The crystal structure analysis confirms the polymeric nature of $[Cu(pz)_2]_x$. The coordination geometry about the Cu atom in $[Cu(pz)_2]_x$ is shown in Fig. 1, and the crystal structure of the polymer in Fig. 2. The coordination geometry about the Cu atom is that of a distorted tetrahedron having exact (crystallographic) D_2 symmetry. The Cu—N distance is 1.957(2) Å. The three unique N—Cu—N angles correspond to N atoms related to one another by the three mutually perpendicular twofold axes intersecting at the metal: that within the six-membered $Cu(N—N)_2Cu$ rings is 99.4(1)° and the others are 94.3(1) and 139.5(1)°. The pyrazolyl rings possess exact C_s symmetry, the mirror plane being perpendicular to that of the five-membered ring and containing atoms C(2) and H(2). The angle between normals to consecutive $Cu(N—N)_2Cu$ ring mean planes along the polymer chain (which extends along the *c* axis) is 53.9°. The fused pyrazolyl and $Cu(N—N)_2Cu$ rings are not strictly coplanar, the angle between normals to the mean planes being 9.1°. The Cu atoms are displaced 0.236 Å from the pyrazolyl mean planes. The shortest interchain distance between non-hydrogen atoms is $C(1)\cdots C(1) = 3.456(5)$ Å.

Obviously this material is different from that reported by Vos and Groeneveld since they predicted a square-planar Cu(II) ion from ligand field spectral data on their compound. The present structure can be compared to those of the monomeric complexes $[Me_2Gapz_2]_2Cu$ and $[Me_2Gapz''_2]_2Cu$ (pz″ = 3,5-dimethylpyrazolyl) reported earlier (7). In the former complex the Cu atom displays a square-planar coordination mode (average Cu—N = 1.987 Å) with the $Ga(N—N)_2Cu$ six-membered rings being in the boat conformation. The latter complex, containing the 3-Me and 5-Me substituents on the pyrazolyl rings, cannot adopt the same geometry about the Cu centre and the result is a distorted tetrahedrally coordinated transition metal (average Cu—N = 1.959 Å) with planar $Ga(N—N)_2Cu$ six-membered rings. From a study of molecular models a square-planar environment about the Cu atoms in the $[Cu(pz)_2]_x$ polymer should be possible but clearly the preference is for a distorted tetrahedral geometry. The dihedral angle between CuN_2 coordination planes (in different six-membered $Cu(N—N)_2Cu$ rings) is 53.9° compared to the larger value of 71.9° found in the $[Me_2Gapz''_2]_2Cu$ complex. The latter value is no doubt dictated by the steric requirement of staggering the Me groups about the three metal atoms in the molecule. The $Cu\cdots Cu$ distance of 3.8893(6) Å in $[Cu(pz)_2]_x$ is slightly longer than the $Ga\cdots Cu$ distance of 3.790 Å in $[Me_2Gapz''_2]_2Cu$, a consequence of smaller angles at the metal atoms within the six-membered $M(N—N)_2Cu$ rings (99.4° in the polymer compared with values of 104.9 and 103.4° at Cu and Ga, respectively). Other related structures include $[Me_2Gapz_2]_2Ni$ (8) which has a square-planar Ni atom and a double-boat conformation and $[H_2Bpz_2]_2Co$ (9) which has a tetrahedral Co atom and a double-boat conforma-

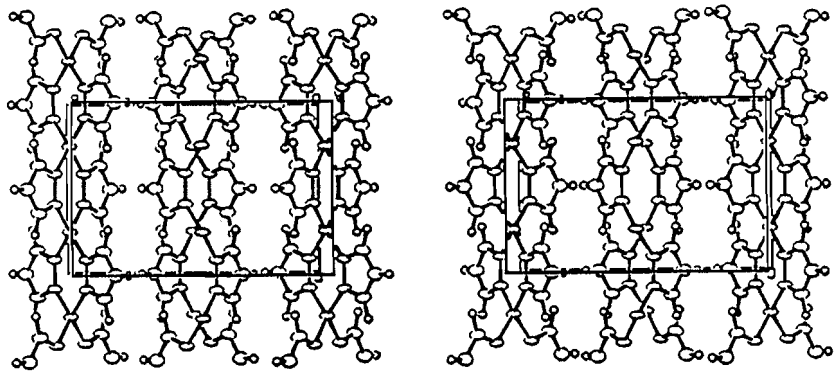

FIG. 2. Stereoscopic view down the *a* axis of the crystal structure of polybis(μ-pyrazolato-*N*,*N'*)copper(II).

tion. Spectroscopic studies of the complex $[Me_2Gapz_2]_2Co$ (10) suggest that planar $Ga(N—N)_2Co$ rings may result from steric interactions.

Electronic spectrum and magnetic properties

For Cu(II) in D_2 symmetry a total of four ligand field bands are expected (11). The $[Cu(pz)_2]_x$ polymer exhibits a single broad absorption band with a maximum at 15 400 cm^{-1}, in the frequency range expected for a CuN_4 chromophore of distorted tetrahedral symmetry (12). This band may involve all four of the *d–d* transitions, unresolved. The band at 25 000 cm^{-1} is too high in energy to be assigned to a ligand field transition and is likely charge transfer in origin.

The effective magnetic moment of $[Cu(pz)_2]_x$ varies from 1.47 BM at 299 K to a low of 0.19 BM at 4.22 K (Table 4) indicating the presence of relatively strong antiferromagnetic coupling between the copper ions. This is confirmed by the magnetic susceptibility versus temperature behaviour which shows a maximum in susceptibility at ~143 K (Fig. 3). The increase in susceptibility with decreasing temperature at the lowest temperatures studied (Fig. 3) probably arises from the presence of a very low concentration of paramagnetic structural impurity as is often observed in antiferromagnetically coupled systems (5).

The susceptibility data below 80 K were obtained using the VSM instrument and the scatter in the data points (Fig. 3) reflects the sensitivity limitations of this equipment. Because of the relatively low susceptibilities exhibited by this compound the reproducibility of the measurement at a given temperature is on the order of only ±5%. Although there is an inherent uncertainty of this order of magnitude, due to packing errors, in the absolute susceptibility determined using the Gouy apparatus, the reproducibility of the measurements of relative susceptibilities using this equipment is considerably better (on the order of ±1%); hence there is much less scatter in the data points above 80 K.

The structure of $[Cu(pz)_2]_x$ consists of infinite chains of copper(II) ions linked by double pyrazolate bridges (see above). Hence, we have analyzed the magnetic data according to the isotropic Heisenberg model for exchange coupled linear chains employing the polynomial expression for the magnetic susceptibility developed by Hall and others (13, 14). Computer fits of the experimental data to the model were obtained as described previously (3) and the best fit (solid line in Fig. 3) was obtained with values of J, g and present paramagnetic impurity of $-78 \pm 2\ cm^{-1}$, 2.12 ± 0.02, and 0.44% respectively. The value of the

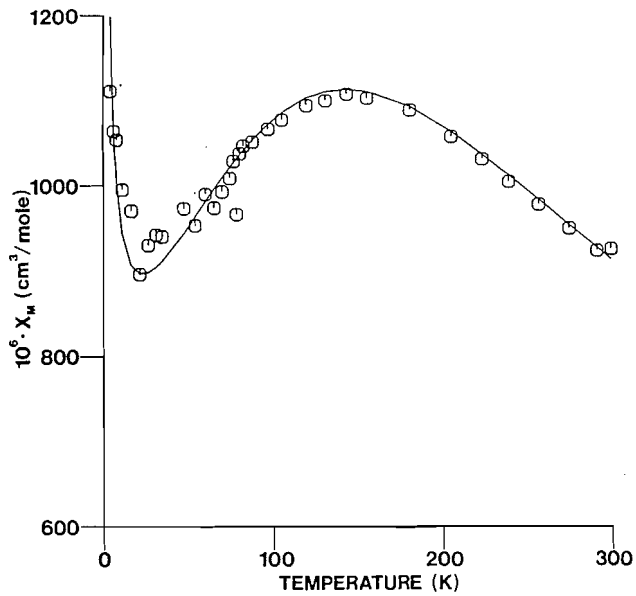

FIG. 3. Plot of the magnetic susceptibility versus temperature for polybis(μ-pyrazolato-*N*,*N'*)copper(II).

fitting function, F (defined in ref. 3), for this fit was 0.0280. The quality of fit is very good and, as expected, the amount of paramagnetic compound required to account for the increase in susceptibility at the lower temperatures is very small.

It is interesting to compare the absolute value of the exchange coupling constant, $|J|$, with values previously reported for other linear chain polymers of copper(II). Phosphinate ligands are known to form double anionic bridges between copper ions analogous to the type of bridges observed here. In the case of the phosphinates, however, the compression of the CuO_4 chromophores is greater, the O—P—O bridging system involves three bridge atoms rather than two, and while the π-system of the O—P—O is considered to contribute to the superexchange mechanism of coupling between the metal centres, it is probably considerably less effective for this purpose than is the π-system of the pz bridge. Accordingly the strongest antiferromagnetic exchange observed previously is in the α-forms of copper(II) *n*-decyl- and *n*-dodecylphosphinate where $|J|$ values of 29 cm^{-1} have been reported (3). The neutral pyrazine (1,4-diazine, $C_4H_4N_2$) ligand is also known to bridge copper centres and form linear chain polymers (15–17). An examination of the exchange coupling constants reported for

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/07/12
For personal use only.

these systems show values ranging up to a maximum of 6 cm^{-1}, but not higher, in spite of the availability of the π-system in the ligand for use as an exchange pathway. Although copper(II) polymeric compounds containing bridging oxide or fluoride are known to exhibit stronger magnetic exchange than that observed here (18), the value of $|J| = 78 \pm 2$ cm^{-1} exhibited by $[Cu(pz)_2]_x$ is considerably greater than for many other chain polymers of copper(II) (14), implying a very high efficiency of the pyrazolate ligands in propagating magnetic exchange. Studies involving other pyrazolate-derived anions as well as other metal ions are currently in progress.

This article is dedicated to Professor Ronald J. Gillespie on the occasion of his 65th birthday

Y. K. Wu and K. A. R. Mitchell. Can. J. Chem. **67**, 1975 (1989).

A new intensity analysis with low-energy electron diffraction is reported for the (2 × 2) surface structure obtained by the adsorption of H_2S on the (111) surface of nickel. Intensity-versus-energy curves were measured with a video LEED analyzer for 10 diffracted beams at normal incidence, and comparisons were made with intensity curves calculated with multiple-scattering methods for models in which S atoms chemisorb at three-fold coordinated adsorption sites, but with the possibilities of both lateral and vertical relaxations in the local metallic structure. Small adsorbate-induced relaxations are found, but the dominant structural feature is that the S atoms adsorb above the "expected" adsorption sites (i.e. those which continue the regular fcc packing) with a 1.50 Å spacing between the S layer and the top-most Ni layer. The S–Ni bond length of 2.10 Å agrees to within 0.02 Å of a prediction using a current bond length – bond order relation, but this value is smaller than two other recent measurements by SEXAFS and ion scattering by 0.06 and 0.10 Å, respectively. This analysis also finds the first two Ni layer spacings are expanded from the bulk value by 2 to 3%.

Key words: LEED, surface structure, S chemisorption, Ni(III) surface.

Y. K. Wu et K. A. R. Mitchell. Can. J. Chem. **67**, 1975 (1989).

On rapporte une nouvelle analyse d'intensité par diffraction d'électrons de faible énergie, pour la structure de surface (2 × 2) obtenue par adsorption de H_2S sur la surface de nickel (111). On a mesuré les courbes d'intensité en fonction de l'énergie à l'aide d'un analyseur vidéo LEED pour 10 rayons diffractés à une incidence normale, et on les a comparées aux courbes d'intensité calculées par la méthode de diffraction multiple pour les modèles dans lesquels les atomes de S absorbent chimiquement au niveau des sites d'adsorption de coordination ternaire, mais avec les possibilités de relaxations latérales et verticales dans la structure métallique locale. On a trouvé des petites relaxations induites de produit adsorbé, mais la caractéristique structurale dominante est celle à l'effet que les atomes de S adsorbent audessus des sites d'adsorption « attendus » (i.e. ceux qui continuent l'entassement régulier fcc) avec un espacement de 1.50 Å entre la couche de S et la couche de Ni la plus élevée. La longueur de liaison S–Ni de 2.10 Å s'accorde à 0.02 Å près avec celle prévue a partir de la relation courante longueur de liaison-ordre de liaison, mais cette valeur est plus faible de 0.06 et de 0.10 Å à celles mesurées récemment par SEXAFS et par diffraction d'ions respectivement. Cette analyse montre également que la distance entre les deux premières couches de nickel est de 2 à 3% supérieure à celle de la valeur totale.

Mots clés : LEED, structure de surface, absorption chimique de S, surface Ni(III).

Introduction

A developing topic in structural chemistry is surface structural chemistry. Studies over the last few years with a range of experimental probes, but especially low-energy electron diffraction (LEED), are helping to establish principles for the detailed atomic arrangements in systems which involve the chemisorption of electronegative atoms or small molecules on well-characterized surfaces of transition metals (1, 2). In certain cases, substantial reconstructions of the metallic structure have been indicated (see, for example, ref. 3), although even where this is not the case relaxations can still occur (4–7), and the investigation of possible adsorbate-induced relaxations provides a topical approach to reanalysis in cases where the results of earlier surface structural studies seem at variance with expectation (2).

An early LEED study for the (2 × 2) surface structure formed by S chemisorbed on the (111) surface of nickel, which restricted to bulk distances for the metal, indicated a S–Ni chemisorption bond length equal to about 2.02 Å (8), whereas the corresponding value predicted with a current bond length – bond order relation is 2.12 Å (2). This early S–Ni distance from LEED is also short compared with subsequent determinations by other techniques, for example 2.16 Å from ion scattering (9) and 2.20 Å from a preliminary SEXAFS study (10). Taken together these observations suggest that reanalysis by LEED is needed for the Ni(111)–(2 × 2)–S surface structure, and this provides the prime objective of the present paper.

Methods used

This work used the conventional procedures of LEED crystallography; specifically intensity-versus-energy ($I(E)$) curves from experiment were compared with those from multiple-scattering calculations in order to find the geometrical model in the calculations which gave the best correspondence with the experimental data (11, 12). The experimental $I(E)$ curves used were measured for normal incidence with a video LEED analyzer following procedures which have been detailed previously (13). The starting point was the preparation of a clean, well-ordered Ni(111) surface as characterized by the cylindrical mirror analyzer showing no detectable Auger signals for impurity elements as well as by LEED showing a sharp (1 × 1) pattern (14). Such a surface at room temperature was exposed to H_2S gas at about 2×10^{-8} Torr, and the sharpness of the (2 × 2) LEED patterns was optimized with exposures held for about 2 min. $I(E)$ curves were then measured for the three integral beams designated (1 0), (0 1), and (1 1), and the seven fractional order beams designated (1/2 0), (0 1/2), (1/2 1/2), (1 1/2), (1/2 1), (3/2 0), and (0 3/2) using the beam notation detailed by Chan and Weinberg (15). Intensity measurements were made over a total energy range of about 1020 eV.

The multiple-scattering calculations of the intensity curves for the structural analysis used the combined-space method (16,

[1]To whom correspondence should be addressed.

For personal use only.

17). Layer diffraction matrices for relaxed surfaces were calculated with up to four atoms per unit mesh, and layer stacking was done with the renormalized forward scattering method (18). The non-structural parameters used in the calculations were very similar to those used previously by Demuth *et al.* (8), and the following details for the present work. The atomic potential in the substrate was characterized by phase shifts (up to $\ell = 7$) derived from a band structure for nickel (19), and the real part of the constant potential (V_{or}) between the atomic spheres was set initially at -11 eV. For the sulphur overlayer region we used the phase shifts obtained by Demuth *et al.* from a superposition potential (20). The Debye temperatures were taken as 440 and 335 K for nickel and sulphur, respectively, while the imaginary part (V_{oi}) of the constant potential between all atomic spheres was equated to $-0.9\,E^{1/3}$ eV (where E is the electron energy in eV). Evaluations of the fit between experiment and calculation were done both visually and with LEED reliability indices, specifically R_P as introduced by Pendry (21) and R_{MZJ}, the modified form of the index introduced by Zanazzi and Jona (22) as given by Van Hove and Koestner (23).

Results and discussion

The normal-incidence LEED patterns for the (2 × 2) surface structure considered here are consistent with the diperiodic space group $p3m1$ which combines three-fold rotation axes and mirror plane symmetry, although models with lower space group symmetries could give rise to the observed LEED pattern when an averaging is taken over different patterns from the possible domains. Nevertheless, since previous evidence suggests the chemisorbed atoms occupy three-fold coordination sites, it seems most reasonable to consider the models of highest symmetry type in each case. When other metal layers of the face-centered cubic (fcc) structure are included, a distinction is needed between those three-fold adsorption sites which do not have an atom immediately below in the second metal layer (the "expected" three-fold sites for fcc packing) and the other three-fold adsorption ("unexpected") sites which do have an atom immediately below in the second layer. Figure 1 indicates the model with adsorption in the "expected" three-fold sites and lateral displacements for the topmost metal layer. The parameter Δ is used to indicate the magnitude of these displacements from the regular bulk positions; positive Δ corresponds to displacements in the directions of the arrows shown in Fig. 1.

A number of previous studies for Ni(111)–(2 × 2)–S indicated that S adsorbs at three-fold sites in this surface structure (8–10, 24, 25), although some of these studies were unable to distinguish between the two types of three-fold sites. Nevertheless, both the initial LEED study by Demuth *et al.* (8) and the ion scattering analysis by Fauster *et al.* (9) concluded that S adsorbs on the Ni(111) surface in the "expected" three-fold sites. This was independently assessed and confirmed in the present study by comparing $I(E)$ curves from experiment and calculation both visually and with LEED reliability indices. For example, without including any relaxations from the bulk metallic structure, R_{MZJ} and R_P are minimized at the values 0.123 and 0.185 respectively for the "expected" adsorption site, while the corresponding values for the "unexpected" adsorption sites are consistently larger at 0.219 and 0.311. The latter structure therefore gives the less good correspondence for the intensity curves, consequently investigations of the adsorbate-induced relaxations in the metal were only done with S chemisorbed in those three-fold sites which continue the fcc packing sequence.

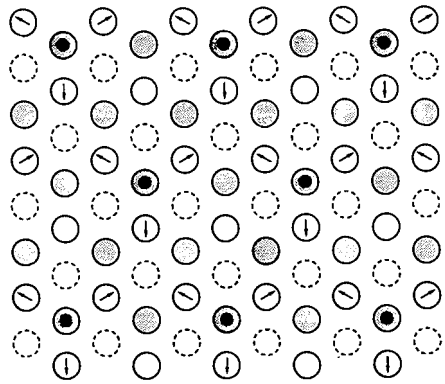

FIG. 1. Model used for the refined structural analysis of Ni(111)–(2 × 2)–S. The small filled circles represent S atoms chemisorbed in the "expected" three-fold adsorption sites; nickel atoms in the first, second, and third metal layers are represented by open circles, dashed circles, and shaded circles, respectively. The arrows define lateral displacements for nickel atoms in the first layer which correspond to positive Δ.

The structural refinement for the Ni(111)–(2 × 2)–S surface structure used the reliability index R_{MZJ}, which was minimized by iteratively varying the geometrical parameters over the ranges: $d_{01} = 1.30$ to 1.65 Å, $d_{12} = 1.903$ to 2.133 Å, $d_{23} = 2.000$ to 2.175 Å, $\Delta = -0.10$ to 0.15 Å, where the d's refer to interlayer spacings and the subscripts identify the particular layers involved. The subscripts 0, 1, 2 ... apply to the chemisorbed layer, first metal layer, second metal layer, ... respectively. At each stage in the minimization, V_{or} and one of the geometrical parameters was varied for optimal correspondence between calculation and experiment, other geometrical parameters being held constant at the optimal value from the previous iteration. The overall best match from this optimization procedure was reached with the geometrical parameters: $d_{01} = 1.50$ Å, $d_{12} = 2.09$ Å, $d_{23} = 2.08$ Å, and $\Delta = 0.03$ Å. Some indications of comparisons of $I(E)$ curves for this model, and the changes from the unrelaxed model, are shown for representative beams in Fig. 2. For the conditions of the favoured structure, R_{MZJ} and V_{or} are 0.105 and -6.0 eV, respectively, while the nearest neighbour S–Ni bond lengths equal 2.10 Å.

There is an overall improvement in the correspondence between the calculated and experimental $I(E)$ curves on including the adsorbate-induced relaxations, although for some beams the changes are relatively insignificant. The best improvement is for the (01) beam as shown in Fig. 2. For the particular calculation procedures and non-structural parameters used here, the uncertainties in the structural parameters found from the analysis appear to be around 0.02–0.03 Å, although with changes in geometrical parameters of this order, the differences in the calculated $I(E)$ curves are still relatively minor as shown in Fig. 3. These examples additionally emphasize the continuing need in LEED crystallography to test and develop improved R-factors that can quantify small changes in the $I(E)$ curve comparisons and translate them to reliable structural parameters.

The lateral displacements found here for the Ni(111)–(2 × 2)–S surface structure are small, but evidence for the (0 3/2) beam shown in Fig. 3 does suggest that Δ is slightly greater than zero. The improvement for the (0 1) beam on including the

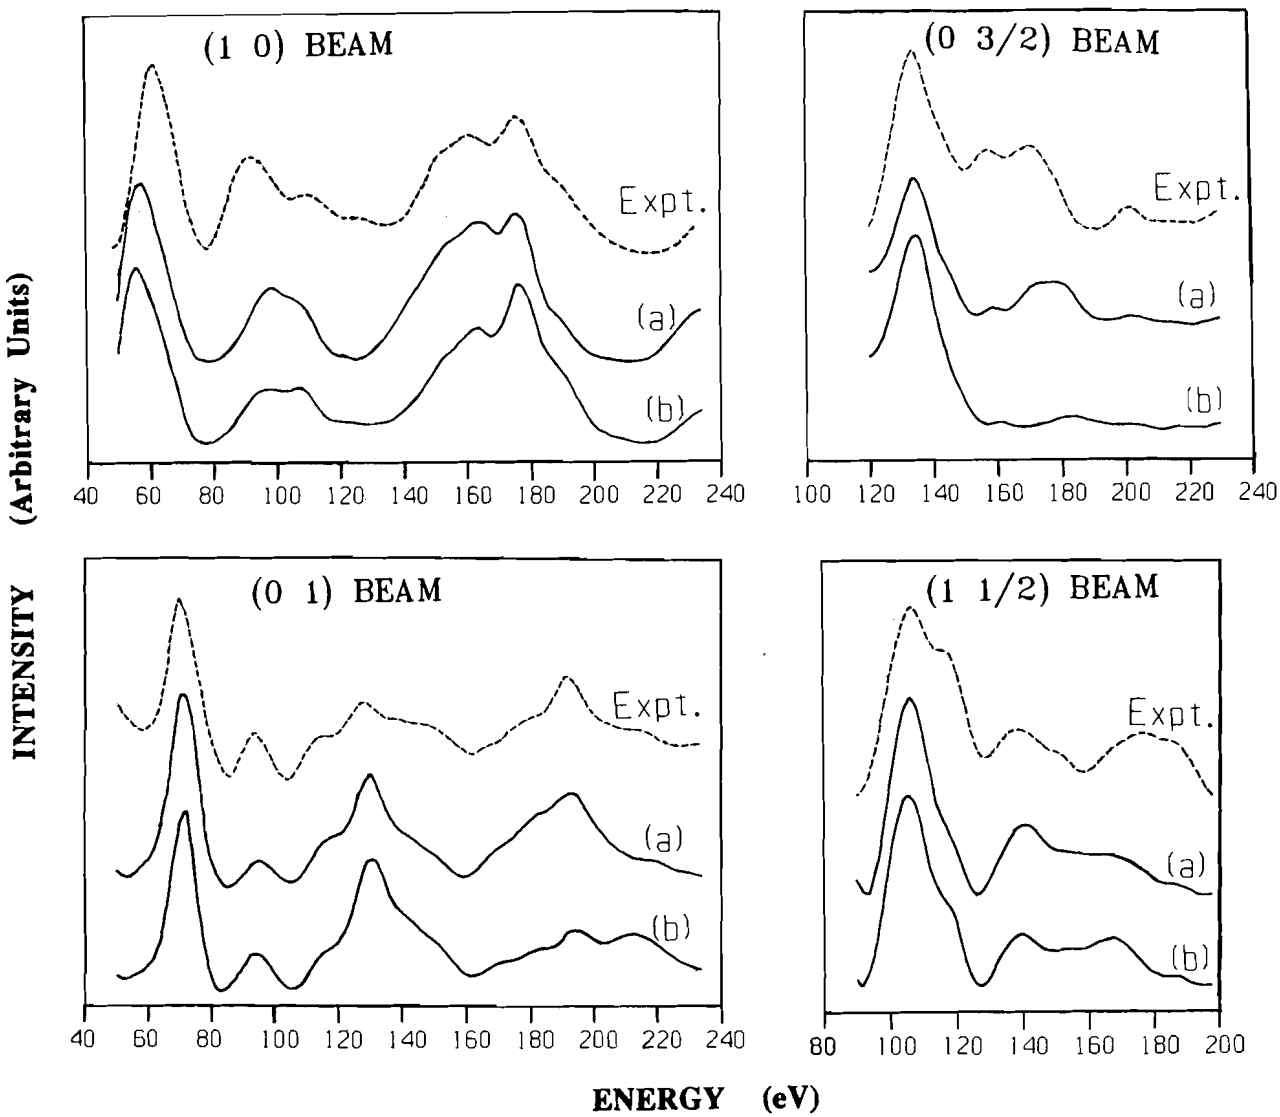

FIG. 2. Comparison of experimental $I(E)$ curves from the Ni(111)–(2 × 2)–S surface structure for the (1 0), (0 1), (0 3/2), and (1 1/2) beams at normal incidence with those calculated for S chemisorbed in the "expected" three-fold adsorption sites with d_{01} = 1.50 Å for (*a*) relaxed model with Δ = 0.03 Å, d_{12} = 2.09 Å, d_{23} = 2.08 Å; (*b*) unrelaxed model with Δ = 0.00 Å, $d_{12} = d_{23}$ = 2.03 Å.

adsorbate-induced relaxation is almost entirely due to changes in the values of d_{12} and d_{23}, the slight change occurring in Δ has a negligible effect on that experiment–calculation comparison. Nevertheless, on balance, small changes in vertical and lateral parameters seem to have an approximately equal effect on the $I(E)$ curves in this analysis, even though these intensity data are for normal incidence where LEED has often been considered less sensitive to lateral displacements than to vertical displacements of similar magnitude (26). Another feature of interest here concerns the small (2 to 3%) increase in the first two interlayer spacings for the metal (the bulk value is 2.033 Å). It is not clear at present whether this increase indicates a reduction in the bonding capability by metal atoms in the vicinity of the surface, perhaps as a consequence of the increased bonding to S, or whether there is some other cause, such as hydrogen incorporation into the metal structure.

Concluding remarks

Much modern bond length information from X-ray crystallography fits to expressions of the type

$$[1] \qquad r = r_0 - 0.85 \log s$$

which relates a particular interatomic distance of bond valence s to r_0, the corresponding distance for a bond of unit valence (27). Equation [1] has been applied to chemisorption X–M bond lengths with the assumption that the sum of bond valences at each chemisorbed atom X equals the atom valence v (e.g. 2 for S) (2). For the case that X adsorbs on a metallic surface with n equivalent neighbouring M atoms, all the bond valences equal v/n, and given r_0 that immediately enables simple predictions for the chemisorption bond length. Such comparisons of experimental and predicted bond distances are needed to assess whether structural determinations on related surface systems fit a consistent conceptual framework; also such comparisons should help note systematic differences which may identify special errors in individual determinations.

*Reference numbers in parentheses.

S chemisorbed on the three low-index crystallographic surfaces of nickel. On the (111) and (100) surfaces, S has three and four nearest neighbours respectively, but on the (110) surface there are four equal bond lengths from S to Ni atoms in the first layer and one different distance to the Ni atom directly below in the second layer. The predicted S–Ni interatomic distances given in Table 1 are determined from eq. [1] with r_0 equal to 1.97 Å (2). The information in Table 1 suggests that the bond length determined here for S chemisorbed on the Ni(111) surface, namely 2.10 Å, is consistent to within about 0.02 Å of the value that may be expected on the basis of previous structural information for S chemisorbed on the (100) and (110) surfaces. Nevertheless, this value appears significantly shorter than the

values of 2.16 Å and 2.20 Å found in the recent measurements by ion scattering and SEXAFS, respectively.

Received January 31, 1989

This paper is dedicated to Professor Ronald J. Gillespie on the occasion of his 65th birthday

SAMUEL C. O'NEAL, WILLIAM T. PENNINGTON, and JOSEPH W. KOLIS. Can. J. Chem. **67**, 1980 (1989).

The reaction of rhenium decacarbonyl with polyselenide anions in DMF solution has been investigated. Two equivalents of K_2Se_3 react with $Re_2(CO)_{10}$ in DMF solution at 100°C, in the presence of excess $[(C_6H_5)_4P]Br$, to produce $[(C_6H_5)_4P]_2[Re_2(Se_4)_2(CO)_6]$. This can be isolated as an analytically pure red crystalline solid in 25% yield. The compound has been characterized crystallographically; space group $P2_1/n$, $Z = 2$, $a = 12.052(3)$ Å, $b = 14.619(5)$ Å, $c = 16.159(4)$ Å, $\beta = 98.31(2)°$, $V = 2817(1)$ Å^3, $R = 0.0583$, $R_w = 0.0653$. In addition to two well-separated tetraphenylphosphonium counterions, the compound consists of the $[Re_2(Se_4)_2(CO)_6]^{2-}$ dianion. This molecule is a rhenium dimer with each metal coordinated to three CO ligands and a Se_4^{2-} chain. One end of the chelating tetraselenide chain is bridging both rhenium atoms, completing an octahedral coordination environment around each metal atom. The bridging distances are slightly asymmetric, leading to the suggestion that the bridging selenide has some dative character.

Key words: selenides, rhenium carbonyls, Zintl ions, p-block clusters.

SAMUEL C. O'NEAL, WILLIAM T. PENNINGTON et JOSEPH W. KOLIS. Can. J. Chem. **67**, 1980 (1989).

On a étudié la réaction, en solution dans le DMF, du décacarbonyl de rhénium avec les anions polysélénures. À 100°C, dans le DMF, deux équivalents de K_2Se_3 réagissent avec le $Re_2(CO)_{10}$, en présence d'un excès de $[(C_6H_5)_4P]Br$, pour fournir du $[(C_6H_5)_4P]_2[Re_2(Se_4)_2(CO)_6]$ qui peut être isolé avec un rendement de 25% sous la forme d'un solide cristallin rouge, analytiquement pur. On a caractérisé ce composé par cristallographie; groupe d'espace $P2_1/n$, $Z = 2$, $a = 12{,}052(3)$ Å, $b = 14{,}619(5)$ Å et $c = 16{,}159(4)$ Å, $\beta = 98{,}31(2)°$, $V = 2817(1)$ Å^3, $R = 0{,}0583$ et $R_w = 0{,}0653$. En plus de deux contre-ions tétraphénylphosphonium bien séparés, le composé comporte le dianion $[Re_2(Se_4)_2(CO)_6]^{2-}$. Cette molécule est un dimère de rhénium dans laquelle chaque atome de métal est coordonnée à trois ligands CO et à une chaîne Se_4^{2-}. Une extrémité de la chaîne de tétrasélénure chélatante agit comme pont entre les deux atomes de rhénium et complète ainsi l'arrangement de coordination octaédrique de chacun de ces atomes métalliques. Les distances des ponts sont légèrement asymétriques; ceci conduit à la conclusion que le sélénure agissant comme pont possède un léger caractère datif.

Mots clés : sélénures, carbonyls de rhénium, ions Zintl, agglomérations «p-block».

Introduction

The chemistry of the group 7 sulfides and selenides is considerably less well developed than their group 6 neighbors (1). There have been relatively few binary manganese and rhenium sulfides and polysulfides reported (2, 3). Several complexes containing selenide atoms coordinated to manganese (4) and rhenium (5) centers have also been described, and one has been characterized (5*a*). However, to our knowledge, there have been no soluble polyselenides or binary selenide anions of group 7 metals reported or characterized.

We have recently reported the reactions of soluble polysulfides and polyselenides with group 6 metal hexacarbonyls under anhydrous condition, to form binary metal chalcogenide anions via an oxidative decarbonylation reaction (6). This is in contrast to the reactions with polytellurides, which form coordinated polytelluride ring complexes (7). Given the synthetic utility of the binary sulfide and selenide anions (8), we have begun investigating the reaction of polychalcogenides with other metal carbonyls. We have found that binuclear metal carbonyls react cleanly with anhydrous polyselenide solution in dry DMF to form novel dimers with bridging polyselenide chelating chains. These can further react to form binary metal selenide anions.[2]

$$M_2(CO)_{10} + \text{"}Se_4^{2-}\text{"} \dashrightarrow [M_2(Se_4)_2(CO)_6]^{2-}$$

M = Mn, Re

$$[M_2(Se_4)_2(CO)_6]^{2-} \xrightarrow{90\,°C} [M(Se_4)_2]^{2-}$$

M = Mn

These reactions involve formal oxidation of the metal center and, presumably, reductive cleavage of polyselenide chains. In this paper we report the preliminary results of the reaction of rhenium carbonyl and anhydrous polyselenide solution to form $[Re_2(CO)_6(Se_4)_2]^{2-}$.

Experimental

General information

Due to the air sensitivity of the reactants, all reactions were carried out under purified argon in dried, degassed solvents using standard Schlenk techniques. Solids were manipulated in an inert atmosphere glove box under purified argon. Infrared spectra were determined as Nujol mulls. Analytical data were provided by Atlantic Microlabs. The polyselenide salt K_2Se_3, used as starting material, was prepared as previously described (6). All other reagents and solvents are commercially available and were used as received.

Preparation of $[(C_6H_5)_4P]_2[Re_2(Se_4)_2(CO)_6]$

In a typical reaction, 0.10 g (0.32 mmol) of a powder of nominal composition K_2Se_3, 0.10 g (0.15 mmol) $Re_2(CO)_{10}$, and 0.26 g (0.62 mmol) $(C_6H_5)_4PBr$ were dissolved in 5 mL DMF and stirred for 30 min at 25°C. The solution was then heated to 100°C for 30 min under

static vacuum. The resulting cherry-red solution was allowed to cool to room temperature, filtered, and layered with 3 mL diethyl ether. The flask was stored at 4°C overnight and a white powder was deposited. The white powder was removed by filtration and 2 mL of fresh diethyl ether was added. Further storage at 4°C overnight produced lustrous red needle crystals of the product in 25% yield based on rhenium. The product was characterized by infrared spectroscopy and elemental analysis in addition to X-ray structural determination. IR (cm^{-1}, Nujol mull): 1981 (s), 1869 (s). *Anal.* calcd. for $C_{54}H_{40}O_6P_2Re_2Se_8$: C 35.03, H 2.16; found: C 34.58, H 2.17.

X-ray structure determination

A bright-red parallelepiped was sealed in epoxy and mounted on a Nicolet R3mV diffractometer. Photographs were used to determine crystal quality and obtain preliminary space group information. The unit cell was determined from 26 well-centered reflections between 25° $< 2\theta <$ 38°. The choice of space group was confirmed by axial photos and systematic absences. Data were collected in the range of 3.5° $< 2\theta <$ 45° for $0 < h < 13$, $0 < k < 16$, $-18 < l < 18$. This resulted in 4106 reflections, of which 2149 were considered observed for $I > 3\sigma(I)$. Absorption correction was performed via the psi scan technique using six intense high angle reflections. The structure was solved by direct methods (SHELXTL) and refined using standard least-squares programs in the Nicolet structure determination package. All non-hydrogen atoms were refined anisotropically and hydrogen atoms were fixed. The structure was refined to R = 0.0583, R_w = 0.0653. The largest peak remaining in the difference map was less than 1.5 electrons in the vicinity of the rhenium atom. Unit cell and structure solution information is given in Table 1. Positional and thermal parameters are given in Table 2, and bond distances and angles are given in Tables 3 and 4 respectively. Complete crystallographic data are available as supplementary material.[3]

Results and discussion

The reaction of anhydrous polyselenide solution with dirhenium decacarbonyl proceeds cleanly in dry DMF to form a dimeric species with two chelating tetraselenide chains (see Fig. 1). Although the formal composition of the selenide starting material is K_2Se_3, the solution is a complex equilibria of a variety of polyselenide species. The oxidation of the metal centers is presumably caused by reduction of a polyselenide in solution, although there is no direct experimental evidence for this.

[3]Complete tables of observed and calculated structure factors, distances and angles, anisotropic thermal parameters, and H-atom coordinates may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

Tables of bond distances and angles and H-atom coordinates have also been deposited with the Cambridge Crystallographic Data Centre, and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, Cambridge CB2 1EW, U.K.

TABLE 3. Selected bond distances (Å)

Bond	Distance	Bond	Distance
Re(1)—Se(1)	2.621(3)	Re(1)—Se(4)	2.612(3)
Re(1)—C(1)	1.953(29)	Re(1)—C(2)	1.847(28)
Re(1)—C(3)	1.805(35)	Re(1)—Se(1A)	2.645(3)
Se(1)—Se(2)	2.402(4)	Se(2)—Se(3)	2.322(5)
Se(3)—Se(4)	2.320(4)	O(1)—C(1)	1.121(36)
O(2)—C(2)	1.215(34)	O(3)—C(3)	1.232(43)

The structure of the molecule was determined by single crystal X-ray diffraction. It consists of two well-separated $(C_6H_5)_4P^+$ cations and the dimeric $[Re_2(CO)_6(Se_4)_2]^{2-}$ anion. The structure was solved successfully in the $P2_1/n$ space group with a crystallographic inversion center in the middle of the rhenium anionic cluster.

The Se—Se bond lengths average 2.348 Å, which is typical for metal polyselenides. In general, the structural parameters for these ligands are similar to those observed for other tetra-

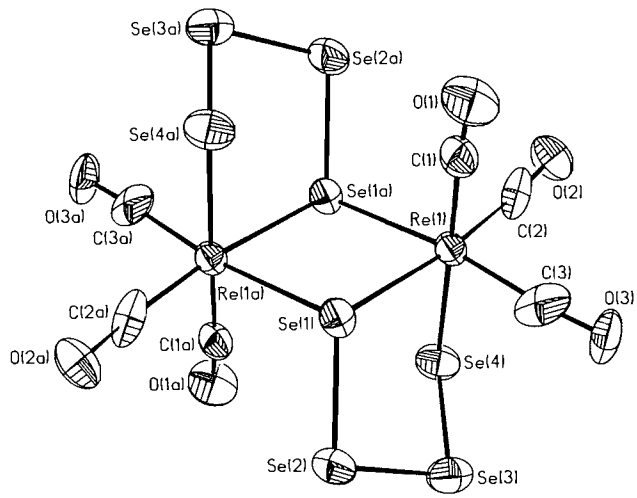

FIG. 1. ORTEP view of rhenium dianion fragment of $[(C_6H_5)_4P]_2[Re_2(Se_4)_2(CO)_6]$ with ellipsoids at 40% probability level.

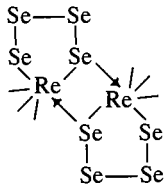
chalcogen chelates. The Re—Se distances range from 2.612(3) to 2.645(3) Å with the bridging distances being longer than the terminal one (see Table 3). These can be compared to the Re—Se distances in the prototype rhenium selenide $ReSe_2$, which is a layered structure with rhenium atoms in a trigonal prismatic coordination environment with Re—Se distances ranging from 2.38 to 2.66 Å (10). The distances may also be compared to molecular complexes such as $[(Me_3P)_2(CO)_3Re]_2Se$, which contains a bridging selenide acting as a four-electron donor, and has a Re—Se distance of 2.65 Å (9). The Re—Re distance in the present molecule is 3.944(1) Å, which is out of bonding range.

The overall geometry of the molecule is unique. Each tetraselenium chain has one terminal and one bridging end. This mode of coordination has previously been observed for some complexes containing polysulfide chains such as $Cu_3(S_6)^{3-}$ (10). The bridging Se_4^{2-} group has also been observed for the first time in the chromium trimer $Cr_3Se_{24}^{3-}$ (11). Recently, a rhodium dimer containing two bridging Se_2 groups has been reported (12), as well as a complex with a pentaselenium chain terminally chelated to two vanadium centers (13). However, in general, bridging polyselenides are rare. In addition, the chemistry of polychalcogens with metal carbonyls is surprisingly undeveloped, in view of the many cyclopentadienyl polychalcogen complexes known (1, 14).



Both five-membered rings are in the envelope conformation with the metal in the base. This conformation type is well known for polychalcogen rings. The rhenium atoms are octahedrally coordinated in facial conformation by the three selenium atoms and three CO ligands. The geometry is only slightly distorted from octahedral. For example C(1)—Re(1)—Se(4) is 177.3(8)° (see Table 4). The IR spectrum shows the two stretches in the carbonyl region expected for localized C_{3v} symmetry.

Although the complex still contains coordinated carbon monoxide ligands, it has undergone oxidation at the metal centers, from 0 to 1+ upon substitution. In a formal sense, these electrons can be thought of as having been removed from the metal–metal bond. Since each metal atom is formally Re(I), each terminal selenide is a two-electron donor, and the bridging selenides are four-electron donors, the metal centers obey the 18-electron rule. It can be noticed that one of the bridging

TABLE 4. Selected bond angles (deg)

Bonds	Angle	Bonds	Angle

Se(1)—Re(1)—Se(1A)	83.0(1)	Se(4)—Re(1)—Se(1A)	83.9(1)
C(1)—Re(1)—Se(1A)	96.2(9)	C(2)—Re(1)—Se(1A)	91.7(9)
C(3)—Re(1)—Se(1A)	170.5(14)	Re(1)—Se(1)—Se(2)	108.6(1)
Re(1)—Se(1)—Re(1A)	97.0(1)	Se(2)—Se(1)—Re(1A)	103.3(1)
Se(1)—Se(2)—Se(3)	102.4(1)	Se(2)—Se(3)—Se(4)	102.0(2)
Re(1)—Se(4)—Se(3)	99.4(1)	Re(1)—C(1)—O(1)	174.9(26)
Re(1)—C(2)—O(2)	175.7(23)	Re(1)—C(3)—O(3)	173.2(35)

Re—Se distances is somewhat longer than the other (2.621(3) Å versus 2.645(3) Å). Thus, we can postulate a valence bond description like that shown below.

In this description, the molecule can be thought of as two 16-electron $[Re(Se_4)(CO)_3]^-$ fragments that complete their coordination environment by each sharing a lone pair of electrons on one of the terminal selenides.

Received March 15, 1989

This paper is dedicated to Professor Ronald J. Gillespie on the occasion of his 65th birthday

OSVALD KNOP, ANTHONY LINDEN, BEVERLY R. VINCENT, S. C. CHOI, T. STANLEY CAMERON, and RUSSELL J. BOYD. Can. J. Chem. **67**, 1984 (1989).

The results of a detailed analysis of typical situations in crystals containing trigonal-pyramidal YEL_3^{ϵ} species are used to argue that, *per se*, the lone electron pair (*E*, LP) on the Y atom determines neither the crystal structure nor the orientation of the YEL_3^{ϵ} units in the crystal. Considered as a space-filling entity, the LP has practically no effective volume of its own. Whatever space-filling or orienting properties may be associated with the presence of the LP, they are not autonomous; they arise from the intrinsic stereochemical involvement of the LP in the geometry of and the charge distribution in the *free* YEL_3^{ϵ} ion or molecule and hence from the consequences of this geometry for crystal packing. *Ab initio* (6-31G*) calculations show that the electron density in the region of the LP in an ion is only slightly perturbed by the charge on the counter ion at distances observed in crystals. There is considerable similarity in the electron density distribution in the LP region of Y between free anionic (SO_3^{2-}) and free cationic (Me_3S^+) species. The problem of the so-called stereochemical inertness of the LP in the 14-electron octahedral YEX_6^{2-} ions in crystals is examined in detail. It is concluded that the crystallographic O_h symmetry of the ion in cubic crystals is the result of dynamic averaging of possible orientations of the inherently noncubic YX_6^{2-} octahedron (cf. the *ab initio* results for $SeCl_6^{2-}$). Such averaging also appears to be responsible for the stereochemical "activation" or "inactivation" of the LP in thermally induced crystallographic transitions in the AYX_3 halide perovskites and related crystals. To provide a firmer basis for the discussion of the LP, the crystal structures of the five title compounds have been determined. The crystal chemistry of these and related compounds is discussed.

Key words: *ab initio* calculations, Me_3S^+ and $SeCl_6^{2-}$; group V trihalides; lone electron pair; trialkylsulfonium salts; VSEPR theory.

OSVALD KNOP, ANTHONY LINDEN, BEVERLY R. VINCENT, S. C. CHOI, T. STANLEY CAMERON et RUSSELL J. BOYD. Can. J. Chem. **67**, 1984 (1989).

En se basant sur les résultats d'une analyse détaillée de situations typiques dans des cristaux contenant des espèces YEL_3^{ϵ}, on suggère que la paire d'électron libre (*E*, PL) sur l'atome Y ne détermine pas *per se* la structure cristalline ou l'orientation des unités YEL_3^{ϵ} dans le cristal. Considérée comme une entité qui occupe du volume, la PL n'a pratiquement pas de volume effectif intrinsèque. Quelles que soient les propriétés associées avec la présence de la PL, elles ne sont pas autonomes; elles découlent de l'implication stéréochimique intrinsèque de la PL dans la géométrie de et de la distribution de charge dans l'ion ou la molécule YEL_3^{ϵ} *libre* et ainsi des conséquences de cette géométrie sur l'empilement cristallin. Des calculs *ab initio* (6-31G*) démontrent que, aux distances observées dans les cristaux, la densité électronique dans la région de la PL d'un ion n'est que légèrement perturbée par la charge du contre-ion. Il existe une grande similarité dans la distribution de la densité électronique dans la région de la PL de Y des espèces anionique libre (SO_3^{2-}) et cationique libre (Me_3S^+). On a procédé à un examen détaillé du problème de la soit-disant inertie stéréochimique de la PL dans les cristaux d'ions YEX_6^{2-}. On en conclut que la symétrie cristallographique O_h observée dans les cristaux cubiques est le résultat d'une moyenne dynamique des orientations possibles de l'octaèdre YX_6^{2-} qui est d'une façon inhérente non-cubique (voir les résultats de calculs *ab initio* sur le $SeCl_6^{2-}$). Il semble que de telles moyennes sont aussi responsables de l'«activation» ou de la «non-activation» stéréochimique de la PL dans des transitions cristallographiques induites par température dans des cristaux d'halogénures de perovskites (AYX_3) ainsi que dans d'autres cristaux apparentés. Afin d'asseoir la discussion des PL sur une base plus ferme, on a déterminé les structures cristallines des cinq composés mentionnés dans le titre. On discute de la chimie cristalline de ces composés ainsi que celle de composés apparentés.

Mots clés : calculs *ab initio*, Me_3S^+ et $SeCl_6^{2-}$; trihalogénures du groupe V; paire d'électrons libres; sels de trialkylsulfonium; théorie de VSEPR.

[Traduit par la revue]

The consequences of the stereochemical activity of the lone electron pair (LP, *E*) for the geometry of free molecular species are of course well known (1, 2). What is less well understood, however, is the extent to which the presence of a LP is responsible for orientational effects in crystals and, more generally, for determining the type, compactness, and symmetry of the crystal packing. In an attempt to focus attention on these problems[3] we examine, in the following, a number of situations typical of crystals containing trigonal-pyramidal YEL_3^{ϵ} ions or

[3]Galy *et al.* (3) have examined the implications of LPs for the crystal chemistry of a large number of oxides, fluorides, and oxyfluorides of elements from rows 3 to 5 of the Periodic Table. However, the aims and premises of their treatment are so different from ours that further reference to their work appears unnecessary in the present paper. We also leave out of account the infrequent *ad hoc* investigations designed to demonstrate the *existence* of the LP as a residual electron density in difference Fourier maps (e.g. refs. 4–6), for the chemistry of the available results is too random to be of much value for our stated purpose.

neutral molecules (Y = mostly second-row elements, $-2 \leq \epsilon \leq 1$; L = simple ligands) and compare them with situations involving the matching tetrahedral (*sensu lato*) $YL'L_3^{\epsilon}$ species. To this end, the meager body of literature information on cationic YEL_3^+ species has been augmented by the determination of the crystal structures of the sulfonium salts Et_3SI, $(Me_3S)_2SnCl_6$ (3MSHS), and $(Et_3S)_2SnCl_6$ (3ESHS) and, for comparison, of the sulfoxonium salts Me_3SOI and $(Me_3SO)_2SnCl_6$ (3MSOHS). The crystal data of these compounds are summarized in Table 1. Details of these determinations and a discussion of the structures are relegated to the end of this paper, but the structural as well as some new *ab initio* results will be drawn upon freely in the sections that immediately follow. Detailed consideration is also given to the so-called stereochemically inert (or inactive) LP in crystals containing $YHal_6^{2-}$ ions of crystallographic O_h symmetry, and to what on the face of it appears to be conversion of an active to an inactive LP in crystallographic transitions.

Rôle of the LP in crystals

The questions we shall ask here are (*1*) Is the LP a space-filling entity? (*2*) Is the electronic charge attributed to the LP responsible for the orientation of the YEL_3^{ϵ} unit in the crystal? (*3*) Under what circumstances is a LP in a crystal stereochemically inactive, and is the inactivity real or apparent, intrinsic or associated with the particulars of the crystal structure?

These questions, with the possible exception of the last one, cannot be answered in absolute terms. Because of the elusiveness of the LP as a geometric and physical entity, the problems implicit in them can be investigated with any confidence (and without assumptions or preconceived notions) only with recourse to matched pairs of $A_m(YEL_3)_n|A_m(YL'L_3)_n$ crystals, isostructural except for L'. Very few such pairs are available. The best three we have found are $PbSO_3|PbSO_4$, $KClO_3|KClO_4$, and $PBr_3|POBr_3$, and these are examined in detail below. However, some $A_m(YEL_3)_n|A_m(YL'L_3)_n$ pairs, while not isostructural, are sufficiently similar to be informative in limited ways. Examples of these are $Me_3SI|Me_3SOI$ and the pairs listed in Table 2.

Spatial extension of the LP in crystals

The notion that a stereochemically active LP should have spatial extension implies that significant electron density is associated, locally, with the LP and that this electron density extends radially and in a particular direction from the parent atom over an appreciable portion of space in the crystal, effectively excluding other atoms from occupation of this space and thus creating a void in the crystal structure.

Effective radius. It may not be possible to establish an "effective radius" of a LP in the same way as one arrives at a self-consistent set of additive atomic or ionic radii from interatomic distances in crystals. In neutral YEL_3 molecular crystals an estimate of the upper effective length of a LP could

be made from the interatomic separation of Y and the nearest coaxial L facing *E*, on the assumption that the size of L in this nonbonding Y···L contact corresponds to the van der Waals radius of L. However, molecular crystals in which there *is* an L neighbour coaxial or nearly coaxial with *E* do not appear to be known. *Ionic* crystals with YEL_3[e] as a component and containing collinear YE···counterion groupings do exist (cf. Table 3), but here the polarization of the electron density on Y in the region of the LP by the charge on the counterion renders the use of the van der Waals radii suspect.

The coaxial and the shortest lateral interatomic Y···L distances in a number of well-studied crystals are compared with the sums of the corresponding van der Waals radii (where applicable) in Table 3. The shortest lateral Y···L and Y···anion separations are all smaller than the van der Waals sums but the difference does not exceed 10%, and this is true also of the O···Br separation in $POBr_3$. However, contrary to expectation, the shortest S···I distance in Me_3SI is larger than the shortest Se···I distance in Me_3SeI, and the shortest P···Br distance in PBr_3 is larger than the shortest P···I distance in PI_3. Again, the shortest O···I distance in Me_3SOI is ~0.8 Å longer than the shortest O···Cl distance in 3MSOHS; allowing 0.4 Å for the size difference between Cl and I leaves a residue of 0.4 Å. Further, the shortest O···I distance in Me_3SOI, 4.73 Å, is much larger than the minimum S···I separation in Me_3SI, 3.95 Å. These inconsistencies suggest that the overall packing requirements in the individual structures dominate the local geometries. The same tendency is evident in the two Me_3SO^+ salts. The O···Cl distance in 3MSOHS is ~7% larger than the van der Waals sum, while in Me_3SOI the shortest non-coaxial O···I distance exceeds the sum by 30% and the axial distance by 33%.

The coaxial Y···M separations which occur in the oxyanion salts of Table 3 are, in the three halogenates, 4–19% longer than the corresponding shortest lateral Y···M separations. While it might be tempting to view this lengthening as due to the existence of directional dependence of the Y···M distance attributable to the LP, in the two sulfites the axial S···M distance is 3–4% shorter than the shortest lateral S···M distances. Furthermore, contrary to what would be expected, the axial Cl···Na distance in $NaClO_3$ is 0.16 Å *longer* than the corresponding Br···Na distance in $NaBrO_3$, in spite of the two crystals being isostructural and the Hal···Na vector coinciding with the C_3 axis of the $P2_13$ unit cell.[4] One is therefore forced to conclude that evidence from interatomic distances in crystals is not likely to lead to meaningful estimates of the effective radius of a LP, since accidents of packing appear generally to obscure whatever systematic effects may arise from the effective size of the LP.

[4]The frequency and temperature dependence of the dielectric constant of $NaClO_3$ have been interpreted (53) as involving inversion of the Cl atom through the plane of the three oxygens, i.e. twofold orientational disorder increasing with temperature. The existence of such disorder would suggest that the orientation of the anion is not determined by the interaction between the LP and the coaxial Na^+ ion at 4 Å (see below).

[a]Distances in Å; ΣvdW, sum of the respective van der Waals radii (Å).
[b]Shortest non-coaxial Y···atom distance on the LP side of YEL_3^{ϵ} or $YL'L_3^{\epsilon}$.
[c]In the square-pyramidal $MeTeI_4^-$ the C—Te···I grouping is 17° off collinear, Te···I = 3.88 Å, ΣvdW = 4.35 Å.
[d]Shortest S···Cl on the LP side of S, 4.10 Å.
[e]Shortest S···I on the LP side of S, 4.60 Å; on the opposite side, 4.38 Å (cf. Table 11).
[f]Shortest Cl···Na distance on the opposite side of LP, 3.52 Å.
[g]Shortest Br···Na distance on the opposite side of LP, 3.65 Å.
[h]Assuming S—H ~ 1.30 Å. S···Cs, 4.82 Å (front), 3.89 Å (back), 3.78 Å (lateral).

Effective volume. If attempts to obtain the effective linear dimension of a LP from crystal data are disappointing, can more promise be expected from examination of crystal structures with a view to estimating the effective *volume* occupied by a LP? A space-filling LP on Y could be regarded as a ligand without a nucleus. The difference $\Delta V_1 = V_1(A_mYL'L_3) - V_1(A_mYEL_3)$ between the volumes per formula unit of the two partners in an isostructural $A_mYEL_3|A_mYL'L_3$ (m = 0–2) pair should then represent the difference between the effective volumes of L′ and the LP, provided that the molecular geometry of the YL_3 part of YEL_3^{ϵ} undergoes only small changes on conversion to $YL'L_3^{\epsilon}$ and ϵ remains the same. Since the two crystals are isostructural and have comparable unit-cell dimensions, the coordination numbers of A and YL_3 or $YL'L_3$ will be essentially unchanged and so will the effective sizes of these entities.

The relative constancy of the molecular geometry is illustrated in Table 4, which reports the equilibrium geometries of free YEL_3^{ϵ} and $YL'L_3^{\epsilon}$ resulting from 6-31G* optimizations as well as geometries obtained from the crystal structures of the isostructural pairs. For the 6-31G* optimized species the contraction of the Y—L bond on adding L′ amounts to 1.5–7% and the increase in the LYL angle to 1–12°, depending on the nature of L′ and the change in ϵ. However, for the three isostructural pairs $PBr_3|POBr_3$, $KClO_3|KClO_4$, and $PbSO_3|PbSO_4$, where the geometries derive directly from experiment, the changes in ⟨Y—L⟩ are only 1.4–3.4% and in ⟨LYL⟩, 3.1–5.0°. Changes of this order seem sufficiently small to justify the validity of comparing V_1 for the stated purpose.

The differences ΔV_1 for the three isostructural pairs as well as for a number of other, not isostructural $A_mYEL_3|A_mYOL_3$ pairs are listed in Table 2.[5] All the ΔV_1 values in this table are positive, i.e. the oxygen ligand occupies a larger effective volume than the LP. The ΔV_1 values appear to fall in two main classes, those for $YO_3^-|YO_4^-$, which average 14–15 Å^3, and those for $SO_3^{2-}|SO_4^{2-}$, for which the mean ΔV_1 is considerably smaller, about 6 Å^3. The spread of ΔV_1 in each class must be attributed to differences in packing density, especially when the $A_mYEL_3 \rightarrow A_mYL'L_3$ conversion is associated with a change of space group. The direction and magnitude of the V_1 change resulting from a change in space-group symmetry (superimposed on the ΔV_1 expected for an isostructural pair) are difficult to assess. In purely molecular organic crystals loss of symmetry is balanced by an increase in packing density (cf. ref. 57), but in ionic and other inorganic crystals containing stereochemically active LPs the trend is much less predictable (see below).

In homologous series of organic molecular crystals the average volume increments (in Å^3) are 11.1/CH(aliphatic), 14.7/CH(aromatic), 17.1/CH_2, 23.5/CH_3, 23.0/NO_2, and 23.1/COOH; the average increments per halogen atom bonded to a carbon are 9.6 for F, 19.9 for Cl, and 26.0 for Br (57). Since the average difference ΔV_1 for $YEL_3^{\epsilon}|YOL_3^{\epsilon}$ is about 15 Å^3, the effective volume V_1(O) of the oxygen ligand would be $V_1(E)$ + 15 Å^3, so that with $V_1(E)$ as small as 5 Å^3 the V_1(O) would be of the same order as V_1(Cl) and, worse still, only about 3 Å^3 smaller than the increments for NO_2 and COOH, each involving *two* oxygen atoms. This clearly is unreasonable, even if one allows for the imprecise nature of the present arguments, and one is forced to conclude that the volume effectively occupied by the LP must be (*a*) quite small and (*b*) comparable to the spread of the ΔV_1 values of Table 2. This means that either the LP has no significant volume of its own (i.e. it does not function as a space-filling ligand on Y) or that accidents of packing invalidate comparisons of V_1 values as a method for establishing $V_1(E)$ or both. Consideration of calculated electron-density distributions in the region where the LP in ClO_3^-, SO_3^{2-}, and Me_3S^+ is expected to be present (see below) tend to support the conclusion that the LP is unimportant as an autonomous space-filling entity.

For *cationic* YEL_3^{ϵ} only the pairs $Me_3SI|Me_3SOI$ and 3MSHS|3MSOHS are available (Table 5). For the iodides ΔV_1 is 8 Å^3, in the expected direction. For the hexachlorostannates, however, ΔV_1 is *negative*, −20 Å^3. This, to our knowledge the first reported case of a decrease in V_1 on $YEL_3^{\epsilon} \rightarrow YL'L_3^{\epsilon}$ conversion, is almost certainly attributable to the loss of crystal symmetry: the highly symmetric (*Pa*3) 3MSHS structure is less densely packed than the *Pnma* structure of the sulfoxonium salt (Fig. 1), and the increase in the packing density on conversion is sufficient to overcompensate the increase in V_1 expected on adding the oxygen ligand. This kind of behaviour is more likely to occur with composite than with simple L ligands and further illustrates the importance of global as opposite to local packing requirements in the crystal.

[5]Where several literature sets of crystallographic data exist for a compound, the spread on the V_1 calculated from them may amount to as much as 0.5 Å^3. Where required the V_1 was corrected for thermal expansion assuming $dV_1/dT = 0.01\%/K$.

LP as an orientation-determining factor

Descriptions and discussions of crystal structures often imply that the LP determines the orientation of the L_3YE^{ϵ} molecule or ion in the crystal. While a case for this can be made for molecular association or ionic interaction in solution or in the gas phase, in crystals the situation is quite different. In the liquid or gas the limit to the approach of Y to an interacting portion of another molecule or ion is ultimately set by the equilibrium interatomic distance in a properly oriented pair of the two free molecules. This distance is governed by the repulsive forces in the pair and is sufficiently small for such local concentration of electron density as may exist in the LP to interact to maximum advantage with local charge on the partner molecule in the pair. In crystals, however, the interatomic distances are determined by Coulombic and packing factors, with the result that generally the LP will be farther removed from a potentially interacting atom or ion than would be the case in the liquid or gas. Moreover, because of the actual shape and size of the L_3YE^{ϵ} unit and the relative magnitude of the crystal factors, the presumed orientation of the LP may not be in the most favourable direction possible in the isolated pair. Both circumstances would lessen the importance of the LP as a structure-determining factor in crystals, and it then becomes necessary to investigate whether the orientation of the LP is in fact the consequence of its interaction with the crystal environment. In this respect the discussion of the LP is reminiscent of the discussion of hydrogen bonding as a structure-determining factor in crystals, especially in ionic crystals.

Typical situations. A summary of the representative features of crystal structures of simple $L_3YL'^{\epsilon}$ compounds (L' = *E*, O, H, C, Br; $\epsilon = -1, 0, 1$) is presented in Figs. 1 and 2. Comparison of the orientation of the L_3YL' axis in these structures is facilitated by the tendency of the molecule to retain its C_3 or C_s skeletal symmetry, which ensures that the orientation of the Y—L' vector in the direction expected to be most effective is clearly displayed. In Fig. 2 the Y atoms and the atoms forming the quadrangular or quinquangular coordination figures (single circles) of L_3YE^{ϵ} and $L_3YL'^{\epsilon}$ are coplanar (in a mirror plane) or near-coplanar, i.e. the YL_3 axis and hence the axis of the LP and the Y—L' vector are in the same plane.[6] The following is observed (not all the structures are shown in the figures):

(*a*) In $NaClO_3$, $NaBrO_3$, $KClO_3$, and K_2SO_3 a cation facing the LP is located on the anion axis at 3.8–4 Å from the halogen and 3.55 Å from the S atom. The collinearity is consistent with the expectation that the anionic charge would reinforce the orienting effect of the LP.

(*b*) In PBr_3 and PI_3 the LP end of the molecule axis points symmetrically (C_s in PBr_3, C_3 in PI_3) between the nearest halogen neighbours at ~3.7 Å from P.

(*c*) In Me_3SI, Me_3SeI, and Et_3SI the LP end of the C_3Y axis points between the nearest I^- ions at Y···I = 3.8–4 Å. In $(CH_2)_5SMe^+I^-$ there is an I atom close to the C_3S axis but at 7.4 Å from the S atom.

(*d*) In Me_3SOI the S—O bond and an I^- neighbour are collinear (O···I ~ 4.9 Å); in $POBr_3$ the P—O bond points *between* Br neighbours of the oxygen.

(*e*) In Et_3NHI the hydrogen bond N—H···I is linear by symmetry, with an N···I separation of 3.60 Å, and in Me_3NHI the N—H···I bond is close to linear, N···I = 3.46 Å. The

[6]This is not a consequence of the LP being present but a requirement for maximizing the density of packing.

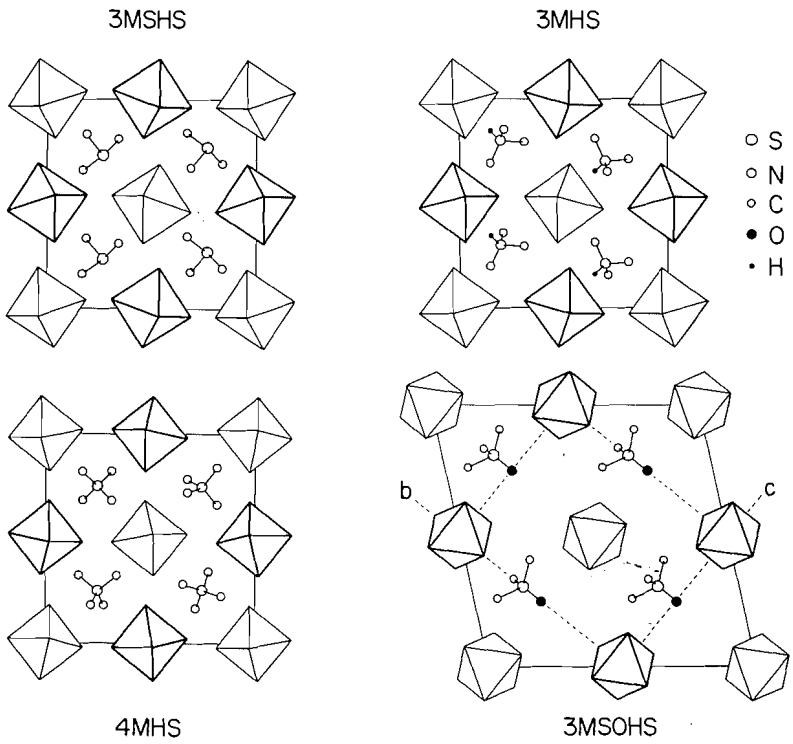

FIG. 1. Consequences of the nature of L′ for the cation orientation in *anti*-fluorite type $(Me_3YL')_2SnCl_6$ structures. Tabulated unit cells have been transformed where necessary to match as far as possible the attitudes of the $SnCl_6$ octahedra at the origin (upper left-hand corner); H_C atoms have been omitted for clarity. 3MSHS: YL′ = S*E*, lower half of the *Pa*3 unit cell; coordinates of Table 14 transformed as $x \rightarrow z$, $y \rightarrow -x$, $z \rightarrow \frac{1}{2} - y$. 3MHS: YL′ = NH, lower half of the unit cell (60). 4MHS: YL′ = NMe, lower half of the first octant of the *Fd*3*c* cell of ref. 62. 3MSOHS: YL′ = SO; solid lines, lower half of a cell related to the cell of Table 1 (broken lines) by **a**′ = **a**, **b**′ = **b** + **c**, **c**′ = −**b** + **c**.

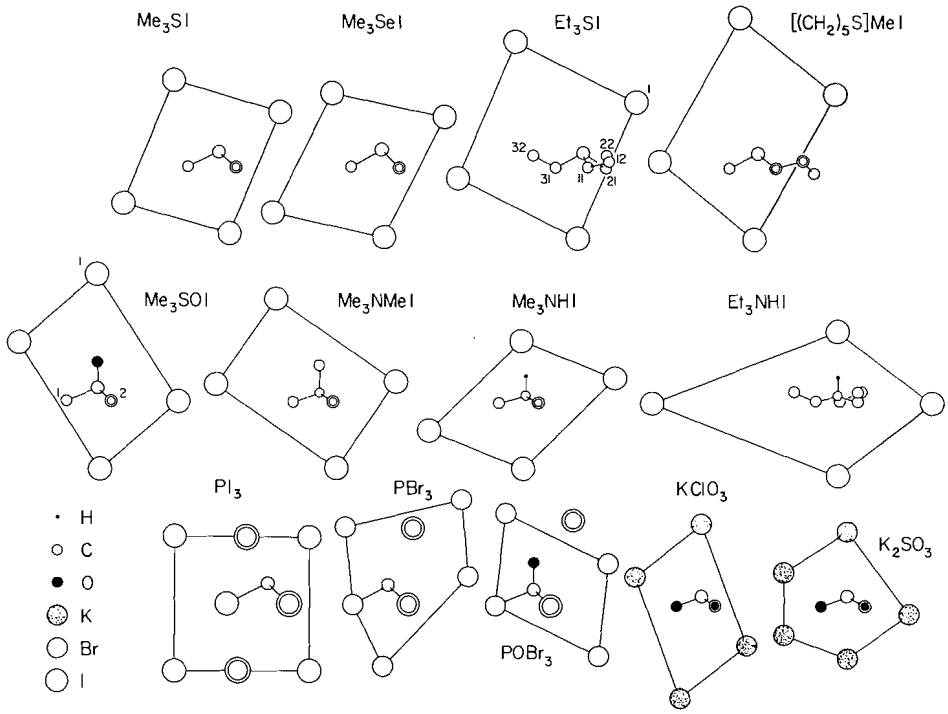

FIG. 2. Orientations of lone pairs in Me_3SI (48), Me_3SeI (49), Et_3SI (this work), $[(CH_2)_5SMe]I$ (67), PI_3 (51), PBr_3 (40), $KClO_3$ (16, 17), and K_2SO_3 (34) compared with the orientations of the SO, PO, NH, and NC bonds in Me_3SOI (this work), $POBr_3$ (42, 43), Me_3NHI (58), Et_3NHI (59), and Me_4NI (11). The central atom of the trigonal-pyramidal grouping is S, Se, N, P, or Cl; the axis is oriented vertically in the page. The central atom, the atom bonded to it on the left, and the atoms of the contour figure are coplanar or very nearly so. Double circles, pairs of mirror or pseudo-mirror images.

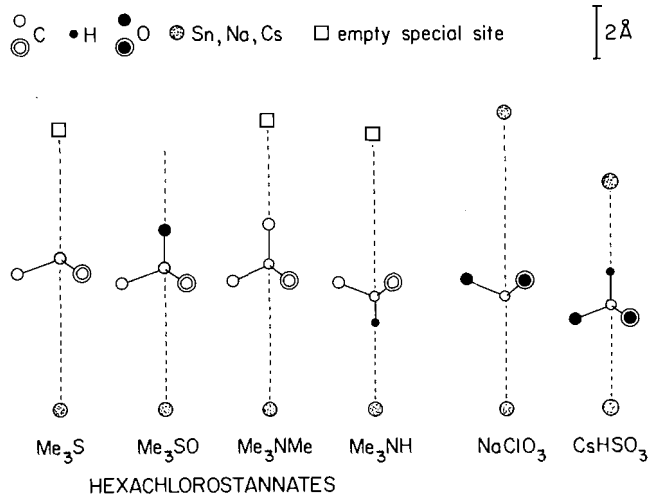

FIG. 3. Orientations of the skeletal configurations of YEL_3^{ϵ} and $YL'L_3^{\epsilon}$ ions in A_2SnCl_6 hexachlorostannates and in $NaClO_3$ and $CsSHO_3$. The ion axes are C_3 except for Me_3SO^+ which has C_s symmetry. Double circles, eclipsed ligand atoms. The Sn atom (*bottom*) is at (0, 0, 0) and the empty special site is at $(\frac{1}{2}, \frac{1}{2}, \frac{1}{2})$ of the cubic unit cells of $(Me_3S)_2SnCl_6$ and $(Me_3NH)_2SnCl_6$, and at $(\frac{1}{4}, \frac{1}{4}, \frac{1}{4})$ of the $Fd3c$ cell of $(Me_4N)_2SnCl_6$.

existence of a hydrogen-bonding interaction is corroborated from ir studies (60, 61).

(*f*) In $Cs^+HSO_3^-$ the S—H···Cs grouping is collinear by symmetry, S···Cs = 4.82 Å, H···Cs ~ 3.5 Å.

(*g*) In the 2:1 salts (Fig. 1) the Y atom is on a C_3 axis or, in 3MSOHS, in a mirror plane. If the cation orientation is disregarded, 3MSHS and $(Me_3NH)_2SnCl_6$ (3MHS) are isostructural; $(Me_4N)_2SnCl_6$ (4MHS) also is cubic, but here the doubling of the unit-cell dimensions (62) results in only one quarter of the cations being located on C_3 axes, the others have S_4 symmetry. The positioning of the cations on the C_3 axes and their orientation relative to the nearest coaxial Sn atom are shown in Fig. 3. The difference in the orientation is clearly seen. While in 3MSHS, 3MSOHS, and 4MHS the LP axis or the Y—L′ vector point at an empty site in the structure, in 3MHS the N—H bond points at the nearest $SnCl_6$ octahedron, engaging three of the Cl atoms in a symmetrically trifurcated hydrogen bond (60); the Me_3NH^+ ion is significantly displaced toward the coaxial Sn atom.

From these examples it is clear that among the interactions that could be singled out as primarily responsible for the orientation of the $YL'L_3^{\epsilon}$ molecule the least disputable is the Y—H^+···anion hydrogen bonding. For YEL_3^{ϵ}, however, it cannot generally be claimed that the orientation of the molecule is caused mainly by preferential interaction of the LP with the YEL_3^{ϵ} environment. Thus the PI_3 structure (51) consists of a hexagonal closest packing of I atoms and the P atoms, with their LPs, have no other choice but to protrude into the octahedral interstices of the hcp packing (P—I = 2.46 Å, P···I = 3.67 Å). This quasi-interstitial nature of Y is even more evident in the AsI_3 (As—I = 2.59 Å, As···I = 3.47 Å, ref. 65) and SbI_3 (Sb—I = 2.87 Å, Sb···I = 3.32 Å, ref. 66) crystals which, though not isostructural with PI_3, also consist of hcp packings of I atoms.

Matched pairs. In PBr_3 and $POBr_3$ (Fig. 2) the immediate environments of the LP and of the oxygen atom are so similar that the same explanation would have to be proposed for the orientational effect of *E and* of L′ = O. An argument based on simple charge interaction would be difficult to make here. We do not yet have *ab initio* results for the $PBr_3|POBr_3$ pair, but we can examine the almost certainly isostructural (40, 41) $PCl_3|POCl_3$ pair with the same effect. The calculated net charges (Table 6) in a free PCl_3 molecule are ϵ(P) = 0.646, ϵ(Cl) = −0.215; in a free $POCl_3$ molecule, ϵ(P) = 1.034, ϵ(Cl) = −0.151, and ϵ(O) = −0.582. If these respective charge distributions are assumed to be substantially unchanged in the two molecular crystals, the three negatively charged Cl neighbours closest to the PCl_3 or $POCl_3$ axis would see a positive net charge on the P atom in the PCl_3 crystal but a *negative* net charge on the oxygen atom in the $POCl_3$ crystal. Yet in PBr_3 in comparable circumstances the P···Br distance is practically the same as the sum of the van der Waals radii of P and Br, whereas in $POBr_3$ the O···Br distance is ~0.3 Å shorter than the corresponding van der Waals sum. Since the P^+···Br^- interaction would be expected to produce a shortening of that distance but the O^-···Br^- interaction a lengthening of the O···Br distance, it can hardly be argued that either interaction is of primary importance in determining the structure of the crystal and hence the orientation of the anion.

TABLE 6. Changes in the net charges (e) on atoms in YEL_3^{ϵ} molecules or ions resulting from addition of a fourth ligand on Y[a]

Species	ϵ(Y)	ϵ(L)	ϵ(L′)

[a]From Mulliken population analysis on 6-31G* optimized structures. For Me_3S^+ see Table 7.

The problem of electrostatic charge interaction can be examined in more detail with reference to the $PbSO_3|PbSO_4$ and $KClO_3|KClO_4$ pairs, the two partners in each pair being isostructural if the L′ = O ligand is disregarded (Fig. 4). $PbSO_3$ and $PbSO_4$ crystallize with the same space group, *Pnma*. The ratios of their respective unit-cell dimensions are 0.932, 1.016, and 0.978, and the largest difference in their stated positional parameters of the atoms in common is only about 0.2 Å. The $KClO_3|KClO_4$ pair at room temperature is not isostructural in the strict crystallographic sense, the space groups being $P2_1/m$ and *Pnma*, respectively. However, $P2_1/m \subset Pnma$, and the difference in space-group symmetry does not affect the immediate environment of the anion in the two crystals significantly. Moreover, HT-$KClO_3$ (44) *has* the same space group as $KClO_4$ (with one dimension doubled); even though the structure determination of HT-$KClO_3$ is not accurate, comparison with $KClO_4$ reveals the essential indifference of the ClO_3^- ion in LT-$KClO_3$ and HT-$KClO_3$ to its orientation in the crystal. The ratio b(LT-$KClO_3$)/b($KClO_4$) = 0.990 and the ratio $2ac$(LT-$KClO_3$)/ac($KClO_4$) = 0.974. There also is considerable metric similarity between the *Pnma* structures of the two model compounds $KClO_4$ and $PbSO_4$, the ratios of their respective unit-cell dimensions being 1.041, 1.047, and 1.040.

For personal use only.

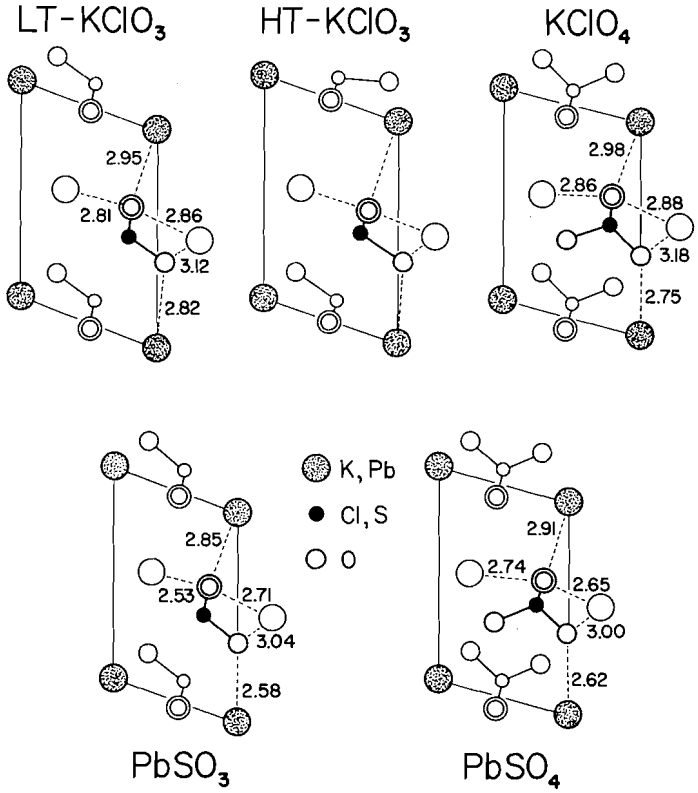

FIG. 4. Comparison of the structures of LT-$KClO_3$, HT-$KClO_3$, $KClO_4$, $PbSO_3$, and $PbSO_4$ (cf. Table 2). Heavily outlined single circles and shaded circles, atoms in m at $y = \frac{1}{4}$; heavily outlined double circles, oxygens at $\frac{1}{4} \pm y$ belonging to anions with Cl or S at $y = \frac{1}{4}$; thinly outlined double circles, oxygens at $\frac{3}{4} \pm y$ and $-\frac{1}{4} \pm y$ belonging to anions with Cl or S at $y = \frac{3}{4}$ and $-\frac{1}{4}$. O···K and O···Pb distances are in Å (broken lines). The atomic positions in HT-$KClO_3$ are too uncertain to be of value for numerical comparisons.

In $PbSO_3$ and $PbSO_4$ the distance between S and the nearest near-coaxial Pb atom is 3.42 and 4.01 Å, respectively, and the geometry of the anion environment in the two structures is quite similar (Fig. 4), i.e. the L′ = O ligand in SO_4^{2-} replaces the LP in SO_3^{2-} with relatively small changes in the crystal structure. The similarity of the anion orientation can then be interpreted in two ways: either the LP and the Y—L′ = S—O bond have much the same orientation effects, or the structure is determined by the YL_3 part of the anion, with the LP and L′ = O having little involvement in the process. The same observations are made for the $KClO_3$|$KClO_4$ pair, where the Cl···K distances are 3.97 and 4.27 Å, respectively, and the lateral O···K in the two structures match even more closely than the O···Pb distances in the Pb salts (Fig. 4).

The calculated net charges on the atoms of free SO_3^{2-}, SO_4^{2-}, ClO_3^-, and ClO_4^- are given in Table 6. In SO_3^{2-} and ClO_3^-, $\epsilon(Y) > 0$, $\epsilon(L) < 0$; in SO_4^{2-} and ClO_4^-, $\epsilon(Y) > 0$ and $\epsilon(L) = \epsilon(L') < 0$. The charges are not likely to be critically affected by the incorporation of the anion in a crystal and by the ensuing distortion of its symmetry. When SO_3^{2-} is converted to SO_4^{2-}, the $\epsilon(O)$ decreases by only ~10%, but the nearest near-coaxial Pb^{2+} ion in $PbSO_4$ now faces a net charge on the L′ = O atom of −0.88 at 2.6 Å, whereas before conversion it faced a net charge on S of +0.90 at 4.0 Å. Similarly, on converting ClO_3^- to ClO_4^-, the nearest near-coaxial K^+ ion in $KClO_4$ faces a net negative charge on L′ = O of −0.71 at ~2.9 Å, whereas before conversion it faced a net positive charge on Cl of +1.4 at ~4.3 Å. In spite of these changes in the net charge facing the coaxial or near-coaxial cation the distances from the three oxygen atoms of the SO_3^{2-} or ClO_3^- ion to other neighbouring cations are largely indifferent to the insertion of the L′ = O ligand. As Fig. 4 shows, the (uncorrected) O···K distances on conversion from $KClO_3$ to $KClO_4$ undergo a mean change of only 0.05(2) Å; for the O···Pb distances on conversion from $PbSO_3$ to $PbSO_4$ the mean change is only 0.08(6) Å. This strongly suggests that the position of the L_3YE^{ϵ} anion (and indeed the crystal structure itself) is determined by Coulombic interactions between the symmetrically disposed L atoms and their cation neighbours, and that the interaction between the LP and the coaxial cation at Y···cation separations of 4 Å or more is by itself not sufficiently strong to constitute an effective anion-orienting factor.

Lone pair on the anion: the influence of the cation. The above interpretation finds support in the magnitude of the changes which are observed in the calculated electron-density distributions in the free anion when a cation is brought coaxially in the vicinity of the LP. The anion–cation combination chosen to illustrate this point is $^-O_3Cl\cdots Na^+$, for which a calculation utilizing a 6-31G* basis set can be expected to produce an at least qualitatively reasonable result (cf. refs. 54–56). Moreover, the spatial cation–anion relationships in $NaClO_3$ are well established (cf. refs. 13 and 14; also ref. 22 for the isostructural $NaBrO_3$): the Na^+ ion is coaxial with its ClO_3^- partner by symmetry, both the Na and Cl atoms being located on a C_3 axis and about 4 Å apart; the three non-coaxial, C_3-related Na^+ ions on the LP side of the anion are at 3.35 Å from the Cl atom but the Cl···Na vector forms a 69° angle with the C_3 axis; and the three nearest Na^+ neighbours of an oxygen atom of the anion are at 2.4, 2.5, and 3.5 Å.

In the free ClO_3^- ion the local concentration of electron density ρ in the region of the LP is evident (Fig. 5*C*). The deformation of the shapes of the contour lines is not extreme but clearly present. On fixing an Na^0 atom coaxially at 4 Å from the Cl atom of ClO_3^0 and optimizing the geometry of this initial $Na^0\cdots ClO_3^0$ assembly the net charges which result are $\epsilon(Cl) = +1.328$ and $\epsilon(O) = -0.755$ compared to $\epsilon(Cl) = +1.381$ and $\epsilon(O) = -0.794$ in the free ClO_3^-, and $\epsilon(Na) = +0.938$.[7] The outermost ρ contours of the chlorine opposite the Na atom are displayed by small but significant amounts relative to free ClO_3^-. However, the contours for $\rho > 0.02$ au are shifted by no more than the thickness of a line in the plot, i.e. the polarization of ρ(Cl) in the LP region where ρ is appreciable is negligible. This is evident even more in the companion $\nabla^2\rho$ plot (Fig. 5*D*).

To see whether the magnitude of the perturbation of ρ(Cl) in the region of the LP is any different from that produced under comparable circumstances by an Na^+ ion on a Cl^- ion, i.e. in the absence of a LP, we carried out a 6-31G* calculation on an $Na^0\cdots Cl^0$ assembly at a 4 Å separation.[8] The resulting $Na^+\cdots Cl^-$ pair is less ionic ($\epsilon(Na) = +0.868$) than the $Na^+\cdots ClO_3^-$ pair (Fig. 5*F*). The shifts of the ρ contour lines between free Cl^- and the Cl^- in the $Na^+\cdots Cl^-$ pair (*A*) are appreciably larger than the corresponding shifts for the chlorate ion in $Na^+\cdots ClO_3^-$ relative to free ClO_3^- (*B*):

[7]The calculated Cl—O bond length in the $Na^+\cdots ClO_3^-$ assembly, 1.4770 Å, is ~0.01 Å shorter and the OClO angle, 109.86°, about 1.3° larger than in free ClO_3^- (Table 4).

[8]The equilibrium Na—Cl distance is 2.82 Å in NaCl crystal (RT, 1 atm), 2.361 Å in NaCl molecule (6-31G*, 2.397 Å), and 3.306 Å in tetrahedral $NaCl_4^{3-}$ (6-31G*, ref. 54).

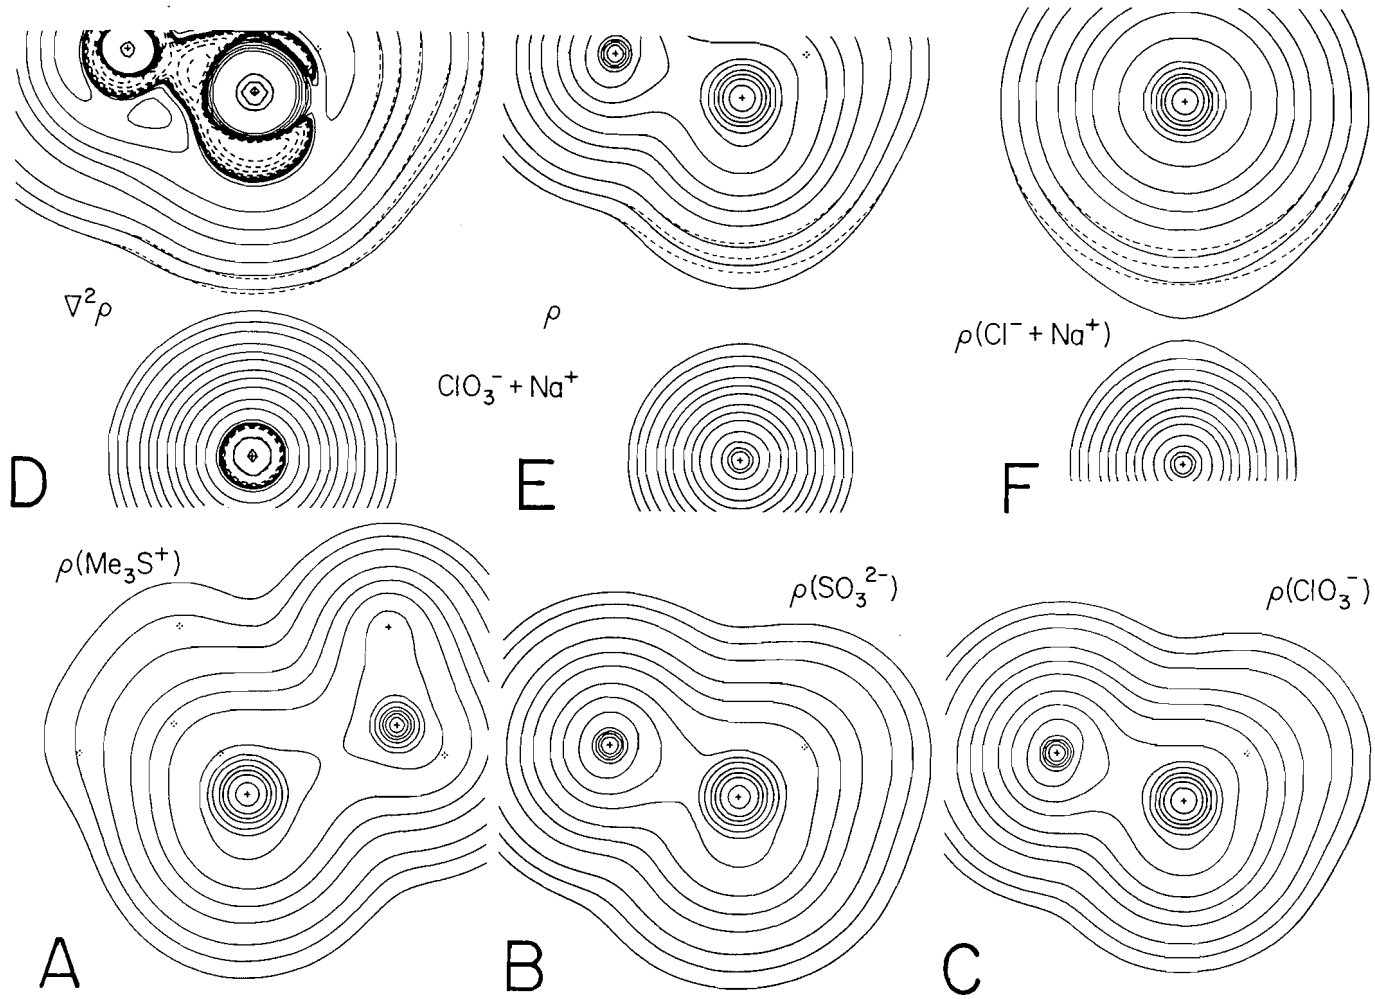

FIG. 5. Electron density (ρ) distribution in free Me_3S^+ (*A*), SO_3^{2-} (*B*), and ClO_3^- (*C*) ions and in ClO_3^- + Na^+ (*E*, ρ; *D*, $\nabla^2\rho$) and Cl^- and Na^+ (*F*) pairs (6-31G* optimization; sections coincide with an *m* of C_{3v}). The Na···Cl separation in *D* − *F*, 4 Å, matches that in $NaClO_3$ crystal. The broken lines in *E* are the ρ contours of free ClO_3^- (*C*); in *F* they are the ρ contours of a free Cl^- ion. The broken lines associated with the outer contours in *D* are the $\nabla^2\rho$ contours of free ClO_3^-. The outermost contour represents 0.002 au and is followed by the 0.004, 0.008, 0.02, 0.04, 0.08, 0.2, 0.4, and 0.8 au contours (1 au = 6.749 e/Å^3).

Contour	*A*	*B*
ρ = 0.002 au	0.36 Å	0.19 Å
ρ = 0.004 au	0.15 Å	0.10 Å
ρ = 0.008 au	0.06 Å	0.05 Å

Smaller but unmistakable displacements are observed in the ρ(Na) contours relative to free Na^+: ρ = 0.002 au, ~0.13 Å for $Na^+\cdots Cl^-$ and ~0.05 Å for $Na^+\cdots ClO_3^-$. Also, the radius of a given ρ contour in free Cl^- is larger than the radius, in the axial direction, of the corresponding contour in free ClO_3^-. The comparison of the $Na^+\cdots ClO_3^-$ with the $Na^+\cdots Cl^-$ pair can be no more than qualitative, and the cation–anion interaction in an isolated ion pair does not completely reflect the situation in a crystal. Nevertheless, it is reasonably clear that the ρ(Cl) distribution in ClO_3^- is relatively unaffected by the polarizing action of the cation and remains practically the same except in regions where ρ is quite low, perhaps ≤0.02 e/Å^3. In view of this it is unlikely that the interaction between the LP and the coaxial Na^+ in the $NaClO_3$ crystal is sufficiently strong to be orientation-determining.[4] The primary reason for the ClO_3^- orientation should be sought in the charge interaction between Na^+ and the oxygen atoms at 2.4–2.5 Å, unless one admits that lateral interaction between the LP and non-coaxial Na^+ ions at 3.35 Å from the Cl atom is sufficiently effective to be responsible for the orientation, alone or in conjunction with the O···Na interactions. Since the lateral $E\cdots Na^+$ interaction cannot be divorced from the O···Na interaction when considering the crystal as a whole, the question of the cause–effect relationship in this situation may receive only incomplete answers.

Lone pair on the cation. In the cationic YEL_3^+ species the ion as a whole carries a positive charge. A counter anion on or near the cation axis would thus face a positive charge on the Y atom in the simultaneous presence of a local electron-density concentration which constitutes the LP. In Me_3S^+, ε(S) = +0.630, ε(H) = +0.253 and +0.273 (Table 7). Comparison of the calculated ρ distributions (Fig. 5*A*) shows that the ρ contour geometry in the LP region of the free ion is quite similar to that in free SO_3^{2-} (ε(S) = +0.895), even though the ionic charges differ both as to sign and magnitude. Estimated contour radii (in Å) in the axial direction for the two ions and for ClO_3^- are

Contour	Me_3S^+	SO_3^{2-}	ClO_3^-
0.002 au	2.01	2.10	1.90
0.02 au	1.42	1.49	1.38
0.2 au	0.72	0.77	0.82
0.4 au	0.46	0.46	0.54
0.8 au	0.39	0.39	0.37

Similar arguments would therefore be valid for the lack of importance of coaxial $Me_3S^+\cdots$anion interactions as orienting factors in crystals as are set forth above for $^-L_3YE\cdots$cation interactions. Specifically, it seems unreasonable to suppose that in $(CH_2)_5SMe^+I^-$ (Fig. 2) there is sufficient interaction between S and the near-coaxial I^- at 7.4 Å, and similarly between O and the coaxial I^- at ~4.9 Å in Me_3SOI, and that the cation orientation in these structures is due to axial $E\cdots I^-$ or $O\cdots I^-$ interaction when much shorter $H^+\cdots I^-$ separations are present. It seems equally unreasonable to suppose that there can be any effective interaction between LPs in 3MSHS (Fig. 1), where two LPs face each other along a C_3 axis, across an inversion centre, at an S···S separation of ~9.9 Å; even lateral $E\cdots$Cl interactions appear unimportant in determining the cation orientation within the highly symmetric *anti*-fluorite $SnCl_6$ framework when the overall packing arrangements in Fig. 1 are compared.

In Me_3SI, Me_3SeI, and Et_3SI (Fig. 2) the LP ends of the cation axes point between coplanar I atoms while an approximately coaxial cation···I arrangement would be expected. Thus either the $E\cdots$I interaction is not sufficiently strong to overcome other tendencies in the crystal, or lateral (unsymmetric) $E\cdots$I interactions at unfavourable angles must be admitted as an orienting factor.

Similar situations exist in $SBr_3^+SbF_6^-$ (68), $SeBr_3^+SbF_6^-$ (69), $TeBr_3^+AsF_6^-$ (69) and in related salts. In SBr_3SbF_6 the S atom has on the LP side a coaxial (~10° off the cation axis) F neighbour at ~4.7 Å, i.e. too far for an effective $E\cdots$F interaction, but also three F atoms, each from a different anion, at a mean S···F distance of 2.84 Å and at a mean angle of ~49° from the cation axis. There appears to be significant interaction between the Br and F atoms, the mean Br···F separation being 2.83 Å, almost 0.5 Å smaller than the van der Waals sum of 3.3 Å.

Conclusion

As demonstrated above, and contrary to first impression, there are various reasons for believing that the rôle of LPs in determining a crystal structure or structure type is subordinate. This applies even to their rôle in determining the orientation of the LP-containing entity, especially in ionic crystals without hydrogen bonding between cations and anions. In any event, if a LP *has* an orienting effect, this effect cannot be divorced from other, equally or more important interactions in the crystal, be they ionic or dipolar or yet other in character, so that the consequences of the presence of a LP cannot be investigated in isolation. The LP of course has indirect stereochemical consequences in the crystal in the sense that it is an integral component of the molecular geometry of the free YEL_3^ϵ species and this geometry is a structure-determining factor.

The *symmetry* of a crystal containing YEL_3^ϵ is most often the result of a compromise between the tendency to attain maximum packing density and minimum lattice energy while at the same time preserving as much as possible the intrinsic geometry and symmetry of the ion or molecule. A symmetric orientation of the LP axis in a crystal is often a natural consequence of this compromise, in that high-density arrangements of units of a given symmetry (subgroups of C_{3v}) require for their realization space groups which preserve and reflect this symmetry (cf. ref. 57). This accounts, for example, for the frequent occurrence of arrangements of symmetry *Pnma* (with the LP axis in a mirror plane) and its subgroups $Pn2_1a$, $P2_12_12_1$, $P2_1/m$, $P2_1/n$, or of $R\bar{3}m$ (LP axis $\|C_3$) and its subgroups $R3m$, $R\bar{3}$, $R3$, $C2/m$. These space-group symmetries are equally frequently encountered with crystals containing $YL'L_3^\epsilon$ units, with the Y—L′ bond in a similar orientation as the LP axis in the YEL_3^ϵ species. This fact further minimizes the importance of the LP *per se* as an orienting factor.

Stereochemically inactive LP in crystals

If Y is a nontransition element of the g-th group of the Periodic Table, then a free $(2n + 2)$-electron molecule or ion YL_n^{g-n-2} with $n = g - 1$ halogen ligands (e.g. $GeCl_3^-$, $SnCl_6^{4-}$, $TeCl_6^{2-}$) will contain a stereochemically active LP on Y which will function as a $(n + 1)$-th ligand in determining the equilibrium configuration of the molecule. Provided the identity of YL_n^{g-n-2} as a mononuclear species is preserved,

the molecule will retain its geometry on incorporation in a crystal if allowance is made for distortions (usually minor) due to accidents of crystal packing. However, sometimes the molecular geometry as revealed by a crystal-structure determination will have a symmetry *higher* than observed or calculated for the free molecule; in particular, with $n = 6$ or 8 the YL_n^{g-n-2} molecule appears to assume the optimum geometry of a YL_n^{g-n} molecule (e.g. the 14-electron $TeCl_6^{2-}$ may exhibit the same symmetry as the 12-electron $SnCl_6^{2-}$, see below). These apparent exceptions to expectation from the VSEPR theory are described by saying that in the crystal the LP is stereochemically inactive or inert.[9]

14-electron species: observed geometry. Probably the most frequently quoted examples of such exceptions are the SeX_6^{2-} and TeX_6^{2-} (X = Cl, Br, I) ions. Their salts with simple cations contain discrete and, against expectation, *regular* YX_6 octahedra, often of crystallographic O_h symmetry. Where distortions occur they are quite small and do not increase significantly even when the crystal undergoes crystallographic transitions on cooling, e.g. in $(NH_4)_2TeBr_6$ (71), K_2TeBr_6 (72), and Rb_2TeBr_6 (73).[10] However, several structures have been reported (refs. 74–78 and Table V of ref. 78) in which the difference between the shortest and the longest bond in the YX_6 octahedron at room temperature amounts to as much as 10% of the mean bond length: in the triclinic $(C_{22}H_{24}N_2O_4S_4)TeCl_6$ structure (74), which contains $TeCl_6$ octahedra of C_i as well as C_1 symmetry, the first octahedron is practically undistorted, whereas in the second the $(Te—Cl)_{max} - (Te—Cl)_{min}$ difference is ~0.22 Å. Abriel (75–79) found that in contrast to the appreciably distorted $TeCl_6$ octahedron in $[H_3N(CH_2)_3NH_3]$-$TeCl_6$ the $SnCl_6$ octahedron in the corresponding hexachlorostannate(IV) is undistorted. The distortion observed in the $TeCl_6^{2-}$ and $TeBr_6^{2-}$ ions is accompanied by lifting of the degeneracy of the $\nu_3(t_{1u})$ and $\nu_4(t_{1u})$ fundamentals in the ir spectra; however, the ν_3 and ν_4 absorption bands appear to be broadened even in cubic Rb_2TeBr_6, where Te is at a site of O_h symmetry. Abriel took the static distortion of the SeX_6 and TeX_6 octahedra to be a manifestation of the expected stereochemical activity of the LP, and the lack of distortion a manifestation of dynamic averaging of instantaneous orientations of the intrinsically distorted 14-electron YX_6^{2-} ion. From his observations he concluded that the diffraction geometry of the SeX_6 or TeX_6 octahedron is imposed by the symmetry of the crystal environment (i.e. the site symmetry at Se or Te), and that the octahedron is to be expected undistorted when the Se or Te site is centrosymmetric but distorted when the site is noncentrosymmetric. An SnX_6^{2-} ion, by contrast, does not contain a LP and would therefore be insensitive to the site symmetry at Sn, although the actual geometries of all these octahedra would respond to particulars of the crystal packing.[11]

The range of values of the distortion index Δ (see footnote of Table 8) in the structures surveyed by Abriel (78) is, for centrosymmetric sites, zero (for O_h site symmetry) to 2.8 for $TeCl_6^{2-}$, 0–1.5 for $TeBr_6^{2-}$, and 0–0.1 for TeI_6^{2-}; for noncentrosymmetric sites, 2.9–187 for $TeCl_6^{2-}$ and 56–157 for $TeBr_6^{2-}$; and for $SnCl_6^{2-}$ in both types of sites, 0–5.7. However, one of the values for $TeCl_6^{2-}$ (C_2) is only 2.9, and the only Δ value for a noncentrosymmetric (C_s) $SeBr_6^{2-}$ is rather low, 7.8. Extension of Abriel's survey to discrete YX_6^{4-} (Y = Sn, Pb) and YX_6^{3-} (Y = Sb, Bi) ions (Table 8) yields Δ = 0–9.4 for centrosymmetric sites, whereas for the noncentrosymmetric sites the range is 0.2–38. For the square-antiprismatic XeF_8^{2-} ion in $(NO)_2XeF_8$ Δ is 97.

To obtain an idea of the magnitude of the distortions attributable to crystal packing we have examined 31 $SnCl_6^{2-}$ octahedra in crystal structures determined recently by Vincent (96). The choice of the organic N-containing cations (some of them quite large) in these hexachlorostannates was unrelated to the present considerations. Fifteen of the 31 octahedra are centrosymmetric (C_i), the remainder having C_1, C_2, and C_s symmetries; the anisotropic thermal parameters of the Sn and Cl atoms were unexceptionable. For the centrosymmetric octahedra, Δ = 0.1–12, with a mean of 7.2 (σ(mean) = 4.1, $\gamma_1 = 0.04$, $\gamma_2 = 1.5$); for the noncentrosymmetric octahedra, Δ = 0.1–24, with a mean of 6.6 (σ(mean) = 4.7, $\gamma_1 = 0.34$, $\gamma_2 = 1.7$); very little change results when Δ is calculated from Sn—Cl distances corrected for rigid-body motion.[12] The distortions due to factors unrelated to the LP are thus not negligible even for the centrosymmetric octahedra and can be substantial when the octahedra are noncentrosymmetric. In addition, an uncertainty of perhaps 1–2 units of Δ arising from the bond-length esd's must be included.

It would therefore seem prudent to conclude for the present that a *large* Δ value (perhaps >50) for discrete YL_n^{g-n-2} coupled with a small Δ value for the corresponding YL_n^{g-n} (e.g. in matching Te/Sn, Sb/In, Pb/Cd pairs) is evidence of static distortion attributable to the LP. For smaller Δ values and where the companion YL_n^{g-n} structure is lacking, a similar conclusion would seem much less well founded, and it is not clear from the small data set currently available whether dynamic averaging in a discrete YL_n^{g-n-2} in a crystal *is* in fact contingent on the presence or absence of an inversion centre or on some other symmetry criterion yet to be formulated.

[9]For a recent review and bibliography (with particular attention to Group IV) see ref. 70.

[10]Rb_2TeBr_6 was investigated down to 12.5 K (73).

[11]It is noteworthy that in Abriel's compounds the U_{ii} values are larger in the 14-electron anions than in $SnCl_6^{2-}$ not only in the centrosymmetric pair *a*, where this might be expected, but also (and more dramatically) in the noncentrosymmetric pair *b*, where the 14-electron anion *is* distorted and dynamic averaging not claimed; and further, that the U_{ii} and their anisotropy are large even in the cubic *d* ($Fd3c$, ref. 80), where Te occupies a centrosymmetric C_{3i} site:

Type	Symmetry	Compound pair	$\bar{U}_{ii}$(Y)	$\langle\bar{U}_{ii}(X)\rangle$*
a	Y(C_i)	$[H_3N(CH_2)_2NH_3]TeCl_6$|$[H_3N(CH_2)_2NH_3]SnCl_6$	223|166	377(16)|275(10)
b	Y(C_s)	$[H_3N(CH_2)_3NH_3]TeCl_6$|$[H_3N(CH_2)_3NH_3]SnCl_6$	477|306	809(77)|481(35)
c	Y(C_s)	$[H_3N(CH_2)_3NH_3]TeCl_6$| —	277| —	422(31)| —

[a]In a discrete YL_n^{ϵ} ion a ligand is not shared by other Y atoms. $\Delta = 10^5[\sigma(\bar{d})/\bar{d}]^2 = (10^5/n)\Sigma[(d_i/\bar{d}) - 1]^2$, n = number of ligands, d_i = individual bond length, $\bar{d}$ = mean bond length; this index of distortion is used for convenience of comparison with the corresponding $SnCl_6^{2-}$, $SeCl_6^{2-}$, $TeCl_6^{2-}$, $TeBr_6^{2-}$, and TeI_6^{2-} species tabulated in ref. 78.

[b]S_4 at 4.7 K (86).

[c]Isostructural with Rb_3BiBr_6 but crystal structure not determined.

[d]Not included in Table V of ref. 78.

14-electron species: "genuine" stereochemistry. The question that should perhaps be asked in the first place is, what is the "genuine" stereochemistry of a YL_n^{g-n-2} species, i.e. what is the optimized equilibrium geometry of the isolated molecule or ion. With the exception of XeF_6 (98, 99), IF_6^- and TeF_6^{2-} (99), the equilibrium geometries of the 14-electron molecules do not appear to have been investigated by *ab initio* methods. The main result of interest here of the recent all-electron SCF calculation using a large Gaussian basis set (99) is the effect of symmetry on the total electronic energy E and on Δ of XeF_6, IF_6^-, and TeF_6^{2-}. For the three configurations investigated, $E(C_{3v}) < E(C_{2v}) < E(O_h)$ for all three molecules, but the difference between the first two was not large. The distortions calculated from the optimized geometries are[13]

Species	$\Delta(C_{3v})$	$\Delta(C_{2v})$
TeF_6^{2-}	524	662
IF_6^-	234	268
XeF_6	115	113

On the assumption that these trends remain unchanged for the Cl and Br ligands, it is not unreasonable to take the C_{3v} configuration as the "genuine" geometry of YX_6^{6-n-2}. Some support for this comes from the observed geometry of $SeBr_6^{2-}$ in $[H_3N(CH_2)_3NH_3]SeBr_6$ (78) which, although at a site of C_s symmetry, closely simulates C_{3v} symmetry, and from $TeCl_6^{2-}$ (C_s) in $[H_3N(CH_2)_3NH_3]TeCl_6$ (76) which may be regarded as a distorted C_{3v} configuration. In an attempt to corroborate this assumption we have optimized the equilibrium geometry of free $SeCl_6^{2-}$ at the STO-3G* level both in O_h and C_{3v} symmetry. The result[14] is similar to that obtained for TeF_6^{2-} (99): $E(C_{3v})$

[13]These distortions seem to indicate that for SbF_6^{3-} and SnF_6^{4-} Δ would be even larger. These fluoride species may not exist as discrete ions, but for the other SbX_6^{3-} and SnX_6^{4-} ions only small distortions have been observed even at noncentrosymmetric sites (Table 8). However, the number of such ions for which structural detail is known is very small and no general conclusions can be drawn at present. It is possible that for Δ beyond a certain limit other geometries or chemistries prevail. The Mössbauer ^{129}I spectrum of $CsIF_6$ (100) indicates a significant EFG at the I atom; it has been suggested (126) that the iodine in this crystal might in fact be seven-coordinated, the increased c.n. lowering the symmetry at I and thus causing the LP to become stereochemically active.

[14]$E(O_h) = -5101.78976$ au, Se—Cl = 2.3224 Å. For the C_{3v} configuration, $E = -5101.79843$ au; the Cartesian coordinates (Å) are Se (0, 0, 0), Cl(*1*) (2.28768, 0, 0.97861), Cl(*1'*) (−1.14384, 1.98119, 0.97861), Cl(*2*) (0.86724, 1.50211, −1.33674), Cl(*2'*) (0.86724, −1.50211, −1.33674); Se—Cl(1) = 2.4882 Å, Se—Cl(2) = 2.1898 Å, Cl(*1*)SeCl(*1'*) = 105.54°, Cl(*2*)SeCl(*2'*) = 86.62°, Cl(*1*)SeCl(*2*) = 82.88°; ϵ(Se) = 0.8231, ϵ[Cl(*1*)] = −0.6378, ϵ[Cl(*2*)] = −0.3033.

is lower than $E(O_h)$ by 0.00867 au ~ 5.5 kcal/mol. The equilibrium bond length for O_h and the mean bond length for C_{3v} are both ~0.1 Å shorter than found for $SeCl_6^{2-}$ (O_h) in $(NH_4)_2SeCl_6$ at room temperature, 2.411(1) Å (125); $\Delta(C_{3v})$ = 407.

Evidence for dynamic averaging. A 14-electron YX_6^{2-} octahedron of C_{3v} symmetry consists of a larger and a smaller X_3 triangle with the LP on the C_3 axis toward the larger triangle. This configuration can be dynamically reconciled with the observed O_h symmetry at Y in the crystal by an eight-fold orientational disorder of the LP axis. The disorder cannot be static, with a random distribution of the LP orientations over the Y sites, for no quadrupole splitting has been detected in the Mössbauer ^{125}Te spectra of cubic A_2TeX_6 at 80 K (127), and nqr, Raman, and other results (cf. refs. 79 and 128) also are consistent with the cubic symmetry of the anion. However, fast reorientations of the LP resulting in dynamic averaging of the X positions would be expected to manifest themselves in the magnitude and anisotropy of the thermal parameters U_{ii}(X) of TeX_6^{2-}(O_h) relative to those in the corresponding SnX_6^{2-}(O_h).

This has been considered, for several symmetries, by Abriel and Zehnder (79), who based their examination on their U_{ii} values for cubic Rb_2TeBr_6, Cs_2TeBr_6, and Rb_2SnCl_6 at 298 and 160 K. This very small sample places them at a disadvantage in their arguments, as does the difficulty which arises from comparing the two hexa*bromotellurates* with a hexa*chloro-stannate*, i.e. YX = TeBr with YX = SnCl. When their data are combined with the U_{ii} of cubic K_2TeBr_6 at 463 K (72) and with the room-temperature thermal parameters for A_2SnCl_6 (A = K, Rb, Cs) from refs. 128 and 139–141, the following emerges from a scrutiny of the A_2SnCl_6 and A_2TeBr_6 sets: (*1*) $\bar{U}$(A) at constant temperature decreases with the increasing mass of A; (*2*) $\bar{U}$(Sn) and $\bar{U}$(Te) at constant temperature show little variation with A; (*3*) the ratio $R = U_{ii}(X)\perp / U_{ii}(X)\parallel$ for Rb_2TeBr_6 and Cs_2TeBr_6 is, within the statistics, independent of temperature;[15] (*4*) this ratio, which measures the anisotropy of the thermal motion of X, at room temperature decreases with the size of A and increases with $\bar{U}$(A) in both series (Fig. 6), and its variation with A arises essentially from the variation in the $U_{ii}\perp$ component.

The reduction of U_{ii} on cooling from room temperature to 160 K is, within the statistics, quite uniform (by a factor of 1.83(14) ~ 298/160)[16] for all the values in Table II of ref. 79. Analysis of variance (both one- and two-way) justifies rejecting the hypothesis that the variation in the reduction factor of the individual U_{ii} is not due to chance, at the 99.5% significance level. In particular, no statistically significant difference can be

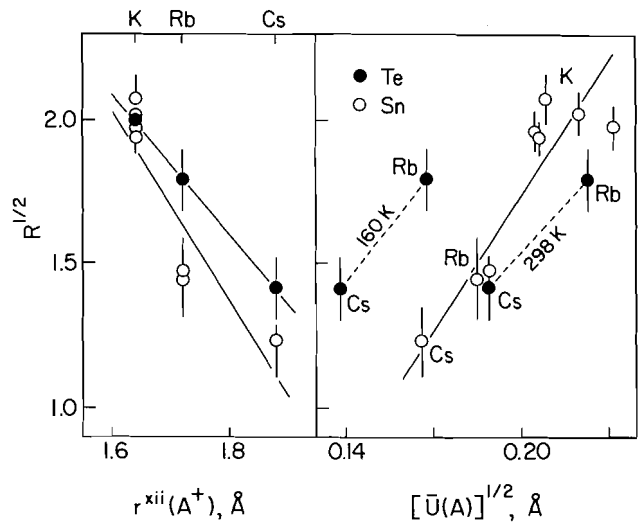

FIG. 6. Variation of the anisotropy of thermal motion of X in A_2YX_6 (Y = Sn, Te; X = Cl, Br) with the size and rms displacement of A. $r^{xii}(A^+)$, Shannon's effective ionic radius of A^+ in 12-coordination; $[\bar{U}(A)]^{1/2}$, rms displacement of A; $R^{1/2}$, ratio of the rms displacements of X ⊥ and ∥ to the Y—X bond. A_2TeBr_6 (A = Rb, Cs), 298 and 160 K (72, 79); A_2SnCl_6 (A = K, Rb, Cs) (79, 128, 139–141).

claimed to exist in this data set between the Sn and the Te compounds. This makes it especially difficult to understand the dramatic difference in the ratio $R_{TLS}(U_{ij},298)/R_{TLS}(U_{ij},160)$ of the discrepancy indices for the rigid-body motion of the $TeBr_6$ octahedron on one hand and of the $SnCl_6$ octahedron on the other: for $TeBr_6$ on cooling $R_{TLS}(U_{ij})$ increases about four-fold, whereas for $SnCl_6$ it *decreases* by a factor of ~14.[17] While increasing departure from the rigid-body character of the YX_6 motion on cooling may be expected, variation in the opposite direction is surprising, especially when the approximation to the model is, at 160 K, as close as the $R_{TLS}(U_{ij})$ = 0.2% would indicate.[18]

The quantity which *is* appreciably affected by the size *and* the vibrational displacement of the A atom (both of which in turn depend on the atomic number of A) is the anisotropy $R^{1/2}$ of the thermal motion of the X atom (Fig. 6).[19] As far as can be established from the available data, the variation of $R^{1/2}$ with $r^{xii}(A^+)$ or $[\bar{U}(A)]^{1/2}$ for A_2TeBr_6 more or less parallels that for A_2SnCl_6. In these circumstances it is difficult to know what would be the particular manifestation in the thermal parameters of a difference that might exist between the thermal motions of SnX_6^{2-} and TeX_6^{2-}.[20]

[15]The difference between $R^{1/2}$(293 K) and $R^{1/2}$(160 K) is −0.03(12) for Rb_2TeBr_6, +0.15(11) for Cs_2TeBr_6, and −0.11(8) for Rb_2SnCl_6. For the structurally related $Pm3m$ perovskite $KMgF_3 = K_2Mg\square F_6$ Muradyan *et al.* (129) found $R^{1/2}$ to fall from 1.48 at 293 K to 1.38 at 123 K, i.e. ~0.04%/K. This would correspond to a decrease of the order of −0.1 in $R^{1/2}$ of the chloro and bromo compounds, i.e. to a change comparable to the experimental uncertainty in $R^{1/2}$. In their study, which was designed to investigate the temperature variation of the thermal parameters of $Pm3m$ perovskites well away from phase transitions, Muradyan *et al.* point out that routine application of standard procedures may yield unreliable U_{ii} values.

[16]This uniformity is far greater than that observed in ref. 129 for the simple $Pm3m$ perovskite $KMgF_3$ between 293 and 123 K.[15] The F atom in $KMgF_3$ is situated between two Mg atoms, forming a symmetric Mg—F—Mg bond, in contrast to A_2YX_6, where the X atom in the Y—X bond is unattached to another Y atom.

[17]In ref. 79 it is suggested that soft modes may be present which affect the motion of the $SnCl_6$ octahedron differently from the TeX_6 octahedra, but evidence for this seems lacking.

[18]The mean amplitude of the librational motion about a C_4 axis of the YX_6 octahedron (calculated from the U_{ij} of ref. 79) is, at 298 and 160 K, respectively, 4.3° and 3.4° for Rb_2TeBr_6, 3.2° and 2.1° for Cs_2TeBr_6, and 3.3° and 2.7° for Rb_2SnCl_6; the $U_{ij}(Rb_2SnCl_6,298)$ from ref. 128 yield 3.2°, in agreement with ref. 79. The mean translational amplitude is 0.14 Å for all the 298 K data and 0.10 Å for all the 160 K data. For K_2TeBr_6 at 463 K, the U_{ij} of ref. 72 give $R_{TLS}(U_{ij})$ = 0.02% (unweighted), 8.0°, and 0.21 Å, respectively.

[19]Such anisotropy is well known from the $Pm3m$ AYX_3 perovskites, where it sometimes is very large (see below and ref. 143).

[20]Dynamic averaging would lead to an octahedron of virtual O_h symmetry even if the site symmetry (as determined by the crystal packing) were a *non*centrosymmetric cubic subgroup of O_h.

For the present one would be inclined to the view that a much more extensive investigation of the temperature dependence of U_{ij} in matching $TeX_6|SnX_6$ series would be required if evidence in support of dynamic averaging were to be extracted from analysis of the thermal motion of the YX_6 octahedra. However, while it cannot be argued conclusively from the available X-ray results that dynamic averaging is responsible for the discrepancy between the observed and the "genuine" geometry of the 14-electron YX_6^{2-} species, the observation that the ν_3 and ν_4 fundamental absorptions are well separated in the ir spectrum of Rb_2SnCl_6 but coalesced to broad unresolved bands in the spectra of Rb_2TeCl_6 and Cs_2TeBr_6 (79) suggests that such averaging in TeX_6^{2-} does occur and is present even at very low temperatures. The difference in the ir spectra is in fact the most convincing evidence in support of the averaging at present.

We shall return to the problem of dynamic averaging in a somewhat different context in the next section.

Active LP ↔ inactive LP conversion

Leaving aside the precise nature of the symmetry criterion under which dynamic averaging in discrete YX_6^{g-n-2} octahedra is quenched, we observe that crystallographic transitions in crystals where Y is at a centrosymmetric site preserve the centre of symmetry, and if the octahedron is undistorted or only weakly distorted, Δ does not increase significantly as a result of the transition (e.g. in Rb_2TeBr_6 (73) or Rb_2TeI_6 (102)).[21] The interesting problem of occurrence of temperature-induced transitions in YX_6^{g-n-2} salts where Δ is large and Y at a noncentrosymmetric site does not appear to have been investigated. However, the transitions that occur in $A^+Y^{2+}X_3$ (Y = Ge, Sn, Pb) are of considerable interest in this context in that some of them appear to affect the inversion centre at Y, i.e. on the face of it they "activate" or "inactivate" the LP. The high-temperature phases are of the cubic perovskite type ($Pm3m$, $Z = 1$), with O_h as the diffraction site symmetry at Y, so that the LP in them can be said to be stereochemically inactive. The A^+ ions are accommodated in the three-dimensional framework formed by the corner-sharing $[YX_{6/2}]$ octahedra. Although these octahedra are not discrete, their $m3m$ symmetry makes them a suitable subject for investigating the effect of the LP (Table 9).

Transitions from the $Pm3m$ to a lower-symmetry phase are basically of three types, those preserving the topology (connectivity) of the perovskite structure, those which generate structures containing discrete YX_3^- ions, and those resulting in systems of YX_6 octahedra of various connectivities. Transitions of the first type are displacive, often involving symmetry changes via tetragonal subgroups of $Pm3m$ and preserving the crystallographic inversion centre at Y. They are not of interest in the present context.

Transitions of the second type (e.g. **A** in Table 9) may also be viewed as displacive (in principle via trigonal subgroup descent from $Pm3m$), but the atomic displacements in the YX_6 octahedra are clearly dissociative, $[YX_{6/2}]^- \rightarrow [YX_3X'_3]^- \rightarrow YEX_3^-$. Breaking up the framework of the corner-sharing $[YX_{6/2}]^-$ octahedra, i.e. one half of the Y—X bonds in the $Pm3m$ structure, substantially changes the character and physical properties of the halide and leads to an essentially ionic structure. These transitions entail a loss of the centre of symmetry at Y and may be described as producing distorted X_3—Y···X_3 coordination octahedra. The mean interatomic distance $\bar{d} = \frac{1}{2}\langle Y—X\rangle + \frac{1}{2}\langle Y\cdots X\rangle$ in the low phase closely matches the Y—X distance in the YX_6 (O_h) octahedron in the $Pm3m$ phase (Fig. 7), even though the asymmetry of the X_3—Y···X_3 coordination figure (viewed as a distorted octahedron), as measured by $\sigma(\bar{d})$ and $\Delta = 10^5[\sigma(\bar{d})/\bar{d}]^2$, is considerable. The volume change also is small, $V_1(Pm3m) - V_1$(low phase) ~ 1% for $CsGeX_3$ and $CsSnCl_3$.

Transitions of the third type (**B** in Table 9) result in the formation of a low phase in which YX_6 octahedra are linked into chains. Although these octahedra (noncentrosymmetric in **B**) are distorted as a result of the inhomogeneous connectivity, Δ is remarkably small. The mean value for the **B**-type compounds of Table 9, $\langle\Delta\rangle = 154$, is only twice as large as $\langle\Delta\rangle = 66$ for the corresponding Cd compounds of this type,[22] in which there is no LP on the Y atom. The distortion due to the LP in the Ge, Sn, and Pb octahedra is thus only minor at best (cf. also ref. 84). The $\bar{d}$ values for the two **B** phases which have a known $Pm3m$ high phase, $CsSnI_3$ and $CsPbBr_3$, are about 4% larger than the Y—M distances in the $Pm3m$ phases; the volume change $V_1(Pm3m) - V_1(\mathbf{B}) \sim 7\%$ for $CsSnI_3$ and $CsPbBr_3$, i.e. larger than for transitions of the second type.

The close similarity of $\bar{d}$ in the low phase to Y—X in the $Pm3m$ phase for the compounds in Fig. 7 suggests that this similarity is due to dynamic averaging in the high phase. A feature characteristic of all cubic perovskites is the strong anisotropy R of the thermal motion of the X atom (see above). This anisotropy increases with the so-called tolerance factor t of the perovskite[23] and with the decreasing temperature difference $T - T_{tr}$ (T_{tr}, upper transition temperature; cf. Fig. 27 of ref. 143). Conventional refinement of accurate neutron data based on the ideal cubic perovskite structure gave $R = 7.6(4)$ for $CsPbCl_3$ at 331 K and 6.5(3) for $CsPbBr_3$ at 425 K; even larger R values can be obtained depending on the particulars of the model (124, 149–151).[24] The rms displacements of the atoms in $CsPbCl_3$ at ~330 K from their ideal $Pm3m$ positions were 0.29 Å for Cs, 0.17 Å for Pb, 0.44 Å for Cl perpendicular and 0.16 Å parallel to the Pb—Cl bond.[25] This shows that while a transition on cooling may not result in the appearance of a discrete YX_3^- ion, where it does the atomic displacements in the $Pm3m$ phase are such that they can accommodate, dynamically, the dimensions and geometry of the YX_3^- ion. For example, on the reasonable assumption that the rms displacements in the cubic $CsSnCl_3$ are about the same as in $CsPbCl_3$, moving the Sn and three adjacent Cl atoms in the $m3m$ $SnCl_6$ octahedron in a concerted fashion from their ideal positions by amounts corresponding to the rms displacements and in such a way that the $SnCl_3$ group shrinks symmetrically,

[21] In $[H_3N(CH_2)_2NH_3]YCl_6$ ($P\bar{1}$; Y = Pt, Sn, Pb, Te; ref. 103) only the Pt compound has a transition (T_{tr} = 357.2 K) between 77 K and the decomposition temperature.

[22] The Δ values in the $ACdX_3$ of the **B**-type are 79 for $RbCdCl_3$ (144), 65 for NH_4CdCl_3 (145), 67 for $RbCdBr_3$ (146), and 79 for $TlCdI_3$ (147); the $\sigma(\bar{d})/\bar{d}$ in these compounds is ~0.027, compared with $\langle\sigma(\bar{d})/\bar{d}\rangle = 0.037$ for the **B** compounds of Table 9.

[23] The tolerance factor in turn depends on the relative sizes of the atoms: $t = [r^{xii}(A) + r(X^-)]/[r^{vi}(Y) + r(X^-)]\sqrt{2}$.

[24] For comparison, the room-temperature R for the LT-$CsGeX_3$ perovskites (**A** of Table 9, X-ray data) are 2.9(2) for Cl, 3.2(2) for Br, and 3.8(2) for I (106).

[25] Contrary to refs. 124 and 149–151, Mair (152) considers the motion of the Cl atom *not* to be highly anharmonic: soft modes contribute significantly to the Cl vibrations and at temperatures sufficiently above T_{tr} a temperature-independent component enters into the expression for the rms displacement.

TABLE 9. $A^+Y^{2+}X_3$ (Y = Ge, Sn, Pb) halides some of which exist as cubic perovskite phases[a]

[a] V_1 (Å^3), volume per formula unit. ⟨Y—X⟩ (Å), mean bond length, with σ(mean); for the discrete YX_3^- ions this represents the mean of the 3 (Y—X) + 3 (Y···X′) distances corresponding to the coordination $[YX_{3/2}X'_{3/2}]$, Y—X < Y···X′. For the distortion index Δ see Table 8.

[b] Space group and site symmetry at Y. (**A**) $A^+[YX_{3/1}]^-$ (or $A^+[YX_{3/2}X'_{3/2}]^-$, see footnote *a*), $R3m$. The cations and the X atoms form a trigonally distorted cubic close packing arrangement, with the Y(C_{3v}) in octahedral interstices; LP axis in C_3 and pointing between the three X′ neighbours at the larger distances from Y. (**B**) NH_4CdCl_3 type, $Pnma$, Y(C_s); double chains of distorted $[YX_{2/2}X_{3/2}X_{1/3}X_{1/1}]^-$ octahedra. These chains are preserved on hydration: $KPbBr_3 \cdot 2H_2O$ (⟨3.24(14)⟩ Å, Δ = 150), $NH_4PbBr_3 \cdot 2H_2O$ (⟨3.24(14)⟩ Å, Δ = 155), and $RbPbBr_3 \cdot 2H_2O$ are isostructural among themselves (118). $KPbBr_3 \cdot H_2O$ ($Cmc2_1$, Pb(C_s), ref. 119) contains chains of distorted $[PbBr_{2/2}Br_{2/2}Br_{1/2}Br_{1/1}]^-$ octahedra, ⟨3.06(20)⟩ Å, Δ = 436; $KSnCl_3 \cdot H_2O$ (120) at room temperature is likely to be isostructural or closely related.

[c] Probably tetragonal (142).

[d] Mössbauer QS(^{119}Sn) ~ 0.

[e] Single line in the ^{81}Br nqr spectrum (142).

[f] There are further displacive transitions on cooling (121–123), but they are not of interest in the present context.

[g] Corrected to room temperature, cf. Table 2.

[h] Or $[YX_{3/2}X'_{3/2}]^-$, see footnote *a*.

[i] No transition between room temperature and the decomposition temperature.

[j] Transition reversible, first-order in $CsGeBr_3$ and $CsGeI_3$ (106). For $CsGeCl_3$ the evidence concerning the order of the transition is contradictory (105, 106).

[k] Air- and light-sensitive.

[l] Easily supercooled down to room temperature; reversal to the LT phase very sluggish at room temperature, but ref. 109 states that the reversal is very fast at 80 K. As against this, "traces of water may catalyze the transition to the low phase; completely dry HT-$CsSnCl_3$ was stable at room temperature for at least a year and was also found stable down to 77 K" (110).

[m] The possibility cannot be excluded that the LT-$CsSnCl_3$ of ref. 108 may have been partially hydrated.

[n] Mössbauer QS(^{119}Sn) = 0.90 mm/s at 80 K.

[p] Transition to the LT phase sluggish or irreversible.

[q] Single line in the ^{127}I nqr spectrum (110).

[r] Black melt (mp 453°C) solidifies to a material black at room temperature (110).

[s] At ordinary rates of cooling the transition to **B** is irreversible. The $Pm3m$ phase undergoes transitions to a series of perovskite-derived phases ($Pm3m \rightarrow P4/mbm \rightarrow Pmbn$, refs. 121 and 124) which are not of interest in the present context. The white $CsPbBr_3$ (**B**) when dry can at room temperature be kept indefinitely, but on heating it transforms at 130°C irreversibly to the $Pm3m$ phase (116).

[t] Unstable at room temperature; monoclinic?

[u] $[PbI_{4/2}I_{2/2}]^-$ chains.

[v] $[PbI_{4/2}I_{2/1}]^-$ chains.

results in a C_{3v} $SnCl_3$ pyramid with Sn—Cl ~ 2.57 Å, in fair agreement with the bond lengths observed in the $SnCl_3^-$ ion in the low phase. It is thus clear even on this simplistic argument that the cubic phase implies dynamic averaging of all the possible orientations and positions of the YX_3^- ion under O_h symmetry. The overall result of this averaging is not necessarily representable either by conventional refinement of the ideal $Pm3m$ structure or by models in which the X atoms are offset, by amounts to be refined, from their ideal $Pm3m$ positions (e.g. with X in a *single* 12(*h*) or 12(*j*) or 12(*l*) equipoint of $Pm3m$ with fractional occupancy) and allowed to refine conventionally for thermal motion.

Solid Group V YX_3 (N to Bi; X ≠ F) halides

Most of these structures consist of clearly distinguishable YX_3 molecules, i.e. the presence of a LP is well displayed. The observed tendency of the Y atom toward c.n. ≥ 6 results from a compromise between preservation of discrete YEX_3 geometry and, especially in the $R\bar{3}$ iodides, closest packing of the halogen atoms. The YX_3 molecule is coordinated by three X atoms to form a more or less distorted X_3—Y···X_3 octahedron or trigonal prism; in the latter case additional 1–3 X atoms capping the prism on the side faces may be present at comparable or longer Y···X distances. The LP on Y points along the actual or idealized C_3 axis of the coordination polyhedron in the

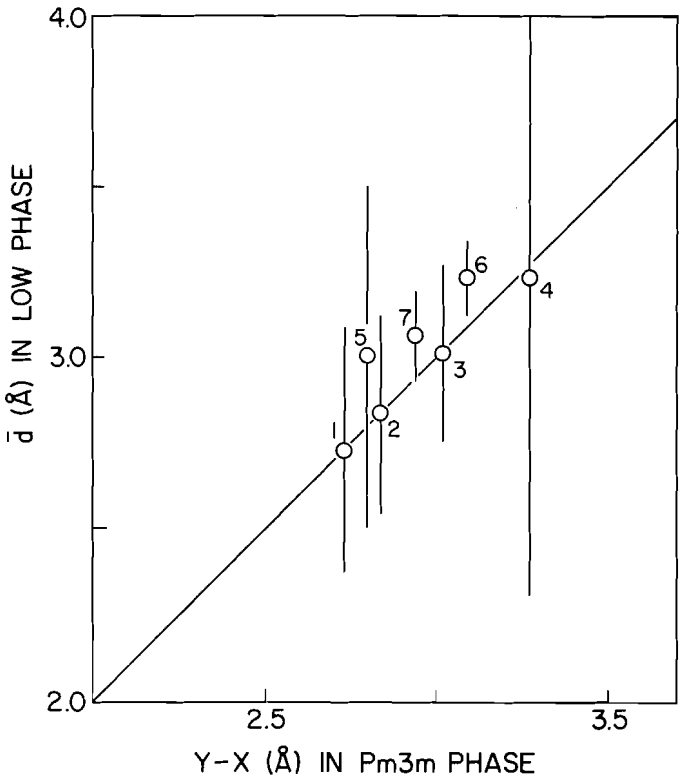

FIG. 7. Correlation of $\bar{d}$ (= mean of Y—X and Y···X distances for c.n. 6) in the low AYX_3 phase with the Y—X distance in the corresponding $Pm3m$ perovskite phase. A = Me_4N for *4*, Cs for *1–3*, *5–7*. YX: *1*, *4*, GeCl; *2*, GeBr; *3*, GeI; *5*, SnCl; *6*, SnI; *7*, PbBr. Length of vertical bar represents $\sigma(\bar{d})$. For references see Table 9.

direction of the more distant X_3 triangle. When the coordination of Y is octahedral, the situation resembles, locally, the coordination of the Ge atom in the rhombohedrally distorted $CsGeX_3$ perovskites (A compounds, Table 9). In the absence of information on the occurrence of crystallographic phase transitions in YX_3 on heating, one may ask how likely are these potentially pro-cubic X_3—Y···X_3 octahedra to undergo transitions of the second type (see above), i.e. to become metrically regular YX_6 octahedra?

Although the Y—X and Y···X distances in an YX_3 crystal may differ widely, the mean interatomic distance $\bar{d} = \frac{1}{2}[\langle Y—X\rangle + \langle Y\cdots X\rangle]$ is remarkably constant from compound to compound. It oscillates about 3 Å except in NCl_3 (this remarkable structure contains N atoms in octahedral, trigonal-prismatic as well as tetrahedral coordination (130), with $\bar{d}$ = 2.54 Å in the octahedron and 2.71 Å in the trigonal prism). In Fig. 8 the standard deviation $\sigma(\bar{d})$ is normalized to $\bar{d}$ and plotted against the mean bond length $\langle Y—X\rangle$ in the YX_3 molecule. The trend which emerges[26] is consistent even at spreads corresponding to $\sigma(\bar{d})$ ~ 30% of $\bar{d}$. The $\sigma(\bar{d})/\bar{d}$ value may be taken as an inverse measure of the density of packing in the YX_3 crystal, which ultimately depends on the relative effective sizes of the Y and X atoms and the XYX angles. In this respect $\sigma(\bar{d})/\bar{d}$ again confirms the unimportance of the spatial extension of the LP as a structure-determining factor. In the present context we take it to estimate the tendency of a YX_3 crystal to undergo conversion to a form in which the LP appears to be stereochemically inactive.

With $\sigma(\bar{d})/\bar{d} \sim 0$, the geometric condition for dynamic averaging is in fact almost satisfied in BiI_3. This $R\bar{3}$ structure is at the upper limit of packing density: the arrangement of the I atoms is very close to hcp. As a consequence the BiI_6 coordination octahedron is very nearly regular, but as its symmetry is only C_3, the averaging is not expected to be uniform.

For SbI_3, AsI_3, and PI_3 the $\sigma(\bar{d})/\bar{d}$ values fall between ~0.05 and 0.2, which corresponds to a Δ range of 250–4000. In crystals containing discrete YX_3^- ions transitions to cubic phases are known to occur even when $\Delta > 4000$ (Table 9). While this might suggest that in these triiodides the existence of transitions associated with a loss of stereochemical activity of the LP cannot be excluded, it may not be realistic to compare the molecular triiodides with the ionic AYX_3 for the present purpose, and the dimorphism that exists in $SbBr_3$ and SbI_3 is not indicative of a tendency in that direction. However, the transition at 155°C in $BiBr_3$ (apparently as yet uninvestigated) provides some grounds for optimism that transitions may yet be found and may prove to be of the averaging type, and so does the existence of polymorphism in trihalides such as $CrCl_3$ (low-$CrCl_3$, hcp BiI_3-type structure; high-$CrCl_3$, ccp YCl_3-type structure) and the variety of mutually related structure types found among the trihalides of Group III and 4*f* elements.

Structure determinations

The positional and thermal parameters for the structures described in the following and the corresponding interatomic distances and bond angles are listed in Tables 10–19.[27] The distances and angles in alkylsulfonium and alkylsulfoxonium salts are compared in Table 20 and discussed at the end of this section.

Me_3SOI

This *Pnma* structure consists of I^- anions and of Me_3S^+ cations practically of C_{3v} skeletal symmetry. The cation/anion packing is of a distorted CsCl type, as may be clearly seen from a projection of the structure on (100). The S—O bond is situated in a mirror plane and is collinear with the I atom at 4.87 Å from the oxygen (Table 11, Fig. 2). The O···I separations are all well in excess of the sum of the van der Waals radii, 3.55 Å.

Et_3SI

The unit-cell dimensions were reported by Mussgnug (8) (cf. Table 1), who also narrowed the choice of space group to *Pnma* or $Pn2_1a$, the latter group being considered the correct one because of the detection of a weak piezoelectric effect. In the present investigation the structure was refined in both space groups (in the $Pna2_1$ and *Pnam* settings).

In the $Pna2_1$ refinement, with z(I) fixed at $\frac{1}{4}$, the z coordinates of the S and C(32) atoms were found to be very close to $\frac{1}{4}$ (Table 14), but those of all the other atoms differed appreciably from $\frac{1}{4}$. The structure could be refined as completely ordered, without constraints on the bond lengths, to R = 2.05%.

In the *Pnma* refinement from the same data set (d/p = 6.2, R = 1.96%, R_w = 2.25%) z(I) and z(S) were taken as $\frac{1}{4}$ but the rest of the cation was treated as being in two-fold positional disorder with respect to the mirror plane, with no constraints

[26]The curves in Fig. 8 are quadratic regression lines: r^2 = 0.96, σ = 0.020 for c.n. 6, r^2 = 0.93, σ = 0.024 for c.n. $\geq$ 6. Inclusion of the additional X atoms in the coordination figure in $\bar{d}$ does not change the trend significantly. The only solid Group V trifluoride for which structural information appears to be available, SbF_3 (138), does not belong to the set treated in the regression.

[27]The parameters of the H atoms in Et_3SI and 3ESHS, respectively, are listed in Tables A and B (see footnote 28). The parameters for special positions ($\frac{1}{4}$, $\frac{1}{2}$) in Tables 10, 12, 14, 16 and 18 have not been multiplied by a power of ten.

applied. When S was allowed to refine freely, the resulting z(S) was 0.2497(3), with negligible differences in the other parameter values. Although a few of the refined parameter values differed by more than 3 esd's from those obtained in the $Pna2_1$ refinement, the structures resulting from the two refinements were scarcely distinguishable (Tables 12 and 13). No correlation coefficients larger than 0.5 were present in either refinement. We have adopted the noncentrosymmetric structure as correct solely on the strength of Mussgnug's report of the piezoelectric effect.

The Et_3SI structure consists of I^- anions and trigonal-pyramidal Et_3S^+ cations of skeletal symmetry approaching C_{3v}. The I^- ions are on a distorted fcc lattice. The cation has a fully extended, *anti–anti* configuration similar to that of the Et_3NH^+ ion in Et_3NHI (59) and related to that of the cation in $(CH_2)_5SMe^+I^-$ (67) (Fig. 2). The two shortest S···I distances, 3.96 and 4.61 Å (Table 13), are comparable to those in Me_3SI (48), 3.95 and 4.42 Å. The I atom at 4.61 Å is close to the axis of the cation on the Me_3 side, and both S···I vectors and the cation axis are in the $y = \frac{1}{4}$ plane. The orientation of the cation axis in this plane is shown in Fig. 2.[29]

On heating the iodide undergoes a transition at ~325 K. This transition probably involves a cation disordering across the pseudo-mirror of the $Pna2_1$ structure, and the *Pnam* of our centrosymmetric refinement may well be an appropriate description of the high-phase structure. While the $\exp(\Delta S_{tr}/R) \sim 6.3$ estimate from the dsc experiments is too large for a simple two-fold orientational disorder, the latter may be at least a partial feature of the transition. The reversal of the transition on cooling is remarkably sluggish (see Experimental).

[28]These tables can be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

[29]Mussgnug (153) noted a similarity in the unit-cell dimensions of Et_3SI and Et_3NHI (cf. ref. 11) when the latter is referred to an orthohexagonal setting, $a_{ohex} = a_{hex}\sqrt{3}$. However, this similarity is accidental. The cation axis on the LP side of Et_3S^+ avoids the two nearest coplanar I^- neighbours, unlike the N—H bond in Et_3NHI (59), which points directly at the nearest I^- ion and forms a N—H···I bond coincident with a crystallographic C_3 axis (Fig. 2).

$(Me_3S)_2SnCl_6$ (3MSHS)

The space group $Pa3$ suggested by Wyckoff (9) is confirmed as well as the proposed distribution of the S, Cl, and C atoms (Table 14). The equivalence of the Cl atoms is consistent with the observation of a single line in the ^{35}Cl nqr spectrum of 3MSHS (and the corresponding Pt, Se, and Te compounds) (10).

The ion packing is of the *anti*-fluorite type (Fig. 1). Each cation, of C_3 symmetry, is inside a subcube (of $\frac{1}{2}a$ edge length) the alternate corners of which are occupied by the anions. The centroid of the cation lies on a body diagonal of the subcube 0.41 Å from the centre of the subcube and 0.84 Å from the S atom. The LP end of the cation axis points at an unoccupied corner of the subcube. Each such corner (site symmetry C_{3i}) is associated with a pair of S atoms with their LPs facing each other across the centre of symmetry, S···S = 9.87 Å (Table 15).

The $SnCl_6$ octahedra, of symmetry C_{3i}, are metrically almost regular. The shortest S···Cl distance, 3.50 Å, is somewhat smaller than the sum of the van der Waals radii, 3.65 Å. Four of the H···Cl distances also are shorter than the sum of the radii, 3.0 Å (Table 15). The C(1)—H(1) bond is not far from collinear both with the Sn atom at $(0, \frac{1}{2}, 0)$ (~164°) and the centroid of the Cl—Cl(K)—Cl(L) anion face into which the bond is directed (~161°). The other two C—H bonds are oriented approximately tangentially at the nearest Cl corners of the neighbouring $SnCl_6$ octahedra.

The ion packing in 3MSHS can be characterized, and contrasted with that in 3MHS (60), if both $Pa3$ crystals are regarded as consisting of $SnCl_6^{2-}$ anions and $[Me_3S\cdots SMe_3]^{2+}$ or $[Me_3NH\cdots HNMe_3]^{2+}$ cation pairs. The Y atoms in each pair face each other across a centre of symmetry, at S···S = 9.87 Å and N···N = 8.60 Å ($H_N\cdots H_N \sim 6.6$ Å). With the centres of symmetry of the cation pairs located in equipoint 4(*a*) — 0, 0, 0 etc. of $Pa3$, the Sn atoms can be placed in 4(*b*) or in 4(*a*). In 3MSHS they are in 4(*b*) — 0, 0, ½ etc. and the ion packing is of the NaCl type, but in 3MHS they are in 4(*a*), i.e. at the centres of symmetry of the $[Me_3NH\cdots HNMe_3]^{2+}$ pairs, which results in a "molecular" fcc crystal consisting of hydrogen-bonded $[Me_3NH\cdots Cl_3SnCl_3\cdots HNMe_3]^0$ units. The 3MSHS structure

[a] U_{iso}.

itself may be classified as belonging to the *anti-C*2 (*anti*-pyrite) type: in FeS_2, Fe is in 4(*b*) and S in 8(*c*) — *xxx* etc., $x = 0.144$.[30] It is also related to the 3ESHS structure (see below).

$(Me_3SO)_2SnCl_6$ (3MSOHS)

The 3MSOHS structure is of an orthorhombically distorted *anti*-fluorite type and shows considerable resemblance to $(Me_2NH_2)_2SnCl_6$ (60): in the former the S—O bond is situated in the mirror plane, in the latter the mirror plane bisects the HNH angle. The structure and its relation to the other *anti*-fluorite structures of interest here are shown in Fig. 1. The $SnCl_6$ octahedron (C_{2h}) is metrically almost regular, $\Delta = 1.4$ (Tables 16 and 17).

$(Et_3S)_2SnCl_6$ (3ESHS)

Figure 9 provides an instructive comparison of the structures of 3ESHS and 3EHS (61). In the latter the ion packing is of a monoclinically distorted *anti*-fluorite type. The N—H bonds form nearly symmetrically bifurcated N—H···2Cl bonds. Each $SnCl_6^{2-}$ ion has associated with it two cations in such a way that the N—H···Sn···H—N groupings are collinear, with the Sn at a centre of symmetry. The centres of these cation pairs thus coincide with the centres at Sn, and if the structure is viewed as consisting of $[Et_3NH\cdots Cl_3SnCl_3\cdots HNEt_3]^0$ "molecules", the packing is of a distorted fcc type. By contrast, in 3ESHS the centres of cation pairs (at S···S = 4.32 Å) and the Sn atoms form a distorted lattice of the NaCl type, i.e. the structure may be regarded as consisting of $[Me_3S\cdots SMe_3]^{2+}$ and $SnCl_6^{2-}$ ions, with the cation and anion centres on separate fc lattices. In this sense the packing in 3EHS is associative (through hydrogen bonding), whereas in 3ESHS it is non-associative (cf. 3MSHS above).

[30] A distorted structure of this type occurs in β-HgO, *Pbca* ⊂ *Pa*3, Hg in 4(*b*), $x(0) = 0.075$, $y(0) = 0.062$, $z(0) = 0.095$ (11).

TABLE 11. Me_3SOI: interatomic distances (Å) and bond angles (deg)

Atoms		Atoms	Angle
S—O	1.426(5)	O—S—C(1)	112.1(3)
S—C(1)	1.735(7)	O—S—C(2)	112.9(3)
S—C(2)	1.748(7)	C(1)—S—C(2)	106.1(3)
C(1)···C(2)	2.784(9)	C(2)—S—C(2C)	106.2(3)
C(2)···C(2C)	2.796(9)	S—O—I	180.0
O···I	4.872(5)	Symmetry code:	
O···I(A)	4.387(5)	A $\frac{1}{2}+x$ $\frac{1}{4}$ $\frac{1}{2}-z$	
O···I(B)	4.734(5)	B $-x$ $\frac{3}{4}$ $1-z$	
S···I(F)	4.375(1)	C x $\frac{1}{2}-y$ z	
S···I(D)	4.593(1)	D $\frac{1}{2}-x$ $\frac{3}{4}$ $\frac{1}{2}+z$	
S···I(E)	4.599(1)	E x $\frac{1}{4}$ $1+z$	
S···I(A)	4.976(1)	F $\frac{1}{2}+x$ $\frac{1}{4}$ $\frac{3}{2}-z$	

The LP axes in the cation pairs are not collinear, which is to be attributed to packing geometry rather than to a tendency of the LPs to avoid each other. The shortest S—Cl distance, 3.57 Å (Table 19), is only slightly smaller than the sum of the van der Waals radii, 3.65 Å.

The $SnCl_6$ octahedron, of C_i symmetry, is only slightly distorted, $\Delta = 2.0$. Its thermal parameters are consistent with rigid-body motion: $R(U_{ij}) = 1.5\%$, $\text{rms}(U_{ij}) = 0.0006$.

Cation geometry

Inspection of the available data (Table 20) shows that although the ranges of the uncorrected S—C bond lengths and CSC angles are quite narrow, the S—C bonds in the sulfoxonium ions tend to be shorter and the CSC angles larger than in the sulfonium ions. The mean values are 1.80(3) Å and 102.2(14)° for the sulfonium and 1.75(1) Å and 106.1(3)° for the sulfoxonium ions. The hypothesis that the means come from the same population can be rejected, both from analysis of variance and from *t* statistics, at the 99% significance level for the bond lengths and at the 99.5% level for the angles. The S—O bond lengths average about 1.43 Å.

The observed geometry of the Me_3S^+ ion is in close agreement with the result of a 6-31G* optimization, in which the initial unconstrained configuration of C_3 symmetry ended up as a configuration of C_{3v} symmetry (Table 7). The larger CSC angle in the sulfoxonium ion is consistent with the predictions from the VSEPR theory. Indeed, as shown in Table 4, conversion of a trigonal-pyramidal YEL_3^{ϵ} species to a tetrahedral (T_d or C_{3v}) $YL'L_3^{\epsilon}$ species generally results in an opening up of the LYL angle. The increase may be quite substantial, over 10° in some instances, and is associated with a shortening of the Y—L bond. The change is particularly dramatic when it involves a change in the ionic charge, e.g. for $PF_3 \rightarrow PF_4^+$.

The shortest S···Hal distances are too few to permit generalization, but it seems that in most cases they are somewhat smaller than the respective sums of the van der Waals radii, 3.65 Å for S···Cl and 4.00 Å for S···I. This apparent shortening may be the consequence of a Coulombic interaction between the net positive charge on the S atom and the anionic charge on X^-.

Structure type and ion packing

The space groups of trialkyl onium salts represented in Table 21 are often those which in molecular crystals consisting of neutral $YL'L_3$ (L' = *E*, O, H) units of C_{3v} subgroup symmetry would generate a closest packing ($C_1 \subset C_{3v}$) or a packing of maximum density ($C_s \subset C_{3v}$): molecular symmetry $C_1 \rightarrow P\bar{1}$, $P2_1$, $P2_1/c$, $Pca2_1$, $Pna2_1$, $P2_12_12_1$ (also $Pnnm \subset P2_1/n$); molecular symmetry $C_s \rightarrow Pmc2_1$, $Cmc2_1$, *Pnma* (cf. ref. 57). In some cases where the trigonal symmetry has not been lost, the observed space group is a supergroup of one of

[b]$\times 10^3$.

the above nine: $P6_3mc \supset Cmc2_1$ (3EHS), $Pa3 \supset (P2_12_12_1, P2_1/c)$ (3MSHS, 3MHS); this is presumably associated with some loss of economy of packing.

The fact that the above space-group symmetries do occur in onium salts is somewhat unexpected, as the requirements for high packing density are not the same when *two* dissimilar constituents are present. The rationale for the similarity of packing behaviour, at least with the hydrogen-bonded species, may be that a cation–anion or $(cation)_2$–anion pair may function and pack as a single building unit of symmetry C_1 or C_s, e.g. $Et_3NH^+\cdots X^-$ of symmetry $C_{3v} \supset C_s$.

TABLE 15. $(Me_3S)_2SnCl_6$: interatomic distances (Å) and bond angles (deg)

		H $\frac{1}{2}-x$ $\frac{1}{2}+y$ z	
		J $\frac{1}{2}-x$ $1-y$ $\frac{1}{2}+z$	
		K $\frac{1}{2}-x$ $\frac{1}{2}+y$ z	
		L $\frac{1}{2}+z$ x $\frac{1}{2}-y$	

The 3MSHS, 3ESHS, 3MHS (60), and 3EHS (61) structures may be thought of as deriving from the *anti*-pyrite $Pa3$ aristotype. Assuming that the symmetry centres of the cation pairs occupy the $4(a)$ — 0, 0, 0 etc. equipoint and the Y atoms are in $8(c)$ — xxx etc. with $x < \frac{1}{4}$, the type of packing will be determined by the choice of equipoint adopted by the Sn atom. In the sulfonium salts the Sn atoms occupy the $4(b)$ — $\frac{1}{2}$, 0, 0 etc. positions, giving rise to a NaCl-type packing. In the ammonium salts Sn is in $4(a)$, which results in a fcc packing of internally hydrogen-bonded [cation···anion···cation]^0 units.

The *orientation* of the cation···cation pair axes in 3ESHS (Fig. 10) can be related to those in 3MSHS and 3ESHS through dichromatic subgroups of the common group *Cmca*:

$$Pa3 \supset Pbca \xleftarrow{P_Cbca} Cmca \xrightarrow{Cm'ca'} C2/c$$

3MSHS β-HgO_2 3ESHS
3MHS
FeS_2
CO_2

A similar relationship holds for 3EHS.

Experimental

Preparation

Crystals of Me_3SOI and Et_3SI suitable for single-crystal X-ray studies were obtained by recrystallizing commercial material from water and from ethanol, respectively. The hexachlorostannates were prepared by allowing an aqueous solution of the respective chloride and H_2SnCl_6 to crystallize by slow evaporation. For this purpose commercial Me_3SI and Et_3SI were converted to the chlorides by ion exchange on a resin column.

Evidence of transition in Et_3SI

Heating a ~0.1 g sample of the recrystallized material (m.p. 146–149°C) in a sealed pan of a differential scanning calorimeter (indium standard) revealed an endothermic peak at ~325 K, with an estimated thermal effect of 4.9 kJ/mol (average of three separate

runs with virgin material). The sample was allowed to cool to room temperature in the calorimeter and the heating was repeated, but the endothermic peak did not reappear. In subsequent runs using new samples the transformed material was cooled to room temperature and allowed to stand (*a*) for 15 min before reheating; (*b*) overnight; (*c*) in liquid N_2 for 5 min followed by 10 min at 310 K; (*d*) in liquid N_2 for 5½ h; (*e*) in liquid N_2 overnight; (*f*) in liquid N_2 for 2 days; (*g*) at 310 K for 3 h. Reheating the *a* and *b* samples produced no recovery of the endothermic peak. For *c* the recovery was partial but small; for *d* to *g* it was larger but still not complete.

Structure determinations

The crystals were mounted on glass fibres or (3MSHS) sealed in glass capillaries (crystal dimensions, mm: Me_3SOI, 0.3 × 0.3 × 0.4; 3MSHS, 0.5 × 0.5 × 0.5; 3MSOHS, 0.1 × 0.2 × 0.4; 3ESHS, 0.3 × 0.3 × 0.6). A CAD-4 four-circle diffractometer (ω:2θ scans; 20°C) was used in the data acquisition (cf. Table 1). Lorentz, polarization, and empirical absorptions corrections (7) were applied. Scattering factors for neutral or ionized atoms and corrections for anomalous scattering were taken from ref. 154. The structures were solved as indicated below. Except where otherwise stated all calculations were performed with the SHELX-76 (155) system. After the nonhydrogen atoms had been located, full-matrix least-squares ($w\Delta|F|$ = mini-

[b]Sulfur atom in twofold disorder across the CCC plane.
[c]1-Me-1-thioniacyclohexane iodide; $S—C_{Me}$ = 1.80(2) Å.
[d]1-Me-5-thia-1-thioniacyclooctane iodide; $S—C_{Me}$ = 1.791(5) Å.

mum) refinement was carried out with isotropic temperature factors until R was reduced to a reasonably low value. The H atoms were then placed, consistent with the difference maps, and the refinement was continued with anisotropic temperature factors on the nonhydrogen atoms and isotropic factors on hydrogens. The final difference maps were featureless except as noted below. The anisotropic temperature factor is defined as $T = \exp[-2\pi^2(U_{11}h^2a^{*2} + U_{22}k^2b^{*2} + U_{33}l^2c^{*2} + 2U_{23}klb^*c^* + 2U_{13}hla^*c^* + 2U_{12}hka^*b^*)]$. The structure factors are listed in Tables C–G.[28]

Me_3SOI. Systematic absences: $hk0$, h odd; $0kl$, $k + l$ odd. Space group *Pnma* or $Pn2_1a$. There were slight changes in the crystal during data collection as witnessed by a ~20% increase in the intensity of the standard reflections over the collection period. All nonhydrogen atoms were located using the Patterson solution routine of SHELXS-86 (156). Hydrogen atoms were placed geometrically and constrained to ride on their carbon atoms. The weighting scheme was $w = 2.93/[\sigma^2(F) + 0.01366F^2]$. Seven reflections were omitted from the final refinement because of suspected extinction. The highest residual peak in the final difference map was 1.66 e/Å^3 near the I atom and the deepest trough was −2.57 e/Å^3. Satisfactory solution of the structure in *Pnma* without any indication of the presence of disorder confirmed the centrosymmetric group as the correct choice.

Et_3SI. Systematic absences: $h0l$, h odd; $0kl$, $k + l$ odd. Space group *Pnma* or $Pna2_1$. The 200 reflection contained extra intensity and was omitted from refinement. Complete refinement was carried out in both space groups; the results are compared in Table 12 (E statistics suggest centric). The I atom was located from a Patterson map and the remaining atoms from a difference map. In the $Pna2_1$ refinement z(I) was fixed at $\frac{1}{4}$. Hydrogen atoms were placed geometrically and allowed to refine. The weighting scheme (*Pnma*) was $w = 0.2344/[\sigma^2(F) + 0.005F^2]$. The highest residual peak in the final difference map was 0.4 e/Å^3.

3MSHS. Systematic absences: $hk0$, h odd; $0kl$, k odd; h, k, l not permutable. A Patterson map revealed the Sn and Cl positions. The remaining atoms were located from difference maps. The H atoms were located from a difference map and refined with the C—H distance loosely constrained; the refined positions were close to the original

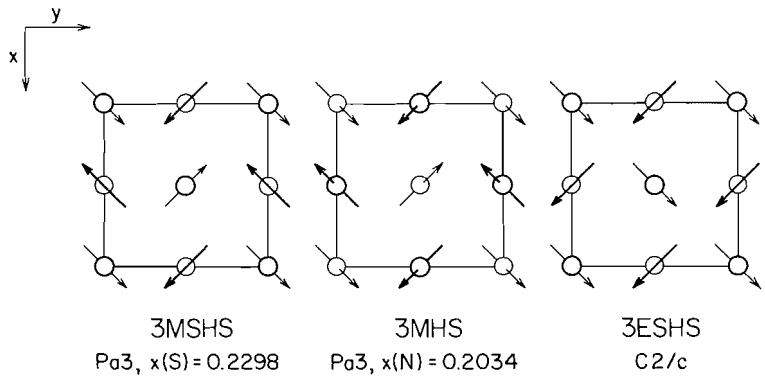

FIG. 10. Schematic representation of the relationship between the $(R_3YL')_2SnCl_6$ structures (see text). The arrow indicates the orientation of the cation–cation axis with respect to z. Light circles, Sn at $z = 0$; heavy circles, Sn at $z = \frac{1}{2}$. Light arrows, cation pair centre at $z = 0$; heavy arrows, cation pair centre at $z = \frac{1}{2}$.

positions in the difference map. A small residual peak of 0.4 e/Å^3 at (0, 0, 0) in the final difference map was initially attributed to partial occupancy of that site by H_2O, but FT-ir spectra showed no evidence of H_2O absorptions. The weighting scheme was $w = 2.235/[\sigma^2(F) + 0.000277F^2]$. Three reflections were omitted from the final refinement because of suspected extinction.

3MSOHS. Systematic absences: $h0l$, $h + l$ odd; $0kl$, $k + l$ odd. Space group *Pnnm* or *Pnn*2. Satisfactory solution of the structure in *Pnnm* without the need to invoke disorder indicated that the centrosymmetric group described the structure correctly. A Patterson map revealed the Sn position. The remaining atoms were located from difference maps. The hydrogens were located but in the refinement were placed geometrically and then allowed to refine freely. The weighting scheme was $w = 0.3211/[\sigma^2(F) + 0.005F^2]$. The highest peak in the final difference map was 0.6 e/Å^3.

3ESHS. Systematic absences: $h0l$, l odd; hkl, $h + k$ odd. Four reflections were omitted because of extinction. Structure solved by direct methods (MULTAN 80) which revealed the Sn and some Cl atoms. All remaining atoms were found from subsequent difference maps. All H atoms appeared in the difference maps and were allowed to refine. The highest peak in the final difference map was 0.4 e/Å^3. The weighting scheme was $w = [\sigma^2(F) + 0.005F^2]^{-1}$.

Ab initio *calculations*

Details of the 6-31G* optimizations and associated procedures will be found in refs. 54–56. For practical reasons the equilibrium molecular geometry of the $SeCl_6^{2-}$ in O_h and C_{3v} symmetries was optimized at a somewhat lower level, STO-3G*.

Acknowledgments

This work was supported by grants from the Natural Sciences and Engineering Research Council of Canada to O.K., T.S.C., and R.J.B. We thank Miss K. N. Robertson for most of the preparative work and Dr. M. A. White and Miss Allyson Perrott for the dsc results. We are also pleased to acknowledge the assistance provided by Randy Barkhouse, Aidan Evans, and the staff of the Dalhousie University Computing and Information Service.

Mechanistic aspects of the reaction of hydrogen sulfide with dinuclear palladium(I) complexes containing bis(diphenylphosphino)methane and related ligands

A. FREDDY BARNABAS, DOMINIQUE SALLIN, and BRIAN R. JAMES
Department of Chemistry, University of British Columbia, Vancouver, B.C., Canada V6T 1Y6

Received March 1, 1989

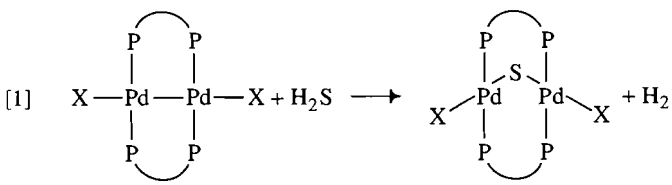
This paper is dedicated to Professor Ronald J. Gillepsie on the occasion of his 65th birthday

A. FREDDY BARNABAS, DOMINIQUE SALLIN, and BRIAN R. JAMES. Can. J. Chem. **67**, 2009 (1989).

Kinetic and low temperature nmr data are presented for the reaction of hydrogen sulfide with $Pd_2X_2(\mu\text{-dpm})_2$ species in dichloromethane solution (X = halide, dpm = bis(diphenylphosphino)methane. The reactions form the corresponding bridged-sulfide, A-frame complex via oxidative-addition of H_2S across the Pd—Pd bond to give a hydrido(mercapto) intermediate, that subsequently liberates H_2 to give $Pd_2X_2(\mu\text{-S})$ $(\mu\text{-dpm})_2$ species. Quantitative kinetic data showing first order behaviour in both Pd_2 dimer and H_2S concentrations are given for the bromide system over the temperature range 0–35°C, as well as more limited data for the photosensitive iodide system; plausible mechanisms are discussed. Some qualitative findings are presented for related systems containing 1,1-bis(diphenylphosphino)ethane.

Key words: palladium complexes, hydrogen sulfide, bis(diphenylphosphino)methane.

A. FREDDY BARNABAS, DOMINIQUE SALLIN et BRIAN R. JAMES. Can. J. Chem. **67**, 2009 (1989).



On présente des données relatives à la cinétique ainsi qu'à la rmn à basse température pour la réaction du sulfure d'hydrogène avec les espèces $Pd_2X_2(\mu\text{-dpm})_2$ (dans lesquelles X = halogénure et dpm = bis(diphénylphosphino)méthane), en solution dans le dichlorométhane. Par le biais d'une addition oxydative du H_2S à travers la liaison Pd—Pd, les réactions forment le complexe correspondant, de structure en A et comportant un pont sulfure, qui conduit à un intermédiaire hydrido(mercapto) et qui libère par la suite du H_2 pour fournir des espèces $Pd_2X_2(\mu\text{-S})$ $(\mu\text{-dpm})_2$. Des données cinétiques quantitatives démontrent que, pour le système du bromure à des températures allant de 0 à 30°C et pour des données plus limitées relatives au système photosensibilisé de l'iodure, les réactions sont du premier ordre relativement aux concentrations tant du dimère Pd_2 que du H_2S; on discute de divers mécanismes plausibles. On présente quelques données qualitatives concernant des systèmes apparentés contenant du 1,1-bis(diphénylphosphino)éthane.

Mots clés : complexes de palladium, sulfure d'hydrogène, bis(diphénylphosphino)méthane.

[Traduit par la revue]

Introduction

Work from this laboratory has reported on reaction [1], which involves (at least for the chloride and bromide systems) quantitative reduction of H_2S to H_2 and S^{2-} (1, 2):

[1] $X—Pd(P,P)—Pd—X + H_2S \rightarrow Pd_2X_2(\mu\text{-S})(\mu\text{-dpm})_2 + H_2$

1 **2**

a, X = Cl; *b*, X = Br; *c*, X = I; P P = $Ph_2PCH_2PPh_2$(dpm)

Corresponding reactions occur with H_2Se (3) and H_2Te (4), and possibly H_2O (3, 4). Oxidative-addition of H_2S to transition metal centres to give hydrido(mercapto) species is well-established (2), but reaction [1] was the first reported (1) to show generation of H_2 from H_2S; two other such systems were reported very soon after in completely independent studies, one based on zirconocene species (5) and one base on a rhodium-(triphos) species, triphos = $MeC(CH_2PPh_2)_3$ (6). Related reactivities of the zirconocene species (and titanium and hafnium analogues) toward H_2Se (7) and H_2O (8) have also been reported.

Outside of Kuehn and Taube's work on replacement of the aquo ligand of $Ru(NH_3)_5(H_2O)^{2+}$ by H_2S (9), we are unaware of any solution kinetic studies on the interaction of H_2S with transition metal centres. Reaction [1] is important in terms of possible H_2-recovery from feedstock gases (10), and thus kinetic and mechanistic information on the process is critical for any potential application, as well as for initiating a data base of kinetics for oxidative-addition type reactions of H_2S. This paper reports quantitative kinetic data for reaction [1] with X = Br, some semi-quantitative data for the iodide system, and qualitative observations on the chloride system and related systems using 1,1-bis(diphenylphosphino) ethane (dpmMe).

One suspects that kinetic studies on H_2S systems have been curtailed because of the imposed, obnoxious smell which we can verify to be more difficult to contain in kinetic versus synthetic work. Nevertheless, in contrast to the enforced and sometimes unpleasant working atmosphere, the kinetic data on the bromide systems turned out to be remarkably clean, and an account of this H_2S work dedicated to Ronald Gillespie seems particularly appropriate for an individual who has made seminal contributions to group 6 (now group 16) chemistry.

Experimental section

The materials used, synthetic procedures for the ligands and complexes, and instrumentation used for ^{31}P and ^1H nmr spectra and UV / vis spectra, have been largely described previously (2). D_2S was prepared by the action of 10 mL DCl / D_2O solution (Stohler Isotope Chemicals) on 2 g CaS; the resulting gas was bubbled through D_2O to remove any sulfur oxide impurities and HCl, and then dried over $CaCl_2$. The D_2S (4 mL at 1 atm) was added via a syringe to a CH_2Cl_2 solution of **1***a* (25 mg) in a 10 mL Schlenk tube under vacuum at room temperature (RT); the originally orange solution precipitated the μ-S product **2***a* completely after 30 min. The isolated **2***a*, redissolved in CD_2Cl_2, gave a ^1H nmr spectrum (2) showing a CH_2:phenyl integration ratio of 1:10 and thus no incorporation of deuterium at the methylene groups; consistent with this finding, analysis of the gas phase by low range mass spectroscopy, following removal of D_2S and CH_2Cl_2 at liquid-N_2 temperature, revealed only D_2.

