulness of mercury microelectrodes in studies of heterogeneous mass transfer processes is demonstrated. In addition a large part of these studies was dedicated to the evaluation of the quality of microelectrodes by ac impedance techniques.

Experimental

Reagents

Analytical grade chemicals and Millipore water were used to prepare aqueous solutions. *N*,*N*-Dimethylformamide (DMF) was dried with calcium hydride then it was distilled at reduced pressure under argon atmosphere. Tetrabutylammonium perchlorate (TBAP) was recrystallized from distilled water and dried *in vacuo* over P_2O_5 at 50°C. *p*-Dicyanobenzene (Aldrich) was used without additional purification.

Electrodes

Platinum microelectrodes were prepared by sealing a platinum wire (25 μm in diameter, Goodfellow Metals) in Pyrex glass. Before use the glass tube containing the wire was cut perpendicularly to its length and the surface of the electrode was polished with an extra fine carborundum sandpaper followed by polishing with 0.3 μm alumina.

A hemispherical mercury microelectrode was prepared by the electrodeposition of an exact amount of mercury on the Pt microelectrode. The process was carried out under controlled current conditions from a saturated aqueous solution of KBr containing 0.1 *M* $HgBr_2$ (high concentration of Br^- ions was necessary to ensure direct reduction of $HgBr_4^{2-}$ complex to Hg without formation of Hg_2Br_2). After the deposition the electrode was cycled several times in 0.1 *M* $NaClO_4$ between 0 and −1.0 V in order to spread the Hg over the platinum disk. Each Hg/Pt microelectrode before its use was carefully examined with an optical microscope in order to eliminate electrodes improperly sealed into glass or incompletely covered with mercury. For convenience and reproducibility the deposition process was totally controlled by microcomputer. The effective radius of the microelectrode, as determined from a low sweep rate voltammetric experiment, varied no more than ±7% for electrodes deposited under identical conditions.

Electrochemical measurements

In all electrochemical measurements the reference electrode was an aqueous calomel electrode containing a saturated solution of NaCl.

In non-aqueous media the reference electrode was separated from the analyzed solutions by a sintered glass junction and an intermediate solution containing 0.1 *M* TBAP in DMF. Prior to all electrochemical experiments the solutions were deaerated for 10 min with argon.

Microvoltammetric measurements were done without a potentiostat in a two electrode cell. The electronic system consisted of an Apple IIe microcomputer equipped with an 3.6 MHz accelerator card and a 12-bit A/D converter (both from Applied Engineering) as well as an AdaLab card (Interactive Structures) containing 12-bit D/A convertor and four 16-bit timers. The current passing through the system was monitored by a Current Preamplifier EG&G-PAR Model 181 with a sensitivity 10^{-3} A/V to 10^{-9} A/V and a bandwidth of 100 kHz at 10^{-6} A/V. The output of the preamplifier was connected to the A/D convertor through a low pass filter. The low pass filter was made of a 1 kΩ resistor and interchangeable capacitors.

A machine language program written in this laboratory enabled cyclic voltammetry experiments at sweep rates up to 220 V/s. A potential ramp used in these experiments was numerically generated and had the form of a staircase function with the step height dependent on the sweep rate. For sweep rates lower than 55 V/s the step height was always 2 mV, for sweep rates between 55 and 110 V/s the step height was 4 mV, and finally for sweep rates greater than 110 V/s it was 8 mV. However, due to the action of the low pass filter at the current preamplifier output the results obtained with this experimental setup closely resembled ones obtained under standard linear sweep voltammetry conditions. The significance of using the low pass filter will be discussed later.

The double layer capacitance measurements at microelectrodes were carried out using a EG&G-PAR Model 273 Potentiostat/Galvanostat and a EG&G-PAR Model 5301EC Lock-In amplifier.

Convolution programs were created in this laboratory using the Zbasic compiler. All computations were carried out on a Macintosh Plus microcomputer.

Results and discussion

Data analysis

As it was shown by Myland *et al.* (6) in the case of spherical diffusion the concentration of the depolarizer at the surface of the electrode can be obtained from the convolution of current which for species present in the electrolytic solution (diffusion outside the sphere) can be expressed as:

$$[4] \quad C_O^S = C_O^0 - \frac{I_{out}}{3nFV}$$

$$[5] \quad C_R^S = C_R^0 + \frac{I_{out}}{3nFV}$$

In eqs. [4] and [5] C_O^S and C_R^S are the surface concentrations of the oxidized and reduced forms of a depolarizer respectively, C_O^0 and C_R^0 are the initial, bulk concentration of the oxidized and reduced forms of a depolarizer, V is the volume of the electrode, and other symbols have their usual meaning. I_{out} is the convoluted current which can be calculated as:

$$[6] \quad I_{out} = \int_0^t i(t)\sigma_{out}(t-\tau)d\tau$$

where $i(t)$ is the faradaic current passing through the electrode and $\sigma_{out}(t-\tau)$ is the mass transport symmetry function for the diffusion outside a sphere given by:

$$[7] \quad \sigma_{out}(z) = \left(\pi \frac{Dz}{r^2}\right)^{-1/2} - \exp\left(\frac{Dz}{r^2}\right) \operatorname{erfc} \sqrt{\frac{Dz}{r^2}}$$

In this equation D is the diffusion coefficient of the reduced or oxidized form of a depolarizer and r is the radius of the electrode. Note that in order to calculate the surface concentration of the oxidized form of a depolarizer from eq. [4], the diffusion coefficient of the oxidized form must be used in eq. [7], and vice versa. In many cases, however, the diffusion coefficients of reduced and oxidized forms of a depolarizer are practically identical (in this work such an assumption was made in the case of *p*-DCB).

For the diffusion inside the sphere (metals dissolved in mercury) the corresponding equations have the form:

$$[8] \quad C_M^S = C_M^0 + \frac{I_{in}}{3nFV}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 93.93.197.157 on 09/07/12
For personal use only.

$$[9] \quad I_{in} = \int_0^t i(t)\sigma_{in}(t-\tau)d\tau$$

and

$$[10] \quad \sigma_{in}(z) = 3 + 2\sum_j^{\infty} \exp\left(\frac{-y_j D_M z}{r^2}\right)$$

where C_M^S and C_M^0 are the surface concentration and the initial, bulk concentration of the amalgam, respectively, D_M is the diffusion coefficient of the depolarizer in amalgam, I_{in} and $\sigma_{in}(z)$ are the convoluted current function and the mass transport symmetry function for the diffusion inside a sphere, y_j is the jth positive root of the equation $y = \tan(y)$ and other symbols have the same meaning as in eqs. [4], [6], and [7].

The numerical method used in computations of integrals [6] and [9] was similar to one described by Myland *et al.* (6).

In computer-controlled voltammetric experiments applying the potential in a form of a staircase function, directly from a D/A convertor, is always simpler than interfacing the computer with an analog linear sweep generator. In addition, charging currents under staircase voltammetry conditions are usually smaller than under linear sweep voltammetry conditions (16). However, the interpretation of data obtained under staircase voltammetry conditions is more complex. In order to compute correct values of the I_{in} and I_{out} functions, $i(t)$ in eqs. [6] and [9] must represent the average faradaic current passing through the circuit during a given sampling period. It was shown (17) that the current–potential function in staircase voltammetry changes significantly depending on the sampling parameter:

$$[11] \quad s = 1 - t_s/t_0$$

where t_0 is the width of the step and t_s is time at which current is sampled (counted from the beginning of the step). Stefani and Seeber (18) show the excitation potential in staircase voltammetry can be represented as a sum of the linear ramp and a sawtooth function; consequently the current response of the electrode can be expressed as a current expected for the linear sweep voltammetry (linear sweep component) and a periodic current created by the sawtooth polarization (ac component). The ac component reaches zero for a certain value of the sampling parameter s_0. It was calculated that for a totally reversible process $s_0 = 0.7$. Unfortunately, for quasi-reversible processes the value of s_0 varies, depending on the electrode potential and kinetic parameters of the studied system. In the case of microelectrodes the situation is complicated even more due to the non-linear symmetry of mass transport. To avoid problems with the interpretation of the data, the sampling parameter was always equal to 0.5 and the voltage output of the current preamplifier was smoothed by passing it through a low pass filter. The time constant of the filter (T_f) was exactly known and it was always within the range:

$$[12] \quad 3W_E < T_f < 6W_E$$

where W_E is the width of the step in the applied potential program.

While the filter removed the ac component of the current sufficiently, it also caused some distortion of the linear sweep component. This distortion can be described by:

$$[13] \quad V_2(t) = V_1(t) + T_f(dV_2/dt)$$

where V_1 and V_2 are voltages at the output of the current-to-voltage convertor and the output of the filter, respectively.

Equation [13] was actually used to correct the linear sweep component of the current for the distortion caused by the filter.

Under the experimental conditions used in this work the charging current was practically the same as it would be under linear sweep voltammetry conditions. Charging currents were subtracted from the *CV* curves using the procedure suggested by Nadjo *et al.* (4).

Double layer capacitance studies

Since the electron transfer kinetics is affected by the nature of electrode surface, it was necessary to establish whether the interfacial properties of Hg/Pt microelectrodes are the same as traditional mercury electrodes. This was accomplished by carrying out detailed ac impedance studies of hemispherical Hg/Pt microelectrodes in aqueous solutions of $NaClO_4$. The first group of experiments involved double layer capacitance measurements over a large range of frequencies. Measurements at high frequencies 100 kHz to 10 Hz were done using a lock-in amplifier, while at low frequencies the Fast Fourier Transform (FFT) technique was employed. In both cases ac impedance software from EG&G was used; however, in order to increase the sensitivity of the measurements a Model 181 current preamplifier was used as a current-to-voltage convertor. In Fig. 1 a typical frequency dependence of the apparent capacitance (C_d) of the hemispherical Hg/Pt microelectrode (25 μm in diameter) and the in-phase impedance of the cell, Z_{in}, is shown. The measurements were taken in 0.1 *M* aqueous solution of $NaClO_4$ at −1.0 V vs. SCE. The apparent capacitance was calculated as:

$$[14] \quad C_d = (2\pi Z_{out}\omega r^2)^{-1}$$

where Z_{out} is the out-of-phase impedance of the cell, ω is the angular frequency, and r is the radius of the working electrode.

At high frequencies Z_{in} approaches 2800 Ω which is the sum of the actual solution resistance retained by the working microelectrode, R_s, and the resistance of a junction between the analyzed solution and the reference electrode (all measurements were carried out in a two electrode system). At frequencies lower than 1 kHz, Z_{in} increases rapidly with a decrease in frequency. This may be caused by a systematic error in the measurements. At low frequencies the flow of current is limited mostly by the impedance associated with the double layer capacitance, the phase angle of the current approaches 90°, and consequently, the in-phase component of the current and the in-phase impedance of the circuit can no longer be determined exactly. The apparent double layer capacitance is remarkably stable over a large range of frequencies; it was found equal to 112 pF (11.4 μF cm^{-2}) at 64 kHz and 129 pF (13.1 μF cm^{-2}) at 100 Hz. C_d increases significantly only at frequencies lower than 10 Hz. It is obvious that the quality of Hg/Pt microelectrodes is much higher than microelectrodes made of carbon fiber sealed into polyethylene (19). First of all, the determined value of C_d is in reasonably good agreement with one expected for the Hg/0.1 *M* $NaClO_4$ interface (about 15 μF/cm^2); the small discrepancy may be caused by an error in the determination of the surface area of the electrode or, less likely, by contamination of the electrode with surfactants. The frequency dispersion of the capacitance observed at low frequencies may be explained by the presence of a narrow pore, filled with the electrolyte, between the metal and the insulator. The impedance of porous electrodes was discussed in detail by DeLevie (20). Porous behavior may also be emulated by a residual ionic conductivity

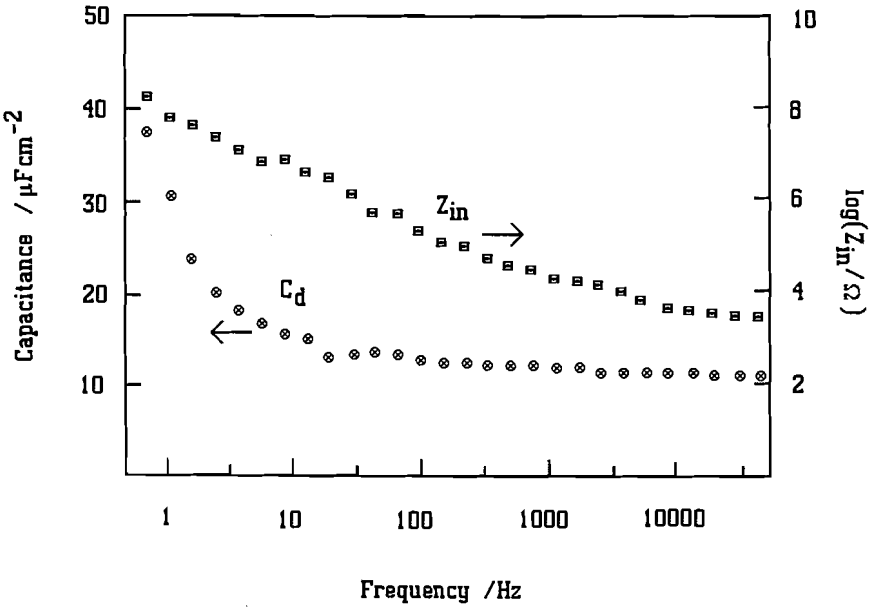

FIG. 1. Frequency dependence of the apparent differential capacitance, C_d, and the in-phase impedance, Z_{in}, of a hemispherical Hg/Pt electrode (12.5 μm in radius) in 0.1 *M* aqueous $NaClO_4$ at −1.0 V vs. SCE.

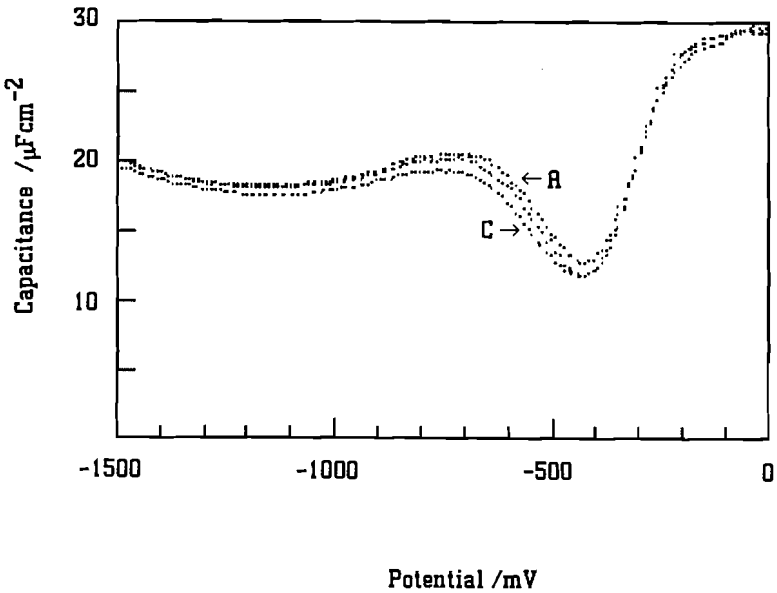

FIG. 2. Apparent differential capacitance of a hemispherical Hg/Pt electrode (12.5 μm in radius) in 10^{-3} *M* aqueous $NaClO_4$ measured at 1020 Hz. *A*: recorded immediately after immersing the electrode into the solution; *B*: 15 min after (*A*); *C*: 30 min. after (*A*).

of glass surrounding the microelectrode. Finally, residual faradaic processes occurring at the electrode may produce an apparent increase in C_d and R_s parameters. This is possible because current flow caused by irreversible faradaic processes becomes more significant at low frequencies when the impedance associated with the double layer capacitance becomes large. In any case the frequency dispersion of the double layer capacitance is much smaller at Hg/Pt electrodes than at carbon fiber or Pt electrodes (19), perhaps because mercury creeps onto the walls of the platinum wire (between the wire and the insulator) sealing all existing pores or, more likely, because the surface of mercury is much cleaner than the surface of most solid electrodes and consequently currents associated with residual faradaic processes are much smaller on mercury than on solid electrodes.

In another series of experiments the differential capacitance of Hg/Pt microelectrodes was measured as a function of potential in aqueous solutions containing 0.1 to 10^{-5} *M* $NaClO_4$. At low concentration of the supporting electrolyte the differential capacitance curves show a characteristic minimum indicating the zero charge potential, PZC (Fig. 2). It was interesting to find that on some Hg/Pt microelectrodes the PZC shifts with time in the direction of positive potentials. Time scale and range of the PZC shift varied considerably from

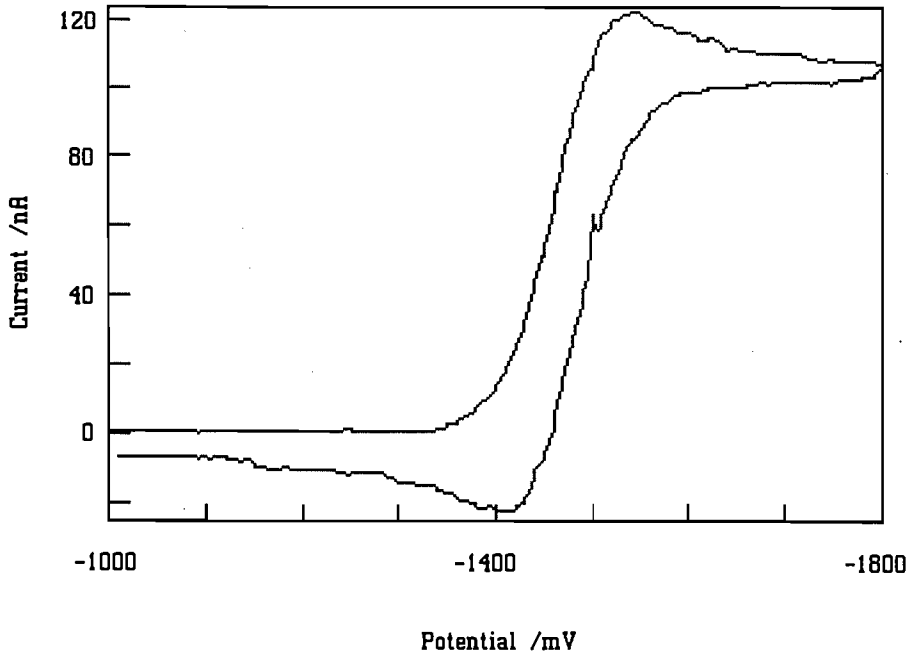

FIG. 3. Current–voltage curve obtained for 10^{-2} *M p*-DCB in 0.1 *M* TBAP in DMF. A hemispherical Hg/Pt electrode (12.5 μm in radius) was used. The sweep rate was 0.1 V/s.

experiment to experiment; in some cases a shift of up to 250 mV was observed in 16 min, in other cases the shift did not occur at all in a 1 h time period.

It was thought that this phenomenon can be caused by slow dissolution of platinum in mercury. In order to verify this hypothesis a saturated platinum amalgam was prepared and its PZC was determined using the streaming electrode technique. It was found, however, that the zero charge potentials of mercury saturated with Pt and pure mercury are the same within an experimental error of ±2 mV. Thus, other possible causes must be considered. The PZC may change if, in some areas of the electrode, the mercury layer is lost and the solid background material is uncovered. This process may be triggered by a drift of the electrode potential in the positive direction due to corrosion by traces of oxygen during a period between experiments. Since the surface energy of both the mercury and the base material (Pt or solid Pt–Hg compounds) depends on the electrode potential, the change in the electrode potential may cause a change in the spreading coefficient of mercury on the solid phase. It is worth mentioning that a significant potential dependence of the spreading of Hg on Ni and Fe was in fact observed (21, 22). Consistent with this hypothesis the drift of PZC was never observed if the electrode was kept at a potential of −1.5 V between the measurements. Another phenomenon often observed in this series of experiments was a slight broadening of the PZC minimum with time, as shown in Fig. 2. These last changes are most likely caused by the adsorption of impurities present at trace level in the studied solutions. Due to fast mass transport, contamination of microelectrodes with surfactants occurs much faster than in the case of standard size electrodes. Contamination of microelectrodes causes some problems in studies of electron transfer kinetics and it will be discussed later.

Determination of diffusion coefficients

In order to calculate the convolution for the spherical symmetry of mass transport the dimensionless diffusion coefficient of the oxidized form of depolarizer, $\mathcal{D}_O = D_O\Delta t/r^2$, must be known. Of course, the $\mathcal{D}_O$ can be determined from an independent experiment e.g. chronoamperometry; this, however, complicates the experimental procedure. Our primary interest was to examine the possibilities of determining the dimensionless diffusion coefficient using cyclic voltammetry alone. Two electrochemical systems were studied: *p*-DCB in DMF; in this case both reduced and oxidized forms of the depolarizer were in solution and they had a common symmetry of mass transport (semi-infinite, spherical), and Cd^{2+} in water; in this case the reduced form was dissolved in mercury and its mass transport was governed by a finite-volume, spherical symmetry.

In Fig. 3 a cyclic voltammetry curve recorded during the reduction of 0.01 *M* DCB in a DMF solution of 0.1 *M* TBAP is shown. In this experiment a hemispherical Hg/Pt electrode of radius 12.5 μm was used. The sweep rate was 0.1 V/s. Due to a large contribution from non-linear diffusion, the *CV* curve has a characteristic step-like shape with superimposed small anodic and cathodic peaks. The potential dependence of the convolution integral calculated for the linear symmetry of diffusion ($I_{plane} = \lim_{r\to\infty}(I_{out}\sqrt{D_O}/r)$) is shown in Fig. 4. Soon after the cathodic peak is reached concentration of the depolarizer at the surface of the electrode drops to zero; this should produce a time-independent value of integral I_{plane}. In Fig. 4, however, I_{plane} does not reach a plateau but rather increases constantly with time. This is caused by the time-independent flux resulting from non-linear mass transport to the electrode. It is obvious that in the case of microvoltammetry at low sweep rates, the linear diffusion convolution does not allow determination of surface concentration of a depolarizer. It should be noted, however, that the slope of the plot in the region between two current peaks carries information about the dimensionless diffusion coefficient. A direct determination of the diffusion coefficient from the shape of the curve in this region is very difficult, however, because the shape of the curve is affected in a complex way by the electron transfer kinetics, *IR* drops etc.

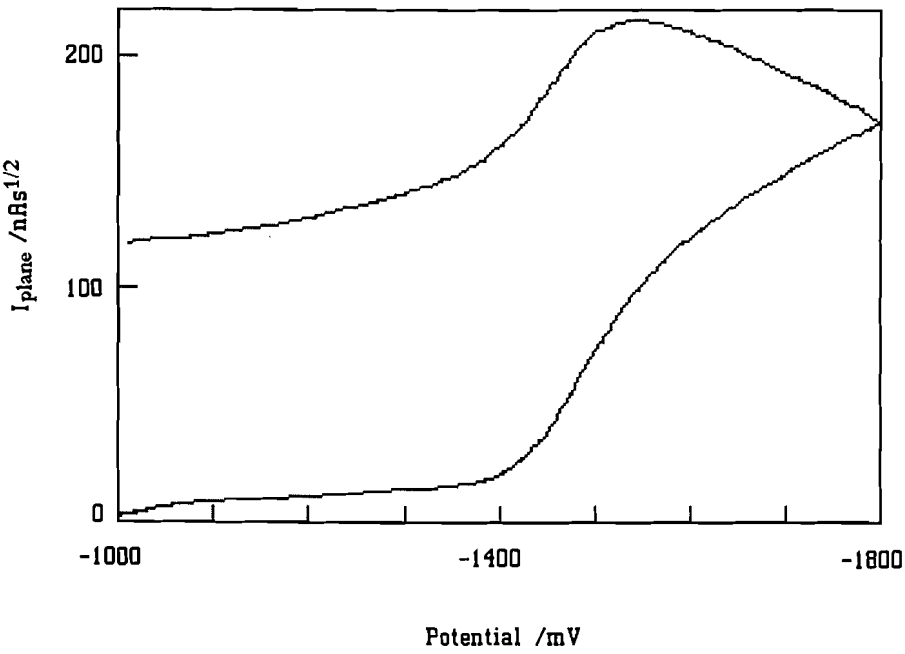

FIG. 4. Potential dependence of the plane convolution of current, I_{plane}, obtained by the semi-integration of the curve shown in Fig. 3.

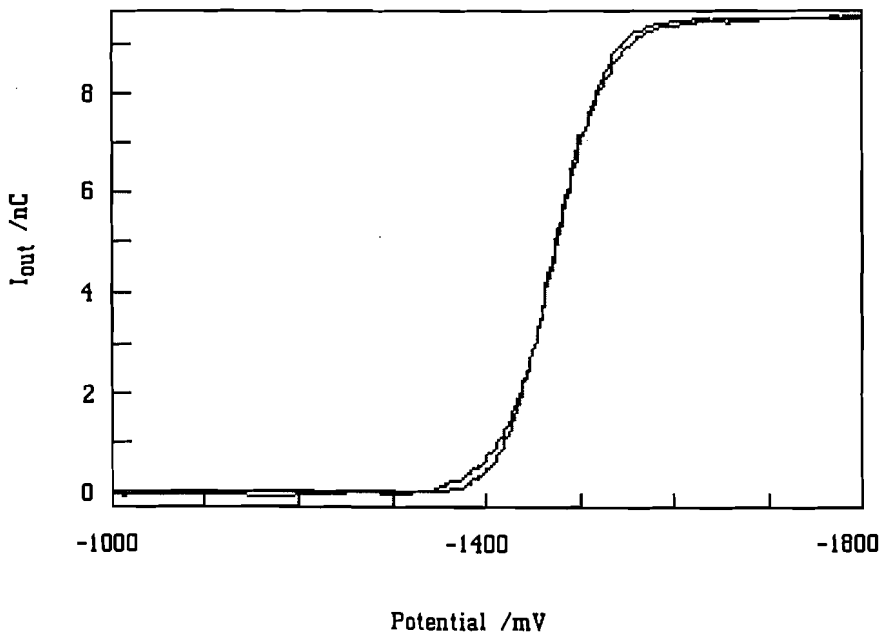

FIG. 5. Potential dependence of the spherical convolution of current, I_{out}, obtained by the successive approximation method for the curve shown in Fig. 3.

Instead, $\mathcal{D}_O = D_O\Delta t/r^2$ was determined by a successive approximation method:

[15] $(\mathcal{D}_O)_{n+1} = (\mathcal{D}_O)_n(1 + S_n/H_n)$

where $(\mathcal{D}_O)_n$ and $(\mathcal{D}_O)_{n+1}$ are the old and new values of the dimensionless diffusion coefficient, H_n is the average value of the convoluted current, and S_n is the average slope of the convoluted current (dI_{out}/dt) in the potential region: $E_c + 5RT/nF$ to E_v (where E_c is the cathodic peak potential and E_v is the vertex potential).

At first the convolution was performed assuming an arbitrarily chosen value of $(\mathcal{D}_O)_{n=0}$ (usually 10^{-5} cm^2 s$^{-1} \times \Delta t/r^2$) in order to find $S_{n=0}$ and $H_{n=0}$ parameters, then the first approximation of the dimensionless diffusion coefficient, $(\mathcal{D}_O)_{n=1}$, was calculated from eq. [15]. The result was used to calculate a new table of the mass transport symmetry function, $\sigma_{out}(z)$, then the convolution was repeated and the next approximation of S, H, and $\mathcal{D}_O$ parameters was obtained. This procedure was continued until the relative slope, S_n/H_n, was close enough to zero (in this work the condition $S_n/H_n < 0.02$ was used to exit the loop). It was assumed that the last approximation of H and $\mathcal{D}_O$ parameters represents the true values. The potential dependence of the convoluted current obtained by this method is shown in Fig. 5. The convolution was performed on the *CV* curve from the previously described experiment (Figs. 3 and 4). According to eq. [4] the height of the step in Fig. 5 is

[16] $H = 3nFVC_O^0$

Since $\mathcal{Q}_O = D_O\Delta t/r^2$ is also known, then, in theory, any two experimental parameters (*n*, *r*, D_O, or C_O^0) can be determined, if two others are known. For example, when radius of the electrode and the depolarizer concentration are known the diffusion coefficient and the number of electrons involved in the elemental process can be calculated. This can be useful in studies of complex electron transfer reactions. However, since this is an absolute method it is, in general, less reliable than the relative one described in our previous publication (23). This method fails when the concentration of a depolarizer is lower than about 2×10^{-3} *M* (due to errors introduced by the charging current correction) and when the sweep rate is too high or too low. The last limitation arises from the fact that the parameter *S* in eq. [15] becomes independent of $\mathcal{Q}_O$, when r^2/D_O is much larger or much smaller than the time window of the experiment.

Values of *n* and D_O calculated from *CV* curves obtained at various sweep rates for reduction of DCB in DMF and Cd^{2+} in water are shown in Table 1. For each experiment two sets of parameters are reported; values marked by "L:" were obtained when the initial value of the dimensionless diffusion coefficient, $(\mathcal{Q}_O)_{n=0}$, in eq. [15] was set to 5×10^{-6} cm^2 $s^{-1} \times (\Delta t/r^2)$, "H:" corresponds to $(\mathcal{Q}_O)_{n=0} = 3 \times 10^{-5}$ cm^2 $s^{-1} \times (\Delta t/r^2)$. For sweep rates lower than 0.5 V/s and higher than 10 V/s the difference between the low and the high values of D_O increases indicating diminished precision of the method. The diffusion coefficient of DCB obtained for the intermediate sweep rates (0.5–10 V/s) is in good agreement with a value determined by the polarographic method (1.17×10^{-5} (24)), the *n* oscillates around 1 indicating that the calculations are internally consistent.

The diffusion coefficient of Cd in mercury, in Table 1, was obtained by analyzing the oxidation portions of corresponding *CV* curves. An example of such a curve obtained with a hemispherical Hg/Pt (25 μm in diameter) in aqueous 0.5 *M* solution of Na_2SO_4 contining 0.01 *M* Cd^{2+} at the sweep rate of 10 V/s is shown in Fig. 6. The anodic peak in this voltammogram is narrower and much larger than the corresponding cathodic peak due to preconcentration of cadmium in a small volume of mercury. It should be noted that the finite volume effect is very strong at 10 V/s, although it decreases with an increase in the sweep rates, it cannot be neglected even at 200 V/s. Shape of the current–time curve after the anodic peak is very strongly affected by the value of the $\mathcal{Q}_M = D_M\Delta t/r^2$ parameter. If a correct value of this parameter is used in the convolution transformation the I_{in} function is time independent and equal to zero soon after the anodic peak is reached. If the diffusion coefficient used to calculate the mass transport symmetry function is too small or too large the slope of I_{in} function after the anodic peak is positive or negative, respectively (as it is shown in the upper left corner of Fig. 7). Therefore this slope can be used as a feed-back parameter in the determination of $\mathcal{Q}_M$ by the previously described successive

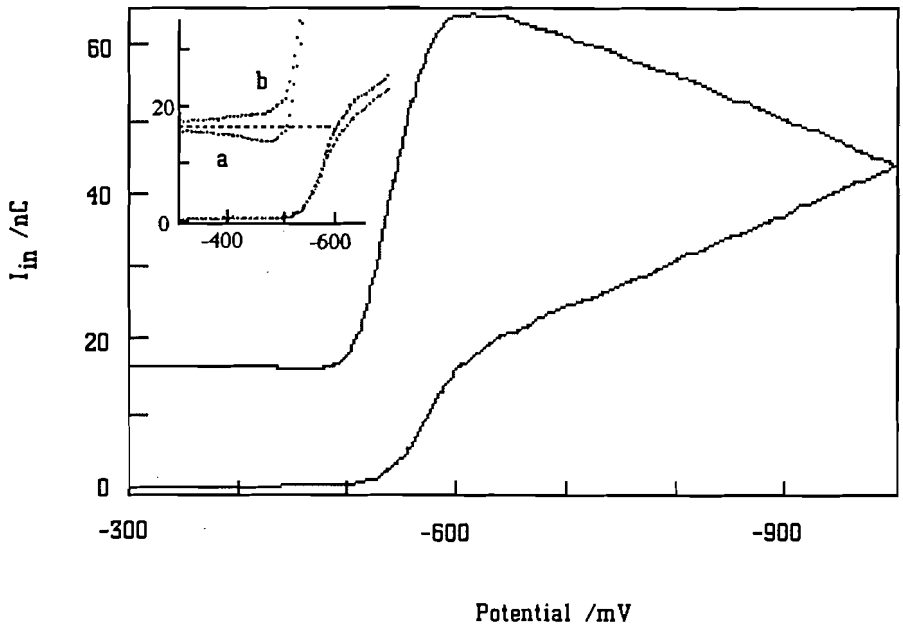

FIG. 7. Potential dependence of the spherical convolution of current, I_{in}, calculated for the curve shown in Fig. 6 using the successive approximation method. In the upper left corner: (*a*) I_{in} function obtained for $D_M = 1.2 \times 10^{-5}$ cm^2/s, (*b*) I_{in} function obtained for $D_M = 1.9 \times 10^{-5}$ cm^2/s.

approximation method. When this method was applied to the *CV* curve shown in Fig. 6 the slope equal to zero was obtained for $D_M = 1.4 \times 10^{-5}$ cm^2/s, which is in an excellent agreement with the literature value (1.48×10^{-5} cm^2/s (25)). However, I_{in} after the anodic peak was not equal to zero (Fig. 7); obviously not all cadmium was oxidized in the anodic cycle. Cadmium may form intermetallic compounds with platinum which are insoluble in mercury; similar compounds between Zn and platinum group metals are well known (22). However, in the case of the Pt–Hg–Cd system the reaction seems to occur only if fresh platinum electrodes are used, and if the amount of Cd introduced to mercury is relatively small (26). It is possible that Cd–Pt compound blocks the Pt–Hg interface and considerably slows down further reaction between Pt and Cd. It is also possible that cadmium reacts with impurities present in platinum rather than platinum itself, since according to manufacturer specifications the Pt wire used in this experiment contains about 75 ppm of Au and other metals. In any case the chemical reaction of Cd on Hg/Pt electrodes can be minimized by cycling the electrode several times in a solution containing Cd^{2+} before an experiment.

It can be shown that in the absence of following chemical reactions the successive approximation method gives not only a correct value of the diffusion coefficient of metals in mercury but also, after the oxidation peak, the zero slope of the I_{in} function coincides with the zero value of that function. Such a relationship was observed for lead (Fig. 8).

In the case of both cadmium and lead the I_{in} function increases with time in the region between the cathodic and anodic peaks; this is an expected behavior caused by the preconcentration of metals in a finite volume of mercury (6).

Determination of the electron transfer rate constant parameters

Properly calculated I_{out} and I_{in} functions allow the determination of the surface concentration of reduced and oxidized forms of a depolarizer using eqs. [4] and [5] or [4] and [8] depending on the studied system. Then the rate constant of the electron transfer process can be calculated using the Butler–Volmer expression:

$$[17] \quad i_f(t) = nFAk_f(E)\{C_O^S - C_R^S \exp[(E - E^0)nF/RT]\}$$

where $k_f(E)$ is the potential-dependent rate constant of the forward reactions, A is the surface area of the electrode, E^0 is the formal potential of a studied redox couple, and other symbols have their usual meaning.

The formal potential used in eq. [17] can be determined from the potential at which the current in the reverse cycle reaches zero (zero crossing potential) following the procedure described by Saveant and Tessier (5):

$$[18] \quad E^0 = E_{i=0} - (RT/nF) \ln [C_O^S(i = 0)/C_R^S(i = 0)]$$

where $E_{i=0}$ is the zero crossing potential, $C_O^S(i = 0)$ and $C_R^S(i = 0)$ are the surface concentrations of the oxidized and reduced form of the depolarizer at $E_{i=0}$.

In order to obtain meaningful kinetic parameters the sweep rate in a cyclic voltammetry experiment must be high enough to ensure irreversibility of the electrode reaction. In both studied cases (*p*-DCB in DMF and Cd^{2+} in H_2O) a significant departure from the Nernstian behavior is observed at sweep rates greater than 100 V/s. The potential dependence of the convoluted current at the sweep rate 200 V/s for the electrode process involving 2×10^{-3} *M* *p*-DCB in a DMF solution of 0.1 *M* TBAP is shown in Fig. 9. The potential dependence of the electron transfer rate constant obtained from this experiment is shown in Fig. 10. The apparent standard rate constant was 0.18 ± 0.05 cm/s and the apparent electron transfer coefficient, α, was 0.51 ± 0.03. Both are in excellent agreement with values previously determined using ac admittance techniques (27). It should be emphasized that these results were obtained without any correction for ohmic drop by software or hardware; in fact no potentiostat was used in these experiments. If a similar experiment (without *IR* compensation) is run using HMDE the ohmic drop causes a major systematic error and the calculated rate constant is about 0.02 cm/s.

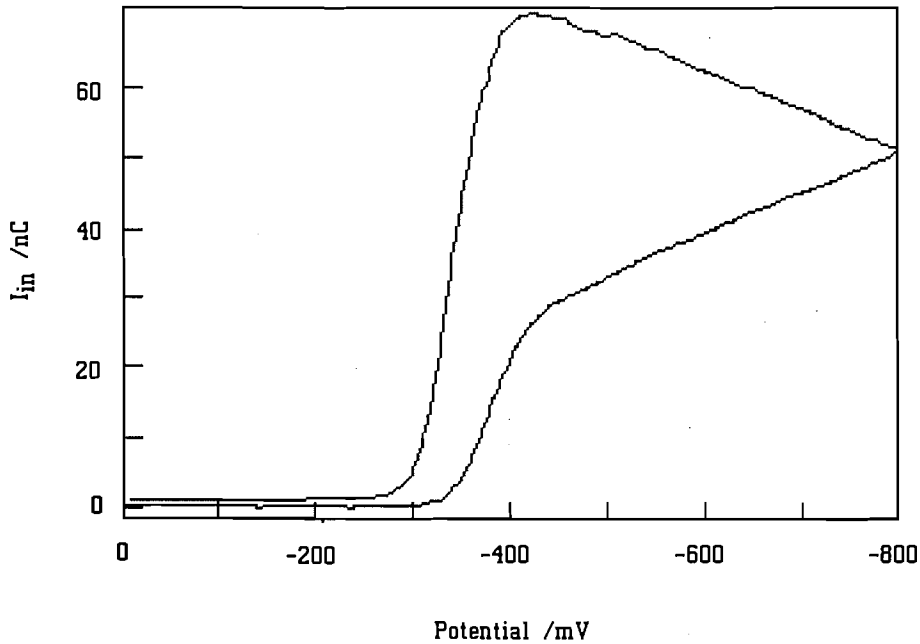

FIG. 8. Potential dependence of the spherical convolution of current, I_{in}, obtained for the reduction–oxidation process of 10^{-2} *M* Pb^{2+} in 0.5 *M* in aqueous $NaClO_4$. A hemispherical Hg/Pt electrode (12.5 μm in radius) was used. The sweep rate was 10 V/s.

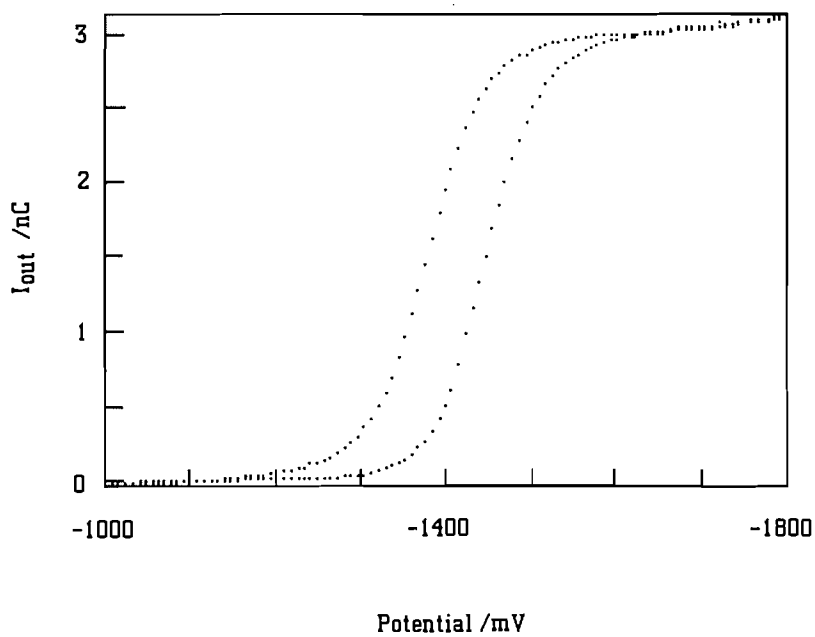

FIG. 9. Potential dependence of the spherical convolution of current, I_{out}, obtained for the reduction–oxidation process of 2×10^{-3} *M* *p*-DCB in 0.1 *M* TBAP in DMF. A hemispherical Hg/Pt electrode (12.5 μm in radius) was used. The sweep rate was 200 V/s.

The kinetic parameters determined for reduction of Cd^{2+} in aqueous solutions of 0.5 *M* Na_2SO_4 at the sweep rate 200 V/s were $k_s = 0.2 \pm 0.05$ cm/s and $\alpha n_\alpha = 1.05 \pm 0.05$ (an average of four measurements at different microelectrodes). This again is in good agreement with literature data, $k_s = 0.24$ cm/s (28).

Microelectrodes can be an important tool in studies of fast electron transfer processes, particularly in poorly conductive media; however, particular care should be taken to keep solutions extremely clean and to avoid unnecessarily long exposure of electrodes to studied solutions. Microelectrodes are very susceptible to contamination by adsorption of impurities. Fast diffusional transport of surfactants and the small surface area of microelectrodes result in 50 to 100 times faster contamination compared to standard size electrodes. Blocking of the electrode is more severe in aqueous than in non-aqueous media. This finding may seem surprising since water can usually be purified much more effectively than organic solvents. On the other hand, however, the adsorption of large molecules at the Hg–solution interface is expected to be much stronger in the case of aqueous solutions than non-aqueous ones. This happens because breaking of the water structure causes a substantial increase in the free energy of large molecules in the bulk of aqueous media. In fact, adsorption of neutral molecules at Hg/organic solvents interface is rarely observed. We believe

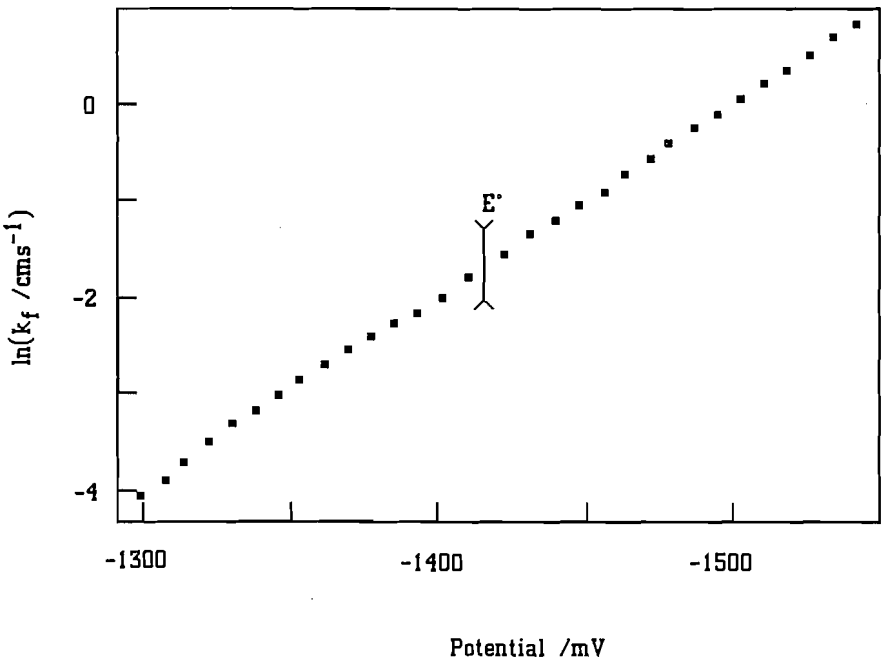

FIG. 10. Potential dependence of the forward rate constant of the electron transfer process calculated from the curve shown in Fig. 9.

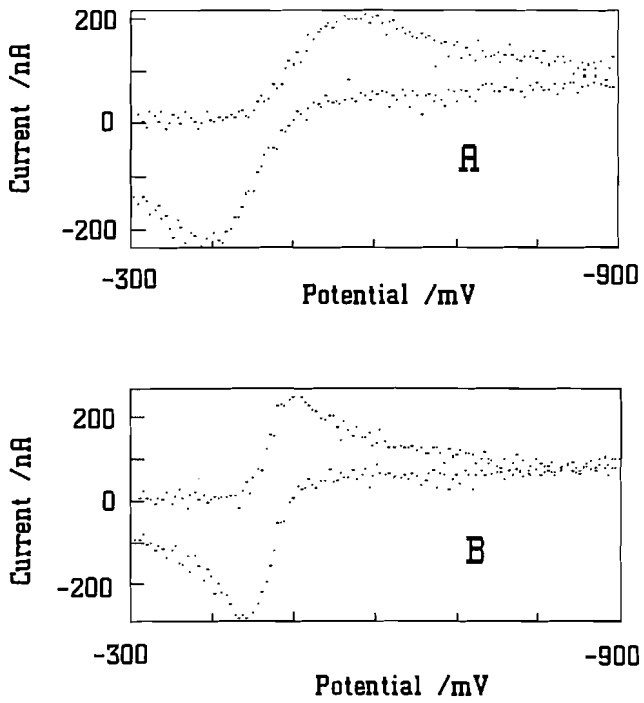

FIG. 11. Cyclic voltammetric curves obtained for 2×10^{-3} *M* Cd^{2+} in aqueous 0.5 *M* Na_2SO_4 with a hemispherical Hg/Pt electrode (12.5 μm in radius). The sweep rate was 100 V/s. *A*: microelectrode was left in the solution for about 15 min; *B*: the same electrode after being washed with concentrated H_2SO_4.

that in these studies the main sources of contamination were salts used as supporting electrolytes and the laboratory air to which solutions were exposed during their preparation.

A voltammogram shown in Fig. 11*A* was obtained in an aqueous solution of 0.5 *M* Na_2SO_4 containing 2×10^{-3} *M* Cd^{2+}; a Hg/Pt microelectrode was left in the solution for 15 min prior to recording the curve. The difference between the cathodic and anodic peak potentials at sweep rate 100 V/s was about 200 mV. This potential difference corresponds to a standard rate constant of about 1.2×10^{-2} cm/s, which is about 20 times less than the correct value. It is obvious that the electrode reaction was inhibited by the adsorption of some kind of surfactants present in solution. Fortunately, it was discovered that a contaminated mercury microelectrode can be cleaned by immersing it for a few seconds into concentrated (98%) sulfuric acid followed by an extensive washing with double distilled water. A *CV* curve shown in Fig. 11*B* was obtained in exactly the same conditions as in Fig. 11*A*, also the same electrode was used but the electrode was cleaned with H_2SO_4 using the procedure described above. The peak separation in this last case was about 60 mV and the standard rate constant determined by the convolution method was 0.27 cm/s.

Conclusion

Mercury microelectrodes were found to be very useful in studies of the kinetics of electron transfer processes. AC impedance studies have shown that Hg/Pt microelectrodes (25 μm in diameter) can be as ideal as standard size HMDE (i.e. they exhibit a correct value of the double layer capacitance and the zero charge potential as well as very small frequency dispersion of the capacitance). It is possible to prepare an almost ideal hemisphere by electrodeposition of Hg on Pt; as it was shown the mass transport to (and inside) such an electrode is governed by the spherical symmetry diffusion. Although preparation of microelectrodes is fast and simple, their stability is rather poor. Microelectrodes are very vulnerable to contamination by surfactants. In the case of Hg/Pt microelectrodes additional problems are caused by poor adhesion of Hg to Pt or solid Pt–Hg phases; under some experimental conditions the Hg coverage of the electrode may be partially lost. One method of improvement would be to replace Pt with a metal which is more easily wetted by Hg. Some brief experiments were done with Ag microelectrodes sealed into a heat shrinkable TFE/FEP Teflon tubing. However, mercury deposited on such electrodes sinks

For personal use only.

relatively fast into an Ag (probably by creeping along walls of the silver wire), as a result the shape of the electrode and its surface area changes with time. Clearly, a satisfactory base metal for preparation of Hg microelectrodes is still to be found. Some recent works indicate that such a metal can be iridium (29, 30). Unfortunately a sufficiently thin iridium wire is not yet available commercially.

Application of the convolution method to analysis of microvoltammetric curves does not present any problems. Convolutive microvoltammetry seems to be particularly promising in studies of kinetics of fast electron transfer processes in poorly conductive media. In this work correct values of the standard rate constants for relatively fast processes were obtained without any correction for *IR* drops. In the case of standard size electrodes three methods of *IR* correction are widely used: positive feed back compensation, current interrupt technique and the convolutive analysis which allows *IR* compensation after the experiment on the software level. If necessary, any of these methods can be applied to microvoltammetry; however, the third one requires particular attention. Although it was not demonstrated in this work due to hardware limitations, the use of microelectrodes allows cyclic voltammetry experiments at very high sweep rates (up to 100 000 V/s) (9). At this speed, an electronic *IR* compensation is not available due to slow response of existing potentiostats. Of course, microvoltammetric experiments can be carried out without a potentiostat (10); in such a case the convolutive analysis is the only method of *IR* compensation. Rough estimates indicate that convolutive microvoltammetry can be used to measure standard rate constants smaller than 1 cm/s in solutions of specific conductivity greater than $10^{-5}\ \Omega^{-1}\ cm^{-1}$. This opens a possibility of studying fast electron transfer reactions at very low temperatures. Such studies of the reduction of η6-(substituted arene)-η5-cyclopentadienyliron complexes are under way in this laboratory.

Another interesting conclusion arising from this work is that microelectrodes enable measurements of the double layer capacitance in poorly conductive media. In the ac impedance technique the capacitance of an electrode can be determined precisely only if the capacitance reactance accounts for at least few percent of the total impedance of the electrodes. It follows that such measurements cannot be done correctly if the solution resistance is too large. Since solution resistance is inversely proportional to the radius of an electrode and capacitive reactance is inversley proportional to the surface area of the electrode, the ratio of the capacitive reactance to the solution resistance is more favorable for small than for large electrodes. According to our experience the double layer capacitance of 25 μm electrodes can be measured without problems in aqueous solutions containing supporting electrolyte at concentration 10^{-5} *M* or higher. Some attempts were made to measure double layer capacitance in distilled water without any supporting electrolyte. At this stage, however, such measurements are not reliable. In order to make the capacitive reactance large enough, the measurements must be carried out at low frequencies (5 Hz or lower); consequently, the results are noisy and data acquisition takes a long time. This together with poor stability of microelectrodes and their non-ideal behavior at low frequencies makes interpretation of results very difficult.

Quelles procédures utiliser en polarisation diélectrique pour mettre en évidence, avec certitude, les interactions entre des dérivés chlorés et bromés de l'éthane et la *N*,*N*-diméthylacétamide

M. GUÉRIN ET L. BENAZIZ

Laboratoire de chimie minérale et laboratoire de physico-chimie des diélectriques, Université de Poitiers, Bât G.O.N., 40 avenue du Recteur Pineau, 86022 Poitiers CEDEX, France

Reçu le 22 septembre 1987

M. GUÉRIN et L. BENAZIZ. Can. J. Chem. **66**, 1047 (1988).

De nombreux travaux ont montré l'efficacité particulièrement grande des méthodes diélectriques, dans la mise en évidence, en solution, des interactions moléculaires spécifiques de faible énergie. Leurs applications exigent au préalable, d'évaluer les interactions non spécifiques entre espèces en solution (interactions désignées ici par effet «normal» du solvant). Or précisément, dans le cas des dérivés halogénés de l'éthane, qui peuvent présenter en solution, simultanément, plusieurs conformères de polarités parfois très différentes, nous ne disposions pas encore de cette possibilité. Dans ces conditions, l'objectif principal de notre travail a été de rechercher toutes procédures acceptables d'évaluation de cet effet de solvant.

M. GUÉRIN and L. BENAZIZ. Can. J. Chem. **66**, 1047 (1988).

Numerous studies have shown the particular usefulness of dielectric methods for observing low energy specific molecular interactions in solution. Before applying these methods, it is necessary to evaluate the non-specific interactions between species in solution (in this paper, these interactions are termed the "normal" effect of the solvent). However, in the particular case of halogenated derivatives of ethane, which can exist in solution as several conformers of different polarities, this possibility was not available. The object of our work has been to study all the procedures that might be acceptable in evaluating this solvent effect.

Introduction

L'étude de la polarisation diélectrique de solutions diluées, binaires et ternaires de composés A et B dissous dans un solvant inerte permet d'évaluer la polarisation totale P_{AB} et la constante de formation K_{AB} d'un complexe AB formé. En fait, pour obtenir avec une bonne précision des grandeurs exploitables il faut tenir compte des effets dus aux interactions non spécifiques de type van der Waals désignées parfois par le terme effet «normal» de solvant (1, 2).

Récemment en procédant ainsi Dumas *et al.* (3) ont pu mettre en évidence le rôle joué par l'halogène dans les interactions entre des dérivés chlorés et bromés du méthane (représentants d'anesthésiques généraux) et deux amines tertiaires (modèle de constituants de la membrane des cellules nerveuses). Une étude peut aussi être envisagée pour une autre catégorie importante d'anesthésiques volatils, les dérivés halogénés de l'éthane. Or ces espèces diffèrent considérablement du point de vue diélectrique, de celles étudiées par Dumas (3), en particulier parce que certaines d'entre elles peuvent présenter en solution simultanément plusieurs conformères de polarités parfois très différentes.

Dans ces conditions, pour pouvoir exploiter avec plus de certitude les résultats expérimentaux, obtenus avec les dérivés halogénés de l'éthane, il convient d'aborder alors le problème suivant: (*i*) les procédures (concernant essentiellement l'effet de solvant) adoptées jusqu'à présent, pour analyser tout mélange binaire et ternaire, sont-elles encore acceptables et suffisantes? et (*ii*) éventuellement quelles modifications y apporter, lorsque le soluté, présent dans ces mélanges, est susceptible d'avoir différents conformères en équilibre?

Des réponses à cette question permettraient alors de traiter, sans exception, tous les anesthésiques volatils et constitueraient ainsi l'outil de base indispensable à l'étude diélectrique des interactions spécifiques, entre tout dérivé halogéné du carbone et les espèces considérées comme modèles simples des constituants de la membrane.

Techniques expérimentales

Les mesures diélectriques ont été effectuées à l'aide d'un dipôlemètre de type DM.01 de «Wissenshaftlich Technische Werkstatten» équipé d'une cellule-DFL1 (capacité 20 cm^3) ou DFL2 (capacité 8 cm^3) thermorégulée à 25,0 ± 0,1°C.

Les masses volumiques des corps purs et des solutions ont été mesurées à l'aide d'un densimètre digital DMA 45 de A. Paar thermorégulé.

Les indices de réfraction des corps purs ont été mesurés à l'aide d'un réfractomètre d'Abbe équipé d'une lampe à vapeur de sodium.

Les solvants (cyclohexane, *n*-heptane, *n*-dodécane, diméthyl-2,2 butane et tétrachlorométhane) produits de qualité spectroscopique, utilisés sans traitement préalable, ont été conservés sur tamis moléculaire. Ces solvants très purs ont permis l'étalonnage des appareils utilisés.

Tous les autres produits (dérivés halogénés de l'éthane, et *N*,*N*-diméthyl acétamide) ont été distillés sous pression réduite d'azote sec, puis conservés sur tamis moléculaire généralement à l'abri de la lumière.

Dans la suite de ce travail, nous avons séparé en deux groupes l'ensemble des dérivés de l'éthane étudiés:

Le groupe G1: espèces polaires ne présentant pas de conformère: trichloro-1,1,1 éthane; pentachloroéthane; trichloro-1,1,1 trifluoro-2,2,2 éthane; dichloro-1,1 éthane; *le groupe G2*: espèces polaires pouvant exister en solution sous plusieurs formes «isomères» de conformation: dichloro-1,2 éthane; dibromo-1,2 éthane; tétrachloro-1,1,2,2 éthane; tétrabromo-1,1,2,2 éthane; bromo-1 chloro-2 éthane; trichloro-1,1,2 éthane.

Méthodes d'exploitation des résultats

1. Exploitation des mesures expérimentales

(a) Mélanges binaires

La détermination du moment dipolaire d'un soluté A dans un solvant apolaire S a été effectuée dans le cadre de la théorie de Debye (4) appliquée à un grand nombre de solutions diluées:

$$[1] \qquad \mu_{A/S} = \sqrt{\frac{9k}{4\pi N}} \cdot \sqrt{(P_{A\infty/S} - R_{M.D})T}$$

Printed in Canada / Imprimé au Canada

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 93.93.197.157 on 09/07/12
For personal use only.

où la constante $\sqrt{9k/4\pi N}$ a pour valeur 0,012813 lorsque μ est exprimé en Debye (D); $P_{A\infty/S}$: polarisation molaire à dilution infinie de A dans S en $cm^3\ mol^{-1}$, évaluée à l'aide de la méthode de Halverstadt et Kumler (5); $R_{M.D}$: réfraction molaire de A pour la raie D du sodium en $cm^3\ mol^{-1}$; T: température de l'expérience en K.

(b) Mélanges ternaires

Pour mettre en évidence quantitativement les interactions spécifiques au sein d'un mélange ternaire A/B/S, les conclusions d'une étude comparée de plusieurs méthodes physico-chimiques (6) nous ont incités à retenir pour cette étude, la méthode diélectrique de Cleverdon, Collins et Smith (7). Cette méthode consiste à déterminer la polarisation molaire à dilution infinie du soluté A lorsqu'il est mis en solution dans le solvant S et dans divers solvants mixtes BS. Les auteurs attribuent alors la totalité des écarts entre $P_{A\infty/BS}$ et $P_{A\infty/S}$ à la formation du complexe (AB) supposé de stoechiométrie 1–1 :

$$[2] \quad \frac{1}{P_{A\infty/BS} - P_{A\infty/S}} = \frac{1}{K_{AB} \cdot \Delta P} \cdot \frac{M_B \cdot V_{BS}}{W_B} + \frac{1}{\Delta P}$$

où ΔP, l'incrément de polarisation du complexe AB est défini par la relation : $P_{AB} = P_A + P_B + \Delta P$; M_B : masse molaire de B; w_B : fraction du soluté B dans le solvant mixte BS de volume massique V_{BS}.

Remarque : En l'absence de toute interaction spécifique ($K_{AB} = 0$ et $\Delta P_{AB} = 0$), l'expression précédente montre que les polarisations $P_{A\infty/BS}$ et $P_{A\infty/S}$ devraient être égales. Une telle identité ne peut pas se vérifier, si l'on admet l'existence générale d'un effet normal de solvant, lorsque le soluté A passe du solvant S au solvant mixte BS (voir ci-dessous). En toute rigueur il convient alors d'effectuer une correction convenable du terme $P_{A\infty/S}$ dans la relation de Cleverdon, Collins et Smith.

2. Procédures d'évaluation de l'effet normal de solvant applicables aux mélanges binaires et (ou) ternaires

(a) Soluté du groupe G1

Il a été montré (2, 8) qu'en l'absence de toute interaction spécifique, l'expression de Barclay–Le Fèvre (9) en particulier permet, pour un soluté donné, de relier les moments dipolaires dans le solvant apolaire S et en phase gazeuse :

$$[3] \quad \mu_S^2/\mu_g^2 = 1 + \left(e^{x^2} - \frac{\epsilon_{\infty S}}{\epsilon_\infty}\right)\frac{\epsilon_S - 1}{\epsilon_S + 2}$$

ϵ_S : permittivité diélectrique du solvant S; $\epsilon_{\infty S}$, ϵ_∞ : permittivités diélectriques à fréquence infinie du solvant et du soluté; e^{x^2} : paramètre associé à la forme de la molécule de soluté, est défini par les dimensions de celle-ci, a (suivant la direction du moment dipolaire), b et c (dans deux directions perpendiculaires à celle du moment) :

$$x^2 = \frac{c^2 - a^2}{a^2} \text{ si } a > b > c; x^2 = \frac{c^2 - a^2}{b^2} \text{ si } b > a > c \text{ et}$$

$$x^2 = \frac{c^2 - a^2}{c^2} \text{ si } b > c > a$$

À partir de cette relation fondamentale [3] peuvent être établies plusieurs autres expressions en termes de polarisation (ou de moment dipolaire) permettant d'évaluer l'effet normal de solvant subi par le soluté polaire lorsqu'il est considéré successivement dans un solvant S puis un solvant différent S'. Leurs formulations ainsi que les conditions de leur utilisation ont déjà été présentées dans la littérature (cf. par ex. les références 3 et 10).

TABLEAU 1. Paramètres physico-chimiques nécessaires à l'évaluation de l'effet de solvant

(*a*)

Solutés	e^{x^2}	ϵ_∞^*
Pentachloroéthane	0,902	2,4504
Dichloro-1,1 éthane	0,926	2,0964
Trichloro-1,1,1 éthane	1,209	2,1717
Trichloro-1,1,1 trifluoro-2,2,2 éthane	1,040	2,0507

*Valeurs calculées selon la méthode de Boyer–Donzelot (11–13).

(*b*)

Solvants	$\epsilon_S = \epsilon_{\infty S}$
Cyclohexane	2,0170
n-Heptane	1,9170
Tétrachlorométhane	2,2275
n-Dodécane	2,0090
Diméthyl-2,2 butane	1,8628

(b) Soluté du groupe G2

Pour rendre compte de l'effet de solvant correspondant, s'il existe, et qui vient s'additionner à celui déjà cité ci-dessus, toujours présent, il convient de mettre en œuvre l'expression proposée par Abraham *et al.* (14–17). En effet, cette dernière, déjà utilisée dans un contexte moins favorable (18), semble, tant par sa nature même que par les nombreuses validations dont elle a été l'objet, tout à fait convenir à cette étude.

Supposons un soluté A du groupe G2 en solution dans un solvant S; A existe sous deux formes limites («isomères» de rotation très différents), les conformères *gauche* et *trans*.

Ces deux derniers, de moments dipolaires respectifs $\mu_{gh/S}$ et $\mu_{tr/S}$ sont considérés en équilibre suivant l'équation de réaction : $A_{gh} \rightleftarrows A_{tr}$. En désignant par $x_{gh/S}$ la fraction molaire de A_{gh} et par $x_{tr/S}$ celle de A_{tr} nous pouvons obtenir les relations suivantes :

$$[4] \quad \bar{\mu}_S^2 = x_{gh/S}\mu_{gh/S}^2 + x_{tr/S}\mu_{tr/S}^2$$

où $\bar{\mu}_S$: moment dipolaire expérimental,

$$[5] \quad \frac{x_{tr/S}}{x_{gh/S}} = K \exp\left(-\frac{\Delta G^S}{RT}\right)$$

K : facteur de poids statistique; $\Delta G^S = G_{tr}^S - G_{gh}^S$ représente la différence d'énergie libre entre les deux conformères A_{gh} et A_{tr} dans le solvant S.

L'expression de Abraham *et al.* (14–17) permet de connaître ΔG^S ou plus précisément ΔE^S, la différence d'énergie de solvatation entre les conformères *gauche* et *trans*, ces auteurs ayant indiqué clairement les raisons qui justifient cette approximation :

$$[6] \quad \Delta E^S - \Delta E^g = \frac{(k_{gh} - k_{tr})X}{1 - lX} - \frac{3(h_{gh} - h_{tr})X}{5 - X} - \left[b_{ghf}\left(1 - \exp\left[\frac{-b_{ghf}}{16RT}\right]\right) - b_{trf}\left(1 - \exp\left[\frac{-b_{trf}}{16RT}\right]\right)\right]$$

$$[7a] \quad X = \frac{\epsilon_S - 1}{2\epsilon_S + 1}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 93.93.197.157 on 09/07/12
For personal use only.

$$[7b] \quad l = \frac{2(n_D^2 - 1)}{n_D^2 + 2}$$

$$[7c] \quad f = \left| \frac{(\epsilon_S - 2)(\epsilon_S + 1)}{\epsilon_S} \right|^{1/2} \quad f = 0 \quad \text{si} \quad \epsilon_S < 2$$

$$[8a] \quad k_i = \frac{\mu_i^2}{a^3}$$

$(i = gh, tr)$

$$[8b] \quad h_i = \frac{3q_i}{2a^5}$$

$$[8c] \quad b_i = 4{,}35\left(\frac{T}{300}\right)^{1/2} \frac{a^{3/2}}{r^3}\left(k_i + h_i \frac{a^2}{r^2}\right)^{1/2}$$

μ_i, q_i: moments dipolaire et quadripolaire du conformère i; a: rayon de la cavité sphérique de Onsager (19),

$$\left(\frac{4}{3}\pi N a^3 = \frac{M}{\rho}\right)$$

occupée par la molécule étudiée, de masse molaire M et de masse volumique ρ; r = distance soluté solvant; ΔE^g: différence d'énergie entre les deux conformères A_{gh}, A_{tr} en phase gazeuse.

La détermination des paramètres h_i et k_i nécessite la connaissance de la géométrie et des moments dipolaires de liaison, en particulier celui de la liaison carbone halogène (C—Hal), du soluté A. De plus pour calculer h, il est nécessaire de connaître aussi le centre de gravité du volume occupé par A. Ce dernier est déterminé selon Abraham *et al.* (16, 20) en affectant à chaque atome j (constituant la molécule du soluté) de coordonnées x_j, y_j et z_j (dans un repère orthonormé ox, oy, oz) un coefficient égal à son volume v_j de van der Waals. Les coordonnées du centre de gravité du volume sont alors (v_j étant calculé à partir du rayon de van der Waals de l'atome j):

$$[9a] \quad x = \frac{\Sigma x_j v_j}{\Sigma v_j}$$

$$[9b] \quad y = \frac{\Sigma y_j v_j}{\Sigma v_j}$$

$$[9c] \quad z = \frac{\Sigma z_j v_j}{\Sigma v_j}$$

L'évaluation de l'effet de solvant (c'est-à-dire le calcul du passage de $\bar{\mu}_S$ à $\bar{\mu}_g$) d'un soluté du groupe G2 est donc abordée ici en combinant les expressions de Barclay–Le Fèvre et de Abraham.

Un premier programme de calcul, correspondant au cas $\mu_{A\,tr} = 0$ (ou $\mu_{A\,tr} \simeq 0$) principalement étudié, permet d'exploiter les expériences réalisées sur les solutions binaires AS.

Dans le cas des systèmes ternaires, un autre programme de calcul reposant sur les mêmes relations [3]–[9c] permet d'accéder aux polarisations $P_{A\infty/BS}$ calc.

Les représentations des conformères *gauche* et *trans* de chaque soluté sont présentées figure 1, les valeurs des principales données décrivant ces formes constituent le tableau 2.

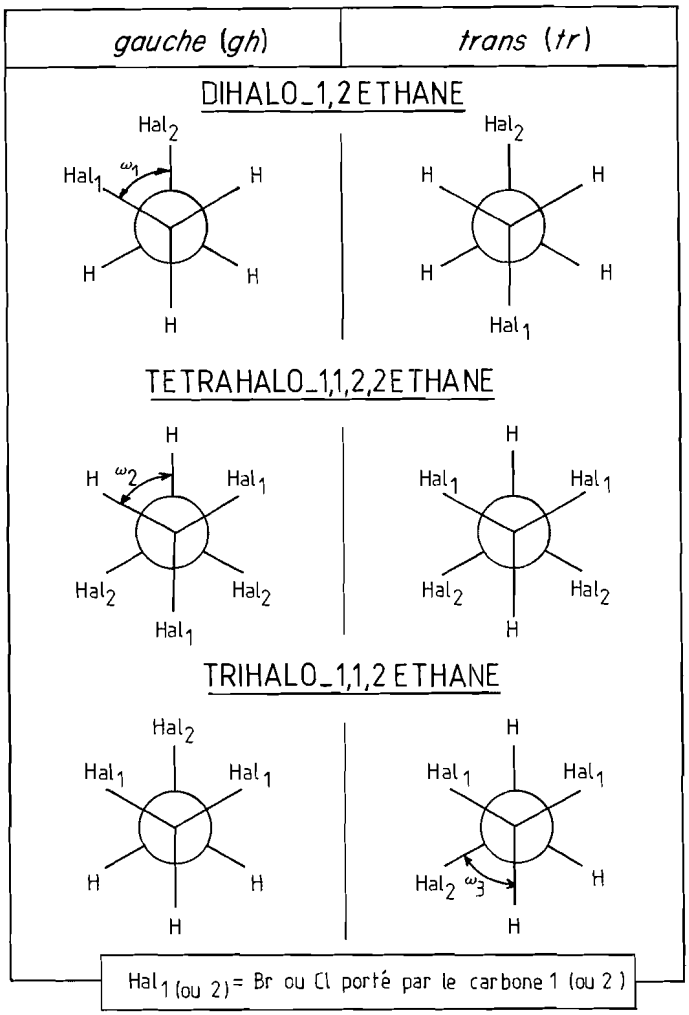

FIG. 1. Géométrie standard des solutés.

TABLEAU 2. Données relatives à la géométrie standard des solutés (indiquée figure 1) (16, 21)

1. Rayons de Van der Waals (en Å) : C (1,60); H (1,20); Cl (1,80); Br (1,95)

2. Longueurs de liaisons (en Å) : C—C (1,53); C—Br (1,93); C—Cl (1,77); C—H (1,09)

Résultats et interprétations

1. Les mélanges binaires

(a) Solutés du groupe G1

Dans le tableau 4 figurent, pour chaque système soluté–solvant, la valeur expérimentale, μ_S, et celle calculée à l'aide de la relation de Barclay–Le Fèvre, μ_g. Pour quelques systèmes, des valeurs de μ_S sont signalées dans la littérature diélectrique classique (les tables de McClellan par exemple). Celles que nous présentons ci-dessous tableau 4 sont généralement en accord avec ces résultats déjà publiés.

L'examen de ces résultats et tout particulièrement la comparaison des valeurs de μ_g calc. à celles de μ_g exp. (qui peuvent être relevées dans la littérature) en tenant compte bien sûr des incertitudes correspondantes, nous amène à constater qu'il y a généralement un bon accord entre ces grandeurs.

Avec ces exemples et par référence aux travaux de Colnay *et al.* (2), il semble bien que l'expression de Barclay–Le Fèvre

TABLEAU 3. Valeurs des différents paramètres utilisés pour l'évaluation de l'effet de solvant

Paramètre	Soluté				
	CH_2ClCH_2Cl	CH_2BrCH_2Br	$CHCl_2CHCl_2$	$CHBr_2CHBr_2$	CH_2BrCH_2Cl
ϵ_∞	2,1986	2,5583	2,4171	3,0641	2,3769
e^2_{gh}	0,840	0,833	1,534	1,934	0,837
a (Å)	3,16	3,25	3,47	3,59	3,21
k^*_{gh}	13,7±0,4	$10,6\pm0,2_5$	4,0±0,1	2,98±0,06	$12,9_5\pm0,3$

*En kJ mol^{-1}.

TABLEAU 4. Valeurs de μ_g calc. obtenues à l'aide de l'expression de Barclay et Le Fèvre appliquée aux valeurs expérimentales μ_S (t = 25°C)

Soluté	Solvant	μ_S (D)	μ_g calc. (D)	$\Delta\mu_S$ exp. ou $\Delta\mu_g$ calc. (D)	μ_g exp. ± $\Delta\mu_g$ exp. (D)
Dichloro-1,1 éthane					2,06±0.05
	C_6H_{12}	1,98	2,00	0,02	
	nC_7H_{16}	2,00	2,01	0,02	
	CCl_4	1,95	2,00	0,02	
	$nC_{12}H_{26}$	1,98	1,99	0,02	
	DM-2,2 B	2,04	2,03	0,02	
Trichloro-1,1,1 éthane					1,78±0,03
	C_6H_{12}	1,84	1,79	0,02	
	nC_7H_{16}	1,83	1,77	0,02	
	CCl_4	1,81	1,76	0,02	
	$nC_{12}H_{26}$	1,82	1,77	0,02	
	DM-2,2 B	1,83	1,79	0,02	
Pentachloroéthane					0,92±0,05
	C_6H_{12}	1,00	0,98	0,02	
	nC_7H_{16}	1,01	0,99	0,02	
	CCl_4	1,00	1,00	0,02	
	$nC_{12}H_{26}$	0,98	0,97	0,02	
	DM-2,2 B	1,02	1,00	0,02	
Trichloro-1,1,1 trifluoro-2,2,2 éthane					(—)
	C_6H_{12}	0,79	0,80	0,02	
	nC_7H_{16}	0,78	0,78	0,02	
	CCl_4	0,82	0,83	0,02	

permette de relier de façon satisfaisante μ_S exp. et μ_g exp. Pourtant ces deux grandeurs correspondent à des états de la matière pour lesquels les forces d'interactions entre les dipôles des différentes molécules sont notablement différentes.

(b) Solutés du groupe G2

Dans le tableau 5 figurent les résultats obtenus après avoir utilisé la méthode de calcul proposée ci-dessus.

Ainsi pour chaque système soluté–solvant, face à la valeur expérimentale $\bar{\mu}_S$ nous avons indiqué, avec quelques grandeurs caractéristiques des espèces, la valeur de $\bar{\mu}_g$ calc. obtenue en combinant les expressions d'effet de solvant de Abraham et de Barclay–Le Fèvre, à comparer à celle correspondante de μ_g exp. (donnée de la littérature) incertitudes expérimentales comprises.

L'examen des résultats portés dans le tableau 5 nous montre que pour tous les solutés étudiés, il existe un bon accord entre les valeurs de $\bar{\mu}_g$ calculées et celle observée expérimentalement. Cette constatation semble donc prouver que la correction introduite est satisfaisante.

Cas du trichloro-1,1,2 éthane:

Comme tout soluté du groupe G2, le trichloro-1,1,2 éthane existe dans le solvant S sous la forme de deux isomères de rotation. Dans ce cas, par contre, le moment dipolaire du conformère *trans* (non nul) n'est plus négligeable comme dans celui du bromo-1 chloro-2 éthane. Cette seule différence, avec les cas examinés ci-dessus, correspond en fait à l'introduction dans tous nos calculs de l'inconnue supplémentaire μ_{tr}.

Pour pouvoir évaluer l'effet de solvant, subi par ce soluté, nous avons donc dû modifier en conséquence certaines parties du programme de calcul précédemment utilisé. Dans ce nouveau mode de calcul nous accèdons uniquement à $\bar{\mu}_S$ calc. La qualité de cette détermination nous est indiquée en comparant la valeur calculée à celle déterminée expérimentalement, incertitudes comprises (tableau 6).

*Nous avons considéré le bromo-1 chloro-2 éthane comme un dihalo-1,2 éthane symétrique, reprenant en cela, l'approximation déjà admise par Abraham *et al.* (20).

TABLEAU 6. Valeurs de $\bar{\mu}_S$ calc. obtenues à l'aide des expressions d'Abraham et de Barclay–Le Fèvre dans le cas du trichloro-1,1,2 éthane à 25°C

	Solvant		
Paramètre	Cyclohexane	Diméthyl-2,2 butane	Tétrachlorométhane
$\mu_{gh/S}$ (D)	2,88	2,85	2,90
$\mu_{tr/S}$ (D)	1,36	1,34	1,36
ΔE^S (kJ/mol)	6,857	7,034	6,565
$x_{gh/S}$ (D)	0,0304	0,0283	0,0340
$\bar{\mu}_S$ calc. (D)	1,43 (±0,02)	1,41 (±0,02)	1,44 (±0,02)
$\bar{\mu}_S$ (D)	$1,46_5$ (±0,02)	1,43 (±0,02)	1,47 (±0,02)

NOTA: Valeur des principaux paramètres utilisés: ϵ_∞ = 2,3018; $e^{x^2}_{gh}$ = 1,655; $e^{x^2}_{tr}$ = 1,500; a (Å) = 3,33; k_{gh} (kJ mol^{-1}) = 11,4; k_{tr} (kJ mol^{-1}) = 2,61; h_{gh} (kJ mol^{-1}) = 2,42; h_{tr} (kJ mol^{-1}) = 10,1 et ΔE^g (kJ mol^{-1}) = 7,94; $\mu_{gh/g}$ = 2,65 D; $\mu_{tr/g}$ = 1,27 D.

2. Les mélanges ternaires

L'étude des systèmes ternaires A/B/S repose sur l'utilisation de l'expression de Cleverdon, Collins et Smith (7) où le terme $P_{A\infty/S}$ (pour tenir compte de l'effet normal de solvant) est remplacé par $P_{A\infty/BS}$ calc. Cette polarisation est calculée à partir de la formule de Barclay–Le Fèvre dans le cas d'un soluté A du groupe G1, et en combinant les expressions d'Abraham et de Barclay–Le Fèvre pour tout soluté A du groupe G2. Toutefois, avant d'aborder (sur la base que nous venons de définir) l'exploitation des expériences réalisées, nous devons nous assurer que pour tout mélange ternaire reconnu sans interaction il y a bien identité entre polarisations calculées et mesurées $P_{A\infty/BS}$.

Nous avons donc examiné le comportement d'un grand nombre de systèmes témoins. C'est pourquoi nous avons déterminé la polarisation diélectrique de solutions diluées d'un soluté A introduit dans un solvant mixte, par ex. soluté B/solvant cyclohexane de concentration variable en B, A et B étant choisis de façon à ne pas mettre en jeu d'interactions spécifiques.

Nous avons retenu par exemple: A: dérivés halogénés du méthane ou de l'éthane (G1 ou G2); B: dérivés halogénés du méthane ou de l'éthane (G1). De plus, si le soluté A est toujours suffisamment polaire ($\mu > 2$ D), le soluté B par contre peut avoir une polarité très variable.

Deux cas se dégagent très nettement:

1. Le solvant mixte est apolaire, ou contient un soluté B assez peu polaire ($\mu \simeq 1$ D) à une concentration réduite ($w_B < 3\%$). Les polarisations expérimentales et calculées peuvent être considérées comme identiques puisqu'elles ne diffèrent pas de plus de 1%. Elles correspondent toujours à des faibles valeurs de ϵ_{BS} (voisines de celle de ϵ_S). Avec de tels solvants mixtes il est alors possible d'exploiter des systèmes ternaires à l'aide de l'expression de Cleverdon, Collins et Smith proposée ci-dessus.

2. Le soluté B est assez polaire ($\mu > 2$ D) et le solvant mixte

TABLEAU 7. Valeurs de l'incrément de polarisation P_{AB} ($cm^3\ mol^{-1}$) et de la constante de formation K_{AB} ($L\ mol^{-1}$) du complexe AB déterminées dans le cyclohexane à 25°C (B = *N*,*N*-diméthylacétamide)

A	ΔP_{AB}	K_{AB}
Solutés du groupe G1		
Trichloro-1,1,1 éthane	200±20	0,2±0,1
Trichloro-1,1,1 trifluoro-2,2,2 éthane	50±3	0,6±0,1
Dichloro-1,1 éthane	133±7	0,6±0,1
Pentachloroéthane	163±8	2,1±0,3
Solutés du groupe G2		
Dichloro-1,2 éthane	82±4	1,6±0,2
Dibromo-1,2 éthane	40±2	1,9±0,2
Tétrachloro-1,1,2,2 éthane	317±15	2,6±0,3
Tétrabromo-1,1,2,2 éthane	190±20	4,3±0,9

NOTA : La très faible auto-association de la *N*,*N*-diméthylacétamide (23) ne perturbe pas les résultats indiqués ci-dessus.

préparé présente une valeur de ϵ_{BS} assez différente de ϵ_S même pour des concentrations très petites de l'espèce B.

Assez systématiquement nous observons P exp. $< P$ calc. et l'écart entre ces deux polarisations devient de plus en plus grand (jusqu'à 10%) quand ϵ_{BS} augmente de façon sensible. S'agissant de systèmes exempts d'interaction, quelles peuvent donc être les causes de tels écarts entre P exp. et P calc. ? Nous pouvons supposer que l'utilisation des expressions d'effet normal de solvant, non adaptées aux systèmes ternaires dans le cas de solvant polaire B_S, nous conduise ainsi à des valeurs erronées de P calc. En fait, en se référant aux travaux d'Abraham et de Barclay–Le Fèvre, plusieurs considérations nous permettent de rejeter cette proposition. En conséquence, il apparait alors que cette anomalie ne peut que provenir de l'adoption de la méthode d'extrapolation à dilution infinie de Halverstadt et Kumler utilisée pour déterminer la valeur de $P_{A\infty/BS}$.

$$[10]\quad P_{A\infty/BS} = P_S + \lim_{w_A\to 0}\left(\frac{\partial P_{ABS}}{\partial w_A}\right) - \lim_{w_A\to 0}\left(\frac{\partial P_{BS}}{\partial w_A}\right)$$

Smith (22) considère que le dernier terme de [10] est négligeable quand le solvant utilisé est apolaire et w_A petit. Aussi ce terme est traditionnellement négligé, certainement par suite de la grande difficulté de l'évaluer avec précision pour des systèmes semblables à ceux que nous considérons dans cette étude.

Or dans le cas d'un solvant mixte composé d'un soluté polaire dilué dans un solvant apolaire l'introduction du terme

$$\lim_{w_A\to 0}\left(\frac{\partial P_{BS}}{\partial w_A}\right)$$

dans l'équation de Halverstadt et Kumler utilisée s'impose (5). Ce qui vient d'être indiqué au sujet de l'expression proposée par Halverstadt et Kumler, peut s'appliquer aussi à plusieurs autres formules d'extrapolation à dilution infinie disponibles dans la littérature. Nos expériences précises sur les systèmes témoins nous ont permis alors d'évaluer ce terme, et de calculer correctement $P_{A\infty/BS}$ à introduire dans l'expression de Cleverdon, Collins et Smith.

Compte-tenu des remarques précédentes nous sommes parvenus aux résultats suivants (tableau 7).

Nous disposons d'assez peu de données pour vérifier totalement la qualité des valeurs de K_{AB} que nous indiquons tableau 7. Pour les systèmes dichloro-1,1 éthane/*N*,*N*-diméthylacétamide/cyclohexane et pentachloroéthane/*N*,*N*-diméthylacétamide/cyclohexane étudiés par calorimétrie (M. Lakraïmi, résultats non publiés) nous avons respectivement :

$$K_{AB} = 0{,}7 \pm 0{,}2\ L\ mol^{-1}, \qquad -\Delta H = 17 \pm 2\ kJ\ mol^{-1}$$

et

$$K_{AB} = 3{,}0 \pm 0{,}3\ L\ mol^{-1}, \qquad -\Delta H = 14 \pm 2\ kJ\ mol^{-1}$$

Nous avons noté, toutefois, une très grande analogie entre nos propres résultats et ceux publiés par Dumas *et al.* (3) concernant les systèmes voisins (dérivés halogénés du méthane/*N*,*N*-diméthylacétamide/cyclohexane). Ces arguments nous suffisent déjà pour considérer ces résultats comme satisfaisants. En effet nous avons pu constater sur de nombreux exemples publiés que la prise en compte de termes correctifs (tels ceux indiqués ci-dessus) dans l'expression de Cleverdon, Collins et Smith permettait d'exploiter avec plus de certitude les données expérimentales ... au point de trouver des valeurs de K_{AB} identiques à celles obtenues par d'autres techniques physico-chimiques.

Conclusion

Disposant de procédures d'évaluation de l'effet normal de solvant acceptables, il est maintenant possible d'entreprendre en polarisation diélectrique toute étude structurale et thermodynamique des interactions entre les dérivés halogénés de l'éthane et les amides (ou toute autre espèce de caractère basique).

Retardation of Cd^{2+} and Zn^{2+} discharge at the dropping mercury electrode by adsorbed phenyl substituted phosphonium cations

A. ANASTOPOULOS, A. CHRISTODOULOU, AND I. MOUMTZIS

Laboratory of Physical Chemistry, Chemistry Department, Aristotelian University of Thessaloniki, 54006 Thessaloniki, Greece

Received April 1, 1987[1]

A. ANASTOPOULOS, A. CHRISTODOULOU, and I. MOUMTZIS. Can. J. Chem. **66**, 1053 (1988).

The effect of adsorbed propargyltriphenyl- and vinyltriphenylphosphonium cations on the discharge of Cd^{2+} and Zn^{2+} at dropping mercury electrode is studied by direct current polarographic measurements. Adsorption characteristics are determined by capacitance measurements. The size parameters of the activated complex and the surfactant particles are derived and an elucidation of the mechanism of the inhibited reaction is attempted.

A. ANASTOPOULOS, A. CHRISTODOULOU et I. MOUMTZIS. Can. J. Chem. **66**, 1053 (1988).

Utilisant des mesures polarographiques à cd, on à étudié l'effet des cations adsorbés de propargyltriphényl- et de vinyltriphénylphosphonium sur la décharge du Cd^{2+} et le Zn^{2+} au dme. On a déterminé les caractéristiques d'adsorption à l'aide de mesures de capacitance. On à dérivé les paramètres de taille du complexe activé et des particules d'agent de surface et on a essayé d'élucider le mécanisme de la réaction inhibée.

Introduction

The study of the inhibitory action of surface active substances undergoing interfacial transformations on simple electrode reactions can be used as a means for testing the extent of applicability of the existing theories and equations (1, 2).