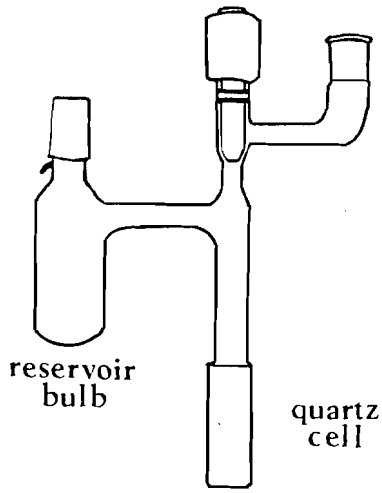

FIG. 1. Spectral cell used for anaerobic UV–visible spectroscopy; the cone on the reservoir bulb can be fitted with a stopper or a septum.

Kinetic measurements

The kinetics of reaction [1] in CH_2Cl_2 (for X = Br, I) were monitored spectrophotometrically in a thermostated Perkin-Elmer 552A instrument using anaerobic cells of the design shown in Fig. 1; cells of path lengths of 1.0 or 0.1 cm were attached by a side-arm to a reservoir bulb, and fitted with a Teflon stopcock and an O-ring joint for attachment to a vacuum/gas-handling line. For an experiment at 1 atm total pressure, a weighed amount of **1** was placed in the quartz cell and the system then evacuated and filled with H_2S gas, while a saturated solution of H_2S in CH_2Cl_2 (10 mL) was pipetted into the reservoir and thermostated at the required temperature (0–35°C); the solid and solvent were then mixed to give a homogeneous solution prior to monitoring optical density changes at some appropriate, fixed wavelength in a thermostated cell-compartment. The cell was agitated periodically to avoid any diffusion problems (e.g. from the H_2 produced). For reactions at lower partial pressures of H_2S ($p' < 1$ atm), complex was placed in the cell, and pure solvent in the reservoir was degassed by employing the freeze–thaw vacuum technique; H_2S was finally added as gas or in solution via a gas-tight syringe, after the ingredients had been mixed and thermostated. The concentrations of **1** ranged from $(0.84–22.3) \times 10^{-4}$ M, and that of H_2S from 0.07–0.53 *M* (see below); thus pseudo-first order conditions were maintained for reaction [1] and standard log (absorbance difference) vs. time plots gave excellent linearity for at least 2.5–3 half-lines, from which the pseudo-first order rate constants, k_{obs}, were readily evaluated.

H_2S solubility measurements

The H_2S solubility in CH_2Cl_2 at specific pressures at 25°C was determined using ^1H nmr spectroscopy. A known volume of CD_2Cl_2 containing either benzene (3 μL) or acetonitrile (5 μL) was degassed in an nmr tube of known volume sealed with a septum; an appropriate volume of H_2S gas was injected into the tube, which was then thoroughly shaken and the solution equilibrated at 25°C. The ^1H nmr spectrum was then run at 25°C, and from the integration intensity of the H_2S peak (δ 0.9 ppm) relative to those of benzene or acetonitrile, the H_2S solubility was determined, and the corresponding partial pressure readily calculated. The H_2S solubility was also similarly measured directly at several temperatures between 0–35°C for a solution initially saturated with H_2S at room temperature and at 1 atm.

Low temperature nmr studies

The ^1H and $^{31}P\{^1H\}$ nmr spectra of the bromide **1***b* (5 mg) in CD_2Cl_2 (0.6 mL) were run at −78°C (solid CO_2/ethanol slush bath). The yellow–orange sample was removed from the probe, and H_2S (5 mL, 1 atm) was injected into the cold, septum-sealed nmr tube via a gas-tight syringe; the H_2S (bp −65°C) condensed inside the tube, and the interface at the CD_2Cl_2 and H_2S liquid layers turned green. The nmr tube was then shaken, replaced into the −78°C probe, and the spectra

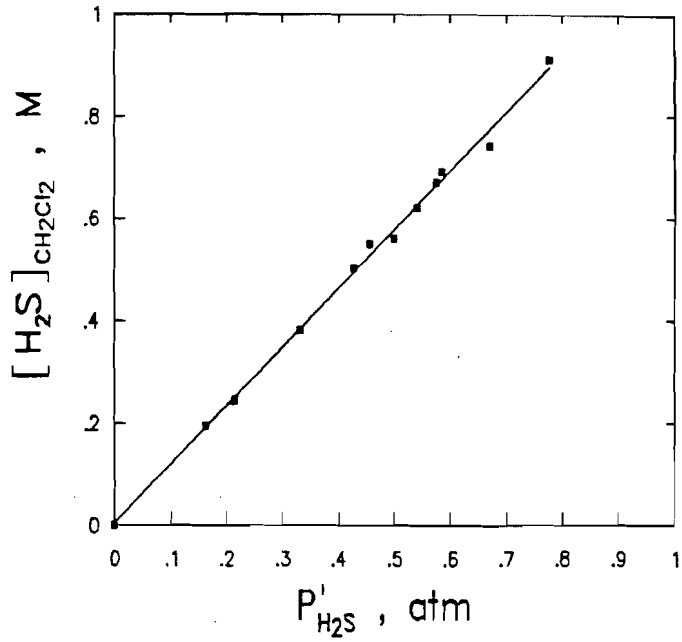

FIG. 2. Solubility of H_2S in CH_2Cl_2 at 25°C at various partial pressures; the partial pressure of CH_2Cl_2 = 0.54 atm (13).

rerun; the spectra were also taken at higher temperatures when the green intermediate disappeared. For the iodide system, **1***c*, H_2S (50 mL, 1 atm, 25°C) was administered into a Schlenk tube, containing 20 mg **1***c* dissolved in 2.5 mL degassed CD_2Cl_2; the tube was cooled to −78°C, and the initially brownish-red solution left until it turned green (10–20 h). A sample was then cannulated into an nmr tube and spectra run at different temperatures from −78 to 20°C. As discussed later, the green colour pertains to a hydrido(mercapto) intermediate; such a species was not seen in the chloride system where only **1***a* and the μ-S product **2***a* were ever detected by nmr.

Results

The rates of reaction [1] at room temperature were noticed qualitatively during synthetic procedures to be dependent on the halide X (1) and on the H_2S concentration used. The reactivity trend at 1 atm total pressure in CH_2Cl_2 (i.e. at ~0.5 atm H_2S) was Cl > Br > I, and, of these, the bromide system was chosen for detailed study because of the convenient reaction half-times for a classical spectrophotometric study at such H_2S partial pressures. Limited, semi-quantitative kinetic data only were obtained at similar conditions for the iodide system, which revealed complexities because of photosensitivity (see below). The chloride system reacts too rapidly at corresponding conditions (even for stopped-flow studies) and requires study under very different conditions, particularly at much reduced H_2S concentrations and pressures, work that is currently in progress.

It was first essential to show in reaction [1] that the evolved H_2 did originate exclusively from the H_2S. The methylene protons of dpm do have acidic character (2, 11) and involvement of the —CH_2— groups seemed at least a possibility; however, this is ruled out in that reaction of **1***a* with D_2S generates D_2 with no accompanying HD or H_2, and the **2***a* product contains only protonated dpm. In related work (12), the synthesis of $Pd_2Cl_2(\mu\text{-}PPh_2CD_2PPh_2)_2$ and its exchange with proton-containing solvents have been studied; reaction of this complex with H_2S correspondingly gives only H_2 and the —CD_2— μ-sulfide product, again showing non-involvement of the methylene protons in the H_2S reactions.

TABLE 1. Temperature dependence for the bimolecular rate constant k of the reaction of **1***b* with H_2S in CH_2Cl_2

Temp, K	$[H_2S]^a$	$k \times 10^4, M^{-1}\ s^{-1}$
273	0.50	1.59
279	0.51	3.61
288	0.525	6.53
298	0.525	17.1
298	0.525[b]	7.09
303	0.54	20.1
308	0.55	25.5

[a]The H_2S solubility was measured directly by ^1H nmr (see Experimental section); the corresponding partial pressures were not estimated.
[b]D_2S used; solubility assumed to be the same as for H_2S.

Quantitative evaluation of the kinetic data for reaction [1] depends on knowledge of the H_2S solubility in CH_2Cl_2. This was readily estimated by ^1H nmr measurements, and Henry's Law was obeyed at partial pressures (p') of H_2S at least up to 0.8 atm, the solubility being determined as 1.14 M atm^{-1} at 25°C (Fig. 2); at this temperature, $p'(CH_2Cl_2) = 0.54$ atm (13), and thus at a total pressure of 1 atm, H_2S is soluble to the extent of 0.53 M. The directly measured $[H_2S]$ values in the kinetic runs at 0–35°C are given later with some rate constant data (Table 1). We have been unable to find literature data for H_2S solubility in CH_2Cl_2; a value in $CHCl_3$ at 20°C, determined by a classical volumetric procedure (14), is 1.3 M atm^{-1}.

Kinetic data

Reaction [1] is readily monitored by solution electronic spectroscopy; species such as **1** are reddish-orange with two to three absorption maxima in the 340–590 nm region (2, 15, 16), while the μ-S products (**2**) are brown and have absorption maxima in the 325–350 and 470–485 nm regions (2, 17). Figure 3 shows spectral changes on treating a CH_2Cl_2 solution of the bromide **1***b* with H_2S at 25°C; rates for the bromide system were followed by observing the decreasing absorption at 428 nm as a function of time, and the observed isosbestic point showed a well-behaved system. The pseudo-first order rate constants, k_{obs}, obtained from the excellently linear semi-log plots (Fig. 3, inset), were strictly first order in $[H_2S]$ (Fig. 4) and were independent of the [**1***b*] from (0.84–22.3) × 10^{-4} M. Thus the rate law takes the simple form

$$[2]\quad \text{Rate} = -\frac{d}{dt}[\mathbf{1}b] = k_{obs}[\mathbf{1}b] = k[H_2S][\mathbf{1}b]$$

where k is the bimolecular rate constant for the reaction. The temperature dependence data for k were obtained at a single, directly determined $[H_2S]$, and with [**1***b*] = 1.0 × 10^{-3} M (Table 1); an Eyring plot gives a reasonably linear straight line and the activation parameters $\Delta H^{\ddagger} = 55 \pm 5$ kJ mol^{-1} and $\Delta S^{\ddagger} = -115 \pm 10$ J K^{-1} mol^{-1}.

Corresponding studies on the slower iodide system were attempted by monitoring visible absorption spectral changes around 450 nm, a region where such changes are maximal during the formation of **2***c* from **1***c*; however, it soon became obvious that the iodide system was photosensitive. An initial isosbestic point was soon lost, and the rates of spectral changes were dependent on the degree of exposure of the reaction solution to light (either laboratory light or that of the spectrophotometer light source). Even when the solution was kept in the dark,

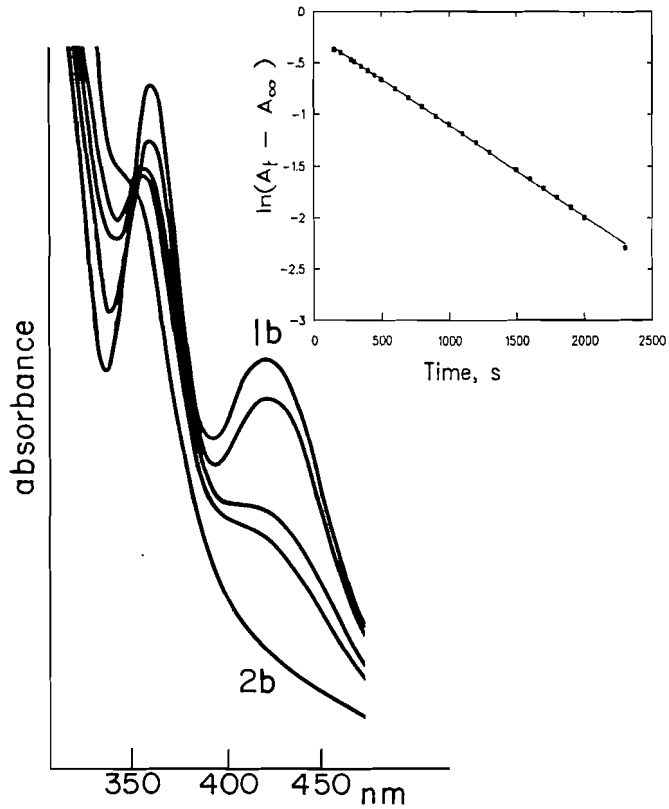

FIG. 3. Visible absorption spectral changes (350–450 nm region) for a CH_2Cl_2 solution of $Pd_2Br_2(\mu\text{-dpm})_2$ **1***b* on addition of H_2S. The inset shows a rate-plot analyzed for a first order dependence on **1***b*; initial [**1***b*] = 1.00 × 10^{-3} M, $[H_2S]$ = 0.53 M at 25°C; A_t and A_∞ represent the absorption at 428 nm at times t and ∞, respectively.

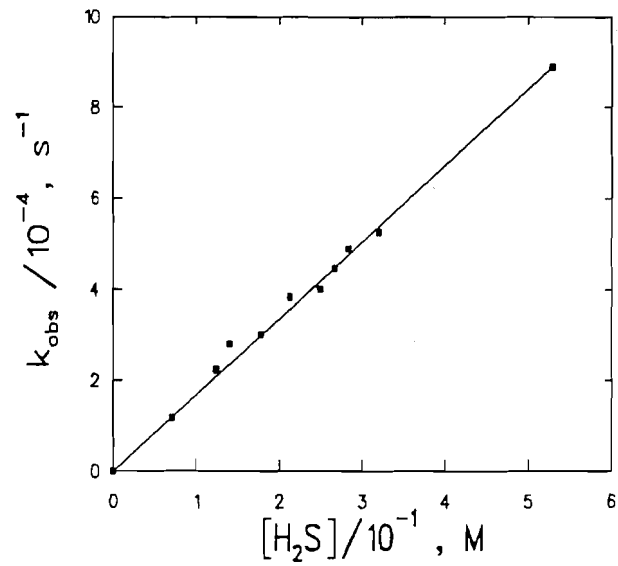

FIG. 4. The dependence of the pseudo-first order rate constants, k_{obs}, on $[H_2S]$ at [**1***b*] = 1.00 × 10^{-3} M, in CH_2Cl_2 at 25°C.

and the optical density recorded at just one wavelength (450 nm) by a sampling rather than continuous monitoring, the kinetic data were irreproducible. Complementary nmr studies at higher concentrations showed that the monomer $PdI_2(dpm)$ (18) was formed during the reaction; indeed, laboratory light readily induces formation of some monomer in solutions of $Pd_2I_2(\mu\text{-dpm})_2$. Analysis of the early visible spectral changes, using an

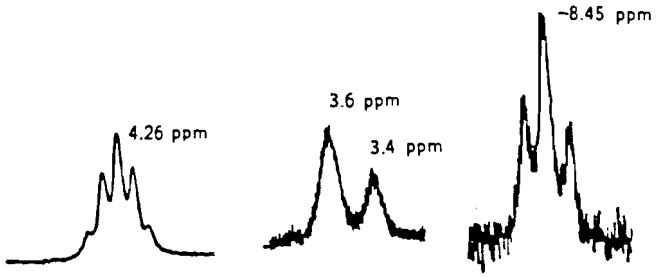

FIG. 5. The ^{1}H nmr spectrum of **1***b* + H_2S in CD_2Cl_2 ~ −78°C; the δ 4.26 quintet is unreacted **1***b*, the other peaks being assigned to **1***b*′. The peaks for **1***b*′ have been expanded.

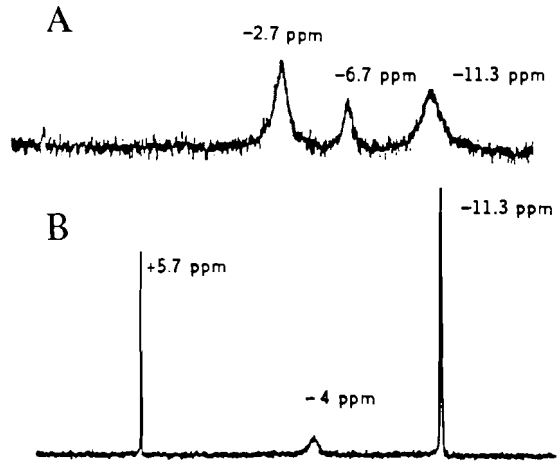
A_∞ value from the known absorption spectrum of **2***c* (2, 17), gave $k_{obs} \sim 10^{-4}$ s^{-1} at 25°C and 1 atm total pressure; this corresponds to a bimolecular rate constant of $\sim 2 \times 10^{-4}$ M^{-1} s^{-1}, assuming the iodide system (like the bromide) obeys a first order dependence on [H_2S]. Unfortunately the data were not sufficiently reproducible to establish firmly the H_2S dependence; nevertheless, the limited data show rates about ten times slower than the bromide system under corresponding conditions (see Table 1).

Attempts to find a kinetic role for intermediate ionic or "dangling" (mondentate) phosphine species were unsuccessful. Addition of a five-fold excess of bromide as NEt_4Br to **1***b* during a reaction with H_2S generated **2***b* in only about 70% yield; several other products were evidenced by UV–visible spectroscopy and by $^{31}P\{^1H\}$ nmr (see below), especially an unidentified species with δ_p = 22.2 ppm. A five-fold excess of dpm complicated the kinetic studies by abstracting sulfur from the μ-S product **2***b*.

Nuclear magnetic resonance detection of the green reaction intermediates

The ^{1}H nmr of **1***b* at −78°C shows the characteristic dpm —CH_2— signal (δ = 4.26, quintet, J_{PH} = 4 Hz) along with the less informative phenyl signals (17); after the addition of H_2S as described in the Experimental section, in addition to the H_2S signal (δ = 0.9), two additional broad resonances at δ 3.4 and 3.6 ppm, and a high-field Pd-H 1:2:1 triplet at δ = −8.45 ppm (J_{PH} = 18 Hz) are seen (Fig. 5); this new species (**1***b*′) is formed only to the extent of ~10%, and the relative proton integrations for the methylene region: high-field region are 4:1, consistent with a monohydride intermediate. With an increase of the temperature to −65°C, the peaks of **1***b*′ decrease rapidly ($t_{1/2}$ < 30 s) in intensity and the characteristic peaks of the μ-S product **2***b* become evident, inequivalent methylene protons with virtual coupling to the remote phosphorus nuclei giving two doublets of quintets centred at δ 2.85 and 4.80 ppm (1, 17). Above −65°C, only signals of **1***b* and **2***b* are observed. The $^{31}P\{^1H\}$ nmr spectral data complement the ^{1}H nmr data and, at appropriate stages, show the singlets (1, 17) of **1***b* (δ −5.5) and **2***b* (δ 5.80), as well as four unresolved, broad peaks (δ ~ 5, 8, 19, and 23 ppm) attributed to the intermediate **1***b*′ species.

The ^{1}H and $^{31}P\{^1H\}$ nmr data for the iodide system reveal an intermediate **1***c*′ species in much the same way as the bromide system, but higher concentrations of **1***c*′ (up to 50%) can be generated. Complex **1***c* at −78°C (δ_H 4.23, quintet) reacts slowly at this temperature (see Experimental section) to generate **1***c*′ (broad singlet resonances at δ_H 5.02, and δ_H −6.05, with 4:1 integration ratios), which above −70°C converts into **2***c* (doublets of quintets centred at δ_H 3.07 and 4.97); a further weak, broad signal at δ_H 0.4 is seen accompanying the resonances for **1***c*′, the maximum intensity observed being about 1/4 that of the high-field Pd—H resonance. The corresponding ^{31}P data (Fig. 6) show the conversion of **1***c* *to* **2***c*; the **1***c*′ peaks appear as two broad resonances at −78°C, and as an averaged −4 ppm signal at −40°C. That the ^{31}P signal of **1***c* at δ −11.3 is broadened at −78°C (like the resonances of **1***c*′) suggests some inhomogeneity in the sample, perhaps resulting from the presence of both H_2S and CD_2Cl_2 liquid phases.



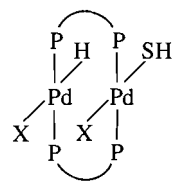


FIG. 6. The $^{31}P\{^1H\}$ spectra for the reaction of $Pd_2I_2(\mu\text{-dpm})_2$ **1***c* with H_2S in CD_2Cl_2 to give $Pd_2I_2(\mu\text{-dpm})_2(\mu\text{-S})$ **2***c* via the intermediate **1***c*′. The signals for **1***c* and **2***c* are the singlets at −11.3 and +5.7 ppm, respectively; the other signals are assigned to **1***c*′. *A* shows the −78°C spectrum measured after 8 h at this temperature; *B* shows the spectrum of the same solution warmed to −40°C, and at higher temperatures the broad −4 ppm signal disappears.

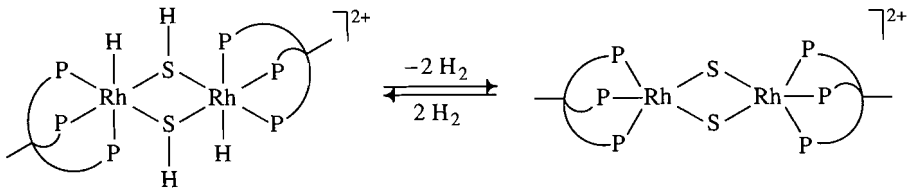
Discussion

For both the bromide and iodide systems, the low temperature ^{1}H nmr data reveal a high-field resonance attributable to a Pd—H intermediate, indicative of oxidative addition of H_2S (2). Oxidative addition reactions to the Pd_2X_2 $(\mu\text{-dpm})_2$ complexes in which the metal–metal bond acts as a nucleophile are well established (11), and such a process with H_2S would lead to an intermediate containing terminal hydrido and terminal mercapto ligands; the detected **1***b*′ and **1***c*′ species are considered to be of

X = Br, **1***b*′
X = I, **1***c*′

this type. The δ_H − 8.45, J_{PH} = 18 Hz signal for **1***b*′ is characteristic of a Pd—H *cis* to two equivalent phosphine ligands (19); The δ(Pd—SH) signal, typically at δ between 1.5 and −1.5 ppm (2), is not seen; it may be buried under the large, broad H_2S signal at ~0.9 ppm, or the SH proton which will certainly be acidic (20) may be undergoing rapid exchange with H_2S protons. The resonances of the —CH_2— protons, which are all inequivalent in a static **1***b*′ structure, appear as two unresolved peaks (δ 3.4, 3.6 ppm). The four unresolved $^{31}P\{^1H\}$ resonances presumably result from the expected AA′BB′ pattern (2). The presumed iodide intermediate **1***c* appears more "fluxional" in that only a single broad resonance is seen for the —CH_2— protons (δ 5.02) and for the Pd—H (δ −6.05), and the



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 194.225.253.170 on 09/07/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 194.225.253.170 on 09/07/12
For personal use only.

two broad $^{31}P\{^1H\}$ resonances at −78°C (δ −2.7, −6.7) collapse to a single broad resonance at −40°C (δ −4.0); the δ_H 0.4 signal could be from the —SH, although the intensity is low.

Generation of the bridged-sulfide products and H_2 via **1***b*′ (**1***c*′) is envisaged as deprotonation of the coordinated SH^- with subsequent protonation of the coordinated hydride. The chemistry has analogies in H_2S reactivity at a Pt(111) surface (21) and addition of H_2S to $Pt_3(\mu_3\text{-CO})(\mu\text{-dpm})_3^{2+}$ (20). Reaction of H_2O with zirconocene species to give a μ-oxo derivative with H_2 evolution was also presented as proceeding via oxidative addition and a subsequent proton transfer (8).

It should be noted that the spectroscopic data (and kinetic data — see below) do not rule out the possibility of the SH^- and / or H^- being bridging ligands. Several plausible alternative structures could be given for **1***b*′ and **1***c*′, because in general the nmr signals are insufficiently resolved to define the structures adequately; however, the high-field ^1H nmr triplet for the bromide system certainly demonstrates the presence of a terminal hydride. Recent work by Bianchini *et al.* (6) has shown the involvement of bridging-SH groups in the following reversible H_2-binding system (where the phosphine ligand is triphos, $MeC(CH_2PPh_2)_3$):

Solutions of the dinuclear Pd_2 (μ-S) species **2** were unreactive toward H_2 at least up to 10 atm pressure.

The kinetic data for the bromide system show simple first order dependence on both $[Pd_2{}^I]$ and $[H_2S]$, and are therefore of somewhat limited use in defining the mechanism. Direct attack by H_2S rather than by SH^- is implied, and indeed SH^- also readily displaces the halide ligands of **1** and **2** (2). The green intermediate **1***b*′ is not seen during the kinetic studies at 0–35°C and thus, assuming a steady state treatment for this species in the following mechanism,

$$[4]\quad \mathbf{1}b + H_2S \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \mathbf{1}b' \xrightarrow{k_2} \mathbf{2}b + H_2$$

gives the rate-law $k_1k_2[\mathbf{1}b][H_2S]/(k_{-1} + k_2)$. If $k_2 \gg k_{-1}$, the rate simplifies to $k_1[\mathbf{1}b][H_2S]$, while if $k_{-1} \gg k_2$, the rate expression becomes $k_2K_1[\mathbf{1}b][H_2S]$ where K_1 = the equilibrium constant (k_1/k_{-1}). The more complete expression for the latter case is $k_2K_1[\mathbf{1}b][H_2S]/(1 + K_1[H_2S])$, but the strictly first order dependence on $[H_2S]$ up to 0.53 *M* (Fig. 4) requires that at 25°C $K_1[H_2S] \ll 1$, as **1***b*′ is not detectable at these conditions.

An extra step with accompanying kinetic / equilibrium parameters is involved if an H_2S adduct is initially formed:

$$[5]\quad \mathbf{1}b + H_2S \underset{k_{-a}}{\overset{k_a}{\rightleftharpoons}} Pd_2Br_2(dpm)_2(H_2S) \underset{k_{-b}}{\overset{k_b}{\rightleftharpoons}} \mathbf{1}b' \xrightarrow{k_2} \mathbf{2}b + H_2$$

Consistency with the observed kinetics requires one of the following: (*a*) the k_a step is rate-determining; rate = $k_a[\mathbf{1}b][H_2S]$. (*b*) k_b governs the rate-determining step, following a rapid K_a pre-equilibrium (k_a/k_{-a}) with the H_2S adduct being undetectable; rate = $k_bK_a[\mathbf{1}b][H_2S]$. The more general case here is when a steady state treatment is applied to the H_2S adduct and $k_2 \gg k_{-b}$; rate = $k_ak_b[\mathbf{1}b][H_2S]/(k_{-a} + k_b)$. (*c*) the k_2 step is rate-determining, the two pre-equilibria K_a and K_b (k_b/k_{-b}) generating undetectable amounts of the H_2S adduct and **1***b*′; rate = $k_2K_aK_b[\mathbf{1}b'][H_2S]$.

The fact that **1***b*′ rapidly converts to **2***b* at temperatures above −65°C shows that *the* k_2 *step in mechanisms outlined in eqs. [4] and [5] cannot be rate-determining at 0–35°C*. Formation of **1***b*′ (or the H_2S adduct) must be rate-determining and this would be consistent with the non-detection of intermediates at ambient conditions. Formation of a possible H_2S adduct (the K_a equilibrium) is expected to be favoured at lower temperatures, because reactions of this type must be entropically unfavourable and therefore exothermic if they are to occur at all. A few H_2S complexes have been characterized: $Ru(NH_3)_5(SH_2)^{2+}$ (9), $W(CO)_5(SH_2)$ (22), $AlBr_3(SH_2)$ (23), and ^1H nmr spectroscopic evidence has been presented for the species $Pt(PPh_3)_2(SH_2)$ en route to formation of a more stable hydrido (mercapto) complex (24). In our Pd systems, the intermediates detected (**1***b*′, **1***c*′) are definitely mono-hydrides and not Pd—SH_2 species, as judged by the relative proton integrations and the J_{PH} value of 18 Hz recorded for **1***b*′ (three-bond coupling within a Pd—SH_2 adduct would be much less). In the recently reported species $Pd_2(CH_3)_2(\mu\text{-dpm})_2$ (μ-H), the hydride appears in the ^1H nmr at δ −7.55, as the expected quintet with J_{PH} = 15.0 Hz (19).

The activation parameters ($\Delta H^{\ddagger}$ = 55 kJ, $\Delta S^{\ddagger}$ = −115 J K^{-1}) are quite typical of those observed for oxidative addition reactions at one metal centre (25–27), but we are unaware of any useful, comparable data for dinuclear systems. For the present $Pd_2{}^I \rightarrow Pd_2{}^{II}$ system, formation of a species such as **1***b*′ necessitates breaking the Pd—Pd bond but the electronic promotional energy (25–27) is now only for a single electron at each Pd centre and will be less than that required for 2e-oxidative addition at one "comparable" metal centre; the other factors contributing to $\Delta H^{\ddagger}$ are breaking of an S—H bond and formation of the Pd—H and Pd—SH bonds. Overall, the activation parameters for the oxidative addition process for the same molecule at one or two metal centres may turn out to be similar. It is not clear from the present study if $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ refer to k_1 (eq. [4]), k_a or k_bK_a (eq. [5]). Corresponding ambiguities arise in oxidation addition of H_2 to give a dihydride species, now that η^2-H_2 complexes as possible intermediates have been recognized (28). Of note, the reaction of **1***b* with CO to give $Pd_2Br_2(\mu\text{-dpm})_2(\mu\text{-CO})$ in dimethylacetamide solution, with $\Delta H^{\ddagger}$ = 15 kJ, $\Delta S^{\ddagger}$ = −121 J K^{-1} (15), is some 10 times faster than the H_2S reaction in CH_2Cl_2 at comparable temperatures, and the difference is reflected entirely in the $\Delta H^{\ddagger}$ values; presumably, the higher value for the H_2S system results from energy required to break an S—H bond.

The measured isotope effect (H_2S vs. D_2S) of 2.4 appears reasonable for an oxidative addition process. Complete cleavage of an S—H versus S—D bond of $H_2S(D_2S)$ in the transition state should give a primary isotope effect of 4.8 (calculated (29)

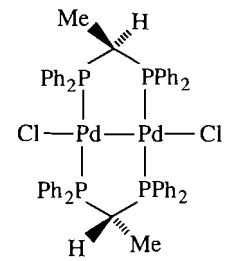
For personal use only.

using ν(S—H) = 2500 cm^{-1}), but this will be "offset" by formation of the Pd—H(D) bond; complete formation of a terminal or a bridged hydride (deuteride) would reduce the primary isotope effect to 1.4 or 2.0, respectively, assuming values of ν(Pd—H) = 2000 and ν(Pd—H—Pd) = 1400 cm^{-1} (30).

It would be particularly useful to have activation parameters for the other halide systems; unfortunately the iodide system was photosensitive under the kinetic conditions (indeed, even Pd_2Cl_2 (μ-dpm)$_2$ decomposes under photolysis with a tungsten lamp (31)), but at 25°C the H_2S reaction is ~10 times slower than for the bromide. The reactivity trend of **1** toward H_2S (X = Cl > Br > I) is opposite to that normally encountered for oxidative addition of gas molecules to single metal centres, where more basic auxillary ligands promote reaction (25–27). Within **1**, the Pd—Pd bond strength is expected to increase in the order I < Br < Cl (16), the reverse of the trans effect of the halides (32), and thus the reactivity trend is not dominated by differences in the metal–metal bond strength. Reactivity of **1** toward CO is also Cl > Br > I *in terms of equilibrium constants*, and this is governed by the rate of CO loss from the μ-carbonyl product that decreases in the reverse order (I > Br > Cl), the forward carbonylation reaction rates being essentially the same for the three halide species (15); it has been suggested that the strength of the metal–carbonyl bond in the product (I < Br < Cl) governs the reactivity trend (15). Such could be the case in the H_2S systems, if the k_{-1} step of the mechanism outlined in eq. [4], or the k_{-a} step of the mechanism given in eq. [5], case (*b*), becomes increasingly important (i.e. these rate constants increase in the order $k_{Cl} < k_{Br} < k_I$).



Invoking the principle of Occam's razor (33), which liberally interpreted means "rationalizing experimental data in terms of the simplest number of steps", leads to the mechanism of eq. [4] being favoured, but the existence of known transition metal – H_2S complexes suggests that the mechanism of eq. [5] is more realistic. That hydrides such as **1***b*′ and **1***c*′ are detected at low temperatures is perhaps surprising; extrapolation of the kinetic data to −78°C (using the activation parameters) shows the rate of formation of **1***b*′ is negligible at this temperature. It should be remembered that the green colour is seen only when the H_2S is present in the liquid phase and therefore in a high, localized concentration (~45 *M*). When liquid H_2S comes in contact with solid **1***b* at −78°C, a green solution is produced presumably containing **1***b*′; **2***b* is formed on warming the solution. Warming an nmr tube containing a lower frozen layer of a CH_2Cl_2 solution of **1***b* and an upper layer of frozen H_2S generated a green colour in the upper part but only in the narrow temperature range of about −78 to −60°C. The dielectric constants at −65°C (34) of CH_2Cl_2 (ϵ = 15), and of liquid H_2S (ϵ = 9), are very similar and the difference in solvent polarity is unlikely to affect the rate (oxidative addition of polar molecules are typically enhanced in more polar media (25–27)). We consider ourselves fortunate to detect the green hydrides — it appears the oxidative addition is detected, perhaps because of high [H_2S], or perhaps because a reverse rate (k_{-1} or k_{-b} step) is slowed down sufficiently at the low temperature.

Related to the H_2S additions to **1**, we have studied recently corresponding reactions with anhydrous HBr and HCl (35). The following stoichiometric, stepwise reactions have been demonstrated, including spectroscopic detection of all the species listed:

[6] **1***b* + HBr → Pd_2Br_2(μ-dpm)$_2$(H)(Br) $\xrightarrow[-H_2]{HBr}$ $Pd_2Br_4^+$(μ-dpm)$_2$ → 2$PdBr_2$(dpm)

The decomposition of the tetrabromo species, which can also be formed by oxidative addition of Br_2 to **1***b*, has been studied by Lindsay and Balch (36). Of importance to the present paper is the detection of the hydride intermediate formed by oxidative addition (δ_H −8.9 ppm, broad singlet), and the demonstration that it can be protonated, in this case by added HBr rather than by coordinated SH^-, to yield H_2 (35).

Finally, the possibility of immobilizing the Pd_2 complexes akin to **1** on a support such as polystyrene led us synthesize related complexes containing methylated dpm (dpmMe), i.e. 1,1-bis(diphenylphosphino)ethane, $Ph_2PCH(Me)PPh_2$ (2, 37). The complex Pd_2Cl_2(μ-dpmMe)$_2$ (**3**) was originally made as the

anti-**3**

anti-isomer, with the Me groups on the opposite side of the Pd—C—Pd plane (37). This species in CH_2Cl_2 is unreactive to H_2S (or CO (37)) at 1 atm; the lack of reactivity may result from a steric problem in what would be the A-frame, bridged-sulfide (or μ-CO) product. The A-frame species generally adopt a boat conformation for both of the two fused rings (11), and hence for *anti*-**3** this would necessitate the location of one Me group in the inside of the boat with consequent steric problems. Of interest, the *syn* isomer of **3** has been isolated in this laboratory by a low-temperature synthesis, and this species reacts readily and quantitatively with H_2S to generate H_2 and *syn*-Pd_2Cl_2(μ-dpmMe)$_2$(μ-S) (38); one assumes that the Me groups can now be readily accommodated, and studies are on-going in attempts to quantify the differences in reactivity btween the *syn*- and *anti*-isomers. The earlier paper (2) reports on the synthetic scale reaction of H_2S with the mixed ligand complex Pd_2Cl_2(μ-dpm)(μ-dpmMe), **4**, which does generate H_2 and a single μ-S product, although it is not known whether this is the *syn*- or *anti*-product with the μ-S and Me on the same or opposite sides of the Pd—C—Pd plane. Qualitatively, the H_2S-reactivity trend in CH_2Cl_2 at ambient conditions is **1***a* > **4** > *syn*-**3**.

Conclusions

Kinetic and mechanistic studies have been initiated on the abstraction from H_2S in solution of sulfur as sulfide by Pd_2X_2(P—P)$_2$ species where X = halide and P—P = μ-dpm and / or μ-dpmMe. The reaction type is important because it allows for recovery of the co-product, H_2. The bromide system Pd_2Br_2(μ-dpm)$_2$ shows first order kinetic dependences on both metal and H_2S concentrations, and the activation parameters and a deuterium isotope effect are consistent with oxidative addition to give a hydrido(mercapto) species en route to the μ-S product.

A hydride intermediate has been detected at low temperature within the bromide and corresponding iodide systems, although the kinetics for the H_2S / iodide system were difficult to study because of photosensitized decomposition reactions. Suitable conditions for studying the faster H_2S / chloride reactions are being sought, but it is evident that the reactivity trend is Cl > Br > I; plausible explanations are presented in terms of mechan-

isms involving oxidative addition to give the hydrido(mercapto) intermediate, perhaps, but not necessarily, via initial H_2S-adduct formation; deprotonation of the coordinated SH^- with subsequent protonation of the coordinated H^- yields H_2 and the bridged sulfide. Incorporation of a Me functionality at the methylene of dpm, for subsequent elaboration of the system to a surface-supported one, decreases reactivity toward H_2S, but efficient, quantitative H_2-generating systems are still realized.

Received March 12, 1989

This article is dedicated to Professor Ronald J. Gillespie on the occasion of his 65th birthday

JEAN-LOUIS ROUSTAN, NASRIN ANSARI, JEAN-PIERRE CHARLAND, and YVON LE PAGE. Can. J. Chem. **67**, 2016 (1989).

$Fe(CO)_2(NO)(CH_3CN)(PPh_3)_2{}^+BF_4{}^-CH_2Cl_2$ **5** crystallizes in the triclinic system, space group $P\bar{1}$, with a = 9.7782 (7), b = 10.2832 (7), c = 20.5752 (14) Å, α = 92.903 (6), β = 99.535 (6), γ = 91.930 (6)°, V = 2035.8 (1) Å^3, Z = 2. The coordination around Fe is trigonal bipyramidal, with CH_3CN and disordered NO and CO in the equatorial plane and the PPh_3 ligands displaced from true apical positions (P—Fe—P = 170.20 (4)°). Comparison of the structure of **5** with those of the two independent molecules $\mathbf{2}_1$, and $\mathbf{2}_2$ of $Fe(CO)(NO)(H)(PPh_3)_2$ **2** shows that upon a formal H^- for CH_3CN substitution, the Fe—P bond lengths shorten by ca. 0.09 Å, the (O)C—Fe—N(O) angle opens up by ca 3° (**5** → $\mathbf{2}_1$) and 8° (**5** → $\mathbf{2}_2$), whereas the P—Fe—P angle decreases by ca. 30°. These variations are interpreted in terms of electron-pair repulsions, with those within the Fe (equatorial ligand) (axial ligand) molecular portions suggested to play a predominant role.

Key words: $D^{7+1}_{NO(Fe)}$ NO/CO complexes, bond repulsions, steric influences in phosphine complexes.

JEAN-LOUIS ROUSTAN, NASRIN ANSARI, JEAN-PIERRE CHARLAND et YVON LE PAGE. Can. J. Chem. **67**, 2016 (1989).

$Fe(CO)_2(NO)(CH_3CN)(PPh_3)_2{}^+BF_4{}^-CH_2Cl_2$ (**5**) cristallise dans le système triclinique, groupe d'espace $P\bar{1}$, avec a = 9,7782 (7) b = 10,2832 (7) et c = 20,5752 (14) Å, α = 92,903 (6), β = 99,535 (6) et γ = 91,930 (6)°, V = 2035,8 (1) Å^3, Z = 2. La coordination autour du Fe est trigonale bipyramidale, avec le CH_3CN ainsi que le NO et le CO désordonnés dans le plan équatorial et les ligands PPh_3 déplacés par rapport aux positions apicales vraies (P—Fe—P = 170,20 (4)°). Une comparaison de la structure du composé **5** avec celles des deux molécules indépendantes ($\mathbf{2}_1$ et $\mathbf{2}_2$) de $Fe(CO)(NO)(H)(PPh_3)_2$ (**2**) montre que, par une substitution formelle du CH_3CN par H^-, les longueurs de la liaison Fe—P raccourcissent par environ 0,09 Å, que l'angle (O)C—Fe—N(O) s'agrandit par environ 3° (**5** → $\mathbf{2}_1$) et 8° (**5** → $\mathbf{2}_2$) alors que l'angle P—Fe—P diminue par environ 30°. On interprète ces variations en fonction de répulsions des paires d'électrons; on suggère que celles des portions moléculaires Fe(ligand équatorial) (ligand axial) jouent un rôle prédominant.

Mots clés : complexes NO/CO du type $D^{7+1}_{NO(Fe)}$, répulsions entre liaisons, influences stériques dan des complexes phosphino.
[Traduit par la revue]

Introduction

The positive linear correlation between the Fe—P bond lengths l(Fe—P) and the degeneracy weighted CO stretching frequency $\langle\nu_{CO}\rangle$ found (1) for the set of closely structurally related pentacoordinated $D^{(8-n)+n}_{NO(Fe)}$ mononitrosyl (n = 1) and NO-free (n = 0) complexes $Fe(CO)_2(NO)(PPh_3)_2{}^+BF_4{}^-$ **1**, $Fe(CO)(NO)(H)(PPh_3)_2$ **2**, $Fe(CO)_2(N_2Ph)(PPh_3)_2{}^+BF_4{}^-$ **3**, and $Fe(CO)_4(PPh_3)$ **4**, has shown that an increase in the metal Lewis basicity does favor a shortening of the Fe—PPh_3 bond lengths.[2] In this particular set of compounds, the involvement of interligand repulsions was only reflected perceptibly in the departure of the metal coordination polyhedra from a regular geometry. This is well exemplified by the two nitrosyl complexes **1** and **2**. The geometry of complex **1** (1), with disordered CO and NO ligands and long Fe—P bonds (average[3] 2.280 [3] Å), is close to a perfect trigonal bipyramid. Alternatively, in the NO/CO disorder-free hydride **2** (3) with short Fe—P bonds (average 2.182 [7] Å), the PPh_3 ligands are severely displaced from true apical positions away from the XO ligands (X = N, C). Another member of the pentacoordinated bisphosphino $D^{7+1}_{NO(Fe)}$ subset is the title compound $Fe(CO)(NO)(NCCH_3)(PPh_3)_2{}^+BF_4{}^-$ **5** (4) with a $\langle\nu_{CO}\rangle$ about halfway between those of complexes **1** and **2**. Like in hydride **2**, the metallic center of complex **5** is expected to be more electron rich than in **1**, but unlike hydride **2**, complex **5** contains three, rather than two, nonphosphinic ligands of a comparable steric demand. This complex was therefore of interest for studying a situation where electronic and steric factors might exert antagonistic influences on the Fe—PPh_3 bond lengths, the l(Fe—P) vs. $\langle\nu_{CO}\rangle$ correlation providing a semi-quantitative basis for an estimate of the magnitude of the steric influence.[4] The X-ray structure of the acetonitrile complex **5** is reported in this paper and compared to the structure of hydride **2**.

Experimental

Single crystals of the title compound **5** (4) were grown under argon at 20°C by slow diffusion of hexane into a solution of the complex in methylene chloride. Crystals for X-ray diffraction were mounted on a glass rod and subsequently coated with a layer of epoxy resin. In the absence of such a coating the crystals slowly decayed into an amorphous yellow solid upon exposure to air.

A red–orange crystal, 0.1 × 0.1 × 0.1 mm, was selected for

intensity measurements at 296 K up to 45° 2-θ with graphite monochromated MoKα radiation on a Enraf-Nonius CAD-4 diffractometer controlled by the NRCCAD software (5). A total of 10514 reflections were collected which reduced to 5262 unique reflections after averaging the symmetry related ones. Among these, 3709 with $I_{net} \geq 2.5\sigma(I_{net})$ were considered observed. The data reduction comprised also corrections for Lorentz and polarisation effects but not for absorption (μ = 0.63 mm^{-1}). No statistically significant change in the intensities of the three standard reflections monitored was noted. The cell parameters (Table 1) were derived from the setting angles of 45 strong reflections in the 2-θ range $40° \leq \theta \leq 45°$ (λ(MoKα$_1$) = 0.70930 Å).

The structure was solved by direct methods and ΔF-maps techniques which disclosed all the atomic positions. The BF_4^- anion was found disordered over two positions unequally occupied (population ratio = 2) and related by a rotation of ca. 60° along a common B—F bond. In the early stage of the refinement, the NO was treated as a CO. All the non-hydrogen atoms were systematically refined anisotropically and the H atoms isotropically by least-squares block diagonal matrices minimizing $\Sigma w(|F_c| - |F_o|)^2$ with $w^{-1} = \sigma^2(F_o) + 0.00025\,F_o^2$. Once the approximate atomic positions were known, a C atom was placed on each one of the two possible positions (G1 and G2 in Fig. 1) and the occupancy factors were refined with a fixed isotropic U value of 0.05 Å^2. The shift of the occupancy factors to 1.040(7) for G1 and 1.145(7) for G2 suggested that the latter might be the actual location of the nitrosylic N atom. During the refinement of the ordered model with N on G2, some H atoms of CH_3CN, CH_2Cl_2, and phenyl rings (H134, H212, H232) displayed unreasonable geometries. Therefore, they were placed in idealized positions (C—H = 1.08 and 0.95 Å for sp^3 and sp^2 carbons, respectively) and included in all the refinement cycles performed subsequently but not refined. At convergence of this first model (R = 0.041, R_w = 0.044, S = 1.69), the Fe—G2(N) bond (1.693(4) Å) was slightly shorter than the Fe—G1(C) bond (1.714(3) Å) but the G2(N)—O2 and G1(C)—O1 bond lengths of 1.143(4) and 1.149(3) Å, respectively, were undistinguishable, contrary to what is generally found in M/NO/CO ordered structures in which the N—O bond is longer than the C—O one (3, 6–8) (with the converse for the M—N and M—C bonds). The alternate model in which N was positioned on G1 ($R = 0.042$, $R_w = 0.044$, $S = 1.70$) had to be rejected also for the Fe—G2(C) and G2(C)—O2 bond lengths of 1.678 (3) and 1.130 (4) Å, respectively, were both shorter than the Fe—G1(N) and G1(N)—O1 bond lengths of 1.734 (3) and 1.153 (4) Å, respectively. In addition, the thermal ellipsoid of G2(C) was abnormally small relative to that of G1(N) (ORTEP included in the supplementary material).[5] A disordered model was finally selected with 0.8 and 0.2 of a N atom placed on G2 and G1 respectively, as suggested by the results of the refinement on the occupancy factors. Composite scattering curves of

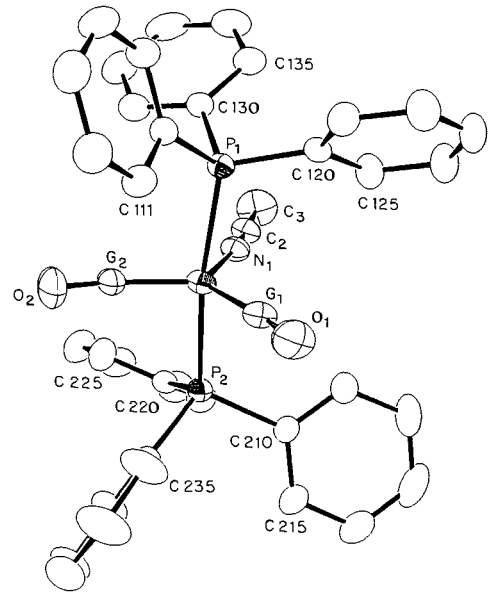

FIG. 1. Perspective view of $Fe(CO)(NO)(CH_3CN)(P(C_6H_5)_3)_2^+$ with the numbering scheme. The thermal ellipsoids have been drawn at the 50% probability level.

the form $af_N + (1 - a)f_C$(a = 0.8 (G2), 0.2 (G1)) were used. The final residuals were $R = 0.041$, $R_w = 0.043$, $S = 1.67$ with 623 parameters for 3709 reflections and $R = 0.0657$, $R_w = 0.0471$ for all reflections. In the final cycle, the maximum shift to σ ratio was 0.35 (aromatic H atom) and in the final ΔF-map the background was below 0.3 e/Å^3, except for a peak of 0.54 e/Å^3 at ca. 1 Å away from the C1 atoms. All computations were performed with the NRCVAX system of programs (9). The scattering curves and anomalous dispersion corrections were taken from ref. 10.

Apart from the variations in the bond lengths of the FeG_iO_i(i = 1, 2) moieties, no significant changes in the other bond lengths and in all the valence angles were noted from one model to another. The final atomic positions are given in Table 2. The list of calculated and observed structure amplitudes, parameters for the H atoms, U_{ij}'s for the non-hydrogen atoms have been deposited as supplementary material.[5]

Results

The crystal structure of complex **5** consists of discrete metallic cations, BF_4^- anions and CH_2Cl_2 molecules of solvent with no unusual intermolecular Van der Waals contact. The BF_4^- anions are disordered on two positions sharing the same B—F1 bond. The structure of the cation with the numbering scheme is presented in Fig. 1 and selected bond lengths and angles are listed in Table 3.

The coordination polyhedron of iron is a distorted trigonal bipyramid. As detailed in the Experimental section, none of the two possible ordered models in which the nitrosylic N atom was placed on either position G1 or position G2 (Fig. 1) led to a set of bond lengths in the FeG_iO_i moities consistent with what is usually observed in ordered M/NO/CO structures (M—N and N—O bonds respectively shorter and longer than the M—C and C—O bonds (3, 6–8). A disordered model with the (O)N and (O)C atoms unequally distributed on positions G1 and G2 was finally retained. Positions G1 and G2 together with the N1 atom of CH_3CN define the equatorial plane which contains Fe, O1, and C2, and from which O2 and C3 deviate by less than 0.02 Å.

[a]Angle sustended at Fe by the O1 and O2 atoms.

In the equatorial plane, the Fe—G1 and Fe—G2 bond lengths of, respectively, 1.723(4) and 1.689(3) Å are shorter than the Fe—(C/N) bond lengths of $Fe(CO)_2(NO)(PPh_3)_2^+BF_4^-$ **1** (1) (range 1.756(4)–1.769(4) Å), but they compare well with the Fe—(C/N) bond lengths found in the NO/CO disordered structure of $Fe(CO)(NO)_2(PPh_3)$ **6** (11) (range 1.690(8)–1.732(8) Å). The G1—O1 and G2—O2 bonds of respectively 1.149(5) and 1.140(4) Å are also similar to the (C/N)—O ones of **6** (range 1.147(11) – 1.158(8) Å). Even if the NO/CO disorder blurs the fine details of the geometry of the Fe(NO)(CO) moiety, there is little doubt that the (O)C—Fe—N(O) angle (G1—Fe—G2) of 117.6(2)° is significantly smaller than those of 120.6(3)° and 125.8(3)° corresponding respectively to the two independent molecules $\mathbf{2}_1$ and $\mathbf{2}_2$ of $Fe(CO)(NO)(H)(PPh_3)_2$, **2** (Table 4).

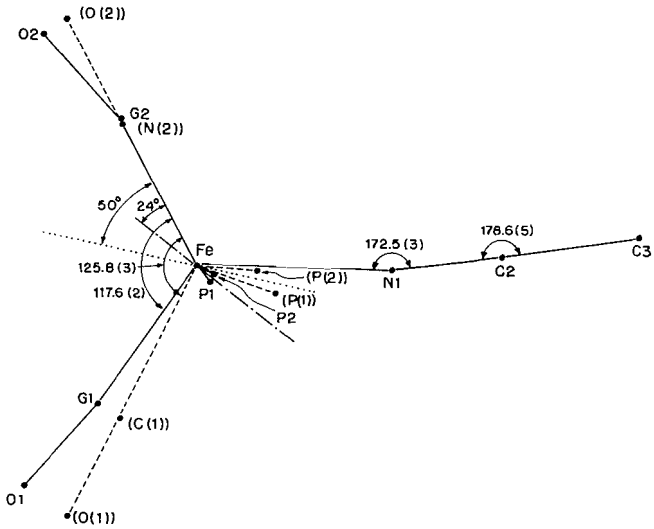

FIG. 2. Orthogonal projections of selected atoms on the G1FeG2 plane of (*a*) $Fe(CO)(NO)(CH_3CN)(P(C_6H_5)_3)_2^+$, **5**; (*b*) $Fe(CO)(NO)(H)(P(C_6H_5)_3)_2$ **2** (molecule II of ref. 3 considered, the labelling of the G_iO_i positions (i = 1, 2) as given in the original publication are enclosed in parentheses).

The structural parameters associated with the acetonitrile ligand are normal (see ref. 12*a*, *b* for other Fe/CH_3CN complexes). The Fe—N1—C2 array is nonlinear with a Fe—N1—C2 angle of 172.5 (3)°. The CH_3CN ligand is tilted towards G2, away from the PPh_3 ligands (Fig. 2), and the N1 atom is involved in the shortest intramolecular equatorial-atom/phenyl C-atom contacts of 3.038 (5) and 3.102 (5) Å with, respectively, C130 and C220.

The Fe—P bond lengths of 2.272 (1) and 2.281 (1) Å of **5** are very similar to the Fe—P distances of $Fe(CO)_2(NO)(PPh_3)_2^+BF_4^-$ **1** (1) (2.278(1) and 2.282(1) Å). Consequently, complex **5** deviates markedly from the l(Fe—P) vs. $\langle\nu_{CO}\rangle$ correlation[4] from which a l(Fe—P) bond length of 2.226 Å is calculated with the $\langle\nu_{CO}\rangle$ value of 1960 cm^{-1} associated with **5** (4). The PPh_3 ligands are displaced from the true apical positions (P—Fe—P = 170.20(4)°) away from G2, and towards the interior of the largest equatorial angle N1—Fe—G1 of 123.7(2)° (Fig. 2).

Discussion

The acetonitrile complex $Fe(CO)(NO)(CH_3CN)(PPh_3)_2^+BF_4^-$ **5** is related to $Fe(CO)_2(NO)(PPh_3)_2^+BF_4^-$, **1**, and $Fe(CO)(NO)(H)(PPh_3)_2$, **2** by the formal substitution of one equatorial ligand.

The CH_3CN for CO substitution converting **1** into **5** has no significant effect on the Fe—P bond lengths, but creates an imbalance in the influence of the XO ligands upon the PPh_3 ones. The P—Fe—P angle closes from 178.45(5)° to 170.20(4)°, and the P atoms are displaced from true apical positions away from the coordination site of the G2O2 ligand.

Interestingly, very similar deformations are observed from $Fe(CO)_2(NO)(PPh_3)_2^+BF_4^-$ to $Mn(CO)_2(NO)(PPh_3)_2$ in which the M to XO (X = C, N) retrodonation is enhanced. In the

[b]This work.
[c]A value with a standard deviation is from the original publication. Other values have been calculated from the data given in the references quoted.

ordered model selected to describe the structure of the Mn complex (13) (P—Mn—P = 170.2 (2))°, the P atoms were found further away from the NO than from the CO ligands. In terms of electron-pair repulsions (14), this observation, and others (3, 6, 11, 15*a*), support the proposal that the repulsive influence of a M···X(O) bond is a more sensitive increasing function of the M···X bond order with a nitrosyl (X = N) than with a carbonyl (X = C) ligand.

Returning to the Fe series, it is only when CH_3CN is replaced by H^- to yield hydride **2** that the Fe—P bonds respond to the additional increase in the metal basicity and shorten to 2.182 [7] Å. Concomittantly, the closing of the P—Fe—P angle is accentuated to 140.9 (1)°, and the P atoms are moved towards the coordination site of the exchanged ligand, as shown in Fig. 2 by the sense of rotation of the trace of the PFeP plane into the G1FeG2 one. The compactness of H (and the M—H bond (14*b*)) suffices to account for these angular variations. Relating the latter with the change in the Fe—P bond lengths suggests that the H ligand, but not the CH_3CN one, allows for the angular deformations required to accommodate shorter Fe—P bonds without increasing unduly the repulsions in the $Fe(XO)(PPh_3)$ (X = N, C) molecular portions. Indeed, even if the Fe—P bonds are shorter by ca. 0.09 Å in hydride **2** than in complex **5**, the P...X intramolecular contacts are longer by ca. 0.05 to 0.11 Å (in **5**: P...G1 = 2.85 [3] Å, P...G2 = 2.94 [2] Å; in the two independent molecules $\mathbf{2}_1$ and $\mathbf{2}_2$ of **2**: P...C = 2.91 [3] Å ($\mathbf{2}_1$)/2.90 [6] Å ($\mathbf{2}_2$), P..N = 3.05 [3] Å ($\mathbf{2}_1$)/3.01 [1] Å ($\mathbf{2}_2$) (calculated from the data in ref. 3)). Consequently, this analysis suggests that in hydride **2**, the Fe—P bond lengths, which correlate well with the electronic parameter $\langle\nu_{CO}\rangle$, are under electronic control, whereas the acetonitrile complex **5** might provide an example of the predominance of steric influence on the Fe—P separations. The steric lengthening relative to the $\langle\nu_{CO}\rangle$ based value is a large 0.05 Å, about half the difference between the lowest and highest *l*(Fe—P) values reported in ref. 1.

The angular deformation of the $Fe(PPh_3)_2$ fragment might also be an important factor for allowing the (OC)—Fe—N(O) angle to expand from **5** (117.62(2)°) to **2** (120.6(3)°($\mathbf{2}_1$), 125.8(3)° ($\mathbf{2}_2$)), as suggested by considering first the variations of the (O)N—M—N(O) angle in pseudotetrahedral D_{NO}^{8+2} dinitrosyl complexes ($M(NO)_2(L)_2^x$(x = 0, +1)) which have been the subject of numerous crystallographic (16) and theoretical (17) studies. In complexes of that type, when localized bonds are considered, some of the observed variations of the (O)N—M—N(O) angle have been interpreted (11, 15) by what is essentially an electron-pair repulsion model (14), with the mutual electrostatic repulsions of the M···N bonds taken as the most influential factor. Applied to the pair of the Fe complex, **5** and **2**, this standard model would allow a straightforward interpretation of the opening of the (O)C—Fe—N(O) angle by considering solely the enhancement of the repulsions in the Fe(CO)(NO) moiety upon a H^- for CH_3CN substitution. However, when examining other triangular bipyramidal complexes, this interpretation fails to account for the closing of the (O)N—M—N(O) angle between the two equatorial NO upon an increase in the M to NO retrodonation from $Mn(NO)_2(L')_3^{+}BF_4^-$ (N—Mn—N (18) = 116.5 (5)°, ν_{NO} (19) = 1760, 1712 cm^{-1}, L' = $P(OMe)_2Ph$) to $Mn(NO)_2(L')_2Cl$ (N—Mn—N = 111.5 (5), 112.1 (5), 113.5 (5) (two crystalline forms and three independent molecules (20, 21)), ν_{NO} (19) = 1713, 1674 cm^{-1}).

We believe that such a model neglecting the bond repulsions in the M(NO)(L) molecular portions, which must also increase with the M···N(O) bond order, is not justified in every case. As shown with the D_{NO}^{8+2} pair of isoelectronic complexes $Co(NO)_2(PPh_3)_2^{+}PF_6^-$ (N—Co—N (22) = 136.7(4)°, ν_{NO} (23) = 1836, 1784 cm^{-1}) and $Fe(NO)_2(PPh_3)_2$ (N—Fe—N (11) = 123.8(4)°, ν_{NO} (24) = 1724, 1678 cm^{-1}), in which the geometry of the $M(PPh_3)_2$ fragment is little affected from one compound to the other, whereas the metal to NO retrodonation increases from the cationic complex to the uncharged one, the (O)N—M—N(O) angle decreases instead of increasing. We consider

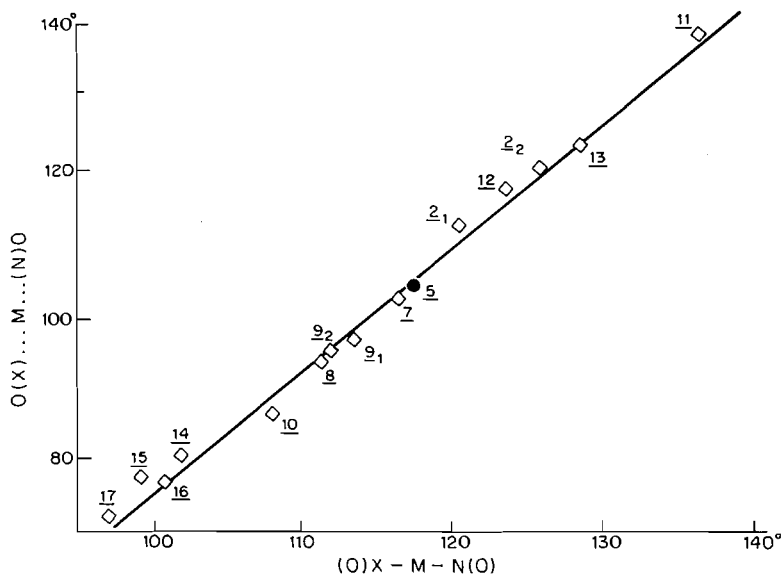

FIG. 3. O(X)...M...(N)O angle sustended at M by the two O atoms of the XO and NO ligands vs. (O)X—M—N(O) angle (X = C, N) for the complexes listed in Table 4 (r = 0.9960, σ = 1.8°, excluding the NO/CO disordered structure **5**).

that this closing is more consistent with the notion that the electrostatic repulsions in the $M(NO)(PPh_3)$ fragments, rather than those in the $M(NO)_2$ subunit, provide the most influential factor. In pentacoordination, we interpret in the same manner the closing of the (O)N—Mn—N(O) angle from the cationic Mn complex to the uncharged chloro derivative. The contrasting behavior of the pair of Fe complexes **5** and **2** could then be rationalized simply by observing that from $Fe(CO)(NO)(CH_3CN)(PPh_3)_2{}^+BF_4{}^-$ **5** to $Fe(CO)(NO)(H)(PPh_3)_2$ **2**, the magnitude of the closing of the P—Fe—P angle might allow for an opening of the (O)N—Fe—C(O) angle, as required by the standard model, while preventing detrimental excessive repulsions in the $Fe(XO)(PPh_3)$ molecular fragments, as required by the suggested modification of this model.

Finally, as shown by the plot of Fig. 3, it is worth noting that in complex **5** the (O)C—Fe—N(O) angle and the O(C)...Fe...(N)O one sustended at Fe by the oxygen atoms nicely follow the trend defined by other NO/CO disorder-free tetra and pentacoordinated complexes containing one M(XO)(NO) (x = C, N) subunit. A correlation of that type was first reported (17*b*) for a variety of tetracoordinated D_{NO}^{8+2} derivatives, and subsequently extended (18) to the pentacoordinated Mn dinitrosyl complexes listed in Table 4. The plot of Fig. 3 shows that this correlation includes also tetra and penta coordinated complexes containing one M(CO)(linear NO) moiety.[6] Unexpectedly, we have also found that some pentacoordinated complexes containing a bent-NO are part of the same correlation, as shown on Fig. 3 by the location of the representative points of the few complexes of that type listed in Table 4.

In conclusion, from $Fe(CO)(NO)(CH_3CN)(PPh_3)_2{}^+BF_4{}^-$ **5** to $Fe(CO)(NO)(H)(PPh_3)_2$, **2**, both the shortening of the Fe—P bond lengths and the opening of the (O)C—Fe—N(O) angle can be related in a simple way to the large closing of the P—Fe—P angle. A closing of this magnitude can be expediently interpreted in terms of the relative differences in the bond repulsions involving $M(PPh_3)(H)$ and $M(PPh_3)$(non-H ligand) molecular portions (14*b*). In addition, when considering an electron-pair repulsion model to account for angular variations in M(XO)(NO) complexes, it is suggested that the repulsions in both the M(XO)(NO) and M((C/N)O)(ancillary ligand) molecular portions need to be taken into account, with those of the second type possibly providing the most influential factor in several cases.

[6]For pseudotetrahedral D_{NO}^{8+2} complexes in C_{2v} symmetry, see ref. 17*b*, *c* for a possible relationship between the (O)N—M—N(O) and M—N—O angles, and consequently between the (O)N—M—N(O) and O(N)...M..(N)O ones.

An orthorhombic crystalline modification of $[(PS)H^+][OTeF_5^-]$ was studied by single crystal X-ray diffraction ($(PS)H^+$ = protonated 1,8-bis(dimethylamino)naphthalene): orthorhombic, space group *Cmcm*, a = 8.607(2), b = 14.048(3), c = 13.365(2) Å, Z = 4, T = −130°C. The structural parameters for the anion and cation in this modification (Mod-B) are very similar to those for the previously reported triclinic modification of this salt (Mod-A). However, variable temperature IR spectra for Mod-B suggest that the $OTeF_5^-$ anion is exhibiting a two-site O/F_{ax} interchange above −70°C. Solid-state ^{19}F NMR spectra suggest that this interchange may be as rapid as 10^4–10^5 s^{-1} at room temperature.

Key words: crystal structure of protonated 1,8-bis(dimethylamino)naphthalene)pentafluorotellurate(VI), polymorphism, solid state ^{19}F NMR.

Faisant appel à la diffraction des rayons-X sur un cristal unique, on a étudié une modification cristalline orthorhombique du $[(PS)H^+][OTeF_5^-]$ ($(PS)H^+$ = bis(diméthylamino)-1,8 naphtalène) : orthorhombique, groupe d'espace *Cmcm*, a = 8,607(2), b = 14,048(3), c = 13,365(2) Å, Z = 4, T = −130°C. Les paramètres de structure de l'anion et du cation de cette modification (Mod-B) sont très semblables à ceux de la modification triclinique de ce sel (Mod-A) rapportée antérieurement. Toutefois, les spectres IR de ce sel (Mod-A) à température variable suggèrent que, à des températures supérieures à −70°C, l'anion $OTeF_5^-$ s'échange entre les deux sites O/F_{ax}. Les spectres rmn du ^{19}F à l'état solide suggèrent que la vitesse de cet échange, à la température ambiante, est de l'ordre de 10^4–10^5 s^{-1}.

Mots clés : structure cristalline du bis(diméthylamino)-1,8 naphtalène protoné, pentafluorotellurate(VI), polymorphisme, rmn du ^{19}F à l'état solide.

[Traduit par la revue]

Introduction

We have recently reported the structure and spectroscopic properties of the $OTeF_5^-$ anion (teflate) in a triclinic modification of $[(PS)H^+][OTeF_5^-]$ ($(PS)H^+$ = protonated 1,8-bis(dimethylamino)naphthalene) (1). This salt did not exhibit the O/F disorder that is characteristic of alkali metal salts of teflate (2). The Te—O distance of 1.803 Å in the pseudooctahedral $OTeF_5^-$ anion is shorter than the Te—F distances, which range from 1.862 to 1.879 Å and average 1.870 Å (1).[3] The average O—Te—F_{eq} bond angle is 95.2°. These results are in harmony with Gillespie's classic theory of molecular structure, VSEPR (3).

We now report the isolation of an orthorhombic modification of $[(PS)H^+][OTeF_5^-]$. At −130°C, X-ray diffraction results show that, like the triclinic modification (Mod-A), the orthorhombic modification (Mod-B) does not exhibit O/F disorder. However, IR spectroscopic data indicate that above −70°C the $OTeF_5^-$ anions in Mod-B are distributed between two inequivalent sites. This solid-state motion of site interchange was investigated by solid-state ^{19}F NMR spectroscopy.

[3]These distances have been corrected for the librational motion of the $OTeF_5^-$ anion.

Experimental

The general procedures and the reagents used were the same as in a previous study (1). The compounds $[N(n\text{-}Bu)_4^+][OTeF_5^-]$ and $[N(n\text{-}Bu)_4^+][H(OTeF_5)_2^-]$ were prepared by literature procedures (4).

Liquid ^{19}F NMR spectra were recorded at 188.2 MHz as previously described (1). All solid-state ^{19}F NMR spectra were recorded at 338.7 MHz on a modified Nicolet NT-360 spectrometer in the NSF Regional NMR Center at Colorado State University. The magic angle spinning (MAS) spectra were obtained at spinning speeds up to 17 kHz (5) using Torlon rotors. All spectra were recorded using a pulse (6.00 μs)–aquire (6.20 ms)–delay (1.00 s) pulse sequence. The sweep width was 125 000 Hz (369.0 ppm), and a 1 024 data point FID was collected and zero-filled to 8 192 data points before Fourier transformation. Chemical shifts (δ scale) were referred to the secondary reference poly(tetrafluoroethylene), which has a chemical shift of −122 ppm relative to $CFCl_3$.

Routine room temperature IR and Raman spectra were recorded as previously described (1). Variable temperature IR spectra were recorded on a Digilab FTS-40 spectrometer using an Air Products Displex cryostat with a Lakeshore Cryogenics silicon diode controller. Temperatures quoted are nominal cryotip temperatures; the actual sample temperatures are higher due to local heating by the incident beam. For all IR spectra peak positions are ±1 cm^{-1}.

$[(PS)H^+][OTeF_5^-]$, Mod-A and Mod-B

Equivalent amounts of Proton Sponge® (1,8-bis(dimethylamino)-naphthalene, PS) and $HOTeF_5$ were mixed in dichloromethane. Slow

evaporation of the solution at 22°C or cooling the solution to 4°C both resulted in crystallization of the salt, but in different crystalline modifications (ca. 90% isolated yield in either case), Mod-A and Mod-B, respectively. The oxygen-18 salts were prepared in a similar fashion using $H^{18}OTeF_5$ (1) in place of $HOTeF_5$. NMR and IR spectra and the structure of Mod-A have been reported by us in an earlier paper (1).

Crystallographic study of $[(PS)H^+][OTeF_5^-]$, Mod-B

A colorless crystal of $[(PS)H^+][OTeF_5^-]$, Mod-B was centered on a Nicolet R3m diffractometer. Centering of 25 reflections allowed least-squares calculation[4] of the cell constants given in Table 1. Other experimental parameters are also listed in Table 1.

The intensities of control reflections (800, 0 10 0, 0 0 10) monitored every 97 reflections showed no significant trend during the course of the data collection. An empirical absorption correction, based on intensity profiles for 16 reflections over a range of setting angles (ψ) for the diffraction vector, was applied to the observed data. The transmission factors ranged from 0.960 to 0.666. Lorentz and polarization corrections were applied to the data.

The structure was solved by direct methods (SOLV).[4] The cation and anion both have crystallographically imposed *mm* symmetry in the lattice. The refinements involved anisotropic thermal parameters for all non-hydrogen atoms. The hydrogen atom bridging the two nitrogen atoms was located and refined isotropically. The other hydrogen atoms were included in calculated positions (C—H = 0.96 Å, $U(H) = 1.2U_{iso}(C)$). Neutral-atom scattering factors (including anomalous scattering) were taken from ref. 6. The weighted least-squares refinements converged (weights calculated as $(\sigma^2(F_o) + |g|F_o^2)^{-1}$), with the average shift/esd < 0.010 over the last six cycles.

In the final difference Fourier synthesis, the maximum and minimum electron densities were 1.54 e $Å^{-3}$ (near Te) and −1.11 e $Å^{-3}$. Analysis of variance as a function of Bragg angle, magnitude of F_o, reflection indices, etc., showed no significant trends.

[4]Calculations for diffractometer operations were performed by using software supplied with the Nicolet R3m diffractometer. All structural calculations were performed on the Data General Eclipse S/140 computer in the X-ray laboratory at Colorado State University with the SHELXTL program library written by Professor G. M. Sheldrick and supplied by Nicolet XRD Corporation.

[a]Estimated standard deviations in the least significant digits are given in parentheses.

[b]The equivalent isotropic *U* is defined as 1/3 of the trace of the U_{ij} tensor except for the refined hydrogen atom, which was refined isotropically.

Table 2 contains a list of atomic positional and isotropic thermal parameters for all unique non-hydrogen atoms of Mod-B. Complete lists of bond distances and angles (Table S-1), anisotropic thermal parameters (Table S-2), hydrogen atom parameters (Table S-3), and observed and calculated structure factors (Table S-4) are available as supplementary material.[5]

Results and discussion

Structure of the two crystalline modifications of $[(PS)H^+][OTeF_5^-]$

Crystallization from dichloromethane solutions at two different temperatures, 22 and 4°C, produced two different modifications of this salt, Mod-A and Mod-B, respectively. Both modifications are stable indefinitely at room temperature. The samples were reversibly cooled from room temperature to 60 K with no change in their respective room temperature IR and Raman spectra, but warming Mod-B to 110°C, a temperature well below the melting or decomposition temperature (170°C), caused it to convert to Mod-A.

The structure of the cation and anion in Mod-B is shown in Fig. 1. The structural results (distances, angles, and thermal parameters) leave little doubt that at −130°C the teflate anion in Mod-B has been oriented, as in Mod-A (1), by the anisotropic cation and does not exhibit the O/F disorder observed for the alkali metal salts of $OTeF_5^-$ (2). As was observed for Mod-A as well as for other $OTeF_5$ compounds (1), the oxygen and fluorine atoms in Mod-B exhibit relatively large amplitude thermal motion (see Tables 2 and S-2), despite the low temperature at which the data set was collected. A standard rigid-body librational analysis was performed (7), $R = 0.033$ for the Mod-B anion. For Mod-B, the Te—O, Te—F1, and Te—F2 distances are 1.773(5) Å, 1.861(4) Å, and 1.857(2) Å, respectively. After correction for librational motion (7), these distances are 1.801 Å, 1.890 Å, and 1.876 Å, respectively. The O—Te—F2 bond angle, which is independent of the librational correction,

[5]Supplementary Tables S-1, S-2, S-3, and S-4 may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

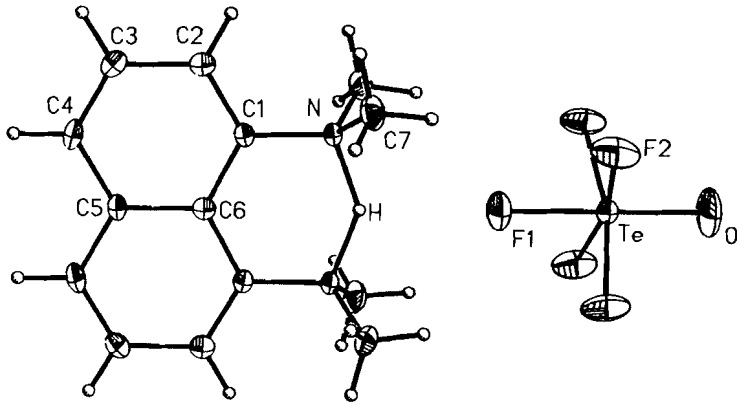

FIG. 1. A drawing of the $OTeF_5^-$ anion and the protonated Proton Sponge cation ($(PS)H^+$) in $[(PS)H^+][OTeF_5^-]$ Mod-B (50% probability ellipsoids). The separation of the ions is to scale.

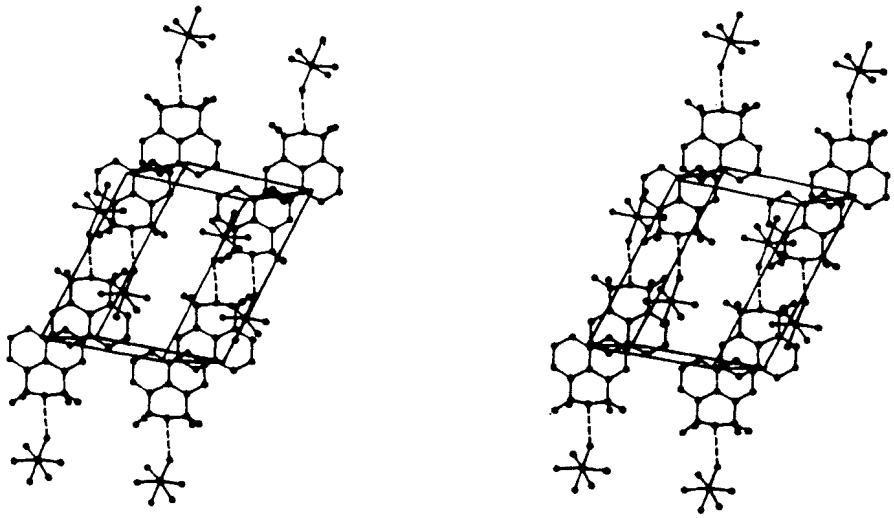

FIG. 2. A stereoview of the unit cell packing for $[(PS)H^+][OTeF_5^-]$, Mod-A.

is 97.2(1)° for Mod-B. Thus, the structure of the teflate anion in orthorhombic Mod-B is nearly the same as in triclinic Mod-A, for which the O—Te—F_{eq} bond angle is 95.2° and the Te—O and average Te—F bond distances, after correction for librational motion, are 1.803 Å and 1.870 Å, respectively.

While the bond distances and angles are nearly the same for Mod-A and Mod-B, the crystal packing of the two modifications is quite different. In Mod-A (Fig. 2), pairs of parallel $(PS)H^+$ cations, with their C5—C6 bonds oriented 180° with respect to each other, exhibit weak π–π overlap at a distance of 4.2 Å (the region of overlap is defined by C3, C4, and C5).[6] The $OTeF_5^-$ anion is in a pocket made up of four $(PS)H^+$ cations such that the librationally corrected distance between the oxygen atom and the N—H—N proton of one cation is 2.78 Å. It is easy to see why there is no O/F disorder in this modification, since O/F interchange would only allow O···H—C contacts to replace the observed O···$H(N)_2$ contact.

On the other hand, as shown in Fig. 3, each teflate anion in Mod-B is sandwiched between two $(PS)H^+$ cations whose naphthalene moieties are parallel and stacked along the x direction. Each of the four F2 atoms is only 3.032 Å from the centroid of a six-membered ring. The three closest F2···C contacts range from 3.201(2) Å to 3.315(2) Å. A distance between the teflate oxygen atom and the two N—H—N protons of these cations is 4.42 Å after correction for the librational motion of the $OTeF_5^-$ anion; the distance between F1, the axial fluorine atom, and the N—H—N proton of a third cation is 2.4 Å after librational correction. The observed crystal packing for Mod-B is also shown in the left side of Fig. 4.

Solid-state fluxional behavior of $[(PS)H^+][OTeF_5^-]$, Mod-B

At room temperature a single crystal of this salt exhibited two ν(TeO) bands in both IR and Raman spectra, at 856 and 869 cm^{-1}. The assignment was confirmed by oxygen-18 substitution, upon which both bands shifted by the appropriate amount, to 815 and 826 cm^{-1} (856/815 = 1.050, 869/826 = 1.052; for a simple TeO oscillator, $\nu(Te^{18}O)/\nu(Te^{16}O)$ = 1.053). At first, this result was surprising, since the solid-state structure of this salt at −130°C contains $OTeF_5^-$ anions in only one type of environment (see Figs. 1 and 3). It did not seem likely that the two bands were the result of coupling of the four symmetry-related TeO oscillators in the unit cell. The teflate anions are far apart and well insulated from each other by the $(PS)H^+$ cations: The closest Te···Te separation is 8.057 Å. Furthermore, the relative intensities of the two ν(TeO) bands are such that $I(856\ cm^{-1}) > I(869\ cm^{-1})$ in both IR and Raman spectra.

[6]The numbering scheme used to define atoms C3, C4, C5, and C6 in Mod-A (ref. 1) is the same used in Fig. 1 for Mod-B.

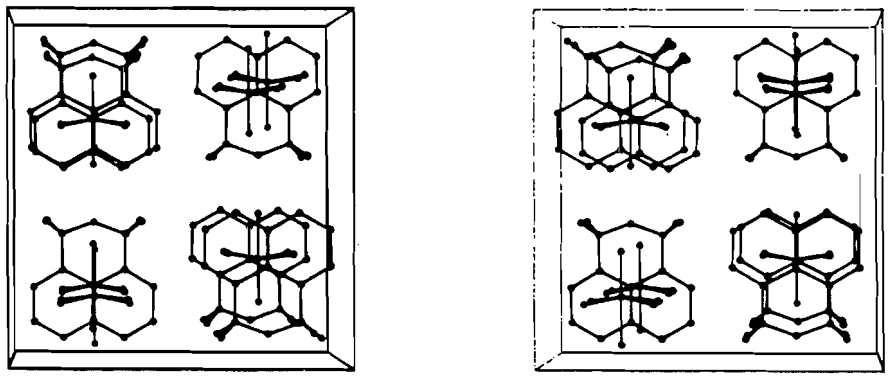

FIG. 3. A stereoview of the unit cell packing for $[(PS)H^+][OTeF_5^-]$, Mod-B.

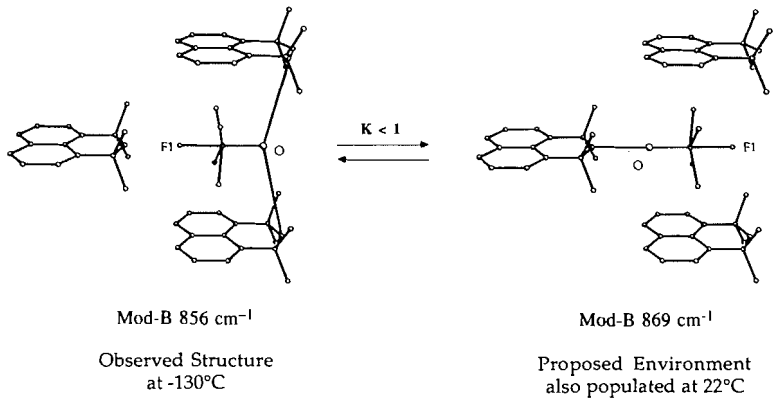

FIG. 4. A representation of the proposed solid-state equilibrium for $[(PS)H^+][OTeF_5^-]$, Mod-B. The oxygen (O) and axial fluorine (F1) atoms are labelled, and the oxygen atoms are linked to the closest N—H—N proton(s) by solid lines. The drawing on the left (the environment that gives rise to ν(TeO) = 856 cm^{-1}) shows the observed structure at −130°C, while the one on the right (the environment that gives rise to ν(TeO) = 869 cm^{-1}) depicts the proposed environment that is also populated at room temperature.

Upon further investigation, we found that the IR intensities of the two ν(TeO) bands are temperature dependent, as shown in Fig. 5. Below room temperature, the less intense 869 cm^{-1} band decreased in intensity as the 856 cm^{-1} band increased in intensity (the 832 cm^{-1} $(PS)H^+$ band served as an intensity standard since its bandwidth was relatively constant over the temperature range studied). The 869 cm^{-1} band disappeared completely below −70°C. We propose that the teflate anions in Mod-B are able to rotate about one or more axes through the tellurium atom with a low activation barrier, and that two nearly degenerate local environments exist for the $OTeF_5^-$ anions. The slightly more stable environment is the one shown in Figs. 1 and 3 and the left side of Fig. 4, which show the structure of Mod-B at −130°C; all teflate anions in Mod-B are in this environment below −70°C and have ν(TeO) = 856 cm^{-1}. The slightly less stable environment would be produced by rotating the anion so that the oxygen and axial fluorine atoms (F1) are interchanged, as shown in the right side of Fig. 4; teflate anions in this environment have ν(TeO) = 869 cm^{-1}. Figure 4 is a representation of this proposed solid-state equilibrium. Based on the intensities of the 856 and 869 cm^{-1} bands in the IR spectra of Mod-B, we conclude that the equilibrium constant $K < 1$ at room temperature and at lower temperatures.

A very simple model of nearest neighbor electrostatic attractions is in harmony with the proposal that O/F1 interchange produces two nearly degenerate environments in the structure of Mod-B. If one assumes that van der Waals and long range electrostatic contributions to the lattice energy (U) are essentially constant (C) for O/F1 interchange, that the N—H—N proton bears a full positive charge, and that the O and F1 atoms bear the amount of negative charge given by our *ab initio* calculations for the free $OTeF_5^-$ anion (1), then for the 856 cm^{-1} environment $U - C \propto [2(0.918/4.42) + (0.525/2.4)] = 0.63$ (recall that O···H = 4.42 Å and F1···H′ = 2.4 Å) while for the proposed 869 cm^{-1} environment $U - C \propto [(0.918/2.4) + 2(0.525/4.42)] = 0.62$. According to this admittedly simple model, the 856 cm^{-1} environment is predicted to be marginally more stable than the 869 cm^{-1} environment, in accord with our observations. Even allowing that the actual atom charges may differ from the values given by theoretical methods (1), it is reasonable to conclude that the two proposed environments for the teflate anion in Mod-B are nearly degenerate.

The activation barrier for the interchange of O and F1 could conceivably be very low for the nearly spherical teflate anion. Many symmetrical anions, such as BF_4^- (8), SbF_6^- (8), and PCl_6^- (9), rotate about one or more axes through the central atom. In many cases, this rotation leads to crystallographic disorder and incompletely solved structures. We decided to investigate the solid-state motion in Mod-B and other teflate salts by solid-state ^{19}F NMR spectroscopy (Figs. 6 and 7, Table 3). While several solid-state ^{19}F NMR studies have been reported since 1959 (10–18), it is only recently that magic angle spinning speeds of 18–20 kHz have allowed high-resolution spectra to be obtained (5, 19).

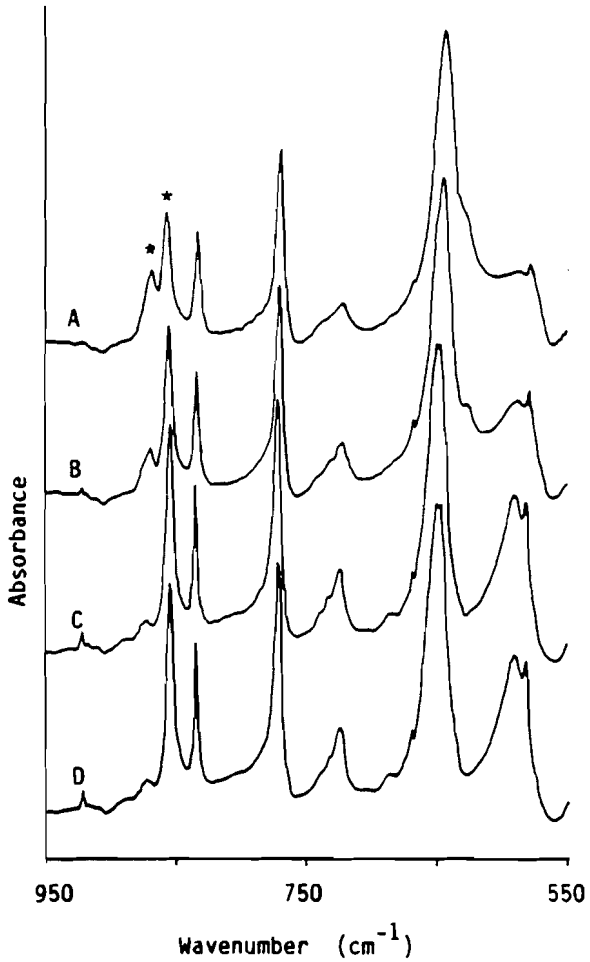

FIG. 5. Solid-state IR spectra of $[(PS)H^+][OTeF_5^-]$, Mod-B at room temperature (*A*), 250 K (*B*), 140 K (the temperature of the X-ray diffraction study of this compound) (*C*), and 60 K (*D*). The peaks at 869 and 856 cm^{-1} in the room temperature spectrum, marked with asterisks, are assigned as ν(TeO) bands based on ^{18}O substitution. Below 200 K, the weak, broad feature at ~860 cm^{-1} did not vary significantly in shape or intensity.

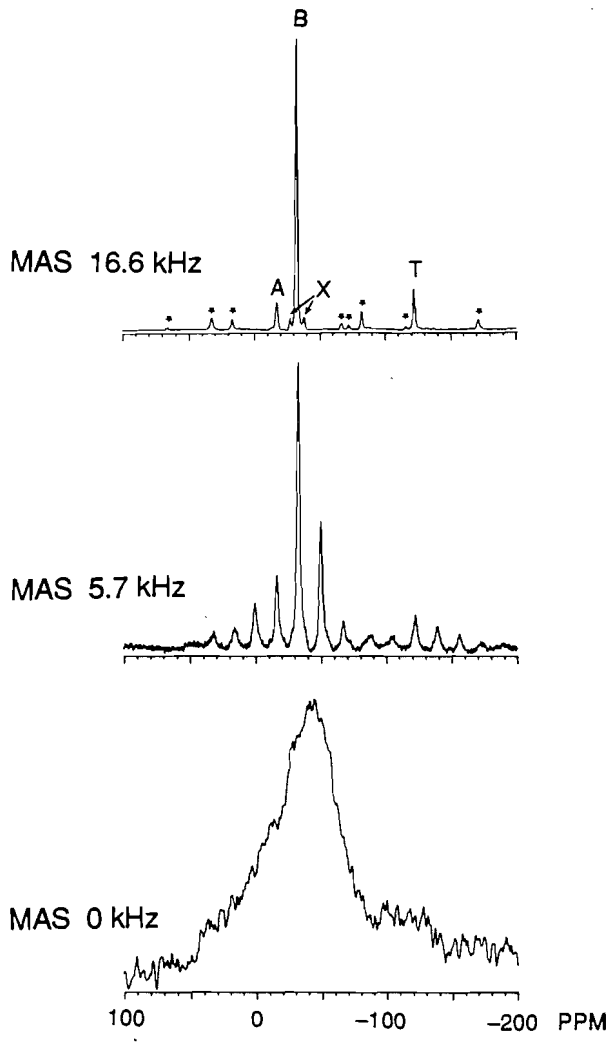

FIG. 6. Solid-state 338.7 MHz ^{19}F NMR spectra of $[(PS)H^+][OTeF_5^-]$, Mod-B as a function of MAS speed. The resonances in the 16.6 kHz spectrum are assigned as follows: axial fluorine, *A*; equatorial fluorines, *B*; ^{125}Te satellites for the equatorial fluorines, *X*; Torlon rotor, *T*. The spinning sidebands are labelled with asterisks.

The spectral lines for the four compounds we investigated, $[(PS)H^+][OTeF_5^-]$, Mod-A and Mod-B, $[N(n\text{-}Bu)_4^+][OTeF_5^-]$, and $[N(n\text{-}Bu)_4^+][H(OTeF_5)_2^-]$, were easily narrowed using high-speed magic angle spinning (MAS). However, the linewidths for each sample run at a MAS speed of about 10 kHz were essentially equal to those measured at MAS speeds greater than 16 kHz. This is evidence for the lack of strong homonuclear dipole–dipole interactions in these samples, since for strongly homonuclear dipolar coupled systems, the residual linewidth continues to decrease with increasing MAS speed until the spinning speed is much larger than the static linewidth, which for Mod-B is 18 kHz (Fig. 6). The linewidth observed in the static spectra (i.e. ~18 kHz for Mod-B) may be due to chemical shift anisotropy (CSA). However, an ^{19}F CSA of only 18 kHz seems too small, given that CSAs for fluoropolymers such as poly(tetrafluoroethylene) are ~46 kHz (19). Rapid rotation of the $OTeF_5^-$ anion, which would lead to O/F1 interchange in Mod-B, could explain the small static linewidth and the relatively low MAS speed needed to narrow the spectra, since such rotation would average, to some extent, dipolar interactions and CSA.

The two crystalline modifications of $[(PS)H^+][OTeF_5^-]$ have significantly different chemical shifts for their respective axial and equatorial fluorine atoms, both sets of which are different than the chemical shifts for $[N(n\text{-}Bu)_4^+][OTeF_5^-]$ (Table 3). Furthermore, the two crystallographically unique teflate groups in $[N(n\text{-}Bu)_4^+][H(OTeF_5)_2^-]$ also have different δ_A and δ_B values. Since the chemical shifts are so sensitive to the environment of the individual teflate groups, it is surprising that the equatorial fluorine atoms in $[(PS)H^+][OTeF_5^-]$ Mod-A, $[N(n\text{-}Bu)_4^+][OTeF_5^-]$, and in each of the two teflate groups in $[N(n\text{-}Bu)_4^+][H(OTeF_5)_2^-]$ do not display a *range* of chemical shifts: note that the δ_B linewidths for these compounds are no larger than that for Mod-B, in which the equatorial fluorine atoms are symmetry (and magnetically) equivalent. We tentatively conclude that the non-equivalent equatorial fluorine atoms in these compounds are being rendered magnetically equivalent by rapid rotation of each teflate group about, for instance, its O—Te—F_{ax} axis.

Rapid rotation of the teflate anion in Mod-B about an axis perpendicular to its O—Te—F_{ax} axis would lead to the facile room temperature interchange of O and F1 in this compound. This type of motion is supported by the observed anisotropic

Liquid	3643	3643	3654	3552

[a]Chemical shifts are relative to $CFCl_3$. Liquids experiments were dichloromethane solutions. All solid chemical shifts are ±0.3 ppm. $\Delta\nu_{1/2}$ values are in Hz. The MAS spinning speeds were (compound, speed (kHz): Mod-A, 16.3; Mod-B, 16.6; $[N(n\text{-}Bu)_4^+][OTeF_5^-]$, 15.2; $[N(n\text{-}Bu)_4^+][H(OTeF_5)_2^-]$, 15.6.
[b]Determined by spectral deconvolution.

thermal parameters for F2 (Table S-2): U along the ***b*** axis (the O—Te—F1 axis), 0.070(1) Å^2, is considerably larger than U along the ***a*** and ***c*** axes, 0.022(1) and 0.024(1) Å^2, respectively. Thus, the two different δ_A resonances that might be expected for the two $OTeF_5^-$ environments in Mod-B are time averaged to yield only one observed resonance. Assuming that $\Delta\delta_A$ (for F1) would be ~3 ppm for the two $OTeF_5^-$ environments in Mod-B (this is less than $\Delta\delta_A$ for $[N(n\text{-}Bu)_4^+][H(OTeF_5)_2^-]$), then the rate of O/F1 interconversion in the solid-state may be 10^4–10^5 s^{-1}. Of course, it is possible that the δ_A chemical shifts for the two proposed teflate environments in Mod-B are accidentally equal and that the rate of exchange is slow. We have attempted to study the solid-state motion of Mod-B by ^{19}F NMR $T_{1\rho}$ measurements, which can in principle be used

to measure rates of motion on this time scale. However, correlation times could not be extracted from the observed $T_{1\rho}$ values, since a plot of $1/T_{1\rho}$ versus the excitation field strength went through a minimum. This behavior is not predicted by any known theory (20). Perhaps it is due to modulation of the experimental $T_{1\rho}$ values by the MAS, the rate of which is on the same order of magnitude as the proposed time of motion.

In principle, MAS ^{19}F NMR experiments at temperatures low enough to slow down the proposed two-site interchange would allow the two δ_A resonances for Mod-B to be observed. However, achieving low temperatures while spinning the sample fast enough to average strong ^{19}F–^{19}F dipolar coupling is difficult due to the large volume of gas which must be cooled to spin the sample (5). Once these technical problems are solved, solid-state MAS ^{19}F NMR spectroscopy will become a valuable tool for the study of dynamic processes in solids.

A Raman spectral study of the equilibria of zinc bromide complexes in DMSO solutions

JEFF VAN HEUMEN, TORU OZEKI,[1] AND DONALD E. IRISH[2]

Department of Chemistry, University of Waterloo, Waterloo, Ont., Canada N2L 3G1

Received March 1, 1989

This paper is dedicated to Professor Ronald J. Gillespie on the occasion of his 65th birthday

JEFF VAN HEUMEN, TORU OZEKI, and DONALD E. IRISH. Can. J. Chem. **67**, 2030 (1989).

Using Raman spectroscopy, the stepwise formation of zinc bromide complexes in dimethylsulfoxide (DMSO) solution has been investigated. The presence of four different zinc bromide complexes is suggested and their Raman spectra have been extracted. The formation constant of each reaction has been estimated by the application of factor analysis to the spectra. The usual methods of factor analysis have been extended by the introduction of constraints imposed by the equilibria.

Key words: zinc bromide complexes, solvation in DMSO, Raman spectroscopy, factor analysis.

JEFF VAN HEUMEN, TORU OZEKI et DONALD E. IRISH. Can. J. Chem. **67**, 2030 (1989).

Faisant appel à la spectroscopie Raman, on a étudié la formation par étapes de complexes du bromure de zinc en solution dans le diméthylsulfoxyde (DMSO). Ces données suggèrent la présence de quatre complexes différents du bromure de zinc et on en a extrait leurs spectres Raman. Par l'application de l'analyse factorielle aux spectres, on a pu évaluer la constante de formation de chacune des réactions. Les méthodes usuelles de l'analyse factorielle ont été étendues par l'introduction des contraintes imposées par l'équilibre.

Mots clés : complexes du bromure de zinc, solvatation dans le DMSO, spectroscopie Raman, analyse factorielle.

Introduction

Professor Ronald J. Gillespie has had a long standing interest in the shapes of complexes and molecules. It is a pleasure to dedicate this article to him on the occasion of his 65th birthday.

Ahrland and co-workers have reported the results of detailed studies of metal complex formation between Group IIB metals and halide ions in the dipolar aprotic solvent, dimethylsulfoxide (DMSO) (1–9). Emphasis was placed on the thermodynamics of the stepwise equilibria and evidence for structural changes between successive complexes. The solvent, DMSO has been investigated quite extensively as a neat liquid (10–12), and as a solvent in which complex formation occurs. The complexes are more stable in DMSO than in water because the former has a lower dielectric constant (1, 3, 9). The uncomplexed metal cations — zinc, cadmium, or mercury — are believed to exist as octahedral species, the ions being solvated via oxygen by six DMSO molecules (6, 13, 14). However, evidence suggests that their coordination symmetry changes from six-coordinate octahedral to four-coordinate tetrahedral as higher halide complexes are formed. Enthalpy and entropy values for the cadmium halide system suggest that a coordination change occurs at the second step of complex formation: a step from $CdBr^+$ to $CdBr_2$ (2). For the zinc bromide complexes Ahrland *et al.* have suggested the possibility that the change occurs at the first step of complex formation in 1 *M* NH_4ClO_4 media: a step from Zn^{2+} to $ZnBr^+$ (4). In a succeeding paper (7), they reported that the step giving rise to the coordination change depends upon the co-existing salt and ionic strength of the solution, such that this change in coordination of the zinc bromide complex might occur at the second step in 0.1 *M* NH_4ClO_4 media. Several other methods such as NMR (15, 16) and X-ray diffraction (17) have also been used to study this kind of phenomenon. All reports support the view that the complex finally formed — $ZnBr_4^{2-}$ or $CdBr_4^{2-}$ — is a tetrahedral complex.

Raman spectroscopy is a useful tool for investigation of the structure of these complexes because the latter have Raman-active vibrational modes (18–21); and the technique is, in principle, capable of providing information about their geometry. From the Raman intensities information about the concentrations of each species can be obtained and hence the stability and equilibrium constants can be estimated. This work was undertaken to complement recent studies of zinc and cadmium bromide complexes in water (20, 21) and to extend those works to nonaqueous solutions. This work is focussed on zinc bromide complex formation in DMSO solutions, especially on the determination of the stepwise stability constants and the stage at which the coordination change takes place.

Experimental

Nine solutions were prepared by dissolving given amounts of zinc bromide (J. T. Baker, "Baker Analyzed") $ZnBr_2$ and different amounts of sodium bromide (BDH, Laboratory Reagent) NaBr in solvent DMSO (BDH, Analytical Reagent) $SO(CH_3)_2$. To prepare solutions with different R values (the molar ratio of total bromide to total zinc) sodium bromide was added. In the case of $R < 2.0$, zinc perchlorate (GFS Chemicals) $Zn(ClO_4)_2 \cdot 6H_2O$ was used in place of sodium bromide. The introduction of a small amount of water is not expected to introduce a serious problem as DMSO solvates zinc(II) much more strongly than water does (5, 9). R values of the sample solutions and their compositions are given in Table 1. Concentrations are given in mol kg^{-1} of DMSO.

Samples were placed in glass capillary tubes for Raman measurements. To avoid solvent evaporation the open end of the capillary was flame-sealed. All spectra were collected at a temperature of 25°C by using a thermostatted capillary tube holder.

Raman spectra were recorded using a Jarrell-Ash 25-100, 1.0 meter Czerny-Turner monochromator equipped with a digital cosecant stepping drive, an RCA 31034 selected photomultiplier tube, and an SSR model 1105/1120 photon counting system. Spectra were excited by the 514.5 nm line of a Spectra-Physics Ar^+ Laser, Model 165, operating at a power of 1400 mW. The spectrometer was interfaced to Commodore-Pet Model 2001 and 2040 computers. The digitized data were also analyzed by the DEC-PRO 380 and VAX 11/785 computers, using procedures such as spectral band fitting, exponential baseline correction, and factor analysis.

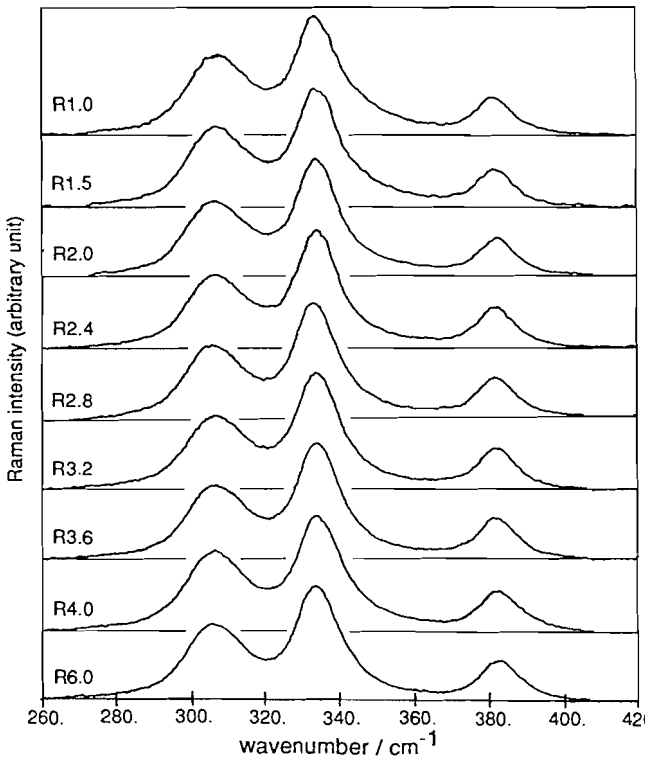

FIG. 1. The 260 to 420 cm^{-1} region of the Raman spectra of samples with the specified values of R.

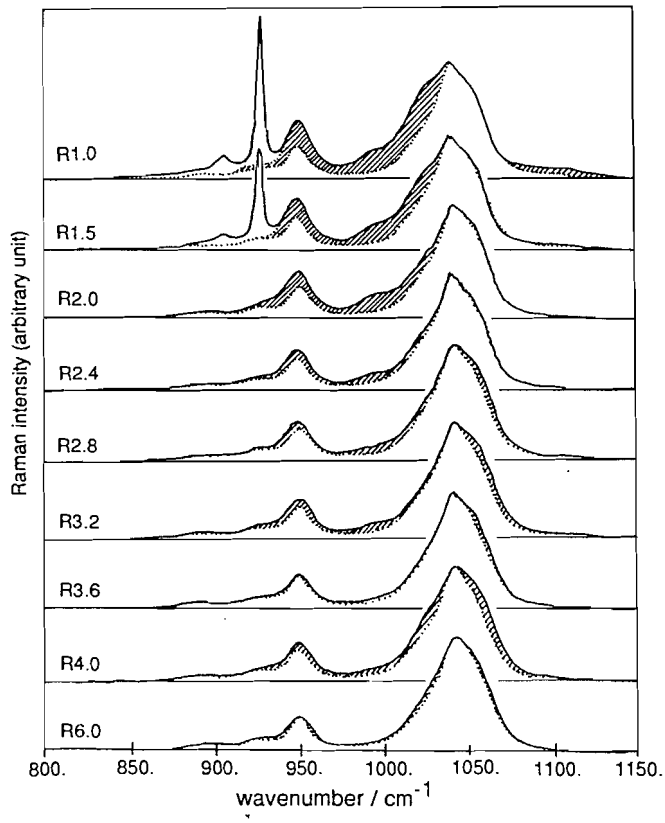

FIG. 2. The 800 to 1150 cm^{-1} region of the Raman spectra of samples with the specified values of R. Dotted lines are Raman spectra of pure DMSO solvent. The shaded part is the difference between the spectrum of the sample and that of pure DMSO.

Results and discussion

Four spectral regions: (*a*) 260 to 420 cm^{-1}, (*b*) 800 to 1150 cm^{-1}, (*c*) 600 to 750 cm^{-1}, and (*d*) 150 to 230 cm^{-1} are considered below.

(a) 260 to 420 cm^{-1} region of the Raman spectra

This region, shown in Fig. 1, contains the symmetric and the antisymmetric deformation bands of the carbon–sulfur–oxygen bond at 382 and 333 cm^{-1} respectively, as well as a carbon–sulfur–carbon deformation band at 305 cm^{-1}. No additional bands were observed and the three bands showed no significant change in band shape with the change in R value.

(b) 800 to 1150 cm^{-1} region of the Raman spectra

The bands of this region arise from the sulfur–oxygen vibration of DMSO. Figure 2 illustrates the effect of complexing on the sulfur–oxygen vibration of the DMSO molecule as the R value increases. Solid lines are the Raman spectra of each sample and dotted lines show the spectra of neat DMSO. Sharp peaks observed at 930 cm^{-1} for R = 1.0 and 1.5 samples correspond to the $\nu_1(a_1)$ symmetrical stretching vibration of perchlorate ion. The shaded area between the solid and the dotted lines indicates the difference between the spectrum of the neat solvent and that of the sample solution; it arises from the perturbed sulfur–oxygen bond, resulting from the solvation by DMSO molecules of the zinc cation (cf. ref. 6). The decrease in the shaded area suggests the decrease in the amount of DMSO solvating the zinc cation as the bromide concentration increases. The sulfur–oxygen stretching band, seen in Fig. 2 at 1042 cm^{-1}, provides indirect information for the zinc–DMSO bonding. If some interaction occurs between zinc cation and oxygen of the DMSO molecule, the metal cation will attract the electron cloud of the sulfur–oxygen bond, and as a result reduce the bond order of the sulfur–oxygen bond. Consequently, the vibrational energy will be lowered and the Raman band position will shift to a lower wavenumber. The evidence for this shift is clearly seen at R = 1.0 in Fig. 2; a new band appears at 1017 cm^{-1} (1021 cm^{-1} in the solid solvate (6)). On increasing the R value, obviously there is seen a decrease in the intensity of this new band. At R = 3.2, the new peak no longer exists. This fact is interpreted as desolvation of DMSO from the solvation sphere of the zinc cation to the free bulk state.

(c) 600 to 750 cm^{-1} region of the Raman spectra

This wavenumber region is dominated by a symmetric stretching band at 670 cm^{-1} and an antisymmetric stretching band at 700 cm^{-1}, both due to the carbon–sulfur bonding in the DMSO molecule. Figure 3 provides comparison of the

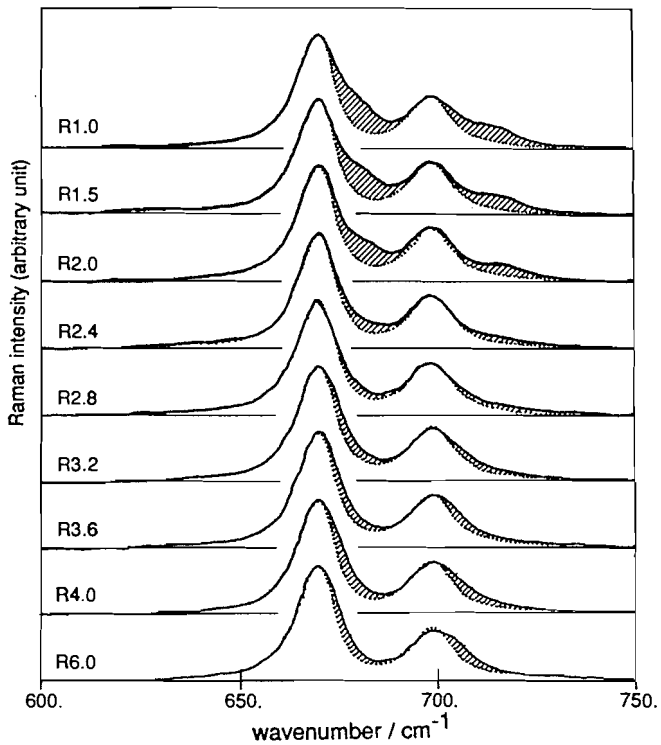

FIG. 3. The 600 to 750 cm^{-1} region of the Raman spectra of samples with the specified values of R. Dotted lines are Raman spectra of pure DMSO solvent. The shaded part is the difference between the spectrum of the sample and that of pure DMSO.

Raman spectra of the neat DMSO (dotted lines) and the DMSO/Zn^{2+}–Br^- mixtures (solid lines). The shaded area between the two spectra indicates the difference between the spectrum of the neat solvent and that of the sample solution. At the lowest R value, $R = 1.0$, two additional peaks appear at higher wavenumbers, 681 and 714 cm^{-1} (683 and 717 cm^{-1} in the solid solvate (6)). As described in the previous section the solvation of zinc ion by DMSO molecules reduces the bond order of the sulfur–oxygen bond. This may cause the adjacent carbon–sulfur bond to acquire extra electron density and its bond strength to increase. As a matter of fact, the peak wavenumber of the carbon–sulfur vibration shifts to a higher wavenumber. It is important to note that with an increasing R value the intensity of the shifted peak decreases considerably. At approximately $R = 2.8$ to $R = 3.2$ these additional bands have essentially disappeared, again. This intensity decrease seems to be consistent with the decrease in the number of DMSO molecules solvating zinc cation.

(d) 150 to 230 cm^{-1} region of the Raman spectra

The fourth region contains the vibrations due to the zinc bromide complexes as a whole (Fig. 4). These original spectra contain an exponential background due to the Rayleigh scattering. This background was subtracted by using an exponential-quadratic base-line correction program (22, 23), to give Fig. 5.

Three Raman bands at 197, 180, and 166 cm^{-1} corresponding to zinc bromide complexes are clearly seen in Fig. 5. At the low R values the presence of an additional band is also expected at 207 cm^{-1}. (A very weak shoulder at ~176 cm^{-1} for $R = 1.0$ (Fig. 4) corresponds to a band of the hexasolvate observed by Sandström *et al.* (6).) The band at 166 cm^{-1} is detected only for $R > 3.2$. These four bands seem to be related to four complexes: $ZnBr^+$, $ZnBr_2$, $ZnBr_3^-$, and $ZnBr_4^{2-}$. Ahrland *et al.* have

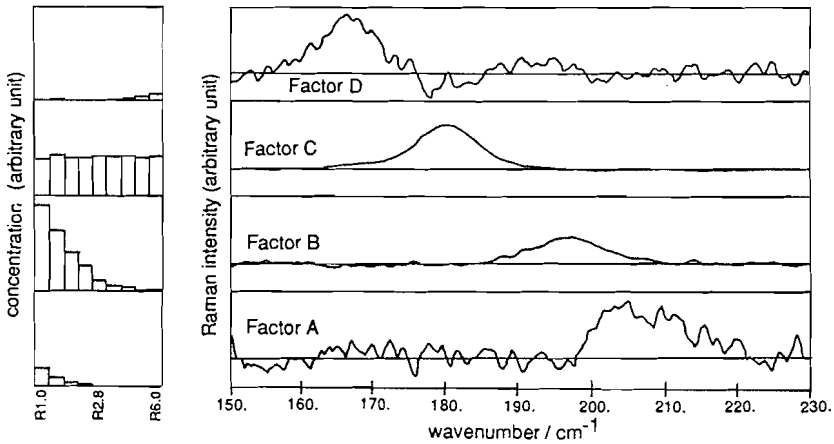

FIG. 7. The Raman spectrum of each species and its concentration distribution obtained after applying the equilibrium constraints among species.

reported the presence of three complex species — $ZnBr^+$, $ZnBr_2$, and $ZnBr_3^-$ (7, 8) — and have calculated their formation constants from calorimetric data. When the concentrations of the species are calculated using their formation constants, it is proposed that the dominant species at $R = 3.2$ is $ZnBr_3^-$; this proposal is consistent with the fact that the Raman spectrum has only one peak at 180 cm^{-1} for the $R = 3.2$ sample (Figs. 4 and 5). This fact allows an identification of the bands as follows: 207 ($ZnBr^+$), 197 ($ZnBr_2$), 180 ($ZnBr_3^-$), and 166 cm^{-1} ($ZnBr_4^{2-}$). The obvious appearance of the 166 cm^{-1} peak at $R > 3.2$ confirms the existence of the $ZnBr_4^{2-}$ complex.

In order to isolate the spectrum of each species from the overlapped spectra, factor analysis was applied to this spectral region after base-line correction. It was difficult to obtain the absolute intensities of each spectrum from experiments. Thus all spectra were normalized assuming the intensity at 180 cm^{-1} to be constant (see Fig. 5): $ZnBr_3^-$ standard. The procedure for the factor analysis is described in Appendix A. The analysis showed that three or four factors are necessary to reproduce the measured spectra. The indication of four factors (four complexes) was adopted, as this is consistent with the existence of four bands described above. In this case, the spectra shown by the dotted lines in Fig. 5 were reproduced and are in good agreement with the measured spectra as shown by solid lines in Fig. 5.

The extracted spectra of each pure species and their concentration distributions are shown in Fig. 6. The spectrum of Factor A and that of Factor D show some negative Raman intensities; and this fact indicates that this result is not necessarily correct. In factor analysis, many combinations of spectra and concentration distributions, namely **R** and **C** matrices (being introduced in Appendix A), reproduce the same spectral data (**I**). We can rotate the bases of these two matrices **R** and **C**, while keeping their product **I** constant. To carry out a meaningful rotation of the matrix, we adopted a new method, called Factor Analysis with Equilibria Constraints (FAEC) described in Appendix B, which took into account information about the equilibria among species. As a result, the spectrum of each species and its concentration change as shown in Fig. 7 were obtained. The spectra of Factors A and D still have a large contribution from the noise component, but no longer have any significant negative intensity. The formation constants were also obtained by the treatment of Appendix B and are tabulated in Table 2, together with the values determined calorimetrically (4–7). The calorimetric results suggested that the formation constants depend strongly on the ionic media; for example, in the case of 1 *M* NH_4^+, interaction between NH_4^+ and Br^- is expected. Recognizing such dependence upon the solution composition, the formation constants obtained in this work are fairly consistent with the others. Our analysis does not lead to precise estimates of the errors associated with the formation constants, other than the goodness of fit to the original spectra (Fig. 5).

TABLE 2. Stepwise stability constants of zinc bromide complexes in DMSO

Parameter	Value			
	1 *M* NH_4^+	0.1 *M* NH_4^+	1 *M* Na^+	This work
log K_1	0.85	1.86	1.56	1.6
log K_2	2.89	3.31	3.11	3.2
log K_3	1.35	1.98	2.05	2.2
log K_4	—	—	—	−0.6

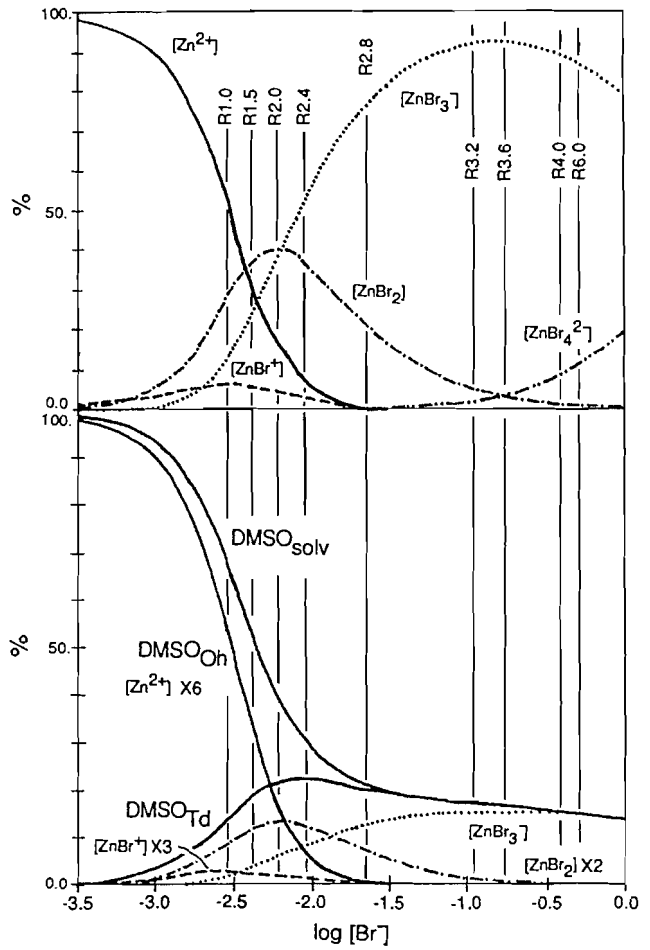

FIG. 8. The calculated concentration distribution of zinc-containing species (upper figure) and the fractions of DMSO molecules solvating the zinc-containing species (lower figure).

Considering errors in base-line construction and signal noise, uncertainties of ±10% would not be unreasonable. Raman spectroscopy is particularly valuable for identifying species and equilibria but lacks the precision available from such methods as potentiometry for quantitative analysis.

Distribution curves for each species are shown in Fig. 8. In the upper panel of Fig. 8, the fractions of each species are plotted versus logarithmic values of the free bromide concentration. Nine vertical lines show the corresponding positions of log $[Br^-]$ of the sample solutions used for this work, labelled with each R value. The figure indicates that the predominant equilibrium is between $ZnBr_2$ and $ZnBr_3^-$ in the range from $R = 2.4$ to 3.2. On the other hand, when log $[Br^-] > -1$, namely $[Br^-] > 0.1$, the contribution from the species $ZnBr_4^{2-}$ becomes important. Ahrland *et al.* reported that $ZnBr_4^{2-}$ is negligible; it was not required in the previous interpretation of the calorimetric data (7, 8). Our results, however, positively suggest the presence of $ZnBr_4^{2-}$. This ion is well characterized in aqueous solutions (20, 24).

Ahrland *et al.* have concluded that the complex with two or more bromide ions is tetrahedral; but $ZnBr^+$ might be octahedral in some ionic media (7, 8). The ~15 cm^{-1} equi-interval shift of Raman bands of successive zinc bromide complexes to lower wavenumbers, as shown in Fig. 7, may suggest that the four complex species have the same coordination; thus $ZnBr^+$ may also be a tetrahedral ion, and only the Zn^{2+} solvated ion is octahedral. The concept that $ZnBr^+$ has tetrahedral coordination is consistent with the earlier report of Ahrland, carried out in 1 *M* NH_4ClO_4 media (4).

The lower panel of Fig. 8 gives the calculated result for the fraction of DMSO molecules solvating zinc ion plotted versus log $[Br^-]$ (*i.e.*, logarithmic values of the free bromide concentration), assuming that free Zn^{2+} ion has octahedral solvation The amount of DMSO octahedrally solvating zinc ion, $DMSO_{O_h}$ of Fig. 8, rapidly decreases and becomes almost zero at $R = 2.8$. The total amount of DMSO molecules tetrahedrally solvating zinc ion, $DMSO_{T_d}$ of Fig. 8, increases with the increase of the R value. Comparing Fig. 2 and Fig. 3 with the lower panel of Fig. 8, the following picture can be imagined: the DMSO which is responsible for the shifted Raman bands, the shaded parts of Fig. 2 and Fig. 3, is octahedrally solvating the "free" zinc ion, not the tetrahedral species. Thus the shaded parts disappear at about $R = 2.8$. This opinion is still speculative, but seems to be reasonable when we consider that any zinc bromide complex has a less positive central charge due to the effect of the negative charge on the attached bromide; and an effective attraction for the electrons of DMSO by the complex becomes weaker than in the case of the di-charged free zinc ion. It is also worth noting that the hexaaquozinc ion gave a Raman signal, but not the bromide-containing complexes (20). Equilibria among Zn^{2+}, $ZnBr^+$, $ZnBr_2$, $ZnBr_3^-$, and $ZnBr_4^{2-}$ explain all the properties of the Raman spectra observed for DMSO solutions.

In conclusion, the Raman spectra of DMSO solutions containing zinc bromide complexes give information about the stepwise formation of the zinc bromide complexes as well as information about the structure arising from the solvating DMSO molecules.

Appendix A: General procedure of factor analysis

Factor analysis is a powerful procedure for the analysis of overlapped spectra (25–28). A data matrix **I** is formed from the Raman intensities; in this work nine solutions were prepared and the intensities of 80 wavenumber points were used for each spectrum. All spectra used were normalized at 180 cm^{-1} so as to have constant intensity. The data matrix **I** consists of 80 rows and 9 columns. Each column corresponds to the intensity-normalized (at 180 cm^{-1}) spectrum of each sample solution. A second-moment matrix (sometimes called covariance matrix) **Z** is obtained by multiplication of the data matrix **I** with its transposed matrix $^t\mathbf{I}$.

$$[1] \quad \mathbf{Z} = {}^t\mathbf{I}\,\mathbf{I}$$

Using the Jacobi method, an eigenvalue matrix **E** and an eigenvector matrix **Q** are obtained.

$$[2] \quad \mathbf{Z} = {}^t\mathbf{Q}\,\mathbf{E}\,\mathbf{Q}$$

The eigenvalue matrix **E** will have the same number of rows as **Z**. The number of independent components in the sample spectra, NC, can be obtained from the *IND* function introduced by Malinowski (29) or by checking the original data matrix **I** with the reproduced data matrix **I**′ assuming a proper number of NC.

In the case of NC factors, the eigenvectors corresponding to the NC largest eigenvalues can be taken out and aligned in rows to construct a new matrix **C**, known as the first expression for the concentration matrix. By multiplying the transpose of the concentration matrix **C** with the data matrix **I** a new matrix **R** is obtained, which is known as the spectral matrix.

$$[3] \quad \mathbf{R} = \mathbf{I}^t\mathbf{C}$$

When the spectral matrix **R** is multiplied with the concentration matrix **C**, a theoretical data matrix is reproduced.

$$[4] \quad \mathbf{I}' = \mathbf{R}\,\mathbf{C}$$

The reproducibility of the theoretical data matrix can be examined by calculating the error function *ER*, which is the sum of the squares of the differences of each element of two matrices **I** and **I**′ (26, 27).

$$[5] \quad ER = (\Sigma_i\Sigma_j((\mathbf{I})_{ij} - (\mathbf{I}')_{ij})^2)^{1/2}/(\Sigma_i\Sigma_j((\mathbf{I})_{ij})^2)^{1/2}$$

where $(\mathbf{I})_{ij}$ indicates the element at ith row and jth column of the matrix **I**. The optimum number of factors, NC, can be selected as the number where convergence of *ER* is observed.

In this work *IND* function proposed the presence of three factors; and *ER* function proposed three or four factors as independent factors. From the discussion of the number of complexes in the sample solutions (see text), factor number NC = 4 was adopted. The result from the *IND* function simply implies that the contribution of the peak at 207 cm^{-1} ($ZnBr^+$) to the observed Raman spectra is very small. As a result, a spectral matrix **R** of 80 rows and four columns, and a concentration matrix **C** of four rows and nine columns were obtained. Each column of **R** corresponds to the spectrum of each constituent as shown in Fig. 6, and each row of the concentration matrix **C** corresponds to a concentration distribution of this constituent.

Appendix B: Rotation of bases of R and C based on the equilibria among the species — Application of FAEC (Factor Analysis with Equilibrium Constraints)

The **R** and **C** matrices sometimes contain negative values. The result of Appendix A is such a case. Now the bases of matrices can be rotated to avoid such negative values.

$$[6] \quad \mathbf{R}^0 = \mathbf{R}\,\mathbf{T}_R$$

$$[7] \quad \mathbf{C}^0 = \mathbf{T}_C\,\mathbf{C}$$

If the square rotation matrices $\mathbf{T}_R$ and $\mathbf{T}_C$ have the following relationship,

$$[8] \quad \mathbf{T}_R\,\mathbf{T}_C = \mathbf{U}$$

where **U** is the unit matrix having unit value as diagonal elements and zero value as other elements, the product of $\mathbf{R}^0$ and $\mathbf{C}^0$ remains exactly the same as **I**′ (eq. [4]).

We assume the following equilibrium reaction for the stepwise zinc bromide complex formation:

$$[9] \quad AX_{m-1} + X = AX_m$$

Then, we can express the stepwise formation constant K_m as follows,

$$[10] \quad K_m = [AX_m]/[AX_{m-1}][X]$$

where the relation between the cumulative stability constant β and the stepwise formation constant K_m is expressed as follows,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/07/12
For personal use only.

[11] $\beta = K_1 K_2 \cdots K_m$

In this work, we assume the presence of four zinc bromide complexes; thus we have four K's. If the values of K's and the total amount of the reagents (zinc ion and bromide ion) are known, the real concentration of each species in each solution, which corresponds to the elements of the true concentration matrix $\mathbf{C}^0$, can be calculated assuming the activity coefficients are unity. The matrix obtained from factor analysis, $\mathbf{C}$, can be related to this $\mathbf{C}^0$ by using the proper rotation matrix $\mathbf{T}_C$ through eq. [7]. The elements of the rotation matrix, $\mathbf{T}_C$, can be obtained by applying the nonlinear least squares method to minimize the following function *LSM* (30).

[12] $LSM = \Sigma_i \Sigma_j ((\mathbf{C}^0)_{ij} - (\mathbf{T}_C \mathbf{C})_{ij})^2$

A set of K values gives one *LSM* value. By iterative refinement of K values so as to give a minimum *LSM* value, finally an optimum set of K's and $\mathbf{T}_C$ is obtained. Thus the optimum matrices $\mathbf{C}^0$ and $\mathbf{R}^0$ are also obtained using eqs. [6]–[8]. As a result, this procedure produced the spectra and the concentration distributions as shown in Fig. 7, as well as a set of formation constants as tabulated in Table 2. As a matter of course, the concentration of the free bromide ion used for the abscissa in Fig. 8 were also determined. For initial values of the parameters, K's, the literature values of Ahrland and Persson were used (8).

New pentafluorothio(SF_5) alkylsulfonic acids

ROBERT J. WILLENBRING, JAVID MOHTASHAM, R. WINTER, AND GARY L. GARD
Department of Chemistry, Portland State University, Portland, Oregon, U.S.A. 97207-0751

Received February 16, 1989

This paper is dedicated to Professor Ronald J. Gillespie on the occasion of his 65th birthday

ROBERT J. WILLENBRING, JAVID MOHTASHAM, R. WINTER, and GARY L. GARD. Can. J. Chem. **67**, 2037 (1989).

New pentafluorothioalkylsulfonic acids, $F_5SCXHCY_2SO_3H$ (X, Y = H, F), and the corresponding salts have been prepared from pentafluorothioalkyl bromides or olefins with sodium sulfite or sodium bisulfite. The compounds are characterized by ir, nmr (^1H, ^{19}F, ^{13}C), and mass spectra.

Key words: new pentafluorothioalkylsulfonic acids.

ROBERT J. WILLENBRING, JAVID MOHTASHAM, R. WINTER et GARY L. GARD. Can. J. Chem. **67**, 2037 (1989).

On a préparé de nouveaux acides pentafluorothioalkylsulfoniques, $F_5SCXHCY_2SO_3H$ (X, Y = H, F), ainsi que les sels correspondants à partir des bromures de pentafluorothialkyles (ou des oléfines correspondantes) et du sulfite ou du bisulfite de sodium. On a caractérisé les composés par spectroscopies ir, rmn (^1H, ^{19}F et ^{13}C) et de masse.

Mots clés : nouveaux acides pentafluorothio (SF_5) alkylsulfoniques.

[Traduit par la revue]

Introduction

In our continuing efforts in preparing new fluoroalkylsulfonic acids for use as fuel cell electrolytes we have found that pentafluorosulfur fluoroolefins can add the hydrogen sulfite ion in the presence of a free radical initiator to give β-SF_5 – fluoroethyl sulfonic acid salts in low yields. However, a more promising method involved the substitution of β-SF_5 – fluoroethyl bromides with sulfite ion.

Previously, only the pentafluorosulfur sulfonic acids $F_5SCHFSO_3H$ (1), and $F_5SCH_2SO_3H$ (2) have been reported.

Results and discussion

We have found that treatment of $F_5SCXHCY_2Br$ (X, Y = H, F) with sodium sulfite afforded the corresponding salt:

[1] $$F_5SCHXCY_2Br + Na_2SO_3 \xrightarrow{50\%\ CH_3CH_2OH} F_5SCHXCY_2SO_3Na + NaBr$$

In the case where X, Y = H, $F_5SCH{=}CH_2$ was found as a by-product; in this case the sulfite acts as a dehydrohalogenating agent.

The reaction of alkylhalides with sulfite is usually considered a nucleophilic displacement of the halogen by the sulfite ion:

[2] $$F_5SCHXCY_2Br + SO_3^{2-} \rightarrow F_5SCHXCY_2SO_3^- + Br^-$$

An alternate radical anion mechanism has been suggested for similar reactions (3). This would result in the following scheme:

[3] $$F_5SCHXCY_2Br + SO_3^{2-} \rightarrow F_5SCHXCY_2Br^{\cdot-} + SO_3^{\cdot-}$$

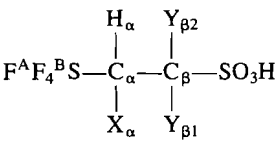
[4] $$F_5SCHXCY_2Br^{\cdot-} \rightarrow F_5SCHXCY_2\cdot + Br^-$$

[5] $$SO_3^{2-} + F_5SCHXCY_2\cdot \rightarrow F_5SCHXCY_2SO_3^{2\cdot-}$$

[6] $$F_5SCHXCY_2SO_3^{2\cdot-} + F_5SCHXCY_2Br \rightarrow F_5SCHXCY_2SO_3^- + F_5SCHXCY_2Br^{\cdot-}$$

Extraction of the dried residue, which contained the metal sulfite salt formed in eq. [6] ($F_5SCHXCY_2SO_3Na$) and NaBr, with 100% ethanol did not afford the pure salts, except for the compound where X, Y = H. However, when the solid residue was treated with excess aqueous hydrochloric acid only the sulfonic acids dissolved; the other by-products were removed by filtration.

[7] $$F_5SCHXCY_2SO_3Na + \text{excess } HCl_{(aq)} \rightarrow F_5SCHXCY_2SO_3H + NaCl_{(s)}$$



Evaporation of the filtrate left behind sulfonic acid hydrates (or in one case an acid) that were purified by sublimation. In this manner, the two acid hydrates, $F_5SCHFCF_2SO_3H\cdot H_2O$ and $F_5SCH_2CF_2SO_3H\cdot H_2O$, as well as the anhydrous $SF_5CH_2CH_2SO_3H$ were prepared. $F_5SCF_2CF_2Br$ failed to produce the corresponding sulfonic acid in sufficient yield and purity.

As a second method, metal bisulfite addition to SF_5-fluoroolefins in a buffered solution and in the presence of benzoyl peroxide was investigated:

[8] $$F_5SCX{=}CF_2 + NaHSO_3 \xrightarrow{(\phi COO)_2,\ \Delta} F_5SCHXCF_2SO_3Na \qquad X = H, F$$

The yields of these reactions were low; this pathway does not seem to be a useful method for preparing SF_5 containing sulfonic acids.

The nmr spectra of all compounds are in accord with the proposed structures:

X, Y = H, F

In the ^1H nmr spectra of the acids and their salts, it is observed that the chemical shifts of the protons are in the region expected for SF_5 hydrocarbons; the protons are found in the ~4–7 ppm range (4, 5). In three cases the couplings of the equatorial fluorines (SF_4) and the couplings of the aliphatic fluorines to the α protons could be determined; for the rest a complex multiplet was observed. These couplings are in line with the expected values. The acid protons appeared at a strongly deshielded position (>12 ppm) as somewhat broadened singlets.

In the ^{19}F nmr spectra, the SF_5 group was observed as an AB_4 system in all cases. When a CH_2 group is α to the SF_5 group, the chemical shift values are $\phi_A \sim 80$ ppm and $\phi_B \sim 70$ ppm, but with a fluorine atom substituted in the α-CH_2 group these values are shifted to $\phi_A \sim 70$ ppm and $\phi_B \sim 53$ ppm. These results are in agreement with the literature (4, 5). The coupling constants observed for the SF_5 group (J_{AB}) range from 145–150 Hz (4, 5).

In the ^{13}C spectra of the acids, the chemical shift sequence of $C_\alpha C_\beta$ in $F_5SC_\alpha C_\beta$ is inverted in going from $F_5SCH_2CH_2SO_3H$ to the two fluorinated acids. The two carbons appear as a pentet and are readily identified by the magnitude of the CB_4 coupling: $J_{C_\alpha B_4}$ = 14–23 Hz and $J_{C_\beta B_4}$ = 0–7 Hz, as established by measuring the ^{13}C spectra of SF_5 and SF_4X compounds (2, 6). In no case was coupling of the axial fluorine of the SF_5 group to either C_α or C_β observed.

The most prominent feature of the infrared spectra for the new compounds are the sulfur–fluorine symmetric and antisymmetric stretching modes in the region from 830 to 885 cm^{-1}. The other major bands are consistent with the assigned structures, with the SO_3 symmetric and antisymmetric modes from 1059 to 1100 cm^{-1} and 1180 to 1280 cm^{-1}, respectively, and the CF-stretching modes appearing at slightly higher frequencies, between 1100 and 1300 cm^{-1}. Because of this overlap, unambiguous assignment of the bands is not possible. The SO_3 scissor and wag vibrational modes are visible at 550 and 570 cm^{-1}.

The mass spectra of $F_5SCH_2CH_2SO_3H$, $F_5SCH_2CF_2SO_3H\cdot H_2O$, and $F_5SCHFCF_2SO_3H\cdot H_2O$ are similar, especially for the lower molecular weight fragments. *m/e* values of 127 (SF_5^+), 108 (SF_4^+), 89 (SF_3^+), 70 (SF_2^+), and 51 (SF^+) provide evidence for the presence of the SF_5 group in all three acids. The SF_3^+ fragment is the base peak in each case, while none of the compounds had a molecular ion. The remainder of the cracking patterns are consistent with the structures assigned to these compounds. The fast atom bombardment technique was used to obtain mass spectra of the sodium salts in a glycerol matrix. Two prominent peaks in all three salts corresponded to a composition MNa^+ and M_2Na^+. The fragmentation pattern was similar to the acids, especially for low molecular weight fragments. The peaks attributable to the SF_5-group are not as apparent, as only the SF_3^+ fragment had an appreciable intensity.

Experimental

General procedure

Gaseous materials were handled in a conventional Pyrex-glass vacuum apparatus. $F_5SC_2H_4Br$, $F_5SCH_2CF_2Br$, $F_5SCHFCF_2Br$, $F_5SCF{=}CF_2$, and $F_5SCH{=}CF_2$ were made according to the literature (7–9). Infrared spectra were obtained by using solid samples between KBr or KRS-5 disks on a Nicolet 20 DX spectrometer. The nmr spectra were recorded with a Varian model EM-390 spectrometer (90 MHz for proton, 84.67 MHz for fluorine). ^{13}C spectra were obtained on a General Electric QE-300 spectrometer operating at 75 MHz. Melting points were determined with a Mel-Temp capillary melting point apparatus and are uncorrected. Mass spectra were taken on a VG 7070 mass spectrometer at 70 eV; perfluorokerosene was the internal standard. Elemental analyses were determined by Beller Mikroanalytisches Laboratorium, Göttingen, West Germany.

1. Synthesis of $F_5SCH_2CH_2SO_3H$

1a. $F_5SCH_2CH_2SO_3Na$ from $F_5SC_2H_4Br$ and Na_2SO_3

In a 250 mL round bottomed flask, fitted with a Frederick condenser, 11.65 g (49.6 mmol) of $F_5SCH_2CH_2Br$, 6.24 g (49.5 mmol) of Na_2SO_3, and 164 mL of 50% aqueous ethanol were gently refluxed with stirring for 72 h. The solvent was removed by evaporation and the residue was transferred to a Soxhlet unit and extracted with 150 mL 100% ethanol. After evaporation of the solvent, 10.0 g of $F_5SCH_2CH_2SO_3Na$ was left behind as a white powder; dec. ≈ 260°C. Yield: 78.4%. A pure sample was obtained by first forming the free acid, subliming and titrating it, as described in Part 1*b*.

^{19}F nmr spectrum (D_2O, $CFCl_3$ ext): AB_4 system (SF_5), ϕ_A = 84.1 ppm (9 lines); ϕ_B = 65.6 ppm (d–m), J_{AB} = 144 Hz, J_{BCH_2} = 7.8 Hz. Int. A:B = 1.0:4.2.

^1H nmr (D_2O, $Si(CH_3)_4$ ext.): δ_1 = 4.58 ppm (m, $F_5SC\underline{H}_2CH_2$); δ_2 = 3.96 ppm (m, $F_5SCH_2\underline{CH}_2$). Int. δ_1:δ_2 = 1.0:1.0.

^{13}C nmr (D_2O, $Si(CH_3)_4$ ext.): δ_α = 65.4 ppm (p); δ_β = 46.9 ppm (p); J_{BC_α} = 15.86 Hz; J_{BC_β} = 4.72 Hz.

1b Acidification of $F_5SCH_2CH_2SO_3Na$ with HCl

A 200 mL three-necked round bottomed flask containing 19.1 g of the evaporation residue from above (before Soxhlet extraction), dissolvd in ~100 mL of H_2O, was fitted with a reflux condenser and a gas bubbler. Excess HCl was bubbled into the stirred solution. A white precipitate formed and the solution turned yellow. The mixture was filtered, reduced in volume by heating, transferred to a 50 mL round bottomed flask, and dried under vacuum. Sublimation (100°C, <10 μ) left 4.3 g of $F_5SCH_2CH_2SO_3H$ as a colorless crystalline solid; mp 60°C. Yield = 13.0% (with respect to 0.077 mol of starting $SF_5CH_2CH_2Br$). The equivalent weight was 231 g/equiv. (theoretical 236 g/equiv.). The solution was clarified with activated charcoal, filtered, and brought to dryness, leaving pure $F_5SC_2H_4SO_3Na$.

^{19}F nmr (D_2O, $CFCl_3$ ext.): SF_5, ϕ_A = 82.5 ppm (9 lines), ϕ_B = 65.4 ppm (d–m), J_{AB} = 145 Hz. Int. A:B = 1.0:4.1.

^1H nmr (CD_3CN, $Si(CH_3)_4$ ext.): δ = 4.34 ppm (m, $F_5S\underline{CH}_2$), int. = 2.0; δ = 3.94 ppm (m, $F_5SCH_2\underline{CH}_2$), int. = 1.0; δ = 12.1 ppm (s, $SO_3\underline{H}$), int. = 1.0; J_{BH_α} = 7.4 Hz.

^{13}C nmr (D_2O, $Si(CH_3)_4$ ext.): δ_α = 65.4 ppm (p); δ_β = 46.9 ppm (p); J_{BC_α} = 15.9 Hz; J_{BC_β} = 4.7 Hz.

Infrared, cm^{-1}: 3400 (s, br); 2943 (s, br); 1720 (s, br); 1291 (m); 1171 (vs); 1069 (m); 1005 (s); 885 (vs); 851 (vs); 614 (m); 576 (s); 454 (m).

Mass spectrum (CI^+, *m/e*, species): 135, $F_4SC_2H_3^+$; 127, SF_5^+; 111, $FSC_2H_4S^+$; 109, $C_2H_4SO_3H^+$; 89, SF_3^+; 82, CSF_2^+; 81, SO_3H^+; 80, SO_3^+; 70, SF_2^+; 67, SOF^+; 65, SO_2H^+, CH_2SF^+; 64, SO_2^+; 51, SF^+; 48, SO^+; 47, $C_2H_4F^+$, 46, CH_2S^+; 45, CHS^+; 44, CS^+; 43, C_2F^+.

2. Synthesis of $F_5SCH_2CF_2SO_3H\cdot H_2O$

2a $F_5SCH_2CF_2SO_3Na$ from $F_5SCH_2CF_2Br$ and Na_2SO_3

Procedure 1*a* was employed. From 3.81 g (14.1 mmol) of $F_5SCH_2CF_2Br$ and 1.92 g (15.2 mmol) of Na_2SO_3 in 50 mL of 50% aqueous ethanol, 3.5 g of crude $F_5SCH_2CF_2SO_3Na$ was obtained after refluxing for 44 h, filtering, evaporating away the solvent, extracting the solid residue with 100% ethanol, and bringing the solution to dryness, dec. ≈ 279°C. Yield: 85%. A pure sample was obtained by titrating the corresponding acid with NaOH, as described in Part 1*b*.

^{19}F nmr (D_2O, CCl_3F ext.): ϕ_A = 80.0 ppm (9 lines); ϕ_B = 73.2 ppm (d–m), ϕ_{CF_2} = −108.6 ppm (m). Int. A:B:CF_2 = 1.0:3.9:1.9. J_{AB} = 144 Hz; J_{ACF_2} = 2.1 Hz; $J_{CH_2CF_2}$ = 15.2, 17.8 Hz (*gauche* and *anti* coupling).

^1H nmr (D_2O, $Si(CH_3)_4$ ext.): δ = 5.20 ppm.

Mass spectrum (FAB, *m/e*, species): 610, $(M_2Na - H)^+$; 317, MNa^+; 297, $(MNa - HF)^+$; 215, $C_2F_5O_2S_2^+$; 191, $F_5SCH_2CF_2^+$; 171, F_5SCHCF^+; 149, $C_2F_2NaS_2^+$; 137, $SC_2HSO_3^+$; 126, $Na_2SO_3^+$; 115, CSO_3Na^+; 107, $C_2FSO_2^+$; 105, $C_2HSO_3^+$; 89, SF_3^+; 75, C_2SF^+; 65, CH_2SF^+; 63, CSF^+; 61, $CHSO^+$; 57, C_2HS^+; 45, CHS^+; 43, C_2F^+.

Infrared, cm^{-1}: 3116 (w); 3038 (w); 2987 (w); 1656 (m); 1420 (s); 1337 (w); 1267 (vs); 1229 (vs); 1096 (s); 1049 (w); 990 (s); 915 (m);

Anal. calcd. for $C_2H_2F_7NaO_3S_2$: C 8.16, H 0.68, F 45.2, S 21.77; found: C 8.28, H 0.71, F 44.8, S 21.58.

2b Alternate synthesis of $F_5SCH_2CF_2SO_3Na$

Into a 75 mL stainless steel autoclave, 9.7 g (51.1 mmol) of $F_5SCH{=}CF_2$, 5.3 g (51 mmol) of $NaHSO_3$, 1.0 g (2.6 mmol) of $Na_2B_4O_7 \cdot 10H_2O$, 1.5 g (6.2 mmol) of benzoyl peroxide, and 26 mL of distilled water were added. The autoclave was closed, evacuated and heated with shaking (every 15 min) for 18 h to 115°C. The solvent was removed and the residue was extracted with hot ethanol. The extract was dried under vacuum (17 days). The resulting off-white solid (1.2 g) had the same ir spectrum as a sample prepared by method 2*a*. Yield: 7.7%.

2c Acidification of $F_5SCH_2CF_2SO_3Na$ with HCl

In a 100 mL round bottomed flask, 13.16 g (44.8 mmol) of $F_5SCH_2CF_2SO_3Na$ and 40 mL of 12 *M* HCl were added. Since no precipitate was observed, the solution was evaporated to half of its volume, transferred to a 50 mL round bottomed three-necked flask and treated with excess gaseous HCl, as described in Part 1*b*. After filtration, removal of the solvent and sublimation (100°C, $<20\mu$) 8.13 g of $F_5SCH_2CF_2SO_3H \cdot H_2O$ remained. Yield: 62.6%. ^{19}F nmr spectroscopy indicated an impurity, which was removed by treatment with 30% H_2O_2. Thus, 1.7 g of the impure material was stirred (14 days, 40–50°C) with 30% H_2O_2 (2 mL were added every 2 days), leaving after filtration and evaporation of the solvent ~1 g of pure $F_5SCH_2CF_2SO_3H \cdot H_2O$. Equivalent weight was 280 g/equiv. (calcd. 288 g/equiv.). The salt solution was purified as described in Part 1*b*.

^{19}F nmr (D_2O, CCl_3F ext.): ϕ_A = 79.0 ppm (9 lines), ϕ_B = 72.5 ppm (d–m), ϕ_{CF_2} = −110.3 ppm (m). Intensity A:B:CF_2 = 1.0:4.0:2.0; J_{AB} = 150 Hz; J_{ACF_2} = 2.2 Hz; J_{BCH_2} = 7.7 Hz; $J_{CH_2CF_2}$ = 17.4, 15.9 (*gauche* and *anti* coupling).

^1H nmr (CD_3CN, $Si(CH_3)_4$ ext.): δ_1 = 4.78 ppm (CH_2, m); δ_2 = 13.7 ppm (SO_3H, s); δ_3 = 9.2 ppm. Int. δ_1:δ_2:δ_3 = 2.0:1.0:2.0; J_{BH_α} = 8.2 Hz and J_{CF_2H} = 16.3 Hz.

^{13}C nmr (D_2O, $Si(CH_3)_4$ ext.): δ_α = 66.5 ppm (t-p); δ_β = 117.4 ppm (t-p); J_{BC_α} = 17.2 Hz; $J_{C_\alpha CF_2}$ = 20.2 Hz; J_{BC_β} = 2.1 Hz; $J_{C_\beta CF_2}$ = 281.5 Hz.

Infrared, cm^{-1}: 3490 (m, br); 3038 (w); 2988 (w); 1653 (m); 1420 (m); 1296 (m); 1285 (m); 1266 (s); 1229 (vs); 1096 (s); 1054 (m); 991 (s); 909 (m); 896 (m); 855 (s); 834 (vs); 800 (m); 675 (m); 632 (m); 605 (m); 567 (m); 553 (m).

Mass spectrum (CI^+, mass, species): 191, $F_5SCH_2CF_2^+$; 149, $CF_2SO_2H \cdot H_2O^+$; 127, SF_5^+; 89, SF_3^+; 83, F_2SCH^+; 80, SO_3^+; 70, SF_2^+; 65, CH_2SF^+; 64, $CHSF^+$; 63, CSF^+; 61, $CHSO^+$; 57, C_2HS^+; 51, SF^+; 48, SO^+; 45, CHS^+; 44, CS^+.

3. Synthesis of $F_5SCHFCF_2SO_3H$

3a $F_5SCHFCF_2SO_3Na$ from $F_5SCHFCF_2Br$ and Na_2SO_3

Method 1*a* was employed. Thus 23.44 g (81.1 mmol) of $F_5SCHFCF_2Br$ and 10.29 g (81.7 mmol) of Na_2SO_3 in 145 mL 50% aqueous ethanol were refluxed in a 250 mL round bottom flask for 48 h. The extraction of the residue with 100% ethanol gave 19.76 of crude $F_5SCHFCF_2SO_3Na$. Yield; 78.1%. A pure sample was obtained by titration of the free acid with NaOH, as described in Part 1*b*.

^{19}F nmr (D_2O, CCl_3F ext.): ϕ_A = 71.2 ppm; ϕ_B = 53.7 ppm, ϕF_α = −172.7 ppm; $\phi F_{\beta 1}$ = −112.5 ppm; $\phi F_{\beta 2}$ = −123.5 ppm. Int. A:B:F_α:$F_{\beta 1}$:$F_{\beta 2}$ = 1.0:4.0:0.1:0:1.1:1.0. J_{AB} = 147 Hz; J_{AF_α} = 2.6 Hz; $J_{AF_{\beta 1}}$ = 1.7 Hz; $J_{AF_{\beta 2}}$ = 1.7 Hz; J_{BH_α} = 5.1 Hz; $J_{F_\alpha H_\alpha}$ = 41.5 Hz; $J_{BF_{\beta 1}}$ = 15.2 Hz; $J_{BF_{\beta 2}}$ = 11.8 Hz; $J_{F_\alpha F_{\beta 1}}$ = 11.8 Hz; $J_{F_\alpha F_{\beta 2}}$ = 17.3 Hz; $J_{H_\alpha F_{\beta 2}}$ = 20.3 Hz; $J_{F_{\beta 1} F_{\beta 2}}$ = 266.0 Hz.

^1H nmr (D_2O, $Si(CH_3)_4$ ext.): δ = 6.79 ppm.

Infrared, cm^{-1}: 3007 (w); 1653 (m); 1635 (m); 1355 (w); 1285 (vs); 1270 (vs); 1247 (vs); 1154 (s); 1131 (s); 1098 (s); 1008 (vs); 919 (s); 859 (vs); 809 (s); 728 (w); 651 (s); 610 (s); 599 (s); 571 (s); 531 (m).

Mass spectrum (FAB, *m/e*, species): 646, $(M_2Na - H)^+$; 335, MNa^+; 207, $CFCF_2SO_3Na_2^+$; 189, $F_5SC_2F_2^+$; 171, $F_5SC_2HF^+$; 157, $C_2H_2FO_3S_2^+$; 137, $SC_2HSO_3^+$; 126, $Na_2SO_3^+$; 116, $CHSO_3Na^+$; 115, CSO_3Na^+; 114, $CF_2SO_2^+$; 105, $C_2HSO_3^+$; 93, $CHSO_3^+$; 89, SF_3^+; 73, C_2HOS^+, C_2SF^+; 61, $CHOS^+$; 57, C_2HS^+; 45, CHS^+; 44, CS^+; 43, C_2F^+.

Anal. calcd. for $C_2HF_8NaO_3S_2$: C 7.69, H 0.34, F 48.7, S 20.51; found: C 7.82, H 0.38, F 48.8, S 20.64.

3b Alternate synthesis of $F_5SCHFCF_2SO_3Na$

To a 75 mL stainless steel vessel were added 19.4 g (93.3 mmol) of $F_5SCF{=}CF_2$, 9.8 g (94.2 mmol) of $NaHSO_3$, 0.36 g (1.5 mmol) of benzoyl peroxide, 4.4 g (11.5 mmol) of $Na_2B_4O_7 \cdot 10H_2O$, and 38 mL of distilled water. The vessel was sealed with a Whitey (20 V-F4) stainless steel valve, cooled to −196°C, evacuated, and heated from 50 to 114°C (2.4 h) and kept at 114–119°C for 7.5 h. The volatile material ($F_5SCF{=}CF_2$) was removed at room temperature and the aqueous solution was filtered and dried under vacuum. The dry residue (18.9 g) was extracted with hot ethanol, leaving after removal of the solvent, 7.8 g of crude $F_5SCHFCF_2SO_3Na$. The solid was treated with 2.7 g (27.5 mmol) of 100% H_2SO_4 and distilled at reduced pressure. A clear liquid (3.7 g) and a yellow solid were collected at (100–104)°C. This product was re-distilled and gave 1.8 g of $F_5SCHFCF_2SO_3H$, bp 88°C/4μ. Yield: 6.6% (with respect to $F_5SCF{=}CF_2$).

3c Acidification with HCl

This reaction was carried out as previously described in Part 1*b*. To 19.68 g (63.1 mmol) of crude $F_5SCHFCF_2SO_3Na$ dissolved in 100 mL water excess gaseous HCl was added. After filtering and removing the solvent, sublimation (100°C, $<40\mu$) gave 7.14 g of $F_5SCHFCF_2SO_3H \cdot H_2O$. Yield: 36.8%. Equivalent weight was 298 g/equiv. (calcd. 308 g/equiv.). The salt solution was purified as described in 1*b*.

^{19}F nmr (D_2O, CCl_3F ext.): ϕ_A = 71.1 ppm; ϕ_B = 53.0 ppm; ϕF_α = −167.3 ppm; $\phi F_{\beta 1}$ = −113.9 ppm; $\phi F_{\beta 2}$ = −124.9 ppm. Integral A:B:F_α:$F_{\beta 1}$:$F_{\beta 2}$ = 1.0:4.2:1.1:1.0:1.0; J_{AB} = 144 Hz; J_{AF_α} = 2.6 Hz; $J_{AF_{\beta 1}}$ = 1.4 Hz; $J_{AF_{\beta 2}}$ = 1.6 Hz; J_{BH_α} = 5.1 Hz; $J_{BF_{\beta 1}}$ = 15.7 Hz; $J_{BF_{\beta 2}}$ = 11.9 Hz; $J_{F_\alpha H_\alpha}$ = 41.4 Hz; $J_{F_\alpha F_{\beta 1}}$ = 12.7 Hz; $J_{F_\alpha F_{\beta 2}}$ = 16.9 Hz; $J_{F_{\beta 2} H_\alpha}$ = 20.3 Hz; $J_{F_{\beta 1} F_{\beta 2}}$ = 262.0 Hz.

$3SbF_3 \cdot 4SbF_5$ has been prepared from the reaction of SbF_3 with a large excess of SbF_5 and from the reaction of WF_5 with SbF_5 in Genetron 113. An X-ray structure determination has shown that the compound crystallizes in the monoclinic space group $P2_1/c$ with $a = 8.547(10)$, $b = 13.521(8)$, $c = 19.551(12)$ Å, $\beta = 100.3(1)°$, $Z = 4$ with the final residual indices of $R = 0.0486$ and $R_w = 0.0526$ for 4274 unique reflections. If only Sb—F distances of less than 2.1 Å are considered the structure can be viewed in terms of the arrangement $(SbF^{2+})(SbF_2^+)_2(SbF_6^-)_4$. A Raman spectrum from single crystals of the compound is reported.

Key words: X-ray, structure, antimony, fluoride, Raman.

JOHN FAWCETT, JOHN H. HOLLOWAY, DAVID R. RUSSELL, ANTHONY J. EDWARDS et KHALAF I. KHALLOW. Can. J. Chem. **67**, 2041 (1989).

On a préparé le $3SbF_3 \cdot 4SbF_5$ en faisant réagir du SbF_3 avec un large excès de SbF_5 ou en faisant réagir du WF_5 avec du SbF_5 dans du Genetron 113. Faisant appel à la diffraction des rayons-X, on a démontré que le composé cristallise dans le groupe d'espace monoclinique, $P2_1/c$, avec $a = 8,547(10)$, $b = 13,521(8)$ et $c = 19,551(12)$ Å, $\beta = 100,3(1)°$ et $Z = 4$ avec des indices résiduels finals de $R = 0,0486$ et $R_w = 0,0526$ pour 4274 réflexions uniques. Si on ne considère que les distances Sb—F de moins que 2,1 Å, on peut considérer la structure en fonction de l'arrangement $(SbF^{2+})(SbF_2^+)_2(SbF_6^-)_4$. On rapporte le spectre Raman effetué sur des cristaux uniques du composé.

Mots clés : rayons-X, structure, antimoine, fluorure, Raman.

[Traduit par la revue]

Introduction

Ruff and Plato (1) reported an exothermic reaction between SbF_3 and SbF_5. Distillation of the products yielded adducts of the type $nSbF_3 \cdot SbF_5$, in which n was equal to 2 or 5 and possibly 3 or 4. No evidence for a 1:1 compound was obtained. Some years later Woolf (2) reported that SbF_3 was insoluble in SbF_5 and did not increase the conductivity of the pentafluoride, and Davies and Moss (3) were unable to repeat the work of Ruff and Plato, reporting that SbF_3 did not react with SbF_5, even on heating. More recently, Gillespie *et al.* (4) showed that SbF_5 reacts with SbF_3 or antimony metal in liquid sulphur dioxide to form two adducts with different Raman spectra which, on the basis of elemental analysis, were assigned a 1:1 stoichiometry and designated $SbF_3 \cdot SbF_5$(A) and $SbF_3 \cdot SbF_5$(B). These two adducts were not interconvertible and Raman and ^{121}Sb Mössbauer spectra suggested that they had different structures.

In 1974 Edwards and Slim (5) prepared $6SbF_3 \cdot 5SbF_5$ by the direct fluorination of elemental antimony and determined its X-ray structure. Simultaneously, Hewitt *et al.* (6) prepared the same material in a similar reaction and characterised it from the unit cell parameters obtained from single crystals. Raman spectra from single crystals were similar to those of Gillespie's $SbF_3 \cdot SbF_5$(B) and it was suggested that $SbF_3 \cdot SbF_5$(B) was, in fact, Edwards' $6SbF_3 \cdot 5SbF_5$. Very recently, in the course of a study of the reduction of $SbF_3 \cdot SbF_5$(A), Nandana *et al.* (7) obtained single crystals of an adduct whose Raman spectrum was identical to that of $SbF_3 \cdot SbF_5$(B) and similar to, but distinct from, that reported by Hewitt *et al.* (6). Determination of the single crystal structure has shown that this adduct also has the stoichiometry $6SbF_3 \cdot 5SbF_5$, hereafter called β-$6SbF_3 \cdot 5SbF_5$, with a different, but related structure to Edwards' $6SbF_3 \cdot 5SbF_5$, hereafter called α-$6SbF_3 \cdot 5SbF_5$.

In the meantime the adduct $SbF_3 \cdot SbF_5$(A) has been isolated from the products of reaction of antimony pentafluoride with S_4N_4, and the stoichiometry established as correct from an X-ray single-crystal structure determination (8). Raman spectra of the single crystals and bulk $SbF_3 \cdot SbF_5$(A) were shown to be identical.

The complexity of the SbF_3–SbF_5 system has been illustrated further by the identification of $5SbF_3 \cdot 3SbF_5$ (9), $2SbF_3 \cdot SbF_5$ (10), and $3SbF_3 \cdot SbF_5$ (11) by single crystal methods. A feature all of the adducts reported previously have in common is a stoichiometric ratio of SbF_3 to SbF_5 equal to or greater than 1.

We have now obtained the first example of an adduct containing more SbF_5 than SbF_3 by two preparative methods. An X-ray single-crystal structure determination has confirmed the $3SbF_3 \cdot 4SbF_5$ formulation and shown that the structure is best regarded as $[SbF]^{2+}[SbF_2]_2^+[SbF_6]_4^-$. A Raman spectrum of single crystals of the compound has been obtained.

Experimental

Reagents

Antimony pentafluoride was prepared by passing F_2 over antimony powder (Technical grade, BDH) in a nickel boat in a quartz system. The crude SbF_5 was purified in a Pyrex system by trap-to-trap sublimation under static vacuum. Antimony trifluoride (98%, BDH) was resublimed under dynamic vacuum prior to use. Genetron 113 (1,1,2-trichlorotrifluoroethane) (Fluka A.G.) was purified by distillation from P_2O_5.

Preparations

$3SbF_3 \cdot 4SbF_5$ was obtained either from the solid product resulting from the removal of excess of SbF_5 from the mixture remaining after the treating of SbF_3 with a large excess of SbF_5 for at least 48 h, or from the reaction of a 2:1 molar ratio of SbF_5 and WF_5 in Genetron after the removal of volatiles and solvent. The latter reaction appears to take place according to reaction [1].

[1] $6WF_5 + 7SbF_5 \rightarrow 3SbF_3 \cdot 4SbF_5 + 6WF_6$

Characterizations

The products were characterized by single-crystal X-ray structure analysis since chemical analysis of the white powders resulting from the preparations gave total antimony ~60 and fluorine ~39.5%. These values are similar to theoretical percentages of antimony and fluorine in the adducts $SbF_3 \cdot 2SbF_5$, $3SbF_3 \cdot 5SbF_5$, and $3SbF_3 \cdot 4SbF_5$ which are Sb 59.6, F 40.4; Sb 60.2, F 39.8; and Sb 60.7, F 39.3 respectively. Raman spectra were recorded using a Coderg T800 spectrometer. The exciting radiation was the blue line (4880 Å) of a Model 52 Coherent Radiation Laboratories argon-ion laser.

X-ray crystallographic analysis

Crystal data for $F_{29}Sb_7$ are as follows:

$F_{29}Sb_7$ mw = 1403.19

Monoclinic, $P2_1/c$, $a = 8.547(10)$, $b = 13.521(8)$, $c = 19.551(12)$ Å, $\beta = 100.3(1)°$, $V = 2223.3$ Å^3, $Z = 4$, $D_x = 4.19$ g cm^{-3}, μ(Mo-K_α) = 80.05 cm^{-1}, λ(Mo-K_α) = 0.71069 Å, $F(000)$ = 2471.2.

Single crystals were obtained both from the reaction of SbF_3 with SbF_5 and the reaction of SbF_5 with WF_5. The reported structure determination was carried out on crystals from the latter preparation. Crystals were transferred in an inert atmosphere to preseasoned (ClF_3) capillaries. The crystals were colourless, air-sensitive rhomboids of dimensions (distances to faces from centre, 0.162 (1 0 0, $\bar{1}$ 0 0) × 0.093 (0 1 1, 0 $\bar{1}$ $\bar{1}$) × 0.083 (0 1 $\bar{7}$, 0 $\bar{1}$ 7) mm).

The unit cell dimensions of the crystal were determined from an oscillation photograph for the rotation axis ***a***, and from the optimized counter angles of zero and upper layer reflections on a Weissenberg camera for ***b*** and ***c***. The intensities of 5210 unique reflections ($7 \leq 2\theta \leq 60$, $+h +k \pm l$) were measured at 20°C on a Stoe STADI-2 Weissenberg diffractometer using an ω-scan technique. The data were corrected for Lorentz and polarisation effects. An absorption correction (maximum, minimum transmission factors = 0.37, 0.21) was applied to the data, giving 4274 reflections with $I \geq 3\sigma(I)$.

The structure was solved by direct methods using the program MULTAN (12) to locate the antimony atoms, and then difference Fourier techniques using the program system SHELX (13). Neutral atom scattering factors and corrections for anomalous dispersion were used as described in ref. 13. Full-matrix least-squares refinement of positional and isotropic thermal parameters for all atoms reduced R to 0.098. Final cycles, with all atoms anisotropic, employed a weighting parameter $g(0.002\ 26)\{\omega\alpha[1/\sigma^2(F) + gF^2]\}$ and gave the final residual indices R $\{= \Sigma||F_o| - |F_c||/\Sigma|F_o|\}$ 0.0486 and R' $\{= [\Sigma\omega(|F_o| - |F_c|)^2/\Sigma\omega|F_o|^2]^{1/2}\}$ 0.0526. A final difference Fourier was featureless except for peaks of ≤3*e* at ≤1.0 Å from the antimony atoms. An analysis of the weighting scheme over $|F_o|$ and $(\sin\theta)/\lambda$ was satisfactory.

Positional parameters are given in Table 1. Bond distances and angles are listed in Table 2. Thermal parameters and tables of calculated and observed structure factors have been deposited as supplementary material.[2]

Results and discussion

The preparation of $3SbF_3 \cdot 4SbF_5$ was achieved both by heating SbF_3 with a large excess of SbF_5 (contrary to the report of Davies and Moss (3)) in a rigorously dried Pyrex glass apparatus for 2 days and from the reaction of WF_5 with SbF_5 in Genetron 113.

The atomic arrangement in the structure of $3SbF_3 \cdot 4SbF_5$ is shown in Fig. 1. If only Sb—F distances of less than 2.1 Å are considered, then the arrangement corresponds to $(SbF^{2+})(SbF_2^+)_2(SbF_6^-)_4$. Sb(1) has a bond distance to F(1) of 1.82 Å defining the SbF^{2+} cation. This distance is shorter than those in SbF_3 (14) of 1.90 and 1.94 Å.

The two SbF_2 units are defined by Sb(5), F(5), F(24) and Sb(6), F(6), F(25). The mean Sb—F distance in both SbF_2 units (1.92 Å) is similar to that in the SbF_2 unit in the $Sb_{11}F_{43}$ adduct (5, 15*a*) (1.9 Å). Both are V-shaped as expected from VSEPR Theory (16) for two bond pairs and a lone pair of electrons around antimony. Consideration of the bond distances and bond angle, as shown in Table 3, shows that the SbF_2 units in Sb_7F_{29} adduct are comparable with those found in $6SbF_3 \cdot 5SbF_5$ (5).

The four $[SbF_6^-]$ anions, centred on Sb(2), Sb(3), Sb(4), and Sb(7), show slight angular distortion from a regular octahedral arrangement. However, the mean of the terminal Sb(V)—F distances in these octahedra is comparable with those present in the octahedral units in the $SbF_3 \cdot SbF_5$ adducts as shown in Table 4.

The octahedron [Sb(2)—F_6] possesses a bridging fluorine

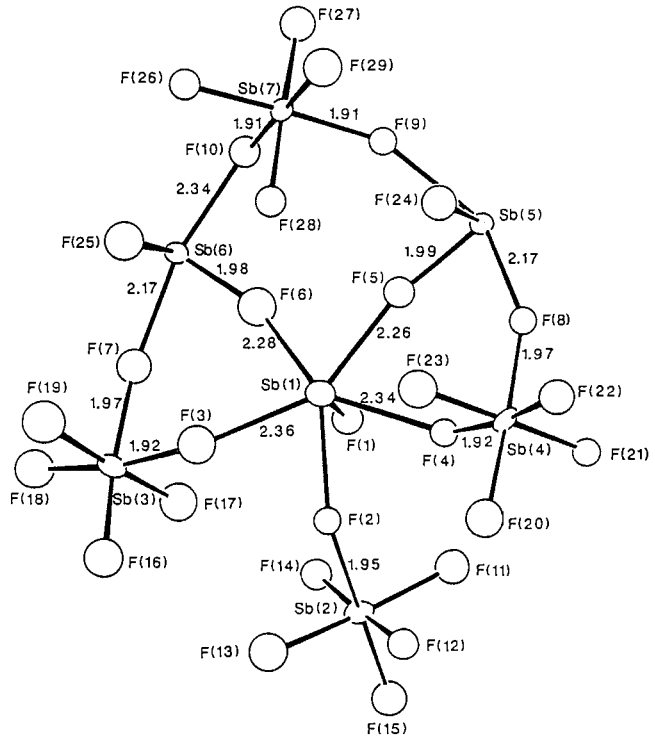

FIG. 1. The atomic arrangement in the structure of $3SbF_3 \cdot 5SbF_5$.

atom, F(2), with a distance of 1.95 Å which is significantly longer than the other Sb(2)—F distances due to the bridging interaction with the Sb(1) atom. Sb(3) and Sb(4) are both linked to the [Sb(1)—F^{2+}] ion via F(3) and F(4), respectively. The Sb(3) atom is also linked to the [Sb(6)—F_2^+] ion through the bridging fluorine atom F(7), while Sb(4) is linked to the [Sb(5)—F_2^+] ion by F(8). The bridge distances Sb(4)—F(4) of 1.92 Å and Sb(4)—F(8) of 1.97 Å are significantly longer than the other Sb(4)—F distances in the octahedra due to the bridging interactions with Sb(1) and Sb(5), respectively.

A similar phenomenon occurs with the Sb(7) atom. This has two bonds, Sb(7)—F(9) of 1.91 Å and Sb(7)—F(10) of 1.91 Å longer than the other non-bridging Sb(7)—F bonds.

All the angles F—Sb—F between *cis* fluorine atoms in the four distorted octahedral anions are in the range 80.6 to 98.9°. This is reasonably close to the 90° for a regular octahedron.

If the Sb—F distances less than 2.5 Å are now considered, no extra bonds to the SbF_6^- units are found. In addition to Sb(1)—F(1), there are five other bonds to Sb(1). These are to F(2), F(3), F(4), F(5), and F(6) which have bond lengths between 2.25 and 2.35 Å. These five atoms are coplanar with $\bar{x}$.20 Å. If the short bond is denoted by X, and the others by Y, Sb(1) can be regarded as having an AXY_5E stereochemistry in the form of a pentagonal bipyramid. F(1) and the lone pair of electrons (E) occupy the axial positions. VSEPR theory (16, 17) predicts that the bonds in the equatorial plane of a pentagonal bipyramid should be longer than the axial bonds. This is, in fact, observed in the [Sb(1)F_6] unit. The F(1)—Sb(1)—F angles are all less than 90°, as shown in Table 2, due to the greater repulsive effect of a lone pair of electrons over that of the bond pair; hence the equatorial plane is displaced towards F(1). The angles between adjacent fluorine atoms in the equatorial plane are close to 72°, which is the angle for a regular pentagon.

This arrangement has been previously recognised for one Sb atom in the [$Sb_2F_4^{2+}$] ion in the 1:1 $SbF_3 \cdot SbF_5$ adduct (8) and

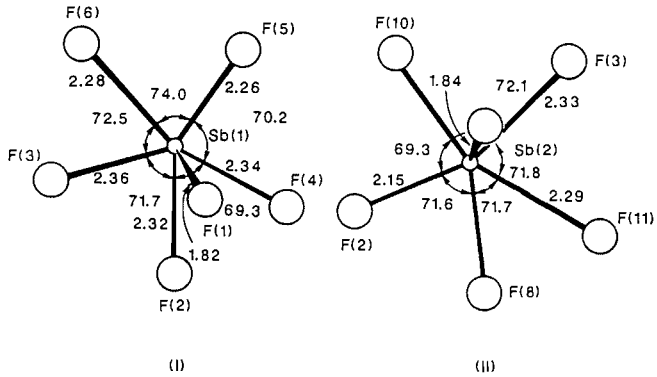

FIG. 2. (*I*) Projection of Sb(1)F_6 unit along the *c*-axis, (*II*) projection of Sb(2)F_6 unit along the *a*-axis in $(Sb_2F_4)^{2+}$ (8).

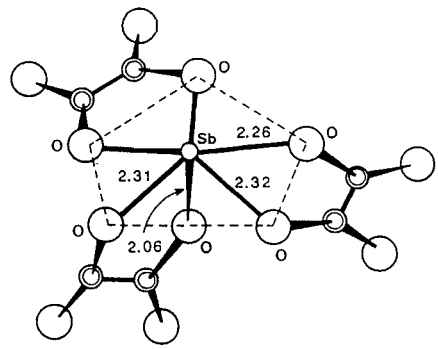

FIG. 3. A projection view of $[Sb(C_2O_4)_3]^{3-}$.

these are compared diagrammatically in Fig. 2. In Fig. 2(*II*) the axial bond length of 1.84 Å is similar to the Sb(1)—F(1) bond length of 1.82 Å in Fig. 2(*I*), while the five equatorial bonds in the range 2.10 to 2.42 Å in Fig. 2(*II*) are close to those of Sb(1)—F between 2.25 to 2.35 Å. The mean angles between the adjacent atoms in equatorial positions in both structures are the same (71.5 and 71.1°), as are the mean F(axial)—Sb—F(equatorial) angles (82.5° (Fig. 2(*I*)) and 82.3° (Fig. 2(*II*)). A similar arrangement has been observed for the $[Sb(C_2O_4)_3]^{3-}$ ion (18) which is also a pentagonal bipyramid. One oxalate group lies in the mirror plane with its two coordinated oxygen atoms bridging one equatorial and one axial site. The other two oxalate groups are mirror related and lie approximately in the equatorial plane, as shown in Fig. 3, with its vacant axial site filled by the non-bonding pair of electrons. The equatorial bond angles at antimony are all in the range 70–72° and are similar to those in Sb_7F_{29} in Fig. 2(*I*). It is interesting to note that the axial Sb—O bond length of 2.06 Å, although longer than that of Sb(1)—F(1) (1.82 Å), is still significantly shorter than the equatorial values which lie between 2.25 and 2.35 Å.

As well as 2 Sb—F distances of less than 2.1 Å, Sb(5) and Sb(6) each have two other bonds between 2.1 and 2.35 Å in length. A similar coordination is found for the iodine atom in $(IF_4^+)(Sb_2F_{11}^-)$ (19) which has two long and two short distances and a lone pair of electrons around the iodine atom. The two long bonds to Sb(5) of 2.17 and 2.35 Å, respectively, are comparable with those to Sb(6) of 2.17 and 2.34 Å, respectively. The antimony atom in these [SbF_4] units can be considered to possess a distorted trigonal bipyramidal coordination of four fluorine atoms and a lone pair of electrons. The lone-pair occupies an equatorial position in the trigonal bipyramid as is expected from VSEPR theory (16). The atoms F(8) and F(9) occupy the axial positions about Sb(5), whilst F(5)

and F(24) are in the equatorial positions. Similarly, F(6) and F(25) are coordinated with Sb(6) in the equatorial positions with F(7) and F(10) in the axial positions.

The repulsion caused by the lone pair-bond pair interaction results in a decrease in the angles between the equatorial bonds from 120 to 88.7° for Sb(5) and 86.5° for Sb(6), and from 180 to 151.4° for Sb(5) and 156.3° for Sb(6) for the axial bonds. These are similar to the corresponding angles in the [Sb(2)F_4] unit in $Sb_{11}F_{43}$ (5, 10) the [Sb(1)F_4] unit in the $2SbF_3 \cdot SbF_5$ adduct (10), the (AsF_2^+) ion in the $AsF_3 \cdot SbF_5$ adduct (20) and the [AsF_4^-] ion in KAs_2F_7 (21).

The bridge formed by F(8) is asymmetric, Sb(4)—F(8) = 1.97 Å and Sb(5)—F(8) = 2.17 Å. Similarly, on the other side of the structure in the asymmetric bridge formed by F(7), Sb(3)—F(7) = 1.97 Å and Sb(6)—F(7) = 2.17 Å. The structural arrangement in the fragments [F_5Sb(4)—F(8)—Sb(5)] and [F_5Sb(3)—F(7)—Sb(6)] is comparable with the [F_5Sb(6)—F(19)—Sb(3)] unit in $2SbF_3 \cdot SbF_5$ in which F(19) forms an asymmetric bridge between Sb(V) and Sb(III). The Sb(V)—F(19) distance of 1.90 Å in $2SbF_3 \cdot SbF_5$ is similar to that of Sb(4)—F(8) (1.97 Å) and Sb(3)—F(7) (1.97 Å) in the two fragments (Fig. 4(*I*) and (*II*)). The Sb(III)—F(19) bond of 2.32 Å in $2SbF_3 \cdot SbF_5$ (Fig. 4(*III*)) is slightly longer than those between Sb(III) and the bridging atoms in $3SbF_3 \cdot 4SbF_5$ (Fig. 4(*I*) and (*II*)) of 2.17. The bridge angle Sb(V)—F(19)—Sb(III) of 150.0° in $2SbF_3 \cdot SbF_5$ (Fig. 4(*III*)) is similar to those of 148.4° in Fig. 4(*II*) and 153.7° in Fig. 4(*I*).

Similarity also exists between the bridging angles of Fig. 4(*I*) and (*II*) and the Sb—F—Cl angle of 143° found in (ClF_2^+)-(SbF_6^-) (22), although the latter has a *trans* bridging antimony atom. The asymmetric bridge formed by the fluorine atom in (ClF_2)$^+$(SbF_6)$^-$ (22) with an Sb—F distance of 1.88 Å and Cl—F distance of 2.33 Å is also similar to those in Fig. 4(*I*) and (*II*).

Another bridging atom is F(4), which bridges Sb(1) and Sb(4) with bond distances Sb(4)—F(4) of 1.92 Å and Sb(1)—F(4) of 2.34 Å. The bridge angle Sb(1)—F(4)—Sb(4) of 129.5° is comparable with that in $SeOCl_2 \cdot SbCl_5$ (23) of 121.5°. The atom F(3) forms the second asymmetric bridge with distances to Sb(3) of 1.92 Å and to Sb(1) of 2.36 Å. Sb(7) is linked to Sb(5) and Sb(6) through the *cis* fluorine atoms F(9) and F(10), respectively. The angles at the bridge atoms F(9), of 141.9°, and F(10), of 144.6°, are very similar to the corresponding angle Sb—F—As of 140.9° in $AsF_3 \cdot SbF_5$ (20).

In conclusion, the three octahedral units for Sb(7), Sb(3), and Sb(4) have two *cis* fluorine bridges linked to pairs of cationic species, whereas the octahedron for Sb(2) possesses one fluorine bridge atom linked to the SbF^{2+} cation. A similar arrangement has been observed in the [$Sb_3F_{16}^-$] ion, in (BrF_2^+)($Sb_3F_{16}^-$) (24) and in (O_2^+)($Sb_3F_{16}^-$) (15*b*) with a bridge angle Sb(outer)—F(bridge)—Sb(central) of 145 and 162.9°, respectively. The first of these angles is comparable with Sb(1)—F(2)—Sb(2) of 143.3°. The bridging fluorine atom in [$Sb_3F_{16}^-$] ion acts between two Sb(V) atoms. The Sb(V) atoms are considered to be more electronegative than Sb(III) atoms, and thus have more attractive forces toward the fluorine atoms. Consequently the Sb(V)—F bonds will be shorter than Sb(III)—F bonds, as is observed with Sb(III)—F(4) of 2.26 Å compared with Sb(outer)—F(bridge) of 2.10 Å in (BrF_2^+)($Sb_3F_{16}^-$) and that of 2.13 Å in (O_2^+)($Sb_3F_{16}^-$).

The overall coordination around each Sb(III) atom is completed by consideration of the longer contacts between 2.5 and 3.2 Å. Sb(6) has an overall coordination of nine, including the lone pair of electrons. The Sb(2) in the cationic species $[Sb_6F_{13}]^{5+}$ of α-$6SbF_3 \cdot 5SbF_5$ has nine coordination with inclusion of the lone pair of electrons. The geometry of Sb(6) with all contacts, including the lone electron pair, filling the ninth position, gives an asymmetric arrangement, as shown in Fig. 5.

The overall coordination number of Sb(5) is ten, including the lone pair of electrons. This also shows an irregular atom geometry, as shown in Fig. 6, similar to the potassium atom coordinated by ten fluorine atoms in KAs_2F_7 (21).

In conclusion, the asymmetric unit contains four distorted octahedral [SbF_6^-] anions, two SbF_2^+, and one SbF^{2+} cations. The Sb(1)F^{2+} cation is in the centre of the asymmetric unit with the [Sb(5)F_2^+] and [Sb(6)F_2^+] cations, together with four [SbF_6^-] anions grouped around it. Furthermore, the two sets Sb(1), Sb(4), and Sb(5), and Sb(1), Sb(3), and Sb(6) atoms form closed trimeric units with fluorine bridges. This type of

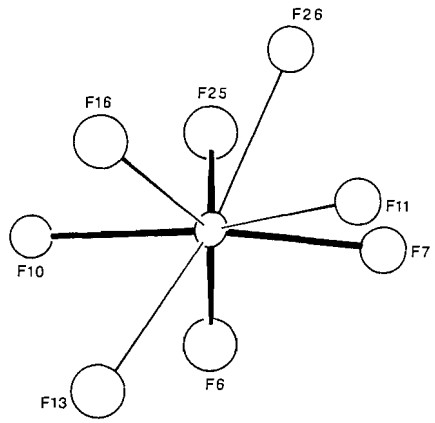

FIG. 5. The coordination of the Sb(6) atom.

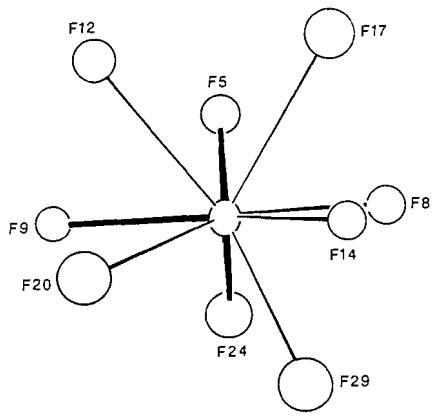

FIG. 6. The coordination of the Sb(5) atom.

arrangement is similar to that observed in $TcOF_4$ (25). The atoms Sb(1), Sb(5), Sb(6), and Sb(7), with fluorine bridges, form a closed tetrameric arrangement which has some similarities to that in pentafluorides (26).

Raman spectra were obtained on single crystals of Sb_7F_{29} in seasoned (ClF_3) Pyrex capillaries. The intensity of the bands was thus dependent upon the orientations observed. Bands were found at 200, 287, 556, 602, 638, 665, 696, and 726 cm^{-1}. The bands at 638 and 665 cm^{-1} were strong in all orientations investigated and are tentatively assigned as SbF_6^- ν_1 and ν_3 respectively. The spectra are distinct from all previously published Raman data for $n \cdot SbF_3 \cdot SbF_5$ (4, 6, 7, 9, 11).

This paper is dedicated to Professor Ronald J. Gillespie on the occasion of his 65th birthday

JOHN BESIDA, THOMAS A. O'DONNELL, and P. GARY ELLER. Can. J. Chem. **67**, 2047 (1989).

Chromyl fluoride provides a nonconducting solution in anhydrous hydrogen fluoride with Raman spectroscopic features indistinguishable from those of the solute in the gas phase, indicating no fluoride or proton transfer in solution. With increasing acidity in the SbF_5–HF solvent system, CrO_2F_2 forms cationic species, the nature of which is discussed. The acidity-dependence of cationic speciation in HF–TaF_5 and in HF–AsF_5 is consistent with that in HF–SbF_5.

Key words: chromyl fluoride, antimony fluoride, Lewis acid, Raman spectroscopy, hydrogen fluoride.

JOHN BESIDA, THOMAS A. O'DONNELL et P. GARY ELLER. Can. J. Chem. **67**, 2047 (1989).

Le fluorure de chromyle, dans le fluorure d'hydrogène anhydre, constitue une solution non conductrice ayant des caractéristiques spectroscopiques de Raman identiques à celles du soluté dans la phase gazeuse indiquant ainsi l'absence de transfert d'ion fluorure ou d'hydrogène en solution. Lorsqu'on augmente l'acidité du mélange SbF_5–HF utilisé comme solvant, le CRO_2F_2 forme des espèces cationiques, dont on discute ici la nature. L'influence de l'acidité sur la spéciation cationique dans les systèmes de solvent HF–TaF_5 et HF–AsF_5 s'accorde bien avec celle du système de solvant HF–SbF_5.

Mots clés : fluorure de chromyle, fluorure d'antimoine, acide de Lewis, spectroscopie de Raman, fluorure d'hydrogène.

Inorganic fluorine chemists have devoted much effort to the synthesis and characterization by spectroscopic and diffraction methods of Lewis acid – Lewis base adducts involving acids like SbF_5 and BF_3 reacting with molecular fluorides of the halogens, the chalcogens, and the heavier noble gases. An early typical example was the adduct $SF_4 \cdot BF_3$, which, considerably later, was shown by X-ray crystallography to be the essentially ionic compound $SF_3^+BF_4^-$ (1). Gillespie and co-workers used conductance measurements and nmr spectroscopy to show that the adduct was completely ionized in solution in anhydrous HF (2) and Brownstein and Shamir found that the Raman spectrum of the adduct in HF was virtually identical with that of the solid (3), i.e., in both the solid and in HF solution, fluoride transfer from SF_4 to BF_3 is complete.

In similar fashion it was shown that BrF_3 and SbF_5 react to form a 1:1 adduct, and later structure determination showed that it also has an essentially ionic formulation, $BrF_2^+SbF_6^-$ (4). Surles, Quarterman, and Hyman demonstrated complete F^- transfer from BrF_3 to SbF_5 in HF solution by recording very similar Raman spectra for the solid adduct and its solution in HF (5).

There do not appear to be many other systems in which there has been the same comprehensive investigation of fluoro adducts both in the solid state and in HF solution, the solvent with which they are compatible. The ability of CrO_2F_2 to react with HF, made acidic with Lewis acids or made basic with F^-, is the subject of study in this paper.

Previously Gard and co-workers (6) prepared 1:1 and 1:2 solid adducts by direct addition of CrO_2F_2 to the Lewis acids SbF_5 and TaF_5. They showed that solid adducts, stable at room temperature, were not formed when CrO_2F_2 was interacted with the weaker, volatile Lewis acids AsF_5, PF_5, and BF_3, indicating qualitatively that CrO_2F_2 is a much weaker fluoride donor than species like SF_4 and BrF_3. Gard and co-workers used infrared and Raman spectroscopy and chemical analysis to support their formulation of the adducts as $CrO_2F \cdot SbF_6$, $CrO_2F \cdot Sb_2F_{11}$, and $CrO_2F \cdot TaF_6$, i.e., they postulated F^- transfer to the strong Lewis acids. They showed also that with very strong fluoride donors like CsF, BaF_2, and ONF solid adducts were formed, with CrO_2F_2 acting as a Lewis acid (6, 7).

It is interesting to compare the dissolution of CrO_2F_2 in acidified HF with that of the formally analogous compound UO_2F_2. By comparison of vibronic and Raman spectra of UO_2F_2 in HF–AsF_5 with those in many aqueous systems, for example $UO_2(ClO_4)_2$ in $HClO_4$, Barraclough, Cockman, and O'Donnell (8) postulated the existence of the HF-solvated cation UO_2^{2+} in acidic HF. Fawcett, Holloway, Laycock, and Russell (9) crystallized the adduct $UO_2F_2 \cdot 3SbF_5$ from HF acidified with SbF_5. An X-ray crystal structure showed UO_2^{2+} as a discrete entity in the solid. In this compound U—F distances for F atoms on bridging SbF_6^- units are 20 to 25% longer than U—F distances in typical uranium fluorides.

In this present work Raman spectroscopy has been used as the principal technique to study speciation of CrO_2F_2 in HF solution as the solvent is made basic with F^- or is made progressively more acidic by the addition of the Lewis acids SbF_5, AsF_5, and TaF_5. The chemical nature of the Lewis acid appears to have little or no effect on the spectra observed. Spectra in HF–AsF_5 and HF–TaF_5 correlate very well with those in HF–SbF_5 on the basis of relative acid strengths, as indicated by values of the Hammett Acidity Function determined by Gillespie and Liang for these solutions (10).

Experimental

Reagents

Chromyl fluoride

CrO_3 was treated with anhydrous HF according to the method described by Engelbrecht and Grosse (11).

Hydrogen fluoride

Commercial reagent (Matheson's 99%) was subjected to three trap-to-trap distillations, discarding "tails".

[1]Author to whom correspondence may be addressed.

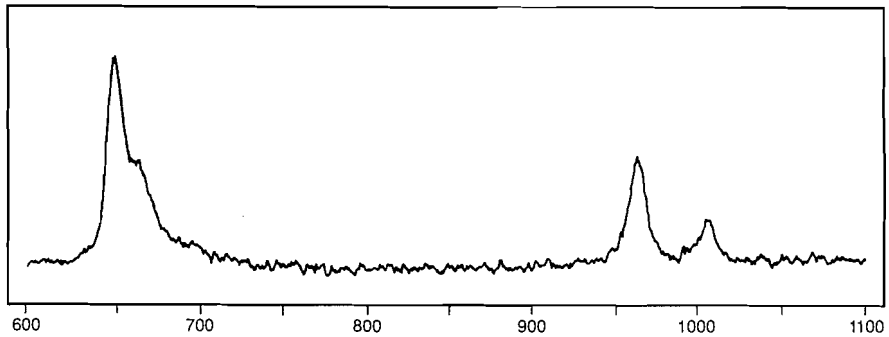

FIG. 1. Raman spectrum of HF solution 0.1 molar in CrO_2F_2 and 1 molal in SbF_5.

Antimony pentafluoride

Commercial reagent (Ozark Mahoning) was purified by distillation as previously described (12).

Arsenic pentafluoride

The commercial reagent (Ozark Mahoning) was distilled directly from the cylinder.

Tantalum pentafluoride

The commercial reagent (Ozark Mahoning) was handled under glove-box conditions.

Ammonium fluoride

Analytical reagent (B.D.H.).

Solution preparation

Concentrated solutions of SbF_5 in HF were progressively diluted with distilled HF to give more dilute solutions, solution molalities being determined by weight differences in KelF traps. Volatile AsF_5 was admitted to HF in a KelF trap via a metal and KelF vacuum line. TaF_5 and NH_4F were weighed into KelF traps under glove-box conditions, HF was added, and molalities determined by reweighing. Molalities were determined in the preparation of HF solutions of Lewis acids and of HN_4F because these could be related to mole percentages of solutes in HF — the method of expression of concentrations used by Gillespie and Liang in their determinations of H_0 values for HF solutions (10).

Solutions of CrO_2F_2 in HF, whether "neutral", acidic, or basic, were all approximately 0.1 molar in CrO_2F_2. CrO_2F_2 concentrations were based on volume of the solvent, rather than weight, because of the very great difference in density of the solvent between the extremes of "neat" HF and 20 molal (40 mol%) SbF_5.

Raman spectra

Raman spectra were recorded for HF solutions in "synthetic sapphire" tubes with a Spex Ramalog 5,14018 Spectrometer using 5145 Å irradiation and multiscan facilities. For most spectra 20 scans were accumulated and integrated.

Conductance measurements

The Kel-F cell with platinum electrodes used for conductance measurements was similar to that described previously (13).

Results and discussion

Figure 1 gives the recorded Raman spectrum for an HF solution 0.1 molar in CrO_2F_2 and 1 molal in SbF_5. Peaks in the 640–670 cm^{-1} region are characteristic of fluoro-antimonate(V) anionic species. The peak at 1007 cm^{-1}, also observed in "neat" HF (Fig. 2) where the solute is present as CrO_2F_2 as discussed below, is in the identical position to that assigned to the Cr=O stretch in gaseous CrO_2F_2 (14). The peak at 965 cm^{-1} is ascribed to a cationic species, either CrO_2F^+ or $CrO(OH)F_2^+$, for the reasons given later in this section. In the Raman spectroscopic study of gaseous CrO_2F_2 a peak at 728 cm^{-1} was assigned to the symmetric Cr—F stretch (14). No peak of sufficient intensity for diagnostic use was observed in the 720–730 cm^{-1} region in HF solutions. Raman peaks associated with metal–fluorine stretches are frequently very weak, this being attributed to the high degree of polarity of these bonds.

For these reasons, monitoring of change in speciation of the solute CrO_2F_2 as the acidity or basicity of HF solutions was changed was based on peak positions around 1000 cm^{-1}, which are associated with chromium–oxygen stretches.

Raman spectra are reproduced in Fig. 2 for HF solutions each approximately 0.1 molar in CrO_2F_2, to which SbF_5 has been added progressively. The spectrum in neat HF shows a peak at 1007 cm^{-1} in the identical position to that observed for gaseous CrO_2F_2 (14), indicating that the solute is present as the molecular entity. Although, in spectroscopy, it is common to observe significant differences between gas phase spectra and those for the same entities in solution, CrO_2F_2 behaves similarly to many other molecular fluorides in HF. MoF_6, UF_6, ReF_6, and ReF_7 have remarkably similar Raman spectra in neat HF and in the gas phase (15, 16), surprisingly, perhaps, when the highly associated state of the solvent is compared with the discrete molecularity of the solutes.

The postulation that CrO_2F_2 is present as the molecular species in neat HF is supported by the fact that addition of CrO_2F_2 to HF has little effect on the conductance of the solvent, 2.2×10^{-4} ohm^{-1} cm^{-1} for HF compared with 2.8×10^{-4} ohm^{-1} cm^{-1} for 0.48 molal CrO_2F_2 in HF. Thus CrO_2F_2 is not acting as a fluoride donor or acceptor or as a proton acceptor in HF to form cationic or anionic species.

As the concentration of SbF_5 is increased, i.e., as the acidity of the medium is increased, a new Raman peak grows in at 965 cm^{-1} at the expense of the 1007 cm^{-1} peak until, at 5 molal SbF_5, there remains little of the peak attributable to molecular CrO_2F_2. We postulate that fluoride transfer occurs from CrO_2F_2 to the HF–SbF_5 solvent system as the concentration of F^- in the solvent system decreases, i.e., as the acidity increases, and we ascribe the peak at 965 cm^{-1} to the solvated cationic species CrO_2F^+. Alternatively proton transfer could be occurring to form $CrO(OH)F_2^+$ as the acidity of the medium is increased.

It is possible to put the threshold for F^- or proton transfer between CrO_2F_2 and the acidified solution on a quantitative basis as a result of measurement by Gillespie and Liang of values of Hammett Acidity Functions (H_0) in HF containing either the base F^- or various Lewis acids, including SbF_5 (10). Reference to Fig. 2 shows no spectroscopic evidence for a cationic species in 0.025 m SbF_5 in HF (for which $H_0 = -19.53$) but there is a very small peak, ascribed to this species, observed in 0.05 m SbF_5 ($H_0 = -19.75$). Gillespie and Liang did not measure H_0 values for HF solutions more concentrated

in SbF_5 than 0.3 molal, but it is known from the general chemistry of the HF–SbF_5 superacid solvent system that the acidity continues to increase with increasing SbF_5 concentration. Figure 2 also includes a Raman spectrum for CrO_2F_2 in neat HF, i.e., as purified by distillation. Gillespie and Liang estimated a value for H_0 of -15.1 ± 0.1 for absolutely pure HF, but, as they point out in their paper, the measured value of H_0 for even the best distilled HF will be about -11 because of unavoidable impurities in the distilled solvent (10).

At 10 molal SbF_5, the peak at about 960 cm^{-1} has broadened significantly. In HF solutions 15 and 20 molal in SbF_5 the peak at 1007 cm^{-1} is no longer discernible, i.e., there is no detectable amount of CrO_2F_2 in the system and the major peak narrows and shifts from 964–965 cm^{-1} (as in 0.1–5 molal SbF_5) to a new position of 959 cm^{-1} in 15 and 20 molal SbF_5. A change in speciation from CrO_2F^{2+} to CrO_2^{2+} or a change from $CrO(OH)F_2^+$ to $Cr(OH)_2F_2^{2+}$ in the strongly acidic medium seems an unlikely explanation for a shift in peak position of only 5 cm^{-1}, when it is recalled that a shift of about 40 cm^{-1} occurred for the change from CrO_2F_2 to the postulated CrO_2F^+. It is more likely a result of changes in the solvation and coordination of the cationic species. The nature of the solvent would be modified massively in moving from an SbF_5 concentration of, say, 1 molal (2 mol% SbF_5 in HF), where the SbF_5 exists almost exclusively as SbF_6^-, to 20 molal (40 mol% SbF_5), where the SbF_5 would be present largely as polymeric anions (17).

The Lewis acids TaF_5 and AsF_5 were investigated very briefly and the Raman spectra for the CrO_2F_2–HF–TaF_5 and CrO_2F_2–HF–AsF_5 solutions are shown in Fig. 3. The spectrum for a saturated solution of TaF_5 (0.4 molal), the Hammett Function for which would be -19.20 (10), gives no evidence for formation of any species except CrO_2F_2 and this is consistent with the fact that CrO_2F_2 is the only detectable species in 0.025 molal SbF_5, for which $H_0 = -19.53$.

The AsF_5 was 2–3 molal and gave the second spectrum in Fig. 3, showing the presence of both CrO_2F_2 and the cation. Gillespie and Liang did not measure H_0 values for HF–AsF_5 solutions containing concentrations of AsF_5 higher than 0.35 molal (10). Comparison with our spectra for CrO_2F_2 in HF–SbF_5 solutions suggests that the H_0 value for our HF–AsF_5 solution should be about -20.5, corresponding with that for a solution about 0.2 molal in SbF_5, and this correlates quite well with extrapolation of Gillespie and Liang's H_0 values for dilute AsF_5 solutions to higher AsF_5 concentrations.

To summarize the experimental observations in acid HF, CrO_2F_2 remains the only spectroscopically observable species until an acidity threshold between that for 0.025 molal SbF_5 ($H_0 = -19.53$) and that for 0.05 molal SbF_5 ($H_0 = -19.75$) is reached. Comparison of spectra in SbF_5, TaF_5, and AsF_5 suggests that the only role of each pentafluoride is to act as a Lewis acid in HF; at reasonable concentrations the chemical nature of the Lewis acid appears to have no effect on the coordination of the cation produced in solution.

Figure 4 gives the Raman spectrum for CrO_2F_2 dissolved in strongly basic HF, namely anhydrous HF made ca. 3 molal in NH_4F. The peak at 1007 cm^{-1} has an identical position to that for CrO_2F_2 in neat HF, indicating strongly that CrO_2F_2 is not a sufficiently strong Lewis acid in solution to accept F^- from either neutral or strongly basic HF. This postulation that CrO_2F_2 is a very weak Lewis acid in HF solution seems to present a situation different, at first sight, from that demonstrated by Gard (6, 7) where direct interaction of F^- in several fluoride donors with CrO_2F_2 led to solid involatile adducts, each of

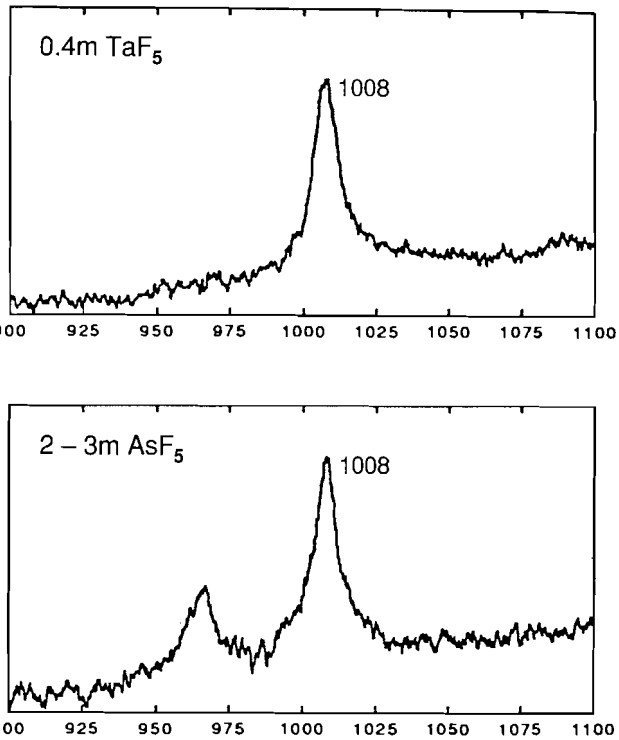

FIG. 3. Raman spectra of solutions 0.1 M in CrO_2F_2 in HF–TaF_5 and HF–AsF_5.

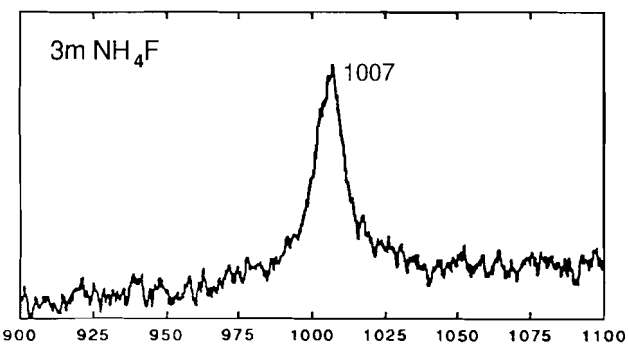

FIG. 4. Raman spectrum of 0.1 M CrO_2F_2 in HF solution 3 molal in NH_4F.

which would have had a high degree of ionic character, containing cations such as NO^+, NO_2^+, Na^+, and Ca^{2+}. However, in solution the weak Lewis acid CrO_2F_2 is competing unsuccessfully with HF for F^- whereas in Gard's systems the F^- is available from very strong fluoride donors to form ionic adducts of very low volatility.

Good experimental evidence has been developed here to show that CrO_2F_2 exists in neat HF as the molecular entity. The Cr=O stretching frequencies are virtually identical in the gas phase Raman spectrum and in the HF solution spectrum, and the addition of CrO_2F_2 to neat HF has no significant effect on the small conductance of the solvent, indicating that no ionic species are formed from the solute by fluoride transfer or by protonation.

Marked increase in the acidity of HF is required to give spectroscopic evidence of change in the nature of the molecular solute. As stated earlier the H_0 value for neat HF is usually about -11 and no new species is detected until the H_0 value is about -19.75, i.e., in 0.05 molal SbF_5. Three possible explanations

could be given for the new speciation taking into account the nature of the acidic solvent system.

The least likely of these in the light of this work, is to postulate that SbF_5 acts as an acid towards the basic oxygen site in CrO_2F_2 to form a species such as $CrF_2(O)OSbF_5$, giving rise to the new Raman peak at 965 cm^{-1}. In attempts to generate polymeric anions such as $Sb_3F_{16}^-$ by reacting stoichiometric amounts of CsF with SbF_5 in liquid SO_2, Bacon, Dean, and Gillespie found that they could isolate $Cs^+Sb_2F_{11}^-$ but that at ratios of SbF_5:CsF greater than 2:1 the complex $SO_2 \cdot SbF_5$ was formed (18). They adduced nmr spectroscopic evidence for anions of higher polymeric complexity when SO_2 was absent, i.e., the reactive matrix was SbF_5. When the available F^- concentration was initially as low as equimolar (relative to SbF_5), the next mole of SbF_5 still complexed with SbF_6^-. Beyond that point the $SO_2 \cdot SbF_5$ complex was formed. In solution, no antimony species other than SbF_6^- would form in the presence of the F^- available from solvent HF. On these grounds significant complexation of SbF_5 with an oxygen site on CrO_2F_2 dissolved in HF would be unlikely. We have shown that a solution 0.1 molar in CrO_2F_2 and 2–3 molal in AsF_5 has a spectrum with peak positions in the same position as in 0.2 molal SbF_5 and that the relative peak heights in each solution are very similar. Different peak positions would be expected for stretching frequencies for species involving Cr—O—SbF_5 and Cr—O—AsF_5 and a greater than 10-fold difference in Lewis acid concentrations would be expected to give very different relative peak heights in each solution even though AsF_5 has approximately half the Lewis acid strength of SbF_5.

It is difficult to distinguish clearly between two ways in which cationic species could be generated from CrO_2F_2 in acidic HF. The first of these would involve protonation of the oxygen site on CrO_2F_2 to give a species such as $CrF_2(O)OH^+$. On the grounds of proton availability this would be expected to occur to a similar extent in 0.2 molal SbF_5–HF and in 2–3 molal AsF_5–HF. It would also be expected to give a Raman frequency of somewhat smaller magnitude than that for the Cr=O stretch, as observed in this work.

The other possibility is that CrO_2F_2 acts like SF_4 and BrF_3 and many other molecular fluorides and also acts like UO_2F_2 in donating F^+ to the acidic, i.e., fluoride-deficient, medium HF–SbF_5, the extent of F^- transfer increasing with increasing acidity of the SbF_5–HF mixtures. This fluoride transfer and resultant formation of CrO_2F^+ would again occur approximately equally in 0.2 molal SbF_5–HF and in 2–3 molal AsF_5–HF because the fluoride level would be fixed at the same low level in each medium. The strongest evidence against this possibility is that on increase in acidity the new Raman frequency grows in at a lower wave number, not higher as would be generally expected for CrO_2F^+.

However, Gard's work on solid adducts (6) is of importance here. He added CrO_2F_2 directly to the Lewis acids SbF_5 and TaF_5. To have obtained protonated cations, there would need to have been present in each experiment an equimolar quantity of adventitious HF, i.e., to have generated solids containing the cation $CrF_2(O)OH^+$ with the anions SbF_6^-, $Sb_2F_{11}^-$, and TaF_6^-. For these compounds Gard's analytical figures for fluoride would have been 5–10% higher than the reported ones that fit the formulations $CrO_2F^+SbF_6^-$, etc. Gard also characterized his solids using infrared and Raman spectroscopy. Spectroscopic data for SbF_6^-, $Sb_2F_{11}^-$, and TaF_6^- matched those previously reported in components of known stoichiometry. He associated peaks in the 940–960 cm^{-1} region with Cr=O stretching frequencies and they correspond well with the frequencies reported in this work.

On balance, the formation of CrO_2F^+ in acidic HF is favoured here in the light of the known fluoride-donor capabilities of many fluorine-containing species including SF_4, BrF_3, and UO_2F_2 and the chemical and spectroscopic properties of the solid adducts $CrO_2F^+SbF_6^-$, $CrO_2F^+Sb_2F_{11}^-$, and $CrO_2F^+TaF_6^-$.

CrO_2F_2 is stable in HF solutions for periods of several months and this is consistent with our observations that CrO_3, CrO_4^{2-}, $Cr_2O_7^{2-}$, CrO_3F^-, and CrO_2F_2 all have the same Raman spectra when dissolved in HF or HF–SbF_5, i.e., solvolysis to CrO_2F_2 occurs for the trioxide and the oxo-anions.

Concerning the internal rotational potential in benzal chloride. $^{37}Cl/^{35}Cl$ isotope effect on the methine ^1H NMR

TED SCHAEFER AND RUDY SEBASTIAN
Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

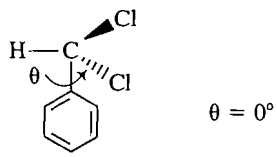
Received April 7, 1989

TED SCHAEFER and RUDY SEBASTIAN. Can. J. Chem. **67**, 2053 (1989).

^1H NMR spectral parameters are reported for benzal chloride in CS_2/C_6D_{12}, $CDCl_3$, and acetone-d_6 solutions. The values of ^6J(H,CH), the long-range spin–spin coupling constant between the side-chain and *para* protons, are consistent with twofold barriers to rotation about the exocyclic C—C bond of 8.6(4), 8.9(4), and 10.2(6) kJ/mol, in the order of the solvents above. These numbers are somewhat smaller than the twofold barrier of 11.6 kJ/mol available from STO-3G MO computations for the free molecule. Alternatively, an internal rotational potential consisting of a twofold term of 17.0 kJ/mol and a fourfold term of −5.5 kJ/mol is also compatible with the ^6J(H,CH) measured for the $CDCl_3$ solution and with the ^{13}C spin-lattice relaxation data reported for such a solution. The ^6J(H,CH) values demonstrate that the conformer with the α C—H bond situated in the benzene plane is the most stable. A local minimum in the potential for a conformer in which this bond lies in a plane perpendicular to the phenyl group, leading to a population of about 8% for this conformer at 300 K and compatible with the magnitude of ^6J(H,CH), is represented by twofold and fourfold terms of 6.0 and 4.5 kJ/mol, respectively. The barrier height is then only 8.0 kJ/mol, however. $^{37}Cl/^{35}Cl$ isotope effects on the methine proton amount to −0.17, −0.19, and −0.22 parts per billion in CS_2, $CDCl_3$, and acetone-d_6 solutions, respectively (increased screening).

Key words: benzal chloride, internal potential, $^{37}Cl/^{35}Cl$ isotope effect on ^1H NMR.

TED SCHAEFER et RUDY SEBASTIAN. Can. J. Chem. **67**, 2053 (1989).



On a déterminé les paramètres des spectres RMN du ^1H du chlorure de benzal en solution dans le CS_2/C_6D_{12}, le $CDCl_3$ et l'acétone-d_6. Les valeurs des constantes de couplage spin–spin à longue distance, ^6J(H,CH), sont en accord avec des barrières binaires à la rotation autour de la liaisons exocyclique C—C de 8,6(4), 8,9(4) et 10,2(6) kJ/mol respectivement pour les solvants mentionnés plus haut. Ces valeurs sont passablement plus basses que la barrière binaire de 11,6 kJ/mol obtenue par calculs d'OM STO-3G effectués sur la molécule libre. Par ailleurs la valeur de la constante ^6J(H,CH) mesurée dans le $CDCl_3$ ainsi que les données de relaxation spin-réseau du ^{13}C obtenues pour une telle solution sont aussi compatibles avec un terme binaire de 17,0 kJ/mol et un terme quaternaire de −5,5 kJ/mol. Les valeurs des constantes ^6J(H,CH) démontrent que le conformère le plus stable est celui comportant la liaison C—H en α dans le plan du noyau benzénique. Un minimum local dans le potentiel d'un conformère dans lequel cette liaison est perpendiculaire au groupement phényle, qui correspondrait à une population de 8% de ce conformère à 300 K et qui serait compatible avec l'amplitude de la constante ^6J(H,CH), est représenté par des termes binaire et quaternaire de respectivement 6,0 et 4,5 kJ/mol. Toutefois, la hauteur de la barrière est de 8,0 kJ/mol. Les effets isotopiques des $^{37}Cl/^{35}Cl$ sur la position du proton méthine (augmentation de la constante d'écran) sont respectivement −0,17, −0,19 et −0,22 ppm dans les solutions de CS_2, de $CDCl_3$ et d'acétone-d_6.

Mots clés : chlorure de benzal, potentiel interne, effet isotopique des $^{37}Cl/^{35}Cl$ sur la RMN du ^1H.

[Traduit par la revue]

Introduction

The study of the internal rotational potential in benzal chloride, **1**, has a curious history.

θ = 0°

1

An early application (1) of the *J* method (2) gave limits of 2.9–10 kJ/mol for an assumed twofold potential for **1** dissolved in CS_2. This method depends on the relationship, $^6J/\text{Hz} = {}^6J_{90}\langle\sin^2\theta\rangle$, where ^6J is the spin–spin coupling constant over six bonds between the *para* and side-chain protons and $^6J_{90}$ is that at θ = 90° in **1**. The expectation value of $\sin^2\theta$ can be related to the internal barrier to rotation by a hindered rotor model or by a classical averaging procedure. The magnitude of $^6J_{90}$ depends on the electronegativity of the substituents on the side chain. The large uncertainty in $^6J_{90}$ at that time (1) led to the range of barriers quoted above, although a value of 9.2 ± 1.3 kJ/mol was assessed with a lesser degree of confidence (1). The measured value of ^6J suggested that **1** was the conformation of lowest energy in CS_2 solution.

Vibrational data for the phenyl ring of 4-fluorobenzal chloride (3) could be interpreted as consistent with C_1 molecular symmetry, whereas those for the $CHCl_2$ group were consistent with C_s symmetry (3). Again, the temperature dependence of the Raman spectra of liquid **1** was analyzed (4) to yield an enthalpy difference of 4.2 ± 1.3 kJ/mol between two conformers. CNDO/2 MO computations gave an internal barrier of 8.7 kJ/mol, with a single minimum at θ = 90° in **1** (4). These results were discounted for a number of reasons (4); a molecular mechanics approach (4) delivered two minima in the internal rotational potential, the lower one at θ = 0°. The upshot of these studies, together with solvent effects indicating hydrogen bonding between the methine proton and molecules like acetone, was that the internal barrier amounted to 4–6 kJ/mol and that the second minimum in the barrier lay 2–4 kJ/mol above the first. In this connection, it is pertinent that the overtone vibrational spectra (5) of liquid **1** are consistent with the presence of a second conformer to the extent of about 10%.

Another Raman and infrared study of liquid **1** (6) came to the conclusion that the internal barrier had an upper limit of 16 kJ/mol, derived on the basis of its assumed sixfoldedness.

By way of contrast, if the carbon atoms of the phenyl group are constrained to a planar hexagon, but other bond lengths and angles are optimized during the SCF cycles, then STO-3G MO computations yield a twofold internal rotational potential of

For personal use only.

11.6 ± 0.1 kJ/mol (7). The conformer with θ as 0° is most stable. Removal of the hexagonal constraint lowers the barrier to 11.4 kJ/mol (7). Furthermore, this constraint gives a barrier of 11.0 kJ/mol in a computation with the 4-31G basis set (5). For the free molecule, at least, these calculations yield no local minimum at θ = 90°.

In $CDCl_3$ solution, the correlation times extracted from the ^{13}C spin-lattice relaxation times, the latter measured as a function of temperature, have been used (8) to find an internal barrier of 17.3 kJ/mol for **1**. This number is 1.3–3.6 kJ/mol larger than the activation energies deduced for the rotational diffusion of the whole molecule about different axes (8).

In principle, the spin-lattice relaxation times yield the height of the internal barrier because an Arrhenius dependence on temperature is assumed; they do not establish the shape of the internal rotational potential. The torsional frequencies, for a barrier substantial in magnitude compared to kT, test the bottom of the potential assumed to consist of sinusoidal components, as do the spin–spin coupling constants. The molecular orbital computations must be corrected for differences in zero-point energies between conformers in order to make comparisons with spectroscopic data; these are unlikely (9) to amount to more than about 0.5 kJ/mol in the present instance. The enthalpy differences between conformers, derived from the temperature dependence of vibrational bands assigned to the conformers, may be compared with the energies computed for the conformers if these energies are corrected for the changes in enthalpy between absolute zero and the temperatures in question. For benzal chloride the MO calculations yield an essentially twofold internal rotational potential (7), so that only one stable conformer is predicted, that with θ = 0° in **1**. Solvent effects on conformer stabilities are also possible, of course.

The purpose of the present work is to extract ^6J for benzal chloride, with a precision considerably higher than that attainable at the time of the original spectral work (1), for solutions in a nonpolar solvent mixture, in a polar solvent, and in $CDCl_3$, the solvent used for the ^{13}C spin-lattice relaxation measurements. More reliable estimates of $^6J_{90}$ are now also available. The internal rotational potentials compatible with the ^6J values are then compared with the theoretical and experimental data in the literature.

As a by-product of the spectral analysis, $^{37}Cl/^{35}Cl$ isotope shifts are found for the methine proton. They are solvent dependent.

Results and discussion

Table 1 presents the ^1H NMR spectral parameters for benzal chloride in three solvents. The somewhat larger magnitudes of the intraring coupling constants in the more polar solutions is a general result in this laboratory and is therefore unlikely to be an artefact of the spectral analyses.

$^6J(H,CH)$ and the internal barrier

$^6J(H,CH) \equiv {}^6J$ yields $\langle \sin^2 \theta \rangle$ if $^6J_{90}$ is known (2, 10–12). In toluene, $^6J_{90}$ is −1.20 Hz (13). An electronegative substituent on the side chain polarizes the C—H bond, decreases the magnitude of the σ–π interaction, and hence lowers the magnitude of $^6J_{90}$. As discussed previously for benzyl chloride (12), the values of $^6J_{90}$ of −1.02 Hz for a CH_2OR group (14, 15) and of −0.95 Hz for CH_2F (16), together with the assumption of a linear dependence of $^6J_{90}$ on the electronegativity of the α substituent, lead to a value of −1.06 Hz for $^6J_{90}$ in benzyl chloride. If a second chlorine substituent is as effective as the first in reducing the magnitude of $^6J_{90}$, intuitively rather unlikely, then $^6J_{90}$ is −0.92 Hz in benzal chloride.

Actually, the apparent twofold barrier in benzal chloride is not very sensitive to the magnitude of $^6J_{90}$. Thus, if $^6J_{90}$ is −0.98 ± 0.06 Hz, then $\langle \sin^2 \theta \rangle$ at 300 K follows as 0.18(1), 0.17(1), and 0.15(1) from the ^6J values of −0.176(2), −0.170(2), and −0.147(2) Hz in CS_2, $CDCl_3$, and acetone-d_6 solutions, respectively (Table 1). These numbers correspond to twofold barriers of 8.6(4), 8.9(4), and 10.2(6) kJ/mol for the three solvents. A very conservative approach then has it that the internal barrier to rotation in benzal chloride is 9.2 ± 1.6 kJ/mol.

Solvent dependence of the barrier

A less pessimistic attitude considers the possibility of a higher internal barrier in acetone-d_6, possibly caused by significant stabilization of the ground state by electrostatic interactions. A similar stabilization of the ground state appears to occur for benzyl chloride (12). In contrast, $^6J(H,CH)$ is independent of solvent for ethylbenzene (10) and isopropylbenzene (11). Of course, the latter are relatively nonpolar molecules. The STO-3G MO calculations (7) on benzyl chloride yield a negligible difference between the dipole moments of the conformers defined by θ = 0° and 90° (the minimal basis set in general yields dipole moments nearly as close to experiment as are 6-31G* results (17)). Therefore simple dielectric continuum models will not account for an increased barrier in acetone-d_6 solution.

Now, it is conceivable that hydrogen bonding of the polar C—H bond of the side chain in benzal chloride with acetone-d_6 molecules (note the relatively large deshielding of the α proton in acetone-d_6 solution in Table 1) causes a decrease in the magnitude of ^6J. An intrinsic solvent effect of more than 16% of its magnitude in CS_2 solution does seem unlikely, however (18).

Solvent perturbations of vicinal or longer range coupling constants between protons are more likely (18) of a size displayed for the intraring coupling constants in Table 1. $^5J_{25}$ increases by 2.4% when benzal chloride is transferred from CS_2 to acetone-d_6 solution. Yet, the same change also occurs for isopropylbenzene (11), in which ^6J is invariant to solvent. It is probable, therefore, that the internal barrier in benzal chloride is somewhat higher in the more polar medium.

The size and shape of the barrier

The apparent twofold barrier of 8.9(4) kJ/mol in $CDCl_3$ solution is smaller than the twofold barrier of 11.6 kJ/mol computed for the free molecule with the minimal basis set (7) and the barrier of 11.0 kJ/mol calculated with the 4-31G basis (5). A twofold barrier with a magnitude of 17.3 kJ/mol, as obtained from spin-lattice relaxation measurements on the $CDCl_3$ solution, requires a $\langle \sin^2 \theta \rangle$ of 0.082 at 300 K. Three possibilities present themselves.

One is that $^6J_{90}$ is very different from that used above. A ^6J of −0.170(2) Hz in the $CDCl_3$ solution will correspond to a $\langle \sin^2 \theta \rangle$ of 0.082 if $^6J_{90}$ is −2.07 Hz. In toluene, $^6J_{90}$ is −1.20 Hz (13). A larger magnitude of $^6J_{90}$ in benzal chloride than in toluene is physically unlikely, is in general contraindicated by INDO MO FPT computations (19) in our laboratory, and is rejected.

A second possibility involves the existence of an angle-independent term in the relationship, $^6J = {}^6J_0 + {}^6J_{90} \sin^2 \theta$, analogous to the equation for β-hyperfine interactions in radicals (20). This matter was recently investigated in some detail (21) for benzylidene diacetate, its 2,6-dibromo derivative, and for 2,6-dichlorobenzalchloride. For the diacetate, a maximum magnitude of 0.02 Hz for $^6J_0$ was derived, although a vanishing

[a]As a 2.5 mol% solution in CS_2, containing also 10.0 mol% of C_6D_{12} and 0.5 mol% TMS.
[b]As a 2.5 mol% solution with 0.5 mol% TMS.
[c]In Hz at 300.135$_2$ MHz to high frequency of the peak due to internal TMS.
[d]Numbers in parentheses are the standard deviations in the last significant figure.
[e]The $^{35}Cl/^{37}Cl$ isotope shift (two bonds) is 0.052(4) Hz or 0.173(4) ppb, the heavier atom causing a shift to low frequency.
[f]The $^{35}Cl/^{37}Cl$ isotope shift is 0.058(4) Hz or 0.193(4) ppb.
[g]The $^{35}Cl/^{37}Cl$ isotope shift is 0.066(5) Hz or 0.220(5) ppb.

$^6J_0$ was also compatible with experiment. In 2,6-dichlorobenzal chloride, no evidence could be adduced for other than a negligibly small $^6J_0$ (21). Nevertheless, assume a $^6J_0$ of −0.02 Hz for benzal chloride. Then $\langle \sin^2 \theta \rangle$ becomes 0.15(1) for the $CDCl_3$ solution and the apparent V_2 rises to 10.2(6) kJ/mol only.

Finally, although not supported by the MO calculations, consider the possible presence of a fourfold component in the internal rotational potential. If V_4 is of opposite sign to V_2, then a V_2 of 17.0 kJ/mol and a V_4 of −5.5 kJ/mol correspond to a $\langle \sin^2 \theta \rangle$ of 0.170 at 300 K; the barrier *height* is then 17.0 kJ/mol (V_4 does not contribute at $\theta = 90°$) and is compatible with the relaxation measurements, but not with the existence of a local minimum at $\theta = 90°$. For isopropylbenzene, STO-3G and 6-31G MO computations (11) yield V_2 and V_4 components of opposite sign for the internal rotation about the C_{sp^2}—C_{sp^3} bond, with V_4 amounting to about 20% of the magnitude of V_2. Similar computations for ethylbenzene (10) also have a negative ratio, V_2/V_4. As the length of the C_{sp^2}—C_{sp^3} is increased, the computed magnitude of V_4 decreases markedly relative to that of V_2, possibly implying that where the distance between the methyl group and the *ortho* C—H bond is sufficiently large, the latter "sees" the methyl group as an "atomic entity" and no longer distinguishes among its individual C—H bonds (10). The computed barrier for benzyl chloride is twofold (12), in agreement with such a rationalization, as is that for benzal chloride.

Of course, the MO computations for the latter might simply be wrong, or the solvent may induce a large negative V_4. Yet, the computed potentials for ethylbenzene, isopropylbenzene, and benzyl chloride are consistent with the ^6J values for these molecules in solution, so that benzal chloride would represent an exception.

A local minimum at $\theta = 90°$ can be had with a positive ratio, V_2/V_4. If V_2 is 6.0 kJ/mol and V_4 is 4.5 kJ/mol, then $\langle \sin^2 \theta \rangle$ is again 0.170 at 300 K and the population (simple two-site approximation) of the conformer at a θ of 90° is about 8%. However, the *height* of the barrier is then very near 8 kJ/mol, incompatible with the spin-lattice relaxation data.

Figure 1 displays four internal potentials for benzal chloride and the figure caption represents a summary of the preceding discussion.

$^{37}Cl/^{35}Cl$ isotope effects

These effects over two bonds have been measured for the ^{1}H NMR spectra of CH_3Cl, CH_2Cl_2, $CHCl_3$, and benzyl chloride (22, 23). Substitution of ^{37}Cl for ^{35}Cl causes an increase in screening of the proton and, in Gombler's notation (24), a negative shift. In the chlorinated methanes these effects decrease in magnitude as the number of chlorine atoms increases and are additive for $CHDCl_2$ and $CDCl_3$ (22). They are also additive for benzyl chloride (23) and are −0.20 and −0.25 ppb for CS_2/C_6D_{12} and acetone-d_6 solution, respectively. For benzal chloride (footnotes to Table 1), the isotope effects are −0.17, −0.19, and −0.22 ppb for the CS_2/C_6D_{12}, $CDCl_3$, and acetone-d_6 solutions, respectively. These numbers are not dramatically different from those for $CHDCl_2$ or $CHCl_3$ (22, 23), but do display a significant solvent dependence.

Solvent-induced changes in isotope effects on nuclear shielding are apparently important (25) when intermolecular hydrogen bonding occurs. The shielding of the methine proton in benzal chloride decreases by 0.64 ppm when the latter is transferred from CS_2 to acetone-d_2 (Table 1), considerably more than the average decrease of 0.18 ppm for the ring protons. However, for benzyl chloride (12) the decreased shielding of the side-chain protons amounts only to 0.24 ppm for the solvent pair in

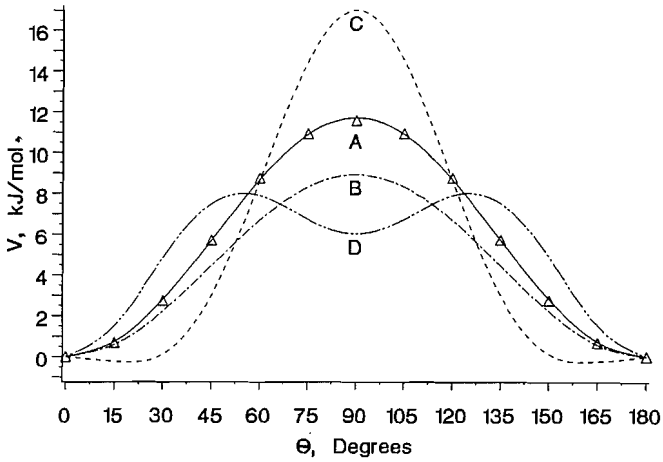

FIG. 1. In A the STO-3G MO potential (7) for rotation about the C_{sp^2}—C_{sp^3} bond in benzal chloride is shown. The computed energies are fit by the equation, $V(\text{kJ mol}^{-1}) = 11.7\sin^2\theta - 0.1\sin^2 2\theta$. In B the twofold potential, $8.9\sin^2\theta$, is compatible with the ^6J measured in $CDCl_3$ solution, θ being zero for the conformer in which the α C—H bond lies in the benzene plane. In C the potential, $V(\text{kJ mol}^{-1}) = 17.0\sin^2\theta - 5.5\sin^2 2\theta$, is displayed. It is consistent with the ^6J and with the ^{13}C spin-lattice relaxation times in $CDCl_3$ solutions; note the negative sign of V_4. In D, the potential, $V(\text{kJ mol}^{-1}) = 6.0\sin^2\theta + 4.5\sin^2 2\theta$, is compatible with a $\langle\sin^2\theta\rangle$ of 0.170 at 300 K and with a population of about 8% for the perpendicular conformer, that with θ = 90°. The height of the barrier, however, is only 8.0 kJ mol^{-1}.

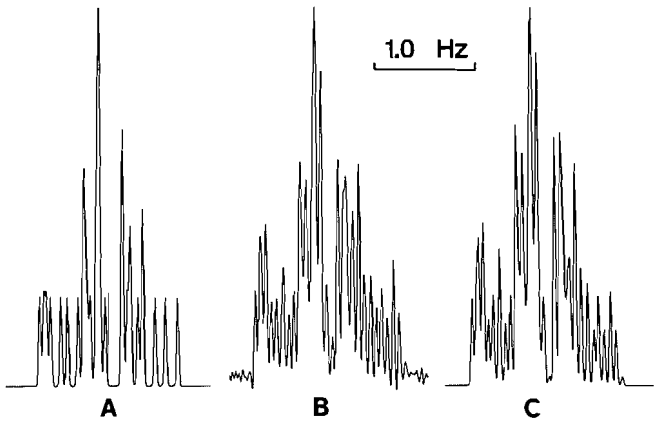

FIG. 2. The ^1H NMR spectrum of the methine proton of benzal chloride, as a 2.5 mol% solution in $CDCl_3$, is shown as B at 300 MHz and 300 K. On the left, A, the spectrum is computed with the spectral parameters in Table 1, but in the absence of $^{37}Cl/^{35}Cl$ isotope effects on the shift of the methine proton. On the right, C, the theoretical spectrum assumes an isotope shift of −0.19 ppb. The agreement with the measured spectrum is not exact, but is clearly better than in A. The ring proton spectrum does not suffer from isotope shifts, so that the long-range coupling constants are obtainable with high precision (Table 1).

question, yet the solvent dependence of the isotope effect is as large for benzyl chloride as for benzal chloride. Hence the perturbations of the electron distribution in the C—H bond by the solvent, as indicated by the observed shifts, are not simply related to those causing the changes in the isotope effect. In fact, significant solvent-induced changes in $^2H/^1H$ isotope effects on ^{13}C shielding have been recently measured for a nonpolar molecule, toluene-α-d_3 (26). In this molecule, however, the isotope effect over two bonds is *smaller* in acetone-d_6 than in $CDCl_3$ solution (26).

Experimental

Dilute solutions of benzal chloride (Aldrich) in CS_2/C_6D_{12}, $CDCl_3$, and acetone-d_6 were transferred to 5 mm o.d. NMR sample tubes. These were degassed by the freeze–pump–thaw procedure and were then flame-sealed to provide symmetrical tops. The ^1H NMR spectra derived from a Bruker AM300 spectrometer in the manner previously described (16). The spectra were analyzed with the computer program NUMARIT (27), as modified in this laboratory by R. Sebastian. The ensuing spectral data are presented in Table 1. Figure 2 illustrates the quality of the spectra, noting also that the presence of $^{37}Cl/^{35}Cl$ isotope effects on the chemical shift of the methine proton leads to complications not present for the ring proton region.

Photochemistry of cyclobutanones with nitrogen acids. A potential nucleoside synthesis

IVY E. E. HAYES, LINDA JANDRISITS, AND EDWARD LEE-RUFF[1]
Department of Chemistry, York University, Toronto, Ont., Canada M3J 1P3

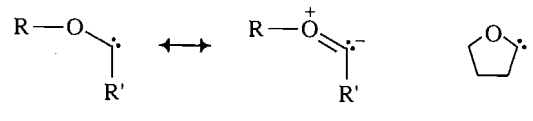
Received September 8, 1988[2]

IVY E. E. HAYES, LINDA JANDRISITS, and EDWARD LEE-RUFF. Can. J. Chem. **67**, 2057 (1989).

Irradiation of 3-methylene-2,2,4,4-tetramethylcyclobutanone with nitrogen acids such as succinimide, phthalimide, imidazole, 3,5-dimethylpyrazole, purine, and benzimidazole gives 1:1 adducts that were identified as cyclic α-aminoacetals structurally related to nucleosides.

Key words: photochemistry of cyclobutanones, oxacarbene, nucleoside analogs.

IVY E. E. HAYES, LINDA JANDRISITS et EDWARD LEE-RUFF. Can. J. Chem. **67**, 2057 (1989).



L'irradiation de la 3-méthylène-2,2,4,4-tétraméthylcyclobutanone en présence d'acides azotés comme la succinimide, la phtalimide, l'imidazole, la 3,5-diméthylpyrazole, la purine et la benzimidazole fournit des adduits 1:1 que l'on a identifiés comme étant des α-aminoacétals cycliques reliés d'un point de vue structural à des nucléosides.

Mots clés : photochimie de cyclobutanones, oxacarbène, analogues nucléoside.

[Traduit par la revue]

The strain associated with small ring systems promotes reactivity that contrasts that of larger ring strain-free molecules. Cyclobutanones undergo a variety of regio and stereoselective ring expansion reactions useful in the preparation of medicinally important compounds (1). Photochemical ring expansion to furanyl derivatives has also been reported to occur stereoselectively (2).

The photochemistry of cyclobutanones proceeds by three competitive pathways, decarbonylation, cycloelimination, and ring expansion to an oxacarbene **3** (3). The distribution of the photoproducts is largely dependent on the nature of the ring substituent and recently we have shown that it is also dependent on solvent effects (4). To date, the cyclic oxacarbene has been trapped by intra or intermolecular reactions with OH functional groups (5, 6).[3] In one case of a related cyclic oxacarbene generated photochemically, a small amount of product derived from olefin insertion was observed (8). Recent studies by Kesselmayer and Sheridan (9) on acyclic oxacarbenes indicate that these can be represented by zwitterionic resonance contributors such as **2** to account for their somewhat unusual reactivity when compared to dialkylmethylenes. The nucleophilic character of such oxacarbenes can readily account for the commonly observed OH insertion products and the lack of olefin insertion, in contrast to the behavior of dialkylmethylenes. We were interested whether oxacarbenes **3** generated from cyclobutanones would be sufficiently basic to insert into N—H bonds. Such a reaction would be of synthetic use in the direct preparation of α-aminofuranosides related to nucleosides. Pirrung and DeAmicis recently reported that N—H insertion of selected acidic amines occurs with an oxacarbene generated from a cyclobutanone (10). Preliminary investigation with cyclobutanone and ketone **4** showed that mixtures with aniline, diethylamine, and cyclohexylamine were photostable under uv irradiation based on gc and ^{1}H nmr analysis of reaction mixtures.[4] On the other hand, more acidic nitrogen acids with pK_a values comparable to, or smaller than, those of alcohols form 1:1 adducts with **4** under uv irradiation. Ketone **4** was chosen since ring expansion to oxacarbene **5** represents the dominant pathway in its photoreaction with alcohols (3). Both photodecarbonylation and cycloelimination are insignificant for **4**.

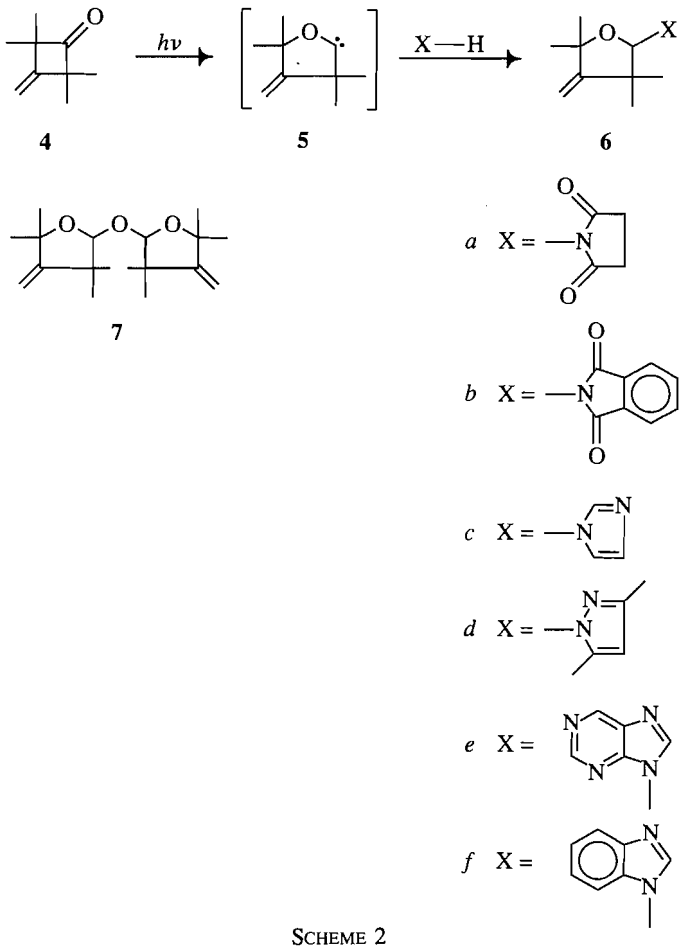
1 **2** **3**

SCHEME 1

Results and discussion

Mixtures of **4** (0.01–0.20 M) and the nitrogen acid (succinimide, phthalimide, imidazole, 3,5-dimethylpyrazole, purine, and benzimidazole) in dry tetrahydrofuran, dichloromethane, or acetonitrile were irradiated using a high pressure mercury lamp for 17.5–78 h. In most cases a single product was obtained and identified as the 1:1 photoadduct(s) **6***a–f* by spectroscopic and analytical data. The proton nmr spectra of **6** were characteristic in the separation of all four methyl protons, the observation of an acetal proton (δ 5.5–6.2 ppm), an almost equivalent AB pattern for the methylene protons (4.8–5.0 ppm), and signals associated with the nitrogen acid. In some cases, when the solvent was not rigorously dried, a 2:1 adduct of ketone **4** with water was obtained and identified as the bis-acetal **7**. This product most likely arises from the photoreaction of the water adduct **6** (X = OH) with oxacarbene **5**. Confirmation of this was obtained by photolysis of **5** in a solution containing 1 equivalent of **6** (X = OH) and the observation of **7** as a major product. Further confirmation of **6***a* was obtained from its acid methanolysis using saturated HCl solutions to give acetal **6** (X = OCH_3), identical in all respects to the photoadduct obtained when **4** was irradiated in methanol solution.

The absence of photocarbene insertion into N—H bonds of simple amines suggests that the basicity of the carbene may be a factor in such reactions. Although C—H insertion by aryl and alkyl carbenes is a common reaction (11), these proceed by



[1]Author to whom correspondence may be addressed.

[2]Revision received June 9, 1989.

[3]There are some examples of 1,2-hydrogen shifts leading to enol ethers. See, for example, ref. 7.

[4]Solutions containing 0.1 g of ketone **4** in 25 mL of CH_2Cl_2 with 5 equivalents of amine were irradiated for 17–20 h. Unreacted cyclobutanone and amine were detected by gc and nmr. Some photodecomposition of **4** to volatile products occurred (presumably 1,1,2,2-tetramethyl-3-methylenecyclopropane and 1,1-dimethyl-2-isopropylidenecyclopropane (19)) but these could not be isolated. However, no reaction products with the amines could be detected.

SCHEME 2

mechanisms not involving proton transfer. Evidence for proton transfer reactions to aryl carbenes has been obtained for the O—H insertions of these species at temperatures slightly below ambient (12). Although oxacarbenes are considered to be nucleophilic carbenes relative to alkyl and aryl carbenes, the proton affinities of methoxylmethylene are about 10 kcal/mol lower than those of methylmethylene (13). This would suggest that if the proton transfer mechanism is involved in the formation of X—H insertion photoproducts, then the X—H acidity would have to be a contributing factor in the efficiency of this reaction. An alternate mechanism for X—H insertion involving electrophilic attack by the carbene at X and formation of an ylide (14) can be ruled out in our case since the more nucleophilic aniline, diethylamine, and cyclohexylamine did not undergo photoreaction with **4**. Although it has been reported that simple amines undergo N—H insertions with a photocarbene generated from a cyclobutanone (10), these photoadducts were not unambiguously characterized and could have been misinterpreted, with their actual structures being the hemiacetal produced from cyclobutanone photolysis with adventitious water present. The nmr data and gc retention times of the amine adducts and the hemiacetal are quite similar.

The possibility of using chiral, stereospecifically substituted cyclobutanones (15) with appropriate substituents in such a photoreaction in the preparation of nucleoside analogues is under investigation. It is known that photolysis of unsymmetric cyclobutanones proceeds in a stereoselective manner (2). The question of stereochemistry at the anomeric center in unsymmetrically substituted furanosides will be investigated.

Experimental

Melting points (mp) were determined on a Reichert melting point apparatus and were uncorrected. Infrared (ir) spectra were recorded on Pye Unicam SP-1000 and SP3-200 spectrophotometers as thin films or KBr pellets. Nuclear magnetic resonance (nmr) spectra were recorded on a Bruker AM-300 (300 MHz) spectrometer using samples dissolved in $CDCl_3$ containing 1% Me_4Si as internal standard. All nmr values are reported as chemical shift δ in ppm downfield from Me_4Si. Mass spectra were recorded on a VG Micromass 16F spectrometer. High resolution mass spectrometry was performed at the McMaster Regional Centre for Mass Spectrometry using a VG ZAB-E instrument in the EI mode at 70 eV. Elemental analyses were performed by Guelph Chemical Laboratories Limited. Photolyses were carried out using a Hanovia 450-W high pressure mercury arc lamp in a water cooled quartz immersion well with a Pyrex filter. The quartz sample tube was strapped around this well and immersed in an ice–water bath. Reaction mixtures were degassed with N_2 for 1 h prior to photolyses. Column chromatography utilized Terochem silica gel (flash chromatography type, 20–45 μm) or Merck silica gel 60 (70–270 mesh). Analytical thin-layer chromatography (tlc) was conducted on precoated plastic sheets (silica gel 60 F_{254}, layer thickness 0.2 mm) manufactured by E. Merck and Co. The sheets were visualized by examination with ultraviolet light (254 nm) or by dipping with a phosphomolybdic acid solution (20% in ethanol) followed by heating the sheet to 75°C. Anhydrous ether was obtained from Fisher Scientific Ltd. Reagent grade tetrahydrofuran (Fisher) was dried over NaOH and distilled from Na before use. Gold label acetonitrile was distilled from CaH_2 and stored over molecular sieves. Glass distilled hexane and dichloromethane were obtained from BDH Chemicals and used without distillation. Nitrogen acids were obtained from Aldrich Chemical Co., Inc. and not further purified unless otherwise stated.

3-Methylene-2,2,4,4-tetramethylcyclobutanone **4**

This ketone was prepared by a modification of the method of Hamon (16) and Lee-Ruff (17). The monophenylimine of 2,2,4,4-tetramethylcyclobutane-1,3-dione (24.2 g) (18) in 121 mL ether was added in one lot to a stirred suspension of dry triphenylphosphonium methyl iodide (50.9 g) and potassium *tert*-butoxide (14.5 g) in ether (606 mL) under an atmosphere of nitrogen. The canary-yellow coloured mixture was stirred overnight. After filtration of the triphenylphosphine oxide, the filtrate was diluted with water and extracted with ether. The ether layer was then dried over anhydrous magnesium sulfate and the ether distilled using a short Vigreux column. The crude imine of **4** (16.1 g) was stirred and refluxed with 50% acetic acid (100 mL). A solid collected in the reflux condenser in a few minutes. This was washed back into the solution and refluxing continued for 1 h. After cooling, the excess acetic acid was destroyed by addition of solid bicarbonate. The mixture was then extracted with ether and the ether layer was washed with water until neutral, dried over anhydrous magnesium sulfate, and distilled through a short column to give an oil. The oil mixture was sublimed at room temperature at 25 Torr (1 Torr = 133.3 Pa) pressure to give a crystalline material **4**, mp 43–44°C (lit. (16) mp 42–43°C) (6.3 g, 40%; 2 steps).

2-Succinimidyl-3,5-tetramethyl-4-methylene tetrahydrofuran **6**a

A solution of 0.25 g (1.81 mmol) of ketone **4** and 0.90 g (9.08 mmol) of succinimide (recrystallized from EtOH) in 150 mL of CH_2Cl_2 was irradiated for 25.25 h. Removal of the CH_2Cl_2 by rotary evaporation and flash chromatography on silica gel (10% tetrahydrofuran/hexane) gave 0.11 g (26%) of **6***a* (recrystallized from pentane); mp 48–49°C; ir (KBr), cm^{-1}: 3090 (=C—H), 2980 (CH), 1790, 1710 (C=O), 1090 (C—O); ^1H nmr δ: 5.68 (s, acetal H), 4.84 (AB *exo* CH_2), 2.67 (s, CH_2 of succinimidyl), 1.51, 1.38, 1.31, 1.10 (s, methyl H's); ^{13}C nmr δ: 176.1 (CO), 163.1 (quat. C of C=C), 101.6 (*exo* CH_2), 88.9 (acetal C), 83.8 (quat. C α to O), 45.7 (quat. 2-Phthalimidyl-3,5-tetramethyl-4-methylene tetrahydrofuran **6**b

A solution of 0.50 g (3.62 mmol) of ketone **4** and 0.48 g (3.26 mmol) of phthalimide in 20 mL of tetrahydrofuran was irradiated for 62 h. Solvent evaporation by rotary evaporation and column chromatography (10% tetrahydrofuran/hexane) gave 0.13 g (14%) of **6***b* (recrystallized from hexane); mp 114–115°C; ir (thin film), cm^{-1}: 3070 (=C—H), 2970 (C—H), 1775, 1720 (C=O), 1610 (C=C), 1050 (C—O); ^1H nmr δ: 7.65 (dd, J = 5.5 Hz, 3.0 Hz, CH of phthalimidyl), 7.77 (dd, J = 5.5 Hz, 3.0 Hz, CH of phthalimidyl), 5.84 (s, acetal H), 4.91 (AB *exo* CH_2), 1.57, 1.42, 1.36, 1.17 (s, methyl H's); ^{13}C nmr δ: 168.0 (CO), 160.1 (quat. C of C=C), 134.3 (phthalimide C-5, C-6), 132.5 (phthalimide C-3a, C-7a), 123.5 (phthalimide C-4, C-7), 105.7 (*exo* CH_2), 89.1 (acetal C), 85.2 (quat. C α to O), 43.3 (quat. C), 29.8, 29.6, 29.5, 29.4 (CH_3's); *m/e*: 286 $(M + H)^+$, 139 $(M^+ - C_8H_4NO_2)$; high resolution ms, *m/e* calcd.: 286.1444; found: 286.1438. *Anal.* calcd. for $C_{17}H_{19}NO_3$: C 71.56, H 6.71, N 4.91; found: C 71.29, H 7.14, N 4.46.

2-Imidazolyl-3,5-tetramethyl-4-methylene tetrahydrofuran **6**c

A solution of 0.23 g (1.66 mmol) of ketone **4** and 0.066 g (0.97 mmol) of imidazole (recrystallized from benzene) in 10 mL of tetrahydrofuran was irradiated for 26.5 h. Solvent removal by rotary evaporation, followed by two flash columns (15% tetrahydrofuran/hexane) gave 0.19 g (95%) of white crystalline **6***c* (recrystallized from hexane); mp 64.5–65.5°C; ir (KBr), cm^{-1}: 3120 (=C—H), 2990 (C—H), 1805 ($R_2C{=}CH_2$), 1520, 1490, 1465, 1378 (azole), 1080 (C—O); ^1H nmr δ: 7.66 (s, H of C-2 of imidazole), (7.04, 7.07) (s, H of C-4 and C-5 of imidazole), 5.48 (s, acetal H), 4.94 (AB *exo* CH_2), 1.53, 1.39, 1.22, 0.80 (s, methyl H's); ^{13}C nmr δ: 162.8 (quat. C of C=C), 135.7 (imidazole C-2), (129.0, 117.1) (imidazole C-4, C-5), 104.5 (*exo* CH_2), 93.1 (acetal C), 82.4 (quat. C α to O), 46.7 (quat. C), 29.9, 28.7, 24.9, 24.1 (CH_3's); ms, *m/e*: 206 (M^+), 139 $(M^+ - C_3H_3N_2)$. *Anal.* calcd. for $C_{12}H_{18}N_2O$: C 69.87, H 8.79, N 13.58; found: C 70.22, H 8.93, N 13.76.

3,5-Dimethylpyrazole adduct **6**d

A solution of 0.50 g (3.62 mmol) of ketone **4** and 1.74 g (18.1 mmol) of 3,5-dimethylpyrazole (recrystallized from EtOH) in 30 mL of CH_2Cl_2 was irradiated for 20.5 h. Removal of the CH_2Cl_2 by rotary evaporation followed by flash column chromatography (10% tetrahydrofuran/hexane) yielded 0.36 g (43%) of a colourless oil **6***d*; ir (thin film), cm^{-1}: 3070 (=C—H), 2960 (C—H), 1655 (C=C), 1555, 1465, 1365 (azole), 1065 (C—O); ^1H nmr δ: 5.73 (s, pyrazole H-4), 5.58 (s, acetal H), 4.85 (AB *exo* CH_2), (2.28, 2.16) (s, pyrazole CH_3's), 1.61, 1.41, 1.32, 0.89 (s, methyl H's); ^{13}C nmr δ: 163.8 (quat. C of C=C), (147, 139.5) (C-3 and C-5 of pyrazole), 105.5 (C-4 of pyrazole), 102.3 (*exo* CH_2), 94.0 (acetal C), 83.8 (quat. C α to O), 47.5 (quat. C), (30.3, 29.3) (pyrazole CH_3's), 29.2, 22.9, 13.5, 11.6 (CH_3's); ms, *m/e*: 234 (M^+), 139 $(M^+ - C_5H_7N_2)$; high resolution ms, *m/e* calcd.: 234.1734; found: 234.1742.

Purine adduct **6**e

A solution of 1.05 g (7.60 mmol) of ketone **4** and 0.52 g (4.33 mmol) of purine in 500 mL of acetonitrile was irradiated for 78 h. Solvent removal by rotary evaporation and column chromatography (20% tetrahydrofuran/hexane) gave 0.35 g (31%) of a yellow oil **6***e*; ir (thin film), cm^{-1}: 2960 (C—H), 1660 (C=C), 1593, 1580, 1495, 1410, 1370 (purine), 1060 (C—O); ^1H nmr δ: 9.16 (s, H-6 of purine), 8.98 (s, H-2 of purine), 8.37 (s, H-8 of purine), 6.23 (s, acetal H), 5.00 (AB *exo* CH_2), 1.59, 1.46, 1.39, 0.88 (s, methyl H's); ^{13}C nmr δ: 162.5 (quat. C of C=C), 152.3 (C-2 of purine), 151.0 (C-4 of purine), 148.3 (C-8 of purine), 143.6 (C-6 of purine), 128.0 (C-5 of purine), 104.6 (*exo* CH_2), 90.0 (acetal C), 82.9 (quat. C α to O), 46.7 (quat. C), 29.6, 28.4, 25.1, 24.4 (CH_3's); ms, *m/e*: 258 (M^+), 139 $(M^+ - C_5H_3N_4)$; high resolution ms, *m/e* calcd.: 258.1482; found: 258.1493.

2-Benzimidazolyl-3,5-tetramethyl-4-methylene tetrahydrofuran **6**f

A solution of 0.56 g (4.05 mmol) of ketone **1** and 0.46 g (3.89 mmol) of benzimidazole in 45 mL of tetrahydrofuran was irradiated for 17.5 h. Solvent removal by rotary evaporation and flash column chromatography gave 0.93 g (93%) of crystalline **6***f* (recrystallized from hexane); mp 138–139°C; ir (KBr), cm^{-1}: 3060 (=C—H), 2980 (C—H), 1662 (C=C), 1615, 1490, 1468, 1370, 1320 (azole), 1060 (C—O); ^1H nmr δ: 8.18 (s, H-2 of benzimidazole), (7.45, 7.82) (m, H-7, H-4 of benzimidazole), 7.28 (m, H-5, H-6 of benzimidazole), 5.89 (s, acetal H), 4.98 (AB *exo* CH_2), 1.60, 1.45, 1.32, 0.87 (s, methyl H's); ^{13}C nmr δ: 163.0 (quat. C of C=C), (143.6, 133.2) (quat. C's of benzimidazole), 141.3 (benzimidazole C-2), (123.0, 122.3) (benzimidazole C-5, C-6), (120.3, 110.5) (benzimidazole C-4, C-7), 104.5 (*exo* CH_2), 91.7 (acetal C), 82.4 (quat. C α to O), 47.2 (quat. C), 29.8, 28.4, 25.3, 24.5 (CH_3's); ms, *m/e*: 256 (M^+), 139 $(M^+ - C_7H_5N_2)$. *Anal.* calcd. for $C_{16}H_{20}N_2O$: C 74.97, H 7.86, N 10.93; found: C 74.61, H 7.92, N 11.10.

*3,3,5,5-Tetramethyl-4-methylene-2-methoxytetrahydrofuran (***6***) (X = OCH_3)*

A solution of 0.64 g (4.63 mmol) of ketone **4** in 20 mL of methanol was irradiated for 24 h. Solvent evaporation and column chromatography (5% tetrahydrofuran/hexane) gave **6** (X = OCH_3), whose ^1H nmr spectrum was similar to the literature (19): ^1H nmr δ: 4.82 (s, 1), 4.78 (s, 1), 4.54 (s, 1), 3.34 (s, 3), 1.37 (s, 6), 1.14 (s, 3), 1.11 (s, 3).

A solution of 0.28 g (2.03 mmol) of **6***a* in 2 mL of a saturated HCl/MeOH solution was stirred under N_2 for 1 h. The product obtained was identical to **6** (X = OCH_3).

*3,3,5,5-Tetramethyl-4-methylene-2-hydroxytetrahydrofuran (***6***) (X = OH)*

A solution of 0.50 g (3.63 mmol) of ketone **4** in 20 mL of tetrahydrofuran and 1 mL of water was irradiated for 12 h. Solvent evaporation was followed by addition of ether (50 mL) to the crude oil. The ether fraction was washed with water (2 × 50 mL), dried with magnesium sulfate, and concentrated by rotary evaporation to give 0.33 g (58%) of a yellow oil; ir (thin film), cm^{-1}: 3390 (OH), 2970 (C—H), 1665 (C=C), 1380, 1365 (*gem* dimethyls), 1080, 1035 (C—O); ^1H nmr δ: 5.06 (s, acetal H), 4.83, 4.78 (AB *exo* CH_2), 4.20 (bs, OH), 1.42, 1.32, 1.11, 1.10 (s, methyl H's); ^{13}C nmr δ: 164.0 (quat. C of C=C), 103.9 (acetal C), 102.8 (*exo* CH_2), 83.3 (quat. C α to O), 47.2 (quat. C), 31.6, 30.5, 28.1, 21.5 (CH_3's); ms, *m/e*: 139 $(M^+ - OH)$.

Bis-acetal **7**

A solution of 0.33 g (2.11 mmol) of the crude alcohol **6** (X = OH) and 0.24 g (1.74 mmol) of ketone **4** in 20 mL of tetrahydrofuran was irradiated for 7 h. Solvent evaporation and column chromatography (5% ethyl acetate/hexane) gave 0.12 g (24%) of a colourless oil **7**; ir (thin film), cm^{-1}: 2960 (C—H), 1375, 1360 (*gem* dimethyls), 1060 (C—O); ^1H nmr δ: 4.87 (s, acetal H), 4.79, 4.76 (AB *exo* CH_2), 1.41, 1.36, 1.14, 1.10 (s, methyl H's); ^{13}C nmr δ: 164.6 (quat. C of C=C), 108.9 (acetal C), 101.8 (*exo* CH_2), 83.8 (quat. C α to O), 47.7 (quat. C), 31.1, 30.6, 29.2, 22.1 (CH_3's); ms, *m/e*: 294 $(M^+$, 8%), 279 $(M^+ - CH_3$, 18%), 139 $(M^+ - C_9H_{15}O$, 100%).

Reçu le 16 février 1989

JACQUES BERTHELOT, CATHERINE GUETTE, PAUL-LOUIS DESBÈNE, JEAN-JACQUES BASSELIER, PATRICK CHAQUIN et DANIEL MASURE. Can. J. Chem. **67**, 2061 (1989).

L'action du tribromure de tétrabutylammonium ($TBABr_3$) sur les phénols et les amines aromatiques conduit exclusivement aux composés monobromés en *para* correspondants. Cette réaction est effectuée à température ambiante dans les solvants aprotiques non basiques. Les rendements en produits isolés et purs sont très élevés. Un mécanisme faisant appel à une substitution électrophile par l'anion Br_3^- est postulé, permettant l'interprétation de cette réaction de bromation régiosélective.

Mots clés : bromation, tribromure de tétrabutylammonium, phénols, amines aromatiques.

JACQUES BERTHELOT, CATHERINE GUETTE, PAUL-LOUIS DESBÈNE, JEAN-JACQUES BASSELIER, PATRICK CHAQUIN, and DANIEL MASURE. Can. J. Chem. **67**, 2061 (1989).

The reaction of tetrabutylammonium tribromide ($TBABr_3$) with phenols and aromatic amines in aprotic and non-basic solvents at 20°C gives exclusively the corresponding *para*-brominated compounds in high yields. A mechanism involving electrophilic substitution by the tribromide anion Br_3^- itself is suggested to account for the results, especially the regioselective *para* bromination.

Key words: bromination, tetrabutylammonium tribromide, phenols, aromatic amines.

La monobromation régiosélective de noyaux aromatiques pose encore des problèmes (1) : en effet, il reste difficile de contrôler le nombre et la position des atomes de brome introduits sur des composés aromatiques activés tels que phénols et amines aromatiques. La bromation par les méthodes classiques conduit le plus souvent à un mélange de composés monobromés en *ortho* et *para* accompagnés de dérivés polybromés (1, 2). Si la bromation effectuée à l'aide des réactifs tels que le bromure d'iode (3), le bromure cuivrique (4), le perbromure de dioxanne (5) et le *N*-bromosuccinimide (6) a permis de limiter le nombre d'atomes de brome introduits, par contre le contrôle de la régiosélectivité de la substitution n'est réalisée que dans des cas limités (7). Pour éviter les inconvénients d'emploi du brome, on a eu recours à des tribromures : de pyridinium (8), de diamino-2,4 thiazole (9), de triméthylphénylammonium (10) et de triméthylbenzylammonium (11). Ils conduisent souvent à une halogénation sélective mais présentent toutefois l'inconvénient d'être soit instables soit faiblement solubles. Le rôle de l'anion Br_3^- et son mécanisme d'action dans ces réactions de bromation sont encore discutés.

Nous avons eu l'opportunité d'utiliser le tribromure de tétrabutylammonium ($TBABr_3$) pour fixer du brome sur des doubles liaisons éthyléniques (12) et des triples liaisons acétyléniques (13) ou pour substituer sélectivement en α des acétals (12). $TBABr_3$ est un solide orangé, stable, non hygroscopique, à degré de brome actif constant et facilement utilisable dans des conditions douces. Il est également employé avec succès dans un milieu aussi complexe que la matrice pétrolière où il permet enfin la mesure d'un indice de brome (14). Des résultats expérimentaux récemment publiés (15) ont montré son efficacité pour bromer très sélectivement des dérivés aromatiques. Nous désirons préciser le rôle et le mécanisme d'action de l'ion Br_3^- dans ces réactions. Dans le présent mémoire, nous montrerons l'intérêt d'utiliser le $TBABr_3$ pour bromer sélectivement des carbures aromatiques et l'importance du solvant employé, et nous proposerons une explication sur la nature de l'agent bromant.

$$C_6H_5\text{-}A + TBABr_3 \longrightarrow p\text{-}BrC_6H_4\text{-}A + TBABr + HBr$$

A : OH, NH_2, NHR, NR_2

SCHÉMA 1

Résultats

Un équivalent de $TBABr_3$ dissous dans le chloroforme ($CHCl_3$) brome un équivalent de phénol (tableau 1) ou d'amine aromatique (tableau 2) d'une façon presque quantitative à température ambiante. La solution initialement orangée devient incolore quand $TBABr_3$ a totalement réagi et indique que la réaction est terminée (schéma 1).

Cette monobromation s'effectue d'une manière très régiosélective en position *para* puisque le rendement en produit secondaire ne dépasse jamais 3%, sauf dans le cas de l'aniline (tableau 2). Quand le sommet *para* est déjà substitué par un groupement alkyle la bromation a lieu en *ortho*, avec d'excellents rendements, mais elle est ralentie. Dans tous les cas les dérivés polybromés sont totalement absents. L'action de $TBABr_3$ sur les naphtols permet d'éviter la formation de produits de désaromatisation du noyau naphtalénique et de composés polybromés qui sont obtenus avec les agents de bromation classiques (2).

$TBABr_3$ se différencie nettement de Br_2 dans son comporte-

Méthoxy-2 phénol	200	Br-4 MeO-2 phénol	95

ment vis à vis de certains carbures aromatiques. Ainsi le mésitylène facilement bromé par Br_2 ne réagit pas en présence de $TBABr_3$ même à l'ébullition du solvant. La substitution électrophile par le dibrome est aisée quand les fonctions phénol et amine sont protégées respectivement sous forme d'ether ou d'anilide. Dans ce dernier cas c'est même la façon la plus simple d'obtenir une amine aromatique monobromée en *para*, après déblocage en milieu basique (1, 2). $TBABr_3$ ne brome ni l'anisole, ni l'acétanilide (tableau 3). Cette différence de réactivité peut être mise à profit en synthèse; ainsi le méthoxy-2 phénol (guaiacol) réagit avec le tribromure dans $CHCl_3$ pour donner presque quantitativement le bromo-4 méthoxy-2 phénol. La pyridine, même en très large excès, dans le chloroforme, ne réagit pas avec $TBABr_3$. Par contre une pyridine substituée par un groupement amino comme l'amino-2 pyridine est bromée rapidement pour donner exclusivement l'amino-2 bromo-5 pyridine.

Influence de différent facteurs

Nous avons pris comme modèle d'étude la bromation d'un équivalent de phénol par un équivalent de $TBABr_3$.

(A) Température

La réaction effectuée à différentes températures (de −3°C à 75°C) dans $CHCl_3$ et CCl_4 ne conduit, dans tous les cas, qu'au *para*-bromophénol avec un rendement voisin de 95%, même si on augmente la durée de bromation (tableau 4).

TABLEAU 4. Evolution de l'action de $TBABr_3$ sur le phénol en fonction de la température[a]

T (°C)	Durée (min)	*p*-Bromophénol (%)
−3	5	95
20	2	95
60	2	95
76	2	94

[a]Ces essais sont effectués sur 4 mmol de phénol, 4 mmol de $TBABr_3$ dans 10 mL de solvant ($CHCl_3$ et CCl_4 pour l'éssai à 76°C). Les rendements sont ceux des produits isolés et purs. La durée indiquée correspond au moment où la solution initialement orangée est devenue incolore. Si on prolonge cette durée de réaction (15 min) pour les différents essais ci-dessus, aucune modification n'a lieu dans la nature et le rendement du produit bromé obtenu.

(B) Dilution

La dilution n'est pas un facteur modifiant la nature et le rendement de la réaction. Des essais, effectués tous avec les mêmes quantités de phénol et de $TBABr_3$ (3 mmol), à température ambiante et respectivement dans 7, 10, 20, 50 et 75 mL de $CHCl_3$, conduisent tous au même composé monobromé en *para* avec un rendement d'environ 95% en produit isolé et pur.

(C) Solvant

Tous les essais ont été effectués à température ambiante :

Dans les solvants aprotiques, peu polaires tels que CCl_4, $CHCl_3$ et CH_2Cl_2 ou plus polaires comme CH_3CN, seul l'isomère *para*-bromé est obtenu avec d'excellents rendements. La bromation en *ortho* et les polybromations sont presque totalement inhibées.

Dans les solvants basiques aprotiques, peu polaire comme le THF ou polaire comme le DMF, la réaction ne livre un mélange de *para*-bromophénol (75%) accompagné d'*ortho* et de polybromophénols qu'après 8 jours.

Dans l'éthanol absolu, milieu protique et moyennement polaire, la bromation donne après 30 min un mélange de 85% de *para*-bromophénol et de 15% d'*ortho*-bromophénol, sans polybromation.

Dans un mélange éthanol–eau (1 : 1) plus protique et plus polaire le pourcentage d'*ortho*-bromophénol atteint 25%, la durée de la réaction étant inchangée.

Ce dernier résultat nous a incité à utiliser un milieu biphasique où $TBABr_3$ est dissous dans $CHCl_3$ et le phénol dans l'eau (le pH est de 4,5). Après 20 min, 90% de *para*-bromophénol sont recueillis accompagnés de 9% de l'isomère *ortho*.

(D) Effet de sel

Le milieu biphasique décrit ci-dessus nous a permis d'examiner l'effet de sels peu solubles en phase organique. L'addition de LiBr à la solution aqueuse du phénol ne modifie pratiquement pas son pH mais induit la formation d'*ortho*-bromophénol (22%) aux dépens de l'isomère *para* (76%) mais sans polybromation. La réaction dure alors 100 min.

Si un excès de $LiClO_4$ (5 équivalents) est ajouté à la phase aqueuse la bromation est terminée au bout de 5 min et ne conduit qu'au seul *para*-bromophénol avec un rendement de 98%.

(E) Modification du pH du milieu réactionnel

Si la réaction est conduite en milieu chloroformique acidifié (par HCl ou H_2SO_4) ou basique (par KOH, ou en présence de butylamine), le phénol par action de $TBABr_3$ conduit au même mélange d'*ortho*, de *para* et de polybromophénols. Ce résultat est analogue à celui observé par action du dibrome sur le phénol.

L'ensemble de ces résultats est rassemblé dans le tableau 5.

Discussion

Le rôle de l'anion Br_3^- comme réactif de bromation et agent électrophile reste encore controversé. Diverses opinions contradictoires ont été formulées sur sa réactivité en la comparant toujours à celle du dibrome. Il est par exemple postulé que Br_3^- n'interviendrait pas lui même dans l'attaque électrophile (17), sa réactivité serait soit supérieure à celle du dibrome pour la bromation d'alkylphénols (18), soit inférieure pour bromer des anisoles (19), soit égale vis à vis d'hydroxy-8 quinoléïne (20). Enfin, certains auteurs ne se prononcent pas sur la réactivité de Br_3^- comme entité électrophile (21). Mais récemment il a été établi (22) qu'un tribromure dans un milieu peu polaire aprotique bromait les alcènes et que le mécanisme d'action de Br_3^- était différent de celui de Br_2.

On sait que l'ion tribromure donne lieu à l'équilibre :

$$Br_3^- \rightleftarrows Br_2 + Br^-$$

et que la position de cet équilibre est fortement influencée par la nature du solvant (tableau 6).

On constate que la proportion de dibrome est faible surtout dans les solvants aprotiques. Si, néanmoins, le Br_2 formé était l'agent bromant dans les réactions décrites précédemment, les bromations par $TBABr_3$ devraient conduire à la formation du mélange d'*ortho*, de *para* et de polybromophénols, par substitution électrophile analogue à celle du dibrome sur un composé aromatique. Un certain nombre d'arguments fondés sur les résultats expérimentaux nous paraissent apporter la preuve que l'ion Br_3^- est bien l'agent bromant quand $TBABr_3$ réagit avec le phénol dans un milieu aprotique : la grande stéréosélectivité observée sur le sommet *para*, l'absence totale de polybromations et la non réactivité avec certains composés aromatiques (anisole ou acétanilide par exemple) facilement bromés par Br_2.

Nous rappelons en outre que dans un précédent mémoire (13) nous avions établi que l'ion Br_3^- pouvait être rendu responsable de la formation stéréosélective d'alcènes dibromés (*E*) quand $TBABr_3$ agit sur un alcyne (schéma 2).

Un facteur important de ces réactions de bromation par $TBABr_3$ est le rôle du solvant qui peut changer la nature du contre-ion. Dans les solvants peu polaires aprotiques, $TBABr_3$ se trouve sous forme de paire d'ions, TAB^+ étant le cation associé à l'anion Br_3^-. Par contre, dans les solvants polaires et protiques, $TBABr_3$ est dissocié et il est connu que les ions trihalogénés de type X_3^- se lient au solvant par liaison hydrogène (25) ce qui revient à changer la nature du réactif. Les paires d'ions sont également modifiées dans les solvants basiques, où en outre il a été établi (26) qu'il se forme une liaison entre l'hydrogène de l'hydroxyle phénolique et le solvant, ce qui modifie la structure du réactif qui se trouve en partie sous forme phénoxyde.

L'eau en plus de son pouvoir dissociant peut avoir un triple rôle : atténuer la réactivité de Br_3^- par création de liaisons hydrogène, augmenter la dissociation de Br_3^- en Br_2 et, comme il a été prouvé (27), accélérer l'addition électrophile du dibrome formé.

L'effet de sel, notamment quand $LiClO_4$ est additionné en excès à la solution, en modifiant la nature du contre-ion permet d'annihiler le rôle de l'eau et on retrouve alors la formation régiosélective presque quantitative de l'isomère *para*. Cet effet de sel se manifeste différemment avec LiBr puisque à la

SCHÉMA 2

modification due au cation se superpose l'action de Br^-. Il en résulte la formation d'*ortho*-bromophénol aux dépens de l'isomère *para*. Une explication de ce résultat sera proposée ultérieurement (28).

Enfin nous rappelons que l'acidification du milieu permet la bromation de l'anisole par $TBABr_3$ pour donner le même mélange de produits mono- et poly-bromés que celui obtenu avec Br_2. Ce résultat nous parait normal car d'une part les hydracides solvatent fortement les anions par liaison hydrogène (29) et d'autre part les composés trihalogénés ne sont pas stables dans les milieux acidifiés et se dissocient facilement selon (25) :

$$Br_3^- + H^+ \rightarrow Br_2 + HBr$$

On peut donc envisager qu'en milieu acide Br_3^- est à la fois fortement dissocié en dibrome qui devient l'espèce réactive et que le proton se fixant comme contre-ion modifie l'aptitude électrophile des anions Br_3^- restants.

Au terme de cette discussion il est manifeste que si la température et la dilution n'apparaissent pas comme des facteurs déterminants, le solvant et les contre-ions jouent un rôle essentiel dans ces réactions de bromation par $TBABr_3$. L'anion tribromure est incontestablement l'agent responsable de ces substitutions électrophiles, comme en témoignant par exemple la grande régiosélectivité avec des rendements élevés, l'inhibition totale des polybromations et la bromation des alcynes. Toutefois le mécanisme de la réaction de l'anion Br_3^- impliquant la sélectivité sur le sommet *para* appelle des études complémentaires (28). Une confirmation de ces premières conclusions est recherchée dans des mesures cinétiques ainsi que dans une étude systématique de l'effet du contre-ion et enfin dans un essai d'approche théorique du mécanisme (28).

Partie expérimentale

Remarques générales

Tous les solvants et les réactifs ont été purifiés selon les procédés courants. Les points de fusion (*F*) ont été déterminés au banc de

Köfler. Le $TABBr_3$ et les produits utilisés proviennent de Janssen Chimica. Les spectres infra-rouges ont été enregistrés à l'aide d'un spectrophotomètre Pye Unicam SP3-200, ceux de rmn ^1H sur un appareil Bruker SY80 (80 MHz, dans $CDCl_3$ avec le TMS comme référence interne, les déplacements étant exprimés en ppm) et les spectres de masse (sm) avec un spectromètre magnétique MS 30 (à 70 eV). La chromatographie en phase gazeuse a été réalisée sur un chromatographe Hewlett Packard 5880 équipé d'un détecteur de flamme (FID) et d'une colonne capillaire Chrompack CP SIL 5 (longueur = 25 m; d_i = 0,22 mm; température de l'injecteur, 200°C). La programmation du four est de 70°C (pendant 5 min) à 200°C en 3°C/min. La pureté des produits a été vérifiée par chromatographie sur couche mince (ccm) sur gel de silice fluorescente (éluant mélange éther – éther de pétrole, de proportions diverses). La purification a été obtenue par chromatographie préparative (cp) sur gel de silice fluorescente Merck PF-254 (plaque 20 × 20 cm et e = 0,1 cm) avec un éluant composé d'un mélange ether – ether de pétrole (en général 20 : 80).

Bromation des composés phénoliques et des amines aromatiques — mode opératoire général : 2×10^{-3} mol de composé aromatique est dissoute dans 10 mL de $CHCl_3$. Sous agitation 2×10^{-3} mol de $TABBr_3$ en solution dans 10 mL de $CHCl_3$ est ajoutée rapidement à température ambiante. Le mélange, de couleur orange, devient rapidement incolore. On ajoute 20 mL d'une solution aqueuse de thiosulfate de sodium à 5% en continuant l'agitation. La phase organique est décantée, lavée à l'eau jusqu'à pH 7, puis évaporée. L'huile restante est reprise par un mélange éther–eau. Après décantation, la phase éthérée est séchée et l'éther est évaporé. Le produit aromatique bromé est ensuite purifié par cp.

Résultats

Produits monobromés obtenus : les rendements sont indiqués en produits isolés et purs.

Bromo-4 méthoxy-2 phénol : *R* % (95), huile identifiée avec un échantillon authentique (32); ir : 3500; rmn : 3,6 (s, 3H), 5,6 (s, 1H), 6,8 (m, 3H); sm : 204–202 ($M^{+\bullet}$, 40), 189–187 [$(M - CH_3)^+$, 100].

para-*Bromoaniline* : *R* % (84); *F* : 66°C (litt. (32) 66°C; rmn : 3,5 (s, 2H), 6,8 (2d, 4H); sm (100 eV, ICIN(N_2), 0,05 Torr) : 172–170 [$(M - H)^-$, 100], 81–79 (Br^-, 60).

Bromo-4 N-*méthylaniline* : *R* % (94), huile identifiée par comparaison avec un échantillon authentique (33); rmn : 2,6 (s, 3H), 3,7 (s, 1H), 6,6 (2d, 4H); sm (100 eV, ICIN(N_2) 0,05 Torr) : 186–184 [$(M - H)^-$, 100], 81–79 (Br^-, 60).

Bromo-4 diéthylaniline : *R* % (99), huile identifiée par comparaison avec un échantillon authentique (33); rmn : 1,5 (t, 6H), 3,1 (q, 4H), 6,6 (2d, 4H); sm : 229–227 ($M^{+\bullet}$, 60), 200–198 [$(M - C_2H_5)^+$, 100], 119 [$(M - C_2H_5 - Br)^-$, 60].

Di(bromo-4 N-*phényl)aniline* : *R* % (99); *F* : 107°C (litt. (33) 106°C); rmn (DMSO-d_6) : 7 (2d, 8H), 8,1 (s, 1H); sm : 329–327–325 ($M^{+\bullet}$, 100), 248–246 [$(M - Br)^+$, 60].

Bromo-4 N-*cyclohexylamine* : *R* % (95), huile identifiée par comparaison avec un échantillon authentique (34); rmn : 1,5 (m, 11H), 6,2 (s, 1H), 6,6 (2d, 4H); sm : 255–253 ($M^{+\bullet}$, 40), 172–170 [$(M - C_6H_{11})^+$, 100].

Amino-2 bromo-5 pyridine : *R* % (98), huile identifiée par comparaison avec un échantillon authentique (35); rmn : 5,9 (s, 2H), 7 (m, 3H); sm : 174–172 ($M^{+\bullet}$, 50), 93 [$(M - Br)^+$, 100].

Réaction de bromation du phénol en milieu biphasique : 2×10^{-3} mol de phénol est dissous dans 10 mL d'eau déminéralisée. Quand la réaction a lieu en présence d'un sel, celui-ci est ajouté à la phase aqueuse et la solution est agitée jusqu'à dissolution complète. $TABBr_3$ (2×10^{-3} mol) dissous dans 10 mL de $CHCl_3$ est ajoutée rapidement à la solution aqueuse. Le mélange est agité et la réaction est considérée comme terminée quand la phase chloroformique est décolorée. Après séparation la phase aqueuse est reprise par trois fois 15 mL de $CHCl_3$. Les phases chloroformiques sont rassemblées, séchées, puis évaporées. La purification est conduite comme il est décrit précédemment.

Remerciements

Nous remercions vivement le Docteur Claude Agami pour les fructueuses discussions et l'intérêt qu'il a porté à ce travail.

Received June 14, 1989

B. Mario Pinto, Blair D. Johnston, and Ruby Nagelkerke. Can. J. Chem. **67**, 2067 (1989).

Nuclear Overhauser enhancement difference experiments and magnetization transfer experiments on 2-benzoyl-5-methyl-5-aza-1,3-dithiacyclohexane **1** at 186 K show conclusively that the *N*-methyl group adopts a preferred axial orientation. The result has implications for evaluation of the origin of the anomeric effect in this and related compounds. The free energy of activation for ring interconversion in **1** is estimated by spin saturation transfer experiments to be 10.7 ± 0.4 kcal mol^{-1}.
Key words: D NMR, conformational analysis, nuclear Overhauser enhancement, saturation transfer.

Des expériences d'effets Overhauser nucléaire et de transfert de magnétisation conduites sur le benzoyl-2 méthyl-5 aza-5 dithia-1,3 cyclohexane **1** à 186 K montrent de façon concluante que ie groupe *N*-méthyle adopte préférentiellement une orientation axiale. les résultats influencent l'évaluation de l'origine des effets anomériques dans ce composé et dans les composés apparentés. Faisant appel à des expériences de transfert de saturation de spin, on a évalué à 10,7 ± 0,4 kcal mol^{-1} l'énergie libre d'activation de l'interconversion du cycle dans le composé **1**.
Mots clés : RMN D, analyse de conformation, effet Overhauser nucléaire, transfert de saturation.

[Traduit par la revue]

Introduction

We recently reported (1) a study of second-row anomeric interactions in 2-substituted 5-methyl-5-aza-1,3-dithiacyclohexanes. The conformational processes of interest in these systems are those of ring interconversion and nitrogen inversion (see Scheme 1). Examination of the ^{1}H NMR spectra at 173 K indicated two sets of signals for each of the H-4$_{eq}$, H-4$_{ax}$, H-2, and N-Me protons. Upon heating, each of these sets coalesced to give averaged signals, and time-averaged spectra were observed at about 300 K. This dynamic behaviour was attributed (1) to one conformational process, namely that of ring interconversion, the barriers for nitrogen inversion being substantially lower (2). Since only two conformers predominated at low temperature, it was of some interest to assign the preponderant orientation of the *N*-alkyl group. Angiolini *et al.* and Katritzky (3) have assigned the *N*-alkyl group in *N*-alkyl-5-aza-1,3-dithiacyclohexanes a preferred axial orientation, based on a comparison of dipole moments of these compounds with those of 1,3-dithiane and *N*-alkyl piperidines. We found it preferable to deduce the orientation of the *N*-methyl group in our compounds by more direct means and present herein the results of nOe difference experiments and magnetization transfer experiments for one of the candidates, namely the 2-benzoyl derivative. The results show conclusively that the *N*-methyl group adopts a preferred axial orientation.

Scheme 1

Experimental

Acetone-d_6 was purchased from Merck Sharpe Dohme Isotopes. ^{1}H NMR spectra were recorded at 400.13 MHz on a Bruker WM-400 NMR spectrometer. Chemical shifts are given in ppm downfield from Me_4Si. The probe thermocouple was used for temperature measurement, after calibration. Temperatures are believed to be accurate to within ±2 K. The sample of 2-benzoyl-5-methyl-5-aza-1,3-dithiacyclohexane **1** (1) in $(CD_3)_2CO$ was degassed using the freeze–pump–thaw technique. The tube was sealed under vacuum. All experiments were performed at 186 K. ^{1}H NMR, **1a** δ: 2.65 (NMe), 3.94 (H-4, 6$_e$), 5.27 (H-4, 6$_a$), 5.84 (H-2); **1e** δ: 2.49 (NMe), 4.32 (H-4, 6$_e$), 5.17 (H-4, 6$_a$), 6.75 (H-2); ^{13}C NMR, **1a** δ: 36.8 (NMe), 41.6 (C-2), 55.5 (C-4, 6); **1e** δ: 36.9 (NMe), 55.9 (C-2), 60.4 (C-4, 6).

Difference nOe experiments

The selected signals were individually irradiated at the centres of the signals with a second rf field at saturating power levels for 4 s. The intensities of the affected signals were obtained by direct integration of the peaks and were calculated as percentages of the irradiated signals (Table 1).

Spin saturation transfer difference experiment

This was based on the Forsén–Hoffman method for measuring rates of exchange (4, 5). The methyl signal of the major isomer **1e** was saturated by irradiation with a second rf field; the irradiation times were 0.025, 0.05, 0.25, 0.5, 1, and 2 s. The complete saturation of the methyl signal of **1e** was verified. Equilibrium magnetization was reached after about 1 s, as judged by the constant normalized area of the methyl signal of **1a** after about 1 s of irradiation. A semilogarithmic least-squares plot of $\log(MzA - MzA_\infty)$ against irradiation time t (5) gave a straight line with slope of $-1.74 \pm 0.12\,s^{-1} = -\tau_{1A}^{-1}$. The value of MzA ($t = 0$)/MzA ($t = \infty$) was then used to evaluate τ_{1A}/T_{1A} (0.38 ± 0.04) and hence, τ_A, the pre-exchange lifetime of the site in **1a** (5). The free energy of activation, $\Delta G^\ddagger$, was then calculated by means of the Eyring equation (5).

The IR spectrum of **1** was recorded in KBr on a Perkin–Elmer 983G spectrophotometer.

Results and Discussion

The spectra were assigned in the following manner. Consideration of the γ-*gauche* effect (6) in the ^{13}C NMR spectrum permitted assignment of the respective signals to the axial and equatorial conformers. Specifically, C-4, 6 in the axial conformer is shielded (4.9 ppm) relative to that in the equatorial conformer. Once the major (COPh equatorial) and minor (COPh axial) isomers had been assigned, the signals in the low

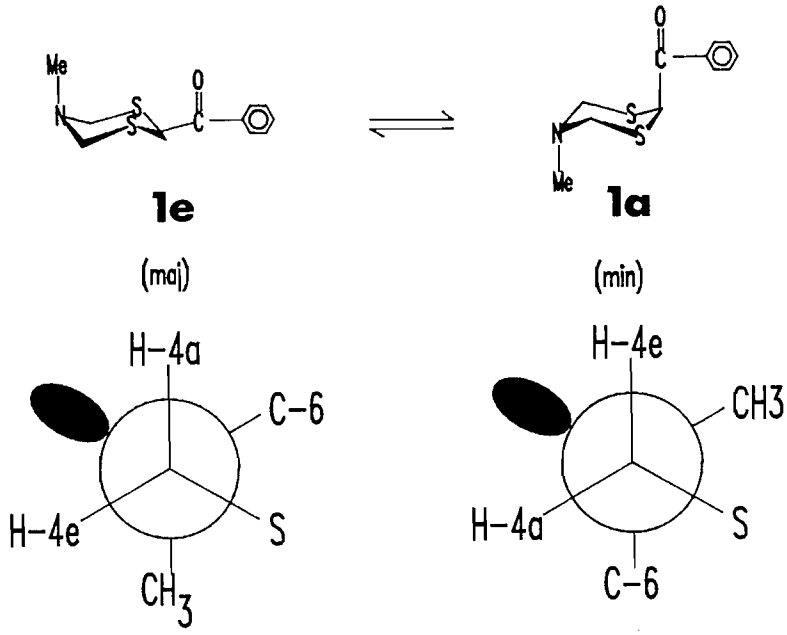

FIG. 2. Newman projections along the C-4—N bond in the preferred conformations of **1e** (B) and **1a** (C).

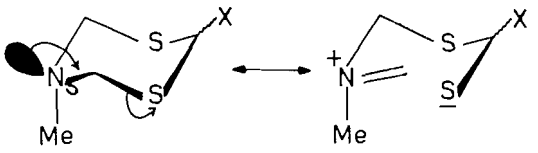
temperature ^{1}H NMR spectrum were assigned. For example, the signals for H-4_a and H-4_e in the minor isomer were distinguished on the basis of the long range coupling (2 Hz) between H-2_e and H-4_e (3*a*, 7). We note also that a value of $^4J_{2e,4e}$ of 2 Hz corroborates the assignment of the minor conformer to that in which the C-2 substituent is axially oriented (3*a*, 7). The distinction of the H-4_e and H-4_a signals in the spectrum of the major isomer followed from the observation of nOe effects between H-2_a and H-4_a (see below).



We initially envisaged that the results of nOe difference experiments would be straightforward, and would be diagnostic of the preferred orientation of the *N*-methyl group in **1**. However, it soon became evident that even though exchange was slow on the chemical-shift time scale at 186 K, it was still faster than the rates of relaxation for sets of protons in the axial and equatorial conformers **1a** and **1e**, respectively; the observed relaxation rate then represents a weighted average of the two contributing relaxation rates. The consequence of the latter effect is that this fast exchange on the relaxation time scale allows transfer of magnetization and population information from one of the resonances in **1a** to its exchange-related counterpart in **1e** (8). Thus, saturation of one of the resonances in **1a** by steady-state irradiation could be transferred to the corresponding resonance in **1e** by exchange. Indeed, nOe effects created in a particular resonance of **1a** were transferred to its counterpart in **1e**, and vice versa, by exchange. The results are summarized in Table 1 and a representative case is illustrated in Fig. 1.

Inspection of the data in Table 1 indicates the following salient features with respect to nOe effects. (1) Irradiation of an *N*-methyl resonance in either conformer (entries 1, 2) resulted in nOe effects only on H-4_e and not on H-4_a. The results are consistent only with a preponderance of conformations in which the *N*-methyl group is axially oriented (conformations B and C in Scheme 1) since otherwise an nOe effect on H-4_a would also have been expected (see Fig. 2). (2) Irradiation of the H-4_e signals of either conformer (entries 3, 4) gave a major nOe effect on H-4_a and a minor effect on the H-2 and *N*-methyl signals. (3) Irradiation of the H-4_a signal in the spectrum of the minor conformer **1a** (entry 6) gave an nOe effect only on H-4_e, as expected for a preferred axial orientation of the *N*-methyl group. (4) Irradiation of the H-4_a signal in the spectrum of the major conformer **1e** (entry 5) gave nOe effects on H-4_e and H-2, as expected. The latter effect derives from the 1,3-diaxial relationship of H-2 and H-4_a, and is also supported by the converse experiment in which H-2 is irradiated (entry 7). The results corroborate the previous assignment (1) of the equatorial orientation of the 2-benzoyl group in the major conformer.

In addition to the nOe effects described above, the effects of magnetization transfer via exchange were also detected. Thus, saturation of the *N*-methyl resonance of the major isomer **1e** (entry 1) resulted in saturation transfer to the *N*-methyl and H-4_a resonances of the minor isomer **1a**. Similarly, irradiation of the *N*-methyl resonance of the minor isomer **1a** (entry 2) gave saturation transfer effects on the H-4_a and *N*-methyl signals of **1e**. A combination of nOe and magnetization transfer effects was also observed upon irradiation of the H-4_e and H-4_a signals in the spectra of both **1a** and **1e**. Thus, saturation of H-4_e in the spectrum of **1e** (entry 3) resulted in magnetization transfer to H-4_a and H-4_e (via a relayed nOe effect) of **1a** and, similarly, saturation of H-4_e in the spectrum of **1a** (entry 4) gave magnetization transfer to H-4_a and to H-4_e (via a relayed nOe effect) of **1e**. Analogous effects were observed upon irradiation of the H-4_a signals of either conformer (entries 5, 6). Saturation transfer effects between H-2's of the two conformers (entries 7, 8) were also observed; in addition, irradiation of H-2 in the spectrum of the minor conformer **1a** also resulted in detectable magnetization transfer effects on H-4_a of the major isomer **1e**. The latter effect results from magnetization transfer via exchange of H-2_e in **1a** with H-2_a in **1e**, coupled with a relayed nOe effect between H-2_a and H-4_a in **1e**. The percentage of saturation transfer from irradiation of a signal attributable to the minor conformer (e.g., H-4_a in **1a**) to the inversion-related signal of the major conformer (e.g., H-4_e in **1e**) was always greater than in the converse experiment (major→minor). This is expected since the ground state population distribution of **1a** and **1e** dictates a lower barrier for ring interconversion in **1a** than in **1e**.

The results presented in Table 1 are consistent only with a

For personal use only.

SCHEME 2

preponderance of conformations B and C (see Scheme 1), at 186 K, in which the *N*-methyl group is axially oriented. The conclusion is also corroborated by the IR spectrum, which indicated the absence of the Bohlmann bands (9) in the C—H stretching region; the bands would only be present if the N lone pair were antiperiplanar to the C-4, 6 axial hydrogens, that is, in the *N*-methyl equatorial conformation. Angiolini *et al.* (3) have suggested that the preference for the axial orientation of the *N*-alkyl groups in *N*-alkyl-5-aza-1,3-dithiacyclohexanes may result from destabilizing N lone pair – S lone pair repulsions in the alkyl-equatorial conformers and the stabilization of the alkyl-axial conformers by easy deformation at nitrogen. We propose further the role of $n_N \rightarrow \sigma^*_{c-s}$ stabilizing orbital interactions in stabilizing the *N*-methyl axial conformation in compounds of this type (see Scheme 2). The N lone pair orientation has implications for the evaluation of the origin of the anomeric effect in such derivatives (1).

As a final point of interest, we comment on the barrier to ring interconversion in **1**. The system was amenable to study using spin saturation transfer techniques since the pre-exchange lifetime τ_A (0.92 s) and the spin-lattice relaxation time T_{1A} (1.53 s) of the spins in the methyl site of **1a** (Site A) are of the same order of magnitude. Instantaneous saturation of the methyl signal of **1e** (Site E) for various times, t, thus leads to a decay of the intensity of the signal at site A to a new equilibrium value, permitting measurement of the rate constant for exchange (4, 5). A free energy of activation, $\Delta G^{\ddagger} = 10.7 \pm 0.4$ kcal mol^{-1}, for interconversion of **1e** to **1a**, was calculated. The value compares favorably with that ($\Delta G^{\ddagger} = 11.0 \pm 0.2$ kcal mol^{-1}) reported (3) for 5-methyl-5-aza-1,3-dithiacyclohexane.

The total assignment of ^{1}H NMR spectra of a pentacyclic triterpene from *Loeselia mexicana* was performed using selected 2D-NMR experiments (COSY, NOE). X-ray diffraction data were obtained from the parent compound as supplemental information to the NMR investigations. The data allowed for the unambiguous assignment of the structure and the stereochemistry of the title compound.

Key words: pentacyclic triterpene NMR, 2D NMR of terpenes, X-ray of triterpenes, triterpenyl angelate NMR, X-ray – 2D NMR structure determination.

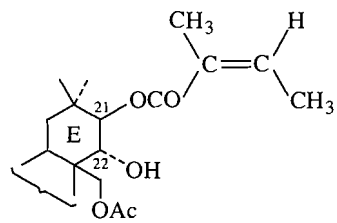
[Traduit par la revue]



Introduction

Triterpenoids are among the most common natural products isolated from plant material (1). In spite of their simple nature, they are quite difficult to characterize because of the similarities observed for the physical and spectral properties of their different isomeric structures. Mass spectrometry, for instance, allows for the assignment of the triterpenic skeleton but fails to locate the functional groups and the unsaturation sites. As such, mass spectrometry is not a reliable technique for unambiguous structure elucidation of triterpenes (2). Two-dimensional NMR correlation experiments along with other pulsing techniques based on establishing long range couplings (3, 4) provide a more reliable method for the total assignment of triterpene structures (5). In this paper we would like to present an example of work where the use of these techniques led to the assignment of the molecular structure of one uncommon triterpenoid derivative from *Loeselia mexicana* (**1**). The parent compound, whose structure was deduced entirely from NMR spectra, was then subjected to X-ray analysis for comparison purposes. This comparison was made necessary because of the number of discrepancies found in the literature on NMR chemical shift assignments, especially for the D and E rings of pentacyclic triterpenes. In this respect, the spectra of several terpene model compounds should be used with great care as incorrect assignments as well as insufficient similarity have often led to major structure reassignments.

The following NMR spectra of the *Loeselia mexicana* triterpenic compound were interpreted: (i) high resolution (500 MHz), (ii) COSY together with COSY relayed, and (iii) NOESY.

4

SCHEME 1

A triterpenic fraction of *Loeselia mexicana*, an important plant of the Polemoneacea family, is widely used in Mexican native medicine because of its diuretic, purgative, emetic, or sudorific properties. This popular shrub, widely spread in the Valley of Mexico, is up to 90 cm high and the extraction of its aerial part produces ca. 1% (w/w; dry) of an amorphous solid residue, which under work-up conditions yields 0.05% of triterpenes. In a previous report (6) we tentatively assigned the structure of [olean-12-en-3β,16α,21α,22α,28-pentol]-yl-16,28-diacetate-22α-angelate (**1**) to the major component (80%) of that fraction. The white crystalline triterpene was first transformed into barringtongenol C (**2**) or into its 3β,16α,21α,28-

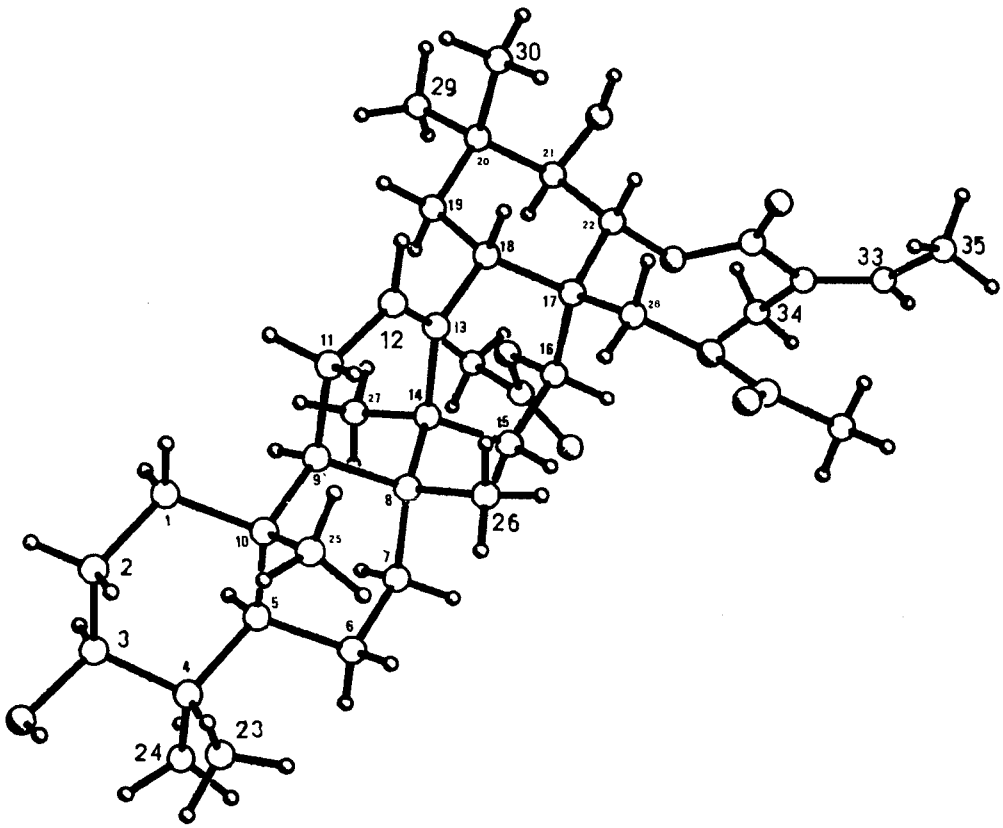

FIG. 1. ORTEP view of the molecular structure of **1**, all atoms of compound **1**.

tetraacetate, (**3**). The 2D-NMR experiments of this study were performed on the diacetate **1**. The major difficulty with this compound was the establishment of the positions of the angelic ester residue on the E ring as well as the assignment of the acetate group (Scheme 1).

X-ray of triterpene 1

The crystal structure of **1**, shown in Fig. 1, displays a few peculiarities. The E ring is in a chair conformation with its two major substituents, namely 21β-hydroxyl and the angelic acid residue at C-22, being *trans* diequatorial. The β-CH_2OCOCH_3 moiety at C-28 and the α-acetate at C-16 are also *trans*, the D–E ring junction being in the *cis* configuration. Looking at the A–E rings, we observe that the C ring shows a slight distortion and that, because of the *trans–anti–trans* steroidal configuration of the A–C rings, the 27-methyl and 19-methylene of the E ring are subjected to some form of 1,3-diaxial interaction. Consequently, the E ring is also deformed, to prevent these two substituents from falling into a 1,3-diaxial conformation.

NMR studies

High-resolution assignments

To assign the proton signals obtained from the high-resolution spectrum of **1** (Table 1) we have divided the 64 triterpene protons into eight regions with 25 non-methyl protons, seven methyls, two acetate methyls, and two vinylic methyls of the angelate residue.

The first system was that of the angelate residue. It was easily assigned using the multiplicity of the observed signals and their respective chemical shifts as criteria.

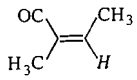
A second system consisted of protons of the C_9, C_{11}, and C_{12} carbon sequence. It was more difficult to unscramble because of the fact that H_9, in particular, is shifted to the very crowded 1.3–1.7 ppm area. The positive assignment of this proton was made after the recording of 2D experiments. However, at this stage of the identification, it was possible to assign both C_{11} protons at 1.87 and 1.92 ppm.

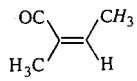
The third system, made up of three protons on C-18 and C-19, was assigned at 2.33 and 2.44 ppm for the two C-19 protons (the first one being axial, distinctive doublets) and 1.36 ppm for the C-18 proton.

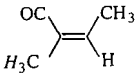
The next system consisted of five protons on C-1, C-2, and C-3. Only the H-3 proton was easily identified at 3.20 ppm with two apparent ^3J couplings indicating an axial position.

The three protons on C-15 and C-16 were identified at 5.28, 1.53, and 1.78 ppm, respectively, as the C-16 equatorial proton and the two C-15 protons displaying a characteristic geminal coupling.

The C-28 methylene moiety was assigned to the bands at 3.75 and 3.82 ppm, related by a large geminal coupling constant (^2J = 11.4 Hz). Their chemical shifts show a characteristic shift (of 0.5 ppm) for the esterification of primary alcohols.







For the next group of protons, namely those on the A and B rings at C-5, C-6, and C-7, the high resolution one-dimensional spectrum does not allow for a direct positive assignment. As discussed below, the upfield protons can be assigned as shown in Table 1 from the 2D COSY spectra in particular.

Finally, the last group of protons, the C-21 and C-22 methines, show a large ^3J diaxial coupling (10.0 Hz).

The seven methyls directly attached to the triterpene skeleton are difficult to assign even with COSY and NOE spectra. From this group of seven singlets only the signals at 1.27 (C-27 methyl) and 0.92 ppm (angular C-25 methyl) can be easily assigned. In the spectrum of compound **1**, the two acetate

methyls at C-28 and C-16 are observed at 1.99 and 2.08 ppm; however, their assignment is still uncertain at this stage.

Apart from these uncertainties, the high resolution one-dimensional NMR spectrum already allows the direct, unambiguous assignment of several protons. A more detailed analysis of the structure, as well as definitive assignments, was carried out using COSY, COSY DELAYED (30 ms), and NOESY (τ_m = 280 ms) experiments as described below.

COSY[2]

Individual proton assignments are presented in Figs. 2*a*–*c*. The eight previously defined systems of protons were analyzed and the resulting additional assignments were added to Table 1. The C-1, C-2, C-3, the C-15, C-16, and the more complex C-5, C-6, C-7 sequences were all positively assigned. COSY experiments allowed further advance in the total proton assignment without, however, providing definitive answers as to the identity of the methyl moieties and the net distinction between *axial* and *equatorial* methylene protons of the skeleton.

COSY DELAYED[2]

This type of experiment allows for the assignment of axial methyls from the ^4J couplings, particularly when both methyls and protons form the W arrangement or are in axial positions. Three additional assignments were made. Taking the C-15eq

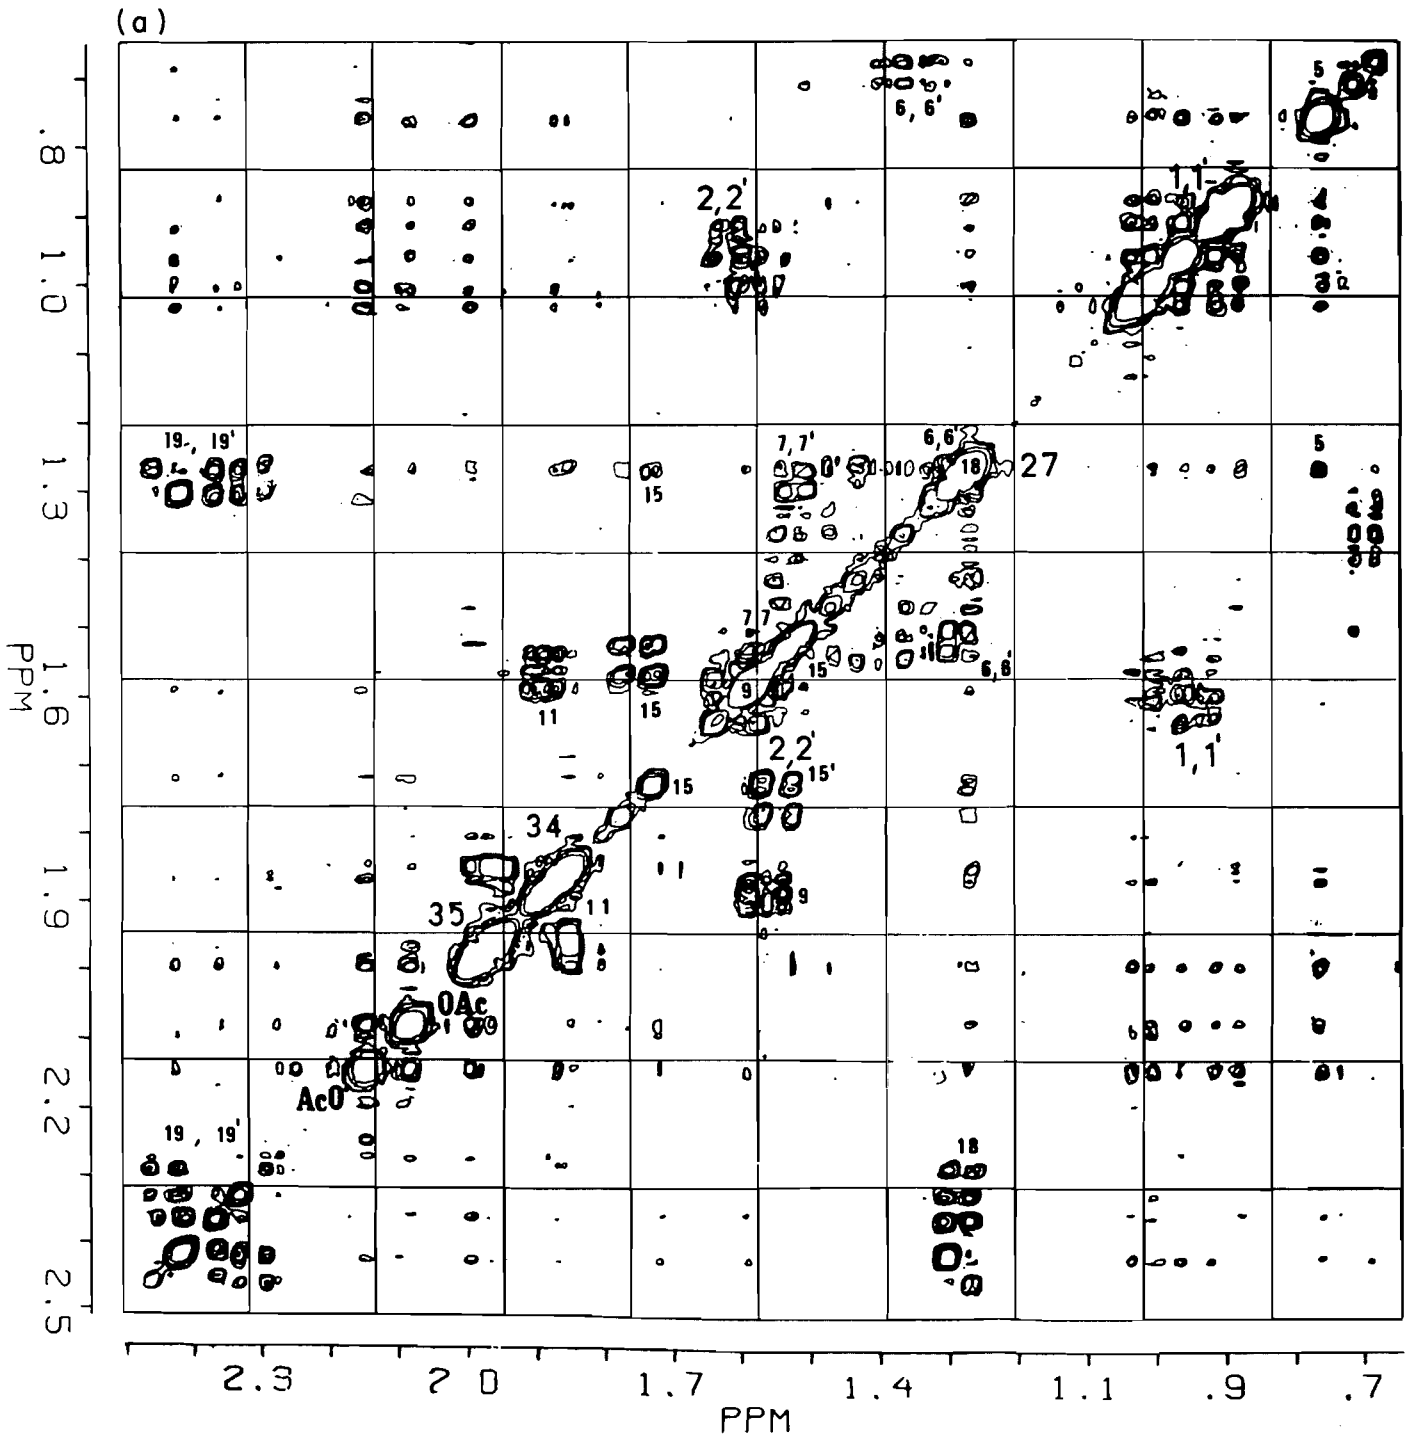

FIG. 2. (a) COSY, 0.7–2.5 ppm area of **1**.

proton as starting point, the C-27 methyl was assigned at 1.27 ppm. A second ^4J system allowed for the assignment of the two protons at C-7ax and C-9 as well as the C-26 methyl. The last sequence of protons at C-19ax and C-21ax and the axial methyl of the non *gem*-dimethyl system at C-20 were assigned and the remaining axial C-30 methyl was finally identified. At the same time we were able to observe a correlation between CH_3-24 and H-3, and between CH_3-25 and H-9 (Fig. 3).

NOESY[2]

A large number of nuclear Overhauser enhancements (NOEs) can be observed via the 2D NOE technique (NOESY). In spite of the fact that the 0.5–2.0 ppm area is very crowded, several dipolar interactions were identified.

The NOE between the vinylic proton at C-12 and the equatorial one at C-19 is particularly strong (δ = 1.90). The expected NOE effect between the C-22 and C-18 protons is not observed, probably due to the deformation of the E ring. The presence of two large substituents on C-21 and C-22 is a logical justification of this explanation.

Important correlation peaks were detected, and circled spots on the spectra connecting lines enabled us to observe the NOE

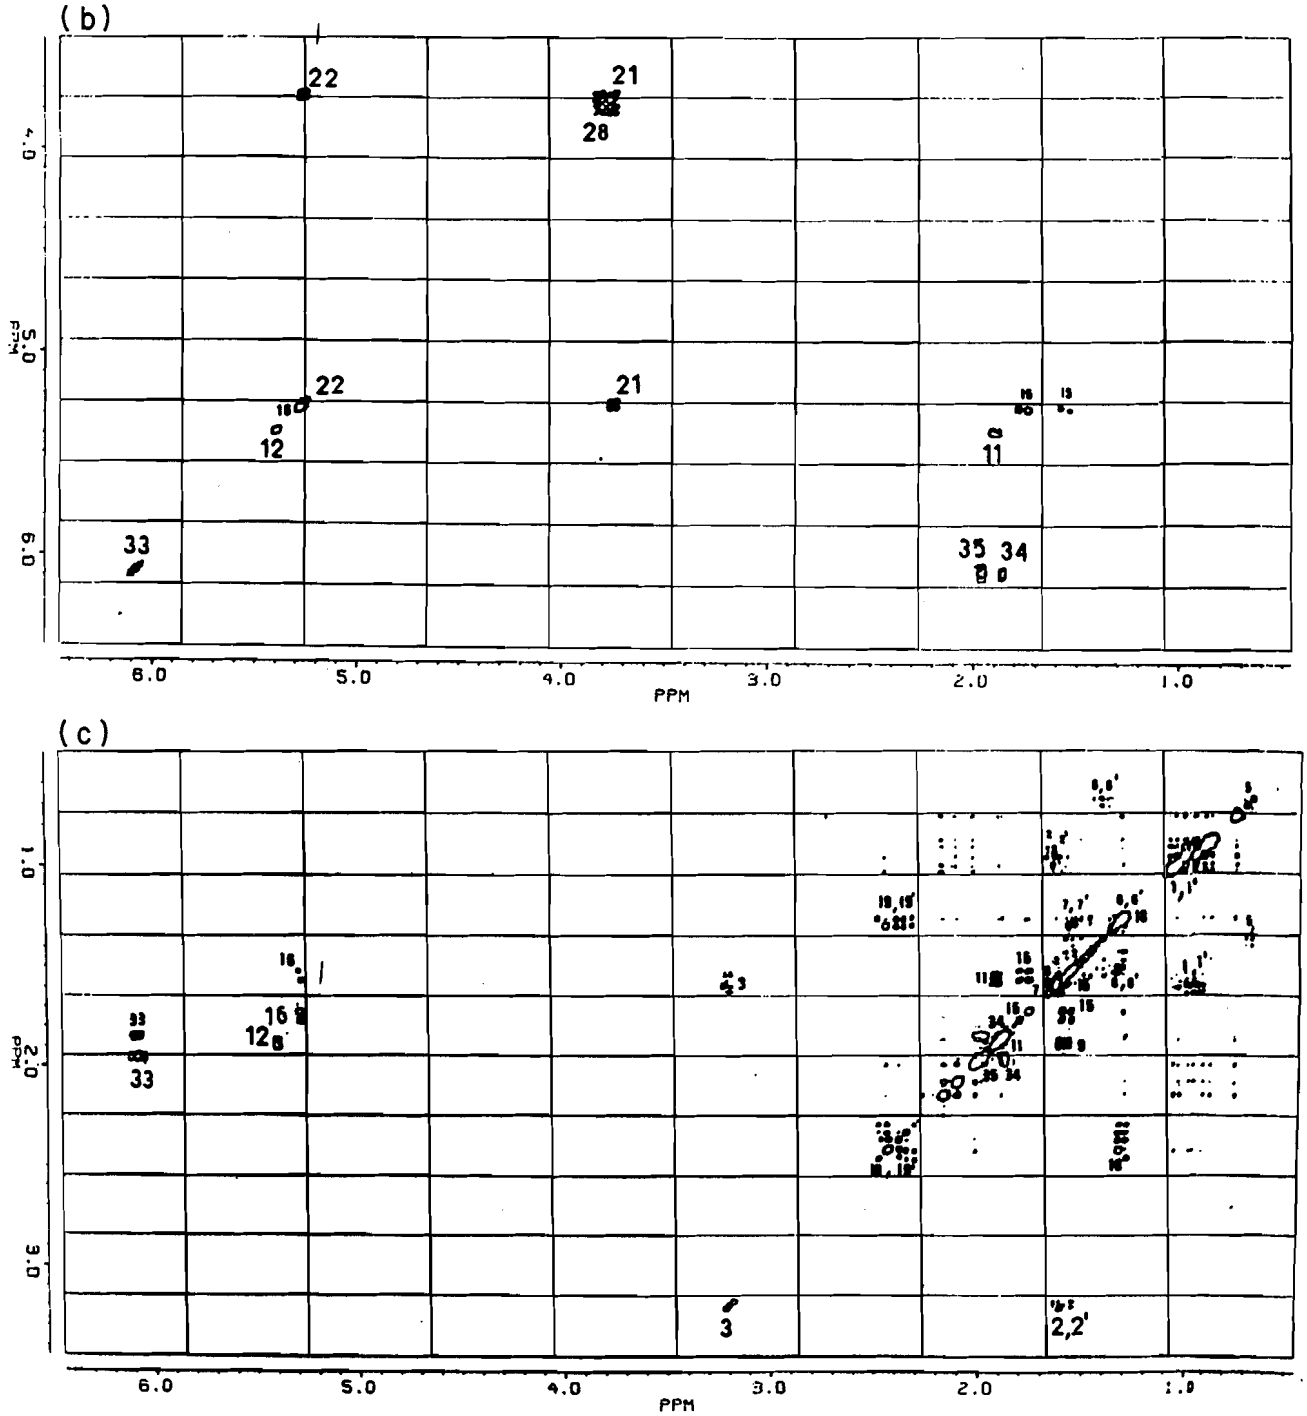

FIG. 2. (b) COSY, 0.5–6.5/0.5–3.5 ppm area of **1**. (c) COSY, 0.5–6.5/3.5–6.5 ppm area of **1**.

between H-33 of the angelic moiety and CH_3-35. Also, the axial protons H-22 have shown NOE correlation with the protons at C-28.

On the other hand, the C-28 protons showed strong NOEs with H-16, H-22, H-15e, H-19e, H-19a, and finally with CH_3-36.

Many stereochemical assignments were assisted by 2D NOE data; e.g., H-21α presents a spatial relationship via NOE with CH_3-29α, H-3α is correlated well with the CH_3-23, the CH_3-30 presents NOE correlation with both CH_3-28 and H-22, the methyl C-26 has shown NOE with H-15e, and a NOE relationship for H-19e with CH_3-28 and H-22 is detected.

The remaining methyls, unassigned from both COSY experiments, have been identified unambiguously by NOESY.

These experiments enabled us to propose the final assignments of protons as presented in Table 1.

Experimental

The triterpenic diacetate **1** was isolated from the *Loeselia mexicana* methanolic extract as previously described (6). The compound, mp 145°C, was analyzed by mass spectrometry (EI, PI, Hewlett–Packard 5485). The molecular ion was recorded at m/z 656 $[M]^{+\cdot}$ corresponding to the formula $C_{39}H_{60}O_8$. The principal fragment ions were m/z 638 $[M - H_2O]^{+\cdot}$, 596 $[M - AcOH]^{+\cdot}$, and 472 [M –

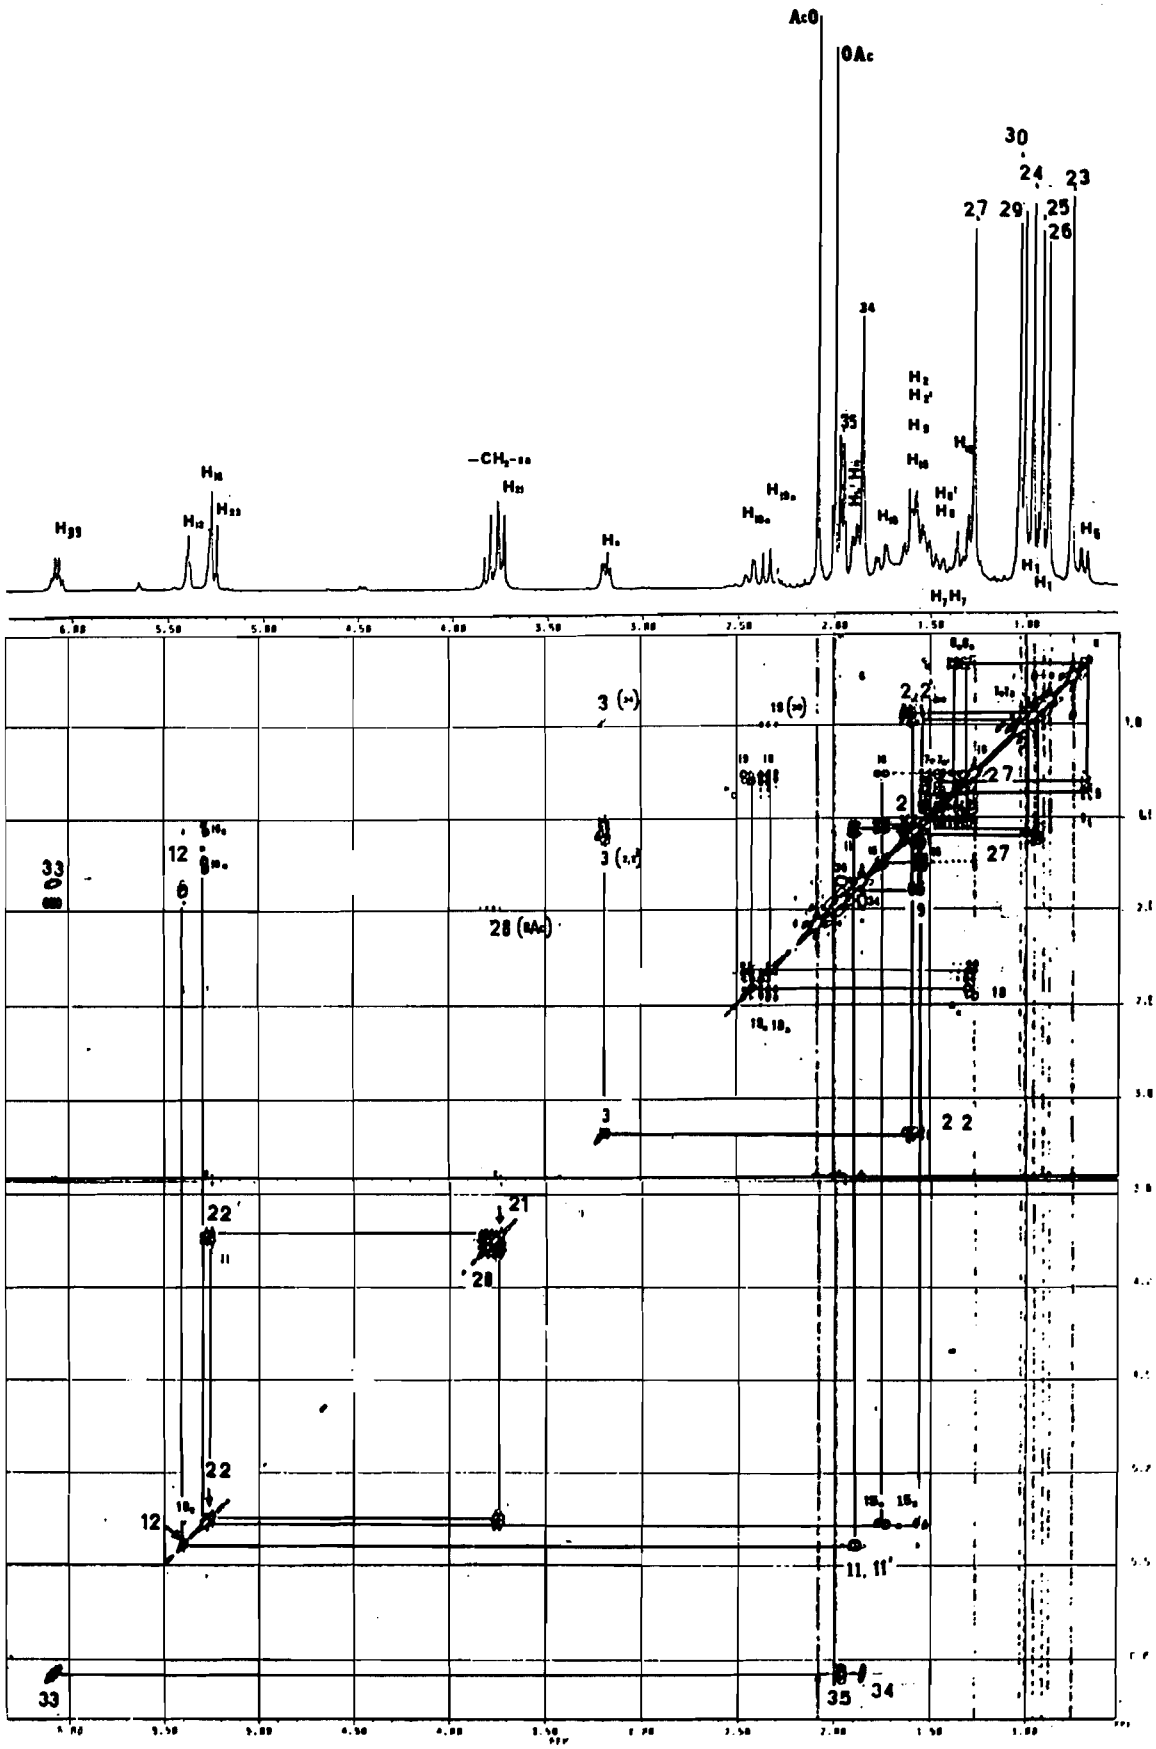

FIG. 3. COSY DELAYED of **1**. High resolution proton NMR spectrum of **1** (500 MHz) is shown on the *x*-axis.

$(CH_3)_2C—CHOH—CH—O—CO—CCH_3=CHCH_3]^{+\cdot}$. The purity of sample has been ascertained by TLC and HPLC. The acetylation of **1** (or **2**) performed according to Yosioka *et al.* (7, 9) and Wulff and Tschesche (8) gives the tetraacetate **3** quantitatively (empirical formula $C_{43}H_{64}O_{10}$). Mass spectrometry reveals a molecular ion at m/z 740 $[M]^{+\cdot}$ as well as a series of typical losses of the acetate residues.

Crystal data of 1

Formula: $C_{39}H_{60}O_8$

Orthorhombic, space group $P2,2,2$, with a = 10.110(4) Å, b = 15.817(6) Å, c = 24.870(9) Å, V = 3977 Å^3, and D_c = 1.167 g cm^{-3} for Z = 4; CuKα radiation (λ = 1.5417 Å, μ(CuKα) = 6.04 cm^{-1}. Cell constants were obtained by least-squares refinement of the setting angles for 25 reflections. All calculations were performed on a PDP 11/23 computer using the usual structure determination package (10).

The ORTEP views of the molecule **1** showing the hydrogen atoms and the carbon skeleton (Fig. 1) were designed using the same package on the PDP 11/23 computer.

Nuclear magnetic resonance

The high resolution ^{1}H NMR spectra of compound **1** were obtained on a Bruker WC-500 spectrometer (CEA, Saclay) operating in FT mode at a probe temperature of 20°C. The spectra were recorded as solutions of 5 mg of compound in 0.5 mL of $CDCl_3$ in a 5-mm tube (^{1}H).

The other NMR spectra were recorded with a Bruker WM 360 WB spectrometer (CNRS, Montpellier) equipped with an Aspect 3000 computer operating in the Fourier transform mode with quadrature detection at 360 MHz for proton.

The 1D spectra were obtained in 16 K time domain addresses and processed with 32 K addresses (accuracy 0.24 Hz/point). The $CDCl_3$ proton residual signal was taken as reference (7.24 ppm).

Connectivities between protons were established by 2D correlated spectroscopy (COSY and DELAYED-COSY) using pulse sequences D_1–90°–D_0–45°–FID (11, 12) and D_1–90°–D_0–90°–D_2–180°–D_2–90°–FID (13) respectively with a transfer delay D_2 of 30 ms.

COSY and DELAYED-COSY were obtained through 512 t_1 values and, prior to Fourier transformation, t_2 and t_1 domains FID were multiplied with a nonshifted sine-bell window function.

With the pulse sequence D_1–90°–D_0–90°–D_9–90°–FID (14), NOESY data were obtained in the phase sensitive mode with a mixing time D_9 = 280 ms through 256 increment delays; $\pi/16$ and $\pi/8$ shifted sine-bell window functions were applied respectively in t_2 and t_1 domains prior to Fourier transformation.

Conclusion

The ^{1}H NMR spectra of some triterpenic *Loeselia* compounds were interpreted successfully from a series of 1D high-resolution and three homonuclear 2D experiments. The comparison of these interpretations with X-ray data has revealed a perfect fit with the geometry of the crystal.

The structure assignment and the unambiguous interpretation of the proton NMR spectra was then possible, without having to perform heteronuclear (carbon–proton) experiments. The theoretical possibility of a C-21 to C-22 *trans*-esterification between the angelate moiety at C-22 and the alcohol at C-21 during the acetylation process (as in structure **4**) is impossible without changing the configurations of both centers. The proton NMR data presented in this report are consistent for the α-C-21 acetate and the β-C-22 angelate configurations. Both NMR and X-ray data confirm deformations of the E and C rings.

Forbeside E: a novel sulfated sterol glycoside from *Asterias forbesi*

JOHN A. FINDLAY, ZHENG-QUAN HE, AND MAHESH JASEJA
Department of Chemistry, University of New Brunswick, Fredericton, N.B., Canada E3B 6E2

Received April 3, 1989

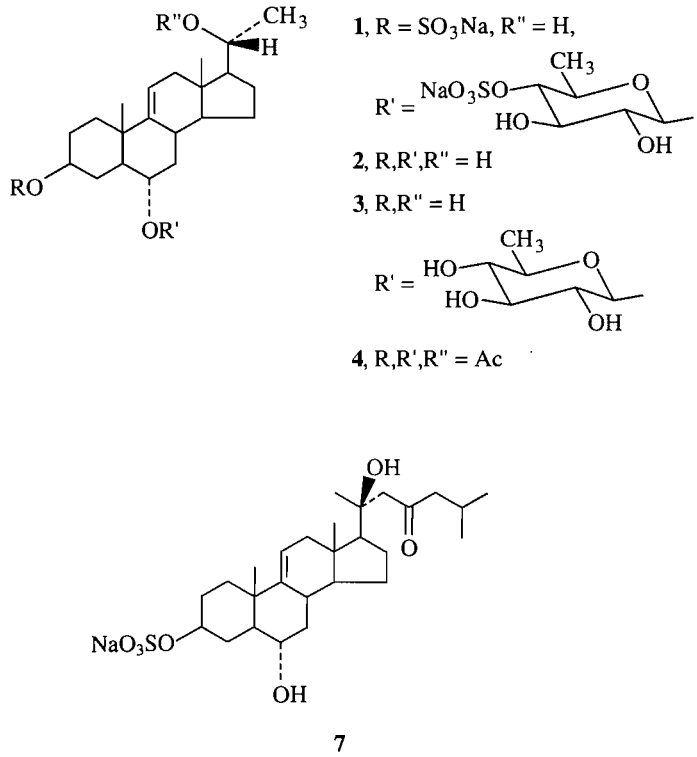
JOHN A. FINDLAY, ZHENG-QUAN HE, and MAHESH JASEJA. Can. J. Chem. **67**, 2078 (1989).

The structure of forbeside E, a minor constituent of the saponin fraction of the starfish *Asterias forbesi*, has been identified as the disodium salt of (20*R*)-5α-pregn-9(11)ene-3β-sulfo-oxy-6α-[*O*-β-D-4-sulfo-oxyquinovopyranosyl]-20-ol, principally by 2D-COSY, DQ COSY, HCORR, and DEPT experiments. Sodium thornasterol-3-*O*-sulfate has been isolated as a natural product from the same organism.

Key words: sulfated sterol glycoside, *Asterias forbesi* metabolites, sodium thornasterol-3-*O*-sulfate, asterogenol rearrangement.

JOHN A. FINDLAY, ZHENG-QUAN HE et MAHESH JASEJA. Can. J. Chem. **67**, 2078 (1989).

En se basant principalement sur des expériences de 2D-COSY, de DQ COSY, de HCORR et de DEPT, on a démontré que le forbéside E, un constituant mineur de la fraction saponine de l'étoile de mer *Asterias forbesi*, est le sel double de sodium du (20*R*)-5α-pregn-9(11)-ène-3β-sulfo-oxy-6α-[*O*-β-D-4-sulfo-oxyquinovopyranosyl]-20-ol. On a aussi isolé le thornastérol-3-*O*-sulfate de sodium à partir du même organisme.



Mots clés : glycoside stérol sulfaté, métabolites *Asterias forbesi*, thornastérol-3-*O*-sulfate, nouvel arrangement d'astérogénol.

For personal use only.

In our continuing investigation of the saponin fraction of the starfish *Asterias forbesi* (Desor), we recently determined the structure of a minor constituent, forbeside E, to be the disodium salt of (20*R*)-5α-pregn-9(11)-ene-3β-sulfo-oxy-6α-[*O*-β-D-4-sulfo-oxyquinovopyranosyl]-20-ol, **1**. This compound, which is less polar than the earlier described saponins forbeside A, B (1), and C (2), has not been previously reported. However, the aglycone **2**, asterogenol, was first isolated by ApSimon *et al.* (3) from the hydrolysed saponin fractions from both *A. forbesi* and *A. vulgaris*, which led them to suggest that this C20 reduced progesterone type derivative is a genuine aglycone in some starfish saponins. This is now confirmed by our isolation of the disulfated quinovoside **1**.

We also found the known sodium thornasterol-3-*O*-sulfate, **7**, in the unhydrolysed saponin fraction from *A. forbesi*. This compound, which has not been reported previously as a natural product, was obtained by enzymatic hydrolysis of the saponin versicoside A from *Asterias amurensis* by Itakura *et al.* (4).

The positive ion FAB mass spectrum of **1** shows a prominent pseudomolecular ion at *m/e* 706 [$M^+(C_{27}H_{42}O_{13}S_2Na_2)$ + Na − H] while other prominent ions at *m/e* 605 [M^+ + H − $NaSO_3$ + Na], 603 [706 − $NaSO_3$], 587 [706 − $NaSO_4$], and 500 [706 − $2NaSO_3$] lend further support to the formulation. The location of the sulfo-oxy group at C3 of the aglycone follows from the assignment of the broad multiplet at δ 4.26 ppm in the ^{1}H nmr spectrum (D_2O) to H3. The same signal appears at δ 4.85 ppm in pyridine-d_5 and is shown by DQ COSY (5) experiment to be coupled to the signal at δ 3.4 ppm assigned to the H4β. The carbohydrate moiety is located at C6 in view of the close agreement of ^{13}C chemical shifts for C5, C6, and C7 with those of similar thornasterol glycosides (1). The nature of the sugar moiety was derived from DQ COSY experiments, which permitted unambiguous assignment of signals and connectivity. Thus the large coupling in pyridine-d_5/D_2O (J = 7.94 cps) for the anomeric H1′ proton and the triplet ($J \approx 9$ cps) nature of each signal for H2′, H3′, and H4′ were consistent only with a quinovose unit. Furthermore, the downfield location of the H4′ signal is compelling evidence for the placement of the second sodium sulfate moiety at C4′. Corroboration of these and other assignments may be derived from HCORR (6) data (see Table 1).

7

Solvolysis of forbeside E was complete after heating in pyridine-d_5/dioxane-d_8/D_2O (12:3:1) at 120°C for 6 h to give the desulfated glycoside, **3**. The course of desulfation was monitored by ^{1}H nmr and no significant difference in the rate of solvolysis at the two sites could be detected. Thus the signals for H3 and H4′ were shifted upfield simultaneously over the 6-h period and no solvolysis was detected by ^{1}H nmr after initially heating the sample at 100°C for 1–4 h.

Confirmation of the structure of the aglycone was realized by heating forbeside E with 2 N HCl at 80–90°C for 10 h followed by acetylation of the hydrolysis product. While the mass spectrum is entirely consistent with that reported for asterogenol triacetate (3) and examination by tlc showed a single spot, it is evident from ^{1}H nmr that a mixture of triacetates resulted.

[a]Assignments from DEPT, HCORR, and comparative chemical shift data (1, 2).
[b]Assignments from COSY, DQ COSY, and HCORR.
[c]$J_1 \approx J_2$.

One component gives rise to a set of signals identical with those reported (3) for asterogenol triacetate while the other gives rise to a doublet (J = 10.7 Hz) at δ 4.45 (~0.5 H) indicative of a secondary acetoxyl proton with a *trans* diaxial partner in a six-membered ring. We formulate the second product as **6** and rationalize the formation of its precursor **5** via a Wagner–Meerwein rearrangement with anchimeric assistance of the migrating C16—C17 bond and consequent configuration inversion at C20 and C17 (Scheme 1). Confirmation of the D ring structural feature of the singularly produced stereoisomer **5** comes from a double irradiation experiment in which irradiation at 1.6 ppm (H17, located from the COSY (7) spectrum) caused the simultaneous collapse of the δ 4.45 ppm doublet together with a partially obscured methyl doublet at 0.81 ppm ($J \approx$ 6 Hz).

Inspection of molecular models reveals that the preferred orientation for the 20*R* hydroxyl in asterogenol is such that the C20—OH bond is antiperiplanar to the C16—C17 bond, thus facilitating the proposed Wagner–Meerwein shift leading to **5**. In contrast, the 20*S* isomer is predicted to experience substantial, if not prohibitive, steric repulsion between C18 and C21 methyls in order to bring the C20—OH bond antiperiplanar to the C16—C17 bond. Hence further support for the 20*R* configurational assignment in **1** and in asterogenol **2** is provided.

6, R = Ac

2, asterogenol

SCHEME 1

Experimental

NMR spectra were recorded on Varian XL200 and XL300 instruments using tetramethylsilane as internal standard. Optical rotations were measured with a Perkin Elmer 241 polarimeter. Mass spectra were recorded with a Kratos MS50 instrument. Preparative tlc was performed with precoated silica gel F254 (1 mm) plates.

Isolation

Crude saponin mixture (4.5 g) obtained from *Asterias forbesi* as previously described (1) was dissolved in H_2O (100 mL) and extracted with $CHCl_3$. The evaporated chloroform extract (1.5 g) was subjected to silica gel (200 g, 230–400 mesh) column chromatography with a $CHCl_3/CH_3OH/H_2O$ (10:1:0.2 → 10:3:0.5) gradient yielding 6 fractions. The third fraction was chromatographed on preparative tlc plates (50 mg per plate) using $CHCl_3/CH_3OH/H_2O$ (10:3:0.5) to afford sodium thornasterol-3-*O*-sulfate, **7** (30 mg, R_f 0.48 and R_f 0.86 using a 66:44:5 ratio of the same solvents), which was identical in ^1H and ^{13}C nmr, EIMS, and mp with reported (4) data.

The aqueous layer was evaporated *in vacuo* and the residue (2.5 g) dissolved in $CHCl_3/CH_3OH/H_2O$ (10:3:0.5) and chromatographed on a silica gel (200 g, 230–400 mesh) column with a discontinuous gradient of $CHCl_3/CH_3OH/H_2O$ (10:3:0.5 → 66:44:5), giving 12 fractions. Fraction 7 was rechromatographed on ptlc plates using $CHCl_3/CH_3OH/H_2O$ (66:44:5) from which forbeside E, **1** (R_f 0.52, 40 mg, amorphous powder), was recovered. By similar treatment, fraction 8 yielded forbeside C (2) (120 mg). Fraction 9 was rechromatographed on silica gel ptlc plates using $CH_3(CH_2)_3OH/CH_3COOH/H_2O$ (12:3:5) to provide pure forbeside B (1) (36 mg, R_f 0.32) and forbeside D (30 mg, R_f 0.26), which is currently under investigation.

Forbeside E: mp 238°C (dec.); $[\alpha]_D$ +9.5° (*c* 0.004, H_2O); ^1H and ^{13}C nmr, see Table 1. FAB (+) MS (magic bullet (8)): *m/z* 706 (7%, M^+ + Na − H), 605 (8.5), 603 (6), 587 (11), 500 (4), 448 (4), 413 (5), 329 (18), 230 (23), 199 (36), 177 (53), 143 (100).