Although the above theories are developed assuming no irregularities during film formation, systems exhibiting interfacial rearrangements (3–5) are found to be in noticeable agreement to the relevant equations. However, we encountered difficulties in correlation of the size parameters. These difficulties can be resolved (3) when the structure of the activated complex and the reaction paths followed are properly determined.

In these frames, the study of phosphonium cations, which in aqueous solutions are known to present irregular development of the adsorption film, would be of interest for the elucidation of the reaction mechanism at high coverages with ionic surfactants. Earlier publications remained qualitative (6) or reached a quantitative level (7, 8) concerning the inhibitory action of the phosphonium cations.

In the present work we attempt a systematic examination of the influence of propargyltriphenylphosphonium bromide ($PgPh_3PBr$) and vinyltriphenylphosphonium bromide (VPh_3PBr) on the Cd^{2+} and Zn^{2+} deposition at the dropping mercury electrode (dme). Here, the size ratio, $r\neq/r_i$, obtained at $0.80 < \theta$ is correlated to an independently determined number of solvent molecules replaced at the interface by each activated complex, $r\neq$, and surfactant particle, r_i, with respect to recent theories (3) on the structure of the activated complex.

Experimental

Direct current polarographic measurements of current against potential and time at the dme, were performed by Radiometer PO-4 and Metrohm Polarecord E-504 systems. The later was also used for phase selective capacitance measurements performed with a 10 mV p.p. signal at a frequency of 75 Hz and a voltage scan rate of 2 mV s^{-1}. A Houston Instrument Omnigraphic 2000 X-Y recorder was used for recording the i–t curves. The dme had a flow rate of 2.12 mg s^{-1} at a reservoir height of 40 cm and an open circuit drop time of 5 s, restricted to 3 s during the i–E and C–E measurements.

The out-of-phase capacitance current vs. potential curves of aqueous 0.2 M KNO_3 were calibrated against Payne's data (9). The reproducibility of the differential capacitance values at the potential region from −1.60 V(SCE) was always better than 1% deteriorating to 1.5–2% at the positive and negative extremes of the potential scale. The reproducibility of the i–E measurements was of the order of 0.5%, while some problems in locating current zero of i–t curves led to a reproducibility of the order of 1–1.5%. All solutions were bubbled by a stream of nitrogen saturated with vapours of the supporting electrolyte solution. All potentials were measured against a large area calomel electrode saturated with KCl. Temperature was kept constant at 25 ± 0.05°C.

Water and mercury were used after double distillation. KNO_3 (Merck, puriss p.a.) and $PgPh_3PBr$ (Fluka, purum) were used without further purification. VPh_3PBr (Fluka, pract. >95%) was twice recrystallized from water–ethanol solutions, and dried at 140°C under reduced pressure.

Results and discussion

Adsorption characteristics of $(PgPh_3P)^+$ and $(VPh_3P)^+$ cations

The adsorption of $PgPh_3PBr$ and VPh_3PBr from 0.2 M KNO_3 aqueous solutions at the dme was studied by means of capacitance measurements for surfactant concentrations ranging from 0.065 to 0.5 mM. The differential capacitance vs. potential curves of aqueous 0.2 M KNO_3 in the presence of VPh_3PBr and $PgPh_3PBr$ additions are given in Figs. 1 and 2, respectively.

As it is seen from Figs. 1 and 2, at concentrations higher than 0.10 mM and for a wide potential range, the capacitance values are practically independent of concentration, indicating the attainment of full coverage of the electrode surface. The irregular shape of the C vs. E curves reveals the occurrence of interfacial rearrangements during film formation, which in the case of Fig. 2 are usually identified with association or condensation of the adsorbed particles. The irregularities during film formation are also reflected to the i–t polarographic curves obtained at the potential region −0.8 to −1.5 V(SCE). Two sets of such curves are provided in Fig. 3.

Curves of this type are known to represent surface coverages controlled by adsorption rate. This may be due (10) to a reduced rate of transfer of the surface active particles from the dissolved into the adsorbed state or to slow association or condensation reaction of the particles in the adsorbed state. The very good linearity (Table 1) of the relation between the time t_s required for saturation coverage and the inverse square of the surfactant

[1]Revision received January 7, 1988.

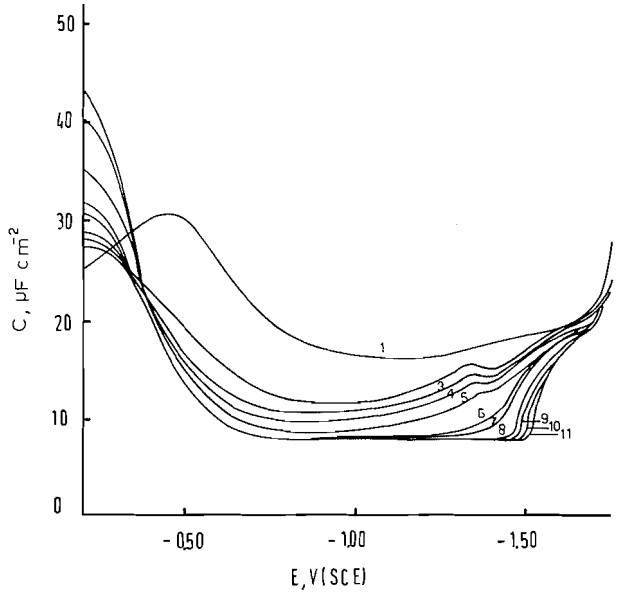

FIG. 1. Dependence of the differential capacitance of the dme against the electrode potential for the following additions of VPh_3PBr in m*M*: (*1*) 0.0, (*2*) 0.065, (*3*) 0.08, (*4*) 0.09, (*5*) 0.10, (*6*) 0.125, (*7*) 0.15, (*8*) 0.20, (*9*) 0.30, (*10*) 0.40, and (*11*) 0.50. Base solution: aqueous 0.2 *M* KNO_3.

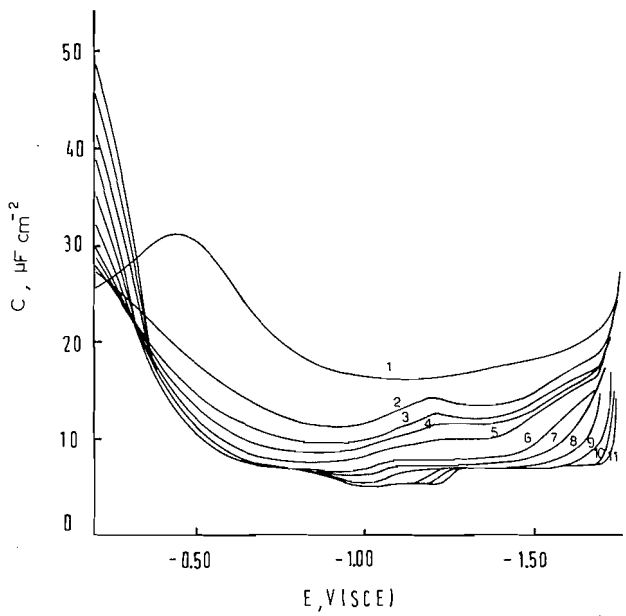

FIG. 2. Dependence of the differential capacitance of the dme against the electrode potential for the following additions of $PgPh_3PBr$ in m*M*: (*1*) 0.0, (*2*) 0.065, (*3*) 0.08, (*4*) 0.09, (*5*) 0.10, (*6*) 0.125, (*7*) 0.15, (*8*) 0.20, (*9*) 0.30, (*10*) 0.40, and (*11*) 0.50. Base solution: aqueous 0.2 *M* KNO_3.

bulk concentration c, according to the relation:

$$[1] \quad t_s = 1.82 \times 10^6 \frac{\Gamma_s^2}{Dc^2}$$

implies that the transfer of the surfactant particles from the dissolved to the adsorbed state is diffusion controlled. Diffusion step is thus presumed to be followed by a time-dependent variation of the electrode coverage, produced by slowly progressing structural changes in the adsorbed film.

The form of the *i–t* curves of Fig. 3 shows that, except for

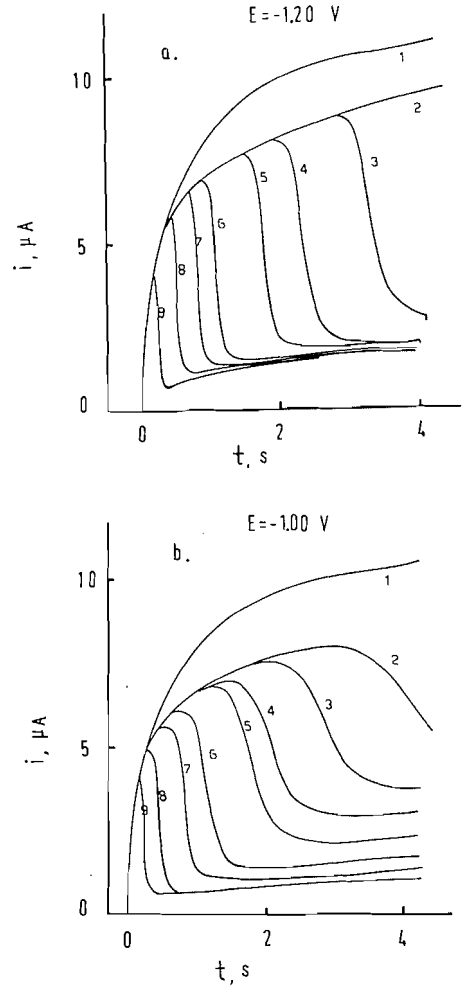

FIG. 3. Polarographic current–time curves for the Cd^{2+} reduction in the presence of the following additions of (*a*) $PgPh_3PBr$ and (*b*) VPh_3PBr in m*M*: (*1*) 0.0, (*2*) 0.065, (*3*) 0.08, (*4*) 0.09, (*5*) 0.10, (*6*) 0.125, (*7*) 0.15, (*8*) 0.20, and (*9*) 0.30. Base solution: aqeuous 0.2 *M* KNO_3. Potentials shown by the figures.

very dilute solutions ($c < 0.1$ m*M*), within the 3 s of the controlled drop time used for *i–E* and *C–E* measurements, the current reaches to a steady state value which can be identified with the weakly time dependent values following its initial increase and the subsequent sudden decrease.

Although full thermodynamic equilibrium is eventually not attained, it can be assumed that the steady state values represent some sort of quasi equilibrium state of the surface coverage under the given conditions of polarization, concentration, temperature, etc.

Figure 3 also shows that in the case of $PgPh_3PBr$ for $c \geq 0.125$ m*M* and $t \gtrsim 1.2$ s, and in the case of VPh_3PBr for $c \geq 0.15$ m*M* and $t \gtrsim 1.0$ s, *i–t* curves almost coincide, thus revealing the fulfillment of the condition $\theta \simeq 1$.

The application of eq. [1] permits the determination of Γ_s, the surface concentration at saturation, which is provided in Table 1. For this calculation, the value of the diffusion coefficient, D, of both organic surfactants equals $(5 \pm 0.2) \times 10^{-6}$ cm^2 s^{-1}, derived polarographically, is used.

The test of our adsorption data against the Frumkin isotherm:

$$[2] \quad \ln \frac{\theta}{(1-\theta)c} = \ln \beta + 2\alpha\theta$$

	−1.00	2.0_2	1.9_4	0.966	Limited agreement			0.880
	−1.10	2.6_7	1.6_6	0.972	Limited agreement			0.865
	−1.20	2.5_3	1.6_2	0.974	No agreement			<0.80

has revealed a very satisfactory agreement as it is evident from the values of the correlation coefficient, R^2, of the linear regression method employed.

The coverage values used in eq. [2] — and hereafter — are determined, in the potential region from −0.90 to −1.30 V, by means of the known (11) relation:

$$[3] \quad \theta_{app} = (c_0 - c)/(c_0 - c_s)$$

and they evidently are of apparent character.

In eq. [2] and Table 2, β is the adsorption equilibrium constant and α is the interaction parameter. The Frumkin isotherm is valid for values of the interaction parameter greater than 1. The values of the interaction parameter must not be correlated to attractive adsorbate–adsorbate interactions, but to positive deviations of the interfacial solvent–adsorbate system from Raoult's law (12).

On the other hand, Flory–Huggins isotherm:

$$[4] \quad \ln \frac{\theta}{c} = \ln \beta + r_i \ln (1 - \theta) + 2\alpha r_i \theta$$

was used for the independent determination of the number, r_i, of water molecules replaced by one adsorbate particle. As it is seen from Table 2, Flory–Huggins isotherm generally fails to describe the adsorption of VPh_3PBr as it is evident from the values of the correlation coefficient, R^2, of the multi-linear regression method used for the fit of eq. [4]. However, good agreement is obtained between the adsorption data of $PgPh_3PBr$ and eq. [4] for $r_i \simeq 1$, which is the case of Frumkin isotherm.

As far as the adsorption equilibrium constant, β, is a measure of the adsorbability of each adsorbate, the maximum value attained at $E = -1.1$ V(SCE) (Table 2) indicates that this potential may be approximately related to the point of maximum adsorption. However, this criterion allows only a rough determination of the potential of maximum adsorption, which can be more accurately defined by means of charge-potential curves (11). Nevertheless, due to the lack of such curves, we confined our discussion only to adsorption data obtained at the potential range: $-1.0 \leq E \leq -1.2$ V(SCE), i.e. at the neighbourhood of maximum adsorption, where relation [3] is applicable (11). In these frames, the values of Γ_s obtained are for both substances equal (Table 1) to about 2.5×10^{-10} mol cm^{-2}, equivalent to a value of an area per adsorbate particle of 66 Å^2. This value is in reasonable agreement with $S_{(PgPh_3P)^+} \simeq 70$ Å^2 and $S_{(VPh_3P)^+} \simeq 64$ Å^2, estimated by space filling models, when an orientation of the adsorbed phosphonium cations with the two phenyl groups and the alhyl residue towards the electrode surface is adopted. This orientation must be favoured at cathodic polarizations as far as the alternative orientation with the three phenyl groups in contact to the electrode, leading to an area of 77 Å^2, is more likely not to be favoured at potentials negative to −1.00 V(SCE). The experimental value of 66 Å^2, when correlated to the area per adsorbed water (13) molecule, $S_{H_2O} = 12.3$ Å^2, gives $r_i \simeq 5$.

The validity of the Frumkin isotherm for both adsorbates examined enables one to claim that each phosphonium cation replaces at the interface a cluster of 5 water molecules. However, the replacement at the interface of solvent associates by adsorbate particles (14) has been critically discussed (15, 16) and for this reason the above results are reported with some caution.

Inhibition characteristics of $PgPh_3PBr$ and VPh_3PBr

Figures 4 and 5 give the maximum instantaneous polarographic current against potential curves of Cd^{2+} and Zn^{2+} discharge, respectively, in the presence of VPh_3PBr and $PgPh_3PBr$. These polarographic curves show the strong inhibitory effect of even small additions of both surfactants on the reduction of Cd^{2+} and Zn^{2+}. The increase of adsorbate concentration does not seem to lead to a remarkable coincidence of the i–E curves at high negative potentials. This means that at these potentials (negative to −1.2 V/SCE) the rate of the electrode reactions is concentration-dependent, even at poten-

tials and concentrations at full coverage as evidenced from the *C–E* curves of Figs. 1 and 2.

Minima are observed in the curves of Figs. 4*a* and 5*a*, which at higher concentrations approximately mark the position of the adsorption maximum ($\simeq -1.15$ V/SCE for VPh_3PBr and $\simeq -1.05$ V/SCE for $PgPh_3PBr$). The form of the curves of Fig. 5*a* is more composite than those of Fig. 4*a*, evidently because of the interfacial rearrangements observed during the development of the adsorption film of $(PgPh_3P)^+$ cations. These rearrangements are not reflected in the form of the curves of Fig. 4*b*.

The curves of Fig. 4*a* are similar to those reported for $C_5H_{11}(C_2H_5)_2PO$, $C_6H_{13}(C_2H_5)_2PO$ (3), and $C_8H_{17}(CH_3)_2PO$ (4), while the curves of Fig. 5*a* look much like those of $[(C_6H_5)_3CH_3P]ClO_4$ (8). The formal rate constants of Cd^{2+} and Zn^{2+} discharge were determined from the *i–E* curves by the

standard Koutecký procedure (17) at the potential range from -0.8 to -1.2 V(SCE) for Cd^{2+} and -1.1 to -1.3 V(SCE) for Zn^{2+}. The cathodic limits of our study were selected to avoid any complications introduced from the discharge of the phosphonium cations which occur in the vicinity of -1.7 V(SCE).

The rate constants were used for the determination of the size ratio $r\neq/r_i$ by means of the known (1) equation:

TABLE 3. Experimental values of the size ratio $r\neq/r_i$ calculated with eq. [5]

$$[5] \quad \ln k_F = -\left(\frac{r\neq}{r_i}\right) \ln c_i + \text{constant}$$

at surfactant concentrations, c_i, greater than 0.1 mM in order to assure coverage values greater than 0.8. The values of the diffusion coefficients of Cd^{2+} and Zn^{2+} employed were found polarographically equal to 6.9×10^{-6} and 6.3×10^{-6} $cm^2 s^{-1}$, respectively, with the reproducibility reported in the experimental part for the polarographic measurements. The results of these calculations are provided in Table 3.

Table 3 shows that the values of $r\neq/r_i$ are always greater than 1.00 and usually greater than 1.50, showing a tendency to increase with increasing negative potentials. Better fit of experimental results to eq. [5] is obtained in the presence of VPh_3PBr, where the correlation coefficient of the linear regression fit is always better than 0.96 for concentrations greater than 0.1 mM and in the potential range $-0.80 < E < -1.3$. Within the above concentration and potential range in the presence of $PgPh_3PB_r$ the correlation coefficient of the linear regression fit to eq. [5] ranges from 0.86 to 0.95. In both cases the fit deteriorates with increasing cathodic potentials.

A discussion about the effect of the presence of $(PgPh_3P)^+$ and $(VPh_3P)^+$ cations on the Cd^{2+} and Zn^{2+} reduction can be carried out by determining the structure of the activated complex through the estimation of its cross-sectional area, $S_{\neq}$. This can be achieved either by deriving the $r\neq = S_{\neq}/S_{H_2O}$ values at $0 < \theta < 1$ by means of the equations (1, 2, 18–20):

$$[6] \quad \log k_F = \log k_0 + r\neq \log (1 - \theta)$$

or

$$[7] \quad \log k_F = \log k_0 + r\neq \log (1 - \theta) - \frac{A_{\neq,i}}{2.3}\theta$$

or by correlating the $r\neq/r_i$ values of Table 3 obtained at $\theta \rightarrow 1$ to the areas occupied by each adsorbate and water molecule viz. $S_{org.}$ and S_{H_2O}, respectively. To start with the former we applied eqs. [6] and [7] to coverage data obtained by eq. [3] from capacitance measurements at the potential range $-1.00 < E < -1.20$ V(SCE), where the potential of maximum adsorption is found to exist. The results of these calculations are collected in Table 4.

To apply eq. [7] a multilinear regression procedure was followed, using $r\neq$ and the interaction parameter $A_{\neq,i}$ as adjustable parameters. This method was used instead of that proposed by Afanas'ev (20) because for the latter the graphical determination of the term $d \ln (k_\theta/k_0)/d\theta$ was found to produce important errors.

However, regardless of the good fit of our data to eqs. [6] and [7], as deduced from the values of R^2 provided in Table 4, the values of $r^{\neq} = S_{\neq}/S_{H_2O}$ lead to $S_{\neq} < S_{H_2O}$, which can hardly be regarded as representing the cross-sectional area of a fully or even a partially hydrated reactant particle. Following the alternative procedure we combined the $r\neq/r_i$ values of Table 3 with the values $S_{H_2O} = 12.3$ Å^2 and $S_{(VPh_3P)^+} \simeq S_{(PgPh_3P)^+} \simeq 66$ Å^2. The resulting $S_{\neq}$ values are collected in Table 5.

The values of $S_{\neq}$ in Table 5 when correlated to the values of $S_{(PgPh_3P)^+}$, $S_{(VPh_3P)^+}$, and S_{H_2O} cannot be viewed as values for hydrated reactant particles. At first sight, they seem to correspond to a reactant–surfactant complex which incorporates a number of 4–5 water molecules. However, the latter case presents some notable weakness. At $\theta \simeq 1$, where the values of $r^{\neq}/r_i$ were determined, the water concentration is very low and therefore the availability of such a number of water molecules cannot be justified. In addition, the positive charges of both reactant and surfactant do not favour the formation of such a complex. On the other hand, there are no indications for concentration independence of the k_F values leading to $r^{\neq}/r_i \simeq 0$, which is the criterion (3) for the occurrence of a surface association reaction between reactant and surfactant preceding the discharge step. The discharge of a fully or partially hydrated reactant ion possibly occurs at low coverages. However, the $S_{\neq}$ values obtained from eqs. [6] and [7] for a wide range of coverage values, $0 < \theta < 1$, are generally smaller than the cross-sectional area of 12.3 Å^2 corresponding to a single H_2O molecule. On the other hand, the i–t curves of Fig. 2 show that the reduction of Cd^{2+} and Zn^{2+} is taking place even at a fully covered electrode surface and also that the polarographic current increases with time even at concentrations where $\theta \simeq 1$.

At low coverages the electrode surface is almost saturated with water molecules, while at high coverages the reactant ions are separated from the electrode surface by a layer saturated with $(VPh_3P)^+$ or $(PgPh_3P)^+$ cations. Therefore, in passing from low to high coverage a change in the reaction mechanism can be reasonably suggested. To the extent that neither the

polarographic i–E curves of Figs. 4 and 5 nor the C–E curves of Figs. 1 and 2 gave some of the known (5) indications of micelle formation, within the concentration range examined, we have to look for some other reaction channel at $\theta \simeq 1$.

In analogy to the views of Jehring (21) and the data reported by Kůta *et al.* (22), we can suppose that a condensation reaction of the adsorbed phosphonium cations might lead to the creation of dense and diluted parts in the adsorption layer. Through these holes the Cd^{2+} and Zn^{2+} discharge takes place at rates gradually decreasing with increasing adsorbate concentrations. However, to the extent that our ac and dc polarographic measurements do not offer a quantitative basis for the safe determination of the inhibited reaction mechanism, which would be possibly enabled by admittance measurements, this assumption remains to a phenomenological level.

Approaches towards the synthesis of a 2,9,16,23-tetrasubstituted phthalocyanine as a pure isomer

SHAFRIRA GREENBERG, A. B. P. LEVER, AND CLIFFORD C. LEZNOFF[1]
Department of Chemistry, York University, North York (Toronto), Ont., Canada M3J 1P3

Received June 26, 1987

SHAFRIRA GREENBERG, A. B. P. LEVER, and CLIFFORD C. LEZNOFF. Can. J. Chem. **66**, 1059 (1988).

Treatment of 4-neopentoxyphthalonitrile with hydrogen sulfide gas yielded 1-imino-6-neopentoxy-3-thioisoindoline and 1-imino-5-neopentoxy-3-thioisoindoline, which on alkylation with iodomethane gave 1-imino-3-methylthio-6-neopentoxyisoindolenine and 1-imino-3-methylthio-5-neopentoxyisoindolenine. The methylthioisoindolenines readily condensed at room temperature to a mixture of tetrasubstituted phthalocyanines and a series of linear open-chained purple compounds characteristic of isoindigos, while condensation at −20°C in the presence of zinc acetate gave, in at least one experiment, 2,9,16,23-tetraneopentoxyphthalocyanine as a pure isomer. The low temperature formation of phthalocyanines is remarkable and the syntheses described herein provide guidelines for the synthesis of pure isomers of 2,9,16,23-tetrasubstituted phthalocyanines. The purple and red compounds are shown to have isoindigo structures rather than a ring-opened phthalocyanine structure as previously reported.

SHAFRIRA GREENBERG, A. B. P. LEVER et CLIFFORD C. LEZNOFF. Can. J. Chem. **66**, 1059 (1988).

La réaction du néopentoxy-4 phtalonitrile et du sulfure d'hydrogène gazeux conduit à l'imino-1 néopentoxy-6 thio-3 isoindoline et à l'imino-1 néopentoxy-5 thio-3 isoindoline qui, par alkylation avec l'iodométhane, conduisent à l'imino-1 méthylthio-3 néopentoxy-6 isoindoline et à l'imino-1 méthylthio-3 néopentoxy-5 isoindoline. À la température ambiante, les méthylthioisoindolines se condensent facilement pour donner un mélange de phtalocyanines tétrasubstituées et une série de composés linéaires pourpres caractéristiques des isoindigos; par ailleurs, une condensation à −20°C, en présence d'acétate de zinc, a conduit—au moins dans une expérience—à la tétranéopentoxy-2,9,16,23 phtalocyanine sous la forme d'un isomère pur. La formation de phtalocyanines à basse température est remarquable et les synthèses décrites dans ce travail fournissent des indications sur les méthodes de synthèse des isomères purs des phtalocyanines substituées en 2,9,16,23. On a démontré que les composés pourpre et rouge possèdent des structures reliées à celle de l'isoindigo plutôt que des structures reliées à celle de la phtalocyanine qui avaient été suggérées antérieurement.

[Traduit par la revue]

Tetrasubstituted phthalocyanines having one substituent on each of the four benzo rings of phthalocyanine have been known for some time (1) but have received more attention recently due to their importance in electrocatalytic studies (2, 3). Most tetrasubstituted phthalocyanines are prepared by self-condensation of a suitable 3 or 4-substituted phthalonitrile or derivative (4, 5). For example, the isoindoline of 4-neopentoxyphthalonitrile will, upon condensation, give not only 2,9,16,23-tetraneopentoxyphthalocyanine (**1**) but also the 2,10,16,24-, 2,9,17,24-, and 2,9,16,24-tetraneopentoxyphthalocyanine isomers (6, 7). Indeed, we have shown that the 2,9,16,23-tetraneopentoxyphthalocyanine zinc(II) (**2**) derivative exhibited peaks in its ^{1}H nmr spectrum, indicating the presence of seven of the possible eight environments collectively present in the four isomers (7). A full discussion of this phenomenon was also recently demonstrated for some quaternized tetra-2,3-pyridinoporphyrazines (8). In this latter example, it was suggested that steric considerations favoured the symmetrical isomer, having C_{4h} symmetry, but that the other isomers were present in lesser amounts. Virtually all tetrasubstituted phthalocyanines known in the literature (1) exist as a mixture of the four possible isomers, and in the case of substituents at the 2 position are usually referred to as the 2,9,16,23-tetrasubstituted isomer. On the other hand, in a very recent paper, Gaspard and Maillard (9) have succeeded in preparing the pure isomer 2,9,17,24-tetra-*tert*-butylphthalocyanine zinc(II), using metallic zinc as the condensing agent.

In connection with our studies on multinuclear phthalocyanine (6, 7, 10) and with the possibility of obtaining one pure isomer of a binuclear phthalocyanine for X-ray diffraction studies, we were interested in exploring synthetic methods of phthalocyanine formation that could give rise exclusively to the 2,9,16,23-tetrasubstituted phthalocyanines as one isomer. In a previous paper we showed that dithioamides do form phthalocyanines with diiminoisoindolines at modest temperatures (11). We envisioned that a 5-substituted iminothioamide should self-condense in one direction to form exclusively a 2,9,16,23-tetrasubstituted phthalocyanine as one isomer, because the imino group on one side of the molecule should displace selectively the methythio group on the other side of a second molecule. It turns out that treatment of phthalonitrile (**3**) with hydrogen sulfide gas gives 1-imino-3-isoindoline (**4**) directly, as reported by Baguley and Elvidge (12), but **4** does not readily condense to phthalocyanine under normal conditions (4, 5). Despite the fact that we were unable to successfully *S*-alkylate dithioamides (11) under a variety of conditions, we found that the iminothioamide **4** is readily alkylated to a separable mixture of *N*-methyl-2,3-dihydro-3-thioxo-1*H*-isoindol-1-one (**5**) and 1-imino-3-methylthioisoindolenine (**6**). The *S*-alkyl derivative **6** readily condenses to phthalocyanine (**7**) under the usual conditions but *at room temperature* instead of 150°C (Scheme 1).

This encouraging result led us to examine the possibility of using a *substituted* 1-imino-3-methylthioisoindolenine in the *exclusive* formation of 2,9,16,23-tetrasubstituted phthalocyanines as one isomer. Treatment of 4-neopentoxyphthalonitrile (**8**) with hydrogen sulfide (12) gave a mixture of 1-imino-6-neopentoxy-3-thioisoindoline (**9**) and 1-imino-5-neopentoxy-3-thioisoindoline (**10**), separable by flash chromatography (13). In separate experiments pure **9** and **10** were treated with iodomethane to give 1-imino-3-methylthio-6-neopentoxyisoindolenine (**11**) and 1-imino-3-methylthio-5-neopentoxyisoindolenine (**12**) respectively. In separate experiments, compounds **11** and **12** self-condensed spontaneously *at room temperature* to 2,9,16,23-tetraneopentoxyphthalocyanine (**1**), *as a mixture*

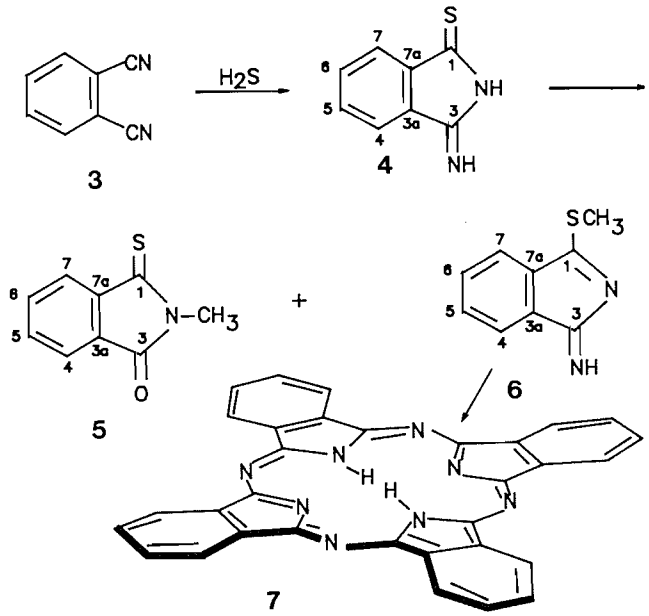

SCHEME 1

of isomers as analyzed previously by ^{1}H nmr spectroscopy (7). In addition a mixture of purple coloured compounds (**13–16**) could be recovered by flash chromatography. The assignments of the structures of compounds **13–16** remain tentative and are based on mass spectroscopy, high resolution mass spectroscopy, nmr, and uv/vis spectroscopy. Mass spectroscopy of this mixture of purple compounds could be accounted for by a mixture of compounds (**13–16**) exhibiting parent ions for all of the compounds. Further purification gave small quantities of pure **13** and **14**, whose structures are consistent with their exact high resolution mass spectra (see Experimental). Interestingly, the ^{1}H nmr spectra of **13** and **14** were consistent with the assigned structures but the absorptions for the neopentoxy substituents indicated that **13** and **14** were formed as one isomer each and that mixtures of isomers in which the position of the neopentoxy groups was different in each benzo ring were not obtained. Alternatively, the absorptions of the different positional isomers of **13** and **14** could have been coincident but this possibility is unlikely.

We were interested in characterizing the precursors **4–6** and **9–11** by ^{13}C nmr spectroscopy but found that it was necessary to obtain ^{13}C nmr spectra of pure 1,3-diimino-5-neopentoxyisoindoline (**17**) (see Experimental) and monoiminophthalimide (**18**) (14) (Fig. 1). Using the ^{13}C nmr of **17** and **18** it was possible to assign the absorptions of **4–6** and **9–11** (Table 1). In addition, the uv spectra of **4–6**, **9–11**, and **17** are recorded in Table 2.

It is well known that aromatic thioamides undergo condensation to isoindigo dyes (12), so that the formation of **13–16** is not too surprising. The presence of the neopentoxy substituents of **13–16** solubilized these normally poorly soluble compounds and allowed us to effect a separation to isolate pure **13** and **14**. The uv/vis spectra of **13** and **14** are unique and neither resembles phthalocyanines nor isoindigos. In a recent paper Fujiki *et al.* (15) describe the preparation of a hydroxygermanium(IV) α,β,γ-triazabenzcorrole formed by a ring contraction of dichlorogermanium phthalocyanine. Illumination of this corrole derivative is reported (15) to give a red compound whose uv/vis is identical to **13** and **14**. These authors propose three structures **19–21** for their red compound, none of which would be consistent with the carbon–carbon double bond structure of **13** and **14**. In light of our results a possible structure for their red compound could be illustrated below.

A representation of their red compound by the structure **22** in Fig. 2 would be likely and would not involve cleavage of a carbon–carbon double bond. Repetition of the work of Fujiki *et al.* (15) using neopentoxy-substituted phthalocyanines would give soluble derivatives of their red compound that could be purified and adequately characterized.

Condensation of **11** or **12** at −20°C in dimethylformamide (DMF) and using $Zn(OAc)_2$ as a template for macrocycle formation gave **2** directly and a mixture of purple compounds, likely **13–16**. In two experiments, condensation of **11** or **12** led to 2,9,16,23-tetraneopentoxyphthalocyanine **2** as mainly one isomer when examined by ^{1}H nmr spectroscopy (Table 3), but larger scale preparations of this reaction again led to **2**, but only as a mixture of isomers. Of course, both 2,9,16,23-tetraneopentoxyphthalocyanine (**1**) and 2,10,16,24-tetraneopentoxyphthalocynanine should exhibit only one peak for the *tert*-butyl groups and the method of synthesis should favour **1**, but the formation of the latter isomer cannot be entirely excluded. It should be pointed out that the mixture of isomers thus obtained was not identical to the statistical distribution of isomers of **2** previously reported (7) (Table 3).

In summary, we have demonstrated the remarkable low temperature formation of phthalocyanines from iminomethylthioisoindolenines, have aided in the characterization of the coloured by-products formed in these as similar reactions, and have initiated experiments directed towards the isolation of pure isomers of tetrasubstituted phthalocyanines.

Experimental

Matheson high purity argon was used to maintain inert atmosphere conditions. Infrared (ir) spectra were recorded on a Pye Unicam SP1000 infrared spectrophotometer using KBr discs for solids or as neat films between NaCl discs. Nuclear magnetic resonance (nmr) spectra for carbons and protons were recorded on a Bruker AM300 nmr spectrometer using deuterochloroform as a solvent and tetramethylsilane as the internal standard unless otherwise stated. The positions of the signals are reported in δ units. (The splittings of the signals are described as singlets (s), doublets (d), triplets (t), quartets (q), or multiplets (m).)

The visible–ultraviolet spectra (uv) were recorded on a Hewlett Packard HP8451A Diode Array spectrophotometer. Mass spectra (ms) were recorded at 70 eV on a VG Micromass 16F mass spectrometer in the EI mode.

Melting points (mp) were determined using a Kofler hot stage melting point apparatus and are uncorrected. Thin-layer chromatography (tlc) was performed using silica gel G as the adsorbent. Flash chromatography was performed using silica gel of particle size 20–45 μm. All reactions were stirred with a magnetic stirrer. All solvents were freshly distilled before use. Microanalyses were performed by Guelph Chemical Laboratories Ltd., Guelph, Ont.

Purification of 5-neopentoxy-1,3-diiminoisoindoline (17)

The crude 5-neopentoxy-1,3-diiminoisoindoline obtained from 134 mg of 4-neopentoxyphthalonitrile (0.63 mmol) by standard procedure (6) was dissolved in ethyl acetate, washed with water, and dried over anhydrous magnesium sulfate. Evaporation of the ethyl acetate and recrystallization from ethyl acetate/hexanes gave in 68% yield 98 mg of pure 5-neopentoxy-1,3-diiminoisoindoline as white crystals, mp 200–203°C; ir (cm^{-1}): 3260 (NH), 3200 (NH), 1695, 1650, 1620–1600, 1540, 1450, 1440, 1315, 1240, 1140, 1065, 1020, 885, 820; ^{1}H nmr δ: 7.59 (d, J = 8.4, 1H), 7.24 (br, 1H), 7.12 (dd, J = 8.4, 2.1, 1H), 3.70 (s, 2H, CH_2O), 1.06 (s, 9H, $(CH_3)_3C$); ms m/z: 231 (M^+, 25), 161 (M^+ − 70, 80), 71 (38), 57 (47), 43 (100). *Anal.* calcd. for $C_{13}H_{17}N_3O$: C 67.51. H 7.41, N 18.17; found: C 68.01, H 7.74, N 18.05.

SCHEME 2

1-Imino-3-thioisoindoline (4)

The 1-imino-3-thioisoindoline was prepared from phthalonitrile and sodium hydrogen sulfide according to the procedure of Baguley and Elvidge (12), mp 220°C (dec.) (lit. (12) mp 218°C); ir (cm^{-1}): 3160 (NH), 1665, 1465, 1390, 1290, 1270, 1240, 1080, 910, 765, 675; ^1H nmr (DMSO-d_6) δ: 10.88 (vbr. 2H, NH), 7.99 (d, J = 7.3, 1H), 7.81–7.67 (m, 3H); ms m/z: 162 (M^+, 100), 146 (20), 135 (30), 129 (92), 76 (47).

1-Imino-3-methylthioisoindolenine (6) and N-methylmonothiophthalimide (5)

A solution of 101 mg of 1-imino-3-thioisoindoline (0.63 mmol) in 1 mL ethanol was methylated with dimethyl sulfate according to the procedure of Baguley and Elvidge (12). The crude product was precipitated from water, filtered, and washed with water to give in 65% yield, 71 mg of **6**. An attempt to recrystallize **6** resulted in decomposition, accompanied by phthalocyanine formation, mp 86–90°C (dec.)

1-Imino-6-neopentoxy-3-thioisoindoline (9) and 1-imino-5-neopentoxy-3-thioisoindoline (10)

A suspension of 15.1 g of sodium sulfide nonahydrate (62.9 mmol) in 5 mL of water was saturated with a slow stream of hydrogen sulfide gas for 1 h. The suspension became cloudy and the stream of H_2S was increased for a further 45 min. The grey solution was then added to a solution of 4.2 g of 4-neopentoxyphthalonitrile (6) (19.6 mmol) in 11 mL of 95% ethanol and the mixture was stirred at room temperature for 48 h. The reaction mixture was diluted with 200 mL of water and the precipitate was filtered and washed with water to yield 3.9 g of crude product. Further purification was done by flash chromatography (13) on silica gel, using ether/petroleum ether (3:2) as eluant. The first 100 mL consisted of dark impurities and a trace of 5-neopentoxydithiophthalimide (11). Continued elution gave a yellow moving band consisting of 1-imino-6-neopentoxy-3-thioisoindoline. Evaporation of the eluant gave in 17% yield 0.84 g of pure **9** as very light brown crystals, mp 126–130°C (dec.); ir (cm^{-1}): 3280–3180 (NH), 1660, 1610, 1490, 1480–1460, 1365, 1255, 1105, 830; ^1H nmr (acetone-d_6) δ: 7.83 (d, J = 8.4, 1H), 7.53 (br, 1H), 7.26 (dd, J = 8.4, 2.3, 1H), 3.82 (s, 2H, CH_2O), 1.06 (s, 9H, $(CH_3)_3C$); ms *m/z*: 248 (M^+, 100), 178 (82), 71 (27), 43 (28). *Anal.* calcd. for $C_{13}H_{16}N_2OS$: C 62.87, H 6.49, N 11.28; found: C 62.95, H 6.70, N 11.42.

Continued elution of the silica gel gave a second yellow moving band consisting of 1-imino-5-neopentoxy-3-thioisoindoline. Evaporation of the eluant gave in 20% yield 0.97 g of pure **10** as golden crystals, mp 189–191°C (dec.); ir (cm^{-1}): 3250 (NH), 1660, 1610, 1495, 1380, 1365, 1325, 1280, 1200, 1050, 1020, 865, 830, 820, 730; ^1H nmr (acetone-d_6) δ: 7.88 (d, J = 8.5, 1H), 7.37 (d, J = 2.2, 1H), 7.32 (dd, J = 8.5, 2.2, 1H), 3.83 (s, 2H, CH_2O), 1.07 (s, 9H, $(CH_3)_3C$); ms *m/z*: 248 (M^+, 42), 178 (80), 71 (52), 43 (100). *Anal.* calcd. for $C_{13}H_{16}N_2OS$: C 62.87, H 6.49, N 11.28; found: C 63.09, H 6.75, N 11.22.

1-Imino-3-methylthio-6-neopentoxyisoindolenine (11) and 1-imino-3-methylthio-5-neopentoxyisoindolenine (12)

A solution of 64.4 mg of 1-imino-6-neopentoxy-3-thioisoindoline (0.26 mmol), 1 mL ethanol, and 0.22 mL of 1.25 *N* sodium hydroxide (0.28 mmol) was diluted with 1 mL of water and stirred while 0.02 mL of methyl iodide (0.32 mmol) was added dropwise at room temperature. After 45–60 min, ice-cold water was added and the product was filtered and washed with water to give in 82% yield 56 mg of 1-imino-3-methylthio-6-neopentoxyisoindolenine as brown crystals. Compound **11** was used directly in the next step, mp 115–117°C (turned green); ir (cm^{-1}): 3260–3180 (NH), 1660, 1605, 1480–1460, 1360, 1250, 1100, 825; ^1H nmr δ: 9.34 (br, 1H), 7.46 (br, 1H), 7.35 (d, J = 8.2, 1H), 7.00 (d, J = 8.2, 1H), 3.69 (s, 2H, CH_2O), 2.72 (s, 3H, SCH_3), 1.05 (s, 9H, $(CH_3)_3C$); ms *m/z*: 262 (M^+, 10), 192 (23), 71 (65), 57 (48), 43 (100). *Anal.* calcd. for $C_{14}H_{18}N_2OS$: C 64.09, H 6.92, N 10.68; found: C 64.06, H 7.02, N 11.05.

Similarly a solution of 101 mg of 1-imino-5-neopentoxy-3-thioisoindoline was methylated with methyl iodide at 0°C for 3 min to give a dark oily product. The crude product was extracted with ether and the organic layer was washed thoroughly with water. After drying over anhydrous magnesium sulfate, the solvent was evaporated to give in 75% yield 80 mg of a very dark oil. Compound **12** is very unstable and therefore it is used directly in the next step. An attempt to purify **12** by flash chromatography caused decomposition, hydrolysis of the

imino group, and phthalocyanine formation; ^{1}H nmr δ: 7.64 (d, J = 9, 1H), 7.44 (d, J = 3, 1H), 6.97 (dd, J = 9, 3, 1H), 3.73 (s, 2H, CH_2O), 2.81 (s, 3H, SCH_3), 1.06 (s, 9H, $(CH_3)_3C$); ms m/z: 262 (M^+, 31), 247 (M^+ − 15, 9), 215 (M^+ − SCH_3, 40), 192 (M^+ − 70, 14), 145 (95), 71 (98), 43 (100).

Phthalocyanine formation from 11

Compound **11** obtained from 100 mg of **9** (0.40 mmol) in 1–2 mL of *N*,*N*-dimethylaminoethanol underwent self-condensation under argon at room temperature for 60 h. The crude reaction product was purified as previously described (6) to give, after flash chromatography, in 5–18% yield, 2,9,16,23-tetraneopentoxyphthalocyanine (**1**) as a mixture of isomers. From the ^{1}H nmr it seemed that some isomers were more selectively formed than others, but complete selectivity was not obtained. If during the self-condensation the argon is bubbling directly inside the reaction mixture, to remove the ammonia that is formed during the reaction, the desired phthalocyanine is not formed at room temperature. Raising the temperature to 60°C (oil bath) increased the yield but reduced the selectivity of the formation of isomers. Phthalocyanine formation was observed to take place when a solution of **11** in ether was left at room temperature overnight or when a sample of **11** was left partially dissolved in DMSO-d_6 inside an nmr tube. In both cases no selectivity towards the formation of one isomer was detected by ^{1}H nmr. During the purification of **1** by flash column chromatography it was observed that some purple material was left on the top of the column. At room temperature the purple colour became very intense. Therefore, after all of **1** was eluted with toluene, the solvent system was changed to 2-methoxyethanol/toluene (1:50). Several fractions were collected and, after evaporation of the solvent, it was found that some fractions contained mixtures of only **13** and **14**. The spectral data of this mixture is given as follows: ir (cm^{-1}): 3400 (NH), 2940, 1765, 1730, 1610, 1490, 1365, 1230, 1045, 1010, 745; uv (ether): 582, 542, 510, 346 nm; ^{1}H nmr δ: 7.75 (d, J = 8.3 Hz), 7.32 (d, J = 2.0 Hz), 7.20 (dd, J = 8.2 and 2.0 Hz), 3.71 (s, CH_2O), 1.06 (s, $(CH_3)_3C$); ^{13}C nmr δ: 168.00, 167.93, 164.83, 135.24, 125.18, 124.27, 120.66, 108.57, 78.80, 31.88, 29.66, 26.44. Further purification on a few mg was achieved by preparative tlc using the same eluting solvent as above to give **13** and **14** in estimated yields of 5% and 7% respectively; ms (high resolution) m/z, calcd. for $C_{39}H_{44}N_4O_5$, **13**, (M^+): 648.35404; found: 648.3555; calcd. for $C_{52}H_{61}N_7O_5$, **14**, (M^+): 863.47337; found: 863.4696.

Compounds of related structure were discussed by Fujiki *et al.* (15).

Phthalocyanine formation from ***12***

Compound **12** obtained from 116 mg of **10** (0.47 mmol) in 1–2 mL of *N*,*N*-dimethylaminoethanol underwent self-condensation under argon at room temperature for 18 h. The crude reaction product was purified as previously described (6) to give, after flash chromatography, in 8% yield, 8 mg of 2,9,16,23-tetraneopentoxyphthalocyanine as a mixture of isomers; some isomers were more selectively formed than others, in comparison with the isomers formed from the self-condensation of 5-neopentoxy-1,3-diiminoisoindoline (**17**) at 150°C. Further elution of the column with 2-methoxyethanol/toluene (1:50) gave purple/red material consisting of **13–16** as analyzed by mass spectroscopy. The physical and spectral data of **1** (except for the ^{1}H nmr) were identical to the ones previously reported (6).

2,9,16,23-Tetraneopentoxyphthalocyanine zinc(II) (2)

A mixure of 20 mg of **11** (0.076 mmol) and 5.7 mg (0.031 mmol) of zinc acetate was cooled in the freezer to −15°C. Cold DMF (−15°C) was added (1 mL); the mixture turned green and was left in the freezer for 1 week. The crude product was purified by flash column chromatography in a cold room (3°C). The column was packed a day in advance and was left in the cold room overnight. The crude product was applied to the column as is, and was eluted with cold toluene at 3°C to give 1 mg of **2** (5% yield); ^{1}H nmr (C_6D_6) δ: 1.26, 1.20; ms *m*/*z*: 922 (M^+, 100), 851 ($M^+ - 71$, 40), 460 ($M^{+2} - 1$, 65). Similarly a mixture of **12** derived from 102 mg of **10** (0.41 mmol) underwent self-condensation in the presence of zinc acetate in DMF at −15 – −18°C. Purification as above gave a mixture of **2** contaminated by **13** and **14**. Further purification by preparative tlc using 2-methoxyethanol/toluene (1:50) as eluting solvent followed by flash column chromatography gave 10.8 mg of **2** in 11% yield uncontaminated by **13** and **14**; ^{1}H nmr (C_6D_6) δ: a major peak at 1.26 and 2 small peaks at 1.23 and 1.21 ppm. This experiment was repeated at −40°C and gradually the temperature was raised to +5°C. Purification as above gave a trace of the desired product as indicated by a faint blue spot on tlc; ^{1}H nmr (C_6D_6) δ: 1.26 ppm. A control experiment using **11** in 2-*N*,*N*-dimethylaminoethanol showed that metal-free phthalocyanine formation did not take place at temperatures below 10°C.

Mechanism of electrodeposition of cadmium selenide from $SeSO_3^{2-}$ solution

JEFFREY P. SZABO AND MICHAEL COCIVERA

The Guelph–Waterloo Centre for Graduate Work in Chemistry, University of Guelph, Guelph, Ont., Canada N1G 2W1

Received August 17, 1987

JEFFREY P. SZABO and MICHAEL COCIVERA. Can. J. Chem. **66**, 1065 (1988).

The mechanism of the electrodeposition of CdSe from selenosulfite and cadmium–NTA complex has been studied by analysis of the Tafel regions of linear sweep voltammograms. The Tafel plots were linear for up to 20% of the peak height, and were used to calculate the dependence of the reduction rate on the concentration of each of the reactants. The electron transfer process was found to be first order with respect to $SeSO_3^{2-}$ and zero order with respect to each of the other reactants. These results are consistent with a two-step reduction of $SeSO_3^{2-}$ to Se^{2-}, followed by precipitation of CdSe. The reduction of $Cd(NTA)^-$ to cadmium metal appears to be blocked or inhibited in the presence of $SeSO_3^{2-}$, resulting in CdSe films of nearly perfect stoichiometry to be deposited.

JEFFREY P. SZABO et MICHAEL COCIVERA. Can. J. Chem. **66**, 1065 (1988).

Faisant appel à une analyse des régions de Tafel des voltampérogrammes à balayage linéaire, on a étudié le mécanisme de l'électrodéposition du CdSe à partir du sélénosulfite et du complexe cadmium–NTA. Les courbes de Tafel sont linéaires jusqu'à 20% de la hauteur du pic et on les a utilisées pour calculer la relation entre la vitesse de réduction et la concentration de chacun des réactifs. On a trouvé que le processus de transfert d'électron est du premier ordre par rapport au $SeSO_3^{2-}$ et d'ordre zéro par rapport à chacun des autres réactifs. Ces résultats sont en accord avec un mécanisme de réduction du $SeSO_3^{2-}$ en Se^{2-} qui impliquerait deux étapes et qui serait suivi d'une précipitation du CdSe. La réduction du $Cd(NTA)^-$ en cadmium métallique semble être bloquée ou inhibée par la présence du $SeSO_3^{2-}$ et il en résulte que ce sont des films de CdSe de stoechiométrie pratiquement parfaite qui se déposent.

[Traduit par la revue]

Introduction

The mechanism of electrodeposition of cadmium selenide from solutions containing selenosulfite ($SeSO_3^{2-}$) and the ethylene diamine tetracetate (EDTA) complex of cadmium is simplified by the fact that the cadmium–EDTA complex is not reducible in the range where reduciton of $SeSO_3^{2-}$ to Se^{2-} occurs (1). If nitrilotriacetate ion (NTA) is used as a ligand in place of EDTA, the resulting CdSe film exhibits sustantially higher light-to-electric power conversion efficiencies (1, 2). Furthermore, the NTA process is very reproducible, providing high quality (high efficiency) films consistently (2). When NTA is used, reduction of cadmium metal occurs at potentials more positive than that for reduction of $SeSO_3^{2-}$, leading to speculation in earlier studies that the formation of CdSe might somehow involve cadmium in the reduction step (2). The aim of the present study is to elucidate the mechanism of the electrodeposition process by determining the reaction order with respect to each of the reactants. After the first few monolayers, the electrochemical process occurs at the CdSe/solution interface. Consequently, during almost all of the film growth, it is the electrochemistry at this interface that is important and is reported in this paper.

Experimental

Preparation of stock solutions

All stock solutions were made from water purified by the Millipore Milli-Q Water System. Selenosulfite stock solutions were prepared by stirring anhydrous Na_2SO_3 and elemental Se together for a few hours, and then slowly adding water. Typically, 2 g of Se and 50 g of Na_2SO_3 were dissolved in 500 mL water. Sodium sulfite stock solution contained 50 g Na_2SO_3 in 500 mL water. NTA (NTA^{3-} = nitrilotriacetate ion) stock solution contained 7.09 g trisodium nitrilotriacetate monohydrate $[N(CH_2CO_2Na)_3 \cdot H_2O]$ in 250 mL. The pH of the NTA stock solution was adjusted with HCl to 9.7, which was the measured pH of the stock selenosulfite solution. Stock solutions of $Cd(NTA)^-$ complex were stable for only a few hours and so were prepared immediately before each set of experiments. Typically, 0.24 g of anhydrous $CdCl_2$ was dissolved in 15 mL of stock NTA solution. The following concentrations will be referred to as "standard": 0.595 *M* Na_2SO_3, 0.0380 *M* Se, 0.0258 *M* $Na_3NTA \cdot H_2O$, and 0.0218 *M* $CdCl_2$. A solution which contains all four species will be referred to as a "deposition solution", or "standard deposition solution" if the concentrations are standard. This standard deposition solution appeared more stable than the $Cd(NTA)^-$ solution and could be used for several days without evidence of chemical precipitation.

Unless stated otherwise $[Na_2SO_3]$ = 15.6 × total selenium and $[Na_3NTA \cdot H_2O]$ = 1.12 × total cadmium. In all cases, concentrations refer to *total* concentrations of a given species, i.e. $[SeSO_3^{2-}]$ = total selenium, $[Cd(NTA)^-]$ = total $CdCl_2$, $[NTA^{3-}]$ = total $Na_3NTA \cdot H_2O$, and $[SO_3^{2-}]$ = total Na_2SO_3. (The former two identities are valid under conditions used here, since the concentrations of unbound selenium and cadmium are extremely low.)

Preparation of CdSe working electrode

Titanium wire 0.81 mm in diameter was etched in 10% HF and rinsed well prior to electrodeposition. CdSe was electrodeposited on the Ti wire according to a previously described method (2). Typically, CdSe films were deposited at −1.000 V vs. SCE for 5–10 min from a standard deposition solution. The electrode area (~50 mm^2) was kept constant for a series of experiments by insulating the top portion with black sealing wax. Figures showing more than one set of data correspond to a single electrode area, unless stated otherwise. Just prior to use of the electrode for cyclic voltammetry (CV), the potential was cycled between −400 and −1300 mV vs. SCE in selenosulfite solution for a few minutes at 100 mV/s. Cycling was done to improve the reproducibility of the CV's. No other post deposition treatments were done.

Cyclic voltammetry

Cyclic voltammograms were done in quiet solutions using a CdSe working electrode, a platinum counter electrode, and a standard calomel reference electrode (SCE). All potentials were reported with respect to SCE. An in-house potentiostat was used for all CV's. The voltage ramp was supplied by the D/A converter of a Tecmar PC Mate Lab Master board installed in an IBM PC computer. The current and potential were recorded using the A/D converters of the Tecmar board. The sweep rates used in this study ranged from 10 to 500 mV/s, and 5 mV/point was the typical resolution used for data collection.

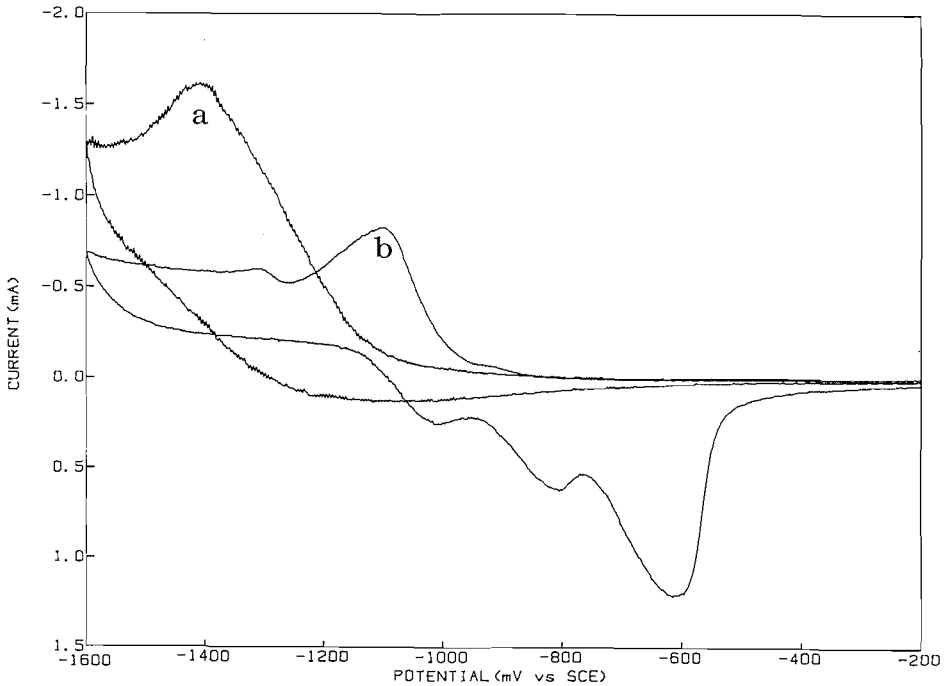

FIG. 1. Cyclic voltammogram at CdSe electrode of solutions which contained (*a*) $SeSO_3^{2-}$ and SO_3^{2-}, (*b*) $Cd(NTA)^-$ and NTA^{3-}. The sweep rate was 20 mV/s and the concentrations of all reagents were standard (see Experimental).

TABLE 1. Concentrations of stock solutions employed for kinetic order determinations

Species	Solution number	Concentrations (M)[a]			
		$[SeSO_3^{2-}]$	$[Cd(NTA)^-]$	$[NTA^{3-}]$	$[SO_3^{2-}]$
$SeSO_3^{2-}$	1	0.04470	0.01087	0.01213	0.7001
	2	—	0.01087	0.01213	0.7001
NTA^{3-}	3	0.03800	0.002328	0.002514	0.7000
$Cd(NTA)^-$	4	0.01948	—	—	1.282
	5	0.01948	0.02681	0.03172	1.282
SO_3^{2-}	6	0.01858	0.004529	0.005090	0.2907

[a]In all cases concentrations refer to *total* concentrations. For instance, $[NTA^{3-}] = [Cd(NTA)^-] + [NTA^{3-}]_f$, where the latter term corresponds to the uncomplexed ligand.

Order of the reaction

The order of the reaction was found with respect to each of the reactants by measuring the relative rate (see Results) for various concentrations of each species. Table 1 illustrates the way in which the concentrations were changed in a controlled manner. The concentration of $SeSO_3^{2-}$ was varied by mixing various aliquots of two stock solutions (#1 and #2, Table 1): one which contained $SeSO_3^{2-}$ and one which did not. Both solutions contained identical concentrations of $Cd(NTA)^-$, NTA^{3-}, and SO_3^{2-}. The concentration of Cd^{2+} could not be varied by adding $CdCl_2$ directly to the deposition solution due to the precipitation of $Cd(OH)_2$ and/or CdSe. The concentration of Cd was varied in two ways. First, the concentration of unbound Cd^{2+} was varied (solution #3, Table 1) by more than 3 orders of magnitude by the addition of NTA^{3-} (in the form of $Na_3NTA \cdot H_2O$), which binds to Cd^{2+} very strongly ($K = 10^{9.8}$, ref. 3). Second, the concentration of bound Cd^{2+} was varied by mixing aliquots of a solution which contained both Cd^{2+} and NTA^{3-} (solution #5), and one which contained neither (solution #4). Both solutions contained equal concentrations of $SeSO_3^{2-}$ and SO_3^{2-}. The concentration of unbound Cd^{2+} was kept constant for this set of experiments by maintaining a constant ratio of $[Na_3NTA \cdot H_2O]:[CdCl_2]$. This precaution proved later to be unnecessary as the ratio was found to have no effect on the reaction rate, so long as $[NTA^{3-}] > [CdCl_2]$. The concentration of SO_3^{2-} was modified by adding Na_2SO_3 to the deposition solution (solution #6). The reaction rate was unaffected by the addition of Na_2SO_3 up to 1.6 M, which changed the ionic strength from 0.93 M to 5.7 M.

Results

Cyclic voltammetry

The reduction wave of $SeSO_3^{2-}$ at the CdSe electrode *in the absence* of $Cd(NTA)^-$ was characterized by a broad irreversible wave with a peak at ~ -1400 mv vs. SCE (Fig. 1(*a*)) and with very small current in the potential range -700 to -900 mV, which was the range employed in this study for kinetic analysis. When subsequent scans were done, the peak current was observed to decrease with each cycle and a reddish-orange species accumulated in the vicinity of the working electrode, although the electrode itself remained unaltered in colour and texture. If the electrode was rinsed and the solution was stirred after each scan, then a plot of the logarithm of the peak height versus the logarithm of the sweep rate was linear with a slope of 0.55 (Fig. 2(*a*)). The CV of $Cd(NTA)^-$, Fig. 1(*b*), was characterized by a sharp reduction peak at ~ -1080 mV and a broad anodic stripping wave. In the absence of $SeSO_3^{2-}$, cadmium metal deposition was significant in the potential range usually used for CdSe deposition, -950 to -1200 mV.

Figure 3 shows a CV for several scan rates of the deposition solution, which contained $SeSO_3^{2-}$ and $Cd(NTA)^-$ in the ratio 1.7:1. There were two irreversible reduction waves, the first of which will be referred to as the "deposition peak", since it occurred in the region where depositions are usually carried out (-1000 to -1200 mV). If the cathodic limit of the CV was quite negative (< -1300 mV) then both peaks were observed to decrease with repetitive scans and the electrode became dark red. If the scan reversal was more positive than -1200 mV, then each cycle produced identical CV's, and the electrode remained

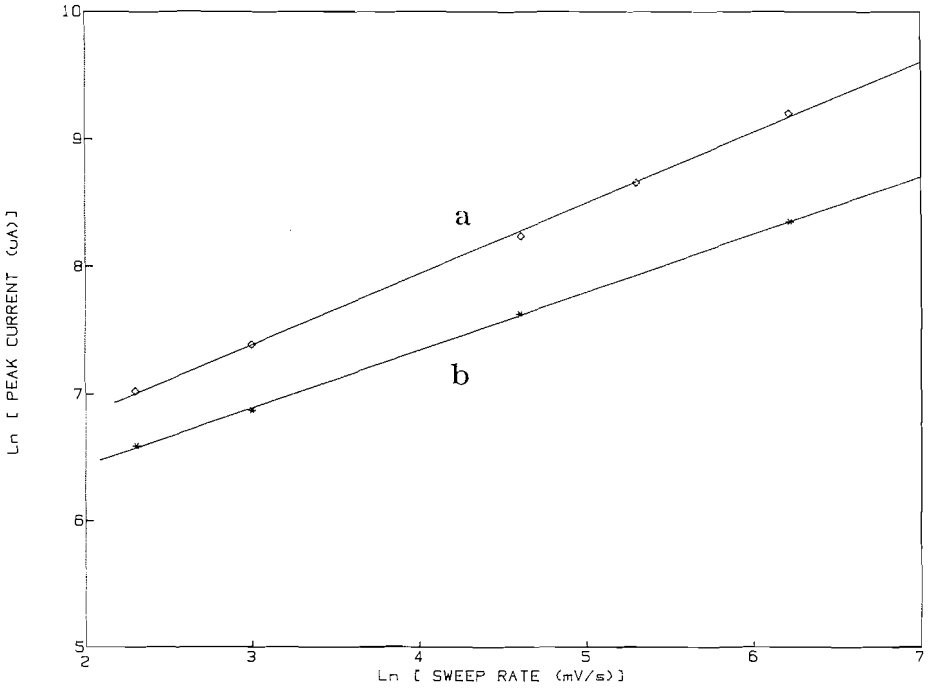

FIG. 2. Plot of logarithm of the peak current versus logarithm of the sweep rate for (*a*) selenosulfite solution, (*b*) deposition peak. Selenosulfite solution contained $SeSO_3^{2-}$ and SO_3^{2-}; the deposition solution contained standard concentrations of all reagents. The deposition peak height used here was corrected for overlap of the second peak (see Results).

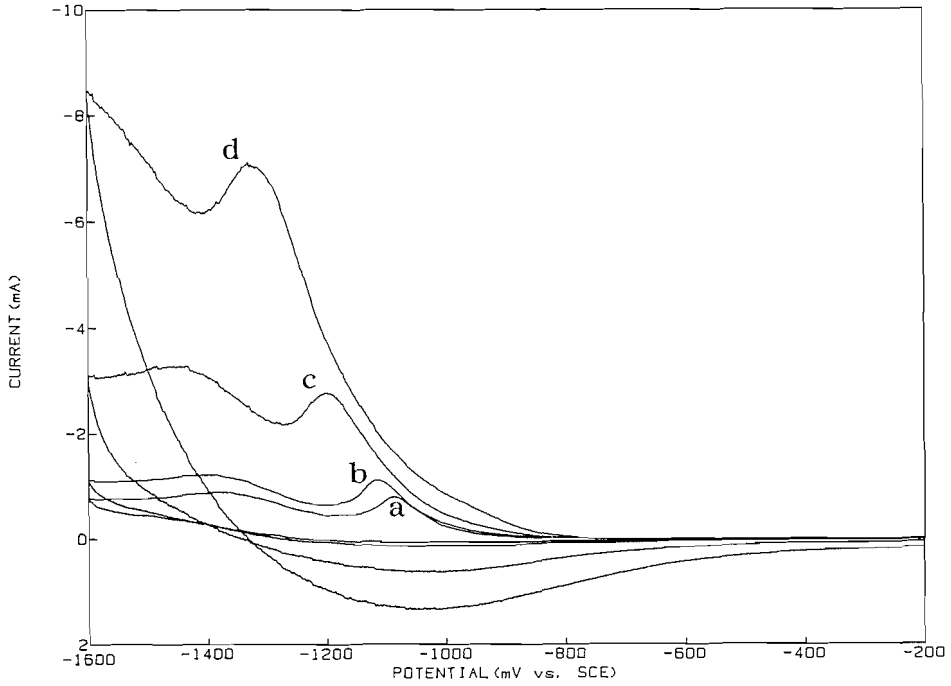

FIG. 3. Cyclic voltammograms of a standard deposition solution at various sweep rates: (*a*) 10 mV/s, (*b*) 20 mV/s, (*c*) 100 mV/s, and (*d*) 500 mV/s. The electrode was rinsed between cycles.

grey. The deposition peak increased and moved negative with increasing scan rate.

The second, more negative peak of the deposition solution had the same broad shape and occurred at the same potential as that for $SeSO_3^{2-}$ reduction in the absence of $Cd(NTA)^-$ (Fig. 1). Since the two waves overlapped, the deposition peak height was estimated by subtracting the cathodic current for $SeSO_3^{2-}$ reduction (Fig. 1) from the deposition solution current (Fig. 3). If the electrode was rinsed and the solution stirred after each scan, then a plot of the logarithm of the corrected peak height versus the logarithm of the sweep rate was linear with a slope of 0.45 (Fig. 2(*b*)). The deposition peak increased and moved *negative* with increasing $Cd(NTA)^-$ concentration (Figs. 4 and 5); the peak increased and moved *positive* with increasing $SeSO_3^{2-}$ concentration. The peak at −1400 mV increased with increasing $[SeSO_3^{2-}]$, but *decreased* with increasing

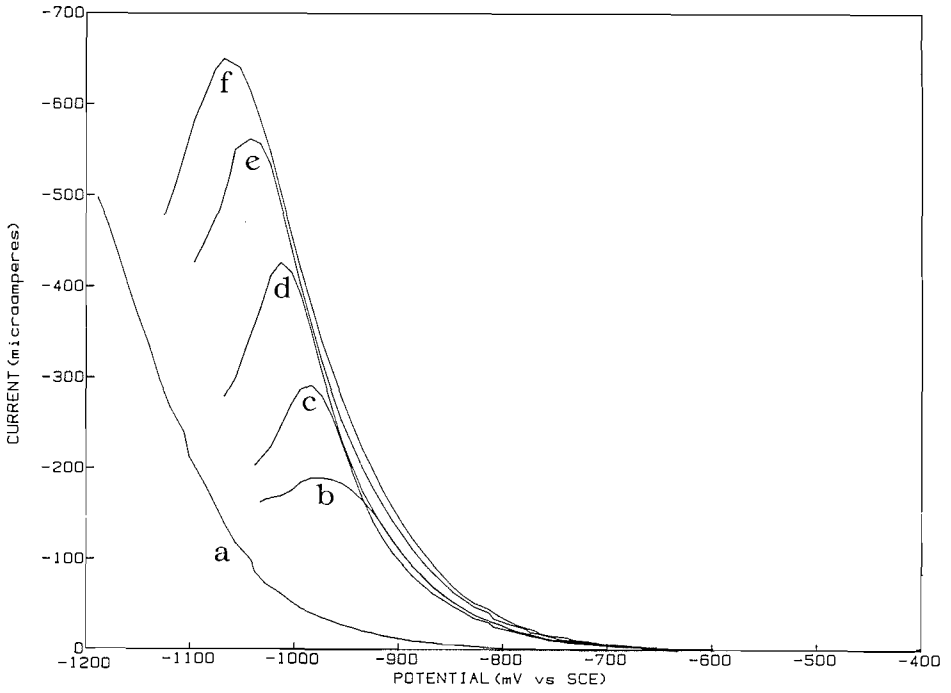

FIG. 4. Linear sweep voltammogramms (i.e. only cathodic half of a cycle) of a deposition solution for various concentrations of $Cd(NTA)^-$: (*a*) 0, (*b*) 1.68×10^{-3} *M*, (*c*) 3.16×10^{-3} *M*, (*d*) 6.71×10^{-3} *M*, (*e*) 1.14×10^{-2} *M*, (*f*) 1.46×10^{-2} *M*. The concentrations of the other species were as follows: $[SeSO_3^{2-}] = 0.01948$ *M*, $[SO_3^{2-}] = 0.3052$ *M*, and $[NTA^{3-}] = 1.12 \times [Cd(NTA)^-]$. Sweep rate was 20 mV/s.

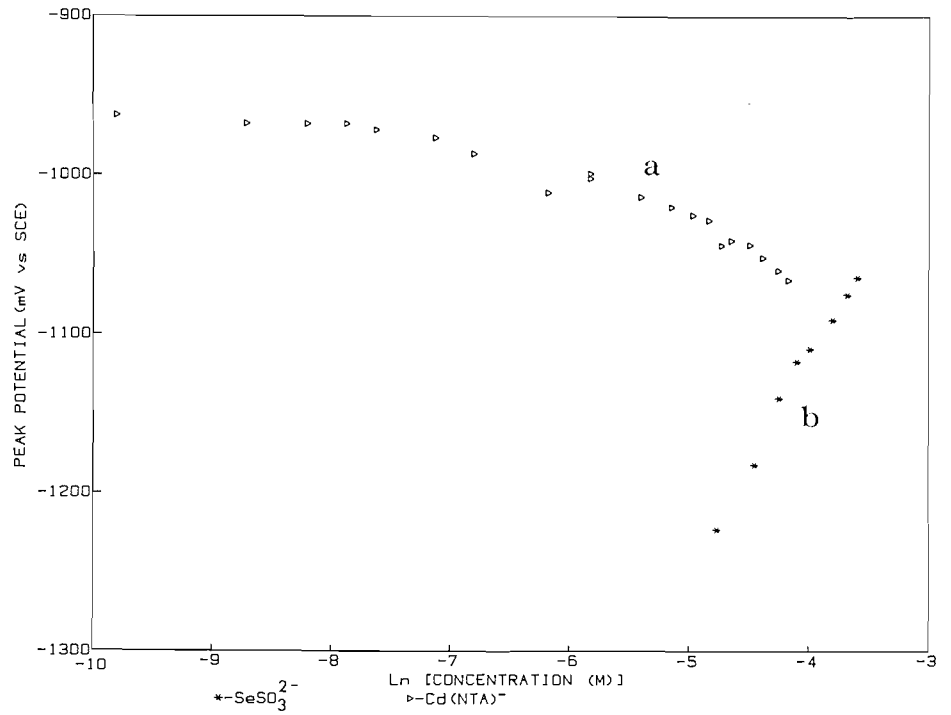

FIG. 5. Peak potential versus logarithm of (*a*) $[Cd(NTA)^-]$ and (*b*) $[SeSO_3^{2-}]$. The concentration of the other reactant was standard.

$[Cd(NTA)^-]$. No anodic stripping wave was observed for the deposition solution if $[SeSO_3^{2-}] > [Cd(NTA)^-]$. For solutions in which the concentration of $Cd(NTA)^-$ was greater than that of $SeSO_3^{2-}$, an anodic stripping wave was observed on the reverse scan.

Composition

A detailed study of the effect of reagent concentrations, thickness, and deposition potential on the composition of the CdSe film has been previously reported (2) and is summarized below. Typically, films have no excess cadmium and are made from solutions in which the ratio $[SeSO_3^{2-}]$: $[Cd(NTA)^-] = 1.7$. For these films, the Cd:Se ratio was found to be close to 0.95 and to be independent of NTA concentration, deposition potential in the range -950 to -1200 mV, and thickness. For depositions made from solutions in which $[Cd(NTA)^-] > [SeSO_3^{2-}]$, the Cd:Se ratio was significantly above 1, indicating metallic cadmium was present along with CdSe.

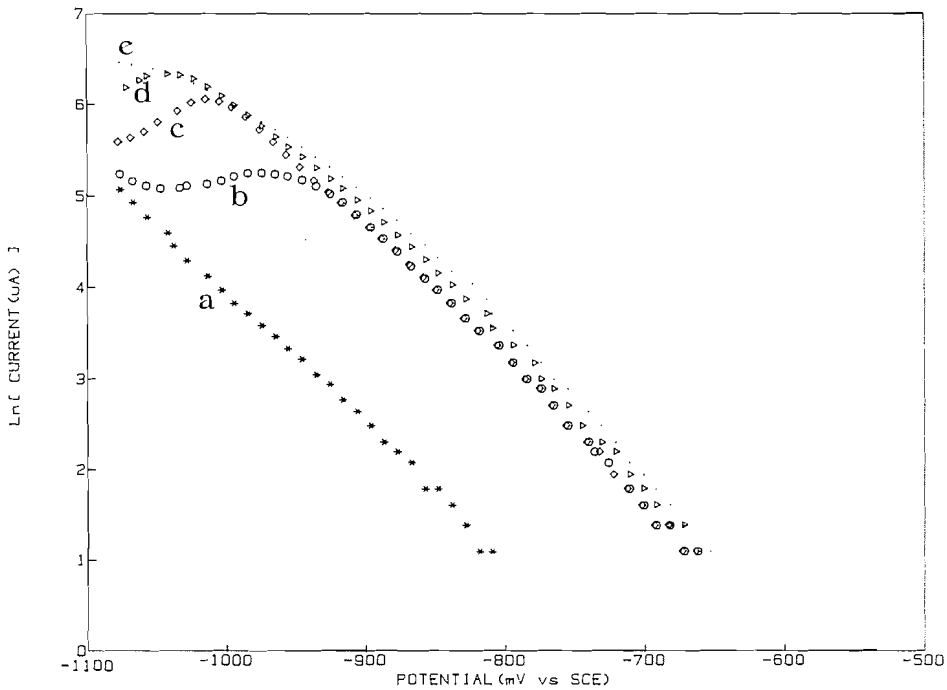

FIG. 6. Tafel plots for various concentrations of $Cd(NTA)^-$: (*a*) 0, (*b*) 1.68×10^{-3} *M*, (*c*) 6.71×10^{-3} *M*, (*d*) 1.14×10^{-2} *M*, (*e*) 1.92×10^{-2} *M*. Other concentrations as in Fig. 4. Sweep rate was 20 mV/s.

Tafel plots

The Butler–Volmer equation describes the current (i) – potential (E) relationship well in the absence of mass transfer effects, i.e. when there is no significant concentration gradient near the electrode surface. The latter may be achieved by stirring the solution or by keeping the current less than 10% of the limiting diffusion current (ref. 4, Chap. 3). Consider the cathodic term of the Butler–Volmer equation (ref. 4, Chap. 3 ref. 5) for which the reactants have concentrations c_1, c_2, ... and reaction orders p_1, p_2, ... :

$$[1] \quad i = nFAk^0 c_1^{p_1} c_2^{p_2} \ldots \exp[-\alpha nF(E - E^0)/RT]$$

In the above equation the anodic term has been neglected because no significant anodic current could be detected during the reverse scan. Most likely the overpotential is large for oxidation of CdSe. In eq. [1], n is the number of electrons (1 in this case), A is the electrode area, α is the charge transfer coefficient, and k^0 is the heterogeneous rate constant at the standard electrode potential E^0. Faraday's constant, the gas constant, and absolute temperature are denoted by F, R, and T, respectively. Taking the natural logarithm of [1] gives

$$[2] \quad \ln i = \ln nFAk + \Sigma_j p_j \ln c_j - [\alpha nF(E - E^0)/RT]$$

In this study, the current/potential data were obtained from the CV's for currents less than 20% of the peak current. This method assured reproducibility because the peak current and potential could be monitored. If the second scan did not reproduce the previous scan, the data were rejected. Tafel plots were constructed from CV's by plotting the natural logarithm of the current for cathodic sweeps versus the potential.

As shown in Fig. 6, these plots were linear for currents less than 10 to 20% of the peak current, which usually corresponded to a potential range from −700 to −900 mV. The value of α determined from the slope ($-\alpha nF/RT$) was fairly constant for a given electrode and set of solutions, e.g. $\alpha = 0.36 \pm 0.02$, assuming transfer of one electron in the rate determining step. For a number of electrodes and solutions, an overall average of $\alpha = 0.3 \pm 0.1$ was found. The Tafel plot for the deposition wave (Fig. 7(*b*)–(*e*)) had the same slope as that for $SeSO_3^{2-}$ reduction in the absence of $Cd(NTA)^-$ (Fig. 6(*a*)). The initial effect of adding small amounts of $Cd(NTA)^-$ (as little as 10^{-5} *M*) to a solution of $SeSO_3^{2-}$ was to shift the Tafel plot 160 mV positive, but additional $Cd(NTA)^-$ produced no further shift in the *foot* of the wave. (As mentioned above, the *peak* moved negative and increased with increasing $Cd(NTA)^-$ concentration.) The Tafel plot for $Cd(NTA)^-$ reduction (Fig. 7(*a*)) differs markedly from the deposition Tafel plots. The $Cd(NTA)^-$ Tafel plot has a much steeper slope and is not linear for small currents. It is possible that cadmium metal deposition on the CdSe electrode is controlled by nucleative growth rate rather than electron transfer rate in the "Tafel region" of the wave. The effect of adding more $SeSO_3^{2-}$ to the deposition solution was to shift the Tafel plot positive (Fig. 7(*b*)–(*g*)). There was no effect on the Tafel plots when extra NTA^{3-} or SO_3^{2-} was added.

Concentration dependence

For $SeSO_3^{2-}$, NTA^{3-}, $Cd(NTA)^-$, and SO_3^{2-}, the kinetic order was determined from Tafel plots generated for solutions in which the concentration of one species was varied, while those for the other three were held constant (see Experimental for details). This process yielded families of Tafel plots (Figs. 6 and 7). From eq. [2], it can be seen that at a given potential, the slope of a plot of ln i vs. ln c_j should be equal to the order of the species j:

$$[3] \quad \frac{\partial \ln i}{\partial \ln c_j} = p_j$$

Figure 8 shows sample order plots for $Cd(NTA)^-$ and $SeSO_3^{2-}$. Table 2 gives the average order found for each species, and the concentration range over which the order is valid (usually 1–2 orders of magnitude). Table 2 also gives the number of trials, n, and the standard error $s/n^{1/2}$ (where s is the standard deviation). As Table 2 shows, the electrodeposition rate is first order with respect to $SeSO_3^{2-}$ but essentially zero order for all other species. Note that the order with respect to $Cd(NTA)^-$ is zero order only for low concentrations. As Fig. 8(*a*) shows, for concentrations

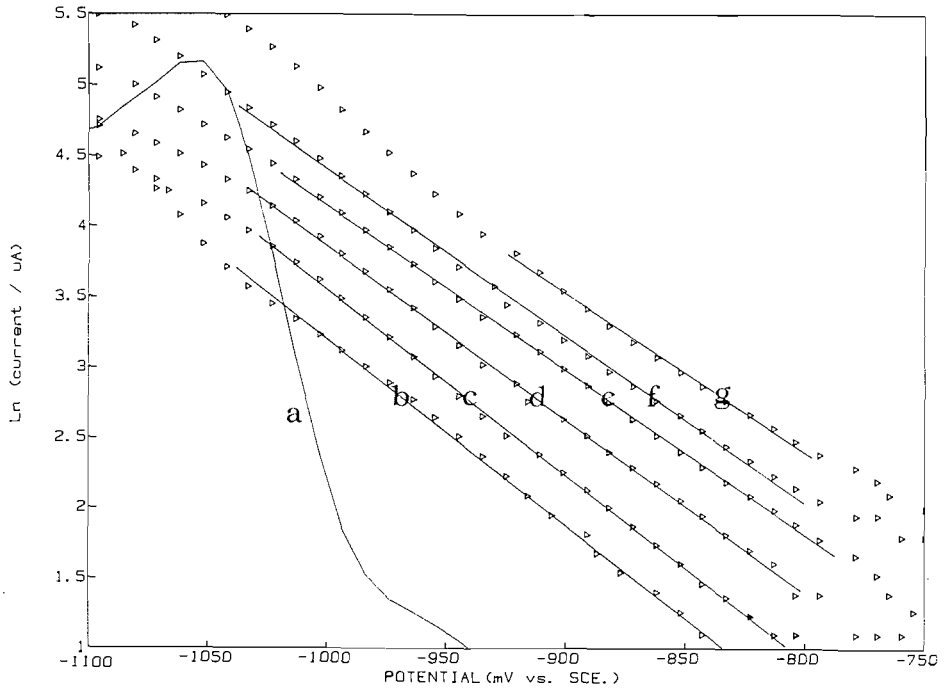

FIG. 7. Tafel plots for various concentrations of $SeSO_3^{2-}$: (*a*) 0, (*b*) 4.71×10^{-3} *M*, (*c*) 8.52×10^{-3} *M*, (*d*) 1.17×10^{-2} *M*, (*e*) 1.43×10^{-2} *M*, (*f*) 1.84×10^{-2} *M*, (*g*) 2.75×10^{-2} *M*. The concentrations of the other species were as follows: $[Cd(NTA)^-] = 0.0100$ *M*, $[SO_3^{2-}] = 0.700$ *M*, and $[NTA^{3-}] = 0.0121$ *M*. Sweep rate was 20 mV/s.

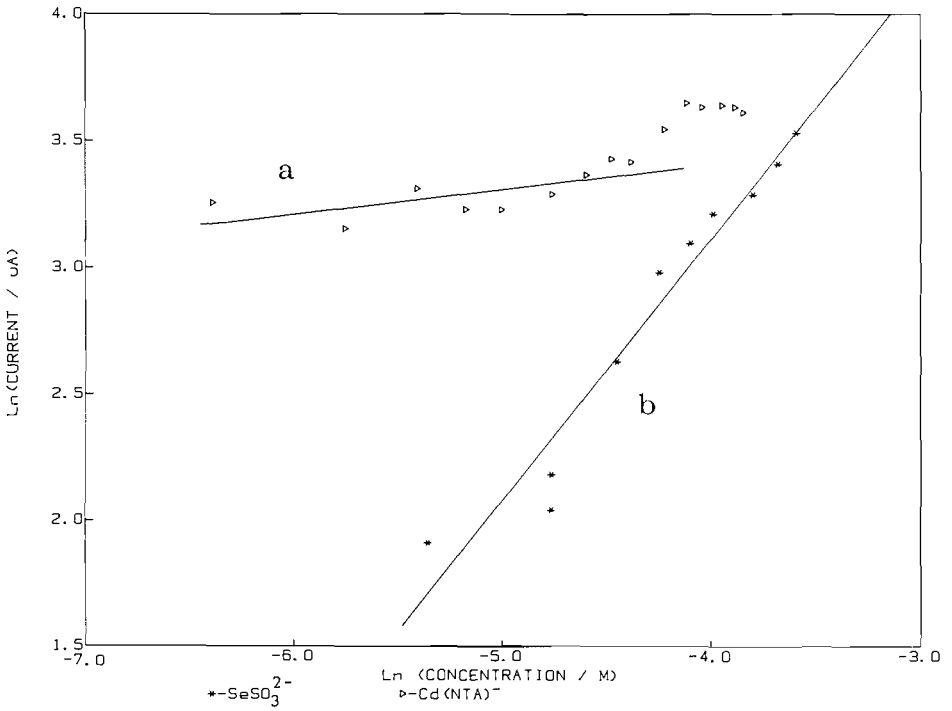

FIG. 8. Effect of $[Cd(NTA)^-]$ and $[SeSO_3^{2-}]$ on reaction rate using data shown in Figs. 6 and 7, respectively. Logarithm of current versus logarithm of concentration for (*a*) $Cd(NTA)^-$ at −800 mV and (*b*) $SeSO_3^{2-}$ at −900 mV. The electrode areas were not the same for (*a*) and (*b*).

of $Cd(NTA)^-$ greater than 4×10^{-3} *M*, the rate rises through a maximum and then falls off with increasing $Cd(NTA)^-$ concentration. The region of the maximum occurs when [Cd] ≈ [Se], and under these conditions a small anodic stripping wave is observed in the cyclic voltammogram. In comparison to the data scatter found at lower $Cd(NTA)^-$ concentration, this maximum observed at higher $Cd(NTA)^-$ is too large to attribute to data scatter. Furthermore, this feature is observed consistently in repeated trials. Probably it indicates the onset of cadmium metal deposition to give nonstoichiometric CdSe films because an anodic stripping current becomes observable in this concentration range.