Acid hydrolysis and acetylation of forbeside E

Forbeside E (15 mg) in 2 N HCl (25 mL) was heated at 80–90°C for 10 h, cooled, and extracted with $CHCl_3$. The dried, evaporated $CHCl_3$ layer afforded the aglycone (5 mg) after ptlc (R_f 0.56, $CHCl_3/CH_3OH$, 9:1). Evaporation of the aqueous layer, dissolution of the residue in CH_3CH_2OH, and crystallization afforded quinovose (2 mg) identified by comparison with an authentic sample. The aglycone (4 mg) was warmed at 50°C for 10 min in pyridine (1 mL)/acetic anhydride (1 mL), and evaporated. The product showed a single spot on tlc; ^1H nmr ($CDCl_3$) δ (ppm): 0.56 (3H, s, H18), 1.01 (3H, s, H19), 1.16 (3H, d, J = 6.1 Hz, H21), 4.7 (br m, H3, H6, H20), 5.4 (1H, br m, H11) of asterogenol triacetate **4** (3) plus 0.79 (3H, s, H18), 0.81 (3H, d, J = 6.1 Hz, H21), 1.00 (3H, s, 19H), 4.40 (1H, d, J = 10 Hz, 20H) assigned to triacetate **6** (signals at δ 4.7 and 5.4 assigned to both **4** and **6**). EIMS: *m/z* 460 (1%, M^+), 400 (23), 340 (45), 280 (100), 265 (44).

Solvolysis of forbeside E

Forbeside E (5 mg) was heated in pyridine-d_5/dioxane-d_8/D_2O (12:3:1, 0.5 mL) at 120°C for 6 h in an nmr tube, affording desulfated

Received April 27, 1989

ERIC J. REINER, ALEX. J. HARRISON, and RICHARD D. BOWEN. Can. J. Chem. **67**, 2081 (1989).

The collision-induced dissociation (CID) mass spectra of the $[MH]^+$ ions of a variety of C_4 to C_6 mono-, di-, and tri-alkyl amines have been determined at 8 keV collision energy and also as a function of collision energy over the range 5–100 eV (laboratory scale). The two major primary fragmentation pathways observed following either mode of activation are (i) production of an alkyl cation by expulsion of ammonia or an alkyl amine, and (ii) formation of a smaller protonated amine by loss of an olefin. In addition, alkane elimination from $[MH]^+$, by a variety of pathways, is a common reaction for protonated dialkyl and trialkyl amines, especially in the 8 keV spectra. However, these alkane elimination reactions are of considerably less importance in the low energy CID spectra because they have high onset energies. The differences observed in the spectra produced by the two methods of activation are discussed in terms of the distributions of internal energies deposited in $[MH]^+$ by the collision process.

Key words: protonated amines, collision-induced fragmentation, energy-resolved mass spectrometry.

ERIC J. REINER, ALEX. J. HARRISON et RICHARD D. BOWEN. Can. J. Chem. **67**, 2081 (1989).

Opérant à une énergie de collision de 8 keV ainsi qu'à des énergies de collision allant de 5 à 100 eV (échelle de laboratoire), on a déterminé les spectres de masse de dissociations induites par collision (DIC) des ions $[MH]^+$ d'un certain nombre de mono-, di- et tri-alkylamines en C_4, C_5 et C_6. Les deux modes principaux de la fragmentation primaire, selon l'un ou l'autre des modes d'activation, sont (i) la production d'un cation alkyle provenant de l'expulsion d'ammoniac ou d'une alkylamine et (ii) la formation d'une amine protonée plus petite provenant de la perte d'une oléfine. De plus, l'élimination d'un alcane à partir de l'ion $[MH]^+$, par le biais de diverses voies, est une voie réactionnelle fréquente pour les amines protonées dialkylées et trialkylées, principalement dans les spectres à 8 keV. Toutefois, à cause de leurs énergies élevées d'activation, ces réactions d'élimination d'alcane sont beaucoup moins importantes dans les spectres de DIC à basse énergie. On discute des différences observées dans les spectres produits par les deux méthodes en fonction des distributions des énergies internes déposées dans les ions $[MH]^+$ par le processus de collision.

Mots clés : amines protonées, fragmentation induite par collision, spectrométrie de masse résolue pour l'énergie.

Introduction

In the proton-transfer chemical ionization mass spectra of alkyl amines, obtained using H_3^+ or $[HCO]^+$ as reagent ions, there often are intense ion signals corresponding nominally to alkane elimination from the protonated amine (1). Although alkane elimination frequently leads to the energetically most favourable products (1), this reaction mode is not observed in the unimolecular metastable ion fragmentation reactions of protonated amines (1, 2) thus suggesting that there may be a barrier to alkane elimination additional to the reaction endothermicity. This conclusion is supported by theoretical calculations on protonated *i*-propyl amine, which showed that there was a large energy barrier for the concerted elimination of CH_4 (1). Nevertheless, the limited high energy collision-induced dissociation (CID) studies of protonated amines have shown that significant fragmentation occurs by way of alkane elimination for species activated in this fashion (3, 4).

These earlier studies (3, 4) of the high energy CID of protonated alkyl amines have been exploratory in nature and have not clearly established how general alkane elimination is nor how useful CID studies are in distinguishing between isomeric amines; in particular, there do not appear to have been any studies of the low energy CID of protonated alkyl amines. In the present paper we report a systematic study of the collision-induced fragmentation of the isomeric protonated butyl amines, their *N*-methyl and *N,N*-dimethyl derivatives, as well as a variety of protonated dialkyl and trialkyl amines containing four to six carbons. This work has involved both high energy (8 keV) and low energy (5–100 eV of laboratory scale) collisional activation of the protonated species. The primary goal was to explore collision-induced dissociation as a means of distinguishing between isomeric even-electron ions. In addition, the variable low energy collisional studies, the so-called energy-resolved mass spectrometric (ERMS) technique (5–7), have provided considerable information on the energy dependence of the fragmentation of protonated amines. In particular, the ERMS results show that alkane eliminations from protonated alkyl amines are high energy processes and the products of such reactions are much more abundant in high energy CID mass spectra than in low energy CID mass spectra, pointing to substantial differences in the distributions of internal energy deposited in $[MH]^+$ by the two methods of activation.

Experimental

All experimental work was carried out using a VG Analytical ZAB-2FQ mass spectrometer, which has been described in detail previously (8). Briefly, the instrument is a reversed-geometry (BE) double-focussing mass spectrometer with a third stage consisting of a deceleration lens system, an rf-only quadrupole collision cell, and a quadrupole mass analyzer. This assembly permits collisional studies to be carried out in

the low energy range. In addition, the instrument is equipped with a collision cell at the first focal point in the field-free region between the magnetic (B) and electric (E) sectors that provides the capability of studying collision processes in the keV energy range (laboratory scale).

In the low energy collisional activation experiments the ions of interest were mass-selected by the double-focussing BE instrument at 8 keV ion energy, decelerated to the appropriate collision energy (5–100 eV, laboratory scale), and introduced into the quadrupole cell where they underwent collision with N_2. The ionic products were analyzed using the final quadrupole. The pressure of N_2 was 1.5×10^{-7} Torr (1 Torr = 133.3 Pa) as indicated by an ionization gauge attached to the pumping line for the region; this resulted in ~30% attenuation of the main beam. The results are presented in the following as graphs of the percentage fragment ion abundance versus the centre-of-mass collision energy. The average relative error in the fragment ion abundances was 7%.

For the high energy collisional activation experiments, the ions of interest were selected by the magnetic sector and underwent collision, at 8 keV kinetic energy, with He in the collision cell located at the focal point between the magnetic and electric sectors. The ionic products were analyzed according to their kinetic energy by scanning the voltage applied to the electric sector, the so-called MIKES technique (9). The He pressure was 1.5×10^{-7} Torr as measured by the ionization gauge on the line pumping the region; this resulted in about 30% attenuation of the main beam. In the MIKES-CID studies all mass and energy resolving slits were fully opened; the spectra in this paper are quoted in terms of peak heights. Relative peak heights were reproducible to better than 10%.

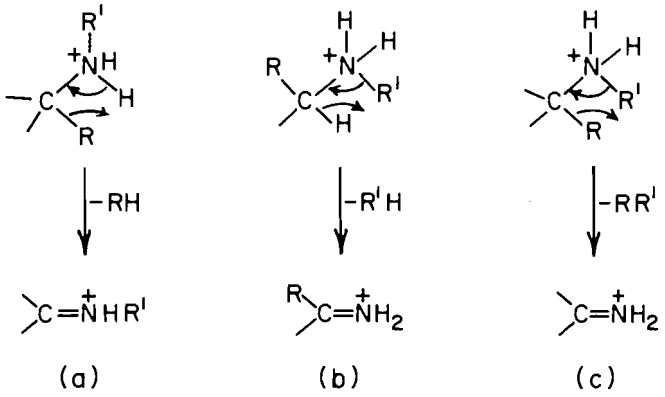
The protonated amines were produced by *i*-butane chemical ionization in the CI source operating at 200°C and either 50 or 100 eV ionizing electron energy. With *i*-butane reagent gas the unimolecular metastable ion fragmentation of the protonated species made a negligible contribution to the spectra recorded. The amines were introduced through the batch heated inlet system. These amines were either commercially available or were synthesized as described previously (2).

Results and discussion

Low energy and high energy CID mass spectra are reported in detail in Tables 1–3 and Figures 1–6 for the $[MH]^+$ ions of 24 alkyl amines containing a total of four to six carbon atoms. In the following discussion of these results, the $[MH]^+$ ions are divided into isomeric groups containing four, five, and six carbon atoms.

Protonated C_4 amines

Table 1 presents the 8 keV CID mass spectra of the $[MH]^+$ ions derived from the isomeric butyl amines, diethyl amine, *N*,*N*-dimethylethyl amine, *N*-methyl-*n*-propyl amine, and *N*-methyl-*i*-propyl amine. The three major primary fragmentation reactions of the $[MH]^+$ ions are elimination of ammonia or an amine, reaction [1], elimination of an olefin, reaction [2], and



[1] $[RNH_2R']^+ \rightarrow R^+ + NH_2R'$

[2] $[RNH_2R']^+ \rightarrow [R'NH_3]^+ + [R—H]$

elimination of an alkane. Alkane loss can occur by three pathways (3) corresponding to the three formal 1,2-eliminations illustrated in Scheme 1. For the C_4 amines these alkane elimination reactions can lead to m/z 58 ($MH^+ - CH_4$), m/z 44 ($MH^+ - C_2H_6$), and m/z 30 ($MH^+ - C_3H_8$). The primary fragment ions can, of course, fragment further.

For the protonated butyl amines reaction [1] leads to formation of the butyl ion (m/z 57), which forms the base peak in all four spectra, with the ammonium ion (m/z 18) produced in reaction [2] being of lesser importance. This is in contrast to the unimolecular metastable ion fragmentation of the $[MH]^+$ ions of *sec*-butyl and *tert*-butyl amines where $[NH_4]^+$ is the dominant product. For the dialkyl and trialkyl amines, reaction [2] is the dominant fragmentation reaction of the $[MH]^+$ ions

SCHEME 1

because of the increased stability of the protonated amine produced relative to the stability of the ammonium ion. Thus, diethyl amine and *N,N*-dimethylethyl amine show *m/z* 46 $[MH^+ - C_2H_4]$ as the base peak while the *N*-methylpropyl amines both show *m/z* 32 $[MH^+ - C_3H_6]$ as the base peak.

The alkane elimination reactions of Scheme 1 are of only minor importance for the $[MH]^+$ ions of the butyl amines. Only pathway (a) should operate, leading to formation of *m/z* 30 ($-C_3H_8$) for the *n*-butyl and *i*-butyl amines, to formation of *m/z* 44 ($-C_2H_6$) and *m/z* 58 ($-CH_4$) for the *sec*-butyl amine, and to formation of *m/z* 58 ($-CH_4$) for the *tert*-butyl amine. Although these peaks are observed there is some nonspecificity in alkane loss, as witnessed by the weak $[MH^+ - C_2H_6]$ ion signal for $[n\text{-BuNH}_3]^+$ and the weak $[MH^+ - C_3H_8]$ signal for $[sec\text{-BuNH}_3]^+$. The low intensity of the signals for the alkane elimination reactions in the monoalkyl amines, which also extends to the C_5 and C_6 monoalkyl amines (10), means that it is difficult to identify the individual isomer by this signal in the CID mass spectrum.

In contrast to the monoalkyl amines, the $[MH]^+$ ions formed from the dialkyl and trialkyl amines show much more fragmentation by alkane elimination. Thus, protonated diethyl amine shows abundant ion signals resulting from elimination of CH_4 (pathway (a)), elimination of C_2H_6 (pathway (b)), and elimination of C_3H_8 (pathway (c)). *N,N*-Dimethylethyl amine can be distinguished from diethyl amine by the much lower abundance of the *m/z* 30 (C_3H_8 elimination) ion. The two *N*-methylpropyl amines show similar fragmentation reactions, with the $[MH]^+$ ions of both showing elimination of CH_4, C_2H_6, and C_3H_8. Expulsion of an alkyl radical from $[MH]^+$ occurs to some extent in these CID spectra. Thus, $[(C_2H_5)_2NH_2]^+$, $[(CH_3)_2NHC_2H_5]^+$, and, for the C_5 amines of Table 2, $[(C_2H_5)_2NHCH_3]^+$ and $[i\text{-}C_3H_7NH(CH_3)_2]^+$ all undergo sizeable amounts of CH_3 loss after collisional activation. This reaction apparently does not necessarily involve the *N*-methyl group(s). It is likely, therefore, that distonic (11)[3] ions may occasionally be formed as the daughter ion in these processes (e.g., $[CH_2NH_2C_2H_5]^{+\cdot}$ by $CH_3^\cdot$ loss from $[(C_2H_5)_2NH_2]^+$). Alkyl radical loss from $[MH]^+$ is formally a violation of the even-electron (13) rule.[4] Such a violation is hardly surprising in view of the large collision energies involved in this work and the opportunity for $[MH]^+$ to eliminate an alkyl radical by simple cleavage of the appropriate bond.

More detailed information on the fragmentation of the protonated amines comes from the energy-resolved data obtained at low collision energies. The results obtained for the $[MH]^+$ ions of the eight amines of Table 1 are shown in Figs. 1 and 2 in the form of breakdown graphs expressing the percentage fragment ion abundances as a function of the centre-of-mass collision energy. For the protonated butyl amines (Fig. 1) the $[C_4H_9]^+$ (*m/z* 57) ion dominates the breakdown graph at low collision energies but, at higher collision energies, there is more fragmentation of this ion to $[C_3H_5]^+$ (*m/z* 41) and $[C_2H_5]^+$ (*m/z* 29) than is observed in the 8 keV CID mass spectra. For the protonated dialkyl and trialkyl amines (Fig. 2), olefin elimination (reaction [2]) is the dominant fragmentation reaction at low collision energies but, with increasing collision energy, alkyl ion formation (reaction [1]) increases in importance and, at higher collision energies, these alkyl ions show a greater relative abundance than they do in the 8 keV CID mass spectra. It appears that the mean internal energy imparted to the ions in the 8 keV collision is less than that imparted to the ions in the 10–25 eV (centre-of-mass) collisions.

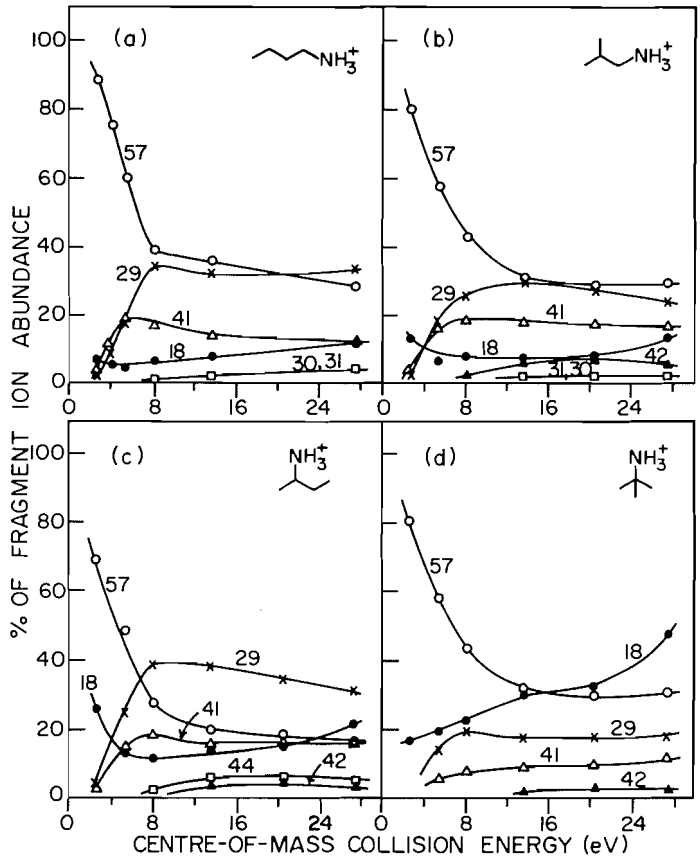

FIG. 1. Breakdown graphs for protonated (a) *n*-butyl amine, (b) *i*-butyl amine, (c) *sec*-butyl amine, and (d) *tert*-butyl amine.

Particularly intriguing results are obtained for the alkane elimination reactions in the low energy CID. As Fig. 1 shows, the alkane elimination reactions are of very little importance for the protonated butyl amines; indeed, this reaction is not observed for protonated *tert*-butyl amine. For the other butyl amines one alkane elimination reaction is observed, giving a product ion of very low abundance, thus reflecting an apparently high onset energy for these processes. For the dialkyl and trialkyl amines (Fig. 2) only one major alkane elimination reaction is observed for each $[MH]^+$ ion, that corresponding to

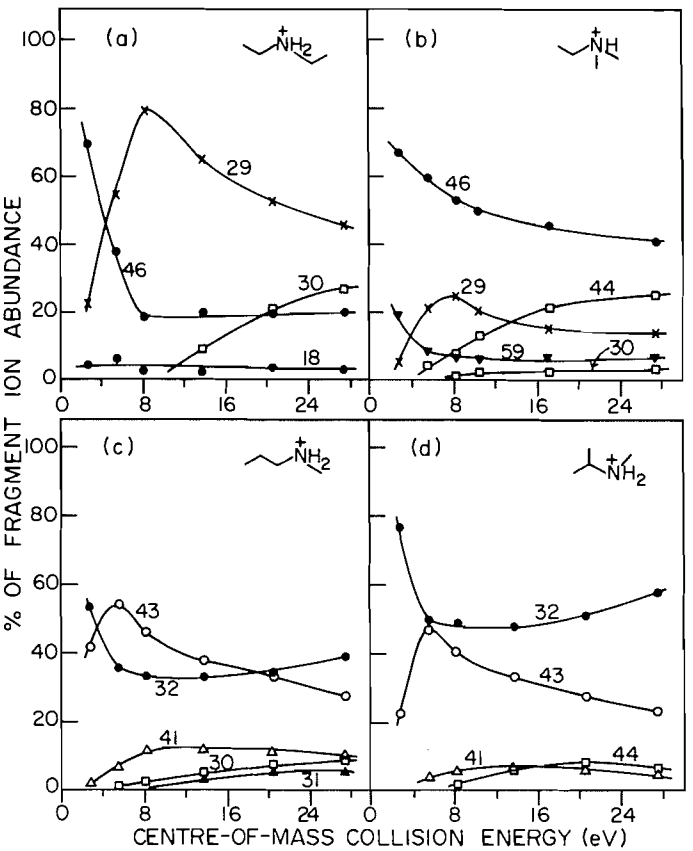

FIG. 2. Breakdown graphs for protonated (a) diethyl amine, (b) dimethylethyl amine, (c) methyl-*n*-propyl amine, and (d) methyl-*i*-propyl amine.

pathway (c) of Scheme 1. This is in sharp contrast to the results obtained in the high energy CID studies. From the low energy CID results *N*,*N*-dimethylethyl amine can be readily distinguished from diethyl amine and, similarly, *N*-methyl-*n*-propyl amine can be distinguished from *N*-methyl-*i*-propyl amine on the basis of the alkane elimination reaction (C_3H_8 and C_2H_6 loss, respectively) observed from $[MH]^+$. However, it should be noted that the alkane elimination reactions observed have onset energies in the 4–8 eV (centre-of-mass) collision energy range. Presumably the other alkane elimination reactions that are observed in the 8 keV studies have higher onset energies than the internal energies that can be achieved in low energy collisional activation.

Finally, it should be noted that the high energy CID mass spectrum observed for protonated diethyl amine is in quantitative disagreement with spectra that have been reported earlier (3, 4), these earlier spectra being in disagreement with each other. Our major disagreement with the spectrum of Sigsby *et al.* (3) lies in the relative intensity of the *m/z* 46 ($[C_2H_5NH_3]^+$) ion signal. They report it to be 37% of the *m/z* 30 base peak while we observe it as the base peak. Sigsby *et al.* reported correcting their spectrum for unimolecular metastable ion fragmentation; since the main metastable ion fragmentation of protonated diethyl amine is formation of $[C_2H_5NH_3]^+$, it appears possible that they may have overcorrected. Under our experimental conditions the signal for unimolecular fragmentation was only about 1% of the CID signal and no correction was made. The spectrum reported by Wagner *et al.* (4) shows much higher ion signals at low mass than do either ours or that of Sigsby *et al.* We note that Wagner *et al.* attenuated their main beam by 67% and clearly were in the multiple collision regime; by contrast, we attenuated the main beam by 30% and were primarily in the single collision regime. Enhancement of low mass signals by sequential collision activation is to be expected in the work of Wagner *et al.* (4).

Protonated C_5 amines

The $[MH]^+$ ions generated from pentyl amines, $C_5H_{11}NH_2$ (spectra not shown here), fragment largely by reactions [1] and [2] in both the high energy and low energy CID with only very low intensities for the products of alkane elimination (10). The $[C_5H_{11}]^+$ ion produced in reaction [1] undergoes extensive fragmentation to form $[C_3H_7]^+$. Without recording the CID mass spectra of all isomers under identical conditions it would be difficult to identify a specific isomer from the CID mass spectrum of the $[MH]^+$ ion.

Table 2 records the 8 keV CID mass spectra of the $[MH]^+$ ions of the isomeric *N*-methylbutyl amines, *N*-ethyl-*n*-propyl amine, *N*-methyldiethyl amine, and the isomeric *N*,*N*-dimethylpropyl amines. A major fragmentation channel for the $[MH]^+$ ion in all cases is olefin elimination, reaction [2], leading to a protonated amine. Thus the *N*-methylbutyl amines show an abundant ion at *m/z* 32 ($[CH_3NH_3]^+$), the dimethylpropyl amines at *m/z* 46 ($[(CH_3)_2NH_2]^+$), methyldiethyl amine at *m/z* 60 ($[CH_3NH_2C_2H_5]^+$), and ethylpropyl amine at *m/z* 46 ($[C_2H_5NH_3]^+$). It is interesting to note that $[n\text{-}C_3H_7NH_2C_2H_5]^+$ does not show elimination of ethylene to give *m/z* 60 ($[C_3H_7NH_3]^+$). This is in agreement with the earlier observation (15) that the infrared multiphoton photodissociation of protonated *N*-ethyl-*i*-propyl amine leads exclusively to formation of $[C_2H_5NH_3]^+$. The rationalization (15) is that the fragmentation reaction proceeds in a stepwise fashion involving formation of the ion–dipole complexes $[C_3H_7^+\text{---}H_2NC_2H_5]$ and $[C_2H_5^+\text{---}H_2NC_3H_7]$; the former complex is more stable than the latter, thus leading to exclusive elimination of C_3H_6. There is substantial evidence that such olefin-elimination reactions do not occur by a concerted mechanism but rather occur in a stepwise fashion involving ion–dipole complexes (1, 2, 15–24). Note, however, that in the present system both $[C_3H_7]^+$ and $[C_2H_5]^+$ are observed, the former in greater abundance. Formation of alkyl ions by reaction [1] also is a favourable reaction for the $[MH]^+$ ion of the methylbutyl amines and $[C_4H_9]^+$ is the base peak in the CID mass spectrum for the *i*-butyl isomer.

The products of alkane elimination from $[MH]^+$ are observed at *m/z* 72 ($MH^+ - CH_4$), *m/z* 58 ($MH^+ - C_2H_6$), *m/z* 44 ($MH^+ - C_3H_8$), and *m/z* 30 ($MH^+ - C_4H_{10}$); all three pathways outlined in Scheme 1 appear to operate and the product ions are of considerable abundance. While some characterization of the amines is possible from the alkane elimination reactions observed from $[MH]^+$, the profusion of peaks creates difficulties in other cases. For example, the CID mass spectra for the *N*-methyl-*sec*-butyl and *N*-methyl-*tert*-butyl compounds are very similar. More specificity in the alkane elimination reactions is observed in the low energy CID mass spectra, as shown by the breakdown graphs of Figs. 3 and 4. Again only the alkane elimination originating by pathway (c) of Scheme 1 is observed and the onset energies are in the range 3–9 eV, indicating processes with high critical reaction energies. The more specific alkane elimination reactions observed in the low energy CID mass spectra make isomer differentiation more reliable in many cases. Thus, *N*-methyl-*sec*-butyl amine can be readily distinguished from *N*-methyl-*tert*-butyl amine by

the m/z 44 ion signal observed for the former. Similarly, the three substituted propyl amines can be distinguished from each other on the basis of the alkane elimination reactions observed. However, to use these ion signals to characterize the amines the collision energy must clearly be greater than 12 eV centre-of-mass (50 eV laboratory scale).

The major features of the breakdown graphs can be rationalized in terms of the occurrence of reactions [1] and [2] with, in the case of the butyl amines, further fragmentation of the alkyl ions formed in reaction [1]. In all cases the protonated amine produced in reaction [2] dominates the breakdown graph at low internal energies with the alkyl ion produced in reaction [1] increasing in importance with increasing collision energy. There is a significant resemblance between the general trends in the energy dependence of reactions [1] and [2] shown by the isomeric pairs of ions $[n\text{-}C_4H_9NH_2CH_3]^+$ and $[\text{iso-}C_4H_9NH_2CH_3]^+$, and $[n\text{-}C_4H_9NH(CH_3)_2]^+$ and $[\text{iso-}C_4H_9NH(CH_3)_2]^+$, Figs. 3 and 5. Similar broad correlations are found for $[sec\text{-}C_4H_9NH_2CH_3]^+$ and $[tert\text{-}C_4H_9NH_2CH_3]^+$ and for $[sec\text{-}C_4H_9NH(CH_3)_2]^+$ and $[tert\text{-}C_4H_9NH(CH_3)_2]^+$. It is interesting to note that the *n*-butyl and *i*-butyl isomers (Fig. 3) that, in the absence of rearrangement, would give the least stable butyl ions show more abundant m/z 57 ion signals than do the *sec*-butyl and *tert*-butyl isomers. Similarly, the $[C_3H_7]^+$ (m/z 43) ion abundance is greater for *N,N*-dimethyl-*n*-propyl amine than for the *i*-propyl isomer. This is consistent with the stepwise mechanism of fragmentation discussed previously (2) involving (alkyl ion)–amine ion/dipole complexes. Those complexes in which the developing cation is a primary alkyl ion are higher in energy than the analogous complexes containing an incipient secondary or tertiary alkyl ion. The developing primary cations undergo exothermic rearrangement to the more stable alkyl ion

isomer(s); the potential energy released by this isomerization enhances the tendency of these rearranged ions to fragment via amine expulsion. By contrast, the complexes originally containing incipient secondary or tertiary alkyl ions are lower in energy and are more likely to fragment to the protonated amine. A suitable potential energy profile for the protonated *i*-butyl- and *tert*-butyl-ammonium systems was presented previously (2).

Protonated C_6 amines

The protonated hexyl amines, $[c_6H_{13}NH_3]^+$, fragment primarily by reactions [1] and [2] with further extensive fragmentation of the hexyl ions formed in reaction [1] (10). In both the high energy and low energy CID mass spectra the abundance of the alkane elimination products is low, making identification of the individual hexyl isomers difficult.

The 8 keV CID mass spectra of the $[MH]^+$ ions of the isomeric *N,N*-dimethylbutyl amines, di-*n*-propyl amine, di-*i*-propyl amine, *N*-ethyl-*n*-butyl amine, and triethyl amine, are presented in Table 3, while the breakdown graphs are presented in Figs. 5 and 6. Reactions [1] and [2] are of major importance in both the high energy and low energy CID. Thus, reaction [2] leads to formation of *m/z* 46 ($[(CH_3)_2NH_2]^+$) for the protonated dimethylbutyl amines, to *m/z* 60 ($[C_3H_7NH_3]^+$) for the protonated dipropyl amines, to *m/z* 46 ($[C_2H_5NH_3]^+$) for protonated ethylbutyl amine, and to *m/z* 74 ($[(C_2H_5)_2NH_2]^+$) for protonated triethyl amine. For the latter four compounds one should note, in the 8 keV CID, the sequential elimination of olefins resulting in formation of $[NH_4]^+$ (*m/z* 18). In the breakdown graphs, representing the low energy CID data, the olefin elimination reaction [2] is the dominant reaction at low collision energies with reaction [1], alkyl ion formation, increasing greatly in importance with increasing collision energy.

For these polyalkyl amines, alkane elimination from $[MH]^+$ becomes very significant in the high energy CID and, for four of the amines, yields the base peak in the CID mass spectra. The alkane elimination reactions result in the ion signals at *m/z* 86 ($MH^+ - CH_4$), *m/z* 72 ($MH^+ - C_2H_6$), *m/z* 58 ($MH^+ - C_3H_8$), *m/z* 44 ($MH^+ - C_4H_{10}$), and *m/z* 30 ($MH^+ - C_5H_{12}$). The alkane elimination reactions in the high energy CID do help in isomer differentiation; for example, protonated di-*n*-propyl and di-*i*-propyl amines give distinctly different patterns of alkane elimination (mainly C_4H_{10} and C_3H_8 losses, respectively, with some C_2H_6 elimination from each ion). In contrast to the high energy CID, the low energy CID mass spectra of Figs. 5 and 6 show only one major alkane elimination reaction for each protonated amine, that corresponding to pathway (c) of Scheme 1. The low energy CID mass spectra thus serve to identify each amine with the exception of *N,N*-dimethyl-*n*-butyl and -*i*-butyl amines, which give very similar spectra. Once again, however, the alkane elimination reactions have high onset energies, with the result that it is necessary to work at high collision energies (50 eV laboratory scale) to characterize the individual isomers.

Conclusions

The relatively large differences observed between the high energy and low energy CID mass spectra of the protonated amines can be rationalized in terms of the energy requirements for fragmentation and the distributions of internal energy deposited in the ions by the collisional activation process. As Wysocki *et*

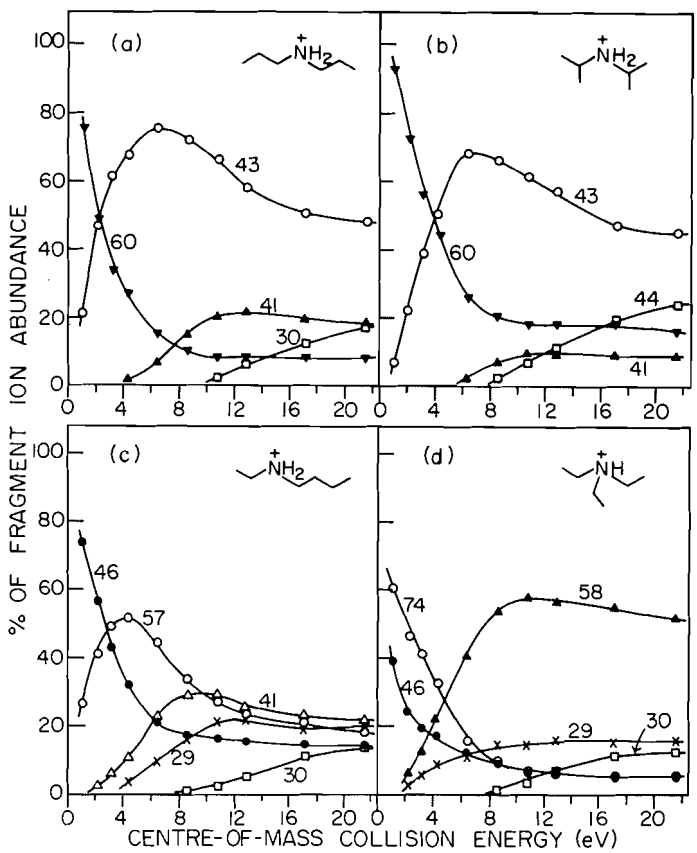

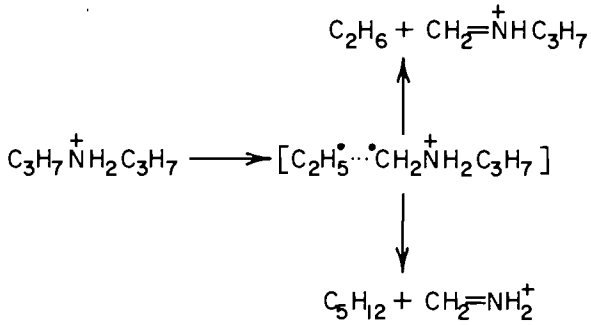

FIG. 6. Breakdown graphs for protonated (a) di-*n*-propyl amine, (b) di-*i*-propyl amine, (c) ethyl-*n*-butyl amine, and (d) triethyl amine.

al. (25) have elegantly shown, although the mean internal energy of ions activated in low and high energy collisions may be similar, there is a significant difference in the internal energy distribution. The distribution achieved in a high energy collision has a high energy tail that is missing when ions are activated in low energy collisions. Clearly, it is ions which are in this high energy tail that have sufficient energy to undergo alkane elimination reactions, particularly those involving pathways (a) and (b) of Scheme 1. At the same time, when one considers the lower energy fragmentation pathways, reactions [1] and [2], and further fragmentation of the alkyl ions produced by reaction [1], it appears that the mean internal energy deposited in collisions at 50–100 eV (laboratory scale) is greater than the mean internal energy transferred in 8 keV collisions.

In thermochemical terms the alkane elimination reactions frequently are the most favourable when assessed in terms of product stability, as the following data for protonated di-*n*-propyl amine show (thermochemical data taken from ref. 26):

	ΔH^0(kJmol^{-1})
$[(n\text{-}C_3H_7)_2NH_2]^+ \rightarrow [i\text{-}C_3H_7]^+ + n\text{-}C_3H_7NH_2$	269
$\rightarrow [n\text{-}C_3H_7NH_3]^+ + C_3H_6$	108
$\rightarrow [n\text{-}C_3H_7NHCH_2]^+ + C_2H_6$	84
$\rightarrow [CH_3CH_2CHNH_2]^+ + C_3H_8$	71
$\rightarrow [CH_2NH_2]^+ + C_5H_{12}$	138

Nevertheless, it is clear that these alkane elimination reactions have high critical reaction energies. The mechanism(s) of alkane elimination is (are) not known. The concerted mechanisms proposed by Cooks and co-workers (3) and outlined in Scheme 1 have been shown by theoretical calculations (1) to involve a

SCHEME 2

substantial potential energy barrier in addition to the reaction endothermicity. Alternatively, it also is possible that the alkane elimination reactions proceed in a stepwise fashion via initial homolytic bond cleavage to form a complex comprising an alkyl radical attached to an incipient radical-cation. Subsequent abstraction of a hydrogen atom or an alkyl radical from the developing distonic ion by the coordinated alkyl radical then results in alkane loss (Scheme 2). It has been shown (27) that distonic radical-cations have a stability similar to the radical-cation of conventional structure (here $[CH_3NHC_3H_7]^{+\bullet}$). It is conceivable that some of the [MH − alkane]$^+$ ions are secondary, rather than primary, products of fragmentation of [MH]$^+$. In the present case, the ions at *m/z* 30 might arise by C_3H_6 loss from $[C_3H_7NH{=}CH_2]^+$; it is known that $[C_3H_7NH{=}CH_2]^+$ ions expel C_3H_6 in both slow and fast dissociations (28). However, in the absence of a substantial peak at *m/z* 72 this explanation for the origin of the *m/z* 30 ions is perhaps less likely than direct C_5H_{12} elimination from [MH]$^+$.

Finally, it might be noted that the high critical reaction energies that obviously are involved in the alkane elimination reactions make it unlikely that such reactions will be prominent in the chemical ionization mass spectra. Rather it is likely that the nominal alkane loss products observed (1) are the results of direct alkide ion abstraction reactions by the reagent ion(s). It also is possible that a portion of the apparent [MH − alkane]$^+$ ions may actually be [M − alkyl radical]$^+$ ions formed by facile dissociation of $M^{+\bullet}$ produced by a small residual electron ionization component in the spectra. The importance of recognizing the possibility of such residual electron ionization components in chemical ionization mass spectra has recently been emphasized (29).

Sclerodin and related compounds from a plant disease causing fungus. Scleroderris yellow

WILLIAM A. AYER, MASAYUKI KAMADA, AND YU-TING MA
Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2
Received June 7, 1989

WILLIAM A. AYER, MASAYUKI KAMADA, and YU-TING MA. Can. J. Chem. **67**, 2089 (1989).

The metabolites of several strains of a fungus that gives rise to the disease of conifers known as Sirococcus shoot blight have been studied. The metabolites are similar to those isolated from *Gremmeniella abietina*, the causative agent of Scleroderris canker of pine. Sclerodin (**1**), scleroderolide (**2**), and Scleroderris blue (**3**) have been isolated, along with the known lactone **4**, trypethelone (**6**), and a new purple compound named scleroquinone (**12**). Another new compound, related to Scleroderris blue (**3**) and Scleroderris green (**7**), which we have named Scleroderris yellow, is shown to possess structure **8**. The sclerodin (**1**) isolated in these studies is not optically pure, in some cases being nearly racemic. It is noted that the optical purity may be a function of the culture medium employed. Scleroderolide (**2**) strongly inhibits the germination of lettuce seeds. In addition to the metabolites noted, squalene, methyl oleate, stearic acid, ergosta-4,6,8(14),22-tetraene-3-one, and ergosterol endoperoxide were also isolated from the cultures.

Key words: Sirococcus, phenalenones, Scleroderris yellow, scleroquinone, sclerodin.

WILLIAM A. AYER, MASAYUKI KAMADA et YU-TING MA. Can. J. Chem. **67**, 2089 (1989).

On a étudié les métabolites de plusieurs souches d'un champignon qui provoque la maladie des conifères connue sous le nom de Sirococcus de la brunissure des pousses. les métabolites sont semblables à ceux isolés du *Gremmeniella bietina*, l'agent qui provoque le Scleroderris de la nécrose du pin. On a isolé la sclérodine (**1**), le sclérodérolide (**2**) et le bleu de scléroderris (**3**) ainsi que la lactone connue **4**, la trypéthélone (**5**) et un nouveau composé violet que l'on a nommé scléroquinone (**12**). On a démontré qu'un autre nouveau composé, lié au bleu (**3**) et au vert (**7**) de scléroderris et qu'on a appelé jaune de scléroderris, possède la structure **8**. La sclérodine (**1**) isolée au cours de cette étude n'est pas optiquement pure et, dans quelques cas, elle est pratiquement racémique. On a noté qu la pureté optique varie avec le milieu de culture utilisé. Le sclérodérolide (**2**) inhibe fortement la germination des semences de laitue. En plus des métabolites mentionnés, on a aussi isolé des milieux de culture du squalène, de l'oléate de méthyle, de l'acide stéarique, de l'ergosta-4,6,8(14),22-tétraène-3-one et de l'endoperoxyde d'ergostérol.

Mots clés : Sirococcus, phénalènones, jaune de scléroderris, scléroquinone, sclérodine.

[Traduit par la revue]

Introduction

The disease of conifers known as Sirococcus shoot blight (1, 2) has many similarities to the pine disease known as Scleroderris canker (3). The latter disease is caused by the Ascomycetous fungus *Gremmeniella abietina* (3). The metabolites produced by *G. abietina* have been studied in detail and have been shown to be substituted phenalenones and derivatives thereof (e.g., sclerodin (**1**), scleroderolide (**2**), Scleroderris blue (**3**)) (4–7). Our interest in the Scleroderris metabolites has led us to examine several strains of a fungus isolated from conifers in West Germany believed to be infected with the Sirococcus fungus.[1] Since we began our studies, it has been determined that the fungus may be *Godronia cassandrae* (2) rather than *Sirococcus strobilinus*.[2] In this article we report on the metabolites of the two strains (strain 20 (UAMH 5402), and strain D (UAMH 5399)) of the disease fungus, which are morphologically closely related to *G. abietina*, and another strain (strain 33b, UAMH 5400), which is morphologically closer to Sirococcus.[3]

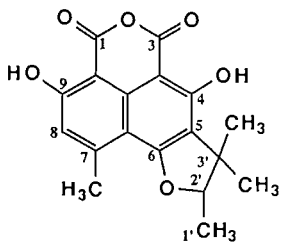
Results and discussion

Strain 33b (UAMH 5400) was grown in liquid culture on potato dextrose–yeast (PDY), V8 juice–glucose (V8G), and Wort media. The V8G medium produced abundant amounts of greenish-gray mycelium, which on extraction with methylene chloride provided a larger yield of metabolites than the other media mentioned. In all cases, extraction of the culture broth provided relatively small amounts of metabolites. Since in our studies on *G. abietina* we had also used the V8G medium (4), this was chosen for the study of strain 33b.

The metabolites were first fractionated by reverse-phase column chromatography over C_{18}-bonded silica gel (to separate fatty acids and glycerides) and the fractions were further separated by chromatography (column and preparative thin layer) over silica gel. This led to the isolation of the known compounds sclerodin (**1**) (4), scleroderolide (**2**) (5), Scleroderris blue (**3**) (4), the lactone **4** (previously obtained by oxidation of sclerodione (**5**) (4)), and a purple compound identified as trypethelone (**6**) (previously isolated from the lichen *Trypethelium eluteriae* (8, 9)). In addition, a yellow crystalline compound $C_{39}H_{36}O_{10}$ and a purple crystalline compound $C_{18}H_{18}O_6$ were isolated. The structures of these two compounds are discussed below.

Sclerodin (**1**) obtained from *G. abietina* is the enantiomer (*S* configuration at C-2′, $[\alpha_D]$ −73°) of the so-called "naphthalic anhydride from atrovenetin" (4, 10), which has been shown by X-ray crystallography to possess the *R* configuration at C-2′ (11). The *R* enantiomer has also been obtained from several other fungi (see refs. 4 and 5). To our surprise, both sclerodin (**1**) and scleroderolide (**2**) isolated from strain 33b are virtually racemic, each showing a slight excess of the *S* enantiomer (**1**, $[\alpha]_D$ −6.5°; **2**, $[\alpha]_D$ −5.9°; the pure enantiomer of **2** shows $[\alpha]_D$ −116° (5)). On one previous occasion, racemic scleroderolide (**2**) was obtained from *G. abietina* (5).

The yellow crystalline compound $C_{39}H_{36}O_{10}$, for which we suggest the trivial name Scleroderris yellow (in analogy to



[1]We thank Prof. O. Kandler for drawing the relationship between the two diseases to our attention, and for providing the cultures used in this work.

[2]We thank Prof. Kandler for this information, and L. Sigler, University of Alberta Microfungus Collection and Herbarium (UAMH), for her taxonomical work and valuable discussion.

Scleroderris blue (**3**) and Scleroderris green (**7**) (6)), elutes from silica gel along with sclerodin (**1**). It is much less soluble than sclerodin in most solvents and may be separated by trituration with Skellysolve B. Recrystallization from chloroform – Skellysolve B provides Scleroderris yellow (**8**, only one tautomer shown) as optically active ($[\alpha]_D$ −16.7°) yellow crystals, mp 289–290°C. The high resolution electron impact mass spectrum (hrms) of Scleroderris yellow shows a weak molecular ion (m/z 664) and strong fragment ions corresponding to cleavage, with hydrogen transfer, of the bond to the central methylene group, giving rise to fragments $C_{20}H_{18}O_5$ (m/z 338) and $C_{19}H_{18}O_5$ (m/z 326), which represent all of the atoms of the parent ion (see Scheme 1). Loss of a methyl radical from each of these fragments gives rise to the most intense peaks (m/z 323 (81%), m/z 311 (100%)) in the spectrum. The nuclear magnetic resonance (nmr) spectra of Scleroderris yellow (**8**) are somewhat complicated due to the presence in solution of more than one tautomer. At room temperature the signals for the phenolic hydrogens appear as complex multiplets at δ 14.62, 13.58, 13.47, and 12.48. At 47°C each of these signals consists of only two lines of approximately equal intensity. This tautomerism is discussed further in connection with the methylation studies described later. The ^{1}H nmr spectrum does show the presence of the *geminal* methyls (6H broadened singlets at δ 1.39 and 1.53),

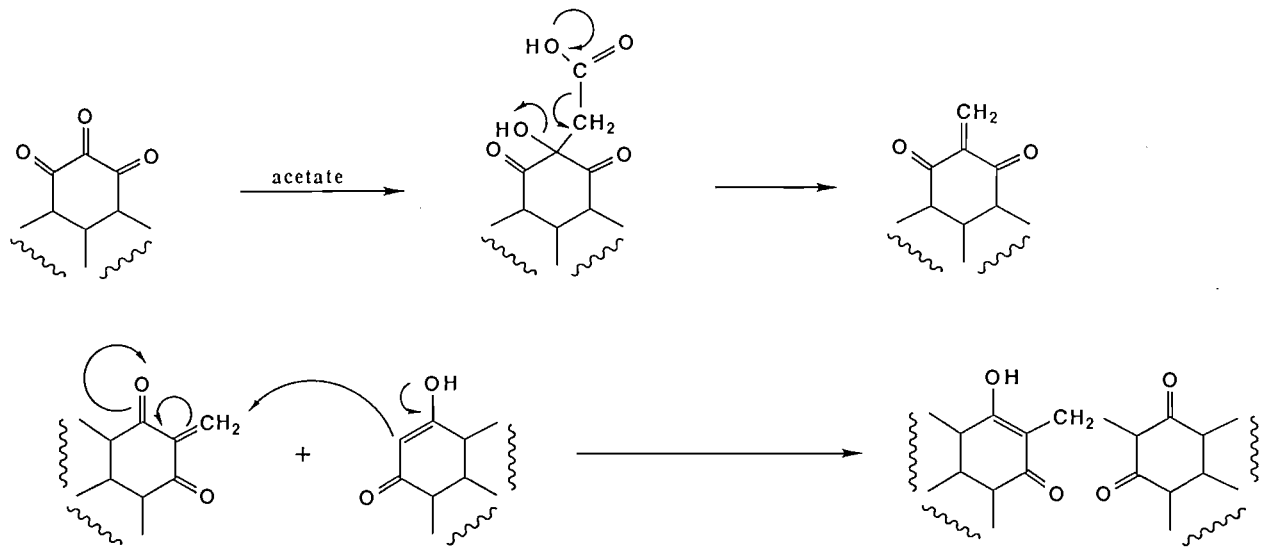
12



13

the secondary methyls (δ 1.54, d, *J* 6 Hz, 6H), the aromatic methyls (δ 2.86, s, 6H), the methine hydrogens (δ 4.72, m, 2H), and the aromatic hydrogens (δ 6.85, s, 2H). Of particular significance is the two-hydrogen singlet at δ 4.14, which is attributed to the methylene group linking the two "halves" of the molecule. The ^{13}C nmr spectrum shows a total of 31 signals, including a single methylene carbon signal at δ 17.6. The infrared (ir) spectrum of **8** shows broad chelated OH absorption (2300–3300 cm^{-1}), weak bands at 1740 and 1710 cm^{-1}, and strong chelated carbonyl absorption at 1613 cm^{-1}.

Treatment of Scleroderris yellow (**8**) with diazomethane gave rise to two different tetramethyl ethers. Since it is known that phenolic hydroxyls that are strongly intramolecularly H-bonded to carbonyl groups do not react readily with diazomethane (12), we considered structures **9**, **10***a*, and **11***a* the most likely possibilities for the tetramethyl ethers.[4] One of the tetramethyl ethers shows four different methoxyl signals and two different OH signals in its ^1H nmr spectrum, and thus may be assigned the unsymmetrical structure **9**. The second tetramethyl ether shows only two methoxyl signals (δ 4.01 and 3.78) and one OH signal (δ 18.52), and thus may be assigned either structure **10***a* or **11***a*. A strong nOe enhancement (23%) of the aromatic hydrogen signal was detected when the hydrogens of one of the methoxyl groups (δ 4.01) were irradiated, indicating that the second ether possesses structure **10***a*. Irradiation of the other methoxyl signal (δ 3.78) of **10***a* caused enhancement (3.2%) of the signal for the "connecting" methylene group (δ 4.46). The methoxyl signals

[4]A similar situation had been encountered previously in the case of Scleroderris green (**7**) (6).

SCHEME 2

for the unsymmetrical ether **9** appear at δ 4.06, 3.92, 3.84, and 3.75. Irradiation of the δ 4.06 signal brings about enhancement of one of the aromatic signals (δ 6.83), irradiation of the δ 3.84 and δ 3.75 signals causes enhancement of the methylene signal (δ 4.46), whereas irradiation of the δ 3.92 methoxyl causes no observable nOe enhancement. The remainder of the ^{1}H nmr spectra of both **9** and **10***a* are in complete accord with the structures formulated and provide strong support for the structure of Scleroderris yellow (**8**) itself. In particular, the spectrum of the symmetrical ether **10***a* shows only the expected ten signals, including the signal at δ 4.46 for the methylene group linking the two identical aromatic parts. We feel that Scleroderris yellow exists predominantly, at least in solution, as a mixture of the tautomers **8**, **10***b*, and **11***b*. Since the methylation experiment was carried out on a small scale (<5 mg) we do not attach any great significance to the fact that the tetramethyl ether **11***a* was not isolated.

The biogenetic origin of the methylene group in Scleroderris yellow (**8**) is not immediately obvious. It has been shown that the phenalenone nuclei in compounds such as Scleroderris blue (**3**) are of heptaketide origin and that the dihydrofuran rings are mevalonate derived (7). It is possible that the methylene group of Scleroderris yellow (**8**) is also acetate (or malonate) derived. Addition of acetate to the central carbonyl of an atrovenetinone-type intermediate followed by dehydrative decarboxylation would lead to an α-methylene ketone that could condense with another phenalenone intermediate as illustrated in Scheme 2. Pathways involving addition of a one-carbon unit (*S*-adenosyl methionine, formate, tetrahydrofolate) may also be envisioned.

The purple compound, $C_{18}H_{18}O_6$, for which we suggest the name scleroquinone is eluted early in the reverse phase chromatography and was obtained as an amorphous solid. It is assigned structure **12**. The uv–visible spectrum (λ_{max} 217, 287, 305, 574 nm) and the color are similar to those of trypethelone (**6**). The ^{1}H nmr spectrum of scleroquinone is like that of trypethelone (**6**) except that there is only one aromatic hydrogen (δ 6.96, s) and there is a methoxyl signal (δ 3.85). The presence of the ester functionality is indicated by ir absorption at 1740 cm^{-1}, not present in trypethelone. We did not have sufficient material to determine the ^{13}C nmr spectrum of **12**. The carbomethoxyl group is placed at C-8 rather than C-6 of the naphthoquinone nucleus since the aromatic hydrogen in **12** is not as far downfield as the C-8 hydrogen in trypethelone (δ 7.26, *peri* deshielding by C-1 carbonyl). Biogenetic considerations also favor C-8 (decarboxylation of a sclerodin (**1**) type intermediae (9)). The alternative *ortho*-quinone structure **13** cannot be completely excluded, but again we feel that the chemical shift of the aromatic hydrogen (δ 6.98, the C-6 hydrogen in trypethelone appears at δ 6.77) favors structure **12** for scleroquinone.

Scleroquinone (**12**) was also isolated from the liquid culture (V8G medium) of strain D (UAMH 5399), again in very small amounts. This strain also produces sclerodin (**1**), scleroderolide (**2**), and Scleroderris blue (**3**). The sclerodin (**1**) isolated from this strain contained an excess of the *R* enantiomer ($[\alpha]_D$ +27°)!

Strain 20 (UAMH 5402) was grown on both PDY and Wort media. Sclerodin (**1**) and Scleroderris blue (**3**) were the only pigments isolated from the Wort medium, while the PDY culture produced the lactone **4** in addition to **1** and **3**. The sclerodin (**1**) isolated from the PDY culture was virtually racemic ($[\alpha]_D$ +2.3°) whereas that isolated from the Wort medium was distinctly levorotatory ($[\alpha]_D$ −28.0°). We find this inconsistency in the optical purity of the metabolites puzzling. The fact that different media give sclerodin (**1**) of different optical purity suggests that a more careful study of the culture conditions (e.g., does rotation change with the length of time of growth?) is necessary before we speculate further. We have now initiated such a study.

Preliminary tests reveal that sclerodin (**1**), scleroderolide (**2**), and Scleroderris blue (**3**) all inhibit the germination of lettuce seeds. Scleroderolide (**3**) is especially active in this respect, a 20 ppm solution causing one hundred percent inhibition of germination. The effect of these metabolites on the germination of lodgepole pine seeds will now be studied, followed by a study of their effect on pine seedlings. Further study of the possible role of these metabolites in the disease of the mature trees will be dictated by the results of these experiments.

Experimental

High resolution electron impact mass spectra (hrms) were recorded on an AEI MS-50 mass spectrometer. Unless diagnostically significant, only those peaks with an intensity of >20% of the base peak are recorded. Chemical ionization mass spectra (cims) were obtained using an AEI-MS-12 mass spectrometer with ammonia as the reagent gas.

The data were processed using DS-55 software and a Nova-4 computer. Fourier transform infrared (Ftir) spectra were recorded on a Nicolet 7199 FTIR interferometer. Nuclear magnetic resonance (nmr) spectra (^1H and ^{13}C) were obtained on Bruker WH-300, WM-360, or WH-400 spectrometers with either Aspect 2000 or Aspect 3000 computer systems. ^1H chemical shifts and coupling constants are reported as if they are first order. Tetramethylsilane was used as an internal standard. Ultraviolet (uv) spectra were obtained on a Hewlett Packard 8450A Diode Array spectrophotometer and optical rotations on a Perkin Elmer 241 polarimeter. Melting points are uncorrected and were determined on a Thomas model 40 melting point apparatus. E. Merck silica gel 60 (230–400 mesh) or 10% C–18 silica gel (30–70μm, Toronto Research Chemicals Inc.) were used for flash chromatography. Preparative thin-layer chromatography (ptlc) was performed on E. Merck precoated 20 × 20 glass plates of silica gel 60 F-254. Analytical thin-layer chromatography (tlc) was carried out on cut sections of E. Merck precoated aluminum sheets of silica gel 60 F-254. Ultraviolet active materials were detected by visualisation under a uv lamp (254 nm). The tlc plates were then dipped in a solution of phosphomolybdic acid for several seconds, and the spots were visualised by gentle heating over a hot plate. All solvents were distilled prior to use. Skellysolve B refers to Skelly Oil Company light petroleum, bp 62–70°C.

The stock cultures used in this study were obtained from Prof. O. Kandler, Botanisches Institut der Universität München, and are deposited at the University of Alberta Microfungus Herbarium under the following assession numbers: Sirococcus 33b (UAMH 5400), Sirococcus D (UAMH 5399), and Sirococcus 20 (UAMH 5402).

Growth and harvesting of Sirococcus

Stock cultures of each strain of *Sirococcus* were maintained in slant tube culture on potato dextrose agar at 4°C. To initiate large-scale cultures, small fragments of agar containing the mycelium were aseptically transferred to Erlenmeyer flasks containing sterile culture medium (200 mL). The medium was either Difco potato dextrose broth containing 0.04% (w/v) yeast extract, or clarified V8 juice (5) containing 1% (w/v) glucose, or Wort medium (malt extract 15 g, peptone 0.78 g, maltose 12.75 g, dextrin 2.75 g, glycerol 2.35 g, K_2HPO_4 1.0 g, NH_4Cl 1.0 g in 1 L H_2O; pH adjusted to 4.8).

The cultures were shaken for 10 days at 15–17°C. The content of each inoculation flask was used to inoculate five 2.8-L Fernbach flasks containing the same liquid medium (1 L, still culture) and the flasks were kept at 15–17°C. After 50–60 days, the mycelium was separated from the broth. The broth was concentrated to one tenth of its original volume and extracted with methylene chloride. The air-dried mycelium was extracted with methylene chloride in a Soxhlet extractor. Concentration of the methylene chloride extracts gave the crude broth and mycelial extracts. Very small quantities of metabolites were present in the broth extract, the mycelial extract containing the bulk of the metabolites of interest in this study.

Separation of metabolites of Sirococcus "33b"

The methylene chloride extract of strain 33b (UAMH 5400) was separated into five fractions by chromatography over silica gel RP 18 (eluant: CH_3OH–H_2O, 4:1). Further separation of fraction 1 by acid–base extraction gave a mixture that contained mainly phenolic compounds. Chromatography of this mixture (silica gel) using gradient elution (Skellysolve B–$CHCl_3$–CH_3OH containing HOAc) led to the isolation of sclerodin (**1**), scleroderolide (**2**), trypethelone (**6**), and small quantities of unidentified pigments. Further separation of fraction 2 by column chromatography (eluant: $CHCl_3$ – ethyl acetate – HOAc, 98:1:1) and preparative thin-layer chromatography led to the isolation of compounds **1**, **2**, Scleroderris yellow (**8**), Scleroderris blue (**3**), and two unidentified red pigments. Fractions 3–5 were found to be composed mainly of triglycerides and were not investigated further.

On another occasion the methylene chloride extract of the mycelium was fractionated over silica gel RP 18. Further purification of each of the six fractions by silica gel chromatography (eluant: $CHCl_3$ – ethyl acetate – acetic acid, 97:2:1) led to the isolation of scleroquinone (**12**) (0.7 mg, fraction 2), compound **2** (1.7 mg) and lactone **4** (2.3 mg, fraction 3), sclerodin (**1**, 4 mg, fraction 4), and ergosta-4,6,8(14), 22-tetraen-3-one (0.8 mg, fraction 5).

TABLE 1. Variation in optical purity of sclerodin (**1**)

Fungus (medium)		$[\alpha]_D$ –	
G. abietina	(V8G)	−73°	Reference 5
Sirococcus 33b	(V8G)	−6.5°	(0.41, $CHCl_3$)
Sirococcus D	(V8G)	+27°	(0.79, $CHCl_3$)
Sirococcus 20	(PDY)	+2.3°	(0.43 $CHCl_3$)
Sirococcus 20	(Wort)	−28.0°	(0.41, $CHCl_3$)

Separation of metabolites of Sirococcus "D"

The methylene chloride extract (3.46 g) of strain D (UAMH 5399) was separated into Skellysolve B soluble extract (2.38 g) and Skellysolve B insoluble extract (1.02 g). The Skellysolve B soluble fraction was separated by repeated chromatography over silica gel. Squalene (1 mg), methyl oleate (9 mg), triglycerides (1.5 g), sclerodin (**1**, 13 mg), ergosta-4,6,8(14),22-tetraen-3-one (9 mg), a 1,2-diglyceride (10 mg), a 1,3-diglyceride (22 mg), and stearic acid (2 mg) were isolated. The Skellysolve B insoluble fraction was separated by repeated silica gel chromatography. Triglycerides (47 mg), sclerodin (**1**, 21 mg), unidentified red pigments, and scleroderolide (**2**, 0.8 mg) were isolated.

Separation of metabolites of Sirococcus "20"

The methylene chloride extract (2.86 g) of strain 20 (UAMH 5402) grown on PDBY was separated into nonpolar, medium polar, and polar fractions by chromatography over silica gel (gradient elution; Skellysolve B – toluene – ethyl acetate – methanol). Further chromatographic separation (gradient elution; Skellysolve B – ether) of the nonpolar fraction (1.16 g) gave sclerodin (**1**, 67 mg), ergosterol endoperoxide (2 mg), and a mixture of fatty acids and triglycerides. Further chromatographic separation (gradient elution; Skellysolve B – ether, then CH_2Cl_2–CH_3OH–HOAc, 96:2:2) of the medium polarity fraction (0.48 g) gave compound **1** (61 mg), lactone **4** (5 mg), and compound **3** (3 mg) whereas further chromatographic separation (gradient elution; Skellysolve B – ethyl acetate, then CH_2Cl_2–CH_3OH–HOAc, 96:2:2) of the polar fraction (1.17 g) gave compound **1** (5.5 mg) and a blue pigment (2 mg).

The methylene chloride extract (1.42 g) obtained from cultures of Sirococcus 20 grown on Wort media was separated as described above. The following metabolites were isolated: sclerodin (**1**, 11 mg), ergosterol peroxide, ergosta-4,6,8(14),22-tetraen-3-one, and the blue pigment.

Characterization of metabolites

Sclerodin (**1**) (from Sirococcus 33b, D, and 20): Identical (ir, ^1H nmr, ^{13}C nmr, hrms) with an authentic sample. Optical rotations, see Table 1.

Scleroderolide (**2**) (from Sirococcus 33b and D): Identical (ir, ^1H nmr, ^{13}C nmr, hrms) with an authentic sample.

Scleroderris blue (**3**) (from Sirococcus 33b and 20): Identical (ir, ^1H nmr, ^{13}C nmr, hrms) with an authentic sample.

Lactone **4** (from Sirococcus 33b and 20): $[\alpha]_D$ −20.71° (*c* 0.14, $CHCl_3$). Identical (ir, ^1H nmr, ^{13}C nmr, hrms) with an authentic sample.

Trypethelone (**6**): R_f 0.33 ($CHCl_3$–CH_3OH – acetic acid, 94:5:1), mp 248–249°C (lit. (8) mp 264 266°C); $[\alpha]_D$ 130° (*c* 0.20, $CHCl_3$); λ_{max} (log ε) (CH_3OH): 275 (4.93), 284 (4.95), 303 (4.42), 525 (3.87) nm; ir ($CHCl_3$): 3040, 2963, 2927, 1735 (w), 1682 (m), 1647 (m), 1602 (s), 1585, 1541, 1460, 1407, 1383, 1363, 1319 cm^{-1}; ^1H nmr (CD_3OD) δ: 1.23 (s, 3H, H–5′), 1.40 (s, 3H, H–4′), 1.46 (d, 3H, *J* 6.5 Hz, H–1′), 2.52 (s, 3H, C–5 CH_3), 4.71 (q, 1H, *J* 6.5 Hz, H–2′), 6.97 (d, 1H, *J* 3 Hz, H–6), 7.36 (d, 1H, *J* 3 Hz, H–8); ^{13}C nmr (CD_3OD) δ: 14.91 (q, C–1′), 20.54 (q, C–5′), 22.34 (q, C–5 CH_3), 26.01 (q, C–4′), 43.90 (s, C–3′), 94.15 (d, C–2′), 116.37 (s, C–4a), 117.84 (d, C–8), 122.16 (s, C–3), 125.43 (d, C–6), 135.63 (s, C–8a), 142.82

(s, C–5), 165.03 (s, C–7), 175.60 (s, C–1), 176.51 (s, C–2), 184.24 (s, C–1); hrms, *m/z* (rel. int.): 272.1049; calcd. for $C_{16}H_{16}O_4$: 272.1054; found: (M^+, 43), 257 ($M^+ - CH_3$, 39), 244 ($M^+ - CO$, 22), 229 ($M^+ - CH_3 - CO$, 100).

Scleroderris yellow (**8**): mp 289–290°C; $[\alpha]_D$ −16.7° (*c* 0.12, $CHCl_3$); ir ($CHCl_3$ cast): 3220, 2960, 2926, 2855, 2480 (br), 1740 (w), 1710 (w), 1613 (s), 1456, 1383, 1360 cm^{-1}; ^1H nmr ($CDCl_3$, rt) δ: 1.39 (6H, br s), 1.53 (6H, br s), 1.54 (6H, d, *J* 6 Hz, -CHC*H*$_3$), 286 (6H, s, ArC*H*$_3$), 4.14 (2H, s, -C*H*$_2$), 4.72 (2H, m, C*H*CH$_3$), 6.85 (2H, s, ArH), 12.48 (1.2H, 4 lines D_2O exchangeable), 13.47 (0.9H, 4 lines, D_2O exchangeable), 13.58 (0.9H, 4 lines, D_2O exchangeable), 14.62 (1.2H, 4 lines, D_2O exchangeable), 15.01–15.54 (1.8H, br, D_2O exchangeable); ($CHCl_3$, 47°C) δ: 1.28, 1.30 (ea 3H, s, H–5′), 1.48, 1.50 (ea 3H, d, *J* 6 Hz, H–1′), 1.53, 1.55 (ea 3H, s, H–4′), 2.88 (6H, s, ArC*H*$_3$), 4.71 (2H, m, H–2′), 6.88 (2H, s, Ar–H), 12.41, 12.42 (ea 0.5H, s), 13.42, 13.43 (ea 0.5H, s), 13.57, 13.58 (ea 0.5H, s), 14.58, 14.59 (ea 0.5H, s); ^{13}C nmr ($CDCl_3$) δ: 14.67, 17.63, 20.65, 24.04, 24.12, 25.72, 43.39, 43.35, 91.51, 91.57, 103.78, 104.75, 105.72, 108.35, 114.99, 115.18, 117.01, 117.09, 118.59, 118.67, 128.98, 148.14, 148.65, 165.10, 165.18, 166.35, 166.55, 168.30, 172.41, 173.13, 176.89; hrms, *m/z* (rel. int.): 664.2309; calcd. for $C_{39}H_{36}O_{10}$: 664.2308; found: (M^+, 1.5), 338 (28), 326 (39), 323 (81), 311 (100), 269 (26); fabms: 665.46 ($M^+ + H$), calcd. for $C_{39}H_{37}O_{10}$; found: 665.2388 (0.4).

Scleroquinone(**12**): λ_{max} (log ε) (CH_3OH): 217 (3.03), 287 (2.94), 305 (2.77), 574 (1.72) nm; ir ($CHCl_3$, cast): 3220 (br), 2925, 2845, 1740, 1695, 1624, 1606, 1540, 1454, 1240, 800 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.41 (3H, s, H–5′), 1.43 (3H, d, *J* 6.5 Hz, H–1′), 1.52 (3H, s, H–4′), 2.58 (3H, s, ArC*H*$_3$), 3.85 (3H, s, OC*H*$_3$), 4.62 (1H, q, *J* 6.5 Hz, H–2′), 6.96 (1H, s, H–6); hrms, *m/z* (rel. int.): 330.1103; calcd. for $C_{18}H_{18}O_6$: 330.1106; found: (M^+, 42), 331 ($M^+ + 1$, 10), 315)10), 302 (61), 300 (19), 299 (9), 287 (82), 285 (29), 284 (16), 283 (13), 270 (43), 256 (17), 255 (100), 242 (34).

Methylation of Scleroderris yellow

Excess ethereal diazomethane (4 mL) was added to a solution of Scleroderris yellow (**8**, 2.5 mg) in dichloromethane (2 mL). After 15 h, the reaction mixture was concentrated and purified by chromatography (Skellysolve B – ethyl acetate – chloroform, 8:1:1) to give compound **9** as a yellow solid; ir ($CHCl_3$ cast): 3320, 2952, 2924, 1720, 1610, 1583, 1451, 1383, 1355, 1320 cm^{-1} ^1H nmr ($CDCl_3$) δ: 1.29, 133 (ea 3H, s, H–5′), 1.46, 1.47 (ea 3H, d, *J* 7, H–1′), 1.54, 1.56 (ea 3H, s, H–4′), 2.77, 2.89 (ea 3H, s, $ArCH_3$), 3.75 (3H, s, OCH_3), 3.84 (3H, s, OCH_3), 3.92 (3H, s, OCH_3), 4.06 (3H, s, OCH_3), 4.46 (2H, s, $ArCH_2Ar$), 4.57, 4.64 (ea 1H, q, *J* 7, H–2′), 6.78, 6.83 (ea 1H, s, Ar*H*), 17.85, 17.93 (ea 1H, s, O*H*); fabms: 722.46 (19), 721.46 (42), (calcd. for $C_{43}H_{45}O_{10}$ (M^+ 1): 721.35) 381.43 (7), 368.33 (26), 367.33 (100), 355.21 (17), 353.17 (16), 351.18 (10).

In another experiment, Scleroderris yellow (**8**, 3.0 mg) was dissolved in excess ethereal diazomethane (5 mL) and the solution was stirred for 15 h. The reaction mixture was worked up as before to give compound **10a** as a yellow solid; ir ($CHCl_3$ cast): 3320, 2954, 2924, 2852, 1740 (w), 1611, 1582, 1454, 1384, 1375, 1356, 1300 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.33 (6H, s, H–5′), 1.47 (6H, d, *J* 7, H–1′), 1.57 (6H, s, H–4′), 2.87 (6H, s, $ArCH_3$), 3.78 (6H, s, OCH_3), 4.01 (6H, s, OCH_3), 4.46 (2H, s, $ArCH_2Ar$). 4.63 (2H, q, *J* 7, H–2′), 6.78 (2H, s, ArH), 18.52 (2H, s, OH); fabms: 722.39 (11), 721.38 (25), (calcd. for $C_{43}H_{45}O_{10}$, ($M^+ + 1$): 721.35) 381.41 (11), 368.34 (21), 367.31 (79), 355.19 (15), 353.17 (17), 351.17 (11), 55.21 (11).

Germination inhibition tests

Lettuce seeds (Heritage Garden Products, Canada No. 1 seed, variety "Salad Bowl") were sterilized by immersion for a few minutes in 2% bleach solution, then washed (2×) with sterile distilled water, and dried on filter paper. The seeds (approximately 100 seeds/test) were placed on doubled filter paper in a sterile Petri dish and the filter papers were saturated with a solution (4 mL, 200 ppm and 20 ppm in water containing Tween 20 (2 drops/5 mL water)) of sclerodin (**1**), scleroderolide (**2**), of Scleroderris blue (**3**). The plates were incubated (20–22°C) for 4 days, receiving 8 h of light per day. The percentage inhibition of germination was as follows: control (5.7%); sclerodin (**1**), 20 ppm (23%), 200 ppm (100%); scleroderolide (**2**), 20 ppm (100%), 200 ppm (100%) Scleroderris blue (**3**), 20 ppm (38%), 200 ppm (100%).

Received October 17, 1988[2]

E. RODRÍGUEZ-CASTELLÓN, P. OLIVERA-PASTOR, A. JIMÉNEZ-LÓPEZ, P. MAIRELES-TORRES, M. J. HUDSON, and P. SYLVESTER. Can. J. Chem. **67**, 2095 (1989).

Aromatic amines such as *o*-phenylenediamine, *m*-phenylenediamine, *p*-phenylenediamine, benzidine, and 2-amino-4-methylpyridine were intercalated into tin(IV) hydrogen phosphate monohydrate (α-$Sn(HPO_4)_2 \cdot H_2O$). *o*-Phenylenediamine and 2-amino-4-methylpyridine form a bilayer, while *m*-phenylenediamine, *p*-phenylenediamine, and benzidine form a monolayer. Phenylenediamines are monoprotonated on the interlayer surface of the phosphate, whereas benzidine is diprotonated. 2-Amino-4-methylpyridine exhibits a different behaviour with respect to pyridine, because the positive charge is localized between the two nitrogen atoms and not delocalised along the aromatic ring as in pyridine. The intercalation of benzidine causes a great shift in the relative position of the phosphate layers to accommodate the organic molecules. All products were characterized by chemical analysis, DTA-TG, IR spectroscopy, diffuse reflectance spectroscopy, and X-ray diffractometry.

Key words: intercalation, aryldiamines, benzidine, 2-amino-4-methylpyridine, α-$Sn(HPO_4)_2 \cdot H_2O$.

E. RODRÍGUEZ-CASTELLÓN, P. OLIVERA-PASTOR, A. JIMÉNEZ-LÓPEZ, P. MAIRELES-TORRES, M. J. HUDSON et P. SYLVESTER. Can. J. Chem. **67**, 2095 (1989).

On a intercalé des amines aromatiques, comme les *o*-, *m*- et *p*-phénylènediamines, la benzidine et la 2-amino-4-méthylpyridine, dans le monohydrate du phosphate acide d'étain(IV) (α-$Sn(HPO_4)_2 \cdot H_2O$). L'*o*-phénylènediamine et la 2-amino-4-méthylpyridine forment une bicouche alors que les *m*- et *p*-phénylènediamines ainsi que la benzidine forment une monocouche. Les phénylènediamines sont monoprotonées sur la surface intercalaire du phosphate alors que la benzidine est diprotonée. La 2-amino-4-méthylpyridine présente un comportement différent de celui de la pyridine parce que la charge positive est localisée entre les deux atomes d'azote et non pas délocalisée sur le noyau aromatique, comme c'est le cas avec la pyridine. Afin d'accommoder les molécules organiques, le fait d'intercaler de la benzidine provoque un déplacement important de la position relative des couches phosphates. On a caractérisé tous les produits par des analyses chimiques, par DTA-TG, par spectroscopie ir, par spectroscopie de réflectance diffuse et par diffraction des rayons-X.

Mots clés : intercalation, aryldiamines, benzidine, 2-amino-4-méthylpyridine, α-$Sn(HPO_4)_2 \cdot H_2O$.

[Traduit par la revue]

Introduction

Intercalation of aromatic amines on layered materials such as insoluble acid salts of general formula $M(IV)(HPO_4)_2 \cdot nH_2O$ (where M(IV) = Ti, Zr, and Sn) have been studied (1, 2). However, intercalation of aromatic compounds with two amine groups in this type of phosphate has not yet been described. Recent papers described the intercalation of some diamines such as *trans*-1,4-*N*,*N'*-diethyl-2-butenediamine and 1,4-diazabicyclo[2,2,2]octane (DABCO) into α-$Sn(HPO_4)_2 \cdot H_2O$ (α-SnP) (3, 4) and the observed intercalation behaviour was different than that observed with other layered materials such as some smectites (5). Miguel and Aragon (6) studied the intercalation compounds of *o*-, *m*-, and *p*-phenylenediamine with nickel cyanide, and they concluded that *o*- and *m*-phenylenediamine were coordinated to Ni(II) through an amine group, and that *p*-phenylenediamine coordinated their amine groups to two consecutive layers of nickel cyanide.

The preparation of intercalation compounds with free functional groups in the interlayer region for possible drafting reaction, and the study of the mechanism of the intercalation and the disposition of the organic molecules inside the layers are the main objectives of this work.

This paper studies the intercalation of *o*-phenylenediamine (OPh), *m*-phenylenediamine (MPh), *p*-phenylenediamine (PPh), benzidine (BZ), and 2-amino-4-methylpyridine (2AMP) into α-SnP. All the organics are monomers and are susceptible of polymerization. These intercalates were characterized by means of chemical analysis, X-ray powder diffractometry (XRD), infrared spectroscopy (IR), diffuse reflectance UV-vis spectroscopy (DRS), and thermal analysis (DTA-TG).

BZ 5:1	—	370	475	

Experimental

Materials and intercalation reactions

All chemicals were of reagent grade and were used without further purification, α-SnP was prepared as described elsewhere (2).

Intercalation of amines into α-SnP was achieved by adding 0.20 g of α-SnP to 50 mL of aqueous solutions of the amines with different molar ratios ranging from 1:1 to 5:1 (amine/α-SnP), except in the case of BZ where a water/ethanol mixture (1:2 or 1:1) was used as solvent. The suspensions were stirred for one day in Teflon-sealed glass bottles at 50°C which were light protected. The solids were filtered and washed several times with water and then with acetone and finally air dried. The same results were obtained when toluene was used as solvent, but the products exhibited a better crystallinity.

Aryldiamine monohydrochlorides and dihydrochlorides were prepared by titration of the amines with aqueous HCl and then evaporating to dryness.

Analytical procedure and instruments

CHN analyses were carried out in a Perkin Elmer 240C analyzer. X-ray powder diffraction patterns were obtained with a Siemens D-500 diffractometer with Cu-Kα radiation and using a graphite monochromator. Diffuse reflectance spectra were recorded on a Kontron Uvikon 810 spectrophotometer with an integrating sphere attachment, using $BaSO_4$ as the reference. Infrared spectra were obtained with a Perkin Elmer 883 spectrophotometer by the KBr disc method. TG and DTA analyses were carried out using a Rigaku-Thermoflex thermoanalyzer, at a heating rate of 10°C min^{-1}. The thermal behaviours of all obtained intercalation compounds are similar. Thermal data (Table 1) show endothermic peaks between 50–180°C which correspond to water loss except for benzidine intercalate. The exothermal effects correspond to the pyrolysis and oxidation of the intercalated amines.

The composition of the complexes with the highest amine content was as follows: $Sn(OPh)_{1.54}(HPO_4)_2 \cdot H_2O$; $Sn(MPh)_{0.74}(HPO_4)_2 \cdot H_2O$; $Sn(PPh)_{1.46}(HPO_4)_2 \cdot H_2O$; $Sn(2AMP)_{1.39}(HPO_4)_2 \cdot 0.5H_2O$; $Sn(BZ)_{1.07}(HPO_4)_2 \cdot H_2O$. Thermogravimetric data agree with CHN analysis.

Results and discussion

The intercalation of OPh, PPh, BZ, and 2AMP occurs as expected, by means of acid–base neutralization reactions. The composition and the increase in basal spacing of the intercalates depend on the added amine (see Table 2). Structural changes of the intercalated phases were examined by X-ray diffractometry. In all cases, the powder X-ray diffraction patterns can be indexed on monoclinic unit cells, where the *a* and *b* lattice constants are very similar to those of α-SnP (Table 3). The data indicate that the layered structures have been preserved and that the interlamellar spaces have expanded. All the starting product *hk*0 lines were present in the intercalates with systematic absences when $h + k = 2n$.

Intercalation of phenylenediamines

X-ray powder diffractograms of all intercalates show the presence of two phases: a swelled phase that appears in the lowest angle region, and the pure α-SnP phase with an interlayer distance of 7.8 Å. The intensity of the characteristic reflection line of the swelled phase increased with an increase in the uptake of phenylenediamine, whereas the diffraction peak of the α-SnP phase persists even in samples with the highest concentration of amine. Figure 1 shows this evolution in the case of the OPh

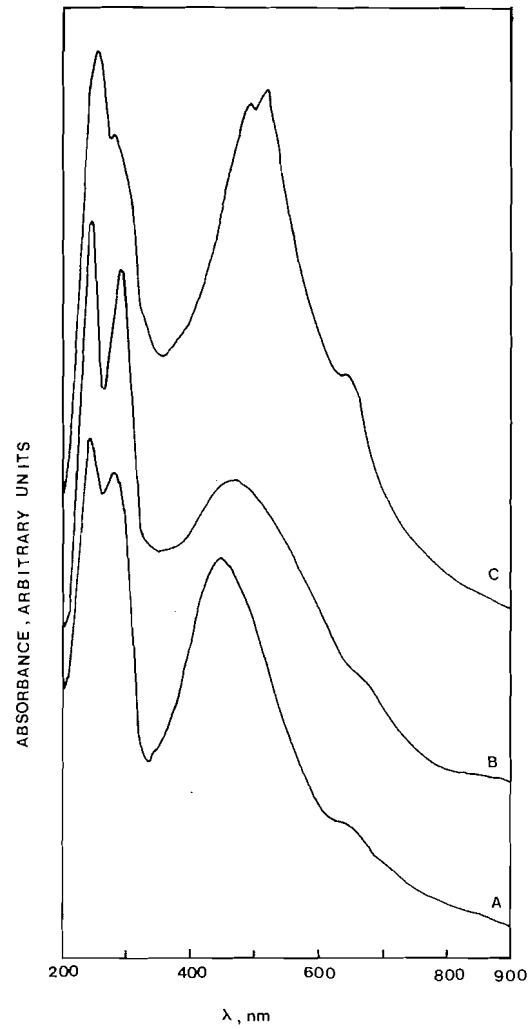

FIG. 2. Diffuse reflectance spectra of (*A*), OPh 3:1; (*B*), OPh monohydrochloride; (*C*) OPh dihydrochloride.

intercalation as an example. At high diamine loadings, several integral reflection orders (004, 006, 008) of the swelled phase of the complexes were observed.

d(002) values of the swelled phases of the intercalates are consistent with the formation of a bilayer of organic molecules for the OPh complex (18.9 Å) and of a monolayer for the MPh (13.1 Å) and PPh (13.5 Å) complexes.

The mechanism of intercalation of amines was monitored by observing the shifts of νNH, δNH_2, and νCN vibration bands in the infrared spectra of the intercalated amine in comparison with the pure amine and its chlorhydrates. Selected infrared absorption bands of the pure amine, mono- and dihydrochloride, and the intercalated amine samples (5:1) are shown in Table 4.

From these data, protonation of arylamines is detected by the presence of a broad band in the 2750–3000 cm^{-1} region and another band between 1513–1568 cm^{-1} corresponding to νNH^+ and δNH_3^+, respectively. The disappearance of the bands at c.a. 3390 cm^{-1} (νNH_a) and c.a. 3300 (νNH_s) of the pure amines implies diprotonation of the diamines. When only monoprotonation occurs, the latter band persists. Comparison of the phenylenediamine–α-SnP intercalate spectra with those of pure, mono- and dihydrochloride amines reveals that these phenylenediamines are not totally protonated in the interlayer region of the phosphate. This occurs probably as a consequence of the low pK_{a2} values of these diamines (0.60, 2.41, and 2.67

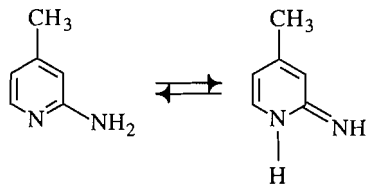
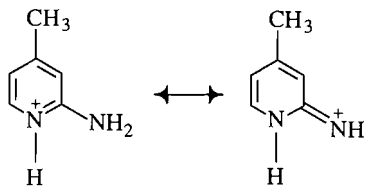
for OPh, MPh, and PPh, respectively (7)) and also of the different acidity of the POH groups (2, 8). Composition data for the OPh and PPh intercalates also support the hypothesis of monoprotonation inasmuch as the molar ratio intercalated diamine/α-SnP exceed unity. OPh molecules are arranged in bilayers, but diprotonation is not detected in spite of the fact that the distance between the —NH_2 groups in this molecule is very similar to the distance between two adjacent POH groups in the α-SnP layer. The situation of the amine groups in OPh impedes the simultaneous interaction of both groups with two adjacent layers of the phosphate and thus bilayer formation occurs, thereby facilitating the strongest interaction possible of this



diamine with the phosphate, as in the case of intercalated aromatic monoamines (2). However, a greater separation between the amine groups such as in MPh and PPh diamines may permit simultaneous interaction with adjacent layers; giving rise the formation of monolayers, although the molecules are not diprotonated. The strongest interaction of an amine with the interlayer surface is achieved when the CN bond is perpendicular to to the layers (9). The geometry of the MPh molecule only permits that one of the two CN bonds to be perpendicular to the phosphate layer in contrast to the PPh molecule and consequently a weaker interaction of MPh with the phosphate should be expected. Composition data suggest this possibility (Table 2).

Diffuse reflectance spectroscopy data for the phenylenediamine intercalates also are coherent with the presence of intercalated monoprotonated diamines. For example, the diffuse reflectance spectrum of OPh 3:1 (Fig. 2) shows four absorption bands at 640, 455, 281, and 243 nm, being very similar to that of *o*-phenylenediamine monohydrochloride (640, 465, 290, and 245 nm), and different from the spectrum of *o*-phenylenediamine dihydrochloride which presents five bands at 640, 522, 490, 288, and 257 nm.



Intercalation of 2-amino-4-methylpyridine

2AMP was intercalated into α-SnP from aqueous solution. The maximum amount of amine taken up was 1.39 mol of 2AMP per mol of α-SnP, with a molar ratio AMP added/α-SnP of 7:1. XRD data of 2AMP 7:1 give an interlayer distance of 18.5 Å, suggesting an arrangement of bilayer within the interlayer space of α-SnP.

It is well known that 2AMP exhibits tautomery, according to the following equilibrium (10):

In the IR spectrum of this substance (Fig. 3), bands at 1268 and 1305, 1640, and 1613 cm^{-1} are assigned to νCN, νCN, and δNH_2, respectively showing the presence of amine and imine groups. Although the electrophilic reaction can take place either on heterocyclic or amino nitrogen (10), the protonation of this substance only gives rise to one product whose more important canonical form can be seen in the following scheme:

a *b*

This is coherent with the existence of a unique pK_a (>6.71). The canonical form *b* supposes a weakness of the C=N aromatic bond and a strengthening of the $C=N^+$ aliphatic bond. The ν C=N aromatic vibration band at 1640 cm^{-1} of the pure amine shifts to 1660 cm^{-1} in the 2AMP intercalate, which is interpreted as a consequence of the contribution of the aliphatic imine ion character of the protonated intercalated molecule. The weak intensity band at 1540 cm^{-1} in the 2AMP intercalate spectrum is assigned to a vibration mode of the pyridinium ion

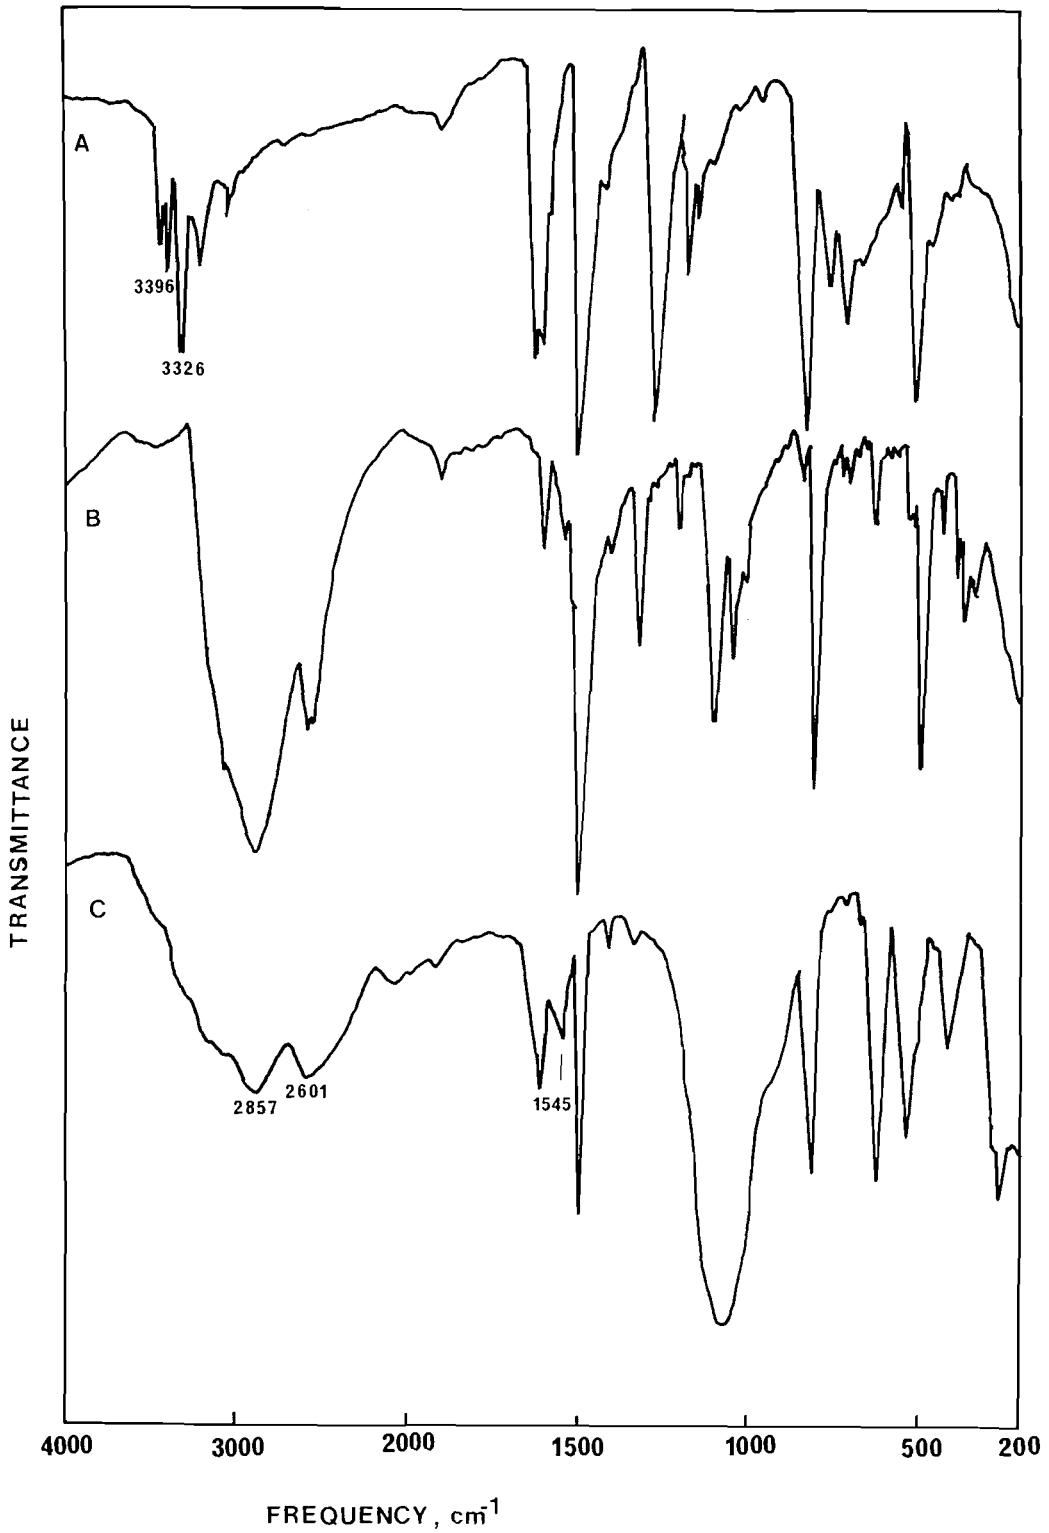

FIG. 5. Infrared spectra of (*A*), benzidine; (*B*), benzidine dihydrochloride; (*C*), BZ 4:1.

(11). The appearance of a band at 1290 cm^{-1} attributed to νC—N of the intercalated amine, instead of two bands at 1305 and 1268 cm^{-1} in the pure amine spectrum may be also due to the participation of the canonical form *b*. The band at 1730 cm^{-1} in the IR spectrum of the intercalate indicates the presence of strongly linked water in the phosphate interlayer space (12); therefore, it is to be expected that the interaction of the 2AMP with the phosphate layers is affected by water molecules through hydrogen bonds. Thus the neutralization of the layer negative charge would be more effective.

Pyridine lies in a flat disposition within the α-SnP interlayer space with the aromatic ring parallel to the layers (2), in contrast to 2AMP. The positive charge of the pyridinium ion is delocalized along the ring, whereas in the 2AMP ion, the positive charge is more localized between the two nitrogen atoms. The charge is also localized in the nitrogen atom of the

anilinium ion, and thus bilayers are formed with the aromatic ring tilted 60° with respect to the phosphate layer, as in the case of alkylamines (9, 13). Intercalation data for aromatic amine into α-SnP appear to suggest that when the positive charge of the amine cation such as anilinium, aryldiammonium, and 2AMP is localized, the basic group has a tendency to orientate toward the oxygen surface of the phosphate layers, whereas when the positive charge is delocalized (like in the pyridinium ion) the flat orientation of the aromatic ring is the most stable arrangement.

Intercalation of benzidine

Benzidine was intercalated into α-SnP using a water/ethanol 1:1 mixture as solvent. The highest content of intercalated BZ was obtained with a molar ratio BZ added/α-SnP 3:1 (1:1 mol of BZ/mol of α-SnP). Under this condition the characteristic reflection line of α-SnP at 7.8 Å is not readily observed, and the increase in basal spacing was 10.1 Å (17.9 Å − 7.8 Å), a value very close to that expected for perpendicular orientation if it is assumed that the $—NH_2$ groups are engaged in a symmetrical hydrogen bond with POH groups of adjacent layers and that the O—H···N bond length and angle are 2.8 Å and 180°, respectively (14). The diffraction peaks appearing at 13.6 Å and its harmonic of higher order at 6.8 Å in the XRD patterns of the 1:1 BZ intercalate may correspond to a phase with no perpendicular orientation of the amine (Fig. 4).

Figure 5 shows the IR spectra of pure BZ, BZ dihydrochloride, and the BZ 4:1 intercalate. The presence of bands at 2857 and 2601, and at 1545 cm^{-1} assigned to νNH^+ and δNH_3^+ respectively, together with the absence of the νNH_2 bands of the pure amine at 3396 and 3326 cm^{-1} in the IR spectrum of the BZ intercalate suggest protonation of both amine groups. Higher basicity of benzidine in comparison with phenylenediamines ($pK_{1a} = 4.97$, $pK_{2a} = 3.75$ (15)) may explain this behaviour. In fact, the intercalation of benzidine supposes the greatest shift in the relative position of the phosphate layers (Table 3) to accommodate the organic molecules, which is believed to be a consequence of the strong interaction of the benzidine molecule with two adjacent layers.

Interfacial behaviour of isopropanol at the Hg electrode from solutions of H_2O–isopropanol–HCl

AMINA A. MAZHAR
Chemistry Department, Faculty of Science, Cairo University, Giza, Egypt

Received March 7, 1989

AMINA A. MAZHAR. Can. J. Chem. **67**, 2102 (1989).

The adsorption of isopropanol on mercury in aqueous solutions of HCl at constant chemical potential of the acid has been determined from capacity and electrocapillary measurements. The maximum adsorption occurs at a charge of $-2.2\ \mu C\,cm^{-2}$. The Frumkin isotherm is obeyed, the α factor in the isotherm changes from a positive value for mixtures rich in water to a negative value for mixtures rich in alcohol. The standard Gibbs energy of adsorption depends quadratically on the potential. The orientation of the alcohol molecule in the interface is discussed.

Key words: interface, medium effects, adsorption isotherm, aliphatic alcohol, Gibbs energy of adsorption.

AMINA A. MAZHAR. Can. J. Chem. **67**, 2102 (1989).

En se basant sur des mesures de capacité et d'électrocapillarité, on a déterminé l'adsorption de l'isopropanol sur du mercure en solutions aqueuses dans le HCl, à potentiel chimique constant d'acide. L'adsorption maximale se produit à une charge de $-2{,}2\ \mu C\,cm^{-2}$. Les données obéissent à l'isotherme de Frumkin et le facteur α de l'isotherme varie d'une valeur positive pour les mélanges riches en eau à une valeur négative pour les mélanges riches en alcool. L'énergie standard d'adsorption de Gibbs varie d'une façon quadratique avec le potentiel. On discute de l'orientation de la molécule d'alcool à l'interface.

Mots clés : interface, effets de solvant, isotherme d'adsorption, alcools aliphatiques, énergie d'adsorption de Gibbs.

[Traduit par la revue]

Introduction

The adsorption characteristics of many organic compounds at the mercury solution interface have been described in the literature. Some unsolved problems related to the adsorption of aliphatic alcohols remain, especially when medium effects are taken into consideration. Mohilner and Nakadomari (1) have suggested that all results concerning the nature of adsorption isotherms could be erroneous if changes in the activity of the supporting electrolyte are neglected in increasing concentration of alcohol.

Since the medium effect is expected to be important only at relatively high concentration of the organic compound, a relatively weakly adsorbable organic substance should be chosen. Thus, higher alcohols, acids, and other adsorbable substances are not a favourable choice for such a study. The electrochemical behaviour of isopropanol adsorbed on Pt in acid medium has been recently reported (2).

Knowing the transfer energies of HCl solutions in the presence of isopropanol (3) enables one to study the role played by this surfactant, contingent upon the following conditions: (*a*) Possible errors due to junction potentials are eliminated by applying constant E potential using an Ag/AgCl electrode (1, 4), which was inserted in a glass bridge connected to the measurement cell, and containing the same solution under study. (*b*) Measurements are carried out not at constant activity as is usually done but at constant μ_{HCl} (μ stands for chemical potential); the value chosen corresponds to a $10^{-2}\ M$ solution in the absence of alcohol. In the presence of alcohol the concentration of HCl was always confined to within $10^{-2}\ M$, Table 1. (*c*) The activities are calculated using the values ΔG_t^0, the free energy of transfer of HCl and the following relation (5, 6):

$$\ln a_{HCl}(x_2) = \ln a_{HCl}(x = 0) - \Delta G_t^0/RT$$

where x_2 is the molar fraction of isopropanol.

It is assumed, as practised by the authors of the above references, that the Debye–Hückel law is applicable to HCl in the concentration range studied.

Isopropanol is chosen in this study to pinpoint the electrochemical behaviour of adsorbed secondary alcohols, permitting a better explanation of the differences in the electrochemical properties of alcohols and related compounds. We try to characterize the position of the adsorption maximum, the orientation of the adsorbed particles, and the type of adsorption isotherm for isopropanol in solutions of constant μ_{HCl}.

Experimental

Measurements of the parameters of the electrocapillary maximum, E_z and γ_z, were carried out by a streaming capillary electrometer similar to that used originally by Grahame *et al.* (7). The method of determination of E_z and γ_z was described elsewhere (8). Differential capacity measurements were made using a simple symmetrical ac bridge of the Wien type (9). The capacity cell and working procedure are the same employed previously (10). As before, the reference electrode was an Ag/AgCl electrode (11). All measurements were made in an air bath adjusted to 25°C using a frequency of 1 kHz. AR grade reagents were used, HCl was from B.D.H. and isopropanol from Merck. Measurements were carried out up to 30% by weight alcohol.

Results

Figure 1 shows the differential capacity curves in pure $10^{-2}\ M$ HCl and in presence of 14 different concentrations of the alcohol at constant μ_{HCl}. The anodic side shifts at higher alcohol concentrations, and as previously observed in the case of perchloric acid (12), and in the presence of SO_4^{2-} ions (13), the adsorption–desorption peaks do not appear. The zero-charge potential E_z shifts to more positive values due to adsorption of the alcohol and are indicated by vertical strokes on the capacity curves. With increase of alcohol concentration a capacity trough is formed; this trough gradually widens and levels down, tending towards a minimum value at the highest concentrations studied, meanwhile the desorption peaks on the cathodic side level up monotonically.

The relation between the electrode charge density σ^M and the potential was obtained by integration of the capacity curves. Starting from E_z in the differential capacity curves where $\sigma^M = 0$ (for each curve) graphical integration was carried out every

10 mV interval towards the far anodic side, then towards the far cathodic side. A computer programme was used to calculate σ^M as a function of potential. From the σ^M–E curves and by adopting the same procedure, integration of these curves provided the lowering in γ as a function of potential. Subsequent subtraction of the values of the lowering in γ from the γ_z determined for each solution by using a capillary electrometer produced γ–E curves. Table 1 lists the values of the zero-charge coordinates.

Figure 2 shows the relation between electrode charge density

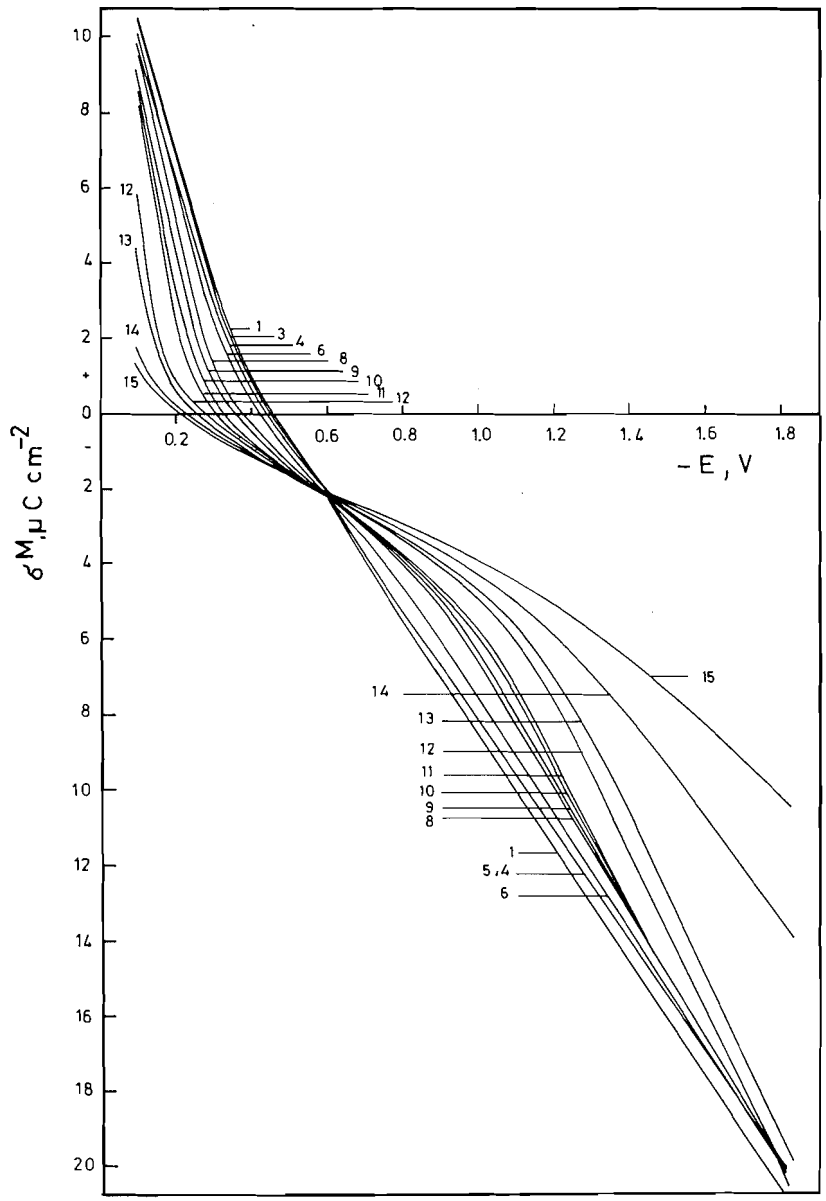

FIG. 2. Dependence of the electrode charge density on the applied potential. Same numbering as Fig. 1.

and potential. It is clear that at extreme negative (−1.8 V) and positive (0.1 V) potentials, desorption is complete for alcohol concentrations up to 5%. The point of intersection of these curves corresponds to σ^M of $-2.2\ \mu C\ cm^{-2}$ and a potential of −0.6 V. Both charge and potential of maximum adsorption are concentration independent. The negative value of σ^M_{max} and the positive shift of E_{max} reveal that at least at maximum adsorption isopropanol dipoles are adsorbed with their positive ends oriented towards the electrode surface. The adsorption of organic compounds having no net dipole moment or showing no effective dipole moment gives σ^M_{max} at −2 to $-4\ \mu C\ cm^{-2}$. For example, σ^M_{max} for pyrazine (14) is $-2\ \mu C\ cm^{-2}$, the more negative value obtained for isopropanol suggests that adsorption occurs with the alkyl group in contact with the mercury surface while the polar OH group points to the solution.

The electrocapillary curves are shown in Fig. 3. The vertical strokes represent E_z, isopropanol shows the common feature of aliphatic alcohols in having their maximum adsorption at potentials more negative than pzc (15–17).

The surface excesses were obtained by using the familiar Gibbs equation, from plots of γ vs. log alcohol concentration at different potentials. The relation between the surface excess Γ at pzc and the concentration of alcohol is shown in Fig. 4. A simple isotherm is obtained with a maximum Γ value of 2.48×10^{14} molecules cm^{-2}, which would give a value of $\simeq 40\ Å^2$ for the area occupied by a single molecule, however, since E_{max} is shifted from E_z, it seems reasonable to calculate Γ_{max} required for further analysis from a plot of $1/\Gamma$ vs. $1/C$ at maximum adsorption. Such a plot is shown in Fig. 5 for both variables of maximum adsorption, i.e., at both $E_{max} = -0.6$ V, and at $\sigma^M_{max} = -2.2\ \mu C\ cm^{-2}$. Extrapolation to $1/C$ organic = 0 should provide a reliable value of Γ_{max}, since the measured concentrations are high (18). The values of Γ_{max} obtained are 3.01 and 3.02×10^{14} molecules cm^{-2}, respectively, with an error of less than ±0.03. These values show that Γ_{max} obtained either at constant E or σ is the same. This yields an area of $33\ Å^2$ which is in remarkably good agreement with that reported for hexafluoro-2-propanol (19), supposing a close-packed monomolecular layer.

The relative surface coverage θ as a function of potential for

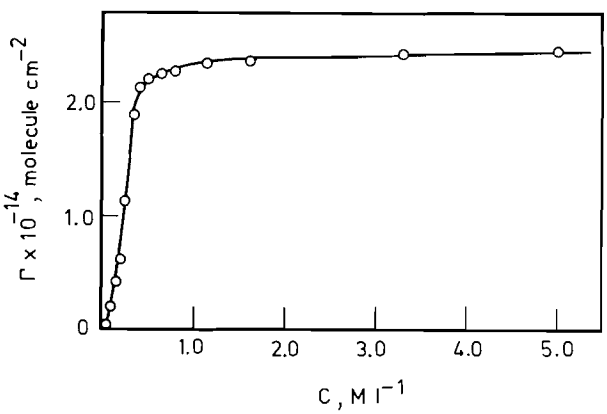

FIG. 4. Variation of $\Gamma_{alcohol}$ with concentration at pzc.

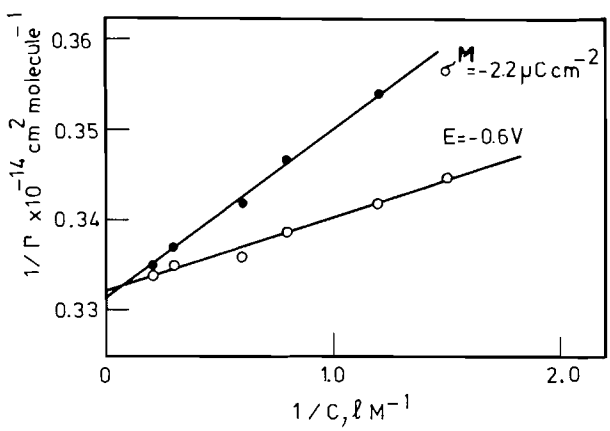

FIG. 5. Dependence of $1/\Gamma$ on $1/C_{org}$ at charge density (σ^M) and potential (E) of maximum adsorption.

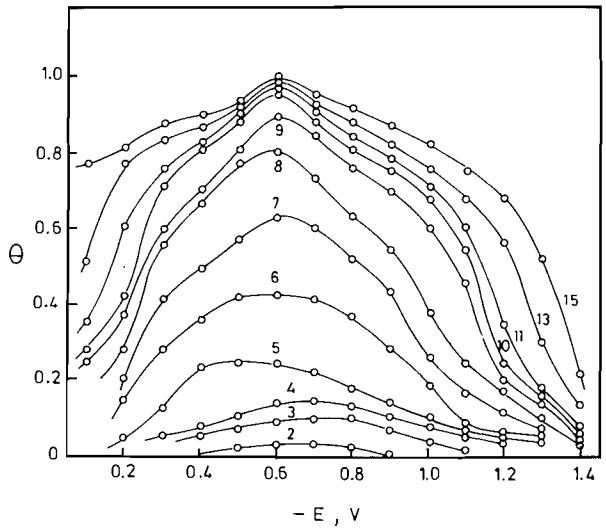

FIG. 6. Variation of surface coverage with potential, numbers correspond to concentrations according to Table 1.

different alcohol concentrations is shown in Fig. 6, the value of Γ_{max} was used in calculating $\theta = \Gamma/\Gamma_{max}$. The figure reveals that at -0.6 V maximum adsorption is reached for all solutions studied, at the highest concentration θ approaches unity. Based on these values of θ the experimental adsorption isotherms were analyzed by using Frumkin relation (20, 21).

$$[1] \quad \beta C = \theta(1-\theta)^{-1} \exp(-2\alpha\theta)$$

where α is the interaction parameter and β the adsorption coefficient. Within the limits of experimental error, a good linearity was obtained for the plot of $\ln \theta/(1-\theta)C$ vs. θ at each potential as plotted on enlarged diagrams, which indicates the applicability of Frumkin's isotherm to the present results. The test of this isotherm is shown in Fig. 7. The striking feature encountered in this analysis is that at relatively higher alcohol concentrations (above 3%) the slope of the relation shown in Fig. 7 is reversed, straight line relations are also obtained but with a negative value instead of a positive one at low alcohol concentrations (below 3%). This latter positive value of α indicates that particle–particle attraction is stronger than particle–solvent attraction (22), it decreases slightly at potentials more positive or negative than -0.6 V, i.e. maximum value of α is at E_{max}. This value of 2.5 is high as compared to 1.11 for isopropanol (23), however, this is normal as it has been reported (15) that the α values of isomeric compounds are systematically higher than the values of the normal chain length alcohols, due to the higher density of molecules in the adsorption layer.

Discussion

The study of the adsorption of isopropanol in HCl solutions of constant chemical potential, μ, indicates that the molecule is adsorbed with the alkyl group oriented towards the Hg surface and the polar OH group directed towards the solution side. By working at a constant μ_{HCl}, the possibility of medium effects playing an unaccounted for role is eliminated. This procedure was adopted, although it has been shown that the deviations could be within experimental error (4, 23). Although Cl^- ions are known to be specifically adsorbed on Hg, by working at constant chemical potential it is considered that the specific adsorption of Cl^- is constant, and hence the varying factor to be considered is the adsorption of isopropanol.

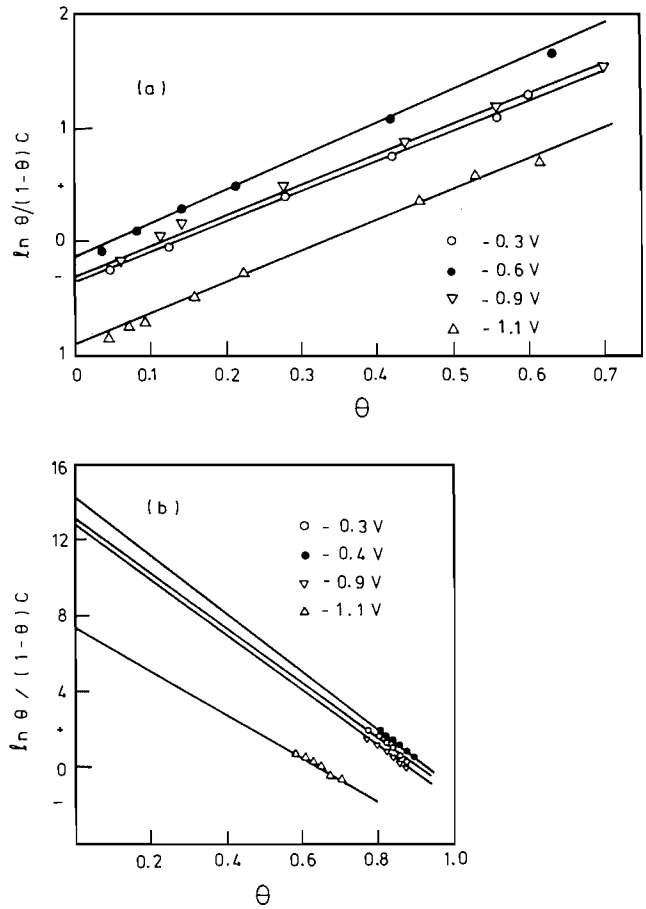

FIG. 7. Test of the Frumkin isotherm (*a*) low concentrations (below 3%) and (*b*) high concentrations (above 3%) at different potentials.

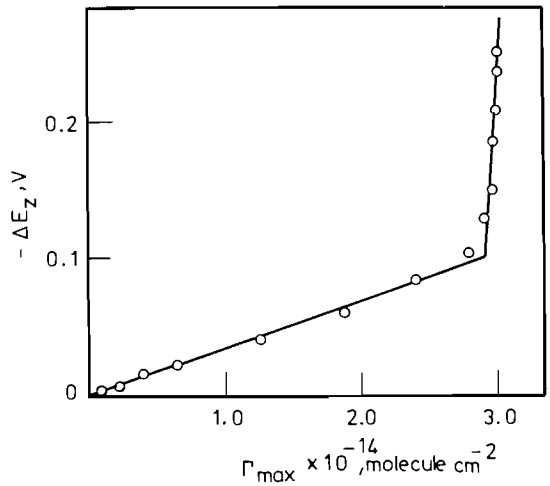

FIG. 8. Zero-charge potential shift at the mercury–solution interface due to adsorption of isopropanol as a function of surface excess Γ at maximum adsorption.

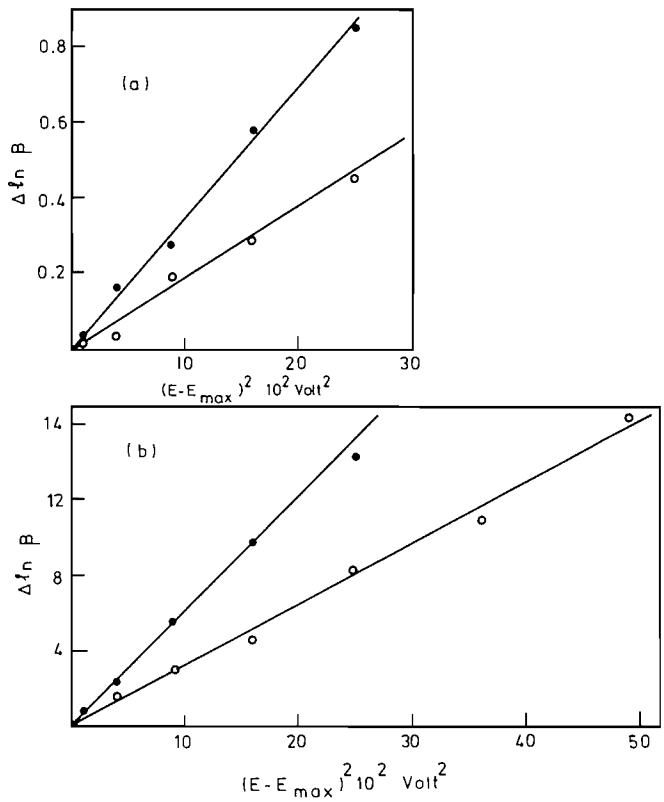

FIG. 9. Dependence of Δ ln β vs. $(E - E_{max})^2$. ●, *E* more positive than E_{max}; ○, *E* more negative than E_{max}; (*a*) low concentrations; (*b*) high concentrations.

A marked change in the adsorption behaviour of isopropanol is observed so that two regions of concentration could be defined, a low concentration region below 3% alcohol and a high concentration region above 3% alcohol. The main difference between these two regions lies in the positive values of α obtained at the low concentrations as compared to negative values of α obtained at the high concentrations. Both follow the Frumkin's isotherm. Tertiary butyl alcohol, which is also a branched alcohol, dissolves in water and induces at high dilutions a considerable reduction of the partial volume. For small values of the molar fraction in *t*BuOH, water seems to be more structured than in the absence of alcohol, whereas for mixtures rich in alcohol the residual water network tends to break up (II). In the present study the change of α from positive to negative values (in passing from solutions rich in water to those rich in alcohol) implies that at high concentrations of alcohol adsorbate–solvent attraction in the interface is stronger than the mean value of adsorbate–adsorbate and solvent–solvent interactions (19), which may be correlated with the breaking up of the residual water network.

This observation could tacitly imply that the molecules have a different orientation at each concentration region, as previously reported for isopropanol which shows a change of orientation with coverage (23). Figure 8 shows the relation between the shift in zero charge potential at the Hg–solution interface due to adsorption as a function of Γ_{max}. It could be immediately observed that two sections with two different slopes are obtained, corresponding to two different orientations of the adsorbate as suggested by Trasatti (15), due to M–A interactions at the metal–solution interface. The change in orientation could be envisaged as a decrease in the number of hydrogen atoms of $-CH_3$ groups lying flat on the Hg surface. This could be caused by the expected change in the surface water structure (16) due to polarisability effects.

It has been reported that when effects due to polarisability prevail, a quadratic dependence of $\overline{\Delta G}_A^0$ on potential will be observed (15), where $\overline{\Delta G}_A^0$ is standard free energy of adsorption related to the adsorption coefficient β by

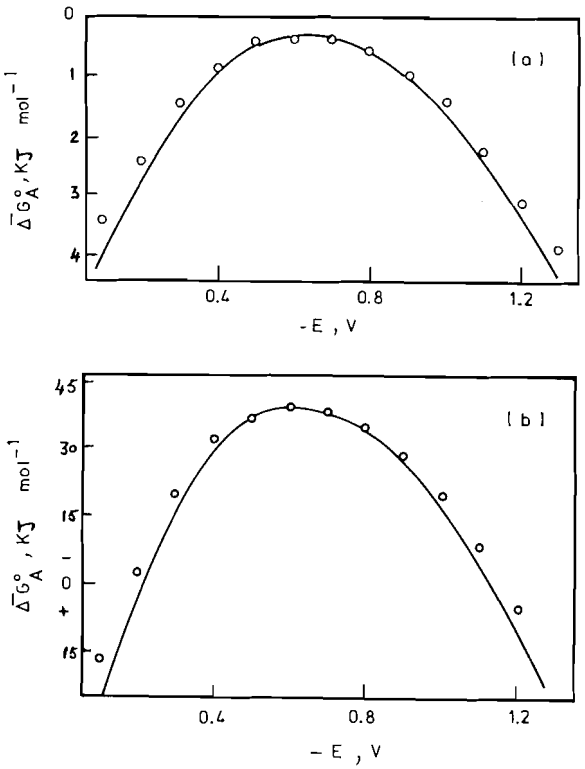

FIG. 10. Dependence of $\overline{\Delta G}_A^0$ on potential, circles are experimental values, (*a*) below 3%, low concentrations, and (*b*) above 3%, high concentrations.

$$[2] \quad \beta = \exp(-\overline{\Delta G}_A^0/RT)$$

Values of ln β can be readily obtained from intercepts of the relation shown in Fig. 7. The dependence of ln β on the square of the potential, $(E - E_{max})^2$, is linear, as shown in Fig. 9. Figure 9(*a*) and (*b*) correspond to the low concentration region and the high concentration region, i.e., to the two different orientations. In each region the linear dependence on the cathodic side has a lower slope than that on the anodic side of E_{max}. These relations fulfill the equation:

$$[3] \quad \overline{\Delta G}_A^0 = \overline{\Delta G}_{A_{max}}^0 + b(E - E_{max})^2$$

where b is the slope, and $\overline{\Delta G}_{A_{max}}^0 = 0.34$ for the orientation obtained at low alcohol concentrations and -38.87 kJ mol^{-1} for the orientation obtained at high concentrations. Perhaps the second value infers that the adsorbate is rearranged to maintain the best orientation for a maximum adsorption. Even so, the value of -38.87 kJ mol^{-1} is much lower than the values of $\overline{\Delta G}_{A_{max}}^0$ reported for molecules that strongly interact with Hg such as thiourea (24). Molecules that weakly adsorb on Hg such as ethylene glycol (25) or L(+) ascorbic acid (11) have $\overline{\Delta G}_{A_{max}}^0$ values of $\simeq -8$ and 24.9 kJ mol^{-1}, respectively. This indicates that isopropanol in both orientations is weakly adsorbed on the Hg surface, and that adsorption is of a physical nature.

The calculated dependence of $\overline{\Delta G}_A^0$ on potential using the preceding relation is given in Fig. 10, where circles are experimental values obtained from intercepts of $\ln \theta/(1 - \theta)c$ vs. θ. A parabolic variation is observed for $\overline{\Delta G}_A^0$ with potential, with a maximum at -0.6 V. The deviations are probably due to a change of the particle–particle interfacial interactions as observed in the case of other adsorbates (26).

Solubility, enthalpy, and heat capacity of solution of tris(2,4-pentanedionato)cobalt(III) in aqueous mixed solvents of 2-butoxyethanol and 2-ethoxyethanol

YASUKI YOSHIMURA

Laboratory of Chemistry, College of Humanities and Social Sciences, Iwate University, Ueda, Morioka, 020 Japan

Received December 22, 1988[1]

YASUKI YOSHIMURA. Can. J. Chem. **67**, 2108 (1989).

The solubility in mole fraction X_s of tris(2,4-pentanedionato)cobalt(III) ($Co(acac)_3$) in aqueous mixtures of 2-butoxyethanol (BE) and 2-ethoxyethanol (EE) has been determined over the temperature range 5–50°C. From these data, the enthalpy ΔH_s^0 and heat capacity of solution $\Delta C_{p,s}^0$ of $Co(acac)_3$ are estimated by using the Clarke and Glew procedure. For the water–BE system, an approximately linear correlation is found between the excess enthalpy of solution $\delta\Delta H_s^0$ of $Co(acac)_3$ and the excess internal pressure δP_i of the mixtures at 25°C. This finding suggests that the composition dependence of ΔH_s^0 in this system is mostly governed by the composition dependence of P_i. On the other hand, $\Delta C_{p,s}^0$ in these mixtures exhibits a characteristic composition dependence and its composition dependence in the water–BE mixtures may be qualitatively explained by considering an effect of the microphase transition which has been shown to occur in the mixture. The composition dependence of both ΔH_s^0 and $\Delta C_{p,s}^0$ in the water–EE mixture is analogous to that in the water–BE mixture and this finding suggests that a microphase formation may also occur in the former mixture.

Key words: tris(2,4-pentanedionato)cobalt(III), temperature dependence of solubility, enthalpy and heat capacity of solution, aqueous mixtures of 2-butoxyethanol and 2-ethoxyethanol, microphase transition.

YASUKI YOSHIMURA. Can. J. Chem. **67**, 2108 (1989).

Opérant à des températures allant de 5 à 50°C, on a déterminé la solubilité, exprimée en fraction molaire X_s, du tris(2,4-pentanedionato)cobalt(III) ($Co(acac)_3$) dans des mélanges aqueux de 2-butoxyéthanol (BE) et de 2-éthoxyéthanol (EE). En se basant sur ces données et en utilisant la méthode de Clarke et Glew, on a évalué l'enthalpie, ΔH_s^0, ainsi que la capacité calorifique de solution du $Co(acac)_3$, $\Delta C_{p,s}^0$. Pour le système eau–BE, on a trouvé une corrélation approximativement linéaire entre l'excès d'enthalpie de solution du $Co(acac)_3$, $\delta\Delta H_s^0$, et l'excès de pression interne, δP_i, des mélanges à 25°C. Ces résultats suggèrent que la relation qui existe entre la composition et le ΔH_s^0 est déterminée principalement par la relation qui existe entre la composition et la P_i. Par ailleurs, le $\Delta C_{p,s}^0$ de ces mélanges présente une relation caractéristique avec la composition et, pour les mélanges eau–BE, on peut expliquer d'une façon qualitative la corrélation qui existe avec la composition en considérant un effet de la transition de la microphase qui se produit dans ce mélange. Pour le mélange eau–EE, la corrélation qui existe entre la composition et le ΔH_s^0 ainsi que le $\Delta C_{p,s}^0$ est analogue à celle qui a été observée avec le mélange eau–BE et ces données suggèrent qu'il y a aussi vraisemblablement formation d'une microphase dans ce mélange.

Mots clés : tris(2,4-pentanedionato)cobalt(III); relation entre la température et la solubilité; enthalpie et capacité calorifique de solution; mélanges aqueux de 2-butoxyéthanol et 2-éthoxyéthanol; transition de microphase.

[Traduit par la revue]

In the previous investigations (1, 2), the enthalpy ΔH_s^0 and heat capacity of solution $\Delta C_{p,s}^0$ of tris(2,4-pentanedionato)-cobalt(III) ($Co(acac)_3$) have been examined in mixtures of water and some organic solvents such as dimethyl sulfoxide (DMSO), 1,4-dioxane (D), and 2-methyl-2-propanol (TBA) and it has been found that the composition dependence of ΔH_s^0 and $\Delta C_{p,s}^0$ in the water–TBA mixtures, in which a microphase transition occurs at the TBA concentration range $0.045 < X_{TBA} < 0.16$ (X_{TBA} = mole fraction of TBA in the mixture) (3), differs characteristically from that in the water–DMSO and water–D mixtures. But the values for ΔH_s^0 and $\Delta C_{p,s}^0$ in the water–TBA mixtures were too uncertain to confirm an effect of the microphase transition because the temperature dependence of the solubility of $Co(acac)_3$ from which the values of ΔH_s^0 and $\Delta C_{p,s}^0$ were estimated could not be measured over a wide temperature range (2).

It has been confirmed by various techniques such as thermodynamic property measurements (4–6), ultrasonic methods (7–9), light scattering methods (10–12), surface properties (13, 14), and others (15, 16) that a microphase transition occurs in the mixture of water and 2-butoxyethanol (BE). Furthermore, the BE molecule is a member of the polyoxyethylene glycol monoalkyl ether $C_nH_{2n+1}O(CH_2CH_2O)_mH$ family of typical nonionic surfactants (17, 18). Thus, the solubility data of $Co(acac)_3$ in the water–BE mixture might be expected to give fundamental information about the solubilization phenomenon of metal chelates with surfactants.

In an examination of mixtures of water and *n*-alkoxyethanols, it has been reported that the microphase transition does not occur in the mixture of water and 2-ethoxyethanol (EE) (4, 7). Therefore, it is interesting to compare the composition dependence of ΔH_s^0 and $\Delta C_{p,s}^0$ of $Co(acac)_3$ in the water–BE mixtures with that in the water–EE mixtures.

Thus, in this study, the temperature dependence of the solubility of $Co(acac)_3$ in both the water–BE mixtures and the water–EE mixtures is determined over the temperature range 5 to 50°C. From these data ΔH_s^0 and $\Delta C_{p,s}^0$ of $Co(acac)_3$ are estimated and their composition dependences are discussed in connection with the microphase formation.

Experimental

Commercial BE and EE (reagent grade, Wako Chemical Industries Ltd.) were dried over molecular sieves (type 4A) for a week, filtered, refluxed over calcium hydride for a day, and then distilled twice under reduced pressure. The water content in the purified BE and EE, measured by Karl Fischer titration, was less than 0.05% by weight. These purified solvents were stored over molecular sieves (4A) in a dry box. The preparation of the mixed solvents, the purification of $Co(acac)_3$, and the solubility measurement were carried out by the same methods as described previously (1, 2).

Commercial *n*-dodecane (reagent grade, Wako Chemical Industries Ltd.) was stirred with fuming sulfuric acid for a day, washed with

dilute sodium hydroxide solution, then with water, dried over calcium hydride, and finally distilled twice under reduced pressure.

To examine whether $Co(acac)_3$ decomposes with addition of BE and EE or on heating, visible and UV absorption spectra of $Co(acac)_3$ were measured in mixed solvents of various compositions at 5, 25, and 45°C. Sample solutions for the absorption spectrum measurement were prepared as follows: in the visible absorption measurement, 5.2 mg of $Co(acac)_3$ was placed in a 5 cm^3 volumetric flask, the desired mixed solvents previously cooled at 5°C were added to the mark, and then $Co(acac)_3$ was completely dissolved by stirring with a magnetic stirrer at 5°C ($Co(acac)_3$ concentration ca. 2.9×10^{-3} mol dm^{-3}); in the UV absorption measurement, 0.125 cm^3 of aqueous solution of $Co(acac)_3$ of concentration 2.91×10^{-3} mol dm^{-3} was transferred with a syringe dispenser into a 10 cm^3 volumetric flask, and then the desired mixed solvents previously cooled at 5°C were added to the mark (ca. 3.6×10^{-5} mol dm^{-3}). As these flasks were not calibrated at 5°C, the concentration values were approximate. The sample solution prepared at 5°C was transferred into absorption cell and the absorption spectrum was recorded on a Shimadzu UV-160 Spectrophotometer equipped with a thermostat by using the blank solution not containing $Co(acac)_3$ as reference. In each run, the working temperature was elevated in the order of 5, 25, and 45°C and each sample solution in the absorption cell was placed in an incubator kept at the desired temperature for a day prior to the measurement.

The partition coefficient P of $Co(acac)_3$ between *n*-dodecane and water or DMSO was determined at 10, 25, and 50°C. The solution of $Co(acac)_3$ in water or DMSO of appropriate concentration and *n*-dodecane were placed in a centrifuge tube (5 cm^3 at 25°C) and then the mixture was equilibrated by stirring with a magnetic stirrer for 2 h in a thermostat kept at the desired temperature. Equilibrium concentration of $Co(acac)_3$ in the two phases was measured as follows: aliquots of the two phases were transferred separately into 5 cm^3 volumetric flasks previously weighed; after letting the flasks stand for 15 min at room temperature, they were again weighed, and then the respective solvents were added to the mark; in the system of DMSO–*n*-dodecane, the aliquots of the two phases allowed to stand at room temperature became turbid because of a decrease in the mutual solubility of the two liquids; to clarify the turbid *n*-dodecane aliquot, a small amount of chloroform was added; the concentration of $Co(acac)_3$ in mol dm^{-3} in these solutions was determined spectrophotometrically from the absorbances at 324 nm (in water), 322 nm (in *n*-dodecane), and 596 nm (in DMSO; since fairly high P value of $Co(acac)_3$ between DMSO and *n*-dodecane required high initial concentration of $Co(acac)_3$ in DMSO, the visible absorption band was used); the equilibrium concentration in mol kg^{-1} m was obtained by calculating the numbers of mole of $Co(acac)_3$ in the withdrawn aliquots from the above concentration values on the basis of the assumption that the volume of the flasks was strictly 5 cm^3 at 25°C. The P value was defined as a ratio of the m value in the water or DMSO phase to that in the *n*-dodecane phase.

Results

Absorption spectra of $Co(acac)_3$ in water–BE and water–EE mixtures

As a typical example, the UV spectra of $Co(acac)_3$ in BE at 5, 25, and 45°C are shown in Fig. 1. A feature of the spectrum at 45°C appears to be strong absorption of BE at the low wavelength. But, when the solution was cooled to 25°C, the spectrum at 25°C in Fig. 1 was not reproduced, that is, the absorption maxima at both 324 and 257 nm due to $Co(acac)_3$ disappeared and two distinct maxima were found at 284 and 226 nm. This maximum at 284 nm could be assigned to the absorption due to 2,4-pentanedione. Furthermore, UV spectra of $Co(acac)_3$ solutions in DMSO, D, TBA, and 1,2-ethanediol (EG) were examined and no change of the spectra on heating was observed. Thus, the spectra in Fig. 1 can be interpreted as showing that $Co(acac)_3$ decomposes at higher temperature in

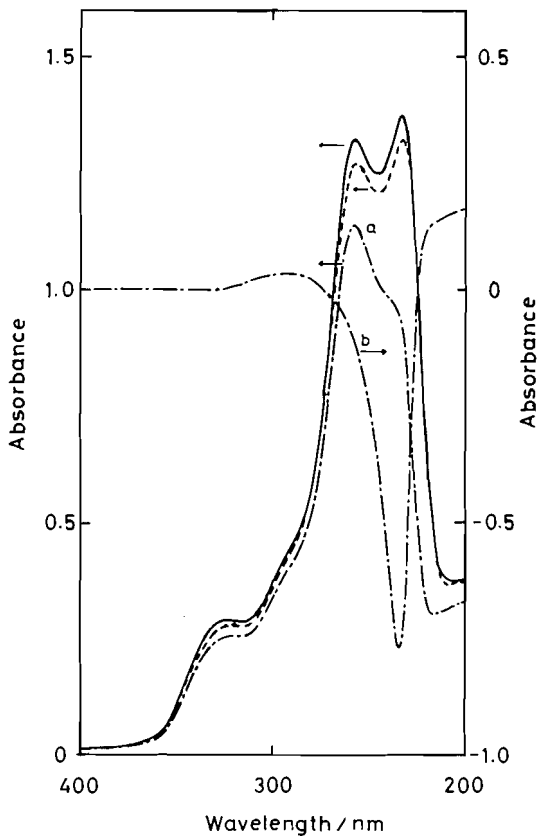

FIG. 1. Change of UV absorption spectra of $Co(acac)_3$ in BE: concentration of $Co(acac)_3$ is 3.6×10^{-5} mol dm^{-3}; — 5°C; - - - 25°C; –·–·– 45°C; *a*, after 1 day; *b*, after 3 days.

BE. A similar change of the UV spectra was found even in the mixture of the composition $X_{BE} = 0.15$ at 45°C.

A change of the spectra of $Co(acac)_3$ is not detectable at temperatures lower than 25°C (see Fig. 1). However, when $Co(acac)_3$ solution in BE was prepared at 25°C, its UV spectrum changed on standing at 25°C and was finally in accord with that at 45°C in Fig. 1. Thus $Co(acac)_3$ seems to decompose even at 25°C under this condition.

The visible spectra of $Co(acac)_3$ were little affected by both the addition of BE and heating except a slight decrease in absorbance. In order to make clearer whether $Co(acac)_3$ decomposed or not under the condition that its concentration was relatively high, the following study was made: the BE solution of $Co(acac)_3$, on which the visible spectrum was recorded at 45°C over 4 days, was diluted to 4.4×10^{-5} mol dm^{-3} with BE and then the UV spectrum was recorded at 25°C. An anomalous feature was not found in the spectrum thus obtained.

A change of the absorption spectra of $Co(acac)_3$ in the water–EE mixtures was similar to that in the water–BE mixtures mentioned above. On the basis of these results, at the present stage the following conclusions may be drawn: in the presence of BE or EE, $Co(acac)_3$ appears to decompose on heating in its dilute solution but the decomposition is not observed in its relatively concentrated solution; the decomposition seems to be an effect characteristic of the solvents BE or EE.

Solubility of $Co(acac)_3$ in water–BE and water–EE mixtures

On the basis of the above results of the absorption spectrum measurement, in the procedure of solubility measurement the

*Errors denote 95% confidence levels.
†Solubility values obtained from absorbance at 323 nm.
‡Solubility values obtained from absorbance at 593 nm.
§Solubility values obtained by the experiment that the solutions equilibrated at the highest temperatures are allowed to attain equilibrium again at 25°C are listed.

mixed solvents cooled at 5°C were added to $Co(acac)_3$ placed in the apparatus.

The solubility of $Co(acac)_3$ in mol kg^{-1}, S_m,[2] in BE and EE is tabulated in Table 1, where the values calculated from the absorbance at both 324 and 593 nm are listed. In all cases, the two solubility values agree with each other within experimental errors which denote deviations of the 95% confidence levels from the mean values. Furthermore, the solubility data at 25°C were reproducible within the errors when the solutions at the end of experiment at the highest temperature were allowed to attain equilibrium at 25°C (see Table 1). These results, together with the results of the absorption spectrum measurement, confirm that any decomposition of $Co(acac)_3$ in the course of the equilibration may be ignored at these relatively more concentrated conditions.

The values for S_m of $Co(acac)_3$ in the water–BE and water–EE mixtures are listed in Tables 2 and 3, respectively. The errors were less than 3% in most cases.

The S_m values were converted to solubilities in mole fraction X_s and $\ln X_s$ was plotted against $1/T$. Typical plots are shown for the water–BE and water–EE mixtures in Figs. 2 and 3, respectively. To better define the solubility curves, solubility values measured at temperatures other than those listed in Tables 2 and 3 are also plotted in these figures. One feature of the solubility curves in the present mixtures differs from that in the mixtures reported previously, that is, while the latter solubility curves become practically linear in mixtures with higher contents of the organic solvents (1, 2), the former curves show marked curvature at about 30°C even in the pure BE and EE.

[2]An aliquot of the saturate solution withdrawn by weight was diluted with water and the concentration of $Co(acac)_3$ in this solution was analyzed spectrophotometrically. The S_m values were obtained by calculating the mole numbers of $Co(acac)_3$ in the aliquot from this concentration. The detailed procedure to calculate the S_m value has been described in ref. 1.

Enthalpy and heat capacity of solution of $Co(acac)_3$ in water–BE and water–EE mixtures

The values for ΔH_s^0 and $\Delta C_{p,s}^0$ were estimated by using the Clarke and Glew procedure for the estimation of thermodynamic parameters and their errors from solubility data (19, 20). The values of $R \ln X_s$ ($R = 8.3144\ \text{J mol}^{-1}\text{K}^{-1}$) were fitted to

$$[1] \quad R \ln X_s = a_0 u_0(x) + a_1 u_1(x) + a_2 u_2(x) + a_3 u_3(x) + \cdots$$

where $x = (T - \theta)/\theta$ (θ in K is a reference temperature), $a_0 = -\Delta G_s^0(\theta)/\theta$ (ΔG_s^0 denotes the free energy of solution), $a_1 = \Delta H_s^0(\theta)/\theta$, $a_2 = \Delta C_{p,s}^0(\theta)$, $a_3 = [\partial \Delta C_{p,s}^0/\partial T]_\theta \theta/2$ (the subscript θ in parentheses denotes the value of the function at θ), $u_0(x) = 1$, $u_1(x) = x/(1 + x)$, $u_2(x) = -x/(1 + x) + \ln(T/\theta)$, and $u_3(x) = x(x + 2)/(1 + x) - 2\ln(T/\theta)$.

In the analysis of the present data, it was found by a test on the basis of a t_5 value that the fifth constant in [1] is zero with a 95% probability. The t-test was as follows: the t_5 value for the fifth constant was calculated by dividing the value of the constant by the square root of its variance; the t_5 value was compared with the t value at the 95% confidence level and if $t_5 < t$, the value of the fifth constant may be taken as zero within the 95% probability. Thus [1] may be terminated at the fourth term.

The composition profile of ΔH_s^0 of $Co(acac)_3$ in the water–BE and water–EE mixtures is shown in Figs. 4 and 5, respectively, where the values of ΔH_s^0 at 10, 25, and 40°C are plotted against X_{BE} or X_{EE}. The profile is represented by drawing smooth curves through the experimental points because of the uncertainty in the ΔH_s^0 values obtained by the above indirect procedure.

The composition profile of $\Delta C_{p,s}^0$ of $Co(acac)_3$ in the water–BE and water–EE mixtures is shown in Fig. 6, where only the $\Delta C_{p,s}^0$ values at 25°C are plotted because the errors of the $\Delta C_{p,s}^0$ values are markedly large in the vicinity of the extremes of the temperature range used in the solubility measurement (19). The composition profile of $\Delta C_{p,s}^0$ passes through a minimum in the present mixtures and differs distinctly

from that in the water–DMSO (1) and water–D mixtures (2) but resembles that in the water–TBA mixtures (2).

Discussion

To examine the validity of the assumption that the activity coefficient of $Co(acac)_3$ in its saturate solution is unity, the partition coefficient P of $Co(acac)_3$ between water or DMSO and *n*-dodecane was determined at 10, 25, and 50°C. The P values are plotted against the initial concentration of $Co(acac)_3$ in water or DMSO in Fig. 7, where the ratio of the S_m values in water or DMSO to those in *n*-dodecane is also plotted. The

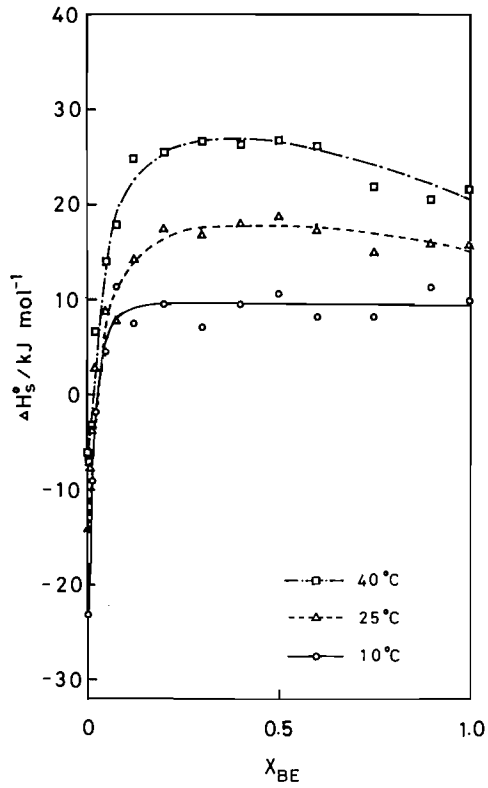

FIG. 4. Composition profiles of enthalpy of solution ΔH_s^0 of $Co(acac)_3$ at 10, 25, and 40°C in water–BE mixtures.

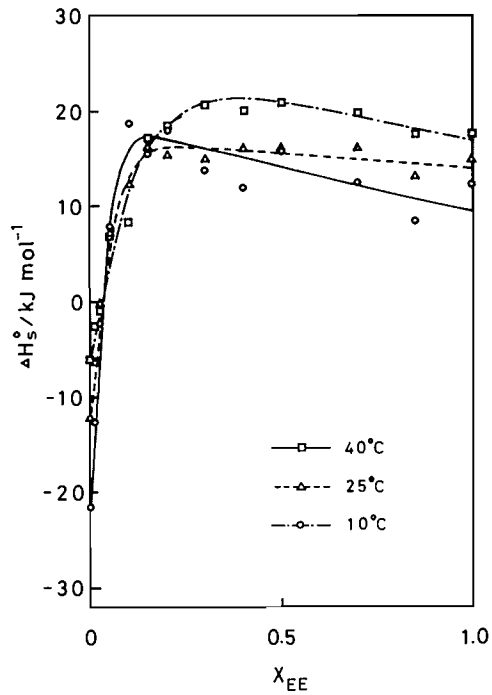

FIG. 5. Composition profiles of enthalpy of solution ΔH_s^0 of $Co(acac)_3$ at 10, 25, and 40°C in water–EE mixtures.

P values were little affected by the initial concentration of $Co(acac)_3$ and agreed nearly with the ratio of the S_m values except water–*n*-dodecane system at 10°C. This finding confirms that the activity coefficient of $Co(acac)_3$ in its saturate solution in water or DMSO may be regarded as unity.

The P values between the water–EE mixture of $X_{EE} = 0.1$

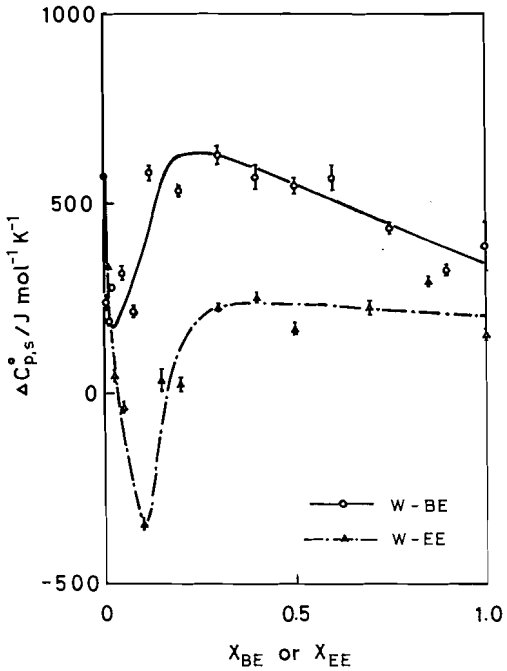

FIG. 6. Composition profiles of heat capacity of solution $\Delta C^0_{p,s}$ of $Co(acac)_3$ at 25°C in water–BE and water–EE mixtures.

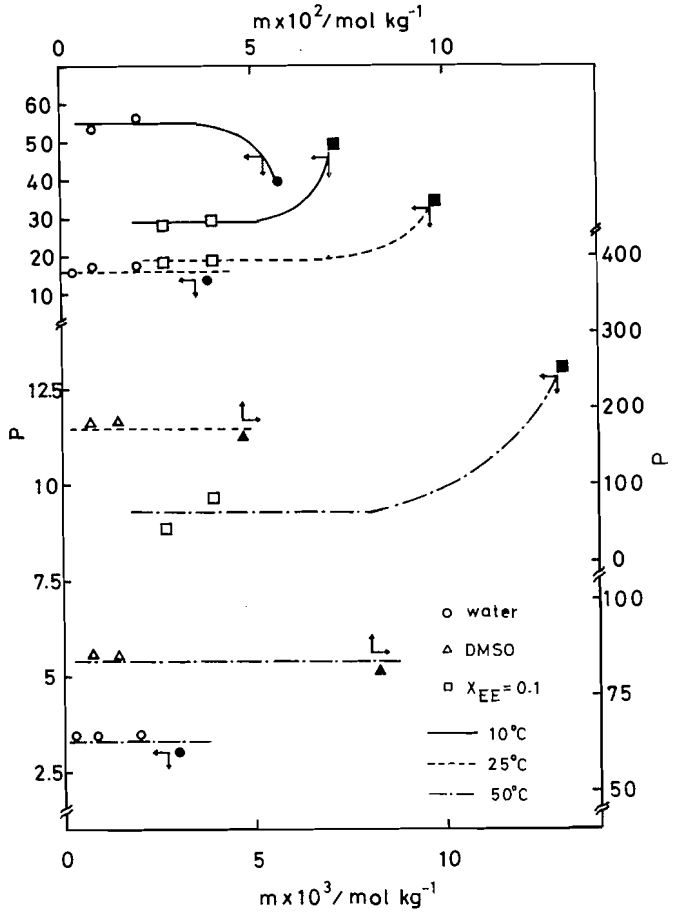

FIG. 7. Concentration dependence of partition coefficient P of $Co(acac)_3$ between n-dodecane and water or DMSO or aqueous EE mixture of $X_{EE} = 0.1$ at 10, 25, and 50°C: the P values were obtained by dividing the concentration in mol kg^{-1} of $Co(acac)_3$ in aqueous or DMSO phase by that in n-dodecane phase; full symbols denote the ratio of S_m of $Co(acac)_3$ in water or DMSO or $X_{EE} = 0.1$ mixture to that in n-dodecane.

and n-dodecane were significantly lower than the ratio of the S_m values (see Fig. 7). This trend was more pronounced for the P values between the water–EE mixture of $X_{EE} = 0.5$ and n-dodecane. EE is completely miscible with n-dodecane. Actually, it was found that in the case of the mixture with $X_{EE} = 0.5$, n-dodecane was considerably transferred into the aqueous EE phase. Therefore, the above results in the aqueous EE mixtures may be attributed to the dissolution of n-dodecane in the aqueous EE mixtures and/or to the dissolution of EE in n-dodecane. Thus, in the case of the aqueous mixtures of EE or BE it seems to be difficult to examine the assumption that the activity coefficient of $Co(acac)_3$ is unity. However, since the S_m values of $Co(acac)_3$ in EE and BE are lower than those in DMSO, in the present study the activity coefficient of $Co(acac)_3$ in its saturate solutions in the aqueous mixtures of BE and EE is tentatively regarded as unity.

Ito *et al.* (10) have analyzed their light scattering data in the water–BE mixtures by postulating the following aggregation equilibrium

$$[2]\quad A_{50} + B \rightleftarrows A_{50}B \rightarrow g(A_{50}B)$$
$$A_4 + B \rightleftarrows A_4B \rightarrow h(A_4B)$$
$$4A_{50} \rightleftarrows 50A_4$$

where A and B denote water and BE molecules, respectively and suggested the following picture for the mixing state in the mixtures. In the concentration range $X_{BE} < 0.02$, several water molecules encage a BE molecule and form a local structure of the type $A_{50}B$. In $0.02 < X_{BE} < 0.2$, these cagelike structures gather together and form a local structure of the type $g(A_{50}B)$. At the same time, BE molecules form a local structure of the type $h(A_4B)$. In this concentration range, $g(A_{50}B)$ is destroyed and the amount of $h(A_4B)$ increases with increasing BE concentration. For $0.2 < X_{BE}$, local structures of types $h'(A_4B)$ and B_1 are formed and the mixture again becomes homogeneous. Analogous pictures for the mixing state of the water–BE mixture have been suggested by numerous investigators (4, 6–9, 11). In these pictures, the microphase transition in $0.02 < X_{BE} < 0.2$ seems to be a phenomenon similar to the micellization of surfactants.

The thermodynamic properties of aqueous surfactant solutions have been satisfactorily explained by application of a mass action model (21–24). Roux *et al.* (22) found that the volume of transfer of surfactant from water to aqueous BE solution could also be explained in a similar manner. Elizalde *et al.* (14) have examined the composition dependence of surface tension in the aqueous BE solutions and found that the surface tension rapidly decreases to reach a constant value at about $X_{BE} = 0.02$. On the basis of this finding, they have also suggested that BE acts as a small-size surfactant.

The author has found that an approximately linear relationship exists between the excess enthalpy of solution $\delta\Delta H^0_s$ of $Co(acac)_3$ in the water–DMSO or water–D mixtures and the excess internal pressure δP_i of the mixtures (1, 2). The relationship is expressed by

$$[3]\quad \delta\Delta H^0_s = (\bar{V}_c - a^3 N\pi/6)(R/82.05)\delta P_i$$

where $\bar{V}_c$, a, and N are the partial molar volume of cavity formation, the hard-sphere diameter of solute, and the Avogadro number, respectively. The definition of $\delta\Delta H^0_s$ and δP_i was previously described (1, 2).

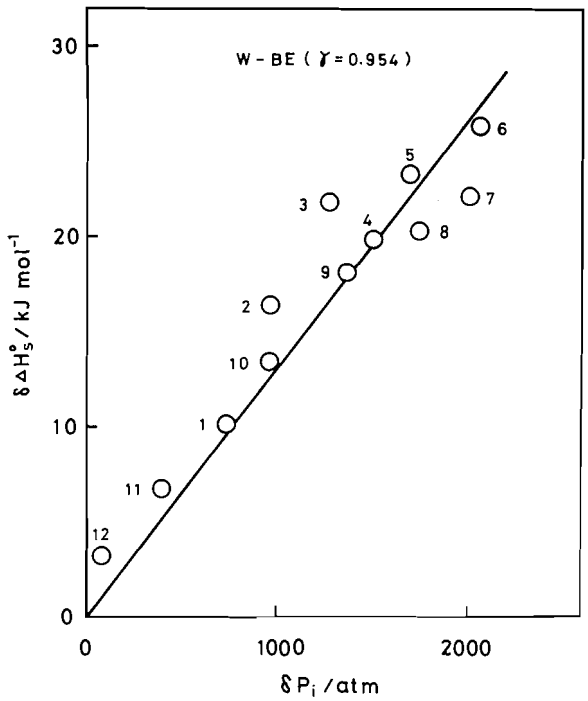

FIG. 8. Correlation between excess enthalpy of solution $\delta\Delta H_s^0$ of $Co(acac)_3$ and excess internal pressure δP_i at 25°C for water-BE mixtures: X_{BE} in the mixtures is as follows; *1*, 0.01; *2*, 0.02; *3*, 0.0472; *4*, 0.0751; *5*, 0.1; *6*, 0.199; *7*, 0.2999; *8*, 0.4; *9*, 0.4999; *10*, 0.5999; *11*, 0.75; *12*, 0.8997; γ is the correlation coefficient.

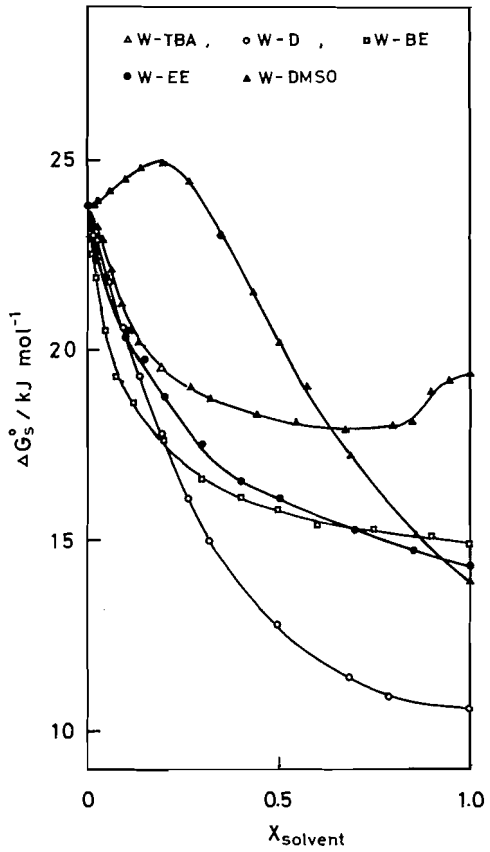

FIG. 9. Composition profiles of free energy of solution ΔG_s^0 of $Co(acac)_3$ at 25°C in mixtures of water and some organic solvents.

In Fig. 8, $\delta\Delta H_s^0$ of $Co(acac)_3$ is plotted against δP_i for the water–BE mixtures at 25°C. The $\delta\Delta H_s^0$ values were not calculated from the smooth curve in Fig. 4 but from the experimental ΔH_s^0 values. The P_i values of the mixtures were calculated by an ordinary procedure (25) from the literature data on the density and specific heat capacity values (4), and on the ultrasonic velocity values (5) of the mixtures. The P_i values of the water–EE mixtures could not be obtained because of lack of the data on the ultrasonic velocity.

Figure 8 shows that in the water–BE mixtures the linear relation expressed by [3] is approximately valid, though the correlation coefficient γ is slightly lower than that in the water–DMSO (γ = 0.980) or water–D mixtures (γ = 0.977). This finding suggests that even though the microphase transition occurs in water–BE mixtures, the composition dependence of ΔH_s^0 is mostly governed by the composition dependence of P_i, that is, of the enthalpy of cavity formation (1, 2) and that a contribution of the microphase formation to ΔH_s^0 is not distinguishable.

A serious difference between the composition profile of $\Delta C_{p,s}^0$ of $Co(acac)_3$ shown in Fig. 6 and that in the water–DMSO and water–D mixtures (1, 2) is that in the former profile the rapid decrease of $\Delta C_{p,s}^0$ is followed by the gradual increase. This difference seems to be assigned to the microphase transition as will be discussed.

It has been sufficiently confirmed that a shift in an equilibrium contributes to heat capacity (26–30). The $\Delta C_{p,s}^0$ of $Co(acac)_3$ in the water–BE mixtures goes through a minimum in the concentration region where the microphase transition occurs as mentioned above. It seems likely that an addition of $Co(acac)_3$ to the water–BE mixture brings about an effect on an aggregation equilibrium of BE.

By analogy to the treatment of Jolicoeur *et al.* (27), the contribution of the effect to ΔH_s^0 of $Co(acac)_3$ may be expressed by

$$[4] \quad \Delta H_s^0 = \Delta H_{s(hyp)}^0 + \Delta\alpha\Delta H_{ag}$$

where $\Delta H_{s(hyp)}^0$, ΔH_{ag}, and $\Delta\alpha$ denote ΔH_s^0 in the hypothetical water–BE mixtures without the microphase formation, the enthalpy of aggregation formation, and a change in the fraction of aggregated BE produced by the addition of $Co(acac)_3$, respectively. By differentiating [4] with respect to temperature, $\Delta C_{p,s}^0$ can be expressed as

$$[5] \quad \Delta C_{p,s}^0 = \Delta C_{p,s(hyp)}^0 + \Delta\alpha\Delta C_{p,ag} + \Delta H_{ag}(\partial\Delta\alpha/\partial T)_p$$

where the subscripts are the same notation as [4].

Hetu *et al.* have examined the transfer functions of some solutes from water to aqueous surfactant solutions and concluded that trends in the transfer functions could be predicted from the relative hydrophobicity of the solutes and surfactants (31, 32). They have also shown that when the solutes displace a monomer–micelle equilibrium of the surfactants, the transfer heat capacity goes through a minimum. On the other hand, an equilibrium displacement due to temperature generally seems to lead to a maximum (27, 29, 30).

Thus, if it is assumed that $\Delta C_{p,s(hyp)}^0$ decreases monotonously with X_{BE} similarly to $\Delta C_{p,s}^0$ in the water–DMSO and water–D mixtures (1, 2), the minimum shown in Fig. 6 may be produced from the second term in [5]. Unfortunately, the information about the displacement of the aggregation equilibrium of BE by $Co(acac)_3$ is lacking but it has been reported that the microphase formation in the water–BE mixtures occurs at a lower BE concentration in the presence of a surfactant (33, 34). Benzene exhibits a significant effect on the aggregation equilibrium of

For personal use only.

BE (31). As $Co(acac)_3$ may also be regarded as a hydrophobic solute (1), it is reasonable to assume that $Co(acac)_3$ displaces the aggregation equilibrium of BE.

In connection with the solubilization phenomenon of metal chelates with surfactants (35), the composition dependence of the solubility of $Co(acac)_3$ in the water–BE mixtures is interesting. Figure 9 shows the composition profile of ΔG_s^0 ($\Delta G_s^0 = -RT \ln X_s$) of $Co(acac)_3$ at 25°C for each mixture so far examined. A distinguishable feature of the profile in the water–BE mixture is recognized in the concentration region $X_{BE} < 0.2$: the solubility values of $Co(acac)_3$ in this region of the mixture are larger than those in other mixtures; in particular, it is worth noting that the solubility values in the water–BE and water–D mixtures reverse at $X_{solvent} = 0.2$. This finding also suggests that the microphase transition in the water–BE mixture brings about the increase of the solubility of $Co(acac)_3$ and that BE may exhibit an effect similar to surfactants (36). Since it has been reported that an addition of surfactants to the water–BE mixture results in the stabilization of the microaggregates of BE (9, 33, 34, 36, 37), it would be interesting to examine the solubility of $Co(acac)_3$ in a ternary system containing water, BE, and surfactant.

The composition profiles of both ΔH_s^0 and $\Delta C_{p,s}^0$ in the water–EE mixtures are practically identical with those in the water–BE mixtures (see Figs. 4, 5, and 6). These results suggest that microphase formation may also occur in the former mixture. But the magnitude of the microphase formation in the water–EE mixture seems to be considerably smaller than that in the water–BE mixture (11).

Reçu le 6 juin 1989

ALAIN FOURNET, BEATRICE VAGNEUR, PASCAL RICHOMME et JEAN BRUNETON. Can. J. Chem. **67**, 2116 (1989).

Cinq aryl-2 et alkyl-2 quinoléines nouvelles ont été isolées des écorces de tiges de *Galipea longiflora* Krause (Rutacées) : la phényl-2 quinoléine **1**, la (méthylènedioxy-3′,4′) phénéthyl-2 quinoléine **2**, la (diméthoxy-3′,4′) phénéthyl-2 quinoléine **3**, la (méthylènedioxy-3′,4′) styryle-2 méthoxy-4 quinoléine **4** et la (pentèn-1′,2′ yl)-2 méthoxy-4-quinoléine **6**. Ces alcaloïdes sont accompagnés de trois quinoléines substituées en 2, la *n*-amyl-2 méthoxy-4 quinoléine **5**, la (méthylènedioxy-3′,4′) phénéthyl-2 méthoxy-4 quinoléine (cusparine) **7** et la phényl-2 méthoxy-4 quinoléine **8**, et de deux furo[2,3*b*]quinoléines déjà connues, l'évolitrine et la skimmianine.

Mots clés : *Galipea longiflora*, Rutacées, quinoléines nouvelles.

ALAIN FOURNET, BEATRICE VAGNEUR, PASCAL RICHOMME, and JEAN BRUNETON. Can. J. Chem. **67**, 2116 (1989).

Five new 2-aryl and 2-alkyl quinoline alkaloids were obtained from *Galipea longiflora* Krause (Rutaceae). These are 2-phenylquinoline **1**, 2-(3′,4′-methylenedioxyphenethyl)quinoline **2**, 2-(3′,4′-dimethoxyphenethyl)quinoline **3**, 2-(3′,4′-methylenedioxystyryl)-4-methoxyquinoline **4**, and 2-(1′,2′-pentenyl)-4-methoxyquinoline **6**. They are accompanied by three known 2-substituted quinolines, 2-*n*-amyl-4-methoxyquinoline **5**, 2-(3′4′-methylenedioxyphenethyl)-4-methoxyquinoline **7**, and 2-phenyl-4-methoxyquinoline **8**, and by two known furo[2,3*b*]quinoline alkaloids: evolitrine and skimmianine.

Key words: *Galipea longiflora*, Rutaceae, new quinolines.

[Traduit par la revue]

Poursuivant l'étude de drogues végétales de l'Amazonie andine traditionnellement utilisées dans le traitement de diverses affections parasitaires (3) nous décrivons dans le présent travail l'isolement, à partir de *Galipea longiflora*, de quinoléines simples non encore décrites à ce jour à partir de sources naturelles.

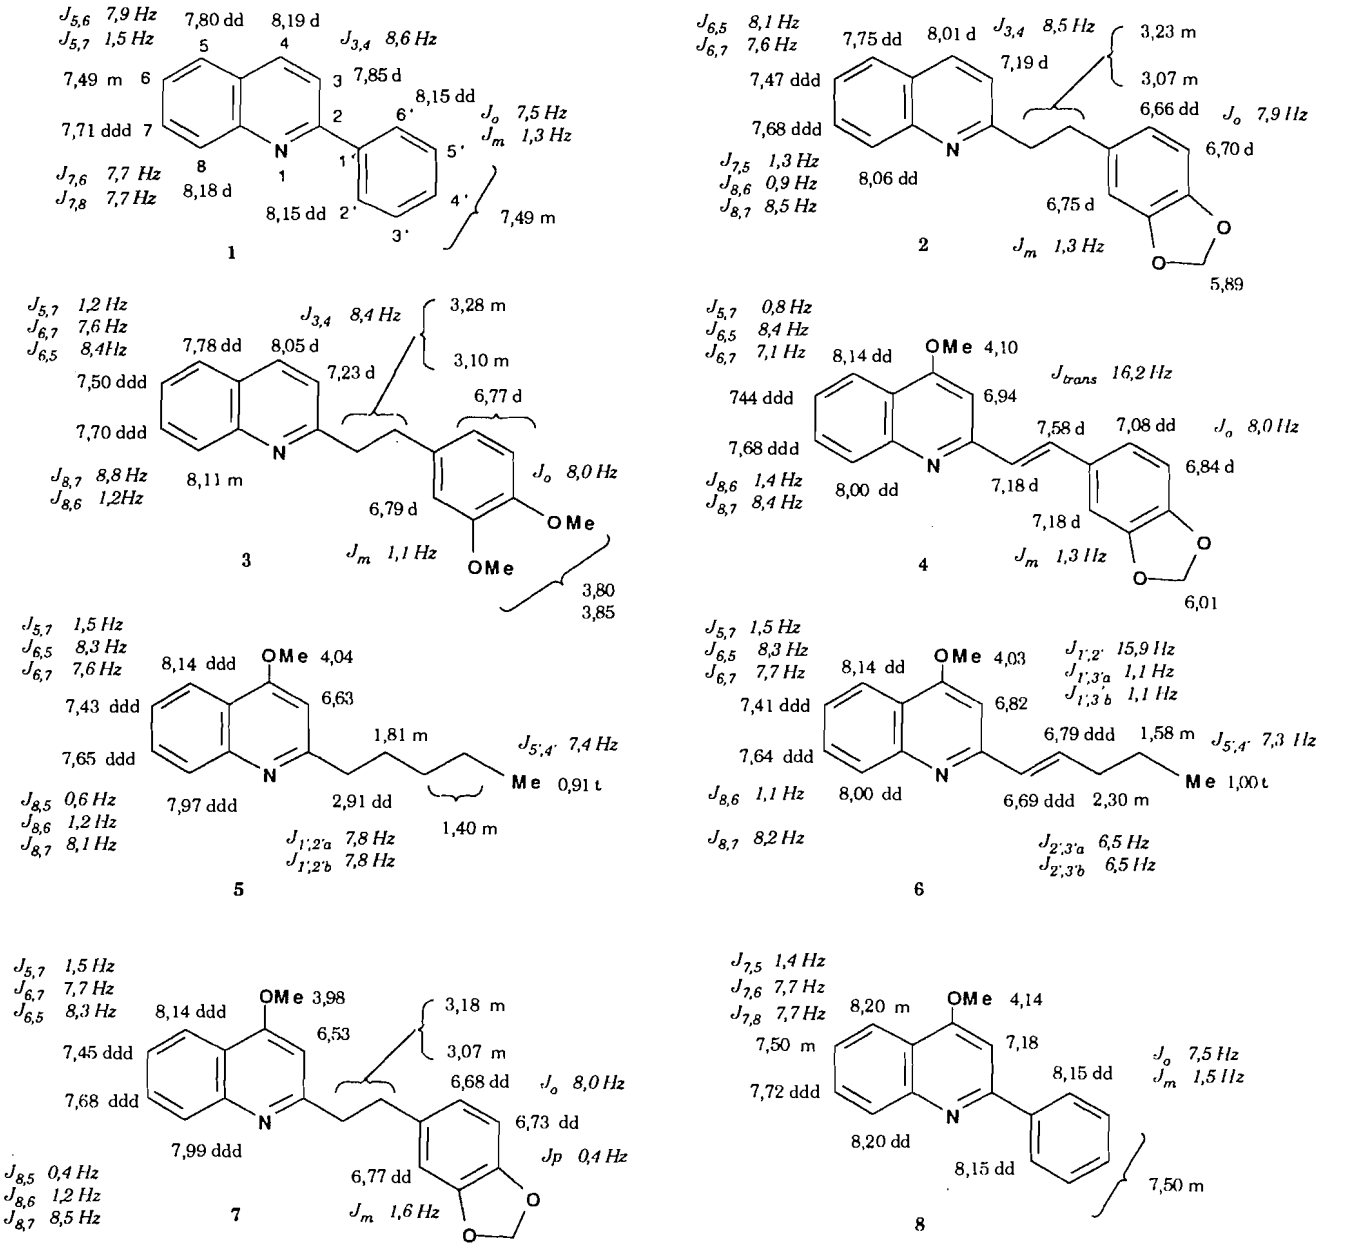
Le genre *Galipea* Aubl. comprend plus de 20 espèces, toutes localisées en Amérique du Sud; parmi celles-ci seul *G. officinalis* Hancock.(= *G. cusparia* St Hill) a fait l'objet d'une étude chimique (4). *Galipea longiflora* Krause (5) est un grand arbre à longues feuilles trifoliolées localisé dans la partie de la forêt amazonienne commune au Sud du Brésil et au Nord-Est de la Bolivie. Les écorces de tiges brunâtres de la plante sont localement utilisées par voie orale pour le traitement d'affections liées à divers parasites. Il nous a donc semblé intéressant d'en étudier la composition.