Discussion

Based on the observed reaction orders, the rate of charge transfer at a particular potential in the Tafel region for solutions in which $[SeSO_3^{2-}] > [Cd(NTA)^-]$ may be written as

$$\text{Rate} = i/nFA = k[SeSO_3^{2-}]$$

TABLE 2. Average kinetic order determined for pertinent species

Species	No. of trials	Average order	$s/n^{1/2}$	Concentration range (M)
SO_3^{2-}	3	−0.162	0.031	6.1×10^{-2} to 1.7
NTA^{3-}	4	0.076	0.110	2.2×10^{-3} to 2.0×10^{-1}
$SeSO_3^{2-}$	2	1.023	0.011	4.8×10^{-3} to 2.7×10^{-2}
$Cd(NTA)^-$	4	0.044	0.037	4.5×10^{-5} to 4.1×10^{-3}

where k is the heterogeneous rate constant. The simplest mechanism that is consistent with the rate law involves a slow one electron reduction of $SeSO_3^{2-}$ followed by rapid transfer of the second electron and a rapid equilibrium:

$$SeSO_3^{2-} + e \xrightarrow{\text{slow}} Se^- + SO_3^{2-} \qquad E_{rev}$$

$$Se^- + e \xrightarrow{\text{fast}} Se^{2-}$$

[A] $$Cd^{2+} + Se^{2-} \rightleftarrows CdSe$$

Overall: $$SeSO_3^{2-} + Cd^{2+} + 2e \rightarrow CdSe + SO_3^{2-} \qquad E_1$$

This process is ascribed to the reduction wave occurring in the region of −1100 mV for the deposition solution. The second wave at −1400 mV (Fig. 3) for this solution occurs at the same reduction potential observed for the $SeSO_3^{2-}$ solution in the absence of $Cd(NTA)^-$ (Fig. 1). In both cases, scans to this potential region result in what appears to be the same reddish-orange precipitate. As a result, we suggest that the same process applies in these two cases. The absence of any oxidation wave indicates removal of the reduced species by a rapid chemical reaction. Composition data (2) show that depositions carried out at potentials more negative than −1250 mV result in formation of deposits that have up to twice as much selenium as cadmium. Consequently we suggest the reaction of selenide ion with selenosulfite ion to produce di- and polyselenide species, which may precipitate with a metal ion subsequently.

$$SeSO_3^{2-} + e \rightarrow Se^- + SO_3^{2-} \qquad E_{rev}$$

$$Se^- + e \xrightarrow{\text{fast}} Se^{2-}$$

[B] $$Se^{2-} + SeSO_3^{2-} \rightarrow Se_2^{2-} + SO_3^{2-}$$

Overall: $$2SeSO_3^{2-} + 2e \rightarrow Se_2^{2-} + 2SO_3^{2-} \qquad E_2$$

Weak adsorption of the product resulting in this first reduction (Se^-) or second reduction step (Se^{2-}) in mechanisms [A] and [B] can be neither confirmed nor precluded by the scan rate information. Weak adsorption is not expected to alter the dependence of the reduction peak current on the square root of the scan rate (ref. 4, pp. 530, 531). Furthermore, although weak adsorption is expected to move the peak potential in the positive direction as the scan rate is increased (ref. 4, pp. 530, 531), this effect may be obscured by the larger negative shift (Fig. 3) due to the irreversible nature of the reduction. Support for adsorption comes from inhibition of Cd(II) reduction (discussed below).

The reversible reduction of $SeSO_3^{2-}$ to Se^{2-} occurring at E_{rev} is not observed because of the succeeding chemical reaction. The effect of the chemical reaction is to cause a positive shift of the reduction potential of $SeSO_3^{2-}$ from E_{rev} to E_2 (6). Mechanism [B] occurs in the absence of $Cd(NTA)^-$ and also in the presence of $Cd(NTA)^-$ when $[SeSO_3^{2-}] > [Cd(NTA)^-]$ as illustrated in Figs. 1 and 3, respectively. For the latter conditions, mechanism [A] occurs also (wave in the region −1100 mV), i.e. reduction of $SeSO_3^{2-}$ occurs at an even more positive equilibrium potential, E_1. This description is consistent with identical values of the charge transfer coefficient, $\alpha = 0.36$, for the selenosulfite solution (Fig. 6(*a*)) and the deposition solution (Fig. 6(*b*)–(*e*)). Consequently, in the deposition solution the wave around −1100 mV depends on diffusion of $Cd(NTA)^-$ to interface (for chemical reaction), while the one near −1400 mV depends on diffusion of $SeSO_3^{2-}$. Both waves are observed when the flux of $SeSO_3^{2-}$ is greater than that of $Cd(NTA)^-$.

An approximation of the maximum value of the positive shift, $\Delta E = E_1 - E_{rev}$, may be calculated from the solubility product of CdSe in water, $K_{sp} = 7 \times 10^{-36}$ (7):

$$\Delta E = -(RT/nF) \ln (K_{sp}/[Cd^{2+}])$$

If a value of $[Cd^{2+}] \cong 10^{-10}$ M is used (the association constant for Cd^{2+} and NTA^{3-} is $10^{9.8}$ (ref. 3)), then $E_1 - E_{rev} = +770$ mV. Consequently, the observed shifts are well within this maximum value, indicating that the proposed model is not unreasonable. An analogous positive shift has been observed in the electrodeposition of CdSe from $SeCN^-$ and $Cd(EDTA)^{2-}$ complex, and was ascribed to the low solubility of the CdSe deposit (8). In this case, the $SeCN^-$ reduction peak potential was shifted 320 mV positive in the presence of $Cd(EDTA)^{2-}$.

The initial effect of small amounts of $Cd(NTA)^-$ is to shift the Tafel plot positive by ~ 160 mV, but there is no further shift in the Tafel plot for a wide concentration range (Table 2). There was also no effect with additional NTA^{3-}. The concentration of $Cd(NTA)^-$ did, however, affect the peak height and peak position (Fig. 4). It seems unlikely that this negative shift in peak potential is due to IR drop because a positive shift occurs when $[SeSO_3^{2-}]$ is increased (the increase in peak current is comparable to that found for $[Cd(NTA)^-]$ increase). An explanation consistent with this result is that at the peak potential, the current is controlled by the subsequent chemical reaction, i.e. is limited by diffusion of $Cd(NTA)^-$ to the electrode. On the other hand, in the Tafel region, the current is limited by the slow electron transfer to $SeSO_3^{2-}$. These results also appear to preclude other mechanisms involving the adsorption of either $Cd(NTA)^-$ or $SeSO_3^{2-}$.

It appears that $SeSO_3^{2-}$ has an inhibiting effect on the reduction of $Cd(NTA)^-$ to Cd metal. The voltammogram of $Cd(NTA)^-$ exhibits a sharp rise in the reduction current at ~ −1000 mV, so one might expect that a mixture of Cd and CdSe would be deposited at potentials more negative than −1000 mV. However, the onset of Cd deposition on CdSe does not occur until $[Cd(NTA)^-] \geq [SeSO_3^{2-}]$ as indicated by the occurrence of a small stripping wave on the anodic scan. For a solution in which $[SeSO_3^{2-}] = 2[Cd(NTA)^-]$, the total charge passed on the anodic half of the cyclic potential scan is less than 2% of the charge passed during the cathodic scan. These results are consistent with composition studies (2), which indicate that stoichiometric films are grown under these conditions. The inhibition of Cd metal deposition may be explained by the adsorption of Se^- or Se^{2-} following the reduction of $SeSO_3^{2-}$. As mentioned above, the results of the scan rate study do not preclude this possibility. An analogous mechanism was used to explain the electrodeposition of CdS from diethylene glycol solutions (9). Finally, an examination of the Tafel plots (Fig. 7) shows that the slope for $Cd(NTA)^-$ reduction is much larger than the one for $SeSO_3^{2-}$ reduction. The fact that there is no change in the slope of the deposition Tafel plots from −800 to −1100 mV is additional evidence that $SeSO_3^{2-}$ reduction dominates in this potential range when $SeSO_3^{2-}$ is present in the

For personal use only.

concentration range employed. Nevertheless, the deviation from zero order for $Cd(NTA)^-$ exhibited in Fig. 8 is an indication that $Cd(NTA)^-$ reduction becomes more important as $[Cd(NTA)^-]$ becomes greater than $[SeSO_3^{2-}]$, i.e. the magnitude of the Tafel slope is expected to increase relative to that for Fig. 7(*g*) as $[SeSO_3^{2-}]$ is decreased further.

Conclusion

The electrodeposition of cadmium selenide from selenosulfite solution occurs via a two-step reduction of $SeSO_3^{2-}$ to Se^{2-} followed by precipitation with Cd^{2+}. Under electron transfer limiting conditions, the rate of reduction depends only on $[SeSO_3^{2-}]$, but at potentials for which mass transfer is limiting, the rate also depends on $[Cd(NTA)^-]$ because the current is controlled by the subsequent chemical reaction. In the presence of $Cd(NTA)^-$, the Tafel plot for $SeSO_3^{2-}$ reduction is shifted 160 mV positive due to the effect of the succeeding reaction with Cd^{2+}.

Received September 14, 1987

KENNETH J. BECKETT and STEPHEN J. LOEB. Can. J. Chem. **66**, 1073 (1988).

The mononuclear complexes $[Rh(\eta^2\text{-}(Ph_2P)_3CH)_2]X$, $[Ir(CO)(\eta^2\text{-}(Ph_2P)_3CH)_2]X$, $[Pd(\eta^2\text{-}(Ph_2P)_3CH)_2]X_2$, and $[Pt(\eta^2\text{-}(Ph_2P)_3CH)_2]X_2$ ($X = Cl^-$, BF_4^-, BPh_4^-, ClO_4^-) are synthesized and fully characterized by $^{31}P\{^1H\}$ nmr and infrared spectroscopy. The complex $[Pt(\eta^2\text{-}(Ph_2P)_3CH)_2][BF_4]_2$ was further characterized by a single crystal X-ray diffraction study. Crystals are triclinic, $a = 12.514(6)$ Å, $b = 13.289(7)$ Å, $c = 12.609(9)$ Å, $\alpha = 120.63(4)°$, $\beta = 104.51(5)°$, $\gamma = 99.45(4)°$, $Z = 1$, space group $P\bar{1}$. The structure was solved by conventional heavy atom methods and refined by full-matrix least-squares procedures to $R(\%) = 6.87$ and $R_w(\%) = 7.28$ for 2995 reflections with $F_o^2 > 3\sigma F_o^2$. The Rh, Pd, and Pt complexes are square planar and shown by $^{31}P\{^1H\}$ nmr to exist in solution as a mixture of *syn* and *anti* isomers. The structure of $[Pt(\eta^2\text{-}(Ph_2P)_3CH)_2][BF_4]_2$ shows the *anti* isomer exists in the solid state for this complex. Both the *syn* and *anti* isomers of the complex $[Rh(\eta^2\text{-}(Ph_2P)_3CH)_2][BF_4]$ react with HX (X = Cl, Br) to give a single octahedral Rh(III) product *trans*-$[RhX(H)(\eta^2\text{-}(Ph_2P)_3CH)_2)][BF_4]$ characterized by $^{31}P\{^1H\}$ and ^1H nmr.

KENNETH J. BECKETT et STEPHEN J. LOEB. Can. J. Chem. **66**, 1073 (1988).

On a synthétisé les complexes mononucléaires $[Rh(\eta^2\text{-}(Ph_2P)_3CH)_2]X$, $[Ir(CO)(\eta^2\text{-}(Ph_2P)_3CH)_2]X$, $[Pd(\eta^2\text{-}(Ph_2P)_3CH)_2]X_2$ et $[Pt(\eta^2\text{-}(Ph_2P)_3CH)_2]X_2$ ($X = Cl^-$, BF_4^-, BPh_4^-, ClO_4^-) et on les a complètement caractérisés par spectroscopies rmn $^{31}P\{^1H\}$ et infrarouge. De plus, on a aussi caractérisé le complexe $[Pt(\eta^2\text{-}(Ph_2P)_3CH)_2][BF_4]_2$ à l'aide de la diffraction des rayons-X. Les cristaux sont tricliniques, groupe d'espace $P\bar{1}$, avec $a = 12{,}514(6)$, $b = 13{,}289(7)$ et $c = 12{,}609(9)$ Å, $\alpha = 120{,}63(4)$, $\beta = 104{,}51$ et $\gamma = 99{,}45(4)°$ et $Z = 1$. On a résolu la structure par les méthodes conventionnelles aux atomes lourds et on l'a affinée par la méthode des moindres carrés (matrice entière) jusqu'à des valeurs de $R(\%) = 6{,}87$ et $R_w(\%) = 7{,}28$ pour 2995 réflexions avec $F_o^2 > 3\sigma F_o^2$. Les complexes du Rh, du Pd et du Pt sont plans carrés et, à l'aide de la rmn du $^{31}P\{^1H\}$, on a démontré que, en solution, ils existent sous la forme d'un mélange des isomères *syn* et *anti*. La structure qui a été déterminée pour le complexe $[Pt(\eta^2\text{-}(Ph_2P)_3CH)_2][BF_4]_2$ démontre que, à l'état solide, il existe sous la forme de l'isomère *anti*. Les isomères *syn* ainsi que *anti* du complexe $[Rh(\eta^2\text{-}(Ph_2P)_3CH)_2][BF_4]_2$ réagissent avec les HX (X = Cl et Br) pour conduire à un seul type de produit Rh(III) octaédrique, les *trans*-$[RhX(H)(\eta^2\text{-}(Ph_2P)_3CH)_2)][BF_4]$, qui ont été caractérisés par rmn du $^{31}P\{^1H\}$ et du ^1H.

[Traduit par la revue]

Introduction

The tridentate phosphorus ligand 1,1,1-tris(diphenylphosphino)methane, $(Ph_2P)_3CH$, exhibits a variety of coordination modes. Complexes in which $(Ph_2P)_3CH$ acts as an $\eta^3\text{–}\mu_3$ bridging ligand (1–7), an $\eta^3\text{–}\mu_2$ bridging-chelating ligand (8, 9), an η^2 or η^3 chelating ligand (9, 10) and an η^1 monodentate ligand (9) have been characterized. As is the case for the small bite-angle, bidentate phosphorus ligand bis(diphenylphosphino)methane, dppm, the bridging modes of coordination are favoured over the chelating modes since the latter requires the formation of a strained four-membered chelate ring (11). Indeed, the tripod ligand, $(Ph_2P)_3CH$, is ideally suited for the complexation of a triangular array of metal atoms and this $\eta^3\text{–}\mu_3$ coordination mode has been well demonstrated by the binding to a triangular metal face in the tetranuclear carbonyl cluster compounds $[M_4(CO)_9((Ph_2P)_3CH)]$, M = Co, Rh, Ir (1, 3–7).

It should also be possible, however, to convert a mononuclear chelated complex to a bi- or trinuclear bridged complex via a chelate ring opening reaction and further metal incorporation. This type of synthetic approach has been successful in the preparation of heterobinuclear complexes bridged by dppm (12–15). As part of our initial studies into the potential use of tripod ligands such as $(Ph_2P)_3CH$ for "building" trinuclear metal complexes, we have prepared some mononuclear chelated complexes of Rh, Ir, Pd, and Pt. We report herein, the synthesis and characterization of complexes of the general formula $[M(\eta^2\text{-}(Ph_2P)_3CH)_2]^{n+}X_n$ and the X-ray structural determination of the complex $[Pt(\eta^2\text{-}(Ph_2P)_3CH)_2][BF_4]_2$.

Experimental

trans-$[RhCl(CO)(PPh_3)_2]$ (16), *trans*-$[IrCl(CO)(PPh_3)_2]$ (17), and 1,1,1-tris(diphenylphosphino)methane (1, 18) were prepared by literature methods. K_2PtCl_4, K_2PdCl_4, $IrCl_3\cdot 3H_2O$, $RhCl_3\cdot 3H_2O$ (Strem), *n*-BuLi, $NaBF_4$, $NaClO_4$, $NaBPh_4$, PPh_3, and bis(diphenylphosphino)methane (Aldrich) were purchased and used as received. Unless otherwise stated, all synthetic procedures were conducted under a dry, dinitrogen atmosphere using dry, deoxygenated solvents and standard Schlenk techniques.

$^{31}P\{^1H\}$ and ^1H nmr spectra were obtained at 121.5 and 300.1 MHz, respectively, on a Brüker AM300 spectrometer using deuterated solvents as lock. Phosphorus chemical shifts were measured relative to external 85% H_3PO_4 with positive shifts downfield. Infrared spectra were recorded on a Perkin Elmer 781 grating spectrometer. Elemental analyses were performed by Canadian Microanalytical Service Ltd., New Westminster, British Columbia.

[Rh(η²-(Ph₂P)₃CH)₂]Cl, *1*a

trans-$[RhCl(CO)(PPh_3)_2]$ (0.50 g, 0.72 mmol) and $(Ph_2P)_3CH$ (0.82 g, 1.44 mmol) were dissolved in benzene (15 mL). The dark orange solution rapidly lightened and produced an orange precipitate after ~5 min. This suspension was stirred for a further 4 h at room temperature. The solid was allowed to settle and the benzene solution removed via syringe. The resulting orange product was washed with benzene (2 × 5 mL) and dried *in vacuo*. The yield was 0.80 g (88%). The complex was recrystallized from CH_2Cl_2/diethyl ether. *Anal.* calcd. for $C_{74}H_{62}ClP_6Rh$: C 69.68, H 4.91; found: C 67.44, H 4.90.

[Rh(η²-(Ph₂P)₃CH)₂]BF₄, **1**b

[Rh(η²-(Ph₂P)₃CH)₂]Cl, **1***a*, (0.25 g, 0.20 mmol) was dissolved in CH_2Cl_2 (15 mL) and $NaBF_4$ (0.033 g, 0.30 mmol) added with stirring. This mixture was stirred for 12 h, the solution filtered over Celite and the solvent removed *in vacuo*. The orange product was recrystallized from CH_2Cl_2/diethyl ether. The yield was 0.25 g (94%). *Anal.* calcd. for $C_{74}H_{62}BF_4P_6Rh$: C 66.98, H 4.72; found: C 65.54, H 4.65. The BPh_4^-, **1***c*, and ClO_4^-, **1***d*, complexes were prepared similarly using appropriate sodium salts. Orange crystals of **1***b*, **1***c*, or **1***d* were easily obtained by slow diffusion of diethyl ether into an acetonitrile or dichloromethane solution of the complex.

[Ir(CO)(η²-(Ph₂P)₃CH)₂]Cl, **2**a

trans-[IrCl(CO)(PPh₃)₂] (0.50 g, 0.64 mmol) and $(Ph_2P)_3CH$ (0.73 g, 1.28 mmol) were dissolved in benzene (15 mL). The solution was stirred for 18 h at room temperature during which time a fine pale yellow precipitate formed. The solid was allowed to settle and the benzene solution removed via syringe. The resulting pale yellow solid was washed with benzene (2 × 5 mL) and dried *in vacuo*. The yield was 0.65 g (73%). The complex was recrystallized from CH_2Cl_2/diethyl ether. *Anal.* calcd. for $C_{75}H_{62}ClIrOP_6$: C 64.67, H 4.50; found: C 62.61, H 4.60; ir: ν(CO), (CH_2Cl_2) 1958 cm^{-1}, (Nujol) 1938 cm^{-1}.

[Ir(CO)(η²-(Ph₂P)₃CH)₂]BF₄, **2**b

This complex was prepared from **2***a* in a procedure identical to that used for **1***b*. The yellow product was recrystallized from CH_2Cl_2/diethyl ether. The yield was 98%. *Anal.* calcd. for $C_{75}H_{62}BF_4IrOP_6 \cdot CH_2Cl_2$: C 59.69, H 4.23; found: C 58.63, H 4.37. Infrared: ν(CO), (CH_2Cl_2) 1958 cm^{-1}, (Nujol) 1950 cm^{-1}. The BPh_4^-, **2***c*, and ClO_4^-, **2***d*, complexes were similarly prepared using the appropriate sodium salts. Yellow crystals of **2***b*, **2***c*, or **2***d*, as the CH_2Cl_2 solvate, were easily prepared by slow diffusion of diethyl ether into a CH_2Cl_2 solution of the complex.

[Pd(η²-(Ph₂P)₃CH)₂]Cl₂, **3**a

K_2PdCl_4 (0.10 g, 0.31 mmol) was dissolved in distilled water (3 mL) and this solution added dropwise to a solution of $(Ph_2P)_3CH$ (0.35 g, 0.62 mmol) in ethanol (20 mL) at ~45°C. The mixture was stirred at this temperature for 2 h during which time an orange precipitate formed. The suspension was then stirred for a further 12 h at room temperature. Solvents were removed, the product washed with distilled water (2 × 10 mL), toluene (2 × 10 mL), and CH_2Cl_2 (2 × 10 mL) and dried *in vacuo*. This product was insufficiently soluble for recrystallization or solution studies but this preparative method provided analytically pure material. The yield was 0.12 g (30%). *Anal.* calcd. for $C_{74}H_{62}Cl_2P_6Pd \cdot CH_2Cl_2$: C 64.37, H 4.62; found: C 63.43, H 4.79.

[Pd(η²-(Ph₂P)₃CH)₂][BF₄]₂, **3**b

[Pd(η²-(Ph₂P)₃CH)₂]Cl₂, **3***a*, (0.10 g, 0.076 mmol) and $NaBF_4$ (0.024 g, 0.22 mmol) were suspended in CH_2Cl_2 (25 mL) and the mixture stirred for 18 h. During this time the solids dissolved to produce a yellow solution and a fine colourless residue. The solution was filtered over Celite, the solvent removed *in vacuo* and the resulting pale yellow solid recrystallized from CH_2Cl_2/diethyl ether. The yield was 0.084 g (84%). *Anal.* calcd. for $C_{74}H_{62}B_2F_8P_6Pd \cdot CH_2Cl_2$: C 59.96, H 4.30; found: C 59.69, H 4.25.

[Pt(η²-(Ph₂P)₃CH)₂]Cl₂, **4**a

This complex was prepared from K_2PtCl_4 in a procedure identical to that used for **3***a*. The product was an extremely insoluble, off-white solid. The yield was 61%. *Anal.* calcd. for $C_{74}H_{62}Cl_2P_6Pt$: C 63.34, H 4.46; found: C 63.32, H 4.53.

[Pt(η²-(Ph₂P)₃CH)₂][BF₄]₂, **4**b

This complex was prepared from **4***a* in a procedure identical to that used for **3***b*. The yield was 98%. Slow diffusion of diethyl ether into an acetonitrile solution of the complex produced single crystals suitable for X-ray diffraction studies.

[RhCl(H)(η²-(Ph₂P)₃CH)₂]BF₄, **5**a

[Rh(η²-(Ph₂P)₃CH)₂]BF_4, **1***b*, (0.10 g, 0.075 mmol) was dissolved in CH_2Cl_2 (10 mL) and HCl(g) introduced in place of the N_2(g) atmosphere. The orange solution immediately turned pale yellow. After stirring this solution for 1 h, with no further change, the excess HCl(g) was purged from the flask and the N_2(g) atmosphere returned. This produced no visible change in the solution. The solution was then taken to dryness and the product washed with diethyl ether (2 × 10 mL). The pale yellow product was air stable. The yield was effectively quantitative. *Anal.* calcd. for $C_{74}H_{63}BClF_4P_6Rh$: C 65.19, H 4.67; found: C 63.22, H 4.89. Infrared: ν(RhH), (CH_2Cl_2) 2095 cm^{-1}. ^{1}H nmr: (CD_2Cl_2) δ(hydride) −11.80 ppm(dq), $^2J_{PH}$ = 12.8 Hz, $^1J_{RhH}$ = 17.5 Hz.

[RhBr(H)(η²-(Ph₂P)₃CH)₂]BF₄, **5**b

The complex was prepared using HBr(g) in a procedure identical to that used for **5***a*. Satisfactory elemental analysis could not be obtained for this compound; however, spectroscopic data are consistent with the formulation and compare well with those found for **5***a*. Infrared: ν(RhH), (CH_2Cl_2) 2093 cm^{-1}. ^{1}H nmr: (CD_2Cl_2) δ(hydride) −10.61 ppm(dq), $^2J_{PH}$ = 12.4 Hz, $^1J_{RhH}$ = 18.4 Hz.

X-ray crystallographic analysis of bis[1,1,1-tris(diphenylphosphino)-methane] platinum(II) tetrafluoroborate, **4**b

Colourless crystals were obtained by vapour diffusion of diethyl ether into an acetonitrile solution of **4***b*. Diffraction experiments were performed on a four-circle Syntex $P2_1$ diffractometer with graphite monochromatized MoKα radiation. The initial orientation matrix was obtained from 15 machine-centred reflections selected from rotation photographs. Partial rotation photographs around each axis were consistent with a triclinic crystal system. Ultimately, 63 high-angle reflections ($11° < 2\theta < 37°$) were used to obtain the final lattice parameters and orientation matrix. Machine parameters, crystal data, and data collection parameters are summarized in Table 1. The observed diffraction symmetry was consistent with space groups $P1$ and $P\bar{1}$. $P\bar{1}$ was confirmed by a successful structure refinement. Intensity data ($\pm h, \pm k, +l$) were collected in one shell ($4.5° < 2\theta < 40.0°$). The intensities of three standard reflections ($\bar{2}\,3\,3$, $\bar{3}\,6\,6$, $\bar{7}\,0\,3$) were collected every 197 reflections and showed no statistically

significant changes over the duration of the data collection. The data were absorption corrected (μ = 22.4 cm^{-1}) empirically by interpolation in 2θ and ϕ between Ψ-scans of reflections $\bar{2}$ 3 3, $\bar{3}$ 6 6, and 1 3 2. The data were processed by using the SHELX-76 program package on the computing facilities shared with the University of Manitoba. A total of 3238 reflections were collected and 2995 with $F_o^2 > 3\sigma(F_o^2)$ were used in the refinement.

The Pt atom was positioned at (0,0,0) with half-occupancy and the remaining unique non-hydrogen atoms were located from successive difference Fourier map calculations. Refinement was carried out using full-matrix least-squares techniques on F minimizing the function $\Sigma w(|F_o| - |F_c|)^2$, where $w = 4F_o^2/\sigma^2(F_o^2)$ and F_o and F_c are the observed and calculated structure factors. Atomic scattering factors (19) and anomalous dispersion terms (20, 21) were taken from the usual sources. In the first cycles of least-squares refinement, all non-hydrogen atoms, with the exception of the phenyl C atoms, were assigned anisotropic thermal parameters. The phenyl rings were constrained to an idealized C_{6h} symmetry with C—C distances of 1.39 Å and assigned isotropic thermal parameters. Fixed H atom contributions were included with C—H distances of 0.95 Å and thermal parameters equal to 1.1 times the isotropic thermal parameter of the bonded C atoms. No H atoms were refined, but all values were updated as refinement continued. This resulted in $R = \Sigma||F_o| - |F_c||/\Sigma|F_o| = 0.0687$ and $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2} = 0.0728$ at final convergence.

The Δ/σ values for any parameters in the final cycles were less than 0.004. A final difference Fourier map calculation showed no peaks of chemical significance; the largest was 2.1 e/Å^3 associated with the Pt atom. Selected bond lengths and angles are summarized in Table 2 and atomic positional and thermal parameters in Table 3. Anisotropic thermal parameters (Table S-1), hydrogen atom parameters (Table S-2), and values of $10|F_o|$ and $10|F_c|$ (Table S-3) are deposited as supplementary material.[2]

[2]Supplementary Tables S-1, S-2, and S-3 may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

[a]Multiplied by 10^4.

Results and discussion

Synthesis and characterization of the complexes

The bright orange complex [Rh(η^2-$(Ph_2P)_3CH)_2$]Cl, **1***a*, is easily prepared by reacting a benzene solution of *trans*-[RhCl(CO)$(PPh_3)_2$] with 2 equivalents of $(Ph_2P)_3CH$ according to reaction [1].

[1] *trans*-[RhCl(CO)$(PPh_3)_2$] + 2$(Ph_2P)_3CH$ $\xrightarrow[\text{R.T.}]{\text{benzene}}$ [Rh(η^2-$(Ph_2P)_3CH)_2$]Cl + 2PPh_3 + CO

The product precipitates from solution, in high yield, as the Cl^- salt. Treatment of **1***a* with an excess of NaX (X = BF_4^-, BPh_4^-, ClO_4^-) in CH_2Cl_2 yields the corresponding X^- salts. The infrared spectra of complexes **1***a*–**1***d* show no absorptions in the

ν(CO) region and the complexes are formulated as the four-coordinate species $[Rh(\eta^2\text{-}(Ph_2P)_3CH)_2]X$. The $^{31}P\{^1H\}$ nmr spectra of **1***a*–**1***d* are identical and also consistent with the formulation of these complexes as salts of the square planar cation $[Rh(\eta^2\text{-}(Ph_2P)_3CH)_2]^+$. Each shows two sets of resonances at room temperature, a broad singlet of intensity 1 at ca. −20 ppm and a broad doublet of intensity 2 at ca. −7 ppm. As the temperature is lowered these resonances sharpen and separate to produce the limiting spectrum at 220 K (Fig. 1). At this temperature there are four separate sets of resonances, two doublets of triplets (δ = −9.6, $^1J_{RhP}$ = 113.5 Hz, $^2J_{PP}$ = 7.8 Hz; and δ = −9.3, $^1J_{RhP}$ = 114.0 Hz, $^2J_{PP}$ = 7.3 Hz) and two doublets of quintets (δ = −21.4, $^3J_{RhP}$ = 2.7 Hz and δ = −22.1, $^3J_{RhP}$ = 2.8 Hz).

This can be explained by the presence of two geometrical isomers of the $[Rh(\eta^2\text{-}(Ph_2P)_3CH)_2]^+$ cation. One isomer, (A), will have uncoordinated PPh_2 groups oriented on the same side of the Rh(P—P)$_2$ coordination plane, and the other isomer, (B), will have uncoordinated PPh_2 groups oriented on opposite sides of the Rh(P—P)$_2$ coordination plane. These isomers are referred to as the *syn*, (A), and *anti*, (B), isomers (Fig. 1). Each isomer shows two sets of resonances due to coordinated PPh_2 groups with appropriate $^1J_{RhP}$ and $^2J_{PP}$ and uncoordinated PPh_2 groups with appropriate $^3J_{RhP}$ and $^2J_{PP}$, in a 2:1 intensity ratio (Table 4). It should also be noted that the relative ratio of these two isomers in solution is approximately 3:1. Although it is impossible to unambiguously determine which isomer is the major component, molecular models indicate that the *anti*-form is the least sterically crowded in terms of intramolecular contacts. Although we have not observed the high temperature averaged spectra, the temperature dependence of the nmr spectra presumably reflects an intramolecular exchange process which interchanges coordinated and uncoordinated PPh_2 groups at the coordinatively unsaturated Rh(I) centre. A mechanism that involved deprotonation of the ligand and inversion at the apical carbon, C(1), is also possible but unlikely under these experimental conditions.

A similar reaction to reaction [1] employing *trans*-$[IrCl(CO)(PPh_3)_2]$ as the starting material gives the pale yellow complex $[Ir(CO)(\eta^2\text{-}(Ph_2P)_3CH)_2]Cl$, **2***a*, and the X^- salts, **2***b*–**2***d*, are readily prepared from treatment with excess NaX in CH_2Cl_2, as for **1***b*–**1***d*. The infrared spectra of **2***a*–**2***d*, in CH_2Cl_2 solution, exhibit a single absorption in the ν(CO) region illustrating that for the iridium complexes the CO group is not lost upon

complex formation as is the case for **1***a*. The $^{31}P\{^1H\}$ nmr spectra of **2***a*–**2***d* are identical but show no temperature dependence. The spectra show only two sets of resonances, a triplet of intensity 2 ($\delta = -45.8$, $^2J_{PP} = 10.3$ Hz) and a quintet of intensity 1 ($\delta = -15.1$). This results in a formulation of complexes **2***a*–**2***d* as salts of the 5-coordinate, coordinatively saturated cation $[Ir(CO)(\eta^2\text{-}(Ph_2P)_3CH)_2]^+$. Since the $^{31}P\{^1H\}$ nmr spectra show only two types of PPh_2 groups, this cation must necessarily have either a square pyramidal structure with a *syn* orientation of the PPh_2 groups or a rapidly fluxional trigonal bipyramidal structure. The square pyramidal geometry is known to be favoured over trigonal bipyramidal geometry for small bite-angle chelate ligands with strongly bound ligands, such as CO, occupying the apical position (22). The observation of only one isomeric form for $[Ir(CO)(\eta^2\text{-}(Ph_2P)_3CH)_2]^+$ is presumably due to large energy differences between the possible ligand arrangements. The presence of the apical CO ligand above the square coordination plane likely stabilizes the *syn* isomer of the complex with the uncoordinated PPh_2 groups oriented away from the CO ligand in order to avoid steric interactions between the $(Ph_2P)_3CH$ ligands and the CO group. The absence of any exchange process enhances this view but could also be the result of coordinative saturation at the Ir(I) centre which would eliminate any associative exchange mechanism necessarily requiring a 6-coordinate, 20-electron intermediate. Any attempt, thermally, photochemically, or chemically to remove CO from complexes **2***a*–**2***d*, to produce the analogs of **1***a*–**1***d*, failed. These reactions resulted in either no reaction or decomposition of the $(Ph_2P)_3CH$ ligand.

It should be noted that others (9, 22) have reported attempts to prepare rhodium complexes of $(Ph_2P)_3CH$ via the complexes $[RhCl(COE)_2]_2$ (COE = cyclooctene) and $[RhCl(CO)_2]_2$. In each case, only uncharacterized dimeric species (9) or ill-defined products were isolated (22). This is interesting since in the course of this study we reacted $[RhCl(COD)]_2$ (COD = 1,5-cyclooctadiene) with two equivalents of $(Ph_2P)_3CH$ in CH_2Cl_2 at room temperature under a CO atmosphere. We found that the only product from this reaction is $[Rh(\eta^2\text{-}(Ph_2P)_3CH)_2][Rh(CO)_2Cl_2]$. The $^{31}P\{^1H\}$ nmr shows a spectrum identical to that of **1***a*–**1***d* and the infrared spectrum shows an extra ν(CO) absorption at 2066 cm^{-1} due to the complex anion. The same reaction with $[IrCl(COE)_2]_2$ produces $[Ir(CO)(\eta^2\text{-}(Ph_2P)_3CH)_2][Ir(CO)_2Cl_2]$ also identified by comparison of $^{31}P\{^1H\}$ nmr and infrared spectroscopy with those of **2***a*–**2***d*. Since the exact reaction conditions of these attempts are not published we can only assume that some type of thermal decomposition was occurring in these other studies.

The Pd(II) and Pt(II), square planar complexes analogous to **1***a* are readily prepared by the reaction of an aqueous solution of K_2MCl_4 (M = Pd, Pt), with $(Ph_2P)_3CH$ in warm ethanol according to reaction [2].

$$[2]\quad K_2MCl_4 + 2(Ph_2P)_3CH \xrightarrow[R.T.]{H_2O/EtOH} [M(\eta^2\text{-}(Ph_2P)_3CH)_2]Cl_2 + 2KCl \qquad M = Pd, Pt$$

The pale yellow Pd, **3***a*, and cream Pt, **4***a*, complexes precipitate from solution. Although very insoluble, both complexes are isolated in moderate yield as analytically pure samples by washing with H_2O, toluene, and CH_2Cl_2 to remove impurities. The BF_4^- salts **3***b* and **4***b* were prepared, as before, from the treatment with an excess of $NaBF_4$ in CH_2Cl_2. Both

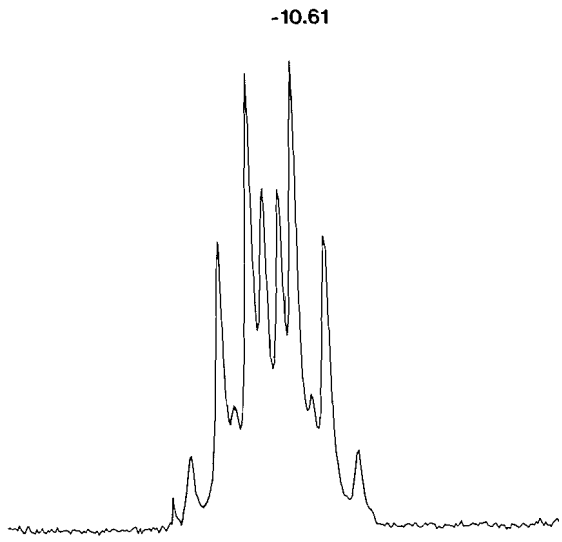

FIG. 2. The ^1H nmr spectrum of *trans*-$[RhBr(H)(\eta^2\text{-}(Ph_2P)_3CH)_2][BF_4]$, **5***a* in CD_2Cl_2 at 300 K showing the hydride resonance only.

complexes are formulated as the square planar dications $[M(\eta^2\text{-}(Ph_2P)_3CH)_2]^{2+}$, (M = Pd, Pt). As was the case for the Rh(I) complexes, the $^{31}P\{^1H\}$ nmr spectra show the presence of two separate *syn* and *anti* isomers in solution for **3***b* and **4***b* (Table 4). However, the exchange process is much slower and a static spectrum is observed near room temperature for both the Pd(II) and Pt(II) complexes. Also, the ratio of major to minor isomer is much larger, approximately 10:1 for both complexes. As noted previously for the Rh(I) complexes, it is impossible to determine which isomer is the major species in solution; however, it appears that one is much more favourable for the Group 10 metals. A detailed X-ray crystallographic analysis of **4***b* shows that in the solid state the only form present is the *anti* isomer (Fig. 3). This evidence makes it likely that the *anti* isomer is also favoured in solution, but such extrapolations are purely speculative.

Since the unreactivity of the $[Rh(\eta^2\text{-}(Ph_2P)_3CH)_2]X$ complexes towards CO did not allow the direct comparison of the Rh(I) and Ir(I) complexes, it was of interest to investigate briefly, the reaction of the coordinatively unsaturated $[Rh(\eta^2\text{-}(Ph_2P)_3CH)_2]^+$ cation (**1***b*, X = BF_4^- was used) towards the oxidative addition of HX (X = Cl, Br).

Reaction of **1***b* with HCl(g) yields the Rh(III) hydride complex *trans*-$[RhCl(H)(\eta^2\text{-}(Ph_2P)_3CH)_2]BF_4$, **5***a*. The same reaction with HBr(g) yields *trans*-$[RhBr(H)(\eta^2\text{-}(Ph_2P)_3CH)_2]BF_4$, **5***b*. Both reactions are clean and produce a pale yellow solid which can be recrystallized from CH_2Cl_2/diethyl ether. Infrared spectra show a characteristically weak ν(RhH) absorption at 2095 and 2093 cm^{-1} for **5***a* and **5***b*, respectively. $^{31}P\{^1H\}$ and ^1H nmr for both reactions are consistent with the formation of a single metal complex with no evidence of isomers. The $^{31}P\{^1H\}$ nmr spectra showed two sets of resonances for each complex, a doublet of triplets of intensity 2 and a quintet of intensity 1 (Table 4). The ^1H nmr spectra showed only one hydride resonance for each complex which appeared as an overlapping doublet of quintets (**5***a*: $\delta = -11.80$, $^1J_{RhH} = 17.5$ Hz, $^2J_{PH} = 12.8$ Hz; and **5***b*; $\delta = -10.61$, $^1J_{RhH} = 18.4$ Hz, $^2J_{PH} = 12.4$ Hz) (Fig. 2). From this evidence, the Rh(III) complexes must be octahedral with a *trans* disposition of the HX addenda and a *syn* arrangement of the $(Ph_2P)_3CH$

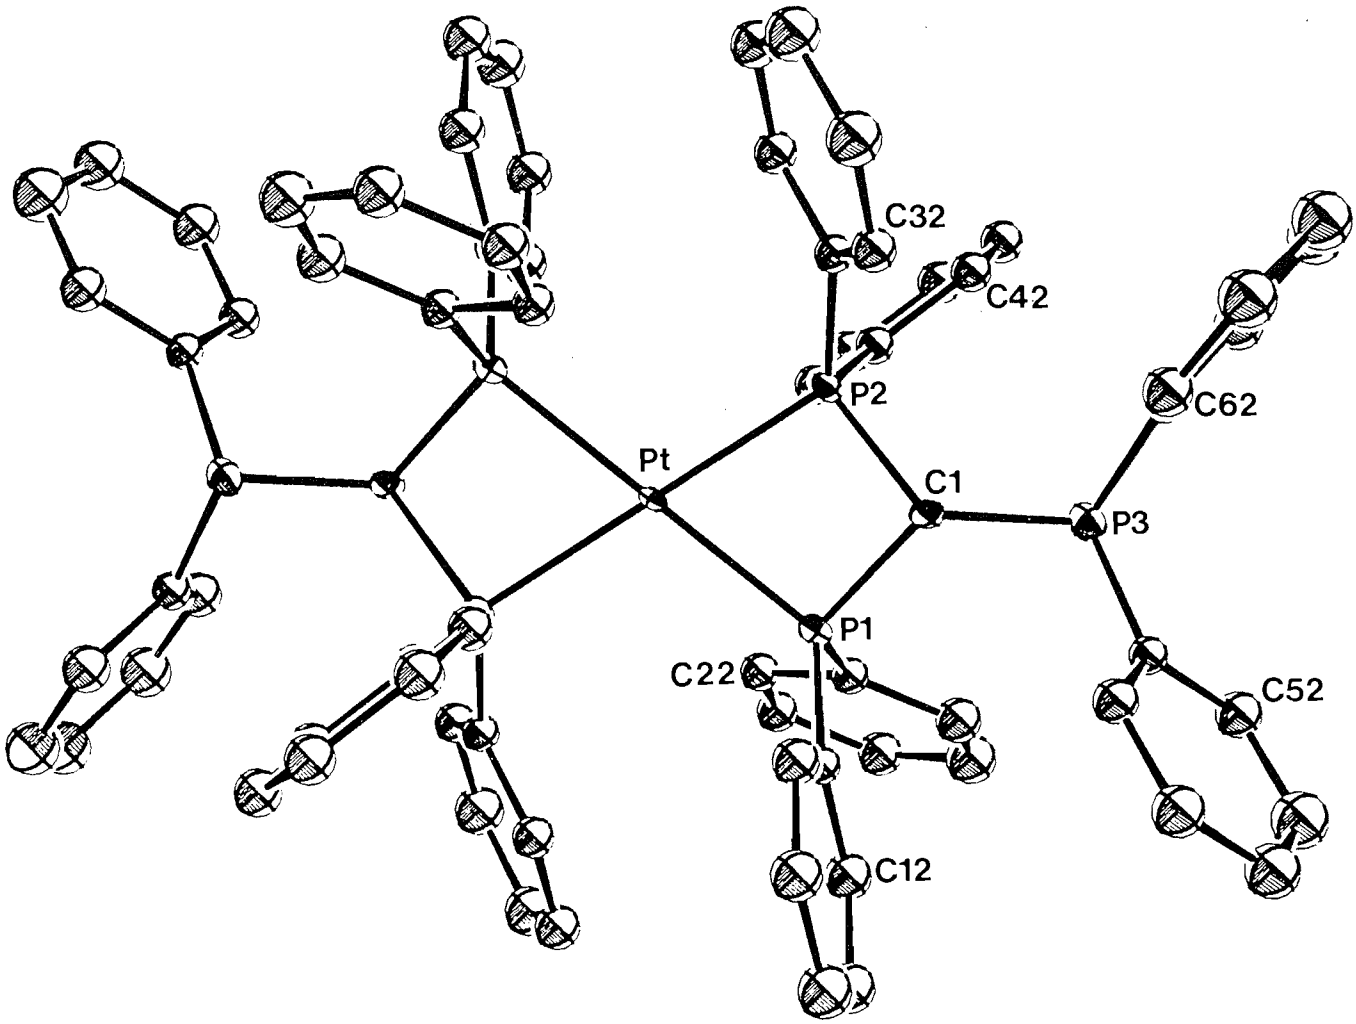

FIG. 3. Perspective ORTEP drawing of the $[Pt(\eta^2\text{-}(Ph_2P)_3CH)_2]^{2+}$ cation of **4***b* showing the numbering scheme. The numbering of phenyl ring carbon atoms starts at the atom bound to phosphorus; 20% thermal ellipsoids are shown.

ligands, likely with the uncoordinated PPh_2 groups oriented towards the smaller hydride ligand.

Structure description of $[Pt(\eta^2\text{-}(Ph_2P)_3CH)_2][BF_4]_2$

A perspective view of **4***a* giving the atom-numbering scheme is shown in Fig. 3, and a representation of the inner coordination sphere of the molecule is shown, with some relevant parameters, in Fig. 4. The unit cell contains one discrete complex dication and two BF_4^- anions. The closest intermolecular non-bonded contact between cations is 2.53 Å between H55 and H15′. The closest intramolecular cation to anion approach is 2.15 Å between F1 and H16 and the closest Pt to anion distance is 3.57 Å to F1. Complete listings of interatomic distances and angles may be found in Table 2.

The complex cation exhibits square planar coordination geometry at the Pt(II) centre and the $(Ph_2P)_3CH$ ligands are arranged in an *anti* conformation with the uncoordinated PPh_2 groups oriented on opposite sides of the coordination plane. The four-membered chelate ring shows considerable distortion as evidenced by a P1—Pt—P2, chelate bite-angle of 72.2(1)° and a P1—C1—P2 angle of 92.1(5)° compared to normal bond angles of 90° and 109°, respectively. The bite-angle is comparable to those found for complexes containing chelated dppm, where the P—M—P angles range from 67–74° (11). The

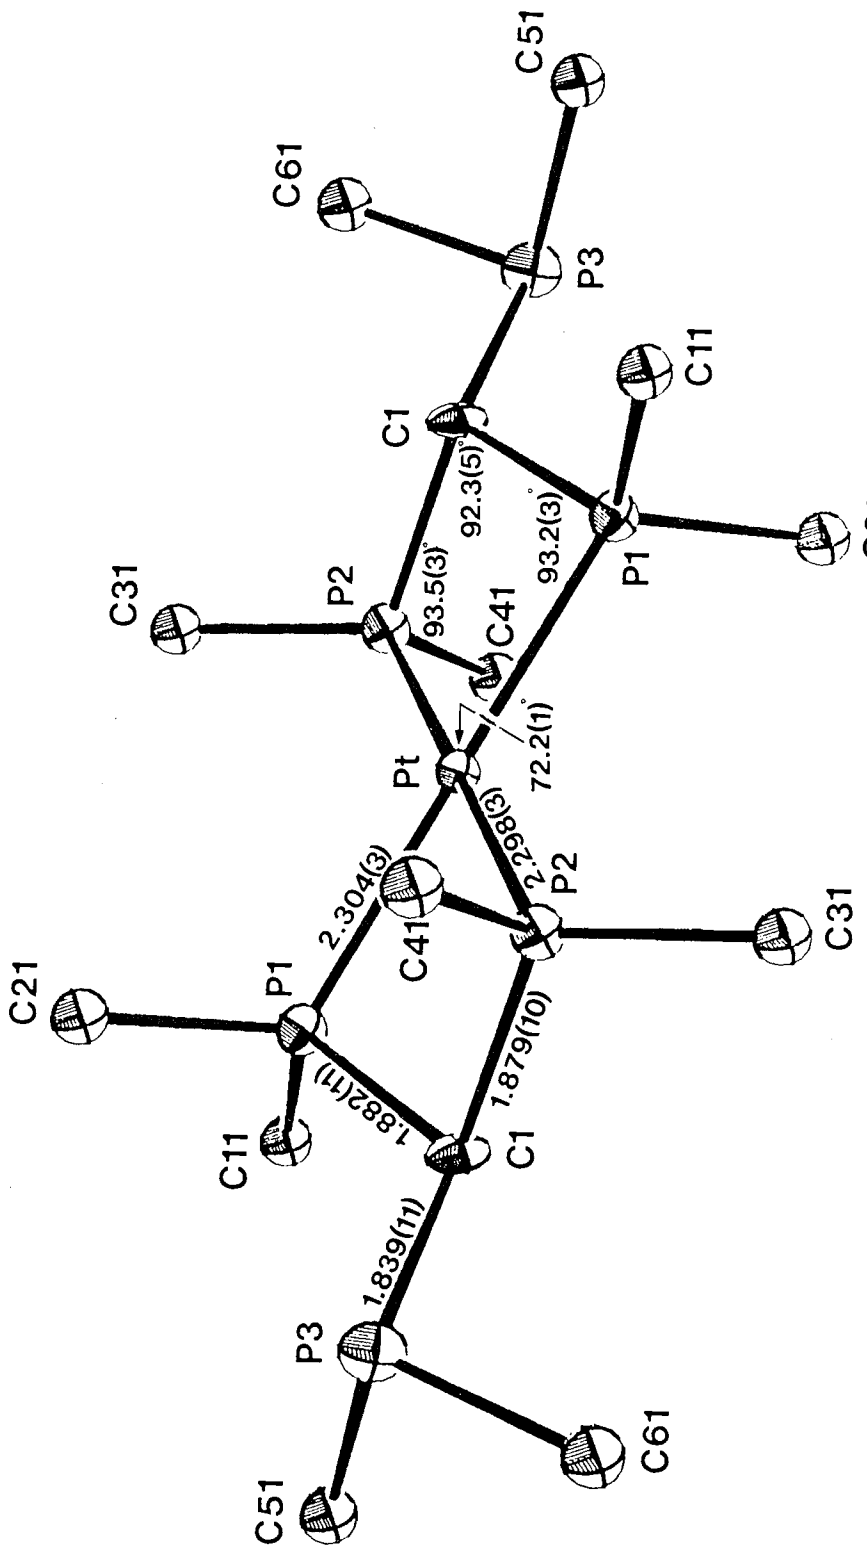

FIG. 4. Perspective ORTEP drawing of the $[Pt(\eta^2\text{-}(Ph_2P)_3CH)_2]^{2+}$ cation of **4***b*, with only the first carbon atom in each phenyl ring and showing some relevant bonding parameters.

P1—C1—P2 angle falls in the range of 91–97° found for dppm complexes (11, 23–26) and between the values of 88° and 103° found for η^3-$(Ph_2P)_3CH$ (9) and η^3,μ^3-$(Ph_2P)_3CH$ (1–7), respectively. These distortions result in a dihedral angle of 30.4° between the planes defined by P1—Pt—P2 and P1—C1—P2. Least-squares plane calculations and torsional angles are summarized in Table 5. This puckering of the chelate ring is slightly greater in **4***a* than in complexes of chelated dppm in which the dihedral angle varies from 16–24° (23–26). This is probably due to the steric requirements of the uncoordinated PPh_2 group in $(Ph_2P)_3CH$ which must be oriented away from the coordination sphere to eliminate intramolecular interactions between phenyl rings.

The phenyl rings are oriented approximately face-to-edge around the metal centre. This also occurs for the complex *trans*-$[RhCl(H)(dppm)_2][BPh_4]$ (23) and other complexes (see, for example, ref. 27) in which four PPh_2 groups occupy a square planar arrangement. All other bond distances and bond angles in the dication and anion are as expected.

On the crossed-aldol reaction of cyclohexane-1,2-dione with acetone, and the preparation of pyrroline derivatives from the product

GEORGE M. STRUNZ AND CHAO-MEI YU

Canadian Forestry Service – Maritimes, P.O. Box 4000, Fredericton, N.B., Canada E3B 5P7

Received October 13, 1987

This paper is dedicated to the memory of Professor Karel Wiesner

GEORGE M. STRUNZ and CHAO-MEI YU. Can. J. Chem. **66**, 1081 (1988).

Acetone reacts with cyclohexane-1,2-dione, on refluxing in the presence of potassium carbonate, to give the crossed-aldol product, 2-hydroxy-2-acetonylcyclohexanone, **2** (R = CH_3). Other methyl ketones react similarly with cyclohexane-1,2-dione. This is believed to be a consequence of unfavorable dipole interaction in the 1,2-dione. The product, on reaction with liquid ammonia, afforded the 5-amino-4-hydroxy-1-pyrroline derivative, **5**, which was reduced with lithium aluminum hydride to the 3-hydroxy-1-pyrroline, **7**.

GEORGE M. STRUNZ et CHAO-MEI YU. Can. J. Chem. **66**, 1081 (1988).

En faisant réagir la cyclohexane dione-1,2 avec l'acétone sous ébullition en présence du carbonate de potasse, on obtient un produit d'aldolisation croisée, soit l'hydroxy-2 acétonyl-2 cyclohexanone, **2** (R = CH_3). D'autres cétones méthyliques réagissent de la même façon avec la cyclohexane dione-1,2. Il s'agit d'un interaction dipolaire entre les groupes carbonyles voisins de la cyclohexane dione-1,2. En faisant réagir ce produit avec l'ammoniac liquide, on a obtenu le dérivé **5**, c.à d. l'amino-5 pyrroline hydroxy-4, qui est réduit en hydroxy-3 pyrroline-1 (**7**) par le tétrahydridoaluminate de lithium.

Reaction of cyclohexane-1,2-dione with methyl iodide and potassium carbonate in acetone was reported by Gibson (1) to give the expected 2-methoxycyclohex-2-enone in only 11% yield. By-products isolated from the reaction were an oil that was not characterized, and a crystalline compound, $C_{13}H_{18}O_4$ (6.5%), tentatively identified as 3-(1-hydroxy-2-oxocyclohexyl)-2-methoxycyclohex-2-enone, **1**. The benzyl enol ether was prepared from cyclohexane-1,2-dione in 35% yield (1).

During the *O*-alkylation of cyclohexane-1,2-dione with methyl bromoacetate, effected in 60% yield under similar conditions,[1] we also observed that the desired product was accompanied by an oily by-product. The major component of this material was identified, on the basis of its spectra, as the crossed aldol 2-hydroxy-2-acetonylcyclohexanone, **2** (R = CH_3), formed from cyclohexane-1,2-dione in some 5% yield. When cyclohexane-1,2-dione was refluxed in acetone solution with potassium carbonate in the absence of an alkylating agent, **2** (R = CH_3) was produced in 65% yield.[2] Several minor products, which were more polar, were not readily separable.

Structurally diagnostic signals in the ^1H nmr spectrum of **2** (R = CH_3) and their assignments are indicated in Fig. 1, and key mass spectral fragmentations are depicted in Fig. 2 (see also experimental section). The infrared spectrum (chloroform solution) shows carbonyl absorptions at 1710 and 1700 (sh) cm^{-1}, and the hydroxyl group is manifested as a band at 3460 cm^{-1}. The characteristics of the hydroxyl absorption, measured at several concentrations, indicate intramolecular hydrogen bonding (2). Inspection of models suggests that the most favorable partner for such bonding is the side-chain carbonyl oxygen.

Four different aldols might, in principle, be formed from a mixture of acetone and cyclohexane-1,2-dione. Aldol condensation involving bond formation at C-3 of cyclohexane-1,2-dione is not, however, a favorable process. This stems from the fact, revealed by Hückel molecular orbital calculations (3), that C-3 of the monoanion (enolate) of the 1,2-dione carries a partial positive charge. In effect, enone-type resonance overcomes electron release from enolate oxygen (3). Furthermore, it is well known that in the base-catalysed self-condensation of acetone, the equilibrium does not favor the aldol, diacetone alcohol (2).

Among the factors that contribute to the accumulation of the crossed aldol **2** (R = CH_3) observed in the present study, the unfavorable dipole interaction of the two adjacent carbonyl groups in cyclohexane-1,2-dione appears to be of central importance. The flexibility of the six-membered ring allows some relief from this energetically unfavorable interaction. It is further alleviated by enolization and, in the absence of solvent, cyclohexane-1,2-dione at 25°C exists as a tautomeric mixture containing about 40% of the enol form (4). The reaction of one carbonyl group of the dione with a suitable nucleophile, for the case in point the acetone enolate, clearly provides an alternative means to remove the unfavorable interaction, and is energetically favorable.

Treatment of cyclohexane-1,2-dione with 2-butanone under similar conditions afforded the aldol **2** (R = C_2H_5) in 33% yield (not optimized), and reaction with acetophenone gave **2** (R = Ph) (75%).

If the dipole interaction of the 1,2-dione provides a driving force for the formation of aldols **2**, it might be predicted that cyclopentane-1,2-diones, which are almost completely enolized (4), should have a lower propensity to undergo comparable condensations. This expectation was borne out when 3-methylcyclopentane-1,2-dione failed to give significant amounts of aldol products when subjected to identical treatment with potassium carbonate in acetone. (Longer reaction time resulted in the formation of a mixture from which a product, tentatively identified as **3**, was isolated in less than 1% yield.)

As a 1,4-diketone, **2** may be considered, *inter alia*, to be a potential precursor of heterocycles. Treatment of 2-monoalkyl- or 2,2-dialkyl-1,4-diketones with ammonia has been reported to yield hydroxypyrrolines, via a Paal–Knorr type

[1]C.-M. Yu: unpublished results.

[2]Although the "saturated ketonic impurity" contaminating his methylation product may have been **2** (R = CH_3), the work-up procedure employed by Gibson (1), in experiments otherwise similar to those described herein, could be expected to remove most of the aldol. We observed that shaking an ether solution of **2** (R = CH_3) with 2 N aqueous potassium hydroxide solution (cf. ref. 1) quite rapidly regenerates cyclohexane-1,2-dione (alkali soluble) by a retro-aldol process.

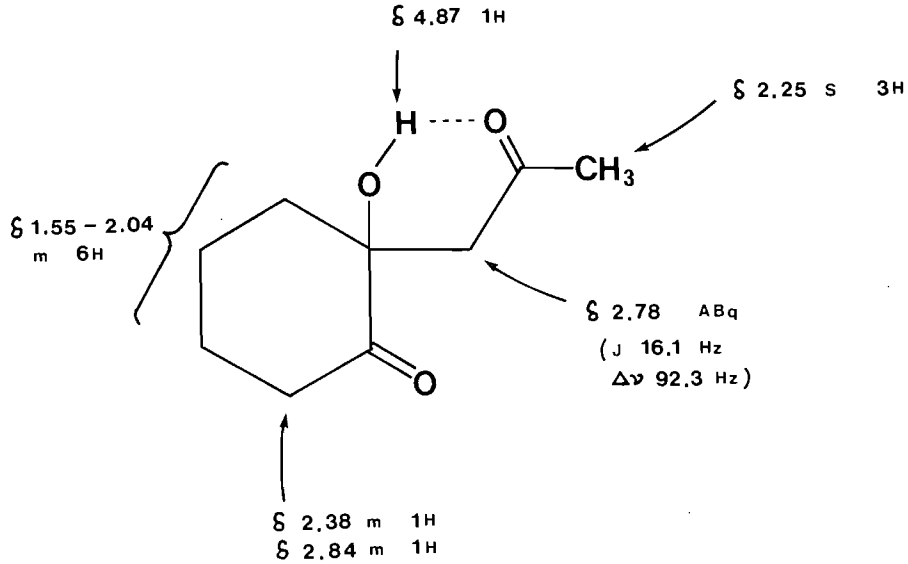

FIG. 1. Signals in the ^1H nmr spectrum of **2** (R = CH_3) and their assignments.

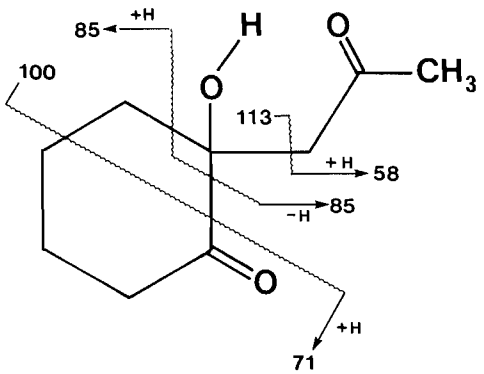

FIG. 2. Key mass spectral fragmentations of **2**.

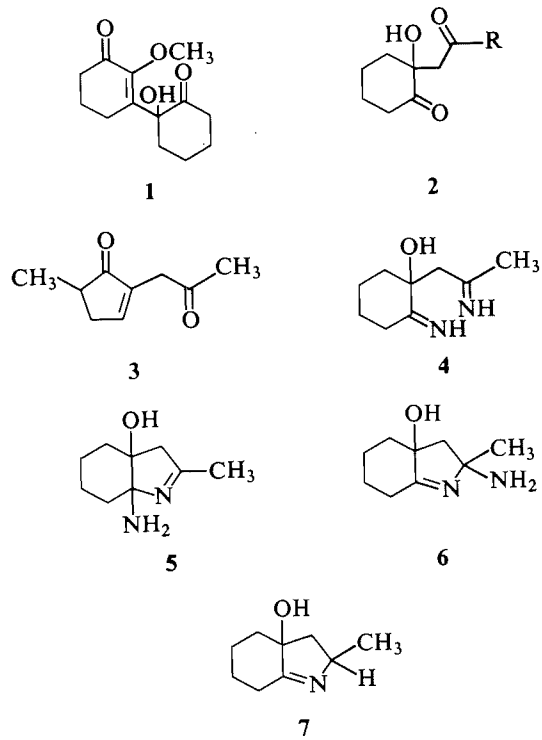
process (5), and the related products from 2-acyl-2-alkyl-1,4-diketones are intermediates in an interesting rearrangement (6). Reaction of **2** (R = CH_3) with an excess of liquid ammonia (cf. ref. 5) afforded a crystalline product whose formula, $C_9H_{16}N_2O$, suggested one of the isomeric structures **4**–**6**. The formulation **4** was excluded by the ^{13}C nmr spectrum, which revealed only one sp^2 hybridized carbon (δ 173.08, s). Of the remaining possibilities, **5** was favored by the ^1H nmr spectrum, which showed a singlet at δ 2.02 ppm for the methyl protons, and an AB quartet, ($|J_{AB}|$ 17.1 Hz; $\Delta\nu$ 24.2 Hz) at δ 2.57 for the methylene protons in the five-membered ring. (No other signals for non-exchangeable protons were evident below δ 2.00.)

The production of **5** from **2** (R = CH_3) contrasts with the behavior of the 2,2-dialkyl-1,4-diketones investigated previously (5). The latter, under similar conditions, reacted with only one equivalent of ammonia, and the products cyclized to hydroxypyrrolines. The different behavior, which is associated with the presence of the 2-hydroxyl function, may be a consequence of the ability of that group to participate in hydrogen-bonded association with ammonia molecules. Treatment of **5** with lithium aluminum hydride afforded the pyrroline **7** in high yield. The reaction occurs presumably by initial reduction of the imino function of **5**, followed by elimination of ammonia, probably during the work-up procedure. The structure and functionality of pyrroline **7** are reminiscent of an oxidation product, **8**, obtained from tetrahydrocarbazole (7). The latter



readily undergoes rearrangement to the spiro derivative **9**, under the action of acid, alkali, or heat (7). The driving force for this rearrangement was considered to be derived from resonance stabilization of the vinylogous lactam system present in **9**. In consonance with this view, **7**, which would not form a conjugated spiro product, was unchanged (tlc) under conditions that result in rearrangement of **8**.

Experimental

Melting points were determined on a hot-stage apparatus and are uncorrected. Infrared spectra were recorded on a Philips Pye Unicam PU9516 infrared spectrophotometer. Nuclear magnetic resonance spectra were run on a Varian XL-200 instrument. Accurate mass measurements were provided by Dr. A. Hogg, University of Alberta. Microanalysis was performed by Spang Microanalytical Laboratory, Eagle Harbor, MI.

Aldol condensation of cyclohexane-1,2-dione with acetone

A mixture of 1,2-cyclohexanedione (1.0 g), acetone (100 mL), and potassium carbonate (1.4 g) was heated under reflux for 5 h, in a flask protected from atmospheric moisture by a calcium chloride drying tube. When cold, the mixture was filtered, and the filtrate evaporated to dryness on a rotary vacuum evaporator. The residue was chromatographed on a column of silica gel using a gradient of chloroform and ether. Elution with chloroform–ether (9:1) afforded pure **2** (R = CH_3) as an almost colorless oil (0.98 g; 65%); ir ($CHCl_3$): 3460, 1710, and 1700 (sh) cm^{-1}; ^1H nmr ($CDCl_3$, 200 MHz) δ: 1.55–2.04 (6H, m), 2.25 (3H, s), 2.38 (1H, m), 2.78 (2H, ABq, J_{AB} = 16.1 Hz, $\Delta\nu$ = 92.3 Hz), 2.84 (1H, m), 4.87 (1H, exch.); mass spectrum (*inter alia*), *m/z* (relative intensity) (ion): 170.0945 (10.8) ($M^{\ddagger}$) (calcd. for $C_9H_{14}O_3$: 170.0943), 152.0839 (7.5) ($C_9H_{12}O_2$; M − H_2O)‡, 113.0603 (28.7) ($C_6H_9O_2$; M − C_3H_5O)$^+$, 100.0524 (100) ($C_5H_8O_2$)‡, 85.0655 (22.9) (C_5H_9O)$^+$, 85.0293 (41.4) ($C_4H_5O_2$)$^+$, 71.0498 (10.3) (C_4H_7O)$^+$, 58.0440 (29.3) (C_3H_6O)‡, 55.0202 (53.4) (C_3H_3O)$^+$.

Aldol condensation of cyclohexane-1,2-dione with 2-butanone

A mixture of 1,2-cyclohexanedione (0.54 g), 2-butanone (30 mL), and potassium carbonate (0.80 g) was heated under reflux for 10 h. The product, after work-up, was chromatographed on a column of silica gel using a gradient mixture of chloroform, ether, and hexane. Elution with chloroform–ether–hexane (7.5:1.5:1) afforded **2** (R = C_2H_5), which was further purified on silica gel preparative layer plates (solvent system, hexane – ethyl acetate (7:3)). The product **2** (R = C_2H_5) was obtained as an almost colorless oil (0.29 g, 33%); ir ($CHCl_3$): 3460, 1710, and 1700 (sh) cm^{-1}; ^1H nmr ($CDCl_3$, 200 MHz) δ: 1.05 (3H, t, *J* = 7.3 Hz), 1.56–2.06 (6H, m), 2.26–3.02 (4H, m), 2.77 (2H, ABq, J_{AB} = 15.9 Hz, $\Delta\nu$ = 91.7 Hz), 4.92 (1H, s); mass spectrum (*inter alia*), *m/z* (relative intensity) (ion): 184.1099 (27.0) ($M^{\ddagger}$) (calcd. for $C_{10}H_{16}O_3$: 184.1099), 166.0995 (4.5) ($C_{10}H_{14}O_2$; M − H_2O)‡, 156.1152 (4.6) ($C_9H_{16}O_2$; M − CO)‡, 127.0761 (42.0) ($C_7H_{11}O_2$; M − C_3H_5O)$^+$, 114.0682 (76.3) ($C_6H_{10}O_2$; M − C_4H_6O)‡, 99.0447 (26.7) ($C_5H_7O_2$)$^+$, 85.0656 (23.7) (C_5H_9O)$^+$, 72.0578 (21.1) (C_4H_8O)‡, 57.0362 (100.0) (C_3H_5O)$^+$.

Aldol condensation of cyclohexane-1,2-dione with acetophenone

A mixture of 1,2-cyclohexanedione (0.53 g), acetophenone (10.0 mL), and potassium carbonate (0.80 g) was heated at 90°C with stirring for 5 h. The product, after work-up, was chromatographed on a column of silica gel, and elution with chloroform–ether–hexane (7:1:2) gave crude **2** (R = Ph) as a pale yellow oil (0.82 g, 75%). A sample was purified by chromatography on silica gel preparative layer plates (solvent system, chloroform–ether–hexane (7:1:2)); ir ($CHCl_3$): 3470, 1715, 1670 cm^{-1}; ^1H nmr ($CDCl_3$, 200 MHz) δ: 1.64–2.09 (6H, m), 2.47 (1H, m), 2.91 (1H, m), 3.38 (2H, ABq, J_{AB} = 16.7 Hz, $\Delta\nu$ = 79.7 Hz), 4.94 (1H, s, $W_{1/2} \sim 6$ Hz), 7.43–7.65 (3H, m), 7.94–7.99 (2H, m); mass spectrum (*inter alia*), *m/z* (relative intensity) (ion): 232.1102 (10.2) ($M^{\ddagger}$) (calcd. for $C_{14}H_{16}O_3$: 232.1099), 214.0998 (1.5) ($C_{14}H_{14}O_2$; M − H_2O)‡, 204.1148 (15.1) ($C_{13}H_{16}O_2$; M − CO)‡, 162.0678 (58.0) ($C_{10}H_{10}O_2$; M − C_4H_6O)‡, 147.0446 (28.9) ($C_9H_7O_2$)$^+$, 120.0577 (23.0) (C_8H_8O)‡, 105.0343 (100.0) (C_7H_5O)$^+$, 77.0393 (44.4) (C_6H_5)$^+$.

Attempted aldol condensation of 3-methylcyclopentane-1,2-dione with acetone

When a mixture of 3-methylcyclopentane-1,2-dione (0.50 g), acetone (50 mL), and potassium carbonate (0.70 g) was heated under reflux for 5 h, little evidence of any reaction was observed. Increasing the reaction time to 36 h afforded a mixture from which a product, tentatively identified as **3**, was isolated by chromatography, in less than 1% yield; ir ($CHCl_3$): 1720 (sh), 1700, and 1635 cm^{-1}; ^1H nmr ($CDCl_3$, 200 MHz) δ: 1.20 (3H, d, *J* = 7.5 Hz), 1.65–2.99 (3H, m), 2.21 (3H, s), 3.34 (2H, s), 7.50 (1H, m, $W_{1/2}$ = 7 Hz).

Preparation of aminopyrroline, 5

Hydroxydiketone **2** (R = CH_3) (1.39 g) was stirred under reflux with anhydrous liquid ammonia (ca. 30 mL) for 5 h. The Dry Ice condenser was then removed and the ammonia was allowed to evaporate. Removal of the last traces of ammonia was effected on a rotary volume evaporator. The residue was crystallized twice from ether, affording colorless crystals of **5** (0.61 g, 45%), mp 98–100°C; ir ($CHCl_3$): 3500–3100, 1640 cm^{-1}; ^1H nmr ($CDCl_3$, 200 MHz) δ: 1.21–1.94 (10H, m), 2.02 (3H, s), 2.57 (2H, ABq, J_{AB} = 17.1 Hz, $\Delta\nu$ = 24.2 Hz), 3.47 (1H, m); ^{13}C nmr ($CDCl_3$) δ: 20.93 (q), 21.16 (t), 22.80 (t), 33.94 (t), 37.68 (t), 49.84 (t), 78.82 (s), 85.00 (s), 173.08 (s); mass spectrum (*inter alia*), *m/z* (relative intensity) (ion): 168.1264 (16.8) ($M^{\ddagger}$) (calcd. for $C_9H_{16}N_2O$: 168.1263), 151.0999 (16.3) ($C_9H_{13}NO$; M − NH_3)‡, 127.0999 (100) ($C_7H_{13}NO$; M − C_2H_3N)‡, 98.0615 (50.2) (C_5H_8NO)$^+$, 57.0600 (50.0) (C_3H_7N)‡.

Reduction of aminopyrroline 5 to pyrroline 7

A solution of **5** (200 mg, 1.19 mmol) in anhydrous tetrahydrofuran (20 mL) was heated under reflux with lithium aluminum hydride (87 mg, 2.29 mmol), in an atmosphere of dry nitrogen, for 3 h. Excess reagent was decomposed by cautious addition of wet ether, and the resulting mixture was filtered. The filtrate was dried over magnesium sulfate, filtered, and evaporated to dryness *in vacuo*. Purification of the product by preparative thin-layer chromatography (silica gel; hexane–acetone, 7:3), and crystallization from ether, gave colorless crystals of pyrroline **7** (155 mg, 85%). A sample, sublimed at 0.1 Torr (1 Torr = 133.3 Pa), melted at 75–77°C. Crystallized **7** displayed ir absorption ($CHCl_3$) at 3600 (sharp), 3500–3100, 1650 cm^{-1}; ^1H nmr ($CDCl_3$, 200 MHz) δ: 1.27 (3H, d, *J* = 6.9 Hz), 1.35–2.07 (6H, m), 2.13–2.29 (2H, m), 2.44–2.55 (2H, m), 3.55 (1H, br, exch.), 4.05 (1H, m); mass spectrum (*inter alia*), *m/z* (relative intensity) (ion): 153.1154 (100) ($M^{\ddagger}$) (calcd. for $C_9H_{15}NO$: 153.1154), 138.0922 (21.8) ($C_8H_{12}NO$; M − CH_3)$^+$, 125.1206 (83.4) ($C_8H_{15}N$; M − CO)‡, 110.0970 (65.9) ($C_7H_{12}N$; M − CO and CH_3)$^+$, 97.0892 (38.3) ($C_6H_{11}N$)‡, 82.0664 (55.8) (C_5H_8N)$^+$, 71.0501 (61.1) (C_4H_7O)$^+$. *Anal.* calcd. for $C_9H_{15}NO$: C 70.55, H 9.87, N 9.14%; found: C 70.61, H 9.94, N 9.12%.

Acknowledgments

The structure of traversianal, a tricyclic diterpenoid fungal metabolite of *Cercospora traversiana*, has been elucidated through detailed ^{1}H and ^{13}C magnetic resonance studies, including homo- and heteronuclear correlation spectra of the natural product and examination of ^{13}C-labelled material obtained by [1,2-$^{13}C_2$]acetate incorporation experiments. Its stereochemistry was established from a series of nuclear Overhauser effect difference spectra. The tricyclic carbon skeleton of traversianal is that of the fusicoccin /cotylenin and ophiobolane terpenes although the oxygenation pattern closely resembles the latter. Incorporation experiments with [2,2,2-$^{2}H_3$, 1-$^{13}C_1$]acetate revealed that traversianal arises by a sequence that differs substantially from that established for the fusicoccanes but rather resembles that previously shown for the ophiobolanes, in the retention of hydride at C-2, -10, and -14. However, the opposite configuration of the methyl group at C-3 suggests that the route to traversianal involves a terminal *trans*-geranylgeranyl unit instead of the *cis* unit implicated in ophiobolin generation.

Le traversianal est un métabolite fongique de la série des diterpénoïdes tricycliques qui est isolé du *Cercospora traversiana*; on en a déterminé la structure grâce à des études détaillées par résonance magnétique nucléaire du ^{1}H et du ^{13}C, y compris des corrélations spectrales homo- et hétéronucléaires du produit naturel, et par un examen du produit marqué au ^{13}C obtenu par des expériences d'incorporations d'unités acétates [$^{13}C_2$-1,2]. On a établi sa stéréochimie à partir d'une série de spectres différentiels de l'effet Overhauser nucléaire. Le squelette carboné tricyclique du traversianal correspond à celui des terpènes fusicoccine/cotylénine et ophibolane, même si la distribution des oxygèns ressemble plus à celle de ces derniers. Les expériences d'incorporation d'acétate [$^{2}H_3$-2,2,2 $^{13}C_1$-1] révèlent que le traversianal provient d'une séquence qui diffère beaucoup de celle établie pour les fusicoccanes, mais qui ressemble plutôt à celle qui a été mise en évidence pour les ophiobolanes et qui comporte une rétention de l'hydrure dans les positions C-2, C-10 et C-14. Toutefois, la configuration inverse du groupement méthyle en C-3 suggère que la voie menant au traversianal implique une unité *trans*-géranylgéranyle terminale plutôt que l'unité *cis* impliquée dans la génération de l'ophioboline.

[Traduit par la revue]

Introduction

In the course of a program on myco- and microbial phytotoxins, we recently isolated a novel diterpenoid aldehyde **1** (1) from a fungus that had been found to infect a field of fenugreek and identified as *Cercospora traversiana* (2). The present paper gives the full experimental evidence that led to the structural and stereochemical assignments. It also describes additional biosynthetic studies, utilizing acetate doubly labelled with ^{2}H and ^{13}C, which throw light on the relationship between this *C. traversiana* aldehyde, which we have named traversianal, and other natural products having the same tricyclic carbon skeleton. Not all of these are of fungal origin; those that are comprise the fusicoccins and cotylenins (3, 4), the classical ophiobolins A–F (3–5), the 6-epiophiobolins (5, 6), ophiobolins G and H (5, 7), and two recently reported 21-dihydroophiobolins (8). Several of these compounds are important as much-studied phytotoxins (3–7) and at least one, ophiobolin H, has been identified as a mycotoxin (5–7). Rather surprisingly, therefore, in tests that will be reported elsewhere, traversianal was found to be essentially inactive as a wilt or necrosis toxin towards a range of plants, although it does cause the efflux of betacyanins from beetroot slices. It is very active in the brine shrimp (*Artemia salina*) bioassay and is strongly molluscicidal. There is, therefore, room for concern about its potential as a mycotoxin.

Results and discussion

Structure

Traversianal crystallized readily on concentration of EtOAc or C_6H_6 extracts of potato-dextrose agar cultures of the fungus, and additional amounts were obtained by chromatography of the mother liquors over silica leading to overall yields of ca. 36 mg/L after 15 days' growth. Recrystallization from C_6H_6 furnished material that melted sharply at 234–235°C and had an optical rotation of $[\alpha]_D^{24}$ −248°. From its empirical constitution of $C_{20}H_{28}O_3$, established by microanalysis and precise mass measurement, the compound appeared to be a diterpene. Its ir spectrum contained hydroxyl absorption (3530 cm^{-1}) and carbonyl bands indicative of a cyclopentanoid ketone (1740 cm^{-1}) and an α,β-unsaturated aldehyde (1678, 2720, 2850 cm^{-1}); the latter chromophore exhibited uv absorption at 234 nm (ε 13 000). The ^{1}Hmr spectrum in CD_2Cl_2 solution showed that the formyl group (δ 9.09) was bonded to a trisubstituted double bond (δ 7.15, dd, J = 8.6, 8.8 Hz, 1H). In addition there was absorption characteristic of an isopropenyl group (δ 1.71 (dd, J = 0.7, 1.3 Hz, 3H), 4.72 (ddq, J = 0.7, 0.7, 2.5 Hz, 1H), and 4.81 (dq, J = 1.3, 2.5 Hz, 1H)), secondary and

tertiary methyl groups (δ 0.78 (d, J = 7.6 Hz) and 1.16 (s)), and one exchangeable hydroxyl proton. These features confirmed the diterpenoid nature of the metabolite. The ^{13}Cmr spectrum exhibited carbonyl signals at δ_C 220.7 and 193.6, attributable to a cyclopentanone and a conjugated aldehyde, respectively, with sp^2 absorption at δ_C 113.8 and 148.3 for the isopropenyl group and at δ_C 146.2 and 167.1, arising from the conjugated double bond. A quaternary carbon signal at δ_C 79.1 indicated the presence of a tertiary alcohol while the higher field sp^3 region contained signals for a quaternary carbon, four methine, five methylene, and three methyl carbons.

The product from the first experiment was examined by ^{1}Hmr in C_6D_6 but the limited solubility of subsequent crops of purer material led to their examination as CD_2Cl_2 solutions. Differences in the relative shieldings of the proton multiplets in the two solvents provided complementary data, which aided detailed interpretation of the proton spectra. However, in the following discussion the CD_2Cl_2 solution data are presented in detail but the ^{1}H results for C_6D_6 solution have been tabulated. ^{1}H–^{1}H and ^{13}C–^{1}H correlation spectra were recorded; the heteronuclear correlation permitted ready identification of the origins of the individual proton multiplets as methylene and methine patterns.

A methylene proton pattern at δ 3.32 and 2.27 was found to be coupled to the olefinic absorption at δ 7.15 and a methine pattern at δ 1.84 that was also coupled to a methine pattern centred at δ 3.03. The latter pattern exhibited strong coupling with methylene protons absorbing near 1.7 ppm and weak coupling to one of the isopropenyl olefinic protons (δ 4.72). The methylene absorption at δ 1.7 was also coupled to methylene protons centred at δ 1.45. These results led to part structure **A**, with which are included the ^{13}C shieldings for the protonated carbons. The proton spectrum, in conjunction with the ^{13}C–^{1}H correlation spectrum, led also to the identification of a second major fragment **B**. Methylene proton absorption at δ 2.52 and 2.59 with J_{gem} = 19.6 Hz was found to be coupled to a methine pattern at δ 2.29, which, in turn, exhibited coupling to the secondary methyl group (δ 0.78) and a methine pattern at δ 2.61. The latter pattern was coupled to two methylene protons (J_{gem} = 14.6 Hz) at δ 1.34 and 1.70.

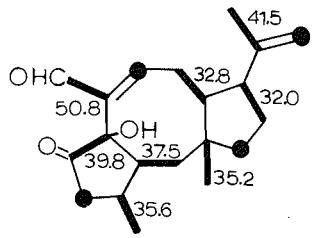
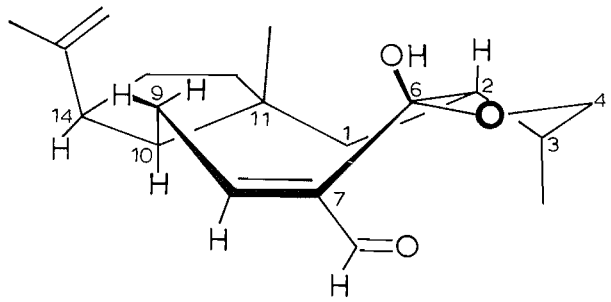
[a]Shieldings in ppm from internal TMS; ^{1}H–^{1}H couplings in Hz listed in parentheses.

These part structures **A** and **B** together with a cyclopentanoid carbonyl, a tertiary carbinyl carbon, and the quaternary carbon bearing the tertiary methyl group account for the 20 carbons and for four sites of unsaturation. Thus, traversianal is tricyclic including one cyclopentanoid unit and, with the assumption that no carbon–carbon rearrangements occur during its generation from geranylgeranyl pyrophosphate, can be most plausibly assigned structure **1**. The ^{1}H and ^{13}Cmr data are presented in Table 1.

To confirm the proposed structure, traversianal was isolated from cultures of the fungus grown on liquid potato-dextrose medium supplemented with [1,2-$^{13}C_2$]acetate with the addition of 10 mL of a 0.04 M solution to each 100 mL of culture on days 10 and 13. The ^{13}Cmr spectrum of $1^{-13}C_x$ isolated on day 16 showed that all carbons were labelled (4.4% specific incorporation) in the pattern **2**, precisely in accord with our expectations. The heavy bonds in **2** represent intact acetate units for which the observed J_{CC} values in Hz are indicated, while the dark circles indicate the carbons arising from C-2 of the four mevalonate units. The relatively high enrichment level signals the formation of multilabelled species, the presence of which will increase the probability of ^{13}C incorporation at contiguous carbons in **1** that arise from different acetate units. Thus, additional information on the carbon connectivities was sought through two-dimensional ^{13}C–^{13}C correlation (COSY) and double quantum coherence (2D-INADEQUATE) spectra (9). From the ^{13}C



2



3

COSY experiment, contour plots of which are shown in Fig. 1, the immediate neighbors of each of the sp^2 carbons and of the carbinyl carbon were readily established (Fig. 1*a*). The connectivities of all of the sp^3 carbons were also revealed (Fig. 1*b*) with the exception of the C-1, -11, -12 linkages, which undoubtedly involve signals at δ_C 42.9, 44.4, and 44.0, respectively. It may be noted that weak, off-diagonal elements confirming the C-10, -14 bonding become observable in plots at higher intensity levels. The 2D-INADEQUATE experiment provided corroboration of these results. Thus the structure of **1** in planar projection was established.

Stereochemistry

To determine the stereochemistry of **1** the intramolecular proton nuclear Overhauser effects were examined by nOe difference spectra. Saturation of the angular methyl protons at δ 1.16 enhanced the methine absorption at δ 2.61 (H-2) and the methylene pattern at δ 3.32 (H-9), which is vicinally coupled to H-10 at δ 1.84, J = 8.6 Hz. Irradiation at δ 3.32 only enhanced the pattern for its methylene partner at δ 2.27, which was also affected by irradiation of the olefinic proton at δ 7.15. It may be noted that the vicinal coupling between the 9-proton at δ 2.27 and H-10 is small, J = 1.0 Hz. Enhancement of the H-10 pattern (δ 1.84) was observed upon saturation of the multiplet at δ 3.03 (H-14) and of that at δ 1.34 (H-1), which is strongly coupled to H-2, J = 12.3 Hz, indicative of an antiperiplanar interaction. The H-1 pattern (δ 1.34) was enhanced by saturation of the secondary methyl protons (0.78) that also affected the multiplets for H-3 (δ 2.29) and the 4-methylene proton at δ 2.52. The latter two protons exhibited vicinal coupling of 2.8 Hz. Saturation of the olefinic methyl protons (δ 1.71) indicated that the olefinic pattern at δ 4.81 arises from the *cis* proton. These results lead to the relative stereochemistry illustrated in **3** with the angular methyl, the isopropenyl group, H-2, and the 6-OH group in β configurations while the secondary methyl group, H-10, and H-14 are α-oriented. Although the orientation of the hydroxyl group was not established, an examination of Dreiding models indicates that a *cis* junction of the cyclopentanoid ring at C-2 and -6 is more favorable than a *trans* ring junction with a 6α-hydroxyl group.

Biosynthesis

The tricyclic carbon skeleton of **1** is the same as that in other diterpenes, namely the fusicoccanes and cotylenins from *Fusicoccum amygdali* (10) and a *Cladosporium* (11), respectively, as represented by fusicoccin A (**4**), the fusicoplagins (12) and anadensin (13) from liverworts, as represented by fusicoplagin A (**5**), and several compounds such as roseanolone (**6**) and roseadione (**7**) from the higher plant *Hypoestes rosea* (14). The same tricyclic skeleton having an extended side chain is also found in the sesterterpenoid ophiobolins such as ophiobolin A (**8**) and 6-epiophiobolin A from *Cochliobolus* (*Helminthosporium*) and *Cephalosporium* spp (6, 15), ophiobolin G (**9**) from *Aspergillus ustus* (5, 7); as well as ceroplastol (**10**) and related compounds from the scale insect *Ceroplastes albolineatus* (16).

Detailed biosynthetic studies of the fusicoccins (17) have established the sequence in Scheme 1 involving successive hydride shifts from C-14 to C-15, from C-6 to C-7, and from C-2 to C-6 with proton loss from C-10 and C-1. Similar detailed studies of the ophiobolin biosynthesis (18) have shown that these protons do not migrate although there is a remarkable "1,5-hydride shift" from C-8 to C-15 (Scheme 2). It was of interest, therefore, to examine the genesis of **1** in more detail than that provided by the [1,2-$^{13}C_2$]acetate incorporation experiments described above to obtain evidence regarding hydride shifts. Two incorporation experiments were carried out for this purpose. In the first, the culture medium was supplemented with [2,2,2-$^2H_3$, 2-$^{13}C_1$]acetate, using the same experimental procedures as those employed in the earlier biosynthetic experiment. The ^{13}Cmr spectrum of **1**-^2H_x,$^{13}C_y$ isolated from

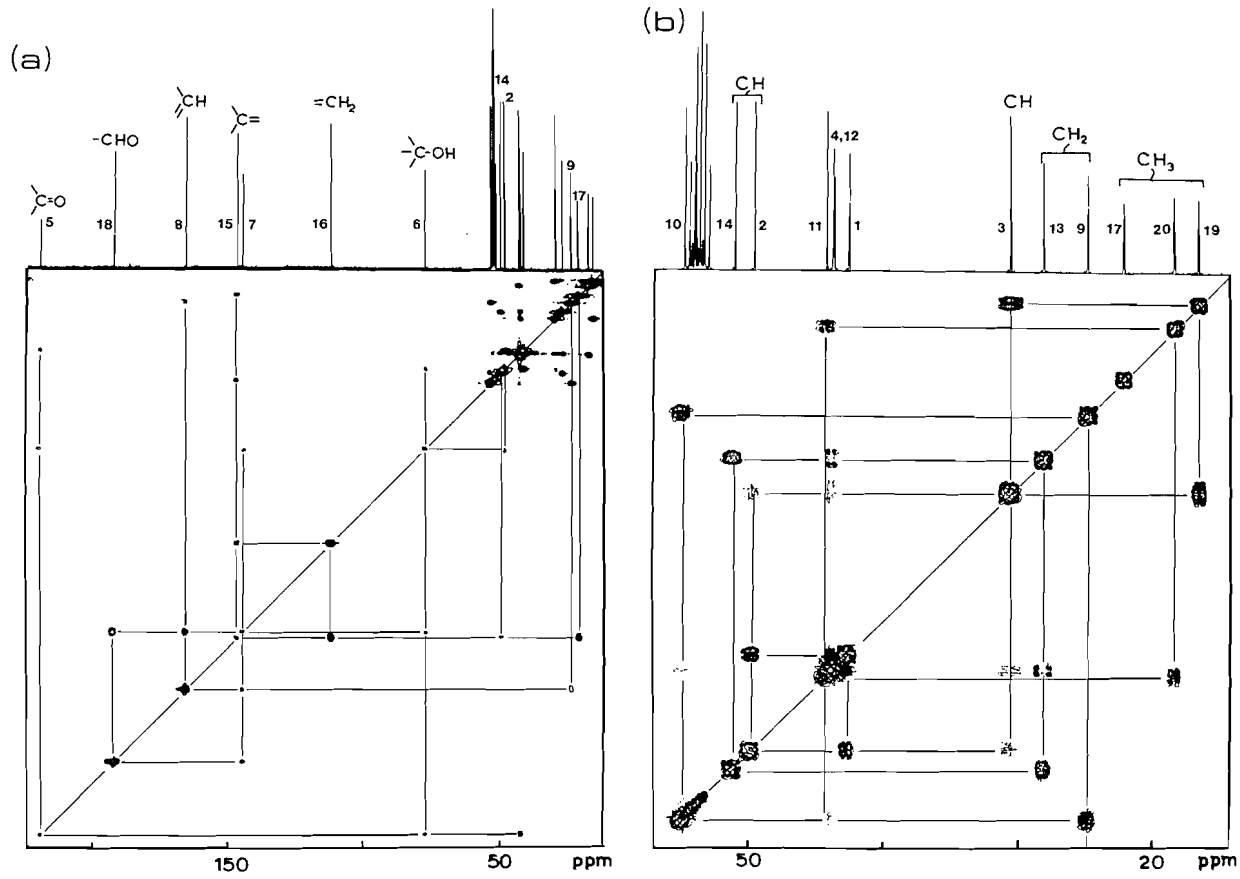

FIG. 1. Contour plots of the ^{13}C COSY spectrum of enriched traversianal: (a) full plot showing connectivities of the carbinyl and sp^2 carbons; (b) an expansion of the sp^3 region of the spectrum. The 1D spectrum of natural **1** is included above each plot for calibration.

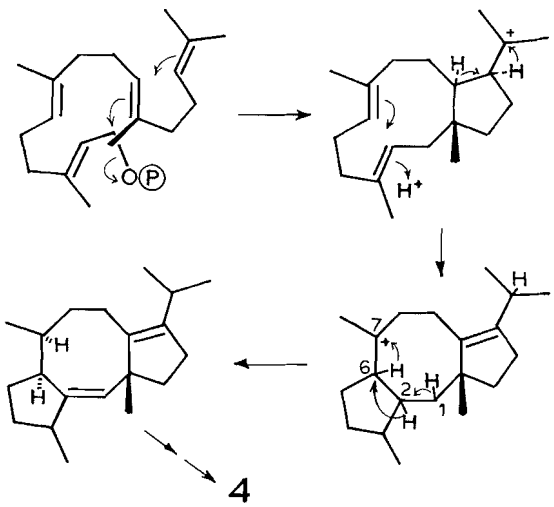
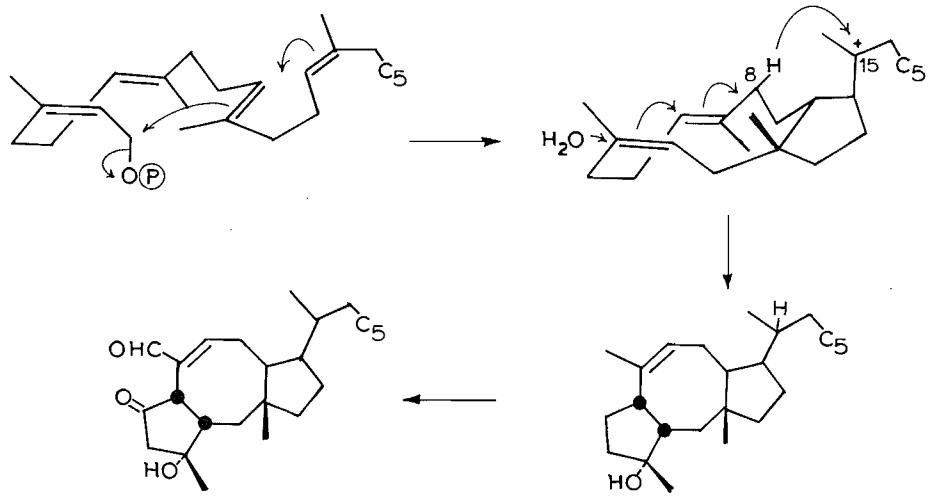


SCHEME 1

this experiment clearly contained isotope-shifted multiplets arising from deuterium directly bonded to labelled carbons at the 2-, 4-, 8-, 12-, 14-, 16-, and 18-positions as well as the three methyl sites, but the situation was not clear for C-10 because of the solvent absorption. Nevertheless, these results are definitely incompatible with a sequence similar to that leading to the fusicoccins for which no directly bonded deuterium would be evident at C-2, -10, and -14 because of hydride shifts. In addition, the absence of any two-bond isotope shifts is consistent with a lack of hydride shifts. It may be noted that two-bond ^2H-induced effects have been employed to identify hydride shifts in other biosynthetic studies (19). In any event, the labelling pattern observed corresponded with that expected for a sequence resembling that found for the ophiobolins. To clarify the picture regarding C-10 and to obtain confirmatory evidence, a second experiment was carried out in which **1**-^2H_x,$^{13}C_y$ was isolated from a culture medium supplemented with [2,2,2-$^2H_3$, 1-$^{13}C_1$]acetate. Its ^{13}C spectrum contained isotope-shifted components arising from ^2H-induced effects through two bonds, i.e., β shifts, for enriched carbons at the 1-, 3-, 7-, 9-, 11-, 13-, and 15-positions. In effect, this experiment reveals the ^2H_x-C-^{13}C fragments arising from incorporation of intact CD_3–$^{13}CO_2$- units and the results show that deuterium is retained through the sequence at C-2, C-10, C-14, C-18, and the three methyl groups. Thus, hydride shifts do not occur from C-2, -10, or -14; this is exactly analogous to the findings for the ophiobolins but contrary to the results for the fusicoccins. The ^2Hmr spectrum of this sample of **1**-^2H_x,$^{13}C_y$ is shown in Fig. 2 together with the proton spectrum. Integration of the deuterium spectrum revealed the relative ^2H content at the various positions to be three at each of the methyl sites (C-17, -19, -20), two at the three methylene positions (C-4, -12, -16), and one at each of C-2, -8, -10, -14, and -18. The signal for the formyl deuterium appears as a doublet because the geminal J_{D-C-C} coupling is sufficiently large to be readily resolved, $J \sim 23$ Hz. All of these data are, therefore, consistent with a biosynthetic sequence closely similar to that for the ophiobolanes although these cannot reveal whether a C-8 to C-15 hydride shift occurred at an intermediate stage.



SCHEME 2

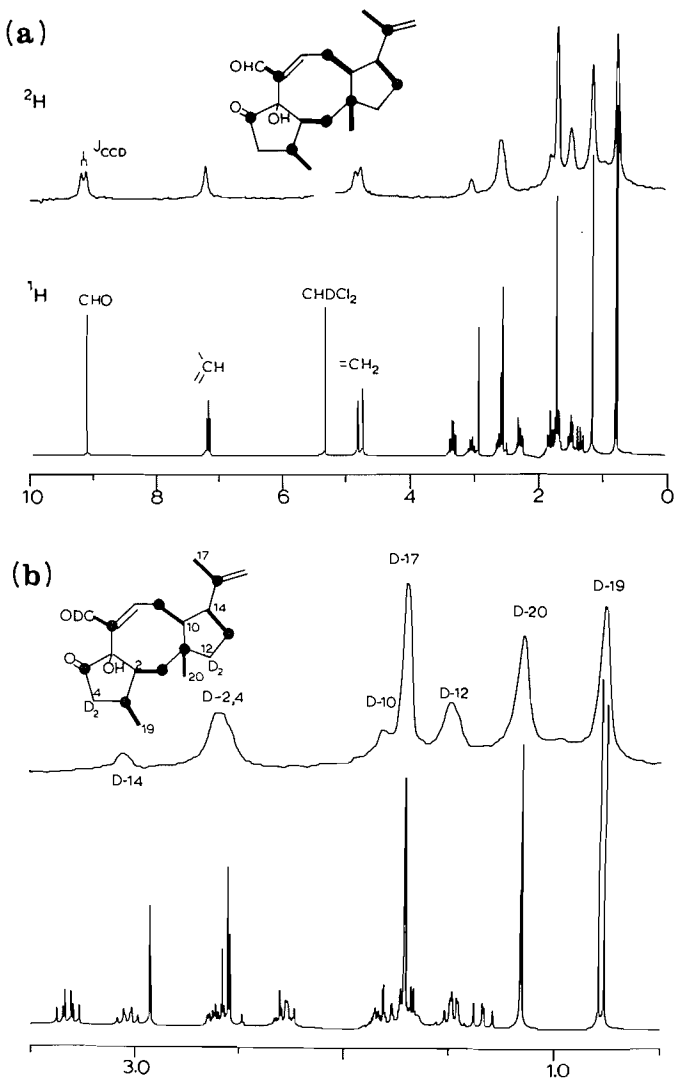


FIG. 2. The ^{2}Hmr spectra of **1**-^2H_x,$^{13}C_y$, arising from [2,2,2-$^2H_3$, 1-$^{13}C_1$]acetate incorporation, shown with the ^{1}H spectra of natural **1**: (a) full spectra, δ 0–10; (b) high field region, δ 0.5–3.5. In the structural formula dark circles indicate enriched carbons while bold bonds denote intact ^2H_x-C-^{13}C units.

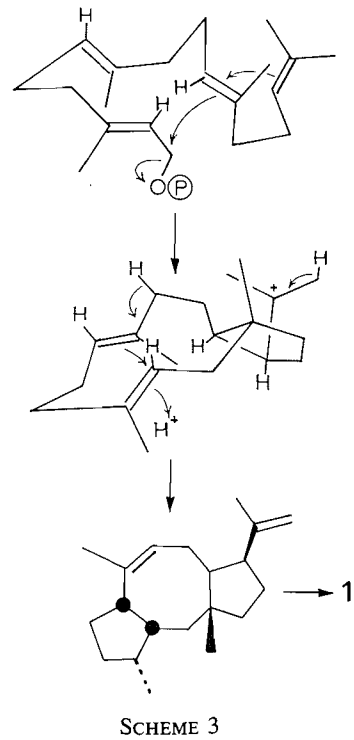

SCHEME 3

While the pathway outlined in Scheme 2 represents the cyclization of *cis*-2-geranylfarnesyl pyrophosphate that is required to generate the observed stereochemistry in ophiobolin A and B, it has been established that the *trans* isomer is efficiently utilized in incorporation experiments. However, the precise stage at which isomerization occurs is not known. It is to be noted that ophiobolins **8**–**10** were isolated from three different organisms and that the stereochemistry of each is different. The stereochemistry of **1** also differs from that of each of these compounds. The α configuration of the 3-methyl group in **1** is opposite to that in the classical ophiobolins A–F and may imply a variation in the biosynthetic pathway. Cyclization of all *trans*-geranylgeranyl pyrophosphate can be envisaged to lead to the observed stereochemistry as shown in Scheme 3. Other variations of this pathway may be involved in the sequences leading to ophiobolins G (**9**) and H, ceroplastol (**10**), and its

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 93.93.197.157 on 09/07/12
For personal use only.

derivatives, since these differ fundamentally in stereochemistry but their biosyntheses have not been investigated.

Although an origin of traversianal from geranylgeranyl pyrophosphate seems most probable, it is not possible to discount at this stage its derivation from a sesterterpene by scission of the extended side chain. The only terpenes previously reported from *Cercospora* spp. appear to be abscisic acid and related compounds from *C. rosicola* (20) and *C. cruenta* (21). The most frequently reported metabolites of *Cercospora* spp. are the polyketide pigments, cercosporin and dothistromin and their derivatives (22, 23), but none of these was detected in our experiments.

Experimental

General purpose solvents were redistilled before use and evaporations were done at the reduced pressure of a water aspirator. Precoated plates of silica gel (Macherey–Nagel Polygram Sil G/UV_{254}, 0.25 mm) were employed for thin-layer chromatography (tlc). Melting points were determined on a Kofler hot stage and are uncorrected. Optical rotations were measured with a Perkin–Elmer 241 photoelectric polarimeter. Shimadzu UV 240 and Pye Unicam PU9516 instruments were used to record uv and ir spectra, respectively. Mass spectra were determined on a Varian MAT 311A system.

The nmr spectra were obtained with a Varian XL-300 system. Although initially some selective decoupling experiments were done to aid analysis, all of the coupling interactions were identified by homonuclear correlation using the HOMCOR pulse sequence of the XL-300 software. The correlated spectrum was obtained using a 1024 × 512 data point matrix transforming 1024 points in both domains with a spectral width of 2068 Hz in both domains. A series of nOe difference spectra were recorded with a spectral width of 2200 Hz, 90° pulses, acquisition time of 2.2 s, and a 20% duty cycle. A total of 24 16-transient blocks, each with four steady-state pulse cycles, was collected at 10 irradiation frequencies, one of which was 5000 Hz off-resonance. Subtraction of the latter free-induction decay (fid) from each of the nine fids containing a saturated absorption before 16K transformation gave the required difference spectra. The ^2H and ^{13}C spectra were obtained at 46.1 and 75.4 MHz, respectively, and the protonation level for each carbon signal was determined by recording the APT spectrum. Specific assignments of the protonated carbon signals were obtained by heteronuclear correlation with the proton spectrum using the HETCOR sequence of the XL software. The ^{13}C–^1H correlation spectrum utilized a 2048 × 128 data matrix with a 14-kHz spectral width for $^{13}C_x$ and a 2.1-kHz width for ^1H transforming 2048 and 512 points, respectively. Assignments for the fully substituted carbons were confirmed from their ^{13}C satellites in the spectrum of **1**-^{13}C isolated from the incorporation experiment with [1,2-$^{13}C_2$]acetate. Additional information on the carbon–carbon connectivities was obtained from ^{13}C–^{13}C correlation and double quantum coherence spectra of this enriched sample. Two ^{13}C COSY experiments utilized the HOMCOR sequence with a 1024 × 256 data point matrix transforming 1024 points in each frequency domain and spectral widths of 16 and 5 kHz in both domains. The 2D-INADEQUATE spectrum was recorded using the CCC2D sequence of the XL software with a 2048 × 128 data point matrix transforming 2048 and 512 points, respectively, with 16-kHz spectral widths in both domains.

The microanalysis was carried out by Guelph Chemical Laboratories Ltd., Guelph, Ont. Labelled sodium acetate precursors for the incorporation experiments were obtained from MSD Isotopes, a division of Merck Frosst Canada Inc., Montreal, P.Q.

Fungal cultures, isolated in 1985 from naturally infected *Trigonella foenum-graecum* L. as described previously (2), were routinely maintained on potato-dextrose agar (PDA) slants kept at room temperature in the dark. Operations on viable fungal material were conducted in a class II, type A biohazard cabinet, employing appropriate aseptic techniques.

Isolation of natural traversianal from PDA cultures

Fragments of mycelium from PDA slants were used to inoculate liquid potato-dextrose medium (24) (40-mL portions in 250-mL Delong flasks) and a mycelial suspension, prepared by homogenizing the contents of three such flasks after 21 days' growth at room temperature in the dark, was then used to inoculate PDA contained in 300 Petri dishes (disposable type, Canlab D2001 L, 10 cm diam; 20 mL/dish). After 15 days' incubation in the dark at room temperature (ca. 25°C), the contents of the dishes were extracted by steeping in MeOH/EtOAc (1:1, 5 L) for several hours. The extract was decanted and the extraction repeated twice with fresh solvent. The combined extracts were strained through cheesecloth, concentrated until mainly aqueous, and extracted 3 times with equal volumes of EtOAc; each extract was washed with the same small portion of water. The residue (945 mg) obtained on evaporation of the combined extracts crystallized from a small volume of EtOAc to give practically pure traversianal (144 mg, mp 228°C). Chromatography of the mother liquors over SiO_2 (Camag DFO, 750 g) with light petroleum ether/EtOAc (1:1, 25-mL fractions) gave another 69 mg of crystalline traversianal (fractions 47–61). In another run, with a 21-day incubation period, a yield of 303 mg of crude traversianal was obtained by crystallization of the extract from 120 Petri dish cultures, together with another 63 mg by chromatography of the mother liquors. Pure traversianal, mp 236–237°C, was obtained by a single recrystallization of the crude product from hot MeOH, but only in low yield. Because of apparent partial decomposition of the material in the MeOH mother liquors, subsequent specimens of traversianal, mp 234–235°C, were obtained by recrystallization from C_6H_6 or EtOAc/CH_2Cl_2; $[\alpha]_D^{24}$ −248 (*c* 1, CH_2Cl_2);uv (EtOH): 234 nm (ε 13 000); ir ($CHCl_3$): 3530 (br), 3075 (w), 3030 (w), 2950, 2925, 2880–2720 (w), 1740 (s), 1678 (s), 1620, 1046, 1032, 893 cm^{-1}; ^1H and ^{13}Cmr: see Table 1; ms *m/e*: 316 (M^+), 301 (M − CH_3), 298 (M − H_2O), 287, 280, 270, 255, 229, 227, 216, 215, 213, 211, 201, 200, 199, 187, 185, 173, 159, 147, 145 (100%). *Exact Mass* calcd. for $C_{20}H_{28}O_3$:316.2038; found: 316.2032. *Anal.* calcd. for $C_{20}H_{28}O_3$: C 75.90, H 8.92, O 15.18; found: C 76.13, H 9.11, O 15.50.

Isolation of labelled traversianal from liquid cultures amended with precursors

Cultures were grown at room temperature in the dark in 1-L Roux bottles, each containing 100 mL potato-dextrose medium (24), which was inoculated with a mycelial suspension of the fungus as described above. In preliminary experiments, individual bottles from a batch of cultures were harvested by filtration on days 4, 7, 11, 14, 16, and 18. Equal aliquots of EtOAc extracts of the filtrates were compared visually by tlc (MeOH–$CHCl_3$, 2:98). Traversianal (red color to vanillin, 0.5% in 60% aqueous phosphoric acid, *Rf* 0.37) was first detected on day 11 with spots reaching maximum intensity on day 16.

(*a*) Each of 15 Roux bottle cultures was treated with 5.0 mL of sterile 0.0408 M sodium [1,2-$^{13}C_2$]acetate (90 at.% ^{13}C) on day 10 and again on day 13, after inoculation. The cultures were filtered on day 16, yielding 106 mg total product on EtOAc extraction. Repeated recrystallization of the crude product from C_6H_6 gave only 5 mg of traversianal-$^{13}C_x$, mp 226–228°C, but another 23 mg, mp 230–232°C after one recrystallization, was obtained by chromatography of the combined mother liquors over SiO_2 (50 g) with 2% MeOH in $CHCl_3$.

(*b*) In an otherwise entirely analogous experiment, 20 cultures were amended with 0.05 M sodium [2,2,2-$^2H_3$, 2-$^{13}C_1$]acetate (98 at.% ^2H, 90 at.% ^{13}C) on days 11 and 13, then harvested on day 17. Direct crystallization and recrystallization of the crude product (54 mg) provided traversianal-^2H_x, $^{13}C_y$, mp 222–225°C, 7 mg, sufficiently pure for spectroscopic examination.

(*c*) Another batch of 20 cultures, amended with 0.05 M sodium [2,2,2-$^2H_3$, 1-$^{13}C_1$]acetate (98 at.% ^2H, 90 at.% ^{13}C) exactly as in (*b*), furnished 77 mg total extract from which 8 mg of traversianal-^2H_x, $^{13}C_y$, mp 222–225°C, was isolated by crystallization.

Structural studies of organoboron compounds. XXIX.[1] 6,6-Diethyl-2,2-diphenyl-1,3-dioxa-6-azonia-2-boratacyclooctane monohydrate

WOLFGANG KLIEGEL

Institut für Pharmazeutische Chemie, der Technischen Universität Braunschweig, 3300 Braunschweig, Beethovenstraße 55, Bundesrepublik Deutschland

AND

STEVEN J. RETTIG AND JAMES TROTTER

Department of Chemistry, University of British Columbia, 2036 Main Mall, Vancouver, B.C., Canada V6T 1Y6

Received June 30, 1987

WOLFGANG KLIEGEL, STEVEN J. RETTIG, and JAMES TROTTER. Can. J. Chem. **66**, 1091 (1988).

Details of the preparation and structure of the title compound are given. Crystals of 6,6-diethyl-2,2-diphenyl-1,3-dioxa-6-azonia-2-boratacyclooctane monohydrate are orthorhombic, $a = 7.0322(2)$, $b = 16.3505(7)$, $c = 16.8164(4)$ Å, $Z = 4$, space group $P2_12_12_1$. The structure was solved by direct methods and was refined by full-matrix least-squares procedures to $R = 0.045$ and $R_w = 0.050$ for 2013 reflections with $I \geq 3\sigma(I)$. The monocyclic eight-membered *B*, *N*-betaine is the first to be structurally characterized. The eight-membered chelate ring has a conformation intermediate between the S_4 and *boat–boat* forms which is probably stabilized by transannular C—H···O interactions. The average libration-corrected O—B and B—C bond lengths of 1.500 and 1.639 Å are, respectively, the shortest and longest yet observed for an *O*,*O*-chelate of diphenylboron.

WOLFGANG KLIEGEL, STEVEN J. RETTIG et JAMES TROTTER. Can. J. Chem. **66**, 1091 (1988).

On rapporte les détails de la préparation et de la détermination de la structure du composé mentionné dans le titre. Les cristaux du monohydrate du diéthyl-6,6 diphényl-2,2 dioxa-1,3 azonia-6 borata-2 cyclooctane sont orthorhombiques avec $a = 7{,}0322(2)$, $b = 16{,}3505(7)$ et $c = 16{,}8164(4)$ Å, $Z = 4$ et groupe d'espace $P2_12_12_1$. On a résolu la structure par des méthodes directes et on l'a affinée par la méthode des moindres carrés (matrice entière) jusqu'à des valeurs de $R = 0{,}045$ et $R_w = 0{,}050$ pour 2013 réflexions avec $I \geq 3\sigma(I)$. La *B*,*N*-bétaïne monocyclique à huit chaînons est la première à avoir été caractérisée du point de vue de sa structure. Le chélate cyclique à huit chaîons possède une conformation qui est intermédiaire entre les formes S_4 et *bateau–bateau* et celle-ci est probablement stabilisé par des interactions transannulaires C—H···O. Les longueurs des liaisons O—B et B—C corrigées pour la libration sont respectivement 1,500 et 1,639 Å et ce sont respectivement les liaisons la plus courte et la plus longue qui aient été observées pour un chélate-*O*,*O* du diphénylbore.

[Traduit par la revue]

Introduction

1,3-Dioxa-6-aza-2-boracyclooctanes **1** are known to undergo intramolecular (transannular) N→B coordination to give very stable bicyclo[3.3.0]octane ring systems **2**, confirmed by chemical and physical investigations (1–6). Generally the extent of the N→B interaction depends on the nitrogen and boron substitution as well as on the conformational conditions. The size and the electronic effects of the substituents markedly influence the magnitude of N—B coordination. In accordance with these findings, replacement of the ring nitrogen atom by oxygen or sulphur led to fairly unstable non-crystalline compounds without any detectable transannular bonding (7).

A cyclooctane system without a transannular N→B interaction should be realized by quaternization of both the tertiary amine and boronate groups of **1**. Direct *N*-alkylation and *B*-arylation of the known (8) compound **1/2** seemed disadvantageous, so the synthesis of **3** was carried out by *N*-alkylation of 2-diethylaminoethanol **6** via the addition of oxirane (ethylene oxide) and subsequent trapping of the zwitterionic intermediate **4** as the diphenylboron chelate **3**. The symmetrical cyclic *B*,*N*-betaine structure **3** has been postulated in a preliminary report (9) on the basis of ^{1}H nmr data which suggest magnetically equivalent ethylene moieties within the ring skeleton, consistent with the formation of **3** by insertion of oxirane into the N—B bond of compound **5** (9).[2] Compound **3** is structurally related to the cyclic six-membered *B*,*N*-betaines **7** (12) and **8** (13). Eight-membered ring systems like **3** were also formulated in patents on polymeric (14) and monomeric (15) boric acid esters of aminoalcohols, but to our knowledge no structural proof has yet been presented.

High quality crystals of **3** can be grown from ethanol but ir and ^{1}H nmr data as well as elemental analyses indicate that this compound exists as a monohydrate. This could result from alternative symmetric structures with hydrogen-bonded (**A**) or covalently bound (**B** and **C**) water. Asymmetric structures such as **D** (from a possible *O*-alkylation of the diethylaminoethanol **1** followed by chelate formation with *N*-(hydroxyethyloxyethyl)diethylamine acting as the ligand), **E** (from hydrolytic ring opening of **3**), or **F** (from chelate formation with ethylene glycol as the ligand) would be unlikely in view of the ^{1}H nmr data. Conductivity measurements and osmometric estimations in DMF solution were unclear. An X-ray crystallographic analysis was undertaken to provide a definitive structural assignment.

Experimental

*6,6-Diethyl-2,2-diphenyl-1,3-dioxa-6-azonia-2-boratacyclooctane monohydrate (**3**·H_2O)*

Methods (a) and (b)

Cooled oxirane (ethylene oxide, 0.5 g, 11 mmol) is added to *N*,*N*-diethylaminoethanol (1.17 g, 10 mmol) in 10 mL ethanol. After dissolving (*a*) oxybisdiphenylborane (1.73 g, 5 mmol) or (*b*) triphenylboron (2.42 g, 10 mmol), the solution is kept at room temperature for 1 h. Crystallization of the product occurs spontaneously at room temperature or upon cooling.

Method (c)

N-(2-diphenylboryloxyethyl)diethylamine dihydrate (**5**·2H_2O, 3.17

[1]Part XXVIII: ref. 12.

[2]Compound **5** has been reported as the diphenylborinic acid ester of diethylaminoethanol (10) and probably contains an intramolecular N—B bond as shown for the *N*-unsubstituted derivative (11). Different samples of **5**, prepared by the methods in ref. 10, contain varying amounts of water.

g, 10 mmol) in 15 mL ethanol is mixed with cooled oxirane (0.7 g, 15 mmol) and kept at room temperature for 4 days. Crystallization begins after cooling the reaction mixture.

Yields: (*a*) 41%, (*b*) 40%, (*c*) 60%. Mp (decomp.) 203–205°C (from ethanol). Lit.[3] 203°C. *Anal.* calcd. for **3**·H_2O: C 69.98, H 8.81, B 3.15, N 4.08. Found: C 69.38, H 8.98, B 3.42, N 4.13. The substance gives a blue color reaction with diphenylcarbazone in methanol, indicating the presence of the diphenylboron moiety (16). Ir (KBr): 3360 cm^{-1} (br, associated H_2O). ^1H nmr (90 MHz, d_6-DMSO/TMS): δ(ppm) = 1.12 (t, J = 7 Hz, $2CH_3$) 3.2–3.8 (m, $6CH_2$, H_2O), 6.7–7.4 (m, BPh_2); (60 MHz, $CDCl_3/F_3CCOOH$/TMS): δ(ppm) = 1.33 (t, J = 7 Hz, $2CH_3$), 3.35 (q, J = 7 Hz, $2CH_2$), 3.60 (m, $2CH_2$), 4.65 (m, $2CH_2$), 7.2–7.7 (m, BPh_2), H_2O associated with CF_3COOH; (60 MHz, d_6-acetone/TMS at 70°C): δ(ppm) = 1.29 (t, J = 7 Hz, $2CH_3$), 2.72 (s, $2CH_2$), 3.57 (q, J = 7 Hz, $2CH_2$), 3.76 (s, $2CH_2$), 6.7–7.7 (m, BPh_2), H_2O not detected. ^{11}B nmr (32.1 MHz, DMSO/-Et_2OBF_3): δ = 4.9 ppm. Crystals suitable for X-ray analysis were obtained by recrystallization from ethanol.

X-ray crystallographic analysis

A crystal bounded by the six faces (followed by the distances in mm between parallel faces): ±(0 −1 1), 0.46, ±(1 0 1), 0.40, {0 1 0}, 0.59, was mounted in a general orientation. Unit-cell parameters were refined by least-squares on 2 sin θ/λ values for 25 reflections (2θ = 76–96°) measured on a diffractometer with Cu-$K\alpha$ radiation ($\lambda(K\alpha_1)$ = 1.540562, $\lambda(K\alpha_2)$ = 1.544930 Å). Crystal data at 22°C are as follows:

$C_{20}H_{28}BNO_2 \cdot H_2O$ fw = 343.3

Orthorhombic, a = 7.0322(2), b = 16.3505(7), c = 16.8164(4) Å, V = 1933.5(1) Å^3, Z = 4, ρ_c = 1.179 Mg m^{-3}, F(000) = 744, μ(Cu-$K\alpha$) = 5.76 cm^{-1}. Absent reflections: $h00$, $h \neq 2n$, $0k0$, $k \neq 2n$, and $00l$, $l \neq 2n$, uniquely indicate the space group $P2_12_12_1$ (D_2^4, No. 19).

Intensities were measured with nickel-filtered Cu-$K\alpha$ radiation on an Enraf-Nonius CAD4-F diffractometer. An ω–2θ scan at 1.2–10.0° min^{-1} over a range of (0.90 + 0.14 tan θ) degrees in ω (extended by 25% on both sides for background measurement) was employed. Data were measured to 2θ = 150°. The intensities of three check reflections, measured every 3600 s throughout the data collection, remained constant to within 4%. After data reduction,[4] an absorption correction was applied using the Gaussian integration method (17, 18). Transmission factors ranged from 0.692 to 0.818 for 96 integration points. Of the 2284 independent reflections measured, 2013 (88.1%) had intensities greater than or equal to 3σ(I) above background where $\sigma^2(I) = S +$

*Superscripts refer to site occupancy factors of 0.52, 0.48, 0.59, and 0.41, respectively.

[3]The melting point of this compound had been mistakenly interchanged with that of another compound in a table in ref. 9.

[4]The computer programs used include locally written programs for data processing and locally modified versions of the following: MULTAN 80, multisolution program by P. Main, S. J. Fiske, S. E. Hull, L. Lessinger, G. Germain, J. P. Declercq, and M. M. Woolfson; AGNOST, absorption corrections, by J. A. Ibers; ORFLS, full-matrix least-squares, and ORFFE, function and errors, by W. R. Busing, K. O. Martin, and H. A. Levy; FORDAP, Patterson and Fourier syntheses, by A. Zalkin; ORTEP II, illustrations, by C. K. Johnson.

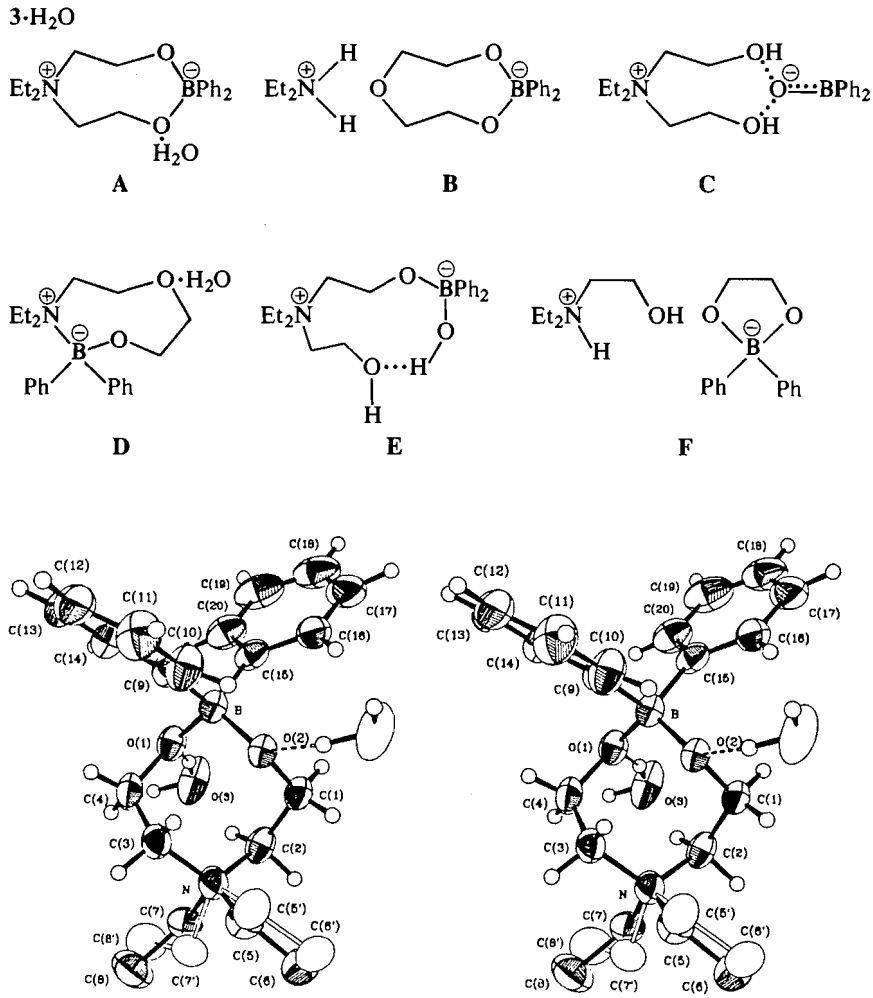

FIG. 1. Stereoscopic view 6,6-diethyl-2,2-diphenyl-1,3-dioxa-6-azonia-2-boratacyclooctane monohydrate; 50% probability thermal ellipsoids are shown for the non-hydrogen atoms. Hydrogen atoms have been assigned arbitrary thermal parameters for the sake of clarity. Broken lines indicate hydrogen bonds.

$2B + (0.04(S - B))^2$ with S = scan count and B = normalized background count.

The structure was solved by direct methods, the coordinates of the non-hydrogen atoms being determined from an E-map. After refinement of the non-hydrogen atoms with anisotropic thermal parameters, anomalous thermal parameters indicated disordering of the N-ethyl groups. A split-atom model was subsequently refined. The site occupancy factors were initially fixed at 0.5 and were subsequently adjusted to give nearly equal average thermal parameters for each group of atoms. In the final stages of refinement the occupancy factors were kept fixed. The ethyl hydrogen atoms were included as fixed atoms (staggered geometry, C—H = 0.98 Å, $U_H \propto U_{\text{bonded atom}}$) and all other hydrogen atoms were refined with isotropic thermal parameters. Scattering factors for all atoms and anomalous scattering factors for O, N, and C were taken from ref. 19. The weighting scheme $w = 1/\sigma^2(F)$, where $\sigma^2(F)$ is derived from the previously defined $\sigma^2(I)$, gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of both $|F_o|$ and sin θ/λ and was employed in the final stages of full-matrix refinement of 343 variables. Reflections with $I < 3\sigma(I)$ were not included in the refinement. An isotropic Type I extinction correction (Thornley–Nelmes definition of mosaic anisotropy with a Lorentzian distribution) was applied (20–22). The final value of g was $6.5(2) \times 10^4$. Convergence was reached at $R = 0.045$ and $R_w = 0.050$ for 2013 reflections with $I \geq 3\sigma(I)$. The mirror-image structure was refined in parallel and rejected at the 99.5% significance level (the R and R_w ratios both = 1.006). The function minimized was $\Sigma w(|F_o| - |F_c|)^2$, $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$ and $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$.

On the final cycle of refinement the mean and maximum parameter shifts corresponded to 0.02 and 0.31σ, respectively. The mean error in an observation of unit weight was 1.158. The largest peak on the final difference map was 0.18 e Å^{-3}. The final positional and thermal parameters appear in Tables 1 and 5,[5] respectively. Measured and calculated structure factors have been placed in the Depository of Unpublished Data.[5]

The ellipsoids of thermal motion for the non-hydrogen atoms are shown in Fig. 1. The thermal motion has been analysed in terms of the rigid-body modes of translation, libration, and screw motion (23). The rms standard error in the temperature factors σU_{ij} (derived from the least-squares analysis) is 0.0030 Å^2. The structural subunits PhB, the eight-membered ring, and $(—CH_2CH_2)_2N(CH_2CH_3)_2$ were separately analysed (rms ΔU_{ij} = 0.0018–0.0059 Å^2). The appropriate bond distances have been corrected for libration (23, 24), using shape parameters q^2 of 0.08 for all atoms involved. Corrected bond lengths appear in Table 2 along with the uncorrected values; corrected bond angles do not differ by more than 1σ from the uncorrected values given

[5]The structure factor table, Table 5 (anisotropic thermal parameters) and other material mentioned in the text may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

Results and discussion

The crystal structure consists of molecules having the originally suggested structure **3A** (9), bridged by hydrogen-bonded water molecules (Fig. 1) to form ribbons extending along the *a*-axis [O(3)—H(O3a)···O(1) and O(3)—H(O3b)···O(2) ($1 + x$, y, z), H···O = 2.06(6) and 1.77(8) Å, O···O = 2.775(3) and 2.761(3) Å, O—H···O = 158(5) and 153(6)°, respectively). These ribbons are reinforced (C(2)—H(2a)···O(3),

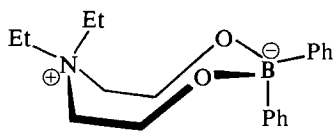
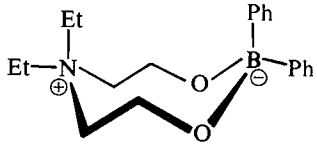
3 boat–boat (flank substitution)



3 boat–chair



3 crown

H···O = 2.41(3) Å, C···O = 3.344(4) Å, C—H···O = 161(3)°) and cross-linked (C(2)—H(2b)···O(3) ($x - 1/2$, $1/2 - y$, $1 - z$), H···O = 2.34(3) Å, C···O = 3.247(4) Å, C—H···O = 141(2)°) by probable C—H···O hydrogen bonds. The water molecule is thus fully utilized as both a donor and an acceptor of hydrogen bonds.

Compound **3** is the first monocyclic eight-membered *B,N*-betaine to be structurally characterized. Other boracyclooctanes having trivalent boron and nitrogen atoms in the 1- and 5-positions are prone to transannular N→B coordination, forming bicyclo[3.3.0]octanes as shown for several different types of boron heterocycles (3, 25, 26). Structural stabilization, weak in eight-membered cyclic boronates with little or no transannular coordination (5, 7), is achieved in **3** by quaternization of both boron and nitrogen resulting in a zwitterionic salt structure. Dissociative and reassociative processes in solutions of cyclic boronates of bis(2-hydroxyethyl)amines (**9** ↔ **10**) have been monitored by dynamic nmr spectroscopy (5). Opening of the bicyclic structure **10** proceeds via an intermediate cyclooctane system **9** having a *boat–boat* (saddle) conformation. The *boat–boat* conformation of cyclooctane itself is one of five conformations within 2 kcal/mol of the minimum energy *boat–chair* conformation, the former being destabilized with respect to the latter primarily by short transannular contacts between inward-pointing hydrogen atoms (27, 28). In the case of **3** these inward-pointing hydrogen atoms are opposite the ring oxygen atoms and cannot cause an energetically unfavorable interaction. Weak attractive transannular C—H···O interactions (C(2)—H(2a)···O(1) and C(3)—H(3b)···O(2), H···O = 2.41(3) and 2.31(3) Å, C···O = 2.843(3) and 2.791(4) Å, C—H···O = 106(2) and 115(2)°) probably contribute to conformational stability. Both the *boat–boat* and the closely related but less symmetrical S_4 conformations have two types of ring positions: "bow/stern" (inner) and "flank" (outer). Disubstitution of a pair of opposite "bow/stern" positions is sterically unfavorable, thus the substituted N and B atoms of **3** occupy "flank" positions. The conformation actually observed for **3** is intermediate between the *boat–boat* (torsion angles of ±52.5°, bond angles of 118 and 119°) and S_4 (torsion angles alternately ±64.9° and ±37.6°, bond angles of 117 and 118°) conformations (28), but nearer to the latter (mean $\Delta\omega$ and $\Delta\theta$ = 5.1 and 2.2° relative to S_4, 9.7 and 2.7° relative to *boat–boat*). Calculations for cyclooctane show that the S_4 conformation is slightly less strained than the *boat–boat* (28). The structure of **3** provides an example of the S_4 conformation for an eight-membered ring, stabilized by the special arrangement of ring heteroatoms and substitutents. Similar situations have been reported for $[NPR_2]_4$, R = Me (29) and NMe_2 (30), and $[OSeO_2]_4$ (31) which also have S_4 conformations with the substituted atoms occupying "flank" positions.

As observed earlier for compounds of the type **7** (12), the largest deviations from "ideal" intracyclic bond angles occur at the boron and nitrogen atoms. If the eight-membered ring in **3** had an undistorted *boat–boat* conformation the molecule would possess a C_2 axis passing through the N and B atoms. For the S_4 conformation, deviation from C_2 symmetry causes a small energy difference between the "flank" position substituent sites. Although the difference is not statistically significant, the pseudo-axial B—C bond is 0.008(6) Å longer than its pseudo-equatorial counterpart. Significant differences between axial and equatorial B—C bonds have been noted for **7** (12), **8** (13), and a phosphorus analog of **7** (32). The average O—B and B—C distances[6] of 1.500 and 1.639 Å are, respectively, the shortest and longest yet observed for an *O,O*-chelate of "Ph_2B^+" (12, 33–35), indicating that the monoanion derived from **4** is among the strongest known donors for the "Ph_2B^+" cation. Relatively strong O—B binding was also observed for **7** (R = (1/2)($(CH_2)_3$) and Me) (12) where average O—B = 1.510 and 1.518 Å and average B—C = 1.625 and 1.623 Å. The sum of bond lengths involving the boron atoms in *O,O*-chelates of diphenylboron has been found to be 6.331(9) Å for compounds containing five-membered chelate rings (33, 34) and is essentially constant for larger rings; 6.277(9) Å (12, 33), 6.276 Å (35), and 6.278 Å for six-, seven-, and eight-membered rings, respectively.

Unlike the short intraannular C—O distances (average 1.376 Å) observed in compounds **7** (12), the values in **3** (1.410(3) and 1.414(3) Å) are close to the normal C—O single bond distance of 1.43 Å and are in good agreement with those observed in other boron chelates with hydroxyalkyl ligands (3, 11, 13, 25, 36). Some bond lengths and angles involving the disordered *N*-ethyl groups deviate significantly from the expected values. This is probably a result of imperfect modelling of the disorder and is commonly observed in such situations. Both phenyl rings are planar within experimental error and show normal substituent-induced geometric distortions (37).

Synthesis and metal ion complexation behavior of polycarboxylate 18-crown-6 ethers derived from tartaric acid

PHILIP J. DUTTON, THOMAS M. FYLES, AND SUSAN J. MCDERMID
Department of Chemistry, University of Victoria, Victoria, B.C., Canada V8W 2Y2

Received September 17, 1987

PHILIP J. DUTTON, THOMAS M. FYLES, and SUSAN J. MCDERMID. Can. J. Chem. **66**, 1097 (1988).

The metal ion complexation behavior of four 18-crown-6 ethers derived from (+)- and *meso*-tartaric acid is examined. Preparations of a *meso*-crown ether diacid and of a crown ether hexacid from three units of (+)-tartaric acid are described. Acidity constants and stability constants for complexation of metal cations in aqueous solution were determined by potentiometric titration. The complexes are substantially stabilized by favourable electrostatic interactions and are of similar stability to complexes of cryptands and EDTA. The complexation behavior of the series can be rationalized in terms of electrostatic interactions, direct coordination of the cations by at least one carboxylate from the crown ether periphery, and rigidification of the ligands as the anionic charge increases. Distributions of charge influence the relative stability of isomeric complexes. Highly charged polycarboxylate crown ethers are effective, but relatively unselective, cation complexing agents for a range of cations. The complexes are stable to pH 3 and the ligands can be used as simultaneous pH and metal ion buffers.

PHILIP J. DUTTON, THOMAS M. FYLES et SUSAN J. MCDERMID. Can. J. Chem. **66**, 1097 (1988).

On a étudié la complexation d'ions métalliques par quatre éthers 18-couronnes-6 dérivés des acides (+)- et *méso*-tartriques. On décrit les préparations, réalisées à partir trois unités d'acide (+)-tartrique, d'un diacide d'éther couronne *méso* et d'un hexacide d'éther couronne. Utilisant des titrages potentiométriques, on a déterminé les constantes d'acidité et les constantes de stabilité pour la complexation de cations métalliques, dans des solutions aqueuses. Les complexes sont très stabilisés par des interactions électrostatiques favorables et leurs stabilités ressemblent à celles des cryptands et de l'EDTA. Pour rationaliser le comportement des membres de la série vis-à-vis de la complexation, on doit faire appel à des interactions électrostatiques, à la coordination directe des cations par au moins un groupement carboxylate de l'éther couronne de la périphérie et à une rigidification des ligands au fur et à mesure que la charge anionique augmente. Les distributions de charge influencent la stabilité relative des complexes isomères. Pour beaucoup de cations, les éthers couronnes portant plusieurs groupement carboxylates hautement chargés sont des agents de complexation efficaces, mais relativement peu sélectifs. À un pH de 3, les complexes sont stables et on peut utiliser les ligands simultanément comme tampons du pH et des ions métalliques.

The underlying theme in the complexation chemistry of macrocycles, is the control of complex formation by control of ligand structure through synthesis (1, 2). From this perspective, crown ethers derived from (+)-tartaric acid possess a number of appealing features as frameworks for the construction of specific complexing agents. Firstly, the carboxyl groups provide an easy synthetic entry to a wide range of derivatives (3–7). Secondly, the tartaric acid units show a strong conformational preference for an *anti* disposition of the carboxylates and other carboxylate derived groups (8–12). This limits overall conformational flexibility (8, 11, 12) and leads to well-defined conformations in which the carboxylate derived groups lie axial to the plane of the macrocycle (8–12). Lateral interactions between substituent groups and bound substrates are thus favored (3, 4, 13, 14). Finally, the presence of charged groups on the macrocyclic periphery leads to markedly enhanced cation complexation relative to uncharged ligands of similar structure (3, 8, 12). This is primarily a result of a favorable electrostatic interaction between the anionic ligand and the complexed cation (5, 8).

Additional effects may be important. The carboxylates could act as additional ligating sites in a fashion similar to the neutral donor arms of lariat ethers (15, 16). Evidence from infrared and nuclear magnetic resonance spectroscopy (12), from electron spin resonance spectroscopy (11), and from analysis of stability constant data (12, 17) suggests that direct and cooperative carboxylate–cation interactions occur, especially with small cations in solvents of moderate polarity. Such contacts probably distort the crown ether such as seen in the crystal structures of the *syn* and *anti* diacid diamide 18-crown-6 derivatives (9). The di- and tetra-acids (Fig. 1) and their derivatives have overall twofold symmetry. In contrast, the complexes of the parent 18C6 prefer an ideal D_{3d} symmetry (18). Thus, both *RR*18C6A$_2$ and 18C6A$_4$ are incapable of symmetrically interacting with a bound cation, either by direct contact or by indirect coulombic attraction without some distortions of the macrocycle from threefold symmetry. At the same time as complex stability is enhanced by increasing charge on the ligand, the complexation selectivity may be lowered (12) or reversed (19).

Nonetheless, the tetraacid 18C6A$_4$ is capable of binding potassium ion in aqueous solution as effectively as the cryptands (5). The general strategy of electrostatic enhancement of cation binding therefore warrants a detailed examination. To this end, we have examined the crown ethers shown in Fig. 1. The diacid *RR*18C6A$_2$ and tetraacid 18C6A$_4$ have been previously reported (8, 21). For comparison purposes the diacid derived from *meso*-tartaric acid, *RS*18C6A$_2$, was prepared. The series also was extended to the hexaacid 18C6A$_6$, derived from three units of (+)-tartaric acid. This material can bear up to six anionic charges and, in principle, could preserve threefold symmetry in its complexes. This report examines the syntheses of *RS*18C6A$_2$, 18C6A$_6$, and the metal cation complexation behavior of the series in aqueous solutions.

Results and discussion

Synthesis of ligands

The syntheses of *RR*18C6A$_2$ and 18C6A$_4$ have been reported (8, 21, 22); the syntheses of *RS*18C6A$_2$ and 18C6A$_6$ follow directly from previous methods (Fig. 2). In particular, the synthesis of the *meso* crown ether **3** is a simple extension (21) starting from the bis-dimethylamide of *meso*-tartaric acid **1**. The dithallium salt of **1** reacted with pentaethylene glycol dibromide to afford the diamide crown ether **2** in 24% recrystallized yield. Acid hydrolysis gave *RS*18C6A$_2$ (**3**) in nearly quantitative

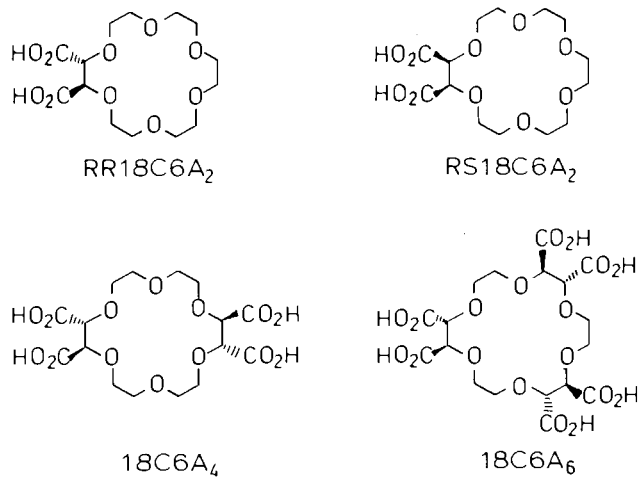

FIG. 1. Structures of the ligands considered with abbreviated names.

yield. Compounds in the *meso* series are significantly easier to crystallize but are otherwise closely similar to previously examined materials from (+)-tartaric acid.

The synthetic plan for $18C6A_6$ (**13**) follows trivially from the structure. Two "half crown" triethylene glycol derivatives, **10** and **11**, are required in the macrocyclization. The derivative **11** has been previously reported (23) and application of similar chemistry was expected to give **10** from a monoprotected tartaramide **5**.

The monoprotection of the tartaramide **4** using one equivalent of thallous ethoxide in DMF followed by treatment with excess benzyl bromide invariably gave close to the theoretical yield of the dibenzyl ether of **4** with only minor amounts of **5**. Partial hydrogenolysis of the dibenzyl ether gave a mixture from which the desired **5** could be isolated by a solvent extraction sequence. A survey of other bases and reaction conditions eventually revealed that the use of one equivalent of sodium hydride with **4**, followed by excess benzyl bromide, produced **5** cleanly without loss of chiral integrity (22, 24). The subsequent coupling of **5** with the tetrahydropyranyl ether of 2-bromoethanol, followed by hydrolysis of the Thp ether **6** gave the alcohol **7** as anticipated (23). Provided that **6** is purified by column chromatography, the alcohol **7** and the tosylate **8** can be adequately purified by a sequence of liquid–liquid extractions (25). Coupling of **8** with a second mole of the sodium salt of **5** gives the "half crown" dibenzyl ether **9**. After column chromatography, **9** is obtained as a crystalline solid. Hydrogenolysis of **9** gives the diol **10**, which can again be purified by a sequence of liquid–liquid extractions.

The final macrocyclization uses sodium hydride as the base to couple **10** and **11** (23) to yield the hexaamide **12** in modest but reliable yields of 20–30%. The product is characterized by the expected simple ^1H and ^{13}C nmr spectra and a strong molecular ion and expected fragmentations in the mass spectrum. Acidic hydrolysis of the amides gives the hexaacid **13** ($18C6A_6$), which was purified by ion exchange and crystallization from water. The hexaacid **13** can be converted to ester and amide derivatives for use in membrane transport experiments; their synthesis will be reported separately.

Determination of complexation constants

Stability constants for metal ion complexation by the polycarboxylate crown ethers were determined by potentiometric titration. The principles have been discussed previously (12, 21); the primary constants determined are cumulative association constants, β_{lmh}, defined by eq. [1] (charges omitted for clarity).

$$[1]\quad lL + mM + hH \rightleftharpoons L_lM_mH_h \qquad \beta_{lmh} = \frac{[L_lM_mH_h]}{[L]^l[M]^m[H]^h}$$

where L = ligand, M = metal ion, H = proton, and l, m, and h are the respective stoichiometric coefficients. Since the ligand and complex activity coefficients are unknown, the β_{lmh} are defined in terms of concentrations. The errors introduced are minimized by use of a high constant ionic strength and low ligand concentration. Of greater chemical utility than the cumulative constants are stepwise formation constants such as apply to the association of a partly protonated ligand with a metal ion. These values can be derived from the β_{lmh} for the system. As an example consider a diprotic ligand H_2L forming two complexes with a metal ion M^+ (i.e., ML^- and HML). The stepwise equilibria of interest are given as eqs. [2]–[5]. The stepwise formation constants K_{a_1}, K_{a_2}, K_{ML}, and K_{HML} are defined in terms of species concentrations and cumulative association constants as indicated. Note as well that the acidity constants follow the convention of *dissociation* while the β_{lmh} values are in term of *association*.

$$[2]\quad H_2L \rightleftharpoons HL^- + H^+ \qquad K_{a_1} = \frac{[HL^-][H^+]}{[H_2L]} = \frac{\beta_{101}}{\beta_{102}}$$

$$[3]\quad HL^- \rightleftharpoons L^{2-} + H^+ \qquad K_{a_2} = \frac{[L^{2-}][H^+]}{[HL^-]} = \frac{1}{\beta_{101}}$$

$$[4]\quad L^{2-} + M^+ \rightleftharpoons ML^- \qquad K_1 = \frac{[ML^-]}{[L^{2-}][M^+]} = \beta_{110}$$

$$[5]\quad HL^- + M^+ \rightleftharpoons HML \qquad K_2 = \frac{[HML]}{[HL^-][M^+]} = \frac{\beta_{111}}{\beta_{101}}$$

The experimental procedure involves the pH-metric titration of the ligand as the free acid with base (Me_4NOH). The resulting titration curve is analysed by a modified version of the program SCOGS (26) to yield β_{10h} and thus the pK_a's for the ligand. Metal ion is then added to the system and the mixture is again titrated. The resulting titration curve, together with the previously determined values of β_{10h}, is again analysed by SCOGS to yield β_{lmh} for the cation. Various checks and controls are outlined in the experimental section and in previous work (12, 21).

The results for the four carboxylate crown ethers are presented in Table 1. The set of β_{lmh} values for each ligand/cation pair permits a calculation of species concentrations as a function of pH. Examples of these curves are given in Fig. 3; Fig. 3*a* shows the protonated forms of $18C6A_6$ in the absence of metal ions while Fig. 3*b* shows the metal containing species present in a potassium ion/$18C6A_6$ mixture. The chief value of such curves is to provide a rapid, visual summary of the species present and their relative importance in describing the solution equilibria. At the concentrations used ($\sim(3–4) \times 10^{-4}$ M in L), any system with log $K > 4.0$ is dominated by the metal complexes of the ligands above pH 3.0. Below pH 3.0 the protonated forms of the free ligands dominate.

The value of log β_{110} for $K^+/18C6A_4$ has been reported previously to be 5.48 (5, 8); our value of 4.5 ± 0.2 is in rather poor agreement with this value. The techniques used differ appreciably; in particular we assess the protonated complexes that were ignored in the previous work. Over the past few years

we have determined the $K^+/18C6A_4$ and $K^+/RR18C6A_2$ systems several times at different concentrations of ligand. In general, as the ligand concentration increases, so also do the log β_{lmh} values (log β_{110} ($K^+/18C6A_4$) = 4.9 at 1.15×10^{-3} M; = 5.3 at 2.61×10^{-3} M; = 5.4 at 5.0×10^{-3} M). This is undoubtedly a result of the variation in activity coefficients, which we ignore in our analysis. The set of data in Table 1 is designed to minimize this effect and to permit internal comparisons; slightly different values would be obtained at other ligand concentrations.

Factors governing metal ion binding

Table 1 provides insights into the behavior of the polycarboxylate crown ethers both as ligands and as polycarboxylic acids. The acidity constants follow expected trends: the monoprotonated ligands are increasingly weaker acids as the total charge increases. The effect is modest, however, and the fully deprotonated ligands are accessible at pH 5 and greater. Furthermore the half-protonated forms ($H18C6A_2^-$, $H_218C6A_4^{2-}$, $H_318C6A_6^{3-}$) occur as the predominant protonated species over a range of pH centered near 3.5 (see Fig. 3*a*). This is due to monoprotonation of each tartaric acid residue; the second protonation requires more acidic conditions.

The stepwise formation constants clearly exhibit the expected electrostatic enhancement of cation binding. An increase in anionic charge clearly increases the magnitude of the formation constants. There is ample evidence to show this is generally the case: (*i*) divalent ions are bound more strongly than monovalent ions, (*ii*) the complexes of the fully deprotonated ligands with divalent ions show a regular increase in stability with increasing charge, (*iii*) many ligand/cation combinations exhibit a regular decrease in stability constant with ligand protonation. Despite these regularities, however, there are some important exceptions that indicate that other structural effects are important in cation binding.

Firstly, there is a clear indication that the donor set of the ligands is inappropriate for complexation of "softer" cations such as Cd^{2+}, Cu^{2+}, and Zn^{2+} compared to the harder alkali

[a]Determined at 25°C, I = 0.05 M with Me_4NCl. Values in parentheses are calculated for the 1:1 association of metal with protonated ligand. The symbol * indicates that the complex of the given stoichiometry was not required to achieve a fit of the experimental data. The symbol ‡ indicates the stoichiometry is inappropriate for the ligand. The dash — indicates the system was not examined. Uncertainty in acidity constants is log $\beta_{10h} \pm 0.1$; in association constants is log $\beta_{lmh} \pm 0.2$.

[b]Logarithm of dissociation constants; follows the convention of pK_a.

[c]log $\beta_{110} \cong 3.9 \pm 0.7$; competition with hydroxo complexes increases uncertainty.

[d]log $\beta_{110} \cong 3.7 \pm 0.7$; competition with hydroxo complexes increases uncertainty.

[e]log $\beta_{106} \pm 0.5$.

[f]log $\beta_{113} = 18.4 \pm 0.5$ (4.1).

metal and alkaline cations. The Ca^{2+}/Cd^{2+} comparison is particularly appropriate since the effective ionic radii of these two ions are closely similar (27) (six coordination: Ca^{2+}, 1.00 Å; Cd^{2+} 0.95 Å; seven coordination: Ca^{2+}, 1.06 Å; Cd^{2+}, 1.03 Å). The surface charge density of the two ions must therefore be closely similar, with a tendency to favor Cd^{2+} in any coulombic interaction. Despite this electrostatic advantage, the Cd^{2+} complexes are all weaker than related Ca^{2+} complexes. In fact the Cd^{2+} complex of *RR*18C6A$_2^{2-}$ is weaker than the complexes of monovalent ions. The Cu^{2+} and Zn^{2+} ionic radii are substantially smaller but the complexes of these ions are also weaker than related Ca^{2+} complexes. Clearly a high anionic charge alone is insufficient to achieve stable complexes.

The second important "irregularity" in the data concerns the Tl^+ complexes of 18C6A$_4^{4-}$ and 18C6A$_6^{6-}$ and the K^+ complex of 18C6A$_6^{6-}$. In each of these cases the monoprotonated complexes are markedly more stable than the complexes of the fully deprotonated ligand. The consequences are readily apparent in Fig. 3*b*; free K^+ passes through a minimum when the monoprotonated complex achieves its maximum concentration. These cases are the interactions of the most highly charged ligands with the cations of lowest surface charge density. On a

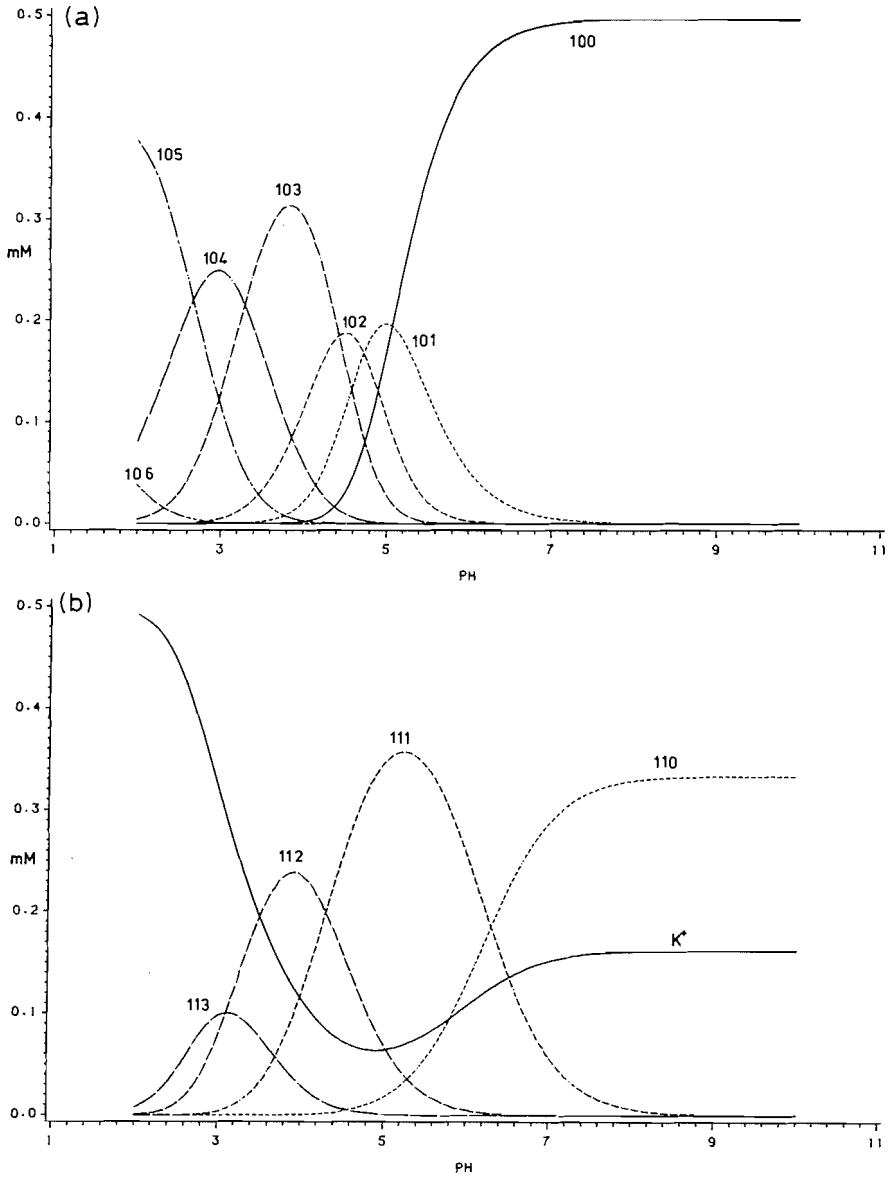

FIG. 3. (a) Protonated forms of $18C6A_6$ as a function of pH; (b) potassium complexes of $18C6A_6$ and free K^+ concentration as a function of pH. $[18C6A_6] = 5 \times 10^{-4}$ *M*, $[K^+] = 5 \times 10^{-4}$ *M*.

purely electrostatic basis Tl^+ and K^+ are least able to organize the donors of the ligand in the face of the strong internal repulsions between the charged carboxylates. The fully deprotonated ligands are thus apparently more rigid than more protonated forms, which can distort to accommodate a range of cations. This is a further example of the principle that "the guest organizes the host" (15, 28).

Since a single deprotonation provokes the effect, it is tempting to argue that one additional donor site is required and that the normal interaction involves seven donor atoms from the ligand. Complexes of moderately charged ligands, or of cations with sufficiently high charge density, easily achieve a seven-coordinate geometry despite the repulsions that occur as the carboxylate moves towards the cation in the macrocycle. For the "irregular" complexes, the energetic cost of this distortion is incompletely compensated by the carboxylate–cation interaction energy. Protonation lowers the total charge, hence reduces the repulsive interactions. Alternatively, the irregular complexes might be simple six-coordinate crown ether complexes.

The issue of carboxylate participation in complexes of charged crown ethers can be examined using the approach described by Eyring and co-workers (17). They divide the total free energy of complexation (ΔG_{tot}) into two components: (*i*) a polyether cavity factor (ΔG_{cav}) due to interaction of the cation only with the crown ether oxygens and (*ii*) an electrostatic interaction (ΔG_{el}) between the cation and the anionic ligand without crown ether participation. The two effects are related to the total free energy change by eq. [6] (17).

$$[6] \quad \Delta G_{tot} = \Delta G_{cav} + \lambda \Delta G_{el}$$

where $\lambda = 0$ for no cation–carboxylate interaction such as occurs with neutral crown ethers, and $\lambda = 1$ for the maximum electrostatic interaction with a fully deprotonated ligand. Intermediate values of λ indicate intermediate degrees of protonation. Squaring eq. [6] yields the relation [7].

$$[7] \quad (\Delta G_{tot})^2 = (\Delta G_{cav})^2 + 2\lambda \Delta G_{cav} \Delta G_{el} + (\lambda \Delta G_{el})^2$$

$(\Delta G_{cav})^2$ is the contribution to metal ion complexation due to the crown ether acting alone, $(\lambda \Delta G_{el})^2$ is the strictly

For personal use only.

coulombic contribution, and $2\lambda\Delta G_{cav}\Delta G_{el}$ is the contribution due to a cooperative interaction of the crown ether and the carboxylates with the cation. This first-order analysis deals only with ion–ligand contributions to ΔG_{tot} and ignores differential solvation effects. Nonetheless eq. [7] provides a convenient means to assess the relative importance of the three contributions to the cation–ligand interaction.

Table 2 provides such an analysis for the alkali metal and alkaline earth complexes of the polycarboxylate crown ethers of Fig. 1. The values of ΔG_{cav} were derived from the literature values for 18-crown-6 complexes of the cations in water (log β_{110}: Na^+, 0.8 (20); K^+, 2.03 (29); Tl^+, 2.27 (29); Ca^{2+}, 0.48 (30); Sr^{2+}, 2.72 (29); Ba^{2+}, 3.87 (29)). The λ values scale to the fraction of protonation, thus half-protonated $H_218C6A_4^{2-}$ has $\lambda = 1/2$ and monoprotonated $H18C6A_6^{5-}$ has $\lambda = 5/6$, etc. The percentage contributions of $(\Delta G_{cav})^2$ (%CE),$(\lambda\Delta G_{el})^2$ (%EL), and $2\lambda\Delta G_{cav}\Delta G_{el}$ (%CO) provide a simple picture of the relative contributions in the ligand–cation interaction.

Since the approach is clearly a first-order approximation and our values of ΔG_{cav} and λ are chosen somewhat arbitrarily, we proceed to examine Table 2 with some caution. A few general conclusions can be readily drawn. Firstly the complexation of Ca^{2+}, and to a lesser extent Na^+, is apparently dominated by the strictly Coulombic component (%EL). This is in accord with both the small size (hence poor "fit") and high surface charge density of these ions. Secondly, the complexes of large cations (K^+, Tl^+, Ba^{2+}) with a modest charge ($\lambda = 0.5$) are dominated by the strictly crown ether contribution (%CE). The electrostatic component in these cases is usually small. Thirdly, in the majority of cases, the cross term for cooperative crown ether and carboxylate interaction (%CO) is quite constant (40–50%) and an important contributor to the cation-ligand interaction. This result is consistent with the view that the normal complexation mode for this series involves a coordinating carboxylate acting in concert with the crown ether oxygens. Finally, the irregular K^+ and Tl^+ complexes noted above are not irregular on Table 2; carboxylate coordination apparently occurs but at the expense of poorly compensated electrostatic repulsions with other non-coordinated carboxylates.

A related consequence of the view that these ligands provide cooperative carboxylate and crown ether binding interactions is the attendant increase in "effective cavity size" compared with a simple six donor atom 18-crown-6. The interrelationship of the number of donors (with their topology) and the effective ionic radius of the bound cation governs binding in flexible neutral ligands (15). The same applies to flexible charged ligands, with the additional complexity that ligand flexibility decreases as charge increases.

To summarize the picture: the ligands normally bind cations with cooperative crown ether and carboxylate donor interactions. Thus a trend favouring larger cations is expected, and found, in the complexes of the diacids *RR*18C6A$_2$ and *RS*-18C6A$_2$. In all cases, the electrostatic interactions favour small, high surface charge cations. Thus as ligand charge increases the trend favoring large cations should reverse (compare Ca^{2+}, Sr^{2+}, Ba^{2+} with *RR*18C6A$_2^{2-}$ and 18C6A$_4^{4-}$). As well as bearing an increased charge, the highly charged forms are enlarged and rigidified by repulsive electrostatic interactions between carboxylates. One consequence is that the complexes of low surface charge cations with highly charged ligands are

destabilized relative to less charged ligands by the energetic demands of moving the carboxylate to the metal ion. Another consequence is to destabilize the complexes of small ions despite their high surface charge. The composite result is a degradation of the selectivity of highly charged ligands such as $18C6A_6^{6-}$.

Comparison of isomeric charged ligands

Tables 1 and 2 also provide a comparison between isomeric ligands, both the configurational isomers, *RR* and *RS*18C6A$_2$, and isomeric distributions of charge, $18C6A_4^{4-}$ vs. $H_2 18C6A_6^{4-}$ for example. The trends generally support the analysis above but provide additional structural insights as well.

Crown ethers derived from *R,R*-(+)-tartaric acid show a marked preference for a diaxial disposition of carboxylates (8–12): the conformational preference of the parent (+)-tartaric acid (31) is carried directly into the crown ethers. We assume the conformations of the parent *meso*-tartaric acid are carried into *RS*18C6A$_2$. This produces one axial and one equatorial carboxylate with a normal *gauche* OCCO dihedral angle (31). Equilibration with an identical form is possible by *gauche*$^+$ to *gauche*$^-$ inversions around the macrocycle. The diaxial conformation of two carboxylates, and two ether oxygens, can be made with CPK molecular models; this is a minor conformer in the parent (31) and involves an unfavourable anti OCCO dihedral angle. Thus it is likely that *RS*18C6A$_2$ bears one axial carboxylate available as a ligating site, and one equatorial carboxylate directed away from the macrocycle. Interconversion of the two is presumably possible in the free ligand, and possibly in the complexes as well.

The complexes of the *meso*-crown ether are generally less stable than those of *RR*18C6A$_2$ by about a factor of 10 on average. Electrostatic stabilization falls off with distance (5) and the equatorial carboxylate is indeed further from the center of the macrocycle than the axial carboxylate, but the pure electrostatic argument fails to account for the data. Certainly the complexes of the dianions should differ, but the complexes of the monoanions, involving one coordinated axial carboxylate, should be closely similar. The *meso*-crown ether forms few detectable protonated complexes and the Tl^+ complex of *RS*18C6A$_2^{2-}$ is in fact weaker than the protonated complex of *RR*H18C6A$_2^-$. If the *meso*-crown ether is in fact equilibrating between a pair of isomers and the complexes have a relatively fixed seven-coordination structure, there will be an unfavourable entropy contribution on complex formation of any type. Since the *RR*-crown ethers have predominantly one conformation, they do not suffer the same unfavourable loss of entropy. This issue would be clarified by a more complete thermodynamic study. Thus in general, the *RS* complexes should be less stable than the *RR* complexes in accord with observation.

Comparisons between other pairs of ligands of like charge reveal that the complexes of the more protonated ligand are less stable by about a factor of 10 despite bearing the same charge and formally bearing the same potential binding sites. Of the dozen cases from Table 1, only the Tl^+ complexes of $18C6A_4^{4-}$ and $H_2 18C6A_6^{4-}$ show the opposite behavior. The more protonated ligands have fewer localized dianionic sites, hence a general electrostatic stabilization effect would be less pronounced. The differences are more marked with divalent cations, in line with an electrostatic component. In addition there must be differences in solvation, especially for comparisons involving fully deprotonated ligands. Intramolecular hydrogen bonding is available to partly protonated ligands but is not possible in fully deprotonated forms. Increased solvation of the free ligand or disruption of hydrogen bonded structures of the free ligand on complexation would act to diminish the formation constant of the complex.

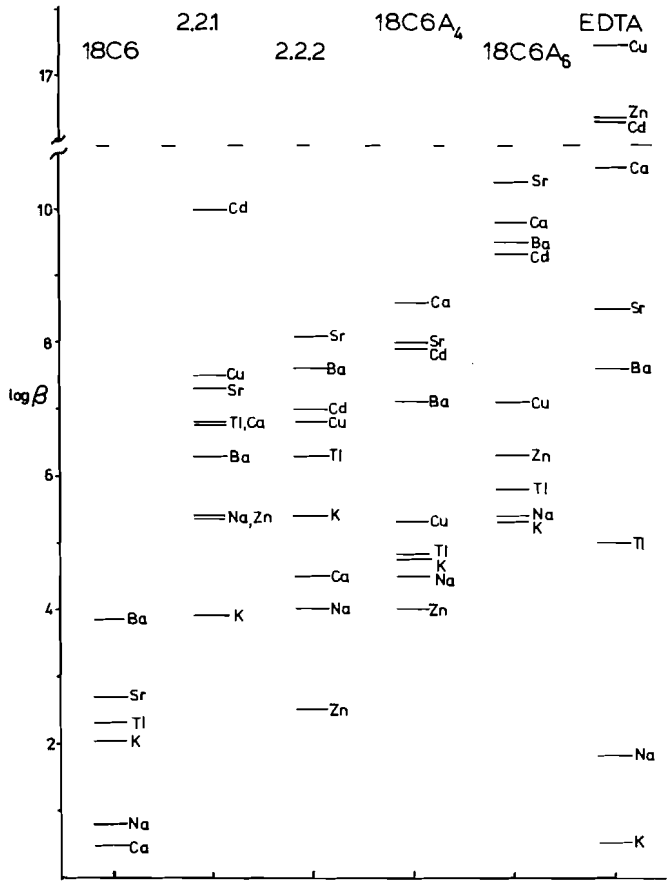

FIG. 4. Comparison of stability constants of crown ethers, cryptands, and EDTA. Literature values (20, 29, 30, 32–34) shown are averaged or "best values" (32). The 18C6A$_4$ and 18C6A$_6$ complexes are the 110 complexes except for Tl^+ and K^+ (18C6A$_6$) where the 111 complexes are more stable.

Comparisons with other metal ion binding ligands

The stepwise formation constants determined are compared with other ligands in Fig. 4. It is clear that the complexes of the charged crown ethers are substantially more stable than those of the parent 18C6 (29, 30) and fall within the range usually associated with the cryptands 2.2.1 and 2.2.2 (33) and the complexone EDTA (32, 34). Direct comparisons of this type must, however, take account of the different set of donors provided by each ligand. Both EDTA and the cryptands provide two nitrogen donors, hence the Cu^{2+}, Cd^{2+}, and Zn^{2+} complexes are particularly stabilized relative to $18C6A_4^{4-}$ and $18C6A_6^{6-}$. Conversely the alkali metal and alkaline earth cation complexes are somewhat disfavoured relative to the same ligands.

With respect to the selectivity of complexation, it is clear that 18C6A$_4$ and 18C6A$_6$ recognize cation charge with relatively little discrimination of cation size. As a result the triad "selectivities" among Ca^{2+}, Sr^{2+}, and Ba^{2+} are poor, especially in comparison to EDTA. Similarly the triad selectivity among Na^+, K^+, and Tl^+ is virtually absent in 18C6A$_4$ and 18C6A$_6$,in poor comparison to the cryptands. It is apparent that 18C6A$_4$

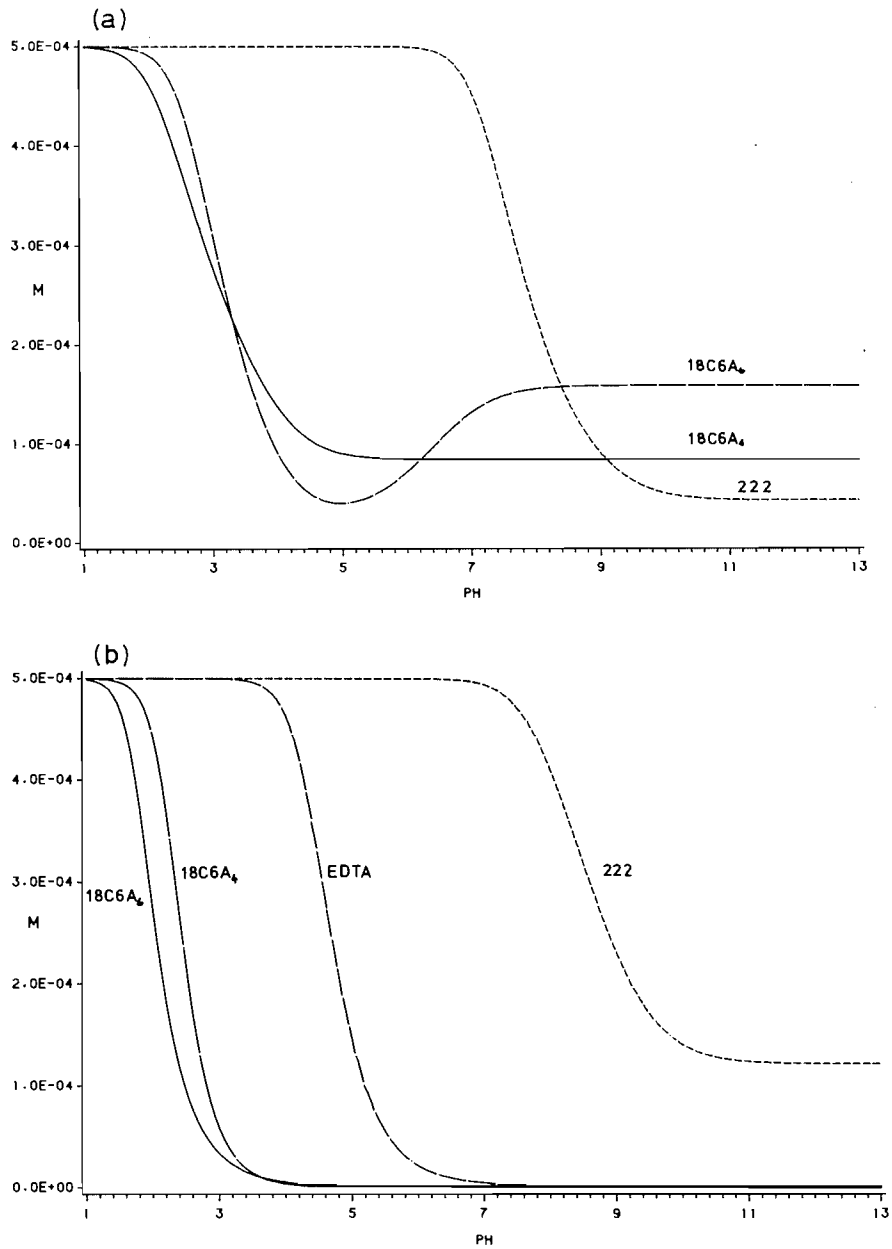

FIG. 5. (a) Calculated free K^+ concentration as a function of pH for 2.2.2 cryptand, $18C6A_4$, and $18C6A_6$ at $[L] = [K^+] = 5 \times 10^{-4}$ M. (b) Calculated free Ca^{2+} concentration as a function of pH for EDTA, 2.2.2 cryptand, $18C6A_4$, and $18C6A_6$ at $[L] = [Ca^{2+}] = 5 \times 10^{-4}$ M.

and $18C6A_6$ are somewhat indiscriminant cation binding agents.

A more unique feature of metal ion complexes of $18C6A_4$ and $18C6A_6$ is their ability to bind cations over a wide pH range. As noted above, the protonated complexes are less stable, but nonetheless do have appreciable stability. In contrast, protonation on nitrogen of the cryptates results in drastic destabilization and decomplexation. The same is true of EDTA. The comparison is readily made in Fig. 5, where free K^+ (Fig. 5*a*) and free Ca^{2+} (Fig. 5*b*) concentrations have been calculated for an equimolar mixture of metal ion and ligand at 5×10^{-4} M as a function of pH. In the K^+ case the concentrations at high pH reflect the order of the stability of the complexes ($2.2.2 > 18C6A_4^{4+} > 18C6A6_6^{6-}$). The minimum in the $18C6A_6$ curve is the result of the greater stability of the monoprotonated complex as discussed above. In any event, it is clear that both polycarboxylate crown ethers can bind K^+ well into acidic solution while 2.2.2 requires strongly basic conditions to achieve a similar result. Similarly the Ca^{2+} results show that pH > 9.5 is required for 2.2.2, pH > 6 for EDTA, while the polycarboxylate crown ethers bind Ca^{2+} to a significant extent even at pH 3.

In addition the polycarboxylate crown ethers have a series of protonation equilibria of the free ligand from pH 5 to 2. One can therefore envisage a simultaneous buffering of protons and metal ions in the pH range of 3–5. As an example consider 1×10^{-3} M $18C6A_6$ at pH 4.5 containing half an equivalent of K^+. Addition of a further one quarter of an equivalent of KOH (to 7.5×10^{-4} M $[K^+]$) provokes a pH change of 0.18 and a pK ($-\log[K^+]$) change of 0.36 (from 1.2 to 2.7×10^{-5} M free K^+). This type of behavior is rare, although some pH buffer systems will bind transition metal ions to produce a similar effect (32).

Conclusions

In summary, the polycarboxylate crown ethers examined show a range of behaviors with respect to the complexation of metal cations. At the two extremes, small, high charge density cations are bound predominantly by coulombic interaction while larger cations are bound by mono- and dianionic ligands predominantly as normal crown ether complexes. For a large number of cases the two effects act cooperatively to produce stabilized complexes involving direct coordination of the bound cation by at least one carboxylate from the ligand. Comparisons between *RR* and *RS*18C6A$_2$, and between ligands with isomeric charge distributions indicate that the final behaviors observed include entropic and solvation effects as well. Nevertheless, polycarboxylate crown ethers act as effective, if somewhat unselective, ligands for alkali metal and alkaline earth cations. They are as effective at ion binding as the cryptands and EDTA but offer an expanded pH range for complexation.