La présente étude a conduit à l'isolement et à l'identification de dix alcaloïdes quinoléiques. Cinq étaient déjà connus : deux furo[2,3-*b*]quinoléines, la skimmianine (réf. 2) (7% des A.T.) et l'évolitrine (réf. 1) (0,1%) isolées à plusieurs reprises de nombreux genres de Rutacées (6), une alkyl-2 quinoléine, la *n*-amyl-2 méthoxy-4 quinoléine **5** (0,4%) anciennement caractérisée chez *Galipea officinalis* (4) ainsi que deux autres quinoléines substituées en 4, la (méthylènedioxy-3′,4′) phénéthyl-2 méthoxy-4 quinoléine **7** (0,6%) décrite sous le nom de cusparine chez le même *G. officinalis* et la phényl-2 méthoxy-4 quinoléine **8** (1,5%) déjà connue chez *Lunasia amara* (7). Tous ces composés connus — et pour certains synthétisés — ont été identifiés par comparaison de leurs constantes physiques et de leurs données spectrales avec celles préalablement publiées.

Les données de rmn à haut champ et de spectrométrie de masse absentes de la littérature ont été déterminées et sont énumérées autour des formules (cf. tableau 1) et dans la partie expérimentale.

Le composé majoritaire **1** (54,4%) cristallise de l'hexane. Sa formule brute : $C_{15}H_{11}N$ (calc.: 205,0890; tr.: 205,0864) et l'absence, sur le spectre de rmn ^1H, de signaux en dessous de 7,3 ppm indiquent que **1** doit être une phényl quinoléine. La preuve finale de la structure de **1**, jamais isolé à l'état naturel, est apportée par la comparaison directe avec le produit de synthèse (Aldrich).

La formule du composé **2** (13,6%, PF = 65°C) s'établit en $C_{18}H_{15}NO_2$ (calc.: 277,1103; tr.: 277,1112). Le spectre de rmn ^1H ($CDCl_3$, 300 MHz, tableau 1) est caractéristique d'un dérivé quinoléique substitué en 2 par un groupement de type phénéthylique puisque deux multiplets de deux protons aliphatiques chacuns apparaissent à 3,07 et 3,23 ppm tandis que trois protons aromatiques résonnent à 6,66 (dd; J_m = 1,3 Hz, J_o = 7,9 Hz), 6,70 (d; J_o = 7,9 Hz) et 6,75 ppm (d; J_m = 1,3 Hz). Les déplacements chimiques des protons quinoléiques sont à leurs valeurs hatituelles, entre 7,4 et 8,1 ppm, et l'attribution des signaux à 7,75 et 8,06 ppm — respectivement au H-5 et au H-8 — peut être effectuée sans ambiguïté après observation d'effets Overhauser réciproques entre le H-4 et le H-5 d'une part, le H-5 et le H-6 d'autre part. Un singulet de deux protons à 5,89 ppm permet finalement d'identifier le substituant situé en α de l'azote à un groupement (méthylènedioxy-3,4) phénéthyle, ce qui confirme sur le spectre de masse la présence d'un fragment intense (75%) à *m/z* 135 ($C_8H_7O_2^+$). Ce composé original est ainsi identifié à la (méthylènedioxy-3′,4′) phénéthyl-2 quinoléine.



Le spectre de masse du composé suivant **3** (0,9%), ($C_{19}H_{19}NO_2$; calc.: 293,1416; tr.: 293,1406), est voisin de celui du dérivé précédent et semble indiquer que le noyau quinoléique n'est substitué qu'en position 2 par un groupement

TABLEAU 1. RMN ^{1}H des aryl-2 et alkyl-2 quinoléines isolées de *Galipea longiflora*.

(diméthoxy-3,4) phénéthyle, le pic de base étant ici déplacé à m/z 151 ($C_9H_{11}O_2^+$). La rmn ^{1}H ($CDCl_3$, 300 MHz, tableau 1) confirme cette hypothèse puisque le spectre enregistré se révèle superposable avec celui de **2** à ceci près que le signal du méthylènedioxyle apparaissant à 5,89 est remplacé par deux singulets de trois protons chacuns à 3,85 et 3,80 ppm qui correspondent donc aux deux méthoxyles phénéthyliques. Ces résultats permettent alors d'attribuer à cette nouvelle quinoléine une structure de (diméthoxy-3',4') phénéthyl-2 quinoléine.

Le composé **4** (0,7%), ($C_{19}H_{15}NO_3$; calc.: 305,1052; tr.: 305,1031), présente un spectre de rmn ^{1}H ($CDCl_3$, 300 MHz, tableau 1) caractéristique d'une quinoléine disubstituée-2,4 : un méthoxyle en position 4 apparaît ainsi très déblindé à 4,10 ppm tandis qu'un groupement de type (méthylènedioxyle-3,4) styrylique est caractérisé par deux doublets de un proton chacun à 7,18 et 7,58 ppm (J = 16,2 Hz), trois signaux d'hydrogènes aromatiques à 6,84 (1H, d, J_o = 8,0 Hz), 7,08 (1H, dd, J_o = 8,0 Hz, J_m = 1,3 Hz) et 7,18 ppm (1H, d, J_m = 1,3 Hz) et le singulet d'un méthylènedioxyle localisé à 6,01 ppm. Les attributions des protons quinoléiques découlent d'une comparaison directe de ce spectre avec celui d'un dérivé connu, la *n*-amyl-2 méthoxy-4 quinoléine, **5**, pour lequel un effet Overhauser est enregistré entre le H-5 et le MeO-4 et dont une expérimentation de type COSY LR permet notamment de corréler le H-5 et le H-3. **4** est ainsi identifié à un nouveau dérivé naturel, la (méthylènedioxy-3',4') styryle-2 méthoxy-4 quinoléine.

Divers éléments sur le spectre de rmn ^{1}H ($CDCl_3$, 300 MHz, tableau 1) du dernier composé **6** (2,5%), ($C_{15}H_{17}NO$, calc.: 227,1301; tr.: 227,1312), peuvent être attribués à la présence

For personal use only.

d'un groupe pentèn-1,2 yle au sein de la molécule. Deux protons éthylèniques apparaissent en effet à 6,69 (1H, ddd, $J_{1',2'} = 15,9$ Hz, $J_{1',3'a} = 1,1$ Hz, $J_{1',3'b} = 1,1$ Hz) et 6,79 ppm (1H, ddd, $J_{2',1'} = 15,9$ Hz, $J_{2',3'a} = 6,5$ Hz, $J_{2',3'b} = 6,5$ Hz), deux protons méthylèniques à 1,58 (2H, m) et 2,30 ppm (2H, m), tandis qu'un méthyle résonne sous forme de triplet ($J_{5',4'} = 7,3$ Hz) à 1,00 ppm. L'étude de la séquence de substitution du noyau quinoléique montre que cette chaîne pentènylique est placée en position 2 puisqu'un méthoxyle substituant le C-4 apparaît à 4,03 ppm et que les attributions des protons aromatiques de l'hétérocycle peuvent découler d'un raisonnement analogue à celui précédemment décrit. La spectrométrie de masse confirme finalement la structure envisagée par la présence d'ions fragments à m/z 212 ($[M - CH_3]^+$, 75%) et m/z 200 ($[M - C_2H_5]^+$, 16%). Ce composé original est donc la (pentèn-1',2' yl)-2 méthoxy-4 quinoléine.

La composition de cette espèce n'apparaît donc pas fondamentalement différente de celles des espèces du même genre ou de genres voisins tels que les *Lunasia* (4). Le nombre de *Galipea* ayant à l'heure actuelle fait l'objet d'études phytochimiques exhaustives apparaît cependant insuffisant pour pouvoir comparer, sur des critères chimiotaxonomiques, ce genre aux autres membres des Rutacées.

Partie expérimentale

Appareillage

Les points de fusion sont mesurés en tube capillaire et ne sont pas corrigés. Les spectres sont enregistrés sur les appareils suivants: uv, Beckman 530, éthanol (λ_{max}, (log ϵ)); ir, Perkin–Elmer 580, KBr (ν cm^{-1}); spectres de rmn ^1H et ^{13}C, Bruker AM 300, $CDCl_3$ (δ ppm, TMS = 0); spectres de masse, Varian MAT 311 (m/z (%)). Les chromatographies sur colonnes sont réalisées sur Kieselgel 60 (Merck 7734) ou 60 H (Merck 7736), et les ccm sur DC Alufolien 60 F 254 (Merck 5554).

Matériel végétal

Les écorces de tiges de *G. longiflora* ont été récoltées à Fatima de Chimane (Alto Beni, Bolivie) le 08-09-1987 et sont référencés sous le n° A.F. 790 dans l'herbier de référence du centre ORSTOM de La Paz.

Extraction et isolement des alcaloïdes

La drogue pulvérisée (1 kg) est épuisée par l'hexane en milieu neutre dans un appareil de Soxhlet; après distillation sous pression réduite de l'hexane on obtient un résidu de 22,4 g contenant essentiellement des alcaloïdes peu polaires (ccm). La poudre séchée est ensuite extraite selon un procédé classique (alcalinisation du marc suivi d'une extraction par le chloroforme et d'une purification par passage à l'état de sels) : le rendement en alcaloïdes totaux est de 0,2%; l'analyse en ccm montre que ces A.T. ne sont pas différent du résidu provenant de l'extraction préliminaire par l'hexane. Le fractionnement des alcaloïdes totaux est obtenu par chromatographie sur colonne de silice pour ccm : solvant hexane – acétate d'éthyle 85 : 15. La purification des différents constituants est obtenue par ccm préparative (support : silice; solvant : hexane – acétate d'éthyle 90 : 10, benzène – acétate d'éthyle 95 : 5, chloroforme–benzène–méthanol–ammoniac 50 : 50 : 0,5 : vap.) ou, quand cela est possible, par cristallisation.

Descripiton des produits isolés

Les constantes physiques et données spectrales des composés antérieurement décrits ne seront pas redonnées ici. Les alcaloïdes furoquinoléiques ont été identifiés par comparaisons avec des échantillons authentiques. Les données spectrales mesurées pour les alcaloïdes **5**, **7** et **8** sont en bon accord avec celles de la bibliographie.

Description des alcaloïdes nouveaux isolés

Phényl-2 quinoléine **1**, PF 84°C (hexane); uv : 208 (4,49), 255 (4,56), 321 (2,84); sm m/z : 205, M^+ (100), 203 (59), 102 (12).

(Méthylènedioxy-3',4') phénéthyl-2 quinoléine **2**, PF 65°C (méthanol); uv : 205 (4,59), 227 (4,58), 300 (3,66), 314 (3,51); sm m/z : 277 M^+ (99), 276 (100), 156 (18), 135 (75), 129 (15).

(Diméthoxy-3',4') phénéthyl-2 quinoléine **3**, amorphe; uv : 206 (4,59), 228 (4,57), 256 (3,74), 276 (3,79), 302 (3,58) 315, (3,55); sm m/z : 293, M^+ (81), 292 (40), 278 (36), 156 (15), 152 (10), 151 (100), 129 (11).

(Méthylènedioxy-3',4') styryle-2 méthoxy-4 quinoléine **4**, amorphe; uv : 206 (4,12), 236 (4,08), 250 (4,00), 285 (3,95), 310 (3,92), 344 (4,21); sm m/z : 305, M^+ (79), 304 (100), 290 (47), 289 (26), 274 (35), 262 (13), 261 (12), 232 (17), 204 (11), 202 (8).

(Pentèn-1',2' yl)-2 méthoxy-4 quinoléine **6**, amorphe; uv : 230 (4,41), 250 (4,47), 289 (3,87); sm m/z : 227 M^+ (98), 212 (75), 199 (100), 198 (93), 184 (19), 173 (39), 154 (39).

Spectres de masse des produits connus (non décrits précédemment)

Photosensitized (electron transfer) carbon–carbon bond cleavage of radical cations: the 2-phenylethyl ether and acetal systems[1]

DONALD R. ARNOLD[2] AND LAURIE J. LAMONT
Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3

Received April 7, 1989

DONALD R. ARNOLD and LAURIE J. LAMONT. Can. J. Chem. **67**, 2119 (1989).

The scope of the photosensitized (electron transfer) carbon–carbon bond cleavage involving radical cations has been defined for 2-phenylethyl ethers and acetals. The thresholds for reactivity of the monophenylethyl and *gem*-diphenylethyl derivatives are compared. While the radical cation of methyl 2,2-diphenylethyl ether (**7**) cleaves to give ultimately diphenylmethane (**2**) and dimethoxymethane (**8**), the radical cation of methyl 2-phenylethyl ether (**9**) was stable under these conditions. In contrast to the lack of reactivity of the radical cation of **9**, the radical cations of methyl 2-phenyl-2-propyl ether (**11**), methyl 2-phenylcyclopentyl ether (**13**), and 2-phenylmethyl-1,3-dioxolane (**16**) cleave. Cleavage in the monophenylethyl series is limited to formation of a carbocation at least as stable as the secondary α-oxyalkyl or di-α-oxyalkyl. The basis for predicting this type of reactivity of radical cations is defined. The rate of carbon–carbon bond cleavage is increased by increasing the oxidation potential of the molecule, by decreasing the carbon–carbon bond strength, and (or) by decreasing the oxidation potential of that fragment that will become the carbocation. The results obtained from the reactions of 2-diphenylmethyl-1,3-dioxolane (**14**) and 2-phenylmethyl-1,3-dioxolane (**16**) cast doubt on the published oxidation potential for the 1,3-dioxolan-2-yl radical.

Key words: photochemistry, radical cation, electron transfer, bond cleavage, radical.

DONALD R. ARNOLD et LAURIE J. LAMONT. Can. J. Chem. **67**, 2119 (1989).

On a défini le champ d'application du clivage, photosensibilisé (par transfert électronique) et impliquant des cations radicaux, de la liaison carbone–carbone d'éthers et d'acétals de la série 2-phényléthyle. On a comparé les seuils de réactivité des dérivés monophényléthylés et *gem*-diphényléthylés. Alors que le cation radical du 1-méthoxy-2,2-diphényléthane (**7**) subit un clivage conduisant éventuellement au diphénylméthane (**2**) et au diméthoxyméthane (**8**), le cation radical du méthoxy-1-2-phényléthane (**9**) est stable dans ces conditions. En opposition au fait que le cation radical du composé **9** n'est pas réactif, les cations radicaux du 2-méthoxy-2-phénylpropane (**11**), du 1-méthoxy-2-phénylcyclopentane (**13**) et du 2-phénylméthyl-1,3-dioxolane (**16**) se clivent. Le clivage dans la série des composés monophényléthylés est limité à la formation d'un cation au moins aussi stable que les α-oxyalkyles ou di-α-oxyalkyles secondaires. On a défini les bases permettant de prédire ce type de réactivité des cations radicaux. Les vitesses de clivage de la liaison carbone–carbone augmentent lorsqu'on augmente le potentiel d'oxydation de la molécule, lorsqu'on diminue la force de la liaison carbone–carbone et (ou) lorsqu'on diminue le potentiel d'oxydation du fragment qui deviendra le carbocation. Les résultats obtenus lors des réactions des 2,2-diphénylméthyl-1,3-dioxolane (**14**) et 2-phénylméthyl-1,3-dioxolane (**16**) permettent de mettre en doute les résultats qui ont été publiés relativement au potentiel d'oxydation du radical 1,3-dioxolan-2-yle.

Mots clés : photochimie, cation radical, transfert d'électron, clivage de la liaison, radical.

[Traduit par la revue]

Introduction

A frequently observed reaction of organic radical cations is cleavage of a carbon–carbon bond to give a carbon-centered radical and a carbocation fragment. This process accounts for many of the fragments in the mass spectrum of an organic molecule. The relative efficiency of the various modes of cleavage of the radical cation, in the gas phase, are predictable and relatively well understood. In marked contrast, when the radical cation is generated in solution by photosensitization (electron transfer), cleavage is much less common; in fact, it is not yet possible to predict when this reaction will occur (3). Other reactions of the radical cation often occur instead. It is now clear that for the carbon–carbon bond cleavage process to compete effectively with these other reactions the nascent fragments, both radical and carbocation, must be relatively stable (1*b*).

The reactivity of the radical cations of several compounds having in common the *gem*-diphenyl moiety has been studied. Even though carbon–carbon bond cleavage of the radical cation of these compounds would give the highly delocalized diphenylalkyl radical, not all react in this way. The photosensitized (electron transfer) reactivity of 1,1,2,2-tetraphenylethane (**1**) is particularly interesting; the efficiency of the cleavage process is temperature dependent in this case. Essentially no cleavage of **1** occurred upon irradiation of an acetonitrile–methanol solution at 10°C, with 1,4-dicyanobenzene (**4**) as the electron-accepting photosensitizer; however, at 80°C, cleavage was relatively efficient and an excellent yield of diphenylmethane (**2**) and methyl diphenylmethyl ether (**3**) was obtained (reaction 1) (1*b*). The energy of carbon–carbon bond cleavage of this radical cation is clearly at the threshold for reactivity.

Reaction 1

$$\underset{\mathbf{1}}{Ph_2CH{-}CHPh_2} \xrightarrow[CH_3CN,\ CH_3OH]{h\nu,\ \text{Sen.},\ 80\,^\circ C} \underset{\mathbf{2}}{Ph_2CH_2} + \underset{\mathbf{3}}{CH_3OCHPh_2}$$

Sens.: 1,4-Dicyanobenzene (**4**)

The proposed mechanism for this reaction is shown in Scheme 1 (1*b*). The temperature dependence of the reaction of the radical cation of **1** was attributed to the cleavage step (step 4) and an estimate of $E_a = 7.2$ kcal mol^{-1} was obtained from the slope of an Arrhenius plot (log (relative efficiency) versus temp^{-1}). This estimate for the bond dissociation energy of the central bond in the radical cation of **1** is in fair agreement with the value (9.3 kcal mol^{-1}) calculated from thermochemical data (Fig. 1*a*) (1*b*).

Some similar 1,1-diphenylethyl derivatives are stable to

irradiation under these conditions, even at the higher temperature (80°C). Apparently, with these unreactive derivatives cleavage cannot compete with other reactions, such as deactivation by back electron transfer (step 3) or deprotonation (step 8). The carbon–carbon bond dissociation energy of the radical cation must be too high. An understanding of the factors that influence the thermodynamics, and more importantly the kinetics, of step 4 will be required to be able to predict whether cleavage of any given radical cation will occur.[3]

[3]If the reaction of the radical with the carbocation, to give the radical cation, has little or no activation energy, the activation energy for the cleavage of the radical cation will be the bond dissociation energy. This may be the case in the gas phase (4); however, solvent reorganization at the transition state must require an activation energy, particularly for solutions in polar solvents.

The main structural features that influence the thermodynamics of step 4 have been identified (Fig. 1) (1*b*). To decrease the bond dissociation energy of the radical cation, one must increase the oxidation potential of the molecule, decrease the carbon–carbon bond dissociation energy, and (or) decrease the oxidation potential of that fragment that will become the carbocation.

The reactivity of 1,1,2,2-tetraphenylethane (**1**) gives an indication of the threshold carbon–carbon bond energy required for cleavage to occur; it is about 10 kcal mol^{-1}. One of our goals is to be able to predict generally, on the basis of the structure of the radical cation, when this cleavage reaction will occur. We have therefore extended our study to the monophenylethyl analogues in an effort to find the threshold for cleavage in this series.

There are conflicting reports in the literature regarding the reactivity of the radical cation of the parent member of this series, 1,2-diphenylethane (**5**) (7). We find that **5** is stable to irradiation under conditions which cause cleavage of **1** (reaction 2); this is consistent with most of the reported behaviour (7). It is

Reaction 2

5

also clear, from consideration of the thermochemical cycle (Fig. 1*c*), that the bond dissociation energy for **5** is significantly greater (29.3 kcal mol^{-1}) than that for **1**.

Can the bond dissociation energy of the radical cation of monophenyl analogues be decreased, by appropriate substitution, to the point where cleavage will occur? For example, will

6

the radical cation of 1,1,2-triphenylethane (**6**) cleave? While the oxidation potentials of **5** and **6** are essentially the same (Table 2), the central carbon–carbon bond in **6** is weaker than that in **5** (5*a*), and the oxidation potential of the diphenylmethyl radical (0.35 V (6))[4] is appreciably less than that of the benzyl radical (0.73 V (6)). Both of these factors tend to favour cleavage of **6** relative to **5** (Fig. 1*b*). But will the combined effect, which lowers the bond dissociation energy of the radical cation of **6** to 16.7 kcal mol^{-1}, be large enough?

Methyl 2,2-diphenylethyl ether (**7**) is readily cleaved under these conditions, even at 10°C (reaction 4) (8). The data

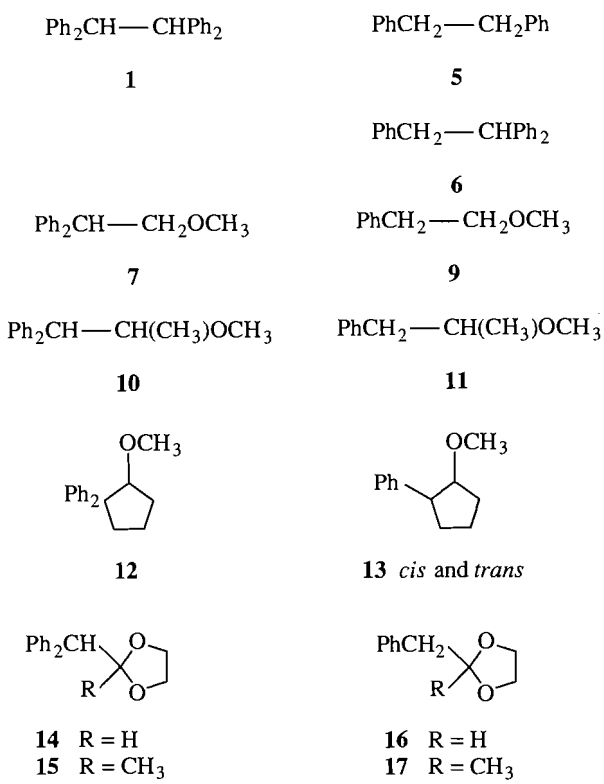
7 **2** **8**

required to complete the thermochemical cycle for the cleavage of **7** are not available; however, the significantly lower oxidation potential of the α-oxymethyl radical (−0.24 V (6)) relative to the diphenylmethyl radical tends to favour cleavage. Substitution of the α-oxymethyl group for the benzylic group in **5** makes an even greater incremental difference in the carbon–carbon bond energy. Will methyl 2-phenylethyl ether (**9**) cleave under these conditions?

Reaction 5

$$PhCH_2—CH_2OCH_3 \xrightarrow[CH_3CN,\ CH_3OH]{h\nu,\ Sen.,\ 80°C} \text{No reaction}$$



9

The radical cations of methyl 1,1-diphenyl-2-propyl and methyl 1-phenyl-2-propyl ethers (**10** and **11**) are even more likely to cleave. The α-oxycarbocation from these derivatives is secondary; the oxidation potential of this secondary radical (−0.45 V (6)) is significantly less than that of the analogous primary α-oxymethyl radical.

The radical cation of methyl 2,2-diphenylcyclopentyl ether (**12**) cleaves to give the 1,5-radical cation under these conditions (1*a*). Would the radical cation of the monophenyl derivative, methyl 2-phenylcyclopentyl ether (**13**), cleave?

The effect of the single oxygen in **7** and **9**–**13** is understood; while the radical α to ether oxygen is stabilized by interaction with the nonbonding pair of electrons, the α-oxycarbocation is stabilized even more. This is evident from the relatively low oxidation potential of the radical. The effect of the two oxygens in the 1,3-dioxolan-2-yl system can also be predicted. Both the radical and the carbocation should be stabilized by more than the stabilization provided by only one adjacent oxygen, although the effect is not additive (9). However, this reasoning is not consistent with the measured oxidation potential of the 1,3-dioxolan-2-yl radical (0.31 V (6)), which is significantly greater than that of the α-oxymethyl radical. It will therefore be interesting to know if the radical cations of the 2-diphenylmethyl-1,3-dioxolanes (**14** and **15**) and the 2-phenylmethyl-1,3-dioxolanes (**16** and **17**) (Chart 1) cleave under these conditions. The reactivity of these compounds will provide another indication of the oxidation potential of the 1,3-dioxolan-2-yl radical.

CHART 1

The specific objective of this work was to determine the reactivity of the radical cations of 2,2-diphenylethyl and 2-phenylethyl ethers and acetals upon photosensitization (electron transfer). The ultimate goal is to provide a firm basis for predicting reactivity in this type of cleavage reaction in general.

Results

The compounds of interest are shown in Chart 1; all except methyl 1,1-diphenyl-2-propyl ether (**10**) were known compounds, prepared by standard methods, and characterized by spectroscopic techniques (^1H nmr, ms). The new compound (**10**), prepared in two steps from 1,1-diphenyl-2-propanone, was fully characterized (ir, ^1H nmr, ^{13}C nmr, ms, and elemental analysis).

The methyl *cis*- and *trans*-2-phenylcyclopentyl ethers (**13**) and methyl 1-phenyl-2-propyl ether (**11**) were obtained by the photosensitized (electron transfer) *anti*-Markovnikov addition of methanol to the corresponding alkenes (10). The ratio of isomers obtained from 1-phenylcyclopentene (*cis*-**13**/*trans*-**13** = 0.4) was similar to that reported (0.6, ref. 10*b*). These isomers were separated by flash column chromatography.

The irradiation procedure was similar to that used in the previous study (1*b*), so the results can be compared directly with those reported. Solutions of the ether or acetal and the photosensitizer, 1,4-dicyanobenzene (**4**), in acetonitrile–methanol (3:1), were degassed by nitrogen ebullition and then were irradiated through a Pyrex filter using a medium-pressure mercury vapour lamp. The irradiation vessel was kept at a constant temperature, 10°C or 80°C, by a circulating water bath.

[4]All of the potentials mentioned in this paper are relative to the saturated calomel electrode (SCE).

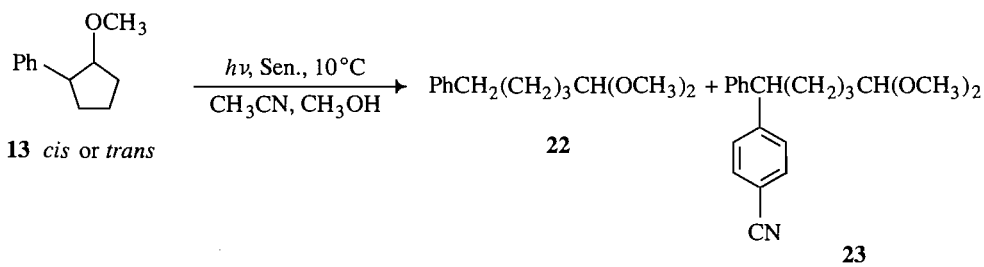
[a]A solution of the compound (0.05 M) and 1,4-dicyanobenzene (**4**) (0.05 M) in acetonitrile–methanol (3:1) at 10°C was irradiated through a Pyrex filter with a medium-pressure mercury vapor lamp. The usual irradiation period was ca. 20 h.
[b]Reference 1*b*.
[c]The temperature of the irradiation was 80°C; there was little or no reaction upon irradiation at 10°C.
[d]Trace amounts of the expected cleavage products were detected by gc/ms.
[e]Reference 1*a*.
[f]The acetal **21** was the only volatile product detected at low conversion; the yield was not determined. The reaction becomes inefficient and the product mixture becomes complex during irradiation.
[g]Tentative structural assignment based upon retention time and mass spectrum (gc/ms).

Progress of the reaction was followed by capillary column gas chromatography with a mass selective detector (gc/ms). The products, including minor amounts of compounds resulting from competing reactions or secondary photolysis, were readily detected. The results of the irradiations are illustrated in reactions 1–13, and are summarized in Table 1. The reported yields are based upon starting material consumed, at greater than 85% conversion, and purified product isolated by column chromatography. The yield of toluene (**19**) was determined by gas chromatography using a calibrated flame ionization detector (gc/fid).

Most of the products are well-known compounds, characterized here by spectroscopic techniques and by direct comparison with authentic samples.



The (4-cyanophenyl)phenylmethane (**20**), isolated by column chromatography, was identified by mass spectrum, ^{1}H nmr, and comparison with reported melting point. The *ortho* ester, 2-methoxy-2-methyl-1,3-dioxolane (**25**), was hydrolyzed to

[d]Reference 13.

[e]Reference 8.

methyl acetate, which was identified by comparison (gc/ms) with an authentic sample.

A minor product formed upon cleavage of methyl 2-phenylcyclopentyl ether (**13**) (reaction 9) was not isolated; a tentative structure, 5-(4-cyanophenyl)-5-phenylpentanal dimethylacetal (**23**), was assigned on the basis of retention time and mass spectrum (gc/ms). *cis*- and *trans*-**13** undergo configurational isomerization under these conditions.

Deuterium incorporation studies were carried out on methyl 2-phenylethyl ether (**9**), and on methyl *cis*- and *trans*-2-phenylcyclopentyl ether (**13**). These compounds were irradiated under the usual conditions except that the solvent was acetonitrile–methanol-d_4 (3:1). Analysis by gc/ms showed that both **9** and **13** had incorporated deuterium at the benzylic position.

Electrochemical measurements for the ethers and acetals are summarized in Table 2. All of the anodic waves were typical of irreversible oxidation. The last column in Table 2 reports the free energy change (ΔG) for the electron transfer step (Scheme 1, step 2), calculated using the Weller equation (eq. [1]) (11).

$$[1] \quad \Delta G = 23.06\left(E^{ox}_{1/2} - E^{red}_{1/2} - \frac{e}{\epsilon\alpha}\right) - E^{*}_{0,0}$$

Discussion

The first step in the proposed mechanistic sequence is excitation of the photosensitizer. The long-wavelength ultraviolet absorption of 1,4-dicyanobenzene (**4**) extends to 290 nm, beyond the absorption cutoff of Pyrex glass. Phenylethyl and *gem*-diphenylethyl compounds are transparent in this spectral region so only the photosensitizer absorbed the light.

Electron transfer, from the phenylethyl or diphenylethyl compound, to the excited singlet state of **4** is energetically favourable in every case (Table 2). Step 2 should be diffusion controlled; quenching of the excited singlet state of **4** at rates approaching the diffusion limit has been observed for some of these compounds (8).

Aliphatic ethers generally have high oxidation potentials. All of the compounds listed in Table 2 have an oxidation potential that falls within the rather narrow range (2.1 ± 0.1 V) typical of monoalkyl aromatics. The singly occupied molecular orbital (SOMO) of these donors must be largely associated with the phenyl ring(s). The fact that the oxidation potentials of the *gem*-diphenylethyl derivatives are generally about 0.1 V less than those of the monophenyl analogues suggests that there may be some additional stabilization, i.e., increased delocalization, in the *gem*-diphenylethyl radical cation.

The corresponding radical anion of diphenylmethane has been studied and there was no evidence, in the electron spin resonance spectrum (esr), for interaction between the rings (14). A very recent esr study of the radical cation of di(9-anthryl)-methane indicated that the unpaired electron is delocalized over only one of the anthracene rings (15). It therefore seems likely

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/07/12

For personal use only.

that any interaction between the two phenyl rings in the radical cation of these *gem*-diphenylethyl derivatives is small.

One factor that is known to inhibit bond cleavage of a radical cation is lack of overlap of the adjacent carbon–carbon bond with the SOMO (1*a*). All of the compounds studied here can attain conformations that allow such overlap, hence this is not a limiting factor.

Back electron transfer from the radical anion of the sensitizer to the radical cation of the donor, step 3, is the major competing reaction. This process is energetically very favourable (ca. −85 kcal mol^{-1}) for all of the donors studied; the rate should be nearly the same in every case. Back electron transfer from the monophenylethyl compounds might, in fact, be somewhat slower than for the *gem*-diphenylethyl compounds because the process is exothermic enough to fall within the inverted-Marcus region (16).

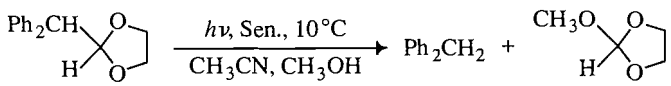
The contrast in reactivity between the 1,1,2,2-tetraphenylethane (**1**) and 1,2-diphenylethane (**5**) continues with 1,1,2-triphenylethane (**6**); no cleavage was observed (reaction 3). This is perhaps not surprising in view of the fact that **1** is on the threshold for reactivity. The bond strength of the radical cation of **6**, estimated to be 16.7 kcal mol^{-1} from the thermochemical cycle (Fig. 1*b*), is too great for cleavage to compete with back electron transfer, even at the higher temperature (80°C).

Cleavage of the radical cation of methyl 2,2-diphenylethyl ether (**4**) occurs at 10°C. Reaction 4 is more favourable than reaction 1; nevertheless, the radical cation of the monophenylethyl analog, methyl 2-phenylethyl ether (**9**), does not cleave, even at 80°C (reaction 5). Apparently, the bond dissociation energy of the radical cation of **9** is too large for cleavage to compete.

When the irradiation of **9** is carried out in acetonitrile–methanol-d_4, deuterium is incorporated at the benzylic position. The acidity of a benzylic hydrogen is greatly increased upon oxidation to the radical cation (17). Deprotonation, followed by back electron transfer from the sensitizer radical anion to the resulting radical and reprotonation (or redeuteration), provides a mechanism for deuterium exchange (steps 8–10).

Progressing through the series of monophenylethyl derivatives of decreasing bond strength, not until methyl 1-phenyl-2-propyl ether (**11**), where the α-oxyalkyl radical is secondary, does the radical cation of a monophenylethyl derivative cleave. Both the *gem*-diphenyl-2-propyl and the monophenyl ethers (**10** and **11**) cleave upon photosensitization (electron transfer) at 10°C (reactions 6 and 7).

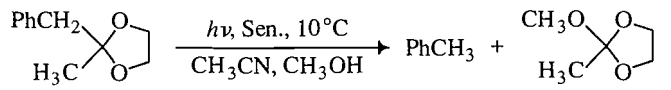
The reaction mixtures involving **11**, and all of the other monophenylethyl derivatives that cleave, are more complex than in the case of the analogous *gem*-diphenylethyl derivatives; (4-cyanophenyl)phenylmethane (**20**) is a major product in these reactions. A key step accounting for the formation of diphenylmethane (**2**) from the *gem*-diphenylethyl derivatives is the reduction of the diphenylmethyl radical by the sensitizer radical anion (step 6). Since the reduction potential of 1,4-dicyanobenzene (**4**) (−1.66 V) is significantly greater (more negative) than that of the diphenylmethyl radical (−1.14 V (6)), reduction of the radical is favourable. Reduction of the benzyl radical (−1.45 V (6)) and α-phenethyl radical (−1.60 V (6)) is less favourable. Formation of (4-cyanophenyl)phenylmethane (**20**) may result from coupling of the benzyl radical and the 1,4-dicyanobenzene radical anion at the *ipso* position followed by loss of cyanide ion. This coupling of the radical and radical anion may become more important as reduction of the radical becomes less favourable. Steric hindrance may also inhibit the coupling reaction involving the more hindered and more delocalized diphenylmethyl radical.



The formation of the 1,5-radical cation upon cleavage of the radical cation of methyl 2,2-diphenylcyclopentyl ether (**12**) has been reported (reaction 8) (1*a*). In view of the fact that the acyclic monophenyl derivative (**11**) cleaves, it is now not surprising that the monophenylcyclopentyl ether (**13**) also cleaves (reaction 9). The observations that *cis*- and *trans*-**13** are equilibrated under these conditions and that deuterium is incorporated at the benzylic position, when the irradiation is carried out in acetonitrile–methanol-d_4, leads to the conclusion that deprotonation–reprotonation (steps 8–10) may be competitive with cleavage in this case. Isomerization could also result from reversible carbon–carbon bond cleavage; there was no evidence for cyclization of the 1,5-radical cation into the terminal phenyl ring.

In addition to the expected cleavage product, 5-phenylphentanal dimethylacetal (**22**), a minor product having a retention time and mass spectrum (gc/ms) consistent with 5-(4-cyanophenyl)-5-phenylpentanal dimethylacetal (**23**) was also detected (not isolated). This product would arise upon coupling of the benzylic radical with the radical anion of 1,4-dicyanobenzene (**4**) at the *ipso* position followed by loss of cyanide ion, the same mechanism as that invoked for the formation of (4-cyanophenyl)-phenylmethane (**20**).

All four of the dioxolanes studied (**14**–**17**) undergo photosensitized (electron transfer) cleavage. Cleavage of the radical cation of **16**, the derivative with the strongest carbon–carbon bond, is particularly interesting. If the reported oxidation potential of the 1,3-dioxolan-2-yl radical (0.31 V (6)) were correct, cleavage of **16** would be less favourable than cleavage of **9**, which does not cleave. This, and other evidence *vide infra*, leads us to question the reported oxidation potentials of the 1,3-dioxolan-2-yl radicals.



The cleavage process (step 4) yields a carbocation and a radical fragment. We have suggested that the direction of this process, that is, which fragment becomes the radical and which becomes the carbocation, is a reflection of the relative oxidation potentials of the two fragment radicals. That fragment radical with the lower oxidation potential becomes the carbocation (1*b*, *c*). In all of the cases involving cleavage of the radical cation of ethers, the radical bearing an α oxygen has an oxidation potential lower than either the benzylic or the diphenylmethyl radical; hence the products observed in reactions 4 and 6–9 are consistent with this hypothesis. There is, however, a quantitative discrepancy between calculated and observed product ratios in the diphenylmethyl–dioxolane (**14**) case.

Reaction 10

Reaction 13

17 **19** **25**

Ph(4-NC—C_6H_4)CH_2

20

When the difference between the oxidation potentials of the two possible radicals is small (ca. 0.1 V), cleavage is less regioselective and all four possible products are obtained. The product ratio in such a case reflects the differences in energy of the two possible modes of separation of the radical and cation, according to eq. [2] (18). Since the difference in the reported

$$R{-}R' \xrightarrow[CH_3CN,\ CH_3OH]{h\nu,\ Sen.,\ (A)} \begin{cases} RH + R'OCH_3 \\ R'H + ROCH_3 \end{cases}$$

$$r = \frac{[R'H]}{[RH]} = \frac{[ROCH_3]}{[R'OCH_3]}$$

$$[2] \quad \ln r = \frac{F}{RT}\,(E^{ox}_{R^{\cdot}} - E^{ox}_{R'^{\cdot}})$$

values for the oxidation potential of the diphenylmethyl radical (0.35 V) and the 1,3-dioxolan-2-yl radical (0.31 V) is only 0.04 V, we would expect some (ca. 5%) methyl diphenylmethyl ether (**3**) from reaction 10; however, none was observed. Less than 1% might have gone undetected (gc/fid), which means the difference in oxidation potential must be >0.10 V. If we accept the oxidation potential of the diphenylmethyl radical, this places an upper limit on the oxidation potential of the 1,3-dioxolan-2-yl radical of <0.25 V, 0.06 V less than the reported value (6). Work in progress will resolve this discrepancy.[5]

Experimental

General information

The ^{1}H nmr spectra were recorded on a Nicolet Instruments Corp. narrow bore 360-MHz spectrometer and are reported in parts per million to high frequency from tetramethylsilane. Infrared spectra were recorded on a Perkin Elmer 283B ir spectrometer and are recorded in wavenumbers. Gas chromatography with mass selective detection (gc/ms) was done on a Hewlett Packard 5890A gc/5970 mass selective detector interfaced with a Hewlett Packard 9816 microcomputer. The column used was a 25 m × 0.2 mm 5% phenyl methyl silicone on fused silica with a film thickness of 0.25 μm. Gas chromatography with flame ionization detection (gc/fid) was carried out on a Hewlett Packard 5890. The column used was a 25 m × 0.25 mm OV-1701 fused silica column. Preparative gas chromatography was carried out on an Aerograph A-700 gc, fitted with a thermal conductivity detector, using a 6 ft × 3/4 in. 10% SE-30 on Chromosorb 60/80 W column. Melting points were taken on a Thermolyne melting point apparatus and are corrected. Combustion analysis was done by Canadian Microanalytical Service Limited, New Westminster, B.C.

Electrochemical measurements

Oxidation potentials were obtained by cyclic voltammetry using a three-electrode cell, which has been described previously (19). The working electrode was a platinum sphere (1 mm diameter) and the counter electrode was a platinum wire. The reference electrode was saturated calomel (SCE). The electrolyte was 0.1 M tetraethylammonium perchlorate (TEAP) in acetonitrile. Substrate concentrations were typically 1 mM.

The electrochemical measurements are summarized in Table 2. The peak potentials were measured using a 100 mV/s sweep rate. No cathodic wave was detected following the anodic sweep. The half-wave potentials were taken as 0.03 V before the anodic peak potentials (12).

[5]The oxidation potential of the di(4-methylphenyl)methyl radical is 0.188 V (18). The product ratio from the cleavage of the radical cation of 2-(di-(4-methylphenyl)methyl)-1,3-dioxolane will allow a more accurate measure of the oxidation potential of the 1,3-dioxolan-2-yl radical if it is greater than 0.1 V.

Irradiations

Irradiations were done in Pyrex tubes using a Canadian General Electric Co. 1-kW medium-pressure mercury vapour lamp (CGE H 1000 DX 36-15) with a quartz cooling jacket immersed in a constant temperature bath held at either 10°C or 80°C. Samples were degassed by bubbling nitrogen through the solution for 5 min prior to irradiation.

Materials

Solvents were distilled prior to use. Acetonitrile and 1,4-dicyanobenzene (**4**) (Aldrich Chem. Co.) were purified as previously described (1*b*). Diphenylacetaldehyde, 1,1-diphenyl-2-propanone, 2-phenylmethyl-1,3-dioxolane (**16**), 1,2-diphenylethane (**5**), 2-phenylethanol, 5-phenylpentanol, 1-phenyl-2-propanone, 1,1,2-triphenylethylene, β-methylstyrene, and phenyl-2-propanone were obtained from Aldrich Chem. Co.

Preparation of compounds

Preparation of 1,1,2-triphenylethane (6)

1,1,2-Triphenylethane (**6**) was obtained by reduction of 1,1,2-triphenylethylene using H_2(g) over 10% Pd on charcoal in hexanes at 170 Torr (1 Torr = 133.3 Pa). The reduction was complete after 2 days of stirring at room temperature. The product was purified by recrystallization using hexanes to yield pure **6** (mp 52–54°C (lit. (20) mp 54.4°C)) in 90% yield; ^{1}H nmr (360 MHz) in $CDCl_3$: 7.12 (m, 15H), 4.23(t, 1H, J = 7.8 Hz), 3.36 (d, 2H, J = 7.8 Hz) (in agreement with that reported (21)).

Preparation of methyl 2-phenylethyl ether (9)

Dimethyl sulphate (11.7 mL, 0.12 mol) was added dropwise to a stirred solution of 2-phenylethanol (5 g, 4.1×10^{-2} mol) and NaH (3 g, 0.13 mol) in anhydrous diethyl ether. The reaction mixture was refluxed for 20 h under nitrogen and was quenched by addition of water. The aqueous layer was extracted with diethyl ether. The combined organic extract was washed with concentrated NH_4OH, then with saturated NaCl solution, dried over magnesium sulphate, and the solvent evaporated to give the crude product. Column chromatography on silica gel (Kieselgel 60) using methylene chloride – hexanes as eluant gave the ether (**9**) in 60% yield; ^{1}H nmr (360 MHz) in $CDCl_3$: 7.19–7.31 (m, 5H), 3.60(t, 2H, J = 7.2 Hz), 3.36(s, 3H), 2.89(t, 2H, J = 7.2 Hz) (in agreement with that reported (22)).

Preparation of methyl 1,1-diphenyl-2-propyl ether (10)

Methyl 1,1-diphenyl-2-propyl ether (**10**) was obtained through a two-step synthesis from 1,1-diphenyl-2-propanone in 55% overall yield. The 1,1-diphenyl-2-pentanone was reduced, using $LiAlH_4$, to the corresponding alcohol (mp 62–63°C (lit. (23) mp 63–64°C), which was recrystallized from hexanes. The ether was prepared from this alcohol using NaH and dimethyl sulphate as described above for the preparation of **9**. Pure **10** (mp 31–32°C) was obtained by column chromatography on silica gel (Kieselgel 60) using methylene chloride and hexanes as eluants; ir (PE 283B) neat: 3070(m), 3030(s), 2980(s), 2930(s), 2900(s), 1600(s), 1500(s), 1455(s), 1375(m), 1340(w), 1140(s), 1090(s), 755(s), 745(s), 700(s); ^{1}H nmr (360 MHz) in $CDCl_3$: 7.20 (m, 10H), 4.01 (m, 1H), 3.80 (d, 1H, J = 3.9 Hz), 3.22 (s, 3H), 1.08 (d, 3H, J = 6.1 Hz); ^{13}C nmr (90 MHz) in $CDCl_3$: 142.7, 129.3, 127.5, 125.2, 78.8 (d), 58.6 (d), 56.6 (t), 17.6 (q). *Anal.* calcd. for $C_{16}H_{18}O$: C 84.91, H 8.02; found: C 84.90, H 8.05.

Preparation of methyl 1-phenyl-2-propyl ether (11) (24)

Methyl 1-phenyl-2-propyl ether (**11**) was obtained by the photochemical method (10*b*). β-Methyl styrene was irradiated at 10°C in the presence of an electron-accepting sensitizer, 1,4-dicyanobenzene (**4**), in acetonitrile–methanol (3:1) solution. The pure ether **11** was obtained in 40% yield by column chromatography on silica gel (Kieselgel 60) with methylene chloride and hexanes as eluant; ^{1}H nmr (360 MHz) in $CDCl_3$: 7.16–7.27 (m, 5H), 3.51 (m, 1H), 3.30 (s, 3H), 2.93 (dd, 1H, ^2J = −14.0 Hz, J = 5.99 Hz), 2.62 (dd, 1H, ^2J = −14.0 Hz, J = 6.74 Hz), 1.10 (d, 3H, J = 6.15 Hz); ^{13}C nmr (90 MHz) in $CDCl_3$: 138.9, 129.3, 128.1, 125.9, 78.0, 56.1, 42.7, 18.8.

Preparation of methyl cis- *and* trans-*2-phenylcyclopentyl ether (*cis- *and* trans-*13)*

The methyl *cis*- and *trans*-2-phenylcyclopentyl ethers were synthes-

ized from 1-phenylcyclopentene using the photochemical method (*10b*).

Bromobenzene (7.8 g, 0.05 mol) was added dropwise to magnesium (1.2 g, 0.05 mol) in anhydrous diethyl ether. Once the magnesium was consumed, the reaction mixture was cooled and cyclopentanone (3.14 g, 0.0375 mol) was added dropwise. The reaction mixture was poured into a concentrated hydrochloric acid – ice mixture, which was then extracted with ether (3×). The organic layers were combined, washed with 5% $NaHCO_3$ solution, and then with water. The extract was then dried with magnesium sulphate and the solvent was evaporated. Pure 1-phenylcyclopentene was obtained in 73% yield by flash column chromatography using hexanes as eluant.

A solution of 1-phenylcyclopentene (173 mg, 1.2×10^{-3} mol) and **4** (124 mg, 9.7×10^{-4} mol) in acetonitrile–methanol (30 mL, 3:1) was irradiated at 10°C for 24 h. Flash column chromatography of the photolysate, using methylene chloride – hexanes (1:1) as eluant, separated the isomeric ethers, *cis*- (17%) and *trans*-**13** (38%), at 97% conversion.

cis-**13**: ^{1}H nmr (360 MHz) in $CDCl_3$: 7.19–7.33 (m, 5H), 3.82 (ddd, 1H, J = 4.8 Hz, J = 4.3 Hz, J = 2.1 Hz), 3.05 (s, 3H), 2.99 (ddd, 1H, J = 4.8 Hz, J = 7.94 Hz, J = 11.06 Hz), 2.01 (m, 2H), 1.92 (m, 2H), 1.88 (m, 2H).

trans-**13**: ^{1}H nmr (360 MHz) in $CDCl_3$: 7.18–7.31 (m, 5H), 3.78 (ddd, 1H, J = 3.15 Hz, J = 5.58 Hz, J = 6.0 Hz), 3.25 (s, 3H), 3.03 (ddd, 1H, J = 6.0 Hz, J = 6.5 Hz, J = 7.0 Hz), 1.65–2.15 (m, 6H).

*Preparation of 2-diphenylmethyl-1,3-dioxolane (**14**)*

2-Diphenylmethyl-1,3-dioxolane (**14**) was prepared from diphenylacetaldehyde using chlorotrimethylsilane and ethylene glycol (25). Pure **14** (mp 74–76°C) was obtained, following recrystallization from methanol, in 95% yield; ^{1}H nmr (360 MHz) in $CDCl_3$: 7.19–7.38 (m, 10H), 5.55 (d, 2H, J = 5.01 Hz), 4.22 (d, 2H, J = 5.01 Hz), 3.78–3.86 (m, 4H) (in agreement with the reported spectrum (26)).

*Preparation of 2-diphenylmethyl-2-methyl-1,3-dioxolane (**15**) (27)*

2-Diphenylmethyl-2-methyl-1,3-dioxolane (**15**) was prepared from 1,1-diphenyl-2-propanone by the reported procedure (25). Pure **15** (mp 86–87°C) was obtained in 95% yield following recrystallization from methanol; ^{1}H nmr (360 MHz) in $CDCl_3$: 7.48–7.50 (m, 4H), 7.18–7.28 (m, 6H), 4.22 (s, 1H), 3.79 (m, 2H), 3.35 (m, 2H), 1.36 (s, 3H); ^{13}C nmr (90 MHz) in $CDCl_3$: 140.7 (s) 129.9, 127.9, 126.3, 111.3 (s), 65.0 (t), 61.0 (d), 25.3 (q).

*Preparation of 2-phenylmethyl-1,3-dioxolane (**16**) (28)*

2-Phenylmethyl-1,3-dioxolane (**16**) was prepared from 1-phenyl-2-propanone by the reported procedure (25). Compound **16** was purified by column chromatography on silica gel (Kieselgel 60) using methylene chloride – hexanes as eluant. Pure **16** was obtained in 80% yield; ^{1}H nmr (360 MHz) in $CDCl_3$: 7.22–7.28 (m, 5H), 3.90 (m, 2H), 3.76 (m, 2H), 2.92 (s, 2H), 1.31 (s, 3H).

Irradiations

*Irradiation of 1,2-diphenylethane (**5**)*

A solution of **5** (83 mg, 4.4×10^{-4} mol) and **4** (68 mg, 5.3×10^{-4} mol) in acetonitrile–methanol (3:1) was irradiated at both 10°C and 80°C. Trace amounts of toluene (**19**), the expected product from carbon–carbon bond cleavage, were observed (gc/ms) after irradiation for 20 h at 10°C and after 15 h at 80°C.

*Irradiation of 1,1,2-triphenylethane (**6**)*

A solution of **6** (157 mg, 6.1×10^{-4} mol) and **4** (96 mg, 7.5×10^{-4} mol) in acetonitrile–methanol (20 mL, 3:1) was irradiated at 80°C for 30 h. Trace amounts of diphenylmethane (**2**), 1,2-diphenylethane (**5**), and methyl diphenylmethyl ether (**3**) were detected (gc/ms).

*Irradiation of methyl 2-phenylethyl ether (**9**)*

A solution of **9** (40 mg, 2.9×10^{-4} mol) and 1,4-dicyanobenzene (**4**) (15 mg, 1.2×10^{-4} mol) in acetonitrile–methanol (2 mL, 3:1) was irradiated at 10°C for 25 h. Only trace amounts of toluene (**19**) and (4-cyanophenyl)phenylmethane (**20**), expected cleavage products, were detected (gc/fid).

A solution of **9** (25 mg, 1.8×10^{-4} mol) and **4** (24 mg, 1.9×10^{-4} mol) in acetonitrile–methanol (2 mL, 3:1) was irradiated at 80°C for 15 h. Only trace amounts of **19** and **20** were detected (gc/fid).

A solution of **9** (20 mg, 1.5×10^{-4} mol) and 1,4-dicyanobenzene (**4**) (11 mg, 8.6×10^{-5} mol) in acetonitrile–methanol-d_4 (2 mL, 3:1) was irradiated at 10°C for 24 h. Analysis (gc/ms) of the photolysate, using selected ion monitoring of the molecular ion and the benzylic fragment (m/z = 91–95), showed that deuterium had been incorporated (9%, one atom deuterium) at the benzylic position.

*Irradiation of methyl 1,1-diphenyl-2-propyl ether (**10**)*

A solution of **10** (600 mg, 2.66×10^{-3} mol) and **4** (340 mg, 2.66×10^{-3} mol) in acetonitrile–methanol (20 mL, 3:1) was irradiated for 23 h. Diphenylmethane (**2**) and 1,1,2,2-tetraphenylethane (**1**) were isolated by flash column chromatography of the photolysate on silica gel (Baker Analyzed) using hexanes and methylene chloride as eluant. After 90% conversion, **2** (70%) and **1** (10%) were isolated.

*Irradiation of methyl 1-phenyl-2-propyl ether (**11**)*

A solution of **11** (15 mg, 1.0×10^{-4} mol), **4** (22 mg, 1.7×10^{-4} mol), and cyclododecane (12 mg, 7.0×10^{-5} mol) in acetonitrile–methanol (2 mL, 3:1) was irradiated for 20 h. The major products of the irradiation were toluene (**19**), 1,2-diphenylethane (**5**), and (4-cyanophenyl)phenylmethane (**20**). Product analysis was done using gc/fid with cyclododecane as an internal calibration standard. The percent yields at 98% conversion were as follows: **19**, 25%; **5**, 15%; and **20**, 25%. The yields for **5** and **20** were confirmed by product isolation following column chromatography.

Irradiation of methyl cis- *and* trans-*2-phenylcyclopentyl ether (*cis- *and* trans-***13***)*

A solution of *cis*- and *trans*-**13** (ca. 1:2) (52 mg, 3.0×10^{-4} mol) and **4** (30 mg, 2.3×10^{-4} mol) in acetonitrile–methanol (2 mL, 3:1) was irradiated at 10°C. After 9 h of irradiation, the only product detected (gc/ms) was 5-phenylpentanal dimethylacetal (**22**), identified by comparison (gc/ms, retention time, and fragmentation pattern) with an authentic sample. After prolonged irradiation, an additional product was detected (gc/ms), to which the structure 5-(4-cyanophenyl)-5-phenylpentanal dimethylacetal (**23**) was tentatively assigned on the basis of the fragmentation pattern: 277, 245, 218, 230, 192, 165, 103 (the molecular ion was neither expected nor observed).

Authentic **23** was synthesized by a two-step process from the corresponding alcohol. 5-Phenylpentanol was oxidized, using chromium trioxide/pyridine, to 5-phenylpentanal in 88% yield by the standard procedure (29). Chlorotrimethylsilane (1.08 g, 0.01 mol) was added dropwise to a stirred solution of 5-phenylpentanal in methanol. The mixture was stirred overnight at room temperature; it was then cooled in ice, and 50 mL aqueous $NaHCO_3$ (5%) was added. The mixture was extracted (3×) with ether, and the organic layers were combined, washed with brine solution, and then dried over magnesium sulphate. The acetal **23** was purified by flash column chromatography on silica gel, eluting with methylene chloride – hexanes (75:25). The yield of pure **23** from the aldehyde was 50%; ^{1}H nmr (360 MHz) in $CDCl_3$: 7.15–7.28 (m, 5H), 4.34 (t), 1H, J = 5.72 Hz), 3.29 (s, 6H), 2.61 (t, 2H, J = 7.73 Hz), 1.62 (m, 4H), 1.39 (m, 2H); ^{13}C nmr (90 MHz): 142.5, 128.3, 125.9, 125.6, 104.4, 52.6, 35.9, 32.4, 31.3, 24.3.

A solution of *cis*- and *trans*-**13** (ca. 1:2) (20 mg, 1.1×10^{-4} mol) and **4** (24 mg, 1.9×10^{-4} mol) in acetonitrile–methanol-d_4 (2 mL, 3:1) was irradiated at 10°C for 24 h. Analysis (gc/ms, using selective ion monitoring) of the photolysate showed that deuterium (2%, one atom deuterium) was incorporated, at the benzylic position, in both isomers.

A solution of methyl *cis*- and *trans*-2-phenylcyclopentyl ether (**13**) in the ratio *cis*:*trans* = 1:64 (12 mg, 6.8×10^{-5} mol) and **4** (18 mg, 1.4×10^{-4} mol) was irradiated at 10°C. The ratio of *cis* to *trans* isomers was monitored by integrated peak areas on the gc/fid. After 45 h of irradiation, the ratio was 1:37.

*Irradiation of 2-diphenylmethyl-1,3-dioxolane (**14**)*

A solution of **14** (443 mg, 1.85×10^{-3} mol) and **4** (273 mg, 2.13×10^{-3} mol) in acetonitrile–methanol (20 mL, 3:1 ratio) was irradiated at 10°C and monitored (gc/fid). The products from the irradiation, 2-methoxy-1,3-dioxolane (**24**), diphenylmethane (**2**), and 1,1,2,2-tetraphenylethane (**1**), were identified by comparison (gc/ms, retention times, and fragmentation pattern) with those of authentic samples. After 23 h of irradiation, diphenylmethane (**2**) and 1,1,2,2-tetraphenyl-

ethane (**1**) were isolated by flash column chromatography in 90 and 10% yield at 75% conversion.

Irradiation of 2-diphenylmethyl-2-methyl-1,3-dioxolane (15)

A solution of **15** (441 mg, 1.74×10^{-3} mol) and **4** (289 mg, 2.26×10^{-3} mol) in acetonitrile–methanol (20 mL, 3:1) was irradiated at 10°C for 23 h. Progress of the reaction was monitored (gc/fid). The products of the irradiation were 2-methoxy-2-methyl-1,3-dioxolane (**25**), diphenylmethane (**2**), and 1,1,2,2-tetraphenylethane (**1**). Diphenylmethane (**2**) and 1,1,2,2-tetraphenylethane (**1**) were identified by comparison (gc/ms, retention times, and fragmentation pattern) with authentic samples. The identity of the *ortho* ester **25** was confirmed by hydrolysis to methyl acetate, as indicated by comparison (gc/ms) with an authentic sample. The hydrolysis was accomplished by refluxing the crude reaction mixture with 20 mL of 15% aqueous HCl for 1 h. The products, diphenylmethane (**2**) (85%) and 1,1,2,2-tetraphenylethane (**1**) (10%), were isolated by flash column chromatography after 85% conversion of **15**.

Irradiation of 2-phenylmethyl-1,3-dioxolane (16)

A solution of **16** (18 mg, 1.1×10^{-4} mol), **4** (14 mg, 1.1×10^{-4} mol), and cyclododecane (16. 5 mg, 9.8×10^{-5} mol) in acetonitrile–methanol (2 mL, 3:1) was irradiated at 10°C for 20 h. The major products of the irradiation were toluene (**19**), 2-methoxy-1,3-dioxolane (**24**), 1,2-diphenylethane (**5**), and (4-cyanophenyl)phenylmethane (**20**). Toluene (**19**), 2-methoxy-1,3-dioxolane (**24**), and 1,2-diphenylethane (**5**) were identified by comparison of retention times and fragmentation pattern (gc/ms) with authentic samples. The (4-cyanophenyl)phenylmethane (**20**) was isolated by column chromatography and identified by comparison (^{1}H nmr and melting point) with reported data. (4-Cyanophenyl)phenylmethane (mp 44–46°C (lit. (14) mp 49–50°C)); ^{1}H nmr (360 MHz) in $CDCl_3$: 7.14–7.56 (m, 9H), 4.02 (s, 2H). Gas chromatography/fid was used to calculate the percent yields of the products at 85% conversion; cyclododecane was used as an internal standard. The yields were toluene (**19**) 40%, 1,2-diphenylethane (**5**) 10%, and (4-cyanophenyl)phenylmethane (**20**) 20%. The estimated error in these values is ±5%. The values for **5** and **20** were confirmed by isolation using column chromatography on silica gel (Kieselgel 60) eluting with methylene chloride and hexanes.

Irradiation of 2-phenylmethyl-2-methyl-1,3-dioxolane (17)

A solution of **17** (22 mg, 1.2×10^{-4} mol), **4** (20 mg; 1.6×10^{-4} mol), and cyclododecane (14 mg, 8.3×10^{-5} mol) in acetonitrile–methanol (2 mL, 3:1) was irradiated at 10°C for 20 h. The major products of the photolysis were toluene (**19**), 2-methoxy-2-methyl-1,3-dioxolane (**25**), 1,2-diphenylethane (**5**), and (4-cyanophenyl)phenylmethane (**20**). Product analysis was done using gc/fid with cyclododecane as an internal standard. The yields of **19**, **5**, and **20** were 35, 5, and 20% respectively, at 95% conversion. The yields of **5** and **20** were confirmed by isolation using column chromatography as described above for the reaction of **16**.

4,5-Dihydro-4,5-dihydroxyimidazoles as products of the reduction of 2-nitroimidazoles. HPLC assay and demonstration of equilibrium transfer of glyoxal to guanine

RICK PANICUCCI AND ROBERT A. MCCLELLAND
Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received April 5, 1989

RICK PANICUCCI and ROBERT A. MCCLELLAND. Can. J. Chem. **67**, 2128 (1989).

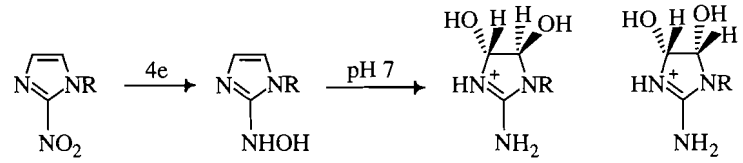
An HPLC method has been employed to study the electrochemical reduction (mercury cathode at −800 mV with respect to calomel electrode) of the 2-nitroimidazole benznidazole (*N*-benzyl-(2′-nitro-1′-imidazoyl)acetamide). The principal product of this reduction is the cyclic guanidinium ion **3***c* (protonated *N*-benzyl-(2′-amino-4′,5′-dihydro-4′,5′-dihydroxy-1′-imidazoyl)acetamide), which forms in a linear fashion as the nitroimidazole is reduced and accounts for 75% of the product upon completion of the reduction. To perform the HPLC analysis quantitatively an authentic sample of this product (isolated as *cis*:*trans* isomers) was prepared as the sulfate salt through the reaction of *N*-benzyl-2-guanidinoacetamide sulfate with aqueous glyoxal. The two isomers of **3***c* arise through the nonreductive decomposition of the 2-hydroxylaminoimidazole, which is the product of a four-electron reduction of the nitroimidazole. Analysis of high field ^{1}H NMR spectra also showed that the two isomers of **3***c* were the principal products following electrochemical reduction, neutral aqueous zinc reduction, and radiation chemical reduction. Previous investigations using NMR of the reductions of misonidazole (3-methoxy-1-(2′-nitro-1′-imidazoyl)-2-propanol) and 1-methyl-2-nitroimidazole have shown that the corresponding dihydroimidazoles **3***a* and **3***b* are the major products. The agreement of these various NMR and HPLC results suggests that the formation of dihydroimidazoles **3** is a general phenomenon for model reductions of 2-nitroimidazoles in neutral aqueous solution. Previous workers have shown that 2-nitroimidazole reduction mixtures, when treated with guanine derivatives, form the adduct **4** derived from the guanine and glyoxal. This work demonstrates that this adduct is also formed when authentic samples of **3***a*, **3***b*, and **3***c* are reacted with 2′-deoxyguanosine. A quantitative HPLC analysis, however, demonstrates that the reaction does not proceed to completion, and in fact the equilibrium for formation of **4** is unfavorable. This suggests that guanines are not useful derivatizing agents for the quantitative assay of "glyoxal-like" products formed in chemical or biological reductions of 2-nitroimidazoles.

Key words: nitroimidazole, reduction of nitroimidazoles, glyoxal from nitroimidazoles.

RICK PANICUCCI et ROBERT A. MCCLELLAND. Can. J. Chem. **67**, 2128 (1989).

On a utilisé une méthode de CLHP pour étudier la réduction électrochimique (cathode de mercure à −800 mV par rapport à l'électrode de calomel) de la 2-nitroimidazole benznidazole (*N*-benzyl-(2′-nitro-1′-imidazoyl)acétamide). Le produit principal de cette réduction est l'ion guanidinium cyclique **3***c* (*N-benzyl-(2′*-amino-4′,5′-dihydro-4′,5′-dihydroxy-1′-imidazoyl)acétamide protoné) qui se forme d'une façon linéaire au fur et à mesure que le nitroimidazole est réduit et qui forme 75% du produit à la fin de la réduction. Afin de réaliser l'analyse quantitative par CLHP, on a préparé un échantillon authentique de ce produit (isolé sous la forme de sulfates des isomères *cis/trans*) par réaction du sulfate de *N*-benzyl-2-guanidinoacétamine avec du glyoxal en solution aqueuse. Les deux isomères du produit **3***c* proviennent de la décomposition non-réductive de la 2-hydroxyaminoimidazole, le produit d'une réduction de la nitroimidazole par quatre électrons. Une analyse des spectres RMN du ^{1}H à haut champ a aussi démontré que les deux isomères du produit **3***c* sont les produits principaux de la réduction électrochimique, de la réduction par le zinc en milieu aqueux neutre et de la réduction chimique par des radiations. Des études antérieures utilisant la RMN ont aussi démontré que les réductions du misonidazole (3-méthoxy-1-(2′-nitro-1′-imidazoyl)-2-propanol) et du 1-méthyl-2-nitroimidazole conduisent principalement aux dihydroimidazoles **3***a* et **3***b* correspondants. La bonne correspondance entre les résultats de la RMN et de la CLHP suggère que la formation de dihydroimidazoles **3** est un phénomène général pour les réductions modèles de 2-nitroimidazoles, en solutions aqueuses neutres. D'autres chercheurs ont démontré antérieurement que les mélanges obtenus lors des réductions de nitroimidazoles réagissent avec des dérivés de la guanine pour former l'adduit **4** dérivé de la guanine et du glyoxal. Dans le présent travail, on démontre que ce genre de dérivé se forme aussi lorsqu'on fait réagit des échantillons authentiques des produits **3***a*, **3***b* et **3***c* avec de la 2′-désoxyguanosine. Une analyse quantitative par CLHP a toutefois permis de démontrer que cette réaction est incomplète et que, de fait, l'équilibre pour la formation de l'adduit **4** n'est pas favorable. Ce résultat suggère que les guanines ne sont pas des agents utiles pour former des dérivés permettant d'analyser quantitativement les produits «ressemblant au glyoxal» qui se forment lors des réductions chimiques ou biologiques des 2-nitroimidazoles.

Mots clés : nitroimidazole, réduction des imidazoles, glyoxal dérivé des imidazoles.



[Traduit par la revue]

2-Nitroimidazoles **1** are currently undergoing clinical trials as radiosensitizers of hypoxic (oxygen-deficient) cells (1, 2), and may also have clinical application in chemotherapy since they show selective cytotoxicity towards hypoxic cells (1). A number of the important biological effects of these drugs are associated with reductive metabolism (3), and this has led to an interest in the reduction chemistry. A variety of reduction methods have been employed to investigate this chemistry, including radiation chemical reduction (4–7), electrochemical reduction (6, 8–10), zinc/ammonium chloride reduction (11, 12), and biochemical reduction (13–18). In general, these experiments have shown a stoichiometry of four electron equivalents per nitroimidazole reduced, for aqueous solutions at pH 7. The product that corresponds to such a stoichiometry is the 2-hydroxylaminoimidazole **2**. Work in our laboratory, however, has shown that such compounds are unstable at neutral pH (6, 10, 19, 20), with half-lives ranging from 2–15 min (21, 22). The major products of their further reaction have been identified as the *cis* and *trans* 2-amino-4,5-dihydro-4,5-dihydroxyimidazolium ions **3** (10, 20, 21).

Several other groups have carried out product analyses by adding to previously reduced solutions reagents that form deriva-

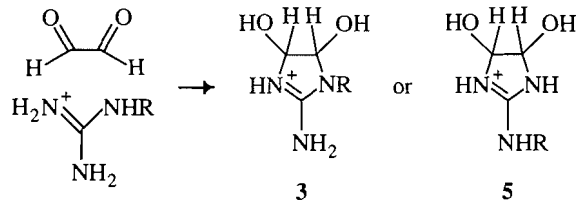
b R = CH_3
c R = $CH_2CONHCH_2C_6H_5$ (Benznidazole)

tives of aldehydes and ketones. Such experiments have been found to result in the appropriate derivatives of the two-carbon dialdehyde glyoxal (7, 12, 17, 23–26). Of particular note in a biological context is the identification of **4**, the known adduct of guanosine and glyoxal (27, 28), by addition of guanosine to a solution obtained by the reduction of various 2-nitroimidazoles with zinc in aqueous ammonium chloride (12, 23). This same derivative has been observed following radiation chemical reduction (7, 26). This adduct, moreover, has been detected upon addition of guanosine to hypoxic cells treated with misonidazole (**1***a*) (29) and by addition of guanosine to the urine of a patient receiving misonidazole (30).

[2] 

4



In general, yields of these glyoxal derivatives relative to the nitroimidazole reduced have been low, with reported numbers ranging from a fraction of a percent (7) to 25% (17). Moreover, there has been some discussion (17, 23) as to whether the reduction mixture actually contains free glyoxal or simply some species capable of reacting with the added reagent to form the glyoxal derivative. Our analyses have supported the latter viewpoint, the dihydroimidazoles **3** being able to react to give glyoxal derivatives (10). This species **3** is in fact the adduct of glyoxal and a monosubstituted guanidinium ion, with the equilibrium in aqueous solution lying well to the adduct side (10). We have moreover found that yields of **3** are high, the two isomers accounting for 80–90% of the initial nitroimidazole when reductions are carried out in the absence of other strong nucleophiles (10, 20). This result obviously contrasts with the situation for the glyoxal derivatives; we have argued that the derivatization procedures do not quantitatively produce the glyoxal adduct when **3** is the starting material.

That the two isomers of **3** constitute the major products of the reduction of 2-nitroimidazoles has come mainly from analyses of high field ^1H NMR spectra, following radiation chemical reduction, electrochemical reduction, and zinc reduction, principally of misonidazole and the model 1-methyl-2-nitroimidazole **1***b* (10). In this paper we report verification of this conclusion with an HPLC analysis conducted using the nitroimidazole benznidazole (**1***c*). This nitroimidazole is used extensively in South America for the treatment of the *Trypanosome cruzi* infection (Chaga's disease) (31), and has also been shown to function as a chemosensitizer of the antitumor agent chloroethylnitrosourea (32, 33). From the point of view of HPLC analysis, it has the advantage (18) of having a phenyl chromophore in its side chain, making the UV spectroscopic detection of **3***c* possible. The derivatives **3***a* and **3***b* are transparent down to 210 nm. We also report here experiments showing that pure samples of **3** can transfer glyoxal to guanine, but the equilibrium is unfavorable. We also provide unambiguous evidence that the structure of the **3** is the 1-substituted derivative, as written in eq. [1].

Results

Carbon-13 NMR analysis of trans *3*b

The assignment of the structure of the products of the reduction as the isomers **3** was based upon a synthesis of analytically pure samples of these species by combining aqueous glyoxal and the appropriate monosubstituted guanidinium ion (10). The ^1H NMR spectra of these products were then shown to match the principal peaks in the spectra of the reduction mixtures. As we have discussed previously, some ambiguity exists as to whether the products are actually the 1-substituted **3** or the adducts **5** where the substituent is on the external nitrogen. In the case of the nitroimidazole reduction mixtures where the substituent starts on N-1, a situation where **5** arises via a ring opening – ring closing sequence could not be rule out (10).

[3] 

3 **5**

We have now obtained unambiguous evidence for the structure **3** based upon an analysis of ^{13}C NMR spectra obtained with *trans* **3***b*. This species was obtained in pure *trans* form through the combination of glyoxal and methylguanidinium hydrochloride. This resulted in a 1:4 *cis*:*trans* ratio; recrystallization from methanol:ether gave pure (>98%) *trans*, as seen from the absence of the characteristic signal for the *cis* isomer in the ^1H NMR spectrum. The decoupled ^{13}C NMR spectrum of *trans* **3***b* (recorded in dilute DCl to suppress *trans*:*cis* equilibration (10)) had the expected four signals, at 161.0, 94.0, 86.8, and 31.8 ppm. The lowest field and highest field signals can be assigned to C2 and the methyl carbon respectively. The other two signals represent C4 and C5 but cannot be assigned from the decoupled spectrum. However, in a proton coupled spectrum (Fig. 1) these signals exhibited a different pattern. The signal at 86.8 ppm in the uncoupled spectrum appears as a doublet of doublets. This can be assigned to C4, with a large one-bond coupling to its directly attached hydrogen H4 (^1J(C4–H4) = 170 Hz) and a small two-bond coupling to H5 (^2J(C4–H5) = 2.4 Hz). The other signal at 94.0 ppm in the uncoupled spectrum, assigned to C5, is expected to have similar ^1J and ^2J couplings with H5 and H4 respectively. This signal, however, shows additional coupling, which must arise

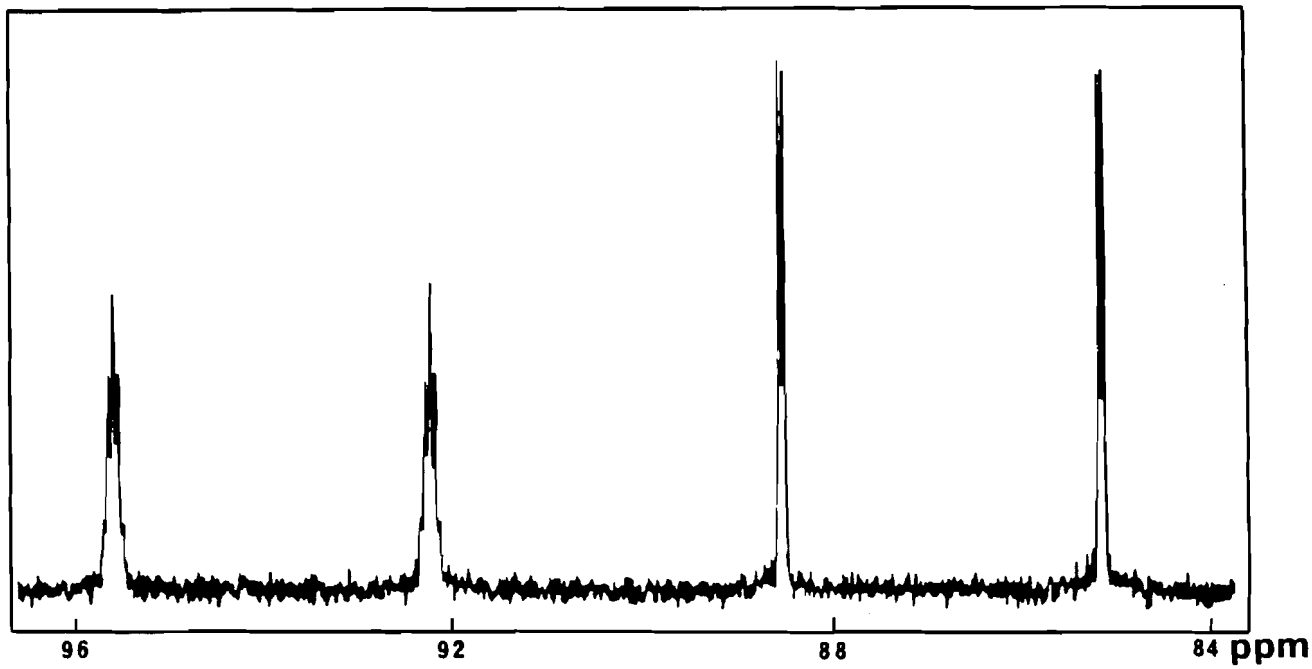

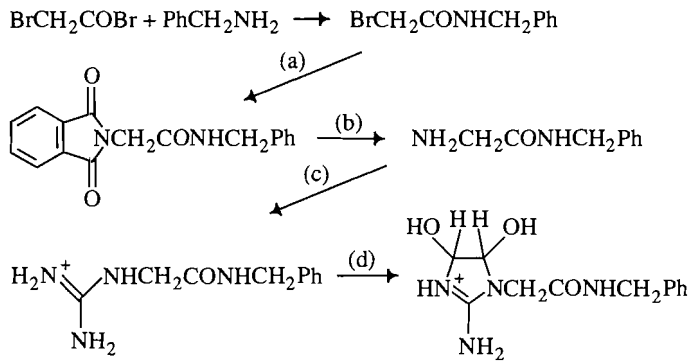

FIG. 1. Proton-coupled 50.4 MHz ^{13}C NMR spectrum (85–95 ppm region) of *trans*-**3***b* in dilute DCl.

from the protons of the methyl group. This requires the methyl group to be attached to the ring nitrogen, three bonds away, rather than to the external nitrogen, which is five bonds away, too far to show significant coupling. A five-line pattern actually results for C5 since ^2J(C5–H4) and ^3J(C5–CH_3) are similar.

Reduction of benznidazole. NMR analysis

Figure 2 shows the ^1H NMR spectrum obtained upon the crude mixture following radiation chemical reduction (4, 6) of benznidazole in phosphate-buffered neutral aqueous solution. Very similar spectra were also obtained following electrochemical reduction and reduction with zinc in aqueous ammonium chloride. The radiation chemical and electrochemical reductions also showed the expected stoichiometries of 4.0 ± 0.2 electron equivalents per nitroimidazole. The products that are consistent with the NMR spectrum and the stoichiometry are the *cis* and *trans* isomers of **3***c*, arising from the further reaction of the 2-hydroxylaminoimidazole, as in eq. [1]. A detailed discussion of the NMR pattern has been presented previously in the context of the methyl derivative **3***b*. In the present case the two pairs of doublets at 5.0–5.5 ppm (see insert) represent H4 and H5 of the two isomers of **3***c*, the major isomer (80%) with the smaller coupling constant being assigned the *trans* geometry. The set of signals at 4.15–4.3 ppm can be assigned to the NCH_2CO group of the side chain, with the two diastereotopic protons of this methylene group being nonequivalent. Again two sets of signals for the two isomers can be recognized (see insert). The remaining signals at 7.4 ppm and 4.42 ppm arise from the phenyl groups and the benzylic methylenes respectively, the latter appearing as a single peak in each isomer with, in fact, almost the same chemical shifts for the two isomers.

Verification of the structure of **3***c* was obtained by the alternate preparation from the reaction of aqueous glyoxal and the appropriate guanidinium ion. The latter was prepared as the sulfate salt, described as follows.

(a) Potassium phthalimide. (b) Hydrazine.
(c) 2-Methyl-2-thiopseudourea sulfate. (d) Aqueous glyoxal, pH 8

This sequence of reactions resulted in an analytically pure sample of the two isomers of **3***c*, whose NMR spectrum in D_2O matched that obtained from the various reductions of the nitroimidazole.

Reduction of benznidazole. HPLC analysis

The previous set of experiments, involving the unambiguous synthesis of the dihydroguanidinium ion and the demonstration of identical NMR patterns with those of reduction mixtures, are the same as those carried out earlier in characterizing the products of misonidazole and 1-methyl-2-nitroimidazole (10). As in those experiments, the two isomers of **3***c* account for virtually all the peaks in the NMR spectra of the benznidazole reduced by the three techniques. Even recognizing that the NMR limits of detection may be as high as 10–20%, particularly for complex systems, the conclusion must be that **3***c* is the major product of these reductions of benznidazole.

As noted above, the phenyl group in the side chain provides a handle for HPLC experiments with spectroscopic detection. This group also has the feature of imparting some hydrophobic

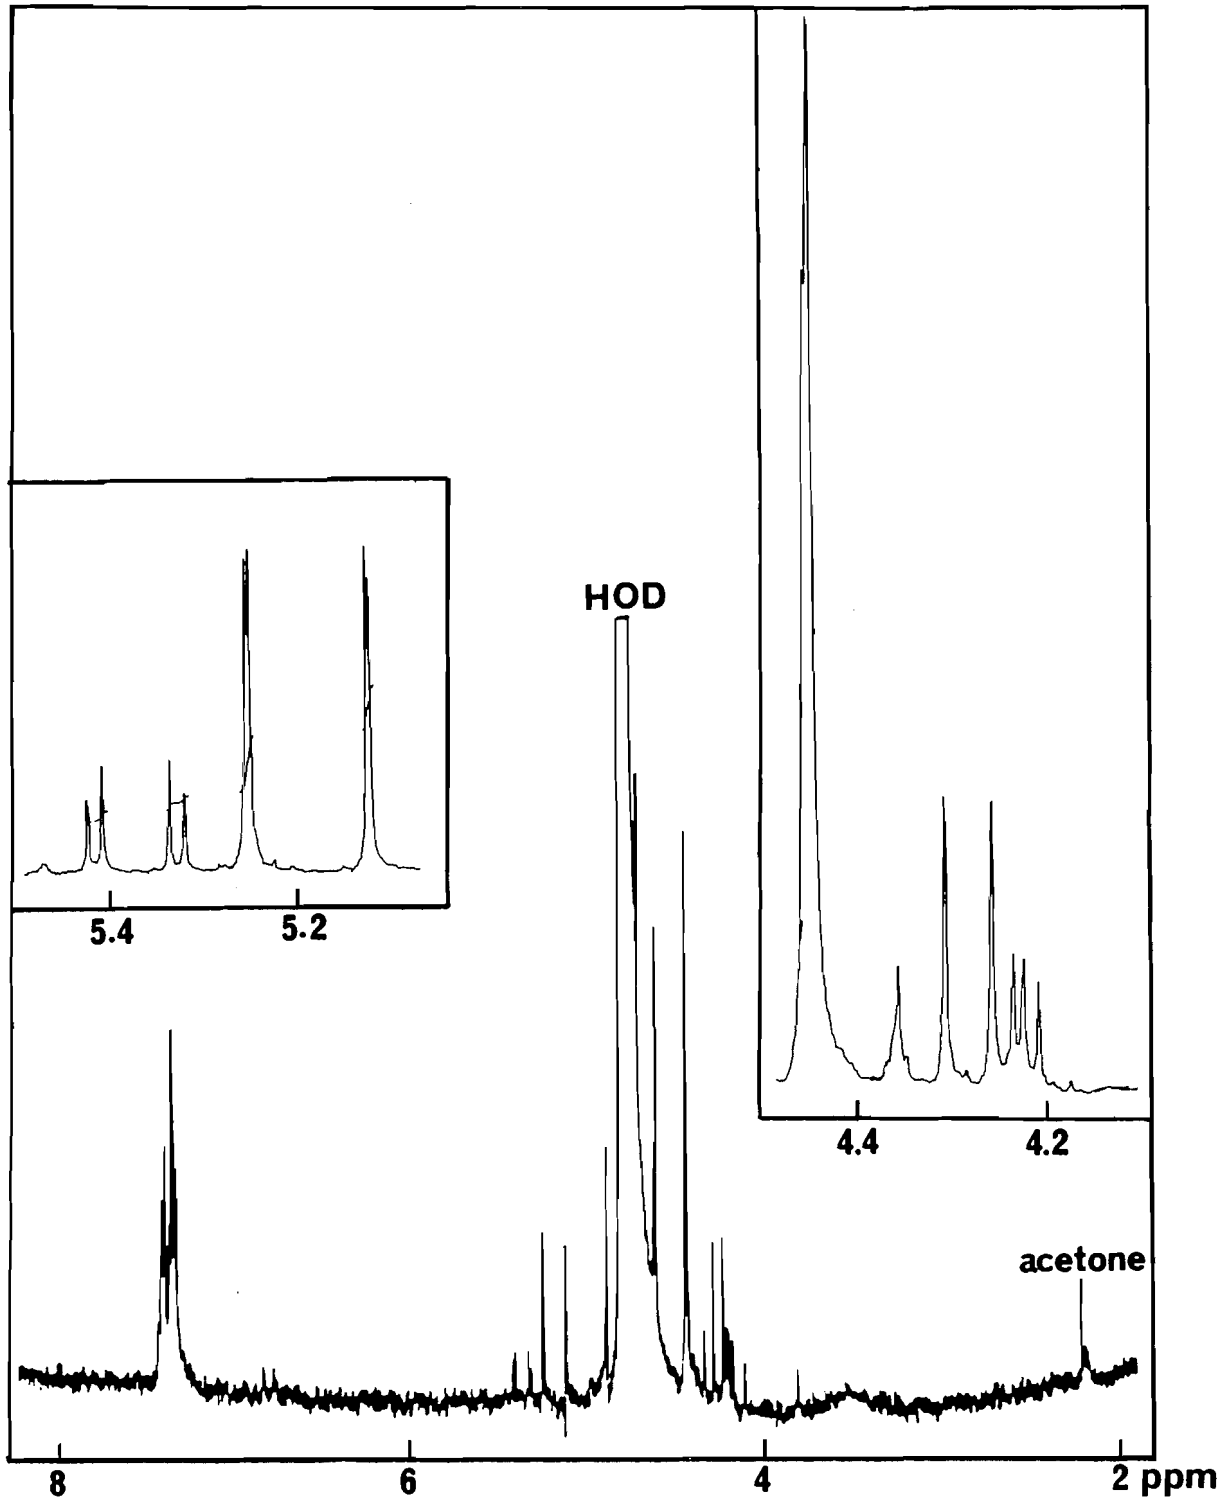

FIG. 2. The 400 MHz ^{1}H NMR spectrum of benznidazole after radiation chemical reduction in phosphate buffered D_2O at pD 7. This spectrum was obtained directly on the irradiated D_2O solution.

character so that the highly polar product ions do not migrate with the solvent front in reversed-phase HPLC. We employed HPLC conditions similar to those previously used to analyze benznidazole and its amine derivative (18), and found that authentic samples of the nitroimidazole and **3***c*, the latter prepared as described above, eluted with retention times of 8.7 min and 4.6 min respectively (the two isomers of **3***c* not separating). Figure 3 shows chromatograms obtained from the analysis of the electrochemical reduction at pH 7 of benznidazole. It is clear that as the nitroimidazole disappears, it is replaced by **3***c*. The situation is shown quantitatively in Figure 4. As expected, the nitroimidazole disappears in a linear fashion with the number of reducing equivalents. In the experiment represented in the figure a total of 9.9 coulombs was required to completely

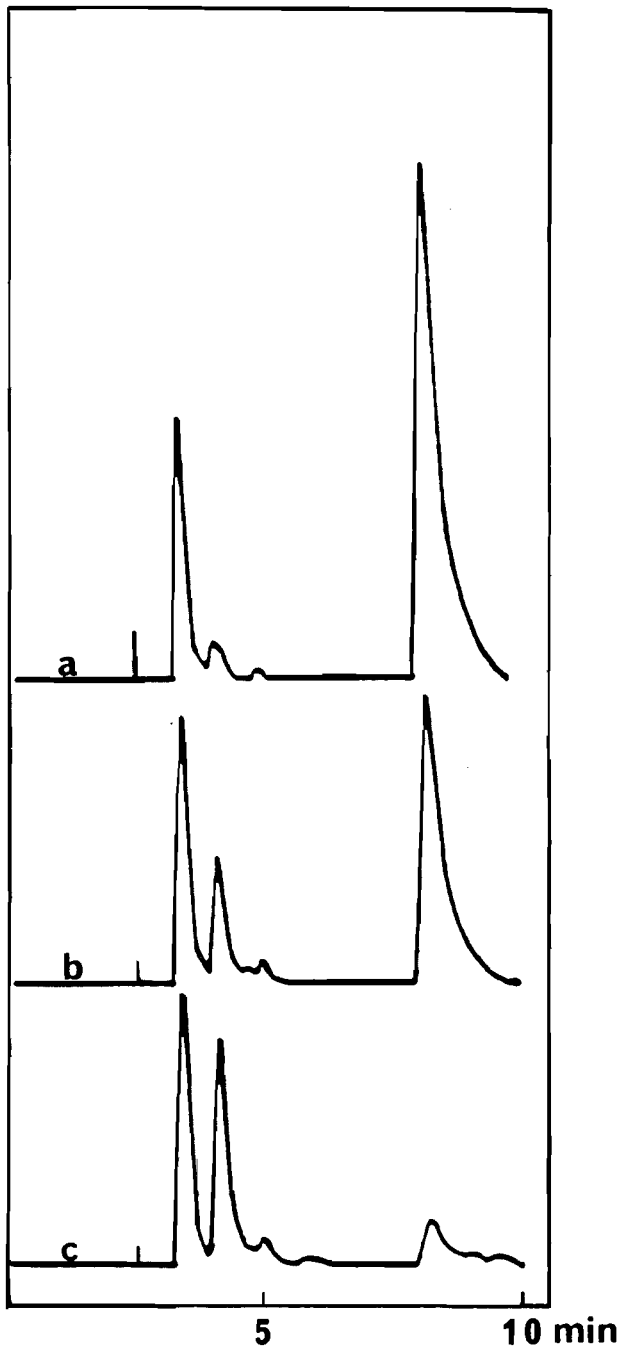

FIG. 3. HPLC chromatograms obtained during the electrochemical reduction at pH 7 of benznidazole; (a) 10% reduced, (b) 50% reduced, and (c) 90% reduced. The peaks at 8.7 min and 4.6 min correspond to benznidazole and **3***c* respectively. The peak at 3.4 min was present in all samples and is believed to be an impurity in the eluting solution. HPLC conditions: detector wavelength = 220 nm, Nova-pak C_{18} column, with eluting buffer of 25% acetonitrile, 0.2 M glycine/hydrochloric acid, pH 2.5, plus 5 mM octanesulfonic acid, flow rate = 3 mL/min.

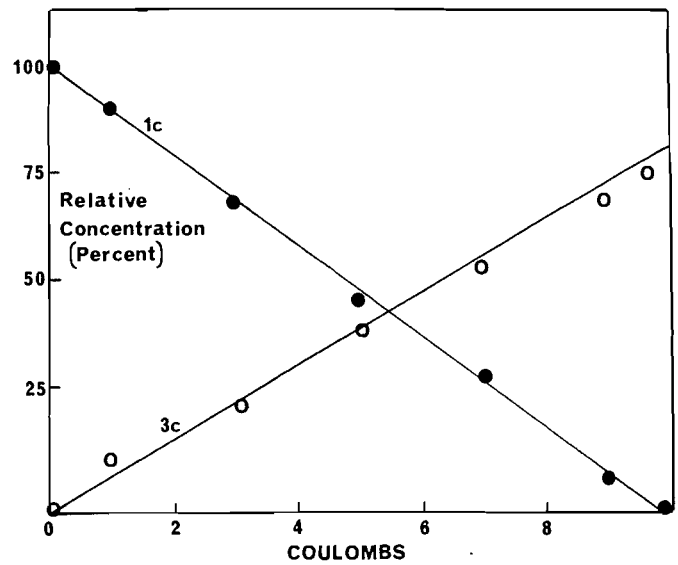

FIG. 4. Relative concentration of benznidazole **1***c* and the product **3***c* as a function of the number of coulombs passed through the solution in the electrochemical reduction of benznidazole. The initial concentration of benznidazole was 1.05 mM in a 25 mL volume (26.3 μmol). The relative concentrations of **1***c* and **3***c* were calculated from relative areas of the HPLC profiles, using standard curves constructed from injections of known amounts of authentic material.

reduce 26.2 μmol. This corresponds to a stoichiometry of 3.92 electrons per nitroimidazole, a result expected from previous studies (4, 6) where UV spectroscopy was employed to analyze for the nitro compound. As **1***c* disappears, **3***c* is formed. This production occurs in a linear fashion with the number of coulombs, indicative of the fact that **3***c* is a primary product of the reduction and that it is also stable under these experimental conditions. Using authentic samples of benznidazole and **3***c*, standard curves relating the HPLC integration units and concentration were constructed. After complete reduction, **3***c* accounts for 75% of the initial starting nitro compound.

Additional products are evident from the HPLC profiles but their identities are unknown. We have shown (10) that when reductions are carried out in phosphate buffers, a monophosphate of **3** is also formed, in yields of 10–20% even in 10 mM phosphate. Such a product is also possible in the present case, since phosphate was necessary to control the pH during the electrolysis. Another likely side product is an azoxy compound formed by coupling of the hydroxylamine product and the nitroso intermediate during reduction. This product is commonly encountered in the reduction of nitroaromatic compounds at neutral pH, and a yellow color observed in the reduced benznidazole solution was consistent with its presence. Whatever the nature of these other products, it is clear that their yields are small and they do not contribute significant signals to the NMR spectra. Moreover, the direct monitoring by HPLC has verified the conclusion of the NMR analysis, namely that **3***c* is the major product.

A product worth commenting upon, which was not present in significant yield with any of the three techniques, was the 2-aminoimidazole derivative, the result of a six-electron reduction. This substance, which was available in pure form as a standard, has in its ^{1}H NMR spectrum a characteristic pattern of doublets at 6.7–6.8 ppm associated with H4 and H5 of the imidazole ring. These doublets were observed in the zinc reduction, but accounted for only 5–10% of the overall reduction mixture. With both the radiation chemical reduction and the electrochemical reduction, no signals remained at >6 ppm.

Reaction of 3 with deoxyguanosine

These experiments were conducted to demonstrate that the dihydroimidazoles **3** can transfer the elements of glyoxal to guanine, and also to quantitatively evaluate the position of the

7

equilibrium. HPLC was used to monitor the course of the reaction, as previously described by Varghese and Whitmore (23). This involved analyzing for the relative concentrations of starting 2′-deoxyguanosine **6** and its adduct **4** by monitoring near the λ_{max} of the guanine chromophore. The HPLC elution profiles showed two peaks (Fig. 5), that for the deoxyguanosine coming at 6.0 min with the glyoxal–guanosine adduct at 4.5 min. An authentic sample of the latter was prepared as previously described, from the reaction of glyoxal and 2′-deoxyguanosine (27, 28). Standard curves were constructed for the two samples. Under the HPLC conditions both gave a single peak, indicative that interconversion between the two was not occurring on the column. As shown in Fig. 5, the dihydroimidazoles **3** did transfer glyoxal. Under the reaction conditions, aqueous solution at 25°C and pH 7.5, the reaction was slow, 2–4 days being required to reach an equilibrium condition. Moreover, the reaction did not proceed to completion. Even with a 50-fold excess of **3** some unreacted deoxyguanosine remained. Equilibrium constants ([**4**][**7**]/[**6**][**3**]) were calculated, the equilibrium concentrations of **4** and **6** being determined from the peak areas in the HPLC chromatograms, the concentration of **7** being set equal to that of **6** and the concentration of **3** being calculated by difference. (We have previously demonstrated that the equilibrium involving **3** and glyoxal plus guanidinium ion lies well to the adduct side in aqueous solution (10), so that the reaction can be represented as written in eq. [4].) Values of the equilibrium constants are summarized in Table 1. This table also shows that there is good agreement between measurements with different initial concentrations of **3**.

Discussion

We have used an HPLC method to demonstrate that the electrochemical reduction of benznidazole under neutral aqueous conditions results in a 75% yield of the corresponding dihydroimidazole **3***c*. This arises from a further nonreductive reaction of the four-electron reduction product, the 2-hydroxylaminoimidazole. The result, which is based on a direct analy-

sis while reduction is proceeding, verifies previous conclusions reached on the basis of ^{1}H NMR spectroscopy that simple model reductions of 2-nitroimidazoles produce high yields of this type of product. 2-Nitroimidazoles are reductively activated to compounds that generate covalent adducts in protein and DNA (34–36) and breaks in DNA (37), and that result in depletion of the intracellular thiol glutathione (38). We have suggested that the unstable hydroxylamine may in part be responsible for these effects, since mechanistically a reactive electrophile capable of binding cellular nucleophiles can be identified for the conversion of the hydroxylamine to products such as **3** (10, 21, 22). In general, in these model reductions the 2-aminoimidazole, which is the product of a six-electron reduction, is not observed or is found only in small quantities. This derivative, however, has been identified in biological systems, in studies both with misonidazole (39, 40) and with benznidazole (17). The origin of this species would appear to be the further reduction of the 2-hydroxylaminoimidazole and what can be proposed is that there is a competition at the hydroxylamine stage between this further reduction and the nonreductive reaction producing products such as **3**. There is evidence in fact for this competition in some of the model systems. In the present study small amounts of the amine were observed in the zinc reduction. Previous workers employing radiation chemical reduction have demonstrated with misonidazole that the amine can be produced with very high radiation doses but not with low doses (4). Moreover, catalytic hydrogenation of 2-nitroimidazoles produces only the amine derivative (41, 42).[1] Our suggestion is that in cells, there are enzymes capable of reducing the hydroxylamine further in competition with the decomposition reaction.

There is evidence that products derived from the hydroxylamine are produced in biological systems, in the findings that the guanosine–glyoxal adduct can be formed in vitro (29) and in vivo (30), and the observation in vitro of a glutathione adduct derived from the hydroxylamine (43). As demonstrated in this study, the dihydroimidazoles can transfer glyoxal to guanine, and we suggest it is these species, not glyoxal itself, that are responsible for the formation of **4** both in the model systems and in the biological systems. Our results, however, show that the reaction is incomplete, the equilibrium in fact being quite unfavorable. On this basis we suggest that guanine (or one of its derivatives) cannot be used to quantitatively analyze for glyoxal in the reduction mixtures of 2-nitroimidazoles. The unfavorable equilibrium also accounts for the low yields of the glyoxal derivative obtained in those cases where this method was employed. It is in fact interesting, considering the position of the equilibrium, that the glyoxal–guanidine adduct was observed in the biological systems. Since the equilibrium for the formation of this derivative is so unfavorable, the implication is that the amount of the precursor must have been considerably higher.

Experimental

General methods

^{1}H NMR and ^{13}C NMR spectra were recorded with a Varian 400 MHz spectrophotometer at the Department of Chemistry. Electrochemical reductions were carried out with an ECO Instruments model 550 potienstat equipped with a model 721 integrator. HPLC experiments were performed with a Varian LC 5500 system equipped with a Varian 601 data system integrator. Radiation chemical reductions were performed using a ^{60}Co Gamma cell (Atomic Energy of Canada) located at the Princess Margaret Hospital.

Materials

Benznidazole and the amine derivative of benznidazole were kindly provided by Paul Workman. 2′-Deoxyguanosine and aqueous glyoxal were from the Aldrich Chemical Co. and were used directly. The glyoxal-2′-deoxyguanosine adduct **4** was prepared as described in the literature (27, 28), and had an ^{1}H NMR spectrum identical to that reported previously. HPLC analysis of this material showed that there was no unreacted 2′-deoxyguanosine. The 4,5-dihydro-4,5-dihydroxyimidazolium salts **3***a* and **3***b* were prepared through the combination of aqueous glyoxal and the appropriate guanidinium ion, as previously described (10). The sample of **3***b*, which was obtained as the >98% *trans* isomer, was isolated in this way by dissolving the *cis*:*trans* mixture in methanol, followed by the slow addition of diethyl ether until a precipitate just formed.

N-Benzyl-2-bromoacetamide was prepared from bromoacetyl bromide (Aldrich) and benzylamine (44). *N*-Benzyl-2-phthalylamidoacetamide was prepared from *N*-benzyl-2-bromoacetamide by reacting with potassium phthalimide (45). *N*-Benzyl-2-aminoacetamide was prepared by the reaction of *N*-benzyl-2-phthalylamidoacetamide with hydrazine (46). *N*-Benzyl-2-guanidinoacetamide was obtained as its sulfate salt ($2RNHC(NH_2)_2 \cdot SO_4$) by the reaction of *N*-benzyl-2-aminoacetamide with 2-methyl-2-thiopseudourea sulfate (47). *N*-Benzyl-(2′-amino-4′,5′-dihydro-4′,5′-dihydroxy-1′-imidazoyl)acetamide was prepared as the sulfate salt ($(\mathbf{3}c)_2 \cdot SO_4$) from the reaction of *N*-benzyl-2-guanidinoacetamide sulfate with aqueous glyoxal (10).

Reduction procedures. NMR analysis

Details of these procedures have been given previously (10).

Electrochemical reduction of benznidazole with HPLC analysis

This reduction was carried out with a standard H-cell with a fritted disc separating the anode and cathode compartments. The anode was a 50 cm^2 sheet of platinum foil; this compartment contained 0.05 M NaCl. A mercury cathode (12 cm^2 surface area) was used; this was set at a constant potential of −800 mV with reference to a calomel electrode. A phosphate buffer was used to maintain pH on the cathode compartment near neutrality (pH 6.5–7.5). Both compartments were continually bubbled with nitrogen during the electrolysis. In a typical experiment 10 mg of benznidazole was dissolved in 25 mL of phosphate buffer. The reduction was monitored by periodically withdrawing 0.1 mL aliquots of the cathode solution, diluting to 1.0 mL, and determining the relative concentrations of unreduced benznidazole and **3***c* by HPLC. The number of coulombs passed at each point was read directly from the integrator. HPLC analyses were carried out on a Nova-pak C_{18} column (3.9 mm × 15 mm) with a mobile phase con-

sisting of 25% acetonitrile (HPLC grade, Aldrich) in 0.2 M glycine buffer, pH 2.5, containing 5 mM octanesulphonic acid. The column was eluted isocratically at a flow rate of 1 mL/min (column pressure 1000 psi; 1 psi = 6.9 kPa) and the absorbance was monitored at 220 nm.

Reactions of 3 with 2'-deoxyguanosine

2'-Deoxyguanosine (0.1 mM) and various concentrations of **3***a–c* were mixed in a phosphate buffer (0.05 M) and the pH adjusted to 7.5. These solutions were stored at 25°C, with aliquots being periodically withdrawn for analysis by HPLC. Generally 5–7 days were required before equilibrium was reached as judged from a constant integration of the two peaks in question. HPLC analyses were carried out using a C_{18}-10μ-Bondapak column (3 mm × 15 mm) with the mobile phase consisting of 0.25 M ammonium acetate:methanol (95:5). The column was eluted at a flow of 1 mL/min (column pressure 1000 psi) with the absorbance monitored at 258 nm.

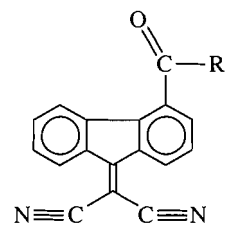
Surface-active derivatives containing fluorenylidene groups were synthesized, with the goal of creating thin-film devices incorporating monolayers of electron-transporting materials. The new compounds were studied in monolayers at the air–water interface, and were further characterized by cyclic voltammetry. The spreading behaviour of long-chain esters of a fluorenylidene malononitrile carboxylic acid was relatively insensitive to the cross-sectional area of the hydrocarbon chain, but was more strongly affected by changes in the polarity of the hydrophilic groups. Conditions for Langmuir–Blodgett deposition of multilayers of two of the new compounds on titanium-coated polyester film were also explored.

Key words: monolayers, Langmuir–Blodgett films, fluorene, surfactants.

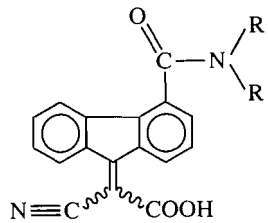
J. W. TAYLOR, C. P. SLOAN, D. A. HOLDEN, G. J. KOVACS et R. O. LOUTFY. Can. J. Chem. **67**, 2136 (1989).

Dans le but de préparer des systèmes de films minces incorporant des monocouches de substances pouvant transporter des électrons, on a synthétisé des dérivés tensio-actifs qui contiennent des groupements fluorènylidènes. On a étudié les nouveaux composés dans des monocouches à l'interface air–eau et on les a aussi caractérisés par voltamétrie cyclique. La propension à se répandre que possèdent les esters en longues chaînes d'un acide fluorènylidène malononitrile carboxylique ne varie pas beaucoup avec des variations de la surface de la section droite de la chaîne hydrocarbonée; elle est toutefois plus affectée par les changements dans la polarité des groupements hydrophiles. On a aussi exploré les conditions d'effectuer une déposition de Langmuir–Blodgett de multicouches de deux des nouveaux composés sur un film de polyester recouvert de titane.



Mots clés : monocouches, films de Langmuir–Blodgett, fluorène, agents tensio-actifs.

[Traduit par la revue]



Introduction

The development of electroactive devices incorporating Langmuir–Blodgett layers is an active area of research within the field of molecular electronics (1). Frequently it is necessary to use surface-active materials that are very different from simple long-chain carboxylic acids or alcohols. In recent years the formation of stable monolayers from a wide variety of substances containing large chromophoric groups has been described. Examples include compounds with naphthalene (2), anthracene (3), anthraquinone (4), phthalocyanine (5), porphyrin (6), and cyanine dye (7) chromophores.

As part of a collaborative research project involving the construction of electrophotographic devices in which components were assembled by monolayer transfer techniques, we required surface-active compounds containing groups that were reversibly reduced by one-electron transfer processes. This publication describes the synthesis and monolayer spreading behaviour of a number of fluorenylidene derivatives that met those requirements. Chart 1 shows that structures of the compounds prepared. Because the fluorenylidene malononitrile series of compounds **1–5** exhibited only moderate collapse pressures in monolayers, additional compounds **6** and **7** were synthesized. These allowed us to take advantage of the additional stabilization imparted to monolayers of carboxylic acids as a result of spreading on subphases containing divalent cations (3*a*, 8).

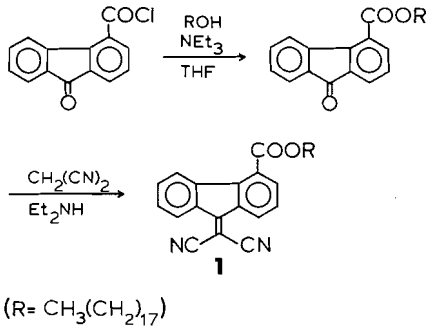
CHART 1

Results and discussion

Synthesis



The general route to fluorenylidene malononitrile derivatives substituted by a long hydrocarbon chain is shown in Scheme 1.

It was also possible to reverse the order of the steps, by first forming the fluorenylidene malononitrile carboxylic acid (9, 10) and then adding the long chain, with comparable overall yields.

In general the extension of known small-molecule chemistry to syntheses involving long-chain compounds was achieved with only minor changes in reaction times or temperatures. An exception was encountered in the synthesis of the cyanoacetic

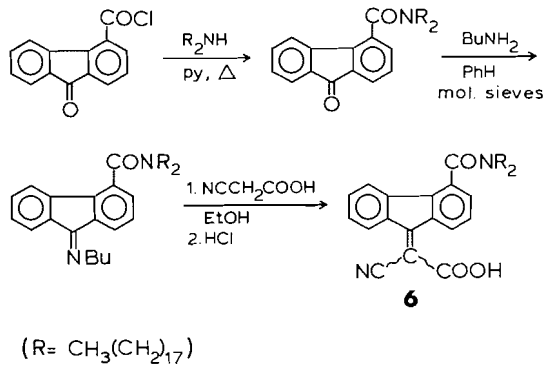
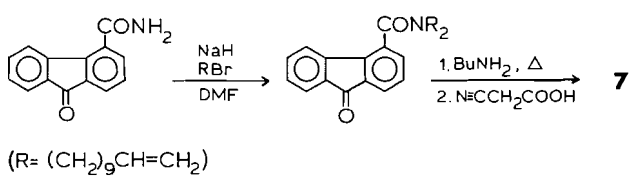


SCHEME 1

acid derivatives **6** and **7**. Attempts to react cyanoacetic acid directly with the fluorenone precursor either gave no reaction, or under more vigorous conditions gave only decarboxylation products (eq. [1]) (10). When the carboxyl group was first



activated by conversion to the *N*-butyl imine, the reaction with cyanoacetic acid proceeded smoothly under conditions as mild as room temperature (Scheme 2).

SCHEME 2

Very few dialkylamines in which both alkyl groups are long hydrocarbon chains are available commercially. For the preparation of *N*,*N*-dialkylamides of the fluorenone derivatives the use of long-chain dialkylamines could be avoided by the method shown in Scheme 3 (11). In this reaction the primary amide was

SCHEME 3

converted to a tertiary amide by nucleophilic displacement in dry DMF, in a reaction involving excess sodium hydride and 2.2 equivalents of a primary haloalkane.

Monolayer spreading behaviour

Figure 1 shows the surface pressure – area curves of the three long-chain esters **1–3** on pure unbuffered water at 25°C. In the case of the octadecyl ester **1** stable monolayers were obtained with collapse pressures of 7.7 mN m^{-1} and collapse areas of 0.43 nm^2 $molecule^{-1}$. Because of the low collapse pressure of monolayers of **1**, other esters **2** and **3** containing bulkier hydrocarbon chains were synthesized in an effort to see whether more stable monolayers would result if the hydrocarbon chains had cross-sectional areas closer to that of the aromatic ring system. The spreading curves of compounds **2** and **3** in Fig. 1 show that this approach was only partially successful. The density and rigidity of the monolayer from the oleyl ester **2** were even less than those of the saturated ester **1**, as shown by the collapse pressure of 5.8 mN m^{-1} around a molecular area of 0.57 nm^2 $molecule^{-1}$. With a branched hydrocarbon chain, as in the phytyl ester **3**, a less marked increase in molecular area was accompanied by a significant increase in the surface pressure reached at the collapse point. Unfortunately the collapse pressure of 10.7 mN m^{-1} was still too low to allow transfer of one-component monolayers to solid supports by the Langmuir–Blodgett method.

A second group of compounds, amides **4** and **5**, was also studied to see whether the stability of the monolayers could be enhanced by the use of other linkages between the hydrophobic and hydrophilic parts of the molecule. Monolayers of the secondary amide **4** reached significantly higher surface pressures, up to 27 mN m^{-1} (Fig. 2), with limiting molecular areas of 0.35 nm^2 $molecule^{-1}$ and apparent collapse area of 0.25 nm^2 $molecule^{-1}$. It is difficult to visualize a mode of packing that would allow compound **4** to pack almost as closely as a planar zigzag hydrocarbon chain, so that it is likely that the spreading of **4** to a monolayer from $CHCl_3$ was incomplete. This is a frequent problem with long-chain primary and secondary amines, which have low solubility in $CHCl_3$ and other common spreading solvents. Monolayers of the tertiary amide **5** were considerably more expanded than those of the esters, and had limiting molecular areas and collapse areas of 1.20 and 0.86 nm^2 $molecule^{-1}$, respectively. Because the maximum

TABLE 1. Deposition ratios d for Langmuir–Blodgett transfer of monolayers of fluorenylidene-containing surfactants to metallized polyester film

Monolayer	Number of layers	Deposition pressure (mN m^{-1})	d^a
1 + eicosanoic acid	1	25	1.09
(3:2)	3	25	0.99
on pure water	5	25	1.03
6 on	1	17	1.01
10^{-3} M $CdCl_2$,	3	17	0.66[b](1.01, 0.74, 0.25)
pH 8.0	5	17	0.56[b](0.99, 0.75, 0.15, 0.66, 0.27)

[a]Deposition of first layer corresponds to withdrawal of film.
[b]Average value; values for individual immersion and withdrawal steps are shown in parentheses.

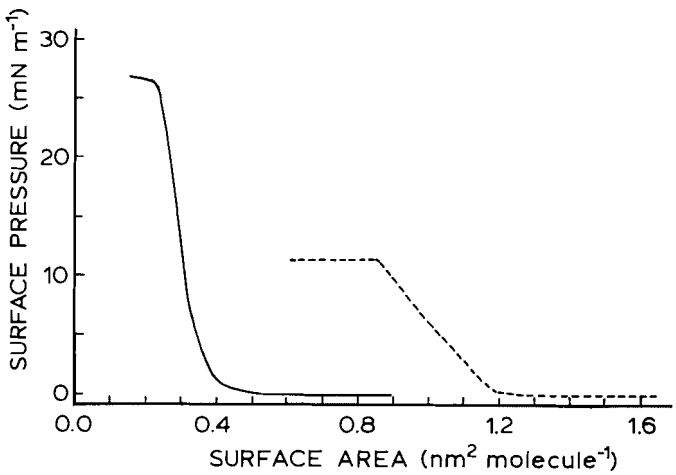

FIG. 2. Surface pressure – molecular area isotherms for monolayers of fluorenylidene malononitrile amides on pure water at 20°C. (—) *N*-octadecylamide **4**; (---) *N*,*N*-dioctadecylamide **5**.

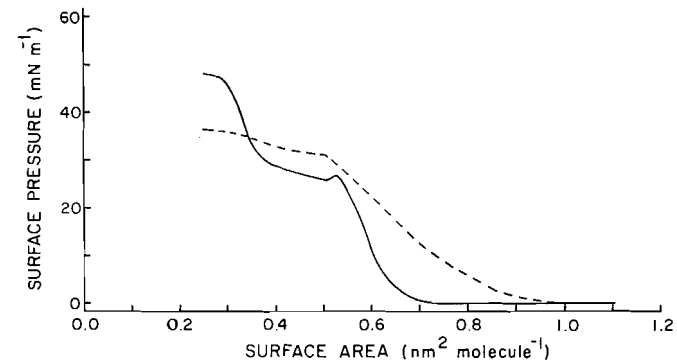

FIG. 3. Surface pressure – molecular area isotherms of surfactants containing the α-fluorenylidene cyanoacetic acid group on 10^{-4} M $CdCl_2$ at 20°C. (—) *N*,*N*-dioctadecylamide **6**; (---) *N*,*N*-di(10-undecenyl)amide **7**.

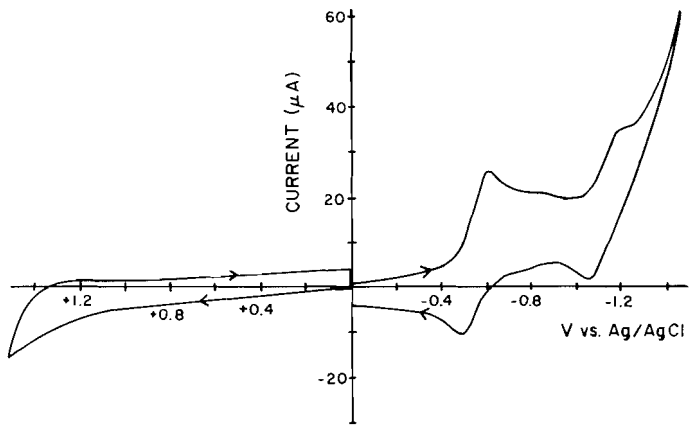

FIG. 4. Cyclic voltammogram of compound **1**, 10^{-3} M in deoxygenated CH_2Cl_2 containing 0.1 M Bu_4N^+ ClO_4^- electrolyte.

surface pressure was only 11 mN m^{-1}, these monolayers would have about the same stability during transfer as those prepared from the phytyl ester.

It became apparent that the best way to increase the stability of these compounds towards manipulation in monolayers was to modify the hydrophilic group. Accordingly compounds **6** and **7**, derived from cyanoacetic acid, were synthesized. In addition to the possibility of strengthening monolayers of these compounds by transferring them as salts with divalent cations, these compounds, since they consist of a mixture of *E* and *Z* isomers, would be expected to be less sensitive toward collapse to the bulk crystalline state. The surface pressure – area curves in Fig. 3 show that this is indeed the case. Both compounds formed monolayers, with collapse pressures over twice as high as for the dicyano derivatives.

Besides the formation of stable monolayers at the air–water interface, an additional requirement for the incorporation of the fluorenylidene derivatives into thin-film devices was the ability to undergo transfer to solid supports. Table 1 lists values of the deposition ratio d, defined in eq [2], for several of the new compounds on titanium-coated poly(ethylene terephthalate) film.

$$[2] \quad d = \frac{\text{Decrease in area of monolayer on the water surface}}{\text{Apparent area of monolayer-coated film}}$$

Because of the low collapse pressures of the dicyano-substituted compounds **1**–**5**, transfer of pure monolayers was not possible using our apparatus. The collapse pressures of mixed monolayers of **1** with eicosanoic acid were, however, sufficiently high to allow transfer, and deposition ratios of 1.0 within experimental error were obtained, which are characteristic of well-defined Langmuir–Blodgett layers. Pure monolayers of the cyanoacetic acid derivative **6** had high enough collapse pressures for direct deposition, but only the first monolayer was transferred with a deposition ratio of 1.0. Subsequent immersion and withdrawal steps showed lower deposition ratios, which are typical of imperfect transfer, and displayed a tendency toward higher deposition ratios on immersion than on withdrawal. Similar behaviour was observed for subphase pH between 4.4 and 8.0. The results of Table 1 establish that

[b]Versus Ag/Ag Cl electrode.

Langmuir–Blodgett transfer of these fluorenylidene-containing surfactants is indeed possible, but that it is worthwhile to seek out a window of conditions of subphase composition, temperature, and dipping speed, which could lead to improved deposition.

Characterization by cyclic voltammetry

Figure 4 shows the cyclic voltammogram of compound **1** in deoxygenated methylene chloride. As is evident from the figure and from the compilation of reduction potentials in Table 2, the dicyano-substituted fluorenylidene compounds have two well-defined reversible reductions in CH_2Cl_2 solution, with typical reduction potentials of −0.5 and −1.1 V vs. the Ag/AgCl electrode. Only in the case of the *N,N*-dioctadecyl amide **5** was the second reduction obscured. It may be that the hydrocarbon environment provided by the two long chains suppressed the second reduction. In the case of the cyanoacetic acid derivative **6** both reductions were irreversible, an indication that a chemical reduction is associated with the one-electron reduction. One possibility is the decarboxylation reaction shown in eq. [1].

Conclusions

This research establishes the incorporation of the redox-active fluorenylidene group into compounds that form stable, transferable monolayers. An effort to create monolayers more resistant to collapse in the form of the cyanoacetic acid derivatives **6** and **7** was successful, but resulted in undesirable changes in the electrochemistry of the redox-active functional group. In terms of ease of synthesis, chemical stability, and transferability of monolayers, the octadecyl ester **1** was the most promising compound, even though it was necessary to dilute it with eicosanoic acid to obtain multilayer films of adequate quality. The assembly and performance evaluation of thin-film devices incorporating these new compounds will be described in a later publication.

Experimental

General methods

The nmr spectra were recorded on Bruker AM-250 and AC-200 spectrometers. Infrared spectra were recorded with a Perkin–Elmer 983 instrument. The uv–visible absorption spectra were recorded on a Cary 118 spectrometer. Mass spectra were recorded with electron impact ionization on a VG 7070 instrument, or with ionization under FAB conditions on a ZAB-E mass spectrometer. Elemental analyses were performed by Guelph Chemical Laboratories, Guelph, Ontario.

Yields refer to compounds that were homogeneous to all available spectroscopic techniques and to tlc, and of sufficient purity for monolayer studies. Thin-layer chromatography was performed using EM-60 silica gel plates, and chromatograms were visualized with short wavelength uv light, using phosphomolybdic acid or *p*-anisaldehyde. Column chromatography was performed using 230–400 mesh silica gel (Merck). Preparative tlc was carried out on 20 × 20 × 0.25 cm precoated silica gel plates (Merck Kieselgel 60 F_{254}).

9-Fluorenone-4-carboxylic acid was provided by Xerox Research Centre of Canada and served as the starting point for the synthesis of the fluorenylidene series of surfactants.

9-Fluorenylidene propanedinitrile-4-carboxylic acid n-*octadecyl ester* **1**

To a solution of 6.06 g 9-fluorenone-4-carboxylic acid (27 mmol) in CH_2Cl_2, 6.3 g of thionyl chloride (53 mmol) and 3 drops of *N,N*-dimethylformamide were added and the mixture was stirred overnight at room temperature. Distillation of the excess $SOCl_2$ and CH_2Cl_2 and drying under vacuum left a green solid, which was used in the next step without further purification; ir (Nujol): 1764, 1715 cm^{-1}.

A solution of 3.0 g of the above acid chloride (12.4 mmol) in 15 mL of dry THF was mixed with 3.35 g 1-octadecanol (12.4 mmol) (Sigma, 99%) in 15 mL of dry THF. After 1.25 g (12.4 mmol) of dry triethylamine was added the mixture was refluxed overnight. The solvent was evaporated at reduced pressure and the solid residue was washed with water and then extracted with benzene. The crude product obtained after evaporation of the solvent and drying *in vacuo* had mp 68–70°C; ir (Nujol): 1726 (br) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.88 (t, 3H, J = 6.7 Hz), 1.25 (unresolved m, 30H), 1.85 (m, 2H), 4.41 (t, 2H, J = 6.7 Hz), 7.26–8.31 (m, 7H).

A solution of 1.5 g (3.15 mmol) of the crude ester, 0.25 g (3.78 mmol) of malononitrile, and 0.5 mL (9.7 mmol) of diethylamine in 110 mL of dry benzene was stirred for 4 h at 35°C. The benzene was removed on a rotary evaporator and the product was extracted into cyclohexane, washed with water, and dried. Following removal of the solvent the product was recrystallized from absolute ethanol. A total of 1.37 g (83%) of a deep yellow solid was obtained; mp 79–81°C; ir (Nujol): 2224, 1729 cm^{-1}; uv (cyclohexane) λ_{max}: 364 nm (ε 20 900 M^{-1} cm^{-1}), 351 (24 300), 304 (19 800), 280 (40 400); ^1H nmr ($CDCl_3$) δ: 0.88 (t, 3H, J = 6.9 Hz), 1.25 (unresolved m, 30H), 1.81 (m, 2H), 4.41 (t, 2H, J = 6.7 Hz), 7.33–7.54 (m, 3H), 7.84 (d, 1H, J = 7.8 Hz), 8.19 (d, 1H, J = 7.8 Hz), 8.45 (d, 1H, J = 7.8 Hz), 8.61 (d, 1H, J = 7.9 Hz); ^{13}C nmr (63.1 MHz, $CDCl_3$) δ: 14.2, 9 resolved signals between 22.80 and 32.02 ppm, 66.23, 12 resolved signals between 113.39 and 141.07, 160.06, 166.64. *Anal.* calcd. for $C_{35}H_{44}N_2O_2$: C 80.11, H 8.45, N 5.34%; found: C 80.41, H 8.64, N 5.01%.

9-Fluorenylidenemalononitrile-4-carboxylic acid cis-*7-octadecenyl ester* **2**

A solution of 10 g (44.5 mmol) of 9-fluorenone-4-carboxylic acid, 3.25 g (49.2 mmol) of malononitrile, and 4.6 mL (89 mmol) of diethylamine in 125 mL of dry THF was stirred for 6 h at room temperature. The precipitate was filtered off and dissolved in hot water. The cooled aqueous solution was acidified with HCl and the precipitate was filtered and dried in air. The product, 9-fluorenylidenemalononitrile-4-carboxylic acid, was dissolved in THF and precipitated into hexane, filtered off, and dried in vacuum; mp 287–290°C; ir: 2222, 1700 cm^{-1}; ^1H nmr (DMSO-d_6) δ: 7.36–8.29 (m, 7H), 13.76 (br s, 1H).

Five grams of the above acid was converted to 9-fluorenylmalononitrile-4-carbonyl chloride **8** with excess thionyl chloride in CH_2Cl_2. After the mixture had become homogeneous, the solvent was removed under vacuum leaving the crude acid chloride; ir: 2220, 1780 cm^{-1}. The acid chloride (0.372 g, 1.28 mmol) and pyridine (1 mL) were added to 40 mL of CH_2Cl_2, followed by 0.413 g (1.50 mmol) of oleyl alcohol (Sigma, 99%). The mixture was refluxed overnight, dilute HCl was added, and the organic layer was extracted with NaCl solution. After evaporation of the CH_2Cl_2 the product was purified by column chromatography on silica gel, eluting with 5% ethyl acetate in hexane. The product (280 mg, 42%) was a viscous orange oil; ir (neat): 2225, 1725 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.88 (t, J = 6.2 Hz, 3H), 1.15–1.60 (br m, 22H), 1.63 (quintet, J = 7.2 Hz, 2H), 2.01 (quartet, J = 5.4 Hz, 4H), 4.42 (t, J = 6.7 Hz, 2H), 5.30–5.37 (m, 2H), 7.32–8.61 (m, 7H); ms m/z: 522 (M^+, rel. intensity 24), 272 (58), 256 (27), 255 (70), 82 (100). *Anal.* calcd. for $C_{35}H_{42}N_2O_2$: C 80.42, H 8.10, N 5.76%; found: C 79.78, H 8.32, N 6.06%.

9-Fluorenylidenemalononitrile-4-carboxylic acid 3,7,11,15-tetramethyl-2-hexadecenyl (phytyl) ester **3**

The phytyl ester of 9-fluorenylmalonitrile-4-carboxylic acid was prepared from the acid chloride **8** and phytol (Aldrich) following the procedure for the oleyl ester, and was purified by column chromatography on silica gel, eluting with 5–35% ethyl acetate in hexane. The product, obtained in 54% yield, was a viscous orange oil; ir (neat): 2226, 1725 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.80–0.90 (m, 12H), 1.00–1.60 (m, 19H), 1.80 (br s, 3H), 2.12 (two overlapping triplets, J = 7.6 Hz, 2H), 4.92 (m, 2H), 5.50 (br t, J = 7.2 Hz, 1H), 7.33–8.60 (m, 7H); ^{13}C nmr ($CDCl_3$) δ: 14 resolved lines between 16.55 and 44.11 ppm, 62.42 (*cis*-), 62.75 (*trans*-phytyl, major isomer), 16 aromatic and olefinic C signals between 113.25 and 144.21 ppm, 159.96, 166.54; ms m/z: 550 (M^+, rel. intensity 2), 272 (60), 255 (42), 227 (10), 124 (33), 123 (77).

9-Fluorenylidenemalononitrile 4-carboxylic acid N-*octadecylamide* **4**

The acid chloride **8** (0.426 g, 1.47 mmol) was dissolved in dry CH_2Cl_2 and excess pyridine was added. After 20 min of stirring, octadecylamine (0.593 g, 2.2 mmol) was added and the mixture was stirred for 2 days at room temperature. After extraction with dilute HCl, the organic layer was washed with dilute Na_2CO_3 and then with brine. After evaporation of the solvent the crude product was chromatographed on silica gel, eluting with 5–30% ethyl acetate in hexane. The eluted product was recrystallized from acetone to give 406 mg (53%) of yellow crystals, mp 147–148°C; ir (Nujol): 2225, 1634 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.88 (t, J = 6.7 Hz, 3H), 1.26 (br s, 30H), 1.66 (quintet, J = 6.9 Hz, 2H), 3.53 (quartet, J = 6.9 Hz, 2H), 5.91 (br t, J = 6.9 Hz, 1H), 7.30–8.51 (m, 7H); ms m/z: 524 (M + 1, rel. intensity 5), 523 (12), 255 (49), 43 (100). *Anal.* calcd. for $C_{35}H_{45}N_3O$: C 80.26, H 8.66, N 8.02%; found: C 80.96, H 9.07, N 7.89%.

9-Fluorenylidenemalononitrile-4-carboxylic acid N,N-*dioctadecylamide* **5**

Compound **5** was prepared from the acid chloride **8** and dioctadecylamine (Fluka) following the procedure for the amide **4**. The yield of yellow crystals, mp 52–54°C, following chromatography and recrystallization from acetone, was 25%; ir: 2253, 2228, 1630 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.88 (t, J = 6.9 Hz, 6H), 1.26 (br s, 62H), 1.76 (m, 2H), 3.10 (m, 2H), 3.58 (m, 2H), 7.26–8.49 (m, 7H); ms m/z: 775 (M − 1, rel. intensity 4), 721 (12), 225 (32), 43 (100). *Anal.* calcd. for $C_{53}H_{81}N_3O$: C 82.01, H 10.52; N 5.41%; found: C 81.65, H 10.52, N 5.71%.

(E,Z)-9-Fluorenylidene cyanoacetic acid-4-carboxylic acid N,N-*dioctadecylamide* **6**

9-Fluorenone-4-carbonyl chloride, prepared from 4.484 g (20 mmol) of the corresponding acid, was dissolved in 50 mL of dry benzene and 13.57 g (26 mmol) of dioctadecylamine was added. After 5 h of refluxing the solvent was evaporated and the crude product was chromatographed on silica gel with 5–100% ethyl acetate in hexane as eluant. The pure product (5.6 g, 39%) was a waxy yellow solid; ir: 1717, 1636 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.87 (t, J = 6.8 Hz, 6H), 1.26 (br m, 62H), 1.78 (m, 2H), 3.15 (m, 2H), 3.61 (m, 2H), 7.26–7.70 (m, 7H); ms m/z 728 (M + 1, rel. intensity 10), 727 (M^+, 2), 700 (26), 535 (60), 507 (91), 479 (38), 207 (100), 169 (42).

The preceding amide (2.64 g, 3.63 mmol) was refluxed in 30 mL benzene over molecular sieves in the presence of 5 mL of butylamine for 2 days under N_2. The benzene was removed and the imine was dissolved in dry ethanol. Cyanoacetic acid (0.401 g, 4.7 mmol) was added and the mixture was heated to 70°C for 4 h. Following evaporation of the ethanol, the product was dissolved in the minimum amount of methanol and ether was then added. On cooling to −10°C, the salt of compound **6** with butylamine precipitated. It was filtered off and dissolved in CH_2Cl_2 and converted to the free carboxylic acid by washing with 5 M HCl. Following evaporation of the CH_2Cl_2 layer the product was purified by preparative tlc on silica gel, eluting with 35% ethyl acetate in hexane. Compound **6**, a yellow solid, was obtained in 30% yield; mp 136–139°C; ir (Nujol): 2199, 1660, 1625 cm^{-1}; uv ($CHCl_3$) λ_{max}: 266 nm (ε 1.60 × 10^4 M^{-1} cm^{-1}), 273 (1.75 × 10^4), 294 (5.06 × 10^3), 330 (7.47 × 10^3), 334 (8.10 × 10^3); ^1H nmr ($CDCl_3$) δ: 0.88 (t, J = 5.5 Hz, 6H), 1.04–1.40 (br m, 62H), 1.77 (br s, 2H), 3.09 (t, J = 6.3 Hz, 2H), 3.59 (t, J = 6.6 Hz, 2H), 7.13–8.55 (m, 7H); ^{13}C nmr ($CDCl_3$) δ: 170.20, 169.92, 145.92, 139.35, 137.10, 136.62, 130.70, 128.68, 127.75, 125.09, 121.78, 119.31, 48.98, 45.24, 31.93, 8 resolved lines between 29.74 and 22.69, 14.09; ms (positive ion FAB, compound dissolved in thioglycerol) m/z: 796 (M^+, rel. intensity 3), 369 (20), 279 (34), 261 (20), 217 (100), 199 (38), 181 (69), 149 (36), 109 (87). A total of 41% of the starting fluorenone 4-carboxylic acid dialkylamide was also recovered.

(E,Z)-9-Fluorenylidene cyanoacetic acid-4-carboxylic acid N,N-*di-(10-undecenyl)amide* **7**

9-Fluorenone-4-carbonyl chloride was converted to the corresponding amide by reaction with excess ammonia gas in CH_2Cl_2. This amide (1.1 g, 4.9 mmol) was dissolved in dry DMF (40 mL) and NaH (0.118 g, 4.9 mmol) was added. The evolution of H_2 ceased after 15 min, and 1-bromo-10-undecene (1.2 g, 5.1 mmol) was added. After 1 h at room temperature NaH (0.141 g, 5.9 mmol) was added, followed 20 min later by a further 1.37 g (5.9 mmol) of 1-bromo-10-undecene. After 4 h at room temperature the solvent was removed on a rotary evaporator. The product was dissolved in CH_2Cl_2 and the organic solution was extracted with dilute HCl, dilute $NaHCO_3$, and water. Following removal of the solvent the compound was chromatographed on silica gel using 5–35% ethyl acetate in hexane as eluant. The product (1.962 g, 76%) was a viscous yellow oil; ir: 1716, 1637 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.03–2.10 (m, 32H), 3.12–3.64 (m, 4H), 4.89–5.06 (m, 4H), 5.69–5.89 (m, 2H), 7.26–7.71 (m, 7H); ms m/z: 528 (M + 1, rel. intensity 30), 389 (7), 208 (17), 207 (100), 179 (19).

The preceding *N*,*N*-dialkylamide (1.90 g, 3.6 mmol) was refluxed with *n*-butylamine (20 mL) and molecular sieves for 30 h. The excess amine was removed and the imine was dissolved in dry ethanol. Following addition of cyanoacetic acid (0.459 g, 5.4 mmol) the mixture was stirred at room temperature for 20 h. The reaction mixture was concentrated by partial evaporation of the solvent and then passed through a short silica gel column to separate unreacted imine. The product was then chromatographed on reverse-phase silica gel, eluting with 35% ethyl acetate in hexane, then again on normal silica gel, eluting with 10–100% ethyl acetate in hexane, followed by absolute ethanol, to yield 0.774 g (36%) of an orange crystalline solid; mp: decomposition with gas evolution between 155 and 170°C; ir: 2198, 1636 cm^{-1}; uv ($CHCl_3$) λ_{max}: 272 nm (ε 2.77 × 10^4 M^{-1} cm^{-1}), 343 (1.10 × 10^4); ^1H nmr ($CDCl_3$) δ: 0.94–2.07 (m, 32H), 3.01–3.63 (m, 4H), 4.88–5.05 (m, 4H), 5.67–5.92 (m, 2H), 7.00–8.34 (m, 7H), 11.4 (br s, 1H); ^{13}C nmr ($CDCl_3$) δ: 9 resolved lines between 26.50 and 33.87 ppm, 45.85, 49.26, 11 resolved lines between 114.20 and 139.19, 149.60, 164.10, 170.55; ms (negative ion FAB, compound in thioglycerol) m/z: 594 (M^+, rel. intensity 16), 550 (35), 202 (52), 186 (100). For monolayer studies this compound was further purified by preparative tlc.

Monolayer studies were conducted using a surface film balance similar to an instrument described in the literature by Albrecht (12). The trough itself was milled from solid Teflon and was attached to a thermostated aluminum base plate with a stainless steel perimeter clamp. Movement of the barrier was achieved by a Teflon-coated threaded rod, driven by a stepping motor that was moved in half-steps (0.9°). The compression speed was typically 0.04 nm^2 $molecule^{-1}$ min^{-1}. Surface pressures were measured by the Wilhelmy hanging plate technique, using 1 cm × 1.5 cm strips of filter paper as the wettable material. The balance was surrounded by a glass enclosure and was isolated from vibration by resting on an air-suspension table (Technical Manufacturing Corp.). Movement of the stepping motor, measurement of surface pressure, recording of subphase temperature, and data analysis and plotting were controlled by a Hewlett–Packard 87XM computer interfaced through a Hewlett–Packard 3421A data acquisition unit. For monolayer studies water was purified with a pair of Millipore filtration systems connected in series. Compounds were spread from approximately 1 mg/mL solutions in $CHCl_3$ by means of a gas-tight 50 μL syringe fitted with a Chaney adaptor. The surface of the film balance was cleaned weekly with a solution of Nochromix (Godax

Laboratories) in concentrated sulfuric acid. The performance of the balance was monitored by running of isotherms for palmitic and stearic acids, and by comparison with results obtained using a second instrument, a circular trough described by Fromherz (13). Transfer of monolayers to metallized polyester film was carried out using the Fromherz round trough and a Lauda filmlift. The substrates were 5 cm × 5 cm squares of 75 μm-thick poly(ethylene terephthalate) foil (Dupont, Mylar D) sputter-coated with titanium under high vacuum to an optical density of 0.73–75 in the visible, and were used without further surface treatment. Monolayers were compressed to the deposition pressure at a compression rate of 0.025 nm^2 $molecule^{-1}$ min^{-1} and transfer was begun as soon as the deposition pressure had been reached. The first layer was deposited on withdrawal from the subphase at a speed of 3.5 mm min^{-1}. Subsequent immersion and withdrawal steps were carried out at a dipping speed of 5 mm min^{-1} without pauses between cycles.

Characterization of compounds by cyclic voltammetry (14) was carried out with a Princeton Applied Research model 174A polarographic analyzer and a model 175 universal programmer. The sample cell contained a platinum working electrode, a platinum wire counter-electrode, and a Ag/AgCl reference electrode. Sample solutions in CH_2Cl_2 were prepared containing 1×10^{-3} M of the compound under study and 0.1 M tetrabutylammonium perchlorate as the electrolyte, and were purged with argon during measurements. The scan rate for all experiments was 200 mV s^{-1}.

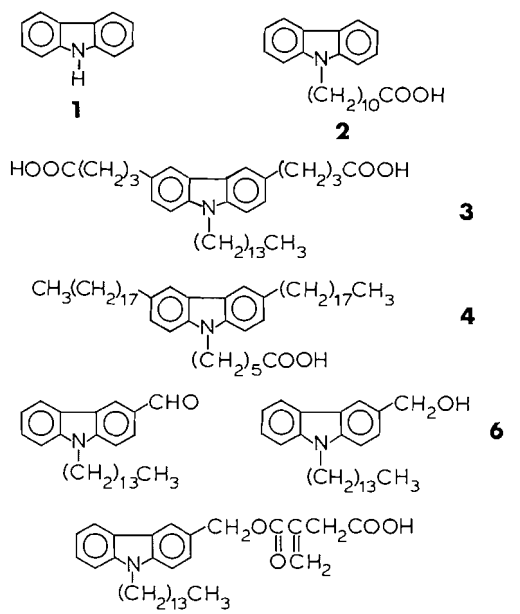
The synthesis of several new surface-active carbazole derivatives is described. These compounds are intended to have applications as hole-transporting materials in thin-film devices assembled by the Langmuir–Blodgett technique. All of the carbazole-containing surfactants gave stable monolayers at the air–water interface with cross sections of 0.35–0.42 nm^2/molecule, characteristic of the carbazole ring system oriented perpendicular to the surface with its long axis parallel to the surface. Conditions for Langmuir–Blodgett deposition of multilayers on titanium-coated polyester film were explored. Further characterization of the carbazole derivatives by cyclic voltammetry and fluorescence decay measurements is also described.

Key words: monolayers, Langmuir–Blodgett films, carbazole, surfactants.

J. W. TAYLOR, C. P. SLOAN, D. A. HOLDEN, G. J. KOVACS et R. O. LOUTFY. Can. J. Chem. **67**, 2142 (1989).



On décrit la synthèse de plusieurs nouveaux dérivés du carbazole qui sont tensio-actifs. On espère pouvoir utiliser ces composés pour le transport de trous dans des couches minces assemblées par la technique de Langmuir–Blodgett. Tous les agents de surface contenant du carbazole ont fourni des monocouches, stables à l'interface air–eau, dont les sections droites, de 0,35–0,42 nm^2/molécule, sont caractéristiques du système cyclique carbazole orienté d'une façon perpendiculaire par rapport à la surface et avec l'axe le plus long parallèle à la surface. On a exploré les conditions qui permettraient d'effectuer un dépôt, selon la technique de Langmuir–Blodgett, de multicouches sur un film de polyester recouvert de titane. On décrit aussi des caractérisations additionnelles des dérivés carbazoles qui ont été réalisées grâce à la voltamétrie cyclique et à des mesures de dégénérescence de la fluorescence.

Mots clés : monocouches, films de Langmuir–Blodgett, carbazole, agents tensio-actifs.

[Traduit par la revue]

Introduction

In the preceding paper the monolayer spreading behaviour of a number of fluorenylidene-containing surfactants was described (1). These compounds are easily reduced but are much more resistant to one-electron oxidation, and their intended role is to function as "monolayer rectifiers" in thin-film devices assembled by the Langmuir–Blodgett technique (2). It is also worthwhile to attempt the synthesis and characterization of monolayer building blocks which are potentially charge-rectifying in the opposite sense. Ideally such compounds would have one-electron oxidation potentials that are of approximately the same magnitude relative to the standard hydrogen electrode as the one-electron reduction potentials of the fluorenylidene malononitrile derivatives described in the preceding paper, but would be resistant to reduction. Suitable oxidation potentials are displayed by aromatic amines (3), a class of compounds that has received extensive attention because of their use as hole-transporting materials in electrophotography (4). For the purpose of this study derivatives of carbazole **1** were chosen, because this allowed us to make use of the extensive patent literature on these compounds (for example, ref. 5). In contrast to the fluorenylidene malononitrile group, the carbazole unit by itself was insufficiently polar to function as the hydrophilic part of a surface-active molecule, and so it was necessary to introduce both a hydrophobic tail and a hydrophilic head-group on the carbazole ring system to obtain a true surfactant. A somewhat different approach was employed recently by Tamai *et al.* (6), who observed that compound **2** gave monolayers at the air–water interface that had collapse pressures of less than 10 mN m^{-1}. Still more recently, the formation of stable monolayers from the 1:1 alternating copolymer of *N*-vinyl carbazole and diethyl fumarate was described by Matsuda and co-workers (7). Although these examples of monolayers from carbazole derivatives were promising, it was necessary to develop other syntheses in order to achieve the desired combination of one-electron oxidizability in a transferable monolayer. The compounds synthesized in the present study included the single-chain dicarboxylic acid **3** and the two-chain

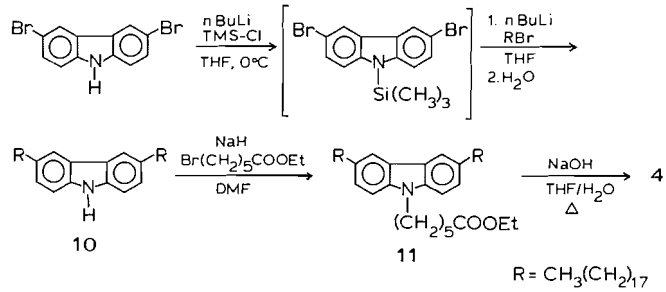
derivative **4**, which reverses the orientation of the carbazole ring system at the interface. In an effort to determine whether adequate monolayer stability required symmetrical substitution on the carbazole ring, compounds **5**–**7**, containing only a single hydrophilic substituent at the 3 position, were prepared.

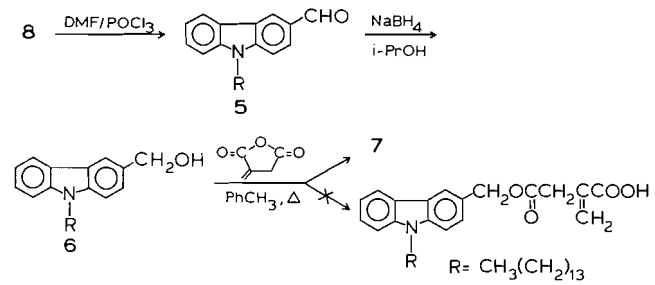
Results and discussion



Synthesis

The preparation of the dicarboxylic acid **3** was achieved by Friedel–Crafts acylation of *N*-tetradecylcarbazole (8) with 2 equivalents of succinic anhydride (9) followed by Wolff–Kischner reduction to **3** (10), as shown in Scheme 1. In an effort

SCHEME 1



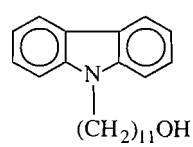
to reverse the orientation of the carbazole ring system at the air–water interface, monoacid **4** was obtained by the sequence of reactions shown in Scheme 2. The *N*-trimethylsilyl-protected

SCHEME 2

3,6-dibromocarbazole was first reacted by metal–halogen exchange and then alkylated with excess 1-bromooctadecane. Deprotection during work-up, followed by chromatographic purification, afforded the 3,6-dialkylcarbazole **10** in a one-pot reaction but in low overall yield. The chemistry used to introduce the hydrophilic group involved nucleophilic displacement of Br^- from an ω-bromo derivative by the sodium salt of carbazole, followed by hydrolysis to the free carboxylic acid **3**. The final step turned out to be the most difficult. Possibly because of the hydrocarbon environment provided by the two alkyl chains, compound **11** proved surprisingly resistant to hydrolysis. It was difficult to locate a window of hydrolysis conditions that could allow formation of the carboxylic acid without substantial decomposition of the product. Finally a solution was reached, involving prolonged refluxing of the ester under nitrogen in peroxide-free THF/H_2O containing sodium hydroxide.

The preparation of the carbazole-containing half-ester **7** made use of chemistry worked out by Rodriguez-Parada and Percec in their synthesis of a series of carbazolylmethyl esters of methacrylic acid (8) (Scheme 3). In principle two regioisomers could be formed by the ring-opening of the anhydride, but in practice only a single product was isolated, as shown by ^1H and

SCHEME 3



^{13}C nmr spectroscopy. This result is in agreement with other literature studies of the preparation of itaconate esters from itaconic anhydride (11).

Monolayer spreading behaviour

Compounds **3**–**7** all formed stable monolayers with molecular areas that reflected the large cross section of the carbazole ring system. Figure 1 shows the monolayer spreading behaviour of the dicaboxylic acid **3** on 10^{-3} M $CdCl_2$ at 20°C. The surface pressure increases smoothly below a limiting molecular area of 0.70 nm^2 $molecule^{-1}$ and reaches a well-defined collapse pressure of 33.7 mN m^{-1} at a molecular area of 0.397 nm^2. Similar spreading behaviour was observed for compound **3** on pure water, except that the monolayers were slightly less compact.

The monolayer spreading behaviour of the carbazole monoacid **4** and its ethyl ester **11** is shown in Fig. 2. Despite the reversal of the positions of the polar substituents and the hydrocarbon chains on the carbazole ring, the spreading behaviour of **4** is quite similar to that of **3**. The high collapse pressure of 39 mN m^{-1}, reached at a molecular area of 0.33 nm^2 $molecule^{-1}$, means that monolayers of pure **4** may be stable enough for transfer to solid surfaces. In contrast, the ethyl ester group of compound **11** has lower polarity, so that monolayers of **11** are more expanded and have much lower collapse pressures: 6.7 mN m^{-1} at a molecular area of 0.75 nm^2 $molecule^{-1}$.

Our original assumption was that monolayers of unsymmetrical carbazole derivatives and compounds in which the hydrophilic group was attached to the carbazole ring system would have lower stability. This turned out not to be the case, as is evident from the surface pressure – area curves shown in Fig. 3. Both the carbazolylmethanol derivative **6** and the itaconate monoester **7** gave stable monolayers, and the limiting molecular areas, collapse areas, and collapse pressures are very close to those of the symmetrical derivatives **3** and **4**. Monolayers of the carboxaldehyde **5** had similar limiting and collapse areas (0.46 and 0.33 nm^2 $molecule^{-1}$) but had a much lower collapse pressure of 6 mN m^{-1}. The collapse pressures of 26.5 and 33.2 mN m^{-1} displayed by compounds **6** and **7** are much higher than the value of <10 mN m^{-1} observed by Tamai *et al.* for monolayers of compound **2**, in which the carbazole unit is at the end of the hydrophobic chain (6). The lower collapse pressures of ω-carbazolyl-substituted surfactants were also verified in our laboratory for monolayers of the alcohol **12**, which showed a collapse

pressure of 8 mN m^{-1} at a molecular area of 0.37 nm^2 $molecule^{-1}$ [2].

Monolayers of **3**–**7** all have similar collapse areas of between 0.33 and 0.42 nm^2 $molecule^{-1}$. A common orientation of the carbazole ring system relative to the water surface that provides a molecular area in this range places the long axis of the carbazole ring sytem close to parallel to the surface, with the aromatic rings stacked parallel to each other and at close to right angles to the surface. The same orientation was concluded by Fukuda *et al.* for a series of 9,10-anthraquinone-containing surfactants on the basis of a similar geometrical analysis (13).

TABLE 1. Deposition ratios *d* for Langmuir–Blodgett transfer of monolayers of carbazole-containing surfactants to titanium-coated polyester films[a]

Compound	Number of layers	Deposition pressure (mN m^{-1})	d^b
3	1	26	1.11
	3	26	0.89[c] (1.15, 0.83, 0.66)
	5	26	0.57 (1.16, 0.84, 0.49, 0.11, 0.24)
7	1	25	1.23
	3	25	0.80 (1.22, 1.00, 0.18)
	5	25	0.75 (1.23, 1.01, 0.18, 1.09, 0.23)

[a]10^{-3} M $CdCl_2$ subphase.
[b]Deposition of 1st layer corresponds to withdrawal of film.
[c]Average value; values for individual immersion and withdrawal steps are in parentheses.

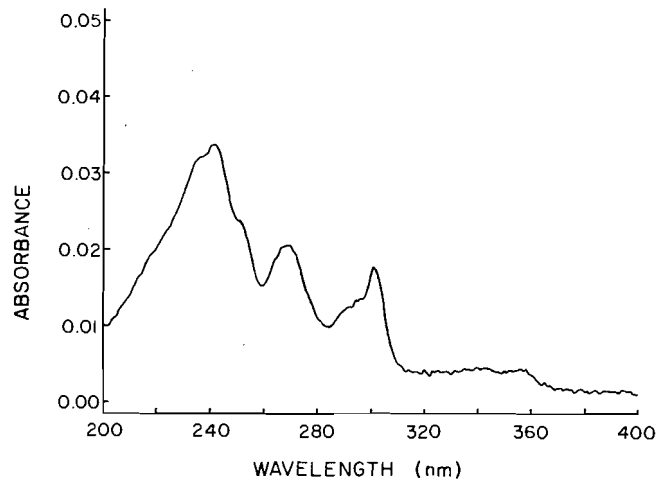

FIG. 4. Ultraviolet spectrum of 3 monolayers of carbazole diacid **3** on each side of a quartz disc.

Table 1 lists the results of a study of the deposition of multilayers of **3** and **7** on titanium-coated polyester foil by the Langmuir–Blodgett technique. It is interesting to note that the deposition ratios *d* for the first monolayer are 1.2 ± 0.05, consistently greater than unity, a result suggesting that some reorganization of the monolayers occurs on transfer (2, 14). Monolayers of the diacid **3** showed decreasing values of *d*, corresponding to propagation of imperfections with each immersion and withdrawal. Similar behaviour was observed for monolayers transferred to quartz discs, as shown by uv spectroscopy. Figure 4 is the uv spectrum of a total of 6 monolayers (3 per side) of **3** transferred as the Cd^{2+} salt to quartz. Although the spectrum is unchanged, the absorbance of a multilayer film prepared by five immersion–withdrawal cycles is only slightly higher than that shown in Fig. 4, a result confirming that the deposition of monolayers of **3** on itself becomes ineffective after the first 2–3 monolayers. The behaviour of compound **7** is slightly different from that of compound **3** in that a pronounced tendency toward X-type deposition (deposition only on immersion) was observed, rather than a monotonic decrease in the deposition ratio with increas-

ing number of immersion–withdrawal cycles. The results summarized in Table 1 show that it would not be possible to create Langmuir–Blodgett assemblies incorporating tens of multilayers. On the other hand, a proposed application of Langmuir–Blodgett multilayers of these carbazole compounds involves their use as charge-blocking layers in electrophotographic devices, and in such an application even single monolayers may be effective.

Redox behaviour of carbazole-containing surfactants

Table 2 compares the redox behaviour of two of the carbazole surfactants, as measured by cyclic voltammetry, with that of some carbazole compounds substituted with short alkyl chains. A typical cyclic voltammogram for compound **3** in argon-saturated CH_2Cl_2 is illustrated in Fig. 5. The small peak at +0.85 V is attributed to an impurity in the supporting electrolyte. Simple *N*-alkyl carbazoles such as 9-butylcarbazole are irreversibly oxidized in CH_2Cl_2 at +1.05 V relative to the saturated calomel electrode. The corresponding oxidation of the carbazole surfactants is shifted by about +0.2 V, and the degree of irreversibility is a function of the substitution on the carbazole ring. Thus compound **6**, substituted at the 3 and 9 positions, showed no cathodic peak on the return cycle, whereas compound **3**, with 3, 6, and 9 substitution, gave a well-defined cathodic peak at +1.21 V vs. SCE. Studies by Ambrose *et al.* established that carbazole derivatives undergo oxidative coupling to give 3,3, 6,6, and 9,9 bicarbazolyl dimers (15). The tendency toward irreversible dimerization was suppressed in carbazole compounds with bulky alkyl substituents at the 3, 6, and 9 positions, as in 3,6-di-*tert*-butyl-9-ethylcarbazole. This accounts for the observed differences between compounds **3** and **6**. The shift of peak potentials for **3** and **6** to more positive values in comparison to *N*-butylcarbazole is attributed to a slower rate of diffusion of the high molecular weight surfactants to the electrode surface, rather than to substantial differences in redox levels. The perturbation arising from the carboxylic acid groups is small: carboxylic acids are known to undergo oxidative dimerization by the Kolbe reaction (16), but the potentials required are not accessible in CH_2Cl_2 solution, as the solvent undergoes oxidation beyond +1.8 V vs. SCE.

Fluorescence behaviour

Figure 6 shows the fluorescence spectra of two of the carbazole surfactants in oxygen-free ethanol. The positions of the 0–0 bands are only slightly red-shifted relative to those of simple *N*-alkyl carbazoles (17) and confirm the absence of pronounced differences in the excited state levels of the long-chain compounds. The fluorescence decay times of several long-chain carbazole compounds, listed in Table 3, are all very close to the decay times of carbazole and *N*-alkyl carbazoles (18), and indicate the absence of additional non-radiative decay pathways for the long-chain compounds,at least in homogeneous solution. Fluorescence spectroscopy is one of the few techniques sensitive enough to provide detailed information on orientation and structure within single monolayers, and these results for homogeneous solutions provide useful background information for such studies.

Summary

The carbazole ring system has been successfully incorporated in a variety of ways into compounds that form stable monolayers at the air–water interface. The collapse pressures of these

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/07/12
For personal use only.

monolayers, typically around 30 mN m^{-1}, were sufficiently high to allow Langmuir–Blodgett deposition without dilution with stabilizing amphiphilic compounds such as fatty acids. While efforts to build up multilayers on titanium-covered polyester foil met with only partial success, and the electrochemical behaviour of the surface-active carbazoles appeared to be affected by the presence of the long-chain substituents, it was still possible to incorporate 1- to 5-monolayer films of these compounds into working Langmuir–Blodgett devices. Details of the assembly and performance evaluation of one such application will be described in the near future.

Experimental

General spectroscopic and chromatographic methods are described in the preceding paper (1).

N-Tetradecylcarbazole ***8***

This compound was prepared from carbazole and 1-bromotetradecane by the method of Rodriguez-Parada and Percec (8). The crude product isolated by precipitation of the reaction mixture into water was dissolved in hexanes, and the solution was filtered and evaporated to dryness. The product after one recrystallization from isopropanol had mp 40–41°C (lit. mp (8) 42–44°C); ir: no NH of carbazole at 3420 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.89 (t, 3H), 1.25 (br s, 22H), 1.80 (m, 2H), 4.27 (t, 2H), 7.11–8.16 (m, 8H); ^{13}C nmr ($CDCl_3$) δ: 14.25, 8 resolved CH_2 signals between 22.84 and 43.15 ppm, 108.72, 118.78, 120.39, 122.94, 125.62, 140.53.

N-Tetradecylcarbazole-3,6-bis(4-(4-oxo)-butanoic acid) ***9*** *(9)*

A mixture of 17.5 g (48 mmol) of **8** and 10.6 g (106 mmol) of succinic anhydride in 250 mL of dry nitrobenzene was cooled to 3–4°C and stirred while 28.25 g (212 mmol) of anhydrous $AlCl_3$ was added slowly enough to avoid a sharp rise in temperature. The reaction mixture was maintained at 2°C for 6 h and then allowed to warm to room temperature. After 2 days the reaction mixture was added to ice and acidified with 50 mL of concentrated HCl. Following steam distillation to remove most of the nitrobenzene, the solid residue was dissolved in 1 M aqueous NaOH and the solution was extracted with ether. The aqueous layer was acidified with HCl and the precipitated product was filtered and dried and recrystallized from a large volume of ethyl acetate; ir (Nujol): 3000 (br), 1702, 1655 cm^{-1}.

N-Tetradecylcarbazole-3,6-bis(4-butanoic acid) ***3***

A total of 5.0 g of the oxoacid **9** (9.6 mmol), 2.0 g (36 mmol) of KOH, and 2.5 g (42 mmol) of 85% hydrazine hydrate were dissolved in 25 mL of diethylene glycol and heated to 140°C for 1.25 h. At this point the condenser was removed and water and unreacted hydrazine were distilled off. The reaction temperature was increased to 190°C and maintained for 4 h. The cooled mixture was acidified with HCl and extracted with ether. The ether solution of the product was chromatographed on silica gel, eluting with 35:15:1 hexane/ether/acetic acid, to yield 1.5 g (32%) of crystalline **3**, mp 76–78°C; ir ($CHCl_3$): 1708 cm^{-1}; (KBr): 3000 (br) cm^{-1}; uv (methanol) λ_{max}: 357 nm (ε 2.50×10^3 M^{-1} cm^{-1}), 343 (2.36×10^3), 302 (1.30×10^4), 270 (1.50×10^4); ^1H nmr δ: 0.87 (t, 3H), 1.23 (br s, 22H), 1.83 (m, 2H), 2.05 (m, 4H), 2.44 (t, J = 7.3 Hz, 4H), 2.84 (t, J = 7.4 Hz, 4H), 4.22 (t, J = 7.1 Hz, 2H), 7.21–7.29 (m, 4H), 7.88 (s, 2H); ^{13}C nmr ($CDCl_3$) δ: 14.22, 12 resolved CH_2 lines between 21.13 and 35.13 ppm, 43.26, 60.53, 108.54, 119.89, 122.81, 126.33, 131.37, 139.46, 180.26; fluorescence spectrum (λ_{ex} = 297 nm): emission maxima at 364, 382.5 nm; (λ_{em} = 390 nm): excitation maxima at 301, 343, 357 nm. *Anal.* calcd. for $C_{34}H_{49}NO_4$: C 76.22, H 9.22, N 3.01%; found: C 76.38, H 9.31, N 2.61%.

3,6-Dioctadecylcarbazole ***10***

A solution of 3,6-dibromocarbazole (Aldrich, 3.69 g, 11.4 mmol) in 300 mL of dry THF was cooled to 0°C under N_2. *n*-Butyllithium (5.6 mL of 2.24 M solution in hexane, 12.4 mmol) was added by syringe, followed after 1 h by 1.36 g (12.5 mmol) of trimethylsilyl chloride. The mixture was then cooled to −78°C and 2.3 equivalents of *n*-BuLi (11.7 mL of 2.24 M solution in hexane) were added. After 1 h at −78°C 1-bromooctadecane (15.2 g, 45.6 mmol) was added and the mixture was allowed to warm to room temperature overnight. Following addition of a trace of water, filtration, and evaporation of the solvent the product mixture was chromatographed on silica gel, eluting with 5–35% ethyl acetate in hexane. Additional purification by column chromatography was necessary to obtain material that was homogeneous by fluorescence decay measurements. Compound **10** (962 mg, 13%) was a white waxy solid, mp 68–69°C (acetone); ir: 3424, 2915, 1462 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.87 (t, 6H), 1.10–1.60 (br s, 60H), 1.60–1.75 (quintet, 4H), 2.76 (t, 4H), 7.17–7.28 (m, 4H), 7.28–7.83 (m, 2H); ms m/z: 672 (M^+, rel. intensity 2), 476 (58), 419 (11), 236 (30), 43 (100).

6-(3,6-Dioctadecyl-9-carbazolyl)hexanoic acid ethyl ester ***11***

A solution of 900 mg (1.34 mmol) of **10** in 10 mL of dry DMF was added by syringe to a suspension of 1.4 equivalents of NaH (90 mg of 50% NaH dispersion in mineral oil) in 15 mL of DMF. Evolution of hydrogen ceased after 30 min. Ethyl 6-bromohexanoate (340 mg, 1.74 mmol) was added and the mixture was stirred at room temperature for 4 h. The DMF was removed on a rotary evaporator and the crude product was chromatographed on silica gel, eluting with 5–50% ethyl acetate in hexane. The product (893 mg, 82%) was a colorless oil, which crystallized on standing for 1 week; mp 49–50°C (acetone); ir: 2925, 1725, 1467, 908, 735 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.88 (t, 6H), 1.15–1.30 (br s, 67 H), 1.60–1.75 (br quintet, 4H), 1.80–1.92 (m, 2H), 2.25 (t, J = 7.3 Hz, 2H), 2.77 (t, J = 7.7 Hz, 4H), 4.09 (quartet, J = 7.3 Hz, 2H), 4.23 (t, J = 7.1 Hz, 2H), 7.24 (unresolved m, 4H), 7.86 (unresolved m, 2H); ^{13}C nmr ($CDCl_3$, 63.1 MHz) δ: 14.25, 8 resolved CH_2 lines between 22.83 and 36.16 ppm, 43.02, 60.34, 108.24, 119.69, 122.90, 126.24, 133.20, 139.20, 173.58; ms m/z: 814 (M^+, rel. intensity 1.3% of base peak). *Anal.* calcd. for $C_{56}H_{95}NO_2$: C 83.62, H 11.90, N 1.74%; found: C 83.41, H 11.70, N 2.02%.

6-(3,6-Dioctadecyl-9-carbazolyl)hexanoic acid ***4***

The ethyl ester **11** (893 mg, 1.1 mmol) was dissolved in 30 mL of THF and 5 mL of H_2O was added. Following addition of 3 mL of 1M aqueous NaOH (3 mmol), the mixture was stirred and refluxed under nitrogen for 3 days, followed by 2 days at room temperature. The solvent was removed and the sodium salt of the product was converted to the free carboxylic acid by extraction with dilute aqueous HCl and CH_2Cl_2. Evaporation of the organic layer gave 654 mg (76%) of **4** as a white crystalline solid; mp 52–53°C (acetone); ir: 2913, 1717, 1465, 1026, 730 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.88 (t, 6H), 1.05–1.50 (br s, 66H), 1.50–1.80 (br quintet, 4H), 2.28 (t, J = 7.0 Hz, 2H), 2.77 (t, J = 7.7 Hz, 4H), 4.24 (t, J = 7.1 Hz, 2H), 7.25 (unresolved m, 4H), 7.85 (unresolved m, 2H); ^{13}C nmr ($CDCl_3$) δ: 14.25, 7 resolved CH_2 signals between 22.81 and 36.14 ppm, 108.23, 119.69, 122.85, 126.25, 133.22, 139.17, 178.22; ms (negative ion FAB, compound dissolved in thioglycerol) m/z: 785 ($M^+ - 1$, rel. intensity 4), 298 (8), 297 (44), 148 (100); fluorescence spectrum (ethanol): emission λ_{max} 362, 380 nm (excitation at 297 nm).

3-Formyl-9-tetradecylcarbazole ***5****(5a)*

N-Tetradecylcarbazole **8** was formylated with $POCl_3$/DMF by the method of Rodriguez-Parada and Percec (8). Isolation of the product was achieved by cooling the reaction mixture in an ice bath until a solid precipitated. The filtered product was recrystallized from acetone/hexane to yield a yellow solid having mp 81–83°C (lit. (8) mp 81–83°C); ir: 1689 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.88 (t, 3H), 1.25 (br s, 22H), 1.90 (m, 2H), 4.32 (t, 2H), 7.22–8.62 (m, 7H), 10.12 (s, 2H).

(9-Tetradecyl-3-carbazolyl)methanol ***6***

A solution of 2.43 g (6.2 mmol) of **5**, 0.31 g (8.1 mmol) of $NaBH_4$, and 7 mL of 0.13 M aqueous NaOH (9.0 mmol) in 100 mL of isopropanol was stirred at 60°C for 3 h. The homogeneous solution was poured into ice water and the precipitated solid was filtered and dried under vacuum. Recrystallization from hexanes gave compound **6**; mp 73–74°C (lit. (8) mp 72–74°C); ir: 3253 (br) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.90 (t, 3H), 1.29 (br s, 22H), 1.6–2.0 (m, 2H + 1H (OH)), 4.29 (t,

2H), 4.85 (s, 2H), 7.11–8.18 (m, 7H); ^{13}C nmr ($CDCl_3$, 50.5 MHz) δ: 14.22, 7 resolved CH_2 lines between 22.81 and 32.03 ppm, 43.26, 66.24, 12 resolved aromatic C between 105.74 and 140.88 ppm. *Anal.* calcd. for $C_{27}H_{39}NO$: C 82.39, H. 9.98, N 3.56%; found: C 82.19, H 9.98, N 3.94%.

2-Methylenebutanedioic acid mono((9-tetradecyl)-3-carbazolyl)methyl ester 7(17)

A solution of 0.65 g (1.7 mmol) of alcohol **6** and 0.206 g (1.8 mmol) of itaconic anhydride (Aldrich) in 20 mL of dry toluene was refluxed for 18 h. Most of the toluene was removed on a rotary evaporator and the crude product was passed through a short silica gel column and eluted with 10–100% ethyl acetate in hexane. The last two bands were rechromatographed, eluting with 35% ethyl acetate/hexane. The crystalline product was the second elution band; mp 95–97°C; ir: 3000 (br), 1723, 1698, 1632, 1601 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 0.88, (t, 3H), 1.23 (br s, 22H), 1.84 (m, 2H), 3.38 (s, 2H), 4.27 (t, 2H), 5.33 (s, 2H), 5.81 (unresolved m, 1H), 6.44 (unresolved m, 1H), 7.19–8.09 (m, 7H); ^{13}C nmr ($CDCl_3$, 50.5 MHz) δ: 14.24, 8 resolved CH_2 lines between 22.81 and 32.03 ppm, 37.51, 43.26, 67.94, 14 lines between 108.80 and 140.88 ppm (12 aromatic and 2 olefinic C), 170.75, 171.40. *Anal.* calcd. for $C_{32}H_{43}NO_4$: C 76.00, H 8.66, N 2.77%; found: C 76.00, H 8.60, N 2.59%.

The Langmuir balance and the techniques for monolayer chracterization are described in the accompanying manuscript (1). Conditions of compression speed, substrate preparation, and Langmuir–Blodgett deposition are all identical to those used for the fluorenylidene-containing surfactants (1). Techniques for determination of redox potentials by cyclic voltammetry are described in the accompanying paper (1). A saturated calomel reference electrode was used, and curves were recorded at a slower sweep rate of 50 mV s^{-1}. Fluorescence spectra were recorded using a Hitachi–Perkin Elmer MPF-2A instrument. Dilute solutions (2×10^{-5} M) of the carbazole compound in HPLC-grade ethanol were deoxygenated with high-purity nitrogen before spectra were recorded. A 1 cm square quartz fluorescence cell was used for all measurements. Fluorescence decay times were measured by the single photon counting technique (19) on a commercial instrument (PRA International). Details of the analysis procedures have appeared in earlier publications (12, 20).