Experimental

General details

Melting points were taken on a Koefler hot stage microscope (uncorrected). Proton nmr spectra were recorded with a Perkin Elmer R32 (90 MHz, CW) or Bruker WM250 (250 MHz, FT) spectrometer in $CDCl_3$ solvent with Me_4Si as internal standard unless otherwise noted. Carbon spectra were recorded at 93.8 MHz (WM250) in $CDCl_3$ with the central solvent line as standard (77.0 ppm relative to Me_4Si) or in D_2O with CH_3OH as internal standard (49.0 ppm relative to Me_4Si). The mass spectra were recorded with a Finnegan 330 gs–ms instrument with methane chemical ionization. Optical rotations were recorded using a Perkin Elmer polarimeter in 95% ethanol as solvent (concentration in g/100 mL). Elemental analyses were performed by Canadian Microanalytical Services, Vancouver, B.C.

In general, products obtained as oils gave poor microanalyses due to entrapped chlorinated solvent. Solid derivatives and the final compounds, however, gave satisfactory microanalyses.

Materials

(*a*) *meso-N,N,N′,N′*-Tetramethyltartaramide (**1**) was prepared from *meso*-tartaric acid by dimethylammonolysis of the diester; mp 156–160°C; ir (cm^{-1}): 3400 (OH), 1630 (amide I); ^{1}H nmr δ: 5.22 (brs, OH), 4.45 (AA′, CH), 3.03 and 2.85 (2s, NCH_3); ^{13}C nmr δ: 172.4 (C═O), 68.7 (CH), 37.4 and 36.0 (NCH_3); ms (*m/e*); 205 (*M* + 1).

(*b*) 1,14-Dibromo-3,6,9,12-tetraoxatetradecane was prepared from the dichloride (35) by the method of Babler and Spina (36) using H_2CBr_2 and NaBr in DMF; ^{1}H nmr δ: 3.70 and 3.51 (A_2B_2, J_{AB} = 7 Hz, OCH_2CH_2Br), 3.60 (brs, all other protons); ms (*m/e*): 363, 365, 367 ($^{79}Br_2$ *M* + 1, $^{79}Br^{81}Br$ *M* + 1, $^{81}Br_2$ *M* + 1), peaks for the dichloride and chlorobromide absent.

(*c*) 2-(2-Bromoethoxy)tetrahydropyran (23), thallous ethoxide (21), and (2*R*,3*R*)-*N,N,N′,N′*-tetramethyl-2,3-bis(2-(tosyloxy)ethoxy)succinamide (**11**) (23) were prepared as previously. All other materials were commercially available. DMF was dried over activated 4 Å molecular sieves added directly to commercially available solvent.

meso-N,N,N′,N′-Tetramethyl-2,3-carboxamido-1,4,7,10,13,16-hexaoxacyclooctadecane (2)

To a solution of **1** (15.0 g, 0.0734 mol) in dry DMF (600 mL) was added thallous ethoxide (10.8 mL, 0.15 mol) with vigorous stirring at room temperature. After 15 min 1,14-dibromo-3,6,9,12-tetraoxatetradecane (22.2 g, 0.0619 mol) was added. The mixture was stirred at 85°C for 6 h, cooled, and purified using the procedure described previously (21) to yield 9.9 g of crystalline **2**; mp 130°C; ir (cm^{-1}): 1660 (amide), 1110 (C–O); ^{1}H nmr δ: 5.02 (2H, s, CH), 3.74 (20H, br, CH_2O); 3.26 and 3.06 (12H, 2s, NCH_3); ^{13}C nmr δ: 170.0 (C═O), 78.0 (CH), 70.2, 69.8 and 69.7 (CH_2O), 37.3 and 36.3 (NCH_3); ms (*m/e*): 407 (*M* + 1). *Anal.* calcd. for $C_{18}H_{34}N_2O_8$: C 53.19, H 8.43, N 6.89; found: C 53.15, H 8.23, N 6.68.

meso-4,7,10,13,16-Hexaoxacyclooctadecane-2,3-dicarboxylic acid (3)

Compound **3** was prepared from **2** by acidic hydrolysis as described previously (21) in 94% recrystallized yield as the monohydrate; mp 70–73°C (loss of H_2O evident); ir (cm^{-1}): 3700–3000 (OH), 1740 (CO); ^{1}H nmr δ: 4.60 (2H, s, CH), 3.69 (20H, brs, CH_2O); ^{13}C nmr δ: 172.8 (C═O), 79.9 CH, 70.6, 69.8 and 69.6 (CH_2O); ms (*m/e*): 353 (M + 1). *Anal.* calcd. for $C_{14}H_{26}O_{11}$ (**3**·H_2O): C 45.40, H 7.07; found: C 44.96, H 7.00.

(2R,3R)-N,N,N′N′-Tetramethyl-2-benzyloxy-3-hydroxysuccinamide (5)

Sodium hydride (5.2 g, 60% in oil, 130 mmol) was washed with pentane (3×) under an Ar atmosphere. Dry dimethylformamide (DMF, 500 mL) was added and the suspension stirred while tartaramide (**4**) (25 g, 122 mmol) was added as a solid. The suspension was stirred until clear (ca. 1 h) and benzyl bromide (25 g, 150 mmol) was added rapidly. The temperature was raised to 80°C for 7 h. The solvent was removed by evaporation under reduced pressure and the product dissolved in 500 mL of water. The aqueous solution was extracted with 250-mL portions of pentane (2×), Et_2O (2×) (disubstituted side product; ^{1}H nmr δ (2s, 12H, 4 × NCH_3), (brs, 4H, 2 × OCH_2), (s, 2H, 2 × $CHOCH_2$), (s, 10H, 2 × C_6H_5)), and CH_2Cl_2 (3×). The combined CH_2Cl_2 extracts were dried over $MgSO_4$, evaporated, and evacuated overnight at 34–40°C to give the monobenzyl ether (**6**) as a viscous oil (23 g, 78 mmol, 64%): $[\alpha]_D^{22}$ +53.2° (*c* 0.87); ^{1}H nmr and ^{13}C nmr; Table 3; ms (*m/e*): 295 (*M* + 1).

(2R,3R)-N,N,N′,N′-Tetramethyl-2-benzyloxy-3-(2-tetrahydropyranyloxy)ethoxysuccinamide (6)

Thallous ethoxide (5.4 mL, 77 mmol) was added by syringe to a solution of **5** (21 g, 71 mmol) in dry DMF (300 mL). The solution was warmed to 60°C over 1 h and 2-(2-bromoethoxy)tetrahydropyran was added. The reaction proceeded at 60°C for 15 h, was cooled, and the thallous bromide removed by filtration (Celite). The DMF was evaporated, the product evacuated overnight, taken up in CH_2Cl_2, and filtered again. The product after evaporation was preadsorbed on neutral Al_2O_3 (100 g) and loaded on a short (16–20 cm) column of neutral Al_2O_3 (1000 g) packed with CH_2Cl_2. The product was eluted rapidly with 0.5% MeOH/CH_2Cl_2; appropriate fractions were identified by thin-layer chromatography (tlc) (R_f 0.79, 5% MeOH/CH_2Cl_2, Merck silica gel 60 silanized) and combined to give the product as an oil after evaporation and evacuation (22.6 g, 54 mmol, 75%); ^{1}H nmr and ^{13}C nmr: Table 3.

(2R,3R)-N,N,N′,N′-Tetramethyl-2-benzyloxy-3-(2-hydroxy)ethoxysuccinamide (7)

The Thp ether **6** (22 g, 53 mmol) was dissolved in MeOH (200 mL) and concentrated HCl (3 drops) was added. The solution was heated at reflux for 1.5 h. The solvent was evaporated and the product evacuated to give **7** as an oil (18.8 g, 55 mmol, 100%), which was used without further purification; $[\alpha]_D^{22}$ +43.9 (*c* 1.56); ^{1}H nmr and ^{13}C nmr: Table 3.

(2R,3R)-N,N,N′,N′-Tetramethyl-2-benzyloxy-3-(2-tosyloxy)ethoxysuccinamide (8)

The alcohol **7** (8.9 g, 26 mmol) was stirred in CH_2Cl_2/Et_3N (100 mL/6 mL) at 0°C and *p*-toluenesulfonyl chloride (TsCl) (6 g, 31 mmol) was added. The flask was fitted with a drying tube and allowed to warm slowly to room temperature. The reaction was stirred overnight, water was added, and the product extracted into CH_2Cl_2 (3×), washed with cold 10% HCl (2×) and cold saturated sodium bicarbonate, dried over $MgSO_4$, filtered, evaporated, and evacuated. The product was triturated with boiling pentane (12 × 100 mL). The oil obtained (10 g, 20 mmol, 78%) was used without further purification; $[\alpha]_D^{22}$ +23.7 (*c* 2.23); ^{1}H nmr and ^{13}C nmr: Table 3.

(3R,4R,9R,10R)-N,N,N′,N′,N″,N″,N‴,N‴-Octamethyl-3,4,-9,10-tetracarboxamido-2,5,8,11-tetraoxa-1,12-diphenyldodecane (9)

Sodium hydride (3.82 g, 60% NaH in oil, 95.5 mmol) was washed with pentane (3×) under inert atmosphere. Dry DMF (400 mL) was

added and the suspension was mechanically stirred while the monobenzyl ether **5** (28.1 g, 95.5 mmol) was added slowly as a solution in dry DMF (500 mL). The mixture was stirred at room temperature until clear, and the tosylate **8** (47 g, 95.5 mmol) in dry DMF (250 mL) was added rapidly. The temperature was raised to 65°C for 12 h, the solvent was evaporated under reduced pressure, and the product evacuated. The product was dissolved in water and extracted with CH_2Cl_2 (3×). The combined CH_2Cl_2 extracts were dried, evaporated, and evacuated to give the product as an oil (50 g, 91 mmol, 95%). Attempts to use the product in unpurified form were unsuccessful. A portion of the original product (20 g, 32.6 mmol) was preadsorbed on deactivated Al_2O_3 (100 g, Brockman III), loaded onto a deactivated Al_2O_3 (1000 g, Brockman III) column packed with CH_2Cl_2, and eluted with a methanol gradient. Product containing fractions (0.25–0.5% MeOH) were identified by tlc (R_f 0.53, 5% MeOH/CH_2Cl_2, Merck silica gel 60 silanized), combined, dried, evaporated, and evacuated to give the solid product (8.5 g, 13.8 mmol, 43%); mp 92–94°C; $[\alpha]_D^{22}$ +57.6 (*c* 1.05); ^1H nmr and ^{13}C nmr: Table 3. *Anal.* calcd. for $C_{32}H_{46}N_4O_8$: C 62.5, H 7.5, N 9.1; found: C 60.2, H 7.4, N 8.8.

The dibenzyl ether **9** (6.83 g, 11.1 mmol) was dissolved in 95% EtOH (20 mL) and poured over 10% Pd/C (250 mg, 2 mol% Pd). Two drops HCl were added. The suspension was hydrogenated at 50 psi (1 psi = 6.9 kPa) (Parr apparatus) for 36 h. The catalyst was filtered from the solution and evaporation and evacuation gave a solid. The product was dissolved in H_2O, neutralized with $NaHCO_3$, and continuously extracted with CH_2Cl_2 for 20 h. The organic layer was dried, evaporated, and evacuated to give the product as a gum (4.8 g, 11.1 mmol, 100%); $[\alpha]_D^{22}$ +47.9 (*c* 1.83); ^1H nmr and ^{13}C nmr: Table 3. *Anal.* calcd. for $C_{18}H_{34}N_4O_8$: C 49.8, H 7.8, N 12.9; found: C 48.2, H 7.8, N 12.3.

*(2R,3R,8R,9R,14R,15R)-N,N,N′,N′,N″,N″,N‴,N‴,N^{iv},N^{iv},-N^{v},N^{v}-Dodecamethyl-1,4,7,10,13,16-hexaoxacyclooctadecane-2,3,8,9,14,15-hexacarboxamide (**12**)*

Sodium hydride (0.12 g, 97% as a powder, 4.6 mmol) was handled in a glove bag and charged into a 3-neck 500-mL round-bottomed flask. While under inert atmosphere, dry DMF (20 mL) was added and the suspension was stirred at 0°C. The diol **10** (1 g, 2.3 mmol) was dissolved in dry DMF (30 mL) and added rapidly to the NaH suspension, and the resulting solution was stirred 1 h. The ditosylate **11** (1.38 g, 2.3 mmol) in dry DMF (30 mL) was added rapidly and the reaction allowed to proceed for 9 h at 70°C. The solvent was evaporated and the product evacuated overnight. The product was dissolved in H_2O (100 mL) and extracted with a series of solvents (Et_2O 3 × 100 mL, CH_2Cl_2 3 × 100 mL, continuous CH_2Cl_2). The crude product was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 93.93.197.157 on 09/07/12
For personal use only.

obtained upon drying, evaporating, and evacuating the continuous extract (0.85 g, 1.2 mmol, 53%).

Products from a variety of cyclizations were combined for chromatography. The combined crude product (3.5 g, 5 mmol) was dissolved in CH_2Cl_2 and loaded onto a neutral Al_2O_3 (200 g) column packed with CH_2Cl_2. The column was eluted with a methanol gradient (0–0.5%, flush with 2.5%). Product was obtained in seven fractions at 0.25% $MeOH/CH_2Cl_2$. The combined fractions were dried, evaporated, and evacuated to give a white powder (2.1 g, 3 mmol, 60%) (cyclization yield 32%); $[\alpha]_D^{22}$ +87.6 (*c* 1.92); ^1H nmr and ^{13}C nmr: Table 3; ms (*m/e*) 691 (*M* + 1). *Anal.* calcd. for $C_{30}H_{54}N_6O_{12}$: C 52.2, H 7.8, N 12.2; found: C 51.5, H 7.7, N 11.9.

*(2R,3R,8R,9R,14R,15R)-1,4,7,10,13,16-Hexaoxacyclooctadecane-2,3,8,9,14,15-hexacarboxylic acid (**13**, 18C6A$_6$)*

The hexaamide **12** (1.9 g, 2.7 mmol) was dissolved in 2.5 M HCl (100 mL) and heated at 80°C for 24 h. The solvent was evaporated and the product evacuated to give a solid that was redissolved in deionized water and passed through a strong acid ion exchange resin (30 g, Dowex 50 × 8–100). Product was obtained by evaporation of the first four fractions as a white solid (1.5 g, 2.8 mmol, 100%). The product was recrystallized from hot deionized H_2O (1.0 g, 1.9 mmol, 70%).

The level of trace contamination by sodium and potassium (by Atomic Absorption Spectroscopy) was not acceptable for the sample used for the potentiometric titration. The hexaacid **14** (0.50 g) was dissolved in doubly distilled deionized H_2O (8 mL) and loaded onto a strong acid ion exchange column (15 g, Dowex 50W × 2 pa, washed with 500 mL of 1 M Fluka Puriss, p.a., H_2SO_4 followed by 2× distilled deionized water until neutral) and eluted with doubly distilled deionized H_2O. Fractions (1 mL) with pH <3 were combined, evaporated, and evacuated to give the product as a white powder (0.464 g, 94%). A sample was recrystallized from 2× distilled deionized water by slow evaporation. The large crystals obtained from water are hydrates; evacuation produces powdery, anhydrous materials used for potentiometric titration and elemental analysis; mp 113–116°C; $[\alpha]_D^{22}$ +122.1 (*c* 1.74); ^1H nmr and ^{13}C nmr: Table 3. *Anal.* calcd. for $C_{18}H_{24}O_{18}$: C 40.9, H 4.6; found: C 40.4, H 3.8.

Stability constant determinations

The general procedures and apparatus have been described previously (12, 21). The pH electrode (Fisher glass electrode) was soaked in tetramethylammonium chloride (TMACl)/HCl solutions for several weeks before initial use and stored in distilled deionized water between uses. The reference electrode (Fisher calomel) was linked to the cell via a porous plug bridge containing 0.05 M TMACl. The electrodes were calibrated with commercially available buffers at pH 2.00 and 6.86 and linearity was checked at pH 4.01. All titrations were performed in a sealed cell under a slight positive pressure of argon. For pK_a determinations, a 5.0-mL solution of ligand free acid ($(3–4) \times 10^{-4}$ M) in 0.05 M TMACl was titrated with standardized TMAOH containing 0.05 M TMACl to beyond the strong acid/strong base end point (~80 μL per ligand equivalent using 2.5×10^{-2} M TMAOH) in 2–4 μL aliquots (20 points per ligand equivalent). The data file was stored and processed as previously (21) to yield β_{10h} for the ligand. For stability constant determinations two procedures were used. One followed the procedure for pK_a determination directly, with the addition of an equivalent of metal chloride solution to the free acid before titration with base. The other used the solution resulting from the pK_a titration by addition of an equivalent of metal chloride to the basic solution. This mixture was titrated with 2.5×10^{-2} M HCl (containing 0.05 M TMACl) back to the starting acidic pH (~20 aliquots per ligand equivalent). The second method is inappropriate for metals that form insoluble hydroxo complexes. The β_{lmh} values determined by the two methods were the same within the experimental uncertainty of log β ± 0.2. Computations of the Cd^{2+}, Zn^{2+}, and Cu^{2+} systems included literature values for chloro and hydroxo complex formation (34): log β (species): 1.90 ($CdCl^+$), 2.44 ($CdCl_2$), 3.15 ($CdCl_3^-$), 3.8 ($CdOH^+$), 4.71 ($ZnOH^+$), 9.86 ($Zn(OH)_2$), 15.5 ($Zn(OH)_3^-$), 5.70 ($CuOH^+$), 13.10 ($Cu(OH)_2$), 16.9 ($Cu_2(OH)_2^{2+}$), 33.7 ($Cu_3(OH)_4^{2+}$). The calculated values for 18C6A$_4$ and 18C6A$_6$ with Zn^{2+}, Cu^{2+}, or Cd^{2+} were relatively insensitive to the literature values chosen. The values calculated for *RR*18C6A$_2$ with the same ions are much more dependent upon the values chosen. Consequently the uncertainties are greater in these cases. Ternary complex species such as 18C6A$_6^{4-}$/$CuOH^+$ (CuLOH) were tolerated by SCOGS and in some cases improved the fit considerably but this may be an artifact of the β values chosen for the hydroxo complexes. Computations of buffer capacity and species distribution as a function of pH used the algorithm COMPLEX (37) adapted for use on an HP85 microcomputer.

Nucleofugality effects in the pyridine promoted formation of esters from 2-substituted ethanesulfonyl chlorides[1]

JAMES FREDERICK KING, JOHN HENRY HILLHOUSE, TOYANNE MARIE LAURISTON, AND KISHAN CHAND KHEMANI

Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received October 6, 1987

JAMES FREDERICK KING, JOHN HENRY HILLHOUSE, TOYANNE MARIE LAURISTON, and KISHAN CHAND KHEMANI. Can. J. Chem. **66**, 1109 (1988).

The products of reaction of a series of 10 2-substituted ethanesulfonyl chlorides, X—$CH_2CH_2SO_2Cl$ (1), with neopentyl alcohol and pyridine-d_5 in nitromethane-d_3 showed three reaction pathways depending on the nucleofugality of the substituent, X. These routes lead, respectively, to (*i*) the corresponding neopentyl ester (**4**), via the sulfene (**3**) (low substituent nucleofugality); (*ii*) a mixture of ester **4** and neopentyl ethenesulfonate (**5**), by the same route except for a partial loss of the 2-substituent during trapping of the sulfene (**3**) (intermediate nucleofugality); and (*iii*) a mixture of the ethenesulfonate (**5**) and the pyridino-betylate (**4***g*) esters, arising from initial elimination of HX to form ethenesulfonyl chloride (**2**) followed by its further reaction (high substituent nucleofugality). A set of nucleofugality values closely related to, and partly complementing, those derived by Stirling and co-workers can be estimated from the product ratios in those reactions proceeding (at least in part) by route (*ii*) above. Old reports of anomalous products from 1,2-ethanedisulfonyl chloride (**1***i*) and 2-chloroethanesulfonyl chloride (**1***j*) are simply accounted for on the basis of the initial conversion to ethenesulfonyl chloride (**2**).

JAMES FREDERICK KING, JOHN HENRY HILLHOUSE, TOYANNE MARIE LAURISTON et KISHAN CHAND KHEMANI. Can. J. Chem. **66**, 1109 (1988).

Les produits provenant des réactions d'une série de 10 chlorures d'éthanesulfonyle substitués en position 2, X—$CH_2CH_2SO_2Cl$ (**1**), avec l'alcool néopentylique et la pyridine-d_5, dans le nitrométhane-d_3 proviennent de trois voies différentes qui dépendent de la nucléofugacité du substituant X. Ces voies conduisent respectivement à (*i*) ester néopentylique correspondant (**4**), par la biais du sulfène **3** (lorsque la nucléofugacité du substituant est faible); (*ii*) un mélange de l'ester **4** et l'éthènesulfonate de néopentyle (**5**) qui proviennent de la même voie, excepté pour la perte partielle du substituant en position 2 qui se produit lors du piégeage du sulfène **3** (lorsque la nucléofugacité du substituant est intermédiaire); et (*iii*) un mélange des esters éthènesulfonate (**5**) et pyridinio-bétylate (**4***g*) qui proviennent d'une élimination initiale de HX, conduisant au chlorure d'éthènesulfonyle (**2**), qui est suivie de sa réaction (lorsque la nucléofugacité du substituant est élevée). En se basant sur les rapports des produits qui se forment au cours des réactions (au moins en partie) qui suivent la voie (*ii*) mentionnée plus haut, on peut évaluer un ensemble de valeurs de nucléofugacité qui ressemble et qui complète celui de Stirling et ses collaborateurs. Des rapports antérieurs concernant la formation de produits anormaux à partir des chlorures d'éthanedisulfonyle-1,2 (**1***i*) et de chloro-2 éthanesulfonyle (**1***j*) peuvent facilement être expliqués en se basant sur une conversion initiale en chlorure d'éthènesulfonyle (**2**).

In the course of an extended investigation of the mechanism of sulfonyl transfer (1–4), we have looked at the reactions of a number of 2-substituted ethanesulfonyl chlorides (**1**) with water or alcohols in the presence of tertiary amines, and have been struck by the variation in the nature of the reaction products. We now report a more systematic examination of this reaction with substrates bearing substituents having a sizeable range in nucleofugality (or "leaving group ability"). Our results enable us to (*a*) assign the mechanistic pathways leading to the various observed products, (*b*) estimate nucleofugality values as defined by Stirling and co-workers (5, 6) for some of these leaving groups, and also (*c*) to provide insight into some inadequately explained observations with 1,2-ethanedisulfonyl and 2-chloroethanesulfonyl chlorides (**1***i* and **1***j*) dating back over many years.

Results and discussion

Reaction conditions and products

Compounds **1***a* – **1***j* were treated with pyridine-d_5 and neopentyl alcohol in nitromethane-d_3 at room temperature; the ^{1}Hmr spectrum was run within 20 min and the product composition so determined summarized in Table 1. Neopentyl alcohol was chosen because (*a*) its sulfonic esters are comparatively unreactive and hence less subject to subsequent transformation than those of other alcohols, and (*b*) the neopentyl grouping gives characteristic, uncluttered ^{1}Hmr spectra with both starting materials and products; nitromethane was found to be a suitable solvent capable of keeping both covalent and ionic products in solution. In all cases the products were found to be stable to the conditions of the reaction, i.e., the product composition given in Table 1 is that of the primary, kinetically controlled reaction products.

Reaction pathways to products

Inspection of the results in Table 1 reveals three patterns of reactivity: (*i*) ordinary formation of the corresponding ester (**4**), illustrated by the reactions of **1***a–c*; (*ii*) production of a mixture of the corresponding ester (**4**) and the ethenesulfonate ester (**5**), exemplified by the reactions of the 2-phenylthio- and 2-acetoxyethanesulfonyl chlorides (**1***e* and **1***f*); and (*iii*) generation of a mixture of the ethenesulfonate (**5**) and betylate (**4***g*) esters displayed by the disulfonyl chloride (**1***i*) and 2-chloroethanesulfonyl chloride (**1***j*). Two of these patterns have been observed previously. The first of these is, of course, just the normal formation of alkanesulfonic esters via the sulfene (**3**), i.e., the regular "sulfene route". The third set of products, i.e., the ~2:1 mixture of **5** and **4***g*, has also been obtained from the reaction of ethenesulfonyl chloride under the same conditions (1). The simplest explanation of this result is that these products arise by initial conversion of the starting sulfonyl

TABLE 1. Relative proportions of esters (**4**, **4***g*, and **5**) in the reaction of 2-substituted ethanesulfonyl chlorides (**1**) and related compounds[a]

Substrate	Relative proportions 4	4*g*	5	Mechanistic pathway
1*a* (X = H)	100	—	—	Sulfene route (**1** → **3** → **4**)
1*b* (X = HO)	100[b]	—	—	
1*c* (X = $NpOSO_2$)	>95[c]	—	—	
1*d* (X = $PhSO_2$)	97	—	3	Sulfene + elimination route (**1** → **3** → **4** + **5**)
1*e* (X = PhS)	85	—	15	
1*f* (X = MeCOO)	40	—	60	
1*g* (X = pyridinio)	33	(33)	67	Sulfene + elimination and alkene routes[d]
1*h* (X = 3,5-$(NO_2)_2C_6H_3COO$)	9	10	81[e]	
1*i* (X = $ClSO_2$)	—	33	67[f]	Alkene route (**1** → **2** → **3***g* → **4***g* + **5**)
1*j* (X = Cl)	—	32	68	
CH_2=$CHSO_2Cl$ (**2**)	—	33	67	(**2** → **3***g* → **4***g* → **5**)[g]
$ClCH_2CH_2SO_2Br$ (**6**)	—	33	67	Alkene route (like **1***i*)

[a]Conditions: sulfonyl halide (~0.3 M), pyridine-d_5 (1.5–2.0 M), and neopentyl alcohol (~0.6 M) in nitromethane-d_3 at room temperature. Ester ratios were determined from ^{1}Hmr spectra (T-60 or XL-200), which also showed the esters (**4**, **4***g*, and **5**) to be the principal products (usually >90%), often along with small amounts of hydrolysis products.

[b]Actual product composition: **4***b*, 16%, $C_5H_5N^+CH_2CH_2SO_3^-$, 84% (see also ref. 4).

[c]No sign of **4***g* or **5** in the T-60 ^{1}Hmr spectrum.

[d]Incursion of about 20% of the alkene route in the reaction of **1***g* is deduced from labelling experiments described elsewhere (1). In the reaction of **1***h* the ratio of sulfene to alkene routes is ~70:30 with most (87%) of the sulfene (**3***h*) undergoing elimination to give **5** and a small amount (13%) going to **4***h* (see text).

[e]Actual product composition: **5**, 50%; **4***g*, 7%; **4***h*, 7%; neopentyl 3,5-dinitrobenzoate, 13%; pyridinium 2-(3,5-dinitrobenzoyloxy)ethanesulfonate, 7%; pyridinium ethenesulfonate, 16%. The last three probably arise largely by trapping of the sulfene (**3***h*) by the liberated 3,5-dinitrobenzoate anion (cf. ref. 2), followed by further reaction of the resultant mixed anhydrides.

[f]The product showed no sign of any **4***c*, which would have been formed if any **4***i* (=**1***c*) had been produced.

[g]The assignment of this mechanism is discussed elsewhere (1).

chloride into ethenesulfonyl chloride (**2**) (the "alkene route"), followed by vinylogous attack of pyridine on **2** to give the cationic sulfene (**3***g*), which in turn forms the characteristic mixture of ethenesulfonate (**5**) and betylate (**4***g*) (ref. 1, cf. also ref. 3). Reaction of **1***j* with a tertiary amine such as 2,6-lutidine or triethylamine is, in fact, the usual preparative route to **2**, and the transitory presence of **2** in the reaction of **1***j* with pyridine is to be expected. In accord with this we found that **1***i* with 2,6-lutidine gave a product with the characteristic ^{1}Hmr spectrum of **2**.

Except for the special case of **1***g*, the other product composition pattern, namely the mixture of the ethenesulfonate (**5**) and 2-substituted ethanesulfonate (**4**), has evidently not been noted before. The normal esters (**4**) presumably arise from the sulfene (**3**), since the deuterated alcohol yields α-deuterated esters. The ethenesulfonate esters **4***e–f* and **4***h* cannot arise from ethenesulfonyl chloride (**2**) because under these conditions **2** always gives a roughly 2:1 mixture of **5** and **4***g* (1), and the latter is not present in any detectable amount in the reaction products from **1***e*, **1***f*, and **1***h*. Accordingly, we propose that **4***e–f* and **4***h* are formed from the sulfenes (**3***e–f* and **3***h*) by elimination of X^- in the course of the trappng reaction.

Such a proposal requires a mechanistic picture in which it is possible to account for the conversion of 2-acetoxyethanesulfonyl chloride (**1***f*), for example, into the sulfene (**3***f*) without any loss of acetate anion to form **2**, and, at the same time, in the sulfene trapping step to lose acetate anion more quickly than protonation to form the acetoxy-ester (**4***f*). This requirement is nicely consistent with the variable transition state mechanism for elimination reactions, with the conversion of **1***f* into **3***f* proceeding by an E1cB-like E2 reaction, and the trapping of the sulfene (**3***f*) with the alcohol a stepwise process going via a discrete carbanion (**7**, X = AcO), which

$$XCH_2CH_2SO_2OR \leftarrow \underset{\mathbf{4}}{} XCH_2\bar{C}H—SO_2OR \rightarrow \underset{\mathbf{7}}{}$$

$$CH_2{=}CHSO_2OR + X^- \quad (\mathbf{5})$$

either eliminates X^- (AcO^- in this case) to give **5** or is protonated by the (unspecified) proton source to give **4**; this mechanism has already been discussed in connection with the trapping of **3***g* in aqueous media (3). With such a picture only a *partial* negative charge is enough to extrude the comparatively nucleofugal chloride anion from **1***f* to give **3***f* (without any loss of acetate anion to form **2**), but, with the formation of the full negative charge on the carbon in **7** in the sulfene trapping step, loss even of the less nucleofugal acetate anion competes successfully with the alternative reaction, the rapid protonation of the α-sulfonyl carbanion.

The reaction of the 3,5-dinitrobenzoyloxy compound (**1***h*) illustrates the particularly delicate balance between the possible pathways in each of the two stages of the reaction. Since formation of the betylate (**4***g*) from the pyridinio-sulfene (**3***g*) is accompanied by roughly twice the quantity of ethenesulfonate ester (**5**), the 10% yield of **4***g* indicates that about 30% of the total product is formed via **2**, while the remaining 70% arises by direct conversion to the sulfene (**3***h*); the reaction pathways may be summarized as follows: **1** → **3** → **4***h*, 9%; **1** → **3** → **5**, 61%; **1** → **2** → **5**, 20% (total yield of **5**, 81%); **1** → **2** → **4***g*, 10%. Reaction of **1***h* obviously gives the highest yield of **5** of any of the substrates used in this study, but it would appear unlikely

SCHEME 1

that direct quantitative formation of **5** can be obtained (with the present conditions, at least) merely be altering the leaving group (X), since increased reactivity in the leaving group would probably lead to more **2** and so to more betylate (**4***g*), whereas diminished reactivity would likely result in more **4** relative to **5**.

In principle, the balance among the different reaction pathways should be alterable by changing the leaving group on the sulfur atom. The reaction of 2-chloroethanesulfonyl bromide (**6**) was looked at with an eye to seeing if the more reactive bromide would lead to preferential formation of the sulfene (**3**, X = Cl) rather than the ethenesulfonyl halide, but the product was the same as that from **2** (see Table 1) and therefore presumably arose by way of ethenesulfonyl bromide and the pyridinio-sulfene (**3***g*).

Other possible pathways

Scheme 1 includes a number of dashed arrows representing reactions which, though a priori reasonable, may be shown to participate, at most, only to a very limited extent under the conditions of this study. As has already been noted above, interconversion of products under the specified conditions is excluded by control experiments. Much longer intervals than those used in the experiments summarized in Table 1, however, may lead to change; the composition of the mixture of **4***g* and **5**, for example, alters from 33:67 to 88:12 on long standing, thereby providing a convenient route to **4***g* (1). Also, the required authentic specimen of **4***j* was obtained by allowing **1***j* to react for 10 days with neopentyl alcohol in CH_2Cl_2 (without added base), i.e., by the direct conversion **1***j* to **4***j*. That such a direct reaction is not important in the presence of pyridine, however, is shown by the deuteration products observed with neopentyl alcohol-*d*. With a 10-fold excess of neopentyl alcohol-*d* (93% NpOD, 7% NpOH), 2-phenylthioethanesulfonyl chloride (**1***e*) gave (in addition to 14% of **5**) a mixture of $PhSCH_2CHDSO_2ONp$ and $PhSCH_2CH_2SO_2ONp$ (**4***e*) in the ratio of 87:13; when one recalls that protons are introduced into the reaction mixture by the formation of the sulfene (**1** → **3**), it is clear that the reaction products are readily accounted for by the sulfene mechanism (**1** → **3** → **4**) without any detectable incursion of the direct displacement reaction. Similar results were encountered in deuteration experiments with **1***g* and **1***h*. Ethanesulfonyl chloride (**1***a*) is the only substrate that shows any sign of the direct displacement process. With a 10-fold excess of NpOD (containing 12% of NpOH) **1***a* gave a 56:44 mixture of the mono- and undeuterated esters, CH_3CHDSO_2ONp and $CH_3CH_2SO_2ONp$ (**4***a*). It seems likely that a portion of this reaction product arises via the direct reaction (**1** → **4**). It should be noted that **1***a* is much the least reactive of the substrates used in this study, with reaction completion requiring more than 22 h as compared with 5 min for the other substrates (**1***b*–*j* and **2**); with such slow sulfene formation it is perhaps not surprising that another process, such as a general base or possibly a nucleophilic catalyzed direct displacement, may enter the picture. The much greater ease of sulfene formation from substrates **1***b*–**1***g* is consistent with the above-mentioned E1cB-like E2 picture, since the substituents *b*–*g* are all distinctly electron withdrawing relative to hydrogen and would be expected to facilitate development of the partial negative charge at C-1. This expectation is in accord with Thomas and Stirling's observation (7) that the rate of the closely related detritiation of $PhSO_2CHTCH_2Z$ with ethoxide in ethanol correlated with the σ^* values of the CH_2Z grouping ($\rho^* = 4.89$).

As has been mentioned elsewhere (1) the interconversion **1***g* ⇌ **2** occurs to a minor extent, leading to some $CH_2=CDSO_2ONp$ in the product. This is not seen in the material from **1***e* or **1***h*, nor do any of the reactions with NpOD show any sign of the dideuterated product, $XCH_2CD_2SO_2ONp$ (which would be expected if any XCH_2CHDSO_2Cl had been formed, cf. refs. 3 and 8); hence other **1** ⇌ **2** interconversions are evidently precluded.

The insensitivity of product ratios to changes in concentrations of reagents and the mechanism of trapping of the sulfene (3)

In the hope of gaining insight into the challenging problem of how sulfenes are converted into the final products, we carried out a series of experiments with 2-phenylthioethanesulfonyl chloride (**1***d*) in which the various ingredients of the reaction mixture were systematically altered. The remarkable result was that the product composition changed very little. The ratio of ethenesulfonate to 2-phenylthioethanesulfonate esters (**5**:**4***e*) was not altered (from 16:84) by increasing the concentration of NpOH from 0.66 to 1.53 to 2.70 M; changing the pyridine-d_5 concentration from ~1.5 to 4.2 M lowered the percentage of **4***e* slightly (to 76%), but addition to pyridinium chloride (2.0 M, [pyridine] 3.95 M) made no discernible further change (78% **4***e*). In the presence of NpOD the change in product ratios was less than experimental uncertainty: e.g., with a 51:49 mixture of NpOD:NpOH (in 10-fold excess) the products were **5** (13%), $PhSCH_2CHDSO_2ONp$ (41%), and $PhSCH_2CH_2SO_2ONp$ (46%), and with 93:7 NpOD:NpOH the ratio of the same products as 14:75:11; any isotope effect on either the ratio of **5** to **4***e* or on the isotopic composition of the phenylthio ester would appear to be minimal (i.e., <1.2).

The results would appear to rule out protonation of **7** by NpOH or pyridinium ion from the general body of the solution; uptake of hydrogen ion from the solvent is already excluded by the absence of deuterium in the product from the reaction with NpOH in CD_3NO_3. Recalling our earlier experiments showing that the reaction of phenylsulfene, $PHCH{=}SO_2$, with alcohols is base catalyzed (9), we suggest the following sequence:

$$\underset{\mathbf{3}}{XCH_2CH{=}SO_2} + ROH + B \longrightarrow \underset{\mathbf{7}}{XCH_2\bar{C}HSO_2OR\ \overset{+}{B}H}$$

$$\underset{\mathbf{7}}{XCH_2\bar{C}HSO_2OR\ \overset{+}{B}H} \xrightarrow{k_H} \underset{\mathbf{4}}{XCH_2CH_2SO_2OR} + B$$

$$\underset{\mathbf{7}}{XCH_2\bar{C}HSO_2OR\ \overset{+}{B}H} \xrightarrow{k_E} \underset{\mathbf{5}}{CH_2{=}CHSO_2OR} + B + HX$$

By this scheme the actual hydrogen ion transfer step is a unimolecular ion-pair process. One should note that the ion pair (**7**) as initially formed may be presumed to have the BH^+ ion in the vincinity of the RO group, i.e., well away from the other two sulfonyl oxygens and hence not, in the first instance, in the arrangement preferred for protonation of the α-sulfonyl carbanion (near the C^- in the internal bisector of the O—S—O angle) (cf. ref. 10). Once this latter "preferred" setup is arrived at, it is likely that the hydrogen ion transfer will be extremely fast; we expect on this basis that k_H will not be much influenced by either the particular isotope or the nature of X. It follows that the variation in product ratios from these reactions must be assigned to the intrinsic differences in k_E, the rate constant for the elimination from **7**, and hence that these product ratios may be used to estimate nucleofugalities of the X groups, as discussed in the next section.

Nucleofugalities from product ratios

Stirling and co-workers (5, 6) have placed the "leaving group ability" of nucleofugal groups in alkene-forming reactions on a quantitative basis by examining a series of olefin-forming eliminations of the following general type in which G is a carbanion-stabilizing function like $PhSO_2$, CN, or PhCO, and Z is the "leaving group" or nucleofuge:

$$G{-}CH_2CH_2Z + B^- \underset{k_{-1}[BH]}{\overset{k_1[B^-]}{\rightleftharpoons}} G{-}\bar{C}HCH_2{-}Z \xrightarrow{k_2} G{-}CH{=}CH_2 + Z^-$$

For an $(E1cB)_R$ process (i.e., one in which $k_{-1}[BH] > k_2$) the observed rate constant for the overall conversion of G—CH_2CH_2Z to G—$CH{=}CH_2$ is given by $k_{obs} = k_1k_2/k_{-1}[BH]$, and hence

$$[1] \quad \log k_2 = \log (k_{obs}/k_1) + \log (k_{-1}[BH])$$

Stirling and co-workers define the "leaving group rank" or "nucleofugality" of Z by the function $\log (k_{obs}/k_1) + 11$, i.e., by using the value of $\log k_2$ obtained by assigning $k_{-1}[BH]$ equal to 10^{11}; k_{obs} is obtained by measuring the rate of the overall elimination, and k_1 from the rate of exchange of hydrogens α to G.

In our system it is evident that, if the mechanism in the previous section holds, the product ratio [**5**]/[**4**] is simply equal to k_E/k_H, and hence

$$[2] \quad \log k_E = \log ([\mathbf{5}]/[\mathbf{4}]) + \log k_H$$

If, as we argue above, k_H is insensitive to X, then the function $\log ([\mathbf{5}]/[\mathbf{4}])$ gives a scale of nucleofugalities analogous to Stirling's. The similarities of structure are so great that it is tempting to place our relative results on the same absolute basis by adding the same scaling term, i.e., +11.

The nucleofugalities thus obtained are listed in Table 2. Comparison with Stirling's results, though limited, suggests a measure of correspondence, and at the same time points up some of the difficulties associated with these procedures. The value 9.5 for the phenylsulfonyl group is between those (8.7 and 9.6) derived by Stirling (from reactions in which G = $PhSO_2$ and CN, respectively). That for the acetoxy function (11.2) suggests roughly comparable magnitudes for $k_{-1}[BH]$ and k_2 in the reaction of $AcOCH_2CH_2SO_2Ph$, i.e., a mechanism on the $(E1cB)_I$–$(E1cB)_R$ borderline, in rough accord with the conclusion (which, though reasonable, was not rigorously proved) that this is an $(E1cB)_I$ process (11). It may be noted that the present experiments make it possible to obtain a relative nucleofugality for the acetoxy group, a function for which this is not possible by the Stirling procedure because the appropriate substrates do not react by the requisite $(E1cB)_R$ mechanism.

The nucleofugality of the phenylthio function, relative to that of the phenylsulfonyl group, continues to be puzzling. Stirling (6) reported that PhS was less nucleofugal than $PhSO_2$ in the reactions of Z—CH_2CH_2—CN and about the same in those of Z—$CH_2CH_2SO_2Ph$; we find that PhS is rather *more* nucleofugal than $PhSO_2$ in our system. This anomaly, though by no means fully understood, may well be at least partly steric in origin.

In addition to the above, admittedly approximate, quantitative assignments of nucleofugality, we note that the failure of **1***b* to yield any neopentyl ethenesulfonate (**5**) shows hydroxide to be a weaker nucleofuge than $PhSO_2$. We also saw no sign of **5** from the neopentyloxysulfonyl substrate (**1***c*), but the nmr instrument was less sensitive than that used with the phenylsulfonyl-sulfonyl chloride (**1***d*) and our results do not prove any real difference in nucleofugality between $PhSO_2$ and $NpOSO_2$.

It is also of interest to look at the other end of the reactivity scale represented in this study. In a competition experiment between the disulfonyl chloride (**1***i*) and the chlorosulfonyl chloride (**1***j*) we found that **1***i* reacted almost six times faster than **1***j* (after inclusion of the statistical factor). The chlorosulfonyl

TABLE 2. Nucleofugalities of some of the 2-substituents

Group	log [5]/[4][a]	Nucleofugality[b]
Phenylsulfonyl	−1.5	9.5
Phenylthio	−0.8	10.2
Acetoxy	0.2	11.2
Pyridinio[c]	0.3	11.3
3,5-Dinitrobenzoyloxy[d]	0.8	11.8

[a]Obtained from the yields of **5** and **4** given in Table 1, except as otherwise noted.

[b]Nucleofugality = log ([**5**]/[**4**]) + 11 (see text).

[c]Calculated from the average of the proportions of **4***g* and **5** for the five reactions in Table 1 giving these products (only).

[d]From the ratio [**5**]/[**4***g*] = 61/9 (the respective percentages from **3***g* only), see text.

group, though not commonly regarded as a nucleofuge, has been observed to behave as such in a number of nucleophilic displacements (ref. 12 and refs. cited); the comparative unfamiliarity of reactions involving the loss of the $ClSO_2$ function is due, however, not to low nucleofugality itself but to the ease of other reactions of sulfonyl chlorides such as nucleophilic displacement at sulfur, elimination to form the sulfene, or reduction by nueclophilic attack at the chlorine atom. We must note explicitly that our observations do not permit a numerical assignment of the nucleofugalities of the Cl and $ClSO_2$ groups as defined by Stirling and co-workers. The lack of deuterium in the neopentyl ethenesulfonate formed from **1***j*, NpOD, and pyridine shows that the conversion of **1***j* to **2** is not an $(E1cB)_R$ process, but rather either an E2 or $(E1cB)_I$ reaction, and hence, as Stirling has emphasized (6), not capable of providing a nucleofugality value as defined.

Our results do, as the following argument shows, lead to the conclusion that both the chloro and chlorosulfonyl functions are the most nucleofugal of the 10 groups examined in this study. If we make the reasonable assumption that the sulfonyl chlorides all have the same possible reaction pathways, the finding that **1***h* and **1***j* reacted only by way of **2** can have only two possible causes: (*i*) the sulfene formation (**1** → **3**) is slow for **1***i* and **1***j*, or (*ii*) the C=C bond formation (**1** → **2**) is fast for **1***i* and **1***j*. It is very difficult to imagine, however, how the formation of $ClCH_2CH{=}SO_2$ or $ClSO_2CH_2CH{=}SO_2$ could be so much slower than the analogous reaction yielding $RCOOCH_2CH{=}SO_2$ or, especially, $NpOSO_2CH_2CH{=}SO_2$; this would require a substituent effect leading to quite remarkable differences among similar substituents;[2] it is much simpler to conclude that **1** → **2** is fast with **1***i* and **1***j*, i.e., the chloro and chlorosulfonyl groups are more nucleofugal than 3,5-dinitrobenzoyloxy and the others. The high reactivity of chlorosulfonyl and bromosulfonyl leaving groups relative to other sulfonyl-containing functions has been noted before and ascribed to a fragmentation process in which the SO_2—Hal bond is partly broken in the transition state (14).

Earlier reports of the anomalous reactions of **1**i *and* **1**j

As noted in the introduction there are a number of reports, some dating back to the previous century, describing unexpected reactions of 1,2-ethanedisulfonyl and 2-chloroethanesulfonyl chlorides (**1***i* and **1***j*) (15–22). With nucleophiles of the general formula ZH, such as water, alcohols, or amines, the major products of these reactions were never the orthodox derivatives, $ZSO_2CH_2CH_2SO_2Z$ or $ClCH_2CH_2SO_2Z$, but rather the ethenesulfonate, $CH_2{=}CHSO_2Z$, or the formal product of further addition of ZH, i.e., $ZCH_2CH_2SO_2Z$; thus (*a*) **1***i* with hot water gives mainly SO_2, HCl, and $CH_2{=}CHSO_3H$ (15, 17, 22), and (*b*) **1***j* with aniline yields $CH_2{=}CHSO_2NHPh$ (**8**) and (or) $PhNH_2{}^+CH_2CH_2SO_2NHPh\ Cl^-$ (**9**) (16–21). In the light of the present work it is highly likely that these products arise by initial formation of ethenesulfonyl chloride (**2**) followed by vinylogous reaction to form the sulfene **3** (X = Z^+). If Clutterbuck and Cohen (20) are correct in their assertion that **8** and **9** are both stable to the reaction conditions, then the different ratios of **8** and **9** found under the various reported conditions arise from different ratios of elimination to protonation in the trapping of **3** (X = Z^+). Further work is in order to check aspects of the earlier reports and to sort out the factors that control the variations in product ratios.

Experimental

Instrumentation and methods

Where not otherwise indicated, reagent grade chemicals and solvents were used as received. Melting points were determined on a Reichert Hot Stage and are uncorrected. Infrared spectra were obtained using Beckman 4250 and Bruker IFS 32 FTIR spectrometers and refer to chloroform solutions except as otherwise noted. The ^{1}Hmr spectra were obtained with Varian T60, XL100, XL200, and XL300 spectrometers, with all reported chemical shifts from the latter three instruments. The ^{13}Cmr spectra were run on Varian XL200 and XL300 spectrometers. Spectra recorded in $CDCl_3$ and CD_3NO_2 were calibrated with Me_4Si (TMS) and those recorded in D_2O either with sodium trimethylsilylpropionate (TSP) or sodium trimethylsilylpropanesulfonate (DSS). Mass spectra were run on a Varian MAT-311A spectrometer. The cold finger distillation apparatus used in microdistillation has been described elsewhere (23). Solvent evaporation on work-up was carried out using a Büchi rotary evaporator connected to a water aspirator.

Reactants

(*a*) Ethanesulfonyl chloride (**1***a*), commercial sample distilled, bp 54°C (4 Torr; 1 Torr = 133.3 Pa); ^{1}Hmr δ: 1.57 (t, 3H), 3.82 (q, 2H); neopentyl 2-(chlorosulfonyl)ethanesulfonate (**1***c* = **4***i*) (10), mp 108°C; ^{1}Hmr (CD_3NO_2) δ: 1.12 (s, 9H), 3.89 (t, 2H), 4.06 (s, 2H), 4.35 (t, 2H); 2-(phenylsulfonyl)ethanesulfonyl chloride (**1***d*) (24), mp 172–174°C (lit. (24) mp 173°C); ^{1}Hmr (CD_3NO_2) δ: 3.75–3.95 and 4.1–4.3 (sym A_2B_2 m, 4H), 7.6–8.05 (m, 5H); 2-(phenylthio)ethanesulfonyl chloride (**1***e*) (12); ^{1}Hmr (CD_3NO_2) δ: 3.45–3.62 and 4.15–3.98 (sym m(A_2B_2), 4H), and 7.3–7.57 (m, 5H); 2-acetoxyethanesulfonyl chloride (**1***f*) (25), bp 72–73°C (0.1 Torr); n_D^{25} 1.4639 (lit. (25) n_D 1.4633); ^{1}Hmr ($CDCl_3$) δ: 2.13 (s, 3H), 4.07 (t, 2H), 4.65 (t, 2H); *N*-(2-chlorosulfonylethyl)pyridinium chloride (**1***g*, Cl^-) (3); 2-(3,5-dinitrobenzoyloxy)ethanesulfonyl chloride (**1***h*), see below; 1,2-ethanedisulfonyl chloride (**1***i*) (26), mp 91°C (lit. (26) mp 91°C); ^{1}Hmr (CD_3NO_2) δ: 4.52 (s); 2-chloroethanesulfonyl chloride (**1***j*) (27), bp 58°C (3 Torr); ^{1}Hmr (CD_3NO_2) δ: 4.07–4.14 (app t, 2H) and 4.26–4.33 (app t, 2H). Neopentyl alcohol-*d* was prepared by multiple exchange of a solution of commercial NpOH in organic solution with D_2O; specifically, NpOH (4 g) in D_2O (10 mL) and ether (100 mL), followed by further shaking of the ether layer with three 15-ml D_2O portions, then evaporation of the ether, dissolution in CH_2Cl_2 followed by another D_2O wash (15 mL), followed by separation and evaporation of the CH_2Cl_2 layer, gave 3.1 g of product; deuterium content was estimated at 93% by comparison of the integral of the OH ^{1}Hmr peak (δ 1.72) with the ^{13}C satellite of the CH_2 signal (δ 2.95).

*(b) 2-(3,5-Dinitrobenzoyloxy)ethanesulfonyl chloride (***1**h*)*

3,5-Dinitrobenzoyl chloride (freshly prepared from the acid plus $SOCl_2$ and recrystallized from benzene, mp 73°C; 4.4 g, 19.1 mmol) was fused with sodium 2-hydroxyethanesulfonate (2.5 g, 16.9 mmol)

[2]Orthodox substituent effects have been observed in at least one sulfene-generating reaction: the rates of formation of $ArCH{=}SO_2$ from $ArCH_2SO_2O—C_6H_3—2,4(NO_2)_2$ in an $(E1cB)_I$ reaction process showed an excellent correlation with σ^- (with ρ^- 2.38, r = 0.996) (13).

in a Pyrex test tube (25 mL) over a microburner for 5 min. The almost clear hot liquid so obtained was cooled to room temperature and quenched with water (250 mL) by grinding the test tube in a mortar and pestle. The aqueous solution was filtered and washed several times with CH_2Cl_2 (5 × 100 mL) to remove any dinitrobenzoic acid. The aqueous layer was then concentrated to 50 mL on a rotary evaporator. The white crystals of sodium 2-(3,5-dinitrobenzoyloxy)ethanesulfonate that formed within a few hours were removed by filtration and air-dried, mp 307–310°C (5.6 g, 97%); ir (KBr) ν_{max}: 3100 (m), 2960, 2900 (w), 1740 (s) 1635 (m), 1540 (s), 1460 (m), 1350 (s), 1280 (s), 1200 (vs), 1050 (m), 1000 (m), 925 (m), 800 (m), 770 (m), 750 (m), 700 (s) cm^{-1}; ^{1}Hmr (D_2O) δ: 3.47 (t, 2H), 4.81 (t, 2H), 9.18–9.3 (m, 3H); ^{13}Cmr (D_2O) δ: 52.3, 64.6, 126.1, 135.8, 151.4, and 166.9. The salt (1.22 g, 3.57 mmol) was ground with excess PCl_5 (12 g) in a mortar, which was then covered loosely with a watch glass and put in a preheated oven at 210°C for 10 min. The contents of the mortar were then ground again while still hot, whereupon reaction occurred immediately to yield a pasty mass. Water (30 mL) was then added and the aqueous suspension extracted with CH_2Cl_2 (5 × 100 mL). The organic extracts were combined, dried with anhydrous $MgSO_4$, and evaporated to yield a colorless oil that solidified upon cooling (1.133 g, 94%). Recrystallization from chloroform afforded 2-(3,5-dinitrobenzoyloxy)ethanesulfonyl chloride (**1***h*) as white needles (0.909 g, 75%); mp 115–116°C; ir ($CHCl_3$) ν_{max}: 3110 (m), 2980 (w), 1750 (s), 1630 (m), 1550 (vs), 1380 (s), 1345 (vs), 1275 (vs), 1170 (s), 1155 (s), 1070 (m) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 4.19–4.25 and 5.01–5.06 (symmetrical multiplet, 4H) and 9.19–9.3 (m, 3H); ^{13}Cmr ($CDCl_3$) δ: 59.4, 63.1, 122.9, 129.5, 132.2, 148.6, and 161.7. *Exact Mass* calcd. for $C_9H_7N_2O_8SCl$: 337.9611; found: 337.9613.

*(c) 2-Chloroethanesulfonyl bromide (**6**)*

2-Chloroethanesulfonyl chloride (**1***j*) (719 mg, 4.41 mmol) was stirred with four equivalents of aqueous (8 mL) sodium sulfite (2.22 g, 17.64 mmol) at 0°C for 18 h. Bromine was then added dropwise until the brownish color of bromine persisted. The reaction mixture was quickly transferred to a separatory funnel and extracted with methylene chloride (5 × 50 mL). The extracts were washed with 5% sodium bisulfite solution until the bromine color had disappeared. The CH_2Cl_2 layer was dried with $MgSO_4$ and the solvent evaporated to yield crude **6** (624 mg, 68%); cold finger vacuum distillation (bath temperature 110°C, 1.4 Torr) gave **6** as a pale yellow liquid (574 mg, 63% yield); ir (film) ν_{max}: 2992 (w), 2930 (w), 1364 (vs) 1310 (m), 1157 (vs), 660 (m) cm^{-1}; ^{1}Hmr (CD_3NO_2) δ: 4.40–4.33 and 4.11–4.04 (m, 4H, A_2B_2) ppm; ^{13}Cmr (CD_3NO_2) δ: 70.7 and 37.6 ppm; *Anal.* calcd. for $C_2H_4O_2BrCl$: C 11.58, H 1.94, S 15.45, Br 38.51, Cl 17.09; found: C11.49, H 1.89, S 15.35, Br 38.70, Cl 17.21.

Neopentyl esters

(a) Previously reported esters

Neopentyl 2-hydroxyethanesulfonate (**4***b*) (4), also, see preparation of **4***h*. *N*-[2-(Neopentyloxysulfonyl)ethyl]pyridinium chloride (**4***g*) 1, 23).

*(b) Neopentyl ethanesulfonate (**4**a)*

Pyridine-d_5 (0.713 mL, 8.32 mmol) was added to a solution of ethanesulfonyl chloride (**1***a*) (214 mg, 1.66 mmol) in nitromethane-d_3 and the reaction mixture allowed to stand for 22 h; work-up followed by careful removal of the last traces of CH_2Cl_2 under reduced presure gave **4***a* as a pale yellow liquid (280 mg, 93%); ir ($CHCl_3$) ν_{max}: 2970 (s), 1550 (m), 1465 (m), 1350 (vs), 1165 (s), 960 (vs), 840 (vs) cm^{-1}; ^{1}Hmr (CD_3NO_2) δ: 1.00 (s, 9H), 1.37 (t, 3H), 3.19 (q, 2H), 3.87 (s, 2H); ^{13}Cmr (CD_3NO_2) δ: 8.7, 26.5, 32.7, 45.1, 80.4. *Anal.* calcd. for $C_7H_{16}O_3S$: C 46.64, H 8.95, S 17.79; found: C 46.84, H 9.31, S 17.65.

*(c) Dineopentyl 1,2-ethanedisulfonate (**4**c)*

Pyridine (0.75 mL, 9.3 mmol) was added to a solution of neopentyl 2-(chlorosulfonyl)ethanesulfonate (**1***c* = **4***i*) (10) (0.60 g, 2.15 mmol) and neopentyl alcohol (0.50 g, 5.5 mmol) in methylene chloride (25 mL) and the mixture allowed to stand for 18 h. The diester (**4***c*) was obtained on work-up as a yellowish solid (0.35 g, 50%), which after recrystallization from ethyl acetate – petroleum ether (bp 60–80°C) melted at 150–152°C; ir (CH_2Cl_2) ν_{max}: 3055 (w), 2955 (m), 2860 (w), 1465 (w), 1349 (s), 1215 (w), 1165 (s), 1149 (s), 938 (vs), 915 (s) cm^{-1}; ^{1}Hmr (CD_3NO_2) δ: 1.01 (s, 9H), 3.57 (s, 2H), 3.94 (s, 2H). *Anal.* calcd. for $C_{12}H_{26}O_6S_2$: C43.62, H 7.93, S 19.41; found: C 43.73, H 8.10, S 19.62.

*(d) Neopentyl 2-(phenylsulfonyl)ethanesulfonate (**4**d)*

A mixture of 2-(phenylsulfonyl)ethanesulfonyl chloride (**1***d*) (202 mg, 0.75 mmol), neopentyl alcohol (132 mg, 1.50 mmol), and pyridine (300 mg, 3.79 mmol) in nitromethane (20 mL) was allowed to stand at room temperature for 19 h. Recrystallization from hexanes of the crude product (158 mg, 65%) obtained after work-up gave **4***d* as white needles, mp 110.5–111°C; ir ($CHCl_3$) ν_{max}: 2960 (m), 1360 (s), 1323 (s), 1164 (s), 1145 (s), 950 (s) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 0.98 (s, 9H), 3.63–3.44 (sym m, 4H), 3.95 (s, 2H), 7.61–8.07 (m, 5H); ^{13}Cmr ($CDCl_3$) δ: 25.9, 31.8, 43.2, 50.2, 80.0, 127.9, 130.0, 134.5, 137.6. *Exact Mass* calcd. for $C_{13}H_{20}O_5S_2$: 320.0752; found: 320.0758.

*(e) Neopentyl 2-(phenylthio)ethanesulfonate (**4**e)*

Recrystallization (hexanes) of the crude product (69% yield) obtained from **1***e* exactly as **4***d* was prepared from **1***d* gave needles, mp 71.5–72.5°C; ir ($CHCl_3$) ν_{max}: 2960 (m), 1480 (m), 1440 (w), 1350 (s), 1160 (s), 960 (s), 840 (m) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 1.30 (s, 9H), 3.07 (s, 4H), 3.59 (s, 2H), 7.1–7.6 (m, 5H); ^{13}Cmr ($CDCl_3$) δ: 26.0, 27.5, 31.7, 49.7, 78.8, 127.3, 129.2, 130.5, 133.1. *Exact Mass* calcd. for $C_{13}H_{20}O_3S_2$: 288.0854; found: 288.0853.

*(f) Neopentyl 2-acetoxyethanesulfonate (**4**f)*

The mixture of neopentyl ethenesulfonate (**5**) and neopentyl 2-acetoxyethanesulfonate (**4***f*) (obtained from reaction of 2-acetoxyethanesulfonyl chloride (**1***f*) with neopentyl alcohol and triethylamine) was placed under reduced pressure (0.2 Torr, oil bath temperature 90°C) to evaporate the **5** (bp 62°C, 0.02 Torr). The colorless oily residue gave the following data: ir (neat) ν_{max}: 2970 (m), 1750 (s), 1350 (s), 1240 (s), 1160 (s), 1030 (m), 955 (s), 840 (m) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 1.00 (s, 9H), 2.09 (s, 3H), 3.46 (t, 2H), 3.91 (s, 2H), 4.49 (t, 2H); (CD_3NO_2) δ: 1.01 (s, 9H), 2.08 (s, 3H), 3.63 (t, 2H), 3.95 (s, 2H), 4.57 (t, 2H). *Anal.* calcd. for $C_9H_{18}O_5S$: C 45.36, H 7.61, S 13.46; found: C 45.41, H 7.52, S 13.31.

*(g) Neopentyl 2-(3,5-dinitrobenzoyloxy)ethanesulfonate (**4**h)*

A mixture of 2-hydroxyethanesulfonyl chloride (**4**) (1.99 g, 13.8 mmol), neopentyl alcohol (12.15 g, 137.8 mmol), and trimethylamine (3.25 g, 55.1 mmol) was allowed to stand at room temperature for 2 h. Conventional work-up followed by removal of the excess alcohol over an extended period on the rotary evaporator gave a crude product (2.5 g, 93%) with spectra appropriate to neopentyl 2-hydroxyethanesulfonate, as follows: ir ($CHCl_3$) ν_{max}: 1352 (vs), 1171 (vs), 967 (vs) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 1.00 (s, 9H), 3.38 (t, 2H), 3.91 (s, 2H), 4.06 (t, 2H); ^{13}Cmr ($CDCl_3$) δ: 26.0, 52.3, 56.5, 73.2, 79.1. Reaction of 1 g (5.1 mmol) of this material with 3,5-dinitrobenzoyl chloride, as described above for the preparation of **1***h* followed by work-up gave crude **4***h* (1.7 g, 85%), which after recrystallization from benzene–pentane gave **4***h* as white crystals melting at 90–92°C; ir ($CHCl_3$) ν_{max}: 3095 (m), 1735 (vs), 1625 (m), 1540 (s), 1455 (m), 1350 (vs), 1268 (vs), 1150 (vs), 1067 (m), 950 (vs), 840 (m) cm^{-1}; ^{1}Hmr (CD_3NO_2) δ: 0.99, (s, 9H), 3.77 (s, 2H), 3.99 (s, 2H), 4.87 (t, 2H), 9.09–9.19 (m, 3H); ^{13}Cmr (CD_3NO_2) δ: 2.64, 32.7, 49.6, 61.1, 81.1, 124.0, 130.6, 134.4, 150.0, 163.8. *Exact Mass* calcd. for $C_{14}H_{18}O_9N_2S$: 390.0733; found: 390.0734.

*(h) Neopentyl 2-chloroethanesulfonate (**4**j)*

A solution of 2-chloroethanesulfonyl chloride (**1***j*) (3.5 g, 21.6 mmol) and neopentyl alcohol (1.9 g, 21.6 mmol) in methylene chloride (5 mL) was allowed to stand at 50°C for 10 days. The solvent was evaporated and the oily brown residue distilled under reduced pressure in a short-path cold-finger distillation apparatus (bath temperature 120°C, 0.5 Torr) giving a colorless oil (0.6 g, 15%); ir (neat) ν: 2960 (m), 1355 (s), 1205 (s), 1170 (vs), 995 (s), 935 (s), 845 (m) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 1.00 (s, 9H), 3.70 (m, 4H), 3.93 (s, 2H); (CD_3NO_2) δ: 1.02 (s, 9H), 3.62 (m, 2H), 3.92 (m, 2H), 3.96 (s, 2H). *Anal.* calcd. for $C_7H_{15}ClO_3S$: C 39.16, H 7.04, Cl 16.51, S 14.93; found: C 39.31, H 7.09, Cl 16.42, S 15.03.

Reaction of the 2-substituted ethanesulfonyl chlorides with neopentyl alcohol and pyridine-d_5

Pyridine-d_5 (50–70 μL, 0.6–0.8 mmol) was injected into a solution of the sulfonyl chloride (**1**) (0.10–0.16 mmol) and neopentyl alcohol (0.20–0.26 mmol) in CD_3NO_2 (0.25–0.40 mL) at 37°C and contained in an nmr tube. The ^{1}Hmr spectrum was run (within 5 min), after thorough mixing of the contents of the tube. With **1***c*–**1***j* the reaction was then complete, but with **1***a* and **1***b* the product composition given in Table 1 (determined from integration of Me_3CCH_2O— singlets) was obtained after 18 and 8 h, respectively. The spectra were in all cases found consistent (by comparison with authentic spectra) with the mixture of esters described in Table 1. With **1***e* (which is presumably slightly wet and not readily purified), the spectrum showed peaks corresponding to 18% of the hydrolysis product pyridinium 2-(phenylthio)ethanesulfonate (as shown by comparison with the spectrum of an authentic specimen); with the other reactions small amounts (<5%) of the corresponding hydrolysis products were sometimes in evidence.

The following series of experiments with 2-phenylthioethanesulfonyl chloride (**1***e*) was carried out as above (in CD_3NO_2) using the following quantities given in the order **1***e*, NpOH, pyridine-d_5, total volume, and forming the relative yields of products **4***e*:**5**: (*a*) 72.5 mg (0.307 mmol, 0.033 M), 54 mg (0.613 mmol, 0.66 M), 131 μL (1.53 mmol, 1.65 M), 0.93 mL, gave 84:16; (*b*) 74.7 mg (0.316 mmol, 0.35 M), 55.7 mg (0.632 mmol, 0.70 M), 135 μL (1.59 mmol, 1.77 M), 0.90 mL, gave 82.5:17.5; (*c*) 75.8 mg (0.321 mmol, 0.305 M), 141 mg (1.60 mmol, 1.53 M), 137.5 μL (1.60 mmol, 1.53 M), 1.05 mL, gave 84.6:15.4; (*d*) 68.8 mg (0.29 mmol, 0.27 M), 256 mg (2.80 (mmol, 2.70 M), 124 μL (0.145 mmol, 1.35 M), 1.08 mL, gave 82:18; (*e*) 64.4 mg (0.270 mmol, 0.262 M), 120 mg (1.36 mmol, 1.31 M), 374 μL (4.36 mmol, 4.20 M), 1.04 mL, gave 76:24; (*f*) 58.0 mg (0.245 mmol, 0.245 M), 108 mg (1.23 mmol, 1.23 M), plus a stock solution of pyridinium-d_5 chloride and pyridine-d_5 in CD_3NO_2 to yield a reaction mixture initially 2.05 M and 3.95 M, respectively, total volume 1.0 mL, gave 78:22.

Deuterium labelling experiments

2-Phenylthioethanesulfonyl chloride (**1***e*) (62.3 mg, 0.26 mmol) was mixed with NpOH and NpOD in CD_3NO_2; ^{1}Hmr integration showed a 49:51 ratio of NpOH:NpOD. Pyridine-d_5 was added quickly; initial concentrations of **1***e*, NpOH–NpOD mixture, pyridine-d_5: 0.173, 1.76, 0.88 M; total volume 1.50 mL. The ^{1}Hmr spectrum after 5 min showed (*a*) no sign of unreacted **1***e*, (*b*) ratio of **5** to total (deuterated and undeuterated) neopentyl 2-phenylthioethanesulfonate, 13:86, (*c*) no sign of deuteration on the neopentyl ethenesulfonate; the spectrum after a further 15 min was unchanged. The reaction mixture was worked up by pouring into water and extracting with CH_2Cl_2, followed by drying and evaporation of the solvent. Integration of the two halves of the A_2B_2 pattern in the ^{1}Hmr spectrum of the product ($CDCl_3$, with Eu(fod)$_3$, 41 mg, 0.092 mmol) gave the ratio of $PhSCH_2CH_2SO_2ONp$ to $PhSCH_2CHDSO_2ONp$ as 53:47. A similar experiment with NpOD:NpOH 93:7, the following initial concentrations of the above reagents (same sequence) 0.142, 1.42, 0.707 M, and total volume 1.50 mL, gave a 14:86 ratio of **5** to the phenylthio-ester, with the latter 88% $PhSCH_2CHDSO_2ONp$.

Pyridine-d_5 (47 μL, 0.55 mmol) was added to a solution of **1***h* (37 mg, 0.11 mmol) and NpOD (92% OD, 7% OH) (97.5 mg, 1.09 mmol) in CD_3NO_2 (total volume of solution, 0.86 mL); the C-2 protons of **4***g* and **4***h* appeared as doublets at δ 5.31 and 4.89 in the ^{1}Hmr spectrum, showing them to be largely monodeuterated at C-1, but quantitative estimation of deuteration was not feasible.

The ^{1}Hmr spectra of the following reaction mixtures showed signals appropriate to the indicated product composition: (*a*) from **1***d* (80.4 mg, 0.42 mmol), NpOD (95% OD) (374 mg, 4.20 mmol), pyridine-d_5 (180 μL, 2.10 mmol) in CD_3NO_2 (total volume 1.45 mL), $PhSO_2CH_2CHDSO_2ONp$ 90%, $PhSO_2CH_2CH_2SO_2ONp$ 8%, **5** ~2%; (*b*) the product (total volume 1.11 mL) from **1***j* (36.7 mg, 0.225 mmol), NpOD (95% OD) (201 mg, 2.25 mmol), pyridine-d_5 (97 μL, 1.13 mmol), a roughly 2:1 mixture of **5** (with no sign, i.e. estimated <2%, of $CH_2{=}CDSO_2ONp$) and the betylate, with the C-2 proton signal appearing as a doublet, indicating it to be mostly monodeuterated ($C_5H_5N^+CH_2CHDSO_2ONp$); (*c*) pyridine-d_5 (108 μL, 1.26 mmol) with **1***a* (32.3 mg, 0.25 mmol), NpOD (88% OD) (224 mg, 2.5 mmol) in CD_3NO_2 (total volume 0.69 mL), after 22 h at room temperature, CH_3CHDSO_2ONp 56% and $CH_3CH_2SO_2ONp$ 44%.

Reaction of ethane-1,2-disulfonyl chloride (1i) with 2,6-lutidine

2,6-Lutidine (25 μL, 0.21 mmol) was injected into a solution of the disulfonyl chloride (**1***i*) (36 mg, 0.16 mmol) in $CDCl_3$ (~0.5 mL) in an nmr tube at 37°C. The ^{1}Hmr spectrum was run immediately after thorough mixing and showed the characteristic signals of ethenesulfonyl chloride (**2**) (and the lutidine – lutidinium ion mixture) with no sign of unreacted **1***i*; addition of authentic **2** enhanced the peaks assigned to **2**.

Relative reactivities of 1,2-ethanedisulfonyl and 2-chlorosulfonyl chlorides (1i and 1j)

Pyridine-d_5 (44 μL, 0.52 mmol) was added by microsyringe to a mixture of equivalent amounts (0.52 mmol) of **1***i* (117 mg) and **1***j* (84 mg) with neopentyl alcohol (91 mg, 1.03 mmol) in CD_3NO_2 (0.5 mL) in an nmr tube. The mixture was shaken vigorously and the ^{1}Hmr spectrum run immediately. Integration of the singlet at δ 4.65 due to **1***i* and the pair of triplets at 4.40 and 4.13 due to **1***j*, relative to the sum of the neopentyl methylene singlets at 3.98, 3.80, 3.23 arising from **4***g*, **5**, and unreacted neopentyl alcohol, gave the proportions of unreacted **1***i* and **1***j* as 55 and 95%, respectively. Addition of another 44-μL portion of pyridine led to 8 and 80% of unreacted **1***i* and **1***j*. Values for the rate constant ratio were obtained from the expression

$$k_{1i}/k_{1j} = (\log [1i]/[1i]_0)/(\log [1j]/[1j]_0)$$

and found to be respectively 11.6 and 11.2, from the two sets of results, average, 11.4; the statistically corrected ratio for the rates of elimination to form **2** on a per hydrogen basis from **1***i* vs. **1***j*, 5.7.

Control experiments

(*a*) A solution of **4***f* (30 mg, 0.13 mmol), neopentyl alcohol (18 mg, 0.2 mmol), and pyridine-d_5 (50 μL, 0.6 mmol) in CD_3NO_2 (0.4 mL) showed no observable change in ^{1}Hmr spectrum over a 14-h interval. Pyridinium-d_5 chloride (20 mg, 0.17 mmol) was added; no change in the spectrum was found after a further 4 h. Similar solutions of **4***d*, **4***e*, **4***h*, and **4***j* with pyridine-d_5 and neopentyl alcohol showed unchanged ^{1}Hmr spectra after, respectively, 10, 10, 10, and 90 min at room temperature; after 5 days the solution of **4***j* showed a trace (<5%) of **5** but no sign of **4***g*. (*b*) Pyridine-d_5 (0.1 mL, 0.12 mmol) was added to a solution of **2** (38 mg, 0.3 mmol), neopentyl alcohol (50 mg, 0.57 mmol), and dry acetic acid (6 μL, 0.1 mmol) at 37°C. The ^{1}Hmr spectrum showed **5** (72%) and **4***g* (28%), with no sign of any **4***f*. (*c*) A solution of **1***h* (0.14 mmol) and NpOH (0.14 mmol) in CD_3NO_2 showed no change in ^{1}Hmr spectrum on standing at 50°C for 6 days.

Received September 17, 1987

HENNING AMT, WOLFGANG KLIEGEL, STEVEN J. RETTIG, and JAMES TROTTER. Can. J. Chem. **66**, 1117 (1988).

Details of the preparation and physical properties of the title compound are given. Crystals of 1,9-dimethyl-3,5,7- triphenyl-2,4,6,8-tetraoxa-1,9-diazonia-5-bora-3,7-diboratatricyclo[5.4.0.0^{3,9}]undecane are orthorhombic, a = 9.4026(3), b = 9.4663(2), c = 24.7462(9) Å, Z = 4, space group $P2_12_12_1$. The structure was solved by direct methods and was refined by full-matrix least-squares procedures to R = 0.036 and R_w = 0.038 for 1536 reflections with $I \geq 3\sigma(I)$. The three six-membered and two seven-membered rings comprising the tricyclo[5.4.0.0^{5,9}]undecane ring system all have boat or boat-like conformations. Important bond lengths (corrected for libration) are: B(sp^3)—N = 1.649(6) and 1.668(6), B(sp^3)—O(N) = 1.492(5) and 1.497(6), B(sp^3)—O[B(sp^2)] = 1.444(6) and 1.438(5), B(sp^3)—C = 1.600(6) and 1.594(7), B(sp^2)—O = 1.357(6) and 1.370(6), B(sp^2)—C = 1.574(6) Å.

HENNING AMT, WOLFGANG KLIEGEL, STEVEN J. RETTIG et JAMES TROTTER. Can. J. Chem. **66**, 1117 (1988).

On rapporte les détails de la préparation et de la détermination de la structure du composé mentionnné dans le titre. Les cristaux du diméthyl-1,9 triphényl-3,5,7 tétraoxa-2,4,6,8 diazonia-1,9 bora-5 diborata-3,7 tricyclo[5,4,0,0^{3,9}]undécane sont orthorhombiques avec a = 9,4026(3), b = 9,4663(2) et c = 24,7462(9) Å, Z = 4 et groupe d'espace $P2_12_12_1$. On a résolu la structure par des méthodes directes et on l'a affinée par la méthode des moindres carrés (matrice entière) jusqu'à des valeurs de R = 0,036 et R_w = 0,038 pour 1536 réflexions avec $I \geq 3\sigma(I)$. Les trois cycles à six chaînons et les deux cycles à sept chaînons formant le système tricyclo[5.4.0.0^{3,9}]undécane sont tous dans des conformations bateaux ou qui ressemblent à des bateaux. Les longueurs de liaison importantes (corrigées pour la libration) sont: B(sp^3)—N = 1,649(6) et 1,668(6), B(sp^3)—O(N) = 1,492(5) et 1,497(6), B(sp^3)—O[B(sp^2)] = 1,444(6) et 1,438(5), B(sp^3)—C = 1,600(6) et 1,594(7), B(sp^2)—O = 1,357(6) et 1,370(6) et B(sp^2)—C = 1,574(6) Å.

[Traduit par la revue]

Introduction

The condensation of *N,N'*-methylenebis(*N*-methylhydroxylamine) and phenylboronic acid does not lead to the strained tricyclooctane ring system **1** ("dinoradamantane" skeleton) but gives the bicyclooctane **2** (1) as was confirmed by X-ray crystal structure analysis (2). We have now attempted to synthesize a less strained ring-enlarged homolog of **1** with the tricyclononane structure **4** ("nortwistane" skeleton) by reaction of *N,N'*-dihydroxy-*N,N'*-dimethyl-1,2-ethanediamine **3** with phenylboronic acid. The crystalline reaction product turned out to be neither a tricyclic (**4**) nor a bicyclic (**5**) 1:2-condensate of **3** and phenylboronic acid. Quantitative elemental analyses and nmr spectra revealed instead a 1:3-condensation product **6**. Reaction of **3**[2] and phenylboronic acid in a molar ratio of 1:3 gave **6**, expectedly, in better yield. Unfortunately the chemical and spectroscopic data of **6** were not sufficient to decide between possible alternative structures which include the tricycloundecane ring system A (known as the "4-homotwistane" skeleton (4)) and the bicycloundecane B which both incorporate a seven-membered ring. The tricycloundecane C and the bicycloundecane D, containing eight-membered rings, and the monocyclic undecane ring system E having fluxional N—B coordination are also among the possible structures. An X-ray crystallographic analysis has been carried out in order to provide a definitive structural assignment.

Experimental

N,N'-dihydroxy-N,N'-dimethyl-1,2-ethanediamine, 3

A solution of KBH_4 (3.2 g, 60 mmol) in 50 mL of water is added dropwise to a solution of *N,N'*-1,2-ethanediylidenebis(methanamine)-*N,N'*-dioxide (2.3 g, 20 mmol) (3) in 100 mL of water, warmed to 40°C. The reaction mixture is stirred 24 h at room temperature. Tartaric acid (5 g, 25 mL 20% aqueous solution) is added to the reaction mixture until it is weakly acidic. The reaction mixture is then neutralized (pH 7–8) with $NaHCO_3$. The solution is evaporated to dryness and the remaining solid extracted with 4 × 30 mL hot absolute ethanol. Cooling down of the collected ethanolic solutions yields 1.3 g (55%) of colorless crystals. Melting point 157°C (from ethanol). Infrared (KBr): 3190 cm^{-1} (O—H). ^{1}H nmr (d_6-DMSO/TMS) δ(ppm) = 2.51 (s, 2 CH_3), 2.70 (s, CH_2CH_2), 7.76 (s, br, 2 OH). *Anal.* calcd. for $C_4H_{12}N_2O_2$: C 39.99, H 10.07, N 23.31; found: C 39.83, H 10.04, N 22.99.

1,9-Dimethyl-3,5,7-triphenyl-2,4,6,8-tetraoxa-1,9-diazonia-5-bora-3,7-diboratatricyclo[5.4.0.0^{3,9}]undecane, 6A

3 (0.24 g, 2 mmol) and phenylboronic acid ((*a*) 0.48 g, 4 mmol, or (*b*) 0.72 g, 6 mmol) are heated in 50 mL benzene under reflux conditions for 1 h using a Dean–Stark trap for continuous water removal. The solution is then evaporated, and the dry residue dissolved in benzene. After addition of petroleum ether and cooling a colorless substance crystallizes. Yields: (*a*) 0.27 g (42%), (*b*) 0.65 g (76%). Melting point (decomp.) 201–203°C (from acetone/ether/petroleum ether). ^{1}H nmr (d_6-DMSO/TMS): δ(ppm) = 2.71 (s, 2 CH_3), 3.58 and

[1]Part XXIX: ref. 47.

[2]Compound **3** has been synthesized by reduction of the bis(*N*-methyl)nitrone of glyoxal (3) with potassium tetrahydroborate.

3.78 (m, m, N—CH_2CH_2—N), 7.3–7.4 (m, 9 phenyl-H), 7.8–8.0 (m, 6 phenyl-H). *Anal.* calcd. for $C_{22}H_{25}B_3N_2O_4$: C 63.84, H 6.09, B 7.84, N 6.77; found: C 63.35, H 6.09, B 7.92, N 6.81. Crystals suitable for X-ray analysis were obtained by recrystallization from acetone/ether/petroleum ether (2:1:drops).

X-ray crystallographic analysis

A crystal bounded by the six faces (followed by the distances in mm between parallel faces): {0 0 1}, 0.22, {0 1 0}, 0.32, ±(2 0 1), 0.40, was mounted in a general orientation. Unit-cell parameters were refined by least-squares on 2 sin θ/λ values for 25 reflections (2θ = 50–83°) measured on a diffractometer with Cu-$K\alpha$ radiation ($\lambda(K\alpha_1)$ = 1.540562, $\lambda(K\alpha_2)$ = 1.544390 Å). Crystal data at 22°C are:

$C_{22}H_{25}B_3N_2O_4$ f.w. = 413.9

Orthorhombic, a = 9.4026(3), b = 9.4663(2), c = 24.7462(9) Å, V = 2202.6(1) Å^3, Z = 4, ρ_c = 1.248 Mg m^{-3}, $F(000)$ = 872, μ(Cu-$K\alpha$) = 6.33 cm^{-1}. Absent reflections: $h00$, h odd, $0k0$, k odd, and $00l$, l odd, uniquely indicate the space group $P2_12_12_1$ (D_2^4, No. 19).

Intensities were measured with nickel-filtered Cu-$K\alpha$ radiation on an Enraf-Nonius CAD4-F diffractometer. An ω–2θ scan at 1.7–10.0° min^{-1} over a range of (1.10 + 0.14 tan θ) degrees in ω (extended by 25% on both sides for background measurement) was employed. Data were measured to 2θ = 150°. The intensities of three check reflections, measured every 3600 s throughout the data collection, remained constant to within 4%. After data reduction,[3] an absorption correction was applied using the Gaussian integration method (5, 6). Transmission factors ranged from 0.809 to 0.878 for 120 integration points. Of the 2588 independent reflections measured, 1536 (59.4%) had intensities

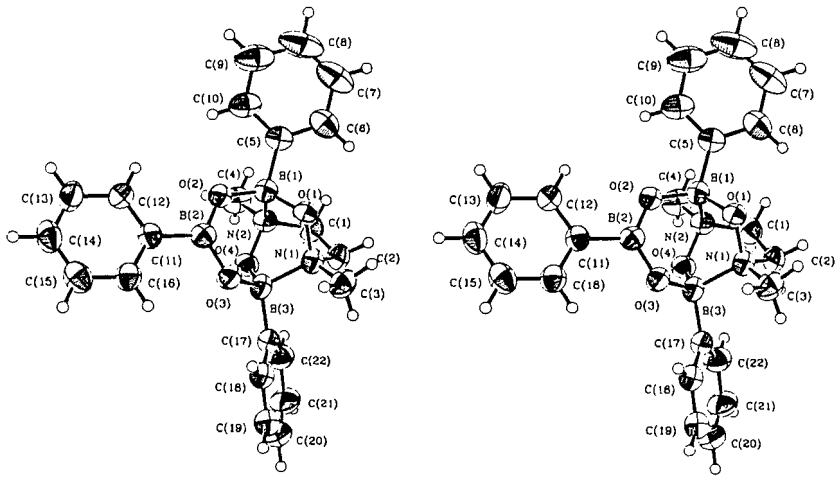

FIG. 1. Stereoscopic view 1,9-dimethyl-3,5,7-triphenyl-2,4,6,8-tetraoxa-1,9-diazonia-5-bora-3,7-diboratatricyclo[5.4.0.0^{3,9}]undecane; 50% probability thermal ellipsoids are shown for the non-hydrogen atoms. Hydrogen atoms have been assigned arbitrary thermal parameters for the sake of clarity.

greater than or equal to $3\sigma(I)$ above background where $\sigma^2(I) = S + 2B + (0.04(S - B))^2$ with S = scan count and B = normalized background count.

The structure was solved by direct methods, the coordinates of all non-hydrogen atoms being determined from an E-map. The non-hydrogen atoms were refined with anisotropic thermal parameters and the hydrogen atoms were fixed in idealized positions (staggered methyls, C(sp^2)—H = 0.97, C(sp^3)—H = 0.98 Å, $U_H \propto U_{\text{bonded atom}}$). Scattering factors for all atoms and anomalous scattering corrections for O, N, and C were taken from ref. 7. The weighting scheme $w = 1/\sigma^2(F)$, where $\sigma^2(F)$ is derived from the previously defined $\sigma^2(I)$, gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of both $|F_o|$ and sin θ/λ and was employed in the final stages of full-matrix refinement of 281 variables. Reflections with $I < 3\sigma(I)$ were not included in the refinement. An isotropic Type I extinction correction (Thornley–Nelmes definition of mosaic anisotropy with a Lorentzian distribution) was applied (8–10). The final value of g was $0.80(9) \times 10^4$. Convergence was reached at $R = 0.036$ and $R_w = 0.038$ for 1536 reflections with $I \geq 3\sigma(I)$. For all 2588 reflections $R = 0.077$. A parallel refinement of the mirror-image structure resulted in R factor ratios of 1.009 on both R and R_w. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$, $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$ and $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$.

On the final cycle of refinement the mean and maximum parameter shifts corresponded to 0.01 and 0.08σ, respectively. The mean error in an observation of unit weight was 0.691. The largest peak on the final difference map was 0.16 e Å^{-3}. The final positional and thermal parameters appear in Tables 1 and 6,[4] respectively. Measured and calculated structure factors have been placed in the Depository of Unpublished Data.[4] The final F_o and F_c values for the intense reflections indicate the possibility of anisotropic extinction. The application of an anisotropic extinction correction in this case, however, was judged inappropriate since only a small number of reflections was involved, and in only one instance was $||F_o| - |F_c||$ greater than $3\sigma(F)$ (3.7σ for 0 0 2).

The ellipsoids of thermal motion for the non-hydrogen atoms are shown in Fig. 1. The thermal motion has been analysed in terms of the rigid-body modes of translation, libration, and screw motion (11). The rms standard error in the temperature factors σU_{ij} (derived from the least-squares analysis) is 0.0031 Å^2. The structural subunits PhB and the tricycloundecane ring system plus the N-methyl carbon atoms were analysed separately (rms ΔU_{ij} = 0.0024–0.0035 Å^2). The appropriate bond distances have been corrected for libration (11, 12). Corrected bond lengths appear in Table 2 along with the uncorrected values. Corrected values for the bond angles and torsion angles for the tricyclo[5.4.0.0^{3,9}]undecane system are within one standard deviation of the uncorrected values given in Tables 3 and 4. Calculated hydrogen coordinates and thermal parameters (Table 5) and a complete listing of torsion angles (Table 7) are included as supplementary material.

Results and discussion

The crystal structure of **6** consists of discrete molecules separated by normal van der Waals distances. The shortest intermolecular contacts between non-hydrogen atoms are C(2)···C(5)($1/2 + x$, $1/2 - y$, $2 - z$) = 3.346(6), C(3)···C(9)(x, $y - 1$, z) = 3,337(7), and O(1)···C(1)($x - 1/2$, $1/2 - y$, $2 - z$) = 3.348(5) Å. The structure analysis confirms the existence of the tricyclo[5.4.0.0^{3,9}]undecane ring system **6A**, a heteroanalog of the "4-homotwistane" system (4). The tricycloundecane system contains three six-membered rings and two seven-membered rings which all have boat or boat-like conformations (see Table 4). The conformational flexibility of the eleven-membered ring allows the formation of two transannular N→B coordinative bonds, resulting in formation of the symmetric homotwistane analog. In the related cyclooctane system only one transannular N→B bond is formed to give the fused-ring compound **2** (1, 2), the strained tricyclo[3.3.0.0^{3,7}]octane system **1** (D_{2d}-dinoradamantane (13)) not existing under normal conditions in the solid state (2). The tricyclic ring system in **6A** contains two sp^3-hybridized boron atoms with a tetrahedral arrangement of ligands and one sp^2-hybridized boron atom. Incorporation of the latter into the ring system is responsible for distortions from an "ideal" homotwistane skeleton, carbocyclic derivatives of which have been synthesized (14).

Bond lengths[5] involving the tetrahedrally coordinated boron atoms in **6A** may be compared with those observed for six other compounds having a PhBN(sp^3)O$_2$ ligand set (2, 15–18). While the individual bond lengths involving the boron atoms vary considerably in these "PhBN(sp^3)O$_2$" compounds (B—C = 1.582–1.641, O—B = 1.438–1.497, and N—B = 1.649–

[4]The structure factor table, Table 6 (anisotropic thermal parameters) and other material mentioned in the text may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

[5]Libration corrected bond lengths (esd's assumed equal to those of the uncorrected values) are employed in the discussion and are compared with similarly treated (11) distances unless otherwise stated.

1.759 Å), the sums of the bond lengths at boron lie within the relatively small range of 6.191–6.297 Å with an average value of 6.228 Å. These bond length sums are sensitive to ring-size and other steric effects and are a good indicator of the overall strain at the boron atom and its substituents. These compounds include monocyclic six-membered boron-containing ring systems (15), fused-ring systems with the N—B bond at the ring junction (2, 16–18), and in the present case a bridged-ring system in which both the B and N atoms occupy bridgehead positions. The average bond length sum in **6A**, 6.191 Å, is the smallest yet observed for a "PhBN(sp^3)O_2" compound and is indicative of a relatively low-strain system. The staggered con-

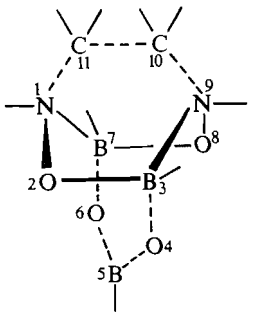
formations about the N—B bonds in **6A** are partially responsible for this. In related systems with fully substituted B and N atoms, steric factors result in less favorable conformations about rather long N—B bonds (2, 15, 16).

The average N—B distance of 1.659 Å in **6A** is the shortest observed for a "PhBN(sp^3)O_2" compound; similar to the values of 1.634 (uncorr.)–1.657 Å observed for relatively strain-free *N,O*-chelates of the type C(sp^2)$_2$BN(sp^3)O (19–24). The bond distances between the tetrahedral boron atoms and the nitrogen-bound oxygen atoms (mean B—O(N) = 1.495(4) Å) are the longest O—B distances yet observed for a "PhBN(sp^3)O_2" compound but are strikingly short compared with corresponding distances of 1.517 (uncorr.)–1.604 Å reported for other boron chelates with *N*-oxide ligands (25–31). The mean B(sp^3)—C distance of 1.597(4) Å in **6A** is close to the uncorrected mean value of 1.602 Å observed for the other "PhBN(sp^3)O_2" compounds (2, 15–18).

The two B(sp^2)—O bonds (1.357(6) and 1.370(6) Å) are relatively short, demonstrating the partial π-bond character resulting from $pp(\pi)$ back-donation from the two oxygen atoms to boron within the trigonal planar phenylboronate system. Similar B(sp^2)—O distances have been reported for the free arylboronic acids $PhB(OH)_2$ (32), mean 1.371(6) Å, and 4-$BrC_6H_4B(OH)_2$ (33), uncorrected mean 1.36 Å. The uncorrected B(sp^2)—O distances in various phenylboronate derivatives range 1.311–1.421 Å with an average value of 1.370 Å (2, 15, 16, 18, 28, 30, 32–42). The B(sp^2)—O—B(sp^3) linkages in **6A** are unique among organoboron compounds in that the B(sp^2)—O distances are normal. This may be ascribed to the fact that both oxygen atoms of the phenylboronate moiety are bonded to B(sp^3) atoms. In all other structurally characterized organoboron compounds containing B(sp^2)—O—B(sp^3) units only one such unit is present, displaying very short B(sp^2)—O bonds (1.311–1.367, uncorrected mean 1.338 Å) and normal B(sp^3)—O distances (1.444–1.495, uncorrected mean 1.471 Å) (2, 15, 16, 18, 28, 40, 42). In the present case it is the B(sp^3)—O[B(sp^2)] bonds which are short at 1.438(5) and 1.444(6) Å.

The B(sp^2)—C distance of 1.574(6) Å is slightly longer than the average uncorrected value of 1.552 Å, but in the range 1.506–1.582 Å observed for other phenylboronate derivatives (2, 15, 16, 18, 28, 30, 32–42). As expected, the B(sp^2)—C bond is shorter than the B(sp^3)—C bonds, indicating a π-interaction between the phenyl ring and the trigonal planar boron atom. The sp^2-hybridized boron atom is displaced 0.026(5) Å from the plane of its substituents and the angle between the normals to the B(2) coordination plane and the associated phenyl mean plane is 7.3°, a typical value for such systems.

It can be concluded that in the case of *N*-methyl and *B*-phenyl substitution the formation of **6A** is favored in the condensation reaction of **3** with phenylboronic acid, even at an adduct ratio of 1:2. **6A** appears to be the thermodynamically most stable structure in this complex-building system. The structure of **6A** can also be interpreted in terms of the boat form of the well-known (43–46) BONBON ring, conformationally locked by the ethylene bridge between the nitrogen atoms, and containing an additional boronate bridge linking the ring boron atoms (see formula **7**).



7

tricyclo[5.4.0.0^{3,9}]undecane system containing the BONBON boat partial structure

Received October 1, 1987

SUJATHA N. GAMAGE, BRIAN R. JAMES, STEVEN J. RETTIG, and JAMES TROTTER. Can. J. Chem. **66**, 1123 (1988).

Two crystalline modifications (I and II) of diethylammonium *trans*-tetrachlorobis(dimethylsulfoxide-*S*)rhodate(III) have been isolated from the same reaction mixture. The compound is formed by hydrolysis, in the presence of hydrochloric acid, of an η^1-ylidic enamine complex of rhodium(III), which is made via dehydrogenation of triethylamine in the presence of *mer*-trichlorotris(dimethylsulfoxide)rhodium(III). Crystals of form I are triclinic, $a = 8.1787(7)$, $b = 10.761(1)$, $c = 10.927(1)$ Å, $\alpha = 86.681(6)$, $\beta = 84.879(7)$, $\gamma = 71.814(8)°$, $Z = 2$, space group $P\bar{1}$, and those of form II are triclinic, $a = 7.931(2)$, $b = 9.489(2)$, $c = 13.302(2)$ Å, $\alpha = 102.03(1)$, $\beta = 97.40(1)$, $\gamma = 107.49(1)°$, $Z = 2$, space group $P\bar{1}$. Both structures were solved by Patterson and Fourier methods and were refined by full-matrix least-squares procedures to $R = 0.024$ and 0.060 for 4959 and 4320 reflections with $I \geq 3\sigma(I)$, respectively. Both crystal structures consist of centrosymmetric $[RhCl_4(Me_2SO)_2]^-$ anions and $(NEt_2H_2)^+$ cations, linked by hydrogen bonds to form infinite chains. In form I the hydrogen bonds are all of the type N—H···Cl (H···Cl = 2.50(4) and 2.49(3) Å), while in form II they are all of the type N—H···O (H···O = 2.25(7) and 2.04(6) Å).

SUJATHA N. GAMAGE, BRIAN R. JAMES, STEVEN J. RETTIG et JAMES TROTTER. Can. J. Chem. **66**, 1123 (1988).

A partir d'un seul mélange réactionnel, on a pu isoler deux modifications cristallines (I et II) du diéthylammonium *trans*-tétrachloro bis(diméthylsulfoxyde-*S*) rhodium(III). Le composé se forme par hydrolyse, en présence d'acide chlorhydrique, d'un complexe η^1-ylidique enamine du rhodium(III) qui est préparé via une déshydrogénation de la triéthylamine en présence du *mer*-trichloro tris(diméthylsulfoxyde) rhodium(III). Les cristaux de la forme I sont tricliniques avec $a = 8,1787(7)$, $b = 10,761(1)$ et $c = 10,927(1)$ Å, $\alpha = 86,681(6)$, $\beta = 84,879(7)$ et $\gamma = 71,814(8)°$, $Z = 2$ et groupe d'espace $P\bar{1}$ alors que ceux de la forme II sont tricliniques avec $a = 7,931(2)$, $b = 9,489(2)$ et $c = 13,302(2)$ Å, $\alpha = 102,03(6)$, $\beta = 97,40(1)$ et $\gamma = 107,49(1)°$, $Z = 2$ et groupe d'espace $P\bar{1}$. On a résolu les deux structures à l'aide des méthodes de Patterson et Fourier et on les a affinées par la méthode des moindres carrés (matrice entière) jusqu'à des valeurs de $R = 0,024$ et 0,060 respectivement pour 4959 et 4320 réflexions avec $I \geq 3\sigma(I)$. Les deux structures moléculaires comportent des anions $[RhCl_4(Me_2SO)_2]^-$ centrosymétriques et des cations $(NEt_2H_2)^+$ qui sont réunis par des liaisons hydrogènes formant des chaînes infinies. Dans la forme I, les liaisons hydrogènes sont toutes du type N—H···Cl (H···Cl = 2,50(4) et 2,49(3) Å); par ailleurs, dans la forme II, elles sont toutes du type N—H···O (H···O = 2,25(7) et 2,04(6) Å).

[Traduit par la revue]

Introduction

We have reported recently on reactions in which tertiary amines are dehydrogenated in the presence of *mer*-$RhCl_3(Me_2SO)_3$, in which one of the dimethylsulfoxide ligands is *O*-bonded (Me_2SO) and two are *S*-bonded (Me_2SO) (1, 2). In the case of triethylamine, the dehydrogenation yields an enamine fragment that is stabilized within an η^1-ylidic enamine complex of rhodium(III), **1**, while the "hydrogen" reduces half of the initially present Rh(III) to Rh(I) (1). The reaction stoichiometry is summarized in equation [1], where the Rh(I) product is probably 4-coordinate containing Cl^- and Me_2SO ligands.

[1] $2RhCl_3(Me_2SO)_3 + NEt_3 \rightarrow$

$Rh(I) + 3Cl^- + 2H^+ + 4Me_2SO +$

$RhCl_3(Me_2SO)_2(CH_2CH{=}NEt_2)$ (**1**)

Complex **1** exists in two forms, the *mer-trans* (**1***a*) and the *mer-cis* (**1***b*); both were isolated and the latter was characterized by X-ray analysis (1). On studying the solution chemistry of these complexes, we discovered an acidification/hydrolysis reaction, [2]; subsequent characterization of product **2** by X-ray analysis showed it to exist in two distinct forms which differ in H-bonding interactions between the diethylammonium cation and the anion, which has *trans* geometry.

[2] $1 + H_2O + HCl \rightarrow (NEt_2H_2)[RhCl_4(Me_2SO)_2]$ (**2**) $+ CH_3CHO$

This paper reports on the preparation of **2**, and particularly on the existence of the unusual solid-state isomers. The *trans*-tetrachlorobis(dimethylsulfoxide-*S*)rhodate(III) anion within **2** has been characterized by X-ray analysis previously, but in association with a sodium cation (3) and the hydrogen-bridged cation $[Me_2SO{\cdots}H{\cdots}OSMe_2]^+$ (4).

Experimental

Spectral or reagent grade solvents and chemicals were used throughout. $RhCl_3{\cdot}3H_2O$ was obtained on loan from Johnson, Matthey Ltd. ^1H nmr spectra were recorded on Bruker WP80 or Varian XL100 instruments operating in the FT mode with TMS as internal standard. Infrared spectra were recorded on a Perkin-Elmer 598 or on a Nicolet 5DX FT spectrometer. Elemental analyses were performed by Mr. P. Borda of this department.

Syntheses of *mer*-$RhCl_3(Me_2SO)_3$ and $RhCl_3(Me_2SO)_2(CH_2CH{=}NEt_2)$, **1**, followed literature procedures (1). Dimethylacetamide hydrochloride (DMA·HCl) was prepared by passing gaseous HCl through neat DMA, and recrystallizing the white adduct formed from ethanol (5).

[Cation] trans-*[$RhCl_4(Me_2SO)_2$], cation = NEt_3H^+, $NEt_2H_2^+$ (2)*

(*a*) $RhCl_3(Me_2SO)_3$ (200 mg, 0.45 mmol) and NEt_3 (0.2 mL, 1.4 mmol) were stirred in acetone (25 mL) under Ar overnight, and the solution concentrated to give an off-white precipitate (NEt_3·HCl) and a red–brown solution — which at this stage contains **1** (1). Addition of DMA·HCl (180 mg, 1.5 mmol) and stirring overnight under Ar yielded

[a]Temperature 295 K, Enraf-Nonius CAD4-F diffractometer, Mo-K_α radiation (λK_{α_1} = 0.70930, λK_{α_2} = 0.71359 Å), graphite monochromator, takeoff angle 2.7°, aperture (2.0 + tan θ) × 4.0 mm at a distance of 173 mm from the crystal, scan range extended by 25% on both sides for background measurement, $\sigma^2(I) = C + 2B + [0.04(C - B)]^2$ (C = scan count, B = normalized background count), function minimized: $\Sigma w(|F_o| - |F_c|)^2$ where $w = 1/\sigma^2(F)$, $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$, $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$, $S = (\Sigma w(|F_o| - |F_c|)^2/(m - n))^{1/2}$. Values given for R, R_w, and S are based on those reflections with $I \geq 3\sigma(I)$.

an orange solution and yellow precipitate. An ir (Nujol) of the crude yellow product showed the presence of $NEt_2H_2^+$ (ν_{N-H} = 3140 cm^{-1}, s), NEt_3H^+ (ν_{N-H} = 2400–2600 cm^{-1}, s) and only a weak peak due to —CH_2—CH=NEt_2 ($\nu_{C=N}$ = 1640 cm^{-1}). Recrystallization from CH_2Cl_2/ether in air yielded $(NEt_3H)[RhCl_4(Me_2SO)_2]$ (40 mg, 20% yield). *Anal.* calcd. for $C_{10}H_{28}Cl_4NO_2RhS_2$: C 23.86, H 5.61, N 2.78; found: C 23.35, H 5.29, N 2.71. ^{1}H nmr (δ, $CDCl_3$, 100 MHz): 1.38 t (9H, CH_3CH_2), 3.13 q (6H, CH_3CH_2), 3.48 s (~11H, *trans*-Me_2SO), 3.53 s (~1H, *cis*-Me_2SO) (6).

The mother liquor from the recrystallization was concentrated to ~1 mL and left in a closed Schlenk tube; after a few days several red crystals appeared (~20 mg). Infrared (KBr): 3140 cm^{-1}, s (ν_{N-H} of $NEt_2H_2^+$), 1128 and 1140 cm^{-1}, s, (ν_{SO} of Me_2SO). X-ray analysis of the crystals (see below) showed them to be two distinct forms with molecular formula $(NEt_2H_2)[trans\text{-}RhCl_4(Me_2SO)_2]$, **2**.

(*b*) The decomposition of **1** (**1***a* or **1***b*) to **2** (see reaction [2]) was monitored by ^{1}H nmr (80 MHz) by dissolving **1** (6 mg, ~0.015 mmol) and DMA·HCl (4 mg, 0.03 mmol) in acetone-d_6 (0.6 mL) which contained ~0.04 mmol H_2O as impurity (δ 2.93 ppm). The resonances of **1** (see ref. 1) and DMA·HCl (δ 2.32, 3H, CH_3CO; 3.10, 6H, $(CH_3)_2N$) were replaced over 2 days by peaks assignable to $NEt_2H_2^+$ (δ 1.4 t, 6H, CH_3CH_2; 3.2 m, 4H, CH_3CH_2), DMA (δ 2.1, CH_3CO; 3.0, 6H, $(CH_3)_2N$) and CH_3CHO (δ 9.8, 1H, CHO, D_2O stable; the CH_3 resonance, expected at δ 2.2, was obscured by resonances of DMA and acetone-d_5). The peak position of Me_2SO remained essentially unchanged (δ 3.5), while the impurity water peak disappeared, presumably as a result of both consumption of the water (reaction [2]) and its proton exchange with those of $NEt_2H_2^+$. A drying of a drop of the nmr solution sample on a NaCl window revealed in the ir the 3140 cm^{-1} peak of $NEt_2H_2^+$ and the absence of $\nu_{C=N}$ of **1** (see above).

X-ray crystallographic analyses

Crystallographic data for the two crystal forms of **2** appear in Table 1. The crystals are red–orange in color, those of form I growing as blocks with faces {1 0 −1}, {0 −1 1}, {1 1 0}, (0 1 −2), and (0 0 1) developed, and those of form II as plates with faces {1 −1 0}, {0 0 1}, and {0 −1 1} developed. Unit-cell parameters were refined by least squares on 2 sin θ/λ values for 25 reflections with 2θ = 45–53° and 45–56° for forms I and II, respectively. The intensities of three standard reflections, measured each hour of X-ray exposure time during the data collections, showed only small random variations for both samples. The data were reduced,[1] and corrected for absorption (numerical integration). Both structures were solved by Patterson and Fourier methods. The non-hydrogen atoms were refined with anisotropic thermal parameters and the hydrogen atoms with isotropic thermal param-

[1]The computer programs used include locally written programs for data processing and locally modified versions of the following: AGNOST, absorption corrections, by J. A. Ibers; ORFLS, full-matrix least-squares, and ORFFE, function and errors, by W. R. Busing, K. O. Martin and H. A. Levy; FORDAP, Patterson and Fourier syntheses, by A. Zalkin; ORTEP II, illustrations, by C. K. Johnson.

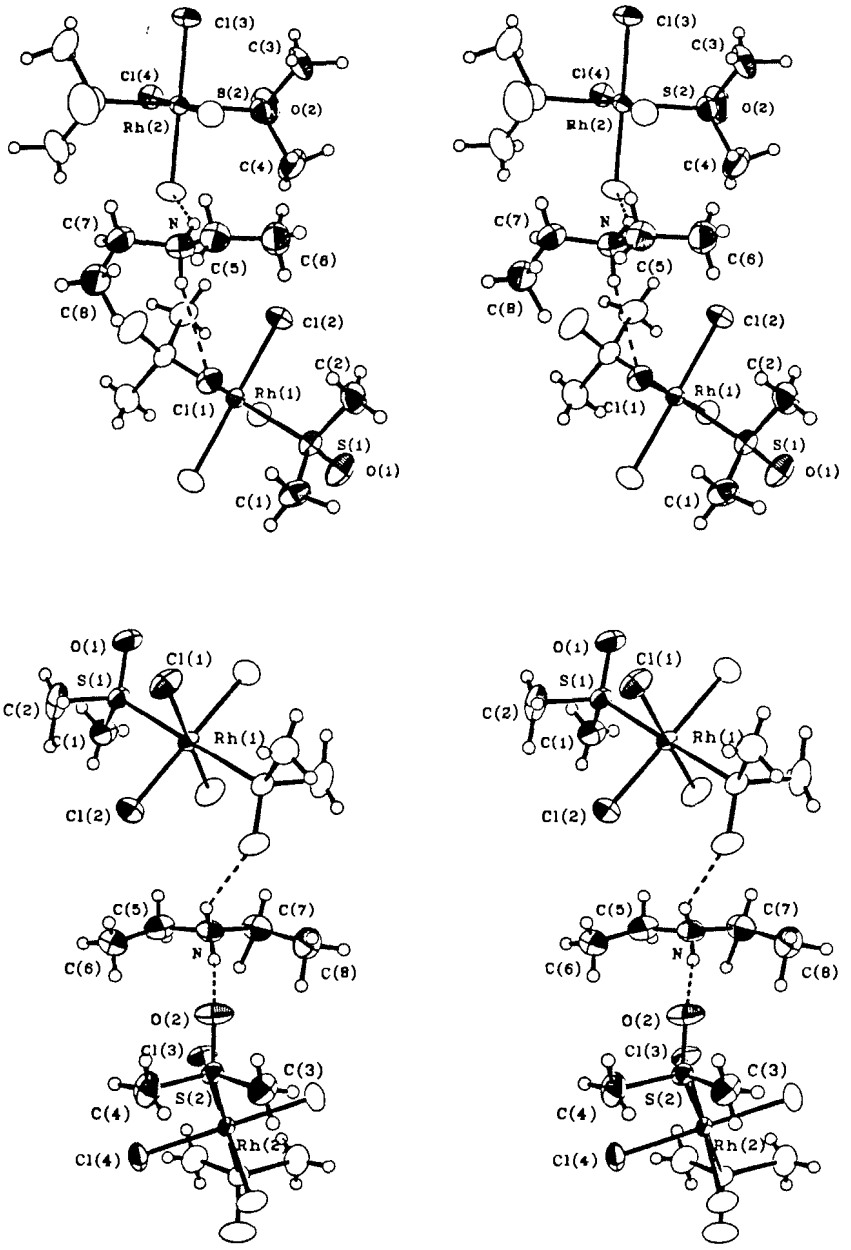

FIG. 1. Stereoscopic views of the structures of **2**, form I (top) and form II (bottom); 50% probability thermal ellipsoids are shown for the non-hydrogen atoms. Hydrogen atoms have been assigned arbitrary thermal parameters for the sake of clarity. Broken lines indicate hydrogen bonds. Shaded non-hydrogen atoms comprise the asymmetric units.

eters, except for those associated with the C(6) methyl group in form I which were fixed in calculated positions (staggered, C—H = 0.98 Å, $U_H \propto U_{\text{bonded atom}}$). Neutral atom scattering factors for all atoms and anomalous scattering corrections for Rh, Cl, and S were taken from ref. 7. The maximum parameter shifts on the final cycles of full-matrix least-squares refinement were associated with hydrogen atoms. The largest peaks on the final difference maps were within 1 Å of the metal atoms. Final positional and isotropic (or equivalent isotropic) thermal parameters are given in Table 2. Bond lengths and angles appear in Table 3. Anisotropic thermal parameters, bond lengths and angles involving hydrogen, torsion angles (Tables 4–7), and measured and calculated structure factors have been placed in the Depository of Unpublished Data.[2]

[2]The structure factor tables and Tables 4–7 may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

Results and discussion

The synthetic procedure for isolation of **2** from $RhCl_3(Me_2SO)_3$, coupled with its *in situ* formation from $RhCl_3(Me_2SO)_2(CH_2CH{=}NEt_2)$, **1**, with concomitant generation of CH_3CHO, are most readily rationalized chemically in terms of reactions [1] and [2]. A corresponding slow decomposition of chloro(enamine)palladium(II) complexes in CH_2Cl_2 containing traces of H_2O to give CH_3CHO (or the expected ketone for a coordinated $—CH_2C(Me){=}NEt(^iPr)$ fragment) has been reported (8); these workers suggested a mechanism incorporating initial hydrolysis to a β-oxoalkylpalladium species which then underwent Pd—C bond cleavage by HCl formed in the hydrolysis; details have not appeared, and the nature of the Pd product(s) was not discussed. Added HCl is required for the decomposition of our Rh(III)–enamine complex, reaction [2],

and an alternative mechanism could involve initial protonolysis of the metal–carbon bond, followed by hydrolysis of the incipient unsaturated enamine-derived cation:

$$\mathbf{1} + HCl \rightarrow (CH_3CH{=}NEt_2)[RhCl_4(Me_2SO)_2]$$

[3] $$\downarrow$$

$$CH_3CHO + (NEt_2H_2)[RhCl_4(Me_2SO)_2] \quad (\mathbf{2})$$

Of note is the fact that **2** (with *trans* sulfoxides) is obtained using either **1***a* or **1***b* which have, respectively, *trans*- and *cis*-disposed sulfoxides. The required isomerization in the **1***b* → **2** transformation could be accommodated within the HCl step, if protonation yielded a 5-coordinate $RhCl_3(Me_2SO)_2$ intermediate (square pyramid ⇌ trigonal bipyramid) that subsequently added chloride.

The isolation of $(NEt_3H)[RhCl_4(Me_2SO)_2]$ during procedure (*a*) of the experimental section presumably arises because the excess NEt_3 used makes NEt_3H^+ available as a possible counter-ion when the DMA·HCl is added. Higher yields of **2** could certainly be attained via a synthetic procedure based on reaction [2].

The most unusual finding in this enamine hydrolysis work, however, is the discovery of two distinct crystal forms of complex **2**. Stereoviews of the two structures are shown in Fig. 1. Both structures possess an asymmetric unit consisting of an $(NEt_2H_2)^+$ cation and two crystallographically independent half-anions, the Rh atoms being located at centres of symmetry. Hydrogen-bonded chains of alternating cations and anions are observed in both crystal structures. In form I the ionic species are linked by N—H···Cl hydrogen bonds (N—H(N)···Cl(3)($-x$, $1-y$, $1-z$) and N—H(N′)···Cl(1), H···Cl = 2.50(4) and 2.49(3), N···Cl = 3.356(2) and 3.353(2) Å, N—H···Cl = 143(3) and 154(3)°, respectively) and in form II by N—H···O hydrogen bonds (N—H(N)···O(1) and N—H(N′)···O(2)($1-x$, $1-y$, $1-z$), H···O = 2.25(7) and 2.04(6), N···O = 2.917(6) and 2.856(6) Å, N—H···O = 143(6) and 160(6)°, respectively). The fact that both forms of **2** can be isolated from the same reaction mixture indicates that the strengths of the N—H···Cl and N—H···O hydrogen-bonding networks in the two polymorphs of **2** must be nearly equal. Crystal polymorphism is a common phenomenon and usually results from differing conditions for crystal growth (9). The isolation of more than one crystal form from the same reaction mixture is not without precedent (e.g. ref. 10). In most cases of crystal polymorphism involving hydrogen-bonded systems, the donor–acceptor pairings remain the same while the hydrogen-bonding motifs may (e.g. ref. 11) or may not (e.g. refs. 10, 12) be different in different crystal forms of the same material. In the present example we have the same motif involving different hydrogen-bond acceptors.

Bond distances and angles observed for the *trans*-$[RhCl_4(Me_2SO)_2]^-$ anions in both crystal forms of **2** are in good agreement with those reported for the Na^+ (3) and $[H(Me_2SO)_2]^+$ (4) salts of the same anion. The effects of the different hydrogen-bonding modes in the two crystal forms of **2** are reflected in the Rh—Cl and S=O bond lengths. The mean Rh—Cl distances are longer in the N—H···Cl hydrogen-bonded form I (2.344(3) vs. 2.334(3) Å), while the mean S=O distances are longer in the N—H···O hydrogen-bonded form II (1.477(6) vs. 1.44(3) Å). The $(NEt_2H_2)^+$ cations are also different in the two forms, that in form I having a *GT* local conformation at nitrogen (C—N—C—C torsion angles of −60.6(3) and −173.3(2)°) while in form II the local conformation is *TT* (torsion angles of 167.9(5) and −167.6(6)°).[3]

Diffusion in associating nonelectrolyte mixtures: stepwise aggregation and micelle formation

DEREK G. LEAIST
Department of Chemistry, University of Western Ontario, London, Ont., N6A 5B7 Canada

Received September 28, 1987

DEREK G. LEAIST. Can. J. Chem. **66**, 1129 (1988).

Equations have been developed to predict diffusion coefficients and Onsager coefficients for associating nonelectrolyte solutes in binary or multicomponent solutions with any number of association equilibria. The equations are used to interpret previously reported data for binary diffusion with stepwise association of ethanol and *N*-methylacetamide in carbon tetrachloride solutions. Diffusion of Triton X-100, a non-ionic micelle-forming surfactant, is also analyzed. In contrast to the gradual decrease in the diffusivity caused by stepwise association, formation of micellar aggregates produces a sharp drop in the diffusivity at the critical micelle concentration. The relation between interdiffusion coefficients and intradiffusion coefficients for associating nonelectrolyte solutes is discussed.

DEREK G. LEAIST. Can. J. Chem. **66**, 1129 (1988).

On a développé des équations qui permettent de prédire les coefficients de diffusion et les coefficients d'Onsager de solutés non-électrolytes qui s'associent dans des solutions binaires ou à plusieurs composants et qui comportent n'importe quel nombre d'équilibres d'association. On a utilisé les équations pour interpréter des données rapportées antérieurement pour de la diffusion binaire impliquant une association par étapes de l'éthanol et du *N*-méthylacétamide dans des solutions de tétrachlorure de carbone. On a aussi analysé la diffusion du Triton X-100, un agent de surface non-ionique qui forme des micelles. Par opposition avec la diminution graduelle de la possibilité de diffusion provoquée par cette association par étapes, la formation d'aggrégats micellaires provoque une diminution importante de la possibilité de diffusion à la concentration micellaire critique. On discute de la relation entre les coefficients d'interdiffusion et les coefficients d'intradiffusion pour les solutés non-électrolytes qui s'associent.

Introduction

Many nonelectrolyte solutes associate (1). Aqueous urea, for example, is extensively dimerized (2, 3). In nonpolar solvents, carboxylic acids and phenols form dimers (4–7). Other solutes, such as nucleic acids (8), amides (9–11), and certain dyes (12), associate in a stepwise manner to form chain-like aggregates. Non-ionic surfactants illustrate an extreme case of association in which micellar clusters containing several hundred molecules can form (13–16).

The work reported here was undertaken to study the diffusion behavior of associating nonelectrolytes. The effects of association on diffusion are interpreted by determining changes in the solute mobility and the free energy gradient, the driving force for diffusion.

Binary diffusion of dimerizing solutes (2, 17–20) and ternary diffusion of solutes A and B that form complex AB (21) have already been studied. The equations developed in the present paper extend the earlier treatments to nonelectrolyte mixtures that contain arbitrary numbers of components and association equilibria.

Weinheimer *et al.* (15) have reported an approximate expression for estimating the diffusion coefficient of micelle-forming nonelectrolytes above the critical micelle concentration. The more general expression developed here allows changes in the rate of diffusion to be followed as the concentration is raised or lowered through the critical micelle concentration.

Theory

Consider isothermal diffusion in a nonelectrolyte solution composed of solvent and n different solute species with n_r independent association reactions. The reaction rates are assumed to be rapid compared to diffusion so that chemical equilibrium exists locally. This is a valid assumption provided the chemical relaxation times are small compared to $\epsilon^2/\Delta D$, where ϵ is a characteristic linear dimension of the system and ΔD is the difference between the diffusivities of the reactants and products (22).

Local chemical equilibrium places n_r restrictions on transport of the n solute species. Therefore, only $n - n_r$ solute flows are independent. Interdiffusion in the solution under consideration can be described by using generalized Fick equations for $N = n - n_r$ constituent solute components (23).

$$[1] \quad J_i = -\sum_{k=1}^{N} D_{ik}\nabla C_k$$

J_i and ∇C_k denote the molar flux densities and the gradients in the concentrations of the solute components. Diffusion coefficient D_{ik} measures the flux of component i produced by the gradient in component k.

Onsager's equations (23)

$$[2] \quad J_i = -\sum_{k=1}^{N} L_{ik}\nabla\mu_k$$

relate the fluxes of the solute components to the gradients in the components' chemical potentials. The two sets of transport coefficients are related by the identity

$$[3] \quad D_{ik} = \sum_{q=1}^{N} L_{iq}\partial\mu_q/\partial C_k$$

In general, the N solute components may be transported as monomers, dimers, trimers, etc. (A_1, A_2, A_3, ...), or, in multicomponent mixtures, as complexes formed with other components (A_1B_1, A_2B_1, A_1B_2, ...). In order to estimate the transport coefficients of associating components, it proves convenient to have transport equations

$$[4] \quad j_p = -\sum_{q=1}^{n} l_{pq}\nabla\hat{\mu}_q$$

for each of the n solute species. j_p and $\nabla\hat{\mu}_q$ stand for the molar flux densities and the gradients in the chemical potentials of the various solute species.

If stoichiometric coefficient ν_{ip} denotes the number of moles of constituent component i contained in one mole of species p, then

$$[5] \quad J_i = \sum_{p=1}^{n} \nu_{ip} j_p$$

$$[6] \quad \nabla\hat{\mu}_q = \sum_{k=1}^{N} \nu_{kq} \nabla\mu_k$$

Substitution of eqs. [4] and [6] into eqs. [5] provides the following general relation between the transport coefficients of the components and the species

$$[7] \quad L_{ik} = \sum_{p=1}^{n} \sum_{q=1}^{n} \nu_{ip} l_{pq} \nu_{kq}$$

Equation [7] can be rerewritten as

$$[8] \quad \mathbf{L} = \boldsymbol{\nu} \mathbf{l} \boldsymbol{\nu}^{\mathrm{T}}$$

where $\boldsymbol{\nu}^{\mathrm{T}}$ denotes the transpose of $\boldsymbol{\nu}$, the $N \times n$ matrix of stoichiometric coefficients.

L_{ik} coefficients

It is a valid approximation, especially for dilute solutions, to express the diffusion velocity of each species (v_i) as the product of the mobility of the species (u_i) and the driving force ($-\nabla\hat{\mu}_i$) acting on the species (22).

$$[9] \quad v_i = -u_i \nabla\hat{\mu}_i$$

Since $j_i = c_i v_i$, where c_i denotes the concentration of species i, we have

$$[10] \quad j_i = -c_i u_i \nabla\hat{\mu}_i$$

Comparisons of eqs. [4] and [10] shows that the off-diagonal l_{ik} coefficients ($i \neq k$) may be neglected (24) and that the diagonal elements are given by $l_{ii} = c_i u_i$. Equation [7] then provides the following approximate relation between the Onsager coefficients of the solute components and the mobilities of the diffusing species.

$$[11] \quad L_{ik} = \sum_{q=1}^{n} \nu_{iq} c_q u_q \nu_{kq}$$

Interchanging i and k in eqs. [11] shows that the reciprocal relations $L_{ik} = L_{ki}$ ($i \neq k$) are satisfied.

Cross-coefficient L_{ik} ($i \neq k$) measures the interaction between flows of components i and k. If components i and k take part in a chemical reaction with species q, then the product $\nu_{iq}\nu_{kq}$ is non-zero, and hence the flows of the two components will interact. Conversely, if components i and k do not react with a common species, then rows i and k of $\boldsymbol{\nu}$ are orthogonal and the two components are predicted to diffuse independently.

D_{ik} coefficients

Einstein's equation (23),

$$[12] \quad D_i = RTu_i$$

which relates the diffusion coefficient and the molar mobility of each species, and eqs. [3] and [11] provide the following approximate expressions

$$[13] \quad D_{ik} = (RT)^{-1} \sum_{p=1}^{n} \sum_{q=1}^{n} \nu_{iq} c_i D_q \nu_{pq} \partial\mu_p / \partial C_k$$

for the diffusion coefficients of the solute components (D_{ik}) in terms of the concentrations and diffusion coefficients (D_i) of the species.

In favorable cases, accurate values of D_i can be obtained from analysis of binary or tracer diffusion data (15, 17–19). If this information is unavailable, values of D_i can be estimated from diffusivities for species with similar molecular structures (25). For solute molecules that are large compared to the solvent molecules, diffusivities can be estimated by using Stokes Law (23), $D_i = kT/6\pi\eta a$, where k, T, η, and a denote Boltzmann's constant, temperature, solvent viscosity, and the effective molecular radius.

Results

The equations that have been developed will now be used to interpret binary diffusion of nonelectrolytes that associate in a step-wise manner or form micelles. One example of ternary diffusion with complex-formation will also be treated.

Binary mixtures

Transport in solutions that contain a single solute component will be considered first. In general, the solute molecules can exist as monomers (designated by A_1), dimers (A_2), trimers (A_3), etc. Aggregation of the solute can be represented by the series of association reactions

$$iA_1 = A_i \qquad K_i$$

in which aggregates of i monomers are formed from i free monomers. Choosing total A the constituent solute component and numbering the solute species $1 = A_1$, $2 = A_2$, $3 = A_3$, ..., defines the following stoichiometric coefficients

$$[14] \quad \boldsymbol{\nu} = (1 \quad 2 \quad 3 \quad 4 \ldots)$$

Equation [11] shows that U, the overall molar mobility of the solute, is weighted in favor of the mobilities of the diffusing species as follows

$$[15] \quad U = \sum_{i=1} i^2 c_i u_i / C = L/C$$

The concentrations of the species can be evaluated by using the conditions of chemical equilibrium

$$[16] \quad K_i = c_i / c_i^i$$

and from the total content of solute A

$$[17] \quad C = \sum_{i=1} i c_i$$

Given values of L from eq. [15], the binary diffusion coefficient of the solute can be evaluated from

$$[18] \quad D = L \mathrm{d}\mu / \mathrm{d}C$$

Differentiation of eqs. [16] and [17] and the expression for the solute's chemical potential

$$[19] \quad \mu_1 = \mu_1^0 + RT \ln C_1$$

gives

$$[20] \quad \mathrm{d}\mu/\mathrm{d}C = RT / \sum_{i=1} i^2 c_i$$

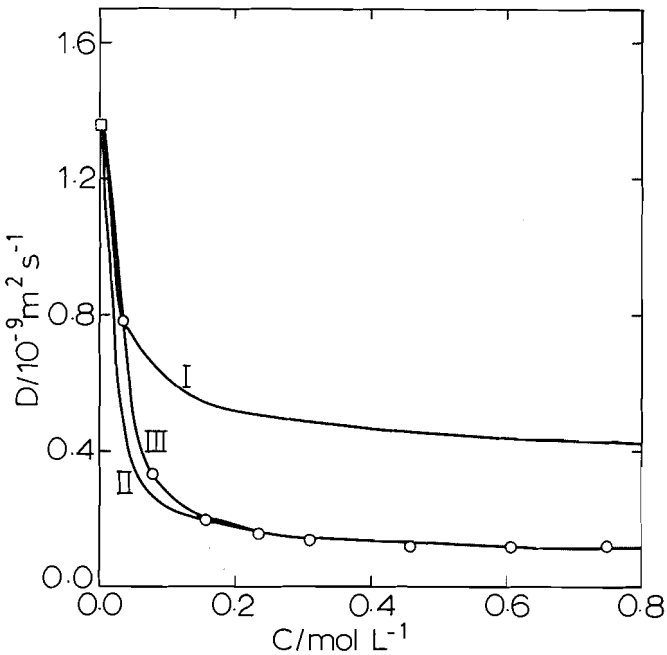

FIG. 1. Diffusion coefficients for *N*-methylacetamide in carbon tetrachloride solutions at 25°C: ○, interdiffusion coefficients measured by Longsworth (25); curve I, predicted values of D, $D_i = D_1 i^{-1/3}$, $K_{12} = 5$ L mol^{-1}, $\bar{K} = 40$ L mol^{-1}; curve II, $D_i = D_1 i^{-0.68}$, $K_{12} = 5$ L mol^{-1}, $\bar{K} = 40$ L mol^{-1}; curve III, $D_i = D_1 i^{-0.68}$, $K_{12} = 1$ L mol^{-1}, $\bar{K} = 25$ L mol^{-1}.

and hence

$$[21] \quad D = \sum_{i=1} i^2 c_i D_i / \sum i^2 c_i$$

Thus D is an $i^2 c_i$-weighted average of the diffusion coefficients of the species.

Equations [15], [17], [18], [20], and [21] have been simplified by dropping subscripts "11" from L and D and subscript "1" from C, U, and μ. In addition, the solute has been assumed to be ideal in the thermodynamic sense.

N-Methylacetamide (NMA) in carbon tetrachloride

Longsworth (25) has used Rayleigh interferometry to measure precise diffusion coefficients for NMA + carbon tetrachloride solutions. Continuous stepwise self-association of NMA in these solutions produces dimers, trimers and larger hydrogen-bonded aggregates. Association of the solute causes D to drop from 1.36×10^{-9} m^2 s^{-1} at infinite dilution to 0.12×10^{-9} m^2 s^{-1} at 0.4 mol L^{-1} and 25°C.

The thermodynamic parameters for self-association of NMA are not known reliably. However, evidence from several independent sources suggests it is a reasonable approximation to use K_2 for the monomer–dimer equilibrium and a second constant, $\bar{K}$, for the subsequent association steps ($i > 2$)

$$A_1 + A_{i-1} = A_i \qquad \bar{K}$$

in which aggregates of i monomers are formed from aggregates of $i - 1$ monomers (9, 10). Since $\bar{K} = K_i/K_{i-1}$, we have $K_i = K_2 \bar{K}^{i-2}$ for $i > 2$. The reported values of K_2 and $\bar{K}$, as inferred from infrared (7, 26, 27) or nmr (10) spectra and from vapor pressure data (28), vary considerably, from about 0.9 to 8 for K_2 and from about 20 to 50 L mol^{-1} for $\bar{K}$, at 25°C.

The value of D_1, the diffusivity of the NMA monomer, was set equal to 1.36×10^{-9} m^2 s^{-1}, the limiting diffusion coefficient of fully-dissociated NMA obtained by Longsworth (25) by extrapolation of D to zero concentration of solute. Values for the diffusivities of the associated NMA species are not available. However, the volume of an aggregate of i monomers is approximately i times larger than the volume of a single monomer. Therefore, values of D_i ($i \geq 2$) can be estimated by using the Stokes law ratios $D_i/D_1 = i^{-1/3}$.

In Fig. 1 the predicted values of D for NMA in carbon tetrachloride (curve I) are compared with the measured D values reported by Longsworth (25). The values of the association constants that were used in the calculations were taken from the middle of the ranges of the reported values: $K_{12} = 5$ L mol^{-1} and $\bar{K} = 40$ L mol^{-1}. Above 0.1 mol L^{-1} NMA, the predicted values of D are significantly too large. This discrepancy might be caused by the higher NMA polymers being more stable than the value adopted for $\bar{K}$ would suggest. In view of the uncertainty in the estimates of the diffusion coefficients of the NMA polymers, this explanation is speculative. For example, the diffusion coefficients of the longer threads of associated NMA molecules will be smaller than the values suggested by Stokes law, which is valid only for spherical particles. To obtain better estimates for the diffusion coefficients of polymeric chains in carbon tetrachloride, Longsworth's (25) limiting diffusivities for the C_7, C_{12}, C_{16}, C_{20}, C_{22}, C_{28}, and C_{32} normal alkanes were used. The plot of ln D_i versus ln i, where i is the number of carbon atoms in the alkane, gave the slope $-0.68(\pm 0.02)$, which suggests $D_i = D_1 i^{-0.68}$. The values of D_2, D_3, ... obtained from this equation together with $K_{12} = 5$ L mol^{-1} and $\bar{K} = 40$ L mol^{-1} were used to calculate the values of D for NMA shown by curve II in Fig. 1. Agreement with the measured values of D is improved remarkably. Below 0.1 mol L^{-1} NMA, however, the calculated D values are too low. This remaining discrepancy can be removed by adjusting the values of the association constants to $K_{12} = 1$ L mol^{-1} and $\bar{K} = 25$ L mol^{-1} (curve III).

Orange II in water

The stepwise association of certain dyes, such as Orange II (29), is described by the isodesmic model in which the stepwise association constant is independent of the size of the aggregate: $\bar{K} = K_i/K_{i-1}$ for $i \geq 2$. In this case the concentrations of the total dye and the dye monomer are related by (29)

$$[22] \quad C = c_1(1 - \bar{K}c_1)^{-2}$$

and D is given by

$$[23] \quad D = \sum_i i^2 \bar{K}^{i-1} c_i^i D_i \Big/ \Big(\sum_i i^2 \bar{K}^{i-1} c_i^i \Big)$$

No experimental binary diffusion coefficients appear to have been reported for isodesmically associating nonelectrolytes.

Ethanol in carbon tetrachloride

Diffusion of ethanol in carbon tetrachloride has also been studied (25, 30, 31). In contrast to the continuous association of NMA or Orange II, association of ethanol molecules proceeds only to the hexamer stage ($K_n(n \geq 7) = 0$). From infrared measurements at 25°C, Coburn and Grunwald (6) obtained the values 0.64, 0.61, 14.3, 27.8, and 54.1 for K_2 through K_6. By extrapolation of diffusion coefficient versus molar volume data for molecules with similar structures, Longsworth (25) assigned the values 1.274×10^{-9}, 0.907×10^{-9}, 0.621×10^{-9}, 0.492×10^{-9}, and 0.464×10^{-9} m^2 s^{-1} to D_2 through D_6. By extrapolation of measured values of D to zero concentration, he also

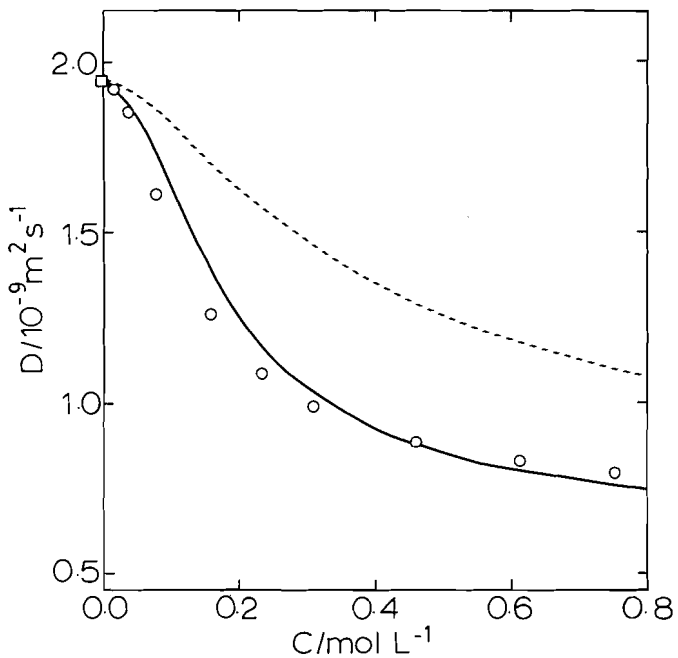

FIG. 2. Diffusion coefficients for ethanol in carbon tetrachloride solutions at 25°C: ○, interdiffusion coefficients measured by Longsworth (25); solid curve, predicted interdiffusion coefficients (eq. [21]); dashed curve, predicted intradiffusion coefficient (eq. [39]).

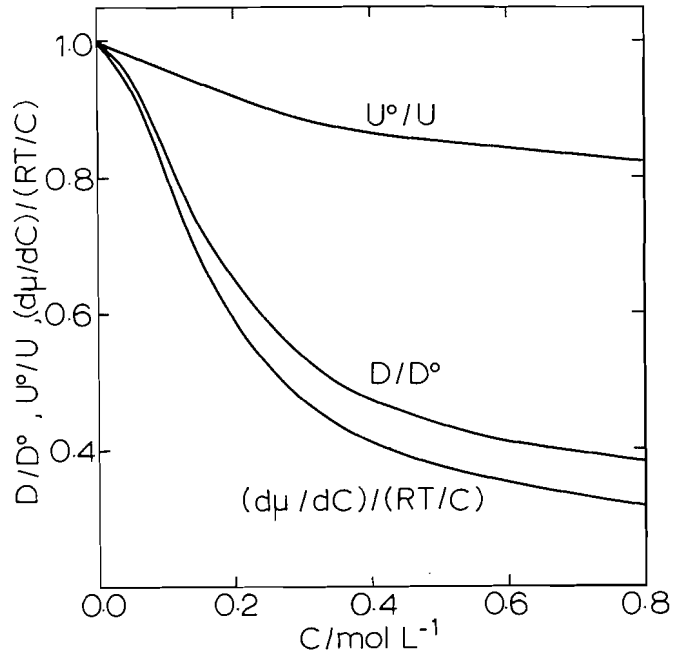

FIG. 3. Comparison of the mobility, diffusion coefficient and thermodynamic factor for ethanol in carbon tetrachloride at 25°C. In the limit $C \rightarrow 0$: $U \rightarrow U^\circ = u_1$; $D \rightarrow D^\circ = D_1$; $C\mathrm{d}\mu/\mathrm{d}C \rightarrow RT/C$.

determined the value 1.95×10^{-9} m^2 s^{-1} for D_1, the diffusion coefficient of the ethanol monomer.

Figure 2 gives a comparison of the predicted values of D which were generated by eq. [21] and the precise optical values measured by Longsworth for ethanol in carbon tetrachloride (25). Agreement is considerably better than that for NMA in carbon tetrachloride, probably because the values of K_i and D_i for the ethanol solutions are known more precisely.

As mentioned earlier, D can be expressed as a product of the mobility and a thermodynamic factor.

$$[24] \quad D = U(C\mathrm{d}\mu/\mathrm{d}C)$$

Figure 3 shows calculated values of the mobility and the thermodynamic factor for diffusion of ethanol in carbon tetrachloride at 25°C. The concentration-dependence of D is seen to be dominated by the thermodynamic factor, which drops as the concentration is raised. By reducing the number of free particles per mole of solute, association leads to lower free energy gradient, the "driving force" for diffusion. At the same time, however, there is less friction per mole of solute if some of the separate solute particles combine into aggregate diffusing particles. This increases the solute's molar mobility. In concentrated solutions, most of the ethanol is transported as hexamers. In this limit, values of D and $C\mathrm{d}\mu/\mathrm{d}C$ approach D_6 and $RT/6$, respectively.

Triton X-100 in water

As a final example of binary diffusion with self-association, transport of a nonionic micelle-forming detergent will be explored. The analysis will be simplified by assuming that the micelles are monodisperse.

Let m stand for the number of monomers held in each micelle. An expression for the diffusion coefficient of the surfactant can be obtained from eq. [21] by saving only those terms containing c_1 or c_m.

Among non-ionic surfactants, diffusion of aqueous Triton X-100 ($(CH_3)_3CCH_2C(CH_3)_2C_6H_4O(CH_2CH_2O)_{10}H$, molecular weight 646 g mol^{-1}) has been most thoroughly studied (15, 16). As the concentration of the surfactant is raised through the critical micelle concentration (cmc) of about 0.25 mmol L^{-1} (14), spherical aggregates containing approximately 140 monomers are formed (13). The diffusion coefficient of the Triton X-100 micelles, D_m is about 0.067×10^{-9} m^2 s^{-1}, the value determined by Weinheimer *et al.* (15) by extrapolation to high concentrations where most of the solute is transported as micelles. The diffusion coefficient of the Triton X-100 monomers, D_1, is difficult to measure because extremely dilute solutions are required to ensure that monomer diffusion is the dominant transport mechanism. At high dilutions, adsorption of solute onto the surfaces of diffusion cells can produce large errors in the measured values of D (15). In the calculations reported here, the value 0.35×10^{-9} m^2 s^{-1} was used for D_1. This estimate was obtained from Stokes law as follows: $D_1 = (140)^{1/3} D_m$. (It is close to the value reported for the diffusion coefficient of polyethylene glycol with molecular weight 600 g mol^{-1} (32).)

Figure 4 gives values of D calculated for aqueous Triton X-100 at 25°C. In this case association, through the thermodynamic factor, produces a sharp drop in D as the concentration is raised through the cmc. Above the cmc, D drops slowly with C and approaches D_m. Formation of submicellar aggregates, which is neglected in the present treatment, would produce a more gradual drop in D at the cmc.

Multicomponent mixtures

The equations developed in this paper can also be used to interpret the transport properties of mixtures containing two or more associating solute components. However, no multicomponent diffusion measurements appear to have been made on such mixtures. The following example merely serves as a brief illustration of how the equations can be applied to the particular case

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 93.93.197.157 on 09/07/12

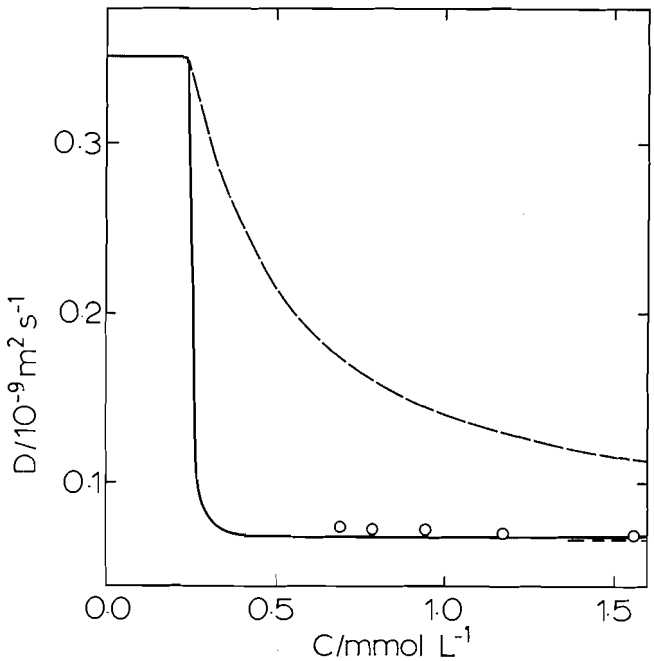

FIG. 4. Diffusion coefficients for aqueous Triton X-100 at 25°C: ○, interdiffusion coefficients measured by Weinheimer *et al.* (15); solid curve, predicted interdiffusion coefficients (eg. [21]); dashed curve, predicted intradiffusion coefficients (eq. [39]). At high concentrations, D approaches D_m, the diffusion coefficient of the micelles (horizontal dashed line).

of mixtures containing two solutes that form a 1:1 complex (21).

$A + B = AB$

If solute monomers A_1 and B_1 associate by forming complex A_1B_1, there are three different solute species and one reaction equilibrium. Only two flows of solute are independent. Diffusion of the solutes is described by ternary flow equations (eqs [1] and [2] with $N = 2$).

If total A and total B are chosen as the constituent solute components and if the solute species are numbered as follows: 1 = A_1, 2 = B_1, and 3 = A_1B_1, then the stoichiometric coefficients are given by

$$[25] \quad \nu = \begin{pmatrix} 1 & 0 & 1 \\ 0 & 1 & 1 \end{pmatrix}$$

Equations [11] and [25] furnish the following expressions for the Onsager coefficients of the solute components

$$[26] \quad L_{11} = (c_1D_1 + c_3D_3)/RT$$

$$[27] \quad L_{12} = L_{21} = c_3D_3/RT$$

$$[28] \quad L_{22} = (c_2D_2 + c_3D_3)/RT$$

Given the concentrations of total A and total B components, c_1 and c_2, respectively, the concentrations of the species can be evaluated by solving the conditions of mass balance and reaction equilibrium: $C_1 = c_1 + c_2$, $C_2 = c_2 + c_3$, $K = c_3/c_1c_2$. Differentiation of the expressions for the chemical potentials of the solute components

$$[29] \quad \mu_i = \mu_i^0 + RT \ln c_i$$

provides

$$[30] \quad \partial\mu_1/\partial C_1 = RT(1 - f_2)/c_1$$

$$[31] \quad \partial\mu_1/\partial C_2 = \partial\mu_2/\partial C_1 = -RTf_2/c_2$$

$$[32] \quad \partial\mu_2/\partial C_2 = RT(1 - f_1)/c_2$$

and hence

$$[33] \quad D_{11} = D_1 + f_2(D_3 - D_1)$$

$$[34] \quad D_{12} = f_1(D_3 - D_1)$$

$$[35] \quad D_{21} = f_1(D_3 - D_2)$$

$$[36] \quad D_{22} = D_2 + f_2(D_3 - D_2)$$

where f_1 and f_2 stand for

$$[37] \quad f_1 = c_2^{-1}/(c_1^{-1} + c_2^{-1} + c_3^{-1})$$

$$[38] \quad f_2 = c_1^{-1}/(c_1^{-1} + c_2^{-1} + c_3^{-1})$$

Equations [33]–[38] can be used to show that the multicomponent diffusivity of each component is not a simple concentration-weighted average of the diffusivities of the species containing that component, i.e. $D_{11} \neq (c_1D_1 + c_3D_3)/(c_1 + c_3)$. f_1 and f_2 can take the values $0 \leq f_i \leq 1$. Consequently, D_{11} and D_{22}, the diffusivities of the components, can take the values $D_3(A_1B_1) \leq D_{11} \leq D_1(A_1)$ and $D_3(A_1B_1) \leq D_{22} \leq D_2(B_1)$.

The expressions for D_{12} and D_{21} suggest that coupled diffusion will be important if the diffusivity of the complex A_1B_1 differs significantly from the diffusivity of species A_1 or B_1. Cross-coefficient D_{12}, for example, gives the flow of component A produced by the gradient in the concentration of component B. Due to the association reaction, an increase in the concentration of component B leads to an increase in the concentration of the complex A_1B_1 and to a corresponding decrease in the concentration of the species A_1. As a result, the gradient in component B (∇C_2) produces a gradient with the same sign in the concentration of the complex A_1B_1 (∇c_3), and an equal but opposite gradient in the concentration of the uncomplexed A_1 species ($\nabla c_1 = -\nabla c_3$). The net coupled flow of component A, which comprises the flow $-D_3(A_1B_1)\nabla c_3$ of complexed A plus the countercurrent flow $D_1(A_1)\nabla c_3$, is therefore proportional to $D_3 - D_1$. As $C_1/C_2 \rightarrow 0$, D_{12} vanishes because the gradient in component B and produce a coupled flow of component A in a solution that does not contain component A. Similarly, D_{21} is proportional to $D_3 - D_2$ and $D_{21} \rightarrow 0$ as $C_2/C_1 \rightarrow 0$.

Discussion

It is tempting to regard the binary diffusion coefficient of a self-associating solute as simply the average of the diffusion coefficients of the various solute species weighted according to the fraction of the total solute carried by each species, i.e.

$$[39] \quad D^* = \sum_i ic_iD_i/\sum_i ic_i = \sum_i ic_iD_i/C$$

In fact, the diffusion coefficient D^* defined in this manner corresponds to the intradiffusion coefficient of the solute (2, 19, 20, 33, 34). Intradiffusion coefficients can be measured by tagging some of the solute molecules with radioactive atoms, then following their motion through an otherwise homogenous solution in which the total concentration of labelled and unlabelled solute is uniform. Intradiffusion can also be measured by using nmr methods (35).

The interdiffusion coefficient (also known as the mutual

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 93.93.197.157 on 09/07/12
For personal use only.

diffusion coefficient), D, studied in this paper, in contrast, describe transport of solute from regions of high concentration to low concentration in non-uniform solutions. Equations [21] and [39] emphasize that D and D^* differ markedly; whereas D is obtained by giving the weight i^2c_i to the diffusion coefficient of an aggregate of i monomers, the weights ic_i give D^*.

The dashed curves in Figs. 2 and 4 give calculated intradiffusion coefficients for ethanol in carbon tetrachloride and for Triton X-100 in water. For a given solution, the interdiffusion coefficient D is smaller than the intradiffusion coefficient D^* because the former is more heavily weighted in favor of the larger aggregates which diffuse relatively slower. If eq. [39] is used to estimate interdiffusion coefficients, the predicted values will be too high. Indeed, this led Longsworth (25) to suspect that association of ethanol is stronger than suggested by infrared measurements. When the diffusivities of the ethanol polymers are weighted according to eq. [21], good agreement with experiment is obtained.

In this paper association constants have been used to predict binary diffusion coefficients. The results for ethanol in carbon tetrachloride suggest that reliable predictions can be made provided reliable estimates of the association constants and the mobilities of the various solute species are available. If reliable mobility estimates are available, as in the case of NMA in carbon tetrachloride, it will be feasible to invert this procedure, namely to use diffusion measurements to determine association constants.

Étude de la metallation des carbamates d'hydroxy-2,3,4 quinoléines

J. M. JACQUELIN, Y. ROBIN, A. GODARD ET G. QUEGUINER

Institut national supérieur de chimie industrielle de Rouen, Institut national des sciences appliquées, B.P. 8, 76130 Mont-Saint-Aignan, France

Reçu le 16 juin 1987

J. M. JACQUELIN, Y. ROBIN, A. GODARD et G. QUEGUINER. Can. J. Chem. **66**, 1135 (1988).

Les *N,N*-dialkyl *O*-quinolyl-3 ou 4) carbamates sont lithiés régiosélectivement en 4 (respectivement en 3) par le DIPAL dans le THF à −78°C. La métallation de l'isomère substitué en position 2 s'éffectue en *ortho* en utilisant le chélate *S*-BuLi/TMEDA dans le THF à −105°C. L'utilisation d'aldéhydes comme électrophiles a permis de mettre en évidence l'importance de l'encombrement stérique autour de l'atome d'azote de la fonction carbamate. De nombreux dérivés disubstitués ont été préparés.

J. M. JACQUELIN, Y. ROBIN, A. GODARD, and G. QUEGUINER. Can. J. Chem. **66**, 1135 (1988).

When *N,N*-dialkyl *O*-(quinolyl-3 or 4) carbamates are reacted with LDA in THF at −78°C lithiation occurs regioselectively at the *ortho* positions (respectively at C4 and C3). With the 2-substituted isomer better results can be obtained by using *sec*-butyllithium/TMEDA chelate instead of LDA in THF at −105°C. Each of the lithiated intermediates is treated with various electrophiles. The results of experiments with aldehydes afford convincing evidence of the influence of steric hindrance around the nitrogen of the carbamate functional group. Various disubstituted hydroxyquinolines have been prepared.

Si les réactions d'additions nucléophiles de réactifs organométalliques sur la quinoléine et ses dérivés sont connues depuis longtemps, la métallation directe par ces mêmes composés n'a été que peu étudiée. La réaction d'addition nucléophile concurrente a longtemps masqué la réaction de métallation. Cependant Bouley, Marsais et coll., dans notre laboratoire, sont parvenus à lithier puis à fonctionnaliser des halogéno-quinoléines avec des bons rendements par réaction avec le DIPAL (diisopropylamidure de lithium) (1, 2). Les premières métallations d'hydroxy-quinoléines masquées ont été réalisées par Gilman et Beel en 1951 (3). Cette réaction a notamment permis à Narasinham *et al.* de préparer des alcaloïdes dans la série des furoquinoléines par métallation des méthoxy-2 et diméthoxy-2,4 quinoléines substituées (4). Le groupement orthodirecteur alkoxy n'a cependant permis que l'obtention de faibles rendements en produits lithiés. Récemment, un nouveau groupement orthodirecteur a été utilisé pour la métallation de phénols et de pyridinols par Snieckus et coll. Ils décrivent la métallation de *N,N*-dialkyl *O*-arylcarbamates (5, 6). Pour ces auteurs, le groupement carbamate est plus puissant que les groupes éther et présente une meilleure régiosélectivité lors de la métallation de sites *ortho* non équivalents.[1]

Le groupe *N,N*-dialkylcarbamate, utilisé pour la première fois par Snieckus (7) en série π déficitaire, en tant que groupement orthoorienteur de la métallation des hydroxypyridines, nous a permis de metaller les hydroxyquinoléines substituées sur le noyau benzènique en utilisant la méthode de déplacement (9). Nous décrivons dans cette publication la métallation des hydroxyquinoléines substituées sur le noyau pyridinique.

Résultats et discussion

N,N-*Dialkyl* O-*(quinolyl-2) carbamates* 1

Les *N,N*-dialkyl *O*-(quinolyl-2) carbamates **1** (R = Me; R = Et) sont métallés par action du DIPAL à −78°C. Cependant les lithio-3 quinoléines formées ne réagissent pas avec des électrophiles car elles subissent *in situ* à −78°C un réarrangement anionique conduisant aux hydroxy amides correspondants **2** (R = Me; R = Et). Cette réaction notée, réarrangement anionique de Fries, a été précédemment constatée par Snieckus lors de l'action d'organométalliques sur les *O*-pyridyl carbamates à température ambiante (fig. 1).

Cependant par action du DIPAL sur le carbamate *N,N*-diethylé **1** (R = Et) à une température plus basse (−105°C) et avec l'utilisation du méthanol deutérié comme électrophile, on prépare le *N,N*-diéthyl *O*-((deutério-3) quinolyl-2) carbamate **4** avec un rendement de 40%. La formation du produit **2** (R = Et) n'est pas évitée. L'utilisation du chélate *sec*-butyllithium/-TMEDA (tetramethyl ethylène diamine) comme agent métallant, dans les mêmes conditions de température et de solvant, permet de porter le taux de conversion en composé **4** à 80% (fig. 2). Ayant mis en évidence la formation du dérivé lithié **3** dans les conditions citées plus haut nous avons testé sa réactivité vis à vis d'aldéhydes. Dans tous les cas la substitution a lieu de façon régiosélective sur le carbone 3 (fig. 3). Nous avons isolé les alcools secondaires attendus **5** (R^1 = Et 30%; R^1 = Ph 28%), ainsi qu'un isomère **6** (R^1 = Et 19% ; R^1 = Ph 24%) auquel nous avons attribué une structure de type quinolinone caractérisée par la présence en infrarouge de deux groupes carbonyle à 1700 cm^{-1} et 1660 cm^{-1}. La transformation **5** → **6** peut s'expliquer par l'attaque nucléophile de l'alcoolate intermédiaire sur la fonction carbonyle du composé **5** (fig. 3).

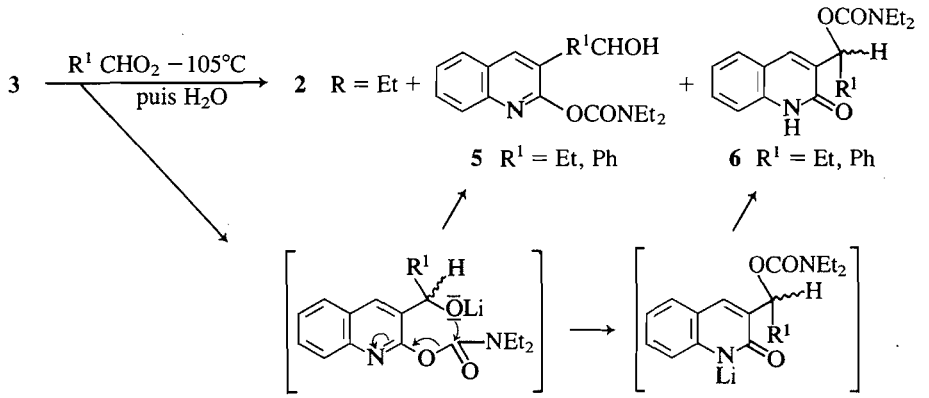

FIG. 3

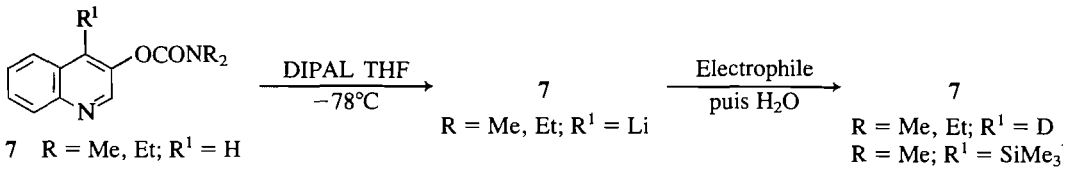

FIG. 4

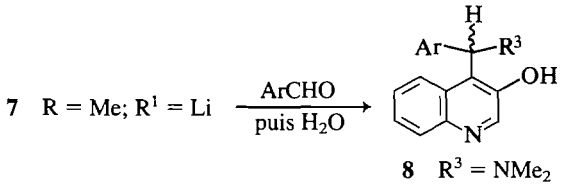

FIG. 5

N,N-*Dialkyl* O-*(quinolyl-3) carbamates* **7**

Les *N,N*-dialkyl *O*-(quinolyl-3) carbamates sont métallés régiosélectivement sur C4 par le DIPAL à −78°C. Les intermédiaires lithiés sont caractérisés sous forme de dérivés deutériés ou silylés obtenus respectivement par action du méthanol deutérié ou du chlorotriméthylsilane à −78°C (fig. 4). La position de métallation est établie en comparant les spectres de rmn ^1H des composés **7**, $R^1 = H$ et $R^1 = D$.

L'absence de tout produit issu d'un réarrangement anionique de Fries montre la bonne stabilité des dérivés lithiés **7** ($R^1 = Li$). De plus les rendements élevés rendent ces réactions très intéressantes en synthèse. Nous avons donc testé la réactivité des quinolyl-lithiums intermédiaires avec plusieurs aldéhydes. Nous avons précédemment montré que la réaction d'aldéhydes aromatiques sur le dérivé lithié du carbamate *N,N*-diméthylé **7** ($R = Me$; $R^1 = Li$) conduisait de façon inattendue aux *N,N*-dimethyl (hydroxy-3 quinolyl)-4 aryl méthane **8** ($R^3 = NMe_2$) avec de bons rendements (Ar = phényl, *para*-méthoxyphényl, *ortho*-méthoxyphényl, diméthoxy-2,4 phényl, chloro-2 phényl, *O*-thiényl, pyridyl-2) (8) (fig. 5).

Rappelons qu'un carbamate **8** ($Ar = C_6H_5$; $R^3 = OCONMe_2$) a pu être isolé lorsque le benzaldéhyde a été utilisé comme électrophile. Cependant ce composé est peu stable et perd facilement une molécule de CO_2 pour donner l'amine **8** ($Ar = C_6H_5$; $R^3 = NMe_2$). L'utilisation des autres aldéhydes donne directement l'amine dans les conditions de la réaction, la même réaction conduite avec le dérive *N,N*-diéthylé **7** ($R = Et$; $R^1 = Li$) et le benzaldéhyde comme électrophile fournit un mélange de carbamate **8** ($Ar = C_6H_5$; $R^3 = OCONEt_2$) et d'amine **8** ($Ar = C_6H_5$; $R^3 = NEt_2$) (fig. 6). Le taux de conversion du réactif est constant (75–80%) mais les proportions amine/carbamate sont variables et dépendent des conditions de traitement du mélange brut réactionnel. Contrairement au dérivé *N,N*-diméthylé la transformation du carbamate *N,N*-diéthylé en amine demande un chauffage prolongé.

Lorsque le *para*-méthoxybenzaldéhyde est utilisé comme électrophile on isole exclusivement le carbamate **8** (Ar = *p*-$MeOC_6H_4$; $R^3 = OCONEt_2$) (fig. 7). Ce composé s'avère stable puisque chauffé dans le xylène pendant 24 h il ne se décarboxyle pas.

L'isolement de carbamates de type **8** ($R^3 = OCONR_2$) permet de proposer un mécanisme en deux étapes :

(*i*) L'obtention du carbamate s'explique par un intermédiaire cyclique obtenu par action de l'alcoolate sur le carbonyle du carbamate initial (fig. 8).

(*ii*) Nous avons envisagé deux mécanismes pour expliquer la décarboxylation, soit une réaction intramoléculaire comprenant l'attaque de l'amine sur le carbone extracyclique dans un intermédiaire cyclique **A**, soit une réaction intermoléculaire avec formation d'une paire d'ions **B** et attaque de l'amine libérée (fig. 9).[2]

Afin de mettre en évidence le mécanisme mis en jeu dans cette derniére étape nous avons effectué la réaction de métallation avec le carbamate *N,N*-diméthylé **7** ($R = Me$; $R^1 = H$) et utilisé le benzaldéhyde comme électrophile. Aprés hydrolyse nous avons, à toutes les étapes du traitement, ajouté de la diéthylamine. Nous avons ainsi obtenu un mélange des deux amines **8** ($Ar = C_6H_5$; $R = NMe_2$, NEt_2). Ce résultat indique qu'un mécanisme intermoléculaire *B* peut être envisagé. Avec l'espèce lithiée issue du carbamate *N,N*-diméthylé **7** ($R = Me$; $R^1 = Li$) les aldéhydes aliphatiques réagissent de façon indentique à celle des aldéhydes aromatiques. Les amines **9** analogues des amines **8** ($R^3 = NMe_2$) sont obtenues avec des rendements de

2. Nous remercions sincèrement Monsieur le professeur V. Snieckus de nous avoir suggéré lors d'une discussion de prendre en considération ce deuxième mécanisme.

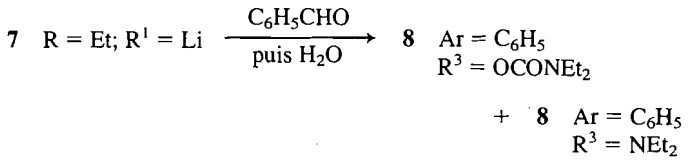

FIG. 6

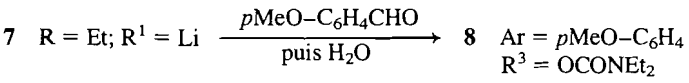

FIG. 7

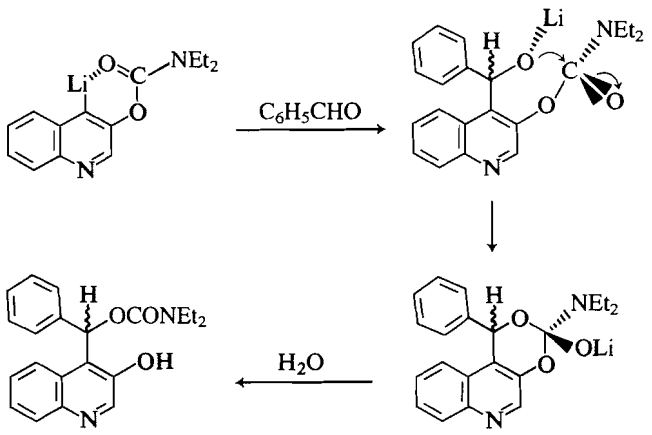

FIG. 8

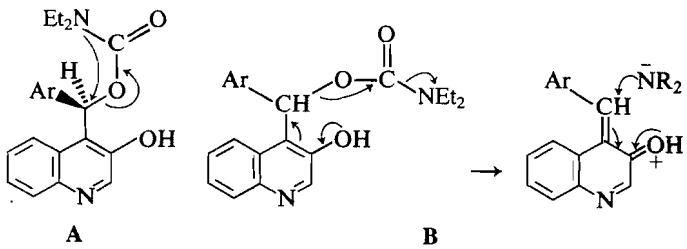

FIG. 9

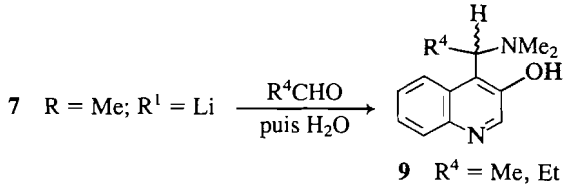
60%. Ces amines **9** peuvent en outre être transformées en dérivés vinyliques **10** par simple chauffage (fig. 10). Par contre, avec l'espèce lithiée issue du carbamate *N,N*-diéthylé **7** (R = Et; R^1 = Li) l'action des aldéhydes aliphatiques conduit aux alcools secondaires **11** avec des rendements assez faibles (25 et 30%) (fig. 11).

N,N-*Dialkyl* O-*(quinolyl-4) carbamates* **12**

Les *N,N*-dialkyl (*O*-quinolyl-4) carbamates **12** sont métallés par action du DIPAL à −78°C dans le THF. La forme lithiée **12** (R = Me; R^1 = Li) issue du carbamate *N,N*-diméthylé **12** (R = Me; R^1 = H) subit le réarrangement anionique de Fries et conduit à la *N,N*-diméthyl carbamoyl-3 1*H*-quinolone-4 **13** (80%) (fig. 12). L'intermédiaire lithié **12** (R = Et; R^1 = Li) provenant du carbamate diéthylé **12** (R = Et; R^1 = H) ne subit pas ce réarrangement et peut être caractérisé par réaction avec divers électrophiles. Les dérivés substitués en position 3 **12** (R = Et; R^1 = D, Me, $SiMe_3$) sont alors obtenus. Les bons rendements (75–95%) et la parfaite régiosélectivité nous ont amené à faire réagir l'intermédiaire **12** (R = Et; R^1 = Li) avec des réactifs carbonylés : des aldéhydes. Ainsi, après action du propanal, l'alcool secondaire **12** (R = Et; R^1 = CHOH—Et) est



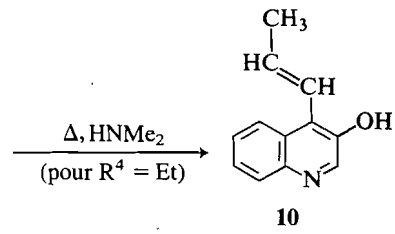


FIG. 10

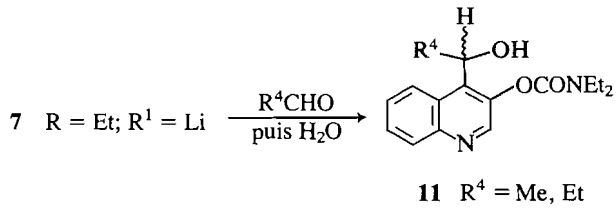

FIG. 11

isolé avec un rendement de 43%. Dans les mêmes conditions, l'action du benzaldéhyde conduit à un mélange de produits que nous n'avons pu séparer et qui, après reflux dans la soude, sont intégralement convertis en un seul dérivé **14**. L'analyse du spectre de rmn ^1H ne permet pas son identification. L'analyse du spectre infrarouge présente une seule vibration attribuée à un groupe carbonyl à 1660 cm^{-1}, caractéristique d'une forme quinolone. L'analyse élémentaire nous permet alors de proposer pour **14** la structure phényl-hydroxyméthyl-3 dihydro-1,4 oxo-4 quinoléine (fig. 12).

Conclusion

Nous avons étendu la méthode de fonctionnalisation proposée par Snieckus dans les séries du benzène et de la pyridine aux carbamates d'hydroxy-2, -3 et -4 quinoléines. L'utilisation d'un groupe orthodirecteur puissant permet dans notre cas l'utilisation du DIPAL moins nucléophile défavorisant les réactions d'addition nucléophile sur le cycle de la quinoléine qui y est très sensible. L'utilisation d'aldéhydes en tant qu'agents électrophiles a montré l'importance de la substitution de l'azote de la fonction carbamate. La mise en oeuvre de cette réaction très régiosélective a permis l'obtention de nombreux dérivés disubstitués. Nous étudions actuellement la possibilité d'utilisation de ces synthons pour la préparation d'alcaloïdes dans la série des furoquinoléines.

Partie expérimentale

Les points de fusion sont déterminés au banc de Kofler. Les spectres infrarouges sont enregistrés sur un spectrophotomètre Beckman Accu-lab TM2. Les microanalyses sont effectuées avec un appareil Carlo Erba CHNOS 1106. Les spectres de rmn ^1H sont enregistrés dans le chloroforme deutérié sauf précision contraire (référence TMS) à 60 MHz sur un appareil Varian EM-360L. **Note** : Dans les conditions d'enregistrement utilisées les sigaux de certains protons mobiles ne peuvent être attribués car ils sont trop étalés. Nous avons noté E pour électrophile.

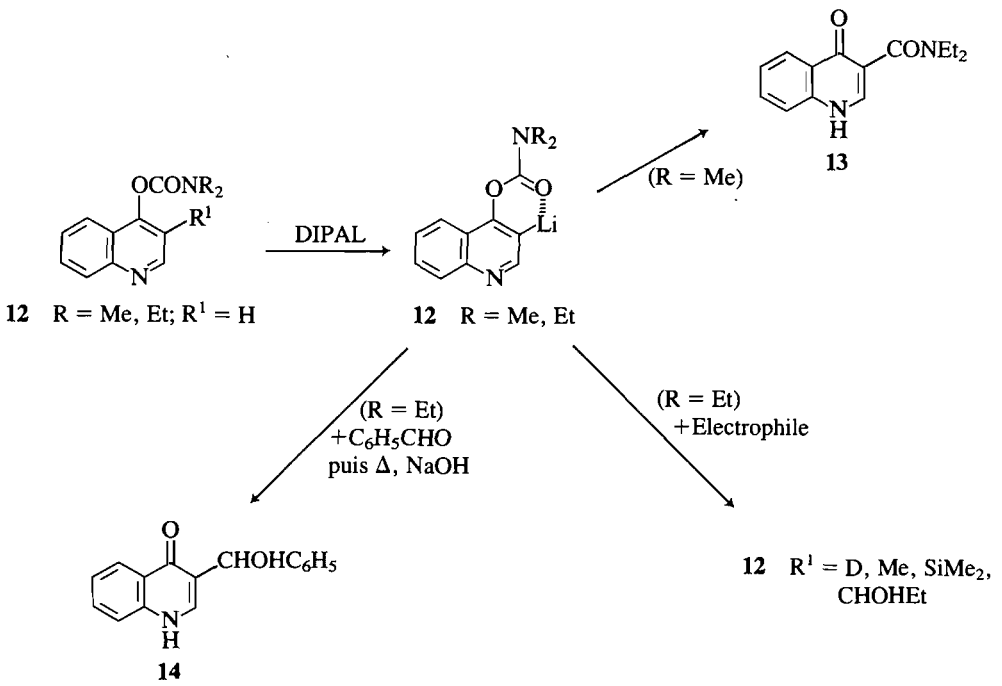

FIG. 12

N,N-*Dialkyl O-(quinolyl-X) carbamates*

Voie A

Dans 30 mL de pyridine, on chauffe durant 12 h 0,05 mol de quinolinol et 0,06 mol de chlorure de *N,N*-dialkylcarbamoyle. Après hydrolyse par 30 mL d'eau, décantation, la phase aqueuse est extraite par 2 × 50 mL de dichlorométhane. Le pyridine résiduelle est éliminée par entraînement azéotropique au toluène et le produit brut et purifié par filtration sur colonne d'alumine neutre (éluant CH_2Cl_2) et recristallisé dans l'hexane.

Voie B

Dans 100 mL de THF anhydre 0,05 mol de quinolinol et 0,06 mol de NaH sont agités 30 min à température ambiante. On introduit alors 0,06 mol de chlorure de *N,N*-dialkyl carbamoyle et le mélange réactionnel est porté à reflux 2 h. Le produit brut est récupéré et purifié de façon indentiques à la voie A.

Voie C

Identique à la voie B en utilisant 3 équivalents d'hydrure de sodium et 3 équivalents de chlorure de *N,N*-dialkyle carbamoyle.

1 (R = Me) : F = 76°C; rendement : 65% (voie B); ir (KBr; cm^{-1}) : 3060, 2920, 1720; rmn ^1H : 2,9(s, 3H, CH_3), 3,05(s, 3H, CH_3), 7,2(d, 1H, H3), 7,6(m, 3H, H5, H6, H7), 8,0 (dd, 1H, H8), 8,15(d, 1H, H4); J_{3-4} = 9 Hz. *Anal.* calc. pour $C_{12}H_{12}N_2O_2$: C 66,65, N 12,95, H 5,59; trouvée : C 66,35, N 12,88, H 5,52.

Techniques générales de métallation

Voie A

À une solution de 0,0050 mol de DIPAL dans 30 mL de THF anhydre, on ajoute à −78°C 0,0045 mol de carbamate dans 8 mL de THF. Après 1 h d'agitation l'électrophile est introduit à cette température et laissé réagir 1 h. Après hydrolyse et extraction au chloroforme à pH neutre le produit brut est purifié par chromatographie liquide sur silice.

Voie B

Une solution de 0,005 mol de chélate *S*-BuLi/TMEDA (préparée à 78°C en coulant la TMEDA dans l'alkyllithium) dans 30 mL de THF est refroidie à −105°C. Le carbamate (0,0045 mol dans 8 mL de THF) est introduit, laissé réagir 1 h, puis l'électrophile est coulé à −105°C. La récupération et la purification du produit brut sont identiques à celles utilisées dans la voie A.