The ionization of trifluoromethane-, methane-, and benzene-sulfonic acids in Me_2SO and in water has been studied by ^{13}C nuclear magnetic resonance. While the protonation shifts of $CF_3SO_3^-$ and $CH_3SO_3^-$ in both solvents are too small to make a quantitative interpretation possible, the $C_6H_5SO_3^-$ shift data in H_2O–H_2SO_4 mixtures, when treated by the method of Cox and Yates, gave a pK_a value of -2.5 for the ionization of $C_6H_5SO_3H$. Our results are discussed in relation to those of other workers. Enthalpies of solution and of ionization of these acids and related compounds have been obtained in both solvents. Single ion enthalpies of transfer from water to Me_2SO have been calculated from our data and from a transfer value for $CF_3SO_3^-$ ($+1.9$ kJ mol^{-1}) based on the tetraphenylarsonium–tetraphenylborate extrathermodynamic assumption. The transfers are endothermic processes for the anions $CH_3SO_3^-$ ($+29.6$ kJ mol^{-1}), $C_6H_5SO_3^-$ ($+20.2$ kJ mol^{-1}), and *p*-$CH_3C_6H_4SO_3^-$ ($+21.8$ kJ mol^{-1}), and exothermic for H^+ (-27.4 kJ mol^{-1}). These results are discussed in terms of the properties of the ions and solvents. The transfer value for H^+ is a valuable measure of the basicity difference between bulk water and Me_2SO.

Key words: sulfonic acids, ionization, dimethylsulfoxide, ^{13}C NMR, calorimetry.

ROBERT L. BENOIT, MONIQUE FRÉCHETTE et DANIELLE BOULET. Can. J. Chem. **67**, 2148 (1989).

On a étudié par résonance magnétique nucléaire du ^{13}C l'ionisation des acides trifluorométhane-, méthane- et benzènesulfonique dans l'eau et le Me_2SO. Si les variations des déplacements chimiques de $CF_3SO_3^-$ et $CH_3SO_3^-$ lors de leur protonation dans les deux solvants sont trop faibles pour être interprétées quantitativement, les données pour $C_6H_5SO_3^-$ dans les mélanges H_2O–H_2SO_4 ont conduit par la méthode de Cox et Yates à un pK_a de $-2,5$ pour l'ionisation de $C_6H_5SO_3H$. Nos résultats sont discutés en relation avec ceux d'autres chercheurs. On a obtenu dans les deux solvants les enthalpies de solution et d'ionisation de ces acides et de composés reliés. Les enthalpies ioniques de transfert de l'eau au Me_2SO ont été calculées à partir de nos résultats et d'une valeur pour le transfert de $CF_3SO_3^-$ ($+1,9$ kJ mol^{-1}), basée sur l'hypothèse extrathermodynamique tétraphénylarsonium–tétraphénylborate. Les transferts sont des processus endothermiques pour les anions $CH_3SO_3^-$ ($+29,6$ kJ mol^{-1}), $C_6H_5SO_3^-$ ($+20,2$ kJ mol^{-1}) et *p*-$CH_3C_6H_4SO_3^-$ ($+21,8$ kJ mol^{-1}), et exothermique pour H^+ ($-27,4$ kJ mol^{-1}). Ces résultats sont discutés sur la base des propriétés des ions et des solvants. La valeur pour le transfert de H^+ est une mesure utile de la différence de basicité entre l'eau-solvant et le Me_2SO.

Mots clés : acides sulfoniques, ionisation, diméthylsulfoxyde, ^{13}C RMN, calorimétrie.

Introduction

Alkanesulfonic acids are moderately strong acids in aqueous solution but estimates of their ionization constants K_{aw} vary. For methanesulfonic acid, K_{aw} values of ~4 and ~13 (1) were obtained from acidity function data, 16 (2) from ^1H nmr results, and 73 (3) and 83 (4) from Raman data. Ethane- and propanesulfonic acids are slightly weaker with K_{aw} values of 48 (Et) and 34 (Pr) respectively (4). Arenesulfonic acids are expected to be stronger acids (5). The ionization of benzenesulfonic acid in particular has been studied in H_2SO_4–H_2O by Cerfontain and co-workers using uv (6), and ^1H (7) and ^{13}C nmr (8). They calculated a -6.56 pK_{aw} with half deprotonation at 82.2% H_2SO_4 ($H_o = -7.7$). However, the same authors also obtained, by ^1H nmr, $pK_{aw} \sim -6.0$ for methane-, ethane-, and some additional alkanesulfonic acids (7), i.e., values completely at variance with those previously quoted (1–4).

In our early search for strong acids in dimethylsulfoxide (Me_2SO) we studied by conductivity the ionization of two sulfonic acids in Me_2SO (9): while CF_3SO_3H behaved as a strong electrolyte, CH_3SO_3H was incompletely dissociated with a value of $pK_{as} = 1.76$. Both these results were essentially confirmed independently (10). The behavior of $C_6H_5SO_3H$ in Me_2SO has not been studied but *p*-toluenesulfonic acid (11) and chlorobenzenesulfonic acid (12) are reported to be strong acids (see, however, ref. 9). In conjunction with our recent studies of the ionization of aminosulfonic acids (13, 14) we further investigated the ionization of sulfonic acids in water and Me_2SO.

In this paper, we report the results of our ^{13}C nmr study of the ionization of trifluoromethane-, methane-, and benzenesulfonic acids in H_2O–H_2SO_4 and Me_2SO–CF_3SO_3H media. We also present related calorimetric results, in particular on the solution and ionization of these acids in water and Me_2SO. This led us to values of single ion enthalpies of transfer from water to Me_2SO for $CH_3SO_3^-$, $C_6H_5SO_3^-$, *p*-$CH_3C_6H_4SO_3^-$, and H^+. The H^+ value is of particular interest since it is a quantitative measure of the superior basicity of Me_2SO.

Experimental

Materials

Trifluoromethanesulfonic acid (CF_3SO_3H) (Aldrich) was distilled under reduced pressure before use, and titration of the acid with standard aqueous NaOH indicated a purity in excess of 99.4%. Methanesulfonic acid (CH_3SO_3H) (Fluka, puriss.) and silver *p*-toluenesulfonate ($CH_3C_6H_4SO_3Ag$) (Aldrich 99+%) were used without further purification. Benzenesulfonic acid ($C_6H_5SO_3H$) (Fluka, purum) had less than 1% water and was dried over P_4O_{10}. Sulfuric acid (Baker), 7% fuming H_2SO_4 (Fisher), and dimethylsulfoxide (BDH and Anachemia) were used as received. Me_2SO-d_6 was from Cambridge Isotope Laboratories.

Nuclear magnetic resonance

Proton decoupled ^{13}C nmr spectra were recorded at 28°C on a Bruker WP-80 Fourier transform spectrometer operating at 20.2 MHz. Chemical shifts, δ (ppm), were determined relative to external dioxane in D_2O (external lock) and converted to the Me_4Si scale by using $\delta_{Me4Si} = \delta_{dioxane} + 67.40$ ppm.

[1]Present address: Department of Chemistry, University of Ottawa, Ottawa, Ont., Canada K1N 6N5.

The ^{13}C nmr spectra were recorded for CF_3SO_3H, CH_3SO_3H, and $C_6H_5SO_3H$, in 0–18 M aqueous H_2SO_4 and in aqueous NaOH. Spectra of CF_3SO_3H, CH_3SO_3H, and $C_6H_5SO_3H$ were also obtained in 7% fuming H_2SO_4, in 0–11.3 M CF_3SO_3H in Me_2SO, and in Me_2SO solutions of strong bases (tetramethylguanidine (TMG) or 4-amino-2, 6-dimethylpyrimidine (Dap)). The concentration of the sulfonic acids was ~0.40 M (except for 0.08 M CH_3SO_3H in aqueous NaOH). The samples were prepared by adding weighed amounts of the sulfonic acids to known volumes of titrated acidic solutions. ^{13}C chemical shift values are within 0.10 ppm.

Calorimetry

The heat of solution of the sulfonic acids in Me_2SO and water as well as their heat of neutralization in 0.05 M Me_2SO solutions of strong bases were obtained at 25.00 ± 0.01°C (except for the solution of CF_3SO_3H in water at 30.00 ± 0.01°C). An L.K.B model 8725-2 isoperibol calorimeter was used as previously described (15). The amount of sulfonic acid dissolved ((1–40) $\times 10^{-4}$ mol) in the 100-mL reaction cell was deduced from the weights of the glass ampoules. For each determination of the heat of solution or neutralization at least three separate experiments were made at different concentrations.

Results and discussion

We will first consider the ^{13}C nmr data on the ionization of the three sulfonic acids CF_3SO_3H, CH_3SO_3H, and $C_6H_5SO_3H$ in acid media, both in water and Me_2SO. We will then examine the calorimetric results on the enthalpies of solution of the acids and related compounds in both solvents.

^{13}C nmr spectra

Data on ^{13}C nmr chemical shifts of a moderately strong acid HA as a function of its concentration c or of the acidity of the media can, in principle, lead to the ionization constant K_a of HA (16). The observed chemical shift, δ, is, under fast exchange conditions, a weighted average of the chemical shifts of the acid δ_{HA} and its anion δ_A, according to

$$[1] \quad \delta = \delta_{HA}\frac{[HA]}{c} + \delta_A\frac{[A^-]}{c}$$

with

$$[2] \quad c = [HA] + [A^-]$$

and

$$[3] \quad K_a = \frac{[H^+]\,[A^-]}{[HA]}$$

where [HA] and $[A^-]$ are the concentrations of the acid and its anion respectively. There are various methods of obtaining K_a from data giving $\delta = f(c)$ or $\delta = f([H^+], c)$, provided δ_{HA} and δ_A are sufficiently different. Let us consider in turn the data obtained for CF_3SO_3H, CH_3SO_3H, and $C_6H_5SO_3H$ in both solvents.

CF_3SO_3H

The chemical shift of the anion $CF_3SO_3^-$ in water, given as the centre of the quartet, is δ = 120.52 ppm. Upon addition of H_2SO_4, δ moves slightly upfield (120.35 ppm (8.9 M H_2SO_4), 119.5 ppm (17.8 M H_2SO_4), and 118.98 ppm (oleum)). It is clear that the variations of δ are too small to obtain any meaningul information on the protonation of $CF_3SO_3^-$ in H_2O–H_2SO_4 mixtures. Now, in Me_2SO-d_6, we observe for $CF_3SO_3^-$ δ = 121.70 ppm. The downfield move of δ (+1.2 ppm) from H_2O to Me_2SO reflects the loss of H-bonding of $CF_3SO_3^-$ in the latter solvent. When the concentration of CF_3SO_3H in Me_2SO is increased δ moves slightly upfield, as shown in Fig. 1, to reach 118.75 ppm for neat CF_3SO_3H (11.3 M). The total variation of δ is 3.0 ppm, but the medium has correspondingly changed from essentially Me_2SO to CF_3SO_3H so that δ for $CF_3SO_3^-$ and CF_3SO_3H may not remain constant, as would be required to solve eqs. [1]–[3]. We note that for 4.4 M CF_3SO_3H, the medium corresponds to 1:2 CF_3SO_3H:Me_2SO and that up to this concentration, δ has only decreased by 0.3 ppm from the value for $CF_3SO_3^-$. This would be consistent with assuming that, up to 4.4 M, CF_3SO_3H is ionized and present as $CF_3SO_3^-$ H^+ $(Me_2SO)_2$, the proton being H-bonded to two Me_2SO (17). We also observe that, on addition of CF_3SO_3H, the methyl carbons from Me_2SO-d_6 move progressively upfield from 40.69 ppm, with the concentration of CF_3SO_3H, to reach 37.1 ppm for 4.4 M CF_3SO_3H, and this δ value would correspond to H^+ $(Me_2SO)_2$. The value of the ^{13}C shift of Me_2SO may then give some information on the ionization of moderately strong acids in Me_2SO, as we shall see for CH_3SO_3H and $C_6H_5SO_3H$. On continuing the addition of CF_3SO_3H, the ^{13}C shift of Me_2SO moves further upfield as $H^+(Me_2SO)$ is formed (17).

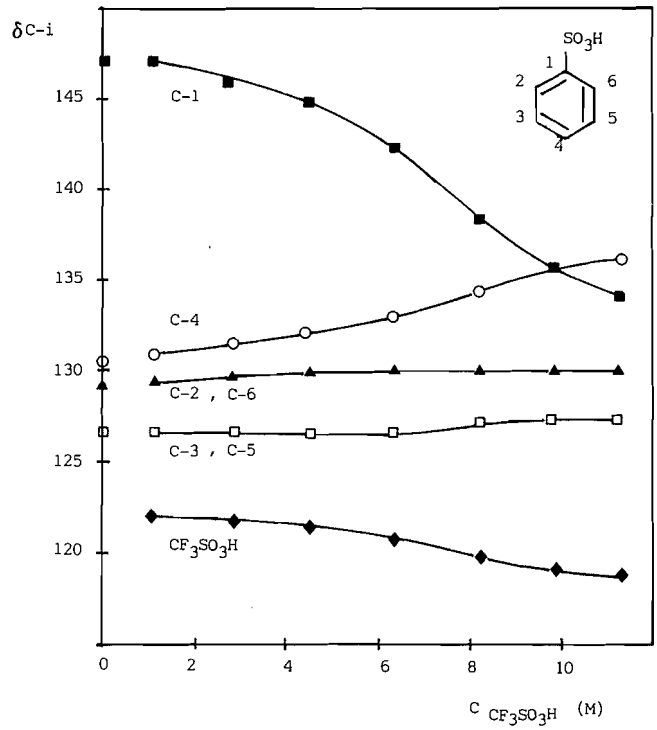

FIG. 1. ^{13}C chemical shifts (ppm) of (0.40 M) $C_6H_5SO_3H$ and CF_3SO_3H in Me_2SO as a function of CF_3SO_3H concentration.

CH_3SO_3H

In water, the chemical shift of $CH_3SO_3^-$ is 39.35 ppm and δ moves very slightly downfield upon addition of H_2SO_4 (39.76 ppm for 12.6 M H_2SO_4, 39.62 for 17.8 M H_2SO_4, and 39.74 ppm for neat CH_3SO_3H). Clearly these data cannot give any information on the protonation of $CH_3SO_3^-$ in H_2O–H_2SO_4 media so that we are left with the conflicting results of earlier authors (1–4) giving K_{aw} values for CH_3SO_3H between 4 and 80, and those of Koeberg-Telder and Cerfontain (7) who found K_{aw} ~$10^{6.0}$ using ^1H nmr. Considering the assumption made by the latter authors to correct for medium effects, we would tend to favour K_{aw} ~80 obtained from Raman data (3–5).

Now, if we turn to CH_3SO_3H in Me_2SO-d_6, the chemical shift of $CH_3SO_3^-$ is 40.91 ppm. As for $CF_3SO_3^-$, there is a

downfield move (+1.5 ppm) from water to Me_2SO due to the loss of H-bonding of $CH_3SO_3^-$ to the latter solvent. Then, we find that upon addition of 1.95 M CF_3SO_3H to 0.2 M CH_3SO_3H, δ moves only to 40.61 ppm and on increasing the CH_3SO_3H concentration up to 3 M the change of δ is also minimal: 40.76 ppm (0.60 M), 40.76 ppm (1.03 M), 40.69 ppm (3.06 M). Since according to the conductivity data (9, 10) CH_3SO_3H should largely be unionized in these solutions, these small variations of δ indicate that the δ values of $CH_3SO_3^-$ and CH_3SO_3H are also very close in Me_2SO and no further information can be obtained. However, that CH_3SO_3H is at least in part unionized in a 3.06 M solution receives some confirmation from the fact that the corresponding ^{13}C shift of Me_2SO is 39.59 ppm, i.e., closer to the shift of H-bonded Me_2SO in solutions of weak acids (2.8 M CH_3CO_2H: 40.25 ppm; 3.4 M CF_3CO_2H: 39.52 ppm) than to the shift of protonated Me_2SO in ionized 3 M CF_3SO_3H: 38.60 ppm.

$C_6H_5SO_3H$

The four ^{13}C shifts observed for $C_6H_5SO_3^-$ in both water and Me_2SO were assigned by taking the most deshielded carbon as C-1, and then C-4 (*para*) > C-2,6 (*ortho*) > C-3,5 (*meta*), in accordance with the effect of an electron-withdrawing substituent on the benzene ring. These assignments are those of Breitmaier and Voelter (18) and Kosugi and Takeuchi (19) but differ (for C-2 and C-3) from those of Cerfontain *et al.* (8) and Sadtler (20). The assignment of the shifts for $C_6H_5SO_3H$ follows from the curves giving the shifts as a function of acidity in H_2O–H_2SO_4 and Me_2SO–CF_3SO_3H media. The C-1 and C-4 curves cross at high acidity ($-H_o$ = 9 in water) so that the assignments of C-1 and C-4 given by Kosugi and Takeuchi (19) should be reversed. The ^{13}C shift curves against acidity are only given in Fig. 1 for Me_2SO–CF_3SO_3H media since for H_2O–H_2SO_4 media our curve is the same as that given by Cerfontain *et al.* (8) after switching C-2 and C-3. The shift curves obtained in both media are essentially similar. While C-1 moves upfield with an increase in acidity, the other carbons move downfield. The shift variations (titration shifts) are C-1 > C-4 ≫ C-2 ~ C-3 and are somewhat larger in Me_2SO than in water because, with the absence of H-bonding to $C_6H_5SO_3^-$ in Me_2SO, in this latter solvent C-1 is moved 6.2 ppm downfield, and C-4 2.8 ppm upfield, from their values in water. The ^{13}C protonation shifts observed for benzenesulfonate are similar in magnitude to those reported for the protonation of aniline (14, 18) and benzoate (18), and much larger than those for the alkylsulfonates, amines, and carboxylates (18).

The curves giving the chemical shifts of the four different types of carbon atoms in $C_6H_5SO_3H$ as a function of H_o in H_2O–H_2SO_4 media are not simple sigmoidal curves. Taking the C-1 curve as an example, there is no plateau at low acidity corresponding to δ ($C_6H_5SO_3^-$) but δ decreases somewhat linearly from 142.5 ($-H_o$ = 1.5) to 140.0 ppm ($-H_o$ = 5.5) and the expected plateau at high acidity for δ ($C_6H_5SO_3H$) is not clearly defined. To get around these difficulties, which may be due to "medium effects", Cerfontain *et al.* (8) essentially assumed that below 50% H_2SO_4, δ was that of $C_6H_5SO_3^-$, and for 98.4% H_2SO_4, δ was that of $C_6H_5SO_3H$. The authors actually used C-2 as intramolecular standard in their treatment, but δ (C-2) is nearly constant. They further assumed that there was a linear medium effect of δ ($C_6H_5SO_3^-$) and no medium effect on δ ($C_6H_5SO_3H$). Under these conditions they calculated pK_{aw} = −6.56 using the H_o^a scale and found that half-protonation was at H_o = −7.7. We treated our own ^{13}C shift data in H_2O–H_2SO_4 mixtures using the method of Cox and Yates as previously described (21) and we obtained pK_{aw} = −2.53 ± 0.12. This value is near −2.8, the value estimated by Guthrie (5), and we prefer it to the pK_{aw} value obtained by Cerfontain *et al.* (8) because of their questionable assumptions concerning possible medium effects.

The ^{13}C shift curves for $C_6H_5SO_3^-$ as a function of the molar concentration of CF_3SO_3H in Me_2SO–CF_3SO_3H media (Fig. 1) are similar to those in H_2O–H_2SO_4: there is no plateau for δ ($C_6H_5SO_3^-$) at low acidity, but only a linear decrease of δ, and the plateau for δ ($C_6H_5SO_3H$) is not reached in pure CF_3SO_3H. The interpretative difficulties are compounded by the absence of an acidity scale in Me_2SO so that we can only conclude from these data that $C_6H_5SO_3H$ is a strong acid in Me_2SO just as in water. This is confirmed by the fact that the shift of the Me_2SO carbons in a 2.06 M $C_6H_5SO_3H$ solution (39.74 ppm) is close to the same shift in a 1.98 M CF_3SO_3H solution (39.59 ppm), so that both acids would have a similar strength in Me_2SO.

Enthalpy data

Enthalpies of solution

On the basis of our nmr data, CH_3SO_3H in water and CF_3SO_3H and $C_6H_5SO_3H$ in water and Me_2SO were taken as strong electrolytes. Possible ion-pairing effects for $CH_3C_6H_4SO_3Ag$ were neglected since $CH_3C_6H_4SO_3^-$ is a weakly coordinating anion and Ag^+ is strongly solvated by both Me_2SO and water.

The enthalpies of solution, Q_s, were determined for the acid CH_3SO_3H in water and for CF_3SO_3H, $C_6H_5SO_3H$, and $CH_3C_6H_4SO_3Ag$ in Me_2SO and water. The plots of Q_s against the number of moles dissolved ((1–40) × 10^{-4} mol) were linear and the least-squares slopes gave the molar enthalpies of solution in Me_2SO (ΔH_{ss}) or in water (ΔH_{sw}) according to

[4] $MA\ (l\ or\ c) = M^+\ (s\ or\ w) + A^-\ (s\ or\ w)$

where M stands for H^+ or Ag^+.

In the concentration range studied ((1–40) × 10^{-3} M), the concentration dependence of ΔH_{ss} or ΔH_{sw} for uni–univalent electrolytes is small ($\Delta H_{ss} = \Delta H_{ss}^\circ + 3.4c^{1/2}$ and $\Delta H_{sw} = \Delta H_{sw}^\circ + 3.1c^{1/2}$) (22) and masked by experimental errors. The ΔH_{ss} and ΔH_{sw} values were thus taken as the enthalpies of solution at infinite dilution, ΔH_{ss}° and ΔH_{sw}°, which are given in Table 1.

For CH_3SO_3H, a weaker acid in Me_2SO, we first determined according to eq. [5] the heats of solution of the acid in 0.05 M basic solutions of proton sponge (PS) and of Dap. The enthalpies of protonation according to eq. [6] of PS (−48.5 kJ mol^{-1}) (23) and of Dap (−42.4 kJ mol^{-1}) (15) were then substracted to give an average value of −46.5 ± 3 kJ mol^{-1} for ΔH_{ss}° of CH_3SO_3H in Me_2SO.

[5] $HA(l) + B(s) = BH^+(s) + A^-(s)$

[6] $H^+(s) + B(s) = +BH^+(s)$

We also attempted to determine separately the solution enthalpy of unionized CH_3SO_3H in Me_2SO, and ΔH_{is}° the enthalpy of ionization of CH_3SO_3H according to

[7] $HA(l) = HA(s)$

[8] $HA(s) = H^+(s) + A^-(s)$

We used for this purpose our corrected experimental value of −41.5 ± 0.3 kJ mol^- for the enthalpy of solution of CH_3SO_3H (1) in 0.10 M CF_3SO_3H in Me_2SO. We calculated α, the

[d]Reference 17.

fraction of ionized CH_3SO_3H, in this medium from the value of the ionization constant of CH_3SO_3H ($K_{as} = 10^{-1.70}$ for an ionic strength $I = 0$) (9, 10) and the ionic activity coefficients calculated according to the appropriate Debye–Hückel equation (24). We then obtained an approximate value for the ionization enthalpy of CH_3SO_3H: $\Delta H_{is}^\circ = -10 \pm 7$ kJ mol^{-1}.

We also determined the heat of solution of CH_3SO_3H in Me_2SO at high dilution ((2–9) $\times 10^{-3}$ M) as -44.6 ± 0.3 kJ mol^{-1}. This value is to be preferrred to -59.0 ± 0.8 kJ mol^{-1}, reported by Arnett *et al.* (25), particularly since the latter value leads with their other data to a surprising +33.5 kJ mol^{-1} for the enthalpy of ionization of CH_3SO_3H in Me_2SO. Our own ionization enthalpy −10 kJ mol^{-1} is also more in line with what would be expected for CH_3SO_3H, an acid with $pK_{as} = 1.70$, since HCl, with a comparable $pK_{as} = 2.0$ (9, 10), has an ionization enthalpy of −5.0 kJ mol^{-1} (17).

Enthalpies of transfer

The enthalpies of solution of our electrolytes in water and Me_2SO are best discussed on the basis of single-ion enthalpies of transfer, where the enthalpy of transfer of an ion such as A^-, from water to Me_2SO, $\Delta H_{ws}(A^-)$, is defined according to

[9] $A^-(w) = A^-(s)$

The enthalpies of transfer of the electrolytes M^+A^- are first deduced from the data in Table 1. These enthalpies are then split into single-ion values on the basis of the well-known tetraphenylarsonium–tetraphenylborate (tatb) extrathermodynamic assumption ($\Delta H_{ws}^\circ(BPh_4^-) = \Delta H_{ws}^\circ(AsPh_4^+)$) (26). We first calculated $\Delta H_{ws}^\circ(CF_3SO_3^-) = +1.9$ kJ mol^{-1} from the published enthalpies of solution of KCF_3SO_3 (Table 1) and the recommended value (26) $\Delta H_{ws}^\circ(K^+) = -35.4$ kJ mol^{-1}. We obtained next from the enthalpies of solution of CF_3SO_3H and $\Delta H_{ws}^\circ(CF_3SO_3^-)$ the value $\Delta H_{ws}^\circ(H^+) = -27.8$ kJ mol^{-1}. Then from the latter value and the solution enthalpies of CH_3SO_3H and $C_6H_5SO_3H$ we calculated $\Delta H_{ws}^\circ(CH_3SO_3^-) = +29.6$ kJ mol^{-1} and $\Delta H_{ws}^\circ(C_6H_5SO_3^-) = +20.2$ kJ mol^{-1}. Finally, we obtained $\Delta H_{ws}^\circ(CH_3C_6H_4SO_3^-) = +21.8$ kJ mol^{-1} from the solution enthalpies of $CH_3C_6H_4SO_3Ag$ and $\Delta H_{ws}^\circ(Ag^+) = -53.3$ kJ mol^{-1} (26). The ΔH_{ws}° values are given in Table 2.

Anion transfer

First we note that the enthalpies of transfer for the anions are all positive, indicating poorer solvation in Me_2SO than in water. This is as expected since the important H-bonding contribution

TABLE 2. Ionic enthalpies of transfer from H_2O to Me_2SO at 25°C

[d]Calculated from $\Delta H_{ws}^\circ(H^+, Cl^-)$ and $\Delta H_{ws}^\circ(Cl^-)$, see text.

to anion solvation is missing in Me_2SO, a dipolar aprotic solvent. The more positive value of ΔH_{ws}° for the aliphatic sulfonate $CH_3SO_3^-$ than for the aromatic sulfonates $C_6H_5SO_3^-$ and $CH_3C_6H_4SO_3^-$ is in line with the positive transfer values for alkanes (27), and a transfer value near zero for benzene (28) because of weak interactions between the benzene ring and Me_2SO. These differences in the transfer of $CH_3SO_3^-$ and $C_6H_5SO_3^-$, from water to Me_2SO, account in part for our finding that while both CH_3SO_3H and $C_6H_5SO_3H$ are strong electrolytes in water, CH_3SO_3H is incompletely ionized in Me_2SO in contrast to $C_6H_5SO_3H$. If we compare now ΔH_{ws}° for benzene, −0.3 kJ mol^{-1}, with $\Delta H_{ws}^\circ = +0.6$ kJ mol^{-1} for toluene (28), we isolate +0.9 kJ mol^{-1} for the transfer of -CH_3. Assuming this group contribution to be additive we calculate, from our $\Delta H_{ws}^\circ = +21.8$ kJ mol^{-1} for $CH_3C_6H_4SO_3^-$, a value of $\Delta H_{ws}^\circ = +20.9$ kJ mol^{-1} for $C_6H_5SO_3^-$, i.e., a value in very good agreement with our direct experimental value +20.2 kJ mol^{-1}.

It is worth noting that the enthalpy of transfer of $CH_3SO_3^-$, +29.6 kJ mol^{-1}, is highly positive. In fact, it is more positive than the transfer values listed for all anions in Marcus' compilation (26), for example, for Cl^-, $\Delta H_{ws}^\circ = +20$ kJ mol^{-1}, for Br^-, $\Delta H_{ws}^\circ = +5$ kJ mol^{-1}. Since the ionic radius of $CH_3SO_3^-$ is certainly larger than that of Cl^- and Br^-, it follows that, for its size, $CH_3SO_3^-$ must be strongly stabilized in water through H-bonding. It is interesting to contrast the ΔH_{ws}° values for closely related $CH_3SO_3^-$ (+29.6 kJ mol^{-1}) and $CF_3SO_3^-$ (+1.9 kJ mol^{-1}). Since, on account of ionic size, the enthalpy of solvation (gas to solvent) ΔH_{gs}° of $CF_3SO_3^-$ in Me_2SO must be less exothermic than that of $CH_3SO_3^-$, it follows that in water $CF_3SO_3^-$ is at least 28 kJ mol^{-1} less exothermically solvated than $CH_3SO_3^-$. Interestingly, a similar situation prevails for the related pair $CF_3CO_2^-$ and $CH_3CO_2^-$. In this case the hydration enthalpy, ΔH_{gw}°, can be calculated from gas phase data and the values are such that $CF_3CO_2^-$ is some 85 kJ mol^{-1} less exothermically solvated than $CH_3CO_2^-$ (29). It is tempting but perhaps not justified to partly explain the large differences in hydration enthalpies (ΔH_{gw}°) for the pairs $CF_3SO_3^-$ − $CH_3SO_3^-$ or $CF_3CO_2^-$ − $CH_3CO_2^-$ in terms of contrasting interactions of the CF_3- and CH_3- groups. However, using for this purpose the neutral compounds CH_4 and CF_4 as models is inconclusive: even though CF_4 is a very hydrophobic solute, the hydrophobic enthalpic effect is small (27) and the solution

enthalpies of CH_4 and CF_4 in water differ by only 1 kJ mol^{-1} (27). At any rate, the ΔH^o_{gw} trend must reflect increasing H-bonding of $-SO_3^-$ when passing from $CF_3SO_3^-$ to $CH_3SO_3^-$.

Finally, our value of ΔH^o_{ws} for $CH_3SO_3^-$ enables us to calculate ΔH^o_{ws} for other alkyl-sulfonate ions, since Krishnan and Friedman (30) computed values of ΔH^o_{ws} as a function of alkyl chain but with an arbitrary constant included because they could not measure the heats of solution of various alkyl-sulfonates in Me_2SO.

Proton transfer

We now come to consider the enthalpy of transfer of the proton, ΔH^o_{ws} (H^+) = −27.8 kJ mol^{-1}. This value is to be compared with the only previously reported value (17) we obtained using experimental enthalpy data on the solution and ionization of HCl in both Me_2SO and water (Table 1). We calculated ΔH^o_{ws} (H^+) = −25.5 kJ mol^{-1} by using the value ΔH^o_{ws} (Cl^-) = +18.8 kJ mol^{-1}. However, if we use the value now recommended by Marcus (26), +20.0 kJ mol^{-1}, for the transfer of Cl^-, we obtain ΔH^o_{ws} (H^+) = −26.7 kJ mol^{-1}, in very good agreement, considering the many steps involved, with our new value (−27.8 kJ mol^{-1}) based on CF_3SO_3H ionization. We can therefore confidently select as our best value ΔH^o_{ws} (H^+) = −27.4 kJ mol^{-1}. This good agreement also gives credence to our value for the enthalpy of ionization of HCl in Me_2SO (17), ΔH^o_{is} = −5.0 kJ mol^{-1}, and casts doubt on the value reported by Arnett *et al.* (25), +54.4 kJ mol^{-1}, from data obtained using both HSO_3F as a strong acid and potassium dimsylate as a strong base in Me_2SO. The values of ΔH^o_{is} quoted for HBr and HI are also likely in error.

The value of the enthalpy of transfer of the proton is useful in that it permits us to rationalize the enthalpy changes observed for protonation or deprotonation reactions when comparing data in water and Me_2SO (23). ΔH^o_{ws} (H^+) can also be used, in conjunction with gas phase acidity measurements involving acids HA, to obtain and compare solvation enthalpies of anions, in Me_2SO, which is a simpler solvent with no contributions of H-bonding interactions to solvation. Finally, the value of ΔH^o_{ws} (H^+) = −27.4 kJ mol^{-1}, which measures the basicity difference between bulk water and Me_2SO, enables us to compare the basicity of Me_2SO with that of other solvents on the basis of their ΔH^o_{ws} (H^+) values: dimethylformamide (−24.6), propylene carbonate (+45.7), acetonitrile (+60.7), and sulfolane (+72 kJ mol^{-1}).[2]

Study of trichloronitrosomethane: regioselective cycloadditions of 2-substituted-1,3-butadienes

CHENG-TUNG LIN[1] AND WEN-JEI HSU

Department of Chemistry, Tunghai University, Taichung 40098, Taiwan, Republic of China

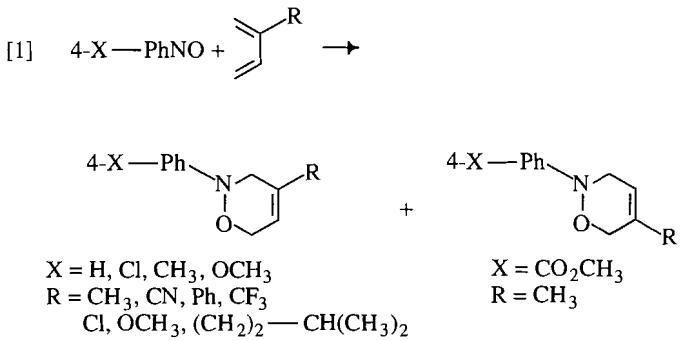
Received December 14, 1988[2]

CHENG-TUNG LIN and WEN-JEI HSU. Can. J. Chem. **67**, 2153 (1989).

The regioselectivity of cycloaddition reactions of trichloronitrosomethane (**1**) with 2-alkyl (R = Me, Et, *i*-Pr, *t*-Bu, CF_3, Bz, and Cl) and 2-aryl (Ar = Ph, 4-CH_3OPh, 4-CH_3Ph, 3-CH_3Ph, and 4-ClPh) 1,3-butadienes is described. The orientation of cycloaddition is substituent dependent, producing 2,5-disubstituted (*para*) and 2,4-disubstituted (*meta*) 3,6-dihydro-1,2-oxazines from 2-alkyl- and 2-aryl-1,3-butadienes respectively. Increasing the bulk of the substituent from methyl to *tert*-butyl in 2-alkyl-1,3-butadienes increases the regioselectivity. Kinetic studies in various solvents indicate that plots of log k_m/k_H vs. Hammett σ^+ values give straight lines with the ρ values lying between −0.60 and −0.91 for the reactions with 2-aryl-1,3-butadienes. A concerted reaction mechanism is proposed and the orientation preference is consistent with frontier molecular orbital predictions for 2-alkyl-1,3-butadienes. In the reactions with 2-aryl-1,3-butadienes, a transition state leading to a spin-paired diradical, which then converts by partial electron transfer to zwitterionic structure, is proposed.

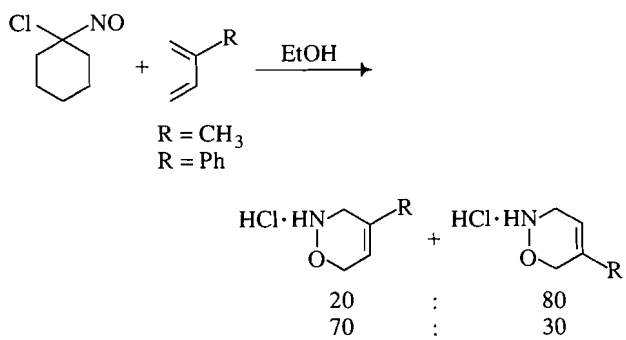
Key words: trichloronitrosomethane, 3,6-dihydro-1,2-oxazine, regioselectivity, [2 + 4] cycloaddition.

CHENG-TUNG LIN et WEN-JEI HSU. Can. J. Chem. **67**, 2153 (1989).



On a déterminé la régiosélectivité des réactions de cycloaddition du trichloronitrosométhane (**1**) sur des 2-alkyl (R = Me, Et, *i*-Pr, *t*-Bu, CF_3, Bz et Cl) et 2-aryl (Ar = Ph, 4-CH_3OPh, 4-CH_3Ph, 3-CH_3Ph et 4-ClPh) buta-1,3-diènes. L'orientation de la cycloaddition dépend du substituant; à partir des 2-alkyl- et des 2-aryl-buta-1,3-diènes, on obtient respectivement des 3,6-dihydro-1,2-oxazines disubstituées en 2,5 (*para*) et en 2,4 (*méta*). Avec les 2-alkyl-buta-1,3-diènes, une augmentation du volume du substituant (en allant du méthyle au *tert*-butyle) provoque une augmentation de la régiosélectivité. Des études cinétiques dans divers solvants suggèrent que les courbes du log k_m/k_H vs. les valeurs σ^+ de Hammett donnent des droites avec des valeurs de ρ variant de −0,60 à −0,91 pour les réactions des 2-aryl-buta-1,3-diènes. Pour les 2-alkyl-buta-1,3-diènes, on suggère un mécanisme réactionnel concerté et la préférence de l'orientation est en accord avec les prédictions des orbitales moléculaires frontières. Dans les réactions des 2-aryl-buta-1,3-diènes, on propose une état de transition conduisant à un diradical dont les spins sont pairés qui se transforme ensuite en une structure zwitterionique par un transfert partiel d'électrons.

Mots clés : trichloronitrosométhane, 3,6-dihydro-1,2-oxazine, régiosélectivité, cycloaddition [2 + 4].



[Traduit par la revue]

Introduction

It has been recognized for many years that carbon-nitroso compounds are reactive heterodienophiles (for reviews see ref. 1). The most useful synthetic application of nitroso compounds is the cleavage of the nitrogen–oxygen bond in the [4 + 2] cycloadduct to generate a 1,4-bifunctional group in a "*syn*" orientation (2). Extensive studies of cycloadditions of substituted nitrosobenzenes reveal that nitroso compounds react regioselectively with unsymmetrical dienes (3). The resulting orientation preference has been rationalized on the basis of the relative stability of a transition state leading to an intermediate lying between nonpolar and zwitterionic structure (3*b*). In most cases of 2-substituted dienes, nitrosobenzenes react so that the nitrogen and oxygen atoms form bonds at the C-1 and C-4 atoms of the dienes, respectively, to afford the "*meta*" adducts (i.e., 4-substituted 3,6-dihydro-1,2-oxazine). The regioselectivity is independent of the electronic effects of substituents on 1,3-butadiene (3*e*). Interestingly, the addition of nitrosobenzene to α-myrcene exhibited a marked dependence on reaction temperature such that increasing the reaction temperature led to the reversed orientation of cycloaddition (4). In contrast, the cycloaddition of a nitrosobenzene having a strongly electron-withdrawing substituent, such as 4-(methoxycarbonyl)nitrosobenzene, with isoprene proceeded with the opposite regioselectivity to yield a "*para*" adduct, eq. [1] (5). This latter work implies that the frontier molecular orbital (FMO) coefficients of nitrosobenzene are reversed by electron-withdrawing substituents.

[1] 

The reaction of α-chloronitrosocyclohexane with isoprene has been found to give opposite regioselectivity to that with 2-phenyl-1,3-butadiene, eq. [2] (6). The observed result in the case of isoprene was rationalized by invoking remote steric factors, but the same argument does not satisfactorily explain the reversed regioselectivity in the reaction with 2-phenyl-1,3-butadiene.

Recently, in cases in which steric effects can be neglected, the predominant *para* cycloadditions of nitrosocarbonyl compounds with electron-rich and electron-deficient 2-substituted 1,4-cyclohexadienes were rationalized by frontier molecular orbital theory, eq. [3] (7*a*). In contrast, the regiochemistry of the cycloaddition reaction of nitrosocarbonyl compounds with 1,2-dihydropyridines indicated a high dependence upon electronic effects of substituents present in the dienamides (7*b*).

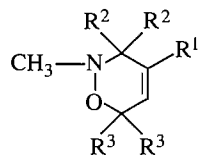
To gain a better understanding of the regioselectivity and reaction mechanism of the [4 + 2] cycloadditions of nitroso compounds, we undertook the investigation of the reactions of trichloronitrosomethane (**1**) with a variety of 2-substituted-1,3-butadienes. The high steric demand of the trichloromethyl group was expected to have a stronger influence than the phenyl group in the developing transition state and thus lead to higher regioselectivity.

[3] 

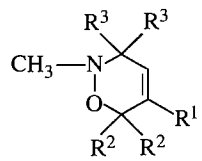
The reactions of **1** in methylene chloride with cycloalkadienes were essentially complete in seconds at −78°C, producing the Diels–Alder cycloadducts in high yields (8, 9). Earlier, we reported that **1** reacted as a nitrosoformic chloride equivalent in the cyclization with acyclic 1,3-butadienes (9). For example, **1** reacted with 2,3-dimethyl-1,3-butadiene to form a moisture-sensitive cycloadduct, 4,5-dimethyl-2-trichloromethyl-3,6-dihydro-1,2-oxazine, which was hydrolyzed to afford the corresponding 2-chloroformyl-1,2-oxazine, eq. [4] (9). We describe herein the results of studies on the regiochemistry of **1** in cycloaddition reactions.

[4] 

Results



Reactions of 1 with 2-alkyl-1,3-butadienes



Cycloaddition of **1** with isoprene proceeded slowly in methylene chloride solution at −78°C, and afforded, after warming the reaction to room temperature and subsequent hydrolysis, an inseparable 1:1 mixture of 1,2-oxazines **2***a* and **3***a*. The ratio was estimated by integration of the two methyl groups of the cycloadducts at δ 1.60 and δ 1.67 in the ^{1}H nmr spectrum of the mixture (9). Reduction of this regioisomeric mixture with lithium aluminum hydride gave N-methyl compounds **4***a* and **5***a* in quantitative yield with no change in the ratio of isomers (9).

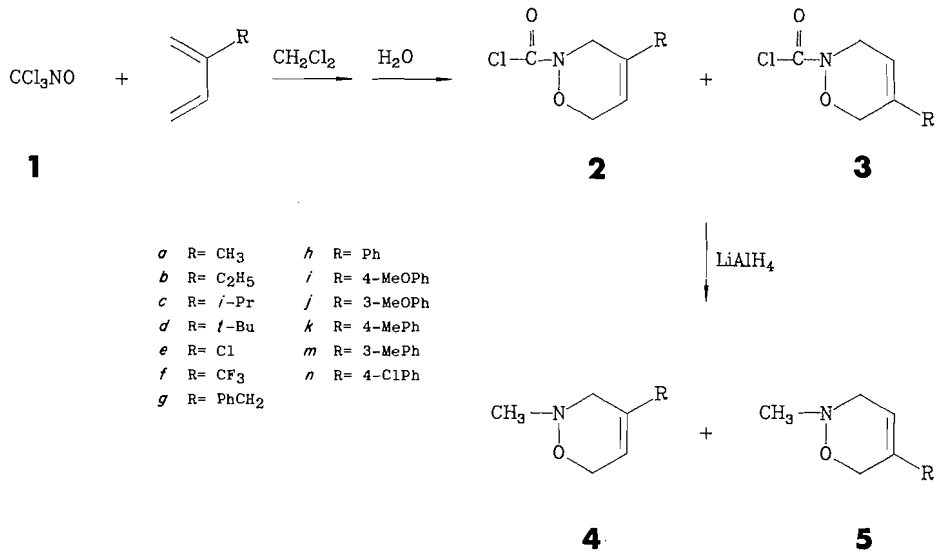
Bz	**2***g*/**3***g*	25/75			

Under the same conditions as above, the reaction of **1** with 2-ethyl-1,3-butadiene also produced a mixture of two inseparable regioisomeric products **2***b* and **3***b*. The nearly overlapping ^{1}H nmr signals of the regioisomers caused difficulty in the determination of the product distribution. However, the ring methylene hydrogens adjacent to the oxygen atom in the 2-methyl-3,6-dihydro-1,2-oxazines were observed at about 1 ppm lower field as compared to the ring hydrogens adjacent to the nitrogen atom (9, 10). Therefore the ratio of products and the assignment of chemical shifts of the methylene hydrogens were determined precisely by analysis of deuterium-labeled products obtained from the reaction of **1** with 4,4-dideuterio-2-ethyl-1,3-butadiene followed by LAH reduction. Thus, the ratio of **2***b*/**3***b* was derived from the integration of the signal at δ 3.11 for NCH_2 in *d*-**4***b* and the signal at δ 4.22 for OCH_2 in *d*-**5***b*. The results are shown in Table 1.



d-**4***b* R^1 = Et, R^2 = H, R^3 = D
d-**4***c* R^1 = *i*-Pr, R^2 = H, R^3 = D
d-**4***h* R^1 = Ph, R^2 = D, R^3 = H

d-**5***b* R^1 = Et, R^2 = H, R^3 = D
d-**5***c* R^1 = *i*-Pr, R^2 = H, R^3 = D

In contrast to 2-methyl and 2-ethyl 1,3-butadienes, the reaction of 2-isopropyl and 2-*tert*-butyl 1,3-butadienes with **1** provided exclusively compounds **3***c* and **3***d*, respectively. The assignments of N—O orientation in **3***c* and **3***d* were made by spin–spin decoupling experiments of the ^{1}H nmr spectra. Double resonance irradiation of the NCH_2 and OCH_2 signals showed an allylic coupling of ca. 1.5 Hz for the OCH_2 and a vicinal coupling of ca. 3.0 Hz for the NCH_2 with the vinylic hydrogen. Reduction of **3***c* with a slurry of LAH yielded the corresponding product **5***c* in high yield. The structural identification of **3***c* was further confirmed by a deuterium labeling experiment in which *d*-**5***c* was obtained from the reaction of **1** with 4,4-dideuterio-2-isopropyl-1,3-butadiene and followed by LAH reduction. The ^{1}H nmr spectrum of *d*-**5***c* lacked the signal at δ 3.16 for NCD_2 and the signal at δ 4.29 for OCH_2 remained.

Electron-deficient dienes such as 2-chloro-1,3-butadiene cyclized well to form 1,2-oxazines, but the inductive effects of the electron-withdrawing substituents did not reverse the

regioselectivity towards *meta* addition. Similar to the reaction of 2-ethyl-1,3-butadiene, 2-benzyl-1,3-butadiene reacted with **1** less regioselectively. However, the diene having a bulky 2-trifluoromethyl substituent reacted with **1** to yield the *para* cycloadduct **3***f* with high regioselectivity (Table 1).

*Reactions of **1** with 2-aryl-1,3-butadienes*

Reaction of 2-phenyl-1,3-butadiene with **1** afforded a regioisomeric mixture of **2***h* and **3***h* in a total yield of 68%. The major product **2***h* was separated chromatographically on silica gel and recrystallized from hexane. The methylene hydrogens neighboring the nitrogen and oxygen atoms of **2***h* were too close to allow double resonance nmr spectral analysis. Therefore the orientation of cycloaddition was again deduced from the ^1H nmr spectrum of the reduced derivative **4***h* in which decoupling was done on the signal of the ring hydrogens on the carbon atom next to nitrogen. The vinylic hydrogen of **4***h* appears as a triplet with a coupling constant of ca. 3.0 Hz with the OCH_2. This decoupling experiment led us to assign the *meta* orientation for **2***h* (6). The chemical shifts of the methylene hydrogens, NCH_2 and OCH_2, in **2***h* were differentiated by the reaction of **1** with 1,1-*d*,*d*-2-phenyl-1,3-butadiene. The minor cycloadduct **3***h* was separated from the mixture by repeated chromatography. The chemical shifts of the ring hydrogens of **2***h* and **3***h* are shown in Table 2.

of reactions performed at different temperatures and in several solvents were determined from ^{1}H nmr spectra via integration of the ring hydrogens (Table 2). The data are recorded in Table 3.

Under the same conditions, the reaction of 2-(4′-methoxyphenyl)-, 2-(3′-methoxyphenyl)-, 2-(4′-methylphenyl)-, 2-(3′-methylphenyl)-, and 2-(4′-chlorophenyl)-1,3-butadiene with **1** in methylene chloride proceeded smoothly to give the corresponding 1,2-oxazines in yields of 60–80%. The substituent on the aromatic ring has very little influence on the chemical shifts of the oxazine methylene hydrogens (Table 2). The addition orientation was established by analysis of the reduced derivatives **4**. The product distributions of cycloadditions under various conditions are recorded in Table 3. The product ratios, while influenced by the *para* substituent on the aromatic ring, are unaffected by the reaction solvent and temperature.

Kinetic studies

To minimize side reactions and obtain pseudo-first-order rate constants, the reactions of **1** were performed by using a 70-fold excess of 2-aryl-1,3-butadienes in methylene chloride, tetrahydrofuran, and chloroform as solvents. The progress of the cycloadditions was followed by observing the disappearance of absorption at λ_{max} 592 nm for **1**. Satisfactory pseudo-first-order kinetic plots covering at least three half-lives were obtained. The k value obtained was equal to the sum of the reaction rates of *para* cycloaddition (k_p) and *meta* cycloaddition (k_m). The data are summarized in Table 4.

The influence of aryl substituents in 2-aryl-1,3-butadiene on the rates of *meta* cycloaddition can be correlated satisfactorily by the Hammett equation using σ^+ values (Fig. 1). The reaction constants were obtained by the method of least squares and

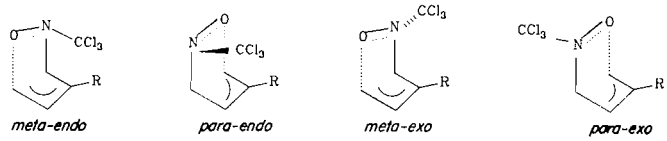

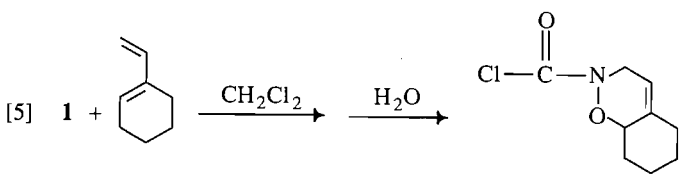

FIG. 2. Steric interaction between **1** and 2-substituted 1,3-butadiene in the path of transition state.

were found to be −0.75, −0.91, and −0.60, with correlation coefficients of 0.983, 0.996, and 0.996 in solutions of methylene chloride, tetrahydrofuran, and chloroform, respectively. Thus the low values of ρ indicate that the reaction rates are not significantly affected by the polarity of solvents. In contrast, a plot of log $k_{X,p}/k_{H,p}$ vs. σ or σ^+ value gives a poor correlation.

Discussion

The product distribution shown in Table 1 indicates the possible existence of different transition states that determine the regiochemistry of cyclization reactions. The observed regiochemical preference for the *para* cycloaddition of **1** with 2-alkyl 1,3-butadienes parallels that of α-chloronitrosocyclohexane, eq. [2] (2). These results can be rationalized in terms of steric effects in the transition state of the Diels–Alder reaction.

Increasing the bulk of the 2-alkyl butadiene substituent from methyl, ethyl, benzyl to *tert*-butyl increases the regioselectivity of the cycloaddition. Apparently the product orientation reflects steric interference between the trichloromethyl group in **1** and the 2-substituent on the diene. We suggest that the importance of the steric effect is reinforced (Fig. 2) by a mechanism involving a concerted nonsynchronous Diels–Alder transition state (11), in which the electrophilic nitrogen of the dienophile forms a bond with C-1 or C-4 of butadiene to a higher degree than the electron-rich oxygen of the dienophile. Therefore, it is not surprising that the "*para-exo*" formation could be the most preferential approach in the development of the transition state. This steric factor was also manifested in the regioselective reaction of **1** with 1-vinylcyclohexene, eq. [5] (9).

The orientational preference of cycloaddition has been found in several cases to be independent of the inductive effect of the 2-substituent (2*a*, 7, 12). That is, replacement of an electron-donating substituent by an electron-withdrawing one does not reverse the regioselectivity. This result can be rationalized by FMO theory assuming that all coefficients of C-1 in the highest occupied molecular orbital (HOMO) of 2-substituted dienes are larger than the coefficients of C-4 (13). The closest pair of FMO's in the transition state is composed of the HOMO(diene) and LUMO(dienophile) and the orientational preference is determined by the combination of the largest coefficient in these MO's. Therefore the similar regioselectivity for the reactions of **1** with butadienes having electron-withdrawing substituents, 2-Cl and 2-CF_3, and the weakly electron-releasing substituent, 2-alkyl, is predicted and observed[3] (Fig. 3).

[3]The coefficients of **1** are not known. We simplify the problem by taking CCl_3 as an electron-withdrawing group having electronegativity $X_{CCl_3} = 3$ (14).

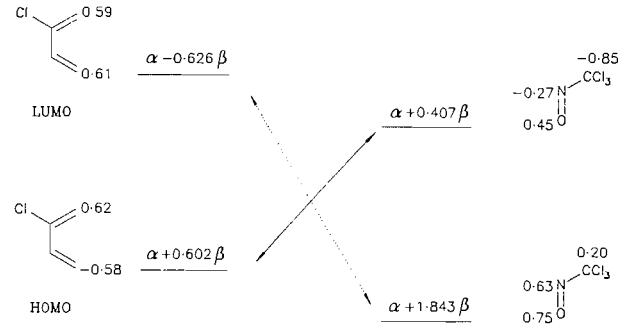

FIG. 3. Frontier orbital coefficients and energies of HOMO and LUMO of 2-chloro-1,3-butadiene and **1**.

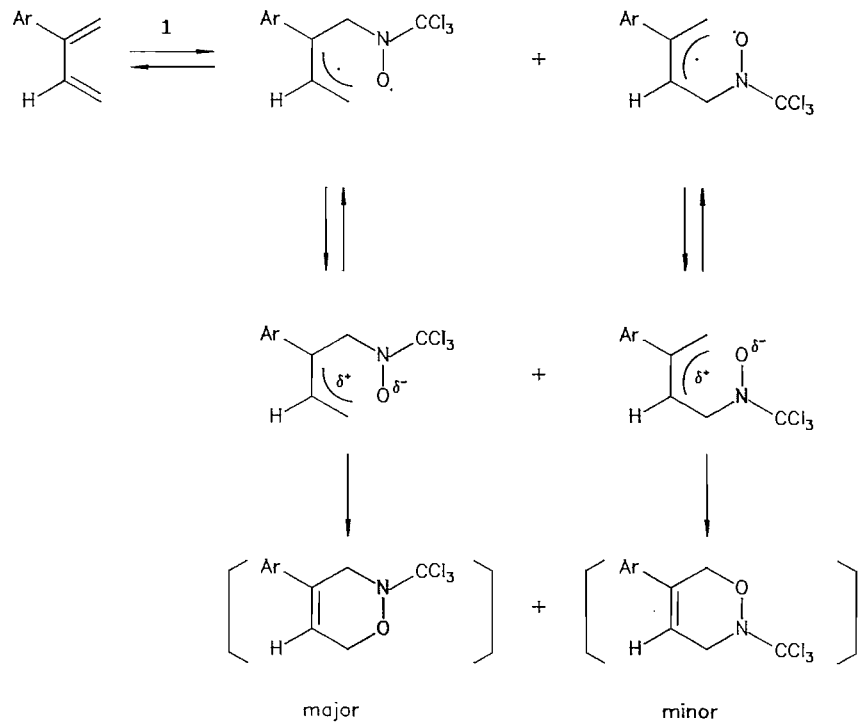

The reversed regioselectivity of the reactions of **1** with 2-aryl-1,3-butadienes is also similar to that of α-chloronitrosocyclohexane, although only the reaction of 2-phenyl-1,3-butadiene with the latter dienophile has been reported, eq. [2] (6*a*). The observed results show that an electron-donating group in the aromatic ring accelerates the cyclization, while an electron-withdrawing group retards it. The negative and low Hammett ρ values are similar to those derived from the Diels–Alder reactions of nitrosobenzene with *para*-substituted 1-phenyl butadienes (3*b*). This result leads us to believe that the cycloaddition of **1** similarly involves an intermediate that has a small but significant degree of polar character with some positive charge on the carbon atom next to the benzene ring. Therefore the forming partially zwitterionic (or polarized) intermediates are stabilized by resonance with a benzene ring, and the ring closure of these intermediates leads to the observed regioselective adducts. The solvent effects on the cycloaddition should be relatively small and, in fact, the relative rates of cycloaddition are within a factor of 4.

Some low ρ values for free radical reactions are reported in the polymerization of styrene (ρ = −0.66) (15) and bromination of toluene (ρ = −0.500) (16). The ρ values observed here suggest the reactions of **1** with dienes involve diradical intermediates.

It seems reasonable to propose that cyclizations between **1** and *para*-substituted 2-phenyl butadienes proceed nonsynchronously (11*a*) (i.e., the N—C bond formed to a higher degree than the O—C bond) to form transition states that lead to diradical intermediates. Subsequently, partial electron transfer from carbon to oxygen occurs to form polarized intermediates as a result of the large difference in electronegativity of the two radicals (17) (Scheme 2).

In conclusion, the intermolecular [2 + 4] cycloadditions between **1** and 2-substituted dienes result in the regioselective construction of 2,3-dihydro-1,2-oxazines. The regioselectivity is substituent-dependent with regard to the butadiene. In the cases of 2-alkyl-1,3-butadienes and electron-deficient dienes, the preference of orientation is *para* cycloaddition. The reaction mechanism can be rationalized by a concerted nonsynchronous approach of **1** and the dienes. Although remote steric hindrance is expected to be a factor of less importance in reactions of 2-substituted dienes (2*a*, 4, 6), the bulky trichloromethyl group, similar to 1-chlorocyclohexyl, would exert control of orientation in cycloaddition. However, the reactions with 2-aryl-1,3-butadienes exhibit the reversed orientation. We adopt the proposal of Kresze and Kosbahn (3*b*) that the cycloaddition reaction proceeds by a two-step mechanism involving a benzene ring stabilized biradical and (or) zwitterionic intermediates.

Experimental

The nmr spectra were recorded on JEOL JNM-FX 100 MHz or Bruker AM 400 MHz spectrometers. The ^{13}C nmr spectra were measured at 25.02 or 100.6 MHz. All chemical shifts are reported relative to tetramethylsilane as internal standard in deuteriochloroform solution, and coupling constants are in hertz. Infrared spectra were run on a Perkin–Elmer 682 infrared spectrophotometer. Kinetic studies were measured on a Perkin–Elmer 552 uv–vis spectrophotometer. Mass spectra were recorded on a JEOL TMS D-100 or JEOL JMS-HX 110 mass spectrometer. Elemental analyses were obtained by the Analytical Center operated by National Taiwan University, Taipei, Taiwan. Melting points and boiling points are uncorrected. Flash chromatography was done on 0.040–0.063 nm silica gel (Merck Kieselgel 60). 4,4-*d*,*d*-2-Isopropyl-1,3-butadiene was synthesized from the Grignard reagent prepared from deuterioiodomethane (99%) (Merck Chem. Co.) and 2-isopropylacrolein (Aldrich Chemical Co.). α,α,α-d_3-Acetophenone was prepared by deuterium exchange of acetophenone. 1,1-*d*,*d*-2-Phenyl-1,3-butadiene was prepared from vinyl magnesium bromide and deuterioacetophenone. Trichloronitrosomethane was prepared by the procedure of Astley and Sutcliffe (18) and was purified several times by trap-to-trap fractionation *in vacuo* before use.

General procedure for cycloaddition of **1** *to 1,3-butadienes*

A 50-mL ampule was filled with a solution of **1** in methylene chloride at −78°C, and a solution of the 1,3-butadiene was injected through a rubber septum in one portion. The stirred solution was slowly warmed to room temperature until the disappearance of the blue color of **1**. After removal of the solvent, the resulting oil was dissolved in ether, followed by hydrolysis for 4 h at room temperature. The aqueous solution was extracted with ether. The combined ether layers were washed with water and brine, and then dried over sodium sulfate. Rotatory evaporation of the solvent followed by silica gel chromatography of the residue with methylene chloride/hexane (1:5) as eluent furnished the 1,2-oxazines. The relative yields of regioisomeric products were obtained from the ^1H nmr integration of the ring hydrogens before chromatography. The results are summarized in Table 1.

*2-Chloroformyl-4-ethyl(and 5-ethyl)-3,6-dihydro-1,2-oxazines (***2***b and* **3***b)*

Treatment of **1** (3.65 g, 24.6 mmol) with 2-ethyl-1,3-butadiene (2.00 g, 24.4 mmol) in methylene chloride (20 mL) afforded a 36:64 mixture of **2***b* and **3***b* in a total yield of 72% (3.09 g). Isomers **2***b* and **3***b* could not be separated by chromatography. The data for **2***b* and **3***b* were determined from a mixture. **2***b*: ^1H nmr δ: 1.08 (t, 3H, J = 7.5), 2.08 (q, d, 2H, J = 7.5 and 1.3), 4.16 (s, 2H, NCH_2), 4.50 (m, 2H, OCH_2), 5.59 (m, 1H); ^{13}C nmr δ: 11.3 (q), 26.1 (t), 47.4 (t), 69.7 (t), 114.9 (d), 134.4 (s), 147.0 (s). **3***b*: ^1H nmr δ: 1.06 (t, 3H, J = 7.5), 2.01 (q, d, 2H, J = 7.5 and 1.3), 4.23 (s, 2H, NCH_2), 4.42 (d, 2H, J = 1.4, OCH_2), 5.55 (m, 1H); ^{13}C nmr δ: 11.25 (q), 24.9 (t), 45.0 (t), 72.0 (t), 113.1 (d), 136.6 (s), 147.2 (s); ir (neat): 1730 (C=O), 1670 (C=C) cm^{-1}; ms m/z: 177 (M^+ + 2), 175 (M^+). *Anal.* calcd. for $C_7H_{10}ClNO_2$: C 47.87, H 5.74, N 7.98; found: C 47.89, H 5.71, N 7.89.

*2-Methyl-4-ethyl(and 5-ethyl)-3,6-dihydro-1,2-oxazines (***4***b and* **5***b)*

Reduction of a 36:64 mixture of regioisomers **2***b* and **3***b* (1.70 g, 9.6 mmol) with LAH (0.36 g, 9.5 mmol) in dry ether (15 mL) afforded a mixture of **4***b* and **5***b* as a colorless oil in 88% yield (1.07 g) without changing the ratio of regioisomers. The data for **4***b* and **5***b* were determined from a mixture. **4***b*: ^1H nmr δ: 1.04 (t, 3H, J = 7.4), 1.82 (q, 2H, J = 7.4), 2.67 (s, 3H), 3.11 (br, 2H, NCH_2), 4.24 (br, 2H, OCH_2), 5.47 (m, 1H); ^{13}C nmr δ: 11.6 (q), 27.0 (t), 45.6 (q), 59.2 (t), 67.9 (t), 117.2 (d), 136.2 (s). **5***b*: ^1H nmr δ: 1.03 (t, 3H, J = 7.4), 1.96 (q, 2H, J = 7.4), 2.66 (s, 3H), 3.18 (br, 2H, NCH_2), 4.22 (br, 2H, OCH_2), 5.47 (m, 1H); ^{13}C nmr δ: 11.6 (q), 24.9 (t), 45.6 (q), 56.1 (t), 70.4 (t), 115.3 (d), 138.0 (s); ir (neat): 1670 (C=C) cm^{-1}; ms m/z: 127 (M^+). *Anal.* calcd. for $C_7H_{13}NO$: C 66.10, H 10.30, N 11.01; found: C 65.88, H 10.43, N 10.42.

Reaction of **1** *with 4,4-*d,d*-2-ethyl-1,3-butadiene*

Treatment of **1** (2.06 g, 13.8 mmol) with 99% purity 4,4-*d*,*d*-2-ethyl-1,3-butadiene (1.17 g, 13.9 mmol) afforded 1.7 g (70%) of *d*-**2***b* and *d*-**3***b* as a 35:65 mixture of regioisomers. *d*-**2***b*: ^1H nmr δ: 1.08 (t, 3H, J = 7.5), 2.08 (q, 2H, J = 7.5), 4.15 (br, 2H), 5.59 (m, 1H); ^{13}C nmr δ: 11.2 (q), 26.1 (t), 47.4 (t), 115.5 (d), 134.5 (s), 147.1 (s).

For personal use only.

d-**3***b*: ^{1}H nmr δ: 1.06 (t, 3H, J = 7.5), 2.01 (q, 2H, J = 7.5), 4.42 (s, 2H), 5.52 (m, 1H); ^{13}C nmr δ: 11.2 (q), 24.8 (t), 71.9 (t), 113.0 (d), 136.6 (s), 147.1 (s); ms m/z (20 eV): 179 (M^+ + 2), 177 (M^+).

Reduction of a 35:65 mixture of deuterated *d*-**2***b* and *d*-**3***b* (1.00 g, 5.63 mmol) with LAH (0.21 g, 5.33 mmol) afforded *d*-**4***b* and *d*-**5***b* with the same relative ratio (0.65 g, 90% yield). *d*-**4***b*: ^{1}H nmr δ: 1.05 (t, 3H, J = 7.5), 1.84 (q, 2H, J = 7.5), 2.66 (s, 3H), 3.11 (br, 2H), 5.48 (m, 1H); ^{13}C nmr δ: 11.5 (q), 24.8 (t), 45.5 (q), 59.1 (t), 117.0 (d), 136 (s). *d*-**5***b*: ^{1}H nmr δ: 1.03 (t, 3H, J = 7.5), 1.96 (q, 2H, J = 7.5), 2.65 (s, 3H), 4.22 (br, 2H), 5.48 (m, 1H); ^{13}C nmr δ: 11.5 (q), 24.8 (t), 45.5 (q), 70.2 (t), 115.0 (d), 138.0 (s); ms m/z: 129 (M^+).

*2-Chloroformyl-5-isopropyl-3,6-dihydro-1,2-oxazine (***3***c)*

Treatment of **1** (6.02 g, 40.5 mmol) with 2-isopropyl-1,3-butadiene (3.84 g, 40.0 mmol) gave **3***c* (6.75 g, 89%) as a yellow oil; bp 43°C/5 Torr (1 Torr = 133.3 Pa); ^{1}H nmr δ: 0.92 (d, 6H, J = 6.8), 2.12 (sept, 1H, J = 6.8), 4.08 (br, NCH_2), 4.32 (d, OCH_2, J = 1.6), 5.38 (m, 1H); ^{13}C nmr δ: 20.47 (q), 30.67 (d), 44.43 (t), 71.03 (t), 112.2 (d), 140.7 (s), 147.0 (s); ir (neat): 1730 (C=O) cm^{-1}; ms m/z: 191 (M^+ + 2), 189 (M^+). *Anal.* calcd. for $C_8H_{12}ClNO_2$: C 50.66, H 6.38, N 7.34; found: C 50.63, H 6.31, N 7.19.

*2-Chloroformyl-5-isopropyl-3,3-*d,d*-3,6-dihydro-1,2-oxazine (*d-**3***c)*: ^{1}H nmr δ: 1.06 (d, 6H, J = 6.9), 2.25 (sept, 1H, J = 6.9), 4.47 (d, J = 1.5, OCH_2), 5.50 (m, 1H); ^{13}C nmr δ: 20.68 (q), 30.89 (d), 44.82 (m, weak), 71.04 (t), 112.1 (d), 140.8 (s), 147.0 (s); ir (neat): ν_{sym} (C–D) 2100 and ν_{asym} 2200 cm^{-1}; ms m/z: 193 (M^+ + 2), 191 (M^+).

*2-Methyl-5-isopropyl-3,6-dihydro-1,2-oxazine (***5***c)*

Treatment of **3***c* (1.49 g, 7.77 mmol) with LAH (0.295 g, 7.76 mmol) in 40 mL of dry ether as in the previous reduction experiment gave 0.96 g of **5***c* (88% yield) as a colorless oil; ^{1}H nmr δ: 0.98 (d, 6H, J = 6.7), 2.14 (sept, 1H, J = 6.7), 2.61 (s, NCH_3), 3.16 (br, NCH_2), 4.25 (br, OCH_2), 5.44 (m, 1H); ^{13}C nmr δ: 20.67 (q), 30.40 (d), 45.12 (q), 55.78 (t), 68.67 (t), 113.9 (d), 141.8 (s); ir (neat): 2850, 1660 (weak, C=C), 1460, 1430, 1380, 1050 cm^{-1}. HRMS for $C_8H_{15}NO$, calcd.: 141.1154; found: 141.1151.

*2-Methyl-5-isopropyl-3,3-*d,d*-3,6-dihydro-1,2-oxazine (*d-**5***c)*: ^{1}H nmr δ: 1.04 (d, 6H, J = 6.9), 2.17 (sept, 1H, J = 6.9), 2.66 (s, NCH_3), 4.29 (br, OCH), 5.49 (m, 1H); ^{13}C nmr δ: 21.15 (q), 30.49 (d), 45.70 (q), 55.60 (m, weak), 69.30 (t), 114.3 (d), 142.4 (s); ir (neat): ν_{sym} (C–D) 2060 and ν_{asym} (C–D) 2200 cm^{-1}; ms m/z: 143 (M^+).

*2-Chloroformyl-5-*tert*-butyl-3,6-dihydro-1,2-oxazine (***3***d)*

Treatment of **1** (2.60 g, 17.5 mmol) with 2-*tert*-butyl-1,3-butadiene (1.85 g, 16.4 mmol) in methylene chloride gave **3***d* (2.30 g, 69%) as a yellow oil; bp 47°C/0.01 Torr; ^{1}H nmr δ: 1.07 (s, *t*-Bu), 4.26 (m, NCH_2), 4.54 (m, OCH_2), and 5.54 (m, 1H); ^{13}C nmr δ: 28.47 (q), 33.93 (s), 45.11 (t), 69.93 (t), 117.7 (d), 143.0 (d), 146.8 (s); ir (neat): 1735 (C=O), 1662 (C=C) cm^{-1}; ms m/z: 205 (M^+ + 2), 203 (M^+). *Anal.* calcd. for $C_9H_{14}ClNO_2$: C 53.08, H 6.93, N 6.88; found: C 53.05, H 6.90, N 6.82.

*2-Methyl-5-*tert*-butyl-3,6-dihydro-1,2-oxazine (***5***d)*

Treatment of **1** (1.20 g, 5.90 mmol) with LAH (0.23 g, 6.1 mmol) gave **5***d* as a colorless oil; ^{1}H nmr δ: 1.05 (s, *t*-Bu), 2.67 (s, NCH_3), 3.21 (br, NCH_2), 4.39 (br, OCH_2), 5.53 (m, 1H); ^{13}C nmr δ: 28.77 (q), 33.54 (s), 45.70 (q), 56.43 (t), 68.00 (t), 113.9 (d), 144.4 (s); ir (neat): 3020, 2880, 1460, 1425, 1385, 1365, 1252, 1110, 1055, 1035, and 1020 cm^{-1}. HRMS for $C_9H_{17}NO$, calcd.: 155.1311; found: 155.1309.

*2-Chloroformyl-4-chloro(and 5-chloro)-3,6-dihydro-1,2-oxazines (***2***e and* **3***e)*

Treatment of **1** (2.00 g, 13.5 mmol) with 2-chloro-1,3-butadiene (1.31 g, 14.8 mmol) afforded an inseparable mixture of **2***e* and **3***e* (1.95 g, 79% yield) as a colorless liquid. The ^{1}H nmr signals are overlapped for both NCH_2 and OCH_2 in **2***e* and **3***e*. The data of the mixture are ^{1}H nmr δ: 4.52 (m, 4H, OCH_2 and NCH_2), 6.12 (m, 1H). The assignment of ^{13}C nmr spectra was correlated to the reduced products **4***e* and **5***e*. **2***e*: ^{13}C nmr δ: 49.2 (t), 69.8 (t), 120.6 (d), 124.8 (s), 147.6 (s). **3***e*: ^{13}C nmr δ: 45.6 (t), 72.0 (t), 118.2 (d), 126.8 (s), 147.6 (s); ir (neat): 1735 (C=O), 1670 (C=C) cm^{-1}; ms m/z: 185 (M^+ + 4), 183 (M^+ + 2), 181 (M^+), 146 (M^+ − Cl). HRMS for $C_5H_5Cl_2NO_2$ (M^+), calcd.: 180.9697; found: 180.9696.

*2-Methyl-4-chloro(and 5-chloro)-3,6-dihydro-1,2-oxazines (***4***e and* **5***e)*

Reduction of a mixture of **2***e* and **3***e* (1.22 g, 6.7 mmol) with LAH (0.25 g, 6.7 mmol) in dry ether gave inseparable **4***e* and **5***e* in a total yield of 85% (0.77 g, 5.7 mmol). **4***e*: ^{1}H nmr (400 MHz) δ: 2.69 (s, 3H), 3.28 (m, 2H, NCH_2), 4.27 (m, 2H, OCH_2), 5.93 (m, 1H); ^{13}C nmr δ: 45.5 (q), 61.3 (t), 67.8 (t), 122.1 (d), 126.6 (s). **5***e*: ^{1}H nmr (400 MHz) δ: 2.67 (s, 3H), 3.28 (m, 2H, NCH_2), 4.27 (m, 2H, OCH_2), 5.93 (m, 1H); ^{13}C nmr δ: 45.5 (q), 56.9 (t), 71.0 (t), 120.2 (d), 129.0 (s); ir (neat): 1660 (C=C) cm^{-1}; ms m/z: 137 (M^+ + 2), 135 (M^+). The ratio of isomeric adducts **2***e*/**3***e* (24:76) was roughly determined from the mixture of **4***e* and **5***e* by integration of the two N-methyl groups.

*2-Chloroformyl-5-trifluoromethyl-3,6-dihydro-1,2-oxazine (***3***f)*

Treatment of **1** (3.00 g, 20.2 mmol) with 2-trifluoromethyl-1,3-butadiene (3.00 g, 24.5 mmol) afforded **3***f* (4.02 g, 91%) as a light yellow liquid; ^{1}H nmr δ: 4.43 (m, 2H, NCH_2), 4.65 (s, 2H, OCH_2), 6.51 (m, 1H); ^{13}C nmr δ: 44.4 (t), 67.0 (t), 116.1 (s), 124.9 (d), 126.9 (CF_3), 147.3 (s); ir (neat): 1730 (C=O), 1682 (C=C) cm^{-1}. HRMS for $C_6H_5ClF_3NO_2$ (M^+), calcd.: 214.9961; found: 214.9954.

*2-Methyl-5-trifluoromethyl-3,6-dihydro-1,2-oxazine (***5***f)*

Reduction of **3***f* (1.90 g, 8.81 mmol) with LAH (0.33 g, 8.7 mmol) in dry ether (30 mL), after chromatography on silica gel with ether–hexane (1:4) as eluent, afforded **5***f* as a colorless liquid in a yield of 87% (1.28 g, 7.66 mmol); ^{1}H nmr δ: 2.70 (s, 3H), 3.30 (m, 2H, NCH_2), 4.42 (s, OCH_2), 6.40 (m, 1H); ^{13}C nmr δ: 45.5 (q), 55.0 (t), 65.2 (t), 117.1 (d), 128.7 (CF_3); ir (neat): 1682 (C=C) cm^{-1}. HRMS for $C_6H_8F_3NO$, calcd.: 167.0558; found: 167.0541.

*2-Chloroformyl-4-benzyl(and 5-benzyl)-3,6-dihydro-1,2-oxazines (***2***g and* **3***g)*

Treatment of **1** (3.40 g, 22.9 mmol) with 2-benzyl-1,3-butadiene (3.28 g, 22.7 mmol) afforded a 25:75 mixture of **2***g* and **3***g* (3.50 g, 65%) as a yellow oil. **2***g*: ^{1}H nmr δ: 3.33 (s, 2H, $PhCH_2$), 4.08 (br, 2H, NCH_2), 4.46 (br, 2H, OCH_2), 5.54 (m, 1H, HC=), 7.20 (m, 5H); ^{13}C nmr δ: 40.1 (t), 47.4 (t), 69.9 (t), 118.5 (d), 126.5 (d), 128.3 (d), 128.5 (d), 132.7 (s), 136.7 (s), 147.3 (s). **3***g*: ^{1}H nmr δ: 3.29 (s, 2H, $PhCH_2$), 4.20 (br, 2H, NCH_2), 4.33 (br, 2H, OCH_2), 5.48 (m, 1H), 7.30 (m, 5H, H_{arom}); ^{13}C nmr δ: 39.0 (t), 45.0 (t), 71.9 (t), 116.3 (d), 126.5 (d), 128.4 (d), 128.5 (d), 134.8 (s), 136.7 (s), 147.3 (s); ir (neat): 1735 (C=O), 1670 (C=C) cm^{-1}; ms m/z: 239 (M^+ + 2), 237 (M^+).

*2-Methyl-4-benzyl(and 5-benzyl)-3,6-dihydro-1,2-oxazines (***4***g and* **5***g)*

Treatment of a mixture of **2***g* and **3***g* (2.00 g, 8.44 mmol) with LAH (0.32 g, 8.43 mmol) in 50 mL of dry ether provided an inseparable mixture of **4***g* and **5***g* (1.37 g, 86%) as a colorless oil; ^{1}H nmr (400 MHz) δ: 2.63 (s, 3H, NCH_3 of **5***g*), 2.66 (s, 3H, NCH_3 of **4***g*), 3.30 (m, 8H, $PhCH_2$ and NCH_2 of **4***g* and **5***g*), 4.20 (m, 4H, OCH_2 of **4***g* and **5***g*), 5.50 (m, 2H, HC= of **4***g* and **5***g*). **4***g*: ^{13}C nmr δ: 41.1 (t), 45.9 (q), 59.0 (t), 68.0 (t), 120.7 (d), 126.1 (d), 128.2 (d), 128.7 (d), 134.2 (s), 138.2 (s). **5***g*: ^{13}C nmr δ: 39.1 (t), 45.9 (q), 56.4 (t), 70.4 (t), 118.8 (d), 126.1 (d), 128.2 (d), 128.7 (d), 136.3 (s), 138.2 (s); ir (neat): 1665 (C=C) cm^{-1}. HRMS for $C_{12}H_{15}NO$, calcd.: 189.1154; found: 189.1148.

*2-Chloroformyl-4-phenyl(and 5-phenyl)-3,6-dihydro-1,2-oxazine (***2***h and* **3***h)*

Treatment of **1** (2.72 g, 18.3 mmol) with 2-phenyl-1,3-butadiene (2.18 g, 16.7 mmol) afforded a mixture of regioisomers **2***h* and **3***h* in a ratio of 68:32 (2.54 g, 68% yield). Attempts to separate **2***h* and **3***h* by chromatography were unsuccessful. Repeated recrystallization (hexane) of residue from the first fraction (isomers **2***h* and **3***h* in a 16:1 ratio) afforded an analytically pure sample of **2***h* as pale white crystals; mp 70°C; ^{1}H nmr δ: 4.62 (br, NCH_2), 4.68 (br, OCH_2), 6.17 (m, 1H), 7.32 (m, 5H); ^{13}C nmr δ: 45.9 (t), 70.3 (t), 119.0 (d), 124.6 (d), 128.0 (d), 131.8 (s), 135.6 (s), 147.8 (s); ir (KBr): 1725 (C=O), 1655 (C=C) cm^{-1}; ms m/z: 225 (M^+ + 2), 223 (M^+). *Anal.* calcd. for

$C_{11}H_{10}ClNO_2$: C 59.06, H 4.50, N 6.26; found: C 59.13, H 4.51, N 6.06. A sample of **3***h* with the highest purity was obtained from the last few fractions as a yellow oil (contaminated with 4% of **2***h*); ^{1}H nmr (400 MHz) δ: 4.43 (br, NCH_2), 4.87 (br, OCH_2), 6.12 (t, t, 1H, J = 1.5, by decoupling the signal at δ 4.43; J = 3.3, by decoupling the signal at 4.87), 7.24–7.45 (m, 5H); ^{13}C nmr δ: 44.89 (t), 71.29 (t), 116.9 (d), 124.8 (d), 128.5 (d), 128.8 (d), 134.4 (s), 135.6 (s), 147.9 (s); ms *m/z*: 225 (M^+ + 2), 223 (M^+). The regioselectivity of cycloaddition was determined from the crude products by integration of the signals at δ 4.62, 4.68 and δ 4.43, 4.87 for **2***h* and **3***h*, respectively, prior to chromatography. The result is given in Table 1.

Treatment of **1** (0.67 g, 4.51 mmol) with 95% deuterated 1,1-*d*,*d*-2-phenyl-1,3-butadiene (0.60 g, 4.54 mmol) afforded *d*-**2***h* and *d*-**3***h* as a 68:32 mixture of regioisomers (0.63 g, 63%). The predominant cycloadduct *d*-**2***h* was separated by the procedure described above; ^{1}H nmr δ: 4.67 (d, J = 3, OCH_2), 6.20 (t, J = 3, vinylic hydrogen), 7.32 (m, 5H); ^{13}C nmr δ: 45.92 (m, weak), 70.12 (t), 119.0 (d), 124.0 (d), 128.2 (d), 128.6 (d), 131.7 (s), 135.7 (s), 147.9 (s).

*2-Methyl-4-phenyl-3,6-dihydro-1,2-oxazine (***4**h*)*

Treatment of **2***h* (0.34 g, 1.52 mmol) with LAH (0.06 g, 16.0 mmol) in 5 mL of dry ether gave **4***h* as a white solid; mp 67°C (lit. (6*a*) mp 65°C); ^{1}H nmr δ: 2.74 (s, 3H), 3.55 (br, NCH_2), 4.46 (br, OCH_2), 6.11 (m, 1H), 7.34 (m, 5H); ^{13}C nmr δ: 45.8 (q), 57.8 (t), 68.1 (t), 121.3 (d), 124.4 (d), 127.1 (d), 128.1 (d), 133.6 (s), 138.0 (s); ir (neat): 2820, 1480, 1440, 1350, 1070, 1030, 750, and 690 cm^{-1}; ms *m/z*: 175 (M^+).

*2-Methyl-3,3-*d,d*-4-phenyl-3,6-dihydro-1,2-oxazine (*d-**4**h*)*: ^{1}H nmr δ: 2.85 (s, NCH_3), 4.62 (br, OCH_2), 6.33 (t, J = 3.0, HC=), 7.53 (m, 5H); ^{13}C nmr δ: 45.8 (q), 57.8 (m, weak), 68.1 (t), 121.4 (d), 124.5 (d), 127.1 (d), 128.1 (d), 133.6 (s), 138.0 (s).

*2-Chloroformyl-4-(4'-methoxyphenyl)-3,6-dihydro-1,2-oxazines (***2**i *and* **3**i*)*

Treatment of **1** (2.70 g, 18.2 mmol) with 2-(4'-methoxyphenyl)-1,3-butadiene (2.50 g, 15.6 mmol) gave **2***i* as pale white crystals (2.31 g, 59%); mp 72°C (hexane); ^{1}H nmr (400 MHz) δ: 3.77 (s, OCH_3), 4.57 (br, NCH_2), 4.64 (br, OCH_2), 6.10 (t, t, 1H, J = 1.7, by decoupling the signal at δ 4.64; J = 3.2, by decoupling the signal at δ 4.57), 6.89 (d, 2H, J = 8.7), 7.28 (d, 2H, J = 8.7); ^{13}C nmr δ: 46.17 (t), 54.96 (q), 69.90 (t), 113.7 (d), 117.0 (d), 125.5 (d), 128.0 (s), 130.9 (s), 159.3 (s); ir (KBr): 1725 (C=O), 1650 (C=C) cm^{-1}; ms *m/z* (M^+ + 2), 253 (M^+). *Anal.* calcd. for $C_{12}H_{12}ClNO_3$: C 56.82, H 4.77, N 5.52; found: C 56.82, H 4.71, N 5.63. **3***i* (mixed with 23% of **2***i*); ^{1}H nmr δ: 3.78 (s, OCH_3), 4.44 (br, NCH_2), 4.84 (br, OCH_2), 6.02 (t, t, 1H, J = 1.7, by decoupling the signal at δ 4.44; J = 3.2, by decoupling the signal at δ 4.84), 6.89 (d, 2H, J = 8.9), and 7.29 (d, 2H, J = 8.9). The regioisomeric ratio was determined as the manner described above from ^{1}H nmr analysis. The result is given in Table 1.

*2-Methyl-4-(4'-methoxyphenyl)-3,6-dihydro-1,2-oxazine (***4**i*)*

Reduction of **2***i* (1.55 g, 6.11 mmol) with LAH (0.25 g, 6.57 mmol) in 30 mL of dry ether gave white crystals of **4***i* (1.15 g, 92%); mp 124°C; ^{1}H nmr δ: 2.77 (s, NCH_3), 3.55 (br, NCH_2), 3.78 (s, OCH_3), 4.48 (br, OCH_2), 6.04 (t, t, 1H, J = 1.2, by decoupling the signal at δ 4.48; J = 2.9, by decoupling the signal at δ 3.78), 6.84 (d, J = 9.0, 2H), 7.27 (d, J = 9.0, 2H); ^{13}C nmr δ: 45.94 (q), 55.68 (q), 58.06 (t), 68.20 (t), 113.6 (d), 119.6 (d), 125.6 (d), 130.6 (s), 133.1 (s), 158.7 (s); ir (KBr): 3000, 2980, 2840, 1600, 1500, 1280, 1240, 1190, 1100, and 1040 cm^{-1}. *Anal.* calcd. for $C_{12}H_{15}NO_2$: C 70.22, H 7.37, N 6.82; found: C 70.21, H 7.46, N 6.75.

*2-Chloroformyl-4-(3'-methoxyphenyl)-3,6-dihydro-1,2-oxazines (***2**j *and* **3**j*)*

Treatment of **1** (3.00 g, 20.2 mmol) with 2-(3'-methoxyphenyl)-1,3-butadiene (2.88 g, 18.0 mmol) afforded an 85:15 mixture of regioisomers **2***j* and **3***j* (3.10 g, 62%). Oxazine **2***j*: mp 67°C (hexane); ^{1}H nmr δ: 3.80 (s, 3H, OCH_3), 4.56 (s, 2H, NCH_2), 4.63 (d, 2H, J = 2.2, OCH_2), 6.20 (m, 1H, HC=), 6.88 (m, 3H), and 7.20 (m, 1H); ^{13}C nmr δ: 46.4 (t), 55.1 (g), 70.0 (t), 110.7 (d), 113.5 (d), 117.0 (d), 119.2 (d), 129.5 (d), 131.8 (s), 137.2 (s), 159.5 (s); ir (KBr): 1735 (C=O), 1655 (C=C) cm^{-1}; ms *m/z*: 255 (M^+ + 2), 253 (M^+). *Anal.* calcd. for $C_{12}H_{12}ClNO_3$: C 56.82, H 4.77, N 5.52; found: C 56.88, H 4.77, N 5.39. **3***j* (with 22% of **2***j*): ^{1}H nmr δ: 3.78 (s, 3H, OCH_3), 4.41 (br, 2H, NCH_2), 4.81 (d, 2H, J = 1.7, OCH_2), 6.09 (m, 1H, HC=), 6.83 (m, 3H), 7.24 (m, 1H); ^{13}C nmr δ: 45.23 (t), 55.08 (q), 71.13 (t), 110.7 (d), 113.4 (d), 117.0 (d, two peaks), 129.5 (d), 134.0 (s), 136.8 (s), 159.5 (s); ms *m/z*: 255 (M^+ + 2), 253 (M^+). The regioisomeric ratio was determined as the manner described above from ^{1}H nmr analysis.

*2-Methyl-4-(3'-methoxyphenyl)-3,6-dihydro-1,2-oxazine (***4**j*)*

Treatment of **2***j* (1.20 g, 4.73 mmol) with LAH (0.18 g, 4.74 mmol) in dry ether afforded **4***j* (0.80 g, 82%) as a white solid; mp 56°C (hexane); ^{1}H nmr δ: 2.75 (s, 3H, NCH_3), 3.55 (br, 2H, NCH_2), 3.77 (s, 3H, OCH_3), 4.77 (br, 2H, OCH_2), 6.13 (m, 1H, HC=), 6.86 (m, 3H), 7.22 (m, 1H); ^{13}C nmr δ: 45.8 (q), 55.0 (q), 56.4 (t), 68.1 (t), 110.5 (d), 112.4 (d), 117.0 (d), 121.6 (d), 129.1 (d), 133.6 (d), 139.5 (s), 159.3 (s); ir (KBr): 1680 (C=C) cm^{-1}; ms *m/z*: 205 (M^+). *Anal.* calcd. for $C_{12}H_{15}NO_2$: C 70.22, H 7.37, N 6.82; found: C 70.32, H 7.24, N 6.71.

*2-Chloroformyl-4-(4'-methylphenyl)-3,6-dihydro-1,2-oxazines (***2**k *and* **3**k*)*

Treatment of **1** (2.00 g, 13.5 mmol) with 2-(4'-methylphenyl)-1,3-butadiene (1.84 g, 12.8 mmol) afforded an 80:20 mixture of regioisomers **2***k* and **3***k* (2.18 g, 72%). Separation of **2***k* and **3***k* was carried out as described above. An analytical sample of **2***k* was obtained by recrystallization from hexane; mp 70°C; ^{1}H nmr δ: 2.31 (s, 3H, $PhCH_3$), 4.54 (m, 2H, NCH_2), 4.61 (d, 2H, J = 1.8, OCH_2), 6.12 (m, 1H, HC=), 7.13 (d, 2H, J = 8.0), 7.20 (d, 2H, J = 8.0); ^{13}C nmr δ: 20.9 (q), 46.2 (t), 69.8 (t), 117.9 (d), 124.2 (d), 129.0 (d), 131.4 (s), 132.7 (s), 138.0 (s), 147.2 (s); ir (KBr): 1740 (C=O), 1680 (C=C) cm^{-1}; ms *m/z*: 239 (M^+ + 2), 237 (M^+). *Anal.* calcd. for $C_{12}H_{12}ClNO_2$: C 60.64, H 5.09, N 5.89; found: C 60.66, H 5.17, N 5.82. The data for **3***k* (mixed with 28% of **2***k*): ^{1}H nmr δ: 2.35 (s, 3H, $PhCH_3$), 4.42 (br, 2H, NCH_2), 4.86 (d, 2H, J = 1.7, OCH_2), 6.09 (m, 1H, HC=), 7.18 (d, 2H, J = 8.0), 7.26 (d, 2H, J = 8.0). The regioisomeric ratio was determined as the manner described above by ^{1}H nmr analysis.

*2-Methyl-4-(4'-methylphenyl)-3,6-dihydro-1,2-oxazine (***4**k*)*

Treatment of **2***k* (1.42 g, 5.98 mmol) with LAH (0.22 g, 5.80 mmol) in 50 mL of dry ether afforded **4***k* (0.95 g, 84% yield); mp 50°C (hexane); ^{1}H nmr δ: 2.30 (s, 3H, $PhCH_3$), 2.75 (s, 3H, NCH_3), 3.53 (br, 2H, NCH_2), 4.45 (br, 2H, OCH_2), 6.08 (m, 1H, HC=), 7.15 (d, 2H, J = 6.0), 7.23 (d, 2H, J = 6.0); ^{13}C nmr δ: 20.9 (q), 45.8 (q), 58.0 (t), 68.1 (t), 120.5 (d), 124.3 (d), 128.8 (d), 133.4 (s), 135.1 (s), 136.8 (s); ir (KBr): 1680 (C=C) cm^{-1}; ms *m/z*: 189 (M^+). *Anal.* calcd. for $C_{12}H_{15}NO$: C 76.16, H 7.99, N 7.40; found: C 76.19, H 8.05, N 7.37.

*2-Chloroformyl-4-(3'-methylphenyl)-3,6-dihydro-1,2-oxazines (***2**m *and* **3**m*)*

Treatment of **1** (3.55 g, 23.9 mmol) with 2-(3'-methylphenyl)-1,3-butadiene (3.40 g, 23.6 mmol) afforded an 82:18 mixture of regioisomers **2***m* and **3***m* (4.40 g, 72%). Separation of **2***m* and **3***m* was carried out as described above. **2***m*: mp 66°C (hexane); ^{1}H nmr δ: 2.35 (s, 3H, $PhCH_3$), 4.67 (br, 4H, OCH_2 and NCH_2), 6.19 (m, 1H, HC=), 7.15–7.24 (m, 4H); ^{13}C nmr δ: 21.3 (q), 46.5 (t), 70.0 (t), 118.7 (d), 121.6 (d), 125.2 (d), 128.4 (d), 129.0 (d), 132.0 (s), 135.2 (s), 138.1 (s), 147.4 (s); ir (KBr): 1725 (C=O), 1675 (C=C) cm^{-1}; ms *m/z*: 239 (M^+ + 2), 237 (M^+). *Anal.* calcd. for $C_{12}H_{12}ClNO_2$: C 60.64, H 5.09, N 5.89; found: C 60.69, H 5.09, N 5.93. **3***m* (mixed with 5% of **2***m*): mp 58°C (hexane); ^{1}H nmr δ: 2.35 (s, 3H, $PhCH_3$), 4.41 (br, 2H, NCH_2), 4.84 (s, 2H, OCH_2), 6.09 (m, 1H, HC=), 7.14–7.34 (m, 4H); ^{13}C nmr δ: 21.43 (q), 45.20 (t), 71.47 (t), 116.8 (d), 122.1 (d), 125.7 (d), 128.9 (d), 129.4 (d), 134.8 (s), 135.9 (s), 138.6 (s), 147.6 (s). The regioisomeric ratio was determined from the mixture of **2***m* and **3***m* by integration of the ring hydrogens at δ 4.67 (NCH_2 and OCH_2) and δ 4.41, 4.84 for **2***m* and **3***m*, respectively, prior to chromatography.

*2-Methyl-4-(3'-methylphenyl)-3,6-dihydro-1,2-oxazine (***4**m*)*

Treatment of **2***m* (1.50 g, 6.32 mmol) with LAH (0.24 g, 6.32 mmol) in 50 mL of dry ether gave **4***m* (1.03 g, 86%) as a white solid; mp 42°C

(hexane), ^{1}H nmr δ: 2.33 (s, 3H, $PhCH_3$), 2.77 (s, 3H, NCH_3), 3.55 (br, 2H, NCH_2), 4.47 (br, 2H, OCH_2), 6.10 (m, 1H, HC=), 7.03–7.30 (m, 4H); ^{13}C nmr δ: 21.5 (q), 45.9 (q), 58.1 (t), 68.2 (t), 121.2 (d), 121.7 (d), 125.3 (d), 128.1 (d, two peaks), 133.8 (s); ms *m/z*: 189 (M^+). *Anal.* calcd. for $C_{12}H_{15}NO$: C 76.16, H 7.99, N 7.40; found: C 76.14, H 8.02, N 7.47.

*2-Chloroformyl-4-(4′-chlorophenyl)-3,6-dihydro-1,2-oxazines (***2**n *and* **3**n*)*

Treatment of **1** (3.00 g, 20.2 mmol) with 2-(4′-chlorophenyl)-1,3-butadiene (3.02 g, 18.4 mmol) gave 3.50 g (74%) of a 67:33 mixture of regioisomers **2***n* and **3***n*. **2***n*: mp 110°C (hexane); ^{1}H nmr (400 MHz) δ: 4.66 (br, NCH_2), 4.77 (d, J = 2.8, OCH_2), 6.31 (m, 1H, HC=), 7.36 (d, J = 8.6, 2H), 7.42 (d, J = 8.6, 2H); ^{13}C nmr δ: 46.23 (t), 69.90 (t), 119.6 (t), 125.8 (d), 128.6 (d), 130.9 (s), 134.1 (s), 147.5 (s); ir (KBr): 1730 (C=O), 1650 (C=C) cm^{-1}; ms, *m/z*: 259 (M^+ + 2), 257 (M^+). *Anal.* calcd. for $C_{11}H_9Cl_2NO_2$: C 51.06, H 3.76, N 5.41; found: C 51.06, H 3.62, N 5.48. The data for **3***n* were determined from a mixture containing 25% of **2***n*: ^{1}H nmr δ: 4.44 (br, NCH_2), 4.83 (br, OCH_2), 6.13 (t, t, 1H, J = 3.5, by decoupling the signal at δ 4.83; J = 1.7, by decoupling the signal at δ 4.43), 7.14–7.44 (m, 4H); ^{13}C nmr δ: 45.23 (t), 70.78 (t), 117.3 (d), 128.5 (d), 128.6 (d), 133.1 (s), 133.7 (s), 147.0 (s). The regioisomeric ratio was determined from the mixture of **2***n* and **3***n* by integration of the ring hydrogens at δ 4.66, 4.77 and δ 4.44, 4.83, respectively, prior to chromatography.

*2-Methyl-4-(*p*-chlorophenyl)-3,6-dihydro-1,2-oxazine* **4**n

Treatment of **2***n* (0.64 g, 2.48 mmol) with LAH (0.10 g, 2.63 mmol) in dry ether gave **4***n* (0.48 g, 92%) as white crystals; mp 73°C (hexane); ^{1}H nmr δ: 2.76 (s, NCH_3), 3.51 (br, NCH_2), 4.46 (br, OCH_2), 6.122 (t, t, 1H, J = 2.9, by decoupling the signal at δ 3.51; J = 1.6, by decoupling the signal at δ 4.46), 7.25 (s, 4H); ^{13}C nmr δ: 45.88 (q), 57.77 (t), 68.14 (t), 120.0 (d), 125.7 (d), 128.3 (d), 132.7 (s), 132.9 (s), 136.4 (s); ir (KBr): 2980, 1495, 1455, 1100, 1080, and 800 cm^{-1}; ms *m/z*: 211 (M^+ + 2), 209 (M^+). *Anal.* calcd. for $C_{11}H_{12}ClNO$: C 63.01, H 5.77, N 6.68; found: C 62.84, H 5.72, N 6.62.

General procedure for kinetic studies

To a uv cell filled with a solution of **1** (1.12×10^{-2} M) in methylene chloride (or THF or chloroform) was added an appropriate diene (ca. 0.77 M, 70 times the moles of **1**) in one portion. The disappearance of **1** was measured by the decreasing intensity of the peak at 592 nm, which is the maximum absorption of **1** in the visible region (ε = 6.0 (19)). The reactions were followed up to 90% completion. The pseudo-first-order rate constants were obtained by measurement of the decaying curve and were the average values of at least two kinetic runs for each reaction. A linear free energy plot using σ^+ substituent constants and pseudo-first-order rate constants is shown in Fig. 1.

Acknowledgement

We are grateful to the National Science Council of the Republic of China for financial support of this research, to Mr. B. Liu (National Tsinghua University) for high resolution mass spectra, and to Professor T. C. Chou for fruitful discussion and encouragement.

The mechanism of hydrolysis of 2-hydroxyethanesulfonyl chloride: the intermediacy of 1,2-oxathietane 2,2-dioxide (β-sultone)[1]

JAMES FREDERICK KING[2] AND KISHAN CHAND KHEMANI

The hydrolysis of 2-hydroxyethanesulfonyl chloride (**1**) has been investigated with the aid of kinetic and product analysis studies. The results are quantitatively consistent with the mechanism of hydrolysis shown in Scheme 1, the chief features of which are (a) formation of β-sultone (**2**) and its rapid further reaction (the major pathway), together with (b) a minor direct hydrolysis route. The kinetics of both the β-sultone formation and the direct hydrolysis shows two terms, one first order in **1** alone, and the other first order in hydroxide as well; the rates of the first- and second-order reactions are lowered by added sodium chloride. It is suggested (a) that the unimolecular β-sultone formation involves **1** in a complex with water (as in **9**) and that the water acts as a general base in the cyclization to **2**, and (b) the hydroxide-promoted reaction proceeds by cyclization of the conjugate base of **1** (i.e., **10**). The unimolecular direct hydrolysis is regarded as a conventional hydrolysis of a sulfonyl chloride with attack of the water with general base assistance from a second water molecule. The hydroxide-promoted direct reaction in D_2O leads to no uptake of deuterium, showing that the reaction does not go by way of the sulfene, and a reaction by way of a six-membered cyclic transition state is tentatively proposed. Evidence is presented that the chloride ion rate suppression is not primarily due to reaction of β-sultone with Cl^- to give back **1**; the possible origins of the effect are discussed.

Key words: sulfonyl chlorides, 2-hydroxyethanesulfonyl chloride, β-sultone, kinetics of sulfonyl chloride hydrolysis, mechanisms of sulfonyl chloride hydrolysis.

JAMES FREDERICK KING et KISHAN CHAND KHEMANI. Can. J. Chem. **67**, 2162 (1989).

Faisant appel à des études cinétiques et à d'autres impliquant une analyse des produits, on a étudié l'hydrolyse du chlorure du 2-hydroxyéthanesulfonyle (**1**). Sur une base quantitative, les résultats sont en accord avec le mécanisme d'hydrolyse représenté dans le schéma 1 et dont les caractéristiques principales sont (a) la formation d'une β-sultone (**2**) et sa rapide réaction subséquente (voie principale) et (b) une voie mineure d'hydrolyse directe. La cinétique de la formation de la β-sultone ainsi que de l'hydrolyse directe présente à chaque fois deux termes : l'un du premier ordre uniquement en composé **1** et l'autre qui est en plus du premier ordre en ion hydroxyde; les vitesses des réactions du premier et du deuxième ordre sont abaissées par l'addition de chlorure de sodium. On suggère : (a) que la formation unimoléculaire de la β-sultone implique que le composé **1** est complexé dans l'eau (comme dans **9**) et que l'eau agit comme base générale dans la cyclisation conduisant au composé **2** et (b) que la réaction catalysée par l'ion hydroxyde se produit par le biais d'une cyclisation de la base conjuguée du composé **1** (soit **10**). On considère l'hydrolyse unimoléculaire directe comme une hydrolyse conventionnelle d'un chlorure de sulfonyle impliquant une attaque de l'eau avec l'assistance d'une seconde molécule d'eau agissant comme base générale. L'hydrolyse directe, dans le D_2O et sous l'influence d'ions hydroxydes, ne provoque aucune incorporation de deutérium; ce résultat démontre que la réaction ne se produit pas par le biais du sulfène et on propose provisoirement que la réaction se produit via un état de transition cyclique à six chaînons. On présente des données démontrant que le ralentissement de la réaction sous l'influence d'ions chlorures n'est pas causé par une réaction de la β-sultone avec le Cl^- pour redonner le composé **1**; l'origine possible de cet effet est discutée.

Mots clés : chlorures de sulfonyle, chlorure de 2-hydroxyéthanesulfonyle, β-sultone, cinétique de l'hydrolyse du chlorure de sulfonyle, mécanismes d'hydrolyse du chlorure de sulfonyle.

[Traduit par la revue]

Introduction

In the course of an extended study of the reactions of the sulfonyl group (2, 3) we prepared the first hydroxyalkanesulfonyl chlorides and looked at some of their reactions (1, 4, 5). As part of our work on the simplest known member of this series, 2-hydroxyethanesulfonyl chloride (**1**), we suggested that 1,2-oxathietane 2,2-dioxide (β-sultone, **2**) was probably formed as a short-lived intermediate under a variety of circumstances, including simple hydrolysis (4).

$HOCH_2CH_2SO_2Cl$ **1**

2

β-Sultone (**2**) has never been isolated or observed directly, though a number of substituted derivatives have been reported (6). The present study was initiated to determine whether or not **2** really was an intermediate in the hydrolysis of **1**, and, if it should prove so, to investigate some of its chemistry. Of particular interest was whether or not **2** would show any tendency to undergo attack by a nucleophile with S—O cleavage. It is well known that the bimolecular reaction of alkyl esters of sulfonic acids with nucleophiles proceeds with cleavage of the C—O bond and formation of a C—Nu bond, except for certain sterically congested esters that react with alkoxide by S—O scission (7, 8). The latter mode of cleavage had also been reported in the alkaline hydrolysis of the cyclohexane-1,2-diyl sulfates by Brimacombe *et al.* (9, 10). Kaiser, Panar, and Westheimer (11) found a small proportion (14%) of S—O cleavage with ethylene sulfate in alkaline solution but none at all with either trimethylene sulfate or dimethyl sulfate. al. (12) reported that hydrolysis of propane 1,3-sultone in strong base also proceeded with 14% S—O cleavage, whereas the corresponding reaction of ethyl ethanesulfonate went exclusively with the normal C—O scission. Westheimer and Kaiser and their co-workers (cf. refs. 13 and 14) had also observed that attack of hydroxide on the sulfonyl group was several orders of magnitude faster with five-membered ring sultones and sulfate esters than with six-membered or acyclic analogues, and it was therefore of interest to see if any similar effect might appear in the reaction of the four-membered ring sultone. The present paper describes kinetic and product analysis experiments that lead us to conclude that the hydrolysis of **1** in the pH range 3–13 proceeds largely by way of β-sultone (**2**). More recent work on the attack of hydroxide at a sulfonyl group describing evidence for, and a rationalization of, the preferred S—O cleavage has been reported in preliminary form (15, 16) and will be given in detail in a subsequent paper; a more extensive treatment of these topics has been presented in thesis form (17).

Results and discussion

Kinetic and product ratio studies; proposal of mechanism

The rates of hydrolysis of 2-hydroxyethanesulfonyl chloride (**1**) were measured under a variety of conditions by the pH-stat technique; a typical rate plot is shown in Fig. 1. The pH–rate profile for the hydrolysis in 0.3 M $NaClO_4$ at 25°C, shown in Fig. 2, corresponds to a rate law of the form

[1] $$k_\psi = k_H + k_{OH}[OH^-]$$

Values of k_H and k_{OH} of $(2.28 \pm 0.49) \times 10^{-4}\,s^{-1}$ and $(5.16 \pm 0.52) \times 10^6\,M\,s^{-1}$ give the curve shown by the solid line in Fig. 2. Also shown in Fig. 2 is the pH–rate profile for the reaction in 0.3 M NaCl; the dashed line has the same shape but is displaced to lower $\log k_\psi$ values, corresponding to a roughly two- to threefold lowering of the rate in the presence of Cl^- as compared to ClO_4^- (0.3 M).

The product of the reaction under kinetic conditions (C_0 = 10^{-3}–10^{-5} M) was almost entirely sodium 2-hydroxyethanesulfonate (**3**) with small but consistently observable amounts (~2–5%) of sodium 2-chloroethanesulfonate (**4***a*). Addition of sodium chloride to the reaction mixture gave more **4***a*. The variation in product composition with change in pH and the concentration of added reagents was studied by carrying out a sizeable series of runs in the pH-stat apparatus and examining the product by ^{1}Hmr; the results are summarized starting with Fig. 3. From the pH–product ratio profile for the hydrolysis of **1** in 1.0 M NaCl over the pH range 1–13 (Fig. 3), one may note immediately that the sloped portions of the pH–rate and pH–product curves (respectively, Figs. 2 and 3) do not correspond. This would indicate different rate-determining and product-determining steps, in full accord with the notion of a reaction proceeding by way of β-sultone (**2**) as an intermediate (see Scheme 1).

The variation in product ratio with change in sodium chloride concentration and at constant pH was determined for a series of pH values; the results are displayed in Figs. 4–7. The product ratio [**4***a*]/[**3**] increases with chloride ion concentration but not linearly, a distinct tendency to plateau being most evident at low pH but visible in all of the plots. That this nonlinearity was probably not simply a result of deviations from ideality accompanying high salt concentrations was shown by the product-ratio curve obtained in the corresponding reaction

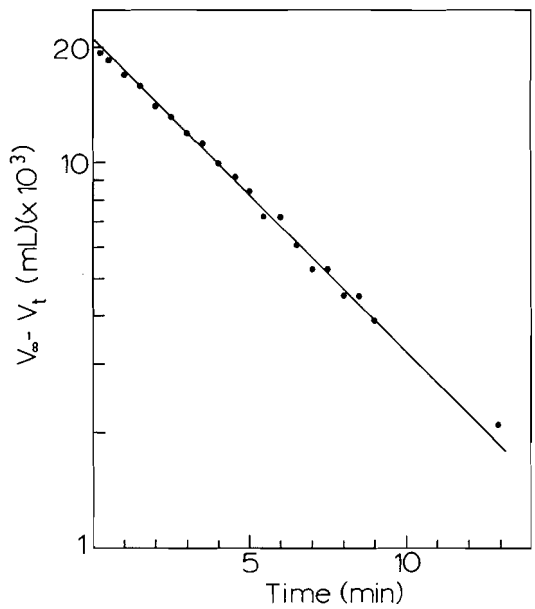

FIG. 1. Typical rate plot for the hydrolysis of 2-hydroxyethanesulfonyl chloride (**1**) (pH 5.0, 25.0°C, 0.1 M NaCl, μ = 0.3 M with $NaClO_4$).

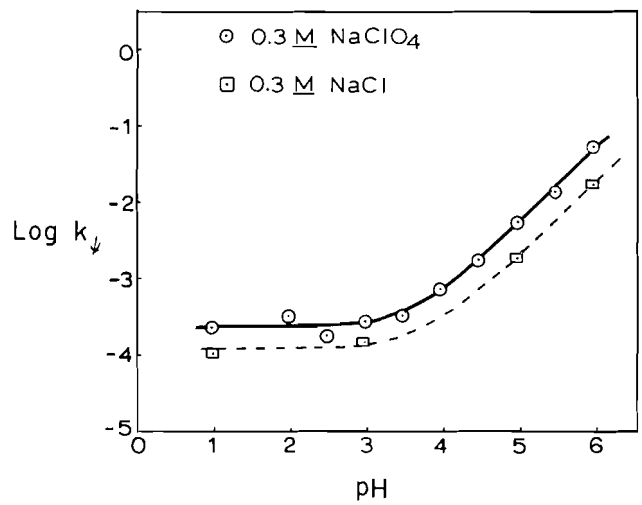

FIG. 2. Dependence on pH of the first-order rate constants for the hydrolysis of 2-hydroxyethanesulfonyl chloride (**1**) at 25.0°C (in 0.3 M $NaClO_4$ and NaCl solutions). The solid line is calculated from $\log k_\psi = \log (k_H + k_{OH}[OH^-])$ where $k_H = 2.28 \times 10^{-4}\,s^{-1}$ and $k_{OH} = 5.16 \times 10^6\,M^{-1}\,s^{-1}$.

of propane 1,3-sultone (**5**) to form a mixture of the 3-hydroxy-1-propanesulfonate (**6**) and 3-chloro-1-propanesulfonate (**7**) salts; the points (Fig. 8) correspond to a line that appears reasonably straight all the way to the highest sodium chloride concentration (1.4 M).

Again, the results with **1** are consistent with reaction via **2**, with the tendency to plateau indicating a dual pathway, one (that via **2**) capable of being diverted by chloride anion, and one not (the latter evidently the minor route). On this basis it seemed likely that thiocyanate anion might prove a more efficient trap for **2** than chloride, and might therefore give product-ratio curves with more clearly defined plateaus, thereby facilitating quantitative interpretation. As may be seen in Fig. 9, this was, in fact, observed. It was also found that addition of sodium

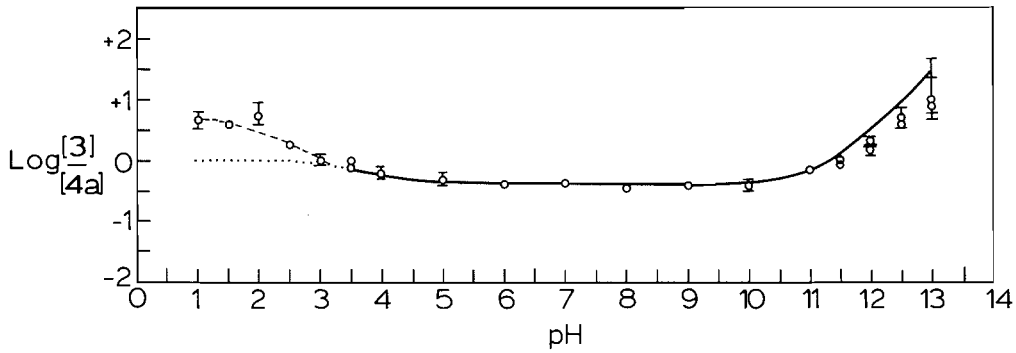

FIG. 3. Dependence on pH of the ratio of 2-hydroxyethanesulfonate (**3**) to 2-chloroethanesulfonate (**4***a*) ion in the product of the reaction of **1** with 1 M aqueous NaCl at 25.0°C. The solid and dotted lines are calculated using only the parameters in Scheme 1; the dashed line is obtained by including (in an appropriately modified form of eq. [A16]) two additional terms involving acid-catalyzed cleavage of **2** (see text and Appendix).

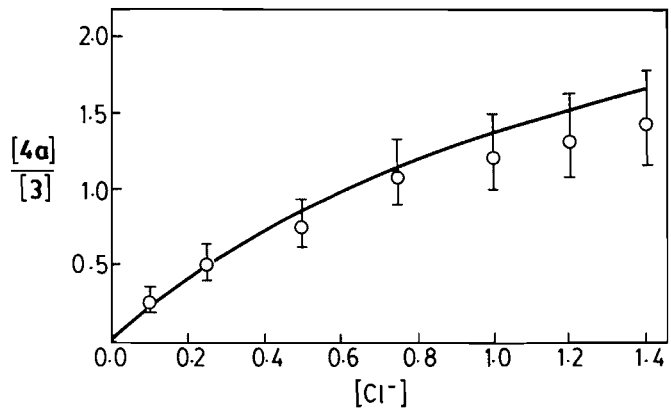

FIG. 4. Variation of the product ratio [**4***a*]/[**3**] with the concentration of sodium chloride in the reaction of **1** with aqueous sodium chloride at pH 3.5. The line is calculated from the parameters in Scheme 1 and eqs. [5]–[7].

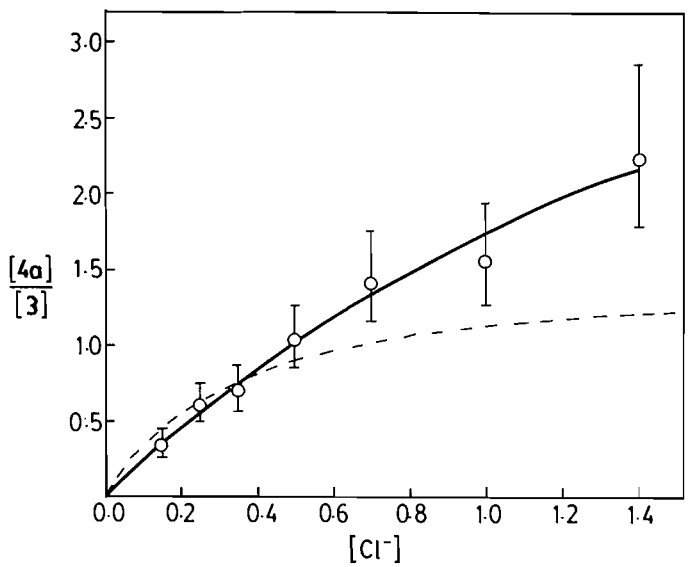

FIG. 5. Variation of the product ratio [**4***a*]/[**3**] with the concentration of sodium chloride in the reaction of **1** with aqueous sodium chloride at pH 4.0. The solid line is calculated from the parameters in Scheme 1 and eqs. [5]–[7], the dashed line from a relationship derived by assuming reaction of **2** with Cl^- to give back **1** as in Scheme 2 (see text and the Appendix).

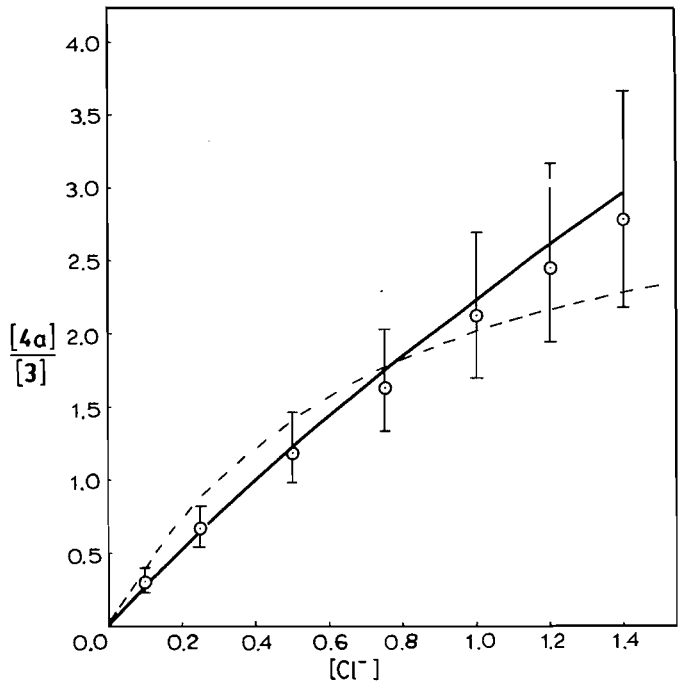

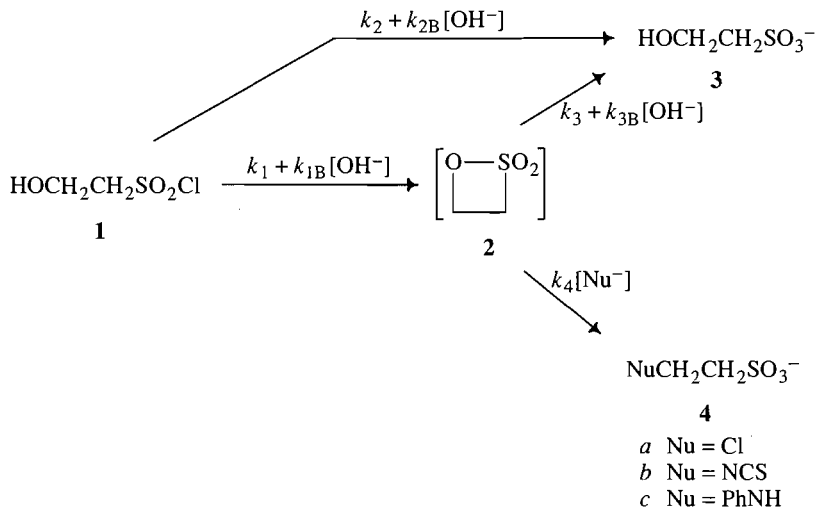

FIG. 6. Variation of the product ratio [**4***a*]/[**3**] with the concentration of sodium chloride in the reaction of **1** with aqueous sodium chloride at pH 6.0. The solid line is calculated from the parameters in Scheme 1 and eqs. [5]–[7], the dashed line from a relationship derived by assuming reaction of **2** with Cl^- to give back **1** as in Scheme 2 (see text and the Appendix).

thiocyanate had no effect on the measured rate at pH 3.0; k_ψ was found to be $1.83 \times 10^{-4}\ s^{-1}$ with 0.1 M NaSCN and $1.85 \times 10^{-4}\ s^{-1}$ without (at 25°C and ionic strength 0.5 M with $NaClO_4$). At the same time the product ratio **4***b*/**3** was determined from a large-scale kinetic run using the same concentration of **1** (3.44×10^{-4} M) as that used for the other kinetic runs; **4***b*:**3** was found to be 48:52 with $k_\psi = 1.80 \times 10^{-4}\ s^{-1}$. Evidently almost half of the product is derived from a reagent that has no detectable effect on the observed rate constant. This is a clear example of the rate–product discrepancy, which requires, minimally, a two-step process involving a slow first step forming an intermediate, which reacts with the "zero-order reagent" in a subsequent fast step. These features, namely a dual pathway (one via a trappable intermediate and one not) and the requirement for a slowly formed, rapidly consumed intermediate giv-

$HOCH_2CH_2CH_2SO_3^-$ + $ClCH_2CH_2CH_2SO_3^-$

6 **7**

ing products consistent with its identification as β-sultone (**2**), lead to the proposal of the mechanism shown in Scheme 1.

Rate and product-ratio expressions; comparisons with experiment

The next stage is to move from qualitative to quantitative tests of the validity of the proposed mechanism, i.e., to find if a set of rate constants and rate constant ratios based on this scheme will reproduce the experimental results summarized in Figs. 2–7 and 9. The hydrolysis of **1** in D_2O was followed by ^{1}Hmr, and in no case were any peaks assignable to β-sultone observed. We may therefore use the steady state approximation, which readily yields eq. [2]:

[2] $$k_\psi = k_1 + k_{1B}[OH^-] + k_2 + k_{2B}[OH^-] = x + y$$

where $x = k_1 + k_{1B}[OH^-]$ and $y = k_2 + k_{2B}[OH^-]$. Comparison with eq. [1] immediately leads to

[3] $$k_1 + k_2 = k_H = 2.28 \times 10^{-4}\,s^{-1}$$

[4] $$k_{1B} + k_{2B} = k_{OH} = 5.16 \times 10^{6}\,M^{-1}\,s^{-1}$$

The product ratio [**4**]/[**3**] may be shown (see Appendix 1) to be given by eq. [5],

[5] $$[4]/[3] = \frac{a_1}{1 + \dfrac{a_2}{[Nu^-]}}$$

where a_1 and a_2 are given by [6] and [7] and $z = k_3 + k_{3B}[OH^-]$.

[6] $$a_1 = x/y$$

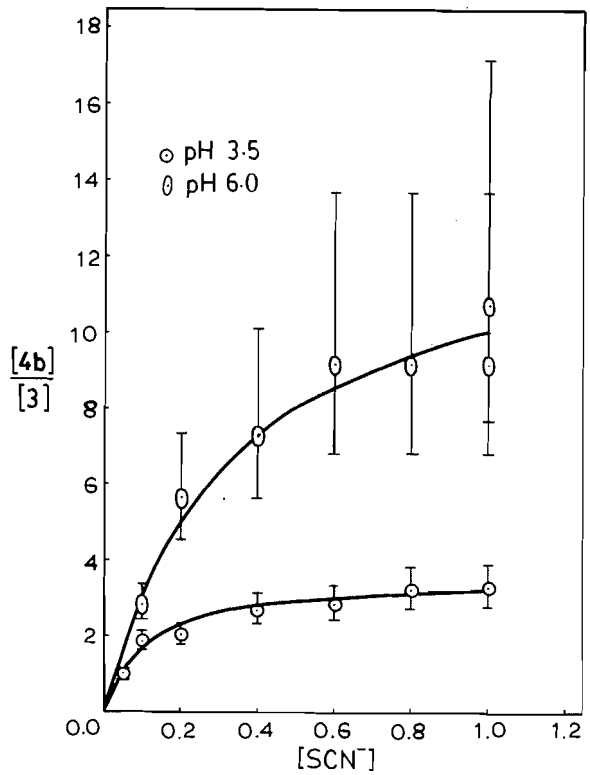

FIG. 9. Variation of the product ratio [**4***b*]/[**3**] with change in sodium thiocyanate concentration in the reaction of **1** with aqueous sodium thiocyanate at pH 3.5 (circles) and pH 6.0 (ellipses). The lines are calculated from the parameters in Scheme 1 and eqs. [5]–[7]

and

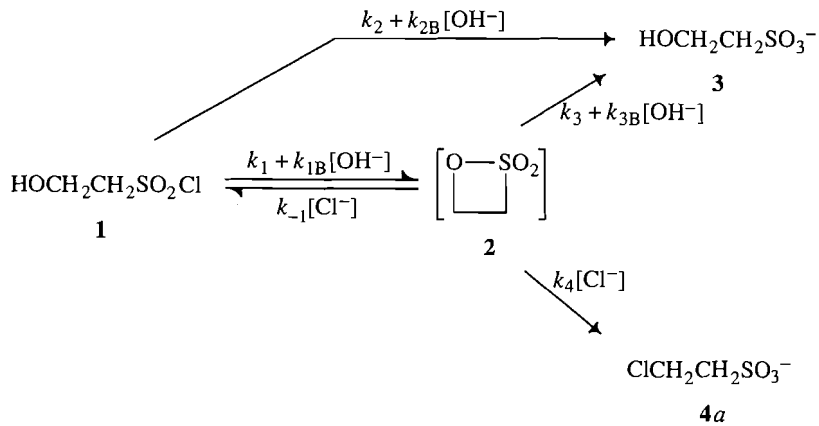
$$[7] \qquad a_2 = (1 + x/y)z/k_4 = \frac{(1 + x/y)(1 + k_{3B}[OH^-]/k_3)}{k_4/k_3}$$

The parameters a_1 and a_2 for each of the curves in Fig. 9 were obtained by a nonlinear least-squares fit to the data,[3] and, as is described in the Appendix, (a) the two values of a_1 so obtained (for pH 3.5 and pH 6.0, respectively) yielded two versions of eq. [6], which, with eqs. [3] and [4] gave the values of k_1, k_2, k_{1B}, and k_{2B} shown in Scheme 1; (b) eq. [7] gave $(k_4/k_3)_{SCN}$, and (c) the data in Figs. 6 and 7 similarly yielded, respectively, $(k_4/k_3)_{Cl}$ and k_{3B}/k_3, as given in Scheme 1.

These parameters, when inserted into eqs. [2] and [5], gave the solid lines shown in Figs. 2–7 and 9. Note that, except as noted below for Fig. 3, the agreement is well within experimental uncertainty, not only for the curves used to generate the parameters (Figs. 2, 6, 7, and 9) but for the others as well.

Figure 3 presents two distinct regions in which there are discrepancies between the calculated values and the experimental points. The dotted line in the region below pH 3.5 is that predicted by eq. [5] and the parameters in Scheme 1. That this line deviates from the experimental points is most simply explained by assuming that there are acid-promoted terms for the cleavage of **2** not included in eq. [5]. One may readily add reactions involving acid-catalyzed hydrolysis and chloride attack on **1** to Scheme 1, and obtain the dashed line shown in Fig. 3 (the specific parameters are $k_{3A}/k_3 \approx 900\,s^{-1}$ and $k_{4A}[Cl^-]/k_3 \approx 300\,s^{-1}$, with each term first order in H_3O^+). The agreement with experiment is satisfactory, and though such acid-catalyzed reactions are not unreasonable, we have no corroborating evidence and shall defer further discussion of the reaction below pH 3.5 until more experimental results are available.

[3]The computer program for the nonlinear least-squares treatment was based on one devised by Professor J. P. Guthrie; we are most grateful to him for his generosity in providing both the program and help in using it.



The mechanism in the high pH region

The other end of the pH–product ratio profile, though indicating qualitative agreement between calculated and observed ratios, would appear to be showing increasing deviation between the two with increasing pH, with the result that the difference between the calculated and observed values at pH 13 may be outside the experimental error.

We feel that the mediocre agreement of the calculated line with the experimental points in the high pH region (pH ≥ 12) of Fig. 3 may well be an artifact arising from the experimental difficulty of maintaining, at the site of the reaction of β-sultone, the hydroxide concentration of the bulk medium. It seems likely that as the hydroxide ion is consumed very rapidly in the first step of the formation of **2**, its concentration in the immediate vicinity of **2** would be considerably depleted as compared to the as yet unused chloride ion, and **2**, being a highly reactive species, would therefore be trapped by chloride ion leading to a higher yield of 2-chloroethanesulfonate (**4***a*). The problem of mixing effects has been taken up by Rys (18), who has concluded that "every chemical reaction that can occur in a time shorter than 0.01–1.00 s may be hindered by mixing processes"; the present reaction could well be such a process. The rate constants of the first step in the hydrolysis of **1** at pH 12.0 and 13.0 can be estimated from eq. [1] and the constants in Scheme 1 to be, respectively, 5.16×10^4 and $5.16 \times 10^5\,s^{-1}$, which translate into lifetimes (τ) of **1** of approximately 10^{-5} s and 10^{-6} s, respectively, in these media; this would lead to a very rapid depletion of hydroxide ion at the point of mixing. Also the linearity of the pH–rate profile between pH 4 and 6 (Fig. 2) indicates that the first step is certainly rate determining to at least pH 6.0. Any alteration such that the second step became rate determining would be the start of a tendency for the k_ψ to plateau. There is no sign of this, and this suggests that even at pH 6.0, **2** is consumed faster than it is formed. If we make the most conservative possible assumption that the consumption of **2** is only twice as fast as its formation at pH 6.0, we can roughly estimate the lifetime of **2** from the observed k_ψ at this pH as ~10 s. At pH >11.0, the $k_{3B}[OH^-]$ term contributes to the trapping of **2**, and a comparison of its value at pH 12.0 with that of k_3 indicates that at pH 12.0 the trapping of **2** is more than eight times as fast as that at pH 6.0 (where only k_3 operates). This then gives us a *maximum* lifetime of ~1 s for **2** at pH >12.0. It is obvious that if Rys's conclusions are correct, then the hydrolysis of **1** at pH >11.0 must be expected to be sensitive to mixing effects. In effect, then, the consistent and increasing deviation of the experimental points in Fig. 3 as the pH is increased from 11.5 to 13.0 may be due primarily to a lower actual concentration of hydroxide at the reaction site than that measured by the pH meter in the bulk solution. This could, perhaps, be expressed by including a horizontal error bar extending to the left of each point in this region to indicate the uncertainty in pH of this part of reaction, but, unfortunately, we have no satisfactory way of assigning a magnitude to such an error bar.

Another aspect of the reaction at high pH arises in connection with our studies on C—O vs. S—O cleavage of sulfonic esters (15, 16). Because it was necessary in that work to be

For personal use only.

SCHEME 2

able to make a convincing case for the formation of **2** from **1** at high pH, we felt it appropriate to carry out confirming experiments. One of these was done at pH 13.0 in a solution 5.9 M in NaCl; the product showed about equal amounts of **3** and **4***a*, in accord with the intermediacy of **2**. In another set of experiments the reaction at pH 13.0 was carried out in the presence of aniline; with 0.1, 0.2, 0.3 M aniline the ratios of **3** to **4***c* were, respectively, 86:14, 71:29, and 56:44. Though it seems likely that mixing effects vitiate any attempts at quantitative interpretation of these results, the qualitative picture is clear. The anilinosulfonate (**4***c*) is almost certainly formed from **2**, which must therefore be formed to the extent of 44%. Since hydroxide ion must trap some of the **2** as well, the amount of **2** produced can only be higher than that; the results are, in fact, fully consistent with 88% of the reaction proceeding by way of **2**, as expected from the values of k_{1B} and k_{2B} given in Scheme 1.

The rate suppression by chloride ion and the detailed mechanisms of formation of the sultone (2)

We have noted above that addition of sodium chloride slows the rate of the reaction (see Fig. 2). As we have noted elsewhere (3), one explanation for the effect of added NaCl is that chloride ion may attack β-sultone at the sulfur atom to give back **1**, i.e., the first step may be reversible in the presence of a sufficiently large amount of Cl^-. Careful quantitative examination of this mechanism leads us to revise our earlier view and to conclude from the following argument that such reversal is probably not of primary importance.

If the proposed mechanism is modified so that the first step is reversed by attack of chloride ion on the sultone (**2**) and this step is assigned the rate constant k_{-1}, we obtain Scheme 2. As is shown in the Appendix, we may readily (a) derive expressions for k_ψ and [**4***a*]/[**3**] as functions of the rate constants and ratios (eqs. [A14] and [A16]), and then (b) test the hypothesis of chloride ion reversal by using either of two procedures to assign reasonable values to the ratios k_{-1}/k_3 and $(k_4/k_3)_{Cl}$ and to insert these along with the rate constants listed in Scheme 1 into eqs. [A14] and [A16]. One of these procedures involved calculating values for the rate constant ratios by taking a value of $(k_4/k_3)_{Cl}$ that would yield a Swain–Scott *s* parameter (19) of 0.8, and estimating k_{-1}/k_3 by a relationship (eq. [A17]) derived from measurements of k_ψ at $[Cl^-] = 0$ and 0.1 M. The parameters so obtained gave (a) the solid line shown in Fig. 10, which is, as expected, in good agreement with experiment, and (b) the curves for [**4***a*]/[**3**] shown as dashed lines in Figs. 5 and 6, which clearly do not concur satisfactorily with measurement. In the second procedure, we used the nonlinear least-squares program to generate parameters (see eq. [A18]) used to calculate the ratios k_{-1}/k_3 and $(k_4/k_3)_{Cl}$. The agreement with experiment with these values was good for the [**4***a*]/[**3**] ratios at pH 4.0 and 6.0 but, as may be seen from the dashed line in Fig. 10, poor in calculating the variation of k_ψ with chloride concentration. In fact, all attempts to find a set of parameters that could provide adequate agreement with experiment on the basis of Scheme 2 were unsuccessful in our hands. A set of compromise values of k_{-1}/k_3 and $(k_4/k_3)_{Cl}$ failed to give satisfactory agreement with the results in either Fig. 10 or Figs. 5 or 6; any adjustments which improved the fit to the points in Fig. 10 worsened the agreement in Figs. 5 and 6, and vice versa. We conclude from this that chloride ion reversal, though it may occur to some measure, cannot, of itself, satisfactorily account for the lowering of k_ψ with increased $[Cl^-]$, and another explanation must be sought.

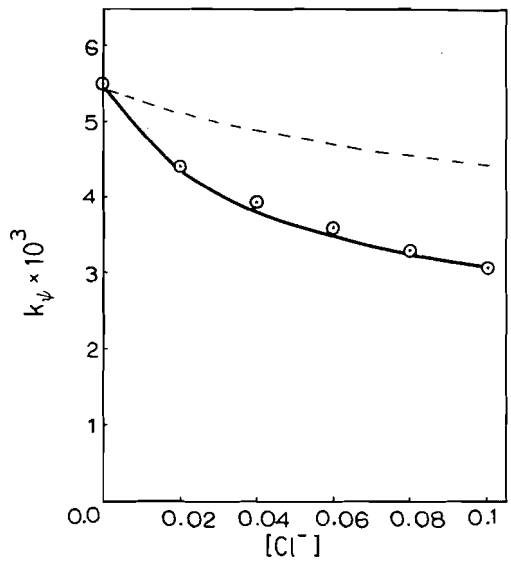

FIG. 10. Dependence on change in sodium chloride concentration of the observed pseudo-first-order rate constant for the hydrolysis of **1** (pH 5.0, 25.0°C, μ = 0.3 with $NaClO_4$). The lines are obtained from the assumption of the reaction of Cl^- with **2** to give back **1** as in Scheme 2; the solid line is calculated from eq. [A14] and the parameters that gave the dotted lines in Figs. 5 and 6 (k_{-1}/k_3 = 13.6 and $(k_4/k_3)_{Cl}$ = 4.96 M^{-1}), and the dashed line from eq. [A14] using k_{-1}/k_3 = 3.01 $(k_4/k_3)_{Cl}$ = 3.28 M^{-1} (values which gave satisfactory agreement with the points in Figs. 5 and 6) (see text and the Appendix).

A further point relevant to the chloride reversal mechanism

is the observation that a significant rate reduction was seen when the reaction was carried out in the presence of either sodium *p*-toluenesulfonate or sodium *p*-sulfanilate; specifically, for 0.2 M solutions (at pH 6.0 and 25.0°C) the rate constant with *p*-$CH_3C_6H_4SO_3^-Na^+$ was $8.56 \times 10^{-3}\ s^{-1}$ and that with *p*-$NH_2C_6H_4SO_3^-Na^+$, $5.72 \times 10^{-3}\ s^{-1}$. These values may be compared with k_{obs} values (at pH 6.0) of $1.70 \times 10^{-2}\ s^{-1}$ with 0.3 M NaCl, and $5.50 \times 10^{-2}\ s^{-1}$ with 0.3 M $NaClO_4$. The rate reductions in the presence of the arenesulfonate salts may or may not have any direct connection with that observed with NaCl, but they do show that suppression of the rate is not unique to chloride and that there must be another mechanism for it in addition to that in Scheme 2.

This conclusion, of course, opens the question of the origin of these rate suppressions and, in the search for a possible answer, of taking a closer look at the rate-determining step, the conversion of **1** to **2**. The simplest possible unimolecular mechanism would presumably go as follows.

$$\underset{\mathbf{1}}{HOCH_2CH_2SO_2Cl} \longrightarrow \underset{\mathbf{8}}{H{-}\overset{+}{O}{-}SO_2} + Cl^-$$

$$\underset{\mathbf{8}}{H{-}\overset{+}{O}{-}SO_2} \xrightarrow{H_2O} \underset{\mathbf{2}}{O{-}SO_2} + H_3O^+ + Cl^-$$

We note that the acidity of the hydrogen that is ultimately removed changes from being close to that of water in **1** to that of a very much stronger acid in **8**. According to Jencks (20), this circumstance should lead to general base catalysis by water and accordingly it seems appropriate to suggest the following modified mechanism in which the proton is transferred to water in the (single) transition state starting from the substrate–water H-bonded complex (**9**).

$$\underset{\mathbf{9}}{H_2O...HOCH_2CH_2SO_2Cl} \xrightarrow{k_1} H_3O^+ + \underset{\mathbf{2}}{O{-}SO_2} + Cl_3^-$$

This picture accords with the proposal of general base catalysis by water in the hydrolysis of sulfonyl chlorides, which may be put forward to explain the solvent isotope effect on changing from H_2O to D_2O, observed by Robertson and Laughton (21).

For the hydroxide-promoted conversion of **1** to **2**, the only reasonable mechanism in the light of Jencks' rule (20) is the specific base-catalyzed process proceeding by way of the conjugate base of **1**, i.e., $^-OCH_2CH_2SO_2Cl$ (**10**). The pK_a of **1** may be estimated by the method of Takahashi *et al.* (22) to be about 13.2; this makes **1** a distinctly stronger acid than water (pK_a 15.7) and hence the transfer of the hydroxyl proton in **1** to hydroxide prior to cyclization a favoured process.

In this context it is at least imaginable that the effect of chloride ion on the rate of cyclization of **1** may arise simply by lowering the concentration of the reacting form of **1** by competing formation of **11**, which because of the low activity of Cl^- as a general base in aqueous solution does not readily form **2**. In other words, chloride ion may be reducing the rate of **1** → **2** by sequestering part of the starting material in a less reactive form (**11**), thereby lowering the concentration(s) of the reactive species (**9**) and (or) (**10**).

The hydrogen-bonding acidity of **1**, by analogy with other

$$Cl^- \cdots (H{-}O{-}CH_2CH_2SO_2Cl)_n$$

11

alcohols bearing electron-withdrawing groups (23), is presumably greater than that of water and, since H-bonding of water to a dissolved anion is an important feature of ion hydration (24), one may expect **1** to be capable of replacing water in the solvation shell of the chloride ion. One may thus predict that **11** ($n = 1$) will be a component of the reaction medium, though it must be questioned whether its concentration will be sufficiently high to give the observed rate suppression; the hydrogen bonding in **11** ($n = 1$) has to compete with hydrogen bonding with water and, except for the bifluoride ion (FHF^-) in which the H-bond is uncommonly strong, such effects would not appear to be important in aqueous solution (25). Species with more than one molecule of **1**, i.e., **11** with $n = 2$ or more, are in principle possible, but would not be expected to be of consequence unless some compensating factor, such as hydrophobic binding, were present; such binding in **11** ($n = 2$) or between **1** and tosylate, for example, is imaginable, but since present knowledge of the interactions of solutes and solvent in aqueous media is very limited, we offer these suggestions with great diffidence.

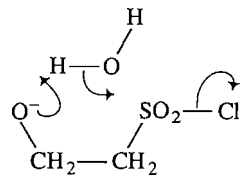
*The mechanisms of the minor reactions, the direct conversions of **1** to **3***

Comparison of k_1 with k_2 shows that in the region in which the reaction of **1** is unimolecular (pH < 3.0), about 33% of the reaction occurs by a direct process not involving **2**. Similarly k_{1B} and k_{2B} indicate that in the higher pH region (>4.0) about 12% of the reaction of **1** proceeds via a hydroxide-promoted direct conversion of **1** to **3** (the "k_{2B} reaction"). The mechanisms of these reactions are discussed in this section.

The rate constant for the uncatalyzed reaction ($k_2 = 7.46 \times 10^{-4}\ s^{-1}$) is in the same order of magnitude as those reported for the simple hydrolyses of methanesulfonyl chloride (1.92×10^{-4} (26), $1.94 \times 10^{-4}\ s^{-1}$ (27)), ethanesulfonyl chloride ($2.99 \times 10^{-4}\ s^{-1}$ (26), 2-chloroethanesulfonyl chloride ($2.05 \times 10^{-4}\ s^{-1}$ (26)) at 25°C, and the mechanism is very probably the same. In much the same way as has already been mentioned in connection with the unimolecular cyclization, Jencks' rule and the solvent isotope effect are in accord with a reaction in which one molecule of water acts as a general base assisting the nucleophilic attack of a second water molecule, perhaps by way of a transition state such as **12**, or perhaps by the very closely related species in which the S—Cl bond is not broken and the partial negative charge rests primarily on the sulfur atom. The question of whether such displacements are one- or two-step processes has been much discussed but not settled; a helpful summary has been presented by Kice (28).

$$H_2O^{\delta+} \cdots H \cdots \underset{\displaystyle H}{\underset{|}{O}} \cdots \underset{\displaystyle CH_2CH_2OH}{\underset{|}{SO_2}} \cdots Cl^{\delta-}$$

12



The normal mode of reaction of hydroxide with alkanesulfonyl chlorides bearing a hydrogen α to the sulfonyl group is the elimination–addition process via the sulfene (29–32). It was therefore reasonable to expect that the k_{2B} reaction would probably also go in this way, and hence that reaction in D_2O in strongly alkaline medium would show roughly 10% of α-monodeuterated product. In the event, the product obtained in D_2O with a pH-meter reading of 12.8 showed the product to be

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/07/12
For personal use only.

almost entirely $HOCH_2CH_2SO_3^-$, with a little (~2%) $ClCH_2CH_2SO_3^-$, and no sign whatever (i.e., <1%) of any $HOCH_2CHDSO_3^-$, thereby showing that the k_{2B} process is not primarily a sulfene reaction. This observation is consistent with the k_{2B}/k_2 ratio of $5 \times 10^9\,M^{-1}$ found in the present study, which is distinctly greater than the range of 10^6–10^8 for the ratio of k_{OH} (hydroxide promoted sulfene formation) to k_H (uncatalyzed hydrolysis) that we see with alkanesulfonyl chlorides.[4]

One simple way from **1** to **3** without deuterium incorporation is by direct attack of the hydroxide on the sulfonyl sulfur atom, but a proposal of any such process would have to include an explanation for why this reaction, which does not manifest itself in the reaction of other alkanesulfonyl chlorides bearing α-hydrogens, should suddenly appear with **1**. The direct hydroxide attack mechanism is indeed found with such substrates as arenesulfonyl and 1-alkenesulfonyl chlorides, and with these species the ratio k_{OH}/k_H ranges from 2×10^3 to $2 \times 10^5\,M^{-1}$ (33, 34); any mechanism with a direct attack on the sulfur atom of **1** would have to account for an "extra" factor of at least 10^4.

One conceivable possibility is a cyclic reaction of **10** and one of the water molecules of the solvation shell as in **13**. This

13

reaction would be an intramolecular general base-catalyzed hydrolysis, and though attractive because of its simplicity, it does suffer from the drawback that reported examples of this general class of reaction appear to show relatively little advantage over their intermolecular analogues. This point has been fully discussed by Kirby (35) whose tabulations show no examples of effective concentration (C_{eff}) greater than about 80 M, whereas the k_{2B} reaction would, for the reasons already presented, require a C_{eff} of $\geq 10^4$ M. The reason offered by Page (36) for the low efficiency of intramolecular general base catalysis (as contrasted with the often remarkable facility of intramolecular *nucleophilic* reactions) is that the general base reactions go through a relatively loose transition state, which provides only a small entropic advantage over the intermolecular analogue. To be sure, the transition state proposed for the present case may well be tighter than those referred to by Page and Kirby. Their examples all involve larger rings in the transition state, and it is at least conceivable that intramolecular general base-catalyzed reactions, provided they have sufficiently tight transition states, can also show higher effective concentrations than those reported. The point would appear to be of sufficient general significance to justify further study, though the hydrolysis of **1**, with the reaction of interest in this context constituting only about one tenth of the total reaction, is not the ideal system for such a project.

Experimental

Reagent grade chemicals and solvents were used without further purification unless otherwise noted. Melting points were determined on a Kofler Hot Stage and are uncorrected. Infrared spectra were obtained with a Beckman 4250 or Bruker IFS-32 FTIR spectrophotometer. The ^{1}Hmr spectra were obtained using Varian T-60, EM-360, XL-100, or XL-200 spectrometers, with all reported chemical shifts from the last two instruments. The ^{13}Cmr spectra were obtained on a Varian XL-200 or XL-300 instrument. Solvent evaporation on work-up was carried out using a Büchi rotary evaporator connected to a water aspirator.

The pH-stat apparatus and the procedure used for the kinetic determinations and all constant pH reactions have been described (4, 34); further details and a full tabulation of observed rate constants and product ratios are given elsewhere (17).

2-Mercaptoethanol (Eastman) was distilled under vacuum and the fraction boiling at 44°C (6 Torr; 1 Torr = 133.3 Pa) collected; ir ($CHCl_3$) ν_{max}: 3663 (m), 3442 (b), 2994 (s), 2932 (s), 2872 (s), 2572 (w), 1457 (w), 1412 (s), 1382 (s), 1335 (w), 1275 (m), 1217 (s, b), 1175 (m), 1052 (vs, b), 927 (m); ^{1}Hmr ($CDCl_3$) δ: 3.79 (t, 2H), 2.82–2.62 (m, 2H), 2.33 (s, 1H), 1.41 (t, 1H); ^{13}Cmr ($CDCl_3$) δ: 64.0, 27.8.

Preparation of 2-hydroxyethanesulfonyl chloride (1)

The following procedure is a distinct improvement over our earlier method (4). A mixture of concentrated H_2SO_4 (10 mL) and water (30 mL) in a 100-mL pear-shaped flask equipped with a stirring bar and mounted over a magnetic stirrer, was cooled to −10°C in an ice–salt bath and saturated (1 min) with a stream of Cl_2 gas (Linde). Vigorous stirring and Cl_2 bubbling was maintained while 2-mercaptoethanol (10 g, 0.13 mol) was added dropwise over 10 min; Cl_2 was then bubbled in for a further 10 min, at the end of which time a yellowish solution was obtained. The reaction mixture was then transferred to a separatory funnel using more cold aqueous sulfuric acid (3 × 5 mL) and extracted with cyclohexane (2 × 250 mL); the extracts were combined and treated with solid $NaHCO_3$ followed by anhydrous $MgSO_4$ and the solvent removed on a rotary evaporator to yield 2-chloroethanesulfonyl chloride (1.1 g, 6.7 mmol, 5% yield, >90% pure by ^{1}Hmr); ^{1}Hmr ($CDCl_3$) δ: 4.03 (s); ^{13}Cmr ($CDCl_3$) δ: 35.5, 65.6.

The aqueous extract was further extracted immediately with CH_2Cl_2 (5 × 250 mL) and, after treatment with $NaHCO_3$ and $MgSO_4$, the solvent was removed to yield **1** (15.005 g, 0.104 mol, 81% yield, >95% pure by ^{1}Hmr). A further 0.92 g of **1** (6.37 mmol, 5% yield, >95% pure by ^{1}Hmr) was recovered from the aqueous layer as follows. The mixture was neutralized with solid $NaHCO_3$ at ice-bath temperature under vigorous stirring and the viscous solution so obtained was transferred to a separatory funnel using cold brine and extracted with CH_2Cl_2 (3 × 250 mL); the extracts were dried and the solvent evaporated. 2-Hydroxyethanesulfonyl chloride (**1**) (86% yield overall) so obtained was then purified by flash distillation. A conventional distillation apparatus was assembled and a vacuum was applied (0.3 Torr) and maintained, and the flask containing **1** and a magnetic stirring bar was then quickly lowered into a preheated oil bath (110°C) mounted on a magnetic stirrer; **1** distilled smoothly (84°C at 0.3 Torr, 70% recovery on a 2.5 g scale) leaving a dark residue in the still-pot; ir ($CHCl_3$) ν_{max}: 3620 (m), 3410 (br, m), 1380 (s), 1175 (s), 1060 (m) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 3.80–4.00 and 4.10–4.30 (A_2B_2 complex multiplet, exact pattern concentration dependent, 4H), 2.80 (s, 1H); ^{13}Cmr ($CDCl_3$) δ: 56.9, 67.6. Two precautionary notes for the above procedure: (a) the entire procedure from the start to the extractions should be finished within minimum time (~1 h) and (b) all rinsing and washing during transferring the reaction mixture from one pot to another should be done with either cold aqueous sulfuric acid (4.5 M) or with cold saturated brine.

2-Hydroxyethanesulfonyl-2,2-d_2 chloride was prepared by carrying out a small-scale version of this reaction using Cl_2 in D_2O with 2-mercaptoethanol-1,1-d_2, prepared by lithium aluminum deuteride reduction of mercaptoacetic acid. The sample of $HOCD_2CH_2SO_2Cl$ so obtained showed the following spectra: ir ($CHCl_3$) ν_{max}: 3600 (m), 3400 (w, b), 3020 (m), 2920 (w), 2340 (w), 2210 (w), 2100 (w), 1375 (vs), 1320 (w, b), 1250 (w), 1165 (s), 978 (s), 652 (m) cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 3.93 (s, 2H), 2.75 (s, 1H); ^{13}Cmr ($CDCl_3$) δ: 67.4.

[4]Unpublished experiments carried out in this laboratory by M. Aslam, S. Skonieczny, and J. Y. L. Lam; cf. also ref. 32.

For personal use only.

*Rate of hydrolysis of **1***

A stock solution was first prepared by dissolving **1** (119.9 mg, 0.83 mmol) in dry acetonitrile (2 mL). The rate of hydrolysis of **1** was determined from a plot of the liberated acid (as determined by pH-stat titration with 0.05 M NaOH) against time. In a typical experiment, 25 mL of 0.1 M NaCl (ionic strength 0.3 M with $NaClO_4$) solution was stabilized at pH 5.0 (0.16 M $HClO_4$) and 25°C; 2 μL of the above stock solution in acetonitrile was then added and the timer started. The reaction was followed by recording (at regular intervals) the amount of titrant (V_t) added with time. Log ($V_\infty - V_t$) was plotted against time lapsed (t), and the rate constant for the hydrolysis calculated from the half-life using the equation, $k_\psi = 0.693/t_{1/2}$.

*Products of hydrolysis of **1** at 25°C*

The hydrolyses of **1** were performed in 50 mL of 1 M aqueous NaCl solution at 25°C and at pH settings varying from 1.0 to 13.0 (with 0.16 M or concentrated $HClO_4$ used to adjust the pH initially) using the pH-stat apparatus. Typically, **1** (114 mg, 0.79 mmol), dissolved in 1 mL of dry CH_3CN, was added dropwise with stirring to the NaCl solution kept at 25°C and a particular pH. Aqueous sodium hydroxide (2 M) was used as titrant to maintain the pH while **1** was being added. The reaction time varied from 132 h (at pH 1.0) to 10 min (at pH 13.0). After the reaction, the pH of the mixture was adjusted to 7.0, and the water evaporated on a rotary evaporator. Repeated azeotroping with benzene gave a white solid, the whole of which was dissolved in D_2O (~10 mL); ^{1}Hmr δ: 3.25 (t, 2H), 3.47 (t, 2H), 3.965 (t, 2H), and 4.03 (t, 2H). Comparison with ^{1}Hmr spectra of authentic $HOCH_2CH_2SO_3^-Na^+$ (**3**) (Aldrich) and $ClCH_2CH_2SO_3^-Na^+$ (**4***a*) (Aldrich) permitted the following assignments: **3**, 3.25, 4.03 ppm and **4***a*, 3.47, 3.97 ppm. The relative yield of the two products in individual runs was estimated from integrations of the triplets at 3.25 (**3**) and 3.47 (**4***a*) ppm.

The same procedure (except for the changes in NaCl concentrations) was used for the experiments with NaCl at pH 3.5, 4.0, 6.0, and 11.0, respectively. The sodium thiocyanate experiments at pH 3.5 and 6.0 were carried out in the same way except that the product ratios were obtained by comparison of the peak due to **4***b* around 3.6 (4H) with that for **3** at 3.3 ppm (2H). The experiments with aniline were also done similarly except for the following points. (a) After acidification to pH 7 the solution was extracted with CH_2Cl_2 (3 × 50 mL) and the CH_2Cl_2 evaporated; the organic soluble material appeared to be entirely aniline with no sign of any $HOCH_2CH_2SO_2NHPh$. (b) The product ratios were determined by integration of the triplets at 3.9 and 3.6 ppm (due to **3** and **4***c*, respectively).

*Preparation of authentic $NCSCH_2CH_2SO_3^-Na^+$ (**4**b)*

Sodium 2-bromoethanesulfonate was prepared by refluxing a mixture of 1,2-dibromoethane (30 g, 0.16 mol) with a solution of Na_2SO_3 (15.1 g, 0.12 mol) in water (75 mL) for 5 h, cooling, removing the excess dibromoethane by washing with CH_2Cl_2, and evaporating the water. The crude product was triturated with absolute ethanol, the undissolved salts removed by filtration, and the ethanol evaporated to give a white residue (4.1 g), the ^{1}Hmr spectrum of which showed, for the principal material (~70%), an A_2B_2 pattern consisting of two multiplets with the largest central peaks at 3.63 and 3.43 ppm. This material (1.98 g, 9.39 mmol), NaSCN (0.76 g, 9.39 mmol), 18-crown-6 (1.24 g, 4.70 mmol), and 20 mL of dry acetonitrile were combined in a 50-mL round bottom flask and the mixture refluxed for 17 h. The acetonitrile was evaporated on a rotary evaporator and the solid obtained dissolved in 15 mL water and washed with CH_2Cl_2 (5 × 50 mL) and then with Et_2O (10 × 50 mL). The pH of the aqueous layer was then adjusted to 7.0 with 0.1 M NaOH. Evaporation of water and azeotroping (with benzene) was followed by recrystallization (from absolute ethanol) to give **5** as a white solid (1.24 g, 70%); mp 204–207°C; ir (KBr) ν_{max}: 2998 (w), 2160.5 (m, sharp), 1615 (w), 1429 (w), 1416 (w), 1385 (w), 1316 (w), 1244 (m), 1200 (vs, br), 1181 (s), 1138 (w), 1051 (s), 743 (w) cm^{-1}; ^{1}Hmr (D_2O) δ: 3.39 (s); ^{13}Cmr (D_2O) δ: 53.05, 30.83. *Anal.* calcd. for $C_3H_4O_3S_2NNa$: C 19.05, H 2.13, N 7.40, S 33.89; found: C 18.89, H 2.20, N 7.13, S 33.56.

*Simultaneous determination of the rate constant and the product ratio in the hydrolysis of **1** in the presence of NaSCN*

Aqueous NaSCN (1.00 L, 1.0 M, ionic strength 0.5 M with $NaClO_4$) in a 2-L thermally protected beaker was adjusted to 25°C and pH 3.0 (with 2.0 M $HClO_4$) and attached to the pH-stat apparatus. A stock solution of **1** in dry acetonitrile (1 mL), such as to give an initial concentration of **1** of 3.44×10^{-4} M, was added to the stirred mixture and the addition of 0.05 M NaOH with time recorded as before. After 1085 min the pH of the mixture was adjusted to 7.0 and the water evaporated. As already described, a plot of log ($V_\infty - V_t$) vs. time gave the rate constant (1.80×10^{-4} s^{-1}), and the ^{1}Hmr spectrum the ratio **4***b*:**3** (48:52).

*Products of hydrolysis of 1,3-propane sultone (**5**)*

In a typical experiment **5** (133 mg, 1.09 mmol) was dissolved in dry acetonitrile and added to 50 mL of 1.4 M NaCl solution at pH 4.0 and 25°C in the pH-stat apparatus as described above. After 24 h of reaction (with stirring and addition of 2.0 M NaOH from the autotitrator, as required to maintain constant pH), the pH was adjusted to 7.0 and the mixture worked up as above. The relative amounts of **6** and **7** were obtained from the integrals of the multiplets at 2.14–2.26 and 2.33–2.47 ppm (due to **6** and **7**, respectively) in the ^{1}Hmr spectrum (D_2O).

*Sodium 3-hydroxypropanesulfonate (**6**)*

Freshly distilled 1,3-propane sultone (**5**, γ-sultone, Aldrich, 3.01 g, 24.6 mmol) was added dropwise to an equivalent amount of sodium hydroxide (985 mg, 24.6 mmol) in 20 mL H_2O at room temperature, and the mixture stirred at room temperature for 23 h. The pH of the mixture was then adjusted to 7.0 and the water removed by evaporation on a rotary evaporator. Repeated azeotroping with benzene followed by pumping at 100°C and 9 Torr for 5 h gave **6** as a free-flowing white powder in quantitative yield; ^{1}Hmr (acetic acid-d_4) δ: 2.04 (m, 2H), 3.04 (m, 2H), and 3.76 (t, 2H); ^{13}Cmr (acetic acid-d_4) δ: 27.95, 49.21, 61.47.

*Sodium 2-anilinoethanesulfonate (**4**c)*

Sodium 2-bromoethanesulfonate (5 g, 23.7 mmol, prepared as described above) was dissolved in water (50 mL), mixed with excess freshly distilled aniline (50 mL), and the mixture refluxed for 15 h. It was then cooled and the excess aniline removed by repeated extraction with methylene chloride (3 × 200 mL). The pH of the clear aqueous layer was then adjusted to ~7.0 using dilute aqueous sodium hydroxide. The solution was further extracted with two fresh portions of methylene chloride. Evaporation of water gave a free-flowing white powder, which was recrystallized from absolute alcohol to yield **4***c* (2.03 g, 35%); ir (KBr) ν_{max}: 3030 (w), 2975 (w), 1603 (s), 1512 (s), 1478 (w), 1401 (s), 1318 (m), 1200 (vs), 1057 (s), 882 (w), 750 (s) cm^{-1}; ^{1}Hmr (D_2O) δ: 7.38–7.31 and 6.99–6.91 (m, 5H), 3.57 (t, 2H), and 3.18 (t, 2H).

*Hydrolysis of **1** in D_2O–OD^-*

To a solution prepared by reacting sodium metal (92 mg) with D_2O (2 mL) and adding further D_2O (15 mL), 2-hydroxyethanesulfonyl chloride (**1**) (100 mg) in CH_3CN was added during 1 min. The reaction mixture was immediately brought to pH 7.0 with concentrated DCl. Removal of water was followed by examination of the ^{1}Hmr spectrum (D_2O), which consisted of two prominent triplets at 3.13 and 3.93 ppm due to $HOCH_2CH_2SO_3^-$, two very small triplets at 3.4 and 3.9 ppm due to **4***a* (~2%), but with no sign whatever of any signals ascribable to $HOCH_2CHDSO_3^-$.

Appendix

Scheme 1 equations and parameters

From Scheme 1 and the steady state approximation we write:

[A1] $$d[\mathbf{4}]/dt = k_4[Nu^-][\mathbf{2}]$$

[A2] $$d[\mathbf{3}]/dt = (k_2 + k_{2B}[OH^-])[\mathbf{1}] + (k_3 + k_{3B}[OH^-])[\mathbf{2}]$$

[A3] $$[\mathbf{2}] = \frac{(k_1 + k_{1B}[OH^-])[\mathbf{1}]}{k_3 + k_{3B}[OH^-] + k_4[Nu^-]}$$

For convenience, we set $x = k_1 + k_{1B}[OH^-]$, $y = k_2 + k_{2B}[OH^-]$, and $z = k_3 + k_{3B}[OH^-]$; substituting [A3] into [A1] and [A2] and dividing, we obtain [A4]:

[A4] $$\frac{d[\mathbf{4}]}{d[\mathbf{3}]} = \frac{xk_4[Nu^-]}{y(z + k_4[Nu^-]) + xz}$$

In any individual experimental run every component of the right-hand side of eq. [A4] is constant and so $d[\mathbf{4}]/d[\mathbf{3}] = [\mathbf{4}]/[\mathbf{3}]$; this, plus division of the top and bottom of the right side of eq. [A4] by $yk_4[Nu^-]$, yields eq. [A5]:

[A5] $$\frac{[\mathbf{4}]}{[\mathbf{3}]} = \frac{x/y}{1 + \dfrac{z/k_4(1 + x/y)}{[Nu^-]}} = \frac{a_1}{1 + \dfrac{a_2}{[Nu^-]}}$$

where

[A6] $$a_1 = x/y$$

and

[A7] $$a_2 = (1 + x/y)z/k_4 = \frac{(1 + x/y)(1 + k_{3B}[OH^-]/k_3)}{k_4/k_3}$$

(Note that eqs. [A5]–[A7] are eqs. [5]–[7] of the main text.) From a nonlinear least-squares fit to eq. [A5] of the data for the product ratios vs. thiocyanate concentration at pH 3.5 and 6.0 (Fig. 9), we obtained $a_1 = 3.56$, and $a_2 = 0.1192$ at pH 3.0, and $a_1 = 13.51$, and $a_2 = 0.3394$ at pH 6.0, which, with eq. [A6] and the definitions of x and y, gives

[A8] $$k_1 + (3.126 \times 10^{-11})k_{1B} = 3.56k_2 + (1.126 \times 10^{-10})k_{2B}$$

and

[A9] $$k_1 + 10^{-8}k_{1B} = 13.51k_2 + (13.51 \times 10^{-10})k_{2B}$$

Equations [3], [4], [A8], and [A9] form a set of linear simultaneous equations; their solution yields the values of k_1, k_2, k_{1B}, and k_{2B} shown in Scheme 1.

From Fig. 3 it is evident that $k_3 = k_{3B}[OH^-]$ at the inflection point (pH ~ 11), and hence $k_{3B}[OH^-]$ may be neglected relative to k_3 at pH 6.0. We then obtain

[A10] $$a_2 = (1 + x/y)/(k_4/k_3)$$

which from $a_2 = 0.3394$ gave $(k_4/k_3)_{SCN} = 42.8\,M^{-1}$.

The data for the variation in [**4***a*]/[**3**] with $[Cl^-]$ at pH 6.0 (Fig. 6), on least-squares analysis similar to that above except that a_1 was given the value obtained from the thiocyanate data (13.51) and only a_2 was allowed to optimize, gave $a_2 = 4.99$; this, when inserted into eq. [A7] (again with the assumption that $k_3 \gg k_{3B}[OH^-]$), yielded $(k_4/k_3)_{Cl} = 2.91\,M^{-1}$.

Finally, the value 13.74 for x/y at pH 11.0 was calculated from the values of k_1, k_2, k_{1B}, and k_{2B} (given in Scheme 1). With this as the constant value for the a_1 parameter in the least-squares treatment of the data for the ratio [**4***a*]/[**3**] vs. $[Cl^-]$ at pH 11.0, we obtained $a_2 = 9.27$, which when inserted into eq. [A7] along with $(k_4/k_3)_{Cl} = 2.91$ yielded $k_{3B}/k_3 = 8.29 \times 10^2\,M^{-1}$.

Scheme 2 equations and parameters

In the same manner as from Scheme 1 we may obtain [A11] and [A12] from Scheme 2:

$$[A11] \quad \frac{d[\mathbf{3}]}{dt} = \frac{xz_4[\mathbf{1}]}{k_{-1}[Cl^-] + k_4[Cl^-] + z} + y[\mathbf{1}]$$

and

$$[A12] \quad \frac{d[\mathbf{4}a]}{dt} = \frac{xk_4[Cl^-][\mathbf{1}]}{k_{-1}[Cl^-] + k_4[Cl^-] + z}$$

From $k_\psi[\mathbf{1}] = d[\mathbf{3}]/dt + d[\mathbf{4}a]/dt$ we may write

$$[A13] \quad k_\psi = \frac{x(k_4[Cl^-] + z)}{k_{-1}[Cl^-] + k_4[Cl^-] + z} + y$$

Note that when k_{-1} or $[Cl^-] = 0$, $k_\psi = x + y$ (cf. eq. [2]). At pH 5.0 (the pH at which the rates in Fig. 1 were determined) $k_3 \gg k_{3B}[OH^-]$; substituting for z, eq. [A13] becomes:

$$[A14] \quad k_\psi = \frac{x(1 + k_4[Cl^-]/k_3)}{1 + k_4[Cl^-]/k_3 + k_{-1}[Cl^-]/k_3} + y$$

Defining r as the ratio of k_ψ when $[Cl^-] > 0$ to k_ψ when $[Cl^-] = 0$, we obtain

$$r = \frac{px + y}{x + y}$$

where

$$p = \frac{1 + k_4[Cl^-]/k_3}{1 + k_4[Cl^-]/k_3 + k_{-1}[Cl^-]/k_3}$$

Rearranging,

$$[A15] \quad p = [r(x + y) - y]/x$$

Also, from eqs. [A12] and [A13] and the line of reasoning already discussed for Scheme 1, it may be readily shown that

$$[A16] \quad \frac{[\mathbf{4}a]}{[\mathbf{3}]} = \frac{xk_4[Cl^-]}{y(k_{-1}[Cl^-] + k_4[Cl^-] + z) + xz}$$

Taking the values of k_ψ at $[Cl^-] = 0.1$ M and 0 (respectively, 3.08×10^{-3} and 5.50×10^{-3} s^{-1}), $r = 0.56$; substituting this and the values of x and y into eq. [A15], we find

$$[A17] \quad k_{-1}/k_3 = 9.142 + 0.9142(k_4/k_3)_{Cl}$$

At this stage we set a chemically reasonable limit to the range of $(k_4/k_3)_{Cl}$ (and hence k_{-1}/k_3) values, and to this end make use of the Swain–Scott s parameter (19). Values of s ranging from 0.69 to 0.82 have been reported for reactions of sulfonic esters (37). Noting that the ratio $(k_4/k_3)_{SCN} = 42.8$ (above) with $n_{SCN} = 4.77$ (19) corresponds to $s = 0.71$, we regard the range of s values from 0.5 to 1.0 as covering the likely possibilities; a systematic examination of the parameters obtained from eq. [A17] over this range (at intervals of 0.1 in s) provided no values that, when inserted into eq. [A16], led to satisfactory agreement with experiment. The set of ratios corresponding to $s = 0.8$, namely, $(k_4/k_3)_{Cl} = 4.96\ M^{-1}$ and $k_{-1}/k_3 = 13.6$, gave what was probably the best agreement; the curves generated from these parameters are shown as the dashed lines in Figs. 5 and 6.