2 (R = Me) (E = MeOD) : F = 220°C; rendement : 90% (voie A); ir (KBr; cm^{-1}) : 3050, 2980, 2930, 1665, 1635; rmn ^1H (DMSO δ ppm/HMDS) : 2,83(s, 3H, CH_3), 2,95(s, 3H, CH_3), 7,2–7,7(m, 4H, H5, H6, H7, H8), 7,95(s, 1H, H4). *Anal.* calc. pour $C_{12}H_{12}N_2O_2$: C 66,65, N 12,95, H 5,59; trouvée : C 66,72, N 13,18, H 5,44.

2 (R = Et) (E = MeOD) : F = 167°C; rendement : 90% (voie A); ir (KBr; cm^{-1}) : 3060, 2980, 2940, 1665, 1630; rmn ^1H : 1,16(t, 3H, CH_3), 1,33(t, 3H, CH_3), 3,36(q, 2H, CH_2), 3,68(q, 2H, CH_2), 7,2–7,7(m, 4H, H5, H6, H7, H8), 7,9(s, 1H, H4). *Anal.* calc. pour $C_{14}H_{16}N_2O_2$: C 68,83, N 11,47, H 6,60; trouvée : C 68,55, N 11,20, H 6,51.

4 (E = MeOD; 5 equiv.) : analyse du produit brut après extraction (bilan massique : 100%) indique la présence du produit **4**. L'intégration

Carbon-13 nuclear magnetic resonance spectroscopy in the solid state (cross polarization/magic angle spinning technique) is a very suitable method for studying the annular tautomerism of pyrazoles. In all the compounds studied, the tautomerism is frozen and the signals are well resolved except for 3,5-dimethyl-4-nitro pyrazole, which shows broad signals. In the case of 4-substituted derivatives of 3(5)-methylpyrazoles, the tautomer present in the solid state is a 4-X-5 methylpyrazole. 3-Phenyl-5-methylpyrazole (4*H* or 4-methyl) is favoured over the 3-methyl-5-phenyl tautomer.

ROBERT FAURE, ÉMILE-JEAN VINCENT, ANDRÉ ROUSSEAU, ROSA MARIA CLARAMUNT et JOSÉ ELGUERO. Can. J. Chem. **66**, 1141 (1988).

La résonance magnétique nucléaire à haute résolution du carbone-13 à l'état solide (technique polarisation croisée/rotation à l'angle magique) est une méthode parfaitement adaptée à l'étude de la tautomérie annulaire des pyrazoles. Pour tous les composés étudiés, l'échange prototropique est bloqué et les signaux sont fins et bien résolus, à l'exception de ceux du diméthyl-3,5 nitro-4 pyrazole qui sont très élargis. Dans le cas des dérivés du méthyl-3(5) pyrazole substitués en position 4, la structure du tautomère présent en phase cristalline est de la forme X-4 méthyl-5. En ce qui concerne les dérivés du phényl-3(5) méthyl-5(3) pyrazole, l'équilibre tautomère est totalement déplacé vers la forme dans laquelle le méthyle est en position 5.

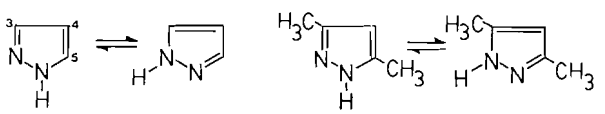
Introduction

In a series of papers (1–5), we have shown that high resolution ^{13}C nmr is a valuable tool for the study of tautomerism of azoles in the solid state, and, particularly, of annular tautomerism, i.e., prototropic tautomerism between nitrogen atoms (6*a*). In crystals, generally only one tautomer is present and, very seldom, two functional tautomers linked by hydrogen bonds have been observed by diffraction methods (6*b*). However, no clear example of the existence of two tautomers in a single crystal has been reported for annular tautomerism. In contrast to other types of tautomerism, annular tautomerism often involves two identical entities as in pyrazole **1***a* ⇌ **1***b* and in 3,5-dimethylpyrazole **2***a* ⇌ **2***b* (this is called autotropic rearrangement or degenerate tautomerism (6*c*)).



1a **1b** **2a** **2b**

In the case of pyrazole **1** (1) (and of all other "parent" azoles (2)) the equilibrium **1***a* ⇌ **1***b* is frozen at room temperature in the solid state. Only in the case of 3,5-dimethylpyrazole have we observed a dynamic behaviour in the crystal at room temperature (3) by ^{13}C CP/MAS spectroscopy. At low temperature (T = 233 K) the **2***a* ⇌ **2***b* interconversion is frozen (3).

To generalize these observations to other pyrazoles substituted at positions 3 and 5 with identical substituents ("symmetrical" pyrazoles) or different substituents ("asymmetrical" pyrazoles) we have studied 14 *N*-unsubstituted pyrazoles. For comparative purposes, we have also studied an *N*-substituted derivative: 1,5-dimethyl-4-bromopyrazole, **14**CH_3. We must stress that all these pyrazoles are microcrystalline compounds and this, in the case of asymmetric pyrazoles, implies that most probably, only one tautomer will be observed (K_T = 0), although the possibility of a hydrogen bonded dimer (K_T = 1) of the two different tautomers cannot be ruled out.

Results and discussion

In Table 1 we have collected the ^{13}C chemical shifts of NH pyrazoles in the solid state (this work, except **1** (1) and **2** (3)) and in DMSO-d_6 solution (7). The ^{13}C chemical shifts of the corresponding *N*-methyl derivatives are necessary to discuss the annular tautomerism of asymmetric pyrazoles. Three kinds of data concerning these last compounds are given in Table 1: (*i*) literature data (7); (*ii*) some new data of pyrazoles synthesized especially for this work (1,3,5-trimethyl-4-nitropyrazole, **4**CH_3, 1,3-dimethyl-5-bromopyrazole, **17**CH_3, and 1,4,5-trimethyl-3-phenylpyrazole, **23**CH_3); (*iii*) several chemical shifts (in italics in Table 1), which have been estimated from the results of ref. 7.

Symmetrical pyrazoles

In solution, the rapid exchange of the tautomeric proton between both nitrogens (6*d*) leads, in compounds **1–8**, to an isochrony of the signals corresponding to the C-3 and C-5 carbon atoms. For these compounds in the solid state at room temperature we observe well-resolved signals and a clear difference between the chemical shifts of C-3 and C-5, the only exceptions being the 3,5-dimethylpyrazole **2** (3) and 3,5-

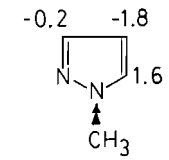
dimethyl-4-nitropyrazole **4** already described. For the last compound the signals corresponding to C-3 and C-5 are large but still clearly different.

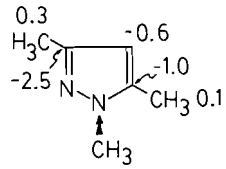
The singular behaviour of compound **4** has two possible explanations: (*i*) a prototropy with a relatively fast exchange rate as in 3,5-dimethylpyrazole **2** (3); (*ii*) an incomplete suppression of the dipolar coupling between ^{14}N and ^{13}C (8). Experiments are on the way (variable temperature studies, nqr, ^{15}N isotopic labelling) to solve this problem[3] but we call attention to the fact that the other 4-nitro derivative **9/10** (see later) shows narrow signals.

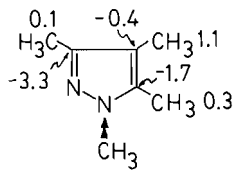
The mean value of the C-3 and C-5 carbon chemical shifts measured in the solid state is close to the value observed in solution. The differences ($\delta_{solid} - \delta_{solution}$:**1**, C: −0.3; **2**, CH: −0.3, C: 0.4; **3**, CH: −0.3, C: 1.7; **4**, CH: 0.5, C: 1.1; **5**, CH: 0.7, C: 0.6; **6**, CH: −1.1, C: 1.2; **7**, CH: 0.0, CH: −0.8, C: 0.6; **8**, CH: 0.8; C: 1.7, C: 0.8) are small enough to assume that pyrazoles in the solid state are good models of fixed tautomers.

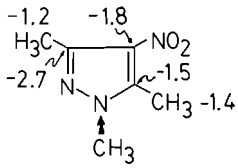
Thus in the following discussion we shall consider the chemical shifts measured in the solid state identical to those the pyrazole would present in solution if there were no tautomerism.

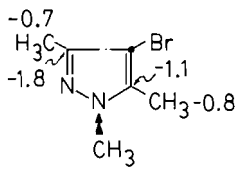
Taking into account the preceding comment, the *N*-methylation effects will be defined as $\Delta\delta = \delta_{N—CH_3\ (solution)} - \delta_{N—H\ (solid)}$. For symmetric pyrazoles, we have calculated the following $\Delta\delta$ values:

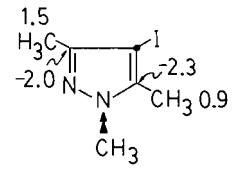




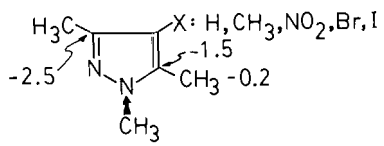








In the case of 3,5-dimethylpyrazoles the effects are quite constant. The averaged values for compounds **2, 3, 4, 5,** and **6** are

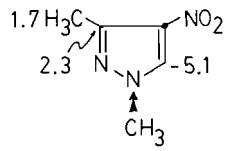


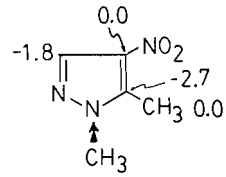
Asymmetrical pyrazoles

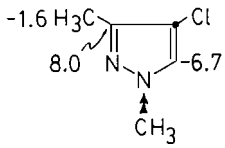
For these pyrazoles, both annular tautomers are of different energy and hence the following equilibria must be considered: **9** ⇌ **10, 11** ⇌ **12, 13** ⇌ **14, 15** ⇌ **16, 17** ⇌ **18, 19** ⇌ **20, 21** ⇌ **22**, and **23** ⇌ **24**. In solution, both tautomers are present in relative amounts that depend on the nature of the substituents, the solvent, the temperature, and the concentration (6*e*). During the crystallization process the equilibrium shifts towards the more stable or the less soluble tautomer, and so only one tautomer is expected in the crystal. A remote possibility exists that both tautomers could crystallize together to form a 1:1 mixed crystal.

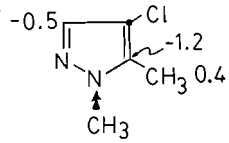
With the exception of 3(5)-phenyl-5(3)-methylpyrazole **21/22**, the remaining pyrazoles show a unique set of signals, thus confirming the existence of a unique tautomer in the solid state. For some compounds, **13/14, 15/16**, and 1,5-dimethyl-4-bromopyrazole, **14**CH_3, a splitting of the methyl signal is observed. We have not considered these supplementary signals for the determination of the tautomeric structure since (*i*) the last compound, unable to show tautomerism, shows this behaviour also; (*ii*) the splitting is not observed for the other signals; (*iii*) some supplementary carbon resonances in the CP/MAS ^{13}C nmr spectra are not of molecular origin (8, 10).

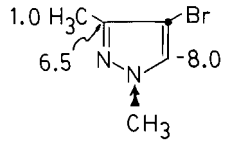
For asymmetric pyrazoles, the effects (defined previously) due to *N*-methylation are

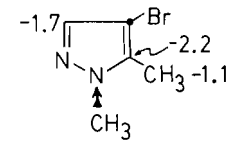


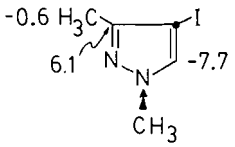


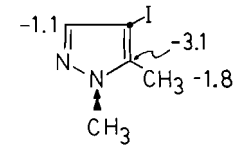


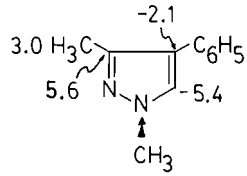


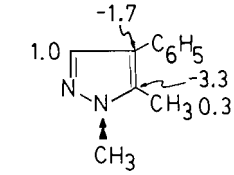


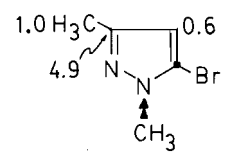


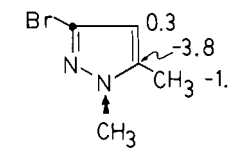


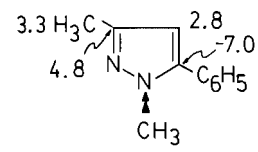


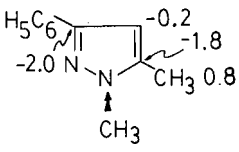












[3] J. Elguero and J. A. S. Smith. Work in progress.

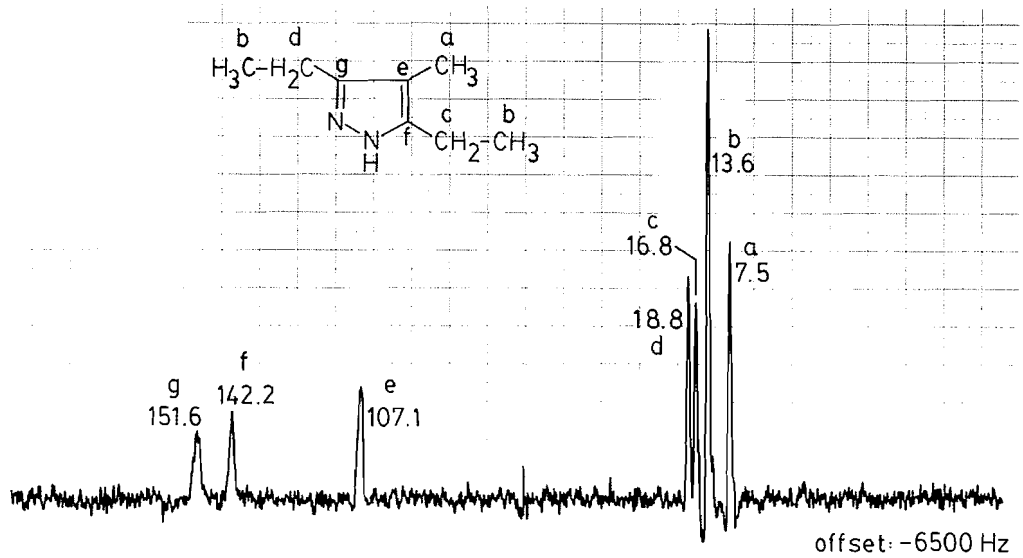


FIG. 1. The ^{13}C nmr spectrum of 3,5-diethyl-4-methylpyrazole **7**.

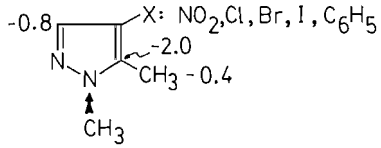
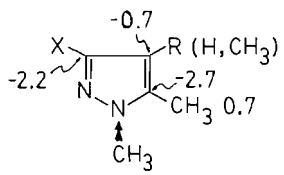
Comparing these values with those obtained for symmetrical pyrazoles, it can be concluded that:

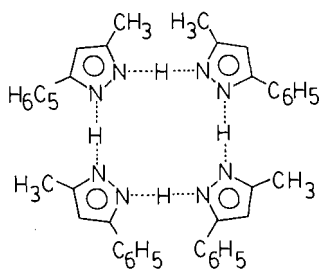
(*i*) 3(5)-Methylpyrazoles substituted at position 4 by an X group (NO_2, Cl, Br, I, C_6H_5) exist in the solid state as 4-X-5-methylpyrazoles **10, 12, 14, 16,** and **20**. As a matter of fact the averaged Δδ values are, as a whole, comparable to those previously reported for symmetrically substituted pyrazoles.



(*ii*) 3(5)-Methyl-5(3)-X-pyrazoles exist in the solid state as 3-X-5-methylpyrazoles **18, 21**, and **23**; the corresponding averaged Δδ values are



The structure of 3(5)-phenyl-5(3)-methylpyrazole **21/22** was determined by neutron diffraction (11). In the solid state, this compound exists as a cyclic tetramer with the tautomeric proton equidistant from both nitrogen atoms.



In this case with the neutron diffraction results it is not possible to determine the tautomer present in the solid state. However, the splitting of some carbon resonances observed in the ^{13}C nmr spectrum recorded at 75 MHz is not attributable to a mixture of tautomers **21** and **22**, since it affects essentially the carbon resonances of the phenyl ring. The 12 lines observed for this substituent could correspond to two different conformations of the phenyl in the crystal. In any case, this compound deserves further study.[3]

Conclusion

This study has corroborated the earlier observation (1, 2) that in the solid state "rapid"[4] annular tautomerism is seldom observed. The reasons why a given tautomer is preferred in the solid state are not clearly understood at the present moment. For 3(5)-methylpyrazole (liquid at room temperature), a solution study (12) shows that the 5-methyl tautomer is slightly more stable (54% in hexamethylphosphoramide at −17°C) than the 3-methyl tautomer. The difference in energy is very small, but this preference of the methyl group for position 5, together with the preferences of the bromo and phenyl substituents for position 3 (6*f*), will favour tautomers **18, 21**, and **23**.

Experimental

Spectra were obtained with a Bruker CXP-200 FT nmr spectrometer (Centre d'études nucléaires de Grenoble), operating at an applied field strength of 4.7 T or a ^{13}C resonance frequency of 50.31 MHz. A typical cross-polarization time was 5 ms with a recycle time of 10–15 s. Spectral width, 20.0 kHz. Spinning rate (estimated from the location of spinning sidebands), 3.2–3.5 kHz. Proton decoupling field, ≥ 1.2 mT. The ^{13}C nmr signal of linear poly(ethylene) pellets was used as internal reference (the poly(ethylene) signal was taken as 33.63 ppm downfield from tetramethylsilane (9)). A typical spectrum (3,5-diethyl-4-methylpyrazole **7**) is given in Fig. 1.

Acknowledgements

We wish to thank Drs. G. Hermann and M. Ziliox (Bruker Spectrospin, Wissembourg, France) for recording the spectrum of 3(5)-phenyl-5(3)-methylpyrazole **21/22** on a Bruker MSL-300 spectrometer (Bruker Analytische Messtechnik GmbH, Karlsruhe, Germany).

[4]Rapid in the sense that it produces broad signals at room temperature with 50- to 75-MHz instruments.

Cationic complexes of titanium(III); phosphine substitution reactions

PATRICIA A. SEEWALD, GRAHAM S. WHITE, AND DOUGLAS W. STEPHAN[1]

Department of Chemistry and Biochemistry, University of Windsor, Windsor, Ont., Canada N9B 3P4

Received October 19, 1987

PATRICIA A. SEEWALD, GRAHAM S. WHITE, and DOUGLAS W. STEPHAN. Can. J. Chem. **66**, 1147 (1988).

The Ti(III) compound $[Cp_2Ti(CH_3CN)_2]_2[ZnCl_4]$, **1**, has been prepared and crystallizes in the space group *Pbca* with a = 28.444(11) Å, b = 15.370(4) Å, c = 15.206(5) Å, and Z = 8. The BPh_4 salt (i.e., $[Cp_2Ti(CH_3CN)_2][BPh_4]$, **2**) is a convenient precursor for Ti(III) cationic phosphine complexes. Reaction of **2** with several monodentate phosphines has been monitored by epr spectroscopy. Compound **2** reacts with PMe_3 in a stepwise fashion, to replace the coordinated CH_3CN molecules, yielding $[Cp_2Ti(CH_3CN)(PMe_3)][BPh_4]$, **3**, and $[Cp_2Ti(PMe_3)_2][BPh_4]$, **4**. Complex **4** exhibits a quasi-reversible cyclic voltammogram at −0.40 V vs. SCE, in the presence of excess PMe_3. This is indicative of a Ti(III)/Ti(II) redox couple thus generating the known Ti(II) species $Cp_2Ti(PMe_3)_2$. Similar reactions of **2** with PEt_3 show that only the monosubstitution product $[Cp_2Ti(CH_3CN)(PEt_3)]^+$, is formed even in the presence of excess phosphine. No substitution was seen with either PCy_3 or PPh_3. The steric and electronic factors affecting substitution are briefly considered.

PATRICIA A. SEEWALD, GRAHAM S. WHITE et DOUGLAS W. STEPHAN. Can. J. Chem. **66**, 1147 (1988).

On a préparé le composé du Ti(III) $[Cp_2Ti(CH_3CN)_2]_2[ZnCl_4]$, **1**, et il cristallise dans le groupe d'espace *Pbca*, avec a = 28,444(11), b = 15,370(4) et c = 15,206(5) Å et Z = 8. Le sel de BPh_4 (soit le $[Cp_2Ti(CH_3CN)_2][BPh_4]$, **2**, est un précurseur approprié pour les complexes cationiques phosphious du Ti(III). Faisant appel à la rpe, on a examiné la réaction du compose **2** avec plusieurs phosphines monodentates. La réaction du composé **2** avec la PMe_3 conduit à un remplacement par étapes des molécules de CH_3CN coordonnées et à la formation des composés $[Cp_2Ti(CH_3CN)(PMe_3)]_2[BPh_4]$, **3**, et $[Cp_2Ti(PMe_3)_2]_2[BPh_4]$, **4**. A −0,40 V vs, SCE, en présence d'un excès de PMe_3, le complexe **4** présente un voltampérogramme cyclique pratiquement réversible. Ce resultat suggère l'existence d'un couple redox Ti(III)/Ti(II) qui génère le composé du Ti(II) $Cp_2Ti(PMe_3)_2$. Des réactions similairés du composé avec le PEt_3 indiquent qu'il se forme un seul produit de monosubstitution, le $[Cp_2Ti(CH_3CN)(PEt_3)]^+$, même en présence d'un excès de phosphine. On n'a observé aucune substitution soit avec le PCy_3 soit avec la PPh_3. On discute brièvement de la nature des facteurs stériques et electroniques qui affectent la substitution.

Introduction

Our interest in early transition metal complexes stems from their utility as synthetic precursors to heterobimetallic species (1–11). Such bimetallic complexes are of interest because of their potential applications in catalysis. Recently, in an effort to expand the arsenal of metalloligands available, we described the synthesis and chemistry of some Ti(IV), Zr(IV), and Ti(III) phosphine chalcogenide complexes (12). It is of interest to further develop the monometallic chemistry of Ti(III) with a view to examining chemistry which may subsequently provide synthetic routes to new heterobimetallic complexes. In this vein, we have examined some simple phosphine substitution chemistry of Ti(III) cations. Such cationic Ti(III) complexes are of interest in their own right. Whereas cationic Ti(IV) and Zr(IV) complexes have found numerous applications in the activation of organic substrates (13–16), little of the chemistry of analogous Ti(III) species has been investigated (17).

Experimental section

All preparations were done under an atmosphere of dry, O_2-free N_2. Solvents were reagent grade, distilled from the appropriate drying agents under N_2, and degassed by the freeze–thaw method at least three times prior to use. Electron paramagnetic resonance spectra were recorded on a Varian E-12 spectrometer, using DPPH as the reference. Ultraviolet–visible data were recorded on a Hewlett Packard 8451A diode array spectrophotometer. Cyclic voltammetry experiments were performed using a BAS CV-27 potentiostat. A platinum disk electrode was used and the potentials reported are relative to SCE. $Na[BPh_4]$ was used as the supporting electrolyte. Combustion analyses were performed by Galbraith Laboratories Inc., Knoxville, TN. $[Cp_2Ti(CH_3CN)_2][BPh_4]$, **2**, was prepared by the literature method (17). Cp_2TiCl_2 was purchased from the Aldrich Chemical Co.

Preparation of $[Cp_2Ti(CH_3CN)_2]_2[ZnCl_4]$, 1

Following the procedure of Green and Lucas (18) for the preparation of $Cp_2TiCl_2ZnCl_2TiCp_2$, 8.3 g (33.3 mmol) of Cp_2TiCl_2 was suspended in 200 mL of THF. Zn dust (2.3 g, 35.2 mmol) was added and the mixture was stirred for 4 h. During this time the solution went from its initial red–orange colour to dark green. The solution was filtered and concentrated to 75 mL. Addition of 25 mL of CH_3CN resulted in a colour change to dark blue. Addition of 100 mL of diethyl ether, and allowing the mixture to stand overnight, led to the precipitation of dark blue crystals. The crystals were isolated by filtration. Yield 5.0 g (6.87 mmol, 41%). *Anal.* calcd for $C_{28}H_{32}Cl_4N_4Ti_2Zn$: C 46.22, H 4.43, N 7.70; found: C 45.83, H 4.49, N 7.66. Electron paramagnetic resonance (CH_3CN): g = 1.983; $a\langle^{47}Ti/^{49}Ti\rangle$ = 12.0 G. Visible (CH_3CN; λ, nm (ε, M^{-1} cm^{-1})): 578 (80).

Reaction of 2 with PR_3 (R = Me, Et, Cy, Ph), formation of $[Cp_2Ti(CH_3CN)(PR_3)][BPh_4]$ (R = Me, 3, R = Et, 5)

2 (20 mg, 0.063 mmol) were combined with 1, 2 or excess equivalents of the phosphines. The solutions were stirred overnight and the epr of the reaction mixtures were recorded. Approximate integrations of the epr spectra were obtained from simulations and were used to determine the equilibrium constants. **3**: epr (THF): g = 1.986; $a\langle^{31}P\rangle$ = 20.3 G, $a\langle^{47}Ti/^{49}Ti\rangle$ = 9 G. **5**: epr (THF): g = 1.985; $a\langle^{31}P\rangle$ = 19.3 G, $a\langle^{47}Ti/^{49}Ti\rangle$ = 9 G.

Preparation of $[Cp_2Ti(PMe_3)_2][BPh_4]$, 4

To a solution of 300 mg (0.52 mmol) of **2** in 40 mL of THF was added 220 mg (2.89 mmol) of PMe_3. The mixture was stirred for 48 h. During this time the solution became pale blue in colour. The solution was filtered and pentane was added slowly. On standing, a light blue solid precipitated from solution which was isolated by filtration. Yield 200 mg (59%); mp 255–260°C(dec). *Anal.* calcd for $C_{40}H_{48}BP_2Ti$: C 73.97, H 7.44; found: C 69.54, H 7.17.[2] Electron paramagnetic resonance (THF): g = 1.989; $a\langle^{31}P\rangle$ = 30.0 G, $a\langle^{47}Ti/^{49}Ti\rangle$ = 9.6 G.

[1]Author to whom all correspondence should be addressed.

[2]In this instance poor analytical results were obtained despite recrystallizations and repeated analyses. Such discrepancies have been seen with other Cp_2Ti compounds (6, 7) also see ref. 40.

TABLE 1. Crystallographic parameters

Formula	$C_{20}H_{32}Cl_4N_4Ti_2Zn$
Crystal colour, form	Dark blue prisms
Crystal system	Orthorhombic
Space group	*Pbca*
a (Å)	28.444(11)
b (Å)	15.206(5)
c (Å)	15.370(4)
Volume (Å^3)	6648(4)
Density (g cm^{-3})	1.45
Z	8
Crystal dimension (mm)	0.44 × 0.44 × 0.46
Absorption coefficient, μ (cm^{-1})	14.50
Radiation λ, Å	Mo Kα (0.71069)
Temperature (°C)	24
Scan speed (deg/min)	2.0–5.0
Scan range (deg)	1.0 below $K\alpha_1$, 1.0 above $K\alpha_2$
Background/scan time ratio	0.5
Unique data	3577
Data $F_o^2 > 3\sigma(F_o^2)$	1596
Number of variables	252
R (%)	6.00
R_w (%)	6.42
Max Δ/σ in final cycle	0.001
Maximum residual electron density (e/Å^3), atom associated	0.74, C25, C29

Cyclic voltammogram (THF with excess PMe_3 added): −0.40 V vs. SCE. Ultraviolet–visible (THF, λ, nm (ε, M^{-1} cm^{-1})): 368 (330).

X-ray data collection and reduction

Dark blue crystals of **1** were obtained by crystallization from CH_3CN/diethyl ether. Diffraction experiments were performed on a four-circle Syntex $P2_1$ diffractometer with graphite-monochromatized Mo Kα radiation. The initial orientation matrix was obtained from 15 machine-centred reflections selected from a rotation photograph. These data were used to determine the crystal system. Partial rotation photographs around each axis were consistent with an orthorhombic crystal system. Ultimately, 30 high-angle reflections ($15° < 2\theta < 25°$) were used to obtain the final lattice parameters and the orientation matrix. Machine parameters, crystal data, and data collection parameters are summarized in Table 1. The observed extinctions were consistent with the space group *Pbca*. $+h$, $+k$, $+l$ data were collected in one shell ($4.5° < 2\theta < 40.0°$). During the data collection three standard reflections were recorded every 197 reflections. The intensities of the standards showed no statistically significant change over the duration of the data collection. The data were processed using the SHELX-76 program package on the computing facilities at the University of Windsor. A total of 1596 reflections with $F_o^2 > 3\sigma F_o^2$ were used in the refinements. No absorption correction was applied to the data.

Structure solution and refinement

Non-hydrogen atomic scattering factors were taken from the literature tabulations (19, 20). The Ti and Zn atom positions were determined using direct methods. The remaining non-hydrogen atoms were located from successive difference Fourier map calculations. The refinement was carried out by using full-matrix least-squares techniques on *F*, minimizing the function $\Sigma w(|F_o| - |F_c|)^2$ where the weight, *w*, is defined as $4F_o^2/\sigma^2(F_o^2)$ and $|F_o|$ and $|F_c|$ are the observed and calculated structure factor amplitudes. In the final cycles of the refinements the metal atoms, Cl, N, and C atoms of the acetonitrile moieties were assigned anisotropic temperature factors. The carbon atoms of the cyclopentadienyl rings were described by isotropic thermal parameters. Hydrogen atom positions were allowed to ride on the carbon to which they are bonded assuming a C—H bond length of 0.95 Å. Hydrogen atom temperature factors were fixed at 1.10 times the isotropic temperature factor of the carbon atom to which they are bonded. In all cases the hydrogen atom contributions were calculated, but not refined. The final values of $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$ and $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma wF_o^2)^{1/2}$ are given in Table 1. The maximum Δ/σ on any of the parameters in the final cycles of the refinement and the location of the largest peak in the final difference Fourier map calculations are also given in Table 1. The residual electron density was of no chemical significance. The following data are tabulated: positional parameters (Table 2); selected bond distances and angles (Table 3). Thermal parameters (Table S1), hydrogen atom parameters (Table S2) bond distances and angles associated with the cyclopentadienyl rings and $ZnCl_4$ dianion (Table S3) and values of $10|F_o|$ and $10|F_c|$ (Table S4) have been deposited as supplementary material.[3]

Results and discussion

The reduction of Cp_2TiCl_2 by Zn dust is a well known route to the Ti(III) chloro-bridged dimer (18). The intermediate, i.e., $Cp_2TiCl_2ZnCl_2TiCp_2$, in this reaction has been previously described (18). Cleavage of the Zn bridged species by a donor ligand results in the formation of the Ti(III) cations and $[ZnCl_4]^{2-}$. Use of acetonitrile to effect this cleavage results in the formation a dark blue crystalline product, **1**. The epr spectrum of **1** shows a central resonance with a *g* value of 1.983. Hyperfine couplines to ^{49}Ti and ^{47}Ti of 12.0 G are also observed. Based on the spectroscopic data and elemental analyses, **1** is formulated as $[Cp_2Ti(CH_3CN)_2]_2[ZnCl_4]$. This formulation was confirmed by X-ray crystallography (*vide infra*).

An X-ray crystallographic study of **1** revealed that the crystals were made up of orthorhombic unit cells each containing eight formula units. The closest nonbonded distance between the cations and the anion is 2.572 Å (Cl2—H2B). The closest nonbonded distance between cations is 2.523 Å (H2A—H8A). Selected interatomic dimensions are given in Table 3. An ORTEP drawing of the cations is given in Fig. 1. The geometry of the dianion is tetrahedral with Zn—Cl distances averaging 2.268(5) Å. The geometries of the Ti atoms are pseudotetrahedral. Two π-bonded cyclopentadienyl rings and two nitrogen atoms of the acetonitrile moieties comprise the Ti coordination sphere. The Ti—C distances in the two crystallographically distinct cations are not statistically different. The average Ti—C distance is 2.36(2) Å. Ti—N bond distances average 2.16(2) Å. The Cp—Ti—Cp angles are 134.8(5) and 135.1(5)° in the two cations in the asymmetric unit. This is in the range seen in a wide variety of Cp_2MX_2 type complexes (21–36). The N—Ti—N angles in the two independent cations are 80.6(5) and 80.8(5)°, respectively. This angle is similar to that seen in the Ti(III) species $Cp_2Ti(PMe_3)Cl$ (Cl—Ti—P angle 80.4(1)°) (32). It is larger than the O—Ti—O, angles of 78.6 and 76.9° found in the two crystallographically independent cations of $[Cp_2Ti(THF)(acetone)]^+$ (23) yet considerably smaller than the X—M—X angles seen in the other d^1 complexes $[Cp_2MoCl_2]BF_4$ (87.9°) (21) and Cp_2NbCl_2 (85.6°) (21). It is noteworthy that the N—Ti—N angle is also lower than that predicted from the EHMO calculations of Lauher and Hoffman for the X—M—X angles of d^1 Cp_2MX_2 complexes (approximately 85°) (36).

Preliminary attempts to effect phosphine substitution on the cation of **1** showed that the anion was a source of interfering side reactions. Thus, to examine such reactions, it was necessary to employ $[Cp_2Ti(CH_3CN)_2][BPh_4]$. This salt, **2** was prepared by known methods from $[Cp_2TiCl]_2$ (17).

The reaction of **2** with PMe_3 was performed and monitored by

epr spectroscopy. Addition of one equivalent of PMe_3 gave rise to a complex epr spectrum (Fig. 2*b*), in which signals arising from three species in equilibria are present. The equilibria involved are given in reactions [1] and [2]. The equilibrium constants for these reactions simplify to $K_{eq_1} = [\mathbf{3}]^2/[\mathbf{2}][PMe_3]$ and $K_{eq_2} = [\mathbf{4}]^2/[\mathbf{3}][PMe_3]$. Estimations of these equilibrium constants were obtained by simulation of the spectrum where 1 equiv. of PMe_3 was added; $K_{eq_1} \simeq 50$, $K_{eq_2} \simeq 10$.

[1] $[Cp_2Ti(CH_3CN)_2]^+ + PMe_3 \rightleftharpoons$

2

$[Cp_2Ti(CH_3CN)(PMe_3)]^+ + CH_3CN$

3

[2] $[Cp_2Ti(CH_3CN)(PMe_3)]^+ + PMe_3 \rightleftharpoons$

3

$[Cp_2Ti(PMe_3)_2]^+ + CH_3CN$

4

In the presence of excess PMe_3, the equilibria shift such that they are dominated by species **3** and **4**. The epr spectrum (Fig. 2*c*) shows resonances arising from only two species. Overlapping doublet and triplet signals are observed. These signals arise from the coupling of the unpaired electron to one or two phosphorus nuclei in **3** and **4**, respectively. The *g* value for **3** is 1.986, while for **4** it is 1.989. The *A* values are 20.3 and 30.0 G for **3** and **4**, respectively. Molecular orbital calculations (36), as well as single crystal epr studies (37) of d^1 complexes of the form Cp_2ML_2 show that the unpaired electron resides in an orbital that is in the TiL_2 plane. The greater *A* value for **4** implies a better overlap of this a_1 Ti orbital (i.e., the singly occupied orbital) with the orbitals on phosphorus. Such an increase in overlap would result from an increase in the L—Ti—L angle. In the case of **4**, steric interactions between the phosphine substituents may account for such an increase. The suggestion of steric effects affecting the L—Ti—L angle is consistent with the geometry changes observed in the structurally related Ti(II) complexes $Cp_2Ti(CO)_2$, $Cp_2Ti(CO)(PMe_3)$, and $Cp_2Ti(PMe_3)_2$ (32, 33, 35).

Compound **4** can be isolated from the equilibrium mixture, where excess PMe_3 is present, by precipitation with hexane. The epr spectrum of **4** in THF shows the expected triplet (Fig. 2*d*). The absence of other signals indicates that, at least in THF, phosphine dissociation does not ocur.

Compounds **2** and **4** were studied by cyclic voltammetry in THF or CH_3CN using a Pt electrode and $Na[BPh_4]$ as the supporting electrolyte. Under these conditions, no reversible

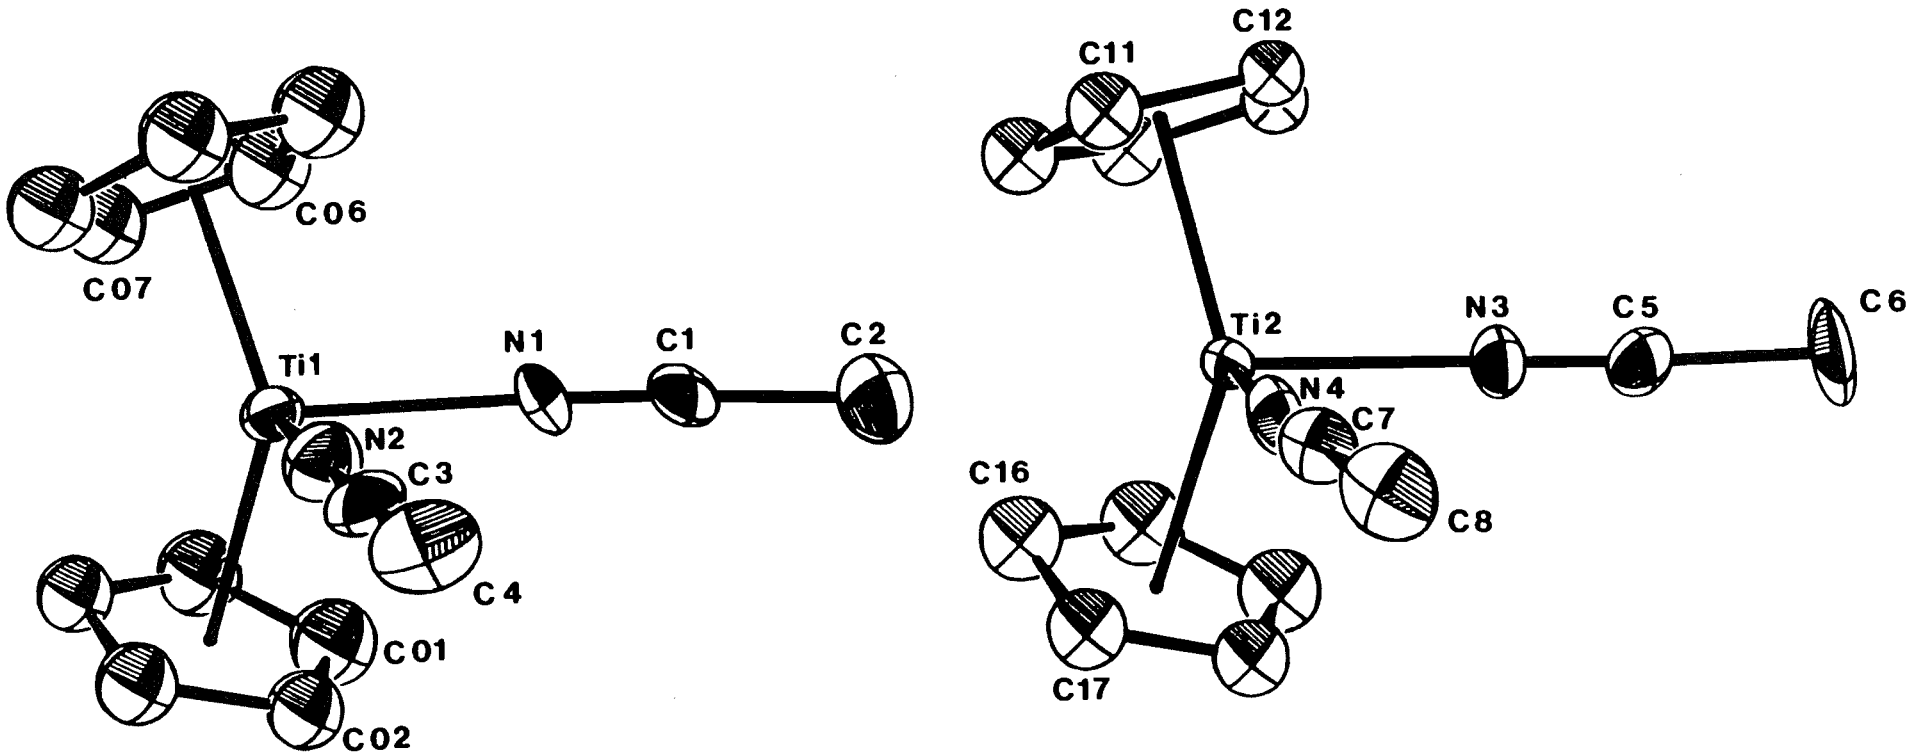

FIG. 1. ORTEP drawing of the cations of **1**, 30% thermal ellipsoids are shown, hydrogen atoms are omitted for clarity.

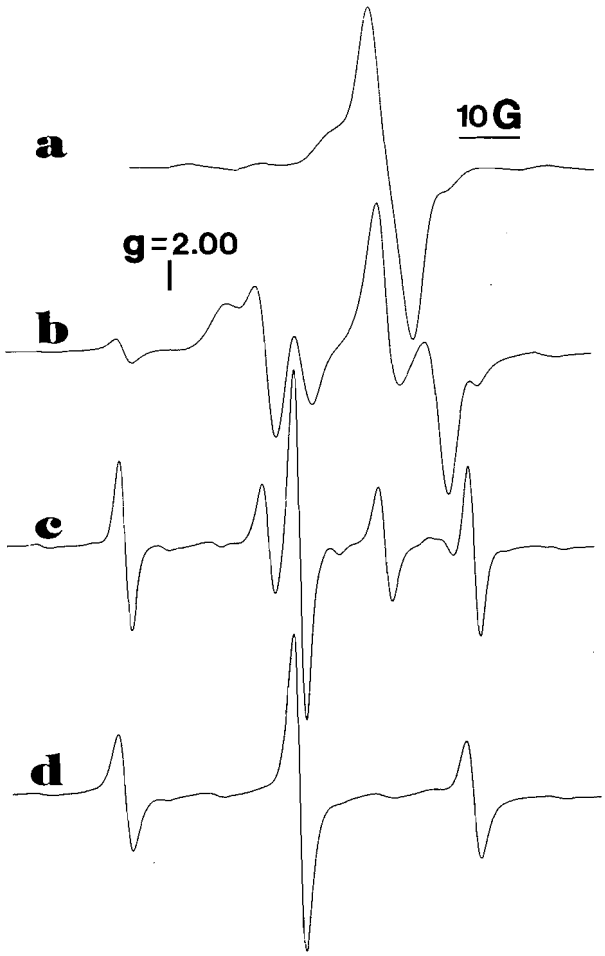

FIG. 2. EPR spectra recorded in THF at 25°C of (*a*) **2** (*b*) the reaction of **2** with 1 equivalent of PMe_3, (*c*) the reaction of **2** with a large excess of PMe_3, (*d*) isolated **4**.

electrochemical features were observed between 0.5 and −1.5 V vs. SCE, despite variations in the scan rate between 50 and 500 mV/s. In the case of **4**, following addition of excess PMe_3, a quasi-reversible redox wave centred at −0.40 V vs. SCE was observed (Fig. 3). The peak separation suggests a one electron process and the potential is consistent with a Ti(III)/Ti(II) redox couple (reaction [3]). Reduction of **4** yields the known compound $Cp_2Ti(PMe_3)_2$, **6**, (33). Rausch *et al.* have described the equilibrium in which dissociation of PMe_3 from **6** occurs (reaction [4]) (34). Presumably the addition of excess PMe_3 inhibits the

[3] $[Cp_2Ti(PMe_3)_2]^+ + e \rightleftharpoons Cp_2Ti(PMe_3)_2$

4 **6**

[4] $Cp_2Ti(PMe_3)_2 \rightleftharpoons Cp_2Ti(PMe_3) + PMe_3$

6 **7**

dissociation of phosphine from the electrochemically generated **6**. In the absence of excess phosphine, **6** is in equilibrium with $Cp_2Ti(PMe_3)$, **7**, and thus the reversible Ti(III)/Ti(II) redox couple is only observed in the presence of excess PMe_3.

Similar substitution reactions of **2** with PEt_3 were performed. The extent of reaction was much less than in the case of the reactions with PMe_3. The epr spectrum of the reaction mixture of **2**, in the presence of excess PEt_3, shows resonances attributable to only two species, the starting compound **2** and $[Cp_2Ti(CH_3CN)(PEt_3)][BPh_4]$, **5**. No evidence of disubstitution was observed.

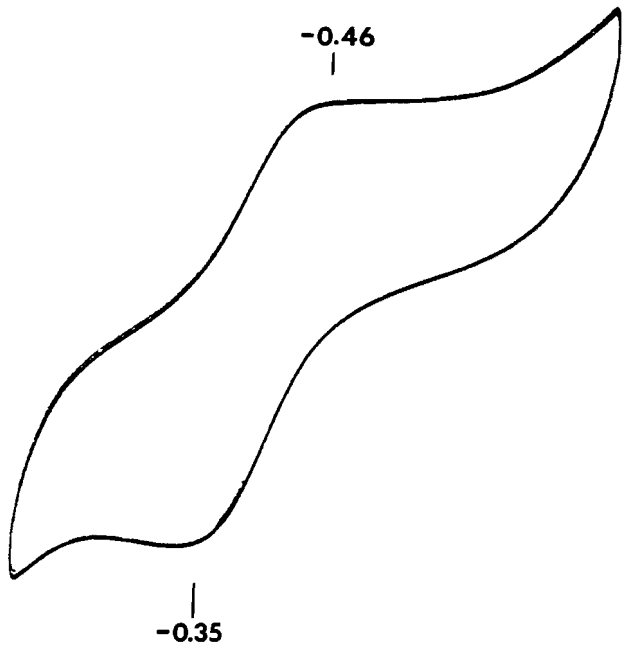

FIG. 3. Cyclic voltammogram of **4** in the presence of excess PMe_3 in THF using $Na[BPh_4]$ as the supporting electrolyte.

Reactions of **2** with PCy_3 or PPh_3 were also examined. Even in the presence of excesses of these phosphines, the epr spectral data were consistent with very limited degrees of reaction. No spectral features attributable to the PCy_3 or PPh_3 analogs of **3** and **4** were discernable, although some broadening of the central resonance arising from **2** was observed.

The greater degree of substitution seen with PMe_3 clearly reflects the favourable basicity and steric properties of this ligand. Since the basicities of PMe_3, PEt_3, and PCy_3 are similar, the degree of substitution in these cases seems to be sterically controlled. Tolman's calculation of the cone angles for these ligand are 118, 132, and 170°, respectively (38). It seems that even small differences in the steric bulk of these ligands inhibits substitution. This presumably arises from the interaction of β hydrogen atoms with the cyclopentadienyl protons. It is noteworthy that similar steric inhibition of substitution reactions has been observed for the reactions of phosphines with $Cp_2Ti(CO)_2$ where only PF_3 gave a disubstitution Ti(II) product (39). With other phosphines (PEt_3, PPh_3) only Ti(II) monosubstitution products could be prepared (i.e., $Cp_2Ti(CO)(PR_3)$ (39).

In the case of attempts to react **2** with PPh_3, both steric (Tolman cone angle 145°) (38) and basicity factors are unfavourable for substitution. It is interesting to note that while no reaction is observed with **2**, substitution to give the related monophosphine Ti(II) complex $Cp_2Ti(CO)(PPh_3)$ does proceeed (39). The instability of the Ti(III) substitution product $[Cp_2Ti(CH_3CN)(PPh_3)]^+$ may reflect the poorer ability of Ti(III) to secure the bonding of PPh_3 via π back donation.

Summary

The crystal and molecular structure of $[Cp_2Ti(CH_3CN)_2]_2[ZnCl_4]$ has been established. Substitution reactions in which phosphines replace the coordinated acetonitrile of this Ti(III) cation are very sensitive to both the steric and electronic nature

of the phosphine. Of the phosphines employed, only PMe_3 is both basic enough and small enough to afford disubstitution.

Electron paramagnetic resonance study of the reactions of the spin trap 3,5-dibromo-4-nitrosobenzenesulfonate[1]

FOR ERRATA SI
V.66 1988 P.3190

PETER SMITH[2] AND JILL SUZANNE ROBERTSON

Paul M. Gross Chemical Laboratory, Department of Chemistry, Duke University, Durham, NC 27706, U.S.A.

Received September 30, 1987

PETER SMITH and JILL SUZANNE ROBERTSON. Can. J. Chem. **66**, 1153 (1988).

Using rapid-mixing, continuous-flow $TiCl_3$-based techniques and also by means of static-sample studies involving the thermal decomposition of symmetric aliphatic azo compounds, we have characterized by electron paramagnetic resonance 22 spin adducts of 3,5-dibromo-4-nitrosobenzenesulphonate, **1**, in aqueous solution at 25°C. These spin adducts, all nitroxides, exhibit a moderately wide range of α-nitrogen and β-CH proton splitting constants, which we discuss in terms of steric and electronic effects. In connection with these studies, blank experiments showed that aqueous solutions of **1** gave no radicals when exposed to light and heat. In addition, we have studied by electron paramagnetic resonance at 25°C static samples of aqueous solutions of **1** both by itself and in the presence of each of several acrylic and methacrylic monomers and in both the presence and absence of light. These solutions yielded radicals, namely, nitroxides, only when containing methacrylic monomers, the presence of light having no effect. These observations support the "ene" addition/oxidation mechanism of nitroxide formation.

PETER SMITH et JILL SUZANNE ROBERTSON. Can. J. Chem. **66**, 1153 (1988).

Opérant en solutions aqueuses, à 25°C, faisant appel à la résonance paramagnétique électronique et utilisant des techniques de mélange rapide, à flux continu et basées sur le $TiCl_3$ ainsi que des études à l'aide d'échantillons statiques impliquant la décomposition thermique de composés azo aliphatiques symétriques, on a caracterisé 22 adduits de spin du dibromo-3,5 nitroso-4 sulfonate, **1**. Ces adduits de spin, tous des nitroxydes, présentent tous un éventail assez large de constantes de couplages avec l'azote en α et le proton CH en β. Pour fins de comparaison, on a démontré que des solutions aqueuses ne contenant que du composé **1** ne donnent pas de radicaux lorsqu'on les expose à la lumière ou à la chaleur. De plus, opérant à 25°C et faisant appel à la résonance paramagnetique electronique, on a étudié dans échantillons statiques du composé **1**, en solutions aqueuses, soit seul ou en présence de plusieurs monomères acryliques et méthacryliques différents, tant en présence qu'en absence de lumières. Ces solutions ne fournissent des radicaux, soit des nitroxydes, que lorsqu'elles contiennent des monomères méthacryliques; la présence de lumière est sans effet. Ces résultats suggèrent que la formation du nitroxyde implique un mécanisme d'addition/oxydation de nature «ene».

[Traduit par la revue]

Introduction

One way of studying a highly reactive radical, R·, in solution in systems where the steady-state concentration is below the usual epr detection limit is the so-called spin trap method (1). This method depends upon the addition to the reaction system of a low concentration of a diamagnetic substance (the spin trap, ST) with high affinity for R·. The product of this trapping reaction, R(ST)·, the spin adduct, must be a particularly persistent (2) radical whose concentration builds to a readily detectable level,

[1] $R\cdot + ST \rightarrow R(ST)\cdot$

The most commonly employed spin traps have been either nitrones or nitroso compounds, yet, although the latter generally yield more informative spin-adduct epr spectra than the former (3–9), few nitroso compounds have seen use in aqueous solution studies. One recently discovered water-soluble nitroso compound is 3,5-dibromo-4-nitrosobenzenesulphonate, Z—N=O, or **1** (10). Although there have been few reports of its use (11–14), the synthesis of **1** is inexpensive and easy and, unlike other nitroso compounds frequently employed (3–5) as spin traps, **1** is insensitive to laboratory light.

Because of the minimal variation of epr splitting constants for adducts of any one spin trap, contrasted with the greater variation of such constants for adducts of a particular radical with different spin traps (3–9), it is advantageous to employ more than one spin trap to attempt to trap a radical of interest. Thus, because a major problem with spin trapping is the unambiguous determination of spin-adduct structures, the introduction of new spin traps whose characteristics will aid in identifying which radical was indeed trapped provides a broader foundation for this technique. In particular, there is a pressing need to obtain and characterize new water-soluble nitroso spin traps to further the study of reactions in aqueous media, for example, biological systems. To that end, we have generated and characterized several spin adducts of **1**. To assist in unambiguous assignment of spin-adduct spectra, we employed rapid-mixing, continuous-flow techniques, first generating and characterizing the radical of interest, R· and then, by allowing an aqueous solution of **1** to enter the flowing stream, trapping and characterizing the spin adduct. Also, as a further unambiguous, static-sample, radical generating method, we used the thermal decomposition of symmetric aliphatic azo compounds. In addition, we investigated the stability of **1** to light, heat, and several olefins. Our results show that **1** traps a wide variety of carbon-centered radicals, is stable to light and heat, and exhibits enophilicity (15, 16) toward certain olefins. Because the spin adducts of **1** display a moderately wide range of values for the splitting constants $a_{\beta\text{-H}}$(CH) and $a_{\alpha\text{-N}}$, which vary with the nature of the radical trapped, it can be a useful and diagnostic spin trap, one that complements spin traps currently in use.

Experimental

The epr spectrometer, its accessories, and the general experimental arrangements and procedures were as before (17), unless otherwise specified. The continuous-flow studies employed a Borg mix-and-flow cell (18) in conjunction with a three-stream continuous-flow system as in earlier work in this laboratory (19). The static-sample investigations employed a Varian V-4548 aqueous-solution sample cell. All samples were at 25.0 ± 1.0°C and all spectra recorded were as the first derivative with a field-modulation amplitude of 2.0×10^{-1} G.

We synthesized **1** from 3,5-dibromosulphanilic acid (Aldrich) via the method of Kaur *et al.* (10), recrystallized the crystals so obtained twice from 95% ethanol (Apper Alcohol), and stored the final product (yield, 71%) in the dark at −10°C until used. The substrates examined were methanol (**2**), ethanol (95%) (**3**), isopropanol (**4**), acetone (**5**), trioxane (**6**), acrylic acid (**7**), methyl acrylate (**8**), ethyl acrylate (**9**), butyl acrylate (**10**), methacrylic acid (**11**) methyl methacrylate (**12**), isobutyl methacrylate (**13**), acrylonitrile (**14**), methacrylonitrile (**15**), 2,2′-azobis-(2-methylpropanonitrile) (**16**), 2,2′-azobis-(2-methylbutanonitrile) (**17**), 4,4′-azobis-(4-cyanopentanoic acid) (**18**), 2,2′-azobis-(2,4-dimethylpentanonitrile) (**19**), 2,2′-azobis-(2-ethylbutanonitrile) (**20**), dimethyl-2,2′-azobis-(2-methylpropanoate) (**21**), and 2,2′-azobis-(2-methylpropane) (**22**).

All substrates were either synthesized and purified (20) samples available in our laboratory (**17, 19–21**) or were as received from Apper Alcohol (**3**), Aldrich (**18**), Alfa (**22**), Kodak (**14** and **16**), Mallinckrodt (**2, 4–6**), or Rohm and Haas (**7–13**).

$TiCl_3$–H_2O_2 radical generating system studies

The three-stream, continuous-flow system was as follows: a reducing stream 0.004 M in $TiCl_3$ and an oxidizing stream, 0.1 M in H_2O_2, with both streams 0.02 M in substrate and 0.1 M in H_2SO_4; and a third stream, 0.003 M in **1**, which joined the oxidizing stream via a T-piece and stopcock, S, which allowed these two solutions to mix just prior to entering the cell. With S closed, thus using only the oxidizing and reducing streams, we first optimized the signal from the radical to be trapped, following which, with S open, this signal disappeared and in its place that from the spin-adduct nitroxide appeared. Total flow rates for both processes were 6–7 mL s^{-1}, with those of the oxidizing, reducing, and **1** streams, respectively, in the approximate ratios first 3:1:0, and then 3:1:3. The substrates so studied were **2–15**.

$TiCl_3$–$(CH_3)_3COOH$ radical generating system studies

The procedures and conditions were as for the $TiCl_3$-H_2O_2 work except for the replacement of the H_2O_2 in the oxidizing stream by *tert*-butylhydroperoxide, $(CH_3)_3COOH$ (Aldrich, 70%) (21), in the same concentration, and the omission of substrate from the oxidizing and reducing streams; the total flow rate was 2–3 mL s^{-1}, with the rates of the reducing, oxidizing, and **1** streams, respectively, in the approximate ratios first 1:1:0, and then 1:1:3.

$FeSO_4$–H_2O_2 radical generating system studies

All procedures and conditions were as for the $TiCl_3$–H_2O_2 work except for the replacement of the $TiCl_3$ in the reducing stream by 0.0025 M $FeSO_4 \cdot 7H_2O$ and ethylenediaminetetraacetic acid (1:1) (22–24). The only substrates so examined were **3** and **4**.

Azo-compound thermal decomposition studies

We heated at 100°C for 3 min with stirring a mixture of 25 mL of deionized water containing 2.0×10^{-4} moles of dissolved **1** with the same number of moles of the solid azo compound, then cooled this slurry in a constant temperature bath for 15 min to 25.0 ± 1.0°C, and next removed an aliquot of aqueous layer for epr examination as a static sample. All azo compounds, **16–22**, received this treatment.

In addition, we prepared at 25°C slurries of the type described above and, while keeping the temperature at 25.0 ± 1.0°C, exposed them to radiation from a sunlamp (Kenmore, 275 W, 110–125 V) for periods of 1–3 h. The spectra obtained were identical to those obtained by the thermal decomposition method, but less intense. All spectroscopic data reported refer to thermal decomposition studies. In addition we ran blank experiments for both the thermal and photochemical decomposition studies where the procedures followed were as described, except for the omission of the azo compounds, these giving no signals.

As a further examinination of the stability of **1** to light, we exposed aqueous solutions of **1** to normal laboratory light at room temperature for days and examined them by epr. No detectable signals were present.

*Demonstration of the enophilicity of **1***

We stirred aqueous solutions ca. 5.45 mM in both **1** and olefin at 25.0 ± 1.0°C for a minute and then removed static samples at 30-min intervals over a 3-h period for epr examination. We carried out all the procedures both in the presence of normal laboratory light and under photographic darkroom conditions, there being no observable difference, for example, in intensity or splitting-constant values, between the spectra obtained. The olefins so studied were **7–15** but, as expected, the only ones found to undergo reaction were **11–13** and **15** (15, 16).

Results and discussion

Table 1 presents the numbering scheme for all substrates employed and spin adducts observed. Tables 2–6 summarize the epr spectroscopic data obtained.

Tables 2–4 give the results of all studies involving the use of rapid-mixing, continuous-flow radical generating systems. Of the three such systems employed, only that producing the methyl radical (21) gave a spin-adduct spectrum in the absence of any substrate, namely, that of **23**. The other two systems, which generate ·OH radicals, gave no spin adduct, as expected (3, 10, 13, 14). In the absence of **1**, each substrate treated with an ·OH radical generating system yielded an optimized spectrum consistent with the presence of only one radical, namely, a substrate-derived species. For substrates **2–9**, **11**, **12**, **14**, and **15**, these spectra were in agreement with the literature (27–32); for the rest, **10** and **13**, which do not appear to have received previous epr investigations under conditions comparable to those of our work, the spectra were fully characterizable in terms of the expected (33) single ·OH-addition radicals, **39** and **40**. The epr data for **39** and **40** are in reasonable agreement with those for analogous species taken under comparable conditions, see Table 4 (27, 31, 32). Upon including **1** in the mixing streams, the signal from the substrate-derived radical disappeared and, with one exception, in its place appeared one fully consistent with that of its expected spin adduct, which was thus unambiguously assignable.

This exception was for the $FeSO_4$–H_2O_2/CH_3CH_2OH reaction system:

[2] $Fe(II) + H_2O_2 \rightarrow Fe(III) + \cdot OH + {}^-OH$

[3] $\cdot OH + CH_3CH_2OH \rightarrow \cdot CH(CH_3)OH + H_2O$

[4] $\cdot OH + CH_3CH_2OH \rightarrow \cdot CH_2CH_2OH + H_2O$

Here, although because of the electrophilic character of the hydroxyl radical (24) we would expect the rate constant for [3], k_3, to be greater than k_4, the optimized spectrum was from $\cdot CH_2CH_2OH$, because the reactivity of Fe(III) towards radicals is selective, paralleling stabilities of corresponding carbonium ions (24)

[5] $\cdot CH(CH_3)OH + Fe(III) \rightarrow {}^+CHCH_3OH + Fe(II)$

[6] $\cdot CH_2CH_2OH + Fe(III) \rightarrow {}^+CH_2CH_2OH + Fe(II)$

i.e., $k_5 \gg k_6$. However, on allowing **1** to enter the flowing stream, as the spectrum from $\cdot CH_2CH_2OH$ disappeared, that which took its place was almost entirely from **25**, the spin adduct of $\cdot CH(CH_3)OH$. The kinetic complexity (22–24) of the $FeSO_4$–H_2O_2 radical generating system restricts a detailed analysis of this topic here. However, it is reasonable to expect that $\cdot CH(CH_3)OH$ would be more susceptible to trapping than $\cdot CH_2CH_2OH$ because the α-OH group renders the α-carbon more nucleophilic (34), while steric differences between these two radicals would appear unimportant, and our observations fit this simple expectation. As well as the spectrum from **25**, there was one other present, a low-intensity absorption (5% of the whole) probably corresponding to trapped $\cdot CH_2CH_2OH$, as expected; i.e., $\cdot CH_2CH_2OH$ is the minor product of ·OH attack on CH_3CH_2OH in the absence of any effect from the presence of Fe(III) (24). These results contrast with a recent report (13*b*)

6	**29**	— 	11.96(3)	5.34(2)	—	32	0.8[j]

[a]At 25.0 ± 1.0°C and pH ca. 2.

[b]Except for **23** and **27**, all trapped radicals were hydrogen-atom abstraction species generated by the $TiCl_3$–H_2O_2 radical generating system.

[c]Unless otherwise stated, all protons at a given site are magnetically equivalent.

[d]Each number in parentheses is the standard deviation of the mean, σ_{n-1}, times 10^2 and the maximum error limits are approximately $\pm 2\sigma_{n-1}$ based on the reported error limits for the standard (25).

[e]The two CH phenyl-ring protons.

[f]Δg value = $(g - 2.00600)$ and σ_{n-1} times 10^5 for all radicals is 1. The maximum error limits of the g values are ±0.00006 based on the reported error limits for the standard (25, 26).

[g]$TiCl_3$–$(CH_3)_3COOH$ radical generating system.

[h]$FeSO_4$–H_2O_2 radical generating system. The only comparable study in the literature (10) (for the corresponding spin adducts generated from the deuteriated analogue of **1**, 2,6-dideuterio-3,5-dibromonitrosobenzenesulphonate, **1′**, by photolysis of H_2O_2–$(CH_3)_2CHOH$–**1′**–H_2O mixtures at 20°C) reports that the α-N splitting is 14.0 G and the two β-H(CH) protons are nonequivalent, with a values 9.8 and 11.25 G.

[i]The chiral γ carbon renders these two β-H(CH) protons nonequivalent but, based on the observed ΔH_{pp}, this nonequivalence must be <0.2 G.

[j]This large value is attributable to unresolved splittings, e.g., from *meta*- and δ-CH protons.

published since the completion of our work that the $TiCl_3$– and $FeCl_2$–H_2O_2/CH_3CH_2OH/**1** reaction systems at room temperature both yielded only the spin-adduct spectrum of the ·CH_2CH_2OH radical. The difference between our results and these other findings presumably arises from the use by the other workers (13*b*) of reaction conditions very different from those we followed, namely, static samples and reactant concentrations in general considerably higher than those of our work.

In contrast, using the $FeSO_4$–H_2O_2/$(CH_3)_2CHOH$ reaction system, the optimized radical spectrum was from ·$CH_2CH(CH_3)OH$ and the spectrum in the presence of **1** was fully interpretable as arising from **27**, the spin adduct of this

same species. Acknowledging, once more, the kinetic complexity of the $FeSO_4$–H_2O_2 radical generating system, this observation agrees with simple expectation, i.e., the expected greater stability of $^+C(CH_3)_2OH$ over $^+CH_2CH(CH_3)OH$ and the greater steric hindrance to the trapping of $\cdot C(CH_3)_2OH$ over $\cdot CH_2CH(CH_3)OH$.

Table 5 summarizes the results of all static-sample, R—N=N—R thermal decomposition studies. Thermal decomposition of each R—N=N—R compound in the presence of **1** yielded a spin-adduct spectrum fully consistent with trapping the expected single radical (35), R·. There was no evidence for the trapping of >Ċ—C≡N radicals in the >C=C=N· form (36–38), a result in accord with the general finding that nitroso compounds do not readily trap N-centered radicals (3–9, 39) and the relative strengths of C—N and N—N bonds (40).

Two of the spin adducts characterized in this study, **23** and **24**, have been the subject of the already mentioned epr investigation (13*b*) using static samples and the $TiCl_3$– and $FeCl_2$–

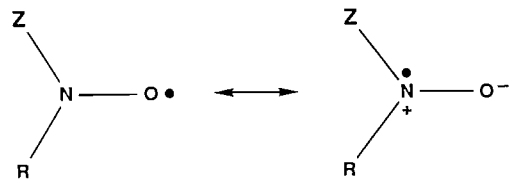
[a]See Table 5, footnote *a*.
[b]See Table 2, footnote *d*. The β-CH protons are magnetically inequivalent.
[c]See Table 2, footnote *e*.
[d]See Table 2, footnote *f*.
[e]Only one δ-CH proton splitting detected.
[f]The large value of ΔH_{pp} is attributable to unresolved splittings, e.g., from *meta*- and δ-CH protons.

H_2O_2 radical generating systems, and there is reasonable agreement between our epr data for these radicals and those of the other work (13*b*). Also, there has been a report of the splitting constants for spin adducts similar to **23**, **24**, **25**, **27**, and **45** where the spin trap used was 2,6-dideuterio-3,5-dibromonitrosobenzenesulfonate, **1′** (10). These trapped radicals were formed (10) from photolysis of H_2O_2–substrate–H_2O mixtures at 20°C and, except in the case of **27**, there is reasonable agreement between these literature values and our data, bearing in mind the difference in solvent conditions. However, for **27**, there is an appreciable difference between our results and the literature with respect to the size of the β-CH_2 proton splittings, see Table 2, a difference for which we are unable to account.

The spectra for **29–38** and **41–47** showed no *meta*-CH proton splittings, consistent with the large ΔH_{pp} values, 0.8–1.8 G, in comparison with those of the spectra from **23–28**, 0.2–0.4 G, for which *meta*-CH proton splittings were clearly resolvable, see Tables 2, 3, and 5.

We would expect the nitroxide function to be sensitive to substituents on the nitrogen (41), as demonstrated by resonance structures,



52 53

where structure **52** is favored when the R group is electron withdrawing, either −M or −I (ref. 34, Chaps. 1, 9), and will have lower α-N splittings than structure **53**, which is favored by the presence of an electron-donating, +M or +I, R group. In agreement with this, adducts **24, 25**, and **26** show that as the number of methyl groups is increased, the α-N splitting constant increases, because the methyl group is +M. For groups **28–38** and **41–46** and groups **23–27** and **47**, respectively, the R moieties are of −M and +M character, respectively. Thus, as expected, the average α-N splitting constant for the former, 13.1 G, is lower than that for the latter, 14.0 G. We need to view individual cases in terms of all β substituents and their ability to donate or withdraw electrons. For example, in the case of **29**, for the two ethereal oxygens the electron withdrawal by induction (−I effect) appears to be greater than electron donation by resonance (+M effect) (ref. 34, Chaps. 1, 9), as the α-N splitting constant is very low. While adduct **45** has a strong −M group, it also contains two +M groups, both $-CH_2CH_3$, and these groups account for its seemingly high α-N splitting constant, 13.9 G. As expected on the basis of their −R groups being +M, **23** and **47** have the largest α-N splitting constants.

Ideally, the $a_{\beta\text{-H}}$(CH) values should decrease as the bulk of the trapped group increases (42). This trend holds in general for our data as $a_{\beta\text{-H}}$(CH) values for **29–33** and **37** are considerably smaller than those for **23–25**, **27**, and **28**, which contain much less bulky groups. On these grounds, **23**, as expected, has the highest $a_{\beta\text{-H}}$(CH) value. For **27** and, as previously noted, for spin adducts of 5,5-dimethyl-l-pyrroline-l-oxide (43), the larger $a_{\alpha\text{-N}}$ and $a_{\beta\text{-H}}$(CH) values are probably due to increased spin density on the nitrogen and a decrease in the β-CH dihedral angle caused by intramolecular hydrogen bonding from the hydroxy hydrogen to the nitroxide oxygen (43). A scatter plot (43) of $a_{\alpha\text{-N}}$ versus $a_{\beta\text{-H}}$(CH) values for spin adducts **23–25**, **27–33**, and **37** clearly shows that **1** adequately differentiates between all spin-trap adducts except **30** and **31** and also **32** and **37**.

All the spin-adduct spectra generated in the continuous-flow studies disappeared when the flow was stopped, while the spectra of the azo-compound derived adducts were much more stable, their spectral intensity changing less than 10% over a 3-h period. Check experiments on a solution of **41** prepared in the usual manner, to which a freshly prepared solution of $TiCl_3$, H_2SO_4, and H_2O_2 was quickly added to approximate conditions in the flow studies, showed that the signal from **41** disappeared immediately, suggesting that the source of signal disappearance in the flow studies was from destruction of the spin adducts by components of the $TiCl_3$–H_2O_2 radical generating system, as expected (23, 44). It is interesting to note, however, that the static-sample $TiCl_3$– and $FeCl_2$–H_2O_2/substrate/**1** reaction-system studies previously cited (13*b*) did yield spin adducts sufficiently persistent for epr observation.

Table 6 summarizes the epr results obtained for all substrates susceptible to the enophilicity of **1**, i.e., each methacrylic monomer, CH_2=$C(CH_3)X$, yielded a spectrum fully interpretable in terms of one radical, and this radical, a nitroxide, was that expected to form via the nonphotolytic "ene" addition/oxidation mechanism (15).

The small single proton coupling in **48–51** is attributable to the δ-CH proton oriented toward the oxygen of the nitroxide function. Others have proposed a similar type of 1,6 interaction

54

in a quasi-six-membered cyclic system to explain hyperfine splitting in certain iminoxyl radicals (45). Although the representation of **54** shown here has the quasi-six-membered ring containing the NO· group, the β-, γ-, and δ-carbons, and one δ-CH hydrogen atom planar, the ring probably is twisted about the β-C/γ-C bond because the β-CH hydrogens are magnetically inequivalent. This is not unreasonable, as construction of models supports the presence of ring strain in a planar configuration.

The spectral intensity of the radicals **48–51** changed less than 10% over the 3-h period of the experiment. Though not formed by a spin-trapping reaction, **48–51** are of the Z—N(O·)—R type and exhibit splittings characteristic of that structure (see Tables 2, 3, and 5); therefore their presence could easily interfere with the detection and characterization of concurrently generated spin adducts, pointing to an important potential limitation in the use of **1**. Chatgilialoglu and Ingold (15) have stressed the caution necessary when observing "spontaneous" reactions between nitroso compounds and olefins, for, in many but not all cases studied, they found that such reactions occurred only in the presence of light. We observed radical formation between **1** and all methacrylic monomers studied both in the presence and the absence of light, indicating that **1** can yield nitroxides by nonphotolytic processes, supporting the "ene" addition/oxidation mechanism (15, 16, 46) of nitroxide formation.

2,6-Di-*tert*-butylpyridine: an unusually weak base in dimethylsulfoxide

ROBERT L. BENOIT, MONIQUE FRÉCHETTE, AND DIANE LEFEBVRE

Département de chimie, Université de Montréal, C.P. 6128, Succursale A, Montréal (Québec), Canada H3C 3J7

Received September 30, 1987

ROBERT L. BENOIT, MONIQUE FRÉCHETTE, and DIANE LEFEBVRE. Can. J. Chem. **66**, 1159 (1988).

The ionization constants of the conjugate acids BH^+ of pyridine, 2-picoline, 2,6-lutidine, and 2,6-di-*tert*-butylpyridine (DTBP) have been determined in Me_2SO. The partition coefficients of the bases B between Me_2SO and water, and the enthalpies of solution and protonation of B in Me_2SO have also been obtained. In contrast to its high basicity in the gas phase, DTBP is an abnormally weak base in Me_2SO ($pK = 0.81$). The factors responsible for this very low basicity are analyzed by considering correlations between the gas-phase, Me_2SO, and aqueous basicities of B and by comparing the transfer parameters for B and BH^+. The solvation of DTBP and $DTBPH^+$ in Me_2SO and in water differs. While the solvation of DTBP in Me_2SO is normal, the enthalpy of solution of $DTBPH^+$ in Me_2SO is abnormally low and close to that of a cation whose solvation is nonspecific. This suggests a much reduced H-bonding between sterically hindered $DTBPH^+$ and the large Me_2SO solvent molecule.

ROBERT L. BENOIT, MONIQUE FRÉCHETTE et DIANE LEFEBVRE. Can. J. Chem. **66**, 1159 (1988).

On a déterminé les constantes d'ionisation dans le Me_2SO des acides conjugués BH^+ de la pyridine, de la picoline-2, de la lutidine-2,6 et de la di-*tertio*-butyl-2,6 pyridine (DTBP). On a aussi obtenu les coefficients de partage des bases B entre le Me_2SO et l'eau, et les chaleurs de solution et de protonation de B dans le Me_2SO. En opposition à sa basicité élevée en phase gazeuse, la DTBP est une base anormalement faible dans le Me_2SO ($pK = 0.81$). On analyse les facteurs responsables de cette très faible basicité en considérant des corrélations entre les basicités de B en phase gazeuse, dans le Me_2SO et dans l'eau, et en comparant les paramètres de transfert de B et BH^+. La solvatation de DTBP et $DTBPH^+$ dans le Me_2SO et l'eau diffère. Alors que la solvatation de DTBP dans le Me_2SO est normale, l'enthalpie de solution de $DTBPH^+$ dans le Me_2SO est anormalement basse et proche de celle d'un cation dont la solvatation est non-spécifique. Ceci suggère une liaison-H très affaiblie entre $DTBPH^+$, empêchée stériquement, et la grosse molécule du solvant Me_2SO.

Since it was first synthesized by Brown and Kanner (1), 2,6-di-*tert*-butylpyridine (DTBP) has attracted the interest of many researchers because of its unusually low basicity: with its two alkyl substituents, DTBP is nevertheless a weaker base than unsubstituted pyridine in aqueous solution. Brown and Kanner (1) and others (2) proposed that the abnormally low basicity of DTBP was caused by steric hindrance to hydration of $DTBPH^+$. Recent determinations of gas-phase proton affinities of DTBP and other alkyl-substituted pyridines showed that the basicity of DTBP in the gas phase was normal (2, 3), which confirmed that its weak basicity in water was due to solvent effects on DTBP and (or) $DTBPH^+$. A complete analysis of the thermodynamic cycles linking the protonation processes of DTBP and other pyridines in the gas phase and in aqueous solution led Arnett and Chawla (2) to conclude that there was indeed some hindrance to the hydration of $DTBPH^+$ as reflected in its abnormally low enthalpy of hydration. However, more recently Hopkins *et al.* (3), after investigating the protonation of additional *tert*-butylpyridines and repeating the thermodynamic determinations of Arnett and Chawla (2) of DTBP, concluded from their new data that the hydration enthalpy of $DTBPH^+$ was normal but that the corresponding entropy was abnormal; they suggested that the rotation of the water molecule attached to $DTBPH^+$ and of $-CMe_3$ was restricted. These results and conclusions were in agreement with the gas phase studies of Moet-Ner and Sieck (4) on the attachment of one water molecule to a series of pyridinium cations including $DTBPH^+$.

Since, as we have recently shown (5), contrasting solution and protonation thermodynamic data for bases in water and in a nonaqueous solvent such as dimethylsulfoxide (Me_2SO) can lead to new insights into solute–solvent H-bonding interactions, we have now determined the data needed to compare the behaviour of DTBP in both water and Me_2SO. We have also included pyridine (Py), 2-picoline (MePy), and 2,6-lutidine (Me_2Py) in our investigation to broaden the basis of our comparisons, and we are presenting here the results of our potentiometric, spectroscopic (uv and nmr), and calorimetric study.

Experimental

Materials

Pyridine (Anachemia) was used as received. DTBP (Aldrich), MePy (Aldrich), and Me_2Py (Eastman Kodak) were distilled once or twice; Me_2Py was kept under vacuum in a desiccator over P_4O_{10}. The purity of the bases was checked by titration with standardized $HClO_4$ 0.1 M in HCH_3COO and found to be 100.0 ± 0.4% (Py), 98 ± 1% (DTBP), 99.2 ± 0.1% (MePy), and 98 ± 1% (Me_2Py) respectively. Me_2SO (BDH, analytical reagent (0.20% water) and Anachemia, A.C.S. reagent (0.14% water)), *n*-heptane (American Chemicals "all glass redistilled"), and trifluromethanesulfonic acid (HCF_3SO_3) (Aldrich) were used without further purification. Tetraethylammonium perchlorate (Eastman Kodak) was recrystallized in a 4:1 water–ethanol mixture and dried under vacuum at room temperature.

pK_a determinations

Potentiometric titrations of Me_2SO solutions of the pyridines ((1×10^{-2})–0.4 M) with a standardized solution of HCF_3SO_3 in Me_2SO were carried out at 25.0°C. A constant ionic strength was maintained by making the pyridine solutions initially 0.100 M in Et_4NClO_4. The potentiometric apparatus used as well as the calibration of the glass electrode with standardized HCF_3SO_3 have been previously described (6).

A spectrophotometric procedure was also used to determine the pK_{as} of $DTBPH^+$ in Me_2SO. The absorbances of $(0.7–3.0) \times 10^{-4}$ M solutions of DTBP in 0–1 M HCF_3SO in Me_2SO were measured with a PMQ II Zeiss spectrophotometer using 1-cm thermostated cells at 25.0°C. The ionic strength was maintained at 0.1 M by adding Et_4NClO_4 to solutions with acid concentrations lower than 0.1 M. The values of K and the molar absorptivities "ε" of DTBP were obtained from the absorbances measured at 8 wavelengths between 265 and 285 nm using the graphical method of Rossotti and Rossotti (7).

The protonation of DTBP was also studied by ^{13}C nmr using a Bruker WP-80 spectrometer operating at 20.2 MHz (5). ^{13}C spectra in Me_2SO were taken on 0.14–0.29 M solutions of DTBP to which HCF_3SO_3 was added to give acid to base molar ratios from 0 to 30.5 and thus protonate up to 70% of DTBP. The value of K_{as} was calculated from the chemical shift data by the graphical procedure of Rossotti and Rosssotti (7).

Solubility and partition coefficient determinations

The solubility of DTBP in Me_2SO was determined potentiometrical-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 93.93.197.157 on 09/07/12
For personal use only.

ly. Three separate determinations were made by titrating the saturated solutions with standardized $HClO_4$ 0.1 M in HCH_3COO.

We determined the partition coefficients of Py, MePy, and Me_2Py between water and Me_2SO using *n*-heptane as the common immiscible reference solvent. The partition coefficients of the bases between *n*-heptane and Me_2SO, $P_{h/s}$, and *n*-heptane and water, $P_{h/w}$, were obtained by determining potentiometrically the concentration of each base in Me_2SO and water after equilibration of 5–17 separate 20-mL samples of 0.1–0.95 M solutions in Me_2SO or water with 2, 5, 10, or 20 mL of *n*-heptane. The equilibrium concentration of the bases in *n*-heptane was obtained by difference. The potentiometric titrations of the base solutions were made with $HClO_4$ in HCH_3COO for aqueous Py and MePy and the Me_2SO solution of Me_2Py. The aqueous solution of Me_2Py was titrated with 0.1 or 0.05 M HCl. The base concentrations in *n*-heptane were plotted against the base concentrations in the Me_2SO or aqueous phases to give, by a least-squares procedure, $P_{h/s}$ and $P_{h/w}$ respectively for Py, MePy, and Me_2Py.

Calorimetric measurements

The heats of solution of the liquid pyridines in Me_2SO were measured at 25.00°C with a LKB model 8725-2 isoperibol calorimeter as previously described (6), the amount of the bases dissolved being known from the weight of the glass ampoules. For each base, three to eight separate determinations were made at different concentrations by dissolving (0.2–7.8) $\times 10^{-3}$ mol of base in 100 mL of solvent. The total heats of neutralization were obtained similarly by dissolving (0.25–1.1) $\times 10^{-3}$ mol MePy, Me_2Py, and DTBP in 100 mL of 0.1 M HCF_3SO_3 in Me_2SO.

Results

Ionization constants

The ionization constants K_{as} of the conjugate acids BH^+ in Me_2SO were calculated from the potentiometric neutralization and calibration data by using the program previously described (6). The values of pK_{as} are given in Table 1 together with the corresponding aqueous values pK_{aw} of Hopkins and co-workers (3, 6, 12, 13). No corrections were made for the effect of ionic strength, which would be small for such protonation reactions. For DTBP, pK_{as} was also obtained from the uv absorbance data. Plots of $(\varepsilon - \varepsilon_B)/[H^+]$ were linear, the slopes gave $1/K_{as}$ and the intercept $\varepsilon_{BH^+}/K_{as}$. The pK_{as} value, 0.81 ± 0.07, is in good agreement with the potentiometric value, even though the ionic strength varied from 0.1 to 1.00. The ^{13}C nmr data were treated in a similar manner. However, because of the high DTBP concentration used, corrections had to be made to obtain $[H^+]$ so that the nmr pK_{as} value is less precise but still in fair agreement with the other values. Interestingly, the ^{13}C signals, particularly the C-4 one, were broader when the solutions contained both DTBP and $DTBPH^+$. The slower exchange might indicate some unusual solvent effects on DTBP and $DTBPH^+$, though likely not as marked as for 1,8-bis(dimethylamino)naphthalene and its conjugate acid where separate signals were obtained (5).

Free energies of transfer from water to Me_2SO

The free energies of transfer, $\Delta G^0_{ws}(B)$ (hypothetical 1 M solution as standard state) were obtained for DTBP from its solubility in water as determined by Hopkins *et al.* (3) and our experimental solubility in Me_2SO, 0.29 ± 0.01 M, assuming ideal behaviour. For the more soluble bases Py, MePy, and Me_2Py, ΔG^0_{ws} was calculated from the partition coefficient $P_{s/w}$ obtained by combining the partition coefficients $P_{h/s}$ between Me_2SO and *n*-heptane, which were respectively 0.165 ± 0.007 (Py), 0.368 ± 0.006 (MePy), 0.75 ± 0.06 (Me_2Py), and the partition coefficients $P_{h/w}$ between water and *n*-heptane, 0.36 ± 0.01 (Py,), 1.05 ± 0.03 (MePy), 4.7 ± 0.3 (Me_2Py).

The free energies of transfer of BH^+, $\Delta G^0_{ws}(BH^+)$ were calculated in turn by means of eq. [1] derived from the thermodynamic cycle relating the protonation reaction in water and Me_2SO:

[1] $\Delta G^0_{ws}(BH^+) = \Delta G^0_{ws}(B) + \Delta G^0_{ws}(H^+) + \Delta G^0_{ps} - \Delta G^0_{pw}$

ΔG^0_{ps} and ΔG^0_{pw} are the protonation energies in Me_2SO and water calculated from pK_{2s} and pK_{2w}. The value of $\Delta G^0_{ws}(H^+)$, −19 kJ mol^{-1}, is based on the tetraphenylarsonium-tetraphenylborate (tatb) assumption (8). Our free energies of transfer are given in Table 2.

TABLE 1. Ionization constants K_{2s} and K_{2w} of BH^+ ions at 25°C

BH^+	pK_{as} Me_2SO	pK_{aw} H_2O	$\Delta = pK_{as} - pK_{aw}$	$\Delta G_{pg}(B)$[e] (kJ mol^{-1})

[a]Standard state as hypothetical 1 M solution.

Enthalpies of solution and protonation

The values of the bases' enthalpy of solution in water, ΔH^0_w, and of protonation in water, ΔH^0_{pw}, were taken from the literature (3, 9). The plots of the heats of solution of DTBP, MePy, and Me_2Py in Me_2SO and Me_2SO solutions of 0.1 M HCF_3SO_3 against the number of moles dissolved were linear, and the least-squares slopes gave $\Delta H^0_s(B)$ and $\Delta H^0_{ns}(B)$ according to

[2] B(c or l) = B(s)

[3] B(c or l) + H^+(s) = BH^+(s)

A correction was applied for the incomplete protonation of DTBP. The heat of protonation ΔH^0_{ps} corresponding to

[4] B(s) + H^+(s) = BH^+(s)

was obtained by subtracting $\Delta H^0_s(B)$ from $\Delta H^0_{ns}(B)$. The enthalpies of solution and protonation in water and Me_2SO are listed in table 3 together with protonation gas-phase values, ΔH^0_{pg}, taken from a published account (4).

Enthalpies of transfer from water to Me_2SO

The enthalpies of transfer of the bases from water to Me_2SO, $\Delta H^0_{ws}(B)$, were calculated from their enthalpies of solution in both solvents. $\Delta H^0_{ws}(BH^+)$ was obtained from an equation similar to [1] relating the protonation process in both solvents. The value of $\Delta H^0_{ws}(H^+)$, −25.5 kJ mol^{-1}, is based on the tatb

extrathermodynamic assumption (8). The values of ΔH^0_{ws} are given in Tables 4 and 5.

Transfers from the gas phase

The thermodynamic functions ΔP^0_{gw}(B) for the transfer of B from the gas phase to water (Table 4) are from Hopkins *et al.* (3) (Py and DTBP) and Arnett *et al.* (9) (MePy and Me_2Py). The values of $\Delta P^0_{gw}(BH^+)$ given in Table 5 are calculated by means of eq. [5] derived from the thermodynamic cycle relating the protonation in the gas phase and water:

$$[5]\quad \Delta P^0_{gw}(BH^+) = \Delta P^0_{gw}(B) + \Delta P^0_{gw}(H^+) + \Delta P^0_{pw} - \Delta P^0_{pg}$$

ΔP^0_{pw} and ΔP^0_{pg} are the protonation functions in water and in the gas phase respectively (Tables 1 and 3). The values of $\Delta G^0_{gw}(H^+) = -1092.0$ kJ mol^{-1} and that of $\Delta H^0_{gw}(H^+) = -1129.7$ kJ mol^{-1} are taken from ref. 8. The functions for the gas phase – Me_2SO transfers, ΔP^0_{gs}, given in Tables 4 and 5, are obtained from the corresponding ΔP^0_{gw} values and the water – Me_2SO transfer functions ΔP^0_{ws} listed in Tables 2, 4, and 5.

Discussion

It is clear from Table 1 that the upward pK_s trend that is observed when passing from Py to the alkylpyridines, MePy and Me_2Py, is not followed by DTBP; even more than in water, DTBP is an unusually weak base in Me_2SO, since its pK_{as} is some 2.5 units lower than the pK_{as} of Py while the corresponding pK_{aw} difference is only 0.2. The factors responsible for the very weak basicity of DTBP in Me_2SO can best be analyzed, first, by considering different types of correlation between the aqueous, Me_2SO, and gas phase basicities of Py, MePy, Me_2Py, and DTBP and then by comparing the transfer parameters for the bases B and their conjugate acids BH^+.

Correlation of solution and gas phase basicities

Looking at the correlations between Me_2SO and the aqueous basicities, we first note that for Py, MePy, and Me_2Py the pK_{as} are linearly related to pK_{aw} with $pK_{as} = 0.65\ pK_{aw}$ but that the point for DTBP deviates from the line by nearly 2.3 pK units. Then, in the plot[1] of ΔH^0_{ps} against ΔH^0_{pw}, the DTBP point is also off the line by some 25 kJ mol^{-1}. However, given that the basicity of DTBP is abnormal in water, these results do not necessarily indicate that DTBP behaves abnormally in Me_2SO. More definite conclusions can be drawn by comparing gas phase and Me_2SO basicities, since DTBP basicity is normal in the gas phase. In the plot[1] of the gas phase protonation enthalpy ΔH^0_{pg} vs. the Me_2SO protonation free energy ΔG^0_{ps}, the point for DTBP deviates from the line by some 22 kJ mol^{-1} while in the plot of ΔH^0_{pg} vs. ΔH^0_{ps}, the DTBP point is also some 24 kJ mol^{-1} off the line. We conclude from both results that the abnormally low basicity of DTBP in Me_2SO is primarily due to an enthalpy

[1]Not shown here.

For personal use only.

effect with possibly an additional entropy effect. An enthalpy effect was also found to be responsible for the unusual basicity of DTBP in alcohol–water mixtures (10), but in water there was only an entropy effect (3).

We will now compare and contrast the thermodynamic parameters for the transfer of the pyridines B and their conjugate acids BH^+ from the gas phase to Me_2SO and water to analyze further the enthalpy effect.

Transfer of pyridines

First, the ΔG^0_{gs} and ΔH^0_{gs} parameters for the transfer of the pyridines to Me_2SO in Table 4 show a smooth trend towards higher exothermicity when passing from Py to MePy, Me_2Py, *and* DTBP so that there is at least no large abnormality in the solution of DTBP. This is in opposition to its solution behaviour in water where both the corresponding ΔG^0_{gw} and ΔH^0_{gw} exhibit a discontinuity in the trend observed for the other pyridines, the exothermicity being lower than predicted.

These different patterns of solvation for DTBP in Me_2SO and water are of course reflected in the broken trends of the water – Me_2SO transfer parameters ΔG^0_{ws} and ΔH^0_{ws} for the pyridines (Tables 2, 4). The indicated unusual destabilization of DTBP in water may result from weaker H-bonding interactions with the pyridine N because of steric hindrance of the *tert*-butyl groups or because of hydrophobic interactions of the same groups (3). It is worth noting that in the aliphatic series the water – Me_2SO transfer enthalpy of $-CH_3$ groups corresponds to an "extra stabilization" in water (11), as is observed here when passing from Py to MePy and Me_2Py, but not for DTBP, suggesting that poor H-bonding may be the dominant factor in the weaker than expected solvation of DTBP in water.

Transfer of pyridinium cations

The free energy and enthalpy of transfer of BH^+ from the gas phase to Me_2SO in Table 5 show some decrease in exothermicity from PyH^+ to $MePyH^+$ and Me_2PyH^+, and then a much larger decrease for $DTBPH^+$. For the gas phase – water transfers, the picture is different. There is a smooth decrease in exothermicity of ΔH^0_{gw} from PyH^+ to $DTBPH^+$, but a sharp decrease of ΔH^0_{gw} for $DTBPH^+$ and a corresponding large change of ΔS^0_{gw}. Thus while in water it is the entropy of solution of $DTBPH^+$ which is abnormal, as already concluded by Hopkins *et al.* (3) from their analysis of the parameters for a series of *tert*-butyl pyridines, in Me_2SO it is the enthalpy of solution of $DTBPH^+$ which appears to be abnormally low. We therefore suggest that there is a much reduced H-bonding between the large Me_2SO molecule and the sterically hindered $DTBPH^+$ cation. Actually, the solvation enthalpy of $DTBPH^+$ in Me_2SO, -245 kJ mol^{-1}, is close to that of PSH^+ (PS standing for 1,8-bis(dimethylamino)naphthalene), -254 kJ mol^{-1}, whose solvation in Me_2SO appears to be nonspecific (5).

The variations in the pyridine series of the water–Me_2SO transfer parameters $\Delta G^0_{ws} - \Delta H^0_{ws}$ (Tables 2, 4, 5) reflect, of course, the combined changes of $\Delta G^0_{gw} - \Delta H^0_{gw}$ and $\Delta G^0_{gs} - \Delta H^0_{gs}$ so that a direct interpretation would be difficult. Nevertheless, it is interesting to note that the ΔG^0_{ws} values for B and BH^+ (Table 2) show that the larger $pK_{as} - pK_{aw}$ difference observed with DTBP is largely due to a much stronger stabilization in Me_2SO of DTBP than of the other bases B.

To conclude, we can say that the unusually low basicity of DTBP in Me_2SO as evidenced by the sharp pK_{as} decrease to 0.81 (when passing from Py, MePy, and Me_2Py to DTBP) is mainly due to an abrupt decrease in the free energy and enthalpy of solvation of $DTBPH^+$ because of poor H-bonding to solvent molecules. In water, the more moderate pK_{aw} decrease observed for DTBP is caused by a low free energy of solvation of $DTBPH^+$, in turn linked to an abnormal solvation entropy as discussed by Hopkins *et al.* (3) but opposed, in part, by a less negative free energy of solvation of DTBP. As for the lower basicity of Py, MePy, and Me_2Py in Me_2SO than in water, the water–Me_2SO transfer functions show that this is mainly due to the superior basicity of Me_2SO ($\Delta G_{ws}(H^+) = -25$ kJ mol^{-1}) opposed by a lesser stabilization of BH^+ in Me_2SO ($\Delta G^0_{ws} \sim -10$ kJ mol^{-1}). Further work is being carried out on other substituted pyridines to extend the linear relationship found between pK_{2s} and pK_{2w} and to ascertain to what extent the representative points off the correlation line correspond to pyridines with unusual interactions of B and (or) BH^+ with the solvents, as we have found for DTBP.

Reactions of 1,2-dehydropyrrolidin-5-one with 1,3-dienes. Synthesis of *dl*-gephyrotoxin 223AB[1]

OLIVER E. EDWARDS,[2] AUSTIN M. GREAVES,[3] AND WING-WAH SY[3]

Chemistry Division, National Research Council of Canada, 100 Sussex Drive, Ottawa, Ont., Canada K1A 0R6

Received August 6, 1987

OLIVER E. EDWARDS, AUSTIN M. GREAVES, and WING-WAH SY. Can. J. Chem. **66**, 1163 (1988).

Evidence is presented that the regiospecific and often stereospecific pseudo-Diels–Alder reactions of 1,3-dienes with *N*-acyl immonium salts, derived from 5-ethoxy-2-pyrrolidinone, are stepwise reactions. 6,7-Dehydroindolizidinones, unsaturated lactam esters, and new indene and furan derivatives are described. A synthesis of *dl*-gephyrotoxin 223AB (indolizidine 223AB) from *trans*-1,3-heptadiene was achieved.

OLIVER E. EDWARDS, AUSTIN M. GREAVES et WING-WAH SY. Can. J. Chem. **66**, 1163 (1988).

On présente des données qui suggèrent que les réactions de pseudo-Diels–Alder régiospécifiques et souvent stéréospécifiques dans dienes-1,3- avec les sels de *N*-acyl-immonium dérivés de l'éthoxy-5 pyrrolidinone-2 sont des réactions par étapes. On décrit des déhydro-6,7 indolizidinones, des esters lactames non-saturés ainsi que de nouveaux dérivés de l'indène et du furanne. On a réalisé une synthèse de la (*dl*)-géophyrotoxine 223AB (indolizidine 223AB) à partir de l'heptadiène-1,3-*trans*.

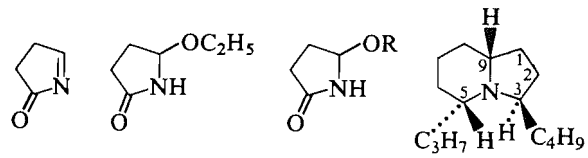
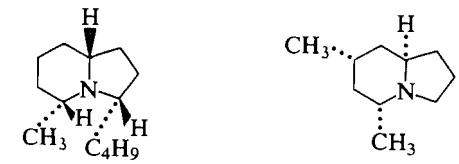
The apparent Diels–Alder reactions of *N*-acylimines or their salts have been the subject of much study (*la–f* and references therein). The initial objective of the present research was to define the mildest conditions under which intermolecular cycloaddition of simple *N*-acylimines to 1,3-dienes would take place, to obtain products from sensitive dienes. However, despite our success in isolating a steroidal *N*-acylimine with hydrogen on the imine carbon (aldimine) (2) it appeared that simpler *N*-acylaldimines such as **1** are too reactive to be readily isolated (see, however, ref. 3 for more stable electronegatively substituted examples).

We hence attempted to isolate crystalline salts of 1,2-dehydropyrrolidin-2-one **1** using the action of acetyl chloride or acetyl perchlorate on the readily available 5-ethoxy-2-pyrrolidinone **2** (4). Again this failed, although reactions showed that these salts were undoubtedly formed (see method D below).

As a consequence we changed our objective to reaction of salts of **1**, generated *in situ*, with simple 1,3-dienes, with the hope of stereo-controlled natural product synthesis. Preliminary studies using **3** (R = OCHO) or **3** (R = $OCOCH_3$), derived from **2**, as sources of the corresponding salts of **1**, using heat or triethylamine failed to give Diels–Alder adducts with 2,3-dimethylbutadiene. Success was achieved using **2** or **3** with a variety of Brönsted or Lewis acids. Low to good yields of 6,7-dehydroindolizidin-3-ones were obtained from a variety of 1,3-dienes, in addition to monocyclic addition products. In this way a precurser to *dl*-gephyrotoxin 223AB (**4**) (5) and possible precursers for monomorine (**5**) (6) and dendroprimine (**6**) (7) were generated.



1 **2** **3** **4**



5 **6**

Results

The reaction of **2** with 1,3-dienes using methods A–E, but with some variation in relative concentrations (detailed in the Experimental), will be described under individual dienes. Method A used formic acid as solvent and catalyst; method B used methanesulfonic acid in dichloromethane; method C involved a stirred two-phase system of chloroform and 36% perchloric acid; method D used preformed salts of **1** in acetonitrile; method E was designed for use with acetoxydienes, using boron trifluoride etherate in acetic acid – acetic anhydride mixtures.

Three methods were used for reaction of **2** with isoprene. From reaction in formic acid (method A) an 80% yield of a mixture of two monocyclic formates was isolated. A negligible amount of the 6,7-dehydroindolizidinone **8** was produced. The ratio of the formates was roughly 2:1. That these had structures **7***a* and **7***b* followed from analysis, ^{1}H nmr spectra, and their nearly identical ^{13}C nmr spectra. Proton decoupling experiments showed that the vinyl hydrogen was coupled (J = 7 Hz) with the methylene carrying the formate group and that the 4′-methylene was only significantly coupled to H-5. Use of method C gave a 10% yield of 6,7-dehydro-6-methylindolizidin-3-one **8**. The complex mixture of monocyclic products was not separated. Using method D a 9% yield of **8** was isolated. The main products were monocyclic lactam dienes, which were not characterized.

The structure of **8** followed from its analysis, mass spectrum, and nmr spectra. The fact that the vinyl hydrogen and the 5-methylene of **8** were not coupled located the methyl group on C-6.

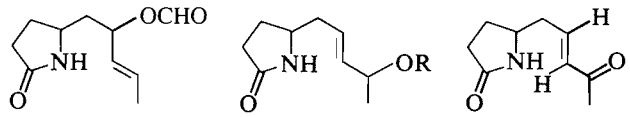
The action of formic acid on *trans*-piperylene (method A) gave a 57% yield of monocyclic formates and an 11% yield of a dehydroindolizidinone. The formate mixture was partially separated on silica, giving a 1.5% yield of a crystalline isomer, mp 102°C. This was assigned structure **9** on the basis of analysis and spectra. Its ^{13}C nmr spectrum showed the presence of a secondary formate (doublet at 72.3 ppm) and its ^{1}H nmr spectrum had signals for a vinyl methyl group (doublet at δ 1.7). The other formates were oils, but after hydrolysis and separation on silica gel these gave two crystalline lactam alcohols. One with mp 117°C (35% yield) had a three-hydrogen doublet at δ 1.22, while the other with mp 72°C (23% yield) had a comparable doublet at δ 1.24, clearly indicating with the other spectral evidence that they were stereoisomers with gross structure **10** (R = H). Oxidation of both gave the same conjugated ketone **11**



9 **10** **11**

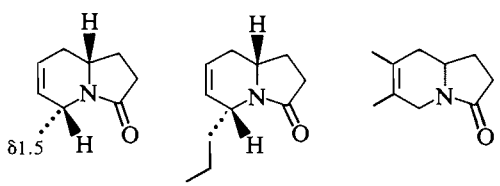
showing that the isomerism was at the secondary alcohol center. The *J* value of 16 Hz for the vinyl hydrogen signal at δ 6.17 showed that the double bond had the *E* configuration. Thus the major formates had structure **10** (R = CHO).

The dehydroindolizidinone was one isomer that from its ^{1}H and ^{13}C nmr spectra clearly had gross structure **12**. By analogy to the chemical shift of the 5-methyl group near the plane of the carbonyl in one of the isomers from 3-methyl-1,3-pentadiene (see below) we conclude that this had an equatorial methyl *anti* to the 9-hydrogen as shown in **12**. It is thus a promising precurser for the synthesis of the trail pheromone of the Pharoah ant, monomorine **5** (6), and its C-3 epimer.

Reaction of **3** with *E*-1,3-heptadiene in formic acid (Method A) gave a 15–20% yield of the desired dehydroindolizidinone **13**, and a mixture of formates that were not separated. The use of method B resulted in a 25% yield of **13**, the remainder being a mixture of lactam dienes that was not further characterized.

The dehydroindolizidinone was one isomer. By analogy to the product from piperylene we assumed that the configuration was that shown in **13** (plus its mirror image) with the 5 and 9 hydrogens *syn* to each other. This was precisely what was needed as a precurser of the proposed structure for gephyrotoxin 223AB (5*a*). As outlined below, the synthesis succeeded (see 5*b* for a preliminary account) and the stereochemistry was confirmed by X-ray analysis (8).

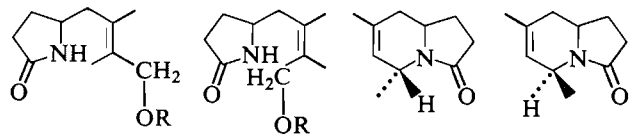
Modest yields of an indolizidinone were obtained from 2,3-dimethylbutadiene. Method A gave a 16% yield of the bicyclic lactam **14** and a 43% yield of a mixture of formates **15***a* and **15***b*



12 **13** **14**

(R = CHO). The ^{1}H nmr spectrum of the formates appeared to be that of one compound, but the ^{13}C nmr spectrum had 24 signals, showing the presence of two isomers. To our surprise, hydrolysis of the formates gave a sharp-melting lactam alcohol, mp 94–95°C. Again its ^{13}C nmr spectrum showed this to be a equimolar mixture of two very similar isomers. The ^{1}H nmr spectrum now showed the presence of two NH groups. We conclude that the isomeric alcohols were **15***a* and **15***b* (R = H) with NH signals at δ 7.7 and δ 8.5 respectively. A comparable yield of **14** (19%) was obtained using method B in benzene with *p*-toluenesulfonic acid.

trans-2-Methyl-1,3-pentadiene gave the highest yield (over 70%) of dehydroindolizidinone of any of the dienes studied, using method A. Although many other products were detected by tlc, only a small amount of formate ester was formed. The bicyclic product was a 1:1 mixture of isomers, separable on silica gel using a 1:1 acetone–hexane mixture. Their very similar ^{1}H and ^{13}C nmr spectra showed them to be stereoisomers with structures **16** and **17**. The assignment of configuration to

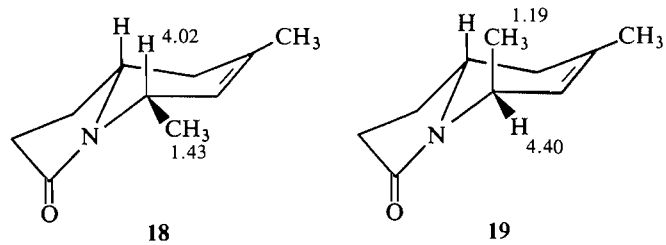


15*a* **15***b* **16** **17**

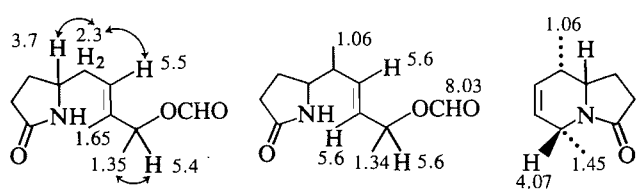
each was possible because the methyl group in the plane of the carbonyl was deshielded relative to that of it epimer (see **18** and **19**). The structure and stereochemistry of **19** make it a potentially valuable precurser of the orchid alkaloid dendroprimine **6** and its 7-epimer (7).

Reaction of *trans*-3-methyl-1,3-pentadiene with **2** following method A gave little, if any, bicyclic product. Monocyclic formates were produced in 75% yield. The ^{13}C nmr spectrum showed this to be a mixture consisting mainly of two closely related isomers. This and the ^{1}H nmr spectrum (see **20**) are consistent with this structure, with the isomers probably being the epimeric formates (see the piperylene case). Demonstrated couplings are indicated by double-headed arrows.

In reaction of *trans,trans*-2,4-hexadiene using method A, only minor amounts of bicyclic product and a 70% yield of monocyclic lactam formates were produced. The ^{13}C nmr spectrum of the formates showed this to contain two nearly identical stereoisomers. This and the ^{1}H nmr spectrum were consistent with structure **21**, with the isomers likely to be the epimeric formates. In contrast, the use of method C gave 20% of bicyclic product. Only one isomer was formed (^{13}C nmr). The chemical shift of the 5-methyl group and 5-hydrogen are close to those for



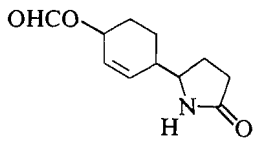
18 **19**



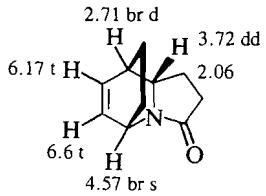
20 **21** **22**

18, hence we assign the stereochemistry shown in **22**, assuming retention of the original diene geometry.

When 1,3-cyclohexadiene reacted with **2** in formic acid following method A, both products of one-bond and of two-bond formation were observed. The one-bond products (42%) were a



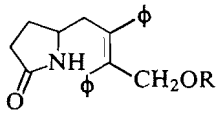
23



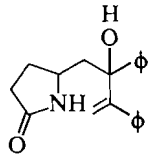
24

mixture of four isomeric formates. The spectra of the mixture were consistent with stereoisomers of structure **23**. In contrast, the two-bond product (40%) gave a single set of ^{13}C nmr signals, hence it was most probably one isomer. We assign structure and stereochemistry shown in **24** to it on the basis of analysis, spectra, and arguments based on maximum orbital overlap in the transition state for cyclization (see Discussion).

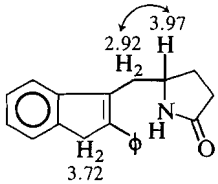
No dehydroindolizidinone was detected when 2,3-diphenyl-1,3-butadiene was treated with **2** in formic acid when method A was used. Instead the major products were a mixture of lactam formates and an indene derivative. The formates were hydrolysed, then the mixture separated in silica gel, giving a hydroxy lactam, mp 177°C (24%), and a second, mp 196°C (4%). The former had an uv spectrum (λ_{max} 234 nm, ε 11 800), analysis, and ^1H and ^{13}C nmr spectra consistent with structure **25**. Although the minor alcohol analysed for an isomer of **25**, its uv spectrum (λ_{max} 252 nm, ε 8440) and ^1H nmr signals were unusual. No ^{13}C nmr spectrum was obtained. Structure **26** seems a reasonable possibility, with the two vinyl hydrogens resonating at δ 4.59.



25



26

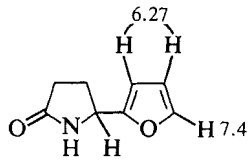


27

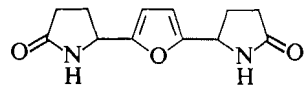
The most interesting product (14%) was assigned the substituted indene structure **27** on the basis of analysis, its uv spectrum (λ_{max} 289 nm, ε 14 800), and its ^1H nmr spectra and the coupling indicated by the double-headed arrow. The presence of five singlets between 134 and 145.8 ppm and eight doublets between 119.4 and 128.6 ppm in its ^{13}C nmr spectrum confirmed this structure.

The use of method C converted 2,3-diphenylbutadiene into a mixture of coupling products, which seemed to be dienes corresponding to proton elimination from original allylic cations.

As would be expected if the reaction were electrophilic attack by the *N*-acyl immonium ion from **1**, methods C and D on furan gave the 2-substituted derivative **28**, mp 82–83°C. The use of $Cu(BF_4)_2$ as catalyst in chloroform and **2** as reagent gave **28** and the product **29** of substitution on the two α positions. The simplicity of its ^1H nmr spectrum is suggestive of a *syn* relationship of the pyrrolidinone rings.



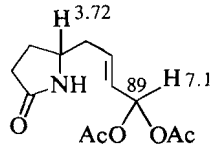
28



29

Using method E, 1-acetoxy-1,3-butadiene gave predominantly monocyclic coupling products. The major one (33%) was crystalline, mp 111–112°C. Its analysis and spectra were only consistent with structure **30** (see figure). Hydrogenation of **30** over Pd(C) gave mainly simple reduction of the double bond. The acylal hydrogen signal became a triplet (J = 5 Hz) at δ 6.8.

Reaction of the sensitive dienes 2-acetoxy- and 2-trimethylsilyloxy-1,3-butadiene with **2** and **3** (R = OAc) under a variety of conditions gave bad mixtures and no products were characterized.



30

Synthesis of *dl*-gephyrotoxin 223AB (**4**) from the dehydroindolizidinone **13** was accomplished in 15% overall yield. The 6,7-dehydro-5-propylindolizidin-2-one **13** was reduced catalytically to **31**. This was transformed using small modifications of a sequence used by Hart and Tsai (8) into **4** (see Flowsheet). The major differences from their procedure was the use of Lawes-

For personal use only.

son's reagent (9) to make the thiolactam **32** and of Raney nickel to desulfurize the dithioketal **36**. Both steps were efficient.

Two epimers at C-3 of the saturated keto lactams (**34** and **35**) were produced, distinguished by the fact that one gave a readily crystalline hydrochloride, while the salt of the other remained amorphous. However, it appeared that the amorphous salt was slowly converted into the crystalline one on standing. A mechanism exists for such an interconversion (eq. [1]), but the

[1] 
phenomenon has not been rigorously examined. The crystalline salt was used for subsequent reactions, and fortunately proved to have the desired stereochemistry shown in **34**.

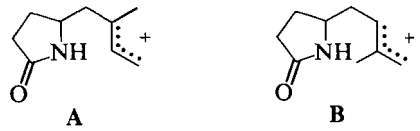
The final product had the same gc retention time as authentic gephyrotoxin-223AB[4] and gave a ^{13}C nmr spectrum identical to that found by Professor Tokuyama and co-workers for natural toxin (10). The ^{13}C nmr spectrum differed significantly from that reported by Macdonald for his synthetic isomer (11) but agreed well with that reported by Royer and Husson (12) for their synthetic optically active toxin. The structure and relative stereochemistry of the hydrobromide of our synthetic base **4** was determined by Pryzbylska and Ahmed (13) using X-ray crystallography.

A parallel series of transformations has been used to convert **12** into analogues of **32** and **33**, thus paving the way to a synthesis of *dl*-monomorine (unpublished work in these laboratories).

Discussion

The apparent Diels–Alder reactions of *N*-acyl imines or their salts have been the subject of much study. Both intermolecular and intramolecular examples have been provided (1*a–f*, and references therein). In the cases where Brönsted or Lewis acids catalysed the reactions, highly polarized acyl immonium salts[5] were present, and the possibility exists that the reactions were stepwise cationic additions. Indeed, in our own cases, the production of varying amounts of products in which only one carbon–carbon bond had been formed, the internal attack on an aromatic ring (for 2,3-diphenyl-1,3-butadiene) (see also ref. 15), and the substitution of furan all argue for a stepwise process. The regiochemistry and stereochemistry of the Diels–Alder-type products can equally well be accounted for with this mechanism (see below). The high temperature intramolecular reactions of Weinreb and Levin (1e) (in the presence of the weak acetic acid) stand a better chance of being true Diels–Alder reactions of the transient *N*-acyl imines.

The regiochemistry of the formate ester production is consistent with attack of the *N*-acyl immonium ion on an unsubstituted end of the 1,3-diene, if available. In all unsymmetrical cases except that of isoprene, this appeared to give the thermodynamically more stable cation. However, calculation of the relative energy of the cations **A** and **B** from isoprene favored **B** by 6 kcal/mol.[6] But the formate arose from **A**, hence kinetic factors determined the site of attack.



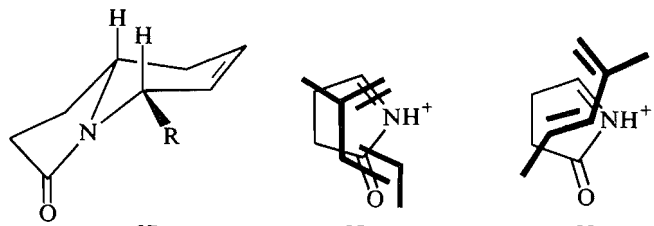
A **B**

The regiochemistry of dehydroindolizidinone formation, however, was consistent in all cases with attack on the least substituted end of the diene, leading to formation of the most substituted (lowest energy) delocalized allylic cation.

The yield of dehydroindolizidinones, using method A (formic acid), from the various dienes studied, varied from traces (isoprene) to over 70% (2-methyl-1,3-pentadiene). This is not simply a consequence of the rotamer populations in the diene. Herman[6] has calculated that only 2,3-dimethyl-1,3-butadiene has more *s-cis* than *s-trans* rotamer present at room temperature. It is also not related to the barrier to rotation or relative stability of the two delocalized allylic cations (see discussion below). Thus the origin of the difference is subtle, and may reflect nonbonded interactions in a reaction complex or transition state.

The factors involved in determining the relative stereochemistry of the bicyclic products can be illustrated with the cases of *trans*-piperylene, *trans*-1,3-heptadiene, and *trans*-2-methyl-1,3-pentadiene. The dehydroindolizidinones from the first two were essentially pure **37** (R = CH_3 and C_3H_7 respectively). These are the thermodynamically more stable isomers, but also those expected from maximum secondary orbital overlap corresponding to the Diels–Alder *endo* rule (see **38**).

That the orbital overlap is a dominant factor is supported by the case of 2-methyl-1,3-pentadiene. We suggest that in this case the steric repulsion between the 2-methyl group and a methylene group of the immonium ion as in **38** partially overrides the electronic effect, resulting in an equal contribution to the transition state of an orientation depicted in **39**. This



37 **38** **39**

rationalizes the fact that nearly equal amounts of stereoisomers **16** and **17** were formed.

Both Krow *et al.* (1*f*) and Weinreb and Levin (1*e*) have invoked similar secondary orbital interactions to account for the stereochemistry they encountered in their apparent Diels–Alder reactions.

If the reactions are stepwise and the above arguments are correct, our steric results demand a good retention of stereochemistry in the initially formed allylic cations. Thus little or no rotation about the 2,3 bond takes place in the cations derived from **38** and its analogues from *trans*-piperylene and *trans*-2-methyl-1,3-heptadiene (see **40**). Herman[6] has estimated a barrier of around 15 kcal/mol (average of the two barrier heights) to rotation in the case where $R^2 = R^3 = CH_3$ (from 2-methyl-1,3-pentadiene) and R^2 = H, $R^3 = CH_3$ (from isoprene), but somewhat higher (17–21 kcal/mol) for the other dienes studied. This is adequate to provide retention of configuration in a stepwise process.

A further test of this steric control would be the geometry of

[4]We cordially thank Dr. T. F. Spande for making this observation and for other exchanges of information.

[5]In accord with traditional usage for amines, an imine should give rise to an immonium salt, not an imminium salt as has often been used.

[6]We warmly thank L. Herman for these calculations, to be reported in a thesis submitted as partial requirement for the Ph.D. degree, Department of Chemistry, Carleton University.

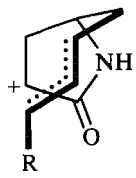
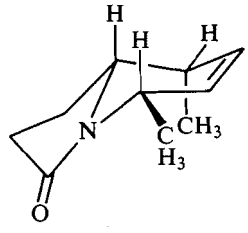
40*a*



40*b*

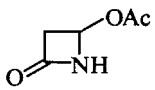


41

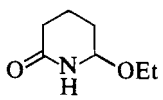
the product from *E,E*-2,4-hexadiene. The dehydroindolizidinone from this had the 5- and 9-hydrogens *syn* (see **41**), as expected for a reaction orientation related to **38**. Thus we predict that the 8-methyl group would be *anti* to the 9-hydrogen as in **41**. Unfortunately we have no evidence defining its configuration.

Our synthesis of (±) gephyrotoxin 223AB (now called indolizidine 223AB) compares favorably in yield and the use of readily available starting materials with the ingenious approaches devised by others (11, 12). The requirement of final resolution to obtain optically active material may make it inferior in practice to the synthesis of Royer and Husson (12). Synthesis of other stereoisomers of gephyrotoxin 223AB have been reported by Hart and Tsai (8), and by Stevens and Lee (16).

The above reactions should be capable of extension to other bicyclic systems fused through nitrogen, using such readily available *N*-acyl imine precursers as **42** (17) and **43** (4).



42



43

Experimental

Separations were done on tlc silica gel with 13% $CaSO_4$ binder and fluorescent indicator, either in a column or 1000-μm plates, or on "flash" silica gel (50–63 μm). Infrared spectra were determined on a Perkin–Elmer model 257 grating spectrometer using dichloromethane solutions. The ^1H and ^{13}C nmr spectra were recorded using a Bruker WP-80 FT spectrometer with deuterochloroform as solvent and TMS as reference. Mass spectra were obtained using electron impact (EI), courtesy of the Ottawa–Carleton mass spectrometry center. Yields were calculated on the basis of the 5-ethoxy-2-pyrrolidinone or 5-acetoxy-2-pyrrolidinone used.

Reagents

5-Ethoxy-2-pyrrolidine 2

This was prepared from succinimide in a manner similar to that of Speckamp and co-workers (4). Simultaneous slow addition of hydrogen chloride in absolute ethanol and solid sodium borohydride, keeping the pH between 4 and 8 and cooling (0–5°C), was necessary to produce moderate yields (ca. 50%).[7] Purification of the ether-soluble product was achieved by passage in ether through a short bed (10-fold weight ratio) of activity II alumina, followed by concentration to small volume and addition of hexane. It formed large prisms, mp 56–58°C, and gave ^1H nmr signals at δ 8.1 (br, NH), 4.97 (br m, 1H), 3.5 (br m, 2H), 2.3 (m, 4H), and 1.20 (t, 3H, J = 7 Hz). More polar fractions yielded needles, mp 63–65°C, which from their ^1H nmr spectra were a 1:1 eutectic of succinimide and **2**.

5-Acetoxy-2-pyrrolidinone 3 (R = Ac)

A solution of 127 mg of 5-ethoxy-2-pyrrolidinone (**2**) in 1 mL of acetic acid and 0.75 mL of acetic anhydride was held at 70°C for 4 h. The reagents were removed under reduced pressure of 0.1 Torr (1 Torr = 133.3 Pa). The oily product (126 mg) gave ^1H nmr signals at δ 7.98 (br, NH), 6.05 (1H, m), 2.8–2.1 (4H, m), and 2.18 (3H, s). It was never obtained completely pure.

E-*1,3-Heptadiene*

A commercial sample (Wiley Organics) gave ^{13}C nmr signals at 137.5, 135.3, 131.2, 114.6, 34.7, 22.5, and 13.7 ppm. It thus appeared to be one isomer, which on the basis of the geometry of derived products (see gephyrotoxin-223AB) had the *E* configuration of the internal double bond.

E-*2-Methyl-1,3-pentadiene*

The commercial sample used (Aldrich) gave ^{13}C nmr signals at 142.2, 134.3, 125.4, 113.8, 18.7, and 18.1 ppm.

1-Acetoxy-1,3-butadiene

A commerical sample (Aldrich) was freshly distilled under reduced pressure. It was an approximately 60:40 mixture of two isomers according to its ^1H nmr spectrum. The main isomer give signals at δ 7.5 (1 H, d, J = 12 Hz), a complex set of signals between 6.5 and 4.6 (4H) and 2.2 (3H, s).

General conditions for 1,3-diene reactions[8]

Method A

A mixture of 301 mg of 5-ethoxy-2-pyrrolidinone **2**, 805 mg of freshly distilled 2,3-dimethyl-1,3-butadiene, 4 mL of 98% formic acid, and 0.6 mL of dichloromethane gave two phases. This was stirred under argon for 3 h. A trace of upper phase persisted. The solvents and the bulk of the formic acid were removed *in vacuo* in 35°C. The residue was dissolved in 15 mL of dichloromethane. The solution was washed with 3 mL of water, then 3 mL of saturated sodium bicarbonate solution. The aqueous layers were washed twice with 15-mL portions of dichloromethane. The organic layers yielded 710 mg of pleasant-smelling oil. This was hydrolysed for 1 h using 326 mg of potassium carbonate in 2 mL of water and 1 mL of methanol (stirring, room temperature). The bulk of the methanol was removed under reduced pressure, then the products were extracted into dichloromethane (3 × 7 mL). The 660 mg of oil recovered from the CH_2Cl_2 was absorbed from this solvent onto 40 g of silica gel. Elution with CH_2Cl and 0.75% methanol in chloroform gave products derived from the diene alone. A 5% methanol in chloroform mixture eluted products less polar than the desired bicyclic product **14**, followed by fractions rich in this compound (447 mg). This was followed by 64 mg of crystalline hydroxy lactam **15** (R = H). The fractions rich in **14** were separated on five silica gel plates using 5% methanol in chloroform into (*a*) 175 mg of a mixture of **14** with a monocyclic product with ν_{max} 3420 and 1696 cm^{-1} (not identified), and (*b*) 102 mg, rich in hydroxy lactam **15** (R = H). The mixture (*a*) was separated on 1000-m alumina plates using 4% ethanol in chloroform. The yield of bicyclic lactam **14** was 45 mg (12%) and of the crystalline lactam **15** (R = H) was 166 mg (39%).

If the crude reaction product was not hydrolysed the product could be separated on silica gel to give **14** (16%) and the formate **15** (R = OCHO) (43%). See also the detail for 2,3-diphenyl-1,3-butadiene.

Method B

Separate solutions of 5.6 g of *trans*-piperylene, 3.27 g of 5-ethoxy-2-pyrrolidinone in 9 mL of dry methylene chloride, and 3.13 g of methanesulfonic acid in 3 mL of methylene chloride were cooled to 0°C, then mixed. The resulting solution was left at 0°C for 64 h, then added to a stirred mixture of 10 mL of chloroform and 20 mL of water. The mixture was carefully neutralized using solid sodium bicarbonate. The layers were separated, and the aqueous layer extracted with three 30-mL volumes of chloroform. The chloroform extracts were washed with 10 mL of saturated brine, dried, and distilled. The residue was adsorbed from methylene chloride onto 200 g of silica gel and the products eluted with 25% ethyl acetate in methylene chloride. Three hundred millilitres of solvent eluted 787 mg of products derived from piperylene alone. Five percent ethanol in methylene chloride (600 mL) eluted 226 mg of unidentified products. The next 300 mL eluted 2.2 g rich in the desired bicyclic adduct but containing more polar and less polar compounds. These were removed on 1000-μm silica gel plates

[7]We thank Paul Desilets for experiments on these conditions. We were unable to obtain the high yields reported in ref. 4.

[8]These are illustrated using specific dienes.

For personal use only.

using 5% ethanol in chloroform. The desired dehydroindolizidinone **12** weighed 530 mg (14%). See also the detail for 1,3-heptadiene.

Method C

A solution of 65 mg of 5-ethoxy-2-pyrrolidinone **2** and 200 mg of *E,E*-2,4-hexadiene in 1 mL of chloroform was cooled to −10°C. To this was added 0.5 mL of 36% perchloric acid. The mixture was stirred at −10°C for 1 week. Chloroform was added, followed by saturated sodium bicarbonate solution to neutralize the acid. The solution was dried using anhydrous sodium sulfate. The products were separated on a silica gel plate using 5% ethanol in chloroform, giving 17 mg (20%) of the dehydroindolizidinone **22**. The other major products derived from **2** appeared to be monocyclic dienes, but were not further characterized.

Method D

A solution of 123 mg of acetyl chloride in 1 mL of dry benzene was added to a solution of 300 mg of silver perchlorate in 2 mL of dry benzene. Silver chloride separated. The mixture was filtered through sintered glass under dry argon into a solution of 190 mg of ethoxy lactam **1** in 1 mL of benzene. A precipitate formed. The bulk of the benzene was removed under reduced pressure, then a solution of 217 mg of isoprene in 3 mL of dry acetonitrile was added. The mixture was left under argon for 4 days at room temperature. The solvent was evaporated, the products extracted into dichloromethane (filtered), then the solution and washings stirred with 1 mL of saturated sodium bicarbonate solution. The water was absorbed using anhydrous sodium sulfate, then the dichloromethane removed. The 263 mg of residue was adsorbed from dichloromethane onto 7 g of silica gel. The products were eluted successfully with dichloromethane, 0.5% methanol in chloroform, then 5% methanol in chloroform. The 70 mg rich in bicyclic lactam (tlc) was further separated on a 100-μm silica gel plate using 7% methanol in chloroform. The desired bicyclic product **8** (ca. 20 mg, 9%) was still contaminated with a slightly more polar product (ν_{max} 3430 and 1687 cm^{-1}), which was probably a monocyclic diene.

In other experiments using the same ratio of silver perchlorate but only half the molar equivalent of acetyl chloride, the yield of bicyclic lactam **8** remained at 9%, but a new product with slightly lower R_f in silica gel was isolated and characterized as a trimer of the *N*-acyl imine **1** with mp 205°C.

Method E

5-Acetoxy-2-pyrrolidinone **3** (R = Ac) was prepared from 127 mg of **2** as described above. This was combined with 300 mg of freshly distilled 1-acetoxy-1,3-butadiene in 0.75 mL of acetic acid and 0.4 mL of acetic anhydride. To this was added 60 mg of boron trifluoride etherate. The clear solution was left for 5 h at room temperature under argon, then the solvents removed under 0.1 Torr at 40°C. Water and dichloromethane were added, followed by enough sodium bicarbonate to bring the pH to 7 (stirring). The dichloromethane layer was separated, then the aqueous layer extracted twice with the same solvent. The organic extracts yielded 131 mg of an oil that crystallized on standing. The crystals were collected using an acetone–hexane mixture. The mother liquors were separated on a silica gel plate giving more of the crystals. The isolated yield of crude lactam acylal **30** was 70 mg (28%), mp 108–110°C.

Reactions of specific dienes

Isoprene

Using method A (516 mg of **2**, 25 mL of 98% formic acid, and 1.5 mL of isoprene for 2 h at room temperature), an 83% yield of the monocyclic formate **7** was obtained, and only a trace of indolizidinone was detected.

Using method C (65 mg of **2**, 200 mg of isoprene, 0.5 mL of 36% perchloric acid, and 0.5 mL of chloroform stirred 7 days at −10°C), a 10% yield of the indolizidinone **8** was obtained.

See also method D, above.

5,9-syn-6,7-Dehydro-6-methylindolizin-2-one 8

This was an oil with ν_{max} 1668 cm^{-1} and ^1H nmr signals at δ 5.40 (1H, br s), 4.24 (1 H, d, J = 5 Hz), 3.56 (1H, br s), 3.49 (1H, d, J = 5 Hz), 2.40 (ca. H, m), 2.12 (ca. H, br s), and 1.71 (3H, s). The vinyl hydrogen was not coupled to any of the other three low-field hydrogens.

Its ^{13}C nmr spectrum had signals at δ 173(s), 131(s), 117(d), 53(d), 40(t), 37(t), 30.5(t), 22.5(t), and 23(q). It gave m/z 152 (9), 151 (75) (M^+), 150 (15), 136 (51), 108 (24), 96 (17), 94 (23), 84 (37), 68 (100). *Anal.* calcd. for $C_9H_{13}NO$: C 71.49, H 8.67, N 9.26; found: C 71.66, H 8.84, N 9.16.

1-Hydroxy-3-methyl-4-(5'-oxo-2'-pyrrolidinyl)-but-2-en-1-ol formate 7

This was a viscous oil with ν_{max} 3430, 1723, and 1700 cm^{-1}. It gave ^1H nmr signals at δ 8.06 (1H, s), 7.1 (br s, NH), 5.43 (1H, t, J = 7 Hz), 4.69 (2H, d, J = 8 Hz), 3.82 (1H, m), and 1.75 (3H, s). Irradiation at δ 2.27 reduced the multiplet at 3.8 to a broad singlet; the doublet at 4.69 collapsed to a singlet when δ 5.4 was irradiated, and irradiation at 4.7 collapsed the triplet at 5.4 to a singlet. Its ^{13}C nmr spectrum had signals at δ 178.0(s), 160.7(d), 138.3(s), 121.0(d), 60.1(t), 52.2(d), 46.5(t), 30.1(t), 26.7(t), and 16.5(q) ppm. Extra signals for a minor isomer were present at 138.8, 121.6, 59.9, 52.5, 26.9, and 23.5 ppm with the same multiplicities as the major peaks. *Anal.* calcd. for $C_{10}H_{15}NO_3$: C 60.89, H 7.67, N 7.10; found: C 61.07, H 7.83. N 7.24.

trans-*Piperylene*

See also method B above.

Following method A(3 g of **2**, 8 mL of *trans*-piperylene in 35 mL of 98% formic acid, 2 h at room temperature), 4 g of less volatile products were obtained. Separation on 160 g of silica gel gave 2.6 g (57%) of monocyclic formates and 600 mg rich in indolizidinone. Further separation of the latter fraction using tlc plates and 5% ethanol in chloroform as solvent gave 369 mg (11%) of bicyclic lactam **12**.

The monocyclic formate was a mixture of at least four isomers. Separation on a 50-fold ratio of silica gel using 5% ethanol in chloroform gave 67 mg (1.5%) of crystalline lactam formate **9**, mp 103°C, as an early eluate. The other isomers were not cleanly separated. Comparison of their ^{13}C nmr spectra showed such close similarity that they were most likely stereoisomers. The mixture was hydrolysed using potassium carbonate in aqueous methanol and the lactam alcohols separated on silica gel, giving 1.4 g (35%) of **10***a* (R = H), mp 117°C, and 0.9 g (23%) of its isomer **10***b* (R = H), mp 72°C.

2-Hydroxy-1-(5'-oxo-2'-pyrrolidinyl)-3-pentene formate 9

This had mp 102–103°C and ν_{max} 3420, 3210, 172) (sh), and 1692 cm^{-1}. Its ^1H nmr spectrum had signals at δ 8.08 (1H, s), 6.71 (br s, NH), 5.2–6.0 (3H, m), 3.69 (1H, m), and 1.72 (3H, d, J = 4 Hz). Its ^{13}C nmr spectrum had signals at δ 178.0(s), 160.5(d), 130.7(d), 128.2(d), 72.3(d), 50.75(d), 41.6(t), 27.5(t), and 17.6(q). *Anal.* calcd. for $C_{10}H_{15}NO_3$: C 60.89, H 7.67, N 7.10; found: C 61.02, H 7.74, N 6.97.

This gave an amorphous lactam alcohol with a ^1H nmr spectrum different from either isomer described below.

Major formates 10 (R = CHO)

This mixture gave ^1H nmr signals at δ 8.08 (1H, s), 7.02 (1H, br s), 5.1–5.8 (3H, m), 3.5–3.9 (1H, m), 1.35 (3H, d, J = 6 Hz). The methyl group was coupled to a proton resonating at δ 5.5. Its ^{13}C nmr spectrum had signals at δ 178.3(s), 160.2(d), 132.6(d), 128.1(d), 70.53(d), 70.46(d), 53.7(d), 39.0(t), 30.0(t), 26.2(t), and 20.0(q) ppm. The signals at 70.53 and 70.46 correspond to epimers at the carbon carrying the formate ester.

*4-Hydroxy-1-(5'-oxo-2'pyrrolidinyl)-2-pentene 10*a (*R = H*)

This had mp 116–117°C and gave ^1H nmr signals at δ 8.57 (NH), 5.6 (2H, br m), 4.53 (1H, OH), 4.24 (1H, m), 3.7 (1H, br m), and 1.22 (3H, d, J = 6 Hz). Its ^{13}C nmr spectrum had signals at δ 179.6(s), 138.9(s), 126.4(s), 68.9(s), 55.2(s), 40.0(t), 31.0(t), 27.15(t), and 22.9(q) ppm. *Anal.* calcd. for $C_9H_{15}NO_2$: C 63.88, H 8.94, N 8.28; found C 63.72, H 9.01, N 8.18.

*4-Hydroxy-1-(5'-oxo-2'-pyrrolidinyl)-2-pentene 10*b (*R = H*)

This crystallized from concentrated ethyl acetate solution, and had mp 70–72°C. It had ν_{max} 3600, 3380, 3220, and 1685 cm^{-1} and gave ^1H nmr signals at δ 7.59 (NH), 5.68 (2H, m), 4.27 (1H, m), 3.79 (1H, t), 3.33 (1H, br s), 1.68 (1H, br s), and 1.24 (3H, d, J = 6 Hz). The

hydrogen resonating at 4.27 was coupled to the methyl group (δ 1.24). Its ^{13}C nmr spectrum had signals at δ 179.2(s), 138.0(d), 125.0(d), 67.6(d), 54.6(d), 39.0(t), 30.7(t), 26.9(t), and 22.8(q) ppm. Its EI mass spectrum gave no parent ion. The base peak was at *m/z* 84. Its CI mass spectrum gave peaks at *m/z* 170 (*M* + 1) and 152 (*M* − 18).

*Oxidation of **10**a and **10**b*

To a solution of 31 mg of **10***b* in 2 mL of dichloromethane was added 855 mg of active manganese dioxide (18) (dried at 45°C *in vacuo*). After the mixture had been stirred 1.25 h, 5 mL of 10% methanol in chloroform was added, then the solid removed by filtration. The filtrate and washings were evaporated, giving 30 mg of residue. This was purified on a 500-μm silica gel plate using 10% methanol in chloroform, giving 20 mg in a main zone. This crystallized from ethyl acetate – ether mixtures, mp 65–68°C. Jones oxidation of **10***b* in acetone gave a 30% yield of the same product.

Manganese dioxide oxidation of ***10a*** as above gave a product with mp 64–67°C. The products from both isomers proved identical (mixture mp and comparison of ir and ^1H nmr spectra).

*Keto-lactam **11***

This had mp 65–68°C and ν_{max} 3420, 3200, 1699, 1675, and 1631 cm^{-1}. Its EI mass spectrum gave no parent ion. The base peak was at *m/z* 84 ($C_4H_6NO^+$). Its CI mass spectrum (ether) gave *M* + 1 at *m/z* 168 and *M* −18 at *m/z* 149. Its ^1H nmr spectrum gave signals at δ 6.88–6.57 (1H, m), 6.55 (br m, NH), 6.17 (1H, d, *J* = 16 Hz), 3.81 (1H, m), and 2.26 (3H, s) superimposed on a 6H multiplet.

E-*1,3-Heptadiene*

The use of method A gave a mixture of formate esters with ^1H nmr signals at δ 8.0 (1H, s), 7.0 (1H, NH), 5.9–5.1 (3H, m), 3.7 (1H, m), and 0.9 (3H, t) typical of the monocyclic lactam formates described from other dienes. The yield of dehydroindolizidinone **13** (ca. 15%) was lower than that using method B, hence the latter method was used in preparative work.

In a minor modification of method B, 5.8 g (45 mmol) of **2** and 17 g (180 mmol) of *E*-1,3-heptadiene in 40 mL of dry dichloromethane was cooled to −5°C. A solution of 4.7 g (49 mmol) of methanesulfonic acid in 15 mL of dichloromethane was added to this with stirring during 15 min. The mixture was stirred at 0°C for 120 h. Separation of the products on silica gel gave two pairs of ethoxy lactams, corresponding to the formate esters from method A, and 1.3 g of pure **13** followed by 0.76 g of **13** contaminated with monocyclic adducts. The latter was purified using silica gel plates, giving a total yield of 1.7 g (21%) of **13**.

*5,9-*syn*-6,7-Dehydro-5-(1'-propyl)indolizidine-3-one (**13**)*

This distilled over a short path of 95°C under 0.05 Torr as a colorless oil. It had ν_{max} 1677 cm^{-1} and ^1H nmr signals at δ 5.75 (2H, m), 4.1 (1H, br), and 3.47 (1H, m), with peaks at 2.29, 1.00, and 0.90. Its ^{13}C nmr spectrum had signals at δ 175.4(s), 129.0(d), 123.9(d), 55.6(d), 52.5(d), 34.5(t), 31.8(t), 31.1(t), 26.6(t), 16.7(t), and 13.9(q). Its mass spectrum gave peaks at *m/z* 179 (5.3), 164 (2.9), 150 (12), 137 (39), 136 (99), and 108 (100). *Anal*, calcd. for $C_{11}H_{17}NO$: 73.70, H 9.56, N 7.81; found: C 73.52, H 9.43, N 7.69.

2,3-Dimethyl-1,3-butadiene

See method A above. The yield of the dehydroindolizidine **14** was around 16%.

*7,8-Dehydro-7,8-dimethylindolizidin-2-one **14***

This was an oil with ν_{max} 1670 cm^{-1}. It gave ^1H nmr signals at δ 4.3, 4.0, 3.56 and 3.2 (br, 3H total), and 1.68 (6H, s). Its ^{13}C nmr spectrum had signals at δ 173.4(s), 123.5(s), 121.7(s), 53.0(d), 44.0(t), 38.1(t), 29.7(t), 24.8(t), 18.7(q), and 15.7(q) ppm. It gave *m/z* 165 (100), 150 (100), 122 (34), 108 (29), 94 (23), 84 (51), 82 (100), and 67 (100). *Anal.* calcd. for $C_{10}H_{15}NO$: C 72.69, H 9.15, N 8.48; found: C 72.47, H 9.01, N 8.29.

*2,3-Dimethyl-4(2'-oxopyrrolidin-5'-yl)-but-2-en-1-ol formate **15** (R = CHO)*

This was an oil distilling over a short path at 150°C, 0.25 Torr. It had ν_{max} 3420, 1718, and 1698 cm^{-1} and gave ^1H nmr signals at δ 8.20 (1H, s) 7.8 (1H, br s), 4.70 (2H, s), 3.85 (1H, br m), and 1.80 (6H, s). Its ^{13}C nmr spectrum had signals at δ 178.2, 161.1, 132.3, 131.8, 126.3, 126.2, 64.9, 64.4, 53.2, 53.0, 52.9, 41.4, 41.1, 30.9, 30.6, 30.5, 30.3, 27.3, 27.1, 27.0, 19.1, 18.5, 17.0, and 16.9 (24 signals, i.e., two isomers). Hydrolysis of this formate in methanol containing potassium carbonate gave the crystalline alcohol **15** (R = H), mp 93°C.

*2,3-Dimethyl-4-(2'-oxopyrrolidin-5'-yl)-but-2-en-1-ol (**15** R = H)*

After recrystallization from acetone–hexane, **15** had mp 94–95°C. It had ν_{max} 3600, 3380, 3220, 3050, and 1680 cm^{-1} and gave ^1H nmr signals at δ 8.45 (0.5H, m), 7.7 (0.5H, m), 3.4–4.6 (4H), 1.9–2.2 (6H), and 1.80 (6H, s) and ^{13}C nmr signals at δ 179.7, 179.0, 131.9, 131.8, 128.3, 127.9, 63.9, 62.6, 53.5, 41.65, 41.1, 30.9, 27.9, 27.4, 19.1, 17.8, 17.4, and 17.0 (18 signals). It was thus a 1:1 mixture of two isomers. *Anal.* calcd. for $C_{10}H_{12}NO_2$: C 65.54, H 9.35, N 7.64; found: C 65.40, H 9.28, N 7.51.

trans-*2-Methyl-1,3-pentadiene*

Method A was followed. A mixture of 2.5 g of ethoxylactam **2**, 4.68 g of freshly distilled *trans*-2-methyl-1,3-pentadiene, and 20 mL of 98% formic acid was stirred under argon for 5 h. Initial cooling was needed to maintain the temperature near 20°C. The reaction mixture was still in two phases. The lower phase was separated, the upper phase washed with 5 mL of formic acid, and the layers again separated. The bulk of the formic acid was removed *in vacuo* and the work-up done as in method A. The 2.25 g (70% calcd. as **16**) of product recovered was predominantly a mixture of the two lactams **16** and **17** in a 1:1 ratio (^1H nmr). These were separated on 100 g of tlc silica gel using a 1:1 mixture of acetone in hexane for elution. Overlapping fractions were separated on 1000-μm tlc plates.

*5,9-*syn*-6-7-Dehydro-5,7-dimethylindolizidin-3-one **16***

The isomer with higher R_f on silica gel (30% acetone in hexane) was an oil, which was distilled over a short path at ca. 90°C, 0.03 Torr. It had ν_{max} 1668 cm^{-1} and gave ^1H nmr signals at δ 5.34 (1H, s), 4.0 (1H, br s), 3.5 (1H, br m), 1.8 (3H, s), and 1.43 (3H, d, *J* = 4 Hz); ^{13}C nmr spectrum, δ: 175.4(s), 130.7(s), 124.7(d), 55.9(d), 48.3(d), 36.9(t), 31.3(t), 26.5(t), 23.0(q), 20.5(q). Its mass spectrum had *m/z* 165 (25) (M^+), 150 (100), and 122 (24). *Anal.* calcd. for $C_{10}H_{15}NO$: C 72.69, H 9.15, N 8.48; found: C 72.44, H 9.03, N 8.33.

*5,9-*anti*-6,7-Dehydro-5,7-dimethylindolizidin-3-one **17***

The isomer with the lower R_f on silica gel (30% acetone–hexane) was distilled over a short path at ca. 90°C, 0.03 Torr. It had ν_{max} 1662 cm^{-1} and gave ^1H nmr signals at δ 5.35 (1H, s), 4.4 (1H, br s), 3.7 (1H, br m), 1.7 (3H, s), 1.15 (3H, d, *J* = 6.6 Hz); ^{13}C nmr spectrum, δ: 173(s), 130.7(s), 123.5(d), 50.0(d), 45.5(d), 37.2(t), 30.0(t), 25.0(t), 23.0(q), and 19.0(q). Its mass spectrum had *m/z* 165(33) (M^+), 150 (100), and 122 (26). *Anal.* calcd. for $C_{10}H_{15}NO$: C 72.69, H 9.15, N 8.48; found: C 72.42, H 9.36, N 8.20.

3-Methyl-1,3-pentadiene

Using method A (65 mg of **2**, 210 mg of 3-methyl-1,3-pentadiene in 3 mL of 98% formic acid for 2 h at room temperature), 80 mg (75%) of monocyclic formate **20** was obtained as an oil.

*5-(5'-Oxo-2'pyrrolidinyl)-3-methylpent-3-en-2-ol formate **20***

This gave ν_{max} 3440, 3220, 1720, and 1695 cm^{-1} and ^1H nmr signals at δ 8.08 (1H, s), 7.13 (1H, br s), 5.4 (2H, m), 3.70 (1H, m), 1.65 (3H, s), and 1.35 (3H, d, *J* = 6.6 Hz). The methyl doublet at δ 1.35 was coupled with a proton resonating near 5.4 (*CH*OCHO) and the singlet at 3.7 and the vinyl hydrogen near 5.5 were coupled to a methylene group resonating near 3.3. Its ^{13}C nmr spectrum showed it to be a mixture of two stereoisomers in nearly equal amounts. The major isomer gave signals at δ 178.4(s), 160.4(d), 137.2(s), 122.5(d), 75.3(d), 54.1(d), 34.5(t), 30.2(t), 26.5(t), 19.0(q), and 12.1(q). *Anal.* calcd. for $C_{11}H_{17}NO_3$: C 62.54, H 8.11, N 6.63; found: C 62.34, H 8.02, N 6.47.

E,E-*2,4-Hexadiene*

Use of method A (61 mg of ethoxy lactam **2**, 190 mg of 2,4-hexadiene in 3 mL of 98% formic acid for 2 h at room temperature) resulted in formation of 71 mg (70%) of monocyclic formate **21**. Little if any dehydroindolizinone was formed.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 93.93.197.157 on 09/07/12
For personal use only.

As described above, a 20% yield of the dehydroindolizidinone **22** was formed using method C.

*5-(5'-Oxo-2'-pyrrolidinyl)-hex-3-en-2-ol formate **21***

This was an oil with ν_{max} 3440, 3220, 1720, and 1691 cm^{-1} and ^1H nmr signals at δ 8.03 (1H, s), 7.65 (br s, NH), 5.56 (main peak of a 3H, mult.), 3.51 (1H, m), 1.34 (3H, d, J = 6 Hz), and 1.06 (3H, d, J = 6.6 Hz). Its ^{13}C nmr spectrum showed it to be a mixture of two very similar isomers. The main one gave signals at δ 178.9(s), 160.3(d), 134.1(d), 130.6(d), 70.7(d), 59.0(d), 41.9(d), 30.3(t), 24.2(t), 20.4(q), and 16.3(q). *Anal.* calcd. for $C_{11}H_{17}NO_3$: C 62.54, H 8.11, N 6.63; found: C 62.23, H 7.94, N 6.72.

*5,8,9-*syn*-6,7-Dehydro-5,8-dimethylindolizidin-3-one (**22**)*

This was an oil with ν_{max} 1675 (s) and 1650 (w) cm^{-1} and ^1H nmr signals at δ 6.1–5.4 (2H, m), 4.07 (1H, br), 3.69 (1H, br), 1.45 (3H, d, J = 6 Hz), and 1.0 (3H, d, J = 7 Hz). The methyl group resonating at 1.45 was coupled with the proton at 4.07, but the methyl at 1.0 was not strongly coupled with any low-field proton. It gave ^{13}C nmr signals at δ 176.8(s), 130.1(d), 129.5(d), 58.7(d), 48.9(d), 32.5(d), 31.2(t), 21.8(t), 21.0(q), and 14.3(q). Its mass spectrum had peaks at m/z 165 (M^+) (36), 150 (77), 122 (14), 108 (8), 94 (11), 84 (58), and 82 (100). The compound was distilled over a short path *in vacuo* for analysis. *Anal.* calcd. for $C_{10}H_{15}NO$: C 72.69, H 9.15, N 8.48; found: C 72.45, H 8.98, N 8.30.

1,3-Cyclohexadiene

Method A was used (65 mg of **2**, 190 mg of cyclohexadiene, and 0.5 mL of 98% formic acid stirred for 4 h at room temperature). After separation on silica gel, using 5% methanol in chloroform, 33 mg (40%) of tricyclic product and 44 mg (42%) of the bicyclic formate were obtained.

*8,9-*syn*-6,7-Dehydro-5,8-ethanoindolizidin-3-one (**24**)*

This distilled over a short path at 50–60°C under 0.1 Torr. It had ν_{max} 1675 cm^{-1} and gave ^1H nmr signals at δ 6.6 and 6.17 (1H each, pseudo triplets, J_1 = 8 Hz and J_2 = 5 Hz from decoupling experiments), 4.57 (1H, br s), 3.72 (1H, dd, J_1 = 9 Hz, J_2 = 5 Hz), and 2.71 (1H, br d, J = 6 Hz). The following couplings were demonstrated: 6.6–6.17; 6.6–4.57; 6.17–2.71; 3.72–2.1. It gave ^{13}C nmr signals at δ 178.1(s), 136.8(d), 130.7(d), 60.1(d), 44.8(d), 35.0(d), 31.8(t), 28.5(t), 24.5(t), and 22.9(t). Its mass spectrum had peaks at m/z 163 (5), 134 (9), 106 (5), 84 (100), 80 (88), and 79 (57). *Anal.* calcd. for $C_{10}H_{13}NO$: C 73.59, H 8.03, N 8.58; found: C 73.41, H 7.95, N 8.73.

*4-(5'-Oxo-2'-pyrrolidinyl)-cyclohex-2-en-1-ol formate (**23**)*

The ^{13}C nmr spectrum of this product showed it to be a mixture of four stereoisomers with correct chemical shifts and multiplicities for **23**. Its ^1H nmr spectrum had signals near δ 8.1 (CHO), 7.4–8.1 (NH), 5.95, 5.82 (vinyl hydrogens), 5.33 (CHN), and 3.6 (CHO-). It was not further characterized.

2,3-Diphenylbuta-1,3-diene

The diene (897 mg, mp 47°C) (19) and 563 mg of ethoxy lactam **2** in 3 mL of dichloromethane and 4 mL of formic acid formed two oil layers. This mixture was stirred under argon for 29 h. An extra 201 mg of ethoxy lactam **2** was added, then stirring continued (total time 71 h). The bulk of the solvent and formic acid were removed on a rotating evaporator at 50°C. The residue was dissolved in dichloromethane, then washed free of acid using aqueous sodium carbonate. The 1.12 g of oil recovered from the dichloromethane was adsorbed on a column of 15 g of tlc silica gel. Dichloromethane eluted 451 mg of diphenylbutadiene, followed by 136 mg of nitrogen-free products (formate esters). Chloroform containing 5% (v/v) of methanol eluted 505 mg of condensation products. This solvent and 10% methanol in chloroform eluted 71 mg of a mixture of more polar products, which was not further investigated.

The 505 mg contained the indene derivative **27** and two formoxy amides. This was partially separated on four 1000-μm silica gel plates using 5% methanol in chloroform. A small zone (R_f 0.7, 51 mg) contained a lactam (1682 cm^{-1}) and gave a weak NH band. It was not identified. Bands rich in indene (R_f 0.6, 218 mg) and formate ester (R_f 0.5, 80 mg) were still mixtures. They were combined and hydrolysed by refluxing for 1 h in aqueous methanol containing potassium carbonate. The product was again separated on three 1000-μm silica gel plates using 7% methanol in chloroform, giving 90 mg of indene **27** (R_f 0.65), 167 mg of hydroxy lactam **25** (R_f 0.5), and 30 mg of hydroxy lactam **26** (R_f 0.3).

In a parallel run, the indene **27** and formate mixture was carefully separated on a 50-fold ratio of flash silica gel using 5% methanol in chloroform, giving quite pure indene **27** in the early eluates and formoxy lactam **25** (R = H) as a more strongly adsorbed fraction.

*2,3-Diphenyl-4-(5'-oxo-2'pyrrolidinyl)but-2-en-1-ol formate (**25**, R = OCHO)*

This was an oil with ν_{max} 3420, 1721, and 1692 cm^{-1} and λ_{max} 233 nm, ε 11 000, Its ^1H nmr spectrum had signals at δ 7.84 (1H, s), 5.85 (br, s, NH), 4.72 (2H, s), and 3.4 (1H, t, J = 5 Hz). Its ^{13}C nmr spectrum had signals at δ 177.8(s), 160.6(d), a cluster of doublets at 127.7–129.0, 141.3, 139.5, and 135.4 (singlets), 65.6(t), 52.7(d), 42.0(t), 29.9(t), and 27.0(t). This was hydrolysed by potassium carbonate in aqueous methanol to the hydroxy lactam **25** (R = H).

*2,3-Diphenyl-4-(5'-oxo-2'-pyrrolidinyl)but-2-en-1-ol (**25**, R = H)*

Yield 24%. This crystallized from acetone as buttons, mp 176–177°C. It had ν_{max} 3380, 3220, and 1675 cm^{-1} and λ_{max} 234 nm, ε 11 800. It gave ^1H nmr signals at δ 87 (1H, br s), 7.1–7.7 (10H, m), 3.8–4.4 (3H, m, includes the OH signal) reduced to a pair of doublets at 3.90 and 4.34 (J = 11 Hz) when exchanged with D_2O, 3.4 (1H, t, J = Hz), and 1.3–2.7 (6H, m), and ^{13}C nmr signals at δ 180.0(s), 141.0(s), 140.3(s), 140.2(s), 137.5(s), 129.0, 128.6, 127.3, 126.9 (aryl doublets), 65.1(t), 53.3(d), 42.0(t), 31.0(t), and 27.1(t). *Anal.* calcd. for $C_{20}H_{21}NO_2$: C 78.14, H 6.89, N 4.56; found: C 77.96, H 6.91, N 4.17.

When warmed with a formic acid – acetic anhydride mixture this gave the formate ester (**25**, R = CHO) described above.

*2,3-Diphenyl-4-(5'-oxo-2-pyrrolidinyl)but-1-en-3-ol (**26**)*

Yield 4%. It crystallized from methanol–acetone mixtures as short needles, mp 195–196°C. It had ν_{max} 3430, 3300, and 1684 cm^{-1} and λ_{max} 252 nm, ε 8440. Its ^1H nmr spectrum had signals at δ 7.07 (10H), 6.55 (br s, NH), 4.59 (2H, m), 3.59 (1H, br m), 2.6–3.2 (2H, m,), 2.4 (OH), 2.0–2.6 (4H, m). *Anal.* calcd. for $C_{20}H_{21}NO_2$: C 78.14, H 6.89, N 4.56; found: C 78.02, H 7.02, N 4.38.

*2-Phenyl-3-(5'-oxo-2'-pyrrolidinylmethyl)indene (**27**)*

Yield 14%. This remained as a thick oil with λ_{max} 289 nm, ε 14 800, λ_{min} 248 nm and λ_{max} 227 nm. It had ν_{max} 3424 and 1694 cm^{-1} and ^1H nmr signals at δ 7.37 (10H), 6.41 (br s, NH), 3.97 (1H, m), 3.72 (2H, s), 2.92 (2H, d, J = 6.7 Hz), and 2.12 (4H, br s). The signals at δ 3.97 and 2.9 were coupled. It gave ^{13}C nmr signals at δ 177.8(s), 145.8(s), 143.9(s), 142.6(s), 137.2(s), 134.8(s), 128.6, 128.4, 128.2, 127.3, 126.5, 125.0, 123.7, 119.4 (doublets), 53.6(d), 42.3(t), 32.8(t), 30.0(t), and 27.2(t). *Anal.* calcd. for $C_{20}H_{19}NO$: C 83.01, H 6.62, N 4.84; found: C 82.88, H 6.70, N 4.72.

Furan

Method C (259 mg of **2**, 425 mg of furan, 1 mL of 30% perchloric acid, 1.5 mL of chloroform for 2 h) gave 251 mg (83%) of crude 5-(2'-furyl)-2-pyrrolidinone **28**, mp 75°C.

Method D (304 mg of **2**, 242 mg of silver perchlorate, 1.5 mL of benzene, and 117 mg of acetyl chloride, then 325 mg of furan in 1 mL of dry acetonitrile, left 4 h at room temperature. After addition of 197 mg of furan the mixture was left for 0.5 h) gave 153 mg of products. After separation on 6 g of silica gel the only compound identified was 70 mg (39%) of **28**.

Copper fluoroborate catalysis

A mixture of 202 mg of **2**, 345 mg of $Cu(BF_4)_2$, and 210 mg of dry furan in 1 mL of dry ethanol-free chloroform gave a green gum and colorless solution. This was stirred for 3 h at room temperature. The solution was diluted with dichloromethane, then washed successively with water (3 mL) and saturated sodium bicarbonate solution (3 mL). Repeated extraction (3×) of the aqueous layers gave 167 mg of oil. This was separated on two 1000-μm silica gel plates using 8% methanol in chloroform giving 40 mg of **28** (17%) and 39 mg of 2,5-bis-(5'-oxo-2'-pyrrolidinyl)furan **29**. The combined aqueous layers were evaporated to near dryness. Dichloromethane was added, then the

For personal use only.

remaining water removed using sodium sulfate. A further 41 mg, rich in **29**, was obtained. The total yield of **29** was 70 mg (19%).

*2-(5'-Oxo-2'-pyrrolidinyl)furan (**28**)*

This crystallized as rectangular prisms from acetone–hexane, mp 82–83°C. It gave ^{1}H nmr signals at δ 7.4 (1H, M), 6.78 (1H, br s, NH), 6.27 (2H, m), 4.80 (1H, poorly resolved triplet), and 2.33 (4H, m). *Anal.* calcd. for $C_8H_9NO_2$: C 63.56, H 6.00, N 9.27; found: C 63.66, H 5.93, N 9.12.

*2,5-Bis(5'-oxo-2'-pyrrolidinyl)furan (**29**)*

This was an oil with ν_{max} 3430, 3210, and 1700 cm^{-1}. It gave ^{1}H nmr signals at δ 6.8 (2H, NH), 6.1 (2H, s), 4.8 (2H, m), and 2.0–2.7 (8H).

1-Acetoxy-1,3-butadiene

Method E (see above) gave no significant amount of bicyclic product, and the only compound characterized was the acylal **30** (28%). A comparable yield of **30** was obtained when **2** was used as the reagent. In a large run the only other product obtained reasonably pure (7% yield) was also a lactam acylal with higher R_f than **30**. Only two acetoxy groups were present (^{1}H nmr and probably 12 other carbons), hence it appeared to arise from two diene molecules and one molecule of **2**. No structure was deduced.

*1,1-Diacetoxy-4-(5'-oxy-2'-pyrrolidinyl)but-2-ene (**30**)*

After recrystallization from ethyl acetate this had mp 111–112°C and ν_{max} 3420, 3200, 1760, and 1699 cm^{-1}. It gave ^{1}H nmr signals at δ 7.0 (1H, d, J = 5 Hz), 6.8 (1H, br s, NH), 6.15–5.3 (2H, m), 3.72 (1H, m), and 2.1 (6H, s). Its ^{13}C nmr spectrum had signals at δ 178.3(s), 168.7(s), 132.5(d), 127.0(d), 89.2(d), 53.5(d), 39.1(t), 30.1(t), 26.5(t), and 20.8(q). *Anal.* calcd. for $C_{12}H_{17}NO_5$: C 56.46, H 6.71, N 5.49; found: C 56.29, H 6.66, N 5.39.

Hydrolysis of **30** using a saturated solution of sodium bicarbonate in 1:1 methanol–water gave a mixture containing an unsaturated aldehyde with ν_{max} 3420, 3330, and 1690 cm^{-1} and a ^{1}H nmr doublet at δ 9.65 (J = 7 Hz). It was not further characterized.

Lactam acylal of unknown structure

This amorphous product had ν_{max} 1760, 1680, and 1650 cm^{-1} and ^{1}H nmr signals at δ 7.1 (1H, d, J = 5 Hz), 6.3–5.3 (4H, m), 4.5 (1H, br), 3.65 (1H, br), 2.1 (6H, s). Its ^{13}C nmr spectrum had signals at δ 173.8(s), 168.6(s), 133.2(d), 127.0(d), 126.5(d), 125.0(d), 89.3(d), 51.0(d), 49.1(d), 36.3(t), 32.1(t), 30.0(t), 25.1(t) and 20.9(1) (14 signals).

Synthesis of gephyrotoxin 223AB

*5,9-syn-5(1'-Propyl)indolizidin-3-one (**31**)*

Unsaturated lactam **13** (679 mg) in 5 mL of ethanol was added to a suspension of 136 mg of 30% palladium on charcoal in 15 mL of ethanol, which had been previously saturated with hydrogen. The mixture was shaken under hydrogen. An initial rapid uptake of 30 mL of hydrogen was followed by slower reaction. After 2 h, 81 mL of hydrogen had been absorbed. The solution was filtered through a bed of Celite, and the filtrate and washings evaporated, leaving 620 mg of colorless oil. This was further purified by adsorption from dichloromethane onto a column of 50 g of silica gel (flash). Elution with 10% ethyl acetate and 2% ethanol in dichloromethane gave 24 mg of impurities, then 554 mg of quite pure (tlc on silica, 5% ethanol in chloroform) saturated lactam. An analytical sample was prepared by purification on 1000-μm silica gel plates (5% ethanol in chloroform) followed by distillation at 95°C, 0.05 Torr. It gave ^{1}H nmr signals at δ 3.2 (2H br), 2.2, 1.0, and 0.98. Its ^{13}C nmr spectrum had signals at δ 174.0(s), 59.5(d), 57.2(d), 34.4, 31.8, 31.6, 29.5, 24.9, 22.6, 19.8 (triplets), and 13.9(q). *Anal.* calcd. for $C_{11}H_{19}NO$: C 72.88, H 10.57, N 7.73; found: C 73.06, H 10.55; N 7.90.

Thiolactam 32

A mixture of 377 mg of dihydrolactam **31** and 512 mg of Lawesson's reagent (10) in 8 mL of pure dry dimethoxyethane was stirred under argon for 2 h. A further 88 mg of Lawesson's reagent was then added, and the solution left overnight at 5°C. Thin-layer chromatography still showed the presence of some starting material, so the mixture was heated to 50°C for 15 min. The bulk of the dimethoxyethane was removed under reduced pressure, then the thick oil adsorbed from dichloromethane onto 50 g of silica gel (flash). Sulphurous impurities (30 mg) were followed by 406 mg of crystalline solid. This was distilled over a short path at 135°C, 0.02 Torr, giving 390 mg (95%) of crystalline thiolactam. This had mp 52°C and ν_{max} (film) 1675 cm^{-1}. Its ^{1}H nmr spectrum had signals at δ 0.8–2.5 (ca. 14H), 2.75–3.05 (2H, m), 3.65–4.0 (1H, m), and 4.15–4.45 (1H, m). Its ^{13}C nmr spectrum had signals at δ 13.9(q), 14.7, 19.9, 21.6, 27.7, 29.4, 32.7, 44.2 (triplets), 46.2(d), 54.8(d), and 198.5(s). Its mass spectrum had m/z 197 (90), 196 (25), 168 (26), 164 (27), 155 (100), and 122 (74). *Anal.* calcd. for $C_{11}H_{19}NS$: C 66.97, H 9.71, N 7.10, S 16.22; found: C 67.08, H 9.81, N 7.20, S 16.25.

α,β-Unsaturated ketone 33

A solution of 437 mg of crystalline thiolactam **32** and 495 mg of 1-bromo-2-butanone in 5 mL of dry ether was prepared. The solution became milky and in 2.5 h an oil had separated. The ether layer was separated and evaporated. An ether extraction of the residue left more insoluble gum. The combined ether-insoluble product was dissolved in 5 mL of dry dichloromethane. Triphenylphosphine (597 mg) was added, followed by a solution of 451 mg of dry triethylamine in 2 mL of dry dichloromethane. The mixture became warm and a yellow color developed. This was left overnight at room temperature (now burgundy color). The solvent was removed *in vacuo* leaving a mush of crystals and oil. This was suspended in 10 mL of 10% ethyl acetate in hexane. The crystals were removed by filtration, then washed with 5 mL of the same solvent. The filtrate was evaporated, then extracted with more 10% ethyl acetate in hexane. This left a small amount of dark tar. The solution gave 685 mg of reddish brown oil. This was adsorbed from CH_2Cl_2 on 30 g of tlc silica gel and eluted with 20% ethyl acetate in dichloromethane. Early eluates gave 121 mg of orange crystals, followed by the desired product (567 mg). This was distilled over a short path at 150°C, 0.2 Torr, giving 434 mg (83%) of thick yellow oil. This had λ_{max} 308 nm, ε 31 000, and ν_{max} (film) 1652 and 1550 cm^{-1}. Its ^{1}H nmr spectrum had signals at δ 1.05 (3H, t, J = 7 Hz), 1.3–3.1 (15H), 3.3–3.85 (3H), and 4.85–5.15 (1H, m). Its ^{13}C nmr had signals at δ 88(d), 163.5(s), and 197.2(s). Its mass spectrum had m/z 235 (21), 206 (73), 192 (26), 164 (30), 138 (21), and 136 (100). *Anal.* calcd for $C_{15}H_{25}NO$: C 76.54, H 10.7, N 5.95; found: C 76.32, H 10.82, N 5.88.

Keto bases 34 and 35

The α,β-unsaturated keto base **33** (433 mg) was dissolved in 3 mL of methanol containing 141 mg of sodium cyanoborohydride. Bromocresol green indicator was added. A 2 N solution of hydrogen chloride in methanol was added dropwise with stirring until the solution remained yellow. After a total of 1 h the solution was evaporated, sodium carbonate solution added, and the product extracted into dichloromethane. The 456 mg of product was converted to its sulfate in methanol, then the solvent removed *in vacuo*. A cold solution of the salt in 4 mL of acetone was oxidized with a small excess of Jones' reagent (20); the excess after 10 min was destroyed with 2-propanol. The acetone solution and chromium salts yielded 379 mg of dichloromethane-soluble light brown oil. This was converted to its hydrochloride in methanol, the solvent removed, then acetone added. Addition of ether gave some crystalline hydrochloride. The remainder was separated on three 1000-μm silica gel plates using 15% ethanol in chloroform. A narrow blue band was followed by a zone rich in the crystalline hydrochloride, then one rich in amorphous hydrochloride. The crystalline hydrochloride from both zones (acetone–ether or ethyl acetate) was combined with the first crop of crystals, giving 200 mg (40%) of the hydrochloride of **34**. The amorphous hydrochloride (mainly that of **35**) weighed 198 mg (39%).

Keto base 34

The base liberated from the pure crystalline hydrochloride was an oil with ν_{max} 1712 cm^{-1} (film) and ^{1}H nmr signals at δ 2.8–3.3 (1H, m), 2.2–2.7 (4H, m), 1.13, 1.08, and 0.98. Its ^{13}C nmr spectrum had signals at δ 210.1(s), 55.8, 54.3, 52.9, 46.7, 37.0, 32.5, 29.8, 27.9, 23.4, 20.8, 19.2, 14.4, and 7.7. *Anal.* calcd. for $C_{15}H_{27}NO$: C 75.89, H 11.46, N 5.90; found: C 75.91, H 11.47, N 6.03.

Its hydrochloride crystallized from acetone–ether as needles or tiny prisms with mp 154°C, ν_{max} ($CHCl_3$) 1715 cm^{-1}, and ^{1}H nmr signals at δ 4.45 (1H br) and 3.85 (1H br). It gave ^{13}C nmr signals at δ 206, 63.3,

59.7, 56.0, 39.8, 36.8, 32.5, 27.8, 27.3, 27.1, 26.6, 22.5, 18.5, 13.5, and 7.2.

Keto base 35

The base liberated from the amorphous hydrochloride was an oil with ν_{max} 1712 cm^{-1} (film) and ^1H nmr signals at δ 3.7–4.0 (1H, br), 2.0–2.7 (7H, m), 1.16, 1.07, and 0.96. Its ^{13}C nmr spectrum had signals at δ 211.5(s), 59.4(d), 56.9(d), 55.0(d), 39.1, 37.0, 36.1, 32.3, 30.8, 29.7, 27.5, 24.7, 18.9, 14.6, and 7.9. It gave *m/z* 237 (3.2), 194 (100), 166 (90), and 122 (46). *Anal.* calcd. for $C_{15}H_{27}NO$: C 75.89, H 11.46, N 5.90; found: C 75.92, H 11.27, N 5.98.

Ethylene thioketal hydrochloride 36

Crystalline keto base **34** hydrochloride (mp 153°C, 78 mg) was dissolved in 1 mL of dry ethanol-free chloroform, then 0.3 mL of 1,2-ethanedithiol and 0.4 mL of freshly distilled $BF_3 \cdot Et_2O$ added. The mixture was left at room temperature for 4 h, then evaporated *in vacuo*. The semisolid residue was dissolved in dichloromethane, then the solution washed with dilute aqueous sodium hydroxide. The base recovered from the dichloromethane extracts was converted to its hydrochloride using HCl in methanol. The methanol was evaporated and the product crystallized from ethyl acetate, giving 93 mg, mp 173°C (90%). This was recrystallized for analysis from dichloromethane – ethyl acetate, giving tiny rosettes, mp 172–174°C. It gave ^1H nmr signals at δ 4.25 (1H, br m) and 3.32 (4H, s). *Anal.* calcd. for $C_{17}H_{32}ClNS_2$: C 58.35, H 9.22, N 4.00; found: C 60.37, H 9.62, N 4.10.

dl-*Gephyrotoxin 223AB* (*4*)

To a solution of 105 mg of ethylenethioketal **36** in 4.5 mL of absolute ethanol was added 430 mg of freshly prepared W2 Raney nickel (14). The suspension was refluxed under argon for 3.5 h, cooled, then filtered through a bed of Celite. The filtrate and ethanol washings were acidified using hydrogen chloride in ethanol, then evaporated under reduced pressure. The residue (66 mg, 87%) crystallized. This was purified on a 1000-μm silica gel plate using 15% ethanol in chloroform for development. A faint mauve band (R_f 0.6) was followed by the toxin hydrochloride. The 49 mg (63%) of salt crystallized from ethyl acetate – ether as flat needles, mp 129–131°C. The base liberated from the hydrochloride distilled over a short path at 95°C under 0.4 Torr. It gave ^{13}C nmr signals in $CDCl_3$ at δ 59.1, 58.6, 56.7, 36.0, 32.5, 31.1, 30.2, 29.3, 26.5, 25.1, 24.8, 23.0, 19.0, 14.6, and 14.2. In C_6D_6 the signals were at δ 59.0, 58.7, 56.4, 36.6, 33.1, 31.5, 30.8, 29.6, 27.1, 25.3, 23.4, 18.7, 14.9, and 14.4 (apparently two signals near 25 ppm were coincident).

The spectrum in deuteriochloroform was nearly identical to that reported by Royer and Husson (12) for their synthetic isomer, and to that recorded for natural gephyrotoxin 223AB by Professor T. Tokuyama and co-workers (10) (see glc comparison for the salt).

dl-*Gephyrotoxin 223AB hydrochloride* (*4 hydrochloride*)

The analytic specimen, mp 131°C, gave ^1H nmr signals at δ 3.85 (1H, br), 2.95 (2H, b), 2.08, 2.0, and 0.94 (center of a poorly resolved triplet) and ^{13}C nmr signals at δ 62.9(d), 59.95(d), 59.6(d), 32.6(t), 27.9(t), 27.54(t), 27.46(t), 27.36(t), 26.4(t), 24.9(t), 22.9(t), 22.4(t), 18.7(t), 13.7(q), and 13.6(q).

Comparison with various stereoisomers (glc) was kindly made by T. F. Spande[4] using a 30.5-m glass capillary column with SP-1000 stationary phase at 140°C, helium carrier gas, and flame ionization detector. The hydrochloride was shown to contain 98.6% of gephyrotoxin 223AB (**4**) (5*E*,9*E* isomer) and 1.4% of the 5*E*,9*Z* diastereoisomer.[9]