Another approach is to rewrite [A16] as

$$[A18] \quad \frac{[\mathbf{4}a]}{[\mathbf{3}]} = \frac{xk_4/yw}{1 + \dfrac{(1 + x/y)z/w}{[Cl^-]}} = \frac{b_1}{1 + \dfrac{b_2}{[Cl^-]}}$$

where $w = k_4 + k_{-1}$. From the data for pH 6.0 shown in Fig. 6 and the nonlinear least-squares program, we obtained $b_1 = 6.999$ and $b_2 = 2.295$. At pH 6.0, $z = k_3$ (see above), and so

$$[A19] \quad b_1/b_2 = \frac{(x/y)(k_4/k_3)}{1 + x/y}$$

With $x/y = 13.51$ (see above), [A19] gives $(k_4/k_3)_{Cl} = 3.28\ M^{-1}$. From $b_1 = xk_4/yw$ (by definition), $k_{-1}/k_3 = 3.01$. These parameters, when inserted into eq. [A14] with k_1, k_2, k_{1B}, and k_{2B} from Scheme 1, gave the dashed line in Fig. 10.

Comparison of an intramolecular Michael-type addition with its intermolecular counterpart: an *ab initio* theoretical study

C. I. BAYLY AND F. GREIN

Departmemt of Chemistry, University of New Brunswick, Fredericton, N.B., Canada E3B 6E2

Received February 21, 1989

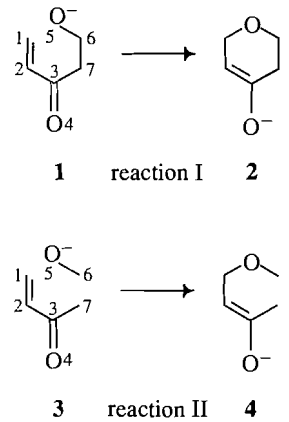
C. I. BAYLY and F. GREIN. Can. J. Chem. **67**, 2173 (1989).

Ab initio theoretical calculations were carried out on the intramolecular addition of 3-ketopent-4-en-1-olate **1** to form 1-oxacyclohex-3-en-4-olate 2 (reaction I; Scheme 1) and the corresponding intermolecular Michael addition of methanolate to butenone forming 4-methoxybut-2-en-2-olate **4** (reaction II; Scheme 1). The calculations were carried out at the RHF level using an augmented 4-31G basis set; single point energies were then taken using the 6-31+G* basis set. The overall energy change of the reaction in going from reactants to products is very similar for both reactions, with products being about 8.3 kcal/mol more stable than reactants; the major difference energetically between the two reactions is at the level of the transition state: the transition state energy for reaction I (intramolecular) is 6 kcal/mol higher than that for reaction II (intermolecular). The transition state geometry of reaction II conforms quite closely to the stereoelectronic requirements for a Michael addition, but that of reaction I is very distorted, reflecting significant compromises in the stereoelectronic requirements.

Key words: *ab initio* theoretical study, Michael-type addition, intramolecular, transition state.

C. I. BAYLY et F. GREIN. Can. J. Chem. **67**, 2173 (1989).

On a effectué des calculs théoriques *ab initio* sur l'addition intramoléculaire du céto-3 pente-4 olate-1 **1** qui conduit à l'oxa-1 cyclohexen-3 olate-4 **2** (réaction I; schéma 1) et sur l'addition de Michael intramoléculaire du méthanolate sur la buténone conduisant au méthoxy-4 buten-2 olate-2 **4** (réaction II; schéma 1). On a effectué les calculs au niveau RHF en utilisant un ensemble de base 4-31G elargi; on a obtenu les énergies ponctuelles en utilisant l'ensemble de base 6-31+G*. Les changement global d'énergie de la réaction, en partant des réactifs aux produits, est très voisin pour les deux réactions, avec des produits dont la stabilité est d'environ 8, 3 kcal/mol plus élevée que celle des réactifs. La principale différence d'énergie entre les deux réactions se situe au niveau de l'état de transition : l'énergie de l'état de transition pour la réaction I (intramoléculaire) est de 6 kcal/mol plus élevée que celle de la réaction II (intermoléculaire). La géométrie de l'état de transition de la réaction II se rapproche beaucoup des conditions stéréoelectroniques requises pour une addition de Michael, mais celle de la réaction I est très deformée reflétant ainsi des compromis significatifs dans les conditions stéréoélectroniques nécessaires.

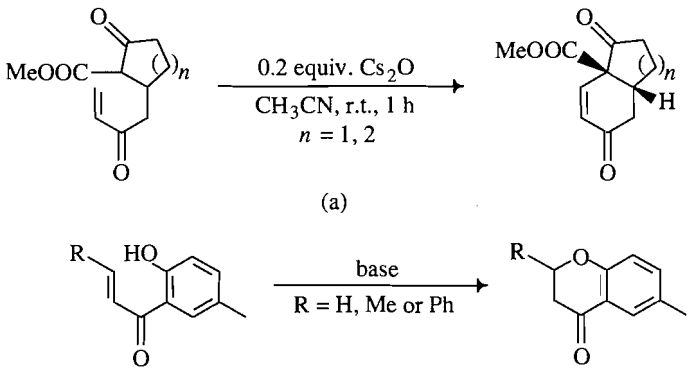


Mots clés : étude théorique *ab initio*, addition de Michael, intramoléculaire, état de transition.

[Traduit par le revue]

Introduction

In comparing the reactivity of an intramolecular system with its intermolecular counterpart, an important factor is the difference between the respective potential energy reaction profiles. Although the electronic changes taking place in both systems may be very similar, the extra spatial constraints on the reacting termini of the intramolecular system often disallow the "optimum" trajectory (in an intermolecular sense), requiring instead a different and higher energy trajectory as a reaction pathway. If the spatial distortion of the trajectory is big enough, the resulting increase in the potential energy for the transition state can be so great that the reaction will simply not occur under "normal" conditions (i.e., those used for the intermolecular reaction). The well-known Baldwin's rules (1) qualitatively classify ring-forming reactions as being favoured or disfavoured based on this principle. To study how an intramolecular system responds, both geometrically and energetically, to a large distortion from the optimum (intermolecular) reaction trajectory, an intramolecular Michael addition (1,4-nucleophilic addition to an α,β-unsaturated carbonyl moiety) was examined using theoretical methods.



Ab initio theoretical calculations were carried out on the intramolecular addition of **1** to form **2** (reaction I, Scheme 1), which is a cyclization forming a six-membered ring. These calculations were then compared to those on the corresponding intermolecular Michael addition of **3** to form **4** (reaction II, Scheme 1). The structures of reaction I were chosen by analogy with experimental ones given in Scheme 2(a) (2), where **1** is constructed by replacing the ring by hydrogens and the β-ketoester fragment by oxygen. These replacements gave a system of computationally feasible size with a nucleophilic center of the same charge and approximately the same size and nucleophilicity as the experimental case. Reaction I is also very similar to the reaction given by Baldwin *et al.* (3) as an example of a 6-*endo*-trig process (Scheme 2(b)). Both of these intramolecular cyclizations reacted experimentally without difficulty.

SCHEME 1

While a 6-*endo*-trig process (such as reaction I) is a favored reaction according to Baldwin's ring closure rules (1), nevertheless the stereoelectronic requirements for Michael addition (4) would indicate that the intramolecular cyclization in reaction I could only take place via a significantly distorted transition state. One of these requirements is that the newly forming bond

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/07/12
For personal use only.

SCHEME 2

should be coplanar with the enone π system. That is, the torsion angle around the α-carbon–β-carbon bond should be ideally 90°. However, even a fully formed six-membered ring can achieve only a 60° torsion angle around this bond. In principle a partially formed six-membered ring could reposition the nucleophile to improve this torsion angle, but then the forming bond angle (the Burgi – Dunitz "attack angle" (5)) would be much smaller than the "allowed" range of 100°–110° suggested by these authors. Furthermore, in the system under study, such a repositioning would almost certainly break the coplanarity of the enone system itself to some extent, where this coplanarity is another stereoelectronic requirement for reactivity. What geometric "compromise" is made by the real systems, and at what energy cost, to accommodate both the stereoelectronic requirements of the Michael addition and the spatial restrictions of the intramolecular framework?

A previous theoretical study, using the MNDO semiempirical method, was carried out on an intramolecular Michael addition of an oxygen nucleophile to an α,β-unsaturated carbonyl group (6). In this case the reactant carbon skeleton was one methylene group shorter than **1**, and the forming ring was thus five membered instead of six membered. This process was hence a 5-*endo*-trig process (disfavored according to Baldwin's rules) as opposed to the favored 6-*endo*-trig process studied in this work. These authors found a potential energy barrier of 21 kcal/mol to the intramolecular cyclization. The corresponding intermolecular system was not investigated by these authors, so an intramolecular–intermolecular comparison is not possible without further study.

Calculations

Calculations were carried out at the RHF (restricted Hartree–Fock) level using the GAUSSIAN 82 (7) computer program. The 4-31G basis set was used, augmented with polarization (6d, exponent 0.8) and diffuse functions (*s* and *p* functions, exponent 0.680) (8) on the oxygens only. This basis set (referred to henceforth as 4-31G(O*+)) was chosen in the light of basis set comparisons made in a previous study (9), which indicated that without diffuse functions on at least the anionic centers the reaction profile may not be even qualitatively correct. With each structure, the C—H bond lengths and the H—C—C bond angles of C6 and C7 (i.e., the two adjacent methylenes in reaction I and the methyls in reaction II (cf. Scheme 1)) were optimized together; all other internal degrees of freedom were optimized independently. The forming nucleophile–carbon bond (the C1—O5 internuclear distance, cf. Scheme 1) was used as the reaction coordinate (RC) for both reactions I and II. Single-point energies at the 6-31+G* basis set level were calculated for the critical points (for both systems) obtained using the 4-31G(O*+) basis set, in order to check the smaller basis set.

[c]The energy (in hartree) of the global minimum is −343.108864.

Exploratory calculations were carried out to verify that the transformations went through a single energy maximum and to help locate that maximum. The RC was held constant at several intermediate values situated on either side of the transition state, and then partial optimizations were carried out to determine the energy trend. For reaction II, a transition state (TS) optimization was then carried out directly to obtain the structure and energy of the TS.

For reaction I, the TS optimization algorithm (7) did not behave properly (the geometry diverged), so the TS was located by varying the RC by hand, completing the optimization holding constant the RC value, and inspecting the energy gradient along the RC. At 2.10 Å, the gradient of the optimized structure indicated the RC would increase if optimized, and at 2.08 Å, it would decrease. Quadratic interpolation of the energies gave 2.091 Å for the location of the TS on

the RC; optimization at this location gave an energy higher than the point on either side and a value of the energy gradient along the RC that was lower than the cutoff for the TS optimization algorithm. This structure is given as the TS of reaction I.

Results and discussion

The optimized structures and relative energies for reactions I and II are given in Tables 1 and 2, respectively; for reaction I the structures at 2.08 Å and 2.10 Å have been omitted because they resemble the TS so closely. Shown in Fig. 1 are the 4-31G(O*+) energy profiles of both reactions; the TS structure for reaction I is shown in Fig. 2a and that for reaction II is shown in Fig. 2b. The "reactant" molecules for both reactions I and II are local energy minima, most likely corresponding to a charge–dipole complex (9, 10). The structures in Fig. 2 each contain two dummy atoms X1 and X2 (having neither mass nor electrons nor nuclear charge) as a strictly geometric convenience to aid in the following discussion. They are placed as vectors perpendicular to a plane to show the amount of twist in that plane. For both structures, the dummy atom X1 is normal to the terminal methylene H1—C1—H2 plane, and X2 similarly is normal to the H3—C2—C3 plane. The dihedral angle between these two centers, i.e., X1—C1—C2—X2, shows the amount of twist taking place along the reacting double bond.

From Fig. 1 it may be seen that the overall energy change of the reaction in going from reactants to products is very similar for both reactions I and II, with products being about 8.3 kcal/mol more stable than reactants. The 6-31+G* single point energies given in Tables 1 and 2 gave this difference to be 10.9 and 11.5 kcal/mol for reactions I and II respectively. The structures calculated for reactants and products are as expected from the stereoelectronic requirements (*vide infra*) (i.e., boat-like conformations for reaction I) and theoretical studies (10). The major difference energetically between the two reactions is at the level of the TS; for the following comparisons the 6-31+G* single point energies will be given in parentheses after the 4-31G(O*+) energies. The TS energy for reaction I (intramolecular) is 14.5(13.8) kcal/mol above reactants, whereas the corresponding energy difference for reaction II (intermolecular) is 8.5(7.6) kcal/mol. The barrier for the intramolecular reaction is thus 6.0(6.2) kcal/mol higher than that of the intermolecular reaction. The 6-31+G* single point energies reflect the

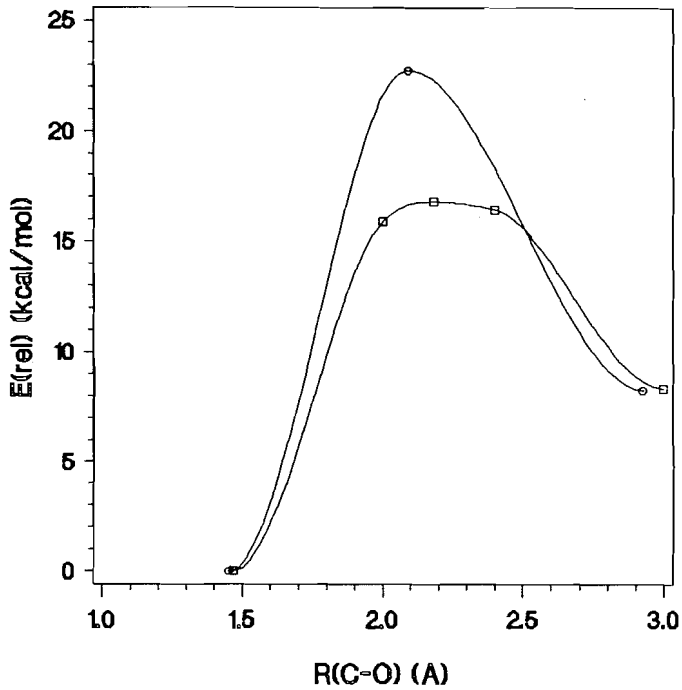

FIG. 1. Reaction profiles for reactions I and II; ○, reaction I (intramolecular); □, reaction II (intermolecular). Energies relative to products. R(C—O) is the C1—O5 internuclear distance, the reaction coordinate.

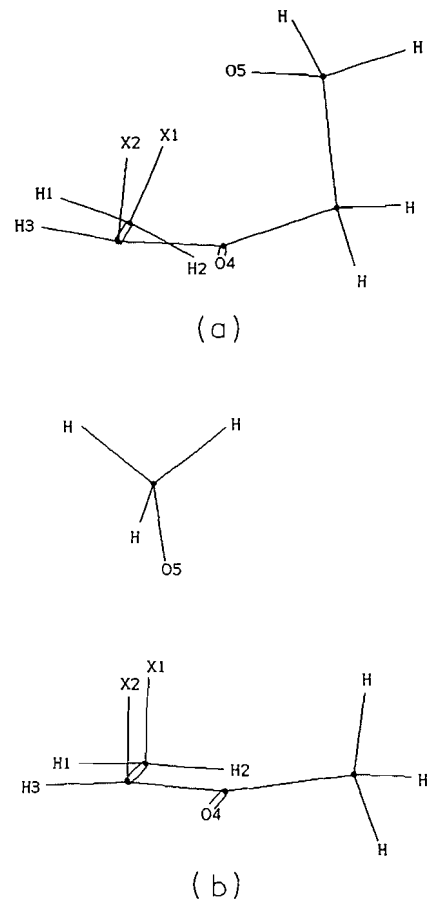

FIG. 2. Transition state structures for (a) reaction I (intramolecular) and (b) reaction II (intermolecular).

reactant–TS relative energy changes of the 4-31G(O*+) basis set to within 1 kcal/mol. Overall, the good agreement between the 6-31+G* and the 4-31G(O*+) basis sets validates the use of the much smaller 4-31G(O*+) basis set for this study as shown in previous work (9, 10).

The TS geometry of reaction II, shown in Fig. 2b, conforms quite closely to the stereoelectronic requirements outlined previously for a favorable reaction pathway. The pyramidalization of the methylene terminus, indicated by an X1—C1—C2 angle of 102° (this angle would be 90° with no pyramidalization), shows that bond formation is occurring, with a length of 2.18 Å for the incipient C1—O5 bond (the reaction coordinate). The forming C2—C1—O5 bond angle is 117°, falling outside the range of 100°–110° suggested by Burgi *et al.* (5) for this attack angle. The angle of approach of the nucleophile on the enone (i.e., the C3—C2—C1—O5 dihedral angle) is 85°, close to the ideal angle of 90°. The dihedral angle of 183° for the main chain atoms C1—C2—C3—O4 shows that the enone system is virtually planar; also the substituents of the vinyl group show that the double bond has almost no twist, as indicated by the X1—C1—C2—X2 dihedral angle of 1°.

In contrast, the TS geometry of reaction I, shown in Fig. 2a, is quite distorted from the intermolecular pathway, reflecting significant compromises in the stereoelectronic requirements outlined previously. As before, the methylene terminus is pyramidalizing, where an X1—C1—C2 angle of 106° shows that bond formation is occurring, with a slightly smaller length of 2.09 Å for the incipient C1—O5 bond. The C2—C1—O5 attack angle is in this case 107°, differing from the intermolecular case, but now agreeing with the 100°–110° range proposed by Burgi, Dunitz *et al.* (5). It is in the other aspects of the orientation that the large differences occur: the angle of approach of the nucleophile on the enone (i.e., the C3—C2—C1—O5 dihedral angle) is only 49°, far from the ideal 90° approach. Also, while the enone system is coplanar from the standpoint of the C1—C2—C3—O4 dihedral angle (181°) (note that this angle was not constrained in the calculations), the vinyl group is clearly distorted from planarity through the twisting of the methylene terminus towards the nucleophilic oxygen. The extent of this twist is shown by the X1—C1—C2—X2 dihedral angle of 18°, and is indicative of a distortion of the enone π system towards the nucleophile. Interestingly, the vinyl carbon away from the terminus is also pyramidalizing, having an X2—C2—C1 angle of 75° (this angle would be 90° with no pyramidalization)! This carbon, α to the carbonyl group, is planar in the reactant (part of the vinyl group) and in the product (as part of the resulting enolate; see the C3—C1–1-C2—H3 dihedral angle of reactant and product entries in Table 1). It is likely that this transient pyramidalization is a consequence of the transient distortion in the π system; this π distortion is not needed in either the reactant or the product.

Conclusions

The results of this study show that the additional spatial constraints of an intramolecular reaction (reaction I) can induce severe geometric distortions of the transition state from that of its intermolecular counterpart (reaction II). The corresponding energy increase can be viewed as the extra potential energy required to distort the transition state from the optimum geometry adopted by the intermolecular system, i.e., the energy cost for the compromise in the stereoelectronic requirements for

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/07/12
For personal use only.

this reaction. In this study, the potential energy of the transition state was raised from 8.5 kcal/mol above reactants (reaction II) to 14.5 kcal/mol (reaction I), a difference of 6 kcal/mol. While this increase is not trivial, neither is it prohibitive, especially in light of the fact that this potential energy difference could be offset by other contributions to the free energy of activation. Improving the level of the theoretical treatment, especially through the inclusion of correlation energy, could be expected to decrease the size of the potential energy barrier, as it has in previous studies (9, 10). The smooth additions given in Scheme 2 (refs. 2 and 3), both of which are closely related to reaction I, experimentally support the ease of such Michael additions that have significantly distorted transition states, confirming that the cost in potential energy of this distortion is not prohibitive. This study suggests that while the proposed stereoelectronic requirements for Michael-type additions are indeed reflected in the optimum pathway of the intermolecular system (reaction II), these requirements should not be viewed as prerequisite for the reaction to occur.

A theoretical study of adiabatic proton transfer to simple substituted acetylenes in their ground and excited states

PETER S. MARTIN, KEITH YATES,[1] AND IMRE G. CSIZMADIA
Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received December 8, 1988[2]

PETER S. MARTIN, KEITH YATES, and IMRE G. CSIZMADIA. Can. J. Chem. **67**, 2178 (1989).

RHF SCF 3-21G calculations are reported for the $^1\Sigma_g^+$, $^1A_1$, $^3A'$, and $^{1,3}A''$ states of simple substituted acetylenes (Y—C≡C—H, where Y = H, F, Cl, CH_3, and CF_3), the $^1A_1$, $^1A'$, and $^{1,3}A''$ states of their Markovnikov (*M*) vinyl cations (Y—C^+=CH_2), the $^1A'$ and $^{1,3}A''$ states of their anti-Markovnikov (*aM*) vinyl cations (YCH=C^+H), and the corresponding hydrated vinyl cations. Equilibrium electronic structures and the mechanism of adiabatic protonation are described qualitatively via Lewis/resonance schematic representations of the species involved. Calculated proton affinities (PA) suggest that relative to ground state Y—C≡C—H ($^1\Sigma^+/^1A_1$), Y—C≡C—H* ($^{1,3}A''$) is of greatly enhanced basicity with respect to protonation of both regiocenters. A graphical representation of the ordered pairs PA(*M*) versus PA(*aM*) as a function of substituent Y and electronic state, leads to the conclusions: (*1*) irrespective of both regiocenter (*M*/*aM*) and state ($^1\Sigma_g^+/^1A_1$, ^3A, $^{1,3}A''$) the PA's for Y—C≡C—H decrease in the order $CH_3 > H > Cl > F > CF_3$; (*2*) in proceeding from $CH_3C{\equiv}CH$ to $CF_3C{\equiv}CH$, a change in protonation regiospecificity (*M* → *aM*) is experienced to approximately the same extent for both S_0 and S_1; (*3*) T_2 exhibits no significant protonation regioselectivity. Critical comparison of the calculated results is made with available experimental data. An approximate picture of the energy profiles for the adiabatic hydrations of Y—C≡C—H via its ground, triplet and singlet states has been developed, based on the fixed points acetylene, vinyl cation and hydrated vinyl cation. Predicted relative reactivities of these three states are in excellent accord with available experimental data on rates of hydration.

Key words: excited states, proton transfer, photohydration.

PETER S. MARTIN, KEITH YATES et IMRE G. CSIZMADIA. Can. J. Chem. **67**, 2178 (1989).

On a effectué des calculs RHF-SCF 3-21G sur les états $^1\Sigma_g^+$, $^1A_1$, $^3A'$ et $^{1,3}A''$ d'acétylènes substitués simples (Y—C≡CH, dans lesquels Y = H, F, Cl, CH_3 et CF_3, sur les états $^1A_1$, $^1A'$ et $^{1,3}A''$ de leurs cations vinyles Markovnikov (*M*) (Y—C^+=CH_2), sur les états $^1A'$ et $^{1,3}A''$ de leurs cations vinyles *anti*-Markovnikov (*aM*) (YCH=C^+H) ainsi que sur les cations vinyles hydratés correspondants. On décrit qualitativement les équilibres des structures électroniques et le mécanisme de la déprotonation adiabatique en fonction de représentations schématiques de Lewis et de résonance des espèces impliquées. Les valeurs calculées pour les affinités protoniques (AP) suggèrent que, par rapport à l'état fondamental Y—C≡C—H ($^1\Sigma_g^+/^1A_1$), la basicité de l'état excité Y—C≡C—H* ($^{1,3}A''$) est fortement augmentée par rapport à la protonation à l'un ou l'autre des deux régiocentres. Une représentation graphique des AP(*M*) vs AP(*aM*) en fonction des substituants Y et des états électroniques conduit aux conclusions suivantes : (*1*) quels que soient le régiocentre (*M*/*aM*) et l'état ($^1\Sigma^+/^1A_1$, $^3A'$, $^{1,3}A''$), les AP des composés Y—C≡C—H diminuent dans l'ordre $CH_3 > H > Cl > F > CF_3$; (*2*) lorsqu'on passe de $CH_3C{\equiv}CH$ à $CF_3C{\equiv}CH$, on observe un changement dans la régiospécificité de la protonation (*M* → *aM*) qui est pratiquement le même pour les états S_0 et S_1; (*3*) l'état T_2 ne présente pratiquement pas de régiosélectivité par rapport à la protonation. On fait une comparaison critique des résultats des calculs avec les données expérimentales disponibles. En se basant sur des acétylènes, des cations vinyliques et des cations vinyliques hydratés à points fixes, on a développé une représentation approximative des profils d'énergie pour les hydratations adiabatiques des composés Y—C≡C—H par le biais de leurs états fondamentaux, triplets et singulets. Les réactivités relatives prévues pour ces trois états sont en excellent accord avec les données expérimentales sur les vitesses d'hydratation.

Mots clés : états excités, transfert du proton, photohydratation.

[Traduit par la revue]

Introduction

The photohydrations of aryl-substituted acetylenes (1), ethylenes (1), and allenes (2) have been investigated experimentally over a range of aqueous acid solutions (from pH 7 to $H_0 \approx -2$). The reactions are facile and subject to general acid catalysis (3) in most cases, with limiting quantum yields at the higher acidities in the $\Phi = 0.5$–1.0 range. In the majority of cases the reactions take place via the lowest singlet state (S_1) and are regiospecific in the Markovnikov (*M*) sense, as are the corresponding thermal reactions. The rate constants for proton transfer from H_3O^+ to S_1 have been measured for a variety of substrates and are in the 10^6–10^8 M^{-1} s^{-1} range (3), which represents a rate enhancement over the ground state (S_0) analogues of about 10^{11}–10^{14}, depending on the particular substituent and side-chain present in the aromatic system. In a few special cases, notably *m*- and *p*-nitro substituted systems, the analogous triplet state (T_1) reactions are also regiospecific, but in the anti-Markovnikov (*aM*) sense, but acid-catalysis is not observed in all of these systems. Estimates of the ground- and excited-state (S_1) basicities of the above types of substrate indicate pK shifts ($\Delta pK = pK_{S_1} - pK_{S_0}$) of at least 10 logarithmic units on electronic excitation (4), which are believed to be primarily responsible for the greatly increased photochemical versus thermal reactivity of these systems.

Previous LCAO-MO-SCF calculations (5) on acetylene itself, in its ground and low lying singlet and triplet states, have indicated that the properties of greatly enhanced basicity and reactivity are not uniquely characteristic of the aryl substituent in the systems investigated experimentally. On the basis of RHF-SCF 3-21G and 6-31G** calculations, it was predicted that the increase in proton affinity on going from $S_0(^1\Sigma_g^+)$ to $S_1(^1A_u)$ would be very large and that S_1 would be *trans*-bent and inherently zwitteronic in character, thus diminishing the need for rehybridization on proton transfer. On the other hand, the T_1 state ($^3B_2$) was predicted to be a *cis*-bent non-polar vinyl

biradical, which would be expected to undergo abstraction-recombination reactions in preference to polar additions. However, the next higher triplet state (^3A_u) also showed greatly enhanced basicity relative to $^1\Sigma_g^+$, and was also *trans*-bent and zwitterionic in character. On account of the striking analogies which were found between the experimental studies of the singlet reactions of substituted phenylacetylenes (1) and the preliminary theoretical study of acetylene itself (5), and in light of the fact that nitro-substituted phenylacetylenes *are* observed to undergo acid-catalyzed photohydration via *aM* protonation of T_1, it seemed worthwhile to extend these theoretical investigations to related systems. It was therefore decided to investigate several substituted acetylenes Y—C≡C—H (where Y = CH_3, H, CF_3, F, Cl) to determine and compare the effects of both electron-donating and -withdrawing groups on proton affinity, reactivity, and regioselectivity in the hydration reactions of the ground and low-lying excited states of these systems.

Computational details

Ab initio LCAO-MO-SCF calculations were performed utilizing the program MONSTERGAUSS,[3] in conjunction with a GOULD 32/9705 minicomputer. The split valence 3-21G (7) basis set was employed in this study. Proper spin eigenfunctions were obtained for all closed (ground) and open (excited) shell systems via Restricted Hartree-Fock (RHF) (8) theory. The geometries of the ground and low lying excited states were energy optimized by the Optimally Conditioned (OC)[4] gradient, variable metric technique. All optimizations were terminated when the gradient length, $g = [(\Sigma_i(\delta E/\delta q_i)^2/N]^{1/2}$, where q_i are the internal coordinates and the sum is over the N optimized q_i, was reduced to below 5×10^{-4} mdyn, and subject to the condition that all internal coordinate derivatives ($\delta E/\delta q_i$) were less than 1×10^{-3} mdyn. This criterion generally yields structures within 1×10^{-4} Å, or 0.01° of the true theoretical optimum values, and energies stable below the μ-Hartree level.

Ground state geometries were taken as those predicted by the Valence Shell Electron Pair Repulsion Theory (VSEPR) (10). Starting covalent bond lengths were selected from a standard geometrical model (11) based on Lewis/resonance structures of the molecule in question. Low-lying excited states of YCCH were assumed to be of valence type, arising from $\pi \rightarrow \pi^*$ excitation and possessing planar bent (C_s) structures. For $YCCH_2^+$ and $YCHCH^+$, the "π" → "*p*" valence states were constrained to C_s geometries.

Results and discussion

1. Electronic states and geometries

The 3-21G predicted structural parameters for the ground states of Y—C≡C—H (Y = F, Cl, CH_3, CF_3) are given in Table 1 and can be seen to agree quite well with their experimentally determined counterparts (12–15), with the exception of r(Cl—C), as expected (16).

In $C_{\infty v}$ (Y = F, Cl) and C_{3v} (Y = CH_3, CF_3) geometries, the ground state MO configurations are $.....(n\pi)^4(^1\Sigma^+)$ or $.....(ne)^4(^1A_1)$, which can be represented as an "*sp*—*sp*—*sp*" (F_1Cl), "sp^3—*sp*—*sp*" (CH_3) or an "$(sp)_3$—sp^3—*sp*—*sp*" (CF_3) hybridized skeleton with two mutually perpendicular π(F, Cl) or "π"(CH_3, CF_3) bonds. All Frank–Condon valence excited states arising from "π" → "π*" excitation, are derived from the configurations $.....(n\pi)^3((n+1)\pi^*)^1$ or $.....(ne)^3((n+1)e^*)^1$. These states are obtainable from the direct-product decompositions $^2\Pi \times {}^2\Pi = {}^{1,3}\Sigma^- + {}^{1,3}\Sigma^+ + {}^{1,3}\Delta$ or $^2E \times {}^2E = {}^{1,3}A_1 + {}^{1,3}A_2 + {}^{1,3}E$.

[a]See refs. 12–15.

On *cis*-planar deformation, the $n\pi$ or *ne* highest occupied MO(HOMO) splits into an in-plane "σ" and out-of-plane "π" component of symmetry species a' and a'', respectively, with orbital energies $a' > a''$. This order is reversed for *trans*-bending. Similarly, the $(n+1)\pi^*$ or $(n+1)e^*$ lowest unoccupied MO(LUMO) also separates into an in-plane "σ*" and out-of-plane "π*" MO, but in this case the energies and symmetries are such that $a'(\text{"}\sigma^*\text{"}) \ll a''(\text{"}\pi^*\text{"}) \approx (n+1)\pi^*$ or $(n+1)e^*$ for *both cis* and *trans* distortions. Thus it is predicted on the basis of Walsh's rules (17), that the strongly bent "σ*" manifold excited states $A'(a'(\text{"}\sigma\text{"}) \times a'(\text{"}\sigma^*\text{"}))$ and $A''(a''(\text{"}\pi\text{"}) \times a'(\text{"}\sigma^*\text{"}))$ are stabilized forms of the lowest lying Frank–Condon valence states, and likewise for the more weakly bent "π*" states $A''(a'(\text{"}\sigma\text{"}) \times a''(\text{"}\pi^*\text{"}))$.

The energy ordering of the various excited states is analogous to that found for HCCH itself (5), when the symmetry correlations in going from the linear Frank–Condon states to either *cis* or *trans* bent states are taken into account, namely $C_{2h}(trans\text{-}C_s) \leftrightarrow D_{\infty v}$, $(C_{3v}) \leftrightarrow C_{2v}(cis\text{-}C_s)$, as shown in Table 2. In all cases (Y = H, F, Cl, CH_3, CF_3) the lowest triplet states ($^3B_2$ or $^3A'$) are *cis*-bent, while the lowest singlets (^1A_u or $^1A''$) are *trans*-bent. It is also to be noted that the stabilization of the $^{1,3}\Delta(C_{\infty v})$ and $^{1,3}E(C_{3v})$ states by planar bending to the *cis* and *trans* bent $^3A''$ and $^1A'$ states is consistent with the Renner–Teller (19) and Jahn–Teller (20) effects, respectively.

As a consequence of the symmetry reduction associated with substitution of Y- for H-, the *cis*- and *trans*-bent forms relinquish their status as distinct electronic states to become geometrical isomers of the same nonlinear, equilibrium state, e.g. the $^1B_2$ and ^1B_u states of HCCH correlate with the *cis* and *trans* isomers of the $^1A'$ state for YCCH (Y ≠ H). Furthermore, the fact that the present methodology is limited (21) to investigation of the lowest energy state of a given symmetry

[3]The program (6*a*) incorporates the integral, SCF, and analytic energy gradient routines for both UHF and closed shell RHF from Gaussian 80 (6*b*) and automatic geometry optimization by the Optimally Conditioned (OC) method. The RHF open shell SCF is an extensively modified version of the program GSCF (6*c*). The RHF energy gradients were programmed following refs. 6*d* and *e*.

[4]Reference 9*a*. The routine is described in ref. 9*b*.

[b]$^1A'$ states not included, for reasons given in text.

type, at a particular geometry, such states are excluded from consideration given that S_0 is always of the totally symmetric representation. Fortunately this is not the case for $^3A'$ states, in that $\langle {}^1A'(S_0)|H|{}^3A'(T_1)\rangle = 0$ by virtue of orthogonal spin functions. However, because the lowest lying, valence excited states of the conjugate acid are of A'' symmetry, $^1A'$ states are unimportant as far as adiabatic protonation is concerned, and as such warrant structural discussion only.

As a result of the conformational (CX_3) and geometrical (*cis* or *trans*) isomerism associated with each of the excited states, $^3A'$, $^3A''$, and $^1A''$, there is a wealth of structural data to be examined. For practical purposes the data were categorized appropriately and subjected to statistical analysis, a synopsis of which, in terms of mean values and standard deviations, is presented next. Since ClCCH $^1A'$ is calculated to be *cis* dissociative, it was excluded from the numerical investigation.

The calculated bond lengths and angles for the $^3A'$ and $^{1,3}A''$ states are given in Table 3. It can be seen that while there is a significant difference between the states $^3A'$ and $^{1,3}A''$ with respect to r_{CC}, with the former having a shorter CC bond, all the adjacent bonds appear to be symmetry invariant. It is also interesting to note that the $^3A'$ states give the same bond lengths and angles independent of both substituent and isomerism. The same is not true for the $^{1,3}A''$ states for the bond angles ∠YCC and ∠HCC, as shown in Table 3.

Where Y = CH_3, CF_3, there is the additional complication of conformational isomerism in the C_s open shell states $^3A''$ and $^{1,3}A''$, when rotation of the CX_3C bond is taken into account. The present cases are directly analogous to CH_3C rotation in acetaldehyde (22). For a given geometrical isomer of a particular state, the *syn* and *anti* conformers are at a minimum and maximum, respectively, with the exception of *trans*-$CF_3CCH(^1A'')$ where the two are essentially equivalent in energy. However, there exists no case in the present work where the energy difference between rotamers exceeds 2 kcal/mol.

2. *Schematic representations of electronic states*

In the same manner as was accomplished (5) for the $^{1,3}A_{2u}$ and $^{1,3}B_{2u}$ states of HCCH, a schematic representation of the electronic structure for the states $^3A'$ and $^{1,3}A''$ of YCCH is now developed. For both symmetry types the doubly occupied core and framework (including the lone pairs) CMO's are of the configuration $\ldots((m-1)a')^2\ldots((n-1)a'')^2$. On the other hand, the valence CMO's are unique to each, and are given in order for A' and A'' as $(na'')^2(ma')^1((m+1)a'^*)^1$ and $(ma')^2(na''^1)(m+1)a')^1$. To formulate a qualitative LMO description that can be represented as a Lewis/resonance diagram, the appropriate linear combinations are taken amongst the $(m-1)a'$ and $(n-1)a''$ orbitals, to generate the inner shell "1*s*" core, "sp^2—*s*" C—H, "sp^2—sp^2" C—C, "*sp*—sp^2"

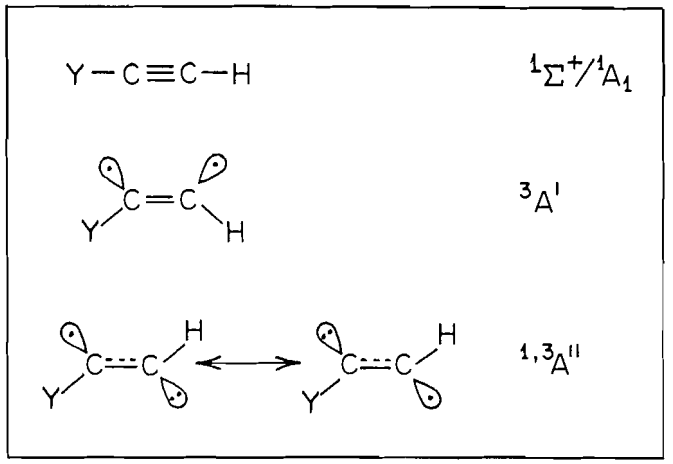

FIG. 1. Lewis/resonance structures for the $^1\Sigma^+/^1A'$ and lowest energy geometric isomers of the $^3A'$ and $^{1,3}A''$ states of YCCH (Y = F, Cl, CH_3, and CF_3).

(CX_3) or "sp—sp^2" (F, Cl) Y—C and "s—sp^3" (CH_3) or "sp–sp^3" (CF_3) X—CX_2 bonding and lone pair (F, Cl, CF_3) LMO's. The two remaining "sp^2" LMO's and the "π" bond associated with the acetylenic chromophore can be similarly obtained by suitable combination of the two valence orbitals ma' and $(m + 1)a'$ in conjunction with the na'' CMO.

The Lewis/resonance diagrams associated with the LMO description for the states $^3A'$ and $^{1,3}A''$ are shown in Fig. 1 and clearly illustrate the dissimilarity between the two types, i.e. $^3A'$ possess the LMO occupancy ...("π")^2("sp^2")^1("sp^2")^1 and can thus be regarded as a "vinyl biradical", whereas $^{1,3}A''$ is an unequal composite of the two, oppositely polarized, resonance contributors, ..."π")^1("sp^2")^2("sp^2")^1 and ...("π")^1(sp^2")^1("sp^2")^2, and is therefore zwitterionic-like. Given that (r(CC, $^{1,3}A''$)) = 1.37(2) Å is indistinguishable from the value calculated for benzene (1.38 Å) (23), with a corresponding bond order of 1.5, this suggests that the two valence "sp^2" LMO's of $^{1,3}A''$ are largely NBO's. For $^3A'$, which possesses a filled "π" orbital, this is inconsequential since the individually occupied BO and ABO would contribute nothing to the overall bond order of 2 and thus (r(CC, $^3A'$)) = 1.31(1) Å is in excellent agreement with that calculated for ethylene (1.31 Å) (23). By comparing the squared atomic orbital (AO) coefficients of the filled ma' with those of the singly occupied $(m + 1)a'$ CMO, one is able to assign the predominant resonance form for YCCH($^{1,3}A''$) as that which associates the pair of electrons with the β (unsubstituted) carbon of the acetylenic moiety when Y ≠ CF_3 and conversely with the α carbon when Y = CF_3. The "vinyl biradical" pictorial representation for YCCH($^3A'$) is also consistent with the angular geometry, (∠HCC(Y), $^3A'$) = 131°, in that VSEPR (10) would predict (∠YCC, $^3A'$) ≠ (∠HCC, $^3A'$) > 120° for the repulsion of two "sp^2" BO in the presence of one "sp^2" NBO containing a single electron. Alternatively for the zwitterionic-like YCCH ($^{1,3}A''$), where Y ≠ CF_3, one would expect (∠HCC, $^{1,3}A''$) ≠ 120°, in that the major resonance contributor requires the spatial rejection of two "sp^2" BO in the presence of one doubly occupied "sp^2" NBO on the β carbon and (∠YCC, $^{1,3}A''$) ≠ (∠YCC, $^3A'$).

The difference in bond angles between the various *cis* and *trans* states shown in Table 3 can be attributed to the steric repulsions of *cis* displaced Y and H groups, which are not present in the *trans* isomers.

Again, as a result of the structural (M/aM), geometrical (*cis/trans*) and conformational (CX_3) isomerism present in the Markownikoff, $FCCH_2^+$, $ClCCH_2^+$, $CH_3CCH_2^+$, and $CF_3CCH_2^+$ and the *anti*-Markownikoff vinyl cations, $FCHCH^+$, $ClCHCH^+$, CH_3CHCH^+, and CF_3CHCH^+, categorization and statistical evaluation of the calculated bond lengths and angles was necessary. (These are given in ref. 30 for both ground and excited states.) In the ground state, both r(CC) and r(CH) are found to be independent of substituent and isomerism. This is not true for r(Y—C), with the possible exception of r(CF_3—C), where structural isomerism is important. The fact that r(Y—C^+) < r(Y—C) for Y ≠ CF_3 is readily explained by lone pair "π" donation (Y = F, Cl) and hyperconjugation (Y = CH_3), through which the designated substituents are able to stabilize the M- in relation to the aM-vinyl cation.

In C_s geometries the M vinyl cations $YCCH_2^+$ for Y = CX_3 and all substituted aM vinyl cations $YCHCH^+$, possess the ground ($^1A'$) state configuration ...$(ma')^2$ ... $(na'')^2$, whereas the two remaining $YCCH_2^+$ of C_{2v} symmetry are of the ground ($^1A_1$) state configuration ...$(ra_1)^2$ ... $(sb_1)^2$ .. $(tb_2)^2$. Both $YCCH_2^+(S_0)$ and $YCHCH^+(S_0)$ can be described in terms of a "sp^x—sp—sp^2" and "sp^x—sp^2—sp" "σ" framework respectively, or an "$(sp)^3$—sp^3—sp—sp^2" and "$(sp)^3$—sp^3—sp^2—sp" hybridized "σ" framework for the CF_3 system with a mutually perpendicular "π" (na'' or sb_1) bond and empty "p" ($(m + 1)a'$ or $(t + 1)b_2$) orbital at the electron deficient "sp" carbon. Although the lowest lying, valence excited states originate from the configurations ...$(na'')^1((m + 1)a')^1$ or ...$(sb_1)^1((t + 1)b_2)^1$, arising from "π" → "p" excitation, because the $(m + 1)a'$ or $(t + 1)b_2$ LUMO is reduced in energy relative to the na'' or sb_1 HOMO upon YCC (M) or HCC (aM) bending, the Frank–Condon states are stabilized, as per Walsh's rules (17), by the "sp^x—sp—sp^2"/"sp^x—sp^2—sp" → "sp^x—sp^2—sp^2" (F, Cl, CH_3) or "$(sp)^3$—sp^3—sp—sp^2"/"$(sp)^3$—sp^3—sp^2—sp" → "$(sp)^3$—sp^3—sp^2—sp^2" (CF_3) rehybridization of the $YCCH_2^+$*/$YCHCH^+$* nuclear framework. For $YCCH_2^+$*, where Y = F and Cl, this results in the $C_{2v} \rightarrow C_s$ symmetry reduction.

Lewis/resonance illustrations corresponding to the LMO descriptions for the $^{1,3}A''$ states of $YCCH_2^+$ and $YCHCH^+$, comprising "sp—sp^2—sp^2" (F, Cl), "sp^3—sp^2—sp^2" (CH_3) or "$(sp)_3$—sp^3—sp^2—sp^2" (CF_3) skeletons with individually occupied "π" (a'') BO's and "sp^2" NBO's of orthogonal orientation, are shown in Fig. 2. These are in accord with the C—C bond lengths and bond angles obtained. The fact that the values of r_{FC}, r_{ClC}, and r_{CH_3C} are intermediate between their distinguishable ground state counterparts, ((Y—C^+)) (M) and ((Y—C)) (aM), is indicative of lone pair "π" donation (F, Cl) and hyperconjugation (CH_3), whereby the half-filled "π" BO is stabilized in both $YCCH_2^+$($^{1,3}A''$) and $YCHCH^+$($^{1,3}A''$). This is in contrast to the ground state, where both mechanisms act to stabilize the empty "p" orbital on the charge bearing carbon of $YCCH_2^+$ only.

With the Lewis/resonance structures in hand for YCCH ($^{1,3}A''$), $YCCH_2^+$($^{1,3}A''$), and $YCHCH^+$($^{1,3}A''$), it is possible to formulate a qualitative schematic representation for the process of adiabatic proton transfer, which for the purposes of illustration will be arbitrarily segmented into the three stages of resonance, polarization and product formation as is outlined in Scheme 1. In the so-called resonance stage, there is only the isolated *trans*-YCCH($^{1,3}A''$) molecule as described by its two unequal resonance contributors. In the second stage, the substrate is subjected to regiospecific electrophilic attack by H^+ in either of two directions, i.e. at the α (aM) or at the β (M) carbon. As the distance of approach narrows along either

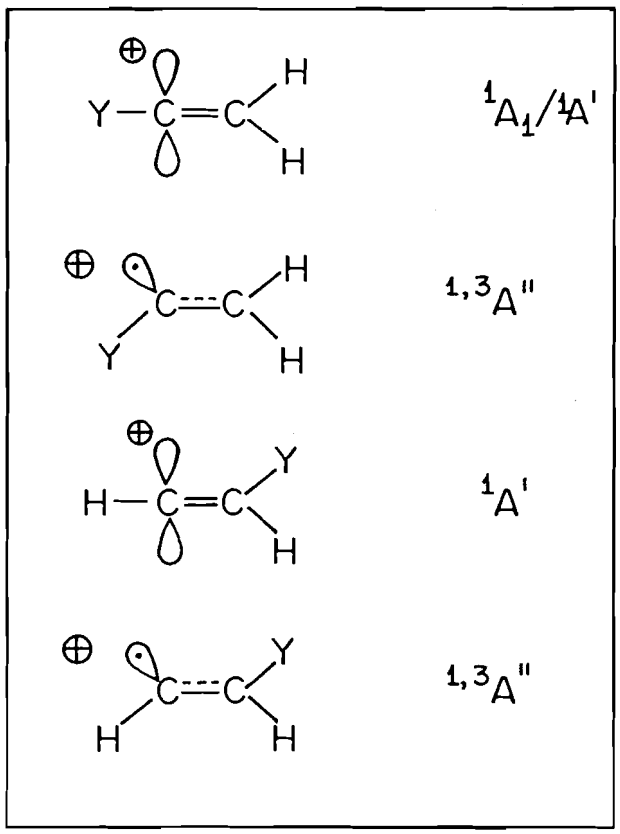

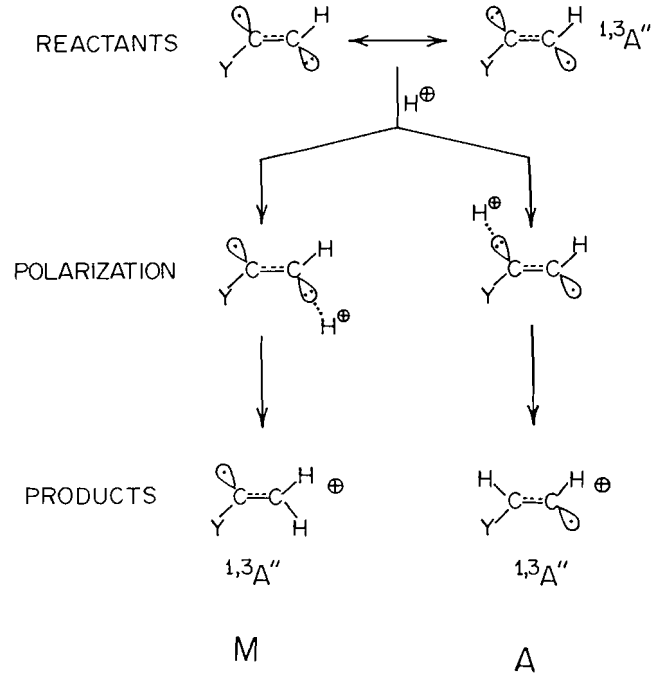

FIG. 2. Lewis/resonance structures for the $^1A_1/^1A'$ and $^{1,3}A''$ states of $YCCH_2^+$ and $YCHCH^+$ (Y = F, Cl, CH_3, and CF_3) (*trans*-$YCHCH^+$ ($^{1,3}A''$) shown only).

reaction coordinate, $YCCH(^{1,3}A'')$ is polarized by the electric field of the proton such that the resonance form corresponding to that which places the lone pair on the carbon that is the focus of attack, gradually dominates to the extent that just prior to product formation (stage 3), the contribution of the alternate form is completely eliminated. From a CMO perspective, one would say that $YCCH(^{1,3}A'')$ was polarized in such a manner as to increase the electron density at the attacked carbon by appropriately modifying the AO coefficients of the doubly occupied *ma''* orbital, e.g. attack at the β carbon would require the coefficients for AO's centered on the α carbon to diminish in magnitude relative to those for β in order that electron density be directed toward the incoming proton. On the basis of this description, one would predict that β attack for $Y \neq CF_3$ would be favored over α attack, in that the predominant *in vacuo* resonance contributor corresponds to that for which direct covalent bonding with H^+ is facilitated, and *vice versa* for cases where $Y = CF_3$.

3. Ground and excited state energies

In Figs. 3–6 the energies of the ground and excited states for YCCH ($^1\Sigma^+/^1A_1$, $^3A'$, and $^{1,3}A''$), $YCCH_2^+$ ($^1A_1/^1A''$ and $^{1,3}A''$), and $YCHCH^+$ ($^1A'$ and $^{1,3}A''$), where Y = F, Cl, CH_3, and CF_3, respectively, are plotted relative to that for YCCH ($^1\Sigma^+/^1A_1$). For illustrative convenience enumerative symbology is adopted, e.g. $S_2(t)$ denotes the *trans* isomer of the second lowest singlet state of YCCH. As a result of the small energy differences (<2 kcal/mol) between the conformational isomers of CX_3CCH ($^3A'$, $^{1,3}A''$), $CX_3CCH_2^+$ ($^{1,3}A''$), and CX_3CHCH^+ ($^1A'$, $^{1,3}A''$), and even between the geometrical isomers of $CX_3CCH_2^+$ ($^{1,3}A''$) and CX_3CHCH^+ (^1A, $^{1,3}A''$), only the most stable forms are displayed graphically.

SCHEME 1. Qualitative schematic representation for the process *trans*-YCCH ($^{1,3}A''$) + $H^+ \rightarrow YCCH_2^+$ ($^{1,3}A''$)/*trans*-$YCHCH^+$ ($^{1,3}A''$).

From Figs. 3–6, it is immediately obvious that the excited states of both $YCCH_2^+$ are red shifted relative to those of YCCH and therefore the YCCH* is of enhanced basicity with respect to both *M* and *aM* protonation. Careful examination also reveals that (*1*) similar energy differences exist between geometric isomers for the pairs FCCH ($^3A'$, $^{1,3}A''$)/ClCCH ($^3A'$, $^{1,3}A''$) and CH_3CCH ($^3A'$, $^{1,3}A''$)/CF_3CCH ($^3A'$, $^{1,3}A''$), and (*2*) the energy differences, $\Delta E = E_{SCF}(YCHCH^+{}^*) - E_{SCF}(YCCH_2^+{}^*)$, are such that for all Y, $|\Delta E(HS_0^+)| > |\Delta E(HS_1^+)| \gg |\Delta E(HT_1^+)|$. Evaluation of the following expressions for proton transfer:

$$PA(M) \simeq E_{SCF}(YCCH^*) - E_{SCF}(YCCH_2^+{}^*)$$

$$PA(aM) \simeq E_{SCF}(YCCH^*) - E_{SCF}(YCHCH^+{}^*)$$

generates the ordered pairs PA(*M*) and PA(*aM*), which are plotted against each other for all Y (including H) in Fig. 7. It must be emphasized that these proton affinity values in every case involve adiabatic proton transfer between the directly correlating states shown below.

$$S_0(^1\Sigma^+, {}^1A_1) \rightarrow HS_0^+(M)(^1A_1, {}^1A')$$

$$S_0(^1\Sigma^+, {}^1A_1) \rightarrow HS_0^+(aM)(^1A')$$

$$T_2(^3A'') \rightarrow HT_1^+(M)(^3A'')$$

$$T_2(^3A'') \rightarrow HT_1^+(aM)(^3A'')$$

$$S_1(^1A'') \rightarrow HS_1^+(M)(^1A'')$$

$$S_1(^1A'') \rightarrow HS_1^+(aM)(^1A'')$$

The solid line in Fig. 7 is of unit slope, and gives the demarcation between *M* (points above) and *aM* (points below) preference. Examination of the different sets of points in Fig. 7 (for S_0, T_2, and S_1) enables one to conclude the following: (*1*) with minor exceptions to be noted subsequently, irrespective of both regiocenter (*M*/*aM*) and state ($S_0/T_2/S_1$), the PA's for YCCH decrease with respect to Y, including H, in the order $CH_3 > H > Cl > F > CF_3$; (*2*) in proceeding from CH_3CCH

through CF_3CCH, a change in protonation regiospecificity ($M \rightarrow aM$) is experienced to approximately the same extent for both YCCH(S_0) and YCCH(S_1); (*3*) regardless of Y, YCCH(T_2) exhibits no significant protonation regioselectivity. Note that to within 1 kcal/mol, PA($ClCCH(S_0)$) ≃ PA($HCCH(S_0)$), PA($CF_3CCH(S_0)(aM)$ ≃ PA($FCCH(S_1)(aM)$) which represent minor exceptions to (1) above.

4. Comparisons with experimental results

Unfortunately, there are available only two experimentally determined PA's with which exact comparison can be made. Gas phase spectroscopic measurements have established PA($FCCH(S_0)(M)$) = 161 kcal/mol (24) and PA($CH_3CCH(S_0)(M)$) = 182 kcal/mol (25), which the present RHF—SCF calculations overestimate by only 1 and 2 kcal/mol, respectively, including correction for differential zero-point energy, due mainly to the two (F) and three (CH_3) extra degrees of vibrational freedom present in the vinyl cation, and finite temperature.

Although excited state basicity enhancement has been shown (26) for cyclodecyne and di-*n*-butylacetylene, which undergo sensitized photochemical addition of acetic acid to produce enol acetates under conditions that these compounds are thermally inert, no evidence yet exists in cases where the aliphatic alkyne is asymmetrically substituted and for which there is the possibility of regiospecific protonation. However, as previously indicated, facile acid catalysed photohydration has been demonstrated for substituted phenylacetylenes (1, 3) and although direct comparison with the theoretical predictions of this study

FIG. 5. FIG. 7. Correlation diagram of proton affinities (PA) for YCCH (Y = H, F, Cl, CH_3, and CF_3) in $S_0(^1\Sigma^+/^1A_1)$, $T_2(^3A'')$ and $S_1(^1A'')$, resulting in Markownikoff (*M*) and anti-Markownikoff (*aM*) protonation products, i.e. $YCCH_2^+(^1A_1/^1A', ^{1,3}A'')$ and $YCHCH^+(^1A', ^{1,3}A'')$ respectively. $PA(HCCH(^3A_u)) \neq PA(HCCH(^1A_u))$, taken from ref. 3.

is not strictly valid because of the conjugating aromatic ring, some interesting analogies can be drawn:

(*1*) For non-nitro substituted phenylacetylenes, the increase in photohydration efficiency and concurrent fluorescence quenching with decreasing pH indicates that the reaction proceeds via rate limiting *M* protonation of a zwitterionic-like S_1, which is approximately 10^{11}–10^{14} times more reactive than S_0. On the basis of the present calculations for simple aliphatic alkynes without strong electron withdrawing substituents (i.e. Y ≠ CF_3), S_1, in contrast to S_0, is predicted to be strongly polarized such that electron density is displaced toward the terminal (β) carbon. Also, with the exception of Y = CF_3, the present calculations give $PA(YCCH(S_1)(M)) > PA(YCCH(S_1)(aM))$ by approximately 10 kcal/mol, which is consistent with the completely regiospecific *M* protonation observed experimentally for phenylacetylenes substituted by H or electron-donating groups.

(*2*) Plots of fluorescence quenching versus pH are sigmoid with inflection points around pH = 0 (1), which suggests that S_1 of substituted phenylacetylenes is of greatly enhanced basicity compared to S_0. Assuming that phenylacetylenes are weaker bases than benzonitriles (27) in their S_0 states, this implies that $\Delta pK = pK(S_1) - pK(S_0) > 10$ (4). The present calculations support this qualitatively in that $\Delta PA = PA(S_1) - PA(S_0)$ is very large in every case calculated.

(*3*) Although triplet sensitization failed to produce photohydration products (acetophenones) in the above cases, T_1 was not found to be photochemically unreactive, but led to a multiplicity of products including polymer. From the present investigation it is predicted that for simple alkynes T_1 would be a non-polar "vinyl biradical", thereby facilitating abstraction–recombination reactions.

(*4*) For nitro-substituted phenylacetylenes, which are believed to react via T_1 on direct irradiation, the complete *aM* addition of water to give phenylacetaldehydes, the observed acid-catalysis, and the complete quenching of reaction by di-*t*-butyl nitroxide all suggest the mechanistic involvement of a reverse polarized, zwitterionic-like T_1 state. According to the present study, T_2 of the closest analogue, CF_3CCH, *is* of the appropriate polarization and enhanced basicity, but based on the PA values for *M* and *aM* protonation, it is predicted to react non-regiospecifically. It is, however, well-known that NO_2 is more electron-withdrawing than CF_3 in ground state molecules, and this difference is probably enhanced in their excited states (28). However, until calculations on nitroacetylene can be performed, no clear prediction can be made.

5. *Reactivity comparisons*

In addition to the calculations of PA values for the various excited states of YCCH, it was of interest to make estimates of the energies of proton transfer (E_{PT}) and hydration (E_H) based on the gas phase reactions:

$$YC{\equiv}CH + H_3O^+ \rightarrow YC^+{=}CH_2 \text{ (or } YCH{=}{}^+CH) + H_2O$$

$$Y^+C{=}CH_2 + H_2O \rightarrow YC(^+OH_2){=}CH_2$$

$$\text{(or } YCH{=}{}^+CH + H_2O \rightarrow YCH{=}CHO^+H_2)$$

where Y = H, CH_3, or CF_3. For these reactions,

$$E_{PT} \simeq E_{SCF}(H_2O) + E_{SCF}(BH^+) - E_{SCF}(H_3O^+) - E_{SCF}(B)$$

$$E_H \simeq E_{SCF}(BH(O^+H_2)) - E_{SCF}(H_2O) - E_{SCF}(BH^+)$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/07/12
For personal use only.

where B, BH^+, and $BH(O^+H_2)$ refer to the acetylene, vinyl cation (*M* or *aM*), and hydrated vinyl cation (*M* or *aM*), respectively. The necessary values for acetylene itself have been reported previously (29), and those for CH_3CCH and CF_3CCH are given in ref. 30. Calculations (at the 3-21G level) were carried out for S_0, T_1, T_2, and S_1 of the acetylene, and for S_0, T_1, S_1, of the vinyl cation and hydrated vinyl cation. The reason for including T_2 for the starting acetylene is that in considering the energetics of reaction, strictly speaking only those processes occurring between directly correlating states should be considered, as illustrated below for acetylene.

$$B + H_3O^+ \rightarrow BH^+ + H_2O \rightarrow BH(O^+H_2)$$

$$S_0D_{\infty h}(^1\Sigma_g^+) \rightarrow SC_{2v}(^1A_1) \rightarrow S_0C_s(^1A_1)$$

$$T_2C_{2h}(^3A_u) \rightarrow T_1C_s(^3A'') \rightarrow T_1C_s(^3A'')$$

$$S_1C_{2h}(^1A_u) \rightarrow S_1C_s(^1A'') \rightarrow S_1C_s(^1A'')$$

This means that gas phase proton transfer to triplet states can involve states higher than T_1, although the cations and hydrated cations produced are in their lowest triplet states in every case. The changes in E_{SCF} on protonation, followed by hydration, are shown graphically for acetylene to form a reaction coordinate diagram in Fig. 8. Although this is obviously skeletal in that it is based on only the three fixed points for which RHF-SCF calculations were possible, it is nonetheless reasonable to draw several conclusions about the photochemical versus thermal reactivity of the acetylene system. Firstly it is immediately obvious that electronic excitation greatly decreases the energy of proton transfer, whichever excited state is involved. This has been discussed in a previous section. Secondly, the hydration of the vinyl cation intermediate is strongly exothermic in every case. This implies that whether the hydration step is adiabatic or not, the rate-determining step would be proton transfer. This is fully consistent with the observed general acid catalysis for the S_1 reactions of substituted phenylacetylenes, and not inconsistent with the hydronium ion catalysis observed for the T_1 reactions of nitro-substituted analogues. In the latter cases, general acid catalysis has not yet been demonstrated experimentally, although it seems likely that these behave in a way similar to the S_1 reactions. Finally, although calculation of a complete reaction profile is not feasible at present, it seems clear from the degree of endo- or exothermicity of the first step, that S_0 will be relatively unreactive, since this step is a distinctly uphill process. Similarly it is implied that S_1 will be more reactive than either T_1 or T_2, but that any of these excited state reactions will be much faster than the thermal hydration. From what is known experimentally of the H_3O^+-catalyzed rates of substituted phenylacetylenes in their ground, triplet and singlet states, the predicted behavior of this simple model system is in excellent accord, in a *relative* reactivity sense. For example, typical thermal hydrations of acetylenes have values of $k_{H_3O^+}$ in the 10^{-5}–10^{-7} M^{-1} s^{-1} range (31), whereas analogous singlet state reactions have $k_{H_3O^+}$ in the 10^6–10^8 M^{-1} s^{-1} range (1, 3). Although the rates for corresponding triplet states are less well established, recent estimates[5] place these in the 10^4–10^5 M^{-1} s^{-1} range. Assuming a diffusion-controlled limit of 10^{10} for hydrations in aqueous solution, the above rate ranges correspond to $\Delta G^{\ddagger}$ values of 21–23 kcal, 7–8 kcal and 3–5 kcal for the ground, triplet, and singlet reactions, respectively. However, it must be emphasized that solvation energies will lower the energies of the cationic intermediates considerably compared to those involved in any calculated gas phase processes. Therefore although the above $\Delta G^{\ddagger}$ values are generally consistent with the relative reactivities implied in Fig. 8, the possible impact of solvent effects on the present conclusions cannot be overlooked.

[5]These estimates are based on slopes of Stern–Volmer plots of product quantum yield versus $[H_3O^+]$ (32).

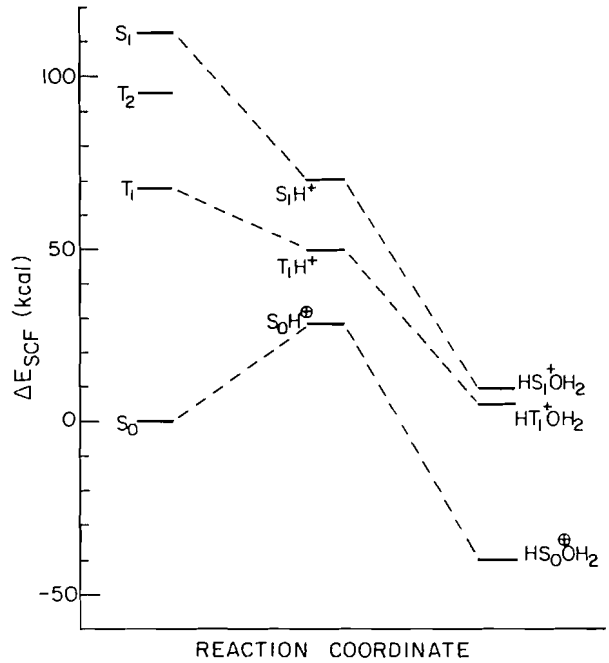

FIG. 8. Reaction coordinate diagram for adiabatic hydration of acetylene.

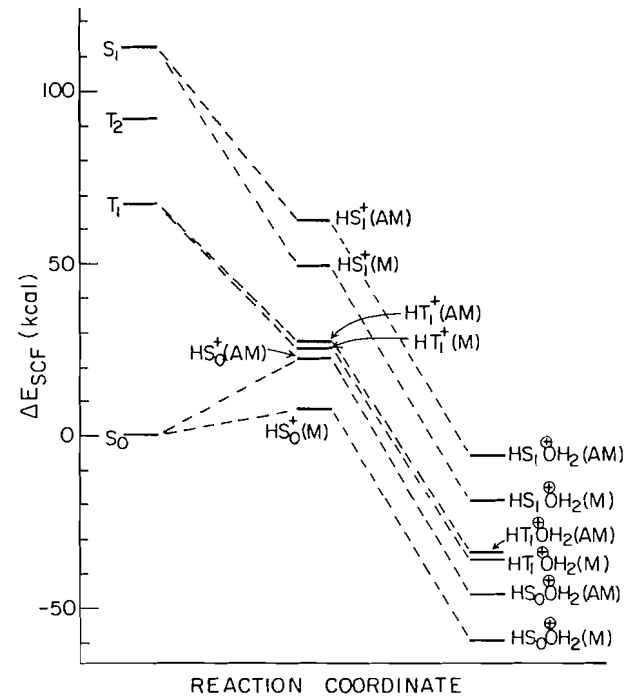

FIG. 9. Reaction coordinate diagram for adiabatic hydration of methylacetylene (*M* = Markownikov, *aM* = anti-Markownikov).

Corresponding reaction profiles for the hydration of CH_3CCH and CF_3CCH in their ground and low lying excited states are shown in Figs. 9 and 10, where both *M* and *aM* processes are included. The main difference for the methyl derivative (Fig. 9)

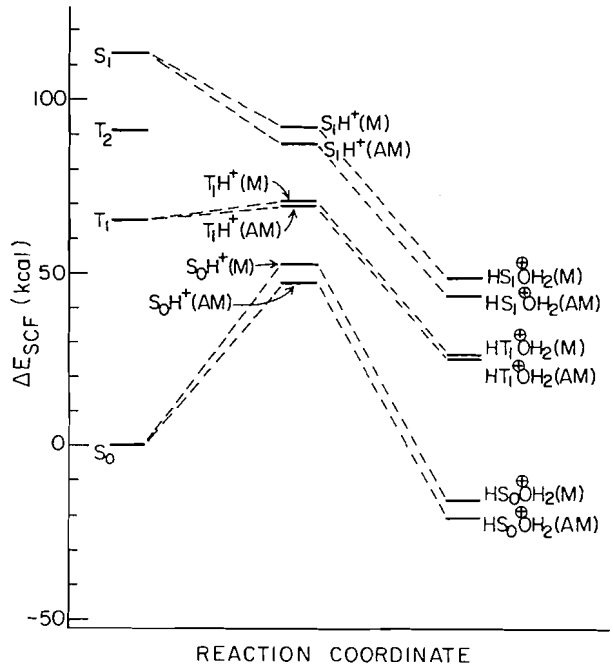

FIG. 10. Reaction coordinate diagram for adiabatic hydration of trifluoromethylacetylene. (M = Markownikov, aM = anti-Markownikov).

is that all the energies of proton transfer are lowered, compared to that of acetylene, although the relative reactivities of the singlet, triplet and ground states are maintained. In addition, the M mode of hydration is clearly favored for S_1 and S_0, as discussed previously, while the triplet (T_1 or T_2) shows no strong regioselectivity. For the trifluoromethyl derivative (Fig. 10), all the energies of proton transfer are raised, relative to that of acetylene, but again the relative singlet, triplet, and ground state reactivities are not materially affected. In this case, however, aM hydration is preferred for S_1 and S_0 (although to a less extent), but the triplet again shows no significant regioselectivity. In every case (Y = CH_3 or CF_3, M or aM) the hydration step is again strongly exothermic, supporting the idea that in both ground and excited state hydrations, proton transfer would be the rate-determining step.

The changes in E_{PT} on CH_3- or CF_3-substitution are in accord with reported Hammett-type relationship for substituted phenylacetylenes, where the ρ value is large and negative for both the thermal (33) and photochemical (singlet only) hydration.[6]

Conclusion

It is concluded that overall, the agreement between the predicted behavior of these simple model acetylene systems, with substituents of different types, is in very good accord with what is known experimentally about the photochemical versus thermal reactions of analogous systems. This is particularly true for the calculated basicity and reactivity enhancements on electronic excitation. As far as observed regioselectivity is concerned (in both thermal and photochemical hydrations), the calculations are in accord with experiment only for S_0 and S_1 reactions of systems with electron-donating substituents. For analogous triplet reactions, the predicted lack of regioselectivity remains to be tested experimentally via triplet sensitization experiments on CF_3 substituted systems, which are currently in progress. It also remains to be seen whether eventual calculations on nitro-containing systems will lead to a predicted reversal of regioselectivity ($M \rightarrow aM$), even for triplet states, as observed experimentally.

Finally, it is worth pointing out that although the present calculations on YCCH systems were carried out only at the 3-21G level for practical reasons, the previously reported investigation of HCCH itself (5) was carried out at the STO-3G, 3-21G, and 6-31**G levels. It was found that none of the general conclusions with respect to geometries, excited state isomerism, state energy ordering, proton affinities, and energies of hydration were materially affected by increasing the size of basis set or by inclusion of polarization functions. The general correspondence between the present calculated results and conclusions based on YCCH systems, with those on the parent system should help to allay possible concerns based on the size of basis set used in the present work.

[6]Although the ρ value for photohydration of phenylacetylenes has not been measured directly, a plot of log k_H^+ versus log k_H^+ for styrene photohydration has a slope of ~0.6 (34). Since ρ for styrenes (1) is −5.6, this indicates a ρ value for phenylacetylenes of approximately −3.4 versus ground state σ values.

A theoretical study of adiabatic proton transfer to simple substituted allenes in their ground and excited states

PETER S. MARTIN, KEITH YATES,[1] AND IMRE G. CSIZMADIA
Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received December 6, 1988[2]

PETER S. MARTIN, KEITH YATES, and IMRE G. CSIZMADIA. Can. J. Chem. **67**, 2188 (1989).

RHF-SCF 3-21G calculations are reported for the $^1A'$, $^{1,3}A''$, $^12A'$, and $^{1,3}2A''$ states of simple substituted allenes $YCHCCH_2$, where Y = CH_3, H, F, Cl, CF_3, and the $^1A'$ and $^{1,3}A''$ states of their Markovnikov (*M*) and anti-Markovnikov (*aM*) cations, $CHYCHCH_2^+$ and $CHYCCH_3^+$, respectively. Equilibrium electronic structures and the mechanism of adiabatic protonation are described qualitatively in terms of Lewis/resonance schematic representations. Calculated proton affinities (PA) suggest that relative to the ground state ($^1A'$), the excited states $^{1,3}2A''$ are of greatly enhanced basicity with respect to protonation at either regiocenter. A graphical representation of PA(*M*) versus PA(*aM*) leads to the following conclusions: (*1*) irrespective of both regiocenter (*M*/*aM*) and state ($^1A'/^32A''/^12A''$), the PA's for $YCHCCH_2$ decrease with respect to Y in the order $CH_3 > H > Cl > CF_3$; (*2*) the F-substituent gives a PA value greater than that for H- in the ground state, but less than that for H- in the two excited states; (*3*) for all substituents Y, including CF_3, protonation of both $^1A'$ and $^12A''$ is predicted to be regioselective in the *M* direction; (*4*) regardless of Y, $^32A''$ exhibits no significant protonation regioselectivity. Critical comparison of these theoretical predictions is made with available experimental evidence.

Key words: proton transfer, excited states, photohydration, allenes.

PETER S. MARTIN, KEITH YATES et IMRE G. CSIZMADIA. Can. J. Chem. **67**, 2188 (1989).

On a effectué des calculs RHF-SCF 3-21G sur les états $^1A'$, $^{1,3}A''$, $^12A'$ et $^{1,3}2A''$ des allènes substitués simples $YCHCCH_2$, dans lesquels Y = CH_3, H, F, Cl et CF_3, ainsi que sur les états $^1A'$ et $^{1,3}A''$ de leurs cations Markovnikov (*M*) et anti-Markovnikov (*aM*), respectivement $CHYCHCH_2^+$ et $CHYCCH_3^+$. On décrit qualitativement les équilibres des structures électroniques et le mécanisme de la déprotonation adiabatique en fonction de représentations schématiques de Lewis et de résonance. Les valeurs calculées pour les affinités protoniques (AP) suggèrent que, par rapport à l'état fondamental ($^1A'$), la basicité des états excités $^{1,3}2A''$ est fortement augmentée par rapport à la protonation à l'un ou l'autre des deux régiocentres. Une représentation graphique des AP(*M*) vs. AP(*aM*) conduit aux conclusions suivantes : (*1*) quels que soient le régiocentre (*M*/*aM*) et l'état ($^1A'/^32A''/^12A''$), les AP des composés $YCHCCH_2$ diminuent par rapport à Y dans l'ordre $CH_3 > H > Cl > CF_3$; (*2*) dans l'état fondamental, le produit substitué par un F possède une AP plus grande que celle du produit substitué par un H; toutefois, dans les deux états excités, l'ordre est l'inverse; (*3*) pour tous les substituants, y compris le CF_3, il est prédit que la protonation des états $^1A'$ et $^12A''$ sera régiosélective dans la direction *M*; (*4*) quelle que soit la nature de Y, l'état $^32A''$ ne présente pas de régiosélectivité importante pour la protonation. On fait des comparaisons critiques de ces prédictions théoriques avec les données expérimentales disponibles.

Mots clés : transfert du proton, états excités, photohydratation, allènes.

[Traduit par la revue]

Introduction

The often dramatic changes in the acidity or basicity of organic molecules on electronic excitation can be simply rationalized in terms of the Forster equation (1) $\Delta pK = pK^*_{BH^+} - pK_{BH^+} = Nh(\nu_B - \nu_BH^+)/2.3RT$ from which it follows that if the transition $BH^+ \rightarrow BH^{+*}$ is red-shifted relative to $B \rightarrow B^*$ (i.e. $\nu_B > \nu_{BH^+}$) then B* must be a stronger base than B (i.e. $pK^*_{BH^+} > pK_{BH^+}$), and vice-versa for a blue-shifted transition. However for gas-phase molecules, the proton affinity (PA), defined to be $-\Delta H_{298}$ for the reaction $B + H^+ \rightarrow BH^+$, is used as a measure of intrinsic basicity. LCAO-MO-SCF calculations provide the estimate $PA(B) \approx E_{SCF}(B) - E_{SCF}(BH^+)$, rather than the p*K* definition usually employed in the measurement of basicities in solution.

From experimental work on the photohydration of phenylallenes (2) to give cinnamyl alcohols efficiently, even in dilute aqueous solution, it was concluded that reaction proceeds via rate-limiting Markovnikov[3] protonation of a polarized S_1 state, which is of greatly enhanced basicity relative to S_0. On the basis of RHF-SCF 3-21G calculations on allene itself (3), it was predicted that $\Delta PA(S_1(M)) > \Delta PA(S_1(aM)) \gg 0$ where $\Delta PA = PA(S_1) - PA(S_0)$, and that S_1 is *trans* bent and zwitterionic-like, thus diminishing the need for rehybridization on proton transfer, and thereby facilitating photohydration. However, it was found experimentally (2) that, nitro-substituted phenylallenes, which intersystem cross efficiently to the T_1

[2]Revision received July 6, 1989.

[3]Strictly speaking, the Markovnikov/anti-Markovnikov terminology is not applicable to the regioisomeric cations which can be formed by adding an electrophile such as H^+ to a substituted allene. However, it has been adopted here by analogy with the addition of H^+ to the β-carbon of a substituted acetylene or ethylene, to give the expected more stable (Markovnikov) cationic intermediate. In the case of a substituted allene $YCHCCH_2$, analogous β-protonation would lead to the more stable allylic cation YCH^+CHCH_2 (Markovnikov). This terminology allows more direct comparison with related studies of the protonation of YCCH systems (3).

state, gave only nitrophenylacetones as photoproduct, indicating anti-Markovnikov (3) protonation as the rate-limiting step.

It was therefore decided to extend the calculations on allene, to investigate the intrinsic basicity of some simple substituted model compounds ($CHYCCH_2$, where Y = F, Cl, CH_3, and CF_3) as a function of both protonation regiocenter and electronic state.

Computational details

Ab initio LCAO-MO-SCF calculations were performed utilizing the program MONSTERGAUSS[4] in conjunction with a GOULD 32/9705 minicomputer. The split valence 3-21G (6) constitutes the basis set employed in this study. Proper spin eigenfunctions were obtained for all closed (ground) and open (excited) shell systems via Restricted Hartree-Fock (RHF) (7) theory. The geometries of the ground and low-lying excited states were energy optimized by the Optimally Conditioned (OC)[5] gradient, variable metric technique. All optimizations were terminated when the gradient length, $|g| = [\Sigma_i\{\delta E/\delta q_i\}^2/N]^{1/2}$, where q_i are the internal coordinates and the sum is over the N optimized q_i, was reduced to below 5×10^{-4} mdyn, and subject to the condition that all internal coordinate derivatives $[\delta E/\delta q_i]$ were less than 1×10^{-3} mdyn. This criterion generally yields structures within 1×10^{-4} Å, or 0.01° of the true theoretical optimum values and energies stable below the μ-Hartree level.

Ground state geometries were taken as those predicted by the Valence Shell Electron Pair Repulsion Theory (VSEPR) (9). Starting covalent bond lengths were selected from a standard geometrical model (10) based on Lewis/resonance structures of the molecule in question. Low-lying excited states of $CHYCCH_2$ and $CHYCHCH_2^+$ were assumed to be of valence type, arising from $\Pi \rightarrow \Pi^*$ excitation and possessing planar bent (C_s) structures. Similarly for $CHYCCH_3^+$, the "Π"→"*P*" valence states were constrained to C_s symmetry.

Results and discussion

Electronic states and geometries

The 3-21G predicted geometrical parameters for the ground states of YCH=C=CH_2 are in reasonable agreement with their experimental (11–13) counterparts, as shown in Table 1, with the exception of $r(ClC_\alpha)$ as expected (14).

In C_s geometries the ground state ($^1A'$) MO configurations are $...(ma')^2...(na'')^2$. These can be represented by an "sp—sp^2—sp—sp^2" (F, Cl), "sp^3—sp^2—sp—sp^2" (CH_3), or "$(sp^3)_3$—sp^3—sp^2—sp—sp^2" (CF_3) hybridized "σ" skeleton with two mutually perpendicular "π" bonds. The Frank–Condon valence excited states, arising from "π"→"π*" excitation, are derived from the configuration $...(ma')^2(na'')^1((m+1)a')^1$. Because the "π" MO lies in the "σ" plane it is of a' symmetry, and these states are obtainable from the direct product decomposition $^2A'' \times {}^2A' = {}^{1,3}A''$. The molecules are able to achieve the greatest degree of stabilization via bending and twisting about the CCC axis to achieve the planar structure of MO configuration $...(na'')^3((n-1)a'')^1(ma')^1$, which comprises the electronic structure of the equilibrated T_1 and S_1 states.

In the same manner as was accomplished (3) for the parent $CH_2CCH_2(^{1,3}A_2)$, it is possible to develop a qualitative LMO description of $CHYCCH_2(^{1,3}A'')$. Taking the appropriate linear combination among the doubly occupied $(m-1)a'$ and $(n-1)a''$ core and framework CMO's allows for generation of the inner shell "1s" core, two "sp^2—sp^2" C—C, three "sp^2—s" C—H, "sp—sp^2" (F, Cl) or "sp^3—sp^2" (CX_3) Y—C and "s—sp^3" (CH_3) or "sp—sp^3" (CF_3) CX_2—X bonding and lone pair (F, Cl, and CF_3) LMO's. The remaining "sp^2" LMO on the central C atom and the "π" system is obtained from the valence ma' together with the na'' and $(n+1)a''$ CMO's. From the Lewis/resonance diagrammatic representation of the LMO description for $CHYCCH_2(^{1,3}A'')$, as given in Fig. 1, it is apparent that these states are biradical-like as a result of the LMO occupancy $...(\text{"}1\pi\text{"})^2(\text{"}sp^2\text{"})^1(\text{"}2\pi\text{"})^1$. Unfortunately, "π" radicals of this type are plagued by an instability (15) characterized by the tendency of RHF-SCF wavefunctions to localize the odd electron and the "π" bond at opposite ends of the three-center, two-electron "π" system. This results from their inability to describe adequately the electrostatic repulsion between the single electron in the NBO and the one of opposite spin in the "π" BO. In other words, because the single configuration RHF wavefunction is unable to describe the two valence bond contributors simultaneously by converging on an intermediate geometry, inappropriate to both, there is incorrect geometry prediction in these cases (16). Since $CHYCCH_2(^{1,3}A'')$ are not amenable to proper structure analysis and are unimportant insofar as adiabatic protonation is concerned, they do not warrant further consideration.

Stabilization of $^{1,3}A''$ Frank–Condon states involving less drastic electronic reorganization is achieved via simple planar deformation, as per Walsh's predictions (17), in that the $(m+1)a'$ LUMO is reduced in energy relative to the na'' HOMO upon CCC bending. Taking the $(m-1)a''$ and $(n-1)a''$ core and framework CMO's in suitable combination, permits the formation of the inner shell "1s" core, "sp^2—sp^2" and "sp^2—sp^3" C—C, "sp^2—s" and two "sp^3—s" C—H, "sp—sp^2" (F, Cl) or "sp^3—sp^2" (CX_3) Y—C and "s—sp^3" (CH_3) or "sp—sp^3" (CF_3) CX_2—X bonding and lone pair (F, Cl, and CF_3) LMO's. The two still unaccounted for LMO's, namely the "sp^2" of the central (β) and "sp^3" of the terminal (δ) C atom, and the "σ" bond can be generated by the appropriate

[4]Reference 4*a*. The program incorporates the integral, SCF and analytic energy gradient routines for both UHF and closed shell RHF from GAUSSIAN 80 (4*b*), in addition to automatic geometry optimization by the Optimally Conditioned (OC) method (ref. 8). The RHF open shell SCF is an extensively modified version of the program (4*c*). The RHF energy gradients were programmed following ref. 5.

[5]Reference 8*a*. The routine is described in ref. 8*b*.

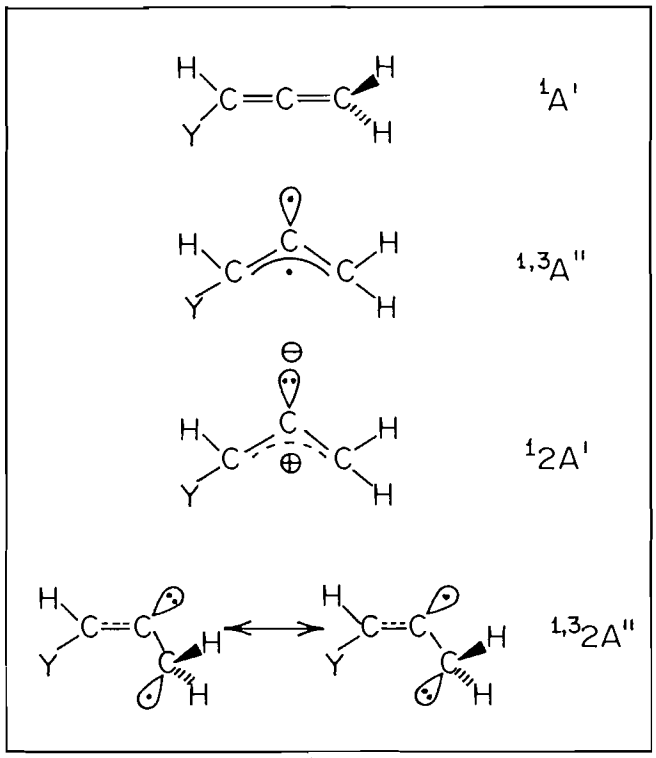

FIG. 1. Lewis/resonance structures for the $^1A'$ and *cis* isomers of the $^{1,3}A''$, $^12A'$, and $^{1,3}2A''$ states of $CHYCCH_2$.

combination of the valence ma' and $(m + 1)a'$ CMO's in association with the na'' orbital. In LMO terms then, $CHYCCH_2(^{1,3}2A'')$ are represented by an admixture of the two, oppositely polarized, resonance contributors $\ldots(\text{“}\pi\text{”})^1(\text{“}sp^2\text{”})^2(\text{“}sp^3\text{”})^1$ and $\ldots(\text{“}\pi\text{”})^1(\text{“}sp^2\text{”})^1(\text{“}sp^3\text{”})^2$, and are thus zwitterionic-like states. The Lewis/resonance structures corresponding to the LMO descriptions for $CHYCCH_2(^{1,3}2A'')$ are given in Fig. 1, where the broken line is indicative of a one-electron, two-center "π" bond.

Full details of the calculated excited state geometrics are given in ref. 18, with selected illustrative values being presented in Table 2 for the $^{1,3}2A''$ states. For these states, the $C_\alpha C_\beta$ and $C_\beta C_\gamma$ bonds appear to be essentially independent of both substituent and isomerism, and statistically indistinguishable. Also, the adjacent bonds are isomer invariant, although they obviously vary with substitution. Similarly, the angular geometry (∠CCC) and dihedral angle (∠HCC) fail to discriminate on the basis of both substitution and isomerism.

The value for $r(C_\alpha C_\beta)$, as indicated by the squared AO coefficients of the na'' CMO, is consistent with an asymmetric "π" bond in which the density of the individual electron is skewed toward the "sp^2" α-C atom, thereby lengthening the bond relative to that of benzene (r(CC) = 1.38 Å) (19) and decreasing the bond order below 1.5. On the other hand $r(C_\beta C_\gamma)$ is considerably shorter than a typical single bond, e.g. for propene r(CC) = 1.51 Å (19), and is suggestive of hyperconjugation, whereby the half filled "π"(na'') MO is stabilized via the a'' CMO of the δ "sp^3" CH_2 group. The fact that the squared AO coefficients of the doubly occupied ma' and single electron containing $(m + 1)a'$ CMO localize the electron density on the "sp^2" C(ma') and the "sp^3" γ-C ($(m + 1)a'$), indicates that the "sp^2" and "sp^3" valence LMO's are largely NBO's. Moreover, in light of the fact that $\langle\angle CCC^{1,3}2A''\rangle$ is consistent with VSEPR (9) expectations for the spatial arrangement of two "sp^2" BO in the presence of a filled "sp^2" NBO, it thus appears reasonable to represent $CHYCCH_2(^{1,3}2A'')$ mainly by the resonance contributor that associates the electron pair with the β-C atom, i.e. $\ldots(\text{“}\pi\text{”})^1(\text{“}sp^2\text{”})^2(\text{“}sp^3\text{”})^1$ rather than a composite of $\ldots(\text{“}\pi\text{”})^1(\text{“}sp^2\text{”})^2(\text{“}sp^3\text{”})^1$ and $\ldots(\text{“}\pi\text{”})^1(\text{“}sp^2\text{”})^1(\text{“}sp^3\text{”})^2$. Note that the "$sp^2$" pair and the single "$sp^3$" electron are *trans* displaced as a result of the ±110° dihedral angle that the two "sp^3" H atoms make on average with the "sp^2" α-C, i.e. inversion about the γ-C atom appears to be controlled by a single minimum potential.

TABLE 2. Calculated $^{1,3}2A''$ excited state[a] geometries for $YCH{=}C{=}CH_2$

Bond lengths (Å)		
	$r(C_\alpha C_\beta) = 1.43$ $r(C_\beta C_\gamma) = 1.45$	Y = F, Cl, CH_3, CF_3
	$r_{FC} = 1.35$	
	$r_{ClC} = 1.83$	
	$r_{Cl_3C} = 1.50$	
Bond angles (deg)		
	∠CCC = 122 ∠HCC = 110	Y = F, Cl, CH_3, CF_3

[a] $^{1,3}A''$ Frank–Condon states not included for reasons given in text.

Besides geometrical isomerism, there is the additional possibility of conformational isomerism in $CHCX_3CCH_2(^{1,3}2A'')$ when single bond rotation of CX_3 is considered. From the results it is apparent that while $CHCX_3CCH_2(S_o, {}^{1,3}2A'')$ have *syn* and *anti* conformers as minima and maxima, respectively, in no instance does the energy difference between the two rotamers for a given geometric isomer exceed 2 kcal/mol. Insofar as geometric isomerism in $CHYCCH_2(^{1,3}2A'')$ is concerned, it is noteworthy that while the *cis* isomer is more stable than the *trans* for Y = F and Cl, the opposite holds true for Y = CX_3, and the maximum energy difference between isomers, which occurs for Y = Cl, is never greater than 4 kcal/mol.

On account of the structural (*M*/*aM*), geometrical (*cis*/*trans*), and conformational (CX_3) isomerism present in the Markownikoff, $CHYCHCH_2^+$ and the *anti*-Markownikoff cations, $CHYCCH_3^+$, the geometric data were subjected to categorization and subsequent statistical analysis (see ref. 18 for full details). For ground state $CHYCHCH^{2+}$ (*M* cation), both $r(C_\alpha C_\beta)$ and $r(C_\beta C_\sigma)$ appear to be substituent independent and statistically indistinguishable at 1.37 Å. However, the adjacent bonds r_{YC} are substantially shorter (1.30, 1.73, 1.48 Å) respectively for Y = F, Cl, CH_3, than their counterparts in the unprotonated substrate (see Table 1). This is indicative of lone pair Π donation (F, Cl) and hyperconjugation (CH_3) whereby the electron deficient "Π" is stabilized. This is not the case for Y = CF_3, where r_{YC} for the cation is actually longer (1.51 Å versus 1.48 Å) than in the neutral molecule.

In C_s geometries the *M* allyl cations $CHYCHCH_2^+(^1A')$ possess the ground state MO configuration $\ldots(ma')^2\ldots(na'')^2$. These can be simply represented by an "sp—sp^2—sp^2—sp^2" (F, Cl), "sp^3—sp^2—sp^2—sp^2" (CH_3) or "$(sp)_3$—sp^3—sp^2—sp^2—sp^2—sp^2" (CF_3) hybridized "σ" framework with a perpendicular "π" system, i.e. taking the occupied CMO's in suitable combination allows one to generate the inner shell "1s" core, two "sp^2—sp^2" C—C, four "sp^2—s" C—H, "sp—sp^2" (F, Cl) or "sp^3—sp^2" (CX_3) Y—C, and "s—sp^3" (CH_3) or "sp—sp^3" (CF_3) CX_2—X bonding and lone pair (F, Cl, and CF_3) LMO's. The three-center, two-electron "π" system can be accounted for by the remaining na'' CMO. Although the

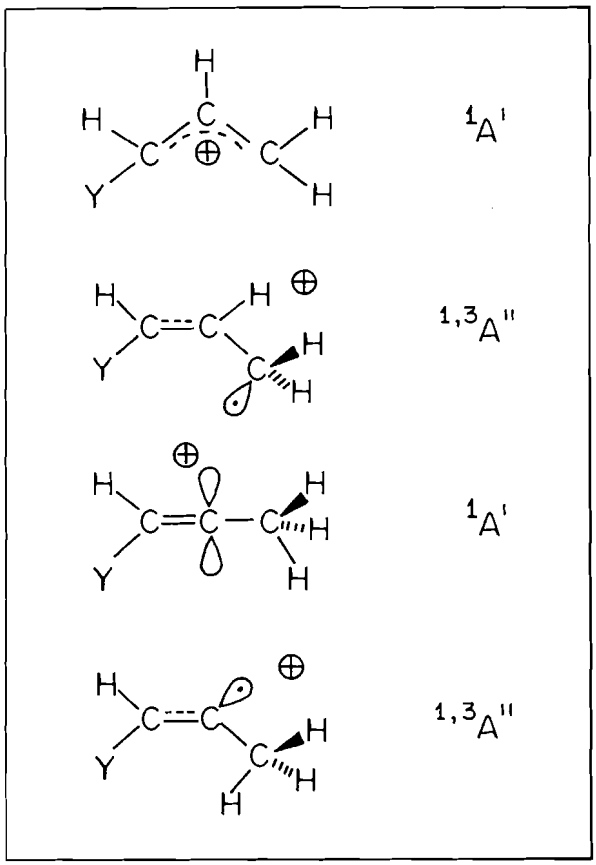

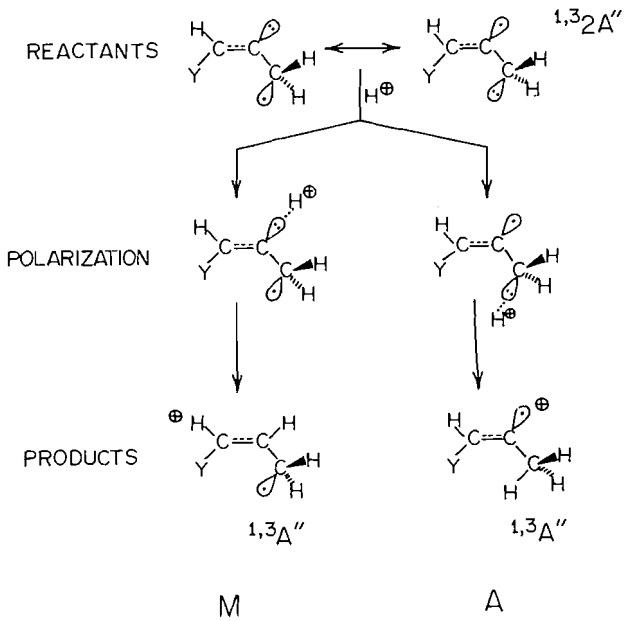

FIG. 2. Lewis/resonance structures for the $^1A_1$ and $^{1,3}A''$ states of $CHYCHCH_2^+$ and $CHYCCH_3^+$. Only the *cis* isomers of $CHYCHCH_2^+$ ($^1A_1$, $^{1,3}A''$) and $CHYCCH_3^+$ ($^{1,3}A''$) are shown.

lowest-lying, valence-excited states are obtainable from the configuration $...(ma')^2(na'')^1((n+1)a'')^1$, arising from "$\pi$" → "$\pi$" excitation, the virtual $(n+1)a''$ orbital is reduced in energy relative to the filled na'' CMO by concurrent twisting and bending of the γCH_2 group in the ground state. Thus the Frank–Condon states are stabilized, as per Walsh's rules (17), by the transformation and associated "sp^2" → "sp^3" rehybridization of the γC atom, i.e. $^{1,3}A'(na'' \times (n+1)a'') \rightarrow {}^{1,3}A''((n+1)a'' \times ma')$. A LMO representation of $CHYCHCH_2^+(^{1,3}A'')$, consisting of a "sp—sp^2—sp^2—sp^3" (F, Cl), "sp^3—sp^2—sp^2—sp^3" (CH_3) or "$(sp)_3$—sp^3—sp^2—sp^2—sp^3" (CF_3) hybridized "σ" framework with a singly occupied "π"$((n+1)a'')$ BO and "sp^3"(ma') NBO, is given in Fig. 2. While the value of $r(C_\alpha C_\beta)$ (1.41 Å) is not that different from that calculated for benzene (1.38 Å) (19) and thus not unreasonable for a one electron "π" bond, the same is not true of $r(C_\beta C_\gamma)$ (1.46 Å). Just as for $CHYCHCH_2^+(S_0)$, the shrinkage of $(r(Y—C, {}^{1,3}A''))$ relative to those of $CHYCCH_2(S_0)$ is a manifestation of lone pair "π" donation (F, Cl) and hyperconjugation (CH_3) whereby the one electron "π" bond is stabilized. However, on account of the asymmetric "π" bond that displaces the density of the single electron in the direction of the αC atom in $CHYCCH_2(^{1,3}2A'')$, this process is unimportant in these states and as such $(r(Y—C, {}^{1,3}2A''))$ are not appreciably different from $(r(Y—C)$ of $CHYCCH_2(S_0)$. In analogous fashion to $CHYCCH_2(^{1,3}A'')$, $CHYCHCH_2^+(^{1,3}2A'')$ possesses an average dihedral angle greater than 90° with respect to the αC atom, i.e. $(\angle HCC, {}^{1,3}A'') = \pm 100$, with the single exception of *cis,anti*-$CHCF_3CHCH_2^+(^3A'')$ in which, for unknown reasons, $\angle HCC = \pm 86°$. Although it is not always true that the *syn* and *anti* conformers of $CHCX_3CHCH_2^+(S_0, {}^{1,3}A'')$ are a minimum and maximum with respect to single bond CX_3 rotation within a given geometric isomer, and that the *trans* is more stable than the *cis* isomer for a given rotamer, it is always the case that the lowest energy form is the *trans,syn* isomer. The energy differences between pairs of isomers never exceed 3 kcal/mol, with the exception of *trans*, and *cis,syn*-$CHCH_3CHCH_2^+(S_0)$ for which it is 5 kcal/mol.

In C_s geometries the *aM* cations $CHYCCH_3^+$ are of the ground state MO configuration $...(ma')^2...(na'')^2\ ^1A'$. These can be simply represented by an "sp—sp^2—sp—sp^2" (F, Cl), "sp^3—sp^2—sp—sp^2" (CH_3) or "$(sp^3)_3$—sp^3—sp^2—sp—sp^2" (CF_3) hybridized "σ" skeleton with a mutually perpendicular "π"(na'') bond and an empty "p"$((m+1)a')$ orbital occupying the electron deficient "sp" central C atom. While both $r(C_\alpha C_\beta)$ and $r(C_\beta C_\gamma)$ appear to be both substituent- and isomer-independent at 1.27 and 1.43 Å respectively, the adjacent bonds are only isomer invariant, and such that r_{FC} = 1.33 Å, r_{ClC} = 1.80 Å and r_{CX_3C} = 1.54 Å. The fact that $r(C_\alpha C_\beta)$ is considerably shorter than a typical single bond, e.g. for propene $r(CC)$ = 1.51 Å (17), is indicative of hyperconjugation, through which the vacant "p"$((m+1)a')$ orbital of the "sp" central C atom is stabilized via electron density from the "σ" "sp^3—s" C—H bond of the γCH_3 group. The lowest-lying, valence excited states are obtained from the configuration $...(na'')^1((m+1)a')^1$, arising from "π" → "p" excitation, and are therefore of the symmetry type $^{1,3}A''$. However, because the $(m+1)a''$ LUMO is lowered in energy relative to the na'' HOMO upon CCC planar deformation of the ground state, the Frank–Condon states are stabilized, in accordance with Walsh's predictions (16), by the "sp" → "sp^2" rehybridization of the βC atom. A Lewis/resonance schematic representation of the LMO description for $CHYCCH_3^+(^{1,3}A'')$, comprising a "sp—sp^2—sp^2—sp^3" (F, Cl), "sp^3—sp^2—sp^2—sp^3" (CH_3) or "$(sp)_3$—sp^3—sp^2—sp^2—sp^3" (CF_3) hybridized "σ" framework with an individually occupied "sp^2"$((m+1)a')$ NBO and "π"(na'') BO, is given in Fig. 2. Both $r(C_\alpha C_\beta)$ (1.39 Å) and $\angle CCC$ (138°) are consistent with values expected for a one electron "π" bond, (i.e. for benzene, which possesses a bond order 1.5, it is calculated that $r(CC)$ = 1.38 Å (19)), and with the expected angle from VSEPR (9) theory for the spatial repulsion of two "sp^2" BO in the presence of a "sp^2" NBO containing a single electron. The adjacent bond lengths, r_{CY}, with the exception of Y = CF_3, are once again indicative of lone pair "π" donation (F, Cl) and hyperconjugation (CH_3, $C_\gamma H_3$) in view of their reduced lengths in relation to those of $CHYCCH_3^+(S_0)$ (F, Cl, and CH_3) and propene ($C_\gamma H_3$).

With Lewis/resonance structures available for $CHYCCH_2$-$(^{1,3}2A'')$, $CHYCHCH_2^+(^{1,3}A'')$ and $CHYCCH_3^+(^{1,3}A'')$, and in the same manner as was done (3) for $CH_2CCH_2(^{1,3}A'')$, it is possible to develop a qualitative pictorial representation (Scheme 1) for the process of adiabatic proton transfer. As the proton approaches along the Markownikoff reaction coordinate, (i.e. towards the central (β) C atom) $CHYCCH_2(^{1,3}2A'')$ is polarized in such a way that the resonance form that assigns the valence lone pair to the β-C completely predominates over its alternate. Conversely for *aM* protonation, $CHYCCH_2(^{1,3}2A'')$ is subject to the opposite polarization which causes the resonance structure with the terminal (γ) lone pair to become the sole contributor as the transition to $CHYCCH_3^+(^{1,3}A'')$ is made. On the basis of this model, one would predict *M* attack

SCHEME 1. Qualitative schematic representation for the process *cis*-$CHYCCH_2(^{1,3}2A'')$ + H^+ → *cis*-$CHYCHCH_2^+(^{1,3}A'')(M)$ or *cis,syn*-$CHYCHCH_3^+(^{1,3}A'')(aM)$.

to be favored over *aM* attack in that the major resonance contributor of $CHYCCH_2(^{1,3}A'')$, in the absence of the proton's electric field, corresponds to that which direct dative bond formation with the central C atom is facilitated.

Energies of proton transfer

In Figs. 3–6 the energies of the ground and low-lying excited states of $CHYCCH_2(^1A, ^{1,3}A'', ^{1,3}2A'')$, $CHYCHCH_2^+(^1A'$ and $^{1,3}A'')$ are plotted relative to that for ground state $CHYCCH_2$-$(^1A')$, where for illustrative convenience enumerative symbolism is employed, e.g. S_2 denotes the second (open shell) excited singlet state of $CHYCCH_2$ etc.. On account of the small energy differences (<2 kcal/mol) found between geometric and rotational isomers, only the lowest energy forms are graphically displayed. Note that although $CHYCCH_2(^{1,3}A'')$ are RHF-SCF unstable, they are included for qualitative comparison purposes only. A visual examination reveals that with the exception of the diradicaloid $CHYCCH_2(^{1,3}A'')$, the excited states of $CHYCHCH_2^+$ and $CHYCCH_3^+$ are red-shifted relative to those of $CHYCCH_2$ and hence that $CHYCCH_2$* is of enhanced basicity with respect to both regiocenters. Furthermore it is evident that the energy differences $\Delta E(H^+) = E_{SCF}(CHYCCH_3^+) - E_{SCF}(CHYCHCH_2^+)$ are such that for all Y, $|\Delta E(HS_0^+)| > |\Delta E(HS_1^+)| \gg |\Delta E(HT_1^+)|$. In other words, a strong Markovnikov preference is shown only by the two singlet state protonations, for all substituents Y, including CF_3.

Only adiabatic proton tranfers (i.e. between directly correlating states) will be considered, as shown below:

$$S_0(^1A') \rightarrow HS_0^+(M)(^1A')$$
$$S_0(^1A') \rightarrow HS_0^+(aM)(^1A')$$
$$T_2(^3 2A'') \rightarrow HT_1^+(M)(^3A'')$$
$$T_2(^3 2A'') \rightarrow HT_1^+(aM)(^3A'')$$
$$S_2(^1 2A'') \rightarrow HS_1^+(M)(^1A'')$$
$$S_2(^1 2A'') \rightarrow HS_1^+(aM)(^1A'')$$

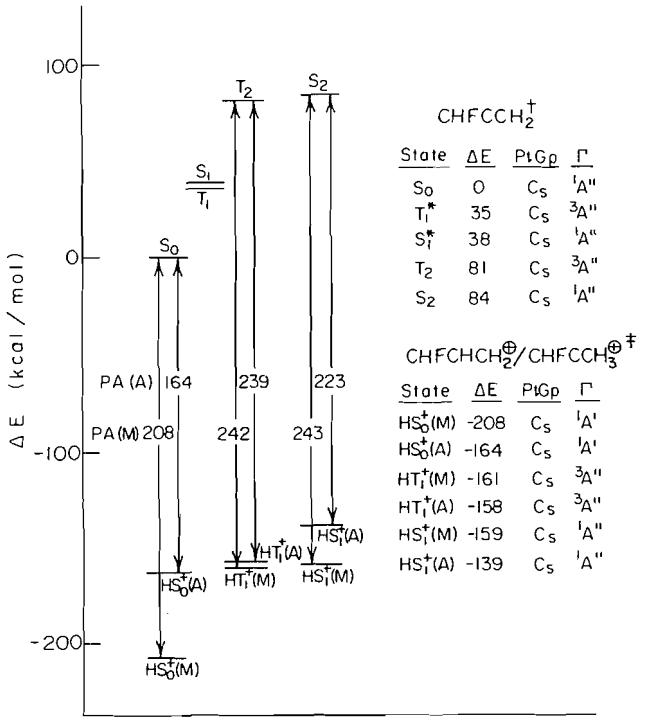

FIG. 3. Relative energies‡ of the ground and low-lying excited states for $CHFCCH_2$ ($^1A_1$, $^{1,3}A''$, $^12A'$, and $^{1,3}2A''$), $CHFCHCH_2^+$ ($^1A'$ and $^{1,3}A''$), and $CHFCCH_3^+$ ($^1A'$ and $^{1,3}A''$) with PA's evaluated between the lowest directly correlating states, $S_0(^1A') \leftrightarrow HS_0^+(M)$-$(^1A')/HS_0^+(aM)(^1A')$, $T_2(^32A'') \leftrightarrow HT_1^+(M)(^3A'')/HT_1^+(aM)(^3A'')$ and $S_2(^12A'') \leftrightarrow HS_1^+(M)(^1A'')/HS_1^+(aM)(^1A'')$ (*RHF unstable, †lowest energy geometric isomers, ‡lowest energy geometric/conformational isomers only. $\ddagger\Delta E_{SCF} = E_{SCF} - E_{SCF}(CHFCCH_2(S_0))$, where $E_{SCF}(CHFCCH_2(S_0)) = 213.529$ au).

The proton affinities are calculated from the relation PA-$(CHYCH_2)(M/aM) = E_{SCF}(CHYCCH_2) - E_{SCF}(CHYCH$-$CH_2^+/CHYCCH_3^+)$. This yields the ordered pairs for each electronic state, PA(*aM*) and PA(*M*), which are plotted against each other for all Y, including Y = H, in Fig. 7. The solid line in this figure gives the demarcation between *M* (points above) and *aM* (points below) regioselective protonations. Unlike the previously examined case of protonation of substituted acetylenes (23) (with the same Y substituents as in the present case), where changes in regioselective preference were found as a function of Y, all points in Fig. 7 lie either essentially on the 1:1 correspondence line or clearly above it.

Examination of the groups of points in Fig. 7 leads to the following conclusions: (*1*) with the exception of $CHFCCH_2$, irrespective of both regiocenter (*M*/*aM*) and state ($S_0/T_2/S_2$), the PA's for $CHYCCH_2$, decrease with respect to Y in the order $CH_3 > H > Cl > CF_3$, (*2*) regardless of Y, $CHYCCH_2(T_2)$ exhibits no significant protonation regioselectivity, (*3*) the dependence of PA(*M*) and PA(*aM*) on substituent for S_0 is such that for all Y ≠ F, PA(*M*) > PA(*aM*) by ≥20 kcal/mol on average, (*4*) for S_2, excluding $CHFCCH_2$, PA(*M*) − PA(*aM*) ≃ 14 kcal/mol, i.e. relatively speaking, regioselectivity appears to be independent of substituent for S_0 and S_2, and (*5*) proceeding in the order $S_0 \rightarrow S_2 \rightarrow T_2$, not only is the protonation regioselectivity diminished, but also the perturbational ability of the individual substituents (Y), i.e. both the mean value of PA(*M*) − PA(*aM*), and the associated standard deviation about the mean decreases.

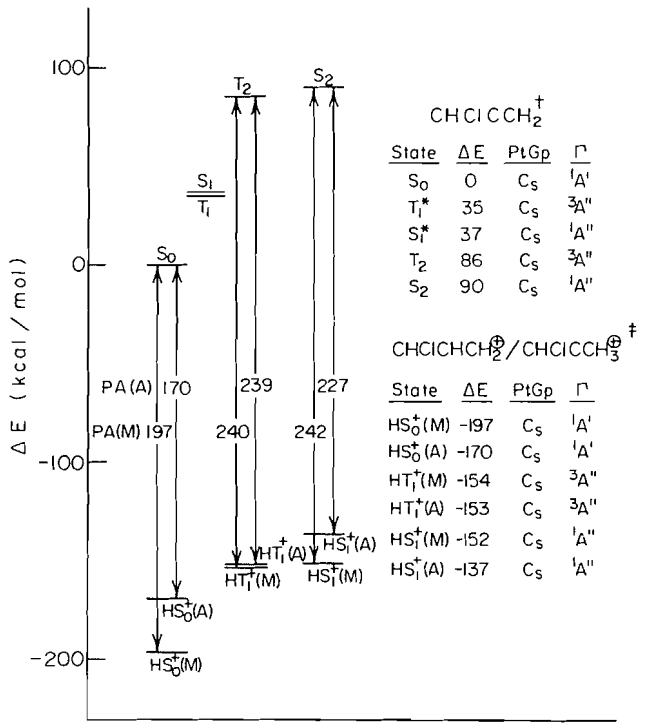

FIG. 4. Relative energies§ of the ground and low-lying excited states for $CHClCCH_2$ ($^1A_1$, $^{1,3}A''$, $^1 2A'$, and $^{1,3}2A''$), $CHClCHCH_2^+$ ($^1A'$ and $^{1,3}A''$) and $CHClCCH_3^+$ ($^1A'$ and $^{1,3}A''$), with PA's evaluated between the lowest directly correlating states, $S_0(^1A'') \leftrightarrow HS_0^+(M)(^1A')$, $T_2(^3 2A'') \leftrightarrow HT_1^+(M)(^3A'')/HT_1^+(aM)(^3A'')$ and $S_2(^1 2A'') \leftrightarrow HS_1^+(M)(^1A'')/HS_1^+(aM)(^1A'')$. (*RHF unstable, †lowest energy geometric isomers only, ‡lowest energy geometric/conformational isomers. $\S\Delta E_{SCF} = E_{SCF} - E_{SCF}(CHClCCH_2(S_0))$, where $E_{SCF}(CHClCCH_2(S_0)) = -571.929$ au).

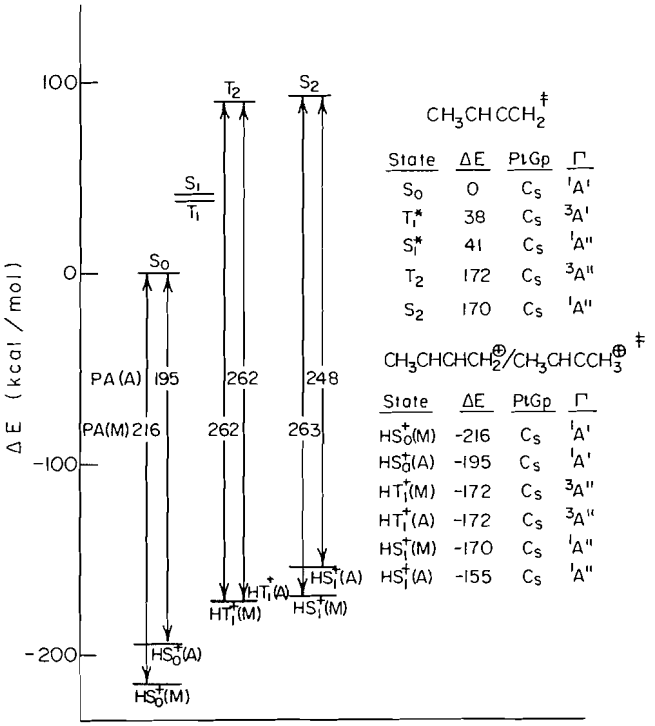

FIG. 5. Relative energies‡ of the ground and low-lying excited states for $CHCH_3CCH_2$ ($^1A_1$, $^{1,3}A''$, $^1 2A'$, and $^{1,3}2A''$), $CHCH_3CHCH_2^+$ ($^1A'$ and $^{1,3}A''$), and $CHCH_3CCH_3^+$ ($^1A'$ and $^{1,3}A''$), with PA's evaluated between the lowest directly correlating states, $S_0(^1A') \leftrightarrow HS_0^+(M)(^1A')/HS_0^+(aM)(^1A')$, $T_2(^3 2A'') \leftrightarrow HT_1^+(M)(^3A'')$ and $S_2(^1 2A'') \leftrightarrow HS_1^+(M)(^1A'')/HS_1^+(aM)(^1A'')$. (*RHF unstable, †lowest energy geometric/conformational isomers only, $\ddagger\Delta E_{SCF} = E_{SCF} - E_{SCF}(CHCH_3CCH_2(S_0))$, where $E_{SCF}(CHCH_3CCH_2(S_0)) = -154.041$ au).

With regard to $CHFCCH_2$ and points (*1*), (*3*) and (*4*) above, it is apparent that its anomalous behavior can be traced to the F atom's extraordinary ability to act, relative to the H atom, as an electron donor in $CHFCHCH_2^+(S_0)$, as an electron acceptor in $CHFCHCH_2^+(S_1)$, and as an electron acceptor of comparable degree to Y = CF_3 in both S_0 and S_1 of $CHFCCH_3^+$. It should be pointed out that such ambivalent behavior is not unusual for the F substituent, since it is well-known that its σ-type substituent constants can vary from −0.07 to +0.35, depending on whether its resonance or inductive effect is dominant (21).

Comparison with experimental evidence

Although excited state basicity enhancement has not yet been demonstrated for the simple model systems considered in this study, it has been observed for both aliphatic and aromatic substituted allenes, e.g. 1,2-cyclononadiene (25) and tetraphenylallene (26) undergo photoaddition of acetic acid and methanol, respectively, to produce the corresponding allyl acetate and allyl ether, while 1,1-phenylmethylallene (2) photohydrates in the presence of acid to yield a cinnamyl alcohol. Thus they all experience regiospecific photoprotonation of an excited singlet in the Markownikoff sense, under solution conditions in which they would be thermally inert. Consideration of the theoretical results (Fig. 7) suggests that this behavior is not altogether unexpected, given that for the reactive singlet, i.e. the zwitterionic-like S_2, as opposed to the relatively nonpolar, diradicaloid S_1, it is predicted that on average $\Delta PA(S_2(M)) \approx 47$.

Recent studies of the thermal and photochemical hydrations of substituted phenylallenes have shown that although both are acid-catalyzed reactions, the photochemical reaction takes place efficiently at much lower acidities than the thermal analogue. The implication is that electronic excitation greatly increases the basicity of S_1 relative to S_0. This is supported by the fact that fluorescence quenching of phenylallene itself, as a function of pH, is sigmoid with an inflection point around pHO^2, which is similar to the behavior shown by the S_1 states of substituted styrenes and phenylacetylenes (24). Although the ground state pK of phenylallene is not known, the fact that its thermal hydration required 70–83% H_2SO_4 to effect reasonable conversion (2), suggests that it is a very weak base. Hence $\Delta pK^* = pKS_1 - pKS_0$ for such allenes is probably very large. This is in accord with the PA values calculated for the simple model compounds in the present study.

Although phenylallene and α-methylphenylallene both hydrate regiospecifically in the *M* direction via S_0 or S_1, which is also in accord with the present calculations, *m*- and *p*-nitrophenylallenes do not. Thermally, these compounds give both *M* and *aM* products and hence are non-regiospecific. Photochemically, they react via T_1 after efficient intersystem crossing from S_1, and do react regiospecifically, but in the *aM* direction (2). Neither of these results is in accord with theoretical expectations based on $YCHCCH_2$ models, where Y is a strongly electron-withdrawing group such as CF_3. Since it is well known that NO_2 is more strongly electron-withdrawing than CF_3 in ground state molecules and that this difference is probably accentuated in

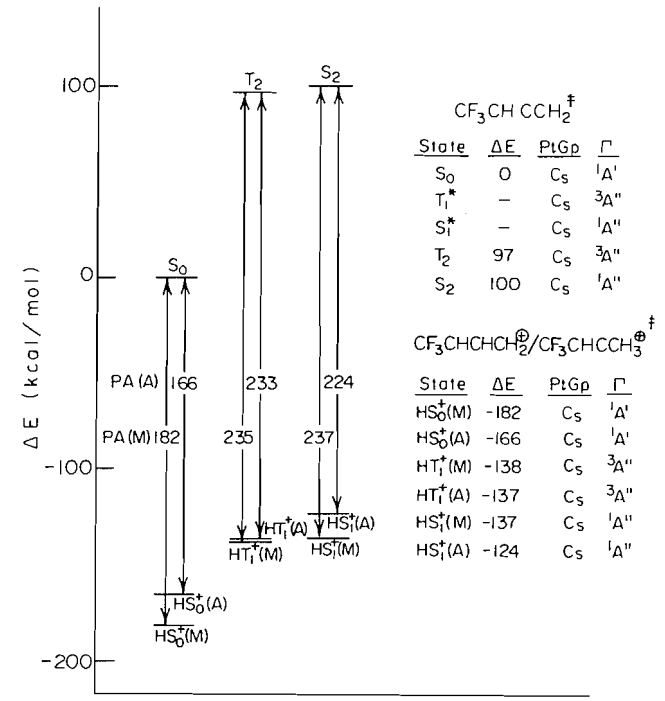

FIG. 6. Relative energies‡ of the ground and low-lying excited states for $CHCF_3CCH_2$ ($^1A_1$, $^{1,3}A''$, $^1 2A'$, and $^{1,3}2A''$), $CHCF_3CHCH_2^+$ ($^1A'$ and $^{1,3}A''$), and $CHCF_3CCH_3^+$ ($^1A'$ and $^{1,3}A''$), with PA's evaluated between the lowest directly correlating states, $S_0(^1A') \leftrightarrow HS_0^+(M)(^1A')/HS_0^+(aM)(^1A')$, $T_2(^3 2A'') \leftrightarrow HT_1^+(M)(^3A'')/HT_1^+(aM)(^3A'')$ and $S_2(^1 2A'') \leftrightarrow HS_1^+(M)(^1A'')/HS_1^+(aM)(^1A'')$ (*RHF unstable, †lowest energy geometric/conformational isomers only, $\ddagger \Delta E_{SCF} = E_{SCF} - E_{SCF}(CHCF_3CCH_2(S_0))$, where $E_{SCF}(CHCF_3CCH_2(S_0)) = -449.031$ au).

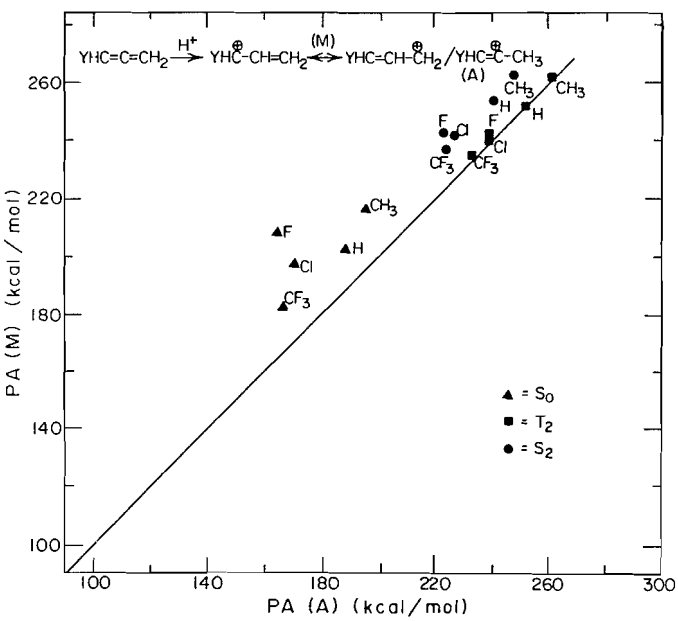

FIG. 7. Correlation diagram of proton affinities (PA) for $CHYCCH_2$ (Y = H*, F, Cl, CH_3 and CF_3) in $S_0(^1A_1)$, $T_2(^3 2A'')$, and $S_2(^1 2A'')$ states, resulting in Markownikoff (M) and anti-Markownikoff (aM) protonation products, i.e. $CHYCHCH_2^+$ ($^1A'$, $^{1,3}A''$) and $CHYCCH_3^+$ ($^1A'$, $^{1,3}A''$), respectively (*values of ($PA(CH_2CCH_2(aM))$ and ($PA(CH_2CCH_2(M))$ taken from ref. 4).

their excited states (27), attempts were made to carry out RHF-SCF calculations on excited states of nitroallene. However, as found previously for nitro acetylene (20), these were completely unsuccessful in locating stable minima on either the singlet or triplet surfaces. It appears from all experimental evidence to date that NO_2 group is able to produce reverse-polarized T_1 states, in the sense that these react regiospecifically for nitrophenylacetylenes (24), -acetylenes (24) and -allenes (2) but in the opposite (aM) sense to what is observed for corresponding S_1 states, which are all regiospecific in the expected M direction. It remains to be seen whether this behavior can be explained theoretically by eventual SCF calculations on NO_2 containing systems. In addition, the fact that 1,2-nonadiene (2) is observed to undergo photochemical addition of HOAc via γ protonation of the singlet state upon direct irradiation, although reasonable given that $\Delta PA(CHYCCH_2(S_2)(aM)) \approx 56$ kcal/mol, this process is not predicted to be as energetically advantageous as β protonation. Note that excited state aM protonation of the αC atom is incompatible with the present model, and to the best of the authors knowledge all of the examples known to date (26) experience regiospecific protonation via the β(M) or γ(aM) C atoms only.

Reçu le 24 avril 1989

JAN A. HERMAN, RODICA NEAGU-PLESU, URSZULA KRZEMIEN et KRZYSZTOF BEDERSKI. Can. J. Chem. **67**, 2196 (1989).

Les réactions ion/molécule de $C_2H_3Cl^+$ avec le propane ou le *n*-butane ont été étudiées dans un spectromètre de masse à photoionisation dans l'intervalle de pression de 0,01 à 1 Torr. Les principales voies de disparition de l'ion $C_2H_3Cl^+$ avec les propane et *n*-butane sont les processus de transfert de H^-, H_2^- et de charge dans le cas du *n*-C_4H_{10}. Les ions $C_nH_{2n+1}^+$ et $C_nH_{2n}^+$ formés dans ces transferts réagissent préferentiellement avec le chlorure de vinyle neutre dans des réactions de condensation accompagnées d'élimination du HCl ou Cl$^\cdot$.

Mots clés : réactions ion/molécule, spectrométrie de masse, chlorure de vinyle, propane, *n*-butane.

Ion–molecule reactions of $C_2H_3Cl^+$ with propane or *n*-butane have been studied using a photoionization mass spectrometer over the pressure range 0.01–1 Torr. The principal reasons for disappearance of the $C_2H_3Cl^+$ ion in propane and *n*-butane are the H^-, H_2^- transfer processes and charge transfer in the case of *n*-C_4H_{10}. The ions $C_nH_{2n+1}^+$ and $C_nH_{2n}^+$ formed in these transfers react preferentially with neutral vinyl chloride in condensation reactions with elimination of HCl or Cl$^\cdot$.

Key words: ion–molecule reactions, mass spectrometry, vinyl chloride, propane, *n*-butane.

[Journal translation]

Introduction

Dans une publication récente (1) nous avons montré la possibilité d'utiliser les ions moléculaires du chlorure de vinyle ionisés à 10,64 eV comme agent de transfert de charge sur l'isobutane, dont le potentiel d'ionisation est très proche, PI = 10,57 eV (2). Outre ce transfert de charge sur l'isobutane, faisant apparaître l'ion iso-$C_4H_{10}^+$, le deuxième processus d'importance est le transfert de H^- de l'isobutane sur l'ion $C_2H_3Cl^+$, engendrant une deuxième espèce ionique, *t*-$C_4H_9^+$. En raison de la très faible réactivité de ces deux ions, les seules réactions observées étaient celles avec l'isobutane neutre, lesquelles sont caracterisées par des coefficients de vitesse très faibles ($< 5 \times 10^{-14}$ cm^3 s^{-1}).

Ces expériences de photoionisation à 10,64 eV ont été étendues, dans ce travail, aux mélanges du chlorure de vinyle + propane, et chlorure de vinyle + *n*-butane. Nous nous attendons à des effets différents par rapport aux résultats obtenus dans le mélange : C_2H_3Cl + iso-C_4H_{10}, en raison des réactivités accrues des ions $C_nH_{2n}^+$ et $C_nH_{2n+1}^+$ (n = 3, 4) de structure primaire formés par le transfert de H_2^- et H^- des alcanes sur les oléfines ionisées (3, 4). Soit, dans le cas présent sur l'espèce $C_2H_3Cl^+$.

Le potentiel d'ionisation du propane étant 10,95 eV + 0,05 (2), l'ion moléculaire du chlorure de vinyle formé à 10,64 eV ne peut transferer sa charge sur le propane, et les seules réactions primaires prévisibles seront les transferts de H^- et de H_2^- produisant les ions $C_3H_7^+$ et $C_3H_6^+$. Par ailleurs, le potentiel d'ionisation du *n*-butane est 10,53 eV ± 0,1 eV (2). Donc dans ce cas, en plus des processus de transfert des anions H^- et H_2^- du *n*-butane sur l'ion $C_2H_3Cl^+$, on peut aussi s'attendre à un transfert de charge de l'ion $C_2H_3Cl^{+\cdot}$ excité sur le *n*-butane. Une ionisation directe du *n*-C_4H_{10} par les photons de 10,64 eV n'est également pas exclue. Ainsi les phénomènes observés pourront être plus complexes. Cependant, la photoionisation du *n*-butane près du seuil d'ionisation ne devrait pas être importante car, nous présumons, que le rendement quantique de photoionisation est faible, $< 0,1$.

Conditions experimentales

Les expériences ont été executées dans le spectromètre de masse à photoionisation et à haute pression déjà décrit (5, 6). La source d'émission des photons de hautes énergie est une lampe à décharge de krypton décrite par Ausloos *et al.* (7). L'intérieur de la chambre de collision du spectromètre de masse est libre de tout champ électrique. À la sortie les ions sont accélerés par un faible champ électrique, 5 V/cm, et sont focalisés sur l'entrée d'un filtre quadripolaire. La température de la chambre de collision est 28 ± 2°C. Les mesures sont effectuées dans un intervalle de pression situé entre 0,01 et 1 Torr (1 Torr = 133,3 Pa) et la pression est mesurée par un manomètre électronique Barocell fonctionnant dans la région de 10^{-4} à 10 Torr.

Un certain nombre de manipulations a été effectué sur un spectromètre de masse à secteur magnétique. Les résultats obtenus ont confirmé ceux réalisés sur l'instrument à photoionisation.

Les réactifs : chlorure de vinyle, propane et *n*-butane, de Matheson Co. sont de pureté supérieure à 99,5% et sont utilisés tels quels. Les mélanges de proportions connues sont préparés dans un système à vide ($\sim 10^{-6}$ Torr) raccordé à l'entrée du spectromètre de masse.

Résultats

Le Kr excité par une décharge micro-onde émet un rayonnement surtout composé de deux raies de résonance de 10,03 et 10,64 eV. Leurs intensités relatives dépendent entre autre de la pression du gaz. Dans notre cas les intensités relatives des raies de résonance transmises par les fenêtres en LiF sont respectivement de 82% pour celle de 10,03 eV et de 18% pour celle de 10,64 eV. Sieck *et al.* ont mesuré un rendement quantique de photoionisation du chlorure de vinyle de 0,037 à 10,03 eV et de 0,47 à 11,6–11,8 eV (raies de résonance de l'argon) (8). À partir des spectres de photoionisation du chlorure de vinyle (9) nous avons estimé le rendement quantique de photoionisation à 0,35 ± 0,04 à 10,64 eV. Dans ces conditions environ 70% des ions moléculaires du chlorure de vinyle sont formés par absorption du rayonnement à 10,64 eV.

Mélange : chlorure de vinyle – propane

Les expériences de photoionisation sont faites sur un mé-

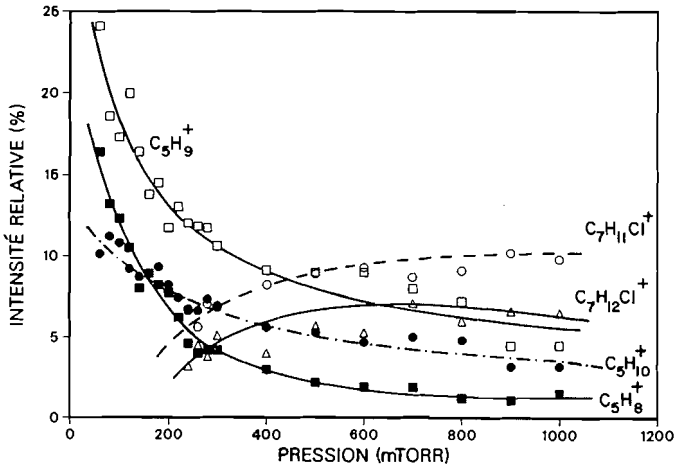

FIG. 1. Variations des intensités relatives des ions majoritaires en fonction de la pression dans le mélange $C_3H_8 : C_2H_3Cl = 9:1$.

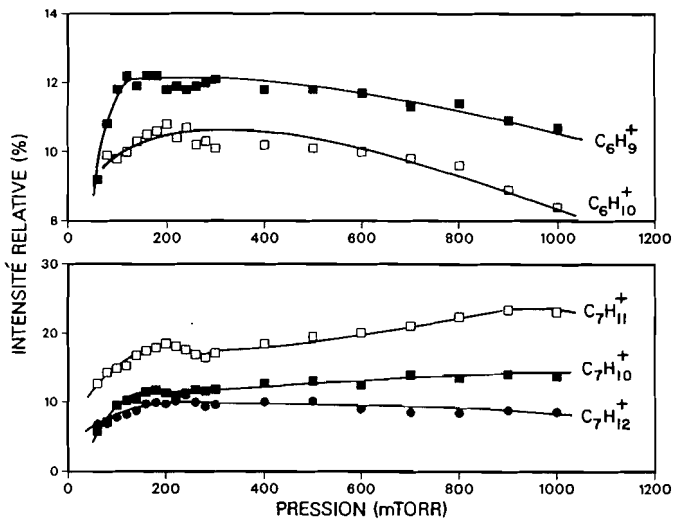

FIG. 2. Variations des intensités relatives de certains ions secondaires en fonction de la pression dans le mélange $C_3H_8 : C_2H_3Cl = 9:1$.

lange de 90% de propane et de 10% de chlorure de vinyle, de manière à favoriser les rencontres entre l'ion $C_2H_3Cl^+$ et les molécules neutres du propane.

Les résultats sont présentés dans les figures 1 et 2. Dans un mélange de telle proportion l'ion moléculaire du chlorure de vinyle n'apparait pas, de même que les des produits provenant des réactions ion–molécule du chlorure de vinyle pur (8, 10–14). Les ions les plus importants mis en évidence par les spectres de masse sont les suivants: $C_5H_8^+$, $C_5H_9^+$, $C_5H_{10}^+$ (fig. 1), et $C_6H_9^+$, $C_6H_{10}^+$, $C_7H_{10}^+$, $C_7H_{11}^+$ et $C_7H_{12}^+$ (fig. 2). Un groupe d'ions qui apparaissent aux pressions élevées sont ceux correspondant aux masses 130, 132 et 131, 133 auxquels nous attribuons les formules $C_7H_{11}Cl^+$ et $C_7H_{12}Cl^+$, et qui comptent ensemble pour moins de 17% en intensité (fig. 1). On trouve aussi sur tout l'intervalle de pression en faible intensité (<6%) les ions $C_4H_9^+$ et $C_4H_{10}^+$, qui ne sont pas rapportés sur les figures. Ceux-ci proviennent soit des réactions ion/molécule lentes entre les ions $C_3H_6^+$ et $C_3H_7^+$ et le propane, ou bien de l'ionisation de molécules de butane qui peut être contenu en trace dans le mélange de départ.

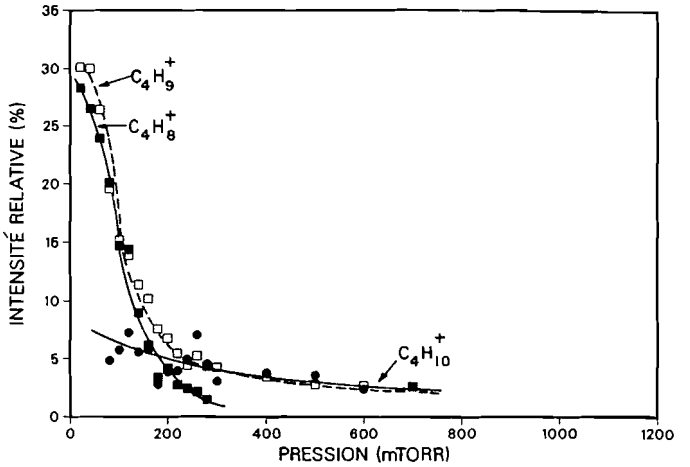

FIG. 3. Disparition des ions en C_4 en fonction de la pression dans le mélange $n\text{-}C_4H_{10} : C_2H_3Cl = 9:1$.

Mélange chlorure de vinyle – n-butane

L'importance de l'ionisation directe du *n*-butane d'une part, et du processus de transfert de charge du $C_2H_3Cl^+$ d'autre part est étudiée sur trois mélanges de proportions différentes, $n\text{-}C_4H_{10} : C_2H_3Cl = 9:1$; 1:1 et 0,5:9,5.

Dans les figures 3–5 nous rapportons les résultats obtenus pour le mélange $n\text{-}C_4H_{10}$ (90%) + C_2H_3Cl (10%) où certains processus réactionnels sont bien mis en évidence. Pour ce mélange aucun des ions observés ne provient des réactions ion/molécule du chlorure de vinyle pur. À basse pression le spectre de masse du mélange est dominé par les ions *m/z* 56 et 57 correspondants aux ions $C_4H_8^+$ et $C_4H_9^+$ (fig. 3). Ces derniers sont formés par transfert de H_2^- et H^- sur l'ion moléculaire du chlorure de vinyle. La masse *m/z* 58 représentant l'ion du *n*-butane, $C_4H_{10}^+$, est aussi présente mais en moins grande concentration. À pression totale égale, l'intensité de cet ion est environ dix fois plus importante dans le mélange $n\text{-}C_4H_{10}$ (90%) + C_2H_3Cl (10%) que dans le *n*-butane pur, ce qui est une indication que la majorité des ions $C_4H_{10}^+$ sont formés par transfert de charge,

[1] $C_2H_3Cl^{+\cdot} + n\text{-}C_4H_{10} \rightarrow n\text{-}C_4H_{10}^+ + C_2H_3Cl$

et seule une faible proportion provient de la photoionization directe.

Toujours dans le mélange à 90% de *n*-butane l'évolution des ions en fonction de l'augmentation de la pression (figures 4 et 5) font apparaitre deux familles d'ions d'intensité inégale: $C_5H_{11}^+$, $C_5H_{12}^+$ et $C_6H_{11}^+$, $C_6H_{12}^+$, $C_6H_{10-13}Cl^+$. Toutes ces espèces ne peuvent provenir que des réactions ion/molécule entre les deux constituants du mélange.

Le spectre de masse du mélange à 50% en *n*-butane est riche en produits, mais facile à dépouiller. On aperçoit des ions provenants aussi bien des processus ion/molécule propre au chlorure de vinyle pur (8, 10–14), que ceux observés dans le mélange $n\text{-}C_4H_{10}$ (90%) + C_2H_3Cl (10%) décrit ci-dessus. Dans les figures 6 et 7 nous présentons l'évolution des intensités relatives en fonction de la pression pour quelques ions seulement. Dans le but d'alléger les figures nous avons choisi de ne pas montrer les produits de réactions ion/molécule du chlorure de vinyle pur, à l'exception des ions $C_4H_5Cl^+$ et $C_4H_6Cl^+$. Ces derniers étant des produits majeurs de réaction dans le chlorure de vinyle pur nous voulons indiquer leur im-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/07/12

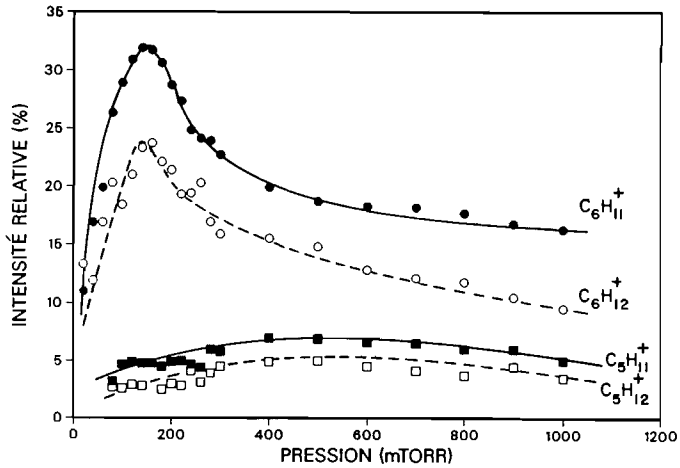

FIG. 4. Evolution en fonction de la pression des intensités relatives de certains ions principaux dans le mélange n-C_4H_{10} : C_2H_3Cl = 9 : 1.

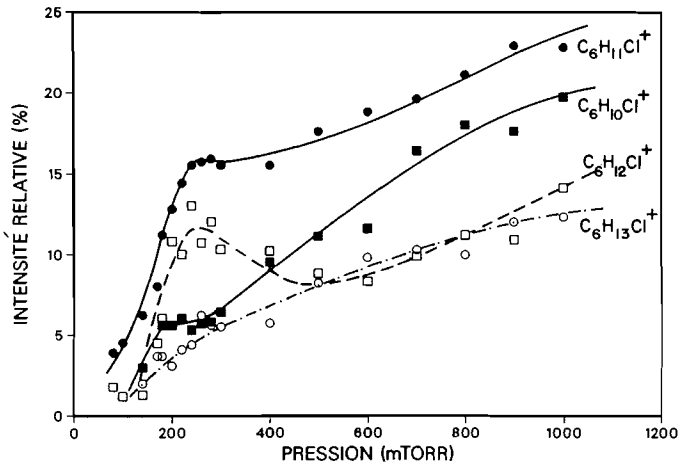

FIG. 5. Evolution en fonction de la pression des intensités relatives de certains ions chlorés dans le mélange n-C_4H_{10} : C_2H_3Cl = 9 : 1.

portance dans le spectre de masse du mélange (fig. 7). On découvre une nouvelle espèce dans le spectre, $C_4H_7Cl^+$, dont l'intensité maximale est ~10% à 30 mTorr et qui décroit rapidement avec l'augmentation de la pression. À cet ion peuvent être affiliées deux autres espèces apparaissant à pression élevée (>60 mTorr), $C_4H_9Cl^+$ et $C_4H_{10}Cl^+$, dont l'intensité totale ne dépasse pas 6%.

Le troisième mélange, riche en chlorure de vinyle (95%), montre surtout les produits des réactions ion/molécule du C_2H_3Cl pur. Cependant à basse pression on remarque, quoique en moindre quantité, la présence des $C_4H_8^+$ et $C_4H_9^+$ qui disparaissent rapidement avec l'augmentation de la pression pour former les ions $C_6H_{10}^+$, $C_6H_{11}^+$ et $C_6H_{12}^+$.

Nous avons consigné ci-dessous les valeurs du rapport des intensités (I) de l'ion $C_2H_3Cl^+$ à ceux des espèces $C_4H_8^+$ + $C_4H_9^+$ + $C_4H_{10}^+$ du butane normal pour les trois mélanges à 5 mTorr de pression totale, c'est à dire au tout début des séquences des réactions ion/molécule :

mélange C_2H_3Cl + n-C_4H_{10}	1 : 9	1 : 1	9,5 : 0,5
$I(C_2H_3Cl^+)/I(C_4H_8^+ + C_4H_9^+ + C_4H_{10}^+)$	0	1,1	2,2

On y voit clairement l'importance des processus de transfert,

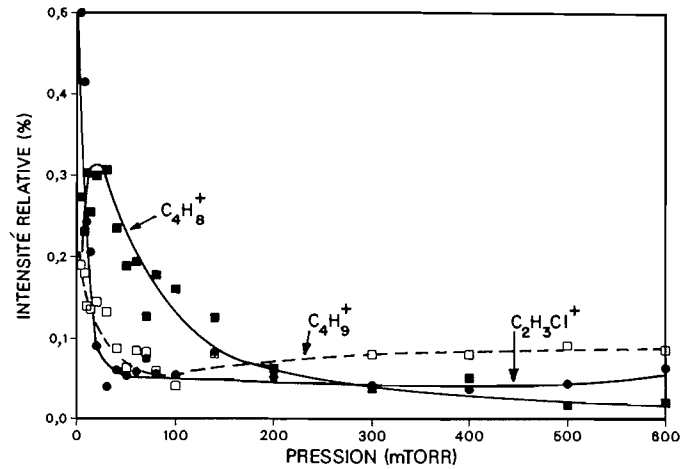

FIG. 6. Disparition des ions primaires en fonction de la pression dans le mélange n-C_4H_{10} : C_2H_3Cl = 1 : 1.

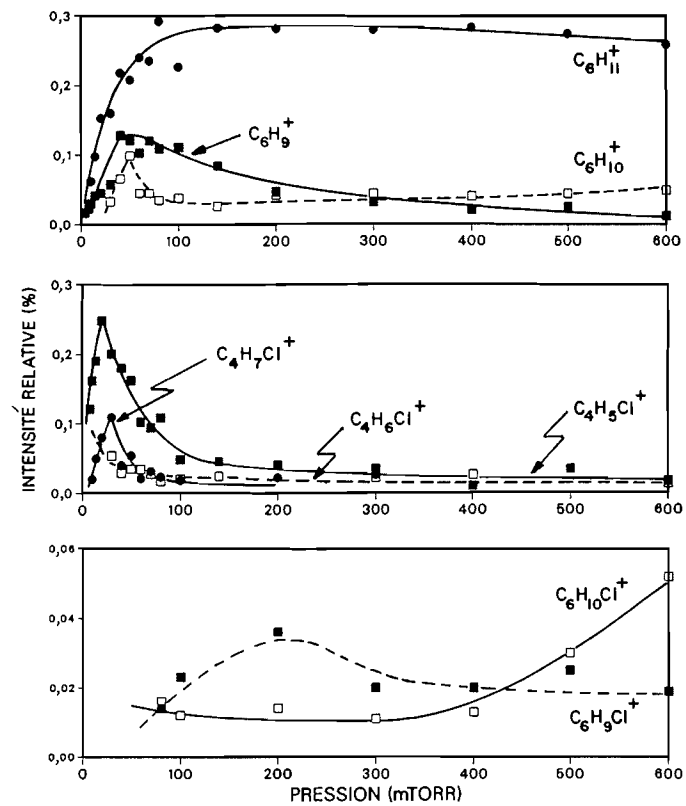

FIG. 7. Variations des intensités relatives de certains ions secondaires en fonction de la pression dans le mélange n-C_4H_{10} : C_2H_3Cl = 1 : 1.

lesquels même aux concentrations elevées du chlorure de vinyle restent encore des canaux de réactions très importants.

Discussion

La séquence des réactions ion/molécule dans le chlorure de vinyle pur est bien établie (8, 10–14). À pression elevée elle est completée par les processus [5]–[13] (15):

[2] $C_2H_3Cl^+ + C_2H_3Cl \rightarrow C_4H_5Cl^+ + HCl$

[3] $\rightarrow C_4H_6Cl^+ + Cl^\cdot$

[4] $\rightarrow C_3H_4Cl^+ + CH_2Cl^\cdot$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/07/12
For personal use only.

[5] $C_4H_5Cl^+ + C_2H_3Cl \rightarrow C_6H_7Cl^+ + HCl$

[6] $\rightarrow C_6H_8Cl^+ + Cl^\cdot$

[7] $C_4H_6Cl^+ + C_2H_3Cl \rightarrow C_6H_8Cl^+ + HCl$

[8] $\rightarrow C_6H_9Cl^+ + Cl^\cdot$

[9] $C_3H_4Cl^+ + C_2H_3Cl \rightarrow C_5H_6Cl^+ + HCl$

[10] $\rightarrow C_5H_7Cl^+ + Cl^\cdot$

[11] $C_6H_7Cl^+ \xrightarrow{M(?)} C_6H_7^+ + Cl^\cdot$

[12] $C_6H_8Cl^+ \xrightarrow{M(?)} C_6H_7^+ + HCl$

[13] $C_6H_7^+ + C_2H_3Cl \rightarrow C_8H_9^+ + HCl$

À pression elevée (>100 mTorr) les produits des réactions [11]–[13] s'accumulent probablement en raison de leur faible réactivité vis-à-vis du chlorure de vinyle neutre.

Dans les spectres de masse des mélanges du chlorure de vinyle + propane et chlorure de vinyle + *n*-butane à concentration elevée, tous les produits des réactions [2]–[13] sont clairement identifiables. Donc, la séquence des réactions [2]–[13] est en competition avec les processus de transfert de H^- et de H_2^- [14], [15] et éventuellement de charge [1]:

[14] $C_2H_3Cl^+ + C_nH_{2n+2} \rightarrow C_nH_{2n+1}^+ + C_2H_4Cl^\cdot$

[15] $\rightarrow C_nH_{2n}^+ + C_2H_5Cl$

Les travaux qui portent sur le transfert de H^- dans certains mélanges d'hydrocarbures d'alkyles (16) ou encore sur des mélanges «alcane + oléfine», où seule l'oléfine est ionisée (4), mettent en évidence le caractère général de ces types de réactions.

Les coefficients de vitesse des réactions [1], [14], [15] ne sont pas connus. Si par analogie nous supposons que les constantes de vitesse des réactions [14] et [15] sont comparables à celles de l'ion $C_2H_4^+$ avec le propane ($k \sim 8 \times 10^{-10}$ cm^3 s^{-1}) (17, 18) ou avec le *n*-butane ($k \sim 1 \times 10^{-10}$ cm^3 s^{-1}) (3*b*), alors nous devons nous attendre à des processus très efficaces, ce qui expliquerait l'importance de ces réactions dans les mélanges étudiées.

Mélange : chlorure de vinyle + propane

Dans ce mélange à 10% en C_2H_3Cl les processus [14] et [15] sont pratiquement les seuls à être envisagés et, en conséquence, les ions $C_3H_6^+$ et $C_3H_7^+$ seront les premiers à amorcer les réactions subséquentes. Les coefficients de vitesse des réactions ion/molécule des ions $C_3H_6^+$ et $C_3H_7^+$ avec le propane sont d'environ 3×10^{-11} cm^3 s^{-1} (3*b*, 19, 20) ce qui caractérise des processus relativement lents. En supposant que ces constantes de vitesse sont au moins d'un ordre de grandeur inférieur à celles caractérisants les réactions entre les ions $C_3H_6^+$ et $C_3H_7^+$ et le C_2H_3Cl, on peut s'attendre que les réactions qui suivent les processus [14] et [15] impliquent exclusivement le chlorure de vinyle:

[16] $C_3H_6^+ + C_2H_3Cl \rightarrow C_5H_9^+ + Cl^\cdot$

[17] $C_3H_6^+ + C_2H_3Cl \rightarrow C_5H_8^+ + HCl$

[18] $C_3H_7^+ + C_2H_3Cl \rightarrow C_5H_9^+ + HCl$

[19] $C_3H_7^+ + C_2H_3Cl \rightarrow C_5H_{10}^+ + Cl^\cdot$

Les ions insaturés obtenus alors: $C_5H_8^+$, $C_5H_9^+$ et $C_5H_{10}^+$ (fig. 1) réagissent à leur tour préferentiellement avec le chlorure de vinyle dans des processus de condensation avec ou sans élimination du $Cl^\cdot$, du HCl ou du $CH_2Cl^\cdot$:

[20] $C_5H_{5+n}^+ + C_2H_3Cl \rightarrow C_7H_{8+n}Cl^+$

[21] $\rightarrow C_7H_{8+n}^+ + Cl^\cdot$

[22] $\rightarrow C_7H_{7+n}^+ + HCl$

[23] $\rightarrow C_6H_{6+n}^+ + CH_2Cl^\cdot$

où n = 3, 4 et 5. Toutes ces espèces ioniques sont effectivement présentes dans le spectre de masse. Leurs intensités relatives indiquent que les processus [17] et [18], impliquant l'élimination du chlorure d'hydrogène, contribuent le plus à la formation des produits (figures 2, 3).

Mélange : chlorure de vinyle + n-butane

Il est reconnu que les ions $C_4H_8^+$ et $C_4H_9^+$ formés dans les processus [14] et [15] de même que l'ion $C_4H_{10}^+$ ne réagissent que lentement avec le *n*-butane neutre ($k < 10^{-12}$ cm^3 s^{-1}) (3). Il est donc normal de constater que ces ions réagissent préferentiellement avec le chlorure de vinyle dans des processus dont les coefficients de vitesse (pas encore mesurés) devraient être au moins un ordre de grandeur plus élevés. Les séquences de réactions observées sont similaires à celles décrites pour le mélange $C_2H_3Cl + C_3H_8$:

[24] $C_4H_{8+m}^+ + C_2H_3Cl \rightarrow C_6H_{11+m}Cl^+$

[25] $\rightarrow C_6H_{11+m}^+ + Cl^\cdot$

[26] $\rightarrow C_6H_{10+m}^+ + HCl$

[27] $\rightarrow C_5H_{9+m}^+ + CH_2Cl^\cdot$

où m = 0, 1, 2. Tous ces ions à l'exception du $C_5H_9^+$ sont présents dans le spectre de masse. De nouveau les processus caractérisés par l'élimination du HCl contribuent le plus à la formation des produits.

Les réactions du genre:

[28] $C_6H_{10+p} + C_2H_3Cl \rightarrow C_8H_{12+p}^+ + HCl$

où p = 0–3, qui correspondent aux processus [20]–[23], n'ont pas été observé clairement dans ce mélange. On aperçoit un amas de pics de faible intensité (~1%) de masse: $110 < m/z < 130$, emergeant du fond spectral mais difficile à dépouiller convenablement. Il n'est donc pas souhaitable pour l'instant de les considerer comme preuve de l'occurrence des processus [28].

Dans le mélange riche en chlorure de vinyle apparait une nouvelle voie réactionnelle:

[29] $C_2H_3Cl^+ + n\text{-}C_4H_{10} \rightarrow C_2H_4Cl^+ + C_4H_9^\cdot$

Cet ion, $C_2H_4Cl^+$, peu abondant réagit ensuite de la même manière que l'ion $C_2H_3Cl^+$ en formant des produits d'une unité de masse plus élevé que l'ion parent du chlorure de vinyle. Cela ne fait que compliquer les spectres de masse des mélanges à proportion élevée en C_2H_3Cl.

Les différences de réaction entre le chlorure de vinyle et le *n*-butane d'une part, et l'isobutane (1), d'autre part, peuvent se comprendre aisement. La structure ouverte primaire ou secondaire des espèces $C_4H_9^+$ et $C_4H_8^+$ permet à ces ions de réagir relativement facilement avec les oléfines. La structure tertiaire des ions *t*-$C_4H_9^+$ et iso-$C_4H_8^+$ rend ces espèces dans leur état fondamental peu ou pas du tout réactives avec les molécules neutres.

Nous terminons par un commentaire général. Le problème des réactions consécutives du type [13], [22] et [28] qui conduiraient à des produits lourds, polymérisation ionique, ne

reçoit pas ici de solution claire. Certe, on aperçoit des produits ioniques correspondant à une troisième ou même quatrième étape de condensation, mais leurs intensités relatives suggèrent qu'à chaque condensation consécutive il y a ralentissement de la vitesse de réaction. Il est probable que les structures de plus en plus complexes de ces ions à plusieures liaisons insaturées, ayant une charge délocalisée, soient responsables de cette diminution de la vitesse de condensation. On peut donc supposer qu'après à peine quelques étapes de condensation la vitesse de croissance des produits lourds formés dans des réactions ion/molécule soit égale ou inférieure à la vitesse de polymérisation radicalaire, et alors c'est cette dernière qui va emporter dans le processus global.

Conclusion

Les réactions ion/molécule dans le propane et dans le *n*-butane de l'ion $C_2H_3Cl^+$ formé à 10,64 eV, sont dominées par les processus de transfert H^-, H_2^-, et en plus par le transfert de charge dans le cas du *n*-C_4H_{10}. Ces processus sont en compétition avec les réactions ion/molécule du chlorure de vinyle pur. La faible réactivité des ions $C_nH_{2n}^+$ et $C_nH_{2n+1}^+$ avec le propane et le *n*-butane favorise les réactions de condensation avec le chlorure de vinyle avec ou sans élimination du HCl ou Cl$^\bullet$.

Remerciements

On the correlation of the excess surface heat capacity and the surface molar volume of liquids

DOUGLAS EUGENE GOLDSACK AND LISE JEANNE PAQUETTE
Department of Chemistry, Laurentian University, Sudbury, Ont., Canada P3E 2C6
Received September 20, 1988[1]

DOUGLAS EUGENE GOLDSACK and LISE JEANNE PAQUETTE. Can. J. Chem. **67**, 2201 (1989).

Excess surface heat capacity values $\Delta\bar{C}_{ps}$ have been calculated using several surface density models. It is expected that calaculated $\Delta\bar{C}_{ps}$ values would be negative to be thermodynamically consistent. Using bulk liquid volume data as a means of calculating first estimates of surface volumes yields positive $\Delta\bar{C}_{ps}$ for a group of compounds of wide polarity. However, a simple linear or non-linear surface density model relating bulk density to surface density and reduced temperatures has been shown to yield negative values of $\Delta\bar{C}_{ps}$. This new surface density model is applicable to both polar and non-polar compounds and thus should prove useful for calculating molar surface areas for polar compounds which are necessary for calculating the surface tensions of polar–polar liquid mixtures.

Key words: excess surface heat capacity, surface density, monolayer model.

DOUGLAS EUGENE GOLDSACK et LISE JEANNE PAQUETTE. Can. J. Chem. **67**, 2201 (1989).

On a calculé les valeurs des capacités califiques $\Delta\bar{C}_{ps}$ des surfaces en excés, en utilisant plusieurs modéles de densité de surface. On prévoit que les valeurs de $\Delta\bar{C}_{ps}$ calculées seront négatives compte tenu de leurs propriétés thermodynamiques. L'utilisation des données à partir de gros volumes de liquide dans le but d'effectuer une première évaluation des volumes de surfaces, conduit à des valeurs positives de $\Delta\bar{C}_{ps}$ pour un groupe de composés de polarité très variée. On montre cependant qu'un modèle simple, linéaire ou non-linéaire, de densité de surface reliant la densité globale à la densité de surface et des températures réduites donnent des valeurs de $\Delta\bar{C}_{ps}$ négatives. Ce nouveau modèle de densité de surface est applicable à la fois aux composés polaires et non polaires qui sont nécessaires pour le calcul des tensions de surface des mélanges liquides polaire–polaire.

Mots clés: surface en excès, capacité calorifique, densité de surface, modèle monocouche.

[Traduit par la revue]

The various definitions of the surface tension, σ, of the surface of a liquid have been discussed in detail by Aveyard and Haydon (1). The reversible isothermal work done by a liquid to increase its surface area is associated with a free energy change which can be called the excess surface free energy. "This free energy is not the total free energy of the surface molecules but the excess free energy which the molecules possess by virtue of their being in the surface" (ref. 1, p. 2).

For the surface of a pure liquid, the combined first and second laws yield

$$[1] \quad d\bar{U}_s = Td\bar{S}_s - Pd\bar{V}_s + \sigma\, d\bar{a}$$

where $\bar{U}_s$ is the molar excess internal energy of the molecules in the surface, T, P and σ are the temperature, pressure, and surface tension of the liquid respectively and $\bar{S}_s$, $\bar{V}_s$, and $\bar{a}$ are the excess molar entropy, excess molar volume, and molar area of the liquid in the surface phase, respectively.

The excess Helmholtz free energy in the surface is defined as (ref. 1, p. 11, eq. [1.9]).

$$[2] \quad \bar{A}_s = \bar{U}_s - T\bar{S}_s$$

Total differentiation of this expression and utilizing eq. [1] leads to:

$$[3] \quad d\bar{A}_s = -\bar{S}_s dT - Pd\bar{V}_s + \sigma d\bar{a}$$

One definition, then, of the surface tension of the liquid surface is:

$$[4] \quad \sigma = \left(\frac{\partial \bar{A}_s}{\partial \bar{a}}\right)_{T,\bar{V}_s}$$

For n moles of liquid in the surface layer, the total area $a = n\bar{a}$ and the total excess Helmholtz surface free energy is $A_s = n\bar{A}_s$, hence the surface tension is also given by:

$$[5] \quad \sigma = \left(\frac{\partial A_s}{\partial a}\right)_{T,\bar{V}_s}$$

Hence, the surface tension can be considered as the Helmholtz free energy per unit area of the surface.

A useful equation is obtained by integrating eq. [3] at constant, T, P, and σ:

$$[6] \quad \bar{A}_s = -P\bar{V}_s + \sigma\bar{a}$$

Defining a molar Gibbs excess surface free energy as (ref. 1. p. 11, eq. [1.17])

$$[7] \quad \bar{G}_s = \bar{A}_s + P\bar{V}_s$$

then

$$[8] \quad \bar{G}_s = \sigma\bar{a}$$

To emphasize that $\bar{G}_s$ is the excess surface Gibbs free energy we introduce the Δ notation and define

$$[9] \quad \Delta\bar{G}_s = \sigma\bar{a} = \bar{G}_s$$

To relate the molar surface area $\bar{a}$ of the surface layer of the liquid to the molar volume of the liquid in the surface layer $\bar{V}_s$, it is necessary to invoke a model of the surface layer. The simplest model to utilize for the surface layer is that of a monolayer. The relation between $\bar{a}$ and $\bar{V}_s$ for such a monolayer is (2):

$$[10] \quad \bar{a} = X\bar{V}_s^{2/3}$$

Hence eq. [9] becomes:

$$[11] \quad \Delta\bar{G}_s = X\sigma\bar{V}_s^{2/3}$$

The geometric factor, X, has a value of 10.21 when $\Delta\bar{G}_s$ values are in J/mol, assuming spherical geometry for the molecules in a surface monolayer, with σ and $\bar{V}_s$ in units of ergs/cm^2 and cm^3/mol, respectively.

Given this expression for $\Delta\bar{G}_s$, all other thermodynamic

For personal use only.

surface difference properties can be obtained by appropriate differentiation. In particular, the molar excess heat capacity difference at constant pressure of the liquid, $\Delta\bar{C}_{ps}$, can be obtained from the temperature dependence of $\Delta\bar{G}_s$ by the relation:

$$[12] \quad \Delta\bar{C}_{ps} = -T\left[\frac{d^2\Delta\bar{G}_s}{dT^2}\right]_p$$

where T is the absolute temperature. Combining eqs. [11] and [12] leads to the following relation for $\Delta\bar{C}_{ps}$:

$$[13] \quad \Delta\bar{C}_{ps} = -TX\sigma\bar{V}_s^{2/3}\left\{\frac{1}{\sigma}\frac{d^2\sigma}{dT^2} + \frac{4\alpha_s}{3\sigma}\frac{d\sigma}{dT} + \frac{2}{3\bar{V}_s}\frac{d^2\bar{V}_s}{dT^2} - \frac{2}{9}\alpha_s^2\right\}$$

where α_s is the coefficient of thermal expansion of the liquid in the surface phase.

Since the difference in molar heat capacity of liquids between the bulk liquid and the vapor phase, $\Delta\bar{C}_{p,vap}$, is always negative (except at the critical point), then it should be expected that $\Delta\bar{C}_{ps}$, which is the difference in molar heat capacity between the liquid and surface phases, will also be negative. It has been observed that at the boiling point, $\Delta\bar{C}_{p,vap}$, is about -42 J/mol for a large variety of liquids (3). Therefore, it would be expected that $\Delta\bar{C}_{ps}$ under these conditions would be a fraction of this value, and in particular that $\Delta\bar{C}_{ps}$ should have a negative value for all liquids. It would be expected that for a large number of similar liquids, this value of $\Delta\bar{C}_{ps}$ should also be roughly constant similar to the constancy of $\Delta\bar{C}_{p,vap}$ and $\Delta\bar{S}_{vap}$ under these conditions (4).

In order to calculate $\Delta\bar{C}_{ps}$ values from observed surface tension and molar volume data according to eq. [13], it is necessary to have analytical expressions for these data as a function of temperature. In the case of surface tension, there are very few systems for which data are available over a wide range to obtain a value of $d^2\sigma/dT^2$ accurately. One such set of data is given by Moelwyn-Hughes (5) for CCl_4:

$$[14] \quad \alpha = 62.99 - 1.301 \times 10^{-1}\,T - 1.276 \times 10^{-5}\,T^2 + 7.33 \times 10^{-8}\,T^3$$

Since it is expected that $\Delta\bar{C}_{ps}$ should be negative, and since $d\sigma/dT$ is always negative, therefore ignoring the last two terms of eq. [13] for the moment, it is implied that the second derivative $d^2\sigma/dT^2$ must be positive and that the term

$$\frac{1}{\sigma}\frac{d^2\sigma}{dT^2}$$

must be greater than

$$\frac{4\alpha_s}{3\sigma}\frac{d\sigma}{dT}.$$

Equation [14] indeed gives values of $d^2\sigma/dT^2$ which are positive but only if the T^3 term in the equation of σ as a function of temperature is taken into account. Hence to calculate $\Delta\bar{C}_{ps}$ data for a number of systems, either surface tension must be available with high accuracy as a cubic expression of T or another analytic temperature-dependent function for σ must be used. One such function which has been found to apply to a large number of materials over a wide temperature range is the Guggenheim relation (6):

$$[15] \quad \sigma = \sigma_0(1 - T/T_C)^n = \sigma_0(1 - T_r)^n$$

where σ_0 is a constant for a particular material, T_C is the critical temperature for that material, T_r is the relative or corresponding temperature, and n is a constant generally found to be approximately equal to 11/9 for a large number of materials. From eq. [15] it is easily shown that the following relations hold:

$$[16] \quad \frac{d\sigma}{dT} = -\frac{n\sigma_0}{T_C}(1 - T_r)^{n-1}$$

$$[17] \quad \frac{d^2\sigma}{dT^2} = \frac{n(n-1)}{T_C^2}\sigma_0(1 - T_r)^{n-2}$$

For $n = 11/9$, these latter equations show that $d\sigma/dT$ is always negative and $d^2\sigma/dT^2$ is always positive. Furthermore, the relative values of the first and second terms of eq. [13] are then related by:

$$[18] \quad \frac{1}{\sigma}\frac{d^2\sigma}{dT^2} = -\frac{(n-1)}{T_C}(1 - T_r)^{-1}\frac{1}{\sigma}\frac{d\sigma}{dT}$$

Hence if

$$\frac{(n-1)}{T_C}(1 - T_r)^{-1}$$

is greater than α_s, then $\Delta\bar{C}_{ps}$ will always have a negative value, provided that the last two terms of eq. [13] can be neglected.

The simplest model used to obtain values for $\bar{V}_s$ and hence α_s, has been to equate the bulk and surface volume properties in order to obtain first estimates of various surface thermodynamic properties. This approximation is known not to be valid and several models have been developed to account for the difference between bulk and surface volume properties of the liquid (7–9). None of these models, however, lead to simple analytic relations between the bulk and surface volumes.

To obtain values of $\Delta\bar{C}_{ps}$ under comparable conditions, data were gathered from the literature (11–13), to calculate this parameter at the normal boiling points of a variety of non-polar and polar systems (Table 1). The normal boiling point is roughly a corresponding temperature for most materials and hence the various properties of liquids should have similar values under these conditions. $\Delta\bar{C}_{ps}$ values were calculated using first, bulk density data, to approximate the values of $\bar{V}_s$, the required values of α_s, and the first and second temperature derivatives of $\bar{V}_s$ at the boiling point. The results of these calculations are given in Table 2 and they indicate that by utilizing bulk values for $\bar{V}_s$ and α_s, positive values of $\Delta\bar{C}_{ps}$ are obtained in practically all cases in contradiction to what should be expected thermodynamically.

Another estimate of $\bar{V}_s$ and α_s can be obtained by assuming that $\bar{V}_s$ is proportional to $\bar{V}_B$ and that the temperature dependences of $\bar{V}_s$ and $\bar{V}_B$ are linear between the boiling and critical points. If $\bar{V}_C$ is the critical volume of the liquid, and if $\bar{V}_s = M\bar{V}_B$ where M is a constant, then the above assumptions yield:

$$[19] \quad \frac{d\bar{V}_B}{dT} = \frac{\bar{V}_C - \bar{V}_B}{T_C - T_B}$$

$$[20] \quad \alpha_B = \frac{1}{\bar{V}_B}\frac{d\bar{V}_B}{dT} = \frac{\left(\frac{\bar{V}_C}{\bar{V}_B} - 1\right)}{T_C\left(\frac{1 - T_B}{T_C}\right)}$$

$$[21]\quad \frac{d\bar{V}_s}{dT} = \frac{\bar{V}_C - \bar{V}_s}{T_C - T_B}$$

$$[22]\quad \alpha_s = \frac{1}{\bar{V}_s}\frac{d\bar{V}_s}{dT} = \frac{\left(\frac{\bar{V}_C}{\bar{V}_s} - 1\right)}{T_C\left(1 - \frac{T_B}{T_C}\right)}$$

At the boiling point, to a first approximation, $T_B = \frac{2}{3}T_C$ and $\bar{V}_B = \frac{1}{3}\bar{V}_C$ for many liquids (4). Under these conditions

$$[23]\quad \alpha_s = \alpha_B\left(\frac{3}{2M} - \frac{1}{2}\right)$$

Thus if $\bar{V}_s = 2\bar{V}_B$, then $\alpha_s = \frac{1}{4}\alpha_B$. One would expect that the surface thermal expansion coefficient α_s would be larger than the bulk liquid value α_B. That it is smaller would imply that the coordination number in the surface layer is smaller than that of the bulk layer (ref. 1, p. 2).

The calculation for $\Delta\bar{C}_{ps}$ was repeated using the above equations for $\bar{V}_s$ and α_s with $M = 2$. The results of these calculations are displayed in Table 3. It can be seen from these results that this second approximation to $\bar{V}_s$ now yields negative values for $\Delta\bar{C}_{ps}$ for all the cases concerned including non-polar and polar substances. In fact, eq. [13] shows that whereas the first term in brackets is independent of the model used for surface molar volume estimates, any model which predicts larger surface molar volumes and smaller surface coefficients of thermal expansion would make the $\Delta\bar{C}_{ps}$ values more negative than those calculated using bulk liquid parameters.

However, this improved model for $\bar{V}_s$ has two problems with it. First, it yields zero values for the $d^2\bar{V}_s/dT^2$ term and secondly, the maximum value that $\bar{V}_s$ can have is 3 times that of $\bar{V}_B$, which is an arbitrary upper value. A better approximation to

$\bar{V}_s$ can be obtained if instead of a linear relation between $\bar{V}_s$ and $\bar{V}_B$ being assumed, a more reasonable temperature dependence is utilized.

Guggenheim (ref. 5, p. 168) has shown that, for a variety of liquids, the bulk density of the liquid ρ_B, is related to the critical density of the liquid, ρ_C, and the reduced temperature T_r by the following equation:

$$[24] \quad \rho_B = \rho_C + \frac{3}{4}\rho_C(1 - T_r) + \frac{7}{4}\rho_C(1 - T_r)^{1/3}$$

For the surface volume to be larger than the bulk volume, assume:

$$[25] \quad \rho_s = \rho_C + \frac{3}{4}\frac{\rho_C}{M}(1 - T_r) + \frac{7}{4}\frac{\rho_C}{M}(1 - T_r)^{1/3}$$

where M is a constant, so that at T_C, ρ_s equals ρ_C independent of the value of M.

Taking the appropriate derivatives, eq. [24] and [25] lead to relations for α_s and $d^2\bar{V}_s/dT^2$ evaluated at the boiling points with $T_r = 2/3$:

$$[26] \quad \bar{V}_s = \frac{\bar{V}_C}{\left(1 + \dfrac{2.51}{M}\right)}$$

$$[27] \quad \alpha_s = -\frac{1}{\rho_s}\left(\frac{d\rho_s}{dT}\right)_p = \frac{1.96}{T_C(M + 1.46)}$$

$$[28] \quad \frac{1}{\bar{V}_s}\frac{d^2\bar{V}_s}{dT^2} = -\frac{1}{\rho_s}\left(\frac{d^2\rho_s}{dT^2}\right) + 2\alpha_s^2$$

If eqs. [26] through [28] are substituted in eq. [13], then an analytic expression is obtained for $\Delta\bar{C}_{ps}$ at the boiling points in terms of critical parameters $\bar{V}_C$, T_C, and M as follows:

$$[29] \quad \Delta\bar{C}_{ps} = -\frac{TX\sigma\bar{V}_C^{2/3}}{\left(1 + \dfrac{2.51}{M}\right)^{2/3}} \cdot \left[\frac{1}{\sigma}\frac{d^2\sigma}{dT^2} + \frac{2.61}{T_C(M + 1.46)} \times \frac{1}{\sigma}\frac{d\sigma}{dT} + \frac{1.63}{T_C^2(M + 1.46)} + \frac{4.26}{T_C^2(M + 1.46)^2}\right]$$

Values of $\Delta\bar{C}_{ps}$ were calculated using values of $M = 1$ to $M = 5$ and are displayed in Table 3. A value of $M = 5$ yields values of $\bar{V}_s \simeq 2\bar{V}_B$ and hence these calculated values of $\Delta\bar{C}_{ps}$ can be compared to those of the simpler linear $\bar{V}_s$ model under comparable conditions. Except for $M = 1$, which corresponds to the bulk density relations of eq. [24], calculation of $\Delta\bar{C}_{ps}$ values for $m = 2$ through $M = 5$ yield negative values for all cases of non-polar to extremely polar compounds.

Conclusions

From the calculated values given in Tables 2 and 3, thermodynamically consistent values of $\Delta\bar{C}_{ps}$ for all compounds are obtained only if models are utilized which yield $\bar{V}_s$ values which are larger than bulk values, $\bar{V}_B$. Furthermore, even a simple linear model for the temperature dependence of $\bar{V}_s$ between the boiling and critical temperatures yields thermodynamically consistent values of $\Delta\bar{C}_{ps}$.

It has been shown earlier (14) that improved values of the surface tension of mixtures of non-polar compounds are obtained if a model for calculating the surface volume is available to calculate molar surface area values. These calculations of $\Delta\bar{C}_{ps}$ show that either a linear temperature dependent relating $\bar{V}_s$ to $\bar{V}_C$ and $\bar{V}_B$ or the more general non-linear model of Guggenheim can be utilized as improved models for obtaining better estimates of molar surface area values than those calculated using bulk volume data. This conclusion is important to note particularly since these models seem to be applicable to even polar systems. Hence it would be expected that improved calculations of the surface tensions of mixtures of polar compounds would be possible if one of the above models were utilized in calculating surface molar area values for these polar compounds.

It is interesting to note that even for an order of magnitude change in the parameters affecting the $\Delta\bar{C}_{ps}$ equation, roughly constant values are obtained for a wide range of polarity of compounds for both the linear and non-linear models for the surface density equations.

Alkali metal salt solvation study in 1,1,3,3-tetramethylurea using nuclear magnetic resonance spectroscopy

LAURA ANN CIOLINO AND BARBARA JANE BARKER[1]
Department of Chemistry, Xavier University, Cincinnati, OH 45207-1096, U.S.A.

Received August 18, 1988[2]

LAURA ANN CIOLINO and BARBARA JANE BARKER. Can. J. Chem. **67**, 2206 (1989).

The solution behavior of a series of alkali metal tetraphenylborates, perchlorates, and iodides in 1,1,3,3-tetramethylurea (TMU) has been studied by proton nuclear magnetic resonance (NMR) spectroscopy. TMU has a simple proton NMR spectrum consisting of one singlet at 2.75 ppm. Alkali metal tetraphenylborates and perchlorates were observed to be dissociated in TMU. Sodium iodide, however, was observed to be associated in TMU. Present results are compared with those from other NMR investigations in TMU and related nonaqueous solvents.

Key words: alkali metal salt solvation, tetramethylurea, nuclear magnetic resonance, solute–solvent interactions.

LAURA ANN CIOLINO et BARBARA JANE BARKER. Can. J. Chem. **67**, 2206 (1989).

Faisant appel à la rmn du ^1H, on a étudié le comportement d'une série de tétraphénylborates, de perchlorates et d'iodures de métaux alcalins en solution dans la 1,1,3,3-tétraméthylurée (TMU). La TMU possède un spectre rmn du ^1H qui est simple et qui ne comporte qu'un singulet à 2,75 ppm. On a observé que, dans la TMU, les tétraphénylborates et les perchlorates des métaux alcalins sont dissociés. Toutefois, on a observé que l'iodure de sodium est associé dans la TMU. On compare ces résultats avec ceux obtenus au cours d'autres études par rmn tant dans la TMU que dans d'autres solvants apparentés et non-aqueux.

Mots clés : solvatation des sels de métaux alcalins, tétraméthylurée, résonance magnétique nucléaire, interactions soluté–solvant.

Introduction

Nuclear magnetic resonance (NMR) continues to be a useful technique for the study of electrolyte solution behavior. The occurrence of solute dissociation and solvation is inferred from probing either solute or solvent atom nuclei as a function of solute concentration.

In solution a variety of states is possible for solute and solvent molecules: solvated cations, solvated anions, solvent-separated ion pairs (all dissociated states); cation–anion pairs or aggregates (associated states); and bulk solvent. Since exchange among states is rapid, chemical shifts of either solute or solvent atom nuclei represent the average of all states.

If solvent protons are probed the chemical shift will be a linear function of salt concentration until association into ion pairs or aggregates occurs. If the cation is probed the chemical shift will be independent of salt concentration until association occurs.

Early reports described solution behavior of alkali metal salts in water (1–4). These salts remained dissociated and solvated until salt concentrations approached 5 to 15 molal (1, 2).

Later papers described solution behavior of alkali metal salts in nonaqueous solvents (5–10). Specific solvents included *N*-methyl-2-pyrrolidone (5, 6), 3-methyl-2-oxazolidone (7, 8), 1,3-dimethyleneurea (9), and 1,1,3,3-tetramethylurea (10).

Proton NMR revealed that alkali metal salts in *N*-methyl-2-pyrrolidone and 3-methyl-2-oxazolidone were dissociated until concentrations approached 1 molar (6–8). Proton NMR, used in the dimethyleneurea (DMEU) study, followed the chemical shifts of the solvent's methyl and ethylene protons. The salts, which included a variety of tetraphenylborates, perchlorates, and iodides, were dissociated until 0.75 molar (9).

Sodium-23 NMR, used in the tetramethylurea (TMU) study, followed the chemical shift of sodium for a variety of sodium salts. Sodium tetraphenylborate and perchlorate were dissociated until 0.5 molar. Sodium iodide formed contact ion pairs or aggregates which increased linearly with concentration (10).

The present investigation extends the study of alkali metal salt solution behavior in TMU. The chemical shift of the solvent protons is probed as a function of concentration for a series of tetraphenylborates, perchlorates, and iodides.

Experimental

1,1,3,3-Tetramethylurea was an Eastman Reagent Grade solvent. Cyclohexane was a Spectrochemical Grade NMR reference obtained from Matheson, Coleman, and Bell.

Sodium iodide (Mallinckrodt Analytical Reagent) and sodium perchlorate (Alfa Products) were recrystallized from acetone–ether solutions and dried *in vacuo* prior to use. Sodium tetraphenylborate (Baker Analyzed Reagent), lithium and potassium perchlorate (both Alfa Products), potassium iodide (Fisher Scientific, certified ACS reagent), and rubidium iodide (Alfa Products) were dried at 100°C for several hours before use. Potassium, rubidium, and cesium tetraphenylborates were prepared by mixing aqueous, equimolar solutions of potassium perchlorate, rubidium iodide, or cesium nitrate (Ventron Alfa Products) with sodium tetraphenylborate. The tetraphenylborate salts were then recrystallized from acetone–ether solutions and dried for several hours.

A 100 MHz Jeol Model JMH-100 NMR spectrometer was used to verify the purity of TMU. A Varian T-60 NMR spectrometer with a constant probe temperature of 35°C was used to measure solution chemical shifts. Wilmad Glass Co. and Norell, Inc. were the suppliers of NMR tubes.

Tetramethylurea was refluxed for several hours and vacuum distilled over barium oxide powder (G. Frederick Smith Chemical Co.). The distilled TMU was used immediately. Cyclohexane served as the internal reference at a nominal level of 5% by weight. Each salt solution was prepared by independent weighings. Concentrations were measured in molality since weight measurements used in molality determinations are unaffected by differences between ambient and probe temperatures. The usable concentration range was limited to 0.90 molal because of low solubility.

All NMR spectra were obtained immediately after solution preparation. Positions of the TMU and cyclohexane NMR signals were approxi-

mated to 0.2 Hz. The peak position of any broad NMR signal was determined by triangulation.

Blank determinations of the pure solvent shift accompanied each set of experiments. The NMR shifts of salt solutions were calculated relative to that of the pure solvent, with upfield shifts considered positive and downfield shifts considered negative. In most cases the experimental data were obtained from two independent sets of measurements.

Results and discussion

Tetramethylurea is a polar solvent with a dipole moment of 3.37 Debye units (11). TMU's intermolecular dipole–dipole interactions are strong as evidenced by its high boiling and melting points of 177°C and −1°C, respectively.

TMU has a moderately low dielectric constant of 23.45 (12) and a moderately high Gutmann donor number of 29.6 (13). The first factor is an indication that electrolyte dissociation is unfavorable. The second factor is an indication that electrolyte solvation is favorable. The expected result will be dissociation and solvation for some salts, and association for other salts in TMU.

A solvated cation will interact with TMU through its electronegative sites: the carbonyl oxygen and/or the two amide nitrogens. The oxygen site is more sterically accessible than the nitrogen sites. A solvated anion will interact with TMU through the electropositive carbonyl carbon. In both cases the ion–dipole interaction is expected to further polarize the TMU molecules in the solvation shell. The resulting polarization decreases electron density around the TMU protons of those molecules.

All of the solvent proton shifts are upfield for the tetraphenylborate salts in TMU (Table 1). This behavior for tetraphenylborate salts has also been observed in other nonaqueous

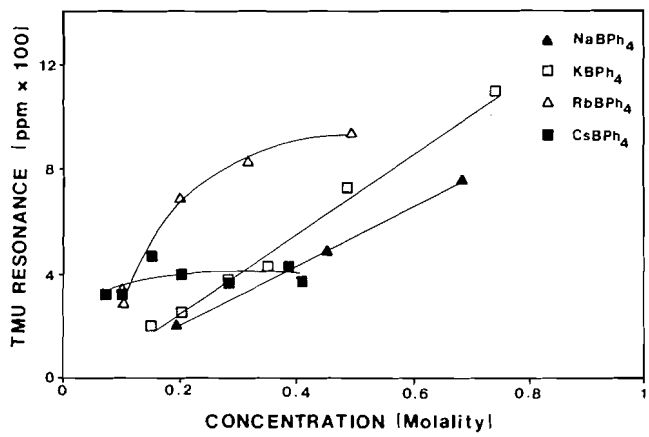

FIG. 1. Proton nuclear magnetic resonance shifts for tetramethylurea – alkali metal tetraphenylborate solutions. Shifts are upfield relative to pure TMU.

solvents (7–9). The increase in electron density around solvent protons is probably associated with the proximity of the protons to the π electron system in tetraphenylborates. An anion–dipole interaction can not explain the observation because it will be small due to the small charge density of the anion. Furthermore, it is expected to cause a downfield shift resulting from polarization of the TMU molecule.

The sodium and potassium tetraphenylborate shifts increase linearly with concentration over the range studied (Fig. 1). Linearly increasing shifts are consistent with complete dissociation and solvation of cations and anions. The rubidium and cesium tetraphenylborates display curved or flat relationships,

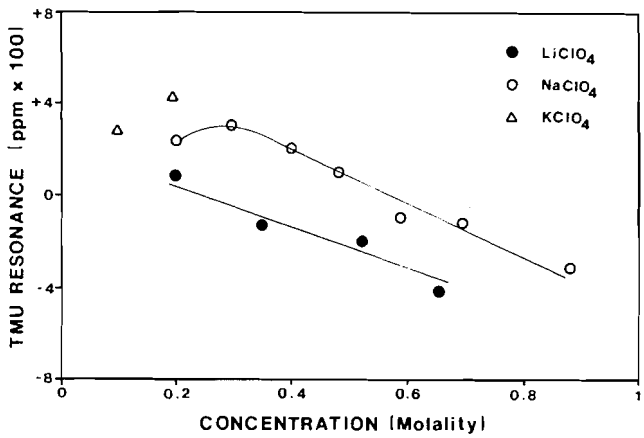

FIG. 2. Proton nuclear magnetic resonance shifts for tetramethylurea – alkali metal perchlorate solutions. Positive shifts are upfield and negative shifts are downfield relative to pure TMU.

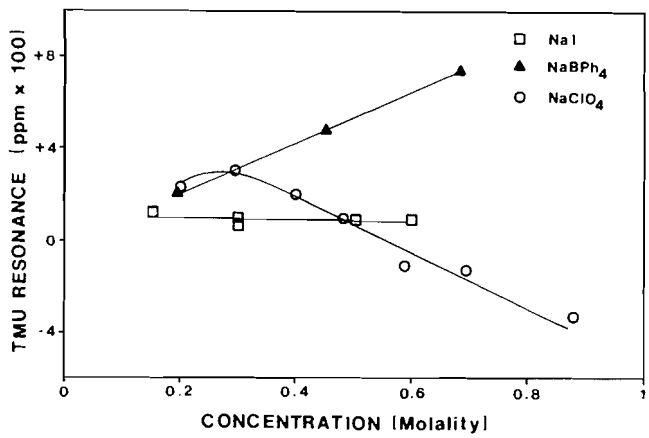

FIG. 3. Proton nuclear magnetic resonance shifts for tetramethylurea – sodium salt solutions. Positive shifts are upfield and negative shifts are downfield relative to pure TMU.

respectively, with increasing concentration. This observation suggests the formation of cation–anion pairs or aggregates which essentially eliminates the ionic interaction with the solvent.

The magnitude of the upfield shifts for the tetraphenylborates decreases in the order $Rb^+ > K^+ > Na^+$. This increase in downfield shift from rubidium to sodium correlates with the increasing strength of the cation–dipole interaction in the series. The increasing charge density from rubidium to sodium corresponds to increasing solvent polarization.

The perchlorates display slight upfield shifts below 0.4 molal, followed by linear downfield shifts above 0.4 molal (Fig. 2). The perchlorate anion has no special mode of interaction with TMU. It is expected to have only a small polarizing (downfield) effect due to its large size. Thus, the chemical shifts are expected to be primarily due to cation–TMU interactions.

The perchlorates are considered to be dissociated and solvated throughout the range studied. The initial upfield shifts are interpreted as "structure breaking." Dipole–dipole interactions between solvent molecules are being replaced by ion–dipole interactions between cation and solvent molecules. Although the latter are stronger interactions, they disrupt the bulk solvent structure such that the number of dipole–dipole interactions decreases disproportionately to the number of new cation–dipole interactions. At higher concentrations the number of ion–dipole interactions is sufficient to provide an overall net polarization. The direction of the shifts changes to downfield; the shifts increase linearly with concentration.

The magnitude of the downfield shift is larger for lithium than for sodium. This observation is consistent with the greater strength of the lithium ion – TMU dipole interaction. The higher charge density of lithium relative to that of sodium causes greater polarization.

The chemical shifts for sodium iodide in TMU are concentration independent over the range investigated (Fig. 3). The shifts versus bulk solvent are near zero. These two results indicate that there is no net increase in TMU–salt interaction as concentration increases and that the effect on proton environments is small. Therefore, sodium iodide is considered to be associated in TMU.

Results from the present investigation agree well with those from the sodium-23 NMR study in TMU (10). Solution behavior for the salts studied in common was observed to be the same; i.e., dissociation for sodium tetraphenylborate and sodium perchlorate, and association for sodium iodide.

Chemical shift data from the present investigation for TMU are analogous to chemical shift data for DMEU (9). Studied in common were sodium and potassium tetraphenylborate, lithium and sodium perchlorate, and sodium iodide. Sodium iodide, however, was considered to be dissociated in DMEU (9), even though the shifts showed no concentration dependence.

Synthesis of complexes of the type *cis*-Pt(amine) (unsaturated ligand)Cl_2 and crystal structure of *cis*-Pt(methylamine) (dimethylhexynediol)Cl_2

F. D. ROCHON, R. MELANSON, AND MONIQUE DOYON

Département de chimie, Université du Québec à Montréal, C.P. 8888, succ. A., Montréal (Qué.), Canada H3C 3P8

Received August 2, 1988[1]

F. D. ROCHON, R. MELANSON, and MONIQUE DOYON. Can. J. Chem. **67**, 2209 (1989).

Complexes of the type *cis*-Pt(L)(un)Cl_2 where L = primary amine or methyl derivative of pyridine and un = cyclopentene, cyclohexene, or dimethylhexynediol, have been synthesized from the reaction of K[Pt(L)Cl_3] with the unsaturated ligand in water. The compounds were characterized and studied by ^{1}H NMR and IR spectroscopy. The crystal structure of *cis*-Pt(CH_3NH_2)-((CH_3)$_2$C(OH)—C≡C—C(OH)(CH_3)$_2$)Cl_2 was determined by X-ray diffraction methods. The crystals are monoclinic, space group $P2_1/c$, with a = 6.544(2), b = 14.304(7), c = 15.508(7) Å, β = 109.39(2)°, and Z = 4. The coordinates and the anisotropic thermal factors were refined by full-matrix least-squares analysis to a R factor of 0.048 and wR = 0.047. The coordination around the platinum atom is square planar and the acetylenic ligand is perpendicular to the Pt plane.

Key words: platinum complexes, crystal structure, methylamine, dimethylhexynediol, synthesis.

F. D. ROCHON, R. MELANSON et MONIQUE DOYON. Can. J. Chem. **67**, 2209 (1989).

Des complexes de type *cis*-Pt(L)(un)Cl_2 où L = amine primaire ou un dérivé méthyle de la pyridine et un = cyclopentène, cyclohexène ou diméthylhexynediol, ont été synthétisés par la réaction de K[Pt(L)Cl_3] avec le ligand insaturé en milieu aqueux. Les composés ont été caractérisés et étudiés par spectroscopie IR et par RMN du proton. La structure cristalline de *cis*-Pt-(CH_3NH_2)((CH_3)$_2$C(OH)—C≡C—C(OH)(CH_3)$_2$)Cl_2 a été déterminée par diffraction des rayons-X. Le composé appartient au groupe spatial $P2_1/c$, a = 6.544(2), b = 14.304(7), c = 15.508(7) Å, β = 109.39(2)° et Z = 4. Les coordonnées et les facteurs thermiques anisotropes ont été affinés par moindres-carrés à matrice entière jusqu'à R = 0.048 et wR = 0.047. La coordination autour de l'atome de Pt est plane et le ligand acétylénique est perpendiculaire au plan du platine.

Mots clés: complexes de platine, synthèse méthylamine, diméthylhexynediol, structure cristalline.

Introduction

No general method for the synthesis of complexes of the type *cis*-Pt(amine)(un)Cl_2 where un = alkene or alkyne derivatives, has been reported yet, except for *cis*-Pt(NH_3)(C_2H_4)Cl_2 (1), *cis*-Pt(pyridine)(C_2H_4)Cl_2 (2) and a few compounds with very bulky amines (3, 4). These compounds are usually prepared from the monoamine compound K[Pt(amine)Cl_3]. Although K[Pt-(NH_3)Cl_3] (5, 6) and K[Pt(pyridine)Cl_3] (7) have been reported, the methods used to synthesize these compounds are not suitable for the preparation of primary amine analogs.

Trans compounds containing pyridine derivatives and unsaturated ligands have been known for a long time (2, 8, 9). Compounds of the type K[Pt(un)Cl_3] have been reported (8, 10–12) and their reactions with pyridine derivatives (py) give *trans*-Pt(py)(un)Cl_2 because of the large *trans* effect of alkenes and alkynes. Much of the work reported on alkynes has been done with bulky ligands like (CH_3)$_3$C—C≡C—C(CH_3)$_3$ and glycols of the type R_2C(OH)—C≡C—C(OH)R_2 since ligands like R—C≡C—H do not form stable Pt(II) π complexes.

Crystal structure analysis of several platinum – unsaturated ligand complexes consistently showed that the olefin or alkyne was perpendicular to the platinum coordination plane (10–13).

Recently, we have reported a new method to synthesize K[Pt(amine)Cl_3] with primary amines (14). The reactions of these compounds with two cyclic alkenes and with dimethylhexynediol (DMHD) have been studied. Compounds of the type *cis*-Pt(amine)(un)Cl_2 have been isolated and characterized mainly by IR and ^{1}H NMR spectroscopy. A few compounds *cis*-Pt(py)(un)Cl_2 with pyridine derivatives were also synthesized and characterized. One of the compounds *cis*-Pt(CH_3NH_2)-((CH_3)$_2$C(OH)—C≡C—C(OH)(CH_3)$_2$)Cl_2 gave crystals suitable for crystallographic studies and its structure was determined. The results are discussed below.

[1]Revision received June 27, 1989.

Experimental Section

K_2PtCl_4 was bought from Johnson Matthey and Co. Limited and was recrystallized from water. The elemental analyses were performed by Galbraith Laboratories. The IR spectra were measured on a P.E. 783 or Digilab FT50 (CsI beamsplitter). The ^{1}H NMR spectra were recorded on a Varian EM-360L (60 MHz) equipped with a signal averager V-2048.

K[Pt(amine)Cl_3]

These compunds were synthesized according to the method described recently (14).

K[Pt(pyridine)Cl_3]

These compounds with py = 2-picoline, 3-picoline, and 2,4-lutidine were synthesized according to the method already reported (7). Yield 85–90%

cis-*Pt(pyridine)(un)Cl_2 (un = cyclopentene (CPE) and cyclohexene (CHE)*

One millimole of K[Pt(py)Cl_3] is dissolved in a minimum quantity of water and the solution is filtered. Four millimoles of the unsaturated ligand is added to the filtrate and the mixture is stirred at room temperature for 24 h (or 48 h for cyclohexene). The precipitate is then filtered, washed with cold water, dried, washed with ether, and dried under vacuum in the presence of P_2O_5.

cis-*Pt(2,4-lutidine)(CPE)Cl_2* dec. 143–155°C; IR(cm^{-1}): ν(C=C aromatic) 1622 and ν(Pt—Cl) 341,320; NMR(DMSO-d_6), δ(ppm); 5.70 (un).

cis-*Pt(2,4-lutidine)(CHE)Cl_2* dec. 150–185°C; IR(cm^{-1}): ν(C=C aromatic) 1627 and ν(Pt—Cl): 341,315; NMR(DMSO-d_6) δ(ppm): 5.50 (un).

cis-*Pt(2-picoline)(CPE)Cl_2* dec. 143–168°C; IR(cm^{-1}): ν(C=C aromatic) 1602, 1560 and ν(Pt—Cl) 337,321; NMR (acetone-d_6) δ(ppm): 5.70 s + d (un) $J(^{195}Pt—H_{un})$ = 82 Hz.

cis-*Pt(3-picoline)(CPE)Cl_2* dec. 138–149°C; IR(cm^{-1}): ν(C=C aromatic) 1604, 1582 and ν(Pt—Cl) 337,323; NMR (acetone-d_6) δ(ppm): 5.69 s + d (un) $J(^{195}Pt—H_{un})$ = 82 Hz.

cis-*Pt(2-picoline)(CHE)Cl*$_2$ dec. 142–188°C; IR(cm^{-1}): ν(C═C aromatic) 1606, 1563 and ν(Pt—Cl): 338,320; NMR(dimethylacetamide) δ(ppm): 5.60 s (un).

cis-*Pt(2,4-lutidine)(DMHD)Cl*$_2$ *(DMHD = dimethylhexynediol)*

One millimole of K[Pt(2,4-lutidine)Cl$_3$] is dissolved in a minimum quantity of water and the solution is filtered. Three millimole of DMHD are added and the mixture is stirred at 10°C for 5 days. The precipitate is then filtered, washed with cold water, dried, washed with ether, and dried under vacuum over P_2O_5. Dec. at 127–132°C; IR (cm^{-1}): ν(O—H) 3422, ν(C≡C) 2001, ν(C═C aromatic) 1623 and ν(Pt—Cl) 339,311; NMR(CD_3OD) δ(ppm): 3.16 s + d (2-CH_3) $^4J(^{195}Pt—H)$ = 10 Hz, 2.41 s (4-CH_3), 8.87 d + dd (H_6) $^3J(H_6—H_5)$ = 6 Hz and $^3J(^{195}Pt—H_6)$ = 38 Hz, 7.25 m (H_3 + H_5) and 1.65 m (DMHD).

cis-*Pt(amine)(un)Cl*$_2$

These compounds were prepared by the method described for the synthesis of *cis*-Pt(2,4-lutidine)(DMHD)Cl$_2$ except that the mixture was stirred for 48 h.

cis-*Pt(CH_3NH_2)(CPE)Cl*$_2$ dec. 122–128°C, IR (cm^{-1}): ν(N—H) 3236, 3201, 3191, δ(N—H) 1582, ν(Pt—Cl) 337, 318; *cis*-Pt(CD_3ND_2)(CPE)Cl$_2$ IR (cm^{-1}): ν(N—D) 2421, 2367, 2318, δ(N—D) 1168; NMR (acetone-d_6) δ(ppm): 2.61 t + dt (CH_3) ^3J(H—H) = 7 Hz and $^3J(^{195}Pt—H_{un})$ = 40 Hz, 5.40 s + d (un) J(Pt—H_{un}) = 80 Hz.

cis-*Pt($C_2H_5NH_2$(CPE)Cl*$_2$ dec. 128–135°C, IR (cm^{-1}): ν(N—H) 3242, 3195, 3124, δ(N—H) 1579, ν(Pt—Cl) 338, 310; NMR (acetone-d_6) δ(ppm): 1.23 t (CH_3) ^3J(H—H) = 8 Hz, 5.30 s + d (un) $J(^{195}Pt—H_{un})$ = 80 Hz.

cis-*Pt(CH_3NH_2)(DMHD)Cl*$_2$ dec. 160–173°C, IR (cm^{-1}): ν(N—H) 3264, 3206, 3140, ν(O—H) 3465, ν(C≡C) 2007, δ(N—H) 1581, ν(Pt—Cl) 340, 320; NMR (CD_3OD) δ(ppm): 2.45 t + dt (CH_3) ^3J(H—NH_2) = 7 Hz, ^3J(Pt—H) = 44 Hz, 1.70 s (DMHD).

cis-*Pt(cyclobutylamine)(DMHD)Cl*$_2$ dec. 140–150°C, IR (cm^{-1}): ν(N—H) 3214, 3116, ν(O—H) 3385, ν(C≡C) 2001, δ(N—H) 1577, ν(Pt—Cl) 336, 316; NMR (CD_3OD) δ(ppm): 1.70 s (DMHD).

cis-*Pt(cyclopentylamine)(DMHD)Cl*$_2$ dec. 150–155°C, IR (cm^{-1}): ν(N—H) 3246, 3183, 3105, ν(O—H) 3420, ν(C≡C) 2006, δ(N—H) 1582 ν(Pt—Cl) 339, 321; NMR (CD_3OD) δ(ppm): 1.70 s (DMHD).

Collection and reduction of X-ray data

Crystals of *cis*-Pt(CH_3NH_2)((CH_3)$_2$C(OH)—C≡C—C(OH)(CH_3)$_2$)Cl$_2$) were recrystallized from acetone. A yellow hexagonal plate was selected for structure anaysis after examination under a polarizing microscope for homogeneity. The crystal was mounted roughly along the *c* axis. Precession photographs showed that the crystal was monoclinic with the systematic absences of $P2_1/c$. The unit cell parameters were obtained by least-squares refinements of angles 2θ, ω, and χ for 15 well-centered reflections on a Syntex P$\bar{1}$ diffractometer using graphite-monochromatized MoKα radiation. Scan rates and data treatment have already been described (15). A total of 4010 independent reflections were measured with 2θ < 60°. Corrections were made for absorption and Lorentz-polarization effects. Anomalous dispersion terms (16) were also included in the calculations. A set of 2700 observed reflections was used for the structure determination.

Crystal data

$C_9H_{19}NO_2Cl_2Pt$ mw = 439.25

Monoclinic, $P2_1/c$, a = 6.544(2), b = 14.304(4), c = 15.508(8) Å, β = 109.39(2)°, V = 1369.3(7) Å^3, Z = 4, F(000) = 832, D_x = 2.130, D_m = 2.16(3) Mg m^{-3}, λ(MoKα) = 0.71069 Å, μ(Mokα) = 10.728 mm^{-1}, and T = 295 K.

Structure solution

The coordinates of the platinum atom were found from a three-dimensional Patterson synthesis. The positions of all the other non-hydrogen atoms were obtained by structure factor and Fourier-map calculations. The refinements were done by using full-matrix least-squares minimizing $w(F_o - F_c)^2$. Isotropic secondary-extinction corrections (17) were included in the calculations. The two H atoms in the —NH_2 group were fixed at their calculated positions with isotropic B = 0.06 Å^2. Attempts were made to locate the H atoms in the methyl groups but without success. Individual weights $w = 1/\sigma^2(F)$ were applied. The refinement of the scale factor, coordinates and anisotropic temperature factors of all atoms converged to R = 0.048 and wR = 0.047. The ratio of maximum least-squares shift to esd in final refinement cycle was 0.20. There were a few residual peaks (<1.35 e A^{-3}) in the close environment of the Pt atom. The final positional parameters are listed in Table 1.

TABLE 1. Positional parameters with their esd's and temperature factors (10^4) $U_{eq} = (1/3)\Sigma_i\Sigma_j U_{ij} a_i^* a_j^* \bar{a}_i \cdot \bar{a}_j$

The atomic scattering factors of Cromer and Waber (18) were used for Pt, Cl, O, N, and C atoms, and those of Stewart, Davidson, and Simpson (19) were used for H. The calculations were done on a Cyber 830 with programs already described (15). Tables of final observed and calculated structure factors, and anisotropic thermal parameters are available.[2]

Results and discussion

Complexes of the type *cis*-Pt(L)(un)Cl$_2$ were prepared from the reaction of K(Pt)(L)Cl$_3$] with the unsaturated ligand in water.

$$K[Pt(L)Cl_2] + un \xrightarrow{H_2O} cis\text{-}Pt(L)(un)Cl_2 + KCl$$

In water, only the *cis* isomers are formed since the *trans* effect of Cl > N ligands. With un = cyclopentene (CPE), compounds with L = methylamine, ethylamine, 2-picoline and 2,4-lutidine were synthesized. When un = cyclohexene (CHE), the synthesis with primary amines was not successful. Only compounds with 2-picoline, 3-picoline, and 2,4-lutidine could be isolated. When L = dimethylhexynediol (DMHD), compounds with methylamine, cyclobutylamine, cyclopentylamine, and 2,4-lutidine were prepared. No compounds with isopropylamine or *t*-butylamine could be prepared with any of the three unsaturated ligands, probably because of steric hindrance caused by two

[2]Lists of the elemental analysis of the complexes *cis*-Pt(L)(un)Cl$_2$ (Table S1), the anisotropic thermal parameters (Table S2), the weighted least-squares planes (Table S3), the distances and angles for hydrogen bonds (Table S4), the fixed coordinates of the H atoms (Table S5), and the final observed and calculated structure factors (Table S6, 15 pages) may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

bulky ligands in *cis* position. The results of the elemental analyses have confirmed the composition $Pt(L)(un)Cl_2$ (see footnote 2 for supplementary material). The compounds were characterized by IR spectroscopy and by proton NMR.

The stretching bands $\nu(C{\equiv}C)$ and $\nu(Pt{-}Cl)$ for the complexes are shown in the Experimental section. The $\nu(C{\equiv}C)$ band for the complexes containing DMHD was observed between 2001 and 2007 cm^{-1}. This vibration absorbs at 2010 cm^{-1} in $K[Pt(DMHD)Cl_3]$ and at 2035 cm^{-1} in *trans*-$Pt(DMHD)(py)Cl_2$ (12). Therefore the *cis* isomers seem to absorb at lower frequency that the *trans* isomers. The free ligand DMHD absorbs in Raman at 2248 cm^{-1} (20). This reduction of frequency upon coordination has been explained by the nature of the Pt—DMHD bond (12).

All the *cis* compounds showed two $\nu(Pt{-}Cl)$ bands between 311 and 341 cm^{-1}. *trans*-$Pt(py)(DMHD)Cl_2$ with py = pyridine, 2-picoline, and 2,6-lutidine showed only one stretching $\nu(Pt{-}Cl)$ band at 337–340 cm^{-1} (8). Courtot *et al.* (2) also observed one $\nu(Pt{-}Cl)$ for *trans*-$Pt(py)(C_2H_4)Cl_2$ at 340–346 cm^{-1} and two bands for the *cis* isomers between 315 and 343 cm^{-1}. These results on the vibrations $\nu(C{\equiv}C)$ and $\nu(Pt{-}Cl)$ show that IR spectroscopy is a good method to determine the geometry of such isomers.

The ^1H NMR spectra of the compounds *cis*-$Pt(L)(un)Cl_2$ were measured in deuterated DMSO, DMF, acetone, or methanol but the compounds are not very soluble. The *cis* complexes partly isomerise in DMSO. For the pyridine derivatives, the values are very similar to those of the free ligands, but for the amine complexes, the resonances were observed at slightly higher field (~0.3 ppm). The observed shielding might be explained by a slight modification of the secondary anisotropic field caused by the π electrons of the unsaturated ligand. The coupling constants $J(^{195}Pt{-}{}^1H_{un})$ = 80–82 Hz slightly larger than the values observed for C_2H_4 complexes (61–67 Hz) (1, 2, 4). A coupling constant $^3J(^{195}Pt{-}{}^1H)$ of 40 Hz (for the methyl protons) was also observed in the complex *cis*-$Pt(CH_3NH_2)(CPE)Cl_2$. This value agrees well with the value of 44 Hz reported for $K[Pt(CH_3NH_2)Cl_3]$ (14). In the complexes *cis*-Pt(amine)$(DMHD)Cl_2$ the methyl groups of DMHD appear as a singlet around 1.70 ppm while in *cis*-Pt(2,4-lut)$(DMHD)Cl_2$ they appear as a multiplet.

Crystal structure

A labelled diagram of the molecule *cis*-$Pt(CH_3NH_2)(DMHD)Cl_2$ is shown in Fig. 1. The bond distances and angles are listed in Table 2. As expected from IR spectroscopy, the compound is the *cis* isomer. The coordination around the Pt atom is square planar, and the mid-point X of C(4)—C(5) triple bond occupies the fourth corner of the plane. The deviations from the best plane are Pt, 0.0000(3); Cl(1), −0.006(3); Cl(2), 0.007(3); N, 0.050(8) and X, −0.087 Å, and the angles around the Pt atom are close to the expected 90 and 180°.

The Pt—Cl (2.300(3) and 2.302(3) Å and the Pt—N (2.055((8) Å) bonds are normal and agree well with published values found in aminochloroplatinum(II) complexes (10, 11, 14). There is no lengthening of the bond in *trans* position to the acetylenic ligand. Therefore the *trans* influence of acetylenic ligands is not large. The Pt—C distances are 2.138(9) and 2.118(9) Å while the Pt—X distance is 2.039 Å. The acetylenic ligand is perpendicular to the platinum plane as observed in other Pt – acetylenic glycol complexes (10, 11). The angle between the best plane through C(3), C(4), C(5), and C(6) and the Pt plane is 92.4°. The two acetylenic carbon atoms C(4) and C(5) are located at 0.520(8) and −0.694(9) Å, respectively, from the platinum plane.

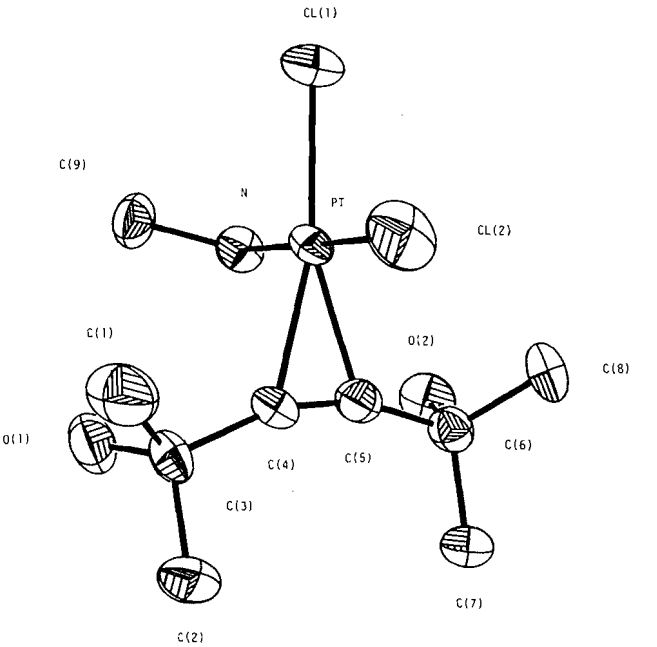

FIG. 1. Labelled diagram of the molecule *cis*-$Pt(CH_3NH_2)(DMHD)Cl_2$.

TABLE 2. Bond distances (Å) and angles (deg)

Bond	Distance	Bond	Distance
Pt—Cl(1)	2.300(3)	C(3)—C(4)	1.51(1)
Pt—Cl(2)	2.302(3)	C(5)—C(6)	1.52(1)
Pt—N	2.055(8)	C(3)—C(1)	1.51(2)
Pt—C(4)	2.138(9)	C(3)—C(2)	1.52(1)
Pt—C(5)	2.118(9)	C(6)—C(7)	1.56(1)
Pt—X	2.039	C(6)—C(8)	1.52(1)
N—C(9)	1.48(1)	C(3)—O(1)	1.47(1)
C(4)—C(5)	1.22(1)	C(6)—O(2)	1.47(1)

Bonds	Angle	Bonds	Angle
Cl(1)—Pt—Cl(2)	90.0(1)	C(4)—C(3)—C(1)	112.1(8)
Cl(1)—Pt—N	88.9(2)	C(4)—C(3)—C(2)	108.9(8)
Cl(2)—Pt—N	178.1(3)	C(4)—C(3)—O(1)	107.4(7)
Cl(1)—Pt—X	177.4	C(1)—C(3)—C(2)	113.1(8)
Cl(2)—Pt—X	89.6	C(1)—C(3)—O(1)	105.9(8)
Pt—N—C(9)	115.5(6)	C(2)—C(3)—O(1)	109.2(8)
N—Pt—X	91.6	C(5)—C(6)—O(2)	106.6(7)
C(3)—C(4)—C(5)	160.2(9)	C(7)—C(6)—C(8)	112.2(8)
C(4)—C(5)—C(6)	161.2(9)	C(7)—C(6)—O(2)	109.4(7)
C(5)—C(6)—C(7)	109.5(7)	C(8)—C(6)—O(2)	108.0(7)
C(5)—C(6)—C(8)	111.0(8)		

The triple bond distance C(4)—C(5) is 1.22(1) Å, which is not significantly different from a normal triple bond. However, the C(3)—C(4)—C(5)—C(6) segment of the coordinating ligand is not linear. The C(3) and C(6) atoms are displaced, producing a *cis* deformation in the direction opposite to the platinum atom. The C—C≡C angles are 160.2(9) and 161.2(9)°. These results are similar to those observed in other Pt – acetylenic glycol structures (10, 11). The two hydroxyl groups are in *cis* position to each other, on the same side of the plane through C(3), C(4), C(5), and C(6) towards the CH_3NH_2

ligand. The deviations from the best plane are O(1) −1.407(7) and O(2) −1.369(7) Å.

The packing of the molecules consists of layers of molecules parallel to the ***ac*** plane and centered at $y = 0$ and $\frac{1}{2}$. The amino groups are hydrogen bonded to one of the hydroxyl groups while the hydroxyl groups are hydrogen bonded to the cloro ligands.

Solubility of ammonia in chloroform: analysis in terms of Henry's law and the equilibrium constant for hydrogen-bonded complex formation

JOHN F. SMITH, CHARLES LI, MYRON ROTH, AND LOREN G. HEPLER
Department of Chemistry, Univerity of Alberta, Edmonton, Alta., Canada T6G 2G2
Received March 15, 1989

JOHN F. SMITH, CHARLES LI, MYRON ROTH, and LOREN G. HEPLER. Can. J. Chem. **67**, 2213 (1989).

We have measured the solubility of ammonia in chloroform at several pressures and at three temperatures (25, 30, and 35°C). Results of these measurements have been analysed in terms of the Henry's law constant that applies to "simple" dissolution of the type B(g) = B(dissolved) and the equilibrium constant K for the liquid phase complex-forming equilibrium represented by A + B = AB where A and B represent chloroform and ammonia, respectively. As expected on the basis of this analysis, ammonia is more soluble (same pressure and temperature) in chloroform than in carbon tetrachloride, where no hydrogen-bonded complex can be formed.

Key words: gas solubility, hydrogen-bonded complexes, Henry's law constant, ammonia–chloroform complex, chloroform–ammonia complex.

JOHN F. SMITH, CHARLES LI, MYRON ROTH et LOREN G. HEPLER. Can. J. Chem. **67**, 2213 (1989).

On a mesuré la solubilité de l'ammoniac dans le chloroforme à plusieurs pressions et à trois températures (25, 30 et 35°C). On a analysé les résultats de ces mesures en fonction de la loi de Henry qui s'applique à des dissolutions « simples » du type B(g) = B(dissous) et de la constante d'équilibre K pour l'équilibre de la formation du complexe dans la phase liquide qui est représenté par l'équation A + B = AB dans laquelle A et B représentent respectivement le chloroforme et l'ammoniac. Comme on peut s'y attendre sur la base de cette analyse, l'ammoniac est plus soluble (à des pression et température semblables) dans le chloroforme que dans le tétrachlorure de carbone dans lequel il ne peut se former de complexes par liaisons hydrogènes.

Mots clés : solubilité des gaz, complexes par liaisons hydrogènes, constante de la loi de Henry, complexe ammoniac–chloroforme, complexe chloroforme–ammoniac.

Introduction

Analyses of the thermodynamic properties of non-electrolyte solutions are generally made by comparing the measured properties with the properties the solution would have if it were ideal. Attempts are then made to explain the observed deviations in terms of some model (or theory) of solutions. As a first step in the development of such a model it is often convenient to separate the deviations from ideality into "physical" and "chemical" contributions, with the latter being due to the formation of distinct new chemical species in the solution. This separation is an artificial one because there is no sharp dividing line between interactions that may be regarded as physical and those that may be regarded as chemical. Nevertheless, the distinction between the two contributions is useful if one of the contributions is much smaller than the other.

For mixtures of non-electrolytes in which chemical reactions are expected (or known) to occur between the components, a first approximation to the treatment of non-ideality can be made by considering all of the deviations from ideal solution properties to arise from chemical interactions. That is, physical interactions (usually accounted for by activity coefficients) are taken to be negligible in comparison to chemical interactions. The solution is, therefore, considered to be an ideal solution (activity coefficients equal to unity) of all the species present at equilibrium. This is known as the ideal associated solution model (1–3). A solution of A + B in which A and B interact according to the equilibrium

[1] $$A + B = AB$$

is treated by the ideal associated solution model by considering the solution to be an ideal mixture of A + B + AB.

Several studies (4–9) have shown that the ideal associated solution model can be applied successfully to many associated systems (A + B = AB) in which A and B are liquids. This success suggests the possibility that the model may be useful in the investigation of systems in which a dissolved gas, B, interacts chemically with the solvent, A, to form an associated complex, AB. In this case the solubility of the gas (and hence the equilibrium speciation of the system) is determined by both the liquid–vapour equilibrium and the association (in the liquid phase) equilibrium. The liquid–vapour equilibrium represents the physical process of dissolution of gas. For a dilute solution this process can be described by Henry's law. The association equilibrium represents the chemical interaction that results in the formation of complex. This type of chemical interaction may be approximated usefully by the ideal associated solution model.

In this paper we present a method in which data collected in investigations of gas solubility can be used to evaluate the equilibrium constant and the Henry's law constant for any system in which a reasonably stable 1:1 complex forms between the dissolved gas and the solvent. The use of this method is illustrated by applying it to the chloroform + ammonia system.

Solubilities of ammonia in chloroform (containing 0.1% ethanol) at 25°C and ammonia partial pressures of 2–60 kPa have been determined by Seward (10). We have made new measurements of the solubility of ammonia in pure chloroform at three temperatures and ammonia partial pressures of 50–300 kPa.

Derivation of equations

Consider a system in which a gas B is dissolved in a solvent A and a complex forms between the dissolved gas and the solvent according to eq. [1]. The gas molecules in solution exist either as dissolved B or as the complex AB. Therefore, the solubility of the gas depends on the Henry's law constant, k_H, for the system and on the equilibrium constant, K, for reaction [1]. In

TABLE 1. Mass balance in the liquid phase for reaction [1]

Species	Stoichiometric amount/mol	Stoichiometric mole fraction	Equilibrium[a] amount/mol	Equilibrium[b] mole fraction
A	N_A	x_A	$N_A - n_{AB}$	$z_A = (x_A - r)/(1-r)$
B	N_B	x_B	$N_B - n_{AB}$	$z_B = (x_B - r)/(1-r)$
AB	—	—	n_{AB}	$z_{AB} = r/(1-r)$

[a]Total number of moles at equilibrium is $(N_A + N_B - n_{AB})$.
[b]$r = n_{AB}/(N_A + N_B)$.

this section we derive a relationship between gas solubility (which can be determined experimentally) and the two constants (K and k_H) using the ideal associated solution model.

Assuming that the ideal association solution model is a valid approximation to the system (i.e., assuming that the system is an ideal solution of A + B + AB), we can express the association equilibrium constant in terms of the equilibrium mole fractions, z_i:

$$[2] \quad K = z_{AB}/z_A z_B$$

From mass balance considerations for an A + B = AB system (see Table 1) we can express the equilibrium mole fractions in terms of the stoichiometric mole fractions (x_i) and the extent of association (r):

$$[3] \quad z_A = (x_A - r)/(1 - r)$$

$$[4] \quad z_B = (x_B - r)/(1 - r)$$

$$[5] \quad z_{AB} = r/(1 - r)$$

Combining eqs. [2]–[5] with $x_A = 1 - x_B$, we obtain an expression for the equilibrium constant in terms of x_B (the mole fraction solubility of B in A) and r:

$$[6] \quad K = r(1 - r)/[x_B(1 - x_B) - r + r^2]$$

Equation [4] may be rearranged to obtain

$$[7] \quad r = (x_B - z_B)/(1 - z_B)$$

Substitution of eq. [7] into the numerator of eq. [6] yields (after rearranging)

$$[8] \quad r(1 - r) = (x_B - z_B)(1 - x_B)/(1 - z_B)^2$$

Similarly, substitution of the expression for r given by eq. [7] into the denominator of eq. [6] yields (after considerable rearranging)

$$[9] \quad x_B(1-x_B)-r+r^2=z_B(1-x_B)(1-2x_B+z_Bx_B)/(1-z_B)^2$$

Combination of eqs. [8] and [9] with eq. [6] then leads to an expression for the equilibrium constant for process [1] in terms of the mole fraction solubility of B in A (x_B) and the mole fraction of unassociated B in the solution at equilibrium (z_B):

$$[10] \quad K = (x_B - z_B)/[z_B(1 - 2x_B + z_Bx_B)]$$

Now we write Henry's law (in terms of the equilibrium mole fraction of unassociated B) as

$$[11] \quad p_B = k_H z_B$$

where p_B represents the partial pressure of gas above the solution and k_H represents Henry's law constant. Combination of eqs. [10] and [11] leads to

$$[12] \quad K = (k_H x_B - p_B)/[p_B(1 - 2x_B + p_B x_B/k_H)]$$

In the limit of $K = 0$ (no complex formation), $z_{AB} = 0$ and $z_B = x_B$ so that both eqs. [11] and [12] become $p_B = k_H x_B$, which is the conventional form of Henry's law for gases that do not react to form a complex with the solvent.

Using eq. [12] in the interesting case when $K \neq 0$ is complicated for two reasons. First, this equation cannot be rearranged into any other form such that a suitable graph of some function of "measurables" against another function of measurables will lead to a straight line with slope and intercept that will permit easy calculation of K and k_H. Second and more important, the partial pressure of gas B(p_B) and the stoichiometric mole fraction of B in solution (x_B) come directly from measurable quantities only in the special case of a solvent with negligible vapour pressure so that the measured total pressure may be taken equal to p_B.

Experimental

Chloroform (Caledon Lab Ltd.) was purified and stored as described previously (5). Ammonia (Medigas Ltd.) was used without further purification.

The measurements of gas solubility were made using an isobaric equilibrium solubility method and apparatus similar to that previously described by Morrison and Billett (11) and Hayduk, Walter, and Simpson (12). In this method a known amount of solvent is injected in a thin film into apparatus containing a known pressure of gas. As the gas dissolves in the solvent, a constant pressure is maintained inside the apparatus by addition (or removal) of a known volume of mercury. The amount of gas dissolved is then calculated from the change in gas volume, using an equation of state for the gas. The experimental quantities measured in this technique are the mass of solvent injected, m_A, the mass of mercury added to maintain the system at constant pressure, m_{Hg}, and the total pressure, P_t. Further details of the design and operation of this apparatus are given by Yan, Zhang, Singh, and Hepler (13) and Singh (14).

The experimental quantities, m_A and m_{Hg}, were measured for the chloroform + ammonia system at 298.15, 303.15, and 308.15 K over a pressure range of 80–300 kPa. Three values of m_A and m_{Hg} were measured at each temperature and pressure.

Pycnometers were used to measure the density of chloroform, and values of 1.4793 g cm^{-3} at 298.15 K, 1.4733 g cm^{-3} at 303.15 K, and 1.4679 g cm^{-3} at 308.15 K were obtained.

A new method and apparatus that are described in detail in ref. 15 were used to obtain a value of 30.3 cm^3 mol^{-1} for the partial molar volume of ammonia in dilute solution in chloroform.

Analysis of results

As we pointed out in the second section of this paper, use of eq. [12] to analyse gas solubility data is complicated when the solvent has appreciable vapour pressure. Because the vapour pressure of chloroform (A) is not negligible (at the temperatures of our investigations) and also depends on the amount of ammonia (B) that is dissolved (Raoult's law applied to the solvent), we have a "cyclic problem" that involves needing to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/07/12
For personal use only.

know p_B and x_B to obtain K and k_H from eq. [12]. Our method for solving this cyclic problem is described as follows.

Our general method is to find an estimate of k_H and then to find the values of all the other quantities that are most consistent with this estimate. In this way an estimate of K is found for each experiment and the average and standard deviation of these K values is calculated at each temperature. The estimate of k_H is now adjusted so that the standard deviation of K values is reduced. A new set of quantities that is consistent with this new estimate of k_H is obtained and the average and standard deviation of the resulting K values is calculated. The estimate of k_H is again adjusted and the procedure is repeated until the standard deviation of the K values at each temperature has been minimized.

We begin by noting that from Henry's law (in the form of eq. [11]) the last term in the denominator of eq. [12] can be expressed as $p_B x_B/k_H = z_B x_B$. Since formation of complex AB from B makes $z_B < x_B$, we see that $z_B x_B < x_B^2$ and thence that $z_B x_B < 2x_B$. We therefore obtain our first approximation to k_H by neglecting $p_B x_B/k_H$ in the denominator of eq. [12] and rearranging to obtain

$$[13] \quad x_B/p_B \sim (K/k_H)(1 - 2x_B) + (1/k_H)$$

This approximate expression shows that the extrapolated intercepts of (not quite linear) graphs of x_B/p_B against $(1 - 2x_B)$ for each temperature give first approximations to k_H at these same temperatures.

To find our first approximations for k_H from eq. [13] we need estimates of p_B and x_B for each experiment. First we express the measured total pressure (P_t) as the sum of the partial pressures of chloroform (p_A) and ammonia (p_B):

$$[14] \quad P_t = p_A + p_B$$

Because all of our solutions are dilute, we know that the vapour pressure of the solvent is in accord with Raoult's law expressed in terms of the equilibrium mole fraction of solvent in the solution (z_A) and the vapour pressure of pure A (p_A^0):

$$[15] \quad p_A = z_A p_A^0$$

Recognizing that z_A is close to unity for a dilute solution, we initially set $p_A = p_A^0$ in eq. [14] to obtain $p_B = P_t - p_A^0$ for further use. Vapour pressures of pure chloroform of 26.220 kPa at 298.15 K, 32.329 kPa a 303.15 K, and 39.542 kPa at 308.15 K were taken from the compilation of Smith and Srivastava (16).

Now we let ΔV represent the change in volume of the vapour space in the solubility apparatus when the solvent is introduced and mercury is added (or removed) to keep the total pressure constant. This ΔV can be expressed as

$$[16] \quad \Delta V = V_A + \bar{V}_B \Delta N_B + V_{Hg}$$

Here $\bar{V}_B$ represents the partial molar volume of solute B in dilute solution in solvent A. V_A and V_{Hg}, calculated from $V = m/\rho$, represent the volume of solvent added to the apparatus and the volume of mercury added to maintain constant pressure in the apparatus, respectively. ΔN_B represents the total number of moles of gas dissolved in the solvent at equilibrium. Since the amount of dissolved gas is small compared with $V_A + V_{Hg}$, a good first estimate of ΔV is obtained by setting $\Delta N_B = 0$ in eq. [16].

The volume of the vapour space (V) and the amount of gas in the vapour space (N_B) are related by the equation of state

$$[17] \quad p_B V = N_B(RT + \beta p_B)$$

in which β is the second virial coefficient of gaseous B. Subtracting eq. [16] for initial conditions from eq. [16] for final conditions and rearranging leads to

$$[18] \quad \Delta N_B = p_B \Delta V/(RT + \beta p_B)$$

We now insert in eq. [18] our estimates of p_B, ΔV (obtained as described above), and β (obtained by interpolation of the data compiled in ref. 17) to obtain a first estimate of ΔN_B, the amount of gas dissolved at equilibrium. Combination of this value of ΔN_B with the known number of moles of A injected (N_A) and with the defining equation for mole fraction of B in solution

$$[19] \quad x_B = \Delta N_B/(\Delta N_B + N_A)$$

leads to a value for the stoichiometric mole fraction of dissolved B (x_B). At each temperature and pressure the first approximation for x_B was taken to be the average of the three x_B values calculated from the three replicate measurements of m_A and m_{Hg}.

After carrying out the calculations (for each total pressure) outlined above in eqs. [14]–[19], we use the resulting estimates of p_B and x_B with eq. [13] to obtain first approximations for k_H at each temperature.

Our next step is to find the value of the equilibrium constant K that is most consistent with each value of k_H. Combination of the first approximations to k_H (obtained as above) with each x_B,p_B pair leads by way of eq. [12] to values of the equilibrium constant K. The average of all of these values of K at each temperature is calculated. We then solve the quadratic eq. [6] for r. Combination of the resulting equation with $x_A + x_B = 1$ and the defining equation for z_A (eq. [3]) gives

$$[20] \quad z_A = 1 - [K + 1 - [(1 + K - 2Kx_A)^2 + 4Kx_A^2]^{1/2}]/2Kx_A$$

Use of our average K value at each temperature with values of x_A (from the estimate of x_B for each experiment) now permits calculation of estimates of z_A. Substitution of these values of z_A into Raoult's law (eq. [15]) gives new estimates of p_A, and thence with eq. [14] we obtain new estimates of p_B. New estimates of ΔV are calculated from eq. [16] using the current estimates of ΔN_B. These values of ΔV are combined with the corresponding p_B values in eq. [18] to obtain new estimates of ΔN_B, which are then combined with N_A (number of moles of solvent injected) in eq. [19] to give new estimates of x_B. The x_B,p_B pairs are inserted in eq. [12] along with the first approximation for k_H to obtain new estimates of K for each experiment. Again the average of the K values is calculated and the iterative process is repeated until successive estimates of K differed by no more than 0.1% for each experiment. A maximum of four iterations was necessary to meet this requirement. At this point the average value of K at each temperature is taken to be the first approximation to K (i.e., the value of K that is most consistent with the first approximation to k_H).

Now we adjust the values of k_H so that the standard deviation of the K values at each temperature is reduced. We then use the procedure described above to find the value of K that is most consistent with the new approximation to k_H at each temperature. The value of k_H is further adjusted until the standard deviation of the individual K values at each temperature has been minimized. The values k_H, K, and all the other quantities (x_B, p_B, z_B, etc.) that correspond to this minimum are taken to be the "best" values for describing the chloroform + ammonia system and are internally consistent with measured total pressures, amounts of solvent added, Henry's law, and Raoult's

law. The values of k_H and K for the ammonia + chloroform system that were found in this way are listed in Table 2. The values of experimental total pressure, along with the derived values of partial pressure of ammonia (p_B), the stoichiometric mole fraction of dissolved ammonia (x_B), and the equilibrium mole fraction of free ammonia (z_B) are listed in Table 3.

Discussion

No published reports of the equilibrium constant for the formation of chloroform–ammonia complex are available for comparison with our results.

Our results are consistent with the expected strength of chloroform–ammonia association, as we now show. Ammonia is generally considered to be a weaker base than triethylamine (due to the inductive effect of the ethyl group) and a stronger base than benzene. We therefore expect the chloroform–ammonia complex to be less stable than the chloroform–triethylamine complex and more stable than the chloroform–benzene complex. On this basis we predict that the association equilibrium constant for chloroform + ammonia should be smaller than that for chloroform + triethylamine ($K = 2.6$ at 298 K; ref. 4) and larger than that for chloroform + benzene ($K = 0.45$ at 298 K; ref. 5). We have found, using the ideal associated solution model, that the chloroform + ammonia association equilibrium constant has a value of $K = 0.58$ at 298 K (see Table 2). This value is intermediate between $K = 2.6$ and $K = 0.45$ and thus is consistent with our prediction. Further studies (possibly spectroscopic) are necessary to investigate the accuracy of association equilibrium constants obtained using the method described in this paper.

Combining our values of K and k_H with a rearranged version of eq. [12], we calculate the mole fraction solubility of ammonia in chloroform at 298.15 K and a partial pressure of ammonia of 101.325 kPa to be 0.139. This is in excellent agreement with the value of 0.141 obtained by extrapolation (18) of the results of Seward (10) at 298.2 K to a partial pressure of ammonia of 101.325 kPa.

Matsui, Hepler, and Fenby (19) showed that in a very dilute solution of B in A (where A and B associate according to A + B = AB) the equilibrium amount of AB (n_{AB}) is related to the stoichiometric amount of B (N_B) by

$$[21] \quad n_{AB} = [K/(K + 1)]N_B$$

where K represents the association equilibrium constant. Substituting our value of $K_{298} = 0.58$ into eq. [21], we calculate that in a dilute solution of ammonia in chloroform 63% of the ammonia is in the uncomplexed form and 37% is in the complexed form.

The analysis of the chloroform + ammonia system presented in this paper is based on the premise that a 1:1 associated complex forms between the two components. That this is a reasonable proposal is seen by comparing the solubility of ammonia in chloroform with that of ammonia in carbon tetrachloride. The mole fraction solubility of ammonia in carbon tetrachloride (18, 20) is 0.0281 at 293.2 K and a partial pressure of ammonia equal to 101.325 kPa. We would expect a slightly smaller solubility at 298.15 K. The much larger solubility of ammonia in chloroform than in carbon tetrachloride indicates that interactions in addition to "simple" dissolution occur in the chloroform + ammonia system. Since chloroform (unlike carbon tetrachloride) has the capacity to form hydrogen bonds with ammonia, we attribute the high solubility of ammonia in chloroform to the formation of hydrogen bonds between the two components.

The enthalpy of solution of ammonia in chloroform can be separated into a contribution from dissolution (no complex formation) and a contribution from formation of the complex. The contribution from the dissolution process, ΔH_d^θ, can be obtained from the temperature dependence of Henry's law constant, $(\partial \ln k_H/\partial T)_p = \Delta H_d^\theta/RT^2$. Using this equation and the values of k_H listed in Table 2 we calculate a value of $\Delta H_d^\theta = -22$ kJ mol^{-1}. Over the temperature range of our measurements the relative uncertainties in the association equilibrium constant are too large for the van't Hoff equation, $(\partial \ln K/\partial T)_p = \Delta H^\theta/RT^2$, to yield reliable values of ΔH^θ for the formation of the chloroform–ammonia complex.

The synthesis of O-(2-hydroxyethyl)-*N*,*N*-dimethylhydroxylamine and its reaction with oxybis(diphenylborane) to yield the title compound are reported. Crystals of 2,2-dimethyl-3,3-diphenyl-1,4-dioxa-2-azonia-3-boratacyclohexane are orthorhombic, $a = 7.0332(6)$, $b = 9.2269(6)$, $c = 22.967(2)$ Å, $Z = 4$, space group $P2_12_12_1$. The structure was solved by direct methods and was refined by full-matrix least-squares procedures to $R = 0.051$ and $R_w = 0.047$ for 1247 reflections with $I \geq 2\sigma(I)$. The molecule exhibits the longest N—B and the shortest O—B distances (1.723(6) and 1.468(5) Å, respectively, corrected for libration) yet reported for a six-membered *N*,*O*-chelate of diphenylboron.

Key words: crystal structure, boron compound, organoboron compound.

KLAUS DRÜCKLER, WOLFGANG KLIEGEL, STEVEN J. RETTIG et JAMES TROTTER. Can. J. Chem. **67**, 2218 (1989).

On rapporte la synthèse de la *O*-(2-hydroxyéthyl)-*N*,*N*-diméthylhydroxylamine et sa réaction avec l'oxybis(diphénylborane) qui conduit au composé mentionné dans le titre. Les cristaux du 2,2-diméthyl-3,3-diphényl-1,4-dioxa-2-azonia-3-boratacyclohexane sont orthorhombiques, avec $a = 7{,}0332(6)$, $b = 9{,}2269(6)$ et $c = 22{,}967(2)$ Å, $Z = 4$ et groupe d'espace $P2_12_12_1$. On a résolu la structure par des méthodes directes et on l'a affinée par la méthode des moindres carrés (matrice entière) jusqu'à des valeurs de $R = 0{,}051$ et $R_w = 0{,}047$ pour 1247 réflexions avec $I \geq 2\sigma(I)$. La molécule présente la plus grande distance N—B et la plus courte distance O—B (respectivement 1,723(6) et 1,468(5) Å, corrigées pour la libration) rapportées jusqu'à maintenant pour un chélate à six chaînons du diphénylbore.

Mots clés : structure cristalline, composé du bore, composé du organobore.

Introduction

As part of an ongoing study of boron chelates of polyfunctional hydroxylamine derivatives, *N*,*N*-dialkyl-*O*-(2-hydroxyalkyl)hydroxylamines and their potential as ligands in chelate formation have been investigated. Since these compounds are not available by direct *O*-alkylation of *N*,*N*-dialkylhydroxylamines with epoxides,[2] the *O*-alkylation was carried out via an *N*,*N*-bisacyl-protected hydroxylamine. The preparation of compound **3** via **1** and **2** has been reported (2, 3). Compound **3** is an isoelectronic analog ("oxalog") of 3-dimethylaminopropanol, **4**, but shows a distinctly lower basicity. The difference, revealed by potentiometric titration in water at 21°C, appeared as $pK_a = 2.85$ for **3** and $pK_a = 9.77$ for **4**.

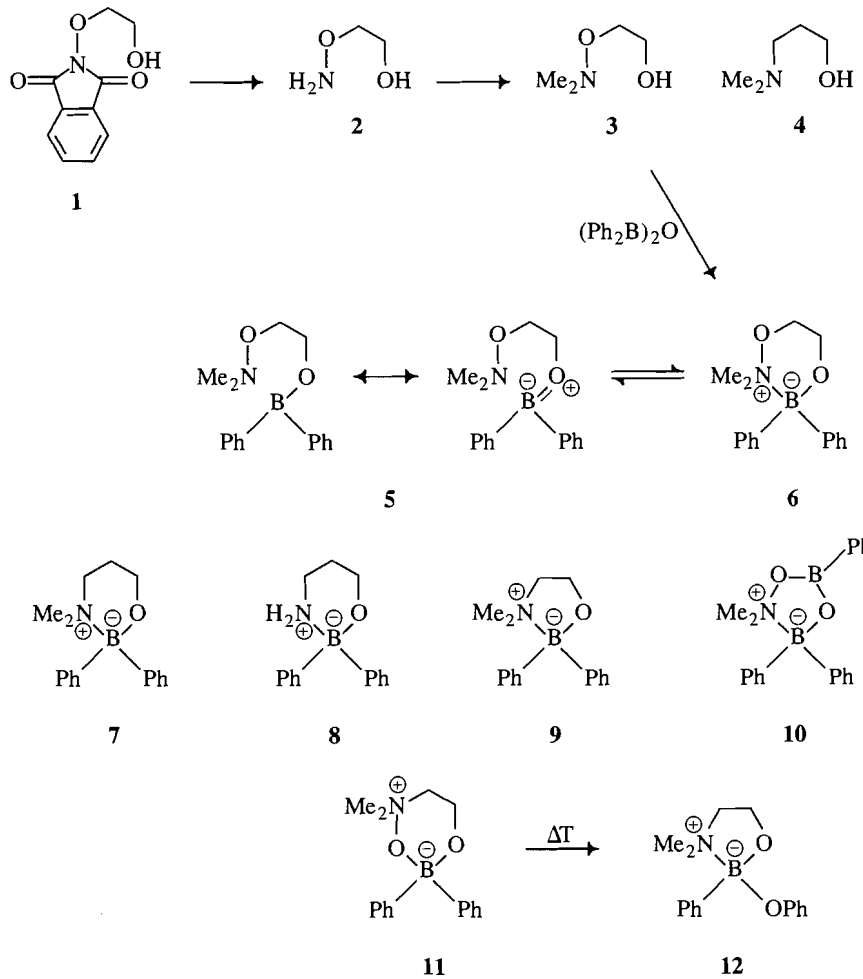
Esterification of **3** with diphenylborinic acid anhydride results in a crystalline compound, melting at 82–83°C, with an elemental composition consistent with either the open-chain diphenylborinate **5** or the intramolecular N → B coordinated ring isomer **6**. The diphenylborinate of 3-dimethylaminopropanol, **7**, could serve as a model for **6**. It has been reported in a drug patent (4) as a crystalline compound with a postulated chelate structure **7** and displays the relatively high melting point of 160°C. The cyclic structure of **7** could be deduced from the structurally characterized ring system (5) of the *N*-unsubstituted compound **8** that melts at 187°C (4) or 190–192°C (6). While the presence of N—H···O hydrogen bonding in the structure of **8** may be invoked to explain why this compound has a melting point that is 30°C higher than that reported for the *N*,*N*-dimethylated analog **7**, other factors must be taken into account to rationalize the relatively low melting point of **5/6** (82–83°C). The presence of the second oxygen atom in **5/6** (replacing a CH_2 group in **7**) will result in a change in the dipole moment. This factor, along with differences between the van der Waals interactions in the solids, and possibly a weaker N → B coordination in **5/6** contribute to the differences between the melting points. A weaker N → B bond in **5/6** is consistent with the lower basicity of the dimethylamine ligand in the hydroxylamine derivative. A certain sensitivity of **5/6** to moisture, which is not noticed for compounds **7** and **8**, is indicative of reduced coordinative stability. From these considerations, the question of competing O—B $(pp)\pi$-interaction (in **5**) and N → B coordination (in **6**) arises. To establish the molecular structure of **5/6** in the solid state, an X-ray crystallographic analysis was undertaken.

Experimental

O-(2-hydroxyethyl)-N,N-dimethylhydroxylamine, 3

O-(2-Hydroxyethyl)hydroxylamine, **2** (2), is methylated according to the literature (3) with formaldehyde/formic acid, yielding 24% of **3**; or with methyl iodide by analogy to the method of ethylation with ethyl iodide (7), yielding 46% of **3**. Bp 60–64°C/30 mm Hg; lit. (3) bp 64–66°C/25–26 mm Hg. Infrared (liquid film): 3400 cm^{-1} (broad, O—H). ^1H nmr ($CDCl_3$/TMS): δ(ppm) = 2.60 (s, Me_2N), 3.77 (s, CH_2CH_2 and OH, exchangeable).

2,2-Dimethyl-3,3-diphenyl-1,4-dioxa-2-azonia-3-boratacyclohexane, 6



O-(2-Hydroxyethyl)-*N*,*N*-dimethylhydroxylamine, **3** (0.42 g, 4 mmol), and oxybis(diphenylborane) (0.70 g, 2 mmol) are dissolved in 5 mL ethanol and refluxed for 15 min. Upon cooling, 0.92 g (86%) of

[1]Previous paper in this series: ref. 17.

[2]Epoxide addition to *N*,*N*-dialkylhydroxylamines results in the formation of *N*-(2-hydroxyalkyl)-dialkylamine *N*-oxides (1).

colorless crystals are obtained. Mp 82–83°C (from *n*-hexane/dichloromethane). ^{1}H nmr ($CDCl_3$/TMS): δ(ppm): 2.67 (s, Me_2N), 3.95 (s, CH_2CH_2), 7.1–7.7 (m, BPh_2). *Anal.* calcd. for **6**: C 71.40, H 7.49, B 4.02, N 5.20; found: C 71.09, H 7.49, B 4.37, N 5.19. Mass spectrum (30°C, 70 eV): *m/e* = 269 (73%, P^+), 238 (57%), 192 (39%, P − C_6H_5), 182 (25%, Ph_2BOH), 181 (23%, Ph_2BO), 165 (100%, Ph_2B), 148 (25%), 137 (26%), 105 (75%), 78 (11%), 61 (12%), 46 (19%). The methanolic solution of the substance gives a dark blue color reaction with diphenylcarbazone, indicating the presence of the diphenylboron moiety (7). Crystals suitable for X-ray analysis were obtained by recrystallization from *n*-hexane/dichloromethane (1:1).

X-ray crystallographic analysis of **6**

A crystal bounded by the six faces (followed by the distances in mm between parallel faces): {0 1 2}, 0.25, and ± (2 0 −1), 0.35, was mounted in a general orientation. Unit-cell parameters were refined by least-squares on 2 sin θ/λ values for 25 reflections (2θ = 35–42°) measured on a diffractometer with Mo-$K\alpha$ radiation ($\lambda(K\alpha_1)$ = 0.70930, $\lambda(K\alpha_2)$ = 0.71359 Å). Crystal data at 22°C are:

$C_{16}H_{20}BNO_2$ f.w. = 269.15

Orthorhombic, a = 7.0332(6), b = 9.2269(6), c = 22.967(2) Å, V = 1490.4(2) Å^3, Z = 4, ρ_c = 1.199 Mg m^{-3}, $F(000)$ = 576, μ(Mo-$K\alpha$) = 0.72 cm^{-1}. Absent reflections: $h00$, h odd, $0k0$, k odd, and $00l$, l odd, uniquely indicate the space group $P2_12_12_1$ (D_2^4, No. 19).

Intensities were measured with graphite-monochromated Mo-$K\alpha$ radiation on an Enraf-Nonius CAD4-F diffractometer. An ω-2θ scan at 1.2–10.0° min^{-1} over a range of (0.75 + 0.35 tan θ) degrees in ω (extended by 25% on both sides for background measurement) was employed. Data were measured to 2θ = 60°. The intensities of three check reflections, measured every 4000 s throughout the data collection, showed small (<4.5%) random fluctuations. Of the 2476 independent reflections measured and processed,[3] 1247 (50.4%) had intensities greater than or equal to $2\sigma(I)$ above background where $\sigma^2(I) = S + 2B + (0.04(S - B))^2$ with S = scan count and B = normalized background count.

The structure was solved by direct methods, the coordinates of all non-hydrogen atoms being determined from an *E*-map. The non-hydrogen atoms were refined with anisotropic thermal parameters and the hydrogen atoms were fixed in idealized positions (methyl groups staggered, C(sp^2)—H = 0.97, C(sp^3)—H = 0.98 Å, $U_H \propto U_{\text{bonded atom}}$). Scattering factors for all atoms were taken from ref. 8. The weighting scheme $w = 1/\sigma^2(F)$, where $\sigma^2(F)$ is derived from the previously defined $\sigma^2(I)$, gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of both $|F_o|$ and sin θ/λ and was employed in the final stages of full-matrix refinement of 182 variables. Reflections with $I < 2\sigma(I)$ were not included in the refinement. An isotropic Type I extinction correction (Thornley–Nelmes definition of mosaic anisotropy with a Lorentzian distribution) was applied (9–11). The final value of g was 11.3(25) × 10^4. Convergence was reached at R = 0.051 and R_w = 0.047 for 1247 reflections with $I \geq 2\sigma(I)$. No attempt was made to determine the chirality of the crystal used for data collection. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$, $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$ and $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$.

On the final cycle of refinement the mean and maximum parameter

shifts corresponded to 0.01 and 0.06σ, respectively. The mean error in an observation of unit weight was 1.790. The largest peak on the final difference map was 0.24 e Å^{-3}. The final positional and thermal parameters appear in Tables 1 and 6,[4] respectively. Measured and calculated structure factors have been placed in the Depository of Unpublished Data.[4]

The ellipsoids of thermal motion for the non-hydrogen atoms are shown in Fig. 1. The thermal motion has been analysed in terms of the rigid-body modes of translation, libration, and screw motion (12). The rms standard error in the temperature factors σU_{ij} (derived from the least-squares analysis) is 0.0025 Å^2. Three separate structural subunits were analysed: two PhB and the atoms of the six-membered heterocycle plus the two *N*-methyl carbon atoms (rms ΔU_{ij} = 0.0016–0.0029 Å^2). The appropriate bond distances have been corrected for libration (12, 13), using shape parameters q^2 of 0.08 for all atoms involved. Corrected bond lengths appear in Table 2 along with the uncorrected values; bond angles are given in Table 3 and intra-annular torsion angles in Table 4. Calculated hydrogen parameters (Table 5) and a complete listing of torsion angles (Table 7) have been deposited.[4]

[4]Libration corrected bond lengths (esd's assumed equal to those of the uncorrected values) are employed in the discussion and are compared with similarly treated (12) distances unless otherwise stated.

Results and discussion

The crystal structure of 2,2-dimethyl-3,3-diphenyl-1,4-dioxa-2-azonia-3-boratacyclohexane consists of well-separated molecules, the shortest intermolecular contacts between non-hydrogen atoms being O(1)···C(3)($1 - x$, $\frac{1}{2} + y$, $\frac{1}{2} - z$) = 3.259(5) Å, O(2)···C(1)($-x$, $y - \frac{1}{2}$, $\frac{1}{2} - z$) = 3.484(5) Å, and C(4)···C(8)($1 + x$, y, z) = 3.446(6) Å. The structure analysis shows the presence of a six-membered chelate ring with intramolecular N → B coordination, **6** (Fig. 1), resembling the six-membered chelate structures of diphenylborinates of aminoalkanols like that proposed for **7** and established for **8** (5), as well as related five-membered chelates such as **9** (5).

The N—B bond distance[4] in **6** (1.723 Å) is longer than in the diphenylborinates of aminoalkanols, e.g. **8** (1.643 Å), and the more strained five-membered system **9** (1.691 Å) (5). This is consistent with a weakened N → B coordinative bond in **6** and demonstrates the lower basicity of the nitrogen ligand compared to the aminoalkanol derivatives. A similar N—B bond length (1.728 Å) has been reported for another *N,N*-dimethylhydroxylamine derivative with a five-membered diphenylboron chelate structure, **10** (14). The O—B bond in **6** (1.468 Å), on the other hand, is the shortest yet reported for a compound of this type. This may be connected with the possibility of a facile ring opening to **5**, including a transition of tetracoordinated (sp^3)boron to trigonal planar (sp^2)boron. The O—B(sp^2) distance in **5** would be comparable to that observed for diphenylborinic acid, 1.354 Å (5). Compound **6** is less stable to air (moisture) than other diphenylboron chelates, such as those of the aminoalkanols, and also melts at a lower temperature.

Compound **6** represents an isomer of the *N*-oxide derivative **11** and its rearrangement product **12**, available by a thermally induced isomerization (15). Both compounds, **11** and **12**, have been structurally characterized by X-ray analyses (16). One of the striking differences between the *O*-alkylhydroxylamine derivative **6** and the *N*-oxide derivative **11** is found in the N—O bond length which is more than 0.04 Å longer in **6** (1.478 Å) than in **11** (1.434 Å). Conformationally, the six-membered chelate ring in **6** has a slightly distorted chair conformation (see Table 4) with a distinct difference between opposite side lengths N—B = 1.723 Å and C(1)—C(2) = 1.495 Å when compared to corresponding bonds in **11**: O(1)—B = 1.552 Å and C(1)—C(2) = 1.502 Å. The two B—C distances in **6** are equal within experimental error, whereas in **11** and in other diphenylboron chelates (ref. 16 and references therein) the axial B—C bond is usually significantly longer than the equatorial B—C bond. The N—Me bond lengths are essentially equal in the three isomeric compounds **6**, **11**, and **12**.

Metal halide, nitrile, antimony pentachloride complexes. I. Tetrakis(benzonitrile)copper(I) hexachloroantimonate(V) and hexakis(benzonitrile)copper(II) bis[hexachloroantimonate (V)][1]

SYDNEY BROWNSTEIN, NAM FONG HAN, ERIC GABE, AND YVON LE PAGE
Division of Chemistry, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R9
Received December 20, 1988[2]

SYDNEY BROWNSTEIN, NAM FONG HAN, ERIC GABE, and YVON LE PAGE. Can. J. Chem. **67**, 2222 (1989).

Tetrakis(benzonitrile)copper(I) hexachloroantimonate(V) crystallizes as a yellow solid in the triclinic space group $P\bar{1}$ with a = 8.217(4) Å, b = 14.116(5) Å, c = 14.296(9) Å, α = 86.88(4)°, β = 87.49(5)°, and γ = 81.92(3)°. Hexakis(benzonitrile) copper(II) bis[hexachloroantimonate(V)] is a green solid which also crystallizes in space group $P\bar{1}$ with a = 10.3286(8) Å, b = 11.0954(8) Å, c = 11.9722(5) Å, α = 85.536(4)°, β = 80.530(6)°, and γ = 84.051(6)°. Both compounds are synthesized from cuprous chloride, benzonitrile and antimony pentachloride depending on relative concentrations, while the latter is also prepared from cupric chloride and antimony pentachloride in benzonitrile solution.

Key words: copper complexes, crystal structures.

SYDNEY BROWNSTEIN, NAM FONG HAN, ERIC GABE et YVON LE PAGE. Can. J. Chem. **67**, 2222 (1989).

L'hexachloroantimonate(V) de tétrakis(benzonitrile)cuivre(I) cristallise sous forme d'un solide jaune dans le groupe d'espace triclinique $P\bar{1}$ avec a = 8,217(4) Å, b = 14,116(5) Å, c = 14,296(9) Å, α = 86,88(4)°, β = 87,49(5)° et γ = 81,92(3)°. Le bis[hexachloroantimonate(V)] de héxakis(benzonitrile)cuivre(II) est un solide vert qui cristallise également dans le groupe d'espace $P\bar{1}$ avec a = 10,3286(8) Å, b = 11,0954(8) Å, c = 11,9722(5) Å, α = 85,536(4)°, β = 80,530(6)° et γ = 84,051(6)°. On a préparé les deux composés à partir du chlorure cuivreux, du benzonitrile et du pentachlorure d'antimoine, dépendant des concentrations relatives, tandisque le dernier composé est également obtenu à partir du chlorure cuivrique et du pentachlorure d'antimoine dans une solution de benzonitrile.

Mots clés : complexes de cuivre, structures cristallines.

[Traduit par la revue]

Introduction

It has long been known that antimony pentachloride is a very strong chloride ion acceptor which reacts with a variety of chlorine-containing compounds to give the corresponding cations and $SbCl_6^-$ (1). A few ternary complexes of a metal halide, acetonitrile, and $SbCl_5$ have been isolated (2) and similar examples with SbF_5 and BiF_5 are also known (3, 4). The current investigations are to study the generality of these ternary complex formations. Since the oxidation potential for conversions of Cu(I) to Cu(II) is near zero and dependent upon the co-ordinating ligands (5), and since the co-ordination about copper is quite variable (6), copper chloride appeared to be a metal halide which might give some interesting sterochemical results.

Antimony pentachloride and pentafluoride form 1:1 adducts with many ligands such as acetonitrile, dimethyl sulfoxide, and dimethyl formamide (7–11). The crystal structures for binary adducts of cuprous chloride with acetonitrile or benzonitrile have been determined (12, 13).

Experimental

Chemicals

Cuprous chloride, cupric chloride (Anachemia Chemicals), benzonitrile, (PhCN, Eastman Chemicals), antimony pentachloride (Baker Chemicals), and hexanes (BDH Chemicals) were used as received.

Preparation of $[Cu(PhCN)_4]$ $[SbCl_6]$ I: CuCl (0.3 g, 3.0 mmol) was stirred in 25 mL of PhCN at room temperature for 15 min followed by slow addition of $SbCl_5$ (0.8 g, 2.7 mmol). The reaction was exothermic and the resultant mixture was stirred for another 5 min after which it was filtered. Yellow crystals of **I** were obtained when the yellow–brown filtrate was added slowly to 40 mL of hexanes. **I** was washed with hexanes (3 × 10 mL) and dried *in vacuo*. Yield 0.95 g, **I** is stable in air for a long period of time. *Anal.* calcd. for $C_{28}H_{20}N_4Cl_6CuSb$: C 41.48, H 2.47, N 6.91; found: C 41.07, H 2.59, N 7.27. Melting point 89–91°C. ν(CN) 2228 cm^{-1}. **I** is also characterized by a single crystal X-ray structural study.

Preparation of $[Cu(PhCN)_6]$ $[SbCl_6]_2$ II: The synthesis was done in the same fashion as for **I** except that CuCl (0.3 g, 3.0 mmol), 25 mL of PhCN and $SbCl_5$ (1.8 g, 6.0 mmol) were used. About 40 mL of hexanes was added to the green filtrate and a green crystalline solid of **II** precipitated and was separated from the mother liquor by filtration. **II** was isolated, washed, and dried as for **I** (yield 2.21 g). **II** is sensitive to hydrolysis in air but can be stored under a dry N_2 atmosphere. *Anal.* calcd. for $C_{42}H_{30}N_6Cl_{12}CuSb_2$: C 37.31, H 2.22, N 6.22; found: C 37.04, H 2.20, N 6.11 Melting point: 128–130°C. ν(CN) 2226 cm^{-1}. **II** is also characterized by a single crystal X-ray structural study.

Microanalyses were performed by Mr. H. Seguin of the National Research Council of Canada. Infrared spectra were obtained on KBr pellets with a Perkin-Elmer 683 spectrometer. Melting points were determined with a Gallenkamp melting point apparatus and are reported without correction.

X-ray diffraction intensities were collected at room temperature on an Enraf-Nonius CAD-4 diffractometer with graphite monochromatized MoK_α radiation, λ = 0.70932 Å, using the $\theta/2\theta$ scan technique with profile analysis (14). The crystal data are listed in Table 1. The structures were solved by direct methods and refined by full-matrix least-squares techniques.

All calculations were performed using the NRCVAX program system (15). For **II** the final residuals are R_f 0.034 and R_w 0.021 for the significant reflections using counting statistics weights. For **I** the final residuals are R_f 0.092 and R_w 0.113 for the significant reflections using unit weights. All atoms except hydrogen were refined anisotropically for **II**. Only Cu, Sb, and Cl atoms were anisotropically refined for **I** and its hydrogen atoms were placed at the calculated positions. The high R values for **I** are a consequence of the small crystal size, resulting in weak reflections and therefore a large number of unobserved reflections as shown in Table 1.

The final atomic positional parameters and the mean of the principal

Setting angles No.		25	40
2θ range		36 to 42	30 to 35

axes of the thermal ellipsoids for **I** are listed in Table 2. Similar information for **II** is listed in Table 3. The anisotropic temperature factors and the final structure factors for both compounds are deposited as supplementary material.[3]

Results and discussion

It is possible to prepare both copper(II) and copper(I) complexes from cuprous chloride, benzonitrile, and antimony pentachloride by changing the relative ratio of CuCl and $SbCl_5$. Therefore, with benzonitrile as ligand, the oxidation potential for $Cu^+ \rightarrow Cu^{2+} + e^-$ must be very close to zero. Analogs of the Cu(II) complex have been prepared by first synthesizing a nitromethane solvated species, $Cu(CH_3NO_2)_6$, and subsequently reacting this with an appropriate ligand, L, to give CuL_n^{2+}, where n is 3 or 6 and L is NC—$(CH_2)_2$—CN, NC(C_6H_4)CN, or NC—$(CH_2)_{10}$—CN (16, 17). Cu(I) complexes of nitriles and complex anions have not been reported. The green complex **II** is sensitive to hydrolysis by moisture in the air but is stable when submerged in hexanes and sealed in glass capillaries. Crystals were chosen for this study by working in a bath of hexanes. In contrast, the yellow complex **I** is stable in air.

The structure of complex **I** is shown in Fig. 1 and the key bond distances and angles are listed in Table 4. A complete set of bond distances and angles are deposited as supplementary material.[3] The benzonitrile ligands are arranged about Cu(I) in a nearly regular tetrahedron with average Cu—N bond lengths of 2.05(4) Å. The C—N and nitrile carbon to aromatic carbon bonds are 1.10(5) and 1.43(4) Å, respectively. There is a single absorption for the C—N stretching frequency at 2228 cm^{-1}. Both increases and decreases of the C—N stretching frequency

upon co-ordination have been reported so this parameter does not appear useful in describing the metal ligand bonding (18–20).

The structure of complex **II** is shown in Fig. 2 and the key bond distances and angles are listed in Table 5. A complete set of bond distances and angles are deposited as supplementary material.[3] As required by the Jahn–Teller effect the co-ordination about copper is not a regular octahedron (21). An elongated rhombic octahedron with tetragonality of 0.854 has been observed for copper–oxygen bonds (22), the full range has been observed as a function of temperature for copper–nitrogen bonds (23). Only a single absorption is found at 2226 cm^{-1} for the C—N stretching frequency, essentially the same as for **I**. The average Cu—N bond length of 2.13 Å in **II** is slightly, but significantly, longer than that in **I**. There is no significant difference in the C—N and nitrile carbon to aromatic carbon average bond lengths of **II** and the corresponding bond lengths in **I**. Apart from the major difference in stereochemistry only the Cu—N bond distances seem to be slightly sensitive to the changed valence of the central copper atom.

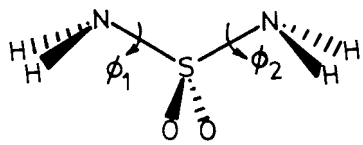
Ab initio calculations have been used to study the conformational potential surface of sulfamide, by considering the S—N bond rotations and the nitrogen inversion processes. The lowest energy conformation (**b**) is found for a *cis–trans* arrangement of the amino groups, although conformations with *cis–cis* (**a**), *trans–trans* (**c**), and near staggered (**c′**) arrangements lie close in energy. Nitrogen inversion barriers are very low, and consequently one may expect forms **b** and **c′** to be the only ones present in the gas phase. Conformer **a** is very polar, its dipole moment being twice that of **b**, so it may be favored in condensed media or in polar-solvent solutions. The relative stability of the different isomers is governed by interactions between the amino protons and between the nitrogen lone pairs. Our results show that $d-\pi$ backbonding, involving the *d* orbitals on sulfur, is responsible for the multiple bond character of the S—O linkage, but is very small in the S—N interactions. The role of the sulfur *d*-orbital exponent, when a 6-31G* basis is used, is analyzed on a series of model compounds containing S^{II}, S^{IV}, and S^{VI}. Although the inclusion of *d* functions on sulfur is crucial to describing correctly the bonding in sulfamide, the results obtained do not change appreciably if a second set of *d* functions is centered on sulfur. Nevertheless, only when polarization functions are also included for first-row atoms is the description of the system reliable.

Key words: sulfamide, inversion and rotational barriers, sulfur *d*-functions.

OTILIA MÓ, JOSÉ L. G. DE PAZ, MANUEL YÁÑEZ, IBON ALKORTA, JOSÉ ELGUERO, PILAR GOYA et ISABEL ROZAS. Can. J. Chem. **67**, 2227 (1989).

On a utilisé des calculs *ab initio* pour étudier le potentiel de surface conformationnel du sulfamide, en considérant les rotations de la liaison S—N et les processus d'inversion de l'azote. On a trouvé que la conformation d'énergie minimale (**b**) implique un arrangement *cis–trans* des groupements aminés, même si les conformations avec des arrangements *cis–cis* (**a**), *trans–trans* (**c**) et pratiquement décalé (**c′**) possèdent des énergies très voisines. Les barrières à l'inversion de l'azote sont très basses et, en conséquence, on peut s'attendre à ce que les formes **b** et **c′** soient les seules présentes en phase gazeuse. Le conformère **a** est très polaire, son moment dipolaire est le double de celui de **b**; il est possible qu'il soit favorisé dans les milieux condensés ou dans des solutions dans des solvants polaires. La stabilité relative des divers isomères est gouvernée par les interactions entre les protons des groupements amino et les paires libres des azotes. Nos résultats démontrent que la liaison en retour $d-\pi$, impliquant les orbitales *d* du soufre, est responsable pour le caractère de liaison multiple de la liaison S—O; ce type de liaison est toutefois très faible dans les interactions S—N. Utilisant une série de composés modèles contenant des S^{II}, S^{IV} et S^{VI} et faisant appel à une base 6-31G*, on a étudié le rôle du caractère de l'orbitale *d* du soufre. Même si l'inclusion des fonctions *d* du soufre est cruciale pour décrire correctement les liaisons dans le sulfamide, les résultats obtenus ne changent pas beaucoup si on ajoute un deuxième ensemble de fonctions *d* sur le soufre. Toutefois, on n'obtient une description adéquate du système que lorsque des fonctions de polarisation sont ajoutes aux atomes de la première couche.



Mots clés : sulfamide, barrières à l'inversion et à la rotation, fonctions *d* du soufre.

1. Introduction

The >N—SO_2—N< group, present in sulfamide (1) and in 1,2,6-thiadiazine 1,1-dioxides (2), has interesting biological properties that are reputed to be related to the CO/SO_2 bioisosterism. But unlike urea, H_2N—CO—NH_2, which has been the subject of careful theoretical calculations (3–6), to our knowledge there is only a rather limited *ab initio* study (7) on sulfamide, H_2N—SO_2—NH_2. We therefore decided to study theoretically the conformational energetics of this molecule with regard both to rotation and to inversion of the amino groups, which can shed light on the fundamental problem of >N—SO_2— conjugation in relation to the nitrogen lone-pair position.

In sulfamide there are two rotational degrees of freedom, which correspond to the two S—N bond rotations, ϕ_1 and ϕ_2 (see Scheme 1). Using the Newman projections along these bonds we can identify the rotamers included in Fig. 1, for 90° rotations about both S—N bonds. As we shall illustrate later, some are relative minima (stable isomers) and some are saddle points of the hypersurface. To complete our discussion of the general stereochemistry of this compound the corresponding nitrogen inversion processes were also investigated. Accordingly, three different transition states, which correspond to conformations in which N1 (conformers **h** and **i**) or N1 and N2 (conformer **j**) have sp^2 hybridization, were studied. Finally, the structures of the stable conformers were optimized at a high level of accuracy.

SCHEME 1

We shall also investigate the bonding characteristics of the

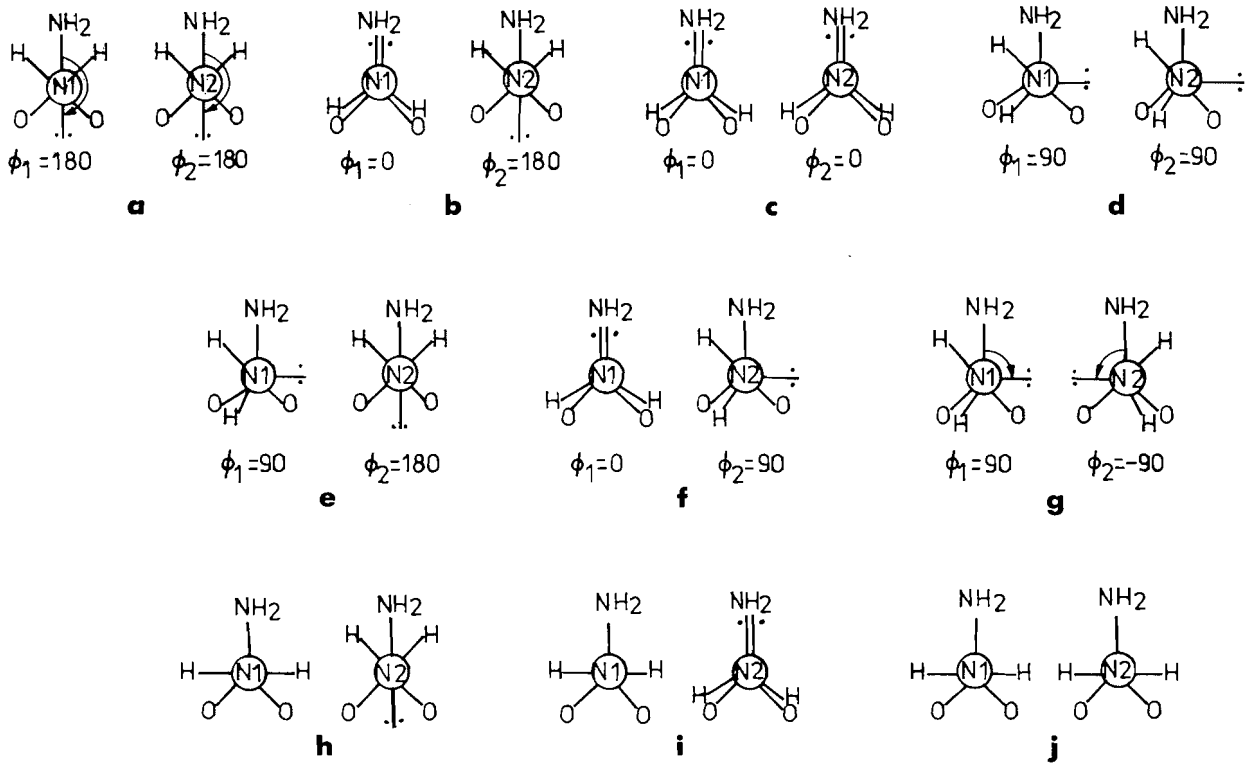

FIG. 1. Newman projections of the different rotamers of sulfamide corresponding to 90° S—N bond rotations. Conformers **h**, **i**, and **j** correspond to the transition states of the nitrogen inversion processes for this system.

S—O and S—N linkages by analyzing the corresponding canonical and localized molecular orbitals. The latter will be obtained employing the method of Boys (8).

Regarding the concrete aspects of the SCF *ab initio* treatment of sulfamide, it is worth noticing that the choice of the basis set, which constitutes one of the most crucial problems of any *ab initio* calculation, becomes particularly relevant in the present case, where the second-row atom displays a hypervalent coordination (7, 9–17). Moreover, the high electronegativity of the ligands bonded to sulfur in this system will likely render polarization effects quite important, so that a proper description of the polarization of the first-row atoms would also be unavoidable. For this reason, we carried out our calculations at the 6-31G* level (10) to include polarization functions, not only on sulfur but also on the other heavy atoms of the system. However, and taking into account that polarization functions centered on a central atom in any species are expected to be more important than those on the peripheral ones due to the higher angular dependence of the local charge distribution near the former, we have also analyzed the effect of including an additional set of *d* functions centered on S. It seems also clear that a reliable description of the geometry and charge distribution of a hypervalent system requires a careful choice of the exponent (α_d) of the *d* functions centered on the hypervalent atom to supplement a reasonably sized *sp* basis. Accordingly, an investigation of the effect of α_d on energies, geometries, and charge distributions of different model sulfur compounds was undertaken, as a first step of our study, to have a reliable *d* exponent for a correct treatment of S^{II}, S^{IV}, and S^{VI} compounds, and of sulfamide in particular.

Finally, we shall also discuss the performance of such cheaper polarized basis sets as the STO-3G* (18) and 3-21G$^{(*)}$ (19), where the polarization functions are included exclusively on the second-row atom, but which can be a necessary alternative for the theoretical treatment of increasingly large compounds.

2. Computational details

To discuss the internal rotational potential surface of sulfamide we have fully optimized, at the STO-3G* level, the geometries of the different rotamers corresponding to values of ϕ_1 ranging from 0° to 180° and of ϕ_2 ranging from −180° to 180°, in steps of 30°. Then, single-point calculations at the 6-31G* level were carried out using these STO-3G* fully optimized structures. These closed-shell SCF calculations were performed using the Gaussian-80 series of programs (20) and suitable gradient optimization procedure (21).

The specific study of the stable conformers of sulfamide was carried out at different levels of accuracy employing "standard" and "non-standard" basis sets. More precisely, calculations at the 3-21G$^{(*)}$ levels were performed using the standard set of exponents (19). At the 6-31G* level we employed the standard exponents (10) except for the *d* functions centered on S, for which an optimal value (see next section), α_d = 0.70, was adopted.

The importance of achieving a proper polarization of the central atom was investigated by using two different polarized split-valence bases, which include two sets of *d* functions on S. These bases were constructed from the standard 6-31G* one, by replacing the standard set of *d* functions on sulfur by two sets of exponents, 0.39 and 1.18 in one case (22), and 0.30 and 0.80 in the other (14). Energies obtained with the first set of exponents were systematically lower than those obtained with the second; we shall therefore discuss exclusively the results obtained with the former basis, which will be denoted as 6-31G*+d_s.

A C_{2v} symmetry was adopted for conformers **a**, **c**, and **j**; a C_s for **b**, **g**, **h**, **i**, and a C_2 symmetry for conformer **d**. For the

remaining nuclear arrangements no symmetry constraints were imposed. In all cases all geometrical parameters were fully optimized at each of the levels of accuracy considered in this work.

Charge distributions were obtained using the well-known Mulliken population analysis.

3. Results

3.1. α_d *exponent optimization*

To obtain the optimized exponent of the set of *d* functions on sulfur to be used within a 6-31G* quality basis, we have selected the following sets of normal valence (II) compounds: SH_2, SH_2(linear), SF_2, SF_2(linear), ethylene episulfide (CH_2—S—CH_2), and thiete (CH=CH—CH_2—S); and hypervalent (IV and VI) compounds: SO_2(linear), SO_2, SC_2(linear), SC_2, ethylene episulfoxide (CH_2—CH_2—S=O), aminosulfurous acid (NH_2— SO—OH), SO_2F_2, SO_3, SF_3N, ethylene sulfone (CH_2—CH_2— SO_2), H—SO_2—NH_2, and sulfamide.

The exponents of the *d* functions on S were allowed to vary between 0.40 and 0.80 in steps of 0.05. The geometries used were previously optimized using the standard 6-31G* (α_d = 0.65) basis set. The values of the optimized α_d exponents and the corresponding energies have been summarized in Table 1.

We have found that the energy of hypervalent compounds is much more sensitive to the α_d value than that of normal valence systems, illustrating that a proper polarization of sulfur is particularly crucial for the former.

It should also be remarked that the optimal values reported here are referred to a basis that includes polarization functions on the remaining heavy atoms of the system and, therefore, they are different from those recently reported by Yadav *et al.* (23) to supplement a 3-21G basis. In the same paper it was also shown that the S—O bond lengths depend strongly on the α_d value chosen, and an optimization of this exponent to obtain the shortest S—O bond was proposed. Since we are interested in obtaining a reliable geometrical structure of sulfamide, it seems necessary to assess whether similar behavior should be expected when the basis set also includes polarization functions in the remaining heavy atoms of the system. To investigate this particular point we have considered the following model compounds: SO_2, SO_3, SO_2F_2, for which the molecular geometry was fully optimized for each value of α_d. In Table 2 we present, as an example, the results obtained for SO_3. First, it is conspicuous that the optimum α_d value is identical to that obtained above when the geometry was not allowed to vary and was kept identical to the 6-31G* optimized level. Second, the S—O bond length systematically decreases as α_d increases and no minimum is found in the range of α_d values investigated. Moreover, the S—O bond length varies little in the neighborhood of the minimum.

TABLE 2. Optimized total energies (in au) and S—O bond lengths (in Å) of SO_3 as a function of the exponent of the sulfur *d* orbital (α_d) when a 6-31G* type of basis is employed

α_d	Total energy	S—O bond length
0.40	−621.93313	1.430
0.50	−621.96353	1.417
0.55	−621.97267	1.412
0.60	−621.97850	1.408
0.65	−621.98157	1.405
0.70	−621.98238	1.402
0.75	−621.98136	1.400
0.80	−621.97893	1.398

We may conclude then that the criterium of the shortest S—O bond is not always meaningful as it depends on the quality of the basis set which is implemented. In fact, the shortening of the S—O and S—N bonds produced by including polarization functions on the sulfur atom is not at all dramatic at the 6-31G* level, because the shortening caused by the polarization functions centered on first-row atoms is already notorious.

3.2. Internal rotation potential surface

The calculated potential surface for S—N bond rotation (see Figs. 2 and 3) shows that **b** ($\phi_1 = 0$, $\phi_2 = 180$) is the most stable conformer of sulfamide, although conformers **a** and **c** are also minima in this surface. Both figures also show the existence of another local minimum **c'** ($\phi_1 \simeq 30$ and $\phi_2 \simeq 30$), close and slightly more stable than conformer **c**. The rotational barriers (between 3.7 and 7.7 kcal/mol, depending on the path) are much lower than those calculated for formamide (14.2 kcal/mol) (24) but similar to those reported by Vishveshwara and Pople (25) for glycine. Due to the competing effect of the two NH_2 groups, the barrier in urea is 5.8 kcal/mol lower than in formamide, for the rotation of one amino group, the second one remaining planar (3). The simultaneous rotation of both amino groups (sp^3 nitrogens in the transition state) is a much more energetic process (6). All this illustrates that in sulfamide the conjugative interaction between the NH_2 and the S=O groups is much weaker than that between the NH_2 and the carbonyl group in formamide and in urea, because in the former system the amino groups lie in a plane perpendicular to that defined by the SO_2 moiety. This seems to be in disagreement with the conclusions of Fraenkel *et al.* (26), which explain the low rotational barrier of a sulfone as a direct consequence of a conjugative interaction involving the *d* orbitals in sulfur. To clarify this point, we have carried out an analysis of the MO's of conformers **a** and **c**, which upon rotation about one S—N bond yield the most stable conformer **b**. This analysis shows that there is an interaction between the in-phase combination of the

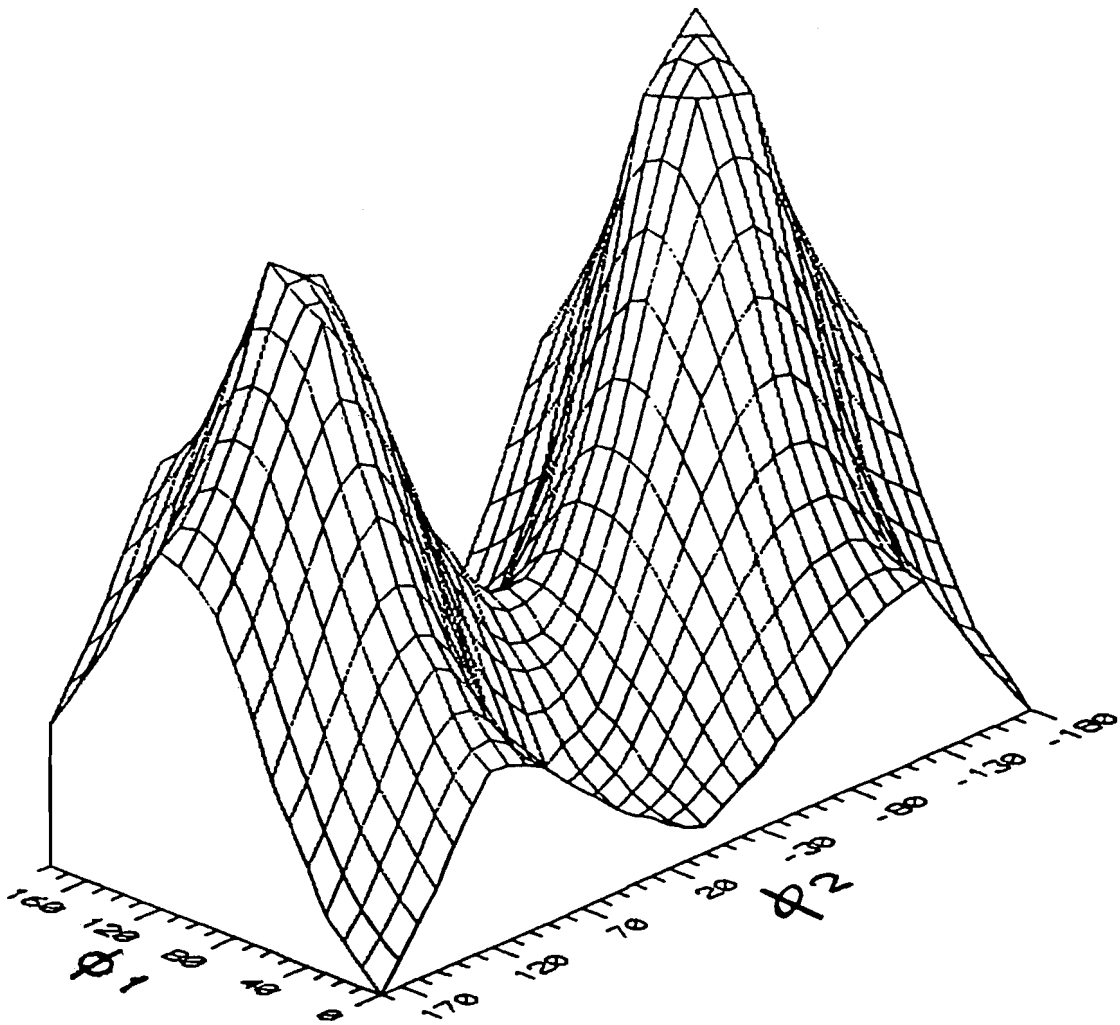

FIG. 2. Potential surface for S—N bond rotations of sulfamide, obtained at the 6-31G* level on STO-3G* fully optimized structures. The rotational angles ϕ_1 and ϕ_2 have been defined in Scheme 1.

nitrogen lone pairs (LPN^+) and the $2p_z + 3d_{x^2-y^2}$ orbitals of sulfur (see Fig. 4), but this conjugation is noticeably smaller than that between the *d* orbitals of sulfur and the oxygen lone pairs, as we shall discuss later. There is another feature that indicates that this conjugation plays a nonsignificant role in the magnitude of the rotational barrier. Actually, although the conjugation decreases when the NH_2 group rotates, it is still significant for conformations very close to the maximum of the barrier ($\phi_1 = 90$ or $\phi_2 = 90$), although involving the $2p_x$ orbital of sulfur instead of the $2p_z$. Moreover, for the most stable conformer **b**, it is weaker than in **a** or **c**.

We can therefore conclude that the rotational barriers in sulfamide arise mostly from the repulsions between the protons of the two amino groups. The three-dimensional picture of Fig. 2 reveals that the rotational barrier between **b** and **a** is much higher (7.7 kcal/mol) than that between **b** and **c** (3.7 kcal/mol), as a direct consequence of this effect. Starting from isomer **b**, a ϕ_1 rotation involves a decrease of the four distances between the protons of the two amino groups, which becomes maximum for $\phi_1 \simeq 120$, coinciding with the maximum of the barrier. After this point one of the distances becomes larger and the energy lowers to reach conformer **a**. If one considers how the separation between the amino protons evolves on going from **b** to **c** (ϕ_2 rotation), the situation is markedly different. Only one of the four distances rapidly decreases and reaches its minimum around $\phi_2 \simeq 60$. The other proton–proton distances remain practically unchanged or become slightly larger and the rotational barrier becomes less than half the previous one. In fact, in isomer **c** the distances between the amino protons are, on average, larger than in isomer **b**, but the repulsive interaction between the nitrogen lone pairs is considerably greater, raising the total energy of the former. The existence of another stable conformation **c′** close to **c** confirms this analysis. In conformer **c′** the NH_2 groups rotate enough to alleviate the lone-pair repulsion that takes place in **c**, without substantially increasing the repulsion between the amino protons. The result is a conformation that lies only 0.3 kcal/mol above conformer **b**. In a similar way, it can also be observed that the potential surface for $\phi_2 > 0$ is systematically lower than for $\phi_2 < 0$, because in the latter case, where the amino protons tend to be simultaneously above (or below) the NSN plane, the repulsive interaction between the amino protons is greater. Figure 3 shows that the two absolute maxima appear for ($\phi_1 \simeq 120$, $\phi_2 \simeq 120$) and ($\phi_1 \simeq 120$, $\phi_2 \simeq -120$), the latter being about 2.0 kcal/mol higher than the former.

The weak conjugative interaction between the amino groups and the SO_2 moiety is also shown by the pyramidal structure of the two amino groups. This structure changes very little upon

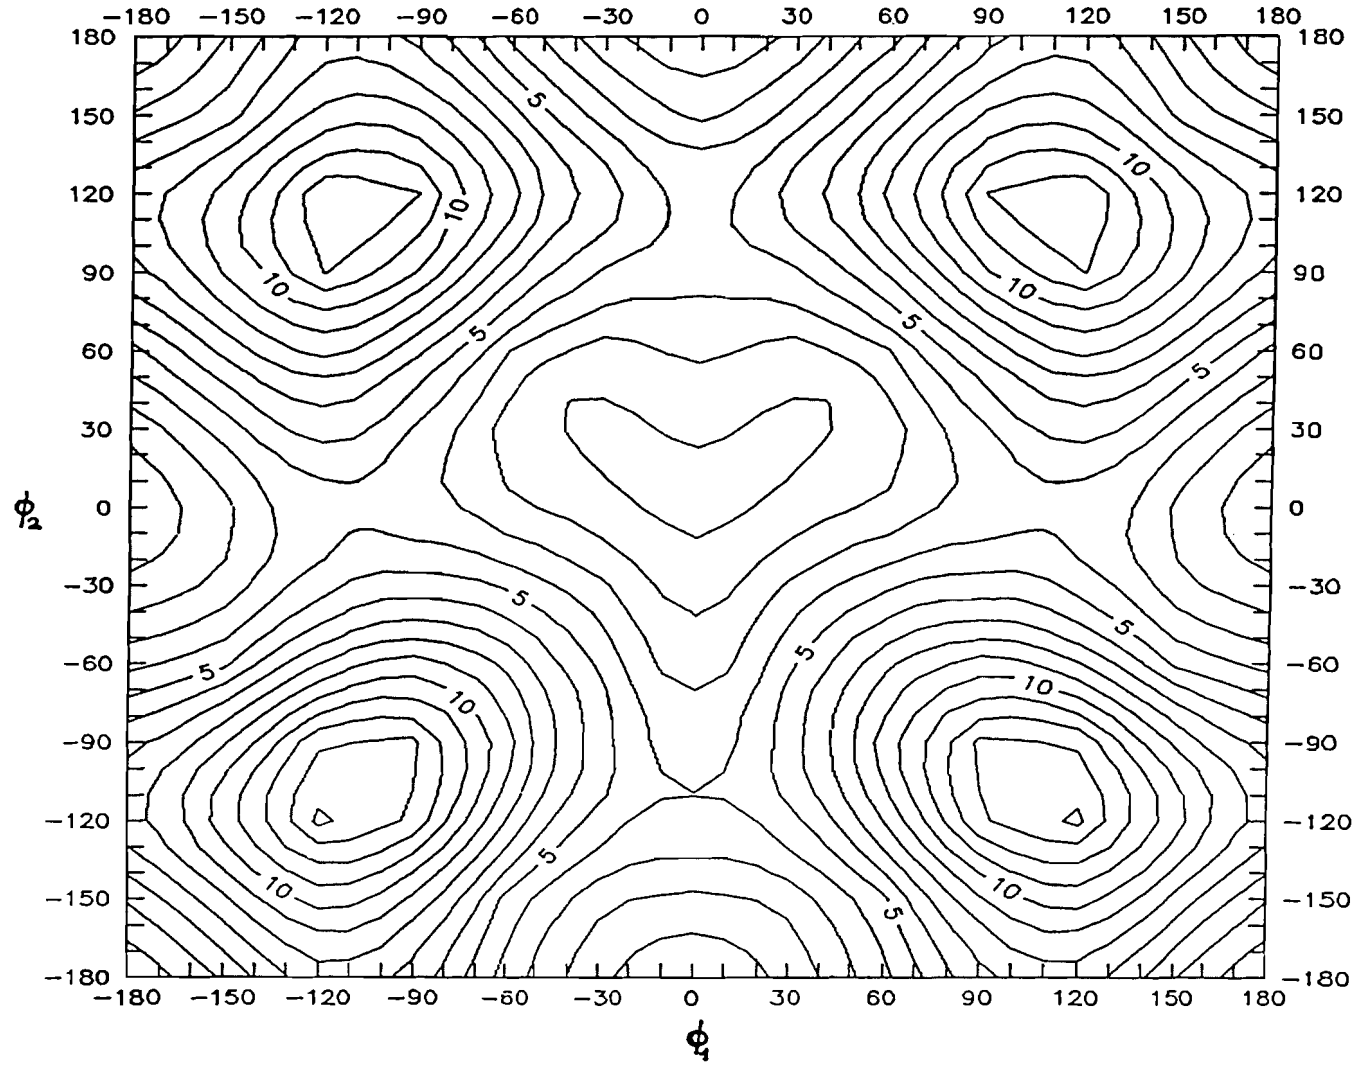

FIG. 3. Two-dimensional plot of the potential surface of Fig. 2. Contour labels refer to the energy (in kcal/mol) relative to the absolute minimum ($\phi_1 = 0$, $\phi_2 = 180$).

S—N rotation, and the H—N—S angle remains typically around 106°, and only for species **a** and **c** increases to about 112°.

3.3. Sulfamide isomers. Structure and stability

Once the local minima of the potential surface were localized we carried out a full geometry optimization for each of them at the 6-31G* ($\alpha_d = 0.7$) and 6-31G*+d_s levels. The corresponding optimized geometrical parameters have been summarized in Table 3. This table also contains the corresponding total energies and dipole moments, together with the X-ray experimental structure (27).

We shall discuss first the results obtained at the 6-31G* level and later the effect of including an additonal set of *d* functions on sulfur. These results confirm that conformer **b** is the most stable in the gas phase, although conformers **c**, **a**, and **c′** are only 0.6, 2.7, and 0.3 kcal/mol less stable, respectively. Since there is a considerable variation in their dipole moments (for instance that of isomer **a** is more than twice that of isomer **c**), this relative stability can change considerably in polar solvents or in condensed media, where dipole interactions can strongly favor the most polar isomers. This, and the existence of a network of hydrogen bonds, explains why only conformer **a** is present in the crystal (27). In general, there is reasonably good agreement between theoretical optimized parameters and those determined by X-ray diffraction (27). This also means that there are no significant changes either in the bond lengths or in the bond angles among the different isomers considered. Actually these variations are smaller than 0.1 Å for the former and smaller than 2° for the latter.

The relative stability of the isomers of sulfamide is a consequence of several factors. Similar to what has been

discussed by Ehrhardt and Alrichs (28) for $FNSF_2$, and as we mentioned above (see Fig. 4), a *cis* arrangement of the $-NH_2$ groups with respect to the SO_2 moiety facilitates the delocalization of the nitrogen lone pairs into the low-lying orbitals of the $-SO_2$ fragment. Consequently, the participation of the AO's of sulfur in the nitrogen lone pair MO's is greater in conformer **c** than in isomer **a**, resulting in a slight increase of the S—N overlap population. Since, as discussed above, this delocalization is quite small, the stabilizing effect is not large and the destabilization of form **a** with respect to **c** comes basically from the coulomb repulsion between the protons of the amino groups, which are in an eclipsed conformation in **a**. In this respect it should be noted that the local structure of the $S(NH_2)_2$ moiety reflects the lack of lone-pair interactions and smaller repulsions among the amino protons in conformer **c'**, which presents a near staggered arrangement of the amino groups ($\phi_1 = \phi_2 \simeq 47.5$ degrees) and an N—S—N bond angle about 5°–10° smaller than in the other isomers.

On the other hand, it must be taken into account that there is a large difference in dipole moments between the isomers. Therefore, one of the reasons for the differences in stability may be favorable dipole interactions of the $S(NH_2)$ and SO_2 moieties. In fact, assuming that the bond dipoles may be represented by point charges in a very simple model, the differences in coulombic interactions for isomers **a** and **c** would be of the order of a few kcal/mol.

3.4. Nitrogen inversion processes

Since the different isomers are quite close in energy we have considered it worthy to study also the N-inversion processes that permit going from one conformer to another. Therefore, the geometries corresponding to conformations **h**, **i**, and **j** were also fully optimized, at the 6-31G* level, although they are not local minima of the potential hypersurface but transition states. The geometrical parameters are available from the authors. The total energies (−658.37738, −658.37918, and −658.37600 au, respectively) show that the barriers for single (2.8 and 1.7 kcal/mol, respectively) and double (3.7 kcal/mol) nitrogen inversions are quite low. Therefore, the interconversion between **c** and **b** or **a** and **b** through an N-inversion process may occur, under normal conditions, in the gas phase. Then, one should expect conformer **a** not to be present in the gas phase while, assuming a Maxwell–Boltzman distribution, the proportion of forms **c** and **b** should be 37 and 63%, respectively, and therefore the observed dipole moment should be about 3.9 D or lower, since 6-31G* results usually overestimate this first-order magnitude. However, the excellent agreement between this predicted value and that measured in solution (29) (dioxane at 20°C, see Table 3) may be fortuitous.

The low barriers to nitrogen inversion that were found indicate that the transition state, in which the amino protons lie in a plane perpendicular to that defined by the SN_2 moiety, is relatively stable with respect to isomers **a** and **c**, respectively, i.e., that the stability of the system is not very sensitive to the degree of pyrimidalization of the NH_2 groups. To explain this finding, let us then consider first the characteristics of the nitrogen lone pairs in conformers **a** and **c**. As illustrated in Fig. 4, the *s* character of the LPN^+ orbital of **c** is smaller than that of **a**. This is so because, in the former, the *s* contribution would considerably increase the repulsive interaction beween both lone pairs, while in the latter the situation is just the opposite. Accordingly, the LPN^+ of form **a** lies much lower in energy than that of conformer **c** (MO energies are available from the authors). This is also corroborated by the fact that the amino protons of isomer **c** are more acidic than in isomer **a**, since in the former the *s* character of the other hybrids centered on the nitrogens is greater. Therefore, when one of the nitrogens of isomer **c** inverts, the destabilization of the corresponding lone pair is not very significant, since in its ground state the lone-pair *s* character is already small. Accordingly, the inversion barrier is not very high. Following the same arguments, the nitrogen inversion barrier of isomer **a** should be considerably greater, since the loss of *s* character on going from the ground to the transition state is more significant. Nevertheless, it must be taken into account that, simultaneously, the distance between the protons of the two amino groups considerably increases, tending to stabilize the system. Both effects are practically counterbalanced and the inversion barrier becomes very small. Similar arguments can be used to explain the magnitude of the double inversion barrier.

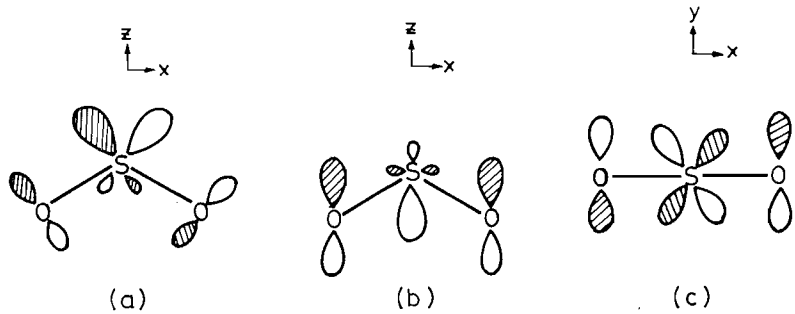
As for rotation, the inversion processes reveal that the conjugative interaction between the amino and the SO_2 groups is very weak and it is not favored in the transition state. In fact, the net atomic charges indicate that electron population at nitrogen is larger in the transition state than in conformers **a** or **c**, just the opposite of what would be expected if a delocalization of the nitrogen lone pair took place. Similar findings have been reported by Wiberg and Laidig (30) for formamide.

Experimental results (by DNMR) on sulfonamides >N—SO_2—Ar in which the nitrogen atom is part of a three-(aziridine) or a six-membered ring (piperidine) have been reported. Initially, the activation energies were assigned to inversion process (31, 32) but, as Mislow and co-workers pointed out (33), slow rotation about the N—S bond cannot be ruled out as the rate-determining process. The calculations described here, as well as those in simpler compounds (34), indicate that since both processes have similar activation energies, depending on ring size and on nitrogen substituents, either of them can be responsible for the experimental behaviour.

3.5. S—O bonding characteristics

An important structural feature of hypervalent sulfur compounds like sulfamide is the characteristics of the S—O bonds. Both the canonical and the localized sets of molecular orbitals indicate that S—O bonds in sulfamide are the result of a σ-type interaction between the corresponding atomic orbitals of oxygen and sulfur and π-type delocalizations involving the oxygen lone pairs and linear combinations of *p* and *d* orbitals of sulfur. These π interactions have been schematically depicted in Fig. 5. In the first case the interaction involves the out-of-phase combination of the oxygen lone pairs (LPO^-) and the in-phase combination ($p_x + d_{xz}$) of sulfur. In the third, the LPO^- combination interacts with the d_{xy} atomic orbital of sulfur and in the second the interaction involves the in-phase combination of the oxygen lone pairs (LPO^+) and the ($d_{3z^2-r^2} - 2p_z$) combination of sulfur AO's. The picture obtained from the corresponding localized MO's is consistent with the previous one. The S—O bonds appear as the result of a σ-type S—O interaction and $p\pi-d\pi$ delocalizations involving three lone pairs (one lying in the SO_2 plane and two perpendicular to it) of oxygen and the *d* orbitals of S (see Scheme 2).

Therefore we cannot strictly speak of an S—O double bond in sulfamide, since the π-type bond one would expect between the oxygen *p* orbital lying in the SO_2 plane and the orbitals on S is practically identical in nature to the $p\pi-d\pi$ backbonding type involving the oxygen lone pairs that lie out of this plane. In



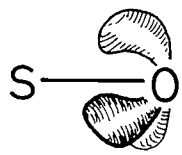


FIG. 5. Schematic representation of the interactions between the oxygen lone pairs and the $p + d$ orbitals of sulfur. (a) Interaction between the LPO^- on oxygen and the $(p_x + d_{xz})$ combination on sulfur. (b) Interaction between the LPO^+ and the $(d_{3x^2-r^2} + p_z)$ on sulfur. (c) Interaction between the LPO^- and the d_{xy} atomic orbital of sulfur.

SCHEME 2

summary, oxygen practically retains three lone pairs and it is their polarization toward the S ($p\pi-d\pi$ backbonding) that is largely responsible for the multiple bond character of the S—O linkage, similar to what has been discussed by Hehre *et al.* (35) for the particular case of the P—O bond in trimethylphosphine. The contribution of these MO's, together with the fact that the centroid of charge of the S—O σ bond is very close to the oxygen atom, yields a considerably polar S—O linkage, which is reflected by the atomic populations and by the high dipole moment of the different conformers of sulfamide. Another consequence of the strong depopulation of sulfur is that the nitrogen atoms must satisfy their electronegativity, withdrawing a considerable amount of charge from the amino protons, which explains the acidic character of sulfamide as compared, for instance, with ammonia (1, 36, 37). The strong withdrawing effect of the oxygens of the SO_2 group may be also responsible for the low rotational barrier observed (26) in 4,4-dioxy-4-thia-1-acetyl-1,4-dihydropyridine. As discussed previously, a similar backbonding interaction is found for the nitrogen lone pairs, but this effect is quantitatively much smaller than that observed in the S—O linkages, and the participation of the sulfur *d* orbitals in the corresponding localized MO's is almost negligible.

3.6. Influence of the second set of d *functions on sulfur*

A perusal of Table 3 clearly shows that the inclusion of two sets of *d* functions on S yields a shortening of both the S—N and S—O bonds. Although this effect is greater in the latter (about 0.02 Å), in general these geometrical changes are not important. More significantly, the relative stability of the different isomers and the description of their charge distributions also do not change appreciably, and only a slight decrease of the dipole moment is observed. This latter effect arises from a slight increase (about 0.25 e^-) of the electronic charge on sulfur, which comes from the population of the diffuse *d* components.

It is interesting to notice that the second set of *d* functions plays the role of real polarization functions. It has been frequently claimed that *d* functions on hypervalent sulfur compounds are indeed necessary to portray accurately the multiple bond character of, for instance, S—O linkages. Therefore, to treat first- and second-row atoms on an equal footing it would be necessary to include a second set of *d* functions on sulfur, which would play the role of true polarization functions, i.e., functions that describe the electronic charge distribution in regions away from the nucleus. Our results confirm this picture. As has been found for compounds containing first-row atoms (38), the inclusion of a second set of polarization functions on S yields shorter bonds and increases the electronic population in the S—O and S—N bond regions. This would imply, in principle, that an adequately balanced basis should include two sets of *d* functions on second-row elements if first-row atoms have been conveniently polarized. Nevertheless our results also show that, at least for the case studied here, the effect of a second set of *d* functions on the charge distributions, geometries, and relative stabilities of the different isomers is quite small.

3.7. Performance of smaller basis sets

Let us now briefly consider the results obtained with smaller basis sets, which may be the only possible alternative in treating more complicated systems containing sulfur.

The cheapest basis including *d* functions on sulfur is the STO-3G*. This basis set also predicts **b** as the most stable conformer of sulfamide, but the relative order of stability of the remaining conformers is not well reproduced. More precisely, the STO-3G* basis indicates that **a**, **c**, and **c'** are 4.5, 4.8, and 4.1 kcal/mol less stable than **b**, respectively. This is a consequence of the minimal character of this basis with repect to first-row atoms, which render it not flexible enough to describe the stabilizing interactions between the oxygen lone pairs and the amino protons in conformer **c** and which underestimates the repulsive interaction between these protons in **a**. Similarly, both the rotational and the inversion barriers are also overestimated.

The next alternative, from the economic point of view, is the 3-21G(*) basis set, which is of a split-valence quality, including polarization functions on sulfur. This basis set yields only one stable conformation for sulfamide, in which the nitrogen atoms present a pratically pure sp^2 hybridization. It is well known that an adequate description of the pyramidalization of the amino groups requires the inclusion of polarization functions on the nitrogen (39, 40) but, in the present case, the lack of these functions has an outermost effect. Probably the amino group tends to be practically planar to achieve a more efficient overlap between the diffuse *p* orbitals on nitrogen and the *d* orbitals on sulfur.

In summary, we may conclude that the best alternative for a reliable treatment of large systems would be to carry out single-point calculations at the 3-21G(*) on fully optimized

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 186.148.149.217 on 09/07/12
For personal use only.

STO-3G* structures, since, as mentioned above, the latter reproduces reasonably well the most important structural features obtained at the 6-31G* level, and the former corrects some of the aforementioned deficiencies of a minimal basis, so that conclusions will be at least qualitatively valid.

4. Concluding remarks

As mentioned in the Introduction, and although sulfamide itself is devoid of relevant biological properties, it constitutes a suitable benchmark case to thoroughly study the characteristics of the >N—SO_2—N< group present in many compounds with well-known activities. This study provides valuable information for the future analysis of structure–activity relationships of hypoglycemic sulfamylureas (44, 45), and, in particular, of herbicidal 2,1,3-benzothiadiazin-4-one 1,1-dioxides and 1,2,4,6-thiatriazine 1,1-dioxides (2). A further step will be the study of the related >N-C_6H_4-SO_2-N< and >N-C_6H_4-SO_2-C_6H_4-N< groups, present in antibacterial and in antileprotic sulfanilamides, respectively (46).

From the results discussed in this paper we can conclude that, under normal conditions, sulfamide may be present in the gas phase as a mixture of conformers **b** and **c'**. However, since the dipole moments of the different stable conformations are very different, the most polar one (conformation **a**) may be favored in condensed media or in polar-solvent solutions.

Internal rotational barriers of sulfamide are lower than in formamide, and similar to those predicted for glycine. However, they are higher than those calculated for sulfuric acid, corresponding to S—OH rotations (41–43), probably because in sulfamide they are mainly due to the electrostatic repulsions between the protons of the two amino groups. The barriers to nitrogen inversion are quite low, because the energy of the system is not very sensitive to the degree of pyramidalization of the amino groups.

The relative stability of the different conformers depends essentially on interactions between the amino protons and between the nitrogen lone pairs. The latter are made evident by the different ordering of the highest occupied MO's of the different isomers.

Our results show that although the π-type delocalization of the oxygen lone pairs into the *d*-orbitals of sulfur is quite significant, and this $p\pi-d\pi$ backbonding interaction is responsible for the multiple bond character of the S—O linkages, similar effects involving the N lone pairs are very weak.

From a more technical point of view, it should be remarked that the inclusion of a second set of *d* functions on sulfur does not alter significantly the results obtained when only one set of polarization functions are included in the basis. More importantly, the 3-21G$^{(*)}$ basis predicts practically planar amino groups with the result that, at this level of accuracy, only one nuclear conformation is predicted to be stable.

An approach to the synthesis of bruceantin. The synthesis of a tetracyclic intermediate

SULTAN DARVESH, ANDREW S. GRANT, DAVID I. MAGEE, AND ZDENEK VALENTA
Department of Chemistry, University of New Brunswick, Bag Service no. 45222, Fredericton, N.B., Canada E3B 6E2

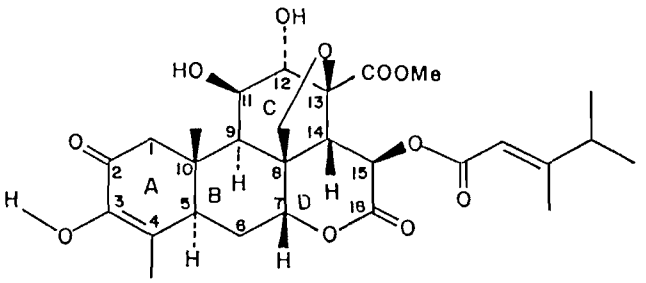
Received August 15, 1988[1]

SULTAN DARVESH, ANDREW S. GRANT, DAVID I. MAGEE, and ZDENEK VALENTA. Can. J. Chem. **67**, 2237 (1989).

An intermediate (**20**) containing four of the five rings and seven of the ten chiral centers of bruceantin (**1**) was prepared. In a key reaction, 3-iodo-1-trimethylsilyl-5-hexen-1-yne (**9**) was found to add chemoselectively and stereoselectively to a dianion. The sequence also includes a selective attack by a sulfinate (**17**) on the terminal acetylene C-atom of the dianion of a keto acetylene, a concomitant cyclization in which the acetylene acts as an electrophile, and the use of the resulting allyl sulfoxide for the introduction of oxygen functionality by a reductive rearrangement.

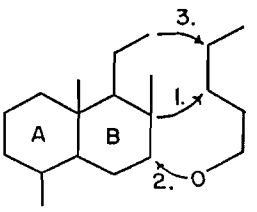
Key words: bruceantin, sigmatropic rearrangement, stereoselective alkylation.

SULTAN DARVESH, ANDREW S. GRANT, DAVID I. MAGEE et ZDENEK VALENTA. Can. J. Chem. **67**, 2237 (1989).



On a préparé un intermédiaire (**20**) contenant quatre des cinq cycles et sept des dix centres chiraux de la brucéantine (**1**). Dans une réaction clé, on a observé que le 3-iodo-1-triméthylsilylhex-5-ène-1-yne (**9**) s'additionne à un dianion d'une façon qui est à la fois chimiquement et stéréochimiquement sélective. La séquence comporte aussi une attaque sélective d'un sulfinate (**17**) sur l'atome de carbone terminal de l'acétylène du dianion d'un céto-acétylène qui est accompagnée d'une cyclisation concomitante au cours de laquelle l'acétylène agit comme un électrophile, et l'utilisation du sulfoxyde allylique qui en résulte pour l'introduction, par le biais d'une transposition réductive, d'une fonction oxygénée.

Mots clés : brucéantine, transposition sigmatropique, alkylation stéréosélective.



[Traduit par la revue]

Structural diversity (1), biological activity (2), and synthetically challenging functionality have recently made the quassinoids frequent targets for total synthesis (3). We wish to report an exceptionally selective alkylation and the development of an efficient cyclization–O-functionalization sequence in a synthetic approach to the natural quassinoid bruceantin (**1**). The overall strategy is shown in the structural formula **2** in which the three arrows point towards the electrophilic centers and the numbers indicate the order in which the bonds were formed.

The necessary A,B-ring intermediate **8** was readily prepared from 2-methylcyclohexane-1,3-dione as shown in Scheme 1.[2] Addition of HCN to the selectively blocked diene dione **7**, mp 148–150°C, gave a chromatographically separable mixture of cyanoketones **8***a*, mp 163–167°C and 192–197°C (C_{10}-methyl ^{1}H nmr signal at δ 1.47), and **8***b*, mp 182–183°C (C_{10}-methyl signal at δ 1.10) in a varying ratio.[3] Treatment of **8***a* + **8***b* with 2.2 equivalents of lithium pyrrolidide[4] followed by a reaction with 1.2 equivalents of iodide **9**[5] gave the alkylated product **10**.[3] Figure 1 suggests a possible arrangement of the two reacting species to explain the observed enantioselectivity (C_{14} in **10**). This is supported by the X-ray study, which shows the side chain in **10** to be in a conformation similar to that shown in Fig. 1.

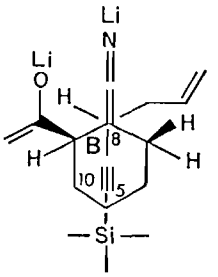

FIG. 1

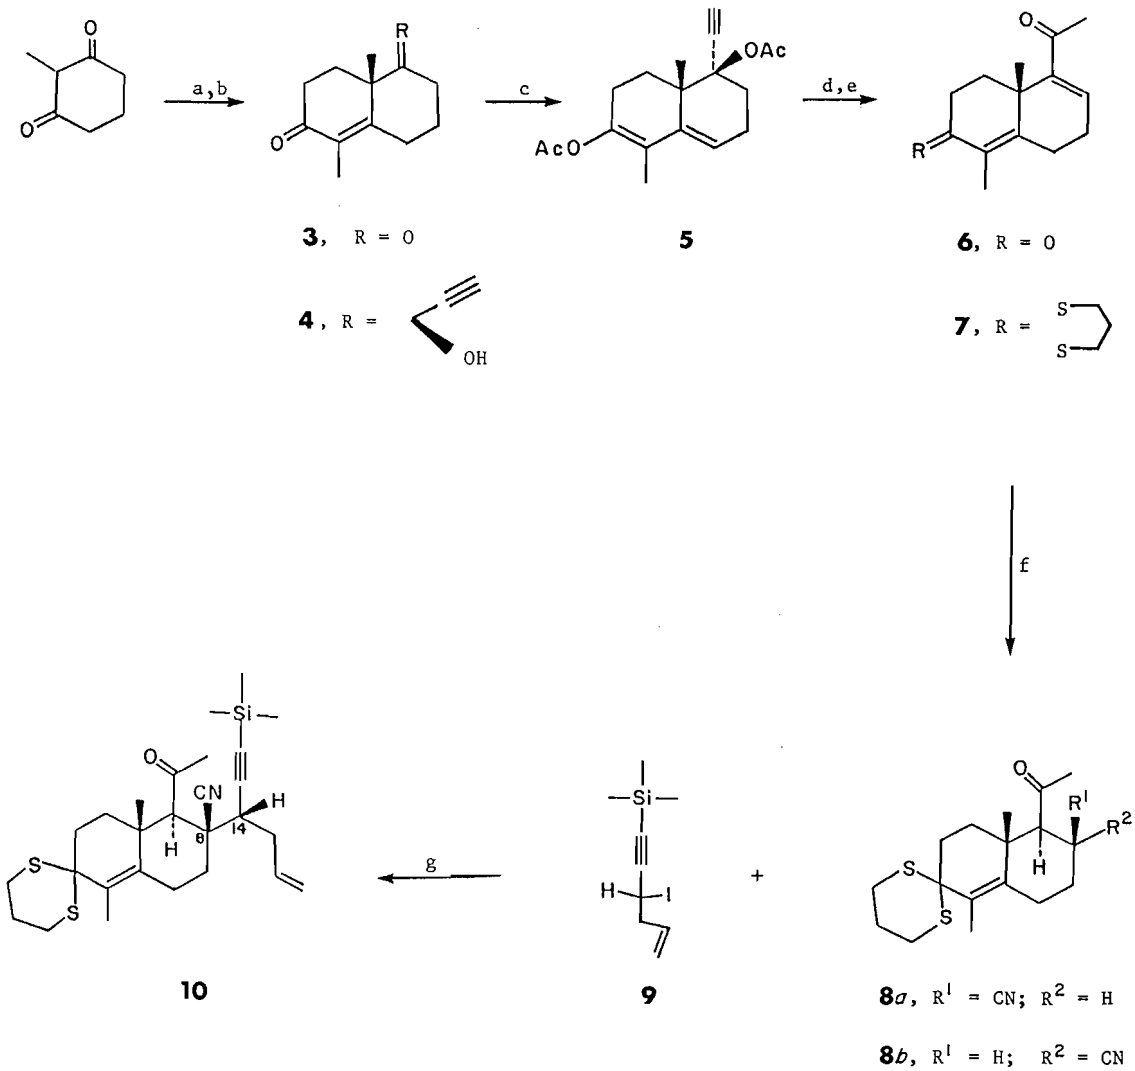
[1]Revision received July 17, 1989.



[2]All compounds described here are racemic. Enantiomerically pure compounds should be readily available using known methods (4).

[3]The structures of **8***a* and **10** were determined by X-ray analysis by Dr. Peter S. White of this department.

[4]This base, rather than a more conventional hindered base was used because it alone achieved an efficient dianion formation from both epimers of **8**. The resulting pyrrolidine did not react with **9** under the reaction conditions.

[5]**9** was prepared most conveniently in a seven-step sequence (32% overall yield) from propargyl alcohol via its THP derivative, silylation, hydrolysis of THP-ether, oxidation with pyridinium dichromate, allyl-Grignard reaction, mesylation, and displacement by I^-.

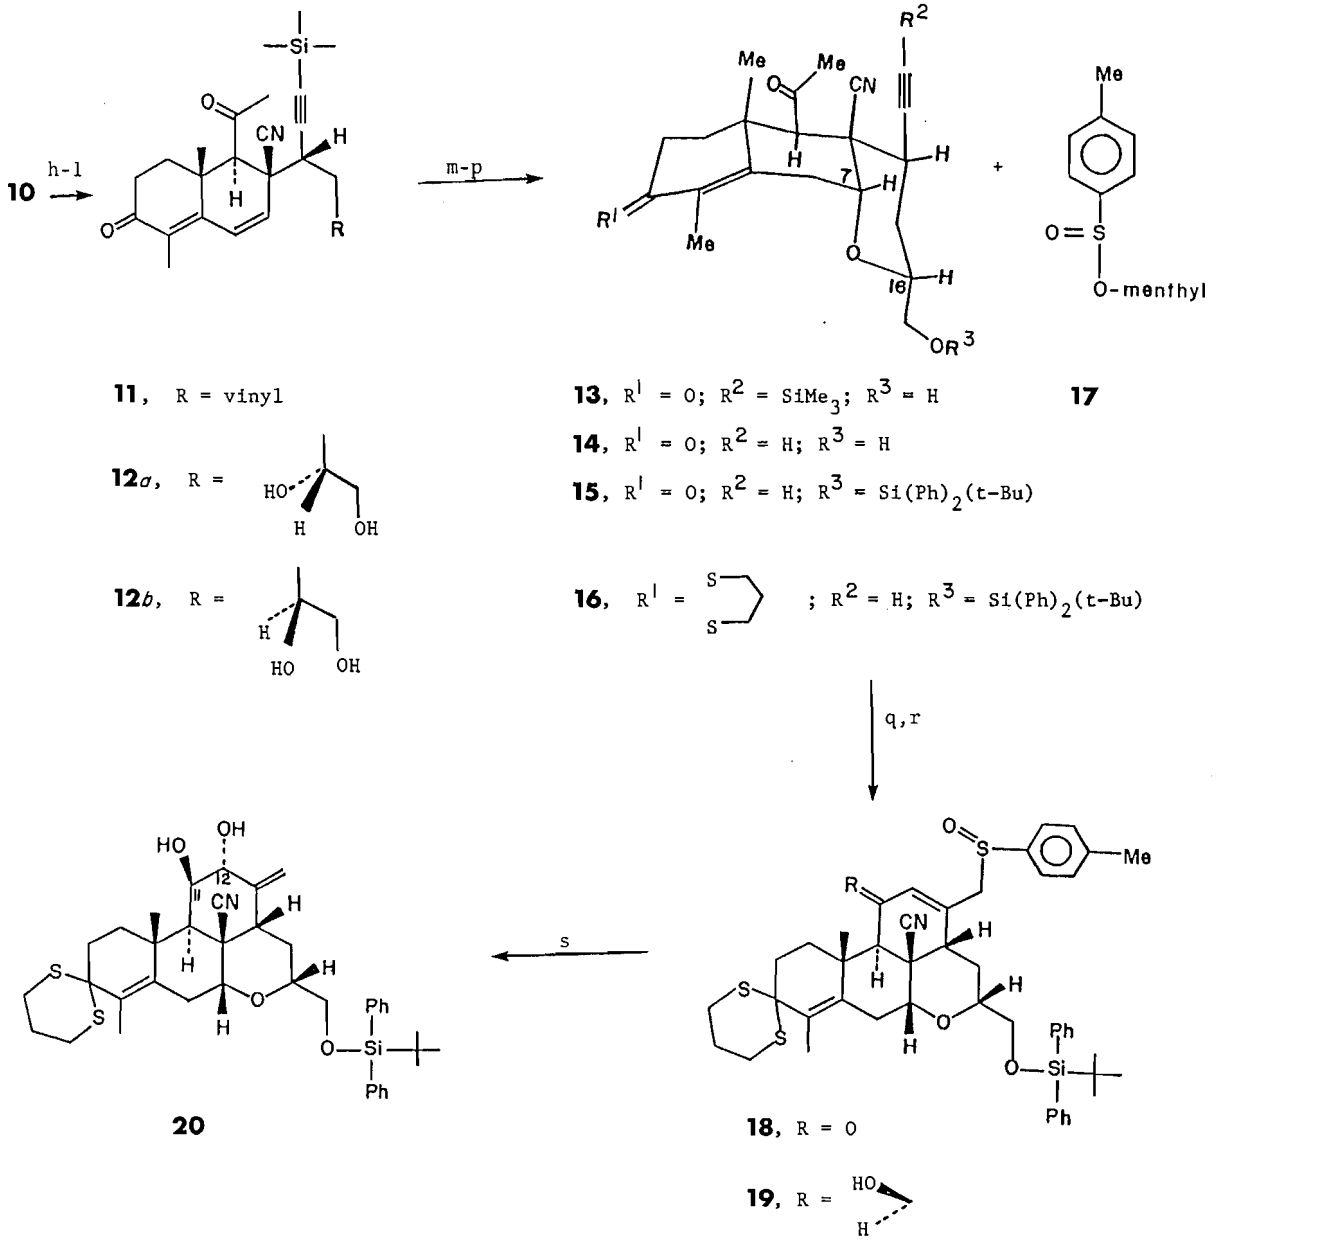
(a) Ethyl vinyl ketone, KOH, MeOH, 65°C, 3 h; pyrrolidine, C_6H_6, 80°C, 30 h (71%) (ref. 5); (b) LiC≡CH, liq. NH_3, 1 h (87%) (ref. 6); (c) Ac_2O, *p*-TSA, 20°C, 16 h (91%) (ref. 6); (d) 90% HCOOH, reflux, 2 h (68%) (ref. 6); (e) $HSCH_2CH_2CH_2SH$, $BF_3.Et_2O$, Et_2O, 20°C, 18 h (82%); (f) KCN, NH_4Cl, DMF–H_2O, 80°C, 16 h (77%); (g) Li pyrrolidide, THF, −78°C, 2 h; **9**, −78°C, 1 h (93%).

SCHEME 1

Intermediate **10** contains all the C-atoms necessary for the construction of the bruceantin skeleton, but the preferred conformation of the side chain attached to C_8 is not suited for the closing of rings C and D. Since the construction of one of these rings starting from **10** would establish the (rigid) geometry necessary for the closure of the other ring, and since the conversion of the keto acetylene moiety of **10** into ring C appeared more problematic, it was decided to construct ring D first. Scheme 2 shows the 9-step conversion of **10** to the required tricyclic intermediate **16**, mp 180–183°C. The chemoselective oxidation of **11** led to the diol mixture **12***a* + **12***b*, which was used without separation in the next three steps. Separation of the two C_{16} isomers at stage **15** on SiO_2 then showed a 6:1 ratio with the ether formed from **12***a* (and drawn in formulae **13** → **16**) predominating.[6] A very large excess of 1,3-propane diol (60 equiv.) and *p*-toluenesulfonic acid (30 equiv.) was required to achieve the cyclization **12** → **13**.[7] The C_7 configuration in **13** follows from the ^{1}H nmr spectrum (1H, t, J = 4 Hz at δ 4.21).



To cyclize ring C, it was decided to render the acetylene group in **16** electrophilic and to provide, at the same time, for the subsequent introduction of the required O-functionality. Reaction of the dianion of **16** with **17**[8] gave the enone sulfoxide **18**[8] (ir ν_{max} 1680 cm^{-1}, uv λ_{max} 247 nm, (basic) 369 nm). Reduction of **18** with $LiBH_4$ then gave the axial alcohol **19**. For a good yield, it proved essential to achieve a fast reaction by using a large excess of $LiBH_4$ (40 equiv.) and by adding MeOH (1 part) to THF (10 parts) (8, 9). Finally, the two (sulfoxide)

[6]All subsequent reactions described here have been performed with the pure major isomer. The ^{1}H nmr data show that the C_{16}-H atom in this isomer is axial.

[7]This is a heterogeneous reaction (droplets of 1,3-propane diol in benzene) and it is assumed that protonated 1,3-propane diol exerts a specific protonation–deprotonation action at the interface. The acetal of **12** or **13** does not form even at 80°C.

[8](−)-Menthol, used for the preparation of **17** (7), or isopropanol proved convenient secondary alcohols. A reaction with the corresponding methyl ester proved unsatisfactory. The two sulfoxide diastereoisomers of **18** were formed in roughly equal quantities in all cases (^{1}H nmr signals for C_{12}-H at δ 5.54 and 5.62).

(h) HgO, H_2SO_4, THF, 40°C, 4 h (100%) (ref. 12); (i) $HC(OEt)_3$, *p*-TSA, C_6H_6, 20°C, 1 h (89%) (ref. 13); (j) $C_5H_6N^+Br_3^-$, THF–H_2O, 20°C, 20 min (88%); (k) DBN, THF, 20°C, 20 min (78%); (l) *N*-methylmorpholine oxide, OsO_4, *tert*-butanol–THF–H_2O, 20°C, 24 h (84%) (ref. 14); (m) $HOCH_2CH_2CH_2OH$, *p*-TSA, C_6H_6, 40°C, 4 h (80%); (n) $N^+(butyl)_4Cl^-$, KF, CH_3CN, 20°C, 1 h (100%) (ref. 15); (o) $ClSi(Ph)_2t$-butyl, imidazole, DMF, 20°C, 12 h (84%) (ref. 16); (p) $HSCH_2CH_2CH_2SH$, $BF_3.Et_2O$, Et_2O, THF, 20°C, 3 h (96%); (q) *n*-BuLi (3 equiv.), THF, −78°C, 15 min; **17** (1.8 equiv.), −78°C to 20°C, 5 h (81%); (r) $LiBH_4$, THF, MeOH, 20°C, 20 min (77%); (s) $P(OEt)_3$, EtOH, 40°C, 120 h (75% for **19***a*).

SCHEME 2

diastereoisomers of **19** proved separable on SiO_2. One of them, **19***a*, rearranged, on treatment with triethyl phosphite (10) in EtOH at 40°C for 5 days, to diol **20** in 75% yield,[9] while the other, **19***b*, did not react under these conditions. However, similar treatment of **19***b* at 75°C for 48 h gave a cyclic imino ether (C_{11}-OH in **20** adding to CN) (ir ν_{max} 1700 cm^{-1}, no —CN) in 75% yield, while heating of **20** in EtOH at 75°C resulted in its conversion to the same imino ether. This proves that the C_{11}-OH in **19** and **20** is axial and shows that the sigmatropic rearrangement of the two diastereoisomers of **19** proceeds from the same face of ring C, but at a different rate.[9]

The overall yield of the 18-step sequence 2-methylcyclohexane-1,3-dione → **19** is 4% and the average yield per step is 84%. Further synthetic elaboration of **20** and the general utility of the sequence **16** → **18** → **20** are under active study.

[9]The configurational assignment at C_{12} in **20** is based on a strong nOe (10% enhancement) between C_{12}-H (δ 4.18) and $=CH_2$ (δ 5.26 and 5.32), on a presumed preference for an axial attack of the ring C quasi-chair (11) in both rearrangements and on models that show that the *p*-tolyl group in one of the diastereoisomers of **19** presents a hindrance to the rearrangement proceeding at the α-face.

Total synthesis of 12-*O*-benzoyl-6,7,14,15-tetradehydro leukotriene B_4 methyl ester: precursor of labeled LTB_4

RENÉE PONTIKIS, LALATIANA R. RANDRIANASOLO, YVES LE MERRER, NGUYEN HOANG NAM, ROBERT AZERAD, AND JEAN-CLAUDE DEPEZAY

Laboratoire de chimie et biochimie pharmacologiques et toxicologiques, Institut national de la santé et de la recherche médicale—Centre national de la recherche scientifique (Unité associée 400), Université René Descartes, 45 rue des Saints Pères, 75270 Paris CEDEX 06, France

Received July 24, 1989

RENÉE PONTIKIS, LALATIANA R. RANDRIANASOLO, YVES LE MERRER, NGUYEN HOANG NAM, ROBERT AZERAD, and JEAN-CLAUDE DEPEZAY. Can. J. Chem. **67**, 2240 (1989).

12-*O*-Benzoyl-6,7,14,15-tetradehydroleukotriene B_4 methyl ester **1**, the direct precursor of isotopically labeled LTB_4's, has been prepared. This synthesis was accomplished by the assembly of two key chirons: α-hydroxyaldehyde of *R* configuration, **2**, and propargylic alcohol of *S* configuration, (*S*)-**7**. The first was obtained from D-mannitol whereas the second was obtained by enzymatic resolution.

Key words: leukotriene B_4, tetradehydroleukotriene B_4, labeling, chiral α-hydroxyaldehyde, enzymatic resolution.

RENÉE PONTIKIS, LALATIANA R. RANDRIANASOLO, YVES LE MERRER, NGUYEN HOANG NAM, ROBERT AZERAD et JEAN-CLAUDE DEPEZAY. Can. J. Chem. **67**, 2240 (1989).

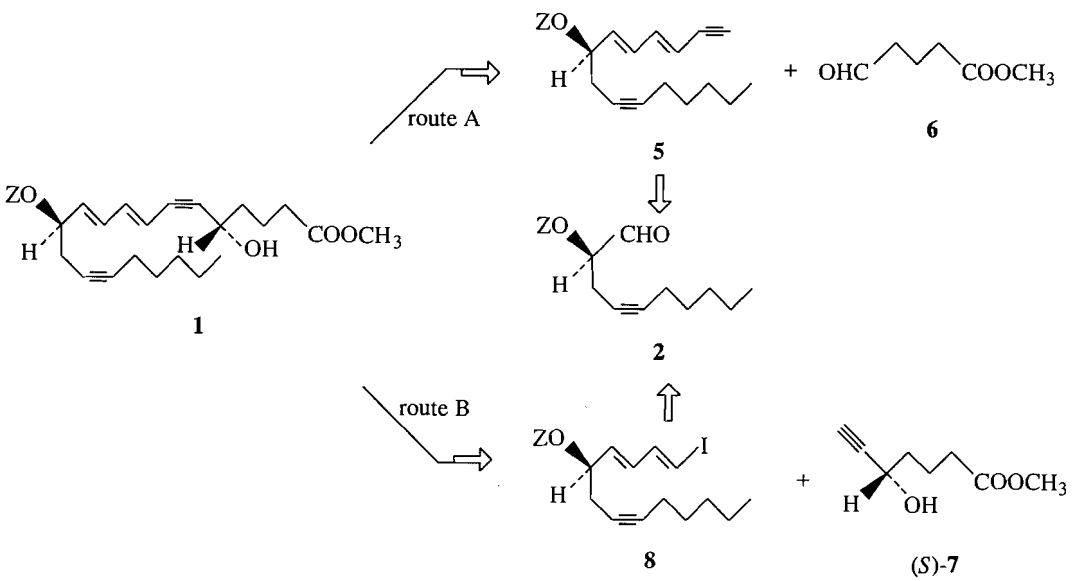
Pour obtenir le leucotriène B_4 radiomarqué par quatre atomes de tritium, la synthèse totale convergente d'un précurseur diacétylénique (ester méthylique du 12-*O*-benzoyl-6,7,14,15-tétradehydroleucotriène B_4 **1**) a été réalisée à partir de deux synthons chiraux : α-hydroxyaldéhyde de configuration *R* **2** et alcool propargylique de configuration *S* **7**. Le premier a été obtenu à partir du D-mannitol, le second par dédoublement enzymatique.

Mots clés : leukotriène B_4, tétradéhydroleukotriène B_4, molécule marquée, α-hydroxyaldéhyde chiral, dédoublement enzymatique.

Leukotriene B_4 (LTB_4), a dihydroxy metabolite of arachidonic acid, is the most potent chemotactic mediator implicated in allergic and inflammatory processes (1). It is metabolized to biologically less active ω-oxidized products, primarily in polymorphonuclear leukocytes but also in liver cells (2–4). To evaluate other possible metabolic pathways and the uptake of LTB_4 in different tissues, a radiolabeled version of this mediator was required. The [14,15-^{3}H]-LTB_4 was prepared by Leblanc *et al.* (5) at a specific activity of 40 Ci/mmol. The availability of a material labeled with four atoms of tritium, which could allow a specific activity of 80–100 Ci/mmol to be attained, prompted us to embark on the synthesis of a suitable precursor: 6,7,14,15-tetradehydro LTB_4 **1**.

At the final synthetic step, selective tritiation of the two acetylenic bonds to *cis* olefins will allow the incorporation of four tritium atoms.

X = H(LTB_4), D or T

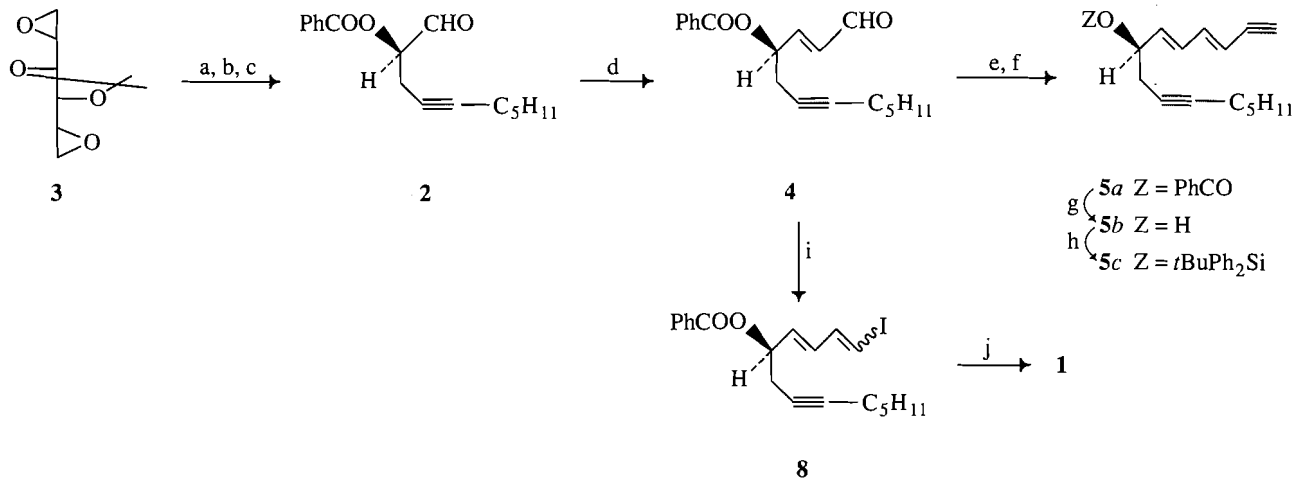


Two retrosynthetic routes could be considered (Scheme 1). Each is based on our method, recently published (6*a*,*b*), of using D-mannitol as a precursor of enantiomerically pure α-hydroxyaldehydes.

Protected (*R*)-α-hydroxyaldehyde **2** was prepared (Scheme 2) from the "D-mannitol diepoxide" **3** (7) by regiospecific nucleophilic opening with lithium heptynide followed by benzoylation *in situ*, removal of the acetonide group, and oxidative cleavage of the resulting 3,4-diol (68% overall yield). Two-carbon homologation of **2** with formylmethyl triphenylphosphorane led exclusively to the (*E*)-α,β ethylenic aldehyde **4** (75%). Condensation of **4** with the ylide derived from (trimethylsilylpropargyl)triphenylphosphonium bromide gave a 7:3 mixture of *E* and *Z* stereoisomers, which could be separated by flash chromatography (8). Removal of the trimethylsilyl group with fluoride ion generated the terminal acetylene **5***a*.

Electrophilic trapping (route A) of the lithium acetylide derived from **5***a* by methyl 5-oxopentanoate **6** (9) should produce the acetylenic alcohol **1**. However, all attempts to carry out this coupling reaction failed in our hands. Nevertheless, we found that coupling occurred, but with a poor yield (20%), when the secondary alcohol function of **5** was free (Z = H, **5***b*) or protected by a silyl ether group (Z = *t*$BuPh_2Si$, **5***c*).

This unsuccessful approach encouraged us to prepare the diacetylenic precursor **1** via a strategy (route B) involving Pd^0–Cu^I catalyzed coupling of terminal acetylene **7** with vinyl halide **8** (10*a*, *b*).



Key chiron (*S*)-**7** was prepared via an enzymatic method. Thus, starting from the racemic methyl ester (±)-**7**,[1] enantioselective hydrolysis using α-chymotrypsin led to the optically

SCHEME 1

[1]Monolithium acetylide condensed with the aldehyde **6** (THF, −78°C, 2 h) afforded racemic **7** in 80% yield.

(a) $C_5H_{11}C{\equiv}C{-}Li$ (2.4 equiv.), THF, HMPA (2.2 equiv.), 64°C, 4 h, followed by PhCOCl (2.7 equiv.), 0°C, 90%
(b) CF_3COOH, H_2O 9:1, 0°C, 3 h, 90%
(c) $Pb(O\,Ac)_4$ (1.1 equiv.), CH_2Cl_2, −10°C, 2 h 30, 92%
(d) $Ph_3P^+CH_2CHO$, Cl^- (1.2 equiv.), NEt_3 (1.5 equiv.), benzene, RT, 24 h, 75%
(e) $Ph_3P^+CH_2C{\equiv}C{-}Si\,Me_3$, Br^- (1.3 equiv.), *n*BuLi (1.1 equiv.), THF, −78°C→−40°C, 50 min, then **4**, −78°C→0°C, 1 h 15, 45%
(f) nBu_4NF/silica gel (1.8 equiv.), THF, −10°C, 2 h, 95%
(g) K_2CO_3 (1.5 equiv.), MeOH, 20°C, 3 h, 90%
(h) tBuPh$_2$SiCl (2.0 equiv.), Im (3 equiv.), DMF, 20°C, 20 h, 92%
(i) $CrCl_2$ (6.0 equiv.), CHI_3 (1.2 equiv.), THF, 0°C, 3 h 70%
(j) $[Pd(Ph_3P)_4]$ (0.05 equiv.), benzene, RT, 30 min then (*S*)-**7** (1.1 equiv.), nBuNH$_2$ (2.0 equiv.), CuI (0.2 equiv.), 2 h, 68%

SCHEME 2[5]

active methyl ester (ee >98%),[2] whose absolute configuration was assigned to be *S* by comparison of the $[\alpha]_D$ value (−9°(*c* 5.25, $CHCl_3$)) with literature data (11): $[\alpha]_D$ −9°(*c* 1.56, CCl_4). This correlation established that α-chymotrypsin preferentially hydrolyzed the methyl ester (*R*)-**7**.

The vinyl iodide **8** was obtained as an 8:2 mixture of *E* and *Z* isomers from aldehyde **4** using $CrCl_2$–CHI_3 according to the recently reported method of Takai *et al.* (12). The reaction mixture must be protected from light to avoid a larger proportion of the more thermodynamically stable *Z* isomer.

Coupling of **8** with propargylic alcohol (*S*)-**7**, under the catalytic action of tetrakis(triphenylphosphine) palladium and copper iodide, followed by flash chromatography, led to the diyne **1**[3] (68% yield) and its $\Delta^{8,9}$-*cis* isomer (17%).

This compound is the direct precursor of the isotopically (deuterium, tritium) labeled LTB_4, but also of the naturally occurring leukotriene.[4]

[2](±)-**7** (952 mg) in 0.1 M phosphate buffer pH 7.35 (30 mL) was treated at 25°C with α-chymotrypsin (400 mg, Sigma, type II). The pH was maintained by continuous addition of 1 N NaOH and after 27 h (69% hydrolysis) the solution was extracted four times with ethyl ether to give 96 mg of (*S*) residual ester. Enantiomeric excess (by GPC of the *S*-acetyllactyl ester): 98%.

[3]$[\alpha]_D$ −45° (*c* 0.62, CH_2Cl_2); ^{1}H NMR (250 MHz, $CDCl_3$) δ: 0.85 (t, 3H, *J* = 7 Hz, H-20), 1.29 (m, 4H, H-18, 19), 1.44 (m, 2H, H-17), 1.78 (m, 4H, H-3, 4), 2.13 (m, 2H, H-16), 2.38 (t, 2H, *J* = 7 Hz, H-2), 2.64 (m, 2H, H-13), 3.68 (s, 3H, OCH_3), 4.50 (m, 1H, H-5), 5.61 (q, 1H, *J* = 6.5 Hz, H-12), 5.65 (dd, 1H, *J* = 1.5, 15 Hz, H-8), 5.91 (dd, 1H, *J* = 6.5, 15 Hz, H-11), 6.38 (dd, 1H, *J* = 11, 15 Hz, H-10), 6.57 (dd, 1H, *J* = 10.5, 15 Hz, H-9), 7.44, 7.56, and 8.06 (m, 5H, Ph).

[4]Synthetic LTB_4 methyl ester obtained by semihydrogenation and debenzoylation was correlated with an authentic sample in two different HPLC systems: Waters μ Porasil, hexane/*i*PrOH, 92:8, 1 mL/min flow rate, R_t = 14 min; and Spherisorb ODS-2, linear gradient in 40 min from $H_2O/CH_3CN/H_3PO_4$, 85:15:0.05, to CH_3CN/H_3PO_4, 100:0.05, at a flow rate of 1 mL/min.
